Biomimetic aromatization of Hantzsch 1,4-dihydropyridines with sodium periodate catalyzed by a new polystyrene-bound manganese porphyrin

Majid Moghadam, Masoud Nasr-Esfahani, Shahram Tangestaninejad, Valiollah Mirkhani, and Mohammad Ali Zolfigol

Abstract: Efficient oxidation of Hantzsch 1,4-dihydropyridines with sodium periodate catalyzed by a polystyrene-bound manganese(III) porphyrin is reported. This catalyst shows high activity in the oxidation of various 1,4-dihydropyridines at room temperature. This heterogeneous catalyst can be reused five times without significant loss of its activity.

Key words: biomimetic oxidation, supported metalloporphyrin, periodate, 1,4-dihydropyridine.

Résumé : On a effectué l'oxydation efficace des 1,4-dihydropyridines de Hantzsch par le biais d'une réaction avec du periodate de potassium catalysée par une porphyrine de manganèse(III) liée à du polystyrène. Ce catalyseur présente une grande activité pour l'oxydation, à la température ambiante, de diverses 1,4-dihydropyridines. Ce catalyseur hétérogène peut être réutilisé jusqu'à cinq fois dans perte significative de son activité.

Mots clés : oxydation biomimétique, métalloporphyrine déposée sur un support, periodate, 1,4-dihydropyridine.

[Traduit par la Rédaction]

Introduction

In the last two decades, metalloporphyrins have been successfully used as models for the cytochrome P-450 enzyme with respect to the oxidation of organic compounds such as hydrocarbons (1–3). Development in this area is based on different strategies with the aim of designing selective, stable, and high turnover catalytic systems (4). Several simple oxidants such as iodosylbenzene, hypochlorite, *m*-chloroperbenzoic acid, hydrogen peroxide, and periodates have been extensively studied in oxygenation reactions catalyzed by metal complexes to understand the mechanism of the cytochrome P-450 monooxygenation enzyme (5–10). Great efforts have been made toward the chemical modification of the metalloporphyrin microenvironment in the studies of the cytochrome P-450 model. One method is to immobilize the metalloporphyrins onto solid supports. Such immobilization not only modifies the metalloporphyrin microenvironment, but also increases the catalytic activity of metalloporphyrins, so one can prepare the catalysts, which are easier to handle and easily separate from reaction medium. Among the metalloporphyrin microenvironment models, polystyrene derivatives are often utilized because they can provide a suitable microenvironment for the "accommodation" of the porphyrin catalytic center.

Amlodepine besylate, nifedepine, and related dihydropyridines are Ca^{2+} channel blockers and are rapidly emerging as one of the most important classes of drugs for the treatment of cardiovascular diseases, including hypertension cardiac arrhythmias (11). In the human body, it has been observed that these compounds undergo oxidation to form pyridine derivatives by the action of cytochrome P-450 in the liver. This observation led us to investigate the ability of this biomimetic catalyst to act in the oxidation of 1,4-dihydropyridines. These oxidized compounds are largely devoid of the pharmacological activity of the parent compounds (12, 13).

Recently, we reported on the oxidation of 1,4-dihydropyridines with tetra-*n*-butylammonium periodate catalyzed by homogeneous Mn(TPP)Cl (14). In this paper, we report on the efficient oxidation of 1,4-dihydropyridines with sodium periodate at room temperature catalyzed by a Mn(TPyP) supported on chloromethylated polystyrene (CMP) (Scheme 1).

Results and discussion

The manganese(III) tetrapyridylporphyrin supported on polystyrene (Mn(TPyP)–CMP) is easily prepared from commercially available porphyrin and chloromethylated polystyrene (Fig. 1).

The high catalytic activity of this heterogeneous catalyst in the alkene epoxidation and alkane hydroxylation and oxidation of alcohols (15, 16) prompted us to investigate its ability in the oxidation of 1,4-dihydropyridines with sodium periodate at mild reaction conditions. The oxidation of 1,4-dihydropyridines by Mn(TPyP)–CMP and sodium periodate yielded the corresponding pyridine derivative in CH_3CN–

H_2O (1:1) as solvent, whereas trace amounts of the product was detected when the identical reaction was carried out in the absence of periodate. The effects of other oxidants were also studied in the oxidation of 4-phenyl derivatives of 1,4-dihydropyridines. The obtained results showed that $NaIO_4$ is more effective than H_2O_2, NaOCl, *t*-BuOOH, and urea-hydrogen peroxide adduct (UHP) (Table 1). To choose the reaction media, different solvents were investigated in the oxidation of 4-phenyl derivatives of 1,4-dihydropyridines. As shown in Table 2, among the studied solvents, the 1:1 mixture of CH_3CN–H_2O was chosen as solvent because a higher amount of pyridine derivative was observed. The blank experiment, in the absence of catalyst, showed that the presence of catalyst is crucial in oxidation reactions. In biomimetic systems using metalloporphyrins as catalyst, addition of an axial base is necessary to obtain high catalytic activity. One observation is that this catalytic system shows higher catalytic activity in the absence of imidazole. When imidazole is added as axial ligand to this catalytic system, the reaction times become longer in the oxidation of 1,4-dihydropyridines. For instance, the oxidation of 4-phenyl and 4-nitrophenyl derivatives was completed in 60 and 90 min, respectively; but addition of imidazole as co-catalyst led to longer reaction times of 90 and 150 min for 4-phenyl and 4-nitrophenyl derivatives, respectively. These observations show that the 1,4-dihydropyridines can play the axial ligand role. The Mn(TPyP)–CMP–$NaIO_4$ catalytic system can be used for oxidizing a wide variety of 1,4-dihydropyridine derivatives to their corresponding pyridine derivatives giving excellent yields at room temperature. All reactions were completed during the appropriate time (until no starting material is detected by TLC) and gave only the corresponding pyridine derivatives. The results are summarized in Table 3. As shown in Table 3, the oxidation of the 4-isopropyl derivative accompanied by expulsion of this substituent gave the dealkylated pyridine derivative (Table 3, entry 12), which was previously reported by Ortiz de Montellano et al. (17) in the oxidation of 1,4-dihydropyrines by cytochrome P-450. This approach shows that this synthetic model behaves in the same way as cytochrome P-450.

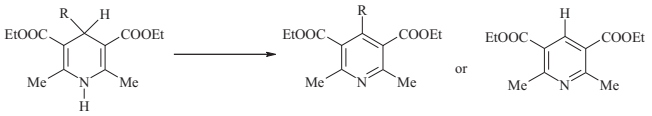
Table 1. Effect of various oxidants on the oxidation of 4-phenyl derivatives of 1,4-dihydropyridines.

Oxidant	Solvent	Yield (%)[a]
$NaIO_4$	CH_3CN–H_2O	97
H_2O_2	CH_3CN	40
H_2O_2–urea	CH_3CN	32
NaOCl	CH_3CN	17
t-BuOOH	CH_3CN	10

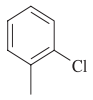
[a]Isolated yields.

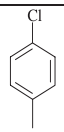
Table 2. Effect of solvent oxidation of 4-phenyl derivatives of 1,4-dihydropyridines.

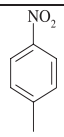
Solvent	Yield (%)[a] after 60 min
CH_3CN–H_2O	97
CH_3COCH_3–H_2O	75
CH_3OH–H_2O	58
CH_3CH_2OH–H_2O	42
$CHCl_3$–H_2O	15
CH_2Cl_2–H_2O	33
CCl_4–H_2O	8

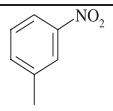


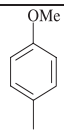
[a]Isolated yields.

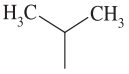












We also studied recycling of the used Mn(TPyP)–CMP in the repeated oxidation reactions. After the first run, the polymer was recovered by filtration followed by washing with water and acetonitrile and then reused. The catalyst was reused five consecutive times without loss of its activity. No manganese was detectable in the filtrates by atomic absorption spectrometry.

From a synthetic point of view, the oxidation of Hantzsch 1,4-dihydropyridines is an old reaction in synthetic organic chemistry. In recent years, several new methods have been reported for dehydrogenation of Hantzsch 1,4-dihydropyridines with ferric or cupric nitrates on a solid support: ceric ammonium nitrate, pyridinium chlorochromate, *t*-BuOOH, photochemical oxidation, NO gas, inorganic acidic salts – $NaNO_3$ – wet SiO_2, and $NaHSO_4$–$NaNO_2$ (18). Most of the reported procedures suffer from disadvantages such as producing by-products that are difficult to remove from the desired product, using the reagents that are either highly toxic or present serious environmental problems (or both such as NO), and nonreusability of heterogeneous catalysts. The comparison of our reported system with the previously re-

ported systems shows that the Mn(TPyP)–CMP–$NaIO_4$ catalytic system has the following advantages: mild reaction conditions, robustness of the catalyst, nontoxicity of reagents, and reusability of the catalyst without loss of its activity.

Experimental

All materials were commercial reagent grade. The tetrapyridylporphyrin ligand (TPyP) was purchased from the Fluka Chemical Company (Dubai, UAE), and metalated and supported according to literature procedures (19, 14). All Hantzsch 1,4-dihydropyridines were synthesized by the reported procedures (20). ^{1}H NMR spectra were obtained with a Bruker AW80 (80 MHz) spectrometer.

General procedure for oxidation of 1,4-dihydropyridines with $NaIO_4$ catalyzed by Mn(TPyP)–CMP

All of the reactions were carried out at room temperature under air in a 25 mL flask equipped with a magnetic stirrer bar. A solution of $NaIO_4$ (2 mmol) in H_2O (10 mL) was added to a mixture of 1,4-dihydropyridines (1 mmol) and MnTPyP–CMP (20 μmol) in CH_3CN (10 mL). The progress of the reaction was monitored by TLC. After the reaction was completed, the reaction mixture was filtered and the pyridine derivative was extracted with CH_2Cl_2 (2 × 20 mL). The pyridine derivatives were obtained after evaporation of the solvent. Further purification was followed using a silica gel plate. IR and ^{1}H NMR spectral data confirmed the identities of the products.

Prediction of the photoelectron spectrum for XPY_2 (X = H, F, Cl; Y = O, S) type of molecules by ab initio and DFT methods

Didier Bégué, Jean-marc Sotiropoulos, Claude Pouchan, and Daisy Y. Zhang

Abstract: The present study reports the theoretical vertical ionization potentials (IPs) for all the valence electrons in six XPY_2 molecules by utilizing the corrected orbital energies calculated with three theoretical methods, namely, the ab initio Hartree–Fock (HF), and both the pure and hybrid density functional theory (DFT) methods at, respectively, the BLYP/6-311+G* and B3lYP/6-311+G* levels of theory. Evaluation of the numerical corrections to the orbital energies was achieved by comparisons with the IP values obtained via explicit computation of the energy differences between the neutral molecules and the corresponding radical cations (the ΔSCF method) and shows values from –0.9 to –1.9 eV for the HF, and positive values from 2.9 to 3.9 eV and from 1.8 to 2.4 eV for the pure and hybrid DFT methods, respectively. In contrast to the orbital energies, the ΔSCF method is shown to give consistent values among the three methods, as well as reasonable agreement with the experimental IP values.

Key words: ionization potential, phosphorane, Koopmans' theorem, Janak's theorem.

Résumé : Dans ce travail, on a calculé les potentiels théoriques d'ionisation (PI) verticale pour tous les électrons de valence de six molécules XPY_2 en faisant appel à des énergies d'orbitales corrigées calculées par trois méthodes théoriques, soit les méthodes de Hartree–Fock (HF) ab initio ainsi que par des méthodes pure ainsi qu'hybride de la théorie de la densité fonctionnelle (TDF) aux niveaux respectivement BLYP/6-311+G* et B31YP/6-311+G*. On a réalisé l'évaluation des corrections numériques des énergies d'orbitales par des comparaisons avec des valeurs de PI obtenues par des calculs explicites de différences d'énergie entre les molécules neutres et les cations radicaux correspondants (la méthode de différences autocohérentes, ΔCAC) et les valeurs s'étalent entre –0,9 et –1,9 eV pour la méthode HF et entre +2,9 et 3,9 eV et +1,8 et 2,4 eV pour les méthodes de la TDF respectivement pure et hydride. Par opposition aux énergies d'orbitales, on montre que la méthode des ΔCAC conduit à des valeurs qui en accord entre elles pour chacune des trois méthodes et, de plus, elles sont en bon accord avec les valeurs expérimentales de PI.

Mots clés : potentiel d'ionisation, phosphorane, théorème de Koopmans, théorème de Janak.

[Traduit par la Rédaction]

Introduction

The title molecules, known as monomeric metaphosphate (RPO_2) and dithioxophosphorane (RPS_2), have been the focus of much research. As Nobel Prize laureate Arthur Kornberg wrote in his recollections on ATP and inorganic pyro- and poly-phosphate in 1993 (1), "My attachment to poly P withstood 35 years of a devotion to DNA replication … Unlike children and friends, shaped and altered by passage of time, the face of poly P has remained fresh with the mystery and allure of a new acquaintance".[2] As well as the essential roles that metaphosphate plays in the ATP hydrolysis mechanism (2–4), these phosphorus-containing molecules are fundamentally important to the study of chemistry, in particular, the study of bonding theory. As π and σ bond models, they are ideal systems for the investigation of bonding structures; the results provide insights into the role of the 3d orbitals in valence bonding (5–8), and furthermore, help to discern the much debated issue of normal valency vs. hypervalency.

Experimental potential energy surfaces (PESs) of FPS_2, $ClPS_2$, and $ClPO_2$ were recorded by Bock and co-workers (9, 10) using thermal decomposition (around 500 K) of pyridinium-FPS_2 betaine compounds. The spectra of FPS_2 and $ClPS_2$ were clearly identified with bands at mainly 10.1, 10.5, 11.3 and 9.8, 10.2, 10.7 eV, respectively. For the oxygen analogue, the bands were stabilized at 11.9, 12.4, 13.0, and 13.5 eV. The assignments were supported by Koopmans' correlations with MNDO eigenvalues from geometry-optimized semiempirical ΔSCF calculations. More elaborate analysis was necessary to reinvestigate the photoelectron spectra, and in light of a better quantum calculation, we assigned the four previous PESs and predicted bands for the other compounds.

Recognizing that quantum mechanical calculations have become an essential tool in chemical research, many re-

searchers have been engaged in the evaluation of various theoretical methods in the calculation of the ionization potentials (IPs) (11–13). Reliable predictions for the IPs are certainly invaluable in understanding the chemical structures, as well as helping to identify the molecules in photoelectron spectroscopy experiments.

The most commonly used practice to produce the IP data by theoretical methods is to use the orbital energy values. As is known, the negative values of the Hartree–Fock (HF) orbital energies can be used to predict the vertical IPs via the application of Koopmans' theorem (14), and in the DFT analogy of Janak's theorem (15). However, it is also known that those orbital energies do not always match the IP values accurately. In Koopmans' theorem, it is due to the assumption that the orbitals for the cation are identical to those in the neutral molecule, which results in neglecting two major changes in the electronic structure of the radical, namely, the orbital relaxation after the ionization process and the overestimation of the electron correlation in the cation. In Janak's theorem, it is due to the self-interaction error, as the exchange–correlation functionals do not completely cancel the spurious Coulomb interaction of an electron with itself. Therefore, a more accurate way to predict the vertical IP is by using the so-called ΔSCF method, which calculates the IPs via explicit computation of the energy difference between the neutral molecule and the corresponding radical cation. While this method yields much more accurate IP values, its application is limited by the fact that it is time-consuming and is not practical for large systems if high levels of theory for the calculations are desired.

Herein, we report a case study of six title molecules on the numerical corrections to the orbital energies generated by three computational procedures, namely, the ab initio HF and both the pure (BLYP) and hybrid (B3LYP) DFT methods. With these values, a complete photoelectron spectrum is therefore constructed theoretically for each of the six molecules. We believe that these numerical values provide some general information that would allow for a more accurate prediction of the IP values by applying Koopmans' or Janak's theorem.

Computation methodology

All calculations were carried out using the Gaussian 98 suite of programs (16). Full geometry optimization was performed at the BLYP/6-311+G*, B3LYP/6-311+G* (17–19), and CCSD(T)/cc-pVTZ (20–22) levels of theory, and all molecules were found to be of C_{2v} symmetry at the optimized structures, each of which was further confirmed as a stationary point on the PES by the vibrational analysis calculations, such that all frequencies were found to be real.

The vertical IPs were computed by taking the electronic energy difference (ΔSCF) between the neutral molecule and the corresponding radical cation at the same geometry but by using the unrestricted method. Zero-point energy (ZPE) corrections were included for the neutral molecules but not for the cations. The size of ZPE ranges from 0.29 eV for the largest molecule of series, namely, $ClPS_2$, to 0.80 eV for the smallest molecule of HPO_2. With this procedure, the four lowest possible ionization energies were computed at the (U)B3LYP/6-311+G* and (U)CCSD(T)/cc-pVTZ levels of theory, which correspond to having the unpaired electron in the radical cation occupying the MOs of $^2A_1$, $^2A_2$, $^2B_1$, and $^2B_2$ symmetries.

Table 1. Structural data for the six XPY_2 molecules computed at the B3LYP/6-311+G* and CCSD(T)/cc-pVTZ levels of theory.

XPY_2	r (X—P)	r (P—Y)	α (Y-P-Y) (°)
FPO_2	1.58/1.55	1.46/1.45	136.5/135.8
$ClPO_2$	2.02/2.00	1.46/1.46	134.7/134.5
HPO_2	1.41/1.40	1.47/1.47	135.2/134.8
FPS_2	1.61/1.57	1.91/1.90	135.6/136.1
$ClPS_2$	2.07/2.04	1.92/1.91	132.7/134.0
HPS_2	1.41/1.41	1.92/1.92	133.6/134.3

Results and discussion

The computed structural results at the B3LYP/6-311+G* and CCSD(T)/cc-pVTZ levels of theory are listed in Table 1. The energy data are summarized in Tables 2–7. There, ε_i stands for the negative value of the orbital energy; in the notations for the MOs, *n* stands for the orbital space in the region of a specific atom; σ or π corresponds to the symmetry of the orbital with respect to the molecular plane; and the negative and positive signs indicate the out-of-phase and in-phase interactions among the orbitals, respectively. Photoelectron spectroscopy data from the literature for the ionization energies for $ClPO_2$ (9), $ClPS_2$ (9), and FPS_2 (10) have also been included in these tables.

The structural results

Both the ab initio values at the CCSD(T)/cc-pVTZ level and the DFT method at the B3LYP/6-311+G* level yield structural data similar to each other, as well as to the experimental results (9, 10, 23, 24). As is shown, the P—Y bond length is insensitive to the nature of X, in spite of the large differences in electronegativity among F, Cl, and H. In all three molecules, the P—O and P—S bond lengths are consistently around 1.46 and 1.91 Å, respectively, which are close to the typical P=O and P=S bond lengths (25). In contrast, the X—P bonds are predicted to be slightly shorter in XPO_2 than in XPS_2, with X being a halogen. This can be understood as the reduced back-electron donating from X to P in XPS_2, where P bears a less positive charge than in XPO_2. The substituent effect on the bond lengths supports a conventional hypervalent Lewis structure of these molecules.

Explicit computation of the ionization energies

Explicit computation of the energy difference between the neutral molecule and the radical cation in one of the four electronic states are listed under ΔSCF in Tables 2–7. As the first four frontier molecular orbitals (FMOs) in all cases are of the four different symmetries for a C_{2v} molecule, these four ΔSCF values, therefore, correspond to the four lowest ionization energies in a photoelectron spectrum.

Both (U)B3LYP/6-311+G* and (U)CCSD(T)/cc-pVTZ calculations yield very similar ΔSCF values. In most cases, the ΔSCF values vary by less than 0.2 eV. Among the total of 24 ΔSCF values, only four cases show a difference of greater than 0.3 eV.

Note: All values are in eV.

Furthermore, these ΔSCF values are also in reasonably good agreement with the experimental values, with a difference in the range of 0.1–0.6 eV. In all cases, when the difference is significant, i.e., 0.6 eV, the ΔSCF values are always less than the experimental IP values. This could be explained by the possible over-excitation of the electrons in the photoelectron experiments, as the radical cations are often formed in a vibrationally excited state. Therefore, extra energy is absorbed during the formation of the cation, resulting in a higher IP in comparison to the ΔSCF values, which corresponds to the energy difference between the two electronic states at the vibrationally ground states.

Orbital energies

The orbital energies for the FMOs containing all the valence electrons are listed for the halogen- and hydrogen-containing XPY_2 molecules. Overall, the two methods predict the same pattern for the layout of the relative energies of the FMOs. In only a few cases where the orbitals are very close in energy, the order of the highest occupied molecular orbital (HOMO) and HOMO-1 are switched between the two methods. For example, the HOMOs are of the B_2 symmetry for all six XPY_2 molecules according to the B3LYP calculations, but are predicted to be of A_2 symmetry for four out the six molecules by the CCSD(T) method. Nevertheless, the first and the third band were assigned to the ionization of a chalcogen–chlorine antibonding combination in the σ plane, and the second band was well-resolved with the antibonding combination of the $\pi_{P=O\ (S)}$. All of the next assignments are listed in Tables 2–7.

Consistent with the understanding that the atomic orbitals in O are more low-lying than in S, the FMOs are consistently lower in the XPO_2 molecules by around 2 eV in com-

parison to XPS_2. This is also consistent with the high reactivities reported for dithioxophosphoranes.

Data in Tables 2–7 show that the orbital energies obtained by the pure GGA BLYP method are consistently lower than the ΔSCF values by 3 to 4 eV, and those obtained by the hybrid method of B3LYP are lower by a less amount of around 2 eV. These results are consistent with the well-known fact that the DFT methods usually give orbital eigenvalues that are too high in energy and, therefore, give ionization energy values that are too low (26–28). In contrast, the HF values are all higher than the ΔSCF values by 1 to 2 eV. This is also understandable, as electron correlation is not involved in the HF method, the lack of consideration of the orbital relaxation in the cation results in the overestimate of the energy of the cation and, therefore, gives IP values that are too high.

Numerical corrections to the orbital energies

Table 8 lists the numerical corrections to the orbital energies so that the corrected orbital energies match with the IP values calculated by the ΔSCF method. They were obtained by taking the averaged differences between the orbital energies and the average of the two ΔSCF values, which are extremely close to each other. The size of the corrections is insensitive to the nature of X for the DFT methods, but demonstrates a slight variation in the ab initio method. The corrections are smaller in the sulfur series by 0.5–1.0 eV, in comparison with the oxygen analogs.

By using these corrections, we have attempted to evaluate the IP values for the IPs involving exciting lower-lying electrons. These results are listed under ΔSCF as values in parentheses in Tables 2–7. These values were taken as the averaged values of the orbital energies computed by the three methods, with the corresponding corrections included.

Table 8. Averaged numerical corrections (eV) to the orbital energies.

Molecules		BLYP	B3LYP	HF
XPO_2	$ClPO_2$	3.8	2.4	–1.5
	FPO_2	3.9	2.4	–1.9
	HPO_2	3.9	2.4	–1.9
XPS_2	$ClPS_2$	3.0	2.0	–0.9
	FPS_2	3.2	2.1	–0.8
	HPS_2	2.9	1.8	–1.3

As is shown, these high IP values match remarkable well with the experimental values, especially among those of relatively lower IP values. For instance, the first two IP values calculated with this approach vary between 0.1 and 0.4 eV from the experimental values.

Conclusions

We have shown that the theoretical IPs predicted by the ΔSCF method agree very well with the experimental values, both by ab initio and DFT methods at the (U)CCSD(T)/cc-

pVTZ and B3LYP/6-311+G* levels of theory, respectively. With these values, corrections to the orbital energies were evaluated and were therefore used to predict the IP values for all the valence electrons by the application of the Koopmans'and Janak's theorem. Re-evaluation of the experimental results occurred, and the numerical corrections from this study provide some general information that would allow for a better prediction of the IP values in systems where ΔSCF calculations are not practical.

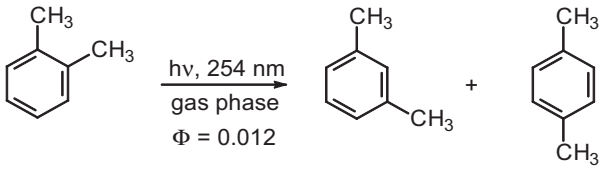
Steric effects in the phototransposition reactions of dialkylbenzenes

C.M. Gonzalez and J.A. Pincock

Abstract: The photochemistry, photophysical properties, and temperature dependence (–25 to +65 °C) of fluorescence by quantum yields and excited singlet state lifetimes in acetonitrile have been examined for three sets of dialkylbenzene derivatives: Set 1 — *ortho*-xylene (**10**), tetralin (**11**), and indan (**12**); Set 2 — 2,3-dimethylbenzonitrile (**9-23**), 5-cyanotetralin (**T-23**), and 4-cyanoindan (**I-23**); and Set 3 — 3,4-dimethylbenzonitrile (**9-34**), 6-cyanotetralin (**T-34**), and 5-cyanoindan (**I-34**). Phototransposition reactions occur for **10**, **9-23**, **9-34**, and **T-34**. Fitting of the temperature-dependent fluorescence data to an Arrhenius expression gave A and E_a values for all substrates studied except **I-23** and **I-34**. The fluorescence intensity of these two compounds was essentially independent of temperature. For the other compounds, the data revealed that the activation barrier separating the excited singlet state (S_1) from the reactive intermediate, a prefulvene biradical, was the important one in determining the reaction efficiency. The dominant mode of decay of the reactive intermediate was internal return to the starting material. Moreover, the general observation was made that nitrile substitution ortho to one of the alkyl groups in these dialkylbenzene derivatives reduced the rate at which they were converted to the reactive intermediate and, therefore, also the efficiency of the phototransposition reactions.

Key words: phototranspositions, substituted benzenes, temperature-dependent fluorescence, activation parameters.



Résumé : En se basant sur les rendements quantiques ainsi que les temps de vie de l'état singulet excité observés lors de réactions dans l'acétonitrile, on a étudié la photochimie, les propriétés photophysiques et la relation entre la température (–25 à +65 °C) et les rendements quantiques pour trois ensembles de dérivés benzéniques dialkylés, soit l'ensemble 1 formé d'*ortho*-xylène (**10**), de tétraline (**11**) et d'indane (**12**); l'ensemble 2 formé de 2,3-diméthylbenzonitrile (**9-23**), de 5-cyanotétraline (**T-23**) et de 4-cyanoindane (**I-23**); l'ensemble 3 formé de 3,4-diméthylbenzonitrile (**9-34**), de 6-cyanotétraline (**T-34**) et de 5-cyanoindane (**I-34**). Il se produit des réactions de phototransposition pour les composés **10**, **9-23**, **9-34** et **T-34**. Un ajustement des données de fluorescence influencées par la température à une expression d'Arrhenius permet de calculer les valeurs A et E_a pour tous les substrats étudiés, à l'exception de **I-23** et **I-34**. L'intensité de la fluorescence de ces deux composés est essentiellement indépendante de la température. Pour les autres composés, les données ont permis de déterminer que la barrière d'activation qui sépare S_1, l'état singulet excité, de l'intermédiaire réactif, un biradical préfulvène, est celle qui est importante dans la détermination de l'efficacité de la réaction. Le mode dominant dans la désactivation de l'intermédiaire réactif est le retour interne vers le produit de départ. De plus, on a observé que la présence d'un substituant nitrile en position ortho par rapport aux groupes alkyles de ces dialkylbenzènes provoque une réduction de la vitesse avec laquelle ils se transforment en intermédiaires réactifs et que, en conséquence, l'efficacité des réactions de phototransposition est aussi réduite.

Mots clés : phototranspositions, benzènes substitués, fluorescence dépendante de la température, paramètres d'activation.

[Traduit par la Rédaction]

Introduction

Phototransposition reactions were first reported in 1964 by Wilzbach and Kaplan (1) for the xylenes (eq. [1]) and by Burgsthaler et al. (2) for di-*tert*-butylbenzenes. It was demonstrated (3), by photolysis of [1,3,5-$^{14}C_3$]-mesitylene (eq. [2]), that these rearrangements occurred by a fundamental transposition of the ring carbons and not by alkyl group detachment. These, and related reactions, lead to a proposed mechanism involving formation of a prefulvene (or substituted prefulvene) biradical **1** from S_1 followed by ring closure to form benzvalene (or substituted benzvalenes) **2**, as outlined in Scheme 1 (path A) for benzene itself. Either opening of the benzvalene intermediate by cleavage of the

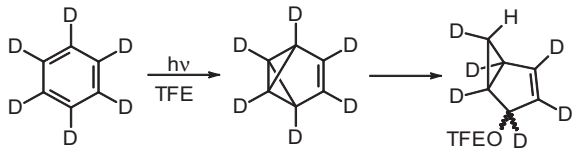


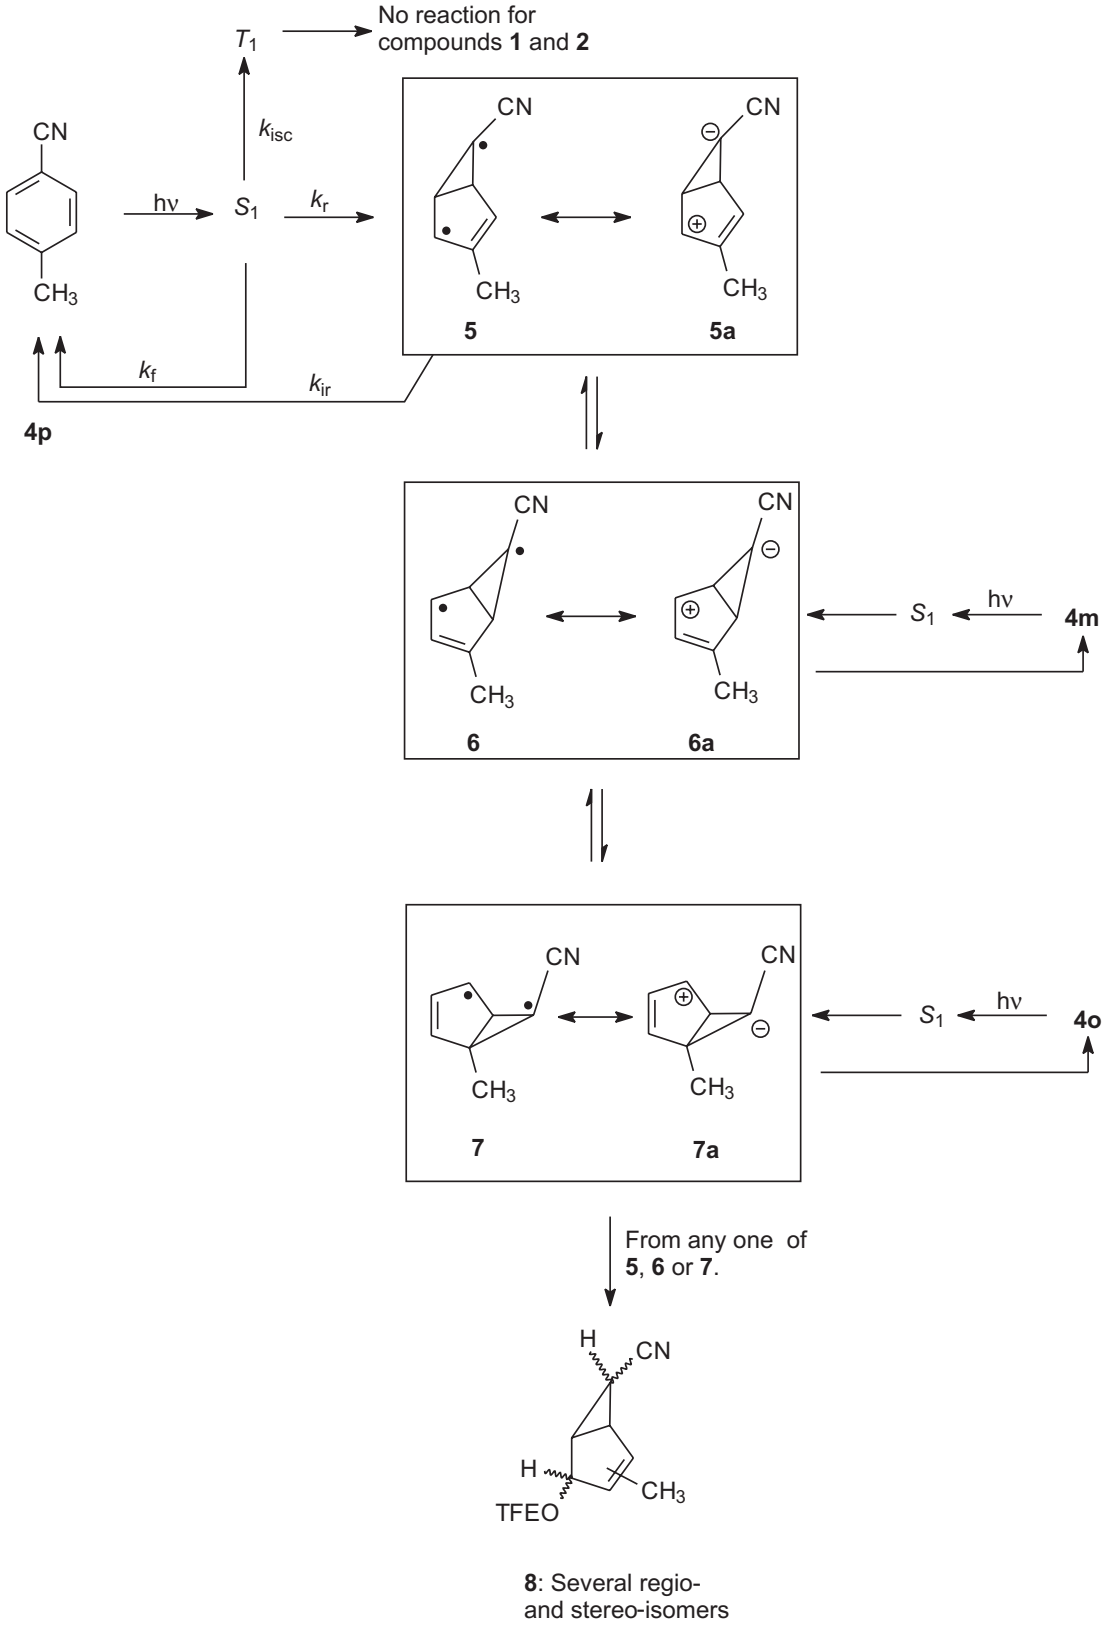
Scheme 1. Proposed mechanism for the photochemical formation of benvalene and the phototransposition reactions of benzene itself.

C1—C2 bond or a 1,5-migration of C1 in the prefulvene biradical (path B) leads to a rearranged biradical **3** that then returns to benzene but with interchange of two adjacent carbons, C1 and C6.

[2] 

This mechanism received strong support by the isolation of benzvalene from the photolysis of benzene (4) and by the formation of bicyclo[3.1.0]hexenyl derivatives (eq. [3]) for benzene-d_6 in 2,2,2-trifluoroethanol (TFE) on photolysis in alcohol solvents (5, 6). Research in this area up until 1980 has been the subject of several reviews (7–10).

[3] 



More recently, we have observed both phototransposition reactions in acetonitrile (AN) (11) and photoaddition reactions of TFE (12) for nitrile-substituted benzene compounds. Scheme 2 summarizes the results for the three isomers (para (**4p**), meta (**4m**), and ortho (**4o**)) of methylbenzonitrile. Photolysis of labelled 2,6-dideuterio-**4p** gave 5,6-dideuterio-**4m**, consistent with the nitrile-substituted carbon being the active one in the phototransposition reactions, that is, the critical intermediates are **5**, **6**, and **7**. This mechanism was strongly supported by isolation of the bicyclo[3.1.0]hexene adducts **8** (several stereo- and regio-isomers) by photolysis of **4p** in TFE, indicating that the intermediates may have considerable ionic character, as shown in **5a**, **6a**, and **7a**. This also implies that these intermediates are singlet states in agreement with the fact that they are formed from the excited singlet state (S_1) of starting materials. Substituted benzvalenes have not been included in this scheme because no evidence has been obtained for their formation as intermediates in these transformations. The more recent results on phototransposition and photoaddition reactions to substituted benzenes have also been recently reviewed (13, 14).

Further support for the importance of the nitrile-substituted carbon came from the photochemistry of the set of six dimethylbenzonitriles **9-34**, **9-23**, **9-26**, **9-35**, **9-24**, and **9-25** (15). The results indicated that these compounds are divided into two independent triads as shown in eqs. [4] and [5]. For instance, photolysis of **9-34** in AN gave only **9-23** and **9-26** (eq. [4]), with no mixing with the other triad. This result is easily explained if the phototransposition reactions involve the nitrile-substituted carbon exchanging position with either of its two neighbours.

During these studies, we observed that substrates with methyl groups ortho to the nitrile-substituted carbon were quite unreactive. For instance, the relative reactivity of **4p**:**4m**:**4o** = 32:4:1 and **9-34**:**9-23**:**9-26** ≅ 50:1:0. These observations suggested that the rate-determining step in these photoreactions was the conversion of S_1 of the substrate to the prefulvene biradical and that this step was slowed by the presence of a methyl group occupying a bridgehead position in the biradical. However, as shown in Fig. 1 for **4p**, several

barriers on the reaction coordinate diagram need to be considered: first, the one from S_1 to intermediate **5**, and second, the ones that allow conversions among **5**, **6**, and **7**. Which of these barriers is more important can, at least partially, be assessed by examining the barrier separating S_1 and **5**.

To probe this question, we have examined the photochem-

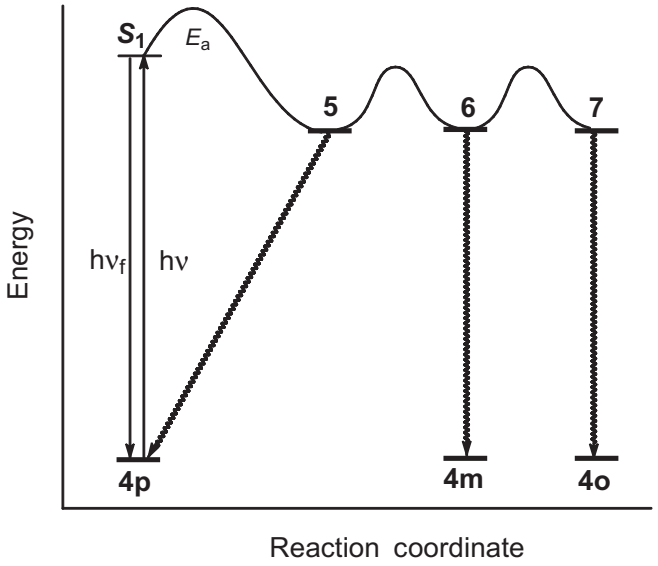
istry and photophysics of the three sets of substrates: Set 1 — *ortho*-xylene (**10**), tetralin (**11**), and indan (**12**); Set 2 — 2,3-dimethylbenzonitrile (**9-23**), 5-cyanotetralin (**T-23**), and 4-cyanoindan (**I-23**); and Set 3 — (3,4-dimethylbenzonitrile (**9-34**), 6-cyanotetralin (**T-34**), and 5-cyanoindan (**I-34**).[2] Set 1 was included to provide results for the cases without the nitrile group and because some previous literature values are available for comparison. We expected that the geometric changes required to form the bicyclic diradical intermediate (the important one in the phototransposition reactions) would be inhibited moving from left to right in each set.

Results and discussion

Synthesis of compounds



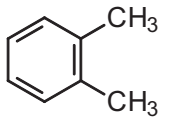
Compounds **10**, **11**, and **12** are commercially available. Compounds **9-23** and **9-34** were prepared in our laboratory previously (15). Compounds **T-23**, **I-23**, and **I-34** were synthesized in the same way by Sandmeyer reaction with CuCN from the corresponding amines, as described previously (16, 17). The amine precursor for **T-34** was prepared by nitration of tetralin, reduction of the mixture of 5- and 6-nitrotetralin to the mixture of amines with Sn–HCl, and separation of the amines by column chromatography with Florisil and 1% ethyl acetate in hexanes as the eluant.

Photolysis of compounds

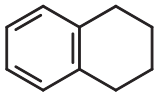
Set 1

The phototransposition reactions of **10** have been described in the early literature (1, 18) and have been repeated in AN by Pincock and co-workers more recently (13). The ratio of meta to para isomers is 11:1 (obtained at very low conversion), indicating that both one-step and two-step phototranspositions are occuring in the primary photochemical event. This result is explained by rapid interconversion of the reactive intermediates, as in Scheme 2 for the methylbenzonitriles. Moreover, the addition of TFE to give the bicyclo[3.1.0]hexene addition products is efficient (13). Both **11** and **12** are photochemically unreactive in AN. However, any phototransposition reaction occurring would be undetectable.

Fig. 1. Proposed reaction coordinate diagram for the phototransposition reaction of methylbenzonitriles **4p** to **4m** and **4o**.



Set 2



As described in the Introduction, **9-23** is very unreactive to phototransposition in AN and is only very slowly converted at 25 °C to a mixture of **9-34** (2.8%) and **9-26** (2.3%) after 760 min of irradiation. Photolysis at 50 °C is somewhat more efficient, giving 10.2% of **9-23** and 1.3% of **9-26** after the same length of time, indicating that the phototransposition reaction is an activated one as expected. Neither **T-23** nor **I-23** show any conversion to the possible transposi-

[2] The numbering system used is chosen to indicate the analogy of the position of the nitrile substituent relative to the two alkyl groups in each set with the acyclic compounds, *ortho*-xylene (**10**), 2,3-dimethylbenzonitrile (**9-23**), and 3,4-dimethylbenzonitrile (**9-34**) being the basis for comparison.

tion products **T-34** or **I-34**, respectively, in AN even on irradiation at 50 °C.

Set 3

In contrast to Set 2, the acyclic compound, **9-34**, is quite reactive. After 760 min of irradiation in AN at 25 °C, only 40% remained, giving **9-23** (53%) and **9-26** (7%). Surprisingly, a very similar conversion was obtained after the same time of irradiation at 50 °C. The cyclic tetralin **T-34** also reacts in AN giving the only possible phototransposition product **T-23**, although not quite as efficiently as for **9-34** with 36% conversion after 750 min irradiation. After 2500 min of irradiation, a photostationary state is reached with the ratio of **T-34**:**T-23** = 41:59. The indane derivative **I-34** again does not undergo phototransposition in AN or photoaddition in TFE, even at 50 °C.

Photophysical properties of the compounds of Sets 1–3

Values of λ_{max} (nm), ε ((mol/L)$^{-1}$ cm^{-1}), $E_{0,0}$ (kJ mol^{-1}, from overlap of the fluorescence and excitation spectra), Φ_f, τ (from nanosecond single photon counting), k_f (from $k_f = \Phi_f/\tau$), and k_f^{calc} (from eq. [6], the Strickler–Berg relationship (19), and $k_t = 1/\tau$) are given in Table 1.

$$[6] \qquad k_f = 2.88 \times 10^{-9} n^2 < \bar{\upsilon}_f^{-1} > \int \varepsilon d \ln \bar{\upsilon} = n^2 k_f^0$$

In eq. [6], the general theoretical relationship between the radiative lifetime ($\tau_f = 1/k_f$) and the absorbance spectrum, n is the refractive index of the solvent, υ_f is the expectation value for the frequency of the fluorescence spectrum, and the final term is the integrated molar absorptivity over the S_0 to S_1 transition in the absorbance spectrum. The constant gives k_f in units of s^{-1} if the frequency values are expressed in wavenumber (cm^{-1}) and molar absorptivity ε in the usual units ((mol/L)$^{-1}$ cm^{-1}). This equation is derived on the basis of the oscillator strength model and the important assumption that the excited singlet state and the ground state have similar geometries. The agreement in Table 1 between k_f (from experimental measurement of Φ_f and τ) and k_f^{calc} is excellent and confirms that the singlet excited state of each of these compounds is a spectroscopic minimum with little change in geometry from the ground state. We have made similar observations in the past for the use of eq. [6] for aryl-substituted methyl, allyl (20), and adamantyl (21) ethers. The one exception in Table 1 is for **I-23** with k_f^{calc} (3.8×10^7 s^{-1}) significantly larger than the experimental value (2.6×10^7 s^{-1}). However, the ε value, which is directly related to the calculated value of k_f by eq. [6], also seems anomalously high. Although we have rechecked the ε value several times for this compound, including with a repurified sample, and both NMR spectra and GC analysis indicated no

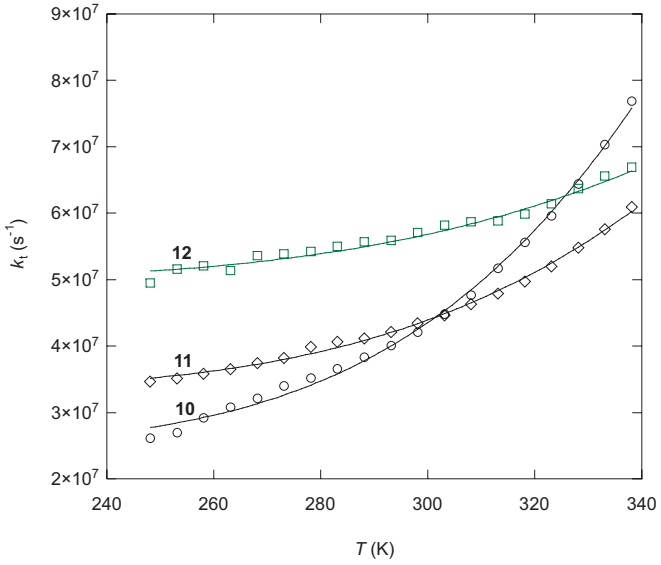
impurities, we suspect that this value is incorrect. The important conclusion reached from the data in Table 1 is that for these nitrile-substituted benzene derivatives, the photophysical properties (absorption spectra, excited singlet state energy, fluorescence quantum yields, and fluorescence rate constants (k_f)) are essentially the same for each compound of Sets 2 and 3.

Measurement of rate constants of reaction of S_1 by the temperature dependence of fluorescence

Recently, we have shown that the measurement of excited singlet state lifetimes (τ) or quantum yields of fluorescence (Φ_f) as a function of temperature provide a simple method for obtaining rate constants of reaction and other modes of decay of the excited singlet states of substituted benzene derivatives (22, 23). This method has also been used very effectively by the laboratories of Lewis for arylalkenes (24) and Zachariasse for arylamines (25).



The basic concept is described by eqs. [7] and [8], where the total rate constant of decay of the excited singlet state (k_t) is the sum of all the rate constants of the individual processes: fluorescence (k_f), internal conversion (k_{ic}), intersystem crossing (k_{isc}), and the reaction itself (k_r). Equation [8] results from the assumptions that nonactivated internal conversion for substituted benzenes is very slow (~10^3 s^{-1}) (26), and that k_r is the only activated process and follows an Arrhenius expression. From Scheme 2 and Fig. 1, the k_r process leads to a reactive intermediate, which may proceed to rearranged products or return to S_0 by internal return (k_{ir}). This latter process has the same outcome as internal conversion but does not occur directly from S_1 and, therefore, is part of k_r. This possibility demonstrates that the measurement of quantum yields of formation of products cannot, in general, give reliable values of k_r.

$$[7] \qquad k_t = k_f + k_{ic} + k_{isc} + k_r$$

$$[8] \qquad k_t = k_f + k_{isc} + A \exp(-E_a/RT)$$

Values for k_t as a function of temperature for applying eq. [8] have normally been obtained by measuring S_1 lifetimes (τ_s), but this is a very time-consuming process. Nevertheless, we used that method for Sets 2 and 3, and the results are given in Tables S2 and S3.[3] A more rapid method is to use τ_s and Φ_f at 25 °C (Table 1) to obtain $k_f = \Phi_f/\tau_s$. Then measurement of relative fluorescence quantum yields over a wide temperature range (–25 to 65 °C) gives k_t (t °C) = [k_t (25 °C) Φ_f (25 °C) / Φ_f (t)]. This method assumes that k_f is a constant, independent of temperature. The values for the compounds of Set 1 were obtained by this method and are given in Table S1.[3]

Fig. 2. Fits of k_t vs. T according to eq. [8] for the compounds of Set 1.

Plots of k_t vs. T are shown in Figs. 2, 3, and 4 for Sets 1, 2, and 3, respectively. The plots for the two cyanoindan derivatives **I-23** (Fig. 3) and **I-34** (Fig. 4) are different from the rest, as they have very low, but negative, slopes. The fits shown in Figs. 2–4 are to a linear expression. Considering the experimental scatter, these slopes may not be significantly different from zero. However, negative slopes are, in

fact, expected, even if all of the rate constants of eq. [8] are temperature independent. The reason for this is given by eq. [9], where n is the refractive index of the solvent and n^0 is the refractive index of vacuum. Therefore, k_f should decrease slightly with temperature because n also decreases slightly with temperature (27). Equation [9] has been used previously to show that k_f^0 is independent of temperature for aromatics like benzene, toluene, *ortho*-xylene, and tetralin in hydrocarbon solvents (28). For other compounds studied with significant positive dependence of k_t with temperature, the very small negative changes in k_f with temperature were ignored and k_f was assumed to be constant.

$$[9] \qquad k_f = k_f^0 n^2$$

The more significant point to make about the plots for these two cyanoindan derivatives is that the plots have slopes that are essentially zero. Therefore, the activation energy for any aromatic ring deformation that could lead to reactive intermediates like the bicyclic structures of Scheme 2 must be too high over the temperature range examined for those processes to compete with fluorescence and intersystem crossing for deactivation of S_1. However, from the data in Table 2, the k_f values for each compound of Sets 2 and 3 are essentially the same. Therefore, the higher values of k_t for

© 2006 NRC Canada

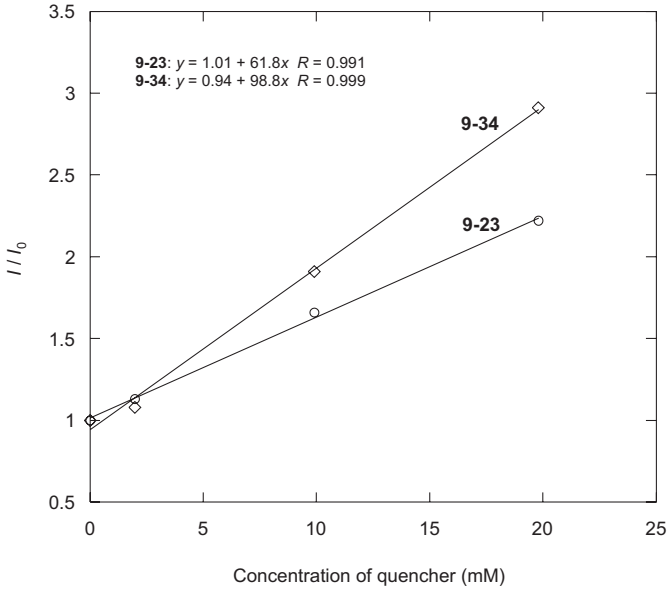
compounds **I-23** and **I-34** at the lower temperatures reflect faster rates of intersystem crossing for the indan derivatives compared with their tetralin and acyclic analogues for each set. We have no explanation for this observation.

For the remaining compounds studied, the plots have obvious upward curvature, some more than others. Excellent fits of this data to eq. [8] were obtained ($r > 0.988$ in all cases), giving an intercept equal to $k_f + k_{isc}$ (assuming $k_{ic} = 0$) and Arrhenius A and E_a values from the curved portion. These values are given in Table 2. Previous literature values (28) for k_t obtained from –70 to +80 °C in methylcyclohexane for **10** gave $k_f + k_{isc} = (1.5 \pm 0.1) \times 10^7$ s^{-1}, $A = (2.1 \pm 1.8) \times 10^{11}$ s^{-1}, and $E_a = (25 \pm 3)$ kJ/mol in good agreement with our values in AN: $k_f + k_{isc} = (2.5 \pm 0.1) \times 10^7$ s^{-1}, $A = (1.4 \pm 0.5) \times 10^{11}$ s^{-1}, and $E_a = (22 \pm 1)$ kJ/mol. An important observation from similar measurements for benzene (28) is that although the k_f value obtained ((0.16 ± 0.01) $\times 10^7$ s^{-1}) is independent of the solvent, Φ_f (0.06, 0.05, 0.04, 0.029, and 0.025) and τ (34, 30, 28, 20, and 15 ns) decrease significantly as the solvent polarity increases (cyclohexane, methylcyclohexane, ethanol, methanol, and acetonitrile). The reason for this must be that k_r, the rate of formation of the prefulvene biradical **1** in Scheme 1, increases with solvent-ionizing ability. We have observed the same effect for the methylbenzonitriles (23) and arylboronate esters (29) on going from AN to TFE.

Surprisingly, the plot for indan itself (Fig. 2), in contrast to the other two indane derivatives with the nitrile substitutent, does show a slight upward curvature indicating a temperature-dependent process is occurring. However, in a recent publication (23), we used artificial data to assess the reliability of the temperature vs. fluorescence method for obtaining rate constants of reaction for S_1. The conclusion reached from our experimental method, which involves a limited temperature range (–25 to +65 °C), was that reliable values of k_r can only be obtained if $A > 0.5 \times 10^{11}$ s^{-1} and $E_a <$ 25 kJ/mol in order that the k_r process contributes significantly enough over the temperature range examined to compete with the other modes of deactivation. Zachariasse and co-workers (25) have overcome this problem by measuring Φ_{isc} (by laser flash photolysis of triplet yields), τ, and Φ_f from –151 to +284 °C for aminobenzonitriles in hydrocarbon solvents (25*d*). The low temperature data was analyzed to determine the temperature dependence of intersystem crossing because k_r (which, in the absence of any observable photochemical conversion, is described as an activated internal conversion (k_{ic})) did not contribute significantly to the overall rate of decay of the excited singlet state. At higher temperatures, the internal conversion process became the dominant one and its activation parameters could then be separated from those for intersystem crossing. Unfortunately, we cannot make measurements over such a wide temperature range because of the limitations of our instruments and quartz cuvettes. Nevertheless, we have shown that this method provides values for rate constants and quantum yields for the reactions of excited singlet states for benzene, toluene, and *ortho*-xylene that agree with those obtained by much more difficult experimental methods, particularly for intersystem crossing (22).

On this basis, the data for **12** and **T-23** (Table 2) do not satisfy the criteria that we have established. **T-23** is particularly obvious because of the very low A and E_a values obtained. Similar low values of A (~10^8 s^{-1}) and E_a (<10 kJ/mol) have been reported previously for activated intersystem crossing (23, 25). Therefore, the k_r value obtained from eq. [8] for the tetralin **T-23** is expected to be the contribution that activated k_{isc} makes to intersystem crossing. At room temperature for **T-23**, the total rate of intersystem crossing will then be $k_{isc} + k_r = 7.9 \times 10^7$ s^{-1} and $\Phi_{isc} = 0.76$, the remainder of the deactivation of S_1 being fluorescence, $\Phi_f = 0.24$. The activation parameters for **12** suggest that some activated bond deformation is leading to a low value of k_r; a surprising observation in view of the complete lack of reactivity of the cyanoindan derivatives **I-23** and **I-24**. However, photolysis at 254 nm of even the more highly strained benzocyclobutene yields two bicyclo[3.3.0]octatriene (also known as "dihydropentalenes") derivatives and the proposed mechanism included prefulvene (also known as "prebenzvalenes") as the critical intermediates (30).

Reliable values of k_r should be obtained for **10**, **11**, **9-23**, **9-34**, and **T-34**. The first conclusion to be reached, one that reinforces our previous reports (22, 23), is the general one that although the k_r process results in significant quantum yields, the actual quantum yields of reaction are considerably smaller. Therefore, internal return of the prefulvene biradical **1** (Scheme 1) is one of the dominant modes of deactivation of S_1 for substituted benzenes.



Also, the effect of ortho nitrile substitution is very evident for the tetralin derivatives, with both the unsubstituted case **11** and **T-34** having similar rates of reaction (1.0 and 1.5 × 10^7 s^{-1}, respectively); whereas for **T-23** this pathway is completely shut off and only intersystem crossing occurs. The preferred reaction pathway for nitrile-substituted benzene rings involves an intermediate with the nitrile group at C6 of the bicylic intermediate (Scheme 2). This geometry change looks possible for formation of **13** from **T-34**, but because of bridgehead strain, improbable for formation of **14** from **T-23**. For the acyclic nitrile-substituted cases, a similar steric effect is present but much less severe, k_r for **9-34** (5.0×10^7 s^{-1}) is only a factor of five times greater than for **9-23** (1.0×10^7 s^{-1}), in agreement with the observation from the preparative scale photochemistry that **9-34** is converted efficiently to **9-23**, but **9-23** is converted very slowly, even at 50 °C, back to **9-34**.

Triplet state reactivity of 9-23 and 9-34

Because of the very high quantum yields of intersystem crossing of 0.66 and 0.40 for **9-23** and **9-34**, respectively, the possibility of triplet state (T_1) reactivity must be considered. Previously, we have shown that the methylbenzonitriles **4p** and **4m** do not react from the triplet state and, therefore, S_1 was the reactive state for their phototransposition reactions. This was done by selective quenching of T_1 by 2,3-dimethyl-1,3-butadiene. The fluorescence of AN of **9-23** and **9-34** is also quenched by this diene giving Stern–Volmer ($k_q\tau$) slopes of 61.8 and 99.0 (mol/L)$^{-1}$, respectively (Fig. 5), and k_q values of 6.6 and 11.1×10^9 (mol/L)$^{-1}$ s^{-1}, respectively, close to the diffusional limit. Therefore, at a quencher concentration of 1.0×10^{-3} mol/L, the percentage of excited singlet states that are being quenched is 6% for **9-23** and 11% for **9-34**. Making the usual assumption that T_1 will be much longer lived than S_1 and that the quenching will also be dif-

© 2006 NRC Canada

Fig. 5. Stern–Volmer plots for the fluorescence quenching of **9-23** and **9-34** by 2,3-dimethyl-1,3-butadiene.

fusion controlled, the percentage of triplet states being quenched should be much higher. Irradiation of either **9-23** or **9-34** under these conditions resulted in only minor decreases in the efficiencies of the phototransposition reactions, suggesting that T_1 is, at most, a minor contributor to the phototransposition reactions of these two substrates. Irradiation of **9-34** at a higher concentration of the diene gave cycloaddition products (*m*/*z* 213 by GC–MS) as expected for quenching of the excited singlet states of substituted methylbenzonitriles by dienes (11).

Conclusions

The results presented clearly show that for compounds that undergo phototransposition reactions, significant barriers exist on the surface that connects S_1 to the reactive intermediate (E_a in Fig. 1). The major pathway for reaction of this substituted prefulvene biradical is return to the starting material by cleavage of the bond that was formed (meta bonding) from S_1. The first formed reactive intermediate equilibrates with its isomeric forms, which allows phototransposition to occur (Scheme 2). The barriers on this surface will not be easy to determine experimentally, but perhaps can be modelled by high level computational methods.

As expected, the effect of incorporating the substituted benzene into a bicyclic structure, as in the tetralin and indan derivatives, decreases the efficiency of formation of the reactive intermediate, particularly for the cyanoindans, **I-23** and **I-34**. Ortho substitution of the nitrile group to the alkyl groups also decreases reactivity for **9-23** and particularly for cyanotetralin, **T-23**.

Experimental

General procedures

Routine proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (NMR) spectra were obtained in $CDCl_3$ on a Bruker AC 250 F NMR spectrometer in automation mode. GC–MS analyses were performed on a PerkinElmer Autosystem XL instrument with a mass selective detector. The column used was a Supelco 30 m × 0.25 mm MDN-5S 5% phenyl methylsiloxane, film thickness 0.50 mm, temperature programmed: 60 °C for 1 min; 20 °C per minute to 240 °C; and 240 °C for 10 min. GC-FID analyses were done on the same instrument. Mass spectral data are reported in units of mass over charge (*m*/*z*) for all values between 50 and the molecular ion if greater than 10% of the base peak. Intensities are reported as a % of the base peak. HR-MS were obtained on a CEC 21-110 instrument with a resolution of 5×10^3 to 10×10^3. The acetonitrile (HPLC grade, Caledon, Georgetown, Ontario) used for photochemical reactions and fluorescence measurements was used as received.

Preparation of compounds

ortho-Xylene (**10**), tetralin (**11**), and the benzonitriles (**9-23** and **9-34**) were obtained from Aldrich and purified by bulb-to-bulb distillation. Indan (95%, Sigma-Aldrich, Oakville, Ontario) was purified by silica gel chromatography using hexanes as the solvent, followed by bulb-to-bulb distillation.

The cyanotetralins (**T-23** and **T-34**) and cyanoindans (**I-23** and **I-34**) have all been reported previously (16, 17). All were prepared by diazotization of the corresponding amines, followed by reaction with CuCN. All four of these compounds were at least 99% pure (GC-FID). UV spectra are reported in Table 1. Other spectral data, not reported in the initial publications describing their preparation, are given in the following.

5-Cyanotetralin (T-23)

^{1}H NMR ($CDCl_3$) δ: 7.43 (1H, d, *J* = 7.5 Hz), 7.27 (1H, d, *J* = 8.0 Hz), 7.16 (1H, t, *J* = 7.5 Hz), 2.95 (2H, t, *J* = 6.0 Hz), 2.78 (2H, t, *J* = 6.0 Hz), 1.89–1.79 (4H, m). ^{13}C NMR ($CDCl_3$) δ: 22.5, 22.5, 28.0, 29.7, 112.7 (-CN), 118.2, 125.8, 130.2, 133.6, 138.7, 140.8. Irradiations

A solution of ~100 mg of the appropriate compound in 100 mL of acetonitrile was purged with nitrogen and then irradiated in a Rayonet photochemical reactor using 16 lamps (75 W, 254 nm). The temperature was controlled at the desired value by circulating water in an immersion tube. Reaction progress was monitored by GC.

Absorbance measurements

Absorbance spectra were recorded at 1 nm resolution using a Cary 100 UV–vis spectrometer thermostatted at 25 °C. The integrated spectra needed to obtain k_f values from eq. [6] were obtained by summing the 1 nm incremental areas (the absorbance values converted to ε by dividing by the molar concentration) over the complete absorption band. These areas are somewhat uncertain at the short wavelength end because of the overlap with the long wavelength tail of the S_2 band so that the absorbance does not reach zero. The wavelength for the minimum in absorbance was used as the cut-off point for the S_1 band.

Fluorescence measurements

All samples were degassed by three freeze–pump–thaw cycles and then thermostatted at 25 °C. Fluorescence intensity measurements were done using a PTI-210M fluorescence spectrometer with dual model 101 monochromators, a 75W xenon lamp, and a model 814 photomultiplier detector. Corrected spectra were obtained. Fluorescence quantum yields were determined using solutions of matched absorbance by comparison with the known fluorescence quantum yield for anisole of 0.29 (31) in cyclohexane. As a result of uncertainties in the standards and accumulation of errors, absolute values at 25 °C are probably accurate to 10%. Relative values are probably considerably better. The expectation values necessary for calculating the k_f values from eq. [6] were obtained by summing the 1 nm incremental areas over the complete emission band. For temperature-dependent quantum yield measurements, a 1 cm cuvette was thermostatted with stirring in a cuvette holder equipped with a Quantum Northwest TLC 50 temperature controller, which allows relative fluorescence measurements at 5 °C intervals from –25 to 65 °C in acetonitrile over a 3 h time span. The stability of the lamp over this time period was normally confirmed by rerunning the fluorescence spectrum at 25 °C at the end. The values of ϕ_f as a function of T were obtained this way for **10**, **11**, and **12** and used to calculate k_t (see previous text and Table S1).[3]

Singlet lifetimes were measured by monitoring fluorescence decay using a PRA time-correlated single photon counting apparatus with a hydrogen flash lamp of pulse width about 1.8 ns. The temperature was controlled (±0.1 °C) by circulating methanol from an external constant-temperature bath and checked by measurement in the fluorescence cuvette with a digital thermocouple probe. The values of $k_t = 1/\tau$ reported for **9-23**, **I-23**, **T-23**, **9-34**, **T-34**, and **I-34** were obtained this way (see Tables S2 and S3).[3]

Preparation, spectroscopic characterization, and deprotonation reactions of $Si(NHR)_4$ (R = *i*-Pr, *t*-Bu, *p*-tolyl) — EPR identification of persistent radicals formed by oxidation of polyimidosilicates

Andrea F. Armstrong, Tristram Chivers, and Jari Konu

Abstract: Treatment of $Cl_2Si(NH\text{-}t\text{-}Bu)_2$ (**6a**) with *t*-$BuNH_2$ in boiling toluene yields trisamino(chloro)silane $ClSi(NH\text{-}t\text{-}Bu)_3$ (**7**); formation of the tetraaminosilane $Si(NH\text{-}t\text{-}Bu)_4$ is not observed. The reaction of $SiCl_4$ with 4 equiv. of LiNHR produces the corresponding tetraaminosilanes $Si(NHR)_4$ (**2a**, R = *i*-Pr; **2b**, R = *t*-Bu; **2c**, R = *p*-tol) in good yields. When the sterically demanding adamantyl derivative LiHNAd is employed, only disubstitution occurs to form $Cl_2Si(NHAd)_2$ (**6b**). Oxidation of the dimeric imidosilicates $\{Li_3[Si(NR)_3(NHR)]\cdot THF\}_2$ (**3a**, R = *i*-Pr; **3b**, R = *t*-Bu) with 1 mol of iodine produces the persistent radicals $\{Li_2[Si(NR)_3(NHR)]\cdot LiI\cdot 3THF\}^{\cdot}$, which, on the basis of EPR spectra, exist as SiN_3Li_3I cubes in solution. The spirocyclic tetraimidosilicate monoanion radical $\{[(THF)_2Li(\mu\text{-}Nnaph)_2Si(\mu\text{-}Nnaph)_2Li(THF)_2]\}^{-\cdot}$ (**10**) is formed upon oxidation of the tetralithiated species $\{Li_4[Si(Nnaph)_4]\cdot 4Et_2O\}$ (**1**) and $\{[Li(12\text{-crown-}4)]_2[(Et_2O)_2Li(\mu\text{-}Nnaph)_2Si(\mu\text{-}Nnaph)_2Li(Et_2O)_2]\}$ (**8**) with iodine. The spectroscopic characterization of hexa(amino)disiloxane $(t\text{-}BuNH)_3SiOSi(NH\text{-}t\text{-}Bu)_3$ (**14**) formed from the reaction of $Cl_3SiOSiCl_3$ with 6 equiv. of LiNH-*t*-Bu is discussed.

Key words: imido ligands, silicate, radicals, EPR spectra, lithium.

Résumé : Le traitement du $Cl_2Si(NH\text{-}t\text{-}Bu)_2$ (**6a**) par de la *t*-$BuNH_2$ dans du toluène bouillant conduit à la formation de trisamino(chloro)silane, $ClSi(NH\text{-}t\text{-}Bu)_3$ (**7**); on n'a pas observé de formation du tétraaminosilane, $Si(NH\text{-}t\text{-}Bu)_4$. La réaction du $SiCl_4$ avec quatre équivalents de LiNHR conduit à la formation des tétraaminosilanes correspondants, $Si(NHR)_4$ (**2a**, R = *i*-Pr; **2b**, R = *t*-Bu; **2c**, R = *p*-tol), avec de bons rendements. Lorsqu'on effectue la réaction avec le LiHNAd, un dérivé de l'adamantane dont les contraintes stériques sont plus grandes, on ne se produit qu'une disubstitution conduisant à la formation du $Cl_2Si(NHAd)_2$ (**6b**). L'oxydation des imidosilicates dimères $\{Li_3[Si(NR)_3(NHR)\cdot THF\}_2$ (**3a**, R = *i*-Pr; **3b**, R = *t*-Bu) avec une mole d'iode conduit à la formation des radicaux persistants $\{Li_2[Si(NR)_3(NHR)\cdot LiI\cdot 3THF\}^{\cdot}$ qui, sur la base de leurs spectres RPE, existeraient en solution sous la forme de cubes de SiN_3Li_3I. L'oxydation par de l'iode des espèces tétralithiées $\{Li_4[SiNnaph)_4]\cdot 4Et_2O\}$ (**1**) et $\{Li[12\text{-couronne-}4]_2[(Et_2O)_2Li(\mu\text{-}Nnaph)_2Si(\mu\text{-}Nnaph)_2Li(Et_2O)_2]\}$ (**8**) conduit à la formation du radical monoanion tétraimidosilicate spirocyclique $\{[(THF)_2Li(\mu\text{-}Nnaph)_2Si(\mu\text{-}Nnaph)_2Li(THF)_2]\}^{-\cdot}$ (**10**). On discute de la caractérisation spectroscopique de l'hexa(amino)disiloxane $(t\text{-}BuNH)_3SiOSi(NH\text{-}t\text{-}Bu)_3$ (**14**) qui se forme par réaction du $Cl_3SiOSiCl_3$ avec six équivalents de LiNH-*t*-Bu.

Mots clés : ligands imido, silicate, radicaux, spectre RPE, lithium.

[Traduit par la Rédaction]

Introduction

An ongoing area of research in main group chemistry is the synthesis and characterization of imido $[NR]^{2-}$ (R = alkyl, aryl) analogues of common *p*-block oxoanions such as sulfate and phosphate (1–3). The chemistry of the tetraimidophosphate trianion $[P(NR)_4]^{3-}$, formally isoelectronic[2] with orthophosphate $[PO_4]^{3-}$, has been extensively explored. Both main group (4–7) and transition-metal (8) derivatives are known; the coordination behaviour (6, 7) and radical chemistry (6, 7, 9, 10) of this important member of the family of polyimido anions have been examined.

In contrast, the chemistry of the isoelectronic tetraimidosilicate tetraanion ($[Si(NR)_4]^{4-}$) remains essentially unknown; only one example, $\{Li_4[Si(Nnaph)_4]\cdot 4Et_2O\}_x$ (**1**), has been characterized (11). This naphthyl derivative was originally targeted because, unlike the majority of primary amines, 1-aminonaphthalene can be doubly deprotonated

[2]The original definition of "isoelectronic" (isosteric) compounds restricts the term to species having the *same number of atoms* and the same number of electrons (I. Langmuir. J. Am. Chem. Soc. **41**, 1543 (1919)). Thus, according to this definition, N^{3-} is isoelectronic with O^{2-}. However, nitrides are compositionally different to oxides as a result of the different charges on the anions.

Fig. 1. Solid-state structures of **3a**, **4**, and **13**. The *i*-Pr (**3a**), *t*-Bu (**4a**, **13**), and Ad (**4b**) groups are omitted from cluster N atoms for clarity.

3a **4** **13**

[1] $SiCl_4 + 4$  $\xrightarrow[-4\ LiCl]{Et_2O} \{Li_4[Si(Nnaph)_4]\bullet 4Et_2O\}$

(12, 13). The metathesis reaction between dilithiated amide (Li_2Nnaph) and silicon tetrachloride ($SiCl_4$) in diethyl ether proceeds with the elimination of lithium chloride (LiCl) to yield **1** (eq. [1]) (11).

Unfortunately, it has not proven possible to grow crystals of **1** that are suitable for X-ray analysis; in consequence, the solid-state structure of **1** remains unknown. In an effort to structurally characterize a tetraimidosilicate, the preparation of the isopropyl analogue of **1** was also attempted by the reaction of tetraaminosilane $Si(NH\text{-}i\text{-}Pr)_4$ (**2a**) with 4 equiv. of *n*-butyllithium. Regardless of the reaction conditions, only trilithiation was achieved, resulting in the isolation of $\{Li_3[Si(N\text{-}i\text{-}Pr)_3(NH\text{-}i\text{-}Pr)]\cdot THF\}_2$ (**3a**) (11). This behaviour is reminiscent of observations reported for trisamino(imino)phosphoranes, for which only twofold deprotonation of $(i\text{-}PrNH)_3PNSiMe_3$ is observed under a variety of reaction conditions (10). However, it should be noted that the reaction of the *tert*-butyl analogue $(t\text{-}BuNH)_3PNSiMe_3$ with *n*-BuLi yields the tetraimidophosphate $[P(N\text{-}t\text{-}Bu)_3(NSiMe_3)]^{3-}$ via triple deprotonation under mild reaction conditions (5). Thus, it is of interest to attempt the tetralithiation of $Si(NH\text{-}t\text{-}Bu)_4$ (**2b**) to determine whether a similar increase in reactivity over **2a** is observed.

An examination of the extant literature (14) regarding **2b** revealed that no practical synthetic route to this compound has been reported, though **2a** is well-known and can be prepared by the reaction of excess isopropylamine with $SiCl_4$ (15). However, only a 6% yield of the desired product **2b** is recovered from the analogous reaction of $SiCl_4$ with excess *tert*-butylamine, even at elevated reaction temperatures (14). Thus, the synthesis of **2b** has been reinvestigated, as only minimal experimental detail is available from previous work.

The isoelectronic relationship between the tetraimidosilicate tetraanion $[Si(NR)_4]^{4-}$ of **1** and the tetraimidophosphate trianion $[P(NR)_4]^{3-}$ is especially intriguing in light of the remarkably stable radicals formed upon oxidation of $\{Li_3[P(NR)_3(NSiMe_3)]\}_2$ (**4a**, R = *t*-Bu; **4b**, R = Ad) with halogens (9, 10). As the synthesis of radicals of the p-block elements is a topical area of research (16), it will, thus, be of interest to examine the one-electron oxidation of **1** to see if similar behaviour is observed. Furthermore, the fact that **3a** is isostructural with **4** (Fig. 1) suggests that the oxidation of **3a** may well result in the formation of cubic radicals that are isostructural with the tetraimidophosphate radicals $\{Li_2[P(NR)_3(NSiMe_3)]\cdot LiX\cdot 3THF\}^{\cdot}$ (**5a**, R = *t*-Bu; **5b**, R = Ad; X = Cl, Br, I) described previously (9, 10).

In this contribution, we describe the synthesis and multinuclear NMR spectroscopic characterization of (*i*) the tetraaminosilanes $Si(NHR)_4$ (**2a**, R = *i*-Pr; **2b**, R = *t*-Bu; **2c**, R = *p*-tol), (*ii*) the aminochlorosilanes $Cl_2Si(NHAd)_2$ (**6b**) and $ClSi(NH\text{-}t\text{-}Bu)_3$ (**7**), and (*iii*) the hexa(amino)disiloxane $(t\text{-}BuNH)_3SiOSi(NH\text{-}t\text{-}Bu)_3$ (**14**) and the tetraimidosilicate complex $\{[Li(12\text{-crown-}4)]_2[(Et_2O)_2Li(\mu\text{-}Nnaph)_2Si(\mu\text{-}Nnaph)_2\text{-}Li(Et_2O)_2]\}$ (**8**). We also report the characterization, by EPR spectroscopy, of persistent radicals formed by oxidation of tetramido- and aminotris(imido)-silicates with iodine.

Experimental

Reagents and general procedures

All experiments were carried out under an argon atmosphere using standard Schlenk techniques. Toluene, diethyl ether, and tetrahydrofuran (THF) were dried over Na–benzophenone, distilled, and stored over molecular sieves prior to use. 12-Crown-4 (98%), $Cl_3SiOSiCl_3$ (>98%), *n*-BuLi (2.5 mol/L solution in hexanes), *tert*-butylamine, and $SiCl_4$ (99%) were used as received from Aldrich. The lithiated amides LiHNR (R = *i*-Pr, *t*-Bu, *p*-tol) were prepared by standard procedures involving the reaction of the corresponding primary amines with *n*-BuLi in hexane (*i*-Pr, *t*-Bu) or Et_2O (*p*-tol) at –78 °C. Iodine was sublimed prior to use. Com-

pounds **1** (11), **3b** (11), and **13** (17) were prepared by the methods reported in the literature.

Instrumentation

^{1}H, ^{7}Li, ^{13}C, ^{29}Si, and ^{31}P NMR spectra were collected on a Bruker DRX-400 spectrometer with ^{1}H and ^{13}C chemical shifts referenced internally to ^{1}H impurities and natural abundance ^{13}C in the deuterated solvents, respectively; external standards were used for the ^{7}Li (LiCl in D_2O), ^{29}Si ($SiMe_4$ in $CDCl_3$), and ^{31}P (85% H_3PO_4 in D_2O) spectra. All spectra were collected at 22 °C (unless otherwise noted). IR spectra were recorded as Nujol or Fluorolube mulls on KBr plates using a Nicolet Nexus 470 FT IR spectrometer in the range 4000–400 cm^{-1}. Mass spectra were recorded on a Bruker Esquire 3000 ESI ion trap mass spectrometer. Elemental analyses were provided by the Analytical Services Laboratory, Department of Chemistry, University of Calgary, Calgary, Alberta and by Canadian Microanalytical Service Ltd., Vancouver, British Columbia. EPR spectra were recorded at 22 °C on a Bruker EMX 113 spectrometer; spectral simulations were carried out using WINEPR SimFonia; spectra were plotted using WinEPR (18). The *g* values of the radicals were calculated using the field–frequency ratio of each sample.

Preparation of Si(NH-*i*-Pr)$_4$ (2a)

$SiCl_4$ (1.3 mL, 1.93 g, 11.3 mmol) was added dropwise to a white slurry of LiHN-*i*-Pr (3.040 g, 46.74 mmol) in diethyl ether (50 mL) at 0 °C. The reaction mixture was stirred for 3 h, then warmed slowly to 22 °C and stirred for an additional 15 h. The pale yellow slurry was centrifuged; the supernatant liquid was filtered, leaving a colourless filtrate. The solvent was removed in vacuo and the product was washed with hexane (5 mL), giving Si(NH-*i*-Pr)$_4$ as a white powder (2.292 g, 8.80 mmol, 78%). ^{1}H NMR (C_6D_6) δ: 3.22 (sept, 1H, CH_3-C*H*, ^{3}J(H,H) = 7 Hz), 1.10 (d, 6H, C*H*$_3$-CH, ^{3}J(H,H) = 7 Hz, Me). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 42.65 (s, CH), 28.34 (s, CH_3). Literature values (from ref. 15): ^{1}H NMR (C_6D_6) δ: 3.21 (sept, 1H, CH_3-C*H*, ^{3}J(H,H) = 6.7 Hz), 1.10 (d, 6H, C*H*$_3$-CH, ^{3}J(H,H) = 6.7 Hz, Me). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 42.6 (s, CH), 28.3 (s, CH_3).

Preparation of Si(NH-*t*-Bu)$_4$ (2b)

A solution of $SiCl_4$ (0.79 mL, 6.90 mmol) in diethyl ether (15 mL) was added to a white slurry of LiHN-*t*-Bu (2.191 g, 27.71 mmol) in diethyl ether (50 mL) at 0 °C. The reaction mixture was stirred for 1 h, then warmed slowly to 22 °C and stirred for an additional 3.5 h. The white slurry was filtered, and the solvent was removed from the colorless filtrate in vacuo, giving Si(NH-*t*-Bu)$_4$ as a white powder (1.830 g, 5.78 mmol, 84%). ^{1}H NMR (C_6D_6) δ: 1.28 (s, *t*-Bu). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 48.69 (s, *C*Me$_3$), 33.99 (s, C*Me*$_3$). $^{29}Si\{^{1}H\}$ NMR (C_6D_6) δ: –52.9 (s). MS (EI): 316.6 ($[M]^+$). Anal. calcd. for $C_{16}H_{40}N_4Si$: C 60.70, H 12.73, N 17.70; found: C 60.28, H 11.47, N 17.97.

Preparation of Si(NH-*p*-tol)$_4$ (2c)

$SiCl_4$ (0.11 mL, 0.16 g, 0.96 mmol) was added dropwise to a white slurry of LiHN-*p*-tol·Et_2O (0.606 g, 3.723 mmol) in diethyl ether (35 mL) at 0 °C. The reaction mixture was stirred for 2 h, then warmed slowly to 22 °C and stirred for an additional 15 h. The pale orange slurry was centrifuged; the supernatant liquid was filtered, leaving a yellow filtrate. The solvent was removed in vacuo, giving Si(NH-*p*-tol)$_4$ as a pale orange powder (0.338 g, 0.747 mmol, 78%). ^{1}H NMR (C_6D_6) δ: 6.90, 6.71 (d of d, 4H, C_6H_4, $^{2}J(^{1}H,^{1}H)$ = 76.8 Hz, $^{3}J(^{1}H,^{1}H)$ = 8.2 Hz), 3.80 (s, 1H, N*H*), 2.11 (s, 3H, *p*-CH_3). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 142.66 (s, *C*-NH), 130.22 (s, *o*-*C*H), 128.53 (*m*-*C*H), 117.59 (*C*-CH_3), 20.53 (CH_3). $^{29}Si\{^{1}H\}$ NMR (C_6D_6) δ: –52.9 (s). Anal. calcd. for $C_{28}H_{32}N_4Si$: C 74.29, H 7.13, N 12.38; found: C 73.22, H 7.13, N 11.91.

Preparation of Cl$_2$Si(NH-*t*-Bu)$_2$ (6a)

A solution of $SiCl_4$ (4.0 mL, 34.9 mmol) in diethyl ether (20 mL) was added to a solution of *t*-$BuNH_2$ (25.0 mL, 0.238 mol) in diethyl ether (150 mL) at 22 °C over 5 min, resulting in a dense white slurry. The reaction mixture was stirred for 16 h, then filtered through a sintered glass frit, yielding a clear colourless filtrate. The white solid (*t*-$BuNH_3$)Cl was washed with diethyl ether (100 mL). The solvent was removed from the filtrate in vacuo, giving $Cl_2Si(NH$-*t*-Bu$)_2$ as a colourless liquid (7.024 g, 28.88 mmol, 83%). ^{1}H NMR (C_6D_6) δ: 1.48 (br, N*H*), 1.11 (s, *t*-Bu). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 50.61 (s, *C*Me$_3$), 32.63 (s, C*Me*$_3$). $^{29}Si\{^{1}H\}$ NMR (C_6D_6) δ: –38.9 (s). Literature values (from ref. 18): ^{1}H NMR (C_6D_6) δ: 1.49, 1.11. $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 50.6, 32.5.

Preparation of Cl$_2$Si(NHAd)$_2$ (6b)

$SiCl_4$ (0.26 mL, 2.27 mmol) was added to a white slurry of LiHNAd (0.714 g, 4.54 mmol) in toluene (30 mL) at 0 °C. The reaction mixture was allowed to warm to 22 °C and stirring was continued for 28 h. The reaction mixture was filtered and the solvent was removed from the filtrate in vacuo, giving $Cl_2Si(NHAd)_2$ as a white solid (0.731 g, 1.83 mmol, 81%). ^{1}H NMR (C_6D_6) δ: 1.90 (br, 1H, C*H*), 1.79 (d, 2H, *CH*$_2$-C-NH), 1.49 (t, 2H, CH-*CH*$_2$-CH). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 51.20 (s, *C*-NH), 46.25 (s, *C*H), 36.45 (s, *CH*$_2$-C-NH), 30.35 (s, CH-*CH*$_2$-CH). $^{29}Si\{^{1}H\}$ NMR (C_6D_6) δ: –38.8 (s). Anal. calcd. for $C_{20}H_{30}N_2SiCl_2$: C 60.13, H 8.07, N 7.01; found: C 59.85, H 8.24, N 7.13.

Preparation of ClSi(NH-*t*-Bu)$_3$ (7)

tert-Butylamine (10.0 mL, 95.16 mmol) was added to a solution of $Cl_2Si(NH$-*t*-Bu$)_2$ (3.078 g, 12.65 mmol) in toluene (20 mL) at 22 °C, resulting in a clear colorless solution. The reaction mixture was refluxed at 113 °C for 24 h. The resulting white slurry was cooled to 22 °C and filtered through a sintered glass frit, resulting in a clear colorless filtrate. The white solid (*t*-$BuNH_3$·HCl) was washed with toluene (5 mL). The solvent was removed from the filtrate in vacuo, giving spectroscopically pure $ClSi(NH$-*t*-Bu$)_3$ as a colourless liquid (3.138 g, 11.21 mmol, 89%). ^{1}H NMR (C_6D_6) δ: 1.20 (s, *t*-Bu). $^{13}C\{^{1}H\}$ NMR (C_6D_6) δ: 49.47 (s, *C*Me$_3$), 33.28 (s, C*Me*$_3$). $^{29}Si\{^{1}H\}$ NMR (C_6D_6) δ: –45.2 (s).

Preparation of {[Li(12-crown-4)]$_2$[(Et$_2$O)$_2$Li(μ-Nnaph)$_2$Si(μ-Nnaph)$_2$Li(Et$_2$O)$_2$]} (8)

n-Butyllithium (4.65 mL, 11.62 mmol) was added to a solution of 1-aminonaphthalene (0.833 g, 5.817 mmol) in diethyl ether (30 mL) at –78 °C and stirred for 1 h. $SiCl_4$

© 2006 NRC Canada

(0.17 mL, 1.484 mmol) was added to the reaction mixture dropwise. After 30 min, the reaction mixture was warmed to 22 °C and stirred for an additional 24 h. The resulting yellow slurry was then filtered, yielding a clear yellow solution. 12-Crown-4 (0.48 mL, 3.024 mmol) was added to the solution at 22 °C, resulting in a yellow slurry, which was stirred for 1 h. The solvent was then removed in vacuo, giving **8** as a bright yellow powder (1.489 g, 1.166 mmol, 80%). ^{1}H NMR (d_8-THF) δ: 8.5 (br), 8.10 (d, 4H), 7.44 (d, 4H), 7.09 (t, 4H), 7.02 (t, 4H), 6.90 (t, 4H), 6.40 (t, 4H), 3.40 (q, 16H, Et_2O), 3.33 (s, 24H, 12-crown-4), 1.14 (t, 24H, Et_2O). ^{13}C{^{1}H} NMR (d_8-THF) δ: 162.37, 137.44, 128.61, 128.24, 127.06, 124.63, 124.19, 120.70, 108.46, 106.92, 68.82 (s, 12-crown-4), 65.52 (s, $(CH_3CH_2)_2O$), 14.59 (s, $(CH_3CH_2)_2O$). ^{7}Li NMR (d_8-THF) δ: 0.63 (s). Anal. calcd. for $C_{72}H_{100}N_4SiO_{12}Li_4$: C 68.12, H 7.94, N 4.41; found: C 67.20, H 8.00, N 4.83.

Preparation of (*t*-BuNH)$_3$SiOSi(NH-*t*-Bu)$_3$ (14)

A solution of $Cl_3SiOSiCl_3$ (1.479 g, 5.191 mmol) in diethyl ether (10 mL) was added to a white slurry of LiHN-*t*-Bu (2.463 g, 31.15 mmol) in diethyl ether (40 mL) at 0 °C. After 30 min, the white slurry was warmed to 22 °C and stirred for an additional 15 h. The resulting pale yellow slurry was filtered and the solvent was removed from the filtrate in vacuo, giving (*t*-BuNH)$_3$SiOSi(NH-*t*-Bu)$_3$ as a pale yellow solid (1.770 g, 3.505 mmol, 68%). Sublimation of the crude product at 135 °C under reduced pressure resulted in the isolation of a white powder (1.177 g, 2.331 mmol, 45%). IR (cm^{-1}) ν: 3412 (m, (N-H)), 1230 (vs, (Si-O-Si)). ^{1}H NMR (C_6D_6) δ: 1.34 (s, *t*-Bu), 1.31 (s, *t*-Bu, minor resonance) (relative intensities ca. 5:1), 1.21 (N*H*). ^{13}C{^{1}H} NMR (C_6D_6) δ: 49.10 (s, *C*Me$_3$), 33.84 (s, C*Me*$_3$), 48.80, 33.87 (minor resonances). ^{29}Si{^{1}H} NMR (C_6D_6) δ: –54.5 (s). Anal. calcd. for $C_{24}H_{60}N_6Si_2O$ (**14**): C 57.09, H 11.98, N 16.64; $C_{28}H_{71}N_7Si_2O$ (**14** + *t*-BuNH$_2$): C 58.17, H 12.38, N 16.96; found: C 56.32, H 12.19, N 15.99, Cl < 0.3.

Results and discussion

Preparation and NMR characterization of Cl$_2$Si(NHAd)$_2$ (6b), ClSi(NH-*t*-Bu)$_3$ (7), and Si(NHR)$_4$ (2a, R = *i*-Pr; 2b, R = *t*-Bu; 2c, R = *p*-tol)

With only limited information available (14) regarding previous attempts to synthesize **2b**, the reaction of $SiCl_4$ with *t*-BuNH$_2$ was reinvestigated. As reported in the literature (19), treatment of $SiCl_4$ with an excess of *tert*-butylamine at room temperature results in the aminolysis of two silicon–chlorine bonds and the formation of **6a** in 83% yield. Further treatment of **6a** with an excess of *t*-BuNH$_2$ in boiling toluene resulted in the formation of **7**, a colourless liquid, in 89% yield. While several physical properties of **7** have been determined, including the boiling point and refractive index (14), no spectroscopic data for this compound have been reported. The *tert*-butyl ^{1}H NMR resonance of **7** (1.20 ppm) is shifted slightly downfield as compared with that of **6a** (1.11 ppm), while the ^{29}Si NMR signal (–45.2 ppm) of **7** appears at higher field than the corresponding resonance of **6a** (–38.9 ppm). The α-carbon signal in the ^{13}C NMR spectrum of **7** is shifted to higher field (49.5 vs. 50.6 ppm), while the methyl groups resonate at lower field (33.3 vs. 32.6 ppm).

Attempts to prepare **2b** by the reaction of **7** with an excess of *tert*-butylamine at elevated temperatures were unsuccessful; in all cases, no reaction could be detected by ^{1}H NMR spectroscopy. In consequence, an alternative synthetic route, based on the method by which the trisamino(imino)phosphoranes (RNH)$_3$PNSiMe$_3$ (R = *i*-Pr, Cy, *t*-Bu, Ad) have been prepared (5, 10) (eq. [2]), was adopted whereby $SiCl_4$ was treated with 4 equiv. of LiHN-*t*-Bu at 22 °C (eq. [3]). This reaction proceeds with the elimination of 4 equiv. of LiCl and produces the desired compound **2b** in 84% yield. The identity of **2b** was established by multinuclear NMR, mass spectrometry (M^+ at 316.6), and elemental (C, H, N) analysis. The trends in multinuclear NMR data that were observed on moving from the bisamino compound **6a** to the trisamino species **7** continue with this tetraaminosilane: the ^{1}H NMR signal is at still lower field (1.28 ppm) as is the C*Me*$_3$ peak in the ^{13}C NMR spectrum (34.0 ppm), while the second ^{13}C NMR resonance (48.7 ppm) and the ^{29}Si NMR signal (–52.9 ppm) appear at higher field. No trace of contamination from unreacted **6a** or **7** was detected in the NMR spectra of this compound.

[2] $$Cl_3PNSiMe_3 + 3LiHNR \xrightarrow[0\ ^\circ C]{Et_2O} (RNH)_3PNSiMe_3 + 3LiCl$$

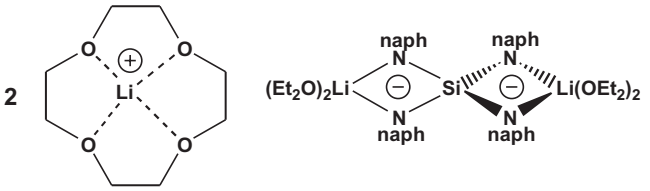
[3] $$SiCl_4 + 4LiHN\text{-}t\text{-}Bu \xrightarrow[0\ ^\circ C]{Et_2O} Si(NH\text{-}t\text{-}Bu)_4 + 4LiCl$$

The ease with which this reaction (eq. [3]) occurs indicates that electronic effects rather than the steric influence of the bulky *t*-BuNH$_2$ group, as previously postulated (14), preclude the formation of **2b** in solvothermal reactions between $SiCl_4$ and *t*-BuNH$_2$. The formation of LiCl presumably provides a sufficient driving force for complete aminolysis to occur. The utility of this synthetic approach is not limited to the *tert*-butyl group: the known derivatives **2a** and **2c** have also been prepared in ca. 80% yields by this procedure and identified by multinuclear NMR spectra.

Following the success of this synthetic methodology for producing **2b**, it was of interest to determine whether other, perhaps even more sterically hindered tetraaminosilanes, could be prepared in the same manner. To that end, the synthesis of "Si(NHAd)$_4$" (**2d**) was attempted via the analogous reaction of $SiCl_4$ with lithium adamantylamide (LiHNAd). However, the disubstituted compound **6b** was isolated in 81% yield in this case. As the electron-withdrawing effects of NHAd and NH-*t*-Bu groups are expected to be quite similar to one another, this failure to generate tris- or tetra-(adamantylamino)silanes must be attributed to the greater steric bulk of the adamantyl cages as compared with that of the *tert*-butyl substituents of **2b**.

Attempted preparation of {Li$_4$[Si(NR)$_4$]} (R = *t*-Bu, *p*-tol) — Synthesis and NMR characterization of {[Li(12-crown-4)]$_2$[(Et$_2$O)$_2$Li(μ-Nnaph)$_2$Si(μ-Nnaph)$_2$Li(Et$_2$O)$_2$]} (8)

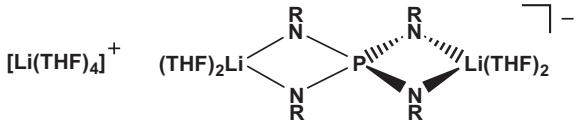
With an efficient synthetic route to Si(NH-*t*-Bu)$_4$ established, an attempt to tetralithiate this species with *n*-BuLi was carried out. The two reagents were combined in hexane



© 2006 NRC Canada

at 22 °C. The ^{1}H NMR spectrum of the product of this reaction, a fine white powder, contained two *t*-Bu resonances at 1.64 and 1.48 ppm in a 1:3 ratio, as well as a broad signal attributable to a NH fragment; unreacted *n*-BuLi was also detected. These spectroscopic data are consistent with the formation of a trilithiated species $\{Li_3[Si(N\text{-}t\text{-}Bu)_3(NH\text{-}t\text{-}Bu)]\}_2$ (**3b**) (11), which is isostructural with **3a**. The reaction was repeated under various conditions. In all cases, a significant amount of unreacted *n*-BuLi was observed in the ^{1}H NMR spectrum of the product, along with a broad signal that was attributed to a NH fragment, the presence of which was confirmed by IR spectroscopy. Reactions between **2b** and Mg-*n*-Bu_2 under a variety of conditions also resulted in incomplete deprotonation, as revealed by sharp N–H stretching vibrations in the IR spectra of the products.

In light of the limited reactivity of **2b** toward *n*-BuLi, it was decided to undertake similar reactions with Si(NH-*p*-tol)$_4$ (**2c**), as the increased acidity of the NH protons of arylamino substituents compared with that of alkylamino groups has been observed to facilitate complete lithiation in related trisamino(thio)phosphate systems (20). The spectroscopic data obtained from these experiments were inconclusive, but did not provide any strong evidence to support the formation of "$\{Li_4[Si(N\text{-}p\text{-}tol)_4]\}$". Based on these results, it is proposed that fourfold deprotonation of $Si(NHR)_4$ (R = alkyl, aryl) is not possible using alkyl lithium reagents, as they are not sufficiently basic to effect the removal of the fourth proton. The synthesis of **1** requires the double deprotonation of 1-aminonaphthalene prior to reaction with $SiCl_4$ (11); since H_2Nnaph is the only primary amine that can be dilithiated, the naphthyl derivative **1** may be a unique example of a tetralithiated tetraimidosilicate.



With the library of viable R groups thus curtailed, the preparation of a crown ether complex of **1** was undertaken, with the expectation that the resulting material would be more crystalline than the diethyl etherate **1**. The synthesis of **1** by the literature procedure (11) was modified by the addition of 2 equiv. of 12-crown-4 after filtration to remove the LiCl by-product. The resulting bright yellow powder was characterized by ^{1}H and ^{13}C NMR spectroscopy, as well as by an elemental (C, H, N) analysis. The overlapping multiplets in the aromatic region of the ^{1}H NMR spectrum of the product render it difficult to interpret. However, only 10 distinct signals were observed in the aromatic region (106.9–162.4 ppm) of the ^{13}C NMR spectrum, in addition to the resonances for 12-crown-4 and diethyl ether ligands, indicating the equivalence of the four Nnaph substituents. Based on these data, this novel tetraimidosilicate complex is thought to exist in a spirocyclic conformation $\{[Li(12\text{-crown-}4)]_2[(Et_2O)_2Li(\mu\text{-Nnaph})_2Si(\mu\text{-Nnaph})_2Li(Et_2O)_2]\}$ (**8**), with two Li^+ cations sequestered by 12-crown-4; the remaining two Li^+ cations are each *N*,*N*′-chelated by the naphthylimido groups and bis-solvated by two diethyl ether ligands.

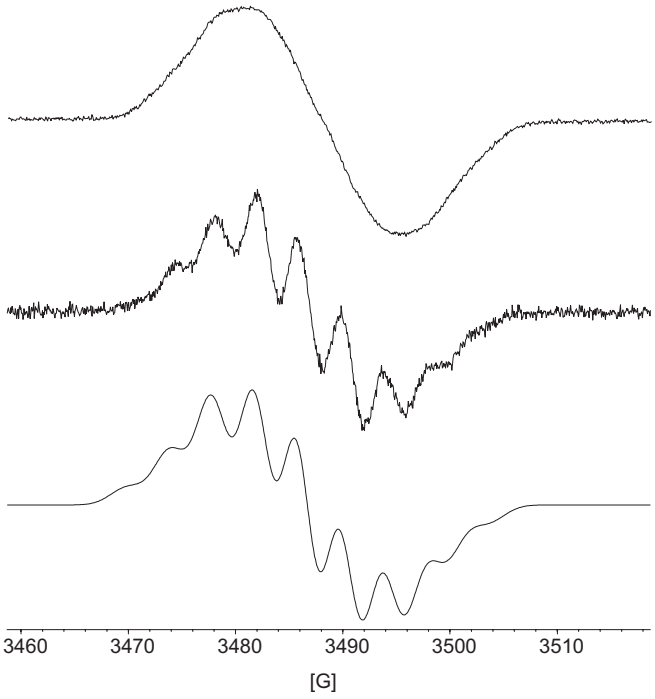
Though single crystals of **8** are readily obtained from THF–hexane solutions, they are not of sufficient quality for X-ray analysis; thus, the proposed structure of **8** has not been confirmed in the solid state. However, the proposed

8

spirocyclic geometry has been observed in the solid state for the isoelectronic tetra(naphthylimido)phosphate $\{[Li(THF)_4][(THF)_2\text{-}Li(\mu\text{-Nnaph})_2P(\mu\text{-Nnaph})_2Li(THF)_2]\}$ (**9a**) (4) and in solution for the *tert*-butyl analogue $\{[Li(THF)_4]\{Li(THF)_2[(\mu\text{-N-}t\text{-Bu})_2P(\mu\text{-N-}t\text{-Bu})_2]Li(THF)_2\}$ (**9b**) (10).

9

Surprisingly, only one signal (0.63 ppm) was observed in the ^{7}Li NMR spectrum of **8** in d_8-THF, indicating that the chemically inequivalent lithium cations exchange rapidly in solution despite the presence of 12-crown-4. This can be rationalized by taking into account the presence of four highly nucleophilic imido groups and the large negative charge of the tetraimidosilicate tetraanion. These two factors combine to render chelation by the $[Si(Nnaph)_4]^{4-}$ preferable to, or at least competitive with, an η_4 mode of coordination by the crown ether. A variable-temperature ^{7}Li NMR study in d_8-THF showed that the spectrum is highly dependent upon temperature, confirming that the lithium cations are in dynamic equilibrium in solution. The single resonance broadens significantly even at 0 °C, then resolves into several sharp resonances at lower temperatures (–45 to –60 °C). It is expected that further lowering of the temperature would eventually result in two singlets in a 1:1 ratio attributed to the *N*,*N*′-chelated lithium ions and the $[Li(12\text{-crown-}4)]^+$ cations. However, this resolution could not be achieved above the temperature at which the NMR solvent began to gel.



Formation and EPR characterization of persistent polyimidosilicate radicals

Oxidation reactions of the tetraimidosilicate **1** were explored to determine whether **1** is capable of forming stable radicals,[3] in a manner similar to that reported for the isoelectronic tetraimidophosphates $\{Li_3[P(NR)_3(NSiMe_3)]\}_2$ (**4a**, R = *t*-Bu; **4b**, R = Ad) (6, 9, 10). The addition of 0.5 mol of iodine to a bright yellow solution of **1** in THF resulted in a deep green-brown solution, indicating the formation of a paramagnetic species, presumably a lithiated derivative of trianion radical $[Si(Nnaph)_4]^{3-\cdot}$. An EPR spectrum of this solution (Fig. 2) at 22 °C displayed a single broad resonance (ca. 15 G), with no resolved hyperfine coupling (HFC) to the four nitrogen nuclei of the tetraimidosilicate radical. Though this was initially surprising, it

[3] In this article, a "stable" radical is one that is inherently stable as an isolated species and does not decompose under an inert atmosphere at room temperature (16). A "persistent" radical is one that has a relatively long lifetime under the conditions that are used to generate it; radicals less stable than this are termed "transient".

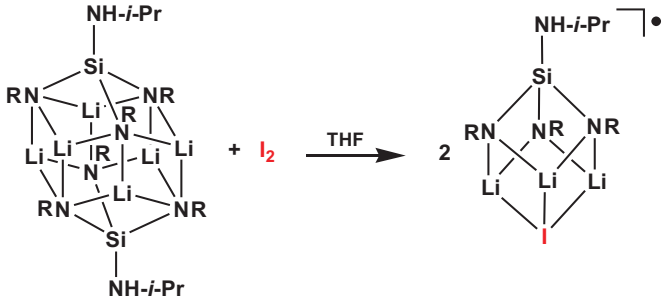
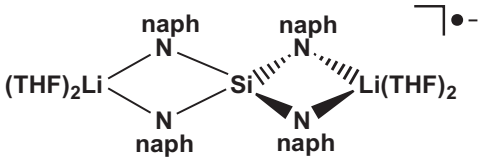
Fig. 2. Experimental EPR spectra of iodine-oxidized **1** (top) and **10** (middle); simulated EPR spectrum of **10** (bottom).



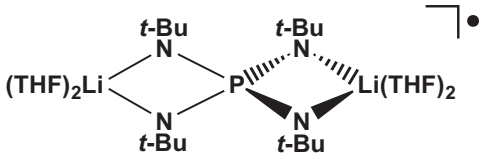
should be noted that extensive line broadening is often observed in fluxional radical systems: the variable-temperature ^{7}Li NMR data obtained for the related crown ether complex **8** are certainly indicative of considerable solution dynamics, and lithium exchange is expected to occur still more readily in the absence of any crown ether.

In an attempt to resolve the nitrogen and lithium HFCs in the EPR spectrum of the $[Si(Nnaph)_4]^{3-\bullet}$ radical, the crown ether complex **8**, believed to be less fluxional than **1**, was oxidized with iodine. An EPR spectrum (Fig. 2) of this dark-green reaction mixture revealed a nine-line pattern, which is consistent with coupling to four equivalent ^{14}N (I = 1, 99.6%) nuclei; the g value of this radical is 2.0037. The pronounced "S-curve" shape of the spectrum and the broadness of the spectral lines are attributed to unresolved HFC (21) to the lithium cations (^{7}Li, I = 3/2, 92.6%) in the spirocyclic radical monoanion $\{[(THF)_2Li(\mu\text{-}Nnaph)_2Si(\mu\text{-}Nnaph)_2Li(THF)_2]\}^{-\bullet}$ (**10**).



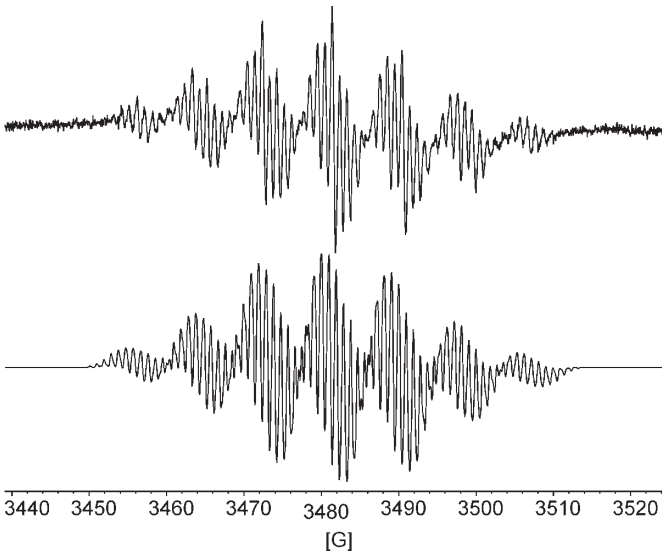
A good simulation of this spectrum (Fig. 2) was obtained by using hyperfine coupling constants (HFCCs) of 3.8 G to four nitrogen atoms and 0.7 G to two lithium cations. These HFCCs are slightly smaller than those observed for the isostructural tetraimidophosphate radical $[(THF)_2Li(\mu\text{-}N\text{-}t\text{-}Bu)_2P(\mu\text{-}N\text{-}t\text{-}Bu)Li(THF)_2]^{\bullet}$ (**11**) for which the corresponding HFCCs are 4.30 G (^{14}N) and 1.08 G (^{7}Li) (10). However, the value of the ^{7}Li HFCC for **10** should be regarded as approximate, since the broadness of the spectral lines precludes direct measurement of this coupling. The striking difference between the line widths produced by the two symmetrical spirocyclic radicals **10** (ca. 3 G) and **11** (ca. 0.5 G) is thought to be caused by spin delocalization into the naphthyl groups of **10**, and the resultant presence of numerous inequivalent ^{1}H hyperfine couplings. This is not an unreasonable hypothesis, since Li_2Nnaph is reported to be paramagnetic and the EPR spectrum contains sufficiently large ^{1}H HFCCs to produce a signal that is approximately 17 G in width (12).

Scheme 1. Oxidation of **3a** by iodine to form two cubic radicals **12** (R = *i*-Pr).



While the green colour formed upon oxidation of **1** and **8** persists for more than 24 h in both instances, the EPR signals were surprisingly weak, indicating the presence of only a small amount of paramagnetic material in the solutions. This observation suggests that either the tetraimidosilicate radical has only a short lifetime or that radical formation is not quantitative, i.e., that the radical **10** is not the exclusive product of these oxidation reactions. Attempts to isolate the tetraimidosilicate radical were unsuccessful owing to the limited stability of this persistent radical. Overall, the stability of **10** is comparable to that of the isostructural neutral radical **11** (10).

Previous work with tetraimidophosphate radicals has shown that cubic derivatives are significantly more stable than spirocycles such as **10** and **11** (6, 7, 9, 10). Oxidation of the dimeric aminotris(imido)silicate **3a** with iodine is expected to proceed in an analogous fashion to oxidations of the structurally similar cluster **4**. As depicted in Scheme 1, this process can be viewed to involve disruption of the Li_6N_6 core of **3a**, yielding two molecules of the cubane radical $\{Li_2[Si(N\text{-}i\text{-}Pr)_3(NH\text{-}i\text{-}Pr)]\cdot LiI\cdot 3THF\}^{\bullet}$ (**12**). In practice, the addition of 1 equiv. of I_2 to a slurry of **3a** in THF yields an intensely yellow solution that gives rise to a somewhat stronger EPR signal than do the products of the corresponding reactions with **1** and **8**. The EPR spectrum of the reaction mixture is primarily a seven-line pattern with multiple smaller HFCs present as well (Fig. 3); the g value of this radical is 2.0044. The best simulation of this spectrum was obtained by including HFCCs to three equivalent nitrogen atoms (8.1 G), one unique nitrogen atom (2.0 G), three lith-



10

Fig. 3. Experimental (top) and simulated (bottom) EPR spectra of **12**.

ium cations (0.9 G), and an iodine atom (0.4 G) (Fig. 3). Thus, this EPR spectrum is consistent with the formation of the cubic radical **12** and confirms that **3a** undergoes an analogous reaction to **4** when oxidized.

Like the tetraimidosilicate radical **10**, the amidotris(imido)silicate **12** is considered to be a persistent radical, since it decomposes in solution within 72 h.[3] This is somewhat surprising, as cubic tetraimidophosphate radicals are more stable than related spirocyclic species and they can be isolated and structurally characterized in the solid state (6, 7, 9, 10). However, it must be noted that the isopropyl substituents of **10** provide only modest steric protection to prevent dimerization of the radical: stable tetraimidophosphate radicals occur only when bulkier *tert*-butyl or adamantyl groups are in place (10). Thus, oxidation of the *tert*-butyl derivative **3b** with 1 mol of iodine was undertaken, with the expectation that a highly persistent or stable radical would result. Surprisingly, the paramagnetic species generated from this reaction was found to be even less stable than **12**, persisting in solution for only a few seconds. An EPR spectrum of the reaction mixture produced a very weak signal, consisting of a poorly resolved seven-line pattern. While this suggests HFC of the unpaired electron to three equivalent ^{14}N nuclei, consistent with the formation of a cubic radical, the experimental parameters used to acquire this spectrum were not optimal owing to the low sample concentration. Oxidation of the related dimer $\{Li_3[PhSi(N\text{-}t\text{-}Bu)_3]\}_2$ (**13**) (17), an organic derivative of a trisimidosilicate that exists as a Li_6N_6 hexagonal prism bicapped by the two Si–Ph units (cf. **3a** in Fig. 1), also yielded a transient radical. The lower stability of this radical as compared with that of **12** can be attributed to a combination of the smaller steric bulk of the phenyl group (cf. the NH-*i*-Pr unit), combined with the fewer number of electronegative (i.e., N) atoms over which the unpaired electron can be delocalized. However, no explanation can be given at the present time as to why the oxidation of the more sterically protected **3b** leads to less stable radicals than the corresponding reactions of the isopropyl derivative **3a**.

Preparation and characterization of $(t\text{-}BuNH)_3SiOSi(NH\text{-}t\text{-}Bu)_3$ (14)

As an alternative precursor to polyimidosilicate radicals, we targetted hexa(*tert*-butylamino)disiloxane $(t\text{-}BuNH)_3SiOSi(NH\text{-}t\text{-}Bu)_3$ (**14**), which was synthesized by the reaction of hexachlorodisiloxane with 6 equiv. of LiHN-*t*-Bu at 0 °C in diethyl ether (eq. [4]) and purified by sublimation. The resultant white powder was characterized by IR and multinuclear NMR spectra, GC–MS, and elemental analyses.

$$[4]\qquad Cl_3SiOSiCl_3 + 6LiHN\text{-}t\text{-}Bu \xrightarrow{Et_2O} (t\text{-}BuNH)_3SiOSi(NH\text{-}t\text{-}Bu)_3 + 6LiCl$$

The ^1H NMR spectrum of the product exhibits a minor resonance at 1.31 ppm in addition to the major peak at 1.34 ppm. The integrated relative intensities of these two resonances exhibit an approximately 1:5 ratio. The ^{13}C NMR spectrum is consistent with this observation, showing one major set of *tert*-butyl resonance (49.10 and 33.84 ppm) and a second set of minor resonances at 48.80 and 33.87 ppm. These minor resonances, with the same relative intensities, persist in the NMR spectra of samples purified by either sublimation or recrystallization. The ^{29}Si NMR spectrum of the product exhibits a single sharp resonance at –54.6 ppm. Furthermore, the GC–MS revealed only a single component. Since the two signals in the ^1H NMR spectrum are very close together, the integration of the relative intensities must be regarded as approximate, and we have considered the possibility that the ratio of the intensities is 1:6 with the smaller resonance attributed to a component with a single *t*-BuN group. The possible candidates for the "single *t*-BuN" species include *t*-BuNHLi, $t\text{-}BuNH_2$, or $[t\text{-}BuNH_3]Cl$, each of which could form a hydrogen-bonded adduct with the O atom of **14**. The product shows no resonance in the ^7Li NMR spectrum, thus ruling out *t*-BuNHLi as an additional component. Elemental analyses show that the product contains insignificant amounts of Cl (<0.3%), thus excluding $[t\text{-}BuNH_3]Cl$ as an impurity. Although we cannot count out the possibility of one molecule of $t\text{-}BuNH_2$ as a hydrogen-bonded component of the product, the IR spectrum (Fluorolube mull) shows only extremely weak, broad bands in the 3120–3240 cm^{-1} region, which could be assigned to hydrogen-bonded $t\text{-}BuNH_2$, in addition to a sharp, medium-intensity band at 3412 cm^{-1} attributed to υ(N-H) of **14**. We also note that the CHN analyses are in better agreement with the calculated values for **14** than with the alternative (**14** + $t\text{-}BuNH_2$). We are led to the tentative conclusion, therefore, that the best explanation of the combined spectroscopic and analytical data for **14** involves some sort of intermolecular interaction in solution that leads to inequivalence of one of the N-*t*-Bu groups. Unfortunately, numerous crystals of **14** obtained by recrystallization or sublimation were only weakly diffracting, and consequently, we have been unable to obtain a solid-state structure by X-ray crystallography. In view of the uncertainty about the structure of **14**, we have not pursued the hexalithiation.

Conclusions

The reaction of $SiCl_4$ with lithiated primary amides LiHNR (R = alkyl, aryl) in diethyl ether provides a versatile

© 2006 NRC Canada

and efficient route to tetraaminosilanes $Si(NHR)_4$. Fourfold deprotonation of $Si(NHR)_4$ does not appear to be possible using either *n*-BuLi or $MgBu_2$, suggesting that the preparation of tetraimidosilicates $[Si(NR)_4]^{4-}$ can only be achieved if the amine is doubly deprotonated prior to reaction with $SiCl_4$, i.e., by the use of Li_2NR. EPR studies of the products of the one-electron oxidation of tetraimido or amidotris(imido)silicates with iodine indicate the formation of persistent spirocyclic and cubic radicals, respectively. The reasons for the lower stability of these polyimidosilicate radicals as compared with that of the analogous tetraimidophosphate radicals are not yet fully understood and merit further investigation.

Total synthesis of 14β-fluorosteroids via a transannular Diels–Alder reaction

Sylvie Beaubien and Pierre Deslongchamps

Abstract: 14β-Fluorosteroids **3** and **4** were synthesized to give a new class of unnatural cardenolides. The total synthesis of racemic 14β-fluorosteroids was accomplished using a highly diastereoselective transannular Diels–Alder reaction on a trans-cis-cis macrocyclic triene. The α-fluoro analog **4** provided a comparable inhibitory activity to natural digitoxigenin **1**.

Key words: fluorosteroid, bioisostere, cardiovascular diseases, transannular Diels–Alder reaction (TADA), macrocyclization.

Résumé : Les 14β-fluorostéroïdes **3** et **4** ont été synthétisés en vue d'obtenir une nouvelle classe de cardénolides non-naturels. La synthèse totale racémique des 14β-fluorostéroïdes a été accomplie en utilisant la réaction diastéréosélective de Diels–Alder transannulaire à partir d'un triène macrocyclique trans-cis-cis. L'α fluoro-analogue **4** donne une activité inhibitrice comparable à la digitoxigénine **1**.

Mots clés : fluorostéroïde, bioisostère, maladies cardiovasculaires, réaction de Diels–Alder transannulaire (DATA), macrocyclisation.

Introduction

The (+)-digitoxigenin **1** is derived from the biologically active trisaccharide digitoxin **2**, which is extracted from the *Digitalis purpura* plant (1) (Fig. 1). These cardenolide steroids belong to the large digitalis family, and the principal use of this type of molecule is the treatment of cardiovascular diseases (2).

Compounds from the digitalis family are considered to be dangerous because the therapeutic dose can correspond to up to 60% of the lethal dose. The therapeutic dose for cardiovascular disease is very small (1) (0.2 mg for digitoxin **2**). For this reason, many efforts have been made to synthesize cardenolide analogs to diminish the toxicity of this type of compound.

Bioisosterism is an approach used to decrease the toxicity of a drug (3). Based on this method, we decided to consider fluoro analogs of digitoxigenin **1**, since fluorine is a bioisostere of the hydroxyl group. In addition, some analogs of digitoxigenin **1** are known to possess an α,β-unsaturated ester instead of butenolide at the C-17 position (4). We, therefore, decided to synthesize the racemic fluoro analogs **3** and **4** of digitoxigenin **1** with a fluorine atom at the C-14 position and an α,β-unsaturated ester at the C-17 position. The biological activity of these analogs could then be measured and compared with that of digitoxigenin **1**.

To synthesize these two fluoro analogs, we used the transannular Diels–Alder (TADA) (5) reaction to construct the tetracyclic skeleton. Our past studies on the TADA reaction (6, 7) have shown that a 13-membered ring with a trans-cis-cis olefin geometry can lead to an A.B.C.[6.6.5] tricycle having a trans-syn-cis (TSC) ring junction configuration (8). In this reaction, four asymmetric centers are created simultaneously with high stereoselectivity. The challenging synthesis of the fluorinated compound, which represents a new class of unnatural cardenolides, is reported herein.

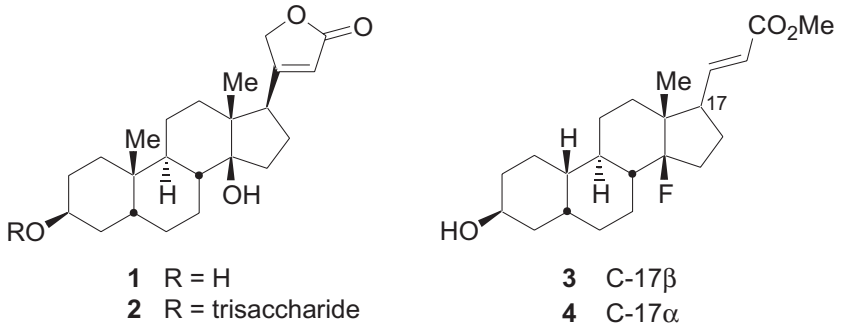
Results and discussion

Retrosynthesis



The retrosynthetic analysis of fluoro analogs **3** and **4** is presented in Scheme 1. These fluoro analogs can be obtained by Birch reduction of the aromatic ring and by homologation of the C-17 ketone of tetracycle **5** to form the α,β-unsaturated esters **3** and **4**. Tetracycle **5** (TSC) can be obtained via the TADA reaction of trienic macrocycle **6** possessing an *E,E*-diene and an *E*-dienophile. Macrocycle **6** can be formed from the β-keto ester **7** by macrocyclization. This β-keto ester can be obtained from compound **8** by alkylation. Homologation of diol **9** with two different Horner–Emmons reactions can produce compound **8**. Finally, the diol **9** can be prepared from commercially available compound **10** in a few steps.

Synthesis of β-keto ester 7

The synthesis of β-keto ester **7** starts with the reduction of the commercially available ketone **10** with lithium aluminium hydride to give the corresponding alcohol followed

by dehydratation to produce the olefin **11** in a quantitative yield (Scheme 2). Ozonolysis of this olefin was performed followed by treatment with sodium borohydride (9) to give diol **9** in 86% yield. The selective oxidation of the benzylic alcohol of diol **9** was accomplished with manganese dioxide and the hydroxyaldehyde **12** was obtained in 85% yield. This hydroxyaldehyde was protected as a TBDMS ether and a Horner–Emmons (10) reaction was performed to produce the α,β-unsaturated ester **13** with very good yield as a single detectable geometrical isomer. Reduction with DIBALH of the α,β-unsaturated ester **13** afforded the corresponding alcohol, which was protected as a TBDPS ether to give disilylated compound **14**. The selective deprotection of TBDMS in the presence of the TBDPS ether was performed with a catalytic amount of PPTS in ethanol, and alcohol **15** was obtained in 98% yield. Swern oxidation (11) then led to aldehyde **16** in quantitative yield.

The fluorine atom, which is required at the 14β position in the final targets **3** and **4**, was introduced at this step with a Horner–Emmons (10) reaction. The aldehyde **16** was treated with the anion of fluorophosphonate **17** (12), and α,β-unsaturated ester **8** was obtained in 93% yield (Scheme 2). The isomer with the E geometry (12) was the only compound observed by ^{1}H NMR. With this key intermediate in hand, we could synthesize β-keto ester **7** for the macrocyclization reaction.

To this end, α,β-unsaturated ester **8** was reduced with lithium aluminium hydride to provide a quantitative yield of the alcohol, which was converted to the allylic chloride **18** with hexachloroacetone and triphenylphosphine (13). The introduction of the β-keto ester was accomplished by treating allylic chloride **18** with the dianion of methyl acetoacetate (14) to afford β-keto ester **19** in 65% yield. Deprotection of the silyl ether was carried out with TBAF, and the resulting

© 2006 NRC Canada

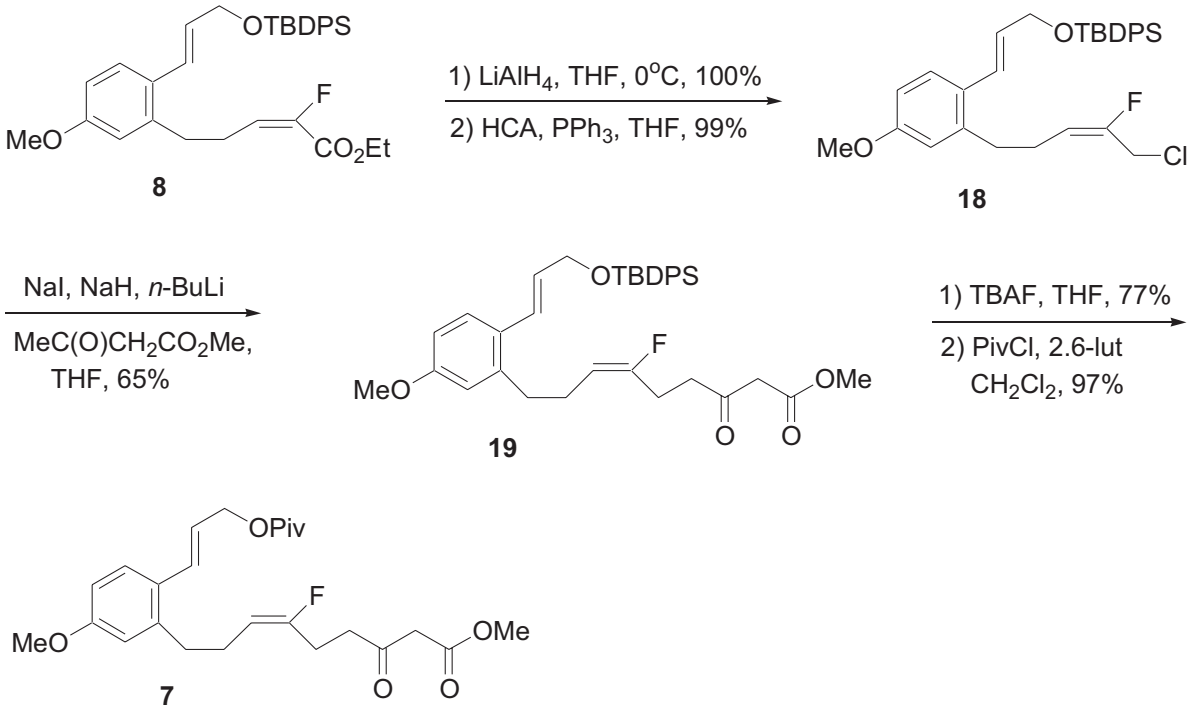
Scheme 2.

alcohol was converted to a pivaloate ester to give β-keto ester **7**, the desired macrocyclization precursor (Scheme 3).

Macrocyclization and TADA reaction

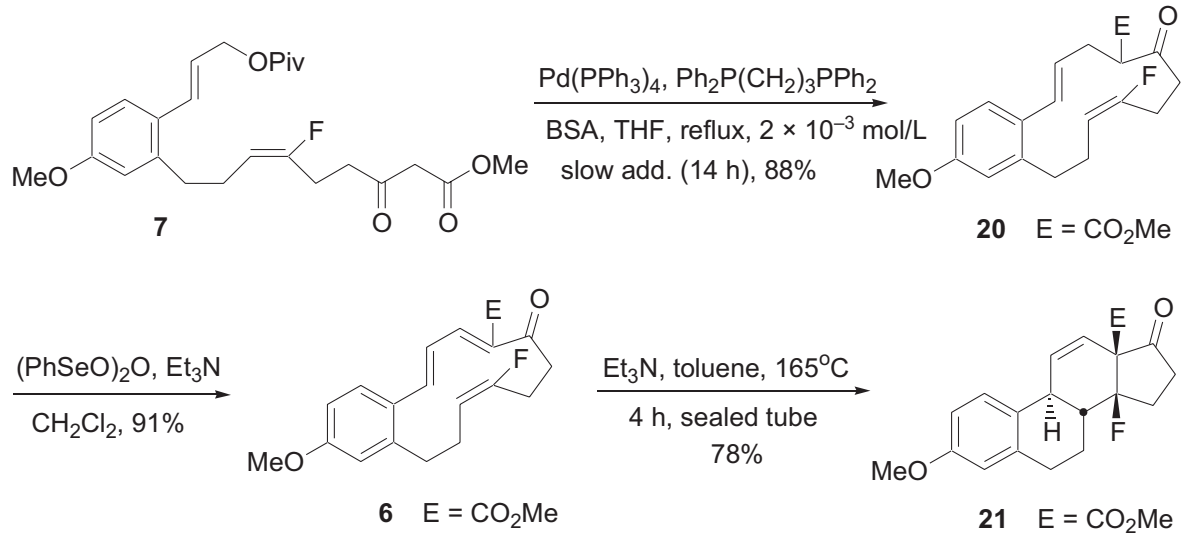
The key steps in this synthesis are the macrocyclization and the TADA reaction. To achieve macrocyclization, the silyl enol ether of β-keto ester **7** was prepared with *N*,*N*-bistrimethylsilylacetamide and subsequent slow addition (14 h) of this silyl enol ether to a solution of palladium catalyst at a high dilution (2 mmol/L). This concentration is essential to eliminate polymer formation. Under these reaction conditions (8, 15), the macrocyclization took place to afford the 13-membered ring macrocycle **20** in an excellent yield of 88% (Scheme 4). Now, we have to introduce an *E*-olefin to make the necessary diene for the TADA reaction. Macrocycle **20** was thus treated with benzeneseleninic anhydride (16, 17), and the trienic macrocycle **6** was obtained in 91% yield.

The macrocycle **6** contains the *E*-dienophile and *E,E*-diene that are necessary to obtain the TSC tetracycle after the TADA reaction. This key step was accomplished by heating macrocycle **6** at 165 °C in the presence of triethylamine in a sealed tube for 4 h. The TSC tetracycle **21** was obtained in 78% yield as a single isomer. In this step, four new chiral centers were formed simultaneously with a high degree of stereoselectivity.



The selective formation of the TSC tetracycle can be explained by considering the transition state of the TADA reaction. As seen in Scheme 5, in transition state **22**, the olefins are perfectly aligned for the TADA reaction without any severe steric interaction. The other possible TADA product, CST tetracycle **21a**, cannot be obtained owing to improper orbital alignment (transition state **22a**). Thus, this transannular process allows complete control in the formation of TSC tetracycle **21** (18). The desired key 17β-fluoro racemic intermediate was thus obtained with a very good yield at each step.

Installation of the C-13 methyl group and a model study for the homologation at the C-17 position



Having built the key intermediate **21**, the next step was to

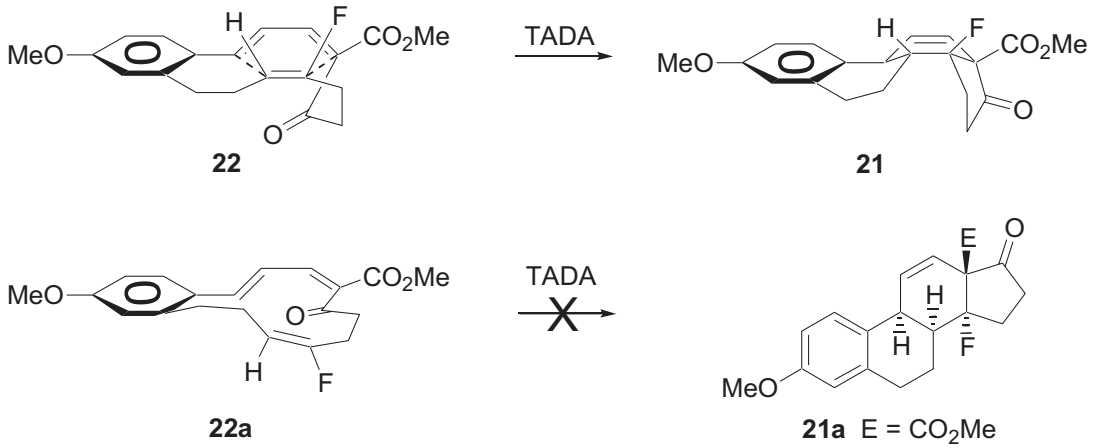
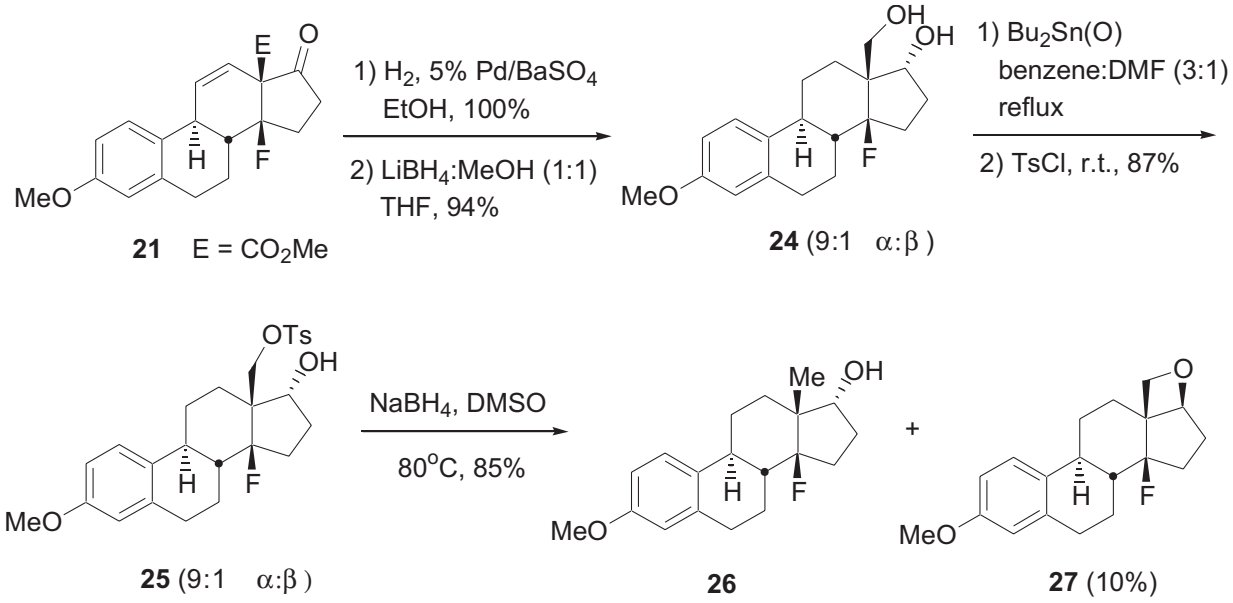
Scheme 3.

Scheme 4.



obtain a methyl group at the C-13 position and explore the homologation at the C-17 position.

Hydrogenation of the olefin in tetracycle **21** (Scheme 6) was carried out, and compound **23** was obtained in quantitative yield. Reduction of the ester and ketone moieties was performed to give diol **24** as a 9:1 mixture of α:β isomers at C-17, which could not be separated. Selective tosylation of the primary alcohol of this diol mixture was then achieved in two steps (19). First, the diol **24** was treated with dibutyltin oxide at reflux in a mixture of benzene and DMF with a Dean–Stark trap and the corresponding ketal tin intermediate was formed. Tosyl chloride was then added to produce a 9:1 mixture (α:β isomers) of tosylate **25** in 87% yield. This mixture was reduced with sodium borohydride, and compound **26** was obtained pure in 85% yield after chromatography. Oxetane **27** was also obtained as a side product in 10% yield. This compound must come from the intramolecular displacement of the C-17 tosylate by the β-secondary alcohol of the minor β isomer of **25**.



Having tetracycle **26** with the desired methyl group at the C-13 position in hand, homologation at the C-17 position was then investigated. Many types of reactions for C-17 homologation of steroids are known in the literature (20). In our case, many attempts were made to add one carbon at this position. Several homologation methods were tried (Wittig (21), epoxidation (22, 23), S_N2 reaction, etc.), but the best results were obtained with a coupling reaction. The alcohol was first oxidized with TPAP–NMO (24) to give ketone **5** in 87% yield (Scheme 7). This ketone was treated with KHMDS to form the corresponding enolate. Comins reagent (25) was

© 2006 NRC Canada

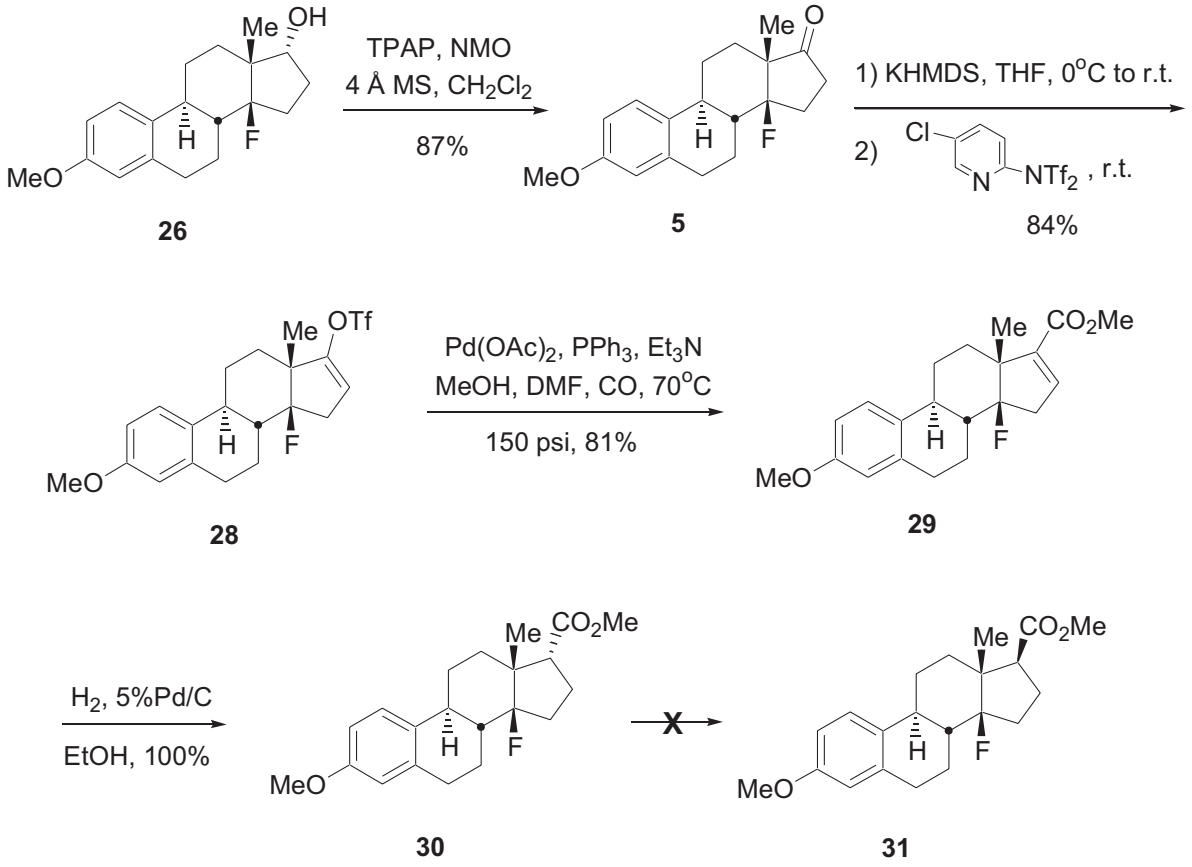
Scheme 5.

Scheme 6.

then added, and the triflic enol ether **28** was obtained in 84% yield.

Palladium-catalyzed coupling of **28** was then investigated. Carbonylation (26) of compound **28** catalyzed by $Pd(OAc)_2$ led to the α,β-unsaturated ester **29** in 81% yield. This unsaturated ester was reduced with a catalytic amount of palladium to give ester **30** in a quantitative yield as a single isomer. Unfortunately, the isomer obtained at the C-17 center was α rather than the desired β isomer (confirmed by ^{1}H NMR shift of the β proton). To obtain the C-17 β isomer **31**, epimerization conditions were explored but without success. A survey of the literature (27) indicated that with an ester at C-17, both the kinetic and thermodynamic isomers correspond to the α isomer when the C–D ring junction is cis.

The only method to obtain the β C-17 center with the C–D cis ring junction is by using a nitrile (28). The coupling reaction was therefore performed on the triflic enol ether **28** with $Pd(PPh_3)_4$ and LiCN (29) from which α,β-unsaturated nitrile **32** was obtained in 79% yield (Scheme 8). Hydrogenation of this α,β-unsaturated nitrile provided a mixture of α- (**33a**, 37%) and β- (**33b**, 58%) nitriles, which were separated by chromatography. The structure of β-nitrile **33b** was confirmed by a X-ray diffraction analysis (Fig. 2). Having obtained the desired β-nitrile, the model study for the C-17 homologation was thus completed (Table 1).[2]



Functionalization of ring A

Starting from alcohol **26**, Birch reduction (30) with lithium metal was performed at –78 °C, and the corresponding enol ether was hydrolyzed with 1 N HCl to afford the α,β-

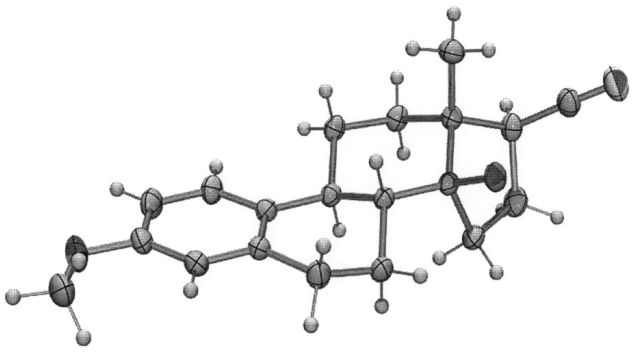
Scheme 7.

Scheme 8.

unsaturated ketone **34** in 77% yield (Scheme 9). The proton at the C-10 position was β, as expected. We were pleased to see that the fluorine atom was not hydrogenolyzed at –78 °C, since this had occured at –30 °C.

To obtain the desired cis A–B ring junction, hydrogenation of the α,β-unsaturated ketone **34** was accomplished with a catalytic amount of palladium (Scheme 9) to yield the cis and trans isomers **36** and **35** in 60% and 37% yields, respectively. The two isomers were easily separated and the synthesis was continued with tetracycle **36**, which had the A–B cis ring junction. Oxidation of tetracycle **36** with TPAP–NMO (23) furnished the diketone **37** in 99% yield.



Selective reduction of the ketone at the C-3 position should be possible with a hydride source sensitive to the steric hindrance (31). In addition, with such a hydride source, the reduction of the C-3 center to afford the β alco-

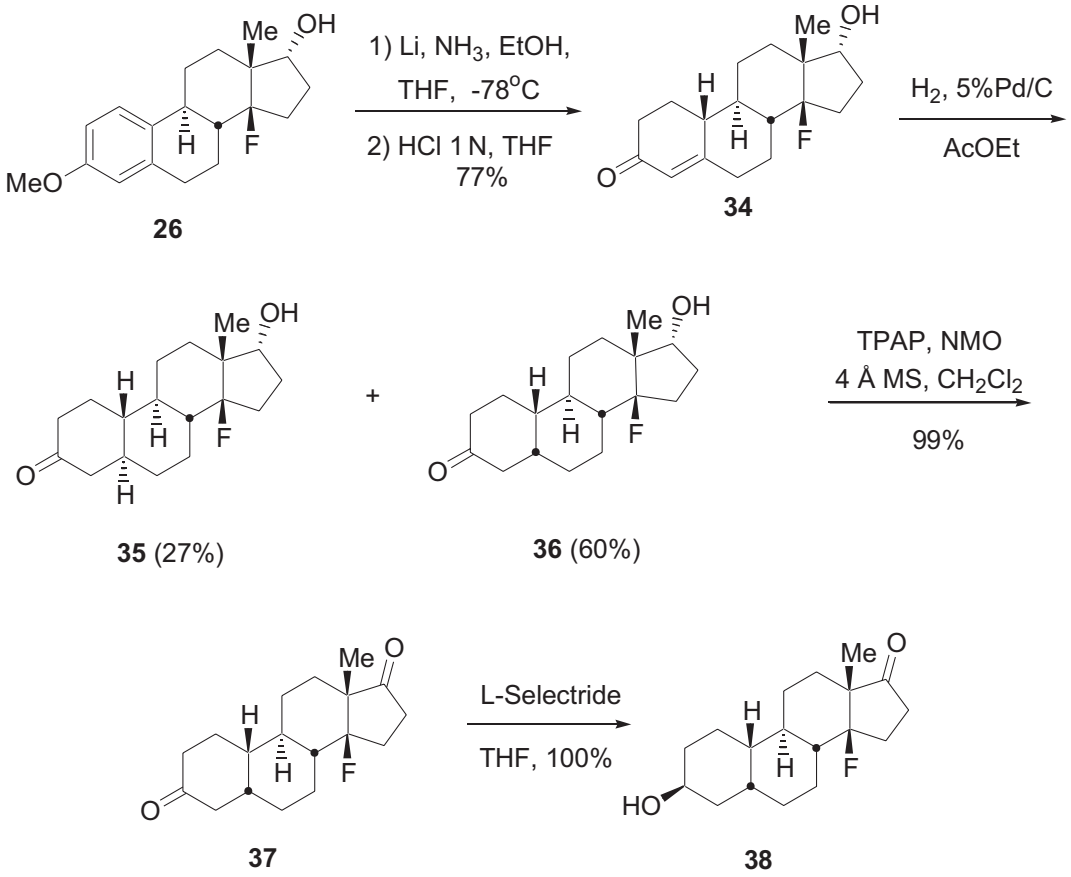
hol should be favored (32). Indeed, the use of L-Selectride as the reducing agent on diketone **37** gave a quantitative yield of the β C-3 alcohol **38** (Scheme 9).

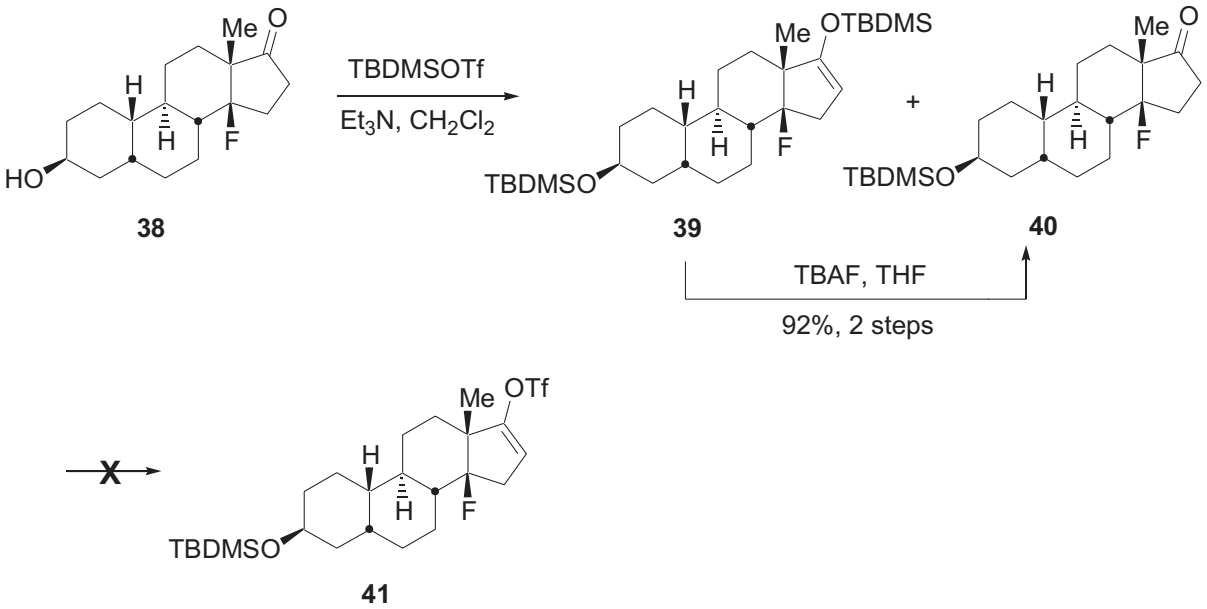
Fluoro analog synthesis and biological activities

To complete the synthesis of the fluoro analogs, we had to carry out the nitrile homologation at the C-17 position developed in the model study and to introduce the α,β-unsaturated ester at the C-17 position.



Alcohol **38** was protected with TBDMSOTf (Scheme 10), and a mixture of the desired silyl ether **40** and silyl enol ether **39** was obtained. This mixture was treated with TBAF, and the silyl ether **40** was the only compound obtained in 92% yield for the two steps. This compound was treated under the same conditions used for the model compound **5** (Scheme 7) to prepare the triflic enol ether **41** without success. The starting material was recovered with some decomposition. We tried other bases (LiHMDS, NaHMDS, and LDA) to make this triflic enol ether, but the same negative results were obtained. We therefore looked for an alternative method via a vinyl iodide intermediate (33).

Starting with ketone **38**, the corresponding hydrazone was formed with hydrazine at reflux over 5 days, and this hydrazone was treated with iodine to provide the desired vinylic iodide **42** in 91% yield for the two steps (Scheme 11). The coupling reaction (LiCN, $Pd(PPh_3)_4$, 12-C-4) on this compound having a free alcohol was attempted, but gave a very poor yield. Thus, the alcohol was protected with TBDMSOTf to give compound **43** in a quantitative yield. The same coupling reaction (LiCN, $Pd(PPh_3)_4$, 12-C-4) was performed with vinylic iodide **43**, and the desired α,β-unsaturated nitrile **44** was obtained in 45% yield. This unsaturated nitrile was then hydrogenated to give the β-nitrile **45b** (53%) and the α-nitrile **45a** (47%), which were separated by chromatography.



Deprotection of the silyl ethers **45a** and **45b** was accomplished under acidic conditions to furnish the corresponding compounds **46a** and **46b** in a quantitative yield. To confirm the stereochemistry of the β-nitrile **46b**, the *p*-nitrobenzoate **47** was prepared and an X-ray diffraction analysis was ob-

© 2006 NRC Canada

Scheme 9.

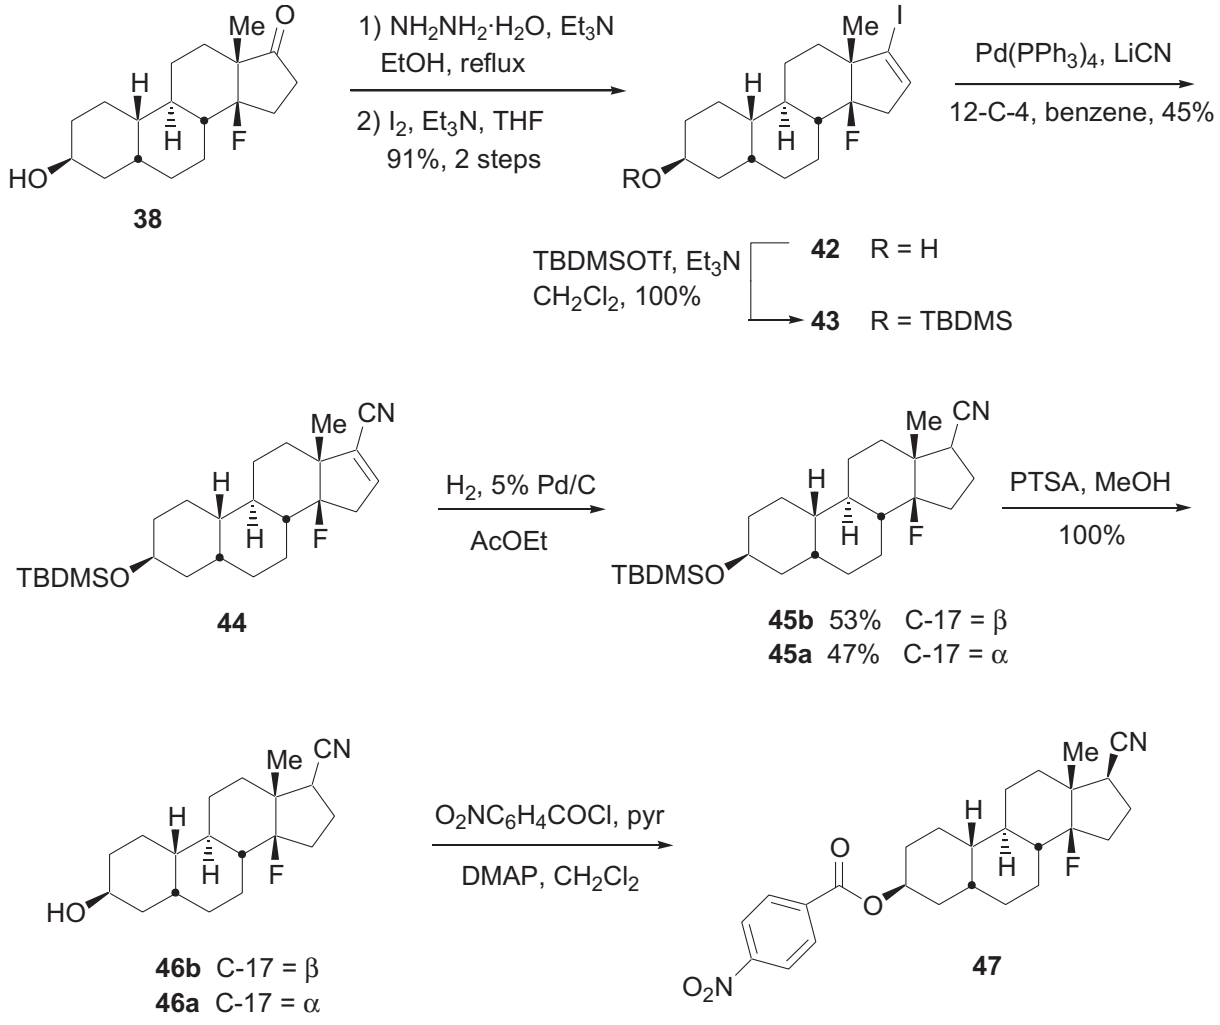
Scheme 10.

tained, which confirmed the stereochemistry of all the asymmetric centers (Fig. 3).

To complete the synthesis, only two steps were required: the reduction of the nitrile to an aldehyde, and a Horner–Emmons reaction to introduce the α,β-unsaturated ester at the C-17 center. DIBALH was used to reduce the nitriles **46a** and **46b**. Reduction of the α-nitrile **46a** at 0 °C gave two compounds (Scheme 12), which were identified as aldehydes **48** and **49**, each containing an olefin. Clearly, the fluoride is sensitive to the presence of Lewis acid. In an attempt to resolve this problem, many other reducing agents were tried ($LiAlH(OEt)_3$, $LiAlH_4$, Raney Ni), but in each

© 2006 NRC Canada

Scheme 11.



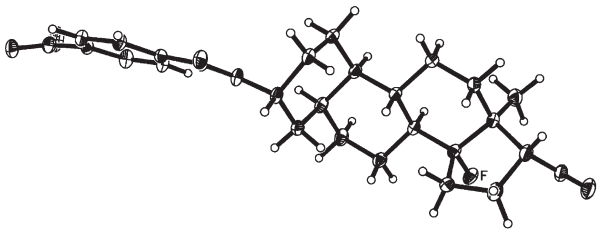


Fig. 3. Single crystal X-ray structure of *p*-nitrobenzoate **47**.

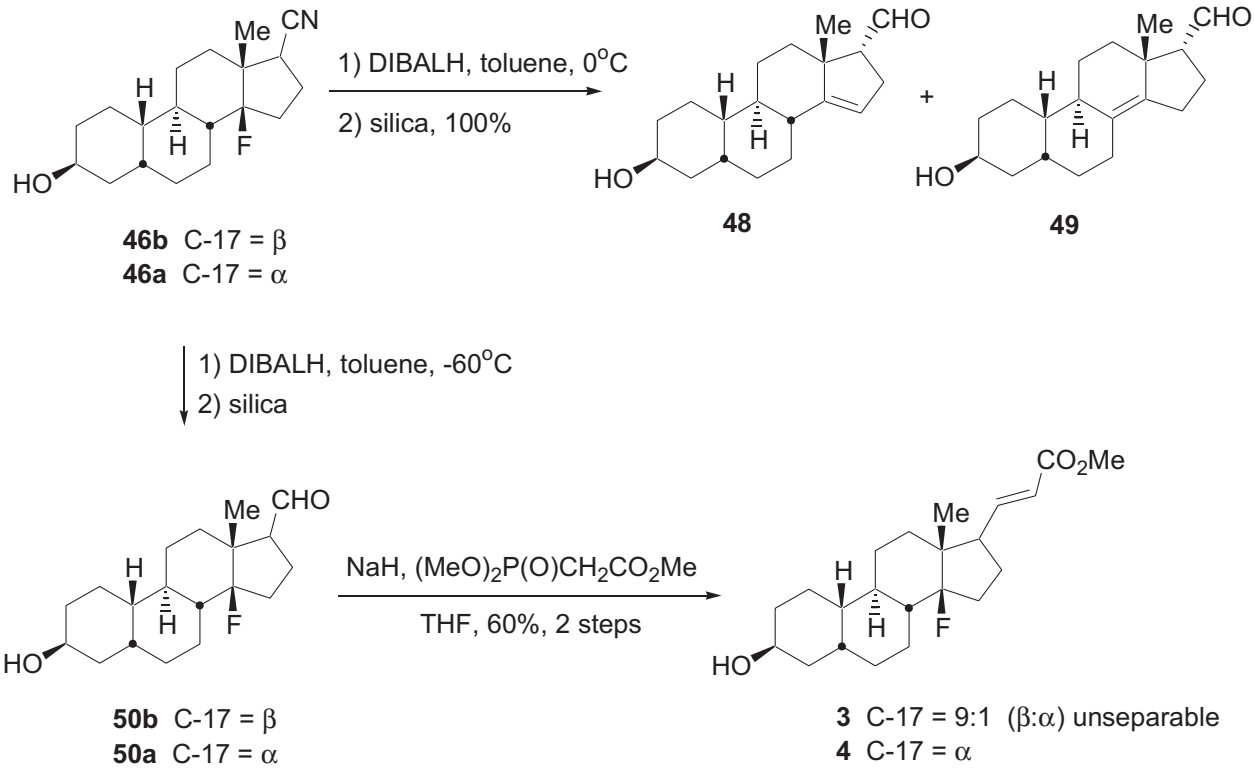
case, the starting material was recovered with some decomposition products. After considering these results, we decided to attempt the reduction of the α-nitrile **46a** with DIBALH at a lower temperature. When the reduction was performed at –78 °C, the starting material was recovered. The corresponding imine was obtained when the reaction was performed at –60 °C with 10 equiv. of DIBALH. To hydrolyze this imine, the residue was passed through a silica gel pad and α-aldehyde **50a** was obtained. The Horner–Emmons reaction was carried out on this aldehyde to furnish the desired α-fluoro analog **4** in 60% yield for the two last steps.



To complete the synthesis of the β-fluoro analog **3**, we had to repeat the last two steps previously discussed on the β-nitrile **46b**. Reduction of β-nitrile **46b** with DIBALH worked well to give the corresponding imine, but when this imine was passed through the silica gel pad, partial isomerization of the β- to α-aldehyde took place (Scheme 12).

To resolve this problem of epimerization, we tried to use aqueous conditions to hydrolyze the β-imine but with no success. Better results were obtained when the β-imine was passed rapidly through a short silica gel pad, and the corresponding aldehyde was obtained as a mixture of β-aldehyde **50b** and α-aldehyde **50a** (9:1). The Horner–Emmons reaction was performed on this mixture of aldehydes to give an unseparable 9:1 mixture of the β-fluoro analog **3** and α-fluoro analog **4**. This mixture was used to study the biological activity for the β-fluoro analog.

The biological activities of these two racemic fluoro analogs **3** and **4** were studied and compared with digitoxigenin **1**. Radioligand binding studies were performed to measure ligand–receptor affinities for **1**, **3**, and **4** at the ouabain receptor (i.e., ATPase (Na^+/K^+) expressed in the MDCK (dog kidney) cell line). [^{3}H]ouabain was used as the radioligand for competitive displacement. Compound binding affinities are reported as IC_{50} values, indicative of the drug concentration needed to inhibit 50% of [^{3}H]ouabain binding to the Na^+,K^+-ATPase. The results are very surpris-

Scheme 12.

ing. We expected that the inhibitory activity of the β-fluoro analog **3** would be superior to that α-fluoro analog **4**, but it was not the case. The β-fluoro analog **3** exhibited no activity, while the α-fluoro analog **4** had an IC_{50} of 12 μmol/L, in comparison to the natural product digitoxigenin **1** (IC_{50} of 0.35 μmol/L). No explanation can be provided to rationalize this result. However, the primary result obtained with the α-fluoro analog **4** has encouraged us to continue with the synthesis of other analogs to optimize the biological activity of this class of fluoro-steroids, and the results will be presented in another publication.

Summary

In summary, the synthesis of the fluoro analogs **3** and **4** was carried out via the formation of β-keto ester **7** with excellent yields. The macrocyclization reaction with this β-keto ester afforded the 13-membered macrocycle **6** with the trans-cis-cis olefin geometry, the precursor needed for the TADA reaction. The key step of the synthesis, the TADA reaction, was performed on this macrocycle to give the steroidal tetracycle **21** with the desired TSC configuration at the ring junction. With this TADA reaction, four new centers were created in one step to give the expected tetracycle **21**. This key tetracycle was obtained in 19 steps with very high yields and complete control of the diastereoselectivity. The functionalization of the A ring was accomplished and the homologation of the C-17 position was performed to give the desired α- and β-fluoro analogs.

The fluoro analog syntheses have been achieved in 35 steps in a linear sequence with 0.7% overall yield. The chemoselectivity, regioselectivity, and stereochemistry were controlled at each step of the synthesis except for the reduction of the β-nitrile **46b** to the corresponding aldehyde at the end of the sequence that gives 10% epimerization. The biological activity was measured for the two fluoro analogs. Surprisingly, the α-fluoro analog **4** provided 5% of the inhibitory potency of natural digitoxigenin **1**.

Experimental section

General

All reactions were performed under a nitrogen atmosphere with oven (150 °C) or flame-dried glassware. All solvents were distilled prior to use: ether and tetrahydrofuran from sodium–benzophenone; toluene, dichloromethane, and dimethyl sulfoxyde were distilled over calcium hydride, and methanol from magnesium–iodine. Most amines were dried over calcium hydride and distilled. All other starting materials and reagents were obtained commercially and used as such. For reaction workups, all organic phases were dried over magnesium sulphate. Analytical TLC was carried out on precoated glass plates (0.25 mm) with silica gel 60 (230–400 mesh). The following abbreviations were used for NMR data: singlet (s), doublet (d), triplet (t), quadruplet (q), multiplet (m), broad (br). Chemical shifts are reported in ppm δ units relative to chloroform (7.26 ppm for ^{1}H NMR and 77.0 ppm for decoupled ^{13}C NMR) as internal standard. ^{1}H and ^{13}C NMR spectra are referenced with respect to the residual signals of the solvent; they are described using standard abbreviations. ^{13}C NMR spectra of fluoro compounds give more carbon signals (one to five) owing to fluorine coupling with carbon. Melting points (mp) are uncorrected. Mass spectra (MS) were obtained with electronic ionization (70 eV).

Olefin 11

To a stirred solution of ketone **10** (20 g, 113 mmol) in tetrahydrofuran (500 mL) at –78 °C was added lithium aluminium hydride (2.2 g, 57 mmol). The mixture was stirred at –78 °C for 1 h and sodium sulfate decahydrate was added. The mixture was stirred at room temperature for 1 h and the precipitate was filtrated and washed with dichloromethane. The solvent was evaporated and crude alcohol was diluted in benzene. *p*-Toluenesulfonic acid (215 mg, 1.13 mmol) was added and the mixture was stirred at reflux with a Dean–Stark for 1.5 h. Satd. aq. $NaHCO_3$ was added and the aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The crude compound was filtered on a silica gel pad and washed with ethyl acetate – hexanes (3:7) to give olefin **11** as a colorless oil (19 g, 100%). IR ($CHCl_3$, cm^{-1}) ν: 3030, 2933, 2830, 1606, 1569, 1500, 1464, 1428, 1253. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 6.96 (1H, d, J = 9.1 Hz, Ph), 6.71–6.68 (2H, m, Ph), 6.42 (1H, dt, J = 9.3, 1.9 Hz, PhCH=C*H*CH_2), 5.90 (1H, dt, J = 9.3, 4.4 Hz, PhC*H*=$CHCH_2$), 3.80 (3H, s, $ArOCH_3$), 2.78 (2H, t, J = 8.2 Hz, $PhCH_2CH_2$), 2.33–2.26 (2H, m, $PhCH{=}CHCH_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 158.53, 137.08, 127.32, 127.14, 126.78, 125.81, 113.79, 111.02, 55.13, 27.97, 22.96. MS (*m*/*e*): 160 ($[M]^+$). HR-MS calcd. for $C_{11}H_{16}O_3$: 160.0888 ($[M]^+$); found: 160.0887 ± 0.0005.

Diol 9

To a stirred solution of olefin **11** (26.0 g, 160.3 mmol) in methanol (2 L) at –78 °C, O_3 was bubbled at –78 °C for 1.5 h. Nitrogen was bubbled for 15 min and sodium borohydride (12.1 g, 319.9 mmol) was added. The mixture was stirred at room temperature for 2 h and sodium borohydride (6.1 g, 160.0 mmol) was added. The mixture was stirred for 1 h and solvent was evaporated. The crude compound was diluted in tetrahydrofuran (1 L) and an aqueous solution of 2.5 mol/L NaOH (330 mL) and 30% hydrogen peroxide (230 mL) were added. The mixture was stirred at room temperature for 18 h. Aqueous sodium thiosulfate solution (10%) was added and the aqueous phase was extracted with chloroform. The combined organic phases were dried, filtered, and evaporated to give diol **9** as an amorphous white solid (27.1 g, 86%). IR ($CHCl_3$, cm^{-1}) ν: 3327, 2939, 2875, 1610, 1580, 1500, 1460, 1256, 1160, 1111, 1055, 1031, 942, 819. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.22 (1H, d, J = 8.3 Hz, Ph), 6.78 (1H, d, J = 2.7 Hz, Ph), 6.72 (1H, dd, J = 8.3, 2.7 Hz, Ph), 4.63 (2H, s, $ArCH_2OH$), 3.80 (3H, s, $ArOCH_3$), 3.57 (2H, t, J = 5.9 Hz, CH_2CH_2OH), 2.82 (2H, t, J = 7.3 Hz, $ArCH_2CH_2$), 2.49 (2H, broad, $ArCH_2OH$, CH_2CH_2OH), 1.93 (2H, quint, J = 6.1 Hz, $CH_2CH_2CH_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 159.34, 142.05, 131.06, 130.80, 115.02, 110.88, 62.41, 60.74, 55.17, 33.63, 27.26. MS (*m*/*e*): 196 ($[M]^+$). HR-MS calcd. for $C_{11}H_{16}O_3$: 196.1099 ($[M]^+$); found: 196.1108 ± 0.0006.

Hydroxyaldehyde 12

To a stirred solution of diol **9** (9.5 g, 48.5 mmol) in a mixture of pentane–dichloromethane (4:1) (100 mL) was added MnO_2 (21.0 g, 242.5 mmol) and the mixture was stirred at room temperature for 30 min. MnO_2 was added in portions of 21.0 g every 30 min until the reaction was finished. The mixture was filtered on a silica gel pad and was further washed with ethyl acetate. The solvent was evaporated to give hydroxyaldehyde **12** as a yellow oil (8.0 g, 85%). IR ($CHCl_3$, cm^{-1}) ν: 3414, 2942, 2872, 1682, 1599, 1566, 1496, 1463, 1431, 1290, 1251, 1121, 1057, 1025, 813. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 10.06 (1H, s, C*H*O), 7.78 (1H, d, J = 8.6 Hz, Ph), 6.89 (1H, dd, J = 8.6, 2.5 Hz, Ph), 6.82 (1H, d, J = 2.5 Hz, Ph), 3.90 (3H, s, $ArOCH_3$), 3.68 (2H, t, J = 6.1 Hz, CH_2CH_2OH), 3.15 (2H, t, J = 7.8 Hz, $ArCH_2CH_2$), 2.06–1.85 (3H, m, $CH_2CH_2CH_2OH$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 191.54, 163.85, 147.53, 135.56, 127.29, 116.40, 111.68, 61.52, 55.44, 34.50, 28.93. MS (*m*/*e*): 194 ($[M]^+$). HR-MS calcd. for $C_{11}H_{14}O_3$: 194.0943 ($[M]^+$); found: 194.0948 ± 0.0006.

Ester 13

To a stirred solution of hydroxyaldehyde **12** (8.7 g, 44.8 mmol) in tetrahydrofuran (200 mL) were added imidazole (7.6 g, 112 mmol) and *tert*-butyldimethylsilyl chloride (10.1 g, 67.2 mmol). The mixture was stirred at room temperature for 45 min and satd. aq. NH_4Cl was added. The aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (10% ethyl acetate, 90% hexanes) to give the corresponding silyl ether as a yellow oil (13.8 g, 100%). IR ($CHCl_3$, cm^{-1}) ν: 2959, 2929, 2856, 2734, 1689, 1600, 1463, 1225, 1102, 1029, 836. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 10.14 (1H, s, C*H*O), 7.80 (1H, d, J = 8.6 Hz, Ph), 6.85 (1H, dd, J = 8.6, 2.6 Hz, Ph), 6.77 (1H, d, J = 2.6 Hz, Ph), 3.87 (3H, s, $ArOCH_3$), 3.68 (2H, t, J = 6.1 Hz, $CH_2CH_2OTBDMS$), 3.07 (2H, dd, J = 7.9, 6.1 Hz, $ArCH_2CH_2$), 1.84 (2H, dt, J = 9.5, 6.1 Hz, $CH_2CH_2CH_2OTBDMS$), 0.91 (9H, s, $Si\text{-}C(CH_3)_3$), 0.06 (6H, s, $Si(CH_3)_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 190.75, 163.7, 147.8, 134.31, 127.5, 116.18, 111.71, 62.19, 55.43, 34.84, 29.95, 25.95, 18.3, –5.3. MS (*m*/*e*): 251 ($[M - C_4H_9]^+$). HR-MS calcd. for $C_{13}H_{19}O_3Si$: 251.1103 ($[M - C_4H_9]^+$); found: 251.1108 ± 0.0007.

To a suspension of sodium hydride 60% in oil (2.5 g, 61.8 mmol) in tetrahydrofuran (350 mL) was added triethyl phosphonoacetate (12.3 mL, 61.8 mmol). The mixture was stirred at room temperature for 15 min and a solution of aldehyde (12.7 g, 41.2 mmol) in tetrahydrofuran (50 mL) was added. The mixture was stirred at room temperature for 20 min and satd. aq. NH_4Cl was added. The aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was filtered on a silica gel pad and washed with 10% ethyl acetate in hexanes to give ester **13** as a yellow oil (15.2 g, 97%). IR ($CHCl_3$, cm^{-1}) ν: 2954, 2857, 1712, 1603, 1495, 1464, 1366, 1295, 1257, 1159, 1105, 1032, 979, 837. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.95 (1H, d, J = 15.8 Hz, PhC*H*=CH), 7.56 (1H, d, J = 9.2 Hz, Ph), 6.76–6.73 (2H, m, Ph), 6.28 (1H, d, J = 15.8 Hz, PhCH=C*H*), 4.27 (2H, q, J = 7.1 Hz, $CO_2CH_2CH_3$), 3.84 (3H, s, $ArOCH_3$), 3.77 (2H, t, J = 6.3 Hz, $CH_2CH_2OTBDMS$), 2.81 (2H, dd, J = 9.7, 6.1 Hz, $ArCH_2CH_2$), 1.81 (2H, dt, J = 9.7, 6.1 Hz, $CH_2CH_2CH_2OTBDMS$), 1.35 (3H, t, J = 7.1 Hz, $CO_2CH_2CH_3$), 0.93 (9H, s, $SiC(CH_3)_3$), 0.08 (6H, s, $Si(CH_3)_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 167.26, 161.01, 143.91, 141.48, 128.14, 125.57, 116.95, 115.15,

Alcohol 15

To a stirred solution of disilyl ether **14** (40.3 g, 70.2 mmol) in ethanol 95% (500 mL) was added *p*-toluenesulfonate pyridinium salt (1.8 g, 7.02 mmol) and the mixture was stirred at room temperature overnight. Satd. aq. $NaHCO_3$ was added and the aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (50% ethyl acetate, 50% hexanes) to give alcohol **15** as a yellow oil (31.5 g, 98%). IR ($CHCl_3$, cm^{-1}) ν: 3390, 3048, 2937, 2859, 1607, 1496, 1465, 1380, 1256, 1202, 1110, 1057, 967. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.75 (4H, dd, *J* = 7.5, 1.7 Hz, Ph), 7.48–7.38 (7H, m, Ph), 6.89 (1H, dt, *J* = 15.6, 1.7 Hz, PhC*H*=CH), 6.78–6.73 (2H, m, Ph), 6.11 (1H, dt, *J* = 15.6, 4.7 Hz, PhCH=C*H*), 4.41 (2H, dd, *J* = 4.7, 1.9 Hz, CH_2OTBDPS), 3.82 (3H, s, ArOCH_3), 3.65 (2H, t, *J* = 6.3 Hz, CH_2CH_2OH), 2.75 (2H, dd, *J* = 7.9, 6.2 Hz, ArCH_2CH_2), 1.89–1.80 (2H, m, $CH_2CH_2CH_2$), 1.61 (1H, massif, CH_2O*H*), 1.11 (9H, s, SiC(CH_3)$_3$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 158.94, 140.71, 135.56, 133.72, 129.71, 128.63, 128.35, 127.73, 127.25, 126.29, 114.84, 111.85, 64.68, 62.19, 55.25, 33.78, 29.74, 26.86, 19.32. MS (*m*/*e*): 403 ([M – C_4H_9]$^+$). HR-MS calcd. for $C_{25}H_{27}O_3Si$: 403.1729 ([M – C_4H_9]$^+$); found: 403.1734 ± 0.0012.

Aldehyde 16

To a stirred solution of DMSO (14.6 mL, 205.5 mmol) in dichloromethane (700 mL) at –78 °C were slowly added oxalyl chloride (12.0 mL, 137.0 mmol) and the alcohol **15** (31.5 g, 68.5 mmol) in dichloromethane. The mixture was stirred at –78 °C for 45 min and triethylamine (38.5 mL, 274.0 mmol) was added. The mixture was stirred at room temperature for 1 h and satd. aq. NH_4Cl was added. The aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was filtered on a silica gel pad and washed with 50% ethyl acetate in hexanes to give aldehyde **16** as a yellow oil (31.5 g, 100%). IR ($CHCl_3$, cm^{-1}) ν: 3078, 2935, 2857, 2721, 1925, 1607, 1496, 1428, 1256, 1110, 967. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 9.78 (1H, s, C*H*O), 7.73 (4H, dd, *J* = 7.5, 1.6 Hz, Ph), 7.49–7.38 (7H, m, Ph), 6.83 (1H, dt, *J* = 15.6, 1.8 Hz, PhC*H*=CH), 6.77 (1H, dd, *J* = 5.8, 2.8 Hz, Ph), 6.71 (1H, d, *J* = 2.8 Hz, Ph), 6.11 (1H, dt, *J* = 15.5, 4.7 Hz, PhCH=C*H*), 4.41 (2H, dd, *J* = 4.7, 1.9 Hz, CH_2OTBDPS), 3.82 (3H, s, ArOCH_3), 2.98 (2H, dt, *J* = 7.4 Hz, ArCH_2CH_2), 2.71 (2H, t, *J* = 7.24 Hz, CH_2CH_2CHO), 1.11 (9H, s, SiC(CH_3)$_3$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 201.26, 139.06, 135.56, 133.68, 129.76, 129.03, 128.54, 127.83, 127.76, 127.67, 127.51, 125.70, 114.77, 112.26, 64.57, 55.27, 44.74, 26.87, 25.97, 19.33. Ester 8

To a stirred solution of fluorophosphonate **17** (10.2 g, 42.3 mmol) in tetrahydrofuran (700 mL) at –78 °C was added a 1.4 mol/L solution of *n*-butyl lithium in hexanes (32.0 mL, 42.3 mmol). The mixture was stirred at –78 °C for 10 min and aldehyde **16** (12.9 g, 28.2 mmol) in tetrahydrofuran was added. The mixture was stirred at –78 °C for 45 min and satd. aq. NH_4Cl was added. The aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (10% ethyl acetate, 90% hexanes) to give ester **8** as a colorless oil (14.3 g, 93%). IR ($CHCl_3$, cm^{-1}) ν: 3048, 2935, 2858, 1728, 1607, 1496, 1465,

β-Keto ester 19

Solution 1

To a suspension of 60% sodium hydride in oil (592 mg, 14.8 mmol) in tetrahydrofuran (20 mL) at 0 °C was added methyl acetoacetate (2.8 mL, 26.3 mmol) and the mixture was stirred at 0 °C for 30 min. A solution of 1.6 mol/L *n*-butyl lithium in hexanes (8.6 mL, 13.8 mmol) was added and the mixture was stirred at 0 °C for 30 min.

Solution 2

To a stirred solution of chloride **18** (1.03 g, 1.97 mmol) in tetrahydrofuran (20 mL) was added sodium iodide (885 mg, 5.9 mmol) and the mixture was stirred at room temperature for 30 min.

Solution 1 was added to solution 2 and the mixture was stirred at room temperature overnight. Satd. aq. NH_4Cl was added and the aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (30% ethyl acetate, 70% hexanes) to give β-keto ester **19** as a yellow oil (770 mg, 65%). IR ($CHCl_3$, cm^{-1}) ν: 3020, 2955, 2860, 1745, 1720, 1608, 1496, 1433, 1315, 1217, 1110, 967, 756. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 12.05 (RC(O)C*H*=C(OH)R′), 7.75 (4H, dd, *J* = 7.4, 1.7 Hz, Ph), 7.49–7.37 (7H, m, Ph), 6.92–6.87 (1H, m, CH=C*H*Ph), 7.77 (1H, dd, *J* = 8.5, 2.7 Hz, Ph), 6.70 (1H, d, *J* = 2.7 Hz, Ph), 6.11 (1H, dt, *J* = 15.5, 4.6 Hz, C*H*=CHPh), 5.06 (1H, dt, *J* = 21.7, 8.1 Hz, C*H*=CFR), 4.43 (2H, dd, *J* = 4.6, 1.8 Hz, CH_2OTBDPS), 3.82 (3H, s, $ArOCH_3$), 3.73 (3H, s, CO_2CH_3), 3.39 (2H, s, $C(O)CH_2C(O)$), 2.72 (2H, t, *J* = 7.3 Hz, $ArCH_2CH_2$), 2.55–2.20 (6H, m, $CH_2CH_2C(O)$, $CH_2CH_2C(O)$, CH_2CH=CFR), 1.13 (9H, s, Si-$C(CH_3)_3$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 167.36, 160.38, 158.83, 157.12, 139.99, 135.54, 133.72, 129.71, 128.70, 128.61, 127.73, 127.25, 126.01, 115.17, 112.07, 105.57, 105.28, 64.58, 55.25, 52.35, 48.89, 39.14, 33.58, 26.86, 22.02, 21.65, 19.31. Macrocycle 20

Solution 1

To a stirred solution of pivaloic ester **7** (1.67 g, 3.73 mmol) in tetrahydrofuran (15 mL) degassed with Ar was added *N*,*O*-bis(trimethylsilyl)acetamide (1.8 mL, 7.46 mmol). The mixture was stirred at reflux for 5 h.

Solution 2

To a stirred solution of tetrakis(triphenylphosphine) palladium(0) (1.07 g, 0.93 mmol) in tetrahydrofuran (1.9 L) degassed with Ar was added 1,3-bis(diphenylphospino)propane (384 mg, 0.93 mmol) and the mixture was stirred at reflux for 1 h.

Solution 1 was slowly added to solution 2 at reflux for 14 h and the resulting mixture was heated for 4 h. The solvent was evaporated and the residue was purified by flash chromatography (5% ethyl acetate, 35% dichloromethane, 60% hexanes) to give macrocycle **20** as a white solid (1.14 g, 88%); mp 129–131 °C. IR ($CHCl_3$, cm^{-1}) ν: 3020, 2956, 1743, 1714, 1607, 1493, 1436, 1250, 1216, 1165, 1115, 1078, 1041, 970, 762. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.21 (1H, d, J = 8.4 Hz, Ph), 6.73 (1H, dd, J = 8.4, 2.8 Hz, Ph), 6.67 (1H, d, J = 2.8 Hz, Ph), 6.57 (1H, d, J = 15.7 Hz, PhC*H*=CH), 5.77 (1H, ddd, J = 15.6, 8.6, 5.3 Hz, C*H*=CHPh), 5.00 (1H, dt, J = 20.7, 7.7 Hz, C*H*=CFR), 3.80 (3H, s, ArOCH_3), 3.77 (3H, s, CO_2CH_3), 3.80–3.75 (1H, m, C(O)C*H*C(O)), 3.04–1.86 (10H, m, PhCH_2CH_2CH=CFR, CH=C(F)CH_2CH_2C(O), CH_2C(H)CO_2Me). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 204.00, 169.54, 160.98, 159.09, 157.11, 140.77, 131.98, 129.24, 128.38, 126.07, 114.54, 111.63, 105.80, 105.52, 57.71, 55.19, 52.58, 39.06, 33.90, 32.01, 27.89, 22.42. MS (*m*/*e*): 346 ($[M]^+$). HR-MS calcd. for $C_{20}H_{23}O_4F$: 346.1580 ($[M]^+$); found: 346.1576 ± 0.0010.

Triene 6

To a stirred solution of 70% benzeneseleninic anhydride (10.2 g, 19.8 mmol) in dichloromethane (200 mL) was added triethylamine (4.6 mL, 32.9 mmol) and the mixture was stirred for 15 min. A solution of macrocycle **20** (2.30 g, 6.65 mmol) in dichloromethane was added and the mixture was stirred for 15 min. Satd. aq. $NaHCO_3$ was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (5% ethyl acetate, 95% dichloromethane) to give triene **6** as a yellow solid (2.05 g, 91%); mp 147–149 °C. IR ($CHCl_3$, cm^{-1}) ν: 3020, 2954, 1696, 1603, 1583, 1436, 1275, 1241, 1158, 1077, 1045. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.43 (1H, d, J = 11.5 Hz, PhCH=CH=C*H*), 7.21 (1H, d, J = 8.5 Hz, Ph), 6.96 (1H, d, J = 16.2 Hz, CH=C*H*Ph), 6.76 (1H, dd, J = 8.4, 2.7 Hz, Ph), 6.71 (1H, d, J = 2.7 Hz, Ph), 6.64 (1H, dd, J = 16.2, 11.5 Hz, PhCH=C*H*), 5.26 (1H, dt, J = 22.1, 8.7 Hz, C*H*=CFR), 3.82 (3H, s, ArOCH_3), 3.81 (3H, s, CO_2CH_3), 2.97–2.93 (2H, m, $CH_2CH_2C(O)$), 2.87–2.81 (2H, m, PhCH_2CH_2), 2.58 (2H, dt, J = 22.1, 6.9 Hz, $CH_2CH_2C(O)$), 2.22–2.14 (2H, m, PhCH_2CH_2). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 203.17, 164.94, 160.41, 159.01, 155.73, 144.16, 142.15, 136.13, 131.88, 126.46, 123.62, 117.45, 111.76, 107.23, 106.93, 55.29, 52.14, 39.48, 37.15, 26.02, 23.61. Ester 30

To a stirred solution of α,β-unsaturated ester **29** (15 mg, 0.044 mmol) in ethanol (2 mL) was added 5% palladium(0) on activated carbon (9 mg, 0.0044 mmol) and hydrogen was bubbled through the solution for 10 min. The mixture was stirred for 1 h under a hydrogen atmosphere and filtered on a silica gel pad. The solvent was evaporated to give ester **30** as a colorless oil (15 mg, 100%). IR ($CHCl_3$, cm^{-1}) ν: 2945, 2862, 1732, 1610, 1502, 1466, 1260, 1199, 1166, 1044, 961. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.18 (1H, d, *J* = 8.6 Hz, *Ph*), 6.72 (1H, dd, *J* = 8.6, 2.8 Hz, *Ph*), 6.64 (1H, d, *J* = 2.8 Hz, *Ph*), 3.78 (3H, s, $ArOCH_3$), 3.71 (3H, s, CO_2CH_3), 3.05 (1H, t, *J* = 9.2 Hz, C*H*CO_2Me), 2.91–2.86 (2H, m, $PhCH_2CH_2$), 2.50–2.42 (1H, m, PhC*H*), 2.29–1.78 (7H, m), 1.58–1.30 (4H, m), 1.21 (3H, d, *J* = 1.1 Hz, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 174.38, 157.62, 137.69, 131.23, 126.80, 113.69, 111.90, 110.58, 55.20, 53.16, 51.47, 42.10, 41.81, 40.05, 31.15, 30.06, 29.69, 29.29, 28.96, 26.05, 23.01, 22.22, 17.58. MS (*m*/*e*): 346 $([M])^+$. HR-MS calcd. for $C_{21}H_{27}O_3F$: 346.1944 ($[M]^+$); found: 346.1940 ± 0.0010.

α,β-Unsaturated nitrile 32

To a stirred solution of triflic enol ether **28** (41 mg, 0.094 mmol) in benzene (10 mL) were added lithium cyanide (18 mg, 0.56 mmol), tetrakis(triphenylphosphine) palladium(0) (11 mg, 0.0094 mmol), and 12-C-4 ether (2 μL, 0.0094 mmol). The resulting mixture was stirred at room temperature overnight and a catalytic amount of palladium (11 mg, 0.0094 mmol) was added. The mixture was stirred for an additional 24 h and water was added. The aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (10% ethyl acetate, 90% hexanes) to give α,β-unsaturated nitrile **32** as an amorphous solid (23 mg, 79%). IR ($CHCl_3$, cm^{-1}) ν: 3054, 2932, 2568, 2219, 1610, 1502, 1422, 1265, 1041, 883. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.22 (1H, d, *J* = 8.6 Hz, *Ph*), 6.74 (1H, dd, *J* = 8.6, 2.7 Hz, *Ph*), 6.65 (1H, d, *J* = 2.7 Hz, *Ph*), 6.59 (1H, t, *J* = 2.6 Hz, C*H*=C(CN)R), 3.79 (3H, s, $ArOCH_3$), 2.93–2.88 (2H, m, $PhCH_2CH_2$), 2.84–2.68 (1H, m), 2.47–2.38 (1H, m), 2.31–2.10 (3H, m), 1.90 (1H, qd, *J* = 11.9, 2.1 Hz), 1.57–1.22 (4H, m), 1.31 (3H, d, *J* = 2.6 Hz, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 157.79, 142.09, 137.52, 130.03, 127.22, 125.12, 115.38, 113.78, 112.12, 107.07, 104.62, 55.22, 52.57, 52.31, 42.78, 42.48, 40.35, 38.99, 38.63, 37.93, 29.94, 25.69, 23.10, 14.96. α,β-Unsaturated ketone 34

To a stirred solution of tetracycle **26** (227 mg, 0.75 mmol) in tetrahydrofuran (10 mL) at –78 °C was added 95% ethanol (1 mL), and gaseous ammonia was condensed (20 mL). Metallic lithium was added by portion until the solution was blue and the resulting mixture was stirred at –78 °C for 2 h. Solid NH_4Cl was added slowly until the blue color disappeared and ammoniac was evaporated at room temperature. Water was added and the aqueous phase was extracted with ether. The combined organic phases were dried, filtered, and evaporated. The residue was dissolved in tetrahydrofuran (10 mL) and 1 mol/L HCl (1 mL) was added. The mixture was stirred at room temperature overnight. Satd. aq. $NaHCO_3$ was added and the aqueous phase was extracted with ether. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (60% ethyl acetate, 40% hexanes) to give α,β-unsaturated ketone **34** as a colorless oil (168 mg, 77%). IR ($CHCl_3$, cm^{-1}) ν: 3611, 3432, 3016, 2949, 2874, 1662, 1619, 1454, 1364, 1220, 1067, 1007, 952. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 5.81 (1H, s, C*H*=CRR′), 4.18 (1H, t, *J* = 7.6 Hz, RR′C*H*OH), 2.52–1.46 (17H, m), 1.26–1.10 (3H, m), 1.05 (3H, s, C*H*$_3$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 199.85, 165.58, 124.76, 108.73, 106.36, 80.00, 47.23, 47.00, 45.78, 43.74, 43.45, 42.73, 36.36, 35.04, 27.91, 27.84, 26.34, 25.26, 25.02, 15.93. MS (*m*/*e*): 292 ([M]$^+$). HR-MS calcd. for $C_{18}H_{25}O_2F$: 292.1838 ([M]$^+$); found: 292.1832 ± 0.0008.

Ketones 35 and 36

To a stirred solution of α,β-unsaturated ketone **34** (126 mg, 0.43 mmol) in ethyl acetate (10 mL) was added 5% palladium(0) on activated carbon (91 mg, 0.043 mmol) and hydrogen was bubbled for 10 min. The mixture was stirred for 1 h under a hydrogen atmosphere and filtered on a silica gel pad. The solvent was evaporated and the residue was purified by flash chromatography (50% ethyl acetate, 50% hexanes) to give ketone **36** (cis) as a colorless oil (76 mg, 60%) and ketone **35** (trans) as a colorless oil (33 mg, 27%). Ketone **36** (cis): IR ($CHCl_3$, cm^{-1}) ν: 3444, 3019, 2932, 2882, 1706, 1466, 1216, 1077, 958. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.22 (1H, t, *J* = 7.8 Hz, RR′C*H*OH), 2.52 (1H, t, *J* = 13.9 Hz, RC(O)CH$_2$C*H*), 2.31–1.44 (19H, m), 1.39–1.10 (3H, m), 1.07 (3H, s, C*H*$_3$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 212.42, 108.91, 106.54, 80.33, 44.79, 44.51, 42.75, 40.31, 37.70, 36.43, 34.95, 30.10, 28.25, 28.00, 27.89, 27.80, 27.30, 24.42, 19.32, 16.12. Diketone 37

To a stirred solution of alcohol **36** (76 mg, 0.26 mmol) in dichloromethane (5 mL) were added molecular sieve 4 Å (130 mg), 4-methylmorpholine-*N*-oxide (61 mg, 0.52 mmol), and tetrapropylammonium perruthenate (9 mg, 0.026 mmol). The resulting mixture was stirred at room temperature for 1 h and filtered on a silica gel pad. The solvent was evaporated to give diketone **37** as a colorless oil (76 mg, 99%). IR ($CHCl_3$, cm^{-1}) ν: 3020, 2930, 2879, 1740, 1708, 1461, 1215, 929, 746. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 2.59–2.37 (2H, m), 2.32–2.08 (6H, m), 1.88–1.05 (14H, m), 1.12 (3H, d, *J* = 1.5 Hz, C*H*$_3$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 219.46, 211.74, 106.80, 104.42, 44.52, 44.24, 42.63, 40.28, 37.45, 36.32, 35.06, 33.07, 31.91, 30.11, 27.20, 26.09, 25.75, 24.22, 19.10, 12.62. MS (*m*/*e*): 292 ([M]$^+$). HR-MS calcd. for $C_{18}H_{25}O_2F$: 292.1838 ([M]$^+$); found: 292.1844 ± 0.0008.

Alcohol 38

To a stirred solution of diketone **37** (71 mg, 0.24 mmol) in tetrahydrofuran (10 mL) at –78 °C was added a solution of 1 mol/L L-Selectride in tetrahydrofuran (360 µL, 0.36 mmol). The mixture was stirred at –78 °C for 1.5 h. A 2 mol/L NaOH solution and a 30% hydrogen peroxide solution were added and the aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (70% ethyl acetate, 30% hexanes) to give

Silyl ether 40

To a stirred solution of alcohol **38** (36 mg, 0.12 mmol) in dichloromethane (3 mL) were added triethylamine (84 μL, 0.60 mmol) and *tert*-butyldimethylsilane trifluoromethanesulfonate (41 μL, 0.18 mmol). The mixture was stirred at room temperature for 1 h. Satd. aq. NH_4Cl was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was dissolved in tetrahydrofuran (2 mL) and tetrapropylammonium fluoride (1 mol/L) in tetrahydrofuran (60 μL, 0.060 mmol) was added. The mixture was stirred at room temperature for 15 min. Satd. aq. NH_4Cl was added and the aqueous phase was extracted with ethyl acetate. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (10% ethyl acetate, 90% hexanes) to give silyl ether **40** as a colorless oil (46 mg, 92%). IR ($CHCl_3$, cm^{-1}) ν: 3020, 2931, 2882, 1739, 1471, 1446, 1252, 1212, 1050, 930. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.06 (1H, t, J = 2.6 Hz, RR′C*H*OTBDMS), 2.47–2.34 (2H, m), 2.29–2.05 (3H, m), 1.89–1.13 (17H, m), 1.09 (3H, d, J = 1.4 Hz, CH_3), 0.89 (9H, s, SiC(CH_3)$_3$), 0.02 (6H, s, Si(CH_3)$_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 220.18, 107.37, 105.00, 67.10, 44.83, 44.57, 41.43, 34.70, 34.58, 34.14, 33.15, 32.21, 32.13, 31.10, 29.28, 27.70, 26.07, 25.84, 25.81, 25.73, 24.38, 21.01, 19.73, 18.06, 12.65, 12.55, –4.89. Vinylic iodide 42

To a stirred solution of ketone **38** (101 mg, 0.34 mmol) in ethanol (7 mL) were added triethylamine (952 μL, 6.80 mmol) and hydrated hydrazine (165 μL, 3.40 mmol). The mixture was stirred at reflux for 5 days and water was added. The aqueous phases were extracted with dichloromethane and the combined organic phases were dried, filtered, and evaporated. The residue was dissolved in tetrahydrofuran (5 mL) and triethylamine (1 mL) was added. Iodide was added until a brown color appeared and the mixture was stirred for 5 min. Water was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were washed with saturated aqueous sodium thiosulfate and the organic phase was dried, filtered, and evaporated. The residue was purified by flash chromatography (40% ethyl acetate, 60% hexanes) to give vinylic iodide **42** as an amorphous white solid (125 mg, 91%). IR ($CHCl_3$, cm^{-1}) ν: 3386, 2931, 2873, 1459, 1447, 1380, 1263, 1000. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 6.06 (1H, t, J = 2.5 Hz, C*H*=CIR), 4.14 (1H, t, J = 2.8 Hz, RR′C*H*OH), 2.62–2.40 (2H, m, CH_2CH=CIR), 2.19–2.13 (1H, m), 1.86–1.10 (16H, m), 1.08 (3H, d, J = 2.8 Hz, CH_3), 1.05–0.83 (2H, m). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 132.48, 109.80, 105.63, 103.18, 66.85, 45.97, 45.68, 40.96, 40.63, 40.27, 37.36, 34.93, 33.17, 30.90, 29.28, 27.03, 24.26, 21.13, 20.75, 17.11. MS (*m*/*e*): 404 ($[M]^+$). HR-MS calcd. for $C_{18}H_{26}OFI$: 404.1012 ($[M]^+$); found: 404.1008 ± 0.0012.

Silyl ether 43

To a stirred solution of alcohol **42** (148 mg, 0.37 mmol) in dichloromethane (10 mL) were added triethylamine (1.3 mL, 1.85 mmol) and *tert*-butyldimethylsilane trifluoromethanesulfonate (94 μL, 0.41 mmol). The mixture was stirred at room temperature for 1 h. Satd. aq. NH_4Cl was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (10% ethyl acetate, 90% hexanes) to give silyl ether **43** as an amorphous white solid (190 mg, 100%). IR ($CHCl_3$, cm^{-1}) ν: 3019, 2930, 2856, 1509, 1424, 1364, 1217, 1048. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 6.07 (1H, t, J = 2.4 Hz, C*H*=CIR), 4.05 (1H, t, J = 2.4 Hz, RR′C*H*OTBDMS), 2.62–2.43 (2H, m, CH_2CH=CIR), 2.22–2.13 (1H, m), 1.89–0.91 (17H, m), 1.08 (3H, d, J = 2.8 Hz, CH_3), 0.89 (9H, s, SiC(CH_3)$_3$), 0.02 (6H, s, Si(CH_3)$_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 132.48, 109.92, 105.70, 103.24, 67.17, 54.23, 53.98, 46.08, 45.80, 41.13, 40.65, 40.29, 37.44, 35.11, 34.11, 31.20, 29.28, 27.80, 25.83, 24.35, 21.17, 20.90, 17.14, –4.87. MS (*m*/*e*): 461 ($[M - C_4H_9]^+$). HR-MS calcd. for $C_{20}H_{31}OFISi$: 461.1173 ($[M - C_4H_9]^+$); found: 461.1178 ± 0.0014.

α,β-Unsaturated nitrile 44

To a stirred solution of vinylic iodide **43** (47 mg, 0.091 mmol) in benzene (3 mL) were added lithium cyanide (18 mg, 0.55 mmol), tetrakis(triphenylphosphine) palladium(0) (11 mg, 0.0091 mmol), and 12-C-4 ether (2 μL, 0.0091 mmol). The resulting mixture was stirred at reflux for 30 min and water was added. The aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (7% ethyl acetate, 93% hexanes) to give α,β-unsaturated nitrile **44** as an amorphous white solid (17 mg, 45%). IR ($CHCl_3$, cm^{-1}) ν: 3019, 2930, 2546, 2127, 1610, 1504, 1368, 1215, 1168, 1086, 1049. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 6.54 (1H, t, J = 2.6 Hz, C*H*=C(CN)R), 4.05 (1H, massif, RR′C*H*OTBDMS), 2.83–2.54 (2H, m, CH_2CH=C(CN)R), 2.24–2.20 (1H, m), 2.03–1.96 (1H, m), 1.90–0.90 (16H, m), 1.26 (3H, d, J = 2.5 Hz, CH_3), 0.88 (9H, s, SiC(CH_3)$_3$), 0.02 (6H, s, Si(CH_3)$_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 141.97, 125.37, 115.51, 107.41, 104.95, 67.06, 52.47, 52.21, 45.28, 45.00, 41.02, 39.55, 39.18, 37.4, 34.81, 34.07, 31.10, 29.18, 27.76, 25.80, 24.33, 21.16, 18.06, 14.81, –4.89. MS (*m*/*e*): 402 ($[M - CH_3]^+$), 360 ($[M - C_4H_9]^+$). HR-MS calcd. for $C_{21}H_{31}OFNSi$: 360.2159 ($[M - C_4H_9]^+$); found: 360.2166 ± 0.0014.

Nitriles 45a and 45b

To a stirred solution of α,β-unsaturated nitrile **44** (15 mg, 0.036 mmol) in ethyl acetate (2 mL) was added a catalytic amount of 10% palladium(0) on activated carbon and hydro-

© 2006 NRC Canada

gen was bubbled through the solution for 15 min. The mixture was stirred for 2 h under a hydrogen atmosphere and filtered on a silica gel pad. The solvent was evaporated and the residue was purified by flash chromatography (10% ethyl acetate, 90% hexanes) to give nitrile β-**45a** as an amorphous white solid (8 mg, 53%) and nitrile α-**45b** as an amorphous white solid (7 mg, 47%). Nitrile α-**45a**: IR ($CHCl_3$, cm^{-1}) ν: 2930, 2856, 2363, 1460, 1444, 1252, 1216, 1047. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.05 (1H, t, J = 2.6 Hz, RR′C*H*OTBDMS), 2.98 (1H, t, J = 9.0 Hz, RR′C*H*CN), 2.27–0.95 (22H, m), 1.15 (3H, s, CH_3), 0.88 (9H, s, SiC(CH_3)$_3$), 0.02 (6H, s, Si(CH_3)$_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 120.70, 109.17, 106.76, 67.1, 48.42, 48.18, 44.74, 44.48, 41.38, 39.18, 34.52, 34.14, 31.27, 31.18, 30.25, 29.92, 29.26, 27.67, 25.81, 24.82, 24.14, 20.96, 18.07, 16.66, –4.90. MS (*m*/*e*): 404 ([M – CH_3]$^+$), 362 ([M – C_4H_9]$^+$). HR-MS calcd. for $C_{24}H_{39}OFNSi$: 404.2785 ([M – CH_3]$^+$); found: 404.2773 ± 0.0012. Nitrile β-**45b**: IR ($CHCl_3$, cm^{-1}) ν: 3019, 2930, 2856, 2240, 1527, 1477, 1426, 1215, 1048. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.05 (1H, t, J = 2.5 Hz, RR′C*H*OTBDMS), 2.65 (1H, t, J = 6.0 Hz, RR′C*H*CN), 2.28–1.96 (5H, m), 1.87–1.03 (17H, m), 1.30 (3H, s, CH_3), 0.88 (9H, s, SiC(CH_3)$_3$), 0.02 (6H, s, Si(CH_3)$_2$). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 121.92, 109.58, 107.18, 67.10, 48.46, 48.21, 44.71, 44.44, 41.46, 40.04, 36.65, 34.25, 34.12, 31.23, 30.85, 30.51, 29.24, 27.69, 25.80, 25.59, 21.17, 20.97, 18.06, 16.20, –4.88. Alcohols 46a

To a stirred solution of nitrile **45a** (7 mg, 0.017 mmol) in methanol was added a catalytic amount of PTSA and the mixture was stirred at room temperature for 3 h. Satd. aq. $NaHCO_3$ was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (50% ethyl acetate, 50% hexanes) to give alcohol **46a** as an amorphous white solid (5 mg, 100%). ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.15 (1H, t, J = 2.8 Hz, RR′C*H*OH), 2.98 (1H, t, J = 9.5 Hz, RR′C*H*CN), 2.23–2.16 (2H, m), 2.04–1.06 (21H, m), 1.15 (3H, s, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 120.68, 109.07, 106.67, 66.83, 48.46, 48.22, 44.70, 44.43, 41.27, 39.21, 34.38, 33.24, 31.33, 30.93, 30.29, 29.96, 29.29, 27.00, 24.80, 24.16, 20.97, 16.68. MS (*m*/*e*): 287 ([M – H_2O]$^+$). HR-MS calcd. for $C_{19}H_{26}FN$: 287.2049 ([M – H_2O]$^+$); found: 287.2045 ± 0.0008.

Alcohol 46b

The procedure used for the synthesis of alcohol **46a** was used with alcohol **46b** to give alcohol **46b** as an amorphous white solid (5 mg, 100%). IR ($CHCl_3$, cm^{-1}) ν: 3423, 3019, 2933, 2360, 1523, 1423, 1216, 928. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 4.14 (1H, t, J = 2.8 Hz, RR′C*H*OH), 2.66 (1H, t, J = 7.7 Hz, RR′C*H*CN), 2.28–1.96 (6H, m), 1.82–1.00 (17H, m), 1.30 (3H, s, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 121.86, 109.46, 107.42, 66.79, 48.45, 48.21, 44.62, 44.35, 41.30, 40.02, 36.56, 34.19, 33.22, 30.94, 30.51, 29.69, 29.23, 26.93, 25.51, 21.04, 20.94, 16.18. MS (*m*/*e*): 287 ([M – H_2O]$^+$). HR-MS calcd. for $C_{19}H_{26}FN$: 287.2049 ([M – H_2O]$^+$); found: 287.2045 ± 0.0008.

p-Nitrobenzoate 47

To a stirred solution of alcohol **46b** (1 mg, 0.0033 mmol) in dichloromethane (250 μL) were added pyridine (250 μL), *p*-nitrobenzoyle chloride (6 mg, 0.033 mmol), and 4-dimethylaminopyridine (catalytic amount). The resulting mixture was stirred at room temperature for 3 h. HCl (1 mol/L) was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (30% ethyl acetate, 70% hexanes) to give *p*-nitrobenzoate **47** as a white solid (1 mg); mp 210 to 211 °C. IR ($CHCl_3$, cm^{-1}) ν: 2934, 2856, 2244, 1719, 1280, 1118. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.30 (2H, d, J = 9.0 Hz, Ph), 8.21 (2H, d, J = 9.0 Hz, Ph), 5.40 (1H, t, J = 2.4 Hz, RR′C*H*OC(O)Ar), 2.68 (1H, t, J = 6.6 Hz, RR′C*H*CN), 2.31–1.07 (22H, m), 1.32 (3H, s, CH_3). MS (*m*/*e*): 472 ([MNH_4]$^+$). HR-MS calcd. for $C_{26}H_{35}O_4FN_3$: 472.2611 ([MNH_4]$^+$); found: 472.2623 ± 0.0014.

α,β-Unsaturated ester 4

To a stirred solution of nitrile **46a** (4 mg, 0.013 mmol) in toluene (1 mL) at –60 °C was added a 1.5 mol/L solution of DIBALH in toluene (26 μL, 0.039 mmol) and the mixture was stirred at –60 °C for 1 h. Sodium sulfate decahydrate was added and the mixture was stirred at room temperature for 1 h. The residue was filtered and the solvent was evaporated to give the corresponding imine. This imine was passed rapidly through a short silica gel pad to give aldehyde **50a** (4 mg) as a crude material. To a stirred suspension of 60% NaH in oil (5 mg, 0.13 mmol) in tetrahydrofuran (1 mL) was added trimethyl phosphonoacetate (21 μL, 0.13 mmol). The mixture was stirred at room temperature for 15 min and crude aldehyde **50a** (4 mg, 0.013 mmol) in tetrahydrofuran (1 mL) was added. The resulting mixture was stirred at room temperature for 30 min. Satd. aq. NH_4Cl was added and the aqueous phase was extracted with dichloromethane. The combined organic phases were dried, filtered, and evaporated. The residue was purified by flash chromatography (40% ethyl acetate, 60% hexanes) to give α,β-unsaturated ester **4** as a colorless oil (3 mg, 60% for two steps). IR ($CHCl_3$, cm^{-1}) ν: 3501, 2932, 2875, 1718, 1654, 1540, 1558, 1437, 1281, 1216, 1002. ^1H NMR (300 MHz, $CDCl_3$, ppm) δ: 6.91 (1H, dd, J = 15.6, 8.7 Hz, C*H*=CHCO$_2$Me), 5.83 (1H, J = 15.6 Hz, CH=C*H*CO$_2$Me), 4.14 (1H, t, J = 2.6 Hz, RR′C*H*OH), 3.73 (3H, s, CO$_2$CH_3), 2.81 (1H, q, J = 8.7 Hz, RR′C*H*CH=CHCO$_2$Me), 2.22–1.03 (23H, m), 1.00 (3H, d, J = 1.1 Hz, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 149.70, 149.57, 121.97, 66.93, 51.45, 51.33, 49.00, 45.09, 44.81, 41.27, 34.39, 34.27, 33.26, 31.00, 30.41, 30.06, 29.96, 29.37, 26.97, 25.04, 24.69, 20.98, 20.74, 16.81. MS (*m*/*e*) (source temperature: 100 °C): 364 ([M]$^+$), 344 ([M – HF]$^+$). HR-MS (source temperature: 100 °C) calcd. for $C_{22}H_{33}O_3F$: 364.2414 ([M]$^+$); found: 364.2403 ± 0.0011.

α,β-Unsaturated ester 3

Oxyhalogen-sulfur chemistry — Kinetics and mechanism of the oxidation of cysteamine by acidic iodate and iodine

Alice Chanakira, Edward Chikwana, David H. Peyton, and Reuben H. Simoyi

Abstract: The oxidation of cysteamine by iodate and aqueous iodine has been studied in neutral to mildly acidic conditions. The reaction is relatively slow and is heavily dependent on acid concentration. The reaction dynamics are complex and display clock behavior, transient iodine production, and even oligooscillatory production of iodine, depending upon initial conditions. The oxidation product was the cysteamine dimer (cystamine), with no further oxidation observed past this product. The stoichiometry of the reaction was deduced to be $IO_3^- + 6H_2NCH_2CH_2SH \rightarrow I^- + 3H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 3H_2O$ in excess cysteamine conditions, whereas in excess iodate the stoichiometry of the reaction is $2IO_3^- + 10H_2NCH_2CH_2SH \rightarrow I_2 + 5H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 6H_2O$. The stoichiometry of the oxidation of cysteamine by aqueous iodine was deduced to be $I_2 + 2H_2NCH_2CH_2SH \rightarrow 2I^- + H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 2H^+$. The bimolecular rate constant for the oxidation of cysteamine by iodine was experimentally evaluated as 2.7 $(\text{mol L}^{-1})^{-1}\ \text{s}^{-1}$. The whole reaction scheme was satisfactorily modeled by a network of 14 elementary reactions.

Key words: cysteamine, cystamine, Dushman reaction, oligooscillations.

Résumé : L'oxydation de la cystéamine par l'iodate et l'iode aqueux a été étudiée dans des conditions allant de neutre à faiblement acides. La réaction est relativement lente et dépend fortement sur la concentration en acide. La dynamique de la réaction est complexe et présente un comportement d'horloge avec production transitoire d'iode allant jusqu'à une production oligooscillatoire d'iode suivant les conditions initiales. Le produit de l'oxydation est le dimère de la cystéamine, la cystamine, sans oxydation apparente ultérieure de ce produit. On a déduit que, dans les conditions où la cystéamine est en excès la stoechiométrie de la réaction est $IO_3^- + 6H_2NCH_2CH_2SH \rightarrow I^- + 3H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 3H_2O$ alors que lorsque l'iodate est en excès, la stoechiométrie de la réaction est de la forme $2IO_3^- + 10H_2NCH_2CH_2SH \rightarrow I_2 + 5H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 6H_2O$. On a établi que la stoechiométrie de la réaction d'oxydation de la cystéamine par l'iode aqueux est de la forme $I_2 + 2H_2NCH_2CH_2SH \rightarrow 2I^- + H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 2H^+$. La valeur établie expérimentalement pour la constante de vitesse bimoléculaire d'oxydation de la cystéamine par l'iode est de 2,7 $(\text{mol L}^{-1})^{-1}\ \text{s}^{-1}$. On peut faire une modélisation complète du schéma réactionnel sur la base de quatorze réactions élémentaires.

Mots clés : cystéamine, cystamine, réaction de Dushman, oligooscillations.

Introduction

Organosulfur compounds dominate much of synthetic, analytical, and medicinal chemistry. Oxidations of organic sulfur compounds appear to be involved in many cellular functions, including regulation of protein synthesis and protection of the cell from oxidative damage (1). Owing to the nucleophilic nature of the thiol group, a better understanding of the biological activities of these compounds can be derived from their oxidation mechanisms. Studies of the oxidation mechanisms of organosulfur compounds have been hampered by the propensity of sulfur chemistry to produce complex and exotic dynamics (2), which are fueled by free-radical mechanisms (3), autoxidations, and production of varied products and intermediates (4, 5). With the sulfur center having an oxidation state range of –2 to +6, it is easy for these intermediates to assert themselves.

Cysteamine is a very important biological molecule. Medically known as Cystagon, it can be used as oral therapy for prevention of hypothyroidism and enhances growth in patients with nephropathic cystinosis (6, 7). This is a lysosomal storage disorder that was long considered primarily a renal disease but is now recognized as a systemic disorder that eventually affects many organ systems in children (8). This disorder is characterized by cystine accumulation within cellular lysosomes, and cysteamine converts this disulfide into cysteine and a mixed disulfide, cysteamine–cysteine, which can easily be eliminated from the cystinotic lysosomes, thus effecting depletion of cellular cystine (9).

Cysteamine and its disulfide, cystamine, can also be used in topical eye drops to dissolve corneal cystine crystals (10).

Cysteamine is an excellent scavenger of ·OH and HOCl; it also reacts with H_2O_2 and other oxygen-based toxic metabolites (11). In addition to protection against radical damage in DNA, cysteamine can also act as a repair agent for DNA through the formation of the protective $RSSR^{-}$, which reacts with the DNA^{+} radical ion to regenerate DNA and form cystamine (12). It has been shown that cysteamine and its metabolite hypotaurine are far more likely to act as antioxidants in vivo than is taurine, provided that they are present in sufficient concentration at sites of oxidant generation (13). Cysteamine is oxidized to the sulfinic derivative (hypotaurine) only in the presence of cofactorlike compounds such as sulfide, methylene blue, and hydroxyalamine (14). Most metabolic pathways give hypotaurine as a precursor to taurine (15, 16).

In some of our recent work, we examined the reactivity of the cysteamine metabolites: hypotaurine (cysteamine sulfinic acid) and taurine (cysteamine sulfonic acid) (17). Oxidation of hypotaurine by chlorite and chlorine dioxide occurred simultaneously at the sulfur center (giving taurine) and at the nitrogen center (to give the chloramines) (18). On the other hand, taurine is relatively inert to oxidation by chlorine dioxide, a reactive radical species, and acidified bromate (19). When subjected to the strong oxidizing agent HOCl, the C—S bond is not cleaved, and reaction occurs exclusively at the nitrogen center, giving chlorotaurine (17).

The key to understanding the physiological role of cysteamine is through its oxidation pathway: its reactive intermediates and oxidation products. In this manuscript we report on the oxidation of cysteamine by the mild oxidizing agents acidic iodate and aqueous iodine. In a nonenzymatic pathway, could the oxidation of cysteamine yield hypotaurine or go all the way to taurine? Specifically, we are aware that the action of most goitrogenic mechanisms involves the consumption of the iodine atom, which is needed for thyroid activity (20). What then, is the rate and mechanism by which cysteamine reacts with molecular iodine?

Experimental

Materials

Cysteamine hydrochloride (CA, 2-aminoethanethiol hydrochloride) (98%), iodine, potassium iodide (Aldrich), sodium perchlorate (98%) (Acros), cystamine dihydrochloride (MP Biomedical), potassium iodate, perchloric acid (72%), soluble starch, sodium thiosulfate, and hydrochloric acid (Fisher) were used without further purification. The concentration of iodine was determined by standardization against thiosulfate with starch as indicator. This standardization allowed us to evaluate the absorptivity coefficient of iodine at its isosbestic point of 460 nm with triiodide as 770 $(\text{mol L}^{-1})^{-1}$ cm^{-1}. This standardization was carried out before each series of kinetic experiments were performed because of the volatile nature of iodine. CA solutions were prepared just before use and not kept for more than 24 h. All solutions were prepared using distilled–deionized water from a Barnstead Sybron Corporation water purification unit. Inductively coupled plasma mass spectrometry (ICPMS) was used to show that our aqueous reaction media did not contain enough metal ions to affect the overall reaction kinetics and mechanism (21). The highest metal ion concentration was cadmium at 1.5 ppb, followed by lead at 0.43 ppb.

Methods

All experiments were carried out at 25.0 ± 0.5 °C and at a constant ionic strength of 1.0 mol L^{-1} ($NaClO_4$). CA, sodium perchlorate, and perchloric acid solutions were mixed in one reactant vessel and iodate (or iodine) solutions in another. All kinetics measurements were performed on a Hi-Tech Scientific SF61–DX2 double mixing stopped-flow spectrophotometer. Spectrophotometric determinations were performed on a PerkinElmer Lambda 25 UV–vis spectrophotometer.

Stoichiometric determinations

The stoichiometry for the CA–IO_3^- was determined both in excess iodate and in excess CA. In excess iodate the total oxidizing power was determined by titration. Excess acidified iodide was added to the reaction solution, and the released iodine was titrated against standard thiosulfate. Spectrophotometry was also used to determine the amount of iodine formed in excess iodate by its absorbance at 460 nm. In the I_2–CA reaction the stoichiometry was determined by titrating standardized iodine solution from a burette into a solution of CA of known strength. The end point, which was enhanced by starch indicator, was detected as the point where the blue-black color lingered.

Results

Stoichiometry

The stoichiometry of the reaction was strictly 1:6, with 6 mol of cysteamine reacting with 1 mol iodate. This suggested a one-electron oxidation of the sulfur center, and the only product possible after one-electron oxidation of an organosulfur center was the disulfide ($H_2NCH_2CH_2S$-$SCH_2CH_2NH_2$, RSSR). Both spectrophotometric and titrimetric techniques were used to deduce the following stoichiometry:

$$[R1]\quad IO_3^- + 6H_2NCH_2CH_2SH \rightarrow I^- + 3H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 3H_2O$$

Stoichiometry [R1] was obtained only at the stoichiometric ratio of 1:6. In lower concentrations of iodate, the reaction mixture produced a mixture of both cysteamine and cystamine. These products were confirmed by the NMR spectrum of the mixture. In stoichiometric excess of iodate, the reaction products included iodine, which was then spectrophotometrically examined to deduce the overall stoichiometry of [R2]:

$$[R2]\quad 2IO_3^- + 10H_2NCH_2CH_2SH + 2H^+ \rightarrow I_2 + 5H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 6H_2O$$

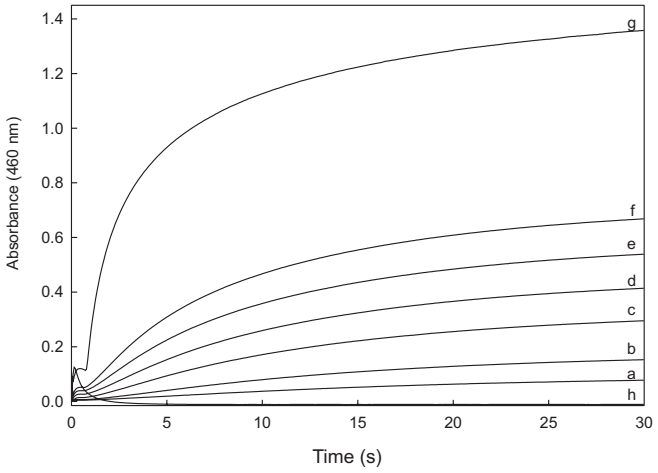
If the iodate-to-substrate ratio was greater than 1:5, then the amount of iodine produced was determined by the amount of cysteamine as the limiting reagent. There was an increase in the amount of iodine produced as the ratio was

© 2006 NRC Canada

increased from 1:6. At 1:5, however, the increase saturated, and no further increase in the production of iodine was observed. The direct reaction of aqueous iodine and cysteamine was determined by a rapid and careful titration aided by starch indicator. Although the end point of the titration shifted upon prolonged standing, the correct stoichiometry was attained at the first end point of 1:2, as shown below.

$$[R3] \quad I_2 + 2H_2NCH_2CH_2SH \rightarrow 2I^- + H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + 2H^+$$

The complications observed after allowing the titrated solution to incubate arose from two equilibria: the sulfide–disulfide equilibrium (22), which sought to reestablish itself after the depletion of the iodine because of titration with thiosulfate, and the iodine–thiol equilibrium (23, 24), which is well-known and has been extensively discussed in this manuscript under "charge-transfer" complex formation (see below). Stoichiometry [R3] could also be obtained spectrophotometrically in an excess of iodine and under high acid conditions, where both of these complicating equilibria were suppressed.



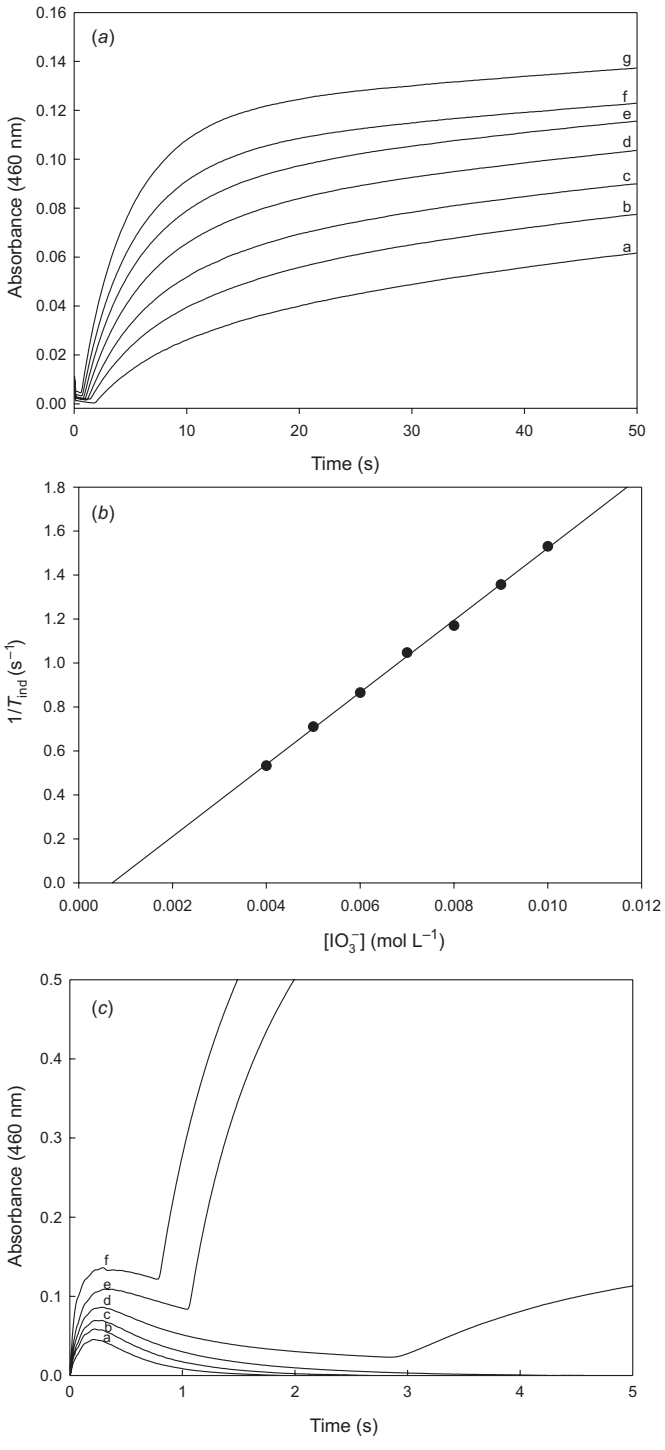
Confirmation of products

Reactions run in excess iodate did not afford sulfate as a product, as shown by the lack of precipitation of barium sulfate with barium chloride. Before barium chloride was added, excess iodate was removed by the use of excess acidified iodide, followed by evaporation of the iodine formed to avoid precipitation of barium iodate. Standard proton NMR spectra were also used to confirm the formation of the disulfide. Reagent grade cysteamine gave the expected spectrum of two triplets owing to the methylene proton sets on the carbon skeleton. This reagent-grade quality cysteamine also showed some cystamine impurity. Addition of DCl destroyed the resolution of the cysteamine triplets and also shifted them downfield because of the protonation of the amino center. The NMR spectrum of the product confirmed that the product was the dimeric cystamine. These product identities were confirmed by an HPLC technique, which utilized an isocratic 98%:2% water–methanol medium. The aqueous medium was 0.05 mol L^{-1} phosphate at pH 4.0. Both cysteamine and cystamine were modified by addition of acid, and so a control spectrum was initially obtained with cystamine mixed with acid before product UV spectral analyses were performed.

Reaction dynamics

The reaction dynamics were complex, with oligo-oscillatory production of iodine (25), transient formation of iodine, and clock reaction behavior (26). Figure 1 shows all three types of complex dynamics. This is much more evident if the region between $t = 0$ and 5 s is expanded and magnified. Trace h, for example, is at the 1:6 stoichiometric ratio of rxn. [R1] and should produce no aqueous iodine at the end of the reaction. Trace h shows, however, an initial rapid formation of iodine, followed by an equally rapid consumption, all within 3 s. The rest of the traces, a–g, have stoichiometric excess of iodate according to [R1], while only traces a and b have the stoichiometric ratio that satisfies stoichiometry [R2]. Traces a–e display clock reaction characteristics: an initial quiescent period followed by formation of iodine. Trace g, on the other hand, shows two peaks in iodine concentrations (oligooscillations), with one peak after approximately 1 s and the other peak (which represented the maximum concentrations obtained) at 60 s (truncated from Fig. 1). The only difference in the traces shown in Fig. 1 is the oxidant-to-reductant ratio, $R = [IO_3^-]_0/[CA]_0$. The increase in final iodine concentrations formed in going from trace a to g is justified from the premise that stoichiometry [R2] is a stepwise combination of rxn. [R1] and the Dushman reaction, [R4] (5[R1] + [R4]) (27).

