Synthesis of substituted 4-azaisoindoles — New tacrine analogues

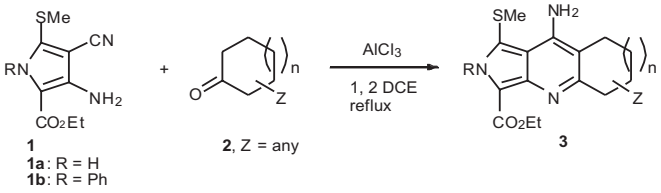
Henri Bekolo and Gilbert Kirsch

Abstract: The regioselective Friedländer reaction of 3-amino-4-cyanopyrroles with a series of cyclic ketones has enabled the first reported synthesis of substituted 4-azaisoindoles. Structurally, this new class of compounds stands for the first reported 4-azaisoindole tacrine analogues. A reaction mechanism for the formation of the reported 4-azaisoindoles is proposed.

Key words: 4-azaisoindoles, tacrine, Friedländer reaction, pyrroles, mechanism.

Résumé : La réaction de Friedländer des 3-amino-4-cyanopyrroles avec une série de cétones cycliques a permis la synthèse d'une nouvelle famille de composés: les 4-azaisoindoles substituées. Ces nouveaux composés sont de nouveaux analogues de la tacrine soit les 4-azaisoindoles analogues de la tacrine dont nous proposons aussi le mécanisme de formation.

Mots-clés : 4-azaisoindoles, tacrine, réaction de Friedländer, pyrroles, mécanisme.



Introduction

We have previously developed an efficient synthesis of 3-amino-4-cyanopyrrole derivatives (1–3) and have set out to investigate their reactivity. Herein we give a preliminary account of our investigations, since pyrroles **1a** (1) and **1b** (3) have proven to be good synthons for the preparation of substituted 4-azaisoindoles **3** (Scheme 1).

While the derivatives of 4-azaindole have been extensively synthesized (4), the synthesis of the derivatives of the isomeric 4-azaisoindole seems to have been neglected despite their possible potential as bioactive molecules. A related example is the potent antitumor agent camptothecin, whose B and C rings system is a reduced tautomeric form of 4-azaisoindole (5). This lack of interest in the synthesis of 4-azaisoindoles stems from the current research endeavour aimed at developing a potent side effect free anti-Alzheimers's disease drug based on a tacrine analogue lead compound. Many research groups have been synthesizing and screening various kinds of heterocyclic system tacrine analogues for biological activities, but none has ever reported a synthesis nor a biological evaluation of 4-azaisoindole tacrine analogues, or any other "pyrrolo" tacrines (6–14), i.e., tacrine analogues having a pyrrole ring in place of the benzene ring of tacrine **4** (Fig. 1).

Tacrine was the first drug approved in the USA for the palliative treatment of Alzheimer's disease. However, its severe side effects, such as hepatotoxicity and gastrointestinal upset, represent an important drawback. Despite these limitations, tacrine appears as an important reference (9). So, a great synthetic and pharmacological research effort has been undertaken to design a tacrine analogue, which would be a more potent and side effect free drug.

Scheme 1. Friedländer synthesis of **3** from **1** and **2**.

Results and discussion

We have prepared 4-azaisoindole tacrine analogues **3a**–**3q** (Tables 1–8) in which, as in the previously reported analogues, the cyclohexane-fused ring (**3b**, **3h**) has been contracted (**3a**), enlarged (**3c**, **3d**), and replaced by functionalized cyclohexane rings (**3e**, **3f**, **3g**, **3l**, **3m**, **3n**, and **3p**) (14), a nitrogen-containing six-membered heterocyclic ring (**3j**) (14), and unlike the previously reported analogues, replaced by a pyran (**3q**) and a thiopyran ring (**3i**).

In most cases the Friedländer cyclizations (9) (Scheme 1) were complete within 2 h, yielding the 4-azaisoindoles **3** in good to quantitative yields, which is noteworthy as the primary amino group of **1** is expected to be weakly nucleophilic (15) and the "pyridine ring" might form at either substituent ortho to the primary amino group.

The α tetralone-type ketones **2e**, **2f**, **2n**, and **2o** were slow to react and required higher reagent–reactant concentrations. Considering the mechanistic pathway 2 (Scheme 2) that we have postulated, this slowness is probably the result of the

reduced electrophilicity of the corresponding aluminium chloride coordinated carbonyls **5** whose α aromatic rings act by mesomeric effects as electron suppliers to the developing positive charge induced at the benzylic position by $AlCl_3$, thus slowing the enamine formation steps. As can be seen in Tables 2 and 7, the formations of azaisoindoles **3e** and **3f** assembled from **1a**, and **3n** and **3o** assembled from **1b**, required longer reaction times than those of **3b** and **3h**, respectively.

In the case of the formation of **3e** and **3f**, many unidentified by-products were detected, which would account for the modest obtained isolated yields of 50% and 55%, respectively.

In line with our reasoning, ketone **2o**, whose α pyrrole ring has a greater electron supplying ability than the furan ring of **2n**, reacted poorly with **1b** even after 24 h of reflux

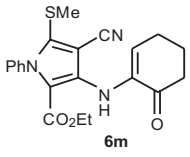
to yield traces (5%) of the corresponding azaisoindole **3o** along with the remaining starting materials **1b** and **2o**. A prolonged reaction time (5 days) resulted in recovering **1b** and **2o**; the expected product **3o** was not detected under these reaction conditions.

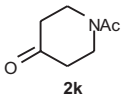
To gain further insight into the mechanistic pathway 2, we made the pyrrole ring of **2o** electron-deficient by protecting its NH group as the benzenesulfonylamide **2p**, which, as expected, reacted with **1b** within 2 h, more rapidly than did **2o**. All these facts have supported our proposed mechanistic pathway 2 for the formation of the 4-azaisoindoles of type **9**, and we have made it general for the formation of compounds **3**.

The 4-azaisoindole **3p** was isolated in only 40% yield. This is propably due to the slow intramolecular cyclization of the presumed enamine intermediate **6p** (Fig. 2), whose benzenesulfonyl group raises the energy barrier for the cyclization. Therefore, the uncyclized enamine **6p** might have enough time to undergo competing side reactions. A similar reasoning would account for the low isolated yield (25%) obtained in the case of **3m**; the CO group α to the corresponding enamine intermediate (**6m**) double bond would compare to the benzenesulfonyl group in **6p**. For similar reasons, the "pyridine ring" nitrogen atom might have prevented the possible further intramolecular cyclization of **3m** by raising the energy barrier for cyclization.

The good reactivity of the α tetralone-type ketone **2q** may then be surprising. We believe that the presumed corresponding enamine intermediate might have formed from **2q**

Fig 2. The likely intermediates **6p** and **6m**.





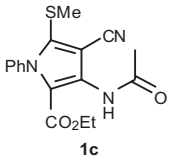


Fig 3. Ketone **2k** and pyrrole **1c**.

coordinated to $AlCl_3$ on both oxygen atoms. The aluminium chloride coordinated pyran ring oxygen would have made the carbonyl group somewhat more electrophilic by an electron-withdrawing inductive effect. The subsequent intramolecular enamine cyclization would have occured within an enamine species whose pyran ring oxygen was free of $AlCl_3$. This presumed positive electronic effect was probably less beneficial to the reactivity of ketone **2f** whose *p*-methoxy group oxygen is relatively far from the carbonyl group.

The mixture of **1b**, $AlCl_3$, and *N*-acetyl-4-piperidone (**2k**) (Fig. 3) was insoluble in refluxing 1,2 dichloroethane (1,2 DCE) and had to be heated for 24 h for complete consumption of pyrrole **1b**. We postulated that the amide functionality (Lewis base) part of piperidone **2k** was sufficiently basic to coordinate to $AlCl_3$ (Lewis acid) to form an insoluble complex, which plagued the reaction and led to the acylation of pyrrole **1b** as we isolated pyrrole **1c** (Fig. 3) as the major product (25%) among numerous by-products we could not separate. Not surprisingly, the basic 1-methyl-4-piperidone and 2,2,6,6-tetramethyl-4-piperidone that we attempted to react with **1b** and $AlCl_3$ in refluxing 1,2 DCE formed insoluble mixtures from which we could isolate what seemed to be degradation products from the ^{1}H NMR of the material we obtained after flash chromatography. We then prepared the less basic *N*-tosyl-4-piperidone (**2j**), which refluxed in a

© 2007 NRC Canada

homogeneous reaction mixture to provide **3j** cleanly in 70% isolated yield within 2 h.

In our effort to improve the yield (5%) of **3o**, the reaction was run in nitrobenzene as solvent at a higher temperature (130 °C) for 1 h, and we isolated some undentified material besides the remaining pyrrole **1b** and ketone **2o**. The use of extra pure H_2SO_4 as the catalyst, instead of $AlCl_3$, in refluxing 1,2 DCE led to complete consumption of **1b** and **2o** and the formation of a presumed new product, whose structure could not be determined by ^{1}H NMR. The acid catalyst, *p*-toluenesulfonic, did not help effect the desired transformation; **1b** and **2o** were recovered after 6 h of reflux in 1,2 DCE.

Attempts to improve the reactivity of 1-methyl-4-piperidone were made. Thus, acetic acid was used as cosolvent. It was believed that its presumed in situ protonated amino group would not coordinate to $AlCl_3$. Unfortunately, the expected cyclization did not proceed under these conditions as **1b** and the piperidone were recovered essentially after a 3 h reflux in CH_3CO_2H–1,2 DCE (1.5:8.5). The mixture of 1-methyl-4-piperidone, **1b,** and $AlCl_3$ in nitrobenzene as solvent at 110 °C resulted in complete disappearance of both reactants within 1 h, and no product was detected by TLC analysis. The use of polyphosphoric acid, instead of $AlCl_3$, in refluxing 1,2 DCE for 3 h was not helpful; only the two reactants were detected in the crude mixture by TLC analysis.

Conclusion

In summary, the standard Friedländer cyclization has enabled the first reported preparation of substituted 4-azaisoindoles and the first reported 4-azaisoindole tacrine analogues that we plan to have tested for biological evaluation.

Experimental

General

Melting points were determined on a Stuart Scientific SMP 3 capillary melting apparatus and were uncorrected. ^{1}H and ^{13}C spectra were recorded on a Brucker AC250 spectrometer using $CHCl_3$ as internal standard. The chemical shifts (δ) are reported in ppm. Commercially available ketones and $AlCl_3$ were used as purchased. Ketones **2j** (16) and **2p** were prepared using standard procedures. Pyrroles **1a** (1) and **1b** (3) were prepared as previously reported. For indications on the preparation of **1b**, please see the following.

Typical procedure for the preparation of 4-azaisoindoles 3

A mixture of pyrrole **1** (0.62 mmol), ketone **2** (3.1 mmol), and $AlCl_3$ (anhyd. granules, 99%, 3.1 mmol) in distilled 1,2 DCE (10 mL) was placed in an oil bath held at 115–120 °C for 2 h. After cooling to RT, a solution of aq. NaOH (pH 14) – THF (1:2, 15 mL) was added. The mixture was stirred for 15 min. Solvents were removed under reduced pressure. To the residue, CH_2Cl_2 (15 mL) and aq. NaOH (20 mL, pH 14) were added. The layers were separated and the aqueous layer was extracted with CH_2Cl_2 (3 × 15 mL). The combined extracts were dried ($MgSO_4$) and concentrated. Purification by flash chromatography (FC) on silica gel (MeOH–CH_2Cl_2, 6:94) afforded **3**.

8-Amino-1-methylsulfanyl-2,5,6,7-tetrahydro-2,4-diaza-s-indacene-3-carboxylic acid ethyl ester (3a)

Yield 81%; yellow crystals; mp 170 °C. ^{1}H NMR ($CDCl_3$) δ: 6.51 (br s, 2H, NH_2), 4.35 (q, *J* = 7.12 Hz, 2H), 2.99 (t, *J* = 7.62, 2H), 2.75 (t, *J* = 7.32 Hz, 2H), 2.48 (s, 3H), 2.25–2.05 (m, 2H), 1.35 (t, *J* = 7.01 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 149.2, 138.4, 114.2, 111.3, 110.8, 59.6, 32.0, 26.5, 22.6, 20.5, 13.9. The efficient and chemoselective MoO_3-catalyzed oxidation of sulfides to sulfoxides and sulfones with H_2O_2

Mohammad Mehdi Khodaei, Kiumars Bahrami, and Mohammad Khedri

Abstract: Hydrogen peroxide together with MoO_3 as catalyst can efficiently and chemoselectivity oxidize sulfides to sulfoxides and sulfones in the presence of other oxidized functional groups in ethanol at 50 °C in short reaction times.

Key words: oxidation, sulfides, sulfoxides, sulfones, H_2O_2–MoO_3 system.

Résumé : En opérant dans l'éthanol à 50 °C pour de courtes périodes, le peroxyde d'hydrogène en présence de MoO_3 comme catalyseur peut oxyder d'une façon efficace et chimiosélective les sulfures en sulfoxydes et en sulfones, en présence d'autres groupes fonctionnels oxydés.

Mots-clés : oxydation, sulfures, sulfoxydes, sulfones, système H_2O_2–MoO_3.

[Traduit par la Rédaction]

Introduction

Sulfoxides are important intermediates in organic chemistry because of their application in fundamental research and other extended usage (1–7). As the sulfoxides are important for carbon–carbon bond formation and functional group transformation, the search for new methods for the selective oxidation of sulfides to sulfoxides continues despite the existence of a number of methods available for this transformation. Selective oxidation of sulfides to sulfoxides and sulfones with the same reagent system under adjusted reaction conditions is an important process in synthetic organic chemistry and only a few reports are available in the literature (8–13).

Aqueous hydrogen peroxide is an attractive oxidant because it is cheap, safely stored and handled, environmentally friendly, contains effective oxygen, and produces only water as a byproduct, which is easy to deal with after reactions. There are many reports on oxidation reactions of sulfides carried out by a combination of H_2O_2 and a catalyst that often increase the efficiency of the oxidant, and therefore the presence of the catalyst as an activator in the reaction can be necessary (14–26).

Results and discussion

In continuation of our research on the oxidation of organic compounds (27–29), we report here our efforts in developing new catalytic procedures for the oxidation of sulfides to sulfoxides and sulfones using aqueous hydrogen peroxide catalyzed by MoO_3 (Scheme 1).

A range of sulfides, dialkyl, diaryl, alkyl, aryl, and cyclic sulfides were subjected to the developed reaction procedure to afford sulfoxides with high chemoselectivity and excellent yields. The procedure proved to be compatible with other functional groups and to work under neutral conditions. Hydrogen peroxide was used as a 30% solution in water.

We carried out our initial studies with dibenzyl sulfide to find optimal reaction conditions. After studying various amounts of catalyst, we found that 0.05 equiv. of the catalyst was the best choice. Ethanol was selected as the best solvent as lower catalytic activity was observed with other solvents such as chloroform, dichloromethane, acetonitrile, and water. The optimum amount of H_2O_2 (30%) in this system was found to be 1.3 mmol; when higher amounts of oxidant was employed, a significant increase in the sulfone was observed. For dibenzyl sulfide, a separate experiment showed that the presence of the catalyst is necessary, since oxidation with H_2O_2 alone occurs rather slowly. Looking at the results reported in Table 1, it is readily seen that the reaction is very efficient, affording excellent yields of sulfoxides, generally around 95%, with a reaction time as short as 9 min. The selectivity with respect to the formation of sulfone is also high.

The chemoselectivity of sulfoxidation of sulfides containing a double bond was examined. As shown in Table 1, entry 13, high chemoselectivity was found as the sulfoxide was obtained in high yield without any detectable epoxidation of the double bond. Further selectivity of the proposed method was investigated and the results are indicated in Scheme 2. As can be seen, sulfides were selectively converted to

Scheme 1.

Scheme 2.

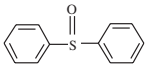
sulfoxides, while the oxime, acylal, and alcohol remained untouched under the same reaction conditions.

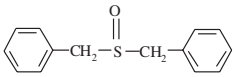
For the synthesis of sulfones several experiments were carried out with a 2.0:1 H_2O_2–substrate molar ratio to check whether sulfone could be efficiently obtained by using just a stoichiometric amount of oxidant and also whether in this case the high chemoselectivity found in the synthesis of sulfoxides could be observed. It was found that with 2.6 equiv. of oxidant a very efficient synthesis of sulfones is possible using higher concentrations of catalyst and longer reaction times than those used for the synthesis of sulfoxides. In all cases sulfones were isolated in almost quantitative yields. Sulfones were also obtained without any detectable formation of the corresponding epoxides (Table 2, entry 24). The results of the synthesis of sulfoxides from sulfides in different reaction conditions are listed in Table 3, which shows that our conditions were more effective than some others with respect to the yield and to the time of the reaction.

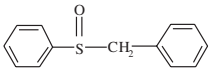
In conclusion, this catalytic system efficiently promoted the oxidation of sulfides to sulfoxides and sulfones. The method is simple, mild, and inexpensive. A further advantage of this method is its chemoselectivity in the presence of other oxidized functional groups.

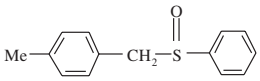
Experimental

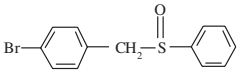
General experimental procedure for the preparation of sulfoxides

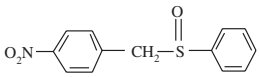


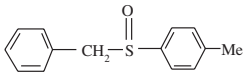


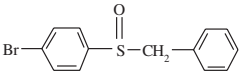


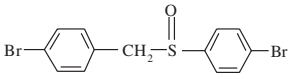


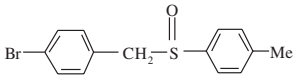


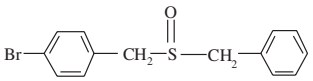


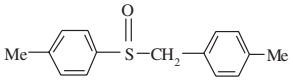


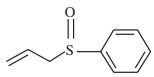


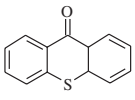


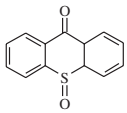












In a round-bottomed flask, H_2O_2 30% (0.15 mL, 1.34 mmol) was added to a mixture of sulfide (1 mmol) and MoO_3 (0.05 mmol, 0.007 g) in EtOH (2 mL). This mixture was stirred at 50 °C for the appropriate time according to Table 1. The progress of the reaction was followed by TLC. After completion of the reaction, H_2O (15 mL) was added to the reaction mixture and filtered. The solid residue was recrystallized from ethanol to obtain the pure product in 95%–98% yields.

General experimental procedure for the preparation of sulfones

To a mixtuure of sulfide (1 mmol) and MoO_3 (0.05 mmol, 0.007 g) in EtOH (2 mL), 30% aq. H_2O_2 (0.3 mL, 2.67 mmol) was added and the mixture was refluxed for 8–30 min (Table 2). The progress of the reaction was followed by TLC. After completion of the reaction, H_2O (15 mL) was added to the reaction mixture and filtered. The solid residue was recrystallized from ethanol to obtain the pure product in 92%–98% yields.

Electron-donating methoxyl group position effect on properties of diarylethene derivatives having a pyrazole unit

Tianshe Yang, Shouzhi Pu, Bing Chen, Jingkun Xu

Abstract: New types of asymmetrical photochromic diarylethene derivatives having a pyrazole unit, namely 1-[1,3,5-trimethyl-1-pyrazol-4-yl],2-[2-methyl-5-(4-methoxylphenyl)-1-thien-3-yl]perfluorocyclopentene (**1a**), 1-[1,3,5-trimethylpyrazol-4-yl],2-[2-methyl-5-(3-methoxylphenyl)-1-thien-3-yl] perfluorocyclopentene (**2a**), 1-[1,3,5-trimethyl-pyrazol-4-yl],2-[2-methyl-5-(2-methoxylphenyl)-1-thien-3-yl]perfluorocyclopentene (**3a**), and 1-[1,3,5-trimethyl-pyrazol-4-yl],2-[2-methyl-5-phenyl-1-thien-3-yl]perfluorocyclopentene (**4a**), were synthesized. Their optical and electrochemical properties, such as photochromism, photochromic cyclization–cycloreversion kinetics, and fluorescence and electrochemical properties were investigated in detail. The results show that all of these compounds have good photochromism, high cycloreversion quantum yield, and relatively strong fluorescence. Their cyclization–cycloreversion processes were determined to be zeroth to first order reactions. The oxidations of diarylethenes **1a**–**4a** were initiated at 0.73, 1.11, 0.79, and 1.03 V, respectively. Furthermore, introduction of the electron-donating methoxyl group at different positions of the terminal phenyl ring was found to strongly influence these optical and electrochemical properties.

Key words: photochromism, diarylethene, electron-donating group, optical and electrochemical properties.

Résumé : On a effectué la synthèse de nouveaux types de dérivés diaryléthènes asymétriques et photochomiques comportant une unité pyrazole, soit le 1-[1,3,5-triméthyl-1-pyrazol-4-yl]-2-[2-méthyl-5-(4-méthoxyphényl)-1-thién-3-yl]perfluorocyclopentène (**1a**), le 1-[1,3,5-triméthyl-1-pyrazol-4-yl]-2-[2-méthyl-5-(3-méthoxyphényl)-1-thién-3-yl]perfluorocyclopentène (**2a**), le 1-[1,3,5-triméthyl-1-pyrazol-4-yl]-2-[2-méthyl-5-(2-méthoxyphényl)-1-thién-3-yl]perfluorocyclopentène (**3a**) et le 1-[1,3,5-triméthyl-1-pyrazol-4-yl]-2-[2-méthyl-5-phényl-1-thién-3-yl]perfluorocyclopentène (**4a**). Les propriétés optiques et électrochimiques, telle la photochromie, la cinétique de la cyclisation/cycloréversion photochromique, la fluorescence et les propriétés électrochimiques ont toutes été étudiées en détail. Les résultats montrent que tous ces composés ont une bonne photochromie, un rendement quantique de cycloréversion élevé et une fluorescence relativement forte. On a déterminé que le processus des réactions cyclisation/cycloréversion est d'ordre zéro/un. Les oxydations des diaryléthènes **1a**–**4a** sont respectivement initiées à 0,73, 1,11, 0,79 et 1,03 V. De plus, on a observé que l'introduction du groupe méthoxy électrodonneur dans différentes positions du noyau benzénique terminal influence fortement les propriétés optiques et électrochimiques examinées plus haut.

Mots-clés : photochromie, diaryléthène, groupe électrodonneur, propriétés optiques et électrochimiques.

Introduction

Photochromic compounds have attracted considerable attention because of their potential application in photonic devices such as optical memories, photo-switches, and full-color displays (1–3). For practical application in optoelectronic devices, photochromic compounds should have good thermal stability at room temperature and high sensitivity. In addition, it is required to further develop thermally irreversible photochromic compounds whose photogenerated colored isomers are very stable and never return to the initial colorless isomers in the dark (4). Recently, several thermally irreversible photochromic compounds, such as furylfulgides, phenoxynaphthacene-quinones, and diarylethenes have been developed (5). Of these compounds, diarylethene derivatives are the most promising candidates for these applications because of their excellent thermal stability in both isomers, fatigue-resistant character, rapid response, and high reactivity in the solid state (6, 7).

To date, a large number of results concerning the synthesis and photochromic properties of diarylethenes with heterocyclic aryl rings have been reported. Among diarylethene derivatives synthesized to date, most are composed of thiophene or benzothiophene hetero-aryl groups (6–13). These compounds are known to exhibit excellent thermal

stability of both isomers and fatigue-resistant characteristics (6). In particular, diarylethenes with thiophene ring systems bearing terminal phenyl groups have been of considerable interest because the end group can be substituted by an electron-donating or -withdrawing group. These groups can inevitably influence the optoelectronic properties of corresponding diarylethenes (14). Besides diarylethene derivatives with thiophene or benzothiophene moieties, other hetero-aryl moieties, such as thiazole, (15–17), pyrrole (18), indole (19, 20), indene (21), benzofuran (22), crysothiophene (23) have also been reported. The photochromic performance of each kind of diarylethene derivative is strongly dependent on the aryl moieties. For example, diarylethenes with indole rings exhibit strong fluorescence (19), whereas those with pyrrole rings are thermally unstable and return to open-ring isomers even in the dark (22). When the aryl groups have low aromatic stabilization energy, the derivatives undergo thermally irreversible photochromic reactions (21). Pyrazole is an attractive aryl unit because of its low aromatic stabilization energy and the structure is similar to isothiazole and so is expected to undergo thermally irreversible photochromic reactions. Until now, photochromic hybrid diarylethene derivatives with pyrazole and thiophene moieties have not been reported, with the exception of one letter published by us (24).

For this paper, one of our research goals was to develop a new class of diarylethene derivatives that show good photochromic behavior. We also want to discuss the effect of electron-donating methoxyl group position on the optical and electrochemical properties of diarylethenes. Therefore, we have synthesized four asymmetrical diarylethene derivatives bearing a pyrazole unit and a thiophene moiety with methoxyl group at the para, meta, and ortho positions of terminal phenyl group, i. e. 1-[1,3,5-trimethyl-1-pyrazol-4-yl], 2-[2-methyl-5-(4-methoxylphenyl)-1-thien-3-yl]perfluorocyclopentene (**1a**), 1-[1,3,5- trimethylpyrazol-4-yl],2-[2-methyl-5-(3-methoxylphenyl)-1-thien-3-yl]perfluorocyclopentene (**2a**), 1-[1,3,5-trimethyl-pyrazol-4-yl],2-[2-methyl-5-(2-methoxylphenyl)-1-thien-3-yl]perfluorocyclopentene (**3a**), 1-[1,3,5-trimethyl-pyrazol-4-yl],2-[2-methyl-5-phenyl-1-thien-3-yl] perfluorocyclopentene (**4a**). The photochromism of diarylethenes **1a**–**4a**, which are discussed in this study, is shown in Scheme 1.

Experimental

General methods

All solvents were purified by distillation before usage. NMR spectra were recorded on a Bruker AV400 (400 MHz) spectrometer using $CDCl_3$ as solvent and tetramethylsilane as an internal standard. IR spectra were recorded on a Bruker Vertex-70 spectrometer and mass spectra were measured with an Agilent MS Trap VL spectrometer. The absorption spectra were measured using an Agilent 8453 UV–vis spectrometer. Photo-irradiation was carried out using an SHG-200 UV lamp, a CX-21 UV fluorescence analysis cabinet, and a BMH-250 visible lamp. Light of appropriate wavelengths was isolated by different light filters. Fluorescence spectra were measured using a Hitachi F-4500 spectrophotometer. Electrochemical examinations were performed in a one-compartment cell using a Model 263 potentiostat–galvanostat (EG&G Princeton Applied Research) under computer control at RT. Platinum electrodes (diameter 0.5 mm) served as working electrode and counter electrode. Platinum wire was used as a quasireference electrode. It was calibrated using the ferrocene (Fc – Fc+) redox couple that has a formal potential, $E_{1/2}$, of +0.35 V vs. platinum wire. The typical electrolyte was acetonitrile (5.0 mL), which contained $LiClO_4$ (0.10 mol/L) and diarylethene (4.0×10^{-3} mol/L). All solutions were deaerated by a dry argon stream and maintained at a slight argon overpressure during electrochemical experiments.

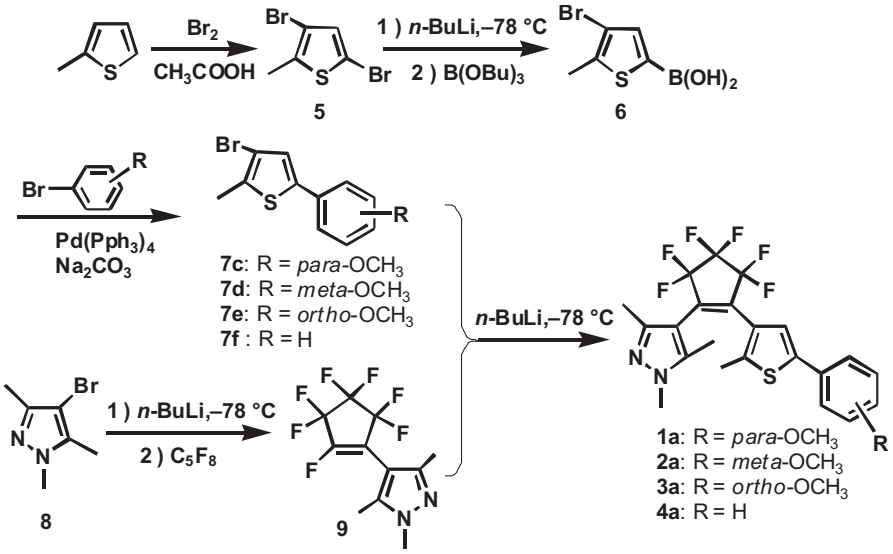
Synthesis

The four diarylethenes **1a**–**4a** were prepared by the method shown in Scheme 2, and experimental details are given in the following.

Synthesis of 3,5-dibromo-2-methylthiophene (5)

To a stirred solution of 2-methylthiophene (24.0 g, 244.8 mmol) in acetic acid (100 mL) at 0 °C was slowly added a Br_2–acetic acid solution (*v*/*v*, 29:40). The reaction mixture was stirred overnight at this temperature. The reaction was stopped by the addition of water. The mixture was neutralized by Na_2CO_3 and extracted with ether. The ether extract was dried, filtrated, and concentrated. The residue was purified by distillation in vacuo. Compound **2** was obtained as a colorless oil, 50.7 g in 81.2% yield. ^{1}H NMR (400 MHz, $CDCl_3$, TMS) δ: 2.94 (s, 3H), 7.61 (s, 1H).

Synthesis of 3-bromo-2-methyl-5-thienylboronic acid (6)



To a stirred solution of **2** (16.3 g, 63.7 mmol) in dry ether (150 mL) was added a 1.6 mol/L *n*-BuLi–hexane solution (40.6 mL, 65.0 mmol) at –78 °C under nitrogen atmosphere. Stirring continued for 30 min, and boric acid tri-butyl ester (18.8 mL) was quickly added to the reaction mixture. After increasing the temperature to RT, the reaction was stopped by the addition of 4% HCl (10 mL). The mixture was extracted with 4% NaOH (100 mL), and the aq. NaOH solution was neutralized by 10% HCl. The residue was washed, filtrated, and dried. The product **3** was obtained as yellowish solid, 12.0 g in 85.5% yield. ^{1}H NMR (400 MHz, $CDCl_3$, TMS) δ: 2.51 (s, 3H), 4.59 (s, 2H), 7.33 (s, 1H).

3-Bromo-2-methyl-5-(4-methoxylphenyl)thiophene (7c)

Compound **7c** was prepared by reacting compound **6** (5.0 g, 22.6 mmol) with 4-bromoanisole (4.23 g, 22.6 mmol) in the presence of $Pd(PPh_3)_4$ (0.8 g) and Na_2CO_3 (6.40 g, 60 mmol) in tetrahydrofuran (THF) (80 mL containing 10% water) for 15 h at 70 °C. Compound **7c** was purified by col-

umn chromatography on SiO_2 using hexane as the eluent and obtained as baby-yellow solid in 78.3% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.40 (s, 3H, -CH_3), 3.83 (s, 3H, -CH_3), 6.89–6.91 (d, 2H, *J* = 8.8 Hz, phenyl-H), 6.99 (s, 1H, thienyl-H), 7.42–7.44 (d, 2H, *J* = 8.8 Hz, phenyl-H).

3-Bromo-2-methyl-5-(3-methoxylphenyl)thiophene (7d)

Compound **7d** was prepared by a method similar to that used for **7c** and obtained as a buff solid in 75.3% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.41 (s, 3H), 3.83 (s, 3H), 6.82–6.84 (d, 1H, *J* = 8.0 Hz, phenyl-H), 7.03 (s, 1H, thienyl-H), 7.08–7.10 (t, 2H, *J* = 4.0 Hz, phenyl-H), 7.25–7.29 (t, 1H, *J* = 8.0 Hz, phenyl-H).

3-Bromo-2-methyl-5-(2-methoxylphenyl)thiophene (7e)

Compound **7e** was prepared by a method similar to that used for **7c** and obtained as a buff solid in 70.2% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.41 (s, 3H, -CH_3), 3.91 (s, 3H, -CH_3), 6.95–6.99 (m, 2H, *J* = 7.6 Hz, phenyl-H), 7.27 (s, 1H, thienyl-H), 7.30 (s, 1H, phenyl-H), 7.53–7.55 (d, 1H, *J* = 8.0 Hz, phenyl-H).

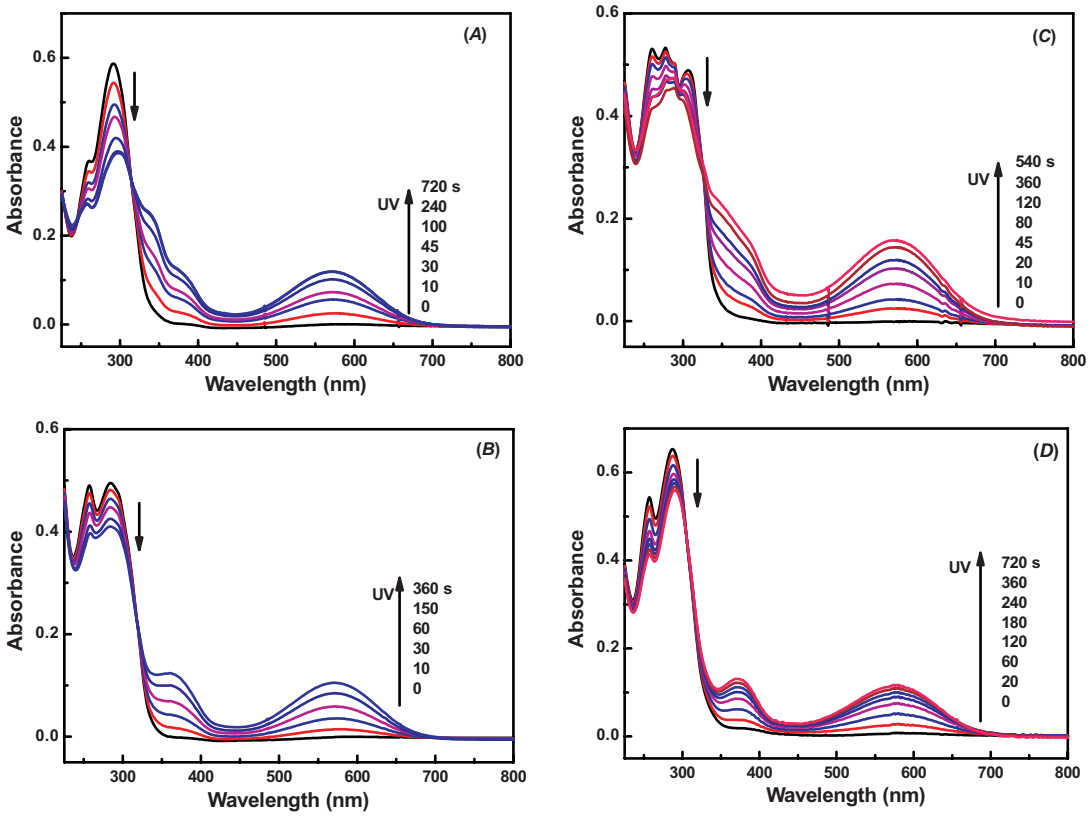
3-Bromo-2-methyl-5-phenylthiophene (7f)

Compound **7f** was prepared by a method similar to that used for **7c** and obtained as a buff solid in 70.0% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.28 (s, 3H, -CH_3), 6.84 (s, 1H, phenyl-H), 7.12 (s, 1H, thienyl-H), 7.33–7.35 (d, 2H, *J* = 8.0 Hz, phenyl-H), 7.56–7.58 (d, 2H, *J* = 8.0 Hz, phenyl-H).

1-(1,3,5-Trimethylpyrazole)perfluorocyclopentene (9)

To a stirred solution of 4-bromo-1,3,5-trimethylpyrazole (**8**) (2.84 g, 15 mmol) in 50 mL of THF was added dropwise a 1.6 mol/L *n*-BuLi solution (9.4 mL, 15 mmol) at –78 °C under argon atmosphere. Stirring was continued for 30 min at the low temperature. Perfluorocyclopentene (2.04 mL, 15 mmol) was added to the reaction mixture at –78 °C, the mixture was stirred for another 1 h at this temperature, and then the reaction temperature was increased spontaneously to RT. The reaction was stopped by the addition of water. The mixture was extracted with ether and washed with aq. HCl (1 mol/L) and water, respectively. The organic layer was dried over $MgSO_4$, filtrated, and evaporated. The crude product was purified by column chromatography on SiO_2 using petroleum ether – acetic ether (4:1) as the eluent to give 2.98 g of compound **9** as a yellow oil in 65.8% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.20 (s, 3H, -CH_3), 2.22 (s, 3H, -CH_3), 3.77 (s, 3H, -NCH_3). ^{19}F NMR (400 MHz, $CDCl_3$) δ: –107.61 (2F), –118.36 (2F), –129.22 (1F), –130.51 (2F).

1-[1,3,5-Trimethyl-1-pyrazol-4-yl],2-[2-methyl-5-(4-methoxylphenyl)-1-thien-3-yl]perfluorocyclopentene (1a)



To stirred anhyd. THF (30 mL) containing **7c** (0.568 g, 1.66 mmol) was added dropwise a 1.6 mol/L *n*-BuLi solution (1.05 mL) at –78 °C under argon atmosphere. After the mixture was stirred for 30 min at –78 °C, compound **9** (0.5 g, 1.66 mmol), dissolved in anhyd. THF solvent, was added quickly. The reaction mixture was continuously stirred at –78 °C for 2 h, and the reaction was allowed to slowly warm to RT. The reaction was quenched by the addition of water. The product was extracted with ether, dried with $MgSO_4$, and concentrated in vacuo. The crude product was purified by column chromatography (petroleum ether – acetic ether, 4:1) to afford 0.35 g of diarylethene **1a** as yellow solid in 45.0% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.94 (s, 3H, -CH_3), 1.97 (s, 3H, -CH_3), 2.03 (s, 3H, -CH_3), 3.70 (s, 3H, -OCH_3), 3.84 (s, 3H, -NCH_3), 6.90–6.92 (d, 2H, *J* = 8.4 Hz, phenyl-H), 7.13 (s, 1H, thiophene-H), 7.44–7.47 (d, 2H, *J* = 8.4 Hz, phenyl-H). ^{13}C NMR (400 MHz, $CDCl_3$) δ: 10.54, 12.86, 14.30, 36.27, 55.40, 106.29, 114.38, 121.43, 122.87, 125.72, 126.23, 139.17, 139.63, 141.92, 146.46 159.48. IR (KBr, cm^{-1}) ν: 800, 821 (benzene 1,4-substituted), 1124 (-CF_2), 1255 (C-N, st), 1341, 1477, 1550 (thiophenene bond), 1611 (benzene skeleton), 2841 (-OCH_3), 2927, 2960 (-CH_3). ^{19}F NMR (400 MHz, $CDCl_3$) δ: –109.43 (2F), –110.52 (2F), –132.58 (2F). MS *m*/*z* (M^+): 487.2 (+H), 509.2 (+Na)

Results and discussion

Photochromism of diarylethenes 1–4

In hexane solution, the photochromic reactivity of diarylethenes **1**–**4** was examined. Figure 1 shows their absorption spectral changes induced by UV light at RT (2.0×10^{-5} mol/L). Compounds **1a**–**4a** exhibited good photochromic properties and can be toggled between their colorless open-ring isomers (**1a**–**4a**) and colored closed-ring isomers (**1b**–

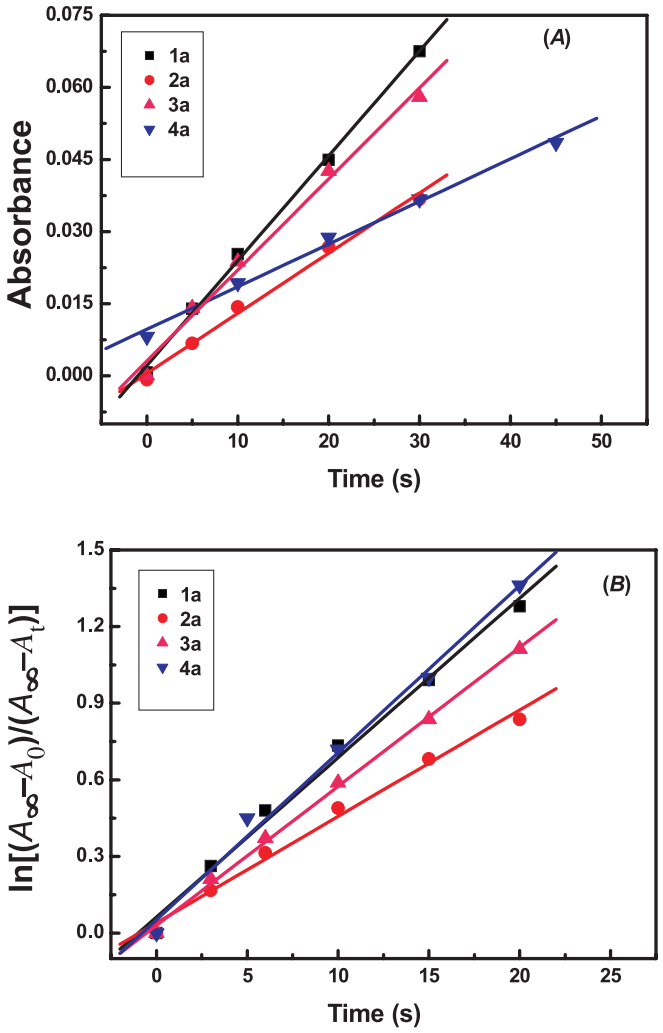
4b) by alternating irradiation with UV and visible light, as monitored using UV–vis absorption and ^{1}H NMR spectroscopy. Upon irradiation with 313 nm light, absorption bands in the visible region appear and the solutions turns blue as a result of the cyclization reactions to produce **1b–4b** (Fig. 1 and Table 1). In the photostationary state, the content of the closed-ring isomer can be easily analyzed with ^{1}H NMR spectroscopy by comparing the relative intensities of thiophene proton signals. According to this method, ^{1}H NMR spectroscopic studies performed on $CDCl_3$ (1.0×10^{-3} mol/L) solutions of **1a–4a** reveal that the contents of the closed-ring isomers (**1b–4b**) in photostationary states are 67% for **1b**, 69% for **2b**, 68% for **3b**, and 69% for **4b**, respectively. All the solutions of **1b–4b** can be decolorized by irradiating them with visible light of wavelengths greater than 500 nm to induce the cycloreversion reactions and reproduce **1a–4a**. The coloration–decoloration cycles of the four compounds could be repeated more than 20 times and a clear isosbestic point was observed at 315, 318, 327, and 309 nm for diarylethenes **1**, **2**, **3**, and **4**, respectively. The absorption spectral properties of the four compounds are summarized in Table 1. The quantum yields were determined by comparing the reaction yields of diarylethenes **1–4** in hexane against 1,2-bis(2-methyl-5-phenyl-3-thienyl)perfluorocyclopentene in hexane (25), and the results are also shown in Table 1. These data suggest that the maximum absorption wavelengths of closed-ring forms and the molar absorption coefficients of both open- and closed-ring forms of the four diarylethene compounds are not evidently different. However, the maximum wavelengths of open-ring forms and their cyclization–cycloreversion quantum yields are relatively remarkable. Among diarylethenes **1–4**, the quantum yields of cyclization and cycloreversion reactions of the *para*-methoxyl substituted derivative (**1**) are the greatest ($\Phi_{O\text{-}C}$ = 0.47, $\Phi_{C\text{-}O}$ = 0.57), while those of the the non-methoxyl substituent derivative (**4**) are the smallest ($\Phi_{O\text{-}C}$ = 0.27, $\Phi_{C\text{-}O}$ = 0.40). The values of the other two compounds are between those of diarylethenes **1** and **4**. As shown in Table 1, all cyclization–cycloreversion quanta of diarylethene derivatives with methoxyl group substituent (**1a–3a**) are much higher than that of the diarylethene with no methoxyl group (**4a**). The results indicate that the cyclization–cycloreversion quantum yield could be effectively increased when the electron-donating methoxyl group was introduced into the benzene rings. In addition for diarylethenes **1–4**, the values of their cycloreversion quantum yields are much higher than those of cyclization quantum yields (Table 1). This is an interesting characteristic of diarylethene derivatives having a pyrazole unit and is a significant difference between the diarylethenes reported here and other diarylethenes reported to date.

The property of fatigue resistance, i.e., the number of times photocyclization and ring-opening reaction cycles can be repeated without loss of performance, was examined at RT according to ref. 18. The hexane solution of compound **1** was irradiated alternatively with UV light (313 nm) and visible light (510 nm). The irradiation time was long enough for coloration to reach the photostationary state and for the color to be completely bleached. The absorbance of the open-ring form remained almost constant even after 200 coloration–decoloration cycles and a clear isosbestic point was observed at 315 nm after 200 cycles. Compounds **2–4** showed similar properties to that of **1**. The results suggested that the diarylethene derivatives bearing heterocyclic pyrazole ring show excellent fatigue resistance.

Photochromic cyclization–cycloreversion kinetics of diarylethenes 1–4



The photochromic cyclization and cycloreversion kinetics of diarylethenes **1–4** in hexane were investigated by irradiation by UV–vis (313 nm, from open to closed form) or visible light ($\lambda > 500$ nm, closed to open form), as shown in Fig. 2. The concentration of all solutions was 2.0×10^{-5} mol/L. All absorption data were collected at the maximum wavelength of every solution, i.e., at the maximum optical density. As shown in Fig. 2*a*, the cyclization kinetics of diarylethenes **1–4** in hexane show that the photochromic cyclization reaction follows zeroth-order kinetics; the relationships between absorbance and exposure time (A vs. t) show good linearity (linear correction factors >0.99) upon irradiation with UV light (313 nm) in all solutions. The slopes of the A vs. t lines gave the zeroth order rate constant, $k_{o\text{-}c}$. According to this method, all the k values for the cyclization process ($k_{o\text{-}c}$) of diarylethes **1–4** can be readily obtained in hexane and are 2.18×10^{-3}, 1.25×10^{-3}, 1.89×10^{-3}, and 0.89×10^{-3} mol/L s^{-1}, respectively. Similarly, the cycloreversion kinetic curves shown in Fig. 2*b* can be plotted according to eq. [1] (26),

$$[1] \qquad kt = \ln\left[\frac{A_\infty - A_0}{A_\infty - A_t}\right]$$

where k is the first-order rate constant, A_0, A_∞, and A_t are the observed absorption data measured at the beginning, at the end, and at time t of the reaction, respectively. The data in Fig. 2*b* represent a perfect linear fit, indicating that the

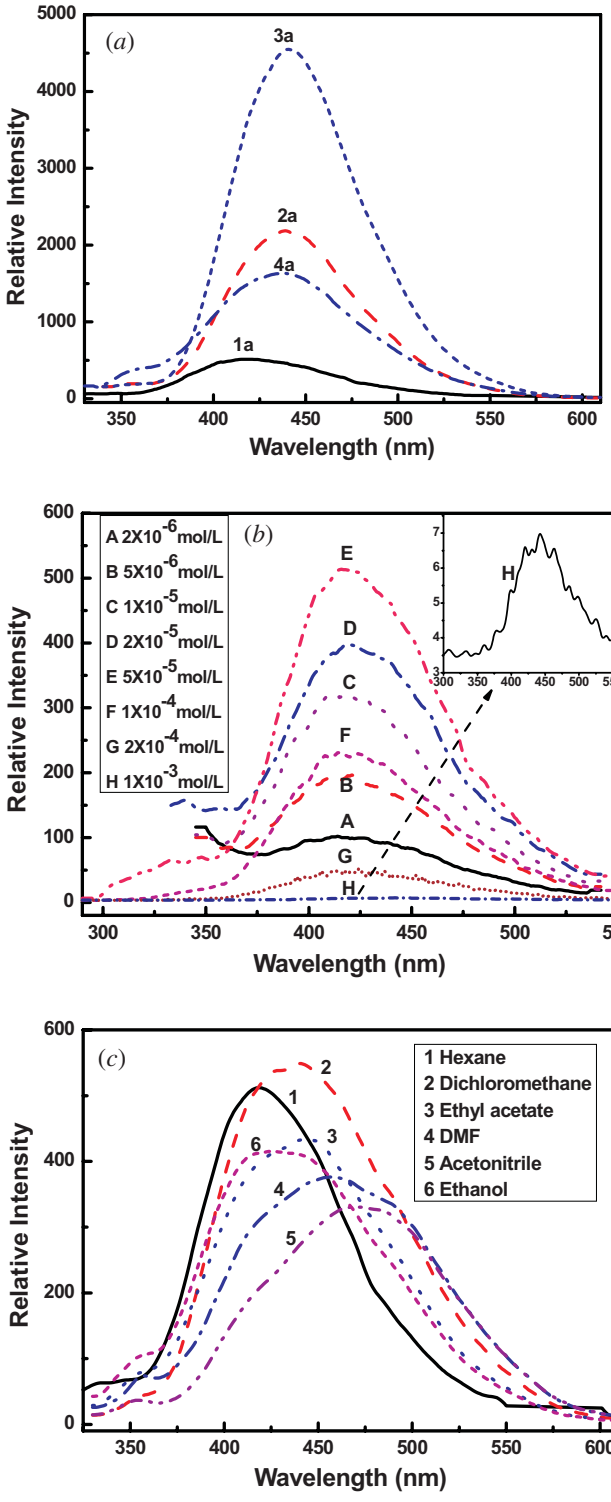
Fig. 2. The cyclization–cycloreversion kinetics of diarylethenes **1–4** in hexane (2.0×10^{-5} mol/L): (*A*) Cyclization kinetics upon irradiation with light (λ = 254 nm), (*B*) Cycloreversion kinetics, upon irradiation with visible light (λ > 510 nm).



photochromic cycloreversion process follows first-order reaction kinetics. From Fig. 2*b*, the rate constant k of the cycloreversion process ($k_{c\text{-}o}$) of diarylethenes **1–4** in hexane were calculated to be 6.25×10^{-2}, 4.17×10^{-2}, 5.44×10^{-2}, and 6.55×10^{-2} mol/L s^{-1}, respectively. Of the four compounds, the $k_{o\text{-}c}$ of diarylethene **4** in hexane is the smallest, while its $k_{c\text{-}o}$ is the greatest in hexane. The result showed that the methoxyl group can effectively accelerate the photochromic cyclization reaction and suppress the cycloreversion reaction.

Fluorescence of diarylethenes 1–4

The fluorescence spectra of diarylethenes **1a–4a** (5.0×10^{-5} mol/L) in hexane at RT are illustrated in Fig. 3*a*. All exhibited good fluorescence at different wavelengths in hexane solution, when excited by their respective excitation wavelength. From Fig. 3*a*, we can clearly see that the hexane solutions containing diarylethenes **1a–4a** showed relatively strong fluorescence at 416, 438, 441, and 439 nm when excited at 280, 317, 315, and 320 nm, respectively.

Fig. 3. (*a*) Fluorescence spectra of diarylethenes **1a–4a** in hexane solution (5.0×10^{-5} mol/L) at RT, excited at 280, 317, 315, and 320 nm, respectively. [a]No fluorescence peak.

The fluorescence maxima of the four compounds were observed to be between 416 and 441 nm, indicating that the effect on the fluorescence peak of the electron-donating methoxyl group and its position was relatively significant. On the other hand, the fluorescence intensities of diarylethenes **1a**–**4a** changed dramatically with the substituent position. The fluorescence intensities increased rapidly from the *para*-substituted **1a** to the *ortho*-substituted **3a** derivatives. The value of non-methoxyl-substituted diarylethene **4a** is located between those of the *para*-methoxyl-substituted **1a** and the *meta*-methoxly-substituted **2a** derivatives. Among the four compounds, the relative fluorescence intensity of the *ortho*-substituted derivative is the strongest, and that of the *para*-substituted derivative is the weakest. The result is exactly contrary to that reported in our previous paper (27). In that paper, the electro-withdrawing fluorine substituent position did not significantly affect the fluorescence peak of dithienylethene, but had a remarkable effect on the fluorescence intensity; the fluorescence intensity of the *ortho*-substituted derivative was the weakest, and that of the *para*-substituted derivative was the strongest. The possible reasons are due to the electro-donating nature of the methoxyl substituent of the terminal phenyl group and that the pyrazole ring can also possibly affect the fluorescence properties of the three diarylethenes. Upon irradiation with 313 nm light, their fluorescence intensity decreased, along with the photochromism, from open-ring form to closed-ring form, suggesting that all of the closed-ring forms of these four diarylethenes showed no fluorescence or that their fluorescence was very weak. These results are consistent with those of most reported diarylethenes (28–31).

The concentration dependence of fluorescence spectra of **1a** was measured in hexane solution at RT, shown in Fig. 3*b*. With the concentration increased from 2.0×10^{-6} to 5.0×10^{-5} mol/L, the maximum emission occurred almost at 416 nm when excited at 280 nm, and the relative fluorescence intensity increased dramatically. However, when the concentration was increased further from 5.0×10^{-5} to 1.0×10^{-3} mol/L, the maximum emission appeared redshifted from 416 to 442 nm, and the relative fluorescence intensity decreased remarkably. The hexane solution showed very weak fluorescence when the concentration was increased to 1.0×10^{-3} mol/L. This self-quench phenomenon perhaps resulted from the formation of excimers and (or) exciplexes in high concentration solutions so that a deactivation effect could occur during the excited state lifetime (32). Moreover, the concentration effect on the fluorescence spectra of diarylethenes **2a**–**4a** were also measured, and the results are summarized in Table 2. As shown in Table 2, compounds **2a**–**4a** showed similar fluorescent properties as **1a**, depending on the concentration employed. At high concentration, e.g., 1.0×10^{-3} mol/L, the fluorescence peak of each diarylethene was obviously redshifted comparing to other concentrations. For all four compounds, the relative fluorescence intensity showed a remarkable initial increase with subsequent dramatic decrease with increasing concentration. The greatest and the smallest values were obtained at 5.0×10^{-5} and 1.0×10^{-3} mol/L, respectively. The systematic redshift at high concentrations and the relatively remarkable fluorescence intensity decrease with increased concentration demonstrated that molecular aggregation and fluorescence quench may occur at higher concentration (31, 33).

The effects of the solvent on the fluorescence spectra of diarylethenes **1a**–**4a** were also investigated. Figure 3*c* shows the fluorescence spectra of **1a** (5.0×10^{-5} mol/L) in different solvents at RT. As shown in Fig. 3*c*, when excited at 320 nm, the fluorescence peaks of diarylethene **1a** were observed at 418, 440, 443, 456, 470, and 426 nm in hexane, dichloromethane, ethyl acetate, DMF, acetonitrile, and ethanol, respectively. The solvent effect on the fluorescence of diarylethenes **2a**–**4a** was also measured, and the fluorescence properties of these four diarylethenes in various solvents at RT are summarized in Table 3.

From these data, one can readily see that the fluorescence spectra depended remarkably on the polarity of solvent. The maximum fluorescence peaks of the four compounds appeared to be redshifted as the polarity of the solvent increased, except for ethanol for which the contrary occurred. The reason may be possibly attributed to its specific solvent–solute interaction such as hydrogen bonding with the fluorine atoms of the diarylethenes. In addition, the solvent effect on the relative fluorescence intensity showed relatively complex and irregular changes (Table 3). Under the same experimental conditions, the fluorescence intensities in ethanol are the strongest, except for diarylethene **1a**, for which the strongest intensity appeared in dichloromethane.

Electrochemistry of diarylethenes 1–4

It is reported that the ring-opening and -closing transformation of some diarylethenes can be initiated not only by

[b]No spectrum peaks.

UV or visible light irradiation but also by electrochemical or chemical, i.e., electrochromic, oxidation (34–36). The electrochemical properties of diarylethenes can be potentially applied to molecular scale electronic switches. Electrochemical examinations by the linear sweep method under the same experimental conditions using diarylethenes **1**–**4** were performed, and the results are shown in Fig. 4. As shown in Fig. 4, *para*-methoxyl and *ortho*-methoxyl substituted diarylethenes (**1** and **3**) showed similar electrochemical behavior. The oxidation onsets of **1a**, **1b**, **3a**, and **3b** initiated at 0.79, 1.00, 0.73, and 0.78 V, respectively. Both of the oxidation onsets of the open-ring forms of compounds **1** and **3** are lower than those of the corresponding closed-ring forms. This indicates that the electron-donating effect of the methoxyl group is more significant in the open-ring form. However, the oxidation onsets of compounds **2** and **4** were opposite to those of compounds **1** and **3**; the oxidation onsets of **2a**, **2b**, **4a**, and **4b** were 1.11, 0.87, 1.03, and 0.94 V, respectively. The oxidation onsets of the open-ring forms are higher than those of the closed-ring forms. This implies that the electron-donating effect of the methoxyl group or hydrogen atom is more significant in the closed-ring form of compounds **2** or **4**, respectively. Moreover, the differences between the open- and closed-ring forms of diarylethenes **1**–**4** (ΔV_{a-b}) were 0.21 for **1**, 0.24 for **2**, 0.05 for **3**, and 0.09 for **4**, respectively. At the same applied potential, the current density of **2b** was higher than that of **2a**, which is exactly opposite to the characterisitcs of **1a** and **1b**. The electronic current of compounds **3** and **4** at the same applied potential intersected. From the previous description together with Fig. 4, a reasonable conclusion can be drawn that the substitution of the electron-donating methoxyl group has a great effect on **1**–**3**. For ortho or meta position substitution of the methoxyl group, the oxidation potential onset showed a remarkable difference with ΔV_{a-b} greater than 0.2 V for **1** and **2**. On the other hand, when substituted at the ortho position, the electron-donating effect together with its steric effect plays a main role, which made the oxidation potential onsets of **3a** and **3b** similar to each other (ΔV_{a-b} = 0.05 V). A similar result was observed when the *ortho*-methoxyl group was substituted by a hydrogen atom (**4a** and **4b**, ΔV_{a-b} = 0.09 V). In addition, three oxidation processes can be readily observed during the anodic oxidation of **2a** and **2b**, while only two oxidation processes can be observed during anodic oxidation of the other three compounds. The three oxidation processes may involve the oxidation of a pyrazole ring, a thiophene ring, together with the benzene ring of compound

Fig. 4. The anodic polarization curves of diarylethenes **1**–**4**.

2. However, the substitution of the methoxyl group, or hydrogen atom, at the para and ortho position made the oxidation process of benzene unclear for **1a**, **1b**, **3a**, **3b**, **4a**, and **4b**. All these electrochemical results indicated that the substitution of the methoxyl group on the benzene and pyrazole units had great effect on both the open- and closed-ring forms of the three diarylethene derivatives. A detailed explanation requires further investigation.

Conclusions

Four new asymmetrical diarylethenes bearing a pyrazole unit were synthesized for the investigation of their optical and electrochemical properties. The effect of different substitution positions on the optical and electrochemical performances of diarylethenes was investigated. The results suggested that the optical and electrochemical properties of these diarylethene derivatives, such as photochromic properties, fluorescence, and their electrochemical characteristics, were significantly dependent on the effect of the electron-donating methoxyl substituent position and the pyrazole unit. The reason may be attributed to the different electron-donating effects when the methoxyl group was substituted on the different positions of the terminal benzene ring and the different aromatic stabilization energy of pyrazole unit from that of thiophene unit. All the diarylethenes reported in this study exhibited good photochromism and strong fluorescence. Significantly, their cycloreversion quantum yields are much higher than those of their cyclization quantum yields.

© 2007 NRC Canada

The results are very useful for the design of efficient photoactive and diarylethene compounds with excellent characteristics.

Regioselective synthesis of novel *N*-aminotriazolophanes

Madhukar S. Chande, Pravin A. Barve, Rahul R. Khanwelkar, Shailesh S. Athalye, and Deepak S. Venkataraman

Abstract: Bis-[4-amino-l,2,4-triazoles] were prepared by fusion of dibasic acids and thiosemicarbazide by condensation of aromatic acid hydrazides with hydrazine hydrate and carbon disulphide. Regioselective alkylation of these bis-[4-amino-1,2,4-triazoles] with 1,ω-dihaloalkanes in the presence of potassium hydroxide in aqueous methanol afforded novel *N*-aminotriazolophanes. The stereochemistry and antibacterial activity of these *N*-aminotriazolophanes were studied. In the case of the triazolophanes **5h**, **8d**, and **8f**, both N-NH_2 groups were observed trans to each other, whereas for case of other triazolophanes both N-NH_2 groups were observed cis to each other.

Key words: 4-amino-l,2,4-triazole, 1,ω-dihaloalkane, S-alkylation, regioselective, *N*-aminotriazolophanes.

Résumé : On a préparé des bis[4-amino-l,2,4-triazoles] par fusion d'acides dibasiques et de thiosemicarbazide, par condensation d'hydrazides d'acides aromatiques avec de l'hydrate d'hydrazine et du sulfure de carbone. L'alkylation régiosélective de ces bis-[4-amino-1,2,4-triazoles] avec des 1,ω-dihalogénoalcanes en présence d'hydroxyde de potassium, en solution dans le méthanol, fournit de nouveaux *N*-aminotriazolophanes. On a étudié la stéréochimie et l'activité antibactérienne de des *N*-aminotriazolophanes. Dans les cas des triazolophanes **5h**, **8d** et **8f**, on a observé que les deux groupes N–NH_2 sont trans l'un par rapport à l'autre alors que dans les autres cas les deux groupes N–NH_2 sont cis.

Mots-clés : 4-amino-l,2,4-triazole, 1,ω-dihalogénoalcane, S-alkylation, régiosélective, *N*-aminotriazolophanes.

[Traduit par la Rédaction]

Introduction

Crown compounds have generated considerable interest during the last three decades because of their ability to form stable complexes with variety of metal and organic cations and anions (1). They also have wide application in phase transfer catalysis (2). In recent years various structural changes have been made to the basic "crown ether" structure to enhance the selective activity of the ligands (3). These changes involve the insertion of aromatic and (or) heterocyclic ring systems into the macrocycles. The incorporation of a heterocyclic subunit provides rigidity to the macrocycle and assists in increasing the stability of complexes formed with both metals and organic cations (3). The development of crown compounds, especially macrocyclic compounds containing a heterocyclic subunit, has gained importance because of their wide range of applications. Many reviews and monographs have been published that highlight their synthesis and application in synthetic organic chemistry as phase transfer catalysts and in analytical chemistry as ligands for complexation (2, 4).

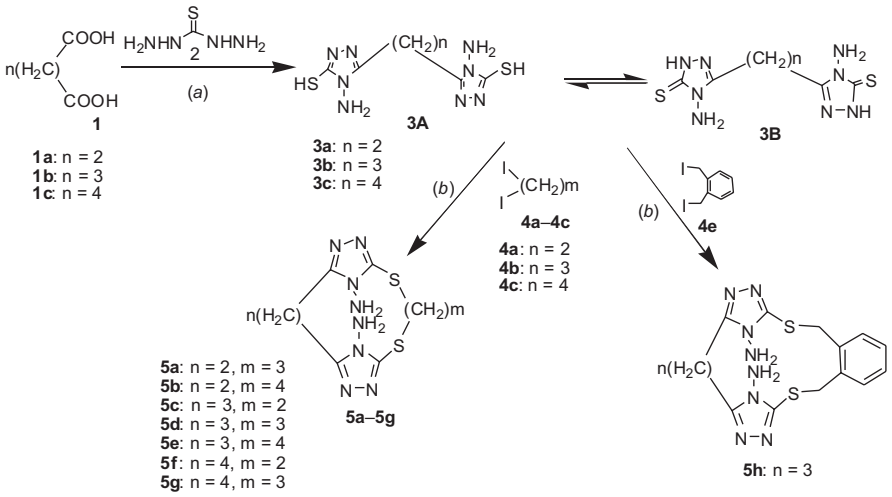
In recent years, attention has been increasingly paid to the synthesis of bisheterocyclic compounds, which exhibit various biological activities (5) including antibacterial, antifungicidal, tuberculostatic, and plant growth regulative properties. Bisheterocyclic compounds displayed much better antibacterial activity than heterocyclic compounds (6). Various 1,2,4-triazoles are found to be associated with diverse pharmacological activities such as antiasthmatic (7), antiviral (ribavirin) (8), antifungal (fluconazole) (9), antimicrobial (10), antibacterial (11), insecticidal (12, 11*c*), amoebicidal (13), hypnotic (14), cytotoxic (15), and hypotensive (16) activities. This moiety was also found in potent agonist and antagonist receptor ligands (17) in HIV-1 protease inhibitors (18) and in thrombin inhibitors (19). Along with these significant pharmaceutical uses, 1,2,4-triazole derivatives are effectively used in polymers, dyestuff, photographic chemicals, and agricultural chemicals (20).

We have previously reported on the regioselective synthesis of novel oxadiazolophanes (21) and *N*-aminotriazolophanes (22). In continuation of this ongoing program in the synthesis of novel macrocyclic ligands (21, 22), their computational studies (21*b*), and their application as phase transfer catalysts (PTC) (22*c*), we now report a facile regioselective synthesis of novel *N*-aminotriazolophanes.



Results and discussion

Synthesis

The present work describes the versatile synthetic strategy for the regioselective synthesis of novel *N*-aminotriazolophanes

 doi:10.1139/V06-181 © 2007 NRC Canada

that have been specially designed to study their stereochemistry.

Aminotriazole derivatives are well-known to be biologically active (23); e.g., 3-amino-1,2,4-triazole (amitrole) is known for its biological (24) and herbicidal (25) activities. 4-Amino-1,2,4-triazoles are potentially good corrosion inhibitors (26). Bisheterocyclic compounds prepared using 4-amino-1,2,4-triazoles derivatives exhibit significant biological activity (27, 5*f*). Hence, we decided to incorporate 4-amino-1,2,4-triazole as a basic unit in heterophane to further enhance heterophane's biological activity.

The obtained heterophanes (*N*-aminotriazolophanes) would be similar to lariat ether (28) with N-NH_2 groups as side arms. The study of the stereochemistry of these compounds is of interest because the two N-NH_2 groups would be either cis or trans to each other depending on the alkyl chain joining the two heterocyclic units and the thermodynamic stability of the molecule. This would in effect influence the properties of macrocycles such as cavity size.

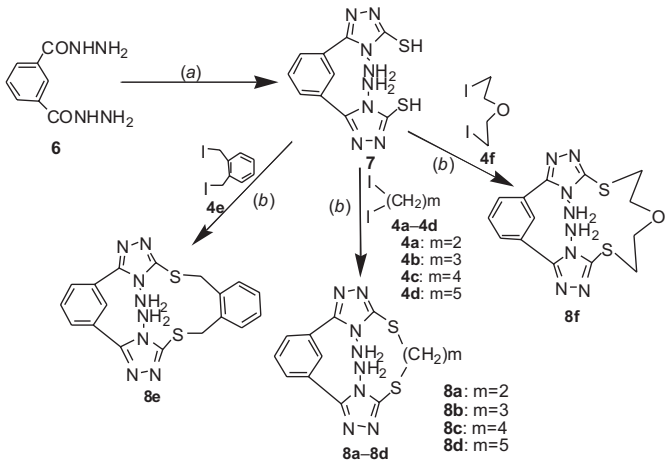
There are many methods found in the literature for the synthesis of 3,5-disubstituted-4-amino-1,2,4-triazoles (29), but none of them concerns the synthesis of heterophanes. Bis-*N*-aminotriazoles **3a**–**3c** (30) were prepared in high yield by direct fusion of aliphatic diacids **1a**–**1c** with thiocarbohydrazine **2** (Scheme 1). The compound **3**, containing thioamido groups, has an amphoteric nature and can exist in tautomeric forms **3A** and **3B**. On alkylation of **3** with 1,ω-dihaloalkane, multiple products could form depending on the reaction condition.