Fig. 1. CA variation in excess oxidant shows higher rates of iodine production, as well as higher final concentrations of iodine, at the end of the reaction as the CA concentration is increased. Trace h shows that at the stoichiometric ratio there is just a transient formation of iodine. $[IO_3^-]_0 = 0.005$ mol L^{-1}, $[H^+]_0 =$ 0.02 mol L^{-1}, $[CA]_0$ = (a) 0.0005, (b) 0.001, (c) 0.002, (d) 0.003, (e) 0.004, (f) 0.005, (g) 0.015, (h) 0.03 mol L^{-1}.



$$[R4] \quad IO_3^- + 5I^- + 6H^+ \rightarrow 3I_2 + 3H_2O$$

The collapse of observed iodine concentration in increasing $[CA]_0$ to trace h arises from the decrease in R (which is $[IO_3^-]_0/[CA]_0$) to below that expected for stoichiometry [R2]. Figure 2*a* shows a series of experimental traces obtained by varying initial iodate concentrations while keeping all other species concentrations constant. Traces c–g satisfy stoichiometry [R2], and thus, at $t = \infty$ all these traces give the same iodine absorbance. Expansion of the first 4 s of the reaction shows a distinct induction period, which could be related to the initial concentration of iodate. We define an induction period as the time taken before a rapid and monotonic formation of iodine commences. A linear relationship (see Fig. 2*b*) exists between the inverse of this induction period and initial iodate concentrations. The intercept on the iodate axis, the concentration of iodate for an induction period of $t = \infty$ ($1/t = 0$), confirmed stoichiometry [R1]. The intercept is approximately 0.0005 mol L^{-1} iodate for an initial concentration of 0.003 mol L^{-1} CA (a 1:6 ratio). An induction time of infinity indicates that no iodine is formed. Any higher iodate concentration over 0.0005 mol L^{-1} will yield iodine as a final product and stoichiometry will shift from [R1] towards [R2]. In Fig. 2*c*, increasing the initial acid concentration relative to Fig. 2*a* and amplifying the first 5 s

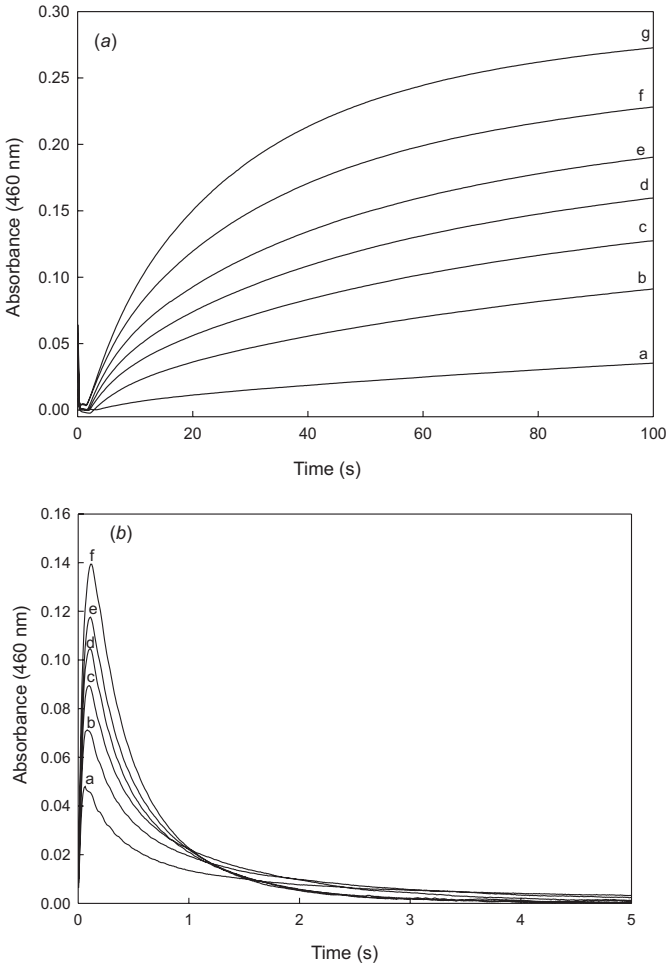
Fig. 2. (*a*) Effect of $[IO_3^-]$ variation at constant $[H^+]$ and [CA] showing a finite and measurable induction period before formation of iodine. The initial rate of reaction increased as $[IO_3^-]_0$ increased; $[CA]_0 = 0.003$ mol L^{-1}, $[H^+]_0 = 0.001$ mol L^{-1}, $[IO_3^-]_0$ = (a) 0.004, (b) 0.005, (c) 0.006, (d) 0.007, (e) 0.008, (f) 0.009, (g) 0.01 mol L^{-1}; (*b*) Linear plot of reciprocal induction time vs. $[IO_3^-]_0$ for data shown in Fig. 2*a*; (*c*) Effect of progressively increasing $[IO_3^-]$ at constant acid and [CA] close to stoichiometry show oligooscillations. Traces below stoichiometry and at stoichiometry a–c show just the transient formation of iodine. $[CA]_0 = 0.015$ mol L^{-1}, $[H^+] = 0.02$ mol L^{-1}, $[IO_3^-]_0$ = (a) 0.0015, (b) 0.002, (c) 0.0025, (d) 0.003, (e) 0.004, (f) 0.005 mol L^{-1}.



shows, instead of an induction period, a transient peak in iodine concentrations, followed by a final and rapid formation of iodine. In all cases shown in Fig. 2*c*, the reactions that form iodine initially dominate those that consume iodine (even in stoichiometric excess of CA), and hence the observed initial iodine peak. Iodine formation is also almost instantaneous. The onset of prolonged and monotonic iodine formation is determined by the initial iodate concentrations. For traces e and f, for example, the high ratio ensures rapid consumption of the substrate, leaving only the Dushman reaction, [R4], to form iodine without any other reactions in the reaction medium that consume iodine.

Lower acid concentrations did not produce such oligooscillatory behavior: only a period of no iodine formation is observed, followed by monotonic iodine formation. The strong catalytic effect of acid on the Dushman reaction is responsible for the olligooscillations. The effect of acid on the reaction appears much more complex than that of iodate (see Figs. 3*a* and 3*b*). There are several reactions that are viable in this reaction mixture, and it would appear all of them are affected by acid; hence, a clean assessment of the effect of acid is not easily obtained. However, what is obvious from Fig. 3*a* is that acid concentrations catalyze the formation of iodine after the induction period. In all traces shown in Fig. 3*a*, the final iodine concentrations were the same (6×10^{-4} mol L^{-1}, absorbance ~ 0.46). While trace g went to completion in less than 250 s, it took more than 2000 s for trace a to go to completion. A very interesting set of data are shown in Fig. 3*b*. In this set of data the reaction conditions are set to the stoichiometric ratio of [R1], and at $t = \infty$ no iodine is (nor should be) observed. Acid variations at these conditions show that acid catalyzes the formation of iodine and retards the consumption of iodine. Hence, high acid concentrations will show a wider "excursion" away from the equilibrium conditions before settling down to stoichiometry [R1].

Figure 4 shows the expected catalytic effect of iodide ions. In this case, very low iodide ion concentrations can drastically reduce the induction period (upon expanding the first 2 s of the reaction). They also increase the rate and amount of iodine obtained. This is expected in conditions where the oxidant to reductant ratio (R) is greater than 0.2, where the iodide ions initially added to the reaction mixture combine with those formed in stoichiometry [R1] to fuel the Dushman reaction, [R4]. This is also evident from Fig. 4, which shows a long enough time evolution of the reaction. Other experimental data (not shown) demonstrated a saturation of the reduction of the induction period when the added iodide ions equaled or exceeded the concentrations of the substrate. Iodide acts solely as a catalyst: in stoichiometric excess of the substrate (stoichiometry [R1]), it is used and released intact at the end of the reaction. Iodide ultimately does not participate in the overall stoichiometry except in high excess of iodate conditions, where it is ultimately converted to molecular iodine. Strictly speaking, the Dushman reaction (27) is an extraneous reaction that only asserts itself after stoichiometry [R1] of our fiduciary reaction has been satiated. No simple relationship could be deduced between induction period and (or) rate of formation of iodine with iodide (see Fig. 2*b* for the iodate dependency). This is due to the fact that the effect of iodide on the whole reaction is

© 2006 NRC Canada

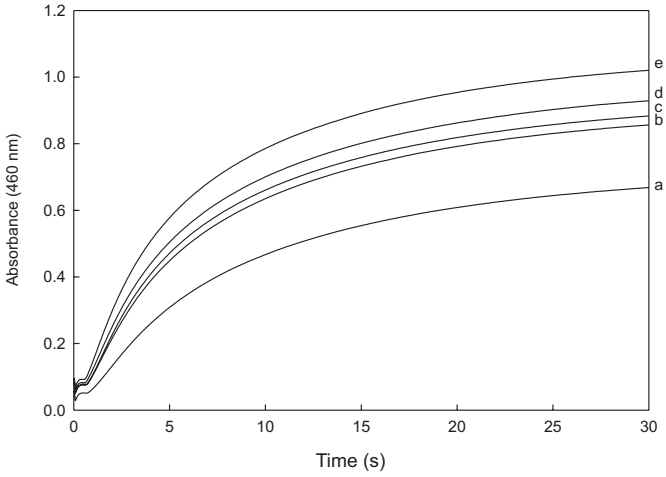


Fig. 3. (*a*) Effect of varying acid concentration on the oxidation of CA by iodate. There is an increase in rate of iodine formation as acid concentration is increased. $[CA]_0$ = 0.003 mol L^{-1}, $[IO_3^-]_0$ = 0.003 mol L^{-1}, $[H^+]_0$ = (a) 0.001, (b) 0.0015, (c) 0.002, (d) 0.0025, (e) 0.003, (f) 0.00375, (g) 0.005 mol L^{-1}; (*b*) Effect of acid variation at stoichiometric point (trace h from Fig. 1). The effect of acid can be seen in the form of a higher maximum iodine concentration. $[CA]_0$ = 0.03 mol L^{-1}, $[IO_3^-]_0$ = 0.005 mol L^{-1}, $[H^+]_0$ = (a) 0.005, (b) 0.0075, (c) 0.01, (d) 0.0125, (e) 0.015, (f) 0.02 mol L^{-1}.

complex and most likely involves a multiterm rate law. Alternatively (as proved later) iodide ions most likely affect both the formation and consumption of iodine reactions.

The simple and direct oxidation of CA by aqueous iodine was also studied spectrophotometrically at 460 nm. Figure 5*a* shows that this reaction is relatively slow and is mildly inhibited by acid. Under low acid concentrations, Fig. 5*b* shows that there is an inverse relationship between the acid concentrations and rate of consumption of iodine. The positive intercept is important: it suggests two pathways, one inhibited by acid and one that is not. The gentle slope of the plot suggests very mild inhibition by acid. This linearity is lost at high acid concentrations (Fig. 5*c*). The effect of iodide was much more complex (Fig. 6). After mixing iodine and CA, a rapid equilibrium sets up, which forms some adduct that also absorbs at 460 nm. We could not locate a wavelength where this adduct did not adversely affect

Fig. 4. $[I^-]$ effect on the iodate oxidation of CA. The effect of iodide can be seen on the reduced induction period and increased final absorbance of iodine as the iodide concentration is increased. $[CA]_0$ = 0.005 mol L^{-1}, $[H^+]_0$ = 0.02 mol L^{-1}, $[IO_3^-]_0$ = 0.005 mol L^{-1}, $[I^-]_0$ = (a) no iodide, (b) 0.00025, (c) 0.0005, (d) 0.00075, (e) 0.001 mol L^{-1}.

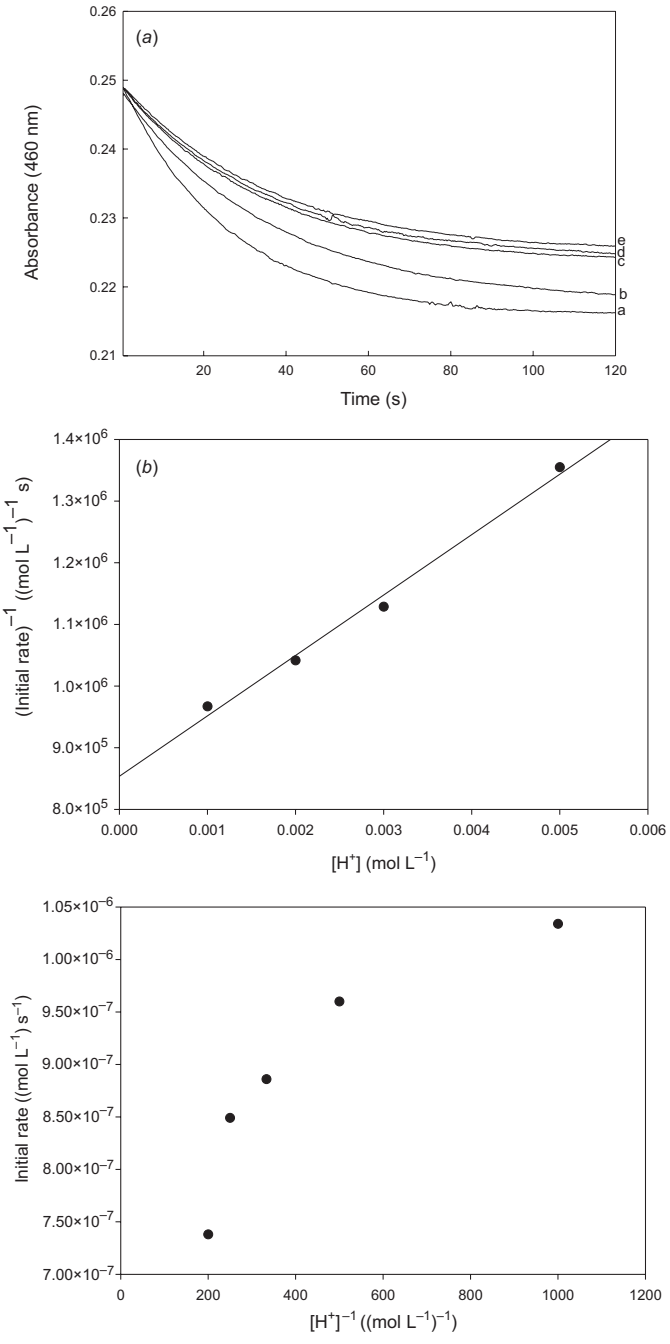
the optical observation of the iodine–CA reaction. Hence, data interpretation of the iodide effect was not possible, although a cursory glance showed that the iodide effect was mildly inhibitory.

Mechanism

The mechanistic basis of the oxidation of CA by iodate–iodine had fewer possible intermediates in going from CA (reactant) to cystamine (product) when compared with other organosulfur oxidations in which the oxidation pathway involves formation of sulfinic and sulfonic acids, as well as cleavage of the C—S bond to yield sulfate (28, 29). There are only two possible pathways towards formation of the dimer: through the cysteamine-thiyl radical (30) and (or) the cysteamine sulfenic acid. In metal–ion mediated oxidation of cysteamine, the radical pathway is highly favored (31).

[R5] $H_2NCH_2CH_2SH + M^{n+} \rightleftharpoons H_2NCH_2CH_2S^{\cdot} + M^{(n-1)+} + H^+$

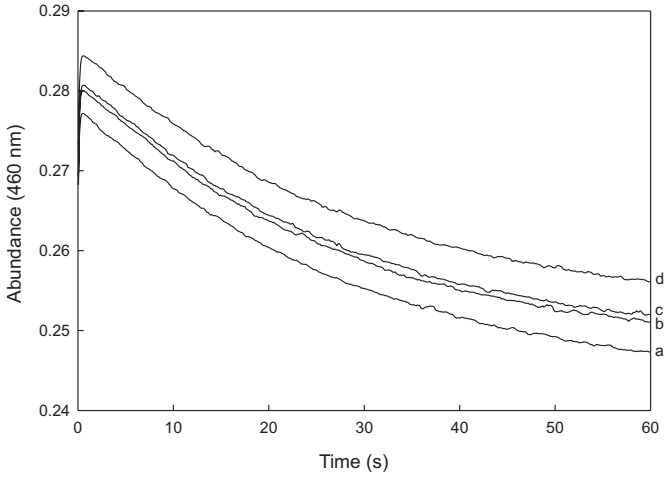
Our reaction environment has been stripped of metal ions, making the radical pathway unlikely. Oxyiodine species are known to predominantly oxidize via two-electron steps, making the pathway through the unstable sulfenic acid the most likely pathway (32).



[R6] $H_2NCH_2CH_2SH + H_2O \rightarrow H_2NCH_2CH_2SOH + 2H^+ + 2e^-$

The sulfenic acid should rapidly combine with an unoxidized CA molecule (a condensation reaction) to form cystamine.

[R7] $H_2NCH_2CH_2SOH + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2S\text{-}SCH_2CH_2NH_2 + H_2O$



© 2006 NRC Canada

Fig. 5. (*a*) Effect of varying acid concentration on the reaction of CA and iodine. The initial rate of reaction decreases as the acid concentration is increased. $[CA]_0$ = 0.001 mol L^{-1}, $[I_2]_0$ = 0.00044 mol L^{-1}, $[H^+]_0$ = (a) 0, (b) 0.001, (c) 0.002, (d) 0.003, (e) 0.004 mol L^{-1}; (*b*) Plot of inverse of the initial rate vs. acid concentrations of the I_2–CA reaction for low acid variations for the type of data shown in Fig. 5*a*. $[CA]_0$ = 0.001 mol L^{-1}, $[I_2]_0$ = 0.00044 mol L^{-1}; (*c*) Types of initial rates vs. inverse acid dependence plots for the I_2–CA reaction for a wider range of acid concentrations than those selected for Fig. 5*b*. $[CA]_0$ = 0.001 mol L^{-1}, $[I_2]_0$ = 0.00044 mol L^{-1}.

Any uncondensed sulfenic acid left after all the CA has been consumed will rapidly disproportionate through standard pathways to form thiosulfinates (33) as well as CA.

Fig. 6. Effect of iodide variation on the I_2–CA reaction. There is an increase in the initial absorbance with addition of iodide, but no parallel nature of the absorbance traces shows little effect of iodide on the reaction rate, only a change in the equilibrium position of the I_2–CA reaction mixture. $[CA]_0$ = 0.0002 mol L^{-1}, $[I_2]_0$ = 0.00044 mol L^{-1}, $[I^-]_0$ = (a) 4.0×10^{-5}, (b) 6.0×10^{-5}, (c) 8.0×10^{-5}, (d) 1.0×10^{-4} mol L^{-1}.

This can bring about some stoichiometric uncertainties, but if rxn., [R7] is very rapid, there will be very little deviation in the expected 1:6 stoichiometry.

Iodate oxidations are strongly acid-catalyzed and will not proceed except in low pH environments (34). All iodate oxidations reported in this manuscript were at pH conditions lower than 3.0. We expect, at these pH conditions, that the amino group of the cysteamine will be protonated and that the prevailing form of cysteamine will be $[H_3NCH_2CH_2SH]^+$. The accepted pK_a value of $[H_3NCH_2CH_2SH]^+$ is 10.8, with a K_b of the amino group of cysteamine as 6.3×10^{10} (mol L^{-1})$^{-1}$, which calculates to a full protonation of the amino group in pH conditions lower than 4.0. Thus any further protonation to cysteamine will be in addition to the one already resident on the amino group. Since this protonation is distal to the active thiol group, it does not strongly influence its reactivity. We shall represent cysteamine, in this manuscript, however, as the neutral form.

Sulfenic acids are stronger acids than thiols and, if they are long-lived, would exist predominantly as zwitterions (produced in rxn. [R6] and others), $^+N(H)_3CH_2CH_2SO^-$. However, the strongly acidic environment would protonate the oxygen atom, and it would exist predominantly as $^+N(H)_3CH_2CH_2SOH$.

Oxyiodine oxidizing species

The chemistry of oxyiodine species has been extensively studied, and it is well-established that the major oxidizing species are HIO_2, HOI, and molecular iodine (I_2). These species are derived from iodate through a series of well-known reactions (35, 36).

[R8] $IO_3^- + 2H^+ + I^- \rightleftharpoons HIO_2 + HOI$

[R9] $HOI + H^+ + I^- \rightleftharpoons I_2 + H_2O$

In the absence of iodide, the initiation reaction involves the direct oxidation of CA by iodic acid.

© 2006 NRC Canada

[R10] $IO_3^- + H^+ \rightleftharpoons HIO_3$

[R11] $HIO_3 + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SOH + HIO_2$

[R12] $HIO_2 + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SOH + HOI$

[R13] $HOI + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SOH + H^+ + I^-$

Equations [R10]–[R13] are relevant at the beginning of the reaction before iodide ions accumulate. After iodide concentrations have built up to effective levels, the reaction will proceed through rxn. [R8], as it is the overall rate-determining step in the consumption of CA. In the presence of added iodide ions, as in Fig. 4, eqs. [R10]–[R13] are completely shunted out and are insignificant. The sum of rxns. [R8] + [R10] + [R11] + [R12] + 2[R13] shows that in each initial reaction cycle, 1 mol of iodide ultimately produces 2 mol of iodide in a quadratic autocatalytic sequence. This is obvious because each iodate ion, whose reactivity is triggered off by iodide, will ultimately end up as iodide, effectively doubling the number of iodide ions initially present. Reaction [R13] is the major oxidation route. This leaves two important oxyiodine reactions, which involve the disproportionation of HOI (37). This disproportionation ensures that there is no accumulation of HOI in the reaction medium, especially after all the reducing substrate has been consumed. The stable species allowable at the end of the reaction are iodate, iodine, and iodide.

[R14] $HIO_2 + I^- + H^+ \rightleftharpoons 2HOI$

[R15] $IO_3^- + HOI + H^+ \rightleftharpoons 2HIO_2$

Iodine oxidation

Acid dependence experiments (Figs. 5*a* and 5*b*) clearly indicate an electrophilic mechanism with an initial attack by iodine on the nucleophilic sulfur atom of CA.

[R16] $H_2NCH_2CH_2SH + I\text{-}I \rightarrow H_2NCH_2CH_2S(H)I^+ + I^-$

[R17] $H_2NCH_2CH_2S(H)I^+ + H_2O \rightarrow H_2NCH_2CH_2SOH + 2H^+ + I^-$

The product is then formed by rxn. [R7]. This step ([R16] + [R17]) was qualitatively proved by the experimental observations of an immediate drop in pH upon mixing iodine and CA. Thus, acid dependence experiments can be justified from the basis of an initial protonation of the thiol group, which subsequently reacts much more slowly with the electrophilic iodine atom.

[R18] $H_2NCH_2CH_2SH + H^+ \rightleftharpoons [H_2NCH_2CH_2SH_2]^+$; K_b

[R19] $H_2NCH_2CH_2SH + I_2 + H_2O \rightarrow H_2NCH_2CH_2SOH + 2I^- + 2H^+$; k_1

[R20] $[H_2NCH_2CH_2SH_2]^+ + I_2 + H_2O \rightarrow H_2NCH_2CH_2SOH + 2I^- + 3H^+$; k_2

In this reaction scheme we are ignoring the iodine–triiodide equilibrium (38, 39) by assuming that triiodide reacts just as rapidly as iodine.

[R21] $I_2 + I^- \rightleftharpoons I_3^-$; $K_I = 770\ (\text{mol L}^{-1})^{-1}$

This assertion was based on our experiments that showed that the effect of iodide on the reaction rate was inconclusive. Addition of iodide to the reaction medium changed the original absorbance, but did not alter the subsequent rate of consumption of iodine (see Fig. 6).

Using [R18]–[R20], we can derive the following overall rate law for the consumption of iodine.

$$[1] \qquad \text{Rate} = -\frac{d[I_2]}{dt} = \frac{[CA]_0[I_2]}{(1 + K_b[H^+])}(k_1 + k_2K_b[H^+]$$

In eq. [1], $[CA]_0$ represents the amount of cysteamine added to the reaction mixture. This is then partitioned between the protonated and unprotonated forms of the thiol, based on the acid concentrations and K_b. Equation [1] will give different acid dependence behavior depending upon the relative values of k_1 and k_2. If $k_1 >> k_2$, the general form of the equation for the initial rate of reaction vs. the inverse of the acid concentration will give a nearly straight line at acid concentrations where $K_b[H^+] << 1$, with the second term in eq. [1] assumed to be negligible. The plot shown in Fig. 5*b* was restricted to low acid concentrations. The high acid concentration kinetics data were discarded. The low acid concentrations plot allows us to estimate the values of k_1 and K_b by assuming that the observed retardation is due to the removal of active cysteamine by the protonation equilibrium. After deleting the second term in eq. [1], the equation can then be rearranged and written as:

$$[2] \qquad \frac{1}{\text{mod(rate)}} = \left(\frac{K_b}{k_1[CA]_0[I_2]_0}\right)[H^+] + \left(\frac{1}{k_1[CA]_0[I_2]_0}\right)$$

Equation [2] is then used to plot the inverse of the modulus of the initial rate vs. the acid concentrations (see Fig. 5*b*), from where we can evaluate values of k_1 and K_b. From the intercept, a value of $k_1 = 2.7 \pm 0.3\ (\text{mol L}^{-1})^{-1}\ \text{s}^{-1}$ was deduced. The slope gave $K_b = 117 \pm 15\ (\text{mol L}^{-1})^{-1}$. This value of K_b has no thermodynamic significance apart from the fact that it fits kinetics data through eq. [2]. This is a value that is only relevant for the conditions used for Figs. 5*a* and 5*b*. Literature quotes the pK_a of the thiol group of cysteamine as 8.6, but the protonation of the amino group precludes an accurate measurement of pK_a for $[H_2NCH_2CH_2SH_2]^+$, should this exist. Another possible mechanism for the observed acid retardation of iodine oxidation is the loss of nucleophilicity of the water molecules, owing to the formation of the hydronium ions. However, this retardation would be kinetically indistinguishable to the one suggested through rxn. [R20]. A plot of inverse acid dependence, which includes both high and low acid concentrations, is shown in Fig. 5*c*. This is not a linear plot, as expected from the form of eq. [1]. We could then work with the curve generated in Fig. 5*c* and curve-fit it to variables k_1, k_2, and K_b. This fitting procedure gave $k_2 = 0.37\ (\text{mol L}^{-1})^{-1}\ \text{s}^{-1}$.

Table 1. Cysteamine–iodate–iodine reaction.

Reaction No.	Reaction	k_f and k_r
M1	$H^+ + IO_3^- \rightleftharpoons HIO_3$	1×10^7, 1×10^9
M2	$HIO_3 + RSH \rightarrow HIO_2 + RSOH$	2.5×10^2
M3	$HIO_2 + RSH \rightarrow HOI + RSOH$	5×10^2
M4	$HOI + RSH \rightarrow I^- + H^+ RSOH$	1×10^3
M5	$RSOH + RSH \rightarrow RSSR + H_2O$	5×10^8
M6	$IO_3^- + I^- + 2H^+ \rightleftharpoons HIO_2 + HOI$	2.8, 1.44×10^3
M7	$HIO_2 + I^- + H^+ \rightleftharpoons 2HOI$	2.1×10^8, 90
M8	$HOI + I^- + H^+ \rightleftharpoons I_2 + H_2O$	3.1×10^{12}, 2.2
M9	$IO_3^- + HOI + H^+ \rightleftharpoons 2HIO_2$	8.6×10^2, 2.00
M10	$I_2 + I^- \rightleftharpoons I_3^-$	6.2×10^9, 8.5×10^6
M11	$I_2 + RSH + H_2O \rightarrow RSOH + 2H^+ + 2I^-$	2.7
M12	$I_3^- + RSH + H_2O \rightarrow RSOH + 2H^+ + 3I^-$	1.5
M13	$RSH + H^+ \rightleftharpoons RSH_2^+$	1×10^8, 8.5×10^5
M14	$RSH_2^+ + I_2 + H_2O \rightarrow RSOH + 3H^+ + 2I^-$	0.37

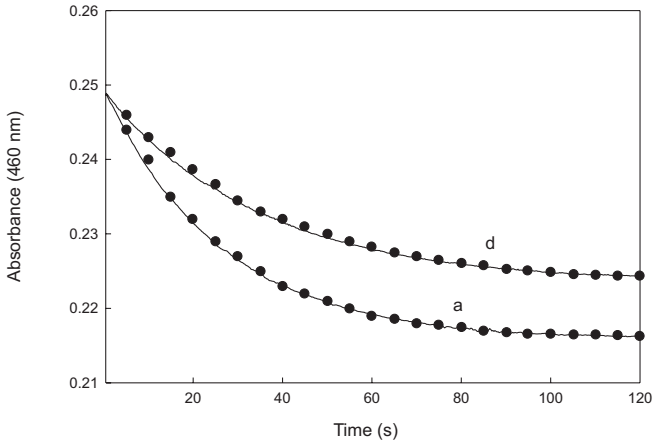
Note: RSH = cysteamine; RSOH = unstable cysteamine sulfenic acid intermediate; RSSR = cystamine.

Computer modeling

The reaction scheme was modeled using the Kintecus software generated by James Ianni. The whole reaction scheme is shown in Table 1. The 14-reaction scheme was able to model satisfactorily all of the reaction dynamics observed in Figs. 1–4. The data for the direct reaction of iodine and CA could also be simulated by the same model after nullifying rxns. [M1]–[M7] (i.e., setting all their rate constants to zero).

Charge-transfer complexes

While the calculations were able to simulate the general dynamics of the data shown in Figs. 1–4, they gave much lower absorbance readings than those shown in these figures. The absorbance readings only matched the calculations at the beginning and at the end of the simulations. The experimentally observed intermediate values were much higher, owing to the expected charge-transfer complexes that cysteamine is known to form with molecular iodine (23, 40).



[R22] $H_2NCH_2CH_2SH + I_2 \rightleftharpoons [H_2NCH_2CH_2SH\text{-}I^+][I^-]$

Absorbance readings from experiments and simulations coincided under conditions where iodate was in stoichiometric excess over cysteamine such that at the end of the reaction cysteamine concentrations had vanished, thus precluding the possibility of rxn. [R22]. While reactions of the [R22]-type have been reported (40), no specific measurements have been performed for the cysteamine–iodine mixtures. Reaction [R22] is suppressed in high acid conditions, such that it was easier to fit simulations to the data in Fig. 5*a*. Figure 7 shows a typical fit to the experimental data in Fig. 5*a* at separate acid concentrations.

Adoption of rate constants

The model presented had very few rate constants that needed to be guessed for the best simulations fit. For example, kinetics constants for reactions [M6]–[M10] were obtained from well-established literature values (27, 35, 37, 41, 42). In the absence of added iodide ions (as in data in Fig. 4), the most important reaction in the whole model was

Fig. 7. Comparison of experimental and calculated absorbance traces for the I_2–CA reaction data shown in Fig. 5*a* (traces a and d). The symbols represent calculations.

[M2]. After setting up an initial guess value for k_{M2}, the kinetics parameters for the rest of the reactions in that chain, [M3] and [M4], became instantly irrelevant for as long as they were faster than the set value for k_{M2} and with the relative magnitudes in the order of $k_{M3} < k_{M4}$. Any reversal in this order generated large amounts of HIO_2 (in excess iodate conditions), which never decayed as the reaction reached its end point with respect to iodine production. The data shown in Fig. 4 could be modeled without reactions [M1] through [M4]. We settled on a value of k_{M2} of 250 $(\text{mol L}^{-1})^{-1}\ \text{s}^{-1}$ as the one that gave us the best fit to the induction period. The two protolytic reactions, [M1] and [M13], were set to be faster than all reactions in the mechanism. The role of [M1] was to ensure bimolecular kinetics for rxn. [M2]. The role of [M13] was to simulate acid retardation observed in the direct oxidation of CA by iodine. The values of k_{M13} and k_{-M13} were linked together by the value of K_b derived in this study. The fact that reaction [M13] was rapid in both directions made it insignificant with respect to the sequence [M1]–[M4], since k_{M2}, the rate-determining step for that sequence, was only 250 $(\text{mol L}^{-1})^{-1}\ \text{s}^{-1}$. The effect of sequence [M10] + [M12] was not utilized in the derivation of rate for

© 2006 NRC Canada

eq. [1] and was not very effective in the mechanism for the overall iodate–CA reaction. A very small degree of retardation was observed in the iodine–CA reaction upon asserting this sequence (see Fig. 6). The possible direct reaction of the protonated thiol with triiodide was also not included in the mechanism.

Conclusion

Our study shows that cysteamine, the well-known precursor to taurine (14), is not easily oxidized to taurine by the mild oxidizing agent iodine and without the standard P450-type enzymes and the flavin-containing monooxygenases (43). In its goitrogenic role (9), cysteamine most likely abstracts the iodine atom in a reversible process to form the disulfide, which can be converted back to the thiol by a very mild redox potential.

Ditopic receptors of hexaamide derivatives derived from hexahomotrioxacalix[3]arene triacetic acid

Takehiko Yamato, Shofiur Rahman, Zeng Xi, Fumika Kitajima, and Jeong Tae Gil

Abstract: The lower rim functionalized hexahomotrioxacalix[3]arene hexaamide **7** having an amino acid moiety with cone conformation was synthesized from triol **1** by a stepwise reaction. The different extractability for alkali metal ions, transition metal ions, and alkylammonium ions from water into dichloromethane was discussed. Owing to the strong intramolecular hydrogen bond between the neighboring NH and CO groups in hexaamide **7**, its affinity to metal cations was weakened. Hexaamide **7** shows a single selectivity to n-$BuNH_3^+$. The anion complexation of hexaamide **7** was also studied by ^{1}H NMR titration experiments. Hexaamide **7** binds halides through the intermolecular hydrogen bond among the NH hydrogens of the amide in a 1:1 fashion in $CDCl_3$. Thus, hexaamide **7** serves as a heteroditopic receptor that can complex with halides (Cl^-, Br^-) and n-$BuNH_3^+$ at the same time. The association constants calculated from the chemical shift changes of the amide protons are K_a = 536 ± 32 $(mol/L)^{-1}$ for Cl^- and K_a = 230 ± 17 $(mol/L)^{-1}$ for Br^-.

Key words: hexahomotrioxacalix[3]arenes, ionophores, molecular recognition, ammonium ion, ditopic receptor.

Résumé : Utilisant le triol **1** comme produit de départ, on a réalisé la synthèse par étape de l'hexahomotrioxacalix[3]arène hexaamide **7** dont la ceinture inférieure fonctionnalisée porte une portion d'acide aminé avec conformation en cône. On discute des possibilités de l'extraire de solutions aqueuses vers du dichlorométhane à l'aide de divers ions métalliques alcalins ou métalliques et avec des ions alkylammonium. En raison de la forte liaison hydrogène intramoléculaire entre les groupes voisins NH et CO dans l'hexaamide **7**, son affinité pour les cations métalliques est réduite. L'hexaamide **7** présente une sélectivité particulière pour le n-$BuNH_3^+$. La complexation anionique de l'hexaamide **7** a aussi été étudiée par des expériences de titrage par RMN du ^{1}H. Dans le $CDCl_3$, l'hexaamide **7** se lie aux halogénures par le biais d'une liaison hydrogène intermoléculaire 1 : 1 avec les atomes d'hydrogène NH de l'amide. L'hexaamide **7** peut donc servir de récepteur hétéroditopique qui peut complexer en même temps les halogénures (Cl^-, Br^-) et le n-$BuNH_3^+$. Les constantes d'association obtenues à partir des changements du déplacement chimique des protons de l'amide sont K_a = 536 ± 32 $(mol/L)^{-1}$ pour Cl^- et K_a = 230 ± 17 $(mol/L)^{-1}$ pour Br^-.

Mots clés : hexahomotrioxacalix[3]arène, ionophores, reconnaissance moléculaire, ion ammonium, récepteur ditopique.

[Traduit par la Rédaction]

Introduction

Calixarene and related macrocycles have received considerable attention for their host–guest chemistry as ionophoric receptors and potential enzyme mimics in biology. Chemical modification of calixarene represents a simple though effective and versatile way of producing receptors with highly selective cation-binding properties (1). Shinkai and co-workers (2) reported the complexation of alkali metals to hexahomotrioxacalix[3]arene derivatives with alkylated phenolic oxygens. Hexahomotrioxacalix[3]arene derivatives with C_3 symmetry can selectively bind ammonium ions, which play important roles in both chemistry and biology (3). Thus, Takeshita and Shinkai (2*b*) reported the construction of C_3 symmetry pyrene-functionalized hexahomotrioxacalix[3]arenes, which selectively recognize primary ammonium ions.

On the other hand, the hydrogen bond plays an important role in the self-assembly of molecular recognition and has been investigated in calixarene systems. An intermolecular hydrogen-bonded duplex was formed through the interaction between a calix[4]arene with four carboxyl groups, and a calix[4]arene with stilbazole moieties was reported (4). Arduini et al. (5) also described the formation of a hydrogen-bonded dimer in $CDCl_3$ based on the self-complementarity of carboxylic acid. The intramolecular hydrogen bonding also formed among opposing urea groups, which can bind anionic species, in calix[4]arene (6). Thus, the design of new ditopic ligands (7) for the simultaneous complexation of anionic and cationic guest species is a new exciting area of coordination chemistry of significant relevance to the selective extraction and (or) transportation of metal salts across lipophilic membranes. Rare examples of receptors contain-

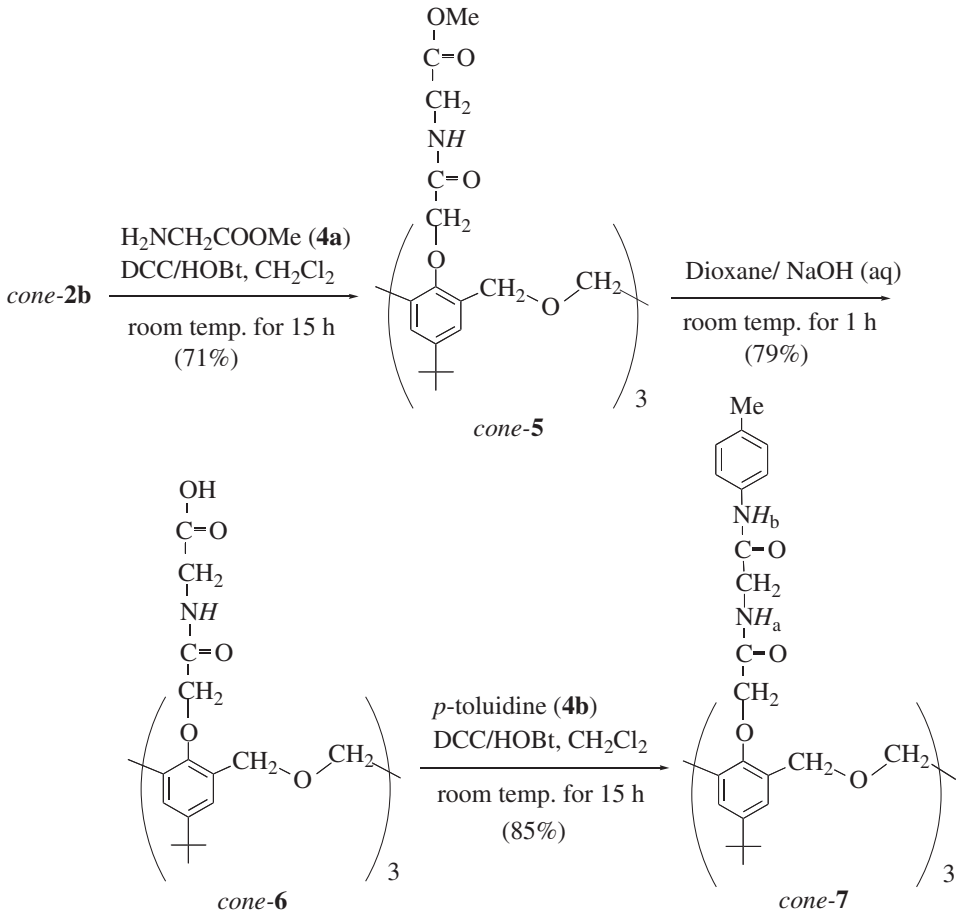
Scheme 1.



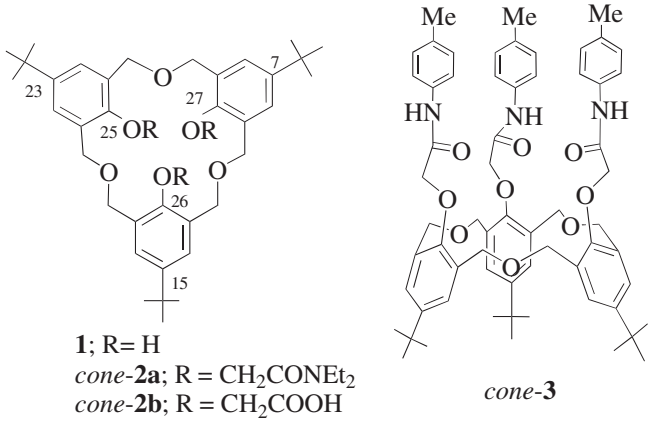


Chart 1.

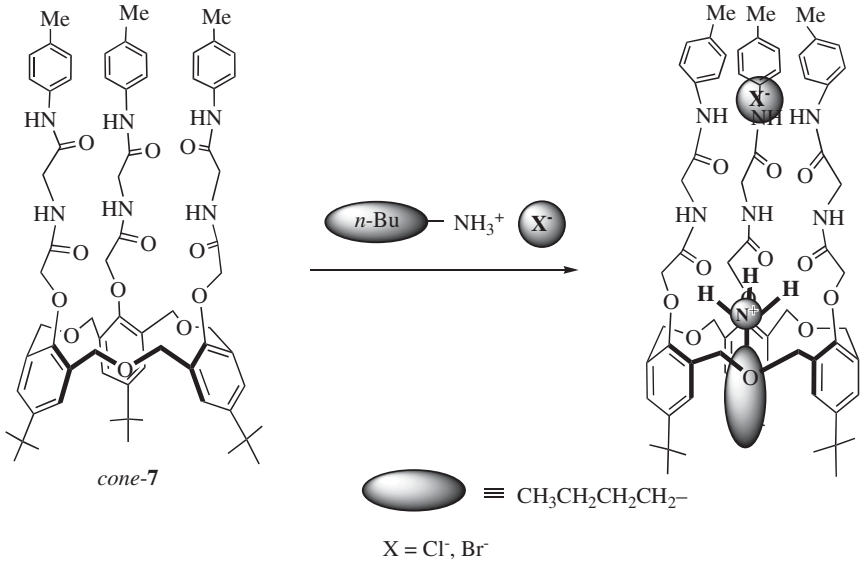
ing appropriate covalently linked binding sites for anions and cations include Lewis acidic boron (8), uranyl (9), polyammonium (10) centers combined with crown ether moieties, and crown ether or urea-functionalized calix[4]arene ionophores (11), which are capable of solubilizing alkali metal salts into organic media (Chart 1).



Recently, we reported a ditopic receptor (*cone*-**3**) incorporating these two types of recognition sites by introducing three amide groups to the phenolic oxygens of homotrioxacalix[3]arene, which can simultaneously bind alkyl ammonium ions and halides (12*a*). On the other hand, the introduction of multiple binding sites for cations and anions is important for the construction of the allosteric host–guest inclusion systems. In the present paper, we describe the synthesis, conformations, and metal and ammonium ion complexation properties of the additional amino acid linked cone *p*-methylphenyl amide derivative having two hydrogen-bonding systems and C_3-symmetric ionophoric cavities.

Results and discussion

cone-Hexahomotrioxacalix[3]arene tricarboxylic acid (*cone*-2**b**) was prepared by hydrolysis of *cone*-[(*N*,*N*-diethylaminocarbonyl)methoxy]hexahomotrioxacalix[3]arene (*cone*-**2a**) with aq. KOH in a mixture of dioxane and water, which was prepared by O-alkylation of **1** with *N*,*N*-diethylchloroacetoamide in the presence of NaH according to the reported procedures (2*d*, 12). *cone*-Hexahomotrioxacalix[3]arene triamide (*cone*-**5**) was prepared by a condensation reaction of *cone*-**2b** with glycine methyl ester (**4a**) in the presence of dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBt) at room temperature for 15 h in CH_2Cl_2. *cone*-**5** was converted to triacid *cone*-**6** by hydrolysis with aq. NaOH in a mixture of dioxane and water at room temperature. *cone*-**6** was treated with *p*-toluidine (**4b**) in the presence of DCC and HOBt similar to that of *cone*-**5** to afford

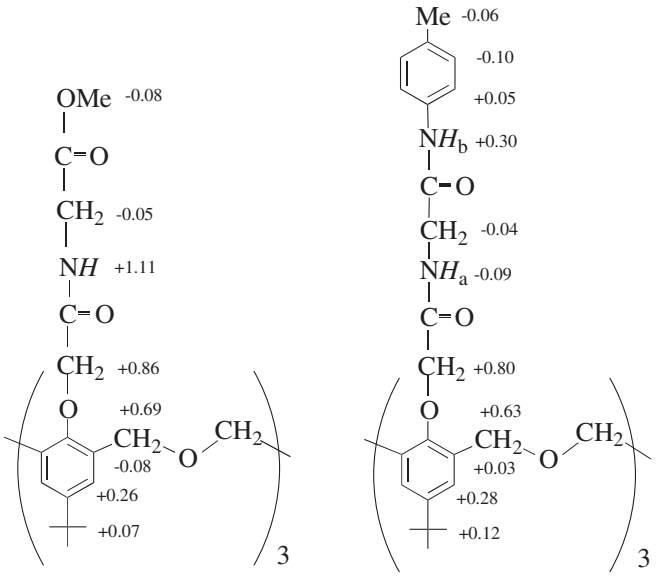
Fig. 1. Binding mode of host *cone*-**7** and *n*-$BuNH_3X$.

the desired compound *cone*-hexahomotrioxacalix[3]arene hexaamide (*cone*-**7**) in 85% yield (Scheme 1).

From the singlet peaks of *tert*-butyl protons and calix benzene protons for *cone*-**7**, it could be seen that the conformation remained in the desired compound with the cone conformation. To investigate the intramolecular hydrogen bond between the neighboring NH and CO groups of *cone*-**7** in detail, a reference compound **9c** was synthesized from 4-*tert*-butyl-2,6-dimethylphenoxyacetic acid (**8**) following a method similar to that used in the preparation of *cone*-**7**.



Conformation assignment for the new hexahomotrioxacalix[3]arene hexaamide (*cone*-**7**) is firmly established by the presence of AB quartets for the bridging methylene protons with a $\Delta\delta$ separation between H_{ax} and H_{eq} of 0.45 ppm in its ^{1}H NMR spectrum ($CDCl_3$). In the calix[4]arenes, the $\Delta\delta$ values of the ArCH_2Ar protons have been correlated to the orientation of adjacent aromatic rings, i.e., $\Delta\delta > 1$ ppm with cone conformation or syn orientation, $\Delta\delta$ of approximately 0.5 ppm with flattened cone or out orientation, and $\Delta\delta$ of 0 ppm with 1,3-alternate or anti orientation (13). The same findings were observed in hexahomotrioxacalix[3]arenes (2*a*). Thus, we can deduce that *cone*-**7** prefers a flattened cone conformation in which hydrogen bonding can form. The intramolecular hydrogen bond was formed between neighboring NH and C=O groups, which induced a large downfield shift for the NH_a proton (δ 8.45 ppm, $\Delta\delta$ = +0.69 ppm) and NH_b proton (δ 9.21 ppm, $\Delta\delta$ = +0.85 ppm) in *cone*-**7** compared with compound **9c** (NH_a proton, δ 7.76 ppm; NH_b proton, δ 8.36 ppm). When the concentration of *cone*-**7** in $CDCl_3$ was diluted about 40 times, there was no change in the chemical shifts for both NH_a and NH_b protons, which is attributed to the concentration-independent intramolecular hydrogen bonds formed in this compound. Interestingly, the chemical shift of the NH_b protons in *cone*-**7** was shifted to a lower magnetic field to δ 9.91 ppm in DMSO-d_6 than in $CDCl_3$ (δ 9.21 ppm, $\Delta\delta$ = +0.70 ppm). This phenomenon was attributed to the intermolecular hydrogen bonding formed between the NH_b proton and DMSO-d_6. The intramolecular hydrogen bonding formed in compound *cone*-**7** was broken, and the new intermolecular hydrogen bonding was formed.

Interestingly, hexaamide *cone*-**7** shows low efficiency for metal cations compared with *cone*-**2a** (2*d*). The ionophoric activity of *cone*-**7** was almost absent. Hexaamide *cone*-**7** shows a single affinity only to *n*-butylammonium ion owing to the C_3-symmetric structure. However, no extractability for isobutyl- or *tert*-butyl-ammonium ion was observed under the conditions used. The ionophores usually form loose ion pairs with metal picrates, which produced the maximum absorption peak at 377 nm (14, 15). Interestingly, the hexaamide *cone*-**7** also forms a contact ion pair with *n*-$BuNH_3^+$ and shows the maximum absorption peak at 365 nm. In comparison with *cone*-**7**, *N*,*N*-diethylamide derivative *cone*-**2a** has a higher affinity to alkali metal ions (Na^+ (93.0% extraction) and K^+ (71.6%)), transition metal ions (Ag^+ (90.4%) and Cu^{2+} (27.5%)), and typical metal ion (Al^{3+} (19.1%)). Higher extractabilities of the *cone*-*N*,*N*-diethylamide derivative for *n*-butyl- (97.8%), isobutyl- (48.1%), and *tert*-butylammonium ion (35.4%) were observed and are attributable to the higher electron density of the oxygen of the carbonyl group by the electron donation ability of the amide group through conjugation N–C=O $\leftrightarrow$ N^+=C–O^- (2*d*, 12*a*, 12*b*). These findings clearly indicate that because of the strong hydrogen-bonding formation between NH and neighboring CO groups in hexaamide *cone*-**7**, there is no affinity shown for either hard or soft metal cations.

The present binding mode can be demonstrated more clearly by using ^{1}H NMR spectroscopy. There are two modes for *cone*-**7** to bind with *n*-butylammonium ion (Fig. 1), i.e., from the lower rim through substituent moieties or from the upper rim through the π cavity formed by three aromatic rings. As shown in Fig. 2, the chemical shifts of *cone*-**7** are different in the absence or presence of *n*-butylammonium ion. After adding an equivalent of *n*-$BuNH_3Cl$ to a solution of *cone*-**7** (5×10^{-3} (mol/L)$^{-1}$) in $CDCl_3$ at 27 °C, methylene protons of Ar$CH_2O CH_2$Ar and Ar′OCH_2CONHCH_2CONH$C_6H_4CH_3$ were dramatically shifted to a lower magnetic field, indicating that the binding mode is occurring through

© 2006 NRC Canada

Fig. 2. Chemical shift changes (Δδ) of *cone*-**5** and *cone*-**7** (5×10^{-3} mol/L) induced in the presence of *n*-$BuNH_3Cl$ (5×10^{-3} mol/L) in $CDCl_3$ at 27 °C. A plus sign (+) denotes a shift to lower magnetic field, whereas a minus sign (–) denotes a shift to higher magnetic field.

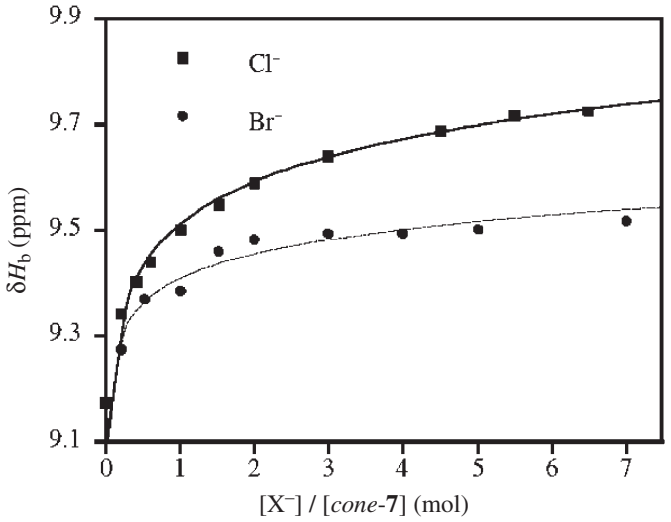
the π cavity formed by the three aromatic rings. This binding is attributed to the π effect of aromatic rings on the C-H protons of the alkyl group because both the host and guest molecules have a C_3-symmetric conformation. With an excess of *n*-$BuNH_3Cl$, the free guest molecule and the encapsulated guest molecule were clearly observed by ^{1}H NMR spectroscopy in which the encapsulated one was shifted upfield: CH_3 (δ 0.95–0.26 ppm, Δδ = –0.69 ppm), CH_3CH_2 (δ 1.45–0.30 ppm, Δδ = –1.05 ppm), $CH_3CH_2CH_2$ (δ 1.77 to –0.25 ppm, Δδ = –2.02 ppm), and CH_2N (δ 3.00–0.30 ppm, Δδ = –2.70 ppm). The NH_b proton in *cone*-**7** was shifted to a lower magnetic field (δ 9.21–9.51 ppm, Δδ = +0.30 ppm) while NH_a was shifted to an upper field (δ 8.45–8.36 ppm, Δδ = –0.09 ppm). This observation indicates that the complexation of the anionic guest Cl^- occurred at the *p*-methylphenyl amide moiety but not at the glycine amide moiety. This is different from the observation that N*H* of the glycine amide in *cone*-**5** was shifted strongly to a lower magnetic field (δ 8.03–9.14 ppm, Δδ = +1.11 ppm).

As mentioned above, Δδ between H_{ax} and H_{eq} of the ArCH_2Ar methylene protons in calix[4]arene serves as a measure of the "flattening". The Δδ value increases from 0.37 to 0.92 ppm in *cone*-**7** upon the binding of *n*-$BuNH_3^+$. These findings imply that *cone*-**7** stands up when the guest is included because *n*-$BuNH_3^+$ enters into the π cavity formed by the three aromatic rings and Cl^- complexes with NH_b by hydrogen-bonding interaction. Similar findings were observed in the case of *cone*-**5** and *n*-$BuNH_3Cl$ (the Δδ value increases from 0.40 to 1.15 ppm).

Intramolecular hydrogen bonding in *cone*-**7** weakens the affinity of *cone*-**7** to metal ions, which were encapsulated through the lower rim of the homotrioxacalix[3]arene derivative. When *cone*-**7** was complexed with *n*-$BuNH_3^+$ through the π cavity, the conformation was changed and intramolecular hydrogen bonding was broken. Thus, the complexation of the anionic guest Cl^- through hydrogen bonding is possible (16). Upon the addition of *n*-Bu_4NI and $PhMe_3NCl$ to a solution of *cone*-**7** in $CDCl_3$ (5×10^{-3} (mol/L)$^{-1}$), no complexation of halide anions was observed. This is due to the strong intramolecular hydrogen bonding, which breaks the anion binding site.

Table 1. Association constants (K_a, (mol/L)$^{-1}$) and free energies of association (ΔG, kJ mol^{-1}) of hosts *cone*-**3**, *cone*-**5**, and *cone*-**7** with halide anions.

	Cl^-		Br^-	
Hosts	K_a	$-\Delta G°$	K_a	$-\Delta G°$
cone-**3**	8520±510	22.6	1731±122	18.6
cone-**5**	1060±60	17.4	220±16	13.4
cone-**7**	536±32	15.7	230±17	13.6



Note: In $CDCl_3$ at 27 °C; host concentration was 5 mmol/L.

Based on this observation, we investigated the complexation of *cone*-**7** with *n*-butylammonium halide counterions. With the addition of ammonium halide counterions, the proton peaks in *cone*-**7** were separated into complex and uncomplex. The downfield shift of NH_b might be attributed to the presence of the anionic guest close to the NH_b group by the intramolecular hydrogen bonding. The chloride anion induces a larger downfield shift for the amide hydrogen of *cone*-**7** than the bromide anion does. For example, significant downfield shifts of Δδ = +0.60 ppm for the NH_b proton in the case of Cl^- and Δδ = +0.40 ppm in the case of Br^- were observed. As the electronegativity of the halogen atom decreased with the series of Cl, Br, and I atoms, the intensity of hydrogen bonding formed between their anions and N*H* protons should be decreased following the same order. In fact, in ^{1}H NMR spectrum of a mixture of *cone*-**7** and *n*-$BuNH_3^+X^-$, a larger downfield chemical shift in the complex of NH_b with Cl^- was observed as compared with Br^- and I^-. The association constants calculated from these changes in chemical shifts of the amide protons are K_a = 536 ± 32 (mol/L)$^{-1}$ ($\Delta G°$ = 15.7 kJ mol^{-1}) for Cl^- and K_a = 230 ± 17 (mol/L)$^{-1}$ ($-\Delta G°$ = 13.6 kJ mol^{-1}) for Br^-. The smaller K_a values for the halide anions than for those of *cone*-**3** and *cone*-**5** might be attributable to the reduced electrostatic attractive interaction between *n*-butylammonium ion and the halide anions arising from the longer distance (Table 1).

Similar to triamide *cone*-**3**, hexaamide *cone*-**7** shows a preference for Cl^- over Br^- complexation (Fig. 3). This finding suggests that the cavity formed by the threefold amide moieties is more complementary to the size of the Cl^- than to that of Br^-, as well as the higher electronegativity of Cl^- than that of Br^-. In the case of tri(urea)-functionalized calix[6]arene, the anion complexation is prefered for Br^- because it has a large calix cavity and the three functionalized moieties in the 1, 3, and 5 positions of calix[6]arene are more complementary to the size of Br^- than to that of Cl^- (16*b*). Calix[5]arene derivatives were reported to complex with alkylammonium ions and to display an enzymelike selectivity (17) towards biologically important ammonium substrates. Since hexahomotrioxacalix[3]arenes and their de-

rivatives have the C_3-symmetric conformation, they can bind with primary ammonium ions, having a potential function not only in chemical but also in biological systems (3).

Conclusions

We have demonstrated that the relationship between the properties of ionophore hosts and their intramolecular hydrogen bonding was taken into account in C_3-symmetric conformation. Owing to the intramolecular hydrogen bonding, the affinities of ionophore *cone*-**7** to metal ions were weakened; *cone*-**7** does not bind alkali metal ions because the binding site was blocked. However, hexaamide *cone*-**7** can bind *n*-butylammonium ion through the π cavity formed by three aryl rings, which can provide functional moieties in biological systems with good affinity and high selectivity. Interestingly, hexaamide *cone*-**7** binds a halide through the intermolecular hydrogen bonding among the NH_b hydrogens of *p*-methyphenyl amide in a 1:1 fashion in $CDCl_3$ in spite of the reduced electrostatic attractive interaction between *n*-butylammonium ions and the halide anions arising from the longer distance. Thus, hexaamide *cone*-**7** serves as a heteroditopic receptor that can complex with Cl^- and *n*-$BuNH_3^+$ at the same time. These results give some insight into the molecular design of new synthetic receptors for use in anion-controlled biomimetic systems.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. ^{1}H NMR spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JMS-01SG-2 mass spectrometer at an ionization energy of 70 eV using a direct inlet system through GLC; *m*/*z* values reported include the parent ion peak. IR spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed using a Yanaco MT-5. UV spectra were measured by a Hitachi 220A spectrophotometer.

Materials

cone-Hexahomotrioxacalix[3]arene triacetic acid (*cone*-**2b**) and (4-*tert*-butyl-2,6-dimethyl)phenoxyacetic acid (**8**) were prepared according to the previously reported procedures (2*d*, 12*a*, 12*b*).

Preparation of *cone*-7,15,23-tri-*tert*-butyl-25,26,27-tris[(methoxyacetylaminocarbonyl)methoxy]-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (*cone*-5)

To a solution of *cone*-hexahomotrioxacalix[3]arene triacetic acid (*cone*-**2b**) (400 mg, 0.532 mmol) and glycine methyl ester (**4a**) (427 mg, 4.80 mmol) in CH_2Cl_2 (30 mL) was added 1-hydroxybenzotriazole (HOBt) (94 mg, 0.697 mmol). To the mixture was added a solution of dicyclohexylcarbodiimide (DCC) (684 mg) in CH_2Cl_2 (10 mL) dropwise at 0 °C. Then the solution was stirred for 15 h at room temperature. After reaction, the solvent was removed; then the residue was dissolved with AcOEt and filtered; the filtrate was washed with 10% citric acid, water, 5% sodium bicarbonate, water, and brine, dried with Na_2SO_4, and condensed under reduced pressure. The residue was chromatographed over silica gel (Wako, C-300; 100 g) with AcOEt as the eluent to give a colorless solid. The solid was recrystallized from methanol to give *cone*-**5** (365 mg, 70.5%) as colorless prisms, mp 90–92 °C. IR (KBr) ν_{max}: 3350, 2958, 2871, 1752, 1678, 1540, 1484, 1200, 1076. ^{1}H NMR ($CDCl_3$) δ: 1.13 (27H, s, *t*-Bu), 3.78 (9H, s, *CH*$_3$), 4.15 (6H, d, *J* = 5.86 Hz, N-*CH*$_2$), 4.38 (6H, d, *J* = 12.7 Hz, Ar*CH*$_2$O), 4.78 (6H, d, *J* = 12.7 Hz, Ar*CH*$_2$O), 4.23 (6H, s, ArO*CH*$_2$), 6.95 (6H, s, Ar-*H*), 8.03 (3H, s, N*H*). *m*/*z*: 964 ([M]$^+$). Anal. calcd. for $C_{51}H_{69}O_{15}N_3$ (964.12): C 63.54, H 7.21, N 4.36; found: C 63.75, H 7.35, N 4.26.

Preparation of *cone*-7,15,23-tri-*tert*-butyl-25,26,27-tris[(hydroxyacetylaminocarbonyl)methoxy]-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (*cone*-6)

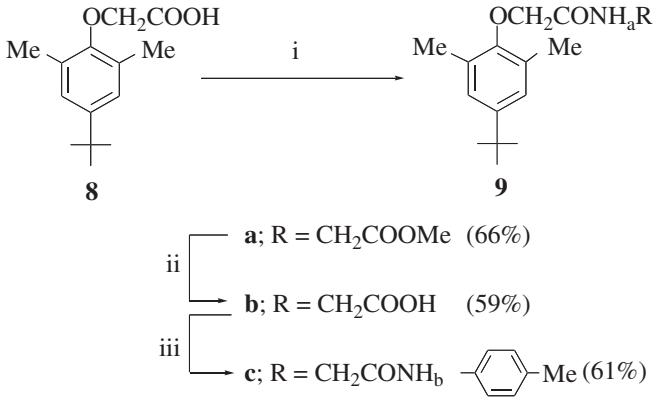
To a mixture of *cone*-**5** (225 mg, 0.23 mmol) in dioxane (35 mL) was added an aqueous 1 mol/L NaOH solution (25 mL), the mixture was stirred at room temperature for 1 h, then the solvent was removed under reduced pressure. The residue was acidified to neutral pH. The dispersion was extracted with ethyl acetate (30 mL × 2). The combined extracts were washed with 10% citric acid (20 mL × 2), 5% sodium bicarbonate (20 mL), water (20 mL), and saturated brine (20 mL), dried with Na_2SO_4, and condensed under reduced pressure. The residue was washed with hexane to give *cone*-**6** (170 mg, 79%) as a colorless solid, mp 215–217 °C. IR (KBr) ν_{max}: 3500–3250, 2958, 2867, 1736, 1661, 1540, 1457, 1363, 1231, 1197, 1093. ^{1}H NMR ($CDCl_3$–MeOH[D_4], 3:1 *v*/*v*) δ: 1.13 (27H, s, *t*-Bu), 4.13 (6H, s, ArO*CH*$_2$), 4.20 (6H, d, *J* = 5.86 Hz, N-*CH*$_2$), 4.42 (6H, d, *J* = 12.7 Hz, Ar*CH*$_2$O), 4.80 (6H, d, *J* = 12.7 Hz, Ar*CH*$_2$O), 6.97 (6H, s, Ar-*H*), 8.18 (3H, t, *J* = 5.86 Hz, *NH*). *m*/*z*: 922 ([M]$^+$). Anal. calcd. for $C_{48}H_{63}O_{15}N_3$ (922.05): C 62.53, H 6.89, N 4.56; found: C 62.72, H 6.73, N 4.40.

Preparation of the hexaamide derivative of homooxacalix[3]arene (*cone*-7)

To a solution of cone triacid homocalix[3]arene (*cone*-**6**) (491 mg, 0.532 mmol) and *p*-toluidine (**4b**) (514 mg, 4.80 mmol) in CH_2Cl_2 (30 mL) was added HOBt (94 mg,

© 2006 NRC Canada

0.697 mmol). To the mixture was added a solution of DCC (684 mg) in CH_2Cl_2 (10 mL) dropwise at 0 °C. Then the solution was stirred for 15 h at room temperature. After reaction, the solvent was removed; then the residue was dissolved with AcOEt and filtered; the filtrate was washed with 10% citric acid, water, 5% sodium bicarbonate, water, and brine, dried with Na_2SO_4, and condensed under reduced pressure. The residue was chromatographed over silica gel (Wako, C-300; 100 g) with AcOEt as the eluent to give a colorless solid. The solid was recrystallized from methanol to give *cone*-**7** (538 mg, 85%) as colorless prisms, mp 147–149 °C. IR (KBr) ν_{max}: 3476, 3410, 3312, 2958, 2867, 1664, 1609, 1541, 1516, 1482, 1197, 818. ^{1}H NMR ($CDCl_3$) δ: 1.11 (27H, s, *t*-Bu), 2.29 (9H, s, Ar′-CH_3), 4.09 (6H, s, ArOCH_2), 4.20 (6H, d, *J* = 5.86 Hz, N-CH_2), 4.34 (6H, d, *J* = 12.7 Hz, ArCH_2O), 4.79 (6H, d, *J* = 12.7 Hz, ArCH_2O), 6.95 (6H, s, Ar-*H*), 7.08 (6H, d, *J* = 8.8 Hz, Ar′-H_a), 7.43 (6H, d, *J* = 8.8 Hz, Ar′-H_b), 8.45 (3H, t, *J* = 5.86 Hz, NH_a), 9.21 (3H, s, NH_b); (DMSO-d_6) δ: 1.23 (27H, s, *t*-Bu), 2.23 (9H, s, Ar′-CH_3), 4.01 (6H, d, *J* = 5.86 Hz, N-CH_2), 4.19 (6H, s, ArOCH_2), 4.47 (6H, d, *J* = 12.7 Hz, ArCH_2O), 4.77 (6H, d, *J* = 12.7 Hz, ArCH_2O), 6.94 (6H, s, Ar-*H*), 7.06 (6H, d, *J* = 8.8 Hz, Ar′-H_a), 7.39 (6H, d, *J* = 8.8 Hz, Ar′-H_b), 8.25 (3H, t, *J* = 5.86 Hz, NH_a), 9.91 (3H, s, NH_b). ^{13}C NMR ($CDCl_3$) δ: 20.89, 31.44, 34.28, 43.98, 70.28, 73.26, 120.20, 127.79, 129.52, 129.52, 131.05, 134.18, 135.16, 147.39, 153.51, 167.74, 170.99. *m*/*z*: 1189 ([M]$^+$). Anal. calcd. for $C_{69}H_{84}O_{12}N_6$ (1189.47): C 69.68, H 7.12, N 7.07; found: C 69.51, H 7.23, N 7.14.



Preparation of 4-*tert*-butyl-2,6-dimethyl[(methoxyacetylaminocarbonyl)methoxy]benzene (9a)

To a solution of (4-*tert*-butyl-2,6-dimethyl)phenoxyacetic acid (**8**) (100 mg, 0.43 mmol), glycine methyl ester (**4a**) (114 mg, 1.28 mmol), and HOBt (75 mg, 0.17 mmol) in CH_2Cl_2 (12 mL) was added a solution of DCC (560 mg) in CH_2Cl_2 (5 mL) dropwise at 0 °C. After the mixture was stirred for 7 h at room temperature, it was condensed under reduced pressure. The residue was extracted with ethyl acetate (30 mL × 2). The combined extracts were washed with 10% citric acid (20 mL × 2), 5% sodium bicarbonate (20 mL), water (20 mL), and saturated brine (20 mL), dried with Na_2SO_4, and condensed under reduced pressure. The residue was recrystallized from methanol to give the title compound **9a** (Scheme 2) (87 mg, 66%) as colorless prisms, mp 101 to 102 °C. IR (KBr) ν_{max}: 3337, 3320, 2968, 2865, 1755, 1734, 1667, 1534, 1488, 1277, 1197, 1182, 1056. ^{1}H NMR ($CDCl_3$) δ: 1.29 (9H, s, *t*-Bu), 2.27 (6H, s, CH_3), 3.80 (3H, s, OCH_3), 4.20 (2H, d, *J* = 5.37 Hz, N-CH_2), 4.33 (2H, s, ArOCH_2), 7.03 (2H, s, Ar-*H*), 7.46 (1H, t, *J* = 5.37 Hz, *NH*). *m*/*z*: 307 ([M]$^+$). Anal. calcd. for $C_{17}H_{25}O_4N$ (307.39): C 66.43, H 8.2, N 4.56; found: C 66.23, H 8.35, N 4.68.

Preparation of 4-*tert*-butyl-2,6-dimethyl[(hydroxyacetylaminocarbonyl)methoxy]benzene (9b)

To a solution of **9a** (150 mg) in dioxane (30 mL) was added an aqueous 1 mol/L NaOH solution (30 mL) at room temperature. After the mixture was stirred at room temperature for 1 h, it was condensed under reduced pressure. The residue was then acidified to neutral condition. The precipitate was extracted with ethyl acetate (30 mL × 2). The combined extracts were washed orderly with water (20 mL) and saturated brine (20 mL), dried with Na_2SO_4, and condensed under reduced pressure. The residue was washed with hexane to give **9b** (Scheme 2) (81 mg, 59%) as a colorless solid, mp 193–195 °C. IR (KBr) ν_{max}: 3383, 2963, 2925, 2867, 1730, 1635, 1540, 1436, 1245, 1229, 1124. ^{1}H NMR ($CDCl_3$) δ: 1.29 (9H, s, *t*-Bu), 2.27 (6H, s, CH_3), 3.10 (1H, broad, COO*H*), 4.25 (2H, d, *J* = 5.37 Hz, N-CH_2), 4.35 (2H, s, ArOCH_2), 7.03 (2H, s, Ar-*H*), 7.46 (1H, t, *J* = 5.37 Hz, *NH*). *m*/*z*: 293 ([M]$^+$). Anal. calcd. for $C_{16}H_{23}O_4N$ (293.37): C 65.51, H 7.9, N 4.77; found: C 65.63, H 7.87, N 4.64.

Scheme 2. Reagents and conditions: (*i*) H_2NCH_2COOMe (**4a**), DCC–HOBt, CH_2Cl_2, room temp. for 15 h; (*ii*) Dioxane–NaOH(aq), room temp. for 1 h; (*iii*) *p*-toluidine (**4b**), DCC–HOBt, CH_2Cl_2, room temp. for 15 h.

Preparation of 4-*tert*-butyl-2,6-dimethyl[(4-methylphenylaminocarbonyl)methoxy]benzene (9c)

To a solution of **9b** (50 mg, 0.17 mmol), *p*-toluidine (**4b**) (55 mg, 0.51 mmol), and HOBt (23 mg, 0.17 mmol) in CH_2Cl_2 (12 mL) was added a solution of DCC (171 mg) in CH_2Cl_2 (5 mL) dropwise at 0 °C. After the mixture was stirred for 15 h at room temperature, it was condensed under reduced pressure. The residue was extracted with ethyl acetate (30 mL × 2). The combined extracts were washed with 10% citric acid (20 cm^3 × 2), 5% sodium bicarbonate (20 mL), water (20 mL), and saturated brine (20 mL), dried with Na_2SO_4, and condensed under reduced pressure. The residue was recrystallized from hexane–CH_2Cl_2 (3:1) to give **9c** (Scheme 3) (83 mg, 61.2%) as colorless prisms, mp 233 to 234 °C. IR (KBr) ν_{max}: 3383, 3320, 3289, 2962, 2948, 2851, 1699, 1609, 1526, 1312, 1195. ^{1}H NMR ($CDCl_3$) δ: 1.29 (9H, s, *t*-Bu), 2.27 (6H, s, CH_3), 2.31 (3H, s, ArCH_3), 4.25 (2H, d, *J* = 5.37 Hz, N-CH_2), 4.36 (2H, s, ArOCH_2), 7.02 (2H, s, Ar-*H*), 7.13, 7.42 (each 2H, d, *J* = 8.8 Hz, Ar-H_a, Ar-H_b), 7.76 (1H, t, *J* = 5.37 Hz, NH_a), 8.36 (1H, s, NH_b). *m*/*z*: 382 ([M]$^+$). Anal. calcd. for $C_{23}H_{30}O_3N_2$ (382.51): C 72.22, H 7.91, N 7.32; found: C 72.45, H 7.73, N 7.48.

Picrate extraction measurements

Alkali metal picrates (2.5×10^{-4} mol/L) were prepared in situ by dissolving 0.1 mol/L of alkali metal hydroxide in 2.5×10^{-4} mol/L of picric acid; triply distilled water was used for all aqueous solutions. Similarly, metallic picrates

© 2006 NRC Canada

were prepared in situ by dissolving 0.1 mol/L of metallic nitrate ($AgNO_3$, $Cu(NO_3)_2{\cdot}3H_2O$, $Al(NO_3)_3{\cdot}9H_2O$) in 2.5×10^{-4} mol/L of picric acid. Alkyl ammonium picrates were prepared by mixing an equimolar amount of alkylamine and picric acid in methanol.

Two-phase solvent extraction was carried out between water (5 mL, [alkali picrate] = 2.5×10^{-4} mol/L) and CH_2Cl_2 (5 mL, [ionophore] = 2.5×10^{-4} mol/L). The two-phase mixture was shaken in a stoppered flask for 24 h at 25 °C. We confirmed that this period is sufficient to attain the distribution equilibrium. This was repeated 3 times, and the solutions were left standing until phase separation was complete. The extractability was determined spectrophotochemically from the decrease in the absorbance of the picrate ion in the aqueous phase as described by Pedersen (18).

Determination of association constants

The measurements were performed by ^{1}H NMR titration experiments in a varying guest concentration of 0–50 mmol/L and a constant concentration of host receptors (5 mmol/L). As a probe, the chemical shift of the amide protons [C(O)NH_b] signal was used. The association constant values were calculated by the integral intensity of NH protons in the complex and free host molecules according to the literature (19).

Solubilities of H_2 in H_2O and D_2 in D_2O with dissolved boric acid and lithium hydroxide

Uncharat Setthanan, David R. Morris, and Derek H. Lister

Abstract: The solubilities of hydrogen (H_2 and D_2) in aqueous (H_2O and D_2O) solutions of lithium hydroxide or boric acid have been measured in the temperature range 25–80 °C. Lithium hydroxide and boric acid cause a salting-out effect for H_2 and D_2. The solubilities of H_2 and D_2 in aqueous electrolyte solutions exhibit similar responses to temperature changes as those for pure water. The solute specific parameter (h_i) for boric acid in light and heavy water is 0.07 ± 0.02 and 0.48 ± 0.26 m^3 $kmol^{-1}$, respectively.

Key words: hydrogen solubility, deuterium solubility, salting-out effect.

Résumé : Opérant à des températures allant de 25 à 80 °C, on a mesuré les solubilités de l'hydrogène (H_2 et D_2) dans des solutions aqueuses (H_2O et D_2O) d'hydroxyde de lithium ou d'acide borique. L'hydroxyde de lithium et l'acide borique provoquent un effet de relargage pour le H_2 et le D_2. Les solubilités du H_2 et du D_2 dans des solutions aqueuses d'électrolyte présentent des réponses semblables aux changements de températures que ceux pour l'eau pure. Les valeurs du paramètre spécifique de soluté (h_i) pour l'acide borique dans l'eau normale et lourde sont respectivement de 0,07 ± 0,02 et de 0,48 ± 0,26 m^3 $kmol^{-1}$.

Mots clés : solubilité de l'hydrogène, solubilité du deutérium, effet de relargage.

[Traduit par la Rédaction]

Introduction

Light and heavy water are used as moderators and heat transport media in nuclear power reactors and may contain dissolved boric acid and lithium hydroxide for reactivity and pH control. In addition, hydrogen is introduced to suppress radiolysis and to minimize oxygen concentration to reduce corrosion of the system components. In this paper, solubilities are reported for H_2 in H_2O and D_2 in D_2O in the presence of dissolved boric acid or lithium hydroxide.

Several models have been proposed to explain salting-in and salting-out phenomena in which gas solubility is, respectively, increased and decreased. These models include the hydration theory, electrostatic theory, van der Waals theory, and the internal pressure concept. However, because of the complexity of the electrolyte–water–gas interactions, it is inconclusive as to which model is most reliable.

The effect of a dissolved species on the solubility of a gas in a solution can be described by the Sechenov relation:

$$[1] \qquad \log_{10}\left(\frac{c_{G,0}}{c_G}\right) = Kc_s$$

The Sechenov constant (K) is an empirical parameter for a specific gas, solute, solvent, and temperature. A shift from the salting-out to salting-in effect was reported by Sergeeva (1) as the ionic radius of a solute increases.

Based upon an extensive analysis of published data for the solubilities of gases in liquids in the presence of dissolved species, Schumpe (2) and Weisenberger and Schumpe (3) derived the expressions

$$[2] \qquad \log_{10}\left(\frac{c_{G,0}}{c_G}\right) = \sum_i (h_i + h_G)\, c_i$$

$$[3] \qquad h_G = h_G^0 + h_T(T - 298.15\ \mathrm{K})$$

The temperature effect is included in the gas-specific parameter, h_G. The solute-specific and (or) ion-specific parameter (h_i) is temperature independent.

Experimental

The solubilities of H_2 and D_2 in light and heavy water, respectively, were measured using apparatus and procedures according to ASTM D2780 (4). The experiments were performed at ambient atmospheric pressure over the temperature range 25–80 °C. The atmospheric pressure was corrected to the standard atmospheric pressure by using data from Weather Underground Inc. (www.weatherunderground.com). The lithium and boron concentrations were in the range 0–1000 ppm and 0–2000 ppm, respectively. The solute-specific parameter (h_i) for boron was then calculated from the experimental data at various temperatures and boron concentrations. The precision of the solubility measurements was estimated as 3%, based upon the uncertainties of measurements of the volume of gas and the system pressure and temperature.

Results and discussion

The measured solubilities of H_2 in H_2O with dissolved boric acid or lithium hydroxide are presented in Table 1 and Figs. 1 and 2. Published data on the solubilities in H_2O have been reviewed by Wilhelm et al. (5). The measured solubilities of H_2 in H_2O reported in this work agree within 6%. Solubilities in lithium hydroxide solutions agree with the data of Weisenberger and Schumpe (3) within 7%. Standard deviation on the solubility measurements averages 4.7%.

The concentrations of various boron species in aqueous solution were calculated using the dissociation constants from Baes and Mesmer (6). Boron is present in solution primarily as $B(OH)_3$. The concentrations of charged species $B(OH)_4^-$, $B_2(OH)_7^-$, $B_3(OH)_{10}^-$, and $B_4(OH)_{14}^{2-}$ are very low and were neglected.

The specific parameter (h_i) for $B(OH)_3$ in the H_2 + H_2O system was calculated from the concentration of $B(OH)_3$, the measured solubilities of H_2 in the $B(OH)_3$ + H_2O solutions, and the correlation of published data from Wilhelm et al. (5) for the H_2 + H_2O system. The gas-specific parameter for H_2 and ion-specific parameters for H^+ and OH^- were obtained from Weisenberger and Schumpe (3).

The measured solubilities of D_2 in D_2O with dissolved boric acid are presented in Table 2 and Fig. 3. Solubilities in D_2O agree with published data within 8% (Scharlin and Battino (7)). Standard deviation on the solubility measurements averages 4.3%.

The solubility of D_2 in D_2O shows a minimum value of 1.70×10^{-5} mol fraction D_2 at about 323 K. This solubility minimum is significantly higher than that for the H_2 + H_2O system (1.30×10^{-5} mol fraction H_2 at about 325 K (5)). The solubilities of D_2 in D_2O are substantially lowered by dissolved boric acid. The combined effects of increasing boric acid concentration and increasing temperature are contrasting (see Fig. 3). At temperatures below that of the minimum solubility for the D_2 + D_2O system (323 K), increasing boric acid concentration causes a progressive decrease of the D_2 solubility. By contrast, at temperatures above 323 K, increasing boric acid concentration from 350 ppm B to 1000 ppm B causes the D_2 solubilities to increase. However, the magnitudes of the standard deviations on the measurements of D_2 solubility are such that the effects described, are not clear.

The specific parameter (h_i) for $B(OD)_3$ in the D_2 + D_2O system was calculated from the concentration of $B(OD)_3$, the measured solubilities of D_2 in the $B(OD)_3$ + D_2O solutions and in D_2O. D_2 was assumed to have the same gas-specific parameter (h_G) as H_2, and $B(OD)_3$ was assumed to dissociate in D_2O to the same extent as $B(OH)_3$ in H_2O. Also, the ion-specific parameters for D_3O^+ and OD^- were assumed to be the same as the values for H_3O^+ and OH^- in H_2O. No comparable data have been found in the literature.

Conclusions

The specific parameter (h_i) for the salting-out effect of $B(OH)_3$ in the H_2 + H_2O system is $h_{B(OH)_3}$ = 0.07 ±

0.02 m^3 $kmol^{-1}$. The specific parameter (h_i) for the salting-out effect of $B(OD)_3$ in the D_2 + D_2O system is $h_{B(OD)_3}$ = 0.48 ± 0.26 m^3 $kmol^{-1}$. The reasons for the high value of $h_{B(OD)_3}$ relative to the value of $h_{B(OH)_3}$ are not known. The large uncertainty value for $h_{B(OD)_3}$ arises from the contrasting effects of increasing temperature and increasing B concentration above and below the temperature of minimum solubility of D_2 in the solutions.

Regioselective synthesis of *vic*-halo alcohols and symmetrical or unsymmetrical *vic*-dihalides from epoxides using triphenylphosphine – *N*-halo imides

Nasser Iranpoor, Habib Firouzabadi, Roya Azadi, and Farzaneh Ebrahimzadeh

Abstract: A simple, novel, and highly regioselective cleavage of epoxides into vicinal halo alcohols and symmetrical or unsymmetrical dihalides is described using different stoichiometries of triphenylphosphine (PPh_3) and *N*-halo succinimide (NXS) or *N*-halo saccharine (NXSac).

Key words: *N*-halo succinimide (NXS), *N*-halo saccharine (NXSac), triphenylphosphine (PPh_3), epoxide, *vic*-halo alcohol, symmetrical dihalide, unsymmetrical dihalide.

Résumé : On a effectué un nouveau clivage simple et hautement régiosélectif d'époxydes qui conduit à des halogénoalcools et des dihalogénures symétriques et non symétriques vicinaux et qui a été réalisé en utilisant des stoechiométries diverses de triphénylphosphine, de *N*-halogénosuccinimide (NXS) ou de *N*-halogénosaccharine (NXSac).

Mots clés : *N*-halogénosuccinimide (NXS), *N*-halogénosaccharine (NXSac), triphénylphosphine (PPh_3), époxyde, halogénoalcool vicinal, dihalogénure symétrique, dihalogénure non symétrique.

[Traduit par la Rédaction]

Introduction

Epoxides are suitable starting materials for the preparation of different functional groups (1). Owing to the importance of vicinal halo alcohols in organic synthesis (2, 3), diverse methods have been developed for their preparation from epoxides. The conventional reagents for epoxide ring opening to halo alcohols are hydrogen halides and hypohalite–water (4). However, the disadvantages of these procedures are an intolerance to acid-sensitive moieties and by-product formation (5). A great effort has been made in the last few years to find milder procedures for converting epoxides into halo alcohols. For example, silyl halides can be added to epoxides to give *O*-silyl protected halo alcohols (6). Other methods include the use of a halogen and triphenylphosphine (PPh_3) (7), or disubstituted borane halogenides (8), β-bromo bis(dimethylamino)borane (9), monochloroborane – dimethyl sulfide (10), $Li_nM_nX_n$ (M = Ni, Cu, Ti) (11), and MX_n (12). Also, different metal salts (13–17) in the presence of halide ions, TMSCl, and phosphaferrocene as the catalyst (18); lithium halides in the presence of silica gel or Amberlyst 15 (19, 20); a combination of elemental halogen and 2-phenyl-2-(2-pyridyl)imidazolidine (PPI) (21), phenyl hydrazine (22), or crown ethers (23); PPh_3–CBr_4 (24), and acyl methylimidazolium halide ([AcMIm]X) (25) are among the reagents used for this transformation. Although there are many methods reported for the conversion of epoxides into vicinal halo alcohols, their conversion to symmetrical or unsymmetrical *vic*-dihalides is rarely found in the literature. The use of reagents such as PPh_3–CCl_4 (26) and PPh_3–X_2 (X = Cl, Br) (27) is reported for the preparation of symmetrical *vic*-dihalides and PPh_3–X_2 (X = Cl, Br) followed by using HCl–THF for the preparation of unsymmetrical *vic*-dihalides (27).

Results and discussion

Recently, we reported a method for the preparation of *vic*-halo alcohols or symmetrical or unsymmetrical dihalides (28) from epoxides using a combination of PPh_3–DDQ–R_4NX (X = Cl, Br, I). In conjunction with this research and in continuation of our previous work on the use of PPh_3 – *N*-halo succinimide (NXS) (29), we now introduce a new, mild, regioselective, and simpler method for the efficient conversion of epoxides to *vic*-halo alcohols or symmetrical or unsymmetrical *vic*-dihalides. In this method, epoxides in the presence of PPh_3–NXS or PPh_3 – *N*-halo saccharine (NXSac) are converted to *vic*-halo alcohols or symmetrical or unsymmetrical *vic*-dihalides depending on the molar ratio and the type of halo imide used (Scheme 1).

We took oxiranylmethyl phenyl ether (Table 1, entry 1) as an example and optimized the reaction conditions for its conversion to *vic*-bromo alcohol. It was observed that the mixture of oxiranylmethyl phenyl ether – PPh_3 – NBS or NBSac with the molar ratio of 1:1.2:1.2 in 1% aqueous acetonitrile at room temperature is suitable for the quantita-

 doi:10.1139/V05-261 © 2006 NRC Canada

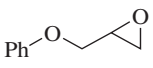
Scheme 1.

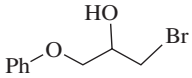
tive conversion of oxiranylmethyl phenyl ether to 1-bromo-3-phenoxy-2-propanol. Aqueous acetonitrile is required to hydrolyze the intermediate to the corresponding vicinal halohydrine. Similar reaction conditions were then applied for the conversion of structurally different epoxides to their corresponding *vic*-halo alcohols. The results are shown in Table 1.

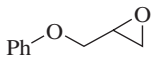
Under these reaction conditions, the ethereal bonds, ester groups, carbon–carbon double bond, and activated aromatic ring do not interfere with the formation of halo alcohols and remain intact. Electronic and steric factors control the orientation of the attack of halide ion. In the case of styrene oxide, owing to electronic factors, the attack of the halide ion occurs mainly at the more substituted position. However, in other epoxides that bear alkyl or electron-withdrawing groups, owing to the combination of steric and electronic factors, the attack occurs at the less hindered site of the ring and 1-halo-2 alcohols are produced as the major product (Table 1).

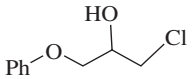
We also investigated the possibility of converting epoxides to symmetrical vicinal dihalides using PPh_3–NXS or PPh_3–NXSac (X = Cl, Br). For this purpose, oxiranylmethyl phenyl ether (Table 2, entries 1 and 2) was treated as a model compound with the PPh_3–NBS or PPh_3–NBSac reagent system using the optimized molar ratio of 2.5:2.5 in refluxing acetonitrile, and the corresponding dibromide was obtained in high yield. The use of NCS or NCSac in this method under the same reaction conditions as used for the preparation of dibromide offers the possibility of producing *vic*-dichlorides. We extended this procedure to other epoxides to obtain symmetrical *vic*-dihalides. The results of this investigation are shown in Table 2.

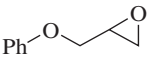
However, the preparation of *vic*-diiodides by this method was not successful. This result is in accordance with the literature (30), which indicates that alkene formation is favoured owing to the ease of elimination of molecular iodine. In all the reactions of epoxides with PPh_3–NIS or PPh_3–NISac (2.5:2.5), alkene formation was the only pathway. For example, the addition of oxiranylmethyl phenyl ether to the mixture of PPh_3–NBS or PPh_3–NBSac (2.5:2.5) in refluxing acetonitrile produced allyl phenyl ether as the only product after 0.5 h. Therefore, the use of a PPh_3–NIS or PPh_3–NISac mixture offers a new mixed reagent system for the deoxygenation of epoxides into their corresponding alkenes.

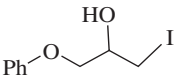


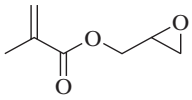


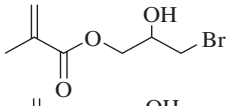


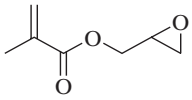


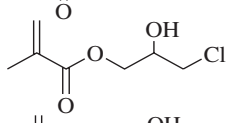


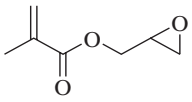


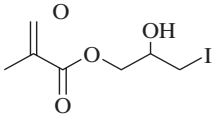


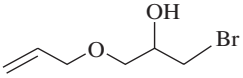


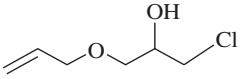


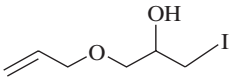


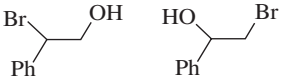


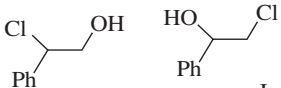


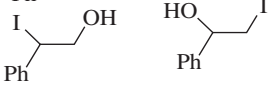


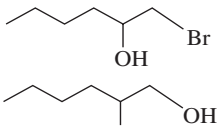


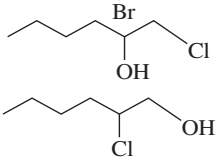


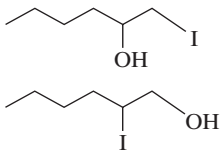












To overcome the problems of using highly acidic conditions for the conversion of epoxides to *vic*-dihalides (27), and to introduce a mild and novel method for this transformation, we applied our method to epoxides. For this transformation, the successive use of two *N*-halo imides having different halide ions produces the desired unsymmetrical *vic*-dihalide in high yield. To optimize the reaction conditions, oxiranylmethyl phenyl ether was added to a mixture of PPh_3–NCS or PPh_3–NCSac with the molar ratio of 1.2:1.2 in acetonitrile at room temperature. When all the epoxide was consumed, the mixture was poured into another mixture containing PPh_3–NBS or PPh_3–NBSac (2.5:2.5) in acetonitrile and refluxed for 8 h. After completion of the reaction, 2-bromo-1-chloro-3-phenoxypropane was obtained in 85% yield (Table 3, entry 2). Since this attempt was successful, we applied it to the preparation of unsymmetrical *vic*-dihalides from other epoxides. By using the proper halide anion in each step, we could easily control the formation of *vic*-dihalides with high regioselectivity. The results obtained for this study are tabulated in Table 3. In these reactions, as we expected, in the first step, the first halide ion attacks the epoxide ring from the same side of the formation of *vic*-halo alcohols. In the second step, the resulting halo alcohol reacts with the mixture of PPh_3–NXS or PPh_3–NXSac and the second halide anion displaces the hydroxyl group to produce the desired unsymmetrical dihalide. It was observed that when one of the nucleophiles was iodide, because of the possibility of the elimination of IX (X = Cl, Br), alkene formation was a competing pathway and lowered the yield of *vic*-dihalides considerably (Table 3, entries 3 and 6).

Although the exact mechanism of these reactions is not clear, it is suggested that, at first, a positively charged adduct (**I**) (31) is formed from the reaction of PPh_3 with NBS (Scheme 2). This positively charged adduct interacts with the oxygen atom of the epoxide and produces (**II**). When *R*-(–)-styrene oxide, the formation of the corresponding β-bromohydrin, which did not show any optical rotation, accounts for the formation of the racemic product through the intermediacy of a benzylic carbocation. Nucleophile attack of the halide ion on (**II**) produces the intermediate (**III**). This intermediate in the presence of water could produce triphenylphosphine oxide, succinimide, and the corresponding *vic*-halo alcohol. Similarly, the attack of another halide ion on this intermediate produces the corresponding vicinal symmetrical or unsymmetrical dihalide.

As shown in Table 3, entries 1 and 4, when the first nucleophile used was bromide, a mixture of two regioisomers was obtained. It is assumed that, in these cases,

[a]All the products are known compounds (16, 20, 21, 24, 28) and are identified by their physical or spectral data.
[b]Isolated yield.
[c]Yield % in parentheses shows the formation of the other regioisomer.

the intermediate (**a**) can release $OPPh_3$ through the anchimeric assistance of bromide to form the bromonium ion (**b**). An attack of the second nucleophile to either side of (**b**) can produce a mixture of two regioisomers (Scheme 3).

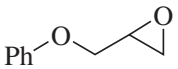
In summary, the present investigation has demonstrated that the use of a PPh_3–NXS or PPh_3–NXSac system offers a simple, novel, and convenient method for the selective conversion of epoxides to either their corresponding *vic*-halo alcohols or symmetrical or unsymmetrical *vic*-dihalides.[3]

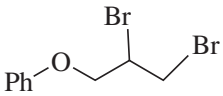
Experimental section

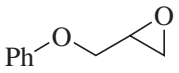
All the solvents and reagents were purchased from Fluka (Switzerland) or Merck (Germany) Chemical Companies. The products were purified by column or thick layer chromatography techniques. FT-IR spectra were recorded on a Shimadzu DR-8001 spectrometer. NMR spectra were recorded on a Brucker Avance DPX 250 MHz instrument. Mass spectra were recorded on a Shimadzu GC–MS-QP 1000PX.

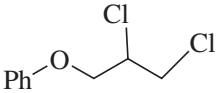
Typical procedure for the conversion of oxiranylmethyl phenyl ether to 1-bromo-3-phenoxy-2-propanol by PPh_3–NBS

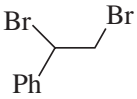
Oxiranylmethyl phenyl ether (0.15 g, 1 mmol) was added to a flask containing PPh_3 (0.314 g, 1.2 mmol) and NBS (0.213 g, 1.2 mmol) in 1% aq. CH_3CN (5 mL) at room temperature. TLC monitoring showed the completion of the reaction after 40 min. (This reaction with 1.2 mmol of NBSac takes 8 min, Table 1, entry 1.) After evaporation of the solvent, column chromatography of the crude mixture on silica gel using *n*-hexane – ethyl acetate afforded 1-bromo-3-phenoxy-2-propanol as a yellow oil in 93% yield. ^{1}H NMR ($CDCl_3$, 250 MHz, ppm) δ: 2.6 (d, 1H, J = 5 Hz), 3.6–3.7 (m, 2H), 4.07–4.10 (m, 2H), 4.15–4.25 (m, 1H), 6.90–7.10 (m, 3H), 7.3–7.6 (m, 1H). ^{13}C NMR ($CDCl_3$, 62.9 MHz, ppm) δ: 35.0, 69.5, 70.3, 114.5, 121.4, 129.6, 158.1. Mass spectra *m/e* (%): 232 ([M + 2], 33.1), 230 ([M], 35.6), 151 ([M – Br], 20.3).

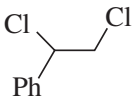


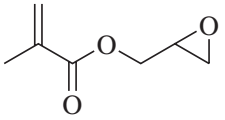


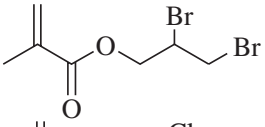


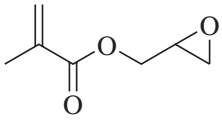


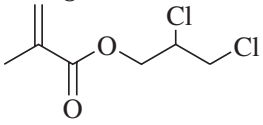


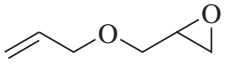


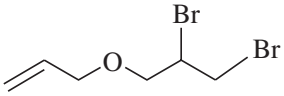


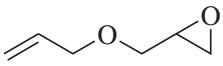


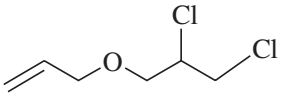


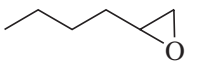


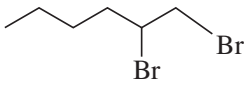


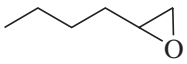


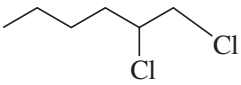


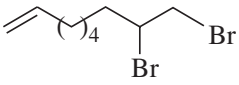


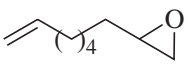


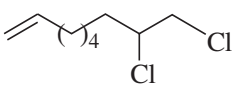


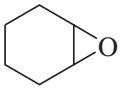


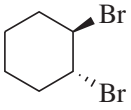


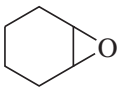


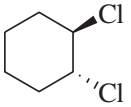












Typical procedure for the conversion of oxiranylmethyl phenyl ether to 1,2-dibromo-3-phenoxy propane by PPh_3–NBS

PPh_3 (0.654 g, 2.5 mmol) was added to a flask containing NBS (0.443 g, 2.5 mmol) in refluxing acetonitrile. Then oxiranylmethyl phenyl ether (0.15 g, 1 mmol) was added. TLC or GC analysis showed the completion of the conversion of oxiranylmethyl phenyl ether to 1,2-dibromo-3-phenoxypropane after 3 h. After completion of the reaction, the solvent was evaporated. 1,2-Dibromo-3-phenoxy propane was obtained in 88% yield after column chromatography of the crude mixture using *n*-hexane – ethyl acetate (5:1) as eluent. ^{1}H NMR ($CDCl_3$, 250 MHz, ppm) δ: 3.8–3.9 (m,

Organo(organooxo)mercury(II) chemistry — Synthesis and structure of methyl(phenoxo)mercury(II)[1]

Allan J. Canty, Janette W. Devereux, Brian W. Skelton, and Allan H. White

Abstract: Methyl(phenoxo)mercury(II) may be obtained from the reaction of methyl(chloro)mercury(II) with silver(I) oxide, followed by addition of phenol. The dominant motif of the structure is a pair of independent MeHgOPh aggregates (Hg—C,O 2.05(2) Å, 2.06(1) Å (x2); C-Hg-O 176.6(5)°, 176.3(5)°) loosely associated about a quasi-inversion centre by Hg···O interactions (2.702(9) Å, 2.719(9) Å) to form a dimer (Hg-O-Hg′ 106.0(4)°, 106.5(4)°; O-Hg-O′ 73.0(3)°, 72.6(3)°), the dimer stacking up the short crystallographic *c* axis (= 6.914(1) Å) at spacings *c*/2. Vibrational spectroscopic studies are insensitive to the associative interactions.

Key words: mercury, methylmercury, organomercury, structure, aryloxide, phenoxide.

Résumé : On peut obtenir du méthyl(phénoxo)mercure(II) par réaction du méthyl(chloro)mercure(II) avec de l'oxyde d'argent(I), suivie d'une addition de phénol. Le motif dominant de la structure est une paire d'agrégats indépendants de MeHgOPh (Hg—C,O 2,05(2) Å, 2,06(1) Å (x2); C-Hg-O 176,6(5)°, 176,3(5)°) faiblement associés autour d'un centre de quasi-inversion par des interactions Hg···O (2,702(9) Å, 2,719(9) Å) qui permettent de former le dimère (Hg-O-HgN 106,0(4)°, 106,5(4)°; O-Hg-ON 73,0(3)°, 72,6(3)°) qui s'empile le long de l'axe cristallographique *c* (= 6,914(1) Å) à des distances de *c*/2. Les études spectroscopiques vibrationnelles sont insensibles aux interactions associatives.

Mots clés : mercure, méthylmercure, organomercure, structure, aryloxyde, phénolate.

[Traduit par la Rédaction]

Introduction

The coordination chemistry of monoorganomercury(II) complexes has been reviewed (1, 2); for arylalkoxides and aryloxides, structural studies are limited to the early study of the 4-bromo-2-chlorophenoxo complex $PhHgOC_6H_3ClBr$ (3, 4), although the structure of a trimethylsiloxo complex, $MeHgOSiMe_3$, has also been described (5). Vibrational spectroscopic data have been interpreted in terms of monomeric structures for MeHgOPh and PhHgOPh in both the solid state and in dichloromethane (**1** in Scheme 1), consistent with osmometric studies in dichloromethane (6). However, in the less polar solvent benzene, ebullioscopic studies indicate that PhHgOPh and relatives PhHgOR′ (R′ = Me, *i*-Pr, *s*-Bu, CMe_2Ph) are associated and consistent with a monomer (**1**) – dimer (**2**) equilibrium (7), and it has also been suggested that PhHgOPh can adopt both dimeric (**2**) and trimeric (**3**) forms (8). Vibrational spectra are also consistent with a dimeric structure in the solid state for PhHgOR′ (R′ = Me, Et) (6). The complex $MeHgOSiMe_3$ is monomeric in benzene (osmometry) (9), and in the solid state an incomplete X-ray structure determination (280 "observed" reflections, R = 0.21) indicated a tetrameric structure (**4**) with short Hg—O (2.11 Å) and long Hg···O (2.75 Å) interactions (5). A weak intermolecular Hg···O interaction is also observed in $PhHgOC_6H_3ClBr$ (2.85(2) Å), although the molecule is essentially a monomer with C-Hg-O 174(1)°, where this angle is opposite a weak intramolecular Hg···Cl interaction (3.03 Å) (3). Noting the additional weak interactions present in these structures and the marked tendency for unsymmetrical coordination geometries for monoorganomercury(II) complexes, geometries for **2**–**4** are drawn to illustrate this behaviour, and additional weak interactions could be anticipated for monomers (**1**) (Scheme 1). Archetypal examples of unsymmetrical geometry are illustrated by the 2,2′-bipyridine complex $[MeHg(bpy)]NO_3$, which has C-Hg-N 164(1)°, Hg—N 2.24(3) Å, Hg···N 2.43(3) Å (10); the D,L-penicillamine complex $MeHgSCMe_2CH(CO_2)NH_2HgMe$, which has C-Hg-N 168.1°, Hg—N 2.216(5) Å, Hg···O 2.708(4) Å (11); and the closely related D,L-selenocysteine complex $MeHgSeCH_2CH(CO_2)NH_3{\cdot}H_2O$, which has C-Hg-Se 177.8(11)°, with associated more distant approaches Hg···O 2.93(2) Å and Hg···Se 3.737(4) Å (12).

In view of the lack of structural characterization for fundamental aryloxo complexes, the propensity for organomercury(II) compounds to adopt unusual geometries for mercury, the various structures proposed on the basis of physical and spectroscopic studies (**1**–**3**), and the structure

reported for the trimethylsiloxo complex (**4**), we have synthesized MeHgOPh and determined its structure in the solid state.

Results and discussion

Although the complex MeHgOPh was prepared by the reported method, the preparation is given in detail here in view of the brief description reported previously (13). Crystals were obtained from dichloromethane – light petroleum. Selected geometries are given in Table 1, and views of the structure are shown in Fig. 1.

The results of the low-temperature single crystal X-ray structure determination are consistent with the formulation of the complex, in terms of stoichiometry and connectivity, as neutral MeHgOPh. Two formula units, devoid of crystallographic symmetry, comprise the asymmetric unit of the structure. These may be viewed essentially as single molecules with almost linear C-Hg-O coordination (Hg—O 2.060(11) Å, 2.063(10) Å; Hg—C 2.046(16) Å, 2.049(18) Å; C-Hg-O 176.6(5)°, 176.3(5)°). The mercury environments lie side-by-side, quasi-inversion related (Fig. 1*a*), with long Hg···O interactions (2.702(9) Å, 2.719(9) Å), appreciably less than the van der Waals radii sum (O, 1.4 Å (14); Hg, ca. 1.73 Å (15)) that perturb the linearity of the C-Hg-O arrays. The $Hg(\mu\text{-}O)_2Hg$ arrays are quasi-planar (χ^2 523) with a fold angle across the Hg···Hg line of 17.4(6)° (Fig. 1*b*). The mercury atoms lie out of the associated C_6 ring planes by 0.17(3) Å and 0.20(2) Å, the Hg(n)-O(n)-C(n1)-C(n2) torsion angles being –8(2)° and –9(2)°. C(11, 21) lie out of the Hg_2O_2 "plane" by 0.22(2) Å and 0.32(2) Å. Despite these distortions, the quasi-dimeric arrays may be considered approximately planar and, as such, stack up the *c* axis of the almost orthogonal cell — Hg above O — these contacts being much longer and at the van der Waals limit (Hg(1)···O(1) (x, 1/2 – y, z – 1/2) 3.318(9) Å; Hg(2)···O(2) (x, 1/2 – y, z – 1/2) 3.368(10) Å) (Fig. 1*c*).

Although the structure determination reveals several interesting features in crystal chemistry, the structure of MeHgOPh conforms broadly to model **1** with the additional presence of weak intermolecular interactions, consistent with the monomeric behaviour exhibited in dichloromethane (6). Structural assignments for the solid state based on IR and Raman spectroscopic data (6), are supported by the structural determination, the spectroscopic data being insensitive to the weak intermolecular Hg···O interactions.

Experimental

Synthesis of MeHgOPh

Freshly precipitated silver(I) oxide (from an aqueous solution of silver(I) nitrate and sodium hydroxide) was collected and repeatedly washed and centrifuged until the pH of the solution was 7. An excess of Ag_2O was added to MeHgCl (6.28 g) in a small volume of water. The resulting aqueous solution was filtered, and phenol (2.35 g) was added. The white crystalline precipitate that formed was collected, washed with water, and dried over phosphorus pentoxide. The product was recrystallized from dichloromethane and then from dichloromethane – light petroleum (bp 40–60 °C) to give the pure complex (3.86 g, 50%). IR spectra are as reported (6).

X-ray data collection, structure determination, and refinement

Following earlier unsuccessful attempts at data acquisition at room temperature using a four-circle instrument (the ma-

Synthesis and coordination chemistry of 2,2′-diboratabiphenyls[1]

Ioan Ghesner, Warren E. Piers, Masood Parvez, and Robert McDonald

Abstract: Dianionic 2,2′-diboratabiphenyl derivatives were prepared as a new class of binucleating ligands. Preliminary investigations into their coordination chemistry involved Rh complexes. Their solution and solid state structures were studied and confirm the preference for η^6–η^6 coordination of the novel ligands, rendering them isoelectronic analogues of the ubiquitous bicyclopentadienyl system. Comparative studies suggest stronger donor properties for the fulvalene ligand as compared with the 2,2′-diboratabiphenyl system.

Key words: dinucleating ligands, bimetallic complexes, rhodium complexes, boron heterocycles, X-ray structure.

Résumé : On a préparé des dérivés dianioniques du 2,2′-diboratabiphényle comme nouvelle classe de ligands binucléaires. Les études préliminaires de leur chimie de coordination ont été réalisées à l'aide de complexes du ruthénium. On a étudié leurs solutions et les structures cristallines et ces études confirment la préférence de ces nouveaux ligands pour une coordination η^6–η^6, ce qui en fait des analogues isoélectroniques du système bicyclopentadiényle qu'on retrouve partout. Des études comparatives suggèrent que, par comparaison avec le système 2,2′-boratabiphényle, le ligand fulvalène est un meilleur donneur.

Mots clés : ligands binucléaires, complexes bimétalliques, complexes du rhodium, hétérocycles du bore, structures par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

It is well-documented that organometallic bi- and polynuclear complexes can promote reactions with no precedence in mononuclear systems, or show increased reactivity compared with monometallic species (1). In addition, the physical properties (nonlinear optical (NLO) activity, luminescence, redox properties) of bimetallic complexes can be easily tuned, rendering them suitable candidates for certain applications in materials science (2). These differences in physical properties and chemical behavior, both in stoichiometric and catalytic reactions, are due to cooperative interactions between the two metals present in close proximity. Among the many bimetallic systems that have been studied, bimetallic fulvalene (bicyclopentadienyl) complexes have attracted the most attention and are still a subject of continuous investigation (3). The special position occupied by the fulvalene system in such research is due to the strong binding properties of the cyclopentadienyl ligand, and also to the fact that it can mediate the electronic communication between adjacent metal centers even in the absence of a direct metal–metal bond. Attempts to modulate the nature and extent of metal–metal communication have led to variations in the nature of the coordinating ligand, as well as the bridging ligand framework.

In this context, we became interested in 2,2′-diboratabiphenyls as dinucleating isoelectronic analogues of fulvalene ligands and report here their synthesis and coordination chemistry. The advantages of using boratabenzene ligands as cyclopentadienyl surrogates are well-documented; they are isoelectronic to Cp^- donors (both are monoanionic 6p electron donors), but offer the possibility for more control of the electronic influence of the boratabenzene ligand in catalytic reactions by adjusting the exocyclic substituents on boron (4). As a result, numerous monometallic complexes containing boratabenzene ligands have been prepared and their reactivity studied in detail (5). Bimetallic D-p-A (D = donor, p = conjugated bridge, A = acceptor) complexes containing boratabenzene ligands have also been prepared and examined for their potential application as heterobimetallic nonlinear optical chromophores (6). For these complexes in which the (boratabenzene)metal fragment acts as an electron acceptor, unexpectedly high first-order hyperpolarizability β values have been measured. More recently, a bimetallic co-

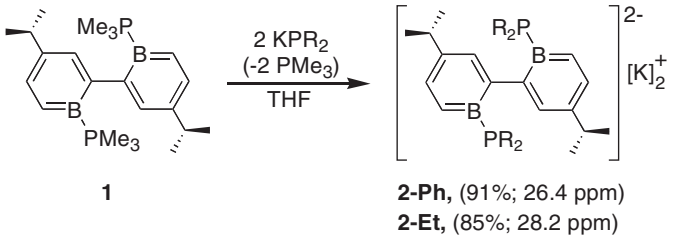
balt complex featuring a bis(boratabenzene)benzene ligand was prepared and the ability of the novel binucleating ligand to facilitate electronic communication between the cobalt centers was evaluated (7).

Results and discussion

Synthesis and characterization of 2,2′-diboratabiphenyl ligands



We have previously reported the synthesis of precursors to Lewis base adducts of 2,2′-diborabiphenyl (8). In this study, we explored the reactivity of bisPMe_3 adducts of 2,2′-diborabiphenyl towards a variety of nucleophiles, as a potentially useful synthetic method leading to dianionic 2,2′-diboratabiphenyl derivatives. This strategy is based on a previous observation that borabenzene–trimethylphosphine reacts with a wide range of anionic nucleophiles providing a versatile route to 1-substituted boratabenzenes (9). First we reacted the bisPMe_3 adduct **1** with KPR_2 (R = Ph, Et) as representative examples of anionic phosphorus nucleophiles and isolated the corresponding dianionic 2,2′-diboratabiphenyls in good yields (Scheme 1; chemical shifts in the schemes throughout indicate ^{11}B NMR data). The progress of the reaction was easily monitored by ^{31}P NMR by following the disappearance of the signal at –23 ppm corresponding to **1**, which was accompanied by increasing intensity for the signals corresponding to products **2-Ph** (–34 ppm) or **2-Et** (–66 ppm) and free PMe_3 (–58 ppm).

Whereas $KPEt_2$ already reacts with **1** at room temperature, prolonged heating at 75 °C is required for the reaction with $KPPh_2$. This difference in reactivity reflects the different donor strengths of the two phosphides. Nucleophilic aromatic substitution of **1** is a convenient way to access 2,2′-diboratabiphenyl derivatives since it requires a single precursor, the product is obtained in a single step, and the PMe_3 by-product is easily removed under vacuum because of its high volatility.

Compounds **2-Ph** and **2-Et** represent dianionic analogs of chelating biaryl diphosphine ligands like Fu's diphenylphosphinoboratabenzene is an anionic version of PPh_3 (10). Unlike Fu's monodentate phosphinoboratabenzene, which coordinates early, mid- and late-transition metals through the phosphorus atom in a "phosphine-like" bonding mode (10) (as opposed to through the boratabenzene π system in a "Cp-like" bonding arrangement), we were unable to coordinate either **2-Ph** or **2-Et** to a transition metal via salt elimination protocols. We investigated the reactivity of compounds **2** towards several transition metal or main group dihalides; in some cases, dissociation of the phosphide ligand with concomitant decomposition of the diborabiphenyl framework was observed.

To expand the scope of this chemistry to include other 2,2′-diboratabiphenyls, we reacted **1** with anionic carbon, nitrogen, oxygen, and sulphur nucleophiles, but were unable to isolate clean products from these reactions. It appears that while nucleophilic substitution is a direct approach, it is sensitive to solubility, steric bulk, and basicity of the incoming nucleophile, and unknown side reactions lead to complex product mixtures. Similar observations were reported by

Bazan and co-workers (11) for the synthesis of alkoxy- and aryloxy-boratabenzene complexes.

An alternative synthetic approach has therefore been developed based on observations that neutral, base-stabilized borabenzene and diborabiphenyl derivatives undergo reaction with protic acids via addition of AH (A = conjugate base) across the B=C bond of the borabenzene framework; deprotonation of the cyclic diboranes restores the aromaticity of the ring, providing a facile route to anionic boron heterocycles (11, 12). This method was applied successfully in the present study using alcohols and primary amines (Scheme 2). Addition of the protic acids to **1** occurred smoothly at room temperature to give bis(alkoxy) boranes **3-Me** and **3-Bn** and bis(amido) boranes **4-Ph** and **4-*p*-OMeBn** within 10 min in excellent yields. In practice, these cyclic diboranes are not isolated but are deprotonated at room temperature using bulky lithium amides, yielding the corresponding dianionic 2,2′-diboratabiphenyl derivatives **5-Me/Bn** and **6-Ph/*p*-OMeBn**. Complete removal of the PMe_3 by-product prior to deprotonation is essential for the success of the reaction. In the case of the bis(amido)diboranes, despite the presence of an acidic proton on nitrogen, selective deprotonation of the cyclic borane can be achieved in good

yields with lithium bis(trimethylsilyl)amide or lithium 2,2,6,6-tetramethylpiperidine. Using less bulky bases such as lithium dimethylamide or lithium diisopropylamide resulted in the formation of mixtures of products.

All compounds were characterized by multinuclear NMR spectroscopy and mass spectrometry. The ^{11}B NMR spectra of the neutral boranes contain diagnostic resonances at ≈48 ppm (**3-Me/Bn**) and ≈41 ppm (**4-Ph/*p*-OMeBn**), which are in the usual range for three-coordinate amino- and alkoxy-boranes. After deprotonation, these signals are significantly upfield shifted to ≈31 ppm (**5-Me/Bn**) and ≈28 ppm (**6-Ph/*p*-OMeBn**), as expected owing to the presence of a delocalized negative charge in the diboratabiphenyl rings. The room-temperature ^{1}H NMR spectra also support the proposed structures with no unexpected features being revealed. However, in the case of **6-Ph** the ^{1}H NMR spectrum measured at room temperature in THF-d^8 contained only broad signals, which made their assignment difficult. Dilution or increasing the temperature to 63 °C greatly simplified the spectrum making the assignment of the signals possible. At this temperature, three signals were observed for the hydrogens in the boratabenzene ring and one doublet centered at 1.21 ppm owing to the methyl protons, indicating a symmetrical structure. Furthermore, the N-*H* protons were observed at 5.48 ppm as a broad singlet, which became weaker in intensity upon prolonged heating because of slow decomposition of **6-Ph** to the previously reported 9,11-diboratacarbazole (12) and free aniline. Upon cooling to −40 °C, two overlapping doublets were observed for the methyl protons of the isopropyl groups, whereas no significant changes in the resonances of the boratabenzene protons were observed. While the variable-temperature NMR data are suggestive of dynamic behavior for **6-Ph** in THF-d^8, probably an equilibrium between monomeric and dimeric species, no assertion can be made on whether a structure with contact ion pairs or solvent-separated ion pairs is operative. The ^{7}Li NMR spectra, which contain one broad singlet between −4.50 and −3.54 ppm at all accessible temperatures, do not shed any further light on the solution structures.

To gain further insight into the structural details of the neutral and dianionic compounds **3**–**6**, single crystals of **3-Bn**, **4-Ph**, **5-Bn**, and **6-Ph** were grown and subjected to X-ray diffraction analysis.[3] Molecular diagrams are shown in Figs. 1 and 2, along with selected metrical parameters. Despite the presence of an sp^3 carbon atom in the boracyclohexadiene rings of structures **3-Bn** and **4-Ph**, the atoms of the two cycles are essentially coplanar. The two boracycles are twisted by 42.3° (**3-Bn**) and 77.5° (**4-Ph**), such that the boron atoms are pointing in opposite directions, which is the most sensible steric arrangement for the benzyloxy and amido groups on boron. In the structure of **4-Ph**, the boron and the nitrogen atoms are both trigonal-planar coordinated and the B—N bond length (1.412(2) Å) is slightly shorter than the 1.45 Å found in lithium 1-(dimethylamido)boratabenzene (13) for which significant double-bond character was assigned. The B—O bond distances of **3-Bn** (1.368(3) and 1.364(3) Å) are only slightly shorter than that found in the structure of $[C_5H_5B\text{-}OPh]_2ZrCl_2$ (1.385(4) Å) (11). The B—C bond lengths are in the range found for single bonds (14), while the C—C bonds of the cyclic boranes alternate between short (C(9)—C(10), C(11)—C(12), C(24)—C(25), and C(26)—C(27) for **3-Bn** and C(7)—C(8) and C(9)—C(10) for **4-Ph**) and long (C(8)—C(9), C(10)—C(11), C(23)—C(24), and C(25)—C(26) for **3-Bn** and C(8)—C(9) and C(10)—C(11) for **4-Ph**), indicating localization of the π bonds in these systems.

The structure adopted by dianionic **5-Bn** and **6-Ph** in the solid state is that of dimers with lithium atoms coordinated exocyclic and endocyclic to the boratabenzene rings (Fig. 2). The endocyclic lithiums are sandwiched by two boratabenzene rings from two diboratabiphenyl molecules and are asymmetrically bonded to the various atoms of the rings. There is a slip distortion of the endocyclic lithiums away from boron and toward the more electron-rich carbons of the ring, i.e., the carbons meta and para to the boron. The exocyclic lithium atoms are η^6 coordinated by a $O_2B_2C_2$ (Fig. 2*b*) or $N_2B_2C_2$ (Fig. 2*a*) framework of the bis(benzyloxy)- and bis(amido)-diboratabiphenyl ligands. The coordination enviroment around each exocyclic lithium atom is further completed by two molecules of THF. The Li—B distances range from 2.497(7) to 2.671(7) Å for **5-Bn** and 2.598(4) to 2.628(5) Å for **6-Ph** and are somewhat longer than the Li—C distances, which range from 2.338(6) to 2.797(23) Å for **5-Bn** and 2.367(4) to 2.484(4) Å for **6-Ph**. Upon deprotonation, the exocyclic B—O and B—N bonds (B—O = 1.418(4)–1.446(4) Å, B—N = 1.481(3) and 1.477(3) Å) are slightly elongated, indicating a less effective B—O and B—N π interaction in **5-Bn** and **6-Ph**.

Rhodium complexes

As inferred from the crystal structures of **5-Bn** and **6-Ph**, π coordination through the boratabenzene rings, as well as chelate coordination through the exocyclic substituents on boron, are possibilities for the coordination chemistry of ligands **5** and **6**. As mentioned earlier, the latter coordination mode could not be demonstrated for the phosphido boratabiphenyls (**2**). Furthermore, the presence of potentially reactive N-H functions in ligands **6** were deemed to be problematic. Therefore, initial investigations into the coordination chemistry of the ligands **5** and **6** focused on the reactions of **5-Bn** with univalent binuclear rhodium species with a view to preparing binuclear complexes bridged by the diboratabenzene framework.

Reaction of the dilithio compound **5-Bn** with 1 molar equiv. of the binuclear rhodium complexes $[(\mu\text{-Cl})\text{-}RhL_2]_2$ (L = CO, L_2 = cod) in THF occurred at room temperature to give complexes *syn*/*anti*-**7-CO** and *syn*/*anti*-**7-COD** as 1:1

mixtures of syn- and anti-facial isomers in high yields (Scheme 3). These isomers arise depending on the relative facial coordination of the second metal fragment once the first is in place; the isomers do not undergo exchange under thermal or photochemical duress. Since their relative abundance is to some degree dependent on the conditions employed in the reaction (for example, in the case of the carbonyl complex **7-CO**, using toluene instead of THF as the reaction medium resulted in an increase in the ratio of the syn product to 3:1), these mixtures are likely kinetic product mixtures. In idealized structures where the B-C_{ipso}-C_{ipso}-B torsion angle is 180 °C, the syn isomers have C_2 symmetry and are present as a pair of enantiomers, while the anti isomers are C_i symmetric, with a centre of inversion at the C_{ipso}-C_{ipso} midpoint, and therefore achiral. In reality, there is some variation in the B-C_{ipso}-C_{ipso}-B torsion angle in the syn isomers (see the following), but they retain C_2 symmetry.

Attempts to separate the isomers by column chromatography were unsuccessful. Enriched samples of s*yn*-**7-CO** could be obtained by fractional crystallization from the 3:1 mixtures prepared in toluene, but complete separation of syn from anti was not possible by this method. In the case of **7-COD**, most of the syn isomer was extracted in isopentane, whereas the anti isomer and small amounts of the syn isomer remained undissolved and were separated by filtration. All complexes were characterized by NMR spectroscopy and high-resolution mass spectrometry, and two examples were studied by X-ray crystallographic methods.

Single crystals of both **7-CO** and **7-COD** were obtained from isopentane solutions and analyzed by X-ray diffraction. CrystalMaker diagrams of *syn*-**7-CO** and of the *anti*-**7-COD** isomer are shown in Figs. 3 and 4 along with selected metrical data. In both complexes, the metal is π coordinated to the boratabenzene rings in an η^6 fashion. The two boracycles are twisted by 73.7° in *syn*-**7-CO**, but are aligned essentially coplanar in anti-**7-COD** such that the substituents on boron are pointing in opposite directions. In both complexes, the Rh—B and Rh—C bond distances are suggestive of slip distortion of the rhodium atom away from boron and toward the carbons meta and para to the boron. For Rh complexes, the magnitude of the $^1J_{RhC}$ coupling constants, as determined from ^{13}C NMR measurements, can be used as an indication of the extent of ring slippage in solution (15). Accordingly, the slippage from η^6 to η^3 coordination is accompanied by smaller $^1J_{RhC}$ observed coupling constants for the less-coordinated atoms. The coupling constant for the bonds between Rh and the C atoms ortho to boron could not be determined owing to broadening of these signals by the quadrupolar boron nucleus. The remaining $^1J_{RhC}$ coupling constants are in the range of 3.1–4.1 Hz for *syn*/*anti*-**7-CO** and 2.8–4.1 Hz for *syn*/*anti*-**7-COD**, with the smaller coupling constants assigned to Rh—C(4) (Fig. 3) and Rh—

syn/anti-**7-CO**, L = CO
syn/anti-**7-COD**, L_2 = cyclooctadiene

C(12) (Fig. 4). Consistent with this observation, the bond lengths of the metal to the carbon atoms C(4) and C(12) are longer than those to C(5), C(6) and C(13), C(14). The average bonding distance of rhodium to the CO ligands in *syn*-**7-CO** is 1.872(3) Å and is slightly longer than the values found in the structure of the fulvalene dirhodium complex $(\eta^5{:}\eta^5\text{-}C_{10}H_8)Rh_2(CO)_4$ (1.861(4) and 1.866(4) Å) (16). In keeping with this finding, carbonyl stretching frequencies in *anti*-**7-COD** were found at higher values (2158 and 2120 cm^{-1}) than those reported for the fulvalene system (2037 and 1978 cm^{-1}) (16), suggesting stronger donor properties for the fulvalene ligand as compared with the 2,2′-diboratabiphenyl system. The related mononuclear complexes cyclooctadiene boratabenzene rhodium $(C_5H_5B\text{-}R)Rh(cod)$ (R = Ph, Me) (17) and bis(ethylene)boratabenzene rhodium $(C_5H_5B\text{-}R)Rh(C_2H_4)_2$ (R = Ph, NMe_2) (18) have been also prepared. These complexes were structurally characterized and show Rh—B distances shorter (2.398 Å, R = Ph) and longer (2.516 Å, R = NMe_2) than those found in *syn*-**7-CO** (2.488(3) Å) and *anti*-**7-COD** (2.439(2) Å), consistent with the differences in π-donating abilities of the exocyclic substituents on boron.

Interestingly, the mononuclear bis(ethylene)boratabenzene rhodium complexes were found to be efficient catalysts for

the C-H activation of alkanes (18). Therefore, the reaction chemistry of **7-CO** was also briefly investigated. First, it should be noted that solutions of *syn*- or *anti*-**7-CO** or **7-COD** cannot be converted to their opposite stereoisomer at any accessible temperature. Photolysis of carbonyl complexes **7-CO** or reactions with trimethylamine-*N*-oxide, showed no evidence for the formation of any products as determined by NMR and IR spectroscopy, the starting materials being fully recovered. Similarly, no product was obtained when **7-CO** was photolysed in the presence of excess cyclooctadiene. On the other hand, $(\eta^5{:}\eta^5\text{-}C_{10}H_8)Rh_2(CO)_4$ was found to react with trimethylamine-*N*-oxide and cyclooctatetraene, yielding the tricarbonyl species $(\eta^5{:}\eta^5\text{-}C_{10}H_8)(\mu\text{-}CO)(CO)_2Rh_2$ and the bis(cyclooctatetraene) complex $(\eta^5{:}\eta^5\text{-}C_{10}H_8)(\eta^4\text{-}1,2,5,6\text{-cyclooctatetraene})_2Rh_2$, respectively (16). Attempts to study the electrochemistry of *syn*-**7-CO** and *anti*-**7-COD** indicate that these compounds undergo irreversible oxidation to unidentified products. This contradicts the findings for the fulvalene system $(\eta^5{:}\eta^5\text{-}C_{10}H_8)Rh_2(CO)_4$ for which reversible oxidation to the corresponding dication with concomitant formation of a Rh—Rh bond was reported (19). These observations can be explained by the poorer donor properties of the diboratabenzene ligands relative to the fulvalene bridge. The present ligand system is thus unable to stabilize coordinatively unsaturated intermediates or higher oxidation state complexes, resulting in relatively unreactive compounds in comparison to the fulvalene congeners.

In previous work, we reported the synthesis of dilithio 9,11-diboratacarbazole heterocycles (12). The structure of this dilithio derivative and computational exploration of the distribution of charge in this novel heterocyclic framework suggested η^6 bonding as the preferential coordination mode as opposed to η^5 coordination through the $B_2N_2C_2$ core. On the other hand, the η^5 mode is emphasized in the coordination chemistry of the isoelectronic fluorenyl anion (20). Indeed, reaction of 10-phenyl-9,11-diboratacarbazole with 1 equiv. of Cp^*ZrCl_3 showed no evidence for the formation of the η^5-coordination product, giving rather complicated mixtures of products. However, similar reactions to those described above with $[(\mu\text{-}Cl)\text{-}RhL_2]_2$ (L = CO, L_2 = cod) in THF allowed us to isolate complexes *syn*/*anti*-**8-CO** and *anti*-**8-COD** in high yields as the only products (Scheme 4). Interestingly, because the diborabiphenyl framework is locked into a chelating arrangement by the bridging $[NR]^{2-}$ fragment, in these compounds the syn isomer is the meso compound (idealized C_s symmetry), while the anti isomer is of C_2 symmetry and therefore present as a pair of enantiomers.

While complex **8-CO** forms as a 1:1 mixture of syn and anti isomers, only the anti isomer of **8-COD** was detected by NMR spectroscopy. Our attempts to isolate the isomers of *syn/anti*-**8-CO** by column chromatography or fractional crystallization failed. However, cooling solutions of *syn/anti*-**8-CO** in isopentane at –35 °C afforded orange single crystals. X-ray diffraction analysis revealed the compound to be the syn isomer (Fig. 5). Single crystals of *anti*-**8-COD** were also grown from a CH_2Cl_2–pentane mixture and also subjected to X-ray diffraction analysis. A molecular diagram is provided in Fig. 6 along with selected metrical data.

The molecular structures of *syn*-**8-CO** and *anti*-**8-COD** confirm the predicted η^6-coordination mode for the 9,11-diboratacarbazole ligand. Related (fluorenyl)rhodium complexes have not been structurally characterized, but the η^5 binding was confirmed by X-ray diffraction for a (fluorenyl)Co(COD) complex (20*a*). Slip distortion of the rhodium atoms, similar to those observed in the structures of *syn*-**7-CO** and *anti*-**7-COD**, is also found in the structures of *syn*-**8-CO** and *anti*-**8-COD**. Accordingly, the Rh—C distances are not equivalent and range from 2.211(5) to 2.527(4) Å for *syn*-**8-CO** and 2.232(2) to 2.397(2) Å for *anti*-**8-COD**, with bonds from rhodium to the carbons ortho to boron being the longest. Distances and angles within the $C_{10}B_2N$ ring are comparable to those found in the structure

© 2006 NRC Canada

of the dilithio 10-phenyl-9,11-diboratacarbazole (12). Using $^1J_{RhC}$ coupling constants as a measure of the Rh—C interaction in solution, one can find values ranging from 2.5–4.4 Hz (**8-CO**) and 2.5–3.9 Hz (**8-COD**), with the smaller values assigned to Rh(1)—C(8) and Rh(2)—C(11) in **8-CO** and Rh(1)—(C12) and Rh(2)—C(22) in **8-COD**. These findings suggest that a similar slip distortion to that found in the solid state is maintained in solution.

Conclusions

2,2′-Diboratabiphenyl derivatives bearing alkoxy, amido, or phosphido exocyclic substituents on boron were prepared and their structural details in solution and the solid state examined. The coordination chemistry of the novel ligands and of the previously reported 9,11-diboratacarbazole was investigated in view of their isoelectronic relationship with the fulvalene and fluorenyl anions. Reactions of 9,11-diboratacarbazole ligand with dinuclear Rh complexes resulted in η^6 coordination of Rh to the flanking six-membered rings of the diboratacarbazole framework. These observations confirm the predicted coordination chemistry of this ligand with transition metals, as the η^5 mode is emphasized in the coordination chemistry of the fluorenyl anion. While preliminary reactions of phosphido-substituted 2,2′-diboratabiphenyl with transition metal dihalides or monohalides gave no isolable products, the η^6-coordination mode was confirmed in the case of the benzyloxy derivatives by the isolation of their Rh complexes as mixtures of syn and anti isomers. Electrochemical studies on these Rh complexes showed no evidence for reversible redox events suggesting that the 2,2′-diboratabiphenyl ligand is not capable of sustaining electronic communication between adjacent Rh centers. This is probably due to the slip distortion of the rhodium atom away from boron and the bridging carbon atoms observed in the solid state and in solution.

Experimental

General considerations

All manipulations were performed under an argon atmosphere using standard glovebox and Schlenk techniques. Toluene, hexane, and THF solvents were dried and purified by passing through activated alumina and Q5 columns (21). Isopentane was dried and distilled from Na. Benzyl alcohol, methanol, aniline, 4-methoxybenzylamine, and lithium bis(trimethylsilyl)amide were purchased from Aldrich Chemical Co. and distilled prior to use. $[Rh(COD)Cl]_2$ and $[Rh(CO)_2Cl]_2$ were purchased from Strem Chemicals. Solid lithium diisopropylamide (LDA) was prepared by addition of a 1.6 mol L^{-1} *n*-hexane solution of *n*-BuLi (100 mL, 0.16 mol) to HN-*i*-Pr_2 (23.5 mL, 0.17 mol) in *n*-hexane (50 mL), followed by evaporation to dryness. Potassium diethylphosphide was prepared as a white solid by addition of $KCH_2C_6H_5$ to Et_2PH at 0 °C. The mixture was stirred for 3 h at room temperature, the volatiles removed under vacuum, and the solid washed with *n*-hexane. The bisPMe_3 adduct of 2,2′-diborabiphenyl **1** (8) and lithium 2,2,6,6-tetramethylpiperidene (22) were prepared according to a reported procedure.

All NMR spectra were performed in dry, oxygen-free C_6D_6 or THF-d_8. ^{1}H, $^{13}C\{^1H\}$, DEPT-135, ^{11}B, ^{7}Li, COSY, and HMQC NMR experiments were recorded on a Bruker DRX-400 spectrometer. ^{1}H and $^{13}C\{^1H\}$ NMR spectra were calibrated using signals from the solvent and are reported downfield from $SiMe_4$, whereas ^{11}B and ^{7}Li NMR spectra are referenced to external $BF_3{\cdot}OEt_2$ and LiCl, respectively.

Mass spectra were recorded on Esquire 3000, Kratos MS80RFA, or Micromass VG7070 spectrometers. The pattern of boron-containing ions was compared with theoretical values.

Melting points were determined by DSC-TG analysis on a Netzsch STA 449C from 25 to 600 °C at a heating rate of 5 K/min.

Synthesis of 2-Ph

Potassium diphenylphosphide (1.14 mL, 0.5 mol L^{-1} in THF) was added at room temperature to a solution of the bisPMe_3 adduct of 2,2′-diborabiphenyl (110 mg, 0.28 mmol) in 6 mL THF. The solution was stirred for 24 h under reflux, and the volatiles were removed under vacuum. The solid was slurred in *n*-hexane, sonicated and then filtered to collect a yellow solid (177 mg, 91%), mp 79 °C. ^{1}H NMR (THF-d_8, 400 MHz) δ: 0.95 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 2.50 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 6.33 (dd, 2H, CH^3, $^3J_{PH}$ = 9.9, 4.4 Hz), 6.82 (d, 2H, CH^6, $^4J_{PH}$ = 5.2 Hz), 6.91 (d, 2H, CH^4, $^3J_{HH}$ = 9.9 Hz), 7.01 (t, 4H, C_6H_5-para, $^3J_{HH}$ = 6.9 Hz), 7.09 (dd, 8H, C_6H_5-meta, $^3J_{HH}$ = 7.2, 7.2 Hz), 7.47 (dd, 8H, C_6H_5-ortho, $^3J_{HH}$ = 6.5, 6.5 Hz). $^{13}C\{^1H\}$ NMR (THF-d_8, 100 MHz) δ: 22.56 (s, CH$_3$-*i*-Pr), 32.80 (s, *C*H-*i*-Pr), 122.74 (s, C_6H_5-para), 124.98 (d, C_6H_5-meta, $^3J_{PC}$ = 6.0 Hz), 125.52 (d, CH^4, $^3J_{PC}$ = 5.0 Hz), 129.04 (s, br, CH^3), 131.22 (dd, CH^6, $^3J_{PC}$ = 9.2 Hz, $^4J_{PC}$ = 3.7 Hz), 132.58 (d, C_6H_5-ortho, $^2J_{PC}$ = 13.1 Hz), 144.46 (s, br, *C*-ipso). ^{11}B NMR (THF-d_8, 128 MHz) δ: 26.42 (s, br). ^{31}P NMR (THF-d_8, 162 MHz) δ: –34.15 (s, *P*Ph_2). ESI-MS *m*/*z*: 721 $[M + K]^+$, 497 $[M - PPh_2]^+$.

Synthesis of 2-Et

Potassium diethylphosphide (134 mg, 1.05 mmol) in 2 mL THF was added at room temperature to a solution of the bisPMe_3 adduct of 2,2′-diborabiphenyl (202 mg, 0.52 mmol) in 6 mL THF. The solution was stirred for 2 h at room temperature, and the volatiles were removed under vacuum. The product was obtained as an orange solid after recrystallization from THF–pentane (217 mg, 85%), mp 92 °C. ^{1}H NMR (THF-d_8, 400 MHz) δ: 1.00 (dt, 12H, PCH_2CH_3, $^3J_{HH}$ = 7.5 Hz, $^3J_{PH}$ = 12.6 Hz), 1.22 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.59 (m, 8H, PCH_2CH_3), 2.77 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 6.57 (dd, 2H, CH^3, $^3J_{HH}$ = 9.9 Hz, $^3J_{PH}$ = 3.8 Hz), 6.87 (ddd, 2H, CH^6, $^4J_{PH}$ = 5.6 Hz, $^4J_{HH}$ = 1.6 Hz, $^5J_{PH}$ = 1.6 Hz), 6.97 (dd, 2H, CH^4, $^4J_{HH}$ = 1.5 Hz, $^3J_{HH}$ = 9.8 Hz). $^{13}C\{^1H\}$ NMR (THF-d_8, 100 MHz) δ: 13.55 (d, PCH_2CH_3, $^2J_{PC}$ = 10.0 Hz), 19.37 (d, br, PCH_2CH_3, $^1J_{PC}$ = 6.1 Hz), 26.09 (s, CH$_3$-*i*-Pr), 36.20 (s, *C*H-*i*-Pr), 127.39 (s, br, CH^3), 127.57 (d, CH^4, $^3J_{PC}$ = 4.6 Hz), 130.79 (s, *C*-ipso), 133.79 (dd, CH^6, $^3J_{PC}$ = 8.4 Hz, $^4J_{PC}$ = 2.3 Hz). ^{11}B NMR (THF-d_8, 128 MHz) δ: 28.26 (s, br). ^{31}P NMR (THF-d_8, 162 MHz) δ: –65.85. ESI-MS *m*/*z*: 529 $[M + K]^+$, 491 $[M + H]^+$, 453 $[M - K + 2H]^+$, 401 $[M - PEt_2K + K]^+$.

Synthesis of 3-Me

Methanol (48 mg, 1.50 mmol) in 2 mL toluene was added dropwise to a stirred solution of the bisPMe$_3$ adduct of 2,2′-diborabiphenyl (290 mg, 0.75 mmol) in 6 mL toluene at room temperature over a period of 10 min. The solution was stirred for 30 min at room temperature, and the volatiles were removed under vacuum. The product was obtained as a colourless solid after recrystallization from isopentane at –35 °C (210 mg, 94%), mp 52 °C. ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.18 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.61 (d, 4H, BCH_2^3, $^3J_{HH}$ = 4.3 Hz), 2.50 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 3.30 (s, 6H, O-CH_3), 5.86 (t, 2H, CH^4, $^3J_{HH}$ = 4.5 Hz), 7.37 (d, 2H, CH^6, $^4J_{HH}$ = 1.6 Hz). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 20.57 (s, br, BCH_2^3), 22.55 (s, CH_3-*i*-Pr), 35.11 (s, *C*H-*i*-Pr), 52.97 (s, O-CH_3), 123.85 (s, CH^4), 143.48 (s, *C-ipso*), 147.25 (s, CH^6). ^{11}B NMR (C_6D_6, 128 MHz) δ: 47.49 (s, br). EI-MS *m*/*z*: 298 [M$^+$], 283 [M$^+$ – CH_3], 266 [M$^+$ – OCH_3Ph], 255 [M$^+$ – $CH(CH_3)_2$], 149 [M$^+$/2], 73 [$(CH_3)_2COCH_3^+$], 43 [$CH(CH_3)_2^+$]. EI-HR-MS calcd. for $C_{18}H_{28}O_2{}^{11}B_2$ (amu): 298.22754; found: 298.22960.

Synthesis of 3-Bn

Benzyl alcohol (112 mg, 1.04 mmol) in 2 mL toluene was added dropwise to a stirred solution of the bisPMe$_3$ adduct of 2,2′-diborabiphenyl (200 mg, 0.52 mmol) in 5 mL toluene at room temperature over a period of 10 min. The solution was stirred for 30 min at room temperature, and the volatiles were removed under vacuum. The product was obtained as a light-brown solid in quantitative yield. Suitable crystals for X-ray diffraction study were grown by cooling a solution of **3-Bn** in isopentane at –35 °C, mp 84 °C. ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.15 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.69 (d, 4H, BCH_2^3, $^3J_{HH}$ = 3.6 Hz), 2.51 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.6 Hz), 4.66 (s, 4H, O-CH_2-C_6H_5), 5.85 (t, 2H, CH^4, $^3J_{HH}$ = 3.6 Hz), 7.09 (m, 6H, C_6H_5-meta + para), 7.25 (m, 4H, C_6H_5-ortho), 7.59 (d, 2H, CH^6, $^4J_{HH}$ = 1.8 Hz). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 21.27 (s, br, BCH_2^3), 22.58 (s, CH_3-*i*-Pr), 35.18 (s, *C*H-*i*-Pr), 67.66 (s, O-CH_2-C_6H_5), 124.12 (s, CH^4), 126.91 (s, C_6H_5-ortho), 127.34 (s, C_6H_5-para), 128.50 (s, C_6H_5-meta), 139.93 (s, *C*-ipso), 142.44 (s,br, *C*-ipso), 143.54 (s, *C*-ipso), 148.41 (s, CH^6). ^{11}B NMR (C_6D_6, 128 MHz) δ: 48.07 (s, br). EI-MS *m*/*z*: 450 [M$^+$], 359 [M$^+$ – CH_2Ph], 267 [M$^+$ – CH_2Ph, – CH_3Ph], 225 [M$^+$ – $2CH_2Ph$ – $CH(CH_3)_2$], 91 [CH_2Ph^+]. EI-HR-MS calcd. for $C_{30}H_{36}O_2{}^{11}B_2$ (amu): 450.29014; found: 450.29381.

Synthesis of 4-Ph

201 mg (0.52 mmol) of the bisPMe$_3$ adduct of 2,2′-diborabiphenyl in 4 mL toluene was added over a period of 10 min to a solution of aniline (97 mg, 1.04 mmol) in 6 mL toluene at room temperature. The solution was stirred for 10 min at room temperature, and the volatiles were removed under vacuum. The product was obtained as a colourless solid after recrystallization from pentane at –35 °C (212 mg, 97%), mp 145 °C. ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.12 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 2.29 (d, 4H, BCH_2^3, $^3J_{HH}$ = 4.3 Hz), 2.43 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 5.92 (t, 2H, CH^4, $^3J_{HH}$ = 4.1 Hz), 6.54 (s, br, 2H, N*H*C_6H_5), 6.84 (m, 6H, C_6H_5-meta + para), 6.94 (d, 2H, CH^6, $^4J_{HH}$ = 1.4 Hz), 7.06 (m, 4H, C_6H_5-ortho). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 21.71 (s, br, BCH_2^3), 22.38 (s, CH_3-*i*-Pr), 34.91 (s, *C*H-*i*-Pr), 46.72 (s, NHCH_2), 120.93 (s, C_6H_5-meta), 122.52 (s, C_6H_5-para), 124.49 (s, CH^4), 129.28 (s, C_6H_5-ortho), 142.21 (s, *C*-ipso), 143.51 (s, CH^6), 144.00 (s, br, *C*-ipso), 144.36 (s, *C*-ipso). ^{11}B NMR (C_6D_6, 128 MHz) δ: 41.83 (s, br). volatiles removed under vacuum. The product was obtained as a yellow solid in quantitative yield. Suitable crystals for X-ray diffraction study were grown by cooling a solution of **5-Bn** in hexane–toluene (20:1) at –35 °C; mp 119 °C. ^{1}H NMR (THF-d_8, 400 MHz) δ: 1.16 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.78 (m, 6H, THF), 2.69 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 3.62 (m, 6H, THF), 4.96 (s, 4H, O-CH_2-C_6H_5), 5.74 (d, 2H, C*H*^{3}, $^3J_{HH}$ = 10.6 Hz), 6.94 (d, 2H, C*H*^{6}, $^4J_{HH}$ = 2.1 Hz), 7.00 (dd, 2H, C*H*^{4}, $^3J_{HH}$ = 10.6 Hz, $^4J_{HH}$ = 2.1 Hz), 7.16 (m, 6H, C_6H_5-meta + para), 7.48 (d, 4H, C_6H_5-ortho, $^3J_{HH}$ = 7.3 Hz). ^{13}C{^{1}H} NMR (THF-d_8, 100 MHz) δ: 25.40 (s, THF), 25.48 (s, *C*H$_3$-*i*-Pr), 35.02 (s, *C*H-*i*-Pr), 67.20 (s, O-*C*H$_2$-C$_6$H$_5$), 67.25 (s, THF), 108.44 (s, br, *C*H^3), 125.41 (s, *C*-ipso), 126.05 (s, *C*$_6$H$_5$-para), 127.15 (s, *C*$_6$H$_5$-ortho), 127.53 (s, *C*$_6$H$_5$-meta), 131.66 (s, *C*H^4), 133.50 (s, *C*H^6), 142.82 (s, *C*-ipso). ^{11}B NMR (THF-d_8, 128 MHz) δ: 31.98 (s, br). ^{7}Li NMR (THF-d_8, 155 MHz) δ: –1.30 (s). ESI-MS *m*/*z*: 527 [**5-Bn**·THF – Li]$^-$.

Synthesis of 6-Ph

Lithium 2,2,6,6-tetramethylpiperidene (44 mg, 0.33 mmol) in 2 mL THF was added dropwise to a stirred solution of **4-Ph** (63 mg, 0.15 mmol) in 4 mL THF at room temperature. The solution was stirred for 1 h at room temperature, and the volatiles removed under vacuum. In the ^{1}H NMR spectrum of the crude product besides **6-Ph**, aniline and the dilithium salt of 9,11-diboratacarbazole were identified as by-products. Recrystallization of the crude product from THF–*n*-pentane gave clean **6-Ph** as light-yellow single crystals (72 mg, 84%), mp 170 °C (dec.). ^{1}H NMR (THF-d_8, 400 MHz, 20 °C) δ: 1.22 (d, br, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.6 Hz), 1.73 (m, 4H, THF), 2.74 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 3.58 (m, 4H, THF), 5.40 (s, br, 2H, N*H*Ph), 6.28 (d, br, 2H, C*H*^{3}, $^3J_{HH}$ = 10.5 Hz), 6.37 (s, br, 2H, C_6H_5-para), 6.89 (m, 8H, C_6H_5-ortho + meta), 6.98 (d, br, 2H, C*H*^{4}, $^3J_{HH}$ = 10.0 Hz), 7.02 (s, br, 2H, C*H*^{6}). ^{1}H NMR (THF-d_8, 400 MHz, 63 °C) δ: 1.21 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 1.73 (m, 4H, THF), 2.76 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 3.58 (m, 4H, THF), 5.48 (s, br, 2H, N*H*Ph), 6.27 (d, 2H, C*H*^{3}, $^3J_{HH}$ = 10.5 Hz), 6.39 (m, 2H, C_6H_5-para), 6.91 (m, 8H, C_6H_5-ortho + meta), 6.96 (d, 2H, C*H*^{4}, $^3J_{HH}$ = 10.3 Hz), 7.14 (s, br, 2H, C*H*^{6}). ^{1}H NMR (THF-d_8, 400 MHz, –40 °C) δ: 1.23 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.21 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.74 (m, 4H, THF), 2.68 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.7 Hz), 3.58 (m, 4H, THF), 5.50 (s, 2H, N*H*Ph), 6.21 (d, 2H, C*H*^{3}, $^3J_{HH}$ = 10.2 Hz), 6.32 (m, 2H, C_6H_5-para), 6.87 (m, 12H, C_6H_5-ortho + meta, C*H*^{4}, C*H*^{6}). ^{13}C{^{1}H} NMR (THF-d_8, 100 MHz, 20 °C) δ: 26.36 (s, THF), 26.66 (s, br, *C*H$_3$-*i*-Pr), 35.89 (s, br, *C*H-*i*-Pr), 68.21 (s, THF), 112.72 (s, br, *C*H^3), 115.20 (s, br, *C*$_6$H$_5$-para), 117.02 (s, br, *C*$_6$H$_5$-ortho or meta), 125.69 (s, br, *C*-ipso), 128.85 (s, br, *C*$_6$H$_5$-ortho or meta), 130.09 (s, br, *C*H^4), 133.08 (s, br, *C*H^6), 136.14 (s, br, *C*-ipso), 151.80 (s, *C*-ipso). ^{13}C{^{1}H} NMR (THF-d_8, 100 MHz, 63 °C) δ: 25.83 (s, THF), 26.00 (s, br, *C*H$_3$-*i*-Pr), 35.45 (s, *C*H-*i*-Pr), 68.20 (s, THF), 112.66 (s, br, *C*H^3), 115.68 (s, *C*$_6$H$_5$-para), 117.36 (s, *C*$_6$H$_5$-ortho or meta), 124.95 (s, br, *C*-ipso), 128.93 (s, br, *C*$_6$H$_5$-ortho or meta), 129.77 (s, *C*H^4), 133.21 (s, *C*H^6), 135.80 (s, br, *C*-ipso), 151.62 (s, *C*-ipso). ^{11}B NMR (THF-d_8, 128 MHz, 20 °C) δ: 25.83 (s, br). ^{11}B NMR (THF-d_8, 128 MHz, 63 °C) δ: 27.73 (s, br). ^{7}Li NMR (THF-d_8, 155 MHz, 20 °C) δ: –4.05 (s, br). ^{7}Li NMR (THF-d_8, 155 MHz, 63 °C) δ: –3.63 (s, br). ^{7}Li NMR (THF-d_8, 155 MHz, –40 °C) δ: –3.54 (s). ESI-MS *m*/*z*: 419 [**6-Ph**, –2Li + H$^+$]$^-$.

Synthesis of 6-*p*-OMeBn

Lithium bis(trimethylsilyl)amide (33 mg, 0.20 mmol) in 1 mL THF was added dropwise to a stirred solution of **4-*p*-OMeBn** (50 mg, 0.10 mmol) in 3 mL THF at room temperature. The solution was stirred for 1 h at room temperature, and the volatiles removed under vacuum. The product was obtained as a yellow solid after washing with pentane (46 mg, 90%), mp 55 °C (decomp.). ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.18 (d, 12H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 1.79 (m, 4H, THF), 2.49 (s, br, 2H, N*H*CH_2), 2.70 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 3.63 (m, 4H, THF), 3.71 (s, 6H, C_6H_4-O-CH_3), 4.01 (s, br, 4H, NHCH_2), 5.84 (d, br, 2H, C*H*^{3}, $^3J_{HH}$ = 10.3 Hz), 6.71 (d, 4H, C_6H_4, $^3J_{HH}$ = 8.2 Hz), 6.90 (s, br, 2H, C*H*^{6}), 6.95 (d, br, 2H, C*H*^{4}, $^3J_{HH}$ = 9.6 Hz), 7.18 (d, 4H, C_6H_4, $^3J_{HH}$ = 8.2 Hz). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 26.53 (s, THF), 26.62 (s, br, *C*H$_3$-*i*-Pr), 36.17 (s, *C*H-*i*-Pr), 48.85 (s, NH*C*H$_2$), 55.43 (s, C$_6$H$_4$-O-*C*H$_3$), 68.38 (s, THF), 112.28 (s, *C*H^3), 114.40 (s, *C*$_6$H$_4$), 125.80 (s, *C*-ipso), 129.22 (s, *C*-ipso), 129.59 (s, *C*$_6$H$_4$), 132.04 (s, *C*H^6), 132.79 (s, *C*H^4), 138.75 (s, *C*-ipso), 159.29 (s, *C*-ipso). ^{11}B NMR (C_6D_6, 128 MHz) δ: 29.62 (s, br). ^{7}Li NMR (THF-d_8, 155 MHz) δ: –2.38 (s, br). ESI-MS *m*/*z*: 513 [**6-*p*-OMeBn** – Li]$^-$.

Synthesis of *syn*/*anti*-7-CO

5-Bn (222 mg, 0.37 mmol) in 4 mL THF was added dropwise to a stirred solution of [Rh(CO)$_2$Cl]$_2$ (143 mg, 0.37 mmol) in 4 mL THF at room temperature. The solution was stirred for 30 min. at room temperature, and the volatiles removed under vacuum. The residue was dissolved in pentane and filtered through a frit covered with Celite to remove the LiCl. The ^{1}H NMR spectrum of an aliquot from the reaction mixture showed the formation of an 1:1 mixture of the syn and anti isomers (274 mg, 97%). A syn:anti ratio of 3:1 could be obtained if the reaction was carried out in toluene instead of THF. Clean syn product was obtained as a light brown solid by dissolving the 3:1 mixture of the two isomers in isopentane followed by cooling the solution at –35 °C. However, part of the syn isomer dissolves in isopentane and clean anti product could not be obtained. Single crystals for X-ray diffraction studies of the syn isomer were grown by cooling an isopentane solution of the syn isomer at –35 °C. syn Isomer: IR (KBr, cm^{-1}): 2158 vs, 2120 vs (ν CO). ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.05 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.07 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 2.20 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), AB spin system: A 4.93 (d, 2H, O-CH_2Ph, $^2J_{HH}$ = 12.7 Hz), B 5.02 (d, 2H, O-CH_2Ph, $^2J_{HH}$ = 12.7 Hz), 5.00 (d, 2H, C*H*^{3}, $^3J_{HH}$ = 9.4 Hz), 6.02 (d, 2H, C*H*^{4}, $^3J_{HH}$ = 9.4 Hz), 7.17 (m, 2H, C_6H_5-para), 7.19 (d, 2H, C*H*^{6}, $^4J_{HH}$ = 1.6 Hz), 7.28 (m, 4H, C_6H_5-meta), 7.49 (m, 4H, C_6H_5-ortho). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 23.83 (s, *C*H$_3$-*i*-Pr), 24.13 (s, *C*H$_3$-*i*-Pr), 33.51 (s, *C*H-*i*-Pr), 68.02 (s, O-*C*H$_2$Ph), 87.13 (s, br, *C*H^3), 106.84 (d, *C*-ipso, $^1J_{RhC}$ = 3.8 Hz), 110.34 (d, *C*H^4, $^1J_{RhC}$ = 4.1), 118.02 (d, *C*H^6, $^1J_{RhC}$ = 3.1 Hz), 123.33 (s, *C*-ipso), 127.34 (s, *C*$_6$H$_5$-ortho), 127.40 (s, *C*$_6$H$_5$-para), 128.57 (s,

Synthesis of *syn*/*anti*-7-COD

$[Rh(COD)Cl]_2$ (64 mg, 0.13 mmol) in 2 mL THF was added dropwise to a stirred solution of **5-Bn** (79 mg, 0.13 mmol) in 2 mL THF at room temperature. The solution was stirred for 1 h at room temperature, and the volatiles removed under vacuum. The residue was dissolved in CH_2Cl_2 and filtered through a frit covered with Celite to remove the LiCl. Removal of the CH_2Cl_2 under vacuum gave 110 mg (97%) of **7-COD** as a 1:1 mixture of syn and anti isomers. Clean syn product was obtained by dissolving the mixture of the two isomers in isopentane followed by filtration of the undissolved solid. However, part of the syn isomer dissolved in isopentane and clean anti could not be obtained. Single crystals for X-ray diffraction studies of the anti isomer were grown by slow evaporation of an isopentane solution containing both isomers. Attempts to separate the two isomers by column chromatography using Al_2O_3 activity level I failed. syn Isomer: ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.13 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 1.17 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.8 Hz), 1.91 (m, 4H, CH_2-COD), 2.09 (m, 10H, CH_2-COD + C*H*-*i*-Pr), 2.30 (m, 4H, CH_2-COD), 4.09 (m, 8H, C*H*-COD), 4.72 (d, 2H, CH^3, $^3J_{HH}$ = 9.1 Hz), AB spin system: A 4.82 (d, 2H, O-CH_2Ph, $^2J_{HH}$ = 13.0 Hz), B 4.89 (d, 2H, O-CH_2Ph, $^2J_{HH}$ = 13.0 Hz), 5.93 (d, 2H, CH^4, $^3J_{HH}$ = 9.1 Hz), 6.57 (s, 2H, CH^6), 7.08 (t, 2H, C_6H_5-para, $^3J_{HH}$ = 7.2 Hz), 7.18 (dd, 4H, C_6H_5-meta, $^3J_{HH}$ = 7.4 Hz, $^3J_{HH}$ = 7.4 Hz), 7.44 (d, 4H, C_6H_5-ortho, $^3J_{HH}$ = 7.5 Hz). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 22.58 (s, *C*H_3-*i*-Pr), 24.05 (s, *C*H_3-*i*-Pr), 32.24 (s, *C*H_2-COD), 32.59 (s, *C*H-*i*-Pr), 33.02 (s, *C*H_2-COD), 67.61 (s, O-*C*H_2Ph), 69.33 (d, *C*H-COD, $^1J_{RhC}$ = 12.8 Hz), 71.09 (d, *C*H-COD, $^1J_{RhC}$ = 13.1 Hz), 85.95 (s, br, *C*H^3), 103.75 (d, *C*-ipso, $^1J_{RhC}$ = 4.1 Hz), 105.52 (d, *C*H^4, $^1J_{RhC}$ = 3.5), 112.32 (d, *C*H^6, $^1J_{RhC}$ = 2.8 Hz), 119.44 (s, br, *C*-ipso), 126.82 (s, C_6H_5-para), 127.14 (s, C_6H_5-ortho), 128.29 (s, C_6H_5-meta), 142.18 (s, *C*-ipso). ^{11}B NMR (C_6D_6, 128 MHz) δ: 23.40 (s, br). anti Isomer: ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.14 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.16 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.75 (m, 4H, CH_2-COD), 1.91 (m, 4H, CH_2-COD), 2.06 (m, 4H, CH_2-COD), 2.19 (m, 6H, CH_2-COD + C*H*-*i*-Pr), 3.85 (m, 4H, C*H*-COD), 4.09 (m, 4H, C*H*-COD), 4.83 (d, 2H, CH^3, $^3J_{HH}$ = 9.0 Hz), AB spin system: A 4.88 (d, 2H, O-CH_2Ph, $^2J_{HH}$ = 12.5 Hz), B 4.97 (d, 2H, O-CH_2Ph, $^2J_{HH}$ = 12.5 Hz), 6.03 (dd, 2H, CH^4, $^3J_{HH}$ = 9.0 Hz, $^4J_{HH}$ = 1.6 Hz), 7.15 (t, 2H, C_6H_5-para, $^3J_{HH}$ = 7.6 Hz), 7.25 (dd, 4H, C_6H_5-meta, $^3J_{HH}$ = 7.4 Hz, $^3J_{HH}$ = 7.4 Hz), 7.38 (d, 2H, CH^6, $^4J_{HH}$ = 1.6 Hz), 7.54 (d, 4H, C_6H_5-ortho, $^3J_{HH}$ = 7.4 Hz). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 23.27 (s, *C*H_3-*i*-Pr), 23.71 (s, *C*H_3-*i*-Pr), 31.78 (s, *C*H_2-COD), 32.59 (s, *C*H-*i*-Pr), 32.79 (s, *C*H_2-COD), 68.07 (s, O-*C*H_2Ph), 70.05 (d, *C*H-COD, $^1J_{RhC}$ = 12.8 Hz), 72.78 (d, *C*H-COD, $^1J_{RhC}$ = 12.9 Hz), 85.64 (s, br, *C*H^3), 105.02 (d, *C*H^4, $^1J_{RhC}$ = 3.6), 105.82 (d, *C*-ipso, $^1J_{RhC}$ = 4.0 Hz), 112.74 (d, *C*H^6, $^1J_{RhC}$ = 3.0 Hz), 113.98 (s, br, *C*-ipso), 127.17 (s, C_6H_5-para), 127.64 (s, C_6H_5-ortho), 128.41 (s, C_6H_5-meta), 142.02 (s, *C*-ipso). ^{11}B NMR (C_6D_6, 128 MHz) δ: 23.84 (s, br). Synthesis of *syn*/*anti*-8-CO

Dilithium 9,11-diboratacarbazole (77 mg, 0.16 mmol) in 4 mL THF was added dropwise to a stirred solution of $[Rh(CO)_2Cl]_2$ (62 mg, 0.16 mmol) in 4 mL THF at room temperature. The solution was stirred for 30 min at room temperature, and the volatiles removed under vacuum. The residue was dissolved in isopentane and filtered through a frit covered with Celite to remove the LiCl. The ^{1}H NMR spectrum of an aliquot from the reaction mixture showed the formation of an 1:1 mixture of the syn and anti isomers as the only products of the reaction. Attempts to separate the two isomers by cooling an isopentane solution of the mixture at –35 °C failed. Instead several single crystals of the syn isomer together with an orange solid formed (93 mg, 91%). ^{1}H NMR (C_6D_6, 400 MHz) δ: 0.95 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 0.99 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.03 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 1.05 (d, 6H, CH_3-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 2.16 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 2.21 (sept., 2H, C*H*-*i*-Pr, $^3J_{HH}$ = 6.9 Hz), 5.56 (d, 2H, CH^3, $^3J_{HH}$ = 9.4 Hz), 5.77 (d, 2H, CH^3, $^3J_{HH}$ = 9.6 Hz), 5.92 (d, 2H, CH^4, $^3J_{HH}$ = 9.6 Hz), 5.93 (d, 2H, CH^4, $^3J_{HH}$ = 9.4 Hz), 6.88 (s, 2H, CH^6), 6.95 (s, 2H, CH^6), 7.07 (m, 2H, C_6H_5), 7.40 (m, 4H, C_6H_5-meta), 7.66 (m, 2H, C_6H_5-ortho). ^{13}C{^{1}H} NMR (C_6D_6, 100 MHz) δ: 23.78 (s, *C*H_3-*i*-Pr), 24.05 (s, *C*H_3-*i*-Pr), 24.18 (s, *C*H_3-*i*-Pr), 24.27 (s, *C*H_3-*i*-Pr), 33.68 (s, *C*H-*i*-Pr), 33.75 (s, *C*H-*i*-Pr), 89.01 (s, br, *C*H^3), 94.59 (s, br, *C*H^3), 103.14 (d, *C*H^6, $^1J_{RhC}$ = 2.6 Hz), 105.31 (d, *C*-ipso, $^1J_{RhC}$ = 3.7 Hz), 105.31 (d, *C*H^6, $^1J_{RhC}$ = 2.5 Hz), 105.71 (d, *C*-ipso, $^1J_{RhC}$ = 3.8 Hz), 110.31 (d, *C*H^4, $^1J_{RhC}$ = 4.4), 111.38 (d, *C*H^4, $^1J_{RhC}$ = 4.0), 122.66 (s, C_6H_5-para), 122.76 (s, C_6H_5-para), 123.91 (s, C_6H_5-ortho), 123.95 (s, C_6H_5-ortho), 129.65 (s, C_6H_5-meta), 129.66 (s, C_6H_5-meta), 147.86 (s, *C*-ipso), 147.95 (s, *C*-ipso), 189.15 (d, Rh-*C*O, $^1J_{RhC}$ = 84.3), 189.42 (d, Rh-*C*O, $^1J_{RhC}$ = 84.4). ^{11}B NMR (C_6D_6, 128 MHz) δ: 25.00 (s, br). EI-MS *m*/*z*: 643 [M^+], 615 [M^+ – CO], 588 [M^+ – 2CO]. EI-HR-MS calcd. for $C_{26}H_{25}N^{11}B_2O_4Rh_2$ (amu): 643.00798; found: 643.00991.

Synthesis of *anti*-8-COD

$[Rh(COD)Cl]_2$ (54 mg, 0.11 mmol) in 2 mL THF was added dropwise to a stirred solution of dilithium 9,11-diboratacarbazole (53 mg, 0.11 mmol) in 2 mL THF at room

Use of ^{1}H NMR chemical shifts to determine the absolute configuration and enantiomeric purity for enantiomers of 3,3′-disubstituted-MeO-BIPHEP derivatives[1]

Evgueni Gorobets, Masood Parvez, Bronwen M.M. Wheatley, and Brian A. Keay

Abstract: The absolute configuration of a series of 3,3′-disubstituted-MeO-BIPHEP derivatives can be determined by the ^{1}H NMR chemical shift of the methoxyl group when the 3,3′-disubsituted-MeO-BIPHEP derivative is mixed with (–)-(2*R*,3*R*)-dibenzoyltartaric acid ((–)-DBTA) (1:2) and its NMR spectrum is run in $CDCl_3$. The chemical shift of the methoxyl group in the S_{ax} enantiomer always occurred at higher field than the corresponding R_{ax} enantiomer. Integration of the corresponding methoxyl signals provides the enantiomeric purity of any mixtures.

Key words: assignment of absolute configuration, 2,2′-bis(diphenylphosphino)-1,1′-biaryls, MeO-BIPHEP derivatives, asymmetric Heck reaction, ^{1}H NMR chemical shifts.

Résumé : La configuration absolue d'une série de dérivés MeO-BIBHEP 3,3′-disubstitués peut être déterminée par RMN du ^{1}H, en utilisant le déplacement chimique du groupe méthoxyle et en procédant à la détermination des spectres RMN des dérivés MeO-BIBHEP 3,3′-disubstitués en présence d'acide (–)-(2*R*,3*R*)-dibenzoyltartrique (1 : 2) dans du $CDCl_3$. Le déplacement chimique du groupe méthoxyle dans l'énantiomère S_{ax} se trouve toujours à un champ plus élevé que celui de l'énantiomère R_{ax} correspondant. L'intégration des signaux des groupes méthoxyles correspondants permet d'évaluer la pureté énantiomérique de tous les mélanges.

Mots clés : attribution d'une configuration absolue, 2,2′-bis(diphénylphosphino)-1,1′-biaryles, dérivés MeO-BIPHEP, réaction de Heck asymétrique, déplacements chimiques en RMN du ^{1}H.

Introduction

Over the past few years, we have been interested in the development of synthetic routes towards the preparation of 3,3′-disubstituted-MeO-BIPHEP derivatives **4**–**11** for use as chiral ligands in a variety of transition-metal-catalyzed asymmetric transformations involving palladium and rhodium (1, 2).[3] During the course of these studies it became necessary to not only resolve the resulting racemic mixtures of biaryl products **2** obtained from Ullmann couplings of the corresponding aryl halides **1** (Scheme 1), but also to assign the absolute configuration to each of the enantiomers. The standard method reported for the optical resolution of **3** is via the mixing of (±)-**3** and (–)-(2*R*,3*R*)-dibenzoyltartaric acid ((–)-DBTA) (1:1.5) in DCM–EtOAc, followed by the crystallization of the (*R*)-**3**:(–)-DBTA complex from the solution (3). We tried to resolve compounds **3**–**6**, **8**, and **10** using this resolution method; however, we were only successful with compounds **4**, **5**, and **8** using either (–)-DBTA or (–)-(2*R*,3*R*)-ditoluoyltartaric acid (DTTA). Two solutions to the resolution problem were developed. The first was to attach the chiral auxiliary (R = $OSiMe_2$-(L)-menthol) to **2** (R^1 = Me, R^2 = OH) to create diastereomers that could then be separated by silica gel chromatography (1*a*). Removal of the chiral auxiliary then gave enantiomers of **2** (R^1 = Me, R^2 = OH) that were then converted to **7**. The second solution was to replace the methyl moiety in **1** (R^1 = Me) with the chiral auxiliary ((*S*)-$H_3CCH(OAc)C{=}O$) and then perform the Ullmann coupling to give a mixture of diastereomers **2** that were easily separated by silica gel chromatography (1*b*). The chiral auxiliary was then replaced by a methyl group, thereby providing biaryls **3**–**10**. However, the absolute configuration of the axis of chirality in biaryls **3**–**11** still had to be determined. This paper describes how the absolute con-

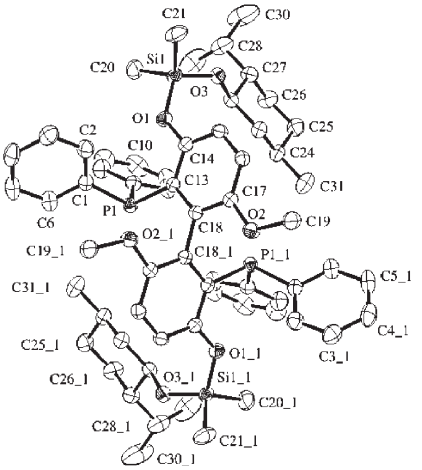
figuration for biaryls **3–11** were assigned and how the absolute configuration of a series of 3,3′-disubstituted-MeO-BIPHEP derivatives can be determined by the ^{1}H NMR chemical shift of the methoxyl group when the 3,3′-disubstituted-MeO-BIPHEP derivative is mixed with (–)-DBTA (1:2).



Results and discussion

Determining the absolute configuration of the axis of chirality in biaryls 3–11

The absolute configurations of biaryls **3–11** were determined by obtaining the X-ray crystal structure of some derivatives of biaryls **3–5** and **7–11** that contain a chiral auxiliary, by using the Flack parameter (4) or using ^{1}H NMR chemical shifts of the methoxy group when the 3,3′-disubstituted-MeO-BIPHEP derivative is mixed with (–)-DBTA (1:2).[4]

The absolute configuration of synthesized MeO-BIPHEP **3** was assigned by comparing the sign of the optical rotation obtained from the synthesized sample with that reported by Schmid et al. (3). Biaryls (*S*)-**4** and (*S*)-**7** were prepared from the corresponding 3,3′-dihydroxybiaryl system (*S*)-**13** (Scheme 2). The absolute configuration of (*S*)-**13** was determined from the X-ray crystal structure of the $SiMe_2$-(L)-menthol derivative **12** (Fig. 1). Figure 1 indicates that **12** has an axis of chirality of *S*. The absolute configuration of (*S*)-**5** was determined by obtaining an X-ray crystal structure of (*S*)-**5** when complexed with two molecules of (L)-DTTA (Fig. 2). The absolute configurations of (*R*)-**7**, (*R*)-**8**, and (*S*)-**9** were determined from the Flack parameter (4) of the X-ray crystal structure of their corresponding phosphine-selenides (*R*)-**14**, (*R*)-**15**, and (*S*)-**16** (Scheme 2 and Figs. 3–5). Finally the absolute configuration of (*R*)-**10** and (*S*)-**11** were determined by the Flack parameter (4) of the X-ray crystal structure of the phosphine oxide (*R*)-**10** (Fig. 6) and the lactate derivative (*S*)-**17** (Scheme 2 and Fig. 7), respectively.

Use of ^{1}H NMR chemical shifts of the methoxy group to determine the absolute configuration of MeO-BIPHEP derivatives

As mentioned above, the reported (3) procedure for the resolution of MeO-BIPHEP **3** is by the mixing of (±)-**3** and (–)-DBTA (1:1.5) in DCM–EtOAc, followed by the crystallization of the complex (*R*)-**3**:(–)-DBTA from the solution. While we were successful with the resolution of **8** with (–)-DBTA, we found **4** and **5** were better resolved using

(+)-DTTA. Attempts to resolve compounds **3**, **6**, and **10** by this procedure failed even after trying modified resolution conditions. While trying to resolve the latter grouping of biaryls, we decided to examine the ^{1}H NMR spectrum of compounds (±)-**3**–**6**, **8**, and **10** in the presence of 2 equiv. of (–)-DBTA to determine if indeed diastereomeric complexes were formed. In all cases, a pair of singlets integrating for 3H each were observed between 2.8 and 3.6 ppm. The two signals corresponded to the methoxy groups[5] for each of the diastereomeric complexes in solution. Although the diastereomeric complexes were formed in solution with compounds (±)-**6** and **10** and 2 equiv. of (–)-DBTA, the crystals obtained were always a mix of both diastereomers. Thus enantiomerically pure **3**, **6**, **7**, and **9**–**11** were prepared by alternative methods (1). Once compounds **3**–**11** were obtained, the enantiopurity of the compounds was determined by complexing them with 2 equiv. of (–)-DBTA and observing the region between 2.8 and 3.6 ppm in the ^{1}H NMR spectrum. Once resolved, only one methoxy signal was ob-

served for each of compounds **3–11**, indicating the samples were enantiopure. What was interesting is that when we correlated the absolute configuration of the axis of chirality to the chemical shift of the methoxy signals complexed with 2 equiv. of (–)-DBTA, we found that the chemical shift of the methoxy group of the (*S*)-enantiomer was always upfield of the methoxy signal for the (*R*)-enantiomer (Table 1).

The only 3,3′-disubstituted compound in Table 1 whose absolute configuration was not determined by X-ray crystallography was biaryl **6** (3,3′-diO-*t*-Bu-MeO-BIPHEP). The absolute stereochemistry was assigned based on the ^{1}H NMR shifts of the methoxy groups when complexed with 2 equiv. of (–)-DBTA (Table 1). The individual enantiomers of **6** were separated as previously described (1*b*). Additional support for the hypothesis that the absolute configuration of compound **6** was *R* (based on the NMR shifts in Table 1) came when the corresponding bisphosphine, (+)-(*R*)-**26** (made by the reduction of bisphosphine oxide (+)-(*R*)-**6** (1)) was used in the Heck arylation of 2,3-dihydrofuran (Table 2) (5). With all the reactions recorded with compounds **23–25** and **27–30**, the biaryl enantiomer with the *R*-axis of chirality always gave (*R*)-**20** as the major product. This was also observed with (*R*)-BINAP (entry 9). The reaction with the enantiomer assigned as (*R*)-**26** from the ^{1}H NMR data (Table 1) also provided (*R*)-**20** as the major product, thereby providing additional evidence (although not entirely conclusive) that the absolute configuration of **6** could be assigned by following the general trend shown in Table 1.

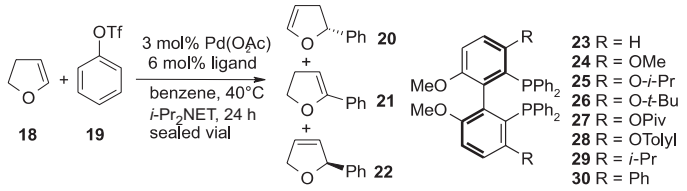
Conclusions

We have shown that the absolute stereochemistry of 3,3′-disubstituted-MeO-BIPHEP derivatives can be correlated to the chemical shift of the methoxy signal when the BIPHEP derivative is complexed with 2 equiv. of (–)-DBTA. In all cases the methoxy signal from the *S*-enantiomer:(–)-DBTA complex appeared at higher field than the *R*-enantiomer:(–)-DBTA complex. In addition, the enantiomeric purity of scalemic mixtures of MeO-BIPHEP derivatives can be obtained by integration of methoxy signals when the MeO-BIPHEP derivative is complexed with 2 equiv. of (–)-DBTA.

Experimental procedures

Compounds **3–11** were prepared as previously described (1). ^{1}H NMR spectra were obtained on a 300 MHz NMR spectrometer. All spectra were obtained in $CDCl_3$, and the chemical shifts (ppm) are relative to the C*H*Cl_3 peak as an internal reference (7.27 ppm for ^{1}H). X-ray crystal structures were determined by Dr. Masood Parvez at the University of Calgary, Calgary, Alberta.

General procedure for preparation of the 1:2 complexes of biaryls 3–11:(–)-DBTA



To a solution of phosphine oxide **3–11** (~10 μmol) in $CDCl_3$ was added a solution of (–)-DBTA (~20 μmol) in $CDCl_3$ (0.4 mL). The clear solution was then analyzed by NMR.

General procedure for the Heck reaction with 2,3-dihydrofuran (18)

Under a nitrogen atmosphere, the chiral phosphine (0.03 equiv.) and $Pd(OAc)_2$ (0.067 equiv.) were placed in a scintillation vial equipped with a magnetic stirring bar. The vial was sealed with a Teflon-faced silicone septum under nitrogen. The reagents were dissolved in dry benzene (1.65 mL/equiv. PhOTf) and stirred at room temperature for 10 min. Phenyl triflate (1 equiv.), DIPEA (3.39 equiv.), and 2,3-dihydrofuran (5.60 equiv.) were added sequentially, and the vial was placed in a preheated, thermostatically controlled 40 °C oil bath for 24 h. Hexanes (8.26 mL/equiv.

Monoclinic *C*2; a = 28.3813(7) Å, b = 9.6063(2) Å, c = 11.1778(4) Å, β = 105.3695(10)°, V = 2938.52(14) Å^3; Z = 2; R = 0.042; wR = 0.083.

X-ray crystal data for compound (*S*)-5

Monoclinic $P2_1$; a = 13.0510(10) Å, b = 23.083(2) Å, c = 21.525(3) Å, β = 95.548(4)°, V = 6454.2(12) Å^3; Z = 4, R = 0.054; wR = 0.147. The asymmetric unit is composed of two independent pairs of molecules of $C_{44}H_{44}O_6P_2$ and $C_{20}H_{18}O_8$, an ordered molecule of CH_3CN, and three disordered half molecules of CH_3CN. The non-hydrogen atoms of the complex molecules and ordered solvate were refined anisotropically; the C and N atoms of the disordered solvates were allowed isotropic displacement parameters. Phenyl rings were constrained as regular hexagons with C—C 1.39 Å and C-C-C 120°. Hydrogen atoms were included at geometrically idealized positions and were not refined; H-atoms of the disordered CH_3CN molecules were ignored.

X-ray crystal data for compound (*R*)-14

Orthorhombic $P2_12_12_1$; a = 18.334(2) Å, b = 18.530(2) Å, c = 33.367(6) Å, V = 11 336(3) Å^3; Z = 8. The asymmetric unit is composed of two independent molecules of $C_{48}H_{48}O_6P_2Se_2$, an ordered molecule of $C_3H_6O_3$, and two disordered half molecules of $C_3H_6O_3$. A *t*-Bu group and an O11,C91-C95 moiety in one of the $C_{48}H_{48}O_6P_2Se_2$ molecules are disordered. Most of the non-hydrogen atoms were refined anisotropically. Phenyl rings were constrained as regular hexagons with C—C = 1.39 Å and C-C-C = 120°. Hydrogen atoms were included at geometrically idealized positions and were not refined; H-atoms of the disordered $C_3H_6O_3$ half molecules were ignored. The final cycle of full-matrix least-squares refinement using SHELXL97 (6) converged with unweighted and weighted agreement factors, R = 0.074; wR = 0.212 (all data), respectively, and goodness of fit, S = 1.01. The absolute configuration was established by the Flack method (4). The Flack parameter for the inverted structure was 0.992(13). Therefore, the inverted structure was rejected as the one present in the crystal.

X-ray crystal data for compound (*R*)-15

Orthorhombic $C222_1$; a = 12.1890(10) Å, b = 17.261(2) Å, c = 22.239(4) Å, α = β = γ = 90°, V = 4679.0(11) Å^3, Z = 4. The final cycle of full-matrix least-squares refinement using SHELXL97 (6) converged with unweighted and weighted agreement factors R = 0.033, wR = 0.072 (all data), respectively, and goodness of fit, S = 1.03. The absolute configuration was established by the Flack method (4). The Flack parameter for the inverted structure was 0.995(6). Therefore, the inverted structure was rejected as the one present in the crystal.

X-ray crystal data for compound (*S*)-16

Monoclinic $P2_1$; a = 13.577(2) Å, b = 18.990(4) Å, c = 17.459(3) Å, α = γ = 90°, β = 98.903(10)°, V = 4447.2(14) Å^3; Z = 2. The asymmetric unit is composed of two molecules of the complex, a CH_3CN of solvation and a half molecule of C_6H_{14} of solvation that was disordered over two sites with partial occupancy factors of 0.25 each. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions and were not

A critical evaluation of homo- and hetero-leptic cadmium complexes using bond valence sums[1]

Gus J. Palenik

Abstract: The effect of the donor atoms in Cd complexes on the determination of R_0 values for the bond valence sum (BVS) is reported. A total of 1321 CdX_mY_n fragments with X and Y = O, N, S, Cl, Br, and I were used to calculate the R_0 values for Cd—X bonds from both homoleptic and heteroleptic fragments. The R_0 values determined from mixed CdX_mY_n fragments agree with those determined from the homoleptic species, with no significant differences in the values as a function of either electronegativity or hard–soft character of the atoms. The new R_0 values derived from the homoleptic series recommended for use in calculating the BVS are as follows: Cd(II)—O of 1.875(13) Å, Cd(II)—N of 1.951(15) Å, Cd(II)—S of 2.279(7) Å, Cd(II)—Cl of 2.216(17) Å, Cd(II)—Br of 2.334(7) Å, and Cd(II)—I of 2.525(7) Å. These R_0 values can be used to calculate the oxidation state of Cd in complexes where Cd is bonded to any combination of O, N, S, Cl, Br, and I donor atoms. Cases where the BVS does not agree with the expected oxidation state are discussed. In particular, the planarity of Cd porphyrins is discussed in terms of the BVS.

Key words: bond valence sums, cadmium complexes, cadmium porphyrins, cadmium distances.

Résumé : On a déterminé l'effet des atomes donneurs présents dans des complexes de cadmium sur la détermination des valeurs de R_0 de la somme des liaisons de valence « SLV ». On a utilisé un total de 1321 fragments CdX_mY_n (dans lesquels X et Y peuvent être égaux à O, N, S, Cl, Br et I) pour calculer les valeurs de R_0 pour des liaisons Cd—X appartenant à des fragments homoleptiques et hétéroleptiques. Les valeurs de R_0 déterminées à partir de fragments CdX_mY_n mixtes sont en bon accord avec celles déterminées à partir d'espèces homoleptiques, sans différences significatives dans les valeurs en fonction de l'électronégativité ou du caractère dur ou mou des atomes. Les nouvelles valeurs de R_0, dérivées des séries homoleptiques et dont l'usage est recommandé dans les calculs de « SLV » sont: Cd(II)—O, 1,875(13) Å; Cd(II)—N, 1,951(15) Å; Cd(II)—S, 2,279(7) Å; Cd(II)—Cl, 2,216(17) Å; Cd(II)—Br, 2,334(7) Å et Cd(II)—I, 2,525(7) Å. Ces valeurs de R_0 peuvent être utilisées pour calculer l'état d'oxydation du cadmium dans des complexes où il est lié à O, N, S, Cl, Br et I comme atomes donneurs. On discute de cas où la somme des liaisons de valence ne conduit pas aux valeurs attendues pour l'état d'oxydation. En particulier, on discute de la planéité du cadmium dans les porphyrines en termes de la somme des liaisons de valence.

Mots clés : somme des liaisons de valence, complexes du cadmium, cadmium dans les porphyrines, distances du cadmium.

Introduction

The concepts of electronegativity (1), hard–soft acid–bases or HSAB (1, 2), and the bond valence sum or BVS (3, 4) have been very useful in many areas of inorganic chemistry. Soft acids bond more readily with soft bases than with hard bases and vice versa. The question is whether the HSAB effect would be manifested in the BVS. The postulate that the BVS is equal to the oxidation state (z_j, as shown in eq. [1]) has been applied to a variety of problems in coordination chemistry (3–6), particularly to verify a postulated oxidation state. The calculation of the valences of the individual bonds (s_{ij} in eq. [1]) from the observed bond lengths can be accomplished using either eq. [2] or eq. [3], where r_{ij} is the observed bond length and R_0 and N are constants dependent upon the nature of the ij pair.

$$[1] \quad z_j = \Sigma_j s_{ij}$$

$$[2] \quad s_{ij} = \exp[(R_0 - r_{ij})/b]$$

$$[3] \quad s_{ij} = (r_{ij}/R_0)^{-N}$$

The R_0 value[2] can be viewed as a bond length of unit valence. One of the first compilations of R_0 values used data in the Inorganic Crystal Structural Database or ICSD (7) with eq. [2] and assumed that $b = 0.37$ (8), a value that has been generally accepted as an almost universal constant (9). Recently, the validity of the universal nature of $b = 0.37$ was investigated using data from alkali halides and chalcogenides (10) and considering not only the distances in the first coordination sphere but neighboring atoms as well. One conclusion was that the assumption that $b = 0.37$ is acceptable for most applications of the BVS. A more extensive discussion

η(X)	6.08	7.23	4.14	4.68	4.22	3.69

Note: For a given X, the R_0 value is given followed by the estimated standard deviation in parentheses, calculated using *n* of the *t* total number of entries. Avg. is the average R_0 value for Cd—X, calculated from the individual R_0 with the estimated standard deviation in parentheses. BA gives the R_0 values from ref. 8; OB gives the R_0 values calculated from the parameters in ref. 9, χ(X) is the Pauling electronegativity from ref. 1(*b*), and η(X) is the hardness from ref. 2.

of the BVS method can be found elsewhere (3, 4, 8–11, and refs. therein).

Although some R_0 values have been obtained by empirical expressions or by extrapolation from known values (3, 8, 9), the majority of the experimental R_0 values have been determined from species containing only one type of donor atom using data initially from the ICSD (7) and later from the Cambridge Structural Base or CSD (12). This restrictive approach was useful in obtaining R_0 values from structural data in the CSD and has led to an appreciation of the usefulness of the BVS and an understanding of the effect of the coordination number and oxidation state on the R_0 value. More recently, the observation was made that the R_0 values obtained from the CSD file appeared to be smaller than the values obtained from the ICSD. The questions were whether the R_0 derived from mixed compounds would differ from those obtained from homoleptic complexes and whether electronegativity and (or) the HSAB characteristics of the atoms would affect the experimentally determined R_0 values.

To answer these questions, the determination of R_0 values has been extended to complexes containing two different atoms in the coordination sphere. This report demonstrates that R_0 values obtained from mixed complexes CdX_nY_m (where X and Y are the donor atoms O, N, S, Cl, Br, and I) are identical, within the calculated standard deviations, to those obtained from homoleptic fragments. These results provide further support for the use of the BVS in inorganic chemistry. The Cd case was chosen to avoid the problems of different oxidation and (or) spin states. We have operated under the assumption that the BVS should always be "correct" and have used the reported bond distances to determine the R_0 value only when the observed and calculated oxidation states are in agreement. Any discrepancies can usually be explained by a careful examination of crystallographic and (or) experimental data, vide infra.

Experimental section

Cd—X bond distances

The Cd—X bond length data for X = O, N, S, Cl, Br, and I were retrieved from the April 2004 release of the CSD with no restrictions. This approach ensures that all the relevant Cd—X distances could be retrieved for further analysis, since one goal of the project was to demonstrate the usefulness of the BVS as a simple diagnostic tool for the noncrystallographer. The fact that structures with a low crystallographic R value can still be incorrect also argues against retrieving only those structures with low R values.

BVS calculations

The R_0 values for the homoleptic fragments were determined using procedures described earlier (5, 13). For the CdX_nY_m fragments, a least-squares procedure was used with all entries given equal weight. The R_0 values, with the number of fragments used for the various X, Y combinations, together with literature values, electronegativities, and HSAB character are given in Table 1. The Cd—X distances from the homoleptic species used in the analysis are summarized in Table 2.

Results and discussion

R_0 values for Cd—X bonds

The values in Table 1 show that an R_0 value for a Cd—X bond determined from homoleptic Cd—X data is the same, within the estimated standard deviation, as that obtained

I	4	128	2.679	2.900	2.785(48)	0.496	1.983

Note: CN is the coordination number; No. is the number of bonds found; Min is the minimum Cd—X distance found for that coordination number; Max is the maximum Cd—X distance found for that coordination number; Avg(σ) is the average Cd—X distance for that coordination number with the estimated standard deviation in parentheses; Val is the valence of the average distance calculated using eq. [2] with b = 0.37 and R_0 = 1.875 Å for X = O, 1.951 Å for X = N, 2.279 Å for X = S, 2.216 Å for X = Cl, 2.334 Å for X = Br, and 2.525 Å for X = I.

from mixed CdX_nY_m fragments. The R_0 values for Cd—X bonds determined from homoleptic fragments are slightly shorter than the experimental values found in ref. 8, as has been noted (14). The reasons for the difference in the R_0 values from the CSD file vs. data from only inorganic structures is not obvious. A comparison of R_0 from homoleptic and mixed species shows no discernable trend with either electronegativity or with hardness. Finally, the values determined experimentally from the CSD data are surprisingly close to the values calculated from the empirical atomic constants (9). Therefore, the values from CSD data for either homoleptic or mixed donor complexes can be used to derive the desired R_0 values, and these values can be used in complexes containing more than one type of donor atom. A final point is that the empirical atomic constant parameter can be used to calculate R_0 values for pairs in which there are very little or no experimental bond distance data.

Cd—X distances

The Cd—X distances in the homoleptic CdX_n complexes used in the analysis are tabulated in Table 2. The range of Cd—X distances is very large; however, the average distance for any bond and coordination number is dictated by the oxidation state and the number of bonds, so that the valence times the number of bonds equals the oxidation state. One implication is that a comparison of a Cd—X distance in a particular complex may not be very meaningful, but the BVS should always equal the oxidation state. The final distances in any coordination complex represent a balance between the donor ability and the steric constraints imposed by the ligand.

Calculation of the oxidation state of Cd(XY) complexes

For the 1321 complexes used in the analysis, the oxidation state of the Cd ion was calculated using the R_0 values given in Table 1 for the homoleptic species. There are only 59 cases, or 4.5%, where the BVS differs from the expected value of 2 by more than 0.30 valence units (vu). The 0.30 is a somewhat arbitrary difference that has been used to determine which structures are to be investigated in more detail. A large deviation of the BVS from the expected value has been a good indication that there are problems, which can include disorder in the crystal, an incorrect space group assignment, an incorrectly assigned oxidation state, a misidentified atom, or weak interactions that may have been overlooked.

BVS and cadmium tetraphenylporphyrins

There is a group of Cd-N and Cd-ON complexes that have a BVS > 2.0, and these are all cadmium tetraphenylporphyrins, or CdTPP, complexes. These include a series of CdTPP clathrate complexes, JIVROV (15),[3] BVS = 2.48; JIVRUB (15), BVS = 2.50; JIVSOW (15), BVS = 2.48; and HALXIB (16), BVS = 2.45, where the Cd ion is on a center of symmetry and therefore in the plane of the TPP ligand, which is very unlikely. The TPP cavity is too small for the large Cd ion, as was nicely illustrated in DIPXAB (17),

[3] We shall give the refcode used in the CSD file in capital letters and the compound name in the reference list.

© 2006 NRC Canada

BVS = 2.11, where the Cd ion is 0.568 Å from the plane of the four nitrogen atoms. If the Cd(II) is coplanar with the TPP ring, the Cd—N distances are too short, and the corresponding BVS too large, as seen in the above examples. The TPP cavity has been examined in some detail by various groups (18–20), and the cavity radius is unlikely to be larger than 2.11 Å, with 2.01 Å being approximately strain free. A Cd—N bond with a valence of 0.5 would be 2.207 Å, and if the ring center to N distance were 2.10 Å, the Cd(II) ion would be 0.70 Å out of the TPP plane. A larger, but unlikely, distortion of the TPP ligand could lower the displacement of the Cd ion relative to the plane of the four nitrogen atoms. Therefore, the BVS suggests that the Cd should not lie in the plane of the TPP ligand, but is displaced by about 0.6 Å from the center of the TPP ligand.

The situation with PHPNCD (21) (BVS = 2.55) is somewhat more complicated since the authors state that the Cd is only 0.028 Å from the plane of the four nitrogen atoms. However, the thermal ellipsoid for Cd is elongated in the direction perpendicular to the TPP plane, suggesting that the Cd is disordered, a view noted in DIPXAB (17). There are also some questions about the formulation of PHPNCD, since the observed and calculated densities differ markedly. The problem in most cases is that the Cd should not be on a center of symmetry and coplanar with the TPP ligand, see DOFXOL (22). Whether the displacement of the Cd from the TPP ring can be resolved becomes a question of the quality of the X-ray data and the effort put into the refinement.

Cd complexes where the BVS << 2

Of the CdO_n complexes used in the analysis, there are only four cases were the BVS differs from the expected value by more than 0.30 vu. Two of the four are the same complex determined by two different groups at two different temperatures, SIGJUN (23) at 298 K (BVS = 1.59) and SIGJUN01 (24) at 193 K (BVS = 1.59). The complex is one of a series of bis(2,6-disubstituted phenoxo)Cd(II) complexes with O bases that includes NULVUL01 (24) (BVS = 1.79) and SEYLIR (24) (BVS = 1.77). The complexes SIGJUN, NULVUL01, and SEYLIR have a BVS that is less than 2, probably resulting from the different steric constraints of the phenoxide ligands. In both NULVUL01 and SEYLIR, there appear to be fewer steric constraints, and the corresponding values are closer to 2. The complexes were described in terms of obviously short or dative bonds (25), with additional longer or secondary bonds (26) used to complete the coordination sphere. A simple description could be made using BVS arguments by stating that the best donor atoms contribute a larger share to the BVS and that the overall result is a balance between steric and electronic constraints. When very bulky ligands are used to synthesize low CN complexes, the severe steric constraints imposed by the ligands usually yield longer bond distances and, consequently, a BVS that is less than the expected value.

In YAYREV (27), the BVS of 1.50 appears to be too small. The crystals were mounted in glass capillaries, but the question of absorption corrections was not discussed in the paper. The effect of absorption on bond distances is usually small, but the thermal parameters can reflect absorption effects. Consequently, at this time the complex appears to be one of the few examples where there does not seem to be any apparent reason for the low BVS value.

The CdS and Cd(NI) complexes afford several examples where the BVS is less than the expected value of 2, but weak interactions increase the BVS to the expected value. The complexes JUXTAX (28) (BVS = 1.65), LOLXUF (29) (BVS = 1.64), and PAGBAA (30) (BVS = 1.64 and 1.65) were classified in the CSD as three-coordinate CdS complexes, while KABPEI (31) (BVS = 1.53) and VIJXOB (32) (BVS = 1.53) were four-coordinate. However, in all cases there are additional weak interactions that increase the BVS to a value close to 2. A similar situation exists with WUQHAR (33) (BVS = 1.57), but when two additional Cd···I interactions are included, the BVS = 1.79. The problem is that the weak interactions are not always recognized by investigators and are difficult to justify and include in the CSD. However, in many of the above cases, the authors recognized the importance of these secondary interactions.

Another example of a low BVS was the two-coordinate complex ZIFKUU (34) (BVS = 0.52). The authors noted two additional Cd···S interactions of 2.918 and 2.972. Å, but these only add 0.60 vu to the BVS. The authors reported the stochiometry as containing 0.66Cd without any discussion of a charge balance. Of the 14 compounds reported in two papers (34, 35), ZIFKUU is the only one that does not have +1 or +3 metal ions. The thermal parameters for the NCS group suggest a disorder about the central C atom, although this would make the BVS even smaller. This paper has been cited for errors in two different publications (36, 37), although not for the complex ZIFKUU. In summary, there are so many questions regarding this paper that the results should be viewed with caution.

For the complex HAXJOF (38) (BVS = 1.32) the number of missing bits of information raises doubts about the validity of the structure report. The compound was prepared by a novel electrochemical method. The solid formed was removed, and the solution was allowed to evaporate. Although the "crystal formed was characterized by elemental analysis", these data were not given. The U_{eq} for the Cd of 0.0522 is larger than that for the coordinated O and N atoms, 0.043–0.050, an unusual result. The molecule is surprisingly distorted for a spherical d^{10} ion. One might speculate that an impurity such as Pb in the Cd electrode was concentrated in the solution and that the metal ion is not Cd but Pb.

ZUSBUK (39) (BVS = 1.50) and ZUSCAR (39) (BVS = 1.59) are azacryptand complexes with either tetrafluoroborate or acetate as the anions. ZUSBUK was assigned the high symmetry space group *P*31*c*, No. 163, and the authors determined that the cation consisted of 85% of the right-handed and 15% of the left-hand molecule, and that the anions were also disordered. The authors apparently did not consider whether a lower symmetry space group would yield an ordered structure. Consequently, the low BVS may reflect the disorder and the choice of the high symmetry space group. In ZUSCAR, the space group is *C*2/*c*, but the authors do not give an ORTEP drawing showing the thermal ellipsoids. An inspection of the deposited data shows that the thermal parameters do not look reasonable, and the structural results should be viewed with some skepticism.

© 2006 NRC Canada

QIZFUA01 (40) (BVS = 1.54) and QIZFOU01 (40) (BVS = 1.98) are both Cd-Mo-S cluster compounds with slightly different S groups, and QIZFUA01 also contains a "disordered" $Co(H_2O)_6^{2+}$ cation. The disordered cation is surprising since there are 22 H_2O molecules, as well as various donors and acceptors on the cluster that would be expected to hydrogen bond to the cation. The question of whether the Co and Cd are disordered was apparently not considered and could account for the lower BVS in QIZFUA01. The thermal parameters, which were not published, might be helpful in evaluating this hypothesis.

The series of complexes MEJQUN (41) (BVS = 1.51), MEJRAU (41) (BVS = 1.66), MEJROI (41) (BVS = 1.64), and MEJRUO (41) (BVS = 1.89) have the same hexadentate macrocyclic ligand with two ether linkages. Only in the case of MEJRUO do the authors postulate that there is an O···Cd bond. However, an examination of the distances in these compounds suggests weak interactions (with both ether O atoms in MEJQUN and MEJRAU and one of the O links in MEJROI) that increase the BVS to 1.76, 1.81, and 1.75, respectively. We see that the BVS provides experimental evidence for an interaction with the O atoms of the macrocycle in all cases.

Cd complexes where the BVS >> 2

The majority of the cases where the BVS was >> 2.0 were discussed above in the TPP examples. There are other factors that can cause the BVS to be larger than the expected, such as a misidentification of the metal atom (42, 43), high thermal motion, and disorder in the crystal structure, all leading to apparently shorter bonds. An incorrect space group assignment masking a disorder, as noted above, can also give a BVS greater than the expected value.

The case of ZETFUZ (44) (BVS = 2.50) is difficult to evaluate since the publication was not available. However, the choice of the space group *F*-43*c* is unusual since only 23 of the 272 066 entries in the CSD file have this high symmetry space group. An incorrect space group assignment could give rise to disordered groups and unusually short distances and a corresponding large BVS.

The tris(ethylenediamine)cadmium(II) cation appears in both ENCDSS (45) (BVS = 1.67) and ENDACD (46) (BVS = 2.62) in the space group *P*31*c* with different anions. Two problems arise with both of the complexes: the high symmetry space group and the large *R* values of 0.177 for ENCDSS and 0.145 for ENDACD. In both structures the anions are "disordered", again reflecting the fact that a lower symmetry space group might be more appropriate. In essence, these two structures should be viewed with caution.

A problem with the choice of a space group arises with RACFEG01 (47) (BVS = 2.32) where the choice of *Cm* in the original report (48) was questioned, and the centric choice *C*2/*m* and averaged parameters were used in the CSD file. There is also a remark in the CSD file that an I and CN group are disordered. The BVS suggests that the data may not be as reliable as the crystallographic *R* factor of 0.080 might suggest.

Conclusions and recommendations

The results presented here demonstrate that the BVS constant R_0 derived from homoleptic Cd-X complexes does not differ significantly from those derived from heteroleptic fragments and appears to be independent of the hard–soft character or electronegativities of the atom pair. Therefore, the homoleptic-derived constants can be used to calculate the BVS for Cd-X complexes, which should be 2.0 ± 0.30 vu. However, the use of R_0 values derived from the data in the ICSD file (7) are usually slightly larger, see Table 1 for examples, and will give larger values for the BVS. The R_0 values derived from empirical atomic constants can provide a reasonable starting value for other atom pairs if no other values are available.

The BVS is recommended as a check of the reliability of a crystal structure report rather than a comparison with other metal atom — X distances. Although for a given coordination number, the bond distances vary over a wide range (see Table 2), the bond order of the average M—X distance is the coordination number divided by the valence. The BVS is particularly useful in recognizing a disorder in the metal atom position, as was noted for the CdTPP complexes. A final recommendation is the use of the BVS to provide experimental data to support the postulate of weak interactions in the solid state.[4]

Hexaruthenium and octaruthenium carbonyl cluster complexes derived from 2-amino-6-methylpyridine — Novel coordination modes for 2-imidopyridines[1]

Javier A. Cabeza, Ignacio del Río, Pablo García-Álvarez, and Daniel Miguel

Abstract: The hexanuclear ruthenium cluster $[Ru_6(\mu_3\text{-}H)_2(\mu\text{-}H)_2(\mu_4\text{-}\kappa^2\text{-ampy})_2(CO)_{14}]$ (**1**) and the octanuclear one $[Ru_8(\mu\text{-}H)(\mu_4\text{-}\kappa^2\text{-ampy})_3(\mu_3\text{-}\kappa^2\text{-Hampy})(\mu\text{-}CO)_2(CO)_{15}]$ (**2**) have been prepared by treating $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ with 2-amino-6-methylpyridine (H_2ampy) in decane at reflux temperature. Their metal atoms are supported by ligands that derive from the activation of one (complex **2**) or both N—H bonds (complexes **1** and **2**) of the H_2ampy amino fragment. Both contain at least one ampy ligand featuring an unprecedented coordination type: the imido N atom caps a triangle of metal atoms while the pyridine nitrogen is attached to an additional metal atom. One of the ampy ligands of cluster **2** also displays another unprecedented coordination type: it caps a distorted square of metal atoms through the imido N atom while the pyridine nitrogen is attached to one of the atoms included in that square.

Key words: ruthenium, cluster compounds, amido ligands, imido ligands.

Résumé : En faisant réagir du $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ avec de la 2-amino-6-méthylpyridine (H_2ampy), dans du décane au reflux, on obtenu les agrégats de ruthénium hexanucléaire $[Ru_6(\mu_3\text{-}H)_2(\mu\text{-}H)_2(\mu_4\text{-}\kappa^2\text{-ampy})_2(CO)_{14}]$ (**1**) et octanucléaire $[Ru_8(\mu\text{-}H)(\mu_4\text{-}\kappa^2\text{-ampy})_3(\mu_3\text{-}\kappa^2\text{-Hampy})(\mu\text{-}CO)_2(CO)_{15}]$ (**2**). Les atomes métalliques sont supportés par les ligands qui dérivent de l'activation d'une (complexe **2**) ou des deux liaisons N—H (complexes **1** et **2**) du fragment aminé H_2ampy. Les deux contiennent chacun au moins un ligand ampy comportant un type jusque là inconnu de coordination: les atomes d'azote imido recouvrent un triangle d'atomes métalliques alors que l'azote de la pyridine est attaché à un atome métallique additionnel. Un des ligands ampy de l'agrégat **2** présente en plus un autre type jusque là inconnu de coordination: l'atome d'azote imido recouvre un carré déformé d'atomes métalliques alors que l'azote de la pyridine est attaché à un des atomes inclus dans le carré.

Mots clés : ruthénium, agrégats, ligands amido, ligands imido.

[Traduit par la Rédaction]

Introduction

An extensive derivative chemistry of triruthenium carbonyl clusters containing 2-amidopyridine ligands has been developed during the last decade. These studies have demonstrated that such ligands help maintain the cluster integrity because they act as strong anchors that hold the three metal atoms in close proximity, preventing cluster fragmentations (1).

We have recently reported that the trinuclear cluster $[Ru_3(\mu\text{-}H)(\mu_3\text{-}\kappa^2\text{-Hampy})(CO)_9]$ (H_2ampy = 2-amino-6-methylpyridine) undergoes condensation with $[Ru_3(CO)_{12}]$ at 110–140 °C to give the hexanuclear derivative $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ in high yield (2, 3) (Scheme 1). This reaction afforded the first example of a 2-imidopyridine ligand in which the imido N atom caps a metallic square. Subsequent reactivity studies using $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ as starting material have shown that its apical $Ru(CO)_3$ fragment, which is not anchored by the N atoms, is labile and that this fact is responsible for the observation of pentanuclear and heptanuclear derivatives on some occasions (4).

Prompted by the fact that the number of known ruthenium carbonyl cluster complexes of nuclearity greater than five that contain N-donor ligands is as yet small (2–6), and having in mind the ability of 2-aminopyridines to undergo N—H bond cleavage processes under thermal conditions when treated with $[Ru_3(CO)_{12}]$ (2, 7, 8), we decided to attempt the

Scheme 1.

synthesis of new high nuclearity ruthenium carbonyl clusters containing ligands derived from 2-amino-6-methylpyridine. The reason for using a methyl-substituted 2-aminopyridine is that the methyl group facilitates the monitoring of the reactions by ^{1}H NMR spectroscopy (1).

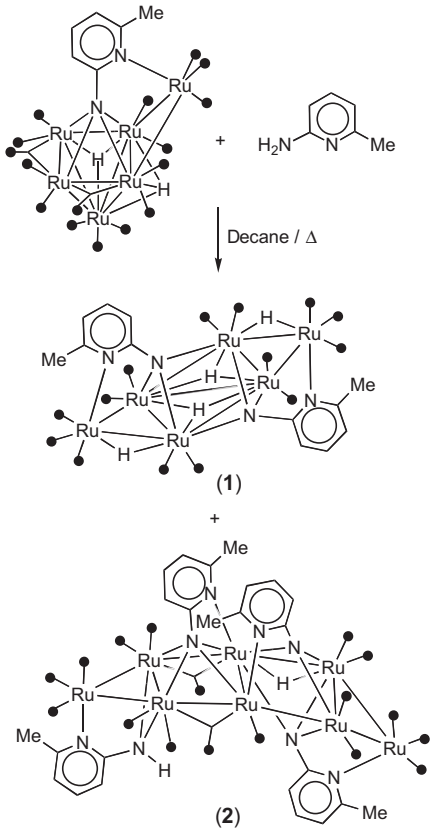
We now report that the treatment of $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ with H_2ampy at high temperature has provided two new high-nuclearity ruthenium carbonyl cluster complexes featuring two novel coordination modes for 2-imidopyridine ligands.

Results and discussion

The reaction of the hexanuclear complex $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ with H_2ampy (1:3 molar ratio) in refluxing decane for 50 min afforded a mixture of carbonyl products along with some intractable black solid. Shorter reaction times resulted in the observation of considerable amounts of unreacted hexanuclear starting complex. A chromatographic workup revealed the presence of trace amounts of several complexes accompanying two major products, which were subsequently identified as the hexanuclear and octanuclear derivatives $[Ru_6(\mu_3\text{-}H)_2(\mu\text{-}H)_2(\mu_4\text{-}\kappa^2\text{-ampy})_2(CO)_{14}]$ (**1**) and $[Ru_8(\mu\text{-}H)(\mu_4\text{-}\kappa^2\text{-ampy})_3(\mu_3\text{-}\kappa^2\text{-Hampy})(\mu\text{-}CO)_2(CO)_{15}]$ (**2**), respectively (Scheme 2).

The X-ray diffraction structure of compound **1** is shown in Fig. 1. A selection of interatomic distances is given in Table 1. The molecule can be described as being formed by two trinuclear moieties related to each other by a noncrystallographic twofold axis. The metal atoms of each trinuclear fragment are capped by an ampy ligand that is also attached to one of the metal atoms of the other trinuclear fragment through the N atom of its imido fragment. The cluster shell is completed by four hydrides (two edge-bridging and two face-capping) and 14 terminal CO ligands. The electron count for this cluster is 92 for which the 18-electron rule predicts eight M—M bonds. However, nine Ru—Ru bonding interactions between the atoms of a double wing edge-bridged butterfly metallic skeleton are clearly observed, two of them are shorter than 2.70 Å and four are longer than 2.95 Å (9). These long distances suggest that a considerable amount of electron density is residing in Ru—Ru antibonding orbitals.

Scheme 2.



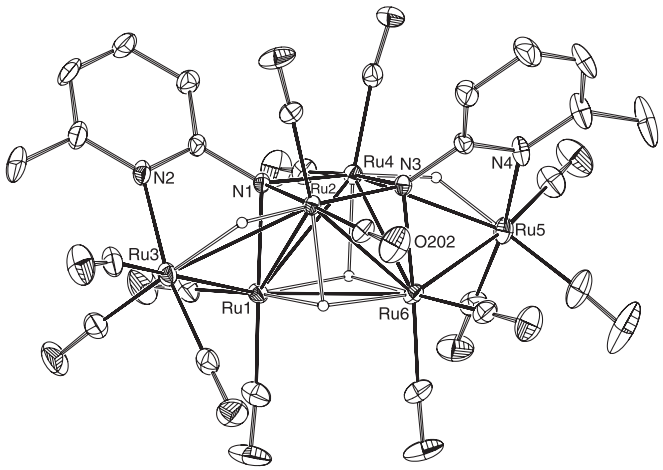


Fig. 1. Molecular structure of compound **1** (H atoms, except hydrides, omitted for clarity).

A remarkable feature of the structure of compound **1** is that its ampy ligands bridge four metal atoms, being attached to one Ru atom through their pyridine N atom and to three additional Ru atoms through the imido N atom. Although triply bridging imido ligands are well-known in cluster chemistry (10), this coordination mode displayed by the ampy ligands in complex **1** is unprecedented for 2-imidopyridine ligands.

Table 1. Selected interatomic distances (Å) in compound **1**.

Interatomic distances (Å)	
Ru(1)—Ru(2)	2.8795(8)
Ru(1)—Ru(3)	2.6961(8)
Ru(1)—Ru(4)	2.9559(8)
Ru(1)—Ru(6)	2.9164(8)
Ru(2)—Ru(3)	2.9598(9)
Ru(2)—Ru(6)	2.9701(8)
Ru(4)—Ru(5)	2.9808(8)
Ru(4)—Ru(6)	2.8731(8)
Ru(5)—Ru(6)	2.6946(8)
Ru(1)—N(1)	2.067(5)
Ru(2)—N(1)	2.102(5)
Ru(2)—N(3)	2.088(5)
Ru(3)—N(2)	2.182(5)
Ru(4)—N(1)	2.087(4)
Ru(4)—N(3)	2.109(5)
Ru(5)—N(4)	2.197(5)
Ru(6)—N(3)	2.064(5)

The solution ^{1}H NMR spectrum of complex **1** corroborates that the symmetric molecular structure found in the solid state is maintained in solution because it only shows the resonances of one ampy ligand and two hydrides (–14.27 and –17.89 ppm, J = 1.7 Hz).

The X-ray diffraction structure of the octanuclear cluster **2** is shown in Fig. 2. A selection of interatomic distances is given in Table 2. Its metallic skeleton can be described as formed by two distorted edge-sharing squares having their most distant edges spanned by two additional metal atoms. Three metal atoms of one of the squares (Ru(1), Ru(2), and Ru(3)) are doubly capped by the imido N atoms of two ampy ligands, one of which has the pyridyl fragment attached to the remaining Ru atom of that square (Ru(4)), while the other has its pyridyl group bonded to the edge-bridging atom Ru(8). An additional ampy ligand is attached to the remaining square in such a way that it caps the four metal atoms with the imido N atom, while the pyridyl fragment is attached to one of these atoms (Ru(1)). The unique Hampy ligand caps the remaining metal triangle, since its amido N atom spans the Ru(5)—Ru(6) edge and its pyridine N atom is attached to Ru(7). The cluster shell is completed with one hydride ligand, which spans the Ru(1)—Ru(3) edge, and 17 carbonyl ligands, two of which asymmetrically span two edges of the imido-capped square. It can be considered that the cluster obeys the 18-electron rule, since its electron count is 122 and has 11 M—M bonds. The long Ru(1)—Ru(4) distance (3.178(1) Å) seems to be compensated for with four distances shorter than 2.72 Å.

The way by which the unique ampy ligand of compound **2** coordinates to the square of metal atoms Ru(1), Ru(4), Ru(5), and Ru(6) is remarkable because, although a few examples of quadruply bridging imido ligands are already known in cluster chemistry (2–4, 6*d*–6*f*, 11), it represents an unprecedented coordination mode for 2-imidopyridine ligands.

The ^{1}H NMR spectrum of cluster **2** is in agreement with its solid state structure, since it shows the resonances of four different 6-methylpyrid-2-yl fragments, along with those of one NH proton (–0.20 ppm) and one hydride ligand (–10.18 ppm).

Fig. 2. Molecular structure of compound **2** (H atoms, except hydride and NH, omitted for clarity).

new high-nuclearity ruthenium carbonyl clusters and has allowed us to observe two new coordination types for 2-imidopyridine ligands.

In the reaction, once coordinated, the H_2ampy ligand undergoes one or two N—H bond activation processes that results in the formation of new ligands containing amido (as in **2**) or imido fragments (as in **1** and **2**). As these new ligands are excellent donors, they easily replace carbonyl ligands of the same metallic fragment (as in **1**) or bind to other metallic fragments that are present in solution (as in **2**).

Experimental

General

Solvents were dried over sodium (hydrocarbons) or CaH_2 (dichloromethane) and distilled under nitrogen prior to use. The hexanuclear cluster $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ was prepared as described elsewhere (3). H_2ampy was purchased from Aldrich. Instrumentation: IR: PerkinElmer FT Paragon 1000X; NMR: Bruker DPX-300, with $SiMe_4$ as internal standard (δ 0); microanalyses: PerkinElmer 2400.

Synthesis of $[Ru_6(\mu_3\text{-}H)_2(\mu\text{-}H)_2(\mu_4\text{-}\kappa^2\text{-ampy})_2(CO)_{14}]$ (1) and $[Ru_8(\mu\text{-}H)(\mu_4\text{-}\kappa^2\text{-ampy})_3(\mu_3\text{-}\kappa^2\text{-Hampy})(\mu\text{-}CO)_2(CO)_{15}]$ (2)

A solution of $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$ (150 mg, 0.129 mmol) and H_2ampy (42 mg, 0.387 mmol) in decane (20 mL) was stirred under nitrogen at reflux temperature for 50 min. At this time, the IR spectrum of the solution did not show any starting material. A change in the color of the solution from dark brown to reddish brown was accompanied by the formation of some black solid. The solvent was removed under vacuum. The solid residue was extracted into dichloromethane (10 mL) and the solution was supported on silica gel (ca. 6 g). The resulting solid was placed onto a silica gel chromatographic column (2 cm × 20 cm) packed in hexane. Three bands, A (brown), B (brown), and C (red-brown), were eluted with hexane–dichloromethane (10:1). Subsequent elution of the column with hexane–dichloromethane (5:1) afforded band D (greenish yellow). Further elution of the column with hexane–dichloromethane (3:1) afforded band E (violet-brown). Bands A and D contained trace amounts of compounds that were not characterized. Band B contained 5 mg of the starting material, $[Ru_6(\mu_3\text{-}H)_2(\mu_5\text{-}\kappa^2\text{-ampy})(\mu\text{-}CO)_2(CO)_{14}]$. Band C

afforded 10 mg of compound **1** (6.4%). Band E gave 7 mg of compound **2** (4.2%).

X-ray diffraction studies

A selection of crystal, measurement, and refinement data for **1** and **2**·0.25(CH_2Cl_2) is given in Table 3. Diffraction data were collected at room temperature on a Bruker AXS SMART 1000 diffractometer, using graphite-monochromated Mo Kα radiation. Absorption corrections were applied with SADABS (12). The structures were solved by direct methods and refined by full matrix least-squares against F^2 with SHELXTL (13). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined isotropically. The edge-bridging hydrides of **1** were located on difference Fourier maps and were freely refined. The positions of the face-capping hydrides of **1** and the hydride of **2**·0.25(CH_2Cl_2) were calculated with XHYDEX (14) and were freely refined. The molecular plots were made with the PLATON program package (15). The WINGX program system (16) was used throughout the structure determinations.[3]

Organogold(I) macrocycles and [2]catenanes containing pyridyl and bipyridyl substituents — Organometallic catenanes as ligands[1]

Nicolle C. Habermehl, Fabian Mohr, Dana J. Eisler, Michael C. Jennings, and Richard J. Puddephatt

Abstract: The synthesis of achiral gold(I) macrocycles [RCH(4-$C_6H_4OCH_2C{\equiv}CAu)_2$(μ-$Ph_2PZPPh_2$)] and the corresponding chiral gold(I) [2]catenanes, bearing substituents R = 2-pyridyl, 4-pyridyl, and 4-(2,2′-bipyridyl), is reported. The gold(I) compounds form by self-assembly on reaction of oligomeric digold(I) diacetylides [{RCH(4-$C_6H_4OCH_2C{\equiv}CAu)_2\}_n$] or the isocyanide complexes [RCH(4-$C_6H_4OCH_2C{\equiv}CAuC{\equiv}N$-*t*-Bu)$_2$] with diphosphine ligands Ph_2PZPPh_2, Z = CC or $(CH_2)_n$ with n = 2–5, or on reaction of [$Au_2(O_2CCF_3)_2$(μ-Ph_2PZPPh_2)] with diacetylenes RCH(4-$C_6H_4OCH_2C{\equiv}CH)_2$ in the presence of a base. The equilibrium between macrocycles and chiral [2]catenanes in solution was established by NMR spectroscopy, while the structures of several [2]catenanes in the solid state were established crystallographically. The coordination of the gold(I) compounds with R = 4-(2,2′-bipyridyl) to platinum(IV), by formation of the corresponding [$PtIMe_3$(bipy)] units, is established, showing that organometallic [2]catenanes can act as ligands.

Key words: gold, macrocycle, catenane, platinum.

Résumé : On a réalisé la synthèse des macrocycles achiraux d'or(I) de formule générale [RCH(4-$C_6H_4OCH_2C{\equiv}CAu)_2$-(μ-$Ph_2PZPPh_2$)] et des [2]caténanes chiraux d'or(I) correspondants portant les groupes R = 2-pyridyle, 4-pyridyle et 4-(2,2′-bipyridyle). Les composés d'or(I) forment des produits d'autoassemblage par réaction des diacétylures de dior(I) oligomères de formule générale [{(RCH(4-$C_6H_4OCH_2C{\equiv}CAu)_2\}_n$] ou des complexes d'isocyanures de formule générale [RCH(4-$C_6H_4OCH_2C{\equiv}CAuC{\equiv}N$-*t*-Bu)$_2$] avec des ligands diphosphine Ph_2PZPPh_2 (Z = CC ou $(CH_2)_n$ avec n = 2, 3, 4, 5) ou par réaction de [$Au_2(O_2CCF_3)_2$(μ-Ph_2PZPPh_2)] avec des dérivés diacétylènes RCH(4-$C_6H_4OCH_2C{\equiv}CH)_2$, en présence de base. On a établit la nature de l'équilibre entre les macrocycles et les [2]caténanes chiraux en solution à l'aide de la spectroscopie RMN alors que plusieurs structures de [2]caténanes à l'état solide ont été établies par diffraction des rayons X. En montrant que les [2]caténanes organométalliques peuvent agir comme ligands avec formation des unités correspondantes [$PtIMe_2$(bipy)], on a démontré que les composés d'or(I) avec R = 4-(2,2′-bipyridyle) peuvent donner une coordination avec le platine(IV).

Mots clés : or, macrocycle, caténane, platine.

[Traduit par la Rédaction]

Introduction

The field of chemistry that encompasses the design, synthesis, and functionalization of mechanically interlocked molecules such as catenanes, rotaxanes, and knots has undergone great advances in recent decades, with the use of the coordinate bond allowing the directed self-assembly of these molecules in high yields (1–7). A natural extension to this field is the synthesis of coordination polymers (8–11) such as poly[2]catenanes (12–15). For example, a poly(bis-[2]catenane) that contains covalent, coordinate, and mechanical linkages has been reported in which a bipyridine unit was incorporated into the backbone of a [2]catenane and then used to coordinate to silver(I) (15). This example suggests a general method for growing more complex architectures from [2]catenane building blocks by introducing donor groups as substituents and then using these donor groups to form complexes with transition metals, as shown in Scheme 1. In the simplest case **A**, a macrocycle can act as a ligand, but a metal centre can also act as template to assemble two or more macrocycles as in case **B**. If the macrocycles form a [2]catenane, then the analogous forms of coordination will give a [2]catenane coordinated to two metal centres (case **C**) or to a polymer of [2]catenanes (case

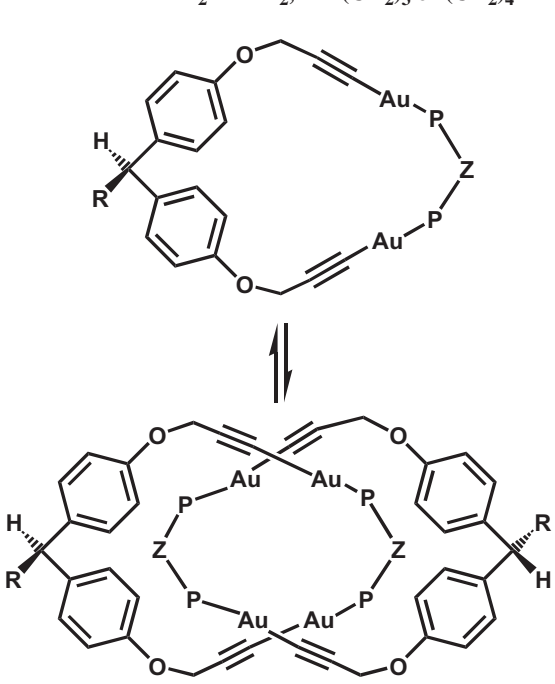
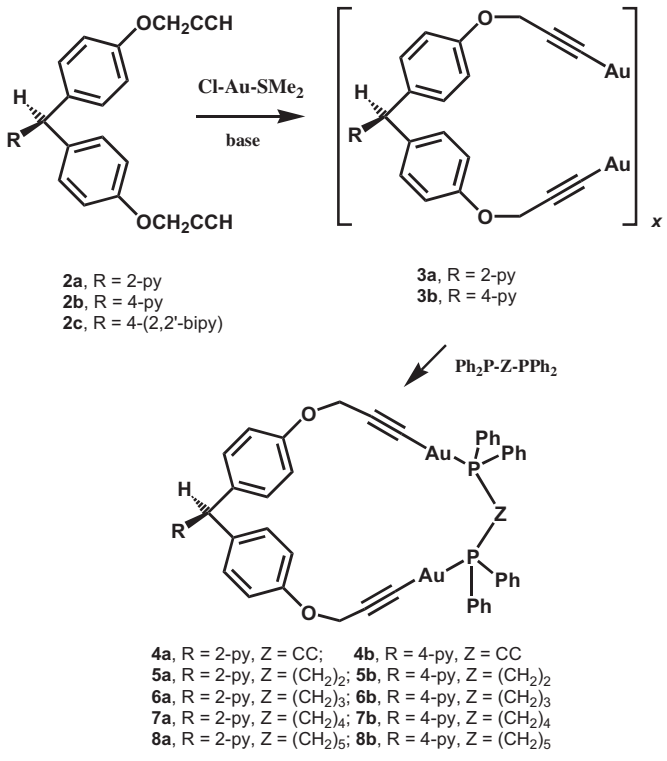
Scheme 1.

D). This article describes attempts to develop this chemistry by using organogold macrocycles and [2]catenanes with pyridyl or bipyridyl groups as substituents, and reports the first example of the use of an organometallic [2]catenane as a ligand.



The ligands pyridine and 2,2′-bipyridyl (bipy) form stable complexes with transition-metal ions (16), and appropriate substitution of the two pyridyl rings in 2,2′-bipyridyl has given many symmetrical or unsymmetrical derivatives that are useful for the synthesis of helicates, ladders, rods, catenanes, and coordination polymers (2, 16–24). In earlier papers, we have reported that macrocyclic organogold(I) complexes, such as $[RCH(C_6H_4OCH_2C{\equiv}CAu)_2(\mu\text{-}Ph_2P(CH_2)_nPPh_2)]$ with R,R′ = H, alkyl, or aryl and n = 3 or 4, may spontaneously and reversibly form [2]catenanes $[RCH(C_6H_4OCH_2C{\equiv}CAu)_2(\mu\text{-}Ph_2P(CH_2)_nPPh_2)]_2$, probably by a mechanism involving cleavage of a gold–phosphorus bond followed by threading/unthreading and recoordination (Scheme 2) (25, 26). It is then a natural extension to prepare the corresponding organogold complexes with R = pyridyl or 2,2′-bipyridyl, to form organometallic [2]catenanes that have the potential to act as ligands. Another important feature of these compounds is that the macrocycles are achiral but the [2]catenanes are chiral, and so the pyridyl and 2,2′-bipyridyl donors may act as chiral ligands (25). The syntheses and structures of the organogold complexes with pyridyl and bipyridyl substituents, and some preliminary studies of their properties, are described in the following.