The reaction of compounds **3a**–**3c** with diiodoalkanes **4a**–**4e** in aq. methanol (80%) in the presence of potassium hydroxide as base gave only products **5a**–**5h** regioselectively in good yield (Scheme 1, Table 1). The intramolecular alkylation, which regioselectively occurs at sulfur, is mainly due to the template formation, which is due to the presence of the hexadentate potassium ions where the two ligands are water molecules (31). The reaction was carried out in a large excess of solvent to ensure intramolecular cyclisation (high dilution condition). Reaction of compound **3** with dibromomethane was unsuccessful, perhaps because of the inability of the methyl group to link the two terminal thiol sulphur atoms.

The elucidation of the structures of **5a**–**5h** was accomplished on the basis of their spectral data and elemental analysis (Table 1). For example, the reaction of **3b** with 1,2 diiodoethane **4a** resulted in the formation of the desired *N*-aminotriazolophane **5c**, which was confirmed on the basis of NMR spectra. The ^{1}H NMR spectrum of the compound showed a triplet at δ: 3.37 for the S-CH_2 group in the ethane chain. The absence of a peak for C=S in the ^{13}C NMR spectrum confirmed the regioselectivity of S-alkylation. It showed a signal for S-CH_2 carbon at 29.6 ppm. From the above data, compound **5c** was identified as 1^4,5^4-diamino-6,9-dithia-1,5(3,5)-di-(1,2,4-triazola)cyclononaphane (32). The other *N*-aminotriazolophanes **5a**–**5h** were similarly synthesized and characterized.

To improve the solubility of the triazolophanes it was thought to incorporate a phenyl nucleus into the structure, which would also help in complexation or phase transfer catalyst (PTC) activity. Hence, the scope of the previous reaction was extended to the synthesis of benztriazolophane **8** (Scheme 2). Bistriazole **7** (33) was synthesized using the Reid and Heindel method [34] by the condensation of isophthalic acid dihydrazide **6** with hydrazine hydrate, carbon disulphide, and potassium hydroxide in methanol in high yield.

The reaction of **7** with **4a**–**4f** in aq. methanol (80%) in the presence of potassium hydroxide as a base gave the desired benztriazolophanes **8a**–**8f** regioselectively in moderate yield (Scheme 2, Table 1). The structure of the product was confirmed on the basis of spectral data and elemental analysis (Table 1). For example, the reaction of **7** with 1,2-diiodoethane **4a** resulted in the formation of the desired aminotriazolophane **8a**, which was confirmed on the basis of NMR spectra. The ^{1}H NMR spectrum of the compound showed a triplet at δ: 2.89 for the S-CH_2 group of the ethane chain. The absence of a peak for C=S in the ^{13}C NMR spectrum confirmed the regioselectivity of S-alkylation. It showed signals for S-CH_2 carbons at 27.9 and 30.0 ppm.



We have discussed in detail the regioselective N-alkylation (22*c*) and S-alkylation (21, 22*a*, 22*b*) for the synthesis of aminotriazolophanes. It was thought worthwhile to use O-alkylation for the synthesis of heterophane with an amino side arm. Hence, in continuation of this work on

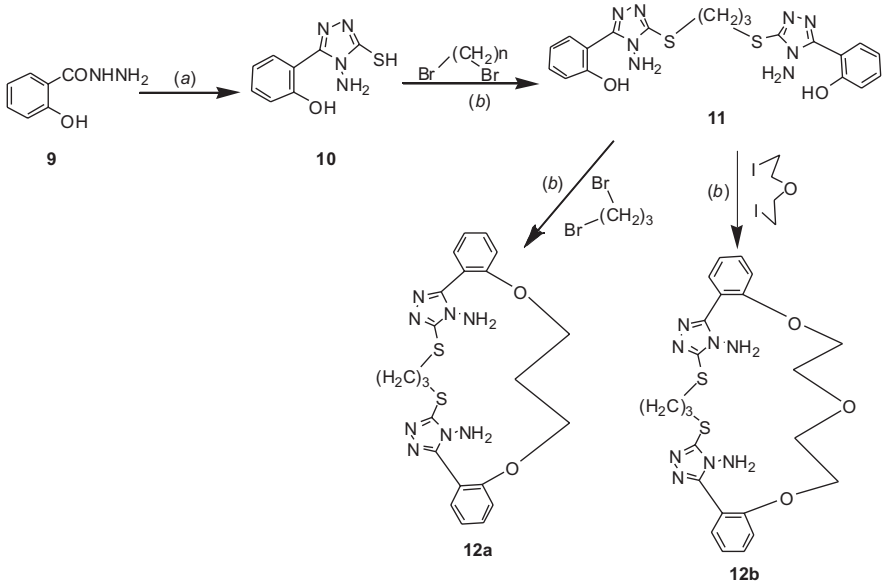
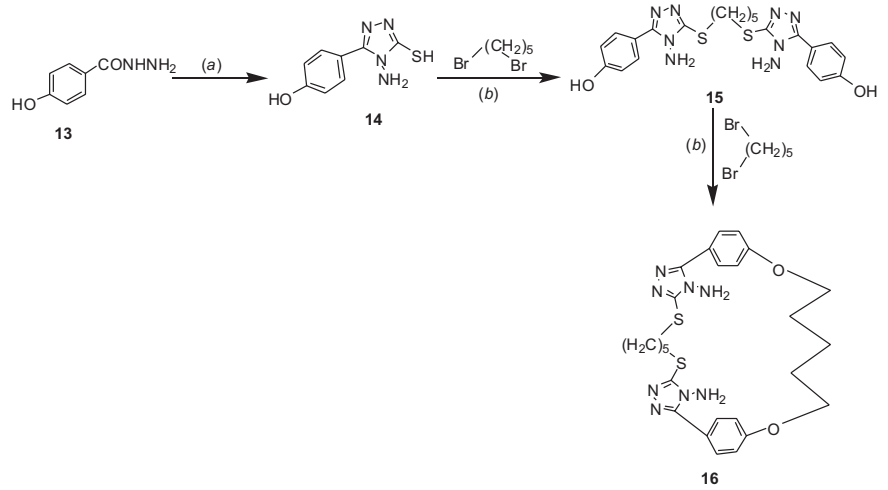
Scheme 2. Synthesis of benztriazolophanes **8.** Reagents and conditions: (*a*) CS_2, $(NH_2)_2{\cdot}H_2O$, KOH, MeOH, 0–5 °C, (*b*) KOH, aq. MeOH (80%), 80 °C.

benztriazolophanes, salicylic acid hydrazide **9** was reacted with hydrazine hydrate, carbon disulphide, and potassium hydroxide in methanol to give compound **10** in high yield (Scheme 3). When **10** was reacted with 1,3-dibromopropane in methanolic potassium hydroxide, compound **11** was afforded regioselectively in good yield (Scheme 3, Table 1). The benztriazolophanes **12a** and **12b** were synthesized regioselectively as the only products in moderate yield by reacting **11** with dihaloalkanes in aq. methanol (80%) containing potassium hydroxide (Scheme 3, Table 1). The structure of the product was confirmed on the basis of spectral data and elemental analysis (Table 1). For example, reaction of **11** with 1,3-dibromopropane resulted in the formation of the desired compound **12a**, which was confirmed on the basis of NMR spectra. The ^{1}H NMR spectrum of the compound showed a triplet at δ: 3.66 for the S-CH_2 group of the propane chain and a triplet at δ: 4.08 for the O-CH_2 group of the propane chain. An M^+ peak at *m*/*z* 496 in the mass spectrum confirmed the formation of **12a**.



Similar reaction conditions were used to prepare compound **16** from *p*-hydroxy benzoic acid hydrazide **13**. When **13** was reacted with hydrazine hydrate, carbon disulphide, and potassium hydroxide in methanol, compound **14** was obtained in high yield. Compound **14** was reacted with 1,5-dibromopentane to afford **15** in moderate yield (Scheme 4, Table 1). Compound **15** was then reacted with 1,5-dibromopentane in methanolic potassium hydroxide to afford **16** in low yield (Scheme 4, Table 1).

Stereochemistry



The stereochemistry of these *N*-aminotriazolophanes was studied using ^{1}H NMR spectral analysis and molecular modeling studies (35). It was observed that in compounds **5a**–**5g**,

© 2007 NRC Canada

Scheme 3. Synthesis of *N*-aminotriazolophanes **12.** Reagents and conditions: (*a*) CS_2, $(NH_2)_2{\cdot}H_2O$, KOH, MeOH, 0–5 °C, (*b*) KOH, aq. MeOH (80%), 80 °C.

Scheme 4. Synthesis of *N*-aminotriazolophanes **16.** Reagents and conditions: (*a*) CS_2, $(NH_2)_2{\cdot}H_2O$, KOH, MeOH, 0–5 °C, (*b*) KOH, aq. MeOH (80%), 80 °C.

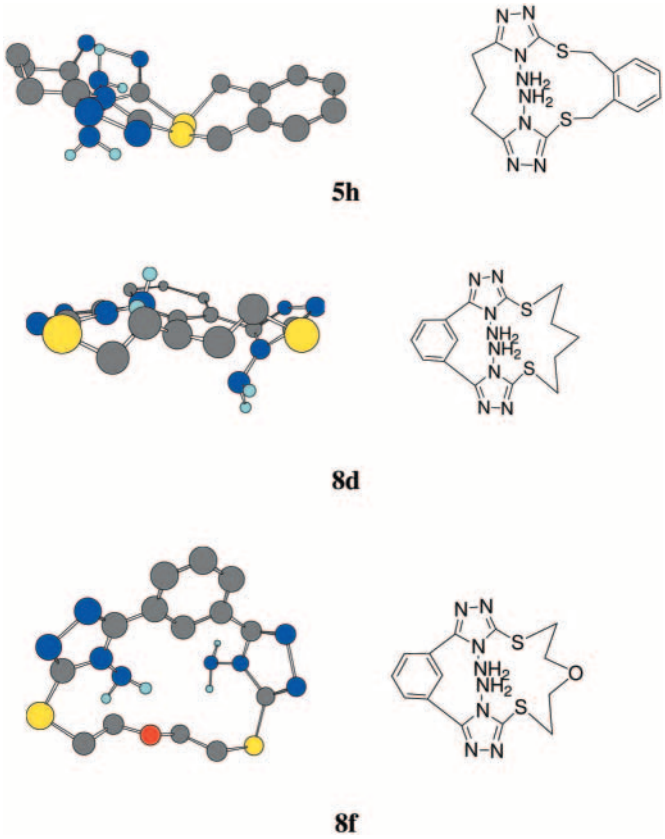
8a–**8c**, and **8e** both N-NH_2 groups appeared as a single peak in the ^{1}H NMR, indicating that both N-NH_2 groups are cis to each other. This was also supported by the molecular modeling study. For compounds **5h**, **8d**, and **8f** (Fig. 1), two different peaks were observed for the N-NH_2 groups, indicating the presence of these groups in different magnetic environments. This showed that both N-NH_2 groups are trans to each other. The molecular model of **5h**, **8d**, and **8f** (Fig.1) showed that one of the NH_2 groups was hydrogen bonded to lone pairs of the ring nitrogen atoms, thus changing the magnetic environment.

Conclusion

In this paper, we have reported on a versatile and convenient route for the synthesis of novel *N*-aminotriazolophanes from aliphatic and aromatic acid hydrazides. For compounds **5h**, **8d**, and **8f**, both N-NH_2 groups are observed in different magnetic environments.

Experimental

General procedure for the synthesis of bis-(4-amino-5-mercapto-1,2,4-triazol-3yl)alkanes (3a–3c)



Compounds **3a**–**3c** were synthesized using a method from the literature [31].

General procedure for the synthesis of 5a–5h, 8a–8f, 11, 12a-12c, 15, and 16

Compounds **3a**–**3c**, **7**, **10**, **11**, **14**, and **15** (for the synthesis of **5a**–**5h, 8a**–**8f, 11, 12a**–**12b, 15** and **16**, respectively) (0.01 mol) were dissolved in aq. methanol (methanol–water, 80:20, 200 mL) containing potassium hydroxide (0.02 mol). A solution of 1,ω-dihaloalkane (0.01 mol) in methanol was

1^4,3^4-Diamino-2(1,3)-benzena-4,10-dithia-1,3(3,5)-di(1,2,4-triazola)cyclodecaphane (8d)

^{1}H NMR (300 MHz, DMSO-d_6) δ: 1.29 (m, 2H, CH_2), 1.69 (m, 4H, 2 × CH_2), 3.13 (t, 4H, 2 × S-CH_2), 6.11 (s, 4H, 2 × NH_2, D_2O exchangeable), 7.38- 7.81 (m, 4H, aromatic H). MS (DI) *m/z*: 374 (M^+), 358, 324, 304, 182, 144, 128, 102, 91, 80, 77.

1^4,3^4-Diamino-2(1,3)-6(1,2)-dibenzena-4,8-dithia-1,3(3,5)-di(1,2,4-triazola)cyclooctaphane (8e)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 4.69 (t, 4H, 2 × S-CH_2), 6.21 (d, 4H, 2 × NH_2, D_2O exchangeable), 7.31- 8.61 (m, 8H, aromatic H). ^{13}C NMR (500 MHz, DMSO-d_6, ppm) δ: 32.6 (2 × S-CH_2), 127.1, 128.1, 128.8, 130.6, 131.2, 132.1, 135.6 (aromatic C), 147.5 (2 × S-C=N), 159.2 (2 × C=N). MS (DI) *m/z*: 408 (M^+), 322, 304, 288, 250, 220, 216, 192, 180, 128, 102, 90, 76.

1^4,3^4-Diamino-2(1,3)-benzena-7-oxa-4,10-dithia-1,3(3,5)-di(1,2,4-triazola)cyclodecaphane (8f)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 3.08 (t, 2H, S-CH_2), 3.54 (t, 2H, O-CH_2), 5.90 (s, 2H, NH_2, D_2O exchangeable), 5.94 (s, 2H, NH_2, D_2O exchangeable), 7.40- 8.55 (m, 4H, aromatic H). ^{13}C NMR (500 MHz, DMSO-d_6, ppm) δ: 31.2 (2 × S-CH_2), 69.2, 70.7 (O-CH_2), 127.6, 129.3, 129.6, 131.3 (aromatic C), 154.1 (2 × S-C=N), 163.2 (2 × C=N). MS (DI) *m/z*: 376 (M^+), 299, 267, 223, 208, 170, 128, 102, 91, 76, 66.

1,3-Di-[4-amino-5(2′-hydroxyphenyl)-1,2,4-triazol-3-yl]mercapto propane (11)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 2.22 (p, 2H, CH_2), 3.37 (t, 4H, 2 × S-CH_2) 6.06 (s, 4H, 2 × NH_2, D_2O exchangeable), 6.97–7.93 (m, 8H, aromatic H), 11.11 (s, 2H, 2 × OH, D_2O exchangeable). ^{13}C NMR (500 MHz, DMSO-d_6, ppm) δ: 29.5 (CH_2), 30.2 (2 × S-CH_2), 113.2, 116.9, 119.6, 129.7, 131.9, 156.2 (aromatic C), 153.9 (2 × S-C=N), 154.0 (2 × C=N).

1^4,9^4-Diamino-2,8(1,2)-dibenzena-3,7-dioxa-10,14-dithia-1(3,5)9(5,3)-di(1,2,4-triazola)cyclotetradecaphane (12a)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 0.73 (p, 2H, CH_2), 1.12 (p, 2H, CH_2), 3.66 (t, 4H, 2 × S-CH_2), 4.08 (t, 4H, 2 × O-CH_2), 5.17 (s, 4H, 2 × NH_2, D_2O exchangeable), 6.87 – 7.45 (m, 8 H, aromatic H). MS (DI) *m/z*: 496 (M^+), 480, 443, 405, 318, 209, 167, 91, 84, 77.

1^4,9^4-Diamino-2,8(1,2)-dibenzena-3,7-dioxa-10,14-dithia-1(3,5)9(5,3)-di(1,2,4-triazola)cyclotetradecaphane (12b)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.12 (p, 2H, CH_2), 3.66 (t, 4H, 2 × S-CH_2), 4.03 (t, 8H, 4 × O-CH_2), 5.62 (s, 4H, 2 × NH_2, D_2O exchangeable), 7.03–7.46(m, 8 H, aromatic H).

1,5-Di-[4-amino-5-(2′-hydroxyphenyl)-1,2,4-triazol-3-yl]mercapto pentane (15)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.56 (p, 2H, CH_2), 1.75 (p, 4H, 2 × CH_2), 3.16 (t, 4H, 2 × S-CH_2), 6.01 (s, 4H, 2 × NH_2, D_2O exchangeable), 6.86–7.80 (dd, 8 H, aromatic H), 9.89 (s, 2H, 2 × OH, D_2O exchangeable). ^{13}C NMR (500 MHz, DMSO-d_6, ppm) 27.1, 28.6 (3 × CH_2), 30.9 (2 × S-CH_2), 115.2, 117.7, 129.4, 138.7 (aromatic C), 152.7 (2 × S-C=N), 154.0 (2 × C=N).

1^4,11^4-Diamino-2,10(1,4)-dibenzena-3,9-dioxa-12,18-dithia-1(3,5)11(5,3)-di(1,2,4-triazola)cyclooctadecaphane (16)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.20 (p, 2H, CH_2), 1.43 (p, 2H, CH_2), 1.53 (p, 4H, 2 × CH_2), 3.12 (t, 4H, 2 × S-CH_2), 4.00 (t, 4H, 2 × O-CH_2), 6.00 (s, 4H, 2 × NH_2, D_2O exchangeable), 6.82–7.88 (dd, 8 H, aromatic H). MS (DI) *m/z*: 552 (M^+), 536, 520, 489, 446, 412, 396, 292, 239, 198, 137, 101, 91, 77.

General procedure for the synthesis of 7

Isophthalic acid dihydrazide **6** (0.01 mol) was dissolved in ethanol (20 mL) in the presence of potassium hydroxide (0.02 mol) and cooled to 5 °C. To this cold solution was added carbon disulphide (0.02 mol) under stirring. The potassium dithiacarbamate salt precipitated out and was filtered, washed with petroleum ether, and dried. This salt was fused with hydrazine hydrate (99%, 0.022 mol) at 90 °C for 4 h. The reaction mixture was poured onto cold water and filtered to remove traces of inorganic material. The filtrate was then treated with dilute hydrochloric acid until the pH of the solution became neutral. The obtained white product was then filtered, washed with cold water, and recrystallized from aq. DMF.

1,3-Bis-(4′-amino-5′-mercapto-1,2,4-triazol-3-yl)benzene (7)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 5.72 (s, 4H, 2 × NH_2, D_2O exchangeable), 7.65- 8.41 (m, 4H, aromatic H), 13.98 (s, 2H, 2 × NH, D_2O exchangeable). ^{13}C NMR (500 MHz, DMSO-d_6, ppm) δ: 126.1, 127.4, 128.6, 129.8 (aromatic C), 148.8 (2 × C=N), 167.1 (2 × C=S).

General procedure for the synthesis of 10 and 14

Salicylic acid hydrazide **9** and *p*-hydroxy benzoic acid hydrazide **13** (for **10** and **14,** respectively) (0.01 mole) were dissolved in ethanol (20 mL) in the presence of potassium hydroxide (0.02 mole) and cooled to 5 °C. To this cold solution was added carbon disulphide (0.01 mole) under stirring. The potassium dithiacarbamate salt precipitated out and was filtered, washed with petroleum ether, and dried. This salt was fused with hydrazine hydrate (99%, 0.011 mole) at 90 °C for 4 h. The reaction mixture was then poured onto cold water and filtered to remove traces of inorganic material. The filtrate was treated with dilute hydrochloric acid until the pH of the solution became neutral. The obtained white product was then filtered, washed with cold water, and recrystallized from aq. DMF.

4-Amino-5(2′-hydroxyphenyl)-3-meracpto-1,2,4-triazole (10)

^{1}H NMR (500 MHz, DMSO-d_6) δ: 5.63 (s, 4H, 2 × NH_2, D_2O exchangeable) 6.92–7.44 (m, 4H, aromatic H), 10.37 (s, 1H, OH, D_2O exchangeable), 13.896 (s, 1H, S=C-NH, D_2O exchangeable). ^{13}C NMR (500 MHz, DMSO-d_6, ppm) 113.1, 116.2, 119.0, 130.9, 132.9, 156.1 (aromatic C), 149.2 (2 × C=N), 165.1 (2 × C=S).

Asymmetric synthesis, crystal structure, and antidepressant activity of 2-aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides

Gao Cao, Ai-Xi Hu, and Xin-Rong Xiao

Abstract: 2-Aryl-3-alkyl-5-methyl-2-morpholinols were synthesized from the reactions of chiral 2-aminopropan-1-ol with 2-bromo-1-phenylpropan-1-one, 2-bromo-1-(3-chlorophenyl)propan-1-one, 1-(4-(benzyloxy)phenyl)-2-bromopropan-1-one, 2-bromo-1-(6-methoxy- naphthalen-2-yl)propan-1-one, and 1-(4-(benzyloxy)phenyl)pentan-1-one in *N*-methyl-2-pyrrolidone (NMP), respectively. The 2-aryl-3-alkyl-5-methyl-2-morpholinols were reacted with hydrogen chloride to give the hydrochloride salts with yields of 56%–77%. The structures of the products were proven by means of their ^{1}H NMR, IR, and MS spectroscopic data. The stereochemical properties of representative products were established unambiguously by the X-ray single crystal analysis. The antidepressant activities of the title compounds were assayed by the mouse forced swimming test (FST). The FST results confirm the antidepressant properties of our products.

Key words: morpholinol hydrochloride, hemiacetal, chiral synthesis, X-ray diffraction, absolute configuration, antidepressant activity.

Résumé : Opérant dans la *N*-méthylpyrrolid-2-one (NMP), on a réalisé la synthèse de 2-aryl-3-alkyl-5-méthylmorpholin-2-ols par les réactions du 2-aminopropan-1-ol avec respectivement de la 2-bromo-1-phénylpropan-2-one, de la 2-bromo-1-(3-chlorophényl)propan-1-one, de la 1-[4-(benzyloxy)phényl]-2-bromopropan-2-one, de la 2-bromo-1-(6-méthoxynaphtalén-2-yl)propan-1-one et de la 1-[4-(benzyloxy)phényl]pentan-1-one. Les réactions des 2-aryl-3-alkyl-5-méthylmorpholin-2-ols avec de l'acide chlorhydrique conduit à la formation des chlorhydrates avec des rendements allant de 56 % à 77 %. On a confirmé l'identité des structures des produits à l'aide de données de résonance magnétique nucléaire du ^{1}H, de spectroscopie IR et de spectrométrie de masse. Les propriétés stéréochimiques de produits représentatifs ont été établies sans ambiguïté à l'aide de la diffraction de rayons X par des cristaux uniques. On a évalué les propriétés antidépressives des composés mentionnés dans le titre en les administrant à des souris impliquées dans un test où elles sont forcées de nager. Les résultats de ces études permettent de confirmer les propriétés antidépressives de ces produits.

Mots-clés : chlorhydrates de morpholinols, hémiacétal, synthèse chirale, diffraction des rayons X, configuration absolue, activité antidépressive.

[Traduit par la Rédaction]

Introduction

2-Aryl-2-morpholinol derivatives have been utilized extensively by chemists because of their pharmaceutical importance in drug design and extensive application in organic synthesis. The biological utility of 2-aryl-2-morpholinol derivatives is wide-ranging, including analeptic, antioxidant, hypocholesterolemic, anorectic, adrenergic blocking, and antifungal properties, and they are especially widely described for their antidepressant activities. 2-Aryl-2-morpholinol derivatives also have been used to treat human diseases such as tardive dyskinesia, minimal brain dysfunction, obesity, migraine, sexual dysfunction, chronic fatigue, restless legs syndrome, Parkinson's disease (1–9).

Research on phenylmorpholinols has led to the discovery of (3,5-difluorophenyl)morpholinol, a novel antidepressant agent and selective inhibitor of norepinephrine uptake, which is active in animal behavioral models that respond to effective clinical antidepressant drugs (10). The racemate compound 2-(3-chlorophenyl)-3,5,5-trimethyl-2-morpholinol has been synthesized and the (+) and (–) enantiomers of the racemate have been subsequently separated via chromatography (11, 12) or dynamic kinetic resolutions (13–15). This product is useful in prophylaxis or therapy, especially as a stimulant and antidepressant for the central nervous system. Musso (16) designed and synthesized a chiral hapten for radioimmunoassay of the antidepressant (2*S*,3*S*,5*R*)-2-(3,5-difluorophenyl)-3,5-dimethyl-2-morpholinol hydrochloride. However, the problem of the synthesis of 2-aryl-2-morpholinol derivatives is that the preparation requires a

Scheme 1. Synthesis of 2-aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides.

long reaction time and that the solvent is volatile and poisonous (17–20).

By structural modification of the drug, it is possible to obtain new compounds with comparable activity and lower toxicity. On the other hand, enantiomers of the same drug can have different pharmacodynamic and pharmacokinetic properties. Today, most new drugs and those under development consist of a single optically active isomer. The current trend in drug markets is a rapid increase in the sales of chiral drugs. Chiral drugs represent close to 40% of all drug sales worldwide in 2001 (21). Therefore, the synthesis of chiral 2-aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides was undertaken.

In this study, we report the synthesis of novel chiral 2-aryl-3-alkyl-5-methyl-2-morpholinols **2a**–**2e** and their hydrochloride salts **1a**–**1e** by the reactions of chiral 2-aminopropan-1-ol with α-bromo-aromatic ketones **3a**–**3e** in *N*-methyl-2-pyrrolidone (NMP) and their antidepressant activities. The synthesis of the title compounds was shown in Scheme 1.

Results and discussion[2]

Synthesis of optically active 2-aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides

The optical rotations of 2-aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides by the reactions of (*S*)-2-aminopropan-1-ol and (*R*)-2-aminopropan-1-ol with α-bromo-aromatic ketones are levorotatory and dextrotatory, respectively. The detailed data are tabulated in Table 1.

2-Aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides synthesized from opposite configuration 2-aminopropan-1-ol have the analogous melting points and the analogous numerical value, but the optical rotation is in the opposite direction. 2-Aryl-3-alkyl-5-methyl-2-morpholinol hydrochlorides synthesized from contrary configuration 2-aminopropan-1-ols should be a pair of enantiomers.

When 2-amino-2-methyl-1-propanol reacted with chiral α-ketotriflate, the enantiopure hydroxylbupropion products conformationally locked at (2*S*,3*S*) or (2*R*,3*R*). The (2*R*,3*S*) or (2*S*,3*R*) isomer was not observed (22). In our products, the ^{1}H NMR spectra show only one double singlet at δ: 0.90–1.10 for the 3-CH_3 group of the morpholine ring, which shows that the synthesized compounds are single enantiomers. If the products are diastereomeric [(2*R*,3*R*,5*S*)-**1a** to (2*R*,3*R*,5*S*)-**1e** and (2*R*,3*S*,5*S*)-**1a** to (2*R*,3*S*,5*S*)-**1e**] or [(2*S*,3*S*,5*R*)-**1a** to (2*S*,3*S*,5*R*)-**1e** and (2*S*,3*R*,5*R*)-**1a** to (2*S*,3*R*,5*R*)-**1e**], the methyl group at the axial position should be in the downfield position because the deshielding effect is stronger than at the equatorial position. So, the 3-CH_3 group of the morpholine ring should have two double singlets in the ^{1}H NMR spectrum.

Single crystal investigation of the representative products

The structure and stereochemical properties of (2*S*,3*S*,5*R*)-3,5-dimethyl-2-(3-chlorophenyl)-2-morpholinol hydrochloride and (2*R*,3*R*,5*S*)-3,5-dimethyl-2-(6-methoxy-2-naphthyl)-2-morpholinol hydrochloride were investigated by X-ray diffraction. Colorless crystals suitable for X-ray diffraction analysis were grown by slow evaporation of the mixture of ethanol and ether (1:1 *v*/*v*). X-ray data were collected on a Bruker AXS SMART 1000 CCD diffractometer equipped with graphite monochromated Mo K_α radiation (λ = 0.710 73 Å). The data set was recorded at RT in ω–ϕ scan mode. Preliminary orientation matrices were obtained from the first frames using SMART (23). The data were empirically corrected for absorption and other effects using

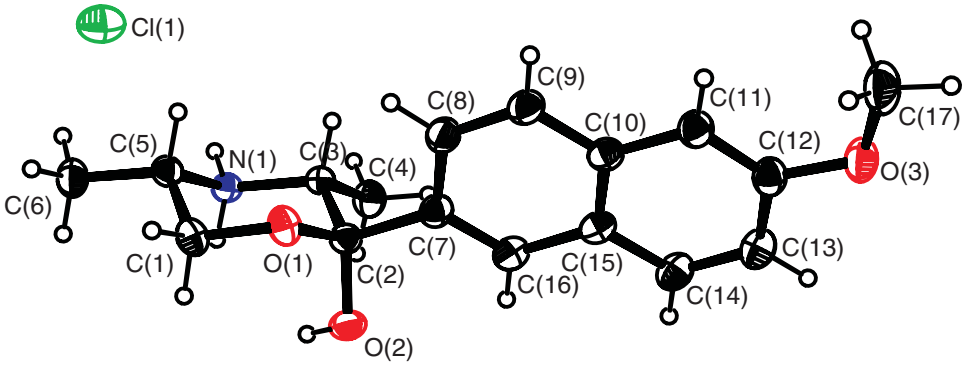
SADABS (24). The structure was solved by direct methods and refined by the full-matrix least-squares methods on F^2 with the program SHELXTL-97 (25). H atoms were positioned at geometrically possible positions and refined using the riding model with U_{eq} set equal to the U_{eq} of the parent atom multiplied by 1.2 (or 1.5 for the methyl groups). O–H and N–H of (+)-**1b** were freely refined. Further details of data collection and structure refinement are given in Table 2.

Absolute configuration of the representative compounds

According to the molecular structure of (–)-**1d** with atom labeling (Fig. 1), the naphthalene ring C(7)–C(16) is essentially planar with a mean deviation of 0.0242(3) Å. The morpholine ring is a distorted chair somewhat flattened at C(2) and sharpened at C(5), and the dihedral angles between the C(3)–C(2)–O(1) and C(1)–C(5)–N(1) planes and the N(1)–C(3)–O(1)–C(1) plane are 45.9(2)° and 52.4(2)°, respectively. The 3-methyl group and the 5-methyl group make dihedral angles of 39.8(3)° and 38.4(3)° with respect to the C(2)–C(3)–N(1) and C(1)–C(5)–N(1) planes; the 2-hydroxy group and the 2-(6-methoxy-2-naphthyl) group make dihedral angles of 38.9(2)° and 31.0(3)° with respect to the C(3)–C(2)–O(1) plane, respectively. The 3- and 5-methyl groups and the 2-hydroxy group are on the same side of the morpholine ring, but the 2-(6-methoxy-2-naphthyl) group is on the reverse side. The chiral carbon atoms of (–)-**1d**, C(2) and C(3) are (*R*)-configuration, and C(5) is (*S*)-configuration. The absolute configuration of (–)-**1d** is (2*R*,3*R*,5*S*).

© 2007 NRC Canada

Fig. 1. The ORTEP (26) plot of the X-ray crystal structure of compound (–)-**1d** with 30% probability displacement ellipsoids.



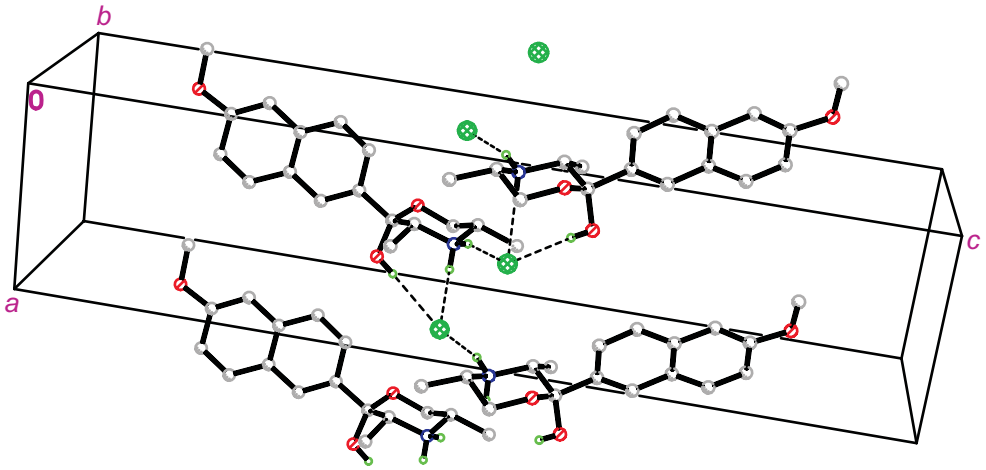


Fig. 2. The crystal packing of (–)-**1d**. For the sake of clarity, H atoms bonded to C atoms have been omitted. Hydrogen bonds have been shown as dashed lines.

The data obtained from the NMR spectral analysis and X-ray investigation are in good agreement, giving evidence of similar conformational behavior in the crystal and in solution. In addition, the structure exhibits intermolecular hydrogen bonds of type N–H–Cl and O–H–Cl. The hydrogen bonds are N(1)–H(1C)–Cl(1)^{i} (2.27 Å, 162.1°) with symmetry codes x–1/2, 1/2–y, –z and N(1)–H(1D)–Cl(1)^{ii} (2.23 Å, 173.6°) and O(2)–H(2)–Cl(1)^{ii} (2.51 Å, 176.7°) with symmetry codes x–1, y–1, z. (Fig. 2).

The molecular structure of (–)-**1d** in crystal is stabilized by the intermolecular hydrogen bonds and the intermolecular electrostatic interactions between the positively charged atom N^+ and Cl^-; the chlorine atom is set apart from the hydroxyl oxygen atom (on the reverse side of the morpholine ring), and the hydroxyl oxygen atom of (–)-**1d** does not itself form a hydrogen bond with the chlorine atom. The structure of (+)-**1b** with atom numbering is shown in Fig. 3 (27).

Compared with (–)-**1d**, the chlorine atom of (+)-**1b** is closer to the hydroxyl oxygen atom and this is probably caused by the 2-Ar substitutes. Atom O(1) in the hydroxyl group acts as a hydrogen-bond donor via H(1) to atom Cl(2) forming the hydrogen bond O(1)–H(1)–Cl(2) (2.29 Å, 166°). Atom N(1) of the morpholine ring acts as a hydrogen-bond donor via H(1C) and H(1D) to two of the other chlorine atoms of the molecule forming the hydrogen bonds N(1)–H(1C)–Cl(2)^{i} (2.27 Å, 173.1°) and N(1)–H(1D)–Cl(2)^{ii} (2.34 Å, 151°) (Fig. 4).

Our synthesis of **1a**–**1e** produced a chair model of a six-membered ring, and the configuration is stable when the aryl and alkyl groups are at an equatorial position. Thus, the two formed chiral carbon atoms C(2) and C(3) in our products maintain "*Z*" shape and not "*E*" shape. The configuration of the products is determined by the chirality of 2-aminopropan-1-ol. The products were (2*R*,3*R*,5*S*)-**1a** to (2*R*,3*R*,5*S*)-**1e**, namely (–)-**1a** to (–)-**1e** when (*S*)-2-aminopropan-1-ol was used. The products were (2*S*,3*S*,5*R*)-**1a** to (2*S*,3*S*,5*R*)-**1e**, namely (+)-**1a** to (+)-**1e**) when (*R*)-2-aminopropan-1-ol was used. (Fig. 5).

When R was an H atom, we did not obtain 2-aryl-5-methyl-2-morpholinol hydrochloride products by the same procedure. α-Bromo-1-aromatic ethanones, such as 2-bromo-1-(4-methoxyphenyl)ethanone, 1-(4-(benzylo-xy) phenyl)-2-bromoethanone, or 2-bromo-1-(6-methoxynaphthalen-2-yl)ethanone, reacted with chiral 2-aminopropan-1-ol during the HCl acidification process initially obtaining a solid, which absorbed water from the environment to form a stagnant oil. The ^{1}H NMR spectra did not indicate cyclic (morpholine) structure, and the IR spectra showed a carbonyl group absorption band of the hydrochloride salt. The hemiketals with R = H are likely to exhibit ring-opening in aq. HCl.

Antidepressant activities of 2-Aryl-3-alkyl-5-methyl-2-morpholinols hydrochloride

Clinical depression is one of the most complex human diseases. It has an unequivocally strong hereditary component and affects about 15% of the population at some point during their lives. The present study was undertaken to investigate the effect of 2-aryl-3-alkyl-5-methyl-2-morpholinols hydrochloride on depression in the mouse

Fig. 5. Absolute configuration of the title compound.

(2*R*,3*R*,5*S*)-(–)-**1a** to (2*R*,3*R*,5*S*)-(–)-**1e** (2*S*,3*S*,5*R*)-(+)-**1a** to (2*S*,3*S*,5*R*)-(+)-**1e**

forced swimming test (FST), an animal model of depression that is widely used to predict the antidepressant action of drugs in humans (28).

Male KM mice (the KM mouse strain is one of the outbred strains of mice introduced from Swiss mice to Kunming City, Yunnan Province, China) weighing 20–30 g were used in this study. The animals were housed in plastic cages under standard light (light on from 0700 to 2100 hours) and temperature (22 ± 1 °C) conditions for at least three days before experimentation with free access to standard laboratory food and tap water. Compounds **1d** and **1e** were chosen as title compounds and were suspended in a CMC solution (1%) with a concentration of 4 mg/mL in a dose volume of 0.1 mL per 10 g body weight in mice. Behavioral observations took place between 0800 and 1500 and each animal was used only once. A standard antidepressant drug amitriptyline was employed to standardize the animal models of depression and to compare the antidepressant efficacy of the title compounds.

Thirty minutes after intraperitoneal (IP) injection of the drugs, the mice were individually placed in a vertical glass cylinder (height of 25 cm, diameter of 12 cm) containing water (depth of 15 cm at 22 °C) and forced to swim. After an initial 2 min period of vigorous activity, each animal assumed a typical immobile posture. A mouse was considered to be immobile when it remained floating in the water without struggling, making only minimum movements of its limbs necessary to keep its head above water. The total duration of immobility was recorded during the next 4 min of a total 6 min test. The changes in immobility duration were studied after administering drugs in separate groups of animals. (Table 3).

According to the results in Table 3, the title compounds showed potent antidepressant activity, where the title compounds (+)-**1d** and (+)-**1e** show better activity than (–)-**1d** and (–)-**1e**, which shows that the configuration of (2*S*,3*S*,5*R*) compounds have greater antidepressant activity than the (2*R*,3*R*,5*S*) configuration.

Following the test, animals were allowed to dry and returned to their home cage. Adverse drug reactions were not observed in the 24 h period after the FST test. These results confirm the antidepressant properties of our products, suggesting the possible use of this drug in depressive patients that may be resistant to classical antidepressant therapy.

Conclusions

In summary, we report herein a rapid and efficient synthesis of some novel 2-aryl-3-alkyl-5- methyl-2-morpholinol hydrochlorides by the reaction of chiral 2-aminopropan-1-ol with α-bromo-aromatic ketones in NMP. Advantages of this approach include short reaction time, ease of operation, and excellent overall yields. The title compounds exhibited potent antidepressant activity in the FST test.

Materials and methods

Instrumentation

All melting points were measured on an X-4 electrothermal digital melting point apparatus and were uncorrected. ^{1}H NMR spectra were recorded on a Varian Inova-400 instrument with TMS as internal standard operating at 399.970 MHz. IR spectra were recorded on Avatar 360FT infrared spectrometer, using KBr discs. ESI-MS measurements were recorded on a Finngan LCQ LC-MS spectrometer. Optical rotations were measured on a WZZ-3 polarimeter. TLC analysis was carried out on glass plates, kept in iodine, using silica gel. X-ray data were collected on a Bruker AXS Smart 1000 CCD diffractometer.

General experimental procedure for the preparation of α-bromo-aromatic ketones

α-Aromatic ketone (0.1 mol) was dissolved in anhydrous ethanol (200 mL) and the mixture was stirred and heated to reflux. Cupric bromide (0.2 mol) was added to the reaction mixture in batches and the course of the reaction was followed by TLC analysis. After the reaction finished, the mixture was filtered and concentrated in vacuo. The resulting residue was taken up in dichloromethane, washed with 10% hydrochloric acid, washed with water until neutral, dried over anhydrous sodium sulfate, and concentrated in vacuo to give racemic α-bromo-aromatic ketones **3a**–**3e** (29).

Preparation of 2-aryl-3-alkyl-5-methyl-2-morpholinols hydrochloride

The general experimental procedure was as follows. α-Bromo-aromatic ketones **3a**–**3e** (0.01 mol) were added to a solution of (*S*)-2-aminopropan-1-ol (0.04 mol) in NMP (10 mL), and stirred for 1 h at RT. When no trace of starting material remained (by TLC analysis), an excess of water (30 mL) was added to the mixture, then extracted with diethyl ether (30 mL). The aqueous layer was extracted further with diethyl ether (15 mL) three times. The organic extracts were combined, washed (10 mL water), and dried by anhydrous sodium sulfate. After filtering, the filtrate was stirred in an ice bath, the pH adjusted to acidity by passing anhyd. HCl through it slowly, yielding a white crystalline substance, which was filtered and washed with acetone, and dried to give (–)-**1a** to (–)-**1e**. Compounds (+)-**1a** to (+)-**1e**) were synthesized using (*R*)-2-aminopropan-1-ol by the same pro-

Cadmium chloride-catalyzed regioselective opening of oxiranes with aromatic amines — An improved protocol for the synthesis of 2-amino alcohols

S. Ramesh Kumar and P. Leelavathi

Abstract: Epoxides undergo rapid $CdCl_2$-catalyzed ring-opening reaction with aromatic amines in mild reaction conditions (room temperature), affording the corresponding 2-amino alcohols with high regioselectivity.

Key words: epoxides, aromatic amines, cadmium chloride, 2-amino alcohols.

Résumé : Sous l'influence d'une catalyse par le $CdCl_2$, les époxydes réagissent avec les amines aromatiques dans des conditions douces (température ambiante) et subissent une rapide réaction d'ouverture de cycle qui conduit à la formation des 2-aminoalcools correspondants avec une régiosélectivité élevée.

Mots-clés : époxydes, amines aromatiques, chlorure de cadmium, 2-aminoalcools.

[Traduit par la Rédaction]

Introduction

The aminolysis of epoxides is a classical route to β-amino alcohols, which are versatile intermediates with major functional groups for the synthesis of various biologically active natural and synthetic products (1). A straightforward synthetic approach for the preparation of β-amino alcohols involves heating an epoxide with an excess of an amine at an elevated temperature. However, this preparation suffers from disadvantages such as high temperature or prolonged reaction times. A variety of activators have been reported, such as metal perchlorates, halides, triflates (2), and ionic liquids (3). Many of these methods involve the use of expensive reagents, and occasionally, give undesirable side reactions or low yields of the desired products (4). Therefore, there is a demand for a new and efficient method for this transformation in more convenient and general conditions. Cadmium chloride is known in the literature as a mild and efficient catalyst for various organic transformations (5).

Results and discussion

As part of our ongoing program in developing new synthetic methods (6), we wish to report our results on regioselective ring opening of various oxiranes with aromatic amines, using a catalytic amount (20 mol%) of $CdCl_2$ in mild reaction conditions.

In a typical experiment, a dichloromethane solution of equimolar amounts of styrene oxide (**1**) and aniline (**2**) was stirred in the presence of $CdCl_2$ at room temperature to obtain the corresponding 2-amino alcohol (**3**) in 93% yield. The reaction was complete within 2 h, the ring opening took place in a regioselective manner, preferentially at the benzylic position. Likewise, styrene oxide and various substituted anilines afforded the 2-amino alcohol (Table 1, entries **a**–**d**).

Similarly, glycidyl phenyl ether and aliphatic alkyl oxiranes reacted smoothly with aryl amines to afford the corresponding 2-amino alcohols in very good yields (Table 1, entries **e**–**l**). The epoxide opening took place in a regioselective manner, preferentially at the unsubstituted oxirane carbon atom, to afford the product (**4**), as shown in Scheme1. Furthermore, cyclohexene oxide reacted smoothly with substituted aromatic amines to afford the corresponding β-amino alcohols (**5**) in excellent yields (Table 1, entries **m**–**p**), as shown in Scheme 2. The *trans* stereochemistry of **5** was deduced from the coupling constants of the ring protons at δ 3.10 (1H, ddd, J = 4.2, 9.5, 11.0 Hz) for HC–O and at δ 3.30 for HC–N (1H, ddd, J = 4.0, 10.0, 10.0 Hz).

All the products were characterized by ^{1}H NMR, IR, and MS. The method applied does not require anhydrous solvents, exclusion of moisture, or stringent reaction conditions. The reactions were clean and highly regioselective, affording high product yields in a reaction time of 2–4 h. The scope and the generality of this process are illustrated

with respect to various epoxides and different substituted amines. The advantage of $CdCl_2$ is its simplicity in handling and the easy workup procedure for the isolation of products.

Experimental section

General methods

All physical and spectroscopic data of the products were compared with those reported in the literature. IR spectra were recorded on a PerkinElmer FT-IR 240-c spectrophotometer. ^{1}H NMR spectra of $CDCl_3$ solutions with TMS as internal standard were recorded on a Gemini-200 spectrometer. Melting points were recorded on a Buchi R-535 apparatus. Mass spectra were recorded on a Finnigan MAT 1020 spectrometer at 70 eV.

General procedure

To a mixture of epoxide **1** (2 mmol) and aniline **2** (2 mmol) in dichloromethane (10 mL) was added $CdCl_2$ (73 mg, 0.4 mmol). The resulting mixture was stirred at room temperature for a specified period (see Table 1); the progress of the reaction was monitored by TLC. After the complete conversion of the starting material, the reaction mixture was diluted with dichloromethane (30 mL). The mixture was washed with water followed by brine solution. The organic layer was dried over Na_2SO_4 and concentrated under reduced pressure to obtain the crude product, which was purified by column chromatography (silica gel 60–120 mesh; ethyl acetate : petroleum ether).

Spectral data for all the compounds

2-Phenyl-2-phenylaminoethanol (3a)

Colourless liquid. IR (neat) ν: 3461, 3397, 3055, 3026, 2926, 2873, 1602, 1503, 1452, 1431, 1354, 1317, 1268, 1180, 1125, 1067, 1028, 926, 872, 752 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.68 (dd, *J* = 6.5, 11.0 Hz, 1H), 3.89 (dd, *J* = 4.0, 11.0 Hz, 1H), 4.42 (dd, *J* = 6.5, 11.0 Hz, 1H), 6.49 (d, *J* = 7.0 Hz, 2H), 6.63 (t, *J* = 7.0 Hz, 1H), 7.04 (t, *J* = 7.0 Hz, 2H), 7.20–7.35 (m, 5H). EI-MS *m*/*z* (%): 213 (12, M$^+$), 182 (100), 104 (27), 77 (31), 51 (22).

2-(2,4-Dichlorophenylamino)-2-phenylethanol (3b)

Brown coloured syrup. IR (neat) ν: 3404, 3064, 2933, 2859, 1594, 1505, 1453, 1397, 1321, 1265, 1157, 1126, 1099, 1067, 1043, 936, 866, 839, 802, 749 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.75–3.85 (m, 1H), 4.40–4.50 (m, 1H), 4.94 (t, *J* = 7.0 Hz, 1H), 6.36 (d, *J* = 8.5 Hz, 1H), 6.88 (dd, *J* = 4.0, 8.5 Hz, 1H), 7.26–7.40 (m, 6H). EI-MS *m*/*z* (%): 285 (10, M$^+$), 156 (25), 125 (100), 103 (20), 91 (85), 77 (15), 63 (18), 57 (20), 51 (20), 43 (26).

2-(2,6-Dimethylphenylamino)-2-phenylethanol (3c)

Colourless oil. IR (neat) ν: 3429, 3371, 3069, 2946, 2837, 1606, 1531, 1442, 1382, 1310, 1271, 1124, 1058, 981, 875, 812, 752 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.70 (br s, OH, 1H), 3.60–3.70 (m, 1H), 3.88 (s, 3H), 3.90–3.95 (m, 1H), 4.48 (t, *J* = 7.0 Hz, 1H), 4.95 (br s, NH, 1H), 6.30 (d, *J* = 7.5 Hz, 1H), 6.52–6.65 (m, 2H), 6.72 (d, *J* = 7.5 Hz, 1H), 7.25–7.40 (m, 5H). EI-MS *m*/*z* (%): 242 (12, M$^+$), 212 (100), 196 (21), 141 (10), 120 (31), 91 (15), 77 (18), 65 (12), 51 (10).

2-(2,4-Difluorophenylamino)-2-phenylethanol (3d)

Brownish oil. IR (neat) ν: 3412, 3326, 3068, 2942, 2851, 1605, 1554, 1436, 1372, 1251, 1128, 1049, 1018, 936, 847, 752 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.75 (br s, OH, 1H), 3.70 (dd, *J* = 6.0, 10.5 Hz, 1H), 3.91 (dd, *J* = 4.0, 11.0 Hz, 1H), 4.95 (t, *J* = 6.5 Hz, 1H), 6.18 (d, *J* = 6.5 Hz, 1H), 6.65–6.80 (m, 1H), 7.25–7.40 (m, 6H). EI-MS *m*/*z* (%): 249 (10, M$^+$), 218 (70), 156 (18), 125 (100), 103 (31), 91 (95), 77 (35), 61 (42), 57(70), 43 (55).

1-Chloro-3-phenylaminopropan-2-ol (3e)

Light coloured solid; mp 38–39 °C. IR (KBr) ν: 3404, 3396, 3062, 2952, 2836, 1602, 1583, 1505, 1456, 1404, 1318, 1259, 1247, 1213, 1169, 1102, 1090, 912, 847, 753 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.85 (br s, 1H), 3.18–3.41 (m, 2H), 3.60–3.70 (m, 2H), 3.98–4.10 (m, 1H), 6.55–6.65 (m, 3H), 7.10–7.20 (m, 2H). EI-MS *m*/*z* (%): 185 (15, M$^+$), 168 (26), 106 (100), 77 (43), 51 (22).

1-Benzyloxy-3-(2,4-dichlorophenyl)aminopropan-2-ol (3f)

Colourless oil. IR (neat) ν: 3414, 3071, 2924, 2855, 1596, 1508, 1454, 1396, 1320, 1269, 1156, 1096, 1048, 869, 842, 753 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.50 (d, *J* = 6.5 Hz, 1H), 3.18–3.45 (m, 2H), 3.65–3.75 (m, 2H), 4.05–4.15 (m, 1H), 4.60 (br s, 1H), 6.60 (d, *J* = 7.5 Hz, 1H), 7.18 (d, *J* = 7.5 Hz, 1H), 7.26 (s, 1H). EI-MS *m*/*z* (%): 312 (10, M$^+$), 253 (10), 178 (80), 174 (100), 111 (12), 79 (13), 57 (14), 43 (87).

3-(2-Methoxyphenyl)-1-(propargyloxy)aminopropan-2-ol (3g)

Light coloured solid; mp 41–42 °C. IR (KBr) ν: 3406, 3389, 3067, 2936, 2839, 1602, 1513, 1458, 1434, 1344, 1295, 1251, 1223, 1177, 1132, 1102, 1026, 908, 843, 743 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.18 (t, *J* = 6.5 Hz, 1H), 3.30 (d, *J* = 6.5 Hz, 1H), 3.58 (d, *J* = 6.5 Hz, 1H), 3.80 (s, 3H), 3.98 (d, *J* = 6.5 Hz, 1H), 6.58–6.82 (m,

4H). EI-MS *m/z* (%): 235 (28, M^+), 136 (100), 121 (57), 77 (23), 65 (15), 51 (12).

1-Chloro-3-(3-chloro-2-methylphenyl)aminopropan-2-ol (3h)

Brown coloured syrup. IR (neat) ν: 3403, 3386, 3072, 2941, 2837, 1605, 1518, 1461, 1404, 1346, 1286, 1231, 1203, 1172, 1134, 1108, 1031, 917, 846, 748 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 2.28 (s, 3H), 2.45 (br s, 1H), 3.25 (q, *J* = 6.5 Hz, 1H), 3.42 (dd, *J* = 4.0, 9.5 Hz, 1H), 3.65–3.75 (m, 2H), 4.00 (br s, 1H), 4.15 (br s, 1H), 6.53 (d, *J* = 7.0 Hz, 1H), 6.80 (d, *J* = 7.0 Hz, 1H), 7.05 (t, *J* = 7.0 Hz, 1H). EI-MS *m/z* (%): 234 (10, M^+), 232 (15), 156 (41), 154 (100), 125 (15), 117 (10), 89 (20), 77 (12), 51 (10), 43 (12).

1-Phenoxy-3-phenylaminopropan-2-ol (3i)

Colourless oil. IR (neat) ν: 3408, 3391, 3056, 2926, 2872, 1602, 1562, 1517, 1491, 1362, 1243, 1123, 1039, 947, 861, 742 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.15 (dd, *J* = 7.5, 12.0 Hz, 1H), 3.36 (dd, *J* = 4.5, 12.0 Hz, 1H), 3.50–3.60 (m, 2H), 4.02–4.35 (m, 1H), 6.55–6.70 (m, 3H), 7.15–7.35 (m, 7H). EI-MS *m/z* (%):243 (18, M^+), 150 (23), 137 (32), 106 (100), 93 (14), 77 (41), 75 (16), 51 (31).

3-(2,4-Dichlorophenyl)-1-(phenoxy)aminopropan-2-ol (3j)

Colourless oil. IR (neat) ν: 3397, 3061, 3047, 2961, 2851, 1631, 1604, 1501, 1487, 1432, 1342, 1213, 1143, 1019, 951, 841, 748 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.18 (dd, *J* = 6.0, 11.0 Hz, 1H), 3.32 (dd, *J* = 4.0, 11.0 Hz, 1H), 3.52–3.63 (m, 2H), 4.05–4.30 (m, 1H), 6.65 (d, *J* = 7.0 Hz, 1H), 7.10 (d, *J* = 7.0 Hz, 1H), 7.30 (s, 1H). EI-MS *m/z* (%): 312 (18, M^+), 275 (10), 219 (23), 175 (18), 163 (12), 146 (31), 134 (21), 109 (100), 90 (24), 74 (36), 49 (21).

3-(4-Nitrophenyl)-1-(propargyloxy)aminopropan-2-ol (3k)

Colourless solid; mp 73–75 °C. IR (KBr) ν: 3409, 3378, 3063, 2951, 2841, 1605, 1509, 1432, 1361, 1302, 1278, 1141, 1109, 1023, 972, 873, 804, 753 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.12 (dd, *J* = 5.0, 10.5 Hz, 1H), 3.30 (dd, *J* = 5.0, 10.5 Hz, 1H), 3.50–3.60 (m, 2H), 3.88 (s, 3H), 3.93–3.98 (m, 1H), 6.32 (d, *J* = 7.0 Hz, 1H), 6.50–6.60 (m, 2H), 6.75 (d, *J* = 7.0 Hz, 1H), 7.30–7.45 (m, 5H). EI-MS *m/z* (%): 250 (22, M^+), 242 (10), 180 (26), 136 (31), 107 (100), 93 (19), 76 (48), 51(21).

3-(3-Chloro-2-methylphenyl)-1-(phenoxy)aminopropan-2-ol (3l)

Light yellow oil. IR (neat) ν: 3403, 3371, 3065, 2943, 2849, 1636, 1606, 1541, 1508, 1431, 1362, 1308, 1256, 1137, 1046, 1012, 937, 851, 749 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 2.37 (s, 3H), 3.18 (dd, *J* = 5.5, 10.5 Hz, 1H), 3.32 (dd, *J* = 5.5, 10.5 Hz, 1H), 3.45–3.58 (m, 2H), 3.90–3.97 (m, 1H), 6.20 (d, *J* = 7.0 Hz, 1H), 6.70–6.85 (m, 1H), 7.30–7.40 (m, 6H). EI-MS *m/z* (%): 291 (21, M^+), 256 (18), 154 (21), 137 (100), 119 (56), 104 (11), 93 (15), 77 (25), 61 (412), 57(37), 43 (51).

1*-trans-*2-(4-Chlorophenylamino)cyclohexanol (3m)

White solid; mp. 61–62 °C. IR (KBr) ν: 3394, 3276, 3081, 2961, 2846, 1739, 1608, 1526, 1452, 1381, 1232, 1112, 1073, 952, 847, 753 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 0.98–1.08 (m, 1H), 1.28–1.41 (m, 3H), 1.70–1.85 (m, 2H), 2.08–2.20 (m, 2H), 2.90 (br s, NH), 3.10 (ddd, *J* = 4.2, 9.5, 11.0 Hz, 1H), 3.30 (ddd, *J* = 4.0, 10.0, 10.0 Hz, 1H), 6.68–6.78 (m, 3H), 7.10–7.20 (m, 2H). EI-MS *m/z* (%): 227 (30, M^+), 191 (25), 167 (51), 114 (19), 96 (21), 77 (100), 56 (31), 52 (37), 45 (23).

1*-trans-*2-(4-Nitrophenylamino)cyclohexanol (3n)

Brown solid; mp 71–72 °C. IR (KBr) ν: 3394, 2928, 2856, 1740, 1622, 1582, 1528, 1453, 1347, 1262, 1133, 1067, 949, 854, 815, 792, 735 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 0.80–0.95 (m, 1H), 1.22–1.45 (m, 3H), 1.70–1.85 (m, 2H), 2.08–2.20 (m, 2H), 3.20 (ddd, *J* = 4.2, 9.5, 11.0 Hz, 1H), 3.40 (ddd, *J* = 4.0, 10.0, 11.0 Hz, 1H), 3.80 (br s, 1H), 6.95 (d, *J* = 7.5 Hz, 1H), 7.30 (t, *J* = 7.5 Hz, 1H), 7.55 (t, *J* = 7.5 Hz, 1H). EI-MS *m/z* (%): 237 (79, M^+), 221(26), 194 (10), 178 (96), 152 (32), 139 (15), 121 (18), 118 (40), 106 (14), 92 (51), 65 (63), 57 (66), 41 (100).

1*-trans-*2-(2-Methoxyphenylamino)cyclohexanol (3o)

White solid; mp 56–57 °C. IR (KBr) ν: 3380, 3063, 3000, 2933, 2858, 1601, 1511, 1457, 1431, 1401, 1343, 1302, 1224, 1177, 1141, 1118, 1068, 1030, 936, 903, 850, 804, 799, 738 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 0.98–1.18 (m, 1H), 1.25–1.41 (m, 3H), 1.70–1.80 (m, 2H), 2.05–2.20 (m, 2H), 2.75 (br s, NH), 3.10 (ddd, *J* = 4.1, 9.2, 11.0 Hz, 1H), 3.40 (ddd, *J* = 4.1, 9.2, 11.0 Hz, 1H), 3.85 (s, 3H), 6.60–6.85 (m, 4H). Copper-mediated N-arylation of electron-deficient pyrroles and indoles

Henri Bekolo[1]

Abstract: We have found that it is possible to N-arylate electron-deficient pyrroles and indoles having no carbonyl group α to the nitrogen ring in good to excellent yields under the Chan and Lam conditions using *N*-Ethyldiisopropylamine (DIEA) base as a substitute for triethylamine (TEA) and pyridine.

Key words: cupric acetate, arylboronic acid, N-arylation, pyrroles, indoles.

Résumé : Nous avons trouvé qu'il est possible de faire la N-arylation des pyrroles et des indoles pauvres en électrons ne possèdant pas de groupement carbonyle en position α de l'atome d'azote du noyau pyrrolique, avec de bons rendements, dans les conditions de Chan et Lam en remplaçant la triéthylamine (TEA) et la pyridine par la *N*-éthyldiisopropylamine (DIEA).

Mots-clés : acétate cuprique, acide arylboronique, N-arylation, pyrroles, indoles.

Introduction

The C–N bond forming reaction using stoichiometric (1–8) or catalytic (9–14) amounts of copper salt, a boronic acid, a nucleophile, and a base is a fast growing methodology that was pioneered by Chan and co-workers in its stoichiometric version (1, 2). Although various substrates have been efficiently N-arylated (15), the reaction outcome is somewhat unpredictable (8). To account for the successful N-arylation of electron-deficient pyrroles and indoles, it has been hypothesized that the presence of a carbonyl group α to the pyrrole ring nitrogen promotes the reaction and is, in part, a key to a successful reaction (5,6). Herein, we report good to excellent N-arylation yields of some commercially available electron-deficient pyrroles (Table 1, **1** and **2**) and indoles (Table 2, **5** and **6**) having no carbonyl group α to the pyrrole ring nitrogen.

Chan and Lam conditions for N-arylation of NH-containing heterocycles include a nucleophile, stoichiometric anhyd. $Cu(OAc)_2$, a boronic acid, and pyridine or Et_3N as a base in dichloromethane (DCM) at RT. Examples in the literature include the N-arylation of azoles (2), purines (3, 4), 2-pyridones and 3-pyridazinones (5). Closely related to this work is the N-arylation of indoles and pyrroles. Pyrrole itself has been N-arylated using catalytic copper salt in 89% yield (9), whereas, under stoichiometric $Cu(OAc)_2$ conditions, Lam et al. (2) and Srirangam and co-workers (6) reported less than 3% and 0% yields, respectively. In Lam et al. (2), indole itself was also reported to have been N-arylated in less than 3% yield.

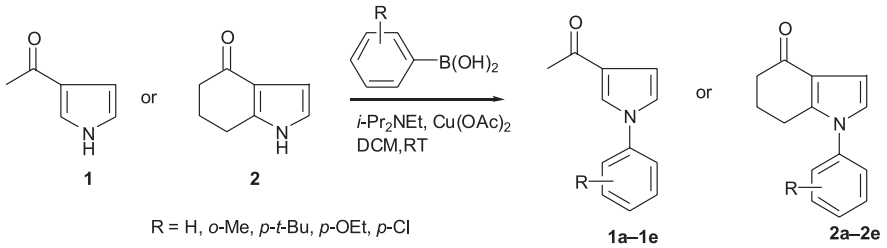
Considering the successful N-arylation of amides, imides, sulfonamides, and ureas (1), Mederski et al. (5) hypothesized that the presence of a carbonyl group at the C-2 position of pyrrole and indole derivatives activates the heterocyclic ring nitrogen, thereby contributing to the positive outcome of the N-arylation process. They demonstrated the concept by N-arylation of the electron-deficient ethyl pyrrole-2-carboxylate in 50% yield and of a series of 2-carboxyindoles in 21% to 50% yields.

Under similar conditions, excellent N-arylation yields of electron-deficient pyrroles were reported by Srirangam and co-workers (6). However, these remarkable yields were restricted to pyrroles having a carbonyl group at either the 2 or the 5 position. Ethyl pyrrole-3-glyoxalate, the only reported example of stoichiometric copper-mediated N-arylation of an electron-deficient pyrrole lacking a carbonyl group α to the ring nitrogen, exhibited very poor reactivity, yielding traces of expected products in three runs out of four and with only 25% of the expected product. According to the authors, the excellent yields with α-deactivated pyrroles "might in part be attributed to the chelation of carbonyl oxygen to the pyrrole nitrogen-Cu complex".



Although reasonable, the above hypothesis suggests the necessity of having a carbonyl group α to the pyrrole ring nitrogen to achieve synthetically useful yields of stoichiometric copper-mediated N-arylation of electron-deficient pyrroles and indoles. This prompted us to investigate the reactivity of electron-deficient pyrroles **1** and **2**, similar to ethyl pyrrole-3-glyoxalate, and indoles **5** and **6**.

Results and discussion

To our knowledge, DIEA has not been reported in experimental screenings as an optimal base in the Cu-mediated arylation of heteroatoms with arylboronic acids. DIEA was tested in the synthesis of the *N*-arylpyrrole **1a** (Table 1), which we isolated in 70% yield. TEA and pyridine did not

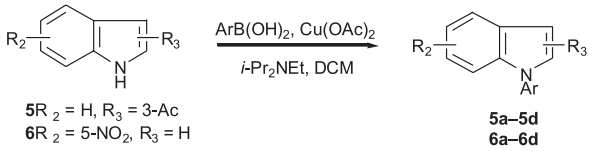
efficiently promote the formation of **1a**. With this result, we decided to test the nonnucleophilic base DIEA with a range of *N*-arylpyrroles (Table 1). The expected products were isolated, along with the remaining starting pyrroles, phenolic by-products (up to 19%) that were already observed by Lam et al. (2), and symmetrical biaryls (up to 16%) that were also reported as side products by Lam et al. (14). These biaryls, characterized as dimers from arylboronic acids, most likely arose from the well-established $Cu(OAc)_2$-mediated oxidative dimerization of arylboronic acids (16).

Trisubstituted pyrrole **3** and tetrasubstituted pyrrole **4** (Fig. 1) were reacted with phenylboronic acid under our standard reaction conditions and found to be poor coupling partners. The reaction mixture with pyrrole **3** turned intensely red over time. After a 10-day reaction, 20% of the starting pyrrole **3** was recovered and 7% of the expected product **3a** (Fig. 1) was isolated (17), along with unidentified reddish by-products. Based on TLC analysis, pyrrole **4** did not react at all, even after a longer reaction time of 14 days.

The dramatic difference in reactivity between pyrroles **1** and **3** or **2** and **4** with phenylboronic acid may be accounted for by the methyl group steric hindrance at the α positions of **3** and **4** as copper-catalyzed coupling reactions are well-known to be extremely sensitive to steric effects in the nitrogen nucleophile. Pyrrole itself was reacted with phenylboronic acid in the dark for three days. The expected *N*-phenylpyrrole was isolated in 4% yield (9). We did not have an electron-rich pyrrole to test.

In this work, $Cu(OAc)_2$ is suspected to oxidize pyrrole anions as dark reddish unidentified by-products formed throughout the preparation of *N*-arylpyrroles. This hypothesis is supported by the fact that $Cu(OAc)_2$ is known to oxidize lithium enolates at temperatures as low as –78 °C (18).

To the best of our knowledge, there has been no report on the N-arylation under the Chan and Lam conditions of electron-deficient indoles having no carbonyl group at the C-2 position. Under the Chan and Lam conditions using DIEA, we have found that 3-acetylindole **5** and 5-nitroindole **6** lacking C-2 carbonyl groups undergo efficient N-arylations (Table 2).