Results and discussion



Synthesis of gold(I) compounds

The ligands $RCH(C_6H_4OCH_2C{\equiv}CH)_2$, containing substituents R = 2-pyridyl (**2a**), 4-pyridyl (**2b**), and 4-(2,2′-bipyridyl) (**2c**), were prepared by condensation of phenyl propargyl ether with the corresponding carboxaldehydes (RCH=O), **1a** (R = 2-pyridyl), **1b** (R = 4-pyridyl), and **1c** (R = 4-(2,2′-bipyridyl) (27, 28)) by the established general method (25, 26). Reaction of the diacetylene ligands **2a** and **2b** with chloro(dimethylsulfide)gold(I) in the presence of a base gave the insoluble oligomeric digold(I) diacetylides ($[RCH(C_6H_4OCH_2C{\equiv}CAu)_2]_x$) **3a**, R = 2-pyridyl, and **3b**, R = 4-pyridyl, as shown in Scheme 3. The C≡C stretching frequencies observed by IR spectroscopy (**3a**, 2000 cm^{-1}; **3b**, 2013 cm^{-1}) are about 100 cm^{-1} lower than the corresponding C≡C stretching frequencies for the free ligands (**2a**, 2120 cm^{-1}; **2b**, 2118 cm^{-1}), which indicates that the

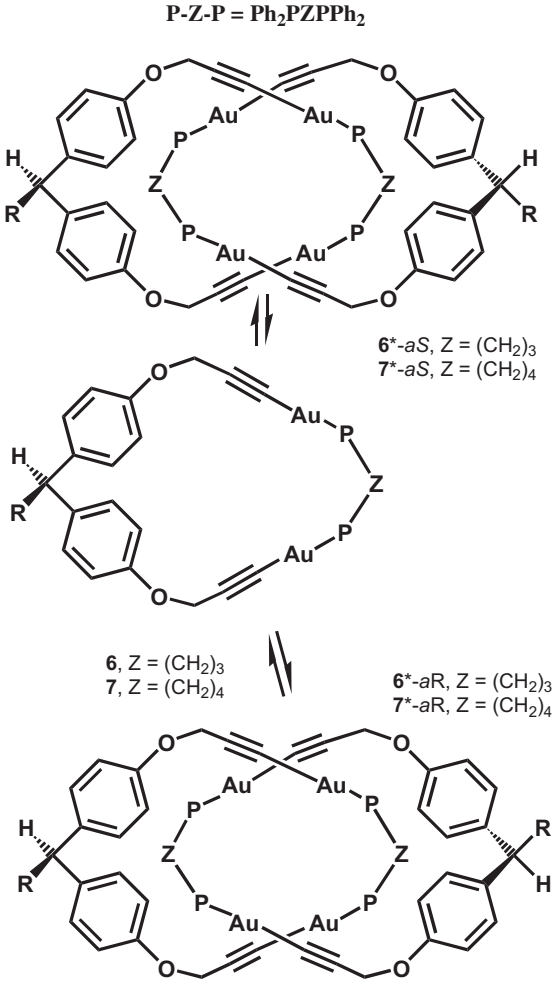
Scheme 4.

diacetylenes are both σ bonded and π bonded to the gold(I) centres to form oligomeric structures (29, 30). Reaction of these oligomeric digold(I) complexes (**3a** and **3b**) with diphosphine ligands then gave the macrocyclic digold(I) complexes, $[RCH(C_6H_4OCH_2C{\equiv}CAu)_2\{\mu\text{-}Ph_2P\text{-}Z\text{-}PPh_2\}]$ (**4**–**8**) (Scheme 3), many of which exist as an equilibrium mixture of the macrocyclic complexes depicted in Scheme 3 and the corresponding [2]catenane. An alternative route to the complexes **4**–**8** is to react the oligomers **3** with *tert*-butyl isocyanide to give the soluble isocyanide derivatives $RCH(C_6H_4OCH_2C{\equiv}CAuC{\equiv}N\text{-}t\text{-}Bu)_2$ and then to displace the isocyanide ligands by the appropriate diphosphine ligand (Ph_2P-Z-PPh_2).



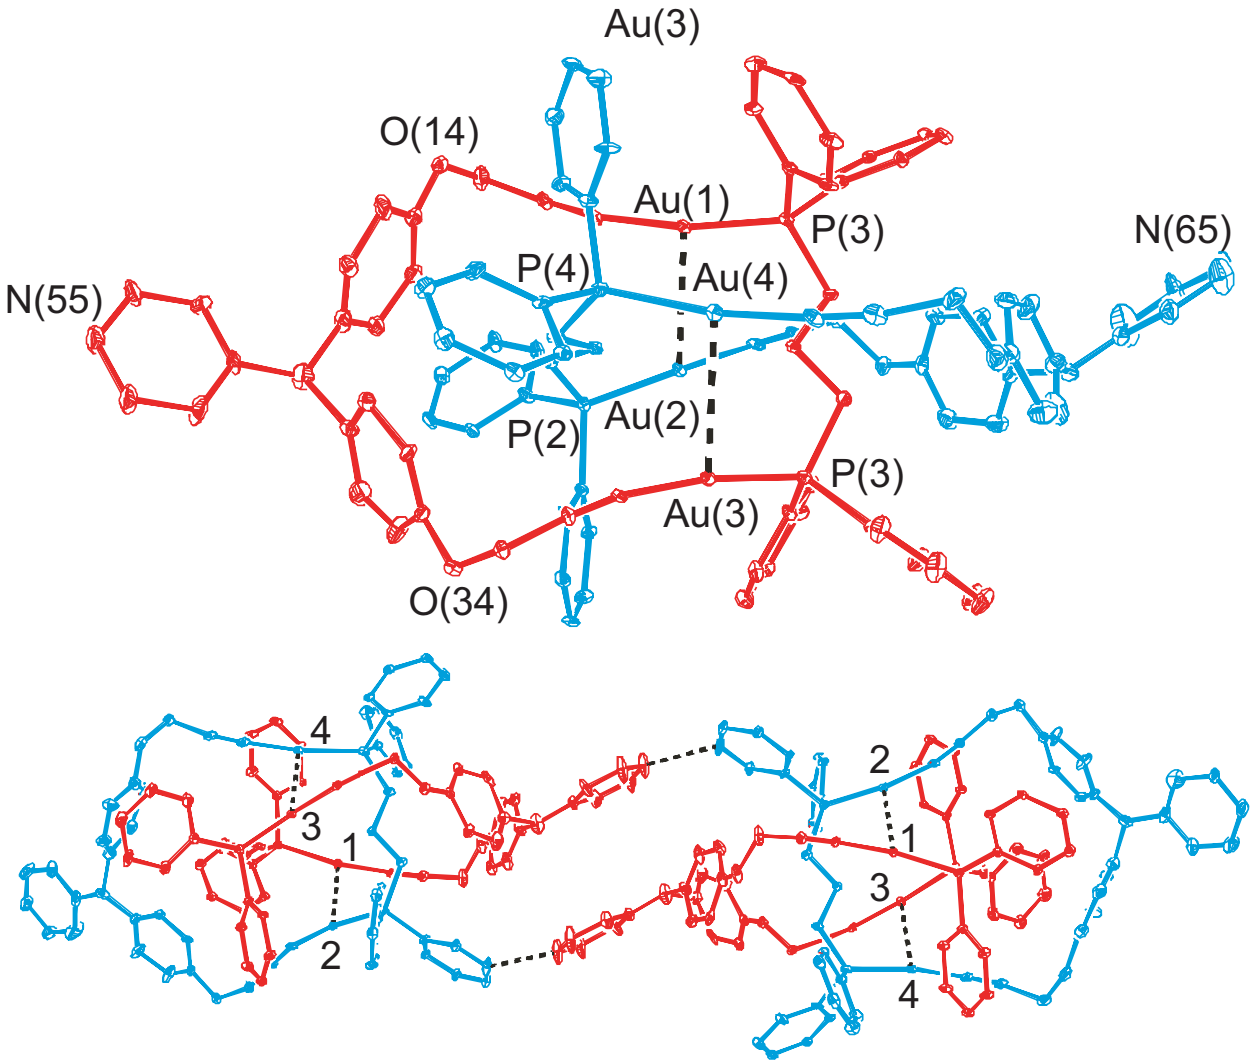
Attempts to prepare the corresponding complexes with R = 4-(2,2′-bipy) by this procedure were unsuccessful because the desired products, $[RCH(C_6H_4OCH_2C{\equiv}CAu)_2\{\mu\text{-}Ph_2P\text{-}Z\text{-}PPh_2\}]$, were always formed as a mixture with the chloride complex $[Au_2Cl_2(\mu\text{-}Ph_2P\text{-}Z\text{-}PPh_2)]$, and this chlorogold impurity was not easily separated. The pure digold(I) complexes containing the 4-(2,2′-bipy) group were therefore prepared by reaction at low temperature of the diacetylene ligand **2c** with $[Au_2(O_2CCF_3)_2(\mu\text{-}Ph_2P\text{–}Z\text{–}PPh_2)]$, which is conveniently prepared in situ from $[Au_2Cl_2(\mu\text{-}Ph_2P\text{–}Z\text{–}PPh_2)]$ and silver trifluoroacetate (Scheme 4).

In cases where the macrocyclic complexes **6** and **7** are in equilibrium with the [2]catenane isomers, the presence of a prochiral carbon at the hinge group (*C*HR) leads to formation of [2]catenanes **6*** and **7***, which are axially chiral with C_2 symmetry (25). These chiral [2]catenanes are formed as racemates, which have the stereochemical descriptors a*R* and a*S* (the symbol "a" in a*R*/a*S* indicates axial chirality (31, 32)), as illustrated in Scheme 5. The interconversion of ring and catenane is known to be catalysed by traces of free phosphine and so probably involves ring-opening by cleavage of an Au—P bond, followed by threading or dethreading (25, 26).

Characterization of the gold(I) complexes

The structures of the singly braided [2]catenane complexes **6a*** (R = 2-py), **6b*** (R = 4-py), **6c*** (R = 4-(2,2′-bipy), and **7a*** (R = 2-py) were determined crystallographically and are shown in Figs. 1–4. They form by [2+2] self-assembly of the appropriate digold(I) diacetylide unit and diphosphine ligand to give two mechanically interlocked rings. The [2]catenanes **6a***, **6b***, and **6c*** are each comprised of two interlocked 24-membered rings, while **7a*** is comprised of two 25-membered rings.

Scheme 5.



Of the complexes studied, only **6b*** (R = 4-pyridyl, Z = $(CH_2)_3$, Fig. 1) showed no disorder, so its structure will be discussed first. The complex crystallized in space group $P2_1/c$ with $Z = 4$, and hence contains equal amounts of the enantiomers **6b***-*aR* and **6b***-*aS*. As seen in previous examples of gold(I) [2]catenanes (25, 26, 33–35), an intermacrocycle aurophilic interaction is observed for the [2]catenane, with Au(1)—Au(2) = 3.2097(8) Å, while the second gold···gold distance (Au(3)—Au(4) = 3.404 Å) indicates only a weak Au···Au interaction (36). A combination of the secondary Au···Au bonding and several intermacrocycle aryl···aryl bonding interactions provides the driving force for the catenation (25, 26, 33–36). There is significant bowing of the P-Au-C-C-C groups away from linearity with angles P-Au-C, Au-C-C, and C-C-C in the ranges 169.3(5)°–171.4(4)°, 167(2)°–174(2)°, and 169(2)°–178(2)°, respectively, and this bowing appears to be correlated to the short Au···Au contacts.

The aryl twist angles, defined as the angles between the planes of the C_6H_4 groups and the C-C-C plane of the "hinge carbon atom", are important in determining the favorability of [2]catenane formation (25, 26). Optimum aryl

Fig. 1. Molecular structure of [2]catenane **6b*** (R = 4-pyridyl, Z = $(CH_2)_3$): above, a single chiral [2]catenane, and below, a racemic pair of [2]catenanes with connecting N···HC hydrogen bonds (only the gold atoms are numbered). Selected bond distances (Å) and angles (°): Au(1)—Au(2) 3.2097(8); Au(1)—P(1) 2.269(4); Au(2)—P(2) 2.275(4); Au(3)—P(3) 2.268(4); Au(4)—P(4) 2.275(5); Au(1)—C(11) 1.97(2); Au(2)—C(21) 2.01(2); Au(3)—C(31) 2.02(2); Au(4)—C(41) 1.93(2); C(11)—C(12) 1.19(2); C(21)—C(22) 1.16(2); C(31)—C(32) 1.15(2); C(41)—C(42) 1.18(2); P(1)-Au(1)-C(11) 169.3(5); P(2)-Au(2)-C(21) 171.4(4); P(3)-Au(3)-C(31) 171.2(4); P(4)-Au(4)-C(41) 170.1(6); Au(1)-C(11)-C(12) 170(2); Au(2)-C(21)-C(22) 167(1); Au(3)-C(31)-C(32) 170(1); Au(4)-C(41)-C(42) 174(2); C(11)-C(12)-C(13) 177(2); C(21)-C(22)-C(23) 178(2); C(31)-C(32)-C(33) 175(2); C(41)-C(42)-C(43) 169(2).

twist angles are in the range 45°–90° (25, 26) and in complex **6b*** these angles are 83° and 82° in one macrocycle and 72° and 71° in the other (the corresponding twist angles in the parent bis(phenol) are 44° and 87°). In the structures of all other known complexes with unsymmetrical hinge groups (R*C*H), there is disorder of the substituent R on either side of the plane of the macrocycle. The well-ordered structure of **6b*** appears to result from favorable pairwise hydrogen bonding between the nitrogen atom of one of the 4-pyridyl substituents and a *meta*-hydrogen atom of a phenylphosphorus group on a neighbouring molecule (37), as shown in Fig. 1. The nitrogen atom N(55) of the 4-pyridyl group of one ring interacts with an aryl CH group of a neighbour with N(55)···C(2C) = 3.22 Å, N···H = 2.35 Å, and angle C-H···N = 154°. No close intermolecular aryl–aryl interactions were observed (38, 39). The pairs of chiral hydrogen-bonded [2]catenanes (Fig. 1) are related by an inversion centre and so comprise a racemic *aR–aS* couple.

The structures of complexes **6a*** and **6c*** (Figs. 2 and 3) are similar to that of **6b*** but they each show disorder in the $RCH(C_6H_4)_2$ region. The aryl twist angles associated with the two disorder components ***A*** and ***B*** in **6a***were for component ***A***: 88°,25° (ring 1) and 85°,29° (ring 2); and for component ***B***: 85°,43° (ring 1) and 89°,41° (ring 2). The values of the aryl twist angles of 25° and 29° are the smallest yet observed in a [2]catenane (25, 26). For comparison, the aryl twist angles in the related bis(phenol) $RCH(C_6H_4OH)_2$ (R = 2-pyridyl) were 87°,44°. The closest gold···gold contacts in **6a*** are the intermacrocycle distances Au(1)—Au(4) = 3.1574(5) Å and Au(2)—Au(3) = 3.555 Å.

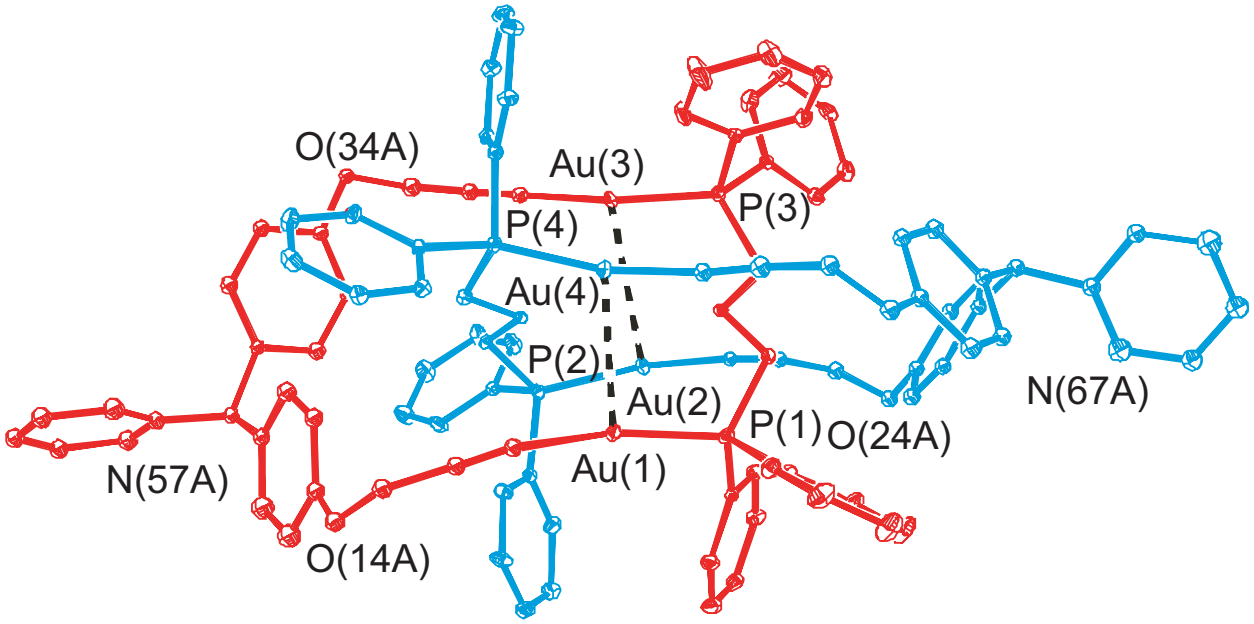
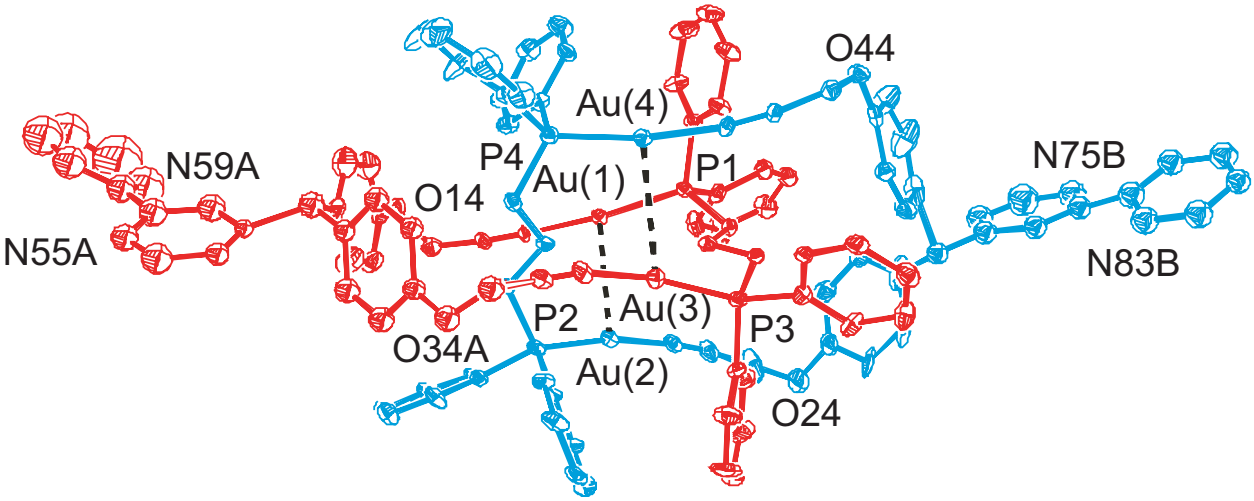
Fig. 2. Molecular structure of [2]catenane **6a*** (R = 2-pyridyl, Z = $(CH_2)_3$) showing only the ***A*** disorder component. Selected bond distances (Å) and angles (°): Au(1)—Au(4) 3.1574(5); Au(1)—P(1) 2.276(2); Au(2)—P(2) 2.275(2); Au(3)—P(3) 2.280(2); Au(4)—P(4) 2.273(2); Au(1)—C(11) 1.990(8); Au(2)—C(21) 1.991(7); Au(3)—C(31) 2.008(8); Au(4)—C(41) 1.990(8); C(11)—C(12) 1.18(1); C(21)—C(22) 1.19(1); C(31)—C(32) 1.18(1); C(41)—C(42) 1.19(1); P(1)-Au(1)-C(11) 170.4(2); P(2)-Au(2)-C(21) 168.3(2); P(3)-Au(3)-C(31) 173.0(2); P(4)-Au(4)-C(41) 168.9(2); Au(1)-C(11)-C(12) 170.4(8); Au(2)-C(21)-C(22) 172.2(7); Au(3)-C(31)-C(32) 175.3(7); Au(4)-C(41)-C(42) 171.7(8); C(11)-C(12)-C(13) 178.9(9); C(21)-C(22)-C(23A) 171(1); C(21)-C(22)-C(23B) 176(1); C(31)-C(32)-C(33) 175.1(9); C(41)-C(42)-C(43A) 173(1); C(41)-C(42)-C(43B) 158(1).





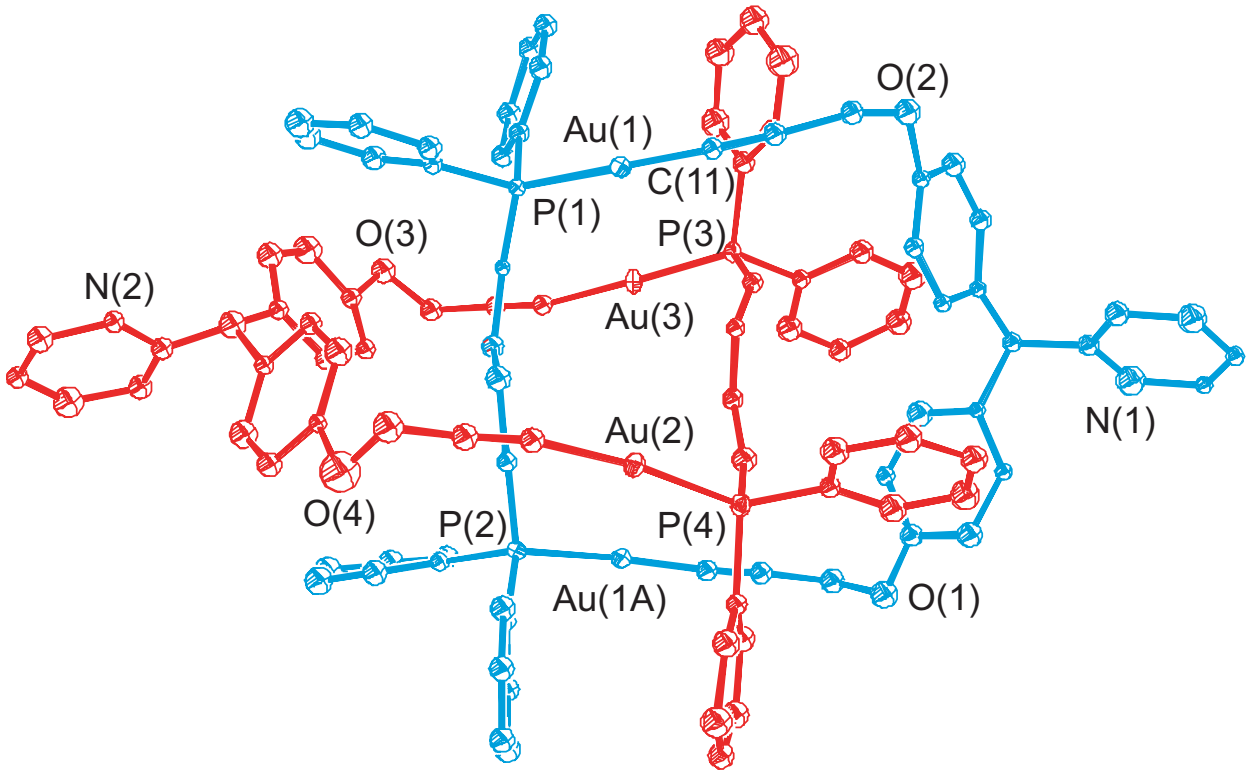


Fig. 3. Molecular structure of [2]catenane **6c*** (R = 4-(2,2′-bipyridyl), Z = $(CH_2)_3$); only one disorder component is shown. Selected bond distances (Å) and angles (°): Au(1)—Au(2) 3.2195(7); Au(1)—P(1) 2.269(3); Au(2)—P(2) 2.281(3); Au(3)—P(3) 2.271(4); Au(4)—P(4) 2.266(3); Au(1)—C(11) 2.02(1); Au(2)—C(21) 1.99(2); Au(3)—C(31) 2.00(2); Au(4)—C(41) 2.04(1); C(11)—C(12) 1.16(2); C(21)—C(22) 1.18(2); C(31)—C(32) 1.18(2); C(41)—C(42) 1.17(2); P(1)-Au(1)-C(11) 170.8(4); P(2)-Au(2)-C(21) 170.2(4); P(3)-Au(3)-C(31) 170.5(4); P(4)-Au(4)-C(41) 171.2(4); Au(1)-C(11)-C(12) 170(1); Au(2)-C(21)-C(22) 174(1); Au(3)-C(31)-C(32) 166(1); Au(4)-C(41)-C(42) 171(1); C(11)-C(12)-C(13) 177(1); C(21)-C(22)-C(23) 174(2); C(31)-C(32)-C(33A) 177(2); C(41)-C(42)-C(43) 175(1).

Complex **6c*** (Fig. 3) was also disordered around the two CH(4-(2,2′-bipy))$(C_6H_4)_2$ units of the [2]catenane and the disorder was modeled as ***A/B*** = 51/49 for each component of the interlocked rings. The aryl twist angles for the two distributions were found to be: ***A***: 88°,52° (ring 1) and 70°,56° (ring 2); and ***B***: 69°,36° (ring 1) and 50°,45° (ring

Fig. 4. Molecular structure of [2]catenane **7a*** (R = 2-pyridyl, Z = $(CH_2)_4$) with only one disorder component shown. Selected bond distances (Å) and angles (°): Au(1)—P(1) 2.361(6); Au(2)—P(4) 2.277(6); Au(1A)—P(2) 2.272(6); Au(3)—P(3) 2.256(7); Au(1)—C(11) 1.94(3); Au(2)—C(22) 2.00(3); Au(1A)—C(5) 1.98(3); Au(3)—C(16) 2.09(3); P(1)-Au(1)-C(11) 176.4(6); P(4)-Au(2)-C(22) 173.1(8); P(2)-Au(1A)-C(27) 176.1(7); P(3)-Au(3)-C(16) 177.8(7); Au(1)-C(11)-C(10) 169(2); Au(2)-C(21)-C(22) 166(3); Au(1A)-C(5)-C(6) 169(2); Au(3)-C(16)-C(17) 168(2); C(5)-C(6)-C(7) 176(3); C(9)-C(10)-C(11) 176(3); C(16)-C(17)-C(18) 170(3); C(20)-C(21)-C(22) 174(3).

2). In complex **6c***, the nitrogen atoms of the two pyridyl rings in each 4-(2,2′-bipy) group adopt an approximately planar s-trans conformation, as is typical for free 2,2′-bipyridyl ligands (16). In the disordered structure, the angles between the two pyridyl rings of each 2,2′-bpy group were: ***A***: 31° and 9°; and ***B***: 34° and 17°. As in the complexes **6a*** and **6b***, there was one strong and one weak Au···Au interaction (36) with Au(1)···Au(2) = 3.2195(7) Å and Au(3)···Au(4) = 3.442 Å in **6c***. No significant intercatenane hydrogen bonding or π stacking of aryl groups was observed in the crystal structure of complex **6c***.

The structure of **7a*** showed disorder at the $RCH(C_6H_4)_2$ units, similar to that in **6a*** and **6c***, but there was a second form of disorder arising from the presence of an inversion centre at the midpoint of the Au(1)···Au(1A) unit. The interlocked 25-membered rings in **7a*** (Fig. 4) are much less congested than the 24-membered rings in **6a***–**6c*** and there are no short gold···gold distances. The shortest intracatenane Au···Au distance is Au(1A)—Au(2) = 5.138 Å, which is too long to be indicative of an aurophilic interaction (36). The main forces favoring catenation in this case are aryl···aryl attractions (25, 26).

NMR spectroscopy

It is possible to distinguish between the macrocycle and [2]catenane structures by NMR spectroscopy based on the molecular symmetry. Thus, the achiral ring complexes **4**–**8** have C_s symmetry so that the two phosphorus atoms are equivalent and will resonate as a singlet in the ^{31}P NMR spectrum. In contrast, the chiral [2]catenanes **6*** and **7*** have C_2 symmetry and so the two phosphorus atoms in each interlocked ring of the [2]catenane will be nonequivalent and will resonate as two doublets in the ^{31}P NMR spectrum (25, 26). The gold(I) complexes **4**, **5**, **7**, and **8**, containing the diphosphines Ph_2P-Z-PPh_2 with Z = C≡C, $(CH_2)_2$, $(CH_2)_4$, and $(CH_2)_5$, respectively, all give a singlet resonance in their ^{31}P NMR spectra and so are presumed to exist in solution as the macrocyclic complexes. In the solid state, the gold(I) complex with R = 2-pyridyl and Z = $(CH_2)_4$ exists as a [2]catenane **7a***, but this is presumed to dissociate back to the macrocycle **7a** in solution. However, the gold(I) complexes **6**, with Z = $(CH_2)_3$, give several resonances in the ^{31}P NMR spectra, indicating that they exist as a mixture of isomers in solution. For example, the macrocyclic complex **6a** (R = 2-py) gave a singlet resonance at δ(^{31}P) 35.93 and was in equilibrium with the [2]catenane **6a***, which gave an "AB" multiplet with δ(^{31}P) 31.89 and 32.18, with coupling $^4J(P^AP^B)$ = 6 Hz. In the ^1H NMR spectra, there are some significant differences in chemical shift between the macrocyclic and [2]catenane structures. For example, **6a** has δ(C*H*py) 5.54 and δ(C_6H_4) 7.01 and 7.12, whereas **6a*** has δ(C*H*py) 5.07 and δ(C_6H_4) 6.16 and 6.78. Ring current effects from the adjacent phenylphosphorus groups in the [2]catenane cause these diagnostic shifts. Slow crystalliza-

© 2006 NRC Canada

tion of this complex (**6a/6a***) gave the pure [2]catenane **6a***, which, on dissolution in CD_2Cl_2, gave only the resonances of the [2]catenane. Equilibration occurred slowly in solution, over a period of several days at room temperature. In dilute solution the equilibrium favours the macrocycle **6a** but, at high concentration, more of the [2]catenane **6a*** and other higher molecular weight isomers (25, 26) are observed. The slow equilibration of **6a** and **6a*** is expected, based on earlier studies (25, 26), and is assumed to result from the very compact structure of **6a*** in which the gold atoms are sterically protected from external reagents.

The NMR features described for **6a** and **6a*** were typical of all the macrocycles and [2]catenanes studied, and full details are given in the Experimental section. In particular, the proton resonances of the [2]catenanes with the diphosphine ligand $Ph_2P(CH_2)_3PPh_2$ occurred at higher field than in the macrocyclic complexes, with large upfield shifts observed for the RC*H* ($\Delta\delta$ ca. 0.45) and C_6H_4 ($\Delta\delta$ ca. 0.4 and 0.8) proton resonances. The shielding arises from the close contacts with the phenyl groups of the interlocked gold macrocycle and is a useful indicator of [2]catenane formation (25, 26).

Coordination and quaternization studies

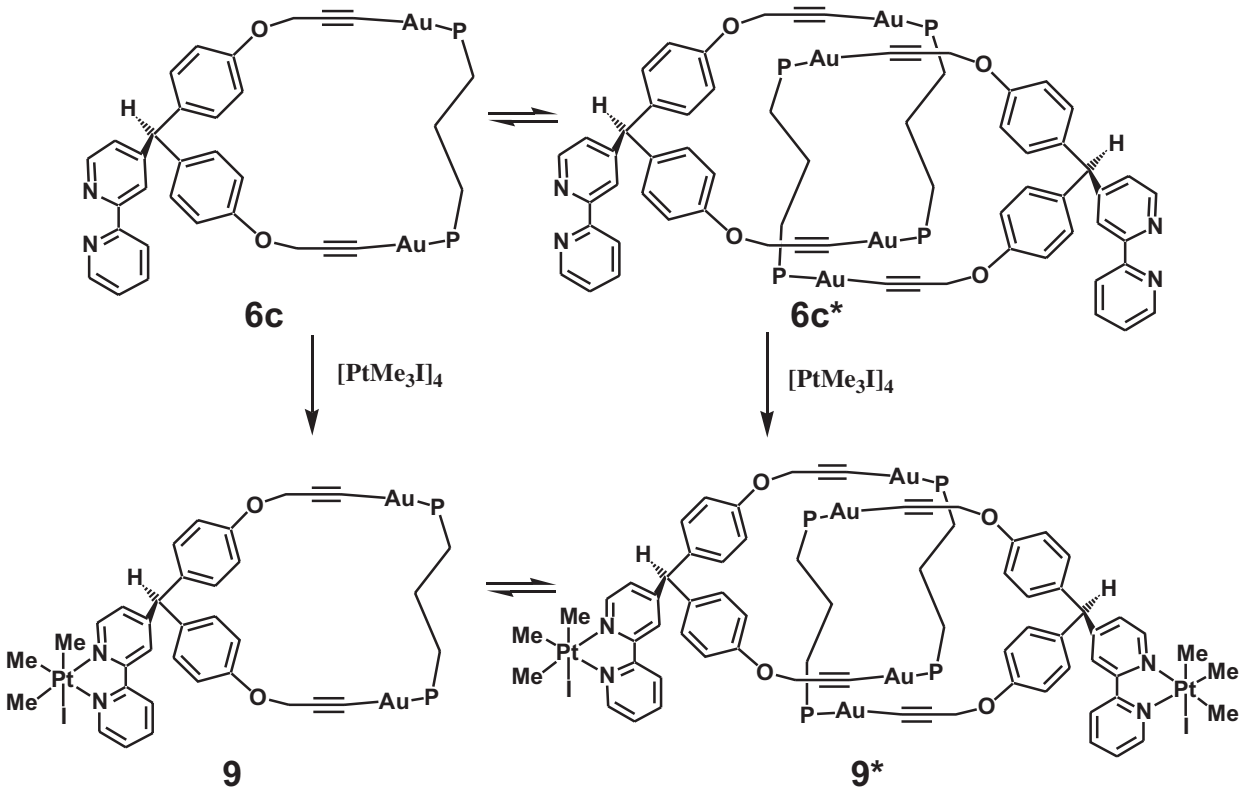
As shown in Scheme 1 for the 4-pyridyl derivative, the gold(I) macrocyclic complexes and [2]catenanes can, in principle, form extended structures by coordination of the pyridyl or bipyridyl groups to suitable metal ions. By variation of the stoichiometry of the reaction (pyridyl:metal) and by use of either the macrocyclic complex or the [2]catenane, the resulting products are the molecularly discrete complexes **A**, **B**, and **C**, and the polymeric complex **D**. Similar chemistry could be achieved by quaternization of the pyridyl nitrogen atoms by reaction with alkyl halides. However, the chemistry proved to be difficult as a result of the lability of the gold(I) centres, especially with respect to cleavage of the gold–acetylide bonds.

The reaction of complex **6b/6b*** with benzyl bromide or with 1,4-bis(bromomethyl)benzene gave only $[Au_2Br_2(\mu\text{-}Ph_2P(CH_2)_3PPh_2)]$ as the isolated gold-containing product. Attempts were then made to quaternize the pyridyl nitrogen atom of the parent diacetylene ligand **2b** with 1,4-bis(bromomethyl)benzene, but this too was unsuccessful. A milder form of self-assembly might be possible by using hydrogen bond donors, such as phenol derivatives, to form secondary bonds to the pyridyl substituents of **6b/6b***. Attempts were made to crystallize **6b/6b*** in the presence of 1,4-$C_6H_4(OH)_2$ and other bis(phenol) derivatives, but they were not successful. Slow decomposition of **6b/6b*** occurred instead. The reaction of complex **6b/6b*** with metal halides MBr_2 (M = Zn, Cd, or Hg) led only to acetylide for bromide exchange reactions to give $[Au_2Br_2(\mu\text{-}Ph_2P(CH_2)_3PPh_2)]$. The 2,2′-bipyridyl complex **6c/6c*** gave similar results, and this complex also reacted with $AgPF_6$ to give an intractable black precipitate. It seems clear then that most electrophiles react with the gold–acetylide bond instead of or in addition to reacting with the free pyridyl or bipyridyl group.

The reaction of 2,2′-bipyridyl with $[PtMe_2(\mu\text{-}SMe_2)]_2$ occurs by displacement of the dimethylsulfide ligands to give $[PtMe_2(bipy)]$ (42), but the reaction of **7c** with $[PtMe_2(\mu\text{-}SMe_2)]_2$ occurred primarily by methyl for acetylide exchange to give $[Au_2Me_2(\mu\text{-}Ph_2P(CH_2)_4PPh_2)]$, identified by comparison of its ^1H and ^{31}P NMR spectra with those of an authentic sample (40, 41). The organoplatinum product was an insoluble solid, whose IR spectrum (KBr disc) showed a band owing to $\nu(C{\equiv}C)$ at 2120 cm^{-1} (cf. **7c**, 2131 cm^{-1}), but which was not fully characterized.

The only successful reaction was that of *fac*-$[PtMe_3I]_4$ (42), which is inert to methyl transfer reactions, with the 2,2′-bipyridine complex **6c/6c***, which gave the products $[PtMe_3I(\mathbf{6c})]$, **9** and $[(PtMe_3I)_2(\mu\text{-}\mathbf{6c}^*)]$, **9***, shown in Scheme 6. The mixture of complexes **9/9*** was isolated as an air-stable, pale-orange solid, but attempts to separate the isomers by recrystallization were unsuccessful, so they were characterized spectroscopically.

The presence of the $PtIMe_3$ group reduces the symmetry of **9** with respect to **6c**, by loss of the plane of symmetry containing the bipyridyl group in **6c**, and so there are also more potential isomers of **9*** compared with **6c***. The nonequivalence that arises from the presence of the $PtIMe_3$ group causes broadening rather than splitting of most resonances as described in the following. The NMR spectra were recorded as a mixture of **9/9*** in about a 3:1 molar ratio, but assignments were possible based on correlations in the COSY ^1H NMR spectrum and on peak intensities. The ^{31}P NMR spectrum of **9** contained a broad singlet shifted from the corresponding resonance of the macrocyclic gold complex **6c** [**9**, δ 34.67; **6c**, δ 35.92]. The ^1H NMR spectrum of **9** contained two broad resonances assigned to the methylplatinum groups in a 1:2 ratio at δ 0.62, $^2J(PtH)$ = 74 Hz and δ 1.46, $^2J(PtH)$ = 70 Hz. In principle, each isomer should give three Me-Pt resonances since the bipyridine is unsymmetrical, but there is evidently accidental degeneracy of the resonances of the methylplatinum groups trans to nitrogen. These ^1H NMR parameters of **9** are typical of complexes $[PtIMe_3(LL)]$ with LL = 2,2 bipyridyl or its derivatives (40–43). The ^{31}P NMR spectrum of **9*** contained a broad AB multiplet resonance shifted from the corresponding resonance of the gold [2]catenane **6c** (**9***, δ 32.73, 32.82, $^4J(PP)$ not resolved; **6c***, δ 31.83, 32.34, $^4J(PP)$ = 6 Hz). The methylplatinum resonances for **9*** were at δ 0.43, $^2J(PtH)$ = 74 Hz and δ 1.14, $^2J(PtH)$ = 70 Hz, significantly shifted from those of the macrocyclic complex **9** as a result of the catenation. The bipyridyl protons and several protons of the macrocycles of **9** and **9*** showed significant deshielding on coordination of the bipyridyl to platinum(IV), as listed in the Experimental section.



Further evidence for coordination of the bipyridyl group to platinum(IV) was obtained by ESI-MS of the mixture of **9/9*** in dichloromethane solution. As expected, based on the easy cleavage of the mechanical link (25, 26), no peaks for the [2]catenane were observed, but a low intensity envelope of peaks was observed at *m*/*z* 1602, assigned to $[\mathbf{9}{\cdot}H]^+$, and a major peak was observed at *m*/*z* = 1474, assigned to $[\mathbf{9} - I]^+$. The IR spectrum of the mixture of **9/9*** gave a single peak owing to $\nu(C{\equiv}C)$ at 2129 cm^{-1}, shifted only slightly from the corresponding peak for **6/6*** at $\nu(C{\equiv}C)$ = 2132 cm^{-1}.

Conclusions

Achiral digold(I) macrocycles and chiral tetragold(I)

© 2006 NRC Canada

Scheme 6.

[2]catenanes, each bearing 2-pyridyl, 4-pyridyl, or 4-(2,2′-bipyridyl) substituents at the hinge group, have been prepared and the structures of four [2]catenane complexes have been determined. The presence of the pyridyl or bipyridyl functional substituent does not complicate the synthesis. However, preliminary studies suggest that the ability of the new gold macrocycles and [2]catenanes to give an extensive coordination chemistry through use of the pendant nitrogen-donor groups will be limited as a result of the lability of the Au—C and Au—P bonds. One successful example was established in the use of the bipyridyl derivative **6c/6c*** as ligand for the inert $PtIMe_3$ group, and this appears to be the first example of the use of an organometallic [2]catenane as a ligand. The aim of using the coordination chemistry to prepare an organometallic poly[2]catenane according to Scheme 1, **D**, is yet to be achieved.

Experimental

NMR spectra were recorded by using Varian Mercury 400 and Varian Inova 400 spectrometers. ^{1}H and ^{13}C NMR chemical shifts are reported with respect to TMS reference and ^{31}P NMR chemical shifts are reported relative to 85% H_3PO_4 as an external standard. IR spectra were recorded as KBr discs or as Nujol mulls between NaCl plates using a PerkinElmer 2000 FT-IR spectrometer. High-resolution mass spectra were measured by using a Finnigan MAT 8400 spectrometer, and ESI-MS by using a Micromass LCT spectrometer, often using formic acid or CsI to aid ionization.

The complexes $[AuCl(SMe_2)]$, $[Au_2Cl_2(\mu\text{-}Ph_2P(CH_2)_3PPh_2)]$, $[Au_2Cl_2(\mu\text{-}Ph_2P(CH_2)_4PPh_2)]$ (44), $[PtMe_2(\mu\text{-}SMe_2)]_2$ (45), and $[(PtIMe_3)_4]$ (42) were prepared according to the literature. Gold compounds were protected from light by use of darkened reaction flasks.

Caution: Some gold acetylides are potentially explosive; they should be prepared in small quantities and not subjected to shock.

(2-C_5H_4N)CH(4-$C_6H_4OCH_2C{\equiv}CH)_2$ (2a)

A solution of 2-pyridinecarboxaldehyde (**1a**, 0.78 g, 7.3 mmol) and phenyl propargyl ether (46) (2.00 g, 15.1 mmol) in glacial acetic acid (5 mL) was cooled to 0 °C. Concentrated sulfuric acid (2 mL) was added slowly, then the mixture was heated for 5 h at 100 °C. The mixture was cooled, water was added, and the solution was neutralized by addition of aq. NaOH. The aqueous phase was extracted with diethyl ether, then the combined organic phases were washed with saturated aqueous sodium bicarbonate and then with water. The organic phase was dried over Na_2SO_4, filtered, and the solvent removed under reduced pressure to give an orange oil. Purification by flash chromatography gave the product as a yellow oil. Yield: 1.66 g (65%). IR (Nujol mull, cm^{-1}): 2120 (C≡C stretch). ^{1}H NMR ($CDCl_3$) δ: 2.51 (t, 2H, $^4J_{HH}$ = 2 Hz, C≡C*H*), 4.65 (d, 4H, $^4J_{HH}$ = 2 Hz, OCH_2), 5.61 (s, 1H, C*H*py), 6.90 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.08 (m, 5H, C_6H_4 + py-H3), 7.13 (ddd, 1H, $^3J_{HH}$ = 8, 5 Hz, $^4J_{HH}$ = 1 Hz, py-H5), 7.60 (dt, 1H, $^3J_{HH}$ = 8 Hz, $^4J_{HH}$ = 2 Hz, py-H4), 8.59 (ddd, 1H, $^3J_{HH}$ = 5 Hz, $^4J_{HH}$ = 2 Hz, $^5J_{HH}$ = 1 Hz, py-H6). ^{13}C NMR δ: 55.77 (OCH_2), 57.56 (*C*Hpy), 75.42 (C≡*C*H), 78.61 (*C*≡CH), 114.72,

130.23, 135.93, 156.16 (C_6H_4), 121.39, 123.62, 136.55, 149.34, 163.42 (py). EI-MS (*m*/*z*) calcd. for $C_{24}H_{19}NO_2$: 353.1415; found: 353.1413.

(4-C_5H_4N)CH(4-$C_6H_4OCH_2C{\equiv}CH)_2$ (2b)

Prepared following the procedure described for **2a**, using 4-pyridinecarboxaldehyde (**1b**, 1.4 mL, 14.7 mmol), phenyl propargyl ether (4.0 g, 30.3 mmol), glacial acetic acid (20 mL), and concd. sulfuric acid (4 mL). The product was isolated as a dark orange oil. Yield: 3.81 g (74%). IR (Nujol mull, cm^{-1}): 2118 (C≡C stretch). ^1H NMR ($CDCl_3$) δ: 2.53 (t, 2H, $^4J_{HH}$ = 2 Hz, C≡C*H*), 4.67 (d, 4H, $^4J_{HH}$ = 2 Hz, OCH_2), 5.40 (s, 1H, C*H*py), 6.91 (d, 4H, $^3J_{HH}$ = 8 Hz, C_6H_4), 7.00 (d, 4H, $^3J_{HH}$ = 8 Hz, C_6H_4), 7.02 (d, 2H, $^3J_{HH}$ = 5 Hz, py-H3 + py-H5), 8.48 (d, 2H, $^3J_{HH}$ = 5 Hz, py-H2 + py-H6). ^{13}C NMR δ: 54.85 (*C*Hpy), 56.04 (O*C*H_2), 75.74 (C≡*C*H), 78.74 (*C*≡CH), 115.09, 130.47, 135.56, 156.58 (C_6H_4), 124.74, 149.98, 153.42 (py). EI-MS (*m*/*z*) calcd. for $C_{24}H_{19}NO_2$: 353.1415; found: 353.1413.

4-(2,2′-bpy)CH(4-$C_6H_4OCH_2C{\equiv}CH)_2$ (2c)

To a solution of phenyl propargyl ether (46) (3.34 g, 25.3 mmol) and 2,2′-bipyridine-4-carboxaldehyde (27, 28) (1.86 g, 10.1 mmol) in glacial acetic acid (25 mL) was added concd. sulfuric acid (15 mL). The reaction mixture was stirred for 17 h then poured into water (150 mL) and neutralized by addition of sodium hydroxide. A brown oil separated and was extracted into diethyl ether (3 × 50 mL). The combined organic phases were washed with aqueous sodium carbonate, then the organic phase was dried ($MgSO_4$), filtered, and the solvent removed under reduced pressure. Chromatography of the residue on a silica gel column with 1:1 petroleum spirits (bp 60–90 °C) – ethyl acetate as eluant gave the product as a yellow oil. Yield: 1.94 g (45%). IR (neat, cm^{-1}): 2121 (C≡C stretch). ^1H NMR ($CDCl_3$) δ: 2.51 (t, 2H, $^4J_{HH}$ = 2 Hz, C≡C*H*), 4.66 (d, 4H, $^4J_{HH}$ = 2 Hz, OCH_2), 5.53 (s, 1H, C*H*bpy), 6.91 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.02 (d, 1H, $^3J_{HH}$ = 5 Hz, bpy-H5), 7.05 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.28 (dd, 1H, $^3J_{HH}$ = 8, 5 Hz, bpy-H5′), 7.79 (dt, 1H, $^3J_{HH}$ = 8 Hz, $^4J_{HH}$ = 1 Hz, bpy-H4′), 8.23 (s, 1H, bpy-H3), 8.37 (d, 1H, $^3J_{HH}$ = 8 Hz, bpy-H3′), 8.58 (d, 1H, $^3J_{HH}$ = 5 Hz, bpy-H6), 8.63 (dd, 1H, $^3J_{HH}$ = 5 Hz, $^4J_{HH}$ = 1 Hz, bpy-H6′). ^{13}C NMR δ: 54.90 (*C*Hbpy), 55.77 (O*C*H_2), 75.53 (C≡*C*H), 78.50 (*C*≡CH), 114.83, 130.27, 135.39, 156.30 (C_6H_4), 121.27 (bpy-*C*3′), 121.95 (bpy-*C*3), 123.66 (bpy-*C*5′), 124.40 (bpy-*C*5), 136.87 (bpy-*C*4′), 149.08 (bpy-*C*6′), 149.23 (bpy-*C*6), 154.32, 156.00, 156.15 (bpy-*C*2, -*C*2′, -*C*4). EI-MS (*m*/*z*) calcd. for $C_{29}H_{22}N_2O_2$: 430.1681; found: 430.1674.

Digold(I) diacetylide 3a

To a solution of [AuCl(SMe_2)] (0.73 g, 2.48 mmol) in THF (40 mL) and MeOH (30 mL) was added a solution of **2a** (0.44 g, 1.31 mmol) and Et_3N (0.2 mL) in THF (5 mL). The mixture was stirred for 30 min, and the pale yellow precipitate of the product was isolated by filtration, washed with THF, MeOH, and ether, and dried under vacuum. Yield: 0.86 g (88%). IR (KBr disc, cm^{-1}): 2000 ν(C≡C). Anal. calcd. for $C_{24}H_{17}Au_2NO_2$: C 38.68, H 2.30, N 1.88; found: C 38.21, H 2.00, N 1.69.

Digold(I) diacetylide 3b

This was prepared similarly and isolated as a beige solid. Yield: 95%. IR (KBr disc, cm^{-1}) : 2013 ν(C≡C). Anal. calcd. for $C_{24}H_{17}Au_2NO_2$: C 38.68, H 2.30, N 1.88; found: C 39.14, H 2.05, N 2.34.

(2-C_5H_4N)CH(4-$C_6H_4OCH_2C{\equiv}CAuC{\equiv}N$-*t*-Bu)$_2$

A mixture of **3a** (0.075 g, 0.10 mmol) and *t*-BuNC (22 mL, 0.195 mmol) in CH_2Cl_2 (10 mL) was stirred for 3 h. The mixture was filtered through Celite, the volume was reduced to 2 mL under vacuum, and pentane (10 mL) was added to precipitate the product as a pale yellow solid. Yield: 0.07 g (90%). IR (KBr disc, cm^{-1}): 2228 ν(N≡C), 2141 ν(C≡C). ^1H NMR (CD_2Cl_2) δ: 1.54 (s, 18H, Bu), 4.73 (s, 4H, OCH_2), 5.53 (s, 1H, C*H*py), 7.89 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.08 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.11–7.13 (m, 2H, py-H3 + py-H5), 7.62 (m, 1H, py-H4), 8.55 (d, 1H, $^3J_{HH}$ = 5 Hz, py-H6). Anal. calcd. for $C_{34}H_{35}Au_2N_3O_2$: C 44.80, H 3.87, N 4.61; found: C 44.71, H 3.30, N 4.56.

(4-C_5H_4N)CH(4-$C_6H_4OCH_2C{\equiv}CAuC{\equiv}N$-*t*-Bu)$_2$

This was prepared in a similar way from **3b** (0.075 g, 0.10 mmol). Yield: 0.065 g (71%). IR (KBr disc, cm^{-1}): 2226 ν(N≡C), 2139 ν(C≡C). ^1H NMR (CD_2Cl_2) δ: 1.54 (s, 18H, Bu), 4.73 (s, 4H, OCH_2), 5.53 (s, 1H, Chpy), 7.89 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.08 (d, 4H, $^3J_{HH}$ = 9 Hz, C_6H_4), 7.11–7.13 (m, 2H, py-H3 + py-H5), 7.62 (m, 1H, py-H4), 8.55 (d, 1H, $^3J_{HH}$ = 5 Hz, py-H6). MALDI-TOF MS *m*/*z*: 912 $[P + H]^+$. Anal. calcd. for $C_{34}H_{35}Au_2N_3O_2$: C 44.80, H 3.87, N 4.61; found: C 45.28, H 3.63, N 4.67.

Macrocyclic complex 4a (R = 2-pyridyl, Z = C≡C)

A mixture of **3a** (0.05 g, 0.067 mmol) and $Ph_2PCCPPh_2$ (0.023 g, 0.058 mmol) in CH_2Cl_2 (10 mL) was stirred for 1 h. The mixture was filtered through Celite, the volume was reduced to 2 mL under vacuum, and pentane (10 mL) was added to precipitate the product as a cream solid. Yield: 0.057 g (85%). IR (KBr disc, cm^{-1}): 2133 ν(C≡C). ^1H NMR (CD_2Cl_2) δ: 4.78 (s, 4H, OCH_2), 5.53 (s, 1H, C*H*py), 7.00 (d, 4H, $^3J_{HH}$ = 8 Hz, C_6H_4), 7.08–7.13 (m, 6H, C_6H_4 + py-H3 + py-H5), 7.45–7.62 (m, 13H, P*Ph* + py-H4), 7.67–7.82 (m, 8H, P*Ph*), 8.53 (d, 1H, $^3J_{HH}$ = 4 Hz, py-H6). ^{31}P NMR δ: 18.85 (s). ESI-MS *m*/*z*: 1272 [**4a** + Cs^+]. Anal. calcd. for $C_{50}H_{37}Au_2O_2NP_2$: C 52.69, H 3.27, N 1.23; found: C 52.21, H 2.91, N 1.28. The following complexes were similarly prepared.

Macrocyclic complex 4b (R = 4-pyridyl, Z = C≡C)

Pale orange solid. Yield: 85%. IR (KBr disc, cm^{-1}): 2132 ν(C≡C). ^1H NMR (CD_2Cl_2) δ: 4.80 (s, 4H, OCH_2), 5.40 (s, 1H, C*H*py), 6.92–7.04 (m, 10H, C_6H_4 + py-H3 + py-H5), 7.46–7.60 (m, 12H, P*Ph*), 7.68–7.78 (m, 8H, P*Ph*), 8.44 (d, 2H, $^3J_{HH}$ = 5 Hz, py-H2 + py-H6).^{31}P NMR δ: 18.82 (s). Anal. calcd. for $C_{53}H_{47}Au_2O_2NP_2$: C 53.68, H 3.99, N 1.18; found: C 53.94, H 3.74, N 1.23.

Synthesis from t-BuNC derivatives — 6a/6a*

To a solution of (2-C_5H_4N)CH(4-$C_6H_4OCH_2C{\equiv}CAuC{\equiv}N$-*t*-Bu)$_2$ (0.022 g, 0.024 mmol) in CH_2Cl_2 (10 mL) was added $Ph_2P(CH_2)_3PPh_2$ (0.01 g, 0.023 mmol). The mixture was stirred for 1 h, the volume was reduced to 2 mL, and pentane (10 mL) was added to precipitate the product. Yield: 0.024 g (89%). Spectroscopic data were as described above for **6a/6a***. **6b/6b*** (90%), **7a** (73%), and **8a** (65%) were similarly prepared.

Macrocyclic complex 6c and [2]catenane 6c* (R = 4-(2,2′-bipyridyl), Z = $(CH_2)_3$)

To a solution of [Au_2Cl_2(μ-$Ph_2P(CH_2)_3PPh_2$)] (0.505 g, 0.58 mmol) in CH_2Cl_2 (20 mL) was added AgO_2CCF_3 (0.254 g, 1.15 mmol). The mixture was stirred for 2 h, then filtered through Celite to remove AgCl. The filtrate was added to a solution of **2c** (0.58 mmol) and Et_3N (3.2 mL) in CH_2Cl_2 (40 mL) at –78 °C, and the mixture was stirred for 2 h then allowed to warm to room temperature. The organic phase was washed with water (50 mL), then dried over $MgSO_4$, and the volume was reduced to 5 mL, and pentane (80 mL) was added to precipitate the product as a pale-orange solid, identified as a mixture of **6c** and **6c***. Yield: 73%. Recrystallization from CH_2Cl_2–pentane gave the pure [2]catenane as a white solid. IR (KBr disc, cm^{-1}): 2132

X-ray crystal structure determinations

Crystals of **6a***·$Cl(CH_2)_2Cl$ were grown by slow diffusion of hexane into a solution of **6a*** in 1,2-dichloroethane. Similarly, crystals of **6b***·CH_2Cl_2 were obtained from dichloromethane–pentane; crystals of **6c***·H_2Cl_2 from dichloromethane–hexane; and crystals of **7a*** from 1,2-dichloroethane – diethyl ether. Data were collected using a Nonius Kappa-CCD diffractometer with Mo-Kα radiation (λ = 0.710 73 Å) at 150 K with COLLECT software (47). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out with the DENZO package (47). The data were scaled using SCALEPACK (47). The SHELXTL-NT V6.1 package (47) was used to solve the structures of **6a***, **6b***, and **6c*** by direct methods, and to solve the structure of **7a*** by Patterson methods. The structure solutions were followed by successive difference Fourier transformations and refined with full-matrix least-squares on F^2. Non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated geometrically, riding on their respective carbon atoms. Crystal data and refinement parameters are listed in Table 1.[3]

2-pyCH(C$_6$H$_4$OH)$_2$

No crystallographic complexity.

6a*·C$_2$H$_4$Cl$_2$

There was disorder associated with the acetylide ligands and they were modeled as 50/50 isotropic for one ring of the [2]catenane and as 65:35 for the other ring of the [2]catenane.

6b*·3CH$_2$Cl$_2$

The molecule showed no disorder. There were three dichloromethane molecules of solvation: one was refined anisotropically, one was refined isotropically, and one was disordered. The disordered dichloromethane molecule was modeled as a 55:45 mixture of isotropic atoms complete with hydrogens. The C—Cl distance was fixed at 1.65 Å, and some of the Cl—Cl distances were fixed at 2.74 Å.

6c*·CH$_2$Cl$_2$

The molecule showed some disorder for the bipyridyl–diacetylide ligands. For one ring of the [2]catenane, the bipyridyl group was modeled as a 51:49 isotropic mixture; in the other ring of the [2]catenane, there was more extensive disorder and the bipyridyl group and one phenylene group were modeled as a 51:49 mixture. There were three

sites of solvation that were modeled isotropically at reduced occupancy (site 200 (15%:10%); site 300 (25%); site 400 (25%:25%)) with fixed bond distances.

7a*

The [2]catenane was 50:50 disordered as a result of an inversion centre at the midpoint of the Au(1)···Au(1A) vector, with all other atoms at 50% occupancy. In addition, 50:50 disorder of the individual pyCH(C_6H_4)$_2$ groups was observed. Because of the extensive disorder, only the gold and phosphorus atoms were refined with anisotropic parameters.

Hydrothermal synthesis, crystal structure, and vibrational and Mössbauer spectra of a new tricationic orthophosphate — $KCo_3Fe(PO_4)_3$[1]

Hassane Assaaoudi, Zhen Fang, Dominic H. Ryan, Ian S. Butler, and Janusz A. Kozinski

Abstract: Crystals of a new potassium cobalt(II) iron(II) triorthophosphate salt, $KCo_3Fe(PO_4)_3$, as well as amorphous nanoparticles of the same material have been produced by hydrothermal reactions, under supercritical water (SCW) conditions, of equivalent quantities of aq. $CoCl_2 \cdot 6H_2O$ (2 mol/L) and $K_4P_2O_7$ (1 mol/L) in concd. HCl in a stainless steel batch reactor at 400–450 °C and 25–32 MPa. The dark-violet crystals of the new salt have been characterized by single-crystal X-ray diffraction and IR, Raman, and Mössbauer spectroscopy. The Fe(II) in the new orthophosphate salt must derive from leaching of iron from the stainless steel walls of the reactor by concd. HCl under the SCW conditions. The salt crystallizes in the orthorhombic space group *Pnnm*, $Z = 4$, with unit cell parameters as follows: $a = 9.672(1)$ Å, $b = 16.457(2)$ Å, $c = 6.2004(8)$ Å, $V = 986.97$ Å^3. Microporous $KCo_3Fe(PO_4)_3$ exhibits infinite chains of corner-sharing [PO_4^{3-}], [FeO_6], and [CoO_5] units, which form two large rhombus tunnels, occupied by K^+ ions, running parallel to [100] in the unit cell. The vibrational spectra have been interpreted partly on the basis of factor group effects and are in accord with the centrosymmetric structure of the material. The particle sizes of this new nanomaterial and their distribution have been determined by scanning electron micrography and laser scattering particle size distribution analysis, while the amorphous nanomaterial has also been characterized by X-ray powder diffraction and Raman spectroscopy.

Key words: crystal structure, vibrational and Mössbauer spectra, orthophosphate, nanomaterial.

Résumé : Les cristaux du nouveau sel tri-orthophosphate de potassium, cobalt(II) et fer(II), $KCo_3Fe(PO_4)_3$, ainsi que des nano particules amorphe du même matériel, ont été produites par réactions hydrothermal dans des conditions supercritique de l'eau. Ils sont obtenus à partir d'un mélange équimolaire des solutions aqueuses $CoCl_2 \cdot 6H_2O$ (2 mol/L), et $K_4P_2O_7$ (1 mol/L), en milieu acide HCl concentré dans un tube en acier inoxydable à températures 400–450 °C, et à pression 25–32 MPa. Les cristaux violets foncés du nouveau sel ont été caractérisés par diffraction des rayons-X sur monocristal, et par spectroscopie IR, Raman et Mössbauer. Le Fe(II) du nouveau sel d'orthophosphate provient d'une infiltration à partir de la parois interne du réacteur en acier inoxydable, sous l'effet de l'acide HCl concentré dans les conditions supercritique de l'eau. Le sel cristallise dans le système orthorhombique de groupe d'espace *Pnnm*, avec $Z = 4$. Les paramètres cristallographiques de la maille sont : $a = 9.672(1)$ Å, $b = 16.457(2)$ Å, $c = 6.2004(8)$ Å, $V = 986.97$ Å^3. La structure microporeuse de $KCo_3Fe(PO_4)_3$ se présente sous forme de chaînes formées des groupements [PO_4^{3-}], [CoO_5] et [FeO_6]. Ils partageant des atomes en commun, créant ainsi deux larges tunnels par maille élémentaire. Ils sont alignés le long de l'axe [100], en forme rhomboèdre, logés par des cations K^+. Les spectres de vibration ont été interprétés en utilisant l'analyse du groupe facteur des groupements PO_4^{3-}. L'absence de coïncidence entre la plupart des fréquences de vibrations IR et Raman est en accord avec la structure centro-symétrique du matériau. La taille et la répartition des nouvelles nanoparticules amorphes ont été déterminées par la micrographie SEM, et l'analyseur de distribution de taille des particules par diffusion laser. Ce matériau est caractérisé par diffraction des rayons-X sur poudre et par spectroscopie Raman.

Mots clés : structure cristalline, spectres de vibration et Mössbauer, orthophosphate, nanomatériau.

Fig. 1. Evolution of products obtained from reaction under SCW conditions (450 °C, 32 MPa, and vol(HCl):vol(Co) = 2:5) after 5, 30, 60, and 120 min.

Introduction

Hydrothermal synthesis has been carried out since the end of the 19th century, mainly in the production of synthetic minerals to imitate natural geothermal processes (1, 2). More recently, both near-critical and supercritical water (SCW) have been used as reaction media for the synthesis of highly crystalline metal oxides (2–5). The use of the SCW approach has only just been demonstrated for phosphate materials in the formation of highly crystalline, micro-sized particles of $LiFePO_4$ (6). Numerous orthophosphates built from discrete PO_4^{3-} tetrahedra (7) have been characterized over the past 20 years, prompted by the discovery of the vast structural variety in aluminum, beryllium, and zinc phosphates. Some new potassium–iron and potassium–cobalt triorthophosphates have also been described, e.g., $KCo_4(PO_4)_3$ (8), $KFe_4(PO_4)_3$ (9), and $K_3Fe_2(PO_4)_3$ (10), and can be obtained from molten mixtures of Co(II) or Fe(II) sulfates or oxides and KBr or KCl in the presence of potassium hydrogen phosphate, at 350 °C and 1000 atm (1 atm = 101.325 kPa). Several cobalt and iron phosphates with similarities to open mineral-type frameworks have also been reported (11, 12).

The design, synthesis, and characterization of new micro- and nano-porous materials, such as polyphosphates, is of enormous interest because of the many potential industrial applications, e.g., heterogeneous catalysis, gas absorption, and ion exchange. Micro- and nano-porous catalysts often display high selectivity because the channel apertures may allow only certain reactants to access the catalytically active interior of the material and only certain products to leave (13, 14). Transition-state selectivity may also be related to the position and degree of substitution of catalytically active sites in the framework structure, where the active site can be a transition metal that might function by selective oxidation, e.g., Fe(II) and Co(II) (15). Further knowledge of the mechanism by which transition metals substitute into the framework structures of porous materials is, therefore, of considerable importance, both for controlling the number of catalytically active sites in such materials and also for fine tuning their function by manipulating the specific positions and coordination environments of the active centers (16).

In this paper, we present analytical, structural, and spectroscopic data for a new crystalline, open framework, tricationic orthophosphate salt, $KCo_3Fe(PO_4)_3$, and amorphous nanoparticles of the same material produced under SCW conditions. The effects of temperature, pH, and reaction time on the size and size distribution of the particles have also been investigated.

Experimental section

Synthesis

Crystals of $KCo_3Fe(PO_4)_3$, as well as nanoparticles of the same material, were obtained from the reaction between equivalent amounts of aqueous cobalt $CoCl_2{\cdot}6H_2O$ (2 mol/L) and $K_4P_2O_7$ (1 mol/L) in a predetermined volume of concd. HCl (35%), (vol(HCl):vol(Co) = 2:5 or 3:5). The final red solution obtained was transferred quickly to a stainless steel batch reactor (volume = 6 mL; length = 105 mm, o.d. = 12.7 mm (1/2 in)). Both temperature and pressure were measured with a pressure transducer fitted with a J-type thermocouple (Dynisco E242). The pressure was also calculated by first calculating the density of water ((weight of water added)/(volume of batch reactor) ≈ 1.6 g/mL), assuming that only water contributed to the pressure. Bassett et al. (17) have compared the pressures obtained by such calculations with the *P–T* boundary of the α–β transition in quartz and have shown that the pressure difference is less than 4% between the two methods. Approximately 1 mL of the final solution was loaded into the reactor, which, after being sealed and connected to a data acquisition system, was submerged in a fluidized sand bath (Omega FSB- 3) or placed into a tubular furnace. The reactor was heated at a rate of 3.5 °C/s to 400–450 °C and then held at this temperature for 5, 10, 30, 60, or 120 min. After each given period, the reactor was quenched in cold water, and the reaction mixture was emptied into a flask. The reactor was washed with water, and the washings were added to the same flask. The solution in the flask was filtered through a membrane filter to yield a solid phase, which was dried at room temperature. Well-shaped, dark-violet crystals (Fig. 1) were produced under the conditions reported in Table 1. The aqueous phase was left at room temperature for about 1 to 2 h, after which a grey-violet powder appeared, which was subsequently filtered and analyzed (Table 1).

Spectroscopic and crystallographic analyses

The powders obtained in the experiments were characterized by X-ray powder diffraction (XRD),[3] ICP chemical analyses, scanning electronic microscopy (SEM), and Raman spectroscopy. Crystalline $KCo_3Fe(PO_4)_3$ was analyzed by SEM and X-ray energy dispersive analysis (EDS) and was further characterized by IR, Raman, and Mössbauer spectroscopy, as well as by single-crystal X-ray diffraction.

A Philips model PW1710, vertical goniometer, X-ray powder diffractometer with a Cu Kα radiation source was used for the powder diffraction measurements. The samples were scanned over the range from 5° or 10° to 60° at a step size (2θ) of 0.02° and a measurement time of 0.5 s/step. Chemical analyses were performed using ICP-AES on a Thermo Jarrell Ash TraceScan axial torch sequential ICP system. The morphology of the particles was investigated using a field emission SEM (model JSM-840), while EDS (model EDAX) was used to characterize the materials (powder and crystals). The size distribution of the particles was determined using a laser scattering particle size distribution analyzer (model Horiba LA-920), which can measure particle size distributions over a wide range of sizes — from 0.02 to 2000 μm — in dry or slurry form.

Infrared spectra were recorded at ambient temperature on a Bomem MB100 FT-IR spectrometer at 2 cm^{-1} resolution (50 scans), using the KBr pellet technique. The wavenumber accuracy is considered to be within ±1 cm^{-1} for sharp bands. Raman spectra were measured on a Renishaw 3000 Raman microscope (20× objective), using the 514.5 nm line of an Ar^+-ion laser for excitation (5–100 mW laser power; 1 cm^{-1} spectral slit width; 5 s exposure time; 10 accumulations). The band positions are considered to be accurate to at least ±1 cm^{-1}. The Mössbauer effect measurements were made at room temperature with a Wissel spectrometer. The spectra were recorded using the radiation from ^{57}Co in Rh with a 512 multichannel analyzer. The velocity was calibrated using iron metal as a standard.

A summary of the X-ray data collection and refinement is given in Table 2. A Bruker D8 Discover diffractometer was used for examination of the crystal. The structure was solved by direct methods using SHELXS97 (19) and was refined by a full-matrix, least-squares technique, SHELXL97 (20). The molecular drawings obtained with ORTEP III (21) were manipulated using the WINGX system of programs (22) and the program Molview (23). The X-ray data resulted in the formula $KCo_3Fe(PO_4)_3$ for the compound after checking the final residuals R, R_w ($I > 2\sigma(I_{obs})$), and GOF for different ratios of Co and Fe atoms and taking anisotropic thermal parameters into account.

Results

Identification of materials

The XRD patterns of the powders obtained from the SCW reactions under the conditions reported in Table 1 showed that the materials were amorphous. The Fe, Co, K, and P analyses of these powders were performed using ICP-AES. The results obtained correspond to the composition shown in Table 1. The morphology of the particles and the distribution of their sizes were determined by SEM (Fig. 2*a*). The composition of crystalline $KCo_3Fe(PO_4)_3$ and the powder were determined using EDS analysis, and the results showed that their compositions were essentially identical except for the amount of Co present (Figs. 2*b* and 2*c*) because, irrespective

of the SCW experimental conditions employed, the powders obtained did not contain any Co. The carbon peak in Figs. 2*b* and 2*c* is associated with the agent used to immobilize the particles for analysis. The powder nanoparticles are spherical, and the particle size ranges from 100 to 800 nm, with an average size of about 500 nm (Fig. 2*a*).

Iron(III) has five electrons in the 3d valence subshell, which makes it spherically symmetric, thereby practically eliminating any electric field gradient and quadrupole splitting (QS). On the other hand, Fe(II) has one extra electron in the 3d valence subshell, thus introducing an asymmetry resulting in an electric field gradient and a detectable QS. From the Mössbauer effect measurements undertaken in this work (Fig. 3), the values obtained for both the isomer shift (IS) and the QS for the iron atoms present in the new orthophosphate material are typical of Fe(II) (24). The expected Fe(II) doublet is observed with IS = 1.2 and QS = 2.9 mm/s. This definitive demonstration of the presence of Fe(II) means that the cobalt atoms in $KCo_3Fe(PO_4)_3$ must be in the Co(II) state to charge compensate for the three PO_4^{3-} ions. The Fe(II) ions must have been produced by iron being leached from the stainless steel walls of the reactor by concd. HCl under the SCW conditions employed.

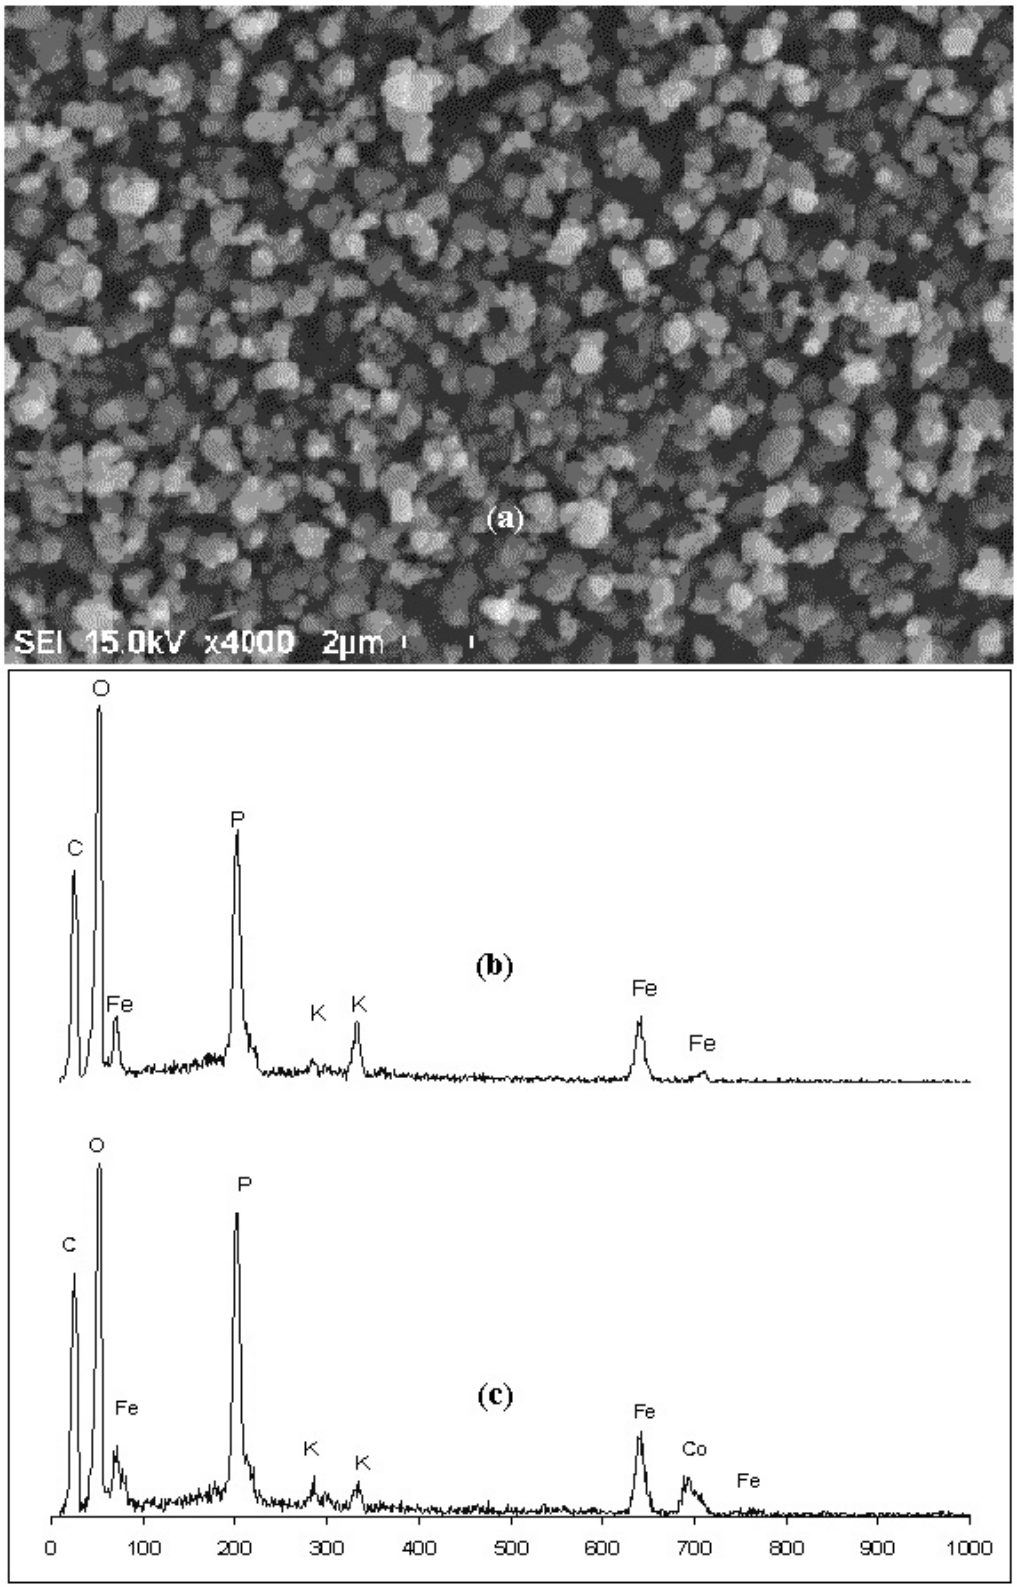
Effect of synthesis temperature

Two temperatures under SCW conditions (400 and 450 °C) were investigated. From the quantity of crystals obtained at these two different temperatures, the production of crystalline $KCo_3Fe(PO_4)_3$ was much more favorable at 450 °C than at 400 °C. The particles produced at 450 °C (with all the other conditions being kept constant) have a slightly narrower size distribution than do those obtained at 400 °C (Fig. 4*a*). This figure also shows that the particles decrease in size with increasing temperature, although the size distribution is quite broad.

Effect of pH

The effect of pH was investigated by adjusting the amount of HCl added. The reaction between equivalent quantities of aqueous cobalt $CoCl_2{\cdot}6H_2O$ (2 mol/L) and $K_4P_2O_7$ (1 mol/L) was limited by the amount of concd. HCl that could be added while avoiding instantaneous precipitation from solution and yet still permitting synthesis of $KCo_3Fe(PO_4)_3$ crystals under SCW conditions (vol(HCl):vol(Co) = 2:5 and 3:5). The particles synthesized at a vol(HCl):vol(Co) ratio of 3:5 tended to exhibit a narrower size distribution than did those obtained for a vol(HCl):vol(Co) ratio of 2:5. The particles had an average size range of 100 μm to submicron (Fig. 4*b*). Compared to the influence of other parameters on the particle sizes produced under SCW conditions and their distribution, the effect of pH was by far the most important.

Effect of residence time



The influence of residence time (τ) in the reactor was investigated by carrying out hydrothermal reactions at 400 °C with τ = 0, 5, 10, 30, 60, and 120 min. The vol(HCl):vol(Co) ratio was maintained at 3:5 to keep the pH of the reactant mixture constant. No significant difference in morphology was observed with changing residence time. The particles produced when τ = 120 min, however, had a narrower size distribution than did those obtained after 10 min (Fig. 4*c*). Similar results were obtained when the reaction temperature was 450 °C, with all other conditions being kept constant.

Crystal structure

The structure of the new orthophosphate is built up from [FeO_6] octahedra, [CoO_5] pentahedra, [KO_8] heptahedra, and [PO_4^{3-}] tetrahedra sharing corners and edges to form a 3-D open framework (Fig. 5). There are three crystallographically distinct P atoms, all with tetrahedral coordination, and two distinct Co atoms. The Co(2), O(3), O(4), and O(7) atoms occupy general positions. All the other atoms occupy special positions on mirror plane symmetry. Atomic coordinates and isotropic thermal parameters are given in Table 3 and selected interatomic distances in Table 4. The Co atoms are arranged in five-vertex polyhedra, like distorted square-based pyramids for both the Co(1) and Co(2) atoms. Their average bond distances are Co(1)—O_{av} = 2.056 Å and Co(2)—O_{av} = 2.084 Å; the Co atoms are surrounded by O atoms from four and five different phosphate anions, respec-

[a] U_{eq} is defined as one-third of the trace of the orthogonalized U_{ij} tensor.

tively (Table 4). The Fe coordination is tetrahedral with Fe—O in the range 1.97–2.18 Å. This tetrahedron is somewhat distorted, however, because of two additional weak Fe···O(3) and Fe···O(3)^I interactions, which are 2.316 Å in length (Table 4). Thus, the Fe coordination can be interpreted as either tetrahedral or octahedral. The latter is used in the figures for simplicity and clarity. The difference in Fe coordination observed here is similar to that in the isotype $KFe_4(PO_4)_3$ (9). The $[Co(1)O_5]$ pentahedron is more distorted than is the $[Co(2)O_5]$ one because of corner sharing via the oxygen atom O(6). But both pentahedra are less distorted than is the $[FeO_6]$ octahedron, which is involved in corner sharing via the oxygen atom O(8) and also has two weak bonds with oxygen atoms O(3) and O(3)^I. The distor-

tion indices, $[(\text{cation-O})_{max} - (\text{cation-O})_{min}]/(\text{cation-O})_{av}$ (25), for Co(1), Co(2), and Fe are 0.095, 0.059, and 0.160, respectively. The $[Co(1)O_5]$ pentahedra share cis-edges with one $[Co(2)O_5]$ pentahedron via oxygen atom O(6), which belongs to a *P*(2) tetrahedron. The $[Co(2)O_9]$ dimer has different angles from an eclipsed conformation when viewed along the Co(1)—Co(2) axis, which confers a general site symmetry to this dimer. There are additional links at the shared corners to $[FeO_6]$ via O(8) and O(3). The structure results in alternating layers of $[Co_4O_{18}]$ units in a flat "S" form (or like "∫") and its opposite face in the *ab* plane, which is linked from those ends to two $[FeO_6]$ octahedra. The K atom is surrounded by six oxygen atoms at the vertices of a distorted trigonal prism (K—O = 2.754–2.885 Å) plus two other oxygen atoms at a distance of 3.166 Å. The K atoms involve a strong network between interlayers holding the structure together. Based on the work of Dumas et al. (26), who consider the K—O threshold bond to be 3.19 Å, the K atoms in $KCo_3Fe(PO_4)_3$ can be considered to form irregular $[KO_8]$ polyhedra (distortion index = 0.142). The K^+ ion, because of its large dimensions (ionic radii = 1.38, 1.46, and 1.51 Å for coordination numbers 6, 7, and 8, respectively (27)), forms more complex polyhedra with the distortion indices being extremely variable, ranging from 0.080 up to 0.199 (28–30). As can be seen from Fig. 6*c*, alternating Co, Fe, and P polyhedra form two large rhombus tunnels, occupied by K^+ ions, running parallel to < 100 > in a unit cell with diagonal lengths 5.49 Å (along the *c* axis) and 5.80 Å (along the *b* axis). Perpendicular to these axes, along the *c* axis, the structure presents other different tunnels with different shapes and sizes (Fig. 6*a*). In the previously reported crystal structures for iron phosphates, such as $LiFePO_4$ (31), Fe_2FPO_4 (32), $(Fe,Zn)_3(PO_4)_2$ (33), $Na_2(Fe_{0.5}^{3+}Fe_{0.5}^{2+})_2Fe^{2+}(PO_4)_3$ (34), $KFeFPO_4$ (35), and $KFe_4(PO_4)_3$ (9), there is

typically at least one unit cell constant that is approximately equal to six or to multiples of this value. The pertinent parameter in our case, c = 6.2004, determines the lattice spacing along the c axis of the unit cell. This value is due to chains of alternating [FeO_6] octahedra and [PO_4^{3-}] tetrahedra, linked by their vertices (Fig. 6*b*).

Vibrational spectra

The new orthophosphate salt, $KCo_3Fe(PO_4)_3$, crystallizes in the orthorhombic space group *Pnnm* (D_{2h}^{12}) with Z = 4. The P atoms lie on C_s sites. The proposed vibrational band assignments for the IR and Raman spectra of the salt are given in Table 5. The absence of the symmetric stretching and antisymmetric H–O(P) bending vibrations at ~2300 and ~1447 cm^{-1}, respectively, confirms that the salt does not contains H atoms. The nature of the four normal vibrations (ν_1, ν_2, ν_3, and ν_4 in Herzberg notation (36)) of the PO_4^{3-} groups was determined by the site group method of Halford (37), in which the normal modes of the free ion are correlated to the vibrations in the site and crystal symmetry.

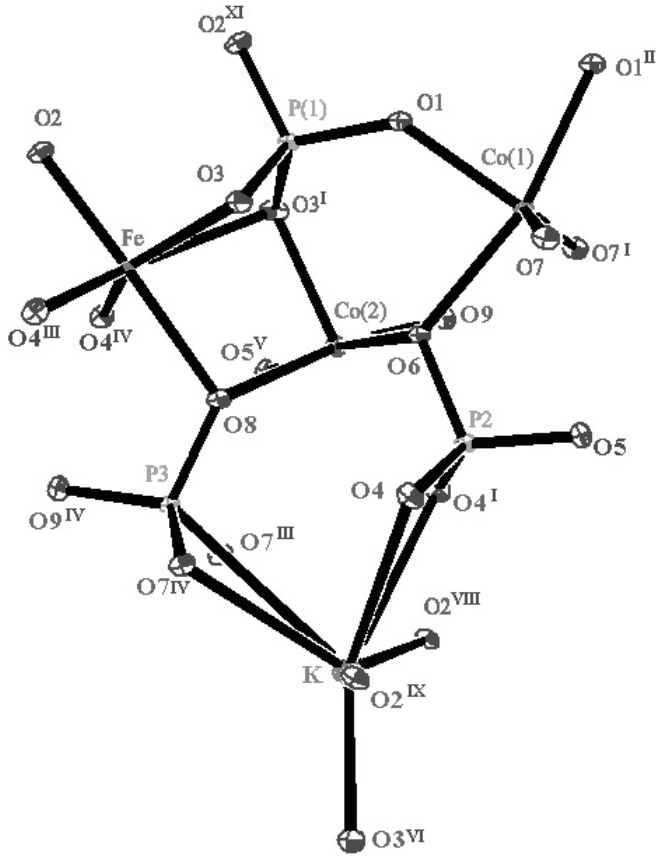
Table 5. Proposed vibrational band assignments for $KCo_3Fe(PO_4)_3$ (cm^{-1}).



IR	Raman	Assignment	
	1070	A_g+B_g	$\nu_{asym}PO$
1067		$B_{1u}+B_2u+B_{3u}$	
	1039	A_g+B_g	
980		B_{1u}	$\nu_{sym}PO$
	970	A_g	
920		B_{1u}	
	915	B_{1g}	
629	608	$B_{1u}+B_2u+B_{3u}$	$\delta_{asym}PO_2$
587	560sh		
533			
520	470sh		
439		$B_{1u}+B_2u+B_{3u}$	
	390	$A_g+B_{1g}+B_{2g}+B_{3g}$	$\delta_{sym}PO_2$
380	300		External modes
365	235		
355	205		
	180		

Theoretically, each vibrational mode of the PO_4^{3-} ions could be split into four components by dynamic coupling between the four anions in the primitive unit cell. The full influence of the site and factor groups on the internal vibrations of the PO_4^{3-} ions is, however, not observed for each mode. If the vibrations of the three different PO_4^{3-} groups were equivalent, only one vibration would be expected in both the IR and Raman spectra under the influence of the site effect. If the factor group effect is predominating, there should be two Raman bands and one IR band observed. However, two bands were observed in the Raman spectrum and another two bands in the IR spectrum, thereby confirming that the PO_4^{3-} groups are indeed different, in agreement with the crystallographic results. Finally, most of the IR bands are noncoincident with those observed in the Raman spectrum, in accord with the centrosymmetric nature of the crystal.

The Raman spectra of the amorphous powders obtained under different SCW conditions indicate the presence of orthophosphate groups, and as expected for amorphous materials, the spectra are characterized by weak, extremely broad bands and a relatively high and featureless background. The bands observed at ~1000 cm^{-1} correspond to the A_g symmetric P–O stretching mode.

Vibrational spectroscopy often plays a prominent role in the structural study of inorganic crystals, especially in cases where X-ray diffraction fails to give unequivocal results, such as for glasses and amorphous materials. The correlation between X-ray diffraction results and vibrational spectroscopy has become of practical importance. A linear empirical correlation was established recently (38) for inorganic crystalline phosphates between the wavenumbers of the Raman-active P–O stretching modes and the associated P—O bond lengths. This correlation has been tested and extended with success to glassy and amorphous phosphate materials, such as $Na_5Ti(PO_4)_3$ glass (39). The unpolarized vibrational spectra of crystals and their amorphous or glassy analogues are often quite similar because the vibrational spectra are determined largely by short-range order. There are two established empirical equations used nowadays (38) to calculate P—O bond lengths (in pm), as follows:

Fig. 5. ORTEP view of asymmetric unit with atomic numbering scheme (ellipsoids drawn at 60% probability level). Symmetry codes ^{I}: x, y, $-z$, ^{II}: $-x+1$, $-y+1$, $-z$, ^{III}: $x-1/2$, $-y+1/2$, $-z-1/2$, ^{IV}: $x-1/2$, $-y+1/2$, $z+1/2$, ^{V}: $x-1/2$, $-y+1/2$, $z-1/2$, ^{VI}: $-x+1/2$, $y-1/2$, $z-1/2$, ^{VII}: $-x+1/2$, $y-1/2$, $-z+1/2$, ^{VIII}: $x+1/2$, $-y+1/2$, $z+1/2$, ^{IX}: $x+1/2$, $-y+1/2$, $z-1/2$, ^{X}: $-x+1/2$, $y-1/2$, $-z-1/2$, ^{XI}: $-x$, $-y+1$, $-z$.

[1] $\nu = 6.3 \times 10^3 - 34.3R$

[2] $\nu_w = 224\,500 \exp(-R/28.35)$

These two equations were used in our case to predict the P—O bond lengths in the amorphous orthophosphates obtained under different SCW experimental conditions. The results agree well with the values found for other orthophosphates (Table 6). The precision in the estimation of a P—O bond length from a measured Raman wavenumber using the bond length – stretching wavenumber correlation is 1 pm. The standard deviation in the estimate of a Raman stretching wavenumber from an absolute P—O bond length is 37 cm^{-1}. The observed Raman bands exhibited slight shifts, but noticeably broadened and decreased in intensity, with the increasing SCW reaction time. For the experiment run at 450 °C for 120 min, a new phase was produced (Fig. 7*d*), which is different from those obtained previously (Fig. 7*a*–7*c*), and this material has yet to be identified.

Thermodynamic investigations of zeolites NaX and NaY[1]

Liyan Qiu, Patricia A. Laws, Bi-Zeng Zhan, and Mary Anne White

Abstract: Understanding of the thermodynamic stability of zeolites is important in the prediction of thermodynamic equilibrium. Therefore, we have undertaken an investigation of the thermodynamic stability of the zeolites NaX and NaY through heat capacity measurements from ca. 30 to 300 K. No phase transitions were observed, and zeolite NaX does not show a significant particle size effect when the particle size is reduced to ca. 30 nm. The results show that the specific heat capacity increases with the Al content in the zeolite. Both NaX and NaY are found to be thermodynamically stable with respect to their elements because of enthalpic stabilization and with slight entropic destabilization. These data are used along with literature data for many other zeolitic materials to show that the thermodynamic stability of zeolites is enhanced with increasing aluminum content.

Key words: zeolite, heat capacity, thermodynamic stability, nano effects.

Résumé : Une compréhension de la stabilité thermodynamique des zéolites est importante pour pouvoir prédire leur équilibre thermodynamique. Nous avons donc entrepris une étude de la stabilité thermodynamique des zéolites NaX et NaY par le biais de mesures de capacité calorifique entre environ 30 et 300 K. Aucune transition de phase n'a été observée et le zéolite NaX ne présente pas d'effet significatif de taille des particules lorsque cette taille est réduite jusqu'à environ 30 nm. Les résultats montrent que la capacité calorifique spécifique augmente avec la teneur en aluminium dans le zéolite. Il a été observé que les zéolites tant NaX que NaY sont thermodynamiquement stables par rapport à leurs éléments en raison d'une stabilisation enthalpique accompagnée d'une déstabilisation entropique. Ces données ont été utilisées de concert avec celles retrouvées dans la littérature pour plusieurs autres zéolites pour montrer que la stabilité thermodynamique des zéolites est rehaussée par une augmentation de la teneur en aluminium.

Mots clés : zéolite, capacité calorifique, stabilité thermodynamique, effets nano.

Introduction

Zeolites are aluminosilicates composed of TO_4 (T = Si, Al) primary building blocks, with about 100 different architectures based on vertex-sharing $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ tetrahedra (1). Zeolites are very useful materials, with applications including catalysis, ion exchange, molecular sieves, photochemistry, and solar energy conversion (2).

The large number of well-established zeolite structures offers an excellent opportunity to explore the relationships between structure and properties of materials. From a thermodynamic perspective, it is interesting that so many structures exist, with rather subtle compositional differences. Since understanding of the thermodynamic stability of zeolites is important to the prediction of thermodynamic equilibrium, we have undertaken an investigation of the thermodynamic stability of several zeolites to learn more of the generalities of their thermodynamic stability. The results are reported herein.

Zeolites and characterization

NaX

Zeolite NaX (also called zeolite X, NaX, Linde X, and molecular sieve 13X) is an analogue of the natural zeolite faujasite. Its structure is shown schematically in Fig. 1.

Zeolite NaX was purchased from Aldrich, calcined in air (4 h, T = 773 K) to remove any organic template residue, and then dehydrated in a quartz tube (24 h vacuum, T = 473 K); DSC showed <0.1 mass% water (limit of detection). Powder X-ray diffraction indicated a well-defined crystalline material with a cubic lattice parameter of 24.7701(1) Å, with the expected diffraction pattern (3) both before and after heating. From X-ray fluorescence analysis, we determined

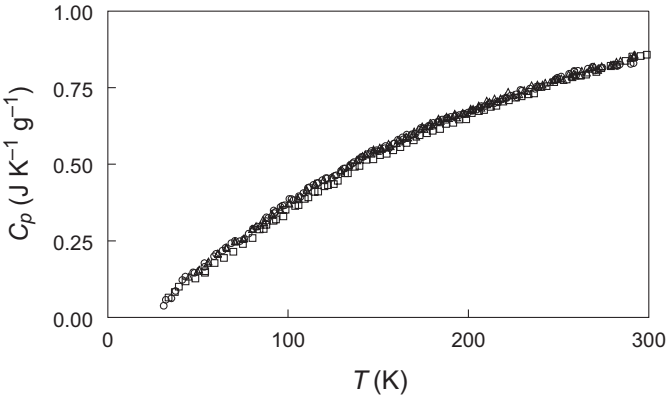
Fig. 1. Framework structure of zeolites NaX and NaY.



that the Si–Al mole ratio was 1.21 ± 0.02. The unit cell is considered to have the ideal chemical formula $Na_{87}Al_{87}Si_{105}O_{384}$. Hereafter, this sample is referred to as *bulk*-NaX.

We have recently developed techniques to produce zeolites with controlled particle sizes: nano- and micro-sized NaX were synthesized from fumed silica (11 nm, Sigma), NaOH (Aldrich), and $Al(OH)_3$ (McArthur Chemical) by these hydrothermal methods (4, 5). *Nano*-NaX was synthesized by crystallization in a shaker (rotation rate 250 rpm) at T = 60 °C for 4 days. *Micro*-NaX was synthesized by heating the fumed silica and sodium aluminate mixture at 90 °C for 2 days without shaking. The powdered products were recovered with centrifugation, washed with distilled water until pH < 8, and then dried at room temperature for 24 h. The samples were dehydrated in vacuum (3 h, T = 473 K). Power X-ray diffraction indicated well-defined crystalline materials with the same structure as for bulk-NaX. From X-ray fluorescence analysis, we found an Si–Al mole ratio of 1.25 ± 0.02 for both nano-NaX and micro-NaX, indicating an empirical formula of $Na_{85}Al_{85}Si_{107}O_{384}$.

High-resolution scanning electron microscopy (uncoated samples, Hitachi S4700 cold-field emission SEM) showed nano-NaX, micro-NaX, and bulk-NaX particle sizes in the range 20–100 nm, ≈800 nm, and ≈2 μm, respectively. Scherrer analysis (6) for the [111], [331], and [642] peaks of nano-NaX gave an average crystallite size of 23 ± 4 nm, indicating that the particles seen in the SEM are predominantly single grains. In the IR spectrum, nano-NaX is distinguished by the presence of a broad band at 860 cm^{-1}, attributed (5) to the silanol (Si-OH) bending mode for Si in a

Fig. 2. Experimentally determined heat capacities of zeolite NaX: nano-NaX (○); micro-NaX (△); bulk-NaX (□).[3]

Q^3 environment, i.e., three Si-O-T (T = Si-O-T) and one Si-O-H linkage, consistent with the high surface-to-volume ratio. The Q^3 species in nano-NaX also were confirmed by solid-state magic angle spinning ^{29}Si (single-pulse and cross-polarization) NMR spectroscopy (5).

NaY

Zeolite Y (also called molecular sieve Y and Linde Y) has the same framework topology as zeolite X, but with a higher Si–Al ratio, typically in the range 1.5 to 3.0 (compared with 1.1 to 1.5 for X). Thus, zeolite Y has fewer exchangeable cations.

Zeolite NaY (Aldrich), dehydrated as for NaX, showed no detectable water (DSC, <0.1 mass% water) and a well-defined crystalline lattice, cubic lattice parameter 24.6609(5) Å. The Si–Al ratio (X-ray fluorescence) was 2.65 ± 0.02, giving an ideal empirical formula of $Na_{53}Al_{53}Si_{139}O_{384}$.

Thermodynamic methods

The heat capacities of nano-NaX, micro-NaX, bulk-NaX, and NaY were determined using adiabatic calorimetry (7). After dehydration, all further sample handling was in vacuum or in a helium atmosphere. Sample masses for bulk-NaX, micro-NaX, nano-NaX, and NaY, respectively, were: 2.908, 2.038, 2.787, and 2.062 g. These masses are relatively small for this calorimeter and were limited by the low density of the zeolites and the volume (≈5 cm^3) of the sealed calorimeter. The small masses of the zeolitic samples here led to rather small contributions of the sample to the total heat capacity, and concomitantly large uncertainties in the heat capacities, namely ±6% for T < 100 K and ±4% for T > 100 K.

Particle size dependence in NaX

The heat capacities of bulk-NaX, micro-NaX, and nano-NaX are shown in Fig. 2.[3] All show smooth heat capacities, with no evidence of phase transitions.

Enhancement of the heat capacity of a material is expected as its particle size is decreased because of the increased motion of the surface atoms relative to the atoms in

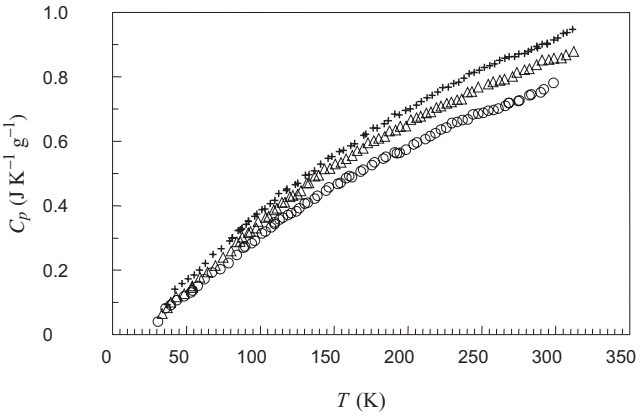
Table 1. Heat capacities of dehydrated zeolites at T = 298.15 K as a percentage of the Dulong–Petit value and Al content.

Zeolite	Formula	Al/(Al+Si)	D–P value (%)	Reference
MTT	SiO_2	0	59	15
BEA	SiO_2	0	61	15
MFI	SiO_2	0	61	16
Faujasite	SiO_2	0	61	15
NaY	$Na_{53}Al_{53}Si_{139}O_{384}$	0.276	63	Present work
nano-NaX	$Na_{85}Al_{85}Si_{107}O_{384}$	0.443	69	Present work
micro-NaX	$Na_{85}Al_{85}Si_{107}O_{384}$	0.443	70	Present work
bulk-NaX	$Na_{87}Al_{87}Si_{105}O_{384}$	0.453	70	Present work
4A	$Na_{96}Al_{96}Si_{96}O_{384}$	0.500	75	14

the bulk. However, it is not clear, a priori, how large this effect would be.

While there might be some enhancement of the heat capacity of NaX with decreasing particle size at the lowest temperatures, it appears to be similar for both nano-NaX and micro-NaX and to be at the limits of uncertainty of the experiment, given the small contribution of the samples to the total heat capacity. Although nano-NaX does exhibit an enhanced external surface area compared with micro-NaX and bulk-NaX, the internal surface area comprises the majority of the total surface area of these open framework porous materials (80% for nano-NaX and 90%–95% for micro-NaX and bulk-NaX) (5). Thus, the external surface energy would have to be significantly different from the internal surface energy to give a large difference in the heat capacity with particle size. Recent calculations have shown only a small difference between the internal and external surface energies for zeolitic materials (8). Therefore, it is not surprising that we find only a small, perhaps negligible, enhancement of heat capacity of NaX as the particle size decreases from ≈1 μm to ≈30 nm.



Dugdale et al. (9) found that the heat capacity of the rutile form of TiO_2 was enhanced only up to 3% for 14 nm particles, in comparison with the bulk. While there has been a report of 6%–11% enhancement of the heat capacity of zeolite ZSM-5 (75 nm particles, compared with 1 μm) (10), TGA characterization of that sample appears to show water loss, indicating incomplete dehydration, which also could account for the apparent heat capacity enhancement. A report of significant (≈20%) enhancement of the heat capacity of the anatase form of TiO_2 with ca. 15 nm particles (11, 12) has been shown to be unphysical and likely owing to a few % of adsorbed water (13).

Relationship between Al content and heat capacity

The heat capacity of NaY as a function of temperature is shown in Fig. 3,[3] in comparison with the heat capacities of bulk-NaX and zeolite 4A (14). Again, the heat capacity of NaY is smooth, showing no evidence of any phase transition in this temperature range. However, it is considerably less than that of NaX or zeolite 4A, for reasons we now consider.

The T = 298.15 K heat capacities of several well-characterized zeolites are presented in Table 1 as a percentage of the Dulong–Petit value and as a function of Al content. The results indicate that the heat capacity increases

Fig. 3. Experimentally determined heat capacities of zeolites: 4A (+) (14); NaX (bulk) (△);[3] and NaY (○).[3]

(vibrational modes are more excited) as the Al content increases. This can be understood in terms of lattice dynamics, considering that the Si—O bond is stiffer than the Al—O bond (17, 18). Therefore, for a given temperature, the vibrational modes will be more activated in zeolites with higher Al content.

The trend of changing heat capacity with Al content also can be understood by estimating the heat capacity by the constituent additivity method (19). This method is based on consideration of the heat capacity of the complex inorganic compound as a combination of the contributions of simpler constituents. At T = 298.15 K, the heat capacities of the constituents for zeolites containing sodium as the charge-balancing cation are as follows: $C_p(SiO_2)$ = 44.97 J K^{-1} mol^{-1} (20), $C_p(Al_2O_3)$ = 78.80 J K^{-1} mol^{-1} (21), and $C_p(Na_2O)$ = 69.10 J K^{-1} mol^{-1} (22). As the proportion of Al increases in a zeolite, the concentration of Na^+ also must increase to balance the framework charge. Therefore the contributions to the specific heat capacity from Al_2O_3 and Na_2O will also increase, resulting in an overall increase in heat capacity.

Thermodynamic stability

The availability of temperature-dependent heat capacities of these zeolites allows quantification of their thermodynamic functions, as presented in Tables 2 and 3.

Using a method similar to the constituent additivity for heat capacity, we can calculate the Gibbs energy of formation of NaX based on the values for zeolitic SiO_2 and

Note: The required extrapolation of the heat capacity to $T = 0$ K was carried out by fitting the data below 100 K to the function $C_v/3R = mC_E + nC_D$, where C_E and C_D are, respectively, Einstein and Debye heat capacity functions represented by their characteristic temperatures, θ_E and θ_D. Here $m = 166$, $n = 497$, $\theta_E = 579 \pm 5$ K, and $\theta_D = 227 \pm 2$ K.

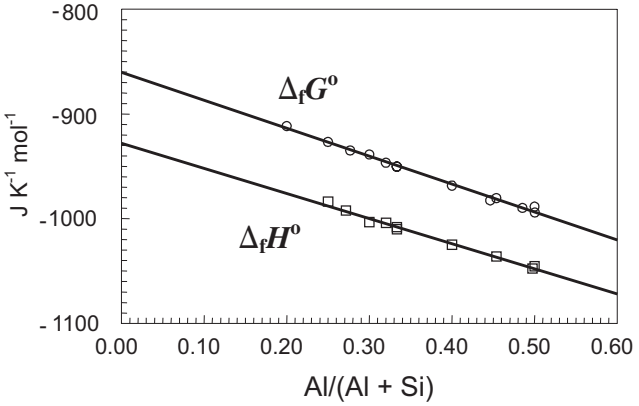
Note: The required extrapolation of the heat capacity to $T = 0$ K was carried out as for NaX, with $m = 157$, $n = 472$, $\theta_E = 629 \pm 8$ K, and $\theta_D = 236 \pm 3$ K.



$Na_2O{\cdot}Al_2O_3$ (23). This gives $\Delta_f G°$(NaX, $Na_{87}Al_{87}Si_{105}O_{384}$) of $–(1.866 \pm 0.002) \times 10^8$ J mol^{-1}, in excellent agreement (within 0.2%) of the value from solubility studies (24). Similarly, the Gibbs energy of formation of NaY can be determined from the present NaX value and SiO_2 (23), giving $\Delta_f G°$(NaY, $Na_{53}Al_{53}Si_{139}O_{384}$) = $–(1.791 \pm 0.002) \times 10^8$ J mol^{-1}.

The entropies of formation for NaX and NaY can be calculated from the data for the elements (22, 23, 25–28) along with the present entropy data, correcting for residual entropy for random Si–Al disorder (S_0(NaX) = 5.79 J K^{-1} mol^{-1}; S_0(NaY) = 4.96 J K^{-1} mol^{-1}). This gives $\Delta_f S°$(NaX, $Na_{87}Al_{87}Si_{105}O_{384}$) = –36.52 ± 0.06 kJ K^{-1} mol^{-1} and $\Delta_f S°$(NaY, $Na_{53}Al_{53}Si_{139}O_{384}$) = –38.43 ± 0.06 kJ K^{-1} mol^{-1}.

Combining these results, we determined $\Delta_f H°$(NaX, $Na_{87}Al_{87}Si_{105}O_{384}$) = $–(1.97 \pm 0.002) \times 10^8$ J mol^{-1} and $\Delta_f H°$(NaY, $Na_{53}Al_{53}Si_{139}O_{384}$) = $–(1.91 \pm 0.002) \times 10^8$ J K^{-1} mol^{-1}. Therefore, we see that the thermodynamic stability of both zeolites NaX and NaY arise from enthalpic and not entropic factors.

It is qualitatively known that thermodynamic stability of zeolites depends on the Si–Al ratio (29), but it appears that there are few quantitative discussions of this matter. In Fig. 4, the values of $\Delta_f G°$ and $\Delta_f H°$ of some dehydrated zeolites (synthetic and natural) and related materials with different Si–Al ratios are presented.[3] The values of the thermodynamic functions depend more strongly on the Si–Al ratio than on the structural details. (Similarly, the thermodynamic stability of pure silica molecular sieves has been found to be nearly independent of structure (30). For exam-

Fig. 4. Thermodynamic formation functions for zeolites as a function of Al content based on the general formula $Na_xAl_xSi_{(1-x)}O_2$, expressed per mol of x. See deposited[3] Table S5 for data and references.

© 2006 NRC Canada

ple, the natural zeolite analcime has almost the same Gibbs energy of formation as the nonzeolitic jadeite (Al/(Al + Si)) = 0.333 and 0.320; $\Delta_f G°$ = –946.6 and –950.3 kJ mol^{-1}, respectively). Overall, the relationship can be expressed in kJ mol^{-1} as:

[1] $\Delta_f G° = -859.6 - 268.4\ [Al/(Al + Si)]$

where the intercept, corresponding to SiO_2, is –860 ± 7 kJ mol^{-1}, very close to the $\Delta_f G°$ of quartz, –856.4 kJ mol^{-1} (22).

The enthalpy of formation of zeolites (Fig. 4) also exhibits a linear relationship with the Al content, which can be expressed in kJ mol^{-1} as:

[2] $\Delta_f H° = -921.4 - 258.3\ [Al/(Al + Si)]$

and again the SiO_2 intercept, –921 kJ mol^{-1}, corresponds well to the $\Delta_f H°$ of quartz, –910.0 kJ mol^{-1} (22).

In Fig. 4, the difference between $\Delta_f G°$ and $\Delta_f H°$ represents the entropy change in the formation of the zeolites, $T\Delta_f S°$. It can be seen that the entropy change is negative, and hence entropy factors decrease the thermodynamic stability of zeolites. Therefore, the thermodynamic stability of zeolites comes from the enthalpic effect, not the entropic effect. Equations [1] and [2] indicate that the entropic effect is almost independent of Al–Si ratio, but not negligible.

From Fig. 4, it can be seen that increasing the aluminum content increases the thermodynamic stability of zeolites. As Si^{4+} is replaced by Al^{3+}, the framework requires more nonframework cations (e.g., Na^+) to compensate. Since the Gibbs energy of formation of 1 mol of SiO_2 (–865.4 kJ mol^{-1} for quartz (22)) is less negative than that of (0.5 mol Al_2O_3 + 0.5 mol Na_2O), –980.7 kJ mol^{-1} (22), increasing the concentration of Al^{3+} decreases the Gibbs energy and, hence, increases the thermodynamic stability of the zeolite. Similar results were found for the dehydrated sodium faujasite frameworks with different Si–Al ratios at T = 977 K (31). An important related matter is that templates are required to synthesize high-Si-content zeolites because they are not as thermodynamically favoured as lower-Si-content zeolites. This finding also reconciles the fact that natural zeolites generally have higher Al content. Furthermore, DTA experiments show (31) that the decomposition temperature of zeolites increases with increasing Si content. This is because Si—O bonds are stronger than Al—O bonds. In this case, thermodynamic stability relative to the constituent elements also corresponds with overall thermal stability.

For further comparison, the formation of relevant proportions of Na_2O, SiO_2, and Al_2O_3 has been considered (as in Fig. 4), and the results are as follows:

[3] $\Delta_f G° = -857 - 123\ [Al/(Al + Si)]$

and

[4] $\Delta_f H° = -912 - 135\ [Al/(Al + Si)]$

indicating the following: lesser thermodynamic stability than the zeolites; enthalpic (not entropic) stability; less dependence of $\Delta_f G°$ and $\Delta_f H°$ on the Al–Si ratio than for the zeolites; nearly the same entropy of formation as the zeolites and with similar independence of the Al–Si ratio.

Conclusions

Experimental heat capacity measurements of zeolite NaX do not show a significant particle size effect. The present measurements show that the specific heat capacity increases with the Al content in the zeolite. Both NaX and NaY are found to be thermodynamically stable with respect to their elements, owing to enthalpic stabilization, with slight entropic destabilization. These data are used along with literature data for many other zeolitic materials to show that the thermodynamic stability of zeolites is enhanced with increasing aluminum content.

Two new high-nuclearity copper(II) chloride oligomers with herringbone stacking patterns synthesized by in situ templation[1]

Zhiyong Fu and Tristram Chivers

Abstract: The use of trichloroiminophosphoranes $Cl_3P{=}NR$ to control the concurrent release of the templating cation $[RNH_3]^+$ and chloride ligand via in situ P—N and P—Cl bond cleavage produced two new copper(II) chloride oligomers. The nature of the organic substituent R was a factor in determining the chain lengths. For *n*-propyltrichloroiminophosphorane, the hexanuclear cluster $[n\text{-}PrNH_3]_2[Cu_6Cl_{14}]$ (**1**) was obtained, while *p*-tolyltrichloroiminophosphorane generated the tetranuclear copper chloride salt $[4\text{-}CH_3C_6H_4NH_3][2\text{-}Cl\text{-}4\text{-}CH_3C_6H_3NH_3][Cu_4Cl_{10}]$ (**2**). In both structures a two-dimensional framework displaying a herringbone arrangement is created by Cu—Cl secondary bonding interactions. The direct addition of the $[n\text{-}PrNH_3]^+$ cation to a $CuCl_2{\cdot}2H_2O$ solution under the same reaction conditions produced $[n\text{-}PrNH_3]_2[CuCl_4]$.

Key words: copper halides, templation, oligomers, two-dimensional frameworks.

Résumé : L'utilisation de trichloroiminophosphoranes $Cl_3P{=}NR$ pour contrôler la libération simultanée du cation $[RNH_3]^+$ servant de gabarit et le ligand chlorure par le biais d'un clivage in situ de liaisons P—N et P—Cl conduit à la formation de deux nouveaux oligomères du chlorure de cuivre(II). La nature du substituant organique R est un facteur dans la détermination des longueurs des chaînes. Avec le *n*-propyltrichloroiminophosphorane, il y a formation de l'agrégat hexanucléaire $[n\text{-}PrNH_3]_2[Cu_6Cl_{14}]$ (**1**) alors que le *p*-tolyltrichloroiminophosphorane génère la formation du chlorure de cuivre tétranucléaire $[4\text{-}CH_3C_6H_4NH_3][2\text{-}Cl\text{-}4\text{-}CH_3C_6H_3NH_3][Cu_4Cl_{10}]$ (**2**). Dans les deux structures, il y a création d'un squelette bidimensionnel comportant un arrangement en chevrons formé par des interactions de liaisons secondaires Cu—Cl. L'addition directe du cation $[n\text{-}PrNH_3]^+$ à une solution de $CuCl_2{\cdot}2H_2O$ dans les mêmes conditions réactionnelles conduit à la formation de $[n\text{-}PrNH_3]_2[CuCl_4]$.

Mots clés : halogénures de cuivre, gabarit, oligomères, squelettes bidimensionnels.

[Traduit par la Rédaction]

Introduction

The use of templating reagents is a common technique in the synthesis of inorganic materials (1, 2). This method employs a cation, e.g., alkylammonium $[RNH_3]^+$, to provide charge balance and to regulate the structural arrangement of anionic frameworks through forces such as hydrogen bonding or van der Waals repulsion (3). The traditional procedure for the synthesis of oligomeric copper(II) halide frameworks involves mixing the copper(II) halide with an appropriate organic cation in a concentrated hydrohalic acid solution (4–6). Willett and co-workers (7–9) have used this approach to produce many copper halide oligomers with fascinating structural features and interesting physical properties. Much of their work has focused on the characterization of quasi-planar bibridged Cu_nX_{2n+2} systems (n = 2–7, 10) (10–16). The "softness" of the copper coordination sphere and the nonstereospecific bridging capability of the halide ions allow the formation of secondary bonding interactions (SBIs) between the oligomers, which give rise to various stacking patterns (17).

Recently, some new open-framework zinc phosphates were prepared under solvothermal conditions by using P—N bond cleavage in hexamethylphosphoramide $OP(NMe_2)_3$ to control the simultaneous release of an organic amine and phosphoric acid (18). As part of our investigations of novel inorganic materials, we are particularly interested in the in situ templation synthesis of new copper(II) halide frameworks. In addition to generating new functional compounds, this indirect templation method may contribute to an understanding of the mechanism of network formation. For example, we have shown that the tris(alkylamido)phosphate $OP[N(H)\text{-}t\text{-}Bu]_3$ functions both as an indirect source of the templating $[t\text{-}BuNH_3]^+$ cation and as a proton acceptor in the

production of a novel copper chloride structural motif that is different from the network synthesized by the direct addition of [t-BuNH$_3$]Cl (19). In the current work we have investigated the use of trichloroiminophosphoranes Cl_3P=NR (R = n-Pr, p-tolyl) as an in situ source of both the organic ammonium cation and the Cl^- ligand in the formation of novel copper halide frameworks. We report here the formation and X-ray structures of two high-nuclearity copper chloride oligomers [n-PrNH$_3$]$_2$[Cu_6Cl_{14}] (**1**) and [4-$CH_3C_6H_4NH_3$][2-Cl-4-$CH_3C_6H_3NH_3$][Cu_4Cl_{10}] (**2**), both of which exhibit a herringbone structure. For the quasi-planar bibridged Cu_nX_{2n+2} oligomers, this stacking pattern has only been reported in the pentanuclear cluster [Cu_5Cl_{10}(n-C_3H_7OH)$_2$] (20). For comparison, the direct addition of [n-PrNH$_3$]$^+$ to a $CuCl_2 \cdot 2H_2O$ solution under the same reaction conditions produced the known copper chloride complex [n-PrNH$_3$]$_2$[$CuCl_4$] (21). The structure of [2-Cl-4-$CH_3C_6H_3NH_3$]$^+Cl^-$ (**3**), a by-product of the reaction involving Cl_3P=N-p-tolyl, is also reported.

Experimental section

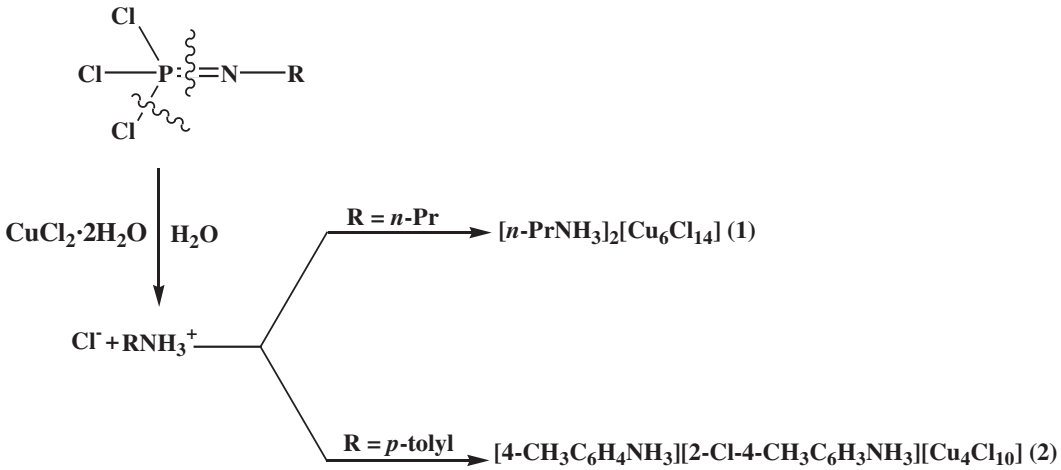
Reagents and general procedures

n-Propyltrichloroiminophosphorane and 4-tolyltrichloroiminophosphorane were prepared according to the literature procedure (22). Tetrachloroethane was dried over CaH_2 and fractionally distilled. Copper chloride dihydrate, phosphorus pentachloride, and chlorobenzene were used as received.

Synthesis of 1

A mixture of copper chloride dihydrate (0.170 g, 1.00 mmol), n-propyltrichloroiminophosphorane (0.194 g, 1.00 mmol), water (0.054 g, 3.00 mmol), and 10 mL toluene were placed in a sealed 23 mL Teflon vessel and heated at 90 °C for 12 h. The reaction vessel was allowed to cool to 23 °C, and yellow crystals of **1** (0.020 g, 12%) were isolated from the yellow precipitate manually.

Syntheses of 2 and 3



A mixture of copper chloride dihydrate (0.170 g, 1.00 mmol), p-tolyltrichloroiminophosphorane (0.243 g, 1.00 mmol), water (0.054 g, 3.00 mmol), and 10 mL toluene were placed in a sealed 23 mL Teflon vessel and heated at 90 °C for 12 h. The reaction vessel was allowed to cool to 23 °C. Yellow crystals of **2** (0.040 g, 18%) and a few pale yellow crystals of **3** were separated from the black precipitate manually.

X-ray structural analyses

Suitable crystals of the complexes (**1**, yellow block (0.18 × 0.12 × 0.12 mm^3); **2**, yellow plate (0.20 × 0.04 × 0.04 mm^3); **3**, pale yellow plate (0.24 × 0.08 × 0.08 mm^3)) were selected, coated with oil (Paratone 8277, Exxon), and mounted on glass fibres. The measurements were made on a Nonius KappaCCD diffractometer with graphite-monochromated Mo Kα radiation. Data were collected at 25 °C, using the ω and ϕ scans to a maximum θ value of 27.5°, 25.02°, and 25.03° for **1**, **2**, and **3**, respectively. The data were corrected for Lorentz and polarization effects and for absorption using the multiscan method (23). Since the crystals did not show any sign of decay during data collection, a decay correction was deemed unnecessary. The structures were solved by direct methods SHELXS-97 (24). The C atoms of the n-propyl groups in **1** were disordered over three positions with unequal site occupancy factors in an approximate ratio of 2:1:1; the C3 and C2a atoms were also disordered at the same position in a 1:1 ratio. In **2**, the cations [4-$CH_3C_6H_4NH_3$] and [2-Cl-4-$CH_3C_6H_3NH_3$] were disordered at the same position with equal site occupancy

factors. All non-hydrogen atoms were refined anisotropically except the disordered atoms. All the hydrogen atoms were included at geometrically idealized positions. Crystallographic data for **1**, **2**, and **3** are summarized in Table 1. Additional data are available in the Supporting information.[3]

Results and discussion

The products obtained from the solvothermal reactions of trichloroiminophosphoranes $Cl_3P{=}NR$ with $CuCl_2{\cdot}2H_2O$ in toluene at 90 °C exhibit distinctly different structural motifs depending on the identity of the R group (Scheme 1). In the case of R = *n*-Pr, the hexanuclear copper chloride chain $[Cu_6Cl_{14}]^{2-}$ is isolated as the $[n\text{-}PrNH_3]^+$ salt, whereas for the aryl subsituent (R = *p*-tolyl), the tetranuclear $[Cu_4Cl_{10}]^{2-}$ fragment is obtained in conjunction with the $[4\text{-}CH_3C_6H_4NH_3]^+$ and $[2\text{-Cl-4-}CH_3C_6H_3NH_3]^+$ cations. The chloride ions in these syntheses are generated by in situ hydrolysis of the P—Cl bonds in $Cl_3P{=}NR$, which is achieved by the addition of a stoichiometric amount of water to the reaction mixture. Concomitantly, the in situ generated organoammonium cations $[RNH_3]^+$ exhibit an indirect templation function in the generation of these anionic copper halide frameworks. The formation of bibridged Cu_nX_{2n+2} oligomers in previous reports is viewed to involve fragments cut from infinite CuX_2 chains by charge-compensating cations acting as "molecular scissors" (10, 12). The weak interaction between the Cl^- ion and the cation results in the termination of the CuX_2 chains. This is a common modification in the formation of copper halide oligomers. In the new synthesis described herein the copper chloride oligomers are built up by replacement of the aqua ligands in the $CuCl_2{\cdot}2H_2O$ monomer (25) by the stronger chloride ligands provided by the hydrolysis of $Cl_3P{=}NR$. The formation of the new cation $[2\text{-Cl-4-}CH_3C_6H_3ClNH_3]^+$ in the synthesis of **2** presumably occurs by the chlorination of the $[4\text{-}CH_3C_6H_4NH_3]^+$ cation during the solvothermal process. The chloride salt $[2\text{-Cl-4-}CH_3C_6H_3NH_3]^+Cl^-$ (**3**) was also isolated from the reaction products and characterized by X-ray crystallography (vide infra). A similar observation has been reported for the bromination of the 3-chloroanilinium cation by $CuBr_2$ in HBr solution to give the 6-bromo-3-chloroanilinium cation (26).

The direct reaction of $[n\text{-}PrNH_3]Cl$ and $CuCl_2{\cdot}2H_2O$ under the solvothermal conditions employed for the synthesis of **1** generated the known mononuclear anion $[CuCl_4]^-$ (21) as the $[n\text{-}PrNH_3]^+$ salt, demonstrating the structure-directing effect of the indirect templation method, as previously reported for the generation of a novel anionic copper halide framework by in situ templation employing $[t\text{-}BuNH_3]^+$, which is provided by the amidophosphate reagent $OP(NH\text{-}t\text{-}Bu)_3$] (19). Interestingly, the outcome of the indirect templation method is sensitive to reaction conditions, notably the polarity of the solvent. When the reaction of $Cl_3P{=}N\text{-}n\text{-}Pr$ with $CuCl_2{\cdot}2H_2O$ takes place in ethanol at 90 °C, the final product is $[n\text{-}PrNH_3]_2[CuCl_4]$. This difference may be attributable to the faster rate of hydrolysis of $Cl_3P{=}N\text{-}n\text{-}Pr$ in the more polar solvent ethanol compared with that in toluene. The rapid cleavage of P—Cl and P—N bonds apparently results in a templation effect similar to that observed for the direct addition of Cl^- and $[n\text{-}PrNH_3]^+$ (in the form of the salt $[n\text{-}PrNH_3]Cl$).

Complexes **1** and **2** were identified by single-crystal X-ray analyses (Tables 2 and 3). As illustrated in Fig. 1, compound **1** contains an anionic hexanuclear copper chloride oligomer with a different stacking pattern from that found in $[C_7H_{10}N]_2[Cu_6Cl_{14}]$ (11). In **1**, the $[Cu_6Cl_{14}]^{2-}$ dianion connects to four neighbours of adjacent stacks via two long Cu—Cl bonds (Cl2—Cu2c = 2.6266(12) Å) and two Cu—Cl secondary bonding interactions (Cl2—Cu1d = 2.8080(13) Å), which extend the structure to a 2D herringbone motif. By contrast, the stacks of oligomers in

Cl(5a)-Cu(2)-Cl(2b)	91.71(6)		

Note: Symmetry transformations used to generate equivalent atoms: $a = -x - 4, -y - 3, -z - 2$; $b = x, y + 1, z$; $c = x, y - 1, z$; $d = -4 - x, -1/2 + y, -3/2 - z$.

$[C_7H_{10}N]_2[Cu_6Cl_{14}]$ are interlocked to give a layer pattern parallel to the *ab* plane. Each copper centre in **1** is coordinated to four chloride ligands. All the copper ions protrude from the ligand plane, displaying a square pyramidal distortion. The central Cu3 atom shows the smallest distortion with a dihedral angle of 2.0° between the Cl7-Cu3-Cl5 and Cl7a-Cu3-Cl6 planes. The most significant deviation from the square plane is observed at the Cu2 center with a dihedral angle of 16.3° between the Cl5-Cu2-Cl3 and Cl6-Cu2-Cl4 planes. The terminal Cu1 atom has a dihedral angle of 8.0° between the Cl4-Cu1-Cl1 and Cl3-Cu1-Cl2 planes. The terminal copper(II)—chloride bond lengths are 2.2581(14) (Cu1—Cl1) and 2.2723(12) Å (Cu1—Cl2), whereas the bridging copper(II)—chloride bond lengths are 2.3381(13) Å

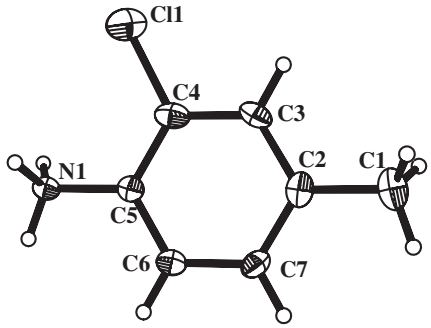
(Cu1—Cl3), 2.3116 Å (Cu1—Cl4), 2.2674(13) Å (Cu2—Cl4), 2.2807(12) Å (Cu2—Cl3), 2.3070(13) Å (Cu2—Cl5), 2.2933(12) Å (Cu2—Cl6), 2.2880(12) Å (Cu3—Cl5), 2.2631(13) Å (Cu3—Cl6), 2.2809 (12) Å (Cu3—Cl7a), and 2.2674(13) Å (Cu3—Cl7), respectively. These values are in agreement with the rule of variations in in-plane bond lengths of bibridged Cu_nX_{2n+2} oligomers, demonstrating a short-long-short··· alternation for the t-b1-b2··· sequence.[4] The bridging Cu-Cl-Cu bond angles range from 94.51° for the terminal fragment to 92.72° for the central units.



The structural characteristics of compound **2** are similar to those of **1** except that the anion is tetranuclear (Fig. 2). The $[Cu_4Cl_{10}]^{2-}$ fragment in $[Me_4N]_2[Cu_4Cl_{10}]$ has the same stacking pattern as that in **2**, but with a different mode of anion–cation interactions. In **2**, the oligomer is linked to four neighbours of adjacent stacks (Cl2—Cu2c = 2.6764(17) Å, Cl2—Cu1d = 3.0724(18) Å), whereas in $[Me_4N]_2[Cu_4Cl_{10}]$ the influence of the cations restricts these interactions to two neighbours (12). The Cu1 atom in **2** displays a small tetrahedral distortion, while the Cu2 atom exhibits a square pyramidal distortion with a dihedral angle of 14.0° between the Cl4-Cu2-Cl5 and Cl3-Cu2-Cl5a planes. The terminal Cl1 and Cl2 ligands coordinate with the Cu1 atom (Cu1—Cl1 = 2.237(2) Å, Cu1—Cl2 = 2.2589(17) Å), whereas the bridging ligands Cl3, Cl4, and Cl5 connect the adjacent copper atoms with a mode (Cu1—Cl3 = 2.3187(17) Å, Cu1—Cl4 = 2.3143(18) Å, Cu2—Cl3 = 2.2743(18) Å, Cu2—Cl4 = 2.2897(16) Å, and Cu2—Cl5 = 2.2846(18) Å). These values are typical and show the short-long-short alternation observed for **1**. The bridging Cu-Cl-Cu bond angles vary from 94.70° to 93.13°.

The X-ray analysis of compound **3** (Table 4) revealed that

Table 4. Bond lengths (Å) and bond angles (°) for **3**.

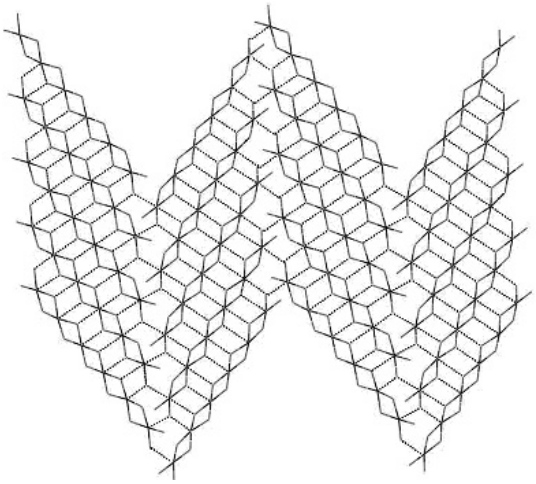
Fig. 3. Molecular structure and atomic numbering scheme for the cation in **3**. Thermal ellipsoids are shown at the 50% level.

chlorination occurred in the position ortho to the NH_3^+ group to give the $[2\text{-Cl-4-}CH_3C_6H_3NH_3]^+$ cation (Fig. 3). The bond lengths and bond angles in this cation (C—Cl = 1.719(5) Å, C6—N1 = 1.454(7) Å; C2-C4-Cl1 = 118.0(4)°, C6-C4-Cl1 = 121.6(4)°) are similar to those reported for the related anilinium cation, $[3\text{-Cl-6-Br}C_6H_3NH_3]^+$ (26).

As illustrated in Fig. 4, the structures of **1** and **2** are both extended into two-dimensional networks by SBIs that give rise to a herringbone motif. The terminal chloride ligand Cl2 in **1** acts as a μ_2 bridge connecting to the copper centres located in the adjacent fragments. The Cu1 and Cu2 atoms adopt a 4+1+1 coordination mode, while the Cu3 atom has a 4+2 coordination geometry, in which the secondary bonding interactions for Cu1, Cu2, and Cu3 are 2.808 and 3.008 Å, 2.627 and 3.213 Å, and 2.981 and 2.960 Å, respectively. In compound **2**, the Cu1 atom adopts a 4+2 coordination mode with SBIs of 3.072 and 3.127 Å. The Cu2 atom has a 4+1+1 coordination mode with SBIs of 2.676 and 3.194 Å. The stacking patterns of **1** and **2** are denoted as 6(3/2, 1/2) and 4(3/2, 1/2), respectively, according to the notation of Willett and co-workers (17). Like most bibridged Cu_nX_{2n+2} oligomers, the charge-compensating cations $[n\text{-PrNH}_3]^+$ in **1** and $[2\text{-Cl-4-}CH_3C_6H_3NH_3]^+$ and $[4\text{-}CH_3C_6H_4NH_3]^+$ in **2** form hydrogen bonds with a pair of trans terminal chloride ligands (N—Cl = 3.245 Å for **1** and 3.253 Å for **2**).



In summary, a new synthetic approach involving the simultaneous in situ generation of Cl^- and $[RNH_3]^+$ ions for

[4] The Ith Cu—Cl bond length is denoted by bI, starting from the terminal atom; b = bridging, t = terminal (27).

2

the production of anionic copper chloride oligomers is introduced in this study. Variation of the R group in the precursors $Cl_3P{=}NR$ creates different lengths of the anionic chains. The structures of both oligomers exhibit a herringbone stacking pattern. These findings provide another example of the generation of new inorganic structural frameworks via *indirect* templation using P-N reagents (18, 19). There is considerable scope for the construction of novel inorganic architectures via variation in reaction conditions in these solvothermal processes, as indicated by the influence of solvent polarity in the current work.

Rhodium(I) acetylacetonato complexes containing phosphinoalkynes as catalysts for the hydroboration of vinylarenes[1]

Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Three novel rhodium(I) acetylacetonato (acac) complexes bearing phosphinoalkynes ($Ph_2PC{\equiv}C$-*t*-Bu, $Ph_2PC{\equiv}CPPh_2$, and $Ph_2PC{\equiv}CC{\equiv}CPPh_2$) have been prepared and characterized fully. Addition of B_2cat_3 (cat = 1,2-$O_2C_6H_4$) to Rh(acac)($Ph_2PC{\equiv}C$-*t*-Bu)$_2$ (**1a**) led to zwitterionic Rh(η^6-catBcat)($Ph_2PC{\equiv}C$-*t*-Bu)$_2$ (**2a**), the first example of this type of compound to contain monodentate phosphine ligands. All new rhodium complexes have been investigated for their ability to catalyse the hydroboration of vinylarenes.

Key words: catalysis, hydroboration, phosphinoalkynes, regioselectivity, rhodium.

Résumé : On a préparé et complètement caractérisé trois nouveaux complexes acétylacétonato du rhodium(I) portant des phosphinoalcynes ($Ph_2PC{\equiv}C$-*t*-Bu; $Ph_2PC{\equiv}CPPh_2$ et $Ph_2PC{\equiv}CC{\equiv}CPPh_2$). L'addition de B_2cat_3 (cat = 1,2-$O_2C_6H_4$) au Rh(acac)($Ph_2PC{\equiv}C$-*t*-Bu)$_2$ (**1a**) conduit à la formation du composé zwitterionique Rh(η^6-catBcat)($Ph_2PC{\equiv}C$-*t*-Bu)$_2$ (**2a**), le premier exemple de ce type de composé à contenir des ligands phosphines monodentates. On a examiné l'utilité potentielle de tous les nouveaux complexes du rhodium comme catalyseurs pour l'hydroboration de vinylarènes.

Mots clés : catalyse, hydroboration, phosphinoalcynes, régiosélectivité, rhodium.

[Traduit par la Rédaction]

Introduction

One of the most important synthetic methodologies to emerge from organic chemistry in the last century has been the discovery that boron–hydrogen bonds add to unsaturated organic molecules to form a class of compounds known as organoboranes (1). Organoboranes possess an incredibly diverse chemistry and are remarkably useful intermediates in organic synthesis today. Indeed, organoboranes can be transformed into any number of functional groups. The simplest boron hydride agent is borane, BH_3, which reacts rapidly with unhindered alkenes to afford initially monoalkylboranes, then dialkylboranes, and finally trialkylboranes. For sterically hindered alkenes, the second and third hydroboration steps become increasingly sluggish. Addition occurs in a controlled cis-fashion (syn-addition), where the boryl (BR_2) fragment adds preferentially to the least hindered carbon of the unsymmetrically substituted double bond. While borane adds rapidly to alkenes at –80 °C (2), some hydroborating agents, such as polyhedral boranes, are slow to react even at room temperature. Likewise, addition of $H_3B{\cdot}THF$ to catechol affords catecholborane (HBcat, cat = 1,2-$O_2C_6H_4$), a relatively stable hydroborating agent, which adds to alkenes and alkynes only at elevated temperatures (ca. 100 and 70 °C, respectively) (3). Catecholborane decomposes thermally or by addition of nucleophiles to give a number of boron-containing products (4).

That transition metals accelerate the addition of B—H bonds to unsaturated organic moieties was initially reported for catalysed hydroborations of alkenes and alkynes using polyhedral boranes (5). Männig and Nöth (6) then demonstrated that rhodium complexes could be used to catalyse the hydroboration of alkenes with HBcat under mild conditions and with *chemoselectivity differing from that of the uncatalysed reaction* (Scheme 1). Indeed, in the catalysed hydroboration of 5-hexen-2-one, addition of HBcat occurred preferentially at the C=C double bond, even in the presence of the more reactive ketone group.

Since this seminal discovery, a considerable amount of research has focused on investigating the mechanism and scope of late metal catalysed hydroboration reactions (7). Although other metals have been found to catalyse hydroborations with HBcat, rhodium-based catalyst systems are usually the most effective for reactions of vinylarenes (8). Unfortunately, these reactions often suffer from poor selectivities or competing pathways (i.e., hydrogenation), and as a result, a considerable amount of research has focused on designing new catalyst systems (9). We report herein on the synthesis and hydroboration of rhodium(I) acetylacetonato complexes containing phosphinoalkyne ligands.

Scheme 1. Hydroboration of 5-hexen-2-one.

Experimental

General

Reagents and solvents used were purchased from Aldrich Chemicals. NMR spectra were recorded on a JEOL JNM-GSX270 FT spectrometer. ^{1}H NMR chemical shifts are reported in parts per million (ppm) and referenced to residual solvent protons in deuterated solvent at 270 MHz. ^{11}B NMR chemical shifts are reported in ppm and are referenced to $BF_3{\cdot}OEt_2$ as an external standard at 87 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 MHz and are reported in ppm. ^{31}P NMR chemical shifts are reported in ppm and are referenced to H_3PO_4 as an external standard at 109 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), multiplet (m), broad (br), and overlapping (ov). All reactions were carried out under an atmosphere of dinitrogen. Microanalyses for C and H were carried out at Guelph Chemical Laboratories (Guelph, Ontario). Phosphines were prepared as described previously and donated as a generous gift from Dr. J.F. Corrigan (10). Rh(acac)(coe)$_2$ was prepared as described previously (11).

Rh(acac)(Ph$_2$PC≡C-*t*-Bu)$_2$ (1a)

A solution of Ph$_2$PC≡C-*t*-Bu (0.25 g, 0.95 mmol) in toluene (1 mL) was added to a solution of Rh(acac)(coe)$_2$ (0.20 g, 0.47 mmol) in toluene (2 mL), and the mixture was stirred for 18 h. The removal of solvent under vacuum afforded an orange solid, which was washed with hexane (3 × 3 mL) and collected by suction filtration to give **1a** (0.31 g, 88%). Spectroscopic NMR data (in C_6D_6): ^{1}H δ: 8.25–8.18 (ov m, 8H, Ar), 7.17–7.04 (ov m, 12H, Ar), 5.20 (s, 1H, C=C*H*), 1.53 (s, 6H, C(O)*Me*), 0.93 (s, 18H, *tert*-butyl). ^{13}C{^{1}H} δ: 184.3, 137.0 (app. quint, $J_{C\text{-}P\text{-}Rh}$ = 26 Hz), 133.9 (t, $J_{C\text{-}P}$ = 6 Hz), 128.7, 127.3 (t, $J_{C\text{-}P}$ = 5 Hz), 114.4 (t, $J_{C\text{-}P}$ = 6 Hz, PC*C*), 99.6, 75.7 (td, $J_{C\text{-}P}$ = 153, 46 Hz, P*C*C), 29.9, 28.2, 26.8. ^{31}P{^{1}H} δ: 31.4 (d, $J_{P\text{-}Rh}$ = 196 Hz). Anal. calcd. for $C_{41}H_{45}O_2P_2Rh$ (%): C 67.02, H 6.19; found: C 66.79, H 6.45.

[{Rh(acac)}$_2$(μ-Ph$_2$PC≡CPPh$_2$-κ^2*P*)$_2$] (1b)

A solution of Ph$_2$PC≡CPPh$_2$ (0.14 g, 0.36 mmol) in toluene (1 mL) was added to a solution of Rh(acac)(coe)$_2$ (0.15 g, 0.36 mmol) in toluene (2 mL), and the mixture was stirred for 18 h. The solvent was removed under vacuum, and the resulting orange precipitate was washed with hexane (3 × 3 mL) and collected by suction filtration to give **1b** (0.18 g, 82%). Spectroscopic NMR data (in C_6D_6): ^{1}H δ: 7.95–7.88 (ov m, 16H, Ar), 7.01–6.89 (ov m, 24H, Ar), 5.26 (s, 2H, C=C*H*), 1.57 (s, 12H, C(O)*Me*). ^{13}C{^{1}H} δ: 184.6, 134.1 (app. quint, $J_{C\text{-}P\text{-}Rh}$ = 27 Hz), 133.4 (t, $J_{C\text{-}P}$ = 6 Hz), 128.9, 127.5 (t, $J_{C\text{-}P}$ = 5.2 Hz), 102.4 (td, $J_{C\text{-}P}$ = 109, 36 Hz, P*C*C), 99.8, 26.9. ^{31}P{^{1}H} δ: 32.1 (d, $J_{P\text{-}Rh}$ = 191 Hz). Anal. calcd. for $C_{62}H_{54}O_4P_4Rh_2$ (%): C 62.42, H 4.57; found: C 62.26, H 4.25.

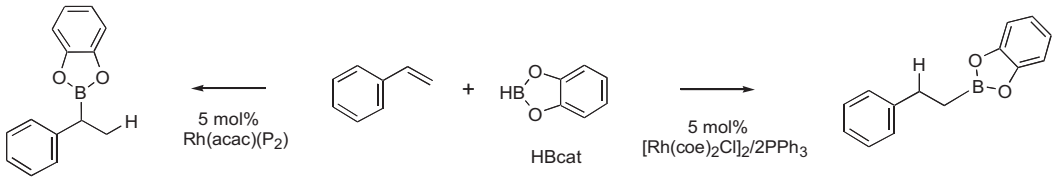
[{Rh(acac)}$_2$(μ-Ph$_2$PC≡CC≡CPPh$_2$-κ^2*P*)$_2$] (1c)

A solution of Ph$_2$PC≡CC≡CPPh$_2$ (0.22 g, 0.52 mmol) in THF (1 mL) was added to a solution of Rh(acac)(coe)$_2$ (0.20 g, 0.47 mmol) in THF (2 mL), and the mixture was stirred for 1 h. The resulting orange precipitate was collected by suction filtration and washed with hexane (3 × 3 mL) to give **3** (0.28 g, 95%). Spectroscopic NMR data (in C_6D_6): ^{1}H δ: 7.94–7.90 (ov m, 16H, Ar), 6.98–6.90 (ov m, 24H, Ar), 5.25 (s, 2H, C=C*H*), 1.52 (s, 12H, C(O)*Me*). ^{31}P{^{1}H} δ: 35.5 (d, $J_{P\text{-}Rh}$ = 193 Hz). Anal. calcd. for $C_{66}H_{54}O_4P_4Rh_2$ (%): C 63.87, H 4.39; found: C 63.42, H 4.49.

Rh(η^6-Bcat$_2$)(Ph$_2$PC≡C-*t*-Bu)$_2$ (2a)

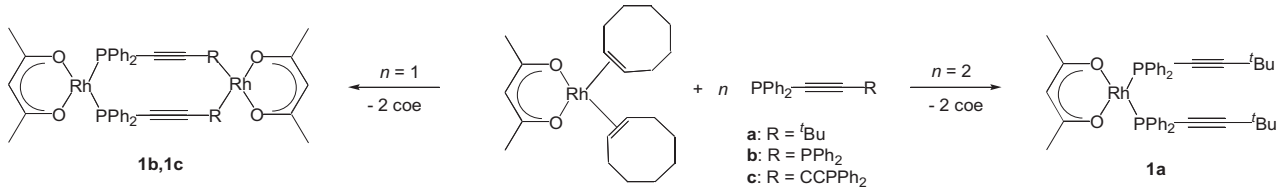
A solution of B_2cat_3 (0.05 g, 0.14 mmol) in toluene (0.5 mL) was added to a solution of Rh(acac)(Ph$_2$PC≡C-*t*-Bu)$_2$ (0.10 g, 0.14 mmol) in toluene (2 mL), and the mixture was stirred for 18 h. The precipitate that formed was removed by suction filtration, and hexane (3 mL) was added to the filtrate, and the solution was stored at –25 °C for 3 days. The resulting red precipitate was collected by suction filtration to afford **2a** (0.080 g, 66%). Spectroscopic NMR data (in C_6D_6): ^{1}H δ: 7.89–7.81 (ov m, 8H, Ar), 7.15–6.96 (ov m, 16H, Ar), 4.83 (m, 4H, η^6-cat), 0.80 (s, 18H, *tert*-butyl). ^{11}B δ: 15.0. ^{31}P{^{1}H} δ: 23.6 (d, $J_{P\text{-}Rh}$ = 213 Hz). Anal. calcd. for $C_{48}H_{46}BO_4P_2Rh$ (%): C 66.83, H 5.39; found: C 67.17, H 5.62.

General procedure for the hydroboration of vinylarenes



Under an atmosphere of dinitrogen, 1 equiv. of catecholborane in 0.5 mL of C_6D_6 was added to a 0.5 mL C_6D_6 solution of the appropriate catalyst and vinylarene. The reactions were allowed to proceed for 18 h, at which point NMR data were collected. Product distributions were confirmed by GC–MS.

X-ray crystallography



Crystals of **1a** and **2a** were grown from satd. Et_2O and toluene–hexane (1:1) solutions, respectively, at –30 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and exposure times of 30 s (**1a**) and 10 s (**2a**). The detector distances were 5 cm (**2a**) and 6 cm (**1a**). Crystals of **1a** were multiple twins; however, only the data for the major isomer lead to a successful structure refinement. The data were reduced (12*a*) and corrected for absorption (12*b*). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (12*c*). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically.

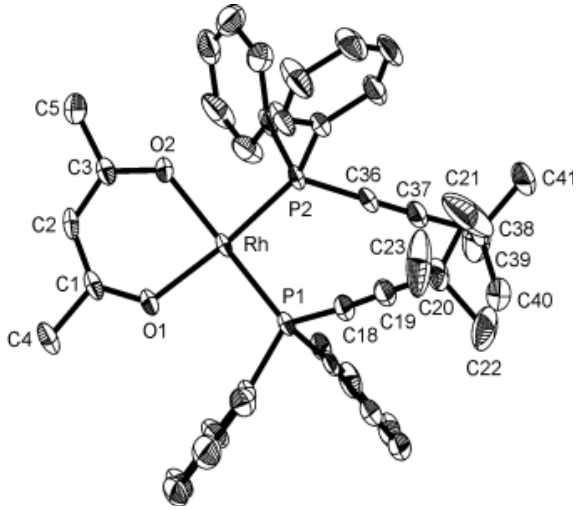
Scheme 3. Synthesis of rhodium complexes **1a**–**1c**.



Results and discussion

Rhodium phosphine complexes are versatile and efficient catalysts for the hydroboration of alkenes using catecholborane (HBcat). Among this group, complexes of the type $Rh(acac)(P_2)$ (acac = acetylacetonato; P_2 = diphosphine) are unique in that they are the only catalyst precursors to have been used in the hydroboration of a tetrasubstituted alkene (13*a*). These complexes are also active and selective catalysts for the hydroboration of a wide range of vinylarenes using HBcat, giving predominantly the corresponding branched isomers (Scheme 2). Although a considerable amount of research has focused on using these complexes as catalysts for this reaction (13), all examples have used chelating bidentate phosphines. In this study, we have prepared the analogous rhodium acetylacetonato complexes bearing monodentate phosphinoalkynes and examined their ability to catalyze the hydroboration of vinylarenes.

Rhodium complexes

The coordination chemistry of bis(diphenylphosphino)acetylene and related alkynyl phosphines is an area of considerable interest (14–17). Although the normal mode of coordination is via the phosphine groups, examples where the alkyne unit is bound to a metal in a η^2-π fashion are also known (15*i*). We have found that alkynyl phosphines **a**–**c** add to $Rh(acac)(coe)_2$ (coe = *cis*-cyclooctene) to give $Rh(acac)(Ph_2PC{\equiv}C\text{-}t\text{-}Bu)_2$ (**1a**), $[\{Rh(acac)\}_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_2]$ (**1b**), and $[\{Rh(acac)\}_2(\mu\text{-}Ph_2PC{\equiv}CC{\equiv}CPPh_2\text{-}\kappa^2P)_2]$ (**1c**), respectively (Scheme 3). All new complexes have been characterized by a number of physical methods, including multinuclear NMR spectroscopy. The $^{31}P\{^1H\}$ NMR spectra all showed doublets with coupling to rhodium with ca. $J_{P\text{-}Rh}$ = 195 Hz. Complex **1a** has also been characterized by a single crystal X-ray diffraction study (Fig. 1),[3] confirming that ligand **a** is bound to the metal centre via the phosphine groups. The rhodium atom lies in a distorted square-planar geometry with typical rhodium–oxygen distances of Rh—O(1) 2.057(3) and Rh—O(2) 2.061(3) Å

Fig. 1. The molecular structure of **1a** showing probability ellipsoids at 30% and hydrogen atoms omitted for clarity. Selected bond distances (Å) and angles (°): Rh—O(1) 2.057(3), Rh—O(2) 2.061(3), Rh—P(1) 2.173(1), Rh—P(2) 2.182(1), C(18)—C(19) 1.186(6), C(36)—C(37) 1.180(6); O(1)-Rh-O(2) 88.3(1), O(1)-Rh-P(1) 90.98(8), O(2)-Rh-P(1) 176.24(9), O(1)-Rh-P(2) 174.28(8), O(2)-Rh-P(2) 86.04(9), P(1)-Rh-P(2) 94.72(4), P(1)-C(18)-C(19) 174.2(4), P(2)-C(36)-C(37) 178.8(4).

found in other rhodium acetylacetonato complexes (18). Likewise, bond distances and angles within the phosphine ligands are similar to those reported previously, with C≡C bond lengths of C(18)—C(19) 1.186(6) and C(36)—C(37) 1.180(6) Å (17). Crystallographic data are given in Table 1. For complexes **1b** and **1c**, coordination of both phosphine groups to rhodium is observed by ^{31}P NMR spectroscopy.

As mentioned previously, phosphinorhodium acetylacetonato complexes are active and selective catalysts for the hydroboration of a wide range of alkenes. However, the catalyst resting state in these systems is believed to be the zwit-

terionic complexes Rh(η^6-catBcat)(P_2), arising from the redistribution of substituents on HBcat. Indeed, hydroborations using these zwitterionic complexes give similar selectivities to those observed for the acetylacetonato precursors (13). In an elegant study, Marder and co-workers (13*d*) found that addition of B_2cat_3 to Rh(acac)(P_2) led to the zwitterionic complexes Rh(η^6-catBcat)(P_2) in high yields, along with concomitant formation of acacBcat. The diboron species B_2cat_3 is generated as an unwanted decomposition product in nucleophilic reactions with HBcat or when HBcat is heated to elevated temperatures (7*f*). We have found that addition of B_2cat_3 to **1a** gave the corresponding zwitterionic complex Rh(η^6-catBcat)($Ph_2PC{\equiv}C$-*t*-Bu)$_2$ (**2a**), which represents the first example of this type of compound to bear monodentate phosphine ligands (13*d*) to be structurally characterized by X-ray diffraction. The $^{31}P\{^1H\}$ NMR spectrum shows a doublet with coupling to rhodium at $J_{P\text{-}Rh}$ = 213 Hz and the ^{11}B NMR has a sharp peak at 15 ppm, consistent with the boron atom being four coordinate (19, 20). The molecular structure of **2a** has been confirmed by a single crystal X-ray diffraction study (Fig. 2) and shows that the P_2Rh fragment is bound to the catBcat$^-$ anion via one of the catecholato groups in a η^6 fashion. As with related systems (19), there appears to be considerable slippage of the P_2Rh group with respect to the π-bound arene ring. Indeed, two bond distances, Rh(1)—C(4) and Rh(1)—C(3), are considerably shorter (2.254(2) and 2.275(2) Å) than the remaining Rh—C bonds (ranging from 2.336(2) to 2.497(2) Å). The potential surface for such distortions is reputably quite shallow. Initial attempts to prepare **1b** and **1c** via this route were complicated by considerable degradation to give rhodium metal and a number of unidentified rhodium phosphine complexes. Interestingly, the reactivity of related rhodium β-diketonate diphosphine complexes with chlorinated solvents has been reported previously (21).

Hydroboration studies

To compare complexes **1a**–**1c** against other rhodium catalysts, we have examined their ability to catalyse the hydroboration of a series of vinylarenes. Initial studies were done on 4-vinylanisole in C_6D_6 (**3**, Table 2), and as with many other rhodium catalysts, all new phosphinoalkyne complexes gave selective formation of the branched isomer **3a**. Interestingly, hydroborations with isolated **2a** also gave exclusive formation of this product. In reactions of 4-fluorostyrene (**4**), however, complexes **1a** and **1c** gave small amounts of diboration product **4c** and hydrogenation product **4d**. Diborated product **4c** presumably arises from hydroboration of the transient vinyl boronate ester 4-F-C_6H_4CH=CHBcat, which is generated from a competing dehydrogenative borylation reaction (22). The vinyl boronate ester products are not observed to any extent, via ^1H NMR spectroscopy, in reactions using these relatively unhindered alkenes. Dehydrogenative borylations are generally believed to occur via initial coordination of the alkene to the metal centre followed by insertion into the Rh—B, and not the Rh—H, bond, with subsequent

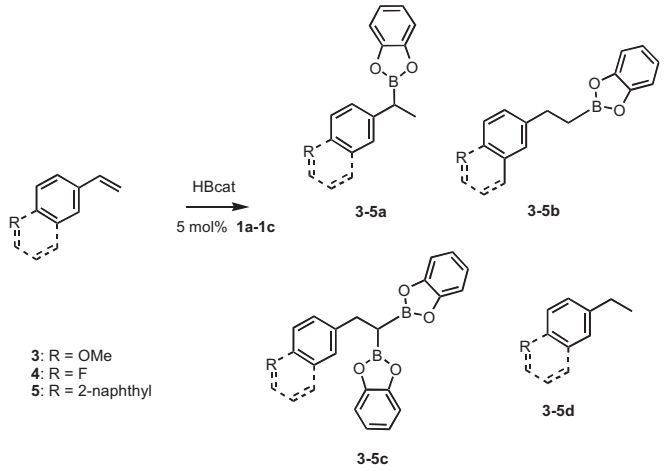
Fig. 2. The molecular structure of **2a** showing probability ellipsoids at 30% and hydrogen atoms omitted for clarity. Selected bond distances (Å) and angles (°): Rh(1)—P(2) 2.2129(5), Rh(1)—P(1) 2.2260(5), Rh(1)—C(4) 2.254(2), Rh(1)—C(3) 2.275(2), Rh(1)—C(2) 2.336(2), Rh(1)—C(1) 2.392(2), Rh(1)—C(5) 2.429(2), Rh(1)—C(6) 2.497(2), B(1)—O(4) 1.461(3), B(1)—O(3) 1.469(2), B(1)—O(2) 1.494(3), B(1)—O(1) 1.511(2), C(25)—C(26) 1.193(3), C(43)—C(44) 1.185(3); P(2)-Rh(1)-P(1) 91.85(2), O(4)-B(1)-O(3) 106.1(2), O(4)-B(1)-O(2) 112.7(2), O(3)-B(1)-O(2) 113.8(2), O(4)-B(1)-O(1) 111.5(2), O(3)-B(1)-O(1) 109.8(2), O(2)-B(1)-O(1) 103.2(2).



β-H elimination to give the corresponding vinyl boronate ester and an active rhodium dihydride species. This latter dihydride is presumably responsible for the hydrogenation of the starting alkene to give **4d**. Similar selectivities were observed in hydroborations of 2-vinylnaphthylene (**5**). Interestingly, dirhodium complex **1b** gave the best selectivities of the three new rhodium complexes examined for these reactions. Ratios of products were determined by multinuclear NMR spectroscopy and confirmed by GC–MS (7*e*, 13*a*).

Hydroborations of electron-deficient 2,3,4,5,6-pentafluorostyrene (**6**) were also examined, and selectivities are similar to that observed in reactions with 4-vinylanisole (Table 3). These results suggest the electronic nature of the arene group does not play a significant role in these hydroborations. Increasing the steric bulk around the alkene group by addition of fluorine groups in the 2 and 6 positions also did not seem to affect selectivities.

We then decided to investigate reactions of 2,4,6-trimethylstyrene (**7**), where the methyl groups further increase the steric crowding around the vinyl group. As expected, catalysed hydroborations of this bulkier vinylarene gave a mixture of branched (**7a**) and linear product (**7b**), along with a considerable amount of diborated product (**7c**), when complex **1a** was used (Table 4). Minor amounts of vinyl boronate ester product are observed by ^{1}H NMR spectroscopy (<1%). Rhodium complex **1c**, containing the dialkyne units, gave a significant amount of the linear product **7b**. It is plausible that reactions using **1b** and **1c** are complicated by addition of HBcat to the sterically uncongested dialkyne unit. Indeed, severe degradation of the starting rhodium complex is often observed in these reactions.

While results with vinylarene **7** show that steric hindrance caused by methyl groups ortho to the arene ring can alter

hydroboration selectivities, reactions with *trans*-β-methylstyrene (**8**), where a methyl group is substituted for a hydrogen in the β position of the vinyl group, gave selective formation of $C_6H_5CH(Bcat)CH_2CH_3$ (**8a**) regardless of the choice of catalyst used to affect this transformation. The other isomer ($C_6H_5CH_2CH(Bcat)CH_3$, **8b**) was not observed to any significant extent. Reactions with α-methylstyrene (**9**), however, where substitution occurs in the α position, gave extremely complicated product distributions (Table 5). The corresponding vinyl boronate ester ($C_6H_5CMe{=}CH(Bcat)$, **9e**) was also observed to a considerable extent in these reactions, especially when complex **1b** was used to catalyse this reaction. Although linear product **9b** could be generated from a traditional catalysed hydroboration reaction, it is also plausible that this product arises from the catalysed hydrogenation of vinyl boronate ester **9e**.

Conclusions

Three novel rhodium(I) acetylacetonato (acac) complexes bearing phosphinoalkynes ($Ph_2PC{\equiv}C$-*t*-Bu, $Ph_2PC{\equiv}CPPh_2$, and $Ph_2PC{\equiv}CC{\equiv}CPPh_2$) have been prepared and characterized fully, including an X-ray diffraction study for $Rh(acac)(Ph_2PC{\equiv}C$-*t*-$Bu)_2$ (**1a**). Addition of B_2cat_3 (cat = 1,2-$O_2C_6H_4$) to $Rh(acac)(Ph_2PC{\equiv}C$-*t*-$Bu)_2$ (**1a**) led to zwitterionic $Rh(\eta^6$-catBcat$)(Ph_2PC{\equiv}C$-*t*-$Bu)_2$ (**2a**), which was also characterized by an X-ray diffraction study. This represents a novel zwitterionic rhodium complex bearing monodentate phosphine ligands. All new rhodium complexes are active catalysts for the hydroboration of a wide range of vinylarenes. Selectivities are excellent for reactions using unhindered vinylarenes (including *trans*-β-methylstyrene) and favour the formation of the corresponding branched hydroboration products. Reactions with hindered vinylarenes, however, give complicated product distributions, arising from a competing dehydrogenative borylation reaction.

Acknowledgements

Thanks are gratefully extended to the Natural Sciences and Engineering Research Council of Canada (NSERC), Canada Research Chairs Programme, Canadian Foundation for Innovation-Atlantic Innovation Fund, and Mount Allison University for financial support. We also thank Roger Smith and Dan Durant for their expert technical assistance, Professor J.F. Corrigan (The University of Western Ontario, London, Ontario) for the generous gift of phosphinoalkynes, and anonymous reviewers for helpful comments.

The synthesis, structure, and electrochemical properties of Fe(C≡CC≡N)(dppe)Cp and related compounds[1]

Mark E. Smith, Richard L. Cordiner, David Albesa-Jové, Dmitri S. Yufit, František Hartl, Judith A.K. Howard, and Paul J. Low

Abstract: The cyanoacetylide complex Fe(C≡CC≡N)(dppe)Cp (**3**) is readily obtained from sequential reaction of $Fe(C{\equiv}CSiMe_3)(dppe)Cp$ with methyllithium and phenyl cyanate. Complex **3** is a good metalloligand, and coordination to the metal fragments $[RhCl(CO)_2]$, $[Ru(PPh_3)_2Cp]^+$, and $[Ru(dppe)Cp^*]^+$ affords the corresponding cyanoacetylide-bridged heterobimetallic complexes. In the case of the 36-electron complexes $[Cp(dppe)Fe\text{-}C{\equiv}CC{\equiv}N\text{-}ML_n]^{n+}$, spectroscopic and structural data are consistent with a degree of charge transfer from the iron centre to the rhodium or ruthenium centre via the C_3N bridge, giving rise to a polarized ground state. Electrochemical and spectroelectrochemical methods reveal significant interactions between the metal centres in the oxidized (35 electron) derivatives, $[Cp(dppe)Fe\text{-}C{\equiv}CC{\equiv}N\text{-}ML_n]^{(n+1)+}$.

Key words: cyanide, cyanoacetylide, crystal structure.

Résumé : Le complexe cyanoacétylure Fe(C≡CC≡N)(dppe)Cp (**3**) est facilement préparé par la réaction séquentielle du $Fe(C{\equiv}CSiMe_3)(dppe)Cp$ avec le méthyllithium et le cyanate de phényle. Le complexe **3** est un bon métalloligand et sa coordination aux fragments métalliques $[RhCl(CO)_2]$, $[Ru(PPh_3)_2Cp]^+$ et $[Ru(dppe)Cp^*]^+$ conduit à la formation des complexes hétérobimétalliques à point cyanoacétylure. Dans le cas des complexes à 36 électrons $[Cp(dppe)Fe\text{-}C{\equiv}CC{\equiv}N\text{-}ML_n]^{n+}$, les données spectroscopiques et structurales sont en accord avec un certain degré de transfert de charge du centre ferrique à rhodium ou au centre ruthénium par le biais du pont C_3N, ce qui conduit à un état fondamental polarisé. Les méthodes électrochimiques et spectroélectrochimiques révèlent l'existence d'interactions importantes entre les centres métalliques des dérivés oxydés (à 35 électrons) de formule générale $[Cp(dppe)Fe\text{-}C{\equiv}CC{\equiv}N\text{-}ML_n]^{(n+1)+}$.

Mots clés : cyanure, cyanoacétylure, structure cristalline.

[Traduit par la Rédaction]

Introduction

The chemistry of organometallic complexes featuring unsaturated ligands has been a source of interest for decades, owing to the unusual physical properties and chemical reactivity that arises from the mixing of metal d and ligand π orbitals. Acetylides and acetylenes are among the most structurally simple unsaturated ligands, offering cylindrical symmetry about the C≡C moiety, and a polarizable π system. However, these structurally simple ligands are remarkably electronically diverse, being capable of formally donating one to six electrons to metal fragments and frameworks through various combinations of the filled ligand σ and π orbitals.

Our interests in complexes featuring C≡C based ligands stem from the rich electrochemical response of bimetallic polyyndiyl systems (1), the coordinative flexibility of (poly)yne ligands (2), and the chemical, physical, and spectroscopic properties of metal complexes featuring polycarbon ligands that depend heavily on the mixing of metal and carbon orbitals (3). In seeking to extend these studies, and at the same time to explore the relationships that exist between acetylide, $[C{\equiv}CR]^-$, and isoelectronic cyanide, $[C{\equiv}N]^-$, based unsaturated ligands, we were drawn to the cyanoacetylide ligand, $[C{\equiv}CC{\equiv}N]^-$.

We have recently developed convenient syntheses of several ruthenium complexes featuring the cyanoacetylide ligand, such as $[Ru(C{\equiv}CC{\equiv}N)(PPh_3)_2Cp]$ (4). In the process

of extending the synthetic methodology, we have had cause to prepare the related iron complex [Fe(C≡CC≡N)(dppe)Cp] (**3**). In this paper we describe the synthesis, molecular structure, and electrochemical response of **3**, together with those of several related complexes.

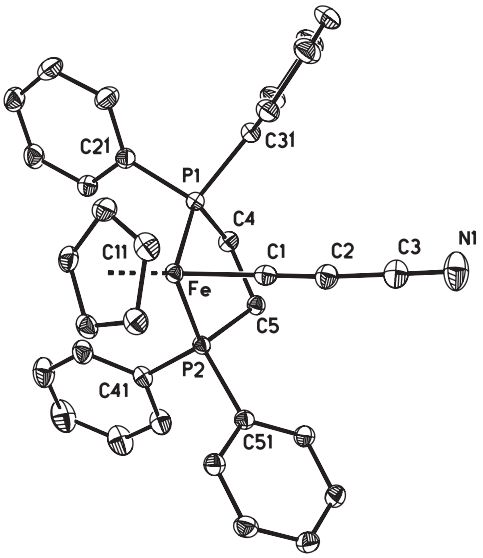
Results and discussion

Acetylide complexes featuring the elementary structure [Fe(C≡CR)(dppx)Cp] (dppx = bis(diphenylphosphino)methane, dppm; 1,2-bis(diphenylphosphino)ethane, dppe) are well-known (5), yet in recent times the development of the chemistry of this system has fallen behind that of the more electron-rich and sterically encumbered [Fe(C≡CR)(dppe)Cp*] analogues (Cp* = η^5-C_5Me_5) (6). This is somewhat surprising given the quite straightforward synthesis of the key reagent [FeCl(dppe)Cp] (**1a**) (7).

In seeking to access an iron cyanoacetylide complex of the general form [Fe(C≡CC≡N)(dppe)Cp], we required access to a synthon for the nucleophilic acetylide anion [Fe(C≡C$^-$)(dppe)Cp]. Although Fe(C≡CH)(dppe)Cp (**2a**) is a known compound (5*b*), the existing synthesis (reaction of Fe(dppe)Cp]$^+$ with [LiC≡CH·TMEDA]) (Scheme 1) was not considered to be optimal given the many advances in synthetic transition metal acetylide chemistry that have been made since the original report of this compound.

We chose instead to examine the possibility of preparing either **2a** or [Fe(C≡CSiMe_3)(dppe)Cp] (**2b**) by formation of the analogous vinylidene, and deprotonation in situ (8). Thus, reaction of [FeCl(dppe)Cp] with excess (4 equiv.) HC≡CSiMe_3 in THF–NEt_3 (1:1 volumetric ratio) resulted in a gradual colour change in the solution from dark purple to orange. Workup gave the orange trimethylsily-protected acetylide complex **2b** in high (~80%) yield (Scheme 2).

Further reaction of **2b** with MeLi (1.6 mol/L in diethyl ether) at low temperature gave an orange-yellow coloured solution containing the intermediate acetylide anion [Fe(C≡C$^-$)(dppe)Cp], which was not isolated but treated in situ with PhOCN to afford the cyanoacetylide complex [Fe(C≡CC≡N)(dppe)Cp] (**3**) as a mustard-yellow coloured solid in 88% yield after chromatography and crystallization (Scheme 2). The cyanoacetylide complex was readily characterized from solution spectroscopic data, which included sharp singlets in the ^{1}H and ^{13}C NMR spectra arising from the Cp ligand (δ_H 4.29, δ_C 80.42), the phosphine resonance in the ^{31}P NMR spectrum (δ_P 104.91), and three carbon resonances arising from the cyanoacetylide ligand (δ_C 153.95, J_{CP} = 37 Hz (C_α); 106.13 (*C*N); 87.02 (C_β)). The C_α resonance, which was unambiguously assigned on the basis of the coupling to the dppe phosphorus nuclei, falls at the higher end of frequencies found in other acetylide complexes, [Fe(C≡CR)(dppe)Cp*] (6*c*). The cyanoacetylide ligand gave rise to two bands of moderate intensity at 2174 and 1991 cm^{-1}, which can be approximated as isolated ν(CN) and ν(CC) vibrations, but could also be a combination of vibrational modes.



The molecular structure of **3** (Fig. 1) was determined by single crystal X-ray diffraction (Table 1), and selected bond lengths and angles are summarized in Table 2. For purposes of comparison, the structure of the related cyanide complex [Fe(C≡N)(dppe)Cp] (**4**) (9) was also determined (Fig. 2), while the complex [Fe(C≡C$C_6H_4NO_2$)(dppe)Cp] (**8**) provides a convenient set of metrical parameters associated with a metal acetylide featuring an electron-withdrawing group (10). The structures of **3**, **4**, and **8** show the expected gross similarities, with the iron centre adopting a pseudo-octahedral environment supported by the Cp ring, the chelating dppe ligand, and the C_nN (*n* = 1 (**4**), 3 (**3**)) or acetylide fragments.

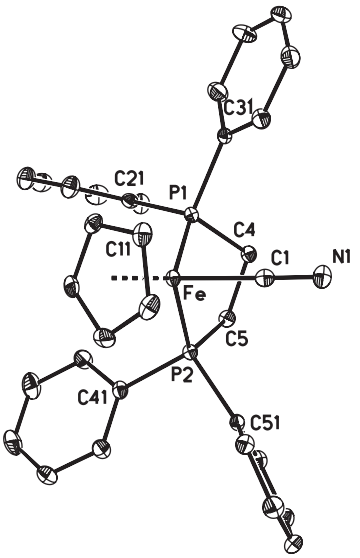
Fig. 1. The molecular structure of Fe(C≡CC≡N)(dppe)Cp (**3**), showing the atom labelling scheme. In this and all subsequent figures hydrogen atoms are omitted for clarity. Selected bond lengths (Å): Fe—C(1), 1.8526(13); C(1)—C(2), 1.2278(19); C(2)—C(3), 1.3672(19); C(3)—N(1), 1.1547(19); Fe—P(1), 2.1726(5); Fe—P(2), 2.1736(5); Fe—Cp(centroid), 1.711(1). Selected bond angles (°): Fe-C(1)-C(2), 176.03(11); C(1)-C(2)-C(3), 176.22(15); C(2)-C(3)-N(1), 178.97(17); P(1)-Fe-P(2), 86.27(2).

The Fe—Cp distances in **3** (2.086(1)–2.105(1) Å, avg. 2.09_5 Å) and **4** (2.093(2)–2.107(2) Å, avg. 2.10_1 Å) are longer than those in **8** (2.060(9)–2.088(10) Å, avg. 2.07_8 Å), as

Table 2. Spectroelectrochemically generated IR data for compounds **3**, **3**$^+$, **[6]**$^+$, **[6]**$^{2+}$, **[7]**$^+$, and **[7]**$^{2+}$.



Compound	ν(C≡CC≡N) (cm^{-1})
3	2174, 1991
3$^+$	2201 (No other band observed)
[6]$^+$	2191, 1976
[6]$^{2+}$	2136, 1932
[7]$^+$	2189, 1984
[7]$^{2+}$	2121, 1946

are the the Fe—P (1, 2) bond lengths (**3**: 2.1736(5), 2.1726(5) Å; **4**: 2.1798(7), 2.1807(7) Å; **8**: 2.158(2), 2.157(2) Å). Interestingly, the intraring C—C distances in the cyclopentadienyl ring (**3**: avg. 1.42_1 Å; **4**: avg. 1.42_3 Å; **8**: avg. 1.37_6 Å) also display a degree of variation between the C_nN and acetylide complexes. Given the significance of back-bonding effects in M—Cp and M—P interactions, the structural trends in M—P and M—Cp bond lengths are consistent with either the decreased σ donation from the C_nN ligands relative to the acetylide ligand in **8**, and (or) a greater degree of iron-to-C_nN back-bonding. The Fe—C_α distance in all three complexes (**3**, **4**, and **8**) are similar (**3**: 1.853(1) Å; **4**: 1.893(2) Å; **8**: 1.856(8) Å), while the acetylide C≡C distance in **3** (1.228(2) Å) is indistinguishable from that in **8** (1.216(10) Å). Both observations argue against any statistically significant structural variation owing to a significant increase in back-bonding in **3** relative to **8**.

Numerous donor ligands (L) are known to react with the dimeric complex $[RhCl(CO)_2]_2$ resulting in cleavage of the chloride bridge, affording monomeric species *cis*-

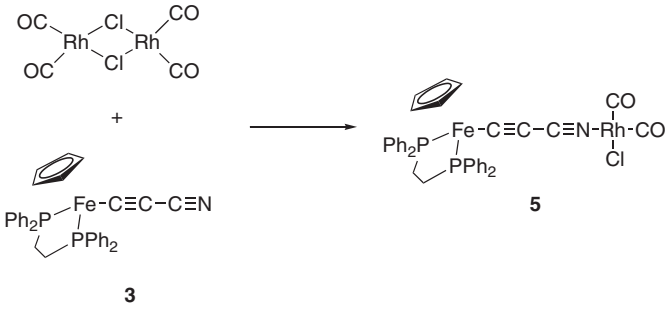
Fig. 2. The molecular structure of Fe(C≡N)(dppe)Cp (**4**), showing the atom labelling scheme. Selected bond lengths (Å): Fe—C(1), 1.893(2); C(1)—N(1), 1.167(3); Fe—P(1), 2.1807(7); Fe—P(2), 2.1798(7); Fe—Cp(centroid), 1.717(1). Selected bond angles (°): Fe-C(1)-N(1), 178.6(2); P(1)-Fe-P(2), 84.84(2).



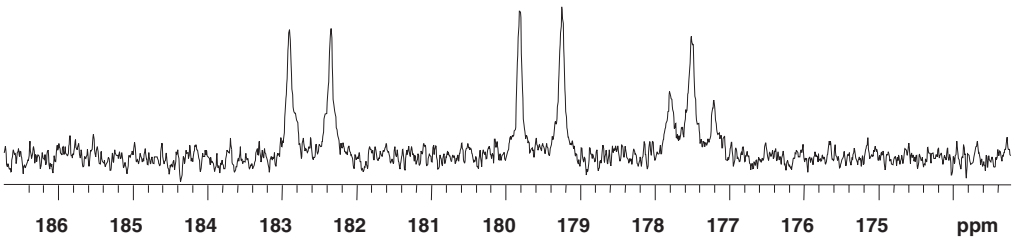
[RhCl(L)$(CO)_2$] or *cis*-[RhCl(L_2)(CO)] (11). The reaction of **3** with [RhCl$(CO)_2]_2$ proceeded smoothly in MeOH to afford *cis*-[RhCl{N≡CC≡CFe(dppe)Cp}$(CO)_2$] (**5**) as a pale orange solid after purification of the reaction mixture by chromatography (Scheme 3).

The cis geometry about the rhodium centre was unequivocally established from the IR spectrum, which revealed ν(CO) bands at 2085 and 2015 cm^{-1} in addition to the characteristic bands of the C≡CC≡N fragment at 2199 and 1978 cm^{-1}, and the ^{13}C NMR spectrum that contained a pair of doublets at 182.28 and 179.25 ppm arising from the two carbonyl ligands that are coupled to the Rh nucleus (Fig. 3). Similar data are associated with complexes derived from aminophosphines and point to the considerable donor character of the iron cyanoacetylide "metalloligand" (11). The ^{13}C NMR spectrum also revealed the remarkably high-frequency C_α resonance, which was observed as a triplet (J_{CP} = 36 Hz) at 177.23 ppm. Whilst the IR data clearly argue against a cumulenic description of the cyanocarbon ligand, the high-frequency ^{13}C shift of C_α supports the concept of a considerably polarized structure, with the electron-rich Fe(dppe)Cp fragment donating considerable electron density to the RhCl$(CO)_2$ fragment via the C≡CC≡N bridge, which also carries a dipole moment in the same orientation.

We have recently described the synthesis of the 36-electron ruthenium and mixed iron–ruthenium diyndiyl complexes [{Cp′(L_2)Ru}(μ-C≡CC≡C){Ru(L_2)Cp′}] and [{Cp*(dppe)Fe}(μ-C≡CC≡C){Ru(L_2)Cp′}] (L = PPh_3, Cp′ = Cp; L_2 = dppe, Cp′ = Cp*), together with the properties of the electrochemically accessible 35- and 34-electron oxidation products (1*b*, 1*c*, 12). The demonstration of considerable interaction between the heterometallic centres in **5** and predominant role of the ruthenium centre in determining the electronic properties of the mixed-metal diyndiyl system prompted us to consider the use of **3** in the preparation of

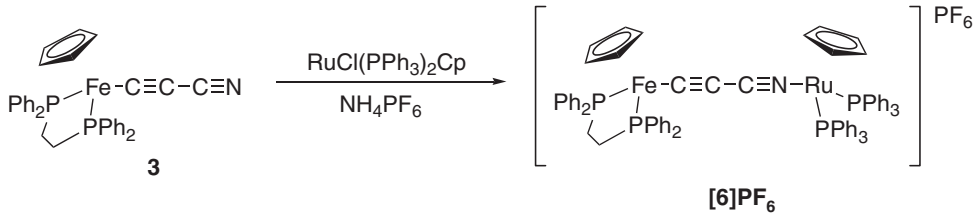
Scheme 3.

the cyanoacetylide-bridged complex, [{Cp(dppe)Fe}(μ-C≡CC≡N){Ru$(PPh_3)_2$Cp]PF_6 (**[6]PF_6**).



Reaction of **3** with RuCl$(PPh_3)_2$Cp in MeOH containing NH_4PF_6 afforded a red solution from which **[6]PF_6** was isolated as a bright yellow crystalline solid after extraction (CH_2Cl_2) and precipitation (hexane) (Scheme 4). Coordination of the Ru$(PPh_3)_2$Cp fragment to the nitrogen centre in **3** was evident from comparison of the spectroscopic data with the properties of model complexes such as **3** and [Ru(NCPh)$(PPh_3)_2$Cp]PF_6 (13, 14). IR spectroscopy revealed a shift in the characteristic cyanoacetylide bands from 2174 and 1991 cm^{-1} in **3** to 2192 and 1977 cm^{-1} in **[6]PF_6**. The presence of the distinct Cp ligands associated with iron and ruthenium were clearly observed in the ^1H NMR spectra (**[6]PF_6**: δ_H(Fe) 4.35; δ_H(Ru) 4.21; **3**: δ_H(Fe) 4.29; δ_H [Ru(NCPh)$(PPh_3)_2$Cp]PF_6 4.55), while the dppe and PPh_3 ligands in **[6]PF_6** gave rise to two singlet resonances in the ^{31}P NMR spectrum at 103.91 (cf. **3**: δ_P 104.91) and 42.20 ppm (cf. [Ru(NCPh)$(PPh_3)_2$Cp]PF_6: δ_P 42.89 ppm), respectively. The complex cation **[6]$^+$** was observed in the ES(+)-MS at *m*/*z* 1260.

The complex [{Cp$(PPh_3)_2$Ru}(μ-C≡CC≡N){Fe(dppe)Cp}]PF_6 (**[7]PF_6**), a coordination (C/N bond) isomer of **[6]PF_6**, was prepared on a previous occasion from the reaction of [Ru(C≡CC≡N)$(PPh_3)_2$Cp] with **1a** (4) (Scheme 5). The spectroscopic properties of **[6]PF_6** and **[7]PF_6** are distinct, which rules out the possibility of ligand isomerism processes occurring during the syntheses. However, as complexes **[6]PF_6** and **[7]PF_6** are the first C/N bond isomers featuring the cyanoacetylide ligand, a concerted effort was made to crystallize both complexes, resulting in samples suitable for single crystal X-ray diffraction (Table 1).



The structures of the cations **[6]$^+$** (Fig. 4) and **[7]$^+$** (Fig. 5) illustrate a number of unusual features. The compounds are isostructural and in both of them the molecules of the metal complex are disordered over two positions (Fig. 4, Fig. 5). The disorder is rather unusual and the two possible orientations differ by interchange of the positions of the ethane bridge and FeCp moiety. Inevitably, three out of four atoms of the central C_3N link in both compounds are also disordered, while the atom coordinated to the Ru centre (N1 (**[6]$^+$**); C1 (**[7]$^+$**)) has large anisotropic displacement parameters. At the same time, the P(1)Ph_2 and P(2)Ph_2 fragments, which are coordinated to the iron centre, are identical in both conformations. The disorder is static, with the structure of **[6]PF_6** remaining disordered in the same fashion at temperatures between 120 and 30 K. The structures of **[6]PF_6**

Scheme 4.

Scheme 5.

and **[7]PF$_6$** also contain disordered PF_6 anions and molecules of the crystallization solvent, CH_2Cl_2.

Although variations in the relative disposition of the metal fragments about a diyndiyl (C≡CC≡C) ligand are common (15), demonstrating the low energy of rotation of the metal fragment about the M—C_α bond, the observation of both cisoid and transoid forms within the same crystal lattice in the case of **[6]PF$_6$** and **[7]PF$_6$** is most unusual. It is also unusual that the same disorder results from the rotation of the Fe(dppe)Cp fragment about both Fe—C (**[6]PF$_6$**) and Fe—N (**[7]PF$_6$**) bonds.

In spite of the disorder, the distinct metal–C/N bond lengths in **[6]PF$_6$** and **[7]PF$_6$** reflect the different metal fragment coordinated at the C and N termini of the C_3N bridge, e.g., Ru—N(1) = 2.054(4) Å in **[6]PF$_6$** and Ru—C(1) = 1.971(5) Å in **[7]PF$_6$**; Fe—C(1) = 1.845(8) Å (transoid) and 1.86(1) (cisoid) Å in **[6]PF$_6$**, Fe—N(1) = 1.904(6) Å (transoid) and 1.92(1) Å (cisoid) in **[7]PF$_6$**. The C(2)≡N(1) bond length in each conformation of **[6]$^+$** (1.183(9), 1.18(1) Å) is longer than the C(3)≡N(4) bond length in the corresponding conformation of **[7]$^+$** (1.16(2), 1.161(9) Å), but the other parameters are generally similar. Curiously, the Fe—P bond lengths are significantly longer in the cisoid conformation of **[6]$^+$** (2.138(2), 2.140(2) Å) than the transoid form (2.117(2), 2.116(2) Å). Back-bonding interactions will influence these Fe—P bond lengths, and we speculate that these Fe—P bond lengths indicate the different conformations observed in the solid state might arise from better transmission of electronic effects among the metal centres in the transoid geometry.

The combination of spectroscopic and structural data associated with the bimetallic complexes provides clear evidence for a degree of interaction between the metal centres through the polarized C≡CC≡N bridging ligand. In an effort to further quantify these interactions, combined electrochemical and spectroelectrochemical (UV–vis–NIR, IR) investigations were carried out. Potentials reported here are referenced against internal ferrocene or decamethyl ferrocene standards as detailed in the Experimental section.

Complex **3** undergoes a single, reversible oxidation event at +0.53 V, which compares to that of the cyanide complex **4** at +0.55 V (16). Under the same conditions, the oxidation potential of [Ru(C≡CC≡N)(PPh_3)$_2$Cp] falls at +0.92 V (4). The bimetallic complexes **[6]PF$_6$** and **[7]PF$_6$** each undergo two oxidation processes, the reversibility of which improves at subambient temperatures. The oxidation potentials of both heterobimetallic complexes, **[6]PF$_6$** (+0.66, +1.34 V) and **[7]PF$_6$** (+0.62, +1.22 V), are similar and do not correlate with a simple model based upon metal-centred oxidation events, but rather indicate a significant donor–acceptor interaction between the iron and ruthenium centres in agreement with the structural data described above.

To access spectroscopic data from the mono- and dioxidized forms of **3**, **[6]PF$_6$**, and **[7]PF$_6$** we turned to spectroelectrochemical methods. Although the oxidation events associated with each complex were reversible on the CV timescale at room temperature, bulk electrolysis reactions in the spectroelectrochemical cells were carried out at ca. –30 °C to restrict complications arising because of decomposition of the electrogenerated oxidation products. Oxi-

dation of [Fe(C≡CC≡N)(dppe)Cp] (**3**) resulted in the collapse of the characteristic ν(C≡CC≡N) bands of the unsaturated ligand and observation of a band at 2201 cm^{-1} of significantly lower intensity (Table 2). The pseudo ν(C≡C) band in this oxidized species, **[3]**$^+$, was not apparent, perhaps because of its low intensity. In contrast, two bands were observed following oxidation of the bimetallic complexes **[6]PF$_6$** and **[7]PF$_6$**, which were shifted to lower energy by ca. 40–70 cm^{-1} in comparison with the spectra of the precursors, and therefore supporting the notion of an oxidation event that involves an orbital with an appreciable degree of ligand as well as metal character. In each case the original spectral profile was recovered after back-reduction of the oxidized samples.

The electronic (UV–vis–NIR) spectrum of **3** changed little upon oxidation, and recovery of the original spectrum after back-reduction demonstrated the chemical reversibility of the electrochemical oxidation. Crucially, the NIR region of the spectrum remained transparent before and after oxidation of **3**. More interestingly, the one-electron oxidation products derived from **[6]PF$_6$** and **[7]PF$_6$** exhibited intense absorptions in the NIR region, each of which could be deconvoluted into three Gaussian-shaped absorption bands (Fig. 6, Table 3). Of these, the particularly low energy band of low intensity ($\bar{\nu}_{max}$(cm^{-1})/ε_{max} = 5260 cm^{-1}/140 (mol/L)$^{-1}$ cm^{-1} (**[6]**$^{2+}$); 5980 cm^{-1}/190 (mol/L)$^{-1}$ cm^{-1} (**[7]**$^{2+}$)) was approximated as a forbidden ligand–field transition associated with the oxidized iron centre (6*h*, 6*k*, 17), which indicates that the

first oxidation event has some iron character in both C/N bond isomers.

Demandis et al. (18) have recently reviewed the properties of strongly coupled, ligand-bridged bimetallic mixed valence complexes, and described the various contributions of metal–ligand orbital mixing, spin-orbit coupling, and low symmetry, which lead to the three transitions that are in principle allowed between d^6 and d^5 metal ions to gather appreciable intensity. While the 35-electron, heterobimetallic dications **[6]**$^{2+}$ and **[7]**$^{2+}$ are not true mixed-valence species, similar considerations apply to the electronic spectra of these complexes. Since spin-orbit effects are relatively minor in lighter first and second row transition elements, the observation of multiple transitions in the NIR region of both species provides further evidence that the electronic structure of these heterometallic systems features a considerable degree of metal–ligand mixing. The band energy and shape are remarkably similar for both **[6]**$^{2+}$ and **[7]**$^{2+}$, and consequently similar transitions, and hence underlying electronic structures, are involved in both isomers.

The relationships originally derived by Hush (19) provide a vehicle for comparison of the electron-transfer processes occurring through the cyanoacetylide ligand in the complexes reported here with those observed in a large number of cyanide-bridged examples (20). Using the deconvoluted band shapes, and assuming that electron-transfer distance is approximated by the crystallographically determined metal–metal separation, a coupling parameter (H_{ab}) may be calculated for each band using the expression give in eq. [1] (Table 3) (19).

$$[1] \qquad H_{ab} = \frac{0.0205\sqrt{\bar{\nu}_{max}\varepsilon\Delta\bar{\nu}_{1/2}}}{d'_{MM}}$$

Typically, values of H_{ab} for heterometallic cyanide bridged d^5/d^6 bimetallic complexes are in the range 1000–1700 cm^{-1} when the NIR band shape data is treated in an entirely similar fashion. We note, however, that the use of the metal–metal distance is only a crude approximation of the electron-transfer distance, and given the involvement of the ligand orbitals in the SOMO, the real electron-transfer distance is likely to be considerably shorter. The values of H_{ab} reported in Table 3 represent a lower limit for the value of this parameter.

Whilst the availability of these 35-electron species as isolated samples would have greatly facilitated this study by allowing ready measurement of the solvent dependence of the NIR bands and permitted access to Mössbauer and magnetic data, it is unfortunate that at the present time we have been unable to chemically isolate samples of **[6]**$^{2+}$ or **[7]**$^{2+}$ as salts with common counterions. However, efforts in this area are ongoing, and with the possibility of exchanging the Cp for Cp* and related substituted cyclopentadienyl ligands, together with the large variety of phosphine ligands that may be introduced at either metal centre, we are hopeful that further information regarding the electronic structure of these unusual cyanoacetylide-bridged heterobimetallic complexes will become available in due course.

Conclusion

The readily prepared substrate FeCl(dppe)Cp is a convenient reagent for the preparation of both acetylide and cyanoacetylide iron complexes. The iron–cyanoacetylide complex, [Fe(C≡CC≡N)(dppe)Cp], is a good metalloligand, readily coordinating to $RhCl(CO)_2$ or $Ru(PPh_3)_2Cp$ fragments to afford heterometallic complexes featuring the μ-η^1(C),η^1(N)-C≡CC≡N ligand. Spectroscopic data are consistent with a significant degree of polarization in the structures of the 36-electron species, and relatively large values of the coupling constant H_{ab} in the electrochemically generated 35-electron (d^5/d^6) dication, [{Cp(dppe)Fe}(μ-C≡CC≡N){Ru(PPh$_3$)$_2$Cp}]$^{2+}$, and its C/N bond isomer, [{Cp(PPh$_3$)$_2$Ru}(μ-C≡CC≡N){Fe(dppe)Cp}]$^{2+}$.

Experimental

All reactions were carried out using standard Schlenk techniques under dry high-purity nitrogen. Solvents were dried using an Innovative Technologies solvent purification system, and degassed prior to use. Preparative TLC was carried out on 20 cm × 20 cm glass plates coated with silica gel (Merck G_{254}, 0.5 mm thick). Reagents were purchased and used as received. Compounds **1a** (7), **4** (9), and **[7]PF$_6$** (4) were prepared according to the literature methods. Crystals of **4** and **[7]PF$_6$** suitable for X-ray diffraction were obtained from CH_2Cl_2–hexane and CH_2Cl_2–MeOH, respectively. IR spectra were recorded on a Nicolet Avatar FT IR spectrophotometer using solution cells fitted with CaF_2 windows. NMR spectra were obtained from solutions in $CDCl_3$ using Varian VXR-400 (^{1}H, 399.97 MHz; ^{13}C, 100.57 MHz; ^{31}P, 161.1 MHz) or Bruker DRX-400 (^{1}H, 400.13 MHz; ^{13}C, 100.61 MHz; ^{31}P, 162.05 MHz) spectrometers. Electrochemical experiments were conducted in CH_2Cl_2 solution containing 0.1 mol/L NBu_4PF_6 using a standard three-electrode cell (all Pt electrodes) and an EcoChemie Autolab PGSTAT-30. Potentials were corrected to SCE using an internal ferrocene/ferrocinium (Fc/Fc^+ = 0.46 V) or decamethylferrocene/decamethylferrocinium couple as standard (Fc^*/Fc^{*+} = 0.084 V).

IR spectroelectrochemical studies

IR spectroelectrochemical experiments at low temperatures were performed with a cryostated, optically transparent thin-layer electrochemical (OTTLE) cell equipped with CaF_2 windows and a Pt minigrid working electrode (32 wires/cm) (21). The electrolyses at room temperature were conducted with another homemade demountable OTTLE cell (22). The CH_2Cl_2 employed solutions were typically 3×10^{-1} mol/L in the supporting electrolyte (NBu_4PF_6) and 10^{-3} mol/L in the analyte. The working electrode potential of the spectroelectrochemical cell was controlled with a PA4 potentiostat (EKOM, Polná, Czech Republic). The IR spectra were recorded with Bio-Rad FTS-7 and Bruker Vertex 70 FT IR spectrometers (16 scans, 1 to 2 cm^{-1} spectral resolution).

UV–vis–NIR spectroelectrochemical studies

UV–vis–NIR were carried out using a Varian Cary 5 spectrophotometer in an OTTLE cell similar to that described previously (23) from solutions in CH_2Cl_2 containing 10^{-1} mol/L NBu_4BF_4 as supporting electrolyte. Typically analyte concentrations were 10^{-1} mmol/L.

[Fe(C≡CSiMe$_3$)(dppe)Cp] (2b)

A Schlenk flask was charged with [FeCl(dppe)Cp] (2.0 g, 3.60 mmol), $NaBPh_4$ (1.48 g, 4.32 mmol), THF (75 mL), and NEt_3 (75 mL), and the resulting dark solution treated with $Me_3SiC{\equiv}CH$ (1.77 g, 2.54 mL, 18.0 mmol). After stirring for 16 h the solution colour had turned deep orange. The solvent was removed and the residue extracted with Et_2O and pentane added. The combined solvent was removed resulting in precipitation of a dark orange solid (1.75 g, 79%). IR (CH_2Cl_2, cm^{-1}): 1984 ν(C≡C). ^{1}H NMR ($CDCl_3$) δ: 0.06 (s, 9H, $SiMe_3$), 2.12 (m, 2H, dppe), 2.81 (m, 2H, dppe), 4.32 (s, 5H, Cp), 7.04–8.11 (m, 20H, Ph). ^{13}C{H} NMR ($CDCl_3$) δ: 1.00 (s, $SiMe_3$), 27.96–28.32 (m, CH_2 dppe), 79.52 (s, Cp), 103.85 (s, C_β), 127.87 (dt, J_{CP} = 58, 4 Hz, m-Ph), 129.13 (d, J_{CP} = 42 Hz, p-Ph), 133.14 (dt, J_{CP} = 248, 5 Hz, o-Ph), 138.00–142.64 (m, i-Ph), 151.39 (t, J_{CP} = 39 Hz, C_α). ^{31}P{H} NMR ($CDCl_3$) δ: 107.71 (s, dppe). ES(+)-MS (*m*/*z*): 616.9 [M + H]$^+$. Anal. calcd. for $C_{36}H_{38}FeP_2Si$ (%): C 70.13, H 6.21; found: C 69.94, H 6.32.

[Fe(C≡CC≡N)(dppe)Cp] (3)

A Schlenk flask was charged with [Fe(C≡CSiMe$_3$)(dppe)Cp] (500 mg, 0.81 mmol) in THF (20 mL). The orange/yellow solution was cooled to –78 °C and MeLi (0.6 mL, 0.96 mmol of a 1.6 mol/L solution in Et_2O) was added at such a rate as to prevent the temperature exceeding –50 °C. After stirring for 1 h the solution was warmed to –20 °C before being cooled again. To the orange/yellow solution was added PhOCN (0.5 mL, 0.9 mmol) and the solution allowed to come slowly to room temperature before the solvent was removed. The dark red/brown residue was dissolved in CH_2Cl_2 and purified by column chromatography on silica, the product eluting with acetone–hexane (30:70). Concentration of the dark red fraction resulted in the formation of a mustard yellow precipitate, which was collected, washed with hexane, and air dried to afford **3**, which was recrystallized from CH_2Cl_2–Et_2O (yield: 400 mg, 88%). IR (CH_2Cl_2, cm^{-1}): 2174, 1991 ν(C≡CC≡N). ^{1}H NMR ($CDCl_3$) δ: 2.32 (m, 2H, dppe), 2.60 (m, 2H, dppe), 4.29 (s, 5H, Cp), 7.74–6.85 (m, 20H, Ph). ^{13}C{H} NMR ($CDCl_3$) δ: 27.88–28.35 (m, CH_2 dppe), 80.42 (s, Cp), 87.02 (s, C_β), 106.13 (s, CN), 127.99 (dt, J_{CP} = 26, 4 Hz, m-Ph), 129.58 (d, J_{CP} = 53 Hz, p-Ph), 132.23 (dt, J_{CP} = 167, 4 Hz, o-Ph), 135.55–140.21 (m, i-Ph), 153.95 (t, J_{CP} = 37 Hz, C_α). ^{31}P{H} NMR ($CDCl_3$) δ: 104.91 (s, dppe). ES(+)-MS (*m*/*z*): 570.1 [M + H]$^+$. Anal. calcd. for $C_{34}H_{29}FeNP_2$ (%): C 71.72, H 5.13, N 2.46; found: C 71.67, H 5.07, N 1.72.

[{Cp(dppe)Fe}(μ-C≡CC≡N){*cis*-RhCl(CO)$_2$}] (5)

A Schlenk flask was charged with [Fe(C≡CC≡N)(dppe)Cp] (73 mg, 0.129 mmol), $[RhCl(CO)_2]_2$ (25 mg, 0.065 mmol), NH_4PF_6 (35 mg, 0.215 mmol), and MeOH (25 mL), and the resulting solution stirred for 48 h. The solvent was then removed and the residue extracted with CH_2Cl_2 and filtered through a small pad of silica. Addition of hexane to the CH_2Cl_2 solution and concentration resulted in an orange precipitate, which was collected, washed with pentane, and air dried (yield: 50 mg, 51%). IR (CH_2Cl_2, cm^{-1}): 2199, 1991 ν(C≡CC≡N); 2085, 2015 ν(CO). ^{1}H NMR ($CDCl_3$) δ: 2.37 (m, 2H, dppe), 2.60 (m, 2H, dppe), 4.36 (s, 5H, Cp), 7.68–7.17 (m, 20H, Ph). ^{13}C{H} NMR ($CDCl_3$) δ: 28.24–28.59 (m, CH_2 dppe), 81.58 (s, Cp), 85.32 (s, C_β), 106.27 (s, CN), 128.30–139.41 (m, Ph), 177.23 (t, J_{CP} = 36 Hz, C_α), 179.25 (d, J_{RhC} = 70 Hz, CO cis to NC), 182.28 (d, J_{RhC} = 70 Hz, CO trans to NC). ^{31}P{H} NMR ($CDCl_3$) δ: 103.45 (s, dppe). Anal. calcd. for $C_{36}H_{29}ClFeNO_2P_2Rh$ (%): C 56.61, H 3.83, N 1.83; found: C 56.22, H 3.96, N 1.37.

[{Fe(dppe)Cp}(C≡CC≡N){Ru(PPh$_3$)$_2$Cp}]PF$_6$ ([6]PF$_6$)

A Schlenk flask was charged with [Fe(C≡CC≡N)(dppe)Cp] (75 mg, 0.132 mmol), $[RuCl(PPh_3)_2Cp]$ (96 mg, 0.132 mmol), and NH_4PF_6 (86 mg, 0.528 mmol). The mixture was suspended in MeOH (15 mL) and refluxed for 1 h after which time a dark red solution had formed. This was

© 2006 NRC Canada

allowed to cool and the solvent removed. The red/brown residue was extracted with CH_2Cl_2 and filtered into hexane. The resulting yellow precipitate was collected, washed with hexane, and air dried to afford **[6]PF$_6$** (yield: 105 mg, 57%). Crystals suitable for X-ray diffraction were obtained from CH_2Cl_2–hexane. IR (CH_2Cl_2, cm^{-1}): 2192, 1977 ν(C≡CC≡N). ^1H NMR ($CDCl_3$) δ: 1.62 (br, 8H, dppe), 4.21, 4.35 (2 × s, 10H, 2 × Cp), 6.97–7.64 (m, 40H, Ph). $^{31}P\{H\}$ NMR ($CDCl_3$) δ: –143.11 (ht, J_{PF} = 711 Hz, PF_6^-), 42.20 (s, PPh_3), 103.91 (s, dppe). ES(+)-MS (*m/z*): 1260 [{Fe(dppe)-Cp}(C≡CC≡N){Ru(PPh_3)$_2$Cp}]$^+$; 691 [Ru(PPh_3)$_2$Cp]$^+$ Despite repeated efforts to remove solvent from the analytical sample, this compound consistently analysed with 1/2 molecule of the CH_2Cl_2 crystallization solvent. Anal. calcd. for $C_{75}H_{64}F_6FeNP_5Ru{\cdot}0.5CH_2Cl_2$ (%): C 62.64, H 4.53, N 0.97; found: C 62.29, H 4.43, N 0.91.

Crystallography

The X-ray data sets for compounds **3**, **4**, **[6]PF$_6$**, and **[7]PF$_6$** were collected on Bruker 3-circle diffractometers with Bruker ProteumM diffractomer and Bede Microsource® (for **3**, **4**, and **[6]PF$_6$**) or SMART 6K (for **[7]PF$_6$**) CCD area detectors using graphite-monochromated sealed-tube Mo K_α radiation. The data collection was carried out at 120 K using cryostream (Oxford cryosystem) open flow N_2 cryostats. Reflection intensities were integrated using the SAINT program, version 6.02a (for **3** and **[6]PF$_6$**) and version 6.45 (for **4** and **[7]PF$_6$**) (24). The crystal structures were solved using direct-methods and refined by full matrix least-squares against F^2 of all data using SHELXTL software (25). All non-hydrogen atoms where refined in anisotropic approximation (for **3** and **4**). In the case of **[6]PF$_6$** and **[7]PF$_6$**, the non-hydrogen atoms located in two different sites, PF_6^- anions, and solvent molecules where refined in isotropic approximation.

Hydrogen atoms were placed in calculated positions and refined using a riding model (for **4**, **[6]PF$_6$**, and **[7]PF$_6$**) or located by different Fourier maps and refined unconstrained (for **3**). All four crystal structures present dichloromethane molecules, and for **[6]PF$_6$** and **[7]PF$_6$** the solvent molecules are highly disordered with connectivity between atoms only visible for one dichloromethane molecule.

Crystal data and experimental details are listed in Table 1.[3]

An acidity scale of phosphonium tetraphenylborate salts and ruthenium dihydrogen complexes in dichloromethane[1]

Tianshu Li, Alan J. Lough, Cristiano Zuccaccia, Alceo Macchioni, and Robert H. Morris

Abstract: Equilibrium constants (K^{DM}) for reactions between acids and bases of the title compounds in CD_2Cl_2 (DM) have been determined by ^{31}P and ^{1}H NMR spectroscopy at room temperature. $[HPCy_3]BPh_4$ and $[HPCy_3]BF_4$, with pK^{DM} assigned by literature convention to 9.7, have been used as the anchor compounds for the pK^{DM} determinations. A continuous scale of pK^{DM} values covering the range 9.7 to 5.7 is created with the acidic compounds $[HPR_3]BPh_4$. Those acids with pK^{DM} greater than 6 are stable, while those with more acidic cations HPR_3^+ protonate BPh_4^- to produce R_3PBPh_3 and benzene. The literature pK^{THF} values reported for $[HPBu_2Ph]BPh_4$, $[HPMePh_2]BPh_4$, and $[HPEtPh_2]BPh_4$ are questionable because of this protonation reaction. NOE and PGSE ^{1}H NMR techniques are used to show that $[HPCy_2Ph]BPh_4$ in DM exists as ion pairs and higher aggregates up to quadrupoles at the concentrations used in the acid–base studies. The new dihydrogen complexes $[Ru(H_2)Cl(PPh_3)_2(dach)]BF_4$ (dach = (1*R*,2*R*)-(–)-diaminocyclohexane) and $[Ru(H_2)Cl\{tmeP_2(NH)_2\}]BF_4$ ($tmeP_2(NH)_2$ = $PPh_2C_6H_4CH_2NHCMe_2CMe_2NHCH_2C_6H_4PPh_2$) were prepared by reaction of $RuHCl(PPh_3)_2(dach)$ and $RuHCl\{tmeP_2(NH)_2\}$ with HBF_4. Their crystal structures are reported, and the pK^{DM} values of their BPh_4^- salts were determined to be 8.6 and 6.9, respectively.

Key words: acidity, dihydrogen complex, hydride, phosphonium, dichloromethane.

Résumé : Opérant à la température et dans le CD_2Cl_2 (DM) comme solvant et faisant appel à la spectroscopie RMN du ^{1}H et du ^{31}P, on a déterminé les constantes d'équilibre, K^{DM}, des réactions entres les acides et les bases des composés mentionnés dans le titre. La valeur de 9,7 attribuée par convention dans la littérature pour les composés $[HPCy_3]BPh_4$ et $[HPCy_3]BF_4$ a été utilisé comme composés de référence pour les déterminations des pK^{DM}. On a créé une échelle continue de valeurs de pK^{DM} s'étalant de 9,7, à 5,7 en faisant appel aux composés acides $[HPR_3]BPh_4$. Ces acides dont les valeurs de pK^{DM} sont supérieures à 6 sont stables alors que ceux des cations plus acides HPR_3^+ se protonent au BPh_4^- pour conduire à la formation de R_3PBPh_3 et de benzène. Les valeurs de pK^{THF} rapportées dans la littérature pour les $[HPBu_2Ph]BPh_4$, $[HPMePh_2]BPh_4$ et $[HPEtPh_2]BPh_4$ ne sont pas fiables en raison de cette réaction de protonation. On a utilisé les techniques d'effet Overhauser nucléaire et d'écho de spin a champ pulsé PGSE en RMN du ^{1}H pour montrer que dans le DM, aux concentrations utilisées pour les études acide–base, le $[HPCy_2Ph]BPh_4$ existe sous la forme de paire d'ions et d'agrégats plus importants allant jusqu'à des quadrupoles. La réaction du $RuHCl(PPh_3)_2(dach)$ et $RuHCl\{tmeP_2(NH)_2\}$ avec du HBF_4 a permid de préparer les deux nouveaux complexes de dihydrogène suivants $[Ru(H_2)Cl(PPh_3)_2(dach)]BF_4$ (dach = (1*R*,2*R*)-(–)-diaminocyclohexane) et $[Ru(H_2)Cl\{tmeP_2(NH)_2\}]BF_4$ ($tmeP_2(NH)_2$ = $PPh_2C_6H_4CH_2NHCMe_2CMe_2NHCH_2C_6H_4PPh_2$) dont on a déterminé les structures cristallines et les valeurs de pK^{DM} de leurs sels BPh_4^- qui s'établissent respectivement à 8,6 et 6,9.

Mots clés : acidité, complexe de dihydrogène, hydrure, phosphonium, dichlorométhane.

[Traduit par la Rédaction]

Introduction

The quantitative study of the acidity of transition metal hydride and dihydrogen complexes serves to better the understanding of the reactions of these species in catalytic reactions, including those of hydrogenases. Our previous work focused mainly on the use of tetrahydrofuran (THF) as a useful solvent in the study of metal hydride and dihydrogen

Received 9 June 2005. Published on the NRC Research Press Web site at http:canjchem.nrc.ca on 1 March 2006.

Dedicated to Dr. Arthur Carty, National Science Advisor to the Prime Minister of Canada, for his exemplary contributions to and support of science in Canada.

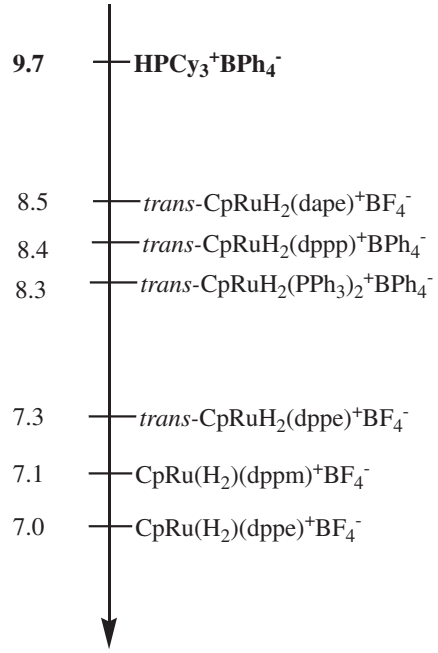
complexes with a wide range of pK_α^{THF} values (1). The use of α in this acidity symbol indicates that the effects of ion pairing on the acid–base equilibria are approximately accounted for by use of the Fuoss equation. This approach has since been used by Leito and co-workers (2). Tetrahydrofuran cannot be used as a solvent for very acidic compounds because it can be protonated and undergo ring-opening reactions. Dichloromethane is a good solvent for this purpose because it is relatively noncoordinating and it dissolves many neutral and cationic metal complexes without reaction, as long as they are not too reducing or nucleophilic. Several pK^{DM} values of metal hydride and dihydrogen complexes in CH_2Cl_2 have been reported by the groups of Jia, Morris, and co-workers (3–7). Only a short continuous ladder of acids in the range of 9.7 to 7.0 was built on the basis of equilibria referenced to $[HPCy_3]BPh_4/PCy_3$ as a standard with pK = 9.7 (Fig. 1) (4). This is the same reference value used for the pK_α^{THF} scale (and pseudo pK_a^{aq} scale) (4, 8), but it will have to be redefined when an absolute value is determined relative to the solvated proton in CH_2Cl_2. There is no continuous ladder based on cationic acids with exclusively one type of anion (e.g., BPh_4^-) in CD_2Cl_2. In this study, we make a limited scale of acidic compounds with BPh_4^- anions. In a second paper we will describe a more extensive ladder involving BF_4^- salts. Although phosphonium salts are of utility as air-stable sources of air-sensitive trialkylphosphines (9), we show here that the tetraphenylborate salts of the more acidic aryl phosphonium compounds are unstable.

We also report the pK^{DM} of two new ruthenium dihydrogen trans-to-chloride complexes. These were prepared while exploring the application of such ruthenium hydrides for the catalytic hydrogenation of compounds with polar bonds (10, 11). Cationic ruthenium dihydrogen complexes have attracted interest with the recent report of Noyori and co-workers (12) that *trans*-[Ru(H_2)(H)((*R*)-binap)((*R,R*)-dpen)]$^+$ is an intermediate in the asymmetric catalytic H_2-hydrogenation of prochiral ketones catalyzed by RuH(BH_4)((*R*)-binap)((*R,R*)-dpen) in isopropanol. Bergens and co-workers (13) spectroscopically identified this unstable dihydrogen complex in deuterated isopropanol and reported that at least 1 equiv. of base is necessary to convert this complex to a catalytically active species.

Results and discussions



The preparation of $[HPR_3]BPh_4$

The tetrafluoroborate salts $[HPR_3]BF_4$ can be readily prepared by protonation of PR_3 (PR_3 = PCy_3, P-*n*-Bu_3, PCy_2Ph, P-*t*-Bu_2Ph) with $H(Et_2O)BF_4$ in diethyl ether (eq. [1]). As reported previously (1), these salts react with $NaBPh_4$ in ethanol to form the corresponding salts $[HPR_3]BPh_4$ (eq. [2]). However, we found that there is a limitation to this preparation. When the phosphonium salts HPR_3^+ (PR_3 = PBu_2Ph, PMe_2Ph, $PEtPh_2$, P(*p*-toly)$_3$, PPh_3) are more acidic than $HPCy_2Ph^+$, the borane adducts $PR_3{\cdot}BPh_3$ are isolated instead of the tetraphenylborate salts $[HPR_3]BPh_4$. A phenyl group of the BPh_4^- is protonated to form benzene (eq. [3]). The $PR_3{\cdot}BPh_3$ compounds were identified by ^{31}P and ^1H NMR.

[1] $PR_3 + H(Et_2O)BF_4 \rightarrow [HPR_3]BF_4$

[2] $[HPR_3]BF_4 + NaBPh_4 \rightarrow [HPR_3]BPh_4 + NaBF_4$

Fig. 1. The acidity ladder of pK^{DM} values of the cationic ruthenium complexes with $[HPCy_3]BPh_4$ as a standard.

[3] $[HPR_3]BPh_4 \rightarrow C_6H_6 + PR_3{\cdot}BPh_3$

There have been scattered reports of the protonation of the tetraphenylborate anion. Our group encountered it in the preparations of cationic hydrogen isocyanide complexes that were sometimes produced instead of the complexes Fe(TIM)$(CNBPh_3)_2$ (14) and RuH$(CNBPh_3)(dppe)_2$ (15), for example. This has also been reported by Pombeiro and co-workers (16) in the preparation of *trans*-[FeH$(CNBPh_3)(dppe)_2$]. The acidic dihydrogen complex [Ir(H_2)H(triphos)]BPh_4 decomposes to IrH_3(triphos), BPh_3, and benzene (17). However, several cationic dihydrogen and hydride complexes with tetraphenylborate counterions have been reported (for example, refs. 18–28), and so these are likely to be less acidic than $HPCy_2Ph^+$.

NOE and PGSE NMR measurements of $[HPCy_2Ph]BPh_4$

Ion pairing in low dielectric constant solvents like CH_2Cl_2 can lead to changes in reactivity and catalytic activity and selectivity (29). Table 1 shows the results of the study of NOE between ions (31) of the compound $[HPCy_2Ph]BPh_4$. Only the *meta*-aryl hydrogens of the anion (mH_a) can be used as a "reporter", since the resonances of oH_c and oH_a are superimposed. These meta protons are at about the same distance from both the hydrogen on the phosphorus and the hydrogen (H1) on each of the two ipso carbons of the cyclohexyl groups (Fig. 2, Table 1), thus demonstrating the interpenetration of the cation and anion. It is not surprising that more acidic salts can readily undergo transfer of the phosphorus proton to a phenyl ring carbon of the BPh_4^- anion, resulting in B—C bond cleavage.

The pulsed field gradient spin-echo (PGSE) NMR diffusion method (32, 33) is a powerful technique in determining the solution properties of ion pairs (34–36). From the mea-

[b]Reference distance.

sured self-diffusion coefficients (D_t), the average hydrodynamic radius (r_H) and volume (V_H) of the diffusing particles were derived, taking advantage of the Stokes–Einstein equation that relates D_t with $1/r_H$. TMSS [tetrakis(trimethylsilyl)silane], whose r_H and V_H are known from the literature (37), was used as internal standard. The methodology to obtain accurate r_H and V_H values has been described elsewhere (38). The average hydrodynamic volumes for cation (V_H^+) and anion (V_H^-) determined from ^{1}H PGSE experiments were contrasted with the van der Waals volume of the ion pair (V_{IP}). The cationic and anionic aggregation numbers (N^+ and N^-) were calculated as the ratios V_H^+/V_{IP} and V_H^-/V_{IP} (Table 2).

The salt $[HPCy_2Ph]BPh_4$ in CH_2Cl_2 forms aggregates higher than ion pairs even at the lowest concentration investigated (entry 1, Table 2). The aggregation number for the cations, N^+, is 1.2 and that of the anions, N^-, is 1.6, indicating a dynamic equilibration of ion pairs, triples (e.g., $(HPCy_2Ph^+)(BPh_4^-)_2$), and quadrupoles. The tendency to aggregate increases as the concentration increases, resulting in N^+ and N^- values of 1.8 and 2.0, respectively, at 0.03 mol L^{-1} (entries 1–3 in Table 2). This is the range of concentrations used in our acid equilibrium studies, and so, such aggregation is a potential complication in interpreting our results.

pK^{DM} determination

The acid (BH^+) and base (B) reaction equilibria are built based on eq. [4]. The equilibrium constants K_{eq} for reactions

Table 2. Diffusion coefficients (D (10^{-10} m^2 s^{-1})), hydrodynamic radii (r_H (Å)), hydrodynamic volumes (V_H (Å^3)), and aggregation number values (N) for $[HPCy_2Ph]BPh_4$ in CD_2Cl_2.

Entry	Concn. (mmol L^{-1})	D^+	D^-	r_H^+	r_H^-	V_H^+	V_H^-	N^+	N^-
1	1.5	11.1	9.90	5.37	5.88	648	850	1.19	1.56
2	9	10.3	9.72	5.68	5.97	767	892	1.40	1.63
3	27	9.42	9.04	6.13	6.35	967	1072	1.77	1.97

Note: N is the ratio between the experimentally determined hydrodynamic volume and the van der Waals volume of the ion pair; + and – refer to the cation and anion of $[HPCy_2Ph]BPh_4$, respectively.

in CD_2Cl_2 were measured by use of quantitative $^{31}P\{^1H\}$ and ^1H NMR at room temperature. In view of the PGSE experiments, eq. [4] is a simplification of the actual ion-pairing equilibria that are present. However the ^{31}P NMR experiment measures the total phosphorus concentration, and these species are all in rapid equilibrium. If the extent and nature of ion pairing is the same for $B_1H^+X^-$ and $B_2H^+X^-$, then eq. [4] represents a practical, first-order description of the chemistry. K_{eq} in the range 10^3 to 10^{-3} can be measured with a 10%–30% error. The difference in pK^{DM} between the two acids $B_1H^+BPh_4^-$ and $B_2H^+BPh_4^-$ is calculated from the equilibrium constants (K_{eq}) by use of eq. [5].

$$[4] \quad B_1 + B_2H^+X^- \overset{K_{eq}}{\rightleftharpoons} B_1H^+X^- + B_2$$

$$[5] \quad \Delta pK^{DM} = \Delta pK_{eq} = pK^{DM}(B_1H^+X^-) - pK^{DM}(B_2H^+X^-)$$

$$[6] \quad \Delta pK^{DM} = \Delta pK_{fi}^{DM} = pK_{fi}^{DM}(B_1H^+) - pK_{fi}^{DM}(B_2H^+)$$

Ideally, we want the pK_{fi}^{DM} values for the free ions BH^+, independent of the counterion X^-, and not the ion-paired species BH^+X^- and its aggregates. If the extent of ion pairing is the same for $B_1H^+X^-$ and $B_2H^+X^-$, then pK^{DM} and pK_{fi}^{DM} values will be approximately the same (eq. [6]). $[HPCy_3]BPh_4$, with a free ion $pK_{fi}^{DM}(HPCy_3^+) = 9.7$, was chosen as the anchor for the scale in CD_2Cl_2, as in the THF scale (1). Overlapping equilibria were examined with more acidic compounds to create a continuous ladder of values (e.g., eqs. [7] and [8]).

$$[7] \quad PCy_3 + [HBu_3]BPh_4 \underset{pK_{eq} = -1.1}{\rightleftharpoons} \underset{9.7}{[HPCy_3]BPh_4} + PBu_3$$

$$[8] \quad pK_{fi}^{DM}(HPBu_3^+) = 9.7 + pK_{eq} = 8.6$$

A short acidity scale ladder of phosphonium tetraphenylborate salts in CD_2Cl_2 was built by this method (shown in Fig. 3). The estimated errors for the equilibrium constants are listed in Tables 3 and 4. The cumulative error in pK^{DM} value is calculated by eq. [9]. The errors in the last digit are shown in parentheses in Fig. 3. They represent the combination of the cumulative errors relative to the reference value of 9.7 and the estimated errors for K_{eq}.

$$[9] \quad \text{Cumulative error in } pK^{DM} = \pm 0.08\ |pK^{DM} - 9.7|$$

The equilibrium constant K_{eq} in the reaction between $HPCy_2Ph^+$ and PBu_2Ph has to be obtained by the immediate measurement of the NMR spectrum after mixing. Right after mixing, a signal due to $HPBu_2Ph^+$ can be observed. Longer standing (1 h) of the mixture causes a decay of $HPBu_2Ph^+$ to produce the $PBu_2Ph{\cdot}BPh_3$ species (Scheme 1). This suggests that $HPCy_2Ph^+$ with the pK^{DM} value of 6.6 is the most acidic BPh_4^- salt that can be obtained.

The pK^{DM} values of Fig. 3 show the expected substituent effect of an increase in acidity of the phosphonium with a change from alkyl to phenyl group. Replacing Cy or Bu by Ph causes a decrease of approx 3 units of pK^{DM}. The pK^{DM} values for phosphonium salts with pK^{DM} value greater than 6.5 are in reasonable agreement with the corresponding pK_α^{THF} values (Fig. 4). However, the reported values (1) of pK_α^{THF} for $[HPBu_2Ph]BPh_4$ (6.7), $[HPMePh_2]BPh_4$ (6.3), and $[HPEtPh_2]BPh_4$ (5.3) are questionable, and these equilibria may in fact involve the protonation of tetraphenylborate.

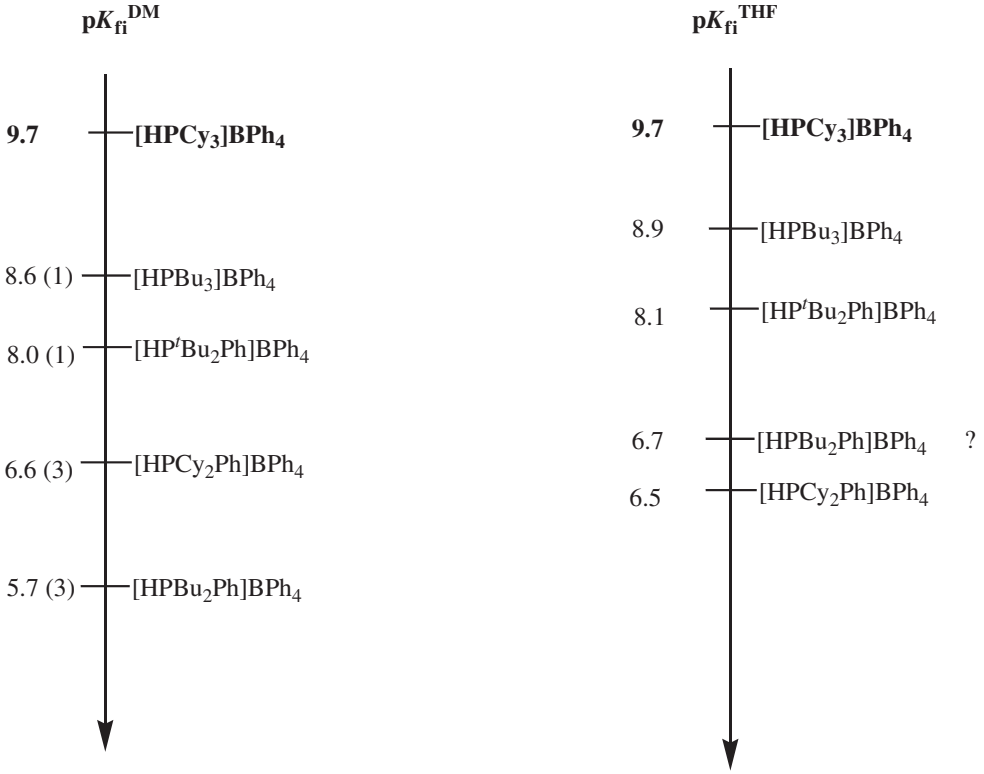
Synthesis and structure of ruthenium dihydrogen complexes

The complex $RuHCl(dach)(PPh_3)_2$ is a precursor to an active ketone hydrogen catalyst, $RuH_2(dach)(PPh_3)_2$ (11). The protonation of $RuHCl(dach)(PPh_3)_2$ by $HBF_4{\cdot}Et_2O$ in THF gives the new dihydrogen complex $[Ru(\eta^2\text{-}H_2)Cl(dach)(PPh_3)_2]BF_4$ (Scheme 2). The molecular structure of this dihydrogen complex is shown in Fig. 5.

The overall geometry is octahedral. The η^2-dihydrogen ligand is situated trans to the chloride. The Ru—H distances to the dihydrogen ligand are both 1.63(5) Å. The H—H distance is 0.78 (6) Å. Hydrogen-bonding interactions of $F_3BF\cdots HN$ (F···H 2.0 and 2.2 Å) and $C_4H_8O\cdots HN$ (O···H 2.1 Å) are observed in the X-ray crystal structure.[3] The trans geometry of the complex appears to be maintained in solution on the basis of the observation of a singlet in the $^{31}P\{^1H\}$ NMR spectrum. The dihydrogen resonance for this complex is a singlet at –10.8 ppm, and it is broad because of the rapid dipolar relaxation of the nuclei in the η^2-dihydrogen ligand.

The dihydrogen complex $[Ru(H_2)Cl(PPh_3)_2(dach)]BF_4$ in C_6D_6 reacts with D_2 gas to give isotopomers, including $[Ru(HD)Cl(PPh_3)_2(dach)]BF_4$. This probably proceeds via H–D exchange with the dach N—H bonds. The observation of $^1J_{HD}$ = 28.5 Hz in the Ru(HD) isotopomer provides more evidence of the side-on-bonded H_2-coordination. This corresponds to an H—H distance of 0.94 Å on the basis of eq. [10] (39). The X-ray derived value of 0.78(6) Å is probably underestimated because of the problem of locating hydrogen atoms by this method and the rotation of the H_2 ligand.

$$[10] \quad d(H\text{—}H) = -0.0167\ (^1J_{HD}) + 1.42$$



Synthesis and structure of $[Ru(\eta^2\text{-}H_2)Cl\{tmeP_2(NH)_2\}]BF_4$

$[Ru(\eta^2\text{-}H_2)Cl\{tmeP_2(NH)_2\}]BF_4$ is observed in the reaction of $RuHCl\{tmeP_2(NH)_2\}$ with HBF_4 in CD_2Cl_2 by NMR

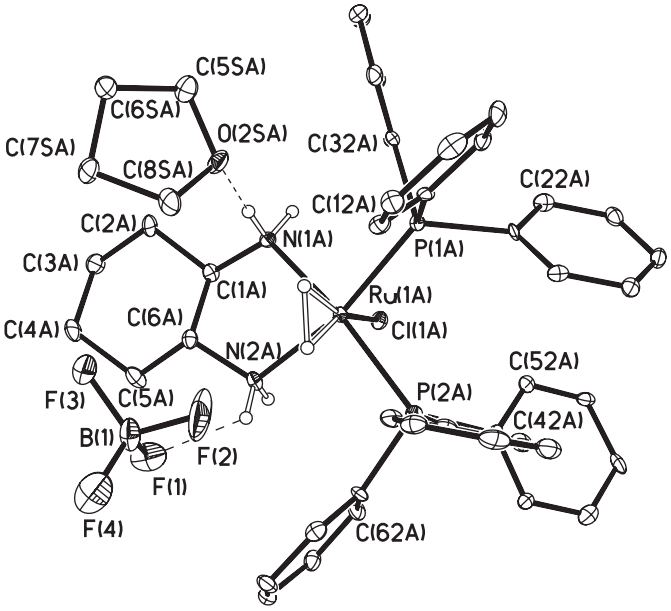
Fig. 4. A comparison of the acidity ladders for $[HPR_3]BPh_4$ salts in CD_2Cl_2 and THF.