When reacted with phenylboronic acid in the presence of DIEA, Et_3N, and pyridine, 3-acetylindole **5** exhibited similar reactivity as 3-acetylpyrrole **1**. That is, the use of DIEA as a base for the preparation of *N*-arylindole **5a** led to the isolation of **5a** in high yield (85%) after a two-day reaction (Table 2), whereas, the use of Et_3N for the same reaction resulted in low isolated yield of **5a** (35%) even after a longer reaction time of four days. The use of pyridine resulted in no formation of the expected product **5a**, as with a base-free reaction. For the most part, the balance of the material was likely the remaining 3-acetylindole **5**, as judged by TLC analysis. The use of DIEA was then extended to the synthesis of other *N*-arylindoles (Table 2), and we were pleased to find that the reactions proceeded uneventfully in high isolated yields. The 3-acetylindole series afforded higher product yields. Low yield (45%) of the expected product was observed for the synthesis of *N*-arylindole **6d**, in the case of which a thick mixture formed within 2 h under our standard reaction conditions that had to be diluted with an additional 3 mL of DCM. Extending the reaction time from 6 to 10 days did not improve the yield.

The modest reactivity of 4-chlorophenylboronic acid in both pyrrole and indole series reflects the known coupling partners dependency of the Cu–$ArB(OH)_2$ N-arylation reactions (1,8).

The electron-rich 5-methoxyindole was allowed to react with phenylboronic acid to assess its reactivity under our re-

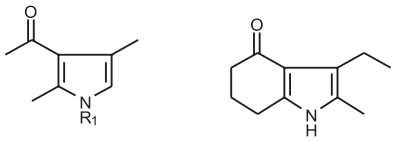
[f]The starting material **6** was recovered in 30% yield.

action conditions. After reacting for a week, the expected 5-methoxy-1-phenylindole was obtained in 7% isolated yield. The starting 5-methoxyindole was recovered in 70% yield. Under the same reaction conditions, the parent indole gave *N*-phenylindole (19) in 16% isolated yield, which is noteworthy. Indole was recovered in 76%.



This efficient room temperature N-arylation of 3-acetylindole and 5-nitroindole complements the N-arylation methodologies for existing indoles that rely on the use of aryl halides as coupling partners at high temperature (19–34) and those that rely on the use of aryl bismuths (35) or arylboronic acids (5) as coupling partners at room temperature.

Conclusion

In conclusion, the reactivity of pyrroles **1** and **2**, indoles **5** and **6**, demonstrates that it is possible to achieve synthetically useful N-arylation yields of electron-deficient pyrroles and indoles having no carbonyl group α to the pyrrole ring nitrogen, under the Chan and Lam conditions using DIEA as a base.

Experimental

Chemicals were purchased from commercial sources and used as received. The ^{1}H and ^{13}C NMR spectra were recorded on an AC Brucker 250 MHz spectrometer using $CDCl_3$ as solvent. The chemical shifts (δ) are reported in ppm. Melting points were determined on a Stuart Scientific SMP 3 capillary melting point apparatus and are uncorrected.

Typical procedure

In a sealed (glass cap and parafilm) oven-dried 25 mL flask, a mixture of pyrrole or indole (1.0 mmol), $ArB(OH)_2$ (2.5 mmol), anhyd. $Cu(OAc)_2$ (2.5 mmol), DIEA (99%, 2.5 mmol) in dry DCM (2 mL) was stirred at RT for the indicated time. DCM was removed under reduced pressure. Water (10 mL) and $HCCl_3$ (10 mL) were added. The aqueous layer was extracted with $HCCl_3$ (2 × 10 mL). The concentrated organic layer was purified by flash chromatography (FC) on silica gel.

Please see ref. 19 for analytical data on **6a** (FC: DCM–cyclohexane, 3:7).

Structures and energetics of CO_2–Ar_n clusters (n = 1–21) based on a non-rigid potential model

M. Böyükata, E. Borges, J.C. Belchior, and J.P. Braga

Abstract: Energetics and possible stable structures of CO_2–Ar_n (n = 1–21) clusters are investigated by performing molecular-dynamics simulations. The pairwise-additive approximation is tested to construct the potential energy function for describing the non-rigid particle interactions in the system. A potential model by Pariseau et al. (*Journal of Chemical Physics*, Vol. 42, p. 2335, 1965) is used for the internal motion of the CO_2 molecule and the Billing form potential (*Chemical Physics*, Vol. 185, p. 199, 1994) is used for all other pair interactions. The stable configurations are determined for the ground state of CO_2–Ar_n clusters, and the growing pattern process of the clusters is determined via rearrangement collisions. Ar atoms tend to surround the CO_2 molecule, and the clusters prefer to form three-dimensional compact structures. Obtained structures and energetics are in quantitative agreement with previous results (*Journal of Chemical Physics*, Vol. 109, p. 1343, 1998) that have used split–repulsion and ab initio potentials in which the molecule was treated as rigid.

Key words: argon, CO_2, cluster, potential energy function, molecular dynamics.

Résumé : Faisant appel à des simulations de dynamique moléculaire, on a étudié les énergies et les structures stables possibles d'agrégats de CO_2–Ar_n (n = 1–21). On a évalué une approximation additive par paire pour construire la fonction d'énergie potentielle qui permettrait de décrire les interactions de particules non-rigides dans le système. On a utilisé un modèle de potentiel proposé par Pariseau et al. (*Journal of Chemical Physics*, numéro 42, p. 2335, 1965) pour le mouvement interne des molécules de CO_2 et la forme de potentiel de Billing (*Chemical Physics*, numéro 185, p. 199, 1994) pour toutes les autres paires d'interactions. On a déterminé les configurations stables pour l'état fondamental des agrégats de CO_2–Ar_n et le processus du patron de croissance des agrégats a été déterminé par le biais de collisions de réarrangement. Les atomes d'argon tendent à entourer les molécules de CO_2 et les agrégats forment de préférence des structures compactes tridimensionnelles. Les structures qui ont été calculées et leurs niveaux d'énergie sont en accord quantitatif avec les résultats rapportés antérieurement (*Journal of Chemical Physics,* numéro 109, p. 1343, 1998) sur la base d'une répulsion divisée et de potentiels ab initio dans lesquels la molécule était traitée comme rigide.

Mots-clés : argon, CO_2, agrégat, fonction d'énergie potentielle, dynamique moléculaire.

[Traduit par la Rédaction]

Introduction

There has been considerable interest in the study of atomic and molecular clusters because of their potential application in the development of new type of materials (nanoparticles) (1–3). However, one of the main problems in the field of cluster science is describing the geometries of intermediate systems. In general, it is difficult to find any global minimum structure for molecular clusters. Even for simpler pair potentials, the number of local minima on the potential energy hyper-surface grows exponentially with increasing cluster size.

Efficient methods have been used to study complex systems. For example, genetic algorithms (GA) have been applied to calculate the lowest energy for a specified potential energy function (PEF) (4, 5). Accurate results compared with ab initio data have shown that the approach can be used with some confidence (5, 6). Other methods such as basin hopping (BH) (7–9) have been widely used for determining global minima, such as using three empirical potentials for describing Si_n clusters (10). Goedecker has also suggested minima hopping (MH) as an alternative search method for complex molecular systems (11). Similarly, simulated annealing (SA) has also been employed to investigate closed-shell systems (12). Additionally, other strategies can be proposed as complementary tools for determining global minima of hypersurfaces as efficiently as possible.

Particularly for pure atomic and alloy systems, there are useful cluster studies, involving rare-gas atoms bound to a chromophore (e.g., HF and HCl) (13–16) for investigating solvation phenomena at the microscopic level (17, 18). The interactions of CO (17) and CO_2 (18) with rare-gas atoms have also received considerable attention because of their atmospheric importance (18). For example, extensive experimental studies of the CO_2–Ar system (19–25) and IR spectra

 doi:10.1139/V06-178 © 2007 NRC Canada

for the CO_2–Ar_2 trimer (26), as primitive model calculations for larger clusters, have been undertaken, along with theoretical investigations (27–33). Accordingly, several intermolecular potentials have been proposed for describing the interaction between CO_2 and Ar atoms (29–32). Similarly, empirical models, based on pairwise-additive approximation, have been used to construct the PEF for studying CO_2–Ar_n. To study CO_2–Ar_n clusters, Severson (18) used three different PEFs, proposed by Hutson et al. (34), Marshall et al. (35), and Bohac et al. (36), modified form of Hough and Howard (37, 38) for describing the molecule–argon (CO_2–Ar) interaction, together with interatomic Aziz potential for Ar–Ar (39). Using these pairwise-additive PEFs, the minimum-energy structures have been found, and rigid-body diffusion Monte Carlo simulations have been carried out for the ground vibrational states of these clusters. The PEFs for studying the CO_2–Ar interaction were fitted against accurate spectroscopic data (34) or calculated using a high level of ab initio methods (29, 35). However, they assumed the rigid body approximation for treating the internal motion of the system.

Similar to ref. 18, other investigations have been performed to find the minimum-energy structures for CO_2–Ar_n clusters with pairwise-additive potentials and also for a rigid molecular case. For example, Sperhac et al. (26) used a pairwise-additive potential proposed by Hough and Howard (37, 38) to describe CO_2 and Aziz potential for clusters up to 17 atoms. These kinds of studies showed that clusters provide a critical testing ground for theories, and a challenge exists to formulate theoretical models of particle bonding for even large-size ranges, which is a demanding task for computational analysis. However, this work may not be enough for modeling and exploring the potential energy surface for CO_2–Ar_n clusters because of the variety of resulting geometries and energetically different results, especially concerning CO_2 as a rigid molecule.

In the present work, the stable structures and energetics of CO_2–Ar_n complexes (n = 1–21) are analyzed by using molecular dynamics (MD) simulation. In addition, a suitable PEF is constructed by allowing the internal motion of CO_2.

The stable configurations of molecular-bonded clusters are determined for the non-rigid ground state of CO_2 in linear structure. This work intends to analyze the applicability of this newly constructed PEF to the cluster formation. The growing pattern of the clusters is investigated via rearrangement collision approaches similar to the studies of ref. 40 that have been efficiently used for structure analysis of metallic (40–42) and rare-gas (43) clusters. The latter works showed that the calculation procedure is efficient to study rare-gas clusters, and hence, the method is also used in the present study of CO_2Ar_n clusters.

Finally, the results of cluster structures and energetics will be compared with previous studies.

Potential-energy function and computational background

Potential energy function

The classical Hamilton's equations were solved to generate the motions of the particles. The Hamiltonian is as follows:

$$[1] \qquad H = \sum_{i=1}^{n} \frac{P_i^2}{2m_i} + V$$

where the first term corresponds to the kinetic energy of the system, P and m are the moment and the mass of the particles, respectively, and V is the potential of the whole system, describing the interaction. The interaction for the described molecule–argon complexes is usually assumed to be pairwise additive for the studies on argon clusters containing a monoatomic, diatomic, or tetraatomic impurities (17, 18). As previously mentioned, there are several potentials for describing the interaction for this particular system (27, 29, 34, 35). However, all of them assumed CO_2 as rigid. In the present study, the PEF for the CO_2–Ar_n clusters is proposed to be the sum of three terms for three different pair interactions. Each term describes a different interaction in the system to keep all particles within non-rigid conditions. The total potential energy of the system is written as

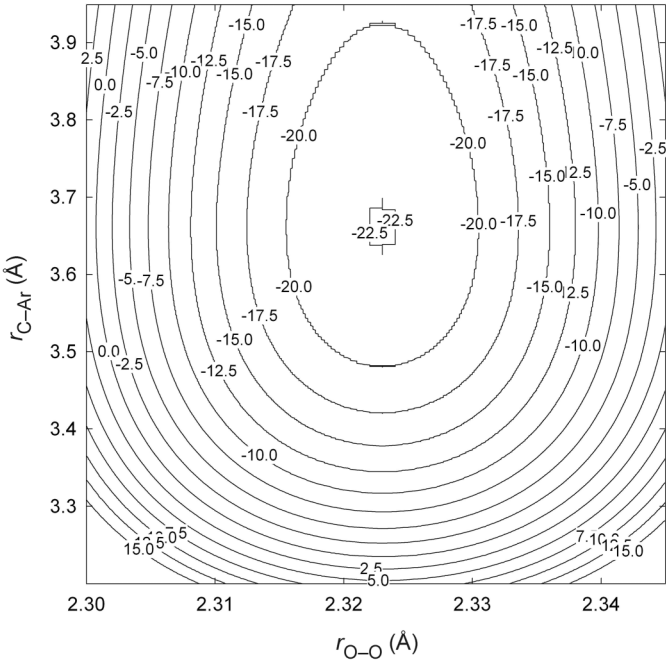
$$[2] \qquad V = V_{CO_2} + \sum_{l=1}^{n} V_{C-Ar_l} + \sum_{k=1}^{2}\sum_{l=1}^{n} V_{O_k-Ar_l} + \sum_{i\neq j}^{n} V_{Ar_i-Ar_j}$$

where i, j, and l specify the argon atoms up to n. The first term, describing the internal potential of CO_2, was based on spectroscopic and molecular beam scattering data (44). In this work, a Taylor series expansion of fourth-order was used for the internal coordinates. Therefore, the CO_2 potential can be written as

$$\begin{aligned}[3] \qquad V_{CO_2} = {} & f_{11}(r_1^2 + r_2^2) + f_{12}r_1r_2 + f_{\alpha\alpha}\theta^2 + f_{111}(r_1^3 + r_2^3) \\ & + f_{112}(r_1^2r_2 + r_1r_2^2) + f_{1\alpha\alpha}(r_1 + r_2)\theta^2 \\ & + f_{1111}(r_1^4 + r_2^4) + f_{1112}(r_1^3r_2 + r_1r_2^3) \\ & + f_{1122}\, r_1^2r_2^2 + f_{11\alpha\alpha}(r_1^2 + r_2^2)\theta^2 \\ & + f_{1\alpha\alpha}(r_1 + r_2)\theta^2 + f_{\alpha\alpha\alpha\alpha}\theta^4\end{aligned}$$

where r_1, r_2, and θ describe the molecular internal coordinates, and the coefficients (f) are the force constants (values in atomic units; f_{11} = 0.5148, f_{12} = 0.0814, $f_{\alpha\alpha}$ = 0.0901, f_{111} = –0.6498, f_{112} = –0.0515, $f_{1\alpha\alpha}$ = –0.0747, f_{1111} = –0.4652, f_{1112} = –0.0429, f_{1122} = –0.1066, $f_{1\alpha\alpha2}$ = 0.5139, $f_{11\alpha\alpha}$ = 0.2281, and $f_{\alpha\alpha\alpha\alpha}$ = –0.014) (44). The second, third, and fourth terms in eq. [2] are Buckingham form (BF) for C–Ar, O–Ar, and Ar–Ar pair interactions, respectively (17). This two-body BF is written according to

$$[4] \qquad V_{pair} = \frac{6\varepsilon e^{\lambda(1-r/r_e)}}{\lambda - 6} - \frac{\lambda\varepsilon}{\lambda - 6}\left(\frac{r_e}{r}\right)^6$$



The pairwise-potential parameters are ϵ = 9.29 meV, r_e = 3.813 Å for C–Ar, ϵ = 7.8 meV, r_e = 3.6 Å for O–Ar, and ε = 12.34 meV, r_e = 3.757 Å for Ar–Ar. ε and r_e are the potential well-depth ($V(r_e) = -\varepsilon$) and equilibrium distance, respectively (17). The intramolecular potential parameters are ε = 10.5 eV and r_e = 1.162 Å for C–O (44). This type of additive potential (BF) was employed by Sevryuk and Billing, who have successfully studied argon–carbonmonoxide complexes for $Ar_n(CO)Ar_n$ clusters (see ref. 17).

Particularly for the Ar–Ar interaction, Aziz and Lennard–Jones (LJ) potential models have been widely used in the lit-

© 2007 NRC Canada

erature and are quantitative for describing Ar clusters (39, 45, 46). In our analysis, these potentials were also used to make a comparison with BF potential results. The LJ potential has advantages, such as permitting the investigation of relatively long-time phenomena, and it reliably describes static and dynamic properties. Our result for the CO_2–Ar structure is a T-shaped configuration, and this result is in good agreement with the global minimum calculated in refs. 18 and 33. However, the results with Aziz potential for larger structures are not as good as expected even though they accurately describe pure argon and Hg–Ar interactions (47). The three Ar–Ar potential energy functions are compared in the discussion part of the latter work. The BF potential is more efficient for describing non-rigid CO_2–Ar_n clusters. In Fig. 1, the contour graph of the PEF is given for the CO_2–Ar system. The potential-energy well corresponds to the T-shaped geometry. It shows that the closest distance between argon and carbon atoms is 3.68 Å in the stable geometry. The minimum-energy value of the CO_2–Ar interaction is –0.0225 eV, which is the "well-depth" of the contour at the distance of 2.323 Å between oxygen atoms in the molecule.

Fig. 1. Contour graph of the PEF used for CO_2–Ar system (energy value is 10^{-3} eV and SR, ab initio, and 3A values are taken from ref. 18).

Computational methodology

Although well-established methods, such as GA, BH, MH, and SA, are efficient ways to determine, in principle, global minima, the rearrangement collision approach based on MD can also be used as an alternative strategy to deal with complex global minimum calculations (41). The method is based on the Ergodic theorem, in which the main hypothesis lies at the foundation of classical statistical mechanics (48). It implies that the trajectory uniformly covers the energetically allowed regions of all classical phase space for a specified total energy (48). This approach has been recently tested for studying LJ-type potential for determining energetics and structures of iron clusters (Fe_n, n is up to 36). The results were compared with quantum mechanical calculations, and their growing pattern was analyzed (41). In the particular case of the CO_2–Ar_n system, the calculations were performed taking into account that to cover the phase space, the total energy had to be high enough to evaluate all the possible minima in the hypersurface. To avoid premature convergence to a local minimum, the whole phase space was searched with enough energy to go to a lower minimum in a similar way to that of the SA method (12).

In the present analysis, the potential energy of the system at $T = 0$ is equal to the target CO_2–Ar_{n-1} atom cluster energy. This energy changes along the motion of the projectile atom towards the target. Therefore, the potential energy value varies and a new value can be determined, depending on the final configuration of the new structure. In this building-up procedure, the colliding atom was sent from a relatively large distance to the target cluster. Formation of the new cluster is related to the translation (collision–kinetic) energy of the new projectile atom. If it is not low enough to keep all particles of the system in the potential well (i.e., the total energy is negative), new cluster formation is not possible. Time-dependent positions and momenta of the particles were described in Cartesian coordinates. The Runge–Kutta of the fifth- and sixth-order algorithm was used as the numerical integration of the classical coupled equations of motion. In the present study, all trajectories were checked to produce energy conservations of the order of 10^{-10} during the integration. The initial kinetic energies (from the collision energy of the projectile atom) are distributed amongst the kinetic energies of all particles in the system after the interaction starts. Moreover, the collision–interaction occurs around the fixed center of mass of the system. The maximum time of each simulation is 3.0×10^6 steps (one time step is 4.0×10^{-17} s). This process is repeated for five different random orientations of the initial configuration.

First, the CO_2 molecule is prepared as a target in an equilibrium linear structure, which is assumed to be the initial condition for the simulations. Through this collision in fusion regime, the CO_2–Ar cluster is constructed. In any collision process, there are three main regimes (fusion, scattering, and fragmentation), depending on the collision energy and impact parameter b (40). To avoid fragmentation, all collisions are realized with low collision energies, low enough to keep all particles together. Additionally, collision sites on the target cluster surface are also effective for these regimes. When the colliding atom, for example, hits the target cluster on any open site, a new structure can be easily constructed. In this study, the orientation space of the target clusters is represented by Euler angles (49) to reduce the effects of the specific target sites of cluster positions.

Upon relaxation, the cluster can be rearranged, and the most stable structure is determined through following each trajectory set and by checking the potential energy of the system at 200 steps up to the end of 3 million steps. The next generated configuration that has the energy nearest the minima in each trajectory set is kept, and after 5×10^4 relaxation steps, it is minimized by removing kinetic energy to find the corresponding structure. This means that, in total, 7.5 million points are searched in the phase space to find the

© 2007 NRC Canada

most stable geometry of each cluster. At the end of the kinetic energy minimization procedure, the Hamiltonian only depends on the potential energy (internal energy) of the system, i.e., the total energy E is equal to the potential energy value of eq. [2] because the kinetic energy is zero. After determining the new cluster, it is used as a seed for a new collision, and these processes are repeated to find a new larger cluster. As previously mentioned, this type of approach has been applied to other clusters (40–43). In this work, we will also discuss an efficient methodology to determine the possible growing mechanism of CO_2–Ar_n (up to $n = 21$) through the structural analysis of this particular system.

Results and discussion

The structural properties and the size-dependent characteristics of carbondioxide–argon complexes are investigated. The minimum-energy structures of CO_2–Ar_n were found by a rearrangement collision (e.g., Ar + CO_2–Ar_{n-1} → CO_2–Ar_n) to realize a building-up process. For all analyses, the colliding Ar atom comes from an asymptotic region. The new CO_2–Ar_n structure was searched in the phase space trajectory during the relaxation time to select its closest-packed coordinates. This selection was repeated five times for five different trajectory spaces of various random-collision sites. It was enough to cover the whole phase space because more searches did not provide any new lower-energy structures. After finding these coordinates, the system was taken into energy-minimization processes. By removing kinetic energy at 100 time steps, the minimum-energy structures were found.

The determined geometries of minimum-energy structures of CO_2–Ar_n ($n \leq 21$) are presented in Figs. 2 and 3. The use of Buckingham form PEF (17) (for C–Ar, O–Ar, and Ar–Ar pair interactions) with the internal potential, suggested by Pariseau et al. (44) for a non-rigid CO_2, in eq. [2] provides all possible minimum-energy structures for the intra- and intermolecular motion of the Ar and CO_2 molecule. Broadly speaking, our results of the structural-growing pattern agree well with the split-repulsion (SR) and ab initio results, particularly with the ab initio (for $n = 6$ and 14) data (18).

Although the probability-distribution functions calculated in ref. 18 are based on quantum mechanics, these calculations can be taken as reference data and should provide insights into classical analysis. As shown in Fig. 2, CO_2–Ar is in a T-shaped structure, which corresponds to an energy of 0.023 eV. The equilibrium distance between Ar and C is 3.66 Å, and this is in fair agreement with the probability-distribution functions for CO_2–Ar in ref. 18, which are almost 3.50, 3.51, and 3.56 Å for 3A, SR, and ab initio PEFs, respectively. Clearly, our result is closer to the ab initio calculation even using a totally different potential model, and hence, it seems that this much simpler potential model is suitable to classically describe CO_2–Ar clusters with particular attention, considering the molecule as non-rigid. Further analysis involving adding another Ar atom to the cluster produces the same trends compared with the structure calculated with those potentials from ref. 18. For CO_2–Ar_2, the distances between the argons and the molecule are also the same. The triangular arrangement of the three argon atoms, with two of them under the equatorial positions, was found, which is in fair agreement with SR and ab initio data; how-

ever, it is slightly closer to the ab initio result. We calculated displacements of argon atoms from the molecule (3.7 and 3.9 Å), and it is again closer to the ab initio result. In the probability-distribution functions for CO_2–Ar_3, Severson (18) found two peaks at 3.6 and 4.25 Å for the ab initio PEFs, 3.5 and 4.35 Å for the SR potential, and only one peak at 3.5 Å using the 3A potential model. Our results also produce two values that can be correlated to the peaks observed in ref. 18. The first one can be considered quantitative, while the second result is assumed qualitative. In the latter case, one observes an equatorial position of Ar atoms surrounding carbon atoms within the same distance. Particularly for n = 4, a distorted tetrahedral geometry is found, with the molecule inserted along one edge of the tetrahedron and the Ar atoms at the vertices of that edge pushed apart and starting to make a lattice for the CO_2. In the minimum-energy structure of CO_2–Ar_5, the three Ar atoms are in near equatorial positions. We observed up to n = 6 minimum geometries in which the structures are within the growing pattern of constructing equatorial regions of the molecule (see Fig. 2). In ref. 18, SR structures for up to n = 5 and ab initio structures for up to n = 6 are very similar to our calculations. However, with the SR potential, Ar atoms start to cover polar sites of the molecule in a different manner for the stable CO_2–Ar_6 structure.

Seven argon atoms interacting with the CO_2 molecule have produced a five-atom ring and started to form a covered shape around one of the oxygens (Fig. 2). Thus, this is the first size where the argon atoms rearrange to start to cover the molecule, and this may provide an efficient growing mechanism. In this geometry, the molecule is slightly oriented towards the argon atoms. The growing mechanism continues to cover the molecule by increasing the number of argons to n = 8. The Ar_9 structure (Fig. 2) consists of a six-membered chair-configuration ring of Ar atoms topped by three more Ar atoms arranged in a triangular shape, and this result is closer to the SR structure rather than the ab initio result. When the number of argons becomes 10, almost half of the molecule and one of the oxygen atoms are totally closed. CO_2–Ar_{11} has two five-atom rings, one of them is around the bond length of C–O, and the other one is over the other covered oxygen with one argon on the top. For n = 10 and 11, the obtained structures are closer to the SR and ab initio results from ref. 18. In the case of Ar_{12}, one can observe that all of the argon atoms almost cover the molecule and there is an open site one of the oxygens. Our result with the same number of surrounding Ar atoms is in line with the corresponding structure in ref. 18, but in a different orientation.

For n = 13, the clusters continue to get closed-shell structures as illustrated in Fig. 3. The first completed solvation shell is found in the minimum-energy structure of CO_2–Ar_{14}. With SR and ab initio PEFs, the first closed-shell geometry was also obtained at the same size, but the structures are totally different (18); however, our result is much closer to the ab initio structure. To keep the lattice of the shell covering, the molecule–argon clusters rechange the forms of argon rings in the n = 14–17 region. For 15 Ar atoms, there is a larger complete solvation shell. This geometry is in good agreement with ref. 18 with particular attention paid to package formation, i.e., both produce the same qualitative cage

Fig. 4. Total energy values for CO_2–Ar_n (n = 1–20). SR, ab initio, and 3A values were taken from ref. 18.

structure surrounding the CO_2 molecule. For 16 Ar atoms surrounding the CO_2 molecule, the minimum-energy structure represents an argon addition outside a different inner solvation shell of 15 Ar atoms in the previous structure. In our observations, the stable structure prefers to grow by adding an atom to the open sites in the equatorial parts of CO_2–Ar_{15}, while the structure in ref. 18 grows in the polar side position.

For the minimum-energy structure of CO_2–Ar_{17} cluster, our result is in fair agreement with three intermolecular potentials in refs. 18 and 26. Therefore, one can state that such a geometry may be expected because the atoms form a closed symmetric shell structure, as also observed for other cases (n = 13 and n = 19). Hence, it seems that for a linear three-atomic molecule surrounded by rare gas atoms such as Ar, one can produce this type of geometry, i.e., it may be a "key" size or structure for comparison. Accordingly, considering that CO_2–Ar_{17} can be taken as a reference structure, one can use it to analyze other atomic-potential models to describe the Ar atom interactions surrounding the CO_2. For example, we consider the analysis taking the most common pair-potential model for Ar atoms, e.g., Aziz and LJ potentials. Obviously, in our particular studies, the BF potential produces better results to describe pair-additive approximation. For n = 18, the minimum-energy structure is in the shape of the argon-added shell structure of CO_2–Ar_{17} as shown in Fig. 3. For both CO_2–Ar_{17}, and CO_2–Ar_{18} clusters, one can verify an agreement with previously calculated geometries (18). CO_2–Ar_{19} and CO_2–Ar_{20} consist of an inner shell of 17 argon atoms. Similarly, in ref. 18, it was reported that for n = 18–20, the minimum-energy structures calculated from both the SR (34) and ab initio (35) PEFs consist of an inner shell of 17 argon atoms, with the remaining argon atoms outside of this shell. However, CO_2–Ar_{21} has an inner shell of 15 argon atoms. Severson also concluded that for CO_2–Ar_n clusters with $n \geq 18$, each of these was found to have an inner shell of either 15 or 17 argon atoms (18). In our analysis, further calculations were performed (n = 21), and similar trends have been observed.

Energy values are compared in Table 1. Clearly, our results are closer to those calculated by using the ab initio potential (18). The energies calculated using two potential models (LJ and Aziz) to describe argon interaction are also shown. In this particular analysis, eq. [2] is modified to con-

[a]See ref. 26.

sider these two potentials. As can be observed from Table 1, for adding up to 2 argon atoms, there are energy modifications in our calculations, and our results are underestimated in comparison with all energies from ref. 18. When compared with the ab initio results, our analysis shows that the pairwise-interaction potential modeled by Sevryuk and Billing (17) produces an almost-quantitative agreement. With respect to the 3A potential energies, Aziz for n = 2 and LJ for n = 4 and 5 are considered better than the BF potential results for describing Ar–Ar pair interaction. However, it seems that they are not valid, in general, for describing Ar_n interactions in these particular systems for $n \geq 3$. For example, the error analysis, with respect to the recent study with ab initio PEF (18), shows that the BF potential gives closer energy values than the LJ and Aziz potentials for all sizes. Moreover, our BF results for n = 3–5 are in better agreement with the ab initio data than the 3A potential. When the energy values are compared with SR results, the BF potential is the best PEF for n = 3, 4, and 5. On the other hand, the energy results are different with respect to the rigid body potential results for larger structures. Above n = 4, neither energetic nor structural similarities were observed using the Aziz potential even though the structural properties with the BF and LJ potentials are well converged. To calculate their energies with the Aziz and LJ potentials, we used the generated structures with the BF function. The energy values generated with both of them are far from the others. It means that although these potentials describe Ar_n clusters well, the obtained structures are not in equilibrium geometries, and the Aziz potential creates an absolutely different growing pattern in which argon atoms prefer to come together rather than surround the molecule. Moreover, the results show that the Aziz and LJ potential models generate different geometries compared with previous results, e.g., the ab initio calculations.

Table 2 shows the energy differences between CO_2–Ar_{17} and CO_2–Ar_1, $\Delta E = E(17) - E(1)$, for the potentials used in this work, and their corresponding relative errors are compared with respect to the ab initio and SR energy values. The BF potential result is similar to those obtained by other potentials (18). Moreover, it is the closest one to the ab initio PEF with 3.0% (better than LJ and SR), and when it is compared with SR, the relative error is 2.0%, as shown in the Table 2. Although the LJ potential can generate similar structures, energetically it does not produce reasonable values with respect to the rigid body potentials. Our results show that the BF function is useful for describing pair interactions in all sizes for both structural and energetic analyses. As shown in Fig. 4, the total energy of the stable structures

calculated with the BF potential is in better agreement with the ab initio and SR energies. Therefore, it seems that for the particular case of a CO_2 molecule surrounded by argon atoms, the BF potential function describes the cluster system well, at least up to n = 21. The interatomic distances are given in Fig. 5. We will also discuss their structural properties.

The ab intio results are assumed to be correct for the purpose of comparison with our classical calculations. Clearly, it seems that, considering the vibrational modes for the molecule, this produces more significant results for small clusters. This should be expected because the relaxation energy is more pronounced when only a few Ar atoms surround the molecule and can affect the cluster system when another Ar atom is added. For higher n's, one observes that the internal-energy relaxation does not affect the cluster structure formed. Therefore, for a higher order, one expects better agreement between our results and those shown in ref. 18, and this can be seen in Figs. 4 and 6. Accordingly, this particular analysis shows that for small clusters, the vibrational and rotational motions should be taken into account for more precise results. Thus, this type of study can be important to the growing mechanism of molecular clusters. Although the structures are similar, one can see that there is a large difference when the internal motion of the molecule is taken into account, and this can certainly affect the growing process. For example, for CO_2–Ar_2 to CO_2–Ar_5, our cluster energies with BF are almost 9% higher than those calculated considering the CO_2 as rigid with the ab initio PEF. For these particular sizes, the mean percentage error values for BF with respect to SR and 3A potentials are less than 6%. However, as the number of atoms surrounding the molecule increases, one observes no effect at all, and this should be expected because the relaxation can be more efficient with the availability of more degrees of freedom.

As in the atomic cluster case, one can determine the second-difference energy, and this can produce possible magic numbers for molecular clusters such as the system un-

der analysis. Second-finite differences of the total energy are presented in Fig. 6 in which the values are calculated as $\Delta_2E = E_{n+1} + E_{n-1} - 2E_n$. This analysis gives information about the energetically relative stability of the geometries. The main trends of our results agree with the ab initio results. However, SR and BF potentials have different behaviors for the particular case of $3 \leq n \leq 9$. Through the peaks in the graph, several exceptionally stable structures are identified. In this work and for these small complexes, the structures CO_2–Ar_5, CO_2–Ar_7, CO_2–Ar_{12}, and CO_2–Ar_{16} are identified as being energetically more stable. The corresponding stable geometries for ab initio PEF are n = 3, 5, 7, 10, 11, and 16 and for the SR potential are n = 3, 6, 8, 10, 12, and 16. We can also see that CO_2–Ar_4, CO_2–Ar_6, CO_2–Ar_9, CO_2–Ar_{11}, and CO_2–Ar_{15} are the energetically less stable structures for the BF potential. On the other hand, n = 4, 6, 9, 11, 15, and 17 for the ab initio and n = 4, 7, 9, 11, 15, and 17 for the SR potential are relatively less stable clusters. Clearly, our results follow the same trends as previous studies (18).

Fig. 6. Second finite difference of the total energy for the obtained minimum-energy clusters (SR and ab initio values are taken from ref. 18).

Particularly for n = 14, the results of ref. 18 showed two structures, and we have also found two structures. One of these structures has a global minimum that is lower than the one found in ref. 18. From n = 14, the higher cluster order in our calculations differs from those in ref. 18 because of the differences in the growing process. Actually, the difference between higher structures arises because CO_2 is considered as non-rigid, and from small structures to large ones this will affect the growing process. For example, by comparing our n = 11 and n = 12 with those in ref. 18, one can observe that the cage formation is slightly twisted and this affects the next atom added to the cage. To analyze this point, the distances between the CO_2 molecule and the Ar atoms was calculated. Figure 5 illustrates the displacements of argon atoms from molecular atoms as a function of the number of surrounding atoms (n) in the optimized structures of the clusters up to CO_2–Ar_{21}. This type of analysis can help to determine the growing pattern. In this case, the system is described by BF potential. Maximum, minimum, and mean distances from first oxygen (Ar–O1), second oxygen (Ar–O2), and carbon (Ar–C) are monitored to demonstrate the close packing of the clusters during the growing process. In the case of CO_2–Ar, the distance between the argon atom and each of the oxygens is 3.84 Å, and this produces a T-shaped configuration. For the CO_2–Ar_2 structure, it is also approximately the same value. The growing process, in principle, can be separated into three regimes, namely, small (n up to 6), medium (n up to 15), and large (n up to 21). For the first regime, argon atoms fill the favorable equatorial sites of the molecule, and hence, for n = 1–6, one observes that the effects of the oxygens on the growing pattern are almost the same. For example, argon atoms prefer to locate in equal distances. However, in the medium-size case, argon atoms start to grow around one of the oxygen atoms (here, it is the O2 atom), and the displacement lines for O1 and O2 are absolutely different. Particularly for n = 7, the maximum distance of the argon atom from O2 is 4.43 Å, and it is shorter than the case for n = 6 (4.69 Å). However, the distance from the other oxygen atom (O1) is 5.64 Å in CO_2–Ar_7. Minimum distances for Ar–O1 vary between 3.84 Å (n = 1), and the lowest value of 3.36 Å (n = 11). For n = 7

© 2007 NRC Canada

and 9, the minimum Ar–O2 distances are 3.43 and 3.94 Å, respectively. In the second regime, argon atoms construct a closed-shell lattice covering one of the oxygen atoms, O2. For n = 7–9, the minimum distances from O2 increase, i.e., the lattice becomes larger around this oxygen. It continues to cover the molecule by adding atoms in the shell towards the oxygen O1.

Increasing the number of atoms leads to a closed-packing system. Especially for Ar–C distances, the internal atoms of the clusters come closer to the molecule, as shown in Fig. 5. The minimum distance of an atom from C is the shifted position of the closest argon atom around the center of CO_2. When the number of argons becomes 15, the closest argon is at a distance of 3.51 Å. However, for n = 7–15, the maximum displacement from the C atom is almost the same (see Fig. 5), and at n = 15, it reaches the lowest value (4.41 Å) in this regime. The different structural reorientations cause sudden increases and fluctuations in the maximum pair distances. For n = 14–18, all the structures are in different orientations even though they are in closed-shells. For example, the addition of an atom to CO_2–Ar_{15} leads to a new reorientation. The minimum and maximum pair distances increase suddenly for Ar–C displacements. The transformation to the spherical form of CO_2–Ar_{17} from CO_2–Ar_{16} decreases the distances. In the CO_2–Ar_{17} structure, argons are in symmetric locations with respect to the molecule, and the minimum and maximum distances between the argon and oxygen atoms are 3.53 and 6.07 Å, respectively. These values are 3.59 and 4.92 Å, respectively, for Ar–C distances. For more than 17 argon atoms, it turns back to an expected growing pattern based on the geometry of the CO_2–Ar_{17} cluster. For higher orders, i.e., n = 18–21, the mean displacements slightly increase. This corresponds to a growing process that seems to be concentrated only on the Ar–Ar potential interaction. For n > 18, it has also been found in ref. 18 that there is a small contribution from the CO_2 interaction, and this does not affect the growing process at all with respect to the molecule.

Summary and conclusion

To predict the structures of CO_2–Ar_n clusters, the primary non-rigid dynamics of the Ar + CO_2–Ar_{n-1} → CO_2–Ar_n collision process has been investigated in detail by means of classical MD analysis. The collision energy of the projectile atom and the orientation of the target cluster produced different trajectories. For all interactions, the energy transfers are obtained in the fusion regime of atom–cluster collision phenomena. The pairwise-additive PEF considered here gives a good structural and energetical agreement with previous available results (18). The potential used in this work (eq. [2]) gives an opportunity for considering the non-rigid molecular case. We obtained similar geometries and comparable energy values of the well depth at the minimum-energy T-shaped structure with the non-rigid pair-additive case. The minimum-energy structures produce similar features for the initial completed first solvation shell for n = 14. The largest value of n, for which all argon atoms are found in the inner solvation shell, is 17. Owing to these good agreements, we believe that the PEF and MD techniques may be used for investigating the effects of internal motion of CO_2 and any other thermodynamic properties, such as melting and fragmentation, for Ar_nCO_2 clusters.

The present study has also shown that the BF potential can also be considered as a model for understanding the growing mechanisms with a suitable construction of the PEF used. In addition, we have described the particle interactions in the system with pair-additive approaches, and the results agree well with previous studies (18). Accordingly, it can be concluded that these studies produced a comprehensive analysis of the dominant effects on cluster-growing phenomena. Finally, we have demonstrated that clusters of atom–molecule complexes can be obtained through one-atom collisions with the stable structures of smaller clusters. The rearrangement collision procedure used in this work provides an efficient tool for generating possible candidates for the ground-state and higher-energy structures of these types of clusters.

Heterogeneities in sol–gel-derived paramagnetics-doped forsterites and willemites — Electron microprobe analysis and stretched-exponential ^{29}Si MAS NMR spin–lattice relaxation studies

J. Stephen Hartman, Arjun Narayanan, Suzie S. Rigby, David R. Sliwinski, Norman M. Halden, and Alex D. Bain

Abstract: We report the synthesis and analysis of sol–gel-derived samples of forsterite (Mg_2SiO_4) and willemite (Zn_2SiO_4), doped with paramagnetic Cu^{2+}, Ni^{2+}, and Co^{2+}, at a range of dopant concentrations. Electron probe microanalysis and backscattered electron imaging show the presence of major micrometre-scale heterogeneities in the distribution of paramagnetic centres. Despite the inhomogeneities, the ^{29}Si NMR spin–lattice relaxation behaviour is well-behaved and is consistent with the stretched-exponential expression $M_z(t) = M_z(\infty)\{1 - a \exp[-(t/T')^n]\}$. The exponent n is 0.5 within the experimental error in some samples. This value is consistent with relaxation by immobile isolated paramagnetic impurities with negligible ^{29}Si spin diffusion from the impurity centres, but careful curve fitting confirms that n is significantly larger than 0.5 in other samples. Relaxation efficiency is highly dependent on the dopant ion and its concentration. Although the purely empirical stretched-exponential function does not provide a unique physical picture, it is noteworthy that it is sufficiently robust to describe spin–lattice relaxation even in highly inhomogeneous systems. Spin–lattice relaxation is a useful probe of paramagnetics-doped solid samples, but NMR does not provide information on homogeneity. Careful sample characterization on the micrometre scale is highly desirable, as a complement to NMR studies.

Key words: MAS NMR, spin–lattice relaxation, ^{29}Si, forsterite, willemite, stretched-exponential relaxation, sol–gel, minor-component heterogeneity, backscattered electron analysis.

Résumé : On rapporte la synthèse et l'analyse d'échantillons dérivés de sol–gels de forsterite (Mg_2SiO_4) et willémite (Zn_2SiO_4) dopés avec des quantités diverses des ions paramagnétiques Cu^{2+}, Ni^{2+} et Co^{2+}. Une microanalyse avec une sonde électronique et l'obtention d'images électroniques avec rétrodiffusion montrent la présence d'importantes hétérogénéités à l'échelle du micrométre dans la distribution des centres paramagnétiques. Malgré les inhomogénéités, le comportement de relaxation spin–réseau du spectre RMN du ^{29}Si se comporte normalement et il est en accord avec l'expression exponentielle étendue $M_z(t) = M_z(\infty)\{1 - a \exp[-(t/T')^n]\}$. Aux erreurs expérimentales près, l'exposant n est égal à 0,5 dans certains échantillons. Cette valeur est en accord avec une relaxation par des impuretés paramagnétiques isolées immobiles avec une diffusion négligeable du spin ^{29}Si à partir des centres d'impureté; toutefois, des ajustements soignés des courbes indiquent toutefois que la valeur de n est largement supérieure à 0,5 dans d'autres échantillons. L'efficacité de la relaxation dépend fortement de l'ion dopant et de sa concentration. Même si la fonction exponentielle étendue qui est strictement empirique ne fournit pas une image physique unique, il est bon de noter qu'elle est suffisamment robuste pour décrire la relaxation spin–réseau même dans des systèmes hautement inhomogènes. La relaxation spin–réseau est un outil utile d'examen des échantillons solides dopés avec des produits paramagnétiques, mais la RMN ne fournit pas d'information sur l'homogénéité. Une caractérisation judicieuse de l'échantillon à l'échelle du micrométre est un complément très désirable aux études de RMN.

Mots-clés : RMN à l'angle magique de spin, relaxation spin–réseau, ^{29}Si, willémite, exponentielle de relaxation étendue, sol–gel, hétérogénéité du composant mineur, analyse électronique avec rétrodiffusion.

Introduction

Forsterite (Mg_2SiO_4) and willemite (Zn_2SiO_4) are relatively simple nesosilicates (i.e., no Si–O–Si bridging, also called orthosilicates, or Q° silicates) (1, 2). Both readily undergo isomorphous replacement of the octahedral Mg^{2+}, or tetrahedral Zn^{2+}, by doubly charged paramagnetic transition-metal 2+ ions and can be readily synthesized by sol–gel (3) as well as classical (4) procedures. Because of this, they appeared to be well suited to serve as model systems for ^{29}Si NMR relaxation behaviour of natural silicate minerals with their trace amounts of various paramagnetic ions. Forsterite has been extensively studied by a variety of NMR techniques involving all possible magnetic nuclei (5–8). We report here our sol–gel synthesis, electron microprobe analysis, and ^{29}Si NMR spin–lattice relaxation studies of paramagnetics-doped synthetic forsterites and willemites.

Since the pioneering work of Lippmaa and coworkers in 1980 (9), high-resolution solid-state ^{29}Si NMR with magic angle spinning (MAS) (10, 11) has become an important tool in mineralogy (12–14) and materials science (15). It soon became evident that different samples of the same natural silicate mineral can give widely differing ^{29}Si NMR resolution and sensitivity (16–20). The variations are primarily due to the effects of dilute paramagnetic impurities, normally transition-metal cations replacing diamagnetic cations. Different samples of the same mineral typically have different impurities, present in different concentrations, and even trace amounts of paramagnetic impurities can have profound effects on both spin–lattice and spin–spin relaxation. Even before the advent of MAS, it was recognized that paramagnetic impurities facilitate ^{29}Si spin–lattice relaxation in solids (21).

The presence of randomly distributed paramagnetic centres creates a hierarchy of magnetic nuclei, differing only in their distance from a paramagnetic site. The nearer the ^{29}Si atoms are to the paramagnetic site, the more readily they relax (a T_1 effect) but also the broader the signals become (a T_2 effect (22), which can be supplemented by further broadening arising from magnetic susceptibility (23)). "In ordered systems, the sites are all the same and relax in random order, leading to an exponentially decaying signal. Paradoxically, in disordered systems the sites relax in a hierarchical order because disorder makes the sites different." (24). The NMR signal of a sample with fixed paramagnetic impurities is inherently a composite signal arising from many different local regions, each with its own peak width and its own spin–lattice relaxation time. Iwamiya and Gerstein (25) were apparently the first to recognize that the ^{29}Si spin–lattice relaxation in some zeolites was not exponential. We first reported stretched-exponential ^{29}Si spin–lattice relaxation in doped silicate minerals in 1991 (26) and have explored the phenomenon in other systems (27–29).

Spin–lattice relaxation by fixed paramagnetic impurities occurs via the electron–nuclear dipolar interaction, which has an inverse sixth-power distance dependence. This problem is usually treated by assigning "spheres of influence" to the paramagnetic impurities, each of which causes relaxation of the nuclei that lie within its sphere. Tse and Hartmann (30) considered the case of relaxation by paramagnetic impurities in the absence of spin diffusion and derived the following expression for stretched-exponential relaxation, with $n = 1/2$:

$$[1] \qquad M_z(t) = M_z(\infty)[1 - a \exp[-(t/T')^n]\}$$

In this equation, $M_z(t)$ is the z magnetization at time t, a is a parameter that reflects the z magnetization at time zero, and T' is the time constant for the recovery. If $n = 1$, then the recovery is exponential and T' becomes the normal spin–lattice relaxation time, T_1.

Following synthesis by well-established sol–gel methods, our brightly coloured doped samples appeared to be homogeneous by optical microscopy, but electron microprobe studies unexpectedly revealed a high degree of heterogeneity in the dopant ion distribution on the micrometre scale. Thus, our samples, being heterogeneous, cannot serve as model homogeneously doped systems. However, minor-component inhomogeneity turns out to be a common, and often overlooked, feature of naturally occurring minerals, as well as synthetic samples (31–34). This work emphasizes the desirability of element-specific electron microprobe analysis in the study of sol–gel-derived samples, especially those involving dopant ions, before drawing conclusions from solid-state NMR studies.

Experimental section

Preparation of materials

Two different modifications of sol–gel preparation methods (3), referred to as methods A and B, were used in preparing the paramagnetics-doped mineral samples listed in Tables 1 and 2. Both synthetic methods give colourless undoped forsterite and willemite but coloured paramagnetics-doped materials: Cu^{2+} (blue), Ni^{2+} (green), and Co^{2+} (pink forsterites but blue willemites, consistent with the change in Co^{2+}-site coordination from octahedral in forsterite to tetrahedral in willemite (35)). Additional approaches to doped forsterite samples were attempted, based on the methods of Kido et al. (36) and Selvaraj et al. (37), but with less success. Attempts to obtain materials doped with Mn^{2+} and Fe^{2+} using similar methods led to complications because of oxidation of the transition-metal ion. We are confident that the +2 oxidation state is retained for the Ni, Cu, and Co dopants on the basis of (*i*) the colours of the samples, and (*ii*) the fact that the +2 oxidation state is the most stable state for all of these metal ions, with weak-field ligands such as oxides (35).

Method A

Based on the approach to the synthesis of undoped forsterite developed by Kazakos et al. (38), this method was used to prepare paramagnetics-doped forsterites and willemites. For forsterites, $Mg(NO_3)_2{\cdot}6H_2O$ (Aldrich, USA) and the desired molar proportion of the transition-metal nitrate $Cu(NO_3)_2{\cdot}5H_2O$, $Ni(NO_3)_2{\cdot}6H_2O$, or $Co(NO_3)_2{\cdot}6H_2O$ (all from Aldrich, USA) were weighed into a Teflon beaker and dissolved with stirring in 95% ethanol, followed by pipetting in the stoichiometric quantity of tetraethylorthosilicate (TEOS; Aldrich, USA) while stirring. Solvents were removed between 60 °C and 80 °C in a water bath, whereupon gelation occurred. The clear, coloured gels were dried at 110 °C in air, followed by heating for 2 h at 400 °C in a

tube furnace in platinum-lined combustion boats, followed by firing overnight at 1050 °C. Similar procedures, using $Zn(NO_3)_2{\cdot}6H_2O$ instead of $Mg(NO_3)_2{\cdot}6H_2O$, were carried out to prepare paramagnetics-doped willemites.

Method B

Based on the work of Rehspringer et al. (39), this method was used to prepare further paramagnetics-doped forsterites. Magnesium ethoxide (Johnson Matthey Electronics, London, UK) and the transition-metal alkoxide ($Cu(OEt)_2$, Johnson Matthey Electronics, London, UK) or transition-metal acetylacetonate ($Cu(acac)_2$, $Ni(acac)_2$, or $Co(acac)_2$, all from Gelest Inc., PA, USA) were dissolved in dry methanol and glacial acetic acid in a Teflon beaker, and an alcoholic solution of TEOS was added with stirring. Typically, to prepare forsterite with 3% of its Mg replaced by Ni, 2.42 g (0.0212 mol) of $Mg(OEt)_2$ and 0.163 g (6.3×10^{-4} mol) of $Ni(acac)_2$ were added to a Teflon beaker, then 30 mL of dry methanol were added, followed by 5 mL of glacial acetic acid, under continuous stirring. After 5 min, a clear green solution was obtained. 2.43 mL (0.0109 mol) of TEOS was then pipetted into the beaker, followed by 3 mL of distilled water. Heating the solution between 60 and 80 °C for 2.5 h under continuous stirring to remove excess solvent led to the formation of a clear green gel, which was dried at 110 °C in air, then fired overnight at 1050 °C. Some samples were further heated at 1200 °C for up to a week, but this gave negligible change in their NMR behaviour.

Characterization of materials

Powder-pattern X-ray diffraction analysis was carried out on a Picker X-ray diffractometer with Cu Kα radiation (λ = 1.5418 Å), scanning at 1° per minute at a chart speed of 1 inch per minute. Mineral phases were identified by their *d* spacings. Alternatively, a Phillips PW1710 Automated Powder Diffractometer System instrument was used, with a dedicated IBM PC computer system using the Fein–Marquardt PDSM–Micro Powder Diffraction Search Match program. The analyses showed the desired mineral (forsterite or willemite) as the only major component, with typically up to a few percent of a single minor component: periclase (MgO) or enstatite ($MgSiO_3$) in forsterites, or zincite (ZnO) in some willemite samples. All of these are consistent with slight deviations from the desired stoichiometry of the reaction mixture. No attempt was made to quantify the amount of minor components.

The synthetic forsterites and willemites were analyzed for Ni, Cu, and Co by direct current plasma atomic emission (DCP) spectroscopy (40), using a Beckmann Spectra Scan DCP optical emission spectrophotometer. Background scans for each analyte were performed on standard solutions.

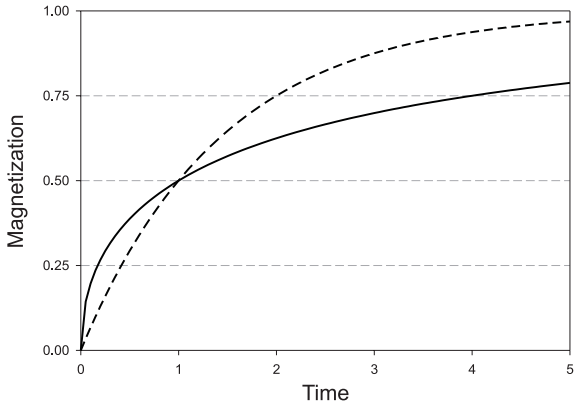
Wavelengths used were 312.598 nm for Cu, 340.512 nm for Co, and 231.604 nm for Ni. Forsterite samples were dissolved in a 1:8:2 mixture of nitric, hydrofluoric, and perchloric acids, and the solutions were diluted with 1% nitric acid. The undoped mineral, forsterite or willemite, was dissolved and added to the standard solutions used in the calibration to match the matrices of the sample solutions.

Electron microprobe studies (41) of selected samples were carried out using backscattered electrons (BSE) and point analysis on a CAMECA SX100 instrument in wavelength-dispersive mode. Small amounts of each sample were mounted in epoxy resin, care being taken to separate as many grains as possible. The very fine-grained nature of the samples resulted in the development of a few large aggregations consisting of a number of crystals. Within individual aggregations, the grain size of the willemite and forsterite crystals typically ranged from 10 to 50 μm; some grains and fragments were as large as 100 μm. The samples were gently polished and carbon coated. The willemite samples took a better polish, while the forsterite samples had a tendency to form a more "spongy" or rough surface. Beam conditions were established at 20 kV and 20 nA for Co, Ni, Cu, and Zn analysis, and 15 kV and 20 nA for Si and Mg. A beam diameter of 1 μm was used for point analysis. Well-characterized forsterite, willemite, and cuprite mineral standards were used to calibrate Mg, Si, Cu, and Zn, and a compound Co and Ni silicate standard was used for Co and Ni.

NMR instrumentation and methods

^{29}Si MAS NMR spectra were obtained on Bruker AC-200 and AM-500 spectrometers at magnetic fields of 4.7 T (frequency of 39.76 MHz) and 11.7 Tesla (frequency of 99.32 MHz), respectively. At 4.7 T, a home-built MAS probe of the Andrew–Beams type was used with a spinning speed of about 3 kHz. Typical spectra were obtained with 8 K data points and spectral widths of 10–50 kHz. Spectra at 11.7 T were obtained using a Doty 5 mm MAS probe with spinning speeds of 3 and 8 kHz. The 90°-pulse widths on the Bruker AC-200 and AM-500 instruments were typically 15–25 and 5.5 μs, respectively.

The saturation-recovery method (saturating comb – τ – 90°) (22) was used for the determination of spin–lattice relaxation behaviour. For the faster-relaxing samples, a train of 50–100 very closely spaced 1–5 μs pulses was used. The delays between pulses should not all be the same; we used various schemes and found that a repeating sequence of three different delay times in the ratio of 10:9:8 gave effective nulling of the magnetization. To adequately determine the exponent n as well as the time constant T' of eq. [1], data sets of 15 to 20 τ values were obtained.



The closely spaced saturating comb of 90° pulses of the saturation-recovery method damaged the capacitors of our home-built 4.7 T MAS probe, so the inversion-recovery method (180° – τ – 90° – fixed delay) was used on this instrument for the fastest-relaxing samples. However, systematic errors can arise if the fixed delay between repetitions of the inversion-recovery pulse sequence is inadequate (22), and the "long-tailed" nature of the stretched-exponential decay curve (Fig. 1) exacerbates this problem. Conservative fixed delays of $100 \times T'$ (rather than the $5 \times T_1$ that is adequate for greater than 99% magnetization recovery when relaxation is exponential) were chosen to ensure equilibration. Inversion-recovery and saturation-recovery methods were both employed for some samples, and excellent agreement between them was obtained, provided that inversion-recovery fixed delays of at least $100 \times T'$ were used. However, the inversion-recovery method is impractical with slow-relaxing samples, especially when relaxation is stretched-exponential.

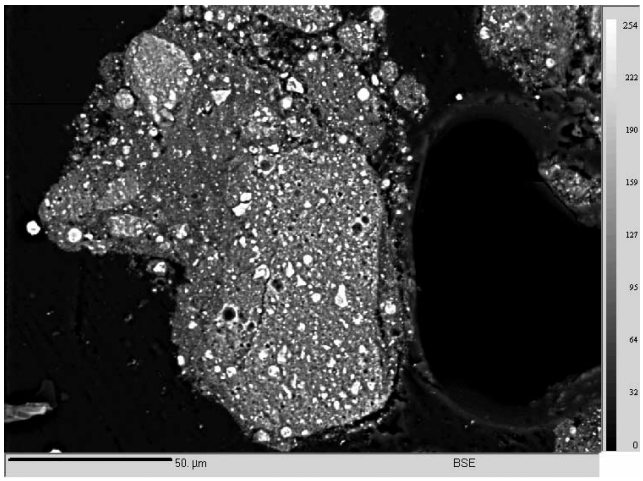
Data analysis

The time constant T' and the exponent n, indicating the degree of stretch of the stretched-exponential decay function, were obtained by fitting the data to the four-parameter

© 2007 NRC Canada

Fig. 1. Recovery of magnetization, following saturation, for a normal exponential (dashed line) and stretched exponential with $n = 0.5$ (solid line). Both recoveries have half-lives of 1 time unit.

stretched exponential function, where $M_z(\tau)$ is the macroscopic z magnetization at a time τ after a perturbing radio frequency pulse. Note that T', the time constant for nonexponential relaxation, differs from T_1, the time constant for exponential relaxation, unless the exponent n is equal to 1. The fits were carried out as described previously (28, 29), using commercially available software (Deltagraph Professional, Deltapoint Inc., Monterey, CA) as well as the program STRETCHR, developed by one of us (ADB), and were generally quite good despite the complication of allowing n to vary between 0.5 and 1 (29). The standard errors obtained from the fit are reported in Tables 1 and 2 along with the T' and n values. The 95% confidence intervals are usually 2–3 times the standard errors for both T' and n (29). We have shown (29) that the exponent n and the time constant T' are best determined if the τ values are chosen preferentially in the optimal regions 0, 0.2 T', 2.5 T', and 10 T'. With 15 to 20 τ values in each run, the optimal regions were well represented.



Results

Characterization of samples

Comparison of DCP analyses of the dopant concentrations with those calculated from the stoichiometry of the sol–gel synthesis starting mixtures showed that incorporation of copper was 10% to 20% less than expected, apparently because of volatilization during heating. Loss of copper was confirmed by the appearance of a green colour in the quartz tube of the tube furnace after heating at 1050 °C. In contrast, DCP analysis showed that the concentrations of Co and Ni in forsterites prepared by method B are normally 10% to 20% higher than expected from the starting material composition, consistent with some loss of silicon during the synthesis. A possible mechanism for the loss of silicon is through the exchange of ethoxy groups of TEOS with methoxy groups of methanol, which would give a more volatile silicon alkoxide. Similar problems have been reported when tetramethylorthosilicate (TMOS) was used as a sol–gel silicate precursor (42).

Optical microscopy at a magnification of 180 indicated that our initially prepared paramagnetics-doped samples were homogeneous. However, later electron microprobe

Fig. 2. Backscattered electron (BSE) image of a sol–gel synthesized nickel-doped forsterite sample in which 6.7% of the Mg is replaced by Ni, as determined by direct current plasma atomic emission (DCP) spectroscopy. The brightness scale corresponds to the level of Ni concentration, with the bright spots representing high Ni concentration.

studies, using backscattered electrons (BSE), on a selection of the willemite and forsterite samples showed that all of them are heterogeneous to varying extents on the micrometre scale. Figures 2 and 3 show BSE images of nickel-doped forsterite and willemite samples. Because the backscattering effectiveness of the transition-metal ions is much greater than that of Mg^{2+}, the BSE image gives a picture of the distribution of the paramagnetic ions. The mottled and zoned BSE patterns, on a scale of a few micrometres, show that the paramagnetic ions are inhomogeneously distributed. The mottled and zoned patterns of heavy element distribution have been confirmed by X-ray mapping and point analysis of these samples. Samples prepared by methods A and B were similarly heterogeneous.

The willemites show considerable variation in grey level in their backscattered electron images, corresponding to significant spatial variations in composition. The main variation observed is in the Zn/Si ratio. Light regions, typically rimming 20 µm grains, have a Zn/Si atomic ratio of about 1.8; darker (interior) regions have a ratio of about 1.2. In addition to the significant grey level variation within grains, there was also some variation between grains. Analysis of a number of bright grains showed that they consisted of ZnO, consistent with the powder pattern X-ray diffraction analysis. In the willemite of Table 2 and Fig. 3, where the overall Ni^{2+} content is nominally 5.8%, we get values of 0.52, 0.74, 0.53, and 0.64 atomic% Ni. This confirms that much of the Ni^{2+} has not been incorporated into the willemite lattice, consistent with its having partitioned into a minor component.

It was more difficult to get good electron microprobe analyses on the forsterite samples. Individual grains were relatively soft, so their surface did not polish well. However, significant grey level variations were observed, indicating chemical heterogeneity. In cases where multiple analyses were done on single grains, the most notable feature was the variation in the Mg/Si ratio. For example, the sample with a

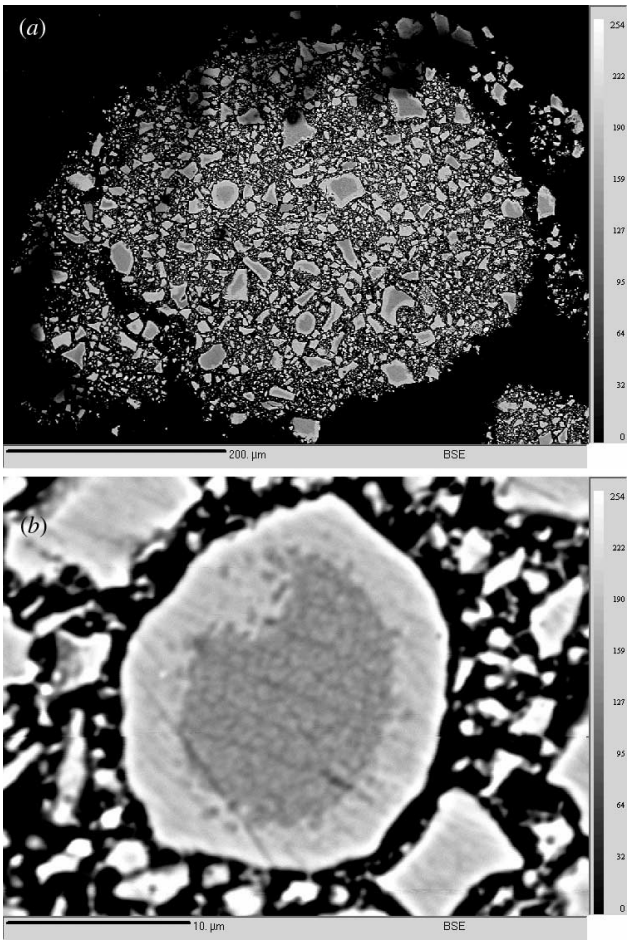

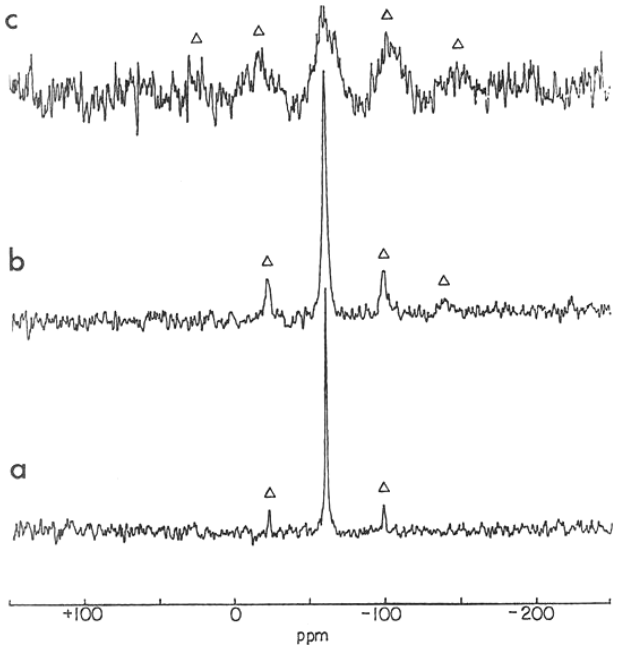

Fig. 4. 9.4 T (79.46 MHz) ^{29}Si MAS NMR spectra of Co^{2+}-doped forsterite at concentrations of (*a*) 0.018, (*b*) 0.87, and (*c*) 4.4 mol% (Co^{2+}/Mg^{2+}), from an early study of paramagnetics-doped forsterite in this laboratory.[2] Peaks marked with Δ are spinning sidebands.

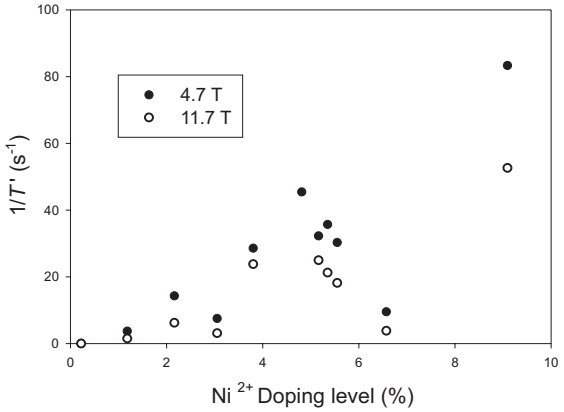
nominal concentration of 0.09 atomic% Cu^{2+} showed a Cu content of 0.01 atomic% by microprobe analysis; Mg/Si ratios at the same spots varied from 1.4 to 2.05, and other paramagnetic species were not detected. In the sample with a nominal Co content of 5.7 atomic%, electron microprobe analyses detected 0.58 and 0.62 atomic% and a Mg/Si ratio of 1.97 and 1.64, respectively. Other samples gave much better agreement between electron microprobe analysis results and the values expected from sample composition. As with the willemite samples, this variation suggests that in some samples, only a fraction of the paramagnetic ion is incorporated into the forsterite lattice.

NMR studies



The single sharp ^{29}Si MAS NMR peaks of forsterite (–61.7 ppm from TMS; lit. –61.9 ppm) (43, 44) and willemite (–70.7 ppm) are consistent with the single silicon environment in each mineral and the lack of bridging oxygens (1). Increasing the concentration of the paramagnetic ion increases the number and relative intensity of the spinning sidebands and broadens the peaks, in the usual fashion (Fig. 4, Tables 1 and 2) (19, 45, 46), but does not appreciably change the chemical shift. The paramagnetic ions broaden the signal to different extents: $Ni^{2+} < Cu^{2+} << Co^{2+}$ for forsterites but $Co^{2+} < Cu^{2+} << Ni^{2+}$ for willemites, for similar concentrations of the transition-metal ions. Nuclear relaxation in paramagnetic systems can be complex and is affected by a number of factors related to the electronic states of a transition-metal ion (47, 48), which we have not investigated in the present work.

Tables 1 and 2 give the spin–lattice relaxation data for the paramagnetic-ion-doped forsterites and willemites at magnetic field strengths of 4.7 and 11.7 T. All samples exhibit stretched-exponential spin–lattice relaxation behaviour, with the exponent *n* being within experimental error of the theoretically expected (30, 49, 50) 0.5 in some cases (e.g., the Cu^{2+}-doped forsterites), but appreciably larger in other cases, with *n* values typically in the range of 0.6 and 0.7 (e.g., the Ni^{2+}-doped forsterites). Because of instrument time limitations, few relaxation studies were carried out on the slow-relaxing Ni^{2+}-doped willemites. Undoped synthetic forsterite and willemite relax extremely inefficiently, confirming that relaxation in our paramagnetics-doped samples is dominated by the dopant. Within each series, there is the expected trend to faster relaxation with increasing dopant concentration, but with a large amount of scatter (Fig. 5), consistent with widely varying incorporation of the para-

Fig. 5. Stretched-exponential relaxation rate ($1/T'$), measured at two magnetic fields: 4.7 T and 11.7 T, as a function of Ni^{2+}-doping level in forsterites, as determined by direct current plasma atomic emission (DCP) spectroscopy on the bulk sample. The scatter is consistent with widely varying incorporation of Ni^{2+} into the forsterite lattice.

magnetic ion into the crystal lattice. The paramagnetic ions differ greatly in their ^{29}Si relaxation efficiency at equivalent concentrations, in the order of $Ni^{2+} > Cu^{2+} >> Co^{2+}$ for forsterites (Table 1) but $Co^{2+} >> Cu^{2+} > Ni^{2+}$ for willemites (Table 2). In the forsterites, Ni^{2+} gives the sharpest ^{29}Si signal and also the most efficient relaxation; whereas, it gives the broadest ^{29}Si signal and is the least effective in promoting spin–lattice relaxation in the willemites. This is consistent with the zoning seen in the willemite of Fig. 3.

The additional parameter makes it inherently more difficult to fit the stretched-exponential curve with variable n than the simple exponential ($n = 1$) curve (29), and errors are large in the determination of the exponent n. Moreover, in the fit, there is a high correlation between the parameters T' and n (29, 51). However, it is clear that at both magnetic fields, the Ni^{2+}-doped forsterites consistently have $n > 0.5$, while the Cu^{2+}-doped forsterites have n within experimental error of 0.5, the value expected for relaxation by randomly distributed paramagnetic impurities in the absence of spin diffusion (30, 49, 52). The Co^{2+}-doped forsterites probably have $n > 0.5$, but there are large uncertainties. The Cu^{2+}- and Co^{2+}-doped willemites have exponents approximately equal to, and greater than, 0.5, respectively.

Spin–lattice relaxation is less efficient at 11.7 T than at 4.7 T (Fig. 5), as expected from spectral-density considerations (22). There is also the possibility that there might be some residual spin diffusion effect when the stretched exponent is greater than 0.5. In that case, because of the larger Curie moment at higher magnetic field, the barrier radius to spin diffusion would increase, thus increasing the efficiency of nuclear relaxation. There was no apparent increase in spin–lattice relaxation efficiency when samples were stationary rather than spinning or (at 11.7 T) when spinning at 3 kHz rather than 8 kHz. Magic-angle spinning can suppress spin diffusion (53) and its contribution to spin–lattice relaxation. The absence of a spinning-rate dependence in this work supports our proposal that spin diffusion has a negligible effect on spin–lattice relaxation in our systems.

Discussion

Sample inhomogeneity

Our samples are intriguingly complex on the micrometre scale, but this is not evident from their NMR spectra. Attaining sample homogeneity from multicomponent sol–gel systems is difficult because the different components can hydrolyse at very different rates, and often more than a single phase is obtained (54, 55). The existence of a second phase in many of our samples, as described in the experimental section, allows partitioning of the transition-metal ion between major and minor phases: forsterite and MgO, forsterite and enstatite ($MgSiO_3$), or willemite and ZnO. This allows the transition-metal ion concentration in the major forsterite or willemite phase to differ greatly from that calculated from the overall sample composition. Partitioning preferentially into the minor phase, or along grain boundaries (as is evident in Fig. 3*b*), would deplete its concentration in the major phase and diminish its effectiveness in promoting spin–lattice relaxation.

We have found NMR evidence for such partitioning in a related study in which both forsterite and enstatite are present as major phases. Ni^{2+} doping, whether at a level of 0.2% or 5% replacement of Mg^{2+}, causes ^{29}Si in enstatite to relax faster than ^{29}Si in forsterite by a factor of ~4; whereas, Cu^{2+} doping at the same levels causes ^{29}Si in forsterite to relax more efficiently than ^{29}Si in enstatite. Clearly Ni^{2+} partitions into enstatite, while Cu^{2+} prefers forsterite. Such partitioning also occurs in natural mineral assemblages. Thus, Fe^{3+} partitions into kyanite in preference to quartz, making ^{29}Si spin–lattice relaxation far more efficient for the kyanite than for the quartz phase (27).

However minor-component inhomogeneity is not limited to systems containing more than one phase. Although it has often been assumed that minor impurities within a single phase are homogeneously distributed, it is possible to generate oscillatory zoning in synthetic single crystals (34). Trace element variation is also a feature of many natural minerals (31) and is most commonly seen in the form of oscillatory banding. Microbeam analytical techniques are necessary to detect micrometre-scale mineral zoning (32, 33). In natural systems, such variations are thought to be the product of differential diffusion of the various components that make up the phase, and similar processes may be in operation during the synthesis of our samples. Minor and trace elements can also accumulate along mineral cleavages, fractures, and grain boundaries (56).

Other complexities can arise in paramagnetics-doped systems. For example, if clusters of paramagnetic ions form, each cluster could simulate a single paramagnetic centre, with the result that there are fewer such centres, and relaxation should be less efficient. From such reasoning, Sen and Stebbins have concluded that clustering of Nd^{3+} ions must be occurring in SiO_2 glass (57).

Trends in ^{29}Si spin–lattice relaxation among samples

The much greater effectiveness of Ni^{2+} on spin–lattice relaxation in forsterite than in willemite is of interest. Ni^{2+} should be capable of substitution into the distorted octahedral Mg^{2+} sites in forsterite and into the tetrahedral Zn^{2+} site in willemite, and both octahedral and tetrahedral Ni^{2+} have

© 2007 NRC Canada

two unpaired electrons. We cannot exclude major differences in electron T_1 in the two very different Ni^{2+} environments, which would affect the likelihood of nuclear spin flips. Also, we cannot exclude clustering of the paramagnetic ion in willemite, as proposed by Sen and Stebbins for clustering of Nd^{3+} in SiO_2 glass (57). However, the great broadening of the ^{29}Si NMR signal by Ni^{2+} in willemites is consistent with the very inhomogeneous distribution of Ni^{2+}, with a high concentration at the grain boundaries, as shown in Fig. 3*b*. This should give rise to a large anisotropy in bulk magnetic susceptibility and large paramagnetics-induced line broadening (58, 59) but should be poor at relaxing the ^{29}Si. Essentially little Ni^{2+} is incorporated in these samples because we find that their T' values are similar to the value of the undoped willemite (Table 2).

Although forsterite has a relatively simple structure compared with many silicates, it does have two crystallographically nonequivalent sites for the M^{2+} ions (1). It has been shown that Ni, Co, and Zn prefer to go into the smaller M1 site, while Mn prefers to go into the M2 site (1). Moreover, several workers have found that the Mg^{2+}–M^{2+} distribution in natural and synthetic olivines (of which forsterite is the Mg end member) is not random as previously assumed, but is dependent upon temperature, oxygen fugacity, and composition (60, 61). Such complicating factors would be important in highly homogeneous monophasic samples; however, given the micrometre-scale inhomogeneity of our samples, we can neglect them here.

Alternative approaches to describing nonexponential relaxation

Nonexponential spin–lattice relaxation is often observed for ^{29}Si and other rare-spin nuclei in solids. ^{29}Si relaxation has been dealt with by either a stretched-exponential (27–29, 62, 63) or a power law (57, 64, 65) approach, with the latter having the feature that the power law exponent is directly proportional to the fractal dimension of the material (64). Nonexponential spin–lattice relaxation of other nuclei has also been handled by the stretched-exponential (66, 67) and power-law (68, 69) expressions. The two are not mutually exclusive, but the power law is valid only in the early stages of the relaxation process, before the "spheres of influence" of individual paramagnetic centres begin to overlap. A modified model has been developed, in which the relaxation behaviour is expressed as an error function (51). These authors discuss the relative merits of the different models of nonexponential relaxation and emphasize that all of them are approximations with their own strong and weak points.

Another possible approach is via multiple exponentials (70, 71). Istratov and Vyvenko discuss the complications arising when there are several exponents with similar time constants (70). The stretched exponential, although not discussed by these authors, could be considered as a limiting case of this, with a very large number of individual components. However, Istratov and Vyvenko conclude that the use of multiple exponents with similar time constants is inherently an "ill-posed problem"; there seems to be no advantage over the stretched-exponential approach.

Exponents intermediate between 0.5 and 1, such as we report here (Tables 1 and 2), have been observed in a number of earlier studies (28, 29, 64, 72, 73). Yesinowski and Baker (66), in studying ^{13}C spin–lattice relaxation in diamond formed by chemical vapour deposition, have concluded that electron–electron dipolar interactions, causing mutual electron–electron spin flips that will affect nearby nuclei, can be responsible for increasing the value of the exponent n. They also found that n diminished and the T' value increased as the spin rate increased, indicating that spin diffusion was not fully quenched despite the low natural abundance of ^{13}C. We detected no dependence of ^{29}Si spin–lattice relaxation effectiveness on spin rate, consistent with the results of Hayashi et al. in some of their mineral systems (74–76), indicating that spin diffusion among ^{29}Si atoms, which would be decreased by MAS, is ineffective. However Hayashi did find a dependence on spin rate in some systems (77). In ^{29}Si-enriched materials spin diffusion does appear to be effective because relaxation is exponential rather than stretched-exponential (78).

Some caveats

This work illustrates the following concerns that apply to many NMR studies of solids and need to be more widely recognized.

(1) Both natural and synthetic minerals can be inhomogeneous on the micrometre scale, and often have features such as banding of minor components, even when only one phase is present. Electron microprobe methods have great value in detecting such features.

(2) Spin–lattice relaxation in solids is often nonexponential, and this possibility should always be considered. Various models exist to deal with nonexponential spin–lattice relaxation, and one of the most generally applicable is the stretched-exponential model. The inability to obtain a good null for any value of the variable delay time, following the 180° inversion pulse in an inversion-recovery experiment, indicates a hierarchy of relaxation environments. The faster-relaxing broad signal recovers more quickly while the slower-relaxing sharp signal is still inverted so that, at the closest approach to a null, an inverted sharp peak is superimposed on a broad peak with positive intensity. Such a pattern is often observed in inversion-recovery NMR experiments on solids (e.g., see Fig. 7 in ref. 73 and Fig. 6 in ref. 79) and indicates that relaxation is not exponential and that a T' rather than a T_1 value should be determined.

(3) T_1 calculation software normally assumes exponential relaxation and readily generates "pseudo-T_1" values even when relaxation is nonexponential. We find that these are often within a factor of 2 of the actual T' values, so they can give at least an order-of-magnitude estimate of relaxation efficiency. However, such values can be misleading and are not adequate for quantitative work.

(4) When relaxation is nonexponential, the inversion-recovery sequence (fixed delay – 180° – τ – 90° – AQ) (80, 81) should not be used because of the very long "tail" of the recovery curve. Unless relaxation is very fast, no feasible value of fixed delay is likely to be long enough to ensure full recovery of the magnetization. This is illustrated by Fig. 1. A fixed delay that would be adequate for exponential relaxation will not allow the detection of whole populations of nuclei far from a

© 2007 NRC Canada

paramagnetic centre, which relax very slowly, leading to a reported relaxation time based mainly on the faster-relaxing regions of the sample. The saturation-recovery sequence (saturating comb – τ – 90° – AQ) eliminates this problem because it does not require equilibrium magnetization to be established, and it should be used instead. However, the use of peak height to determine signal intensity can introduce error, since peak widths differ in different local regions. Peak area rather than peak height can be determined, or sufficient line broadening can be applied so that the height advantage of the inherently sharp components becomes negligible.

(5) Letting n in eq. [1] vary rather than fixing it at 0.5 improves the fit in many systems in which relaxation is stretched-exponential, but the physical significance of fractional n values larger than 0.5 is not clear. It must be kept in mind that all of the models for nonexponential relaxation involve approximations (51, 70).

Conclusions

Preparing synthetic paramagnetics-doped minerals to avoid the complexities associated with natural minerals may merely replace one set of complexities by yet another, since the dopant ions themselves do not readily become homogeneously distributed. The stretched-exponential expression does provide a useful empirical description of spin–lattice relaxation caused by immobile paramagnetic impurities in solids even if the distribution of the paramagnetics is highly inhomogeneous. NMR alone gives little indication of the degree of inhomogeneity in such samples, and it is desirable to determine sample homogeneity on the micrometre scale by a microbeam analytical technique such as BSE before drawing structural conclusions from NMR studies.

The trends in spin–lattice relaxation with paramagnetic-ion concentration in our doped forsterites and willemites are as expected, while the striking dependence on the specific paramagnetic ion merits further study.

Towards the development of a covalently tethered MALDI system — A study of allyl-modified MALDI matrixes

Sanela Martic, John D. Brennan, Michael A. Brook, Suzanne Ackloo, and Noemi Nagy

Abstract: An emerging application of matrix-assisted laser desorption ionization (MALDI) mass spectrometry is the analysis of low molecular weight (LMW) compounds, often via coupled liquid chromatography – MALDI-MS methods. However, in many cases, the low molecular weight region of MALDI mass spectra is obscured by the presence of signals originating from the matrix, suggesting that the development of tethered MALDI matrixes may be required to optimize MS performance for such compounds. To gain insight into potential sites for covalent attachment of MALDI matrixes, we have systematically investigated the role played by a variety of functional group motifs in determining matrix efficiency for three common MALDI matrixes, as judged both by total signal intensity and background noise from matrix decomposition for a set of LMW compounds. A series of allyl derivatives of standard matrixes was prepared, and the efficiency of these materials in the MALDI experiment was measured. All modifications of established matrixes, e.g., 2,5-dihydroxybenzoic acid (DHB), α-cyano-4-hydroxycinnamic acid (CHCA), and caffeic acid (CA), or close analogues led to decreased absolute signal intensity and signal-to-background levels. Improved performance was generally observed with (*i*) the presence of a phenolic group (carboxylic acids were less effective) (*ii*) crystalline derivatives, and (*iii*) compounds that had high extinction coefficients at wavelengths near to that of the exciting laser (337 nm). The most interesting derivatives were the *O*-allyl ether (**15**) and *N*-allyl amide (**16**) of caffeic acid. These compounds did not facilitate signals from all four analytes tested. However, the observed spectra contained fewer signals from the matrix than from the parent compound CA. These compounds demonstrate that functionalization of MALDI matrixes, ultimately leading to tethered matrixes, is possible without jeopardizing signal intensity.

Key words: MALDI, protected matrix, phenol, caffeic acid, allyl ether.

Résumé : L'analyse de composés de faibles masses moléculaires (FMM) est une application émergente de la spectrométrie de masse à désorption-ionisation au laser assistée par la matrice (SM MALDI), souvent couplée à des méthodes de chromatographie liquide. Toutefois, la région des faibles masses moléculaires des SM MALDI est souvent obscurcie par la présence de signaux provenant de la matrice ce qui suggère l'intérêt de développer de matrices MALDI liées pour optimiser la performance de la SM de tels composés. Afin d'identifier des sites potentiels de liaison pour relier d'une façon covalente les matrices MALDI et en se basant sur l'intensité totale du signal et le bruit de fond provenant de la décomposition de la matrice pour un ensemble de composés de faible masse moléculaire, on a examiné systématiquement le rôle qui est joué par une variété de motifs de groupes dans la détermination de l'efficacité de la matrice de trois matrices MALDI usuelles. On a préparé une série de dérivés allyliques de matrices standards et on a mesuré l'efficacité de ces matériaux dans l'expérience MALDI. Les modifications aux matrices établies, telles celles de l'acide 2,5-dihydroxybenzoïque (ADHB), de l'acide α-cyano-4-hydroxycinnamique (ACHC) et de l'acide caféique (AC) ou de produits fortement apparentés ont toutes conduit à des diminutions absolues de l'intensité du signal et des niveaux de signal à bruit de fond. On a généralement observé une amélioration de la performance avec: (*i*) une présence de groupe phénolique quoique celle d'acides carboxyliques ait été moins efficace, (*ii*) des dérivés cristallins et (*iii*) des composés dont le coefficient d'extinction est élevé à des longueurs d'onde se rapprochant de celle (337 nm) du laser excitant. Les dérivés les plus intéressants sont les dérivés de l'acide caféique comportant un groupe éther *O*-allyle (**15**) ou un amide *N*-allyle (**16**). Ces composés n'ont pas facilité les signaux de chacun des quatre analytes examinés. Toutefois, les spectres observés comportaient moins de signaux provenant de la matrice que celui de l'acide caféique fondamental. Ces composés démontrent qu'il est possible de fonctionnaliser des matrices MALDI, conduisant finalement à des matrices liées, sans mettre en péril l'intensité du signal.

[Traduit par la Rédaction]

Introduction

Since the development of matrix-assisted laser desorption ionization (MALDI) mass spectrometry in late 1980s (1), numerous advances have been made to expand its applicability and usability. Generally, MALDI is less demanding with respect to the purity of the sample than the electrospray ionization (ESI) technique. Other advantages such as reduction in signal suppression (2, 3), the presence of predominantly singly charged ions (i.e., relatively simple spectra), higher sensitivity, tolerance for salts and impurities (4, 5), and wide mass range (~300 kDa) make this method highly desirable for rapid and automated qualitative analysis.

Typically, UV–MALDI involves the use of an organic UV-absorbing molecule that co-crystallizes with the analyte, absorbs UV laser light, and effectively transfers energy to the analyte, and thus in turn leads to analyte desorption and ionization. MALDI has been successfully employed in the study of biomolecules (peptides, proteins, oligonucleotides, nucleic acids, carbohydrates, and so forth) and synthetic polymers. In general, a large molar excess of matrix:sample (from 100:1 to 1000 0:1) is used, since the matrix serves as the primary (and highly efficient) absorber of the UV laser radiation and breaks down rapidly, expanding into the gas phase (6).

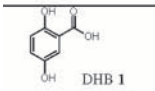
Although the choice of matrix is generally a product of trial and error, several characteristics are generally considered to be necessary for good MALDI performance of the matrix. These include the following: efficient UV absorbance near the irradiation wavelength, crystallization of the matrix, and the presence of relevant chemical functionalities that act as a proton source. The organic molecules that are currently used as MALDI matrixes strongly absorb near 337 nm (emission wavelength of a nitrogen laser), undergo extensive crystallization, and are generally substituted phenols, carboxylic acids, and (or) amines, such as 2,5-dihydroxybenzoic acid (DHB) (**1**), α-cyano-4-hydroxycinnamic acid (CHCA) (**2**), caffeic acid (CA) (**3**), and so forth.

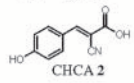
An emerging application of MALDI-MS is the analysis of low molecular weight (LMW) compounds (5, 7, 8, 9), either directly or via coupled liquid chromatography – MALDI-MS methods (5). However, a potential drawback of MALDI-MS is that the analysis of LMW species is difficult, since the clusters and multimers formed by the matrix can lead to LMW peaks that obscure those of the analyte (10, 11).

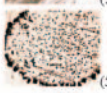
A number of different approaches have been developed to minimize the extent to which matrix-related interferences are present in the low molecular mass region of the spectrum. For example, in the case where it is convenient to use more analyte than matrix, it is possible to suppress matrix signals (8). However, analytes in normal applications are frequently available only in very low quantities, for example, from compound libraries; a matrix that generates obscuring signals in such cases in not practicable. In an alternative approach, interfacing of MALDI with tandem mass spectrometry (MS-MS) can allow selective detection of LMW compounds with minimal matrix background (5,7). However, this requires more specialized instrumentation, and thus, the method cannot be utilized with conventional MALDI-TOF MS systems. Alternatively, several materials that do not contain an organic matrix have been used as MALDI supports, including porous silicon (DIOS) (12, 13) and fine metal oxide inorganic particles, such as TiO_2 and ZnO (14). These newly developed methods use materials of high photoabsorptivity, low heat capacity, and large surface area. The methods produce minimal molecular fragmentation of analytes and can allow for great sensitivity. However, they exhibit limited capacity in terms of number of shots per spot. Thus, there is still a need for improved MALDI matrix materials, particularly for the analysis of compounds in the LMW region.

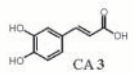
An alternative approach incorporates a photoactive matrix within a supporting film through either physical or covalent interactions. For example, Hutchens et al. have developed the surface-enhanced neat desorption (SEND) technique, in which energy-absorbing CHCA was covalently attached to the polymer by a photolabile ester linkage and was able to ionize covalently bound biomolecules as CHCA adducts (15). Alternatively, simply premixing the organic matrix, at various concentrations, with the silica precursor $Si(OEt)_4$ (TEOS), in the sol, leads to a photoactive film suitable for LMW compound analysis, which has been labeled sol–gel-assisted laser desorption ionization (SGALDI) (16, 17, 18). In yet another approach, a chemically modified silica gel, developed using an isocyanate spacer as a linker between the organic matrix and the preformed sol–gel, was successfully used as a MALDI support (19). The use of such silicas as MALDI supports can lead to the successful ionization and desorption of analytes; however, average signal intensity and therefore limits of detection are greatly compromised.

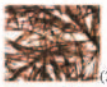
Given that there is a precedent both for covalent immobilization of matrix molecules to polymers (15) and for the use of silica as a support for MALDI (16–19), we are interested in exploring the development of sol–gel-based silica materials containing covalently bound matrix molecules as supports for MALDI-MS. To gain insight into potential sites for covalent attachment of MALDI matrixes, we have systematically investigated the role played by a variety of functional group motifs in determining matrix efficiency for three common MALDI matrixes, as judged both by total signal intensity and background noise from matrix oligomers for a set of LMW compounds. We report here the preparation of a series of derivatives of classical matrixes and analyze their ability to facilitate the MALDI experiment for a series of representative analytes.

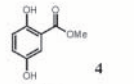


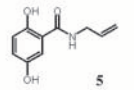


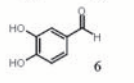


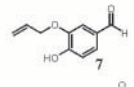


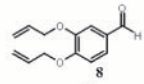


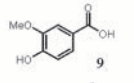


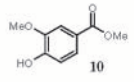


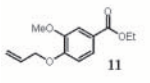


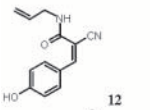


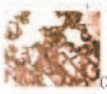


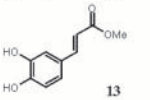


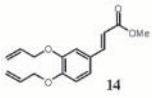


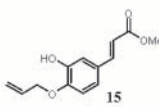


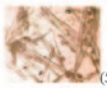


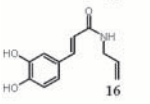












Results

Synthesis

The compounds examined as potential, new MALDI matrixes (Table 1) are derivatives of 2,5-dihydroxybenzoic acid (DHB) (**4**, **5**), related phenol aldehydes (**6**, **7**, **8**), acid derivatives (**9**, **10**, **11**), an α-cyano-4-hydroxycinnamic acid deriva-

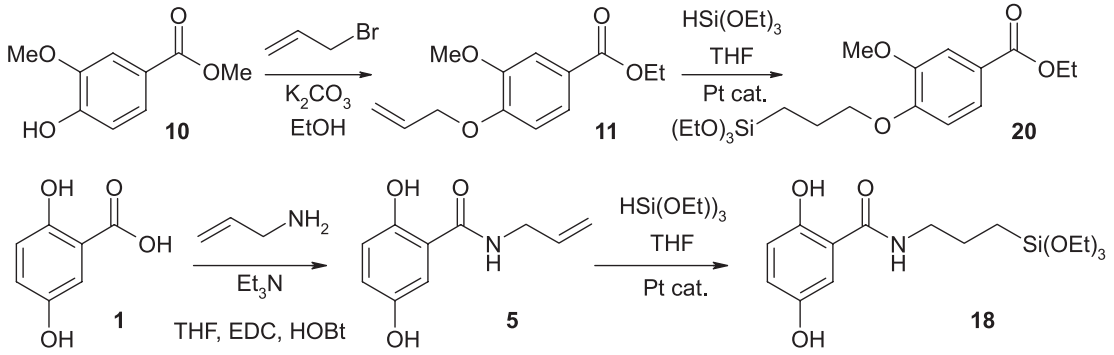
[e]This compound exhibited particularly inconsistent relative intensities among TMP, FLU, and HP.

tive (CHCA) (**12**), and caffeic acid (CA) derivatives (**13**, **14**, **15**, **16**), respectively. In general, all compounds were prepared using protecting group chemistry to allow the introduction of allyl groups in various forms and at various locations. Such groups are well established starting points for further elaboration to triethoxysilyl derivatives, based on hydrosilylation with $HSi(OEt)_3$, catalyzed by Karstedts Pt(0) catalyst, to create compounds such as those represented by **17**–**20**, which should permit the incorporation of these materials into sol–gel-derived T or TQ resins (20).[3] Although hydrosilylation is generally a very efficient reaction (Scheme 1), certain functional groups, particularly amines and aldehydes, can complex with the platinum catalyst or divert the reaction to undesired products. For example, it was not possible to silylate **8**, **12**, or **16** under a variety of conditions.

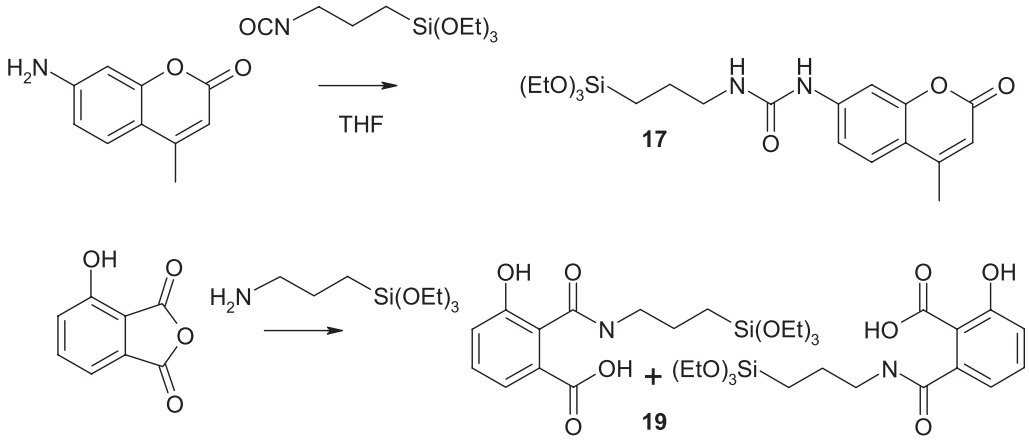
The starting compounds noted above are polyfunctional, usually containing both phenols and (or) carboxylic acids. Allyl groups were usually introduced in one of two complementary ways, using either Williamson etherification of phenols or amidation of carboxylic acids by the carbodiimide-catalyzed reaction of allylamine with the carboxylic acid (Scheme 1). During phenol etherification and subsequently for hydrosilylation experiments with triethoxysilane, it was generally necessary to protect carboxylic acids (20). We note that other chemical approaches can also be used to prepare silylated starting materials, including the modification of hydroxyphthalic anhydride with a common silane linker aminopropyltriethoxysilane (APTS) and the direct reaction of isocyanatopropyltriethoxysilane (IPTES) with 7-amino-4-methylcoumarin (Scheme 2). However, for the purposes of this study, it was sufficient to prepare allyl derivatives to allow for investigation of the roles of functional groups in supporting the MALDI process.

UV studies and crystal morphology



It has been reported that MALDI performance strongly correlates with both UV absorbance (21) and crystallinity (22, 23); however, some matrixes that lack crystal structure can perform well (24). The UV characteristics and representative optical micrographs of the parent compounds and allylated derivatives are collated in Table 1 (the synthetically modified matrix analogues were each (~20 mg) typically dissolved in 0.1% TFA:acetonitrile (1 mL; 50:50 *v*/*v* or 25:75 *v*/*v*) mixtures and were deposited on a MALDI support, such as a stainless steel plate, to give the micrographs shown). The solvent composition was varied for most matrixes to obtain optimal crystals (highest degree of crystallinity, without occluded solvent) that would lead to maximal signal intensities of the analytes. Multiple spots of these matrixes were used to generate average analyte intensities.

The nature of the functional groups greatly affected the UV molar extinction coefficients at the wavelength of the ni-



[3]T resins are derived from trifunctional silicon species, e.g., $RSi(OR')_3 + H_2O \rightarrow 3\ R'OH + RSi(O_{3/2})_n$, the latter is a T resin. Analogously, silica is a Q (quatrafunctional silicon species) resin: $Si(OR')_4 + H_2O \rightarrow 4\ R'OH + Si(O_{4/2})_n$. This nomenclature, commonly used for silicones, can also be used in combination (M, monofunctional; D, difunctional; T, trifunctional; and Q, quatrafunctional), for example, in TQ resins, see ref. 20.

trogen laser, 337 nm, typically used in the MALDI experiment. Notably, a laser change to 355 nm did not enhance the matrix performance in the samples studied, and therefore, the N_2 laser was the standard source used. Modifications of DHB did not significantly change the extinction coefficient (**4**, **5**), but derivatives of 3,4-dihydroxybenzoic acid (**6**–**11**), the CHCA derivative (**12**), and the CA derivatives (**13**–**16**) all had lower extinction coefficients. Therefore, the performance of these materials is expected to be less than that of the parent compounds.

Chart 1. Structures of fluorescein, trimethoprim, and haloperidol.

Effect of functional groups on MALDI efficiency

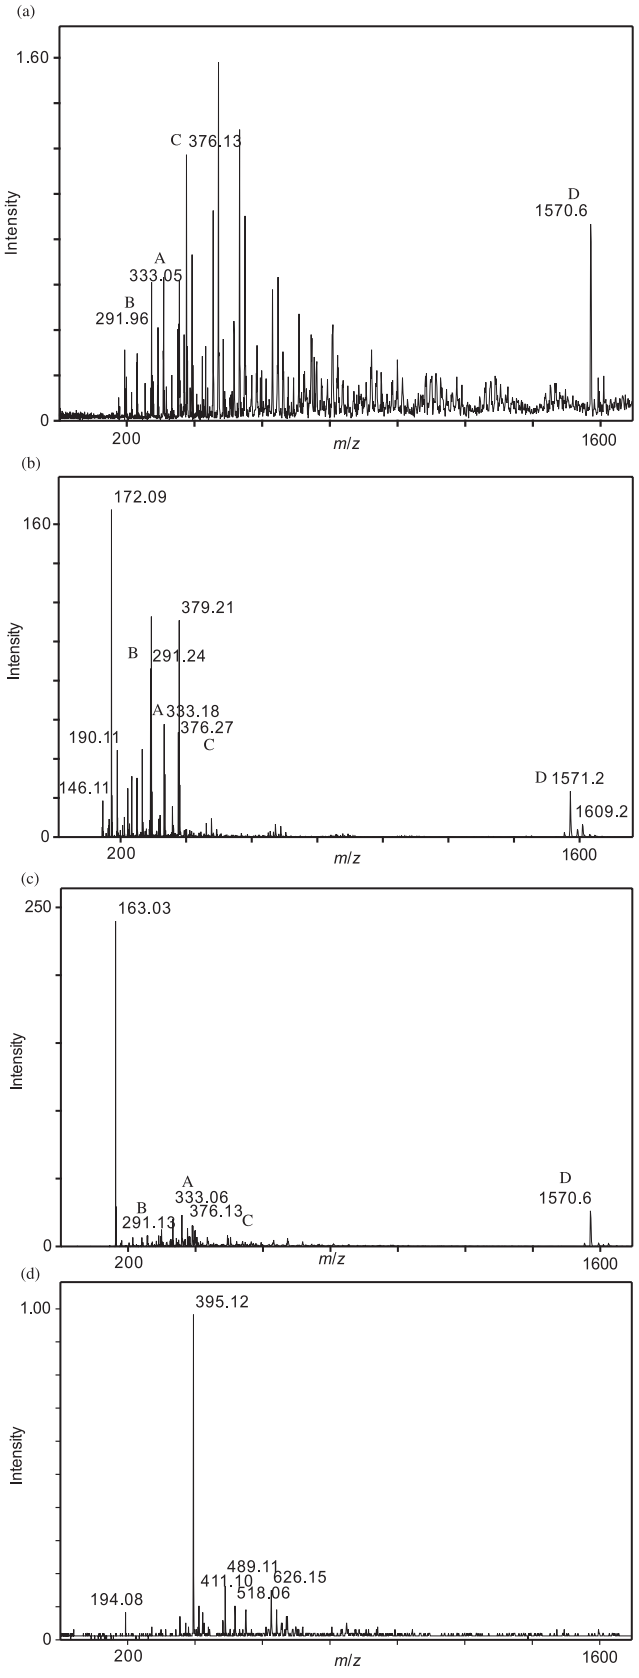
Four representative analytes were chosen for the study: haloperidol (HP, neutral, MW 375), trimethoprim (TMP, cationic, MW 290), fluorescein (FLU, anionic, MW 332) (see Chart 1), and the oligopeptide glu-fibrinopeptide (glu-fib, EGVNDNEEGFFSAR, MW 1570, a higher molecular weight, anionic, oligopeptide analyte). Preliminary experiments using conventional MALDI matrixes (DHB and CHCA) led to the following optimized conditions for MALDI experiments: 50:50 *v*/*v* acetonitrile : 0.1% trifluoroacetic acid (in water) solvent composition, 16 μJ laser intensity, 20 mg/mL matrix concentration, and 2.5 ng/μL analyte concentration. The same conditions were applied to the derivatized matrixes to study their efficiency solely as a function of chemical modification (i.e., a head-to-head comparison of the parent matrixes and their derivatives). The matrix performance under these conditions was judged solely on average signal intensity and matrix interference. We have also studied the effect of matrix:analyte ratio, where analyte concentrations used were 0.01 ng/μL, 0.04 ng/μL, 0.1 ng/μL, 1 ng/μL, and 2.5 ng/μL (20 mg/mL matrix concentration) to determine the detection limit of most matrixes. We found that most matrixes performed optimally when 1–2.5 ng/μL analyte concentration was used. In the second study, a laser intensity was varied in the range of 4–31 μJ. With the increase in laser power, the analyte signal increased, but this was accompanied by a significant increase in the overall matrix signal intensity, making the spectral in-

© 2007 NRC Canada

terpretation more complex. A laser intensity of 16 μJ led to adequate analyte signals with minimal matrix interference, and it was adopted as the optimized condition.

When MALDI-MS of glu-fib, trimethoprim, haloperidol, and fluorescein was performed using three standard matrix compounds, DHB **1**, CHCA **2**, and CA **3**, ionization of all four analytes was generally achieved (Table 1). The spectra were typically confounded by many peaks originating from the matrix (Fig. 1). However, it was interesting to note that the highest signal typically corresponded to the highest ϵ_{337nm} (CHCA > CA > DHB), which suggests that the facility for photoexcitation is a critical factor for the activation of the specific matrixes. These data provide a positive control for the remaining matrix compounds. Because these matrixes possess both phenols and an acid, it was unclear which of the functional groups plays the most important role in facilitating the ionization.

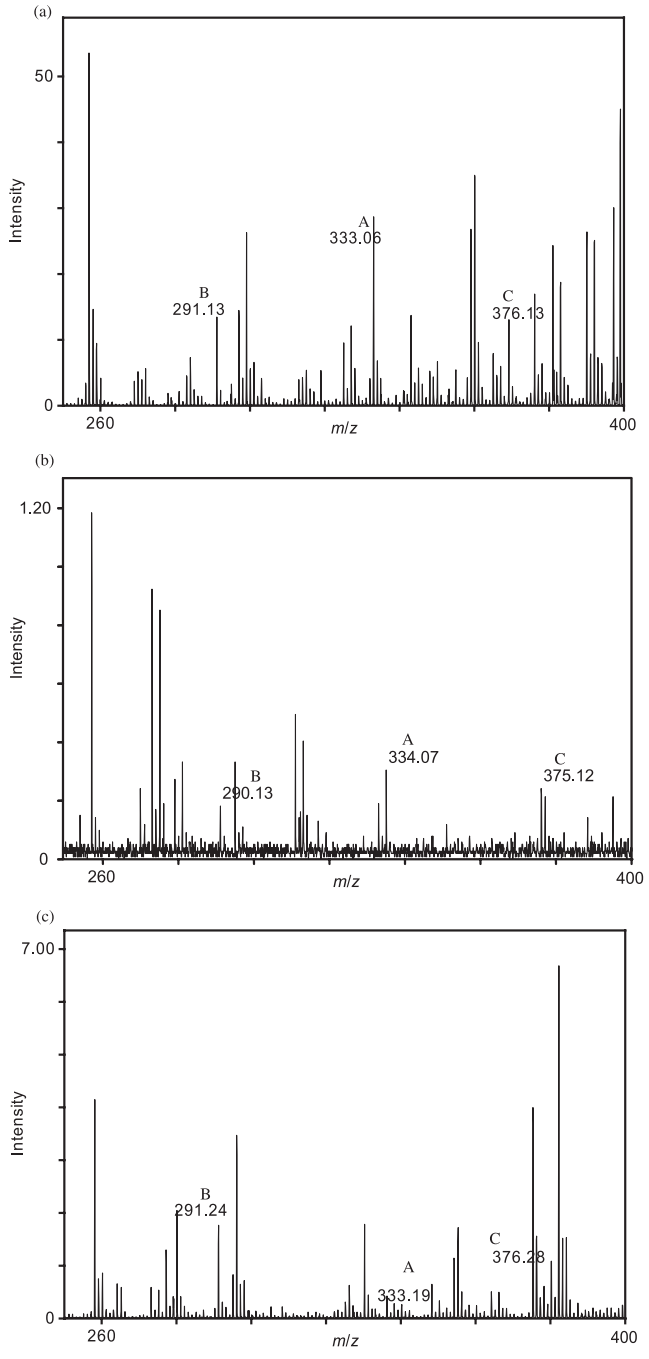
Two general classes of modifications were made on the original matrixes. In the first case, phenols remained uncapped, but carboxylic acids were replaced by aldehydes, esters, or amides. In the second case, phenols were capped, and free carboxylic acids were present. The results of the MALDI experiments obtained under identical conditions are shown in Table 1. Among the compounds studied, the best MALDI performance (for fluorescein, haloperidol, and TMP, but not glu-fib, Fig. 2), as judged by signal to background (S:B) ratios, was obtained using matrixes that possessed either one or two phenol groups, irrespective of the presence of an acid group, and a conjugated carbonyl group ion, e.g., allyl ether (**15**), and *N*-allylamide derivatives of CA (**16).** However, several compounds did not result in any analyte ionization. These could be divided into two classes: those with free phenols but protected carboxylic acids (**4**, **5**), and those with absorption wavelengths far from 337 nm (**7**, **8**, **14**). Note that two compounds (**10**, **11**) with λ_{max} far from 337 nm were still effective matrixes, but only for TMP.



For those derivatized compounds that were effective matrixes, absolute ion intensities were far lower than with their parent compounds (Table 1). The efficiency of the matrix to promote analyte ionization is, thus, highly dependent on the nature of the available matrix functional groups. A significant suppression of matrix signals was observed with some matrixes. For example, the matrix noise correlated with DHB is almost 100 times higher than the matrix noise observed for its allylamide (**5**) derivative (Fig. 1*d*). Regrettably, the lower noise in these cases is not accompanied by higher signal:background levels (Table 1).

Discussion

Ionization mechanisms in MALDI are believed to involve chemical and (or) thermal ionization mechanisms, such as gas-phase photoionization, ion–molecule reactions, disproportionation, excited-state proton transfer, energy pooling, thermal ionization, and desorption of preformed ions (25).



In the case of standard acidic matrixes, gas-phase proton transfer reactions between matrix ions and analyte are regarded as the main ionization pathway (21). MALDI spectra are generally populated with singly charged protonated, sodiated, or potassiated ions, as well as numerous matrix-related signals in the low mass region. Several studies, dem-

onstrating that the source of protons is a phenol rather than a carboxylic acid, have been published (26–29). It is certain that the acidic properties of the aromatic derivatives are strongly enhanced when molecules are laser-excited, and phenols are known to be more acidic in the gas phase than carboxylic acids (30).

Some authors found the derivatization of the phenolic groups to strongly degrade MALDI efficiency of the matrix, whereas others came to the opposite conclusion (31). It was further demonstrated that, with some free matrixes, exchangeable protons are not needed for ionization to take place. These results suggested that alternative mechanisms may be at play in the MALDI process. The explanation of what makes a material function as a matrix remains ambiguous. Irrespective of the specific mechanisms of ionization, factors including high UV-absorptivity at the wavelength of the laser, exchangeable protons, and, it has been argued, ease of crystallization and co-crystallization with analyte have been identified as key parameters affecting MALDI performance. These features have been examined in the series of allylated matrix analogues prepared, all of which led to significantly lower analyte signals than the standard matrixes DHB, CA, and CHCA, respectively.

It has been proposed that crystallization may be a key factor for effective MALDI matrixes (22). This contention is generally supported by the characteristics of the compounds prepared. Crystalline derivatives were in general more effective MALDI matrixes than amorphous compounds, e.g., **15** and **16**. However, this is not always true. For example, highly crystalline derivatives such as methyl 2,5-dihydroxybenzoate (**4**) failed to work as a matrix, while highly amorphous matrixes such as that derived from 3-methoxy-4-hydroxybenzoic acid (**9**) were effective at promoting selective TMP desorption and ionization, despite the absence of obvious crystals.

It was initially expected that compounds with a high extinction coefficient at 337 nm, the laser wavelength, would be highly effective matrixes. Indeed, compounds with absorption wavelengths far from 337 nm were not effective matrixes; however, many of the compounds with absorption maxima near this wavelength were also inactive as matrixes. Even compounds with relatively high extinction coefficients and λ_{max} close to 337 nm were not always effective, e.g., **13**. Thus, similar to the observations of Bashir et al. (26), UV absorption alone is not a sufficient criterion for selecting a useful matrix; two similarly absorbing molecules may perform completely differently.

It has been reported that an exchangeable phenolic or carboxylic acid proton is needed for proton transfer in the MALDI process (31). The synthesized compounds that acted as matrixes possessed at least one free phenol group (**9**–**13**, **15**, **16**). However, neither the presence of a phenol or a carboxylic acid is a guarantee of efficacy. For example, compounds **4** and **5**, both subtle, crystalline variations of DHB with similar λ_{max} and extinction coefficients, were not effective matrixes. By contrast, the most effective matrixes had free phenols and additionally were β-substituents of α,β-unsaturated carbonyl systems. These findings strongly suggest that such species should form a useful starting point for the preparation of silylated derivatives and ultimately covalently bound matrix systems.

The generally prepared protected matrixes exhibited different analyte selectivities from their non-modified parent compounds in addition to a significant attenuation of total signal and signal to background levels. The clearest demonstration of this is the comparison of compounds **13** and **15**. The latter exhibits a strong signal for HP and TMP, while the former only excited FLU effectively. In both cases, the matrixes lead to useful but selective signals. Utilization of these matrixes, therefore, needs to be accompanied by experiments to assess sensitivity to the analytes of interest.

© 2007 NRC Canada

Based on the objective to reduce LMW noise and to show efficacy across different analyte types, compounds **15** and **16** are of most interest. With respect to the key factors affecting matrix efficiency, a comparison of these compounds with their precursors CHCA **3** and **13** and the related derivative **14** is instructive. The order of efficacy based on the ability to enhance MALDI analyte signal intensity over background follows the order **3** » **15**, **16** > **13** » **14**. All compounds but **13** are crystalline; all have reasonably large extinction coefficients with λ_{max} values reasonably close to 337 nm, again except **14**. Compound **14** also has no free, acidic protons to be used for the proton transfer to analyte. It is not therefore surprising that **14** is an ineffective matrix.

The other compounds have, with the exception of **3**, which has a much higher extinction coefficient, very similar chemical and physical characteristics. The subtle differences are associated with the location and number of protecting groups. Free phenolic groups suffice to excite some of the analytes. The reduced signal to background ratio for **15** and **16**, when compared to **3**, is partially compensated for by the decrease in low molecular signals arising from the matrix (Fig. 2). An important finding is that the presence of the allyl group, key for the introduction of synthetic handles to permit binding to mineral oxide surfaces, reduces the efficacy of the MALDI matrix but does not destroy activity. This provides an opportunity to tether these materials to a variety of mineral oxide surfaces or to make mineral oxide films containing the matrix and use them as MALDI targets. Current work in this area is ongoing and shall be the subject of future reports.

Experimental

Chemicals

Allylamine, allyl bromide, 3-aminopropyltriethoxysilane (APTS), benzyl bromide, 3,5-dihydroxybenzaldehyde (**6**), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide, 1-hydroxybenzotriazole hydrate, 3-hydroxyphthalic anhydride, 3-methoxy-4-hydroxybenzoic acid (**9**), (3-isocyanatopropyl)triethoxysilane, tetraethyl orthosilicate (TEOS, 99.999%), platinum (0)-1,3-divinyl-1,1,3,3-tetramethyldisiloxane in xylene ($Pt_2[CH_2{=}CHSiMe_2OSiMe_2CH{=}CH_2]4$ 2–3% Pt in xylene (Karstedt's catalyst)), triethylamine, and trifluoroacetic acid (99.8%) were obtained from Aldrich Chemical Company Inc. (Milwaukee, WI, USA). 2,5-Dihydroxybenzoic acid, α-cyano-4-hydroxycinnamic acid, coumarin, caffeic acid, triethoxysilane, sulfuric acid (98%), 3,4-dihydroxycinnamic acid, and 0.1 N HCl were obtained from Sigma-Aldrich (St. Louis, MO). Methanol, diethyl ether, ethyl acetate, dimethylformamide, dimethylsulfoxide, tetrahydrofuran, ethanol, potassium carbonate, dichloromethane, hexane, potassium hydroxide, sodium hydroxide, sodium chloride, magnesium sulfate, thionyl chloride, and pyridine were purchased from Caledon Laboratories, Ltd. (Georgetown, ON). Silica gel and sodium bicarbonate were purchased from EMD Chemicals Inc. (Darmstadt, Germany), while sodium carbonate was purchased from EM Science (Gibbstown, NJ), and 7-amino-4-methylcoumarin was purchased from INDOFINE Chemical Co. (Hillsborough, NJ).

Characterization

^1H and ^{13}C NMR were performed on either a Bruker AC-200 (200.13 MHz) or a Bruker AC-300 (300.13 MHz) spectrometer. Solid state ^{13}C NMR was performed on a Bruker AC-300 (at 300.13 MHz for ^{13}C) solid state spectrometer. Samples were dissolved in chloroform-*d* ($CDCl_3$), DMSO-d_6, or methanol-d_4 with chemical shifts (ppm, δ) reported relative to TMS as a reference. Coupling constants *J* were recorded in Hertz (Hz).

FTIR studies were recorded on a Bruker Equinox 55 spectrometer. Peaks were reported in wavenumbers (cm^{-1}), and the samples were run pure in their solid or liquid state.

Mass spectrometry to characterize the structures of the synthesized matrixes was performed using electron ionization (EI), chemical ionization (CI), liquid-chromatography mass spectrometry (LC–MS), or electrospray ionization (ESI) techniques.

Optical microscopy (Olympus BX41) was used to study crystal morphologies of the matrixes on MALDI plates.

UV-absorption measurements of solutions were made in 96 well plates using a Tecan SAFIRE platereader (monochromator based with XFLUOR software) with a wavelength resolution of 1 nm. All spectra were obtained at the ambient temperature and had appropriate background signals subtracted. In general, the products were characterized using ^1H and ^{13}C NMR, EI-MS, CI-MS, ESI-MS, UV, LC–MS, FTIR, and fluorescence.

Synthesis of the protected matrixes

Methyl 2,5-dihydroxybenzoate (4)

To 2,5-dihydroxybenzoic acid (1.154 g, 7.487 mmol), dissolved in methanol (5.28 mL), was added 98% H_2SO_4 (0.678 mL, 8.970 mmol). After the reaction mixture was refluxed at 65 °C for 29 h, the solution was extracted using diethyl ether. After the evaporation of the organic fractions and recrystallization from water, a white solid was obtained (yield: 0.488 g, 72%; mp 76 °C).

λ_{max} = 332 nm, ϵ_{337nm} = 4347.44 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 416 and 496 nm. FTIR (neat) ν (cm^{-1}): 3745, 3335, 1686, 1337, 1216. ^1H NMR (MeOH-d_4, 200 MHz) δ: 4.10 (3H, s), 7.04 (1H, dd, *J* = 3.7, 8.9 Hz), 7.18 (1H, d, *J* = 3.2, 8.9 Hz), 7.44 (1H, t, *J* = 3.4 Hz), 10.5 (1H, s, 2-OH). ^{13}C NMR (MeOH-d_4, 200 MHz) δ: 52.4, 114.7, 118.5, 121.1, 124.1, 147.8, 154.9, 155.6. CI^+-MS *m*/*z* (%): 168 [M^+] (73), 136 [M^+ – OH] (100), 108 (21), 80 (8). EI^+-MS *m*/*z* (%): 168 [M^+] (36), 136 [M^+ – OH] (100), 121 (44), 108 (32), 80 (13). ESI-MS *m*/*z*: 196 (13), 169 [M + H]$^+$(100), 155 (16), 83 (8). LC–MS: r_t = 9.45 min.

N-*Allyl 2,5-dihydroxybenzamide (5)*

To 2,5-dihydroxybenzoic acid (3.1004 g, 0.0201 mol), dissolved in dry tetrahydrofuran (160 mL), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide (EDC) (4.307 g, 0.0221 mol, 1.1 equiv.), 1-hydroxybenzotriazole hydrate (HOBt) (2.723 g, 0.0201 mol, 1 equiv.), triethylamine (3.08 mL, 0.02211 mol, 1.1 equiv.), and DMAP (0.1608 g, 5%) were added. Previously dissolved allylamine (1.513 mL, 0.0201 mol, *d* = 0.76 g/mL) in THF was then added to the reaction flask. The mixture was stirred at room temperature overnight. Once the mixture was evaporated to dryness, the solid was dissolved in 0.1 N HCl and washed with ethyl acetate. Organic frac-

© 2007 NRC Canada

tions were washed with $NaHCO_3$, H_2O, NaCl, and brine and dried over $MgSO_4$. Column chromatography was performed with hexane : ethyl acetate (60:40 *v/v*) to remove residual allylamine and isolate the pure product as a white powder (yield: 1.0648 g, 34.3 %; mp 103 °C).

λ_{max} = 324 nm, ϵ_{337nm} = 4691.03 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 399, 441, 494 nm. FTIR (neat) ν (cm^{-1}): 3399, 3334, 1576, 1546, 1226, 993, 947. ^{1}H NMR (MeOH-d_4, 200 MHz) δ: 3.99 (2H, d, *J* = 5.2 Hz), 5.17 (1H, dd, *J* = 1.2, 10.3 Hz), 5.23 (1H, dd, *J* = 1.2, 17.2 Hz), 5.92 (1H, m, *J* = 5.2, 10.3, 19.4 Hz), 6.74 (1H, d, *J* = 8.8 Hz), 6.85 (1H, dd, *J* = 2.8, 8.8 Hz), 7.22 (1H, d, *J* = 2.8 Hz). ^{13}C NMR (MeOH-d_4, 200 MHz) δ: 42.8, 114.8, 116.2, 117.7, 118.9, 122.3, 135.5, 150.9, 153.5, 170.1. CI-MS *m/z* (%): 193 [M^+] (100), 175 (14), 164 (18), 136 (44), 108 (11). ESI-MS *m/z* (%): 306 [M + TFA]$^-$ (74), 238 [M + 45]$^-$ (97), 192 [M – H] (100), 138 (12), 112 (22). ESI-MS *m/z* (%): 194 [M + H]$^+$ (100), 65 (68), 216 [M + Na]$^+$ (12). CI-MS *m/z* (%): 193 (M^+). LC–MS: r_t= 8.18 min.

3-Allyloxy-4-hydroxybenzaldehyde + 4-allyloxy-3-hydroxybenzaldehyde (7); 3,4-diallyloxybenzaldehyde (8)

To 3,5-dihydroxybenzaldehyde (4.0234 g, 29.1 mmol), dissolved in 150 mL of absolute methanol, was added previously oven dried potassium carbonate (4.0273 g, 29.1 mmol). The mixture was heated to 50 °C, and allyl bromide (3.04 mL, 1.39 g/mL, 34.9 mmol) was added to the flask dropwise through a septum. The mixture was further heated to 60 °C and then refluxed overnight (16 h). After the solvent was evaporated, the brown liquid was dissolved in ethyl acetate and washed with 1 mol/L HCl until an acidic pH was obtained (pH = 6.2). After the separation and extraction with ethyl acetate, the organic fractions were washed with brine and dried with anhyd. $MgSO_4$. The organic solvent was evaporated, and the brown liquid was then separated using silica gel column chromatography with 3% methanol in dichloromethane as the solvent. Three different fractions were recovered: (*i*) monoallyloxy derivative (0.970 g, 24.5%; brown gel), (*ii*) diallyloxy derivative (0.8501 g, 21%; brown liquid), and (*iii*) mono/diallyloxy derivative mixture (yield: 1.8256 g, 45%; approximate mono/diallyloxy ratio in the mixture was 3.1:1 (from LC–MS intensity ratio)). Each fraction was separately characterized.

Monoallyl derivatives

λ_{max}= 322 nm, ϵ_{337nm} = 2411.54 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 395 and 433 nm. FTIR (neat) ν (cm^{-1}): 3420, 3090, 2980, 2860, 1681, 1548, 1508, 1271, 1125, 993. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 4.68 (2H, d, *J* = 5.4 Hz), 5.34 (1H, d, *J* = 19.5 Hz), 5.41 (1H, dd, *J* = 1.0, 17.3 Hz), 6.04 (1H, m), 6.94 (1H, d, *J* = 8.2 Hz), 7.38 (1H, dd, *J* = 1.8, 8.1 Hz), 7.48 (1H, d, *J* = 1.9 Hz), 9.80 (1H, s). ^{13}C NMR ($CDCl_3$, 200 MHz) δ: 69.9, 111.5, 114.4, 119.3, 124.5, 130.7, 131.9, 146.4, 150.9, 191.2. Methyl 4-hydroxy-3-methoxybenzoate (10)

After 3-methoxy-4-hydroxy benzoic acid (1.14 g, 6.7 mmol) was dissolved in methanol (50 mL) and cooled to 0 °C, thionyl chloride (2.44 mL, 33.8 mmol) was added dropwise through a rubber septum. The reaction mixture was stirred at room temperature for 20 h. The solvent was evaporated, and the mixture was extracted with diethyl ether, washed with sodium bicarbonate, water, sodium chloride, and brine. Organic fractions were evaporated to recover an ester as a white solid (yield: 0.974 g, 85.4%; mp. 59 °C).

λ_{max}= 292 nm, ϵ_{337nm} = 1054. 94 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 392 and 432 nm. FTIR (neat) ν (cm^{-1}): 3537, 3100, 3050, 2940, 1697, 1602, 1512, 1462, 1297, 1217, 1155, 777. ^{1}H NMR (MeOH-d_4, 200 MHz) δ: 3.84 (OCH_3, 3H), 3.88 (OCH_3, 3H), 6.82 (1H, d, *J* = 8.7 Hz), 7.51 (1H, s), 7.54 (1H, s). ^{13}C NMR (MeOH-d_4, 200 MHz) δ: 52.4, 56.4, 113.4, 115.9, 122.5, 124.9, 148.9, 152.8, 168.6. CI-MS *m/z* (%): 182 [M]$^+$ (85), 151 [M – OMe]$^+$ (100).

Ethyl 4-allyloxy-3-methoxybenzoate (11)

To a solution of 3-methoxy-4-hydroxy-ethyl benzoate (0.974 g, 5.35 mmol) in absolute ethanol (20 mL) was added previously oven dried potassium carbonate (0.739 g, 5.35 mmol). When the reaction mixture was heated to 50 °C, allyl bromide (0.539 g, 0.377 mL, 4.45 mmol) was added dropwise through a septum. The mixture was refluxed over night (16–18 h). After the solvent was evaporated, the brown liquid was dissolved in ethyl acetate and washed with 1 mol/L HCl until an acidic pH was obtained (pH = 6.2). After the separation of the organic fractions and extraction with ethyl acetate, the organic fractions were washed with brine and dried with anhyd. $MgSO_4$. The organic solvent was evaporated, and the brown liquid was then purified using silica gel column chromatography with hexane : ethyl acetate (60:40 *v/v*) mixture as the solvent. The yellow liquid was recovered in 42.5% yield (0.409 g).

λ_{max} = 294 nm, ϵ_{337nm} = 1076.60 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 392 and 433 nm. FTIR (neat) ν (cm^{-1}): 3084, 2981, 2930, 1708, 1599, 1511, 1267, 1214, 1018, 761. ^{1}H NMR (MeOH-d_4, 200 MHz) δ: 1.38 (3H, t, *J* = 7.2 Hz), 3.86 (OCH_3, 3H, s), 4.31 (2H, q, *J* = 7.2, 14.2 Hz), 4.62 (2H, d, *J* = 5.1 Hz), 5.26 (1H, d, *J* = 10.5 Hz), 5.41 (1H, dd, *J* = 1.4, 17.3 Hz), 6.05 (1H, m, *J* = 1.4, 16.7, 10.6 Hz), 6.96 (1H, d, *J* = 8.4 Hz), 7.54 (1H, d, *J* = 1.5 Hz), 7.60 (1H, q, *J* = 1.6, 8.4 Hz). ^{13}C NMR (MeOH-d_4, 200 MHz) δ: 14.6, 56.4, 61.9, 70.6, 113.4, 113.5, 118.1, 124.1, 124.6, 134.3, 150.5, 153.7, 167.9. CI-MS *m/z* (%): 237 [M^+] (100), 195 (28), 151 (9).

N-*Allyl-2-cyano-3-(4-hydoxy-phenyl)-acrylamide (12)*

To α-cyano-4-hydroxycinnamic acid (1.995 g, 0.0105 mol), dissolved in dry tetrahydrofuran (160 mL), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide (EDC) (2.2238 g, 0.0116 mol, 1.1 equiv.), 1-hydroxybenzotriazole hydrate (HOBt) (1.418 g, 0.0105 mol, 1 equiv.), triethylamine (1.617 mL, 0.0116 mol, 1.1 equiv.), and DMAP (0.0997 g, 5%) were added. Previously dissolved allylamine (0.788 mL, 0.0105 mol) in THF (3 mL) was added to the reaction flask. The mixture was stirred at room temperature overnight. After evaporating to dryness, the solid was dissolved in 0.1 N HCl and washed with ethyl acetate. The organic fractions were washed with $NaHCO_3$, H_2O, NaCl, and brine and dried over $MgSO_4$. Column chromatography was performed with hexane : ethyl acetate (60:40 *v*/*v*) to remove residual allylamine and isolate the pure product as the yellow powder (yield: 1.737 g, 87 %; mp 255 °C).

λ_{max} = 326 nm, ϵ_{337nm} = 8511.54 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 434 nm. FTIR (neat) ν (cm^{-1}): 3327, 3190, 2970, 2218, 1649, 1568, 1538, 1053. ^{1}H NMR (MeOH-d_4, 200 MHz) δ: 3.96 (2H, d, *J* = 5.3 Hz), 5.15 (1H, dd, *J* = 1.2, 10.5 Hz), 5.22 (1H, dd, *J* = 1.3, 18.9 Hz), 5.88 (1H, m, *J* = 6.9, 10.2, 18.3 Hz), 6.90 (2H, d, *J* = 8.7 Hz), 7.88 (2H, d, *J* = 8.7 Hz), 8.10 (1H, s), 9.76 (1H, 4-OH, s). ^{13}C NMR (MeOH-d_4, 200 MHz) δ: 41.7, 99.2, 114.4, 114.9, 115.3, 122.8, 132.5, 133.0, 151.3, 161.6, 161.9. CI^+-MS *m*/*z* (%): 228 [M^+] (94), 221 [M-17] (37), 290 (17), 172 (48), 123 (28), 107 (100).

Methyl 3,4-dihydroxycinnamate (13)

To 3,4-dihydroxycinnamic acid (4.7096 g, 26 mmol) in methanol (150 mL) at 0 °C was added thionyl chloride (13.5 mL, 0.183 mol) dropwise over 30 min. After stirring the mixture for 24 h, the solvent was evaporated, and the white solid was isolated. From the acidic medium/diethyl ether workup, the organic layers were combined, and the solvent was evaporated. Further purification, using silica column chromatography, was performed with chloroform:methanol (9:1 *v*/*v*). The final white solid was obtained in the 85% yield, 4.001 g; mp 158 °C.

λ_{max} = 324 nm, ϵ_{337nm} = 8544.87 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 426 nm. FTIR (neat) ν (cm^{-1}): 3501, 3450, 3319, 3019, 1704, 1257, 1177. ^{1}H NMR (MeOH-d_4, 200 MHz) δ: 3.74 (3H, s), 6.25 (1H, d, *J* = 15.9 Hz), 6.77 (1H, d, *J* = 8.1 Hz), 6.93 (1H, d, *J* = 8.1 Hz), 7.02 (1H, s), 7.53 (1H, d, *J* = 15.9 Hz). ^{13}C NMR (MeOH-d_4, 200 MHz) δ: 52.0, 114.8, 115.1, 116.5, 122.9, 127.7, 146.9, 149.6, 156.5, 169.7. ESI^+-MS *m*/*z* (%): 406 [2M + NH_4]$^+$ (23), 389 [2M + H]$^+$ (7), 221 (100), 194 [M + H]$^+$ (55). LC–MS: r_t= 15.18 min.

3,4-Diallyloxy-methyl cinnamate (14); 3-allyloxy-4-hydroxy-methyl cinnamate; 4-allyloxy-3-hydroxy-methyl cinnamate (15)

Anhydrous DMF (50 mL) was added to caffeic acid methyl ester (3.772 g, 0.0191 mol), sodium carbonate (3.314 g, 0.0385 mol), sodium iodide (1.005 g, 0.0064 mol), and allyl bromide (3.344 mL, 0.0401 mol). After the reaction was refluxed at 47 °C for 48 h, the solution was washed with aq. HCl and extracted with ethyl acetate. The combined organic fractions were evaporated to give a brown liquid that was separated using flash chromatography with a mixture of hexane: ethyl acetate (60:40 *v*/*v*). The monoallylated ester derivative was obtained as a white solid (yield: 0.6327 g, 17%). The diallyl derivative was isolated (yield: 0.4686 g, 12%) but was contaminated with the monoallyloxy species. The approximate mono/diallyloxy ratio in the mixture was 2.9:1 from LC–MS intensity ratio. The products were then recrystallized from hexane.

Monoallyl derivative

λ_{max} = 322 nm, ϵ_{337nm} = 10221.79 M^{-1} cm^{-1}, λ_{ex} = 340 nm, λ_{em} = 435 nm. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 3.78 (3H, s), 4.64 (2H, d, *J* = 5.0 Hz), 5.33 (1H, d, *J* = 10.6 Hz), 5.40 (1H, d, *J* = 17.4 Hz), 5.78 (1H, s, 3-OH), 6.01 (1H, m, *J* = 5.9, 10.5, 17.7 Hz), 6.28 (1H, d, *J* = 15.9 Hz), 6.83 (1H, d, *J* = 8.3 Hz), 6.99 (1H, d, *J* = 8.6 Hz), 7.10 (1H, s, *J* = 1.1 Hz), 7.58 (1H, d, *J* = 15.9 Hz). ^{13}C NMR ($CDCl_3$, 200 MHz) δ: 51.7, 69.9, 111.00, 113.4, 116.0, 118.0, 121.8, 128.3, 132.4, 144.8, 146.2, 147.6, 167.8. Synthesis of silylated matrixes

(N-(3-Triethoxysilylpropyl)-N′-(7-(4-methylcoumarin)) urea (17)

7-Amino-4-methylcoumarin (AMC, 0.092 g, 0.522 mmol) was dissolved in dry THF (25 mL). After the mixture was stirred for 35 min at room temperature, (3-isocyanatopropyl)triethoxysilane (IPTES) (2.575 g, 0.999 g/mL, 10.4 mmol) was added, and the mixture was refluxed at 75 °C under nitrogen for 50 h. After the mixture was cooled to room temperature, the solvent was evaporated. The white powder was dissolved in dry dichloromethane (10 mL); hexane (20 mL) was added slowly to precipitate the product. After the mixture was allowed to sit for 3 days, the product was isolated as a white solid (yield: 0.0651 g, 71.1%; mp 198 °C) with suction filtration and washed with hexane (2 × 5 mL).

λ_{max} = 329 nm, ϵ = 22000 M^{-1} cm^{-1}, λ_{ex} = 334, λ_{em} = 390 nm. FTIR (neat) ν (cm^{-1}): 3480, 3320, 2974, 2940, 1677, 1539, 1073, 954, 773. ^{1}H NMR (MeOH-d_4, 200 MHz) δ: 0.67 (2H, m, *J* = 7.3 Hz), 1.24 (9H, t, *J*= 7.1 Hz), 1.57 (2H, m), 2.42 (3H, CH_3, s), 3.29 (2H, m), 3.72 (6H, q, *J* = 6.8 Hz), 6.18 (1H, s), 7.26 (1H, s), 7.55 (1H, d, *J* = 8.1 Hz), 7.61 (1H, d, *J* = 7.9 Hz). CI-MS *m/z* (%): 499 (12), 438 (28), 393 (37), 332 (21), 227 (22), 196 (90), 136 (100). MALDI *m/z*: 771, 699, 654, 444, 430, 380 [M + Na]$^+$, 286.

6-Hydroxy-N-(3-aminopropyltriethoxysilyl)-phthalamic acid; 3-hydroxy-N-(3-aminopropyltriethoxysilyl)-phthalamic acid (19)

3-Hydroxyphthalic anhydride (0.1588 g, 0.90 mmol) was dissolved in DMSO (3 mL). 3-Aminopropyltriethoxysilane (0.217 mL, 0.213 g, 0.965 mmol) and anhyd. pyridine (0.217 mL, 0.213 g, 3.13 mmol) were added to the reaction mixture. After stirring for 39 h, the resulting green fluorescent mixture was further evaporated to remove any residual solvent. The yellow-green crystals were recovered as a mixture of isomers (yield: 0.317 g, 98%; mp 116 °C). The ^{1}H NMR, ^{13}C NMR, ^{29}Si NMR, UV, ESI-MS, and fluorescence were obtained for the product in solution. FTIR and ^{29}Si CPMAS were performed on the isolated solid.

λ_{max} = 347, λ_{ex} = 340 nm, λ_{em} = 516 nm. FTIR (neat) ν (cm^{-1}): 3200–2500, 2928, 1687, 1610, 1456, 1402, 1366, 1204, 735. ^{1}H NMR (DMSO-d_6, 200 MHz) δ: 7.17 (1H, q, *J* = 7.6, 7.8 Hz), 6.74 (1H, d, *J* = 7.9 Hz), 6.53 (1H, d, *J* = 7.1 Hz), 3.48 (6H, q, *J* = 6.9 Hz), 3.21 (2H, q, *J*= 6.9, 2.6 Hz), 1.65 (2H, m, *J* = 7.3 Hz), 1.06 (9H, t, *J* = 6.9 Hz), 0.61 (2H, m, *J* = 7.4 Hz). ^{1}H-^{1}H gradient COSY showed that methyl and methylene protons in the terminal ethoxy groups are coupled together, as were methylene protons in the propyl chain. ^{13}C NMR (DMSO-d_6, 200 MHz) δ: 18.7, 18.9, 22.8, 56.5, 58.1, 119.6, 120.3, 120.3, 129.3, 131.2, 156.2, 166.5, 167.9. ESI-MS$^-$ *m/z* (%): 384.4 [M – H]$^-$ (100), 356 (38), 328 (10), 300 (27). ^{29}Si CPMAS NMR (solid state, 300 MHz) δ: –67.53, –61.31, –53.37.