Scheme 2.

spectroscopy. There are two isomers, A and B, of the RuHCl complex in the ratio of 3:2 (40). Isomer A is believed to have two NH hydrogen atoms that are syn to the hydride. Isomer B has one NH hydrogen atom syn to the hydride and the other NH hydrogen atom syn to the chloride. Therefore, two isomers of the Ru dihydrogen complex are formed by protonation of isomers A and B (shown in Scheme 3).

A crystal of one isomer of the dihydrogen complexes was obtained from the reaction. The molecular structure of the dihydrogen complex (Fig. 6) is derived from isomer B with one NH hydrogen atom syn to the chloride. The distances Ru—H1 and Ru—H2 are 1.79(2) and 1.79(3) Å, respectively. These long Ru—H distances might signal a weak Ru—H_2 interaction, and this interaction might explain why the dihydrogen ligand is usually lost during isolation. There is an intramolecular electrostatic NH···Cl interaction observed in the structure with an H···Cl distance of 2.5 Å. $[Ru(\eta^2\text{-}H_2)Cl(dach)(PPh_3)_2]BF_4$ has an NH···Cl distance of 2.8 Å. The other NH hydrogen atom is syn to the dihydrogen ligand and hydrogen bonds with the BF_4 anion (NH···F distance of 2.0 Å). The ^{31}P NMR spectrum suggests that two isomers are formed in the ratio of 1:2 (A:B). Isomer A exhibits a singlet at 36.4 ppm. Isomer B exhibits two doublets at 40.6 and 30.5 ppm. The dihydrogen resonance for this complex is similar to that of $[Ru(\eta^2\text{-}H_2)Cl(dach)(PPh_3)_2]^+$ and

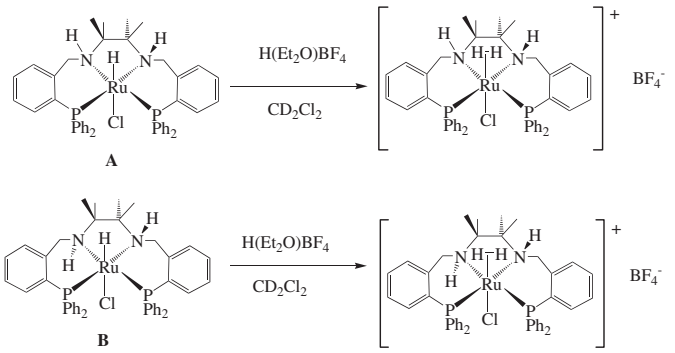


Fig. 5. Structure of $[Ru(\eta^2\text{-}H_2)Cl(dach)(PPh_3)_2]BF_4 \cdot THF$ as determined by single crystal X-ray diffraction.

exhibits a broad singlet at –10.9 ppm. $[Ru(HD)Cl\{tmeP_2(NH)_2\}]BF_4$ was prepared by the reaction of $RuHCl\{tmeP_2(NH)_2\}$ and HBF_4–D_2O in CD_2Cl_2. The observation of $^1J_{HD}$ = 28 Hz in the Ru(HD) isotopomer suggests an H—H distance of 0.95 Å on the basis of eq. [10]. When

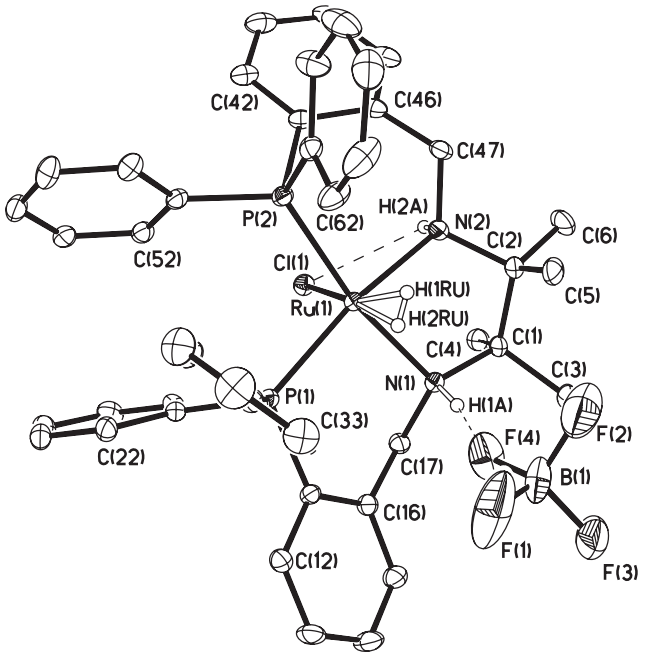
Scheme 3.

$[Ru(\eta^2\text{-}H_2)Cl\{tmeP_2(NH)_2\}]BF_4$ reacts with D_2, there is no hydride signal in the ^1H NMR spectrum, consistent with the formation of $[Ru(\eta^2\text{-}D_2)Cl\{tmeP_2(NH)_2\}]BF_4$. Apparently there is no D–H exchange between D_2 and the NH groups.

The pK^{DM} measurements for the dihydrogen complexes



The equilibria between the hydrido complexes $RuHCl(dach)(PPh_3)_2$ or $RuHCl\{tmeP_2(NH)_2\}$ and the phosphonium salts were established within 1 h at 20 °C (Figs. 7 and 8). The equilibria involving the BPh_4^- salts $[HPBu_3]BPh_4$, $[HP\text{-}t\text{-}Bu_2Ph]BPh_4$, and $[HPCy_2Ph]BPh_4$ produced an average pK^{DM} value of 8.6 ± 0.2 for the dihydrogen complex $[Ru(\eta^2\text{-}H_2)Cl(dach)(PPh_3)_2]BPh_4$. A corresponding reaction with $[HPBu_3]BF_4$ gave a pK^{DM} value of 8.5 ± 0.2 for the corresponding BF_4^- salt of the dihydrogen complex. The variation in the values obtained could be a result of ion-pairing effects and NH···FBF_3^- hydrogen bonding in the case of equilibria involving the BF_4^- anion.

Three equilibria were established between $RuHCl\{tmeP_2(NH)_2\}$ and phosphonium tetraphenylborate salts $[HPBu_3]BPh_4$, $[HP\text{-}t\text{-}Bu_2Ph]BPh_4$, and $[HPCy_2Ph]BPh_4$, to give a consistent pK^{DM} value of 6.9 for $[Ru(\eta^2\text{-}H_2)Cl\{tmeP_2(NH)_2\}]BPh_4$. Two equilibria between $RuHCl\{tmeP_2(NH)_2\}$ and $[HPBu_2Ph]BF_4$ and $[HPCy_2Ph]BF_4$ suggest an average pK^{DM} value of 6.7 for $[Ru(\eta^2\text{-}H_2)Cl\{tmeP_2(NH)_2\}]BF_4$.

Comparison of the acidity of ruthenium dihydrogen complexes

The pK^{DM} values of some related dihydrogen complexes are listed in Table 5. The complexes $[Ru(H_2)Cl(dppe)_2]PF_6$ and $[Ru(H_2)Cl(dppp)_2]PF_6$ are dihydrogen complexes with four phosphorus (phosphine) donors and have pK^{DM} values of approximately 4.7 and 3.3, respectively (entries 1 and 2, Table 5) (41, 42).[4] $[Ru(H_2)Cl\{tmeP_2(NH)_2\}]BPh_4$ and $[Ru(H_2)Cl(dach)(PPh_3)_2]BPh_4$ are a different class of dihydrogen complex with two phosphorus (phosphine) and two nitrogen (amine) ligands, and they have pK^{DM} 6.9 and 8.6, respectively (entries 4 and 5, Table 5). The replacement of phosphine ligands with more electron-donating amine ligands decreases the acidity of the complexes. However, $[Ru(H_2)Cl(PPh_3)(PMP)]BF_4$ with three phosphorus (phosphine) ligands and one nitrogen (pyridyl) ligand (6) does not follow this trend (entry 3, Table 5), suggesting that the pyridine donor is more like a phosphine than an amine on ruthenium.

Fig. 6. Structure of $[Ru(H_2)Cl\{tmeP_2(NH)_2\}]$ BF_4 as determined by single crystal X-ray diffraction.

Conclusions

A continuous acidity ladder of five phosphonium tetraphenylborate salts in CD_2Cl_2 at room temperature has now been established by use of ^{31}P NMR spectroscopy. The pK^{DM} values are generally consistent with values previously measured in THF. NOE and PGSE measurements show that ion pairs and higher aggregates are present in solution, complicating the interpretation of the results. When the pK^{DM} is lower than 6.6, the BPh_4^- salts tend to decompose. The acidities of the new dihydrogen complexes, $[Ru(H_2)Cl(PPh_3)_2(dach)]BPh_4$ and $[Ru(H_2)Cl\{tmeP_2(NH)_2\}]BPh_4$, are determined to be p$K^{DM}$ 8.6 and 6.9, respectively, through the use of several consistent equilibria with phosphonium salts. The pK^{DM} values for the BF_4^- salts are similar. The crystal structures of $[Ru(H_2)Cl(PPh_3)_2(dach)]BF_4$ and $[Ru(H_2)Cl\{tmeP_2(NH)_2\}]BF_4$ are determined. We will describe elsewhere the use of tetrafluoroborate salts to extend the ladder to lower pK^{DM} values, below the limit set by the decomposition of BPh_4^- salts.

Experimental

General methods

All preparations and manipulations were carried out under hydrogen, nitrogen, or argon atmospheres with the use of standard Schlenk, vacuum line, and glovebox techniques in dry, oxygen-free solvents. Tetrahydrofuran (THF), diethyl ether (Et_2O), and hexanes were dried and distilled from sodium benzophenone ketyl. Dichloromethane was dried and distilled from calcium hydride. Deuterated solvents were degassed and dried over activated molecular sieves. NMR

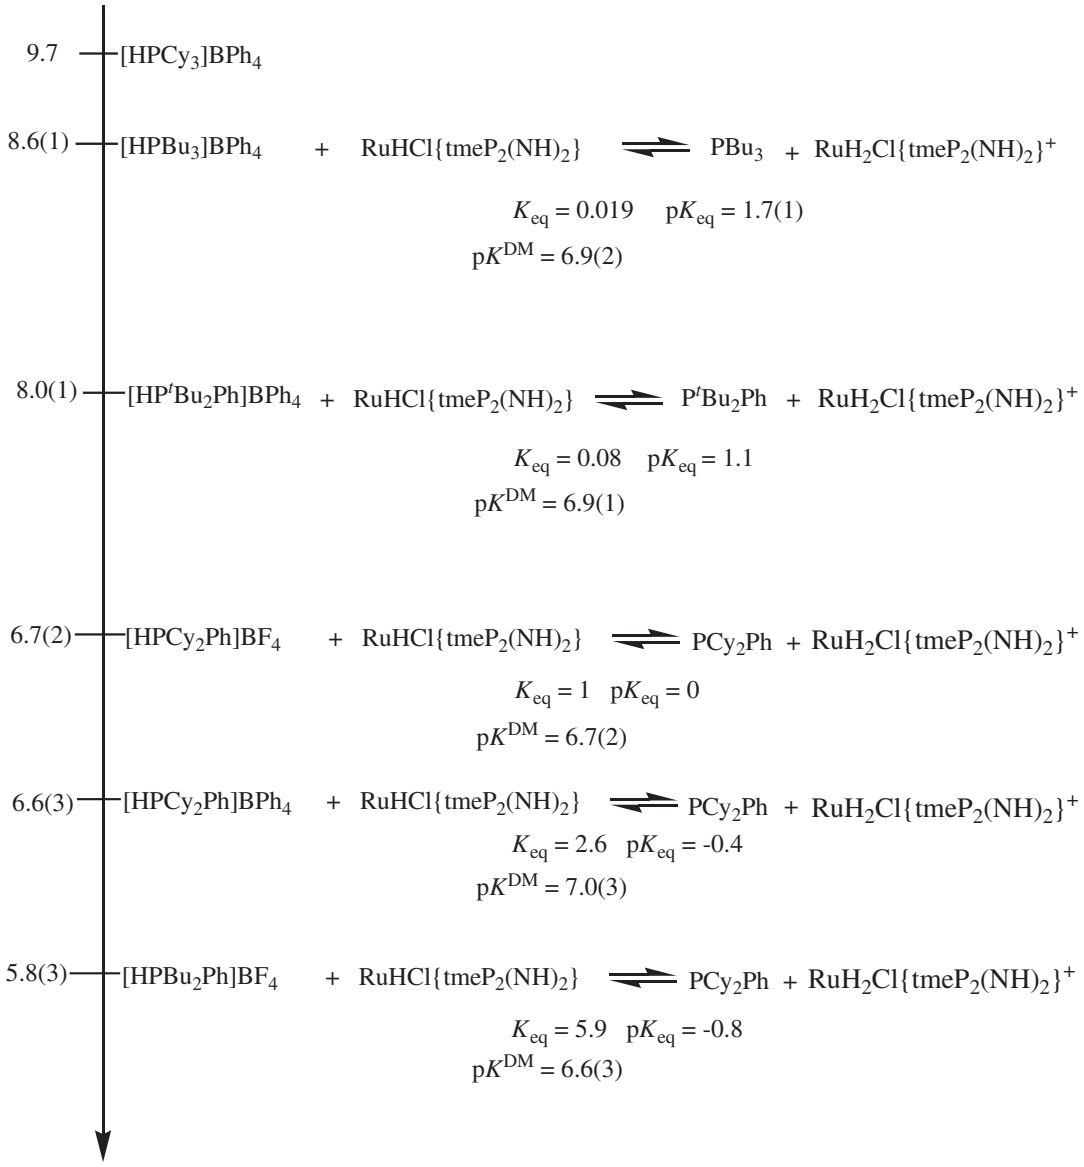
Table 5. Comparison of the acidity of ruthenium dihydrogen complexes.

Entry	Type	Complex	pK^{DM}	Ref.
1	$[RuP_4(H_2)Cl]X$	$[Ru(H_2)Cl(dppe)_2]PF_6$[a]	4.7	42
2		$[Ru(H_2)Cl(dppp)_2]PF_6$[b]	3.3	41
3	$[RuP_3N(H_2)Cl]X$	$[Ru(H_2)Cl(PPh_3)(PMP)]BF_4$[c]	4.0[d]	6
4	$[RuP_2N_2(H_2)Cl]X$	$[Ru(H_2)Cl\{tmeP_2(NH)_2\}]BPh_4$	6.9	This work
5		$[Ru(H_2)Cl(dach)(PPh_3)_2]BPh_4^-$	8.6	This work

[a]dppe = 1,2-bis(diphenylphosphine)ethane.
[b]dppp = 1,3-bis(diphenylphosphine)propane.
[c]PMP = 2,6-$(Ph_2PCH_2)_2C_5H_3N$.
[d]The literature value of 5.1 has been adjusted (42).

spectra were recorded on a Varian Unity-500 (500 MHz for ^1H), a Varian Unity-400 (400 MHz for ^1H), or on a Varian Gemini 300 MHz spectrometer (300 MHz for ^1H and 121.5 MHz for ^{31}P). All ^{31}P chemical shifts were measured relative to 10% $P(OMe)_3$ in C_6D_6. This reference solution was placed in a 2 mm capillary tube inside the 5 mm sample NMR tube. ^1H chemical shifts were measured relative to partially deuterated solvent peaks but are reported relative to tetramethylsilane. The phosphine compounds were received from commercial suppliers (Aldrich Chemical Co., Stem Co.) and used without further purification. $NaBPh_4$ was supplied by Aldrich Chemical Co. $RuCl_3$ hydrate was obtained from Johnson Matthey. The compounds $RuHCl(PPh_3)_2$-(dach) (10) and *trans*-$RuHCl\{tmeP_2(NH)_2\}$ (40) were prepared according to literature procedures. Protonated salts that have not already been reported in the literature have been found to have the correct elemental analyses by the Analyst Laboratory of the University of Toronto.



$[HPR_3]BPh_4$

All phosphonium salts $[HPR_3]BPh_4$ (PR_3 = PCy_3, P-*n*-Bu_3, P-*t*-Bu_2Ph, PCy_2Ph) were isolated by use of the reported preparation (4), with typical yields of 80%–90%. The attempted preparations of $[HPR_3]BPh_4$ (PR_3 = PBu_2Ph, PMe_2Ph, $PEtPh_2$, PPh_3) were unsuccessful as these decompose. $PR_3 \cdot BPh_3$ (PR_3 = PBu_2Ph, PMe_2Ph, $PEtPh_2$, PPh_3) compounds were obtained instead. The ^{31}P NMR chemical shifts are reported in Table 6. NMR data for $[HPCy_2Ph]BPh_4$ (CD_2Cl_2, 299 K, *J* values in Hz, refer to Fig. 2 for the labelling) follow.

^1H NMR δ: 7.83 (t, $^3J_{HH}$ = 7.7, pH_c), 7.64 (td, $^3J_{HH}$ = 7.8, $^4J_{HP}$ = 3.3, mH_c), 7.39 (m, oH_a), 7.36 (dd, $^3J_{PH}$ = 19.4,

$^3J_{HH}$ = 7.8, *o*H_c), 7.09 (t, $^3J_{HH}$ = 7.5, *m*H_a), 6.95 (tt, $^3J_{HH}$ = 7.3, $^4J_{HH}$ = 1.3 *p*H_a), 5.08 (dt, $^1J_{PH}$ = 471.0, $^3J_{HH}$ = 6.3, P-H), 2.30 (m, H_1), 1.81, 1.66, 1.35, 1.15 (m, cyclohexyl resonances).

$[Ru(H_2)Cl(PPh_3)_2(dach)]BF_4$

$RuHCl(PPh_3)_2$(dach) (203 mg, 0.26 mmol) was dissolved in THF (2 mL). HBF_4 (54 wt% in Et_2O, 90 mg, 0.30 mmol) was added to the solution under Ar and stirred for 0.5 h. Et_2O (6 mL) was added to give a yellow-green precipitate. The solid was filtered and washed with diethyl ether (2 × 3 mL). The solid product was obtained by filtration and dried under vacuum. Crystals of $[Ru(H_2)Cl(PPh_3)_2(dach)]BF_4$ were prepared by slow diffusion of diethyl ether into a saturated solution of the complex in THF. Yield: 190 mg, 87%. ^{1}H NMR (C_6D_6) δ: 7.4–7.0 (m, 30H, Ph), 3.3 (br, 2H, NH_2), 2.8–2.6 (m, 8H, CH_2), 2.2 (br, 2H, NH_2), 1.2 (m, 2H, C*H*), –10.75 (br, 2H, RuH_2). ^{31}P NMR δ: 46.1 (s). Anal.

Table 6. ^{31}P NMR chemical shifts of phosphines and phosphonium salts in CD_2Cl_2.

Bases	δ ^{31}P	Acids	δ ^{31}P
PCy_3	9.8	$[HPCy_3]BPh_4$	29.5
		$[HPCy_3]BF_4$	29.5

calcd. for $C_{42}H_{46}N_2P_2BClF_4Ru$: C 58.08, H 5.46, N 3.33; found: C 58.40, H 5.33, N 3.24.

The reaction of RuHCl{tmeP_2(NH)$_2$} with HBF_4

A mixture of two isomers (see Discussion) of RuHCl{tmeP_2(NH)$_2$} (10 mg, 0.012 mmol) was dissolved in CD_2Cl_2 (1 mL) in an NMR tube under Ar. HBF_4 (54 wt% in Et_2O, 10 mg, 0.06 mmol) was added to the solution. ^{1}H NMR δ: 7.6–6.8 (m, 28H, Ph), 4.8 (m, C*H*$_2$), 4.6 (m, C*H*$_2$), 4.4 (m, N*H*), 3.9 (m, N*H*), 1.8–1.2 (m, 12H, C*H*$_3$), –10.9 (brs, 2H, Ru*H*$_2$); T_1 = 19 ms at 400 MHz NMR spectrometer at 293 K. ^{31}P NMR δ: 41.0 (d, $^2J_{PP}$ = 25 Hz, 40%, isomer B), 30.5 (d, 37%, isomer B), 37.0 (s, 23%, isomer A). Crystals of [Ru(H$_2$)Cl{tmeP_2(NH)$_2$}]BF_4 were prepared by slow diffusion of diethyl ether into the NMR solution of the complex in CD_2Cl_2 under Ar.

The reaction of [Ru(H$_2$)Cl(PPh$_3$)$_2$(dach)]BF_4 with D_2

[Ru(H$_2$)Cl(PPh$_3$)$_2$(dach)]BF_4 (10 mg, 0.011 mmol) was dissolved in C_6D_6 (1 mL) in a 5 mm NMR tube under Ar. The solution was frozen in liquid N_2 and degassed – refilled with D_2 gas for three cycles. The NMR tube was sealed with a flame under D_2 and warmed up to room temperature. An ^{1}H NMR spectrum was collected immediately and after 15 h. A 1:1:1 triplet of 1:2:1 triplets at –10.74 ppm ($^1J_{HD}$ = 28.5 Hz, $^2J_{HP}$ = 8.7 Hz) was observed over time due to Ru(HD).

The reaction of [Ru(H$_2$)Cl{tmeP_2(NH)$_2$}]BF_4 with D_2

The procedure used for the dach complex was followed. No H–D coupling was observed. The hydride signal at –10.9 ppm disappeared after 15 h.

The reaction of RuHCl{tmeP_2(NH)$_2$} with HBF_4(Et$_2$O)–D_2

RuHCl{tmeP_2(NH)$_2$} (isomer A, 10 mg, 0.012 mmol) was dissolved in CD_2Cl_2 (1 mL) in an NMR tube. DBF_4 (1 drop, prepared by mixing HBF_4, 54 wt% in Et_2O, 0.40 g, 0.025 mol and degassed D_2O, 1.1 g, in a Schlenk flask) was added to the solution. A 1:1:1 triplet of triplets was observed over time due to Ru(HD). ^{1}H NMR δ: –10.9 (tt, RuHD, $^1J_{HD}$ = 28.5 Hz, $^2J_{HP}$ = 8.4 Hz). ^{31}P NMR δ: 40.6 (d, $^2J_{PP}$ = 25 Hz, isomer B), 30.5 (d, isomer B).

Determination of equilibrium constants in CD_2Cl_2

Solutions of samples were mixed under N_2 as described in Tables 3 and 4. In general, equilibrium constants were determined by ^{1}H and ^{31}P{^{1}H} NMR. Usually, signals for all of the species in equilibrium could be located and integrated in the ^{31}P{^{1}H} NMR and, in the case of hydride complexes, in the ^{1}H NMR spectra as well. The chemical shifts for the pure phosphines and phosphonium salts (Table 6) were determined and referenced to the P(OMe)$_3$ standard at 141.5 ppm. In some cases, when the chemical shifts of two species are very similar, mass-balance arguments can be used to estimate the equilibrium concentration of the species from their starting concentrations. Thermodynamic data for the equilibria in CD_2Cl_2 are shown in Tables 3 and 4.

NOE measurements

The ^{1}H NOESY NMR experiment was acquired by the standard three-pulse sequence (43). Each transient (direct dimension) was acquired using 2K points; the number of transients (indirect dimension) was 1K, and the number of scans was set at 16. A relaxation delay of 2 s and a mixing time of 0.5 s were used. The average interionic distances were obtained taking into account that the volumes of the NOE cross peaks are proportional to ($n_I n_S/n_I+n_S$), where n_I and n_S are the number of equivalent I and S nuclei, respectively (30).

PGSE measurements

^{1}H PGSE NMR measurements were performed using the standard stimulated echo pulse sequence (32) on a Bruker AVANCE DRX 400 spectrometer equipped with a GREAT 1/10 gradient unit and a QNP probe with a Z-gradient coil, at 299 K without spinning. The shape of the gradients was rectangular, their duration was 5 ms, and their strength (G) was varied during the experiments. All the spectra were acquired using 32K points, a spectral width of 5000 Hz, and processed with a line broadening of 1.0 Hz. The semilogarithmic plots of $\ln(I/I_0)$ vs. G^2 (where I and I_0 are the intensities of the observed spin echo in the presence or in the absence of the field gradient, respectively) (34, 35) were fitted using a standard linear regression algorithm; the R factor was always higher than 0.99. r_H, V_H, and N values were derived from experimentally determined D_t data as described in ref. 31.

X-ray diffraction structure determination of [Ru(H$_2$)Cl(PPh$_3$)$_2$(dach)]BF_4 and [Ru(H$_2$)Cl{tmeP_2(NH)$_2$}]BF_4

Crystals suitable for X-ray diffraction were obtained by vapor diffusion. Data were collected on a Nonius Kappa-CCD diffractometer using monochromated Mo Kα radiation and were measured using a combination of ϕ scans and ω scans with κ offsets, to fill the Ewald sphere. The data were processed using the Denzo-SMN package (44). For the second structure (the tmeP_2(NH)$_2$ complex), absorption corrections were carried out using SORTAV (45). The structures were solved and refined using SHELXTL V6.1 (46) for full-matrix least-squares refinements that are based on F^2. The H atoms of the dihydrogen were refined independently with isotropic displacement parameters, but in the first structure these parameters were tied to the U_{eq} values of the Ru atoms. All other H atoms were included in calculated positions and allowed to refine in riding-motion approximation with U_{iso} tied to the carrier atom. Crystallographic data for the compounds are given in Tables 7 and 8, and selected bond distances and angles in Tables 9 and 10.

Acknowledgment

This work was supported by a discovery grant to RHM from the Natural Sciences and Engineering Research Council of Canada (NSERC) and by a grant to AM from the Ministero dell'Istruzione, dell'Università e della Ricerca (MUIR) (PRIN 2004-2005). We thank J. Matthey for a loan of ruthenium salts and Dr. K. Abdur-Rashid for assistance with some experiments.

The series $Os_4(\mu_x\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14-n}$ (n = 0, 1, 2; x = n + 2) — Models for site-specific surface catalysts[1]

John P. Canal, Michael C. Jennings, Glenn P.A. Yap, and Roland K. Pomeroy

Abstract: The cluster $Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14}$ (**1**) has been prepared from the reaction of $Os_4(CO)_{14}$ and C_2Ph_2 in CH_2Cl_2 at 25 °C. Other minor products include the known clusters $Os_3(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{10}$ and $Os_3(\mu\text{-}\eta^4\text{-}C_4Ph_4)(CO)_9$. The structure of **1** reveals an approximately planar C_2Os_4 skeleton with a dimetallacyclobutene ring (C—C = 1.32(4) Å) and a flat butterfly Os_4 unit (Os—Os range = 2.859(2)–2.916(2) Å). The $^{13}C\{^1H\}$ NMR spectrum of **1** indicates the carbonyl ligands are rigid at room temperature. Stirring **1** in CH_2Cl_2 for 2 days (ambient temperature) afforded $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (**2**). The Os atoms in **2** also have an almost flat butterfly arrangement (Os—Os range = 2.7392(7)–2.8947(6) Å) with the alkyne ligand located over one of the Os_3 triangles. The ^{13}C NMR data for **2** are consistent with rapid rotation on the NMR timescale of the hinge $Os(CO)_3$ units at 21 °C, but slow rotation at –50 °C. Heating **2** at 40 °C gave $Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (**3**) after 2 days. Cluster **3** has the common butterfly arrangement of Os atoms with the C_2Ph_2 bound to all four metal atoms (Os—Os range = 2.7457(5)–2.8742(5) Å). The $^{13}C\{^1H\}$ NMR spectra of **3** at 21 and 90 °C indicate there is rapid CO exchange of the carbonyls of the two types of $Os(CO)_3$ units, but not between the units. The spectrum at –90 °C indicates one of the rotations (presumed to be that involving the carbonyls of the wingtip $Os(CO)_3$ units) is slowed on the NMR timescale. Compounds **1**–**3** form a unique series of clusters that have an alkyne ligand bound to two, three, and four metal atoms. Compound **1** is a model for a corner, compound **2** for a planar surface, and compound **3** a step site, in site-specific surface catalysts.

Key words: osmium cluster, diphenylacetylene, dimetallacyclobutene, carbonyl exchange, surface catalysis.

Résumé : On a préparé l'agrégat $Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14}$ (**1**) par réaction du $Os_4(CO)_{14}$ avec du C_2Ph_2, dans le CH_2Cl_2, à 25 °C; il était accompagné d'autres produits mineurs, dont les agrégats connus $Os_3(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{10}$ et $Os_3(\mu\text{-}\eta^4\text{-}C_4Ph_4)(CO)_9$. La structure de **1** comporte un squelette C_2Os_4 approximativement plan avec un cycle dimétallacyclobutène (C—C = 1,32(4) Å) et une unité de Os_4 en forme de papillon applati (Os—Os = 2,859(2) à 2,916(2) Å). Les spectres RMN $^{13}C\{^1H\}$ du composé **1** indiquent que les ligands carbonyles sont rigides à la température ambiante. Par agitation pendant deux jours dans du CH_2Cl_2, à la température ambiante, le composé **1** conduit au $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (**2**). Les atomes d'osmium dans le composé **2** adoptent aussi un arrangement en forme de papillon pratiquement plat (Os—Os = 2,7392(7) à 2,8947(6) Å) dans lequel le ligand alcyne se trouve au-dessus de l'un des triangles Os_3. Les données de la RMN du ^{13}C pour le composé **2** sont en accord avec une rotation rapide, à l'échelle de temps de la RMN et à 21 °C, des unités charnières $Os(CO)_3$; la rotation est toutefois lente à –50 °C. Par chauffage à 40 °C pendant deux jours, le composé **2** conduit à la formation du $Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (**3**). Dans l'agrégat **3**, les atomes d'osmium adoptent l'arrangement habituel en forme de papillon et le C_2Ph_2 est lié aux quatre atomes métalliques (Os—Os = 2,7457(5) à 2,8742(5) Å). Les spectres RMN $^{13}C\{^1H\}$ du composé **3** à 21 et 90 °C indiquent qu'il se produit un échange rapide de CO des carbonyles des deux types d'unités $Os(CO)_3$, mais qu'il n'y a pas d'échange entre les unités. Le spectre à –90 °C indique qu'une des rotations (probablement celle impliquant les carbonyles des unités $Os(CO)_3$ au bout des ailes) est ralentie à l'échelle de temps de la RMN. Les composés **1**, **2** et **3** forment une série unique d'agrégats comportant un ligand alcyne lié à deux, trois et quatre atomes métalliques. Les composés **1**, **2** et **3** sont respectivement un modèle pour un coin, pour une surface plane et pour un site étagé dans les catalyseurs de surface à site spécifique.

Mots clés : agrégat d'osmium, diphénylacétylène, dimétallacyclobutène, échange de carbonyle, catalyseur de surface.

Introduction

Alkynes form a plethora of complexes with group 8 metal carbonyls that have a remarkable structural diversity (1–3). For example, over 20 types of complexes have been isolated from the reaction of alkynes with $Fe_3(CO)_{12}$; they possess up to five metal atoms and three alkyne units (2, 4). Carty and co-workers (5, 6) have made notable contributions to the area, particularly alkyne derivatives of carbonyl clusters of ruthenium. The reaction of alkynes with $Os_3(CO)_{12}$ also provides novel products (3, 7–10).

In contrast to $Os_3(CO)_{12}$, the common carbonyl cluster of osmium (11), $Os_4(CO)_{14}$ readily undergoes substitution with two-electron donor ligands under mild conditions (12, 13). Here we describe the reaction of the tetraosmium cluster with diphenylacetylene to give the unique series $Os_4(\mu_x\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14-n}$ (n = 0, 1, 2; $x = n + 2$) in which a C_2Ph_2 molecule is successively bound to two, three, and four metal atoms. The dimetallacyclobutene cluster (i.e., the μ_2 compound) is of particular interest and is proposed as a model of corner sites of site-specific surface catalysts.

Experimental section

Unless otherwise stated, manipulations of starting materials and products were carried out under a nitrogen atmosphere with the use of standard Schlenk techniques. Hydrocarbon solvents were refluxed over potassium, distilled, and stored over molecular sieves before use. Dichloromethane was dried in a similar manner except that P_2O_5 was employed as the drying agent. The $Os_4(CO)_{14}$ was prepared by a literature procedure (13). The reactions were carried out in Carius tubes of volumes between 25–50 mL; each was fitted with a Teflon valve. NMR spectra were recorded on a Bruker AMX400 spectrometer at the appropriate operating frequencies for the ^1H and $^{13}C\{^1H\}$ NMR spectra. Samples of the complexes used for $^{13}C\{^1H\}$ NMR spectra were enriched to ~30% ^{13}CO. The samples were prepared from ^{13}CO-enriched $Os_4(CO)_{14}$, which in turn was prepared from ^{13}CO-enriched $Os_3(CO)_{12}$ (~40% ^{13}CO) (14).

Preparation of $Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14}$ (1)

To a solution of $Os_4(CO)_{14}$ (25 mg, 0.017 mmol) in CH_2Cl_2 (25 mL) at room temperature was added an excess of C_2Ph_2 (~20×) (C_2Ph_2 = diphenylacetylene). The solution was stirred for 105 min during which time the color of the solution changed from a red-brown to a deep red. The solvent was removed on the vacuum line and the remaining solid subjected to chromatography on a silica gel column (1.5 cm × 15 cm). Elution with hexanes removed the excess C_2Ph_2. Elution with hexanes–CH_2Cl_2 (90:10 by volume) gave several colored bands. The first (yellow) band was a trace amount of the known cluster $Os_3(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{10}$. (In the preparations described below, the orange band of $Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (**3**) eluted next). This was followed by a red band that afforded $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (**2**) in approximately 25% yield, then a purple band of another known cluster, $Os_3(\mu\text{-}\eta^4\text{-}C_4Ph_4)(CO)_9$, in <5% yield. Finally, a deep red band of the desired cluster **1** was obtained in about 70% yield. The analytical sample of **1** was obtained as air-stable, dark red (almost black) needles by recrystallization from CH_2Cl_2 and dried overnight under vacuum. Preparation of $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (2)

Cluster **2** was prepared in the same manner used to prepare **1**, except only a slight excess of C_2Ph_2 was used (~1:1.1) and the solution was allowed to stir at room temperature for 2 days. Again the solution changed from brown-red to a red over the reaction period. The desired product was isolated as described previously in about 60% yield. The analytical sample of **2** was obtained as air-stable, deep red crystals by recrystallization from CH_2Cl_2–hexanes. IR (hexanes, cm^{-1}): ν(CO) 2117 (m), 2078 (vs), 2046 (vs), 2040 (vs), 2012 (m), 1998 (m), 1987 (w), 1981 (w), 1963 (w), 1956 (w, sh). ^1H NMR (CD_2Cl_2) δ: 7.15–7.07 (m), 6.98–6.96 (m). ^{13}C NMR (CD_2Cl_2, RT) δ: 185.6 (1C, J_{CC} = 38.7 Hz), 182.6 (1C, J_{CC} = 37.2 Hz), 180.5 (1C), 176.5 (6C), 173.2 (1C), 169.3 (1C), 130 (2C, Ph-*C*), 127.8 (2C, Ph-*C*), 127.6 (1C, Ph-*C*). ^{13}C NMR (CD_2Cl_2, –50 °C) δ: 185.6 (1C), 181.8 (1C), 180.2 (1C), 177.6 (2C), 175.8 (2C), 175.2 (2C), 172.8 (2C), 169.0 (2C). MS (LI-MS) *m/z*: 1303.6 [M^+] (calcd. for M^+ = 1304 (100%), 1303 (87.4%)). Anal. calcd. for $C_{27}H_{10}O_{13}Os_4$: C 24.85, H 0.77; found: C 25.01, H 0.98.

Preparation of $Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (3)

The same reaction conditions used to produce **2** were employed except the reaction mixture was heated to 40 °C for 2 days. Over the time period the solution went from brown-red through dark red to orange-red as the initially produced **1** went to **2** and then **3**. The desired product in ~90% yield was isolated in the normal manner. (In an alternate procedure, **3** was isolated in 90% yield when either **1** or **2** was allowed to stir at room temperature in hexanes for 18 days). The analytical sample of **3** was obtained as air-stable, sparkling red-orange crystals by recrystallization from CH_2Cl_2. IR (hexanes, cm^{-1}): ν(CO) 2098 (m), 2071 (vs), 2046 (vs), 2041 (vs), 2019 (s), 2000 (s), 1982 (w), 1971 (m). ^1H NMR

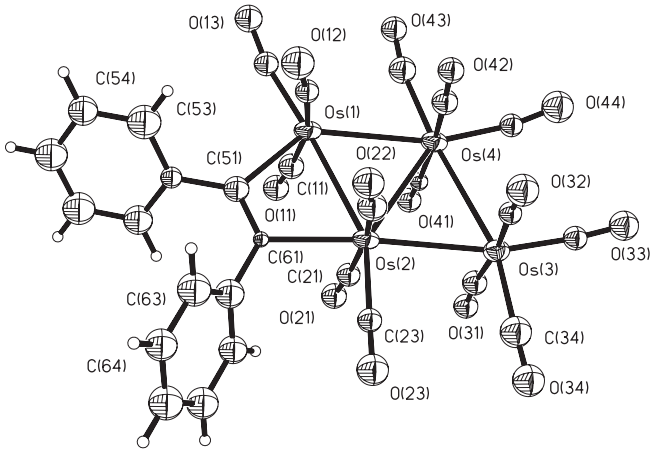
X-ray structural determinations



The structure of **1** was determined at the University of Western Ontario, London, Ontario. Crystals of **1**·CH_2Cl_2 were grown from a concentrated dichloromethane solution. A red-orange, flat needle was cut and mounted on a glass fiber. Data were collected at low temperature (–123 °C) on a Nonius Kappa-CCD diffractometer. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out with the program DENZO and the data were scaled with the program SCALEPACK. The crystal data and refinement parameters for **1**·CH_2Cl_2 are listed in Table 1. The reflection data and systematic absences were consistent with a monoclinic space group, $P2(1)/n$. The SHELXTL-NT V6.1 (G. Sheldrick) suite of programs was used to solve the structure by direct methods. Subsequent difference Fourier syntheses allowed the remaining atoms to be located. The osmium atoms were refined with anisotropic thermal parameters. The remaining atoms were refined isotropically. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The solvent molecule was refined fully anisotropically and the C—Cl distances were fixed at 1.72 Å. Due to the poor quality of the crystal, good data was only obtained to 20° on θ. The largest residue electron density peak (2.02 e/Å^3) was associated with one of the osmium–osmium bonds. Full-matrix least-squares refinement on F^2 gave R_1 = 6.22 for 2σ data and wR_2 = 12.64 for all data (GOF = 1.134).

The structures of **2** and **3** were determined at the University of Ottawa, Ottawa, Ontario. Suitable crystals were selected, mounted with Paratone oil on glass fibres, and flash-cooled to the data collection temperature of –70 °C. Unit-cell parameters were obtained from 60 data frames, 0.3° θ, from three different sections of the Ewald sphere. No symmetry higher than triclinic was observed in the diffraction data for **2** and solution in the centrosymmetric space group option, *P*-1, yielded chemically reasonable and computationally stable results of refinement. The unit-cell parameters and systematic absences in the diffraction data of **3** were uniquely consistent with the space group $P2_1/c$. The data sets were corrected for absorption with the Bruker SADABS program based on redundant data. Two symmetry-unique, but chemically equivalent molecules were located in the asymmetric unit of **2**. Features remaining in the final difference Fourier electron density map of **2** were located <0.9 Å from osmium atoms and were ignored as noise artifacts. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were treated as idealized contributions. Structure factors are contained in the SHELXTL 6.12 program library. A summary of the data collection and refinement for each structure are given in Table 1.[4]

Fig. 1. Molecular structure of $Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14}$ (**1**).

Results and discussion

$Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14}$ (1)

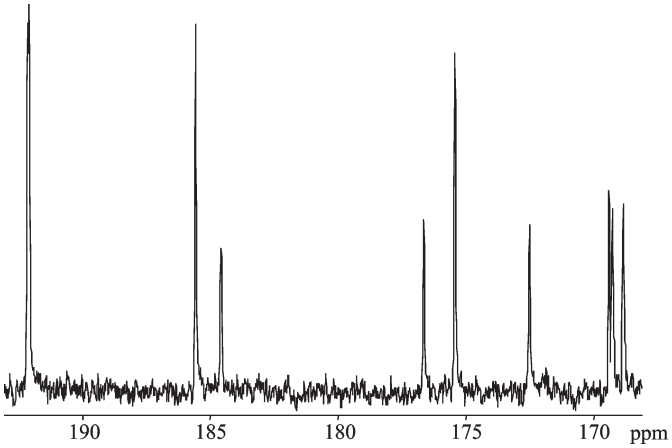
Compound **1** was isolated as dark red needles in about 70% yield from the reaction of $Os_4(CO)_{14}$ in CH_2Cl_2 with an excess of C_2Ph_2 at room temperature (eq. [1]).

[1] $$Os_4(CO)_{14} + C_2Ph_2 \xrightarrow[CH_2Cl_2]{25\ ^\circ C} Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14}\ (\mathbf{1}) + \text{other products}$$

(By comparison, the reaction of $Os_3(CO)_{12}$ with C_2Ph_2 requires temperatures of 160 °C or above to proceed at a measurable rate (9)). An excess of the acetylene ensured that **1** formed quickly as it slowly loses CO to give $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (**2**). Besides **2**, other products isolated from the reaction shown in eq. [1] were the known clusters $Os_3(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{10}$ (7) and $Os_3(\mu\text{-}\eta^4\text{-}C_4Ph_4)(CO)_9$ (8, 9). The stereochemical nonrigidity of the former cluster has been investigated by variable-temperature $^{13}C\{^1H\}$ NMR spectroscopy (15) and found similar to the nonrigidity exhibited by $Os_3(\mu_3\text{-}\eta^2\text{-}C_2R_2)(CO)_{10}$ (R = Me, Et) (10). All products are brightly colored and were readily separated by column chromatography. The derivatives appeared air stable, although crystals of **1** deteriorated on standing. This can be attributed to either loss of CO (to give **2**) or loss of the CH_2Cl_2 of crystallization. (Crystals of **1** suitable for the structural determination were obtained only after some difficulty).

Compound **1** was characterized by C/H/N analysis, IR, mass (parent ion), ^1H and ^{13}C NMR spectroscopy, and X-ray crystallography. The structure of **1** (as the CH_2Cl_2 solvate) reveals an approximately planar Os_4C_2 unit (Fig. 1); selected bond lengths and angles for **1** are given in Table 2. The Os_4 unit adopts a flat butterfly arrangement with five Os—Os bonds that range in length from 2.859(2) to 2.916(2) Å. These lengths are typical for open Os carbonyl clusters and may be compared with the average Os—Os bond distance in $Os_3(CO)_{12}$ of 2.877 Å (16). If it is assumed that the Os—Os bonds are single nondative covalent bonds, then Os(1) has a 17 electron count and Os(4) a 19 electron count. The Os(1)—Os(4) can therefore be regarded as a dative metal–metal bond with the Os(4) atom donating two electrons to Os(1) (17). Interestingly, it is the shortest Os—Os bond in **1**. We have reported numerous complexes that contain unsupported Os—M (M = transition metal) dative bonds (18).

Table 2. Selected bond lengths (angstroms) and angles (degrees) for **1**.



Bond lengths (Å)

Os(1)-C(51)-C(52)	126(2)
Os(1)-C(51)-C(61)	108(2)
Os(2)-C(61)-C(51)	113(2)
Os(2)-C(61)-C(62)	119(2)
C(52)-C(51)-C(61)	126(3)
C(62)-C(61)-C(51)	128(3)

Cluster **1** possesses a dimetallacyclobutene ring (i.e., Os(1)-Os(2)-C(61)-C(51)). The geometry about each C atom of the unit is approximately trigonal planar, although the internal Os-C-C angles (108(2)° and 113(2)°) are somewhat compressed from the ideal value of 120°. The C—C bond length of 1.32(4) Å is consistent with an uncoordinated C=C double bond. The Os—C bond lengths to the alkyne are 2.13(3) (to Os(1)) and 2.28(3) Å (to Os(2)). Because of the somewhat poor quality of the data, it is not clear that the difference is significant, or a genuine electronic effect: Os(1) is six-coordinate, whereas Os(2) is seven-coordinate. The lengths may be compared with the Os—C lengths to the carbonyl ligands in **1** that are in the range 1.84(4) to 1.95(3) Å.

Dimetallacyclobutene compounds are comparatively rare and a search of the literature (SciFinder Scholar) of this term yielded only 11 publications containing compounds with this bonding motif (1, 19–23). Some recent examples are $Ir_2(\mu\text{-}\eta^2\text{-}C_2R_2)(\eta^5\text{-}C_9H_7)_2(CO)_2$ (R = Ph, Tol) (20) and $Re_2Cp^*_2(\mu\text{-}\eta^2\text{-}C_2(CO_2CH_3)_2(CO)_4$ (21). Only one compound, $Ir_4[(\mu\text{-}\eta^2\text{-}C_2(MeCO_2)_2]_2[(\mu_4\text{-}\eta^2\text{-}C_2(MeCO_2)_2]_2(CO)_8$, contains more than two metal atoms, that is, it is a cluster compound (22). The bond lengths and angles in **1** are comparable to those found in $Os_2[\mu\text{-}\eta^2\text{-}C_2(CO_2Me)_2](CO)_8$ (C—C bond = 1.33(1) Å; both Os—C bonds = 2.138(5) Å; Os-C-C angle = 111.2(2)°) (23). The C—C bond length in **1** may be also be compared with the corresponding length (1.53(3) Å) in the saturated Os-C-C-Os unit in $Os_2(\mu\text{-}\eta^2\text{-}C_2H_4)(CO)_8$ (24).

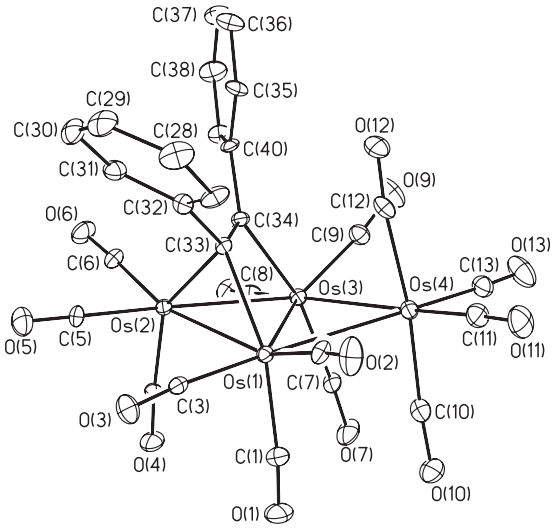
Fig. 2. The $^{13}C\{^1H\}$ NMR spectrum (CO region) of **1** (^{13}CO enriched) in CH_2Cl_2–CD_2Cl_2 (4:1) at 21 °C.

The $^{13}C\{^1H\}$ NMR spectrum of **1** (^{13}CO enriched) in CD_2Cl_2–CH_2Cl_2 at ambient temperature exhibits four signals of intensity 2 and six signals of intensity 1 in the carbonyl region (Fig. 2). This observation is consistent with the view that **1** has the same structure in solution as that in the solid state, and the carbonyls are rigid on the NMR timescale at this temperature. Typically, resonances due to axial carbonyl ligands come to low field of those due to equatorial carbonyls (14, 25). As can be seen from Fig. 2, one signal of intensity 2 is shifted to higher field and one signal of intensity 1 to lower field. These atypical signals are tentatively assigned to the carbonyls attached to Os(1) because of the unusual bonding at this atom.



$Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (2)

When **1** was stirred in CH_2Cl_2 at room temperature for 2 days cluster **2** was produced in good yield (eq. [2]). The product was isolated after chromatography as red crystals that were characterized by C/H/N analysis, IR, mass (parent ion), ^1H and ^{13}C NMR spectroscopy, and X-ray crystallography.

[2] $$Os_4(\mu\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{14} \xrightarrow[2\text{ days}]{25\ ^\circ C} Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}\ (\mathbf{2}) + CO$$

The structure of **2** has two independent molecules in the unit cell that differ in the orientation of the phenyl rings, but are otherwise identical. A view of one of the molecules (molecule **2A**) is given in Fig. 3; selected bond lengths and angles for each molecule are collected in Table 3. The structure of **2** consists of an almost flat butterfly arrangement, as found in **1**, with the alkyne spanning one of the Os_3 triangles. The peripheral Os—Os lengths associated with the alkyne in each molecule (range = 2.7392(7)–2.7740(7) Å) are significantly shorter than the peripheral Os—Os lengths that involve Os atoms not directly bound to the C_2Ph_2 (range 2.8665(6)–2.8947(6) Å). The shorter Os—Os bonds can be attributed to the bonding requirements of the bridging C_2Ph_2 ligand. The unbridged Os—Os bonds are typical for open Os clusters. The hinge Os—Os bonds in each molecule are of intermediate length (2.8204(6) and 2.8007(7) Å).

Fig. 3. Molecular structure of $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13}$ (**2**).

The 18-electron rule requires that the alkyne fragment donates two electrons to the wingtip Os atom (e.g., Os(2) in molecule **2A**) and one electron to each hinge Os atom (e.g., Os(1) and Os(3) in **2A**). The Os—C(alkyne) lengths that involve the wingtip Os atoms (e.g., Os(2) and Os(6)) are in the range 2.27(1)–2.29(1) Å and are somewhat longer than the other Os—C(alkyne) lengths in **2** (range 2.15(1)–2.18(1) Å). The bonding may be viewed as a dimetallacyclobutene unit with the C=C double bond acting as a typical alkene ligand toward the wingtip Os atom. The length of the C—C bond (1.42 Å) of the alkyne unit suggests a formal bond order less than two, as observed in similar compounds (7, 10, 26, 27). The bonding of the alkyne to the Os_3 triangle in **2** is similar to that in compounds such as $Os_3(\mu_3\text{-}\eta^2\text{-}C_2R_2)(CO)_{10}$ (R = Et (10), R = Ph (7)), $Os_5(\mu_3\text{-}\eta^2\text{-}C_2H_2)(CO)_{17}$ (26), and $Os_7(\mu_3\text{-}\eta^2\text{-}C_2Me_2)(CO)_{19}$ (27).

The $^{13}C\{^1H\}$ NMR spectra in the carbonyl region of **2** (^{13}CO enriched) in CD_2Cl_2–CH_2Cl_2 at –50 and 21 °C are shown in Fig. 4. The lower temperature spectrum exhibits eight signals in an approximate 1:1:1:2:2:2:2:2 (low to high field). This is consistent with the view that **2** has the same structure in solution as in the crystalline state, and that the carbonyls are rigid on the NMR timescale at –50 °C. The two signals at lowest field (i.e., at δ 185.6 and 181.8) exhibit satellites and are therefore readily assigned to the C atoms of the two chemically different axial CO ligands on the unbridged wingtip Os atom (i.e., the C atoms C(23) and C(25) in Fig. 3). This is because only these peaks would be expected to exhibit observable ^{13}C–^{13}C coupling owing to the mutual trans arrangement of these carbonyls. (Recall the complex was ^{13}CO enriched.) The remaining signal of intensity 1 (at δ 180.2) is attributed to the axial carbonyl atom on the bridged wingtip Os atom (i.e., C(17)). The signal at δ 177.6 is assigned to the two C atoms of the axial carbonyls on the hinge Os atoms (i.e., C(14) and C(20)). As stated previously, ^{13}C NMR resonances due to C atoms of axial carbonyls usually appear to lower field than the corresponding signals of equatorial carbonyls. The resonances at δ 175.8 and 175.2 are assigned to the C atoms of the equatorial carbonyls on the hinge Os atoms on the basis of their exchange behavior described in the following paragraph. The remain-

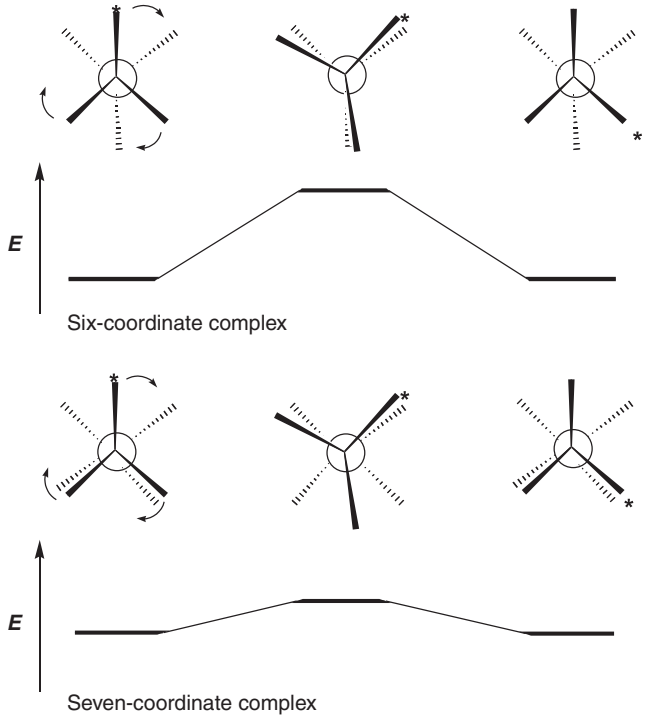
ing resonances at δ 172.8 and 169.0 are attributed to the C atoms of the equatorial carbonyls on the wingtip Os atoms. The latter signal is attributed to the carbonyls of the $Os(CO)_4$ grouping since it remains sharp in the spectrum at ambient temperature (see the following paragraph).

In the spectrum at 21 °C, three of the resonances have coalesced to a broad singlet (Fig. 4), indicative of exchange between the carbonyls that give rise to the signals in the spectrum at lower temperature. This is attributed to carbonyl exchange of the hinge $Os(CO)_3$ groupings. Rotation of $Os(CO)_3$ units in condensed Os carbonyl clusters is common. Examples are $Os_6(CO)_{17}(L)$ (L = CO, PPh_3) (28, 29) and $Os_7(CO)_{21}$ (30). The hinge Os atoms are seven-coordinate, whereas the wingtip Os atoms are nominally six-coordinate (if the bond to the C_2Ph_2 is a conventional metal–alkene bond). It is well-known that mononuclear six-coordinate complexes are usually rigid, whereas the corresponding seven-coordinate complexes are invariably nonrigid in solution.



Although the reason for the difference in activation barriers to exchange may be based upon electronic considerations, it can be rationalized by using simple steric arguments. We have shown that the ground-state and transition-state energies are both important in determining a barrier to rotation of the arene ring in (η^6-arene)$Fe(CO)_2(SiCl_3)$ complexes (31). In six-coordinate complexes, the trigonal prismatic transition state for $M(CO)_3$ rotation has three eclipsing interactions as depicted in Scheme 1. Also of importance is that in the ground state all the substituents are perfectly staggered with their nearest neighbors and hence it is at a low

Fig. 4. The $^{13}C\{^1H\}$ NMR spectrum (CO region) of **2** (^{13}CO enriched) in CH_2Cl_2–CD_2Cl_2 (4:1) at 21 and –50 °C.

Scheme 1.

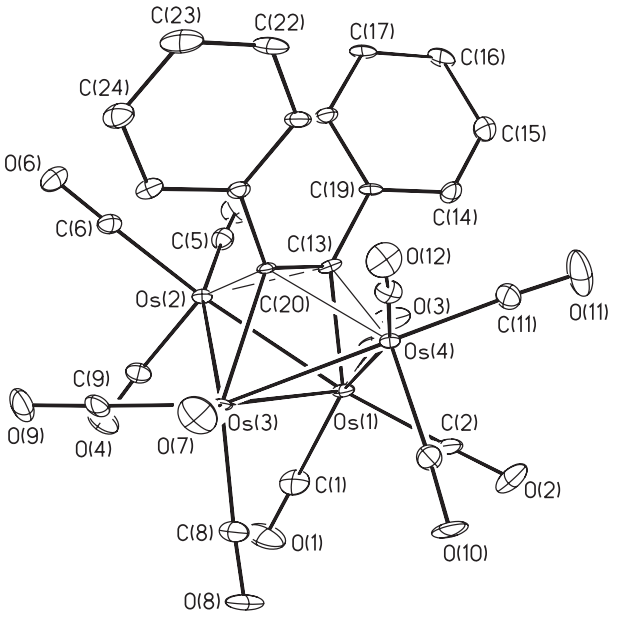
energy. In a seven-coordinate complex, the transition state to rotation of a trigonal unit only has two close eclipsing interactions in the transition state and therefore might be expected to be at a lower energy than the transition-state energy in the six-coordinate case (Scheme 1). What may not be realized is that in the seven-coordinate configuration the ground state is destabilized relative to the six-coordinate configuration because in the higher coordination case there are still close interactions in the lowest energy conformation.

In the spectrum at 21 °C, the signals attributed to the wingtip $Os(CO)_3$ group have broadened relative to the signals owing to the wingtip $Os(CO)_4$ unit. This probably indicates the onset of rotation on the NMR timescale of this $Os(CO)_3$ group and is relevant to the discussion on the rotation of the $Os(CO)_3$ units in **3** discussed in the following. The NMR spectrum of **2** at higher temperatures was not investigated because of its ready decarbonylation to **3**.

$Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (3)

When the reaction shown in eq. [2] was carried out at 40 °C, $Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (**3**) was isolated in ~90% yield (eq. [3]). The cluster, as bright orange-red, air-stable crystals, was characterized by C/H/N analysis, IR, mass (parent ion), ^1H and ^{13}C NMR spectroscopy, and by X-ray crystallography. Compound **3** has remarkable thermal stability. Overnight pyrolysis of **3** in C_6F_6 under vacuum at 230 °C had little effect on the cluster; decomposition (in part to $Os_3(CO)_{12}$) only commenced at 250 °C. Even after 4 days at 250 °C **3** had not completely decomposed.

[3] $Os_4(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{13} \xrightarrow[2\text{ days}]{40\text{ °C}} Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12} + (\mathbf{3})\ CO$



Although the Ru analogue of **3** has been known since 1977 (32), the Os compound has not been previously reported (SciFinder Scholar). A view of the structure of **3** is shown in Fig. 5. The structure is typical of clusters of the formula, $M_4(\mu_4\text{-}\eta^2\text{-}C_2RR')(CO)_{12}$ (M = Fe, Ru, Os) (1–3, 6, 32–34). These clusters may be viewed as electron-deficient butterfly clusters with 60 cluster valence electrons, or as *closo* octahedral clusters with seven skeletal electron pairs according to PSEPT (6). In **3** the peripheral Os—Os bonds range in length from 2.7457(5) to 2.7652(5) Å (Table 4), lengths that are typical of Os—Os lengths in condensed Os clusters. The hinge Os(1)—Os(3) bond is longer at 2.8742(5) Å. The four Os—C lengths of the alkyne unit to the wingtip Os atoms (Os(2) and Os(4)) are slightly longer (2.251(7)–2.274(8) Å) than the Os—C lengths to the hinge Os atoms (2.179(8), 2.201(8) Å). The pattern of the Os—Os and Os—C lengths closely match those previously found in $Ru_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (32) and $Os_4(\mu_4\text{-}\eta^2\text{-}C_2H_2)(CO)_{12}$ (34). The C—C bond length (1.49(1) Å) of the alkyne ligand in **3** is the longest of the three alkyne C—C lengths determined in this study and is close to that of a C—C single bond length.

Carbon-13 NMR spectra in the carbonyl region of **3** (^{13}CO enriched) at different temperatures are shown in Fig. 6. If the carbonyl groups were rigid, each chemically distinct $Os(CO)_3$ (i.e., wingtip and hinge moieties) unit would give rise to a 2:1 or 1:1:1 pattern of signals in the NMR spectrum (32). It is apparent that at 21 and 90 °C there is rapid rotation of the two different types of $Os(CO)_3$ groupings in **3**, but that migration of CO ligands between the wingtip and hinge Os atoms does not occur on the NMR timescale. This is also observed in clusters such as $Os_6(CO)_{18}$ (28).

In the spectrum at –90 °C, one of the signals has collapsed almost to the baseline, indicative of slowed exchange

Fig. 5. Molecular structure of $Os_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (**3**).

of one of the pairs of $Os(CO)_3$ units. This was also observed in the variable-temperature ^{13}C NMR spectra of $Ru_4(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)(CO)_{12}$ (32). Given the fluxional behavior of the $Os(CO)_3$ units in **2**, it is probable that the carbonyls that are still undergoing rapid exchange in **3** are those of the hinge $Os(CO)_3$ units.

Clusters 1–3 as models for surface catalysts

As mentioned in the Introduction, **1**–**3** form a unique series of clusters in which an alkyne ligand is successively bound to two, three, and four metal atoms. Indeed, any series of structurally characterized clusters that involves the stepwise loss of two carbonyls are rare. One such series, however, is $Co_4(CO)_x(PNR_2)_2$ (x = 8, 9, or 10) recently reported by Carty and co-workers (35).

Muetterties et al. (36, 37) first pointed out that the structures of molecular clusters may provide insight to the understanding of surface catalysis. Despite its importance and intense study, the precise nature of the active sites in surface catalysts is still unknown (38–42). Recent investigations by physical techniques indicate that the catalytic properties of small particles depend on their size and imperfections (43, 44). For example, a recent study by Wei and Iglesia (44) of CH_4 reactions on Ru-based catalysts concluded that edge and corner atoms, with fewer Ru neighbors than those on terraces, were primarily responsible for C-H activation. We believe that compounds **1**–**3** may provide insight to the understanding of these active sites. In Table 5 the C—C and Os—C bond lengths for **1**–**3** are collected together for ready comparison. Scheme 2 summarizes the preparation of the clusters from $Os_4(CO)_{14}$.

Cluster **1** is a model for an alkyne bound to a corner site of a metal surface; compound **2** is a model for an alkyne bound to a planar metal surface; whereas **3**, with its butterfly arrangement of metal atoms, is a model for an alkyne bound to a step site of a metal surface. Although step sites have been proposed as the active sites of surface catalysts (6, 37, 38), the data in Table 5 indicates that the alkyne is tightly bound to the Os atoms in **3** and as such would be unreactive. Consider, for example, the thermal stability of **3**. The alkyne also appears to be tightly bound to the Os_4 unit in **2**, although less so than in **3**

On the other hand, the C_2Ph_2 molecule in **1** is bound to the Os_4 nucleus via two σ bonds, one of which is long (Table 5). It might be expected that there would also be considerable ring strain in the diosmacyclobutene unit. Furthermore, because of the proximity of the osmium atoms the frontier orbitals about the C atoms in the bound C_2Ph_2 will

Table 5. The C—C and Os—C bond lengths of the alkyne-Os unit in **1**–**3**.

Compound	C—C bond lengths (Å)	Os—C bond lengths (Å) (σ)	Os—C bond lengths (Å) (π)
1	1.32(4)	2.13(3), 2.28(3)	—
2A[a]	1.42(2)	2.15(1), 2.18(1)	2.27(1), 2.29(1)
2B[a]	1.42(2)	2.17(1), 2.16(1)	2.29(1), 2.29(1)
3	1.49(1)	2.179(8), 2.201(7)	2.251(7), 2.255(8), 2.265(7), 2.274(8)

[a]Two independent molecules in the unit cell.

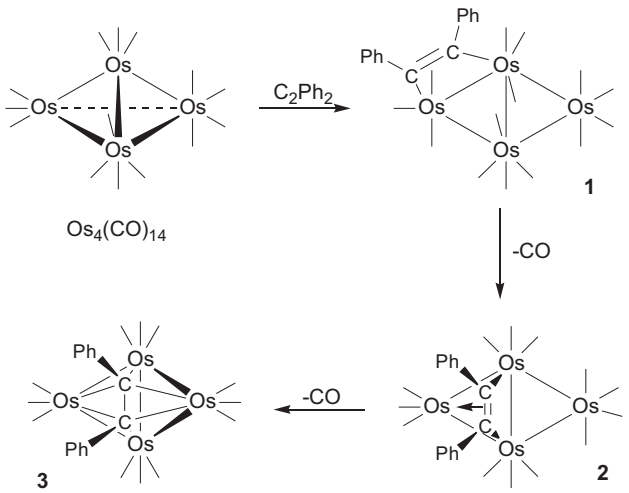

Fig. 6. The $^{13}C\{^1H\}$ NMR spectrum (CO region) of **3** (^{13}CO enriched) in CH_2Cl_2–CD_2Cl_2 (4:1) at 21 and –90 °C, and at 90 °C in C_7D_8.

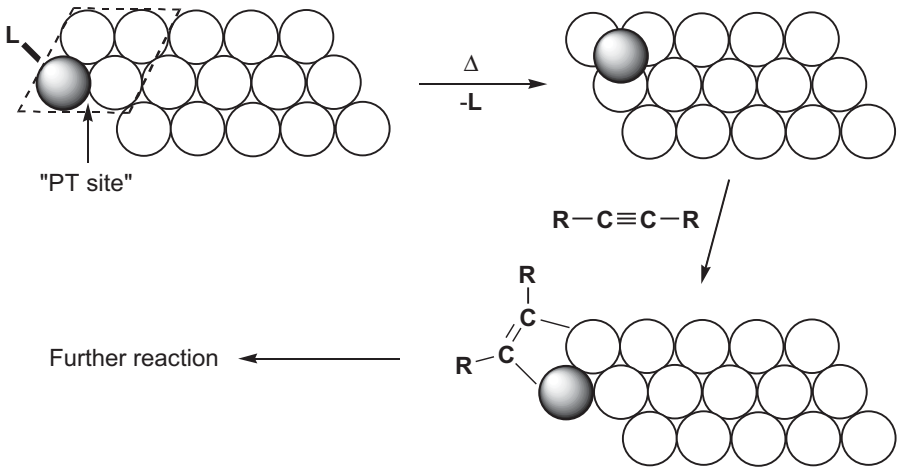
be different from uncoordinated C_2Ph_2 that may also result in enhanced reactivity of the coordinated alkyne.

The catalytic half-hydrogenation of alkynes to *cis*-alkenes is an important industrial process and is normally carried out with solid Pd catalysts that have been poisoned (e.g., Lindlar's catalyst) (40, 45). Some homogeneous half-hydrogenation catalysts are however known (46). The mechanism of the hydrogenation is not fully understood, but a mechanism that involves a dimetallacyclobutene unit appears to be an attractive possibility. Partial hydrogenation of the alkyne in the dimetallacyclobutene unit could take place by reaction with coordinated hydrogen (the Langmuir–Hinshelwood mechanism) or by direct attack by molecular H_2 (the Rideal mechanism) (38, 47).

Scheme 2.



The intermediacy of an organic substrate bound to two low-coordinate metal atoms on a surface may have more general applicability to the understanding of the action of site-specific surface catalysis. The precursory cluster $Os_4(CO)_{14}$ (that has a tetrahedral Os_4 nucleus) is prepared by pyrolysis of $Os_4(CO)_{15}$. The latter cluster has a planar structure and hence is a model for a metal surface. Both $Os_4(CO)_{14}$ and $Os_4(CO)_{15}$ have unusual bonding that is not found in higher nuclearity Os clusters (48, 49).

Some corners and imperfect edges of metal surfaces resemble these clusters. This is shown in Scheme 3 for a corner site; the active site is designated a "PT" (planar-tetrahedral) site. To allow the unique metal atom to hop from the planar to the tetrahedral site (Scheme 3) probably requires the atom not to be coordinated to a metal atom below the plane it originates from.

There would be more of these atoms the greater the surface area and in freshly prepared catalysts. It is a general observation for surface catalysts that they are usually more active the more finely divided they are and if they are freshly prepared (38). It may be that after the surface and step sites are saturated (i.e., analogous to **2** and **3**) there must be surface reformation in order for the PT sites to be activated. A ligand must also dissociate from the dangling atom to allow formation of the tetrahedral form of the PT site. Both steps might explain the lag time that some catalysts exhibit before catalysis begins (38). The model also explains why only certain metals are active and why bimetallic catalysts can be more active than catalysts comprised of the individual atoms (38). The metal atoms of the PT site have few metal–metal

Scheme 3.

contacts and might be expected to have frontier orbitals like the corresponding metal atoms in mononuclear complexes. The most active metals for surface catalysts usually contain metal atoms that are present in the most active homogeneous mononuclear catalysts (e.g., Rh and Pd) (50). In the model, the substrate is bound to just two metal atoms and therefore it will have different susceptibilities to attack depending on whether it is coordinated to metals that are identical or different. Catalysts are often more effective with oxide promoters (38). If the atoms directly below or adjacent to the PT site were oxide ions, then the reactivity of the site would be strongly influenced by the ions.

Studies on the reactivity of clusters **1**–**3** (and derivatives thereof) with hydrogen and other small molecules are currently in progress.

The synthesis and characterization of the pendant-armed ligand *N*,*N*′-bis(2′-pyridylmethyl)-1,7-dithia-4,11-diazacyclotetradecane (L_4) and crystal structures of L_4 and the copper(II) complex $[Cu(L_4)](ClO_4)_2$ — Crystal structure of the nickel(II) complex of *N*-(2′-pyridylmethyl)-1,4,7-trithia-11-azacyclotetradecane (L_2), $[Ni(L_2)(CH_3CN)](ClO_4)_2 \cdot CH_3CN$[1]

B.C.M. Chak and A. McAuley

Abstract: The synthesis and characterization of the mixed donor ligand *N*,*N*′-bis(2′-pyridylmethyl)-1,7-dithia-4,11-diazacyclotetradecane (**L_4**) containing two pendant pyridine arms is described. The macrocycle formation involves reaction of *N*-tosylbis(2-bromoethyl)amine with *N*-tosylbis(3-mercaptopropyl)amine at high dilution followed by detosylation at the nitrogen atoms using $LiAlH_4$ in view of the presence of the thioether groups. An X-ray study of the ligand shows the sulphur atoms lie exo to the macrocyclic ring. The nickel(II) and copper(II) complexes of **L_4** have been characterized and the X-ray structure of the Cu(II) ion exhibits a five-coordinate copper ion despite the presence of six available donor atoms. In the case of ligand *N*-(2-pyridylmethyl)-1,4,7-trithia-11-azacyclotetradecane (**L_2**), with a single pendant N donor, the Ni(II) complex is distorted octahedral with a molecule of acetonitrile in the sixth site. Details of UV–vis, ESR spectra, and electrochemical studies on the complexes are presented.

Key words: synthesis, pendant-armed, mixed donor S,N macrocycles, copper, nickel.

Résumé : On décrit la synthèse et la caractérisation du ligand donneur mixte *N*,*N*′-bis(2′-pyridylméthyl)-1,7-dithia-4,11-diazacyclotétradécane (**L_4**) qui contient deux noyaux pyridines comme bras pendants. La formation du macrocycle implique la réaction du *N*-tosylbis(2-bromoéthyl)amine avec la *N*-tosylbis(3-mercaptopropyl)amine à dilution élevée, suivie d'une détosylation des atomes d'azote à l'aide de $LiAlH_4$ en raison de la présence de groupes thioéthers. Une étude par diffraction des rayons X du ligand montre que les atomes de soufre se trouvent en position exo par rapport au cycle macrocyclique. Les complexes du **L_4** avec le nickel(II) et le cuivre(II) ont été caractérisés et la structure de l'ion Cu(II) telle que déterminée par diffraction des rayons X comporte un ion cuivre pentacoordiné malgré la présence de six atomes donneurs disponibles. Dans le cas du ligand *N*-(2-pyridylméthyl)-1,4,7-trithia-11-azacyclotétradécane (**L_2**) qui ne comporte qu'un seul azote donneur pendant, le complexe de nickel(II) se présente sous la forme d'un octaèdre déformé comportant une molécule d'acétonitrile sur le sixième site. On rapporte aussi les détails des données UV–vis, des spectres RPE et des études électrochimiques des complexes.

Mots clés : synthèse, bras pendant, macrocycles à donneurs mixtes S,N, cuivre, nickel.

[Traduit par la Rédaction]

Introduction

Historically, the most commonly studied macrocyclic ligands are tetraazatetradentate with cyclam as a typical example. X-ray diffraction studies show that most of these complexes have square-planar geometry in which the ligand cyclam encircles the metal ion in the equatorial plane (1–4). The coordination chemistry of the thia analogue (i.e.,

[14]aneS_4) has been investigated (5) and solid-state studies show the free ligand isomorphs exhibit exo conformations of the S lone pairs. The chemistry of thioether ligands has also been reviewed (6).

In contrast to the N_4 and S_4 donor sets, there have been relatively fewer studies on macrocyclic ligands involving sulphur and nitrogen mixed donor sets (7, 8). Black and McLean (9) synthesized the macrocyclic sexadentate ligand 1,4,10,13-tetrathia-7,16-diazacyclooctadecane ([18]aneN_2S_4). The associated Co(II) and Ni(II) complexes were assumed to be octahedral with the N donors in the apical sites. Rorabacher and co-workers (10) have prepared a series of N_xS_{4-x} donor sets (where x = 1–3) and also Cu complexes of cyclic polythiaethers. Kaden and co-workers (11, 12) have provided details of two sets of 12-, 14-, and 16-membered N_2S_2 macrocycles, dependent on the cis and trans arrangement of the donors within the ring, and have described the synthesis and solution chemistry of the Cu(II) and Ni(II) complexes. The use of mixed donor macrocycles as ligands for the selective interaction of Ag(I) has also been explored (13). In these laboratories, a focus has been on the synthesis of polymacrocylic ligands with these donors and the nature of the various oxidation states that may be stabilized owing to the mixed donor systems (14–16). Continuing interest in the coordination chemistry of these systems arises from the potential similarity of the coordination environment around metal centres in copper proteins. A recent review (17) has focussed on the role of macrocyclic ligands with pendant arms as Cu models related to electron transport and activation of small molecules in biological systems. In this paper, the synthesis of two macrocycles with attached pyridine moieties is described in an ongoing investigation of nitrogen and sulphur mixed donor macrocycles. The ability to complex a variety of metal ions in differing oxidation states is increased by the presence of both hard and soft donor centres within the macrocyclic framework.

Experimental

Ligand syntheses

The preparation of 1,4,7-trithia-11-azacyclotetradecane **L_1** and the pendant-armed methylpyridine derivative **L_2** have been reported previously (18).

L_1 L_2

N-*Tosylbis(2-(tosyloxy)ethyl)amine (2)*

Diethanolamine (**1**, 27.5 g, 0.262 mol) was dissolved in 500 mL of distilled CH_2Cl_2 in a three-necked flask. The solution was cooled to 0 °C in a stream of dry nitrogen and 122 mL of triethylamine (88.6 g, 0.88 mol) was added. With the temperature maintained at 0 °C, solid *p*-toluenesulfonyl chloride (157 g, 0.823 mol) was added in portions with vigorous stirring over the course of 5 h. The reaction mixture was stirred at ambient temperature overnight. The Et_3NHCl formed was filtered off and the resulting pale yellow filtrate was washed three times with 1 mol/L HCl, followed by 5 × 200 mL portions of water and 5 × 200 mL portions of satd. $NaHCO_3$ solution. The organic layer was dried over anhydr. $MgSO_4$. Removal of the solvent by rotatory evaporation gave a white product (**2**). Yield: 120 g (ca. 80%), mp 98 °C. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 7.2–7.9 (m, 12H, ArH), 4.14 (t, J = 6 Hz, 4H, CH_2OTs), 3.4 (t, J = 6 Hz, 4H, CH_2NTs), 2.47 (two singlets, 9H, $ArCH_3$). MS (CI): 568 [M + 1], 396 [M – OTs].

N-*Tosylbis(2-bromoethyl)amine (3)*

To a solution of the tritosylate **2** (43 g, 0.076 mol) in 250 mL of DMF was added NaBr (40 g, 0.39 mol). The resulting suspension was stirred in an oil bath at 120 °C for 4 h. After cooling to room temperature, the reaction mixture was concentrated to about 50 mL. The viscous milky product mixture was poured into a rapidly stirred ice–water mixture (1 L) where a white solid separated out. This material was filtered, washed with water, and air dried. Yield: 24 g (ca. 80%), mp 56–58 °C. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 7.36–7.75 (m, 4H, ArH), 3.5 (s, 8H, CH_2NTs, CH_2Br), 2.45 (s, 3H, CH_3Ar). MS (EI): 383, 385, 387 [M^+ in a ratio of 1:2:1].

N-*Tosylbis(3-(tosyloxy)propyl)amine (4)*

Bis(3-hydroxypropyl)amine (65 g, 0.488 mol) was dissolved in 800 mL of distilled CH_2Cl_2 in a 2 L, three-necked round bottom flask. The solution was cooled to –5 °C in a stream of dry nitrogen and triethylamine (218 mL, 1.56 mol) was added. With the temperature kept below 0 °C, solid *p*-toluenesulphonyl chloride (285 g, 1.49 mol) was added in portions to the above solution over the course of 2 h. The reaction mixture was stirred in an ice bath for 3 h and then at ambient temperature overnight. The white triethylamine hydrochloride formed was filtered off and washed with CH_2Cl_2. The pale yellow filtrate was washed with water (5 × 250 mL), 1 mol/L HCl (5 × 250 mL), water (5 × 250 mL), and satd. $NaHCO_3$ solution. The CH_2Cl_2 layer was dried over anhydr. $MgSO_4$. Removal of the solvent by rotatory evaporation resulted in a pale yellow viscous oil that was triturated to a white solid by the addition of diethyl ether. Yield: 232 g (80%), mp 68 to 69 °C. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.74 (d, J = 8 Hz, 4H, ArH), 7.58 (d, J = 8 Hz, 4H, ArH), 7.25–7.39 (m, 6H, ArH), 4.00 (t, J = 7 Hz, 4H, CH_2OTs), 3.05 (t, J = 7 Hz, 4H, CH_2NTs), 2.42 (s, $ArCH_3$, 6H), 2.40 (s, $ArCH_3$, 3H), 1.84 (tt, J = 7 Hz, 4H, $CH_2CH_2CH_2$). ^{13}C{^{1}H} NMR ($CDCl_3$) δ: 144.9, 143.6, 135.4, 132.7 (quat. ArC), 129.9, 129.8, 127.8, 127.1 (ArC), 67.62 (CH_2OTs), 45.76 (CH_2NTs), 28.62 ($CH_2CH_2CH_2$), 21.54, 21.41 ($ArCH_3$). MS (CI) 596 [M + 1], 424 [M + 1 – 172]. An analytically pure sample was obtained by recrystallizing the white solid twice with hot ethanol. Anal. calcd. for $C_{27}H_{33}NS_3O_8$ (%): C 54.44, H 5.58, N 2.35, S 16.14; found: C 54.33, H 5.43, N 2.38, S 16.53.

N-*Tosylbis(3-mercaptopropyl)amine (5)*

To a solution of tritosylate (**4**) (20.2 g, 0.034 mol) dissolved in 200 mL of 95% ethanol in a 500 mL round-bottomed flask was added thiourea (5.6 g, 0.074 mol). The

© 2006 NRC Canada

suspension was refluxed for 12 h. After cooling to room temperature, the reaction mixture was concentrated (rotovap) and pump-dried. A crystalline white solid of the isothiouronium salt was obtained. A solution of NaOH (13 g, 0.325 mol) in 215 mL of water (6% NaOH) was prepared and bubbled with nitrogen for 15 min. To the isothiouronium salt was added the deaerated 6% NaOH solution and the reaction mixture was well-stirred and refluxed in a nitrogen atmosphere for 2 h. After the mixture was cooled to room temperature, and subsequently in an ice bath, 6 mol/L HCl was added dropwise until the pH of the solution reached 1. The milky solution obtained was saturated with NaCl and extracted with 3 × 100 mL CH_2Cl_2. The organic layers were combined and dried with anhydr. $MgSO_4$, concentrated by rotovap, and pumped dry. The desired product was isolated as a colorless viscous oil. Yield: 90%. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 7.35–7.75 (m, 4H, ArH), 3.20 (t, 4H, J = 6 Hz, CH_2NTs), 2.6 (q, 4H, J = 6 Hz, CH_2S), 2.40 (s, 3H, CH_2Ar), 1.90 (m, 4H, $CH_2CH_2CH_2$), 1.45 (t, 2H, J = 6 Hz, SH). MS (CI): 318 [M + 1], 348 [M + 29], 360 [M + 41].

N,N′-*Bistosyl-1,7-dithia-4,11-diazacyclotetradecane (6)*

To a 5 L three-necked round flask equipped with a mechanical stirrer, condenser, and a dropping funnel was added oven-dried Cs_2CO_3 (14.8 g, 0.0454 mol) and 1 L of freshly opened DMF. The resulting suspension was stirred vigorously in a nitrogen atmosphere and warmed to 50 °C. A solution containing the dibromide (**3**) (4.82 g, 0.0125 mol) and dithiol (**5**) (4 g, 0.0125 mol) in 500 mL of DMF was prepared and bubbled in nitrogen for 20 min. This solution was then added to the Cs_2CO_3–DMF suspension via high dilution a rate of 4 to 5 mL/h. After the addition of all reactants, the mixture was stirred overnight. Upon cooling to room temperature, DMF was removed by rotatory evaporation. After extraction of the residual pale yellow solid with $CHCl_3$ several times, the resultant yellow solution obtained was taken to dryness and evacuated, yielding a pale brown oil that was purified by column chromatography (silica gel, CH_2Cl_2–EtOAc, 95%:5%). Fractions with R_f = 0.7 were collected. The desired product was isolated as a white crystalline solid. Yield: 30%. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 7.8 (m, ArH), 7.35 (m, ArH), 3.00–3.5 (m, CH_2NTs), 2.5–2.9 (m, CH_2S), 2.45 (s, CH_3Ar), 2.00 (m, $CH_2CH_2CH_2$). MS (CI): 543 [M + 1], 571 [M + 29].

1,7-Dithia-4,11-diazacyclotetradecane (L_3)

A sample of (**6**) (0.5 g, 0.92 mmol) was added slowly under a nitrogen atmosphere to a stirred suspension of $LiAlH_4$ (0.41 g, 10.8 mmol) in 40 mL of dry THF. The reaction mixture was stirred under reflux for 72 h. After cooling to room temperature, the excess $LiAlH_4$ was destroyed by dropwise addition of 30 mL of THF–H_2O (2:1 *v*/*v*). The mixture was filtered and the precipitate was carefully washed with CH_2Cl_2. Evaporation of the solvent afforded 150 mg of $\mathbf{L_3}$ as a white crystalline waxy solid, which was used for subsequent reactions without further purification. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.6–2.8 (m, 16H, CH_2S, CH_2N), 1.8 (m, 4H, $CH_2CH_2CH_2$), 1.45 (s, 2H, NH). MS (CI): 235 [M + 1], 263 [M + 29], 275 [M + 41].

N,N′-*Bis(2′-pyridylmethyl)-1,7-dithia-4,11-diazacyclotetradecane (L_4)*

To a two-necked, round-bottomed flask equipped with a magnetic stirrer, reflux condenser, and nitrogen inlet was added a solution of $\mathbf{L_3}$ (1.30 g, 6.1 mmol), triethylamine (4.5 mL, 32.3 mmol, 5 equiv.), and 2-(chloromethyl)pyridine hydrochloride (2 g, 12.2 mmol) in 50 mL of absolute ethanol. The solution was heated to a gentle reflux under a nitrogen atmosphere for 12 h. After cooling to room temperature, $CHCl_3$ (3 × 100 mL) was added to the orange-red reaction mixture. The organic phase was washed with water (5 × 100 mL) and dried over anhydr. Na_2SO_4. $CHCl_3$ was removed by rotoevaporation and the brown oil obtained was purified by column (silica gel, EtOAc–CH_2Cl_2, 60%:40%). Fractions with a R_f value of 0.2 were collected. The title product was obtained as a pale yellow oil that yielded clear white crystals. Yield: 500 mg, 20%. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 8.42, 7.61, 7.56, 7.38, 7.07 (m, 8H, pyridine Hs), 3.74 (s, 2H, CH_2-pyridine), 3.62 (s, 2H, CH_2-pyridine), 2.60–2.73 (m, 8H, CH_2S), 2.51 (t, J = 7 Hz, 8H, CH_2N), 1.75 (tt, J = 7 Hz, 4H, $CH_2CH_2CH_2$). ^{13}C{^{1}H} NMR ($CDCl_3$) δ: 159.9, 159.6 (quat. ArC), 148.8, 136.3, 136.1, 122.7, 122.6, 121.8, 121.7 (ArC), 61.3, 61.0 (*C*H_2-pyridine), 52.6, 52.1 (*C*H_2N), 29.3, 29.2 (S*C*H_2), 27.1 (CH_2*C*H_2CH_2). MS (CI): 417 [M + 1], 445 [M + 29].

Syntheses of Co(II), Ni(II), and Cu(II) complexes

[Co(L_2)(CH_3CN)(NO_3)$_2$]·CH_3CN (complex A)

An acetonitrile solution of $\mathbf{L_2}$ (0.06 g, 0.175 mmol) in a round-bottomed flask was purged with nitrogen for 20 min. A solution of [Co(H_2O)$_6$](NO_3)$_2$ (0.0496 g, 0.17 mmol) in acetonitrile was added dropwise to the ligand solution. The reaction mixture, now pink, was stirred at room temperature under a nitrogen atmosphere overnight to ensure complete complexation before concentration to ~1 mL on the rotovap. Slow evaporation of the solvent at room temperature yielded pink crystals of X-ray quality. Yield: 40 mg. Anal. calcd. for $C_{20}H_{32}N_6S_3O_6Co$ (%): C 39.51, H 5.31, N 13.83; found: C 38.91, H 5.20, N 13.46.

[Co(L_2)(ClO_4)](ClO_4) (complex B)

A solution of 0.57 g (0.156 mmol) of [Co(H_2O)$_6$](ClO_4)$_2$ in dry nitromethane was added dropwise to a similar N_2-purged solution of the ligand (0.0546 g, 0.159 mmol). The mixture turned deep red instantly and was refluxed gently under N_2 for about 1 h. After cooling, the solvent was removed and the resultant red oil was triturated with EtOH to a reddish-brown solid that was dried in vacuo. Yield: 0.089 g (92%). Anal. calcd. for $C_{16}H_{26}N_2S_3O_8Cl_2Co$ (%): C 31.07, H 4.56, N 4.53; found: C 30.97, H 4.26, N 4.67.

Compounds A and B are stable in air and, when dissolved in acetonitrile or nitromethane, show different spectroscopic characteristics and electrochemical behavior.

[Ni(L_2)(CH_3CN)](ClO_4)$_2$·CH_3CN

An acetonitrile solution of $\mathbf{L_2}$ (0.170 g, 0.496 mmol) was purged with nitrogen for 20 min and a solution of [Ni(H_2O)$_6$](ClO_4)$_2$ (0.145 g, 0.396 mmol) in acetonitrile was added dropwise to the ligand solution. The reaction mixture changed to purple and was stirred at room temperature under

© 2006 NRC Canada

nitrogen overnight to ensure complete complexation after which it was concentrated to ~1 mL. Slow evaporation of the solvent at room temperature yielded purple crystals of X-ray quality. Yield: 200 mg (83%). Anal. calcd. for $C_{18}H_{32}N_4S_3Cl_2O_8Ni$ (%): C 35.20, H 4.73, N 8.21; found: C 35.05, H 4.60, N 7.79.

[Cu(L$_2$)](ClO$_4$)$_2$

A solution of **L$_2$** (0.059 g, 0.172 mmol) in CH_2Cl_2 in a round-bottomed flask was purged with nitrogen for 20 min. An ethanolic solution of $[Cu(H_2O)_6](ClO_4)_2$ (0.060 g, 0.16 mmol) was added dropwise to the ligand solution. The reaction mixture changed to bluish green and was stirred at room temperature under nitrogen overnight to ensure complete complexation. The green precipitate formed was filtered, washed with diethyl ether, and air dried. Yield: 55 mg (57%). The green powder was recrystallized by dissolving it in EtOH–CH_3CN, yielding a microcrystalline green solid. Anal. calcd. for $C_{16}H_{26}N_2S_3O_8Cl_2Cu$ (%): C 31.76, H 4.33, N 4.63; found: C 31.86, H 4.18, N 4.69.

[Cu(L$_4$](ClO$_4$)$_2$

A method similar to that described previously using solutions of **L$_4$** (0.068 g, 0.164 mmol) in CH_2Cl_2 and $[Cu(H_2O)_6](ClO_4)_2$ (0.058 g, 0.156 mmol) in ethanol was used. Yield: 66 mg (66%). The powder was recrystallized by dissolving it in EtOH–CH_3CN, giving green crystals of X-ray quality. Anal. calcd. for $C_{22}H_{32}N_4S_2O_8Cl_2Cu$ (%): C 38.91, H 4.75, N, 8.25; found: C 38.83, H 4.69, N 8.19.

[Ni(L$_4$](ClO$_4$)$_2$

To a solution of the ligand (0.11 g, 0.0264 mmol) dissolved in a CH_2Cl_2–MeCN (1:1) solution was added dropwise an acetonitrile solution of $[Ni(H_2O)_6](ClO_4)_2$ (0.096 g, 0.262 mmol). The colour changed to blue and the mixture was stirred under N_2 at room temperature. After reduction to dryness, the resultant solid was dissolved in a MeOH–H_2O–acetone solution and a mixture of blue and purple solids was obtained. The latter was reduced to dryness, yielding a brown oil and a blue solid. Isolation of the blue material and dissolution in a minimum volume of ethanol yielded a blue solid that was washed with Et_2O and dried in vacuo. Anal. calcd. for $C_{22}H_{32}N_4S_2O_8Cl_2Ni$ (%): C 39.19, H 4.78, N 8.31; found: C 39.08, H 4.85, N 8.22.

(Caution: Perchlorate complexes may be hazardous and should be prepared in small quantities).

Electrochemistry

Cyclic voltammograms were recorded with a Princeton Applied Research model 273 potentiostat/galvanostat interfaced to an IBM PC computer. All measurements were carried out in acetonitrile, which was dried before use by distilling over calcium hydride overnight under a nitrogen atmosphere. A solution of 0.1 mol/L *n*-Bu_4NPF_6 in acetonitrile was used as the supporting electrolyte. Platinum beads were used as the working electrode and counter electrode. The reference electrode was $Ag/AgNO_3$ (0.01 mol/L in CH_3CN) linked to the cell via a salt bridge containing an acetonitrile solution of *n*-Bu_4NPF_6 (0.1 mol/L).

Crystallography

Crystals were mounted in glass Lindemann tubes. The unit cells and space groups were determined by using Weissenberg and precession photography after which the crystals were transferred to a Picker four-circle diffractometer automated with a PDP 11/10 computer or an Enraf Nonius CAD4 diffractometer to collect the data. Intensity measurements were obtained with Zr-filtered Mo radiation, λ = 0.710 69 Å, or Cu radiation (1.542 Å). Background counting was introduced at the end of each scan. A set of three internal standard reflections preceded each batch of 50 measurements, with no noticeable change in intensity observed during the collection. The solution of the phase problem was achieved with MULTAN (19) and refined by direct methods with SHELX-76 (20). The atomic scattering factors used were those included in the SHELX-76 program together with the metal *f* curve from the *International Tables* (21). Completion and refinement of the structure was carried out by using difference electron density maps and least-squares techniques. All atoms were refined anisotropically except for hydrogen atoms, which were observed and refined isotropically when possible; otherwise the H-atom positions were calculated. In general, the refinement converged with a maximum shift/esd of less than 0.2 on the final cycle.

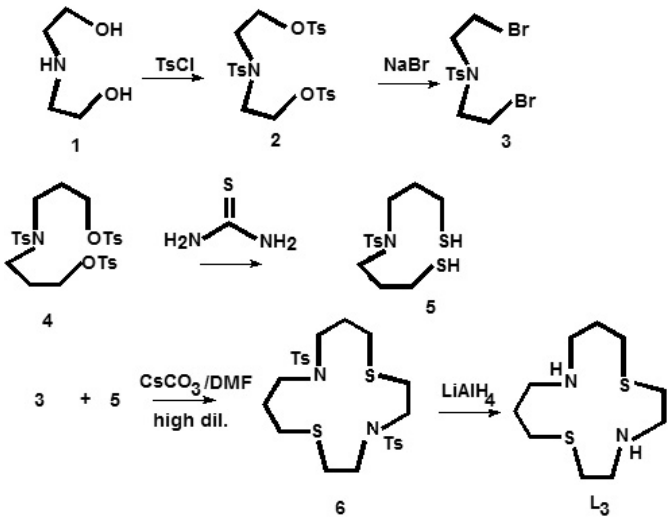
Electron spin resonance

ESR spectra were obtained by use of a Varian E6 ESR spectrometer using DPPH as the external standard. Spectra were obtained at 77 K using a quartz insert dewar.

Nuclear magnetic resonance

^{1}H NMR spectra were recorded on a 90 MHz PerkinElmer R-32 instrument; high-field ^{1}H and ^{13}C NMR spectra were obtained on either a Bruker WM 250 or AMX 360 instrument. Two-dimensional NMR spectra (e.g., ^{1}H COSY and ^{1}H–^{13}C correlated spectra) were recorded on the Bruker AMX 360 instrument. All chemical shifts are reported relative to tetramethylsilane (TMS). Simulated ^{1}H and ^{13}C NMR spectra were calculated using NMRPLOT (22).

Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, British Columbia.



Results and discussion

Syntheses

The synthetic route leading to **L$_3$** is summarized in Scheme 1. The tosylated amine **2** can be used directly for the cyclization or converted to the corresponding dibromide (Scheme 1) via nucleophilic substitution of tosyl oxy groups by NaBr in DMF. Both can serve as the leaving groups in the formation of C—S bonds in the cyclization. The dithiol (**5**) required for the cyclization was obtained in good yield (ca. 85%) by refluxing an ethanolic solution of **4** and thiourea for 12 h, followed by the base hydrolysis of the isothiuronium salt. The cyclization reaction leading to **6** was carried out under medium dilution conditions (final concentration of reagents ca. 0.01 mol/L) using Cs_2CO_3 as the base in dry DMF. Detosylation of **6** was complicated by the presence of thioether functional groups that are prone to cleavage when acidic procedures sufficient to remove tosyl groups were used. To avoid this problem, a reductive

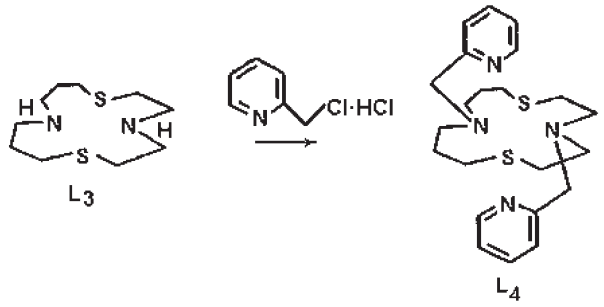
© 2006 NRC Canada

Scheme 1.

detosylation involving $LiAlH_4$ was employed (23). Ligand $\mathbf{L_3}$ was obtained in satisfactory yields (ca. 70%). The preparation of the bispyridine adduct ($\mathbf{L_4}$) is shown in Scheme 2.

Two isomers of $\mathbf{L_3}$ have been prepared previously (11, 12), and comparisons with the present metal–ion complexes are made. The nickel(II) and copper(II) complexes of $\mathbf{L_2}$ were prepared by the reaction of equimolar quantities of the ligand with $[Ni(H_2O)_6](ClO_4)_2$ or $[Cu(H_2O)_6](ClO_4)_2$ in dry CH_3CN under a nitrogen atmosphere. X-ray quality crystals were obtained by slow diffusion of diethyl ether into the acetonitrile solution of the complexes. In the case of the cobalt(II) complex of $\mathbf{L_2}$, two compounds were isolated vide infra.

Crystal structures



Experimental crystallographic data for three molecules are provided in Table 1.

$[Ni(L_2)CH_3CN)](ClO_4)_2$

The molecular structure is shown in Fig. 1, and significant interatomic distances and bond angles are given in Table 2. Complete details on distances and bond angles are provided in Supplementary tables S1–S5.[3]

As illustrated, the nickel centre is located in a pseudo-octahedral environment, coordinated to the three thioether sulphur atoms and three nitrogen atoms (from the macrocycle, the pyridine ring, and acetonitrile) with differing Ni—N bond lengths observed. The Ni—N(1)pyr (2.04 Å) is slightly shorter than the ideal strain-free Ni—N bond length (2.10 Å) (24). However, it is close to the values found for related high spin mixed donor macrocyclic complexes reported (8, 11, 25). Three distinct Ni—S bond distances, ranging from 2.37 to 2.48 Å, are observed in the cation. The shortest, Ni(1)—S(1) trans to the pyridine N(1), the results from the trans influence of a S atom being greater than the nitrogen donor. For S(3), trans to N(3), the bond length of Ni—S is 2.40 Å. This value is comparable to other mixed donor macrocyclic complexes such as $Ni([9]aneNS_2)_2]^{2+}$ ($[9]aneNS_2)_2$ = 1-aza-4,7-dithiacyclononane) (2.41 Å) (26). The longest (Ni—S(2)) bond is consistent with earlier findings of the trans influence sequence thioether S > N(tert) > N(py). The folded structure has been observed in the Pd and Pt analogues (18).

Scheme 2.

$[Co(L_2)(NO_3)_2{\cdot}CH_3CN]{\cdot}CH_3CN$

Attempts made at characterizing this complex crystallographically were not completely successful (R = 0.115, R_w = 0.114). However, the broad outlines of the structure are identifiable and the proposed molecular structure is shown in Fig. S1,[3] where it is seen that the cobalt ion is in an octahedral environment. It is coordinated to three nitrogen atoms from the macrocycle, the pyridyl ring, and the solvent acetonitrile. However, the remaining coordination sites are occupied by a monodentate and bidentate nitrate ion. These two modes of coordination have also been established by IR spectroscopy, with N—O stretches at 1360 and 1461 cm^{-1} corresponding to a monodentate nitrate ion (27) and those at 1285 and 1021 cm^{-1} consistent with a bidentate configuration. In contrast to the structure of the nickel(II) complex of $\mathbf{L_2}$ discussed previously, none of the thioether sulphur atoms in the macrocycle $\mathbf{L_2}$ is coordinated to the metal. The ligand adopts a conformation similar to that observed in the free ligand [14]aneS_4 (5), consistent with the lone pairs on the thioether atoms being directed out of the ring. This species is of interest in that it is an example of a rare precursor to complexation with the macrocyclic ligand.

Ligand L_4 and $[Cu(L_4)](ClO_4)_2$

Both the free ligand $\mathbf{L_4}$ and its Cu(II) complex have been characterized crystallographically. The molecular structures are shown in Figs. 2 and 3, respectively, and crystallographic parameters for the copper(II) ion are listed in Table 2. Complete interatomic distances and bond angles of $\mathbf{L_4}$ are provided in Tables S7–S9,[3] and those of $[Cu(\mathbf{L_4})](ClO_4)_2$ are presented in Tables S10–S13.[3]

For the free ligand $\mathbf{L_4}$, the interatomic distances between the nitrogen and sulphur donor atoms inside the macrocyclic

Fig. 1. Crystal structure of $[Ni\mathbf{L_2}(CH_3CN)]^{2+}$.

cavity are: N(1)···S(1) = 3.011 Å, S(1)···N(2) = 4.511 Å, N(1)···S(2) = 4.099 Å, N(2)···S(2) = 4.737 Å, N(1)···N(2) = 5.762 Å, and S(1)···S(2) = 5.905 Å. The average of the C—S bond distance is 1.833 Å, which is similar to that observed in [14]aneS$_4$ (5). The geometry of the ligand in the solid state indicates that the S lone pairs are exocyclic and those on the nitrogen atoms are oriented in different directions such that binding to the metal centre requires conformational changes within the ligand.

In the complex ion $[Cu(\mathbf{L_4})]^{2+}$, the copper ion is in a distorted square-pyramidal environment (Fig. 3). It is coordinated by three nitrogen atoms and two thioether sulphur atoms. One tertiary nitrogen atom in the macrocycle is not coordinated. The Cu—N bond distances range from 2.00 to 2.14 Å. The apical Cu—S(1) bond distance is 2.51 Å, which is very close to the value in 17-thia-1,5,8,12-tetrazaabicyclo[10.5.2]nonadecane ($[Cu(bicycloSN_4)]^{2+}$, 2.55 Å) (14*b*) where there is a similar N,S five-membered chelate ring. A comparison with the interatomic bond distances in $\mathbf{L_4}$ indicates that there are no major changes in bond lengths within the macrocycle upon coordination to copper. From the mean plane calculation (Table S12),[3] the copper ion is 0.258 Å above the plane defined by the basal atoms N(1), N(3), and N(4). In addition, S(2) is 0.9059 Å below this plane. A consequence of the nonplanarity between the copper ion and the nitrogen and sulphur donor atoms is that the bond angle S(1)-Cu-S(2) is 130.5°. The bond angles in the equatorial plane are: N(4)pyr-Cu-S(2) = 90.2°, N(4)pyr-Cu-N(3) = 91.7°, S(2)-Cu-N(1)pyr = 86.8°, and N(1)-Cu-N(3)pyr = 81.7°, consistent with deviations from an ideal square-pyramidal structure that probably arises from the strain imposed by the ligand.

ESR spectra

The ESR spectral data for the Cu(II) and Co(II) complexes studied in this work are listed in Table 3. For the complexes $[Cu(\mathbf{L_1})]^{2+}$ and $[Cu(\mathbf{L_3})]^{2+}$ (L_3 = 1,7-diaza-4,10-dithiacyclotetradecane), the ESR spectra are characteristic of a tetragonally distorted d^9 ion in a tetragonal elongated environment, with $g_\parallel > g_\perp$. Hyperfine lines are also observed in the $g_\parallel$ region, with the coupling constants ranging from 115 to 125 G. The $g_\parallel$ value of $[Cu(\mathbf{L_1})]^{2+}$ is greater than for $[Cu([14]aneS_4)]^{2+}$ ($g_\parallel$ = 2.10; $A_\parallel$ = 165 G) and also other Cu(II) N_2S_2 complexes prepared by Kaden and co-workers (12). Isotropic spectra were obtained even at 77 K for the copper(II) complexes with pyridine pendant arms, $[Cu(\mathbf{L_2})]^{2+}$ and $[Cu(\mathbf{L_4})]^{2+}$. The signals span a range of 500 G, and no hyperfine coupling was observed. A possible explanation for the spectra is that consistent with the structure of $[Cu(\mathbf{L_4})]^{2+}$ shown in Fig. 3, the possibility exists of a dynamic exchange between the Cu-coordinated nitrogen atom from the pyridine and that of the tertiary amine. Although the crystal structure of $[Cu(\mathbf{L_2})]^{2+}$ is not available currently, a five-coordinate geometry is anticipated and a fluxional process may be present.

For the Co(II) complexes of $\mathbf{L_2}$, only ion B, $[Co(\mathbf{L_2})(ClO_4)]^+$, is active. The spectrum at 77 K exhibits characteristics of a low spin d^7 ion in a distorted octahedral environment, with $g_\parallel$ = 2.020 and $g_\perp$ = 2.290. This is consistent with a Co(II) ion coordinated to the N and S donor at-

oms from $\mathbf{L_2}$ and perchlorate ion in a tetragonal elongated geometry. Since no hyperfine coupling from the nitrogen atoms was observed, the tertiary amine and pyridine moiety from the ligand are most likely coordinated in the equatorial plane of the distorted octahedron in a manner similar to the corresponding nickel(II) complex (Fig. 1). The eight hyperfine lines observed in the $g_\perp$ region arise from the interaction of the unpaired electron with the Co nucleus (^{59}Co, I = 7/2). For the complex $[Co(\mathbf{L_2})(NO_3)_2(CH_3CN)]$, no ESR signal was detected. Instead, a paramagnetic ^{1}H NMR spectrum spanning from –30 to +50 ppm was obtained, consistent with the persistence of the crystalline structure (Fig. S1)[3] in solution, although the paramagnetic spectrum was not amenable to further analysis.

UV–vis spectra

The UV–vis spectral data for various Ni(II), Cu(II), and Co(II) complexes studied in this work are presented in Table 4. The Ni(II) complexes exhibit typical octahedral geometry, with solvent coordinated axially. Molar extinction coefficients, ranging in the visible from 20 to 40 (mol/L)$^{-1}$ cm^{-1}, are very similar to the Ni(II) complex of 1,8-dithia-5,11-diazacyclotetradecane, a ligand isomer reported in the literature (12), and are typical of octahedral geometry with solvent participation in the axial sites. This is confirmed by the similarity with the six-coordinate $Ni(\mathbf{L_7})_2^{2+}$ ion ($\mathbf{L_7}$ = 7-aza-1,4-dithiacyclononane) (26).

The Cu(II) complexes are green in acetonitrile and their UV–vis spectra show absorptions bands in the regions 324–380 nm and 704–760 nm that are assigned as ligand-to-metal charge transfer (LMCT) and d–d transitions, respectively. However, the presence of axial donors apparently induces a difference in spectra from the planar N_2S_2 systems (12).

The spectra of the two Co(II) complexes of $\mathbf{L_2}$ show slightly different characteristics. Although both isomers have an absorption band around 500 nm, compound B has a slightly larger extinction coefficient. In addition, it has an additional absorption band at 800 nm. These observations can be rationalized by the different coordination environment at the cobalt centre in the two species. The ESR spectrum of B at 77 K is consistent with a Co(II) ion coordinated to all of the donor atoms in $\mathbf{L_2}$ with weak interaction with an axial perchlorate ion. For A (Fig. S1),[3] the nature of the primary coordination sphere is expected to produce a different ligand field at the metal centre.

Table 5. Electrochemical data.

Complex	E vs. Fc/Fc$^+$	ΔE (V)
Cu(II)/(I)		
$[Cu(\mathbf{L_2})]^{2+}$	$E_{1/2}$ = –0.024	0.077
$[Cu(\mathbf{L_4})]^{2+}$	$E_{1/2}$ = –0.137	0.086
$[Cu(\mathbf{L_5})]^{2+}$	$E_{1/2}$ = –0.045	0.150
Ni(II)/(I)		
$[Ni(\mathbf{L_2})]^{2+}$	$E_{1/2}$ = –1.18	a
$[Ni(\mathbf{L_4})]^{2+}$	$E_{1/2}$ = –1.23	0.14
$[Ni(\mathbf{L_1})]^{2+}$	$E_{1/2}$ = –1.29	a
Co(II)/(III)		
$[Co(\mathbf{L_2})]^{2+}$ (B)	$E_{1/2}$ = 0.18	0.23
$[Co(\mathbf{L_2})(NO_3)_2MeCN]$ (A)	$E_{1/2}$ = 1.71	b
	E_{red} = –1.83	a

Note: a = irreversible oxidation, b = irreversible reduction.

Electrochemistry

The redox chemistry of the Cu(II), Ni(II), and Co(II) complexes of $\mathbf{L_2}$–$\mathbf{L_4}$ was studied by cyclic voltammetry. The results are summarized in Table 5. For the Cu(II) complexes, the reduction to Cu(I) is, at best, quasi-reversible. It has been shown (28) that coordination geometry greatly influences redox potentials for these couples. Since Cu(II) complexes are generally tetragonal distorted and Cu(I) species prefer tetrahedral coordination, rearrangement of the structure of the complexes is required when Cu(II) is reduced to Cu(I). This process probably involves the "square scheme" discussed recently (10) that will contribute to the value of ΔE being greater than the theoretical value for a reversible one-electron reduction.

Both the cyclic voltammograms of $[Ni(\mathbf{L_2})]^{2+}$ and $[Ni(\mathbf{L_1})]^{2+}$ show irreversible reduction waves to Ni(I) at –1.18 and –1.29 V vs. Fc/Fc$^+$, respectively. However, for the complex $[Ni(\mathbf{L_4})]^{2+}$, a quasi-reversible reduction from Ni(II) to Ni(I) is observed at –1.23 V with peak potentials separated by 0.14 V. In this case, since the ligand can impose octahedral geometry on the metal centre, there is less reorganizational energy required for the electron transfer.

For the complex $[Co(\mathbf{L_2})(ClO_4)]^+$ (compound B), a quasi-reversible oxidation to Co(III) was observed at $E_{1/2}$ = 0.18 V vs. Fc/Fc$^+$. The peak to peak separation is 0.23 V. This Co(II)/Co(III) couple occurs at a more positive value relative

© 2006 NRC Canada

to other thioether complexes such as $[Co([9]aneS_3)]^{2+}$ (0.02 V vs. Fc/Fc^+) (29) and $[Co([10]aneS_3)_2]^{2+}$ (0.01 V vs. Fc/Fc^+) (30). A much more reversible situation is observed in preliminary observations of the reduction Co(II)/Co(I) of the hexacoordinate $Co(\mathbf{L_4})^{2+}$ ion ($E_{1/2}$ = –1.33 V, ΔE = 80 mV).

Conclusion

The preparation of mixed N,S-coordinating macrocycles has been achieved by reaction of thiols with either tosylated amines or the corresponding dibromides, where either can serve as the leaving groups in the formation of C—S bonds in the cyclization. Reductive detosylation, under mild conditions, results in satisfactory yields (ca. 70%). Complexes with pendant arms exhibit thermodynamic stabilities similar to their aza analogues. Interesting differences have been observed in the formation of cobalt(II) species dependent on the solvent used in the reaction. Although in the potentially hexacoordinating ligand with two pendant arms the S donors are exocyclic, in the copper(II) ion they are coordinated to the metal centre as are only three of the four other aza donors, confirming the preference for five-coordinate geometry at this metal centre. This observation contrasts with the corresponding Ni(II) complex where the octahedral ion permits possible access to Ni(I) and Ni(III) species.

Copper tellurolate clusters in trimethylsilylated MCM-41 — Preparation and condensation[1]

Collin M. Kowalchuk, Harald Rösner, Dieter Fenske, Yining Huang, and John F. Corrigan

Abstract: The copper tellurolate cluster $[(Cu_6(TePh)_6(PEtPh_2)_5]$ (**1**) has been loaded into the pores of a trimethylsilylated MCM-41 (TMS–MCM-41) framework. Solutions of **1** in tetrahydrofuran lead to good impregnation weight % (~10 wt%, **1**). The resulting material was analysed by powder X-ray diffraction (PXRD), nitrogen sorption isotherms, thermogravimetric analysis (TGA), energy dispersive X-ray (EDX) analysis, ^{31}P CP MAS NMR spectroscopy, and transmission electron microscopy (TEM). It was observed that the loading process proceeds with the intact cluster **1** being present within the hexagonal architecture. The intact nature of **1** makes it an ideal candidate for condensation by photochemical or thermal means. Both of these condensation treatments increase the Cu:Te ratio of **1** to approach that observed in binary semiconductor Cu_2Te. The condensation process was analysed by GC–MS spectrometry and characterization of the condensed, isolated composites was performed by TGA, EDX analysis, ^{31}P CP MAS NMR spectroscopy, nitrogen adsorption, and TEM measurements. Thermal condensation results in the formation of Cu_2Te particles, whereas photochemical condensation yields larger copper-tellurolate nanoclusters.

Key words: copper, tellurium, cluster, MCM-41, trimethylsilylated, photolysis, thermolysis, Cu_2Te, composite, mesoporous material.

Résumé : L'agrégat de tellurolate de cuivre $[(Cu_6(TePh)_6(PEtPh_2)_5]$ (**1**) a été introduit dans les pores d'un squelette de MCM-41 triméthylsilylé (TMS–MCM-41). Des solutions du composé **1** dans le tétrahydrofurane conduisent à de bonnes imprégnations allant jusqu'à 10% de **1**, en poids. On a analysé le produit qui en est résulté par diffraction des rayons X par des poudres, par des isothermes de sorption d'azote, par analyse thermogravimétrique (ATG), par analyse de la dispersion d'énergie de rayons X (DEX), par spectroscopie RMN du ^{31}P, à l'angle magique de rotation avec polarisation croisée (RMN du ^{31}P « CP MAS ») et par la microscopie de transmission électronique (MTE). On a observé que le processus d'imprégnation se produit tout en maintenant l'agrégat **1** intact dans l'architecture hexagonale. La nature intacte du composé **1** en fait un candidat idéal pour des condensations par des méthodes photochimiques ou thermiques. Ces deux traitements de condensation augmentent le rapport Cu : Te du composé **1** pour lui permettre d'approcher celui observé dans le semiconducteur binaire Cu_2Te. On a analysé le processus de condensation par le biais de la spectroscopie de masse liée à la chromatographie gazeuse et on a procédé à une caractérisation des composites qui ont été isolés de la condensation par le biais de l'ATG, d'analyses de DEX, de RMN du ^{31}P CP MAS, d'adsorption d'azote et de mesures de MTE. La condensation thermique conduit à la formation de particules de Cu_2Te alors que la condensation photochimique conduit à des nano-agrégats plus gros de tellurolate de cuivre.

Mots clés : cuivre, tellure, agréagat, MCM-41, triméthylsilylé, photolyse, thermolyse, Cu_2Te, composite, matériel mésoporeux.

[Traduit par la Rédaction]

Introduction

A wide array of transition-metal–chalcogen nanoclusters has been prepared and characterized with diverse composition, size, and structure (1). Numerous routes to metal–chalcogenide particles have been described from the controlled decomposition of the appropriate metal–chalcogenolate precursor, although the reports detailing copper telluride nanocomposites with this method are relatively rare (2). Copper telluride (Cu_2Te) is a photoemmissive semiconductor with a band gap energy calculated to be 0.673 eV (3). Copper tellurolate clusters represent convenient "premixed"

single source precursors that exhibit ease of handling (4, 5) and represent facile, viable routes for the preparation of solid copper telluride. These Cu(TeR) precursors decompose via the established tellurolate–telluride decomposition pathway (eq. [1]) (6, 7).

[1] $Cu(TeR)_2 \xrightarrow{\Delta} CuTe + TeR_2$

$Cu_6(TePh)_6(PEtPh_2)_5$ (**1**) is a model cluster for the investigation of thermal decomposition reactions (4). It may be prepared in high yield (80%) from Cu(1) salts, it is stable for short durations under atmospheric conditions and exhibits good solubility in common organic solvents. The cluster **1** consists of a Cu_6Te_6 core, which is shielded by aryl and alkyl groups with a roughly spherical ~1.6 nm structure.

1

Similar metal–chalcogenolate species have been shown to produce nanometer-sized particles (8), accessed from molecular complexes via the thermal ejection of ER_2 from $M(ER)_2$ centers (E = S, Se, and Te) (4–6, 9). Cluster **1** also condenses via photolytic treatment to produce the layered structure, $[Cu_{50}(TePh)_{20}Te_{17}(PEtPh_2)_8]^{4-}$, formed via the ejection of $PEtPh_2$ and TeR_2 from the Cu(TeR) centers present in **1** (4). As cluster **1** may condense both thermally and photochemically, it represents an ideal model as a single source precursor to larger copper tellurium nanomaterials and the condensation of such a cluster in a size-restricted environment may allow for general control of particle size.

MCM-41 is a silicate material consisting of one-directional, nonintersecting channels arranged in a hexagonal fashion (10). The favourable framework architecture of mesoporous MCM-41 makes it an ideal host for the encapsulation and subsequent preparation of one-directional ordered nanomaterials, and this has allowed for particle sizes to be controlled within the mesopore, which may be varied between 2 and 10 nm. Diverse size-restricted nanocomposites have been generated within mesoporous materials from small molecular precursors (11), and preformed nanoparticles have also been deposited within the pore architecture of mesoporous materials (12, 13). It is known that solutions diffuse through mesoporous materials and that these frameworks may be utilized as separation media both for small contaminants (14) and large molecules, with demonstrated size exclusion properties of inorganic nanomaterials (12). A trimethylsilyl-modified mesoporous framework has been demonstrated to be effective for solution phase infiltration where larger impregnation wt% were absorbed into the organic/inorganic functionalized framework vs. the unmodified siliceous counterpart (15). We recently reported the loading of **1** into the pores of MCM-41 via a solid-state impregnation technique (16). This method is, however, rather specific for **1** and it proceeded with cluster modification through loss of the phosphine shell, although the copper tellurolate core was maintained. A more general and facile impregnation technique was targeted that would provide access to a wider array of metal–chalcogen nanoclusters. Herein, we present the full details of the solution impregnation of **1** into trimethylsilylated MCM-41 (TMS–MCM-41), which proceeds with the cluster integrity being maintained. This intact cluster was subsequently condensed by thermal and photochemical means to form larger copper tellurium composites.

Experimental section

General

All experimental manipulations were performed with standard Schlenk techniques under an inert nitrogen atmosphere. Prior to all combinations of TMS–MCM-41 with **1**, dehydration of the mesoporous framework was performed at 130 °C and 10^{-3} Torr (1 Torr = 133.3224 Pa) for 4 h.

Preparation of starting materials

MCM-41 was prepared according to the literature procedure under hydrothermal conditions and calcined at 540 °C to remove the surfactant (10). Trimethylsilylated MCM-41 (TMS–MCM-41) was synthesized according to the literature procedure (10), after 1.50 g of calcined MCM-41 was rehydrated for 6 days from atmospheric humidity. The cluster $Cu_6(TePh)_6(PPh_2Et)_5$ (**1**) was prepared according to the literature procedure (4).

Preparation of the mesoporous matrices

Matrix I was prepared from the combination of 25.00 mL of a 8.14×10^{-6} mol L^{-1} solution of **1** in tetrahydrofuran with 0.10 g of TMS–MCM-41 under stirring for 24 h. The mother liquor was removed via pipet and filtered to eliminate any residual I. UV–vis spectra were obtained on the filtered mother liquor and compared with the 8.14×10^{-6} mol L^{-1} stock solution. A higher concentration solution of **1** (1.9×10^{-2} mol L^{-1} of **1**) in THF was utilized to prepare matrix II. The solution of **1** was combined with 0.50 g TMS–MCM-41 and stirred for 3 days. Following an adequate settling process, removal of residual nonabsorbed **1**–THF solution was performed by pipet and treatment in vacuo for 1 h yielded the desolvated matrix II. Matrix II was a yellow microcrystalline powder.

Preparation of PPh_2Et–TMS–MCM-41 (III)

TMS–MCM-41 (0.08 g) was combined with 0.018 mL of $PEtPh_2$ and 2.0 mL of THF. The sample was stirred for 3 days at room temperature, followed by removal of the solvent by pipet and treatment in vacuo for 1 h.

Preparation of $Ph_2EtP{=}O$–TMS–MCM-41 (IV)

TMS–MCM-41 (0.10 g) was combined with 0.025 g of $Ph_2EtP{=}O$ and 5 mL of CH_2Cl_2. The mixture was stirred overnight and then the solvent was removed in vacuo and dried for 1 h.

© 2006 NRC Canada

Condensation reactions of II (1–TMS–MCM-41)

Photolysis of the **1**–TMS–MCM-41 matrix II was carried out on two different scales, both in the solid state. Firstly, 0.05 g (10.4 wt% of **1**) was combined with ~0.2 g dry KBr and photolysed in a diffuse reflectance cell fitted with a quartz window for 3.5 h; UV–vis-DR (diffuse reflectance) measurements were obtained at regular intervals. Matrix V was prepared from 0.20 g of II (11.4 wt% of **1**) in a slurry of hexanes, photolysed behind a Pyrex filter ($\lambda > 350$ nm) for 3 h. Excess hexane was subsequently removed via pipet and the sample dried in vacuo for 4 h. Isolated matrix V was an orange-brown microcrystalline powder. Condensed matrix VI was prepared by solvothermal treatment in heptane at reflux temperature (98 °C) on 0.20 g of II (11.4 wt% of **1**) for 3 h. After condensation treatment the mother liquor was removed from VI by pipet and the brown-black powder treated in vacuo for 24 h.

Instrumentation

Powder X-ray diffraction patterns were obtained on a Rigaku diffractometer with Co Kα radiation ($\lambda = 1.799\ 260$ Å). Nitrogen sorption data were obtained on a Micromeritics ASAP 2010 isotherm instrument. Prior to nitrogen adsorption measurements, the calcined MCM-41 and TMS–MCM-41 complexes were outgassed at room temperature (~25 °C) overnight (24 h) to eliminate any water from the sample introduced during sample transfer under atmospheric conditions. Adsorption/desorption measurements were performed at 77 K. The BET surface area, pore diameter, and the BJH pore volume were obtained using the Micromeritics ASAP V5.01 software. Thermogravimetric analyses were performed on a Mettler Toledo TGA/SDTA851^e analyzer. TGA measurements were carried out with a dynamic temperature program of 25–1000 °C with a heating rate of 10 °C/min. The ^{31}P cross polarization MAS spectra were obtained on a Varian/Chemagnetic Infinitypulse 400 wide bore spectrometer at the field strength of 9.4 T, with resonance frequencies of 399.491 and 161.719 MHz for ^{1}H and ^{31}P, respectively. A Varian/Chemagnetic 3.2 mm double-tuned MAS probe was used. The rotor frequency was 22 kHz. ^{31}P CP MAS NMR spectra were referenced to 85% H_3PO_4 using $(NH_4)H_2PO_4$ as a secondary reference. The Hartmann–Hahn condition was determined using $(NH_4)H_2PO_4$. The proton 90° pulse length was typically 2 μs with an optimized contact time of 2 ms. The variable amplitude CP (17) and two pulse phase modulated (TPPM) decoupling (18) methods were utilized. The proton recycle delay was 10 s. The samples for the TEM characterization were prepared by dropping a suspension of ethanol containing the samples onto carbon-coated copper grids. TEM investigations were performed in a Philips Tecnai F20 ST operated at 200 kV using an extraction voltage of 4.1 keV for the field emission gun. The point resolution of this microscope is about 0.235 nm at Scherzer focus and an information limit of about 0.14 nm was obtained. The TEM was equipped with an EDAX® energy-dispersive X-ray SiLi detector with a S-UTW (super-ultra-thin window). EDX analyses were carried out in the STEM (scanning transmission electron microscopy) mode using nanometre-sized probes (1 nm spot size for the presented EDX measurements). For this purpose, an extraction voltage of 4.5 keV was used. Use of a double tilt holder (Gatan) was made. High-resolution micrographs were taken with a 1K × 1K CCD camera and analysed with the software package Digital Micrographs (version 3.5.2, Gatan Company, Pleasanton, California) to perform Fourier transformations.

EDX analyses were also obtained on an EDAX® Phoenix model EDX system with light element detection capability coupled to a Hitachi S-4500 SEM. A 20 kV electron beam rastered over a 100 μm × 100 μm area was used to obtain semiquantitative analysis with the manufacturer's standardless software. UV–vis measurements were performed on a Varian Cary Bio 100 spectrometer with a scan rate of 600 nm/min and a sweep width from 700 to 200 nm. A Varian diffuse reflectance attachment was utilized for the UV–vis-DR studies.

Results and discussion

Solution UV–vis spectra of **1** display two absorption maxima at 278 and 350 nm (4). The high energy absorption at 278 nm is assigned to π–π* transitions of the aromatic rings, whereas the peak at 350 nm has been ascribed to ligand-to-metal charge transfer (LMCT) (4). This assignment is consistent with what has been observed for other copper–chalcogenolate complexes (19). Matrix I was prepared from the treatment of TMS–MCM-41 with an 8.14×10^{-6} mol L^{-1} solution of **1** in THF for 24 h. This treatment was deemed sufficient to allow loading within mesopores of cluster **1**. Figure 1 demonstrates that the intensity of the absorptions in the UV–vis spectra of the mother liquor after the preparation of the **1**–TMS–MCM-41 matrix (I) decreased (Fig. 1*b*) as compared with the initial stock solution (Fig. 1*a*). This concentration decrease of **1** in solution was measured from the absorption maxima at 260 nm to be ~45%. These data demonstrate that **1** is taken up from the solution when allowed to interact with TMS–MCM-41. When a similar UV–vis study was performed with silicalite-1 (a siliceous zeolite with a small pore) in place of TMS–MCM-41, no detectable decrease of intensity was observed in the UV–vis spectrum of the filtered mother liquor vs. the stock solution after identical treatment (not shown). TMS–MCM-41 and silicalite-1 have very similar external surfaces, but silicalite-1 has much smaller micropores (~5.1 Å), which are too small to allow penetration of **1** into the internal surface area. Therefore, we conclude that the majority of **1** must be restricted within the pores of the TMS–MCM-41 framework following the preparation of matrix I.

Thermogravimetric analysis of TMS–MCM-41 was performed to obtain a decomposition profile for the grafted trimethylsilyl organic groups (Fig. 2*a*). The framework is hydrophobic as demonstrated by the minimal quantity of water adsorbed from the atmosphere during transfer to the TGA (0.73 wt%). There is a much larger weight loss observed upon heating from 200 to 900 °C, which arises from the decomposition of grafted TMS groups (6.56 wt%). Chemisorbed water is also expected to be ejected over this temperature region, as TMS groups do not graft to these units (20). When TMS–MCM-41 is treated with a THF solution of **1** (1.9×10^{-2} mol L^{-1}, matrix II), the TGA curve of II (Fig. 2*b*) displays a marked change vs. that for TMS–MCM-41. A single, new decomposition is observed between 120 and 220 °C, which overlaps with the thermal decomposition

of crystalline **1** (not shown). This feature is consistent with the formation and ejection of $TePh_2$ and the elimination of $PEtPh_2$, as observed for crystalline **1** (16*c*). A calculated loading of 11.4 wt% of **1** associated with matrix II can be obtained from this decomposition. To verify that the decomposition of II arises from the presence of **1** and not an interaction of THF (the solvent utilized for loading) with TMS–MCM-41, THF was allowed to interact with TMS–MCM-41. The TGA of THF–TMS–MCM-41 displays a high temperature decomposition (see Supplemental information, Fig. S1),[4] which has previously been assigned to chemisorbed THF on dehydrated silica (21). Due to the greatly different temperatures at which weight loss occurs in II vs. THF–TMS–MCM-41, the decomposition displayed in Fig. 2*b* can be assigned to the presence of **1** within TMS–MCM-41 (II).

The individual atomic components that constitute cluster **1**, namely Cu, Te, P, and C, and the framework Si and O of II, were simultaneously probed by EDX analysis on 100 × 100 nm^2 areas (see Supplemental information, Fig. S2).[4] The relative wt% and atomic ratios obtained from the EDX provide a semiquantitative determination of the elements present. The relative atomic ratios are as expected, with a 1:2 ratio of Si:O and a ~1:~1:~1 ratio of Cu:Te:P, which remains close to the stoichiometry of pure cluster **1**. From this data, an approximate formula for II of $0.15Cu_6(TePh)_6(PEtPh_2)_5{:}38SiO_2$ is obtained. This is in agreement with the TGA data.

Powder X-ray diffraction (PXRD) is an effective technique to probe the microcrystalline one-dimensional ordered porous environment of MCM-41 and when electron dense materials such as **1** are present, provide evidence of occlusion (22). The PXRD pattern of TMS–MCM-41 (Fig. 3*a*) has the characteristic pattern of this framework with the reflections h_{100}, h_{110}, and h_{200} being observed (10). The presence of the higher ordered diffractions suggests a well-ordered architecture with long length pores. The PXRD pattern of II (Fig. 3*b*) exhibits identical diffractions albeit with decreased intensity. Since II does not have large quantities of occluded THF as determined by TGA, the intensity decrease is a result of contrast matching (22) because of the presence of **1** within the pores. The position of the d_{100} peak is similar for II and TMS–MCM-41, which translates into an identical $a_o d_{100}$ calculation ($a_o d_{100} = 2/3^{1/2} d_{100}$). Framework integrity

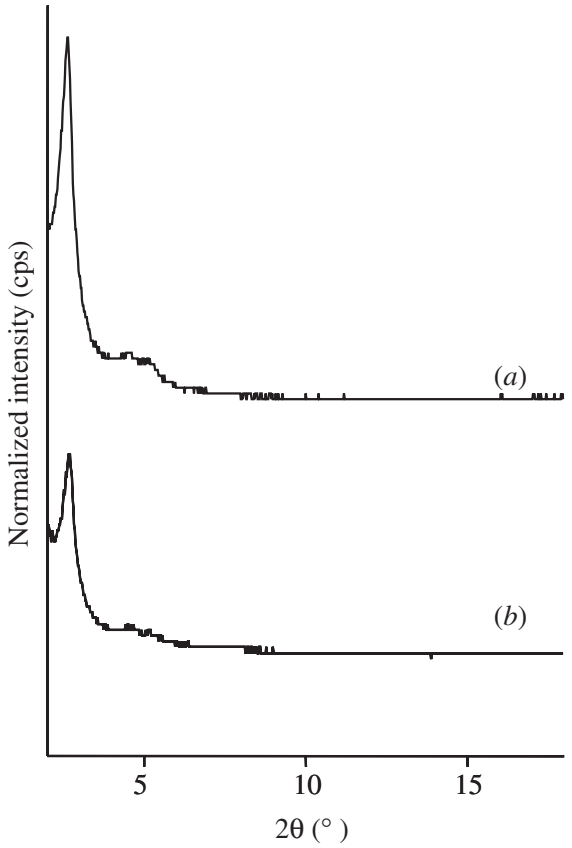
Fig. 3. PXRD patterns, 2°–18°2θ, normalized to the d_{100} diffraction of TMS–MCM-41: (*a*) TMS–MCM-41; (*b*) **1**–TMS–MCM-41 (II).



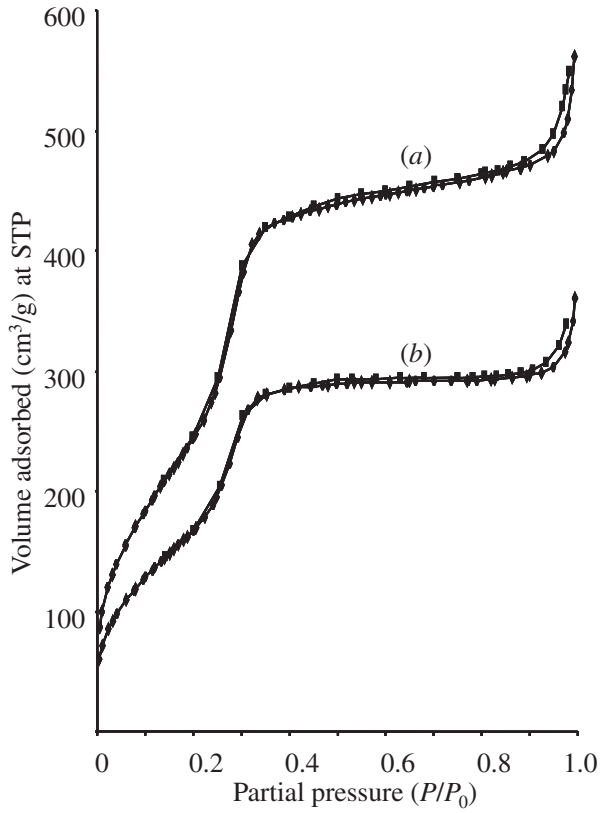


Fig. 4. Nitrogen adsorption/desorption isotherms at 77 K; samples subjected to outgassing prior to adsorption at 25 °C for 24 h: (*a*) TMS–MCM-41; (*b*) **1**–TMS–MCM-41 (II).

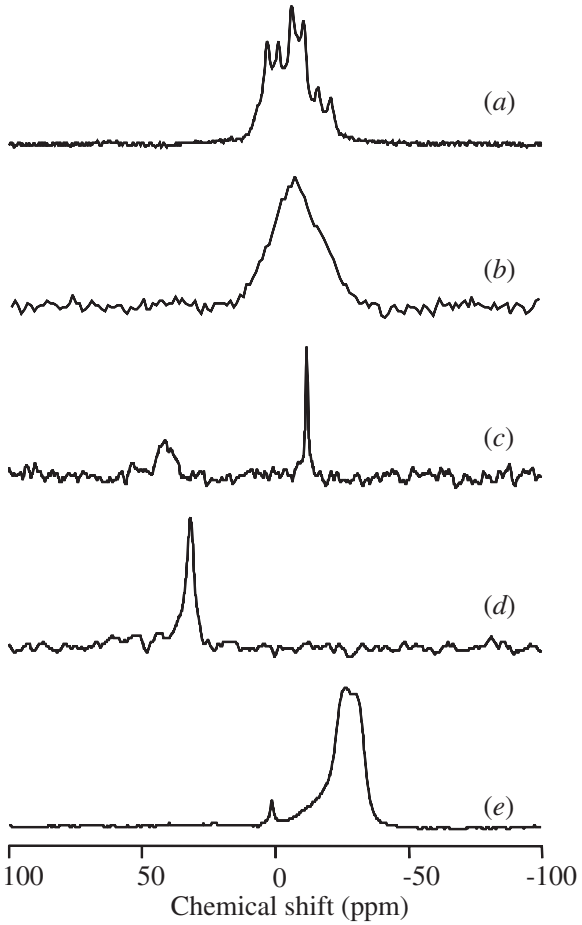
is therefore maintained. No reflections owing to **1** are present, suggesting that cluster **1** in the channels has no long-range ordering.

Nitrogen adsorption/desorption isotherms of II provide additional evidence for the occlusion of **1** within the pores of TMS–MCM-41. The N_2 isotherm of TMS–MCM-41 (Fig. 4*a*) is type IV with distinct capillary condensation and no hysteresis, characteristic of mesoporous M41s materials (23). The nitrogen adsorption isotherm of II (Fig. 4*b*) remains type IV and therefore is mesoporous, although II adsorbs a decreased volume of nitrogen vs. TMS–MCM-41. The structural parameters extracted from these two isotherms demonstrate that **1** is in fact occluded within the pores of TMS–MCM-41 for II. The BET surface area decreases from 746 m^2/g for TMS–MCM-41 to 498 m^2/g for II. Similarly, the BJH pore volume decreases by 0.19 cm^3/g for II vs. TMS–MCM-41.



TEM images and the corresponding electron diffraction patterns (by fast Fourier transformation) of II parallel to the pores verify the previous analysis by PXRD and nitrogen adsorption that the hexagonal porous structured architecture is maintained during the impregnation of **1** (see Supplementary information, Fig. S3).[4] Expectedly, no occluded clusters are visible within the channel network nor is there any apparent electron-dense material on the TMS–MCM-41 surface. It was previously observed that the solid-state impregnation of **1** into MCM-41 proceeded with loss of the phosphine shell and formation of several surface phosphorus-containing species (16*c*). To probe the structural integrity of cluster **1** within TMS–MCM-41, a ^{31}P CP MAS NMR study was performed on II. The ^{31}P CP MAS spectrum of pure crystalline **1** (Fig. 5*a*) exhibits *J* coupling between ^{31}P and $^{63/65}Cu$ (I = 3/2). The observed coupling constants are 1–1.5 kHz, which are consistent with those reported in the literature (24). The ^{31}P CP MAS NMR spectrum displayed in Fig. 5*b* of II has an identical chemical shift as observed for the pure cluster, however without the ^{31}P–$^{63/65}Cu$ *J* coupling being resolved. A large FWHH (full width at half height, 3.2–3.4 kHz) for the peak centered at –8 ppm indicates cluster-coordinated phosphines with broad FWHH originating from orientational disorder in slightly different environments.

To verify that the ^{31}P NMR peak at –8 ppm for II arises from copper-bonded phosphine ligands, the phosphine-loaded samples $PEtPh_2$–TMS–MCM-41 (III) and $Ph_2EtP{=}O$–TMS–MCM-41 (IV) were prepared and analysed by ^{31}P CP MAS NMR spectroscopy (Figs. 5*c* and 5*d*, respectively). Spectra of III display a sharp peak at –11 ppm that results from physiosorbed phosphine within the framework (an identical solution shift in C_6D_6 is obtained, not shown), and demonstrates what feature would be present in the ^{31}P CP MAS NMR of II if $PEtPh_2$ was not coordinated to copper. The formation of $Ph_2EtP{=}O$ is not observed during the preparation of II, as the ^{31}P NMR spectra of IV displays a peak at +33 ppm, which is also not observed for II.

The occlusion of intact **1** within the pores of TMS–MCM-41 presents an opportunity to probe condensation reactions

of the cluster, to generate larger clusters or a copper telluride composite. It has been demonstrated that photochemical condensation of **1** in solution results in the generation of the larger condensed cluster, $[Cu_{50}(TePh)_{20}Te_{17}(PEtPh_2)_8][PEtPh_3]_4$, through ejection of $TePh_2$ and phosphine moieties and NMR spectra of the photolysis mixture also suggested that other CuTe clusters were present, but these species were not isolated (4). Controlled thermolysis of other metal–chalcogenolate complexes has also yielded nanometer-sized particles via the elimination of ER_2 from $M(ER)_2$ centers (E = S, Se, and Te) (6, 7, 9). Suspending II in hydrocarbon solvent allows for even treatment of the sample and elimination through solvent transport of condensation by-products out of the pores. Cluster **1** is insoluble in hydrocarbon solvents and is not likely to be leached out of the mesoporous host, whereas expected by-products from condensation reactions should be. Photolysis of II suspended in hexanes (Pyrex filter, λ > 350 nm) using a Hg lamp leads to a gradual darkening of the sample to yield V. Thermolysis was achieved by solvothermal treatment of II in heptane at reflux temperature (98 °C) to produce VI. A similar thermolysis procedure is commonly utilized to produce binary composites from metal–chalcogen coordination complexes (25).

A UV–vis-DR time-resolved experiment was performed on II (10.4 wt% of **1**), evenly distributed throughout a KBr matrix. It is observed that over 3 h of irradiation through a quartz window that II darkens in colour from an initial yellow to a dark brown, which is accompanied by a red shift of the band edge region as irradiation time increases (see Supplementary information, Fig. S4).[4] The effect that photolytic treatment of II has on the sample colour and the red shift observed by UV–vis-DR suggests that a condensation process does indeed occur. From V (photolysis of II (11.4 wt%) suspended in hexanes, 3 h), GC–MS spectra of the reaction solvent identified four distinct species: EtTePh, EtTeTePh, $TePh_2$, and $PEtPh_2$. GC–MS analysis of the reaction solvent of composite VI (thermolysis of II (11.4 wt%) suspended in heptane, 3 h) proved to proceed with the ejection of only $TePh_2$ and $PEtPh_2$. The effect of both thermal and photochemical condensation treatments on the unmodified TMS–MCM-41 host was examined. It was found that the TMS–MCM-41 framework is inert toward both photolysis and thermolysis under identical treatment as for the preparation of V and VI as determined via PXRD (not shown). Since no decrease in the intensity of the d_{100} peak occurred, it may be concluded that the solvent used for thermolysis experiments can be completely removed from TMS–MCM-41 by treatment in vacuo.

TGA of V and VI (not shown) indicated that for both condensed composites a single weight loss occurred over an identical temperature range as for II, but the magnitude of weight loss was 5.5 wt% for V (vs. 8.2 wt% in II) and 5.2 wt% for VI. Complete condensation of **1** would presumably result in the formation of Cu_2Te, however this does not occur and residual cluster/nanocluster fragments are likely present.

The deconvoluted atom % of P, Cu, and Te from composite V (photolysis) and VI (thermolysis) as obtained from EDX analysis are summarized in Table 1. The initial 1:1 ratio of Te:Cu within II is reduced by the condensation reactions. The ratio of Cu:Te after photolysis suggests that the Cu:Te stoichiometry in the final composite approaches the binary semiconductor Cu_2Te. Thermolysis of II produces an end product in which the Cu:Te is 2:1.

The phosphorus content retained within composites V and VI was probed with ^{31}P CP MAS NMR spectroscopy. The ^{31}P CP MAS NMR spectrum of V suggests very different phosphorus chemical environments of the photolysed product (Fig. 5*e*). The original peak for the cluster-coordinated phosphines (Fig. 5*b*) at –8 ppm is no longer present as only new peaks in the region of –30 ppm are observed. The broad nature of these peaks for V suggests that the phosphorus-31 nucleus may be bonded to copper in a disordered environment. As the photolysis of II leads to the formation of EtTePh and EtTeTePh, phoshido (μ-PPh_2) complexes may be present. Phosphido groups that bridge copper have been reported in the literature (25–28). Phosphorus-31 NMR spectra of these Cu_2(μ-PPh_2) coordination complexes are not commonly demonstrated because of their atmospheric instability and insolubility in common organic solvents (27), although recently a resonance of δ –25 ppm has been determined (28). Cu_2(μ-PPh_2) coordination complexes may also undergo

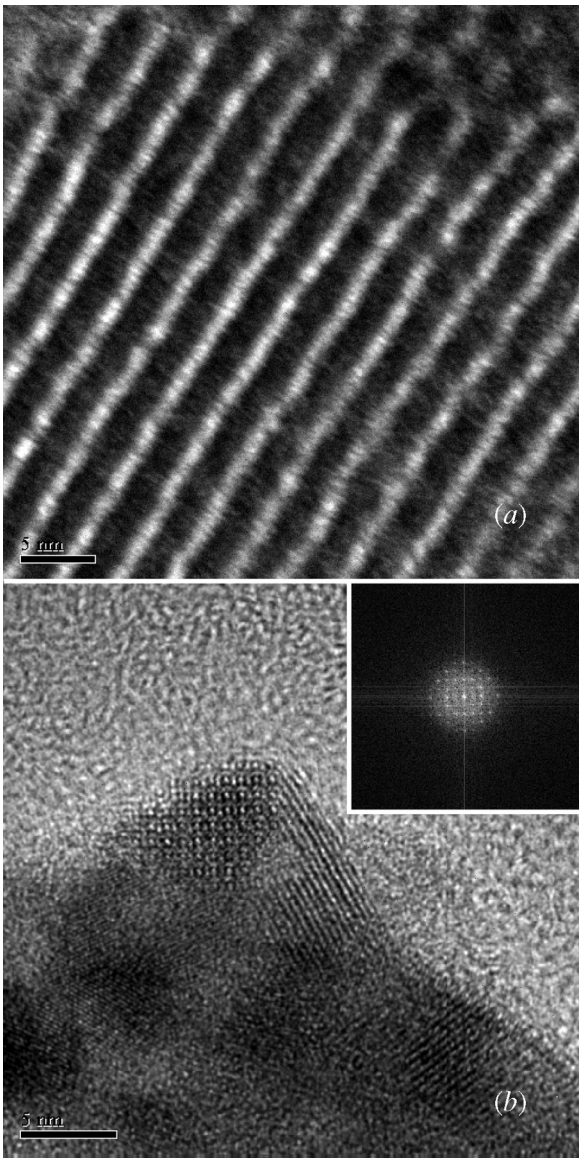
Table 1. Results from the EDX analysis for the photolysis of **1**–TMS–MCM-41 using a Pyrex filter in a slurry of hexanes to generate V and thermolysis in a slurry of heptane to generate VI.



Compound	P (atom %)	Te (atom %)	Cu (atom %)	Cu:Te ratio
1–TMS–CM-41	1.58	1.70	1.87	1.1:1
Composite V (photolysis)	0.27	0.25	0.40	1.6:1
Composite VI (thermolysis)	0.35	0.28	0.55	2.0:1

chalcogen insertion reactions into the Cu—P bonds (26, 27); this is less likely however for tellurium. EDX analysis of composite VI also suggests some phosphorus is present, however no phosphorus-31 signals were observed in the ^{31}P CP MAS NMR spectrum.

Type IV isotherms are retained for V and VI, although a smaller quantity of nitrogen is adsorbed vs. II (not shown). BET surface areas of 498 m^2/g for II decrease to 421 and 384 m^2/g for composites V and VI, respectively. A similar trend is obtained for the pore volume assessment as it decreased from the initial 0.36 to 0.30 cm^3/g for composite V and 0.24 cm^3/g for composite VI.

HR-TEM images of V and VI were obtained in an attempt to directly observe the condensed metal–chalcogen material (Fig. 6). The TEM images for V demonstrate that the TMS–MCM-41 framework remains intact (Fig. 6*a*). There is no direct evidence of nanoparticles or nanowires within the pores. This is likely due to a poor electron density (better contrast) difference between photolysed **1** and the framework and small amounts present. The micrograph, however, illustrates that no noticeable leaching of the copper telluride composite has occurred from the pores. Leaching does appear to present a problem for the thermolysed sample, as illustrated in Fig. 6*b*. The HR-TEM image of VI demonstrates that thermal treatment results in the formation of particles outside of the porous framework. This electron-dense material has smaller spacing and different periodicity than that of TMS–MCM-41. From the electron diffraction pattern (by fast Fourier transformation), the material has two axes of equal length (Fig. 6*b*, inset) and a corresponding *d*-spacing value of 0.76 nm (29). The electron-dense material has a rodlike morphology. During the thermal condensation of cluster **1**, limited solubility in hot heptane likely results in partial leaching from the TMS–MCM-41 framework where it aggregates and condenses to form Cu_2Te particles. This condensed Cu_2Te particle, however, does not represent the majority of the sample as PXRD of this composite only exhibits peaks for the TMS–MCM-41 framework.

Fig. 6. HR-TEM analysis of the condensed composites (measurement bars displayed on the micrographs represent 5 nm): (*a*) V produced by photolysis of II; (*b*) VI produced by thermolysis of II. The inset is the electron diffraction pattern (by fast Fourier transformation) of the large piece of condensed material.

Conclusions

The preparation of occluded $Cu_6(TePh)_6(PEtPh_2)_5$ (**1**), which remains completely intact within the TMS–MCM-41, has been demonstrated. Subsequent condensation chemistry of **1** has been determined to be possible either by photochemical or thermal means, both of which reduce the Cu:Te ratio to approach the 2:1 observed for the binary semiconductor Cu_2Te. Photolysis and thermolysis proceeds with condensed material being present within the pores, although thermal condensation also resulted in limited leaching. Similar impregnation and condensation studies could potentially allow access to virtually any size-restricted metal–chalcogen material of interest through the utilization of other metal–chalcogenolate clusters.

Preparation of hydrido(vinyl)iridium(III) complexes from functionalized olefins by C—H activation[1]

Bernd Papenfuhs, Thomas Dirnberger, and Helmut Werner

Abstract: The four-coordinate iridium(I) precursor *trans*-[IrCl(N_2)(PPh_3)$_2$] (**1**) reacts with functionalized olefins RCH=C(R′)C(O)R″ by displacement of the dinitrogen ligand and oxidative addition of the C—H bond to the metal center to give six-coordinate hydrido(vinyl)iridium(III) complexes [IrH(Cl){κ^2(*C*,*O*)-C(R)=C(R′)C(R″)=O}(PPh_3)$_2$] (**2**–**12**) in good to excellent yields. The reaction of [IrH(Cl){κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$] (**2**) with $AgClO_4$ affords the cationic compound [IrH{κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$]ClO_4 (**15**), which in solution equilibrates with the uncharged isomers [IrH($OClO_3$){κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$] (**15a** and **15b**). In contrast, five-coordinate [IrH{κ^2-(*C*,*O*)-CH=CHC(Et)=O}(PPh_3)$_2$]ClO_4 (**16**), prepared from **3** and $AgClO_4$, is stable and undergoes addition reactions with CO, PPh_3, C_2H_4, $CH_3C{\equiv}CH$, MeCN, and PhCN to give the six-coordinate complexes [IrH(L){κ^2(*C*,*O*)-CH=CHC-(Et)=O}(PPh_3)$_2$]ClO_4 (**17**–**22**). The neutral hydrido(thiolato) compound [IrH(SPh){κ^2(*C*,*O*)-CH=CHC(Et)=O}(PPh_3)$_2$] (**23**) was obtained on treatment of **21** with NaSPh.

Key words: iridium, C—H activation, hydrido complexes, vinyl complexes, phosphine complexes.

Résumé : Le précurseur tétracoordiné de l'iridium(I), *trans*-[IrCl(N_2)(PPh_3)$_2$] (**1**), réagit avec les oléfines fonctionnalisées RCH=C(R′)C(O)R″ par déplacement du ligand diazote et par addition oxydante de la liaison C—H du centre métallique pour conduire à la formation des complexes hexacoordinés hydrido(vinyl)iridium(III) [IrH(Cl){κ^2(*C*,*O*)-C(R)=C(R′)C(R″)=O}(PPh_3)$_2$] (**2**–**12**) avec de bons rendements. La réaction du [IrH(Cl){κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$] (**2**) avec du $AgClO_4$ conduit à la formation du composés cationique [IrH{κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$]ClO_4 (**15**) qui s'équilibre en solution avec formation des isomères non chargés [IrH($OClO_3$){κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$] (**15a** and **15b**). Par opposition, le composé pentacoordiné [IrH{κ^2(*C*,*O*)-CH=CHC(Et)=O}(PPh_3)$_2$]ClO_4 (**16**) qui a été préparé à partir du composé **3** et de $AgClO_4$ est stable et il donne des réactions d'additions avec le CO, le PPh_3, le C_2H_4, le $CH_3C{\equiv}CH$, le MeCn et le PhCN pour conduire à la formation de complexes hexacoordinés [IrH(L){κ^2(*C*,*O*)-CH=CHC(Et)=O}(PPh_3)$_2$]ClO_4 (**17**–**22**). Le traitement du composé **21** avec du NaSPh conduit à la formation du composé neutre [IrH(SPh){κ^2(*C*,*O*)-CH=CHC(Et)=O}(PPh_3)$_2$] (**23**).

Mots clés : iridium, activation de C—H, complexes hydrido, complexes de vinyle, complexes de phosphine.

[Traduit par la Rédaction]

Introduction

As part of our investigations on the reactivity of low-valent iridium complexes containing alkenes and alkynes as ligands, we reported (1) that upon low-temperature UV irradiation in toluene the four-coordinate ethene derivative *trans*-[IrCl(C_2H_4)(P-*i*-Pr_3)$_2$] partly rearranges to the five-coordinate hydrido(vinyl) isomer [IrH(Cl)($CH{=}CH_2$)(P-*i*-Pr_3)$_2$]. This compound is thermodynamically unstable and on warming to room temperature reconverts to the starting material. If, however, instead of the ethene complex *trans*-[IrCl(C_2H_4)(P-*i*-Pr_3)$_2$] the related methyl acrylate and dimethyl fumarate derivatives *trans*-[IrCl($CH_2{=}CHCO_2Me$)(P-*i*-Pr_3)$_2$] and *trans*-[IrCl{(*E*)-$CH(CO_2Me){=}CH(CO_2Me)$}(P-*i*-Pr_3)$_2$] are used as the precursors, UV irradiation in benzene leads to a quantitative conversion to the six-coordinate isomers [IrH(Cl){κ^2(*C*,*O*)-C(R)=CH(OMe)=O}(P-*i*-Pr_3)$_2$] in which the hydrido(vinyl)iridium moiety is stabilized by an additional linkage of one C=O group to the metal center (2).

The present paper describes a synthetic protocol for a series of neutral and cationic hydrido(vinyl)iridium(III) complexes with Ir(PPh_3)$_2$ as a building block in which the substituted vinyl group also behaves as a bidentate ligand. Due to this coordination mode, the order of thermodynamic stability [Ir](H)(CH=CHR) < [Ir](η^2-CH_2=CHR), found by Bergman (3) and Perutz (4) and their co-workers for [Ir] = (η^5-C_5Me_5)Ir(PMe_3) and (η^5-C_5H_5)Ir(C_2H_4), is reversed and the hydrido(vinyl) compounds can be isolated as stable enti-

ties. Some preliminary results related to this study have already been communicated (5).

Results and discussion

The dinitrogen complex *trans*-[IrCl(N_2)(PPh_3)$_2$] (**1**), prepared by Collman and Kang (6) from *trans*-[IrCl(CO)(PPh_3)$_2$] and benzoyl azide, reacts in benzene with the Michael acceptors CH_2=CHC(O)R (R = Me, Et, Ph) to give the six-coordinate hydrido(vinyl)iridium(III) compounds **2**–**4** in about 80%–90% yield (Scheme 1). Although the displacement of the dinitrogen ligand proceeds slowly at room temperature, attempts to detect the olefin species *trans*-[IrCl{η^2-CH_2=CHC(R)=O}(PPh_3)$_2$], supposed to be generated in one of the initial steps of the reaction, by NMR spectroscopy failed. Nevertheless, we assume that these compounds are formed as intermediates but presumably are short-lived and react by intramolecular C—H activation to give the thermodynamically more stable products. In this context we note that recently Esteruelas, Oro, and co-workers (7) reported the preparation of the four-coordinate iridium(I) complex [Ir(κ^2-acac){η^2-CH_2=CHC(O)Me}(PCy_3)] from [Ir(κ^2-acac)(C_8H_{14})(PCy_3)] and methyl(vinyl) ketone, which is stable and upon heating rearranges to a mixture of two six-coordinate hydrido(vinyl)iridium(III) stereoisomers.

The hydrido(vinyl) complexes **2**–**4** are yellow or orange solids, which are not air-sensitive and readily soluble in common polar organic solvents. A characteristic feature in the IR spectra of **2**–**4** is the ν(C=O) stretching mode at 1525–1550 cm^{-1}, which is shifted by ca. 120–150 cm^{-1} to lower wavenumbers compared with the free ketones. Since this shift is consistent with a coordination of the carbonyl group to the metal center, an octahedral geometry for compounds **2**–**4** (as shown in Scheme 1) can be assumed. The ^{1}H NMR spectra of **2**–**4** display two doublets at about δ 9.60 and 6.20 (for **2** and **3**) and δ 9.97 and 6.86 (for **4**), which in agreement with results by Nesmeyanov et al. (8) and one of us (9) are assigned to the vinylic protons in α and β positions. For the hydrido ligand, there appears in the high-field region a triplet resonance at, respectively, δ –22.42 (for **2**), –22.55 (for **3**), and –21.88 (for **4**), which is split into a triplet owing to ^{1}H–^{31}P coupling. Since the chemical shift of these signals is quite similar to that of the bis(triisopropylphosphine) complex [IrH(Cl){κ^2(*C*,*O*)-$C(CO_2Me)$=CHC(OMe)=O}(P-*i*-Pr_3)$_2$], which has been characterized crystallographically (10), we assume that the hydrido ligand is trans to the oxygen and not to the carbon atom of the chelate ring. The observation of only one signal in the ^{31}P NMR spectra of **2**–**4** confirms that the phosphine ligands are trans disposed. The ^{13}C NMR spectrum of **2** displays the signals for the vinyl carbon atoms at δ 197.3 and 133.1 ppm. Due to the cis disposition of the α-C atom and the PPh_3 groups, the signal at δ 197.3 ppm is split into a triplet, while the resonance at δ 133.1 ppm appears as a singlet.

The starting material **1** not only reacts with the ketones CH_2=CHC(O)R (R = Me, Et, Ph), but also with the related derivatives RCH=CHC(O)Me (R = OMe, Me, Ph, CO_2Me), MeCH=C(Me)C(O)Et, and PhCH=CHC(O)Ph to give the corresponding hydrido(vinyl)iridium(III) complexes **5**–**10** in good to excellent yields. These reactions are considerably slower than those leading to **2**–**4**, and thus the corresponding reaction mixture has to be stirred for 18 h at 80 °C in toluene. In contrast to the conditions employed to obtain **2**–**7**, for the preparation of **8**–**10** an excess of the olefinic sub-

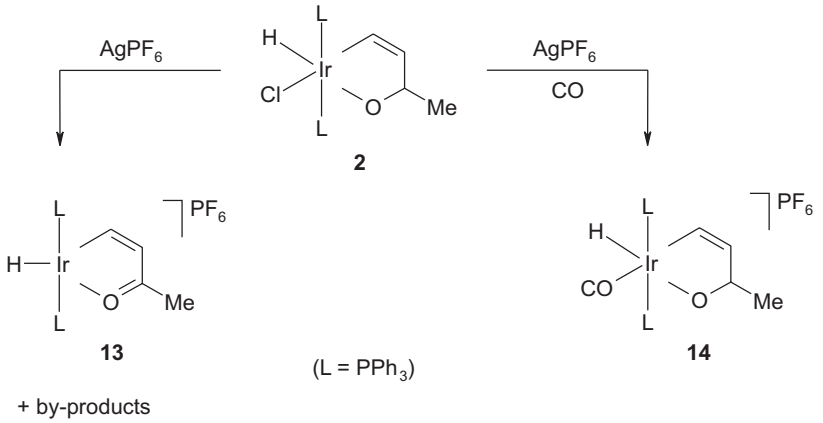
strate has to be used. If the dinitrogen complex **1** was treated with an equimolar amount of MeCH=C(Me)C(O)Et, the carbonyl iridium(I) compound *trans*-[IrCl(CO)(PPh_3)$_2$] (11) is generated as the dominant product. With regard to the formation of **8** from **1** and MeC(O)CH=$CHCO_2$Me, the remarkable feature is that the oxidative addition of the C—H bond adjacent to the CO_2Me functionality occurs exclusively. Moreover, it is worth mentioning that upon treatment of **1** with PhCH=CHC(O)Ph only the activation of the olefinic C—H and not that of an aromatic C—H bond is observed. The reactivity of **1** is thus different to that of the bis(triisopropylphosphine)iridium(I) derivative *trans*-[IrCl(C_8H_{14})(P-*i*-Pr_3)$_2$], which reacts with PhCH=CHC(O)Ph to give a 1:1 mixture of the two isomers [IrH(Cl){κ^2(*C*,*O*)-C(Ph)=CHC(Ph)=O}(P-*i*-Pr_3)$_2$] and [IrH(Cl){κ^2(*C*,*O*)-C_6H_4C(CH=CHPh)=O}(P-*i*-Pr_3)$_2$] (12). The ^{13}C NMR spectrum of **10** displays a triplet resonance at δ 215.0 (with ^2J(PC) = 6.1 Hz), which appears at a similar chemical shift (δ 209.4, ^2J(PC) = 5.3 Hz) as that of [IrH(Cl){κ^2(*C*,*O*)-C(Ph)=CHC(Ph)=O}(P-*i*-Pr_3)$_2$] (12) and thus supports the proposed structure.

Similarly to the Michael acceptors used for the preparation of **2**–**10**, methyl acrylate and acrylic acidamide also react with the dinitrogen compound **1** to afford the air-stable hydrido(vinyl) complexes **11** and **12** in 66% and 89% yield, respectively (Scheme 2). The IR spectrum of **12** shows the band for the ν(C=O) stretching mode at 1555 cm^{-1}, which is at nearly the same position as for **2** and **3**. In the ^{1}H NMR spectra of **11** and **12**, the hydride resonance appears at δ –25.07 (**11**) and δ –24.19 (**12**) and is significantly shifted upfield compared with **2**–**10**. We assume that this shift is due to the stronger electron-donating effect of the OMe and NH_2 functionalities compared with that of the alkyl and phenyl groups. The reaction of **1** with acrylonitrile does not lead to a stable iridium(I) or iridium(III) complex, but yields a pale yellow solid, which, according to the IR spectrum, presumably is a polymer with terminal CH_2CN and $CH(CH_3)CN$ groups (13).

To obtain a coordinatively unsaturated hydrido(vinyl)iridium(III) compound, considered to be a potential precursor for addition/insertion reactions, we attempted to eliminate the chloro ligand from **2** by using $AgPF_6$ and $AgClO_4$, respectively. The reaction of **2** with $AgPF_6$ in dichloromethane is quite rapid at room temperature and yields, after separation of AgCl and chromatographic workup of the solution, a brownish solid that owing to the ^{1}H and ^{31}P NMR spectra consists mainly (ca. 90%) of the expected compound [IrH{κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$]PF_6 (**13**). Attempts to separate the by-products by fractional crystallization or repeated column chromatography failed. Typical spectroscopic data of **13** are the ^{1}H NMR resonances for the vinylic protons at δ 9.73 and 6.02 (see **2**: δ 9.58 and 6.18), the hydride signal at δ –21.38 (see **2**: δ –22.42), and the singlet in the ^{31}P NMR spectrum at δ 21.7 (see **2**: δ 14.7). Treatment of **2** with $AgPF_6$ in the presence of CO gave the cationic six-coordinate hydrido(vinyl)iridium(III) carbonyl **14** (Scheme 3) for which a correct elemental analysis was obtained. The IR spectrum of **14** (being an off-white, air-stable solid) displays a strong band for the CO ligand at 2060 cm^{-1} and a medium-to-strong absorption for the ν(C=O) stretching mode at 1580 cm^{-1}. The latter is shifted by 30 cm^{-1} to higher

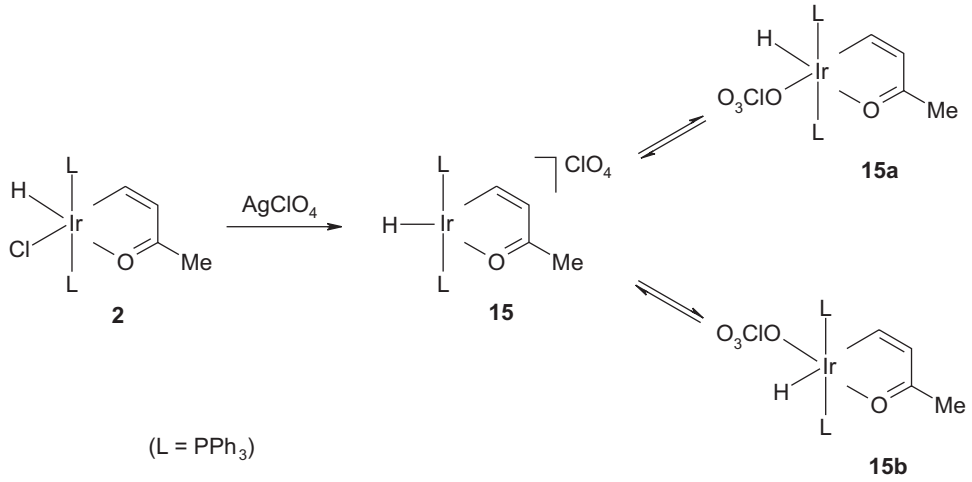
Scheme 2.

wavenumbers compared with the coordinatively unsaturated compound **13**. The hydride signal appears in the ^{1}H NMR spectrum of **14** at δ –19.09 and is thus shifted by ca. 2.3 ppm to lower fields compared with **13**.



The reaction of **2** with $AgClO_4$ was carried out under similar conditions as with $AgPF_6$ and resulted in the formation of the hydrido(vinyl) complex **15** (Scheme 4). While the poor solubility of **15** in hydrocarbons is in agreement with the formulation as an ionic compound analogous to **13**, the molar conductivity (Λ) in nitromethane (36 $cm^2\ \Omega^{-1}\ mol^{-1}$) is considerably lower than expected for a 1:1 electrolyte (see **14**: Λ = 65 $cm^2\ \Omega^{-1}\ mol^{-1}$). The ^{31}P NMR spectrum of **15** in $CDCl_3$ at room temperature shows two singlets at δ 23.1 (sharp) and δ 17.5 (broad), which after decoupling change into doublets. In CD_2Cl_2 at –80 °C three doublets appear, two of which collapse to a broadened resonance after increasing the temperature to 0 °C. Although these results have to be interpreted with caution, we assume that in solution an equilibrium between the cationic species **15** and the uncharged isomers **15a** and **15b** exists. It is well-known that not only for iridium (14), but also for various other transition metals (15), the perchlorate anion can behave as a weakly coordinated ("noninnocent") ligand that is readily replaced by better nucleophiles. It should be mentioned that the ^{1}H NMR spectrum of the product obtained from **2** and $AgClO_4$ also displays two sets of signals for the =CH, CH_3, and IrH protons, which is in agreement with the equilibrium between **15** and the nonionic species **15a** and **15b**.

Similarly to **2**, the corresponding iridium(III) counterpart **3** reacts with $AgClO_4$ in CH_2Cl_2 to give the cationic complex **16** (Scheme 5), which, however, appears to have no tendency to coordinate the perchlorate anion. The ^{1}H as well as the ^{31}P NMR spectrum of **16** shows only one sharp resonance for the IrH proton and the phosphine ligands, respectively, and these resonances do not broaden or split into two signals by decreasing the temperature. We note that the chemical shifts of the signals observed in the ^{1}H and ^{31}P NMR spectra of **16** are nearly identical to those assigned to the cation of **15**, and thus we are convinced that the proposed structure with a five-coordinate metal center is correct.



The open coordination site in the cation of **16** can easily be occupied by CO, PPh_3, ethene, propyne, acetonitrile, and

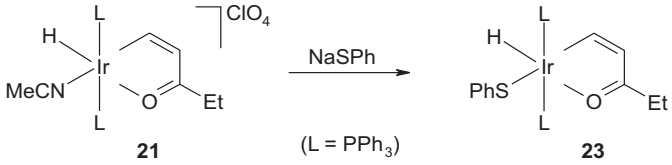
Scheme 5.



benzonitrile. With the exception of **19**, the related hydrido(vinyl)iridium(III) compounds **17**, **18**, and **20**–**22** are exceedingly stable and decompose between 112 (**20**) and 179 °C (**21**). Owing to the ionic nature, they are soluble in acetone, nitromethane, CH_2Cl_2, and $CHCl_3$, but almost insoluble in benzene and other hydrocarbons. Conductivity measurements confirm the presence of 1:1 electrolytes. The ethene complex **19** is only stable under a C_2H_4 atmosphere and has been characterized by ^1H and ^{31}P NMR spectroscopy. Typical features of **19** are the ^1H NMR signal for the ethene protons at δ 3.55 (triplet with $^3J(PH)$ = 3.1 Hz) and the singlet resonance for the ^{31}P NMR nuclei at δ 13.9, the latter being shifted upfield by 8.6 ppm compared with **16**. When we attempted to remove the volatiles and isolate compound **19**, the precursor **16** was regenerated.

In contrast to **19**, the analogous propyne complex **20** is rather inert and neither undergoes an insertion of the alkyne ligand into the Ir—H bond nor rearranges to the vinylidene isomer [IrH(=C=CHCH$_3$){κ^2(*C*,*O*)-CH=CHC(Et)=O}(PPh$_3$)$_2$]ClO$_4$ (16). However, compound **20**, as well as the nitrile iridium(III) analogues **21** and **22**, smoothly react with CO to afford the corresponding carbonyl complex **17**.

© 2006 NRC Canada

Scheme 6.

The acetonitrile ligand in **21** can not only be replaced by CO but also by thiophenolate. The reaction of **21** with NaSPh in THF proceeds slowly at room temperature and gives the neutral hydrido(thiophenolato) complex **23** in 78% yield (Scheme 6). **23** is an orange air-stable solid that has been characterized by elemental analysis and spectroscopic techniques. Attempts to also displace the acetonitrile ligand in **21** by methyl xanthogenate, K[SC(S)OMe], led to the formation of a mixture of compounds that could not be separated by fractional crystallization or column chromatography.

In summarizing, the present work has shown that, provided the olefinic substrate RCH=CHR′ possesses a substituent R′ such as C(O)R, C(O)NH_2, or C(O)OMe, the reaction of the starting material *trans*-[IrCl(N_2)(PPh_3)$_2$] (**1**) with RCH=CHR′ leads preferentially to the hydrido(vinyl)-iridium(III) complexes **2**–**12**. These compounds are remarkably stable and neither thermally nor photochemically react by intramolecular reductive elimination to give the four-coordinate olefin iridium(I) isomers *trans*-[IrCl(η^2-RCH=CHR′)(PPh_3)$_2$]. A rearrangement of this type does not occur with the cationic species [IrH(L){κ^2(*C*,*O*)-CH=CHC(R)=O}(PPh_3)$_2$]$^+$, independent of whether the ligand L is a good σ donor (MeCN, PhCN) or a destinctive π-acceptor ligand (CO, $CH_3C{\equiv}CH$). There is no doubt that the driving force for the formation of **2**–**12** from **1** and the functionalized olefin is the formation of the chelating five-membered IrC_3O ring, which remains intact even in the presence of excess CO. In this context, we note that in contrast to [IrH(Cl)(CH=CH_2)(P-*i*-Pr_3)$_2$], the related hydrido(phenyl) complex [IrH(Cl)(C_6H_5)(P-*i*-Pr_3)$_2$] is also quite stable and reacts with CO by addition and not by reductive elimination (17).

Experimental

All experiments were carried out under an atmosphere of argon by using standard Schlenk techniques. The starting material **1** was prepared as described in the literature (6). IR spectra were recorded on a PerkinElmer 1420 IR spectrometer and NMR spectra on Jeol FX 90 Q as well as Bruker AC 200 and Bruker AMX 400 instruments. Melting points (dec. temp.) were determined by DTA. Conductivity measurements were carried out in nitromethane with a Schott Konduktometer CG 851. Abbreviations used: singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broadened signal (br); $N = {}^1J(PC) + {}^3J(PC)$.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-CH=CHC(Me)=O}(PPh_3)$_2$] (2)

A solution of **1** (94 mg, 0.12 mmol) in 6 mL of benzene was treated with methyl(vinyl)ketone (11 μL, 0.12 mmol) and stirred for 2 h at room temperature. The solvent was evaporated in vacuo, the residue was dissolved in 3 mL of benzene–hexane (1:1), and the solution chromatographed on Al_2O_3 (neutral, activity grade V, length of column 6 cm). With benzene–hexane (1:1) a yellow fraction was eluted, which was brought to dryness in vacuo. The remaining yellow, air-stable solid was washed twice with 5 mL portions of hexane (30 °C) and dried. Yield: 78 mg (80%), mp 184 °C (dec.). IR (KBr, cm^{-1}): 2190 ν(IrH), 1550 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.58 (d, 1H, *J*(HH) = 7.5 Hz, IrCH), 7.59–7.19 (m, 30H, C_6H_5), 6.18 (d, 1H, *J*(HH) = 7.5 Hz, IrCH=C*H*), 1.53 (t, 3H, *J*(PH) = 1.4 Hz, CH_3), –22.42 (t, 1H, *J*(PH) = 16.4 Hz, IrH). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 208.0 (s, C=O), 197.3 (t, *J*(PC) = 7.0 Hz, IrCH), 133.1 (s, IrCH=*C*H), 134.3 (vt, *N* = 11.6 Hz, *ortho*-C of PC_6H_5), 131.9 (vt, *N* = 54.7 Hz, ipso-C of PC_6H_5), 129.6 (s, *para*-C of PC_6H_5), 127.7 (vt, *N* = 10.1 Hz, *meta*-C of PC_6H_5), 24.0 (s, C(O)*C*H_3). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 14.7 (s, d in off-resonance). Anal. calcd. for $C_{40}H_{36}ClIrOP_2$: C 58.42, H 4.41; found: C 58.34, H 4.55.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-CH=CHC(Et)=O}(PPh_3)$_2$] (3)

A solution of **1** (140 mg, 0.18 mmol) in 15 mL of toluene was treated with ethyl(vinyl)ketone (18 μL, 0.18 mmol) and stirred for 6 h at room temperature. The solvent was evaporated in vacuo, the remaining yellow, air-stable solid was washed twice with 5 mL portions of hexane (50 °C) and dried. Yield: 137 mg (91%), mp 178 °C (dec.). IR (KBr, cm^{-1}): 2240 ν(IrH), 1540 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.60 (d, 1H, *J*(HH) = 7.6 Hz, IrCH), 7.58–7.28 (m, 30H, C_6H_5), 6.21 (d, 1H, *J*(HH) = 7.6 Hz, IrCH=C*H*), 1.95 (q, 2H, *J*(HH) = 7.3 Hz, CH_2CH_3), 0.69 (t, 3H, *J*(HH) = 7.3 Hz, CH_2CH_3), –22.55 (t, 1H, *J*(PH) = 16.5 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 13.6 (s, d in off-resonance). Anal. calcd. for $C_{41}H_{38}ClIrOP_2$: C 58.88, H 4.58; found: C 58.37, H 4.51.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-CH=CHC(Ph)=O}(PPh_3)$_2$] (4)

A solution of **1** (140 mg, 0.18 mmol) in 15 mL of toluene was treated with phenyl(vinyl)ketone (23 μL, 0.18 mmol) and stirred for 18 h at room temperature. (Owing to the high tendency of PhC(O)CH=CH_2 to polymerize, preparation of the ketone (18) in situ from β-chloropropiophenone is recommended). The reaction mixture was worked up analogous to that described for **3**. An orange, air-stable solid was obtained. Yield: 134 mg (84%), mp 189 °C (dec.). IR (KBr, cm^{-1}): 2145 ν(IrH), 1525 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.97 (d, 1H, *J*(HH) = 7.4 Hz, IrCH), 7.72–7.17 (m, 35H, PC_6H_5 and CC_6H_5), 6.86 (d, 1H, *J*(HH) = 7.4 Hz, IrCH=C*H*), –21.88 (t, 1H, *J*(PH) = 16.5 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 13.4 (s, d in off-resonance). Anal. calcd. for $C_{45}H_{38}ClIrOP_2$: C 61.11, H 4.33; found: C 60.74, H 4.35.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-C(OMe)=CHC(Me)=O}(PPh_3)$_2$] (5)

A solution of **1** (140 mg, 0.18 mmol) in 15 mL of toluene was treated with 4-methoxybut-3-en-2-one (18 μL, 0.18 mmol) and stirred for 18 h at 80 °C. After the solution was cooled to room temperature, the solvent was evaporated

in vacuo, the remaining pale yellow, air-stable solid was washed twice with 5 mL portions of hexane (50 °C) and dried. Yield: 120 mg (78%), mp 226 °C (dec.). IR (KBr, cm^{-1}): 2175 ν(IrH), 1515 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 7.71–7.22 (m, 30H, C_6H_5), 5.17 (s, 1H, C*H*C(Me)=O), 2.54 (s, 3H, IrC(OC*H*$_3$)=CH), 1.76 (s, 3H, C(CH_3)=O), –21.92 (t, 1H, *J*(PH) = 16.0 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 9.8 (s, d in off-resonance). Anal. calcd. for $C_{41}H_{38}ClIrO_2P_2$: C 57.77, H 4.49; found: C 57.44, H 4.67.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-C(Me)=CHC(Me)=O}-(PPh_3)$_2$] (6)

The procedure was analogous to that described for **5**, using **1** (140 mg, 0.18 mmol) and pent-3-en-2-one (17 μL, 0.18 mmol) as starting materials. A yellow, air-stable solid was obtained. Yield: 125 mg (83%), mp 191 °C (dec.). IR (KBr, cm^{-1}): 2200 ν(IrH), 1535 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 7.78–7.23 (m, 30H, C_6H_5), 6.07 (s, 1H, C*H*C(Me)=O), 1.83 (s, 3H, C(CH_3)=O), 0.92 (s, 3H, IrC(C*H*$_3$)=CH), –22.67 (t, 1H, *J*(PH) = 16.4 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 11.6 (s, d in off-resonance). Anal. calcd. for $C_{41}H_{38}ClIrOP_2$: C 58.88, H 4.58; found: C 59.37, H 4.71.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-C(Ph)=CHC(Me)=O}-(PPh_3)$_2$] (7)

The procedure was analogous to that described for **5**, using **1** (140 mg, 0.18 mmol) and 4-phenylbut-3-en-2-one (25 μL, 0.18 mmol) as starting materials. An orange, air-stable solid was obtained. Yield: 133 mg (82%), mp 194 °C (dec.). IR (KBr, cm^{-1}): 2230 ν(IrH), 1540 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 7.68–7.11 (m, 30H, PC_6H_5), 7.01–6.56 (m, 5H, CC_6H_5), 1.95 (t, 3H, *J*(PH) = 1.2 Hz, C(CH_3)=O), –22.10 (t, 1H, *J*(PH) = 15.9 Hz, IrH), signal of =CH proton probably covered by signal of CC_6H_5 protons. ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 10.7 (s, d in off-resonance). Anal. calcd. for $C_{46}H_{40}ClIrOP_2$: C 61.50, H 4.49; found: C 61.43, H 4.37.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-C(CO_2Me)=CHC(Me)=O}-(PPh_3)$_2$] (8)

The procedure was analogous to that described for **3**, using **1** (107 mg, 0.14 mmol) and methyl-4-oxo-2-pentenoate (24 mg, 0.28 mmol) as starting materials. An orange, air-stable solid was obtained. Yield: 97 mg (79%), mp 228 °C (dec.). IR (KBr, cm^{-1}): 2210 ν(IrH). ^1H NMR (400 MHz, $CDCl_3$) δ: 7.59–6.81 (m, 30H, PC_6H_5), 2.89 (s, 3H, CO_2CH_3), 2.03 (t, 3H, *J*(PH) = 1.2 Hz, C(CH_3)=O), –22.89 (t, 1H, *J*(PH) = 16.0 Hz, IrH), signal of =CH proton probably covered by signal of C_6H_5 protons. ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 11.5 (s, d in off-resonance). Anal. calcd. for $C_{42}H_{38}ClIrO_3P_2$: C 57.30, H 4.35; found: C 57.49, H 4.46.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-C(Me)=C(Me)C(Et)=O}-(PPh_3)$_2$] (9)

The procedure was analogous to that described for **5**, using **1** (140 mg, 0.18 mmol) and 4-methylhex-4-en-3-one (69 μL, 0.54 mmol) as starting materials. A yellow, air-stable solid was obtained. Yield: 123 mg (79%), mp 218 °C (dec.). IR (KBr, cm^{-1}): 2145 ν(IrH), 1550 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 7.69–7.23 (m, 30H, PC_6H_5), 2.10 (q, 2H, *J*(HH) = 7.3 Hz, C*H*$_2$CH$_3$), 1.10 (s, 3H, IrC(CH_3)=C), 0.79 (t, 3H, *J*(HH) = 7.3 Hz, CH_2C*H*$_3$), 0.75 (s, 3H, =C(CH_3)C), –21.91 (t, 1H, *J*(PH) = 16.1 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 11.7 (s, d in off-resonance). Anal. calcd. for $C_{43}H_{42}ClIrOP_2$: C 59.75, H 4.90; found: C 59.80, H 4.68.

Preparation of [IrH(Cl){κ^2(*C*,*O*)-C(Ph)=CHC(Ph)=O}-(PPh_3)$_2$] (10)

The procedure was analogous to that described for **5**, using **1** (140 mg, 0.18 mmol) and benzylidenacetophenone (75 mg, 0.36 mmol) as starting materials. An orange, air-stable solid was obtained. Yield: 131 mg (76%), mp 212 °C (dec.). IR (KBr, cm^{-1}): 2160 ν(IrH), 1520 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 7.96–6.62 (br m, 40H, C_6H_5), –21.43 (t, 1H, *J*(PH) = 16.4 Hz, IrH), signal of =CH proton probably covered by the broad signal of phenyl protons. ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 215.0 (t, *J*(PC) = 6.1 Hz, IrC), 199.3 (s, C=O), 144.7 (s, IrC(Ph)=*C*H), 136.9, 131.5, 131.0, 129.4, 128.5, 128.1, 126.7, 125.2 (all s, CC_6H_5), 134.7 (vt, *N* = 11.1 Hz, *ortho*-C of PC_6H_5), 131.4 (vt, *N* = 53.8 Hz, ipso-C of PC_6H_5), 129.5 (s, *para*-C of PC_6H_5), 127.3 (vt, *N* = 10.2 Hz, *meta*-C of PC_6H_5). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 10.3 (s, d in off-resonance). Preparation of [IrH{κ²(*C*,*O*)-CH=CHC(Me)=O}-(PPh₃)₂]ClO₄ (15)

A solution of **2** (140 mg, 0.17 mmol) in 15 mL of dichloromethane was treated with $AgClO_4$ (35 mg, 0.17 mmol) and stirred for 15 min at room temperature in the dark. The solution was filtered and the residue was washed twice with 1 mL portions of CH_2Cl_2. The filtrate was brought to dryness in vacuo, the remaining brown-yellow solid was washed three times with 5 mL portions of hexane and dried. Yield: 130 mg (86%), mp 131 °C (dec.). Conductivity (CH_3NO_2) Λ = 36 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2180 ν(IrH), 1550 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 9.72 (d, 1H, *J*(HH) = 7.4 Hz, IrCH), 7.56–7.12 (m, 30H, PC_6H_5), 5.96 (d, 1H, *J*(HH) = 7.4 Hz, IrCH=C*H*), 1.43 (s, 3H, $C(CH_3)$=O), –21.14 (t, 1H, *J*(PH) = 15.3 Hz, IrH); data for isomers **15a** and **15b** (see Scheme 3): δ: 9.59 (d, *J*(HH) = 7.4 Hz, IrCH), 6.22 (d, *J*(HH) = 7.4 Hz, IrCH=C*H*), 1.48 (s, $C(CH_3)$=O), –21.90 (br t, *J*(PH) ~ 15 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 23.1 (s, d in off-resonance; at –80 °C in CD_2Cl_2 two doublets in off-resonance with δ 22.1 and 21.4). Anal. calcd. for $C_{40}H_{36}ClIrO_5P_2$: C 55.17, H 4.41; found: C 55.24, H 4.32.

Preparation of [IrH{κ²(*C*,*O*)-CH=CHC(Et)=O}(PPh₃)₂]-ClO₄ (16)

The procedure was analogous to that described for **15**, using **3** (140 mg, 0.17 mmol) and $AgClO_4$ (35 mg, 0.17 mmol) as starting materials. An orange, moderately air-sensitive solid was obtained. Yield: 133 mg (87%), mp 128 °C (dec.). Conductivity (CH_3NO_2) Λ = 50 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2185 ν(IrH), 1545 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 9.74 (d, 1H, *J*(HH) = 6.9 Hz, IrCH), 7.44–7.12 (m, 30H, PC_6H_5), 6.04 (d, 1H, *J*(HH) = 6.9 Hz, IrCH=C*H*), 1.75 (q, 2H, *J*(HH) = 7.4 Hz, CH_2CH$_3$), 0.64 (t, 3H, *J*(HH) = 7.4 Hz, CH$_2$CH_3), –21.10 (t, 1H, *J*(PH) = 15.6 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 22.5 (s, d in off-resonance). Anal. calcd. for $C_{41}H_{38}ClIrO_5P_2$: C 54.70, H 4.25; found: C 54.51, H 4.41.

Preparation of [IrH(CO){κ²(*C*,*O*)-CH=CHC(Et)=O}-(PPh₃)₂]ClO₄ (17)

A solution of **16**, generated in situ from **3** (100 mg, 0.12 mmol) and $AgClO_4$ (25 mg, 0.12 mmol) in 10 mL of dichloromethane, was stirred for 15 min at room temperature in the dark. The solution was filtered and a slow stream of CO was passed through the filtrate for 1 min. The solvent was evaporated in vacuo, the remaining yellow solid was washed twice with 1 mL portions of CH_2Cl_2 and three times with 5 mL portions of hexane and dried. Yield: 100 mg (89%), mp 118 °C (dec.). Conductivity (CH_3NO_2) Λ = 56 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2195 ν(IrH), 2040 ν(CO), 1575 ν(C=O). ^1H NMR (200 MHz, $CDCl_3$) δ: 9.42 (d, 1H, *J*(HH) = 9.1 Hz, IrCH), 7.81–7.47 (m, 30H, PC_6H_5), 6.73 (dt, 1H, *J*(HH) = 6.9, *J*(PH) = 2.1 Hz, IrCH=C*H*), 1.80 (qt, 2H, *J*(HH) = 7.2, *J*(PH) = 2.4 Hz, CH_2CH$_3$), 0.53 (t, 3H, *J*(HH) = 7.2 Hz, CH$_2$CH_3), –19.20 (t, 1H, *J*(PH) = 12.4 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 11.1 (s, d in off-resonance). Anal. calcd. for $C_{42}H_{38}ClIrO_6P_2$: C 54.34, H 4.13; found: C 54.71, H 4.25.

Preparation of [IrH{κ²(*C*,*O*)-CH=CHC(Et)=O}(PPh₃)₃]-ClO₄ (18)

A solution of **16**, generated in situ from **3** (100 mg, 0.12 mmol) and $AgClO_4$ (25 mg, 0.12 mmol) in 10 mL of dichloromethane, was treated with PPh_3 (32 mg, 0.12 mmol) and stirred for 5 min at room temperature in the dark. The solution was filtered, the filtrate was brought to dryness in vacuo, and the remaining white, air-stable solid was washed three times with 5 mL portions of toluene and twice with 5 mL portions of hexane and dried. Yield: 114 mg (82%), mp 136 °C (dec.). Conductivity (CH_3NO_2) Λ = 59 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2215 ν(IrH), 1550 ν(C=O). ^1H NMR (90 MHz, $CDCl_3$) δ: 8.43 (ddt, 1H, *J*(HH) = 7.3, *J*(P_{eq}H) = 7.3, *J*(P_{ax}H) = 4.2 Hz, IrCH), 7.39–6.82 (m, 30H, PC_6H_5), 6.66 (d, 1H, *J*(HH) = 7.3 Hz, IrCH=C*H*), 2.25 (m, 2H, CH_2CH$_3$), 1.11 (t, 3H, *J*(HH) = 7.1 Hz, CH$_2$CH_3), –21.47 (td, 1H, *J*(P_{ax}H) = 18.1, *J*(P_{eq}H) = 10.3 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 2.5 (d, *J*(PP) = 17.6 Hz, dd in off-resonance, ax-PPh_3), –3.1 (d, *J*(PP) = 17.6 Hz, dt in off-resonance, eq-PPh_3). Anal. calcd. for $C_{59}H_{53}ClIrO_5P_3$: C 60.95, H 4.59; found: C 60.34, H 4.25.

Preparation of [IrH(C₂H₄){κ²(*C*,*O*)-CH=CHC(Et)=O}-(PPh₃)₂]ClO₄ (19)

A solution of **16**, generated in situ from **3** (100 mg, 0.12 mmol) and $AgClO_4$ (25 mg, 0.12 mmol) in 10 mL of $CDCl_3$, was stirred for 15 min at room temperature in the dark. The solution was filtered and a slow stream of ethene was passed through the filtrate for 5 min. The solution was concentrated to ca. 1 mL in vacuo and the product, which is only stable in an ethene atmosphere, characterized by NMR spectroscopy. ^1H NMR (90 MHz, $CDCl_3$) δ: 10.04 (d, 1H, *J*(HH) = 8.6 Hz, IrCH), 7.51–7.18 (m, 30H, PC_6H_5), 6.45 (dt, 1H, *J*(HH) = 8.6, *J*(PH) = 2.2 Hz, IrCH=C*H*), 3.55 (t, 4H, *J*(PH) = 3.1 Hz, C_2H_4), 1.97 (qt, 2H, *J*(HH) = 7.3, *J*(PH) = 2.4 Hz, CH_2CH$_3$), 0.83 (t, 3H, *J*(HH) = 7.3 Hz, CH$_2$CH_3), –20.85 (t, 1H, *J*(PH) = 14.2 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 13.9 (s, d in off-resonance).

Preparation of [IrH(CH₃C≡CH){κ²(*C*,*O*)-CH=CHC(Et)=O}-(PPh₃)₂]ClO₄ (20)

A solution of **16**, generated in situ from **3** (100 mg, 0.12 mmol) and $AgClO_4$ (25 mg, 0.12 mmol) in 10 mL of

dichloromethane, was stirred for 15 min at room temperature in the dark. The solution was filtered and a slow stream of propyne was passed through the filtrate for 1 min. The solvent was evaporated in vacuo, the residue was dissolved in 4 mL of CH_2Cl_2–hexane (3:1) and chromatographed on Al_2O_3 (neutral, activity grade V, length of column 5 cm). With CH_2Cl_2–hexane (3:1) a brown fraction was eluted, which was concentrated to ca. 2 mL in vacuo. A brown, slightly air-sensitive solid precipitated, which was washed three times with 5 mL portions of hexane and dried. Yield: 100 mg (87%), mp 112 °C (dec.). Conductivity (CH_3NO_2) Λ = 52 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2185 ν(IrH), 1820 ν(C≡C), 1540 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.60 (d, 1H, *J*(HH) = 7.6 Hz, IrCH), 7.66–7.00 (m, 30H, PC_6H_5), 6.21 (d, 1H, *J*(HH) = 7.6 Hz, IrCH=C*H*), 2.55–0.61 (br m, 9H, $CH_3C{\equiv}CH$ and C_2H_5), –22.54 (t, 1H, *J*(PH) = 16.6 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 13.7 (s, d in off-resonance). Anal. calcd. for $C_{44}H_{42}ClIrO_5P_2$: C 56.20, H 4.50; found: C 56.14, H 4.23.

Preparation of [IrH(MeCN){κ²(*C*,*O*)-CH=CHC(Et)=O}-(PPh_3)$_2$]ClO_4 (21)

A solution of **16**, generated in situ from **3** (100 mg, 0.12 mmol) and $AgClO_4$ (25 mg, 0.12 mmol) in 10 mL of dichloromethane, was added dropwise to a solution of acetonitrile (19 μL, 0.36 mmol) in 5 mL of dichloromethane. After the reaction mixture was stirred for 5 min at room temperature, the solution was filtered. The filtrate was brought to dryness in vacuo, the remaining white, air-stable solid was washed three times with 5 mL portions of hexane and dried. Yield: 101 mg (87%), mp 179 °C (dec.). Conductivity (CH_3NO_2) Λ = 61 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2175 ν(CN), 1565 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.77 (d, 1H, *J*(HH) = 8.3 Hz, IrCH), 7.51–7.23 (m, 30H, PC_6H_5), 6.37 (dt, 1H, *J*(HH) = 8.3, *J*(PH) = 1.7 Hz, IrCH=C*H*), 1.82 (qt, 2H, *J*(HH) = 7.6, *J*(PH) = 2.2 Hz, CH_2CH_3), 1.69 (t, 3H, *J*(PH) = 1.0 Hz, CH_3CN), 0.69 (t, 3H, *J*(HH) = 7.6 Hz, CH_2CH_3), –21.72 (t, 1H, *J*(PH) = 14.9 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 17.3 (s, d in off-resonance). Anal. calcd. for $C_{43}H_{41}ClIrNO_5P_2$: C 54.86, H 4.39, N 1.49; found: C 54.85, H 4.88, N 1.49.

Preparation of [IrH(PhCN){κ²(*C*,*O*)-CH=CHC(Et)=O}-(PPh_3)$_2$]ClO_4 (22)

The procedure was analogous to that described for **21**, using **16** (100 mg, 0.12 mmol) and benzonitrile (37 μL, 0.36 mmol) as starting materials. A pale yellow, moderately air-sensitive solid was obtained. Yield: 108 mg (90%), mp 148 °C (dec.). Conductivity (CH_3NO_2) Λ = 59 $cm^2\ \Omega^{-1}\ mol^{-1}$. IR (KBr, cm^{-1}): 2200 ν(CN), 1555 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.75 (d, 1H, *J*(HH) = 7.3 Hz, IrCH), 7.79–7.15 (m, 35H, C_6H_5CN and PC_6H_5), 6.47 (d, 1H, *J*(HH) = 7.3 Hz, IrCH=C*H*), 1.84 (q, 2H, *J*(HH) = 7.3 Hz, CH_2CH_3), 0.65 (t, 3H, *J*(HH) = 7.3 Hz, CH_2CH_3), –21.33 (t, 1H, *J*(PH) = 15.2 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 17.1 (s, d in off-resonance). Anal. calcd. for $C_{48}H_{43}ClIrNO_5P_2$: C 57.45, H 4.32, N 1.40; found: C 57.68, H 4.60, N 1.44.

Preparation of [IrH(SPh){κ²(*C*,*O*)-CH=CHC(Et)=O}-(PPh_3)$_2$] (23)

A suspension of **21** (120 mg, 0.13 mmol) in 15 mL of THF was treated with NaSPh (17 mg, 0.13 mmol) and stirred for 15 h at room temperature. The solvent was evaporated in vacuo, the residue was suspended in 10 mL of toluene, and the solution was filtered. The filtrate was brought to dryness in vacuo, the remaining orange, air-stable solid was washed twice with 10 mL portions of hexane and dried. Yield: 92 mg (78%), mp 157 °C (dec.). IR (KBr, cm^{-1}): 2180 ν(IrH), 1570 ν(C=O). ^{1}H NMR (90 MHz, $CDCl_3$) δ: 9.68 (d, 1H, *J*(HH) = 8.0 Hz, IrCH), 7.62–7.21 (m, 30H, PC_6H_5), 6.78–6.58 (m, 5H, SC_6H_5), 6.47 (d, 1H, *J*(HH) = 8.0 Hz, IrCH=C*H*), 1.64 (q, 2H, *J*(HH) = 7.1 Hz, CH_2CH_3), 0.35 (t, 3H, *J*(HH) = 7.1 Hz, CH_2CH_3), –22.53 (t, 1H, *J*(PH) = 15.4 Hz, IrH). ^{31}P NMR (36.2 MHz, $CDCl_3$) δ: 16.8 (s, d in off-resonance). Anal. calcd. for $C_{47}H_{43}ClIrO_5P_2S$: C 62.03, H 4.76; found: C 61.83, H 4.55.

Ethylene and 1-hexene polymerization using zirconium iminophosphonamide complexes[1]

Robert Tomaszewski, Rainer Vollmerhaus, Abdulaziz Al-Humydi, Qinyan Wang, Nicholas J. Taylor, and Scott Collins

Abstract: Ethylene polymerization was studied using a variety of iminophosphonamide (PN_2) complexes of zirconium. Bis(PN_2) dichloride complexes $[Ph_2P(NR')_2]_2ZrX_2$ (X = Cl; **1a**: R′ = *p*-tolyl; **1b**: R′ = Bn; **1c**: R′ = C_6F_5) or dimethyl complexes (X = Me; **2a**: R′ = *p*-tolyl; **2b**: R′ = Bn) and cyclopentadienyl(PN_2)zirconium dichloride complexes $[\eta^5\text{-}C_5R''_5][R_2P(NR')_2]ZrCl_2$ (**3a**: R′ = *p*-tolyl, R = Ph, R″ = H; **3b**: R′ = $SiMe_3$, R = Et, R″ = H; **3c**: R′ = C_6F_5, R = Ph, R″ = H; **3e**: R′ = 3,5-$(CF_3)_2$Ph, R = Ph, R″ = H; **3f**: R′ = 3,5-$(CF_3)_2$Ph, R = Ph, R″ = Me) or dimethyl analogs $[\eta^5\text{-}C_5H_5][R_2P(NR')_2]ZrMe_2$ (**4a**: R′ = *p*-tolyl, R = Ph; **4b**: R′ = $SiMe_3$, R = Et) were evaluated under a range of conditions using methylaluminoxane (PMAO) activator. Complexes **1** and **2** behave as precursors to single-site polymerization catalysts under the conditions studied, while complexes **3** or dialkyls **4** show more complex behavior and formation of poly(ethylene) with a bimodal molecular weight distribution. In contrast, activation of dialkyl complexes **4** with $[Ph_3C][B(C_6F_5)_4]$ and polymerization in the presence of small amounts of PMAO or TIBAL as scavenger, led to single-site behavior. PMAO reacts with the neutral dialkyls via ligand abstraction to produce a number of P-containing species that may explain the multi-site behavior observed when using this activator. Dialkyls **4** react cleanly with $[Ph_3C][B(C_6F_5)_4]$ in haloarene or even dichloromethane solution to furnish the corresponding cationic alkyls **5**, which were characterized by multinuclear NMR spectroscopy. Fluxional dinuclear species are formed in the presence of excess dialkyl and these are susceptible to C—H activation to form μ-Me,μ-CH_2 complexes one of which could be isolated in pure form. The cationic alkyls initiate the polymerization of 1-hexene at room temperature in chlorobenzene solution, but extensive chain transfer occurs and the systems are not living.

Key words: single site, early metal olefin polymerization catalysis.

Résumé : On a étudié la polymérisation de l'éthylène à l'aide d'une variété de complexes à base d'iminophosphonamide (PN_2) du zirconium. Utilisant le méthylaluminoxane (PMAO) comme activateur dans une grande variété de conditions, on a évalué les complexes avec le dichlorure de bis(PN_2) $[Ph_2P(NR')_2]_2ZrX_2$ (X = Cl, **1a** : R′ = *p*-tolyl; **1b** : R′ = Bn; **1c** : R′ = C_6F_5) ou les complexes diméthylés (X = Me; **2a** : R′ = *p*-tolyl; **2b** : R′ = Bn), et le dichlorure de cyclopentadiényl(PN_2) $[\eta^5\text{-}C_5R''_5][R_2P(NR')_2]ZrCl_2$ (**3a** : R′ = *p*-tolyl, R = Ph, R″ = H; **3b** : R′ = $SiMe_3$, R = Et, R″ = H; **3c** : R′ = C_6F_5, R = Ph, R″ = H; **3e** : R′ = 3,5-$(CF_3)_2$Ph, R = Ph, R″ = H; **3f** : R′ = 3,5-$(CF_3)_2$Ph, R = Ph, R″ = Me) ou de leurs analogues diméthylés $[\eta^5\text{-}C_5H_5][R_2P(NR')_2]ZrMe_2$ (**4a** : R′ = *p*-tolyle, R = Ph; **4b** : R′ = $SiMe_3$, R = Et). Dans les conditions étudiées, les complexes **1** et **2** se comportent comme des précurseurs de catalyseurs à site unique alors que les complexes **3** ou les dialkyles **4** présentent un comportement plus complexe avec une formation de poly(éthylène) présentant une distribution bimodale des poids moléculaires. Par ailleurs, l'activation des complexes de dialkyles avec du $[Ph_3C][B(C_6F_5)_4]$ avec des polymérisations en présence de faibles quantités de PMAO ou de TIBAL comme piège conduit à un comportement à site unique. Le PMAO réagit avec les dialkyles neutres par le biais d'un enlèvement de ligand conduisant à la formation de diverses espèces contenant du phosphore qui peuvent expliquer le comportement multisite observé quand on utilise ce composé pour faire l'activation. Les complexes dialkyles **4** réagissent proprement avec le $[Ph_3C][B(C_6F_5)_4]$ en solution dans des halogénoarènes et même dans le dichlorométhane et ces réactions conduisent à la formation des complexes cationiques alkyles correspondants **5** qui ont été caractérisés par spectroscopie RMN multinucléaire. Il se forme des espèces binucléaires fluxionnelles en présence d'excès de dérivés dialkyles et ces espèces sont susceptibles à une activation C—H conduisant à la formation de complexes μ-Me et μ-CH_2 desquels un a pu être isolé dans une forme pure. Les complexes alkyles cationiques initient la polymérisation du

hex-1-ène à la température ambiante, en solution dans le chlorobenzène, mais il se produit beaucoup de transfert de chaîne et les systèmes ne sont pas vivants.

Mots clés : précurseurs de catalyseurs à site unique de la polymérisation d'alcènes par des métaux de transition.

[Traduit par la Rédaction]

Introduction

The synthesis of novel group 4 complexes is of considerable interest in the context of olefin polymerization using "non-metallocene" catalysts (1). A wide variety of complexes based on the use of surrogates for the Cp ligand have been prepared and many are active in ethylene or α-olefin polymerization. However, the polymerization activities of isoelectronic (or even isolobal) complexes differ dramatically and often in a contradictory manner. Establishing fundamental trends in, e.g., catalyst activity with respect to parameters such as total electron count, and the steric and electronic effect of ligand substituents has been problematic. These difficulties arise through a number of complicating factors such as the efficiency of activation of catalyst precursors with typical cocatalysts, particularly methyl aluminoxane (PMAO), the stability of the active catalyst (or precatalyst) with respect to irreversible deactivation or reversible inhibition processes, and intrinsic electronic or steric effects on monomer coordination and insertion rates.

Some time ago, a number of workers elected to study group 4 complexes based on the amidinate ligand [$RC(NR')_2$=CN_2] as catalysts in ethylene or propylene polymerization. This ligand is a hard σ donor, which can contribute up to 5e ($3\sigma + 2\pi$) on coordination to a d^0 metal (2). On activation with PMAO in hydrocarbon media, both bis(CN_2) (3) and mixed Cp(CN_2) (4) complexes of Ti and Zr were active in ethylene, while the former were also active in propylene polymerization; however, compared with Cp_2ZrX_2 complexes, these 14 electron complexes were approximately 10^2–10^3 times less active under similar conditions of temperature and pressure. Further, some of these complexes (e.g., Cp(CN_2)$ZrCl_2$, R = $SiMe_3$, R′ = Ph) were said to be almost inactive in olefin polymerization (4*a*, 4*b*); in these cases, thermal instability of cationic alkyls generated in situ from neutral catalyst precursors was believed responsible for this finding.

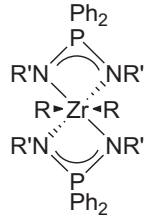
More recently, less-hindered versions of mixed Cp(CN_2)$ZrMe_2$ complexes (Cp = η^5-C_5H_5, η^5-Cp*; R = Me and R′ = Et, *c*-Hx, *t*-Bu, etc.) have been shown to effect the living polymerization of 1-hexene or other sterically hindered alkenes in chlorobenzene solution on activation with either [$PhNMe_2H$][$B(C_6F_5)_4$] or [Ph_3C][$B(C_6F_5)_4$] (5). Detailed study of these cationic alkyl–Zr complexes has indicated that they are reasonable stable in such media and are less prone to β-H elimination than their Cp_2 counterparts. Further, bimolecular alkyl group exchange processes are facile at higher Zr concentrations (5*e*, 5*f*) and are responsible for erosion of tacticity seen using chiral initiators of this type. Although the polymerization of ethylene or propylene has not been reported in the open literature using these initiators, the activity in hexene polymerization (≤10^5 g C_6H_{12} / (mol Zr × h)) suggests that values in the range of 10^6–10^7 g monomer / (mol Zr × h) at 25 °C in this polar solvent are not unlikely.

Several years ago we were intrigued by the origins for the low activities observed for CN_2 complexes of group 4 in ethylene polymerization, at least when activated under conventional conditions using PMAO in hydrocarbon media. We suspected that either the precatalysts were inefficiently activated using PMAO, were insufficiently stable under the conditions studied, or that unfavorable steric and (or) electronic effects were at play here. Further, although the CN_2 ligand is sterically demanding with a cone angle comparable to Cp or Cp* depending on substitution (2), it is an inherently two-dimensional ligand that might make such complexes more susceptible to bimolecular inhibition and (or) degradation processes, compared with their Cp analogues.

We reasoned that a more three-dimensional analogue, such as the iminophosphonamide [$R_2P(NR')_2$=PN_2] ligand (6), where the tetrahedral P(V) atom is thought to represent a minimal electronic perturbation to trigonal C(IV), would be a suitable choice of ligand to investigate such issues. Preliminary work revealed that zirconium complexes derived from these ligands had ethylene polymerization activities that rivaled bent metallocene complexes when activated by PMAO under comparable conditions (7). In a recent paper, we provided detailed syntheses and structural characterization of a variety of bis(PN_2) and mixed Cp(PN_2) complexes of titanium and zirconium (8). Herein we report full details on the use of the zirconium complexes (Chart 1) in ethylene polymerization,[3] some solution chemistry of the cationic alkyls derived from these complexes, and their use for the polymerization of 1-hexene.

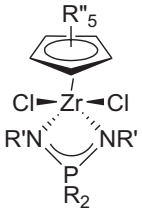
Results and discussion

Ethylene polymerization using PN_2 complexes and PMAO activator



Bis(PN_2) complexes **1** and **2**, along with the mixed cyclopentadienyl(PN2) complexes **3** and **4**, were initially evaluated in toluene slurry using PMAO as activator at a 2000:1 or 1000:1 Al:Zr ratio, respectively.[4] The ethylene polymerization results are summarized in Tables 1 and 2.

The bis(PN_2) dichloride or dialkyl complexes **1** and **2** behave as single-site catalysts on activation with PMAO. They furnish poly(ethylene) with a somewhat broadened, but unimodal molecular weight distribution (MWD), where polydispersity is generally higher at higher temperatures. The activity of these complexes is actually higher at lower



[3] The titanium complexes have been evaluated in ethylene polymerization (ref. 7), but they are all much less active than their Zr analogs.
[4] These catalysts were also evaluated at Nova Chemicals Corporation under conditions relevant to their industrial processes for polyethylene manufacture. Details of these tests are contained with a patent (7*b*).

temperatures suggesting limited thermal stability of the propagating species. Electron-deficient complexes **1c** are less active than electron-rich analogs **1a**, which may reflect intrinsic insertion rates and (or) the effectiveness of alkylation/ionization by PMAO. Since the activity of dialkyl **2a** is largely indistinguishable from that of dichloride **1a** (Table 1, entries 1 and 2 vs. 6 and 7), we suspect that the differences in activity between electron-deficient and electron-rich dichloride complexes is largely intrinsic.

In contrast, activation of the Cp(PN_2) dichloride or dialkyl complexes **3** and **4** with PMAO led to multisite behavior and formation of polymer with a broad and (or) bimodal MWD (Table 2). Also, in contrast to the bis(PN_2) complexes, activity was generally much higher at more elevated temperatures

[c]Bimodal MWD with low and high MW components.

[d]Complex **4b** injected into a solution of cocatalyst and TMA in toluene, presaturated with monomer; MAO subsequently introduced after a period of several minutes with no monomer uptake.

(Table 2, compare entries 2 and 3, 5 and 6, 7 and 8, or 9 and 10). The relative amounts of the two different MW polymers formed was sensitive to both catalyst structure and temperature. Generally speaking, the amount of higher MW polymer increased with increasing temperature (Table 2, entries 2 vs. 3, 5 vs. 6, and 9 vs. 10), although the C_6F_5-substituted catalyst **3c** shows the opposite behavior (Table 2, entry 7 vs. 8); surprisingly, in two cases, the use of a dichloride vs. dialkyl precursor of the *same* $Cp(PN_2)$ complex led to different behavior (Table 2, entries 1 vs. 2 and 4 vs. 6).

It is largely a matter of speculation as to why different catalyst precursors show different activities and produce polymer of differing MW, etc., since based on these results it is not even clear which are the active catalysts! Possible explanations for the behavior observed include time-dependent chain transfer to PMAO as has been observed with Fe catalysts (9), aluminoxane-mediated degradation of the neutral precursors into different precatalysts, and (or) thermally induced or aluminoxane-induced transformation of one active catalyst into another. As the relative amount and MW of both polymer components was rather insensitive to Al:Zr ratios (over the range 500:1 to 8000:1) or polymerization time, it would appear that the latter two explanations are more likely.

With a view to clarifying the situation, ethylene polymerization using catalyst precursors **4a** and **4b** and $[Ph_3C][B(C_6F_5)_4]$ as activator in the presence of various alkylaluminum scavengers was studied and the results are summarized in Table 3. Generally speaking, single-site behavior was observed when **4a** or **4b** were premixed with the trityl borate activator prior to introduction into the reactor and highest activities were generally seen when using PMAO as scavenger. The use of trimethylaluminum as a scavenger strongly inhibited polymerization activity (Table 3, entry 3 vs. 4), while addition of PMAO ameliorated this behavior (Table 3, entry 4 vs. 5 vs. 6). Triisobutylaluminum was less inhibitory than $AlMe_3$, but appears to function as a chain-transfer agent at higher concentration (Table 3, entries 7 and 8). Tentatively, it would appear that the species responsible for polymer formation on ionization with $[Ph_3C][B(C_6F_5)_4]$ is the same as that responsible for formation of high MW polymer in PMAO-activated catalysts (Table 2, entry 3 vs. Table 3, entry 2, and Table 2, entry 6 vs. Table 3, entry 6) based on the similarity in MW of the polymer formed.

Qualitatively, the results appear similar to those observed when using β-diketimine complexes of group 4 (10), where PMAO as scavenger serves to assist with complete ionization of the neutral dialkyl precursors (through reversible formation of heterodinuclear Zr, Al adducts) and also as an agent for sequestration of excess $AlMe_3$ in the reactor, thus regulating the concentration of this inhibitor. Unfortunately, unlike the diketimine complexes (10), the dialkyl precursors and their derived ion pairs are incompatible[5] with the principle hydrolysis product of $MeAl(BHT)_2$ (2,6-di-*tert*-butyl-4-methylphenol) (11) and polymerization is not observed in the presence of this otherwise "noninteracting" scavenger.

Cationic alkyls **5** could be cleanly prepared from either **4a** or **4b** and $[Ph_3C][B(C_6F_5)_4]$ in bromobenzene or chlorobenzene solution (Scheme 1). These compounds are even stable in CH_2Cl_2 for short periods of time at room temperature and can be isolated as off-white solids from this solvent, following extraction of triphenylethane with hexane. Solutions of these cationic alkyls appear stable for indefinite periods of time at room temperature in haloarene solvent, although the ion pairs decompose on heating to furnish a variety of unidentified products, including methane. Spectroscopic data for ion pairs **5a** and **5b** are summarized in the Experimental section.

Key features in the ^1H NMR spectrum of **5b** that distinguish it from its neutral precursor **4b** are that the Et groups on P are inequivalent (*both* the CH_2 and CH_3 groups) on the NMR timescale at room temperature (Figs. 1*c* vs. 1*a*). Evidently, either rotation of the PN_2 ligand about the P—Zr axis or ion-pair reorganization are slow (with the other process being rapid) on the NMR timescale. Since the latter scenario seems unlikely, especially in a polar solvent like bromobenzene, we suspect there is hindered rotation about the P—

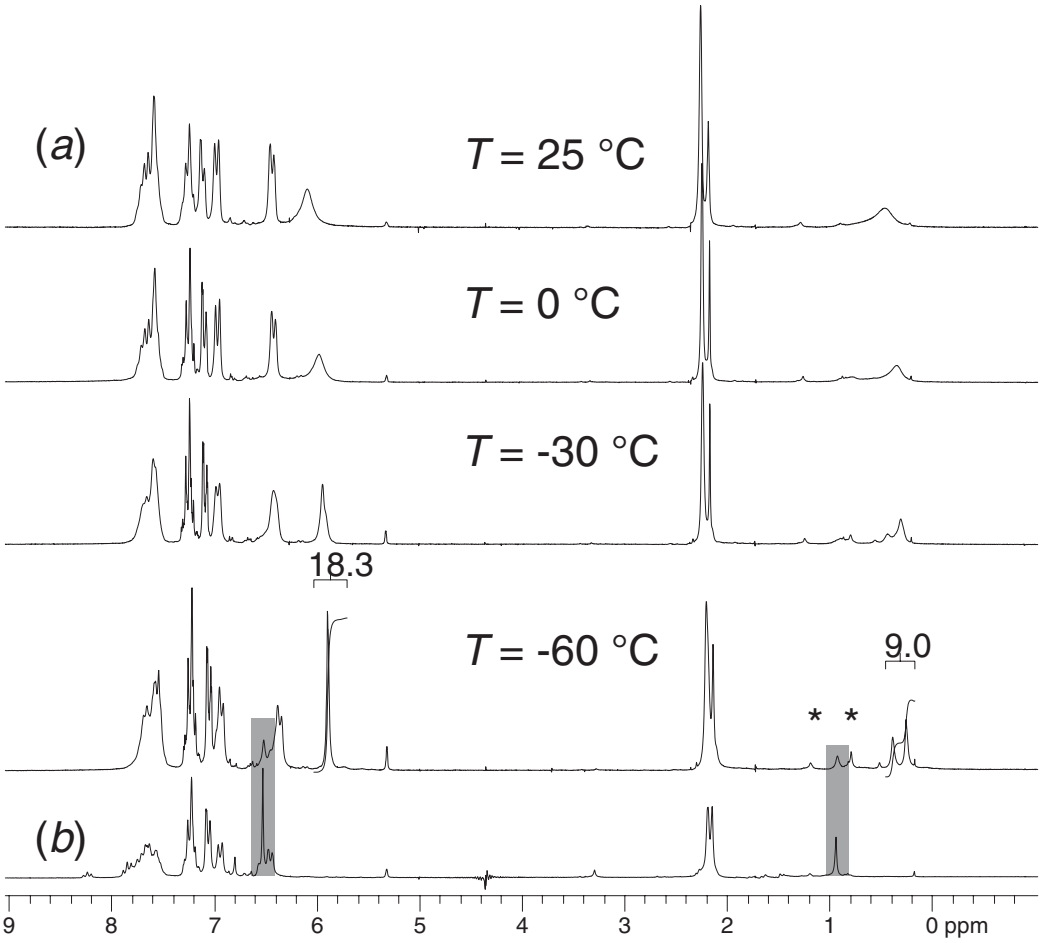
Fig. 2. Variable-temperature ^{31}P NMR spectra (80.96 MHz, CD_2Cl_2) of a ca. 2:1 mixture of **4b** and $[Ph_3C][B(C_6F_5)_4]$. The signal owing to excess **4b** is marked with an asterisk, while the exchange-broadened signal for the minor isomer of **6b** (Scheme 1) is highlighted in grey.



tive chain transfer processes with these quasi-living initiators. The ^1H NMR spectra of **6** are deceptively simple with equivalent PEt_2 groups in the case of **6b** at room temperature (Fig. 1*b*). Since complex **5b** appears static on the NMR timescale at room temperature, while complexes **4b** are fluxional and with a low barrier to rotation about the PN_2 ligand in solution (8, 12), it is possible that degenerate Me exchange (5) is the process responsible for higher effective symmetry observed for complexes **6** at room temperature. Both isomers (Scheme 1) should otherwise exhibit inequivalent PEt_2 groups even if intramolecular exchange between isomers were fast on the NMR timescale; alternately, it could be that as with **4**, rotation of the PN_2 ligand about the Zr—P axis is rapid in these dinuclear complexes.

Although we were unable to attain the slow exchange limit on the ^1H NMR timescale, separate ^{31}P NMR signals in an ~9:1 ratio and which may correspond to the different stereoisomers expected for **6b** (Scheme 1), were observed on cooling a solution of **4b**:$[Ph_3C][B(C_6F_5)_4]$ (~2:1) to –80 °C in CD_2Cl_2 (Fig. 2, signal owing to the minor isomer at δ 40.8 highlighted in grey). We did not observe a separate signal for **5b** at this temperature, although a signal owing to a slight excess of **4b** is evident in this experiment (Fig. 2, signal at δ 44.8 indicated by an asterisk). Thus, exchange between **4b** and **6b** appears slow on the NMR timescale at low temperature (only a single ^{31}P resonance is seen at room temperature) implying that the fluxional behavior observed at this low temperature is intramolecular and involves the

Fig. 3. (*a*) Variable-temperature ^{1}H NMR spectra (200 MHz, CD_2Cl_2) of a 2:1 mixture of **4a** and $[Ph_3C][B(C_6F_5)_4]$ and (*b*) ^{1}H NMR spectrum (200 MHz, CD_2Cl_2, –60 °C) of a 1:1 mixture of **4a** and $[Ph_3C][B(C_6F_5)_4]$. Signals marked with an asterisk are due to *n*-hexane.

two stereoisomers possible for **6b**. However, as the ^{1}H NMR spectrum exhibits equivalent, but line-broadened PEt_2 signals at –80 °C, we have been unable to confirm this hypothesis.

Similar behavior was observed for the *p*-tolyl analogues **4a** and **5a**, although it would appear that the rates (and mechanisms) of fluxional behavior are sensitive to the nature of the substituents on N. Thus, the room-temperature spectrum of a ca. 2:1 mixture of **4a** and $[Ph_3C][B(C_6F_5)_4]$ exhibits line-broadened resonances for the CpH and Zr-Me groups (Fig. 3*a*), and on cooling, decoalescence of the Cp and Zr–Me resonances were observed. At low temperature, separate signals owing to residual **5a** are observed (Fig. 3*a* vs. 3*b*), while the two remaining Zr-Me and one Cp-H signals are consistent with there being one isomer of **6a** present in solution. The signals owing to terminal and bridging Zr-Me groups of **6a** should be in a 2:1 ratio, but integration of these exchange-broadened resonances at –60 °C is only approximately consistent with this (Fig. 3*a*). An alternative explanation in which there are two isomers present in slow exchange with each other but featuring rapid exchange between terminal and bridging methyl groups for each isomer has to be rejected since this process would *also* interconvert the two stereoisomers.

On attempted crystallization of **6b**, crystals of dinuclear complex **7** (Scheme 1) separated on standing in CH_2Cl_2–chlorobenzene solution after several days at –30 °C. Although the X-ray structure of the cation is disordered (the anion is perfectly ordered),[6] this complex is also analogous to a μ-Me, μ-CH_2 dinuclear bis(amidinate) complex reported by Sita and co-workers (5). In the present case, this must form by a intramolecular C—H activation reaction involving dinuclear complexes **6** since there is no $PhNMe_2$ present as in the reaction reported by Sita and co-workers. Similar behavior was exhibited by **4a** and $[Ph_3C][B(C_6F_5)_4]$ in concentrated toluene solution (ca. 0.05 mol/L); a complex analogous to **7** is formed directly along with methane. We suspect that dissociation of **6** is unfavorable in nondonor media so that intramolecular C—H activation is more facile than complete ionization of **4a** by $[Ph_3C][B(C_6F_5)_4]$.

[6] Space group *C*2/*c*, *Z* = 4 based on $[C_{32}H_{71}N_4Si_4P_2Zr_2][C_{24}BF_{20}]$-$CH_2Cl_2$: Unit cell: *a* = 29.128(3) Å, *b* = 10.690(1) Å, *c* = 23.627(2) Å, β = 103.916(3)°; *V* = 7141(2) Å^3 at 180 K. The dinuclear cation sits on an inversion centre, while the borate counteranion and methylene chloride sit on diads. The disorder appears to arise from the coexistence of two different phases (ca. 80:20) in the lattice. N.J. Taylor. Unpublished results.

[c]Initiator efficiency $f = \frac{M_n^{theor}}{M_n^{exp}} \times 100$ with $M_n^{theor} = \frac{[1-Hx]}{[\mathbf{4a}]} \times \frac{Conv.(\%)}{100} \times 84.18$.
[d]Initiator was $Cp[MeC(NEt)(N\text{-}t\text{-}Bu)]ZrMe_2$ (see ref. 5).

As for the multisite behavior exhibited by alkyls **4** (or halides **3**) on activation with PMAO (Table 2), it would seem that side reactions between PMAO and alkyls **4** is partly responsible for the behavior seen. As shown in Fig. 4, a mixture of ^{31}P-containing compounds is produced on treatment of **4a** with 50.0 equiv. of PMAO in bromobenzene-d_5 solution at room temperature. The major product present has a broadened resonance at a chemical shift similar to that **5a** in this solvent, while unreacted alkyl **4a** is seen and also the product of PN_2 ligand abstraction by $AlMe_3$ viz. $Me_2Al(N\text{-}p\text{-tolyl})_2PPh_2$ as verified by reaction of the PN_2 ligand with $AlMe_3$ (Fig. 4*d*). It is unclear whether this compound forms from **4a** or **5a**, but the expected Zr by-product in either case (i.e., $CpZrMe_3$ or $[CpZrMe_2][PMAO\text{-}X]$) is known to be a viable polymerization catalyst (13), and which could account for the bimodal MWD seen.

© 2006 NRC Canada

We also evaluated complex **4a** and various activators for the living polymerization of 1-hexene at or above room temperature. The results are summarized in Table 4. The activity of this complex when activated with $[PhNMe_2H][B(C_6F_5)_4]$ is about 6.5 times lower than that reported for the less sterically hindered amidinate complex Cp[MeC(NEt)(N-*t*-Bu)]$ZrMe_2$ when evaluated under the same conditions (Table 4, entry 2 vs. 3). Activity was a function of the activator employed, where $[Ph_3C][B(C_6F_5)_4]$ gave rise to the most active systems and $B(C_6F_5)_3$ the least active as might be expected based on the coordinating ability of the counterion.

However, as can be appreciated from the results summarized in Table 4, complex **4a** provides much lower MW polymer than the amidinate system, even at similar levels of conversion. As can be seen from the last column of Table 4, initiator efficiencies are all well over 100% at room temperature with this catalyst, and thus there is extensive chain transfer occurring despite the relatively narrow polydispersity observed. We suspect the narrow MWD reflects inefficient fractionation of these low MW hexene oligomers by the GPC column set and the use of a light-scattering detector rather than anything intrinsic.

Analysis of these polymers by ^{13}C NMR spectroscopy revealed the presence of unsaturated alkylidene end groups. Tentatively, it would appear that alkyl complexes homologous to **5a** have an increased tendency towards β-H elimination compared with their amidinate analogues, which must be intrinsic. Although steric effects are undoubtedly important here, it would seem that the more electron-rich PN_2 complexes (PN_2 ligands are about 10^3 times less acidic than their amidinate analogues (14)) are more prone to chain transfer at least relative to their tendency towards incorporation of monomer through insertion.

Conclusions

Bis(PN_2) and Cp(PN_2) complexes of Zr (**2** and **3**, respectively) are a promising new class of polymerization catalyst with ethylene polymerization activities that approach that of bent metallocene complexes on activation with PMAO or single component activators such as $[Ph_3C][B(C_6F_5)_4]$. The use of an excess of aluminum alkyl (or the corresponding Zr–dialkyl) as scavenger in polymerizations involving the latter activator inhibits activity, probably through formation of hetero- or homo-dinuclear complexes. Multisite behavior is observed on activation of the complexes **3** with PMAO and this appears at least in part related to side reactions of the neutral precursor with $AlMe_3$ or PMAO present. Although stable cationic alkyls **5** can be prepared from precursors **3**, and appear to be one of the active species in PMAO-activated systems, they do not elicit living polymerization of 1-hexene under conditions analogous to those reported by Sita and co-workers (5) for amidinate complexes. Evidently, the more electron-rich PN_2 complexes suffer from faster chain transfer via β-H elimination relative to insertion.

Experimental

All reactions were conducted under an atmosphere of dry N_2. Standard techniques for the manipulation of air-sensitive compounds were employed (15). All solvents were reagent grade and were purified using a solvent purification system similar to that described in the literature (16). Complexes **2**–**4** were prepared and characterized as described in the literature (8).

^1H and ^{13}C NMR spectra (referenced to residual protonated solvent) were recorded on Bruker AC 200, AM 250, AC 300, or Varian Innova 400 MHz spectrometers. Chemical shifts are referenced to residual undeutrated solvent. ^{31}P NMR spectra (referenced to external 85% H_3PO_4) and ^{19}F NMR spectra (referenced to external $CFCl_3$) were obtained in the solvent indicated on a Bruker AC 200 or Varian Innova 400 MHz spectrometer. IR spectra were recorded on a Bomem MB-100 FT-IR instrument. Elemental analyses were performed by Oneida Research Services, Whitesboro, New York.