Ethyl 3-methoxy-4-(3-propyltriethoxysilyl)benzoate (20)

To ethyl 3-methoxy-4-allyloxybenzoate (0.3677 g, 1.65 mmol) in dry THF (10 mL) were added triethoxysilane (0.514 g, 0.604 mL, 3.3 mmol) and Karstedt's catalyst (three drops). The completion of reaction was ensured with ^{1}H NMR. After solvent evaporation, unreacted triethoxysilane was removed under high vacuum, and the brown liquid was purified by flash chromatography using hexane : ethyl acetate (30:70 *v/v*) mixture as the solvent. The pure brown liquid (yield: 84.6%, 0.311 g) was then characterized.

λ_{max} = 291 nm, λ_{ex} = 340 nm, λ_{em}= 437 nm. FTIR (neat) ν (cm^{-1}): 2975, 2950, 2910, 1712, 1600, 1512, 1270, 1073, 881, 790. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 0.75 (2H, t, *J* = 8.2 Hz), 1.21 (9H, t, *J* = 6.9 Hz), 1.38 (3H, t, *J* = 7.1 Hz), 1.98 (2H, m, *J* = 7.3, 8.5 Hz), 3.81 (6H, q, *J* = 6.9 Hz), 3.90 (3H, s, OMe), 4.05 (2H, t, *J* = 6.9 Hz), 4.34 (2H, q, *J* = 7.1 Hz), 6.87 (1H, d, *J* = 8.4 Hz), 7.53 (1H, d, *J* = 1.6 Hz), 7.65 (1H, q, *J* = 1.8, 8.4 Hz). CI-MS *m/z* (%): 373 (20), 358 (62), 239 (18), 249 (39), 205 (35), 197 (100), 163 (32). MALDI-TOF *m/z*: 401 [M + H]$^+$, 355 [M – 45], 315, 283, 253.

MALDI preparation

Four types of molecules were used for MALDI analysis to test the applicability of our system for various analytes, including small peptides and small organic molecules: Glu^1-fibrinopeptide B (32) (Glu-fib) (MW 1570), trimethoprim (TMP, MW 290), haloperidol (HP, MW 375), and fluorescein (FLU, MW 332). The final molarity of each analyte in water or in 0.1% TFA:acetonitrile was calculated to be Glu-fib (6.36 pmol/μL), TMP (34.48 pmol/μL), halo-

© 2007 NRC Canada

peridol (26.66 pmol/μL), and fluorescein (30.12 pmol/μL). The standard analyte solution was prepared at a 1:1:1:1 ratio (*v*/*v*) of Glu-fib, TMP, haloperidol, and fluorescein. 40 μL of the matrix solution (~20 mg/mL) was combined with 10 μL of a standard analyte mixture (final concentration after volume correction of each analyte was 2.5 ng/μL), and 1 μL aliquots of matrix–analyte mixture were applied to stainless-steel plates prior to MALDI analysis.

MALDI-TOF experiments

MALDI analysis was done using Breadboard MALDI-TOF mass spectrometer (research instrument provided by MDS Sciex), equipped with a 337 nm N_2 laser and a 20 kV acceleration voltage. Mass spectra were generated from the average of 300 laser shots, at 10 Hz laser rate, 210 mL/m focusing-gas flow, 90 mL/m cooling-gas flow, and 70% laser energy. The instrument was later made available as the proTOF™ 2000 MALDI O-TOF Mass Spectrometer (PerkinElmerSCIEX). The compounds **9**, **10**, and **11** were later tested, at which point only the proTOF™ instrument was accessible from the collaborating company. Average signals reported were obtained by guiding the laser from spot-to-spot within the same plate and the given values represent the average of at least three measurements per matrix derivative used. The experimental setup was used to obtain normalized signal intensities, and MALDI spectra presented herein are based on normalized data.

Conclusion

A series of allyl-protected compounds were prepared as potential MALDI matrixes. The MALDI response to four different analytes was much lower with all the synthesized compounds than with standard matrixes. Phenolic groups were generally beneficial, particularly when the UV-absorbing system was part of an α,β-unsaturated carbonyl system, because these functional groups facilitate charge transfer to analyte more effectively than carboxylic acids. The allyl derivatives (**15**, **16**) showed fewer matrix signals than the parent compound **3**.

The performance of silylated compounds in the MALDI experiment will form the basis of future reports and can be easily obtained from the allyl-protected compounds described herein. Ultimately, we shall report on the ability of a subset of these compounds, modified with hydrolysable silane groups, to serve as MALDI targets on their own or when processed into thin layers containing biomolecules.

Heteropoly acid in ionic liquid — An efficient and recyclable system for one-pot three-component Mannich reaction

Meghana S. Rasalkar, Sachin V. Bhilare, Amol R. Deorukhkar, Nitin B. Darvatkar, and Manikrao M. Salunkhe

Abstract: This paper describes a one-pot three-component Mannich reaction, catalyzed by phosphotungstic acid ($H_3PW_{12}O_{40}$), a heteropoly acid in ionic liquid. The catalyst was found to be mild and efficient, and the protocol affords β-amino ketones in good yields under ambient conditions. Several ionic liquids and conventional organic solvents were employed for the reaction. The ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim]BF_4) offered the best results in terms of yield of the products. It was observed that a homogeneous reaction medium proved beneficial for the yield of the reaction.

Key words: Mannich reaction, β-amino ketones, phosphotungstic acid, ionic liquid, recyclability.

Résumé : Dans ce travail on a réalisé une réaction de Mannich monotope à trois composants, catalysée par l'acide phosphotungstique ($H_3PW_{12}O_{40}$), un hétéropolyacide, dans un milieu ionique. On a trouvé que ce catalyseur est doux et efficace et que la méthode conduit à la formation de β-aminocétones avec de bons rendements, en opérant dans des conditions ambiantes. Pour réaliser cette réaction, on a utilisé plusieurs liquides ioniques ainsi que plusieurs solvants organiques conventionnels. Le liquide ionique du nom de tétrafluoroborate de 1-butyl-3-méthylimidazolium ([bmim]BF_4) est celui qui donne les meilleurs résultats en terme de rendement des produis. On a observé que le milieu réactionnel homogène s'avère utile pour le rendement de la réaction.

Mots-clés : réaction de Mannich, β-aminocétones, acide phosphotungstique, liquide ionique, possibilité de recycler.

[Traduit par la Rédaction]

Introduction

The Mannich reaction is very useful in the preparation of nitrogen-containing compounds (1–4). The reaction essentially proceeds via the condensation of an amine, an aldehyde, and a ketone to form β-amino carbonyl compounds. These compounds are very important biologically active molecules. Novel modifications of the Mannich reaction have been attempted by other researchers (5–10).[2] Some groups have reported the reaction of silyl enol ethers with imines in the presence of Lewis acids (11–13). Lanthanide triflates are quite attractive catalysts for Mannich reaction because of their high catalytic activity and low toxicity (14, 15). However, their high cost restricts their use. Other reports involve the use of HCl in H_2O–SDS and HBF_4 in organic solvent – H_2O systems (16, 17).

Recently, the research in the field of heterogeneous catalysis has experienced considerable growth. Heteropoly acids (HPAs) are polyoxometalate inorganic cage structures belonging to a promising class of solid acid catalysts. They may adopt the Keggin form (18) with the general formula $H_3MX_{12}O_{40}$, where M is the central atom and X is the heteroatom. Typically, M can be either phosphorous (P) or silicon (Si) and X can be tungsten (W) or molybdenum (Mo). HPAs have an enormous potential in catalyzing various types of synthetic organic transformations, which has not yet been fully realized. The low cost, availability, and environment-friendly nature make them suitable candidates for replacing

hazardous and expensive catalysts. HPAs are Brönsted acids, composed of heteropoly anions, with protons as the counter cations. They are more efficient than many conventional solid acid catalysts, such as mixed oxides, zeolites, and so forth. Some reactions, e.g., Friedel–Crafts acylation (19) and Fries rearrangement (20), are catalyzed by HPAs. The HPA catalysts are easily separated from the reaction mixture and recycled. The chemistry and general physical properties of these catalysts have been extensively discussed in a number of review articles (21, 22).

In the past decade, a new approach has been adopted for catalyst separation and recycling in catalytic reactions involving the use of room-temperature ionic liquids, especially those based upon 1-*n*-alkyl imidazolium cation. Ionic liquids, also called "the designer solvents", have been largely successful in replacing obnoxious organic solvents. Their high thermal stability and ability to solvate various substrates have made them highly useful in a variety of organic reactions (23, 24). Amongst other reports, an asymmetric version of the Mannich reaction, employing L-proline in ionic liquids, demonstrated by Barbas et al. (25) is worth mentioning (26–28). For the past few years, our group has been actively involved in exploring the field of ionic liquids (29–31) and has investigated various aspects of the different reactions using ionic liquid as solvents.

Realizing the growing significance of the use of heterogeneous solid acids as recyclable catalysts in organic synthesis, we describe here, for the first time, the use of a heteropoly acid in conjunction with an ionic liquid for a one-pot three-component Mannich reaction (Scheme 1). Our technique combines and maximizes the individual advantages of using heteropoly acids and ionic liquids in organic syntheses while satisfying the basic principles of green chemistry.

Results and discussion

Because it is more efficient to perform a direct Mannich reaction, which eliminates a separate step for imine preparation prior to the reaction, a one-pot reaction between benzaldehyde, *p*-anisidine, and acetone with heteropoly acid as the catalyst was carried out as a prototype. Initially, we chose a hydrophilic ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim]BF_4) for the reaction. A simple procedure was used to carry out the Mannich reaction, wherein all the substrates, namely, an amine (1 mmol), HPA, an aldehyde (1 mmol), and a ketone (in excess) were mixed with the ionic liquid, respectively. To begin with, we decided to screen various heteropoly acids for the model reaction. We employed three different heteropoly acids, namely, phosphotungstic acid ($H_3PW_{12}O_{40}$) (PW_{12}), tungstosilicic acid ($H_4SiW_{12}O_{40}$) (SiW_{12}), and phosphomolybdic acid ($H_3PMo_{12}O_{40}$) (PMo_{12}) for the reaction. All the HPAs completely dissolved in the ionic liquid. 5 mol% of each of these HPAs were used. The reaction mixture was stirred at room temperature.

The reaction furnished the product 4-(4-methoxyphenylamino)-4-phenylbutan-2-one. However, it was observed that the substrates completely disappeared after 18 h only with PW_{12}. In case of other heteropoly acids, TLC showed the presence of *p*-anisidine even after prolonged reaction times.

Scheme 1. One-pot three-component Mannich reaction catalyzed by a heteropoly acid.

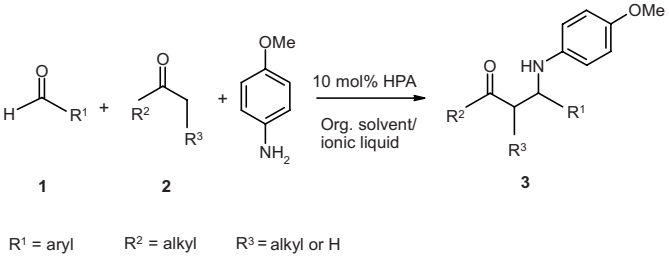

Table 1. Comparison of different heteropoly acids (HPAs) employed for Mannich reaction between *p*-anisidine, benzaldehyde, and acetone in [bmim]BF_4 at room temperature.

Heteropoly acid[a]	Time (h)	Yield[b] (%)
$H_3PW_{12}O_{40}$	18	70
$H_4SiW_{12}O_{40}$	18	61
$H_3PMo_{12}O_{40}$	18	45

[a]5 mol% of the HPA was used.
[b]Isolated yields.

These HPAs vary in their acidity, and hence, it was expected that this would affect the outcome of the reaction in terms of the yield. Studies have proven that PW_{12} is the strongest and most active heteropoly acid (32). It was observed that the yield of the reaction was directly related to the acid strength of the catalyst, as the yield for the various catalysts decreased in the order of $PW_{12} > SiW_{12} > PMo_{12}$. Hence, the best yield of the product of the reaction, i.e., 4-(4-methoxyphenylamino)-4-phenylbutan-2-one (70%), was obtained in 18 h with the strongest of the three heteropoly acids, i.e., phosphotungstic acid (PW_{12}). Considering PW_{12} as the superior heteropoly acid for the present study, we employed it in further investigations. The results are presented in Table 1.

The amount of catalyst was optimized to improve the yields. The yield was quite low (~40%) when phosphotungstic acid was used in low concentrations (1 mol%). Marked improvement in yields (88%) and reduced reaction times (12 h) were observed when the catalyst loading was increased to 10 mol%.

We carried out the reaction in various other hydrophilic as well as hydrophobic ionic liquids and conventional organic solvents to compare the outcome of the reaction in terms of the yield and the rate of the reaction. HPA dissolved in organic solvents like DMSO, DMF, and acetonitrile and hydrophilic ionic liquids, such as 1-butyl-3-methylimidazolium chloride ([bmim]Cl) and 1-methoxyethyl-3-methylimidazolium methanesulphonate ([moemim]OMs), to produce a homogenous system. However, HPA was insoluble in hydrophobic ionic liquids, such as 1-butyl-3-methylimidazolium hexafluorophosphate ([bmim]PF_6) and 1-hexyl-3-methylimidazolium tetrafluoroborate ([hmim]BF_4), and solvents like toluene. Better yields were obtained when the catalyst was soluble in the reaction medium compared with those obtained when the catalyst was insoluble in the reaction solvent. From these observations, it can be deduced that the solubility of the catalyst in the medium plays an important

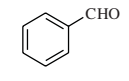
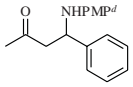
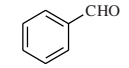
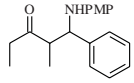
Note: 10 mol% of PW_{12} was used.
[a]Isolated yields.

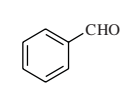
role in enhancing the outcome of the reaction and that a homogeneous system produces better yields.

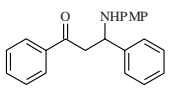


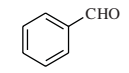


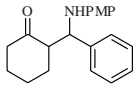


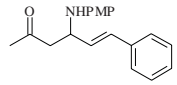


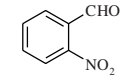


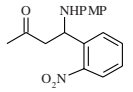


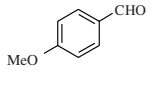


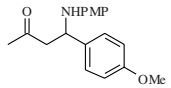


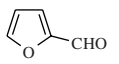


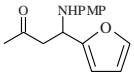


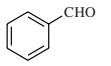


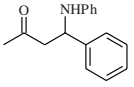


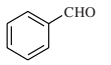


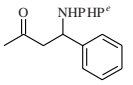


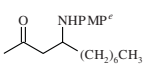












Amongst the various ionic liquids and organic solvents that were employed for the present study (see Table 2), the use of [bmim]BF_4 and DMSO resulted in good yields. The rate of the reaction was only slightly better in case of [bmim]BF_4 compared with DMSO. However, DMSO is highly obnoxious and has a detrimental effect on the environment. Hence, taking into account the various environmental constraints, [bmim]BF_4 was employed for further investigation.

Having ascertained the efficiency of the protocol for the model reaction between *p*-anisidine, acetone, and benzaldehyde, we next turned our attention to its synthetic utility in [bmim]BF_4 (Table 3). All the reactions were stirred for 24 h. At first, we decided to employ various aromatic aldehydes (**1**), keeping the ketone (**2**) and the amine moieties constant. Substituted benzaldehydes with electron-withdrawing or electron-donating groups (Table 3, entries 6 and 7) responded well to the reaction conditions, as the corresponding β-amino ketones (**3**) were obtained in 77% and 80% yield, respectively. A heteroaromatic aldehyde, namely, furfuraldehyde, was also chosen as a substrate, and it furnished the product in 72% yield (Table 3, entry 8). On the other hand, cinnamaldehyde, as an α,β-unsaturated aldehyde, gave comparatively lower yield (Table 3, entry 5).

Likewise, we altered the ketone moiety. Aliphatic ketones, such as 3-pentanone and cyclohexanone, and aromatic ketones, such as acetophenone, were selected. 3-Pentanone (Table 3, entry 2) gave better results than cyclohexanone (Table 3, entry 4). On the other hand, acetophenone (Table 3, entry 3) gave a moderate yield. Ketones were taken in excess to avert the formation of bis-Mannich product. Further, we chose two different amines, namely, aniline and *p*-amino phenol. The results were quite similar to those obtained with *p*-anisidine, albeit the yields were slightly lower. To examine the applicability of the protocol to aliphatic aldehydes, we decided to synthesize Mannich base taking *n*-octanal (Table 3, entry 11). However, the reaction yield was very low. The results are presented in Table 3.

The combination of the heteropoly acid and [bmim]BF_4 provides a homogeneous system for the reaction; hence, this prompted us to investigate the possibility of recycling the complete system of HPA and ionic liquid. The result was quite fruitful. The entire product could be isolated from the reaction mixture simply by ether extraction, and the system of the catalyst and the ionic liquid could be recovered and recharged with fresh substrates. We screened the system for two subsequent runs; the product was obtained in 83% and 75% yields, respectively.

for the Mannich reaction using a combination of heteropoly acid and ionic liquid in the syntheses of β-amino carbonyl compounds. Both the catalyst and the ionic liquid could be easily recovered and recycled. The absence of undesirable side-products and ambient reaction conditions also enhanced the synthetic utility of the reaction.

Experimental

General procedure for Mannich reaction

To a mixture of the ionic liquid (2 mL) and phosphotungstic acid (0.1 mmol), an amine (1 mmol) and an aldehyde (1 mmol) were added. This was followed by the addition of a ketone (10 mmol). The resulting mixture was stirred at room temperature for 24 h. The progress of the reaction was monitored by TLC. The crude product was isolated by extracting the reaction mixture with diethyl ether (4 × 15 mL). The combined ether extractions were dried over Na_2SO_4, concentrated, and purified by CC to obtain the desired β-amino ketones, which were characterized by IR and ^{1}H NMR spectroscopy.

4-(4-methoxyphenylamino)-4-(phenyl)butan-2-one (Table 3, entry 1)

General procedure for the recyclability of the system of the ionic liquid and heteropoly acids

The system containing the ionic liquid and the catalyst was regenerated from the total reaction mixture by consecutive extractions with diethyl ether, and then it was recharged with the amine, aldehyde, and ketone to carry out the next set of reactions. Then, a similar procedure as the previously mentioned was followed.

Montmorillonite K-10 clay as reusable heterogeneous catalyst for the microwave-mediated solventless synthesis of phthalazinetetraones

Davood Habibi, Nosratollah Mahmoodi, and Omid Marvi

Abstract: Different phthalazino[2,3-b]phthalazine-5,7,12,14-tetraones were synthesized in a simple and environmentally benign method from the reaction of some phthalic anhydrides with semicarbazide or thiosemicarbazide using montmorillonite K-10 clay as solid heterogeneous acidic catalyst and microwaves under solvent-free conditions in good yields and short reaction times. The present method has many obvious advantages compared with those reported in the literature, including high efficiency, higher yield, operational simplicity, environmental benignity, and the possibility of recycling the solid clay. The solid clay catalyst used in the first cycle of the reactions was successfully recovered and reused in the second cycle, showing a gradual decrease in activity.

Key words: montmorillonite K-10 clay, microwave, solvent-free condition, phthalazinetetraones, semicarbazide, thiosemicarbazide.

Résumé : Faisant appel à une méthode simple et environnementalement bénigne, on a réalisé la synthèse de divers phtalazino[2,3-b]phtalazine-5,7,12,14-tétrones avec de bons rendements en faisant réagir des anhydrides phtaliques avec de la semicarbazide ou de la thiosemicarbazide, en présence d'argile de montmorillonite K-10 comme catalyseur acide solide et hétérogène, dans des conditions sans solvant, sous l'influence de microondes et des temps de réaction courts. Cette méthode présente des avantages évidents par comparaison avec celles rapportées dans la littérature, dont le fait qu'elle est environnementalement bénigne, sa grande efficacité, son rendement plus élevé, sa simplicité d'opération et la possibilité de recycler l'argile solide. De plus, de l'argile utilisée dans un premier cycle de réactions a été réutilisée avec succès dans un second cycle, ce qui démontre que la diminution de son activité n'est que graduelle.

Mots clés : argile de montmorillonite K-10, microonde, condition sans solvant, phtalazinetétrone, semicarbazide, thiosemicarbazide.

Introduction

In the past few decades, the synthesis of new heterocyclic compounds has been a subject of great interest because of their wide applicability. Heterocyclic compounds occur very widely in nature and are essential to life. Nitrogen-containing heterocyclic molecules constitute the largest portion of chemical entities and are part of many natural products, fine chemicals, and biologically active pharmaceuticals that are vital for enhancing quality of life (1).

Heterocyclic skeletons provide scaffolds on which pharmacophores can be arranged to yield potent and selective drugs (2). In this regard, the phthalazine scaffold has shown its potential as a useful structure for the generation of druglike libraries in the drug discovery process (3). Moreover, heterocyclic fused phthalazines have been found effective in the inhibition of p38 MAP kinase (4), the selective binding of the GABA receptor (5), as antianxiety drugs (6), as antitumor agents (7), and as high-affinity ligands to the $\alpha_2\delta$-1 subunit of the calcium channel (8). Despite their wide applicability among the various reported studies on fused nitrogen heterocycles (9), only a limited number of phthalazinetetraone derivatives have been synthesized (10). Cardia et al. (11) presented the most recent method for the synthesis of phthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone. Most of these procedures involve the use of corrosive reagents such as polyphosphoric and acetic acids and the reported yields are far from satisfactory. Therefore, the use of inexpensive and environmentally safe solid acids would extend the scope of these transformations. Recently, the use of solid acidic catalysts like clays, zeolites, and ion-exchange resins, has received much research interest in different areas of organic synthesis because of their environmental compatibility, reusability, greater selectivity, noncorrosiveness, low cost, and ease of handling.

In particular, the clay catalysts make the reaction process more convenient, economical, environmentally benign, and

act as both Bronsted and Lewis acids in their natural and ion-exchanged forms, enabling them to function as efficient catalysts for various transformations (12). Montmorillonite clays have been used as catalysts for a number of organic reactions and offer several advantages over classical acids: strong acidity, noncorrosive properties, recyclability, low cost, mild reaction conditions, high yields and selectivity, and the ease of setup and workup (13). Neat reactions, on the other hand, have their own practical problems such as overheating and charring of compounds because of ineffective dissipation of energy.

Also, in the last few years a growing interest has been shown in the use of microwave irradiation in organic synthesis (14). Microwave-assisted rapid organic reactions constitute an emerging technology that makes experimentally and industrially important organic syntheses more effective and more ecofriendly than conventional reactions (15). In addition, microwave-mediated solvent-free synthesis offers advantages for reducing hazardous explosions and the need to to remove solvents with high boiling points from the reaction mixtures. Moreover, coupling solventless synthesis with microwaves shows benefits of shorter reaction times, uniform heating, and higher yields (16, 17).

In continuation of our study on microwave-assisted reaction on solid surfaces (18, 19), herein we describe a convenient and simple method to synthesize some of the phthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraones using montmorillonite clay K-10 as a heterogeneous acidic catalyst and microwave irradiation under solvent-free conditions. The solid montmorillonite clay was successfully recovered later and reused in subsequent reactions.

Results and discussion

Different substituted phthalic anhydrides and either semicarbazide or thiosemicarbazide reacted for 3–7 min under solvent-free conditions using microwave irradiation at 180 °C on montmorillonite K-10 clay (Scheme 1). Under classical heating conditions, the reactions were carried out at a similar temperature but for longer reaction times (40–70 min) and lower yields.

The polarity of the carbonyl group of semicarbazide is greater than its thiocarbonyl analog in thiosemicarbazide, so the $-NH_2$ group in thiosemicarbazide is a better nucleophile than the $-NH_2$ group in semicarbazide and hence will produce better yields. It seems that the nature of the substituents of phthalic anhydride has some effects on this reaction. It is of interest to note that the presence of electron-withdrawing groups like Cl and NO_2 gave high product yields and short reaction times compared with the unsubstituted phthalic anhydride. The use of the solid clay as an efficient heterogeneous acidic solid catalyst as well as microwave irradiation offer high product yields compared with conventional procedures. A comparison has been given in the general procedure section. Among the other advantages of our method is the recyclability of solid clay. The clay catalyst used in the first cycle was recovered by filtration, washed with methanol, and reused. Recyclability details of the clay have been explained in the footnote of Table 1. It is notable that all attempts to prepare the products in the absence of montmorillonite K-10 clay failed (despite 15 min irradiation at 180 °C). Therefore, the role of montmorillonite K-10 clay as a solid catalyst in this reaction is essential. Furthermore, the use of reusable solid acid makes this method quite simple, more convenient, and economically viable. Finally, in a second series of experiments the reactions were carried out under the conventional heating conditions using an oil bath at similar temperatures (170–180 °C, solvent-free) without microwave irradiation. It was observed that under classical heating the reactions gave the products with relatively lower yields and longer reaction times. Moreover, the reactions required continuous stirring to prevent charring. Comparison of the results clearly shows the preference of microwave irradiation over conventional heating. The results for the obtained products under both conditions are listed in Table 1.

Experimental

Melting points were measured on an Electrothermal 9100 apparatus. The IR spectra were obtained on a PerkinElmer FT IR GX instrument using KBr discs. The ^1H NMR and ^{13}C NMR spectra were recorded on a FT-NMR JEOL FX 90Q spectrometer using TMS as internal standard (δ given in ppm). Mass spectra were measured with a GCMS Agilent 5973N instrument. Elemental analyses were performed using a Heraeus CHN Rapid analyzer. Chemicals were purchased from the Sigma-Aldrich and Merck chemical companies and used without further purification. Note: The results given in parentheses correspond to those reactions that were carried out under classical heating conditions (solvent-free, 170–180 °C, oil bath, without microwave irradiation).

[a]Isolated yields after recrystallization. The solid clay portion used in the first cycle was filtered off, washed with methanol (2 × 20 mL) under stirring for 1 h, and dried at 120 °C for 5 h under reduced pressure, to be reused in the subsequent reaction, which showed a gradual decrease in activity.

[b](**a**, **f**) Phthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone; (**b**, **g**) octachlorophthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone; (**c**, **h**) 1,11-dinitrophthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone; (**d**, **i**) 2,10-dinitro-phthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone; (**e**, **j**) 1,11-difluorophthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone.

was purchased from Fluka chemical company [surface area: 200 m^2/g; pH 2.5–3.5; chemical composition (average value): SiO_2 (73.0%), Al_2O_3 (14.0%), Fe_2O_3 (2.7%), CaO (0.2%), MgO (1.1%), Na_2O (0.6%), K_2O (1.9%)].

Typical procedure for microwave-mediated synthesis of phthalazino[2,3-b]phthalazine-5,7,12,14- tetraones

In a typical experiment, phthalic anhydride (2.2 mmol, 0.330 g), thiosemicarbazide (1 mmol, 0.091 g), and montmorillonite K-10 clay (1 g) were mixed in a mortar and the mixture was placed in a pyrex tube and introduced into a Synthewave 402® (Prolabo, France) single mode focused microwave reactor for 5 min at 180 °C (monitored temperature (20)) with continuous rotation. The reaction mixture was then allowed to cool to room temperature. The resulting product was extracted into dichloromethane (2 × 25 mL), filtered off, and the solvent was removed by rotary evaporation. The obtained product, phthalazino[2,3-*b*]phthalazine-5,7,12,14-tetraone (**f**), was very thoroughly washed with distilled water, dried in an oven, and recrystallized from acetic acid. Melting point 332–336 °C. Yield with the fresh K-10 clay, 67% and 0.195 g; yield with the recovered K-10 clay, 61% and 0.178 g (lit. values (11) mp 343 to 344 °C, yield 55%, reaction time 1.5 h using polyphosphoric acid). The solid clay portion was washed with methanol and dried at 120 °C under reduced pressure to be reused in the subsequent reactions, which showed a gradual decrease in activity (Table 1). With this procedure compounds, **a**–**j** were synthesized. The physical data (mp, IR, NMR, and MS) of known compounds **a** and **f** were found to be identical with those of authentic samples. Unknown compounds were characterized by mp, spectra (IR, NMR, and MS), and elemental analyses.

Modular syntheses of oxazolinylamine ligands and characterization of group 10 metal complexes

Christine A. Caputo, Florentino d.S. Carneiro, Michael C. Jennings, and Nathan D. Jones

Abstract: The syntheses of aminoalkyloxazoline and pyrrolidinyloxazoline ligands, each of which bear a pair of chiral centres, by both known and new routes are reported. Variable temperature NMR studies show that the known stepwise syntheses of the pyrrolidinyl compounds are not complicated by epimerization; however, coordination of one of the aminoalkyl derivatives to Pt(II) under conditions of prolonged heating to 80 °C does give mixtures of diastereomeric *N*,*N*′-chelated complexes that result from inversion of the chiral centre associated with the aminoalkyl fragment. A new synthesis of pyrrolidinyloxazoline ligands that involves the Zn-catalyzed cyclization of Cbz-protected 2-cyanopyrrolidine and β-amino alcohols is also reported. This procedure offers the advantages of economy, shorter time, and fewer purification steps over the previously reported synthesis. In addition, the crystal structure of an enantiopure Pd(II) complex of an *N,N*′-chelated pyrrolidinyloxazoline is disclosed. This compound has a pseudo-C_2 axis of symmetry, which may make it suitable for asymmetric catalytic applications.

Key words: chiral ligands, ligand design, oxazolines, variable temperature NMR spectroscopy, asymmetric catalysis, coordination compounds, palladium, platinum

Résumé : Faisant appel à des méthodes connues et d'autres nouvelles, on a réalisé la synthèse de ligands aminoalkyloxazolines et pyrrolidinyloxazolines qui portent une paire de centres chiraux. Des études de RMN à température variable ont permis de montrer que la méthode synthèse connue par étape pour les composés pyrrolidinyles ne sont pas compliquées par l'épimérisation; toutefois, la coordination d'un des dérivés aminoalkyles du Pt(II), dans des conditions de chauffage prolongé à 80 °C, ne conduit pas à des mélanges de complexes *N,N*′-chélatés diastéréomères résultant de l'inversion du centre chiral associé au fragment aminoalkyle. On a aussi réalisé une nouvelle synthèse des ligands pyrrolidinyloxazolines qui implique une cyclisation catalysée par le zinc de β-amino-alcools sur la 2-cyanopyrrolidine portant un groupe protecteur Cbz. Par rapport aux méthodes antérieures, cette méthode présente l'avantage d'être plus économique, d'impliquer des temps de réaction plus courts et moins d'étapes de purification. De plus, on a déterminé la structure cristalline du complexe énantiopur du Pd(II) avec une pyrrolidinyloxazoline *N,N*′-chélatée. Ce produit présente un axe de symétrie pseudo-C_2 qui pourrait le rendre susceptible d'être utilisé dans des applications de catalyse asymétrique.

Mots clés : ligands chiraux, développement de ligands, oxazolines, spectroscopie RMN à température variable, catalyse asymétrique, composés de coordination, palladium, platine.

[Traduit par la Rédaction]

Introduction

Beginning in the late 1980s and continuing to the present day, the oxazoline (4,5-dihydrooxazole) ring has featured prominently as the chiral component of a broad range of ligands that have been used to great effect in asymmetric catalytic transformations (1, 2). In particular, the C_2-symmetric bis(oxazoline) class has seen widespread and very successful application, e.g., in cycloaddition, aldol, Michael, carbonylene, and related Lewis acid-catalyzed reactions (3). More recently, C_1-symmetric compounds bearing oxazoline rings that have been elaborated with aminoalkyl functional groups predominantly in the 2-position (e.g., Chart 1, **I**) (4) have come to the fore as an important subclass of ligands in their own right and as building blocks for more elaborate ligand systems (Chart 1, **II**–**IV**) (5–7). Less common variations bearing aminomethyl groups in the 4-position have also appeared (Chart 1, **XIV**) (8).

The advantages of the ligand family **I** have been documented in a recent report by Rajaram and Sigman (4): the compounds are conveniently made in a modular manner from readily available, optically pure starting materials, bear multiple independently variable stereocentres, and are amenable to further elaboration through manipulation of the amine (e.g., to give **II**–**IV**) (5–7, 9). We also point out that the presence of N*H* protons may have important ramifications for the use of these ligands in the asymmetric hydrogenation of C=O bonds. Variations on this theme have also included oxazolines incorporating pyrrolidine (**V**) (10), quinoline (**VI**) (11), aniline (**VII**, **XIII**) (12–14),

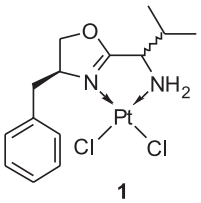
Chart 1. Examples of oxazolinylamine ligands.

Scheme 1. General synthesis of pyrrolidinyloxazolines by the Zn-catalyzed cyclization of *N*-protected 2-cyanopyrrolidine and β-amino alcohols.

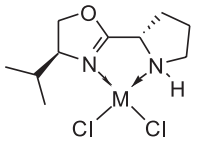
azabicyclo[2.2.1]heptane (**IX**) (15), pyrrole (**XI**) (16–18), and pyridine (not shown) ring systems (21).

To date, access to the pyrrolidinyloxazoline ligands **V** has been limited to a stepwise synthetic route outlined by McManus et al. (10). Herein, we propose an alternate approach that involves the Zn-catalyzed cyclization of Cbz-protected 2-cyanopyrrolidine and β-amino alcohols (Scheme 1). This new approach is quicker, more economical, and requires fewer purifications. It also puts the diversification step later in the synthesis, which allows expansion of ligand libraries more easily.



Ligands in classes **I** and **V** bear two stereocentres and are, in principle, susceptible to epimerization. Through careful stepwise synthesis, we show in this report that there is no epimerization of **V** either during ligand synthesis by the McManus route or during metal complexation. However, epimerization does occur during the coordination of a ligand of type **I** to Pt(II); two diastereomers of **1** (Chart 2) result from the reaction of the appropriate ligand and $PtCl_2(SMe_2)_2$ in boiling dichloroethane.

The compounds shown in Chart 1 have been used as ligands in asymmetric allylation (**II**, **XIII**) (5,13), alkylation (**IV**) (7,9), and crotylation (**XIII**) of aldehydes (13), Diels-Alder (**XI**) (16), hetero-Diels-Alder (**III**, **XI**) (6), and transfer hydrogenation (**V**, **VI VII**, **VIII** and **IX**) reactions (10–12,14,15); phosphine derivatives (**X**, **XII**) (19,20) have also been made and applied successfully in asymmetric hydrogenations.



Catalysts for these reactions have typically been generated in situ. Therefore, well-characterized examples of *N,N′*-chelated oxazolinylamine metal complexes are rare. Those *N,N′*-chelated complexes that have been structurally characterized are for the most part confined to the pyridinyloxazolines (21) and to the adducts of **VII** (12) and **XI** (16). As part of our ongoing exploration of modularly-made chiral *N,N′*-chelating ligands, we also present in this work the synthesis and

characterization of group 10 metal complexes of ligands of type **I** and **V**, including an X-ray structural determination of a Pd(II) complex of **V** (Chart 2, **3**).

Experimental section

General considerations

Reagents were obtained from commercial sources and used as supplied unless otherwise indicated. These were of American Chemical Society (ACS) grade or finer. Solvents were dried and deoxygenated either by N_2 purge followed by passage through alumina columns (Innovative Technology or MBraun solvent purification systems) or by distillation under N_2 from the appropriate drying agent. All reactions were carried out under N_2 atmosphere using standard Schlenk techniques unless stated otherwise. Amino alcohols were prepared by the reduction of corresponding amino acids using a standard procedure (22). The metal complexes, *trans*-$PdCl_2(PhCN)_2$ and $PtCl_2(SMe_2)_2$, were prepared according to literature procedures (23, 24).

Thin-layer chromatography was performed using 250 μm silica gel glass plates with fluorescent indicator (254 nm, Rose Scientific, Edmonton, Alberta) and viewed by exposure to UV light and (or) immersion in a staining solution (ninhydrin, $KMnO_4$, or phosphomolybdic acid) followed by heating. Flash chromatography was performed using ACP ultra pure silica gel, 60 Å, 230–400 mesh (Silicycle, Québec, Quebec), using the eluent(s) specified. All solvent mixtures are reported as volume percentages.

^1H, $^{13}C\{^1H\}$, $^{19}F\{^1H\}$, correlated spectroscopy (COSY), and heteronuclear multiple quantum coherence (HMQC) NMR data were recorded on a 400 MHz Varian Mercury (400.085 MHz for ^1H, 100.602 MHz for ^{13}C, 376.458 MHz for ^{19}F) or a 400 MHz Varian Inova spectrometer (399.762 MHz for ^1H, 100.520 MHz for ^{13}C). Unless otherwise indicated, spectra were recorded at room temperature (RT) in a $CDCl_3$ solution using residual solvent proton (relative to external $SiMe_4$, δ 0.00) or solvent carbon (relative to external $SiMe_4$, δ 0.00) as an internal reference. Downfield shifts were taken as positive. Data for the ^1H NMR spectra are reported as follows: chemical shift (δ), multiplicity, integration, assignment, and coupling constant(s). All coupling constants are reported in Hertz (Hz) and the spin multiplicities are indicated as follows: singlet (s), triplet (t), quartet (q), multiplet (m), pseudo (p), and broad (br). Peaks due to the minor geometrical (*E* or *Z* isomer) when present in ^1H or ^{13}C spectra are denoted by *. Fractional values for the ^1H NMR integrations indicate the relative concentrations of *E* and *Z* isomers in solution.

High resolution mass spectrometry data were recorded using a Finnigan MAT 8200 instrument. IR spectra were recorded using a Bruker Vector 33 FT-IR spectrometer; samples were run either neat between KCl plates or prepared as KBr pellets. Data are reported in cm^{-1}; peak intensities are given as follows: strong (s), medium (m), weak (w), very (v).

Syntheses of oxazolinylamine ligands

1-{(4S)-4-Benzyl-4,5-dihydro-oxazol-2-yl}-(2S)-2-methyl-propylamine-carbamic acid ester 9H-fluoren-9-ylmethyl (4)

The title compound was made according to the method of Rajaram and Sigman (4). ^1H NMR (DMSO-d_6, 353 K) δ: 0.89 (pt, 6H, $CH(CH_3)_2$), 2.00 (m, 1H, $CH(CH_3)_2$), 2.70 (dd, 1H, $CHH'Ph$, $^2J_{HH}$ = 13.8, $^3J_{HH}$ = 6.8), 2.85 (dd, 1H, $CHH'Ph$, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 6.4), 3.93 (pt, 1H, ox $OCHH'$), 4.03 (pt, 1H, ox $OCHH'$), 4.23–4.36 (m, 5H, Fmoc C*H*, Fmoc CH_2, NHC*H*, ox NC*H*), 7.18 (m, 1H, Ph), 7.22–7.26 (m, 4H, Ph), 7.32 (m, 2H, Fmoc Ar), 7.39 (t, 2H, Fmoc Ar, $^3J_{HH}$ = 7.6), 7.72 (pt, 2H, Fmoc Ar), 7.87 (d, 2H, Fmoc Ar, $^3J_{HH}$ = 7.6). $^{13}C\{^1H\}$ NMR δ: 18.40, 19.15, 30.17, 41.15, 46.66, 54.81, 65.66, 66.53, 71.31, 120.07, 125.32, 125.36*, 126.09, 127.01, 127.61, 128.15, 129.25, 138.23, 140.69*, 143.76*, 143.85, 156.05, 165.55*. HRMS calcd. for $C_{29}H_{30}N_2O_3$: 454.2256; found: 454.2268.

1-{(4S)-4-Benzyl-4,5-dihydro-oxazol-2-yl}-(2S)-2-methyl-propylamine (5)

The synthesis by Rajaram and Sigman (4) was modified to use Et_2NH instead of piperidine. A 50 mL round-bottomed flask was charged with **4** (0.303 g, 0.662 mol) and MeOH (6 mL) was added to give a white suspension. Et_2NH (5 mL) was added over a period of 10 min at RT. The resulting pale beige solution was stirred for 30 min. The solution was concentrated in vacuo and the residue was purified by silica gel chromatography (MeOH–CH_2Cl2 10%–20%). The title compound was obtained as a beige oil. Yield 0.154 g (97%). ^1H NMR δ: 0.91 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 0.93 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 1.77 (br s, 2H, NH_2), 1.91 (m, 2H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 2.62 (dd, 1H, $CHH'Ph$, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 8.4), 3.06 (dd, 1H, $CHH'Ph$, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 5.2), 3.28 (d, 1H, NH_2CH, $^3J_{HH}$ = 5.2), 3.97 (dd, 1H, $OCHH'$, $^2J_{HH}$ = 8.8, $^3J_{HH}$ = 7.2), 4.16 (pt, 1H, $OCHH'$), 4.36 (m, 1H, NC*H*), 7.16–7.29 (m, 5H, Ph). $^{13}C\{^1H\}$ NMR δ: 17.79, 19.58, 32.38, 42.02, 55.77, 67.17, 72.10, 126.74, 128.75, 129.10, 129.17, 129.30, 129.49. HRMS calcd. for $C_{14}H_{21}N_2O$: 233.1660; found: 233.1648.

Syntheses of Fmoc- and Cbz-protected pyrrolidinyloxazolines

Compounds **7** and **9** were made according to modifications to the methods reported by McManus et al. (10), who developed them for the analogous Cbz-protected pyrrolidine derivatives **8** and **10**. Room temperature spectroscopic data for **8** and **10** matched those given in the literature. However, high-temperature NMR spectroscopic data were acquired by us to ensure that the reported splitting and broadening of peaks was in fact due to *E* and *Z* isomers arising from the amide and (or) carbamate (Cbz) bonds and not instead to the presence of diastereomers resulting from epimerization. This

© 2007 NRC Canada

determination was made based on the coalescence at high temperature of the isopropyl methyl peaks from a multiplet into two doublets of equal intensity and of the benzyl CH_2 multiplet into a sharp singlet. Both sets of data (low and high temperatures) are given for comparison.

Compounds **11** and **12** were prepared by deprotection of the Cbz group using Pd–C and H_2 gas as the hydrogen source. This differed from the procedure of McManus et al. (10), which used cyclohexene as the hydrogen source.

(2S)-Chlorocarbamoyl-pyrrolidine-1-carboxylic acid 9H-fluoren-9-ylmethyl ester (6)

Thionyl chloride (1.29 mL, 17.8 mmol) was added dropwise over a period of 2 min to a 100 mL round-bottomed flask charged with Fmoc-Pro-OH (3.38 g, 10.0 mmol) and dry toluene (30 mL). The mixture was heated to dissolve all solids and held at reflux for 2 h. The yellow solution was cooled to RT, then concentrated in vacuo to afford a yellow oil, which crystallized when stored at 5 °C. The product was used without further purification. IR (neat) ν: 1793 (s, C=O COCl), 1707 (s, C=O Fmoc).

(2S)-{(1S)-Hydroxylmethyl-2-methyl-propylcarbamoyl}-pyrrolidine-1-carboxylic acid 9H-fluoren-9-ylmethyl ester (7)

A solution of L-valinol (0.290 g, 2.40 mmol) and NEt_3 (0.390 mL, 2.80 mmol) in dry CH_2Cl_2 (5 mL) was added dropwise to a 100 mL Schlenk tube containing **6** (1.00 g, 2.80 mmol) and dry CH_2Cl_2 (30 mL) that had been cooled to 0 °C and flushed with N_2. The mixture was stirred at 0 °C for 20 min, warmed to RT, and stirred overnight. The mixture was concentrated to ~15 mL and washed with satd. aq. NH_4Cl (3 × 50 mL), H_2O (2 × 50 mL), and brine (50 mL). The organic layer was dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by silica gel chromatography (MeOH–CH_2Cl_2 2%) to afford a nearly colourless oil. Yield 0.91 g (91%). ^{1}H NMR δ: 0.87 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 0.89 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 1.81–2.02 (m, 4H, CH(CH$_3$)$_2$, pyr NCH$_2$CH_2, pyr NCHCHH'), 2.16–2.30 (m, 1H, pyr NCHCHH′), 3.41–3.66 (m, 6H, pyr NCH_2, CONHCH, CH_2OH, OH), 4.21 (pt, 1H, Fmoc CH), 4.32–4.45 (m, 4H, Fmoc OCH_2, pyr NCH), 6.37* (br s, 0.3H, CONH), 6.83 (d, 0.7H, CONH, $^3J_{HH}$ = 6.8), 7.30 (pt, 2H, Fmoc Ar), 7.39 (pt, 2H, Fmoc Ar), 7.57 (d, 2H, Fmoc Ar, $^3J_{HH}$ = 7.6), 7.75 (d, 2H, Fmoc Ar, $^3J_{HH}$ = 7.2). ^{13}C{^{1}H} NMR δ: 18.79, 19.78, 24.86, 28.78*, 29.04, 47.33, 57.57, 61.01, 63.68, 68.00, 120.24, 125.21, 127.30, 128.00, 141.49, 143.91, 156.43, 172.56. HRMS calcd. for $C_{25}H_{31}N_2O_4$: 423.2292; found: 423.2278.

(2S)-{(1S)-Hydroxylmethyl-2-methyl-propylcarbamoyl}-pyrrolidine-1-carboxylic acid benzyl ester (8)

The title compound was made according to the procedure reported by McManus et al. (10). ^{1}H NMR (298 K) δ: 0.84 (pd, 3H, CH(CH_3)$_2$), 0.87 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 7.2), 1.80 (m, 1H, CH(CH$_3$)$_2$), 1.91 (m, 2H, pyr NCH$_2$CH_2), 2.17 (br s, 1H, pyr NCHCHH′), 2.32 (br s, 1H, pyr NCHCHH'), 3.46–3.66 (m, 5H, CH_2OH, NHCH, pyr NCH_2), 4.35 (m, 1H, pyr NCH), 5.06–5.20 (m, 2H, Cbz OCH_2), 6.19 (s, 0.4H, CONH), 6.75 (s, 0.6H, CONH), 7.13–7.38 (m, 5H, Cbz Ar). ^{1}H NMR (353 K) δ: 0.84 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 0.88 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 1.81 (m, 1H, CH(CH$_3$)$_2$), 1.91 (m, 3H, pyr NCH$_2$CH_2, pyr NCHCHH′), 2.28 (br s, 1H, pyr NCHCHH'), 3.49–3.68 (m, 5H, CH_2OH, NHCH, pyr NCH_2), 4.35 (m, 1H, pyr NCH), 5.15 (s, 2H, Cbz OCH_2), 7.28–7.36 (m, 5H, Cbz Ar).

(2S)-2-{(4S)-4-Isopropyl-4,5-dihydro-oxazol-2-yl}-pyrrolidine-1-carboxylic acid 9H-fluoren-9-ylmethyl ester (9)

In a 100 mL Schlenk tube, a solution of **7** (0.384 g, 95.0 mmol) in dry CH_2Cl_2 (50 mL) was cooled to –78 °C. Diethylaminosulfur trifluoride (DAST) (0.137 mL, 1.05 mmol) was added dropwise over 5 min and the resultant pale yellow solution was stirred at –78 °C for 1 h, warmed to RT over ~3 h, and stirred overnight. The mixture was poured into satd. aq. $NaHCO_3$ (70 mL). The aqueous layer was discarded and the organic layer was washed with H_2O (2 × 50 mL). The aqueous layer was extracted with CH_2Cl_2 (2 × 50 mL). Combined organic layers were washed with brine (25 mL), dried over $MgSO_4$, and concentrated in vacuo. The residue was purified by silica gel chromatography (EtOAc–hexanes 30%–50%) to afford the title compound as an off-white foam. Yield 0.31 g (85%). ^{1}H NMR δ: 0.80 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 0.84 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 1.61 (m, 1H, CH(CH$_3$)$_2$), 1.91 (m, 3H, pyr NCH$_2$CH_2, pyr NCHCHH′), 2.17 (m, 1H, pyr NCHCHH'), 3.83 (pq, 1H, Fmoc CH), 3.93 (pt, 1H, ox OCHH′), 4.17 (pt, 1H, ox OCHH'), 4.25 (m, 2H, pyr NCH_2), 4.35 (m, 1H, ox NCH), 4.45 (br d, 1H, Fmoc OCH_2, $^3J_{HH}$ = 8.8), 7.33 (pt, 2H, Fmoc Ar), 7.41 (pt, 2H, Fmoc Ar), 7.65 (d, 2H, Fmoc Ar, $^3J_{HH}$ = 7.6), 7.86 (d, 2H, Fmoc Ar, $^3J_{HH}$ = 7.2). ^{13}C{^{1}H} NMR δ: 18.12, 19.60*, 22.93*, 22.95, 28.14, 28.28*, 30.13, 31.76*, 46.49*, 46.60, 46.61, 47.25*, 55.61*, 55.62, 59.51, 59.76*, 61.30, 61.40*, 66.44, 66.99*, 120.11, 125.16, 125.31*, 125.69, 127.14*, 127.67, 127.68*, 128.21*, 128.90, 140.61*, 140.74, 143.39, 143.78*, 143.93, 143.94* 153.96, 171.65, 172.02*. HRMS calcd. for $C_{25}H_{28}N_2O_3$: 404.2100; found: 404.2107.

(2S)-2-{(4S)-4-Isopropyl-4,5-dihydro-oxazol-2-yl}-pyrrolidine-1-carboxylic acid benzyl ester (10)

The title compound was made according to the procedure reported by McManus et al. (10). ^{1}H NMR (DMSO-d_6, 298 K) δ: 0.73 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 0.80 (m, 3H, CH(CH_3)$_2$), 1.53–1.58 (m, 0.6H, CH(CH$_3$)$_2$), 1.59–1.66 (m, 0.4H, CH(CH$_3$)$_2$), 1.81–1.90 (m, 3H, pyr NCH$_2$CH_2, pyr NCHCHH′), 2.10–2.20 (m, 1H, pyr NCHCHH'), 3.73–3.78 (m, 1.2H, pyr NCH_2), 3.84–3.87 (m, 0.8H, pyr NCH_2), 3.90 (pt, 0.6H, ox OCHH'), 3.98 (pt, 0.4H, ox OCHH'), 4.07 (pt, 0.6H, ox OCHH′), 4.16 (pt, 0.4H, ox OCHH′), 4.41 (dd, 0.4H, pyr NCH, $^3J_{HH}$ = 3.2, 8.8), 4.46 (dd, 0.6H, pyr NCH, $^3J_{HH}$ = 2.8, 8.0), 4.98–5.12 (m, 2H, Cbz OCH_2), 7.29–7.36 (m, 5H, Cbz Ar). ^{1}H NMR (DMSO-d_6, 393 K) δ: 0.79 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 0.83 (d, 3H, CH(CH_3)$_2$, $^3J_{HH}$ = 6.8), 1.61 (m, 1H, CH(CH$_3$)$_2$), 1.89 (m, 3H, pyr NCH$_2$CH_2, pyr NCHCHH′), 2.17 (m, 1H, pyr NCHCHH'), 3.83 (pq, 1H, pyr NCH_2), 3.81 (pq, 1H, ox NCH), 3.92 (pt, 1H, ox OCHH'), 4.14 (m, 2H, ox OCHH′), 4.48 (pd, 1H, pyr NCH), 5.08 (s, 2H, Cbz OCH_2), 7.29–7.35 (m, 5H, Cbz Ar).

Syntheses of (4*S*)-4-isopropyl-2-pyrrolidin-(2*S*)-2-yl-4,5-dihydrooxazole (11)

By deprotection of Fmoc

A 100 mL round-bottomed flask charged with **9** (0.310 g,

© 2007 NRC Canada

0.810 mmol) and MeOH (10 mL) was cooled to 0 °C before Et_2NH (5 mL) was added dropwise. The mixture was warmed to RT with stirring over 1.5 h. Volatiles were removed in vacuo. The residue was purified by silica gel chromatography (MeOH–CH_2Cl_2 4%–10%) to afford **9** as a nearly colourless oil. Yield 0.30 g (55%). Spectroscopic data were identical to those reported by McManus et al. (10).

By deprotection of Cbz

A solution of **10** (1.0 g, 3.16 mmol) in MeOH (30 mL) was added slowly to a 100 mL Schlenk tube containing Pd–C 10% *w/w* (0.30 g, 30 wt%.). The flask was purged with H_2 and was stirred under H_2 atmosphere at RT for 24 h. The suspension was filtered through a pad of Celite that was subsequently rinsed with MeOH (30 mL). The filtrate was concentrated in vacuo to give a pale yellow oil that was purified by silica gel chromatography (MeOH–CH_2Cl_2 5%) to afford **11** as a colourless oil. Yield 0.35 g (61%). Spectroscopic data were identical to those reported by McManus et al. (10).

Synthesis of (4S)-4-Benzyl-2-pyrrolidin-(2S)-2-yl-4,5-dihydrooxazole (12)

A solution of **18** (0.990 g, 2.70 mmol) in MeOH (40 mL) was deprotected according to the method described in the immediately preceding section. Yield 0.19 g (30%). Spectroscopic data matched those reported by McManus et al. (10).

Synthesis of cyanopyrrolidine derivatives

Our syntheses of **13** and **15** are modifications of those reported by Wallén et al. (25) for the analogous Boc-protected pyrrolidines **14** and **16**. The compounds were previously made by a different route by Cobb et al. (26, 27); they are now commercially available but are very expensive. To the best of our knowledge, only RT ^{1}H NMR characterization data have been reported in the open literature.

(2S)-2-Carbamoyl-pyrrolidine-1-carboxylic acid benzyl ester (13)

Ethyl chloroformate (3.99 mL, 41.7 mmol) was added dropwise to a cooled solution (–5 °C) of Cbz-Pro-OH (4.60 g, 18.5 mmol), NEt_3 (2.57 mL, 18.5 mmol), and THF (60 mL) in a 100 mL round-bottomed flask. The resulting slurry was stirred for 20 min at –5 °C and satd. aq. NH_4OH (5 mL) was then added dropwise. The solution was stirred at RT for 18 h. Volatiles were removed in vacuo and the residue was taken up in EtOAc (60 mL). The undissolved white precipitate was filtered off and rinsed with EtOAc (30 mL). The organic layer was dried over $MgSO_4$ and concentrated in vacuo to give an off-white amorphous solid, which was used without further purification. Yield 4.59 g (>99%). ^{1}H NMR δ: 1.87–1.99 (m, 2H, NCH_2CH_2), 2.16 (br s, 1H, NCHC*H*H′), 2.31 (br s, 1H, NCHCH*H′*), 3.44–3.54 (m, 2H, NCH_2), 4.28–4.35 (m, 1H, NC*H*), 5.10–5.18 (m, 2H, OCH_2Ar), 5.74* (br s, 0.5H, NH_2), 5.84 (br s, 0.5H, NH_2), 6.06* (br s, 0.5H, NH_2), 6.72 (br s, 0.5H, NH_2), 7.34 (m, 5H, Cbz Ar). ^{13}C{^{1}H} NMR δ: 23.39*, 24.28, 28.73, 30.97*, 46.78, 47.23*, 60.00, 60.38*, 67.04, 127.62, 127.87, 128.30, 136.20, 154.67*, 155.65, 174.63, 175.50*. HRMS calcd. for $C_{13}H_{16}N_2O_3$: 248.1161; found: 248.1169.

(2S)-2-Carbamoyl-pyrrolidine-1-carboxylic acid tert-butyl ester (14)

The title compound was made by the method of Wallén et al. (25). Yield >99%. ^{1}H NMR (DMSO-d_6, 353 K) δ: 1.39 (m, 9H, $O(CH_3)_3$), 1.72–1.87 (m, 3H, $NCH_2CH_2CH_2$, NCH_2CH_2CHH'), 2.07 (m, 1H, NCH_2CH_2CHH'), 3.28–3.40 (m, 2H, NCH_2) 4.03 (pdd, 1H, NC*H*CN). ^{13}C{^{1}H} NMR (DMSO-d_6) δ: 23.85, 24.54*, 28.68, 28.80*, 30.66*, 31.66, 46.06, 47.01, 47.22*, 59.99*, 60.20, 78.99, 79.08*, 154.00, 154.28*, 174.94*, 175.32. IR (neat) ν: 3406 (m, N-H), 1683 (s, CO amide), 1403 (m, C-N). HRMS calcd. for $C_{10}H_{18}O_3N_2$: 214.1317; found: 214.1312.

(2S)-2-Cyano-pyrrolidine-1-carboxylic acid benzyl ester (15)

A 250 mL round-bottomed flask was charged with **13** (4.37 g, 17.6 mmol) and dry THF (60 mL). The solution was cooled to 0 °C and NEt_3 (5.88 mL, 42.3 mmol) was added dropwise. Against a flow of N_2, trifluoroacetic anhydride (TFAA) (2.94 mL, 21.1 mmol) was added dropwise and the mixture was stirred for 1 h at 0 °C. The reaction was quenched by the addition of H_2O (25 mL) and all volatiles were removed in vacuo. The residue was taken up in CH_2Cl_2 (50 mL) and H_2O (20 mL) was added. The organic layer was washed with satd. aq. $NaHCO_3$ (20 mL) and brine (20 mL), dried over $MgSO_4$, and concentrated in vacuo. The resultant yellow oil was used without further purification. Yield 2.44 g (83%). ^{1}H NMR δ: 2.04–2.31 (m, 4H, NCH_2CH_2, $NCH_2CH_2CH_2$), 3.38–3.44 (m, 1H, NCH_2), 3.55–3.62 (m, 1H, NCH_2), 4.54–4.63 (m, 1H, NC*H*CN), 5.14–5.20 (m, 2H, OCH_2), 7.26–7.43 (m, 5H, Cbz Ar). ^{1}H NMR (333 K) δ: 2.01–2.30 (m, 4H, NCH_2CH_2), 3.42–3.48 (m, 1H, NCH_2), 3.56–3.61 (m, 1H, NCH_2), 4.58 (br s, 1H, NC*H*CN), 5.20 (s, 2H, OCH_2), 7.32–7.40 (m, 5H, Cbz Ar). ^{13}C{^{1}H} NMR δ: 23.68, 24.58*, 30.72*, 31.69, 45.86*, 86.26, 46.92, 47.45*, 67.57*, 67.75, 118.63*, 118.81, 128.08, 128.22, 128.50, 135.80*, 135.99, 153.54*, 154.24. HRMS calcd. for $C_{13}H_{14}N_2O_2$: 230.1055; found: 230.1061.

(2S)-2-Cyano-pyrrolidine-1-carboxylic acid tert-butyl ester (16)

The title compound was made using the method of Wallén et al. (25). Yield 82%. ^{1}H NMR δ: 1.46–1.50 (m, 9H, $C(CH_3)_3$), 2.01–2.24 (m, 4H, NCH_2CH_2, $NCH_2CH_2CH_2$), 3.30–3.39 (m, 1H, NC*H*H′), 3.42–3.55 (m, 1H, NCH*H′*), 4.42 (pdd, 0.5H, NC*H*), 4.55 (pd, 0.5H, NC*H*). ^{1}H NMR (DMSO-d_6, 353 K) δ: 1.46 (s, 9H, $C(CH_3)_3$), 1.94 (m, 2H, NCH_2CH_2), 2.12–2.25 (m, 2H, $NCH_2CH_2CH_2$), 3.34 (m, 2H, NCH_2), 4.60 (dd, 1H, NC*H*, $^3J_{HH}$ = 3.6, 8.0). ^{13}C{^{1}H} NMR δ: 24.13, 25.01*, 28.62, 30.88*, 31.71, 46.37, 46.67*, 47.41*, 47.55, 80.65, 120.53, 153.16, 153.83*. IR (neat, cm^{-1}) ν: 2980 (m, C-H), 2240 (vw, C≡N), 1701 (vs, C=O). HRMS calcd. for $C_{10}H_{16}O_2N_2$: 196.1212; found: 196.1213.

(2S)-2-Cyano-pyrrolidine·TFA salt (17)

Via an addition funnel, TFA (34 mL) was added dropwise over a period of 10 min to a 100 mL round-bottomed flask containing a cooled (0 °C) CH_2Cl_2 (124 mL) solution of **16** (2.44 g, 12.4 mmol). The solution was stirred for 2 h at 0 °C, then concentrated in vacuo to give an off-white oil. Et_2O (30 mL) was added slowly to produce a white crystalline solid. The slurry was filtered, and the solid rinsed with Et_2O (10 mL) before being dried under vacuum to obtain the

© 2007 NRC Canada

title compound as a white crystalline solid. Yield 1.10 g (56%), mp 92–94 °C. ^{1}H NMR (CD_3OD) δ: 2.07–2.33 (m, 3H, $NHCH_2CH_2$, $NHCHCHH'$), 2.43–2.52 (m, 1H, $NHCHCHH'$), 3.35–3.47 (m, 2H, $NHCH_2$), 4.68 (pt, 1H, NHCH), 4.92 (s, 1H, NH). $^{13}C\{^1H\}$ NMR δ: 23.15, 29.65, 45.14, 45.97, 116.53. $^{19}F\{^1H\}$ NMR δ: –77.37 (s). IR (neat) ν: 2261 (vw, C≡N), 1681 (vs, C=O). HRMS calcd. for $C_5H_9N_2$: 97.0766; found 97.0760; calcd. for $C_2F_3O_2^-$: 112.9850; found: 112.9683.

Syntheses of pyrrolidinyloxazolines via 2-cyanopyrrolidines

(2S)-2-{(4S)-4-Isopropyl-4,5-dihydro-oxazol-2-yl}-pyrrolidine-1-carboxylic acid benzyl ester (10)

A solution of **15** (1.55 g, 6.70 mmol) and L-valinol (1.08 g, 10.5 mmol) in chlorobenzene (120 mL) was added to a 250 mL round-bottomed flask containing $ZnCl_2$ (1.43 g, 10.5 mmol). The mixture was heated to reflux for 24 h. Solvent was removed in vacuo and the yellow residue was purified by silica gel chromatography (EtOAc–Hexanes 30%). The title compound was obtained as a yellow oil. Yield 1.82 g (85%). Spectroscopic data for this compound matched those reported by McManus et al. (10).

(2S)-2-{(4S)-Benzyl-4,5-dihydro-oxazol-2-yl}-pyrrolidine-1-carboxylic acid benzyl ester (18)

A similar procedure to that outlined earlier was carried out using **15** (0.605 g, 2.63 mmol), L-phenylalaninol (0.665 g, 4.40 mmol), and $ZnCl_2$ (0.599 g, 4.40 mmol) to obtain **18**. Yield 0.99 g (quant.). Spectroscopic data matched those reported by McManus et al. (10).

Syntheses of oxazolinylamine metal complexes

{1-((4S)-4-Benzyl-4,5-dihydro-oxazol-2-yl)-2-methylpropylamine}dichloroplatinum(II) (1)

A 100 mL round-bottomed flask was charged with $PtCl_2(SMe_2)_2$ (0.084 g, 0.215 mmol), **5** (0.050 g, 0.215 mmol), and 1,2-dichloroethane (20 mL). The mixture was heated to reflux and held for 7 h. After cooling to RT, stirring was continued overnight (18 h). Volatiles were removed in vacuo and Et_2O (10 mL) was added. The suspension was sonicated for 5 min to produce a dark yellow powder, which was filtered and rinsed with Et_2O (10 mL). The yellow solid (isolated as a mixture of diastereomeric metal complexes) was dried under vacuum. Yield 0.10 g (95%). ^{1}H NMR δ: 0.83 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 0.95 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 1.07* (d, 6H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 1.13* (d, 6H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 2.19 (m, 1H, $CH(CH_3)_2$), 2.34* (m, 1H, $CH(CH_3)_2$), 2.68* (dd, 1H, $^2J_{HH}$ = 13.2, $^3J_{HH}$ = 10.4, $CHH'Ph$), 3.01 (dd, 2H, $CHH'Ph$, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 8.4), 3.38 (dd, 1H, $CHH'Ph$, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 2.6), 3.73* (dd, 1H, $CHH'Ph$, $^2J_{HH}$ = 13.2, $^3J_{HH}$ = 2.4), 4.03 (dd, 1H, NH_2CH, $^3J_{HH}$ = 10.4, $^3J_{HH}$ = 5.2), 4.36–4.63 (m, 6H, NH_2CH*, NCH, NCH*, $OCHH'$, $OCHH'$*, $OCHH'$*), 4.78 (pt, 1H, OCH), 5.84 (t, 2H, NH_2), 5.98* (t, 2H, NH_2), 7.13–7.39 (m, 10H, Ph, Ph*). Anal. calcd. for $C_{14}H_{20}Cl_2N_2OPt$: C 33.74, H 4.05, N 5.62; found: C 33.99, H 4.18, N, 5.32. Crystals of the title compound suitable for X-ray diffraction analysis were grown by slow diffusion of iPr_2O into a concentrated solution of **1** in CH_2Cl_2.

Dichloro{(4S)-4-isopropyl-2-pyrrolidin-(2S)-2-yl-4,5-dihydro-oxazole}platinum(II) (2)

A 50 mL round-bottomed flask was charged with $PtCl_2(SMe_2)_2$ (0.227 g, 0.580 mmol), **11** (0.107 g, 0.580 mmol), and 1,2-dichloroethane (20 mL). The mixture was heated to reflux and held for 4 h. The suspension was filtered and rinsed with Et_2O (10 mL). The yellow solid was dried under vacuum. Yield 0.11 g (42%). ^{1}H NMR (DMSO-d_6) δ: 0.74 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 0.79 (d, 3H, $CH(CH_3)_2$, $^3J_{HH}$ = 6.8), 1.68 (m, 1H, $NHCH_2CHH'$), 1.91 (m, 1H, $NHCHCHH'$), 2.00 (m, 1H, $NHCH_2CHH'$), 2.17 (m, 1H, $NHCHCHH'$), 2.47 (m, 1H, $CH(CH_3)_2$), 2.99 (m, 1H, $NHCHH'$), 3.35 (m, 1H, $NHCHH'$), 4.01 (m, 1H, NHCH), 4.27 (pq, 1H, NCH), 4.63 (t, 1H, $OCHH'$, $^2J_{HH}$ = 9.2), 4.77 (m, 1H, $OCHH'$, $^2J_{HH}$ = 9.2, $^3J_{HH}$ = 4.4), 7.29 (q, 1H, NH, $^3J_{HH}$ = 4.8). Anal. calcd. for $C_{10}H_{18}Cl_2N_2OPt$: C 26.79, H 4.05, N 6.25; found: C 26.62, H 4.04, N 6.12.