General polymerization procedure

Propylene polymerizations were conducted in either a 1 or 2 L Autoclave Engineers Zipperclave reactor. The temperature of the reactor was controlled using a Neslab RTE-110 constant temperature bath by circulation of coolant (ethylene glycol – water, 50:50 *v*/*v*) through an external jacket. The consumption of monomer (propylene) during the course of polymerization was monitored using a calibrated Matheson mass flow meter, which was controlled by a Matheson Dynablender model 8219 power supply / readout device. The progress of polymerization was monitored using Labtech Acquire data acquisition software, which converted the digital input reading to the desired value (mmol/s of monomer) using appropriate conversion factors.

Prior to each polymerization, the reactor was conditioned by evacuation for ~4 h at 100 °C, and then cooled under nitrogen after three refill–evacuation cycles. Two general procedures were followed for the polymerization of ethylene. Method A was followed when PMAO was used as cocatalyst, whereas method B was used for activators such as $[Ph_3C][B(C_6F_5)_4]$.

Method A

The reactor was charged with 450 mL of toluene followed by PMAO in 25 mL of toluene via syringe under an atmosphere of N_2 through a septum port. The reactor was then saturated with C_2H_4 at 75 psig (26 kPa) and at the indicated temperature. After 30 min at process temperature and pressure, the zirconium complex dissolved in toluene (25 mL) was injected by using a sample cylinder, pressurized to ca. 80 psig using dry N_2.

Method B

The reactor was conditioned as above. Instead of PMAO, the reactor was charged with trimethylaluminum (15 mmol) or triisobutylaluminum (65 mmol) and 475 mL toluene followed by saturation with C_2H_4. The dialkyl (11 μmol) was added to a slight excess of $[Ph_3C][B(C_6F_5)_4]$ in toluene solution (25 mL) and the mixture was then added to the reactor using a sample cylinder.

Reactions were halted by venting the monomer and emptying the reactor contents into methanol. The polyethylene was filtered off and washed with methanolic HCl and methanol and then dried in a vacuum oven at ca. 65 °C. Polymer characterization procedures have been reported in detail elsewhere (17).

NMR characterization of [{CpZr[(*p*-$CH_3(C_6H_4)N)_2PPh_2$]}-CH_3][$B(C_6F_5)_4$] (5a)

A NMR tube was loaded with dialkyl complex **4a** (32 mg, 0.055 mmol) and [Ph_3C][$B(C_6F_5)_4$] (51 mg, 0.055 mmol) and cooled to –78 °C. Methylene chloride-d_2 (0.6 mL) was syringed into the tube resulting in an orange solution. ^{1}H NMR spectra over the temperature range –90 to 25 °C revealed a quantitative 1:1 reaction had taken place to form the title complex. ^{1}H NMR (CD_2Cl_2, ambient) δ: 7.60, 7.25 (m, 10 H, Ph), 7.10, 6.51 (d, 8H, J = 6.5 Hz, *p*-$CH_3(C_6H_4)$N), 6.60 (s, 5H, Cp), 2.20 (s, 6H, *p*-$CH_3(C_6H_4)$N), 1.03 (s, 3H, Zr-Me). ^{19}F NMR (CD_2Cl_2, ambient) δ: –132.8 (br m, 8F), –163.4 (t, 4F), –167.2 (m, 8F). ^{31}P NMR (bromobenzene-d_5, ambient) δ: 41.5.

Synthesis of [CpZr{$Et_2P(NTMS)_2$}Me][$B(C_6F_5)_4$] (5b)

Complex **4b** (0.118 g, 0.262 mmol) and [Ph_3C][$B(C_6F_5)_4$] (0.242 g, 0.262 mmol) were weighed into a Schlenk flask and stirred for 2 min to mix the two solids. Then methylene chloride (20 mL) was added and the mixture was stirred at room temperature for 10 min to give a pale yellow solution. The solvent was removed in vacuo to give an off-white solid. The solid was stirred with hexane (20 mL) for 2 h and the resulting white solid filtered off (0.257 g, 88%). ^{1}H NMR (CD_2Cl_2, ambient) δ: 6.85 (s, 5H, Cp), 2.04 (overlapping dq, total 4H, CH_2CH_3), 1.22 (overlapping dt, total 6H, CH_2CH_3), 0.91 (s, 3H, Zr-CH_3), 0.24 (s, 18H, $SiCH_3$). ^{19}F{^{1}H} NMR (CD_2Cl_2, ambient) δ: –132.0 (br dd, 8F), –163.7 (t, 4F, J = 24.5 Hz), –167.4 (br m, 8F). ^{31}P{^{1}H} NMR (CD_2Cl_2, ambient) δ: 34.0 (s). Attempted recrystallization from dichloromethane–hexane led to oiling out and (or) decomposition; a satisfactory combustion analysis was not obtained.

NMR characterization of [{CpZr[(*p*-$CH_3(C_6H_4)N)_2PPh_2$]}$_2$-(μ-Me_3)][$B(C_6F_5)_4$] (6a)

A NMR tube was loaded with complex **4a** (30 mg, 0.052 mmol) and [Ph_3C][$B(C_6F_5)_4$] (24 mg, 0.026 mmol) and cooled to –78 °C. Methylene chloride-d_2 (0.6 mL) was syringed into the tube resulting in an pale yellow solution. Variable-temperature (–90 to 25 °C) ^{1}H NMR spectra revealed a quantitative 2:1 reaction had taken place to provide the title complex. ^{1}H NMR (CD_2Cl_2, ambient) δ: 7.68 and 7.24 (m, 20H, Ph), 7.00, 6.44 (d, 16H, J = 6.8 Hz, *p*-$CH_3(C_6H_4)$N), 6.09 (s, br, 10H, Cp), 2.18 (s, 12H, CH_3), 0.50 (br s, 9H, μ-CH_3). ^{19}F NMR (CD_2Cl_2, ambient) δ: –132.8 (s, br, 8F), –163.4 (m, 4F), –167.2 (s, br, 8F).

Synthesis of [{CpZr[$Et_2PN_2TMS_2$]}$_2$(μ-$Me)_3$][$B(C_6F_5)_4$] (6b)

Complex **4b** (0.225 g, 0.500 mmol) and [Ph_3C][$B(C_6F_5)_4$] (0.231 g, 0.250 mmol) were weighed into a Schlenk flask and stirred for 2 min to mix the two solids. Then methylene chloride (15 mL) was added and the mixture was stirred at room temperature for 10 min to give an orange-yellow solution. The solvent was removed in vacuo to give an orange solid, which was slurried in hexane and filtered to give the crude material (0.389 g, 88%). ^{1}H NMR (CD_2Cl_2, ambient) δ: 6.54 (s, 10H, Cp), 1.89 (dq, 8H, J = 8.2 Hz, CH_2CH_3), 1.23 (dt, 12H, J = 7.5 Hz, CH_2CH_3), 0.27 (s, 9H, μ-CH_3), 0.18 (s, 36H, $SiCH_3$). ^{19}F NMR (CD_2Cl_2, ambient) δ: –132.9 (br m, 8F), –163.7 (t, 4F), –167.5 (br m, 8F). ^{31}P{^{1}H} NMR (CD_2Cl_2, ambient) δ: 42.2 (s). Attempted recrystallization of **6b** from chlorobenzene – methylene chloride led to the formation of complex **7** (see the following).

Synthesis of [{CpZr[$Ph_2PN_2TMS_2$]}$_2$(μ-CH_2)(μ-CH_3)]-[$B(C_6F_5)_4$] (7)

$CpZr[Ph_2PN_2TMS_2]Me_2$ (0.200 g, 0.444 mmol) and [Ph_3C][$B(C_6F_5)_4$] (0.205 g, 0.222 mmol) were weighed into a Schlenk flask and stirred for 2 min to mix the two solids. Then methylene chloride (15 mL) was added and the mixture was stirred at room temperature for 10 min. The solvent was removed in vacuo and the remaining orange solid was stirred with hexane (20 mL) for 1 week. The solvent was removed in vacuo to give an orange solid, which was dissolved in a chlorobenzene – methylene chloride mixture (1 mL : 0.5 mL) and placed in a –30 °C freezer to give orange crystals (0.199 g, 52%). Alternatively, placement of a chlorobenzene – methylene chloride solution of complex **6b** in a –30 °C freezer also gave the title complex. ^{1}H NMR (CD_2Cl_2, ambient) δ: 6.49 (s, 10H, Cp), 2.17 (m, 4H, CH_2CH_3), 1.60 (m, 4H, CH_2CH_3), 1.44 (dt, 6H, J = 7.3 Hz, CH_2CH_3), 1.10 (dt, 6H, J = 7.3 Hz, CH_2CH_3), 0.47 (s, 2H, μ-CH_2), 0.28 (s, 3H, μ-CH_3), 0.20 (s, br, 36H, $SiCH_3$). ^{19}F NMR (CD_2Cl_2, ambient) δ: –133.0 (br m, 8F), –163.7 (t, 4F), –167.5 (m, 8F). Anal. calcd. for $C_{56}H_{71}N_4P_2Si_4BF_{20}Zr_2 \cdot CH_2Cl_2$: C 41.93, H 4.50, N 3.43; found: C 41.52, H 4.11, N 3.08.

Acknowledgments

Syntheses, characterization, and crystal structures of the tetramethylammonium salts of the novel weakly coordinating anions $[MeCO_2\{B(C_6F_5)_3\}]^-$ and $[MeCO_2\{B(C_6F_5)_3\}_2]^-$ [1]

Simona Mitu and Michael C. Baird

Abstract: The novel compounds $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ and $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ are prepared and characterized spectroscopically and crystallographically. The compounds are salts of the unisolable acids $MeCO_2H{\cdot}B(C_6F_5)_3$ and $MeCO_2H{\cdot}2B(C_6F_5)_3$, respectively, which are sufficiently strong that they can protonate isobutene and initiate its carbocationic polymerization. The 1:1 adduct contains a conventional, monodentate acetate ion coordinated to the $B(C_6F_5)_3$, while the 2:1 adduct contains a bridging acetate ligand.

Key words: weakly coordinating anions, carbocationic polymerization, isobutene, polyisobutene.

Résumé : On a préparé les nouveaux composés $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ et $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ et on les a caractérisés sur des bases spectroscopiques et cristallographiques. Les composés sont respectivement des acides $MeCO_2H{\cdot}B(C_6F_5)_3$ et $MeCO_2H{\cdot}2B(C_6F_5)_3$ qui ne peuvent pas être isolés, mais qui sont suffisamment forts pour protoner l'isobutène et initier sa polymérisation carbocationique. L'adduit 1 : 1 contient un ion acétate monodentate conventionnel qui est lié par coordination au $B(C_6F_5)_3$ alors que l'adduit 2 : 1 comporte un ligand acétate qui agit comme pont.

Mots clés : anions faiblement coordinés, polymérisation carbocationique, isobutène, polyisobutène.

[Traduit par la Rédaction]

Recent years have seen extraordinary developments in the once esoteric field of "weakly coordinating anions" (1). For present purposes, weakly coordinating anions may be defined loosely, if narrowly, as anions that, in solution, bind sufficiently weakly to cationic species such as H^+, carbocations, or metal ions that they are readily displaced by such normally poor electron pair donors as unsaturated hydrocarbons (1). Of great relevance here are the clearly similar, important properties of weakly coordinating anions in the complementary fields of the coordination polymerization of olefins such as ethylene and 1-alkenes (2) and of the carbocationic polymerization of, e.g., the more sterically hindered, electron-rich isobutene (3). As well-known examples of coordination polymerization catalysis, active catalysts are often generated from neutral zirconocene precursors, as in Scheme 1 (2).

Since monomer access to the active metal site of $[Cp'ZrMe]^+$ may be effectively blocked if the counteranion X^- binds too strongly to the metal, it is clearly important that X^- be an exceedingly poor ligand if olefin coordination and subsequent polymerization are to occur (Scheme 2).

In a similar vein, initiation of carbocationic polymerization of an olefin such as isobutene involves interaction of a molecule of monomer with, e.g., a strong acid, as in Scheme 3.

The carbocationic center so formed is stabilized by solvent and (or) counteranion X^-, and the latter must be a very poor Lewis base, otherwise the ions will combine to give the neutral compound Me_3CX. Chain propagation involves displacement of X^- by monomer and repeated additions of alkene molecules to the carbocationic center, which migrates well away from the site of initial attack (Scheme 4).

Weakly coordinating counteranions result in higher molecular weights (3*d*, 3*e*), and thus, in chemistry reminiscent of coordination polymerization, the C=C bond must be the most nucleophilic species in the system. Indeed, many cationic transition metal complexes function as both coordination catalysts and carbocationic initiators (3*f*, 4).

Much attention has been paid to the development of catalysts utilizing the chemistry of Scheme 1 (2, 5–8), and many new weakly coordinating anions X^- have been designed on the premise that delocalization of negative charge over as many atoms as possible in a large anion should be of advantage (5–8). Thus, there have been reported several very bulky anions in which the perfluorophenyl groups of $[BMe(C_6F_5)_3]^-$ have been substituted by more complex perfluoroaryl groups (5*g*–5*p*). Alternative, synthetically less

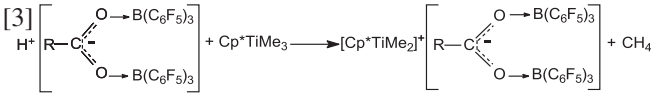
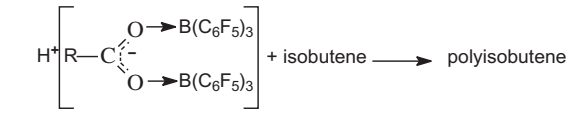
challenging procedures involve interaction of $B(C_6F_5)_3$ with various anions Y^- (Y^- = e.g., OH^- (6), CN^- (5*f*, 7*a*), N_3^- (7*b*), OR^- (6*b*–6*d*, 6*j*), SR^- (6*b*–6*d*), imidazolate (7*c*)) to form complex anions of the types $[YB(C_6F_5)_3]^-$ and $[(\mu\text{-}Y)\{B(C_6F_5)_3\}_2]^-$. In addition, we have recently reported utilization of $[Me_3CH_2B(C_6F_5)_3]^-$ in which the sterically demanding neopentyl group renders the borate anion much less weakly coordinating than is the above-mentioned methyl analogue, $[BMe(C_6F_5)_3]^-$ (8).

Complementing aspects of the above-mentioned research, we have reported the synthesis and utilization for isobutene polymerization of strong acids of the types $[ROH\{B(C_6F_5)_3\}_{1,2}]$ and $[RCO_2H\{B(C_6F_5)_3\}_{1,2}]$ (R = alkyl, aryl) (9, 10). Carboxylic acids, RCO_2H, do not by themselves initiate isobutene polymerization but are apparently activated via formation of adducts with $B(C_6F_5)_3$, as in eqs. [1] and [2].



[1] 

A



[2] 

B

These can then react with metallocene-type compounds, as in eq. [3], generating the cationic $[Cp^*TiMe_2]^+$, a known initiator for both coordination and carbocationic olefin polymerization reactions (10*a*), or they can be used directly to initiate the carbocationic polymerization of, e.g., isobutene and similarly polymerizable olefins (eq. [4]) (10*b*–10*d*).

[3] 

C

[4] 

The species formed when a carboxylic acid is combined with 2 equiv. of the borane is thus a novel type of Brønsted acid, sufficiently strong to protonate isobutene; presumably its conjugate base, $[RCO_2\{B(C_6F_5)_3\}_2]^-$, is stabilized by extensive delocalization of the negative charge. However, to this point the nature of the species in solution had been inferred only from the chemistry observed, and we have possessed only spectroscopic information concerning the structures of the putative products of eqs. [1] and [2].

Complicating our attempts to investigate spectroscopically the nature of the species in solution, we have found that the 1:1 and 2:1 adducts **A** and **B** are sufficiently acidic that cleavage of the B—C_6F_5 bonds occurs readily above about –30 °C to give pentafluorobenzene. We wished, however, to determine unequivocally the nature of the borane–carboxylate species in solution, and we have now accomplished this by isolating and characterizing salts of the conjugate bases of the products of eqs. [1] and [2]. Although the best carbocationic polymerization initiators found previously have involved long-chain carboxylic acids (10), we decided that we might have better success obtaining crystalline materials if we were to use short-chain carboxylic acids, and we have now accomplished the successful syntheses and characterization of the 1:1 and 2:1 acetato compounds $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ and $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$. Crystal structures of both tetramethylammonium salts confirm their structures. A subsequent paper will consider the nature of the conjugate acids of these types of anions and their roles in initiating carbocationic polymerization of isobutene.

We note reports elsewhere of isobutene polymerizations being effected in the presence of other dinuclear counteranions (4*g*, 11), and it seems clear that counteranions, which are weakly coordinating because of combinations of steric factors and extensive delocalization of charge, do indeed play a role similar to those mentioned above for coordination polymerization catalysts.

Experimental

Most synthetic procedures, unless otherwise noted, were carried out under an atmosphere of nitrogen or argon purified by passing through a column of BASF catalyst heated to 140 °C and a column of 5 Å molecular sieves. Manipulation of air-sensitive materials employed standard Schlenk line techniques and an Mbraun Labmaster glovebox. Solvents were dried by passing them through activated alumina col-

umns (Innovative Technology). All chemicals were purchased from Aldrich and were purified as appropriate before use. The compound $B(C_6F_5)_3$ was prepared as described in the literature (12).

The ^{1}H, ^{11}B, and ^{19}F NMR spectra were run on an Avance 400 NMR spectrometer, the residual proton resonances of the deuterated solvents serving as internal references. Mass spectra were obtained on a Quatro Fisons Pro Quadrupole mass spectrometer in EI mode with CH_2Cl_2 as solvent. Canadian Microanalytical Services of Delta, British Columbia, performed elemental analyses. X-ray crystallographic structure determinations were carried out using a Siemens P4 diffractometer with a Bruker SMART CCD 1000 detector and graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å) controlled with a Crysostream controller 700. Typically a crystal was mounted on a glass fibre with epoxy glue. No significant decay was observed during data collection, and the data were processed on a Pentium PC using the Bruker AXS Windows NT SHELXTL software package (version 5.10) (13*a*). Neutral atom scattering factors were taken from Cromer and Waber (13*b*). The raw intensity data were converted to structure amplitudes and their esds using the program SAINT-plus, which corrects for *L*p and decay. Absorption corrections were applied using the program SADABS. The crystals are monoclinic space group $P2_1/c$ for $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ and triclinic space group $P\bar{1}$ for $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ based on the systematic absences, E statistics, and successful refinement of the structure. The structure was solved by direct methods. Full-matrix least-square refinements minimizing the function $\sum w(F_o^2 - F_c^2)^2$ were applied to the compound. For the structure of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$, all non-hydrogen atoms in the structure were refined anisotropically, and only the hydrogen atoms of the solvent molecule were calculated; all the other hydrogen atoms were located directly from the difference Fourier map. For the structure of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$, the solvent molecules ($2.72CH_2Cl_2$) in the crystal are severely disordered, and the SHELXL commands SIMU, DFIX, SAME, and PART were thus used to refine the structure. All non-hydrogen atoms in the structure (**II**) (except C47, C49, Cl13, and Cl14) were refined anisotropically. All hydrogen atoms were calculated,

and their contributions were included in the structure factor calculations with isotropic thermal parameters 1.2 times that of the attached carbon atoms (1.5 times for methyl hydrogens). Crystallographic data for the two compounds studied are summarized in Table 1, with selected bond distances and angles in Table 2. Molecular structures are shown in Figs. 1 and 2, and complete crystallographic data are given in the supporting information.[3]

Preparation of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$

$[Me_4N][MeCO_2]$ was prepared by neutralizing tetramethylammonium hydroxide (6 mL, 25 wt% aqueous solution) with glacial acetic acid (1.43 mL, 0.0250 mol) (14). The solution was evaporated to dryness, and the solid residue was recrystallized from acetone and dried under reduced pressure for 12 h at 150 °C to give 2.1 g of $[Me_4N][MeCO_2]$ (95% yield). IR (Fluorolube mull, cm^{-1}) ν(CO): 1681, 1491. ^1H NMR (CD_2Cl_2) δ: 3.43 (s, 12H, MeN), 1.80 (s, 3H, MeC). To prepare $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$, a mixture of $B(C_6F_5)_3$ (250 mg, 0.49 mmol) and $[Me_4N][MeCO_2]$ (64.9 mg, 0.49 mmol) in dry CH_2Cl_2 (20 mL) was stirred at room temperature for 1 h, after which the solvent was removed under reduced pressure. The resulting white solid was recrystallized from a mixture of CH_2Cl_2 (5 mL) and hexanes (15 mL), filtered off, washed with hexanes, and dried to give 253 mg (80% yield) of product. IR (Fluorolube mull, cm^{-1}) ν(CO): 1682, 1491. ^1H NMR (CD_2Cl_2) δ: 3.13 (s, 12H, MeN), 1.94 (s, 3H, MeC). ^{11}B NMR (CD_2Cl_2) δ: –5.1 (sharp). ^{19}F NMR (CD_2Cl_2) δ: –135.9 (*o*-F), –163.6 (*p*-F), –168.2 (*m*-F). HR-MS (EI) calcd. for $[(CH_3)_4N]$: 74.1460; found: 74.0784. HR-MS (EI) calcd. for $[MeCO_2\{B(C_6F_5)_3\}]$: 571.0296; found: 571.0672. Anal. calcd. for $C_{24}H_{15}BF_{15}O_2 \cdot CH_2Cl_2$: C 41.13, H 2.35, N 1.92; found: C 41.58, H 2.38, N 1.88. Crystallographic quality crystals were grown by layering a solution of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ in CH_2Cl_2 with hexanes.

Preparation of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$

A mixture of $B(C_6F_5)_3$ (500 mg, 0.98 mmol) and $[Me_4N][MeCO_2]$ (64.9 mg, 0.49 mmol) in CH_2Cl_2 (30 mL)

was stirred at room temperature for 1 h, after which the solvent was removed under reduced pressure. The resulting white solid was recrystallized from a mixture of CH_2Cl_2 (5 mL) and hexanes (15 mL), filtered off, washed with hexanes, and dried to give 398 mg (70% yield) of product. IR (Fluorolube mull, cm^{-1}) ν(CO): 1566, 1417. ^1H NMR (CD_2Cl_2) δ: 3.22 (s, 12H, MeN), 2.19 (s, 3H, MeC). ^{11}B NMR (CD_2Cl_2) δ: –1.6 (broad). ^{19}F NMR (CD_2Cl_2) δ: –135.6 (*o*-F), –161.0 (*p*-F), –167.1 (*m*-F). HR-MS (EI) calcd. for $[(CH_3)_4N]$: 74.1460; found: 74.0832. HR-MS (EI) calcd. for $[MeCO_2\{B(C_6F_5)_3\}_2]$: 1083.0147; found: 1083.0642. Anal. calcd. for $C_{42}H_{15}B_2F_{30}O_2$: C 43.59, H 1.31, N 1.21; found: C 43.28, H 1.26, N 1.52. Crystallographic quality crystals were grown by layering a solution of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ in CH_2Cl_2 with hexanes.

Results and discussion

The combination of carboxylic acids and $B(C_6F_5)_3$, especially in a 2:1 $B(C_6F_5)_3$ – carboxylic acid ratio, results in an acid system sufficiently strong to protonate isobutene (IB) and to initiate its carbocationic polymerization (10). Carboxylic acids themselves are too weak to effect this chemistry, of course, and furthermore carboxylate anions are expected to bind very effectively to the carbocation intermediates. However, the inductive effects of carboxylic acid coordination to the strongly electrophilic borane in a species such as **B** would very likely result in an acid much stronger than the free carboxylic acid itself (10), as has been observed elsewhere with other potentially acidic Lewis base donors (6*j*, 15), and it seemed very likely that the reactions described in eqs. [1] and [2] would pertain. The purpose of this research was to prepare, characterize, and determine the structures of salts of the putative counteranions of species **A** and **B**.

Syntheses of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ and $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$

These two compounds were synthesized by reacting $[Me_4N][MeCO_2]$ with 1 and 2 molar equiv. of $B(C_6F_5)_3$, respectively. Both compounds were characterized fully by elemental analyses and IR and NMR spectroscopy; the crystals of the 1:1 adduct contained one molecule of CH_2Cl_2, as shown by the elemental analyses and X-ray crystallography. The IR spectra are illustrated in Figs. 3 and 4, and we note especially that the observed values of ν(CO) of 1682 and 1491 cm^{-1} for the 1:1 adduct and of 1566 and 1417 cm^{-1} for the 2:1 adduct are consistent with the literature for monodentate and bridging acetato ligands as in **D** and **E**, respectively (16).

D **E**

The positions of the symmetric stretches are in both cases uncertain because absorptions of the $B(C_6F_5)_3$ (indicated in the spectra by **B**) and the $[Me_4N]^+$ ion also appear in the region 1300–1800 cm^{-1}.

The ^1H, ^{19}F, and ^{11}B NMR spectra are shown in Figs. 5, 6, and 7, respectively, where they are compared with the spectra of $[Me_4N][MeCO_2]$ (^1H) and $B(C_6F_5)_3$ (^{19}F, ^{11}B). The electron-withdrawing power of the borane is evident in the acetate methyl ^1H resonances, and the changes in the ^{19}F chemical shifts on going from free to coordinated $B(C_6F_5)_3$ are characteristic (5–10). The ^{11}B chemical shifts of the adducts are similar to those of other adducts with O-donors, and the observed narrowing of the resonances is consistent with tetrahedral structures (6*h*, 17*b*–17*d*), although it is not at all clear why the 2:1 complex has a much broader resonance than does the 1:1 complex.

Crystal structures of $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$ and $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$

Crystal structures were obtained for both compounds, with the 1:1 complex containing a molecule of CH_2Cl_2. Selected bond distances and angles are shown in Table 2, and

Fig. 3. IR spectrum (Fluorolube mull) of $[Me_4N]\{[MeCO_2][B(C_6F_5)_3]\}$: * identifies ν(CO); **B** identifies peaks assignable to $B(C_6F_5)_3$.

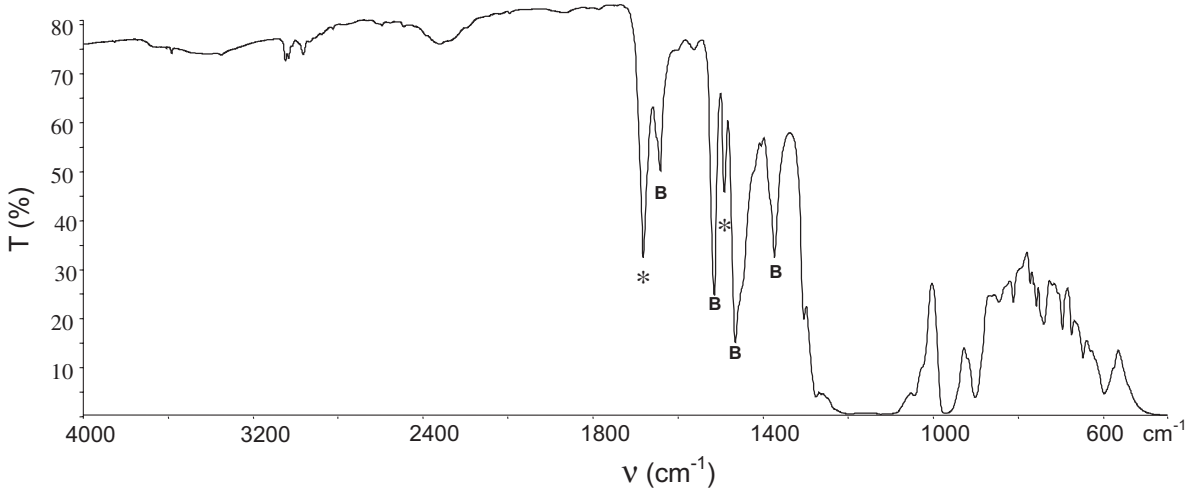

Fig. 4. IR spectrum (Fluorolube mull) of $[Me_4N]\{[MeCO_2][B(C_6F_5)_3]_2\}$: * identifies ν(CO); **B** identifies peaks assignable to $B(C_6F_5)_3$.

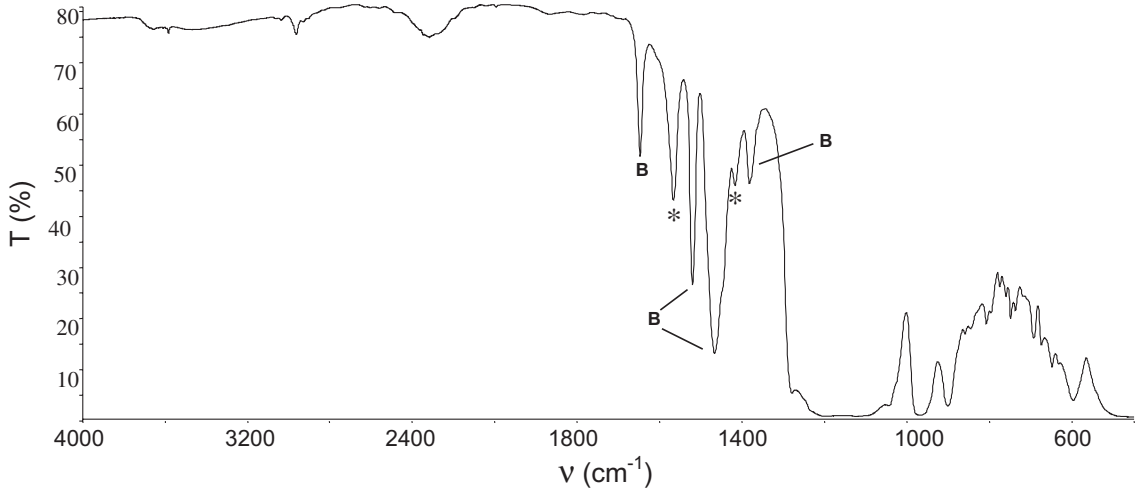

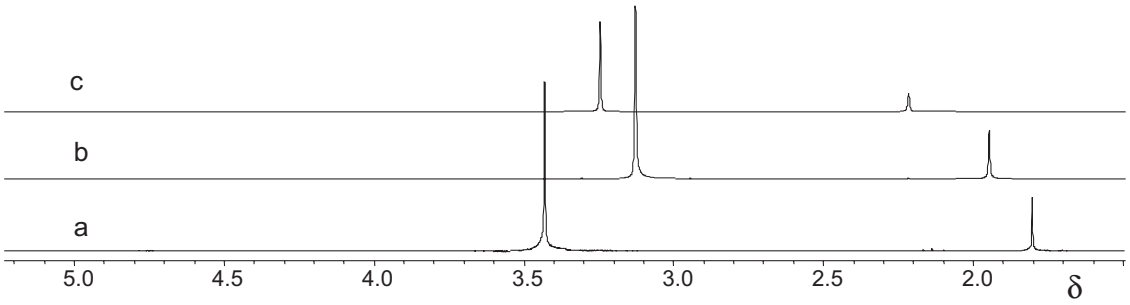

Fig. 5. ^1H NMR spectra of (*a*) $[Me_4N][MeCO_2]$, (*b*) $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$, and (*c*) $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ (CD_2Cl_2).

molecular structures are shown in Figs. 1 and 2. As can be seen, the crystal structures are completely in accord with the modes of bonding suggested by **D** and **E**. Thus the carbon–oxygen bond lengths of the 1:1 adduct are 1.216(2) and 1.321(2) Å, as expected for a double and a single bond, respectively. On the other hand, the two carbon–oxygen distances of the 2:1 adduct are intermediate between these two values and are very similar to each other. Interestingly, the boron–oxygen distance in the 1:1 adduct is significantly shorter than that of the 2:1 adduct, consistent with the expected stronger B—O bond in the former. However, all three B—O distances fall in the range established for a variety of adducts of $B(C_6F_5)_3$ with a variety of other O-donors (6*h*, 6*j*, 17).

Possibly complementing the stronger donor–acceptor interaction in the 1:1 adduct, the average of the B—C_6F_5 bond lengths in this adduct is marginally longer than the average of the 2:1 adduct, although steric repulsions should be more

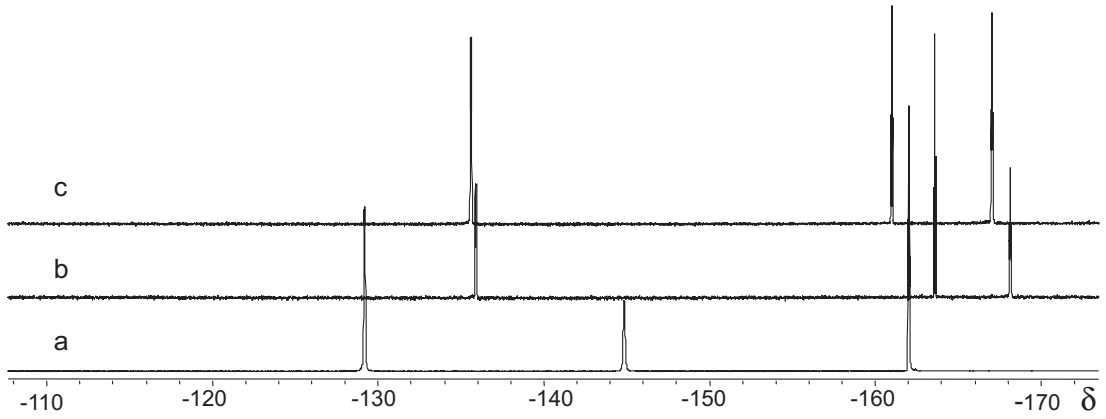
Fig. 6. ^{19}F NMR spectrum of (*a*) $B(C_6F_5)_3$, (*b*) $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$, and (*c*) $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ in CD_2Cl_2.



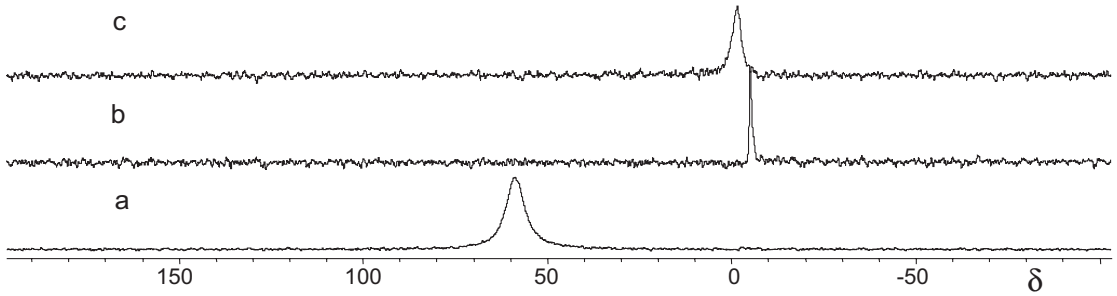


Fig. 7. ^{11}B NMR spectra of (*a*) $B(C_6F_5)_3$, (*b*) $[Me_4N][MeCO_2\{B(C_6F_5)_3\}]$, and (*c*) $[Me_4N][MeCO_2\{B(C_6F_5)_3\}_2]$ (CD_2Cl_2).

important in the latter. The acetate ions are essentially planar in both adducts, but the bond angles vary widely. Thus the O-C-O bond angle of the 1:1 adduct is significantly less than 120°, the two Me-C-O bond angles both being significantly greater. In contrast, the O-C-O bond angle of the 2:1 adduct is 120.7(3)°, while the two (chemically equivalent) Me-C-O bond angles vary widely. The O-B-C_6F_5 and C_6F_5-B-C_6F_5 bond angles vary considerably, but the latter variations seem to be normal (18).

1-Bromoindene — A new synthon for the preparation of (indenyl)Ni(II)(PPh_3)Br[1]

Sylvain Boucher and Davit Zargarian

Abstract: The oxidative addition of the carbon–bromine bond in 1-bromoindene to $Ni(PPh_3)_4$ gives the complex (indenyl)$Ni(PPh_3)Br$ (**1**) in 95% yield. In contrast, other nickel(0) species such as $Ni(PMe_3)_4$ and $Ni(COD)_2$ promote the oxidative coupling of 1-bromoindene to 1,1′-biindene. Complex **1** has been characterized by NMR spectroscopy (^1H, ^{13}C, ^{31}P) and single-crystal X-ray structural analysis.

Key words: indenyl complexes, oxidative addition, oxidative coupling.

Résumé : L'addition oxydante du lien carbone–brome du 1-bromoindène sur le $Ni(PPh_3)_4$ permet d'obtenir le complexe (indényle)$Ni(PPh_3)Br$ (**1**) avec un rendement de 95 %. Par contraste, d'autres espèces du nickel(0) comme le $Ni(PMe_3)_4$ et le $Ni(COD)_2$ promeuvent le couplage oxydatif du 1-bromoindène en 1,1′-biindène. Le complexe **1** a été caractérisé par la spectroscopie de RMN (^1H, ^{13}C, ^{31}P) et par la diffraction des rayons-X d'un cristal unique.

Mots clés : complexes indényles, addition oxydante, couplage oxydatif.

Introduction

A number of transition metal complexes bearing indenyl (Ind) ligands possess greater reactivity, both in catalysis (1) as well as in stoichiometric ligand exchange (2) and insertion (3) reactions, than their cyclopentadienyl (Cp) analogues. The most common synthetic route to Ind complexes is based on the reaction of metal halide precursors with M[Ind] (M = Li, Na, and K), but in some cases the synthesis is complicated by undesirable side reactions such as reduction of the metal precursor. Such complications are particularly prevalent in the syntheses of relatively electron-rich group 10 metal complexes; as a result, generally poor yields are obtained for Ind complexes of Ni (4) and Pd (5) from the reaction of LiInd with their halide precursors.

Our interest in the preparation and catalytic reactivities of Ind complexes of group 10 metals (6) prompted us to seek alternative synthetic procedures that avoid using indenyl anions as the source of Ind ligand. Given the propensity of zerovalent precursors of group 10 metals to oxidatively add alkyl (7), allyl (8), aryl (9), and Cp (10) halides, we set out to explore the feasibility of preparing IndM(II) complexes via oxidative addition of a suitable Ind-halide to L_nM^0 precursors. A search of the literature revealed that 1-bromoindene (1-Br-Ind) can be conveniently prepared from the reaction of 1-(trimethylsilyl)indene and the dioxane·Br_2 adduct (11); moreover, the relatively weak C—Br bond in 1-Br-Ind should make this reagent suitable for our purposes. A preliminary study has indicated that reacting 1-Br-Ind with $Ni(PPh_3)_4$ gives (indenyl)$Ni(PPh_3)Br$ in good yield. The preparation and characterization of this compound is reported herein along with an account of a study on the potential of 1-Br-Ind as a synthon for the synthesis of other Ind-Ni complexes.

Results and discussion

The recently reported catalytic reactivities of (R-Ind)Ni-(PPh_3)Cl make these the most commonly studied group 10 metal Ind complexes. Therefore, we selected the bromo analogue Ind$Ni(PPh_3)Br$ as our first synthetic target. Stirring a toluene solution of 1-Br-Ind and $Ni(PPh_3)_4$ for 1 h at ambient temperature gave Ind$Ni(PPh_3)Br$ (**1**) in 95% yield (Scheme 1), which represents a significant improvement over the 25%–60% yields obtained from the reaction of $(PPh_3)_2$-NiX_2 (X = Cl, Br) with LiInd (4). We envisage this new synthetic route proceeding according to the sequence of steps shown in Scheme 1: oxidative addition of 1-Br-Ind to $Ni(PPh_3)_3$ (12) forms $(PPh_3)_2Ni(\eta^1$-Ind)Br, which undergoes $\eta^1 \rightarrow \eta^{3/5}$ slippage of the indenyl ring to give the observed product. To our knowledge, **1** is the first Ind complex to be obtained through oxidative addition of 1-X-Ind (X = halogens).

Subsequent attempts to apply the above reaction to other precursors have not been successful so far. Thus, reaction of 1-Br-Ind with $Ni(PMe_3)_4$ or $Ni(COD)_2$ did not result in the formation of Ind$Ni(L)Br$; instead, both of these compounds converted 1-Br-Ind to 1,1′-biindene, which was obtained with d,l:meso ratios of ca. 1:1 ($Ni(PMe_3)_4$) and 4:1

Scheme 1.

(Ni(COD)$_2$) (13). This coupling reaction is reminiscent of the homocoupling of benzyl bromide to 1,2-diphenylethane in the presence of Ni(PMe$_3$)$_4$.[3] In addition, Carmona et al. (14) have reported that the complex *trans*-(PMe$_3$)$_2$Ni(η^1-PhCH$_2$)Cl decomposes in the presence of excess PMe$_3$ to give Ni(PMe$_3$)$_3$Cl$_2$, Ni(PMe$_3$)$_4$, and 1,2-diphenylethane. These findings are consistent with our observation that the reaction of beige-coloured Ni(PMe$_3$)$_4$ and colourless 1-Br-Ind gives a deep blue mixture consistent with the formation of (PMe$_3$)$_3$NiBr$_2$ (15). In the reaction involving Ni(COD)$_2$, the formation of 1,1′-biindene was concomitant with the precipitation of an insoluble, orange solid that seems to be NiBr$_2$; the ^{1}H NMR spectrum of the reaction mixture also showed the presence of free COD.

On the basis of the above precedents and observations, we propose the following scenario (Scheme 1) to explain why the reactions with PMe$_3$ and COD derivatives did not lead to the desired Ind complexes. We believe that the initial intermediates arising from the oxidative addition of 1-Br-Ind to Ni(0)L$_n$, i.e., L$_2$Ni(η^1-Ind)Br, do not undergo the requisite η^1→η$^{3/5}$ slippage of the indenyl ring at a sufficiently rapid rate; this is likely caused by the unfavourable dissociation of the more nucleophilic PMe$_3$ and the chelating COD ligands. The hindered slippage then makes possible side reactions that lead to the formation of 1,1′-biindene.[4] There is much debate on the precise mechanism for the Ni-catalyzed coupling of organohalides R-X (16). The most reasonable mechanism for the formation of 1,1′-biindene from Ni(0) precursors involves the redistribution of the initial intermediate L$_2$Ni(η^1-Ind)Br to L$_2$NiBr$_2$ and L$_2$Ni(η^1-Ind)$_2$ (17); reductive elimination of the latter would furnish 1,1′-biindene. Alternatively, a binuclear reductive elimination from L$_2$Ni(η^1-Ind)Br could give 1,1′-biindene and L$_2$Ni^{I}Br; the latter would then be expected to disproportionate to Ni(II) and Ni(0) species (Scheme 1).[5]

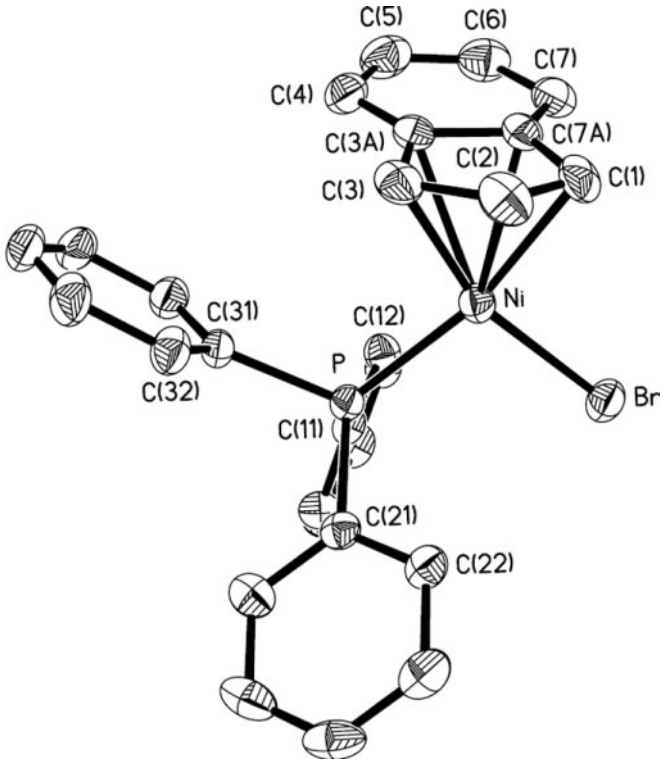
Characterization of 1

Complex **1** was fully characterized to allow structural comparisons with previously studied analogues of this family of complexes. Thus, the ^{31}P{^{1}H} NMR spectrum of **1** consisted of a singlet at ca. 31.0 ppm, somewhat downfield of the corresponding signal in the chloride analogue IndNi(PPh$_3$)Cl (**2**, 28.2 ppm). Such deshielding of the P nucleus with the heavier halide has also been observed in the analogous complexes (1-Me-Ind)Ni(PPh$_3$)X (δ: 31.2 for Cl, 33.9 for Br, and 38.6 for I) (18). We have shown a correlation between the deshielding of the ^{31}P signals in these complexes and the extent of PPh$_3$ donation to Ni, greater donation resulting in more downfield signals (6). This correlation can be attributed to two phenomena: (*i*) the longer Ni—Br and Ni—I bond lengths result in less efficient X → Ni π donation, which reduces the cis-weakening normally associated with such π donation and allows greater R$_3$P → Ni donation (4*b*); (*ii*) the ionic character of the Ni—X bond diminishes on going from Cl to I, which in turn reduces the hardness of the Ni centre and results in greater covalent interaction with the soft PR$_3$ ligand (19).

The ^{1}H NMR spectrum was also valuable for structural comparisons. As was the case for the previously studied chloro analogue **2**, the room-temperature spectrum of **1** contained broad signals for the symmetry-related protons of Ind (H1/H3, H4/H7, H5/H6); the broadness of these signals results from the hindered rotation of Ind. Cooling the sample to ca. 218 K resulted in the appearance of well-resolved signals for these protons, indicating that in the low-temperature regime the complex adopts the C_1 symmetry expected in the solid state (vide infra). The signals rebroadened and eventually disappeared into the baseline (ca. 338 K) with the gradual warming of the sample, indicating that the symmetry of the complex changes to C_s as a result of Ind rotation; unfortunately, however, the coalescence temperature for the two-site exchange process brought about by the hindered rotation of Ind could not be determined because the compound decomposed at around 348 K. Thus, we can only assign a lower limit of ca. 15 kcal/mol (1 cal = 4.184 J) for the energy barrier (20); this value is comparable to the barrier of ca. 16 kcal/mol measured for complex **2** (4*a*).

Other structural information can be inferred from ^{1}H NMR data and especially the chemical shift of H3, which has been found to reflect the solution hapticity of the Ind ligand, with upfield shifts implying greater η^5 → η^3 slippage (6). Thus, the H3 signal of **1** resonates at 3.55 ppm, slightly downfield of the corresponding signal for its chloride analogue (3.31 ppm). Although this chemical shift difference is small (Δδ = 0.24 ppm), its direction is consistent with the previously noted trend in the chemical shifts of H3 signals in the complexes (1-Me-Ind)Ni(PPh$_3$)X (δ: 3.38 for Cl, 3.55 for Br, and 3.86 for I) (18) and (1-Et-Ind)Ni(PPh$_3$)X (δ: 3.37 for Cl, 3.61 for Br, and 3.93 for I) (21), and signals greater Ind hapticity in solution for the Ni-Br analogue.

The ^{13}C{^{1}H} NMR data were also quite valuable for structural comparisons, especially the chemical shift of the ring junction carbons C3a and C7a, which are thought to reflect the hapticity of the Ind ligand. This is based on the



[3] S. Beaudoin and D. Zargarian. Unpublished results.

[4] Unsuccessful attempts were made to circumvent the nearly instantaneous formation of 1,1′-biindene from the Ni(PMe$_3$)$_4$ reaction by placing the reaction vessel under reduced pressure to remove volatile PMe$_3$ from the reaction mixture.

[5] It is worth noting that the coupling of 1-Br-Ind by the PMe$_3$ and COD precursors might proceed through two different mechanisms. Indeed, the different selectivities observed in these reactions for the formation of the *d*,*l*- over *meso*-1,1′-biindene support this possibility.

Fig. 1. ORTEP view of **1**. The thermal ellipsoids are shown at 30% probability and the hydrogen atoms have been omitted for clarity.

notion that coordination of the Cp moiety of Ind to metals disrupts the aromaticity of the benzene moiety, thereby resulting in upfield shifts of C3a and C7a signals (22). The magnitude of this shift in a given complex can be estimated from the $\Delta\delta^{13}C$ parameter[6] as follows: compounds bearing nearly perfectly pentahapto Ind ligands have $\Delta\delta^{13}C$ values as low as –43.7 ppm (Ind_2Fe) (22*c*) and –32.4 ppm ($[Ind_2Co]^+$) (22*c*), whereas those bearing trihapto Ind ligands give values as high as +26 ppm ($IndIr(PMe_2Ph)_3$) (23) and +27 ppm ($[IndFe(CO)_3]^-$) (24), and those featuring intermediate hapticities (η^3–η^5) show near zero values of $\Delta\delta^{13}C$ (e.g., +3.6 ppm for Ind_2Ni) (22*c*). The $\Delta\delta^{13}C$ values for **1** (–3 ppm) and **2** (–2 ppm) indicate that the Ind ligands in these complexes adopt intermediate hapticities (η^3–η^5).

Finally, complex **1** was subjected to an X-ray crystallographic study to confirm the conclusions inferred from the NMR spectra and compare some of its important structural features to those of related compounds (Fig. 1). The crystal data and details of measurement and refinement are given in Table 1, while the most pertinent structural parameters are tabulated in Table 2; the latter also lists the corresponding data for **2** to facilitate comparisons.[7]

The geometry around the Ni center in **1** may be described as being intermediate between a two-legged piano stool (assuming η^5-Ind) and a distorted square-planar (assuming η^3-Ind). The planes formed by the atoms P, Ni, and Br, on the one hand, and C1, C2, C3, C3a, and C7a on the other, are nearly perpendicular to each other (ca. 87°). The atoms P, Br, C1, C2, and C3 are within the expected bonding distance from Ni, while C3a and C7a are considerably farther away. The difference in the Ni—P bond distances in **1** and **2** is

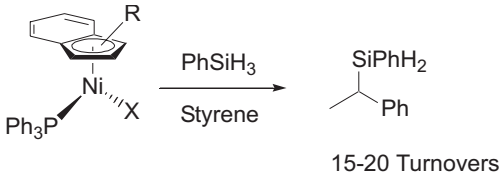
small but significant (10 times esd); the shorter bond in **1** is consistent with the somewhat stronger Ni—PPh_3 interaction inferred on the basis of the more downfield ^{31}P NMR signal obtained in the solution (vide supra).

Perhaps the most important structural feature of **1** concerns the Ni–Ind interactions and the extent of $\eta^5 \rightarrow \eta^3$ slip-fold distortions. Varying degrees of such distortions occur in most η-Ind complexes, but in the present case they can be attributed to the tendency of Ni(II) to avoid forming 18-electron complexes. As was inferred from the $\Delta\delta^{13}C$ values above, the Ni–Ind interactions in solid state structures of **1** and **2** appear to be fairly similar at first glance. For example, the extent of $\eta^5 \rightarrow \eta^3$ slippage is comparable in both complexes, as indicated by the much shorter Ni—C distances involving the allylic carbons (C1–C3) compared with those involving the ring junction carbons (C3a and C7a). The degree of slip-fold distortion can be defined more quantitatively in terms of the slip value (ΔM-C) and the hinge and fold angles (HA and FA);[8] larger ΔM-C, HA, and FA values generally imply greater "slippage" away from the idealized η^5-coordination mode (22*b*, 22*c*). A comparison of these parameters (Table 2) points to a slightly more slip-folded Ind in **1**. In addition, a closer inspection of the Ni—C bond distances reveals a more pronounced "sideways slippage" in **2** (Ni—C1 > Ni—C2 > Ni—C3; Ni—C7a > Ni—C3a) compared with more symmetrical interactions in **1** (Ni—C1 > Ni—C2 ≈ Ni—C3; Ni—C3a ≈ Ni—C7a).



Catalytic reactivity of 1

The complexes (1-R-Ind)Ni(PPh_3)X (R = Me, *i*-Pr; X = Cl, Me) have been shown to catalyze the hydrosilylation of styrene with $PhSiH_3$, giving high regioselectivities for the addition of the $PhSiH_2$ fragment at the α-C (Scheme 2) (25). Previous studies demonstrated that the choice of X in the precursor has some bearing on the catalytic activities, with the Ni-Cl precursor catalyzing the hydrosilylation more efficiently (in the presence of $NaBPh_4$). We have briefly studied the catalytic activity of **1** in the hydrosilylation of styrene to assess the impact of the Ni-Br moiety on the catalysis. The results of this study indicate that **1** is less active than **2**. Thus, a number of catalytic runs using **1** as the catalyst precursor gave 27%–36% yields for the reaction, compared with 42%–82% yields for the reactions catalyzed by **2** under similar conditions. We believe that the higher reactivities of **2** might originate from the more facile formation of Ni-H intermediates from the weaker Ni—Cl bond, whereas the more labile Ni—Cl bond can be attributed to its less covalent nature or to destabilizing X → Ni η-interactions that are greater with Cl vs. Br (vide supra).

Conclusion

The oxidative addition of 1-bromoindene to Ni(PPh_3)$_4$ has provided a convenient and very high yield method for the preparation of IndNi(PPh_3)Br. This new methodology should be particularly practical for the preparation of Ind complexes of those transition metals that are susceptible to side reactions encountered commonly when using various sources of indenyl anions. Despite the unsuccessful attempts to prepare IndNi(II) complexes from Ni(PMe_3)$_4$ and Ni(COD)$_2$, we plan to explore the suitability of this new synthetic route for the preparation of a wide range of Ind complexes, including IndM(CO)$_n$.

Scheme 2.

Experimental section

All manipulations and experiments were performed under an inert atmosphere of nitrogen using standard Schlenk techniques and (or) in an argon-filled glovebox. Dry, oxygen-free solvents were employed throughout. A Bruker AV-300 spectrometer was employed for recording the ^1H (300.1 MHz), $^{13}C\{^1H\}$ (75.5 MHz), and $^{31}P\{^1H\}$ (121.5 MHz) NMR spectra with $SiMe_4$ and H_3PO_4 (85%) as external standards. Ni(COD)$_2$ was purchased from Sigma-Aldrich and used as received; synthetic procedures for the preparation of 1-Br-Ind (11) (from 1-$SiMe_3$-Ind (26) and dioxane dibromide (27)), Ni(PMe_3)$_4$ (28), and Ni(PPh_3)$_4$ (29) have been reported elsewhere.

IndNi(PPh_3)Br

A toluene solution (10 mL) of 1-Br-Ind (88 mg, 0.451 mmol) was added slowly to a stirring solution of Ni(PPh_3)$_4$ (500 mg, 0.451 mmol) in toluene (40 mL) at ambient temperature. The resultant red-brown mixture was stirred for 1 h after the addition and the solvent evaporated to dryness. The residue was washed with hexane (3 × 10 mL) to remove excess PPh_3 and other by-products, then dried under vacuum for a few hours to give the title compound as a brown powder (221 mg, 95%). Recrystallization of a small portion of this solid from a cold (–30 °C) toluene–hexane solution yielded crystals suitable for X-ray diffraction and elemental analysis. ^1H NMR (C_6D_6, 300.1 MHz) δ: 7.62 (m, PPh_3), 7.33 (br, H4/H7), 7.03 (br, H5/H6), 6.98 (m, PPh_3), 6.84 (br, H5/H6), 6.37 (t, J = 3 Hz, H2), 6.10 (br, $\Delta\nu_{1/2}$ = 20 Hz, H4/H7), 5.90 (br, $\Delta\nu_{1/2}$ = 21 Hz, H1), 3.55 (br, $\Delta\nu_{1/2}$ = 19 Hz, H3). $^{13}C\{^1H\}$ NMR (C_6D_6, 75.5 MHz) δ: 134.7 (d, J = 11 Hz, *o*-C of PPh_3), 133.0 (C5/C6), 132.6 (d, J = 44 Hz, *i*-C of PPh_3), 131.7 (C5/C6), 130.4 (d, J = 2 Hz, *p*-C of PPh_3), 128.8 (C3a/C7a), 126.4 (C3a/C7a), 120.8 (C4/C7), 117.1 (C4/C7), 103.0 (C2), 89.2 (C1), 73.0 (C3) ppm; the missing resonances for the *m*-C of PPh_3 are obscured under the residual solvent at ca. 128 ppm. $^{31}P\{^1H\}$ NMR (C_6D_6, 121.5 MHz) δ: 31.0 (s, PPh_3) ppm. Anal. calcd. for $C_{27}H_{22}NiPBr \cdot C_7H_8$ (toluene): C 67.15, H 4.97; found: C 67.23, H 4.97.

[8] HA is the angle between the planes formed by the atoms C(1), C(2), C(3) and C(1), C(3), C(3a), C(7a); FA is the angle between the planes formed by the atoms C(1), C(2), C(3) and C(3a), C(4), C(5), C(6), C(7), C(7a); ΔM-C = [1/2(M-C3a + M-C7a) – 1/2(M-C1 + M-C3)]. See ref. 22*c* for details.

Catalytic hydrosilylation of styrene

The catalytic runs were carried out on NMR scale, in C_6D_6 at ambient temperature for 18–21 h with a Ni–styrene–$PhSiH_3$ ratio of 1 : 50 : (50 or 100). In some runs, 10 equiv. of $NaBPh_4$ were used as an initiator for abstracting Br to generate the catalytically active Ni cation (25). The product of the catalysis was characterized on the basis of its ^1H NMR spectrum; the yields were determined as described previously (30).

Arene–perfluoroarene interactions in crystal engineering. Part 14. 1:1 Complexes of octafluoronaphthalene with fluorene and 9,10-dihydrophenanthrene[1,2]

Jonathan C. Collings, Andrei S. Batsanov, Judith A.K. Howard, and Todd B. Marder

Abstract: The 1:1 molecular complexes of octafluoronaphthalene (OFN) with fluorene (**1**) and with 9,10-dihydrophenanthrene (**2**) were prepared by cocrystallization of the components and characterized by single-crystal X-ray diffraction. The structure of **1** can be described as a mixed-stack or a laminar checkerboard motif of alternating OFN and fluorene molecules, whilst slanted mixed-stack, herringbone, and face-to-face heteromolecular dimer motifs can all be recognised in **2**.

Key words: single crystal, X-ray structure, π stacking, fluoroarene.

Résumé : Nous avons préparé les complexes moléculaires 1:1 de l'octafluoronaphtalène (OFN) avec le fluorène (**1**) et le 9,10-dihydrophénanthrène (**2**) par cocristallisation des constituants, et nous les avons caractérisés par diffraction des rayons X sur un cristal unique. La structure du composé **1** peut être comparée à celle d'un échiquier laminaire ou à un empilement mixte à motif de molécules d'OFN et de fluorène en alternance, alors que dans celle du composé **2** on peut reconnaître des motifs de dimères hétéromoléculaires inclinés en empilement mixte, en face à face et en chevrons.

Mots clés : cristal unique, détermination d'une structure par diffraction des rayons X, empilement π, fluoroarène.

[Traduit par la Rédaction]

Introduction

Arenes and perfluoroarenes have been known for over 40 years to form complexes with each other. The simplest example is the complex formed between benzene and hexafluorobenzene (HFB), which has a crystal structure composed of infinite stacks of alternating benzene and HFB molecules (2), in contrast to the crystal structures of the pure component molecules that are arranged in a herringbone fashion (3). Similar stacked arrangements occur in complexes of HFB with various benzene derivatives and related molecules (4), or in complexes of octafluoronaphthalene (OFN) with various fused-ring polyaromatic molecules (5, 6), tolan (diphenylethyne) (7), biphenyl (8), biphenylene (8), TTF (9), sulfur–nitrogen containing molecules (both acyclic and heterocyclic) (10), etc. Almost always, the components cocrystallize to acquire, spontaneously, a 1:1 stoichiometry, although OFN has also been shown to form a 3:2 complex with ferrocene in which some of the OFN molecules do *not* take part in stacking (11). The mixed-stack motif seems remarkably robust and able to absorb much distortion. Thus, the OFN·naphthalene (5), OFN·acenaphthene (12), and OFN·1,8-diaminonaphthalene (13) complexes form isomorphous crystals, notwithstanding substantial differences in the shapes of arene molecules. Indeed, the latter complex adopts the stacked structure in spite of it being singularly unsuitable for hydrogen bonding.

The causes of such complexation are still under debate. One hypothesis, suggested long ago (14) and recently supported by DFT calculations on the crystal lattices (4*b*), explains parallel stacking of arene and perfluoroarene molecules by electrostatic effects, C—H and C—F bonds having substantial polarity in the opposite sense. Calculations of isolated dimers show that although van der Waals energy contribution is larger than the electrostatic energy contribution (15), it is the latter that makes heterodimers more stable than homodimers (16). On the other hand, Dunitz (16) emphasised the importance of dispersion interactions, and therefore of the anomalously low atomic polarizability of fluorine.

It has been suggested that intermolecular H···F attractions (weak hydrogen bonds) play a significant role in stabilizing the structures (4*a*, 17). Dunitz pointed out that the same reasoning should apply to alkanes and perfluoroalkanes, which

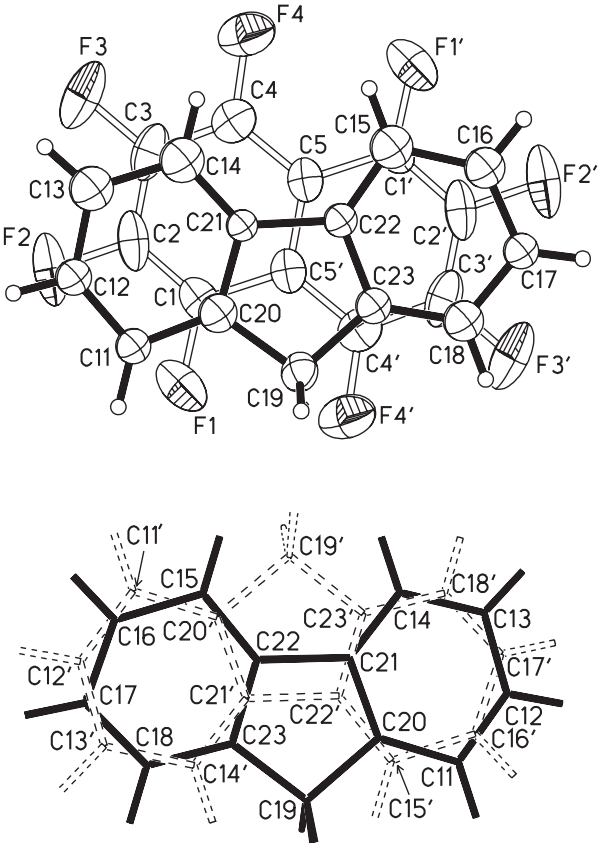
in fact have negative mixing enthalpy and neither mix in the liquid state nor cocrystallize (16). Indeed, partially fluorinated alkanes crystallize in such fashion that fluorinated and non-fluorinated parts form segregated domains in the crystal (18). All this suggests a (relatively) nonstabilizing character of C-H···F interactions. However, gas-phase spectroscopic studies have shown that $CH_3F \cdot CHF_3$, $CH_2F_2 \cdot CH_2F_2$, and similar dimers are held together exclusively by C-H···F bridges (19).

To clarify this topic requires, inter alia, testing the limits of stability of the mixed-stack motif, and of the face-to-face arene–perfluoroarene synthon generally, against various steric distortions. In particular, all previously studied molecules were either entirely planar or planar except for a few hydrogen atoms. In the present work, we have studied complexation of OFN with planar (except for two methylene H atoms) fluorene and with rigidly nonplanar 9,10-dihydrophenanthrene.

Experimental

Synthesis

Octafluoronaphthalene (Bristol Organics), fluorene, and 9,10-hydrophenanthrene were tested for purity by GC–MS and used without further purification. GC–MS was carried out using a Hewlett-Packard HP-5890 series II gas chromatograph equipped with a HP-5971A mass selective detector. A 12 m fused silica (5% crosslinked phenylmethylsilicone) capillary column was used with UHP helium as the carrier gas.



Single crystals of OFN·fluorene (**1**) were obtained as regular blocks by slow evaporation of a solution containing OFN (0.1 mmol) and fluorene (0.1 mmol) in 1 mL of dichloromethane (DCM). Single crystals of OFN·9,10-dihydrophenanthrene (**2**) were obtained by slow evaporation of a solution containing OFN (0.1 mmol) and 9,10-dihydrophenathrene (0.1 mmol) in 1 mL of DCM. Elemental analyses and melting points are presented in Table 1.

X-ray crystallography

X-ray diffraction experiments were carried out on Bruker 3-circle diffractometers with APEX ProteumM (**1**) or SMART 6K (**2**) CCD area detectors, using graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å) from a 60 W microfocus Bede Microsource® with glass polycapillary optics (**1**) or a sealed tube (**2**). The crystals were cooled to 120 K using Cryostream (Oxford Cryosystems) open-flow N_2 cryostats. The structures were solved by direct methods and refined by full-matrix least-squares against F^2 of all data, using SHELXTL software (20). In **1**, all atoms of the OFN molecule were easily located and refined in anisotropic mode, but the Fourier map in the plane midway between the OFN planes showed a blurred pattern, which was rationalized by fitting a fluorene molecule of the literature dimensions (and hence its inversion equivalent) with 50% occupancy. This molecule was refined initially as a rigid body, then all C atoms were refined independently in isotropic approximation with all H atoms included in the "riding" model. The lengths of the C—C bonds related by the *molecular* twofold symmetry were constrained to be identical. All non-H atoms of the molecule proved coplanar within experi-

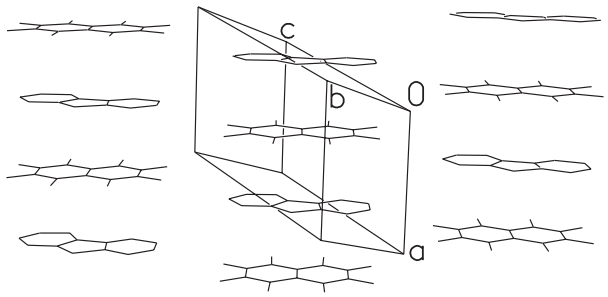
Fig. 1. Top: The molecules of OFN and fluorene (one possible position) in the structure of **1**, viewed down the *a* axis; bottom: disorder of the fluorene molecule. Primed atoms are generated by inversion centres; thermal ellipsoids are drawn at the 50% probability level.



mental error; the mean plane passes through the inversion centre, which falls within the five-membered ring; hence, the alternative position of the molecule lies in the same plane. In **2**, all C and F atoms were refined in anisotropic mode, and all H atoms were located in a difference Fourier map and refined in isotropic approximation. Crystal data and other experimental details are listed in Table 1.[4]

Results and discussion

In both cases, cocrystallization gave the usual 1:1 stoichiometry. The structure of **1** contains infinite stacks of alternating OFN and fluorene molecules, which overlap as shown in Fig. 1. The asymmetric unit comprises half of the chemical formula unit. The OFN molecule has crystallographic C_i symmetry, whereas the fluorene molecule is statistically disordered between two overlapping positions related by an inversion centre (Fig. 1). Such disorder of fluorene has been observed in its cocrystals with

Fig. 2. Crystal packing of complex **1** (H atoms are omitted).

trinitrobenzene (21*a*) and various tetracyano-substituted molecules (21*b*), and phenanthrene is similarly disordered in its complex with OFN (6). Both the OFN and fluorene molecules are planar within experimental error (cf. fluorene is folded by 1.3° in its pure solid (22)), and their mean planes are parallel within 1.6(1)°. The two alternative positions of the disordered fluorene molecule are also coplanar within experimental error. The structure being triclinic implies that all molecules in the crystal are parallel within this range. The mean direction of the stack is parallel to the crystallographic *a* axis and nearly normal to the molecular planes, forming an angle of 85.6(1)° with the OFN plane and 87.3(1)° with the fluorene plane, i.e., the stack is practically columnar rather than slanted. All interplanar separations (*d*) in the stack are uniform, of 3.39 Å. Not surprisingly, the shortest intermolecular contact within a stack (C(19)-H···F4 of 2.53 Å) involves an out-of-plane methylene H atom.

The stacks are combined in the crystal in such a way that each fluorene molecule is closer to OFN than to fluorene molecules of adjacent stacks (Fig. 2). Therefore, the structure can be alternatively described as laminar, containing 2D sheets wherein each fluorene molecule is surrounded by six OFN molecules and vice versa. The sheets are substantially puckered; adjacent (dissimilar) molecules are not strictly coplanar but are shifted above or below the sheet plane by *d*/3. Nevertheless, such packing results in a number of close intermolecular C-H···F contacts (Fig. 3). Whereas the sum of van der Waals radii (23) of F and H is 2.56 Å, structure **1** contains six symmetrically independent interstack distances in the range 2.49–2.60 Å (but none between 2.60 and 2.68 Å), and two even shorter contacts, of 2.31 and 2.41 Å, respectively.[5]

The asymmetric unit of OFN·9,10-dihydrophenanthrene (**2**) is identical with the formula unit, both component molecules having no crystallographic symmetry (Fig. 4). The 9,10-dihydrophenanthrene molecule contains two planar fragments, each comprising a benzene ring with an adjacent methylene carbon atom. The dihedral angle between these moieties is 19.5(1)° (cf. 20.7° in the pure solid 9,10-dihydrophenanthrene (25)), hence, it is meaningless to refer to the mean plane of this molecule. Unlike biphenyl (8), dihydrophenanthrene cannot be easily planarized by

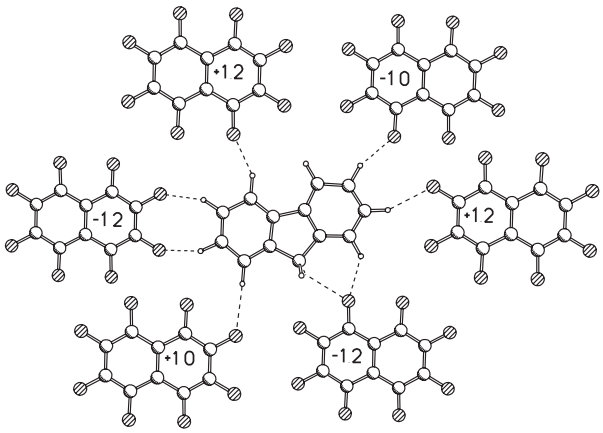
Fig. 3. Laminar packing in structure **1**, showing the distances of OFN molecules from the fluorene plane and H···F contacts of <2.6 Å.



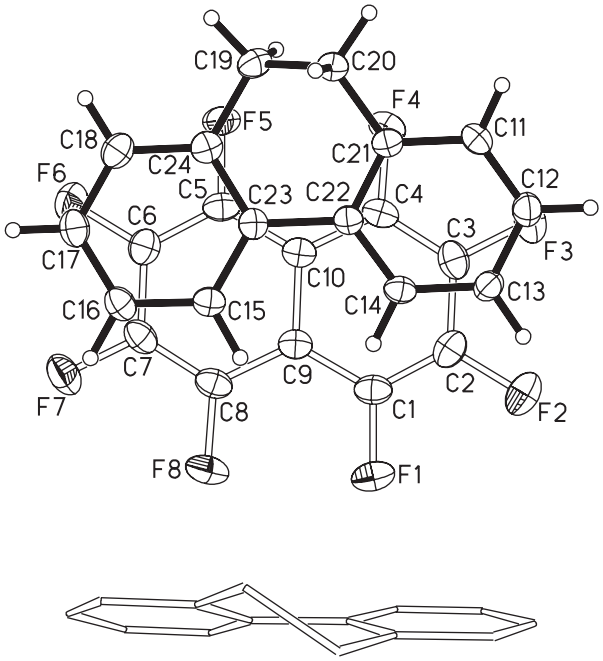


Fig. 4. Top: The molecules of OFN and 9,10-dihydrophenathrene in the structure of **2**, projection on the OFN plane. Bottom: Conformation of the 9,10-dihydrophenathrene molecule (H atoms are omitted).

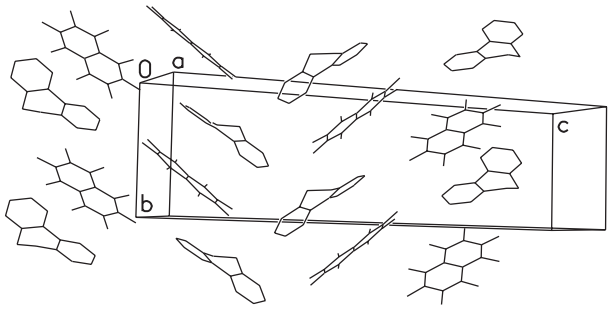
intermolecular forces, thus its combination with the essentially planar OFN results in an awkward packing motif (Fig. 5) that cannot be described by any simple scheme. One can distinguish a strongly slanted stack, or rather a "ladder" of face-to-face heteromolecular dimers. In the dimer, the central C(21)—C(22) bond of the dihydrophenanthrene is parallel to the OFN plane within 3.3(1)°, and the two benzene rings are inclined to this plane by 17.0(1)° and 5.5(1)°. Contacts between the stacks resemble a distorted herringbone pattern with the dihedral angles of 48.3(1)° between contacting OFN molecules. Each dihydrophenanthrene molecule forms seven H···F contacts in the 2.40–2.60 Å range: six in-plane (Fig. 6) and one between stacked molecules, but no such contacts in the 2.60–2.71 Å range.

Fig. 5. Crystal packing of complex **2** (H atoms are omitted).



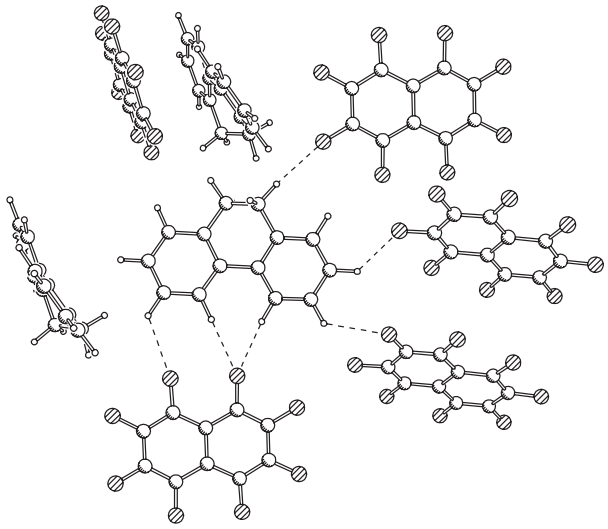


Fig. 6. H···F contacts (≤2.6 Å) in the structure of **2**.

Thus, the crystal packing of **1** is similar to those observed between OFN and *planar* arenes (while contrasting starkly with the herringbone packing of both pure OFN (10) and pure fluorene (22)), especially in the OFN·pyrene complex, which also crystallizes in the space group $P\bar{1}$ with $Z = 1$ and with roughly similar lattice parameters. In the latter, the site occupied by the disordered fluorene molecule in **1** is taken by an ordered pyrene molecule that possesses a crystallographic inversion centre. The molecular volume of OFN·pyrene (477 Å^3) is only 27 Å^3 larger than that of **1**, although the usual rule of 18 Å^3 per non-hydrogen atom requires a difference twice as big. Thus, fluorene does produce a somewhat looser packing, although it is not clear whether it is the effect of the disorder or of the out-of plane hydrogen atoms. In any case, the structure of **1** (and also of OFN·acenaphthene (12)) shows that the latter do not disrupt the typical mixed-stack pattern of arene–perfluoroarenes substantially. On the contrary, the constrained nonplanarity of the 9,10-dihydrophenanthrene molecule causes a complete departure from this pattern and an evident thermodynamic destabilization of the cocrystal, as indicated by its much lower melting point (Table 2). Most arene–perfluoroarene complexes, beginning with the seminal $C_6F_6{\cdot}C_6H_6$, have higher melting points than either of the components (although there are exceptions). Whereas complex **1** conforms to this rule, **2** has a melting point only slightly higher than that of the mean of the components.

Table 2. Melting temperatures (T_m, °C) of arene–perfluoroarene complexes.

	T_m			
Complex Φ·A	A	Φ	A·Φ	ΔT_m
$C_6F_6 \cdot C_6H_6$	5.4	5.0	23.7	18.5
OFN·naphthalene (5)	81	87	132	48
OFN·pyrene (6)	156	87	249	127.5
OFN·biphenyl (8)	71	87	97	18
OFN·biphenylene (8)	110	87	148	49.5
OFN·acenaphthene (12)	96	87	162	81
OFN·phenanthrene (6)	101	87	173	79
OFN·fluorene (**1**) (this work)	116	87	133	31.5
OFN·9,10-dihydrophenanthrene (**2**) (this work)	32.5	87	54	6

Note: $\Delta T_m = T_m(A \cdot \Phi) - 1/2[T_m(A) + T_m(\Phi)]$.

Conclusions

This study has confirmed that arene–perfluoroarene complexes are formed between OFN and two constrained biphenyl derivatives, the planar fluorene and nonplanar 9,10-dihydrophenathrene. However, the packing arrangements of the two complexes differ significantly, in that the OFN·fluorene structure comprises infinite stacks of approximately planar molecules, whereas the OFN·dihydrophenanthrene structure consists of a herringbone arrangement of OFN–dihydrophenanthrene dimers. The cause of this discrepancy is postulated to be due to the rigid nonplanarity of the dihydrophenanthrene molecules. In both structures, there are close intermolecular H···F contacts.

Formation and X-ray structure of the host–guest adduct $[Pd_3(dppm)_3(CO)(NO_3)]^+$ and the mechanism of its electrochemical reduction[1]

David Brevet, Dominique Lucas, Philippe Richard, Alain Vallat, Yves Mugnier, and Pierre D. Harvey

Abstract: $[Pd_3(dppm)_3(CO)]^{2+}$, $[Pd_3]^{2+}$, reacts with NO_3^- to form the host–guest adduct $[Pd_3(dppm)_3(CO)(NO_3)]^+$, $[Pd_3(NO_3)]^+$. The presence of NO_3^- inside the cavity is confirmed by X-ray crystallography. Using a qualitative relationship between λ_{max} (UV–vis) and the association constant of various adducts, the relative binding between NO_3^- and $[Pd_3]^{2+}$ is in the same order of magnitude of that between $CF_3CO_2^-$ and $[Pd_3]^{2+}$. Based on Pd···O distances, the NO_3^- ion is relativity more weakly associated to $[Pd_3]^{2+}$ in comparison with the known $[Pd_3(CF_3CO_2)]^+$. Using variation of $[NO_3^-]$ in the presence of $[Pd_3](PF_6)_2$ and variation of scan rates, the resulting cyclic voltammogramms (CV) were simulated to extract both kinetic and thermodynamic constants associated to a square scheme. Both the anodic and cathodic scans of the title cluster exhibits ECE mechanisms (E = electrochemical process; C = chemical process). For the anodic scan, the EEC event is not ruled out, at least as a minor process.

Key words: nitrate, palladium cluster, adduct, electrochemistry, X-ray structure, rate constant, equilibrium constant.

Résumé : Le $[Pd_3(dppm)_3(CO)]^{2+}$, $[Pd_3]^{2+}$ réagit avec l'anion NO_3^- pour former l'adduit hôte–invité $[Pd_3(dppm)_3(CO)(NO_3)]^+$, $[Pd_3(NO_3)]^+$. La présence de l'anion NO_3^- dans la cavité est confirmée par diffraction des rayons X. Utilisant une relation qualitative entre λ_{max} (UV–vis) et la constante d'association de divers adduits, on a déterminé que les fixations relatives entre NO_3^- et $[Pd_3]^{2+}$ sont du même ordre de grandeur que celles entre $CF_3CO_2^-$ et $[Pd_3]^{2+}$. Sur la base des distances Pd···O, l'ion NO_3^- est associé relativement plus faiblement au $[Pd_3]^{2+}$ que dans le produit connu $[Pd_3(CF_3CO_2)]^+$. Utilisant une variation de la concentration de NO_3^- en présence de $[Pd_3](PF_6)_2$ et une variation des vitesses de balayage, on a pu simuler les voltampérogrammes cycliques pour en tirer les constantes cinétiques ainsi que thermodynamiques associées à un schéma carré. Les balayages tant anodique que cathodique de l'agrégat mentionné dans le titre présentent tous les deux des mécanismes ECE (E = processus électrochimique; C = processus chimique). Pour le balayage anodique, il n'est pas possible d'éliminer la possibilité d'un processus EEC, au moins comme processus mineur.

Mots clés : nitrate, agrégat de palladium, adduit, électrochimie, détermination de structure par diffraction des rayons X, constante de vitesse, constante d'équilibre.

[Traduit par la Rédaction]

Introduction

The use of NO_3^- in electrosynthesis is well-known (1–3) and involves the electrochemical one-electron oxidation to generate the highly reactive intermediate $NO_3^{\cdot}$ via the reaction, $NO_3^- \rightarrow NO_3^{\cdot} + 1\ e^-$. Its properties, whether it reacts with itself or with organics are also well-documented (4–7). The possibility of mediating the electrochemical one-electron oxidation of NO_3^- via a transition metal complex intermediate is interesting, if the oxidation potential to perform this reaction occurs at a lower potential than that of NO_3^- alone. We have recently extensively explored the electrochemical and electrocatalytic properties of the unsaturated cluster, $[Pd_3]^{2+}$ (8–12). The NO_3^- ion can exhibit multiple forms of binding onto metal atoms (13–18). On the other hand, host–guest association complexes of an anion inside the cavity of a metal-containing host are scarce (19). The $[Pd_3]^{2+}$ cluster is one of the rare examples of a host capable of accepting anions inside its cavity formed by the dppm–phenyl groups above the Pd_3 plane (anion = $PO_2F_2^-$ (9),

$CF_3CO_2^-$ (20), PF_6^- for $[Pd_3(dpam)_3(CO)]^{2+}$, where dpam = $(Ph_2As)_2CH_2$ (21)). In relation with the comments made above, the structural analysis of the title cluster, $[Pd_3(NO_3)]^+$, along with analysis of the electrochemical properties, both in oxidation and reduction, are in order. We now wish to report the X-ray structure of $[Pd_3(NO_3)]^+$ and its behaviour upon its reduction by cyclic voltammetry (CV) and rotating disk electrode (RDE). The overall results are interpreted with a six-member square scheme (in which one species is absent or not observed), and the CV and RDE are simulated to extract the reaction rates and equilibrium constants for NO_3^- dissociation in $[Pd_3(NO_3)]^{n+}$ (n = 1 or 0).

Experimental section

Materials

$[Pd_3(dppm)_3(CO)](PF_6)_2$ was prepared according to a literature procedure (20). NBu_4NO_3 was purchased from Fluka and was used as received. Tetrahydrofuran (THF) was distilled under Ar over Na and benzophenone, while CH_2Cl_2 was distilled over P_2O_5. The supporting electrolyte used in each experiment was NBu_4PF_6 (Aldrich). The salt was recrystallized twice in ethanol and dried at 80 °C for at least 2 days before use.

Preparation of ($[Pd_3(dppm)_3(CO)(NO_3)](PF_6)$

The $[Pd_3(dppm)_3(CO)](PF_6)_2$ starting material (10.4 mg, 0.005 81 mmol) was added to a degassed THF solution (10 mL). A mother solution of 177 mg (0.582 mmol) of NBu_4NO_3 in THF (1 mL) was prepared. Ten microlitres of this solution (corresponding to 1 equiv. of NBu_4NO_3) was added to the $[Pd_3(dppm)_3(CO)](PF_6)_2$ solution, which was stirred for 15 min. The deep red solution turned brown immediately. UV–vis (THF, nm) λ: 480. IR (KBr, cm^{-1}) ν(CO): 1816. ^{1}H NMR (acetone-d_6, ppm) δ: 5.08, 4.80 (m, ^2J (H^aH^b) = 14.09 Hz, ($CH^aH^bP_2$)). ^{31}P NMR (acetone-d_6, ppm) δ: –6.93. Anal. calcd. for $C_{76}H_{66}O_1P_6Pd_3{\cdot}(NO_3)_{1.3}(PF_6)_{0.7}{\cdot}1THF{\cdot}1.33H_2O$: C 53.64, H 4.31, N 1.02; found: C 53.23, H 4.48, N 1.07. The presence of THF and H_2O molecules was confirmed by ^{1}H NMR. Additionally, the presence of THF was also observed in the X-ray structure.

Electrochemical experiments

All manipulations were performed using Schlenk techniques in an atmosphere of dry, oxygen-free argon gas. The supporting electrolyte was degassed under vacuum before use and then solubilized at a concentration of 0.2 mol/L. For cyclic voltammetry experiments, the concentration of the analyte was nearly 10^{-3} mol/L. Voltammetric analyses were carried out in a standard three-electrode cell with a EG&G Princeton Applied Research (PAR) model 273A potentiostat, connected to an interfaced computer employing Electrochemistry Power Suite software. The reference electrode was a saturated calomel electrode (SCE) separated from the solution by a sintered glass disk. The auxiliary electrode was a platinum wire. For all voltammetric measurements, the working electrode was a vitreous carbon electrode (ϕ = 3 mm). In these conditions, when operating in THF, the formal potential for the ferrocene$^{\pm}$ couple was found to be +0.56 V vs. SCE.

Digital simulation

The computations were performed using the commercially available program called Digisim (Bioanalytical Systems). The potential increase was set to 10 mV. The uncompensated resistance, here R_u = 1500 Ω, was determined with a PAR 373A potentiostat using the same experimental conditions as for the CV measurements. The double-layer capacitance value was estimated as Cdl/A = 10^{-4} F cm^{-2} using a blank solution prior to voltammetric measurements. The experimental curves were corrected for residual current, also determined using voltammetric measurements of blank solutions.

Crystallography

Crystal suitable for X-ray analysis were obtained from slow diffusion between ether and a THF solution containing the adduct. Data was collected with a Nonius Kappa CCD diffractometer at 110 K. The structure was solved in the $P2_1$ space group via a Patterson search program and refined with full-matrix least-squares methods based on F^2 (SHELX-97) (22) with the aid of the WINGX (23) program. Except for one disordered THF solvate molecule, all non-hydrogen atoms were refined with anisotropic thermal parameters. All H atoms were placed in idealized positions and refined using a riding model [Uiso(H) = 1.2Ueq(C)]. One of the two THF molecules is disordered, the oxygen atom occupies several positions of the ring, and this molecule was modelized by a five-carbon ring with an overall isotropic temperature factor and a common restrained variable C—C distance. The Flack parameter converged to 0.65(2) and could suggest a racemic twin. Table 1 presents a summary of the crystal data, data collection, and refinement parameters.[4]

Results and discussion

Adduct formation

The addition of NBu_4NO_3 to $[Pd_3](PF_6)_2$ induces a PF_6^-/NO_3^- metathesis. Because of the planar geometry and smaller size of NO_3^-, this anion should be trapped by the dppm cavity, hence converting $[Pd_3](PF_6)_2$ into the desired adduct $[Pd_3(NO_3)](PF_6)$. Because of the excess of NO_3^- ion used, some of the counter ion (PF_6^-) was also exchanged based on the chemical analysis. Full exchange into $[Pd_3(NO_3)](NO_3)$ or precise conversion into $[Pd_3(NO_3)](PF_6)$ were unsuccessfully attempted several times, and no further effort was made. It was not necessary for this work since we were only interested in the X-ray structure of the $[Pd_3(NO_3)]^+$ adduct. Nonetheless, from the analysis (and ^{1}H NMR spectra), the formulation $[Pd_3(dppm)_3(CO)(NO_3)](NO_3)_{0.3}(PF_6)_{0.7}{\cdot}THF{\cdot}1.3H_2O$ is obtained for the sample that provided crystals suitable for X-ray studies. Indeed, X-ray crystallography and electrochemistry confirm the presence

of NO_3^- in the cavity. THF is also found in the lattice as solvate molecule (Experimental section). The electrochemical studies were performed with $[Pd_3](PF_6)_2$.

The UV–vis spectrum of $[Pd_3(NO_3)]^+$ in THF is compared to $[Pd_3]^{2+}$ and other adducts in Table 2. The previously reported binding constants (K_1) for the $[Pd_3(X)]^+$ adducts indicate that the interactions increase as $PF_6^- < CF_3CO_2^- < Cl^- < Br^- < I^-$ (20, 21, 24). Interestingly, λ_{max} follows the same trend in reverse order: 496 > 484 > 463 > 459 > 456 nm, respectively, and can serve as a qualitative tool to compare the relative strength of $Pd_3^{2+}\cdots X^-$ interactions. The λ_{max} for $[Pd_3(NO_3)]^+$ is 480 nm, which indicates that the binding strength of NO_3^- is similar to that of $CF_3CO_2^-$. This trend is qualitative because of the broadness of the bands.

X-ray structure

The X-ray data and selected bond distances and angles are presented in Tables 1 and 3. An ORTEP representation is shown in Fig. 1. The NO_3^- ion is placed inside the cavity where the closest distance (Pd···O) is 2.801 Å ($Pd_1\cdots O_2$), which is indicative of electrostatic interactions. The skeleton bond distances are normal as compared to other $[Pd_3(X)]^+$ adducts (Table 4). The O-N-O angles are 118.45° (O_4NO_2), 119.06° (O_2NO_3), and 122.46° (O_4NO_3), and the N—O distances are 1.224 Å (N—O_4), 1.245 Å (N—O_2), and 1.248 Å (N—O_3). There is an obvious deviation from the expected ideal triangular structure, which seems to be associated with steric interactions between the NO_3^- ion and the phenyl groups (Fig. 1). The 2.801 Å distance for Pd···O interactions is longer than that for the $CF_3CO_2^-$ adduct (shortest Pd···O distances are 2.752 and 2.682 Å) (20). The weaker host–guest interactions deduced from X-ray data are entirely consistent with the residual charge on each oxygen atom (1/2 and 1/3 for $CF_3CO_2^-$ and NO_3^-, respectively), reinforcing the electrostatic model.

Electrochemistry

Our group has previously investigated the electrochemical behaviour of $[Pd_3]^{2+}$ (25) and $[Pd_3(X)]^+$ (X = Br (10), I (26)). The CV of $[Pd_3](PF_6)_2$ in a mixture of THF–NBu_4PF_6

(0.2 mol/L) (Fig. 2) exhibits the two electrochemically reversible one-electron reduction waves A_1/A_1' and A_2/A_2' at $E_{1/2}$ = –0.29 and –0.54 V vs. SCE ($E_{1/2} = 0.5(E_{pa} + E_{pc})$; E_p = peak potential, a = anodic, c = cathodic), respectively. THF is used for comparison purposes with previous works (10, 25, 26). The addition of 1 equiv. of NBu_4NO_3 slightly modifies the reduction waves witnessing quantitative formation of $[Pd_3(NO_3)]^+$ according to (eq. [1]).

[1] $$[Pd_3]^{2+} + NO_3^- \rightarrow [Pd_3(NO_3)]^+$$

Both reduction waves are still eletrochemically reversible, but a new reduction wave system (A_3/A_3') appears at $E_{1/2}$ = –0.357 V vs. SCE at the expense of the current intensity of wave (A_1/A_1'). Using spectroscopy, this reaction is easily monitored. The UV–vis spectra exhibit the disappearance of the 496 nm band characteristic to $[Pd_3]^{2+}$ and the appearance of the 480 nm band of the $[Pd_3(NO_3)]^+$ adduct. For ^{31}P NMR, the –3.43 ppm resonance of $[Pd_3]^{2+}$ is replaced by the new one at –6.93 ppm associated with $[Pd_3(NO_3)]^+$. Further addition of NO_3^- ions induces further modification of the CV. System A_3/A_3' moves towards more negative potentials. This can be explained by the EC (E = electrochemical process; C = chemical process) process for the reduction step, where the chemical step corresponds to the dissociation (eq. [2]).

[2] $$[Pd_3(NO_3)]^0 \rightleftharpoons [Pd_3]^+ + NO_3^-$$

In the presence of excess NO_3^- the equilibrium is shifted to the left, so the reduction of $[Pd_3(NO_3)]^+$ becomes more difficult. In an excess of NO_3^-, the system A_3/A_3' super-

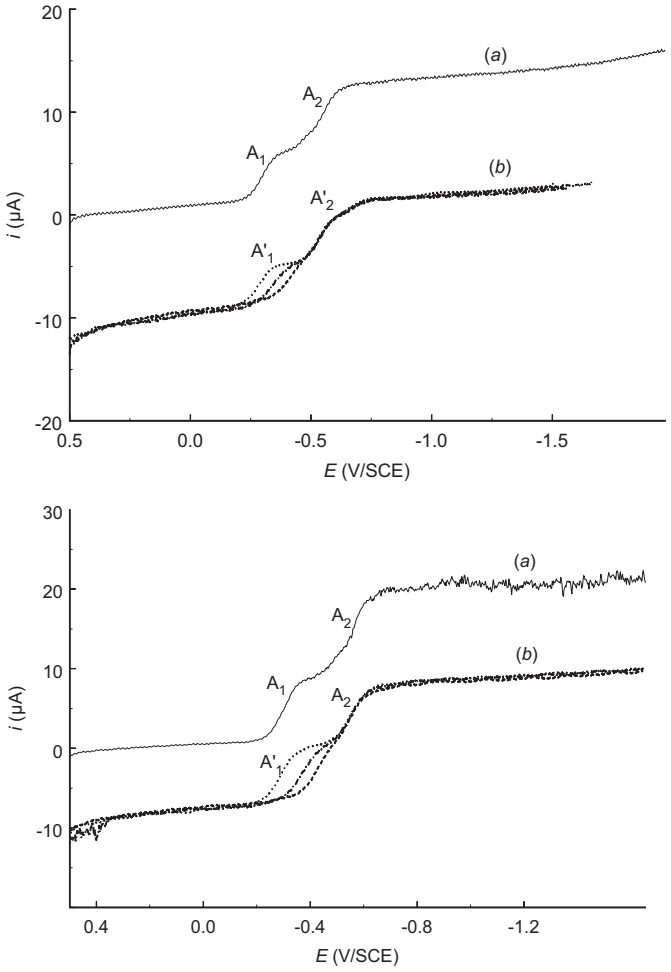
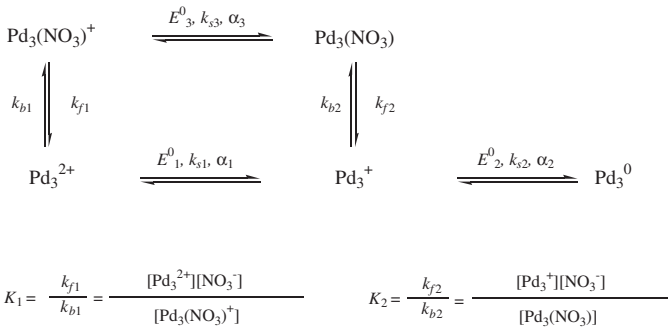
Fig. 2. CV of $[Pd_3]^{2+}$ in THF–NBu_4PF_6 (0.2 mol/L) in the presence of 0, 1, 10, 50, and 200 equiv. of NO_3^- anions. Initial potential: 0 V. Scan rate: 50 mV s^{-1}.



poses wave A_2/A'_2, which makes the evolution of E°_3 impossible from direct measurements in the CV traces.

The reactivity of NO_3^- towards the electrogenerated species $[Pd_3]^+$ and $[Pd_3]^0$ was also investigated. $[Pd_3]^0$ exhibits two oxidation waves, A'_1 and A'_2. In the presence of NO_3^-, no modification of wave A'_2 occurs, but wave A_1' shifts towards more negative potentials. This behaviour indicates that $[Pd_3]^0$ is stable in the presence of NO_3^-. For the second oxidation wave, a clear curve modification is observed with the change in $[NO_3^-]$, demonstrating that an EE mechanism operates in the absence of NO_3^- anion, but becomes an ECE process in the presence of this anion. A similar behaviour is also observed with the electrogenerated $[Pd_3]^+$ species, which exhibits wave A_2 and A'_1 (Fig. 3, bottom).



Both CV and RDE were simulated to establish the reduction mechanism and to extract the kinetic and thermodynamic parameters based on a six-member square scheme (Scheme 1). The $[Pd_3(NO_3)]^-$ species does not exist in this work, so this member is not represented.

(Bottom graph): RDE voltammogramms of: (*a*) $[Pd_3]^{2+}$; (*b*) (solid line) after one-electron reduction and formation of $[Pd_3]^0$; (b_1) (dashed line) in the presence of 1 equiv. of NO_3^-; (b_2) (dotted line) in the presence of 10 equiv. of NO_3^-.

Scheme 1.

The standard potentials (E_1^o and E_2^o), the heterogeneous rate constants (k_{s1} and k_{s2}), the charge transfer coefficients (α_1 and α_2), and the diffusion constant for $[Pd_3]^{2+}$ were evaluated previously (26). The potential E_3^o is not obtained as the potential is influenced by the chemical process. To estimate this value for E_3^o, the following experiments and comparisons were performed.

Table 5. Comparison of $E_{1/2}(A_1/A_1')$ and $E_{1/2}(A_2/A_2')$ of Pd_3^{2+} + NO_3^- in THF and CH_2Cl_2 (V vs. SCE).

Potential	THF (V)	CH_2Cl_2 (V)
$E_{1/2}(A_1/A_1')^a$	–0.298	–0.362
$E_{1/2}(A_3/A_3')^a$	–0.357	–0.410

[a]SCE as reference electrode.

In CH_2Cl_2, the CV exhibits a better separation of the A_2/A_2' and A_3/A_3' waves (eqs. [3] and [4]). The CVs are no longer modified when 250 equiv. of NO_3^- ion are added. In this solvent, $E^o_{(A_3/A_3')} = E_{1/2} = -0.564$ V. By assuming that the potential difference between wave A_1/A_1' and wave A_3/A_3' remains the same for THF and CH_2Cl_2, we can approximatively evaluate E_3^o for $[Pd_3(NO_3)]^+$.

[3] $[Pd_3]^{2+} + 1\ e^- \rightleftharpoons [Pd_3]^+\ A_1/A_1'$

[4] $[Pd_3(NO_3)]^+\ 1\ e^- \rightleftharpoons [Pd_3(NO_3)]\ A_3/A_3'$

The comparison was also made for $[Pd_3]^{2+}$ + 1 equiv. of NO_3^- in THF and in CH_2Cl_2. This comparison of $E_{1/2}(A_1/A_1')$ and $E_{1/2}(A_3/A_3')$ is shown in Table 5. The differences between $E_{1/2}(A_1/A_1')$ and $E_{1/2}(A_3/A_3')$ in THF and CH_2Cl_2 are 0.064 and 0.053 V, respectively. The fact that these values are similar is reassuring. In the presence of 250 equiv. of NO_3^-, $E°(CH_2Cl_2)$ is –0.564 V. By subtracting these values (0.064 and 0.053 V) from –0.564 V, we can then estimate $E° = E_{1/2}(A_3/A_3')$ for $[Pd_3(NO_3)]^+$ in THF (–0.500 V if 0.064 is used, and –0.511 V if 0.053 is employed). At best fits, the simulations predicted $E° = E_{1/2}(A_3/A_3') = -0.515$ V vs. SCE in THF (see the following and Table 6). The transfer coefficient (α_3) was arbitrarily set at 0.5 for the simulation, a value typical for this type of system. The fits were performed with seven variables (k_{s1}, k_{s2}, k_{s3}, K_1, K_2, k_{f1}, and k_{f2}; see Scheme 1 for their description) and were tested against curves that were measured at various $[NO_3^-]$ and scan rates. The variables k_{s1}, k_{s2}, and k_{s3} were generally observed within a small window (Table 6). These seven variables were extracted at best fits (Tables 6 and 7 and Fig. 4), except for k_{f1}, which turned out to have no effect on the computed curves in the explored window ($v <$ 500 mV s^{-1}). The diffusion constant was determined by RDE to be 4×10^{-6} cm^2 s^{-1}.

The cathodic scan is described by an ECE mechanism since the reduction of the $[Pd_3(NO_3)]^0$ species was not observed. This contrasts with the mechanism determined for the stronger $[Pd_3(I)]^+$ adduct (26). For the anodic scan, one must consider two possibilities, ECE and EEC mechanisms. No shift should be observed for the A_2/A_2' wave in an EEC process, while a shift toward more negative potentials should be observed for an ECE mechanism. Experimentally, the ECE mechanism was observed for both anodic and cathodic scans (i.e., there was a shift for both cases). This observation was confirmed from the curve simulation, particularly from the comparison of the K_1 and K_2 values ($K_1 << K_2$). For the anodic scan, the EEC mechanism is not excluded, but must be a minor process if it is present.

Fig. 4. Simulations (solid line) and experimental (symbols) CVs for $[Pd_3(NO_3)]^+$ in THF–Bu_4NPF_6 (0.2 mol/L). (*a*) Alone; (*b*) with 10 equiv. of NO_3^-; (*c*) with 50 equiv. of NO_3^-; (*d*) with 200 equiv. of NO_3^-. Initial potential: 0 V. Scan rate: 50 mV s^{-1}.

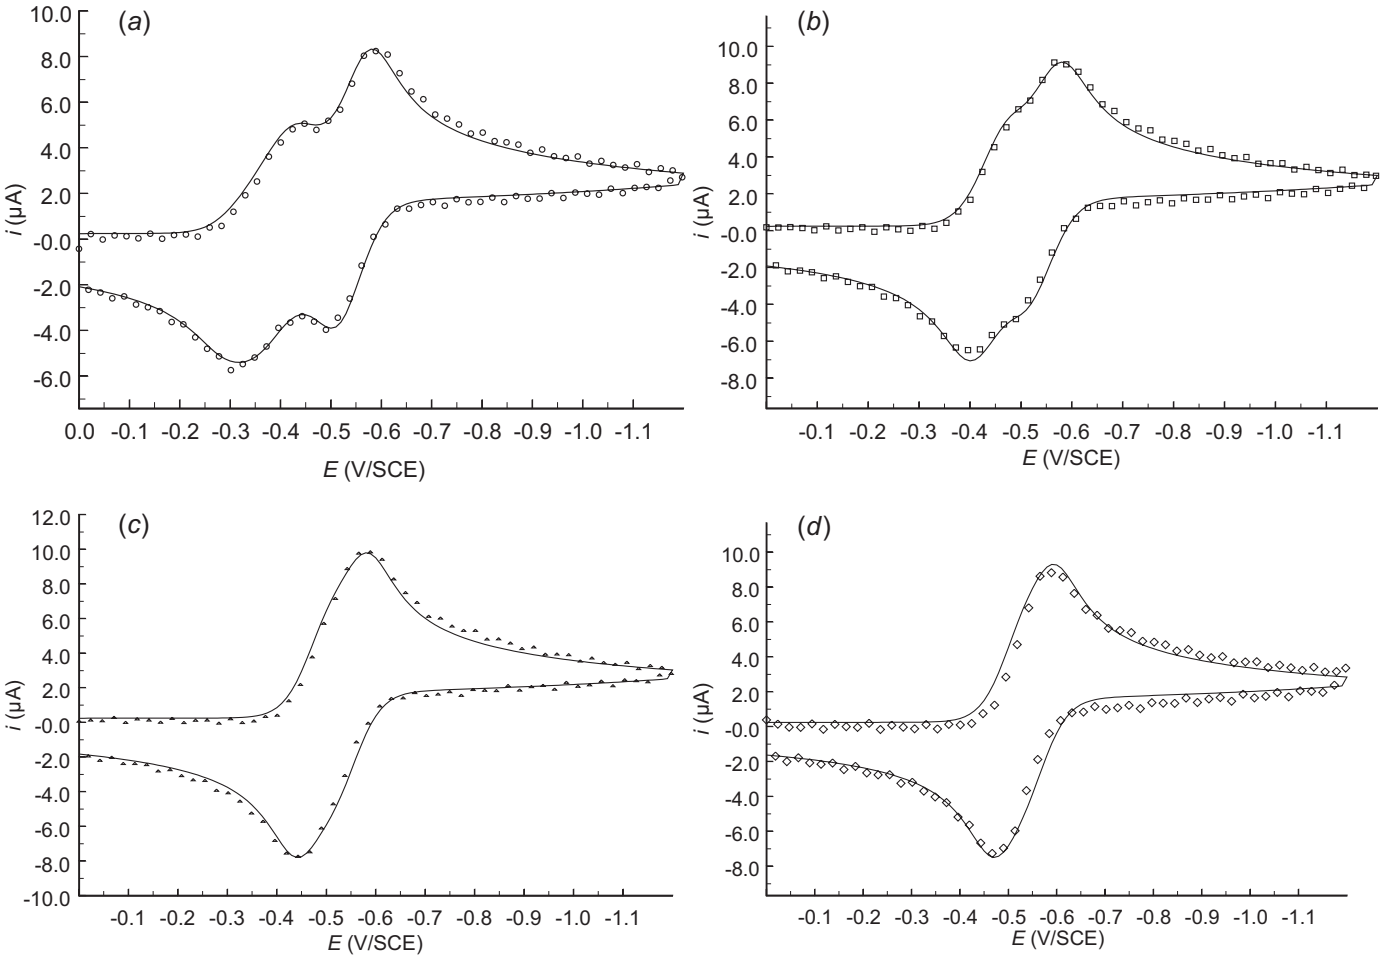

Table 6. Input data for best fits.

E_i^o (V)[a]	k_{si} (cm s^{-1})	α_i
E_1^o = –0.290	k_{s1} = 0.2	α_1 = 0.5
E_2^o = –0.545	k_{s2} = 0.2	α_2 = 0.5
E_3^o = –0.515	k_{s3} = 0.1	α_3 = 0.5

[a]SCE as reference electrode.

Table 7. Simulation results at best fits.

K_i (mol L^{-1})	k_{fi} (s^{-1})
$K_1 = 1.575\times10^{-5}$[a]	k_{f1} = ?[b]
K_2 = 0.1	$k_{f2} = 10^9$

[a]K_1 depend on the E_1^o, E_3^o, and K_2 parameters and was obtained by the relation $E_1^o - E_3^o = \frac{RT}{nF}\ln\frac{K_2}{K_1}$.

[b]This value has no effect within the explored window.

Interactions with RSO_3^- and HSO_4^-

Similar host–guest interactions are observed for *p*-toluenesulfonate and hydrogenosulfate ions with $[Pd_3]^{2+}$. The corresponding adducts, $[Pd_3(p\text{-}CH_3C_6H_5SO_3)]^+$ and $[Pd_3(HSO_4)]^+$, were generated and characterized (Table 2) after the addition of 1 equiv. of the anion on the cluster. Based on the λ_{max} trend discussed, these two substrates bind $[Pd_3]^{2+}$ less strongly than the NO_3^- analogue. Steric hindrance could be at the origin of this difference. Similar conclusions are anticipated for electrochemical properties of adducts, except that both kinetic and thermodynamic parameters should be different.

Conclusion

The properties of the $[Pd_3(NO_3)]^+$ adduct, notably, the structure, the ^{31}P NMR and UV–vis spectroscopy, and the electrochemical reduction behaviour were described. The ECE mechanism is the dominant process, both in the cathodic and anodic scans. Future works will focus on the oxidation of this adduct to find useful catalytic processes. Preliminary results show a large increase in oxidative current at ~+1 V vs. SCE, which represents a decrease of ~0.5 V with respect to that for NO_3^- alone, with the increase of $[NO_3^-]$. This behaviour is indicative of a catalytic process ($NO_3^- \rightarrow NO_3^{\cdot} + 1\ e^-$), presumably mediated by the $[Pd_3]^{2+}$ cluster, via the host–guest interactions established in this work.

A simple synthetic route to the formation of tetracopper(I) 2-mercaptothiazoline compounds — The crystal structures of $[Cu_4(S\text{-}thiaz)_4(PEt_2Ph)_2]$, $[Cu_4(S\text{-}thiaz)_4(PEt_3)_2]$, $[Cu_4(S\text{-}thiaz)_4]_2$, and $[Cu_4(S\text{-}thiaz)_4]_4$[1]

Olaf Fuhr, Lucia Fernandez-Recio, and Dieter Fenske

Abstract: Reactions of copper(I) acetate with 2-mercaptothiazoline (HS-thiaz) in the presence of tertiary phosphines lead to the formation of tetranuclear sulphur-bridged copper complexes. Depending on the reaction conditions, isolated clusters ($[Cu_4(S\text{-}thiaz)_4(PR_3)_2]$ (PR_3 = PPh_3 (**1**), PEt_2Ph (**2**), PEt_3 (**3**)), oligomeric compounds ($[Cu_4(S\text{-}thiaz)_4]_2$ (**4**) and $[Cu_4(S\text{-}thiaz)_4]_4$ (**5**)), or a one-dimensional polymer ($[Cu_4(S\text{-}thiaz)_4]_\infty$ (**6**)) are formed. The structures of the compounds **2**–**5** have been determined by single crystal X-ray analysis.

Key words: copper, 2-mercaptothiazoline, single crystal X-ray analysis.

Résumé : Les réactions de l'acétate de cuivre(I) avec la 2-mercaptothiazoline (HS-thiaz), en présence de phosphines tertiaires, conduisent à la formation de complexes de cuivre tétranucléaires comportant des ponts de soufre. Suivant les conditions réactionnelles, il y a formation d'agrégats isolés, ($[Cu_4(S\text{-}thiaz)_4(PR_3)_2]$ (PR_3 = PPh_3 (**1**); PEt_2Ph (**2**); PEt_3 (**3**)), des composés oligomères, ($[Cu_4(S\text{-}thiaz)_4]_2$ (**4**) ou $[Cu_4(S\text{-}thiaz)_4]_4$ (**5**)), ou d'un polymère unidimensionnel, $[Cu_4(S\text{-}thiaz)_4]_\infty$ (**6**). Les structures des composés **2**, **3**, **4** et **5** ont été déterminées par diffraction des rayons X sur un cristal unique.

Mots clés : cuivre, 2-mercaptothiazoline, diffraction des rayons X par un cristal unique.

[Traduit par la Rédaction]

Introduction

The chemistry of copper(I) in combination with chalcogen derivatives provides a large variety of compounds. Many clusters with increasing numbers of metal atoms have been synthesized, the biggest cluster to date being $[Cu_{146}Se_{73}(PPh_3)_{30}]$ (1). Typically, such clusters reflect the transition from separated molecules or complexes to the infinite bulk phase. Not only structural aspects are of interest, but many polynuclear d^{10} compounds also show interesting photophysical features (2). A third aspect is the fact that many enzymes contain copper–sulphur clusters (3). Therefore, researchers have spent considerable effort on the synthesis of copper(I) complexes with 2-mercaptothiazoline and its derivatives as ligands (4–9).

In this work, we describe a simple route to tetracopper(I) 2-mercaptothiazoline compounds. Those that were unknown so far were characterized by single crystal X-ray analysis.

Experimental

All reactions were performed in a dry, oxygen-free nitrogen atmosphere using standard Schlenk techniques. Solvents were dried with sodium/benzophenone and freshly distilled. Copper(I) acetate (CuOAc) was synthesized by reduction of copper(II) acetate with copper tunings in acetonitrile (10), PEt_3, P-*n*-Pr_3, and PEt_2Ph by common Grignard reactions (11). PPh_3 and 2-mercaptothiazoline were used as received from the commercial source (Sigma-Aldrich).

IR-spectra were recorded as KBr pellets using a FT-IR spectrometer Spectrum GX from PerkinElmer.

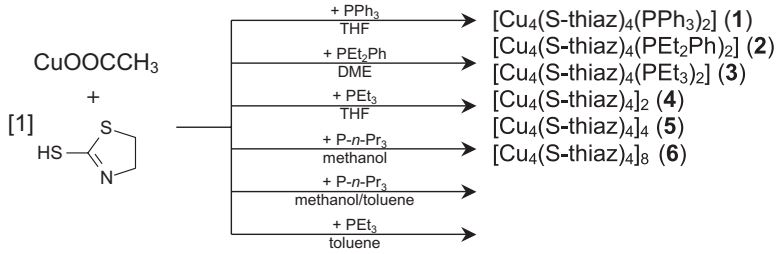
X-ray structure determination

Crystals were removed from the reaction flask under a stream of N_2 gas and immediately covered with a layer of perfluoropolyether oil (Riedel de Häen). A suitable crystal was selected, attached to a glass fibre, and immediately placed in the low-temperature nitrogen stream. The data were collected with a STOE IPDS II diffractometer using MoKα (λ = 0.710 73 Å) radiation produced by a common X-ray tube (2 kW). Structure solution and refinement against F^2 were carried out using SHELXS and SHELXL software (12). Molecular drawings were prepared with Diamond 2.1 (13) and PaintShopPro 7AE (14).

The crystal and refinement data of **2**–**5** are summarized in Table 1.[3]

Synthesis of $[Cu_4(S\text{-}thiaz)_4(PPh_3)_2]$ (1)

A solution of copper(I) acetate (390 mg, 3.18 mmol) and triphenylphosphine (830 mg, 3.18 mmol) PPh_3 in THF (30 mL) was layered with a solution of 2-mercaptothiazoline (380 mg, 3.18 mmol) in THF (5 mL). Within 4 days, colourless plates of **1**·2THF crystallized. Yield: 1.1 g (98%). IR (KBr, cm^{-1}): 3049 (m), 2941 (m), 2850 (m), 1958 (w), 1585 (w), 1571 (w), 1523 (vs), 1480 (s), 1448 (m), 1434 (s), 1304 (s), 1261 (w), 1189 (m), 1157 (w), 1093 (s), 1067 (m), 1026 (vs), 968 (vs), 934 (s), 852 (w), 746 (s), 694 (s), 619 (w), 574 (w), 518 (s), 432 (m). Anal. calcd. for $C_{56}H_{62}Cu_4N_4O_2P_2S_8$: C 48.19, H 4.48, N 4.01, S 18.38; found: C 48.53, H 4.60, N 4.16, S 18,61.



Synthesis of $[Cu_4(S\text{-}thiaz)_4(PEt_2Ph)_2]$ (2)

Copper(I) acetate (150 mg, 1.22 mmol), PEt_2Ph (0.21 mL, 1.22 mmol), and 2-mercaptothiazoline (145 mg, 1.22 mmol) were dissolved in DME (60 mL). After stirring for 1 day, the volume of the reaction mixture was reduced to 10 mL and *n*-heptane (15 mL) was added. From this solution **2** crystallized within 2 h as colourless blocks. Yield: 80 mg (25%). IR (KBr, cm^{-1}): 3084 (w), 2958 (m), 2927 (m), 2870 (m), 2850 (m), 2361 (m), 2342 (m), 1522 (vs), 1453 (m), 1433

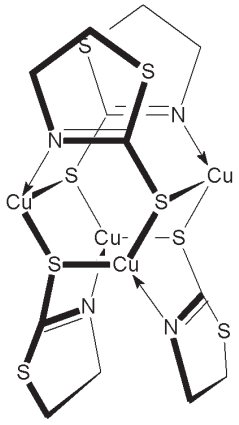
Synthesis of $[Cu_4(S\text{-thiaz})_4(PEt_3)_2]$ (3)

Copper(I) acetate (312 mg, 2.55 mmol) was dissolved in THF (60 mL) by adding triethylphosphine (0.38 mL, 2.55 mmol) to give a light yellow solution. After addition of 2-mercaptothiazoline (300 mg, 2.55 mmol), the reaction mixture turned colourless and was stirred for 6 h. All volatile compounds were removed under reduced pressure and the resulting oily residue was recrystallized from toluene. The product was isolated as big colourless crystals of $\mathbf{3}\cdot C_7H_8$. Yield: 175 mg (26%). IR (KBr, cm^{-1}): 2954 (m), 2929 (m), 2872 (m), 1525 (vs), 1450 (m), 1376 (m), 1304 (m), 1259 (w), 1194 (w), 1025 (vs), 970 (s), 933 (s), 768 (m), 729 (w), 669 (w), 576 (w), 433 (w). Anal. calcd. for $C_{31}H_{54}Cu_4N_4P_2S_8$: C 35.28, H 5.16, N 5.31, S 24.31; found: C 34.94, H 5.31, N 5.62, S 23.78.

Synthesis of $[Cu_4(S\text{-thiaz})_4]_2$ (4)

A solution of 2-mercaptothiazoline (80 mg, 0.7 mmol) in methanol (10 mL) was added at room temperature to a solution of CuOAc (86 mg, 0.7 mmol) and P-*n*-Pr_3 (0.07 mL, 0.35 mmol) in methanol (20 mL). After 30 min, the pale yellow solution was separated from a white precipitate. Within several days compound **4** crystallized from the filtrate as colourless plates. Yield: 50 mg (39%). IR (KBr, cm^{-1}): 3430 (w), 1636 (m), 1532 (s), 1505 (m), 1309 (m), 1026 (s), 970 (m), 931 (m). Anal. calcd. for $C_{24}H_{32}Cu_8N_8S_{16}$: C 19.83, H 2.22, N 7.71, S 35.29; found: C 20.47, H 1.81, N 7.34, S 35.81.



Synthesis of $[Cu_4(S\text{-thiaz})_4]_4$ (5)

A solution of 2-mercaptothiazoline (160 mg, 1.31 mmol) in methanol (10 mL) was added at room temperature to a solution of CuOAc (161 mg, 1.31 mmol) and P-*n*-Pr_3 (0.13 mL, 0.66 mmol) in methanol (40 mL). After 30 min, the pale yellow solution was separated from a white precipitate. Toluene (30 mL) was added to the filtrate; within the next 2 weeks, compound **4** and **5** crystallized from this solution.

Synthesis of $[Cu_4(S\text{-thiaz})_4]_\infty$ (6)

2-Mercaptothiazoline (360 mg, 3.06 mmol) was added to a solution of copper(I) acetate (375 mg, 3.06 mmol) and triethylphosphine (0.45 mL, 3.06 mmol) in toluene (60 mL).

Fig. 1. Principal drawing of the $[Cu_4(S\text{-thiaz})_4]$ cage found in compounds **1**–**6**.

Within a short time a white precipitate was formed, which was redissolved by mild heating. After several hours the product crystallized as colourless bars as $\mathbf{6}\cdot C_7H_8$. Yield: 280 mg (45%). IR (KBr, cm^{-1}): 2852 (w), 1524 (vs), 1447 (m), 1304 (m), 1189 (w), 1025 (s), 970 (s), 937 (s), 737 (m), 697 (w), 676 (w), 469 (w), 427 (w). Anal. calcd. for $C_{19}H_{24}Cu_4N_4S_8$: C 27.86, H 2.95, N 6.84, S 31.32; found: C 27.81, H 2.88, N 6.55, S 33.20.

Results and discussion

When 2-mercaptothiazoline (HS-thiaz) reacts with copper(I) acetate it is deprotonated and sulphur-bridged copper clusters are formed. The main structural motif of these compounds is a $[Cu_4(S\text{-thiaz})_4]$ cage, which is shown in Fig. 1.

The four copper atoms of this unit are bridged by the four exocyclic sulphur atoms of the 2-mercaptothiazoline ligands forming an eight-membered, folded ring. In addition, the heterocycles coordinate via the lone pairs of the nitrogen atoms to the copper atoms of the Cu_4S_4 core. Depending on the reaction conditions — especially the solvent used — different substances can be synthesized: compounds with isolated $[Cu_4(S\text{-thiaz})_4]$ cages (**1**–**3**), as well as oligomeric (**4**, **5**) and polymeric (**6**) products (Scheme 1). All reactions have been carried out in the presence of tertiary phosphines as additional donor components.

In ethereal solvents two phosphine molecules are coordinated to one Cu_4 unit forming clusters of the type $[Cu_4(S\text{-thiaz})_4(PR_3)_2]$ (PR_3 = PPh_3 (**1**), PEt_2Ph (**2**), PEt_3 (**3**)). **1** has been synthesized before starting from copper(II) acetate under reductive conditions (**4**); the crystallographic data pub-

lished could be proven by our samples. Using methanol as solvent, a dimer, $[Cu_4(S\text{-thiaz})_4]_2$ (**4**), is formed, a mixture of methanol and toluene leads to the formation of a tetramer, $[Cu_4(S\text{-thiaz})_4]_4$ (**5**). Finally, in pure toluene a one-dimensional polymer, $[Cu_4(S\text{-thiaz})_4]_\infty$ (**6**), is formed, which is also already described in the literature, obtained via an electrochemical synthesis (5). Again the crystallographic data published there fit with our sample.

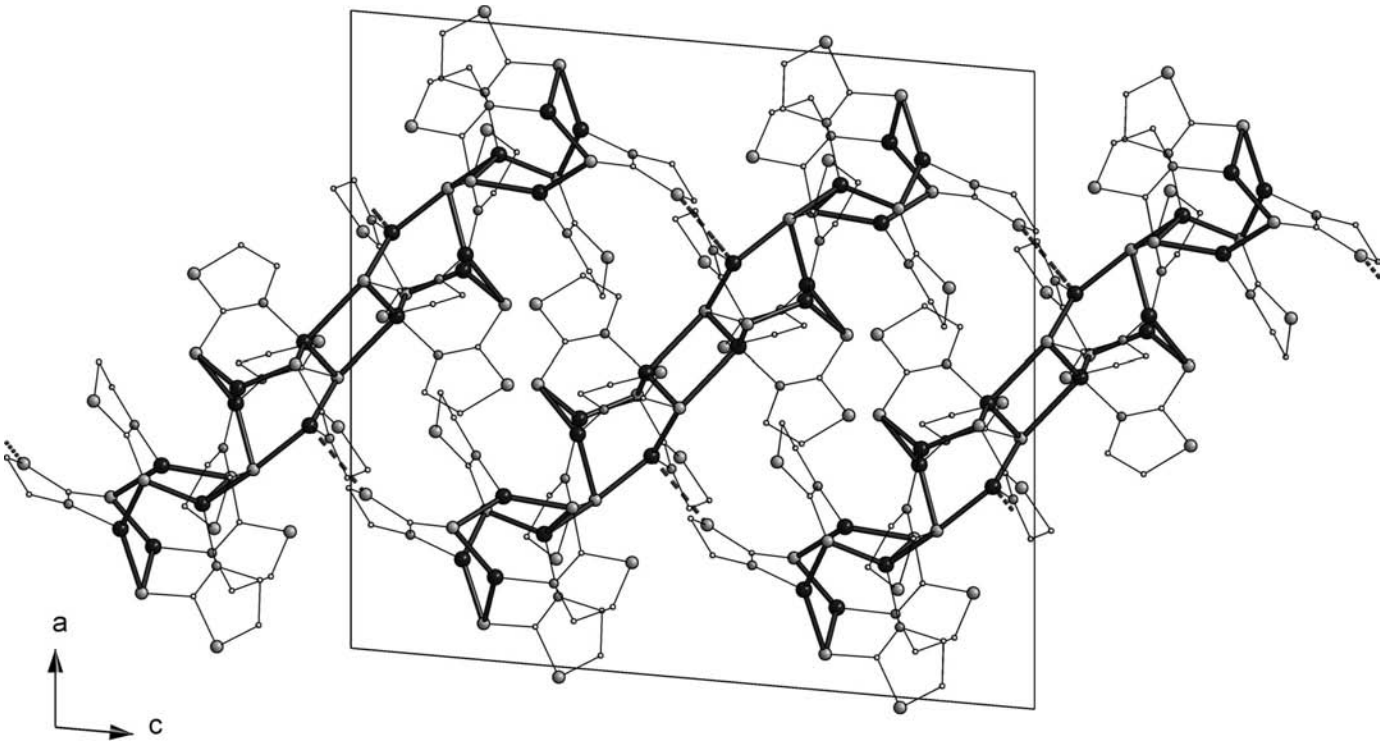
Crystal structures of 2–5

The colourless compound **2** (Fig. 2) crystallizes in the monoclinic space group *C*2/*c* with four molecules per unit cell. There is a twofold axis running through each molecule. The Cu—S distances in the Cu_4S_4 cycle range between 220.2(1) pm (Cu2—S1) and 250.3(1) pm (Cu1—S3′); Cu—N distances are Cu1—N1′, 203.4(3) pm, and Cu2—N2′, 201.4(3) pm. Cu2 and Cu2′ have a nearly trigonal planar coordination sphere (the sum of the bond angles is 358.8°). Both Cu1 and Cu1′ are additionally bonded to a phosphine ligand (Cu1—P1, 227.0(1) pm), whereby these copper atoms achieve a distorted tetrahedral coordination.

3 crystallizes as colourless blocks in the tetragonal space group $P4_32_12$ with four molecules per unit cell and one toluene molecule per formula unit. The molecular structure of **3** is analogous to **2** except for the different phosphine ligands. Therefore, further discussions of the structure are unnecessary.

There is one example in the literature of a similar tetranuclear copper compound with no further coordinating ligands or aggregation of cages, where chiral benzyl-substituted 2-mercaptothiazoline is used as chelating ligand. Indeed, this compound has been published twice, once discussed as a copper(II) species (CCDC no. 174127) (15) and 1 year later as a copper(I) compound (CCDC no. 174125) (16). Though the compounds have been synthesized in different ways, the crystallographic parameters are the same. As both are described as colourless, and each ligand should carry one negative charge, we assume that the description as a copper(I) compound is the right one.

Compound **4** crystallizes as colourless plates in the monoclinic space group $P2_1/c$ with four formula units per elementary cell. Figure 3 shows one dimeric unit of **4**; another crystallographically independent molecule is found in the asymmetric unit having, within experimental errors, the same bonding parameters.



4 consists of two $[Cu_4(S\text{-thiaz})_4]$ clusters connected via the atoms Cu4 and S5. There is an inversion centre in the middle of the so formed Cu_2S_2 ring. Cu—S distances within a Cu_4S_4 cycle range from 223.7(4) to 244.8(3) pm, the Cu4—S5′ bond is slightly longer (255.4(3) pm). This kind of cluster agglomeration is also found in **6** where the Cu_4 units form infinite strands (5). In contrast to **1**–**3** and **6** where no intermolecular bonds are present, the dimers in **4** are interconnected by donor bonding of two endocyclic sulphur atoms (S6, S6′) to copper atoms of neighbouring molecules. In this way layers are formed and this is illustrated in Fig. 4. Therefore, Cu2 is shifted out of the centre of the triangle formed by S1, S3, and N3, whereas Cu1 and Cu3, which have no intermolecular contacts, are nearly in plane with their neighbouring atoms. The average Cu—S_{endo} distances are 289.7 pm, which is significantly shorter than the sum of the van der Waals radii of copper and sulphur (320 pm (17)). The same kind of intermolecular linking was also found in the compound $[Cu_4(S\text{-thiaz})_4(NC_5H_5)]$ (4).

In **5** (Fig. 5) four $[Cu_4(S\text{-thiaz})_4]$ units are bound together forming a tetramer. Compound **5** crystallizes in the monoclinic space group $P2_1/c$ with two molecules per elementary cell and two molecules of toluene per formula unit.

The middle part of **5** is identical with **4**: two $[Cu_4(S\text{-thiaz})_4]$ units being connected via two Cu—S bonds (Cu1—S1′ and Cu1′—S1, 279.0(2) pm). The two additional subunits are both bonded to this inner part by one Cu—S bond (Cu5—S3, 253.6(2) pm). Altogether, the tetramer has a length of 2.16 nm. As in **4** the molecules are agglomerated by interactions between copper atoms (Cu2) and endocyclic

© 2006 NRC Canada

Fig. 6. A section of the layer structure of **5** showing the Cu—S_{endo} interactions (dashed lines).

sulphur atoms (S14) of neighbouring molecules (Cu—S_{endo}, 302.6(1) pm). Layers are also formed in this case as illustrated in Fig. 6.

Conclusion

Tetranuclear copper(I) 2-mercaptothiazoline complexes can be easily synthesized starting from copper(I) acetate by deprotonation of the ligand. Depending on the reaction conditions the [Cu_4(S-thiaz)$_4$] cages are either monomeric (**1**–**3**) with two additional phosphine ligands, or they form oligomeric (**4**, **5**) or polymeric (**6**) aggregates. In **4** and **5** additional intermolecular interactions between endocyclic sulphur atoms and copper atoms of neighbouring molecules are found.

Chiral lithium amides on polymer support — Synthesis and use in deprotonation of ketones[1]

Marek Majewski, Agnieszka Ulaczyk-Lesanko, and Fan Wang

Abstract: A number of chiral secondary amines attached to Merrifield resin or to noncrosslinked (soluble) polystyrene support were synthesized. The corresponding lithium amides, generated from these amines by treatment with BuLi, react with tropinone, a model symmetrical ketone, to give the corresponding enolates enantioselectively (ee up to 75%). The enolates were trapped either as the corresponding aldol adducts by a reaction with benzaldehyde or as ring-opening products in a reaction with a chloroformate.

Key words: chiral lithium amides, polymer-supported reagents, deprotonation, enolates, tropinone.

Résumé : On a réalisé la synthèse d'un certain nombre d'amines secondaires chirales liées à une résine de Merrifield ou à un support de polystyrène non réticulé (soluble). Les sels de lithium des amides correspondants obtenus à partir de ces amines par traitement avec du BuLi réagissent avec la tropinone, une cétone symétrique modèle, pour conduire d'une façon énantiosélective (ee allant jusqu'à 75 %) à la formation des énolates correspondants. Les énolates ont été piégés sous la forme d'adduits aldoliques correspondants par réaction avec du benzaldéhyde ou sous la forme de produits d'ouverture par réaction avec un chloroformiate.

Mots clés : sels de lithium d'amides chiraux, réactifs supportés par un polymère, déprotonation, énolates, tropinone.

[Traduit par la Rédaction]

Introduction

There is a lot of interest in developing chemistry that involves reactants on polymer support that are often described in terms of solid phase synthesis (SPS) for insoluble polymers, and liquid phase synthesis (LPS) for soluble resins (the differences between "solid-phase", "liquid-phase" and "solution-phase" chemistry were discussed in a seminal paper by Janda in 1997) (1) and often the challenge involves adaptation of solution-phase reactions to work on the resin (2). As the popularity of the polymer-supported scaffolds and reagents grows, the more difficult aspects of synthetic chemistry such as stereoselective reactions, and especially their catalytic versions, are developed in the SPS and LPS context (3). It should be noted that applications of substrates and reagents on polymer support are not limited to combinatorial chemistry, there is also a number of potential benefits that could arise from using such reagents including easy recovery of expensive chemicals, easier control of environmental contamination, and new reactor design (2, 3).

We have been interested in development of chiral lithium amide bases for several years (4). Analogous amides supported on a resin are interesting because of a potential connection to solid phase synthesis. At the onset of this work it was not clear if chemistry involving reagents on polymer support would be compatible with highly reactive reagents such as butyllithium or carbanions, since there had been very few precedents (5). Fortunately, no major problems on this score were encountered. The preliminary results of this study have been reported in a communication (6). Recently, other researchers have taken up the theme of lithium amides on polymer support achieving very interesting and useful results in different systems (7). Below, we present a full account of the synthesis of a number of chiral lithium amides on polymer support and their reactions as bases in selected systems.

Results and discussion

Synthesis of chiral amines on insoluble polymer support

Chloromethyl polystyrene **1** (Merrifield resin, 200–400 mesh) was chosen as the solid support for the initial studies. The general method elaborated for the direct attachment of a chiral amine to the resin is shown in Scheme 1.

Replacement of chlorine in **1** with iodine was done using the Finkelstein reaction (8). The N-alkylation of chiral primary amines (**3**–**5**) proceeded smoothly when the amine was used in excess. After the reaction was completed, the resins (**6**–**8**) were separated by filtration, washed with the follow-

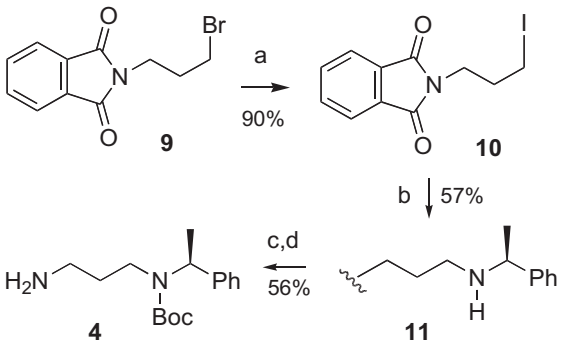
Scheme 1.



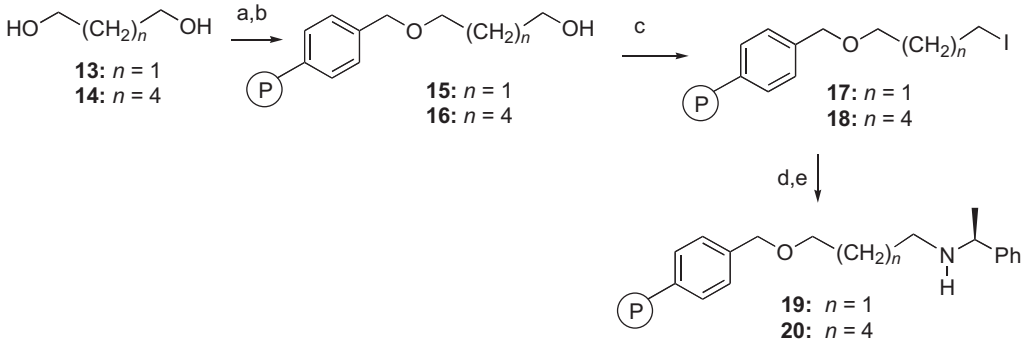
ing solvents: THF, MeOH, aq. MeOH (50%), H_2O, NaOH, H_2O, MeOH, Et_2O, and were dried under vacuum to the constant weight. The rather involved washing procedure results from the fact that the polymers of this type swell in THF or Et_2O, but do not swell in polar protic solvents such as MeOH or H_2O. Thus, the resins were washed with a swelling solvent first, to remove organic impurities absorbed on the polymer. The wash with THF was followed by washing with solvents that do not have good swelling properties, but which remove inorganic and acidic impurities.

Next, a method for determination of the amount of nitrogen (loading) in the polymer-supported reagents had to be elaborated. The Volhard titration method was tried first (9). A known amount of standard HCl solution was added to the polymer-supported amine sample, which gave the corresponding salt. The chloride ions that were not trapped by the amine moieties were precipitated by addition of a known excess of a standard solution of $AgNO_3$. After several experiments, it was found that HCl was being incorporated into the polymer matrix and the apparent N-loading of the resin was higher than the Cl-loading of the original Merrifield resin. This absorption of HCl on the polymer was confirmed by several "blind titration" experiments, i.e., the commercially available Merrifield resin was treated with a known amount of the standard HCl solution, the resin was separated by filtration, and the filtrate was titrated using the Volhard method. Overall, contrary to some reports (9*b*), the Volhard method was not effective. Another method of titration that was tried was the Fajans method, which works in a similar fashion, but relies on the analysis of sulfate ions (9*a*). This method allowed a reasonably accurate determination of the amine loading.

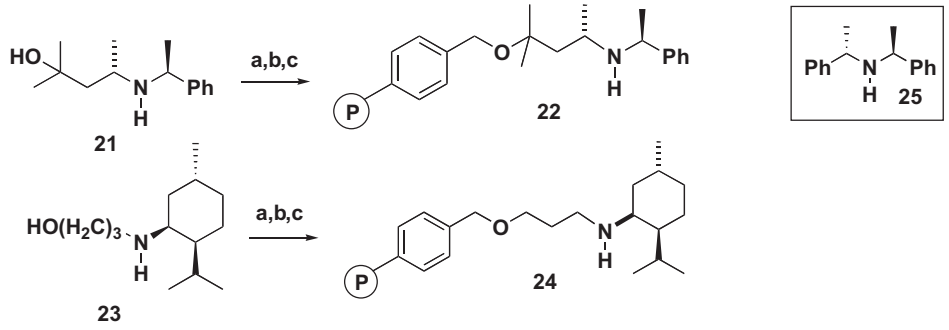
The third method used for determination of the nitrogen content in polymeric amines was elemental analysis. The loading values of all insoluble polymer-supported amines ranged between 0.4 and 1.1 mmol of NH per gram (cf., the Experimental section). Nitrogen loading clearly indicated that, in many cases, the N-alkylation reaction did not go to completion. Since the halide groups attached to the polymer could interfere with subsequent reactions, a dehalogenation procedure was performed according to the method described by Leznoff that involves using an excess of Bu_3SnH (10). A quick, qualitative test of amine incorporation into the polymer structure was done by using a solution of bromophenol blue, similar to the test developed by Lam to monitor progress of reactions of peptides connected to resin beads (11).

Amine **4**, needed for synthesis of the corresponding resin **7**, which was envisaged as the precursor of the bidentate chiral lithium amide, was synthesized as shown in Scheme 2.

Scheme 2. Reagents and conditions: (*a*) NaI, Me_2CO, reflux; (*b*) **3a**, K_2CO_3, THF, reflux; (*c*) Et_3N, $(Boc)_2O$, MeOH; (*d*) 95% NH_2NH_2, EtOH.



Most of the reacting groups in an insoluble polymer-supported reagent are situated inside the polymer bead. These reacting sites are not easily accessible to reagents in solution, but the situation could be improved by distancing the reactive groups from the rigid polymer matrix by a linker. Selection of the proper linker can be critical to the success of SP chemistry (1, 2*b*). Initially, two simple linkers derived from 1,3-propanediol (**13**) and 1,6-hexanediol (**14**) were used. They were attached to the polymer-supported benzyl chloride **1** by a modified literature method (12), involving O-alkylation, followed by functional group manipulation using reactions that are well-known in the context of solution chemistry (Scheme 3) (13). Iodides **17** and **18** served as precursors for the polymer-supported amines **19** and **20**, which were obtained by simple N-alkylation of (*S*)-α-methylbenzyl amine (**3**) with these compounds.



Some examples of attaching a chiral amine moiety to an insoluble polymer support via a linker that had been incorporated into the amine structure as the corresponding amino alcohol were published by other groups working on developing catalysts for stereoselective addition of nucleophiles to aldehydes (2*a*, 12, 14–16). We have synthesized amines **22** and **24** hoping that they might be effective in enantioselective deprotonation (Scheme 4). Compound **22** seemed especially promising owing to its structural similarity to the C_2 symmetrical amine **25** — the lithium amide of this amine is one of the most versatile and effective chiral bases (4). Compounds **21** and **23** used in these studies were synthesized from chiral primary amines by the reductive

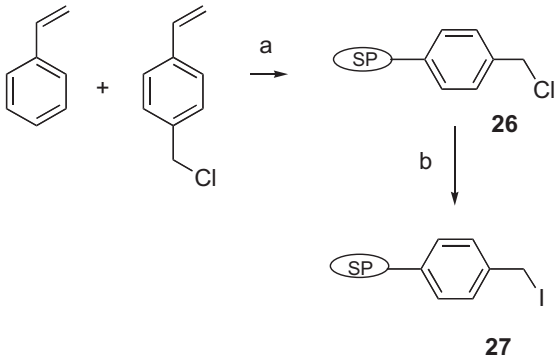
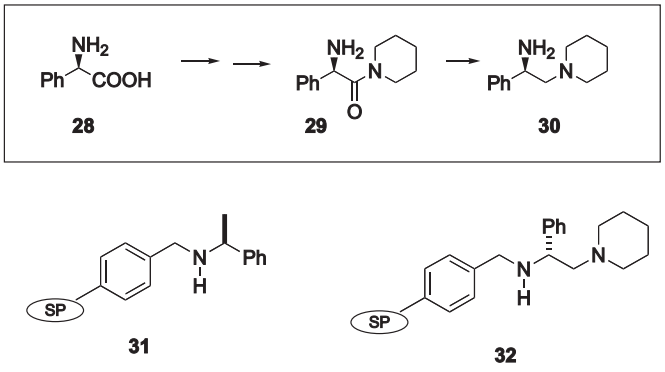
amination method (starting from 4-hydroxy-4-methyl-2-pentanone or menthone, respectively).



Synthesis of chiral amines supported on a soluble polymer

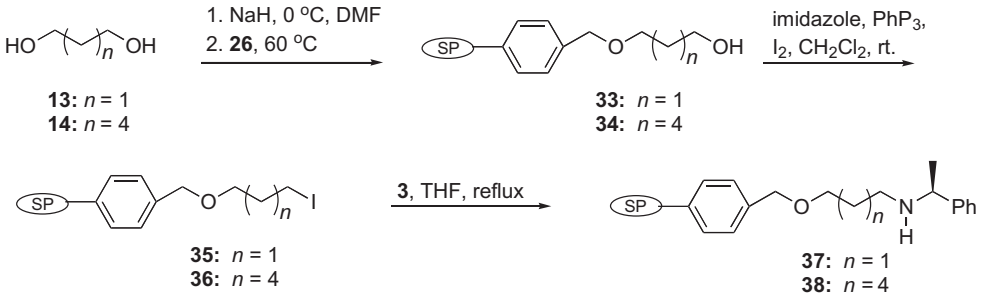
Reagents that are bound to soluble polymers offer a number of advantages while suffering less from reactivity problems often associated with a two-phase system (1). The soluble polymer supports selected for our studies were the noncrosslinked copolymer of styrene and chloromethyl styrene **26**, which was synthesized by free radical polymerization following the procedure of Narita (9*b*, 17) and the corresponding iodo derivative **27** (Scheme 5).



Compound **26** has a number of advantages: it can be easily prepared from the commercially available starting materials; it is soluble in common organic solvents such as THF, CH_2Cl_2, $CHCl_3$, AcOEt, and benzene even at low temperatures, but it is insoluble in MeOH and H_2O. The products of reactions involving this polymer can be purified using aqueous extraction and polymer precipitation. Chiral amines **3** and **30** (the latter was prepared as shown in Scheme 6, using literature procedures, refs. 4*b*, 18) were attached to the polymer backbone using the iodo derivative **27** analogously to the method described above for compounds derived from the Merrifield resin (Scheme 6; cf., Scheme 1). All reactions were easy to carry out, and the resulting resins (**31**, **32**) were isolated by precipitation from cold MeOH.

Attachment of chiral amines to the soluble support via linkers was realized by a three-step procedure shown in Scheme 7. The linker was attached first to the soluble polymer (**26** or **27**) followed by the well-precedented functional group manipulations and attachment of the chiral amine. The linker was expected to distance the amine from the polymer

Scheme 5. Reagents and conditions: (*a*) AIBN, benzene, 70 °C, 48 h; (*b*) NaI, acetone.



Scheme 6.

matrix and it was hoped that this should make it more accessible to BuLi during the generation of the corresponding lithium amide, and also should result in less steric hindrance

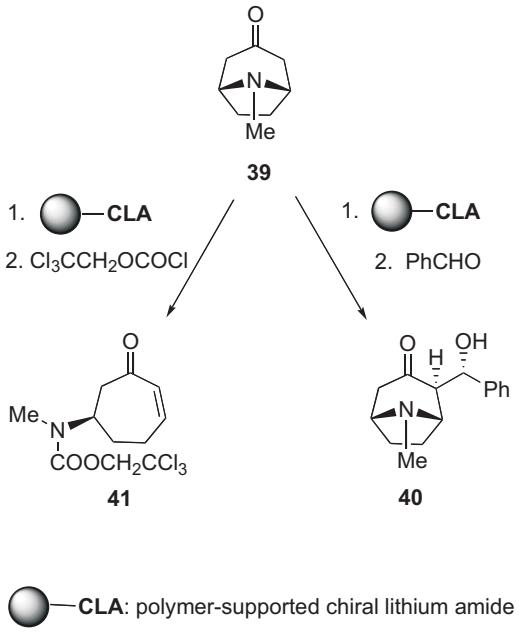
Scheme 7.

during the subsequent deprotonation step. Polymers **37** and **38** were synthesized according to the procedure analogous to that described above for the insoluble amines **19** and **20**.

Synthesis and reactions of polymer-supported lithium amides



After the synthesis of the series of polymer-supported chiral amines was completed, the stage was set for generation of the corresponding lithium amides. Polymer-supported reagents could offer several advantages over the chiral lithium amides generated in solution. Some of these could involve: simplified reaction procedures, possibility of easy regeneration of the polymer bound reagent, and undesired side reactions such as crosslinking could be suppressed by using more solvent (the principle of high dilution) (2*b*). Polymer-bound reagents are usually more stable, and a possibility for the automation of reactions exists when dealing with polymer-supported chiral lithium amides. Generation of lithium amides from secondary amines is a relatively simple reaction in solution and numerous procedures have been described. The reader's attention is directed to a few recent references that illustrate a certain variety of conditions (4, 19). The procedure for generation of polymer-supported lithium amides was designed by analogy with chemistry in solution (cf., Experimental) and involved treatment of the parent amine with BuLi at 0 °C in THF. In the case of insoluble polymer-supported chiral lithium amides, it should be noted that THF is the solvent that swells the polymer matrix the most, which implies that the conditions of the subsequent reaction should be similar to homogenous conditions.

During the generation of both the insoluble and soluble polymer-supported lithium amides from the corresponding chiral amines, color changes were observed (the suspension of the polymer changed color from yellow to light reddish-brown in the case of insoluble reagents and to red or purple in the case of soluble ones). This could be attributed to the formation of unidentified by-products. It was determined experimentally that if the color change did not occur, the subsequent reactions did not proceed well; if the color became dark brown, the yield of the reaction was usually low.

Deprotonation of carbonyl compounds

Chiral lithium amide bases are powerful reagents that are often used for enantioselective deprotonation of symmetrical cyclic ketones (4). The resulting enolates are usually trapped by various electrophiles and the reaction selectivity is measured on the product. Tropinone (**39**), a bicyclic ketone of C_s symmetry provides a good model for deprotonation studies

Scheme 8.

and is also a useful scaffold for construction of tropane alkaloids (4). The aldol addition of tropinone enolate to benzaldehyde is well-known to give only one diastereoisomer of the corresponding aldol (**40**), which simplifies the analysis, and the enantioselectivity can by easily and accurately measured by ^{1}H NMR with chiral solvating agents such as (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol (4). Tropinone enolate undergoes ring opening with chloroformates to give cycloheptenone derivatives (**41**); the enantiomer ratio of these products can be analyzed by NMR or by HPLC (Scheme 8) (4*e*).

Developing proper conditions for reactions involving polymer-supported reagents can be complicated because of a number of variables. The polymer matrix could react with the reagents in solution in an undesirable fashion giving rise to by-products and microenvironmental effects of an unknown nature could be present (20). The reagents that are supported on a polymer have restricted mobility owing to the rigidity of the polymer matrix, and, usually, longer times are required for reactions in which such reagents are employed. After some experimentation we established that generation of lithium amides attached to insoluble polymer supports (i.e., derived from amines **6** or **20**) required up to 8 h, and the subsequent deprotonation of tropinone required

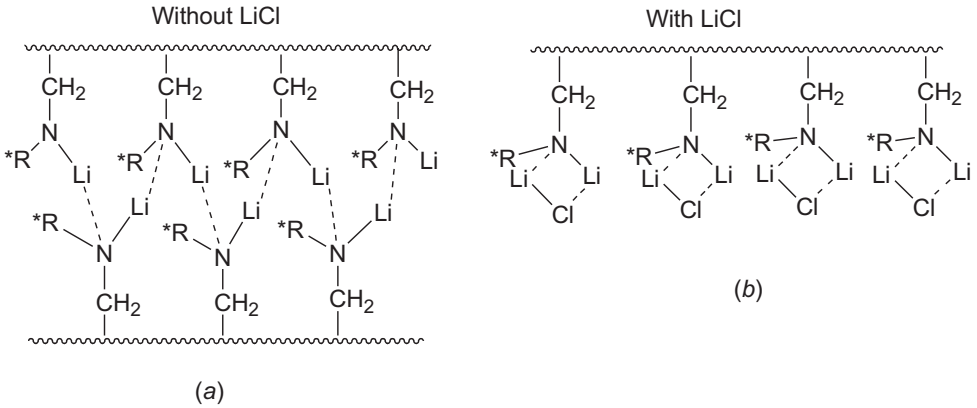
Table 1. Deprotonation of tropinone with chiral lithium amides on polymer support, followed by the aldol reaction of the corresponding enolate.



Entry	Lithium amide	Additive	Yield of **40** (%)	ee of **40**[a] (%)
1	**Li-6**	—	38	14
2	**Li-6**[b]	—	40	20
3	**Li-6**	LiCl (1 equiv.)	45	24
4	**Li-20**	—	30	10
5	**Li-20**	LiCl (1 equiv.)	35	20
6	**Li-31**	LiCl (2 equiv.)	83	75
7	**Li-32**	LiCl (1 equiv.)	51	70
8	**Li-37**	LiCl (1 equiv.)	35	26
9	**Li-38**	LiCl (1 equiv.)	40	35

Note: All reactions were done in THF, the lithium amides were generated at 0 °C, and the aldol reaction was done at –78 °C (cf., the Experimental).

[a]All products were dextrarotatory and the absolute configuration is as drawn for structure **40**.

[b]The ketone was added slowly (over 45 min).

Fig. 1. Hypothetical structures of (*a*) a dimer involving the chiral lithium amide supported on soluble polymer and (*b*) mixed aggregates involving lithium amide and LiCl connected to the polymer.

up to 15 h to proceed to completion (detailed procedures are described in the Experimental section). The analogous reactions in solution are much faster (1 h and 1–2.5 h are usually sufficient for the two steps, respectively).

The second task was to elaborate a proper workup for reactions involving polymer-supported amides. Aldol reactions in solution are usually quenched with an aqueous solution of a weak acid, followed by an extraction. However, with insoluble polymer-supported reagents the reaction mixture could not be extracted before the removal of the polymeric reagent. In the end the following procedure proved to be effective: the reaction was quenched by addition of an aqueous solution of NH_4Cl, the polymers were separated off by filtration and washed with THF. The aqueous layer of the filtrate was then extracted with Et_2O. Both the insoluble polymer reagents **6** and **20** and soluble amines (such as **30**) were recycled, purified, and could be reused without loss of reactivity.

In most cases, both the yield and the enantiomeric purity of the tropinone aldol (**40**) were modest. As far as the insoluble polymers were concerned (Table 1, entries 1–5), we speculated that the heterogeneous conditions were lowering the efficiency and selectivity of the reaction. Soluble polymers proved somewhat better (Table 1, entries 6–10). In this case, the extraction was applied before the precipitation of the polymer, which made the workup much easier. After quenching the reaction, the mixture was simply diluted with AcOEt, and the aqueous layer was further extracted with AcOEt. (cf., the Experimental section).

Lithium chloride appears to be a necessary additive in reactions involving amides on soluble polymeric support. In some cases lithium amides could not be generated without LiCl because of the formation of a gel, which made the reaction mixture heterogeneous. This was especially evident in experiments involving the lithium amide generated from amine **31** — the reaction in the absence of LiCl did not work at all because of gel formation, while when LiCl was added the enantioselectivity increased (albeit slightly) with increasing amounts of LiCl (at 0.5 equiv. of LiCl the ee was 66% and at 2 equiv. of LiCl, it was 75%). This behaviour parallels the reaction in solution (4*a*, 4*e*). It is possible that formation of the gel could be caused by a noncovalent crosslinking of the polymer chains owing to aggregation of the lithium amide moieties. After addition of a LiCl solution, the gel disappears presumably because formation of the mixed aggregates breaks the crosslinking (Fig. 1). The possibility of such phenomena occurring in solution had been previously pointed out by Seebach (21).

Another reaction of tropinone that had been studied is the somewhat unusual ring opening with chloroformates (Scheme 8) (4*e*). The reaction is easy to carry out in solution, and the methods for measuring the enantiomeric excess of product **41** are known (4).

Table 2. Deprotonation of tropinone with lithium amides on polymer support, followed by the ring opening of the corresponding enolate.

Entry	Lithium amide	Additive	Yield of **41** (%)	ee of **41** (%)
1	**Li-6**	—	13	2
2	**Li-6**	LiCl (1 equiv.)	37	59
3	**Li-7**	—	10	–13[a]
4	**Li-7**	LiCl (1 equiv.)	15	36
5[b]	**Li-8**	—	5	–1.5[a]
6	**Li-8**	—	7	–6.5[a]
7	**Li-8**	LiCl (1 equiv.)	10	–13[a]
8	**Li-19**	—	42	3
9	**Li-19**	LiCl (1 equiv.)	48	6
10	**Li-20**	—	22	2
11	**Li-20**	LiCl (1 equiv.)	25	22
12	**Li-22**	—	5	–11[a]
13	**Li-22**	LiCl (1 equiv.)	11	9
14	**Li-24**	—	5	3
15	**Li-32**	LiCl (1 equiv.) and *n*-BuLi (1 equiv.)	57	30

Note: Enantioselectivity was measured with HPLC using a Chiralpack AD column and 15% isopropanol in hexane as the solvent system. All reactions were done in THF, the lithium amides were generated at 0 °C, and the ring-opening reaction was done at 0 °C (cf., the Experimental).

[a]Levorotatory enantiomer of **41** was the major product.

[b]The reaction was done in 2,2,5,5-tetramethyltetrahydrofuran.

The yields and enantioselectivities varied from mediocre to low with only a few exceptions. The highest ee in this series of experiments was obtained with lithium amide derived from amine **6** in the presence of LiCl (Table 2, entry 2). The incorporation of a linker into amine structures, to separate the chiral lithium amide moiety from the polymeric rigid backbone, did not seem to make a difference. Obviously, the steric hindrance that reagent **6** exhibits is necessary for the reaction to proceed with a useful degree of selectivity.

Interesting results were obtained with lithium amides **Li-7** (Table 2, entries 3 and 4) and **Li-22** (Table 2, entries 12 and 13). In both cases, in the absence of LiCl, the major product was the levorotatory enantiomer of **41**; however, after the addition of LiCl the dextrarotatory enantiomer was the major product. The mechanism of deprotonation of ketones with chiral lithium amides is not well understood. It could be suggested that the origins of the LiCl effects lie in a different lithium amides species acting as the deprotonating agent (22). There is much interest in identifying the role of different possible aggregates in deprotonation (23). It should be noted, however, that formation of a dimer by an insoluble, polymer-supported lithium amide is unlikely because of the rigid nature of the polymer matrix. The explanation why different enantiomers form at different conditions has to wait for a detailed mechanistic study.

Table 2 contains only one entry that refers to a lithium amide attached to soluble support (entry 15). We investigated all the lithium amides corresponding to the chiral amines attached to the soluble support in the ring-opening reaction, however, the yields were uniformly very low. In a few cases, such as that involving lithium amide **Li-32**, we were able to improve the yield to a moderate level by adding an extra equivalent of BuLi prior to addition of the electrophile. The overall low yields and the improvement that was realized through addition of extra BuLi were rationalized by the internal proton return. This phenomenon was had been observed by Seebach and co-workers (24) and others (25) and usually appears during attempts to deuterate enolates resulting in low deuterium incorporation. The process can, in principle, manifest itself also when different electrophiles are used. We had recovered substantial amounts of tropinone from experiments that gave low yields of the ring-opening products, suggesting that the internal proton return might be the culprit.

In summary, we synthesized a number of chiral amines attached to polymer supports that were either insoluble or soluble in organic solvents. The corresponding lithium amides were generated efficiently from these amines. The lithium amides were used in the deprotonation of tropinone, resulting, in several cases, in an efficiency and enantioselectivity similar to reactions in solution. These studies comprise a preliminary step towards development of practical lithium amide reagents on polymer support.

Experimental

General

For a general description of solvent and reagent purification and ee measurements see the previous contributions from our group (4*b*, 4*c*). Chiral amines used in this study were either commercially available (compounds **3** and **5**), or were synthesized according to previously published procedures (compound **30**) (4*b*, 18), or are described in the following.

The insoluble resin used as polymer support was the commercially available Merrifield resin (PS-Cl from Argonaut Technologies) and the soluble noncrosslinked polystyrene resin was synthesized as described before (9*b*). All NMR spectra were acquired in $CDCl_3$ on a 300 MHz instrument (Bruker).

© 2006 NRC Canada

General and typical procedures

Conversion of chlorobenzyl to the iodobenzyl moiety on polymer support

Sodium iodide (5.00 g, 33.4 mmol) was added to the preswollen (acetone) Merrifield resin (4.00 g, 4.00 mmol, original loading: 1.00 mmol of Cl per gram) in acetone (50 mL), and the resulting suspension was refluxed for 48 h. The polymer was then separated by filtration and washed with 100 mL of each of the following solvents: acetone, THF, EtOH, MeOH, methanol–water (1:1), 2 N NaOH, water, MeOH, and EtOH. (Note: in the case of soluble, noncrosslinked polymer **27**, the product was washed with water and then MeOH). Polymer **2** was dried to constant weight under high vacuum, yielding 3.862 g of the product.

Amination (typical procedure)

S-(–)-α-Methylbenzyl amine (3.645 g, 3.880 mL, 30.12 mmol) was added to the preswollen polymer **2** (6.026 g, 6.026 mmol, original loading of 1.00 mmol of halide per gram) in THF (100 mL). The mixture was refluxed under N_2 for 48 h. After the reaction was completed, polymer **6** was separated by filtration and washed with the following solvents (150 mL): THF, acetone, methanol, methanol–water (1:1), water, NaOH, water, methanol, ethanol, and Et_2O. The polymer was dried under high vacuum to constant weight, and 6.000 g of the corresponding resin was obtained. The loading of polymeric amine **6** was determined by Fajans titration method and by elemetal analysis and was 0.604 mmol of N per gram. ^{1}H NMR δ: 8.05–5.75 (m, 28H, Ar), 3.87–3.11 (m, 3H, $PhCH_2$-N and CH-N), 2.14–0.44 (m, 12H, CH_2, CH, polymer matrix, and CH_3, amine moiety). ^{13}C NMR δ: 145.8 (C-Ar), 128.1 (C-Ar), 126.9 (C-Ar), 125.9 (C-Ar), 58.1 (CH-N), 52.3 ($PhCH_2$-N), 40.6 (CH, polymer matrix), 24.7 (CH_3). Found: C 81.43, H 6.55, N 1.83, which indicated loading to be 0.604 mmol/g.

Dehalogenation

This procedure was applied in cases involving insoluble polymers only. A solution of tributyltin hydride (3.645 g, 3.300 mL, 12.54 mmol) was added to a suspension of polymer **6** (6.122 g, 4.180 mmol, loading of 0.604 mmol of N per gram) in THF (125 mL), and the reaction mixture was refluxed under N_2 for 48 h. The polymer was separated by filtration and washed with the following solvents (150 mL): hexane, THF, methanol, methanol–water (1:1), water, 2 N NaOH, water, methanol, ethanol, hexane, and Et_2O. The product was dried under reduced pressure to constant weight, yielding 5.387 g of polymer-supported amine **6**.

Connection of the linker using a diol (typical procedure)

1,3-Propanediol (10.94 g, 10.40 mL, 144.0 mmol) was added slowly to a suspension of NaH prewashed with dry pentane (1.728 g, 75.13 mmol) in DMF (100 mL), and the reaction mixture was stirred at 0 °C under N_2 for 2 h. Chloromethyl polystyrene **1** (8.00 g, 8.80 mol, 1.10 mmol of Cl per gram) was then added and the reaction mixture was refluxed under N_2 for 48 h. The reaction was quenched by the addition of water (100 mL) at 0 °C, and polymer **15** was separated by filtration and washed with the following solvents: water, methanol, ethanol, and Et_2O, followed by Soxhlet extraction with a 1:1 mixture of THF and ethanol (150 mL) for 4 h, and drying to the constant weight under high vacuum (8.125 g). (Note: during the synthesis of soluble noncrosslinked polymers **33** and **34**, the product was washed with water and then MeOH only in each case). The loading, as determined by gravimetric analysis, was 0.825 mmol of OH per gram. ^{1}H NMR δ: 8.57–6.30 (m, 24H, Ar), 4.28–3.37 (m, 8H, CH_2Cl, polymer matrix, and $PhCH_2O$-, -OCH_2 and -CH_2OH, alcohol moiety), 2.18–1.09 (m, 8H, CH_2, CH polymer matrix and CH_2, alcohol moiety); ^{13}C NMR δ: 128.4 (C-Ar), 68.1 ($PhCH_2O$-), 62.5 (OCH_2-), 40.5 (CH, polymer matrix), 25.8 (CH_2).

Activation of the linker by iodination (typical procedure)

Imidazole (1.138 g, 16.74 mmol) was added to a solution of triphenyl phosphine (4.386 g, 16.74 mmol) in dry CH_2Cl_2 (150 mL). Iodine (4.252 g, 16.74 mmol) was added next, followed by the addition of polymer **15** (6.973 g, 5.753 mmol, 0.825 mmol of OH per gram). The reaction mixture was protected from light and was stirred under N_2 for 96 h. After the reaction was completed, the polymer was separated by filtration and washed with 200 mL of each of the following solvents: diethyl ether, benzene, water, methanol, and diethyl ether. (Note: during the synthesis of soluble noncrosslinked polymers **35** and **36**, the product was washed with water and then MeOH only in each case). Product **17** was dried to constant weight under high vacuum, yielding 7.210 g of the resin. The loading of the polymer was estimated by gravimetric analysis and was 0.750 mmol of iodine per gram of compound. ^{1}H NMR δ: 8.50–5.90 (m, 148H, Ar), 4.93–4.13 (m, 4H, CH_2Cl, polymer matrix, and $PhCH_2O$-), 3.82–2.85 (m, 12H, -OCH_2 and CH_2I), 2.35–0.80 (m, 52H, CH_2, CH, polymer matrix, and CH_2, iodide moiety). ^{13}C NMR δ: 128.8 (C-Ar), 68.1 ($PhCH_2$-O), 41.0 (CH, polymer matrix), 33.8 (CH_2), 3.7 (CH_2I).

N-(3-Iodopropyl)phthalimide (10) (ref. 26)

A solution of *N*-(3-bromopropyl)phthalimide (0.500 g, 1.86 mmol) in acetone (2 mL) was added to a suspension of sodium iodide (1.40 g, 9.30 mmol) in acetone (15 mL), and the reaction mixture was refluxed for 2.5 h. Acetone was evaporated and the residue was diluted with Et_2O (35 mL), and a saturated solution of $Na_2S_2O_3$ (30 mL) was added. The aqueous layer was extracted with Et_2O (3 × 35 mL). The organic layers were combined, dried with $MgSO_4$, and the solvent was removed in vacuo giving the crude product (0.600 g), which was purified by flash chromatography (hexane, hexane–AcOEt 4:1) yielding pure **10** (0.530 g, 90%); mp 84–86 °C (lit. value (26) mp 86–88 °C). ^{1}H NMR δ: 7.85–7.57 (m, 4H), 3.71 (t, J = 6.76 Hz, 2H), 3.11 (t, J = 7.19 Hz, 2H), 2.19 (quint, J = 7.00 Hz). ^{13}C NMR δ: 168.3, 134.1, 132.0, 123.4, 38.7, 32.6, 1.4.

(*S*)-(–)-(3-Phthalimidopropyl)-1-phenylethylamine (11)

A solution of (*S*)-α-methylbenzylamine (0.363 g, 3.00 mmol) in THF (5 mL) was added to a solution of iodide **10** (0.473 g, 1.50 mmol) in THF (15 mL). The reaction was refluxed for 1.5 h and potassium carbonate (0.207 g, 1.50 mmol) was added. The reflux was continued overnight. The reaction mixture was cooled down to room temperature, a

© 2006 NRC Canada

saturated solution of sodium bicarbonate (20 mL) was added, and the mixture was extracted with Et_2O (3 × 30 mL). The organic layers were combined, washed with brine, and dried with $MgSO_4$. The solvent was removed in vacuo yielding the crude product (0.650 g). The crude product was purified by flash chromatography (hexane, hexane–AcOEt 1:1) yielding pure **11** (0.265 g, 57%); mp 82–85 °C. $[\alpha]^{25}_D$ –34.2° (*c* 1.15, CH_2Cl_2). IR (cm^{-1}): 2958, 1708, 1395. ^1H NMR δ: 7.80–7.70 (m, 2H), 7.65–7.57 (m, 2H), 7.27–7.08 (m, 5H), 3.80–3.52 (m, 3H), 2.70–2.31 (m, 2H), 1.77 (quint., 2H, *J* = 6.65 Hz, *J* = 13.39 Hz), 1.48 (br s, 1H, NH), 1.27 (d, 3H, *J* = 6.55 Hz). ^{13}C NMR δ: 168.3, 145.7, 133.8, 132.1, 128.3, 126.7, 126.5, 123.0, 58.2, 44.6, 35.9, 28.8, 24.3. MS (EI): 293 (M – 1, 97), 231 (6), 188 (32), 160 (42), 134 (16), 105 (100), 79 (11). Anal. calcd. for $C_{19}H_{20}N_2O_2$: C 74.00, H 6.54, N 9.08; found: C 73.98, H 6.49, N 8.94.

(*S*)-(–)-[*N*-*tert*-Butoxycarbonyl-(3-phthalimidopropyl)]-1-phenylethylamine (12)

A solution of 30% Et_3N in MeOH (2.5 mL) was added to a solution of amine **11** (0.500 g, 1.62 mmol) in MeOH (20 mL), followed by the addition of $(Boc)_2O$ (1.769 g, 8.110 mmol) in MeOH (10 mL) during which time the reaction was stirred vigorously. The reaction mixture was refluxed overnight. The mixture was cooled down to room temperature and the solvent was removed in vacuo giving the crude product (0.454 g), which was purified by DFC (hexane, hexane–AcOEt 1:1), giving the pure product **12** (0.433 g, 70% yield); bp 150–152 °C at 0.05 Torr (1 Torr = 133.322 4 Pa). $[\alpha]^{25}_D$ –56.3° (*c* 1.38, CH_2Cl_2). IR (cm^{-1}): 2974, 1710, 1687, 1394, 1365. ^1H NMR δ: 7.80–7.60 (m, 4H), 7.25–7.00 (m, 5H), 5.65–5.14 (br s, 1H), 3.53–3.36 (m, 2H), 3.03–2.85 (br s, 2H), 1.89–1.68 (m, 2H), 1.50–1.41 (d, 3H, *J* = 7.07 Hz), 1.41–1.30 (s, 9H). ^{13}C NMR δ: 167.6, 155.2, 141.2, 133.5, 131.8, 127.9, 126.8, 122.7, 79.2, 59.8, 35.4, 28.0, 20.6, 16.9, 13.9. (*S*)-(–)-3-[*tert*-Butoxycarbonylamino-(1-phenylethyl)]-1-propylamine (4)

A solution of 95% hydrazine (1 mL) was added to a solution of **12** (0.200 g, 0.490 mmol) in EtOH (10 mL), and the reaction was stirred at room temperature overnight. A white solid (phthalazine-1,4-dione) was filtered off and washed with EtOH (10 mL). The filtrate was concentrated in vacuo. The residue was diluted with Et_2O (10 mL), and a saturated solution of sodium bicarbonate was added (10 mL). The aqueous layer was extracted with Et_2O (2 × 10 mL). The organic layers were combined, washed with brine (30 mL), and dried with $MgSO_4$. The solvent was removed in vacuo, and the crude product was obtained (0.150 g). The crude product was purified by DFC (hexane, hexane–AcOEt 1:1), giving pure **4** (0.110 g, 81% yield); bp 235 °C at 15 Torr. $[\alpha]^{25}_D$ –77.3° (*c* 1.11, CH_2Cl_2). IR (cm^{-1}): 2973, 2931, 1685, 1406, 1365, 699. ^1H NMR δ: 7.45–7.09 (m, 5H), 5.59–4.98 (br s, 1H), 3.23–2.70 (m, 2H), 2.65–2.35 (m, 2H), 1.55–1.47 (d, 3H, *J* = 7.00 Hz), 1.47–1.23 (m, 11H). ^{13}C NMR δ: 155.9, 141.9, 128.3, 127.0, 79.6, 53.7, 49.7, 41.4, 39.7, 33.7, 28.5, 17.5. Anal. calcd. for $C_{16}H_{26}N_2O_2$: C 69.03, H 9.41, N 10.06; found: C 69.07, H 9.16, N 9.99.

(*S*)-*N*-(1-Phenylethyl-3-propyl)amino-1-propoxymethyl polystyrene (19)

S-(–)-α-Methylbenzylamine (3.225 g, 3.43 mL, 26.65 mmol) was added to a slurry of polymer **2** (5.331 g, 6.930 mmol) in THF (150 mL). The reaction mixture was refluxed under N_2 for 72 h. After the reaction was completed, polymeric amine **19** was separated by filtration and washed with the following solvents (150 mL): THF, acetone, methanol, methanol–water (1:1), water, NaOH, water, methanol, ethanol, and ether, and then was dried under vacuum to constant weight and 5.00 g of product was obtained. The loading of the polymer was calculated from elemental analysis and was 0.636 mmol of N per gram. Dehalogenation was conducted according to the Dehalogenation procedure. The resulting pure polymeric amine **19** was dried to constant weight under reduced pressure and 4.85 g was obtained. The loading was determined to be the same as before the dehalogention procedure. ^1H NMR δ: 8.35–6.50 (m, 25H, Ar), 4.04–3.15 (m, 5H, $PhCH_2O$, O-CH_2, CH-N), 2.10–0.70 (m, 10H, CH_3, CH_2, CH, polymer matrix, and CH_3, CH_2, amine moiety). ^{13}C NMR δ: 128.5 (C-Ar), 126.7 (C-Ar), 68.8 ($PhCH_2O$-), 66.2 (OCH_2), 58.6 (CH-N), 45.5 (CH_2N), 40.6 (CH, polymer matrix), 31.0 (CH_2), 24.7 (CH_3). Found: C 87.68, H 7.57, N 0.92.

(*S*)-*N*-(1-Phenylethyl-6-hexyl)amino-1-hexoxymethyl polystyrene (20)

The amine **20** was synthesized according to the procedure described for amine **19**. Loading was calculated from elemental analysis and was 0.707 mmol of NH per gram. Dehalogenation was conducted according to the procedure for **19**. ^1H NMR δ: 7.60–6.13 (m, 32H, Ar, polymer matrix and amine moiety), 4.50–4.27 (br s, 2H, $PhCH_2O$-), 3.95–3.70 (br s, 1H, N-CH), 3.58–3.15 (br s, O-CH_2), 2.70–0.70 (m, 25H, CH_3, CH_2, CH, polymer matrix, and CH_3, CH_2, amine moiety). ^{13}C NMR δ: 145.4 (C-Ar), 128.2 (C-Ar), 127.9 (C-Ar), 125.9 (C-Ar), 73.0 ($PhCH_2O$-), 58.6 (CH-N), 45.4 (CH_2N), 44.0 (CH_2), 42.0 (CH_2, polymer matrix), 40.7 (CH, polymer matrix), 29.9 (CH_2), 26.4 (CH_2). Found: C 86.25, H 7.80, N 0.903.

(*S*,*S*)-(+)-4-(1-Phenylethylamino)-2-methyl-1-pentanol (21)

This compound was prepared according to a general procedure for reductive amination of ketones (27). A solution of 4-hydroxy-4-methyl-2-pentanone (1.00 g, 1.07 mL, 8.62 mmol) in MeOH (5 mL) was added to a solution of (*S*)-α-methylbenzylamine (0.949 g, 1.00 mL, 7.84 mmol) in MeOH (25 mL), followed by the addition of $NaBH_3CN$ (0.518 g, 8.23 mmol). The reaction was stirred at room temperature overnight. The solvent was removed in vacuo, a 10% solution of hydrochloric acid (50 mL) was added to the residue, and the aqueous layer was extracted with Et_2O (30 mL). The acidic aqueous layer was cooled down to 0 °C and was made basic by the slow addition of NaOH (ca. 4 g). The basic solution was extracted with Et_2O (3 × 50 mL). The organic layers were combined, washed with brine (75 mL), and dried with $MgSO_4$. The solvent was removed in vacuo giving a mixture of two products in a 5:1 ratio (GC). The products were separated by chromatography (hexane, hexane–AcOEt 1:1), and the major one was obtained (0.866 g, 50% yield); bp 135–139 °C at 6 mmHg (1 mmHg = 133.322 4 Pa). Only the major isomer was fully characterized. $[\alpha]^{26}_D$ +67.7°

(*S*,*S*)-(+)-4-(1-Phenylethylamino)-2-methyl-1-pentanol on polystyrene support (22)

A solution of amine **21** (2.00 g, 9.05 mmol) in dry DMF (5 mL) was added to a prewashed suspension of NaH (0.350 g, 14.6 mmol) in DMF (80 mL) at 0 °C under N_2. The reaction mixture was stirred for 1 h at 0 °C, and the polymer-supported benzyl iodide (**2**, 6.50 g, 7.15 mmol, 1.1 mmol of halide per gram) was added, followed by the addition of dry K_2CO_3 (2.498 g, 18.10 mmol). The reaction mixture was heated at 80 °C for 72 h. The mixture was cooled down to room temperature, and polymer **22** was separated by filtration, washed with H_2O (500 mL), followed by washing with 150 mL of each of the following solvents: MeOH, EtOH, THF, MeOH, and Et_2O. Polymer **22** was dried to constant weight under vacuum (7.0 g). ^1H NMR δ: 8.55–4.80 (m, 105H, Ar and CH-N), 3.70–3.10 (m, 4H, $PhCH_2$-N and N-CH_2), 2.64–0.00 (m, 110H, CH_3, CH_2, CH, polymer matrix, and CH_3, CH_2, amine moiety). ^{13}C NMR δ: 128.2 (C-Ar), 65.3 (C-O), 40.5 (CH, polymer matrix), 28.5 (CH_3-C), 17.3 (CH_3). Found: C 84.12, H 8.07, N 2.72, which indicated the loading of the resin to be 0.414 mmol of NH per gram.

3-[(1*R*,2*R*,5*S*)-2-Isopropyl-5-methylcyclohexylamino]-1-propanol (23)

A solution of 3-aminopropanol (2.212 g, 2.250 mL, 29.50 mmol) in dry MeOH (10 mL) was added to a solution of (–)-menthone (5.00 g, 5.60 mL, 32.5 mmol) in dry MeOH (50 mL), followed by the addition of $NaBH_3CN$ (2.047 g, 32.50 mmol). The pH of the reaction was adjusted to 6 by addition of glacial acetic acid, and the reaction mixture was stirred at room temperature overnight. The mixture was diluted with water (30 mL), and Et_2O (75 mL) was added. The organic layer was extracted with a 10% solution of HCl (3 × 50 mL). The acidic aqueous layers were made basic by slow addition of solid NaOH. The basic solution was extracted with Et_2O (3 × 50 mL). The organic layers were combined, dried with $MgSO_4$, and the solvent was removed in vacuo giving the crude product as two diastereomers in a 1:6 ratio (determined by GC; 7.00 g). The crude product was purified by chromatography (hexane, hexane–AcOEt 1:1) giving pure **23** (3.50 g, 55% yield); bp 145–147 °C at 7 mmHg. $[\alpha]^{29}_D$ +22.4° (*c* 1.14, CH_2Cl_2). IR (cm^{-1}): 3250, 2969, 1600, 1374, 700. ^1H NMR δ: 3.63 (dd, 2H, *J* = 5.15, 5.15 Hz), 2.86 (dt, 1H, *J* = 5.39, 11.20 Hz), 2.73 (d, 1H, *J* = 2.91 Hz), 2.47 (dt, 1H, *J* = 5.70, 11.50 Hz), 1.81 (dd, 1H, *J* = 2.43, 13.78 Hz), 1.61–1.48 (m, 4H), 1.48–1.35 (m, 1H), 1.30 (ddd, *J* = 6.63, 3.23, 13.21 Hz), 1.04–0.87 (m, 1H), 0.75 (d, 3H, *J* = 2.58 Hz), 0.74–0.69 (m, 9H). ^{13}C NMR δ: 64.4, 54.3, 48.1, 47.9, 37.5, 35.2, 31.5, 28.9, 25.6, 24.8, 22.5, 21.4, 20.5. (1*S*,2*R*,5*S*)-*N*-[(2-Isopropyl-5-methyl)cyclohexylamino]-3-propyl-1-propoxymethyl polystyrene (24)

A solution of amine **23** (3.443 g, 16.20 mmol) in DMF (10 mL) was added to a suspension of prewashed NaH (0.450 g, 18.75 mmol) at 0 °C, and the reaction was stirred under N_2 for 2 h. The reaction was warmed up to room temperature, and Merrifield resin (**1**) was added (6.50 g, 7.15 mmol, 1.1 mmol of Cl per gram), followed by the addition of dry K_2CO_3 (2.235 g, 16.20 mmol). The reaction mixture was heated at 80 °C for 72 h. The reaction mixture was cooled down to room temperature, and polymeric amine **24** was separated by filtration. The polymer was then washed with water (500 mL), followed by the following solvents (200 mL): 50% aq. MeOH, MeOH, EtOH, THF, MeOH, Et_2O, and THF, dried under vacuum to constant weight, and 7.0 g of the polymer were obtained. The loading of the polymer was calculated from elemental analysis and was 0.536 mmol of NH per gram. ^1H NMR δ: 8.40–5.60 (m, 44H, Ar), 3.90–3.70 (m, 4H, CH_2Cl, polymer matrix, and $PhCH_2O$-), 3.70–3.40 (m, 8H, OCH_2 and CH_2N), 2.70–1.42 (m, 4H, CH, polymer matrix, CH_2 in the ring), 1.42–0.60 (m, 10H, CH_2, polymer matrix, and CH_3, CH_2, CH, amine moiety). ^{13}C NMR δ: 128.1 (C-Ar), 66.0 ($PhCH_2O$-), 54.5 (CH-i-Pr), 48.8 (CH-N), 45.5 (CH_2N), 40.7 (CH, polymer matrix), 25.8 (CH_3), 15.5 (CH_3). Found: C 88.70, H 8.42, N 0.75.

Generation of the lithium enolate of tropinone using polymer-supported chiral lithium amides

Insoluble polymers

A solution of *n*-BuLi in hexanes (1.45 mol/L, 1.4 mL, 2.049 mmol) was added to a slurry of an insoluble polymer-supported chiral amine (2.049 mmol) in THF (20–25 mL) at 0 °C, and the resulting suspension was stirred for 8 h. Lithium chloride in THF (0.63 mol/L, 2.95 mL, 1.86 mmol) was added, and the stirring was continued for an additional 2 h. After cooling to –78 °C, tropinone (0.258 g, 1.86 mmol) in THF (2 mL) was added dropwise over ca. 3 min, and the resulting mixture was stirred overnight.

Soluble polymers

A solution of *n*-BuLi in hexanes (1.9 mol/L, 0.58 mL, 1.1 mmol) was added to a solution of a soluble polymer-supported chiral amine (1.1 mmol) in THF (25 mL) at 0 °C, and the resulting solution was stirred for 2.5 h. Lithium chloride in THF (1.0 mmol) was added, and the stirring was continued for an additional hour. After cooling to –78 °C, tropinone (0.139 g, 1.00 mmol) in THF (2 mL) was added dropwise for over a period of 3 min, and the resulting mixture was stirred for 3 h. If necessary, a second equivalent of *n*-BuLi (1.9 mol/L, 0.58 mL, 1.1 mmol) was added at this time, and the reaction mixture was warmed up to 0 °C. The stirring was continued for 30 min, followed by cooling down of the reaction mixture to –78 °C before the addition of an electrophile.

Noncrosslinked (*S*)-*N*-(methyl-1-phenylethyl)amino polystyrene (31)

A solution of (*S*)-(–)-α-methylbenzylamine (10.00 g, 10.64 mL, 82.64 mmol) in benzene (20 mL) was added to a solution of polymer **27** (20 g, 20 mmol, 1.0 mmol of halide per gram) in benzene (100 mL), and the reaction was refluxed for 48 h. The reaction was cooled down to room temperature, and the solvent was removed in vacuo. The residue was cooled down to –45 °C and methanol was added (300 mL). Amine **31** precipitated, was separated by filtration and washed with water (100 mL) and MeOH (500 mL), and then was dried to constant weight under vacuum and 20.5 g were obtained. The loading of the polymer **31** was calculated from elemental analysis and was 0.69 mmol of N per gram. ^{1}H NMR δ: 7.41–6.98 (m, 102 H, Ar), 6.98–6.45 (m, 66H, Ar), 4.74–4.54 (br s, 2H, CH_2X), 4.29 (q, J = 6.4 Hz, 2H, CH-N), 4.01–3.55 (m, 9 H, CH_2 and NH), 2.20–1.86 (m, 30H, CH, polymer matrix), 1.78–1.40 (m, 72H, CH_3, amine moiety and CH_2, CH_3, polymer matrix). ^{13}C NMR δ: 145.2 (C-Ar), 128.8 (C-Ar), 128.6 (C-Ar), 128.4 (C-Ar), 128.1 (C-Ar), 127.8 (C-Ar), 127.0 (C-Ar), 126.1 (C-Ar), 125.8 (C-Ar), 57.6 (-CH-N), 51.1 (CH_2N), 46.4 (CH_2Cl), 43.9 (CH_2, polymer matrix), 40.5 (CH, polymer matrix), 24.4 (CH_3, amine moiety). Found: C 89.16, H 7.74, N 1.47

Noncrosslinked (*R*)-[1-phenyl-2-(-1-piperidino)ethylmethyl]amino polystyrene (32)

A solution of (*R*)-(1-amino-1-phenyl)ethyl-1-piperidine (3.023 g, 15.00 mmol) in benzene (25 mL) was added to a solution of soluble polymer-supported benzyl iodide **27** (15.0 g, 15.0 mmol, 1.0 mmol of halide per gram) in benzene (150 mL), followed by the addition of K_2CO_3 (8.28 g, 60.0 mmol). The reaction mixture was refluxed under N_2 for 48 h. The solvent was removed in vacuo, and the residue was cooled down to –45 °C. Methanol (300 mL) was added and amine **32** precipitated. Polymer **32** was separated by filtration and washed with MeOH (200 mL), water (500 mL), and MeOH (750 mL), and then dried to constant weight under vacuum (16.099 g). The loading of amine **32** was estimated by subtracting the molar amount of unreacted amine from the total molar amount of amine used for the attachment to the polymer and was 0.944 mmol of N per gram. ^{1}H NMR δ: 7.25–6.25 (m, 70H, Ar), 3.90–3.65 (m, 2H, CH_2-N), 3.53–3.18 (m, 3H, CH_2-N, CH-N), 2.83–2.58 (m, 2H, CH_2), 2.58–2.28 (m, 4H, CH_2), 2.20–1.10 (m, 40H, CH_2, CH, polymer matrix and CH_2 amine moiety). ^{13}C NMR δ: 145.5 (C-Ar), 143.3 (C-Ar), 128.5 (C-Ar), 128.1 (C-Ar), 127.8 (C-Ar), 127.3 (C-Ar), 125.8 (C-Ar), 66.7 (CH_2N), 55.1 (CH-N), 54.7 (CH_2-N), 40.6 (CH, polymer matrix), 26.4 (CH_2), 24.7 (CH_2). Found: C 87.81, H 7.42, N 1.91.

Noncrosslinked 3-hydroxy-1-propoxymethyl polystyrene (33)

A solution of 1,3-propanediol (6.84 g, 6.58 mL, 90.0 mmol) in THF (20 mL) was added to a suspension of prewashed NaH (1.2 g, 50 mmol) in THF (100 mL) at 0 °C under N_2. After stirring for 2 h, a solution of soluble polymer **26** (15 g, 15 mmol, 1.0 mmol of Cl per gram) in THF (75 mL) was added dropwise, and the reaction was refluxed for 48 h. The reaction was cooled down to 0 °C and water (50 mL) was added. The layers were separated and the aqueous layer was extracted with AcOEt (3 × 300 mL). The organic layers were combined, dried with $MgSO_4$, and the bulk of the solvents were removed in vacuo. The residue was added to cold (–45 °C) MeOH (300 mL) and polymer **33** precipitated and was separated by filtration, washed with water (500 mL) and MeOH (750 mL). The polymer was dried under vacuum to constant weight and 15.5 g were obtained. The loading of **33** was calculated by gravimetric analysis (0.9 mmol of OH per gram). ^{1}H NMR δ: 7.40–6.86 (m, 79 H, Ar), 6.86–6.30 (m, 50H, Ar), 4.55–4.35 (m, 2H, CH_2Cl), 3.89–3.73 (m, 2H, CH_2OH), 3.73–3.55 (m, 2H, CH_2O), 3.45–3.25 (m, 1H, OH), 2.35–2.10 (m, 10 H, CH_2), 2.05–1.73 (m, 25 H, CH, polymer matrix), 1.70–1.24 (m, 47 H, CH_2, CH_3, polymer matrix). ^{13}C NMR δ: 145.4 (C-Ar), 131.2 (C-Ar), 128.9 (C-Ar), 128.1 (C-Ar), 127.8 (C-Ar), 125.8 (C-Ar), 73.3 (CH_2-OAr), 69.3 (-OCH_2), 62.1 (CH_2OH), 45.5 (CH_2Cl), 44.0 (CH_2, polymer matrix), 40.6 (CH, polymer matrix), 32.4 (CH_2, alcohol moiety). Found: C 87.63, H 7.87.

Noncrosslinked 6-hydroxy-1-hexoxymethyl polystyrene (34)

A solution of 1,6-hexanediol (9.912 g, 84.00 mmol) in dry DMF (30 mL) was added to a cold (0 °C) suspension of prewashed NaH (1.2 g, 50 mmol) in DMF (150 mL), and the reaction was stirred under N_2 for 2 h. Soluble polymer **26** (12 g, 12 mmol, 1.0 mmol of Cl per gram) was added. The reaction was heated at 80 °C for 48 h. The bulk of DMF was distilled off under reduced pressure. The residue was cooled down to –45 °C and MeOH (500 mL) was added. Polymer **34** precipitated and was separated by filtration, washed with water (250 mL) and MeOH (500 mL), and dried under vacuum to constant weight and 12.5 g were obtained. The loading of the polymer was calculated by the OH titration method and was 0.98 mmol of OH per gram. ^{1}H NMR δ: 7.45–6.35 (m, 55H, Ar), 4.55–4.34 (m, 2H, CH_2Cl), 3.75–3.60 (m, 2H, O-CH_2Ph), 3.55–3.30 (m, 4H, OCH_2, CH_2OH), 2.35–1.25 (m, 41H, CH_2, CH, CH_3, polymer matrix), 1.1–0.85 (m, 8H, CH_2). ^{13}C NMR δ: 145.4 (C-Ar), 138.0 (C-Ar), 128.1 (C-Ar), 127.8 (C-Ar), 125.8 (C-Ar), 73.5 (CH_2-OAr), 64.3 (OCH_2), 63.0 (CH_2OH), 45.5 (CH_2Cl), 44.4 (CH_2, polymer matrix), 40.6 (CH, polymer matrix), 32.9 (CH_2), 29.9 (CH_2), 26.3 (CH_2), 25.8 (CH_2). Found: C 85.82, H 7.93.

Noncrosslinked 3-iodo-1-propoxymethyl polystyrene (35)

Imidazole (2.652 g, 39.00 mmol) was added to a solution of triphenylphosphine (10.218 g, 39.00 mmol) in dry CH_2Cl_2 (200 mL), followed by the addition of iodide (9.906 g, 39.00 mmol) and polymeric alcohol **33** (10 g, 9.0 mmol, 0.9 mmol of OH per gram). The reaction was protected from light and stirred under N_2 at room temperature for 48 h. The reaction mixture was extracted with a saturated solution of $Na_2S_2O_3$ (3 × 100 mL). The organic layers were dried with $MgSO_4$ and the bulk of CH_2Cl_2 was removed in vacuo. The residue was cooled down to –45 °C and MeOH (500 mL) was added. The polymer precipitated, was separated by filtration, and washed with H_2O (200 mL) and MeOH (500 mL). The polymer was dried under vacuum to constant weight (11.5 g). The loading of the polymer was not determined at this stage. ^{1}H NMR δ: 7.27–6.27 (m, 84 H, Ar), 4.55–4.33 (m, 2H, CH_2Cl), 4.25–3.92 (m, 2H, CH_2-OAr), 3.60–3.41 (m, 2H, OCH_2), 3.39–3.20 (m, 2H, CH_2I), 3.89–3.50 (m, 2H, CH_2), 2.15–1.18 (m, 44 H, CH, CH_2, CH_3,

polymer matrix). ^{13}C NMR δ: 145.3 (C-Ar), 132.1 (C-Ar), 128.1 (C-Ar), 127.8 (C-Ar), 125.8 (C-Ar), 73.2 (CH_2-OAr), 69.5 (O-CH_2), 44.3 (CH_2Cl), 42.0 (CH_2, polymer matrix), 40.6 (CH, polymer matrix), 33.7 (CH_2), 3.7 (CH_2I). Found: C 77.75, H 6.54.

Noncrosslinked 6-iodo-1-hexoxymethyl polystyrene (36)

Compound **36** was prepared according to the procedure described for polymer **35**. The loading of starting alcohol **33** was 0.98 mmol of OH per gram. Polymer **36** was dried under vacuum to constant weight and 10.68 g were obtained; the loading was not determined at this stage. ^{1}H NMR δ: 7.40–6.25 (m, 120H, Ar), 4.57–4.32 (m, 2H, CH_2Cl), 4.3–3.92 (m, 2H, O-CH_2Ar), 3.62–3.35 (m, 2H, OCH_2), 3.30–3.11 (m, 2H, CH_2I), 2.98–2.54 (m, 4H, CH_2, alcohol moiety), 2.38–1.05 (m, 80H, CH_2, CH, polymer matrix, and CH_2 alcohol moiety). ^{13}C NMR δ: 145.4 (C-Ar), 132.2 (C-Ar), 128.6 (C-Ar), 128.0 (C-Ar), 127.8 (C-Ar), 125.8 (C-Ar), 73.0 (CH_2-OAr), 70.3 (OCH_2), 40.5 (CH, polymer matrix), 33.6 (CH_2), 30.4 (CH_2), 29.7 (CH_2), 25.5 (CH_2), 7.5 (CH_2I). Found: C 75.92, H 6.27.

Noncrosslinked (*S*)-*N*-[(1-phenylethyl-3-propyl)amino]-1-propoxymethyl polystyrene (37)

A solution of (*S*)-(–)-α-methylbenzylamine (4.588 g, 4.88 mL, 37.90 mmol) in benzene (10 mL) was added to a solution of polymer **35** (6.321 g, 5.690 mmol, 0.9 mmol of halide per gram) in benzene (150 mL), and the reaction was refluxed under N_2 for 48 h. The reaction was cooled down to room temperature and the bulk of the benzene was removed in vacuo. The residue was cooled down to –45 °C and MeOH (300 mL) was added slowly. Polymeric amine **37** precipitated, was separated by filtration, and washed with water (250 mL) and MeOH (300 mL), and then was dried to constant weight under vacuum and 6.0 g were obtained. The loading was determined from elemental analysis and was 0.985 mmol per gram. ^{1}H NMR δ: 7.50–6.40 (m, 142 H, Ar), 4.59–4.33 (m, 2H, CH_2Cl), 4.28–4.16 (m, 1H, CH-OAr), 3.98–3.80 (m, 1H, CH-OAr), 3.70–3.35 (m, 3H, OCH_2, CH-N), 2.85–2.57 (m, 2H, N-CH_2), 2.53–1.13 (m, 80H, CH_2, CH, CH_3, polymer matrix and CH_2, CH_3, amine moiety). ^{13}C NMR δ: 145.3 (C-Ar), 135.0 (C-Ar), 128.6 (C-Ar), 128.1 (C-Ar), 127.8 (C-Ar), 126.8 (C-Ar), 125.8 (C-Ar), 72.9 (CH_2-OAr), 68.9 (OCH_2), 64.4 (CH-N), 58.7 (CH_2-N), 45.4 (CH_2Cl), 44.1 (CH_2, polymer matrix), 40.5 (CH, polymer matrix), 30.0 (CH_2), 24.5 (CH_3). Found: C 87.50, H 8.03, N 1.17.

Noncrosslinked (*S*)-*N*-[(1-phenylethyl-6-hexyl)amino]-1-hexoxymethyl polystyrene (38)

Amine **38** was prepared according to the procedure described for amine **37**. The product was dried to constant weight under vacuum and 9.5 g were obtained. The loading of polymer **38** was calculated from elemental analysis and was 0.742 mmol N per gram. ^{1}H NMR δ: 7.25–6.25 (m, 179H, Ar), 4.60–4.35 (m, 2H, CH_2Cl), 4.25–4.13 (m, 1H, ArO-CH_2), 3.95–3.70 (m, 1H, ArO-CH_2), 3.55–3.30 (m, 4H, OCH_2, CH-N, NH), 2.65–0.90 (m, 115H, CH_2, CH polymer matrix, and CH_2N, CH_2, CH_3, amine moiety). ^{13}C NMR δ: 145.4 (C-Ar), 134.0 (C-Ar), 128.6 (C-Ar), 128.1 (C-Ar), 125.8 (C-Ar), 73.2 (CH_2-OAr), 70.5 (OCH_2), 64.3 (CH-N), 58.5 (CH_2N), 45.4 (CH_2, polymer matrix), 40.6 (CH, polymer matrix), 29.5 (CH_2), 27.3 (CH_2), 26.2 (CH_3). Found: C 87.62, H 7.69, N 1.05.

(1*S*,2*R*,1′*S*)-2-(1′-Hydroxybenzyl)-8-methyl-8-azabicyclo[3.2.1]octan-3-one (40) (ref. 28)

Synthesis using insoluble polymer-supported chiral lithium amides

Benzaldehyde (0.217 g, 0.208 mL, 2.049 mmol) was added to a solution of tropinone lithium enolate (1.86 mmol) at –78 °C, generated as described previously, and the reaction mixture was stirred for 4 h. The mixture was quenched with a saturated solution of NH_4Cl (10 mL). The polymer was separated by filtration and washed with NH_4Cl solution and Et_2O. The aqueous layer was separated and extracted with Et_2O (3 × 50.00 mL). The organic extracts were combined and dried with $MgSO_4$. The solvents were removed in vacuo and the crude product was obtained. The crude product was purified by chromatography (hexane–AcOH (4:1), CH_2Cl_2–MeOH (85:15)) and the reaction yield and enantioselectivity were determined as described before (28).

Synthesis using soluble polymer-supported chiral lithium amides

Benzaldehyde (117 mg, 0.11 mL, 1.10 mmol) was added to a solution of tropinone enolate at –78 °C (1.0 mmol) generated as described previously, and the reaction mixture was stirred for 1 h. The mixture was quenched with a saturated solution of NH_4Cl (10 mL), and quickly extracted with AcOEt (3 × 100 mL). The organic extracts were combined, dried with $MgSO_4$, and the solvents were removed in vacuo. The residue was cooled down to –40 °C and MeOH (100 mL) was added. A soluble polymer-supported amine precipitated out, and was separated by filtration. The filtrate was concentrated in vacuo, and the crude product was obtained. The crude product was purified by chromatography (hexane–AcOH (4:1), CH_2Cl_2–MeOH (85:15)), and the reaction yield and enantioselectivity were determined as described before (28).

6-[*N*-(2,2,2-Trichloroethoxycarbonyl)-*N*-methyl]-amino-2-cyclohepten-1-one (41) (ref. 4*e*)

With insoluble polymer-supported chiral lithium amides

2,2,2-Trichloroethyl chloroformate (0.434 g, 0.28 mL, 2.05 mmol) was added to a solution of tropinone lithium enolate (1.86 mmol), generated as described previously, and the reaction mixture was stirred for 8 h. The reaction was quenched with a saturated solution of K_2CO_3 (10 mL), and the polymeric amine was separated by filtration and washed with a saturated solution of K_2CO_3 (100 mL) and Et_2O (100 mL). The aqueous layer was separated and extracted with Et_2O (3 × 50.00 mL). The organic extracts were combined and dried with $MgSO_4$. The solvents were removed in vacuo, and the crude product was purified by DFC (hexane, hexane–AcOEt 1:1) and pure **41** was obtained. Spectral characterisctics of compound **41** and the method for measuring ee were described before (4*e*).

With soluble polymer-supported chiral lithium amides

2,2,2-Trichloroethyl chloroformate (277 mg, 0.18 mL, 1.30 mmol) was added to a solution of tropinone lithium

enolate (1.0 mmol), generated by as described previously (with a second equivalent of *n*-BuLi), and the reaction mixture was stirred for 2 h. The mixture was quenched with a saturated solution of K_2CO_3 (10 mL) and was then allowed to warm up to room temperature. The mixture was then extracted with AcOEt (3 × 100 mL). The organic extracts were combined, dried with $MgSO_4$, and the solvents were evaporated. The residue was cooled down to –40 °C and methanol (100 mL) was added. A soluble polymer-supported amine precipitated out and was separated by filtration. The filtrate was concentrated in vacuo, and the crude product was obtained. The crude product was purified by chromatography (hexane, hexane–AcOEt 1:1).

Synthesis and characterization of N-silylated, C_1-symmetric benzamidinates of lithium, sodium, and tin(II)[1]

Floria Antolini, Peter B. Hitchcock, Alexei V. Khvostov, and Michael F. Lappert

Abstract: The synthesis and characterization of complexes obtained from the reactions between Li[*N*-*t*-Bu(SiMe$_3$)] (**A**) or the sodium analogue Na[*N*-*t*-Bu(SiMe$_3$)] (**B**) and the cyanoarene RCN (R = Ph or 4-MeOC$_6$H$_4$) are discussed. These are the THF adduct [Li{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(THF)]$_2$ (**1**), the TMEDA adduct Li[N(*t*-Bu)C(Ph)N(SiMe$_3$)](TMEDA) (**2**), the neutral ligand-free lithium benzamidinate Li[N(*t*-Bu)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)] (**3**), and the THF adduct Li[N(*t*-Bu)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)](THF) (**3a**). The preparation and structure of the crystalline compound [Na{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(OEt$_2$)]$_2$ (**4**) is described. From the lithium benzamidinate **1** and Sn(II) chloride the tin(II) complex [Sn{N(*t*-Bu)C(Ph)N(SiMe$_3$)}$_2$] (**5**) was obtained. The molecular structures of the crystalline compounds **1**, **4**, and **5** were established by X-ray diffraction. In **1** and **4** the benzamidinato ligand is both chelating and bridging, with the Me$_3$Si-substituted nitrogen atom as the bridging site. The central planar (MN)$_2$ four-membered ring is a rhombus in **1**, with almost equal Li—N bond lengths, whereas in **4** the bonds to Na(1) are significantly longer than those to Na(2). In **5**, the ligand is N,N′-chelating.

Key words: alkali metals, tin(II), benzamidinates, NMR spectra, X-ray structures.

Résumé : On discute de la synthèse et de la caractérisation de complexes obtenus par les réactions du Li[*N*-*t*-Bu(SiMe$_3$)] (**A**) ou de analogue sodique Na[*N*-*t*-Bu(SiMe$_3$)] (**B**) avec des cyanoarènes RCN (R = Ph ou 4-MeOC$_6$H$_4$) et isolés sous la forme de benzamidinate de lithium neutre, sans ligand, [Li[N(*t*-Bu)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)] (**3**) ou sous la forme d'adduits avec le THF [Li{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(THF)]$_2$ (**1**) ou [Li[N(*t*-Bu)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)](THF) (**3a**) et avec le TMEDA Li[N(*t*-Bu)C(Ph)N(SiMe$_3$)](TMEDA) (**2**). On a aussi préparer le composé [Na{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(OEt$_2$)]$_2$ (**4**) dont on a déterminé la structure cristalline. La réaction du benzamidinate de lithium (**1**) avec le chlorure d'étain(II) permet d'obtenir le complexe d'étain(II) [Sn{N(*t*-Bu)C(Ph)N(SiMe$_3$)}$_2$] (**5**). On a déterminé les structures moléculaires des composés cristallins **1**, **4** et **5** par diffraction des rayons X. Dans les composés **1** et **4**, le ligand benzamidinato agit à la fois comme pont et comme agent chélatant alors que l'atome d'azote substitué par un groupe Me$_3$Si agit comme pont. Le cycle central planaire à quatre chaînons (MN)$_2$ est rhombique dans le composé **1** et les longueurs de ses liaisons Li—N sont pratiquement égales alors que dans le composé **4** les longueurs des liaisons vers le Na(1) sont beaucoup plus longues que celles vers la Na(2). Dans le composé **5**, le ligand est N,N′-chélatant.

Mots clés : métaux alcalins, étain(II), benzamidinates, spectres RMN, structures déterminées par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

Amidines and amidinates are valuable reagents in organic synthesis (1). The amidinato ligand [N(R^1)C(R^2)N(R^3)]$^-$ (Am$^-$) is widely employed in coordination chemistry; there have already been more than 100 publications in the 21st century. Its role often is that of a spectator ligand. Attractive features are that (*i*) its steric and electronic properties can be widely varied by judicious selection of the substituents R^1, R^2, and R^3, (*ii*) it can display a diversity of bonding modes in its binding to the metal or metals, and (*iii*) it often is firmly bound to the latter. Reviews have dealt with transition metal amidinates (2*a*), s-, p-, d-, and f-block metal *N*,*N*′-bis(trimethylsilyl)benzamidinates (R^1 = SiMe$_3$ = R^3, R^2 = an aryl group) (2*b*), and "paddle-wheel" dinuclear formamidinates of formula [M$_2${N(R^1)C(H)N(R^3)}$_4$(L$_{ax}$)$_n$] (M = Mo, Rh, Ni, or Ru; R^1 = an aryl group = R^3, L$_{ax}$ is the axial ligand; *n* = 0–2) (2*c*).

Some group 4 metal amidinates are catalysts for olefin polymerization, as summarized in a recent survey on advances in non-metallocene olefin polymerization (3). For example, isotactic polypropylene was obtained using tris(amidinato)zirconium(IV) complexes bearing a chiral N-substituted ligand (4); and C_1-symmetric amidinates, $[Zr(Am)_2Me_2]$ (Am: $R^1 \neq R^3$), were moderately active for formation of isotactic poly(1-hexene) (5). Cationic aluminium amidinates, such as $[Al\{(N\text{-}i\text{-}Pr)_2C\text{-}t\text{-}Bu\}Me][B(C_6F_5)_3Me]$, were shown to be active single site catalysts for the living polymerization of ethylene (6). Lanthanide metal amidinates, $[Ln\{(N(c\text{-}C_6H_{11}))_2CR^2\}_3]$ (Ln = Nd, Gd, Yb; R^2 = Me or Ph), were highly active catalysts for the ring-opening polymerization of ε-caprolactam (7).

The more important methods that have been used to prepare metal amidinates are (*i*) metallation of the amidine $HN(R^1)C(R^2)N(R^3)$, (*ii*) ligand transfer reactions from either an alkali metal (8) or trimethylsilyl (9) amidinate and a metal chloride, (*iii*) addition of a metal hydrocarbyl to a carbodiimide (e.g., LiR^2 to $R^1N{=}C{=}NR^3$, $R^1 = SiMe_3 = R^3$, R^2 = aryl), and (*iv*) the reaction between a metal bis(trimethylsilyl)amide and a cyanoarene. As for (*iv*), Sanger (in our laboratory) found in 1973 that $Li[N(SiMe_3)_2]$ and PhCN in Et_2O readily yielded $Li[\{N(SiMe_3)\}_2CPh]$, which was characterized by treatment with Me_3SiCl, yielding the benzamidine $N(SiMe_3)_2C(Ph){=}N(SiMe_3)$ (10); substantial extensions to this methodology up to 1990 have been summarized (5*b*). In the present paper are described reactions of the related, but C_1-symmetric, alkali metal amides M[*N*-*t*-Bu($SiMe_3$)] (M = Li (**A**) (11), M = Na (**B**) (12)) with PhCN or 4-$MeOC_6H_4CN$.

Our prior publications in this area dealt with $[K\{N(SiMe_3)C(C_6H_3Me_2\text{-}2,5){=}C(H)SiMe_3\}]_2$ and $[\{UCl(\mu\text{-}Cl)(L)N(SiMe_3)\}_2][UCl_2(L)(Am)]_2$ (L = $\{N(SiMe_3)C(Ph)\}_2CH$, Am = $N(SiMe_3)C(Ph)NC(Ph){=}C(H)SiMe_3$) (13*a*), M[{N-(CH=$NSiMe_3$)}$_2$CH]$_n$ [*n* = 3 and M = Li (13*b*), Na (13*c*); *n* = 4, Tl (13*c*)); $[Li(Am)(CNPh)]_2$ (13*d*), $[K(Am)]_2$, [SnCl(Am)], $[Sn(Am)_2]$, and $[Hg(Am)_2]$ (Am = $N(SiMe_3)C(Ph)$-$NC(Ph){=}C(SiMe_3)_2$) (13*e*); $Li[N(SiMe_3)C(Ar)NC(Ar){=}C(H)$-$SiMe_3]$(D) (D = TMEDA or THF with Ar = Ph; or D = TMEDA, Ar = 4-MeC_6H_4) (13*f*); $[Li(Am)]_2$, $[M(Am)Cl_2]$ (M = Al or Ga) and $[\{Ln(Am)_2(\mu\text{-}Cl)\}_2]$ (Am = $N(SiMe_3)C$-$(Ph)N(CH_2)_3NMe_2$, Ln = La or Ce) (13*g*); $Li[N(SiMe_3)C$-$(H)NC(H){=}C(H)C(t\text{-}Bu){=}NSiMe_3]$ (13*h*); and $Li[N(Si$-$Me_2OMe)C(C_6H_3Me_2\text{-}2,5)NC(C_6H_3Me_2\text{-}2,5){=}C(H)SiMe_3]$-(TMEDA) (13*i*).

Experimental

General remarks

All manipulations were performed under argon using standard Schlenk techniques. Hexane was dried and distilled over sodium–potassium alloy, THF and diethyl ether were dried and distilled over sodium–benzophenone and stored over a sodium mirror under argon. TMEDA (Aldrich) was distilled from CaH_2 prior use. Nitriles (Aldrich) were dried over molecular sieves. The alkali metal amides M[N-*t*-Bu($SiMe_3$)] (M = Li (**A**) (14), Na (**B**) (12)) were synthesized by published procedures. The NMR spectra were recorded on a Bruker DPX 300 (300.1 MHz for ^{1}H, 75.5 MHz for ^{13}C, and 116.6 MHz for ^{7}Li) or an AMX 500 (49.7 MHz for ^{29}Si) instrument, and referenced externally (^{7}Li, using LiCl; ^{29}Si, using $SiMe_4$) or internally to the residual solvent resonances. Unless otherwise stated, all NMR spectra were measured at 298 K and other than ^{1}H were proton-decoupled. Electron impact mass spectra were taken from solid samples using a Kratos MS 80 RF instrument. Melting points were taken in sealed capillaries and are uncorrected. Elemental analyses were determined by Medac Ltd., Brunel University, Uxbridge, Middlesex, UK.

Preparations

[Li{μ-cis-N(t-Bu)C(Ph)N(SiMe$_3$)}(THF)]$_2$ (1)

A solution of PhCN (0.46 cm^3, 4.49 mmol) in diethyl ether (5 cm^3) was added slowly to a cooled (–78 °C) solution of **A** (1.01 g, 4.49 mmol) in diethyl ether (15 cm^3). The resulting yellow mixture was allowed to warm to room temperature and was stirred for 12 h. The slightly cloudy mixture was filtered and the filtrate was concentrated and stored at –25 °C for 24 h, yielding colorless crystals of the 1:1 ether adduct (0.58 g, 44.7%). As the diethyl ether was not strongly bonded to the molecule, during the drying in vacuo the complex gradually lost the coordinated solvent, compromising the credibility of the analysis. Thus, the diethyl ether adduct was recrystallized from a satd. THF solution and a few colorless crystals of compound **1** were obtained (mp 55–80 °C). ^{1}H NMR (C_6D_6) δ: 0.06 (s, 9H, $SiMe_3$), 1.26 (s, 9H, *t*-Bu), 1.35 (m, 4H, THF), 3.59 (m, 4H, THF), 7.09 (d, 1H, $^3J_{HH}$ = 7.20 Hz), 7.12 (m, 2H, Ph), 7.29 (d, 2H, $^3J_{HH}$ = 7.12 Hz). ^{13}C NMR (C_6D_6) δ: 2.91 ($SiMe_3$), 25.43 (THF), 33.49 (CMe_3), 51.38 (CMe_3), 68.11 (THF), 126.59, 127.49, and 127.83 (Ph), 145.37 (ipso-C), 175.65 (NCN). ^{7}Li NMR (C_6D_6) δ: –0.48. ^{29}Si NMR (C_6D_6) δ at 323 K: –8.08 and –10.65; at 298 K, δ –10.69. MS (*M* denotes the monomer) *m*/*z* (% and assignment): 508 (8%, $[M_2 - 2THF]^+$), 451 (72%, $[M_2 - 2THF - t\text{-}Bu]^+$), 395 (8%, $[M_2 - 2THF - 2t\text{-}Bu + H]^+$), 375 (48%, $[M_2 - 2THF - Ph + H]^+$).

[Li{N(t-Bu)C(Ph)N(SiMe$_3$)}(TMEDA)] (2)

A solution of PhCN (0.32 cm^3, 3.11 mmol) in hexane (5 cm^3), was added to a cooled (0 °C) solution of **A** (0.47 g, 3.11 mmol) in hexane (25 cm^3). The reaction mixture was allowed to warm to room temperature and was stirred for 4 h. TMEDA (0.61 cm^3, 4.04 mmol) was added to the mixture, which was stirred for 12 h. The mixture was filtered; the filtrate was concentrated and stored at 10 °C for 12 h. Being cloudy, it was again filtered; the filtrate was concentrated and stored at 10 °C for a further 12 h to furnish yellow crystals of compound **2** (0.71 g, 61.3%), mp 132–135 °C. ^{1}H NMR (C_6D_6) δ: 0.09 (s, 9H, $SiMe_3$), 1.25 (s, 9H, *t*-Bu), 1.78 (s, 4H, TMEDA), 2.02 (s, 12H, TMEDA), 7.06 (tt, 1H, *p*-H of Ph, $^3J_{HH}$ = 7.6 Hz, $^4J_{HH}$ = 1.2 Hz), 7.15 (m, 2H, *m*-H of Ph), 7.35 (dd, 2H, *p*-H of Ph, $^3J_{HH}$ = 7.9 Hz, $^4J_{HH}$ = 1.2 Hz). ^{13}C NMR (C_6D_6) δ: 4.05 ($SiMe_3$), 34.32 (CMe_3), 50.67 (CMe_3), 125.80, 127.18 (*C*H of Ph), 146.47 (ipso-C), 174.56 (NCN). ^{29}Si NMR (C_6D_6) δ at 50 °C: –15.19. ^{7}Li NMR (C_6D_6) δ: –0.34. MS *m*/*z* (% and assignment): 375 (34%, $[M + Li - H]^+$), 262 (37%, $[M - TMEDA + Li + H]^+$), 247 (79%, $[M - Li - TMEDA]^+$), 191 (100%, $[247 - t\text{-}Bu]^+$).

[Li{N(t-Bu)C(C_6H_4OMe-4)N($SiMe_3$)}] (3)

4-$MeOC_6H_4CN$ (0.49 g, 3.62 mmol) was added in small portions to a cooled (–78 °C) solution of **A** (0.55 g, 3.63 mmol) in diethyl ether (45 cm^3). The reaction mixture was allowed to warm to room temperature and was stirred for 12 h. The cloudy mixture was filtered and the filtrate concentrated and stored at –25 °C for 12 h to afford an amorphous, ether-solvated product (Et_2O–benzamidinate, 1:2; calculated from the NMR integrals), recrystallized from a saturated hexane solution yielding compound **3** (0.29 g, 28%), as a yellow crystalline material (not suitable for X-ray analysis); mp 127–130 °C. ^{1}H NMR (C_6D_6) δ: 0.01 (s, 9H, $SiMe_3$), 1.25 (s, 9H, *t*-Bu), 3.30 (s, 3H, MeO), 6.75 (d, 2H, $^3J_{HH}$ = 8.37 Hz), 7.17 (d, 2H, $^3J_{HH}$ = 9.42 Hz). Anal. calcd. for $C_{15}H_{25}LiN_2OSi$ (%): C 63.5, H 9.41, N 9.83; found: C 62.5, H 8.49, N 9.81.

MS *m*/*z* (% and assignment): 277 (85%, [*M* – Li]$^+$), 263 (38%, [*M* – Li – Me]$^+$), 221 (100%, [*M* – *t*-Bu – H]$^+$), 206 (65%, [*M* – *t*-Bu – Me – H]$^+$), 73 (100%, [$SiMe_3$]$^+$), 57 (12%, [*t*-Bu]$^+$).

[Li{μ-cis-N(t-Bu)C(C_6H_4OMe-4)N($SiMe_3$)}(THF)] (3a)

Evaporation of a THF solution of **3** produced the amorphous complex **3a**. ^{1}H NMR (C_6D_6) δ: 0.11 (s, 9H, $SiMe_3$), 1.29 (s, 9H, *t*-Bu), 1.39 (m, 4H, CH_2 of THF), 3.33 (s, 3H, MeO), 3.64 (m, 4H, OCH_2 of THF), 6.78 (d, 2H, *m*-H of C_6H_4, $^3J_{HH}$ = 8.65 Hz), 7.22 (d, 2H, *o*-H of C_6H_4, $^3J_{HH}$ = 8.48 Hz). ^{13}C NMR (C_6D_6) δ: 3.22 ($SiMe_3$), 25.51 (THF), 33.65 (C*Me*$_3$), 51.35 (*C*Me_3), 54.63 (MeO), 68.16 (THF), 112.90 (*m*-C of C_6H_4), 129.05 (*o*-C of C_6H_4), 138.07 (ipso-C of C_6H_4), 158.75 (*p*-C of C_6H_4), 175.58 (NCN). ^{7}Li NMR (C_6D_6) δ: 1.86. ^{29}Si NMR (inverse gated, d_1 = 25 s, C_6D_6) δ: –11.30. ^{1}H NOE (C_6D_6, η, %) irradiation of MeO: 5.7 (*m*-H of C_6H_4). ^{1}H{^{7}Li} NOE (C_6D_6, – η, %): 0.08 ($SiMe_3$), 0.12 (OCH_2 of THF), 0.15 (*o*-H of C_6H_4).

[Na{μ-cis-N(t-Bu)C(Ph)N($SiMe_3$)}(OEt_2)]$_2$ (4)

A solution of PhCN (0.98 cm^3, 9.56 mmol) in diethyl ether (5 cm^3) was added slowly to a cooled (0 °C) solution of **B** (1.60 g, 9.56 mmol) in diethyl ether (50 cm^3). The resulting solution was allowed to warm to room temperature, stirred for 12 h, concentrated and stored at –25 °C for 24 h, yielding colorless crystals of compound **4** (2.24 g, 69%). ^{1}H NMR (C_6D_6) δ: 0.04 (s, 9H, $SiMe_3$), 1.20 (t, 6H, Et_2O), 1.25 (s, 9H, *t*-Bu), 3.24 (q, 4H, Et_2O), 7.00–7.25 (m, 5H, Ph). ^{13}C NMR (333 K, C_6D_6) δ: 3.70 ($SiMe_3$), 15.30 (C*Me*$_3$), 34.12 (Et_2O), 51.38 (*C*Me_3), 65.91 (Et_2O), 126.28, 127.49, 129.08 (Ph), 146.23 (ipso-C), 175.10 (NCN). ^{23}Na NMR (C_6D_6) δ: 8.54 ($\Delta\nu_{1/2} \approx 2.6$ kHz). ^{29}Si NMR (ineptrd, C_6D_6) δ: –13.37. Anal. calcd. for $C_{18}H_{33}N_2NaOSi$ (%): C 62.8, H 9.65, N 8.13; found: C 62.3, H 9.38, N 8.09.

[Sn{N-t-BuC(Ph)N($SiMe_3$)}$_2$] (5)

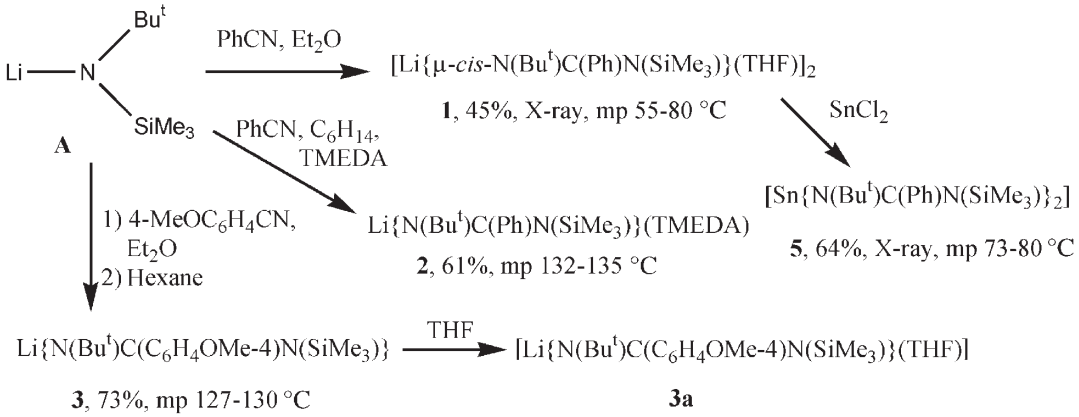
$SnCl_2$ (0.481 g, 2.54 mmol) was added to a cooled (0 °C) solution of **1** (1.48 g, 5.08 mmol) in diethyl ether (40 cm^3). The mixture was warmed to room temperature and stirred for 12 h. The volatiles were removed at 30 °C and 10^{-2} Torr (1 Torr = 133.3224 Pa). The residue was extracted into diethyl ether. The extract was filtered and the filtrate concentrated and stored at –25 °C for 4 months to furnish pale yellow crystals of compound **5** (1.0 g, 64%), mp 73–80 °C. ^{1}H NMR (C_6D_6) δ: 0.11 (s, 9H, $SiMe_3$), 1.24 (s, 9H, *t*-Bu), 7.01 (m, 5H, Ph). ^{13}C NMR (C_6D_6) δ: 2.86 ($SiMe_3$), 33.22 (C*Me*$_3$), 53.94 (*C*Me_3), 126.88, 128.32, 128.99 (Ph), 142.15 (ipso-C), 170.01 (NCN). ^{29}Si NMR (C_6D_6) δ: –1.75. ^{119}Sn NMR (C_6D_6) δ: –258.5. MS *m*/*z* (% and assignment): 614 (25%, [*M*]$^+$), 557 (6%, [*M* – *t*-Bu]$^+$), 367 (27%, [*M* – (*N*-*t*-Bu)C(Ph)$NSiMe_3$)]$^+$), 247 (48%, [(*N*-*t*-Bu)C(Ph)($NSiMe_3$)]$^+$), 233 (50%, [(*N*-*t*-Bu)C(Ph)($NSiMe_3$) – *t*-Bu]$^+$), 191 (100%, [$SiMe_3$N=CPh]$^+$). Anal. calcd. for $C_{28}H_{46}N_4Si_2Sn$ (%): C 54.8, H 6.59, N 9.11; found: C 54.0, H 7.57, N 9.13.

X-ray crystallographic analysis of [Li{μ-*cis*-N(*t*-Bu)C(Ph)N($SiMe_3$)}(THF)]$_2$ (1), [Na{μ-*cis*-N(*t*-Bu)C(Ph)N($SiMe_3$)}(OEt_2)]$_2$ (4), and [Sn{η^3-N(*t*-Bu)C(Ph)N($SiMe_3$)}$_2$] (5)

Diffraction data for compound **1** were collected on a Nonius CAD4 and for **4** and **5** on a Nonius Kappa-CCD diffractometer using monochromated Mo Kα radiation (λ = 0.710 73 Å). Crystals were directly mounted on the diffractometer under a stream of cold nitrogen gas. In complex **4** there was unresolved end-for-end disorder in one ligand giving rise to partial Si/C occupancy for the sites labeled Si(2) and C(25) and some unrealistic ADPs for this ligand. DELU restraints were applied. Dimensions in the disordered ligand are unreliable. In both ligands of complex **5** there was unresolved end-for-end disorder of the $SiMe_3$ and *t*-Bu groups; 0.86:0.14 for Si1 and C8, and 0.65:0.35 for Si2 and C22. Bonds and angles involving these atoms are therefore unreliable. The structures were refined on all F^2 using SHELXL 97 (15). Further details are in Table 1.

Results and discussion

Reactions between Li[*N*-*t*-Bu($SiMe_3$)] (A) and the nitrile RCN (R = Ph or 4-$MeOC_6H_4$)



The initial targets in the nitrile reactions were lithium amidinates derived from Li[*N*-*t*-Bu($SiMe_3$)] (**A**) (11). This was based on an analogy with reactions of Li[N($SiMe_3$)$_2$] (14) with a cyanoarene (10, 2*b*). The results of treating **A** with PhCN and 4-$MeOC_6H_4CN$ are summarized in Scheme 1.

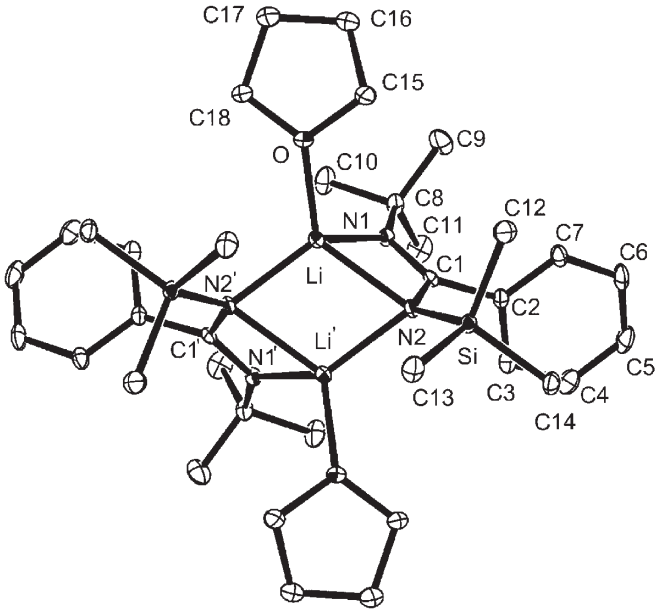
Scheme 1. Synthesis of complexes **1**–**3** and **5**.

The colorless, crystalline, binuclear THF-bound lithium benzamidinate [Li{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(THF)]$_2$ (**1**) was obtained after crystallizing the initially formed weakly bound diethyl ether adduct from THF. Alternatively, by carrying out the reaction between **A** and PhCN in hexane, followed by addition of TMEDA, the product was the yellow, crystalline, and probably (MS) mononuclear TMEDA adduct, Li[N(*t*-Bu)C(Ph)N(SiMe$_3$)](TMEDA) (**2**), as in the X-ray-characterized compounds, [Li{N(SiMe$_3$)C(Ph)N(SiMe$_3$)}-(TMEDA)] (16), [Li{N(myrtanyl)C(Ph)N(SiMe$_3$)}(TMEDA)] (4), and [Li{N(*i*-Pr)C(terpenyl)N(*i*-Pr)}(TMEDA)] (17).



The reaction between **A** and 4-MeOC$_6$H$_4$CN in diethyl ether yielded the expected lithium benzamidinate as an amorphous powder containing weakly bound diethyl ether; crystallization from hexane afforded the neutral donor-free, pale-yellow, crystalline compound [Li{N(*t*-Bu)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)}] (**3**), which in THF solution yielded the adduct [Li{N(*t*-Bu)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)}(THF)] (**3a**).

Compounds **1**, **2**, and **3** gave satisfactory multinuclear (^{1}H, ^{13}C, ^{7}Li and ^{29}Si) NMR and mass (EI) spectra, as well as microanalysis for **3**. Complex **1** was further authenticated by its molecular structure determination by single crystal X-ray diffraction; X-ray quality crystals were not obtained for **2**, **3**, and **3**·THF. Whereas the mass spectrum of **3** was consistent with it being a mononuclear complex, the ^{1}H NMR spectrum in $C_6D_5CD_3$ at ambient temperature gave broad signals, which sharpened only upon heating. In the 231–338 K range, there appeared to be three species present. The heteronuclear ^{1}H{^{7}Li} NOE experiment of the THF adduct **3a** suggests that in benzene solution the compound has the cis-dimeric structure, as found in the crystalline THF adduct **1** (Fig. 1).

The THF-solvated lithium benzamidinate [Li{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(THF)]$_2$ (**1**) was crystallized after storage for 1 day at –25 °C. An ORTEP representation of complex **1** is depicted in Fig. 1. Selected bond distances (Å) and angles (°) are reported, together with data for the related

Fig. 1. Molecular structure of [Li{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(THF)]$_2$ (**1**) (20% ellipsoids, H atoms are omitted for clarity).

compound, [Li{μ-N(SiMe$_3$)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)$_2$}(THF)]$_2$ (**6**) (18, 19), in Table 2.

A fused array of three, four-membered rings forms the core of molecule **1**. The dihedral angles between each of the outer rings and the central are 129.85° and 112.19°. The central [LiN(2)Li′N(2)′] rhomboid core is puckered, being folded by 13.7° around the Li(1)-Li(2) vector. The presence of a *tert*-butyl group imposes a distinct asymmetry on the N-C-N system (N(1)—C(1) = 1.302(3) Å and C(1)—N(2) = 1.370(3) Å). This corresponds to differences in the Li—N(1) and Li—N(2) bond lengths. The two nitrogen atoms of each benzamidinate ligand differ in that the *tert*-butyl-bound N is three-coordinate, whereas the four-coordinated trimethylsilyl-bound N atom bridges the two lithium atoms; thus, each ligand is N,N′-chelating, but also N(SiMe$_3$)-bridging. Due to steric impediments, the *tert*-butyl groups in complex **1** are arranged in a cis fashion. This creates narrower folding angles of the ladder structure core (112.89° and 129.85°) than in **6** (130.4° and 145.3°) (19). Thus, compound **1** exhibits a more compact architecture than that of **6**, evident also in the narrower N(1)-C(1)-N(2) angle in **1** than in **6** (19). A further structural detail concerns the orientation of the phenyl rings. The steric influence of the SiMe$_3$ and *t*-Bu groups imposes, at the aromatic substituents, a nearly orthogonal orientation (80.5° for one phenyl group and 78.2° for the other) with respect to the N-C-N heteroallylic units, which precludes any significant conjugation between the two π systems.

Other examples of dimeric crystalline N-silylated lithium benzamidinates include [Li{μ-N(*n*-Pr)C(Ph)N(SiMe$_3$)}(OEt$_2$)]$_2$ (20*a*), [Li(Am)]$_2$ (Am = N(SiMe$_3$)C(Ph)N(CH$_2$)$_n$NMe$_2$, *n* = 2 (20*b*) or 3 (13*g*)), [Li{N(SiMe$_3$)C(Ph)NC(Ph)=C(SiMe$_3$)$_2$}(NCPh)]$_2$ (13*d*), [Li{N(SiMe$_3$)C(Ph)NC(Ph)=C(H)SiMe$_3$}(THF)]$_2$ (13*f*), [Li{N((1*R*,2*R*)-(–)-2-(trimethylsilylamino)-cyclohexyl)propyl)C(Ph)N(SiMe$_3$)}]$_2$ (20*c*), several phenyl-fluorinated benzamidinates (20*d*), [Li{N(SiMe$_3$)C(4-MeC$_6$H$_4$)N(SiMe$_3$)}(NCC$_6$H$_4$Me-4)]$_2$ (20*e*), and [Li{N-(SiMe$_3$)C(Ph)N(SiMe$_3$)}(NCPh)]$_2$ (20*f*).

Table 2. Selected bond distances (Å) and angles (°) for compounds **1** and [Li{μ-N(SiMe$_3$)C(C$_6$H$_4$OMe-4)N(SiMe$_3$)$_2$}(THF)]$_2$ (**6**) (19).

N(1)-Li-N(2)	65.2(2)	65.5(3)

Reactions between Na[*N*-*t*-Bu(SiMe$_3$)] (B) and PhCN

It had previously been shown that the sodium benzamidinate, [Na{μ-N(SiMe$_3$)C(Ph)N(SiMe$_3$)}(OEt$_2$)]$_2$-(OEt$_2$), had been obtained from the reaction of Na[N-(SiMe$_3$)$_2$] with PhCN (21). Hence, Na[*N*-*t*-Bu(SiMe$_3$)] (**B**) was treated with PhCN in Et$_2$O–hexane at low temperature; an inseparable mixture of starting materials and insertion products was formed. Various attempts to isolate the sodium benzamidinate (the presence of which was inferred by means of ^{13}C NMR spectroscopy of the reaction mixture (δ 174.8 NCN)) failed. It may be that some of the unidentified products consisted of oligomerized PhCN, as in the case of treating PhCN with Li-*n*-Bu (10, 22). In contrast, when the reaction was carried out in Et$_2$O, the expected product, [Na{μ-*cis*-N(*t*-Bu)C(Ph)N(SiMe$_3$)}(OEt$_2$)]$_2$ (**4**), was obtained (eq. [1]).

$$[1]\quad [Na\{N\text{-}t\text{-}Bu(SiMe_3)\}]_3 + 3PhCN \xrightarrow{Et_2O} 3/2[Na\{\mu\text{-}cis\text{-}N(t\text{-}Bu)C(Ph)N(SiMe_3)\}(OEt_2)]_2$$

(**4**, 69%, X-ray)

The sodium benzamidinate **4** was crystallized from the reaction mixture at –25 °C. An ORTEP representation of its molecular structure is shown in Fig. 2. Selected bond distances (Å) and angles (°), together with data for the related compound, [Na{μ-N(SiMe$_3$)C(Ph)N(SiMe$_3$)}(OEt$_2$)]$_2$(OEt$_2$) (**7**) (21), are listed in Table 3.

There is disorder between the silicon and carbon atoms (Si2 and C25) attached to N3 and N4, respectively, of one of the benzamidinato ligands. The N-silylated, four-coordinate nitrogen atom N1 bridges the sodium atoms Na1 and Na2, whereas the *tert*-butyl-bound nitrogen atom N2 is in a three-coordinate environment. Thus, the ligand is both N1,N2-chelating and N1-bridging. The difference between the Na1—N bond lengths of the bridging (N1) and terminal (N2) atoms is 0.38 Å, whereas the corresponding value for compound **7** is 0.19 Å (21). While the angle N1-Na1-N2 is similar in **4** and **7**, the angle N1-C1-N2 is slightly smaller in **4** than in **7** (21). The dihedral angle between the C2-C7 phenyl ring plane and the N1-C1-N2 plane is 78.1°.

Synthesis and characterization of [Sn{*N*(*t*-Bu)C(Ph)N(SiMe$_3$)}$_2$] (5)

As indicated in Scheme 1, the reaction between **1** and SnCl$_2$ in diethyl ether yielded crystalline [Sn{N(*t*-Bu)C(Ph)N(SiMe$_3$)}$_2$] (**5**), which was characterized by ele-

mental analysis, multinuclear NMR spectra in C_6D_6, and its EI mass spectrum. The ^{119}Sn NMR chemical shift value of δ –258.5 for **5** may be compared with the δ –387 for the tin(II) azaallyl Sn[N(SiMe$_3$)C(*t*-Bu)C(H)SiMe$_3$]$_2$, which like **5** has a four-coordinate tin(II) atom at the spiro junction of two strained four-membered rings (23).

An ORTEP representation of complex **5** is depicted in Fig. 3. A list of selected bond distances (Å) and angles (°), together with complementary data on [Sn{N(SiMe$_3$)C(Ph)N-(SiMe$_3$)}$_2$] (**8**) (24), is presented in Table 4.

Fig. 3. Molecular structure of [Sn{*N*-*t*-BuC(Ph)N(SiMe$_3$)}$_2$] (**5**) (20% ellipsoids, H atoms are omitted for clarity).

Crystalline **5** is a monomer with N,N′-chelating benzamidinato ligands. In each of the latter, there is unresolved end-for-end disorder of the SiMe$_3$ and CMe$_3$ groups: 0.86:0.14 for Si1 and C8, and 0.65:0.35 for Si2 and C22; bond lengths and angles involving these atoms are therefore unreliable. The structure of **5** is closely similar to that of **8** (24). The geometric parameters of each of the two Sn-N-C-N′ rings in both **5** and **8** are almost identical. The dihedral angle between the N1-Sn-N2 and N3-Sn-N4 planes in **5** is 86°, while that between each N-C-N plane and the attached aromatic C_6 plane is ca. 78°. There clearly is a stereochemically active lone pair of electrons at the Sn atom.

Other Sn(II) benzamidinates related to **5** and **8** (24) that have been reported include [Sn{N(SiMe$_3$)C(Ph)NC-(Ph)=C(SiMe$_3$)$_2$}$_2$] (13*d*), [Sn{N(SiMe$_2$Ph)C(Ph)N(SiMe$_2$-Ph)}$_2$] (24), [Sn{N(SiMe$_3$)C(Me)N(SiMe$_3$)}$_2$] (25), and [Sn{N(SiMe$_3$)C(C$_6$H$_4$Ph-4)N(Ph)}$_2$] (26).[3]

Conclusions

Five new crystalline benzamidinates bearing the C_1 symmetric [N(*t*-Bu)C(R)N($SiMe_3$)]$^-$ ligand (Am$^-$) have been prepared and characterized: [Li(Am)(THF)]$_2$ (**1**), Li(Am)(TMEDA) (**2**), Li(Am) (**3**), [Na(Am)(OEt_2)]$_2$ (**4**), and [Sn(Am)$_2$] (**5**) (R = Ph in **1**, **2**, **4**, and **5**; R = 4-$MeOC_6H_4$ in **3**). The X-ray structures of **1**, **4**, and **5** are reported. The Am$^-$ ligand in **1** and **4** is both chelating and via N($SiMe_3$) is also bridging. The two structures differ in that the core of the planar M-N-CN′-M′ ring is rhomboidal in **1** (M = Li), but C_2 symmetric with unequal contiguous Na—N bond lengths in **4**. The Am$^-$ ligand in **5** functions as a chelate.

Acknowledgments

We thank Dr. A.G. Avent for recording ^{1}H NOE, ^{1}H{^{7}Li} NOE, ^{29}Si-, ^{119}Sn-, and ^{23}Na-NMR spectra, the EU, and the University of Bologna, Bologna, Italy for provision of a studentship for FA, and the UK Engineering and Physical Sciences Research Council (EPSRC) for a fellowship for AVK.

Hexaethylbenzene complexes of ruthenium and manganese — X-ray crystal structures and NMR spectra of $[(HEB)_2Ru_2(\mu\text{-}Cl)_3][C_5(CO_2Me)_5]$, $[(HEB)Ru(H_2O)_3][BF_4]_2$, $(HEB)RuCl_2[P(OMe)_3]$, *trans*-$RuCl_2(PMe_3)_4$, and $(HEB)Mn(CO)_2Br$[1]

Hari K. Gupta, Philippa E. Lock, Nada Reginato, James F. Britten, and Michael J. McGlinchey

Abstract: Hexaethylbenzene (HEB) and $[(p\text{-cymene})RuCl_2]_2$ react in the melt to yield $[(HEB)RuCl_2]_2$ (**6**), the NMR spectra of which reveal the presence of $[(HEB)_2Ru_2(\mu\text{-}Cl)_3]Cl$ in solution. In $[(HEB)_2Ru_2(\mu\text{-}Cl)_3][C_5(CO_2Me)_5]$ (**7**), the cation has D_{3h} symmetry with alternating proximal and distal ethyl groups. Bridge cleavage of **6** with trimethyl phosphite or with trimethylphosphine gives $(HEB)RuCl_2[P(OMe)_3]$ (**9**) or $(HEB)RuCl_2(PMe_3)$ (**10**), respectively. The latter reaction also yields $RuCl_2(Me_3P)_4$ (**11**), whose structure represents a relatively rare example of a crystallographically characterized trans isomer of this type. In **9**, five of the ethyl ligands are distal, whereas in **10** all six substituents are distal. Attempts to prepare the sandwich dication $[(HEB)_2Ru]^{2+}$ gave instead $[(HEB)Ru(H_2O)_3](BF_4)_2$ (**8**), whose NMR and X-ray data reveal the 1,3,5-distal–2,4,6-proximal arrangement of ethyls both in the solid state and in solution. $(HEB)Mn(CO)_2Br$ (**13**) likewise adopts the 1,3,5-distal–2,4,6-proximal structure in the solid state but, surprisingly, there is no evidence for slowed ethyl rotation in solution.

Key words: hexaethylbenzene conformations, hindered rotations, crystallography, NMR, ruthenium, manganese.

Résumé : L'hexaéthylbenzène (HEB) et le $[(p\text{-cymène})RuCl_2]_2$ réagissent à l'état fondu pour conduire à la formation de $[(HEB)RuCl_2]_2$ (**6**) dont le spectre RMN en solution révèle la présence de $[(HEB)_2Ru_2(\mu\text{-}Cl)_3]Cl$. Dans le $[(HEB)_2Ru_2(\mu\text{-}Cl)_3][C_5(CO_2Me)_5]$ (**7**), le cation est de symétrie D_{3h} avec, en alternance, des groupes éthyles de type distal et proximal. Le clivage du pont du composé **6** avec du phosphite de triméthyle ou avec de la triméthylphosphine conduit, selon le cas, au $(HEB)RuCl_2[P(OMe)_3]$ (**9**) ou au $(HEB)RuCl_2(PMe_3)$ (**10**). La dernière réaction fournit aussi du $RuCl_2(Me_3P)_4$ (**11**) dont la structure correspond à un rare exemple d'un isomère trans de type à être caractérisé par cristallographie. Dans le composé **9**, cinq sur six ligands sont de type distal alors que dans le composé **10** les six ligands sont tous de type distal. Des essais en vue de préparer le dication sandwich $[(HEB)_2Ru]^{2+}$ on plutôt conduit à la formation de $[(HEB)Ru(H_2O)_3](BF_4)_2$ (**8**) dans lequel, selon les données de la RMN et de la diffraction des rayons X, on observe un arrangement 1,3,5-distal–2,4,6-proximal des groupes éthyles tant à l'état solide qu'en solution. La structure du $(HEB)Mn(CO_2)Br$ (**13**) adopte aussi une structure 1,3,5-distal–2,4,6-proximal à l'état solide, mais il est surprenant d'observer que, en solution, on n'observe aucune donnée laissant croire à un ralentissement de la rotation des groupes éthyles.

Mots clés : conformation de l'hexaéthylbenzène, rotations empêchées, cristallographie, RMN, ruthénium, manganèse.

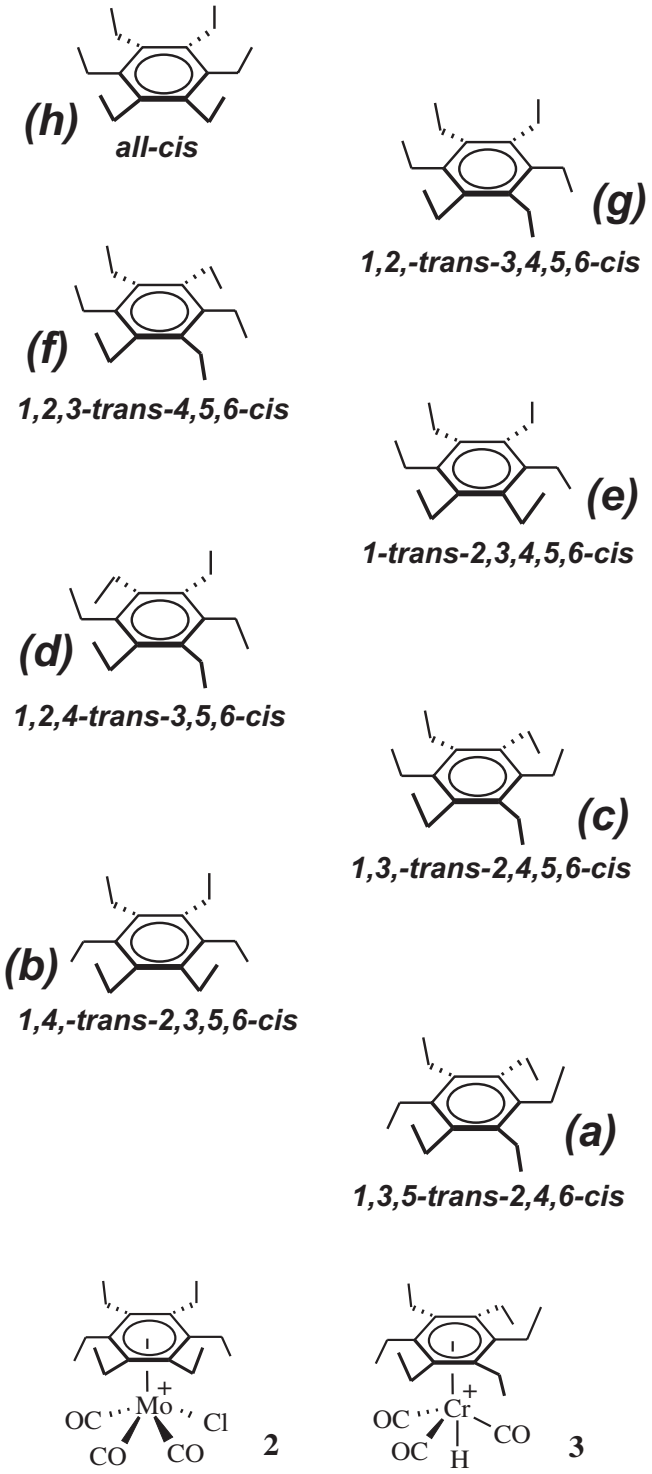
Introduction

Hexaethylbenzene (HEB) is a conformationally versatile ligand! When bonded to organometallic fragments, such as $Cr(CO)_3$ (1), $[Fe(C_5H_5)]^+$ (2), or $[Mo(CO)_3Cl]^+$ (3), the ethyl groups can adopt a variety of conformational patterns (4). The favoured structure — and the one found for the free ligand (5, 6) — is the 1,3,5-distal–2,4,6-proximal isomer exemplified by $[(\eta^6\text{-HEB})Cr(CO)(CS)NO]^+$ (**1**).



1

This particular system, which possesses a chiral tripod, was specifically designed to probe the molecular dynamics of both the HEB ligand and also the ML_3 fragment (7). In the series $(\eta^6\text{-HEB})Cr(CO)L'L''$, where L′ and L″ are CO, CS, or NO^+, the ethyls exhibit uncorrelated proximal–distal exchange with a $\Delta G^{\ddagger}$ value of ≈11.5 kcal mol^{-1} (6–8) (1 cal = 4.184 J). In contrast, tripodal rotation has a markedly lower barrier (≈9.5 kcal mol^{-1}) (7, 8). These studies are complemented, not only by our own work on (pentaethylacetophenone)$Cr(CO)_3$ (9), but also by an elegant series of experiments by Kilway and Siegel (10) who independently measured the alkyl and tripodal rotation barriers in 1,4-bis(4,4-dimethyl-3-oxopentyl)-2,3,5,6-tetraethylbenzene and its tricarbonylchromium complex.

The relative energies of the conformations of hexaethylbenzene have been computed; these are depicted in Fig. 1 together with the labeling scheme originally used by Mislow and co-workers (6). Moreover, it has been shown that in the molecules $(\eta^6\text{-HEB})Cr(CO)_2(PR_3)$, there is a clear correlation between the size of the phosphine and the ratio of distal to proximal ethyl substituents. Thus, X-ray crystallographic data for the complexes $(\eta^6\text{-HEB})Cr(CO)_2(PMe_3)$ (11), $(\eta^6\text{-HEB})Cr(CO)_2(PEt_3)$ (12), and $(\eta^6\text{-HEB})Cr(CO)_2(PPh_3)$ (6), yield structures *c*, *e*, and *h*, respectively.

The ^1H and ^{13}C NMR data for $(\eta^6\text{-HEB})ML_n$ complexes provide a convenient probe for the symmetry of the system. For example, Flood's low-temperature NMR measurements have shown that protonation of a series of $(\eta^6\text{-arene})Cr(CO)_2PR_3$ complexes leads to a square-based pyramidal structure for the corresponding $[(\eta^6\text{-arene})Cr(CO)_2(PR_3)H]^+$ systems (13); likewise, protonation of $(\eta^6\text{-}C_6H_5OMe)Cr(CO)_3$ yields a 2:1 pattern for the ^{13}CO resonances, consistent with a square-pyramidal $Cr(CO)_3H$ unit (14). Since the X-ray crystal structure of $[(\eta^6\text{-HEB})Mo(CO)_3Cl][MoCl_6]$ (**2**) reveals that the ML_4 moiety is square pyramidal and that the hexaethylbenzene ligand in the cation adopts conformer *b* (Fig. 1) (3), one might have anticipated a similar arrangement of ethyls for $[(\eta^6\text{-HEB})Cr(CO)_3H]^+$ (**3**). However, the ^1H and ^{13}C NMR data for **3** show unambiguously that the ethyls adopt the 1,3,5-distal–2,4,6-proximal conformation *a* (Fig. 1), indicating that the proton has attacked along the threefold axis of the molecule (15).

Fig. 1. Relative energies of conformers of hexaethylbenzene (HEB) (data from ref. 6).

3

In a continuation of our ongoing program aimed at rationalizing the structures and dynamic NMR behaviour of hexaethylbenzene–metal complexes (4), and in light of our more recent work (16) on ruthenium complexes of trindane, (tris(cyclopentano)benzene, the condensation trimer of cyclopentanone), we had initiated a study of the syntheses, NMR spectra, and X-ray crystal structures of a series of

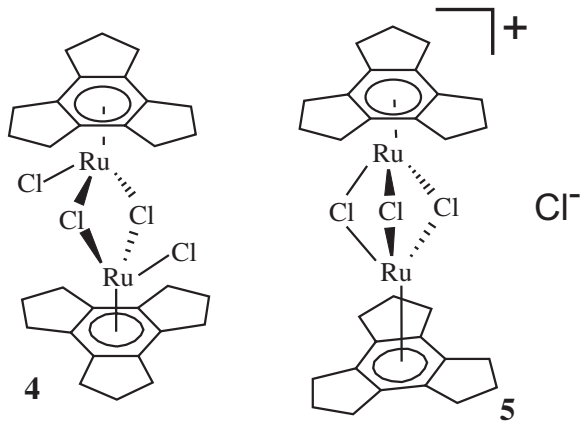
Fig. 2. Molecular structure of the cation $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-}Cl)_3]^+$ in **7** showing (*a*) the alternating proximal and distal ethyl groups and (*b*) eclipsing of the tripod of chlorines relative to the distal ethyl groups. Thermal ellipsoids are drawn at the 50% probability level, and hydrogen atoms are omitted for clarity.

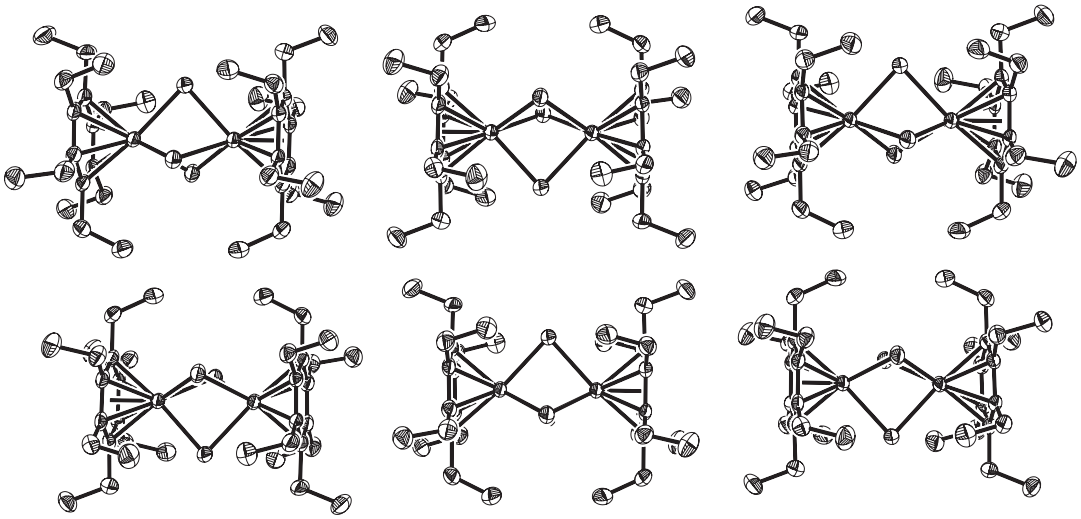


$(C_6Et_6)RuCl_2L$ complexes to explore whether their ^1H and ^{13}C NMR spectra correlated with the solid state structures of these molecules. In a 1997 review on ruthenium–arene systems (17), Bennett made passing mention of some HEB–Ru complexes and, more recently, he and his co-workers (18) have published a fuller account of this work. This prompts us to describe our own findings, which, in some cases, overlap with and confirm Bennett's observations. We therefore describe in detail only those aspects that have not hitherto been reported.

Results and discussion

Molecules of the type $[(\eta^6\text{-arene})RuCl_2]_2$ are generally prepared by the replacement of cymene in $[(\eta^6\text{-cymene})RuCl_2]_2$ (19); this latter system is readily available by reaction of $RuCl_3$ with dipentene, an inexpensive diene (20). We have previously reported (16) the synthesis, X-ray crystal structure, and variable-temperature NMR spectra of $[(\eta^6\text{-trindane})RuCl_2]_2$ (**4**), which dissociates in polar solvents into $[(\eta^6\text{-trindane})_2Ru_2(\mu\text{-}Cl)_3]^+$ Cl^- (**5**). Although trindane is a hexa-alkylated arene, and bears a superficial resemblance to hexaethylbenzene, it lacks the subtle stereochemical probes for molecular symmetry that HEB can, in principle, provide.

When $[(\eta^6\text{-cymene})RuCl_2]_2$ and hexaethylbenzene were melted together at 170 °C in a sealed tube, a product **6**, with empirical formula $(C_6Et_6)RuCl_2$, was obtained. The room-temperature ^1H and ^{13}C NMR spectra of **6** exhibited resonances for only a single ethyl environment, but at –90 °C there was clear decoalescence into two equally populated ethyl groups. Such behaviour appeared to be analogous to that of the trindane–ruthenium complexes (**4** and **5**), whereby dissociation into a triply bridged cation and a chloride anion had occurred. Moreover, the coalescence behaviour of these ethyl resonances is entirely reminiscent of the



previously discussed systems that adopt the 1,3,5-distal–2,4,6-proximal conformation; gratifyingly, the calculated $\Delta G^{\ddagger}$ value of 11.5 ± 0.4 kcal mol^{-1} is in the normal range for such ethyl rotation barriers. We were therefore drawn to the conclusion that **6** exists in solution primarily as $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-}Cl)_3]^+Cl^-$, and that the arene adopts conformation *a* (Fig. 1).

To determine whether this same structure could be found in the solid state, **6** was treated with the potassium salt of penta(carbomethoxy)cyclopentadienide, $K[C_5(CO_2Me)_5]$ (21). Removal of KCl and recrystallization from hexane–dichloromethane yielded X-ray quality crystals of $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-}Cl)_3][C_5(CO_2Me)_5]$ (**7**), and the structure of the cation appears as Fig. 2. $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-}Cl)_3]^+$ has effective D_{3h} symmetry in which each HEB ligand adopts the alternating proximal–distal arrangement of ethyls such that the three bridging chlorines eclipse distal substituents and so minimize steric interactions.

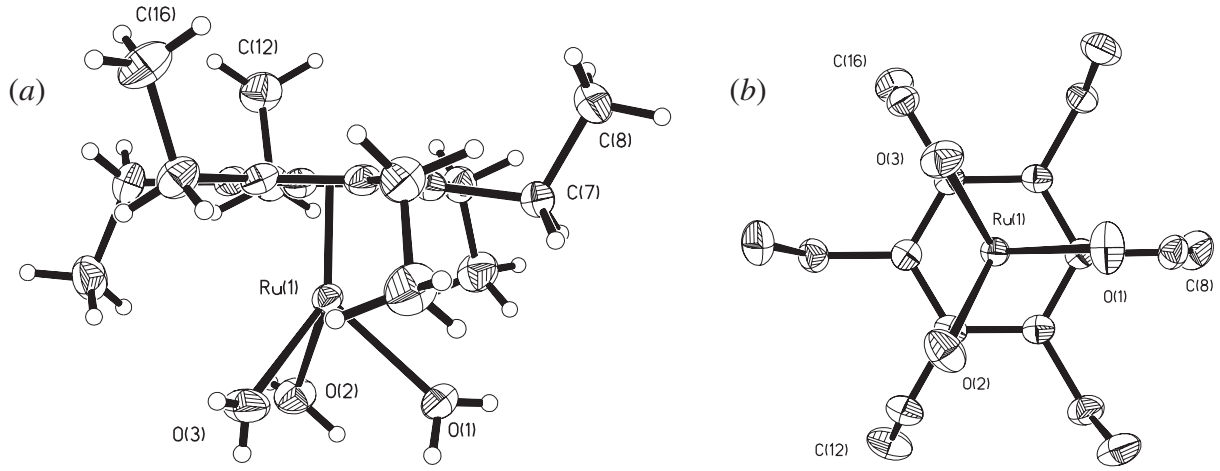
Fig. 3. Packing of the $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-Cl})_3]^+$ cations in **7**.

The ruthenium–arene centroid distance of 1.648 Å is comparable to those observed in systems such as $[(\eta^6\text{-arene})_2Ru_2(\mu\text{-Cl})_3]^+$, where the arene is benzene, toluene, or cymene (22). Interestingly, in $[(\eta^6\text{-benzene})_2Ru_2(\mu\text{-Cl})_3]^+$ the $RuCl_3$ tripod is staggered with respect to the benzene ligand, while in $[(\eta^6\text{-cymene})_2Ru_2(\mu\text{-Cl})_3]^+$ the chlorine atoms eclipse arene ring carbon atoms. As predicted by molecular orbital calculations at the extended Hückel level (22*a*), the methylene substituents are bent slightly towards the metal atoms (an average of 2.5° for distal ethyls and 0.5° for proximal ethyl groups). This enhances the overlap between the arene π manifold and the ruthenium d orbitals. This minor distortion is, however, not as significant as the 6° bend observed in $[(\eta^6\text{-benzene})_2Ru_2(\mu\text{-Cl})_3]^+$ (22*a*). The average Ru—Cl distance in **7** is 2.442 Å and the average Ru—C(arene) distance is 2.183 Å, similar to those observed, for example, in $[(\eta^6\text{-trindane})RuCl_2]_2$ (**4**) (16). Thus, the Ru—Cl distance is similar to that found in the other arene systems mentioned above, but the Ru—C(arene) bond is slightly longer than that in $[(\eta^6\text{-benzene})_2Ru_2(\mu\text{-Cl})_3]^+$ (2.163 Å) or in $[(\eta^6\text{-cymene})_2Ru_2(\mu\text{-Cl})_3]^+$ (2.168 Å) (22).

The penta(carbomethoxy)cyclopentadienide counterion in the structure of **7** is highly disordered, as is sometimes the case for this isolated anion in crystal structures (21), and it has not proved possible to determine its conformation in the solid state. Nevertheless, it is evident from an examination of the packing that the anions and cations form alternating layers as is also seen for $[C_7H_7][C_5(CO_2Me)_5]$ (21). The program PLATON (23) was used to subtract the averaged diffractional contribution of the disordered $[C_5(CO_2Me)_5]^-$ anion from the X-ray intensity data collected for **7**. This not only allowed a more accurate determination of the structure of the $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-Cl})_3]^+$ cation, but also reveals (see Fig. 3) that the cations are arranged in layers such that the intermolecular contacts between distal ethyls are minimized.

The structure of the $[(\eta^6\text{-HEB})_2Ru_2(\mu\text{-Cl})_3]^+$ cation in **7** parallels closely the data previously reported by Bennett and co-workers (18) for the corresponding hexafluorophosphate salt. Those workers had also obtained independently synthesized **6** by treating $(\eta^6\text{-HEB})Ru(\eta^4\text{-1,5-COD})$ with HCl and had shown definitively that, in the solid state, it adopted the doubly bridged structure $[(\eta^6\text{-HEB})Ru(\mu\text{-Cl})Cl]_2$, akin to **4**, whereby all the ethyl substituents are distal, as in conformation *h* (Fig. 1). Finally, since the variable-temperature NMR spectra of **7** in the ethyl region parallel exactly the behavior of **6**, one may conclude that the triply bridged isomer is the major species present in solution in both cases.

We have previously prepared the sandwich cation $[(\eta^6\text{-trindane})_2Ru]^{2+}$ by treatment of $[(\eta^6\text{-trindane})RuCl_2]_2$ with $AgBF_4$ in acetone; the presumed intermediate, $[(\eta^6\text{-trindane})Ru(acetone)_3]^{2+}$, reacted with excess trindane to yield the $[bis(\eta^6\text{-arene})Ru]^{2+}$ dication (16). Interestingly, the $[(\eta^6\text{-arene})Ru(solvent)_3]^{2+}$ structure type is rare; one such molecule for which a crystal structure has been reported is $[(\eta^6\text{-1,3,5-}C_6H_3Me_3)Ru(acetone)_3][BF_4]_2$ in which two of the acetone molecules have coupled (24).



In an attempt to prepare $[(\eta^6\text{-}C_6Et_6)_2Ru]^{2+}$, treatment of "$(C_6Et_6)RuCl_2$" (**6**) with $AgBF_4$ in acetone gave a remarkably stable crystalline material (**8**), whose ^1H and ^{13}C NMR spectra are entirely consistent with a molecule possessing threefold symmetry; once again, at low temperature the familiar pattern of alternating proximal and distal ethyls is apparent. As shown in Fig. 4*a*, the product was characterized by X-ray crystallography as $[(\eta^6\text{-}C_6Et_6)Ru(H_2O)_3][BF_4]_2\cdot H_2O$. In **8**, the cation possesses almost ideal C_{3v} symmetry in which the HEB ligand adopts conformation *a* — the 1,3,5-distal–2,4,6-proximal arrangement — whereby each water ligand is partially encapsulated by two ethyl groups. Figure 3*b* shows the eclipsed tripod of oxygen atoms with respect to the distal ethyl groups. In the closely related structure of $[(\eta^6\text{-}C_6H_6)Ru(H_2O)_3]^{2+}$, the RuO_3 tripod is staggered with respect to the benzene ligand (25).

The ruthenium–arene centroid distance of 1.650 Å in **8** is in the expected range and, while the average Ru—C(arene) of 2.183 Å is very similar to that seen in **7**, it is slightly longer than that observed in $[(\eta^6\text{-}C_6H_6)Ru(H_2O)_3]^{2+}$ (2.164 Å). Moreover, the average Ru—O distance of 2.145 Å in **8** is also slightly longer than the value of 2.127 Å reported for $[(\eta^6\text{-}C_6H_6)Ru(H_2O)_3]^{2+}$ (25).

There is extensive hydrogen bonding observed in the packing diagram for **8** such that water ligands bonded to ruthenium have contacts to fluorine atoms of tetrafluoroborate

© 2006 NRC Canada

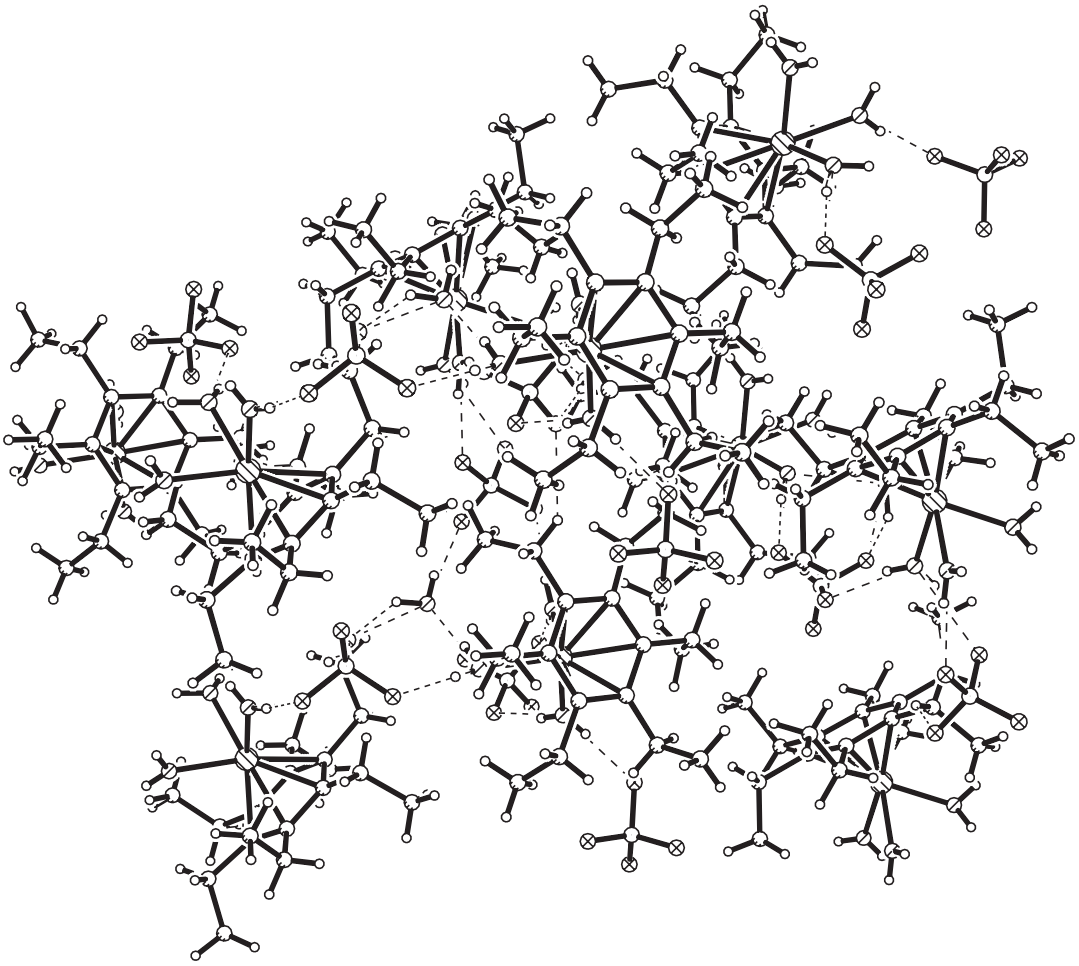
Fig. 4. Molecular structure of the cation $[(\eta^6\text{-HEB})Ru(H_2O)_3]^{2+}$ in **7** showing (*a*) the alternating proximal and distal ethyl groups and (*b*) eclipsing of the tripod of oxygens relative to the distal ethyl groups. Thermal ellipsoids are drawn at the 50% probability level.

anions, and also to lattice water molecules. The lone water of crystallization also has contacts to tetrafluoroborate anions. For example, in one layer, a lattice water molecule has contacts through its hydrogens to two neighbouring BF_4^- anions such that O—H_a is 0.966 Å, and $H_a\cdots F_1$ is 1.889 Å, while the $O\cdots F_1$ distance is 2.742 Å. For the other hydrogen of the same water molecule, O—H_b is 0.822 Å, $H_b\cdots F_2$ is 1.934 Å, and the $O\cdots F_2$ contact is now 2.733 Å. This oxygen also interacts with a neighbouring H_2O ligand bonded to ruthenium, with O···H′ at 1.748 Å, and an O···O′ contact of 2.616 Å. Furthermore, some BF_4^- anions show a long contact to a methylene hydrogen atom of a neighbouring distal ethyl group (e.g., F···H is 2.539 Å). Layers of contacts of the types described above persist throughout the structure, and these interactions are depicted in Fig. 5.

To test the steric limits of the $(\eta^6\text{-HEB})RuL_n$ system, **6** was treated with trimethyl phosphite and with trimethylphosphine to give $(\eta^6\text{-HEB})RuCl_2[P(OMe)_3]$ (**9**) and $(\eta^6\text{-HEB})RuCl_2(PMe_3)$ (**10**), respectively. The ^1H and ^{13}C NMR spectra of both complexes exhibited only a single ethyl environment, even at low temperature. This result suggested that neither molecule possessed the alternating proximal–distal arrangement labelled as *a* in Fig. 1. On the basis of the relative cone angles of $P(OMe)_3$ (107°) and PMe_3 (118°) (26), one might have predicted that the phosphine complex **10** would tend to have the greater number of distal ethyl substituents, and this is indeed the case. As shown in Fig. 6, $(\eta^6\text{-HEB})RuCl_2[P(OMe)_3]$ (**9**) prefers isomer *e* in which there is a single proximal ethyl substituent; in contrast, $(\eta^6\text{-HEB})RuCl_2(PMe_3)$ (**10**) adopts the "all-distal" conformer *h*.

The all-distal structure for $(\eta^6\text{-HEB})RuCl_2(PMe_3)$ (**10**) has already been described by Bennett and co-workers (17, 18, 27) and our data are in accord with theirs. The single proximal ethyl in $(\eta^6\text{-HEB})RuCl_2[P(OMe)_3]$ (**9**) is the one furthest from the relatively bulky phosphite ligand and is analogous to the structure of $(\eta^6\text{-HEB})Cr(CO)_2(PEt_3)$, which likewise exhibits the 5:1 distal-to-proximal ratio (12). In **10**, the $RuCl_2(PMe_3)$ tripod is staggered with respect to the HEB ring, and follows the pattern found in $(\eta^6\text{-HEB})Cr(CO)_2(PPh_3)$, which also adopts conformation *h* (Fig. 1) (6). The orientations of the $RuCl_2(PR_3)$ tripods in **9** and **10** with respect to the HEB ligands are illustrated in Fig. 7. Interestingly, the trimethyl phosphite ligand in **9** crystallizes in a propeller conformation rendering the molecule chiral, whereas in $(\eta^6\text{-HEB})Cr(CO)_2(PEt_3)$ the Et_3P ligand lies in a molecular mirror plane (12).

The reaction of **6** with trimethylphosphine yielded a second crystalline product that was shown by mass spectrometry, and also by ^1H and ^{31}P NMR spectroscopy, to be the known compound *trans*-dichlorotetrakis(trimethylphosphine)-ruthenium(II) (**11**) (28). A search of the Cambridge Crystallographic Database revealed that structures of trans isomers of the type $(Me_3P)_4RuXY$ are rare, although a number of cis complexes have been reported (29). Since we had suitable crystals in hand, the structure was determined and appears as Fig. 8.



While the structure solves to give two independent half-molecules in the asymmetric unit, the symmetry operator of the space group completes the full molecules, and the successful structure gives the trans isomer. The steric problems that arise with four equatorially disposed trimethylphosphines are immediately evident. The PMe_3 ligands undergo a tetragonal distortion such that they are placed alternately above and below their mean plane. The P-Ru-P angles found in the two independent molecules are 165.86(2)° and 165.38(11)°. The nonlinearity is, however, somewhat less than the corresponding P-Rh-P angles (151.46(5)° and 148.29(5)°) found in $[(Me_3P)_4Rh]^+ Cl^-$ (28), and in the P-Ru-P angle (161.41°) found in $trans\text{-}RuH_2[(C_6H_5)P(OC_2H_5)_2]_4$ (30). Apparently, the out-of-plane distortion of the phosphines in $trans\text{-}(Me_3P)_4RuCl_2$ (**11**) is limited by the presence of the two axial chlorine ligands. The cis P-Ru-P angles are close to 90° (with a range of 90.05(3)° to 92.11(4)°).

In a closely related system, $trans\text{-}(PMe_3)_4Ru(N_3)_2$, the molecule crystallizes in the space group *C*2/*c*. All four phosphine ligands are located individually, and there is no ambiguity about the assignment as a cis or trans isomer; it is clearly a trans system (31). Moreover, the P-Ru-P angles between the *trans*-phosphines (163.1° and 163.4°) agree closely with those found in **11**, and so reinforce the structural assignment presented here.

As was the case with ruthenium, our studies on trindane complexes of manganese (32) led us to prepare the analogous hexaethylbenzene derivatives. The cationic complex

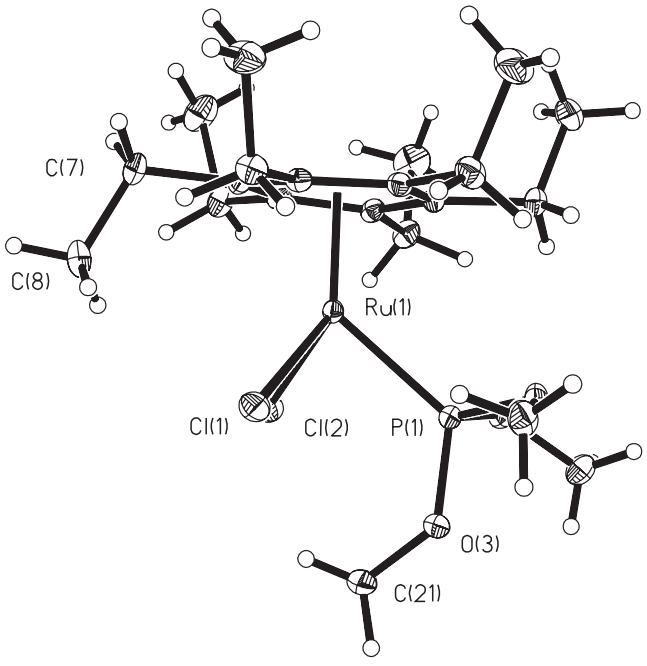

Fig. 5. The extensive hydrogen bonding network in $[(\eta^6\text{-}C_6Et_6)Ru(H_2O)_3][BF_4]_2\cdot H_2O$ (**8**).

$[(HEB)Mn(CO)_3]^+$ behaves entirely analogously to its neutral $(HEB)Cr(CO)_3$ counterpart. The room-temperature ^1H and ^{13}C NMR spectra that exhibit a single ethyl environment show clear decoalescence as the temperature is lowered, and once again reveal that the ligand adopts the favoured 1,3,5-distal–2,4,6-proximal structure; the barrier towards this fluxional behaviour is the usual 11.5 kcal mol^{-1}. With the goal of breaking the threefold symmetry of the tripod, as had been done previously in the $(HEB)Cr(CO)_2L$ series (6–8), $[(HEB)Mn(CO)_3][BF_4]$ (**12**) was treated with trimethylamine *N*-oxide, and subsequently with KBr to yield the neutral complex $(C_6Et_6)Mn(CO)_2Br$ (**13**). (This follows the route described by Eyman and co-workers (33) for the preparation of $(C_6Me_6)Mn(CO)_2Br$.) The ^1H and ^{13}C NMR spectra of the bromo-compound **13** exhibited only a single ethyl environment and were invariant even down to –90 °C. We had anticipated seeing a 2:1:2:1 pattern of ethyl groups attributable to slowed ethyl rotation and slowed tripodal rotation on the NMR timescale; this would have matched the known behaviour of $(HEB)Cr(CO)_2L$, where L is CS or NO^+ (7). However, when the X-ray crystal structure of **13** was determined, it was of the commonly observed 1,3,5-distal–2,4,6-proximal type (see Fig. 9), and it is tempting to propose that several rotameric structures undergo ready exchange with a low barrier in solution, as is known for $[(C_6Et_6)Fe(C_5H_5)]^+$ (2, 34).

In closing, we note that in those cases where the

organometallic moiety imposes a particular conformation, such as 1,3,5-distal–2,4,6-proximal arrangement, on a hexaalkylbenzene ligand, this can be of synthetic advantage, and elegant applications in supramolecular chemistry have been described (35).

Experimental section

All reactions were carried out under an atmosphere of dry nitrogen with use of conventional bench top and glovebag techniques. Silica gel (particle size 20–45 μm) was used for flash column chromatography. ^1H, ^{13}C, and ^{31}P NMR spectra were acquired on Bruker DRX 500, AC 300, or AC 200 spectrometers, and were referenced to the residual proton or ^{13}C signal of the solvent, or to external 85% H_3PO_4. Mass spectra (DEI, DCI, and electrospray) were obtained on a VG analytical ZAB-SE spectrometer with an accelerating potential of 8 KV and a resolving power of 10 000. Where applicable, *m*/*z* values listed are for $^{35}Cl/^{102}Ru$ isotopomers; all peak clusters showed correct isotopic abundance patterns. Infrared spectra were recorded on a Bio-Rad FTS-40 spectrometer, using NaCl windows. Melting points (uncorrected) were determined on a Fisher-Johns melting apparatus. Elemental analyses were performed either by Guelph Chemical Laboratories in Guelph, Ontario or by the Microanalytical Laboratory at University College Dublin.

$RuCl_3 \cdot 3H_2O$, $Mn_2(CO)_{10}$, and $AgBF_4$ were purchased from Sigma-Aldrich Chemical Co., Inc., and used as received. $AlCl_3$ was sublimed before use, and [(*p*-cy-

© 2006 NRC Canada

mene)$RuCl_2]_2$ was prepared as described in the literature (20).

Preparation of [(η^6-hexaethylbenzene)$RuCl_2]_2$ (6)

A mixture of [(*p*-cymene)$RuCl_2]_2$ (1.0 g, 1.63 mmol) and hexaethylbenzene (8.04 g, 32.7 mmol) was sealed under vacuum, immersed in an oil bath at 170 °C for 72 h, and then cooled to room temperature. The residue was washed with a large excess of hexane (250 mL) to remove the unreacted HEB and dissolved in dry CH_2Cl_2 (10 mL). Addition of hexane (25 mL) brought about precipitation of a dark purple-red compound that was filtered, dried, and recrystallized from dichloromethane–hexane to give **6** (0.680 g, 0.81 mmol, 50%); mp 240 °C (dec). ^{1}H NMR (500 MHz, CD_2Cl_2, 30 °C) δ: 2.53 (12H, broadened quartet, J = 7.5 Hz, CH_2), 1.42 (18H, t, J = 7.5 Hz, CH_3). At –90 °C these signals resolve into broadened singlets at δ 2.57 and 2.27 ppm, 1.40 and 1.27 ppm, respectively. ^{13}C NMR (125 MHz, CD_2Cl_2, 30 °C) δ: 94.2 (arene *C*), 20.5 (*C*H_2), 14.2 (*C*H_3). At –90 °C these signals resolve into singlets at δ 99.1, 85.1; 20.3, 17.6; 15.0, 11.2. MS (EI, *m*/*z*) (%): 418 [(HEB)$RuCl_2]^+$ (50), 348 [(HEB)Ru]$^+$ (12), 246 [HEB]$^+$ (52). MS (CI, *m*/*z*) (%): 436 [(HEB)$RuCl_2$ + $NH_4]^+$ (18), 247 [HEB + H]$^+$ (100). MS (+ve ion electrospray, *m*/*z*) (%): 801 [M – Cl]$^+$ (85), 383 [(HEB)RuCl]$^+$ (100).

Preparation of [(η^6-hexaethylbenzene)$_2Ru_2(\mu$-$Cl_3)$]-[$C_5(CO_2CH_3)_5$] (7)

To a solution of [(HEB)$RuCl_2]_2$ (**6**, 0.418 g, 0.5 mmol) in CH_2Cl_2 (25 mL) was added K[$C_5(CO_2CH_3)_5$] (0.792 g, 2.0 mmol) in methanol (50 mL), and the reaction mixture was heated at 70 °C for 3 h during which time the color of the solution gradually became greenish-yellow. After cooling and removal of solvents under reduced pressure, the residue was taken up in CH_2Cl_2 (25 mL) and filtered. Hexane (20 mL) was added and the solution was left to crystallize for 3 days after which time yellow-orange microcrystals were separated and dried to give **7** (305 mg, 0.26 mmol, 53%); mp 216 °C. ^{1}H NMR (500 MHz, CD_2Cl_2, 30 °C) δ: 3.69 (15H, s, OCH_3), 2.39 (12H, quartet, J = 7.5 Hz, CH_2), 1.29 (18H, t, J = 7.5 Hz, CH_3). ^{13}C NMR (125 MHz, CD_2Cl_2, 30 °C) δ: 167.9 (CO), 95.3 (arene *C*), 51.4 (O*C*H_3) 21.5 (*C*H_2), 15.0 (*C*H_3). MS (+ve ion electrospray, *m*/*z*) (%): 801 [(HEB)$_2Ru_2Cl_3]^+$ (30), 383 [(HEB)RuCl] $^+$ (100). Anal. calcd. for $C_{51}H_{75}Ru_2Cl_4O_{10}$ (%): C 52.92, H 6.49; found: C 53.13, H 6.83.

Preparation of [(η^6-hexaethylbenzene)$Ru(H_2O)_3](BF_4)_2$ (8)

To a purple-red solution of [(HEB)$RuCl_2]_2$ (**6**, 0.105 g, 0.125 mmol) in CH_2Cl_2 (10 mL) was added $AgBF_4$ (0.100 g, 0.5 mmol) and the mixture was stirred for 1 h at room temperature during which time the colour of the solution became orange-yellow. After filtration and concentration to a volume of approximately 5 mL, hexane (5 mL) was added, and the mixture left at 0 °C to crystallize. The resulting yellow-orange crystalline solid was separated and dried to give **8** (100 mg, 0.17 mmol, 69%); mp 155 °C. ^{1}H NMR (500 MHz, CD_2Cl_2, 30 °C) δ: 4.14 (broad s, H_2O), 2.66 (12H, broad s, CH_2), 1.39 (18H, t, J = 7.4 Hz, CH_3). At –74 °C these signals resolve into broadened singlets at δ 2.55 and 2.25 and 1.36 and 1.21 ppm, respectively. ^{13}C NMR (125 MHz, CD_2Cl_2, 30 °C) δ: 95.3 (arene *C*), 21.6 (*C*H_2), 14.2 (*C*H_3). MS (+ve ion electrospray in CH_3CN–H_2O, *m*/*z*) (%): 408 [M + H + CH_3CN – $2H_2O]^+$ (100), 192 [M – $H_2O]^{2+}$ (32). Anal. calcd. for $C_{18}H_{36}RuO_3B_2F_8{\cdot}H_2O$ (%): C 36.41, H 6.40; found: C 36.66, H 6.51. Addition of excess HEB to **8**, followed by heating at reflux overnight, led merely to the recovery of starting materials.

Preparation of [(η^6-hexaethylbenzene)$RuCl_2P(OMe)_3$] (9)

To a solution of [(HEB)$RuCl_2]_2$ (**6**, 0.167 g, 0.2 mmol) in dry CH_2Cl_2 (10 mL) was added trimethyl phosphite (100 mg, 0.8 mmol) via syringe and the mixture was stirred at room temperature for 3 h. The resulting orange-red solution was concentrated to about 3 mL under reduced pressure and hexane (5 mL) was added. Recrystallization overnight produced a red crystalline solid, which was separated from the solution and dried to give **9** (174 mg, 0.32 mmol, 80%); mp 150 °C. ^{1}H NMR (200 MHz, CD_2Cl_2) δ: 3.71 (9H, d, $^3J(^1H$-$^{31}P)$ = 10.2 Hz, OCH_3), 2.57 (12H, quartet, J = 7.6 Hz, CH_2), 1.31 (18H, t, J = 7.6 Hz, CH_3). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 103.7 (arene *C*), 54.6 (O-*C*H_3), 22.5 (*C*H_2), 14.9 (*C*H_3). MS (EI, *m*/*z*) (%): 542 [M]$^+$ (37), 507 [M – Cl]$^+$ (14), 418 [M – P(OMe)$_3]^+$ (100), 383 [(HEB)RuCl]$^+$ (44), 348 [(HEB)Ru]$^+$ (37). MS (CI, *m*/*z*) (%): 436 [(HEB)$RuCl_2$ + $NH_4]^+$ (158), 247 [HEB + H]$^+$ (35), 125 [P(OMe)$_3$ + H]$^+$ (100). Anal. calcd. for $C_{21}H_{39}RuCl_2O_3P$ (%): C 46.45, H 7.19; found: C 46.23, H 7.37.

Preparation of [(η^6-hexaethylbenzene)$RuCl_2(PMe_3)$] (10)

To a solution of [(HEB)$RuCl_2]_2$ (**6**, 0.418 g, 0.5 mmol) in dry CH_2Cl_2 (50 mL) was added trimethylphosphine (0.3 mL, 0.24 mmol) via syringe, and the mixture was stirred at room temperature for 24 h. The resulting orange-red solution was concentrated to about 3 mL under reduced pressure and hexane (10 mL) was added. Recrystallization overnight produced a red crystalline solid, which was separated from the solution and dried to give **10** (400 mg, 0.81 mmol, 81%); mp 192 °C. ^{1}H NMR (200 MHz, CD_2Cl_2, 30 °C) δ: 2.55 (12H, quartet, J = 7.6 Hz, CH_2), 1.40 (9H, d, $^2J(^1H$-$^{31}P)$ = 10.5 Hz, P-CH_3), 1.32 (t, J = 7.6 Hz, CH_3), 1.32 (18H, t, J = 7.6 Hz, CH_3). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 100.9 (arene *C*), 23.5 (*C*H_2), 15.9 (d, $^1J(^{13}C$-$^{31}P)$ = 34 Hz, P-CH_3), 15.2 (*C*H_3). ^{31}P NMR (121.5 MHz, CD_2Cl_2) δ: 3.08 (decet, $^2J(^1H$-$^{31}P)$ = 10.5 Hz, *P*-CH_3). MS (EI, *m*/*z*) (%): 494 [M]$^+$ (40), 459 [M – Cl]$^+$ (16), 418 [M – $PMe_3]^+$ (100), 383 [M – PMe_3-Cl]$^+$ (67), 246 [HEB]$^+$ (38), 76 [$PMe_3]^+$ (98). MS (CI, *m*/*z*) (%): 495 [M + H]$^+$ (28), 460 [M – Cl + H]$^+$ (50), 77 [PMe_3 + H]$^+$ (100). From the crystalline sample, red crystals of a minor product were separated and shown by NMR and X-ray crystallography to be the known compound *trans*-$RuCl_2(PMe_3)_4$ (**11**).

Preparation of [(η^6-hexaethylbenzene)$Mn(CO)_3](BF_4)$

A mixture of $Mn(CO)_5Br$ (2.48 g, 9.03 mmol) and $AgBF_4$ (1.75 g, 9.03 mmol) in dry CH_2Cl_2 (50 mL) was heated to reflux for 3 h under nitrogen and then cooled to room temperature. To the reaction mixture, a solution of hexaethylbenzene (2.23 g, 9.03 mmol) in dry CH_2Cl_2 (20 mL) was added, and heating was continued for 16 h. After cooling

and filtration, the filtrate was passed through Celite and concentrated to approximately one-third its volume under pressure, and excess hexane (100 mL) was added. The resulting orange-yellow solid was filtered and dried in vacuo furnishing [(HEB)$Mn(CO)_3$](BF_4) (3.34 g, 7.08 mmol, 79%); mp 266 °C (dec). ^{1}H NMR (500 MHz, CD_2Cl_2) δ: 1.41 (12H, broad singlet, CH_2), 2.68 (18H, broad singlet, CH_3). At 173 K, the methylene protons are resolved into broad singlets at 2.56 and 2.45 ppm. ^{13}C NMR (125 MHz, CD_2Cl_2) δ: 217.8 (Mn-*C*O), 120.3 (arene *C*), 22.6 (*C*H_3), 17.1 (*C*H_2). At 203 K, the aromatic, methylene, and methyl resonances are each resolved into two peaks at 124.0 and 113.6, 23.2 and 19.7, and 20.0 and 13.6 ppm, respectively. IR (NaCl windows, $CDCl_3$, cm^{-1}): υ_{CO} 2058 (s), 1996 (s). MS (+ve ESI, *m*/*z*) (%): 385 $[M]^+$ (100), 386 ($[M + H]^+$ (24), 357 $[M - CO]^+$ (0.5), 329 $[M - 2CO]^+$ (1.2), 301 $[M - 3CO]^+$ (0.5).

Preparation of [(η^6-hexaethylbenzene)$Mn(CO)_2Br$ (13)

A mixture of [(η^6-hexaethylbenzene)$Mn(CO)_3$](BF_4) (0.559 g, 1.187 mmol), Me_3NO (0.089 g, 1.187 mmol), and (n-Bu)$_4$NBr (0.462 g, 1.463 mmol) were placed in a two-neck round-bottom flask that was then evacuated. Upon addition of dry CH_2Cl_2 (30 mL), the resulting solution became deep red in colour, and the solution was stirred for 2 h under N_2. After removal of solvent under reduced pressure, the crude product was chromatographed on a silica gel column (eluent: hexane–acetone, 50:50) to give a thermally sensitive, red-purple solid, **13** (0.356 g, 0.819 mmol, 69%); mp 127–129 °C. (During the acquisition of the NMR spectra, some decomposition into HEB was evident.) IR (NaCl windows, $CDCl_3$, cm^{-1}): υ_{CO} 1974 (s), 1927 (s). ^{1}H NMR (500 MHz, CD_2Cl_2) δ: 2.67 (12H, br. s, CH_2), 1.21 (18H, br. s, CH_3). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 230.3 (Mn-*C*O), 112.0 (arene *C*), 22.6 (*C*H_2), 16.3 (*C*H_3). MS (DEI, *m*/*z*) (%): 357 $[M - Br]^+$ (1), 329 $[M - Br - CO]^+$ (2), 301 $[M - Br - 2CO]^+$ (5), 246 $[HEB]^+$ (100). MS (CI, NH_3, *m*/*z*) (%): 357 $[M - Br]^+$ (1), 329 $[M - Br - CO]^+$ (2), 301 $[M - Br - 2CO]^+$ (14), 246 (100, $[HEB]^+$ (100)). An X-ray quality crystal was obtained by repeated recrystallization from pentane–acetone by slow evaporation at room temperature under an atmosphere of nitrogen.

Crystallographic data for 7–9, 11, and 13

X-ray crystallographic data for **7**–**9**, **11**, and **13** (Table 1) were collected from suitable samples mounted with epoxy on the end of thin glass fibers. Data were collected on a P4 Bruker diffractometer equipped with a Bruker SMART 1K CCD area detector (employing the program SMART) (36) and a rotating anode utilizing graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). Data processing was carried out by use of the program SAINT (37), while the program SADABS (38) was utilized for the scaling of diffraction data, the application of a decay correction, and an empirical absorption correction based on redundant reflections. Structures were solved by using the direct-methods procedure in the Bruker SHELXTL (39) program library and refined by full-matrix least-squares methods on F^2. All non-hydrogen atoms were refined using anisotropic thermal parameters (except for the disordered anion $C_5(CO_2Me)_5$ in **7**, as discussed in the text), and hydrogen atoms were added as fixed contributors at calculated positions, with isotropic thermal parameters based on the carbon atom to which they are bonded.[3]

Metallocenes as references for the determination of redox potentials by cyclic voltammetry — Permethylated iron and cobalt sandwich complexes, inhibition by polyamine dendrimers, and the role of hydroxy-containing ferrocenes[1]

Jaime Ruiz Aranzaes, Marie-Christine Daniel, and Didier Astruc

Abstract: Measurement of the redox potentials ($E_{1/2}$) of ferrocene (**1**), decamethylferrocene (**2**), decamethylcobaltocene (**3**), and [$Fe^{I}Cp^{*}(\eta^{6}$-$C_6Me_6)$] (**4**) ($Cp^{*} = \eta^{5}$-C_5Me_5) in DMF, CH_3CN, THF, DME, CH_2Cl_2, and DMSO were recorded vs. the saturated calomel electrode (SCE), showing that the $E_{1/2}$ value of **1** was more solvent dependent than those of **2**–**4**, and that the difference in $E_{1/2}$ values among **2**–**4** was solvent independent, unlike those found between **1** and **2**–**4**. This shows that **2**–**4** are much more reliable internal references for determining redox potentials than **1**, but using data from this article, one can convert the literature values reported vs. **1** into values vs. **2**, **3**, or **4**. The electrochemistry of **1** and **2** is all the more inhibited by polyamine dendrimers as the dendrimer generation is higher. On the other hand, ferrocenes or other iron sandwich compounds containing hydroxy groups can reestablish reversible cyclic voltammograms. It is shown, using a tetra(ferrocenylmethylamine), that this phenomenon is due to hydrogen bonding between the amido and phenol groups rather than bonding of hydroxy groups to the electrode surface.

Key words: ferrocene, reference, electrochemistry, metallocene, sandwich complex, iron, dendrimer, passivation, hydrogen bond.

Résumé : Utilisant une électrode de calomel saturée (ECS) et opérant dans le DMF, le CH_3CN, le THF, le DME, le CH_2Cl_2 et de DMSO, on a mesuré les potentiels redox ($E_{1/2}$) du ferrocène (**1**), du décaméthylferrocène (**2**), du décaméthylcobaltocène (**3**) et du [$Fe^{I}Cp^{*}(\eta^{6}$-$C_6Me_6)$] (**4**) ($Cp^{*} = \eta^{5}$-C_5Me_5). Les résultats obtenus montrent que la valeur $E_{1/2}$ du composé **1** est plus influencée par le solvant que celles des composés **2**–**4** et que la différence entre les valeurs de $E_{1/2}$ entre les composés **2**–**4** est indépendante du solvant, ce qui n'est pas le cas pour celles observées entre le composé **1** et les composés **2**–**4**. Ces observations montrent que, par comparaison avec le composé **1**, les composés **2**–**4** sont des références internes beaucoup plus fiables pour déterminer les potentiels redox. Il est toutefois possible, en utilisant les données de cet article, de convertir les valeurs obtenues par rapport à la référence **1** et rapportées antérieurement dans la littérature en valeurs par rapport aux références **2**, **3** ou **4**. L'électrochimie des composés **1** et **2** est d'autant plus inhibée par les dendrimères polyamides que la génération de dendrimère est élevée. Par ailleurs, les ferrocènes et les autres composés sandwichs contenant des groupes hydroxyles peuvent rétablir les voltampérogrammes cycliques réversibles. On a démontré, à l'aide de tétra(ferrocénylméthylamine), que ce phénomène est dû à une liaison hydrogène entre les groupes amido et phénol plutôt qu'à une liaison des groupes hydroxyles à la surface de l'électrode.

Mots clés : ferrocène, référence, électrochimie, métallocène, complexe sandwich, fer, dendrimère, passivation, liaison hydrogène.

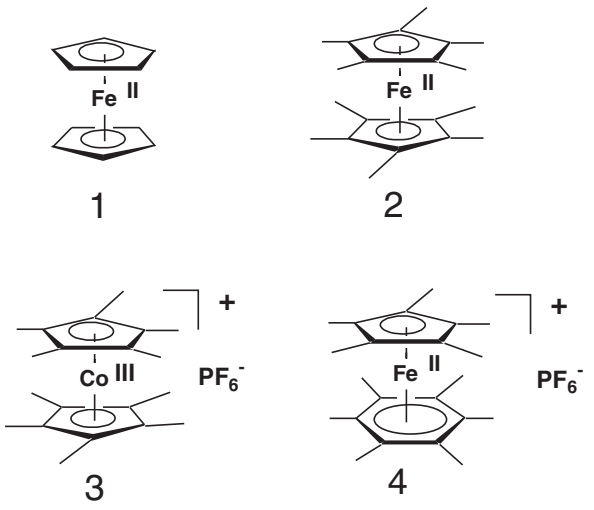
Introduction

The determination of standard redox potentials of compounds is a "Holy Graal" in electrochemistry. The average of the cathodic and anodic peak potentials ($E_{1/2} = (E_{pa} + E_{pc})/2$) in cyclic voltammetry is an excellent approximation of standard redox potential (E^0) (eq. [1], (1)).



$$[1] \qquad E^0 = E_{1/2} - (RT/nF)\ \ln(D_{red}/D_{ox})^{1/2}$$

Indeed, the diffusion coefficient of the reduced and oxidized forms are usually not very different, so the square root of their ratio is not very different from unity, at least in reversible redox systems for which the structures of the reduced and oxidized forms are not very different. The saturated calomel electrode is unstable (2, 3), however, and therefore electrochemists have been seeking internal reference compounds to determine standard redox potentials of compounds more accurately in nonaqueous solvents (1, 4). Internal references overcome the problem of potential variations owing to changes in liquid junction potentials between the solution and the reference electrode (5).

Ferrocene/ferrocenium ($1/1^+$) has been considered as the prototype of electrochemically reversible systems (6). Indeed, its reduced Fe^{II} and oxidized Fe^{III} (ferrocenium) forms are both low spin, therefore the difference in Fe—C bond length between these two compounds is not larger than 0.05 Å (7). Although ferrocenium salts react with nucleophiles (8–10) and dioxygen (11), these reactions usually do not perturb the redox potential because they are slow on the relatively fast electrochemical timescale of cyclic voltammetry and the $Fe^{II/III}$ system remains reversible; even partial chemical irreversibility does not modify the potential (1). Ferrocene now is a popular reference compound commonly used as such by the community of molecular chemists, especially because, in addition, it is a cheap, stable, and easily available compound, and the location of its redox potential is conveniently located in the electrochemical scale. Finally, for these reasons, it has been recommended by IUPAC (12). The use of ferrocene as an internal reference is indeed adequate when a single solvent is used. However, it has been found that the ferrocene/ferrocenium couple was the subject of specific solvation effects that questioned the so-called "ferrocene assumption" (13–15). Therefore, the redox potential of ferrocene varies with the nature of the solvent, this variation reaching up to 0.56 V (16, 17). This is due to the thermodynamics of the ion paring between ferrocenium cation and the anion of the supporting electrolyte in specific solvents. Indeed, the central iron atom is not well-protected against side binding, especially because even large tilting of the ferrocene rings can occur almost without energy change, such as in the protonated form of ferrocene, the Fe^{IV} hydride $[FeCp_2(H)]^+$ (18, 19). This ion pairing decreases the energy necessary to reduce ferrocenium cation, causing a cathodic shift of the redox potential that depends on the natures of both the solvent and anion of the supporting electrolyte. More specifically, it has been shown that two types of solvation effects are involved in ferrocene/ferrocenium: those directed towards the iron center and those directed towards the rings (15, 20, 21).

Clearly, this inconvenience almost vanishes in decamethylferrocene (**2**) (Chart 1) whose electrochemistry of the fully reversible redox $Fe^{III/II}$ system has been largely reported (22–37) including the electrochemical reversibility (fast electron-transfer kinetics) (25, 26).

Chart 1.

The $Cp^*_2Fe^{III/II}$ redox couple has indeed been proposed as an internal standard taking these reasons into account (36, 37). In particular, the shell of the 10 methyl groups encapsulate the iron center in such a way that it is protected against close interactions with substrates. This is ascertained upon scrutiny of the X-ray data for $[Cp^*_2Fe^{II}]$ ($Cp^* = \eta^5\text{-}C_5Me_5$) showing that the inter-ring methyl group contacts are within van der Waals distances (38). As a result, the solvent effects have been found to be very weak as compared with those observed with the $FeCp_2^{II/III}$ redox system (37). Other permethylated first-row, transition-metal sandwich compounds such as $[CoCp^*_2]$ (**3**) and $[Fe^ICp^*(\eta^6\text{-}C_6Me_6)]$ (**4**) that have been called electron-reservoir complexes also fulfill this property. Indeed, the $Fe^{II/I}$ redox change in compounds of the family of **4** involves an e^*_1 orbital that has a high metal character, and the central metal undergoing the redox change is fully protected sterically (39–44). The radii of the permethylmetallocenes $[FeCp^*_2]$ and $[Cp^*_2Co]$ and of $[Fe^ICp^*(\eta^6\text{-}C_6Me_6)]$ are much larger than those of the parent metallocenes, and the ion pairing energy (45) is an order of magnitude lower in permethylmetallocenium salts compared with metallocenium salts. Therefore, we suggest their use as internal references that are more accurate than ferrocene and independent of the solvent and supporting electrolyte. An interest in addressing these three compounds is that they cover the redox scale, which allows using the one that does not overlap with the substrate under study. Detailed studies demonstrate this feature here including the absence of variation of the differences among the redox potentials of these compounds upon changing the solvent (unlike with ferrocene) and how to connect ferrocene to permethylated sandwich references even if ferrocene is continuously used as an internal reference.

In the present context of nanosciences, we have also found that commercial polyamine dendrimers inhibit the electrochemistry of ferrocene and decamethylferrocene (46). Thus, in addition, the reference problem needed to be addressed again. We show that hydroxy-containing ferrocene deriva-

Table 1. $E_{1/2}$ values (V) of transition-metal sandwich complexes determined vs. SCE.

$E_{1/2}$ vs. SCE	DMF	CH_3CN	THF	CH_2Cl_2	DMSO	DME
$FeCp_2^{+/0}$	0.470	0.382	0.547	0.475	0.435	0.580
$FeCp^*_2{}^{+/0}$	–0.125	–0.125	0.102	–0.070	–0.030	0.140
$CoCp^*_2{}^{+/0}$	–1.402	–1.525	–1.295	–1.497	–1.425	–1.260
$FeCp^*(C_6Me_6)^{+/0}$	–1.762	–1.865	–1.645		–1.775	–1.605

Note: $E_{1/2}$ values were determined using the cationic form: $E^0 \sim E_{1/2} = (E_{pa} + E_{pc})/2$. n-$Bu_4N^+PF_6^-$ (0.1 mol/L); cationic complex: 10^{-3} mol/L; v = 400 mV/s, to 20 °C; working and counter electrodes: Pt; reference electrode: SCE; $\Delta E_p = E_{pa} - E_{pc}$ = 40–45 mV (DMF), 45–50 mV (MeCN), 50–55 mV (THF), 50–60 mV (CH_2Cl_2), 50–60 mV (DMSO), 60–70 mV (DME). The shifts vs. the theoretical value of 58 mV at 20 °C are due to variations in ohmic compensation. $E_{1/2}$ values were recorded with an accuracy of ±0.005 V except the $E_{1/2}$ value of $FeCp^*(C_6Me_6)^{+/0}$ in CH_2Cl_2, which is not accurate because of the interference with the reduction of the solvent. In CH_2Cl_2, n-Bu_4N^+ salts with various counteranions and concentrations (vide infra) were used, but the difference between the $E_{1/2}$ values of $FeCp^*_2{}^{+/0}$ and $CoCp^*_2{}^{+/0}$ remained constant (1.390 V). The difference between the $E_{1/2}$ values of $FeCp_2^{+/0}$ and $FeCp^*_2{}^{+/0}$ varied, however, between 0.460 and 0.545 V. The $E_{1/2}$ values vs. SCE obtained for $FeCp_2^{+/0}$ and $FeCp^*_2{}^{+/0}$, respectively, are as follows (V): n-$Bu_4N^+PF_6^-$ (0.1 mol/L: 0.475 and –0.070; 0.4 mol/L: 0.425 and –0.100); n-$Bu_4N^+BF_4^-$ (0.1 mol/L: 0.585 and 0.045; 0.4 mol/L: 0.555 and 0.035); n-$Bu_4N^+Br^-$ (0.1 mol/L: 0.490 and –0.010; 0.4 mol/L: 0.480 and 0.000); n-$Bu_4N^+HSO_4^-$ (0.1 mol/L: 0.545 and 0.065; 0.4 mol/L: 0.515 and 0.055); n-$Bu_4N^+Cl^-$ (0.1 mol/L: 0.590 and 0.070; 0.4 mol/L: 0.570 and 0.070).

Table 2. $E_{1/2}$ values (V) of transition-metal sandwich complexes determined vs. $FeCp^*_2{}^{+/0}$.

$E_{1/2}$ vs. $FeCp^*_2{}^{+/0}$	DMF	CH_3CN	THF	CH_2Cl_2	DMSO	DME
$FeCp^*_2{}^{+/0}$	0	0	0	0	0	0
$FeCp_2^{+/0}$	0.480	0.510	0.440	0.545	0.470	0.440
$CoCp^*_2{}^{+/0}$	1.390	1.390	1.400	1.390	1.395	1.400
$FeCp^*(C_6Me_6)^{+/0}$	1.750	1.745	1.750		1.750	1.750

Note: $E_{1/2}$ values were determined using the cationic form: $E^0 \sim E_{1/2} = (E_{pa} + E_{pc})/2$. n-$Bu_4N^+PF_6^-$ (0.1 mol/L); cationic complex: 10^{-3} mol/L; v = 400 mV/s, to 20 °C; working and counter electrodes: Pt; reference electrode: SCE; $\Delta E_p = E_{pa} - E_{pc}$ = 40–45 mV (DMF), 45–50 mV (MeCN), 50–55 mV (THF), 50–60 mV (CH_2Cl_2), 50–60 mV (DMSO), 60–70 mV (DME). The shifts vs. the theoretical value of 58 mV at 20 °C are due to variations in ohmic compensation. $E_{1/2}$ values were recorded with an accuracy of ±0.005 V except the $E_{1/2}$ value of $FeCp^*(C_6Me_6)^{+/0}$ in CH_2Cl_2, which is not accurate because of the interference with the reduction of the solvent. In CH_2Cl_2, n-Bu_4N^+ salts with various counteranions and concentrations (vide infra) were used, but the difference between the $E_{1/2}$ values of $FeCp^*_2{}^{+/0}$ and $CoCp^*_2{}^{+/0}$ remained constant (1.390 V). The difference between the $E_{1/2}$ values of $FeCp_2^{+/0}$ and $FeCp^*_2{}^{+/0}$ varied, however, between 0.460 and 0.545 V. The $E_{1/2}$ values vs. SCE obtained for $FeCp_2^{+/0}$ and $FeCp^*_2{}^{+/0}$, respectively, are as follows (V): n-$Bu_4N^+PF_6^-$ (0.1 mol/L: 0.475 and –0.070; 0.4 mol/L: 0.425 and –0.100); n-$Bu_4N^+BF_4^-$ (0.1 mol/L: 0.585 and 0.045; 0.4 mol/L: 0.555 and 0.035); n-$Bu_4N^+Br^-$ (0.1 mol/L: 0.490 and –0.010; 0.4 mol/L: 0.480 and 0.000); n-$Bu_4N^+HSO_4^-$ (0.1 mol/L: 0.545 and 0.065; 0.4 mol/L: 0.515 and 0.055); n-$Bu_4N^+Cl^-$ (0.1 mol/L: 0.590 and 0.070; 0.4 mol/L: 0.570 and 0.070).

tives can reestablish a reasonably good and reliable cyclic voltammetry in the presence of these dendrimers allowing the use of these ferrocenes as reference systems. The competition between binding amino groups and hydroxy groups to the Pt electrode has been examined using ferrocenyl amine dendrimers previously reported by Salmon and Jutzi (47) to better understand this positive hydroxy group effect.

Results and discussion

Permethylated iron and cobalt sandwich complexes as references

We have selected the permethylated transition-metal sandwich redox systems decamethylferrocene/decamethylferrocenium $[FeCp^*_2]^{+/0}$, decamethylcobaltocene/decamethylcobaltocenium $[CoCp^*_2]^{+/0}$, and $[FeCp(\eta^6\text{-}C_6Me_6)]^{+/0}$ as alternative and complementary reference systems. The redox potential values of these redox couples are reported in Table 1 vs. SCE in different solvents. Therefore, the mixture of these compounds was analyzed in different solvents. The average values of $E_{1/2}$ between the anodic and cathodic peak potentials recorded by cyclic voltammetry in dimethylformamide (DMF), acetonitrile (CH_3CN), tetrahydrofurane (THF), dimethoxyethane (DME), dichloromethane (CH_2Cl_2), and dimethylsulfoxide (DMSO) are reported vs. SCE in Table 1 and are in accord with previous literature data within 0.2 V. These data show that the variations of $E_{1/2}$ values with the nature of the solvent are smaller with $[FeCp^*_2]$ than with $[FeCp_2]$, as noted by Lay's group who recorded the variation of the $E_{1/2}$ value of **1** and **2** with a large number of solvents (37). These variations vs. SCE are still significant with the three permethylated sandwich compounds because of the different solvent interactions with the cationic forms or to the variations of the SCE electrode reference in different solvents or both. A way to answer this uncertainty consists of determining the potentials ($E_{1/2}$) of the different permethylmetallocenes ($MCp^*_2{}^{+/0}$) vs. one of them, for instance $FeCp^*_2{}^{+/0}$, in the different solvents. In this way, the data will be free of the SCE reference electrode. These values have been determined vs. $FeCp^*_2{}^{+/0}$ using the experimental values of Table 1 and are reported in Table 2. Notice that the less polar solvent CH_2Cl_2 is the one giving the larger difference between the potential values of $[FeCp_2]^{+/0}$ vs. $FeCp^*_2{}^{+/0}$. This is due to the fact that, in such a solvent, the ion pairs are not separated (tight ion pairs), therefore, the anion influence on the cation containing the redox center is

$[CoCp_2]$	DME	–0.74*	–0.86	–0.62	–1.33
$C_{60}{}^{-}$	MeCN–PhMe	–0.515*	–0.51	–0.27	–0.98
$[FeCp^*_2]$	DMF	0	–0.012	0.23	–0.49
	CH_2Cl_2	0	–0.105	0.13	–0.55
Hydrazine	DMSO	0.06	–0.03	0.21	–0.41

Note: Direct measurements vs. $FeCp^*_2{}^{+/0}$ are noted by *. The mono-, di-, and tri-anions of C_{60} are accessible by reduction of C_{60} using $[Fe^{I}Cp(C_6Me_6)]$ (17). The other values vs. $FeCp_2{}^{*+/0}$ are: $C_{60}{}^{3-/4-}$: –1.895 V; $C_{60}{}^{4-/5-}$: –2.39 V; and $C_{60}{}^{5-/6-}$: –2.39 V. The two later values were deduced from the values vs. $FeCp_2{}^{+/0}$ reported in ref. 48. Other standard redox potentials E^0 (V) of oxidants and reductants vs. various references were extracted from ref. 16 and corrected from the $FeCp_2{}^{+/0}$ to the $FeCp^*_2{}^{+/0}$ reference using the ΔE^0 values of Table 2.

more substantial, especially because there is space for interaction between the non-methylated rings in ferrocenium. It now becomes clear from Table 2 that the $E_{1/2}$ values measured vs. $FeCp^*_2{}^{+/0}$ are independent of the solvent for these three permethylated metal sandwich complexes within the accuracy of our experiments. Variations of up to 0.11 V for ferrocene were found, however, showing the significant influence of the solvent on the redox potential of ferrocene compared with the permethylated complexes. The fact that the $FeCp_2{}^{+/0}$ reference is not quite accurate enough in this respect does not mean that the many results that have been reported in the recent literature vs. $FeCp_2{}^{+/0}$ have to be remeasured vs. the more accurate $FeCp^*_2{}^{+/0}$ reference. Indeed, it is possible to take advantage of all the results obtained vs. $FeCp_2{}^{+/0}$ (16) using the conversion of values vs. $FeCp_2{}^{+/0}$ to values vs. $FeCp^*_2{}^{+/0}$ of Tables 2 and 3 in various solvents. Likewise, it is possible to continue using ferrocene as the internal reference and yet to have a solvent- and electrolyte-independent redox potential by conversion using Tables 2 and 3. Accordingly, the standard redox potentials of the main reductants and oxidants, $E^{0\prime}$ vs. $FeCp_2{}^{+/0}$, $FeCp^*_2{}^{+/0}$, SCE, and the normal hydrogen electrode (NHE), are now given in Tables 3 and 4, respectively.

Inhibition of the electrochemistry of ferrocene and decamethylferrocene by polyamine dendrimers

Dendrimers (49) might be essential parts of future biomedical, electronic, optical, and magnetic nanodevices (sensors, switches, memories, transistors) (50). Therefore, electrochemistry involving these nanomolecules is crucial to the analysis of electron-transfer properties (17, 51–54). Among the dendritic redox probes (55–61), ferrocenes occupy a central place, for the same reasons involving physical properties and conveniency that led to its choice as an internal reference for the determination of redox potentials (vide supra). Ferrocenes are also used as mediators between electrodes and buried metal centers of metalloenzymes, a property that has been applied to glucose sensors (62).

The well-known commercial DSM polyamine — or so-called poly(propylene imine) — dendrimers (Chart 2) (63) are shown here to inhibit the electrochemistry of simple ferrocene derivatives such as ferrocene itself and decamethylferrocene.

We will also indicate how this electrochemical activity is reestablished using hydrogen bonding (64–77) between the primary amino groups of these dendrimers and metallocenyl alcohols and phenols (72–76).

Despite the well-known electrochemical behavior of ferrocene, Fig. 1 shows that the electrochemical activity of **2** in CH_2Cl_2 on a Pt electrode at a fixed return potential is all the more inhibited by the presence of a polyamine dendrimer as the dendrimer generation increases, i.e., this inhibition is subjected to a dramatic dendritic effect. Although the cyclic voltammogram (CV) is hardly perturbed in the presence of propylamine (Fig. 1*a*), it almost completely vanishes in the presence of G_4 dendr-$(NH_2)_{64}$ (Fig. 1*d*). Thus, the Pt elec-

Note: Direct measurements vs. $FeCp^*_2{}^{+/0}$ are noted by *. The mono-, di-, and tri-anions of C_{60} are accessible by reduction of C_{60} using $[Fe^ICp(C_6Me_6)]$ (17). The other values vs. $FeCp_2{}^{*+/0}$ are: $C_{60}{}^{3-/4-}$: –1.895 V; $C_{60}{}^{4-/5-}$: –2.39 V; and $C_{60}{}^{5-/6-}$: –2.39 V. The two later values were deduced from the values vs. $FeCp_2{}^{+/0}$ reported in ref. 48. Other standard redox potentials E^0 (V) of oxidants and reductants vs. various references were extracted from ref. 16 and corrected from the $FeCp_2{}^{+/0}$ to the $FeCp^*_2{}^{+/0}$ reference using the ΔE^0 values of Table 2.

trode is passivated by the polyamine dendrimer that shields the redox-active compounds in solution.

The inhibition is all the more marked as the return potential is more positive. This results from modification of the electrode by scanning beyond the potential at which the dendritic polyamine is oxidized (Fig. 2). Thus, the large polyamine dendrimers adsorbed on the passivated Pt electrode are insulating barriers between the Pt electrode and $[FeCp_2]$ (**1**) or $[FeCp^*_2]$ (**2**). What is left in the CV of Fig. 1*d* is reminiscent of the electrochemistry observed with metalloproteins on electrodes, and the shape of the CV might be explainable similarly. If the dendrimer has holes in the surface coverage, then the bulk electrode acts as a microelectrode and the signal that is observed corresponds to a hemispherical diffusion (mixing hemispherical and linear diffusion) (77).

Figure 3 compares the CVs of **2** together with those of various ferrocene derivatives in the presence of G_3 dendr-$(NH_2)_{16}$. First, Figs. 3*a* and 3*b* compare the CVs of a mixture of **1** and **2** in the presence of propylamine (Fig. 3*a*) vs. G_3 dendr-$(NH_2)_{16}$ (Fig. 2*b*) showing that the ferrocene wave is rectified (i.e., the return reduction wave of ferrocenium is strongly reduced or lost) only in the presence of the dendrimer.

The scan rate has little influence on the passivation phenomenon, as shown in Fig. 4. On the other hand, nondendritic amines such as dodecylamine and triethylenetetramine do not show the inhibition phenomenon, which is indicative of the specificity of polyamine dendrimers (Fig. 5).

The key role of hydrogen bonding with the hydroxy group in hydroxy-containing ferrocene references to reestablish the electrochemical activity

In Figs. 3*c* and 3*d*, ferrocene is replaced by a ferrocenyl derivative containing a hydroxymethyl substituent in **5a** (Chart 3, Fig. 3*c*) or a hydroxybenzyl substituent in **6** (Chart 3, Fig. 3*d*) showing that the reversibility is reestablished when a hydroxymethyl or phenol group is present on the ferrocene substituent.

The complex **5b** is less efficient than **5a** owing to the steric effect of the methyl group. Figure 2*d* shows that the effect is more marked with the more acidic phenol-group-containing ferrocene derivative [Fc-CH_2p·C_6H_4-OH] (**6**) (78) that forms stronger hydrogen bonds with amines than **5a**. Altogether, the magnitude of the inhibition follows the sequence:

$$[FeCp^*_2] > [FeCp_2] > FcCH(Me)OH\text{-}Me > [Fc\text{-}CH_2OH] > [Fc\text{-}CH_2p\cdot C_6H_4\text{-}OH]$$

For instance, it is remarkable that the ferrocenyl estradiol derivative **8** (79) gives a reversible CV wave in the presence of G_3 dendr-$(NH_2)_{16}$ (Fig. 6), whereas the CVs of the standard references **1** and **2** themselves are inhibited or strongly rectified under the same conditions. Note, however, that the CV of **8** is slightly rectified by comparison to those of **6**. Indeed, the rigid steroidal frame keeps the redox center away from the phenol group, unlike in **6**. This is also in accord

with the selective OH···H_2N hydrogen bonding with the distal phenol rather than with the tertiary alcohol near the redox center of **8**. The recovery of the CV in hydroxy-containing redox-active compounds can tentatively be taken into account by the dendrimeric linkage between **8** and the Pt electrode via the amino termini of the polyamine dendrimer represented in Fig. 6.

This suggestion implies that the hydrogen bonding between the hydroxy groups and the dendrimer amino group brings **5a**, **6**, or **8** near the electrode, so that they are close enough to remain electroactive. Indeed, it is well-known that dendrimers adsorb strongly (80, 81) and flatten (82, 83) on metal surfaces. It has also been shown that, in the dendrimers containing ferrocenyl termini (84), all the ferrocenyl centers are electroactive with fast electron transfer even in the solid state owing to electron hopping. This is

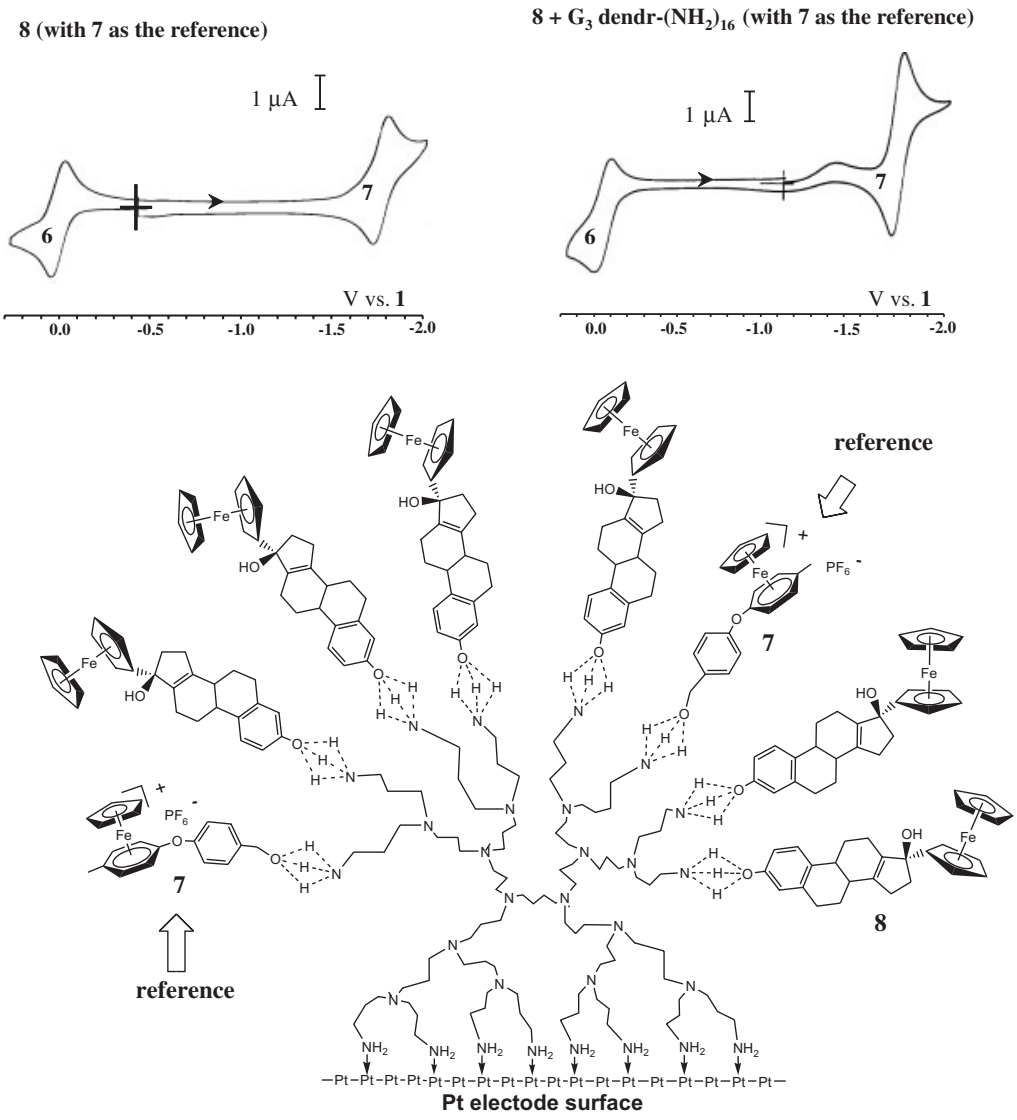
true even with ferrocenyl dendrimers containing several hundred ferrocenyl groups (85, 86). A similar situation is found here in supramolecular dendrimers.

This reversible hydrogen bonding between polyamine dendrimers and phenols is shown by comparison of the ^1H NMR spectra of the phenol derivative **6** and G_3 dendr-$(NH_2)_{16}$ alone with that of a mixture of these compounds (equimolar mixture of hydroxy and amino groups, Fig. 7). Thus, in the ^1H NMR spectrum of the mixture, the signals of the OH and NH_2 groups of the isolated compounds have disappeared and a new broad average signal common to the

Chart 3.



OH + NH_2 groups has appeared. Even though this H-bonding is reversible (as indicated by the concentration dependence of the signal location) owing to the low energy of the hydrogen-bonding interaction, the process is efficient on the relatively large electrochemical timescale of the CV.

To confirm that the OH···NH_2 hydrogen bonding is responsible for the CV of the hydroxy-containing ferrocenes, we considered the other possibility: preferential direct interaction of the hydroxy group of a phenol with the electrode in the presence of a polyamine dendrimer. For this purpose, we recorded the CV of the tetra ferrocenyl dendrimer, G_1 dendr-$(NHCH_2Fc)_4$ (**9**) (Fc = ferrocenyl), already reported together with its detailed electrochemical study by Jutzi (47). It provides additional evidence of the observation of electrochemical redox activity of a ferrocenyl group when it is linked to a polyamine dendrimer (Fig. 8*a*), as already shown by this

Fig. 6. CH_2Cl_2; *n*-Bu_4NPF_6 (0.1 mol/L); reference electrode: Ag^+/Ag; working and counter electrodes: Pt; scan rate: 0.2 V s^{-1}. (*a*) Cyclic voltammogram (CV) of the steroid derivative **8** (5×10^{-4} mol/L) in the presence of the reference compound **7** (5×10^{-4} mol/L), both containing hydroxy groups without (top left) and with (top right) G_3 dendr-$(NH_2)_{16}$ (6.25×10^{-4} mol/L); note the slight rectification for **8**. (*b*) Linkage of redox-active groups to the Pt electrode via G_3 dendr-$(NH_2)_{16}$ (bottom).

author. We have also compared the CV of **9** and *p-tert*-butylphenol with that of their mixture. No dramatic difference was found for the CV of **7** in the presence and absence of *p-tert*-butylphenol (compare Figs. 8*b* and 8*d*). Then, the oxidation wave of *p-tert*-butylphenol at 1 V vs. **1** is no longer observed when **7** is present in the electrochemical cell. The ferrocenyl and amine groups are anodically oxidized at close potentials, giving a broad anodic wave. Scanning beyond this wave is necessary to reach the phenol oxidation wave, but the electrode is modified or passivated by the polyamine dendrimer acting as an insulator, which prevents the observation of this phenol oxidation wave (compare Figs. 8*c* and 8*d*).

These experiments indicate that the phenol is not adsorbed onto the Pt electrode preferentially to the polyamine dendrimer, even a small one. It is also probable that hydrogen bonding with the secondary amine **9** is much less efficient than with primary amines for steric reasons (vide supra **5b** vs. **5a**). Since the adsorption of the polyamine dendrimer is all the stronger as the generation is higher, the electroactivity of redox-active compounds containing a hydroxy group cannot be explained by the direct interaction of the hydroxy group with the Pt electrode in the presence of the polyamine dendrimer. Consequently, the hydrogen bonding shown by NMR and the above experiment indicates that the dendrimer linkage shown in Fig. 4 is responsible for the electroactivity of the hydroxy-bonded redox-active ferrocenes in the presence of polyamine dendrimers.

Figure 8*e* shows the CV of the hexaammonium hexaundecanoate salt resulting from the protonation of **9** by undecanoic acid. The electrochemistry of the hexaammonium hexachloride salt resulting from the protonation of **9** by HCl in DMSO has already been reported (47), but the undecanoate ion now provides solubility in CH_2Cl_2 for comparison with the CV of **9**. This comparison (Fig. 8 including 8*e*) also confirms that *p-tert*-butylphenol does not protonate **9**,

as shown by the disappearance of the anodic oxidation in the CV of this salt, contrary to that of **9** in the presence of *p-tert*-butylphenol. Thus, since the secondary amino groups of **9** are more basic than the primary amino groups of the DSM polyamine dendrimers, the H-bonding responsible for the CV of OH-containing ferrocenes in the presence of a DSM dendrimer does not involve protonation of the amino groups by the phenol.

Conclusion

It has been shown here that (*i*) the difference in $E_{1/2}$ values between the permethylated Fe and Co sandwich complexes are solvent independent within the accuracy of our experiments, in agreement with prior work by Lay's group (37) and our preliminary study (43); (*ii*) this allows using them as solvent-independent internal references for the determination of redox potentials and linking the solvent dependent $E_{1/2}$ obtained in the literature vs. ferrocene $E_{1/2}$ to values vs. decamethylferrocene that are solvent independent (37, 43); (*iii*) polyamine dendrimers inhibit (or strongly rectify) the electrochemistry of simple redox-active compounds such as the ferrocenes **1** and **2** because of their adsorption on Pt electrodes upon anodic oxidation. They do all the more so as they are larger and as the potential is scanned toward more positive values; (*iv*) this CV can be reestablished by bonding between the primary amino groups of the dendrimer and the redox-active compound either by hydrogen bonding or by covalent bonding. Thus, although polyamine dendrimers inhibit the electrochemistry of simple redox-active compounds, they form redox-active dendritic systems by $NH_2\cdots HO$ hydrogen bonding resembling redox-active dendrimers well-known with covalent bonding between the core and redox-active termini. Finally, two or several hydroxymethyl- or phenol-containing redox-active compounds can simultaneously show redox activity, which could potentially be used in combinatorial ways. For instance, a simple application shown here is that compounds such as **8** or **9** are excellent internal references to determine redox potentials in the presence of polyamine dendrimers (see Figs. 2 and 4), whereas the use of the classic references **1** or **2** is not possible under these conditions.

Experimental section

General data

Tetrahydrofuran and diethyl ether were purified before use by distillation from sodium/benzophenone ketyl under nitrogen. Acetonitrile was stirred under nitrogen overnight on phosphorus pentoxide, distilled from sodium carbonate, and stored under nitrogen. Dichloromethane was distilled from calcium hydride just before use. Anhydrous *N*,*N*-dimethylformamide (DMF), [$FeCp_2$], [$FeCp_2$*], DSM polyamine dendrimers G_n-DAB-dend-$(NH_2)x$ were purchased from Aldrich and [$CoCp^*_2$]PF_6 and [$FeCp_2$*]PF_6 were purchased from Strem and used as received. Tetrabutylammonium tetrafluoroborate (Bu_4NBF_4) and tetrabutylammonium hexaflurophosphate (Bu_4NPF_6) were purchased from Fluka. The former salt was crystallized in a methanol–water mixture to eliminate traces of iodide ions and dried under vacuum.

Cyclic voltammetry

Cyclic voltammetry data were recorded with a PAR 273 potentiostat galvanostat. Care was taken in the CV experiments to minimize the effects of the solution resistance on the measurements of potential peaks (the use of positive feedback *iR* compensation and dilute solution (10^{-4} mol/L) maintained currents between 1 and 10 μA). The working electrode and counter electrode were platinum (Pt). The working electrode was a disc of 1 mm diameter and was treated by immersion in 0.1 mol/L HNO_3, then polished before use and between each recording if necessary.

Acknowledgments

We are grateful to Dr. M. Szlosek (University of Bordeaux I, Talence, France) for a sample of tetraferrocenyl dendrimer **9**. Financial support from the Institut Universitaire de France (IUF, D. Astruc), the Centre National de la Recherce Scientifique (CNRS), and the Ministère de la Recherche et de la Technologie (MRT, Ph.D. grant to M.-C. Daniel) and the University of Bordeaux I is gratefully acknowledged.

NMR spectroscopy of the solid-state isomerization of nitrito- and nitro-pentamminecobalt(III) chloride[1]

Kristopher J. Ooms and Roderick E. Wasylishen

Abstract: Cobalt-59 and nitrogen-15 NMR spectra of the *nitrito*pentamminecobalt(III) chloride, $[(NH_3)_5Co\text{-}ONO]Cl_2$, and *nitro*pentamminecobalt(III) chloride, $[(NH_3)_5Co\text{-}NO_2]Cl_2$, isomers in the solid state have been obtained at several applied magnetic field strengths. The ^{59}Co NMR line shapes indicate that both the cobalt nuclear quadrupolar coupling constant (C_Q) and the span of the chemical shift tensor (Ω) decrease when the complex isomerizes from $[(NH_3)_5Co\text{-}ONO]^{2+}$ to $[(NH_3)_5Co\text{-}NO_2]^{2+}$; C_Q decreases from 23 to 10.3 MHz and Ω changes from 1650 to 260 ppm. The ^{15}N NMR line shapes also show a significant change in the nitrogen magnetic shielding tensor upon isomerization, with Ω decreasing from 710 to 547 ppm; also, an indirect spin-spin coupling, $^1J(^{59}Co,^{15}N) = 63$ Hz, is observed in the ^{15}N NMR spectra of the nitro isomer. The NMR parameters are rationalized based on differences in the molecular structure of the two isomers. NMR spectra have also been recorded as the isomerization progresses with time and demonstrate the practicality of the technique for the study of solid-state isomerizations.

Key words: ^{15}N, ^{59}Co, solid-state NMR, linkage isomerization, chemical shift tensor, electric field gradient tensor.

Résumé : Opérant en phase solide et à plusieurs forces de champ magnétique appliqué différentes, on a déterminé les spectres RMN du ^{59}Co et du ^{15}N d'isomères du chlorure de *nitrito*pentamminecobalt(III), $[(NH_3)_5Co\text{-}ONO]Cl_2$ et du chlorure de *nitro*pentamminecobalt(III), $[(NH_3)_5Co\text{-}NO_2]Cl_2$. Les formes des raies des spectres RMN du ^{59}Co indiquent que la constante de couplage quadripolaire nucléaire du cobalt (C_Q) ainsi que l'envergure du tenseur du déplacement chimique (Ω) diminuent toutes les deux lorsque le complexe s'isomérise de $[(NH_3)_5Co\text{-}ONO]^{2+}$ à $[(NH_3)_5Co\text{-}NO_2]^{2+}$; la valeur de C_Q diminue de 23 à 10,3 MHz alors que la valeur de Ω passe de 1650 à 260 ppm. Lors de l'isomérisation, les formes des raies en RMN du ^{15}N présentent aussi un changement significatif dans le tenseur de blindage magnétique de l'azote, avec Ω, qui passe de 710 à 547 ppm; de plus, on observe un couplage spin-spin indirect, $^1J(^{59}Co,^{15}N) = 63$ Hz, dans le spectre RMN du ^{15}N de l'isomère nitro. Les différences dans les paramètres RMN sont rationalisées sur la base de différences dans la structure moléculaire de chacun des isomères. On a aussi enregistré les spectres RMN alors qu'ils s'isomérisent en fonction du temps et on démontrent que cette technique peut être pratique pour l'étude d'isomérisations à l'état solide.

Mots clés : ^{15}N, ^{59}Co, RMN à l'état solide, isomérisation de liaison, tenseur du déplacement chimique, tenseur du gradient du champ électrique.

[Traduit par la Rédaction]

Introduction

Reactions that occur in the solid state are of interest in many areas of research such as pharmaceutical chemistry (1, 2), organometallic chemistry (3), and organic synthesis (4–6). Linkage isomerizations are one class of solid-state reactions that involve a change in the bond(s) between a ligand and a metal centre. The linkage isomerization involving the nitrite anion (NO_2^{-1}) in *nitrito*pentamminecobalt(III) chloride (nitrito), which isomerizes to form the more thermodynamically stable *nitro*pentamminecobalt(III) chloride (nitro), $[(NH_3)_5Co\text{-}ONO]^{2+} \rightarrow [(NH_3)_5Co\text{-}NO_2]^{2+}$, has been known for over 100 years (7). This reaction has been studied in depth by numerous techniques, including solution NMR spectroscopy (8), IR spectroscopy (9–14), single-crystal and powder X-ray diffraction (15–17), and recently, DFT quantum chemical methods (18, 19).

Several studies, primarily employing IR spectroscopy, have determined the rate constants, equilibrium values, and activation energies of the reaction in the solid state (11, 15, 20–23). Typically the isomerization half-life is on the order of hours to days depending on the temperature. One problem with the solid-state investigations to date is that the temperatures at which the kinetic data are measured are usually

above room temperature, while the X-ray diffraction data has been obtained well below room temperature. This makes it difficult to draw connections between the kinetic data and the crystal structures. In addition, there are significant discrepancies in the rate constants reported by different investigators. In principle, solid-state NMR spectroscopy can provide a valuable link between the structural and thermodynamic properties of this system at the same temperature; however, only the solid-state ^{59}Co NMR of the more stable nitro isomer has been reported (24).

In the current study we have determined the ^{59}Co and ^{15}N NMR parameters of both the nitrito and nitro complexes of pentamminecobalt(III) chloride using solid-state NMR. Cobalt-59 is a spin $I = 7/2$ quadrupolar nucleus and has one of the largest chemical shift ranges in the periodic table, >18 000 ppm (25), making it ideally suited for solid-state NMR investigations of cobalt complexes because of its sensitivity to subtle changes in molecular structure (25–29). Nitrogen-15, which is a spin $I = 1/2$ nucleus, is well-suited to follow the effect that structural changes have on the NO_2^- ligand (30, 31). We present the ^{59}Co and ^{15}N solid-state NMR parameters for the $[(NH_3)_5Co\text{-}ONO]^{2+}$ isomer followed by those for the $[(NH_3)_5Co\text{-}NO_2]^{2+}$ isomer. We have also monitored the thermal isomerization reaction using solid-state ^{59}Co and ^{15}N NMR spectroscopy in an effort to determine whether this technique has the potential to provide the relative amounts of each isomer in the solid state.

Experimental

The pink nitrito, $[(NH_3)_5Co\text{-}ONO]Cl_2$, and yellow nitro, $[(NH_3)_5Co\text{-}NO_2]Cl_2$, isomers were synthesized according to literature methods, and the product purity was verified using IR spectroscopy (10, 12). The isotopically enriched ^{15}N samples were prepared using 99% ^{15}N-labelled sodium nitrite obtained from C/D/N Isotopes Inc., Pointe-Claire, Quebec. The precursor compound for the synthesis (chloropentamminecobalt(III) chloride) was synthesized by the addition of 15 mL of concentrated aqueous hydrochloric acid to 5 g of cobalt(II) carbonate in 35 mL of distilled water. The precipitate was filtered twice and 5.05 g of ammonium chloride and 50 mL of concentrated aqueous ammonia were added. The solution was cooled and 80 mL of 6% hydrogen peroxide was slowly added. When bubbling ceased, nitrogen was bubbled through the solution for 1 h. The solution was neutralized with hydrochloric acid, after which an additional 20 mL of concentrated hydrochloric acid were added and the solution was set in a hot water bath for 2 h. The purple precipitate was filtered and washed with water and ethanol, yielding approximately 9 g of sample.

Solid-state NMR spectroscopy was performed on three spectrometers with field strengths of 4.70 T (Chemagnetics CMX Infinity 200), 7.05 T (Bruker Avance 300), and 11.75 T (Bruker Avance 500). Bruker double or triple resonance probes (4 mm o.d. MAS) were used on the Bruker systems, while Chemagnetics double resonance probes (4 mm o.d. MAS and 5 mm o.d. solenoid) were used on the Chemagnetics system. All ^{59}Co NMR chemical shifts were referenced with respect to a 1.0 mol/L aqueous solution of $K_3Co(CN)_6$ at 0.0 ppm, while the ^{15}N NMR chemical shifts were referenced with respect to liquid NH_3 (20 °C) by setting the ammonium peak of labelled, solid $^{15}NH_4NO_3$ to 23.8 ppm (32). Magic angle spinning (MAS) rates were controlled using automated MAS controllers to within ±2 Hz. The ^{59}Co nonselective $\pi/2$ pulse lengths were determined for the setup sample (1.0 mol/L $K_3Co(CN)_6$) and were 4.5, 2.0, and 1.9 μs at 4.70, 7.05, and 11.75 T, respectively. A one-pulse or echo-pulse sequence was used for acquiring ^{59}Co NMR spectra with pulse lengths ($\tau_{p(sel)}$), that selectively excited the central transition ($\tau_{p(sel)} = \tau_{p(nonsel)}/(I + 1/2)$) (33). Nitrogen-15 NMR spectra were acquired using a cross polarization (CP) pulse sequence ($\pi/2(^1H) = 4.5$ μs) and a contact time of 8.0 ms, which was initially setup on solid $^{15}NH_4NO_3$ and then optimized for the samples. High-power proton decoupling was performed during the acquisition of all spectra using the TPPM method (34). The sample temperature was determined using a Chemagnetics temperature controller that had been calibrated using the ^{207}Pb NMR peak of solid lead nitrate (32, 35).

Typically, Gaussian line-broadening functions of 20–50 Hz and 500–3000 Hz were applied when processing the spectra of MAS and stationary samples, respectively. The calculated and experimental spectra were fit by visual inspection using the program WSOLIDS (36).

Ab initio calculations of the nitrogen magnetic shielding tensors were performed using Gaussian 98W (revision A.7) (37) employing the B3LYP method (38, 39) to determine the orientation of the tensor in the molecular frame of reference. Either the 6-311++G(d,p) basis set, or the LANL2DZ basis set with an effective core potential, was used on the cobalt (40); 6-311++G(d,p) basis sets were used on all other atoms. Calculations with both basis sets yielded the same orientation of the magnetic shielding tensor. The calculated magnetic shielding values (σ) were converted to chemical shifts relative to the reference compound, NH_3(*l*, 20 °C), by applying the formula $\delta = \sigma_{ref} - \sigma$, where $\sigma_{ref} = 244.6$ ppm (41). The atomic coordinates of the cations used were calculated from the X-ray crystal structures determined by Boldyreva et al. (15) and Grenthe and Nordin (17); chloride ions were not included in the DFT calculations.

Results and discussion

Solid-state NMR results

Nitritopentamminecobalt(III) chloride

Figure 1 shows the ^{59}Co NMR spectra for the central transition ($m_I = 1/2 \leftrightarrow -1/2$) of stationary samples of the nitrito isomer, $[(NH_3)_5Co\text{-}ONO]^{2+}$, acquired at 4.70, 7.05, and 11.75 T. The parameters used to calculate the spectra are presented in Table 1 and are defined in the table footnote. The spectra in Fig. 1 are influenced by both the ^{59}Co quadrupolar interaction and anisotropic magnetic shielding at all three fields. At 4.70 T the second-order quadrupolar broadening (i.e., the line width without the addition of anisotropic magnetic shielding to the simulation) accounts for approximately 90% of the total breadth, while at 11.75 T it accounts for approximately 33%. The spectra are all between 180 and 220 kHz broad, making uniform excitation of the powder pattern difficult and magic angle spinning impractical.

The ^{59}Co isotropic chemical shift (δ_{iso}) of the nitrito isomer in the solid state is 8650 ± 50 ppm, the span is 1650 ±

Table 1. The experimental chemical shift and EFG parameters determined by fitting the ^{15}N and ^{59}Co NMR spectra for nitrito- and nitro-pentamminecobalt(III) chloride.

		^{59}Co NMR parameters							
Isomer	Structure	δ_{iso} (ppm)	Ω (ppm)	κ	C_Q (MHz)	η	α (°)	β (°)	γ (°)
Nitrito	$[(NH_3)_5Co\text{-}ONO]^{2+}$	8650±50	1650±100	0.8±0.1	±23±1	0.20±0.05	0±5	0±5	0±2
Nitro	$[(NH_3)_5Co\text{-}NO_2]^{2+}$	7505±5	260±20	–0.20±0.05	+10.3±0.1	0.35 0.05	90±5	90±5	3±1
		^{15}N NMR parameters							
Isomer	Structure	δ_{iso} (ppm)	Ω (ppm)	κ	$^1J(^{59}Co,^{15}N)$ (Hz)	α (°)	β (°)		
Nitrito	$[(NH_3)_5Co\text{-}ONO]^{2+}$	611±1	710±6	–0.95±0.05					
Nitro	$[(NH_3)_5Co\text{-}NO_2]^{2+}$	470±1	547±6	0.5±0.1	±63±2	90±2	90±2		

Note: The chemical shift parameters are defined as follows: $\delta_{33} \le \delta_{22} \le \delta_{11}$, $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$, $\Omega = \delta_{11} - \delta_{33}$, $\kappa = 3(\delta_{22} - \delta_{iso})/\Omega$ (62). The components of the chemical shift tensor are $\delta_{ii} = (\nu_{ii} - \nu_{ref})/\nu_{ref}$ (ii = 11, 22, 33). The EFG parameters are $C_Q = eQV_{ZZ}/h$ and $\eta_Q = (V_{XX} - V_{YY})/V_{ZZ}$, where $|V_{ZZ}| \ge |V_{YY}| \ge |V_{XX}|$. The Euler angles α, β, and γ describe the rotations illustrated in Fig. 2.

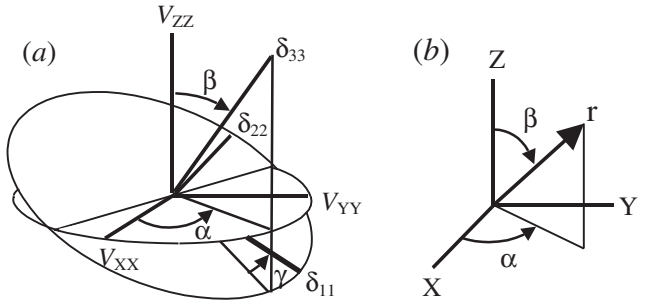

Fig. 1. Calculated and experimental ^{59}Co NMR spectra of stationary samples of $[(NH_3)_5Co\text{-}ONO]Cl_2$ acquired at 4.70, 7.05, and 11.75 T. Each experimental spectrum is the sum of 10 000 – 50 000 scans collected with a 0.1 s pulse delay. The spectrum acquired at 7.05 T has a small amount of nitro isomer present.

100 ppm, and the skew of the tensor is 0.8 ± 0.1. Since ^{59}Co has a large chemical shift range, the large span is not unexpected. In solution, the chemical shift of the nitrito isomer is 7532 ppm (26), corresponding to an 1118 ppm solution-to-solid shift. This is a large change in δ_{iso}, and highlights the sensitivity of the cobalt chemical shift to changes in the local structure (25, 42).

The cobalt electric field gradient (EFG) tensor is nearly axially symmetric ($\eta_Q = 0.20 \pm 0.05$). The fact that a deviation from axial symmetry is observed can be explained by the deviation from C_4 symmetry in the immediate coordination sphere. The quadrupolar coupling constant (C_Q) is 23 ± 1 MHz. While the error is large, it reflects the fact that the

Fig. 2. (*a*) The counter-clockwise rotations defined by the Euler angles α, β, and γ required to bring the PAS of the EFG tensor (V_{XX}, V_{YY}, V_{ZZ}) into coincidence with the PAS of the chemical shift tensor (δ_{11}, δ_{22}, δ_{33}). (*b*) Relative orientation of the ^{59}Co-^{15}N internuclear vector (r) with respect to a tensor.

^{59}Co NMR spectra may not be of the pure nitrito form. Any nitro isomer present in the sample would cause a distortion of the low frequency discontinuity, leading to some uncertainty in the analysis. The Euler angles, which describe the relative orientations of the ^{59}Co EFG and chemical shift tensors, are also obtained from the experiments and are all 0°, placing δ_{11} along V_{XX} and δ_{33} along V_{ZZ} (Fig. 2*a* shows how the angles are defined, ref. 43).

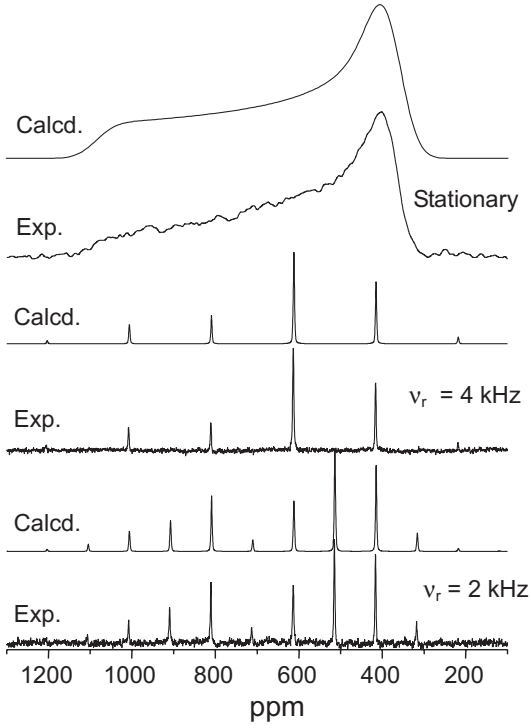

Figure 3 shows the experimental and calculated ^{15}N NMR spectra of nitritopentamminecobalt(III) chloride, with 99% ^{15}N-labelled nitrite, obtained at 4.70 T with MAS rates of 2.0 and 4.0 kHz. The observed spectra were fit with calculated spectra based on the procedure developed by Herzfeld and Berger (44) as implemented in the WSOLIDS program. The experimental and calculated spectra of a stationary sample acquired at 4.70 T are also shown in Fig. 3. Analysis of the spectra yields the experimental NMR parameters listed in Table 1. The tensor is approximately axially symmetric ($\kappa = -0.95 \pm 0.05$), has a span of 710 ± 6 ppm, and the δ_{iso} (611 ± 1 ppm) is only slightly less than that of the nitrogen in sodium nitrite (625.4 ppm) (45). The near axial symmetry is probably fortuitous given the lack of rotational symmetry at the nitrogen of this compound.

Nitropentamminecobalt(III) chloride

The ^{59}Co central transition NMR spectra of freshly synthesized nitro isomer, $[(NH_3)_5Co\text{-}NO_2]^{2+}$, collected at three fields (4.70, 7.05, and 11.75 T) are shown in Fig. 4; the parameters derived from the calculated spectra are given in Ta-

© 2006 NRC Canada

Fig. 3. Calculated and experimental ^{15}N NMR spectra of MAS and stationary samples of $[(NH_3)_5Co\text{-}ONO]Cl_2$ acquired at 4.70 T using CP. Each experimental spectrum was acquired using a pulse delay of 5.0 s and is the sum of 612 and 6144 scans for the MAS and stationary samples, respectively.

ble 1. The spectra suffered from a general broadening, which obscured some of the features, most likely because of direct and indirect spin-spin coupling to the six directly bonded ^{14}N nuclei. From the spectrum of an MAS sample, ν_r = 13 kHz, collected at 7.05 T (Fig. 4*b*), it is straightforward to determine the quadrupolar parameters because the chemical shift anisotropy is averaged by spinning at the magic angle. The values obtained are C_Q = 10.3 ± 0.1 MHz and η_Q = 0.35 ± 0.05. This corresponds to a significant decrease in the ^{59}Co quadrupolar coupling upon conversion from the nitrito isomer (C_Q = 23 ± 1 MHz). δ_{iso} also changes upon isomerization from 8650 ± 50 to 7505 ± 5 ppm.

With the C_Q, η_Q, and δ_{iso} determined from the ^{59}Co NMR spectra obtained with MAS, the spectra of the stationary samples (Figs. 4*a* and 4*c*) were analysed, and the chemical shift tensor and its orientation relative to the EFG tensor were determined. The span of the chemical shift tensor is 260 ± 20 ppm and the skew is –0.20 ± 0.05. The Euler angles are 90 ± 5°, 90 ± 5°, and 3 ± 1° for α, β, and γ, respectively, making the EFG and chemical shift tensors nearly coincident with δ_{11} parallel to V_{ZZ} and δ_{33} parallel to V_{YY}. These ^{59}Co EFG and chemical shift parameters differ from those previously reported (24): C_Q = 11.25 MHz, η_Q = 0.55, Ω = 270 ppm, κ = 0.519, and α = 7°, β = 88°, and γ = 7°. The differences can be related primarily to the different C_Q values; in the previous study, measurements of samples under MAS were not carried out.

Figure 5 shows the centre band region of the ^{15}N NMR spectrum acquired for a sample of the nitro isomer under MAS conditions at 4.70 T. The centre band, as well as the spinning side bands (not shown), are split by indirect spin-spin coupling to the ^{59}Co, $|^1J(^{59}Co, ^{15}N)|$, which is 63 ± 2 Hz. Previous solid-state $^1J(^{59}Co, ^{15}N)$ values have been reported for a series of cobaloxime complexes with either pyridine-^{15}N or aniline-^{15}N ligands; the magnitudes range from 36 to 75 Hz (46). The splitting pattern in the ^{15}N NMR spectrum is influenced by the cobalt quadrupolar coupling parameters because the ^{59}Co–^{15}N dipolar coupling can not be completely averaged by MAS (46–48). For the ^{59}Co–^{15}N pair, the peaks in the ^{15}N spectra are split into eight peaks, corresponding to the eight possible spin states of the ^{59}Co (m_I = –7/2 to +7/2). The peak intensities and splittings are dictated by $^1J(^{59}Co,^{15}N)$, the ^{59}Co–^{15}N dipolar coupling constant, R_{eff}, the ^{59}Co C_Q, η_Q, and the orientation of the ^{59}Co EFG tensor with respect to the ^{59}Co–^{15}N dipolar vector. With the magnitude of the ^{59}Co quadrupolar coupling and η_Q determined from the ^{59}Co NMR spectra and the value of R_{eff} = –402 Hz, calculated based on the Co—N distance obtained from the crystal structure (assuming ΔJ = 0), the experimental spectrum in Fig. 5 can be best fit when the sign of C_Q is positive and the Euler angles that orient the Co-N dipolar vector in the PAS of the ^{59}Co EFG are both 0°, placing V_{ZZ} along the dipolar vector (Fig. 2*b* shows how the angles are defined for a vector with respect to a tensor).

Analysis of the ^{15}N NMR spectrum of a stationary sample of the nitro isomer (Fig. 6) indicates that the span of the nitrogen chemical shift tensor is 547 ± 6 ppm and that the skew is 0.5 ± 0.1 (Table 1). This is a significant change from the nitrito isomer and is accompanied by a change in δ_{iso} from 611 ± 1 to 470 ± 1 ppm. The ^{15}N NMR isotropic chemical shift value of the nitrite ligand in the nitro isomer is significantly less than that reported for the nitrite ion in $NaNO_2$ (δ_{iso} = 625.4 ppm) (45). Also, the span of the nitro nitrogen shielding tensor in the cobalt complex is less than that of the nitrite ion in $NaNO_2$ (Ω = 951 ppm, κ = 0.37) (45).

The^{15}N NMR line shape of a stationary sample of an isolated spin pair, such as ^{15}N coupled to ^{59}Co, depends on the ^{15}N chemical shift tensor, R_{eff}, $^1J(^{59}Co,^{15}N)$, and the orientation of the dipolar vector in the principal axis system (PAS) of the ^{15}N chemical shift tensor (46, 49). The angles that relate the Co-N dipolar vector to the ^{15}N chemical shift tensor, determined from the analysis of the ^{15}N NMR spectrum in Fig. 6 are α = 90° and β = 90°; the δ_{22} component of the nitrogen chemical shift tensor is along the Co—N bond, while δ_{33} is perpendicular to the Co-NO_2 plane.

Relationship between molecular structure and the EFG and chemical shift tensors

To examine the relationship between the molecular structures and the cobalt and nitrogen NMR parameters of the two isomers, it is important to look at the three principal components of the tensors and their orientation in the molecular frame. As mentioned, the magnitude of the cobalt C_Q decreases when the nitrito isomer changes to the nitro form, from 23 to 10.3 MHz. This change indicates that the electronic distribution about the cobalt is more symmetric in the nitro isomer, where the cobalt atom is bonded to six nitrogen atoms, compared with the nitrito isomer, where the cobalt is bonded to five nitrogen atoms and one oxygen atom.

The orientation of the EFG tensors at the cobalt nuclei can

Fig. 4. Cobalt-59 NMR spectra of $[(NH_3)_5Co\text{-}NO_2]Cl_2$ acquired at (*a*) 11.75 T, (*b*) 7.05 T, and (*c*) 4.70 T. The spectrum acquired at 7.05 T is of a MAS sample (ν_{rot} = 13 kHz), while those acquired at the other two fields are ^{59}Co NMR spectra of stationary samples. The spectra are the sum of 359, 869, and 6227 scans for the three fields, respectively, with a 0.1 s pulse delay. The distortions in the baseline of the spectrum obtained with MAS are a result of not being able to spin rapidly enough to completely average the second-order quadrupolar interaction and chemical shift anisotropy.

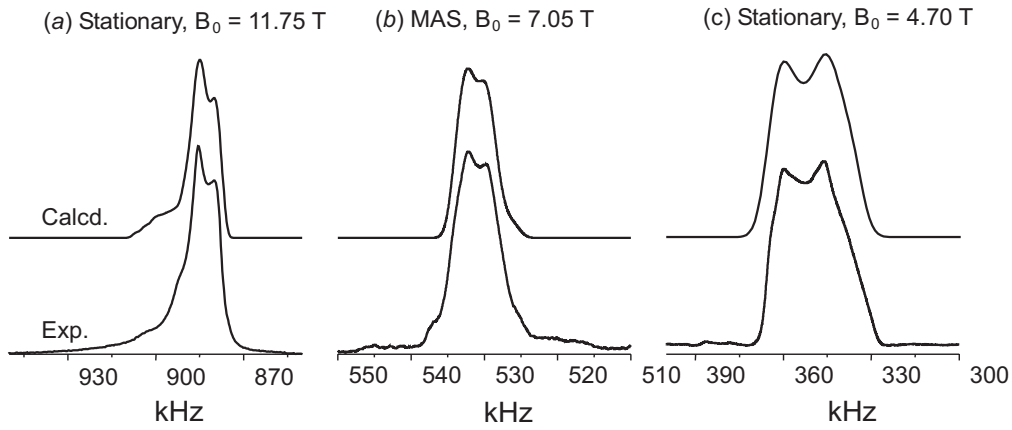

Fig. 5. Calculated and experimental ^{15}N NMR spectra of a MAS sample of $[(NH_3)_5Co\text{-}NO_2]Cl_2$ spinning at 8 kHz obtained using CP acquired at 4.70 T showing the $^1J(^{59}Co,^{15}N)$ coupling to the ^{59}Co. The intensities of the spinning side bands were added to the centre band.

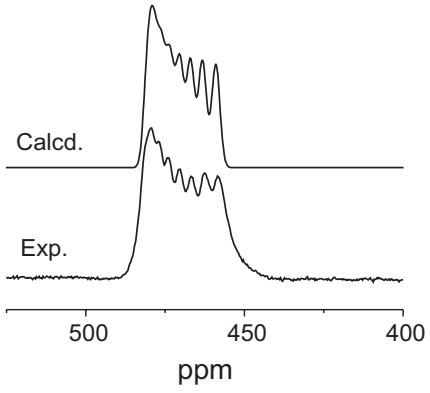

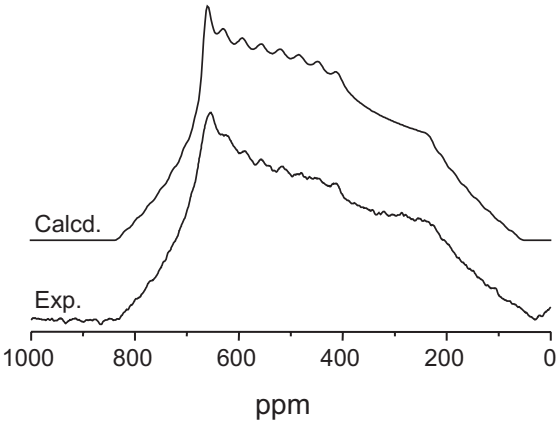

Fig. 6. Calculated and experimental ^{15}N NMR spectra of a stationary sample of $[(NH_3)_5Co\text{-}NO_2]Cl_2$ acquired using CP at 4.70 T. The spectrum is the sum of 17 692 scans using a 5.0 s pulse delay.

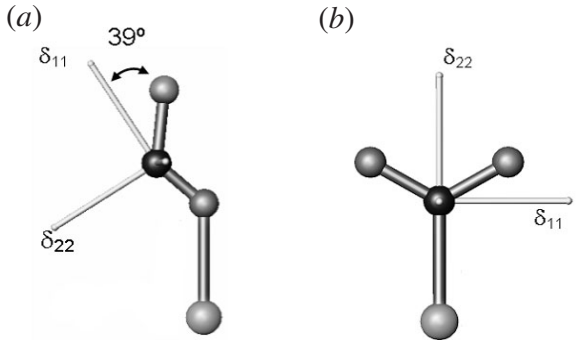
be understood based on symmetry arguments. While it was not possible to obtain the orientation of the ^{59}Co EFG in the molecular frame from the experimental data of the nitrito isomer, the pseudo-C_4 symmetry of the molecule suggests that the unique component of the EFG (V_{ZZ}) is approximately along the *Co—O*NO bond, and the two components that are nearly equal in magnitude are perpendicular to this bond. For the nitro isomer, the ^{15}N spectrum for the sample under MAS indicates that the ^{59}Co EFG tensor orientation is the same: the V_{ZZ} component is parallel to the *Co—N*O_2 bond. The lack of change in the orientation of the EFG tensor and the asymmetry parameter indicates that the isomerization simply results in a scaling of the EFG at the cobalt nucleus.

The orientations of the ^{59}Co chemical shift tensors in both isomers can be fixed in the molecular frame based on their relative orientation to the EFG tensor. The Euler angles determined from the ^{59}Co stationary line shapes of the nitrito isomer indicate that δ_{11} is along V_{XX} and δ_{33} is along V_{ZZ}. Since the tensor is close to axially symmetric, this places the "unique" component of the cobalt chemical shift tensor along the *Co—O*NO bond, as would be expected. The component of the cobalt chemical shift along the bond is 7605 ± 50 ppm, while the two components of the chemical shift tensor that lie in the $Co(NH_3)_4$ plane, perpendicular to the *Co—O*NO bond, are 9255 ± 50 and 9099 ± 50 ppm. The ^{59}Co chemical shift tensor of the nitro isomer is oriented such that the direction of least shielding is along the *Co—*NO_2 bond; δ_{11} has a value of 7643 ± 10 ppm and the two components perpendicular to the bond have values of 7487 ± 10 and 7383 ± 10 ppm. By comparing the values of the components for the two isomers, it is clear that the cobalt shielding along the Co—X bond (δ = 7605 ppm, X = ONO and δ = 7643 ppm, X = NO_2) does not change significantly when the compound isomerizes. In contrast, the shielding perpendicular to the bond increases by approximately 1750 ppm in the nitro isomer.

Correlation of cobalt chemical shifts to octahedral crystal field splitting (Δ_O) has been used for many years to explain the isotropic chemical shifts of octahedral cobalt complexes

© 2006 NRC Canada



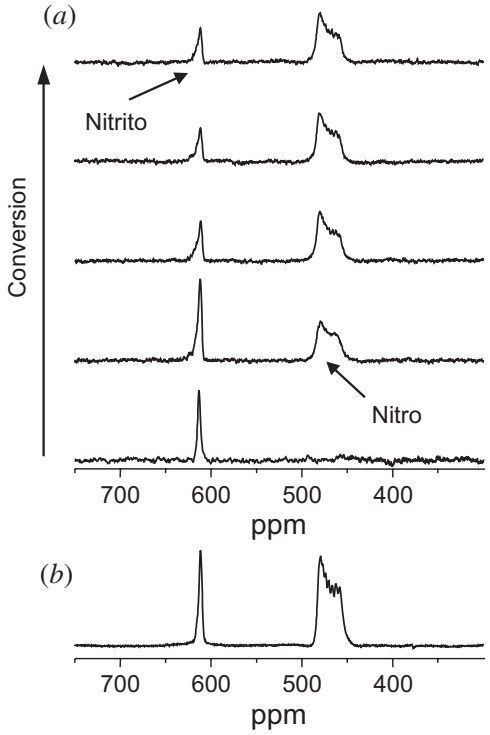
in solution and in the solid state (50–53). The paramagnetic shielding term, as described by Ramsey (54) in his original formalism, depends on the energy difference between electronic states that undergo symmetry-allowed mixing in the presence of a magnetic field and is generally deshielding. The good correlation between the cobalt chemical shifts and the excitation wavelength of the $^1A_{1g} \rightarrow {}^1T_{1g}$ electronic transition in octahedral cobalt(III) complexes was one of the early confirmations of Ramsey's formalism. In the solid state, the correlation can be used for octahedral complexes of high symmetry. Equations describing the dependence of shielding on the transition energies have been derived for numerous symmetries including D_3, C_{4v}, D_{4v}, C_{2v}, etc. (55, 56). In the present study, however, neither complex has high symmetry at the cobalt atom, which limits the application of the derived equations for determining the individual components or isotropic values of the chemical shift tensor. Despite this, an approximate correlation can be made between the overall shielding that occurs as the complex isomerizes and an increase in the Δ_O. The change in colour, from the pink nitrito isomer to the yellow nitro isomer, indicates an increase in Δ_O. The increase in Δ_O leads to a smaller paramagnetic shielding of the cobalt in the nitro isomer and results in the smaller chemical shift. This change is noticed primarily in the components of the shielding tensor perpendicular to the Co—X bond.

The orientation of the nitrogen chemical shift tensor in the nitrito isomer is unavailable from the NMR experiments. In other two-coordinate nitrogen compounds, such as sodium nitrite and bent nitrosyl compounds (45, 57), the nitrogen chemical shift tensor is oriented such that δ_{22} is approximately along the formal nitrogen lone pair and δ_{33} is perpendicular to the ONO plane. Quantum chemical calculations were performed and predict the same orientation for the nitrito isomer (Fig. 7*a*). The calculations reproduced the relative magnitudes of the δ_{11} and δ_{22} tensor components to within approximately 100 and 33 ppm, respectively, using both the 6-311++G(d,p) and LANL2DZ basis sets on the cobalt. Given that the chemical shift range of nitrogen is around 1200 ppm, the errors in δ_{11} and δ_{22} are reasonable and lend confidence to the orientations calculated for these two components. The δ_{33} component was underestimated by approximately 250 ppm, which is quite a large discrepancy. The origin of this difference between theory and experiment most likely arises from the neglect of intermolecular effects in the calculations.

The individual components of the nitrogen chemical shift tensor can be related to the electronic states that are responsible for the paramagnetic term in δ. For certain nitrosyl compounds (57), as well as in this case, mixing of the nitrogen *n* and π* electronic states is expected to be responsible for the paramagnetic shielding term associated with the δ_{11} component of the chemical shift tensor (30). It has also been reported that the orientation of the intermediate component of the nitrogen chemical shift tensor (δ_{22}) is in most cases parallel to the formal nitrogen lone pair for nitrogen atoms bonded to two other atoms such as nitrosyl compounds, oximes, and azides (58–61). The direction of greatest shielding is nearly perpendicular to the ONO plane and arises from the mixing of the in-plane σ and σ* states (57).

The orientation of the nitrogen chemical shift tensor of the nitro isomer as determined from the analysis of the ^{15}N NMR line shape of the stationary sample indicates that δ_{33} is perpendicular to the Co-NO_2 plane and δ_{22} is along the Co—N bond (Fig. 7*b*). The calculations with both the 6-311++G(d,p) and LANL2DZ basis sets on the Co yielded values for δ_{11}, δ_{22}, and δ_{33} that were in excellent agreement with the experimental values, within 11, 16, and 62 ppm of the experimental values, respectively. The process of coordination to the cobalt metal has the most profound effect on δ_{11}, which decreases by 412 ppm when the isomer changes from the nitrito to the nitro form. This is a result of the changes in the nonbonding molecular orbitals of the nitrito isomer as they coordinate to the cobalt centre to form the Co—N σ bond in the nitro isomer. The chemical shift component along the Co—N bond (δ_{22}) in the nitro isomer changes relatively little as a consequence of the coordination, increasing by 103 ppm with respect to the nitrito isomer. This is expected because the δ_{22} component does not involve mixing with the orbitals that form the Co—N σ bond. Finally, δ_{33} in the nitro isomer decreases by approximately 169 ppm with respect to the nitrito isomer.

Fig. 7. Orientation of the nitrogen CS tensor in the molecular frame of reference for: (*a*) the nitrito isomer, obtained from DFT calculations, and (*b*) the nitro isomer, obtained from DFT calculations and experiment.



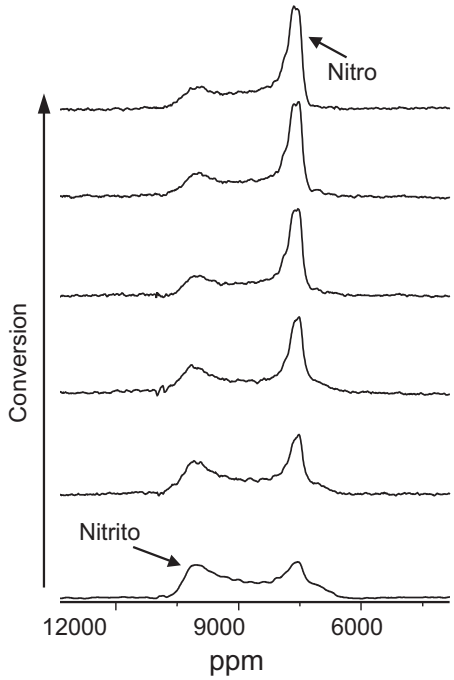
Monitoring the isomerization reaction

The isomerization from the nitrito to the nitro isomer was monitored directly using both ^{15}N and ^{59}Co solid-state NMR. The spectra acquired at 4.70 T as the reaction progressed are shown in Figs. 8 and 9 for ^{15}N and ^{59}Co, respectively. For the ^{15}N MAS spectra a heating scheme was used. The temperature was raised from room temperature (293 K) to 353 K in 5 min, where it was held for 8 min then cooled to room temperature before the spectra were acquired (Fig. 8*a*). In an attempt to drive the reaction to completion, the sample that yielded the top spectrum in Fig. 8*a* was heated at 413 K for 40 min yielding the spectrum in Fig. 8*b*; the sample was allowed to equilibrate at room temperature for 2 h prior to data collection.

The results show the benefit of using NMR to monitor the extent of the reaction. The ^{15}N peak from the nitrito isomer slowly decreases in intensity while a second peak appears at 470 ± 3 ppm, corresponding to the formation of the nitro isomer (Fig. 8*a*). It is clear that in the initial preparation there is very little of the nitro isomer present. Due to the breadth of the peak from the nitro isomer there could be as much as 10% of this form that is not detected because of the

© 2006 NRC Canada

Fig. 8. Nitrogen-15 NMR spectra of a MAS sample of the compound, acquired at 4.70 T. The spectra in (*a*) were obtained at room temperature after successive applications of the heating scheme described (see text). The sample that yielded the top spectrum in (*a*) was then heated at 413 K for an additional 40 min to drive the reaction to equilibrium and the NMR spectrum in (*b*) was acquired. Each spectrum in (*a*) is the sum of 612 scans and (*b*) is the sum of 10 050 scans, both using a 5.0 s pulse delay.



baseline noise. This illustrates one drawback to the ^{15}N NMR of this system; since the peak from the nitro isomer is much broader than that from the nitrito isomer under MAS conditions, when only small amounts of nitro are present it is difficult to get an accurate estimate of the relative amounts of each isomer. However, this is offset by the ability to measure very small quantities of nitrito isomer in a mixture.

While the use of CP generally does not result in completely quantitative peak intensities, the optimal CP parameters were almost identical for the two isomers; hence, it is assumed that the comparison of the integrated peak intensities is a good approximation of the relative amounts of the two isomers. The analysis of the intensities for the spectrum in Fig. 8*b* shows that a final nitro/nitrito equilibrium ratio of 5.0 is reached after the sample was heated at 413 K. This is in excellent agreement with a previous study that measured the equilibrium values based on the reaction rates (11). From the spectra in Fig. 8*a*, it is apparent that the reaction is close to equilibrium after the second heating step.

The ^{59}Co NMR spectra (Fig. 9) were collected on a second sample preparation without any heating to investigate the sensitivity of the experiment to the isomerization over times consistent with the room temperature rate of reaction. Every 2.75 h a spectrum was acquired over a time of

Fig. 9. The ^{59}Co NMR spectra of a stationary sample of the compound, acquired at 4.70 T, collected at room temperature without heating and with 2.75 h between each spectrum; 10 000 scans were added using a 0.1 s pulse delay.

16.7 min. The ^{59}Co NMR spectra show a decrease in the broad nitrito peak, while a new peak from the nitro isomer appears at 7505 ± 10 ppm. Since the line width of the nitro peak is much smaller than that of the nitrito isomer, the ^{59}Co NMR spectra show the opposite sensitivities to those of the ^{15}N NMR spectra. Whereas the ^{15}N NMR spectra are sensitive to small amounts of the nitrito isomer and less so to the presence of the nitro isomer, the ^{59}Co spectra are more sensitive to the presence of the nitro isomer. These two nuclei therefore offer complementary methods of analyzing the relative quantities of the two isomers.

Conclusions

The ^{59}Co and ^{15}N NMR parameters of nitritopentamminecobalt(III) chloride and nitropentamminecobalt(III) chloride have been determined in the solid state. There is a change in both the ^{59}Co quadrupolar coupling constants (23 to 10 MHz), and the spans of the chemical shift tensor (1650 to 260 ppm), for the nitrito and nitro isomers, respectively. The principal components of the ^{59}Co chemical shift tensor that are perpendicular to the Co—X (X = ONO or NO_2) bond decrease by approximately 1750 ppm upon isomerization, while the components parallel to the bond are similar in both isomers. The nitrogen chemical shift tensor also shows significant variations; δ_{iso} moves from 611 to 470 ppm and Ω decreases from 710 to 547 ppm as the ligand changes from the nitrito to nitro form. The orientations of the ^{15}N and ^{59}Co chemical shift tensors and the ^{59}Co EFG tensor in the molecular frame have been related to the molecular structure. The isomerization reaction was monitored directly using both ^{59}Co and ^{15}N NMR and the results suggest that solid-state NMR can be used to measure isomer ratios during the reac-

tion. These results highlight the value of solid-state NMR studies and the potential to use NMR to monitor reactions that occur in the solid state.

Acknowledgments

The authors wish to thank members of the solid-state NMR group at the University of Alberta, Edmonton, Alberta, as well as Dr. Klaus Eichele for helpful discussions. Dr. Guy Bernard, in particular, is thanked for his comments. REW is a Canada Research Chair in Physical Chemistry at the University of Alberta and thanks the Natural Sciences and Engineering Research Council of Canada (NSERC), Alberta Ingenuity, and the University of Alberta for research grants. KJO thanks NSERC, the Alberta Ingenuity Fund, and the University of Alberta for post-graduate scholarships.

Finally, REW thanks Arthur Carty for several fruitful scientific collaborations, and personal encouragement dating back to the late 1960s at the University of Waterloo.

Room-temperature NIR phosphorescence of new iridium (III) complexes with ligands derived from benzoquinoxaline[1]

Hsing-Yi Chen, Cheng-Han Yang, Yun Chi, Yi-Ming Cheng, Yu-Shan Yeh, Pi-Tai Chou, Hsi-Ying Hsieh, Chao-Shiuan Liu, Shie-Ming Peng, and Gene-Hsiang Lee

Abstract: A new series of new iridium (III) complexes (**1**–**5**) bearing ligands derived from benzoquinoxaline were designed and synthesized. X-ray structural analyses of **1** reveal a distorted octahedral geometry around the Ir atom in which the pyrazolate chelate is located opposite to the cis-oriented carbon donor atoms of benzoquinoxaline, while the benzoquinoxaline ligands adopt an eclipse configuration and their coordinated nitrogen atoms and carbon adopt trans- and cis-orientation, respectively. Complexes **1**–**5** exhibit moderate NIR phosphorescence with peak maxima located at around 910–930 nm. As supported by the TDDFT approach, the transition mainly involves benzoquinoxaline $^3\pi$–π^* intraligand charge transfer (ILCT) and metal (Ir) to benzoquinoxaline charge transfer (MLCT) of which the spectroscopy and dynamics of relaxation have been thoroughly investigated. The relatively weak NIR emission can be tentatively rationalized by the low energy gap of which the radiationless deactivation may be governed by nearly temperature-independent, weak-bonding motions in combination with a minor channel incorporating small torsional motions associated with phenyl ring in the benzoquinoxaline sites.

Key words: phosphorescence, NIR, iridium, benzoquinoxaline, isoquinoline, bipyridine, pyrazolate, acetylacetonate.

Résumé : On a préparé une nouvelle série de complexes de l'iridium(III) (**1**–**5**) portant des ligands dérivés de la benzoquinoxaline. L'analyse des données structurales du composé **1**, obtenues par diffraction des rayons X, révèle la présence d'une géométrie octaédrique déformée autour de l'atome d'iridium dans laquelle le chélate pyrazolate se trouve à l'opposé des atomes de carbone donneurs de la benzoquinoxaline orientés en cis, alors que les ligands benzoquinoxaline adoptent une conformation éclipsée et que leurs atomes d'azote coordonnés adoptent respectivement des orientations cis et trans. Les complexes **1**–**5** présentent de la phosphorescence modérée dans le proche infrarouge (PIR) avec un pic maximal situé autour de 910 à 930 nm. Tel que le prédit l'approche TDDFT, la transition implique principalement un transfert de charge interligand (TCIL) $^3\pi$–π^* de la benzoquinoxaline et un transfert de charge du métal (iridium) à la benzoquinoxaline (TCML) dont on a étudié à fond la spectroscopie et la dynamique de relaxation. L'émission relativement faible dans le proche infrarouge pourrait être rationalisée en fonction d'une discontinuité de faible énergie de laquelle la désactivation sans rayonnement pourrait être orientée par des mouvements de faible liaison, pratiquement indépendants de la température, en combinaison avec une voie mineure qui incorporerait de faibles mouvements de torsion du noyau phényle dans les sites benzoquinoxalines.

Mots clés : phosphorescence, PIR, iridium, benzoquinoxaline, isoquinoléine, bipyridine, pyrazolate, acétylacétonate.

Introduction

Transition metal complexes, which exhibit strong emission in fluid solution at room temperature, have been extensively investigated owing to their fundamental interest and key roles in the design of novel systems for solar energy conversion (1), telecommunication and other optical technologies (2), as well as fabrication of high efficiency phosphorescent organic light emitting devices (OLEDs) (3). So far, most of the reported luminescent metal complexes emit in the visible region, while studies of emission properties in the NIR region are relatively rare. One reason lies in that decreasing the energy gap toward NIR may trigger a much faster radiationless decay channel because of the interaction between ground and emitting states, i.e., the so-called energy gap law, giving rise to poor quantum efficiencies (4).

The first class of complexes showing notable NIR luminescence should be credited to the lanthanide complexes incorporating the Nd(III), Yb(III), and Er(III) ions (5). Sharp emission signals for lanthanide complexes are expected simply because the 4f orbitals in the lanthanide elements are buried deep within the atom and would not be seriously coupled with the ligand vibration motions, as opposed to the broad d–d transitions of the transition metals. As a second class, the Pd porphyrinate types of complexes are documented as exhibiting moderate NIR phosphorescence in the fluid state at room temperature, a property which is desirable for application as oxygen sensors for biomedical applications in vivo (6). The third class consists of the polypyridyl complexes involving the Re(I), Ru(II), and Os(II) metal ions with the d^6 electronic configuration (7). Their systematic synthesis has remained as the outstanding issue in view of applications. These complexes typically absorb appreciably in the high energy region of the spectra, accompanied by the MLCT absorptions at lower energy, as well as a certain degree of contribution from direct ^{3}MLCT absorption, a result of the heavy atom enhanced spin-orbit coupling. Accordingly, NIR phosphorescent emissions are achievable for systems with extended electronic delocalization between the metal and ligands in both ground and excited states, making them important as light harvesting sensitizers for solar cell applications.

As an extension of our contribution to the third-row metal phosphorescent materials, we have embarked on the development of Ir(III)-based metal complexes showing detectable luminescence in the NIR spectral region. The key designing feature is to utilize a diphenyl substituted benzoquinoxaline ligand that allows formation of a highly extended π conjugation. The choice of Ir as the central atom renders the advantages of linking the benzoquinoxaline ligand through facile orthometalation, affording a desirable metal–chelate bonding interaction and a presumably rigid molecular skeleton. Along this line, the emission gaps are expected to shift significantly toward the lower energy, i.e., the NIR region, without drastic reduction to the corresponding emission efficiency.

Experimental section

General experiments

The pyrazole ligands, 3-trifluoromethyl-5-(2-pyridyl)pyrazole (fppz)H and 1-(5-*tert*-butyl-2*H*-pyrazol-3-yl)isoquinoline (bpiq)H, were prepared according to the literature methods (8). Commercially available chemicals were used without further purification. All reactions were monitored by TLC with Merck silica gel plates (0.20 mm with fluorescent indicator UV_{254}). Compounds were visualized with 254 or 365 nm UV irradiation. Column chromatography was carried out using silica gel purchased from Merck (230–400 mesh). Mass spectra were obtained on a JEOL SX-102A instrument operating in electron impact (EI) or fast atom bombardment (FAB) mode. ^{1}H and ^{13}C NMR spectra were recorded on a Varian INOVA-500 instrument; chemical shifts are quoted with respect to the internal standard tetramethylsilane for ^{1}H and ^{13}C NMR data. Elemental analysis was carried out with a Heraeus CHN-O rapid elementary analyzer.

Cyclic voltammetry (CV)

CV measurements were performed using a BAS 100 B/W electrochemical analyzer. The oxidation and reduction measurements were recorded, respectively, in anhydr. CH_2Cl_2 and anhydr. THF containing 0.1 mol/L $TBAPF_6$ as the supporting electrolyte, at a scan rate of 100 mV s^{-1}. The potentials were measured against a Ag/Ag^+ (0.01 mol/L $AgNO_3$) reference electrode with ferrocene as the internal standard.

Preparation of 2,3-diphenyl benzo[*g*]quinoxaline

An anhydrous ethanol solution (30 mL) of 2,3-naphthalenediamine (1.0 g 6.33 mmol) and benzil (1.34 g, 6.33 mmol) was heated to reflux for 5 h. Then the solution was gradually cooled to room temperature. The solid deposited from solution was then filtered, washed with a few drops of ethanol, and dried in vacuum overnight to afford 1.8 g of yellow-green 2,3-diphenyl benzo[*g*]quinoxaline (5.42 mmol, 86%), denoted as (dpbq)H. The yellow-colored derivative 2,3-di-*p*-tolyl benzo[*g*]quinoxaline, (dtbq)H, was obtained from 4,4′-dimethylbenzil in a similar fashion.

Spectral data for (dpbq)H

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 8.72 (s, 2H), 8.07 (dd, 2H, J_{HH} = 6.4, 2.8 Hz), 7.56 (d, 4H, J_{HH} = 7.2 Hz), 7.52 (dd, 2H, J_{HH} = 6.4, 2.8 Hz), 7.38–7.32 (m, 6H). MS (EI) *m/z*: 332 [M^+]. Anal. calcd. for $C_{24}H_{16}N_2$: N 8.43, C 86.72, H 4.85; found: N 8.48, C 86.63, H 5.05.

Spectral data for (dtbq)H

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 8.69 (s, 2H), 8.09–8.06 (m, 2H), 7.54–7.51 (m, 2H), 7.46 (d, 4H, J_{HH} = 10 Hz), 7.15 (d, 4H, J_{HH} = 10 Hz), 2.37 (s, 6H). MS (EI) *m/z*: 360 [M^+]. Anal. calcd. for $C_{26}H_{20}N_2$: N 7.77, C 86.64, H 5.59; found: N 7.41, C 86.65, H 5.26.

Preparation of $[(dpbq)_2IrCl]_2$

The chloride-bridged complex $[(dpbq)_2IrCl]_2$ was synthesized according to the method reported by Nonoyama (9), involving treatment of $IrCl_3 \cdot 3H_2O$ (1.0 g, 2.84 mmol) with (dpbq)H (2.83 g, 8.5 mmol) in 2-methoxyethanol (30 mL) for 24 h. Then the solution was treated with water (30 mL) to induce precipitation of a dark brown solid. The solid was then filtered, washed with methanol, and dried under vacuum (1.8 g, 1.22 mmol, 71%).

© 2006 NRC Canada

Preparation of $[(dtbq)_2IrCl]_2$

On the basis of a procedure similar to that described for $[(dpbq)_2IrCl]_2$, the *p*-tolyl-substituted complex $[(dtbq)_2IrCl]_2$ was synthesized in ~75% yield.

Preparation of $[(dpbq)_2Ir(fppz)]$ (1)

A mixture of $[(dpbq)_2IrCl]_2$ (300 mg, 0.168 mmol), 3-trifluoromethyl-5-(2-pyridyl)pyrazole (fppzH, 80 mg, 0.38 mmol), and Na_2CO_3 (100 mg, 0.94 mmol) in 2-methoxyethanol (20 mL) was heated to reflux for 4 h. An excess of deionized water was added after cooling the solution to room temperature (RT). The precipitate was collected by filtration and washed with methanol (10 mL), followed by diethyl ether (10 mL). Black crystals of $[(dpbq)_2Ir(fppz)]$ (**1**) were obtained from a mixture of CH_2Cl_2 and methanol at RT (210 mg, 0.19 mmol, 58%).

Spectral data for 1

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 8.77 (s, 1H), 8.64 (d, 1H, J_{HH} = 5.6 Hz), 8.54 (s, 1H), 8.49 (s, 1H), 8.05 (s, 1H), 7.94–7.88 (m, 4H), 7.75 (d, 1H, J_{HH} = 8.0 Hz), 7.72–7.61 (m, 5H), 7.61–7.55 (m, 3H), 7.45–7.38 (m, 4H), 7.35 (t, 1H, J_{HH} = 6.0 Hz), 7.27–7.32 (m, 2H), 7.25–7.20 (m, 3H), 6.78 (d, 1H, J_{HH} = 7.6 Hz), 6.72 (t, 1H, J_{HH} = 8.0 Hz), 6.65 (t, 1H, J_{HH} = 7.6 Hz), 6.60 (t, 1H, J_{HH} = 7.2 Hz), 6.50–6.47 (m, 2H), 6.36 (d, 1H, J_{HH} = 7.2 Hz). MS (FAB, ^{193}Ir) *m/z*: 1067 [M^+]. Anal. calcd. for $C_{57}H_{35}F_3IrN_7$: N 9.19, C 64.15, H 3.31; found: N 9.09, C 64.21, H 3.62.

Preparation of $[(dpbq)_2Ir(bpiq)]$ (2)

Procedures identical to that of **1** were followed, using 200 mg of $[(dpbq)_2IrCl]_2$ (0.112 mmol), 71 mg of (bpiq)H (0.28 mmol), and 60 mg of Na_2CO_3 (0.57 mmol) in 20 mL of 2-methoxyethanol. Black crystals of $[(dpbq)_2Ir(bpiq)]$ (**2**) were obtained from a mixture of CH_2Cl_2 and hexane at RT (74 mg, 0.085 mmol, 33%).

Spectral data for 2

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 9.00 (s, 1H), 8.50–8.43 (m, 5H), 8.30 (s, 1H), 7.97 (b, 2H), 7.87 (d, 2H, J_{HH} = 8.0 Hz), 7.82 (d, 1H, J_{HH} = 8.0 Hz), 7.72 (d, 1H, J_{HH} = 8.0 Hz), 7.69–7.58 (m, 7H), 7.52 (t, 1H, J_{HH} = 7.2 Hz), 7.44–7.28 (m, 4H), 7.26–7.18 (m, 5H), 6.74–6.66 (m, 2H), 6.64–6.53 (m, 3H), 6.45 (t, 1H, J_{HH} = 7.6 Hz), 6.31 (d, 1H, J_{HH} = 8.0 Hz), 1.37 (s, 9H). MS (FAB, ^{193}Ir) *m/z*: 1105 [M^+]. Anal. calcd. for $C_{64}H_{46}F_3IrN_7$: N 8.87, C 69.54, H 4.19; found: N 8.79, C 69.48, H 4.56.

Preparation of $[(dpbq)_2Ir(bpy)]$ (3)

A mixture of $[(dpbq)_2IrCl]_2$ (200 mg, 0.11 mmol), 2,2′-bipyridine (bpy, 45 mg, 0.29 mmol), and $AgBF_4$ (100 mg, 0.51 mmol) in CH_2Cl_2 (25 mL) was stirred at RT for 3 h. The solution was filtered and the filtrate was evaporated to give the crude product. Black crystals of $[(dpbq)_2Ir(bpy)][BF_4]$ (**3**) were obtained from a mixture of CH_2Cl_2 and hexane at RT (110 mg, 0.09 mmol, 41%).

Spectral data for 3

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 8.71 (d, 2H, J_{HH} = 4.8 Hz), 8.60 (s, 2H), 8.55 (d, 2H, J_{HH} = 8.8 Hz), 8.20 (t, 2H, J_{HH} = 7.6 Hz), 7.96 (d, 2H, J_{HH} = 8.0 Hz), 7.86–7.80 (m, 8H), 7.68–7.64 (m, 8H), 7.49 (t, 2H, J_{HH} = 3.6 Hz), 7.40 (t, 2H, J_{HH} = 7.6 Hz), 7.03 (d, 2H, J_{HH} = 8.0 Hz), 6.75 (t, 2H, J_{HH} = 7.6 Hz), 6.63 (t, 2H, J_{HH} = 7.2 Hz), 6.54 (d, 2H, J_{HH} = 7.6 Hz). MS (FAB, ^{193}Ir) *m/z*: 1011 [M^+]. Anal. calcd. for $C_{58}H_{38}F_4IrN_6$: N 7.65, C 63.45, H 3.49; found: N 7.71, C 63.25, H 3.57.

Preparation of $[(dtbq)_2Ir(fppz)]$ (4)

Procedures identical with that of **1** were followed, using 200 mg of $[(dtbq)_2IrCl]_2$ (0.106 mmol), 113 mg of (fppz)H (0.53 mmol), and 100 mg of Na_2CO_3 (0.94 mmol) in 20 mL of 2-methoxyethanol. Black crystals of $[(dtpz)_2Ir(fppz)]$ (**4**) were obtained from a mixture of CH_2Cl_2 and methanol at RT (120 mg, 0.107 mmol, 50%).

Spectral data for 4

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 8.69 (s, 1H), 8.57 (d, 1H, J_{HH} = 8.0 Hz), 8.49 (s, 1H), 8.44 (s, 1H), 7.98 (s, 1H), 7.91 (d, 1H, J_{HH} = 8.0 Hz), 7.86 (d, 1H, J_{HH} = 8.0 Hz), 7.81 (d, 2H, J_{HH} = 5.2 Hz), 7.72 (d, 1H, J_{HH} = 8.0 Hz), 7.54 (t, 1H, J_{HH} = 1.2 Hz), 7.50–7.41 (m, 5H), 7.40 (t, 3H, J_{HH} = 1.2 Hz), 7.31–7.24 (m, 4H), 7.20–7.12 (m, 3H), 6.63 (s, 1H), 6.57 (d, 1H, J_{HH} = 8.0 Hz), 6.48 (d, 1H, J_{HH} = 8.0 Hz), 6.44 (s, 1H), 6.20 (s, 1H), 2.54 (s, 3H), 2.51 (s, 3H), 1.86 (s, 3H), 1.79 (s, 3H). MS (FAB, ^{193}Ir) *m/z*: 1123 [M^+]. Anal. calcd. for $C_{61}H_{43}F_3IrN_7$: N 8.73, C 65.23, H 3.86; found: N 8.64, C 64.89, H 3.81.

Preparation of $[(dtbq)_2Ir(acac)]$ (5)

A mixture of $[(dtbq)_2IrCl]_2$ (200 mg, 0.106 mmol), acetylacetone (acacH, 300 mg, 3.0 mmol), and Na_2CO_3 (100 mg, 0.94 mmol) in CH_2Cl_2 (20 mL) was stirred at RT for 24 h. After stopping the reaction, the solution was washed with water (3 × 50 mL), dried over $MgSO_4$, and concentrated to dryness. Black crystals of $[(dtbq)_2Ir(acac)]$ (**5**) were recrystallized from CH_2Cl_2 and hexane at RT (90 mg, 0.89 mmol, 42%).

Spectral data for 5

^{1}H NMR (400 MHz, $CDCl_3$, 298 K) δ: 8.84 (s, 2H), 8.65 (s, 2H), 8.03 (d, 2H, J_{HH} = 8.0 Hz), 7.94–7.89 (m, 6H), 7.49–7.42 (m, 8H), 7.06 (d, 2H, J_{HH} = 8.4 Hz), 6.41 (d, 2H, J_{HH} = 8.4 Hz), 6.32 (s, 2H), 4.63 (s, 1H), 2.52 (s, 6H), 1.79 (s, 6H), 1.61 (s, 6H). MS (FAB, ^{193}Ir) *m/z*: 1010 [M^+]. Anal. calcd. for $C_{57}H_{45}IrN_4O_2$: N 5.55, C 67.77, H 4.49; found: N 5.51, C 67.63, H 4.83.

X-ray structural analysis

Single crystal X-ray diffraction data were measured on a Bruker Smart CCD diffractometer using (Mo Kα) radiation (λ = 0.710 73 Å). The data collection was executed using the SMART program. Cell refinement and data reduction were made with the SAINT program. The structure was determined using the SHELXTL/PC program and refined using full-matrix least-squares. All non-hydrogen atoms were refined anisotropically, whereas hydrogen atoms were placed at the calculated positions and included in the final stage of refinements with fixed parameters. The crystallographic refinement parameters for complexes **1** and **3** are summarized in Table 1, and selected bond distances and angles of these complexes are listed in Tables 2 and 3, respectively.

The crystallographic data for complexes **1** and **3** (excluding structure factors) have been deposited.[5]

Spectral and dynamic measurement

Steady-state absorption and emission spectra were recorded with a Hitachi (U-3310) spectrophotometer. The NIR emission spectra were acquired by exciting the sample solution under a rectangular excitation configuration using an Ar ion laser (488 or 514 nm, Innova 90, Coherent Inc., Santa Clara, California) and the continuous wave was chopped by

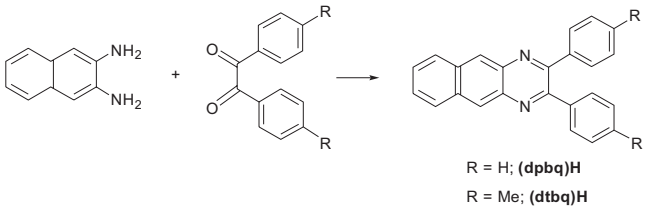
© 2006 NRC Canada

a mechanic chopper operated at 200 Hz. To minimize the reabsorption effect, the excitation beam was focused as closely as possible to the front wall of the quartz cell. The NIR emission was measured by the photomultiplier tube (Hamamatzu R5509-72, operated at –80 °C) coupled with a Lock-in amplifier (SR830, Stanford Research Systems, Sunnyvale, California) and a monochromator (SpectraPro-275, Acton Research Corporation, Acton, Massachusetts) in that the grating was blazed at 1200 nm. IR125 (Exciton Inc., Dayton, Ohio) with $\Phi \sim 0.11$ ($\lambda_{max} \sim 925$ nm) in DMSO solution was used as a standard to calculate the emission quantum yield (10). For the NIR lifetime measurement, the sample was excited by a 532 nm pulse (2nd harmonic of Nd:YAG, 6 ns). The emission trace was detected by a photomultiplier tube (Hamamatzu R5509-72) operated at –80 °C and recorded by a sampling oscilloscope (TDS 3012, Tektronix, Beaverton, Oregon). An average of 100 shots was taken in the lifetime measurement, unless specified elsewhere.

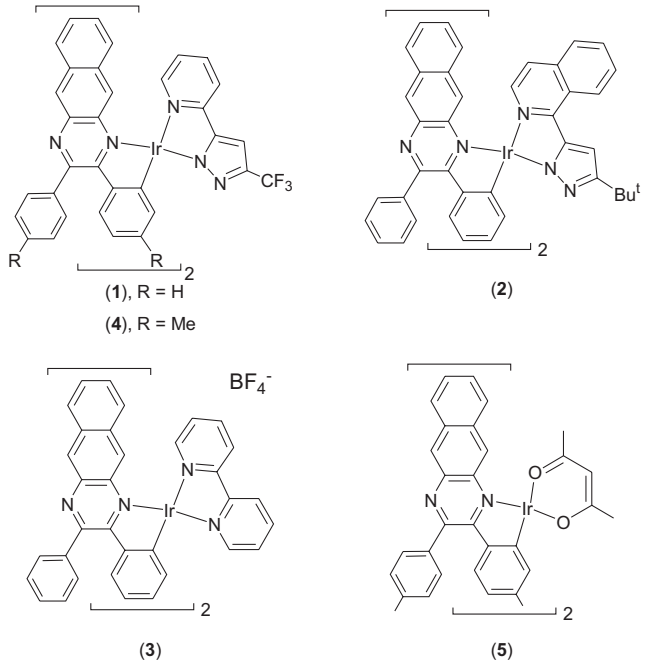
Computational methodology

Calculations on the electronic ground state of complexes **1** and **3** were carried out using B3LYP density functional theory (11, 12). A double-ζ quality basis set consisting of Hay and Wadt's effective core potentials (LANL2DZ) (13) was employed for the Ir atom and a 6-31G* (14) basis for the H, C, N, and F atoms. A relativistic effective core potential (ECP) replaced the inner core electrons of Ir(III), leaving the outer core ($5s^25p^6$) electrons and the $5d^6$ valence electrons. Time-dependent DFT (TDDFT) calculations (15) using the B3LYP functional were then performed based on the structural optimized geometries. Typically, the lowest 10 triplet and 10 singlet roots of the nonhermitian eigenvalue equations were obtained to determine the vertical excitation energies. Oscillator strengths were deduced from the dipole transition matrix elements (for singlet states only). The ground-state B3LYP and excited-state TDDFT calculations were carried out using Gaussian03 (16).



Results and discussion

Syntheses and structural characterization

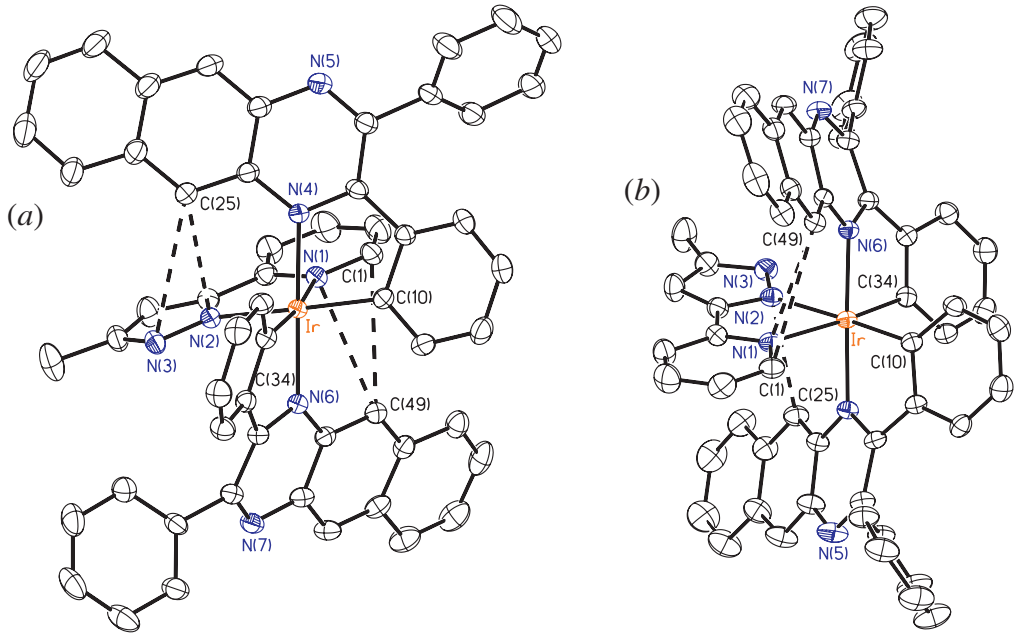


The preparation of highly conjugated ligand chromophores is necessary to achieve the NIR-emitting iridium complexes. As depicted in Scheme 1, the required ligands can be synthesized by treatment of 2,3-naphthalenediamine and dibenzil to produce 2,3-diphenyl-or di-*p*-tolyl-substituted benzo[*g*]quinoxaline in good yields. This synthetic approach follows the literature procedure utilized for the analogous diphenylquinoxaline, and is best prepared from related *o*-phenylenediamine and the corresponding α-diketone in refluxing ethanol (17).

Subsequent reactions of $IrCl_3 \cdot nH_2O$ with (dpbq)H or (dtbq)H in refluxing ethoxyethanol afforded chloride-bridged dimers $[(dpbq)_2IrCl]_2$ or $[(dtbq)_2IrCl]_2$, respectively. These dimer complexes can easily react with the pyrazole chelate ligand (fppz)H in the presence of Na_2CO_3 to afford black-colored complexes $[(dpbq)_2Ir(fppz)]$ (**1**) and $[(dtbq)_2Ir(fppz)]$ (**4**), where (fppz)H = 3-trifluoromethyl-5-(2-pyridyl)pyrazole. Similar reactions towards other bidentate chelates such as 1-(5-*tert*-butyl-2*H*-pyrazol-3-yl)isoquinoline ((bpiq)H), 2,2′-bipyridine (bpy), and acetylacetone (acacH) yielded the corresponding Ir(III) complexes, $[(dpbq)_2Ir(bpiq)]$ (**2**), $[(dpbq)_2Ir(bpy)][BF_4]$ (**3**), and $[(dtbq)_2Ir(acac)]$ (**5**), respectively (see Scheme 2).

Scheme 1.

Scheme 2.



All iridium complexes were easily soluble in organic solvents such as CH_2Cl_2, THF, and acetone, and the corresponding solutions showed negligible decomposition for a period of over 24 h, upon exposure to air. Routine characterizations were conducted using microanalysis, mass spectrometry, and ^1H NMR spectroscopy. Moreover, the fppz complex **1** was further characterized by single crystal X-ray diffraction analysis. Its ORTEP diagram is depicted in Fig. 1, while crucial bond distances and angles are listed in Table 1.

As depicted in Fig. 1, complex **1** reveals a distorted octahedral geometry around the Ir atom, consisting of two cyclometalated phenylbenzoquinoxaline fragments and one (2-pyridyl) pyrazolate ligand. The unique pyrazolate chelate is located opposite to the cis-oriented carbon donor atoms of benzoquinoxaline, while the benzoquinoxaline ligands adopt an eclipse configuration and their coordinated nitrogen atoms (N(4) and N(6)) and carbon atoms (C(10) and C(34)) adopt trans and cis orientation, respectively. This coordinative arrangement is akin to those of the parent phenyl pyridine ligands observed for the chloride-bridged dimer

Fig. 1. (*a*) ORTEP diagram of **1** with thermal ellipsoids shown at the 30% probability level; fluorine atoms of the CF_3 substituent were omitted for clarity. (*b*) Same ORTEP diagram with an emphasis on the spatial distortion of dpbq ligands.

complex $[(ppy)_2Ir(\mu\text{-}Cl)]_2$ (18), the diketonate complex $(ppy)_2Ir(acac)$ (19), and even the pyrazolate derivatives, suggesting that the incoming fppz ligand occupies the positions of the bridging chloride ligands in its starting material, $[(dpbp)_2IrCl]_2$. Moreover, the uncoordinated and cyclometalated phenyl groups show twisting angles of 40°–54°, as well as unusually large deformation angles of 23°–28° with respect to the middle benzoquinoxaline fragments. The deformation angles reveal an unfavorable steric interaction between the chelating ligands and can be gauged by the least-squares calculation using planes defined by the cyclometalated phenyl group and the middle C_6 hexagon of the benzoquinoxaline. It appears to us that the nonbonding repulsion between benzoquinoxaline and pyridyl pyrazolate ligands is the main driving force causing such a large distortion at the cyclometalated phenyl groups, as most of the interligand C···C and C···N nonbonding contacts listed in Table 2 are shorter than a limited value of ca. 3.4 Å, i.e., the sum of the van der Waals radii of the carbon atoms.

For a further comparison, the X-ray structural study on the cationic dipyridine complex **3** was also examined. Comparison of the ORTEP diagram (Fig. 2) and the metric parameters (Table 3) with those of **1** shows no significant variation on the overall molecular architecture, except for the formation of an approximate C_2 rotational axis that bisects the bipyridine ligand and passes through the central Ir metal atom. This increasing molecular symmetry is consistent with the simplification of the ^1H NMR spectral pattern observed in solution at RT (see the Experimental section).

Electrochemistry

The electrochemical properties of these Ir complexes were investigated by CV using ferrocene as the internal standard, and the respective redox data are listed in Table 4. During the anodic scan, all iridium complexes exhibited a reversible oxidation wave with potentials in the region 0.50–0.77 V. It is believed that the oxidation process mainly occurred at the metal center and, in part, with a slight contribution from the surrounding chelate ligands (20). Thus, the formal oxidation potential was strongly dependent on the electronic environment of the Ir(III) cation, i.e., a better electron donor would shift the oxidation potential to a less positive value. This hypothesis was verified by the increased π conjugation of the anionic bpiq ligand in **2**, which decreased the oxidative potential from 0.77 (in **1**) to 0.61 V (in **2**), while the attachment of the 2,2′-bipyridine ligand in **3** led to the complete suppression of the metal oxidation signal owing to its cationic nature. Moreover, replacement of the phenyl substituents with tolyl substituents of benzoquinoxaline also slightly altered the oxidation potential, as supported by the fact that the oxidation potential of **4** is cathodically shifted to 0.70 V in comparison with that of the parent complex **1**. Owing to the presence of an extra methyl substituent, this result could possibly be attributed to a slightly better σ-donor ability of the cyclometalated tolyl group.

Upon switching to the cathodic sweep in THF, two reversible reduction processes, with potentials ranging from –1.33 to –1.96 V, were detected for all complexes (**1**–**5**). We assigned these signals to a sequential reduction of the cyclometalated benzoquinoxaline fragments. For dtbq complex **4**, the first reduction peak is shifted to –1.65 V in comparison with that of the dpbq counterpart **1** (–1.54 V) because of the electron-releasing effect of the *para*-methyl substituents. Conversely, complex **3** showed the lowest reduction potentials, owing to its cationic nature, while complexes **2** and **5** gave the highest reduction potential among the whole series. The results indicate that the third ancillary ligand also significantly affects the redox properties of these Ir complexes, possibly via their enhanced donor capability as well as the extended π conjugation. Qualitatively, this observation is consistent with both the photophysical properties and theoretical predictions elaborated as follows.

Photophysical properties

Figure 3 shows the absorption and emission spectra of complexes **1**–**5** in CH_2Cl_2. As supported by CV measurements as well as the frontier orbital analyses (see the following section), it is reasonable to assign the first S_0–S_1 transition to absorption peaks around 500–600 nm ($\varepsilon \sim 5 \times 10^3$ $(mol/L)^{-1}$ cm^{-1}) to a metal to ligand (benzoquinoxaline part) charge transfer (MLCT) overlapping with the interligand phenyl to benzoquinoxaline transition. Due to a large molecular framework, the composition of higher electronic states is complicated, so that any corresponding assignments for complexes **1**–**5** may not be meaningful. Furthermore, the Ir-metal-enhanced spin-orbit coupling should result in nonnegligible absorptivity for the triplet transition, as indicated by a corresponding small absorption hump around 650–700 nm. However, absorption bands ascribed to the triplet manifolds could not be distinctly resolved mainly owing to their hiding inside the UV region of the strong singlet transitions. Detailed discussion regarding the transition in the triplet manifold will be given in the Theoretical approach section.

Figure 3 also depicts the emission spectra of complexes **1**–**5** in CH_2Cl_2. The spectral feature, quantum efficiency and relaxation dynamics (vide infra) of complexes **1**–**5** show concentration independence up to 10^{-3} mol/L, indicating a negligible aggregation effect in fluid solution. To reveal any differences in the spectral profile, the emission spectra were normalized at the peak wavelength. In comparison, for all complexes studied, only a slight variation was observed in view of the emission spectral feature and peak position. As listed in Table 5, the relaxation dynamics of **1**–**5** are O_2 concentration dependent. For example, the decay time of complex **1** was measured to be 286 ns in the degassed CH_2Cl_2, while it was decreased to 200 ns upon aeration. In the O_2 dependent study, in which the O_2 concentration was monitored by its vapor pressure filled in the vacuum line and deduced by Henry's law, a straight Stern–Volmer plot could be formulated (not shown here), and an oxygen-quenching rate constant of 1.7×10^9 $(mol/L)^{-1}$ s^{-1} was deduced, which is nearly one-nineth of the diffusion-controlled rate of 2.0×10^{10} $(mol/L)^{-1}$ s^{-1} calculated from the Stokes–Einstein equa-

Fig. 4. HOMO and LUMO of complex **1** involved in the low-lying transition.

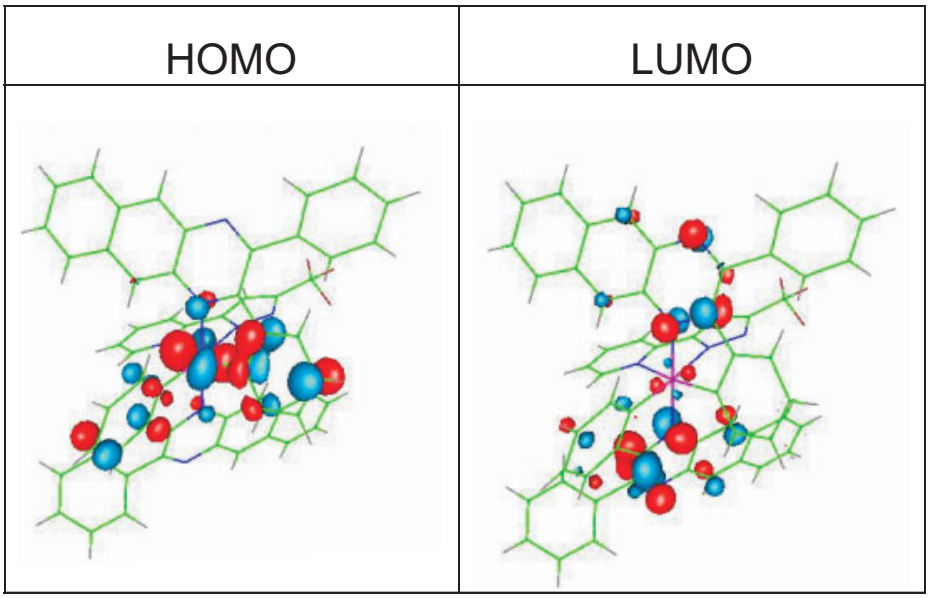

Table 6. The calculated lowest excited singlet and triplet states of complex **1**.

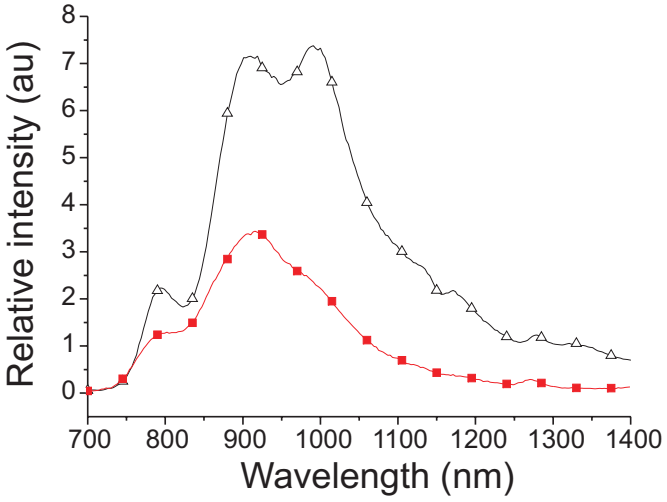
State	Assignment	λ (nm)	*E* (eV)	*f*
S_1	HOMO → LUMO (+95%)	618.3	2.01	0.0067
T_1	HOMO–1 → LUMO (+42%) HOMO → LUMO (+37%) HOMO–1 → LUMO+1 (23%) HOMO–2 → LUMO (11%)	743.6	1.67	~0

tion in CH_2Cl_2. The result is consistent with the O_2-quenching triplet state according to the theory of electron-exchange type (Dexter type) of energy transfer expressed as (21):

$$T + {}^3O_2 \xrightarrow{k_{O_2}} S_0 + {}^1O_2$$

The overall spin must be conserved upon forming a collisional complex. Accordingly, the possibility of each collision producing $^1O_2$ is statistically one-nineth. Perhaps the strongest support for the O_2 quenching is given by the observation of $^1O_2$ ($^1\Delta_g$ ($v'' = 0$) → $^1\Sigma^-_g$($v' = 0$) emission with a peak wavelength at ~1276 nm (22) for complexes **1**–**5** in aerated CH_2Cl_2 (see the arrow in Fig. 3). The results, in combination with the rather small radiative decay rate of $<10^6$ s^{-1}, lead us to unambiguously assign the dominant emission in complexes **1**–**5** to be of phosphorescence character. The spectra show a distinctly 0–0 vibronic onset of the transition, a profile that normally appears in a $^3\pi$–π^* transition of aromatic chromophores with high symmetry. The results provide a clue that the observed phosphorescence possesses, in part, a $^3\pi$–π^* character plausibly originating from a ligand-center chromophore of long conjugation such as benzoquinoxaline. Nevertheless, the involvement of other transitions such as ^{3}MLCT is also possible. Furthermore, the observation of rather small changes in spectral features, as well as peak positions, implies that frontier orbitals responsible for the T_1–S_0 transition may be mainly derived from the same origin for complexes **1**–**5**. It is thus of fundamental importance to gain more detailed insights into the transition properties of the phosphorescence based on the theoretical approaches elaborated as follows.

Theoretical approach



Theoretical confirmation of the photophysical properties of complex **1** was provided by the DFT calculations. In this study, the crystallographic data for **1** was used as the framework for the extended Hückel formalism, and the calculation

© 2006 NRC Canada

was performed via a CACAO program (see the Experimental section). Figure 4 depicts the features of the HOMO to HOMO–3 and LUMO to LUMO+3 frontier orbitals mainly involved in the lower-lying transition, while the descriptions and the energy gaps of each transition are listed in Table 6. The validity of the TDDFT approach can be readily perceived by the calculated $T_1 \rightarrow S_0$ emission peak at 745 nm, which is very close to the 0–0 onset peak (~785 nm) observed experimentally. Based on the results (see Fig. 4 and Table 6), the electron densities of the HOMO are mainly located on the Ir(III) metal center and, to a small extent, the cyclometalated phenyl ligand, while a large portion of the electron densities of HOMO–1 and HOMO–2 is attributed to the π orbitals of benzoquinoxaline overlapping with certain d_π orbitals of the Ir(III) atom. Conversely, the electron densities of LUMO and LUMO+1 are distributed mostly on the benzoquinoxaline moiety. The $S_0 \rightarrow S_1$ and $S_0 \rightarrow S_2$ transitions mainly incorporate HOMO → LUMO (+95%) and HOMO → LUMO+1 (+93%), respectively, and thus are dominated by MLCT (d_π (Ir) → π* (benzoquinoxaline)) overlapping with π–π* ILCT (mainly cyclometalated phenyl site (π) → benzoquinoxaline pyridine site (π*)) in character. As supported by the data shown in Table 6, the higher excited states in the singlet manifold, $S_0 \rightarrow S_n$ ($n > 3$), are relatively much more complicated, the results of which make a definitive frontier orbital assignment meaningless. In contrast, the lowest electronic transition in the triplet manifold, i.e., $S_0 \rightarrow T_1$, mainly incorporates the ligand center benzoquinoxaline $^3\pi$–π^* transition and ^{3}MLCT (d_π (Ir) → π* (benzoquinoxaline)).

The contribution of the $^3\pi$–π* transition is manifested by the low-temperature (77 K) approach to complex **1**. Figure 5 shows the luminescence spectrum of **1** in a 77 K CH_2Cl_2 matrix. Two salient remarks can be pointed out promptly according the spectral layout. First, in comparison to that measured at 298 K, the enhancement of the vibronic progression at 77 K is obvious, showing the notable population switching from perhaps ^{3}MLCT/$^3\pi$–π mixing character to the $^3\pi$–π dominating state under this condition. Nevertheless, one cannot eliminate the possibility that the increase in vibronic resolution upon cooling may just indicate an increase in rigidity of the molecule, making the vibrational levels more identical to one another, as well as the disappearance of hot bands. Secondly, the phosphorescence intensity at 77 K is increased ~2.5-fold with respect to that at 298 K. Similar structural phosphorescence with 2- to ~3-fold increases in intensity was observed for complexes **2**–**5** in 77 K CH_2Cl_2. Thus, temperature-dependent radiationless deactivation pathways may only play a minor role to the relaxation dynamics. Moreover, as listed in Table 5, substitution at non-benzoquinoxaline sites causes neither spectral change nor large alternation of the quantum efficiency. The latter implies that the large amplitude vibration or any torsional motion at non-benzoquinoxaline sites, which generally quenches emission in the NIR region, are not actively involved in the deactivation process. This viewpoint can be rationalized by the negligible contribution of non-benzoquinoxaline ligands to both HOMO (or HOMO–1 and HOMO–2) and LUMO (or LUMO+1). Since complexes **1**–**5** all bear aryl substituents at benzoquinoxaline sites, it is plausible that the torsional motion of phenyl (or tolyl) substituents, the relaxation dynamics of which should be temperature dependent, partly induces the radiationless transition. However, one ought to realize that because of the much smaller NIR energy gap, excitation that causes any weakening of the bond strength may result in crossing of the potential energy surface between T_1 and S_0 states and eventually trigger the rapid radiationless deactivation. In the case of complexes **1**–**5**, these nearly temperature-independent, weak vibrational motions play a key role in accounting for the dominant radiationless deactivation.

Fig. 5. The luminescence spectrum of **1** at room temperature (■) and in the 77 K CH_2Cl_2 matrix (Δ). Note that both spectra were analyzed using the same absorbance and excitation wavelength (514 nm). Thus, the intensity ratio can be directly estimated from the spectral integration.

Conclusion

In summary, we report the syntheses and characterization of a new series of NIR Ir(III) complexes (**1**–**5**). These complexes exhibit moderate NIR phosphorescence with peak wavelengths around 910–920 nm at RT. As supported by the TDDFT approach, the transition mainly involves benzoisoquinoline $^3\pi$–π^* intraligand charge transfer and metal (Ir) to benzoisoquinoline charge transfer. The relatively weak NIR emission can be tentatively rationalized by the low energy gap of which the radiationless deactivation may be governed by the large amplitude vibration and, in part, the phenyl torsional motions at the benzoquinoxaline sites. Knowing that current interest in Ir(III) types of phosphorescence emitter is focused on the Ir(III)-type OLED, to switch gears in research orientation, future applications of the titled NIR complexes and (or) relevant derivatives may be motivated by the strategy of using these complexes in the fabrication of photovoltaic devices (23). Focus on this approach is in progress.

Small bite-angle diphosphines — Synthesis and structure of low-valent complexes of bis(di-*ortho*-tolylphosphino)methane (dotpm) and related ligands[1]

Maria Filby, Antony J. Deeming, Graeme Hogarth, and Mo-yin (Venus) Lee

Abstract: The coordination chemistry of bis(di-*ortho*-tolylphosphino)methane (dotpm) has been studied. It is an excellent chelating ligand and a range of low-valent mononuclear complexes have been prepared; *cis*-[$M(CO)_4(\eta^2$-dotpm)] (M = Cr, Mo, W; **1**–**3**), [$CpRuCl(\eta^2$-dotpm)] (**4**), and *cis*-[$MX_2(\eta^2$-dotpm)] (M = Pt, X = Cl, Br, I; **5a**–**5c**, M = Pd, X = Cl; **6**). The backbone protons are relatively acidic and can be deprotonated using *n*-BuLi or $LiN(SiMe_3)_2$. Subsequent alkylation by RX (X = halogen; R = Me, Et, CH_2Ph) affords *cis*-[$M(CO)_4(\eta^2$-Rdotpm)] (M = Cr, Mo, W, R = Me; **7**–**9**, M = Mo, W, R = Et, CH_2Ph; **12**–**15**), [$CpRuCl(\eta^2$-Medotpm)] (**10**), and *cis*-[$PtI_2(\eta^2$-Medotpm)] (**11**). Thermolysis of *cis*-[$Mo(CO)_4(\eta^2$-Medotpm)] (**8**) yields what is believed to be the coordinately and electronically unsaturated complex [$Mo(CO)_3(\eta^2$-Medotpm)] (**16**), suggesting that derivatives of dotpm (cone angle 194°) are bulky enough to stabilize a 16-electron complex. Crystal structures of **2**, **3**, **7**–**9**, **13**, and **14** have been determined (diphosphine bite angles ranging from 66.58(3)° to 70.96(5)°.

Key words: diphosphine, transition metal, bulky, carbonyl, *ortho*-tolyl.

Résumé : On a étudié la chimie de coordination du bis(di-*ortho*-tolylphosphino)méthane (dotpm). C'est un excellent ligand chélatant et on en a préparé un large éventail de complexes mononucléaires de faible valence, dont les *cis*-[$M(CO)_4(\eta^2$-dotpm)] (M = Cr, Mo, W; **1**–**3**), [$CpRuCl(\eta^2$-dotpm)] (**4**) et *cis*-[$MX_2(\eta^2$-dotpm)] (M = Pt, X = Cl, Br, I; **5a**–**5c**, M = Pd, X = Cl; **6**). Les protons du squelette sont relativement acides et peuvent être déprotonés en utilisant du *n*-BuLi ou du $LiN(SiMe_3)_2$. Des alkylations subséquentes par du RX (X = halogène; R = Me, Et, CH_2Ph) conduisent à la formation des *cis*-[$M(CO)_4(\eta^2$-Rdotpm)] (M = Cr, Mo, W, R = Me; **7**–**9**, M = Mo, W, R = Et, CH_2Ph; **12**–**15**), [$CpRuCl(\eta^2$-Medotpm)] (**10**) et *cis*-[$PtI_2(\eta^2$-Medotpm)] (**11**). La thermolyse du *cis*-[$Mo(CO)_4(\eta^2$-Medotpm)] (**8**) conduit à la formation d'un composé qu'on croit être le complexe coordonné et électroniquement insaturé [$Mo(CO)_3(\eta^2$-Medotpm)] (**16**) qui suggère que les dérivés dotpm (angle du cône de 194°) sont suffisamment encombrants pour stabiliser un complexe à 16 électrons. On a déterminé les structures cristallines des composés **2**, **3**, **7**–**9**, **13** et **14** dans lesquels l'angle de morsure de la diphosphine varie de 66,58(3)° à 70,96(5)°.

Mots clés : diphosphine, métal de transition, encombrant, carbonyle, *ortho*-tolyle.

[Traduit par la Rédaction]

Introduction

Diphosphines are an important subclass of tertiary phosphines that find widespread use in homogeneous catalysis. A key to their success in this area is the ability to tune their spatial demands by variation of substituents at phosphorus and also the nature of the adjoining backbone (1). When metal bound, they can chelate to a single metal atom or act as a bridge between two, thus forming a binuclear complex. In general, the optimum ring size for a diphosphine ligand is five, and while bis(diphenylphosphino)ethane (dppe) is an excellent chelating ligand, in contrast bis(diphenylphosphino)methane (dppm) behaves predominantly as a bridging ligand since chelatation results in the formation of a highly strained four-membered ring (2, 3). Small changes to dppm can, however, lead to marked changes in its coordination chemistry. For example, substitution of both backbone hydrogens for methyl groups, as in 2,2-bis(diphenylphosphino)propane (2,2-dppp), results in a pronounced change in behavior. While dppm acts as a bridg-

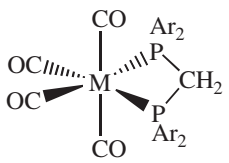
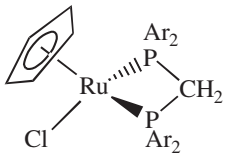
ing ligand in the binuclear complex $[Fe_2(CO)_6(\mu\text{-}CO)(\mu\text{-}dppm)]$ (4), 2,2-dppp in contrast, forms exclusively, and in high yields, the chelate complex $[Fe(CO)_3(\eta^2\text{-}2,2\text{-}dppp)]$ (5).

While the chemistry of diphosphines with two or more backbone atoms has been extensively studied, the effect of varying the steric and electronic properties of dppm and related ligands are far more limited (6–10). Such properties can be fine-tuned in a systematic way by varying both backbone and nonbackbone substituents. In general greater steric crowding at the backbone will lead to a reduction in the bite angle and thus a stronger tendency to chelate. Recently, a number of important developments have been made in this area of small bite-angle diphosphines. Hoge et al. (11) at Pfizer have shown that $[Rh(t\text{-}Bu_2PCH_2P\text{-}t\text{-}BuMe)(COD)]^+$ exhibits superior enantioselectivity with lower catalyst loading than conventional asymmetric catalysts in asymmetric hydrogenation reactions, while Pringle and co-workers (12) have shown that nickel(II) complexes of $Ar_2PN(Me)NAr_2$ (Ar = Ph, *o*-tolyl, *o*-*i*-PrC_6H_4) are very efficient ethylene polymerization catalysts, giving high-molecular-weight linear polymer. Further, while the work described herein was in progress, Pringle's group also showed that nickel complexes with small bite-angle diphosphines based on a methylene backbone were also active towards ethylene polymerization, but produced highly branched low-molecular-weight polymer (13). This report prompted us to describe our work in the area of small bite-angle diphosphines. In this contribution we describe the synthesis of a number of low-valent bis(di-*ortho*-tolylphosphino)methane (dotpm) transition metal complexes together with related backbone substituted (Rdotpm) species. We have used VT NMR spectroscopy and X-ray crystallography to probe the effect of the changes in substituents on the bite angle and conformational preference of the metal-bound ligand.



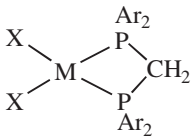
Results and discussion

Synthesis and characterization



Bis(di-*ortho*-tolylphosphino)methane (dotpm) has previously been prepared by Clark and Mulraney (14) upon lithiation of di-*ortho*-tolylphosphinous chloride. We also prepared dotpm via this route, but found the lithiation of commercially available tri-*ortho*-tolylphosphine to be preferable. This method gave higher yields and proved easier to carry out mainly because of the ease of weighing out the tertiary phosphine. In contrast, di-*ortho*-tolylphosphinous chloride as we prepared it was very sticky and proved difficult to fully purify and handle. Dotpm is a white crystalline solid that can be stored indefinitely in air at room temperature. Characterization was straightforward and as found for dppm, the equivalent methylene protons couple only weakly to the phosphorus atoms ($J_{P\text{-}H}$ = 2.5 Hz).

Addition of dotpm to $[NEt_4][Cr(CO)_5]$ or *cis*-$[M(CO)_4(pip)_2]$ (pip = piperidine) afforded the expected tetracarbonyl complexes *cis*-$[M(CO)_4(\eta^2\text{-}dotpm)]$ (M = Cr, Mo, W) (**1**–**3**) in good yields (15). Likewise, thermolysis with $[CpRuCl(PPh_3)_2]$ at 110 °C gave $[CpRuCl(\eta^2\text{-}dotpm)]$ (**4**) in 76% yield after chromatography. Heating dotpm and $[MCl_2(PhCN)_2]$ (M = Pt, Pd) in dry dichloromethane cleanly afforded *cis*-$[PtCl_2(\eta^2\text{-}dotpm)]$ (**5a**) and *cis*-$[PdCl_2(\eta^2\text{-}dotpm)]$ (**6**), while the former was rapidly converted into the analogous dibromide, *cis*-$[PtBr_2(\eta^2\text{-}dotpm)]$ (**5b**), and diiodide, *cis*-$[PtI_2(\eta^2\text{-}dotpm)]$ (**5c**) upon addition of excess NaBr and NaI, respectively.



Characterization was relatively straightforward, key spectroscopic features being the downfield shift observed in the ^{31}P NMR spectrum upon coordination and the increase in the phosphorus-proton coupling constant to the methylene protons ($J_{P\text{-}H}$ = 7.9, 10.2 Hz). In all compounds (except **4**) the methylene protons are equivalent, being observed as a triplet in the ^1H NMR spectrum as expected for approximate C_{2v} symmetry. In **4** (C_s symmetry), the methylene protons are inequivalent being observed as two multiplets at δ 4.94 and 4.54 at 308 K. The different symmetries are also apparent in the tolyl resonances, with all exhibiting a single methyl resonance, except **4** where two methyl resonances are observed at room temperature.

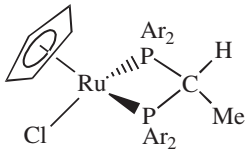
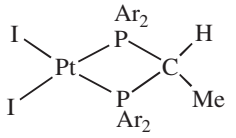
6 M = Pd, X = Cl

All proton NMR spectra show a temperature dependency with most being at the high temperature limit at room temperature or just above. We attribute these changes to the restricted rotation of the aryl groups about the phosphorus–carbon bonds. Variable-temperature ^1H NMR measurements were made for a number of examples; data for **4** being most useful. At 308 K, two sharp equal intensity singlets at δ 2.08 and 2.05 are assigned to the methyl substituents on the aryl rings. The aromatic region is complex at this temperature with some sharp and some broad signals, but each individual component (when identifiable) integrated to two protons. Clear signals at the low field (δ 8.08) and high field (δ 6.73) of this region integrated to two protons. Upon cooling, significant broadening of most of the spectrum is noted to 268 K, below which the peaks begin to sharpen again. At 228 K, three methyl signals are observed at δ 2.21, 2.13, and 1.87 in the ratio 1:1:2 — although application of a Gaussian function to the high-field signal shows that it consists of two closely spaced resonances. Further, the low-field aromatic resonance seen at δ 8.08 at 308 K splits into two equal intensity signals at δ 8.51 and 7.57 at 228 K, while the high-field aromatic signal at δ 6.73 splits into two resonances at δ 6.43 and 6.36. These changes are interpreted in terms of the freezing out of the restricted rotation of the *ortho*-tolyl



© 2006 NRC Canada

groups about the carbon–phosphorus bonds and taking the coalescence temperature for the δ 8.08 as 268 K, a rotational barrier of 50.6 (±1) kJ mol^{-1} can be estimated.



Shaw and co-workers (16–19) have previously shown that when dppm is coordinated to low-valent metal centres the backbone protons become relatively acidic. This is useful since it allows facile backbone functionalization. We have utilized this to prepare a number of backbone-substituted derivatives of dotpm (denoted Rdotpm). For example, backbone deprotonation of **1**–**3** using *n*-BuLi followed by a quench with methyliodide afforded the Medotpm complexes *cis*-[M(CO)$_4$(η^2-Medotpm)] (M = Cr, Mo, W) (**7**–**9**) in good yields, while [CpRuCl(η^2-Medotpm)] (**10**) was prepared similarly from **4** using LiN(SiMe$_3$)$_2$ as a base. Deprotonation of *cis*-[PtCl$_2$(η^2-dotpm)] (**5a**) by LiN(SiMe$_3$)$_2$ followed by addition of methyliodide afforded *cis*-[PtI$_2$(η^2-Medotpm)] (**11**), whereby the halides had also exchanged, while quenching the deprotonated molybdenum and tungsten complexes with ethyliodide or benzylbromide gave *cis*-[M(CO)$_4$(η^2-Etdotpm)] (M = Mo, W) (**12** and **13**) and *cis*-[M(CO)$_4$(η^2-Bzdotpm)] (M = Mo, W) (**14** and **15**), respectively.

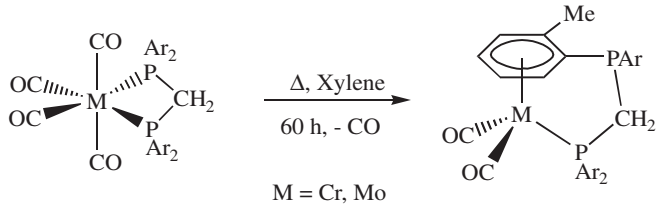
11

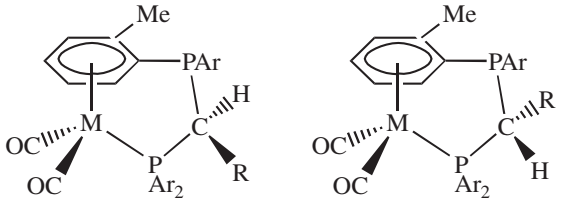
Characterization was again relatively straightforward. For all complexes, the remaining backbone proton was observed as a multiplet resonance being shifted slightly downfield of the analogous signal in dotpm complexes. The introduction of the substituent changes the symmetry of the complexes, such that those previously with C_{2v} symmetry are now in the C_s point group. This results in two sets of *ortho*-tolyl groups; those lying towards the substituent and those pointing away from it, which is reflected in the observation of two distinct methyl resonances in the ^{1}H NMR spectra. We have analyzed the spectrum of *cis*-[Mo(CO)$_4$(η^2-Bzdotpm)] (**14**) in some detail and this has allowed assignment of the benzyl and individual aryl protons (see the Experimental section). The methyl resonance at δ 2.15 is assigned to the aryl groups (Ar$_A$) that lie on the same side of the diphosphine as the benzyl group, while that at δ 1.82 is assigned to the *ortho*-tolyl groups that lie proximal to the remaining backbone proton. All ^{1}H NMR spectra are temperature dependent, which is again attributed to the restricted rotation of the aryl groups. For example, cooling **14** leads to a significant broadening of all peaks in the spectrum except those associated with the benzyl substituent. However, even at 213 K splitting into individual proton signals was not yet observed.

For [CpRuCl(η^2-Medotpm)] (**10**) two possible isomers are possible, with the methyl group pointing towards the chloride (**10a**) or the cyclopentadienyl group (**10b**). The ^{1}H NMR spectrum at room temperature is both complex and broad, making full assignment impossible. However, some regions are quite clear, most notably two sharp singlet resonances at δ 5.21 and 5.15 in an approximate 1:3 ratio being assigned to the cyclopentadienyl protons. This suggests that both isomers are formed and on the basis of adverse steric interactions we suggest that the major isomer is **10a** in which the methyl group points towards the chloride. The tolyl methyl substituents are broad at room temperature and only those assigned to the major isomer can be clearly distinguished, appearing as two broad singlets at δ 2.60 and 2.56. Upon cooling a number of changes occur. Most significantly at 278 K, the δ 2.56 signal splits into two new singlets at δ 2.70 and 2.51, while the δ 2.60 signal broadens significantly. By 258 K, four sharp singlets are seen at δ 2.96, 2.70, 2.50, and 2.22. With coalescence temperatures as 288 and 268 K, respectively, free energies of activation of 54.4 and 53.4 kJ mol^{-1} are calculated, suggesting that a single process with an activation energy of ca. 54 2 kJ mol^{-1} is responsible for the observed changes. This value is similar to that of 50.6 1 kJ mol^{-1} estimated for **4**, the higher barrier in **10a** relating to the greater steric hindrance. At 258 K, two further broad resonances can be seen at δ 2.79 and 2.34, which we assign to the methyl groups in **10b**.



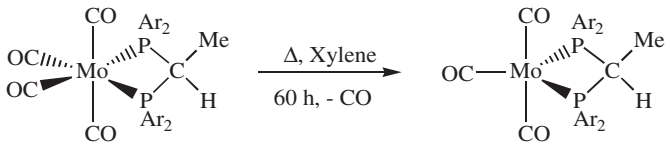
10a

10b



All attempts to replace a second backbone proton were unsuccessful. This is probably a result of the decreasing acidity of the remaining proton upon addition of an electron-releasing substituent and also the decreased kinetic acidity resulting from the increased steric crowding. We did, however, obtain some evidence for a partial deprotonation of [Cr(CO)$_4$(η^2-Medotpm)] (**7**). Addition of an excess of *n*-BuLi followed by a quench with D$_2$O lead to a ^{1}H NMR spectrum in which the backbone proton signal integrated to ca. 60% of that expected for full occupancy.

Complexes **1**–**3** have previously been prepared by Clark and Clark (15). The chromium and molybdenum complexes are reported to slowly lose CO upon heating in decalin to afford novel π-arene complexes.



© 2006 NRC Canada

We were interested in trying to make similar complexes with substituents on the backbone since such species would contain two chiral centres, and we envisaged that high diastereomeric control may occur because of the differing steric interactions between the methyl substituent on the bound arene ring and the backbone substituent.

Heating a toluene solution of **8** for 3 days resulted in no discernable change, however, heating a xylene solution of **8** for 2.5 days resulted in the formation of a dark solid, which we tentatively propose to be the 16-electon complex, $[Mo(CO)_3(\eta^2\text{-Medotpm})]$ (**16**). Characterization was based primarily on the observation of a singlet in the ^{31}P NMR spectrum, an M–CO ion in the +ve FAB mass spectrum, and two absorptions in the carbonyl region of the IR spectrum, the latter being indicative of a tricarbonyl arrangement. Similar properties have been observed for the related 16-electron complex, $[W(CO)_3(P\text{-}i\text{-}Pr_3)_2]$, which is black, poorly soluble in hexane, and shows a singlet in the ^{31}P NMR spectrum (20). In contrast to **16**, however, $[W(CO)_3(P\text{-}i\text{-}Pr_3)_2]$ and related 16-electron tricarbonyl complexes exhibit three carbonyl bands in the IR spectrum. This difference may be due to the differing symmetry at the metal centre. For example, the crystal structure of $[W(CO)_3(P\text{-}i\text{-}Pr_3)_2]$ shows that the P-W-P angle is 160.94(4)° (i.e., approximately trans), while in **16** it is likely to be nearer 66° to 67° observed in the crystallographically characterized molybdenum complexes described in the following section. Unfortunately, owing to the air-sensitive nature of **16** we have not been able to obtain a satisfactory elemental analysis.

8 **16**

While **16** is the major product of the prolonged heating of **8**, close scrutiny of the crude ^1H NMR spectrum of the reaction mixture reveals the formation of a small amount (<10%) of a second species presumed to be the expected π-bound arene complex. A series of unresolved signals between δ 5.5–4.5 is indicative of a π-bound arene, and there are a series of sharp singlets in the methyl region of the spectrum. While it is not possible to fully discern the nature of this species, there appears to be eight resonances between δ 5.5–4.5 falling into two sets in an approximate 2:1 ratio, suggesting that both diastereoisomers are formed.

Structural studies

To gain more insight into the precise structural features of dotpm and Rdotpm ligands we have carried out crystallographic studies on isostructural *cis*-$[M(CO)_4(\eta^2\text{-dotpm})]$ (M = Mo, W) (**2**, **3**), isostructural *cis*-$[M(CO)_4(\eta^2\text{-Medotpm})]$ (M = Cr, Mo, W) (**7**–**9**), *cis*-$[W(CO)_4(\eta^2\text{-Etdotpm})]$ (**13**), and *cis*-$[Mo(CO)_4(\eta^2\text{-Bzdotpm})]$ (**14**). The results of these are summarized in Figs. 1–4 and Tables 1 and 2. In all, the diphosphine subtends a small bite angle, ranging between 66.58(3)° and 70.96(5)°, with molybdenum and tungsten complexes being at the bottom end, and chromium and ruthenium compounds at the top end of the range. The best comparison of dppm and dotpm complexes is that between **2** and *cis*-$[Mo(CO)_4(\eta^2\text{-dppm})]$ (21); bite angles of 67.20(3)° and 67.3(1)°, respectively, being essentially the same, as are most of the other structural parameters except the P-C-P angle, which at 99.9(2)° in **2** is significantly greater than that of 95.6(4)° in *cis*-$[Mo(CO)_4(\eta^2\text{-dppm})]$. This results from a slight elongation (0.037 avg.) of the molybdenum–phosphorus bonds in **2** vs. those in the dppm complex, probably resulting from the greater steric demands of the *ortho*-tolyl vs. phenyl substituents. Introduction of a methyl or ethyl substituent on the backbone leads to a slight increase in the bite angle and a more significant reduction in the P-C-P an-

gle of ca. 2°, while introduction of the bulky benzyl group leads to the smallest bite angle of 66.58(3)° observed in **14**.

In all the structures, the two *ortho*-tolyl groups on each phosphorus atom adopt a staggered-type arrangement, whereby the methyl groups are orientated in opposite directions, presumably to minimize adverse steric interactions. Further, for complexes carrying a backbone substituent, as expected, the *ortho*-tolyl groups lying on the same side as the substituent point away from it and thus the presence of the substituent dictates the orientational preference of the diphosphine ligand. The benzyl substituent in *cis*-[Mo(CO)$_4$-(η^2-Bzdotpm)] (**14**) is orientated such that there is a relatively close contact with one on the tolyl ligands, indicative of a π-stacking-type interaction. The structural arrangement adopted renders all the *ortho*-tolyl groups inequivalent. The appearance of two sets of aryl resonances at room temperature in solution shows that rotation of the benzyl group must be facile at this temperature and it may well be associated with a geared rotation of the *ortho*-tolyl groups.

© 2006 NRC Canada

In conclusion, this work shows that dotpm is an excellent chelating ligand. While similar in some respects to dppm when acting in this capacity, the enhanced steric bulk leading to restricted rotation about the carbon–phosphorus bonds potentially offers a more clearly defined reaction pocket at the metal centre. This can also be easily tuned upon modification of a backbone substituent leading to the facile synthesis of a wide range of derivatives with different spatial properties. In future work we aim to concentrate on the catalytic activity of Rdotpm and related ligands with other ortho substituents, particular focus being placed on group 8 and 10 complexes.

Experimental

All reactions were carried out under a nitrogen atmosphere in dried degassed solvents unless otherwise stated. *ortho*-Bromotoluene and P(*o*-tolyl)$_3$ were purchased from Aldrich and used as supplied, and (*o*-tolyl)$_2$PCl was prepared according to standard procedures (14). NMR spectra were run on Bruker AC300, AMX400, or Avance500 spectrometers and referenced internally to the residual solvent peak (^{1}H and ^{13}C) or externally to P(OMe)$_3$ (^{31}P). Infrared spectra were run on Nicolet 205 or Shimadzu 8700 FT-IR spectrometers. Solid-state spectra were recorded as KBr discs and solution spectra using a cell fitted with calcium fluoride plates, subtraction of the solvent absorptions being achieved by computation. The fast atom bombardment and electron impact mass spectra were recorded on a VG ZAB-SE high-resolution mass spectrometer in the Chemistry Department of University College London, and elemental analyses were performed in house. Chromatography was carried out on deactivated alumina (6% *w*/*w* distilled water) or silica wet packed with light petroleum unless otherwise stated. The solution to be separated was added to the support (3–5 g) and the solvent removed under reduced pressure. The resulting solids were then deposited on top of the prepared column and separation effected by elution with progressively more polar solvents.

Preparation of bis(di-*ortho*-tolylphosphino)methane (dotpm)

(*o*-Tolyl)$_2$PCl (13.17 g, 0.053 mol) was dissolved in dry THF (100 cm^3). Lithium metal (2.10 g, 0.265 mol) hammered and cut into strips was slowly added to the pale yellow solution. The mixture gradually turned blood red and was left to stir at room temperature for 20 h. After cooling to 0 °C, dry dichloromethane (1.7 cm^3, 0.027 mol) was slowly added, the solution turning brown. After 1 h the solution was warmed to room temperature and then refluxed for a further 1 h. After removal of volatiles, the yellow-brown solid produced was redissolved in dichloromethane and washed thoroughly with distilled water. The organic layer was dried over $MgSO_4$ and removal of volatiles under reduced pressure gave a cream solid (3.02 g, 26%). Recrystallization from dichloromethane and methanol afforded dotpm as white needles.

Alternatively, dotpm was also prepared by lithiation of P(*o*-tolyl)$_3$. P(*o*-tolyl)$_3$ (6.0 g, 0.0197 mol) was dissolved in dry THF (100 cm^3). Lithium metal (0.3 g) hammered and cut into strips was slowly added and the mixture was stirred for 20 h. Finely ground NH_4Br (1.96 g, 0.02 mol) was added in small portions to the blood red solution causing the mixture to autoreflux. After 2 h, dry dichloromethane (3 cm^3) was added dropwise and the color turned to pale straw. Approximately 30 cm^3 of methanol was added to remove any remaining lithium. After removal of volatiles under reduced pressure, dissolution of the residue in dichloromethane gave a colorless solution that was washed with distilled water several times and dried over $MgSO_4$. Removal of volatiles under reduced pressure gave dotpm (2.80 g, 65%). ^{1}H NMR ($CDCl_3$) δ: 7.36–7.10 (m, 16H, Ar), 2.60 (t, 2H, *J* = 2.5 Hz, CH_2), 2.30 (s, 12H, Me). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: –60.5 (s). Mass spectrum (EI) *m*/*z*: 440 [M$^+$], 425 [M$^+$ – CH_3], 349 [M$^+$ – *o*-tolyl). Anal. calcd. for $C_{29}H_{30}P_2 \cdot 0.5H_2O$: C 77.51, H 6.90, P 13.81; found: C 77.23, H 6.88, P 13.97.

Preparation of *cis*-[Cr(CO)$_4$(η^2-dotpm)] (1)

[$Cr(CO)_5Cl$][NEt_4] (0.59 g, 1.66 mmol) and dotpm (0.37 g, 0.83 mmol) were dissolved in dry dichloromethane (25 cm^3). The pale green solution was refluxed for 5 h and then filtered. The filtrate was washed thoroughly with distilled water and the dichloromethane extract was dried over $MgSO_4$. Removal of volatiles under reduced pressure yielded **1** as a yellow solid (0.37 g, 73%). IR ν(CO) (CH_2Cl_2, cm^{-1}): 2006 (s), 1896 (s), 1867 (s). ^{1}H NMR ($CDCl_3$) δ: 7.69 (dd, 4H, *J* = 12.4, 8.0 Hz, Ar), 7.30 (t, 4H, *J* = 7.4 Hz, Ar), 7.16 (t, 4H, *J* = 7.5 Hz, Ar), 7.11 (dd, 4H, *J* = 7.5, 1.0 Hz, Ar), 4.38 (t, 2H, *J* = 8.5 Hz, CH_2), 2.00 (s, 12H, Me). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 9.7 (s). Mass spectrum (FAB) *m*/*z*: 604 [M$^+$], 520 [M$^+$ – 3CO], 492 [M$^+$ – 4CO]. Anal. calcd. for $CrP_2O_4C_{33}H_{30}$: C 65.56, H 4.97, P 10.26; found: C 65.03, H 5.06, P 9.79.

Preparation of *cis*-[Mo(CO)$_4$(η^2-dotpm)] (2)

cis-[$Mo(CO)_4(pip)_2$] (0.10 g, 0.26 mmol) and dotpm (0.11 g, 0.26 mmol) were dissolved in dichloromethane (15 cm^3) and the orange solution was refluxed for 4 h. After cooling to room temperature, methanol (15 cm^3) was added and the solution was reduced under vacuum until a precipitate formed. The mixture was filtered and the residue washed with methanol and air-dried. The tan solid was recrystallized from dichloromethane and methanol to yield colorless crystals of **2** (0.10 g, 62%). IR ν(CO) (CH_2Cl_2, cm^{-1}): 2019 (s), 1909 (s), 1872 (s). ^{1}H NMR ($CDCl_3$) δ: 7.63 (dd, 4H, *J* = 13.2, 7.2 Hz, Ar), 7.29 (t, 4H, *J* = 7.5 Hz, Ar), 7.14 (t, 4H, *J* = 7.6 Hz, Ar), 7.11 (d, 4H, *J* = 7.6 Hz, Ar) 4.43 (t, 2H, *J* = 7.9 Hz, CH_2), 2.04 (s, 12H, Me). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: –14.2 (s). Mass spectrum (FAB) *m*/*z*: 650 [M$^+$], 623 [M$^+$ – CO], 594 [M$^+$ – 2CO], 538 [M$^+$ – 4CO]. Anal. calcd. for $MoP_2O_4C_{33}H_{30}$: C 61.11, H 4.63, P 9.57; found: C 60.41, H 4.77, P 9.15.

Preparation of *cis*-[W(CO)$_4$(η^2-dotpm)] (3)

cis-[$W(CO)_4(pip)_2$] (0.23 g, 0.49 mmol) and dotpm (0.22 g, 0.49 mmol) were dissolved in dichloromethane (15 cm^3) and the solution was refluxed for 2.5 h. The resulting yellow solution was pumped to dryness to yield a yellow solid, which was recrystallized from dichloromethane and methanol. Yellow crystals of **3** (0.24 g, 66%) were formed. IR ν(CO) (CH_2Cl_2, cm^{-1}): 2015 (s), 1900 (s), 1866 (s). ^{1}H NMR ($CDCl_3$) δ: 7.62 (dd, 4H, *J* = 13.9, 7.3 Hz, Ar), 7.30 (t,

4H, J = 7.4 Hz, Ar), 7.17 (t, 4H, J = 7.5 Hz, Ar), 7.12 (d, 4H, J = 7.2 Hz, Ar), 4.91 (t, 2H, J = 8.4 Hz, CH_2), 2.03 (s, 12H, Me). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: –37.7 (s, J_{WP} = 197 Hz). Mass spectrum (FAB) *m/z*: 736 [M^+], 707 [M^+ – CO], 680 [M^+ – 2CO], 622 [M^+ – 4CO]. Anal. calcd. for $WP_2O_4C_{33}H_{30}\cdot 0.5CH_2Cl_2$: C 51.64, H 3.98, P 7.96; found: C 52.45, H 3.98, P 7.69.

Preparation of [CpRuCl(η²-dotpm)] (4)

[$CpRuCl(PPh_3)_2$] (0.37 g, 0.51 mmol) and dotpm (0.224 g, 0.51 mmol) were refluxed in toluene (100 cm^3) for 24 h. Chromatography on silica eluting with diethyl ether – light petroleum (2:1) gave a yellow band of [$CpRuCl(PPh_3)_2$], which was discarded. Eluting with diethyl ether – light petroleum (1:1) gave an orange band, which yielded **4** as an orange solid (0.14 g, 76%). IR (KBr, cm^{-1}): 1448 (m), 1132 (m), 1091 (m), 1089 (m), 1066 (m), 804 (m), 748 (s), 725 (s), 709 (m), 461 (s). ^1H NMR (CD_2Cl_2, 308 K) δ: 8.08 (br, 2H, Ar), 7.42–7.15 (m, 8H, Ar), 7.08 (d, 2H, J = 7.4 Hz, Ar), 7.04 (br d, 2H, Ar), 6.73 (t, 2H, J = 7.4 Hz, Ar), 4.94 (dt, 1H, J = 13.8, 8.1 Hz, CH_2), 4.75 (s, 5H, Cp), 4.54 (q, 1H, J = 10.9 Hz, CH_2), 2.08 (s, 6H, Me), 2.05 (s, 6H, Me); (228 K) δ: 8.51 (br, 1H, Ar), 7.58 (br, 1H, Ar), 7.40–6.95 (m, 11H, Ar), 6.86 (t, 1H, J = 7.1 Hz, Ar), 6.43 (br, 1H, Ar), 6.36 (br, 1H, Ar), 4.76 (br, 1H, CH_2), 4.75 (s, 5H, Cp), 4.46 (br, 1H, CH_2), 2.24 (s, 3H, Me), 2.13 (s, 3H, Me), 1.86 (s, 6H, CH_3). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: –4.7 (s). Mass spectrum (FAB) *m/z*: 642 [M^+], 607 [M^+ – Cl], 576 [M^+ – Cp]. Anal. calcd. for $C_{34}H_{35}P_2ClRu\cdot CHCl_3\cdot 2H_2O$: C 51.53, H 5.15; found: C 51.63, H 4.34.

Preparation of *cis*-[$PtCl_2$(η²-dotpm)] (5a)

cis-[$Pt(PhCN)_2Cl_2$] (0.21 g, 0.44 mmol) and dotpm (0.21 g, 0.44 mmol) were dissolved in dry dichloromethane (15 cm^3) and the solution was refluxed for 10 h. A white precipitate was formed and after cooling, hexane (ca. 15 cm^3) was added to precipitate more solids. The mixture was filtered and the residue was washed with hexane and air-dried. A white powder was obtained, which was recrystallized from dichloromethane and methanol to yield **5a** as colorless plates (0.28 g, 92%). IR ν(CH) (KBr, cm^{-1}): 3056 (w), 3011 (w), 2960 (w), 2919 (w), 2904 (w), 2856 (w). ^1H NMR ($CDCl_3$) δ: 7.96 (dd, 4H, J = 8.1, 7.9 Hz, Ar), 7.43 (t, 4H, J = 7.3 Hz, Ar), 7.23–7.20 (m, 8H, Ar), 4.59 (t, 2H, J = 10.0 Hz, CH_2), 2.26 (s, 12H, Me). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: –77.9 (s, J_{PtP} = 3097 Hz). Mass spectrum (FAB) *m/z*: 1484 [$2M^+$+ 2Cl], 1409 [$2M^+$], 742 [M^+ + Cl], 671 [M^+ – Cl], 634 [M^+ – 2Cl]. Anal. calcd. for $PtP_2Cl_2C_{29}H_{30}$: C 49.29, H 4.25, Cl 10.06, P 8.78; found: C 48.70, H 4.08, Cl 10.75, P 8.48.