Dichloro{(4S)-4-isopropyl-2-pyrrolidin-(2S)-2-yl-4,5-dihydro-oxazole}palladium(II) (3)

A solution of **11** (87.0 mg, 0.500 mmol) in CH_2Cl_2 (20 mL) was added to a 25 mL round-bottomed flask containing *trans*-$PdCl_2(PhCN)_2$ (19.2 mg, 0.500 mmol). The resultant orange solution was stirred for 3 h at RT. An orange precipitate began to form within the first 5 min of stirring. The solid was collected by filtration and rinsed with Et_2O (20 mL), then dried under vacuum. Yield 0.12 g (66%). ^{1}H NMR (DMSO-d_6) δ: 0.71 (pt, 6H, $CH(CH_3)_2$), 1.64 (m, 1H, $NHCH_2CHH'$), 1.82–1.92 (m, 2H, $NHCHCHH'$, $NHCH_2CHH'$), 2.07 (m, 1H, $NHCHCHH'$), 2.39 (m, 1H, $CH(CH_3)_2$), 2.84 (m, 1H, $NHCHH'$), 3.23 (m, 1H, $NHCHH'$), 3.86 (m, 1H, NCH), 4.16 (m, 1H, NHCH), 4.47 (pt, 1H, $OCHH'$), 4.60 (pq, 1H, $OCHH'$), 6.58 (m, 1H, NH). Anal. calcd. for $C_{10}H_{18}Cl_2N_2OPd$: C 33.40, H 5.05, N 7.79; found: C 33.66, H 5.25, N 7.48. Crystals of the title compound suitable for X-ray diffraction analysis were grown by slow diffusion of iPr_2O into a concentrated solution of **3** in CH_2Cl_2.

Crystallography

Crystal data for **3** were collected at low temperature (150 K) using a Nonius Kappa CCD area detector diffractometer running COLLECT software (Nonius BV, Delft, The Netherlands, 1997–2002). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using HKL2000 DENZO-SMN (Otwinowski and Minor 1997), and absorption correction was applied using HKL2000 DENZO-SMN (SCALEPACK). The SHELXTL PC V6.14 for Windows NT (Bruker AXS Inc., Madison, Wisconsin) suite of programs was used to solve the structure by direct methods. Subsequent Fourier difference syntheses allowed the remaining atoms to be located. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The absolute structure parameter for **3** was 0.00 (5), which indicated that the correct diastereomer had been refined and that there

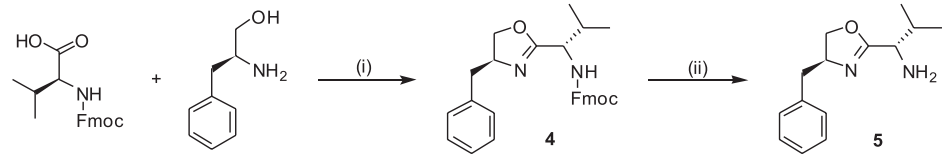
Results and discussion

Aminomethyl-substituted ligands and complexes

The oxazolinylamine ligand **5** was made according to a minor modification of the method by Rajaram and Sigman (4) (Scheme 2). The reaction between Fmoc-protected L-valine and L-phenylalaninol using PPh_3–CCl_4 as the activator and diisopropylethylamine (DIPEA) as the base for both the initial amide bond formation and the subsequent ring closing to install the oxazoline gave the protected precursor **4**. Deprotection by diethylamine gave the desired ligand **5** in 54% overall yield.



The Pt(II) complex **1** was made in 95% yield by the equimolar reaction of **5** and $PtCl_2(SMe_2)_2$ in a refluxing dichloroethane solution (Scheme 3). This yellow compound was soluble in moderately polar chlorinated organic solvents but insoluble in nonpolar solvents such as diethyl ether and hexanes.

The ^{1}H NMR spectrum of the free ligand **5** was consistent, as expected from previous work (4), with a single diastereomer (e.g., the isopropyl methyl peaks appeared as the expected two doublets at δ: 0.91, 0.93). However, the ^{1}H NMR spectrum of the corresponding Pt(II) complex **1** was dependent on the time allowed for the reaction between $PtCl_2(SMe_2)_2$ and **5**. It showed a "doubling" of all of the peaks (e.g., the isopropyl methyl peaks appeared as two pairs of doublets of almost equal intensity at δ: 0.83, 0.95 and 1.07, 1.13) when the reaction time was longer than 18 h; shorter reaction times gave simpler spectra in which doubling was greatly diminished. This phenomenon was consistent with the presence of a pair of diastereomeric metal complexes, which was confirmed by X-ray crystallography. Although the structure of **1** could not be refined sufficiently well for publication, the basic atom connectivity could be determined unequivocally. The unit cell contained equal

Scheme 3. Synthesis of **1**.

Scheme 4. Synthesis of pyrrolidinyloxazolines by the method of McManus et al. (*i*) $SOCl_2$, toluene, 5 h; (*ii*) NEt_3, CH_2Cl_2; (*iii*) NEt_3, DAST, CH_2Cl_2, –78 °C; (*iv*) PG = Fmoc: Et_2NH; PG = Cbz: H_2, 10% Pd–C, MeOH.

numbers of both the expected *S,S*-diastereomer and the unexpected *S,R*-diastereomer of **1**. This showed that the stereocentre associated with the aminoalkyl chain was susceptible to epimerization under the relatively harsh conditions used for the coordination reaction. ^{1}H NMR data indicated that the epimerization could be minimized (<10%) by simply reducing the reaction time to ~8 h. This result is important because catalysts incorporating ligands of this type have typically been generated in situ and have therefore generally not been well characterized; therefore, relationships drawn between the absolute configuration of the active catalyst and the observed *ee* in the product(s) of an asymmetric reaction are necessarily of limited validity. A solution of free ligand in dichloroethane was heated to reflux in the absence of metal for 24 h and, despite some decomposition, no epimerization was seen by ^{1}H NMR spectroscopy.

Pyrrolidine-substituted ligands

The pyrrolidinyloxazoline ligand **11** was made according to Scheme 4 (PG = Fmoc). This general method has been applied previously to the synthesis of **11** (and **12**, not shown) by McManus et al. (10), who instead used the Cbz-protecting group. These workers noted that the NMR spectra of their intermediates **8** and **10** were complicated by a doubling of many of the peaks but did not provide a rationale for this phenomenon.

It is well-known that the *E* and *Z* isomers of amide bonds can be seen by NMR spectroscopy at RT. These are ususally evidenced by a coalescence of some (if not all) peaks at high temperature because of rapid chemical exchange of *E* and *Z* isomers. Given our experience with **1** (vide supra), we were concerned that the doubling observed for all of the compounds **7**–**11** may have resulted not only from the presence of *E* and *Z* isomers but also from diastereomers arising at some stage during ligand synthesis. Presumably, epimerization of the pyrrolidine stereocentre could occur via the intermediate acid chloride **6** or, less likely, during the DAST-induced oxazoline ring-closing step to form **9** and **10**. It has been shown by Wipf and co-workers (28) that DAST is able to induce this cyclization with less than 1.5% racemization of sensitive substrates.

McManus et al. did not report high-temperature NMR data for their compounds. Therefore, we repeated the syntheses of the Cbz-protected compounds and examined both them and our Fmoc-protected species closely by variable temperature NMR spectroscopy. For the open chain compounds **7** and **8**, we concentrated on peaks due to the amide N*H* proton, and for the oxazolines **9** and **10**, on those due to the isopropyl methyl protons. Figure 1*a* shows the amide region of the ^{1}H NMR spectrum of **8** at RT and at 155 °C; Fig. 1*b* shows the isopropyl methyl region of the ^{1}H NMR spectrum of **10** at RT, and at 70 °C in DMSO-d_6 solution.

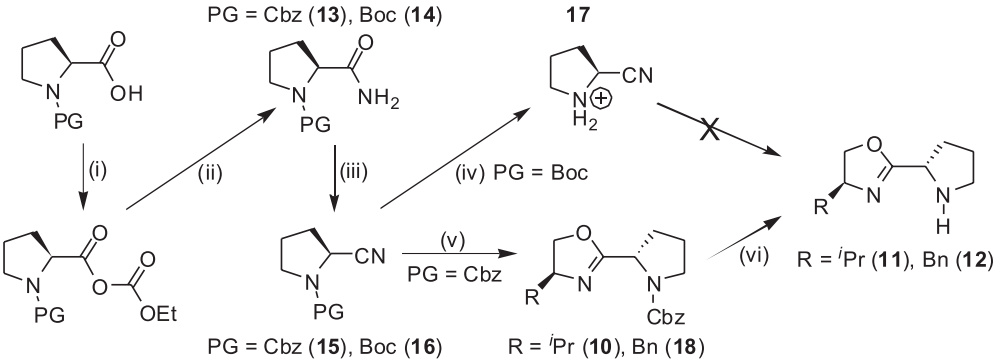
Scheme 5. Synthesis of pyrrolidinyloxazolines by Zn-catalyzed cyclization of 2-cyanopyrrolidine and β-amino alcohols. (*i*) EtOC(O)Cl, NEt_3; (*ii*) NH_4OH; (*iii*) TFAA, NEt_3; (*iv*) TFA; (*v*) amino alcohol, $ZnCl_2$, PhCl; (*vi*) H_2, Pd–C.



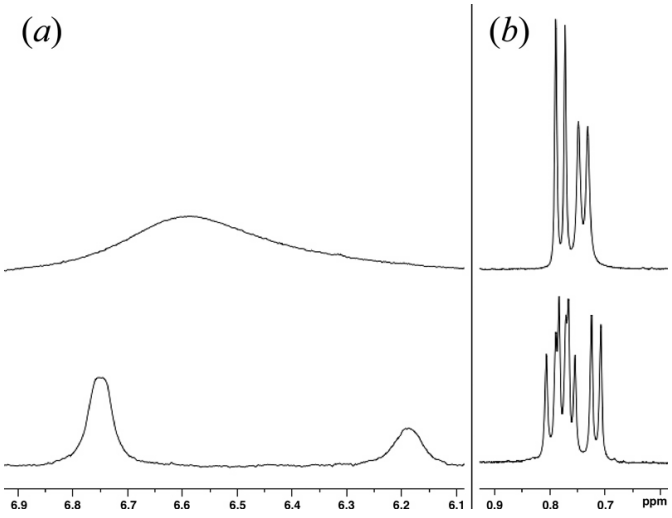


Fig. 1. (*a*) The δ 6.1–6.9 range of the ^{1}H NMR spectra of **8** at 155 °C (top) and at RT (bottom), and (*b*) the δ 0.6–0.9 range of the ^{1}H NMR spectra of **10** at 70 °C (top) and at RT (bottom) in DMSO-d_6 solution.

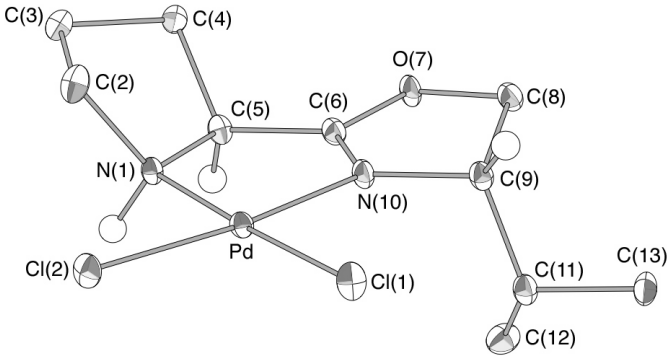
Coalescence of the peaks due to N*H* proton in **8** (from two broad singlets at δ: 6.18, 6.76 in the RT spectrum into a single broad peak at δ: 6.58 at 155 °C) and of those due to the isopropyl methyl protons in **10** (four doublets at δ: 0.73, 0.78, 0.79, 0.82 in the RT spectrum to two doublets at δ: 0.84, 0.88 at 70 °C) indicated that neither the acid chloride nor the DAST cyclization step were implicated in epimerization. The overall number, relative integrations, and splittings of the peaks in the high-temperature spectra were consistent with only a single diastereomer of the compound under study. These experiments implied that the likely cause of the doubling was not the presence of diastereomers but rather of *E* and *Z* isomers resulting from restricted rotation about the carbamate bond in **10** and the amide and (or) carbamate bond in **8**. The NMR spectra of our new Fmoc-protected analogues **7** and **9** were also complicated by the presence of *E* and *Z* isomers. These likewise simplified at high temperature.

Yields for the amide bond forming and cyclization steps in the Cbz- and Fmoc-protected pathways were not significantly different, being between 85% and 91%. However, differences arose in the final deprotection step. When PG = Cbz (Scheme 4), the deprotection was by hydrogenolysis; for PG = Fmoc, on the other hand, deprotection was achieved by treatment with base. These two routes gave isolated yields of 86% and 54%, respectively. The Fmoc deprotection was complicated by the decomposition of some of the intended product into an open chain peptide. The ^{1}H NMR spectra of the final products arising from the Cbz and Fmoc manifolds were identical and unequivocally consistent with the presence of only a single diastereomer.

We investigated an alternate approach to the pyrrolidinyloxazolines starting from protected (2*S*)-2-cyanopyrrolidines (Scheme 5, **15** and **16**), which were made using a modification to the syntheses presented by the groups of Wállen (25) and Ley (26, 27). Judicious choice of protecting group was essential. When PG = Boc, there was no reaction between the cyanopyrrolidine **16** and the amino alcohol; moreover, given the acidic conditions, a putative Boc-protected pyrrolidinyloxazoline would be difficult to deprotect without destruction of the oxazoline ring. Cleavage of Boc prior to oxazoline formation gave the TFA salt **17**, which in our hands could not be induced to react with the amino alcohol either in the presence or absence of $ZnCl_2$ and (or) base. The Fmoc protecting group was also problematic because its corresponding cyanopyrrolidine (not shown) decomposed under the reaction conditions. Finally, we found that treatment of Cbz-protected (2*S*)-2-cyanopyrrolidine **15** with amino alcohols in the presence of $ZnCl_2$ at elevated temperature cleanly gave the intended Cbz-protected pyrrolidinyloxazolines **10** and **18**, which were easily deprotected by hydrogenolysis to give the intended products **11** and **12**.



This route had distinct advantages over the route developed by McManus et al. First, the Cbz-protected 2-cyanopyrrolidine **15** could be made quickly and in high yield (a few hours in ~83% overall yield); second, the diversity-introducing step was placed later in the synthesis; third, the overall cost was reduced by elimination of the expensive DAST reagent; and finally, the number of required purification steps was reduced (there was no need for purification until after $ZnCl_2$-mediated oxazoline formation).

Metal complexes

The Pd(II) complex **3** was made in 66% yield by the equimolar reaction of *trans*-$PdCl_2(PhCN)_2$ and **11** in CH_2Cl_2 solution at RT. The analogous Pt(II) complex **2** was also

Fig. 2. ORTEP representation of the molecular structure of **3** (ellipsoids drawn at 50% probability). Except for those associated with chiral centres, H-atoms have been omitted for clarity. All of the chiral centres have the *S*-configuration.

made in 42% yield by equimolar reaction of $PtCl_2(SMe_2)_2$ and **11** in dichloroethane at 80 °C.

The molecular structure of **3** is represented as a thermal ellipsoid plot in Fig. 2; selected bond distances and angles appear in Table 2. As expected, the coordination geometry about the metal was essentially square planar. The N(1)–Pd–N(10) and Cl(1)–Pd–Cl(2) angles were approximately 81.8° and 93.1°, respectively. Although the Pd–N(10) (Pd–oxazoline) distance (2.008(4) Å) was shorter than the Pd–N(1) (Pd–pyrrolidine) distance (2.054(4) Å), the difference was not reflected in a corresponding trans influence for the chloride ligands: the Pd–Cl bond lengths were nearly identical and approximately 2.30 Å. The Pd–N(1) distance was in the range of those typically observed for Pd(II) complexes of pyrrolidines (2.05–2.11 Å). The mean plane of the oxazoline ring was very nearly coincident with the mean coordination plane containing the metal centre and its four ligated atoms; these two planes intersected at an angle of 7.98°. The pyrrolidine ring adopted an envelope configuration in which C(3) rested 0.639 Å from the mean plane defined by C(2), N(1), C(5), and C(4). This plane made an angle of 53.68° with the mean plane of the oxazoline ring.

The absolute configurations of C(9) and C(5) were both *S*, which was consistent with the expected configurations based on the L-proline and L-valinol starting materials; no epimerization occurred either during the ligand synthesis or on coordination to the metal. These configurations allowed the quadrant analysis typically applied to chiral C_2-symmetric complexes to be superimposed on this formally C_1-symmetric compound. In the orientation shown in Fig. 2, the steric bulk of the ligand occupied the top left and bottom right quadrants; the near 180° C(11)–N(10)–N(1)–C(2) torsion angle of 172.33°, together with the similar C(11)–C(9)–N(10) and C(2)–N(1)–N(10) angles (111.67° and 127.76°, respectively), further strengthened the pseudo-C_2-symmetric approach to thinking about this ligand.

The solid-state structure of **3** featured weak intermolecular N–H...Cl interactions of 3.33 Å that were only very slightly longer than the sum of the van der Waals radii of N and Cl (3.30 Å); the N–H–Cl angle was 156.15°. These interactions in the solid state point to the possibility that the N*H* groups of coordinated pyrrolidine (as well as of oxazolidine (29) and, presumably, related nitrogen heterocycles) are noninnocent and may participate in catalytic cycles (30).

Table 2. Selected bond distances, bond angles, and torsion angles for **3** with standard deviations in parentheses.

Bond distances (Å)	
Pd–N(10)	2.008(4)
Pd–Cl(2)	2.3000(12)
Pd–N(1)	2.054(4)
Pd–Cl(1)	2.3040(13)
Bond angles (°)	
N(10)–Pd–N(1)	81.84(17)
N(1)–Pd–Cl(2)	90.50(11)
N(1)–Pd–Cl(1)	176.39(12)
N(10)–Pd–Cl(2)	172.16(13)
N(10)–Pd–Cl(1)	94.57(13)
Cl(2)–Pd–Cl(1)	93.08(5)
Torsion angles (°)	
Cl(2)–Pd–N(1)–C(2)	58.7(3)
Pd–N(10)–C(9)–C(11)	69.0(6)

Conclusion

We have successfully characterized the first simple *N,N′*-chelated Pt and Pd complexes of oxazolinylamine ligands of type **I** and **V**. Our finding that type **I** ligands may epimerize upon metal complexation illustrates the importance of proper characterization of complexes prior to their use as catalysts. We also highlight the importance of including high-temperature NMR data in the characterization of the *N*-protected intermediates to these ligands as proof of stereochemical purity. We have applied a shorter and more cost effective route to the synthesis of pyrrolidinyloxazoline ligands via the $ZnCl_2$-mediated cyclization of Cbz-protected (2*S*)-2-cyanopyrrolidine with amino alcohols. This allows for quicker and easier access to this important class of chiral ligands. The application of ligands of type **I** and **V** in the asymmetric allylic oxidation of cyclic alkenes is currently under investigation.

Investigations of the mono- and dicycloaddition reactions of $[SNS][MF_6]$ (M = As, Sb) with the dinitriles $NCC(O)CN$ and $NCC(Cl)_2CN$ — Energetics and the preference for $[SNS]^+$ dicycloaddition products in solution and solid state

T. Stanley Cameron, Andreas Decken, Mary Gabriel, Carsten Knapp, and Jack Passmore

Abstract: The stepwise symmetry-allowed cycloaddition reactions of $[SNS]^+$ with the dinitriles NC–X–CN (X = CCl_2, CO) were investigated. The reaction of $[SNS]^+$ and dinitrile in 2:1 ratio yielded the dicycloaddition product quantitatively after 2 weeks (in situ ^{13}C NMR). At a 1:1 ratio, mixtures of mono- and dicycloaddition products were obtained that could not be completely separated from one another. The energetics of the reaction were estimated in the gas phase, in solution (SO_2 and CH_2Cl_2), and solid phases using DFT calculations (PBE0/6-311G*) and a "volume-based thermodynamics" approach for lattice enthalpies. Monocycloaddition products are stable in the gas phase and in solution with respect to disproportionation reactions, but in the solid state the disproportionation of 2 $[NC–X–(CNSNS)][AsF_6]$ into $[X(CNSNS)_2][AsF_6]_2$ and NC–X–CN is strongly favored because of the higher lattice enthalpy of the 1:2 salt. In the gas phase, the second cycloaddition is endothermic because of the charge repulsion of the two positive charges, but in the solid state the reaction is strongly favored because of the lattice enthalpy gain on the formation of the 1:2 ($[X(CNSNS)_2][AsF_6]_2$) from two 1:1 salts ($[NC–X–(CNSNS)][AsF_6]$ and $[SNS][MF_6]$). The crystal structures of the dicycloaddition products $[Cl_2C(CNSNS)_2][AsF_6]_2$ and $[OC(CNSNS)_2][AsF_6]_2$ and the monocycloaddition product $[Cl_2C(CNSNS)CN][AsF_6]$ were obtained. In $[Cl_2C(CNSNS)CN][AsF_6]$, the free nitrile groups interact with neighboring heterocycles further demonstrating that potential of free nitrile groups for introducing intermolecular interactions. $[OC(CNSNS)_2]^{2+}$ is a planar dication, which adopts the conformation with $S^{\delta+}\cdots O^{\delta-}$ contacts to optimize intramolecular electrostatic interactions.

Key words: crystal structure, sulfur–nitrogen, 1,3,2,4-dithiadiazolyium, nitriles, cycloaddition, DFT calculations, thermodynamics, energetics.

Résumé : On a étudié les réactions de cycloaddition permises par la symétrie du cation $[SCS]^+$ avec les dinitriles NC–X–CN (X = CCl_2, CO). La réaction du $[SCS]^+$ avec le dinitrile dans un rapport de 2:1 conduit, après deux semaines, à la formation quantitative du produit de cycloaddition, d'après le RMN du ^{13}C in situ. À un rapport de 1:1, fournit un mélange des produits de mono- et de dicycloaddition qu'il n'a pas été possible de séparer complètement. Faisant appel à des calculs de la théorie de la fonctionnelle de la densité (PBE0/6-311G*) et une approche thermodynamique basée sur le volume pour les enthalpies de réseau, on a évalué les énergies impliquées dans la réaction en phase gazeuse, en solution dans le SO_2 et le CH_2Cl_2 ainsi qu'en phases solides. Les produits de monocycloaddition sont stables en phase gazeuse et en solution par rapport aux réactions de disproportionation, mais à l'état solide la disproportionation de 2 $[NC–X–(CNSNS)][AsF_6]$ en $[X(CNSNS)_2][AsF_6]_2$ et NC–X–CN est fortement favorisée en raison de la grande enthalpie de réseau dans le sel 1:2. En phase gazeuse, la deuxième cycloaddition est endothermique en raison de la répulsion de charge des deux charges positives, mais à l'état solide la réaction est fortement favorisée en raison du gain en enthalpie de réseau lors de la formation du sel 1:2 ($[X(CNSNS)_2][AsF_6]_2$) à partir de deux sels 1:1 ($[NC–X–(CNSNS)][AsF_6]$ et $[SNS][MF_6]$). On a déterminé les structures cristallines des produits de dicycloaddition $[Cl_2C(CNSNS)_2][AsF_6]_2$ et $[OC(CNSNS)_2][AsF_6]$ et le produit de monocycloaddition $[Cl_2C(CNSNS)CN][AsF_6]$. Dans le $[Cl_2C(CNSNS)CN][AsF_6]$ les groupes nitriles libres interagissent avec les hétérocycles adjacents, et ce résultat met

[Traduit par la Rédaction]

Introduction

The general utility of $[SNS]^+$ as a reagent (1) has been greatly enhanced by our recent convenient large-scale synthesis of the synthetically useful $[SNS][SbF_6]$ (2). The cycloaddition chemistry of this simple triatomic cation (1) with various unsaturated centers (e.g., C=C, C≡C, C≡N) has been extensively investigated (3). The reaction with nitriles yields 6π 1,3,2,4-dithiadiazolyium salts in essentially quantitative yields, and it represents the only general synthetic route to the derivatives of the [R–CNSNS] heterocyclic ring system (the 1,3,2,4-dithiadiazolyium salts with R = Me, Ph have also been prepared following a different approach (4)). The 6π 1,3,2,4-dithiadiazolyium cations can be readily reduced to the corresponding 7π radicals, which usually rearrange to the thermodynamically more stable 7π [R–CNSSN] isomers (3). Reactions with compounds containing two or more unsaturated centers (i.e., starting from di- and trinitriles) result in the corresponding stable multiradicals, whose physical properties and electronic structures are of interest.

So far, cycloaddition reactions of $[SNS]^+$ with multifunctional nitriles (e.g., NC–CN, *o*,*m*,*p*-$C_6H_4(CN)_2$) (5) resulted in the transformation of every nitrile group into a 1,3,2,4-dithiadiazolyium moiety (3). Attempts to isolate the intermediates, containing free nitrile groups, have been unsuccessful (3*c*). Only with $K[C(CN)_3]$ has the stepwise cycloaddition and the isolation of the intermediates been achieved (6). A free nitrile group could either (*i*) be used as means to link molecules in the solid state to modify the bulk properties (via –C≡N···S interactions), as has been demonstrated in the solid state structures of NC–C_6F_4–CN_2S_2 (7) and NC–CN_2S_2 (8); (*ii*) be a linker to a transition-metal center (via –C≡N···M coordination), or (*iii*) undergo another cycloaddition reaction to introduce a different functional group (e.g., –C≡N + "S_3^+" → –CNS_3^+ (9)). Thus, the stepwise cycloaddition of $[SNS]^+$ with multifunctional nitriles and the isolation of the intermediate monocycloaddition products is key to opening up new aspects of this area of chemistry. In this paper, we report the reactions of the dinitriles $NCC(Cl)_2CN$ and NCC(O)CN, respectively, with $[SNS]^+$ in a 1:2 ratio and attempts to isolate the monocycloaddition products from reactions using a 1:1 ratio. The underlying thermodynamics for all reactions are discussed, based on DFT calculations of species in the gas phase and in solution and including lattice enthalpies in the solid state.

Experimental

Preparative methods

All reactions were performed in glass vessels equipped with J. Young Teflon valves and a medium sintered glass frit. Techniques and apparatus have been described elsewhere (10).

FTIR spectra were recorded at 293 K on a Thermo Nicolet NEXUS 470 FTIR (resolution: 4 cm^{-1}) as nujol or fluorolube mulls between KBr discs. FTRaman spectra were recorded on a Bruker IFS66 FTIR equipped with a Bruker FRA106 FTRaman accessory, using a Nd-YAG laser (emission wavelength: 1064 nm; maximum laser power: 300 mW) in 5 mm Pyrex NMR tubes. Data were collected in the backscattering mode (180° excitation; resolution: 2.0 cm^{-1}). NMR spectra were recorded on a Varian 400 NMR spectrometer in 10 mm NMR tubes and were externally referenced to TMS (^{13}C) and H_3CNO_2 (^{14}N, ^{15}N). Elemental analyses were carried out by Galbraith Laboratories, Inc., Knoxville, TN, USA.

Sulfur dioxide (99.98%, Matheson) was stored over CaH_2, $CFCl_3$ (99.9%, Matheson) was stored over 3A molecular sieves, and CH_2Cl_2 (Aldrich) was refluxed over P_4O_{10}, and distilled. $NCC(Cl)_2CN$ (97%, Acros) was found to contain ~4% $NCC(Cl)_2CNH_2$ impurity and was purified by cooling to 0 °C and syringing out the dinitrile under an atmosphere of dry nitrogen. NCC(O)CN (11), $[SNS][AsF_6]$ (8), and $[SNS][SbF_6]$ (2) were prepared by the literature methods.

Synthesis of $[Cl_2C(CNSNS)_2][AsF_6]_2$

A mixture of $NCC(Cl)_2CN$ (1.38 g, 10.2 mmol) and $[SNS][AsF_6]$ (5.43 g, 19.8 mmol) was heated (60 °C) in 15 mL SO_2 with stirring for 2 weeks in a two-bulb apparatus with a condenser and a pressure-equalizing side arm (12).[2] Removal of the volatiles yielded a brown precipitate, which was washed with SO_2–$CFCl_3$ (1:1) until the extract became colourless (eight times). The solvent was removed via dynamic vacuum, leaving $[Cl_2C(CNSNS)_2][AsF_6]_2$ as a yellow powder-like, very sparingly soluble solid (4.86 g, 7.3 mmol, 74% isolated yield, based on $SNS[AsF_6]$).

[2] Precautions should be taken to avoid the explosion hazard when heating liquid SO_2 in a closed glass vessel (face shield, leather gloves, carefully built glass vessel). A reaction vessel with a water-cooled condenser and a pressure-equalizing side arm should be used to reduce the pressure in the apparatus.

$[Cl_2C(CNSNS)CN][AsF_6]$

A mixture of $NCC(Cl)_2CN$ (1.65 g, 12.2 mmol) and $[SNS][AsF_6]$ (2.27 g, 8.5 mmol) in 10 mL SO_2 was heated (60 °C) with stirring for 3 weeks in a two-bulb apparatus with a condenser and a pressure-equalizing side-arm (12).[2] Removal of the volatiles yielded a brown precipitate. Fresh SO_2 (8 g) and $CFCl_3$ (8 g) were condensed onto the brown solid, and the mixture was cooled to –70 °C, resulting in a brown solution over a yellow-brown precipitate. The solubles were decanted off, and the process was repeated until the filtrate was colourless (three times), leaving a yellow solid (shown to be a mixture of $[Cl_2C(CNSNS)_2][AsF_6]_2$ and $[Cl_2C(CNSNS)CN][AsF_6]_2$ by NMR). $Cl_2C(CNSNS)CN][AsF_6]_2$ could be only partly extracted from this mixture by washing with CH_2Cl_2. A few colourless crystals of the title compound were obtained from the yellow solid in a SO_2–$CFCl_3$ mixture by slow evaporation of the solvent (temperature gradient: 0–7 °C). Reactions using 1:1 stoichiometry gave similar results.

IR (KBr, nujol) (1300–430 cm^{-1}): 1261 w, 1230 w, 1150 w, 1085 m, 1009 m, 985 w, 960 s, 933 w, 903 s, 820 s, 807 s, 680 s ($\nu_3\ AsF_6^-$), 629 m, 583 m ($\nu_2\ AsF_6^-$), 566 m, 508 w, 470 w 449 s. FTRaman (2300–100 cm^{-1}): 2259 s (νC≡N), 1439 w, 1419 w, 1149 w, 958 w, 821 s, 806 m, 681 s ($\nu_3\ AsF_6^-$), 669 m, 586 s ($\nu_2\ AsF_6^-$), 484 w, 394 m, 371 m ($\nu_5\ AsF_6^-$), 336 w, 306 w, 284 w, 188 w, 168 m. The actual spectra are given in the supplementary data.[3]

The reaction of NCC(O)CN and $[SNS][SbF_6]$ in 1:1 ratio yielded a mixture of $[OC(CNSNS)_2]^{2+}$ and $[OC(CNSNS)CN]^+$, as identified by NMR. ^{13}C NMR (100.6 MHz, SO_2, RT) δ: 110.3 ($[OC(CNSNS)CN]^+$), 154.6 ($[OC(CNSNS)CN]^+$), 165.0 ($[OC(CNSNS)_2]^{2+}$), 194.0 ($[OC(CNSNS)_2]^{2+}$), 195.7 ($[OC(CNSNS)CN]^+$). ^{14}N NMR (28.9 MHz, SO_2, RT) δ: –120 ($\nu_{1/2}$ = 580 Hz, $[OC(CNSNS)CN]^+$), –20 ($\nu_{1/2}$ = 450 Hz, $[OC(CNSNS)_2]^{2+}$ and $[OC(CNSNS)CN]^+$), 27 ($\nu_{1/2}$ = 450 Hz, $[OC(CNSNS)_2]^{2+}$ and $[OC(CNSNS)CN]^+$).

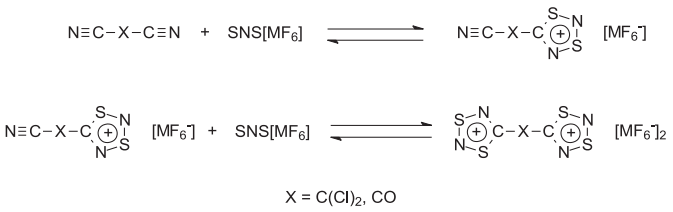
Crystal structure determinations

Suitable single crystals, obtained from SO_2 solution, were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold nitrogen stream of the goniometer. Data were collected on a Bruker AXS P4/Smart 1000 diffractometer (for $[OC(CNSNS)_2][SbF_6]_2$) or a Rigaku AFC5R diffractometer (for $[Cl_2C(CNSNS)CN][AsF_6]$ and $[Cl_2C(CNSNS)_2][AsF_6]_2$). The structures were solved by direct methods and refined by full-matrix least squares on F^2 (SHELXL) (13). The data were corrected for absorption. All figures illustrating structures were prepared using the program Diamond (14). Detailed crystal structure refinement data are given in Table 1.[3]

Quantum chemical calculations

All calculations have been carried out using the PBE0 DFT hybrid functional (15) with a 6-311G* basis set as implemented in Gaussian 03 (16). The free energies in solution were calculated using a polarization continuum model (PCM) with the integral equation formalism (IEF) (17). The following parameters were used to describe the solvent SO_2: dielectric constant (Eps) = 14.0, solvent radius (Rsolv) = 2.021 Å, molar volume (VMol) = 46.75 Å^3, numeral density (Rho) = 0.01288 Å^{-3}, and density = 1.37027 g/mL (18*a*).

Fig. 1. General scheme for the reaction of a dinitrile with $[SNS][MF_6]$.



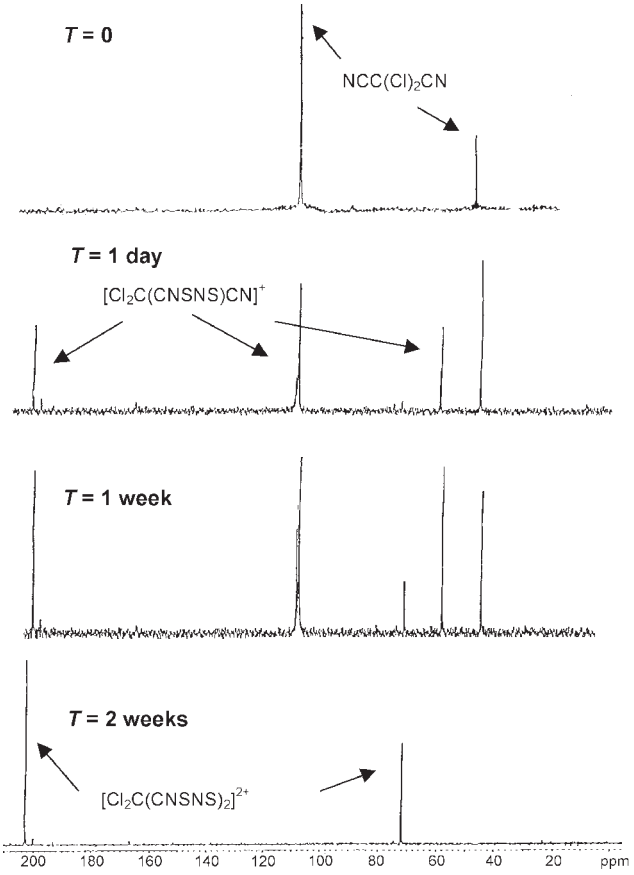


Fig. 2. In situ ^{13}C NMR spectra of the reaction of $NCC(Cl)_2CN$ with 2 $[SNS][AsF_6]$, followed over time.

Results and discussion

The reactions of the dinitriles NC–X–CN (X = CCl_2, CO) with $[SNS][MF_6]$, with 2:1 stoichiometry (SNS^+:dinitrile), in liquid sulfur dioxide gave the corresponding dicycloaddition products $[SNSNC–X–CNSNS]^{2+}$, as $[MF_6]^-$ salts in essentially quantitative yields. Reactions using 1:1 stoichiometries resulted in mixtures of the mono- and dicycloaddition products (Fig. 1).

To gain better insight, the reaction of $NCC(Cl)_2CN$ with $[SNS][AsF_6]$ in 1:2 ratio was followed in situ by ^{13}C NMR spectroscopy (Fig. 2). Immediately after the reaction had commenced, only starting materials were observed. After 1 day, peaks assigned to $[Cl_2C(CNSNS)CN]^+$ appeared, and after 1 week, the reaction mixture contained $[Cl_2C(CNSNS)CN]^+$ and $[Cl_2C(CNSNS)_2]^{2+}$. In reactions with two equivalents of $[SNS]^+$, peaks attributed to the intermediate mono-

Selected bond lengths (Å) and angles (°): C6—O, 1.187(10); C1—C6, 1.503(19); C6—C1′, 1.50(2); C1—N5, 1.292(16); C1′—N5′, 1.30(2); S4—N5, 1.598(12); S2′—N5′, 1.596(9); N3—S4, 1.694(11); S2′—N3, 1.659(6); S2—N3, 1.561(5); N3—S4′, 1.476(10); C1—S2, 1.74(2); C1′—S,4′ 1.73(2); C1–C6–C1′, 104.7(10); dihedral angle between the two CNSNS rings, 18.4(3).

cyloaddition product disappeared after 2 weeks, leaving $[Cl_2C(CNSNS)_2]^{2+}$ as the clean product. Reactions with only one equivalent $[SNS]^+$ always result in a mixture of the mono- and the dicycloaddition product. In general, the dicycloaddition products are less soluble in liquid SO_2. Thus, the separation of the mono- from the dicycloaddition products was attempted by washing with different solvents (SO_2, CH_2Cl_2), but the complete separation of the products was not successful. Isolation of the small amount mono-cycloaddition product formed after 1 day was not attempted because of the necessary separation from an excess $[SNS]^+$ and does not present a feasible synthetic route to the monocycloaddition products.

X-ray crystal structures

The X-ray structures of the cations $[Cl_2C(CNSNS)_2]^{2+}$, $[OC(CNSNS)_2]^{2+}$, and $[Cl_2C(CN)(CNSNS)]^+$ are given in Figs. 3–5, and those of the $[MF_6]^-$ anions are included in the supplementary data.[3] The low quality of the structure determinations (high standard deviations) precludes a detailed discussion of the bond angles and distances; however, aver-

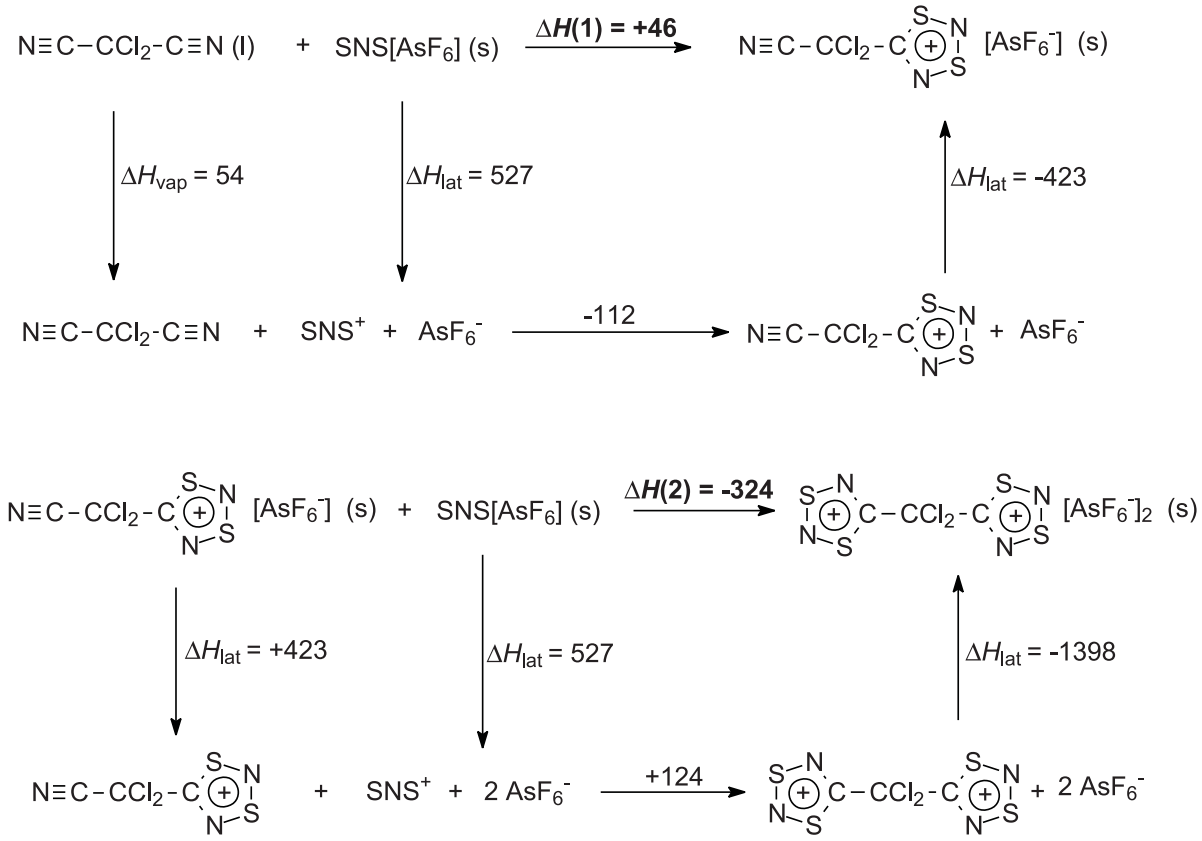
[a]Contains the heat of vaporization (estimated to be +54 kJ/mol, see supplementary data).[3]



aged data for the chemically equivalent bonds agree with previously reported data for related $[R–CNSNS]^+$ cations (3, 5, 6). The structure of $[OC(CNSNS)_2][SbF_6]_2$ shows an interesting disorder of the entire cation, which is discussed in the supplementary data.[3] In the CCl_2 derivative, the $RCNSNS^+$ rings are connected via an sp^3 carbon center, resulting in an angle between the two CNSNS rings of 70.8(3)°, while in the CO compound, the rings are connected via an sp^2 carbon center, leading to an almost planar molecule (dihedral angle between the least-square planes of the two CNSNS rings 18.4(3)°) with the heterocyclic rings and the C=O group in one plane. The orientation of the rings with respect to each other is mainly governed by electrostatics. For $[OC(CNSNS)_2]^{2+}$, three rotational isomers A, B, and C are possibly depending on the orientation of the heterocyclic rings (the rotational isomers, including calculated charges, are given in Fig. 6). Calculations (PBE0/6-311G*) show that the experimental structure (Fig. 4) is also the calculated minimum structure A because of the attractive electrostatic $S^{\delta+}\cdots O^{\delta-}$ interactions. Rotating one ring in A by 180° gives B, which has one additional attractive $S^{\delta+}\cdots N^{\delta-}$ contact, but this is offset by the loss of one $S^{\delta+}\cdots O^{\delta-}$ contact and the additional repulsive $N^{\delta-}\cdots O^{\delta-}$ contact, resulting in an isomer 20 kJ/mol higher in energy. The third isomer C obtained by rotating both rings by 180° is even higher in energy because of the unfavorable electrostatics ($N^{\delta-}\cdots O^{\delta-}$ and $S^{\delta+}\cdots S^{\delta+}$).

Solid-state packing

In $[Cl_2C(CNSNS)_2][AsF_6]_2$, the dications are well separated from each other and surrounded by AsF_6^- anions. In contrast, in $[NCC(Cl)_2CNSNS][AsF_6]$, the cations show some interactions via $S^{\delta+}\cdots{}^{\delta}N{\equiv}C$ contacts between the nitrile groups and sulfur atoms of the neighboring cations (Fig. 7). This shows that the anticipated interactions between sulfur–nitrogen heterocycles can be created via free nitrile groups. Therefore, free nitrile groups are a promising and valuable tool in crystal engineering to introduce intermolecular inter-

actions between sulfur–nitrogen radicals in the solid state, as previously demonstrated by the characterization of the remarkable $NC–C_6F_4–CN_2S_2$ (6).

Energetics

The preference for the dicycloaddition products in reactions of dinitriles with $[SNS]^+$ in 1:1 ratio was puzzling. Previous explanations focused on kinetic factors (3*c*, 19) and suggested charges, atomic orbital coefficients, steric considerations, and possible transition states to account for this phenomenon but did not take any thermodynamic considerations into account. Therefore, the thermodynamics in the solid state, in SO_2 and CH_2Cl_2 solution, and in the gas phase were investigated to gain insight into the energetics of the cycloaddition reactions of $[SNS]^+$ with the dinitriles NC–CN, NC–C(O)–CN, and $NC–C(Cl)_2–CN$. All estimated values are compiled in Table 2. The lattice enthalpies were calculated using the "volume based thermodynamics" approach by Jenkins et al. (20), and full details are given in the supplementary data.[3] Figure 8 shows the Born–Haber cycle for the first and the second cycloaddition for the reaction of $[SNS][AsF_6]$ with $NCC(Cl)_2CN$ as an illustrative example. In the gas phase the first cycloaddition reaction is favorable by 112 kJ/mol, while the second cycloaddition, which transfers a second positive charge onto the molecule, is unfavorable by 124 kJ/mol. However, the situation is reversed in the solid state. Here, the first cycloaddition reaction is unfavorable essentially because the size of the cation ($[SNS]^+$ vs. $[Cl_2C(CNSNS)CN]^+$) is increased, and thus, lattice enthalpy of the salts is reduced. In contrast, the second cycloaddition is favorable because of the larger lattice enthalpy of the resulting 1:2 salt (dication and two monoanions) compared with the 1:1 salts (monocation and monoanion), which overcomes the unfavorable gas phase term. In general, multiple-charged ions are unstable in the gas phase with respect to dissociation into species with a smaller charge (21), but they can be stable as salts in the solid state because of the gain in lattice enthalpy (18). In SO_2 solution, the first and the second cycloaddition are favorable by –29 and –66 kJ/mol, respectively (–10 and –61 kJ/mol in CH_2Cl_2). The situation for other nitriles in all three phases is similar (Table 2); however, the nature (electron donating or withdrawing) and the size of the substituent or spacer groups, as well as different heats of vaporization, slightly change the values but not the general trend.

The thermodynamic preference for the dicycloaddition products becomes even clearer if the disproportionation of the monocycloaddition product into $[SNS]^+$ and the dinitrile (reaction 1) and into the dinitrile and the dicycloaddition product (reaction 2) are investigated (actual values are included in Table 2; Fig. 9 shows the situation for NC–CN as an illustrative example). In the gas phase, in SO_2, and CH_2Cl_2 solution, the monocycloaddition product is stable with respect to disproportionation in both directions, but in the solid state, the higher lattice enthalpy of the 1:2 salt relative to twice that of the 1:1 salt is greater than the gas phase term and makes the disproportionation into the dicycloaddtion product and the dinitrile favorable. Therefore, in the

solid state, the dicycloaddition product is the thermodynamic product in this type of reactions, and the lattice enthalpy gain in the second cycloaddition is the driving force.

However, the situation is much more complicated in reality. In addition to the idealized equilibria in solution and the solid state, experimental lattice enthalpies and solvation energies are reflected in the solubility, which plays an important role. $[SNS][MF_6]$ is soluble in SO_2 (the solubility has been determined to be 230 g/L in SO_2 (22)), while the monocycloaddition products are less soluble, and the dicycloaddition products are only sparingly soluble. Thus, the dicycloaddition product, once formed, precipitates out of solution and drives the equilibrium even further towards the dicycloaddition product.

In addition, kinetic effects also play a role. The activation energies for the first and the second symmetry-allowed cycloaddition are by definition smaller than the corresponding activation energies for the reverse cycloaddition reactions (Fig. 10). This implies that the proposed reverse cycloaddition reactions could also be significantly kinetically hindered. A reverse cycloaddition has been established in related sulfur–nitrogen systems (cf. $[S_3N_2]^{2+}$ (18*b*), $[(R_4C_2)_2S_2N]^+$ (23)), and a kinetic energy barrier for the reverse cycloaddition has been found experimentally in the later case. Our failure to prepare $[NC–CNSNS][MF_6]$ from reactions of an excess of NC–CN and $[SNS][MF_6]$ (5*a*) agrees with the underlying thermodynamics, the decreasing solubility of the dicycloaddition products, and the kinetically hindered and thermodynamically unfavorable reverse cycloaddition reaction.

The strategy to obtain the monocycloaddition products would be to use an $[SNS]^+$ salt of a very large anion to reduce the lattice enthalpy gain for the second step and also to increase the solubility in a solvent with a lower dielectric constant, and to use a lower reaction temperature. The recently published salt $[SNS][Al(OC(CF_3)_3)_4]$ (24), which is very soluble in CH_2Cl_2, is a good candidate and will be the subject of further investigations.[4]

Supplementary data

The supplementary data include the optimized geometries and total energies for all calculated molecules, structural parameters for the MF_6^- anions, disorder in the structure of $[OC(CNSNS)_2][SbF_6]_2$, vibrational spectra and calculated frequencies, details for the thermodynamic estimations, and calculated transition states.[4]

Chemistry of the potassium, silver, and tetra(*n*-butyl)ammonium salts of sydnone *N*-oxide (Traube's anion)

Navamoney Arulsamy, D. Scott Bohle, and Inna Perepichka

Abstract: Traube's dianion, 4-methylcarboxysydnone-3-hydroxylate (2), and its monomethyl ester (**1**) are readily isolated as their di- and mono-potassium salts from the reaction of nitric oxide with dimethylmalonate and potassium methoxide in methanol. Metathesis reactions of **1** with silver nitrate and tetra(*n*-butyl)ammonium bromide yield the silver and tetra(*n*-butyl)ammonium salts of 4-methylcarboxysydnone-3-hydroxylate. In contrast to other known sydnone derivatives, the present sydnones are stable in both acidic and basic solutions. Single crystal X-ray diffraction data obtained for **2** and the silver salt (**3**) reveal planarity and delocalization of double bonds in the sydnone ring, indicating aromatic behavior. The tetra(*n*-butyl)ammonium salt (**4**) is soluble in a range of organic compounds. Cyclic voltammetric data measured for **4** in acetonitrile reveal an irreversible oxidation peak at +1.09 V vs. $Fc–Fc^+$ couple suggesting that the sydnone derivatives can be oxidized with an appropriate oxidizing agent. Differential scanning calorimetry data reveal thermal stability at ambient conditions and exothermic decomposition at high temperatures (>229 °C). The sydnone derivatives are characterized by two strong electronic absorptions in the UV region and rich vibrational (IR and Raman) spectra in the 1800–1500 cm^{-1} region. Density functional theory (B3LYP/6-311^{+++}G**) is applied to estimate the aromaticity of the sydnone ring and to assign the vibrational spectral data.

Key words: sydnone, trans-diazeniumdiolate, *N*-oxide.

Résumé : La réaction de l'oxyde nitrique avec le malonate de diméthyle et le méthylate de potassium en solution dans le méthanol permet d'obtenir facilement les sels di- et mono-potassiques du dianion de Traube, le 4-méthylcarboxysydnone-3-hydroxylate (**2**), ainsi que de son ester monométhylique (**1**). Les réactions de métathèse du composé **1** avec le nitrate d'argent et le bromure de tétra(*n*-butyl)ammonium conduit à la formation des sels d'argent et de tétra(*n*-butyl)ammonium du 4-méthylcarboxysydnone-3-hydroxylate. Par opposition à d'autres sydnones connues, les sydnones décrites dans ce travail sont stables tant en milieu acide qu'en milieu basique. Des données de diffraction des rayons X ont été obtenues pour le composé **2** et pour le sel d'argent (**3**); ils mettent en évidence que les doubles liaisons du noyau sydnone sont planes et délocalisées, ce qui indique un comportement aromatique. Le sel de tétra(*n*-butyl)ammonium du 4-méthylcarboxysydnone-3-hydroxylate est soluble dans une variété de composés organiques. Des mesures de voltampérométrie cycliques pour le composé **4**, mesurées dans l'acétonitrile, révèlent la présence d'un pic d'oxydation irréversible à 1,09 V par rapport au couple $Fc–Fc^+$, ce qui suggère que ces dérivés de la sydnone sont susceptibles d'être oxydés à l'aide d'un agent oxydant approprié. Les données de calorimétrie à balayage différentiel suggèrent que les composés sont thermiquement stables dans les conditions ambiantes et qu'ils donnent lieu à une décomposition exothermique à des températures supérieures à 229°C. Ces sydnones sont caractérisées par deux fortes bandes d'absorption dans la région UV et des spectres vibrationnels (IR et Raman) riches dans la région allant de 1500 à 1800 cm^{-1}. On a fait appel à la théorie de la fonctionnelle de la densité (B3LYP/6-311+++G**) pour évaluer l'aromaticité du cycle sydnone et pour attribuer les données du spectre de vibration.

Mots-clés : sydnone, trans-diazéniumdiolate, *N*-oxyde.

Introduction

The family of heterocyclic sydnones (1–4) and their closely related imines (5) have varied biological activities (6) and have been intensively investigated for their pharmaceutical properties (6, 7). Their general reaction characteristics include base instability and the ability to add a range of dipolarophiles to give new heterocycles (8). Based on their

solid-state structures from X-ray crystallography (9–13) and the pattern in bond length alternation, sydnones are predicted to have little aromatic stabilization offered by the delocalized five-membered ring (10, 14).

[1] $HC(CO_2Me)_2^-$ —(2 NO; 2.5 atm; MeOH–MeOK)→  **1**

We recently discovered a new class of sydnone derivatives, their *N*-oxides or 3-hydroxy analogues (15). These new anions, first described but misformulated by Traube in 1895 (16), are readily prepared by adding two nitric oxides to dimethylmalonate (eq. [1], where 1 atm = 101.326 kPa). Purification by recrystallization from water returns as much as 31% of the monopotassium salt. Unlike their *N*-alkyl analogues, the *N*-oxo deriviatives are remarkably thermally stable, very soluble in water, and decompose only slowly in acid and not at all in base. As ligands they are compact and capable of multidentate coordination with a range of potential metals. As part of our effort to characterize these compounds and to more fully explore their chemistry, we sought to prepare salts that would be useful for cation metathesis and (or) would be soluble in solvents other than water. To this end we report herein (*i*) the isolation and characterization of the dipotassium salt of 4-carboxy-3-sydnone *N*-oxide **2**, (*ii*) the metathesis of the potassium in **1** for silver to give **3**, which is isolated as a hemihydrate and the metathesis of potassium with tetra(*n*-butylammonium) salt to give **4**, (*iii*) the determination of the solid-state structures of two of these solids by single crystal X-ray diffraction, and (*iv*) the comparison of the structures of two of these analogues with the theoretically calculated values as part of an effort to determine the degree of aromaticity in these rings. This new family of derivatives has already been extended by an elegant recent report of their preparation from lithiated terminal alkynes and nitric oxide (17).

2·2H$_2$O

3·(1/2)H$_2$O

Experimental

General procedures and analyses

Many of the instrumental and general procedures for preparation and characterization performed in our lab have been previously described (18, 19). Raman spectra were measured on a Kaiser Optics 5000 Raman microscope with excitation radiation of λ = 785 nm. The electrochemical behavior of tetra(*n*-butyl)ammonium salt **4** was studied by cyclic voltammetry (CV) at room temperature (RT) in anhydrous acetonitrile, using $Bu_4N^+PF_6^-$ as a supporting electrolyte (0.1 mol/L) under nitrogen (scan rates of 100–1000 mV s^{-1}). Experiments were performed with a BAS CV-50W electrochemical analyzer. Platinum wire, platinum disk, and Ag–$AgNO_3$ (in acetonitrile) were used as counter, working, and reference electrodes, respectively. The potential is given vs. ferrocene–ferrocenium (Fc/Fc+) couple, which was used as an internal reference.

Syntheses of new sydnone salts

Potassium 4-methylcarboxysydnone-3-hydroxylate (**1**) and sydnone-3-hydroxylate-4-carboxylate dihydrate (**2**·2H$_2$O) were obtained from the reaction of nitric oxide and dimethylmalonate in the presence of potassium methoxide (15). The dipotassium salt **2** is prepared by saponification of the crude reaction mixture of **1** in a boiling solution of KOH (1 mol/L) for 30 min during purification.

Silver 4-methylcarboxysydnone-*N*-oxide (3)

To a solution of **1** (0.218 g, 1.1 mmol) in water (5 mL) was added a solution of $AgNO_3$ (0.169 g, 1 mmol) in water (5 mL). The white precipitate formed was quickly redissolved by the addition of 3 drops of concd. NH_4OH. The clear solution was allowed to stand overnight in the dark and the black solid formed was filtered off. The colorless filtrate was allowed to evaporate slowly to ~3 mL in a dark room over a period of several days when colorless shiny crystals of **3**·(1/2)H$_2$O formed. The crystals were filtered, washed with cold water (2 mL), and dried in a vacuum oven at RT overnight. Yield: 0.245 g (89%) based on the amount of $AgNO_3$. UV λ_{max} (nm) in 0.1 mol/L aq. NH_4OH (ε (mol/L cm)$^{-1}$): 228 (12 476), 277 (9040). IR (cm^{-1}) ν: 3422w b, 3013w, 2960w, 1812w, 1742s, 1700s, 1649m, 1489m, 1464s, 1430m, 1387s, 1312w, 1208s, 1137s, 1038m, 953m, 808w, 772m, 657w. Anal. calcd. for $C_4H_4N_2O_{5.5}Ag$: C 17.46, H 1.47, N 10.19; found: C 17.32, H 1.12, N 9.96.

Tetra-*n*-butylammonium salt of Traube's anion, tetra(*n*-butyl)-4-methylcarboxysydnone *N*-oxide (4)

To a solution of **1** (0.720 g, 3.64 mmol) in 15 mL of water was added a saturated solution of tetra(*n*-butyl) ammonium bromide (1.41 g, 4.36 mmol) in 2 mL of water at RT. A white precipitate rapidly formed and after 30 min of stirring it was filtered and washed with a minimal amount of cold water. Recrystallization of this material from THF gave 1.20 g (82%) of **4**, mp 136 to 137 °C. UV (CH_3OH) λ_{max} (nm) (ε (mol/L cm)$^{-1}$): 228 (10 400), 276 (6200). IR (KBr, cm^{-1}) ν: 3003w, 2959s, 2873m, 1784w, 1746m, 1733s, 1700s, 1654m, 1506w, 1492w, 1483w, 1456w, 1449w, 1418w, 1382s, 1293w, 1207m, 1193m, 1137w, 1121m, 1024m, 946w, 923m, 880m, 802w, 773m, 760w, 741w, 666w, 649w, 407w. ^{1}H NMR (400 MHz, D_2O, ppm) δ: 0.95 (t, 12H, *J* = 7 Hz, *CH*$_3$-Bu), 1.37 (s ext, 8H, *J* = 7 Hz, *CH*$_2$-Bu), 1.66 (quint, 8H, *J* = 8 Hz, *CH*$_2$-Bu), 3.20 (t, 8H, *J* = 8 Hz, *CH*$_2$-Bu), 3.84 (s, 3H, *CH*$_3$-O). ^{13}C NMR (300 MHz, $CDCl_3$, ppm) δ: 13.9, 20.0, 24.2, 50.9, 59.0, 95.2, 160.1, 166.7. MS (ESI) *m*/*z* calcd. for $[N(C_4H_9)_4][C_4H_3N_2O_5]$: [M] 401; found $[N(C_4H_9)_4]^+$ 242 (100%), $[M + [N(C_4H_9)_4]]^+$ 643 (16%), $[M - [N(C_4H_9)_4]]^-$ 159 (100%), $[2M - [N(C_4H_9)_4]]^-$ 560 (95%). Elemental analysis calcd. for $C_{20}H_{39}N_3O_5$ (401 g/mol): C 59.82, H 9.79, N 10.47; found: C 59.90, H

9.75, N 10.49. Needles for single crystal X-ray diffraction were readily obtained from dichloromethane solutions, but unfortunately the crystals are highly mosaicked along their long axis and do not allow for a satisfactory refinement of the diffraction data.

X-ray crystallographic data

X-ray diffraction data for **2**·2H_2O, **3**·(1/2)H_2O, and **4** were collected on either a Bruker P4 or D8 diffractometer equipped with a molybdenum tube and a graphite monochromator at 25 °C. Table 1 contains diffraction data for **2**·2H_2O and **3**·(1/2)H_2O, whose structures have both been deposited with the CCDC under entries 171269 and 627294, respectively.[2] Unit-cell dimensions were determined from several accurately centered reflections in high 2θ angles using the program XSCANS (20). For the P4 data sets, 3 standard reflections measured after every 97 reflections exhibited no significant loss of intensity. The data were corrected for Lorentz polarization effects and absorption. The structure was solved by direct methods and refined by least-squares techniques on F^2 using the program SHELXTL (21, 22). In the dipotassium salt **2**, the identity of the ring atoms was confirmed by examining the refinement results for other possible structural isomers, e.g., in one case with an exocyclic nitro group. In all cases the resulting thermal parameters S_{gof} and the R values indicate that the best model is that shown in Fig. 4. Similar considerations were used in the structural elucidation for **1** (15) and spectroscopic confirmation of these structural assignments stems from the clear distinctions in the vibrational spectra for these isomers. As discussed later, the best structural agreement is for the *N*-oxide sydnone structures adopted here.

The dipotassium salt **2**·2H_2O crystallizes in the acentric orthorhombic space group $P2_12_12_1$ with four formula units. The refined Flack parameter of –0.01(6) indicates that the correct configuration is modeled in the solution. The ions and the water solvate are well ordered and are located on general positions. All non-hydrogen atoms were located in

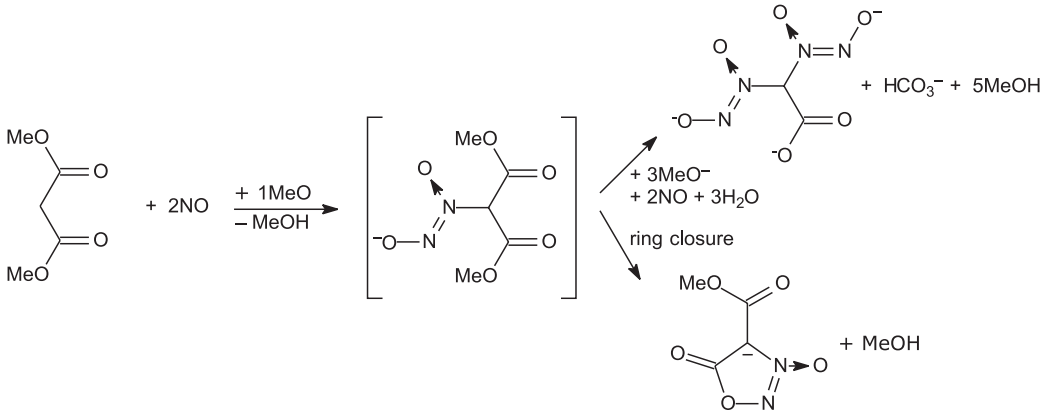
the difference maps during successive cycles of least-squares calculations and were refined anisotropically. The H atoms were placed in calculated positions and refined isotropically by a riding model. Compound **3**·(1/2)H_2O crystallizes in the monoclinic space group *C*2/*c* with four formula units. The cation and anion are located on general positions and are well ordered. The oxygen atom of the water solvate is located on a two-fold axis of symmetry. All non-H atoms located in the difference maps during successive cycles of least-squares calculations and were refined anisotropically. The H atoms of the anion were placed in calculated positions and were refined isotropically. The H atom of the water was located and refined isotropically.

Computational details

We have studied the two anions $[MeO_2CCC(O)N(O) = NO]^-$ (in **2**) and $[O_2CCC(O)N(O) = NO]^{-2}$ (in **1, 3,** and **4**) as well as the neutral protonated derivative of **1**. In each case, the optimized structures were determined. Computations were carried out at the restricted Hartree–Fock (RHF) (23) and density functional theory (DFT). DFT calculations used the hybrid B3LYP functional (24) and triple zeta 6–311++G** basis sets (24, 25). Vibrational frequencies were calculated for all stationary points to define them as either minima or transition states. All of the described calculations were performed using Gaussian 98 (26).

Results

As part of our effort to explore this new approach to sydnone heterocyclic chemistry, we set out to prepare new salts with greater reactivity and (or) solubility. The salts described in this paper are easily purified by recrystallization, a common trait with these derivatives. With the exception of the photolabile silver salt **3**, the new Traube salts are all base stable and can be handled in the open as solutions or stored as solids without difficulty. The photolabile salt **3** becomes gray with age and should be stored cold and wrapped in foil to slow decomposition. Satisfactory elemental analyses of all new derivatives demonstrated their purity with their identity being unambiguously determined by the combination of spectroscopy and X-ray diffraction.



In addition to the sydnone **1**, neutral uncharged radical coupling products, $(MeO_2C)_2CH\text{-}CH(CO_2Me)_2$ and $(MeO_2C)_2CH\text{-}C(CO_2Me)_2\text{-}CH(CO_2Me)_2$, can be isolated in low and variable yields by dichloromethane extraction of the crude reaction precipitate (15). A bisdiazeniumdiolate, $[(O_2C)CH(N_2O_2)_2]^{3-}$, can also be isolated in 15% yield when the reaction is run at ambient temperatures and followed by an alkaline workup (15, 27). Both of these products represent the balance in rates of ring closure to give **1**, vs. one-electron oxidation to give the polymethylcarboxylate chains and second diazeniumdiolation to ultimately lead to the decarboxylated bisdiazeniumdiolation product from the intermediate in eq. [2], $[(MeO_2C)_2C(N_2O_2)]^{2-}$.

The silver and tetra(*n*-butyl)ammonium salts of the methylester of Traube's anion are readily isolated by treating aqueous solutions of **1** with the appropriate countercation. While the silver salt **3** has reduced solubility in many solvents, it retains sufficient solubility to be a useful reagent for halide metathesis reactions. The tetra(*n*-butyl)ammonium salt **4** is remarkably soluble in a wide range of organic solvents and is a useful reagent for sydnone synthesis.

Thermal and redox reactivity

The new sydnone *N*-oxide salts were characterized by DSC for thermal behavior and stability and the results are collected in Table 2. The hydrated salts **2** and **3** dehydrate

endothermically at ~60 and 195 °C, respectively, with further heating resulting in exothermic decomposition at 228 and 319 °C, respectively. The large exothermic release, their high density, and the pronounced stability of these salts suggest they may be useful candidates for solid state rocket propellants. The only reversible process found by DSC is a melting point for **4** at 135 °C with a relatively low endotherm.

In addition to their acid and base stability, seen later, the sydnone *N*-oxides are stable in air and can be stored in the open for prolonged periods with little change in composition or spectroscopic properties. The only significant redox behavior found by cyclic voltametry for **4** is an irreversible oxidation process at E_p = +1.09 V at 1000 mV s^{-1} (Fig. 1). Thus, strong oxidants are expected to react with these compounds and this reaction is currently being explored. No reduction processes were observed.

Electronic spectroscopy

Unlike the *N*-alkyl and the *N*-aryl sydnones, which show a single absorption in the UV spectrum (λ = 290–325 nm, ε ~ 8000 $(mol/L)^{-1}$ cm^{-1}) the sydnone *N*-oxides exhibit two bands at higher energies. In aqueous solution the monomethylester of Traube's anion in **4** has two bands (λ = 228 nm, ε = 10 400 $(mol/L)^{-1}$ cm^{-1}, λ = 276 nm, ε = 6200 $(mol/L)^{-1}$ cm^{-1}) and for the dianion in **2** (λ = 224 nm, ε = 11 130 $(mol/L)^{-1}$ cm^{-1}, λ = 280 nm, ε = 8810 $(mol/L)^{-1}$ cm^{-1}) (15). The energy and intensities of both of these absorption bands are almost invariant with respect to pH, and in strong base or acid there are only minor changes in the spectrum of **2**. In contrast with these results are those for the cis diazeniumdiolates, which exhibit a single strongly solvatochromatically sensitive band at about 260 nm (28). Because of its extensive solubility, the spectrum of **4** has been measured in a variety of solvents and the energy and intensities of its bands are insensitive to either the solvent polarity or its hydrogen-bonding ability (Table 3). There is little evidence from UV–vis spectroscopy to suggest that the sydnone *N*-oxides interact strongly with common solvents.