Preparation of *cis*-[$PtBr_2$(η²-dotpm)] (5b)

5a (0.05 g, 0.08 mmol) and LiBr (0.01 g, 0.15 mmol) were dissolved in dry THF (15 cm^3) and the mixture was stirred at room temperature for 20 h. The solvent was distilled off and the residue was redissolved in dichloromethane. This was washed thoroughly with distilled water and the dichloromethane extract was dried over $MgSO_4$. Removal of volatiles under reduced pressure gave **5b** as a yellow powder (0.05 g, 78%). ^1H NMR ($CDCl_3$) δ: 7.98 (q, 4H, J = 7.7 Hz, Ar), 7.44 (t, 4H, J = 7.3 Hz, Ar), 7.23–7.21 (m, 8H, Ar), 4.65 (t, 2H, J = 10.2 Hz, CH_2), 2.27 (s, 12H, Me). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: –80.3 (s, J_{PtP} = 3056 Hz). Mass spectrum (FAB) *m/z*: 715 [M^+ – Br], 634 [M^+ – 2Br]. Anal. calcd. for $PtBr_2P_2C_{29}H_{30}\cdot CH_2Cl_2$: C 40.90, H 3.52, Br 18.18, P 7.04; found: C 40.92, H 4.44, Br 16.74, P 7.30.

Preparation of *cis*-[PtI_2(η²-dotpm)] (5c)

5a (0.05 g, 0.08 mmol) and LiI (0.02 g, 0.15 mmol) were dissolved in THF (15 cm^3) and the yellow solution was stirred at room temperature for 20 h. Removal of volatiles under reduced pressure yielded a yellow solid. This was redissolved in dichloromethane and was washed three times with water. The yellow solution was pumped to dryness under reduced pressure to give **5c** as a yellow powder (0.04 g, 62%). ^1H NMR ($CDCl_3$) δ: 7.97 (q, 4H, J = 7.7 Hz, Ar), 7.43 (t, 4H, J = 7.6 Hz, Ar), 7.23 (t, 8H, J = 7.7 Hz, Ar), 4.78 (t, 2H, J = 10.3 Hz, CH_2), 2.28 (s, 12H, Me). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: –87.7 (s, J_{PtP} = 2876 Hz). Mass spectrum (FAB) *m/z*: 889 [M^+], 762 [M^+ – I]. Anal. calcd. for $PtP_2I_2C_{29}H_{30}$: C 39.15, H 3.37, I 28.57, P 6.97; found: C 39.08, H 3.69, I 28.63, P 7.18.

Preparation of *cis*-[$PdCl_2$(η²-dotpm)] (6)

cis-[$Pd(PhCN)_2Cl_2$] (0.16 g, 0.42 mmol) and dotpm (0.19 g, 0.42 mmol) were dissolved in dry dichloromethane (15 cm^3) and this was refluxed for 20 h. Removal of volatiles under reduced pressure gave **6** as a brown powder (0.19 g, 75%), which was washed with methanol and was air-dried. IR ν(CH) (KBr, cm^{-1}): 3055 (w), 2963 (w), 2920 (w). ^1H NMR ($CDCl_3$) δ: 7.97 (dd, 4H, J = 8.2 Hz, 7.7, Ar), 7.45 (t, 4H, J = 7.6 Hz, Ar), 7.23–7.19 (m, 8H, Ar), 4.33 (t, 2H, J = 9.9 Hz, CH_2), 2.32 (s, 12H, Me). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: –69.0 (s). Mass spectrum (FAB) *m/z*: 583 [M^+ – Cl], 545 [M^+ – 2Cl]. Anal. calcd. for $PdP_2Cl_2C_{29}H_{30}\cdot 0.2$ PhCN: C 54.83, H 4.85, N 0.44, Cl 11.11, P 9.70; found: C 54.49, H 4.54, N 0.44, Cl 12.80, P 9.70.

Preparation of *cis*-[$Cr(CO)_4$(η²-Medotpm)] (7)

1 (0.33 g, 0.55 mmol) was dissolved in dry THF (25 cm^3). *n*-BuLi (0.7 cm^3, 1.09 mmol) was added and the yellow solution immediately darkened. After stirring at room temperature for 1 h, MeI (0.07 cm^3, 1.09 mmol) was added and the color lightened. The reaction mixture was stirred for 20 h and pumped to dryness under reduced pressure. The solid was redissolved in dichloromethane and was washed thoroughly with distilled water. The dichloromethane extract was dried over $MgSO_4$ and filtered. Removal of volatiles under reduced pressure yielded a yellow powder that was recrystallized from dichloromethane and methanol to give **7** as yellow crystals (0.33 g, 99%). IR ν(CO) (CH_2Cl_2, cm^{-1}): 2006 (s), 1913 (s), 1893 (s), 1865 (s). ^1H NMR ($CDCl_3$) δ: 8.27–8.26 (m, 4H, Ar), 7.38–7.33 (m, 8H, Ar), 7.05 (m, 4H, Ar), 5.39 (sextet, 1H, J = 7.2 Hz, CH), 2.09 (s, 6H, Me), 2.00 (s, 6H, Me), 1.06 (dt, 3H, J = 15.9, 7.3 Hz, Me). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: 27.8 (s). Mass spectrum (FAB) *m/z*: 618 [M^+], 562 [M^+ – 2CO], 534 [M^+ – 3CO], 506 [M^+ – 4CO]. Anal. calcd. for $CrP_2O_4C_{34}H_{32}\cdot 0.75CH_2Cl_2$: C 61.17, H 4.91, P 9.09; found: C 60.64, H 4.96, P 9.21.

Preparation of *cis*-[$Mo(CO)_4$(η²-Medotpm)] (8)

2 (0.30 g, 0.46 mmol) was dissolved in dry THF (15 cm^3). *n*-BuLi (0.37 cm^3, 0.60 mmol) was added to the yellow solu-

© 2006 NRC Canada

tion, which immediately turned darker and was stirred at room temperature for 1 h. MeI (0.04 cm^3, 0.60 mmol) diluted in dry THF (1 cm^3) was then added and the reaction mixture was stirred for 20 h, the color gradually lightening. Removal of volatiles under reduced pressure gave a yellow solid. This was redissolved in dichloromethane, washed thoroughly with distilled water, and dried over $MgSO_4$. Removal of volatiles under reduced pressure gave a yellow solid that was recrystallized from dichloromethane and methanol to give **8** as yellow crystals (0.18 g, 59%). IR ν(CO) (CH_2Cl_2, cm^{-1}): 2020 (s), 1921 (s), 1905 (s), 1869 (s). ^{1}H NMR ($CDCl_3$) δ: 8.14–8.10 (m, 4H, Ar), 7.33–7.22 (m, 8H, Ar), 7.08–7.06 (m, 4H, Ar), 5.38 (sextet, 1H, *J* = 7.7 Hz, CH), 2.14 (s, 6H, Me), 2.07 (s, 6H, Me), 1.08 (dt, 3H, *J* = 14.8, 7.7 Hz, Me). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 4.9 (s). Preparation of *cis*-[W(CO)$_4$(η^2-Medotpm)] (9)

3 (0.11 g, 0.15 mmol) was dissolved in THF (10 cm^3). *n*-BuLi (0.08 cm^3, 0.19 mmol) was added to the yellow solution, which immediately darkened. After 1 h, MeI (0.012 cm^3, 0.19 mmol) was added and the reaction stirred at room temperature for 20 h. After removal of volatiles under reduced pressure, redissolving in dichloromethane gave a yellow solution that was washed three times with water and dried over $MgSO_4$. Removal of volatiles under reduced pressure gave **9** as a yellow powder, which was recrystallized from dichloromethane and methanol to give yellow crystals (0.07 g, 62%). IR ν(CO) (CH_2Cl_2, cm^{-1}): 2016 (s), 1895 (s), 1863 (s). ^{1}H NMR ($CDCl_3$) δ: 8.17–8.11 (m, 4H, Ar), 7.37 (t, 2H, *J* = 7.3 Hz, Ar), 7.32 (t, 2H, *J* = 8.5 Hz, Ar), 7.28 (t, 2H, *J* = 8.3 Hz, Ar), 7.23 (t, 2H, *J* = 7.3 Hz, Ar), 7.06 (d, 2H, *J* = 8.0 Hz, Ar), 7.03 (d, 2H, *J* = 7.0 Hz, Ar), 6.01 (sextet, 1H, *J* = 7.3 Hz, CH), 2.11 (s, 6H, Me), 2.04 (s, 6H, Me), 1.02 (dt, 3H, *J* = 15.5, 7.7 Hz, Me). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: –18.0 (s, J_{WP} = 199 Hz). Mass spectrum (FAB) *m/z*: 750 [M^+], 722 [M^+ – CO], 694 [M^+ – 2CO], 666 [M^+ – 3CO], 636 [M^+ – 4CO – 2H]. Anal. calcd. for $WP_2O_4C_{34}H_{32}\cdot CH_2Cl_2$: C 50.30, H 4.07, P 7.43; found: C 50.23, H 4.01, P 7.46.

Preparation of [CpRuCl(η^2-Medotpm)] (10)

4 (0.10 g, 0.16 mmol) was dissolved in dry THF (5 cm^3) and ca. 0.16 mmol of $LiN(SiMe_3)_2$ was added dropwise. The solution was stirred for 20 h and 0.01 cm^3 of methyl iodide was added dropwise. After a further 2 h of stirring, volatiles were removed under reduced pressure and the residue redissolved in dichloromethane. This was washed with distilled water and dried with $MgSO_4$. Removal of volatiles under reduced pressure afforded **10** (0.07 g, 68%) as a slightly oily orange solid. ^{1}H NMR ($CDCl_3$, 298 K) δ: 8.3–6.2 (m, 16H, Ar), 5.21 (s, ca. 1.2H, Cp, **10b**), 5.15 (s, ca. 3.8H, Cp, **10a**), ca. 4.4 (vbr, 1H, CH), 2.60 (br, 6H, Me), 2.56 (br, 6H, Me), 0.90 (m, 3H, Me). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 20.5 (s, **10a**), 13.0 (s, **10b**). Mass spectrum (FAB) *m/z*: 656 [M^+], 621 [M^+ – Cl].

Preparation of *cis*-[PtI$_2$(η^2-Medotpm)] (11)

5a (0.178 g, 0.25 mmol) was dissolved in THF (5 cm^3) and $LiN(SiMe_3)_2$ (ca. 0.3 mmol) was added and the mixture was stirred for 20 h. MeI (0.016 cm^3, 0.26 mmol) was then added dropwise and the mixture was stirred for a further 2 h. Removal of volatiles under reduced pressure and redissolution in dichloromethane gave a yellow solution that was washed with distilled water and dried over $MgSO_4$. The volume of the extract was reduced (ca. 5 cm^3) under reduced pressure and **11** (0.156 g, 85%) was precipitated as a yellow solid upon addition of ethanol. ^{1}H NMR ($CDCl_3$) δ: 8.16 (br, 2H, Ar), 7.76 (br, 2H, Ar), 7.52–7.29 (m, 10H, Ar), 7.10 (br, 2H, Ar), 5.38 (dd, 1H, *J* = 18.7, 9.9 Hz, CH), 2.47 (br, 6H, CH_3), 2.34 (s, 6H, CH_3), 1.16 (dt, 3H, *J* = 20.5, 11.0 Hz, CH_3); ^{31}P{^{1}H} NMR ($CDCl_3$) δ: –71.4 (s, *J* = 2892 Hz). Mass spectrum (FAB) *m/z*: 903 [M^+], 776 [M^+ – I], 649 [M^+ – 2I]. Anal. calcd. for $C_{30}H_{32}I_2P_2Pt$: C 39.86, H 3.54; found: C 39.28, H 3.49.

Preparation of *cis*-[Mo(CO)$_4$(η^2-Etdotpm)] (12)

2 (0.33 g, 0.50 mmol) was dissolved in dry THF (25 cm^3) to form a pale yellow solution. *n*-BuLi (0.5 cm^3, 0.75 mmol) was added and the solution immediately darkened. After stirring at room temperature for 1 h, EtI (0.06 cm^3, 0.75 mmol) was added and the reaction mixture stirred for a further 20 h. The solvent was removed and the solid was redissolved in dichloromethane and washed thoroughly with distilled water. The dichloromethane extract was dried over $MgSO_4$ and the mixture was filtered. Removal of volatiles under reduced pressure gave **12** as a yellow solid (0.24 g, 72%). IR ν(CO) (CH_2Cl_2, cm^{-1}): 2018 (s), 1906 (s), 1870 (s). ^{1}H NMR (CD_2Cl_2, 308 K) δ: 7.99 (m, 2H, Ar), 7.87 (q, 2H, *J* = 7.5 Hz, Ar), 7.39 (t, 2H, *J* = 7.00 Hz, Ar), 7.33–7.27 (m, 4H, Ar), 7.24 (t, 2H, *J* = 7.4 Hz, Ar), 7.15 (d, 4H, *J* = 7.3 Hz, Ar), 4.83 (septet, 1H, *J* = 4.9 Hz, CH), 2.15 (s, 6H, Me), 2.08 (s, 6H, Me), 1.87 (doublet octets, 2H, *J* = 7.4 Hz, 5.1, CH_2), 0.78 (t, 3H, *J* = 7.4 Hz, CH_3). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 5.9 (s). X-ray data collection and solution

Single crystals were mounted on glass fibres and all geometric and intensity data were taken from these samples using an automated four-circle diffractometer (Nicolet R3mV) equipped with Mo Kα radiation (λ = 0.710 73 Å) at 293 ± 2 K. Lattice parameters were identified by application of the automatic indexing routine of the diffractometer to the positions of a number of reflections taken from a rotation photograph and centred by the diffractometer. The ω–2θ technique was used to measure reflections and three standard reflections (remeasured every 97 scans) showed no significant loss in intensity during data collection. The data was corrected for Lorenz and polarization effects and unique data with $I \geq 2\sigma(I)$ were used to solve and refine the structure. This was solved by direct methods and developed by using alternating cycles of least-squares refinement and difference-Fourier synthesis. All non-hydrogen atoms were refined anisotropically and placed in idealized positions (C—H, 0.96 Å) and assigned a common isotropic thermal parameter (U = 0.08 Å^2).[3]

Reaction of H_2S with $MoRu(CO)_6(dppm)_2$ to give H_2 and a bridged-sulfide product via hydrido-sulfhydryl intermediates (dppm = $Ph_2PCH_2PPh_2$)[1]

Mozhgan Khorasani-Motlagh, Nasser Safari, Craig B. Pamplin, Brian O. Patrick, and Brian R. James

Abstract: Oxidative addition of H_2S to $MoRu(CO)_6(\mu\text{-dppm})_2$ (**1**) at ~20 °C in toluene yields an isolable complex formulated as $Mo(CO)_3(\mu\text{-SH})(\mu\text{-CO})(\mu\text{-dppm})_2RuH(CO)$ (**2**) via the possible intermediate $Mo(CO)_3(\mu\text{-H})(\mu\text{-CO})(\mu\text{-dppm})_2Ru(SH)(CO)$ (**4**) (dppm = $Ph_2PCH_2PPh_2$) that is detectable at lower temperatures. Over 2 days, species **2** in toluene loses H_2 (and CO) to yield the bridged-sulfide product, $Mo(CO)_2(\mu\text{-CO})(\mu\text{-S})(\mu\text{-dppm})_2Ru(CO)$ (**5**) that is also formed directly from the reaction of **1** with elemental sulfur. The solid-state molecular structure of **5** is determined by X-ray crystallography. A further hydrido-sulfhydryl species, possibly $Mo(CO)_3(\mu\text{-SH})(\mu\text{-H})(\mu\text{-dppm})_2Ru(CO)_2$ (**3**), is in equilibrium with **2** at ambient temperature.

Key words: molybdenum, ruthenium, bis(diphenylphosphino)methane, hydrogen sulfide, hydrido-sulfhydryl species, carbonyl complexes, bridged-sulfide complex.

Résumé : L'addition oxydante du H_2S au $MoRu(CO)_6(\mu\text{-dppm})_2$ (**1**), à ~20 °C, dans le toluène, conduit à la formation d'un complexe qui peut être isolé, dont la formule serait $Mo(CO)_3(\mu\text{-SH})(\mu\text{-CO})(\mu\text{-dppm})_2RuH(CO)$ (**2**) et qui se formerait par le biais d'un intermédiaire possible de formule $Mo(CO)_3(\mu\text{-H})(\mu\text{-CO})(\mu\text{-dppm})_2Ru(SH)(CO)$ (**4**) (dppm = $Ph_2PCH_2PPh_2$) qu'on peut détecter à des températures plus basses. Sur une période de deux jours, l'espèce **2** perd une molécule d'hydrogène (et du CO) pour conduire au produit à pont sulfure de formule $Mo(CO)_2(\mu\text{-CO})(\mu\text{-S})(\mu\text{-dppm})_2Ru(CO)$ (**5**) qui se forme aussi directement par réaction du composé **1** avec du soufre élémentaire. On a déterminé la structure moléculaire à l'état solide du composé **5** par diffraction des rayons X. À la température ambiante, une autre espèce hydrido-sulfhydryle, possible de formule $Mo(CO)_3(\mu\text{-SH})(\mu\text{-H})(\mu\text{-dppm})_2Ru(CO)_2$ (**3**) est aussi en équilibre avec le composé **2**.

Mots clés : molybdène, ruthénium, bis(diphénylphosphino)méthane, sulfure d'hydrogène, espèces hydrido-sulfhydryle, complexe de carbonyle, complexe à pont sulfure.

[Traduit par la Rédaction]

Introduction

Interest in the reactivity of hydrogen sulfide toward transition metal complexes continues, particularly because of its relevance in catalytic hydrodesulfurization (1–3), the potential conversion of H_2S into H_2 and elemental sulfur (4, 5), and the importance of metal–sulfur interactions in enzymes such as nitrogenase and hydrogenase (1, 2, 6). Reactions of H_2S with bimetallic complexes to yield a bridged-sulfide with liberation of H_2 is common (4, 7–10), and mechanisms for such processes typically invoke formation of an H_2S adduct, followed by oxidative addition to give a hydrido-sulfhydryl intermediate; a proton, formed from the coordinated SH can then react with the metal-hydride to produce H_2 and a μ-S species (4, 7), or a "second oxidative addition" of the SH moiety can give a dihydride species that subsequently reductively eliminates H_2 (9). Although there are cases where the hydrido-sulfhydryl intermediates are detected in such chemistry (7, 9), detection of any precursor H_2S adduct is relatively rare, and there are only five structurally characterized H_2S complexes, all of which are Ru species (11).

Because of the documented Ru–H_2S chemistry, the fact that Ru is the second-row analogue of Fe, and the key role

of sulfur ligands in Mo–Fe enzyme systems, the complex $MoRu(CO)_6(\mu\text{-dppm})_2$ (**1**) (dppm = $Ph_2PCH_2PPh_2$)[3] seemed an attractive precursor for a study of reactivity toward H_2S, particularly in view of the success of our group and others in forming H_2S adducts with monometallic Ru(II) complexes (11). Subsequent to our first report on the reaction of H_2S with $Pd_2Cl_2(dppm)_2$ to generate H_2 and a bridged-sulfide complex (12), Cowie's group (9, 13, 14) has reported on the reaction of H_2S with several heterobinuclear complexes of the type $MM'(CO)_n(dppm)_2$ (n = 3 or 4, and M and M′ may be the same or different transition metals). Complex **1**, first synthesized by Chaudret and co-workers (15) is commonly written as $(CO)_3Mo(dppm)_2Ru(CO)_3$ containing a Mo—Ru bond, although an X-ray structure reveals five terminal CO ligands and one semi-bridged CO, the structure being complicated by half occupancy at each metal centre; in solution, however, the preferred structure is one with six terminal CO ligands as shown in Scheme 1 (15).

This paper reports on the interaction of the Mo–Ru complex (**1**) with H_2S to form, via several hydrido-sulfhydryl intermediates (tentatively assigned as **2**–**4**), the bridged-sulfide complex, $Mo(CO)_2(\mu\text{-CO})(\mu\text{-S})(dppm)_2Ru(CO)$ (**5**), that can be synthesized also from the reaction of **1** with elemental sulfur (S_8); however, no H_2S adduct was detected. The findings were first presented at a conference (16), which Arthur Carty attended, and so it seems appropriate to remind him of the details, particularly because his favourite metal is involved!

Scheme 1. Reaction of H_2S with $MoRu(CO)_6(dppm)_2$ (P = PPh_2).

Experimental section

All solvents were dried by refluxing over Na benzophenone under Ar, and were distilled immediately before use. Purified Ar (Praxair) and H_2S (Matheson) were used without further treatment. The primary Ru source was $RuCl_3{\cdot}3H_2O$ donated by Colonial Metals Inc., Elkton, Maryland; $Mo(CO)_6$, elemental sulfur, and all other chemicals (Aldrich products) were used as received. All manipulations were conducted under Ar using standard Schenk techniques. The complex $MoRu(CO)_6(dppm)_2$ (**1**) was prepared as reported previously (15).

NMR spectra were recorded in C_6D_6 or toluene-d_8 on a Bruker AV-300 spectrometer operating at 121.49 MHz for ^{31}P (referenced to external 85% aq. H_3PO_4), using an internal deuterated solvent lock; broad (br), singlet (s), triplet (t), quintet (qnt), multiplet (m), pseudo (ps); coupling constants are given in Hz. Deuterated solvents were dried over molecular sieves and freeze–pump–thaw degassed prior to vacuum transfer into 5 mm NMR tubes containing the sample; the NMR tube could be flushed with H_2S. For the variable-temperature NMR experiments, the temperature regulation of the probehead was calibrated using a standard curve based on the chemical shift separation of the resonances of 4% MeOH in MeOH-d_4 (17). IR spectra were recorded as KBr disks on an ATI Mattson Genesis FT IR instrument. Conductivity data (1.0 mmol/L of the complex in CH_2Cl_2), measured on a RCM151B Serfass conductance bridge (A.H. Thomas Co.) at 25 °C with a 3404 cell (Yellow Springs Instrument Co.), were calibrated using 0.0100 mol/L aq. KCl, and are given as Λ_M in units of Ω^{-1} mol^{-1} cm^2. Elemental analyses were performed by P. Borda (Department of Chemistry, University of British Columbia).

Syntheses

$Mo(CO)_3(\mu\text{-}SH)(\mu\text{-}CO)(dppm)_2RuH(CO)$ (2)

Complex **1** (100 mg, 0.084 mmol) was dissolved in toluene (10 mL) and H_2S (5 mL, 0.22 mmol) was added via a gas-tight syringe at room temperature (~20 °C). After ~15 min, the orange solution became dark orange, and addition of hexane (10 mL) yielded an orange precipitate that was collected, washed with hexane, and dried by passing a stream of CO over the product. The complex was stored under Ar. Yield: 88 mg (88%). IR (cm^{-1}): ν_{CO} 1959 (s), 1937 (s), 1880 (s), 1768 (s). ^1H NMR (C_7D_8, ~20 °C) δ: –8.13 (ps t, $^2J_{PH}$ = 18.8 Hz, 1H, Ru*H*), –0.98 (ps qnt, $^3J_{PH}$ = 9.3 Hz, 1H, S*H*), 2.80–3.45 (br m, 4H, CH_2). $^{31}P\{^1H\}$ NMR δ: 35.7 (br m). Anal. calcd. for $C_{55}H_{46}O_5P_4SMoRu$: C 57.95, H 4.07; found: C 57.43, H 4.29. (See Results and discussion section for low-temperature NMR data.) Λ_M = 2.2 (nonconducting).

$Mo(CO)_2(\mu\text{-}CO)(\mu\text{-}S)(dppm)_2Ru(CO)$ (5)

(*a*) Addition of excess sulfur (30 mg, 0.94 mmol "S") to a solution of **1** (100 mg, 0.084 mmol) in toluene (10 mL) im-

[3] In all the bimetallic complexes mentioned subsequently in this paper, the dppm ligands are bridging, but for convenience the μ symbol is omitted.

mediately generated an orange precipitate. The mixture was stirred for 1 h, when hexane (10 mL) was added to complete precipitation of the product that was collected, dried under Ar, and recrystallized from CH_2Cl_2–Et_2O. Yield: 88 mg (90%). IR (cm^{-1}): ν_{CO} 2010 (m), 1954 (s), 1866 (s), 1777 (m). ^1H NMR (C_6D_6, ~20 °C) δ: 2.17 (m, 2H), 5.36 (m, 2H). $^{31}P\{^1H\}$ NMR: AA′BB′ pattern centered at δ 16.3, 25.9 (see below). Anal. calcd. for $C_{54}H_{44}O_4P_4SMoRu{\cdot}0.5CH_2Cl_2$: C 56.80, H 3.94; found: C 56.66, H 4.24. Λ_M = 1.8 (nonconducting). (*b*) H_2S (5 mL, 0.22 mmol) was added via a gas-tight syringe to **1** (50 mg) dissolved in toluene (10 mL). The solution was stirred for 48 h, when addition of hexane (10 mL) precipitated the orange product. Yield: 68 mg (69%). The NMR data were identical to those listed above.

Crystallography

Brown crystals of **5**, grown by diffusion of hexane into a concentrated C_6D_6 solution of the complex, were mounted on a glass fibre. Measurements were made on a Rigaku/ADSC CCD area detector with graphite-monochromated Mo-Kα radiation (λ = 0.710 69 Å), data being collected at –100 ± 1 °C to a maximum 2θ value of 55.8°. A sweep of data was done using φ oscillations from 0.0° to 190.0° at χ = –90.0°, and a second sweep was performed using ω oscillations between –19.0° and 23.0° at χ = –90.0°. The crystal-to-detector distance was 40.51 mm, and the detector swing angle was –5.50°. Data were collected and processed using the d*TREK program (18), and the structure was solved by direct methods and expanded using Fourier techniques (19). The non-hydrogen atoms were refined anisotropically. The weighting scheme was based on counting statistics; the plot of $\Sigma w(|F_o| - |F_c|)^2$ vs. $|F_o|$, the reflection order in data collection sin θ/λ, and various classes of indices showed no unusual trends.

There was disorder in the site occupancy of both Ru1 and Mo1, with the metal at the Ru1 site consisting of disordered Ru and Mo with populations of 0.83 and 0.17, respectively. Residual electron density with geometry consistent with four CO ligands was found near Ru1 and Mo1 and was modeled as such. The populations of the CO ligands were refined, with the result that two of these had a population of ~1 (C52-O2 and C53-O3), while one CO ligand at Mo1 had a population of 0.83 (C51A-O1A), and the second CO ligand on Ru1 had a population of ~0.17 (C51B-O1B). Extra electron density consistent in geometry with a CO was found near S1, while one relatively large peak was found near the bridging C54-O4 ligand; the residual peaks near S1 were modeled as a bridging CO ligand (C54B-O4B), and the peak near C54-O4 as a bridging S ligand (S1B). Final occupancies were refined such that the major fragment consisted of (O3-C53)Ru1-C54A-Mo1(C51A-O1A)(C52-O2)-S1A. Final refinements on the populations gave a ratio of 0.83:0.17 between the major and minor fragments. The material also crystallizes with four molecules of C_6D_6. Some details of the data collection are given in Table 1, while complete crystallographic information is available.[4]

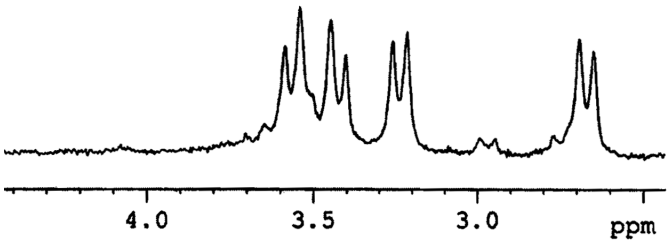
Results and discussion



Isolated products from the reaction of H_2S with $MoRu(CO)_6(dppm)_2$ (1)

A toluene solution of complex **1** reacts rapidly with H_2S at ambient conditions to yield an isolable, orange product believed to be $Mo(CO)_3(\mu\text{-}SH)(\mu\text{-}CO)(dppm)_2RuH(CO)$ (**2**), formed via oxidative addition of H_2S with loss of one CO ligand (Scheme 1). The elemental analysis and spectroscopic data support this formulation. The room-temperature ^1H NMR spectrum shows one broad multiplet at δ 3.40 for the CH_2 protons, implying fluxional behaviour, but in a ^{31}P-decoupled spectrum at –75 °C four doublets are seen (Fig. 1), revealing the expected inequivalence of these protons; a ^1H(COSY) NMR experiment showed coupling between the proton signals at δ 2.67 and 3.24, and coupling between those at δ 3.42 and 3.56. (The room-temperature, broad multiplet must result from a combination of fluxionality and a temperature dependence of the chemical shifts bringing them close together.) A high-field hydride resonance (a pseudotriplet at δ –8.13 implying coupling to two P atoms) is attributed to a terminal hydride at the Ru, and a pseudoquintet at δ –0.98 (coupling to four P atoms) is attributed to a bridging SH. The $^2J_{PH}$ coupling constant for

Fig. 1. $^1H\{^{31}P\}$ NMR spectrum (CH_2 region) of a C_7D_8 solution of $Mo(CO)_3(\mu\text{-}SH)(\mu\text{-}CO)(dppm)_2RuH(CO)$ (**2**) at 198 K.

the hydride is about twice that for the $^3J_{PH}$ coupling for the sulfhydryl hydrogen, and both values are in the reported range (9, 13). The fluxionality of **2** is also evident in the $^{31}P\{^1H\}$ NMR spectrum; at ~20 °C, this shows a broad multiplet centred at δ ~ 35.7, but at 0 °C this resolves into several sharper peaks. Attempts to simulate the expected AA′BB′ spin pattern proved to be impossible, as solutions of **2** always contained an isomer (species **3**, see below) that also gave at room temperature a broad multiplet at δ ~ 40.0, which was also resolved at 0 °C. The lower temperature spectrum was thus extremely complex; data from Cowie's group reveal the complexity of such $^{31}P\{^1H\}$ NMR spectra (9, 13, 14). The H ligand in **2** is considered to be cis to the SH group because such geometry is essential for subsequent loss of H_2 to generate **5** (see below); the H could in principle be attached to the Mo, cis to the SH, but we consider Mo-monohydride formulations less likely. The inability to distinguish which ^{31}P resonances were associated with which metal (see below) made it impractical to carry out $^1H\{^{31}P\}$ decoupling NMR experiments that could have shed light on this problem. Well-resolved ^{13}C NMR data would also be of value; however, at room temperature, the natural abundance ^{13}C spectrum shows a broad single resonance for the carbonyl groups (again consistent with fluxionality), while low-temperature measurements were thwarted by insolubility of **2**. ^{13}C NMR spectra of ^{13}C-enriched samples are needed to substantiate a more definitive formulation for **2**.

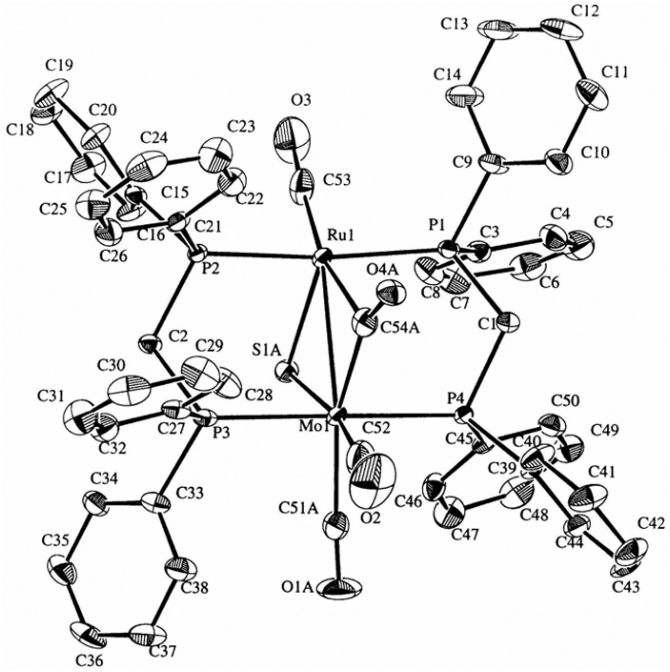
The solid-state IR spectrum (which is essentially of pure **2**) displays three intense ν_{CO} bands in the 1959–1880 cm^{-1} region (attributed to the four terminal carbonyls), and an intense band at 1768 cm^{-1} for the bridging carbonyl. A very weak band at ~2360 cm^{-1} might be due to the μ-SH ligand. The corresponding reaction of **1** with D_2S gave an isolated solid that showed corresponding ν_{CO} bands at 1960, 1883, and 1772 cm^{-1}, but the IR spectrum was of no assistance in detecting a ν_{RuH} band in **2**, which must be buried under the ν_{CO} bands; a ν_{RuH} band for Ru(II) complexes is typically found in the 2000–1850 cm^{-1} region (20, 21), and a small band at 1340 cm^{-1} (not seen for **2**) could be the ν_{RuD} band.

A C_6D_6 solution of **2** on standing for ~30 min at room temperature generates new NMR signals, which are thought to correspond to a species such as **3**, an isomerization product of **2**, in which the terminal hydride has interchanged with the μ-CO ligand (see Scheme 1); the ratio of **2**:**3** equilibrates at a value of ~5:1. The high-field hydride resonance for the μ-H of **3** is seen as a multiplet at δ –11.12, while the μ-S*H* pseudoquintet resonance ($^3J_{PH}$ = 12.6 Hz) occurs at δ –1.38. The complex $^{31}P\{^1H\}$ NMR spectrum of **3** was mentioned previously.

The reaction of **1** with H_2S is similar to its reported oxidative addition reaction with H_2 when the isolated product, again formed with loss of a CO ligand, is $MoRu(H)_2(CO)_5(dppm)_2$; however, the structure was written with five terminal CO ligands (three on Mo and two on Ru) with both hydrides exchanging between bridging and Ru-terminal positions (15). The high-field hydride ^1H NMR signal appeared as a multiplet at δ –7.95, similar to those seen for **2** and **3**; indeed, the formulation of the dihydride was written (15) as $Mo(CO)_3(\mu\text{-}H)_2(dppm)_2Ru(CO)_2$, identical to the structure type assigned to **3** in Scheme 1.

Attempts to obtain single crystals of a hydrido-sulfhydryl species (such as **2** or **3**) led instead to isolation of the bridged-sulfide complex, $Mo(CO)_2(\mu\text{-}CO)(\mu\text{-}S)(dppm)_2Ru(CO)$ (**5**). The conversion of **2** (or a mixture of **2** and **3**) via loss of H_2 and CO to give **5** occurs on heating C_6D_6 (or toluene-d_8) solutions of **2** at ~55 °C for 1 h (Scheme 1), or leaving such solutions for 2 to 3 days under Ar at room temperature. Such conversions of hydrido-sulfhydryl species to bridged-sulfide complexes are well-established for homo- or hetero-bimetallic complexes containing μ-dppm ligands (4, 7, 9, 13, 14). The easiest route for isolation of the air-stable, orange **5** in high yield is via treatment of **1** with elemental sulfur at room temperature, the reaction being complete within a few minutes.

Complex **5**, characterized by X-ray crystallography, elemental analysis, and solution spectroscopic methods, is structurally analogous to $Mn(CO)_2(\mu\text{-}CO)(\mu\text{-}S)(dppm)_2Rh(CO)$ (9), but with Mo and Ru replacing the Mn and Rh, respectively. The IR spectra are also similar, showing three intense ν_{CO} bands in the 2010–1865 cm^{-1} region, and a ν_{CO} band at a lower wavenumber for the μ-CO.



The solid state structure of **5** (Fig. 2), selected bond lengths and angles being reported in Table 2, shows the expected *trans*-$MoRu(\mu\text{-}dppm)_2$ unit, having P-M-P angles of 174.60° (M = Mo) and 172.10° (M = Ru). The P-Mo-P angle is close to that of 173.80° for our previously reported $[Mo(CO)_2(\mu\text{-}I)(\mu\text{-}CO)(dppm)_2Ru(CO)_2]^+$ cation (22), and is in between that of 171.39° for $Mo(CO)_2(\mu\text{-}Cl)(\mu\text{-}CO)(dppm)_2Rh(CO)$ (23) and that of 178.4° for $Mo(CO)_2(\mu\text{-}CO)(\mu\text{-}SO_2)(dppm)_2RhCl$ (24). The Mo—P bond lengths are within 0.05 Å of those in the above Mo–Ru and Mo–Rh analogues. The Ru—P distances (2.365 and 2.378 Å) and the P-Ru-P angle are close to those in $Ru(CO)_2(\mu\text{-}SO_2)(dppm)_2Ru(CO)_2$ (8) and the Mo–Ru cation noted above (22). The Mo—P distances are some 0.06–0.08 Å longer than the Ru—P distances, which is consistent with a Mo(0)–Ru(II) formulation, although an extra factor might be more steric crowding at the octahedral Mo centre as opposed to the formally five-coordinate Ru (ignoring any metal–metal interaction; see the following).

The $MoRuP_4C_2$ ring in complex **5** assumes a chair conformation, resulting in the presence of two distinct axial phenyl groups and two similarly sized cavities into which the μ-S and μ-CO ligands lie. Qualitatively, the situation is similar to that found in $Ru(S_2)(\mu\text{-}CO)(\mu\text{-}S)(dppm)_2Ru(CO)_2$, where similar cavities accommodate the μ-S and μ-CO ligands (8).

The nonlinearity of the Mo-C(54A)-O(4) moiety (153.4°), and Mo—C(54A) and Ru—C(54A) distances of 2.071 and 2.416 Å, respectively, correspond to a semibridging CO; these angles and distances are close to those reported for

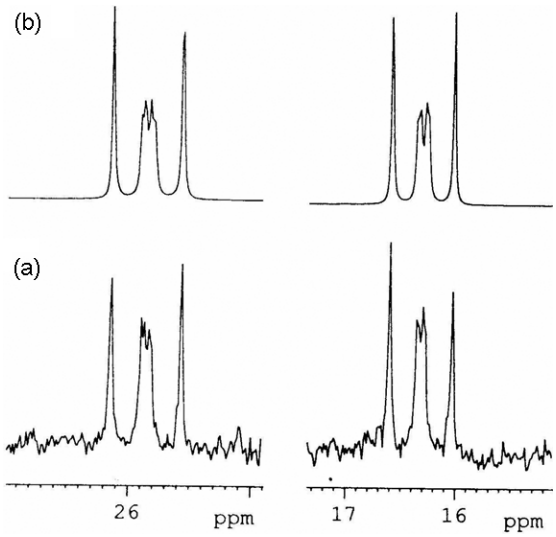
Fig. 2. ORTEP representation (50% ellipsoids) of the molecular structure of $Mo(CO)_2(\mu\text{-}S)(\mu\text{-}CO)(dppm)_2Ru(CO)$ (**5**). H atoms omitted for clarity.



$[(Mo(CO)_2(\mu\text{-}I)(\mu\text{-}CO)(dppm)_2Ru(CO)_2]^+$ in which a semibridging CO is defined by the Mo-C-O angle (155.4°) and Mo—C and Rh—C distances of 2.08 and 2.45 Å, respectively (22). The $Mo(CO)_2(\mu\text{-}Cl)(\mu\text{-}CO)(dppm)_2Rh(CO)$ complex (23, 24) is another related species with a semibridging CO, and there are many others where a semibridging CO is similarly defined (e.g., refs. 8 and 9). That the C(54A)—O(4A) distance of 1.154 Å in **5** is still within 0.02 Å of the values for the terminal CO ligands is not unusual (23).

In complex **5**, the relatively short Mo—C(52) bond (1.953 Å) and somewhat longer C(52)—O(2) bond (1.167 Å), compared with the other metal-C-O linkages, presumably result from this CO being trans to the π-donor sulfide ligand. The metal–metal bond length in **5** (2.986 Å) is ~0.04 Å shorter than in the cationic Mo(μ-I)(μ-CO)Ru species mentioned above (22), and ~0.07 Å shorter than in the precursor complex **1**, where a weak metal–metal interaction is considered likely, especially in solution where all the CO ligands are considered to be terminal (15). Thus, a weak metal–metal interaction may be present in the solid state structure for **5**, but if this is ignored and the semibridged CO is considered as ligated to both metals, **5** is probably best described as consisting of a distorted octahedral Mo(0) centre and a trigonal-bipyramidal Ru(II) centre.

It may be unusual (as suggested by a reviewer of this paper) to have a vacant coordination site trans to a bridging sulfide. In this regard, the structure is complicated by several disorder problems (see the Experimental section) and only the "main fragment" is illustrated in Fig. 2; and, of note, the minor (18%) fragment does show a bridging S trans to the semibridging CO (S(1B)-Ru-C(53) = 152.7(2)°). The structure has been rechecked, and the solution offered is the optimum one; perhaps all we can conclude is that complex **5** in the solid state is a bridged-sulfide species containing four CO ligands.

Fig. 3. $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution of $Mo(CO)_2(\mu\text{-}S)(\mu\text{-}CO)(dppm)_2Ru(CO)$ (**5**) at room temperature. (*a*) Observed, (*b*) simulated with $J_{AA'(Mo)} \sim 87$, $J_{BB'(Ru)} \sim 225$, $J_{AB} = J_{A'B'} \sim 65$, $J_{A'B} = J_{AB'} \sim 4$ Hz.

The room-temperature, solution NMR data for **5** are typical of those for heterobimetallic complexes containing μ-dppm and μ-CO ligands, the closest analogue being complex **2** and $[(Mo(CO)_2(\mu\text{-}I)(\mu\text{-}CO)(dppm)_2Ru(CO)_2]^+$ (22), while related species with a μ-sulfide ligand include Rh–M species (M = Re, Mn, Rh, and Ir (9, 13, 14)), Ir_2 species (14), and Ru_2 species (8). The ^1H NMR spectrum of **5** shows multiplets at δ 5.36 and 2.17 owing to the inequivalent dppm-CH_2 protons. The $^{31}P\{^1H\}$ NMR spectrum displays an AA′BB′ spin pattern that was simulated using $^2J_{PP}$ values of ~225 and ~87 Hz for the *trans*-P atoms at Ru and at Mo, respectively, and values of ~65 and ~4 Hz for the cross-couplings (Fig. 3). These *J* values are comparable to those determined earlier (15) for the precursor **1** (~231 and ~112 Hz and ~90 and ~21 Hz, respectively).

In situ reactions of $MoRu(CO)_6(dppm)_2$ (1) with H_2S

To gain information about possible intermediates in the formation of $Mo(CO)_3(\mu\text{-}SH)(\mu\text{-}CO)(\mu\text{-}dppm)_2RuH(CO)$ (**2**), the title reaction was monitored in situ from –80 to ~20 °C by ^1H and $^{31}P\{^1H\}$ NMR. On exposure of a C_6D_6 solution of **1** to 1 atm H_2S (1 atm = 101.325 kPa) at room temperature, a species (**4**) begins to form "instantaneously" prior to formation of **2**, which is complete after ~15 min; at lower temperatures, **4** can be stabilized. The ^1H NMR spectrum of **4** shows a broad singlet at δ –2.76 (not noticeably changed by ^{31}P decoupling, but tentatively assigned to a terminal S*H* proton at Ru), a pseudoquintet at δ –14.77 ($^2J_{HP}$ = 15.5 Hz, assigned to a μ-H), and two multiplets at δ 3.76 and 4.61 for the dppm-CH_2 protons; the $^{31}P\{^1H\}$ NMR spectrum of **4** (Fig. S1)[4] shows an AA′BB′ pattern centred at δ 39.1 and 25.5 that can be simulated using $^2J_{PP}$ values of ~230, ~115, ~75, and ~35 Hz (cf. the data above for **1** and **5**). The favoured structure for **4** is that shown in Scheme 1 and is a

		P(2)-C(2)-P(3)	111.24(16)

further isomer of species **2** and **3**. The H_2S reaction with **1** can be followed more leisurely at lower temperatures in C_7D_8, but no other intermediates such as an H_2S adduct were observed. Thus, in essence, oxidative addition of the H_2S is likely initiated at the Ru(0) centre with loss of a CO ligand, with the SH ligand found terminal at the Ru and the hydride first detected as a μ-H (species **4**); the SH- and H-ligands then exchange to generate **2**, which also equilibrates with species **3** in which the terminal H exchanges with a μ-CO ligand (see above for comparison with the reaction of H_2 with **1**). If solutions containing species **2**–**4** were subjected to 1 atm CO at room temperature, complex **1** was not regenerated, showing that the H_2S reaction is irreversible. Intermediates such as **4**, containing a bridging hydride and terminal sulfhydryl, have been observed in the reaction of H_2S with $Mn(CO)_2(\mu\text{-}CO)(\mu\text{-}S)(dppm)_2Rh(CO)$ (9) and the $M_2(CO)_3(dppm)_2$ complexes (M_2 = Ir_2 or RhIr) (14).

It is worth noting that the experimental elemental analysis for **2** (formulated as a pentacarbonyl) is in even better agreement with a tetracarbonyl formulation with an added solvate, water, i.e., $MoRu(H)(CO)_4(SH)(dppm)\cdot H_2O$ (calcd. for $C_{54}H_{46}O_4P_4SMoRu\cdot H_2O$: C 57.95, H 4.07). If **2** is a tetracarbonyl, then species **3** (and possibly **4**) would have to be formulated as tetracarbonyls, with likely one less CO at the Mo. However, no evidence was found for an associated water, and the fact that the oxidative addition of H_2S to **1** to

© 2006 NRC Canada

give **4** parallels that of H_2 addition, which involves loss of just one CO ligand (15), makes us favour a pentacarbonyl formulation for **4**. Definitive ^{13}C NMR or crystallographic data, which we were unable to collect, are needed to establish unambiguously the structure of **2** (and thus **3**).

Concluding remarks

Our findings add to the data base on reactions of H_2S with solutions of bimetallic-dppm complexes. Three types of systems could be recognized prior to our study: (*i*) In systems exemplified by $Rh_2(CO)_3(dppm)_2$ (14) and $Ru_2(CO)_5(dppm)_2$ (8), a bridging-sulfide product is formed with concomitant loss of H_2, and no intermediates are detected, even when using low-temperature NMR data. (*ii*) In systems such as $RhRe(CO)_4(dppm)_2$ (13), $Ir_2(CO)_3(dppm)_2$ (14), $RhMn(CO)_4(dppm)_2$ (9), and $Pd_2Cl_2(dppm)_2$ (4, 7), a bridged sulfide and H_2 are the final products, but hydrido-sulfhydryl intermediates, with the H^- and SH^- ligands being terminal or bridging, have been detected; migrations of these two ligands between terminal and bridging positions have also been seen (13, 14). (*iii*) A system such as $RhIr(CO)_3(dppm)_2$ that gives a hydrido-sulfhydryl as a final stable product (14). With all the carbonyl-containing precursors, a CO ligand is lost in the proposed first step, usually considered to involve formation of a H_2S complex, although direct ^1H NMR evidence for the coordinated H_2S in any of these systems is lacking. We were hoping that the $MoRu(CO)_6(dppm)_2$ system would generate a detectable H_2S adduct (see Introduction), but the study reveals that the system is of type (*ii*), with the hydrido-sulfhydryl intermediates being detectable at room temperature, a feature shared with the $RhMn(CO)_4(dppm)_2$ (9) and $Ir_2(CO)_3(dppm)_2$ (14) systems. It is not impossible that H_2S can react in a concerted manner with dimetallic precursors, without prior formation of an adduct.

Reactions of $Fe_3(CO)_{12}$ and $Fe(CO)_5$ with functionalized alkynes in CH_3OH–KOH solution — The crystal structure of $Fe_2(CO)_6(PPh_3)[\mu\text{-}\eta^3\text{-}(H_2CCCH_2)]$[1]

Giuliana Gervasio, Domenica Marabello, Enrico Sappa, and Andrea Secco

Abstract: The complex $Fe_2(CO)_7(H_2CCCH_2)$ (**1**) is obtained starting from a variety of functionalized alkynes that can release C_3 fragments during the reactions with $Fe_3(CO)_{12}$ or $Fe(CO)_5$ in CH_3OH–KOH solutions. Owing to the oily nature of **1**, it was reacted with triphenylphosphine, and the structure of the resulting title compound (**1a**) has been determined by X-ray analysis. Complex **1a** shows a new coordination mode of a $H_2C{=}C{=}CH_2$ ligand to a diiron centre and is, to our knowledge, unprecedented. We have also found that **1** (and **1a**) are by-products, and not intermediates in the formation of complex **3**. A discussion of the possible reaction pathways is given.

Key words: iron carbonyls, alkynols, CO and methanol activation, acetyl and acetate complexes, allenyl iron complexes, crystal structure.

Résumé : Le complexe $Fe_2(CO)_7(H_2CCCH_2)$ (**1**) a été préparé à partir d'une variété d'alcynes fonctionnalisés qui peuvent perdre des fragments en C_3 au cours de réactions avec du $Fe_3(CO)_{12}$ ou du $Fe(CO)_5$ dans des solutions de CH_3OH–KOH. En raison de la nature huileuse du composé **1**, on l'a fait réagir avec de la triphénylphosphine et on a fait appel à la diffraction des rayons X pour déterminer la structure cristalline du produit qui en résulte et qui est mentionné dans le titre (**1a**). Le complexe **1a** présente un nouveau mode de coordination du ligand $H_2C{=}C{=}CH_2$ au centre difer qui, à notre connaissance était inconnu jusqu'à maintenant. On a aussi trouvé que les composés **1** (et **1a**) sont des sous-produits et non pas des intermédiaires dans la formation du complexe **3**. On présente une discussion des voies réactionnelles potentielles.

Mots clés : fer carbonyles, alkynols, activation du CO et du méthanol, complexes acétyles et acétates, complexes d'allényl fer, structure cristalline.

[Traduit par la Rédaction]

Introduction

Propargyl alcohols react with $M_3(CO)_{12}$ carbonyls (M = Fe, Ru, or Os) both under thermal (hydrocarbons, reflux) and basic conditions (CH_3OH–KOH solution, followed by acidification with HCl) undergoing different processes, among which the more important is dehydration. Two main dehydration pathways leading, respectively, to coordinated ene-yne (or vinylacetylene) or to allenylidene ligands have been evidenced (1). The latter is apparently preferred when M = Fe, as discussed in the following. Most of the dehydration–hydration reactions are promoted by acids (2), silica surfaces (3), or silica and alumina slurries (4). Other processes observed are deoxygenation (5) and loss of functionalities (6).

We have recently reported the reactions of $Fe_3(CO)_{12}$ with propargyl alcohol ($HC{\equiv}CCH_2OH$) and propargyl chloride ($HC{\equiv}CCH_2Cl$), both under thermal and basic methanolic conditions. The products obtained were: $Fe_2(CO)_7(C_3H_4)$ (**1**), the allenylidenic $Fe_3(CO)_9(\mu\text{-}CO)(C{=}C{=}CH_2)$ (**2**) in very small yields, $Fe_2(CO)_6[H_2CCC(H)C(=O)OCH_3]$ (**3**), and $Fe_3(CO)_{10}[H_2CCC(H)C(=O)C\{CH_2(O)CH_3\}CCH_2]$ (**4**) (7). The structures of complexes **2**–**4** are shown in Scheme 1.

On the basis of previous results (8), the formation of com-

plexes such as **3** had been explained by invoking the intermediacy of complexes of type **2**, with no evidence for the role of complex **1** in the reaction sequence. In this work the attention has been paid to the synthetic pathways leading to complexes **1** and **3** and on some aspects of their reactivity with the aim of obtaining more details on the reaction mechanisms leading to methoxycarbonyl derivatives (**3**, **4**). The reactions of $Fe(CO)_5$ and $Fe_3(CO)_{12}$ with the alkynes collected in Table 1, under basic methanolic conditions, have been therefore considered. These alkynes, except for the last two, are characterized by $C{\equiv}CCH_2OH$ or $HC{\equiv}CCH_2$ moieties, which could form cumulene systems.

Reacting the oily complex **1** with triphenylphosphine, the title complex (**1a**) was obtained as the major product, and its structure was determined by X-ray analysis. The structural features for this unprecedented derivative are discussed.

Table 1. These alkynes, except for the last two, are characterized by $C{\equiv}CCH_2OH$ or $HC{\equiv}CCH_2$ moieties, which could form cumulene systems.

Ligand	Name
$HC{\equiv}CCH_2OH$	Propargylic alcohol
$ClC{\equiv}CCH_2OH$	Propargyl chloride
$PhC{\equiv}CCH_2OH$	3-Phenyl-2-propyn-1-ol
$(CH_3)_3SiC{\equiv}CCH_2OH$	Trimethylsilyl propargyl alcohol
$(CH_3)_3SiOCH_2C{\equiv}CH$	Propargyloxytrimethylsilane
$H_2NCH_2C{\equiv}CH$	Monopropargylamine
$(CH_3COO)CH_2C{\equiv}CH$	Propargyl acetate
$(Ph)_2(OH)CC{\equiv}CH$	1,1-Diphenyl-2-propyn-1-ol
$(CH_3)_3SiC{\equiv}CH$	Trimethylsilyl acetylene

Experimental

$Fe(CO)_5$, $Fe_3(CO)_{12}$ (Strem Chemicals), and the alkynes (Lancaster Syntheses) were used as received. Methanol, KOH (pellets), and HCl (37%) were laboratory grade chemicals. Solvents (hexane, heptane, toluene, and dietyl ether) were dehydrated (over sodium when possible). The reactions were performed under dry nitrogen in conventional three-necked flasks, equipped with a gas inlet, cooler, mercury check valve, and magnetic stirring.

All reactions of $Fe_3(CO)_{12}$ were performed in CH_3OH–KOH solution and the following "standard" conditions were adopted: dissolution of KOH (20 pellets, ca. 1.5 g) in 200 cm^3 of CH_3OH, then addition and dissolution of 5.0 g (ca. 10 mmol) of $Fe_3(CO)_{12}$, and warming at 40 °C for 10 min; addition of 4.0 cm^3 of the liquid alkynes (or of 1.0 g for the solid ones) and warming at 40 °C for a further 10–15 min. After cooling, the substrate was acidified with HCl (37%) to pH 1. After 1 h, the solution was extracted with three 75 cm^3 portions of *n*-heptane. The solution was then reduced to a small volume under reduced pressure and then purified using TLC (Kieselgel PF Merck; eluants were mixtures of light petroleum (40–70 °C) and diethyl ether in a 9:1 *v*/*v* ratio). Finally, the TLC bands were extracted with diethyl ether.

The reactions of $Fe(CO)_5$ with propargylic alcohol and propargyl chloride were performed under the following conditions: to a solution of 30 pellets of KOH in 200 cm^3 of methanol, 30 cm^3 (ca. 65 mmol) of $Fe(CO)_5$ was added. The resulting solution was stirred and warmed at 40 °C for 30 min after which time 6 cm^3 of the liquid alkynes were added. Stirring and warming were continued for a further 30 min. The resulting solution was allowed to cool and acidified (to pH 1) with HCl (32%). A violent evolution of gases and vapours was observed. After filtering, the solutions were extracted with three 75 cm^3 portions of heptane. After reduction to a small volume under vacuum, the solutions obtained were chromatographed as described previously.

Elemental analyses were performed in the laboratories of the DISTA (Università del Piemonte Orientale). The IR spectra were obtained on a Bruker Equinox 55 (KBr cells, path length 0.5 mm). The ^1H and ^{13}C NMR were obtained on a JEOL GX 270 spectrometer. The EI (and CI) mass spectra were obtained on a Finnigan Mat TSQ-700 mass

spectrometer (Servizio di Spettrometria di Massa, Dipartimento di Scienza e Tecnologia del Farmaco, Università di Torino).

Reactions of propargyl alcohol with $Fe(CO)_5$

After extraction with heptane, the following products were obtained: complex **1** (20%), $Fe_3(CO)_{12}$ (15%), and orange complex **3** (20%).

Complex 1

IR (heptane, cm^{-1}) ν_{CO}: 2098 (m), 2040 (vs), 2020 (vs), 2012 (s sh), 1989 (m), 1980 (m sh). ^1H NMR ($CDCl_3$, r.t.) δ: 3.77 (s, 2H), 2.42 (s, 2H). ^{13}C NMR δ: 70.87 (s), 75.86 (s, CH_2), 186.0 (s, b), 206.1 (s, b, terminal CO), 212.0 (s, CO). EI-MS: M^+ = 348 *m/z*, release of a fragment with 16 *m/z*, then release of 7CO; intense signal at 152 *m/z* [$Fe_2(C_3H_4)$]. Anal. calcd. (%): C 34.5, H 1.15, Fe 32.2; found: C 34.6, H 1.2, Fe 32.1.

Complex 3

IR (cm^{-1}): 2078 (m-s), 2033 (vs), 2008 (s, sh), 1996 (vs), 1979 (m-s). ^1H NMR δ: 4.08 (s, 1H), 3.68 (s, 3H, Me), 3.56 (s, 1H), 2.97 (s, 1H). ^{13}C NMR δ: 54.4 (s, Me), 58.8 (d, CH_2), 66.3 (d, CH), 189.1 (d, C ring?), 197.1 (s, CO), 212.0 (vb, CO acetate). EI-MS: M^+ = 378 *m/z*, release of 6CO, then complex fragmentation. Anal. calcd. (%) C 34.9, H 1.6, Fe 29.6; found: C 35.0, H 1.7, Fe 29.7. The analytical results for complexes **1** and **3** have already been reported in ref. 7. These are given here for comparison with the other complexes described.

Reaction of propargyl chloride with $Fe(CO)_5$

After filtration of the acidified solution a considerable amount of solid residual was observed; this was partially soluble in methanol. The methanolic solution was added to the filtrate. After extraction with heptane, TLC gave the following bands: yellow (ca. 10%, complex **1**), $Fe_3(CO)_{12}$ (30%), orange (ca. 10%, complex **3**) and red (tr, not collected).

Reaction of $Fe_3(CO)_{12}$ with trimethylsilyl propargyl alcohol

After acidification and extraction, the red, clear heptane solution was chromatographed on TLC plates and the following bands were obtained: yellow (10%, complex **1**), triiron dodecacarbonyl (10%), orange (25%, complex **3**), orange-red (20%, complex **5**), and some decomposition.

Complex 5

IR (heptane, cm^{-1}): 2100 (m), 2074 (m-s), 2032 (vs), 2006 (s), 1992 (s, sh), 1974 (m). ^1H NMR δ: 4.18 (d), 3.95 (d), 3.86 (s, 1H), 3.75 (d), 3.67 (d), 3.53 (s, 1H), 3.28 (d), 3.04 (q, 2H), 2.94 (s, 1H), 2.77 (s, 1H), 2.55 (s, 1H). EI-MS: M^+ = 586 *m/z*, release of 12 fragments with *m/z* = 28. Anal. calcd. (%) C 38.1, H 1.7, Fe 29.1; found: C 38.3, H 1.7, Fe 28.8.

Complex 4

IR (cm^{-1}): 2100 (m), 2075 (m-s), 2031 (vs), 2026 (vs), 1992 (s), 1973 (m). ^1H NMR δ: 4.16–4.12 (d, 2H), 3.89–3.78 (d, 2H), 3.68–3.66 (d, 1H), 3.29 (s, 3H, Me), 3.07–3.04 (d, 2H, CH_2). ^{13}C NMR δ: 37.3 (s), 58.4 (s), 66.4 (s), 68.2 (s), 72.3 (s), 203.3 (s), 206.6 (s), 220.0 (s). EI-MS: M^+ = 586 *m/z*, release of 12 fragments with *m/z* = 28. Anal. calcd. (%): C 38.1, H 1.7, Fe 29.1; found: C 38.2, H 1.8, Fe 28.0.

Reaction of $Fe_3(CO)_{12}$ with propargyloxytrimethylsilane

After extraction, the red-yellow heptane solution was chromatographed on TLC plates and the following bands were obtained: dark yellow (15%, complex **1**), $Fe_3(CO)_{12}$ (15%), orange (20%, complex **3**), red (**5**, 10%), trace amounts of a red and a yellow compound (not collected), and decomposition.

Reaction of $Fe_3(CO)_{12}$ with propargyl acetate

After extraction with heptane, TLC showed the following bands: yellow (20%, complex **1**), $Fe_3(CO)_{12}$ (20%), orange (20%, complex **3**), traces of a red compound, and decomposition.

Reaction of $Fe_3(CO)_{12}$ with monopropargylamine

After acidification, the dark yellow heptane extract was chromatographed and the following bands were observed: yellow (complex **1**, 13%), orange yellow (complex **3**, 30%) and some decomposition.

Reaction of $Fe_3(CO)_{12}$ with 3-phenyl-2-propyn-1-ol in methanol

After acidification and extraction, the greenish solution gave the following TLC bands: light yellow (10%, complex **6**), $Fe_3(CO)_{12}$ (15%), orange (15%, complex **7**), and orange, purple, purple (tr, not collected).

Complex 6

IR (cm^{-1}): 2074 (m), 2033 (vs), 2005 (s), 1996 (s, sh), 1978 (m, sh). ^1H NMR δ: 7.26–7.19 (m, 5H, Ph), 4.28 (s, 1H), 3.88 (s, 1H), 3.69 (s, 1H). EI-MS: M^+ = 424 *m/z*, loss of seven fragments with *m/z* = 28. Proposed formula: $Fe_2(CO)_7C_3H_3(Ph)$. Anal. calcd. (%): C 45.3, H 1.9, Fe 26.4; found: C 45.2, H 1.8, Fe 26.5.

Complex 7

IR (cm^{-1}): 2074 (m-s), 2033 (vs), 2005 (s), 1996 (s, sh), 1978 (m-s). ^1H NMR δ: 7.45–7.26 (m, 5H, Ph), 6.30 (s, 1H), 3.88 (s, 1H). EI-MS: M^+ = *m/z* 454, loss of 6CO (see ref. 7). Proposed formula: $Fe_2(CO)_6[RHC_3R'C(=O)OCH_3]$ (R, R′ = Ph, H). Anal. calcd. (%): C 45.0, H 2.2, Fe 24.6; found: C 45.1, H 2.3, Fe 24.5.

Reactions of complexes 1 and 3

Reaction of complex 1 with PPh_3 under thermal conditions

About 0.5 g of complex **1** (ca. 1.5 mmol) were dissolved in heptane; PPh_3 (0.5 g, ca. 1.9–2.0 mmol) and Me_3NO were added and the solution was warmed to reflux (10 min) under nitrogen. After 4 min reflux (after which time the colour turned from yellow to dark red), the suspension was allowed to cool, was reduced to a small volume under vacuum, and chromatographed on TLC plates. The following bands were obtained: orange (50%, complex **1a**) and red (50%, complex

Reaction of complex 1 with CH_3OH under thermal conditions

Approximately 0.2 g of complex **1** (ca. 0.6 mmol) were dissolved in CH_3OH (10 cm^3), brought to reflux (3 min), and allowed to react for 15 min. The dark yellow suspension was brought to dryness under N_2 flow; after TLC purification, only parent **1** could be observed together with some decomposition.

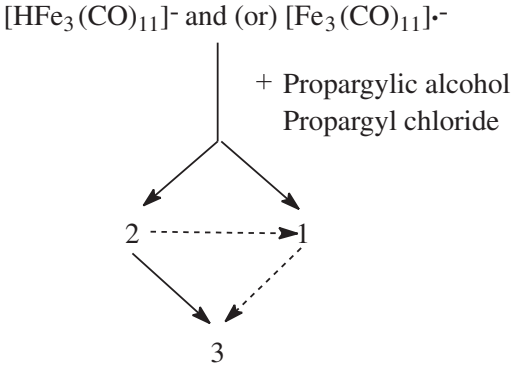
Approximately 0.25 g of complex **1** (ca. 0.72 mmol) were dissolved in 10 cm^3 of CH_3OH (and 0.2 cm^3 of HCl were added), brought to reflux (5 min), and allowed to react for 13 min. No change in colour was observed. The suspension was dried under a nitrogen stream; TLC purification and spectroscopic analyses showed the presence of complex **1** only.

Reactions of 1a with methanol under thermal conditions

Approximately 25 mg of **1a** (crystals used for the X-ray study) were dissolved in 10 cm^3 of CH_3OH under N_2 and allowed to reflux for 5 min. No change in colour was observed. The mixture was brought to dryness under reduced pressure; after TLC separation, only one complex could be obtained (**1c**).

*Complex **1c***

IR (cm^{-1}): 2061 (m-s), 2018 (m-s), 1987 (vs), 1977 (s sh), 1946 (m). ^1H NMR δ: 7.70–7.28 (mm, Ph), 3.58 (s, 1H), 3.51 (s, 1H), 2.31 (s, 1H), 2.19 (s, 3H). CI-MS: M^+ = 584 *m/z*, loss of 6CO. Anal. calcd. (%): C 55.5, H 3.6, Fe 19.2; found: C 55.4, H 3.7, Fe 19.3.



Reactions of 3 with triphenylphosphine

Approximately 0.5 g of complex **3** (ca. 1.3 mmol) were dissolved in heptane under N_2 and a 2:1 molar excess of PPh_3 was added. The suspension was brought to reflux (10 min) and allowed to reflux for 3 min. The colour of the clear solution turned from orange to red. TLC purification gave the following bands: dark yellow (**3**, ca. 10%), red (complex **3a**, ca. 40%) and impure PPh_3.

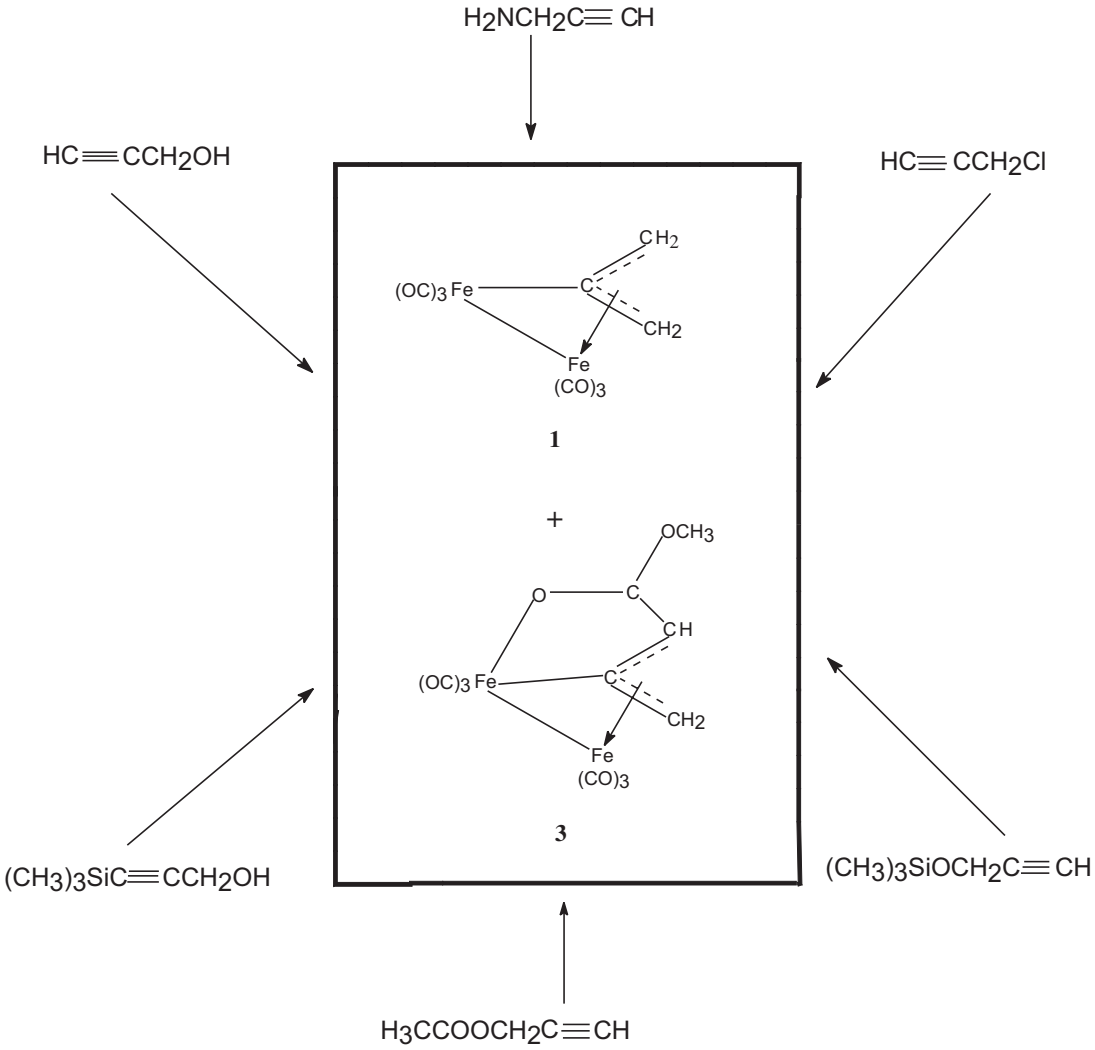
*Complex **3a***

IR (cm^{-1}): 2042 (vs), 1991 (vs), 1977 (s), 1963 (m), 1936 (m b). ^1H NMR δ: 7.55–7.25 (mm, Ph), 3.97 (s, 1H), 3.40 (s, 1H), 3.21 (s, 3H), 2.66 (s, 1H). ^{31}P NMR δ: 30.8 (s). Anal. calcd. (%): C 54.0, H 3.5, Fe 18.7; found: C 54.1, H 3.6, Fe 18.8.

Scheme 2.

X-ray structure analysis for complex 1a

The reflection data were collected on a Siemens P4 diffractometer equipped with a Bruker APEX CCD detector using graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å). The complex **1a** ($C_{27}H_{19}Fe_2O_6P$) crystallized from *n*-heptane in a monoclinic $P2_1/n$ space group, with a = 12.7888(15) Å, b = 9.3735(10) Å, c = 21.4652(26) Å, β = 92.163(2)°, V = 2571.3(5) $Å^3$, MW = 582.09, Z = 4, Dcalcd. = 1.504 g cm^{-3}, μ = 1.230 mm^{-1}. The red crystal used was prismatic and had dimensions of 0.08 × 0.10 × 0.20 mm^3. The θ range for measurement was 1.90°–28.32°; 23 563 reflections were measured at 293 K and 5444 were unique (R_{int} = 0.077). The intensities were corrected semi-empirically for absorption, based on symmetry equivalent reflections. The refinement of 325 parameters was made using full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated and refined with U_{iso} set at 1.2 times U_{eq} of the corresponding C atom. The final parameters were: $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.0732$ for 2975 "observed" reflections having $F_o^2 > 2\sigma(F_o^2)$, $Rw = [\Sigma(wF_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.127$, goodness-of-fit = $[\Sigma w(F_o^2 - F_c^2)^2/(\text{No. of unique reflections} - \text{No. of parameters})]^{1/2} = 0.959$. Programs used were SHELXTL (9) for structure solution, refinement, and molecular graphics, Bruker AXS SMART (diffractometer control), SAINT (integration), and SADABS (absorption correction) (10). The high R values are due to the poor quality of crystals; the intensity measurements were repeated on other crystals with the same results. Therefore, the calculated hydrogen atom positions must be considered with caution.



Results and discussion

Spectroscopic characterization of complexes 5–7

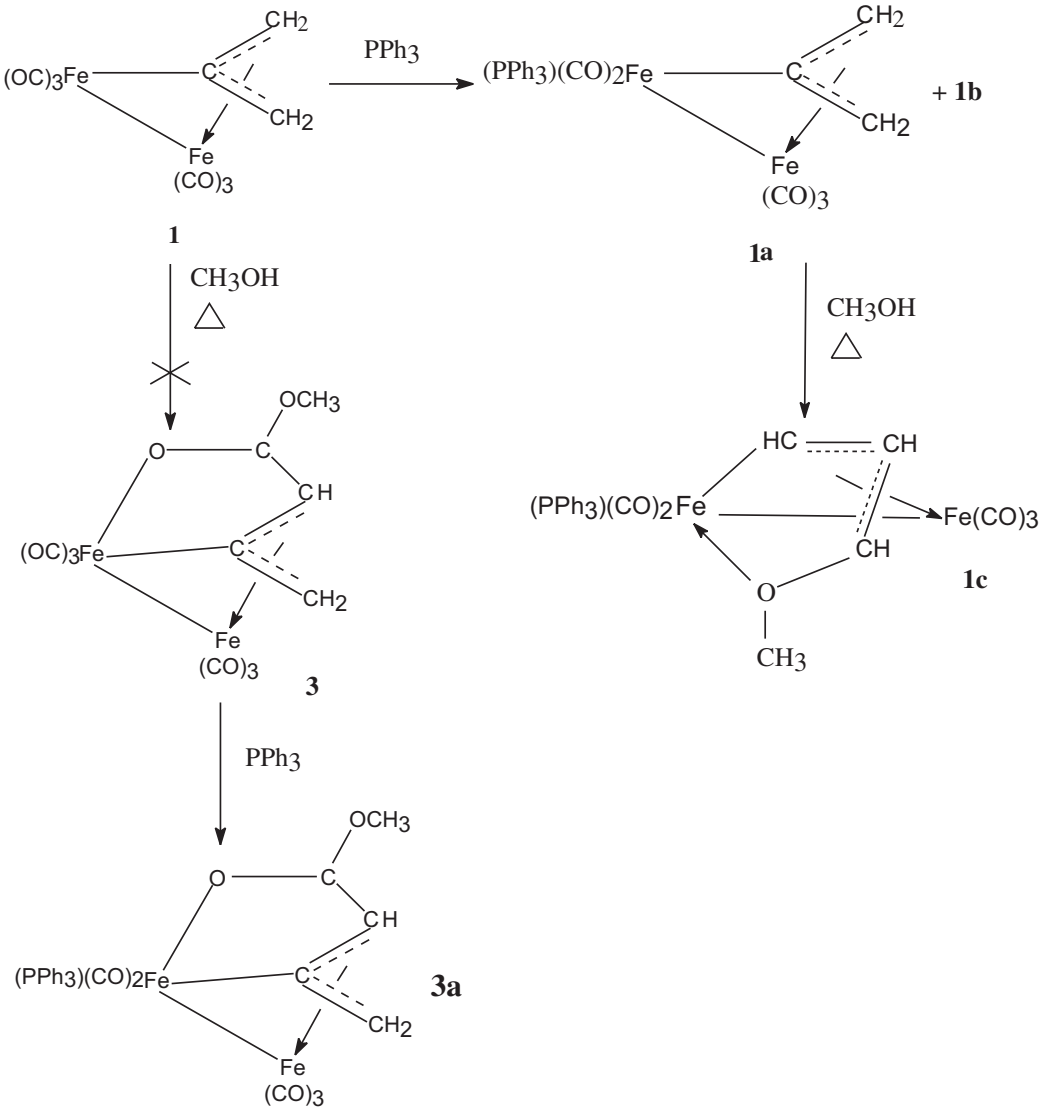
Complex **5** is obtained only from the isomeric ligands trimethylsilyl propargyl alcohol and propargyloxytrimethylsilane. The analytical and spectroscopic data (except for the ^1H NMR) are closely comparable with those of complex **4**. However, in view of the high complexity of the NMR spectrum, we cannot provide a structure. Complex **5** has an isomeric formula with respect to **4** (elemental analysis and mass spectrum) and the NMR spectrum could indicate that "**5**" is a nonseparated mixture of the two isomers. Attempts

© 2006 NRC Canada

Scheme 3.

at obtaining crystals suitable for X-ray analysis were unsuccessful.

Complexes **6** and **7** are the homologues of **1** and **3**, respectively, and contain a phenyl at the site of one of the hydrogens of the C_3 part of the organic ligand. The complexes are obtained from 3-phenyl-2-propyn-1-ol, which apparently behaves like the other alkynes, but does not lose the phenyl group. Complex **7** shows the same analytical data, but a different NMR with respect to the complex reported in ref. 7. Again, it could be an isomer obtained by a different position of the phenyl group in the structure.



Reactions leading to complexes 1 and 3

As previously discussed, the reactions of $Fe_3(CO)_{12}$ with propargylic alcohol and propargyl chloride give, as the main products, complexes **1**, **3**, and **4** and much smaller amounts of the allenylidene complex **2**[7]. No unequivocal evidence, both for the structure of **1** and for its role in the reaction pathways leading to **3**, was obtained. As shown in Scheme 2, two hypotheses can be advanced: (*i*) **1** would be a fragmentation product derived from **2**; however, complex **2** was obtained in yields not allowing a reactivity study, only from the reactions of propargylic alcohol and propargyl chloride. It was observed only in trace amounts in other reactions leading to medium yields of **1**. This could represent indirect evidence for **2** being a labile intermediate in the formation of **1** (as a by-product) and of **3** in a direct reaction. (*ii*) An alternative possibility could be that **1** is an intermediate in the formation of **3**.

The formation of complexes **1** and **3** has been therefore taken into account. The results show that complexes **1** and **3** are obtained in medium yields starting from propargylic alcohol, propargyl chloride, trimethylsilyl propargyl alcohol, propargyloxytrimethylsilane, monopropargylamine, and propargyl acetate (see Table 1). These alkynes can release -C≡CCH_2OH or HC≡CCH_2-, three-carbon atom fragments that could rearrange (and uptake hydrogen atoms) to form the H_2C=C=CH_2 ligand observed in **1** and **1a**. In contrast, complexes **1** and **3** are not obtained from trimethylsilyl acetylene and 1,1-diphenyl-2-propyn-1-ol, which can release only C_2 fragments. The reaction of $Fe_3(CO)_{12}$ with 1,1-diphenyl-2-propyn-1-ol in the same conditions reported for the other alkyne ligands yields only two products in trace amounts (not collected). The reaction of $Fe_3(CO)_{12}$ with trimethylsilyl acetylene gives mostly $Fe_3(CO)_{12}$ and very small yields of a orange, yellow, and red bands showing IR

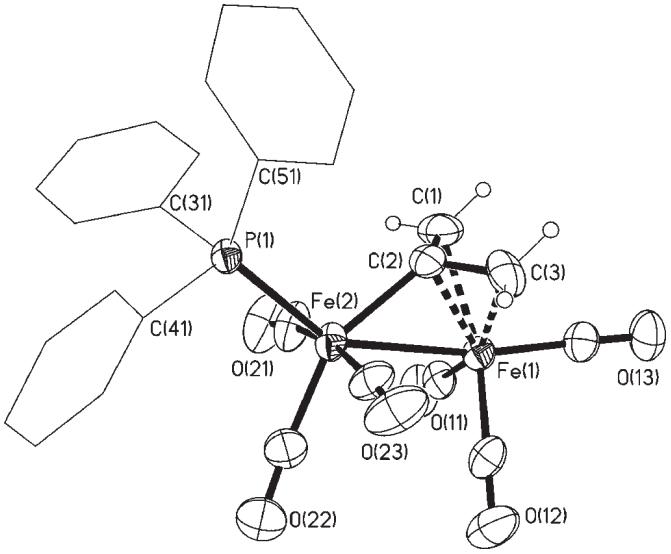
Scheme 4.

and NMR spectra different from those of **1** and of **3**. The "parent" alkynes forming complexes **1** and **3** are shown in Scheme 3.

Interestingly, 3-phenyl-2-propyn-1-ol, which would not easily release the C_6H_5 substituent, gives complexes **6** and **7**, which are the phenyl-containing homologues of **1** and **3**.

It is also worth noting that **1** and **3** are obtained from monopropargylamine: this also indicates that the NH_2 functionality can be lost. Finally, complex **3** is also obtained from propargyl acetate. Mathieu and co-workers (11) have described the synthesis of the acetate open-cluster derivative $Fe_3(CO)_{10}(PPh_2)[CHCCHC(OCH_3)O]$ containing a heterocyclic ring comparable with that of **3**. The complex was obtained from $[HFe_3(CO)_{11}]^-$ and $(CH_3COO)CH_2C{\equiv}CPPh_2$.

It is also interesting to observe that **1** (and **3**) are obtained when reacting propargylic alcohol and propargyl chloride both with $Fe_3(CO)_{12}$ and with $Fe(CO)_5$ in basic methanolic conditions. The intermediacy of the $[HFe_3(CO)_{11}]^-$ anion in these reactions can be hypothesized on the grounds of the following observations: (*i*) its formation from $Fe_3(CO)_{12}$ in the reaction conditions adopted was reported in the literature (1); (*ii*) its presence during the synthesis of $Fe_3(CO)_{12}$ starting from $Fe(CO)_5$ is well-established (12). It is also possible that, in the above reaction conditions, the radical anion $[Fe_3(CO)_{11}]^{\cdot-}$ (13) is present.



Reactions leading to 1a and 1b — Proposed structure of complex 1 on the basis of the X-ray structure of complex 1a

The reaction of complex **1** with triphenylphosphine leads to the monosubstituted **1a**, whose structure is discussed in the following, and to the disubstituted complex **1b** presumably bearing the two phosphine ligands on different iron atoms, as indicated by the ^{31}P NMR spectrum.

Complex **1**, when dissolved in heptane, heptane–toluene, or other solvents and kept at –30 °C, gives large and well-formed orange "crystals"; however, when the solvent is removed, even at low temperature, the crystals collapse quickly forming a thick oil. For **1** a structure is therefore proposed on the basis of analytical and spectroscopic data and on the

Fig. 1. ORTEP plot of $Fe_2(CO)_6(PPh_3)[\mu\text{-}\eta^3\text{-}(H_2CCCH_2)]$ (complex **1a**) with thermal ellipsoids (30% probability).

following observations: (*i*) **1** is formed from several alkynes that can loose a three-carbon atom fragment; (*ii*) in a recent report propargylic alcohol has been shown to react with triruthenium benzoquinoline complexes releasing a (coordinated) C_3H_4 unit (14), albeit different from that proposed for **1**; (*iii*) complex **1** shows a ^1H NMR spectrum indicating the presence of two nonequivalent CH_2 groups. Mass spectra of samples coming from reactions with different alkynes all showed a $P^+ = 348$ *m*/*z* corresponding to $Fe_2(CO)_7(C_3H_4)$. In the light of the structure of **1a** discussed in the following, we now think that the more probable structure is that shown in Scheme 3.

Reactions of complexes 1 and 1a with CH_3OH

Complex 1

These reactions have shown that under thermal conditions complex **1** does not react very easily with methanol. Only trace amounts of complex **3** were observed. Thus, complex **1** should be considered a side product, rather than an intermediate, in the formation of **3**.

Complex 1a

From this reaction, one can see that complex **1a** can add methanol, giving, however, a complex (**1c**) different from **3a**. For complex **1c**, we propose the structure shown in Scheme 4 on the basis of the analytical and spectroscopic results and by analogy with the previous reports of Mathieu and co-workers (11). Thus, complex **1a** is not an intermediate in the formation of the phosphine-substituted **3a**.

Reaction of complex 3 with PPh_3

The monosubstituted complex **3a** was isolated and characterized using spectroscopy; complex **3a** probably follows the behaviour of other ferrole-like complexes, where the phosphine substitution for CO occurs first at the iron atom σ bound to the organic ring (15).

Table 2. Some relevant bond distances (Å) and angles (°) for complex **1a**, $Fe_2(CO)_6(PPh_3)[\mu\text{-}\eta^3\text{-}(H_2CCCH_2)]$.

Bond distances (Å)	
Fe(1)—C(2)	1.952(5)
Fe(1)—C(3)	2.120(5)
Fe(1)—C(1)	2.123(6)
Fe(1)—Fe(2)	2.6479(10)
Fe(2)—C(2)	1.977(5)
Fe(2)—P(1)	2.2514(14)
P(1)—C(51)	1.824(4)
P(1)—C(31)	1.824(5)
P(1)—C(41)	1.835(5)
C(1)—C(2)	1.448(8)
C(2)—C(3)	1.384(8)
Bond angles (°)	
C(3)-C(2)-C(1)	112.5(6)
C(3)-C(2)-Fe(2)	119.4(5)
C(1)-C(2)-Fe(2)	117.9(5)

The crystal structure of 1a

The structure of **1a** is shown in Fig. 1 and significant distances and angles are given in Table 2. The complex is formed by two nonequivalent iron atoms, with an Fe—Fe distance of 2.648(1) Å.

The C_3H_4 ligand is coordinated both to Fe(1), as a formal $3e^-$ donor, and to Fe(2), as a formal $1e^-$ donor. Six COs are terminally bound to Fe(1) and to Fe(2), which is also bound to the PPh_3 ligand disposed cis with respect to C(2), in the less sterically and electronic demanding situation. When considering the C_3H_4 as a four-electron donor and the presence of an Fe—Fe bond, each iron atom would reach the 18-electron configuration. The Fe(2)-C(1)-C(2)-C(3) moiety deviates from planarity with a mean deviation of 0.10 Å. The Fe—C bond distances and their geometry agree with a formal description of a π interaction of Fe(1) with C(1)—C(2) and with C(2)—C(3) elongated double bonds and with a Fe(2)—C(2) σ interaction. This situation corresponds to a π-allyl moiety where a hydrogen atom is substituted by an iron atom. Allyl groups coordinated in this way are commonly found, especially in the nickel triad chemistry. Complex **1a** has been very presumably obtained upon simple substitution of a phosphine for a CO, suggesting a similar formula for **1**.[3]

Conclusions

The results obtained allow the unequivocal characterization of complex **1**. We have found that **1** is a by-product in the synthesis of **3**; it is presumably a fragmentation product of the allenylidenic complex **2**. Complex **1** does not react with methanol to give **3**. In contrast, **1a** gives a product (**1c**)

© 2006 NRC Canada

containing the fragments of methanol, albeit coordinated differently than in **3** or **3a**.

These results confirm the mechanism already proposed for the formation of **3** (see Scheme 2), that is, the intermediacy of complex **2** only. Formation of complexes containing methoxycarbonyl groups upon activation of CO under basic methanolic conditions seems to be a general trend. For example, recently we have observed that $Ru_3(CO)_{12}$ reacts with 1,4-dichloro-but-2-yne in basic methanolic conditions forming the complex $H_2Ru_3(CO)_9[H_2C{=}CC{\equiv}CC(=O)OCH_3]$ (16); the formation of this complex requires loss of chlorine and activation of CO. In our opinion, the mechanisms leading to this type of complex deserve further efforts towards being fully understood, especially in view of organometallic-mediated organic syntheses.

Last but not least, from the reactions described in this paper, complex **1a** was obtained. The structure of this complex is unprecedented and shows, once again, that alkynol-cluster chemistry may lead to unprecedented bonding modes for hydrocarbyls on metal clusters.

Determination of the location of naphthalene in the zeolite ZSM-5 host framework by solid-state $^{1}H/^{29}Si$ CP MAS NMR spectroscopy[1]

Colin A. Fyfe and Darren H. Brouwer

Abstract: The location of naphthalene in the zeolite ZSM-5 has been determined from solid-state $^{1}H/^{29}Si$ cross-polarization (CP) magic-angle-spinning (MAS) NMR data alone. With the peaks in the ^{29}Si spectrum assigned to the inequivalent Si sites in the zeolite from a two-dimensional INADEQUATE spectrum, the rates of cross polarization between the ^{1}H nuclei of the guest sorbate molecules and the ^{29}Si nuclei of the zeolite framework were used to determine the location of the naphthalene molecules by exploiting the proportional relationship between cross-polarization rate constants and $^{1}H/^{29}Si$ dipolar coupling second moments. The NMR structure determination was carried out on three different selectively deuterium-labeled naphthalene molecules (naphthalene-d_0, α-naphthalene-d_4, and β-naphthalene-d_4). The average of the molecule locations in agreement with all three sets of NMR data was found to be in excellent agreement with an existing single crystal XRD structure of the naphthalene–ZSM-5 complex.

Key words: solid-state NMR, cross polarization, zeolites, host–guest complexes, structure determination.

Résumé : On a déterminé la location du naphtalène dans le zéolite ZSM-5 en ne faisant appel qu'à des données de RMN à l'état solide, à l'angle magique de rotation et une polarisation croisée $^{1}H/^{29}Si$. Après avoir attribuer les pics du spectre de ^{29}Si aux sites de silicium inéquivalents de la zéolite en se basant sur un spectre bidimensionnel « INADEQUATE », on a utilisé les vitesses de polarisation croisée entre le noyau ^{1}H des molécules du sorbat invité et les noyaux de ^{29}Si du squelette de zéolite pour déterminer la location des molécules de naphtalène en exploitant la relation proportionnelle entre les constantes de vitesse de polarisation croisée et les deuxièmes moments du couplage dipolaire $^{1}H/^{29}Si$. On a déterminer la structure RMN sur trois molécules de naphtalènes marquées sélectivement de trois façons différentes (naphtalène-d_0, α-naphtalène-d_4, β-naphtalène-d_4). On a trouvé que les locations moyennes de la molécule dans les trois ensembles de données RMN sont en excellent accord avec une structure XRD sur un cristal unique qui a été déterminée antérieurement pour le complexe naphtalène–ZSM-5.

Mots clés : RMN à l'état solide, polarisation croisée, zéolites, complexes hôte–invité, détermination d'une structure.

[Traduit par la Rédaction]

Introduction

A full understanding of the interactions between guest species and host zeolite frameworks, central to the synthesis and applications of zeolites, requires detailed structures for these complexes. For most zeolites, structure determination by X-ray diffraction (XRD) is limited because of their microcrystalline nature and the weak contribution, relative to the framework, of the guest species to the X-ray scattering intensity. Solid-state NMR spectroscopy offers an alternative and complementary method for structure determinations of zeolite host–guest complexes.

We have developed an approach to determine the locations of rigid organic sorbate molecules in highly siliceous zeolite frameworks from solid-state $^{1}H/^{29}Si$ cross-polarization (CP) magic-angle-spinning (MAS) NMR data (1, 2).[4] The peaks in a high-resolution ^{29}Si MAS NMR spectrum of the zeolite framework are first assigned to the inequivalent Si sites in the structure by performing (3) and analyzing (4, 5) a two-dimensional ^{29}Si INADEQUATE correlation experiment (6, 7). The relative rates of $^{1}H/^{29}Si$ cross polarization measured between the ^{1}H nuclei of the sorbate molecules and the ^{29}Si nuclei of the zeolite framework (8) are then used to determine the location of the sorbate molecule by exploiting the proportional relationship (9) that exists between these experimentally measured CP rate constants and calculated $^{1}H–^{29}Si$ dipolar coupling second moments (10).

This proportional relationship between CP rate constants and second moments in zeolite–sorbate complexes was first demonstrated for the high-loaded *p*-xylene–ZSM-5 complex (1, 2), a complex with a previously known structure, and then used to determine the previously unknown location of

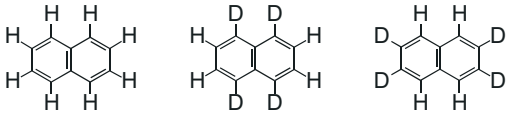
p-xylene in the low-loaded complex with ZSM-5 (2), which was shown to be correct by a subsequent structure determination from single crystal XRD data.[5] An improved protocol for this structure determination approach is described in detail in footnote 4 where the structure of the low-loaded *p*-dichlorobenzene–ZSM-5 complex was determined by solid-state NMR and again shown to be in excellent agreement with an existing single crystal XRD structure. It was also shown that this approach is quite robust, being relatively insensitive to temperature and the exact coordinates of the zeolite framework. We have also shown that paramagnetic molecular oxygen in the vacant spaces of the zeolite–sorbate complexes can give rise to severe line broadening of the ^{29}Si spectra (11) and that rapid ^{1}H $T_{1\rho}$ relaxation can lead to complications in the measurement of the CP rate constants (8).

In the present paper, we describe the determination of the exact location of naphthalene in zeolite ZSM-5 from ^{1}H/^{29}Si CP MAS NMR data using the general method that we have developed. Since a reliable single crystal XRD structure to which these results can be compared has been previously reported (12), this investigation serves to further evaluate the reliability of the approach There are also two lower-quality structures of the naphthalene–ZSM-5 complex derived from powder XRD, which are in general agreement with the single crystal XRD structure (13, 14).

Naphthalene is a very appropriate sorbate molecule with which to further evaluate the solid-state NMR structure determination method since it is a rigid molecule and is a significant departure, in terms of molecular structure, from the previously studied *p*-disubstituted aromatic molecules (2).[4] In addition, it is possible to obtain selectively deuterated naphthalenes so that ^{1}H/^{29}Si CP MAS NMR data can be collected on systems that have differently localized ^{1}H polarization sources, increasing the amount of structural information available from the solid-state NMR data. The experiments and analyses have been carried out on ZSM-5 complexes with three types of naphthalene molecule: completely protonated naphthalene (naph-d_0, **1**) and two complementary selectively deuterated naphthalenes (α-naph-d_4 (**2**) and β-naph-d_4 (**3**)). The polarization transfer profile to the framework ^{29}Si nuclei will be unique to each naphthalene and the acceptable locations will be those that best agree with the ^{1}H/^{29}Si CP MAS NMR data sets from all three naphthalene–ZSM-5 complexes (Scheme 1).



There is also practical interest in the structure of the naphthalene–ZSM-5 complex since the acid form of ZSM-5 has been reported to be a good catalyst for the shape-selective alkylation of naphthalene with methanol to give 2-methylnaphthalene, which is a good starting material for vitamin K synthesis (14).

Experimental section

Sample

The selectively deuterated naphthalene molecules (α-naphthalene-d_4 and β-naphthalene-d_4) were synthesized according to the procedure of Davis and Garnett (15), using a homogeneous $PtCl_4^-$ catalyst to selectively exchange the H or D atoms in the β positions of naphthalene and naphthalene-d_8 with D_2O and H_2O, respectively. The solutions for these selective exchanges consisted of 0.015 mol/L K_2PtCl_4 and 0.02 mol/L NaCl in 1:1 mixtures of H_2O–CH_3COOH or D_2O–CH_3COOD (made from 3:1 mixtures of H_2O or D_2O with acetic anhydride). A typical exchange reaction was carried out by mixing 0.4 g of naphthalene-d_8 or naphthalene-d_0 with 16 mL of the appropriate exchange solution and heating at 70 °C for about 24 h, after which the naphthalene was isolated by quenching with water and filtering. The exchanges were repeated four times with fresh solutions. Multiple exchanges of naphthalene-d_8 (Aldrich) with the $PtCl_4^-$ in H_2O–CH_3COOH solution resulted in α-naphthalene-d_4 as the β-deuterium atoms were selectively exchanged with protons. Likewise, multiple exchanges of naphthalene-d_0 (Aldrich) with $PtCl_4^-$ in D_2–CD_3COOD solution resulted in β-naphthalene-d_4 as the β protons were selectively exchanged with deuterium. The resulting samples were analyzed by ^{1}H solution NMR and mass spectrometry to confirm that the ^{1}H nuclei were primarily located in the desired locations and the majority of the molecules had three or four protons per molecule (see Supplementary data, Table S1).[6]

Scheme 1. Naphthalene molecules.

naph-d_0 **1** α-naph-d_4 **2** β-naph-d_4 **3**

A very highly siliceous and crystalline sample of ZSM-5 was used, which had peak widths of about 0.1 ppm in the ^{29}Si MAS NMR spectrum (16). The zeolite–naphthalene complexes had a maximum loading of four molecules per unit cell and were prepared by mixing an excess of the solid organic with about 200 mg of calcined zeolite powder in a prescored glass ampoule. The ampoule was evacuated on a vacuum line, flame-sealed, and then placed in an oven at between 80 and 100 °C for at least 12 h to equilibrate.

Solid-state NMR

Solid-state NMR experiments were carried out on a Bruker AVANCE DSX-400 NMR spectrometer operating at frequencies of 400.13 MHz for ^{1}H and 79.495 MHz for ^{29}Si, using a Bruker double-frequency CP MAS probe modified with a standard 7 mm stator system from Doty Scientific. ^{29}Si chemical shifts were referenced to tetramethylsilane using Q_8M_8 as a secondary reference (17). Low-temperature MAS was achieved by using precooled nitrogen gas as the bearing gas and room temperature air as the drive gas with the temperature controlled and monitored by a heater–thermocouple system in the probe. The Hartmann–Hahn CP match condition for ^{1}H/^{29}Si CP was initially set up on the

Q_8M_8 reference sample and subsequently checked on the sample itself. The power levels corresponding to the maximum of a relatively broad matching profile were approximately 30 kHz for both ^{1}H and ^{29}Si. ^{1}H decoupling applied during the acquisition time was found to have no noticeable effect on the width of the peaks in the ^{29}Si spectrum, even at the lowest temperatures used, so it was not applied (with the exception of the mixing and evolution times in the ^{29}Si INADEQUATE experiment). All spectra were collected using a spinning rate of approximately 2 kHz. Additional experimental details for the individual spectra are provided in the figure captions.

Data analysis

The deconvolution of the spectra, fitting of the CP and CP drain curves, and the determination of the guest molecule locations were performed using programs written for Mathematica version 3.0 (18).

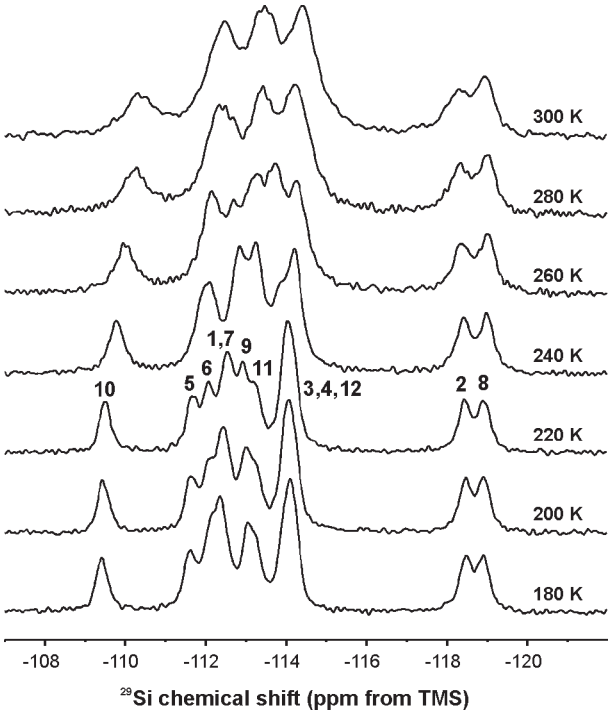
Results and discussion

To determine the best temperature at which to carry out the experiments, a series of ^{29}Si MAS NMR spectra of the ZSM-5–naph-d_0 complex were collected at temperatures between 180 and 360 K, and selected spectra between 180 and 300 K are displayed in Fig. 1. The spectra are not as well-resolved as previous examples (2),[4] and the application of ^{1}H decoupling during the acquisition did not improve the resolution. The line broadening of the ^{29}Si resonances is most likely a result of short T_2 relaxation times arising from the presence of paramagnetic molecular oxygen in the zeolite cavities (11), with the temperature dependence of the line broadening reflecting the changing motions of the oxygen molecules. It should also be noted that the temperature dependence of the line broadening is different from ZSM-5 complexes with *p*-disubstituted aromatics in which the highest resolution is observed at room temperature and very broad spectra are observed around 200 K (11),[4] suggesting that the naphthalene molecules cause a different motional behavior of the oxygen molecules in the zeolite cavities.

The peaks are best resolved at 220 K, so all subsequent experiments were carried out at this temperature. In terms of spectral resolution, these spectra are on the limit from which one could hope to determine a reliable sorbate–zeolite framework structure by solid-state ^{1}H/^{29}Si CP MAS NMR, since only 5 of the 12 ^{29}Si peaks can be resolved with any reliability at all. However, by using data from the different deuterated naphthalene molecules, the number of independent observations is increased, thus increasing the reliability of the structure determination.

The assignment of the ^{29}Si spectrum at 220 K was accomplished using the two-dimensional INADEQUATE experiment (Fig. 2) with a previously described algorithm that was developed to obtain all possible assignment sets consistent with the 2D data (4, 5). Due to the large number of overlapping peaks in the present two-dimensional INADEQUATE spectrum, there are 34 possible sets of peak assignments that are consistent with the observed correlations. However, only three of these assignments are consistent with the assignments for other zeolite–sorbate complexes, with the low-field peaks assigned to Si8 and Si2 and a high-field peak

Fig. 1. Quantitative variable-temperature ^{29}Si MAS NMR spectra of the ZSM-5–naph-d_0 complex. For each spectrum, 16 scans were acquired with 45° pulses, 5 s recycle delay, and no ^{1}H decoupling applied during acquisition. The peak assignments shown for the spectrum at 220 K are from the INADEQUATE experiment shown in Fig. 2.



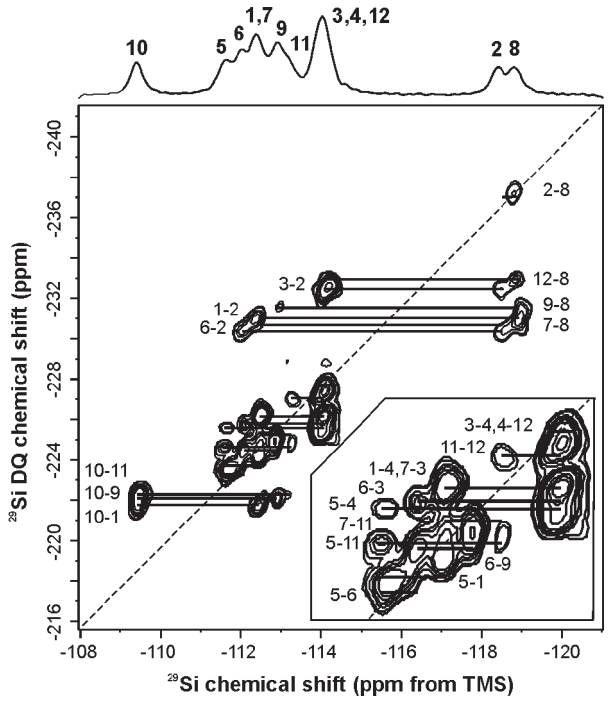


Fig. 2. Two-dimensional ^{29}Si INADEQUATE spectrum of the ZSM-5–α-naph-d_4 complex. See text for a discussion of the peak assignments. Forty experiments, each with 3200 scans and 2 s recycle delay, were acquired in t_1. The sweep widths in f_2 and f_1 were 1040 and 2080 Hz, respectively. The echo delay time during the double quantum preparation period was 14.4 ms.

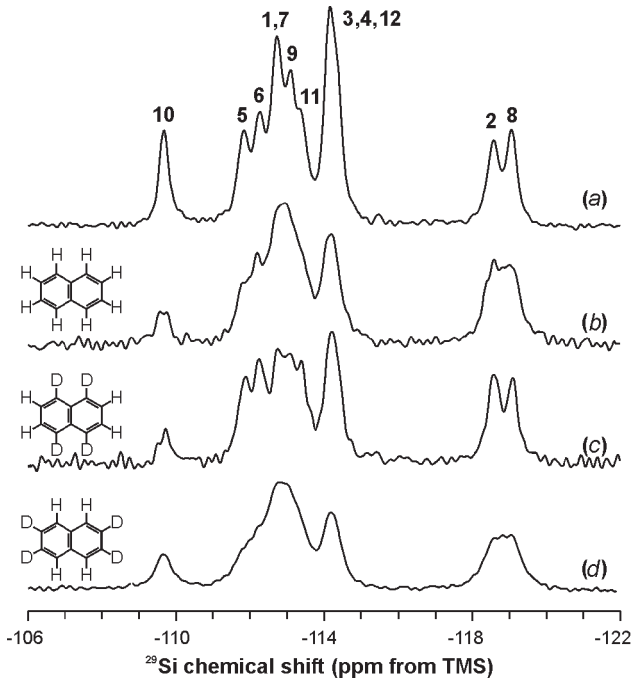
assigned to Si10 (6).[4] Furthermore, only these three assignments show a strong correlation between ^{29}Si chemical shifts and mean Si—Si distances (19), using the ZSM-5–naphthalene single crystal structure data (12) as the source for the Si—Si distances. The three assignment sets are identical with respect to the identity of all of the resolved peaks, but are different with respect to the identity of the unresolved peaks at –112.4 and –114.0 ppm, which could be assigned to {1,7} and {3,4,12} or {1,12} and {3,4,7} or {1,3} and {4,7,12}. During the structure determination (see the following), all three assignment sets were tested and the assignment presented in Fig. 2 was found to give the best agreement between the predicted and experimental ^{1}H/^{29}Si cross-polarization spectra.

With the peaks in the ^{29}Si spectrum assigned to specific Si sites in the zeolite framework, it is now possible to use the ^{1}H/^{29}Si CP MAS NMR experiment to probe the locations of the ^{1}H nuclei with respect to these various Si sites, since the magnetization is transferred in a distance-dependent manner. In Fig. 3, the ^{1}H/^{29}Si CP MAS NMR spectra (collected at 220 K and with a contact time of 10 ms) for ZSM-5 loaded with naph-d_0, α-naph-d_4, and β-naph-d_4 are compared to a quantitative ^{29}Si MAS NMR spectrum. The relative intensities in these CP spectra reveal that some ^{29}Si nuclei are clearly closer to the source ^{1}H nuclei than others. For example, in all the CP spectra, the peaks for Si2 and Si8 are enhanced and that of Si10 is discriminated against, indicating that the naphthalene molecules are not located in the zigzag channels, but rather somewhere in the straight channels, since Si2 and Si8 are on the surface of the straight channel and Si10 is found on the surface of the zigzag channel. Furthermore, there are significant differences between the CP spectra when the ^{1}H nuclei are in different positions of the naphthalene molecules. For example, Si2 is enhanced more than Si8 for the α-naph-d_4 sample, while the signals for Si5 and Si6 are quite weak for the sample. It should be noted that the relative intensities of the peaks in the α- and β-naph-d_4 spectra cannotbe directly compared with those in the naph-d_0 spectrum owing to the larger number of protons involved in the interactions in the latter case.

The ^{29}Si relaxation times were also measured for the various ^{29}Si peaks (see Table 1). The spectra with the poorest resolution (Figs. 3*b* and 3*d*) have the shortest ^{29}Si T_2 relaxation times, indicating that the line broadening of the ^{29}Si resonances is a relaxation effect, most likely owing to paramagnetic molecular oxygen (11). The differences in the spectral resolution for these three samples may have arisen from the exact loading of the naphthalene molecules or the concentration of oxygen in the zeolite cavities. For all three samples, Si8 consistently has a much longer ^{29}Si T_1 relaxation time compared with the other Si peaks, especially compared with Si5 and Si6. If paramagnetic molecular oxygen is the relaxation source, this observation would suggest that the oxygen molecules are in the zigzag channels and the naphthalene molecules are in the channel intersection, as was previously found for the pDBB–ZSM-5 structure (11).



There are subtle details in the measurement of ^{1}H/^{29}Si CP rate constants in zeolite–sorbate complexes that must be accounted for (8). Normally, the rate of ^{1}H/^{29}Si cross polarization is measured by performing a variable contact time ^{1}H/^{29}Si CP MAS experiment and plotting the ^{29}Si peak areas as functions of the contact time. The contact time dependence of the S spin magnetization during $I \rightarrow S$ cross polarization (where the I spins (^{1}H) are abundant and the S spins (^{29}Si) are rare) is described by the following expression (20):

$$[1] \qquad S_{CP}(t) = I_0 \frac{k_{IS}}{(k_{IS} + k_S) - k_I}(e^{-k_I t} - e^{-(k_{IS}+k_S)t})$$

where k_I and k_S are the rate constants for spin-lock relaxation ($T_{1\rho}$) of the I and S spins, respectively, k_{IS} is the rate of cross polarization between the I and S spins, and I_0 reflects the initial magnetization of the I spins. For most systems, the increase in the S spin magnetization is governed by the CP rate constant k_{IS} (assuming k_S is small), and its decay is governed by k_I, the $T_{1\rho}$ relaxation of the I spins. This normal situation is termed the "fast CP regime". However, there exists a "slow CP regime" (21) in which the rate of I spin $T_{1\rho}$ relaxation is fast compared with the rate of $I \rightarrow S$ cross polarization ($k_I > k_{IS}$) such that the dynamics of the S spin magnetization in the CP curve is reversed from the usual assumptions: the rate of growth of the S spin magnetization is governed by k_I, while its decay is governed by $k_{IS} + k_S$.

Due to the presence of paramagnetic oxygen in the cavities of the zeolite–sorbate complexes (11), ^{1}H and ^{29}Si spin lock relaxation can occur quite rapidly, while the rate of ^{1}H/^{29}Si cross polarization can be slow since the dipolar interactions between the ^{1}H nuclei of the sorbate molecules and the ^{29}Si nuclei of the zeolite framework are quite weak. It is important to recognize the slow CP regime in order for

Fig. 3. Comparison of the ^{1}H/^{29}Si CP MAS NMR spectra to the quantitative ^{29}Si MAS NMR spectrum at 220 K. (*a*) Quantitative ^{29}Si MAS NMR spectrum of ZSM-5–α-naph-d_4 (64 scans, 12 s recycle delay, 90° pulses); ^{1}H/^{29}Si CP MAS NMR spectra of ZSM-5 loaded with (*b*) naph-d_0, (*c*) α-naph-d_4, and (*d*) β-naph-d_4 (10 ms contact times, 320–400 scans, 1 or 2 s recycle delays). ^{1}H decoupling was not applied during acquisition.

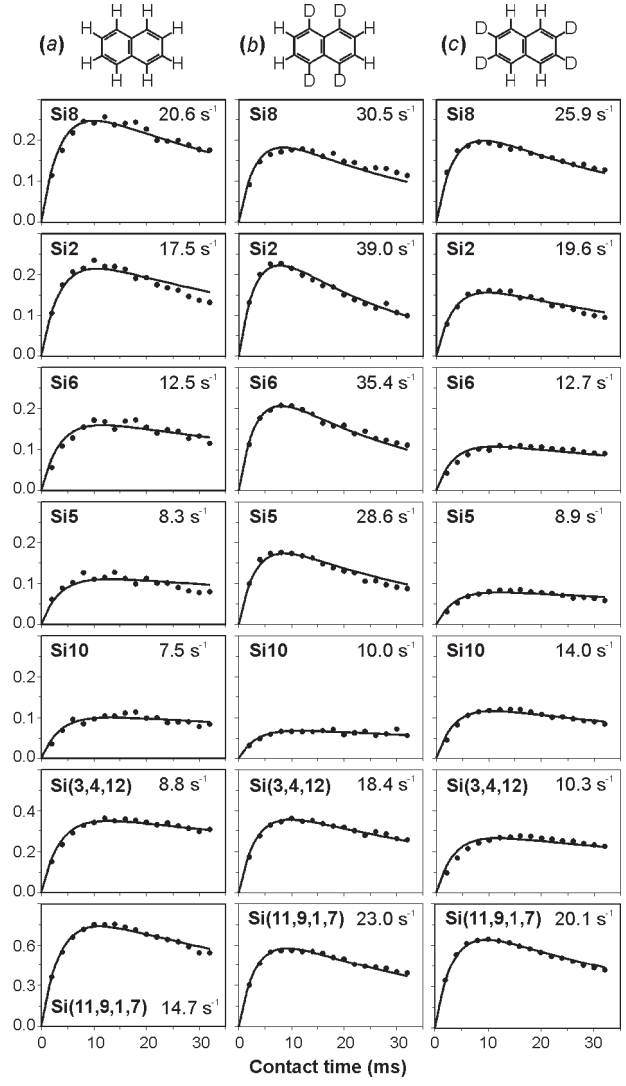
[a]Spectrum fitting parameters determined from a quantitative ^{29}Si MAS NMR spectrum.
[b]Relaxation parameters determined from ^{29}Si saturation recovery (T_1), spin echo (T_2), and spin-locking ($T_{1\rho}$) experiments.
[c]CP rate constants determined from ^{1}H/^{29}Si CP drain (k_{IS}) and standard CP (k_{IS}') experiments.

the measured CP rate constants to be correct, as an analysis assuming normal fast CP may lead to erroneous measurements.



A series of ^{1}H/^{29}Si CP MAS NMR experiments at varying contact times were carried out on the three ZSM-5–naphthalene complexes at 220 K. The intensities for each Si peak were extracted, using peak positions and widths determined from quantitative ^{29}Si spectra, and plotted as functions of the contact time as shown in Fig. 4. There are a number of characteristics of these CP curves that indicate the CP dynamics are in the slow CP regime. Firstly, the CP signal intensities are only on the order of about 20% of those obtained in a quantitative ^{29}Si spectra (rather than being enhanced by up to a factor of $\gamma_H/\gamma_{Si} = 5$), indicating that the CP process is quite inefficient. Furthermore, all of the curves reach their maximum intensities at approximately the same contact time, indicating that the rate of growth of the curves is governed by k_I, the ^{1}H $T_{1\rho}$ relaxation time, which is the same for each curve since all ^{29}Si nuclei are polarized from the same ^{1}H source. An additional characteristic of the slow CP regime is that the maximum intensities of the curves vary. This arises mainly from the varying CP rate constants since the preexponential term in eq. [1] is largely determined by k_{IS} in the slow CP regime, assuming the ^{29}Si nuclei are polarized from the same ^{1}H source such that I_0 and k_I are the same for each curve. The final characteristic is that the rates of decay of the CP curves vary, indicating the slow CP regime since these rates of decay are governed by the different CP rate constants, and perhaps different ^{29}Si $T_{1\rho}$ relaxation times.

The CP rate constants for each Si peak were extracted from the CP curves presented in Fig. 4 by fitting the data to eq. [1], assuming the spin dynamics were in the slow CP regime, neglecting the contribution from ^{29}Si $T_{1\rho}$ relaxation ($k_S = 0$ s^{-1}), and using identical values of I_0 and k_I for all CP curves. In all three samples, the ^{1}H $T_{1\rho}$ relaxation is quite rapid ($k_I \sim 300$ s^{-1}; $T_{1\rho} \sim 3$ ms) compared with the CP rate constants ($k_{IS} \sim 10$ s^{-1}), clearly indicating the slow CP regime. However, even when the slow CP regime is correctly recognized, it is difficult to obtain absolute values for the CP rate constants from fits to standard CP curves, especially when $k_I < k_{IS} \approx k_S$, since k_{IS} is highly correlated to I_0, the contribution from ^{29}Si $T_{1\rho}$ relaxation (k_S) is ignored, and because it is difficult to obtain reliable data at very long contact times. Consequently, the CP rate constants obtained from these CP curves are considered to be relative values and are denoted by k_{IS}'.

To circumvent these potential problems, we have found that absolute CP rate constants in zeolite–sorbate complexes are best measured with ^{1}H/^{29}Si CP "drain" or "depolarization" experiments (22, 23), when possible (8). The dynamics of the S spin magnetization during a cross-polarization drain experiment are described by an exponential decay:

© 2006 NRC Canada

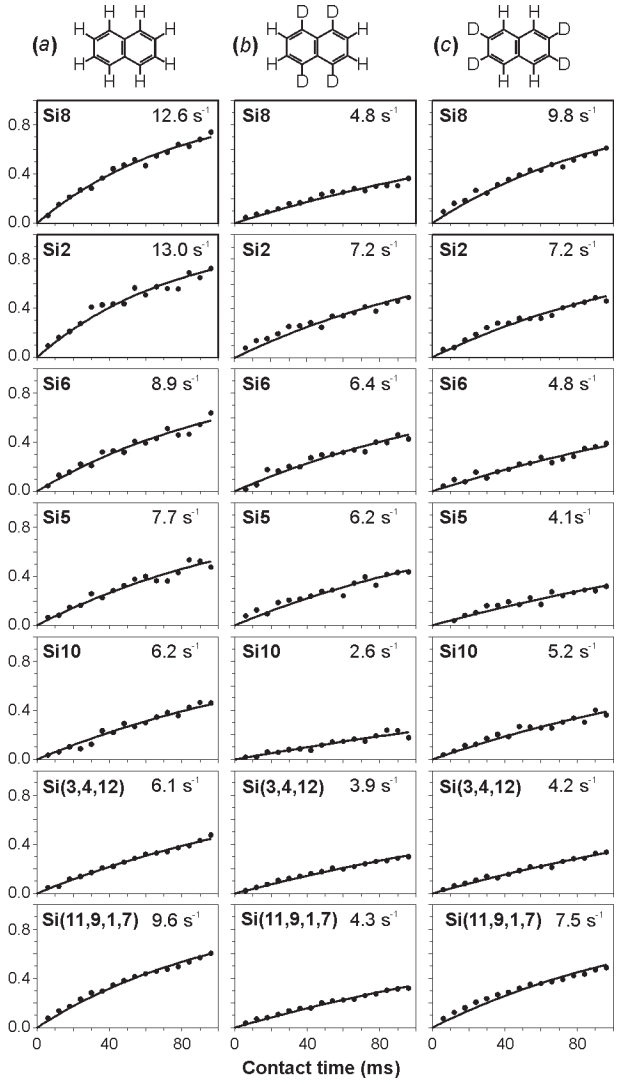


Fig. 4. $^1H/^{29}Si$ cross-polarization curves for the ZSM-5–naphthalene complexes at 220 K: (*a*) naph-d_0; (*b*) α-naph-d_4; and (*c*) β-naph-d_4. The signal intensities are plotted as S_{CP}/S_Q, where S_{CP} is the cross-polarization intensity and S_Q is the intensity of the peaks in the corresponding quantitative ^{29}Si MAS NMR spectrum. The curves were fit to eq. [3] (with $k_S = 0$) using the relative CP rate constants (k_{IS}') indicated and the following I_0 and k_I values: (*a*) $I_0 = 3.66$, $k_I = 275\ s^{-1}$ ($T_{1\rho} = 3.6$ ms); (*b*) $I_0 = 2.34$, $k_I = 303\ s^{-1}$ ($T_{1\rho} = 3.3$ ms); (*c*) $I_0 = 2.89$, $k_I = 300\ s^{-1}$ ($T_{1\rho} = 3.3$ ms). At each contact time, between 320 and 400 scans were collected with a recycle delay of 1 or 2 s.

$$[2] \qquad S(t) = S(0)e^{-(k_S + k_{IS})t}$$

where $S(0)$ is the initial magnetization of the S spins. The exponential decay resulting from the CP drain experiment without the contact pulse applied on the I spins ("reference" experiment, S_0) is due entirely to S spin $T_{1\rho}$ relaxation and has the rate constant k_S since $k_{IS} = 0$. The exponential decay resulting from the CP drain experiment with the contact pulse applied on the I spins (drain experiment, S_d) has the rate constant $k_{IS} + k_S$. The analysis of the CP drain dynamics can be simplified by plotting the data as a normalized difference plot (22), $\Delta S/S_0$, where $\Delta S = S_0 - S_d$, such that the CP rate constant is the only variable in the fit to the data.

Fig. 5. Normalized difference cross-polarization drain curves for the ZSM-5–naphthalene complexes at 220 K: (*a*) naph-d_0; (*b*) α-naph-d_4; and (*c*) β-naph-d_4. The signal intensities are plotted as $\Delta S/S_0$. The curves were fit to eq. [3] using the rate constants indicated. At each contact, reference and drain spectra were acquired with 48 scans with a 12 s recycle delay.

$$[3] \qquad \Delta S/S_0 = 1 - e^{-k_{IS}t}$$

Absolute values for the cross-polarization rates are thus obtained from these normalized CP drain curves, since the contributions from I_0 and both I and S $T_{1\rho}$ relaxation are removed

A series of $^1H/^{29}Si$ CP drain experiments at varying contact times were carried out on the three ZSM-5–naphthalene complexes at 220 K. The intensities for each Si peak were extracted using peak positions and widths determined from quantitative ^{29}Si spectra, and plotted as functions of the contact time as shown in Fig. 5. These curves were fit to eq. [3] to obtain absolute values for the CP rate constants, denoted as k_{IS}. All of the fitting parameters are summarized in Table 1. Although the CP rate constants obtained from both the

© 2006 NRC Canada

$^1H/^{29}Si$ CP and CP drain experiments could potentially be used for structure determination,[4] only the values determined from the CP drain data were subsequently used in the present work to determine the locations of naphthalene molecules in ZSM-5, since these values are considered to be more reliable.

The basis of the strategy to determine the locations of organic guest molecules in host zeolite frameworks from $^1H/^{29}Si$ cross-polarization experiments is the relationship between the measured CP rate constants and the $^1H—^{29}Si$ internuclear distances, via the heteronuclear second moments (M_2) of the dipolar line shapes (9).

$$[4] \qquad k_{IS} \propto M_2 \propto \sum r_{IS}^{-6}$$

If both the I and S nuclei are spin –1/2, the heteronuclear second moment for a powder can be calculated according to Van Vleck (10) as a pair-wise summation of the inverse sixth powers of the $I—S$ internuclear distances (in units of Hz^2).

$$[5] \qquad M_2 = \left(\frac{1}{2\pi}\right)^2 \frac{4}{5}\left(\tfrac{1}{2}\gamma_I\gamma_S\hbar\frac{\mu_0}{4\pi}\right)^2 \sum \frac{1}{r_{IS}^6}$$

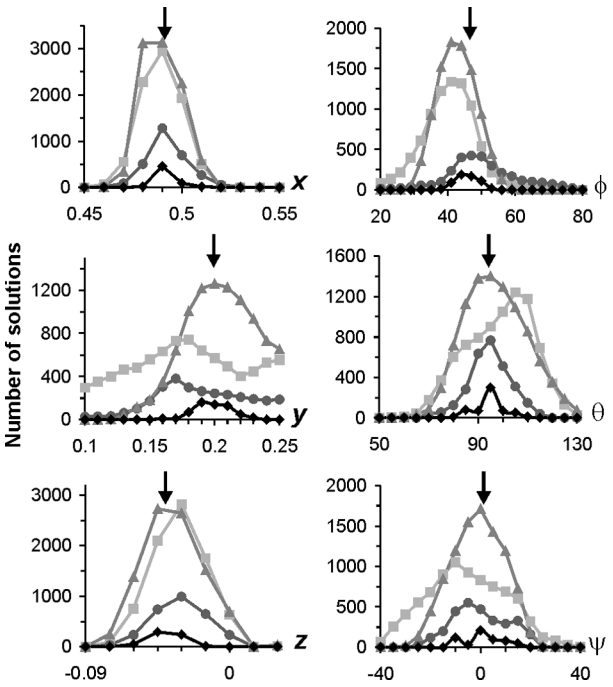
The strategy for determining the guest molecule locations in host zeolite frameworks is essentially to find all possible locations of the guest molecule for which the condition in eq. [4], the proportionality between the set of experimental $^1H/^{29}Si$ CP rate constants and the set of heteronuclear second moments calculated from the H—Si distances, is satisfied (1, 2).[4]

Using the approach outlined in footnote 4, the void space of the ZSM-5 framework was searched for locations of the naphthalene molecules that (*a*) were physically reasonable, (*b*) had a strong linear correlation between the experimental CP rate constants and the calculated second moments, and (*c*) gave good agreement between experimental and the intensities of the groups of overlapping peaks predicted from the linear correlation between k_{IS} and M_2. The last condition was tested for each of the three possible sets of peak assignments that differed only in the identities of the overlapping peaks.

The coordinates for the ZSM-5 framework were taken from the single crystal XRD structure of the ZSM-5–naphthalene complex determined by van Koningsveld and Jansen (12). It should be noted that we have previously shown that it is not necessary to have the exact zeolite framework structure for the structure determination to be successful.[4] For the geometry of the naphthalene molecules, the C—H and C—C bond lengths were assumed to be 1.00 and 1.39 Å, respectively, while the C-C-C and H-C-C angles were assumed to be 120°. The locations of the rigid guest molecules are defined by six parameters: x, y, and z are fractional atomic coordinates of the centre of the molecule, and ϕ, θ, and ψ are Euler angles describing the rotational orientation of the molecule, as described in footnote 4.

Initial tests revealed that high degrees of linear correlation between k_{IS} and M_2 only existed for locations near the intersection of the straight and zigzag channels. Therefore, this region was investigated in detail with a total of 9.6×10^6 locations of the naphthalene molecules tested in the range $0.45 \le x \le 0.55$, $0.10 \le y \le 0.25$, and $-0.09 \le z \le 0.03$, in steps of 0.2 Å, and with Euler rotations of $20° \le \phi \le 80°$, $50° \le \theta \le 130°$, and $-40° \le \psi \le 40°$ in steps of 3° (ϕ) or 5° (θ and ψ). CP rate constants obtained from the $^1H/^{29}Si$ CP drain experiments were used. Structure determinations were performed for the three individual data sets of $^1H/^{29}Si$ CP drain experiments on the different deuterated naphthalene molecules. Locations were selected that had all atoms of the naphthalene molecule >2 Å from the zeolite framework atoms, gave a linear correlation of $r^2 \ge 0.96$ between experimental k_{IS} and calculated M_2 values, and predicted the intensities of the groups of overlapping peaks within the 95% prediction intervals. The intersection of the resulting three sets of naphthalene locations yielded the locations that are consistent across all three sets of cross polarization data.

Fig. 6. Distributions of the locations of naphthalene in ZSM-5 for naph-d_0 (squares), α-naph-d_4 (circles), and β-naph-d_4 (triangles), which are consistent with the $^1H/^{29}Si$ CP drain data (with $r^2 \ge 0.96$). The black diamonds indicate the distribution of locations that are consistent with *all three* sets of data. The arrows indicate the average of these locations that are consistent with all three sets of data (x = 0.492 ± 0.005, y = 0.199 ± 0.014, z = –0.040 ± 0.10, ϕ = 46° ± 3°, θ = 94° ± 6°, and ψ = 1° ± 8°).



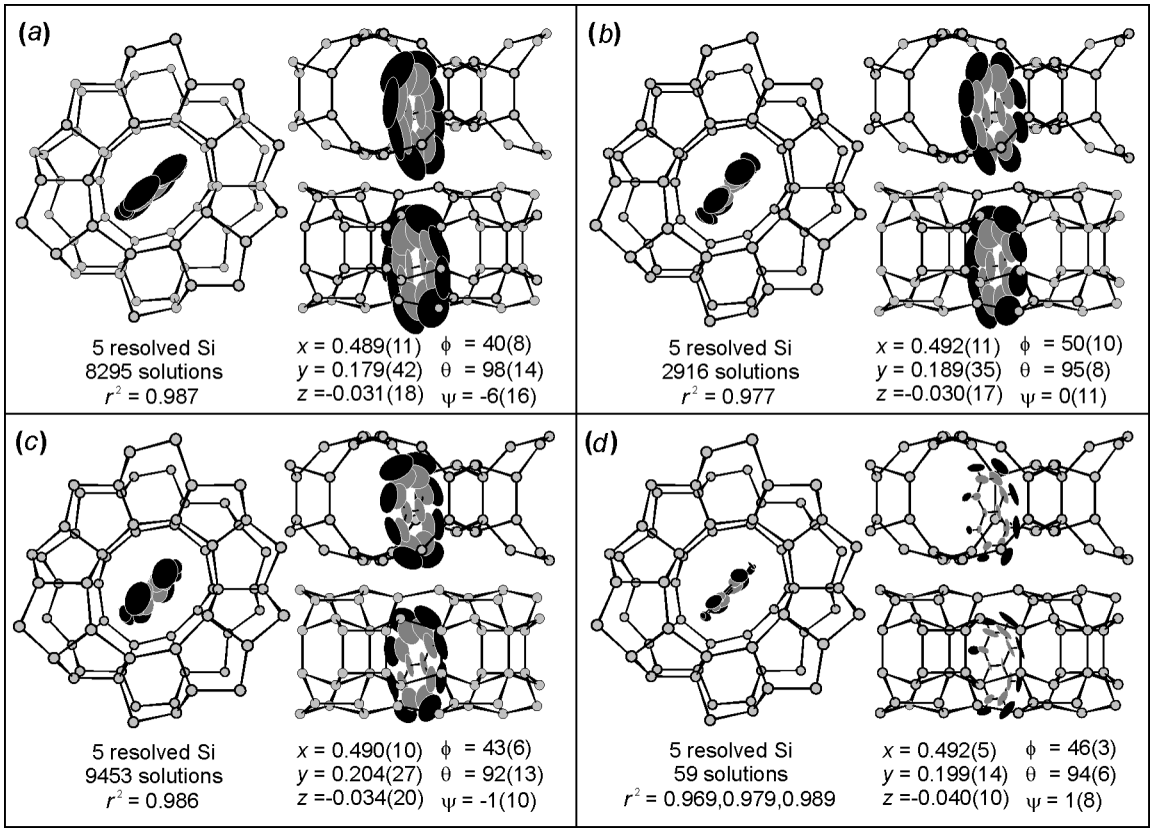


Figure 6 summarizes the range of possible locations that meet the three criteria (with $r^2 \ge 0.96$) found for each $^1H/^{29}Si$ CP drain data set. Each of these distributions was assumed to approximate a normal distribution, so that an "average" location (with standard deviations) could be proposed. These average locations (with error ellipsoids) in the ZSM-5 framework are presented in Fig. 7. The average structures derived from each data set are in quite good agreement. The structures from the completely protonated naph-d_0 data are the least defined, especially along the y axis. This is not unexpected since the eight protons are placed all round the periphery of the molecule. The structures from the deuterated naphthalene data are better defined, especially those from the α-naph-d_4 system,

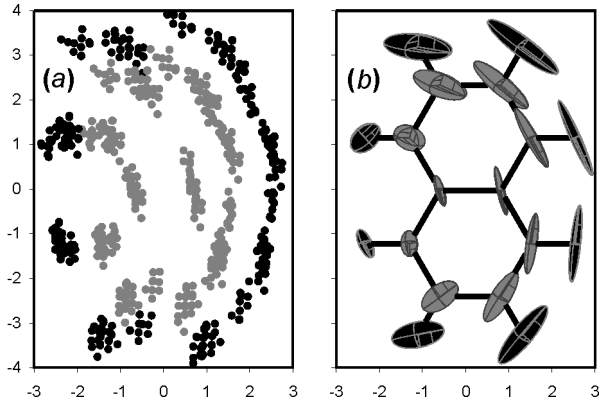
Fig. 7. Average locations (with 50% error ellipsoids) of naphthalene in ZSM-5 determined from $^{1}H/^{29}Si$ CP drain data collected on ZSM-5 loaded with (*a*) naph-d_0, (*b*) α-naph-d_4, and (*c*) β-naph-d_4. (*d*) The average location of naphthalene in ZSM-5 consistent with all three sets of $^{1}H/^{29}Si$ CP drain data (the overlap between *a*, *b*, and *c*). The standard deviation in the last digits for each parameter is given in parentheses.



illustrating the benefit of having well-localized sources of polarization.

When these three sets of locations are examined, there are only 59 locations that fulfill all three criteria (with $r^2 \geq 0.96$) for all three sets of experimental CP drain data. The distributions of these locations are presented in Fig. 6. The average of these locations (indicated by the arrows in Fig. 6) is at $x = 0.492 \pm 0.005$, $y = 0.199 \pm 0.014$, $z = -0.040 \pm 0.10$, $\phi = 46° \pm 3°$, $\theta = 94° \pm 6°$, and $\psi = 1° \pm 8°$. This average location is compared to the average locations found for the three individual data sets in Fig. 7. By selecting the locations consistent with all three data sets, the location of the naphthalene molecule is very well-defined, especially considering the low resolution of the ^{29}Si MAS NMR spectra.

A scatter plot of all the atomic positions for each atom for all naphthalene locations consistent with all three data sets is shown in Fig. 8*a* and demonstrates visually the distribution of the solutions. The scatter for each atom can be represented by an ellipsoid in which the length of each principal axis is proportional to the root mean square distance from the mean position,[4] and Fig. 8*b* shows that these ellipsoids represent the error in the corresponding scatter plot quite well. The fractional atomic coordinates for this average location, along with the elements of the tensors that describe the error ellipsoid for each of the atoms are provided as Supplementary data (Table S2).[6] This average location of naphthalene in the ZSM-5 framework is displayed in Fig. 9, where it

Fig. 8. (*a*) Scatter plot of the atomic positions of all naphthalene locations that are consistent with all three sets of $^{1}H/^{29}Si$ CP drain data (with $r^2 \geq 0.96$). Both plots are viewed in the plane of the molecule with the units in Å (hydrogen (black), carbon (grey)).

can be seen that this location determined by solid-state NMR is in excellent agreement with that previously found by single crystal XRD (12), the only minor difference being the exact location along the straight channel. The naphthalene locations, expressed in terms of fractional coordinates of the molecule's center and Euler rotations, determined by

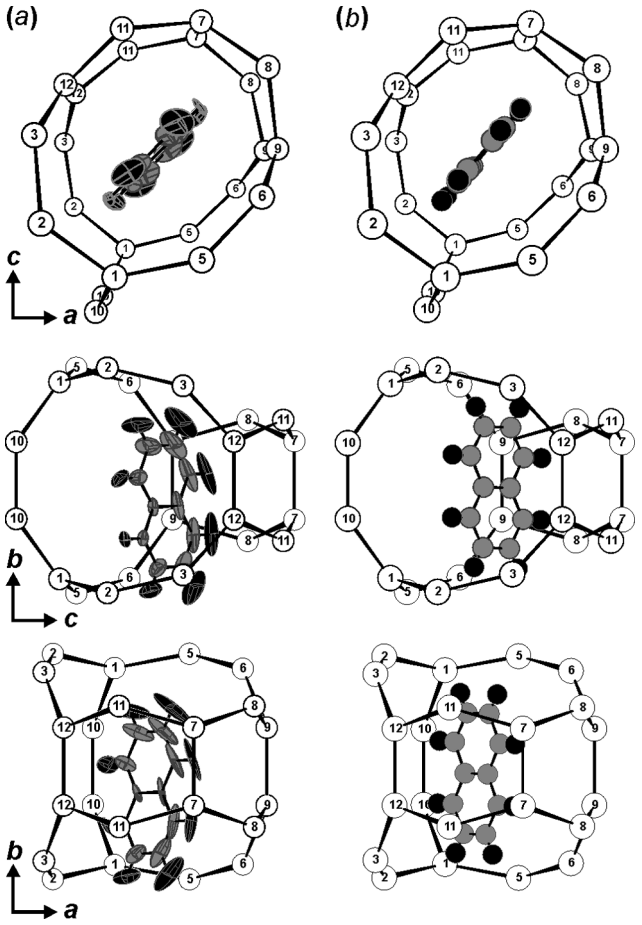

Fig. 9. (*a*) Average location (with 50% error ellipsoids) of the naphthalene molecule in ZSM-5 for solutions that are consistent with all three sets of $^{1}H/^{29}Si$ CP drain data ($r^2 \geq 0.96$) collected at 220 K. (*b*) Representation of the location of the naphthalene molecule determined by single crystal XRD (12). View down straight channels (top), view down zigzag channels (middle), and view perpendicular to straight and zigzag channels (bottom).

solid-state NMR, single crystal XRD (12), and powder XRD (13, 14), are compared in Table 2.

The linear correlation plots (experimental k_{IS} vs. calculated M_2) and the predicted $^{1}H/^{29}Si$ CP drain difference spectra, calculated using the correlation between k_{IS} and M_2, for the average naphthalene location are presented in Fig. 10. These plots demonstrate the high degree of linear correlation between the CP rate constants and the second moments calculated for this average location for all three types of naphthalene molecules, and the close agreement between the predicted and experimental spectra. This final test confirms that the naphthalene location is fully consistent with the experimental $^{1}H/^{29}Si$ cross-polarization data.

In the k_{IS} vs. M_2 plots, the linear correlation lines have non-zero intercepts, which is not entirely consistent with the proportional relationship between k_{IS} and M_2 (eq. [4]). The reason for this is not yet entirely clear to us, however, it is possible that the equations describing the CP dynamics and the relationship between CP rate constants and second moments, which were developed for $^{1}H/^{13}C$ spin systems in organic solids, are not completely valid for the $^{1}H/^{29}Si$ spin systems encountered in these zeolite–sorbate complexes. Nonetheless, this NMR method can correctly determine the location of guest molecules in these complexes.

Figure 11 displays the location of naphthalene in ZSM-5 determined from the solid-state $^{1}H/^{29}Si$ CP MAS NMR data, with several $^{1}H—^{29}Si$ internuclear distances indicated. The different distances between the Si sites and the α and β protons of naphthalene are the source of the different cross-polarization behaviors of these Si peaks in the $^{1}H/^{29}Si$ CP MAS NMR spectra of the naphthalene–ZSM-5 complexes with different deuterated naphthalene molecules (see Fig. 3). In the α-naph-d_4 sample, Si2, Si5, and Si6 have larger signals than Si8 and Si10 in the $^{1}H/^{29}Si$ CP MAS NMR spectra (Fig. 3*c*) owing to their proximity to the β protons (Fig. 11*a*). Likewise, in the β-naph-d_4 sample, the CP signals of Si2 and Si8 are larger than those of Si5, Si6, and Si10 (Fig. 3*d*), owing to their proximity to the α protons (Fig. 11*b*).

Conclusions

The location of naphthalene in ZSM-5 has been determined from solid-state $^{1}H/^{29}Si$ CP MAS NMR data and is in excellent agreement with the structure obtained from single crystal XRD, further demonstrating the usefulness and reliability of this solid-state NMR structure determination approach, particularly since naphthalene is significantly different in structure from the *p*-disubstituted aromatic molecules that to date have mainly been those studied by both NMR and XRD techniques. This example also demonstrates the importance of having localized sources of ^{1}H polarization as was achieved here by using differently deuterated naphthalene molecules, since the structure determined by the fully protonated naphthalene molecule was not very well-defined, particularly the location along the straight channel. Combining the information from samples made with differently deuterated naphthalene molecules increased the reliability of the structure determination, which was particularly important for this system as the resolution of the ^{29}Si spectrum was on the limit of being useful with only five reliably resolved peaks. These results further confirm the validity and reliability of this NMR method for structure determina-

(–)-Sparteine-mediated stereoselective directed ortho metalation of ferrocene diamides[1]

Radoslaw Laufer, Ulrich Veith, Nicholas J. Taylor, and Victor Snieckus

Abstract: The utility of (–)-sparteine-mediated directed ortho metalation (D*o*M) has been investigated in stereoselective preparation of planar chiral ferrocenes derived from 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**). In the synthesis of C_2-symmetric analogs of **5**, the protocol (base, solvent, and two-step D*o*M) was found to be crucial for obtaining high enantio- and diastereo-selectivities of the products. A variety of highly enantioenriched mono and doubly functionalized derivatives of **5** have been synthesized. The synthetic applications of these compounds as chiral ligands in asymmetric alkylation of aldehydes and asymmetric palladium-catalyzed allylic substitutions have been demonstrated.

Key words: directed ortho metalation, stereoselective deprotonation, ferrocene ligands, asymmetric catalysis.

Résumé : On a étudié l'utilité de l'ortho métallation dirigée (*o*MD) orientée par la (–)-spartéine, dans la préparation stéréosélective de ferrocènes chiraux planaires dérivés du 1,1′-*N*,*N*,*N*′,*N*′-tétraisopropylferrocènedicarboxamide (**5**). Dans la synthèse d'analogues de symétrie C_2 du composé **5**, on a trouvé que le protocole expérimental (base, solvant et *o*MD en deux étapes) est crucial si on veut obtenir des valeurs élevées d'énantio- et de diastéréo-sélectivités des produits. On a pu synthétiser avec un degré d'énantioenrichissement élevé une grande variété de dérivés du composé **5** mono- et di-fonctionnalisés avec un degré d'énantioenrichissement élevé. On a démontré l'utilité synthétique de ces composés, en particulier comme ligands chiraux dans l'alkylation asymétrique d'aldéhydes et dans les substitutions allyliques asymétriques catalysées par le palladiium.

Mots clés : ortho métallation dirigée, déprotonation stéréosélective, ligands ferrocènes, catalyse asymétrique.

[Traduit par la Rédaction]

The disclosure, with an interesting socio-chemical history, of the correct structure of ferrocene over half a century ago constituted a landmark achievement that heralded an entirely new theme of organometallic chemistry (1). The continuing significance of the field of ferrocene chemistry (2) is attested by research in areas of asymmetric catalysis (3, 4), enantioselective synthesis (2, 5), diverse material science (2), and biological (6) areas and, most spectacularly, industrial applications (7). Shortly after the excellent summary of the field by Schlőgl (8), Ugi and co-workers (9) reported the effective preparation of optically active planar chiral ferrocenes, which proceeds by diastereoselective directed ortho metalation (D*o*M) and subsequent reaction with electrophiles and which relies on a chiral auxiliary directed metalation group (DMG) for the central to planar chirality transfer. Following these pioneering studies, Kagan and co-workers (10) demonstrated a high diastereoselective D*o*M reaction using chiral sulfoxide DMGs, which was followed by rapid accumulation of reports using other DMGs, providing convincing evidence for the generality of the diastereoinduction process (11, 12) (Scheme 1).

In 1996, stimulated by the results of Hoppe and Hense (13) and Beak et al. (14), we reported on the highly enantioselective synthesis of planar chiral ferrocenecarboxamides **1a** → **2a** by (–)-sparteine-mediated D*o*M chemistry (Scheme 2) (15). This constituted the first general and direct synthetic method to enantiomerically pure ferrocenyls that avoids substrate-specific resolution (9*a*, 16) and chiral auxiliary introduction and removal (10, 17). In subsequent work, we addressed a limitation of the diethyl amide DMG of "seldom allow(ing) functional group modification" (10*b*) by introducing the *N*-cumyl-*N*-ethylferrocenecarboxamide (**1b**), which behaved equally well in sparteine-mediated D*o*M chemistry to afford planar chiral ferrocenes in high yields and % ee, and served, after mild decumylation, as convenient syntheses of optically active Ugi amines, little-known esters, and new phosphines (18). Another limitation, "the disadvantage of the (availability of a) single enantiomeric form of (–)-sparteine" (19) was addressed by showing that 2-TMS-*N*-ethylferrocenecarboxamide (**3**, E = TMS) undergoes C-5 rather than C-1′ deprotonation and thereby allows a latent silicon protec-

Scheme 2.

tion route (4, 20, 21) to the valuable enantiomeric ferrocene (*S*) series (Scheme 2).

As part of efforts to expand the scope of the (–)-sparteine-mediated enantioinduction of planar chirality, we recently reported (22) on the synthesis of highly enantioenriched mono- and double-functionalized derivatives of ferrocenyl 1,1′-bisamides, **6** and **7** (Scheme 3) by combined D*o*M–Pd-catalyzed Suzuki–Miyaura and Stille cross-coupling reactions (23). Herein we present the full details of our studies.

At the outset of our initial investigation, we attempted to establish the optimal reaction conditions for D*o*M of ferrocenyldiamide **5** in Et_2O using chlorotrimethylsilane (TMSCl) as the electrophilic partner. Only later, we discovered that application of TMSCl led to exceptional results. As gleaned from the results in Table 1, use of more than 2 equiv. of both *n*-BuLi and (–)-sparteine led to effective electrophilic trapping of doubly deprotonated **5** (Table 1, entries 2 and 3) in very good yields, however, with unsatisfactory levels of both diastereoselectivity (dr meso:dl, 2:1, **7a**: E = TMS) and optical activity (54% optical purity).[4] Application of *s*-BuLi and (–)-sparteine allowed for quantitative conversions of **5** into **7a** (Table 1, entry 5), but the reaction

[4] Neither (±)-**6a** nor (±)-**7a** could be resolved on chiral HPLC. The requisite homochiral crystals of (+)-**7a** were obtained by recrystallizations of the enantioenriched **7a** from hexanes.

exhibited prohibitively strong preference for the meso diastereomer and very low optical induction for *dl*-**7a** (15% optical purity). Interestingly, in all cases D*o*M-trimethylsilylation of **5** utilizing *n*-BuLi or *s*-BuLi together with TMEDA led to modestly (Table 1, entries 3 vs. 4 and 5 vs. 6) improved contents of racemic *dl*-**7a**.

For electrophilies other than TMSCl, the reactions of 1,1′-ferrocenyldiamide (**5**) with 4.2 equiv. of *n*-BuLi–(–)-sparteine in Et_2O at –78 °C are markedly different. As illustrated in Table 2, the protocol furnished, almost exclusively, products from electrophilic trapping of monolithium anion in good yields but with moderate enantioselectivities. At present, the high yields for the double D*o*M of **5** in the reactions involving TMSCl are difficult to rationalize. Related reactions, involving deprotonation of hindered lithium dialkylamides and in situ TMSCl as the electrophilic trap, have been shown to give superior yields and stereoselectivities. Effects of the in situ generated LiCl has been suggested as the causative agent (24). Despite the apparent incompatibility of *n*-BuLi with TMSCl, we have observed a modest LiCl effect on D*o*M of **5**. Under unchanged reaction conditions, D*o*M of **5** with 4.2 equiv. of *n*-BuLi–(–)-sparteine in the presence of 2.0 equiv. of LiCl followed by a quench with an excess of MeI led to improved yields and greatly enhanced stereoselectivities for both the mono-**6b** (61% yield, 79% ee vs. Table 2, entry 1) and dimethylated **7b**. Compound **7b** was obtained in 16% yield (3:1 dr dl:meso, 80% ee), compared with only trace amounts observed under LiCl-free conditions.

Although double D*o*M–electrophile quench was effected much more efficiently with *s*-BuLi–(–)-sparteine, the same general trend for the unfavorable diastereoselectivities and low enantioinductions was observed with a number of different electrophiles (Table 3). Under these reaction conditions, monocarbinol **6d** was isolated as the only product in low yield and low enantiomeric excess (Table 3, entry 6). Interestingly, unlike 2,2′-bis(diphenylphosphine) (**7c**), which was obtained in respectable yield either directly from **5** utilizing *s*-BuLi (Table 3, entry 5) or stepwise, with *n*-BuLi via **6g** (vide infra, Table 4), all attempts to prepare the 2,2′-bis(diphenylhydroxymethyl) derivative by D*o*M of **5** or monocarbinol **6d** were unsuccessful.

Table 2. Monometalation of **5** in Et_2O (base is *n*-BuLi).

No.	E+	Product (E)	Yield (%)	ee (%)
1	MeI	**6b** (Me)	56	68
2	I_2	**6c** (I)	53	59
3	$Ph_2C{=}O$	**6d** (Ph_2C-OH)	77	64

Note: Conditions: 4.2 equiv. *n*-BuLi–(–)-sparteine; Et_2O; –78 °C for 2 h then 6 equiv. E^+, –78 °C → rt for 4 h.

Gratifyingly, use of solvents of lower coordinating abilities (Table 5, entries 1–3) allowed the preparation of 1,1′,2-trisubstituted derivatives (**6b**–**6i**) in augmented optical and chemical yields. Toluene was found to give the optimal balance between the level of enantioinduction and chemical yield, e.g., the diphenylphosphine derivative **6g** was obtained in 53% yield and 97% ee without a recrystallization (Table 5, entry 9). Interestingly, the opposite solvent effect on the entantioselectivty of (–)-sparteine-assisted D*o*M was observed in applications of *N*,*N*-diisopropylferrocenylcarboxamide (15). Reduction of the amount of *n*-BuLi–(–)-sparteine to 2.2 equiv. caused a slight decline in the chemical yield of the product **6d** (Table 5, entry 5 vs. 6), but did not lead to the erosion of ee. Again, utilization of TMSCl as the electrophile afforded 2,2′-disilylated product **7a** as the major product (71% yield, dr dl:meso, 3:1, 97% optical purity) when 4.2 equiv. of base was used (Table 5, entry 12). Lesser amount of the base (2.2 equiv.) resulted in formation of the monosilylated **6a** as the major product with **7a** isolated as a minor component (16% yield, dr dl:meso, 68:32, 99% optical purity) (Table 5, entry 13).

The enantiomeric excess for stannane **6f** (Table 5, entry 8) was determined by its transformation into carbinol **6d** in a sequence involving a lithiodestannylation–benzophenone quench. Under these unoptimized conditions, the relatively lower ee of **6d** (82% ee) derived from **6f** may be the result of partial racemization, occurring via an intermolecular Li-H

exchange. The heteroatom-tethered phenyl derivatives (thioether, diphenylphosphine, and phenylselenide) **6g**–**6i** (Table 5, entries 9–11) were found to surrender their optical integrity on standing in solution. For example, 2-(phenylthio)-1,1′-ferrocenediamide derivative **6h** undergoes racemization in a mixture of hexanes and *i*-PrOH at a faster rate ($t_{1/2} \approx 9$ h) (25) compared with the corresponding derivative of *N*,*N*-diisopropylferrocenylcarboxamide ($t_{1/2} \approx 24$ h) (15). Noteworthy is the fact that the solution of C_2-symmetric analog, chiral 2,2′-bis(diphenylthio)-1,1′-ferrocenediamide (**7d**), exhibited a very low tendency towards isomerization losing ~30% ee and de on standing at room temperature (rt) for 19 days (25).

Highly diastereo- and enantio-enriched, tetrasubstituted ferrocenyldiamides *dl*-**7** were prepared by subjecting 1,2,1′-trisubstituted ferrocenes **6** to a further asymmetric D*o*M (Table 4). This constituted the first reported preparation of C_2-symmetric ferrocenes outfitted exclusively with the element of planar chirality (26). Quench with electrophiles furnished products **7a**, **7c**, and **7d** with diastereoselective amplification of enantioselectivity as demonstrated by converting **6h** (89% ee) into optically active, 2,2′-bis(diphenylthio)-1,1′-ferrocenediamide (**7d**, 97% ee, 99:1 dl:meso) (27).

To demonstrate the combined potential of D*o*M-cross coupling strategy (28) as a route to aryl-substituted ferrocenes, the iodo (**6c**) and stannane (**6f**) ferrocenediamides were subjected to Suzuki–Miyaura and Gronowitz-modified Stille (29) cross-coupling conditions (Scheme 4). Thus, the reaction of **6c** (89% ee) with (2,4-dimethoxyphenyl)boronic acid afforded the aryl derivatives **6k** in a modest yield (20% yield, 89% ee) together with recovered **6c** (70% yield). Palladium coupling of **6f** and bromobenzene led to a formation of **6l** (35% yield) along with destannylated product **5** (51% yield).

X-ray crystallographic analysis of compounds 7a and 6d

The (*S*) absolute configuration (8), established by single crystal X-ray crystallography analysis of carbinol **6d** (Fig. 1),[5] was provisionally assigned to all of the 2-substituted ferrocenediamides **6a**–**6l**. This is the same sense of enantioinduction as previously seen in (–)-sparteine-assisted D*o*M of *N*-cumyl-*N*-ethyl and *N*,*N*-diisolpropyl ferrocenyl monoamides (15, 18). The (*R*,*R*) absolute configuration of the C_2-symmetric derivatives of **5** (**7a**, **7c**, and **7d**,

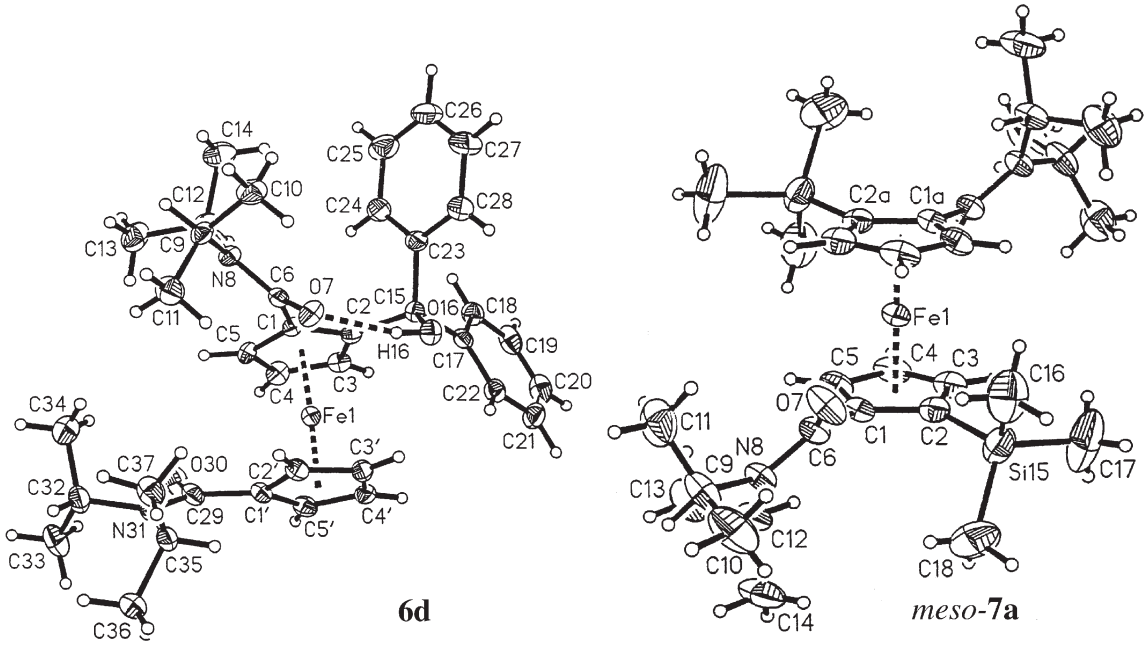
Table 4) must be derived from (*R*) stereochemistry of the corresponding chiral precursors (**6a**, **6g**, and **6h**). The formation of *meso*-**7** products necessitates that the second deprotonation occurs with the opposite stereoselectivity, which may be the result of a cooperative effect of the two DMGs.

In the crystal structure of **6d**, the Cp rings are almost eclipsed with respect to each other, deviating by 14.0° from a fully eclipsed conformation. A hydrogen bond between the carbonyl group of carboxamide and the proximal hydroxyl group (O16—H16, 1.94 Å) is evident. Presumably, owing to packing effects, the two carboxylamides remain in a relative proximity.

Compound *meso*-**7a** proved amenable to X-ray analysis and its crystal structure is shown in Fig. 1.[5] The center of inversion structure entails the staggered conformation for both Cp rings with minimum interactions among the four substituents.

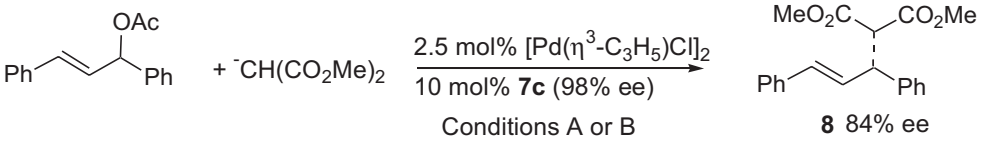
Applications of the ferrocenediamides

In an initial study of utility the new planar chiral ferrocenes in asymmetric synthesis, 1,1′-bis(diphenylphosphino)-2,2′-ferrocenyldiamide (**7c**, 98% ee) was tested as an auxiliary ligand for enantioselective Pd-catalyzed allylic substitution of (±)-phenylcinnamyl acetate (Scheme 5) (30).



The reactions were conducted using palladium allyl chloride dimer (2.5 mol%) as the Pd source utilizing the Trost alkylation conditions (31) or sodiodimethylmalonate. In both cases, alkylated product **8** was obtained in essentially quantitative yield and with good enantiocontrol (96% yield, 84% ee (*R*)). The enantiomeric excess was determined by chiral HPLC and the absolute configuration of the product was assigned by comparison of the optical rotation with literature values (32).

In an additional classic test for enantioinduction, the 1,1′,2-ferrocenyldiamides (**6d**, **6e**, and **6k**) were shown to exhibit moderate to good catalytic activities in the reaction of diethylzinc with benzaldehyde (Scheme 6, Table 6) (33).



Thus, in a typical reaction, a stirred solution of benzaldehyde (1 mmol) and chiral additive (**6d**, **6e**, **6k**) (5 mol%) in either hexane or PhMe under argon, was treated with diethylzinc (1.6 equiv.) and the resultant mixture was stirred at rt for 48–72 h. The crude product was analyzed by chiral HPLC, purified by flash chromatography, and the absolute configuration was determined by a comparison of its

Scheme 6.

optical rotation with the literature values (34). The results are summarized in Table 6. Ethylations of benzaldehyde in hexanes catalyzed by carbinols **6d** and **6e** proceed with the same degree of enantioinduction; however, for **6e**, the chemical yield is greatly diminished, presumably as a consequence of the lower solubility of the catalyst (Table 6, entries 1 and 4). Quite unusual and, to our knowledge, previously unobserved, is the variation in the enantiotopicity of the reaction as a function of the solvent (Table 6, entry 1 vs. entry 2) and use of lithium salt of carbinol **6d** (Table 6, entry 2 vs. entry 3). The lithium salt of the **6d**-catalyzed reaction proceeded in PhMe with greater optical efficiency (47% ee) than the free carbinol **6d** (12% ee) and with a reversal of enantioselection (Table 6, entries 2 and 3). The best optical yield (90% ee) was observed for a nonprotic ligand **6k** (Table 6, entry 5). Attempts to lower the temperature of the process led to prohibitively long reaction times. These variations in the entantiotopiciy of the reaction are currently not understood.

In summary, direct and highly efficient enantioselective syntheses of mono- (**6a**–**6i**) and C_2-symmetric, homoleptic (**7a**, **7c**, and **7d**) ferrocene diamides from achiral ferrocenyldicarboxamide **5** using (–)-sparteine-mediated D*o*M and combined D*o*M-cross coupling (**6k**, and **6l**) have been demonstrated. The preliminary encouraging results in asymmetric synthesis and the current intense activity in ferrocene-

based catalysis (4, 35) may stimulate continuing efforts in the design, synthesis, and application of similar planar chiral ferrocenyl ligands.

Experimental section

General procedures

Melting points were determined on a Buchi SMP-20 or a Fisher hot stage melting point apparatus and were uncorrected. IR spectra were recorded on a BOMEM MB-100 and PerkinElmer 1600 FT-IR spectrophotometer as either neat film, a CH_2Cl_2 solution, or a KBr pellet. ^1H NMR and ^{13}C NMR spectra were recorded on either a Bruker AM-250 or an AC-200 instrument with tetramethylsilane or $CDCl_3$ as an internal standard. ^{31}P NMR spectra were recorded on an AC-200 instrument with H_3PO_4 as an external standard.

Mass spectra (MS) were determined on a high-resolution Varian MAT-CH7 instrument at 70 eV (Monsanto Co., St. Louis, Missouri and Guelph Centre for Mass Spectrometry Service, University of Waterloo Mass Spectrometry Service). Elemental analyses were performed by Chemisar Laboratories, Guelph, Ontario. Stereoselectivities of the reactions were determined using and a Waters HPLC system consisting of a 600E multisolvent delivery system, a Waters 486 UV detector (λ = 254 nm), and a Waters 746 integrator/recorder. The columns used were: Chiralpak, Chiracel OD, and Whelk-O1. Optical rotations were determined using a PerkinElmer 241 polarimeter at λ = 578 or 589 nm at rt. All dry solvents used were purified according to Perrin and Armarego (36): THF and Et_2O were freshly distilled from sodium benzophenone ketyl under nitrogen prior to use. Hexane and PhMe were distilled from CaH_2 and Na, respectively.

n-BuLi and *s*-BuLi were purchased from Sigma-Aldrich Chemical Co., as solutions in hexanes and cyclohexane, respectively. They were stored in resealable containers and titrated periodically against 2,5-dimethoxybenzyl alcohol (37) or *s*-butanol-1,10-phenanthroline (38). *N*,*N*,*N*′,*N*′-Tetramethylenethylenediamine (TMEDA) and (–)-sparteine were dried and distilled over CaH_2 and stored under argon. All commercial materials were purchased from Sigma-Aldrich Chemical Co. or Lancaster Synthesis Ltd. $Pd(PPh_3)_4$ was prepared following a literature procedure (39).

All the reactions were performed in oven-dried glassware under argon, using syringe-septum cap techniques. The –78 °C temperature designation is approximate and achieved by a dry ice – acetone bath. The phrase "standard workup" refers to addition of water or satd. aq. NH_4Cl, extraction with Et_2O, washing the organic extracts (brine), drying ($MgSO_4$), filtration, and concentration under reduced pressure. Flash column chromatography was carried out using Merck silica gel 60 (0.040–0.063 mm).

Standard methods

*(A) Lithiation of 1,1′-*N,N,N′,N′*-tetraisopropylferrocenedicarboxamide (5)*

A solution of (–)-sparteine (0.91 mL, 4.20 mmol) or TMEDA (0.64 mL, 4.20 mmol) in PhMe or Et_2O (20 mL) under Ar was stirred at rt (5 min), cooled to –78 °C, and treated with either *n*-BuLi or *s*-BuLi (4.20 mmol). After stirring (10 min) at –78 °C, a solution of **5** (0.44 g, 1.0 mmol) in either PhMe (4.5 mL) or Et_2O (10 mL) was added dropwise (ca. 1 drop / 10 s). After stirring for 2 h at –78 °C, the reaction mixture was quenched by an addition of electrophile (6 mmol) and then allowed to warm to rt over 4 h. Standard workup afforded the crude product.

*(B) Lithiation of 2-substituted derivatives of 1,1′-*N,N,N′,N′*-tetraisopropylferrocenedicarboxamide (6a, 6g, 6h)*

A solution of (–)-sparteine (0.45–0.91 mL, 2.1–4.2 mmol) in PhMe (20 mL) under Ar was stirred at rt (5 min), cooled to –78 °C, and treated with *n*-BuLi (4.2 mmol). After stirring (10 min) at –78 °C, a solution of a **6** (1.0 mmol) in PhMe (2.5 mL) was added slowly. After stirring for 2 h at –78 °C, the reaction mixture was quenched by addition of the electrophile (3.0–6.0 mmol), allowed to warm to rt over 4 h, and then subjected to standard workup to afford the crude product.

Experimental procedures

1,1′-Ferrocenedicarboxylic acid

A solution of *n*-BuLi (72.2 mL, 1.66 mol/L solution in hexane, 120 mmol) was added to a solution of ferrocene (10.1 g, 53.7 mmol) and TMEDA (20.0 mL, 132 mmol) in hexane (150 mL) under Ar at 0 °C. The reaction mixture was stirred for 12 h at rt. The hexane supernatant solution was removed via cannula and THF (150 mL) was added to dissolve the precipitate. The resultant solution was cooled to –78 °C and purged with carbon dioxide for 1 h. Later the reaction mixture was allowed to warm to rt and treated with H_2O (50 mL). THF was removed under reduced pressure. The aqueous residue was extracted with Et_2O (2 × 100 mL) and acidified with 2 N aq. HCl. The precipitate (bright yellow) was collected by filtration, dried in vacuo, and used without further purification (10.6 g, 72%); mp > 300 °C

(dec). IR (KBr) ν_{max}: 915, 1029, 1167, 1292, 1372, 1403, 1487, 1675, 2825 (br). ^{1}H NMR (DMSO-d_6) δ: 4.30 (s, 4H, Cp-*H*), 4.78 (s, 4H, Cp-*H*), 10.75–11.60 (br, 2H, COO*H*). ^{13}C NMR (DMSO-d_6) δ: 71.2, 72.5, 73.4, 171.0. MS *m*/*z* (rel intensity) (FAB): 274.2 (M^+, 8), 257.1 (11), 231.2 (8). HRMS calcd. for $C_{12}H_{10}{}^{56}FeO_4$: 273.9929; found: 273.9969.

1,1′-N,N,N′,N′-*Tetraisopropylferrocenedicarboxamide (5)*

To a stirred solution of 1,1′-ferrocenedicarboxylic acid (10.0 g, 36.2 mmol) in PhMe (100 mL) at rt, DMF (1.10 mL, 14.1 mmol) and oxalyl chloride (12.8 mL, 149 mmol) were added sequentially. The reaction mixture was stirred for 1 h at rt before PhMe and the excess of oxalyl chloride were removed under reduced pressure. The residue was dissolved in Et_2O (250 mL), cooled to 0 °C, and treated with an excess of HN(*i*-Pr)$_2$ (28.4 mL, 217 mmol). The reaction mixture was stirred for 8–12 h at rt. Standard workup followed by column chromatography (EtOAc–hexane, 1:2) and crystallization gave **5** as an orange solid (11.1 g, 80%); mp 133 to 134 °C (Et_2O–hexane) (lit. value (40) mp 127 to 128 °C). IR (KBr) ν_{max}: 1000, 1050, 1105, 1162, 1198, 1225, 1289, 1377, 1458, 1561, 1684, 2803, 2957, 3091. ^{1}H NMR ($CDCl_3$) δ: 1.05–1.70 (br, 24H, CH(C*H*$_3$)$_2$), 3.30–3.58, 4.35–4.55 (br, 2H, C*H*(CH$_3$)$_2$), 4.37 (t, *J* = 2.0 Hz, 4H, C$_5$*H*$_4$), 4.58 (t, *J* = 2.0 Hz, 4H, C$_5$*H*$_4$). ^{13}C NMR ($CDCl_3$) δ: 21.0, 70.9, 71.3, 83.2, 167.1. MS *m*/*z* (rel intensity) (EI): 440 (M^+, 100), 340 (16), 312 (9), 270 (6), 248 (20), 213 (10), 186 (11), 177 (5), 156 (12), 146 (9), 121 (19), 92 (10), 65 (7). HRMS calcd. for $C_{24}H_{36}{}^{54}FeN_2O_2$: 438.2169; found: 438.2173.

2-(Trimethylsilyl)-1,1′-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (6a)*

According to Standard method A, a solution of (–)-sparteine (0.49 mL, 2.2 mmol) and *n*-BuLi (1.4 mL, 1.65 mol/L solution in hexane, 2.2 mmol) was sequentially treated with a solution of **5** (0.47 g, 1.1 mmol) in PhMe and TMSCl (0.34 mL, 2.7 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:30) afforded compound **6a** as an orange solid (0.42 g, 68%); mp 107.0–107.5 °C (hexanes). $[\alpha]^{23}_{578}$ +67.5° (*c* 0.54, $CHCl_3$). IR (KBr) ν_{max}: 2962, 2883, 1624, 1449, 1325, 1204, 1149, 1040, 829, 754. ^{1}H NMR ($CDCl_3$) δ: 0.23 (s, 9H, Si(C*H*$_3$)$_3$), 0.80–1.60 (br, 24H, CH(C*H*$_3$)$_2$)), 3.2–4.1 (br, 4H, C*H*(CH$_3$)$_2$), 4.20, 4.38, 4.43, 4.49, 4.57, 4.67 (m, 7H, Cp-*H*). ^{13}C NMR ($CDCl_3$) δ: 0.5, 20.7, 21.2, 71.0, 72.03, 72.23, 75.7, 82.4, 93.5, 168.6. MS *m*/*z* (rel intensity) (EI): 512 (M^+, 51), 510 (4), 497 (100), 439 (7), 220 (9), 149 (14), 73 (14). HRMS calcd. for $C_{27}H_{44}{}^{54}FeN_2O_2Si$: 510.2568; found: 510.2551. Two other isolated fractions contained *dl*-**4a** (0.032g, 5%), $[\alpha]^{23}_{578}$ +49.2° (*c* 0.49, $CHCl_3$), 99% op (optical purity) and *meso*-**4a** (0.015 g, 2%).

2-Methyl-1,1′-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (6b)*

According to Standard method A, a solution of (–)-sparteine (0.91 mL, 4.1 mmol) and *n*-BuLi (2.35 mL, 1.75 mol/L solution in hexane, 4.12 mmol) was sequentially treated with a solution of **5** (0.437 g, 0.98 mmol) in PhMe and MeI (0.37 mL, 5.9 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:4) afforded **6b** as an orange solid (0.32 g, 71%); mp 123 to 124 °C. CSP HPLC analysis (Chiralcel OD; eluent: *n*-hexane–*i*-PrOH–Et_2NH (99:1:0.01, flow 0.75 mL/min) determined 92% ee (t_R(major *dl*) = 26.95 min, t_R(minor) = 29.35 min). $[\alpha]^{23}_{578}$ +63.2° (*c* 0.66, $CHCl_3$). IR (KBr) ν_{max}: 1025, 1044, 1111, 1137, 1157, 1204, 1316, 1372, 1453, 1615, 2954, 3001, 3086. ^{1}H NMR ($CDCl_3$) δ: 0.65–1.82 (br, 24H, CH(C*H*$_3$)$_2$)), 2.02 (s, 3H, CpC*H*$_3$), 3.25–3.55 and 3.70–4.05 (br, 4H, C*H*(CH$_3$)$_2$), 4.18 (m, 2H, Cp-*H*), 4.39 (m, 2H, Cp-*H*), 4.57 (m, 2H, Cp-H), 4.67 (br, 1H, Cp-*H*). ^{13}C NMR ($CDCl_3$) δ: 12.7, 20.1, 20.7, 20.9, 21.0, 45.3, 50.2, 67.8, 68.2, 70.8, 71.3, 71.4, 71.6, 72.0, 82.1, 85.1, 88.2, 169.2. MS *m*/*z* (rel intensity) (EI): 454 (27), 426 (4), 169 (6). HRMS calcd. for $C_{25}H_{38}{}^{56}FeN_2O_2$: 454.2283; found: 454.2242.

2-Iodo-1,1′-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (6c)*

According to Standard method A, a solution of (–)-sparteine (0.97 mL, 4.20 mmol) and *n*-BuLi (2.47 mL, 1.70 mol/L solution in hexane, 4.20 mmol) was sequentially treated with solutions of **5** (0.44 g, 1.0 mmol) and iodine (1.52 g, 6.00 mmol) in PhMe (4.5 mL and 14 mL, respectively). Standard workup followed by column chromatography (EtOAc–hexane, 1:10) afforded **6c** as a slowly solidifying orange oil (0.37 g, 70%); mp 113–115 °C. CSP HPLC analysis ((*S*,*S*)-Whelk-O1; eluent: *n*-hexane–*i*-PrOH (96:4, flow 0.5 mL/min) determined 89% ee (t_R(major) = 25.84 min, t_R(minor) = 21.68 min). $[\alpha]^{23}_D$ +33.2 (*c* 0.47, $CHCl_3$). IR (neat) ν_{max}: 807, 1037, 1206, 1316, 1369, 1460, 1635, 2931, 2966. ^{1}H NMR ($CDCl_3$) δ: 0.92–1.72 (m, 24H, CH(C*H*$_3$)$_2$), 3.38–3.70 (m 4H, C*H*(CH$_3$)$_2$), 4.26–6.60 and 4.82–4.88 (m, 7H, Cp*H*). ^{13}C NMR ($CDCl_3$) δ: 20.41, 20.54, 40.64, 45.6, 50.4, 68.9, 70.3, 72.8, 74.1, 74.7, 75.1, 83.7, 92.8, 165.6, 168.0. MS *m*/*z* (rel intensity) (EI): 566 (M^+, 0.5), 502 (8), 414 (6), 219 (25), 131 (40), 69 (100). HRMS calcd. for $C_{24}H_{35}{}^{56}FeIN_2O_2$: 566.1092; found: 566.1103.

2-(Diphenylhydroxymethyl)-1,1′-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (6d)*

Method 1

According to Standard method A, a solution of (–)-sparteine (0.91 mL, 4.1 mmol) and *n*-BuLi (2.36 mL, 1.75 mol/L solution in hexane, 4.1 mmol) was sequentially treated with solutions of **5** (0.433 g, 0.98 mmol) and benzophenone (1.07 g, 5.90 mmol) in PhMe (4.5 mL and 10.0 mL, respectively). Standard workup followed by column chromatography (EtOAc–hexane, 1:15) afforded the title compound (**6d**) as an orange solid (0.56 g, 92%); mp 179–182 °C (Et_2O). CSP HPLC analysis ((*S*,*S*)-Whelk-O1; eluent: *n*-hexane–*i*-PrOH 92:8, flow 0.75 mL/min) determined 94% ee (t_R(major) = 12.06 min, t_R(minor) = 15.15 min). $[\alpha]^{23}_D$ +161.1° (*c* 0.54, $CHCl_3$). IR (KBr) ν_{max}: 704, 752, 765, 818, 832, 1031, 1047, 1134, 1161, 1202, 1320, 1368, 1456, 1594, 2875, 2932, 2966, 3066, 3204. ^{1}H NMR ($CDCl_3$) δ: 0.65–1.48 (br, 24H, CH(C*H*$_3$)$_2$), 2.87, 3.15, 3.44, 4.20 (m, 4H, C*H*(CH$_3$)$_2$), 3.67, 4.29, 4.56, 4.63, 4.92 (m, 7H, Cp-*H*), 5.81 (s, 1H, O*H*), 7.06–7.40, 7.55 (m, 10H, Ph*H*), 7.94 (s, 1H, C*H*(OH)Ph$_2$). ^{13}C NMR ($CDCl_3$) δ: 20.4, 20.5, 40.6, 45.6, 50.4, 68.9, 70.3, 72.8, 74.07, 74.7, 75.1, 83.7, 92.8, 165.6, 168.0. MS *m*/*z* (rel intensity) (EI): 622 (M^+, 2), 614 (8), 502

(50), 414 (42), 354 (3), 218 (78), 131 (100), 70 (98). HRMS calcd. for $C_{37}H_{46}{}^{56}FeN_2O_3$: 622.2858; found: 622.2836.

Method 2

By Sn-Li exchange from 2-(tributylstannyl)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6f).

n-BuLi (0.09 mL, 1.67 mol/L solution in hexane, 0.15 mmol) was added to a cold (–78 °C), stirred solution of 2-(tributylstannyl)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6f**) (0.10 g, 0.14 mmol) in PhMe (5 mL). The resulting solution was stirred for 15 min, benzophenone (0.052 g, 0.28 mmol) in PhMe (0.5 mL) was added, and stirring was continued for 40 min at –78 °C before the reaction mixture was allowed to warm to rt. Standard workup and flash chromatography (EtOAc–hexane, 8:1) afforded pure **6d** (0.022 g, 25%) and also **5** (3 mg, 5%) and unreacted 2-(tributylstannyl)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6f**) (51 mg, 49%). The crude product was analysed by CSP HPLC ((*S*,*S*)-Whelk-O1; eluent: *n*-hexane–*i*-PrOH 97:3, flow 0.5 mL/min) and found to be 82% ee (t_R(major) = 22.88 min, t_R(minor) = 35.98 min).

2-(Diethylhydroxymethyl)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6e)

According to Standard method A, a solution of (–)-sparteine (0.97 mL, 4.4 mmol) and *n*-BuLi (2.31 mL, 1.90 mol/L solution in hexane, 4.40 mmol) was sequentially treated with solutions of **5** (0.459 g, 1.04 mmol) and 3-pentanone (0.63 mL, 6.2 mmol) in PhMe (4.5 and 5.0 mL, respectively). Standard workup followed by column chromatography (EtOAc–hexane, 1:6) afforded **6e** as an orange solid (0.25 g, 45%); mp 121 to 122 °C. CSP HPLC analysis (Chiralcel OD; eluent: *n*-hexane–*i*-PrOH 98:2, flow 0.15 mL/min) determined 90% ee (t_R(major) = 37.02 min, t_R(minor) = 39.18 min). $[\alpha]^{23}{}_{578}$ –31.2° (*c* 0.34, $CHCl_3$). IR (KBr) ν_{max}: 814, 970, 1038, 1038, 1113, 1135, 1157, 1200, 1340, 1453, 1604, 2939, 3343. ^{1}H NMR ($CDCl_3$) δ: 0.47 (t, *J* = 7.5 Hz, 3H, CH_2CH_3), 0.72–1.98 (m, 31H, $CH(CH_3)_2$, CH_2CH_3, CH_2CH_3, 3.29–3.55 (br, 4H, $CH(CH_3)_2$), 4.10–4.32 (m, 3H, Cp*H*), 4.47 (s, 1H, Cp*H*), 4.60 (s, 2H, Cp*H*), 4.73 (s, 1H, Cp*H*), 6.10 (s, 1H, O*H*). ^{13}C NMR ($CDCl_3$) δ: 7.6, 9.2, 20.3, 20.7, 20.9, 29.6, 33.9, 46.2, 50.8, 67.7, 69.5, 71.7, 72.2, 72.6, 82.0, 83.1, 101.4, 168.9, 171.4. MS *m*/*z* (rel intensity) (EI): 526 (M^+, 18), 508 (100), 446 (3), 338 (4), 316 (12), 306 (5), 265 (5), 231 (5), 161 (7), 105 (9), 91 (8), 86 (7). HRMS calcd. for $C_{29}H_{46}{}^{56}FeN_2O_3$: 526.2858; found: 526.2893. Anal. calcd. for $C_{29}H_{46}FeN_2O_3$: C 66.15, H 8.80, N 5.22; found: C 66.17, H 8.65, N 4.93.

2-(Tributylstannyl)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6f)

According to Standard method A, a solution of (–)-sparteine (0.92 mL, 4.2 mmol) and *n*-BuLi (5.17 mL, 1.68 mol/L solution in hexane, 8.69 mmol) was sequentially treated with a PhMe (4.5 mL) solution of **5** (0.903 g, 1.00 mmol) and neat tributyltin chloride (3.51 mL, 12.41 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:10) afforded **6f** as a red oil, which was purified by Kugelrohr distillation (0.86 g, 58%). $[\alpha]^{23}{}_{578}$ +90.4° (*c* 0.44, $CHCl_3$). IR (neat) ν_{max}: 1039, 1158, 1204, 1280, 1323, 1372, 1457, 1614, 2930. ^{1}H NMR ($CDCl_3$) δ: 0.79–1.83 (br, 51H, $CH(CH_3)_2$, Bu-*H*), 3.19–3.68 (br, 4H, $CH(CH_3)_2$)), 4.22–4.33 (m, 3H, Cp- *H*), 4.30–4.52 (m, 2H, Cp-*H*), 4.52–4.68 (m, 2H, Cp-*H*). ^{13}C NMR ($CDCl_3$) δ: 11.22, 13.7, 14.6, 14.8, 21.0, 26.8, 27.4, 28.0, 29.2, 46.1, 50.0, 69.9, 70.4, 71.1, 71.5, 72.0, 74.2, 76.1, 82.3, 88.4, 168.9, 169.4. MS *m*/*z* (rel intensity) (FAB): 730 (M^+, 7), 673 (100), 630 (9), 558 (28), 495 (28), 426 (16), 368 (20). Anal. calcd. for $C_{36}H_{62}FeN_2O_2Sn$: C 59.28, H 8.57, N 3.84; found: C 58.99, H 8.49, N 3.80.

2-(Diphenylphosphino)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6g)

According to Standard method A, a solution of (–)-sparteine (1.04 mL, 4.20 mmol) and *n*-BuLi (2.40 mL, 1.75 mol/L solution in hexane, 4.20 mmol) was sequentially treated with a PhMe (4.5 mL) solution of **5** (0.440 g, 1.00 mmol) and neat chlorodiphenylphosphine (1.1 mL, 6.0 mmol). After stirring for 1 h at –78 °C, the reaction mixture was allowed to warm to 0 °C and quenched with satd. aq. NH_4Cl. Standard workup followed by column chromatography (SiO_2 deactivated by additon of 2% Et_3N, EtOAc–hexane 1:10) afforded **6g** as an orange solid (0.335 g, 54%); mp 142–144 °C (dec). CSP HPLC analysis (Chiracel OD; eluent: *n*-hexane–*i*-PrOH 98:2, flow 0.25 mL/min) determined 97% ee (t_R(major) = 31.31 min, t_R(minor) = 34.24 min). $[\alpha]^{23}{}_D$ +225.5° (*c* 0.31, CH_2Cl_2). IR (KBr) ν_{max}: 2963, 1624, 1449, 1336, 1206, 820, 751, 701. ^{1}H NMR ($CDCl_3$) δ: 0.32–1.75 (br, 24 $CH(CH_3)_2$), 3.03–3.48 (br, 4H, $CH(CH_3)_2$), 3.90, 4.26, 4.34, 4.37, 4.45, 4.51, 4.58, 4.65, 4.80 (m, 7H, Cp*H*), 7.18–7.62 (br, 10H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 20.3, 21.4, 31.6, 71.7, 72.2, 73.4, 74.7, 76.9, 80.3, 82.7, 86.0, 98.3, 128.1, 128.2, 128.7, 133.0, 133.4, 134.1, 134.6, 137.9, 139.2, 166.7. MS *m*/*z* (rel. intensity) (EI): 625 (M^+, 62), 539 (71), 423 (100), 346 (84), 245 (69). HRMS calcd. for $C_{36}H_{46}{}^{56}FeN_2O_2P$: 625.2674; found: 625.2646.

2-(Phenylthio)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6h)

According to Standard method A, a solution of (–)-sparteine (0.93 mL, 4.2 mmol) and *n*-BuLi (2.76 mL, 1.52 mol/L solution in hexane, 4.2 mmol) was sequentially treated with solutions of **5** (0.440 g, 1.00 mmol) and Ph_2S_2 (1.30 g, 5.95 mmol) in PhMe (4.5 mL and 10.0 mL, respectively). Standard workup followed by column chromatography (EtOAc–hexane, 1:6) afforded **6h** (0.39 g, 71%); mp 135–137 °C. CSP HPLC analysis (Chiralcell OD; eluent: *n*-hexane–*i*-PrOH (0.1% solution of Et_2NH of 99.1:0.9, flow mL/min) determined 89% ee (t_R(major) = 17.54 min, t_R(minor) = 21.21 min). $[\alpha]^{23}{}_{578}$ +97.7° (*c* 1.41, $CHCl_3$). IR (KBr) ν_{max}: 738, 814, 814, 840, 1041, 1143, 1205, 1337, 1453, 1611, 2935. ^{1}H NMR ($CDCl_3$) δ: 0.33–1.61 (br, 24H, $CH(CH_3)_2$), 3.12–3.78 (br, 4H, $CH(CH_3)_2$), 4.35–4.98 (m, 7H, Cp-*H*), 7.01–7.37 (m, 5H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 19.99, 20.4, 20.7, 20.9, 45.8, 50.5, 70.6, 71.7, 72.6, 72.9, 73.7, 73.9, 77.7, 79.0, 83.7, 92.8, 125.4, 127.3, 128.7, 139.7, 165.5, 168.6. 2-Phenyl-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6l)

A mixture of $PdCl_2$(dppf) (37 mg, 0.051 mmol), CuO (95 mg, 1.2 mmol), and PhBr (0.02 mL, 0.19 mmol) in DMF (3 mL) was heated to 150 °C for 30 min and treated with a solution of 2-(tributylstannyl)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6f**) (0.107 g, 0.15 mmol, $[\alpha]^{23}_{578}$ +90.4° (*c* 0.44, $CHCl_3$), i.e., ≥82% ee) in DMF (0.3 mL). The resulting reaction mixture was stirred for 18 h at 100 °C, cooled to rt, passed through Celite, concentrated and subjected to standard workup followed by column chromatography (hexane–EtOAc, 6:1) to afford **6l** as a brown oil (27 mg, 35%) and separately 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) (24 mg, 51%). Compound **6l**: $[\alpha]^{23}_{578}$ –266.1° (*c* 0.17, $CHCl_3$). IR (neat) ν_{max}: 764, 815, 1038, 1111, 1135, 1159, 1207, 1261, 1318, 1372, 1457, 1508, 1623, 2926, 2964. ^{1}H NMR ($CDCl_3$) δ: 0.24–1.72 (br, 24H, $CH(CH_3)_2$), 3.13–3.60 (br, 4H, $CH(CH_3)_2$), 4.25–4.92 (br, 7H, Cp*H*), 7.25 (m, 3H, C_6H_5), 7.56 (m, 2H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 19.5, 19.8, 20.8, 20.9, 21.0, 22.7, 29.7, 45.7, 50.6, 68.6, 70.0, 70.9, 72.0, 72.9, 73.4, 74.3, 82.4, 85.6, 90.1, 126.6, 128.1, 137.5, 167.5, 168.9. MS *m*/*z* (rel intensity) (FAB): 517 (MH^+, 22), 416 (5), 330 (3), 277 (8), 185 (100), 116 (5). HRMS calcd. for $C_{30}H_{41}{}^{56}FeN_2O_2$ (MH^+): 517.2518; found: 517.2495.

2,2′-Bis(trimethylsilyl)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (7a)

Method 1

From 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**). According to Standard method A, a solution of (–)-sparteine (0.51 mL, 2.30 mmol) and *n*-BuLi (1.36 mL, 1.69 mol/L solution in hexane, 2.30 mmol) in PhMe (20 mL) was sequentially treated with a solution of 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) (0.24 g, 0.55 mmol) PhMe (4.5 mL) and then TMSCl (0.42 mL, 3.3 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:30) gave separately *dl*-**7a** (0.153 g, 50%), *meso*-**7a** (0.065 g, 21%), and 2-(trimethylsilyl)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6a**) (0.043 g, 16%, $[\alpha]^{23}_{578}$ +64.3° (*c* 0.11, $CHCl_3$)) as orange solids.

dl-*2,2′-Bis(trimethylsilyl)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (7a):* $[\alpha]^{23}_{578}$ +48.0° (*c* 0.51, $CHCl_3$). Optical purity: 97%; mp 192–194 °C (hexanes). Method 2

From 2-(trimethylsilyl)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6a**). According to Standard method B, a solution of (–)-sparteine (0.71 mL, 3.23 mmol), and *n*-BuLi (1.96 mL, 1.65 mol/L solution in hexane, 3.23 mmol) in PhMe (20 mL) was sequentially treated with a solution of 2-(trimethylsilyl)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6a**, 0.39 g, 0.76 mmol, $[\alpha]^{23}_{578}$ +67.5° (*c* 0.54, $CHCl_3$)) in PhMe (2.5 mL) and then TMSCl (0.60 mL, 4.6 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:30) gave the title compounds (**7a**) as orange solids; *dl*-**7a** (0.336 g, 75%) and *meso*-**7a** (0.056 g, 12%), *dl*-**7a** ($[\alpha]^{23}_{578}$ +44.8° (*c* 0.42, $CHCl_3$)); 91% optical purity.

2,2′-Dimethyl-1,1′-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (7b)*

Method 1

From 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) using *s*-BuLi. According to Standard method A, a solution of (–)-sparteine (0.90 mL, 4.1 mmol) and *s*-BuLi (3.44 mL, 1.18 mol/L solution in cyclohexane, 4.06 mmol) in Et_2O (20 mL) was sequentially treated with a solution of 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) (0.447 g, 1.02 mmol) in Et_2O (10 mL) followed by MeI (0.38 mL, 6.1 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:15) afforded a mixture of *meso*-**7b** and *dl*-**7b** diastereomers (0.33 g, 70%) as an orange solid. CSP HPLC analysis (Chiralcel OD; eluent: *n*-hexane–*i*-PrOH 99.4:0.6, flow 1.0 mL/min) determined dr (meso:dl, 76:24) and 52% ee (t_R(major dl) = 5.74 min, t_R(minor dl) = 6.96 min, t_R(meso diastereomer) = 9.30 min). IR (KBr) ν_{max}: 815, 1022, 1037, 1076, 1134, 1156, 1210, 1314, 1346, 1371, 1455, 1629, 2937, 3088. ^{1}H NMR ($CDCl_3$) δ: 0.62–1.78 (br, 24H, $CH(CH_3)_2$), 2.02 (s, 6H, $CpCH_3$), 3.18–4.00 (br, 4H, $CH(CH_3)_2$), 4.15 (m, 2H, Cp-*H*), 4.36 (m, 2H, Cp-*H*), 4.52 (m, 1H, Cp-*H*), 4.66 (m, 1H, Cp-*H*). ^{13}C NMR ($CDCl_3$) δ: [12.06], 12.44, 20.75, [20.48], 45.35, 49.85, [68.50], 69.41, [69.98], 72.11, 84.76, [86.76], 87.10, 167.90. MS *m*/*z* (rel intensity) (FAB): 468 (M^+, 100), 396 (2), 368 (35), 262 (26), 213 (5), 134 (13), 55 (11). HRMS calcd. for $C_{26}H_{40}{}^{56}FeN_2O_2$: 468.2439; found: 468.2390. Values in square parentheses indicate resonances assigned to the dl-diastereomer.

Method 2

From 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) using *n*-BuLi in the presence of LiCl. According to Standard method A, a solution of (–)-sparteine (0.49 mL, 2.2 mmol), vacuum-dried LiCl (0.048 g, 2.1 mmol), and *n*-BuLi (1.32 mL, 1.69 mol/L solution in hexane, 4.2 mmol) in Et_2O (10 mL) was sequentially treated with a solution of 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) (0.23 g, 0.53 mmol) in Et_2O (5 mL) and MeI (0.37 mL, 6.0 mmol). Standard workup followed by column chromatography (EtOAc–hexane, 1:15) afforded a mixture of *dl*-**7b** and *meso*-**7b** diastereomers (0.040 g, 16%). CSP HPLC analysis determined 80% ee and dr = 72:28 (dl:meso); 2) and separately 2-methyl-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6b**) (0.15 g, 61%), 79% ee by CSP HPLC analysis, as well as the starting material 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) (0.018 g, 8%).

2,2′-Bis(diphenylphosphino)-1,1′-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (7c)*

Preparation of *dl*-**7c** from 2-(diphenylphosphino)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6g**). According to Standard method B, a solution of (–)-sparteine (0.30 mL, 1.4 mmol) and *n*-BuLi (0.67 mL, 2.00 mol/L solution in hexane, 1.3 mmol) in PhMe (20 mL) was sequentially treated with a solution of 2-(diphenylphosphino)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**6g**) (0.400 g, 0.91 mmol, 97% ee) in PhMe (2.5 mL) and Ph_2PCl (0.36 mL, 1.9 mmol). The reaction mixture was quenched with satd. aq. NH_4Cl and extracted with CH_2Cl_2. The organic extract was washed with brine and concentrated under reduced pressure. The residue was purified by column chromatography (SiO_2 pretreated with 2% Et_3N, EtOAc–hexane 1:6) to give compound **7c** as a bright yellow solid (0.29 g, 45%); dr(dl:meso) >95:<5 by ^{31}P NMR; mp 233–236 °C (dec) (lit. value (41) mp 228–230 °C). $[\alpha]^{20}_D$ +277° (*c* 0.76, CH_2Cl_2), 98% optical purity. IR (KBr) ν_{max}: 3088, 2938, 1625, 1531, 1454, 1371, 1333, 1279, 1244, 1204, 1154, 1039. ^{1}H NMR ($CDCl_3$) δ: 0.34–1.53 (br, 24H, $CH(CH_3)_2$), 3.04–3.26 and 3.92–4.13 (br, 4H, $CH(CH_3)_2$), 3.53 (s, 2H, Cp-*H*), 4.78–4.82 (m, 4H, Cp-*H*), 7.12–7.43 (br, 20H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 13.7, 19.0, 20.3, 50.0, 72.7, 74.8, 76.7, 81.1, 90.5, 127.9, 128.0, 128.1, 128.2, 129.1, 130.0, 130.4, 132.7, 133.1, 133.5, 133.6, 133.9, 137.9, 138.1, 139.0, 167.0. ^{31}P NMR($CDCl_3$) δ: –22.27. Anal. calcd. for $C_{48}H_{54}{}^{56}FeN_2O_2P_2$: C 71.28, H 6.73, N 3.46: found: C 71.36, H 6.75, N 3.51.

Preparation of meso-**7c** *from 1,1′*-N,N,N′,N′-*tetraisopropylferrocenedicarboxamide (**5**) using* s-*BuLi*

According to Standard method A, a solution of (–)-sparteine (1.9 mL, 8.4 mmol) and *s*-BuLi (7.1 mL, 1.18 mol/L solution in cyclohexane, 8.4 mmol) in Et_2O (40 mL) was sequentially treated with a solution of 1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**5**) (0.883 g, 2.01 mmol) in Et_2O (20 mL) and Ph_2PCl (2.16 mL, 12.0 mmol). The reaction mixture was quenched with satd. aq. NH_4Cl and extracted with excess CH_2Cl_2. The organic extract was washed with brine and concentrated under reduced pressure. The residue was purified by column chromatography (SiO_2 pretreated with 2% Et_3N, EtOAc–hexane 1:6) to give *meso*-**7c** as a bright yellow solid (0.79 g, 49%). The diastereomeric composition was determined by ^{31}P NMR dr(meso:dl) >95:<5; mp 235–237 °C (dec). IR (KBr) ν_{max}: 3063, 2924, 1629, 1451, 1373, 1330, 1205, 1159, 1093, 822. ^{1}H NMR ($CDCl_3$) δ: 0.34–1.68 (br, 24H, $CH(CH_3)_2$), 2.92–3.25 and 3.43–3.96 (br, 4H, $CH(CH_3)_2$), 4.20 and 4.76 (m, 6H, Cp-*H*), 7.12–7.67 (br, 20H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 20.3, 72.8, 81.1, 90.8, 91.2, 128.0, 128.0, 128.2, 128.9, 132.8, 133.1, 134.5, 134.9, 139.6, 139.9, 166.3. ^{31}P NMR ($CDCl_3$) δ: –22.68. Dimethyl 1,3-diphenylprop-2-enylmalonate (8) — Asymetric Pd-catalyzed allylic substitution

Method 1 (utilizing BSA and AcOK)

A solution of 1,3-diphenyl-1-acetoxy-2-propene (0.25 g, 1.0 mmol) (42), 2,2′-bis(diphenylphosphino)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**7c**, 0.071 g, 0.1 mmol, 96% ee), and allylpalladium chloride dimer (0.009 g, 0.025 mmol) in CH_2Cl_2 (3.5 mL) was stirred for 15 min at rt before a solution (CH_2Cl_2, 3.5 mL) of BSA (0.74 mL, 3.0 mmol), dimethyl malonate (0.40 g, 3.0 mmol), and AcOK (0.004 g, 0.04 mmol) was added. The reaction mixture was stirred for 10 h at rt, quenched with water, and subjected to the standard workup. Purification by column chromatography (EtOAc–hexane, 1:5) gave compound **8** as a pale yellow solid (0.313 g, 96%). CSP HPLC analysis (eluent: *n*-hexane–*i*-PrOH 99:1, flow 0.2 mL/min) determined 84% ee (t_R(major) = 58.78 min, t_R(minor) = 63.50 min). $[\alpha]^{23}_D$ +15.9° (*c* 0.71, EtOH). IR (neat) ν_{max}: 2995, 1758, 1605, 1493, 1454, 1316, 1259. ^{1}H NMR ($CDCl_3$) δ: 3.52 (s, 3H, CO_2CH_3), 3.70 (s, 3H, CO_2CH_3), 3.95 (d, *J* = 10.9 Hz, 1H, C*H*(CO_2CH_3)$_2$), 4.27 (dd, *J* = 10.9, 8.0 Hz, 1H, Ph-C*H*), 6.32 (dd, *J* = 8.0, 15.7 Hz, 1H, -C*H*=CH-Ph), 6.51 (d, *J* = 15.7 Hz, 1H, Ph-CH=), 7.19–7.33 (m, 10H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 48.9, 52.0, 52.2, 57.3, 126.1, 126.9, 127.3, 127.6, 127.9, 128.2, 128.4, 128.9, 131.5, 136.5, 140.0, 167.4, 167.9. MS *m*/*z* (rel intensity) (EI): 324 (M^+, 56), 292 (29), 264 (37), 232 (41), 204 (84), 193 (98), 178 (53), 165 (39), 152 (18), 139 (12), 128 (42), 115 (100), 102 (43), 91 (74), 78 (42), 69 (43). HRMS calcd. for $C_{20}H_{20}O_4$: 324.1361; found: 324.1353.

Method 2 (utilizing NaH)

A solution of 1,3-diphenyl-1-acetoxy-2-propene (0.095 g, 0.38 mmol), 2,2′-bis(diphenylphosphino)-1,1′-*N*,*N*,*N*′,*N*′-tetraisopropylferrocenedicarboxamide (**7c**, 0.027 g, 0.038 mmol, 96% ee), allylpalladium chloride dimer (0.004 g, 0.011 mmol), and THF (2 mL) was stirred for 15 min at rt and then treated with a THF (3 mL) solution of NaCH(CO_2Me)$_2$ (prepared by the addition of NaH (60% in oil, 0.05 g, 1.13 mmol) to dimethylmalonate (0.15 g, 1.13 mmol) in THF (3 mL) at 0 °C) at rt. The reaction reaction mixture was stirred for 36 h at rt, quenched with water, and subjected to the standard workup. Purification by column chromatography afforded compound **8** (0.117 g, 96%), which, as determined by CSP HPLC, was 84% ee (R-enantiomer).

1-Phenylpropan-1-ol (9) (Et_2Zn addition to benzaldehyde)

To a stirred solution of benzaldehyde (0.10 mL, 1.6 mmol) and chiral ferrocenyl ligand (**6d**, **6e**, **6k**, **6l**) (0.05 mmol) in either hexane (15 mL) or PhMe (5 mL) was added a solution of Et_2Zn (1.60 mL, 1.0 mol/L in hexane, 1.60 mmol) at rt and the reaction mixture was further stirred for 1–3 days. The reaction mixture was quenched with excess 0.2 mol/L aq. HCl solution at 0 °C. After standard workup, the crude material was analyzed by CSP HPLC (Chiralcel OD column, eluent: *n*-hexane–isopropyl alcohol 99:1, flow 0.5 mL/min, t_R 29.66 min, t_R 27.20 min) and purified by column chromatography (hexane–EtOAc, 10:1) to yield compound **9** as a colorless oil. IR (CH_2Cl_2) ν_{max}: 700, 756, 1097, 1454, 1493, 2875, 2930, 2966, 3030, 3369. ^{1}H NMR ($CDCl_3$) δ: 0.92 (t, *J* = 7.3 Hz, 3H, CH_2CH_3), 1.81 (m, 2H, CH_2CH_3), 1.90–2.00 (br, 1H, O*H*), 4.59 (t, *J* = 6.6 Hz, 1H, C*H*(OH)CH_2), 7.20–7.40 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ: 10.1, 31.8, 76.0, 126.0, 127.4, 128.3. MS *m*/*z* (rel intensity) (EI): 136 (M^+, 32), 117 (2), 107 (100), 97 (0.5). HRMS calcd. for $C_9H_{12}O$: 136.0888; found: 136.0897.

Et_2Zn addition to benzaldehyde catalyzed by the lithium salt of 2-(diphenylhydroxymethyl)-1,1′-N,N,N′,N′-tetraisopropylferrocenedicarboxamide (6d)

A solution of *n*-BuLi (0.05 mL, 1.67 mol/L in hexane, 0.85 mmol) was added to a cold (–78 °C) solution of **6d** (53.4 mg, 0.086 mmol) in PhMe (20 mL). PhCHO (0.19 mL,

© 2006 NRC Canada

0.86 mmol) and Et_2Zn (1.37 mL, 1.0 mol/L in hexane, 1.37 mmol) were added and stirring was continued at rt for 3 days. The reaction mixture was quenched with excess 0.2 mol/L HCl at 0 °C. Standard workup followed by flash chromatography afforded compound **9** (0.082 g, 70%, 47% ee).

Acknowledgements

We warmly thank Dr. Heiner Jendralla, Novartis (formerly Hoechst) for exchange of correspondence and insightful comments. We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for support under the Industrial Research Chair (Monsanto Company) and Research Grant programs. RL was an Ontario Graduate Scholar, 1996 to 1997.

23. New centrally chiral 1,1′-disubstituted ferrocenes and corresponding 1,1′,2-trisubstituted and 1,1′,2,2′-terasubstituted derivatives, mostly incorporating a chiral 1-oxazolinyl substituent, have been prepared by Ikeda, Knochel, and Dai and their coworkers and shown to give good enantioselectivities in several asymmetric reactions, see: (*a*) W. Zhang, Y. Adachi, T. Hirao, and I. Ikeada. Tetrahedron: Asymmetry, **7**, 451, (1996); (*b*) W. Zhang, T. Kida, Y. Nakayashi, and I. Ikeda. Tetrahedron Lett. **37**, 7995 (1996); (*c*) M. Lotz, T. Ireland, J.J. Almena, and P. Knochel. Tetrahedron: Asymmetry, **10**, 1839 (1999); (*d*) L. Schwink and P. Knochel. Chem. Eur. J. **4**, 950, (1998), and ref. 4, and refs. cited therein. As pointed out by Dai, while the 1,1′-disubstituted ferrocene ligands posses only central chirality, coordination with a metal results in systems with three chiral elements (central, axial, and planar), which leads to greater mechanistic interest in the manner of their participation in enantioinduction.

TRIBUTE / HOMMAGE

This special issue of the *Canadian Journal of Chemistry* is dedicated to Doctor Arthur J. Carty for his outstanding accomplishments in organotransition metal chemistry and also for his exceptional contributions to the advancement of science and technology in Canada. As all contributors to this issue will know, Arthur's status in the pantheon of eminent Canadian scientists and scientific administrators is unique, and his position in the history of science in Canada is secure.

Arthur attended Hookergate Grammar School, County Durham, England, from 1952 to 1959, obtaining the G.C.E. Advanced Level in Chemistry, Physics, and Mathematics, with distinction in chemistry and physics and scholarship level chemistry and physics. He held the position of Head Boy from 1958 to 1959 and was Captain of the school soccer and cricket teams from 1957 to 1959. He went on to study chemistry at the University of Nottingham, where he graduated with a First Class Honours B.Sc. in 1962. He then joined the research group of the late Dennis Tuck at Nottingham, obtaining his Ph.D. in inorganic chemistry in 1965.

After a two year period as Assistant Professor of Chemistry at Memorial University, St. John's, Newfoundland, Arthur joined the Department of Chemistry at the University of Waterloo, Waterloo, Ontario, where he rose through the ranks to become Professor in 1975, founding Director of the Guelph–Waterloo Centre for Graduate Work in Chemistry (1975–1979), Chairman of the Department of Chemistry (1983–1989), and Dean of Research (1989–1994). Arthur left Waterloo in 1994 to become President of the National Research Council of Canada (NRC), and left NRC in 2004 to become Canada's first National Science Advisor to the Prime Minister.

Arthur's doctoral studies with Dennis Tuck involved the development of the coordination chemistry of the group 13 metals. His independent research career was launched with spectroscopic (IR, Raman, NMR, and Mössbauer) studies of metal–halide complexes ligated to phosphorus donors, including phosphinoalkynes, and his contributions to chemistry have ultimately spanned the spectrum of the coordination chemistry of main group and transition metal elements, from the bioinorganic chemistry of mercury to organometallic chemistry and materials science.

In particular, his research program has involved the exploration of the chemistry of acetylenic phosphines and diphosphines, with leading edge research into the synthesis of a large series of organometallic complexes. His work with metal carbonyls of the late transition metals and their bonding to phosphinoacetylene ligands led to the development of a world-renowned research program in transition metal cluster chemistry, and his research on the facile phosphorus–carbon bond cleavage reactions of coordinated P-C≡CR ligands provided an elegant entry into metal–acetylide complexes. This work was widely recognized, and resulted in rankings in the 100 most-cited papers published in the world in pure and synthetic chemistry in both 1981 and 1982 (A.J. Carty, S.A. MacLaughlin, and N.J. Taylor. Open and closed ruthenium and osmium clusters with μ_3-acetylide and phosphido bridges. J. Organomet. Chem. **204**, C27 (1981); A.J. Carty. Structural chemistry and reactivity of cluster bound acetylides: Close relatives of the carbides? Pure Appl. Chem. **54**, 113 (1982)). Arthur and his co-workers led the development of C—C and C—N bond forming reactions of coordinated acetylide groups, helping to cement many of the ideas regarding the "cluster-surface analogy" proposed by Muetterties. This work continued its rapid growth through the 1980s and 1990s, with in-depth studies on the synthesis and reactivity patterns of polyunsaturated carbon ligands, including late transition metal allenyl (-C(R)=C=CR′$_2$) and butadiynyl (-C≡C-C≡C-R) complexes.

In most instances, the development of this chemistry was made possible by the flexible nature of ancillary phosphido (PR_2), phosphidoxo (R_2PO), and phosphinidene (PR) ligands, which function as supports to the metal centres, preventing or controlling metal–metal bond cleavage reactions. Arthur and his team also clearly demonstrated that such ligands can play an active role as mediators of reactions on cluster surfaces via P—C and P—O *bond forming* reactions. The reaction chemistry of metal-phosphinidenes also led to the unprecedented development of phosphorus monoxide (PO) chemistry via acid-catalysed hydrolysis of P—N bonds of coordinated aminophosphinidenes and the utility of electrophilic "Fischer-type" phosphinidene complexes in promoting novel P—X bond forming reactions.

Arthur has supervised or co-supervised 18 M.Sc. and 29 Ph.D. students, 35 post-doctoral fellows, and dozens of undergraduate researchers, and has hosted in his laboratories a large number of scientific visitors from Canada and abroad. He and his co-workers have reported their research findings in over 300 papers, five review articles, nine book chapters, and five patents, and Arthur has given an enormous number of invited presentations (over 20 in 2005 alone!). He has received numerous awards in recognition of his outstanding contributions to science, including a Royal Society-Nuffield Foundation Fellowship (1974), the Alcan Award of the Canadian Society for Chemistry (1984), the E.W.R. Steacie Award of the Canadian Society of Chemistry (1995), the Montreal Medal of the Chemical Institute of Canada (1996), the Purvis Award of the Society of Chemical Industry (1997), and the National Merit Award of the Ottawa Life Sciences Council (2000). He is a Fellow of the Royal Society of Canada, an Honorary Fellow of the Chemical Institute of Canada, an Officier de l'Ordre National du Mérite, France, an Honorary Member of the Engineering Institute of Canada, a Fellow of the Fields Institute for Research in Mathematical Sciences, and an Officer of the Order of Canada. He has received nine honorary doctoral degrees from universities in Canada (Carleton, Waterloo, Acadia, McMaster, Queen's, Ottawa, Memorial, Calgary, and Okanagan University College, now UBC Okanagan), as well as one from France (Rennes), and an honorary professorship from Taiwan (National Chiao-Tung University).

He has served as Vice-President and President of the Canadian Society for Chemistry, and as member or chair of over 30 organizations as diverse as the Executive Committee of the Society of Chemical Industry, the Atomic Energy Control Board of Directors, the R&D Advisory Council of the Department of National Defence, the Leaders' Forum on Innovation of The Conference Board of Canada, the Board of Directors of Canadian Light Source Inc., the Board of Directors of Genome Canada, the Canadian Space Agency Advisory Council, the Canadian Nuclear Safety Commission, the Board of Directors of the Ottawa Health Research Institute, the Selection Committee of the Network of Centres of Excellence, the editorial advisory boards of four scientific journals, the advisory boards

© 2006 NRC Canada

of eight international conferences, and the Board of Directors of Opera Lyra (National Arts Centre). Through these activities, as well as in his roles as President of the National Research Council and National Science Advisor to the Prime Minister, Dr. Carty has served and continues to serve as a preeminent advocate for the development of science and technology in Canada.

Despite these many commitments outside of the laboratory, however, and as a testament to his roots, Arthur also continues to maintain an enviable level of productivity in his research and continues to attract the brightest young minds to his research team. As is known to all who have worked with him, his dedication to chemistry, his excellent mentoring skills, and his sincerity, integrity, generosity, and vision have all been instrumental in launching numerous careers in industry and academia. We are very pleased to present this special issue as a token of our admiration and respect.

Mike Baird
John Corrigan

TRIBUTE / HOMMAGE

Ce numéro spécial de la *Revue canadienne de chimie* vise à saluer les réalisations exceptionnelles de M. Arthur J. Carty dans le domaine de la chimie des composés organométalliques ainsi que sa contribution remarquable à l'avancement des sciences et de la technologie au Canada. Comme tous les auteurs qui ont contribué au présent numéro le savent, M. Carty occupe une place unique au panthéon des grands savants et administrateurs scientifiques du Canada. Il est, sans aucun doute, un des grands personnages de l'histoire des sciences au Canada.

De 1952 à 1959, M. Carty a fréquenté l'école Hookergate Grammar School, dans le comté de Durham, en Angleterre, où il a obtenu un certificat général d'éducation (G.C.E.) au niveau avancé en chimie, en physique et en mathématiques, avec distinction et niveau de boursier en chimie et en physique. En 1958 et 1959, il a été capitaine de l'école, et de 1957 à 1959, il a également été capitaine des équipes de football et de cricket. Par la suite, il a étudié la chimie à l'Université de Nottingham, où il a obtenu, en 1962, un baccalauréat *ès* sciences avec spécialisation de première classe. Devenu membre du groupe de recherche de feu Dennis Tuck à Nottingham, il a obtenu son doctorat en chimie inorganique en 1965.

Après deux ans de travail en qualité de professeur adjoint de chimie à l'Université Memorial, à St. John's (Terre-Neuve-et-Labrador), M. Carty est devenu membre du département de chimie de l'Université de Waterloo, à Waterloo (Ontario). Il est monté progressivement dans la hiérarchie pour devenir professeur titulaire en 1975, directeur fondateur du centre Guelph-Waterloo des études supérieures en chimie (1975–1979), directeur du département de chimie (1983–1989) et doyen à la recherche (1989–1994). En 1994, M. Carty a quitté l'Université de Waterloo et a assumé la présidence du Conseil national de recherches du Canada (CNRC). Il a tiré sa révérence au CNRC en 2004 pour devenir le premier conseiller national des sciences auprès du premier ministre du Canada.

Dans le cadre de ses études de doctorat sous la direction de Dennis Tuck, M. Carty a contribué à l'avancement de la chimie de coordination des métaux du groupe 13. Au début de sa carrière de chercheur indépendant, il s'est livré à des études spectroscopiques (IR, Raman, RMN et Mössbauer) des complexes métal-halogénure ligandés au donneur de phosphore, y compris les phosphinoalcynes. Au cours de sa carrière de chercheur, il a contribué à l'avancement de la chimie dans tout le domaine de la chimie de coordination des éléments métalliques des groupes principaux et de transition, de la chimie bio-inorganique du mercure à la chimie organométallique et à la science des matériaux.

Plus particulièrement, ses recherches ont porté sur l'exploration de la chimie des phosphines et diphosphines acétyléniques, et ont donné lieu à des études de pointe sur la synthèse d'une grande série de complexes organométalliques. Ses travaux sur les carbonyles métalliques des métaux de transition lourds et la liaison de ceux-ci aux ligands de phosphinoacétylène ont mené à l'élaboration d'un programme de recherche de renommée mondiale axé sur la chimie des agrégats de métaux de transition. Dans le domaine des réactions faciles de clivage de la liaison phosphore-carbone des ligands coordonnés P-C≡CR, ses recherches ont offert une entrée élégante au domaine des complexes métal-acétylure. Ces recherches ont été chaudement accueillies, et en 1981 et 1982, les mémoires de M. Carty ont été classés parmi les 100 mémoires le plus cités du monde dans le domaine de la chimie pure et synthétique (A.J. Carty, S.A. MacLaughlin et N.J. Taylor, « Open and closed ruthenium and osmium clusters with μ_3-acetylide and phosphido bridges », J. Organomet. Chem. **204**, C27 (1981); A.J. Carty, « Structural chemistry and reactivity of cluster bound acetylides: Close relatives of the carbides? », Pure Appl. Chem. **54**, 113 (1982)). M. Carty et ses collèges ont été chefs de file de l'étude des réactions de formation de liaisons C—C et C—N des groupes d'acétylures coordonnés, ce qui a permis de conforter bon nombre de notions concernant l'analogie agrégat-surface proposée par Muetterties. Les travaux dans ce domaine, qui a connu un grand essor pendant les années 1980 et 1990, ont été caractérisés notamment par des études approfondies de la synthèse et des schémas de réactivité des ligands de carbone polyinsaturés, y compris des complexes allenyles (-C(R)=C=CR′$_2$) et butadiynyles (-C≡C-C≡C-R) des métaux de transition lourds.

Dans la plupart des cas, l'exploration de cette chimie a été rendue possible par la souplesse des ligands auxiliaires phosphido (PR_2), phosphidoxo (R_2PO) et phosphinidène (PR), qui supportent les centres métalliques de manière à empêcher ou à restreindre les réactions de clivage des liaisons métal-métal. Par ailleurs, M. Carty et son équipe ont démontré clairement que ces ligands peuvent jouer un rôle actif comme médiateurs des réactions sur les surfaces des agrégats par des réactions de *liaisons* P—C et P—O. Finalement, la chimie des réactions entre les métaux et les phosphinidènes a mené à l'expansion sans précédent de la chimie du monoxyde de phosphore (PO) au moyen de l'hydrolyse catalysée par acides des liaisons P—N aminophosphinidènes coordonnées et grâce à l'utilité des complexes électrophiles de phosphinidènes de type Fischer pour la promotion de nouvelles réactions de formation de la liaison P—X.

M. Carty a supervisé, seul ou en collaboration, 18 étudiants de maîtrise *ès* sciences, 29 doctorants, 35 boursiers de recherches postdoctorales et des dizaines de chercheurs au premier cycle des études universitaires. Dans ses laboratoires, il a accueilli un grand nombre de scientifiques invités du Canada et de l'étranger. M. Carty et ses collègues ont rapporté les résultats de leurs recherches dans plus de 300 communications, cinq rapports de synthèse, neuf chapitres de livre et cinq brevets. M. Carty lui-même a fait un très grand nombre d'exposés en tant que conférencier invité (plus de 20 en 2005 seulement!). En reconnaissance de ses contributions exceptionnelles à la science, il s'est vu décerner de nombreux prix, entre autres une bourse de la Royal Society et de la Nuffield Foundation (1974), le prix Alcan de la Société canadienne de chimie (1984), le prix E.W.R. Steacie de la Société canadienne de chimie (1995), la médaille de Montréal de l'Institut de chimie du Canada (1996), le prix Purvis de la Society of Chemical Industry (1997) et le prix d'excellence national du Conseil bioscentifique d'Ottawa (2000). Il est membre de la Société royale du Canada, membre honoraire de l'Institut de chimie du Canada, officier de l'Ordre national du mérite de France, membre honoraire de l'Institut canadien des ingénieurs, associé du Fields Institute for Research in Mathematical Sciences et officier de l'Ordre du Canada. Il a reçu neuf doctorats honorifiques d'universités canadiennes (Carleton, Waterloo, Acadia, McMaster, Queen's, Ottawa, Memorial, Cal-

gary et le collège universitaire Okanagan, aujourd'hui UBC Okanagan) et un de l'Université de Rennes, en France. En outre, l'Université nationale Chiao-Tung de Taiwan l'a nommé professeur honoraire.

M. Carty a été vice-président et président de la Société canadienne de chimie, ainsi que membre ou président de plus de 30 groupes très divers, entre autres : le comité de direction de la Society of Chemical Industry, le conseil d'administration de la Commission canadienne de sûreté nucléaire, le comité consultatif sur la R-D du ministère de la Défense nationale, le forum des chefs de file sur l'innovation du Conference Board du Canada, le conseil d'administration de Canadian Light Source Inc., le conseil d'administration de Génome Canada, le comité consultatif de l'Agence spatiale canadienne, la Commission canadienne de sûreté nucléaire, le conseil d'administration de l'Institut de recherche en santé d'Ottawa, le comité de sélection des Réseaux de centres d'excellence, le comité consultatif de rédaction de quatre revues scientifiques, la commission consultative de huit congrès internationaux et le conseil d'administration d'Opéra Lyra du Centre national des arts. En poursuivant toutes ces activités et en jouant ses rôles de président du Conseil national de recherches et de conseiller national des sciences auprès du premier ministre, M. Carty a été, et est toujours, un grand défenseur du développement des sciences et de la technologie au Canada.

Malgré ses nombreux engagements hors du laboratoire, M. Carty reste fidèle à ses origines, car il maintient un niveau enviable de productivité dans ses recherches et continue d'attirer à son équipe de recherche les jeunes scientifiques les plus brillants. Comme le savent ceux et celles qui ont travaillé à ses côtés, son dévouement à la chimie, ses grandes compétences de mentor et sa sincérité, sa probité, sa générosité et sa vision ont grandement contribué au lancement de nombreuses carrières dans les secteurs industriel et universitaire. C'est un grand plaisir pour nous de présenter ce numéro spécial, gage de notre admiration et de notre respect.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2005 Pure or Applied Inorganic Chemistry Award Lecture — Host–guest inclusion chemistry of electroactive, mesoporous transition metal oxides oxidation and 1-D confinement in one step and why amorphous is better

B.O. Skadtchenko and D.M. Antonelli

Abstract: The flexible oxidation states of mesoporous Nb, Ta, and Ti oxides make them unique amongst porous materials allowing reaction pathways and cascades that are not possible for mesoporous silica or microporous materials such as zeolites. This electronic activity coupled with the 20–30 Å pores and the amorphous wall structure, which provides greater bandwidth (*W*) and hence an even greater range of redox potentials, leads to a rich variety of host–guest inclusion chemistry, which serves as an unprecedented 1-D analogue to layered 2-D host–guest inclusion reactions studied for decades. In this paper we survey a series of reactions between these mesoporous hosts and a wide variety of organic and organometallic guest species including alkali fullerides, cobaltocene, and other organometallic sandwhich species, and discuss the electronic and magnetic properties of the resulting composites.

Key words: mesoporous materials, semiconductors, fullerides, superconductors, oxides, nanomaterials, metallocenes.

Résumé : Les états d'oxydation flexibles des oxydes de Nb, de Ta ou de Ti mésoporeux les rendent uniques parmi les matériaux poreux et rendent possibles des voies réactionnelles et des cascades qui ne sont pas possibles avec las silices mésoporeuses ou les matériaux microporeux, tels les zéolites. Cette activité électronique couplée à des pores de 20 à 30 Å et à une structure amorphe des parois qui rend possible une largeur de bande plus grande (*W*) et, en conséquence, des plages plus grandes de potentiels redox, conduit à une chimie d'inclusion hôte–invité riche et variée qui peut servir d'analogue 1-D sans précédent pour des réactions d'inclusion hôte–invité en couches 2-D qui ont été étudiées depuis plusieurs décades. Dans ce travail, on passe en revue une série de réactions entre ces hôtes mésoporeux et une grande variété d'espèces invitées, tant organiques qu'organométalliques, y compris des fullerures et des espèces cobaltocène et autres composés sandwiches organométalliques et on discute des propriétés électroniques et magnétiques des composites qui en résultent.

Mots clés : matériaux mésoporeux, semiconducteurs, fullerures, supraconducteurs, oxydes, nanomatériaux, métallocènes.

Introduction

The study and fabrication of materials on the nanoscale has recently attracted a great deal of attention from scientific disciplines as disparate as physics and medicine (1–4). One of the most important classes of nanoscale materials are those with a regular pore structure on the nanometer scale (5–7). The discovery of M41S mesoporous silica in 1992, a material with extremely high surface areas (up to 1400m^2/g) and pore sizes ranging from 2 to 10 nm (8, 9), represented the first synthesis of a material with ordered pores greater than 15 Å in size. This discovery also led to great strides in the fabrication of materials with ordered structural motifs ranging from the nanometer level all the way up to the micron level (10). While mesoporous silicas have great advantages over microporous zeolites in the diffusion of bulky molecules through the pore channels, their amorphous wall structure leads to a lack of local geometric control on the molecular level, limiting applications to catalysis. In 1995, Antonelli and Ying reported the first successful synthesis of stable, mesoporous transition metal oxides. These materials were based on Ti (11), Nb (12), and Ta (13) oxides and pos-

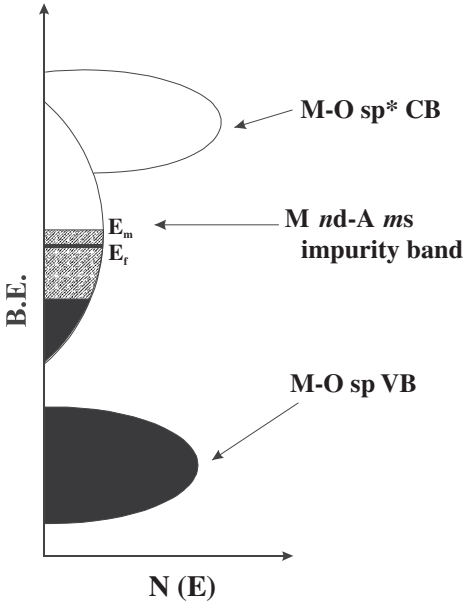
sessed pore sizes of 2–5 nm and surface areas up to 1200 m^2/g. The great advantage of these materials over traditional silica-based materials is that mesoporous transition metal oxides are capable of existing in various oxidation states, a property that could lead to interesting electronic, catalytic, and optical applications because of the presence of d electrons in the walls of the structure. To this end, our group showed that mesoporous Nb, Ti, and Ta can act as stochiometric electron acceptors (14, 15). This was the first example of a full one-electron transfer of a guest species to a porous host. While some Mn oxides possess channel structures and undergo some redox chemistry, these materials cannot accept a full electron equivalent without undergoing a phase change because of redox-induced local distortion (16). The greater capacity to accept electron density in mesoporous Nb, Ta, and Ti oxides is thought to be due to the amorphous nature of the walls, which impart fewer local constraints on the geometry of the transition metal centers (15). Therefore, in some applications, amorphous walls in a mesoporous structure are clearly an advantage. Like redox-active layered materials of the types MO_3 and MX_2 (M = Nb, Ta, Mo, V; X = S, Se), mesoporous Nb, Ta, and Ti oxides can also serve as hosts for a wide variety of guest molecules (17–21), where electron transfer from the guest to the host drives the intercalation process. An important difference, however, is that in the case of the mesoporous systems, the resulting product contains one-dimensional nanophases in the pores, rather than the two-dimensional sheets adopted by the guest phase in a layered host lattice. This may lead to unusual physical properties such as charge density waves and other phenomena associated with 1-D materials. Another interesting result of the amorphous walls in these materials is that an amorphous oxide has a broader distribution of reduction potentials than its crystalline counterpart. This enables mesoporous Nb oxide, for example, to react with up to 0.5 equiv. of cobaltocene (19), where crystalline Nb_2O_5 does not react with cobaltocene at all! More recent unpublished results in our group have also shown that these materials are useful in nitrogen activation and hydrogen storage. In the latter application, the amorphous walls appear to open up space for hydrogen molecules that would otherwise not exist in the crystalline oxide counterparts, again stressing the advantages in some cases of a loosely knit amorphous structure with potential to act as an electron acceptor or as multiple binding sites.

This review will focus on a wide range of host–guest inclusion chemistry of mesoporous Nb, Ta, and Ti oxides, focusing largely on encapsulated low-dimensional nanostructures, and in particular, our extensive efforts to rationalize the electronic properties of low-dimensional alkali fulleride superconductors confined in the host lattice, which have very different properties from bulk-phase fullerides.

Mesoporous transition metal oxides (Nb, Ta, Ti) reduced with alkali metals

In 2000, Vettraino et al. (14). reported the reduction of mesoporous Nb oxide with 0.2–1.0 equiv. of Na-naphthalene in THF to produce a series of new gray to black composites These reduced materials showed full retention of the mesostructure as determined by X-ray powder diffraction (XRD) and nitrogen adsorption/desorption. Systematic X-ray photoelectron spectroscopy (XPS) studies on these materials showed that the Nb 3d 5/2, 3/2 emission shifts monotonically to a lower binding energy corresponding to a decrease in the average oxidation state of the Nb from (V) to (IV) as the Na loading level increases. The observed lack of individual peaks for Nb(IV) and Nb(V) species was attributed to fast electron hopping between two adjacent Nb sites relative to the XPS timescale. This work was subsequently expanded to include all alkali metal reduced mesoporous Nb, Ti, and Ta (15). The order of stability of the mesostructure upon reduction with alkali metal established from the XRD data was found to be Ti < Nb < Ta. This observation is consistent with thermal stability of these mesostructures. XPS studies on the Nb material showed that the different alkali metals gave a progressively higher shift (ca. 0.5 eV per row) to lower binding energy in the 3d emission as the size of the alkali metal increased. This was attributed to the decrease in electronegativity of the alkali metal down the row leading to greater electron density around the transition metal center. The band gaps were calculated from UV–vis spectra and varied from 3.3 to 4.0 eV depending on the material. The closest distance from the impurity band, formed by overlapping of the *n*d transition metal orbital and the ms orbital of the alkali metal, to the conduction band was 2.1 eV. Room-temperature conductivity measurements performed on this series of composites showed that all Nb and Ta materials were insulating with conductivity values below 10^{-7} ohm^{-1} cm^{-1}. The Li/Ti materials, on the other hand, displayed conductivity values up to 10^{-6} ohm^{-1} cm^{-1}. The insulating nature of the Nb and Ta composites was attributed to Anderson localization, an electron localization phenomenon caused by random dislocations in the oxide structure, while the high conductivity of the Li/Ti material was attributed to an Anderson transition (Scheme 1), which occurs in many amorphous systems, including Na-doped Na_xWO_3 (22).



The superconducting quantum interference device (SQUID) magnetometry measurements of these materials revealed paramagnetic behavior. The presence of free electrons in this system was confirmed by electron paramagnetic resonance (EPR), however, no Nb coupling was observed, suggesting that the electrons are not tightly bound to one Nb center. To better understand the electrochemistry of Nb, Ta, and Ti oxides, a series of cyclic voltammograms (CVs) were employed. The Nb and Ta materials exhibited a high level of capacitance suggesting a possible application as supercapacitors. The CV run for the Ti material produced two clear peaks at 0.8 and 1.4 eV indicating reversible reduction/oxidation of the framework, suggesting its potential application in Li batteries and fuel cell fabrication. The difference in behavior of the Nb, Ta, and Ti materials was attributed to a charge mobility problem arising from greater electron localization in case of the Nb and Ta materials vs. the Ti material. This suggestion is consistent with conductivity measurements of the reduced Nb, Ta, and Ti materials.

Unusual magnetic properties in mesoporous Nb oxide – cobaltocene and nickelocene composites

Scheme 1. Graphic illustration of the energy level diagram of alkali A (A = Li, K, Na, Rb) reduced M-TMS1 (M = Ta, Nb, Ti). The electron resides in an *m*s (alkali metal) – *n*d (transition metal) impurity band between the valence and conduction bands of the mesostructure. E_F denotes the Fermi level, while E_m represents the mobility edge. Black areas are filled with electrons, while the area marked by grid lines represents a region of localized states extending down into the black filled levels of the impurity band.

erties of mixed alloy systems and often brings about strong ferromagnetic (23), superconducting (24), and superparamagnetic (25) properties, depending on the alloy or compound. The intercalation of cobaltocne into redox-active layered structures such as $NbSe_2$ has been extensively studied (26). In many ways cobaltocene can be viewed as a pseudo alkali metal, however, it has never been successfully intercalated into layered Nb_2O_5 because of the mismatch of reduction potentials between the host and guest. Since mesoporous Nb oxide possesses amorphous walls and amorphous structures are known to have a broader dispersion of reduction potentials than their crystalline counterparts, we attempted intercalation of cobaltocene into this structure. Surprisingly, mesoporous Nb oxide readily reacts with cobaltocene to give new dark gray solid that exhibits a sudden transition in magnetic behavior from paramagnetic to superparamagnetic on increase of cobaltocene loading at a critical molar ratio for Co–Nb of 0.5:1 (19, 27). These results are very unusual since superparamagnetism is normally observed only in nanometer-sized colloid grains of ferromagnetic transition metals or compounds, and neither cobaltocene or reduced mesoporous Nb oxide is ferromagnetic. XPS studies of this series of composites confirmed electron transfer from cobaltocene to the walls of the mesostructure by the presence of Nb in both the (IV) and (V) oxidation states. Clear emissions for both cobaltocene and cobaltocenium were also present, depending on the Co-loading level. While the materials at Co-loading levels below 0.5 equiv. showed only cobaltocinium, those at higher loading levels (up to 0.8 equiv.) showed a mixture of the oxidized and reduced metallocene. From the magnetic data, it was estimated that there was roughly 20 spins per superparamagnetic domain.

To understand which factors govern the onset of superparagnetism in these materials, a systematic study of the variation of pore size, wall thickness, and composition was conducted (27). The wall thickness and pore sizes were varied from 15 to 20 Å and 23 to 33 Å, respectively. In addition, mesoporous Ta and Ti cobaltocene composites were synthesized to gauge the effect of different mesostructure composition on the magnetic properties. The pore size and wall thickness seemed to have no effect on the magnetic properties of these materials. In contrast to the mesoporous Nb composites, the mesoporous Ta and Ti materials showed paramagnetic behavior and a much lower level of absorbed organometallic. This is not surprising because mesoporous Ti(IV) and Ta(V) oxides are more difficult to reduce than mesoporous Nb(V) oxide, and intercalation reactions are electron transfer driven. Thus, the host material must be reactive enough toward reduction by a guest species to absorb the critical amount of cobaltocene required to initiate superparamagnetic behavior. Initially, all the intercalated cobaltocene is oxidized to cobaltocinium by Nb sites of strong enough oxidizing strength (roughly half, according to the XPS). Additional cobaltocene is absorbed in the neutral form to give a mixed oxidation state cobaltocene/cobaltocinium phase trapped in a reduced mesoporous Nb oxide lattice. Once the critical absorption level is reached, the material undergoes a transition to superparamagnetic behavior owing to the increased density of unpaired electrons arising from neutral cobaltocene in the pore channels. The reason for superparamagnetism is still not understood, but may be related to ferromagnetic coupling induced by rapidly exchanging itinerant electrons, not bound exclusively to one Nb or Co site.

To gauge the effect of the overall spin of the organometallic guest species on the magnetic behavior of these composites, nickelocene, which has two unpaired electrons per Ni center, was introduced into the mesoporous Nb host (28). Similar to the cobaltocene composites, these materials revealed a loading dependent transition, however, in this case the transition was from paramagnetic to spin-glass behavior, which is normally associated with amorphous metal alloys in which the spins become "frozen" in a random orientation below a certain temperature. From the XPS it was found that the loading level of the organometallic species in case of the nickeltocene was much lower than in the case of the cobaltocene composites. This was rationalized by the higher ionization energy of nickelocene as compared with cobaltocene, i.e., fewer Nb sites are strong enough oxidizing agents to strip the electrons from the organometallic guest in the case of Ni as compared with Co.

Pseudo 1-D organometallic molecular wires supported by mesoporous Nb oxide

While intercalation of late metal metallocenes into mesoporous Nb oxide leads to materials that are insulating, but possess unusual magnetic properties, the impregnation of the pores of this material with early metal sandwich complexes leads to a new family of one-dimensional conducting

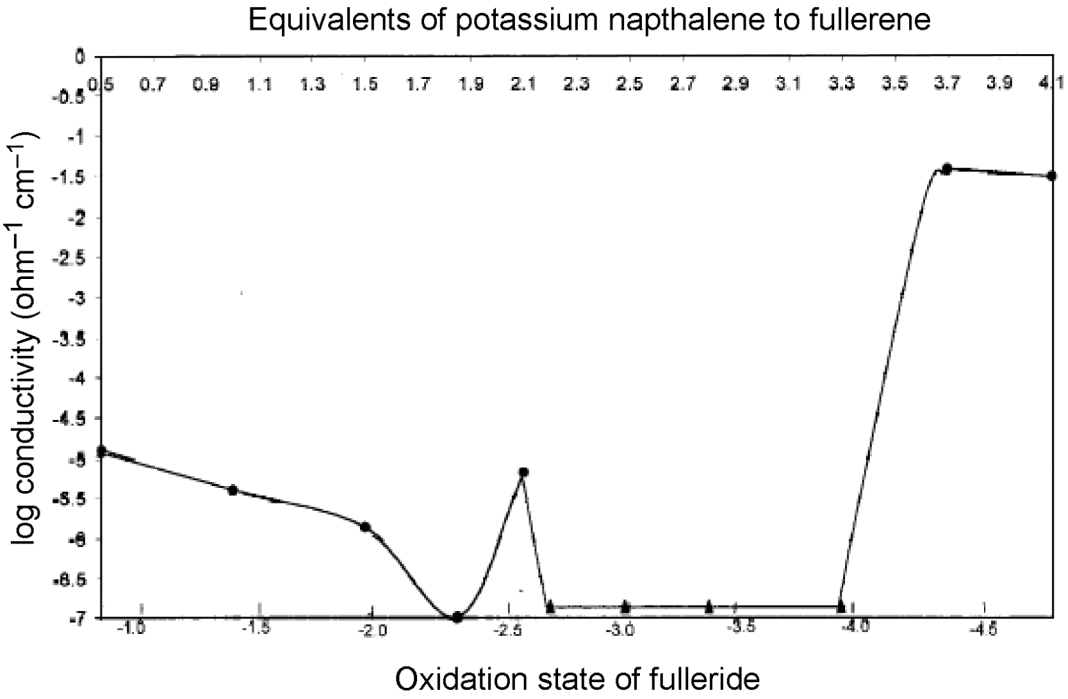
molecular nanowires in the case of Cp_2Cr, Cp_2V, $(C_6H_6)_2Cr$, and $(C_6H_6)_2V$ (17, 29–31). As in the case of cobaltocene, the mesoporous structure acts as an oxidizing agent and creates a mixed-valent cationic organometallic phase encapsulated in the negatively charged walls of the Nb oxide mesostructure. The spontaneity of this reaction is due to the broader distribution of redox potentials in the Nb oxide walls, since none of these organometallic species react with the crystalline bulk Nb oxide. In contrast to the Nb–cobaltocene composites, which are insulating, the electron transport measurements of these organometallic intercalates provided conductivity values as high as 10^{-4} ohm^{-1} cm^{-1}. A series of additional experiments (XPS, EPR, and NMR) suggested that conductivity in these systems arises only from the presence of the mixed oxidation state, low-dimensional organometallic phase, e.g., $(C_6H_6)_2Cr/(C_6H_6)_2Cr^+$. The conductivity in the V- and Cr-based composites was explained by a model where the hole in the mixed oxidation phase, arising from partial oxidation of the organometallic species by the mesostructure, is the charge carrier, since in all cases the presence of both cationic and neutral species were required for conductivity (17, 30), and the reduced mesostructure was previously shown to be insulating (15).

To better understand the nature of electron mobility in these organometallic composites, a systematic study of Cp_2V and Cp_2Cr intercalates using XPS, EPR, and UV–vis spectroscopy was performed (31). The Mott–Hubbard model, describing conductivity and electron localization in solids, was applied to rationalize the results. The estimated values of $W–U$ (W = bandwidth, U = Hubbard potential) for the V and Cr systems provided values of 1.38 and 2.32 eV with conductivities of 10^{-5} ohm^{-1} cm^{-1} and 10^{-6} ohm^{-1} cm^{-1}, respectively, as compared with $W \approx U = 0.05$ eV in the insulating cobaltocene system. The trend in conductivity from V and Cr to Co and Ni fits well into the Mott–Hubbard model. It also was found that in all these materials the electronic properties depend on the electronic configuration, mixed oxidation state of dopants, and the loading level of the organometallic. Solid-state ^{2}H NMR on the ^{2}H-labelled bis(benzene) Cr composite showed no evidence of close proximity between two adjacent organometallic species, suggesting that the Nb oxide walls may be involved in the local electron transfer between Cr(0) and Cr(I) (29).

Mesoporous Ta oxide reduced with bis(toluene) Ti — Metallic mesoporous oxides and dinitrogen cleavage



While sandwich complexes of mid- and late-transition metal species react with mesoporous Nb, Ta, and Ti oxides to give materials with mixed oxidation state organometallic phases in the pores, treatment of mesoporous Nb oxide with bis(toluene) Nb and mesoporous Ti oxides with bis(toluene) Ti leads to complete degradation of the organometallic structure and deposition of low-valent Nb or Ti on the surface of the respective mesostructure (32). The introduction of the organometallic into the pores is similar to a classical redox intercalation reaction in which an electron donor reduces the walls of the inorganic host to create a material with periodic charge regions consisting of an anionic metal oxide phase and a cationic dopant intercalate phase. In the case of bis(toluene) Ti and bis(toluene) Nb, the organometallic reduces the walls of the mesostructure, but does not retain its structural integrity on loss of electrons because the resulting cation is thermally unstable. The complex instead loses the toluene ligands and deposits Ti atoms on the inner and outer surface of the mesostructure. XPS studies of the material synthesized from mesoporous Nb oxide and bis(toluene) Nb reveal Nb(II) and Nb(IV). The XPS spectrum of the Ti analogue was less resolved, but showed emissions consistent with Ti(III) and Ti(II). There was also a broad hump at the Fermi level in both materials, suggesting metallic behavior. This was confirmed by variable-temperature conductivity measurements, which showed a slight increase in conductivity from the room-temperature values of 10^{-1} ohm^{-1} cm^{-1}. This was the first example of metallic behavior in a porous metal oxide structure. The metallic nature of this material can be attributed to the low-valent Nb or Ti coat on the surface (both NbO and TiO are metallic) of the mesostructure and suggests that there are continuous electronic pathways existing in the material that may be exploited in a catalytic process. An immediate example of the enormous potential of these materials in small molecule activation is the reaction of these materials with dinitrogen. Both the Nb and Ti analogues react spontaneously with dinitrogen to give surface nitride, which is subsequently protonated by incipient moisture to ammonia. ^{15}N-labeling studies confirmed that dinitrogen was indeed the source of ammonia. The ease of this reaction is surprising given the great stability of dinitrogen and the resistance to protonation of most metal nitrides. Treatment of mesoporous Ta oxide with bis(toluene) Ti also led to spontaneous ammonia formation in the presence of dinitrogen. Mechanistic studies on this system showed that both dinitrogen cleavage and protonation were fast steps, suggesting that the only barrier to making this process catalytic is the regeneration of the reduced active site on the surface.

Mesoporous Nb oxide as a host for K fulleride nanowires

Since mesoporous transition metal oxides function as insulating hosts for 1-D molecular nanowires and alkali fullerides have attracted much interest because of their metallic and superconducting properties, we began to explore the intercalation of these carbon-based materials into the pores of mesoporous Nb, Ta, and Ti oxides (20, 33–35). The role of the oxidation state in the metallic and superconducting behavior of alkali fullerides is still an area of much debate (36–38). However, it is widely believed that superconductivity in alkali fullerides, A_3C_{60} (A = K, Rb, Cs), arise from structural defects and the actual composition may be slightly different from the nominal A_3C_{60} composition (36). Recent theoretical advances suggest that the triple degeneracy of the t_{1u} band may lead to the removal of strong electron repulsion, the key factor of the Mott–Hubbard model, and thus might also be responsible for metallic and superconducting behavior in A_3C_{60}-type fullerides (39). Because of the subtleties of the solid-state chemistry involved, it is extremely difficult to study nonstoichiometry in C_{60}. The closest attempts to study noninteger oxidation states

came from the group of Prassides, who showed that Li does not give complete charge transfer to fullerides (40).

With the goal in mind of using mesoporous Nb oxide as a kind of "quantum test tube" to study conductivity–oxidation state relationships in isolated fulleride nanophases, we developed methods to impregnate mesoporous Nb oxide with K_3C_{60} (33, 34). The pore size of mesoporous Nb oxide used in this study was 23 Å, which is ideal to fit one unit cell of K_3C_{60} (ca. 14 Å). The reaction between mesoporous Nb oxide and K_3C_{60} in tetrahydrofuran (THF) yields a material with the alkali fulleride inside the pores in an oxidation state of $n = 0.5$ (parent material), as judged by Raman spectroscopy. For fulleride salts of the type A_nC_{60} (A = K, Rb, Cs), the A_g mode shifts roughly 6 cm^{-1} for every integer increment in the value of n (41, 42). The oxidation state of the Nb mesostructure was probed by XPS and revealed a partial reduction equal to that of pure mesoporous Nb oxide reduced with 0.4 equiv. of potassium naphthalene. Attempts to intercalate alkali fullerides into mesoporous silica were unsuccessful, suggesting that charge transfer from the fulleride to the Nb oxide walls was a key feature of stabilizing the composite. The room-temperature conductivity of the Nb composite provided values of up to 1.25×10^{-3} ohm^{-1} cm^{-1}, 10 000 times greater than that observed for the potassium-reduced, fulleride-free samples of mesoporous Nb oxide (14).

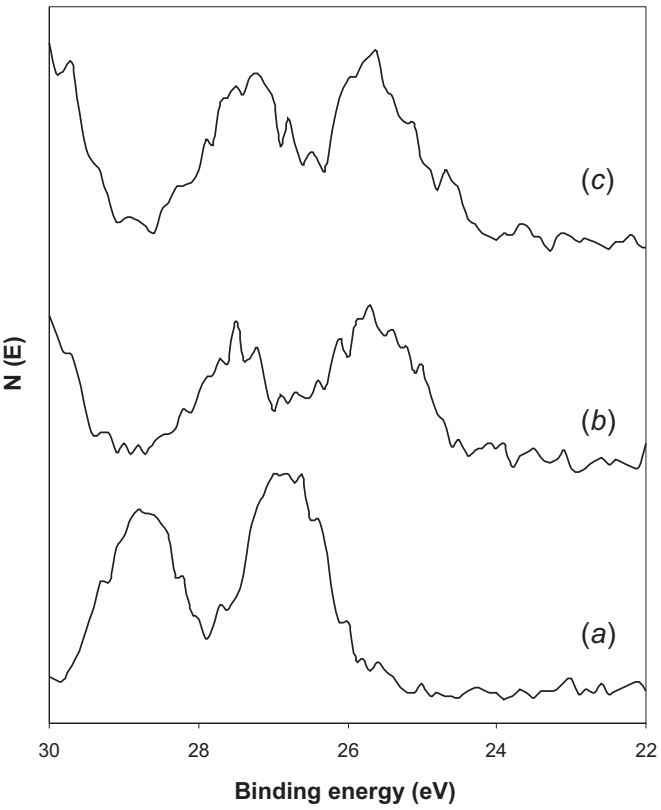
To probe into the possible contributions to the bulk charge transport properties from surface conductivity pathways, a sample of nonporous, amorphous Nb oxide was treated with K_3C_{60} in THF. The XPS measurements indicated partial reduction of the surface by K_3C_{60}, but the conductivity of this was below the instrument threshold of 10^{-7} ohm^{-1} cm^{-1}. This suggests that the conductivity pathway in the mesoporous composites is through the fulleride units occluded in the channels, rather than through the Nb oxide walls of the structure, and the fulleride units are acting as a one-dimensional molecular wire. Since room-temperature conductivity provides only limited information on a material's transport properties, variable-temperature conductivity measurements were performed on this series of materials (20). These studies revealed that some materials behave as semiconductors with a transition to an insulating state below 210 K. The presence of metal–insulator or semiconductor–insulator transition in one-dimensional materials is normally attributed to a Peirls distortion in which electrons become localized in traps owing to charge density waves (22).

An intriguing feature of this material is that it can be sequentially reduced with potassium naphthalene and the oxidation states of the occluded fulleride and Nb oxide mesostructure controlled and monitored by Raman and XPS, respectively. This allows us to study the effect of the oxidation state. To probe into the dependence of conductivity on the oxidation state of the fulleride inside pores, a series of new composites with oxidation states up to $n = 4.5$ were synthesized from the parent material by gradual titration with potassium naphthalene. Surprisingly, two conductivity maximums at $n = 2.6$ and 4.1 with values of 10^{-4} and 10^{-1} ohm^{-1} cm^{-1}, respectively, were observed in these composites (Fig. 1) (35).

The maximum at $n = 2.6$ is unexpected on the basis of conductivity patterns in pure alkali fullerides, but may support the view that metallic behavior in pure K_3C_{60} arises from nonstoichiometry and oxidation state defects in the fcc lattice. The maximum at $n = 4.1$ is particularly intriguing as K_4C_{60} has a calculated density of states at the Fermi level close to that of K_3C_{60}, and according to most models should be metallic because of its 2/3 filled t_{1u} band (43), yet so far

© 2006 NRC Canada

all samples of K_4C_{60} prepared are insulating. Variable-temperature conductivity measurements indicated that the $n = 2.6$ composite behaves similarly to the parent material, while the $n = 4.1$ material displayed metallic behavior. The nature of the conductivity maximum at $n = 4.1$ was explained by an increase in cooperation between the walls of mesostructure and t_{1u} band of the fulleride and is consistent with an observed increase in the density of states near the Fermi level in the XPS. When the parent material was reduced back to the $n = 3.0$ state, the room-temperature conductivity of this composite was lower than 10^{-7} ohm^{-1} cm^{-1} and no further reduction of the mesostructure was observed. This composite proved too insulating to perform variable-temperature conductivity measurements. Such results are quite surprising when compared with bulk fullerides, but not unexpected on the basis of theory, since K_3C_{60}, in accordance with the Mott–Hubbard model, should be an insulator with a half-filled t_{1u} band (44), but shows metallic behavior, possibly owing to accidental vacancies in its structure or perhaps because of lattice distortions lifting the degeneracy of the t_{1u} band.



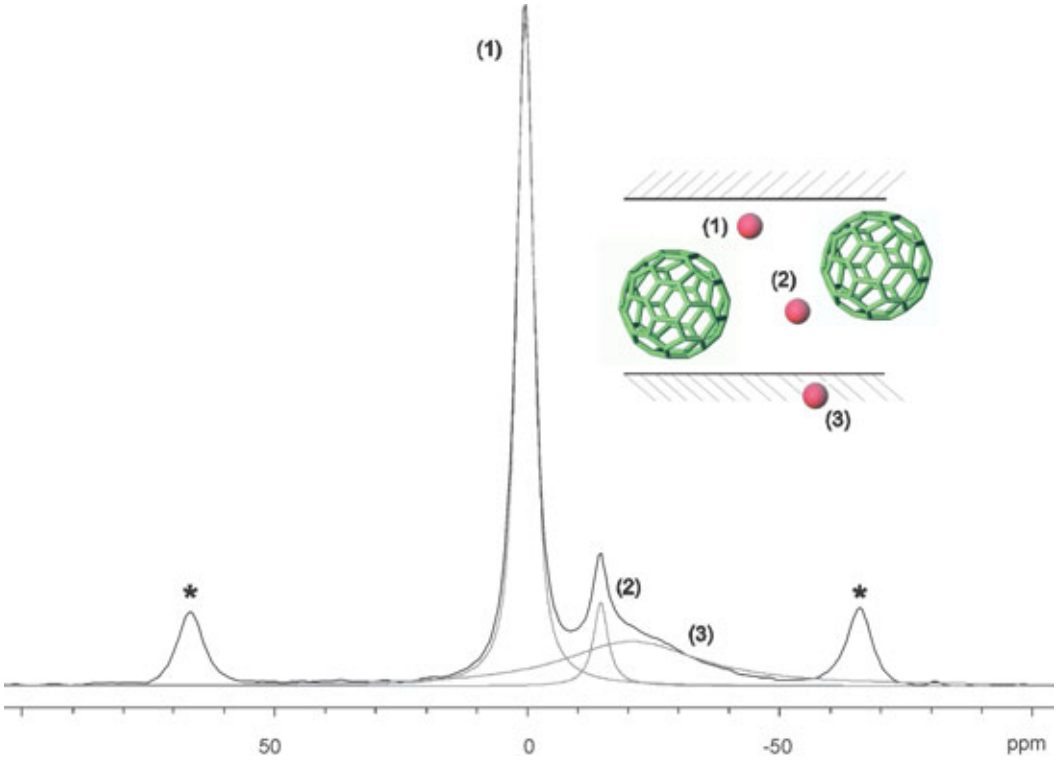
To better understand the unusual properties of this new family of composite materials, the effect of pore size and wall composition were studied. The pore size was expanded from 23 to 32 Å, sufficient to accommodate up to two fulleride units, while mesoporous Ti and Ta hosts were used in place of Nb. It was found that, in general, the change of host produces very little effect with a small difference in the position of the double maximum; however, this difference was too subtle to draw any definitive conclusions. Rather than providing enough room to accommodate two fullerides across the diameter of the pore channel, the expansion of pore size only makes it easier to wash out the fulleride, suggesting that restricted motion inside the narrow pores, and not just Coulombic attractions among the negatively charged walls, the alkali metal cations, and the anionic fullerides, are responsible for holding the structure together. SQUID magnetometry measurements revealed that all composites in this study were paramagnetic with no sign of a transition to superparamagnetic behavior at lower temperatures.

To make a more direct comparison between our mesoporous composites and the bulk materials and elucidate the role of the oxidation state of fulleride on conductivity, further information about the coordination geometry of the fulleride units and possible conductivity pathways was required. These materials are largely amorphous and solid-state NMR is perhaps the only way to gain information about the local structure of the material inside the pores. Since potassium is a difficult nucleus for NMR, we extended our study to include Na, Li, and Rb fulleride intercalates to perform ^{23}Na, ^{7}Li, and ^{87}Rb NMR. In these subsequent studies presented in the following sections, we also focused on mesoporous Ta, rather than Nb or Ti oxides, because of the greater thermal stability of the heavy metal based mesostructure, and its ability to resist reduction and reoxidation without any loss of structure.

Mesoporous Ta oxide impregnated with sodium fulleride

Because no known phase of sodium fulleride has yet demonstrated superconducting properties in the bulk phase, it was anticipated that sodium fulleride composites of mesoporous Ta oxide may have different electronic properties than the potassium analogues. Impregnation of the mesoporous oxide and subsequent Na-naphthalene reduction of the fulleride composites was performed in a manner similar to that used to synthesize the potassium fulleride composites. The oxidation state of fulleride after impregnation was estimated at $n = 0.5$ (parent material) by Raman spectroscopy, consistent with the value previously reported for the potassium analogues (21). XPS also showed a reduction of the Ta oxide walls to an oxidation state between (IV) and (V) (Fig. 2). Conductivity measurements of the parent material yielded values of 10^{-3} ohm^{-1} cm^{-1}, similar to those reported in the case of potassium fullerides.

Fig. 2. XPS spectra of the Ta 4f 7/2, 5/2 region for reduced mesoporous Ta oxide – Na_3C_{60} composites. (*a*) $n = 0.5$, (*b*) $n = 3.0$, and (*c*) $n = 4.5$ materials.



To explore the relationship between the fulleride oxidation state and conductivity in these materials, the parent intercalate was reduced sequentially with Na-naphthalene. The XPS spectra of the reduced materials showed a reduction of the Ta oxide walls of the mesostructure between the parent and $n = 3.0$ states, but almost no further reduction up to a level of $n = 4.5$ (Fig. 2*c*). This behavior is different from that observed in the K_3C_{60}/Nb system in which no reduction of the Nb oxide walls of the mesostructure upon addition of K-naphthalene was observed until the oxidation state of the fulleride units reached $n = 4.0$ (35). This behavior can be rationalized by the different reduction potentials of Nb vs. Ta and K-naphthalene vs. Na-naphthalene.

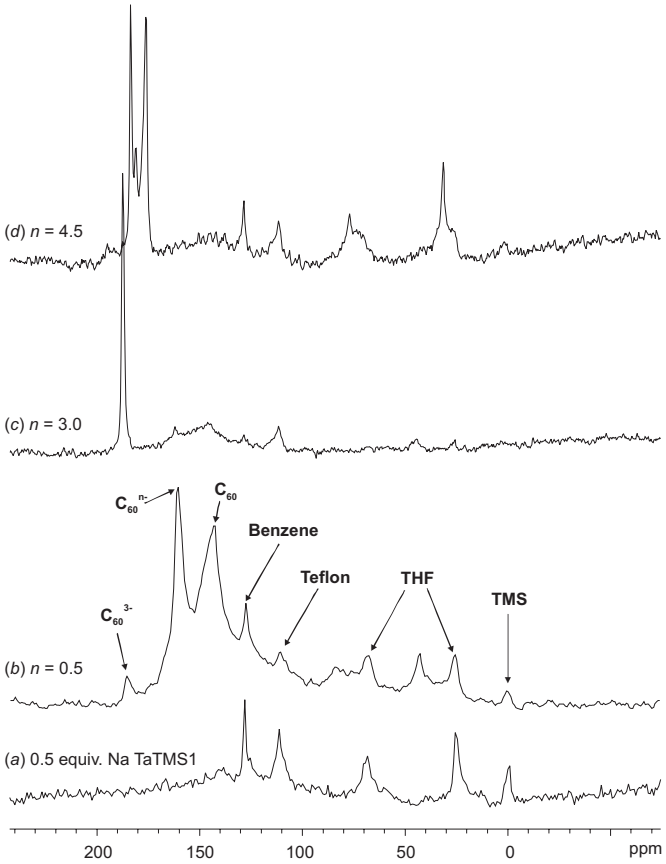
Fig. 3. ^{23}Na rotor-synchronized Hahn-echo MAS NMR spectrum of Na_3C_{60} intercalated into the mesoporous tantalum oxide acquired (spinning sidebands are denoted with asterisks). Inset: highly schematized representation of three different sodium cation sites: Na(1), sodium cations in the Ta oxide channels; Na(2), sodium cations associated with the fulleride species; and Na(3), sodium cations confined within the walls of the mesoporous Ta oxide.



reduced materials showed a progressive decrease in conductivity with increasing anionic charge on the fulleride from the n = 0.5 to the n = 3.0 state, which is totally insulating. After this, there is a sharp rise to n = 4.5, which has a conductivity value of 10^{-2} ohm^{-1} cm^{-1}. The absence of the conductivity maxima at 2.5, observed in the K/Nb analogue, is not totally unexpected, as the electronic properties of Na fulleride are substantially different from that of K fulleride, and there are no reports of superconductivity or metallic behavior in Na_3C_{60}. Variable-temperature conductivity measurements performed on the n = 0.5 and 4.5 composites revealed that both of these materials are semiconductors. This is not unlike the results obtained for potassium fulleride materials, except that the maximum at n = 4.0 in the K/Nb system is metallic rather than semiconducting.

The elemental analysis data for the sodium fulleride materials is puzzling when compared with that of the K/Nb analogues. The %C analysis of composite materials showed that the carbon-loading level remains virtually the same, within only 3% to 4% difference for all materials. This trend is very different from the K_3C_{60}/Nb materials, where progressive leaching of carbon upon reduction was observed, and the insulating n = 3.0 state is more rich in C than the metallic n = 4.0 state. This suggests that the carbon-loading level does not significantly contribute to the conducting properties of the materials. The reason why progressive leaching of fulleride upon reduction does not occur in the Na_3C_{60}/Ta system is not clear, but may be due to the polymerization of the fulleride units in the pores of the mesostructure, which has been reported in bulk Na_4C_{60}.

Solid-state ^{23}Na and ^{13}C NMR studies were conducted in the hope of establishing structural information about the coordination geometry about the alkali metals in the pores of the intercalated materials. ^{23}Na NMR performed on the parent material showed the presence of three distinct sodium species in the series of Na/Ta materials (Fig. 3). These are: (*i*) mobile uncoordinated Na ions in the channels of mesostructure; (*ii*) sodium ions that are closely associated with fulleride cages, and (*iii*) sodium ions confined or buried in the walls of the mesostructure. ^{23}Na NMR measurements for the series of reduced materials revealed the following trends: (*i*) decrease of Na ions associated with fulleride units; and (*ii*) progressive increase in the population of confined and channel sodium ions. ^{13}C NMR of this new series of materials revealed the presence of multiple carbon-containing species (Fig. 4). Three distinct resonances corresponding to C_{60}, C_{60}^{3-}, and C_{60}^{n-} were observed in the parent materials. Of special interest, however, is the spectra of the n = 3.0 material (Fig. 4*c*), as it almost exclusively showed the presence of C_{60}^{3-}. This allows much more direct comparison with the bulk phase and represents the first isolated example of an insulating n = 3.0 fulleride, possibly supporting the view that C_{60}^{3-} is a Mott–Hubbard insulator. In the case of the n = 4.5 materials (Fig. 4*d*), several new C_{60} species were identified that could not be assigned to known fulleride phases. This could be due to polymerization

of C_{60} within the pores of the mesostructure, a picture supported further by the high level of carbon in this material. However, polymerization could not be verified, since the sp^3 resonance associated with polymerized fullerenes falls between 30 and 80 ppm (45) and this region of the spectrum is obscured by multiple solvent species. All of these data suggest a unique and unprecedented fulleride structure in the $n = 4.5$ material in which the fulleride units are surrounded by a double sheath composed of an inner layer of Na ions followed by the reduced anionic walls of the mesostructure comprising the outer layer.

Mesoporous Ta oxide – Li fulleride composites

As mentioned previously, mesoporous Ti oxide impregnated with Li fullerides may be useful in Li batteries owing to the high conductivity imparted by the C-phase to the insulating oxide (15). To improve charge transport to the active sites in insulating Fe phosphate cathodic materials, carbon coating of the insulating inorganic grains has been employed. In the case of mesoporous transition metal oxides, 1-D fulleride nanowires could potentially be used to improve charge transport through the otherwise insulating channels to the redox-active transition metal sites. Although mesoporous Ta oxide reduced with Li naphthalene is an insulator, impregnation of the mesostructure with alkali (K, Na) fullerides clearly leads to improved electron transport through the structure (20, 21, 35). Thus, it stands to reason that impregnation of a Ta oxide mesostructure with a Li fulleride phase could lead to the new cathodic materials with improved electron transport to the active sites. In this regard, we attempted to synthesize a new series of mesoporous Ta oxides impregnated with Li fulleride (46). On paper it seemed feasible to use a similar approach to that used for K and Na fulleride analogues, however, synthesis of Li_3C_{60} itself is extremely difficult and requires high temperature and pressure apparatus (47). Attempts to synthesize Li_3C_{60} in solution were unsuccessful and led to formation of insoluble products that could not be used for impregnation. Thus, an alternative route for the synthesis of these materials was developed. This involved the reduction of the mesostructure with Li naphthalene followed by the treatment of the reduced mesostructure with an excess of C_{60}. This method relies on the unique ability of the alkylated mesostructure to reduce the fullerene in solution and hence trap it as a fulleride in the pores, rather than using alkylated fulleride to reduce the mesostructure. It was established earlier (15) that the materials reduced with less than 1 equiv. of Li naphthalene are less effective reducing agents and absorb less C_{60}, while the materials reduced with more than 1 equiv. of Li naphthalene indicated a partial collapse of the mesostructure. Given these considerations, and for the sake of simplicity, material reduced with 1 equiv. of Li naphthalene and subsequently treated with the maximum amount of C_{60} was chosen for study. Raman spectra of this material revealed a very subtle shift in the position of the A_g band of C_{60} in this composite, indicating that no visible reduction of the fulleride phase had occurred. This was further confirmed by solid-state ^{13}C NMR (Fig. 5), which revealed the presence of a single C_{60} species with a chemical shift almost coincident with that of unreduced C_{60} (48). The absence of other resonances within the 140–170 ppm range, where chemical shifts for fulleride species are normally distributed, further demonstrated that no visible reduction of C_{60} had occurred. Solid-state ^7Li NMR for this material revealed a single broad resonance centered at around 0 ppm. Given the narrow distribution of chemical shifts in the ^7Li NMR, the assignment of a Li environment based on this single resonance is extremely difficult and could be misleading. Conductivity measurements for this composite gave values below 10^{-7} ohm^{-1} cm^{-1}, which is surprising given the conductive behavior of K- and Na-reduced fullerides (20, 21, 33–35). On the other hand, Raman and XPS data suggested that Li does not provide complete charge transfer to C_{60}, nor to the walls of mesostructure. SQUID measurements showed that this material is paramagnetic and contains approximately one unpaired electron per Ta. In our previous studies of K and Na fulleride intercalated systems it was possible to reduce these materials further by simple treatment with alkali naphthalene in THF. This allowed the charting of the dependence of the electronic and magnetic properties of these materials on the oxidation state of C_{60} and the absolute loading level of alkali metal, and hence to draw some comparison with bulk phase alkali fullerides (21, 34, 35). In the case of the Li fulleride material, all further attempts to reduce this material with Li naphthalene were unsuccessful and led to

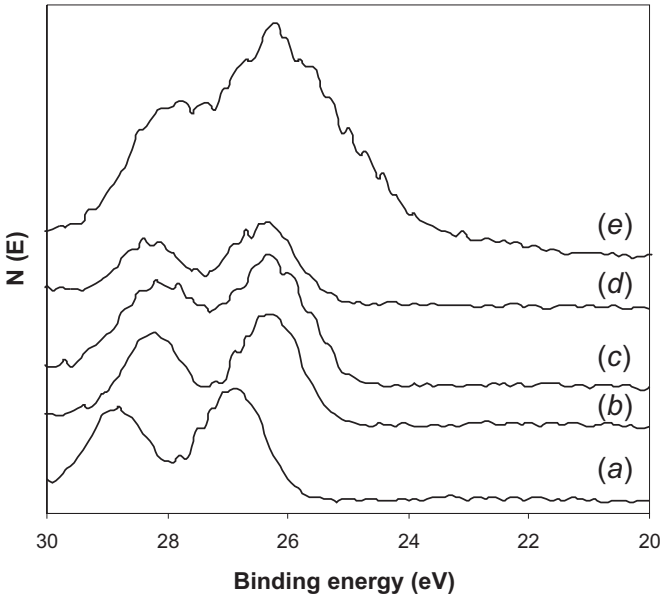
Fig. 5. ^{13}C MAS NMR of the Li fulleride composite. TMS here refers to trimethylsilyl.



no observable reaction. Since Li naphthalene is a strong enough reducing agent to reduce either the walls of the mesostructure or the occluded C_{60}, the fulleride units in these composites are likely blocking the pores and preventing charge transfer to the inside the channels. Given that previous studies of K and Na fulleride materials would likely have the same pore restrictions, it is feasible that reduction in these materials likely occurs via a reaction on the outside of the channels followed by subsequent charge transfer through the channels, rather than gradual diffusion of alkali naphthalene through the pores to the active site. Impregnation of the pores with Li fulleride thus impedes charge transfer through the channels and prevents the possibility of further reduction.

Electrochemical studies were conducted to compare the Li insertion/deinsertion behaviors of this composite with a previously synthesized Na fulleride mesoporous Ta oxide composite and a pristine mesoporous Ta oxide. The results of these studies showed that Li insertion into the fullerene composites is rather irreversible in the Li material and more reversible in the more highly conducting Na analogue. This was attributed to a strong interaction between the inserted Li ions and the walls of the mesostructure, with fullerene doping suppressing the charge transfer owing to the nonconductive fullerene wires. This shows that impregnation of the pores of mesoporous Ta oxide does not improve charge transfer as anticipated, and that these materials would thus be a poor choice for cathodes in a Li battery.

Mesoporous Ta oxide impregnated with rubidium fulleride

Considering the extreme diversity in properties of alkali fullerides and because Rb fullerides have higher T_c as compared with K fullerides (Li and Na fullerides are not superconducting) we extended our study to include Rb fullerides (49). ^{87}Rb is an extremely receptive NMR probe and applying it to Rb composite materials may help reveal more relationships between local structure and the unusual conducting properties of the composite materials. A series of Rb fulleride materials was synthesized in a similar manner to

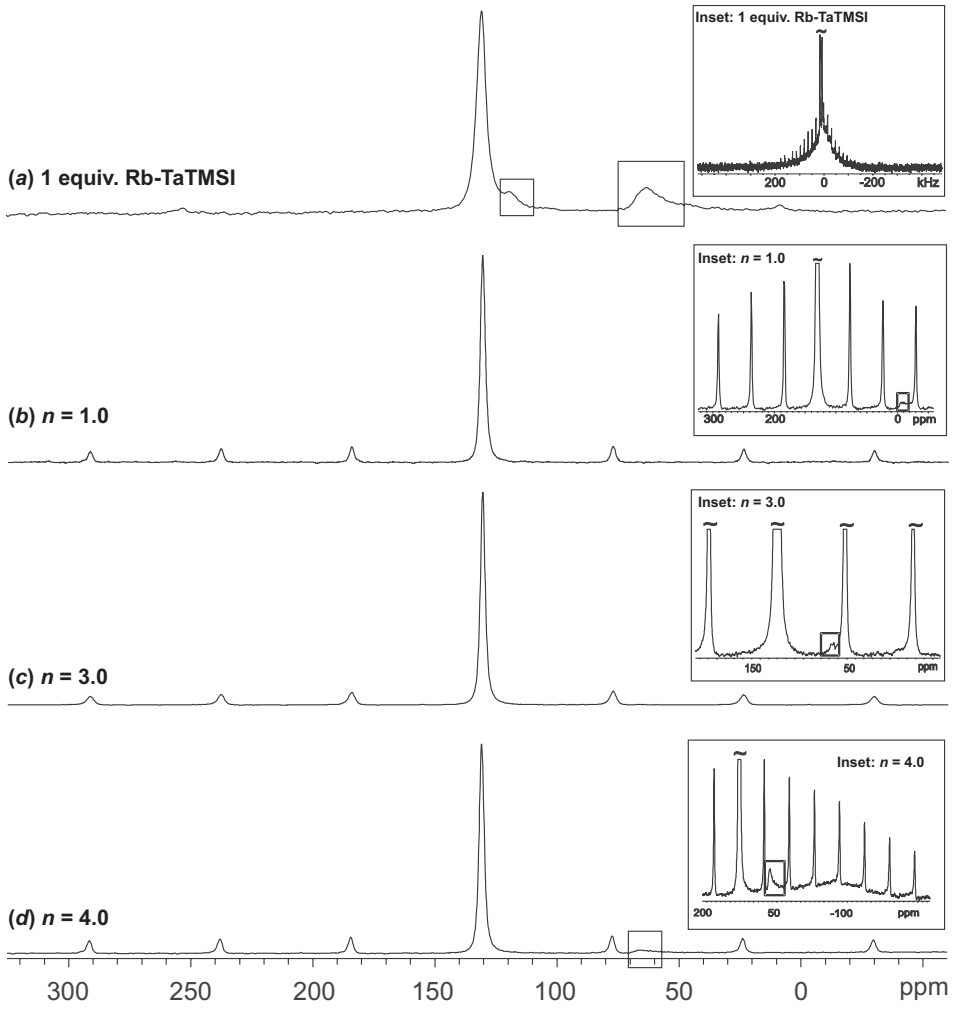


Fig. 6. XPS spectra showing the Ta 4f 7/2, 5/2 region for (*a*) pure mesoporous Ta oxide, mesoporous Ta oxide intercalated with Rb_3C_{60}, and reduced to the oxidation states of (*b*) n = 1.0, (*c*) n = 3.0, (*d*) n = 4.0, and (*e*) mesoporous Ta oxide reduced with only 1 equiv. of Rb-naphthalene (1 equiv. Rb-TaTMSl).

that of the K and Na fulleride analogues by impregnation in THF by the fulleride followed by sequential reduction by Rb naphthalene (35). For the sake of comparison, mesoporous Ta oxide reduced only with 1 equiv. of Rb naphthalene (1 equiv. Rb-TaTMSl), which is "fulleride-free", was also prepared. The oxidation state of C_{60} in the parent intercalate was estimated by Raman spectroscopy at n = 1.0 rather than n = 0.5 in the Na and K systems. This was attributed to the stronger reduction potential of Rb fullerides as compared with K and Na counterparts. XPS spectroscopy recorded for this series of new materials (Fig. 6) indicated that the walls of the mesostructure were reduced to an oxidation state between Ta(IV) and Ta(V) at the initial stage of impregnation of Rb_3C_{60} (Fig. 6*b*) and that no further reduction upon addi-

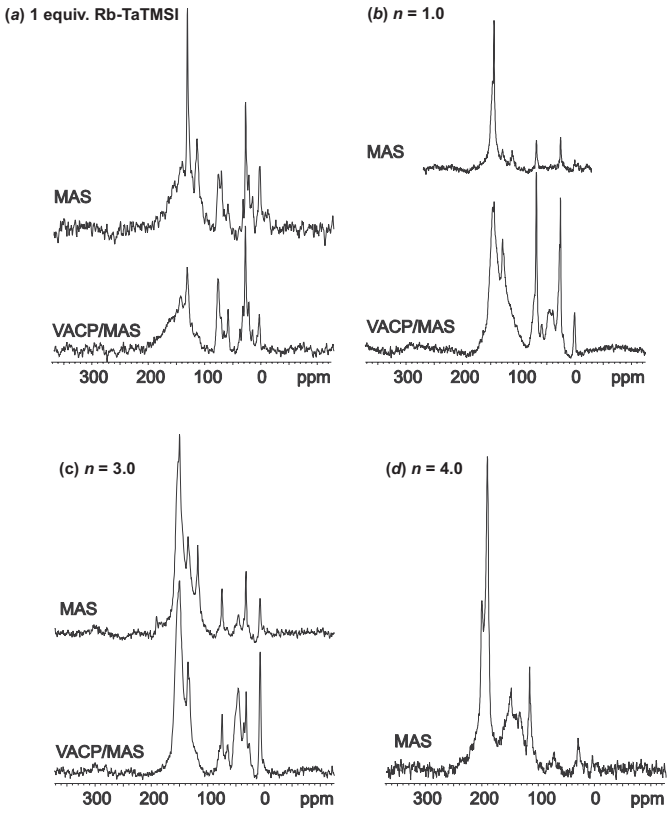
Rb-TaTMSl) and mesoporous Ta oxide intercalated with Rb_3C_{60}, and reduced to the oxidation states of (*b*) n = 1.0, (*c*) n = 3.0, and (*d*) n = 4.0 composites. Inset: Vertical expansions of the isotropic chemical shift regions.



tion of Rb naphthalene to the parent material was detected. There was, however, substantial broadening of the emissions observed. This is indicative, again, of the presence of multiple Ta species at a higher reduction level. The conductivity measurements on a series of these materials revealed a pattern similar to that of Na fulleride materials with a single conductivity maxima at n = 4.0. There was no conductivity maxima at n = 2.5, and the n = 3.0 state was highly insulating. The reason for the lack of conductivity maxima at around n = 2.5 in the Rb and Na composites is not understood, but may be due to different electronic properties of Rb and Na fullerides and K fullerides. Once again, the absolute value of the carbon content in these composites has a negligible effect on conductivity, as the n = 4.0 material had the lowest carbon loading, yet the highest conductivity. Variable-temperature conductivity measurements were performed for the two most conductive samples, n = 1.0 and 4.0. The n = 1.0 material is a typical semiconductor, while the n = 4.0 material is a semi-metal or narrow band gap semiconductor.

Solid-state ^{87}Rb and ^{13}C NMR measurements were conducted to probe into the local geometry of alkali fullerides occluded in the pores of the mesostructure. ^{87}Rb NMR spectra of the parent material (Fig. 7*b*) allowed us to clearly identify two major environments: (*i*) Rb ions in the channels; and (*ii*) Rb ions confined into the walls of the mesostructure. These were not unexpected on the basis of NMR studies on the Na system. There were also several unresolved resonances that likely correspond to Rb ions coordinated to fulleride species. These resonances, however, were much lower in intensity than those observed for Na fullerides. A trend similar to that of Na fullerides was also observed upon reduction, i.e., the population of channel and confined Rb ions progressively grew on addition of Rb-naphthalene. There was, however, an additional resonance at around –75 ppm detected in the n = 4.0 material (Fig. 7*d*). This resonance was attributed to the presence of Rb ions associated with one or more fulleride species. ^{13}C NMR measurements (Fig. 8) revealed an even greater variation of carbon-containing species than in the Na system. In the parent n = 1.0 material (Fig. 8*b*), resonances at 144 and 148 ppm, corresponding to pure C_{60} and C_{60}^{n-}, respectively,

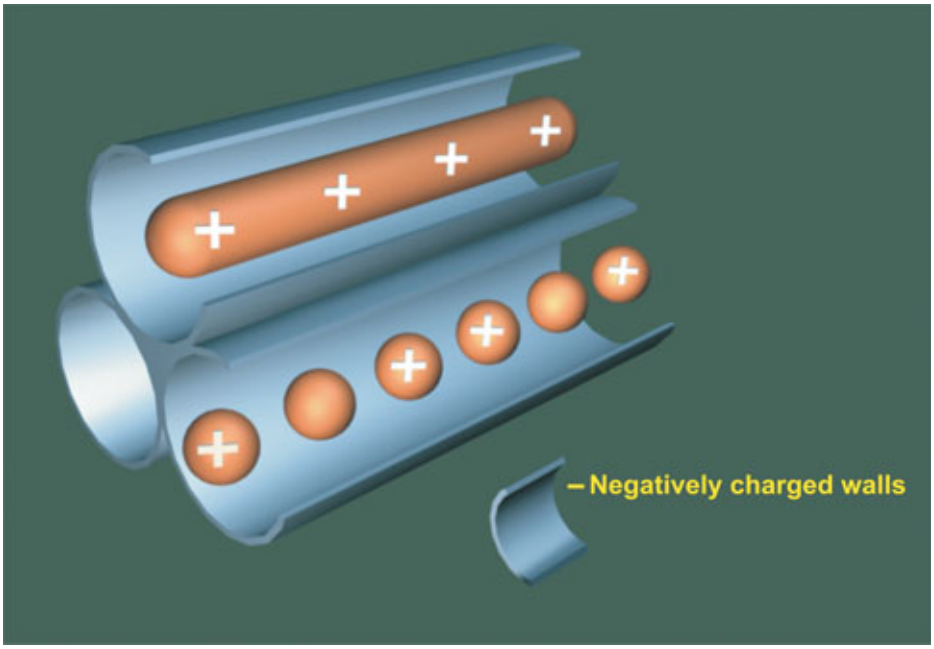
were observed. The spectra of the n = 3.0 material (Fig. 8*c*) is similar in appearance to that of the parent material, with a smaller amount of C_{60} and more C_{60}^{n-}. There is, however, an extremely small resonance at around 184 ppm, corresponding to C_{60}^{3-}. This very surprising result differs significantly from that of the n = 3.0 Na composite, which showed an almost exclusive presence of C_{60}^{3-}! This demonstrates that Raman spectroscopy cannot be relied on to assign fulleride oxidation states in these systems and that combinations of disparate species can lead to insulating behavior and the appearance of an n = 3.0 state. The appearance of the n = 4.0 spectra (Fig. 8*d*) was also intriguing, as it showed a significant amount of C_{60}^{3-} along with a smaller amount of C_{60}^{n-}. The high conductivity values of this material that n = 3.0 fullerides can function as semi-metals as long as they are mixed with a suitable amount of fulleride in a different oxidation state. This suggests that K_3C_{60}, although containing mostly insulating C_{60}^{3-}, may possibly be made metallic by the introduction of oxidation state defects in the lattice, an observation that lends some support to the hole-doped Mott–Hubbard insulator model.



While this study revealed a wide range of electronic behavior and established many firm composition–property relationships, and also represented the first attempt to synthesize and rationalize physical properties of 1-D fullerides, direct comparisons of these composites with bulk fullerides are difficult because of the lack of order in the pores of these materials as well as the 1-D nature of the occluded phases. Low-dimensional solids often undergo temperature-related transitions to insulating behavior owing to the introduction of physical distortion in the conducting chain. In spite of this, the observation of metallic behavior in the n = 4.0 systems is of theoretical interest, while the insulating nature of the pure phase n = 3.0 Na/Ta and mixed-phase n = 3.0 Rb/Ta systems invites some comparisons to the bulk-phase materials. Since 1-D lattice distortions to insulating phases normally occur at lower temperatures, and room temperature provides enough energy for a thermal averaging of sites along a conducting chain, it is not likely that the insulating nature of the pure n = 3.0 Na/Ta phase is due to Peierl's distortion, especially since the n = 4.0 Rb/Ta and K/Nb materials are metallic or semi-metals under these same conditions and possess less C than the insulating n = 3.0 phase, which would tend to make them even more prone to electron localization effects. With this in mind, it appears that the most important conclusion that can be drawn from this long series of studies is that C_{60}^{3-} is indeed a Mott–Hubbard insulator, at least in a 1-D phase, and that addition of oxidation state defects can lead to transitions to semiconducting or even metallic behavior, apparently independent of the net C-loading level.

Summary

The synthesis and study of stable mesoporous transition metal oxides has led to a new series of intercalation reactions in which the guest species occupies a 1-D channel in the host lattice rather than a 2-D sheet, as is the case with layered materials. The redox activity of the walls allows for electron-transfer reactions to occur between the host and guest, similar to what is observed in the reactions of metal chalcogenides. The amorphous nature of the mesostructured walls also provides a broader range of redox potentials than the corresponding bulk oxides. As a result, mesoporous Nb, Ta, and Ti oxides are able to react with guest species that are not strong enough reducing agents for intercalation into the corresponding crystalline oxide. Thus, these materials combine the capacity for quantum confinement into 1-D channels with the capacity for oxidation or partial oxidation in the same step. This has already led to a series of mixed oxidation state, cationic molecular phases encapsulated within a 1-D anionic transition metal oxide lattice. This is illustrated in Scheme 2. Not surprisingly, these composites possess many unusual properties not observed for the corresponding bulk phases of the guest materials. For example, because of these unique properties, cobaltocene becomes superparamagnetic in the pores of mesoporous Nb oxide and metallic K_3C_{60} becomes an insulator, while insulating K_4C_{60} becomes metallic! There is also the possibility that the walls of the structure can cooperate with the guest phases, leading to properties not observed in the pure nanophases of the same encapsulated materials. The extension of this class of materials into continuous phase nanowires with cationic defects supported by the anionic host lattice is ongoing in our group and is almost certain to lead to materials with properties not observed in the bulk-phase or even pure-phase nanowires of the same substance.

LGA-Dock/EM-Dock — Exploring Lamarckian genetic algorithms and energy-based local search for ligand–receptor docking

E. Ashley Wiley, Michael MacDonald, Andreas Lambropoulos, D. Joseph Harriman, and Ghislain Deslongchamps

Abstract: We report the development of LGA-Dock and EM-Dock, two SVL-based docking programs for flexible ligand – rigid receptor docking applications. LGA-Dock is comprised of a stochastic population generator, a docking routine based on a Lamarckian genetic algorithm, and a local search function based on molecular mechanics (MM) energy minimization. Subsequent modifications of LGA-Dock to address performance issues produced EM-Dock, which proved to be as accurate and much faster than its predecessor despite the deletion of the genetic algorithm component. The basic performance of LGA-Dock and EM-Dock, compared with AutoDock and MOE™ 2004.03 docking routines is presented.

Key words: docking, Lamarckian genetic algorithm, molecular mechanics, simulated annealing, tabu search, local search.

Résumé : On a développé deux programmes d'arrimage à base de SVL, le LGA-Dock et le EM-Dock, qui peuvent être utilisés pour des applications d'arrimage entre un ligand flexible et un récepteur rigide. Le LGA-Dock comprend un générateur de population stochastique, une routine d'arrimage sur la base d'un algorithme génétique Lamarckien et une fonction de recherche locale basée sur une minimisation d'énergie de mécanique moléculaire (MM). Des modifications subséquentes du LGA-Dock faites dans le but d'en régler certains problèmes ont conduit au EM-Dock qui s'est avéré être aussi précis et beaucoup plus rapide que son prédécesseur, même si on en avait éliminé la composante de l'algorithme génétique. On présente une comparaison de la performance de base du LGA-Dock et du EM-Dock avec les routines d'arrimage AutoDock et MOE™ 2004.03.

Mots clés : arrimage, algorithme génétique Lamarckien, mécanique moléculaire, annelage, recherche tabu, recherche locale.

[Traduit par la Rédaction]

Introduction

Molecular docking programs are designed to predict the correct thermodynamic binding pose of a ligand within its target receptor (1). Fast, accurate, and general use docking routines promise to be powerful tools for rational drug design and virtual screening activities (2). Much effort has been invested in the development of methodologies for searching docking space and for scoring the resulting poses to identify the most energetically favorable ones (3). Systematic searching schemes are prone to combinatorial explosion, a problem compounded by the consideration of ligand flexibility during docking (4). Therefore, many docking methods perform a stochastic search to adequately sample the ligand's conformational space, as well as its translational and rotational position within the binding site.

The Monte Carlo method has been used to randomly generate docking poses, accepting or rejecting new poses based on the Metropolis criterion (5). Similarly, the Tabu search method randomly samples conformational space while maintaining a list of previously visited solutions, steering the algorithm toward new minima (6). Many of these stochastic methods have been paired with a local search function to home in on the minima within local energy wells. Such optimization approaches have included molecular dynamics, simulated annealing, random searching, and various minimization algorithms.

Genetic algorithms (GA) offer yet another approach to stochastic searching by encoding docking poses as "chromosome" bitstrings and subjecting these to evolutionary processes (7). Accordingly, populations of chromosomes are created, mutated, and subjected to crossovers under some evolutionary pressure to identify the "fittest" progeny. A Lamarckian genetic algorithm (LGA) takes this process one step further by allowing a docking pose, identified by local search, to be written back to a chromosome for further optimization by the GA (8). The popular docking program AutoDock (8), for example, uses an LGA with a pseudo

Fig. 1. LGA-Dock flowchart.

Solis and Wets local search (9), an adaptive stochastic minimization function.

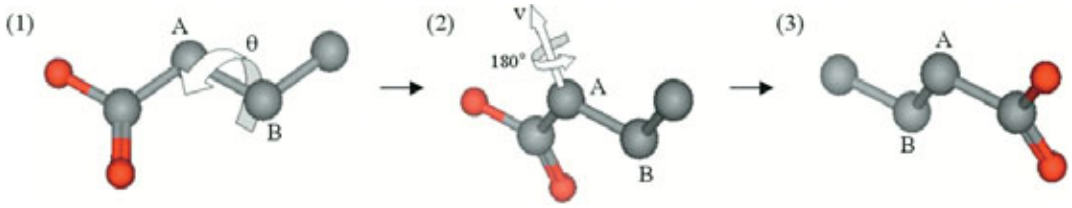
Our interest in the docking arena began with our development of "reverse-docking", a novel approach for developing transition state models of asymmetric reactions catalyzed by conformationally flexible organocatalysts (10). Although AutoDock was used for the actual reverse-docking, all poses were subsequently reminimized, scored, and processed in MOE™ (11). To streamline the methodology, we sought to replace AutoDock with a fast docking algorithm written in scientific vector language (SVL), the native development language for MOE™.

Thus, the ultimate goal was to produce an SVL-based docking routine that performed at least as well as AutoDock for various docking applications. Our initial efforts resulted in LGA-Dock, a program that uses a stochastic population generator, an LGA-based docking routine, and a local search function based on molecular mechanics (MM) energy minimization. Subsequent modifications of LGA-Dock produced EM-Dock (energy minimization-dock), which proved to be much more efficient. Herein, we report the development of LGA-Dock and EM-Dock, and compare their basic performance in simple flexible ligand – rigid receptor docking with MOE™ 2004.03 and AutoDock 3.0.5.

Experimental

LGA-Dock and EM-Dock were written in SVL and implemented in MOE™ 2004.03. A simple GA routine with grid-based scoring was obtained from the Chemical Computing Group Inc. (moredock.svl) and served as the initial template for LGA-Dock development. The core components of LGA-Dock include population, reproduction, mutation, minimization, and repopulation functions (Fig. 1).

Genetic encoding



LGA-Dock incorporates a Lamarckian genetic algorithm with a MM energy-based local search. Key to this approach is the encoding of a ligand pose into a linear chromosome for subsequent genetic manipulation (crossover, mutation, etc.). In this context, the term "pose" refers to a ligand's translation/rotation within the receptor-binding site and to its conformation with respect to rotatable acyclic bonds. Each chromosome is comprised of nine elements. Elements 1–3 specify the molecular translation in Cartesian space (x, y, and z axes) relative to the position of a reference structure. Elements 4–7 specify the molecular rotation relative to that of the reference structure (an angle θ and a 3D vector, Fig. 2). Element 8 is a vector, which stores a dihedral angle for each of the rotatable bonds in the molecule (excluding amide C—N bonds, inter alia). Finally, element 9 stores the index of the reference structure to which transformation elements 1–8 are applied. This feature is required for the phenotype (Cartesian coordinates) to genotype (chromosome) conversion that is necessary for the Lamarckian component. In LGA-Dock, some docking poses (20% probability) are energy-minimized and must be converted from Cartesian space back to genotype for further manipulation by the GA. In short, each chromosome encodes a translational/rotational/conformational change (elements 1–8) to be applied to a reference structure (element 9), usually the starting pose.

Stochastic population generation

The stochastic population function randomly generates an initial population of ligand conformations (default is 50 chromosomes). Once an initial population has been generated, it is scored using the potential energy function of MOE™ (vide infra) and optimized prior to entering the LGA as follows: each individual score is compared with the average score of the five best individuals (hereafter referred to as the "reference score"). Only individuals with a score better than the reference score plus 10% (a relative energy cutoff) are retained otherwise the unfit individuals are eliminated and stochastically replaced with new candidates. The process continues until the scores of all the individuals meet

© 2006 NRC Canada

Fig. 2. Molecular rotation, a two-step procedure, as performed by LGA-Dock: (1) rotation about the A–B axis by angle θ (A is the atom closest to the ligand's Cartesian centroid and B is any one of the atoms bound to A); (2) 180° rotation about a random unit vector **v**; (3) the resultant pose. The whole process can be easily reversed to determine rotation from a given reference structure.

the energy cutoff. The population then enters a cycle involving the remaining four functions.

Scoring

Since a rigid-receptor model was used, docking scores are based on the sum of the MM energy of the ligand plus the ligand–receptor interaction energy. A faster but less accurate grid-based scoring is used to calculate van der Waals and electrostatic ligand–receptor interaction energies for every step of each run. MM-based scoring is used for the intramolecular ligand energy. At the end of each run, explicit scoring is used to calculate the full docking energy (intramolecular and intermolecular components) so as to obtain a more accurate final energy evaluation (which is then written to the output database). LGA-Dock utilizes the built-in functions of MOE™ for precalculating an interaction grid of the protein (van der Waals and electrostatic) and for computing the interaction energy of ligand poses by trilinear interpolation.

Crossover

The reproduction function performs crossovers among individuals using a modification of a strategy recently reported by Chapleur and co-workers (12). The population is divided into two equal halves, termed mothers and fathers. Each father is paired with a randomly chosen mother, and vice versa. Each parent pair undergoes random double-point crossover, producing two children. The best-scoring 10% of the children then replace the worst scoring individuals from the population if their scores are better.

Mutation

Every generation has a user-defined probability for mutation (default is 10%), which is performed on the best 10% of the population. For each chromosome, a random mutation site is chosen and a random perturbation applied. The resultant pose is scored and replaces the current worst scoring individual if it is better; otherwise, mutation is repeated until either a better-scoring individual is created or a maximum number of attempts have been made (default is five).

MM-based local search

Standard MM energy minimization functions, present in MOE™, are used to perform local searches and improve ligand poses within their rigid receptor (i.e., adjust the poses to the bottom of their respective potential wells). Steepest descent minimization is used in the first 25 generations of a run. In later generations, conjugate gradient and truncated Newton methods are also applied for finer minimization. Energy minimization is always performed on the best-scoring chromosome that had not already been minimized.

Repopulation

The final function of the cycle is repopulation. It is very much like the initial populate function, but is only called whenever the population converges. It retains the best-scoring individual and randomly generates the rest of the population until the energy cutoff is met.

Generation cycle

Once a population has been produced, it enters a common GA cycle (referred to as a "generation") of reproduction, mutation, energy minimization, and repopulation (Fig. 1). The cycle continues until either the maximum number of generations has been reached (default is 200) or minimization fails to produce better-scoring poses a number of times (default is 10). If either of these events occurs, the algorithm appends the best-scoring structure to a MOE™ database along with a breakdown of energies.

Ligand–receptor pairs

Ligand–receptor pairs were selected from the Protein Data Bank (http://www.wwpdb.org) to encompass a wide range of ligand size, conformational flexibility, and receptor environments, including several pairs sampled from the development data sets of other docking programs. For the LGA-Dock experiments, the following seven ligand–receptor complexes were chosen, including five described in the original AutoDock training set, five from the FlexX study (13), and three from the GOLD study (14): benzyldiamine–β-trypsin [3PTB], biotin–streptavidin [1STP], methotrexate – dihydrofolate reductase [4DFR], sialic acid – hemagglutinin [4HMG], TIBO-R86183 – HIV-1 reverse transcriptase [1HNV], VX-478 – HIV-1 protease [1HPV], and XK263 – HIV-1 protease [1HVR]. For the subsequent EM-Dock experiments, the set was expanded to include 10 additional ligand–receptor pairs, including five more from the FlexX study, and two more from the GOLD study: hydroxyethylene isostere – HIV-1 protease [1AAQ], D-fucose – L-arabinose-binding protein [1ABF], 1-deaza-adenosine – adenosine deaminase [1ADD], aetiocholanolone – Fab′ fragment of monoclonal antibody Db3 [1DBJ], folate – dihydrofolate reductase [1DRF], rapamycin – Fk506-binding protein [1FKB], L-histidine – histidine-binding protein [1HSL], benzene – lysozyme mutant [1L83], 3-phenylpropylamine–trypsin [1TNK], and palmitic acid – intestinal fatty acid binding protein [2IFB].

Receptor preparation

In MOE™, the ligand and all water molecules were deleted from the PDB file of a given receptor–ligand complex. Atom bonding was checked and corrected as needed; ionization states for all His, Lys, Arg, Asp, and Glu residues were set according to Pang et al. (15). Hydrogens were added and energy-minimized using the AMBER94 force field. Partial charges on the receptor were assigned with the AMBER94 force field in MOE™. For use in AutoDock, receptors were saved in the mol2 format.

Ligand preparation

Ligands were extracted from the corresponding PDB files. All ligands were checked manually for correct atom and bond type. Hydrogens were added and energy-minimized using the MMFF94x force field. Initial ligand geometries were optimized with Gaussian 03 (16) at the HF/6-31G* level to remove any bias from the crystallographic structure. Electrostatic potentials were calculated and used to derive RESP (17) charges with the Antechamber module of Amber 7 (18) for later use in MOE™. For AutoDock, ligand partial charges were computed with the Gasteiger PEOE method (19, 20), and the ligands were manipulated with AutoDockTools (21).

Docking

All docking tests were run against MOE™ 2004.03 and AutoDock 3.0.5. Default settings and the MMFF94x potential energy force field were used for MOE™'s two docking methods (Monte Carlo simulated annealing (MOE-SA) and Tabu search (MOE-Tabu), as well as an unreleased SVL-based genetic algorithm (MOE-GA). AutoDock runs were carried out using the same settings reported in its original publication.

Default settings were used for LGA-Dock: each ligand was tested with 50 runs, a population size of 50, and a maximum generation limit of 200. Mutation probability was set to 10% and minimization probability to 20%. The repopulation limit was set to 10, such that the run would terminate after that many populations converged. The docking boxes were centered on the bound crystallographic ligands and the box dimensions from whichever program created the largest box were applied to all the others (for example, the box size for 1HSL was 13.2 Å × 13.2 Å × 13.2 Å). Initial ligand translation, rotation, and conformation were generated randomly within the box to mitigate bias from their original crystallographic pose.

Results and discussion

To compare the different docking results, root-mean-square deviations (RMSD) were calculated from heavy atom positions in the docking poses relative to their respective crystallographic poses and are reported in Tables 1–4. With the understanding that comparing docking programs via RMSD calculations alone can be misleading (22), all docking poses were visually inspected by superposition to ensure that relative RMSDs within a comparison set were consistent with the observed structural deviations. Representative examples of pose comparisons are shown in Figs. 3 and 4.

For each Table, the following data are reported: 1-RMSD of No. 1 rank (ranked by scoring function), and 2-lowest RMSD with corresponding rank. Docking solutions were considered to be successful if the RMSD was <1.5 Å, which is more stringent than the common 2.0 Å standard. This was deemed important since the test sets included small ligands that might still meet the success cutoff by random placement in small active sites (22).

LGA-Dock

LGA-Dock was tested with seven ligand–receptor complexes. The results were compared with those of AutoDock

and current MOE™ docking programs and are reported in Table 1. LGA-Dock was found to perform at least as well as AutoDock when comparing RMSDs of the No. 1 ranked poses, and outperformed AutoDock in three cases (1STP, 4DFR, 1HNV). Three of the LGA-Dock cases did not assign a No. 1 rank to the lowest RMSD solution, but the RMSD differences were less than 0.28 and are negligible (1STP, 1HNV, 1HVR). Interestingly, LGA-Dock's only failure was with 4HMG, the only system that could not be properly docked by any of the five methods. Visual inspection of the best 4HMG poses superposed over the crystallographic pose of the sialic anion did not shed any light on the anomaly.

MOE-SA performed poorly, resulting in only one successful docking (3PTB). Similarly, MOE-Tabu produced only two successful dockings (3PTB, 1HNV), while MOE-GA only produced one hit (3PTB), perhaps two if the success threshold were relaxed by 0.1 Å (1HNV). All in all, this is an important result since it shows that LGA-Dock performed considerably better than the existing SVL-based docking routines available in MOE™ at the time.

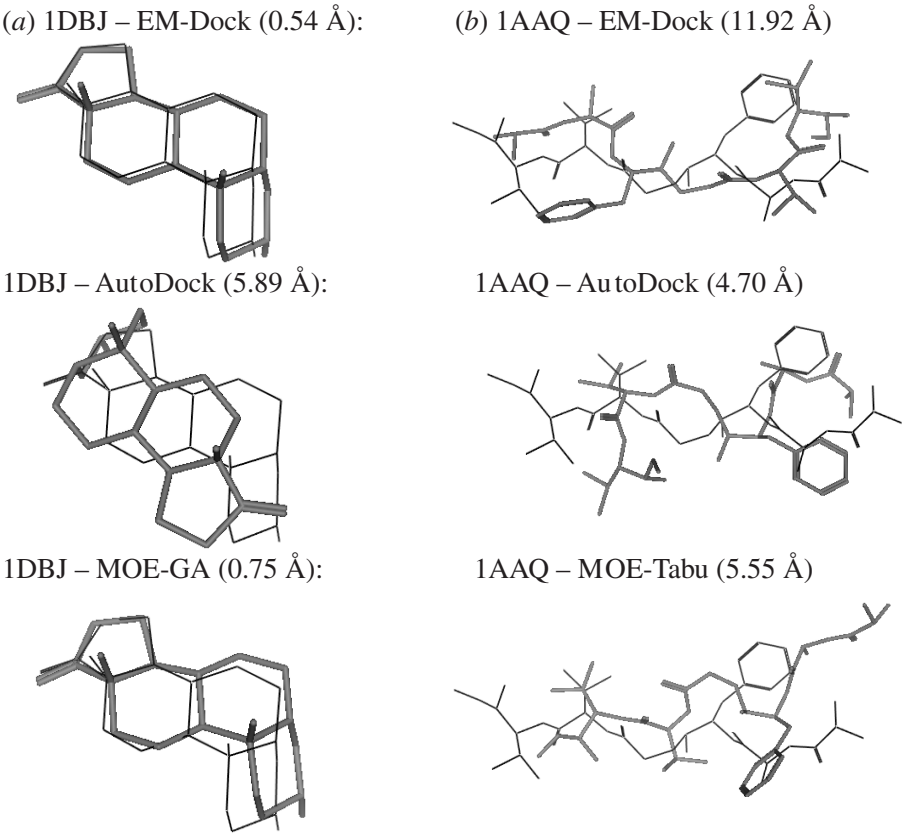
Fig. 3. Representative docking poses of LGA-Dock vs. other docking methods. (*a*) Left column: 1STP; (*b*) right column: 4HMG. Docking poses are shown as cylinders and the crystallographic poses are shown as lines. RMSDs are in parentheses.

All docking results were visually inspected to ensure proper correlation with reported RMSDs. Two representative examples contrasting successful and unsuccessful dockings with LGA-Dock are illustrated in Fig. 3. In the case of 1STP, LGA-Dock was able to dock to a RMSD of 1.11 Å, compared with values of 3.08 and 7.30 Å for AutoDock and MOE-Tabu, respectively (Fig. 3*a*). Note the proper docking of the bicyclic moiety of biotin and general alignment of its carboxylate side chain by LGA-Dock. This is in sharp contrast to the 4HMG docking pair (Fig. 3*b*) in which the sialic acid ligand could not be properly positioned docked by LGA-Dock (4.90 Å) or any of the other docking routines (4.80–6.30 Å). Structural analysis did not reveal any insight into the difficulty of docking this particular ligand–receptor pair.

The numerical results were averaged (Table 2) and showed that, on the whole, LGA-Dock was as capable as AutoDock in producing lowest RMSD poses. LGA-Dock seems to score the poses more accurately, as its average RMSD for No. 1 ranked poses was considerably lower than for the other four docking programs. Although LGA-Dock met the accuracy test, calculation times took 20–30 times longer than AutoDock on some ligands. As such, LGA-Dock was certainly not deemed suitable for high-throughput docking or virtual screening applications.

AutoDock uses an empirical, grid-based scoring function, making for very fast energy calculations, while LGA-Dock uses complete MM-based energy for calculating ligand and interaction energy. In addition, LGA-Dock uses energy minimization for the local search, which will also contribute to the computation time. The performance impact of LGA-Dock's other routines including the stochastic population routine and the LGA itself remained to be established.



EM-Dock

In the process of exploring ways to improve the speed and performance of LGA-Dock, the reproduction and mutation functions were eliminated. These functions were found to be largely responsible for the long CPU times and it was unclear whether they made a significant contribution to the docking success. Preliminary tests using this truncated algorithm showed little loss of performance while speeding up docking times considerably. These tests prompted the development of EM-Dock (energy minimization dock), a second generation program that, ironically, did not retain any of the original genetic algorithm components. However, EM-Dock retained LGA-Dock's stochastic population engine and the MM-minimization-based local search program (23), with one minor modification: when EM-Dock generates an initial population of chromosomes, a simple distance-based test filters out initial ligand translations that collide with receptor atoms, improving the speed of the program. The population is then scored and regenerated until all individuals meet the energy cutoff.

Once the initial population is generated, the algorithm enters a cycle of minimization-based local search and repopu-

Fig. 4. Representative docking poses of EM-Dock vs. other docking methods. (*a*) Left column: 1DBJ; (*b*) right column: 1AAQ. Docking poses are shown as cylinders and the crystallographic poses are shown as lines. RMSDs are in parentheses.

lation. First, the lowest-energy conformation is minimized with MOE™'s minimization methods (the initial coarse minimization phase of LGA-Dock is omitted) and the resultant pose replaces the current worst-scoring individual. The second best chromosome is then minimized, scored, and compared with the first minimized structure. If the second minimized structure's energy is lower than that of the first, the next best pose is minimized and compared with the last; otherwise, the repopulation function is called, seeding the best pose back into the population and randomly recreating the other individuals. This cycle of minimization and repopulation continues until either a maximum number of generations are reached or the program has repopulated a maximum number of times (user-defined). When either of these criteria is met, the algorithm terminates and the best structure is reported.

EM-Dock was tested with the original seven ligand–receptor complexes and produced a series of poses almost identical to those of LGA-Dock. Testing was then extended to an additional set of 10 ligand–receptor complexes. The same docking settings were used, with the exception that 150 runs were performed (as opposed to 50 runs performed for LGA-Dock). EM-Dock results are reported in Table 3.

Analysis of the data in Table 3 revealed that EM-Dock, in similar fashion to LGA-Dock, performed well. For 7 of the 10 dockings, EM-Dock returned RMSDs for the No. 1 ranked poses that were within the 1.5 Å threshold (8/10 if including 1DRF at 41.81 Å). It also performed at least as well as AutoDock or the other MOE™-based programs. EM-Dock surpassed AutoDock in two cases (1DBJ, 2IBF) and MOE™'s three algorithms on over half of the systems.

Once again, all docking results were visually inspected to verify proper correlation with reported RMSDs. Two representative examples contrasting successful and unsuccessful dockings with EM-Dock are illustrated in Fig. 4. In the case of 1DBJ (Fig. 4*a*), EM-Dock's No. 1 ranked pose had a 0.54 Å RMSD and was very similar to that of MOE-GA (0.75 Å), and was much better than the AutoDock result (5.89 Å). In contrast, Fig. 4*b* illustrates the docking of the larger and considerably more flexible hydroxyethyl isostere peptidomimetic (1AAQ), which proved to be much more problematic. Indeed, EM-Dock flipped the ligand lengthwise, while AutoDock and MOE-Tabu rotated it around its longitudinal axis. This ligand was problematic for all docking routines, which is perhaps not surprising because of the large number of conformational rotors present.

Averaging the results (Table 4) reveals that EM-Dock, like LGA-Dock, performed at least as well as AutoDock. Of greater relevance, however, was the observation that EM-Dock calculation times were much shorter than for LGA-Dock (10–15 times faster for most ligands), much shorter than the other MOE™ docking routines, and almost as quick as AutoDock. Although EM-Dock is still not fast enough for virtual screening, its performance was deemed suitable for our reverse-docking and other applications.

An interesting outcome of this study was the efficiency and accuracy of EM-Dock even though its GA component had been culled completely from the program. One must

© 2006 NRC Canada

note that LGA-Dock contained two distinct stochastic engines (population generator and genetic algorithm), while EM-Dock retained only one (population generator); this suggests that LGA-Dock was perhaps overkill for searching the docking space. In the end EM-Dock was found to be an effective docking routine that was almost as fast as AutoDock while retaining a full MM-based scoring scheme (and local searching), resulting in improved overall accuracy.

Conclusion

A new program in the place-and-minimize spirit (EM-Dock) has emerged from modification and optimization of LGA-Dock, an intermediate Lamarckian genetic algorithm. LGA-Dock scored the poses more accurately than AutoDock or the MOE™-based methods, as the RMSD for No. 1 ranked poses was consistently lower for a range of ligand–receptor pairs. However, calculation times were 20–30 times longer than AutoDock on some ligands, prompting the development of EM-Dock. EM-Dock retained the stochastic population generation and MM-minimization-based local search routines while eliminating the genetic algorithm itself. Results showed that EM-Dock was at least as accurate as LGA-Dock. Thus, the deletion of the reproduction and mutation schemes produced a much faster algorithm without sacrificing docking accuracy. Although the default settings were parameterized for a general set of molecular systems, users should adjust values so as to best match particular docking situations.

We have since used EM-Dock successfully for a series of docking and reverse-docking studies and have appreciated its overall performance and integration into MOE™. Further development and applications of EM-Dock will be reported in due course.

Concerted and stepwise mechanisms in the Diels–Alder and Michael reactions of furans with methyl 3-nitroacrylate — Experimental and theoretical studies

Kuniaki Itoh, Kazue Kitoh, and Shigehisa Kishimoto

Abstract: The Diels–Alder reactions of the furans (**1a**–**1c**) and methyl 3-nitroacrylate (**2**) produce the cycloadducts via a concerted mechanism. Then, the products subsequently undergo retro-Diels–Alder reactions to give the Michael adducts via a stepwise mechanism. We have used both experimental and theoretical methods to investigate the mechanism for, and the regio- and stereo-selectivity in, the Diels–Alder and Michael reactions. To account for the selectivity observed in these additions, we examined the frontier molecular orbitals involved, and to locate the transition states (TS), we employed a B3LYP/6-31G* level density functional calculation. We were able to explain the regio- and stereo-selectivity of the four possible Diels–Alder adducts observed in the experiments by a comparison of their calculated activation energies, which ranged from 11 to 18 kcal/mol (1 cal = 4.184 J). The s-cis forms of the dienophile (**2**) were found to be more stable than the s-trans forms, both in the ground state and in the transition state. In addition, the endo transition structures for the ester group exhibited a lower energy barrier by 0.3 kcal/mol than their exo counterparts, a value that is in disagreement with the experimental results. The presence of the nitro group in **2** may play an important role in determining the selectivity. Our attempts to find a stepwise mechanism leading to the Diels–Alder adduct via a zwitterion were unsuccessful. We did find that two stepwise processes lead to the formation of Michael adducts generated via an electrophilic attack by **2** at the α position of **1b** and **1c**, and an intramolecular proton-transfer mediated by the formation of a four-membered structure. The potential energies for these reactions showed values in the following ranges: 17 kcal/mol for **5a** and **5b**, and 11 to 12 kcal/mol for **7a** and **7b** for the first step, and, for the proton-transfer step, 48–51 kcal/mol for **5a** and **5b**, and 41–45 kcal/mol for **7a** and **7b**. Solvent effects in chloroform on the Michael addition did not appear in the electrophilic attack step (less than 4 kcal/mol), but the transition state of the later process was stabilized by 6–13 kcal/mol.

Key words: Diels–Alder reactions, Michael reactions, density functional method, furan, retro-Diels–Alder reactions, solvent effect.

Résumé : Les réactions de Diels–Alder entre les furanes (**1a**–**1c**) et le 3-nitroacrylate de méthyle (**2**) conduisent à la formation de cycloadduits par le biais d'un mécanisme concerté. Les produits formés subissent alors des réactions de rétro-Diels–Alder subséquentes qui conduisent à la formation d'adduits de Michael par le biais d'un mécanisme par étape. On a fait appel à des méthodes tant théoriques qu'expérimentales pour étudier les mécanismes des réactions de Diels–Alder et de Michael ainsi que leurs régio- et stéréo-sélectivités. Pour tenter d'expliquer la sélectivité observée au cours de ces additions, on a examiné les orbitales frontières impliquées alors que pour localiser les états de transition (ET), on a fait appel à des calculs de densité fonctionnelle au niveau B3LYP/6-31G*. On a aussi pu expliquer les régio- et stéréo-sélectivités des quatre adduits de Diels–Alder possibles par le biais d'une comparaison de leurs énergies d'activation calculées qui s'étalent de 11 à 18 kcal/mol (1 cal = 4,184 J). On a trouvé que les formes s-cis du diénophile (**2**) sont plus stables que les formes s-trans, tant dans l'état fondamental que dans l'état de transition. De plus, les structures de transition endo du groupe ester présentent une barrière d'énergie de 0,3 kcal/mol plus basse que celles de leurs contreparties exo; cette valeur n'est pas en accord avec les données expérimentales. La présence d'un groupe nitro dans le composé **2** joue peut-être un rôle important dans la détermination de la sélectivité. On n'a malheureusement pas pu trouver un mécanisme par étape pouvant conduire à l'adduit de Diels–Alder par le biais d'un zwitterion. On a toutefois trouvé deux processus par étape qui peuvent générer la formation d'adduits de Michael par le biais d'une attaque électrophile du composé **2** dans la position α des composés **1b** et **1c** suivie d'un transfert intramoléculaire de proton aidé par la formation d'une structure à quatre chaînons. Les énergies potentielles de ces réactions sont de l'ordre suivant: pour la première étape, 17 kcal/mol pour les composés **5a** et **5b**, 11 à 12 kcal/mol pour les composés **7a** et **7b**; et pour l'étape du transfert de proton, 48 à 51 kcal/mol pour les composés **5a** et **5b** et 41 à 45 kcal/mol pour

les composés **7a** et **7b**. Il ne semble pas que les effets de solvant dans le chloroforme sur l'attaque électrophile de l'addition de Michael semblent inexistants (moins de 4 kcal/mol), mais l'état de transition de l'étape suivante semble stabilisée par 6 à 13 kcal/mol.

Introduction

The Diels–Alder addition of furans, which are poor reactive dienes (1–3), provides an attractive approach to the synthesis of various cycloadducts that are useful building blocks for *C*-nucleosides (1, 4, 5). We have reported the synthesis of a ribofuranoside as a part of a program to synthesis *C*-nucleosides by use of the Diels–Alder reaction of furan with methyl 3-nitroacrylate (6). The reaction not only yielded the endo- and exo-cycloadducts, but also provided indications that these products and their yields changed with reaction times and temperatures (7). We also discussed the presence of an alternate pathway for the Diels–Alder reaction. This alternative involves a Michael reaction of a nitro methyl ester with the furans; here, the orbital energy difference between the HOMO of the diene and the LUMO of the dienophile seems to control the distribution of the Diels–Alder and Michael products of the reaction. In the present paper, we describe the time-dependent change in the reaction state (Scheme 1 and Figs. 1–3) using both experimental results and a theoretical study of frontier molecular orbital (FMO) energies, the orbital coefficients, the energies and geometries of the transition state, and solvent effects.

The mechanism of the Diels–Alder reaction has long been a topic of disussion (8). It may be either synchronous concerted or stepwise involving the formation of a zwitterion or biradical intermediate (9). Several recent theoretical studies devoted to the cycloaddition reaction of furans point out that the mechanism changes from concerted to stepwise with an increased electron deficiency in the dienophile (10, 11). Thus, the Diels–Alder reaction of furan with methyl vinyl ketone takes place in an asynchronous concerted manner. In this theoretical study, we attempt to understand the two pathways, the Diels–Alder and Michael reactions, which involve both regio- and stereo-selectivity.

Computational details

The density functional method computations for the gas-phase calculations were performed with the Spartan 4 for Windows package (12) implemented on an Endeavor MT 7000 workstation. The reactant, product,and transition state (TS) geometries for the above reactions were optimized by DFT calculations at the B3LYP/6-31G* level (13). After the optimization of all transitional structures, we carried out vibrational analyses to check the nature of the stationary points. The transition states are defined by exactly one imaginary frequency. Unless otherwise indicated, all energy changes in the B3LYP/6-31G* optimizations reported in this paper include zero-point energies without scaling. To calculate the free energies of solvation needed to understand the effect of the solvent on the stereoselectivities (14), we used the Q-chem version 2.1 package for Linux (15). To evaluate the solvent effect, we carried out a B3LYP/6-31G* single-point calculation, using the method based on the Onsager model (16). The solvent used in the experimental work was chloroform; therefore, we employed the dielectric constant ($\varepsilon = 4.81$) and the solute radius ($\alpha = 3.92$).

Results and discussion

Experimental reactivity results

Furan (**1a**) reacted with methyl 3-nitroacrylate (**2**) to give the two known Diels–Alder adducts, ***endo*-3a** and ***exo*-3b** (17). However, the adduct ratios (3:2–1:1) and the yields (30%–85%) depended upon the reaction conditions: the reactant concentrations, the ratios of the reactants, and the reaction times (18). The reaction of **1a** with **2** in chloroform at room temperature was followed by ^{1}H NMR for 1 month. The results are given in Fig. 1. They indicated that ***endo*-3a** was produced at up to a 28% yield during the initial stage of the reaction (8 days), at which point this adduct decomposed. In contrast, the yield of ***exo*-3b** slowly increased without decomposition, and after 18 days, an equilibrium composed of ***endo*-3a** (12%) and ***exo*-3b** (18%) was established.

The reaction of 2-methylfuran (**1b**) with **2** for 1 day yielded a product mixture containing the Diels–Alder adducts **4b** in a 16% yield, **4d** in a 23% yield, and a few concomitant products. The reaction, which took place under conditions similar to those used for furan (**1a**), was carefully followed by ^{1}H NMR at room temperature for 2 weeks. The results, presented in Fig. 2, indicate that the yields of the four Diels–Alder adducts (**4a**–**4d**) reached their maximum values (18%, 16%, 6%, and 23% yield, respectively) within 5 days; however, after 10 days, the amounts of these adducts noticeably declined. In contrast, the yield of the Diels–Alder adduct (**4a**) steadily increased up to 19% after 2 weeks. The yield of one of the Michael adducts (**5b**) rose rather slowly during the early stages of the reaction to reach a maximum of 5% at 4 days. Interestingly, the other Michael adduct (**5a**) was not detected during the early stage of the reaction, but was increasingly produced after the three Diels–Alder adducts began to decompose.

The compound 2-methoxyfuran (**1c**), a highly reactive diene for the Diels–Alder reaction, actually reacted with **2** in benzene at room temperature to very rapidly give the Michael adduct (**7a**) in a 72% yield. This reaction, in chloroform solvent, was also followed at a temperature of –10 °C for 50 min. The result obtained was similar to that observed for the reaction of **1b** with **2**. Only two Diels–Alder adducts (**6a** and **6b**) were found, and no other isomer was detected

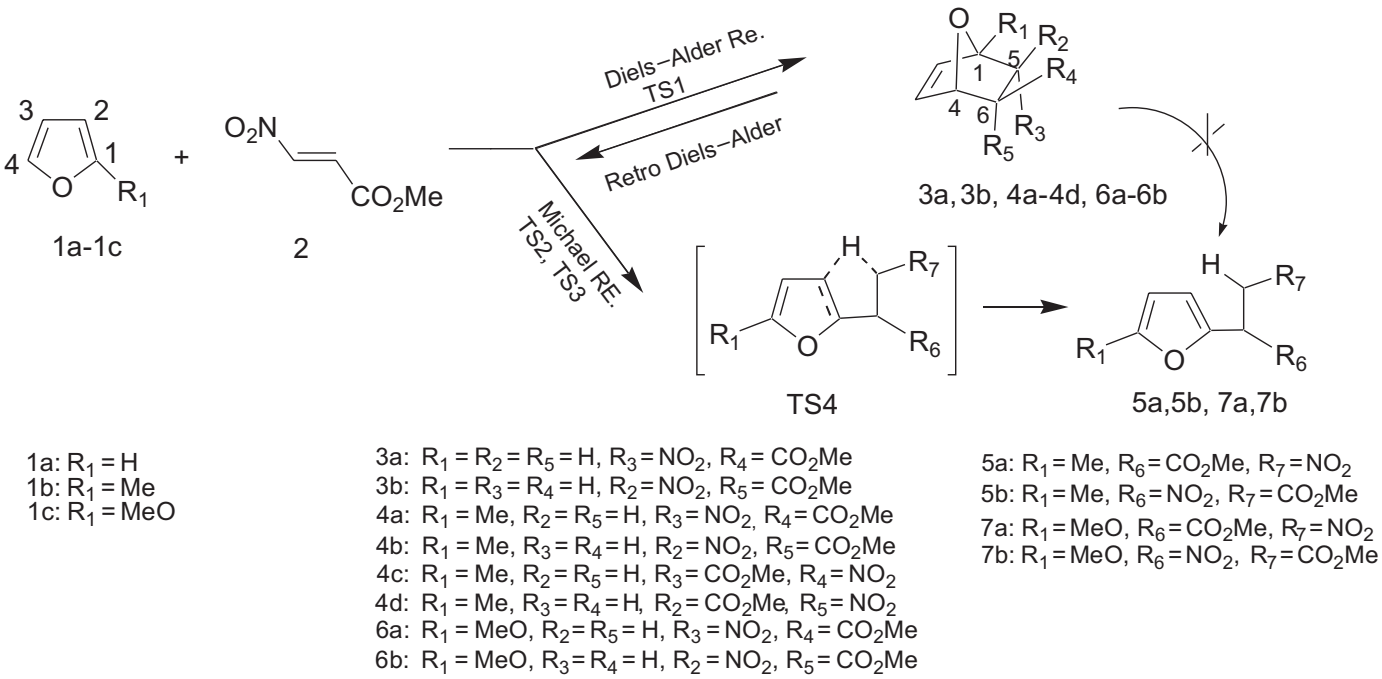
Scheme 1.



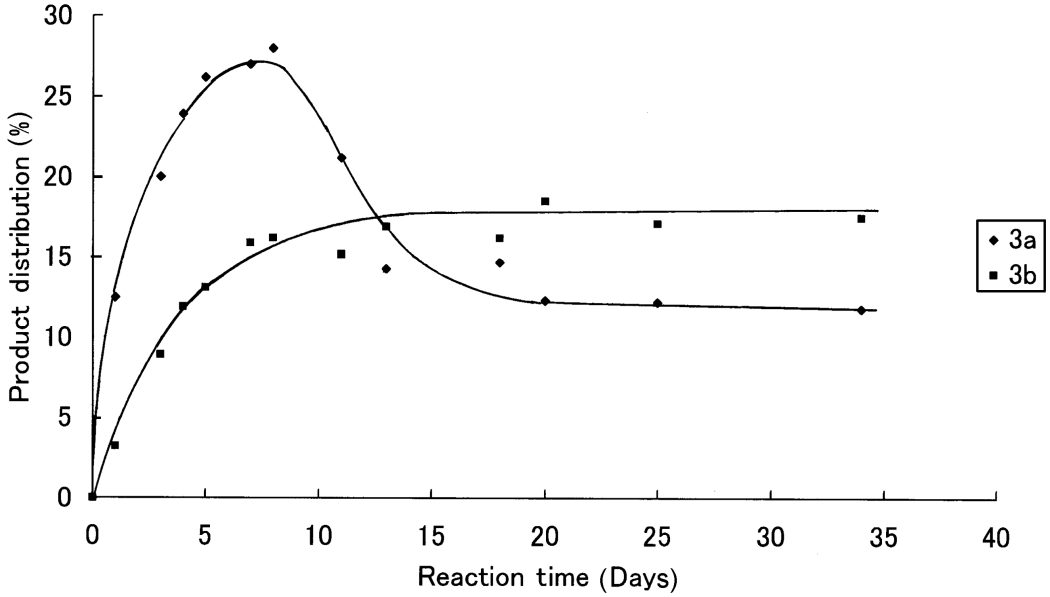


Fig. 1. The reaction of **1a** with **2**.

(Fig. 3). Indeed, one of the Diels–Alder adducts (**6a**, 37% yield at 30 min) was quickly generated, but soon began to disappear, while the other one (**6b**) steadily accumulated. One of the Michael adducts (**7b**) was produced from the beginning, but production of the other one (**7a**) was significantly delayed; it appeared during the course of the reaction (45 min).

The Diels–Alder adducts are known to be kinetic products that are subject to the retroreactions that yield the thermodynamically favored Michael adduct products (7, 19). Figures 2 and 3 clearly demonstrate the conversion of Diels–Alder adducts to Michael adducts. However, the formation of these Michael adducts may also occur directly from the furans (**1a**–**1c**) and the nitroacrylate (**2**). Thus, to check the formation process of the Michael reaction, we followed the thermal decomposition of the Diels–Alder adduct (**4a**) by ^{1}H NMR. The result was that adduct **4a** initially produced the starting materials (**1b** and **2**), and after 2 days, the Michael adduct (**5a**) was obtained.

Computational results

The conformation of methyl 3-nitroacrylate (2)

It is known that methyl acrylates exist as a mixture of s-cis and s-trans conformations involving the C—C bond between the C=O and C=C bonds. Konakaand co-workers (20)

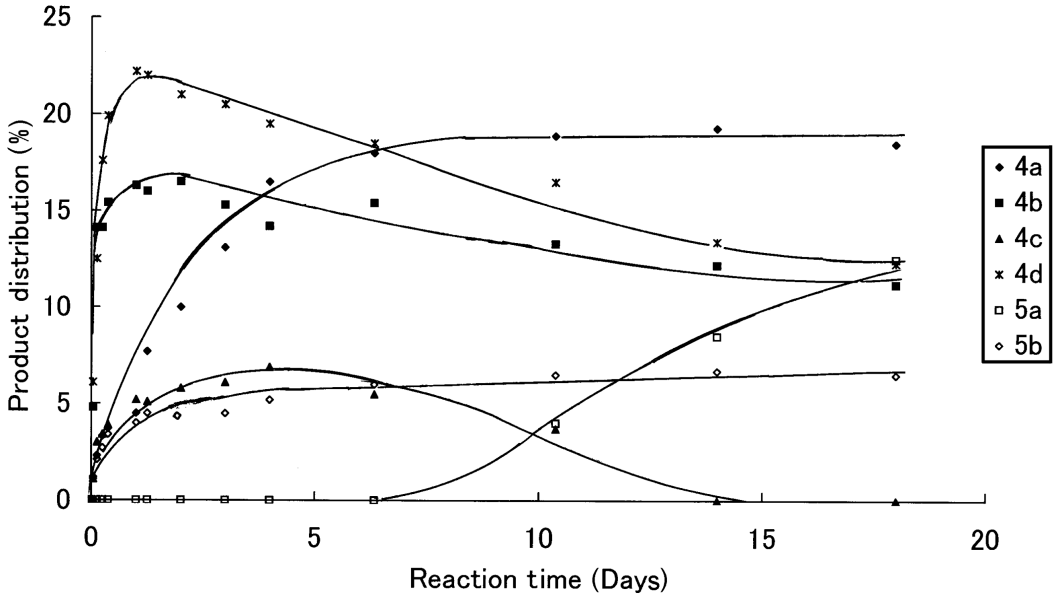
Fig. 2. The reaction of **1b** with **2**.



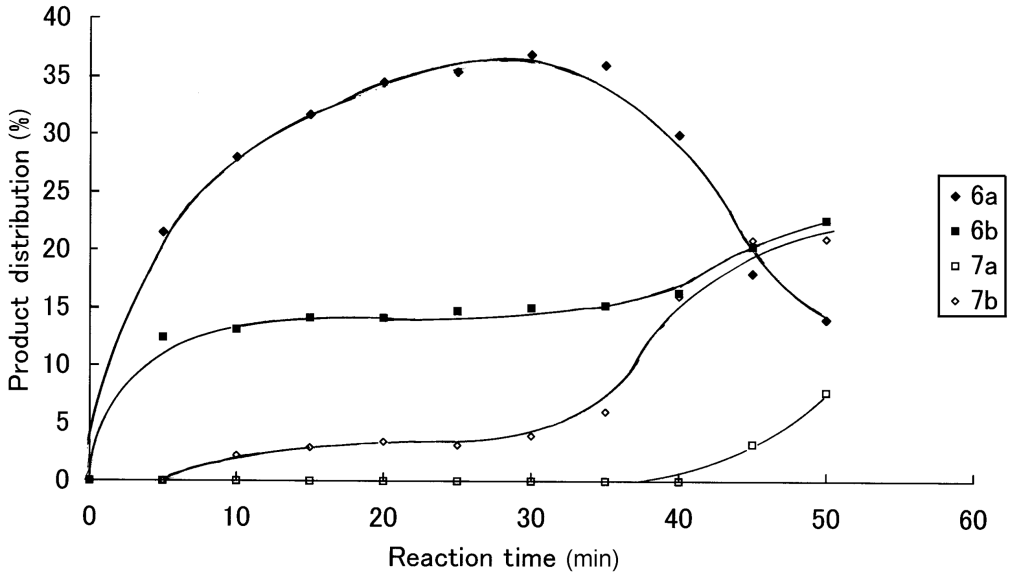


Fig. 3. The reaction of **1c** with **2**.

found that the relative abundance of the s-cis form of methyl acrylate is 67% in the gas phase, and that the vapor of methyl methacrylate exists in the s-trans form (64%). However, the conformations of methyl acrylates in general have never been unambiguously determined. Accordingly, we have compared the stabilities of the two forms of methyl 3-nitroacrylate by calculation. The rotational barriers around its C—C bond are shown in Table 1. The cis-form is more stable than the trans-form by 0.54 kcal/mol (1 cal = 4.184 J) at the HF/6-31G* level and by 0.69 kcal/mol at the DFT/B3LYP level. The cis-form preference can be explained in terms of an electrostatic effect: the lone-pair electrons on the oxygen avoid the π electrons of the double bond in the cis-conformation. The rotation from the s-trans form to the cis-form has a barrier of 6.07 kcal/mol by DFT and 14.05 kcal/mol by HF(6-31G*). Because the difference in stabilities of the two forms are small, we calculated the cycloadditions by both the s-trans,s-cis forms of the dienophiles. However, we considered only the reactions of the cis pathways in the present paper because the pairing of the s-cis,s-trans forms is different.

FMO results

To interpret our experimental results, we used the the PM3 method to calculate the FMO energies and coefficients of the dienes (furans, **1a**–**1c**) and of the dienophile (methyl 3-nitroacrylate, **2**). The LUMO–HOMO energy gaps are presented in Tables 2 and 3. We have found that the highest occupied molecular orbital (HOMO) of **2** is the nonbonding orbital in which the lone-pair electron of the nitrogen and the oxygen atoms are involved, as found in methyl acrylate (21). Therefore, this orbital is not suitable to be associated

with a (4+2) cycloaddition. The nearest occupied orbital to the latter ($HOMO_{-1}$) is 0.096 eV (in the s-cis) lower than the HOMO. Because it possesses a nodal plane coincident with the molecular plane of the dienophilic system, it has the right symmetry to react as a HOMO in a cycloaddition. From now on this orbital, $HOMO_{-1}$ will be considered as the reacting HOMO of **2**. The interactions between the diene HOMO and the LUMO of the dienophile, and between the LUMO of the diene and the dienophile $HOMO_{-1}$, should play significant roles in both the reactivity and regioselectivity of the cycloaddition (22–24). The most favorable FMO interaction is that of the HOMO diene – LUMO dienophile, as shown in Table 3. The reaction, then, is a LUMO dienophile-controlled Diels–Alder reaction.

On the basis of the orbital coefficients of the atoms forming the σ bond, we believe that the LUMO of **2** is quite polarized. However, because the atomic coefficients over both the carbons are similar in the case of furan (**1a**), the dienophile should exhibit no regiochemical preference. On the other hand, when the diene is methylfuran (**1b**), the overlap is the largest between the atom pair C diene – C dienophile, a situation leading to the regioisomers **4a** and **4b** as Diels–Alder adducts and **5a** as a Michael adduct. However, the orbital coefficients of each carbon in the diene are relatively close in magnitude. Therefore, six possible regioisomers (**4a**–**4d** and **5a** and **5b**) may be produced. Further, in the case of methoxyfuran (**1c**), the orbital coefficients of each carbon in the diene are fairly different in magnitude. As we observed experimentally, this difference leads to the selective formation of the regioisomers **6a** and **6b** as the Diels–Alder products and **7a** as the Michael product. Our FMO calculation produced sufficient information to allow us to successfully interpret our experimental results relating to the regioselectivity of the reaction.

A synchronous concerted mechanism for the production of the Diels–Alder adducts

There are several issues of selectivity to be considered in the Diels–Alder reaction of the furans (**1a**–**1c**) with methyl 3-nitroacrylate (**2**). First, there is the issue of regioselectivity in which the carbon bearing the side group of the diene is attached to either the carbon atom bonded to the nitro group (ortho) or to the carbon atom bonded to the ester group (meta, with respect to the nitro group). Second, there is the issue of stereoselectivity, involving the orientation of the dienophile (endo or exo) with respect to the diene. Four different products occur as ortho/endo (**4a**, **6a**), ortho/exo (**4b**, **6b**), meta/endo (**4c**, **6c**), or meta/exo (**4d**, **6d**) adducts. Third, as discussed earlier, the s-cis and s-trans conformations of the dienophile remain unexplained. Overall, this creates a set of eight possible transition structures from each dienophile (see Scheme 2). Figure 4 depicts the TS geometries of the adducts for **4b** of s-cis at TS1-2, on behalf of the geometries of the eight adducts for **4a**–**4d**: TS1-1, TS1-2, TS1-3, and TS1-4. The values of the activation energies and selected geometrical parameters, obtained through B3LYP/6-31G* (DFT) calculations, are given in Table 4.

The activation energies calculated for the Diels–Alder reaction decrease as the dienes change from furan to methoxyfuran (17 to 18 kcal → 16 to 17 kcal → 11 to 13 kcal). The tendencies for the energies and the differences among the energies to decrease in a similar manner are consistent with the experimental results. A comparison of the relative energies of the transition state structures for each reaction reveals a narrow range of 1 to 2 kcal/mol. However, comparing these values in more detail, we have found that

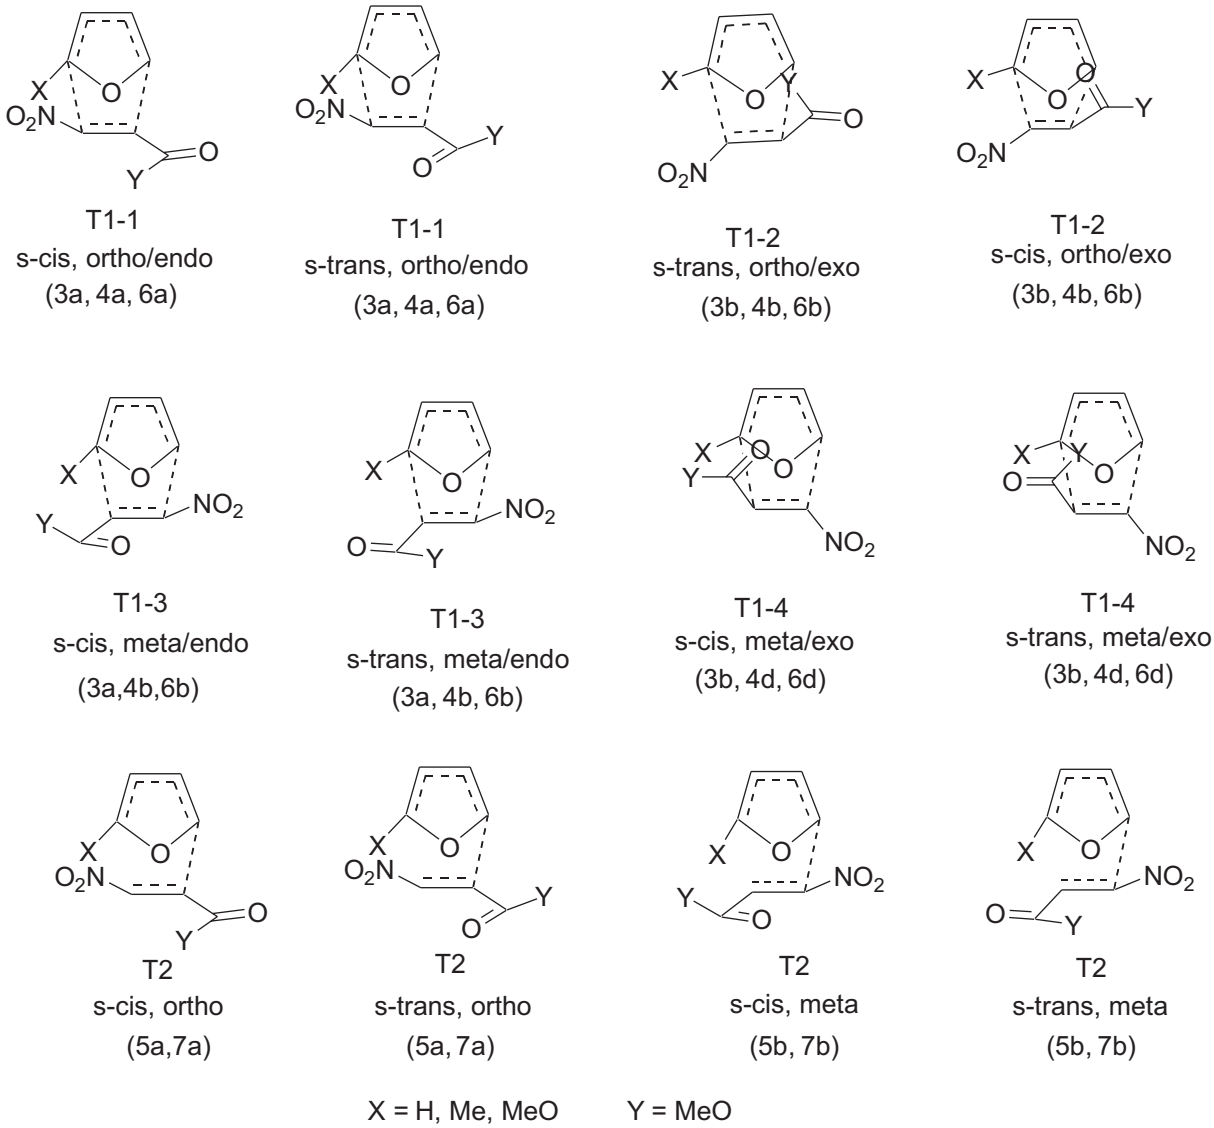
Scheme 2.



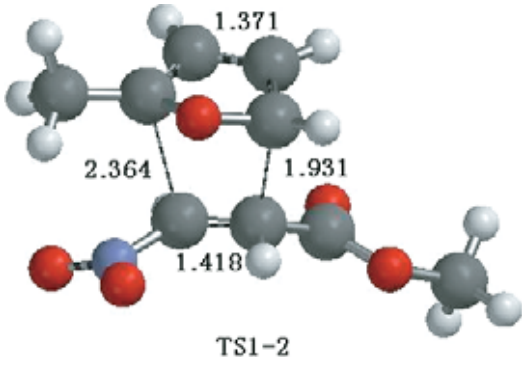


Fig. 4. Transition structure (TS1-2, ortho/exo, s-cis) for the Diels–Alder reaction between methylfuran (**1b**) and methyl 3-nitroacrylate (**2**) by DFT calculation at the B3LYP/6-31G* level. The distances of the C—C bonds are given in angstoms.

the endo/exo and ortho/meta pairings are only slightly different. The calculations suggest that the ortho isomer is more stable than the meta isomer by ca. 0.6 kcal/mol for **4** and 1 to 2 kcal/mol for **6**, a result in good agreement with the observed regio- and stereo-selectivity. As calculated, the endo isomer for the ester group (**4b**, **4d**, **6b**) is more reactive than the exo (**4a**, **4c**, **6a**) by 0.3 kcal/mol, while the experiment did not show good agreement for **4** and **6**. At first glance, this difference in isomer energy appears to be due to a steric effect. However, all of the transition state structures may be crowded to a similar extent, and so steric repulsion is probably not the main factor. The kinetic preference for endo adduct formation is often attributed to a second orbital interaction (25). In this case, there is an interaction between the orbital on the C2 or C3 atom of the furan ring and that on the carbon atom of the ester group at the endo position of the dienophile (see Fig. 4). This second orbital interaction may contribute to an acceleration of the rate. In addition, the endo approach presents a lower activation barrier than the exo ones, a finding which could be explained by the π-facial stereoselectivity of the carbonyl group.

In the case of furan (**1a**), both DFT calculations estimated a lower energy for TS1-1 (TS1-3) than for TS1-2 (TS1-4) by 0.7 kcal/mol. This small difference correlates with the obvi-

ous adduct selectivity observed. In the case of methylfuran (**1b**), we found small TS energy differences of less than 0.7 kcal/mol; a low selectivity for adducts may account for them. On the other hand, in the case of methoxyfuran (**1c**), the energy gap between the TS1-1, TS1-2 group and the TS1-3, TS1-4 group was found to be ca. 1.5 kcal/mol. These large gaps indicate a clear selectivity preference for the products from the TS1-1 and TS1-2 group; in accord with this prediction and the previous FMO prediction, the products from TS1-3 and TS1-4 group were not observed experimentally. This discrepancy may be attributable to an electrostatic attraction between the nitro group and the neighbouring methoxy group of the furan. The more reliable density functional method produced fairly good agreement in selectivity with the experiment. Although we did not necessarily expect accurate quantitative reproductions of the experimental value for each reaction, the relative energies of the transition state, which are little affected by the presence of the solvent, should be well-modeled (26, 27). In addition, the important factor to note is the conformation of the dienophile in the transition structures. The preferred conformation is the same as that found in the starting material, the s-cis conformation. The difference of the energies at the transition structures is less than 0.5 kcal/mol. Due to the small magnitude of the energy variation with transition state structure, it is important to pinpoint the pertinent factors producing the preferred conformation. However, as pointed out by Jimenez and co-workers (21) for the case of methyl acrylate, there will be a relatively larger increase in the delocalization energy for the transition structure than for the reactants.

Intermolecular cycloadditions are entropically very unfavorable because of the geometry restrictions. Thus, the butadiene–ethylene cycloaddition has a very large negative activation entropy of –44.5 cal/mol K, which raises the free energy of activation to 37.4 kcal/mol. Thus, the process is very unfavorable, as can be seen by a production of 78% only under very drastic conditions (165 °C and 900 atm, 1 atm = 101.325 kPa) (28). A general similar large negative entropy (–46 to –55 cal/mol K) was found for the present intermolecular cycloaddition.

However, the free energy of activation was determined to be quite different from the butadiene–ethylene case, having a value of only 14–17 kcal/mol. In addition, the low activation enthalpy at the polar addition contributes to the low activation energy (29). Therefore, this low free energy provides an explanation for the spontaneous intermolecular cycloaddition with the furans under mild conditions without any Lewis acid catalyst.

As noted in the discussion in the Experimental section, the Diels–Alder adducts produce the starting materials (**1b**, **1c**, and **2**); that is, retro-Diels–Alder reactions take place. The activation energies calculated for the retro-Diels–Alder reaction are 21 to 22 kcal/mol for **4** and 18–21 kcal/mol for **6a** and **6b**. Evidently, the reaction has its equilibrium on the Diels–Alder adduct side.[2] Because both the forward and the reverse reactions possess lower activation energies, they are faster and reach equilibrium more quickly. Therefore, the theoretical predication agrees with the experimental observation that no Diels–Alder product could be isolated. In contrast to these findings, the alternative path to the retroreaction from the thermodynamically favored Michael

[2]In the Diels–Alder reaction between 2-methoxyfuran and methyl 3-nitroacrylate, the distances 1.883 and 2.828 Å indicate that only the C4—C6 bond is being formed at TS; the short distance is comparable to that at the TS associated with the Michael addition. Certainly, this cycloaddition is a Michael addition with concomitant ring closure to give the Diels–Alder adduct in a single step.

© 2006 NRC Canada

adduct has a high activation barrier, 37–44 kcal/mol for **5** and 20–29 kcal/mol for **7**. This reaction equilibrium, then, lies to the Michael adduct side.

Solvent effect on the Diels–Alder reaction

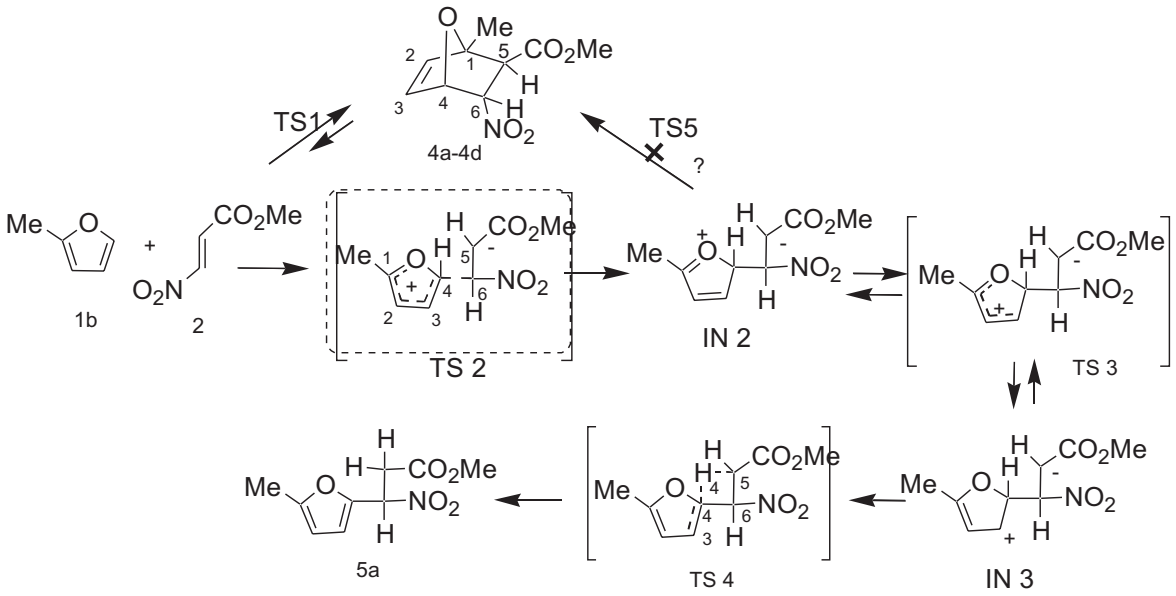
Solvent effects on cycloaddition are well-known (30) and have received considerable attention. Sustamann et al. (30*a*) studied the influence of the solvent effect on the stereoselectivity of Diels–Alder reactions and reported that it favors the transition structure that exhibits the higher dipolar moment. Table 4 shows the relative energies of the stationary points corresponding to the Diels–Alder reaction in chloroform used as the experimental solvent. The solvent effect increases with the polar zwitterionic character of the TS, which is related to the increase of the nucleophilic character of the furan derivative (0.4 kcal/mol → 1 kcal/mol → 4 kcal/mol). This poor solvent effect can be attributed to the low polar character of these cycloadditions. Inclusion of solvent effects does not substantially modify the geometries obtained in the gas phase. Therefore, the inclusion of the solvent effects in the experimental models does not alter the gas-phase analysis.

Geometry of the Diels–Alder reaction in the concerted mechanism

As pointed out by Houk et al. (31) in his discussion of the transition state structures, bond lengths other than those for newly forming bonds fall within small ranges. The TS bond distance C5—C6 increased from that in the starting dienophile to 1.31–1.33 Å and further rose to 1.55 Å in the Diels–Alder adducts. The C2—C3 distance in the diene TS lengthens to about 1.39 Å from that in the starting material, and becomes 1.35 Å in the adducts. The geometrical values obtained are shown in Table 4.

The geometries of the forming bonds reveal an asynchronous transition structure in which the shorter of the forming bonds is the one involving the carbon that attacked the methyl ester group, which corresponds to the more electrophilic site of methyl 3-nitroacrylate, and the nonsubstituted position of furan, the C5, which corresponds to the more nucleophilic site of the substituted furans. Furthermore, the bond length differences between the forming bonds, C1—C5 and C4—C6 in the transition states of the ortho structures of the TS1-1 and TS1-2 group are more asynchronous than those in the meta structure states of the TS1-3 and TS1-4 group. The degree of asynchronicity in the TS is defined as $\alpha = (ra - rb)/(ra + rb)$ (18). The values of this function are 0.15–0.21 at the TS structure in the case of methoxyfuran, much larger than of the TS formed by methylfuran (0.05–0.10). A more balanced measure of the extent of bond formation or bond breaking along a reaction pathway is provided by the bond order of the Wiberg index, derived from the natural bond orbital (NBO) basis (32), which is implemented in the Q-chem package. For **3a** and **3b**, the value of the C1—C5 BO is 0.43, whereas the value of the C4—C6 BO is 0.42. These data demonstrate a synchronous concerted bond formation. For the reaction of methylfuran (**1b**), the BOs of the forming bonds at the carbon bonded to the methyl group in furan are 0.30–0.39, and its other BOs are 0.48–0.55. These data give evidence for steric repulsion by the methyl group of the furan (**1b**). Furthermore, in the reaction of the methoxyfuran (**1c**), the tendency is increased, as the BOs at the carbon bonded to the methoxy group are 0.13–0.22, and the other BOs are 0.58–0.62. Similar tendencies are observed in the bond order of the furan rings. Thus, the values of C4—C6 are larger than the values of C1—C5, and the differences are greater in the methoxyfuran (0.36–0.49) than in the methylfuran (0.09–0.25). The decreasing BO found in the double bond at the olefin and increase obtained for the double bond of the furan are similar. The NBO analysis indicates a need to further evaluate the situation along the cycloaddition.

To achieve the maximum interaction, the π orbitals at the reactive portions should have maximal overlap. The indicators of such an interaction are not only the length of the forming bond but also the bond angles and the torsion angles. The optimal value of the bond angle and the torsion angle are 90° and 0°, respectively (33). Both the bond angles (C2-C1-C5 and C3-C4-C6) deviate only slightly from the optimal angle, so they appear to be sufficient to allow the reaction to take place. However, the deviation of the bond angle in the case of **6** is slightly larger than that seen in the case of **4**. On the other hand, a shift of –1° to –8° in the dihedral angle (C1-C4-C5-C6) was found in the case of **4** for the parallel conformation, and in the case of **6**, the angle showed a –8° to –21° change. Therefore, the vinyl group is almost parallel to the plane of the furan ring. Also, the twist angle produced between the forming bonds (the dihedral angle C1-C5-C4-C6) was found to be 1°–8° in the case of **4**, and 9°–17° in the case of **6**. The angles in the case of **4b** and **4c** (7.7°) when compared with those in **4a** and **4d** (1° to 2°) showed the steric interaction resulting from having the substituents groups located in the ortho position. On the other hand, in the case of the methoxyfuran, the twist angle shows similar larger values regardless of the position of the substituent groups, so the geometry of the TS of **6** is disfavored over that of **4**. Therefore, the asynchronicity of the TSs is not due to steric repulsion but to the more favorable nucleophile and electrophile interaction.



Stepwise mechanism to the Michael adducts

The process leading to the Michael adduct beginning from the electrophilic attack of methyl 3-nitroacrylate (**2**) on the furans (**1b** and **1c**) is shown in Scheme 3. Figure 5 presents the geometry of these transition structures. Tables 5 and 6 show the values of the activation energies and some selected geometrical parameters at the TS, while Fig. 6 and 7 display a schematic representation of the energy profile. Although generally the zwitterionic intermediate produced from the electrophilic attack of the nitroacrylate (**2**) is thought to adopt an anti-periplanar conformation, there may exist the possibility of it being generated in a syn-periplanar conformation because of the competitive Diels–Alder and Michael reactions (29).

The transition structure TS2 corresponds to a nucleophilic attack of the C4 center of the furan ring on the vinyl system of **2** to give the zwitterionic intermediate IN1. Furthermore, TS3 corresponds to the cation transfer from the oxygen atom of the furan to the atom of C3 to give the localized zwitterionic intermediate IN2. Both IN1 and IN2 have similar potential energies, and further, the structures of IN1 and IN2 are similar. However, it is not possible to associate the production of the Michael adduct via the transfer of the H4 atom from the C4 to the C5 center on IN1 without passing

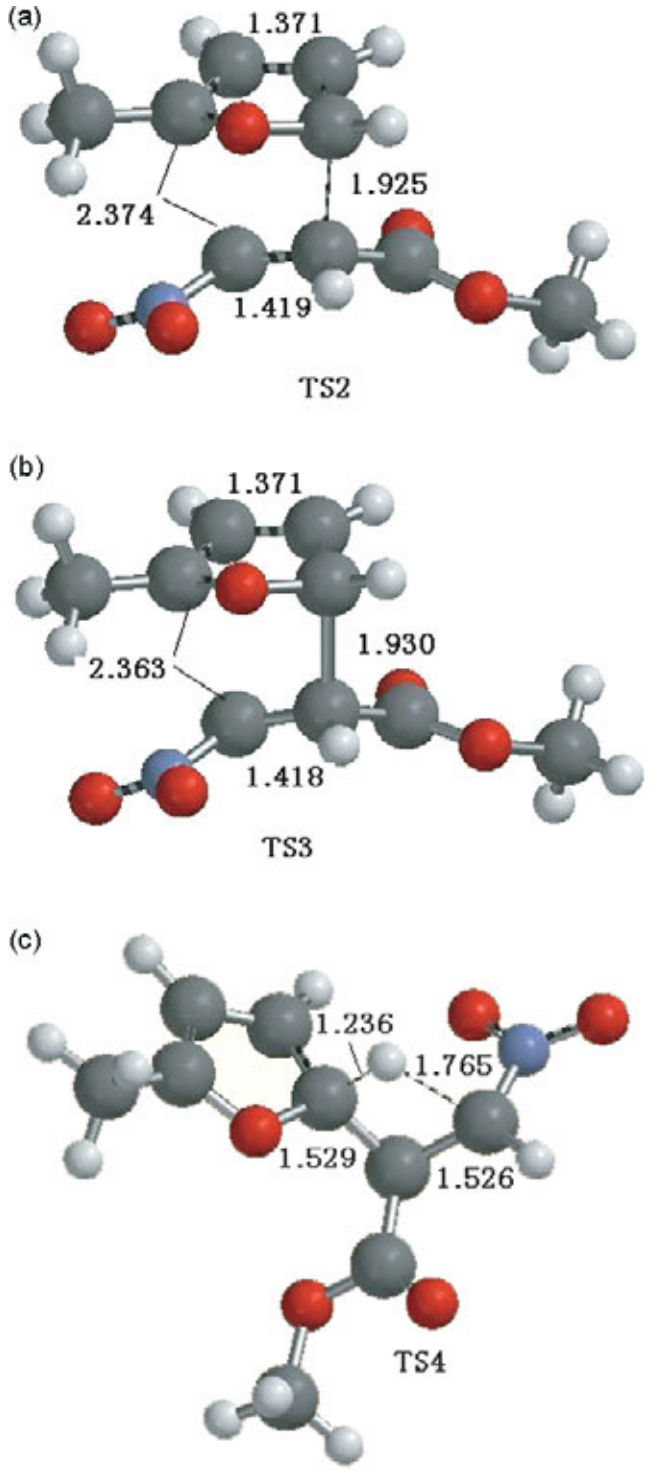
Scheme 3. The reaction mechanism of the addition reaction of furan with methyl 3-acrylate.

through IN2. The energy barriers associated with TS2 are 16.5–17.3 kcal/mol for **5a** and **5b**, 10.9 kcal/mol for **7a**, and 12.3 kcal/mol for **7b**. The length of the new forming bond (C4—C6) linked in TS2 are 1.93–2.02 Å for **5a** and **5b** and 1.87 Å for **7a** and **7b**, whereas the distance of the spacing between C1 and C5 are more narrow (2.23 Å for **5a** and **5b** and 2.53 Å for **7a** and **7b**). These values are similar to that of TS1 for the concerted mechanism of the Diels–Alder reaction (1.93–2.02 Å for C4—C6, 2.23–2.36 Å for C1—C5 in **4a**–**4d**, 1.83–1.86 Å for C4—C6, and 2.73–2.83 Å for C1—C5 in **6a** and **6b**).

The bond angles C2-C1-C5 and C3-C4-C6 in TS2 are 91.4°–96.5° for **5a** and **5b** and 86.9°–90.0° for **7a** and **7b**, and 100.6°–104.3° for **5a** and **5b** and 105.2°–106.6° for **7a** and **7b**, respectively. These values are similar to that of TS1. Furthermore, the values of the C1-C4-C6-C5 dihedral angles in the TS are –0.8° to 8.6° for **5a** and **5b** and 9.9°–11.2° for **7a** and **7b**, again similar to that of TS1. In contrast to the Diels–Alder reaction, the angles in the Michael addition TS structures show the reverse twist. This twist may be caused by steric repulsion between the substituent groups at the side of the molecular opposite to the area where bonds form. Also, the differences between the distances and the angle are larger for the pair **5a**, **7a** than for **5b**, **7b**. This indicates that the vinyl group of the dienophile is twisted out of the plane of the furan ring to a slightly greater extent in the TS for the electrophilic attack of **2** on **5a** and **7a** than it is in the TS of **5b** and **7b**. This difference in conformation may result from a repulsive interaction between the nitro group of **2** and the substituent groups present on the furan ring. However, the activation energy for the formation of the TS for the Michael reaction seems to be smaller as the result of the electron-rich character of the nitro group. Finally, the reactivity may be determined by the balance between the steric repulsion and the electronic attraction. Our result may indicate that the nitro group predominates over an ester in controlling the direction of the Michael additions as has been pointed out by Patterson and McMurry (34).



Previous studies of this reaction and the results summarized in the figures and tables of this paper reveal some interesting characteristic features. The presence of the nitro group on C5 may be necessary for the occurrence of the Michael addition reaction (35); the reaction of the furan (**1a**–**1c**) with diethyl malonate does not lead to a Michael adduct (36), but the reaction of **1b** with 1-nitro-3,3,3-trichloro-1-propene does (37). Furthermore, Just et al. (38) reported that the same reaction afforded Diels–Alder adducts, which were converted into Michael adducts with extended reaction times. It appears that the nitro group can delocalize the charge generated in the formation of the zwitterion (3) as suggested by the calculated high electron density on both C5 and C6.

The intermediate IN2 may undergo a process that leads to the formation of the last molecular adducts **5a**, **5b**, **7a**, and **7b**. This process (TS4) corresponds to an intramolecular proton-transfer process, which presents a high potential energy barrier (48 kcal/mol for **5a**, 50 to 51 kcal/mol for **5b**, 41 kcal/mol for **7a**, and 45 kcal/mol for **7b**) relative to the former steps (TS2, TS3) of the stepwise addition.

The transition structure TS4 corresponds to a four-membered transition structure in which the intramolecular proton (H4) transfers from the C4 to the C5 center. In the transition state, the length of the C4—H4 bond being broken is 1.23–1.28 Å and the C5—H4 bond being formed is 1.66–1.76 Å. These lengths suggest bond orders that indicate a concerted bond breaking – formation process for the intramolecular proton transformation. One of the causes of the high potential energy of TS4 relative to TS2, TS3 is the angular strain associated with the formation of this transition structure. The C3-C4-C6 bond angle is 125°–129° (ca. 104° at TS2, TS3) and the H4-C4-C6 bond angle is 84°–88° (ca. 106° at TS2, TS3). These values show that the C4 center is far from sp^3 hybridized. In addition, the C4-C6-C5 bond angle is associated with the strain that appears during the formation of this four-membered transition structure. To the contrary, the TS2, TS3 route has a lower energy owing to a favorable π–π electric interaction between the furan (**1b**, **1c**) and the olefin (**2**) taking a syn-periplanar conformation.

Fig. 5. Transition structures (TS2, TS3, TS4 at s-cis, ortho/exo) for the Michael reaction between methylfuran (**1b**) and methyl 3-nitroacrylate (**2**) by DFT calculation at the B3LYP/6-31G* level. The distances of the C—C bonds and C—H bonds are given in angstoms.

However, for this intramolecular process, the negative activation entropy is only –4 to –7 cal/mol K compared with the more entropically unfavorable value for the concerted Diels–Alder reaction. In addition, the computed free energy of activation is found to be 5 to 6 kcal/mol. These cooperative factors permit this intramolecular process with the smooth motion of the H4 atom from the C4 to the C5 center.

Solvent effect on the Michael reaction

Solvent effects on the Michael addition are interesting because of the presence of the polar zwitterion intermediate. Table 5 shows the B3LYP/6-31G* relative energies with the inclusion of the solvent effect. The data of TS2 and TS3 do not show a definite difference between carrying out the reaction in the gas phase and in solvent. These intermediates and transition structures are stabilized by 1 to 2 kcal/mol for **5a** and **5b** and 2–4 kcal/mol for **7a** and **7b**, similar to the concerted Diels–Alder reaction. These results are due to the low variation of the dipole moments along the reactive channels, and are related to the effective delocalization of the charge transferred during the nucleophilic attack of **2b** and **2c** to **1**. However, the energy differences of the transition state TS4 in solvent are stabilized by 6–13 kcal/mol over that in the gas phase. The transition structure involving proton transfer is preferentially stabilized relative to the reactants owing to the large charge transfer that is developed along this polar transfer path. The low energy barrier found for the Michael reaction is in good agreement with the fact that, experimentally, this reaction can be carried out completely at room temperature. The large difference in the solvent and gas-phase TS energies is related to localization of the charge around the transfer proton. Moreover, the solvent effect increase for **5a** and **7a** is more dramatic than that of **5b** and **7b**. Thus, inclusion of the solvent effect may accelerate this polar reaction by a larger stabilization of the transition state corresponding to the proton transfer.

Preparation of the Diels–Alder adduct from IN1 via TS5

As mentioned in the previous section, the geometries of the first intermediate (IN1) in the Michael reactions for **5** and **7** are similar to that of transition state of the concerted Diels–Alder reaction. Therefore, as Houk, Domingo and coworkers (9, 10, 39) reported, with a small change of the geometry, the Diels–Alder adduct may be produced from IN1 by the stepwise process. That is, the nucleophilic attack of the anionic C5 center on the C1 atom on IN1 via TS5 gives the cycloadducts **4** and **6** (Scheme 3 and Table 5). For **5a**, s-cis, in which the C1 position is substituted by the methyl group, this cyclization process presents a small potential energy barrier (15.4 kcal/mol). The length of the C1—C5 bond being formed in the TS is 1.60 Å. For **5b**, s-cis, where C6 possesses a NO_2 group, the potential energy barriers are 21.2 kcal/mol, and the forming bond length is 2.33 Å. For **7a** and **7b**, the forming bond lengths are longer, owing to the steric repulsion, at 2.74 and 2.65 Å, respectively. The potential energies (25.0 and 19.7 kcal/mol) are larger than that of **5**. Therefore, these values are different from the experiment results in which the rates of reaction of **6** are faster than that of **4**. After many attempts, we were able to find TS5 for the s-cis form. In addition, we tried to calculate the transition state for the s-trans form. However, the transition state had an unreasonable conformation of the ester group and unrealistic thermal parameters. Any attempts to find the true transition state were unsuccessful. Therefore, the Diels–Alder adducts may be not prepared via the stepwise mechanism via TS5.

Experimental

The proportions of the cycloadducts have been determined by integration of the corresponding methyne and vinyl peaks in the ^1H NMR spectra of their mixtures. We did not fully succeed in separating the different cycloadducts by column chromatography. Their stereochemical assignments were established by a series of 1D and 2D COSY experiments (250 MHz, Tables 7 and 8) (36, 40). They were confirmed by the acquisition of the spectra of **3a**, **4a**, and **5a**.

General

The ^1H and ^{13}C NMR spectra were recorded on JEOR FX-90Q and Bruker AC-250 spectrometers in deuterochloroform. Tetramethylsilane was used as the internal references for the proton spectra. The IR spectra were recorded on a

Reactions

Synthesis of methyl 3-nitroacrylate (2) (ref. 41)

To a dimethyl ether solution (165 mL) of methyl acrylate (16.7 g, 0.2 mol) and iodine (31.5 g, 0.1 mol), silver nitrite (12.7 g, 0.1 mol) was added, and the solution was stirred for 5 days at room temperature. The reaction solution was washed with aqueous sodium thiosulfate, sodium carbonate, and sodium chloride solution. After evaporation of the solvent, methyl 2-iodo-3-nitro-propylate was obtained in a 18.5 g (87%) yield as yellow oil. The dried 2-iodo-3-nitropropylate (18.5 g, 0.1 mol) was added to sodium acetate (9.6 g, 0.1 mol) in dimethyl ether solution (120 mL) and left for 6 h at room temperature. The reaction mixture was then washed as previously described. Methyl 3-nitroacrylate was obtained in nearly quantitatively yield as a yellow oil. The liquid crystallized out on standing in a refrigerator. Yield: 8.0 g (87%); mp 32.0–33.0 °C.

Typical reaction procedure for furan (1a) with methyl 3-nitroacrylate (2)

Furan (18 mg, 0.3 mmol) and methyl 3-nitroacrylate (33 mg, 0.3 mmol) was placed in chloroform (3 mL) in a reaction flask and the reaction followed by ^{1}H NMR spectroscopy.

Separation of the products of the reaction of furan (1a) and methyl 3-nitroacrylate (2)

A mixture of **1a** (631 mg, 9.3 mmol) and **2** (105 mg, 0.8 mmol) was allowed to stand at room temperature for 1 day. After evaporation of the liquid, crystals were obtained from the reaction mixture by recrystallization from dimethyl ether.

***3a**: Methyl 5*-endo-*nitro-7-oxabicyclo[2.2.1]hept-2-ene-6*-exo-*carboxylate (ref. 42)*

Yield: 34 mg (21%); mp 66.0–67.0 °C. ^{1}H NMR ($CDCl_3$) δ: 3.25 (1H, d, *J* = 2.9 Hz), 3.28 (3H, s), 5.35 (1H, d, *J* = 1.4 Hz), 5.47 (1H, dd, *J* = 1.7, 4.8 Hz), 5.54 (1H, dd, *J* = 2.9, 4.8 Hz), 6.39 (1H, dd, *J* = 1.4, 5.8 Hz), 6.73 (1H, dd, *J* = 1.7, 5.8 Hz). ^{13}C NMR ($CDCl_3$, ppm) δ: 48.9, 53.0, 75.7, 83.2, 84.4, 133.7, 138.9, 170.2.

Separation of the products of the reaction of 2-methylfuran (1b) and methyl 3-nitroacrylate (2)

A chloroform solution (5 mL) of **1b** (341 mg, 4.2 mmol) and **2** (357 mg, 2.7 mmol) was allowed to stand at room temperature for 5 days. The isomers were separated by HPLC (benzene–acetone, 50:1).

***4a**: Methyl 6*-endo-*nitro-7-oxabicyclo[2.2.1]hept-2-ene-1-methyl-5*-exo-*carboxylate*

Yield: 40 mg (7%); yellow oil. IR (cm^{-1}): 2960, 1740, 1554, 1440, 1374. ^{1}H NMR ($CDCl_3$) δ: 1.85 (3H, s), 3.60 (1H, d, *J* = 3.0 Hz), 3.73 (3H, s), 4.93 (1H, d, *J* = 3.0 Hz), 5.42 (1H, d, *J* = 1.9 Hz), 6.35 (1H, *J* = 5.8 Hz), 6.49 (1H, dd, *J* = 1.9, 5.8 Hz). ^{13}C NMR ($CDCl_3$, ppm) δ: 17.7, 52.6, 54.2, 83.1, 88.4, 89.4, 134.4, 141.2, 170.0. MS *m*/*z*: 213 (M^+), 167 ($M^+ - NO_2$), 135 ($M^+ - (NO_2 + CH_3OH)$).

***5a**: Methyl 2-[2-(5-methylfuranyl)]-3-nitropropylcarboxylate*

Yield: 68 mg (12%); yellow oil. IR (cm^{-1}): 1744, 1560, 1440, 1380, 1246, 1206. ^{1}H NMR ($CDCl_3$) δ: 2.25 (3H, s), 3.77 (3H, s), 4.54 (1H, dd, *J* = 5.2, 9.3 Hz), 4.69 (1H, dd, *J* = 5.2, 14.5 Hz), 5.06 (1H, dd, *J* = 9.3, 14.5 Hz), 5.92 (1H, d, *J* = 3.1 Hz), 6.15 (1H, d, *J* = 3.1 Hz). ^{13}C NMR ($CDCl_3$, ppm) δ: 13.5, 42.8, 53.1, 73.6, 106.8, 109.7, 144.1, 153.1, 169.1. MS *m*/*z*: 213 (M^+), 166 ($M^+ - NO_2 - H$), 108, 97.

Separation of the products of the reaction of 2-methoxylfuran (1c) and methyl 3-nitroacrylate (2)

A benzene solution (2 mL) of **1c** (17 mg, 1.7 mmol) and **2** (2.93 mg, 2.0 mmol) was allowed to stand at room temperature for 30 min. The product was separated by column chromatography (hexane – dimethyl ether, 1:1).

***7a**: Methoxy 2-[2-(5-methylfuranyl)]-3-nitropropyl carboxylate*

Yield: 282 mg (72%); yellow oil IR (cm^{-1}): 3436, 1726, 1310, 1208, 940, 740. ^{1}H NMR ($CDCl_3$) δ: 3.77 (3H, s), 3.83 (3H, s), 4.47 (1H, dd, *J* = 5.0, 9.0 Hz), 4.65 (1H, dd, *J* = 5.0, 14.5 Hz), 5.03 (1H, dd, *J* = 9.0, 14.0 Hz), 5.09 (1H, d, *J* = 3.3 Hz), 6.18 (1H, d, *J* = 3.3 Hz). ^{13}C NMR ($CDCl_3$, ppm) δ: 42.7, 53.0, 57.8, 73.5, 80.5, 110.5, 135.8, 161.8, 168.8. MS *m*/*z*: 229 (M^+), 182, 167, 124, 113.

The effect of pressure and heating rate on the melting behavior of indium and tin

David E.G. Jones, Ruiping Wang, and Anne-Marie Turcotte

Abstract: The dependence of the phase transition behavior of indium and tin on pressure and heating rate has been investigated using heat flow calorimetry (HFC). The work has shown a significant influence of heating rate on the form of the melting curve, onset temperature for both indium and tin, as well as the enthalpy of fusion for indium. Based on the result for the dependence of onset temperature on pressure, the volume changes on fusion have been estimated using the Clausius–Clapeyron equation and compared with literature results.

Key words: indium, tin, high pressure, heat flow calorimetry calibration, fusion temperature, enthalpy of fusion.

Résumé : Faisant appel à la calorimétrie avec écoulement de chaleur (CEC), on a étudié la relation entre le comportement de la phase de transition de l'indium et de l'étain et la pression et la vitesse de chauffage. Ce travail a permis de montrer qu'il existe la vitesse de chauffage influence fortement la forme de la courbe de fusion, la température de mise en route tant pour l'indium que pour l'étain ainsi que l'enthalpie de fusion de l'indium. Sur la base des résultats relatifs à l'influence de la pression sur la température de mise en route, on a évalué les changements de volume lors de la fusion en faisant appel à l'équation de Clausius–Clapeyron et on les a comparés aux valeurs trouvées dans la littérature.

Mots clés : indium, étain, pression élevée, calibration de la calorimétrie à écoulement de chaleur, température de fusion, enthalpie de fusion.

Introduction

High-pressure thermal analysis has drawn increasing attention in order to better understand the influence of the pressure on the phase transitions and thermal decomposition of solid materials (1–3). Consequently, the pressure dependent properties of standard reference materials (SRMs) used for the calibration of temperature and heat flow are required to calibrate the thermal instruments used in these high-pressure studies. The phase transition behavior of indium and tin, the most commonly used SRMs, has been investigated by means of differential thermal analysis (DTA) (4–6), differential scanning calorimetry (DSC) (7), and X-ray diffraction techniques (8) under pressure. McDaniel et al. (9) developed a technique with a free piston pump to determine the melting curves for indium at pressures up to 10 GPa and for tin up to 0.5 GPa. In 1980, the melting curve of tin was redetermined by DTA with Chromel–Alumel thermocouples in an attempt to minimize the uncertainties of the data reported previously (4). Höhne et al. (7) have studied the pressure dependence of the fusion temperature and the volume change on fusion for indium using DSC with a high-pressure piston-cylinder-type dilatometer. However, due to the difficulties of accurately measuring melting curves under simultaneous application of both high temperature and high pressure, the available data on the changes of fusion temperature and enthalpy of fusion for the calibration substances, including indium and tin under pressure, are still limited, and furthermore, the results do not agree very well. Particularly, to our knowledge, no work on the phase-transition behavior of indium and tin using the heat flow calorimetry (HFC) technique at high pressure has been reported.

In our laboratory, HFC was used in a modified system to study the thermal properties of energetic materials at various pressures up to 69 MPa (10). Indium and tin were selected to calibrate the instrument. This paper describes the effects of pressure and heating rates on the form of the fusion curve, the fusion temperature (T_o), the enthalpy of fusion ($\Delta_{fus}H$), and the volume change (ΔV) on fusion of indium and tin measured using HFC.

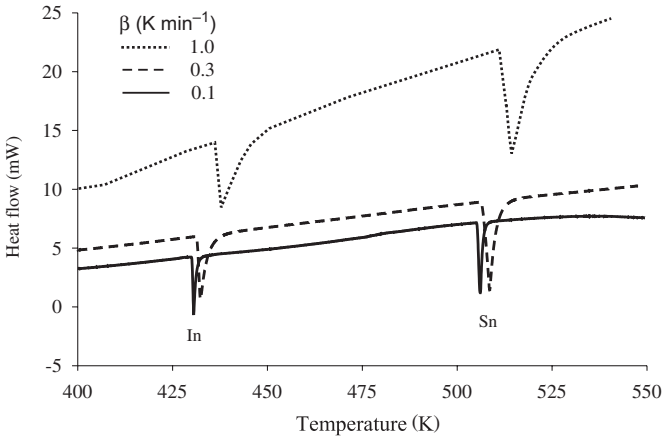
Experimental section

Synthetic sapphire (~100% α-Al_2O_3), biphenyl (99.984%), indium (99.9999%), and tin (99.999%) were purchased from the National Institute of Standards and Technology (NIST, Gaithersburg, Maryland).

A Setaram C-80 heat-flux calorimeter was used to study the thermal properties of energetic materials at pressures up to 69 MPa. Currently, argon at high pressure (~40 MPa) is being used as a pressure source. Baseline experiments with empty vessels at 0.3 K min^{-1} and 0.17 and 33.2 MPa argon showed no significant influence of pressure on the baseline drift, which is on average approximately 4 mW over the temperature range from 370 to 570 K. At β = 1.0 K min^{-1},

 doi:10.1139/V05-256 © 2006 NRC Canada

Fig. 1. Heat flow of indium and tin at β = 0.1, 0.3, and 1.0 K min^{-1} and p = 0.2 MPa.



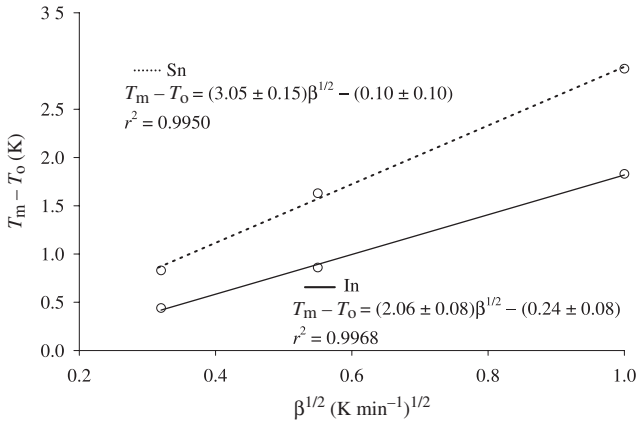


Fig. 2. Dependence of ($T_m - T_o$) of indium and tin on $\beta^{1/2}$ at p = 0.2 MPa.

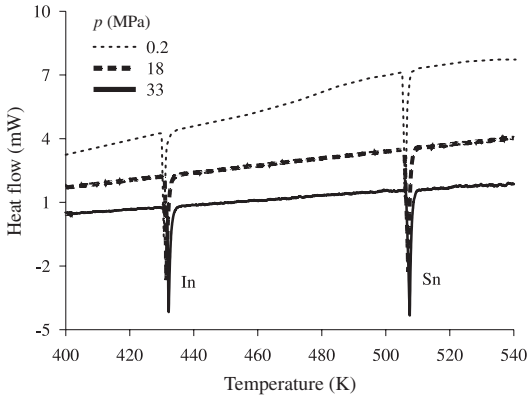
where thermal lag is higher, the difference in heat capacity between the sample and reference cells is exacerbated, resulting in a slightly larger baseline drift.



The verification experiments using biphenyl, indium, and tin at 0.3 K min^{-1} and 0.17 MPa argon demonstrated that T_o and $\Delta_{fus}H$ for biphenyl (341.38 K and 119.93 J g^{-1}) are comparable with the literature values[2] of 342.45 K and 120.41 J g^{-1} at β = 2.5 K min^{-1}; those for indium (429.9 K and 29.0 J g^{-1}) are in good agreement with the literature values[3] of 429.8 K and 28.7 J g^{-1}; those for tin (505.0 K and 60.1 J g^{-1}) agree well with the literature values[4] of 505.11 K and 60.20 J g^{-1}. A more detailed description of this Calvet type microcalorimeter fitted with a high-pressure manifold and vessels was reported elsewhere (10).

The experiments were performed as follows: 94.9 mg of indium was placed in an alumina liner, 71.8 mg of alumina powder was placed on top of the indium, and 71.1 mg of tin was placed on top of the alumina. An equivalent mass of alumina powder was contained in another liner and put into the reference cavity of the calorimeter. In this way, both SRM materials could be analyzed in one experiment. These materials were run at heating rates of β = 0.1, 0.3, and 1 K min^{-1} and various pressures up to about 33 MPa.

Results and discussion

Indium and tin partitioned by alumina were heated from 301 to 553 K at the desired heating rate and pressure of argon. Figure 1 shows an overlay graph of representative experiments at pressure p = 0.2 MPa and heating rates of β = 0.1, 0.3, and 1.0 K min^{-1}. It is noted that the fusion curves for both indium and tin become broader with an increase in the heating rate, which is in agreement with an observation by Van Miltenburg and Cuevas-Diarte (11), who have also reported that the width ($T_m - T_o$) of melting peaks of indium in DSC and DTA, where T_m is the temperature at minimum heat flow, depends on β by a square-root relation at β < 5 K min^{-1}. The HFC results also show that the width ($T_m - T_o$) of melting curves for both indium and tin varies linearly as a function of $\beta^{1/2}$ for β from 0.1 to 1.0 K min^{-1} and at pressures (p) up to 33 MPa. Figure 2 represents the linear dependence of the width ($T_m - T_o$) of melting curves on $\beta^{1/2}$ for indium and tin at p = 0.2 MPa measured using HFC. However, no significant effect of pressure on the width of peaks was observed within the employed pressure range (Fig. 3). The influence of β on the baseline drift was also observed, probably owing to the slight difference in the thermal environment of the reference and sample vessels in the calorimeter. The increase in baseline shift with β may be a result of the delay in equilibration between the sample and reference cells.

Fig. 3. Heat flow of indium and tin at p = 0.2, 18, and 33 MPa and β = 0.1 K min^{-1}.

Indium

The values of the onset temperatures (T_o), the minimum heat flow temperatures (T_m), and the enthalpies of fusion ($\Delta_{fus}H$) for the phase transition of indium at three heating rates and five pressures are summarized in Table 1. From these data, it was noted that there is no apparent effect of pressure on the fusion heat of indium within the employed pressure range at a fixed heating rate (Fig. 4), which is in ac-

cordance with the literature results obtained from high-pressure DSC measurements (7). However, the fusion enthalpies decrease with the heating rate at a constant pressure. Figure 5 demonstrates the decrease of enthalpy ($\Delta_{fus}H$) and the increase of onset temperature (T_o) measured at p = 0.2 MPa as a function of heating rate. Similar behavior is observed at other pressures up to 33 MPa.

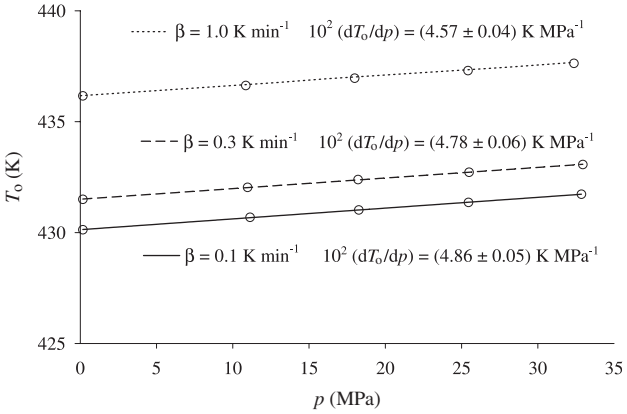

Figure 6 shows the linear increase of T_o with the increase in pressure (p) at heating rates of β = 0.1, 0.3, and 1 K min^{-1}, respectively. For all values of β, the dependence of the fusion temperature of indium on pressure agrees with the results measured by a high-pressure dilatometer at a heating rate of 5 K h^{-1}. This is illustrated in Table 1 by comparison of our observed results from HFC and those calculated from regression eq. [1] reported in the literature (7).

$$[1] \qquad T_f = T_o + (0.04929 \pm 0.0008)p - (3.9 \pm 2) \times 10^{-6}p^2$$

where p is the pressure in MPa and T_o is the onset temperature of indium measured by HFC at 0.17 MPa.

Based on the slope (dT_o/dp) of the plot of T_o vs. pressure (at T_o) and atmospheric-pressure fusion enthalpies, the fusion volume change was estimated at different heating rates

Fig. 6. Effect of p and β on onset temperature of phase transition of indium.

via the Clausius–Clapeyron equation and included in Table 2. These values are compatible with the values of 0.389 (p = 0.1 MPa) and 0.394 cm^3 mol^{-1} (p = 50 MPa) obtained in a high-pressure dilatometer (7). The value of V at

β = 0.0 K min^{-1} was obtained by extrapolating the curve of ΔV vs. β to β = 0.0 K min^{-1}; the uncertainty in this value was determined by extrapolating the 95% confidence interval to β = 0.0 K min^{-1}. For β > 0.0 K min^{-1}, the uncertainties were calculated from the standard deviation of the fits.

Tin

Table 3 summarizes the onset temperatures (T_o), the temperatures of minimum heat flow (T_m), and the enthalpies of fusion ($\Delta_{fus}H$) for the phase change of tin at various heating rates and pressures measured along with indium by HFC. Figures 1 and 2 also show that the width of the fusion curve of tin varies as a function of the square root of heating rate at p = 0.2 MPa, and Fig. 3 demonstrates that no substantial influence of pressure on the width of the fusion curve of tin at p = 0.2 MPa was observed. Moreover, it is noted that there is no significant dependence of fusion enthalpy on pressure, as was also observed for indium (Fig. 4). However, the enthalpies of fusion for tin at specific pressures have not shown an obvious decrease with heating rate, which was observed for indium (Fig. 5). Similar to the observation for indium, T_o and T_m for the phase transition of tin increase with pressure at constant heating rate, and increase with heating rate at constant pressure. Zhou et al. (6) have also reported that the melting point of tin increases with increasing pressure. Figure 7 shows the dependence of T_o on β at p = 0.2 MPa; the derived equation of onset temperature as a function of heating rate has been included in this figure. Similar equations at other pressures have been regressed and are listed in Table 4.

Fig. 7. Dependence of T_o on β for tin at p = 0.2 MPa.

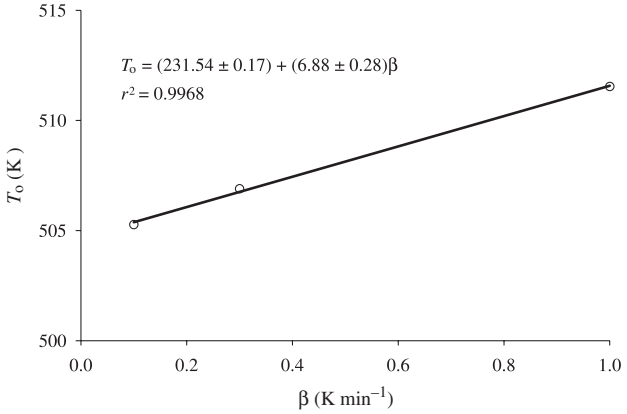

Table 4. Equations of T_o for tin as a function of β at various pressures (p).

p (MPa)	Equation (K)	r^2
11	T_o = (505.19±0.07) + (6.69±0.11)β	0.9994
18	T_o = (505.44±0.09) + (6.60±0.15)β	0.9989
26	T_o = (505.60±0.06) + (6.59±0.10)β	0.9995
33	T_o = (505.86±0.08) + (6.63±0.12)β	0.9993

Plots of T_o vs. pressure (at T_o) at heating rates of 0.1, 0.3, and 1 K min^{-1} in Fig. 8 suggest linear dependence of T_o on pressure with positive slopes (dT_o/dp) of (0.0348 ± 0.0027), (0.0290 ± 0.0014), and (0.0266 ± 0.0017) K MPa^{-1}, respectively, which is in accordance with the result of 0.03 K MPa^{-1} reported by Kennedy and Newton (12) and 0.032 K MPa^{-1} determined by Kingon and Clark (4) using DTA with a piston-cylinder for pressures up to 3.7 MPa.

Based on the slope dT_o/dp of the plot (Fig. 8) of onset temperature vs. pressure and the enthalpy measured at ambient pressure (0.2 MPa), the volume changes have been calculated via the Clausius–Clapeyron relation. These volume changes in Table 5 obtained in this work were compared with the value of 0.46 cm^3 mol^{-1} predicted by Kingon and Clark (4) via the Clausius–Clapeyron equation using the determined slope of 32 K GPa^{-1} for heating rates in the range of 30 to 54 K min^{-1} and the atmospheric-pressure enthalpy (60.80 J g^{-1}) of melting cited in ref. 4. The literature result for ΔV in Table 5 does not agree with the values obtained here, and in particular, it should be noted that the result reported by Kingon and Clark (4) shows an opposite trend

with heating rate than expected on the basis of our HFC results. ΔV (β = 0.0 K min^{-1}) is not meaningful because of the scatter in the ΔV vs. β plot and thus has not been included in Table 5.

Conclusions

The observed melting curves for both indium and tin are broader at high heating rates than those at low heating rates, but the breadth of the thermal curves is independent of pressure within the studied pressure range of 0.2 to 33 MPa. A low heating rate favors generating sharper fusion curves and fusion temperatures closer to the International Practical Temperature Scale value at ambient temperature and less baseline drift in the HFC measurements. The onset temperatures for indium and tin increase with increasing heating rate, while the enthalpy of fusion of indium decreases, and there is no obvious change for tin. At a specific heating rate, no dependence of the enthalpy of fusion on pressure was observed, while the dependence of onset temperature on pressure shows a linear increase. The slope dT_o/dp of the onset temperature vs. pressure curve decreases with increasing heating rate. Based on the values of dT_o/dp and the enthalpy of fusion measured at ambient pressure, the volume changes on melting have been estimated via the Clausius–Clapeyron equation and the volume changes are in agreement with the literature results for indium but are not in agreement with those for tin. The results of this study may help us to calibrate HFC measurements more precisely when conducting thermal decomposition studies at elevated pressures.

Dynamics of percolation and energetics in the clustering of water/AOT/oil microemulsions in the presence of ethanol amines

Andrew van Bommel, Andrew Glennie, Danielle Chisholm, and Rama M. Palepu

Abstract: Temperature-induced percolation in water/AOT/oil microemulsions in the presence of mono-, di-, and triethanol amines have been studied using conductometric measurements. The percolation temperature of water/AOT/oil microemulsions depends on the nature of the alkanol amine added. Mono- and di-ethanol amines hinder the percolation process, while triethanol amine promotes the process. Percolation studies were also conducted with varying $\omega = [H_2O]/[AOT]$ values and varying chain lengths of continuous oil phase (C_6–C_{10}). The results indicate that increases in both ω and the chain length of the oil decrease the percolation temperature. The microemulsion systems have been analyzed in terms of percolation temperature, scaling equation parameters, and activation energies. The energetic parameters of the clustering process have also been determined employing the phase–separation model. The influence of alkanol amines on the percolation phenomenon has been rationalized in terms of the changes in fluidity of the interfacial layer, the viscosity of the water micropool, and the attractive interactions of the microemulsion droplets. The influence of the alkanol amine additives on the stated parameters was discussed in view of the individual effects of the alcohol and amine moieties on the properties of water/AOT/oil microemulsions.

Key words: microemulsion, percolation, conductometry, alkanol amine, surfactant.

Résumé : On a étudié la percolation induite par la température de microémulsions d'eau/AOT/huile en présence de mono-, di- et tri-éthanolamines en se basant sur des mesures de conductométrie. La température de percolation des microémulsions d'eau/AOT/huile dépend de la nature de l'alcanolamine ajoutée. Les mono- et di-éthanolamines inhibent le processus de percolation alors que la triéthanolamine accélère le processus. On a aussi effectué des études de percolation en faisant varier les valeurs de $\omega = [H_2O]/[AOT]$ et en faisant varier les longueurs des chaînes de la phase huileuse continue (C_6–C_{10}). Les résultats indiquent que l'augmentation tant de la valeur de ω que de la longueur de la chaîne de la phase huileuse diminuent la température de percolation. On a analysé les systèmes de microémulsions en termes de température de percolation de paramètres de l'équation d'échelle et d'énergies d'activation. On a aussi déterminé les paramètres énergétiques du processus de formation d'agrégats à l'aide du modèle de séparation de phase. On a rationalisé l'influence des alcanolamines sur le phénomène de percolation en termes de changements dans la fluidité de la couche interfaciale, de la viscosité du microréservoir d'eau et des interactions attractives des gouttelettes de la microémulsion. On discute de l'influence des alcanolamines ajoutées sur les paramètres donnés en fonction des effets individuels des parties alcool et amine sur les propriétés des microémulsions d'eau/AOT/huile.

Mots clés : microémulsion, percolation, conductométrie, alcanolamine, agent de surface.

[Traduit par la Rédaction]

Introduction

Microemulsions are thermodynamically stable phase separations of water-in-oil (w/o) or oil-in-water (o/w) aided by a surfactant (and possibly a cosurfactant) (1, 2). They are polydisperse and isotropic, with droplet radii ranging from 5 to 100 nm (3). Many w/o microemulsions exhibit a dramatic increase in conductivity upon the increase of temperature or a volume fraction of water. This phenomenon is known as percolation (4–12), as a microemulsion undergoes an increase in conductivity, its droplets coalesce and a transfer of charge takes place. Proposed mechanisms of percolation include the hopping mechanism (in which ions hop among droplets) and the fusion–fission mechanism (in which a continuum of droplets forms where charge exchange occurs) (3).

Ion transport in w/o microemulsions is influenced by the presence of additives. The effect of additives on the percolation of microemulsions can be analyzed in terms of changes in various physicochemical parameters. For example, short-chained alcohols soften the interfacial layer, thereby increasing the ease of conduction (13), whereas compounds such as

 doi:10.1139/V06-011 © 2006 NRC Canada

cholesterols (13) and toluene (14) have been reported to block the transfer of ions, rigidifying the microemulsion interface. Other additives, such as electrolytes (15–18), organics (19–21), surfactants (22–24), and bile salts (25, 26), have also been studied in terms of their influence on the percolation phenomenon.

In the present study, percolation temperatures have been obtained for water/AOT/oil microemulsions in the presence of mono-, di-, and tri-ethanol amines. The presence of both amine and hydroxyl groups in alkanol amines make them versatile for industrial applications, particularly in textile, pharmaceutical, and household product industries (27, 28). Oil phase, water content, and percentage of alkanol amine additive have been varied in the present investigation. The scaling parameters, activation energies, and thermodynamics of the droplet clustering process have been determined. The results obtained have been analyzed in terms of changes in the physicochemical properties of the microemulsion, particularly the interfacial layer.

Materials

AOT (sodium bis(2-ethylhexyl) sulfosuccinate), *n*-alkanes, and alkanol amines were purchased from Sigma-Aldrich and were used as received. Solutions were prepared with triply deionized water.

Methods

Conductivity measurements (0.5% accuracy) were made on a CDM conductometer (Radiometer, Copenhagen) using a temperature-compensated cell with a constant of 0.978 cm^{-1} and a measuring frequency of 1 kHz. Microemulsions were prepared with varying amounts of water content and oil chain length (C_6–C_{10}). Conductivity measurements were taken as a function of temperature for the water/AOT/oil systems at a fixed AOT concentration of 0.5 mol/L. The solutions were held in a Haake F3 digital-temperature-controlled circulation water bath at a temperature accuracy of ±0.1 °C. The conductance of the microemulsion sample at a fixed composition was measured at increasing temperatures until a rapid rise in the conductance was observed. The conductivity measurements were made after careful equilibration of the system at each temperature. Similar sets of measurements were taken on samples with different compositions.

Results and discussion

Percolation courses and the threshold temperature of clustering

The amount of water content in the microemulsion can be stated as the molar ratio of water to AOT surfactant, given as:

$$[1] \qquad \omega = \frac{[H_2O]}{[AOT]}$$

The percolation courses upon varying the oil and ω values are given in Fig. 1. Percolation courses in the absence of additive and in the presence of mono-, di-, and tri-ethanol amine additive, as well as courses with varying amounts of additive, are shown in Fig. 2. For the determination of the threshold percolation temperature (θ_t), the sigmoidal Boltzmann equation (SBE) was employed (29):

$$[2] \qquad \ln\sigma = \frac{\ln\sigma_i - \ln\sigma_f}{[1 + \exp(\theta - \theta_t)/d\theta]} + \ln\sigma_f$$

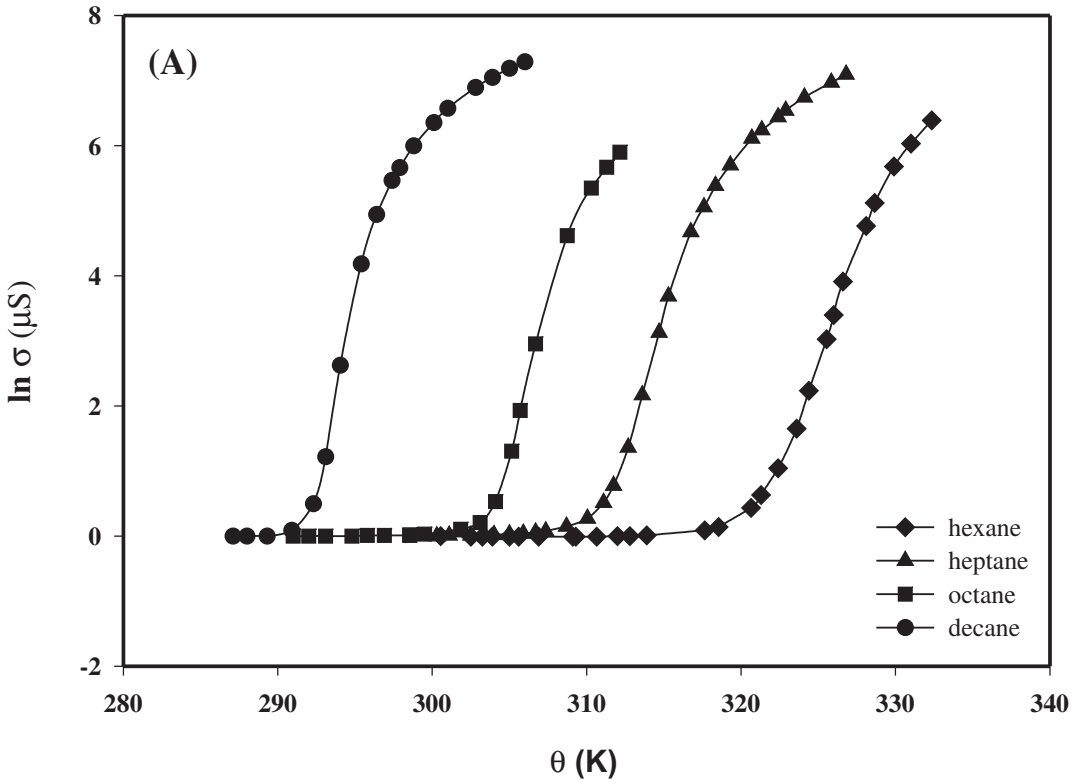
where σ and θ represent conductance and temperature, and the subscripts i, f, and *t* represent the initial, final, and percolation stages, respectively. The value of dθ controls the rise or decay of the profile from $\ln\sigma_i$ to $\ln\sigma_f$.

The θ_t values of the studied microemulsions, which vary in terms of oil, additive, and ω value, are reported in Table 1. Table 1 illustrates that for all solvents, the increase in the ω value is associated with a decrease in the percolation temperature. This trend is in agreement with the trends reported in the literature (11), where greater water content is associated with larger microemulsions and greater attractive interactions among microemulsion droplets, thus forming a continuum structure at a lower thermal requirement.

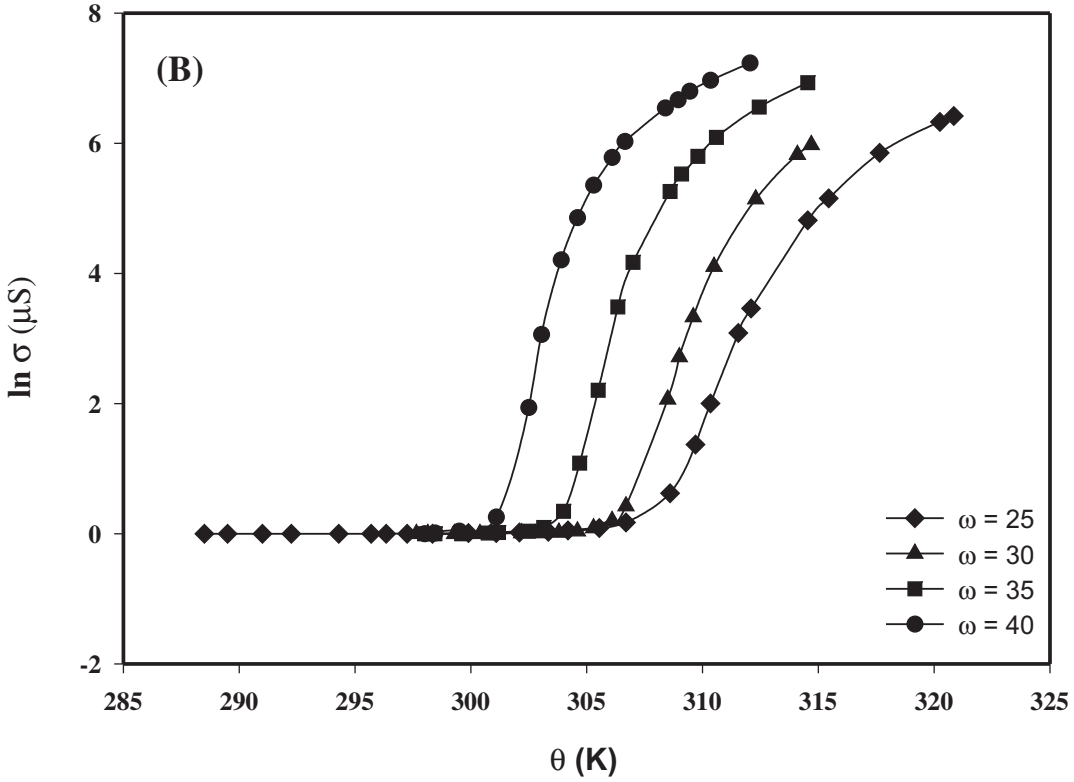
Also, the increase in the chain length of the apolar solvent results in a decrease in the percolation temperature. This has been attributed to the greater droplet interaction with increasing microemulsion size, as well as an increased fluidity of the microemulsion interface (11).

Adding mono- and di-ethanol amines produces an increase in the percolation temperature. Replacing the additive with triethanol amine, however, resulted in a decrease in this threshold temperature. This can be resolved by viewing the nature of both the amine and alkanol functionality of the additives.

Garcia-Rio et al. (30) found that the addition of *n*-alkyl amines to a water/AOT/isooctane microemulsion system resulted in an increase in the percolation temperature, with the threshold percolation temperature increasing with increasing chain length of the *n*-alkyl amine.



In terms of the ethanol moiety of the studied additive, it has been found that small organic molecules, such as short-chained alcohols, reduce the percolation temperature (27). In the present study, the increase in θ_t upon the addition of mono- and di-ethanol amines is due to the dominance of amine functionality in these molecules, while the decrease in θ_t upon the addition of triethanol amine may be attributed to the added effects of the ethanol moieties. Cazabat et al. (31) found that butanol decreases the temperature of percolation of AOT based microemulsions and Shubel and Ilgenfritz (32) stated that small alcohols such as ethanol forced the interfacial curvature to less negative values, decreasing the percolation temperature. Eicke et al. (33) assumed that these alcohols were located among the surfactant head groups, thus decreasing the effective wedge shape (Table 2).



Garcia-Rio et al. (30) made the assumption that *n*-alkyl amines act as cosurfactants, as long chained alcohols do, rigidifying the interface of the microemulsion and increasing the percolation temperature, as observed by other workers (14, 33, 34). Short-chained amines have been reported to increase the percolation temperature (30), whereas short-chained alcohols decrease the percolation temperature. This is indicative of a more complex influence of the amine additives than that of a normal organic substrate (30).

In the case of monoethanol amine, the increase in percolation temperature indicates that it is acting as a short-chained

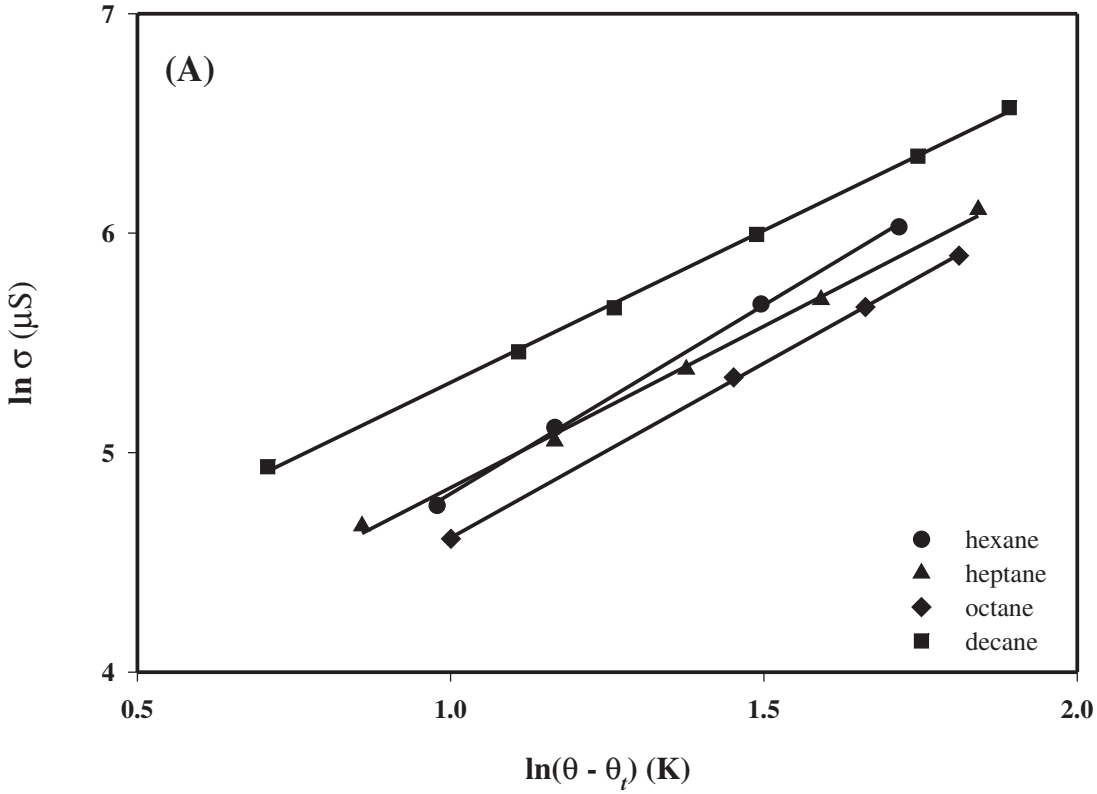
alkylamine rather than as an alcohol. Triethanol amine, with three hydroxyl groups, promoted the percolation process while acting as a short-chained alcohol. The behavior of the diethanol amine falls in between these two alkanol amines. Another possible explanation for their distinct behavior towards the percolation process may be attributed to the effect of these additives on the water pool size of the droplet. The pool size may follow the order triethanol > diethanol > monoethanol amines. Further experimentation is required to exactly pinpoint the actual mechanism.

Performance of the scaling equation

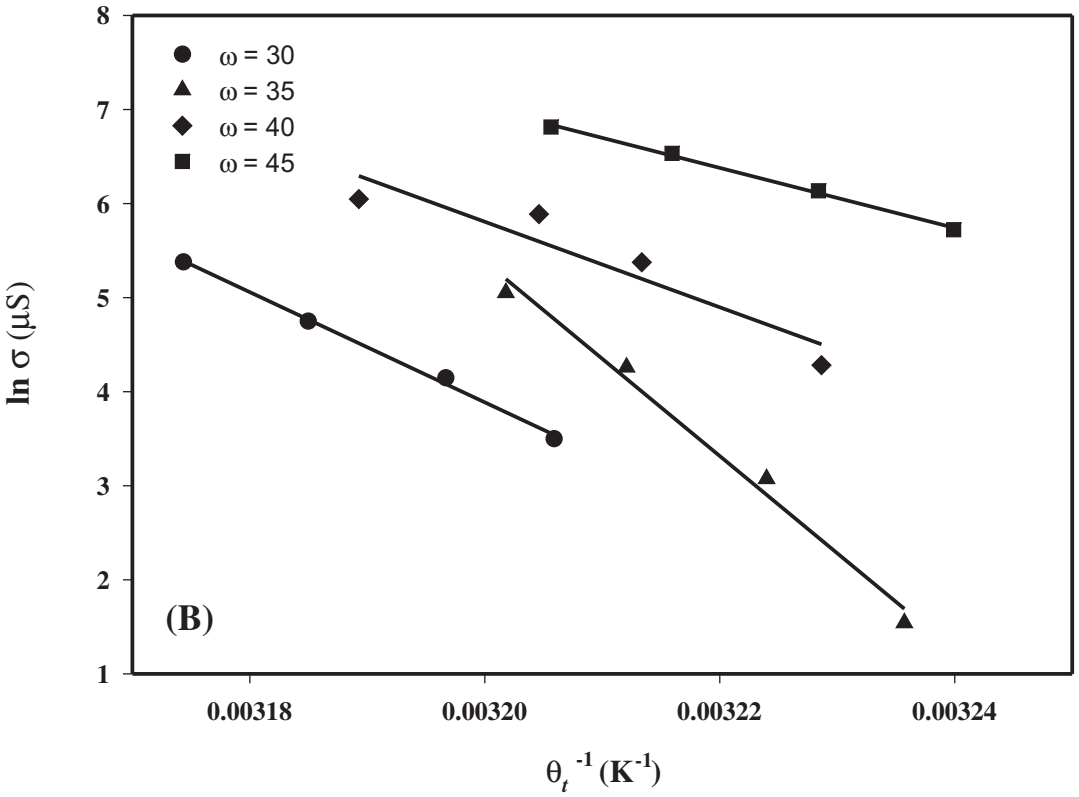
The temperature-related conductivity in the percolation range obeys the following scaling equation

$$\sigma = P(\theta - \theta_t)^n \quad [3]$$

where σ is the specific conductivity corresponding to the temperature (θ), and P and n are constants. The value of n has been shown to be 1.9 for static percolation. However, both higher and lower values are reported in the literature (3). To evaluate ln P and n, the logarithmic form of the equation was used



$$\ln \sigma = \ln P + n\ln(\theta - \theta_t) \quad [4]$$



Therefore, a plot of ln σ vs. $\ln(\theta - \theta_t)$ results in a linear plot with slope and intercept corresponding to n and ln P scaling parameters, respectively. The performance of the scaling equation in the percolation region is illustrated in Fig. 3A. The resultant scaling parameters are given in Table 3.

The deviation of n from the predicted value of 1.9 for static percolation lies in the contribution of dynamic percolation to the microemulsion system. In static percolation, conductance remains virtually zero below the threshold temperature. In dynamic percolation, as is the case for w/o microemulsions, the droplets are constantly in motion and can randomly rearrange and approach each other, leading to conductance before the threshold temperature. In the present investigation, the values of n were lower than 1.9 in the

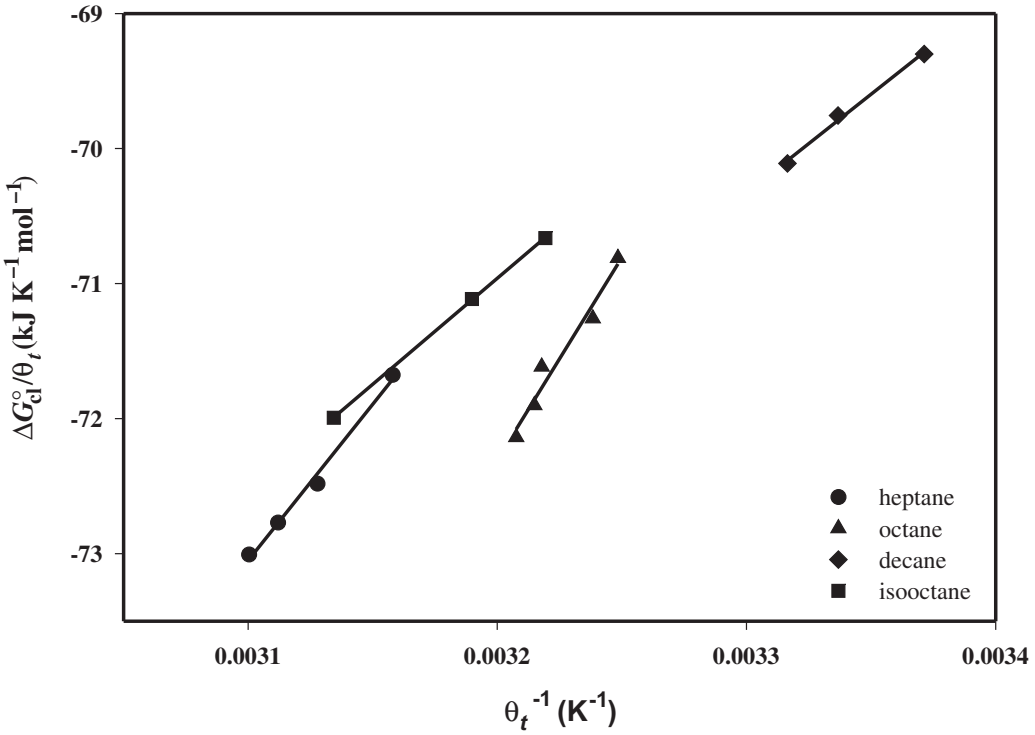
presence of all additives, reflecting that the percolation process is more complex than predicted by the theory.

Activation energy of percolation

The activation energy of conductance percolation (E_p) has been determined using an Arrhenius-type equation



$$[5] \qquad \sigma = Ae^{-E_p/RT}$$

where A is a constant and R and T have their usual significance.

The E_p values have been obtained from the slope (E_p/R) of the ln σ vs. θ^{-1} plot shown in Fig. 3B. The activation energies of the clustering of water/AOT/oil microemulsions are presented in Table 4 with variations of oil chain length, ω value, and alkanol amine. Low activation energy suggests that channels facilitating charge transfer form in the droplet

continuum structure. There has been no observed dependency of activation energy on oil, ω value, or alkanol amine in the present study.

Thermodynamics of droplet association

The phase separation model is employed in the determination of the thermodynamics of droplet clustering, as it is assumed that the droplets and the droplet continuum that is formed at the threshold percolation temperature exist in separate phases. This gives the standard Gibbs free energy change for the clustering process as the following equation:

$$[6] \qquad \Delta G^{\circ}_{cl} = RT \ln X_d$$

where X_d is the mole fraction of droplets in the microemulsion at the point of the percolation threshold. The X_d value can be obtained from the following relationship:

$$[7] \qquad X_d = \frac{n_d}{n_d + n_{oil}} = \frac{A_t M V_t}{(M A_t V_t + 4000\pi r_d^2 N_A V d}$$

where n_d and n_{oil} are the moles of droplet and oil, respectively, A_t is the total surface area covered by the AOT headgroup, and V_t is the total volume of the system. The terms V, d, and M are the volume, density, and molar mass of the oil, respectively, r_d is the average radius of the droplet, and N_A is Avagadro's number. Standard enthalpy changes of clustering follow from the first derivative of ΔG°_{cl} with respect to temperature and were obtained from the Gibbs–Helmholtz equation:

$$[8] \qquad \Delta H^{\circ}_{cl} = \frac{\left(\frac{\Delta G^{\circ}_{cl}}{T}\right)}{d\left(\frac{1}{T}\right)}$$

The entropy of clustering follows from the Gibbs equation:

$$[9] \qquad \Delta S^{\circ}_{cl} = \frac{\Delta H^{\circ}_{cl} - \Delta G^{\circ}_{cl}}{T}$$

To obtain ΔH°_{cl}, water/AOT/oil microemulsions at a fixed ω value of 30 were diluted with several portions of oil, and the θ_t values for all the diluted samples were determined from conductance measurements. The ΔG°_{cl} values were obtained from the sample compositions. $\Delta G^{\circ}_{cl}/\theta_t$ values for the samples were plotted as a function of $1/\theta_t$ to yield the values of ΔH°_{cl} (Fig. 4).

Thermodynamics of the clustering process for selected microemulsion systems are given in Table 5. The values show that the studied process is endothermic and entropically driven, as is depicted in the literature (11). The enthalpic contributions of the clustering process include the breaking of the interfacial layer (endothermic) and the formation of the continuous microemulsion structure at the temperature of percolation (exothermic). As ΔH°_{cl} is positive, the breaking of the interfacial layer serves as the predominating enthalpic contribution.

From the ΔG°_{cl} values, the observation was made that the process of clustering is spontaneous and the increase in the chain length of the oil phase of the microemulsion results in

the decrease in spontaneity of the clustering process. This result is consistent to that reported in the literature (11).

Conclusions

1. The percolation of water/AOT/oil microemulsions was restricted by the addition of ethanol amine additive. The addition of ethanol moieties to this additive further decreased the percolation temperature.
2. An increase in the percolation temperature of water/AOT/oil microemulsions was associated with a decrease in the chain length of the oil, a decrease in the microemulsion's ω value, and an increase in the percentage of alkanol amine additive.

Studies of structure and dynamics in a nominally symmetric twisted amide by NMR and electronic structure calculations

Alex D. Bain, Hao Chen, and Paul H.M. Harrison

Abstract: Amides that are twisted around the C—N bond show unusual spectroscopy and reactivity when compared with planar amides. The diacyl derivatives of 3,4,7,8-tetramethyl-2,5-dithioglycoluril are intriguing examples of this class, since the crystal structures show that the two acyl groups are twisted by different amounts on either side of the molecule owing to a combination of steric and electronic effects. However, the ^{1}H NMR spectra in solution at room temperature exhibit only one acyl resonance, so there must be fast interconversion among pairs of equivalent structures of each compound. We have prepared a number of derivatives with different acyl groups, both on the glycoluril framework as well as on its dithio analogue. The chemical exchange in solution was slowed down sufficiently by cooling to see individual sites for only two compounds: the dithiodipivaloyl and the dithiodiadamantyl derivatives. The barriers were estimated at 41 kJ mol^{-1} for the dipivaloyl derivative and 45 kJ mol^{-1} for diadamantyl derivative. The results show that rotation around the twisted amide bond is slowed by both the steric size of the acyl group and the presence of the thioureido group vs. the ureido group in the glycoluril core. In the solid-state ^{13}C NMR spectra, there is no evidence for any dynamics, even for the diacetyl derivative at ambient temperature. Electronic structure calculations predict a geometry for the dipivaloyl derivative very close to that observed in the crystal structure. These results indicate that the crystal confines, but does not distort the molecule. A mechanism for the exchange is proposed. The relevance of these results to the mechanism of Claisen-like condensations in diacylglycolurils is also discussed.

Key words: ^{1}H and ^{13}C NMR, exchange, dynamics, CP/MAS, solids, line shape analysis, amides, twisted amides, atropisomers, glycoluril.

Résumé : Par comparaison avec les propriétés correspondantes des amides planaires, les propriétés spectroscopiques et la réactivité des amides ayant subi une déformation autour de la liaison C—N présentent des caractéristiques inhabituelles. Les dérivés diaryles du 3,4,7,8-tétraméthyl-2,5-dithioglycouril sont des exemples intriguant de cette classe puisque leurs structures cristallines montrent la présence de deux groupes acyles décalés par des angles différents sur chaque côté de la molécule en raison d'une combinaison d'effets stérique et électronique. Toutefois, le spectre RMN du ^{1}H en solution, à la température ambiante ne présente qu'un seul signal de résonance pour un groupe acyle, ce qui implique qu'il se produit une interconversion rapide entre les paires de structures équivalentes de chaque composé. On a préparé un certain nombre de dérivés avec différents groupes acyles, tant dans le squelette du glycoluril que dans son analogue dithio. Le refroidissement des solutions afin de ralentir suffisamment l'échange chimique en solution ne nous a permis d'observer les sites individuels de deux que dans les cas de deux dérivés, le dithiodipyvaloyle et le dithiodiadamantyle. On a évalué que les barrières sont de 41 kJ mol^{-1} pour le dérivé dipivaloyle et de 45 kJ mol^{-1} pour le dérivé diadamantyle. Les résultats montrent que la rotation autour de la liaison amide déformée est ralentie tant par la grosseur stérique du groupe acyle que par la présence d'un groupe thiouréido vs. le groupe uréido du coeur de glycouril. Dans le spectre RMN du ^{13}C à l'état solide, on n'a relevé aucune donnée pour quelle que dynamique que ce soit, même avec le dérivé diacétyle à la température ambiante. Des calculs de structure électronique permettent de prédire une géométrie pour le dérivé dipivaloyle qui ressemble beaucoup à celle observée dans la structure cristalline. Les résultats indiquent que le cristal sert à confiner les molécules sans toutefois les déformer. On propose un mécanisme pour l'échange. On discute aussi de l'intérêt de ces résultats pour le mécanisme de condensations de type Claisen dans les diacétylglycolurils.

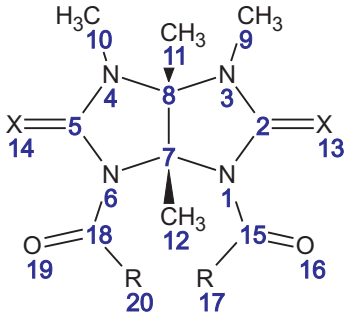
Introduction



Amides are perhaps the most studied three-atom linkage in chemistry (1, 2). Their central role as the backbone of protein structure provides thousands of different examples of the peptide bond, and the dynamics of this bond is central to the protein folding problem. Chemically, amides are quite distinct in their reactivity from simple amines and ketones. Furthermore, there are a number of theoretical challenges in understanding the bonding. The classic model of resonance predicts an interaction of the lone pair on the nitrogen atom with the carbonyl π system, thus weakening the carbonyl bond and imparting partial double bond character to the C—N bond. This prediction is supported by the observation of significant barriers to rotation around the C—N bond. On all of these points, there is a vast literature.

The interaction of the lone pair on nitrogen and the π system is most efficient when the amide linkage is planar. We are assuming that both the carbonyl carbon and the amide nitrogen are sp^2 hybridized, so the local geometry is planar around each atom. In many amides, these two planes coincide (a planar linkage), but many twisted amides have been prepared and studied (3–9). This effect may result from twisting around the C—N bond (owing to the arrangement of covalent bonds or severe steric effects), or through bending of the amide functionality, for example, as a result of pyramidalization (and change of hybridization) at nitrogen. In these cases, the nitrogen lone pair and the attached carbonyl π system are not fully conjugated. The degree of twist gives us an experimental probe of the amide bond. These molecules are of intense theoretical interest because they allow aspects of amide electronic resonance structures to be explored (10–17). The loss of this N-C=O interaction makes the carbonyl carbon unusually electrophilic, so that twisted amides are often highly reactive (14, 15, 18, 19). As such, they have found utility as acylating agents (3, 4, 20–22). Further, they may act as stable model structures for intermediates or transition states in a variety of processes of biological relevance (1).

In the course of the investigations of the glycoluril framework as a scaffold for studying intramolecular Claisen-like reactions (23), we synthesized several 1,6-diacyl-3,4,7,8-tetramethylglycolurils and their 2,5-dithio congeners (e.g., **1**, **2**, and **4**, Fig. 1). The crystal structure (24) of **1** shows that the amides are significantly twisted and that the twisting is different on the two sides of this nominally symmetrical molecule. Compounds **2** and **4** in this series have shown similar, but less dramatic effects (25–27). In solution, however, the NMR spectra at room temperature of all the symmetrically substituted glycolurils prepared by us indicate symmetrical structures. This suggests that there are two mirror-image forms that interconvert quickly at ambient temperatures, but can be observed separately at low temperatures (24). Analysis of the chemical exchange allows us to probe the potential energy surface of these molecules.

Chemical systems that are apparently symmetric, but sterically crowded, relieve the stress by distorting. For example, Iwamura and Mislow (28) refer to molecular machinery in which the crowded groups undergo cogwheellike motions, and there are many further examples of this type of system (29–31). In some of the literature, these systems are often

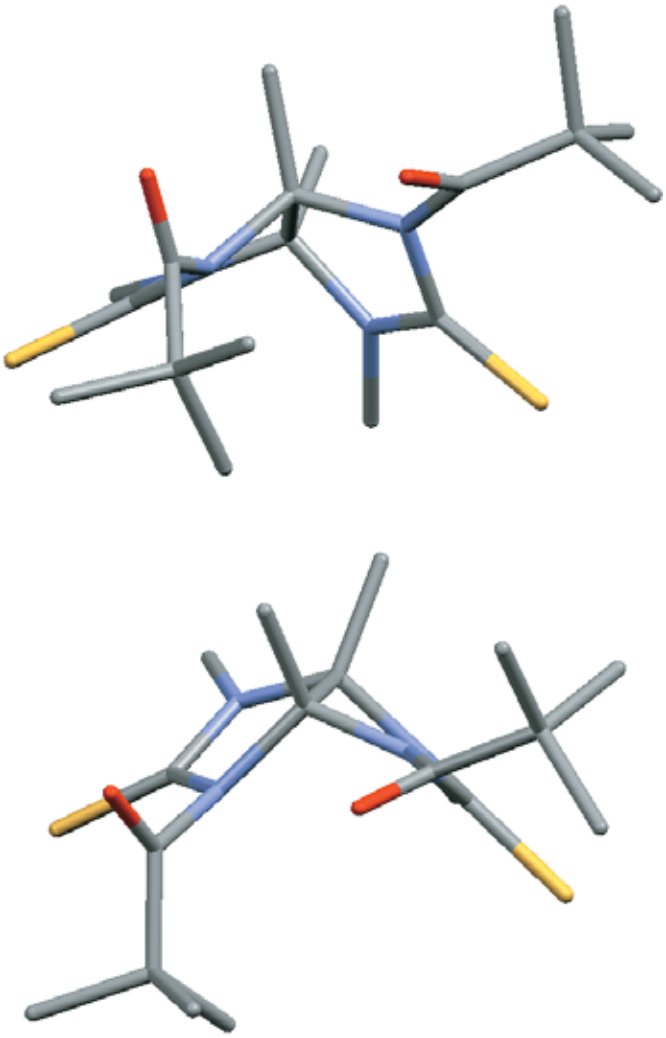
7	R = adamantyl	X = S

referred to as atropisomers (32–37). However, the distortion need not retain any of the original symmetry. The published (24) crystal structure of 1,6-dipivaloyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril (**1**, Figs. 1 and 2) shows that one of the pivaloyl groups attached to the glycoluril framework is twisted down (towards the endo face of the molecule) relative to an average plane through the attached tetrahydroimidazolone ring, but the other acyl group is almost perpendicular to its ring (Fig. 2) and twisted up (towards the exo face). Thus, both acyl groups are twisted, but to different extents and in opposite senses.

These previous results suggested that twisting the acyl groups in the ground-state structure might contribute significantly to the acidity of the acyl groups bearing α protons (18). Loss of the resonance interaction in an amide renders it more ketone-like, and simple ketones are significantly more acidic than amides. Since the first step in the Claisen-like condensation of diacylglycolurils involves deprotonation (38, 39), twisting in the substrates may be an important factor in activating one or both of the acyl groups, leading to the observed fast and efficient condensation.



Therefore, we wished to examine the structures of the diacylglycolurils in greater detail. In this paper we extend our investigation of this phenomenon by looking at the dynamic NMR spectra of a number of derivatives (Fig. 1), supplemented with electronic structure calculations and solid-state NMR spectra.

Results and discussion

In the molecules in Fig. 1, both steric and electronic effects will strongly influence the geometry of the molecule (40, 41). The nitrogen lone pairs, the carbonyl (or

Fig. 2. Three-dimensional drawings of the crystal structure of **1**. The hydrogen atoms have been omitted for clarity. The acyl groups are facing out of the page, and the group N6-C18-O19-R20 is on the left-hand side. In the top figure, the page is roughly perpendicular to the plane of the left-hand ring, showing the twist of the N6-C18-O19-R20 group. In the lower figure, the right-hand ring is roughly perpendicular to the page, showing the opposite twist of the N1-C15-O16-R17 group.

thiocarbonyl) groups in the rings, and the carbonyls of the acyl groups could form conjugated π systems if each side of the molecule were planar, but twisting around the N1—C15 and N6—C18 bonds may remove some of that conjugation. However, planar amides might cause strong steric repulsions, e.g., among the tertiary butyl groups themselves or with the sulfur in the thiocarbonyl. The crystal structure of **1** (Fig. 2) shows the cis ring fusion, giving a butterflylike, but asymmetric, geometry with the two bridgehead methyl groups canted with respect to each other. The pivaloyl groups are also twisted asymmetrically. The twist angle in an amide (τ) was defined by Winkler and Dunitz (42) to give a single descriptive parameter of the torsion angles. It is the average of the two cisoid torsional angles, as defined in Table 1. Yamada (43) suggested restricting the angle to be in the range from 0° to 90° and positive, to make comparisons more clear. However, in the glycoluril derivatives, the sign of the twist is useful, but the signs of torsion angles require careful specification. We use a positive sign to indicate that the carbonyl is twisted upwards (in the view in Fig. 2) or towards the exo face of the molecule. Twisting of the carbonyl towards the endo face is signified by a negative twist angle.

Table 1 gives the relevant geometrical information from the published crystal structure and from electronic structure calculations at the 6-31G(d,p) level (restricted Hartree–Fock method). Density functional methods (B3LYP) were also used and gave essentially identical geometries. The close match between the geometry in the crystal and the calculated gas-phase geometry indicates that the crystal packing has relatively little influence on the geometry as seen in the crystal. However, we will see later that the lattice confines the dynamics greatly.

During a search for the ground-state geometry in the calculations, a local minimum in the potential energy surface was also detected. Approximately 20 random sets of amide twist angles were defined as initial conditions for the geometry optimization. Most converged to the global minimum, but one gave the metastable state. The glycoluril framework is much the same in this metastable state as in the ground state, but the amide incorporating N6 and C18 has a significantly different twist. The twist angle goes from +67° in the ground state to –77° in the metastable state. The change in sign of the twist angle shows that the carbonyl group has been rotated through almost 180° in going from one state to the other. The geometrical parameters for the metastable state are also given in Table 1. This metastable state is approximately 17 kJ mol^{-1} less stable than the true ground state and may represent an intermediate in the exchange reaction.

The effects of dynamics are often observed by NMR spectroscopy (37, 44–46). Similarly, solids can show considerable molecular motion, even though the molecules remain fixed in the crystal lattice (47, 48). The processes that can be studied in the solid may be the same as those in solution or they may be quite different. If the same process can be observed in both solid and liquid, then the role of the crystal lattice can be investigated.

To probe the steric and electronic effects of substituents on the barrier to interconversion of the two acyl sites, the derivatives listed in Fig. 1 were prepared. Changing the thiocarbonyl group to a carbonyl will alter the nature of the electronic π system (as well as change the steric interactions), and the steric bulk of the acyl group was varied from methyl to adamantyl. The low-temperature NMR spectra of **1**–**7** were recorded. As well, the room-temperature CP/MAS spectra of solid samples of the dipivaloyl derivative (**1**) and the diacetyl derivative (**2**) were measured to check for dynamics in the solid state.

In the dipivaloyl and diadamantyl dithio derivatives (**1** and **7**), the chemical exchange can be sufficiently slowed at low temperature in CD_2Cl_2 so that individual sites are observed. The free energies of activation for the positional exchange are approximately 41 (±2) kJ mol^{-1} at 210 K for the dipivaloyl derivative (**1**) and 45 (±2) kJ mol^{-1} at 230 K for the diadamantyl derivative (**7**). The accessible temperature range is not sufficient to separate the free energy into

C5-N6-C18	119.8	119.7	121.4	123.9	130.2
τ(N1-C15)	–54.3	–54.1	–45.7	55.0	45.6
τ(N6-C18)	66.3	68.4	–77.6	–3.8	8.6

Note: The column labeled Metast. indicates the geometry of a calculated local minimum 17 kJ mol^{-1} above the ground state. Distances are in Angstroms and angles are in degrees. The amide twist angle (τ) is based on the definitions of Winker and Dunitz (42) and Yamada (43), and is the average of the two cisoid torsion angles. For the N1-C15 amide, it is [(C2-N1-C15-C17) + (C7-N1-C15-O16)]/2 and for the N6-C18 amide, it is [(C5-N6-C18-C20) + (C7-N6-C18-O19)]/2. A positive sign indicates that the carbonyl is twisted towards the exo face and a negative sign indicates an endo twist. The experimental data for **1** is from ref. 24 and that for **2** is from ref. 25. For **2**, the numbering of the molecule has been changed from ref. 25 to be consistent with Fig. 1. In **2**, it is the N1-C15 amide that is the more twisted in the crystal, but in **1**, it is the N6-C18 amide that is more twisted. The calculated ground state (restricted Hartree–Fock at the 6-31G(d,p) level) for both molecules and metastable state for **1** are from this work.

enthalpy and entropy with any precision. All the other derivatives (**2**–**6**), with smaller acyl groups or with oxygen replacing the sulfur, showed no detectable exchange-based line broadening at the lowest temperature achieved (163 K).

These results can be compared with previous studies. As the substituent on nitrogen of a simple N,N-disubstituted amide is varied from methyl up to *tert*-butyl, there is a marked decrease in the barrier when the groups are *tert*-butyl (49, 50). The suggested cause in this case is that the planar ground state is destabilized by the steric interactions of the *tert*-butyl groups, whereas the transition states are much the same for all cases. Also, when the methyl group attached to the carbonyl in N,N-disubstituted acetamides is replaced by a *tert*-butyl group, the barrier is significantly decreased (2). Similar effects have been seen in other crowded systems (51). The simple amides show a decrease of the barrier when the substituent is changed from methyl to *tert*-butyl, but in the present molecule there is a significant increase.

The difference between the dithio and the dioxo derivatives is interesting. Thioamides tend to have higher barriers (by up to 10 kJ mol^{-1}) than the corresponding amides (12, 49, 52–55). This implies that the double bond character of the carbon–nitrogen bond is larger, and the nitrogen lone pair mixes strongly with the π bond of the thiocarbonyl in the simple thioamides. In the present glycoluril case, we assume that the bond from the nitrogen to the thiocarbonyl (such as **2**) is stronger than that to a carbonyl in an oxoglycoluril (such as **4**). Therefore, less of the lone pair would be available for overlap to the acyl carbonyl, implying less double bond character in the bond to the acyl group. This argument would imply a lower barrier to acyl rotation for the dithio derivative over the dioxo, but the reverse is observed. Therefore, there must be significant steric interaction when a large acyl group tries to rotate past the sulfur in the thiocarbonyl in the ring.

Attempts to find the true transition state for the interconversion by calculations have been unsuccessful, perhaps because there are many degrees of freedom in the *tert*-butyl group. However, the calculated metastable state for the dipivaloyl derivative suggests a route to the transition state. In the metastable state, both carbonyl groups are on the same face of the molecule, whereas they are opposed in the ground state. Furthermore, it appears as if the more twisted amide (Table 1) is the one that rotates to form the intermediate. The evidence of the metastable state and the suggested steric effects between the *tert*-butyl group and the thiocarbonyl lead us to the following mechanism. First, the more twisted amide twists from above the ring to below the ring, with the carbonyl group toward the centre of the molecule and the *tert*-butyl group brushing past the sulfur of the thiocarbonyl. The fact that the adamantyl group has a barrier of about 4 kJ mol^{-1} higher than the *tert*-butyl group of the dipivaloyl derivative implies that the barrier has a significant steric component. This rotation leads to the metastable state as an intermediate. Following that, the other acyl group twists up through the plane and the other *tert*-butyl group passes the sulfur to complete the exchange. It appears that the bridgehead methyl groups must also twist past each other, and the two five-membered rings must change their pucker in this step as well. The observed data are not sufficient to distinguish between the highest transition state lying

15, 18	186.6, 184.9	186.9, 185.3

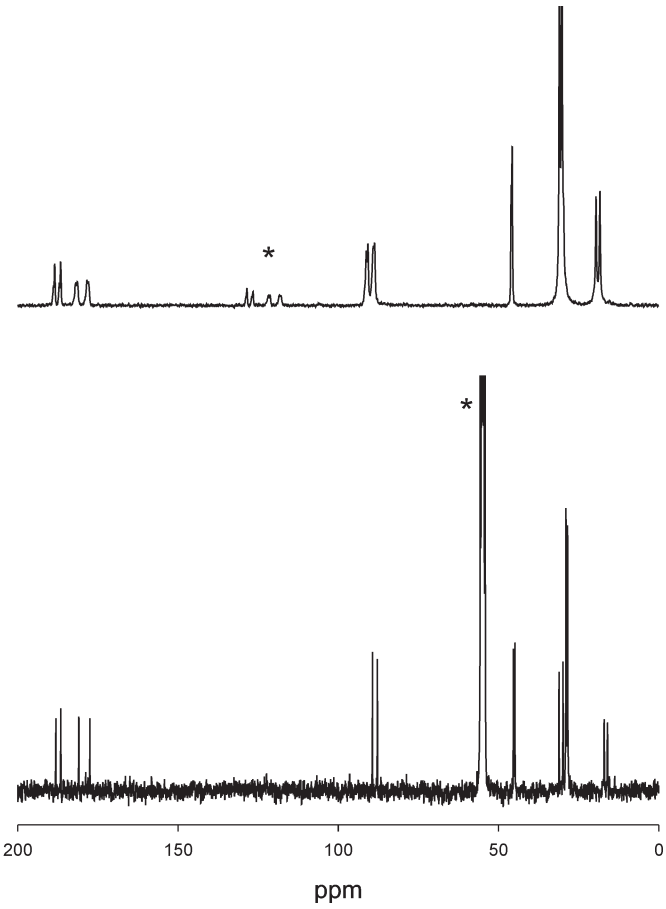
before or after the intermediate on the reaction coordinate. This mechanism fits all the available data.

By contrast, in the solid state there was no evidence for chemical exchange in the molecules studied. The ^{13}C NMR chemical shifts (Table 2, and Figs. 3 and 4) match quite well in the solid and in solution, indicating that the low-temperature solution species is similar to the crystal structure. Only the methyl groups on the bridgeheads have significantly different chemical shifts, presumably because of the different influences of the carbonyl groups). In the crystal, one carbonyl oxygen atom is twisted up from the approximate plane of the attached ring (towards the exo face of the glycoluril) and the other is twisted down (towards the endo face). In solution, there is significantly more motion, so the average magnetic environment will be quite different. The separate shifts for each carbon must be due to the asymmetry, since in the crystal (24), there is only one magnetic environment for the molecule in the unit cell. Separate peaks could arise from different polymorphs, but given the crystal structure this is unlikely. Two-dimensional EXSY experiments (56) on the dipivaloyl (**1**) and diacetyl (**2**) derivatives under CP/MAS conditions at ambient temperature showed no detectable cross peaks, even at mixing times approaching 1 s. It is clear that the crystal packing is sufficiently dense to prevent any exchange, even for the least sterically hindered case (structure **2**).

Conclusions

The acyl derivatives of glycoluril show puckered and asymmetric structures because of interactions among the acyl groups. However, in solution, the NMR spectra show symmetrical structures because of fast exchange among asymmetric conformations. Only for the derivatives with the most bulky groups (dipivaloyl or diadamantyl) and thiocarbonyls in the glycoluril skeleton was it possible to slow the exchange in solution sufficiently to observe separate signals in the NMR spectrum at temperatures around 200 K. The increased steric bulk of the diadamantyl group raised the barrier approximately 4 kJ mol^{-1} over the dipivaloyl group. A change from thiocarbonyl to carbonyl groups in the ring also significantly lowered the barrier. No evidence of exchange broadening was seen in the NMR of **3**, so that rate must be significantly faster. A very rough estimate is that the barrier must be lower by at least 10 kJ mol^{-1}. Therefore, both steric and electronic effects are important in determining the exchange rate. The observation of a metastable state in the cal-

Fig. 3. The ^{13}C CP/MAS spectrum of the solid (upper) and the solution spectrum at 190 K (lower) of 1,6-dipivaloyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril. In the upper spectrum, the peaks marked with an asterisk are spinning sidebands; in the lower spectrum, the marked peaks belong to solvent (CD_2Cl_2).



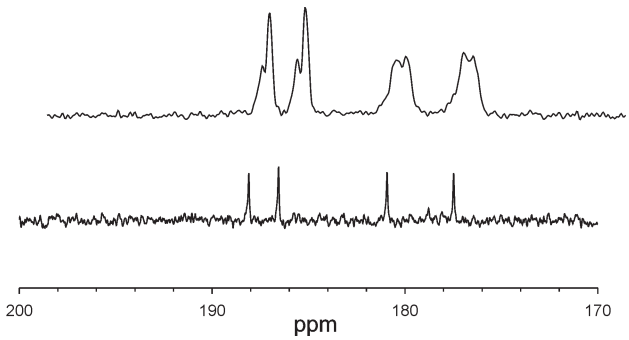


Fig. 4. Expansion of the high frequency region of the specta in Fig. 3, showing the fine structure of the carbonyl and thiocarbonyl peaks owing to dipolar coupling to ^{14}N (59–61). This dipolar coupling is not averaged by spinning at the magic angle, and gives a characteristic 1:2 ratio of peaks. The carbonyl peaks near 188 ppm show this structure in this figure. The thiocarbonyl peaks at lower frequency correspond to carbons bonded to two nitrogens, so they will have three peaks, roughly in the ratio of 1:3:3, as shown in the peaks near 180 ppm.

© 2006 NRC Canada

culations suggests that the exchange may go through this species as an intermediate. One acyl group rotates significantly so that both carbonyls are on the same face, then the other acyl group rotates to complete the exchange.

In the solid-state CP/MAS spectra, the diacetyl and the dipivaloyl derivatives showed no dynamics, even at temperatures of 330 K. Therefore, the crystal lattice plays an important role in restricting the motion of the acyl groups in the solid. This implies that the lattice may affect the geometry of the molecule to some small extent — the geometry in the crystal may not be the lowest-energy geometry of an isolated molecule. However, electronic structure calculations show that the gas-phase structure is very similar to that in solution. Therefore, the crystal lattice confines but does not distort the molecule.

These observations shed light on the intramolecular Claisen-like condensation reactions between the two acyl moieties. There appears to be little restriction on the ground-state conformation of the glycolurils, so the ground state will have little effect on the reaction outcome. Rather, the stability of the enolate formed by the initial deprotonation step is likely to be the major determinant of the regioselectivity of the reaction.

The glycoluril skeleton provides a versatile series of molecules with which to study the structure and dynamics of twisted amides. We are continuing with further investigations.

Experimental

1,6-Dipivaloyl-3,4,7,8-tetramethylglycoluril (3)

The molecule 1,6-dipivaloyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril (**1**) was prepared as previously described (24). The preparation of compounds **2** and **4** are also in the literature (23, 39). The preparation of 1,6-dipivaloyl-3,4,7,8-tetramethylglycoluril (**3**) is reported here. Compound **3** was prepared as a side-product during the attempted sequential acylation of 3,4,7,8-tetramethylglycoluril. Thus, *n*-butyllithium (1.6 mol L^{-1} in hexane, 7.6 mL, 12.1 mmol) was added to a stirred suspension of 3,4,7,8-tetramethylglycoluril (800 mg, 4.04 mmol) in THF (200 mL) at room temperature. The mixture was heated at reflux for 2 h, then cooled to room temperature. Trimethylacetyl chloride (1.5 mL, 18 mmol) was added, and the resulting clear solution was concentrated to dryness. Flash column chromatography (ethyl acetate – hexanes, 30:70) gave pure **3** (120 mg, 8%) as a white solid; mp 138–140 °C. IR (υ_{max}, cm^{-1}): 2967 (C-H), 1733 (C=O), 1707 (C=O), 1436, 1313, 1111, 1077, 940. ^{1}H NMR (300 MHz, CD_2Cl_2, 190 K) δ: 2.81 (s, 6H, NCH_3), 1.69 (s, 3H, CH_3), 1.42 (s, 3H, CH_3), 1.15 (s, 18H, C(CH_3)$_3$). ^{13}C NMR (75 MHz, CD_2Cl_2, 190 K) δ: 181.34 (amide *C*=O), 152.75 (urea *C*=O), 81.71 (N*C*N), 78.57 (N*C*N), 42.98 (*C*Me$_3$), 27.41 (N*C*H$_3$), 26.48 (C(*C*H$_3$)$_3$), 19.69 (*C*H$_3$), 15.92 (*C*H$_3$). MS (EI) *m/e*: 367 (MH^+), 309, 225, 126.

General procedure for preparation of diacyl dithioglycolurils 5–7

To a solution of 2,5-dithio-3,4,7,8-tetramethylglycoluril in dry dichloromethane (7 mL) at room temperature was added the specified base. The mixture was stirred for 5–10 min, then the acyl chloride was added and stirring was continued for 30 min to 1 h. The mixture was extracted with 5% HCl. The organic layer was washed with water, dried over Na_2SO_4, filtered, and concentrated. The product was purified by flash column chromatography in the solvent described.

1,6-Dipropanoyl-2,5-dithioglycoluril (5)

Starting dithioglycoluril (500 mg, 2.43 mmol), proton sponge (501 mg, 2.27 mmol) and propanoyl chloride (0.6 mL, 6.5 mmol) gave, after flash chromatography in 50:50 EtOAc–hexanes, 1,6-dipropionyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril (**5**) (126 mg, 17%). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 3.44 (m, 2H), 3.24 (s, 6H), 2.99 (m, 2H), 1.90 (s, 3H), 1.57 (s, 3H), 1.18 (t, *J* = 7.2 Hz, 6H). Also produced was 1-propionyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril (150 mg, 23%): ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.32 (s, 1H), 3.23–3.38 (m, 2H), 3.32 (s, 3H), 3.16 (s, 3H), 1.74 (s, 3H), 1.62 (s, 3H), 1.42 (t, *J* = 7.2 Hz, 3H).

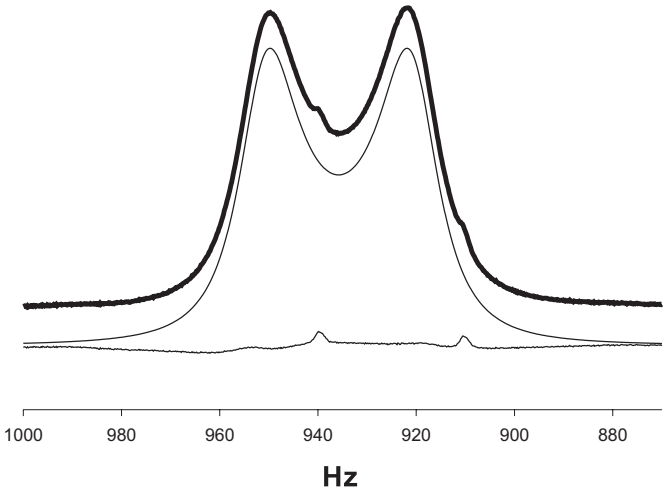
1,6-Diisobutanoyl-2,5-dithioglycoluril (6)

Starting dithioglycoluril (500 mg, 2.43 mmol), triethylamine (0.9 mL, 6.5 mmol), and isobutanoyl chloride (0.7 mL, 6.5 mmol) gave, after flash chromatography in CH_2Cl_2, 328 mg (43%) of **6**. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 4.15 (m, 2H), 3.28 (s, 6H), 1.91 (s, 3H), 1.57 (s, 3H), 1.18 (d, *J* = 6.8 Hz, 6H), 1.14 (d, *J* = 6.9 Hz, 6H).

1,6-Di(adamantane-1′-carbonyl)-2,5-dithioglycoluril (7)

Starting dithioglycoluril (100 mg, 0.43 mmol), Et_3N (0.18 mL, 1.3 mmol), and 1-adamantanecarbonyl chloride (258 mg, 1.3 mmol) gave, after flash chromatography in CH_2Cl_2, 64 mg (30%) of **7**. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 3.23 (s, 6H), 2.03 (s, 3H), 1.57 (s, 3H), 1.19–2.13 (m, 30H).

NMR spectroscopy



For solution-state NMR spectra, approximately 5 mg of material was dissolved in CD_2Cl_2 and put in a 5 mm NMR tube. Spectra were run on a Bruker AV 300 NMR spectrometer using a 5 mm broadband inverse probe. The 90° pulse for protons was 10 μs. The temperature of the sample was controlled with a BVT 3200 controller. Temperatures shown on the controller were checked against a thermocouple in an NMR tube and the two agreed within 1°. Spectra of the dipivaloyl and the diadamantyl derivatives were run at 183, 193, 215, 220, 225, 235, and 240 K. Both ^{1}H and ^{13}C spectra were acquired as a function of temperature.

Solid-state ^{13}C CP/MAS NMR spectra were run on a Bruker DSX 400 at the University of Toronto. A 4 mm rotor was packed with the material, and the spectra were run with a spinning speed of 6.0 kHz. The number of scans was 1000, the delay between scans was 6.0 s, and the contact time (for a ramped cross polarization) was 4 ms. The FID was apodized with a 20 Hz line broadening. Spectra were referenced to the carbonyl signal of glycine at 176.14 ppm.

Exchange rates were measured from the solution spectra using an iterative version of the MEXICO program (57) (Fig. 5). The natural line width was fixed, and the chemical shift difference and the rate were varied during the iteration. The program allows for both a universal natural line width (applied to all lines in the spectrum) and a specific line width for each spin. In a simple case such as this, the two

Fig. 5. Experimental and simulated ^{1}H NMR line shapes of the *N*-methyl signals in 1,6-dipivaloyl-3,4,7,8-tetramethyl-2,5-dithioglycoluril. The sample was dissolved in CD_2Cl_2, and the spectrum was measured at 200 K on a 300 MHz spectrometer. The heavy line represents the experimental spectrum, the lighter line represents the best fit, and the difference is shown at the bottom. The small peaks in the spectrum that remain in the difference spectrum are due to an unknown impurity.

can not readily be distinguished, so only their sum is significant.

Calculations

Electronic structure calculations were performed using the Gaussian03 suite of programs (58) running on an Intel Pentium-based personal computer under RedHat Linux version 9. The calculations were run with both restricted Hartree–Fock (RHF) and density functional methods (B3LYP) at the 6-31G(d,p) level of theory.

Acknowledgements

We would like to thank Brian G. Sayer and Hiltrud Grondey for help with the NMR measurements, and the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support.

One-pot, solvent-free synthesis of α-aminonitriles under catalysis by magnesium bromide ethyl etherate

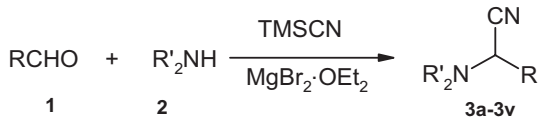
Mohammad M. Mojtahedi, M. Saeed Abaee, and Hassan Abbasi

Abstract: A three-component, efficient, and facile procedure has been developed for the synthesis of α-aminonitriles from aldehydes, amines, and trimethylsilyl cyanide using a catalytic amount of magnesium bromide ethyl etherate in the absence of solvent. Rapid formation of products is observed at room temperature in a one-pot procedure under very mild conditions giving excellent yields of the title compounds.

Key words: catalyzed Strecker's reaction, α-aminonitriles, magnesium bromide, solvent-free.

Résumé : On a développé une méthode simple et efficace pour réaliser la synthèse de α-aminonitriles par réaction monotope d'aldéhydes, d'amines et de cyanure de triméthylsilyle, en présence d'une quantité catalytique du complexe bromure de magnésium/éthérate d'éthyle, en l'absence de solvant. La formation rapide de produits se produit à la température ambiante, dans des conditions très douces et conduit aux composés mentionnés dans le titre avec d'excellents rendements.

Mots clés : réaction de Strecker catalysée, α-aminonitriles, bromure de magnésium, sans solvant.



[Traduit par la Rédaction]

Introduction

A three-component combination of aldehydes, amines, and "cyanide", known as Strecker's reaction (1), facilitates the formation of α-aminonitriles (2), which are equivalent synthones to imminium moieties (3) and acyl anions (4). These compounds are very versatile intermediates for the synthesis of α-amino acids (5, 4*b*), 1,2-diamines (6), amides (7), and various nitrogen-containing heterocycles such as thiadiazoles and imidazoles (8). Recent progress such as the development of one-pot procedures for aminative cyanation of carbonyl compounds (9), use of Lewis acidic conditions (10), and employment of new cyanating reagents, especially trimethylsilyl cyanide (TMSCN) (11, 1*a*), have contributed outstanding elaborations (12) to the classical version of the Strecker's reaction (13). However, use of expensive reagents and strong acidic conditions, long reaction times, deactivation and decomposition of the catalytic systems under the reaction circumstances, and production of toxic disposals are still among the deficiencies of many of these methods. Thus, development of efficient, clean, and catalytic reactions for the synthesis of the title structures are still in demand.

In recent years, magnesium bromide ethyl etherate ($MgBr_2{\cdot}OEt_2$) has found many applications as a mild Lewis acid (14) because of its ease of preparation, oxophilic nature, and coordinating ability for bidentate chelation (15) that makes various chelation-controlled organic transformations easier. Our experiences with the use of such reaction conditions (16) prompted us to look for a mild medium for the synthesis of the title compounds. We would like to introduce here an efficient, three-component combination of aldehydes with various amines and TMSCN at room temperature for the synthesis of α-aminonitriles using a catalytic amount of $MgBr_2{\cdot}OEt_2$ (Scheme 1).

Scheme 1.

Results and discussion

Initial experiments were carried out by subjecting a benzaldehyde, pyrrolidine (piperidine), and $MgBr_2{\cdot}OEt_2$ mixture to reaction with TMSCN at room temperature in the absence of solvent (Table 1). Complete disappearance of the aldehyde and rapid formation of the product were monitored by TLC. Various amounts of the Lewis acid were used to optimize the reaction conditions. A catalytic quantity of $MgBr_2{\cdot}OEt_2$ (5 mol%) proved to be effective for the complete conversion of starting materials to the desired product (**3a** or **3b**) in 5 min (Table 1, entry 1). Use of smaller amounts of the catalyst down to 1 mol% only prolonged the reaction time up to 45 min, leading to nearly quantitative formation of **3a** (or **3b**). Similar reactions using various aromatic aldehydes bearing electron-withdrawing and electron-releasing groups with cyclic amines were conducted under the same conditions. Consequently, more than 90% yields of

[a]Isolated yields.

products **3c**–**3l** were all easily obtained in less than 10 min (Table 1, entries 2–7). The methodology proved to be equally effective for the smooth conversion of aliphatic aldehydes into α-aminonitriles when 3-phenyl-propionaldehyde or butyraldehyde were subjected to the reaction conditions (Table 1, entries 8–10).

Scheme 2.

The procedure was further explored using acyclic amines. Reactions between *N*-trimethylsilyldimethylamine ($TMSNMe_2$), diethylamine ($HNEt_2$), or dibuthylamine ($HNBu_2$) with benzaldehyde (Table 1, entry 11) and $TMSNMe_2$ with *p*-methylbenzaldehyde (Table 1, entry 12) resulted in rapid formation of products **3p** (97%), **3q** (88%), **3r** (94%), and **3s** (91%), respectively. Use of aromatic amines was successfully examined by a reaction between benzaldehyde and aniline leading to 88% formation of **3t** (Table 1, entry 13). Due to the synthetic importance of *N*,*N*-dibenzyl protected α-aminonitriles (17), the present procedure was employed to attempt the preparation of these compounds. As an example, the reaction between benzaldehyde and dibenzylamine in the presence of TMSCN and $MgBr_2{\cdot}OEt_2$ facilitated 90% formation of **3u** (Table 1, entry 14).

To test the diastereoselectivity of the process, a test reaction between (*S*)-1-phenylethylamine and benzaldehyde was conducted under the same sets of conditions leading to formation of **3v** in 90% yield within a few minutes. NMR spectroscopy of the reaction mixture revealed the formation of both possible products with a moderate diastereoselectivity of 3:1 (Scheme 2).

In summary, we have demonstrated a highly efficient, three-component conversion of aldehydes, amines, and TMSCN to α-aminonitriles at room temperature using a catalytic amount of $MgBr_2{\cdot}OEt_2$ in the absence of any solvent. The procedure is applicable to various aromatic and aliphatic aldehydes and amines. The versatility of the reaction, production of pure single compounds, easy procedure and work up, and no use of solvent or extra additives are among other benefits of the present method.