Vibrational spectra

The highly polarized sydnone ring results in strong and characteristic IR spectra for its derivatives. In addition, the extensive delocalized bonding also means that they are highly polarizable with strong features in their Raman spectra. Both of the these predictions are experimentally borne out and vibrational spectroscopy is a useful tool for the characterization of sydnones. Moreover, these assignments, their interpretation, and the energies of these bands are highly diagnostic of the anion's electronic structure. Representative IR and Raman data for the key derivatives described in this paper are collected in Tables 4 and 5, respectively, with representative spectra for **2** juxtaposed in Fig. 2.

Prior discussions of the sydnone vibrational spectra have focused considerable attention on the band assigned to the exocyclic carbonyl stretch, ν(C=O), which typically has a range from 1718 to 1770 cm^{-1} (29, 30). The sydnone salts listed in Table 4 all have strong bands between 1738 and 1703 cm^{-1}, with a second strong band being assigned to the asymmetric carboxylate stretch, $\nu(CO_2)_{asym}$, occurring at slightly lower frequencies between 1700 and 1615 cm^{-1}. The number, energy, and intensities of these bands are not only cation dependent but hydration dependent. Many of these phenomena can be easily understood from the crystal structures discussed later, where carbonyl oxygen–cation interactions are observed for all species except **4**. For 3-phenyl- and 3-ethylsydnone, multiple peaks are also observed in this area and this has been attributed to a Fermi resonance (31). In Fig. 2, the possible splitting due to all of these effects can be seen by contrasting the IR and Raman spectra for the 1800–1700 cm^{-1} region. Whereas the Raman spectrum for anhyd. **2** has three bands, there are four IR active bands in this region. The calculated normal coordinates for the five strong IR active bands between 1500 and 1200 cm^{-1}, Tables S2 and S3, indicate that these framework modes are not as cation-sensitive and can be described as an asymmetric and symmetric ν(NNO), a ring-breathing mode and a symmetric carboxylate stretch combined with a ring-breathing mode.[2] The $\nu(NNO)_{asym}$ involves the exocyclic N–O, which has a large ν(NO) mode coupled to carboxylate stretch; it is observed as a weak band in the Raman spectrum between 1468 and 1459 cm^{-1} and is calculated for the disodium analog to be at 1468 cm^{-1} (Table S3).[2] The IR spectra of all salts contain strong bands in this region and in others as well. The $\nu(NNO)_{sym}$ band is calculated to be at 1386 cm^{-1} and corresponds with strong bands in the IR between 1387 and 1384 cm^{-1}, and between 1399 and 1387 cm^{-1} in the Raman spectrum. The symmetric ring-breathing mode is one of the strongest bands in the Raman spectrum with a range of 1351 to 1289 cm^{-1} and from 1343 to 1310 cm^{-1} in the IR. For the disodium complex it is calculated to be at 1368 cm^{-1}, which

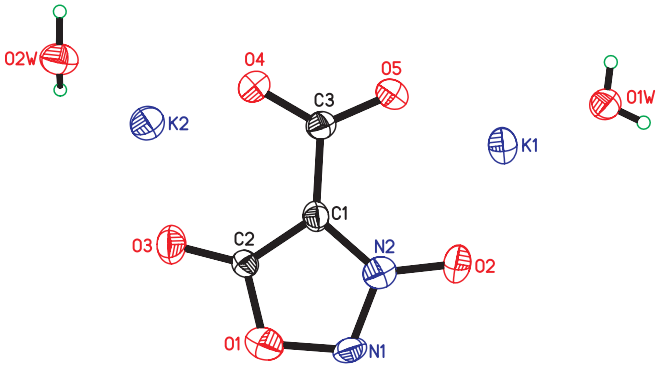
Fig. 2. Midrange IR A (top) and B (bottom) Raman spectra of **1**. IR measured as a KBr suspension and the Raman measured as a crystalline solid with 785 nm excitation.



is only slightly higher than the observed values of 1351 and 1340 cm^{-1} for the Raman and IR spectra of **2**, respectively. The strong combined carboxylate stretch and ring-breathing mode, which is calculated to be at 1262 for the disodium analog of **2**, compares with the experimental values of 1238 and 1228 cm^{-1} for the dipotassium salt **2**. The final mode worth mentioning is the strong Raman active mode at 961 cm^{-1} in the spectrum of **2**, which corresponds well with a ring-breathing mode calculated to have an energy of 976 cm^{-1}. The normal coordinate for this band corresponds to an intracyclic N–O stretch that expands the ring. Taken together, these and other bands for the sydnones make vibrational spectroscopy an insightful method for their characterization.

Crystallographic studies of new sydnone *N*-oxide salts

Crystallography is an important method for the unambiguous characterization of the new salts described in this paper. Common characteristics of the anions is their rigid coplanarity and short exocyclic N–O and C–O bond lengths. Within the rings the bond length ranges are relatively small, 1.324(4)–1.405(3) Å for **1**, 1.334(3)–1.390(3) Å for **2**, and 1.314(4)–1.408(5) Å for **3**. Overall the monoanions in **1** and **3** are similar to one another with the dianion in **2** having a smaller range of intraring distances. The structure of **1** has already been communicated (15). Here we present and contrast the structural results for the dipotassium and silver salts with **1**. As mentioned in the experimental section, attempts to obtain diffraction grade crystals of the tetra(*n*-butyl)ammonium salt **4** have been hampered by the mosaicity of their needle morphology. Consistently, the crystals are heavily zoned along the principal axis of the needle, giving rise to a striated appearance, when viewed by crosspolarized optical microscopy, and broad Bragg peaks on the diffractometer.

Fig. 3. The asymmetric unit in the crystals of **2**·2H_2O. Thermal ellipsoids are drawn at the 50% probability level.

As a result, the diffraction data is of limited quality, with the setting in the most suitable space group, C_2, converging to a good refinement for the cation but to a badly disordered layer of anions. Thus, the best *R* for the more intense reflections is only ~8%, with the disorder in the anions limiting any meaningful interpretation of the metric parameters. These results will not be discussed further.

The dipotassium salt **2** crystallizes as a dihydrate, **2**·2H_2O, with the resulting structure consisting of strongly interacting potassium cations, sydnone-3-hydroxylate-4-carboxylate anions, and water solvates (Fig. 3). The exocylic C=O bond at 1.256(3) Å is slightly longer than a typical carbonyl double bond, 1.20 Å (32), because of its conjugation to the ring. The delocalization of the charges over the entire anion is also illustrated by its interaction with the cations. The carboxylato and exocyclic O atoms (O2, O3, O4, and O5) and a ring nitrogen atom (N1) are involved in ionic interaction with the K^+ ions.

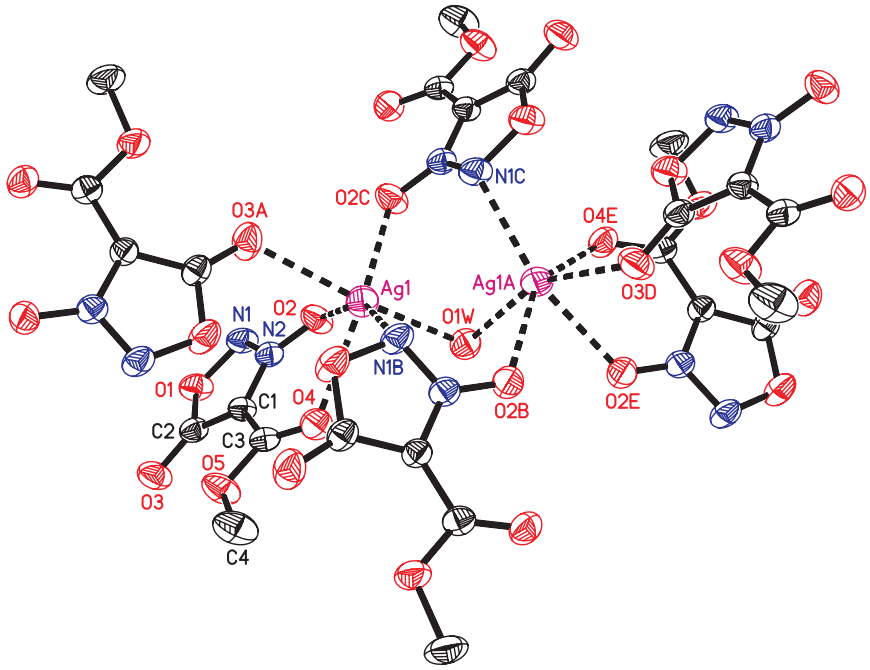
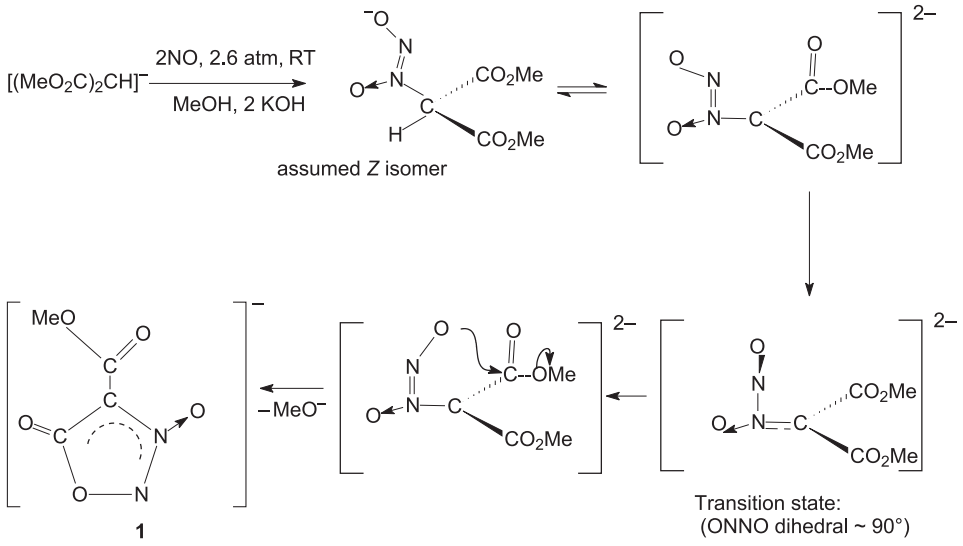
[b]Range of values for nine structurally characterized *N*-alkylsydnones taken from ref. 41.
[c]Taken from ref. 15.
[d]Taken from ref. 17 and corresponds to the sydnone shown below.



One of the cations (K1) is in a seven-coordinate geometry with two pairs of O atoms from two different anions, a diazeniumdiolate O atom, and an N atom of another anion along with a solvate O atom being the ligands. Cation K2 is in an eight-coordinate geometry also with two pairs of O atoms from two anions, a diazeniumdiolate N and O atoms of another anion, and two water solvate O atoms being the ligands. Two anions bridge the cations as shown in Fig. 4, and the remaining anions bind the cations in different coordination modes. The anion and the two water solvates bind two neighboring nonequivalent cations leading to a compact three-dimensional network. In addition, the two water solvates are also involved in hydrogen bonding with each other and both carboxylato oxygen atoms (Tables S4–S8).[2]

The structure of the silver salt **3**·(1/2)H_2O consists of strongly interacting silver cation, 4-methylcarboxysydnone-3-hydroxylate anion, and a half water solvate. The whole of the anion is planar, but the lengthening of the exocyclic C=O double bond and the ring N=N double bond (Table 6) is not as pronounced as for the respective bonds in **2**·2H_2O. The structure of the potassium salt of the anion has been previously characterized (15) and the features of the anions in both salts are nearly identical.



The anion coordinates through the exocyclic N–O and C=O oxygen atoms O2 and O3, the ring nitrogen atom N1, and the carboxylate oxygen atom O4 as shown in Fig. 5. The coordination sphere around the cation is a highly distorted octahedron with the silver being coordinated to four anions and a water solvate. Two of the anions and the water solvate act as bridges between two neighboring silver centers, which are separated by 3.412(5) Å. The solvate water oxygen atom and the exocyclic C=O oxygen atom belonging to neighbor-

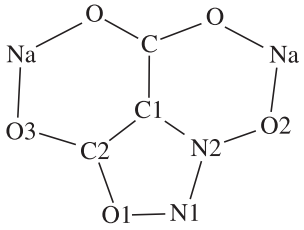
Scheme 1. Proposed mechanism for the formation of sydnone *N*-oxides from the addition of NO to dimethylmalonate.

ing dimers interact with each other through hydrogen bonding with the associated O1W···O3 interatomic distance and the O1W-H1W···O3 bond angle being 2.903(4) Å and 157(7)°, respectively.

The key metric parameters for all three available sydnone *N*-oxides are contrasted with those for the *N*-arylsydnones in Table 6. A common feature in all three structures is the similarity of the core ring structure not only in the three *N*-oxide salts but also between the *N*-oxides and the *N*-arylsydnones. Remarkably, as reflected in the diffraction results, the bonding in the sydnone core in these compounds is not significantly affected by the substituents at either C1 or N2. Within the limits of interpretation imposed by the estimated standard deviations, the major change seen for the *N*-oxides is in the value of C2–O1, the intracyclic C–O bond, which is significantly shorter for the *N*-oxides. Comparing the dianion in **2** with the monoanions in **1** and **3**, there is a trend towards lengthening of the N–N and the exocyclic C–O bonds, while the C–C bond is slightly shorter.

Discussion



The surprisingly facile base-mediated reaction of nitric oxide and dimethylmalonate is one of the few that returns a product with a trans (*E*) arrangement of the ONNO framework (15, 33, 34). A common feature of these and other (35–37) exceptions is their ability to cyclize or ring-close to give a stable NNO-containing heterocyclic product; they also have available low energy transition states that allow for fac-

[a]Metric parameters are from the ground-state optimized structure corresponding to the water-free neutral disodium salt shown immediately following the footnote.

ile *Z* to *E* isomerization. In the case of NO addition to dimethylmalonate, we hypothesized that initial *Z* addition followed by deprotonation, isomerization, and finally ring-closing condensation would account for the observed product (Scheme 1) (15). We have recently made similar observations for the diazeniumdiolates derived from *i*-$PrNH_2$ (33, 34). An alternative mechanism with stepwise addition of nitric oxides has recently been theoretically evaluated (38) and we note that there remains considerable interest in the mechanistic details of these reactions (39, 40).

However the sydnone *N*-oxide products that result from these reactions are interesting and novel heterocycles in their own right, with the combination of the delocalized negative charge and the *N*-oxide group being particularly important features. Heterocycle *N*-oxides often display remarkably different chemistry from the original heterocycle. In this case, N-oxygenation allows for the isolation of the 1,2,3-oxadiazole heterocycle. Unsubstitued N3 sydnones are known as reactive intermediates that are difficult to isolate (2, 41). In general, this is believed to be due to the position of the equilibrium between the heterocycle **A** and its ring-opened valence tautomer, the diazoketone **B**. Thus, the instability may be due to the ease of elimination of nitrogen or nitrous oxide from the putative heterocycle **A** or **B**. We are aware of only a single prior report of a sydnone *N*-oxide related to **1**–**4** in the literature, but this corresponds to an unsaturated ring resulting from the addition of nitrosyl chloride to 2,5-dimethyl-2–4-hexadiene (37). Since our initial communication on the results in this area, this family of heterocycles has been expanded to include products from the addition of NO and terminal alkynes (17).

A **B**

During initial studies to elucidate the structure of **2**, the gas phase ground state structures and vibrational spectra of the dianion and its disodium salt were calculated with density function theory with triple zeta quality basis sets. In related calculations of other nitrogen oxide derived anions we have found this level of theory suitable for modelling their ground states, their dynamics, and their vibrational spectra (19). This level of theory has also recently been applied to the related sydnone *N*-oxides derived from terminal acetylenes and nitric oxide (38). As shown in Table 7, the difference between the ground state structures for the dipotassium salt **2** and the gas phase dianion are substantial. These differences are most likely the consequence of strong cation–anion interactions as the observed metric parameters are markedly closer to those calculated for the ground state of the anhydrous disodium salt shown in Tables 7 and 8.

The calculated vibrational frequencies and activities for the ground state of the anion of **1**, the dianion in **2**, and the disodium analog of **2** are listed in Tables S1–S3, respectively.[2] When contrasted with the experimental results in Tables 4 and 5 for the mono- and di-potassium salts, the sensitivity of the predicted vs. experimental bands to the cation identity is quite clear and it correlates with the trends seen for the various salts. In particular, the bands associated with the exocyclic ν(C=O), which has strong bands at 1738 cm^{-1} in the IR for **1**, is predicted to be at 1809 cm^{-1} in the gas phase. In contrast, the gas phase dianion has a pair of strong active IR bands calculated to be at 1714 and 1636 cm^{-1}, while in the anhydrous salt **2** these bands are shifted apart to 1734 and 1619 cm^{-1}. For the disodium analog of **2**, these bands are calculated to be at 1725 and 1635 cm^{-1}, which are surprisingly close to the gas phase values. Although the specific identity of the cation has a modest influence on their energy, incorporation of the material into a lattice will bring new anion–cation interactions, as seen in Fig. 5 for the silver salt **3**.

The unusual reactivity patterns of the these new sydnone *N*-oxides can also be understood in terms of the theoretical

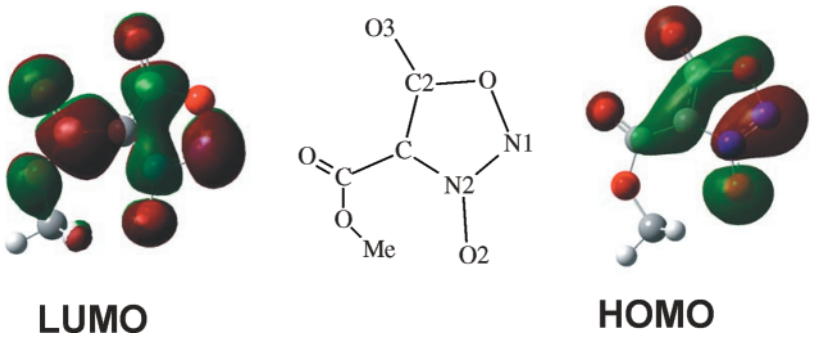
Note: See the numbering scheme shown in Table 6 for atom labels.

Scheme 2. Protonation sites and relative energies for the monoanion.

Structure	**C**	**D**	**E**
Rel. Energy (kcal mol^{-1})	0.0	5.66	5.40



Structure	**F**	**G**	**H**
Rel.Energy (kcal mol^{-1})	8.77	10.12	18.97

density functional calculations. Not too surprisingly the base stability of **1** and **2** is in part due to their anionic charge, which provides some stabilization from nucleophilic attack. This effect would not be seen in the neutral *N*-alkyl and *N*-aryl sydnones, which are both more acid and base sensitive. To understand the profound acid sensitivity in these derivatives we have calculated and optimized the structures shown in Scheme 2, where the various possible protonation sites are shown and ranked by relative energy. With the exception of the highest energy isomers **G** and **H,** all of the isomers have internal H bonds between two oxygens. While strongly hydrogen-bonding solvents might disrupt these intramolecular bonds, the variation of energy would probably not be more than 1 or 2 kcal $mole^{-1}$ (1 cal = 4.184 J) and thus the relative stabilities of the isomers is most likely to be predicted by the gas phase results shown in Scheme 2. In prior calculations for diazenimdiolates we have found that the inclusion of solvent effects with continuum models does not alter the relative energies for related isomers (33). Metric parameters and vibrational frequencies for the optimized neutral structures **C–H** are in the Supplementary data tables, Part I.[2] The lowest energy structure corresponds to N–O protonation, **C**, with the highest energy site being the carbon protonated derivative **H**. Remarkably, N-protonation is predicted to be very unfavored, with **G** being almost 10 kcal mol^{-1} higher in energy than **C**. This follows the general trend for sydnones and diazeniumdiolates, which in general tend not to react or have detectable Lewis acid–base interactions with the nitrogen lone pair. The observation that there is a weak silver–nitrogen interaction in Fig. 5 suggests that new derivatives from the electrophilic addition to nitrogen may be accessible in this system. This reactivity theme will be taken up in subsequent papers.

The debate on the degree of aromaticity of sydnones and how to account for their electronic structures is both sustained and ambiguous (42, 43). Experimentally, these are clearly planar heterocycles with large dipole moments, typically greater than 6 D (2), and they are often termed mesoionic or mesomeric betaines (44). One of their characteristic features has been suggested by Simas et al. (43) to be that the "electrons and charges are delocalized over different regions separated by single bonds. Furthermore, the carbon-

substituted side chain is associated with the HOMO whereas the nitrogen substituent is associated with the LUMO". While these observations rationalize the observed high dipoles and the marked 1,3-dipolarophile reactivity of sydnones, they do not account for the bond length trends observed for *N*-alkyl sydnones in general or in the sydnone *N*-oxides described here. In particular, the C1–N2, N1–O1, and C2–O2 bonds in Table 6 are all shorter than the corresponding single bonds. The applicability of the Simas criteria quoted above for the sydnone *N*-oxides is also suspect, as an inspection of the frontier orbitals in Fig. 6 reveals. Although the HOMO does indeed have an overlapping interaction with its side chain, the LUMO is diffuse and not entirely localized to areas of "large positive π charge" with the two regions separated by "single bonds" as suggested for *N*-alkylsydnones.

Although aromaticity and its chemical consequences remain important themes of research, and there have been many important contributions to understanding its role in heterocycles (45, 46), important recently developed tools in understanding and gauging aromaticity in unusual compounds such as these sydnone *N*-oxides are the nuclear independent chemical shift (NICS) methods, as described by Schleyer and co-workers (47). It is widely expected that sydnones have low aromaticity with a recent text listing a value of 17% aromaticity with respect to benzene (48). However, when NICS methods are used to calculate ring currents for the anion in **1** and the dianion in **2**, we find that their respective NICS(0) and NICS(1) values are –9.5 and –5.19 for **1** and –10.1 and –5.9 for **2**. To determine the influence of ion pairing on these calculated NICS values we performed the computation with sodium cations included in the crystallographically determined potassium positions for **1** and **2**. For the monosodium salt corresponding to **1**, the NICS(0) and NICS(1) values are 9.5 and 7.1, while for the disodium salt of **2** these values are not much changed at 9.5 and 5.19. These small changes in NICS with inclusion of ion interactions are similat to those found for other alkalilmetal salts of the boralkanyl anions (49). The NICS values also contrast with those values for benzene of 8 and –10.2 (47) and those we calculate for 3,4-dimethylsydnone, –9.4 and –7.0. These same NICS methods calculate chemical shifts for the ring carbons in the monoanion in **1** to be 171.2 and 100.8 ppm and for the dianion of **2** to be 175.6 and 108.0 ppm. The experimental values are 171.0 and 98.5 ppm for **1** in $CDCl_3$ and 172.2 and 101.7 ppm for **2** in D_2O, so there is good agreement between theoretical predictions and experiment, in this case. Clearly, NICS methods suggest that there is significant aromaticity in these systems and the challenge is to unambiguously determine the chemical consequences of its presence.

Conclusion

The sydnone *N*-oxides form a new class (48) and new synthetic approach to heterocycles with a 1,2,3-oxodiazole core. In contrast with the known *N*-alkyl and *N*-aryl sydnones, the *N*-oxides share similar structures and spectroscopic properties but are markedly less reactive. These anions have a potentially rich coordination chemistry and in this paper the preparation and characterization of two new salts with silver, **3**, and $N(n\text{-}Bu)_4$, **4**, cations are described. Vibrational spectroscopy is a useful tool for their characterization as many of their bands are strongly IR and Raman active. Descriptions of the bonding in these derivatives remains a fundamental theoretical challenge with one of principal unsolved problems being how do we account for their stability in terms of a bonding description for the heterocycle. Initial theories to account for their relatively weak and diminished aromaticity suggests that other factors may be responsible for their stability, but NICS calculations suggest this may not be the case. Aromaticity is of course a concept initially rooted in our understanding of electron precise rings. Sydnones are dominated by electron-rich elements for which conventional descriptions of aromaticity may not be the most appropriate.

Rhenium and manganese modified activated carbon as catalyst for methanol decomposition

T. Tsoncheva, S. Vankova, O. Bozhkov, and D. Mehandjiev

Abstract: Bicomponent manganese and rhenium modified activated carbon materials, prepared by different methods, are studied and compared with the corresponding monocomponent materials as catalysts in methanol decomposition to CO and hydrogen. The best catalytic activity and stability is observed for the sample obtained by simultaneous deposition of Mn and Re precursors. The complex character of the catalytic active centre, including manganese and rhenium irons in various oxidative states, is discussed. The determining role of the Mn(II) ions in the improvement of the catalytic properties is assumed.

Key words: rhenium, manganese, activated carbon, methanol decomposition.

Résumé : On a étudié divers matériaux à deux composés formés de charbon activé modifié par du manganèse et du rhénium qui ont été préparés par diverses méthodes et on a comparé ces propriétés à celles des matériaux correspondants à un composant aux fins de leur action comme catalyseurs pour la décomposition du méthanol en CO et en hydrogène. La stabilité et l'activité catalytique les plus élevées sont observées avec l'échantillon qui a été obtenu par le dépôt simultané des précurseurs Mn et Re. On discute du caractère complexe du centre d'activité catalytique, y compris les sels de manganèse et de rhénium des atomes de fer dans divers états d'oxydation. On fait l'hypothèse que les ions de Mn(II) jouent un rôle déterminant dans l'amélioration des propriétés catalytiques.

Mots-clés : rhénium, manganèse, charbon activé, décomposition du méthanol.

Introduction

Catalysis plays an important role in the development of clean energy conversion processes (1–3). The main interests include improving energy conversion efficiencies, minimizing emissions, and using "renewable" sources of clean energy (4–6). Among various possibilities in this regard, methanol decomposition to CO and hydrogen attracts considerable interest as an economically viable and sustainable energy conversion process (7–12). It has been reported that decomposed methanol could be a clean and effective fuel for a number of stationary and mobile installations such as vehicles, fuel cells, and gas turbines. The process is also important as a reversible chemical reaction that can be used for the storage of hydrogen. Finally, methanol decomposition is a highly endothermic reaction (ΔH° = +128 kJ/mol), which is why it is well-studied to recover waste heat and (or) to increase the heating value of methanol fuel in combustion engines. However, the wide usage of methanol decomposition for various applications requires the development of highly effective and low cost catalysts that work at lower temperatures with high stability. The main contemporary trends in this area address the development of catalysts with new designs and minimal noble metal loading. Recent progress points to the tailoring of nanoscale metal–metal oxide materials with regulated particle size and morphology (13–15). A possible method for the preparation and stabilization of such materials is by deposition on various porous supports (16, 17). Among the supports, activated carbon is a preferred carrier because of its well-developed porous structure, high specific surface area, a large number of different surface functional groups, and catalytic inertness (18, 19). On the other hand, bimetallic systems reveal additional ways to expand the family of catalysts (14, 16, 20, 21). Both metallic and nanosize effects could be a major sources of changes in the electronic structure of the active phase, producing catalytic properties.

Various materials, usually based on copper and noble metals, have been studied as suitable catalysts for methanol decomposition (7, 9, 10). However, the low catalytic stability and low selectivity due to methane formation were mentioned as the main problems for the former and the latter materials, respectively. At the same time, the data on the catalytic behaviour of manganese-based materials in methanol decomposition are rather insufficient (22–27). Its promotion effect on copper-based catalysts has been established (23, 24, 26). In our previous study, we demonstrated higher catalytic stability but lower activity, in comparison with their copper analogue, in methanol decomposition for manganese

supported on activated carbon materials (27). Recently, we also found that Re additives have beneficial effects on catalytic stability of copper-activated carbon materials (28).

Here we focus our attention on the role of Re additives on the catalytic behaviour of manganese supported on activated carbon materials in methanol decomposition. We also attempt to elucidate the complex character of the active center of the catalyst.

Experimental

Materials

Activated carbon (commercial product derived from apricot pits) with specific surface area of 910 m^2/g and pore volume of 0.64 cm^3/g was used as a support (29). Three methods were applied for metal oxide deposition using a modified incipient wetness technique by spraying the support with the corresponding manganese and (or) rhenium precursor.

Method 1

Activated carbon (AC) (2.0 g) was treated with a solution of $Mn(NO_3)_2$ (7.8%). After drying at 383 K for 1 h, the samples were heated at 573 K for 6 h (heating rate was 0.6 K/min) in vacuum. The prepared material was denoted as Mn/AC. The obtained material was then treated with an aq. solution of NH_4ReO_4 (1%). The sample was dried at 383 K for 1 h and then treated at 573 K for 6 h (heating rate was 0.6 K/min). The sample was denoted as ReMn(1:3)/AC-N.

Method 2

AC (2.0 g) was treated with an aq. solution of NH_4ReO_4 (1%). The sample was dried at 383 K for 2 h and then treated at 573 K for 6 h (heating rate was 0.6 K/min). The prepared material was denoted as Re/AC. The material was then treated for 1 h with solution of $Mn(NO_3)_2$ (7.8%). After drying at 383 K for 1 h, the sample was heated at 573 K for 6 h (heating rate was 0.6 K/min) in vacuum. The obtained material was denoted by ReMn(1:3)/AC-R.

Method 3

AC (2.0 g) was treated with a mixture of aq. solutions of NH_4ReO_4 and $Mn(NO_3)_2$ (Re–Mn 1:3). After drying at 383 K for 1 h, the sample was heated at 573 K for 6 h (heating rate was 0.6 K/min) in vacuum. The obtained material was denoted by ReMn(1:3)/AC-S.

A material denoted by ReMn(1:1)/AC-S with an Re–Mn ratio of 1:1 was also obtained by method 3 and was used as a reference sample in the study.

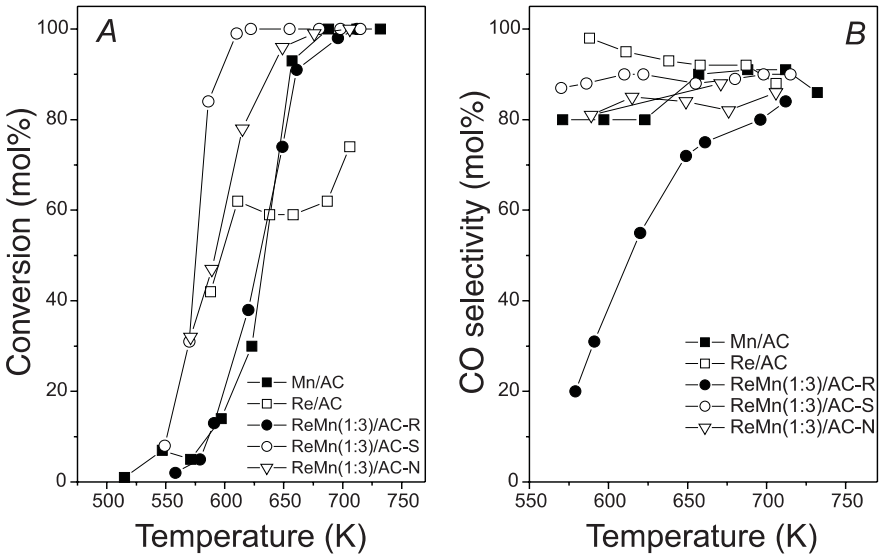
Table 1 presents data for the phase composition and specific surface area for Re and Mn supported on activated carbon materials that were obtained by different sequence of metal oxides deposition.

Methods of investigation

Textural characteristics were determined by low-temperature (77.4 K) nitrogen physisorption. The specific surface area was estimated by the BET method. Mn content in the samples was determined by atomic absorption technique using a Pye Unicam SP90V instrument. Rhenium content in the samples was determined by vacuum thermal extraction followed by quantitative kinetic analysis, based on the catalytic activity of Re to the *N*,*N*-dimethyldithiooxamide (DMDTO) reduction with $SnCl_2$ in alkaline medium. An alkaline extraction of rhenium from the activated carbon, followed by the quantitative kinetic determination, was also done (30, 31). The magnetic measurements were performed with a Faraday type magnetic balance in the temperature range of 298–473 K. EPR spectra were done with a ERS 22Q spectrometer at 100–400 K. XP spectra were performed using an ESCALAB MkII (VG Scientific) instrument. X-ray diffraction powder patterns were obtained on a Philips APD-15 diffractometer equipped with Cu Kα radiation source and graphite monochromator.

Catalytic test

The catalytic experiments were carried out in a flow reactor with a methanol partial pressure of 1.57 kPa, WHSV (weight hourly space velocity) of 1.5 h^{-1}, and under thermoprogrammed conditions at a heating rate 2 K/min. Some experiments were also done under isothermal conditions at 650 K. The gas chromatographic analysis was performed online using a Porapak Q and molecular sieve columns. The results were calculated using the method of absolute calibration. A carbon-based material balance was done. Before the catalytic test, the samples were pretreated for an hour at 373 K in argon.



Results and discussion

Methanol decomposition on various manganese and rhenium modified materials

Figure 1 presents data on the catalytic activity (Fig. 1*A*)

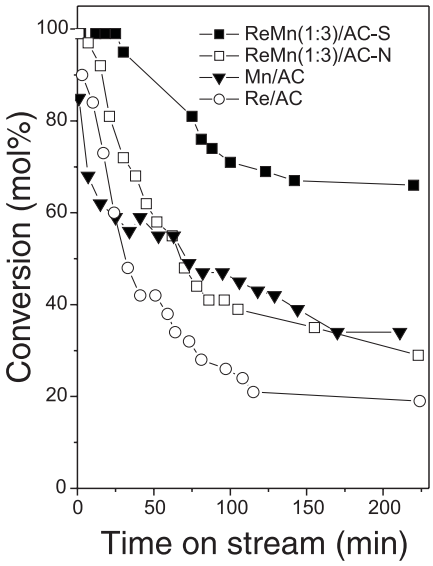
Fig. 1. Methanol conversion (*A*) and CO selectivity (*B*) vs. temperature on various samples containing Mn and (or) Re.



and CO selectivity (Fig. 1*B*) in methanol decomposition for various Re and (or) Mn supported on activated carbon material. Monocomponent Re- or Mn-modified samples exhibit catalytic activity above 550 and 600 K, respectively, CO being the main carbon-containing product. Methane is also registered as a by-product and its yield is higher for Mn/AC. At the same time, the catalytic behaviour of all bicomponent Re and Mn materials differs significantly from their monocomponent analogues and essentially depends on the order of metals deposition. The highest catalytic activity, combined with high selectivity to CO, is observed for the sample obtained by simultaneous deposition of Re and Mn. As a whole, the catalytic activity for both Re–Mn materials, prepared by consecutive deposition of various active components, is lower than ReMn(1:3)/AC-S and it is combined with significant differences in the CO selectivity depending on the order of their deposition (Fig. 1*B*). ReMn(1:3)/AC-S is also characterized by significantly higher catalytic stability under isothermal conditions in comparison with all other studied materials (Fig. 2). The catalytic behaviour of bicomponent samples depends also on the Re–Mn ratio and better catalytic activity above 570 K is achieved with ReMn(1:3)/AC-S than with ReMn(1:1)/AC-S (Fig. 3). The intrinsic rates of conversion for the studied materials at different temperatures are presented in Table 1. As can be seen, a well-defined and the most pronounced tendency for catalytic activity increase at lower temperature, in comparison with Re/AC and Mn/AC, is found only for ReMn(1:3)/AC-S.

Physicochemical characterization of manganese and rhenium modified materials

Despite the variations in the catalytic behaviour of the samples (Figs. 1–3, Table 1), their XRD patterns (not shown) show reflections of almost the same intensity, corresponding to a well-crystallized Mn_3O_4 phase. No reflections of rhenium or other manganese oxides are found. To clarify the catalytic effects described earlier, more precise magnetic measurements combined with EPR and XPS studies of the samples were also performed.

Fig. 2. Methanol conversion vs. time on stream at 650 K for selected samples containing Mn and (or) Re.

Magnetic measurements

Table 2 displays data for effective magnetic moments (μ_{eff}) and Weiss constants (Θ) for the Re–Mn materials obtained by the different preparation methods. Their calculated correlation constants (*R*) are similar and are characterized by high values (0.9923–0.9938), which indicates the preservation of the Curie–Weiss law. The experimental values of μ_{eff}, when compared with the corresponding theoretical ones for the separate ions (32, 33), could be evidence for the presence of Mn ions in different oxidative states. The higher negative values of Θ combined with high values of μ_{eff}, which are observed for ReMn(1:3)/AC-S, could be ascribed to the higher content of Mn(II) in this sample. On the other hand, the predominant presence of Mn ions in higher oxidative states, Mn(III) and Mn(IV), could be assumed for the samples formed by the consecutive deposition of rhenium and manganese. Moreover, based on the observed close val-

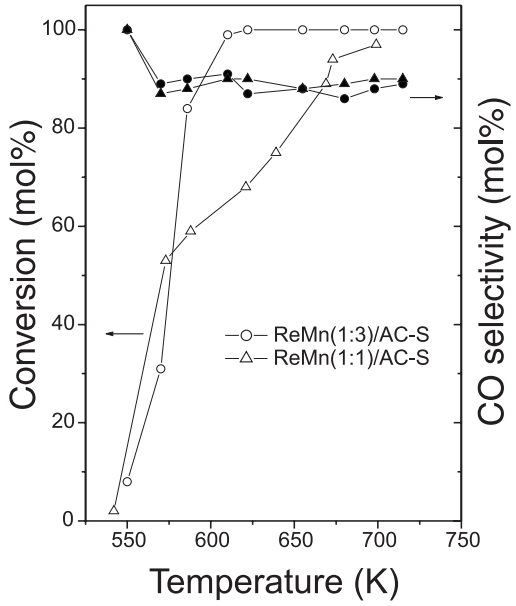

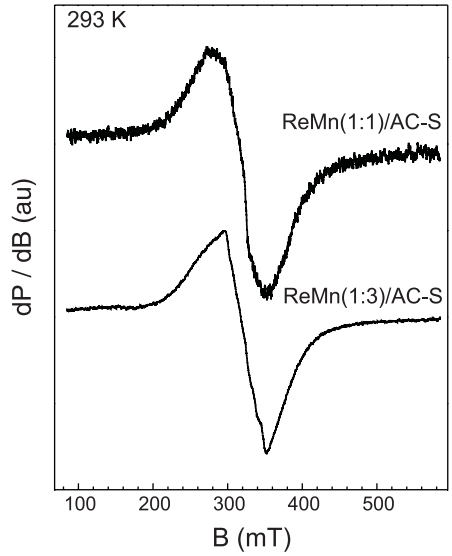

Fig. 4. EPR spectra of samples with various Re–Mn ratios obtained by simultaneous deposition of the precursors.

ues of μ_{eff} and Θ for these samples, less pronounced differences in the Mn ion states depending on the order of Mn and Re deposition could be assumed. The lower value of μ_{eff} observed for ReMn(1:1)/AC-S (μ_{eff} = 4.07 BM), compared with that for ReMn(1:3)/AC-S (μ_{eff} = 5.66 BM), could be an indication of a decrease in the Mn(II) ion content with an Re–Mn ratio increase.

EPR study

EPR measurements for the bicomponent samples with different Re–Mn ratios confirm the magnetic results for the presence of Mn(II) and of Mn(IV) ions, probably in interaction between themselves or with Re species. The room temperature EPR spectra (Fig. 4) show a broad unstructured resonance of about 70 mT in width, which could be ascribed to the predominant presence of antiferomagnetically connected Mn(II) and (or) Mn(IV) ions (34–36), the former being present in higher amounts in ReMn(1:3)/AC-S than in ReMn(1:1)/AC-S. A very broad and low signal with high value of *A*, constant of fine interaction, probably belonging to rhenium in an oxidative state lower than Re(VII) is detected for Re/AC (28). A very slight indication of a sextet in the EPR spectrum (g = 2.002 and *A* = 9.4 mT), typical of isolated Mn(II), is also observed for ReMn(1:3)/AC-S.

XPS measurements

Figure 5 presents $Mn2p_{3/2}$ (Fig. 5*A*) and Re4f (Fig. 5*B*) photoelectron lines for selected materials, prepared by different procedures. Data for binding energies (BEs) are collected in Table 3. The BE of the principal $Mn2p_{3/2}$ peak for both samples is ~642.2 eV, which may correspond mainly to MnO_2. However, according to the literature data (36) a complete and large overlapping of the $Mn2p_{3/2}$ peak position dominates between MnO_2 and Mn_2O_3 on the one hand and Mn_3O_4 and Mn_2O_3 on the other. Thus, determining the manganese oxidation state on the basis of only the $Mn2p_{3/2}$ peak position is difficult. The primary chemical state of Re in these samples features a doublet at 46.2 and 48.6 eV, which could be assigned to Re $4f_{7/2}$ and Re $4f_{5/2}$ spin-orbit components. According to ref. 37, the spectrum of pure Re_2O_7 also exhibits two less distinct lines at 46.9 and 49.3 eV. According to ref. 37 and the refs. cited therein, the BEs of Re $4f_{7/2}$ for the metal Re and Re(VI) ions differ signficantly and are 40.5 and 44.9 eV, respectively. It was also established that the BEs depend upon both the formal oxidative state and on the nearest neighbours of the Re atoms (38). At the same time, in some XPS studies on supported metal particles, the BEs were found to be particle size dependent, increasing by ~0.5 eV as the particle size decreased from 5 to 1 nm (39, 40). Here, the observed lower values of BEs for Re $4f_{7/2}$ compared with that of bulk Re_2O_7 may be explained by the different charging of the activated carbon support vs. the unsupported oxide. They could be also attributed to Re having

Table 3. Binding energies of C 1S, O 1S, Re 4f, and Mn 2p lines for selected Re–Mn supported on AC samples.

Sample	C1S (eV)	O1S (eV)	Re4f (eV)	Mn2p (eV)	Mn–Re ratio (%)
ReMn(1:3)/AC-S		530.5			
	285	532.6	46.2	642.2	1.867
		535.6	48.6		
ReMn(1:3)/AC-R		530.7			
	285	532.8	46.2	642.2	1.500
		536.3	48.6		

a slightly lower oxidative state than +7 because of the partial reduction of Re during the preparation of the samples (41). The existence of additional interactions between Re and Mn ions is also not excluded. The calculated atomic ratios for the samples show higher surface Mn content for the sample prepared by simultaneous metals deposition (Table 3). This could be due to the surface enrichment with Mn or smaller particles size in the case of ReMn(1:3)/AC-S, and it is an additional indication of the influence of Re on the manganese state.

Concluding remarks

Bicomponent Re and Mn supported on activated carbon materials exhibit good catalytic stability and high activity in methanol conversion to CO and hydrogen at lower temperatures compared with the corresponding monocomponent materials. The observed effects depend strongly on the procedures used to modify the activated carbon; e.g., loading of Re and Mn simultaneously produces a better sample. The combined magnetic, EPR, and XPS measurements for all studied Re–Mn materials show the presence of Mn and Re ions in various oxidative states, probably interacting between themselves. Based on the theoretical and experimentally obtained values of μ_{eff}, some calculations for the possible manganese ion combinations in the catalytic active centre for the studied materials were performed (Table 2). It can be seen that the sample with better catalytic activity and stability (ReMn(1:3)/AC-S) is characterized by a higher amount of Mn(II) combined in active centers with Mn(III) and (or) Mn(IV) ions. The assumption of the significant role of Mn(II) ions in methanol decomposition is in accordance with our previous study of monocomponent Mn/AC materials that were prepared from various manganese precursors (27). Their formation seems to be facilitated by the presence of rhenium ions, the effect being most pronounced when simultaneous loading of Re and Mn is applied. The influence of Re is not only due to the increase in manganese dispersion but also probably to additional electronic effects caused by the ability of rhenium to adopt a variety of oxidative states (see the earlier section on XPS measurements).

Biradical radiationless decay channel in adenine and its derivatives[1]

Marek Z. Zgierski, Serguei Patchkovskii, and Edward C. Lim

Abstract: Coupled-cluster calculations of increasing accuracy (approximate doubles: CC2; doubles: EOM-CCSD; connected triples: CR-EOM-CCSD(T)) for CIS-optimized potential energy profiles of adenine and its derivatives indicate that the ultrafast internal conversion of the optically excited $\pi\pi^*$ state occurs through a state switch to a biradical state, which intersects the ground state at a lower energy. The electronic nature of the biradical state is defined by an electronic configuration in which one unpaired electron occupies a π^* orbital confined to the five-membered ring. The second unpaired electron is localized very strongly on a p-type C2 atomic orbital of the six-membered ring. The biradical state minimum has a strongly puckered six-membered ring and a C2–H bond, which is twisted nearly perpendicular to the average ring plane. Consistent with the biradical-mediated internal conversion, the $\pi\pi^*$ state lifetime is extremely short in adenine and 9-methyladenine, which have barrierless crossing to the biradical state. The lifetime is slightly longer in *N*,*N*-dimethyladenine, which has a small barrier for the state switch. In 2-aminopurine the biradical state is found above the $\pi\pi^*$ state, preventing the biradical state switch and dramatically increasing the lifetime. These results, combined with an earlier work on pyrimidine bases, strongly suggest the importance of a direct decay of the doorway $\pi\pi^*$ state via a biradical state switch in the photophysics of DNA, even though the nature of the biradical state is somewhat different in purines and pyrimidines.

Key words: adenine, guanine, DNA damage, radiationless decay, biradical, ab initio, coupled clusted.

Résumé : Des calculs d'agrégats couplés de plus en plus précis (approximation de doubles : CC2 ; doubles : EOM-CCSD ; triples liés : CR-EOM-CCSD(T)) effectués sur des profils d'énergie potentielle optimisés au niveau CIS de l'adénine et de ses dérivés indiquent que la conversion interne ultra rapide de l'état optiquement excité $\pi\pi^*$ se produit par le biais par un changement d'état vers un état biradicalaire qui intercepte l'état fondamental à une énergie inférieure. La nature électronique de l'état biradicalaire est définie par une configuration électronique dans laquelle un électron non pairé occupe une orbitale π^* confinée dans un cycle à cinq chaînons. Le deuxième électron non pairé est très fortement localisé sur une orbitale atomique C2 de type p du cycle à six chaînons. Le minimum d'énergie de l'état biradicalaire comporte un noyau à six chaînons fortement plissé et une liaison C2–H qui est repliée d'une façon presque perpendiculaire par rapport à la position moyenne du cycle. En accord avec la conversion interne catalysée par un biradical, le temps de vie de l'état $\pi\pi^*$ est extrêmement court pour l'adénine et la 9-méthyladénine pour lesquels il existe un passage sans barrière vers l'état biradicalaire. Dans le cas de la 2-aminopurine, on a trouvé que l'état biradicalaire est à un niveau supérieur à celui de l'état $\pi\pi^*$ ce qui a comme effet d'empêcher le passage à l'état biradicalaire et d'augmenter d'une façon dramatique le temps de vie. Ces résultats, combinés à ceux obtenus antérieurement dans un travail sur les bases pyrimidines, suggèrent fortement l'importance d'une décroissance directe de l'état $\pi\pi^*$ initial par le biais d'un état biradicalaire dans la photophysique de l'ADN, même si la nature de l'état biradicalaire est quelque peu différente dans les purines et les pyrimidines.

Mots clés : adénine, guanine, dommage à l'ADN, décroissance sans rayonnement, biradical, ab initio, agrégat couplé.

[Traduit par la Rédaction]

Introduction

The high degree of photostability of DNA and RNA, despite strong adsorption by the natural bases (adenine, guanine, thymine, cytosine, and uracil) in the near UV region is one of the most enduring mysteries of photobiology (1). Radiationless decay of electronically excited states in oligonucleotides and native nucleic bases is complex, with multiple time constants required to describe the evolution of the excited state population (1, 2). The outcome of the decay is also highly sensitive to the local environment and secondary structure (3). Even decep-

tively simple DNA duplexes exhibit very complex photochemical behavior in solution (1) with up to four decay constants (4) and evidence of extensive nuclear dynamics in excited states (4).

Recent improvements in high-power pulsed lasers and molecular beam preparation techniques (5–7) allowed studies of photodynamics of isolated DNA bases in the gas phase. The observation of rapid radiationless decay for all natural nucleobases in the gas phase (8–10) indicated that photostability is a relatively simple intrinsic property of the bases, especially because the initial experiments were consistent with monoexponential excited state decay for most of the bases (10). Later experiments in transient multiphoton ionization (8–16) and time-resolved photoelectron spectroscopy (17–19) revealed the complex nature of the radiationless decay in isolated bases as well. For all natural DNA bases excited state decay is multiexponential (13, 17), indicating the presence of intermediate states and (or) multiple competing ionization channels. The excited state lifetimes are also highly sensitive to the excitation wavelength (9, 14, 17, 20) as would be expected for competing activated decay channels.

To further complicate matters, coinciding lifetimes of the excited states do not guarantee that the decay mechanisms are identical even in chemically closely-related species. For example, the measured exponential time constants in 9H-adenine and 9-methyl-adenine are essentially identical, an observation used to discount (12, 13) the $\pi\sigma^*$ decay channel (21, 22) in adenine. However, as revealed by time-resolved photoelectron spectra, the rapidly decaying component in adenine is largely attributable to the $\pi\sigma^*$ channel (18, 19). Moreover, experimental evidence also exists for hydrogen ejection (16, 23, 24), excited state proton transfer (11, 24), and long-lived optically active (25) and dark (10, 16, 26) states.

The abundance of available high-resolution gas phase data for the free bases and their analogs (20, 27–31) led to a recent explosion in theoretical investigations of radiationless decay. Many possible deactivation mechanisms were considered in DNA bases, including the proximity effect (32) (see ref. 1 for a recent overview) and a two-state process mediated by an $n\pi^*$ state (33). The classic aromatic biradical decay mechanism, extensively studied in ethylene and benzene (34–37), was first seen (38) but not initially recognized in thymine. This mechanism provides an efficient one-step decay pathway from the initially prepared $\pi\pi^*$ state to the ground state. It was extensively explored for pyrimidine bases (39–43) and used for a successful prediction of the lifetime for a pyrimidine base analog (6F-uracil) (41). Although the biradical mechanism appears to account for most of the decay in free pyrimidine bases at low excess energies, other mechanisms were also investigated and may become important at shorter wavelengths and in different environments. In particular, decay mediated by a dark $n_O\pi^*$ state was studied in cytosine (44) and uracil (45). Another classic decay mechanism, mediated by $\pi\sigma^*$ states dissociative along the X–H coordinate (46), was studied in uracil (47) although no experimental evidence for this pathway was found in the closely related thymine (16). Excited state proton transfer (40, 48–50), excitation transfer to a second stacked (51) or hydrogen-bonded (50, 52) base, and decay pathways involving accidental three-state crossings (53, 54) were also examined for pyrimidine bases. The latter process was claimed to be dominant in cytosine (53).

Perhaps unsurprisingly, electronically richer purine bases and their analogs present an even more complicated picture. Two optically active $\pi\pi^*$ states are known to be important (1). The stronger ^1L_a state involves partial charge transfer from the five- to six-membered ring. The more stable ^1L_b state involves an excitation localized on the six-membered ring. Additionally, one or more optically inactive $n\pi^*$ states and Rydberg states correlating to $\pi\sigma^*$ excitations localized on N–H (21, 22) or C–C (55) bonds are believed to be involved. Among the excited state relaxation mechanisms explored for guanine are excited state tautomerization (56, 57), tautomerism due to multiple minima in N–H bonds in excited state (57), proton (40, 49, 58), excitation (59) transfer to a hydrogen-bonded base, and proton transfer to the solvent (60). Dynamical surface-hopping calculations on guanine and analogs (61, 62) also reveal the importance of large-scale off-plane distortions of the six-membered ring (52, 58). Even more possibilities were examined for a simpler, more extensively studied adenine and its analogs (most importantly 2-aminopurine). The proposed mechanisms include twisting of the $-NH_2$ substituent (25, 63), decay mediated by the lowest $n\pi^*$ state (33, 64, 65), and $\pi\sigma^*$ states involving azine N–H (21, 22) and amino N–H (55) bonds. Other possibilities include excited state proton transfer (50, 66, 67), most likely mediated by protic solvents (66) although no evidence for such transfer was found in a recent condensed-phase experimental study (2). Opening of the five-membered ring of adenine leading to fragmentation was predicted to occur at higher energies (55). Deactivation through accidental triple-state crossings was also suggested to be important in adenine (54).

Despite the initial indications (68) of planar structures for the low-lying $\pi\pi^*$ excited states in adenine and suggestions that nonplanar structures may be biologically not relevant due to steric constraints in DNA (64), large-amplitude deviations from planarity are clearly involved in most low-energy deactivation pathways in purine bases (guanine (61, 62), adenine (31, 50, 55, 64, 65, 69–72)). In an attempt to quantify the role of nonplanar distortions in the excited state decay pathways in adenine and its analogs, several studies appeared in the last two years (31, 55, 64, 65, 70–72). Two of these investigations (31, 65) employ a DFT–MRCI technique, while no less than five publications (55, 64, 70–72) explore deactivation pathways at the CASPT2//CASSCF level.

Multiple competing deactivation pathways were identified in all studies (31, 55, 64, 65, 70–72). Discounting the biologically irrelevant pathway involving the N_9–H $\pi\sigma^*$ state, all studies agree that at low excess energies the most efficient mechanism proceeds through conical intersection(s) with the S_0 ground state reached by a large-amplitude out-of-plane twisting of the C_2–H fragment. The distortion is accompanied by disruption of the π-conjugation between the C_2 carbon and the rest of the π system. As a result, the lowest excited singlet state at these geometries is best described as a biradical formed by unpaired electrons localized respectively on the C_2 carbon atom and the five-membered ring of adenine (31, 55, 64, 65, 70–72). Because of negligible overlap between the unpaired electrons a nearby triplet state must also be present, opening possible pathways to intersystem crossing and long-lived dark states. The low-energy decay pathway in adenine is thus qualitatively similar to the biradical channel in pyrimidine bases.

The detailed electronic and nuclear dynamics leading to the biradical conical intersection is quite complicated and is sensitive to the assumptions and approximations made in the calculations. For instance, in ref. 65 the initially excited $\pi\pi^*$ ^1L_b state

© 2007 NRC Canada

converts barrierlessly to the $n\pi^*$ state, which then decays to the ground state through a conical intersection separated from it by a small barrier. The corresponding conical intersection is characterized by a large out-of-plane twist of the C_2–H bond. In refs. 55, 64, the initially excited $\pi\pi^*$ ^1L_a state decays barrierlessly to the ground state through a "CI_{32}" conical intersection identical to the intersection of ref. 65. The more stable ^1L_b $\pi\pi^*$ state can either cross (essentially barrierlessly) to the ^1L_a surface and decay through CI_{32} or convert to the $n\pi^*$ state and then decay through a "CI_{16}" intersection, separated from $n\pi^*$ by a barrier. The CI_{16} intersection is characterized by a large-amplitude out-of-plane twist of the C_6–NH_2 bond (55, 64). Both conical intersections are qualitatively similar to the main surface-hopping regions previously identified in the dynamical simulation of guanine radiationless decay (62). The excited state decay mechanism elaborated later in refs. 70–72 is qualitatively similar to that described in refs. 55, 64, 65. The electronic nature of the CI_{32} intersection is somewhat ambiguous and is characterized as a crossing between $n\pi^*$ and S_0 states by refs. 65, 70 and as a crossing between ^1L_a $\pi\pi^*$ and S_0 states by refs. 55, 64, 71, 72.

Despite the quantitative differences between the paths taken by the system to reach the CI_{32} intersection, the *existence* of the low-energy state crossing of this type appears to be the determining factor in the rapid decay of 9H-adenine (55, 64, 65, 70–72) and a significant excited-state lifetime found in 2-aminopurine (31, 72). Therefore, for a *qualitative* analysis and understanding of radiationless decay in purine bases, it appears to be reasonable to ignore the detailed dynamics leading to the biradical conical intersection CI_{32} and concentrate on the qualitative properties of the intersection itself.

In this respect, it is important to realize that despite exaggerated claims of the accuracy and rigor of computational results sometimes made (72) any prediction for a system of the complexity of adenine necessarily involves models and approximations. Due to the exorbitant computational cost, these approximations are not always easily controllable. As an example, consider the 0–0 transition energies for the lowest $n\pi^*$ and $\pi\pi^*$ states of adenine calculated in refs. 55, 64, 70–72 using very similar computational techniques and basis sets (Table 1). The calculated excitation origins for both states are scattered over 0.5 eV. More importantly, except for ref. 71, all calculations overestimate the relative stability of the $n\pi^*$ state by amounts likely to be significant in biological settings. Clearly, the judgment calls made by the authors in the construction of the CASSCF active spaces constitute a critical (and unavoidable) factor in these calculations. In fact, it is possible to argue that the results of ref. 71, while in worse numerical agreement with experiment, come from a more balanced model and are therefore the most appropriate for the discussion of inter-surface transitions.

Although CASPT2//CASSCF and related MRQDPT2 techniques are unquestionably the most accurate computational approaches currently available for studies of excited states in medium-sized molecules, such calculations remain extremely labor-intensive (see the Supplementary information of ref. 72 for an illustration). Therefore, it is important to examine whether the *qualitative* features of radiationless decay in adenine and its analogs can be reproduced by simpler and less onerous techniques.

In this work, we explore the radiationless decay of the doorway $\pi\pi^*$ state of adenine and its analogs, such as

Table 1. Published CASPT2//CASSCF energies (in eV) of the two lowest 0-0 transitions from the ground state of adenine, in comparison with experimental and coupled cluster results.

[b]DELTA-CR-EOM-CCSD(T) excitation energy, where the triples correction is applied to the excited state only. This value is expected (76) to provide better balance for singles-dominated excited states.

N,*N*-dimethyladenine and 2-aminopurine. According to ref. 13, methylation of the amino group increases the lifetime by a factor of $\sim$ 2, while transfer of this group to another position in the six-membered ring (from C6 to C2) stabilizes the $\pi\pi^*$ state allowing for a large emission quantum yield. We demonstrate that simple, black-box type coupled-cluster methods (approximate doubles: CC2; doubles: EOM-CCSD; connected triples: CR-EOM-CCSD(T)) are able to explain differences in lifetimes of the $\pi\pi^*$ states of these three molecules. The simplicity of use of the coupled-cluster techniques becomes essential in investigations of much larger fragments of the DNA chain, such as cytidine and its derivatives (73).

Methods

The cc-pVDZ basis set is used in all calculations presented in this paper. We use a simple configuration interaction singles (CIS) method to find partially optimized geometries and utilize these geometries to perform calculations of the energies of the excited electronic states with inclusion of electron correlations. To this end, a coupled cluster method with an approximate inclusion of double excitations (CC2 (74)) is applied to all four molecules. For adenine, the completely renormalized equation of motion coupled cluster (CR-EOM-CCSD(T)) method (75, 76) is used as an additional check. The multiconfigurational complete active space self-consistent field (CASSCF) technique is often the method of choice for similar investigations of small regions of potential energy surfaces. However, designing sufficiently large, consistent CASSCF active spaces becomes very time-consuming and laborious for regions where the H–C5–C4–H angle changes from nearly 0° (as in the initially populated $\pi\pi^*$ state) to almost 150° in the biradical state. CASSCF also tends to miscalculate the ordering of the $\pi\pi^*$ and $n\pi^*$ states (39, 42, 44), known to be sensitive to dynamical correlations involving low-lying σ orbitals (69). The coupled cluster method, on the other hand, provides consistent $\pi\pi^*$ and $n\pi^*$ results for the complete range of geometries explored and is therefore the method of choice for studying the problem. CIS calculations were performed with the use of Gaussian98 program (77), while the equation of motion coupled cluster dou-

bles calculations, extended to include completely renormalized perturbatively connected triples (CR-EOM-CCSD(T)) (75, 76), were done with the GAMESS program (78). Unless mentioned otherwise, type IID triples corrections were used. This type of approach has been shown to produce meaningful results as long as the contribution from multiply excited configurations does not change drastically on the explored potential energy surface of the excited state (41, 42).

The CC2 model has been previously demonstrated to provide reliable results for vertical excitations in π-electron systems, even with relatively small basis sets (74, 79, 80). The lack of diffuse functions in the cc-pVDZ basis in fact has a beneficial side effect of shifting the intruding Rydberg states to higher energies (80), simplifying analysis and interpretation of the results. At the same time, energies of the valence excitation are reproduced well (80), possibly with a small underestimation relative to the basis set limit (81).

It should be emphasized that the electronic ground states of DNA bases acquire significant multiconfigurational character away from the ground state equilibrium geometry and may be poorly approximated by a closed-shell Hartree–Fock solution. As a result (79, 82), calculated CC2 energies for distorted structures are at best qualitative estimates so that quantitative agreement with experiment should not be expected. This can be seen from the values of the D1 diagnostics (82) for the ground-state CC2 solutions. Values in the range 0.07–0.08 are found at the ground-state geometries, increasing somewhat to 0.07–0.09 for the CIS-optimized geometries of the first $\pi\pi^*$ excited state. Dramatic increases to 0.2–0.3 are found for the CIS-optimized biradical geometries, indicating that the calculated values are to be treated with extreme caution (82). At the same time, calculated excited states at all geometries are dominated by single excitations, with $r1$ amplitudes accounting for 88%–95% of all presently reported excited states.

The reduced excitation level (REL) diagnostic in EOM-CCSD calculations does not exceed 1.1 at all geometries presently studied, indicating the dominant single excitation character with respect to the lowest single-determinant solution. Excited states of this type are typically well-described by EOM-CCSD even when the ground state is no longer of a single-determinantal character. As an additional accuracy check, we calculated the ground-state energy of selected adenine and 2-aminopurine structures at the CR-CC(2,3) (83) level. This approach is explicitly constructed to provide accurate description of a subset of multiconfigurational states, specifically states of biradical type. Unfortunately, CR-CC(2,3) is currently available only for states defined by the CCSD cluster operator with a single-determinant reference (typically the ground state). As a result, meaningful exploration of excited state surfaces in not possible with this technique. At the optimized CIS biradical geometries of both adenine and 2-aminopurine (see later), absolute CR-CC(2,3) energies are just 25 mH (0.7 eV) below the corresponding CR-EOM-CCSD(T) IID results. The close agreement between the two approaches suggests that the approximate treatment of multiconfigurational wavefunctions in CR-EOM-CCSD(T) calculations is adequate for adenine and its analogs.

All CC2 calculations were performed using Turbomole (84) version 5.7, using resolution-of-the-identity CC2 implementation (85) with the standard (82) RI-optimized fitting basis sets. Transition moments (81) are calculated in the dipole gauge.

Adenine and 9-CH_3-adenine

CIS–cc-pVDZ geometry optimization places the minimum of the $\pi\pi^*$ doorway (L_b) state 0.119 eV (960 cm^{-1}) below the minimum of the $n\pi^*$ state. The $\pi\pi^*$ state minimum possesses planar six- and five-membered rings, and only the hydrogen atoms of the amino group are not in the plane of the rings. The out-of-plane deformation of the N3–C2–N1–C6 dihedral angle is the lowest frequency vibration in the $\pi\pi^*$ state with the unscaled frequency of just 114 cm^{-1}. On the other hand, the CIS-optimized $n\pi^*$ state has a strongly out-of-plane deformed six-membered ring and the N3–C2–N1–C6 dihedral angle is equal to $-36.36°$ with the C2 and N3 atoms displaced in the opposite directions from the plane. The N3–C2–N1–C6 dihedral angle deformation mode has the unscaled frequency of 338 cm^{-1}. The biradical state minimum, which was confirmed by vibrational analysis, occurs at the N3–C2–N1–C6 dihedral angle of $-58.74°$. The C2 hydrogen atom is twisted to be almost perpendicular to the average plane of the molecule with a C6–N1–C2–H dihedral angle of 83.1°. The CIS energy of the biradical state is only 0.061 eV below the minimum of the CIS $\pi\pi^*$ state. The structure of the minimum of the biradical state is similar to the calculated structure of the conical intersection between the L_a (64, 72) or $n\pi^*$ (65) and the ground state. The CIS energies of the $\pi\pi^*$, $n\pi^*$, and biradical states as functions of the N3–C2–N1–C6 dihedral angle, with all other parameters fully optimized for each state, are depicted in the left panel of Fig. 1. The structure of the biradical state is shown in Fig. 2. The singly occupied orbitals (SOMOs) in this state are illustrated in Fig. 3. The lower energy SOMO is dominated by the five-membered ring, while the higher energy SOMO is strongly localized on the C2 atom. The biradical state correlates at planar geometry to the ^1L_a $\pi\pi^*$ state. The CIS calculations place the minimum of the biradical state only 1.769 eV above the ground-state potential. Inclusion of a perturbative CIS(D) correlation correction (86, 87) decreases the gap to 0.21 eV.

The vertical excitation energies for the lowest $\pi\pi^*$ and $n\pi^*$ states obtained by CR-EOM-CCSD(T) calculations are 4.90 and 4.94 eV, respectively. This compares well with the recent CASPT2 calculations, which give the respective energies at 4.74 and 5.00 eV (70), 4.96 and 5.16 eV, (72), or 5.01 and 5.05 eV (71). The relative CIS and CC2 energies of the CIS minima of the the electronic excited states of adenine and of its 9-CH_3 derivative with respect to the minimum energy of the ground state are given in Table 2. The differences between the energy of the biradical state and the ground state at the biradical geometry are collected in Table 3. We can see that the difference between the CR-EOM-CCSD(T) energy of the biradical state and the CCSD energy of the ground state (the DELTA-CR-EOM-CCSD(T) approximation (76)) becomes negative, indicating crossing of the two surfaces before the minimum of the biradical state is reached. Except for the (uncorrelated) CIS approach, this gap is calculated consistently to be below 1 eV, indicating very efficient internal conversion to the ground state. Because the geometries of the biradical and ground states are very different, many soft modes will become efficient accepting modes in the radiationless decay process, not unlike the situation found for the superfast decay of the excited electronic state in butadiene (88). Methylation of the C9 atom changes the relative energies of the $\pi\pi^*$ and biradical states only marginally, shifting both excitations to the red and slightly closing the gap

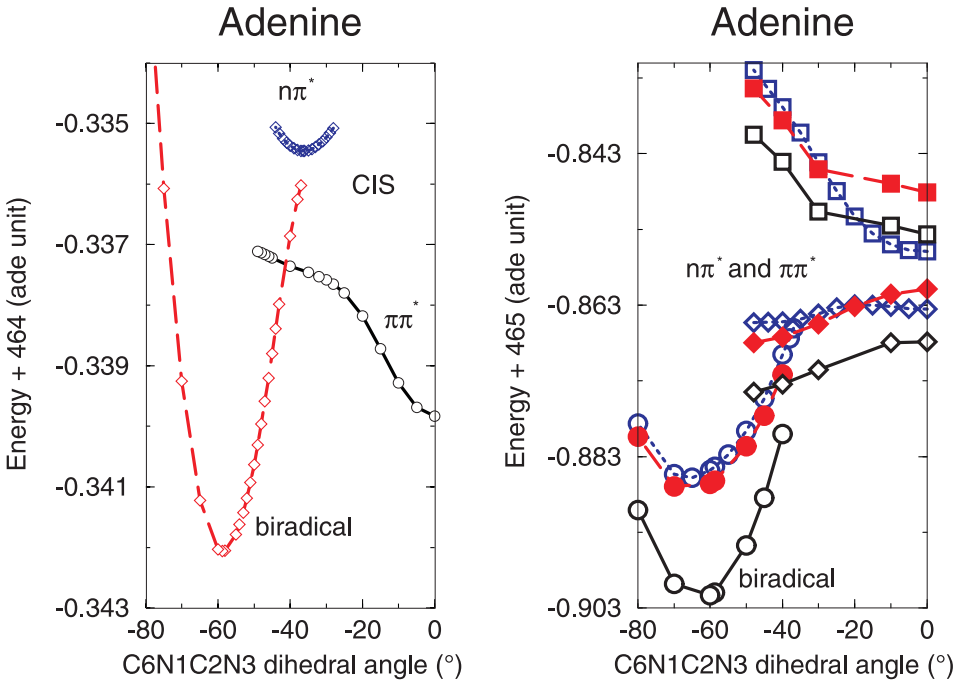
Fig. 1. Energies of the low-lying states of adenine as functions of the C6–N1–C2–N3 dihedral angle for the CIS (left panel) and CC2, CCSD, and CCSD(T) (right panel) levels of calculations. EOM-CCSD (dashed, red lines) and CR-EOM-CCSD(T) (solid, black lines) energies in the right panel are shifted upward by 0.01 and 0.03 au, respectively, with respect to the CC2 (dotted, blue lines) energies. The squares, diamonds, and circles refer to the three different electronic states ($\pi\pi^*$, $n\pi^*$, and biradical). All energies are calculated at the optimized CIS–cc-pVDZ geometries along the C6–N1–C2–N3 minimum energy path.



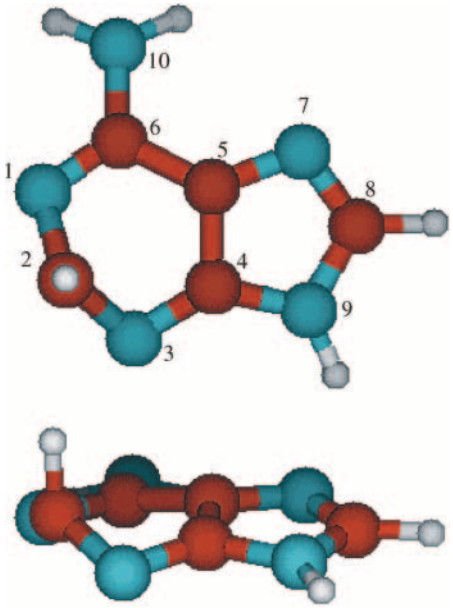


Fig. 2. Two different projection of the structure of the biradical state of adenine and the numbering of the atoms.

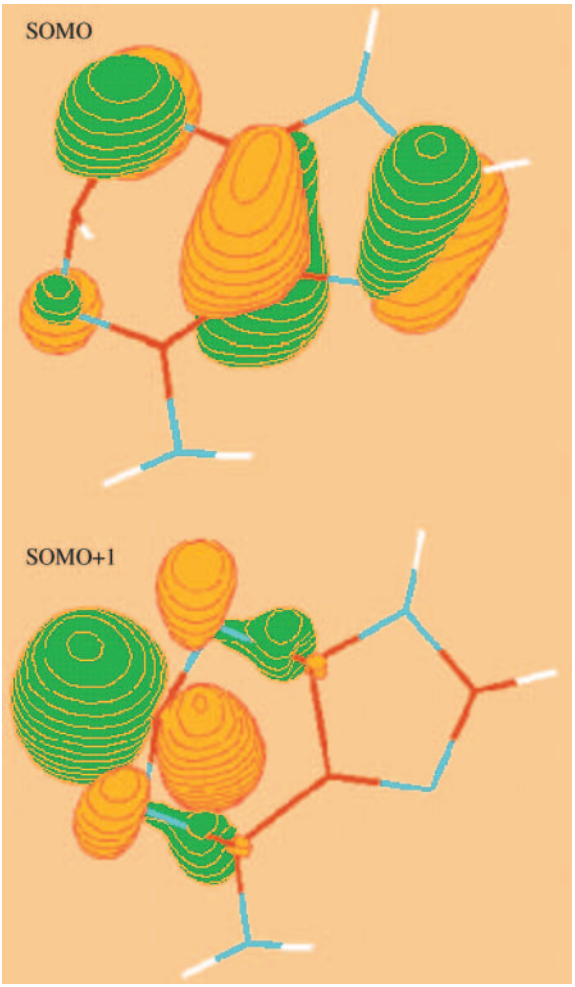
between the two minima. One could expect that such a minor change would lead to a negligible increase in the lifetime of the $\pi\pi^*$ state. Indeed, the excited-state lifetime of 9-methyladenine is only about 10% longer than that of adenine (13). The CIS minimum energy paths along the C6–N1–C2–H dihedral angle in adenine were used to calculate single-point energies of the $n\pi^*$, $\pi\pi^*$, and biradical states by CC2, EOM-CCSD, and CR-EOM-CCSD(T) correlated methods. The results are presented

Table 2. Energies (eV) of the minima of the excited state surfaces with respect to the singlet ground state minimum.

State	Adenine		9-CH_3-adenine		2-aminopurine	
	CIS	CC2	CIS	CC2	CIS	CC2
$\pi\pi^*$	6.078	5.126	6.023	4.931	5.536	4.318
$n\pi^*$	6.197	4.911			5.728	4.351
biradical	6.017	4.352	5.995	4.330	6.295	4.502

Table 3. Energy differences (eV) between the biradical state and the singlet ground state surface at the CIS-optimized biradical geometry.



Level	Adenine	9-CH_3-adenine	2-aminopurine
CIS	1.769		2.972
CIS(D)	0.208	0.145	1.611
CC2	0.726	0.679	1.989
EOM-CCSD	0.782		2.104
CR-EOM-CCSD(T)[a]	−0.164		1.297

[a]DELTA-CR-EOM-CCSD(T) excitation energy, where the triples correction is applied to the excited state only. This value is expected (76) to provide better balance for singles-dominated excited states.

in the right panel of Fig. 1. Solid (black) lines refer to the highest level (CR-EOM-CCSD(T) calculations), dashed (red) lines refer to the EOM-CCSD results, while the dotted (blue) lines show the CC2 energies. Inclusion of electron correlation and multiple excitations strongly stabilizes the biradical state. Thus, at the CR-EOM-CCSD(T) level, the minimum of the biradical state is ∼ 1.3 eV below the original vertically excited $\pi\pi^*$ ^1L_b

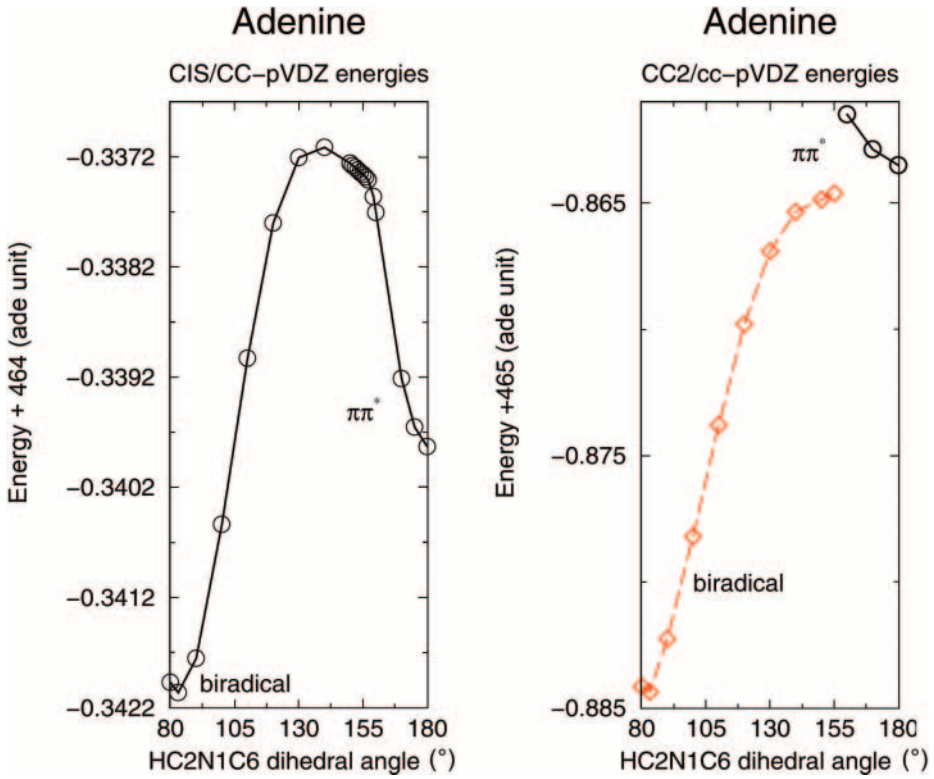
Fig. 3. The two singly occupied molecular orbitals in the dominant electronic configuration of the biradical state of adenine from CIS–cc-pVDZ calculationS.

state. The corresponding values at the CCSD and CC2 levels are 1.1 and 0.8 eV, respectively. The nπ^* and $\pi\pi^*$ states are involved in a conical intersection around −30° and are strongly mixed in the vicinity. The nπ^* state is found 0.38 eV (CR-EOM-CCSD(T)), 0.34 eV (EOM-CCSD), or 0.21 eV (CC2) below the $\pi\pi^*$ state at the planar ring geometry.

Because the qualitative behaviour of the reaction paths at the CR-EOM-CCSD(T) level is similar to the (much cheaper) CC2 results, we have adopted the CC2//CIS level for the calculation of reaction paths in adenine derivatives. As can be seen in Fig. 2, the value of the HC–2N1–C6 dihedral angle is very different in the biradical state compared with that in the planar $\pi\pi^*$ ^1L_b state. Constrained CIS optimization of the lowest singlet state leads to a continuous minimum energy path connecting these two states (Fig. 4, left panel). The corresponding CIS reaction barrier along this path is only 0.135 eV. No barrier is found along the same path in single point CC2 calculations, which place the biradical state below the $\pi\pi^*$ state in the whole range of HC–2N1–C6 dihedral angle (Fig. 4, right panel). In this respect, it should be noted that while a constrained minimum energy path does not necessarily give a faithful representation of the reaction coordinate, the existence of a *barrierless* reaction path is sufficient to demonstrate the absence of an activation barrier. Thus, the initially populated $\pi\pi^*$ ^1L_b state should decay to the biradical state very rapidly in a barrierless fashion. The biradical state will, in turn, upon approaching the ground state potential energy surface, undergo fast internal conversion to the vibrationally hot ground electronic state. Subsequent vibrational cooling returns molecule to its initial condition before absorption of a photon. It should be emphasized that this radiationless decay mechanism is identical to the pathway previously discovered in guanine (62) and recently located in adenine and its derivatives (31, 55, 64, 65, 70–72).



N,*N*-dimethyladenine

Experimentally, substitution of two methyl groups into the amino group of adenine extends the lifetime of the optically excited $\pi\pi^*$ state by a factor of 2–3 (13). If decay through the biradical state dominates in this adenine derivative as well, then the elongation of the lifetime of the initially prepared state would indicate either some destabilization of the biradical state or the introduction of a small energy barrier between the two states, or possibly both.

Figure 5 (top) depicts the optimized CIS structure of the biradical state minimum for *N*,*N*-dimethyladenine. This minimum was verified by force field calculations showing that all harmonic frequencies are real. Except for the two methyl groups, this structure is almost identical to the biradical state structure of adenine (Fig. 2). Figure 6 presents the results of the CIS (solid black lines for the $\pi\pi^*$ state and dashed red lines for the biradical state) and CC2 (solid maroon lines and dashed blue lines) calculations for the minimum energy paths along the C6–N1–C2–N3 dihedral angle on the energy surfaces of the $\pi\pi^*$ and biradical states. As in adenine, the vertically excited $\pi\pi^*$ (^1L_b) state relaxes to a geometry with a flat 6-membered ring, a slightly pyramidalized amino group, and the N10 atom displaced away from the ring plane. The CIS minimum of the biradical state is calculated to be 0.211 eV above the minimum of the $\pi\pi^*$ state. There is also a small pyramidalization of the amino group of the biradical state, however, the N10 (amino) atom remains in the same plane as the five-membered ring. The out-of-plane deformation is limited (as in the case of adenine) to the N3–C2–N1–C6 dihedral angle of −58.7° and to the H–C2–N1–C6 dihedral angle of 83.0°, both values being almost the same as in adenine. Single-point CC2 energies of the two states at optimized CIS geometries are shown by solid (maroon) lines for the $\pi\pi^*$ state with different degrees of amino group pyramidalization and the dashed (blue) line for the biradical state. The two minima on the CC2//CIS $\pi\pi^*$ state surface correspond to distinct conformations of the amino group with respect to the five-membered ring plane. In the lower Franck–Condon minimum the N10–C6–C5–N7 dihedral angle is 37.8°, while in the higher minimum at N3–C2–N1–C6 and N10–C6–C5–N7 it is 40° and 3.1°, respectively. At the CC2//CIS level of theory the biradical state lies ∼ 0.169 eV below the minimum of the $\pi\pi^*$ state. CIS(D) calculation places the minimum of the biradical state 0.56 eV below the minimum of the $\pi\pi^*$ state (similar calculation for adenine gives the value of 1.25 eV for the same energy difference). Thus, our calculations suggest that methylation of the amino group of adenine leads to a slight destabilization of the biradical state, even though it remains well below the minimum of the $\pi\pi^*$ state. At the same time a modest energy barrier develops between the two states along the mini-

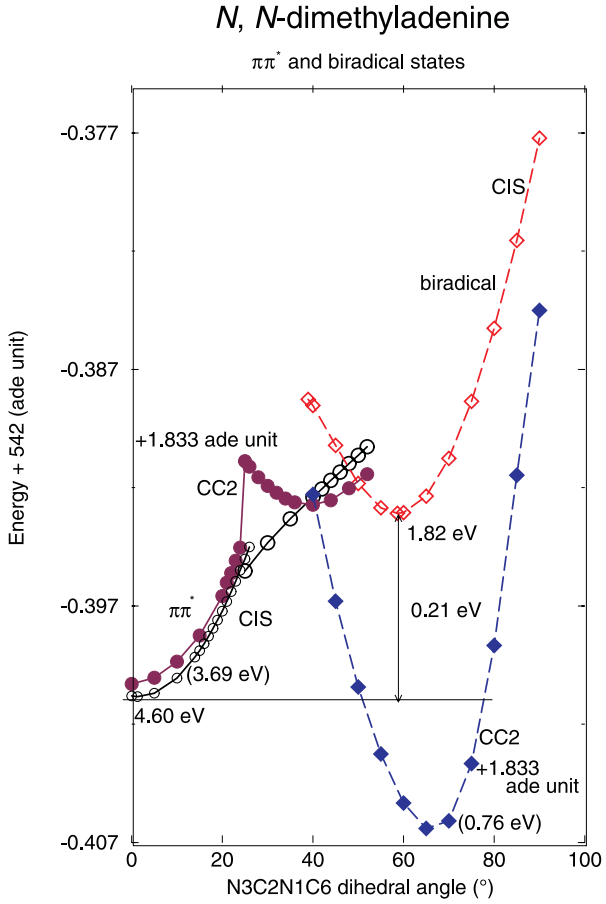
mum energy path corresponding to the increasing N3–C2–N1–C6 dihedral angle. Both effects should lead to a modest increase of the lifetime of the initially excited $\pi\pi^*$ state, as is observed experimentally (13). Note that a deeper minimum appears near the planar geometry on the $\pi\pi^*$ potential energy surface of *N*,*N*-dimethyladenine (Fig. 6) than in adenine. This should lead to a relatively long lifetime of a few low-lying vibronic levels of the $\pi\pi^*$ electronic manifold. Indeed, it is observed that below 125 K the quantum yield of fluorescence from the initially excited $\pi\pi^*$ state of *N*,*N*-dimethyladenine suddenly increases and that at 80 K the lifetime reaches 2 ns (89). This observation is in a qualitative agreement with our results.

2-Aminopurine



This isomer of adenine, in which the amino group is switched from the C6 atom to the C2 atom shows a long lifetime of the excited $\pi\pi^*$ state and a large fluorescence quantum yield (90). Obviously, replacement of the C2 hydrogen by an amino group closes a very effective internal conversion channel of the lowest $\pi\pi^*$ state. 2-Aminopurine (2AP) readily replaces adenine (6-aminopurine) in DNA forming pairs with thymine and also with cytosine (91). It is used extensively as an intrinsic fluorescence probe in DNA (92, 93). Broo (33), Rachofsky (69), and others (1) have argued that the vibronic coupling of the $\pi\pi^*$ (S_1) state with the close-lying $n\pi^*$ (S_2) state determines the efficiency of internal conversion in 2AP via the proximity effect (32, 94–96). This proposal is consistent with the dramatically longer lifetime of 2AP (13, 90) compared with adenine (with a smaller S_2-S_1 gap), and the dramatic increase in the fluorescence yield of 2AP with increasing solvent polarity (which increases the S_2-S_1 gap

Fig. 5. The CIS-optimized structure of the biradical states in (top) *N*,*N*-dimethyladenine and (bottom) 2-aminopurine.

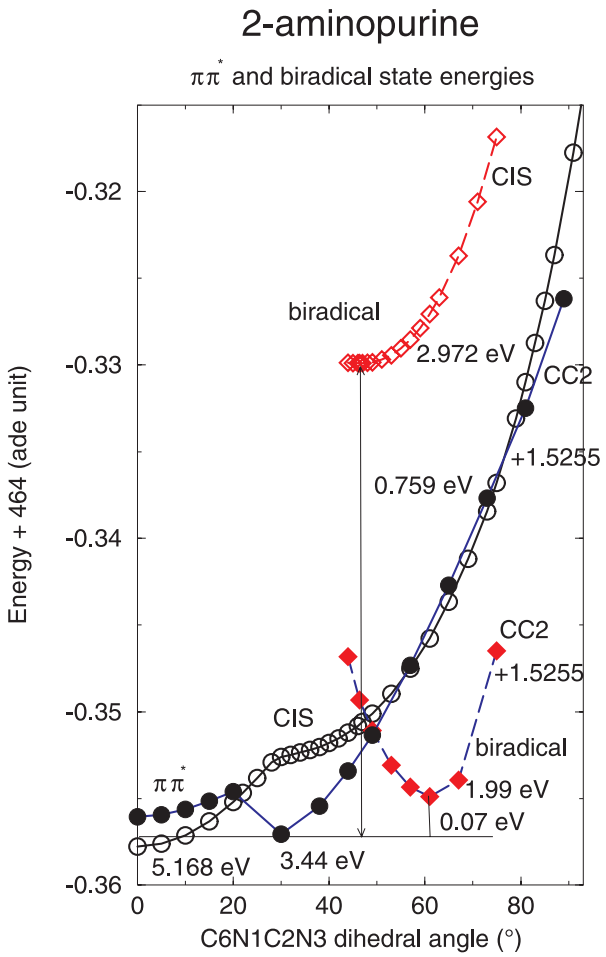
Fig. 6. Energies of the $\pi\pi^*$ and biradical states of *N*,*N*-dimethyladenine as functions of the C6–N1-C2-N3 dihedral angle with all remaining parameters optimizes at the CIS–cc-pVDZ level. Solid (black) lines and open circles show CIS energies of the $\pi\pi^*$ state with the two opposite pyramidalizations of the dimethylamino group. Dashed (red) lines and diamonds give CIS energies of the biradical state. CC2 energies are shown by solid (maroon) lines and filled circles for the $\pi\pi^*$ state and by the dashed (blue) line and filled diamonds for the biradical state. All CC2 energies are shifted uniformly upward by 1.833 au. The numbers near the minima indicate the energy gap (in eV) relative to the singlet ground state surface at the same geometry.

by stabilizing the lowest $\pi\pi^*$ (^1L_a) state with respect to the $n\pi^*$ state (69). As originally found by Marian and co-workers (31) and later confirmed by more elaborate calculations (72), the biradical channel decay in 2AP becomes relatively unimportant at the same time. It is however important to confirm that our simple CC2//CIS calculations lead to the same outcome.

Figure 5 (bottom) depicts the CIS structure of the minimum of the biradical state for 2-aminopurine. Again, force field calculations show that all harmonic frequencies are real. The relative CIS and CC2 energies of the minima of the the electronic excited states of 2-aminopurine with respect to the minimum energy of the ground state are collected in Table 2. The CC2 results for vertical excitation energies are in good agreement with previous CIPSI and TDDFT calculations for this molecule (63) as well as with MCQDPT results (69). They also agree with the recent CASPT2//CASSCF calculations (72). The CC2//CIS energies of the minima of the $\pi\pi^*$, $n\pi^*$ and biradical states in 2-aminopurine are all within a range of 0.2 eV, with the minimum of the $\pi\pi^*$ found at the lowest energy. The differences between the energies of the biradical state and the ground state at the same geometrical configuration are given in Table 3. While the change in calculated relative stability of the $\pi\pi^*$ and $n\pi^*$ states is small in comparison to adenine, the location of the minima of the biradical states of the two molecules changes dramatically. Both CIS and CC2 methods predict the minimum of the biradical state above the minimum of the $\pi\pi^*$ state with an energy barrier between the two states along the reaction path defined by the N3–C2–N1–C6 dihedral angle. It appears that substitution of an electron-donating group on the C2 carbon atom destabilizes the p orbital on C2, which has to accommodate a localized unpaired electron in the biradical state. The energy gap between the minimum of the biradical state and the ground state potential energy surface is also much larger than 1 eV. Both of these factors would make the biradical channel inactive in the internal conversion process of the optically excited $\pi\pi^*$ state, at least at low excess photon energies. Given this conclusion, the interpretation of 2AP photophysics based on the proximity effect appears very reasonable. Figure 7 depicts the CIS and CC2 minimum energy paths along the N3–C2–N1–C6 dihedral angle in the $\pi\pi^*$ and biradical states of 2-aminopurine. Solid lines and circles refer to the $\pi\pi^*$ state while dashed line and diamonds refer to the biradical state. Again, as in *N*,*N*-dimethyladenine, there are two possible pyramidalization structures of the amino group in the $\pi\pi^*$ state. Since the minimum of the biradical state lies above any of the two minima of the lowest excited $\pi\pi^*$ state, the decay of the latter via the biradical state is switched off in 2-aminopurine. This justifies the long lifetime of the $\pi\pi^*$ S_1 state and thus, the high fluorescence quantum-yield observed in this molecule.



Summary and conclusions

The rate of radiationless decay of the optically prepared $\pi\pi^*$ state of adenine and its derivatives and isomers depends critically on the substituents. Methylation of the C6 amino group slows down the process almost threefold, while moving the amino group from the C6 to the C2 position produces a highly fluorescent isomer with a very slow internal conversion to the ground state. We have confirmed that the previously proposed direct decay of the $\pi\pi^*$ state through a switch to a biradical state and subsequent crossing the ground state potential energy surface satisfactorily explains the observed differences in lifetimes of the doorway state in adenine derivatives and isomers. Consistent with this mechanism, the excited-state lifetimes are very short in adenine and 9-methyladenine, which have barrierless crossing of the initially excited $\pi\pi^*$ state to the biradical state, slightly longer in *N*,*N*-dimethyladenine that has a small barrier for the state switch and very long in 2-aminopurine that has the biradical state above the $\pi\pi^*$ state, and thus the biradical channel is shut off.

All qualitative features of the biradical channel are well-reproduced at the simple, computationally inexpensive CC2//CIS technique. At this level, routine calculations are possible on much larger and more biologically relevant systems, such as base pairs, nucleotides, and short strands of DNA and RNA. The CC2 results are in a close agreement with much more elaborate CR-EOM-CCSD(T) and CASPT2 calculations.

Fig. 7. The energies of the $\pi\pi^*$ and biradical states of 2-aminopurine as functions of the C6–N1–C2–N3 dihedral angle. The solid CIS (black) and CC2//CIS (blue) lines show the energies of the lowest $\pi\pi^*$ state (^1L_a) with the two opposite pyramidalizations of the amino group. The dashed CIS (red) and CC2 (blue) lines show the energies of the biradical state. The CC2 energies are shifted uniformly upward by 1.5255 au. The numbers near the minima indicate the energy gap (in eV) to the ground state surface at this geometry.

The same conclusions apply also to another DNA purine base, guanine, in which the biradical state, with the NH_2 group positioned almost perpendicular to the average plane of the six-membered ring, plays a leading role in an ultrafast radiationless decay of the intitially excited $\pi\pi^*$ state.[3] The latter is characterized by a very shallow minimum with a negligible energy barrier for switching to the biradical state.

The mediating biradical state is somewhat similar in nature to the intermediate state present in pyrimidine bases (41, 42), where it is also very sensitive to chemical substitutions and thus strongly influences the internal conversion process of an initially prepared $\pi\pi^*$ state. The purine biradical state involves a strong ruffling of the six-membered ring and out-of-plane deformation of the C2 substituent with respect to the average ring plane. The biradical character of the intermediate state arises because of the separation of two initially paired π electrons, with one electron localized on a carbene-like p orbital of the C2 atom and the other electron confined to a π^* orbital in the five-membered ring. In pyrimidines, both unpaired electrons are localized on the neighboring p orbitals of C5 and C6 atoms. The similarity of the biradical state in adenine with those in pyrimidines is however not complete, since, in the former this state evolves from the higher planar L_a $\pi\pi^*$ state when the six-membered ring deformed, necessitating a state switch to access it. Our results for adenine are in accord with a series of recent papers (55, 64, 65, 70–72). Those for 2-aminopurine concur with the conclusions presented in ref. 31 as well as with ref. 72, which appeared after the completion of our work.

The biradical-mediated radiationless decay mechanism appears to be conserved by the molecular evolution of the DNA bases. We speculate that the mechanism confers evolutionary advantage by minimizing the probability of mutations among all competing pathways. Indeed, the biradical decay channel in cytosine, thymine, and uracil operates without disrupting hydrogen bonding in canonical DNA base pairs. In adenine, only one hydrogen bond is affected with all high-amplitude distortions confined to the (light) hydrogen atom at C2. At the same time, the hydrogen remains strongly covalently bonded, such that the base pairing is restored immediately upon the biradical state decay.

Very recent work in our laboratories has shown that cyclohexanyl guanosine, cyclopentanyl cytosine, and cyclopentanyl uracil, in which the twist of the C2–N bond in guanine and the C5–C6 bond in pyrimidine bases are strongly hindered by the presence of an exocyclic aliphatic ring, do not exhibit ultrashort (subpicosecond) excited-state lifetimes (Marek Z. Zgierski, Serguei Patchkovskii , Takashige Fujiwara, William G. Kofron, and Edward C. Lim. Manuscript in preparation.). The result provides strong support to the biradical decay mechanism presented in this paper.

Aluminum pentafluorophenyl–amide complexes

Carsten Cornelissen, Gigi Chan, Jason D. Masuda, and Douglas W. Stephan

Abstract: The pentafluoroaryl amine $(C_6F_5)_2NH$ (**1**) reacts with $AlH_3{\cdot}NEtMe_2$ to give $[(C_6F_5)_2N]AlH_2{\cdot}NEtMe_2$ (**2**) and $[(C_6F_5)_2N]_2AlH{\cdot}NEtMe_2$ (**3**). The related fluorinated-aryl amine $(C_6F_5)(n\text{-}C_4H_9)NH$ (**4**) also reacts with $AlH_3{\cdot}NEtMe_2$ to give $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}NEtMe_2$ (**5**). This latter compound undergoes ligand exchange with PMe_3 or *N*-methylimidazole to form $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}PMe_3$ (**6**) and $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}$(Me-imid) (**7**), respectively. The latter amine also reacts with $AlMe_3$, affording $[Me_2AlN(C_6F_5)(n\text{-}C_4H_9)]_2$ (**8**).

Key words: almunium, amides, pentafluorophenylamine.

Résumé : L'amine pentafluorée $(C_6F_5)_2NH$ (**1**) réagit avec le complexe $AlH_3{\cdot}NEtMe_2$ pour conduire à la formation du $[(C_6F_5)_2N]AlH_2{\cdot}NEtMe_2$ (**2**) et du $[(C_6F_5)_2N]_2AlH{\cdot}NEtMe_2$ (**3**). L'amine aromatique fluorée apparentée $(C_6F_5)(n\text{-}C_4H_9)NH$ (**4**) réagit aussi avec le complexe $AlH_3{\cdot}NEtMe_2$ pour conduire à la formation du $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}NEtMe_2$ (**5**). Ce dernier produit subit une réaction d'échange de ligand avec le PMe_3 ou le *N*-méthylimidazole pour conduire à la formation du $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}PMe_3$ (**6**) et du $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}$(Me-imid) (**7**) respectivement. Cette dernière amine réagit aussi avec le $AlMe_3$ avec formation du $[Me_2AlN(C_6F_5)(n\text{-}C_4H_9)]_2$ (**8**).

Mots-clés : aluminium, amides, pentafluorophénylamine.

[Traduit par la Rédaction]

Introduction

Lewis acids play dominant roles as co-catalysts in olefin polymerization and as catalysts in a variety of reactions in organic chemistry. The borane $B(C_6F_5)_3$ has been studied in such applications (1, 2), and a number of studies have targeted structural modifications. For example, Marks and co-workers (3–9), as well as Piers and co-workers (1, 10–13), have developed elegant syntheses to both elaborate the substituents on B or to access *bis*-borane compounds. Related alanes have also been prepared and evaluated for a variety of applications in catalysis (14–16). Generally, fluoroarylalanes have been effective in these applications (17–23), although they have proved to be dangerous, as species such as $Al(C_6F_5)_3$ are known to be heat and shock sensitive. In an effort to develop new Al-based Lewis acids, we began an exploration of the Al–amide derivatives, incorporating pentafluoroaryl substitutents. In this paper, we describe the synthesis and structure of several such compounds. An initial attempt to apply these species to the activation of early metal-catalyst precursors is also briefly described.

Experimental section

General data

All preparations were done under an atmosphere of dry, O_2-free N_2, employing both Schlenk line techniques and an MBraun or Vacuum Atmospheres inert-atmosphere glovebox. Solvents were purified, employing a Grubbs-type solvent purification system, manufactured by Innovative Technologies. All organic reagents were purified by conventional methods. ^1H, $^{31}P\{^1H\}$, ^{19}F, and $^{13}C\{^1H\}$ NMR spectra were recorded on Bruker Avance-300 and -500 spectrometers. All spectra were recorded at 25 °C. Trace amounts of protonated solvents were used as a reference for ^1H NMR spectra, while the solvent was used as a reference for $^{13}C\{^1H\}$ spectra, and chemical shifts for ^1H and $^{13}C\{^1H\}$ spectra were reported relative to $SiMe_4$. $^{31}P\{^1H\}$ NMR spectra were referenced to external 85% H_3PO_4. IR spectra were recorded on a Bruker FTIR spectrometer. Combustion analyses were done in-house, employing a PerkinElmer CHN Analyzer. $(C_6F_5)_2NH$ (**1**) was purchased from Aldrich Chemical Co. $(C_6F_5)(n\text{-}C_4H_9)NH$ **(4)** was prepared following a literature procedure (24).

Synthesis of $[(C_6F_5)_2N]AlH_2{\cdot}EtMe_2$ (2)

A solution of $(C_6F_5)_2NH$ (0.524 g, 1.5 mmol) in toluene (10 mL) was added dropwise to a solution of $AlH_3{\cdot}NEtMe_2$ (3.0 mL, 1.5 mmol, 0.5 mol/L in toluene) at 25 °C. The reaction mixture was stirred overnight, and the solvent was removed in vacuo to yield 0.653 g (1.45 mmol, 97%) of a light yellow oil. ^1H NMR (CD_2Cl_2): 2.85 (q, $^3J_{HH}$ = 7 Hz, 2H, NCH_2Me), 2.48 (s, 6H, NMe_2), 1.18 (t, $^3J_{HH}$ = 7.3 Hz, 3H, NCH_2Me). ^1H NMR (CD_2Cl_2, –80 °C): 3.39 (br s, 2H, Al*H*), the resonance for Al*H* was not observed. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 144.9 (dm, $^1J_{FC}$ = 239 Hz, *o*-C_6F_5), 138.4 (dm, $^1J_{FC}$ = 246 Hz, *m*-C_6F_5), 138.0 (dm, $^1J_{FC}$ = 250 Hz, *m*-C_6F_5), 126.2 (m, C_6F_5), 54.4 (s, NCH_2Me), 44.5 (s, NMe_2), 8.6 (s, NCH_2Me). ^{19}F NMR (CD_2Cl_2): –149.2 (d, $^3J_{FF}$ = 23 Hz, *o*-C_6F_5), –164.7 (t, $^3J_{FF}$ = 23 Hz, *p*-C_6F_5), –165.5 (m, *m*-C_6F_5). Anal. calcd. for $C_{16}H_{13}AlF_{10}N_2$: C 42.68, H 2.91, N 6.22; found: C 42.46, H 2.56, N 6.13.

Received 13 November 2006. Accepted 6 December 2006. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 27 February 2007.

Synthesis of $[(C_6F_5)_2N]_2AlH{\cdot}NEtMe_2$ (3)

$AlH_3{\cdot}NEtMe_2$ (5 mL, 2.5 mmol, 0.5 mol/L in toluene) was added dropwise to a vigorously stirring solution of $(C_6F_5)_2NH$ (2.618 g, 7.5 mmol) in toluene (5 mL) at 25 °C. After stirring overnight, the white product was collected on a frit, washed three times with pentane, and dried in vacuo. For a second fraction, the solvent was removed in vacuo, and the crude product **3** was recrystallized from pentane to yield 1.94 g (overall, 1.7 mmol, 68%) of a white solid. ^{1}H NMR (CD_2Cl_2): 2.98 (q, $^3J_{HH}$ = 7 Hz, 2H, NC*H*$_2$Me), 2.52 (s, 6H, NMe_2), 1.14 (t, $^3J_{HH}$ = 7 Hz, 3H, NCH_2*Me*), the resonance for Al*H* was not observed. ^{1}H NMR (CD_2Cl_2, –80 °C): 3.21 (br s, 1H, Al*H*). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 145.6 (dm, $^1J_{FC}$ = 246 Hz, *o*-C_6F_5), 139.0 (dt, $^1J_{FC}$ = 251 Hz, $^3J_{FC}$ = 13 Hz, *p*-C_6F_5), 138.0 (dm, $^1J_{FC}$ = 255 Hz, *m*-C_6F_5), 124.3 (m, *i*-C_6F_5), 53.0 (s, N*C*H$_2$Me), 43.0 (s, N*Me*$_2$), 6.7 (s, NCH_2*Me*). ^{19}F NMR (CD_2Cl_2): –147.6 (d, $^3J_{FF}$ = 20 Hz, *o*-C_6F_5), –161.7 (t, $^3J_{FF}$ = 21 Hz, *p*-C_6F_5), –164.7 (m, *m*-C_6F_5). Anal. calcd. for $C_{28}H_{12}AlF_{20}N_3$: C 42.18, H 1.52, N 5.27; found: C 41.66, H 1.56, N 5.73. Single crystals suitable for X-ray diffraction experiments were obtained by cooling a saturated pentane solution to –30 °C overnight.

Synthesis of $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}NEtMe_2$ (5)

$AlH_3{\cdot}NEtMe_2$ (5 mL, 2.5 mmol, 0.5 mol/L in toluene) was added dropwise to a vigorously stirring solution of $(C_6F_5)(n\text{-}C_4H_9)NH$ (**4**) (1.794 g, 7.5 mmol) in toluene (5 mL) at 25 °C. After stirring overnight, the solvent was removed in vacuo. The crude product was recrystallized from pentane to yield 1.466 g (1.8 mmol, 72%) of a white solid. ^{1}H NMR (CD_2Cl_2): 3.18 (q, $^3J_{HH}$ = 7 Hz, 2H, NC*H*$_2$Me), 2.92 (m, 6H, NC*H*$_2$CH$_2$), 2.62 (s, 6H, N*Me*$_2$), 1.17 (t, $^3J_{HH}$ = 7 Hz, 3H, N*CH*$_2$Me), 1.04 (m, 6H, NCH_2CH_2), 0.92 (m, 6H, CH_2CH_2Me), 0.76 (m, 9H, CH_2CH_2*Me*). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 147.4 (dm, $^1J_{FC}$ = 235 Hz, *o*-C_6F_5), 138.2 (dm, $^1J_{FC}$ = 250 Hz, *m*-C_6F_5), 127.6 (m, *ipso*-C_6F_5), 52.1 (s, N*C*H$_2$Me), 51.5 (s, N*Me*$_2$), 43.4 (s, N*C*H$_2$CH$_2$), 32.9 (s, NCH$_2$*C*H$_2$), 20.5 (s, CH$_2$*C*H$_2$Me), 14.0 (s, CH$_2$*C*H$_2$*Me*), 5.3 (s, NCH_2*Me*), the resonances for *p*-C_6F_5 were masked by the *m*-C_6F_5 signal. ^{19}F NMR (CD_2Cl_2): –147.2 (d, $^3J_{FF}$ = 20 Hz, *o*-C_6F_5), –165.1 (t, $^3J_{FF}$ = 21 Hz, *p*-C_6F_5), –166.6 (m, *m*-C_6F_5). Anal. calcd. for $C_{34}H_{38}AlF_{15}N_4$: C 50.13, H 4.70, N 6.88; found: C 50.01, H 4.55, N 6.54. Single crystals suitable for X-ray diffraction experiments were grown from pentane.

Synthesis of $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}PMe_3$ (6) and $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}$(Me-imid) (7)

These compounds were prepared in a similar fashion, using the appropriate reagent; thus, only one preparation is detailed. PMe_3 (0.17 mL, 1.67 mmol) was added to a solution of **5** (545 mg, 0.67 mmol) in toluene (5 mL) and stirred overnight at 25 °C. The solvent was removed in vacuo, and the crude product was recrystallized from pentane to yield 145 mg (0.18 mmol, 27%) of a white microcrystalline solid **6**. ^{1}H NMR (C_7D_8): 3.05 (m, 6H, NC*H*$_2$), 1.06 (m, 12H, C*H*$_2$C*H*$_2$Me), 0.78, (t, $^3J_{HH}$ = 7 Hz, 9H, CH$_2$*Me*), 0.71 (d, $^2J_{PH}$ = 8 Hz, 9H, P*Me*$_3$). $^{13}C\{^1H\}$ NMR (C_7D_8): 146.0 (dm, $^1J_{FC}$ = 240 Hz, *o*-C_6F_5), 137.9 (dm, $^1J_{FC}$ = 252 Hz, *m*-C_6F_5), 136.8 (dm, $^1J_{FC}$ = 253 Hz, *p*-C_6F_5), 136.2 (m, *ipso*-C_6F_5), 49.7 (s, N*C*H$_2$), 33.3 (s, NCH$_2$*C*H$_2$), 20.2 (s, *C*H$_2$Me), 13.7 (s, CH$_2$*Me*), 10.7 (d, $^1J_{PC}$ = 23.2 Hz, P*Me*$_3$), *ipso*-C_6F_5 resonances was not detected. ^{19}F NMR (C_7D_8): –149.4 (d, $^3J_{FF}$ = 23 Hz, *o*-C_6F_5), –165.2 (m, *m*-C_6F_5, *p*-C_6F_5). $^{31}P\{^1H\}$ NMR (C_7D_8): –50.3 (s, *P*Me$_3$). Anal. calcd for $C_{33}H_{36}AlF_{15}N_3P$: C 48.48, H 4.44, N 5.14; found: C 48.22, H 4.21, N 5.01. Compound **7**: 162 mg, white solid (0.2 mmol, 100%). ^{1}H NMR (CD_2Cl_2): 8.00 (s, 1H, NC*H*N), 7.03 (s, 1H, NC*H*CHN), 7.00 (s, 1H, NCHC*H*N), 3.82 (s, 3H, N*Me*), 3.09 (m, 6H, NC*H*$_2$), 1.10 (m, 12H, C*H*$_2$C*H*$_2$Me), 0.76 (t, $^1J_{HH}$ = 7 Hz, 9H, CH$_2$*Me*). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 146.2 (d, $^1J_{CF}$ = 234 Hz, *o*-C_6F_5), 139.6 (s, N*C*HN), 138.0 (m, *m*-C_6F_5), 127,1 (s, NCH*C*HN), 122.4 (s, MeN*C*H), 49.6 (s, N*C*H$_2$), 35.6 (s, N*Me*), 33.7 (s, NCH$_2$*C*H$_2$), 20.5 (s, *C*H$_2$Me), 14.1 (s, CH$_2$*Me*), resonances for *p*-C_6F_5 and *ipso*-C_6F_5 were not detected. ^{19}F NMR (CD_2Cl_2): –150.4 (d, $^3J_{FF}$ = 20 Hz, *o*-C_6F_5), –167.5 (m, *m*-C_6F_5), –168.7 (m, *p*-C_6F_5). Anal. calcd. for $C_{34}H_{33}AlF_{15}N_5$: C 49.58, H 4.04, N 8.50; found: C 49.21, H 4.13, N 8.67.

Synthesis of $[Me_2AlN(C_6F_5)(n\text{-}C_4H_9)]_2$ (8)

A solution of $(C_6F_5)(n\text{-}C_4H_9)NH$ (1.436 g, 6 mmol) in toluene (6 mL) was added slowly to a solution of $AlMe_3$ (95 μL, 2 mmol) in toluene (3 mL) at –30 °C. The solution was allowed to warm to 25 °C overnight. After the solvent was reduced in vacuo to half of its volume, the solution was stored at –30 °C overnight to yield colourless crystals. The product was collected on a frit in dried in vacuo to yield 862 mg (1.5 mmol, 73%). ^{1}H NMR (C_6D_6): 3.18 (m, 4H, NC*H*$_2$), 1.23 (m, 4H, NCH$_2$C*H*$_2$), 0.97 (m, 4H, *CH*$_2$Me), 0.73 (t, $^3J_{HH}$ = 7 Hz, 6H, CH$_2$Me), –0.04 (m, 6H, $AlMe_2$), –0.73 (m, 6H, $AlMe_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): 145.3 (dm, $^1J_{FC}$ = 244 Hz, *o*-C_6F_5), 139.6 (dm, $^1J_{FC}$ = 255 Hz, *p*-C_6F_5), 138.0 (dm, $^1J_{FC}$ = 257 Hz, *m*-C_6F_5), 122.9 (m, *ipso*-C_6F_5), 55.9 (s, N*C*H$_2$), 29.6 (s, NCH$_2$*C*H$_2$), 20.3 (s, *C*H$_2$Me), 13.7 (s, CH$_2$*Me*), –9.6 (br, Al*Me*$_2$), –10.5 (br, Al*Me*$_2$). ^{19}F NMR (C_6D_6): –140.3 (d, $^3J_{FF}$ = 23 Hz, *o*-C_6F_5), –155.2 (t, $^3J_{FF}$ = 23 Hz, *p*-C_6F_5), –161.9 (dd, $^3J_{FF}$ = 23 Hz, $^3J_{FF}$ = 23 Hz, *m*-C_6F_5). Anal. calcd for $C_{24}H_{30}Al_2F_{10}N_2$: C 48.82, H 5.12, N 4.74; found: C 48.61, H 5.11, N 4.65. Single crystals suitable for X-ray diffraction experiments were obtained by storing a concentrated pentane solution at –30 °C overnight.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glovebox, thus, maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data were collected in a hemisphere of data in 1329 frames with 10 s exposure times. The observed extinctions were consistent with the space groups in each case. The data sets were collected ($4.5° < 2\theta < 45–50.0°$). A measure of decay was obtained by recollecting the first 50 frames of each data set. The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing packages. An empirical absorption correction, based on redundant data, was applied to each data set. Subsequent solution and refinement was performed, using the SHELXTL solution package.

the literature tabulations (25). The heavy-atom positions were determined, using direct methods, employing the SHELXTL direct methods routine. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on *F*, minimizing the function $w(|F_o| - |F_c|)^2$, where the weight *w* is defined as $4F_o^2/2\sigma(F_o^2)$, and F_o and F_c are the observed and calculated structure factor amplitudes, respectively. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases, atoms were treated isotropically. H-atom positions were calculated and allowed to ride on the carbon to which they are bonded, assuming a C–H bond length of 0.95 Å. Hydrogen-atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C atom to which they are bonded. The H-atom contributions were calculated but not refined. The locations of the largest peaks in the final difference Fourier map calculation, as well as the magnitude of the residual electron densities in each case, were of no chemical significance. Additional details are provided in the supplementary data.[2] Crystallographic data for **1**, **2**, **4**, and **8** are given in Table 1.

Results and discussion

The pentafluoroaryl amine $(C_6F_5)_2NH$ (**1**) has not been frequently used as a ligand in main-group or tranisition-metal chemistry. In initiating work with this species, we were able to obtain X-ray quality crystals of **1** (Fig. 1). The reaction of this amine with AlH_3·$NEtMe_2$ in a 1:1 ratio affords a light-yellow oil **2** in 97% isolated yield. The ^{1}H NMR data were consistent with the presence of coordinated $NEtMe_2$, although resonances attributable to Al–H fragments were not observed at 25 °C. At –80 °C, a resonance appeared at 3.39 ppm, and it was attributed to two protons on Al. The ^{19}F NMR spectrum of **2** showed the resonances expected for the amide substituents. Based on these data and elemental analyses, compound **2** was formulated as $[(C_6F_5)_2N]AlH_2$·$NEtMe_2$ (Scheme 1).

Using 1:3 stoichiometry, the reaction of AlH_3·$NEtMe_2$ with $(C_6F_5)_2NH$ proceeds upon stirring at 25 °C for 12 h to afford the product **3** (Scheme 1). The product was recrystallized from pentane to yield a white crystalline material in 83% yield. For compound **3**, the ^{1}H NMR spectrum showed resonance attributable to coordinated $NEtMe_2$, although no resonances attributable to AlH were observed. Nonetheless, similar to **2**, cooling to –80 °C resulted in the observation of a ^{1}H NMR resonance at 3.21 ppm attributable to the single Al–H atom. The $^{13}C\{^1H\}$ NMR spectrum revealed the corresponding ^{13}C resonances, as well as signals arising from C_6F_5 rings. Similarly, the ^{19}F NMR data are consistent with the presence of the $(C_6F_5)_2N$ fragments. Suitable crystals were obtained from a pentane solution at

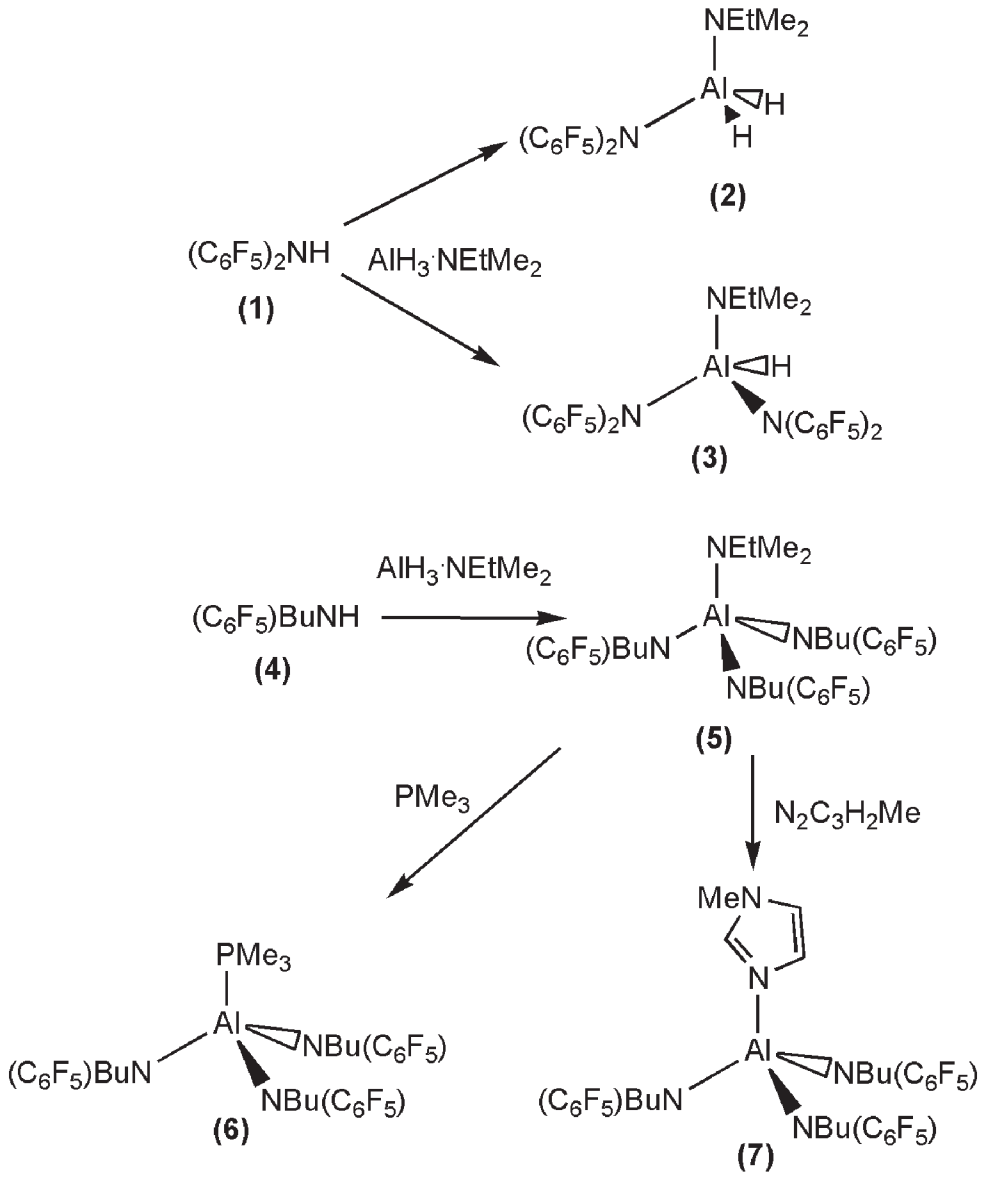

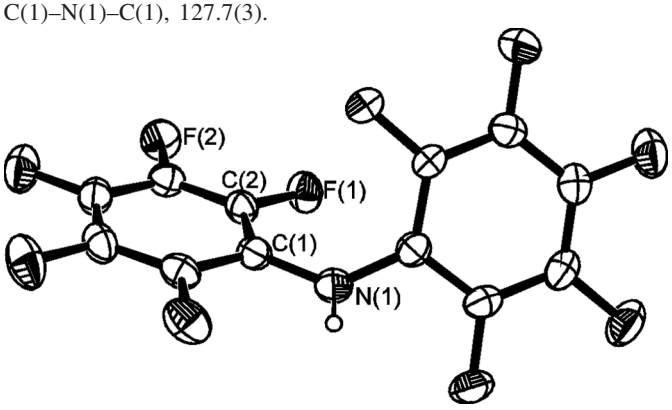

Fig. 1. ORTEP drawing of **1** (30% thermal ellipsoids are shown). Selected distances (Å) and angles (°): N(1)—C(1), 1.389(3); C(1)–N(1)–C(1), 127.7(3).

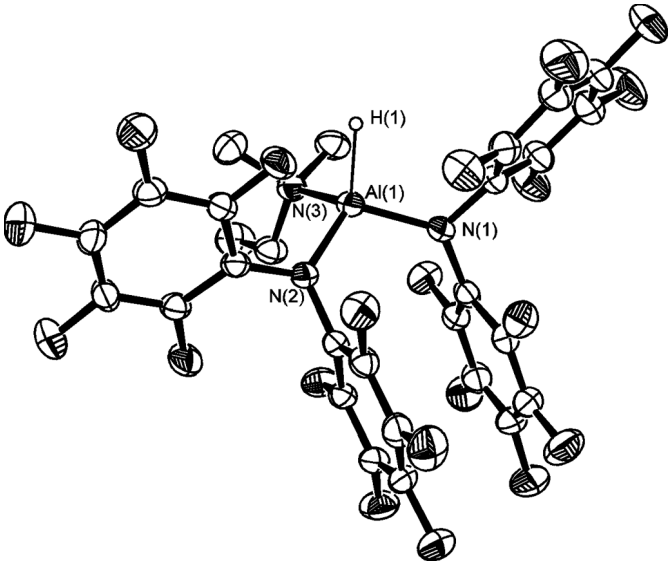

–30 °C, allowing the unambiguous determination of the nature of **3**, as $[(C_6F_5)_2N]_2AlH{\cdot}NEtMe_2$, by a single-crystal X-ray diffraction study (Fig. 2). The geometry about Al is pseudo-tetrahedral, with the amide Al—N distances averaging 1.855(3) Å. The coordinated tertiary amine gives rise to an Al—N distance of 2.006(3) Å. The resulting N–Al–N angles range from 105.48(12)° to 113.78(13)°. The Al-bound H atom was located and refined, giving rise to an Al–H distance of 1.62 Å. Similar Al—H distances have been reported for $(i\text{-}Pr_2C_6H_3N)C(Me)CHPPh_2(NC_6H_3\text{-}i\text{-}Pr_2)AlH_2$ (26). Adjacent arene rings on the two amide ligands are oriented in an approximately parallel offset π-stacking arrangement. The distance between these rings is 3.284 Å, while the angle between the planes is 2°.

The related fluorinated-aryl amine $(C_6F_5)(n\text{-}C_4H_9)NH$ (**4**) was prepared via a known method (24). Reactions of this less bulky and more basic amine with $AlH_3{\cdot}NEtMe_2$ in 1:1 and 2:1 ratios afforded unresolved mixtures of products.

© 2007 NRC Canada

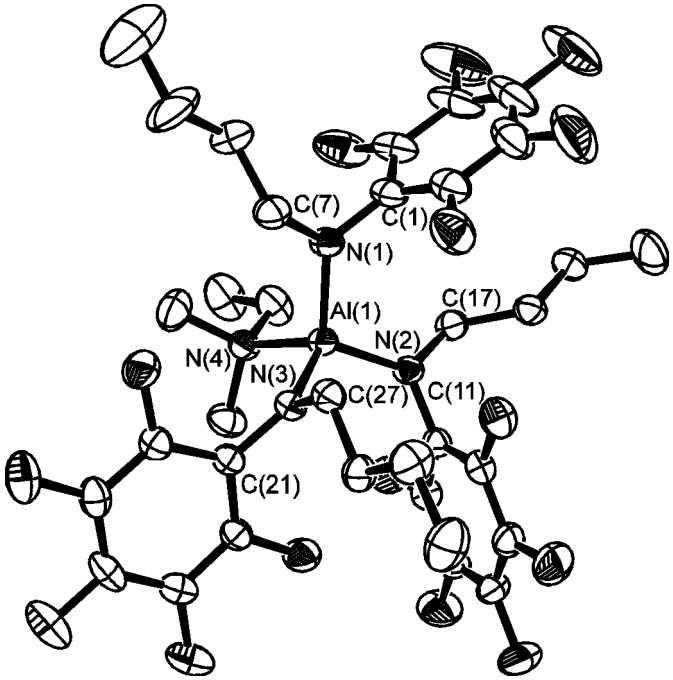

Fig. 2. ORTEP drawing of **2** (30% thermal ellipsoids are shown). All hydrogen atoms except the AlH are omitted for clarity. Selected distances (Å) and angles (°): Al(1)—N(1), 1.855(3); Al(1)—N(2), 1.856(3); Al(1)—N(3), 2.006(3); N(1)–Al(1)–N(2), 111.44(13); N(1)–Al(1)–N(3), 113.78(13); N(2)–Al(1)–N(3), 105.48(12).

However, the reaction of **4** in a 3:1 ratio with $AlH_3{\cdot}NEtMe_2$ proceeded to give a white solid **5** in 72% isolated yield. ^1H NMR data were consistent with a ratio of amide to coordinated $NEtMe_2$ of 3:1. $^{13}C\{^1H\}$ and ^{19}F NMR data also supported the formulation of **5** as $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}NEtMe_2$ (Scheme 1). This view was subsequently confirmed via X-ray crystallography (Fig. 3). The Al center in **5** has a pseudo-tetrahedral geometry with Al—N distances for the amide ligands ranging from 1.827(3) Å to 1.838(4) Å. These distances are slightly shorter than those reported earlier for **3**, consistent with the increased basicity of the amide derived from **4**. The coordinated amine $NEtMe_2$ gave rise to an Al—N distance of 2.043(4) Å. Interestingly, this distance is significantly shorter than that seen in **4**, suggesting that although the Al in **5** has three amide ligands, the Al center is more accessible to the donor, presumably because of the lesser steric demands of the amide substituents.

Compound **5** reacts with other donors to afford the replacement of the coordinated amine. For example, the reaction with PMe_3 results in the formation of the white microcrystalline product **6**, albeit in a relatively low isolated yield of 27%. ^1H NMR confirms the displacement of the coordinated $NEtMe_2$ by PMe_3. In addition, the observation of a $^{31}P\{^1H\}$ NMR signal at –50.3 ppm is consistent with coordination to Al, and thus, the formulation of **6** as $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}PMe_3$ (Scheme 1). In a similar fashion, the reaction of **5** with *N*-methylimidazole $MeN_2C_3H_3$ results in the displacement of the amine, affording the product $[(C_6F_5)(n\text{-}C_4H_9)N]_3Al{\cdot}$(Me-imid) (**7**) in quantitative yields (Scheme 1). NMR data supported this formulation, although repeated attempts to isolate X-ray quality crystals of **7** were unsuccessful. The dramatically higher yields of **7** than **6** are consistent with hard–soft donor considerations, as well as the lesser steric congestion provided by the imidazole N-atom donor.

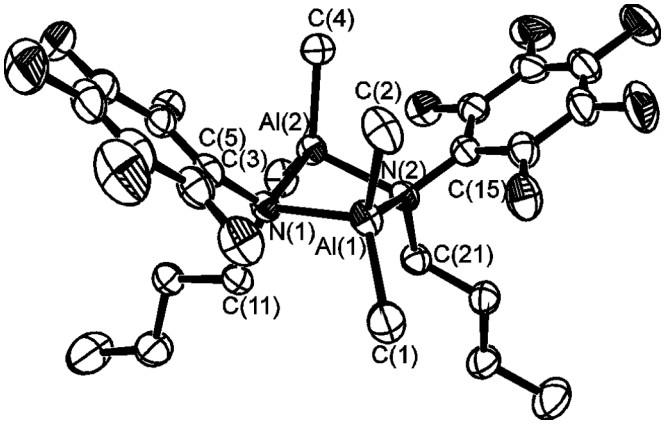

Fig. 3. ORTEP drawing of **4** (30% thermal ellipsoids are shown). Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°): Al(1)—N(1), 1.838(4); Al(1)—N(2), 1.833(3); Al(1)—N(3), 1.827(3); Al(1)—N(4), 2.043(4); N(3)–Al(1)–N(2), 114.55(15); N(3)–Al(1)–N(1), 111.01(16); N(2)–Al(1)–N(1), 112.25(14); N(3)–Al(1)–N(4), 106.37(14); N(2)–Al(1)–N(4), 105.66(15); N(1)–Al(1)–N(4), 106.34(14).

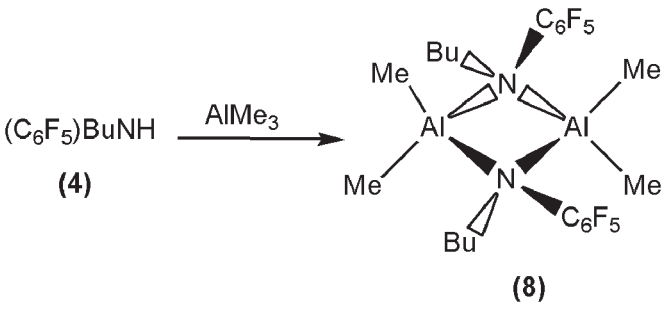

In contrast to the reactions with $AlH_3{\cdot}NEtMe_2$, the amine **4** reacts with $AlMe_3$ in a 1:1 ratio to form the colorless crystalline product **8** in 73% isolated yield. The ^1H NMR spectrum of **8** is consistent with replacement of one methyl group by an amide ligand. However, this spectrum also shows two resonances at –0.04 and –0.73 ppm, attributable to Al-bound methyl groups. This suggests molecular dissymmetry and the formulation of **8** as $[Me_2AlN(C_6F_5)(n\text{-}C_4H_9)]_2$ (Fig 4, Scheme 2). The $^{13}C\{^1H\}$ and ^{19}F NMR and elemental analysis data were also consistent with this formulation. Single crystals of **8**, suitable for X-ray diffraction experiments, were grown from a concentrated pentane solution at –30 °C. The X-ray data confirmed the dimeric formulation of **8**, in which the amido-N atoms bridge the two Al centers. The substituents on N are oriented such that the C_6F_5 rings are on *cis*. It is this feature that accounts for the inequivalent methyl groups on the Al atoms. The Al—N distances were found to range from 1.993(3) Å to 2.031(3) Å, significantly longer than the terminal Al–amide distances described earlier. The geometry and metric parameters are similar to those recently reported for a series of Al-dimers $[Me_2AlN(C_6F_nH_{5-n})H]_2$($n$ = 1, 2, 4, and 5) (27). The Al—C distances range from 1.947(4) to 1.959(3) Å, similar to those seen in the previously mentioned Al-dimers and in $[Me_2Al(NPt\text{-}Bu_3)]_2$ (28). The Al-centers are pseudo-tetrahedral, with C–Al–C′ and N–Al–N′ angles averaging 122.4(2)° and 86.8(1)°, respectively. In addition, the Al_2N_2

Fig. 4. ORTEP drawing of **8** (30% thermal ellipsoids are shown). Hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°): Al(1)—C(1), 1.947(4); Al(1)—C(2), 1.956(4); Al(1)—N(2), 1.993(3); Al(1)—N(1), 2.031(3); Al(1)—Al(2), 2.8280(14); Al(2)—C(4), 1.958(3); Al(2)—C(3), 1.959(3); Al(2)—N(1), 2.002(3); Al(2)—N(2), 2.030(3); C(1)–Al(1)–C(2), 123.70(18); C(1)–Al(1)–N(2), 112.08(15); C(2)–Al(1)–N(2), 109.36(14); C(1)–Al(1)–N(1), 111.89(14); C(2)–Al(1)–N(1), 106.70(15); N(2)–Al(1)–N(1), 86.87(10); C(4)–Al(2)–C(3), 121.04(18); C(4)–Al(2)–N(1), 110.78(14); C(3)–Al(2)–N(1), 113.11(14); C(4)–Al(2)–N(2), 107.39(14); C(3)–Al(2)–N(2), 112.50(14); N(1)–Al(2)–N(2), 86.65(10); Al(2)–N(1)–Al(1), 89.02(10); Al(1)–N(2)–Al(2), 89.33(10).

Scheme 2.

core is essentially planar, and thus, this results in an Al—Al′ separation of 2.8280(14) Å.

Summary

Several Al compounds incorporating hexafluorophenylamido-ligands have been prepared and characterized. The amides derived from the amines $(C_6F_5)_2NH$ and $(C_6F_5)(n\text{-}C_4H_9)NH$ react with $AlH_3.NEtMe_2$ to give the momeric Al products **2**, **3**, and **5**, with varying numbers of amido-substituents. The degree of substitution appears to be dominated by the steric demands of the amide subsitutents. Donor exchange is facile for **5**, readily affording **6** and **7**. The amine $(C_6F_5)(n\text{-}C_4H_9)NH$ also reacts with $AlMe_3$ to give the dimeric product **8**. These Al–amido species proved to be generally difficult to handle and demonstrated poor reactivity. We will continue to develop new main-group chemistry that will result in new activators for applications in olefin polymerization catalysts.

The reactivity of an anionic gallium *N*-heterocyclic carbene analogue with a solution stable digermene

Paul A. Rupar, Michael C. Jennings, and Kim M. Baines

Abstract: The reaction of the anionic gallium(I) *N*-heterocyclic carbene (NHC) analogue **3** with the solution stable digermene **5** results in the formation of the gallium NHC – germylene complex **8**. The gallium NHC – germylene complex **8** was derivatized with CH_3I and $(CH_3)_3SiCl$.

Key words: digermene, carbene analogue, germylene, gallium(I).

Résumé : Le composé **3**, un analogue du carbène *N*-hétérocyclique (CNH) anionique du gallium(I), réagit avec une solution stable de digermène **5** pour conduire à la formation du complexe CNH du gallium – germylène, **8**. On a préparé les dérivés de ce complexe avec le CH_3I et le $(CH_3)_3SiCl$.

Mots-clés : digermène, analogue de carbène, germylène, gallium(I).

[Traduit par la Rédaction]

Introduction

There is a growing interest in the chemistry of low-valent gallium compounds because of their inherently interesting structure and bonding and their potential utility in the synthesis of novel transition-metal and main-group species (1). Although many stable gallium(I) compounds have been reported, the synthesis of the negatively charged gallium *N*-heterocyclic carbene $KGa\{N(Ar)CH\}_2$ (Ar = 2,6-diisopropylphenyl) (**3**) was particularly significant, since it can be synthesized reliably in high yield, and thus, it is a readily accessible reagent for the synthesis of new gallium-containing compounds (2). For many years, we have been interested in the reactions of digermenes, with a focus on cycloaddition reactions and the formation of small ring systems (3). The lack of synthetic methods for small rings, containing both gallium and germanium (4), and the accessibility of **3** prompted us to examine its reaction with digermenes, as a potential method for the synthesis of a three-membered ring containing both gallium and germanium.

Recently, the reaction between **3**·tmeda (tmeda = tetramethylethylenediamine) and two digermenes ($R_2Ge{=}GeR_2$, R = $CH(SiMe_3)_2$ (**1a**) and R = 2,4,6-triisopropylphenyl (**2a**)) has been reported (5). Complex **4** was isolated from the reaction of **3**·tmeda with digermene **1a** (see Scheme 1). Digermene **1a** readily dissociates to germylene **1b** in solution, and thus, the formation of the anionic complex **4** is most likely because of the direct reaction of **3**·tmeda with the germylene **1b**. No reaction was observed between digermene **2a** and **3**·tmeda. Unlike digermene **1a**, digermene **2a** does not readily dissociate in solution at room temperature (6), providing a plausible explanation for the difference in reactivity between the two digermenes.

We now report on the reaction between gallium(I) **3** and the digermene, tetramesityldigermene (**5a**), which does not dissociate in solution,[2] and we will compare our results to those of the previous study (5).

Results and discussion

The addition of two equivalents of **3** to a yellow THF solution of **5a** initially results in the formation of a dark-red solution, which rapidly changes colour to orange (Scheme 2). After the removal of the solvent, analysis of the product mixture by ^{1}H NMR spectroscopy revealed the presence of a new compound **8** and hexamesitylcyclotrigermane (**6**) in a 9:1 ratio. The ^{1}H NMR spectrum of compound **8** revealed that it contained a $\{N(Ar)CH\}_2$ ligand and two equivalent mesityl groups. Compound **8** was purified by successive washes with hexanes. Crystals of **8** were grown from toluene at –30 °C and unambiguously identified by X-ray crystallography as the anionic, donor-stabilized germylene (Scheme 2).

Compound **8** crystallized as a symmetrical dimer, half of which is shown in Fig. 1. The structural metrics of **8** are similar to those previously reported for **4** (5). The unsolvated potassium is directly associated with the germanium with a bond length of 3.3987(15) Å. Furthermore, the potassium

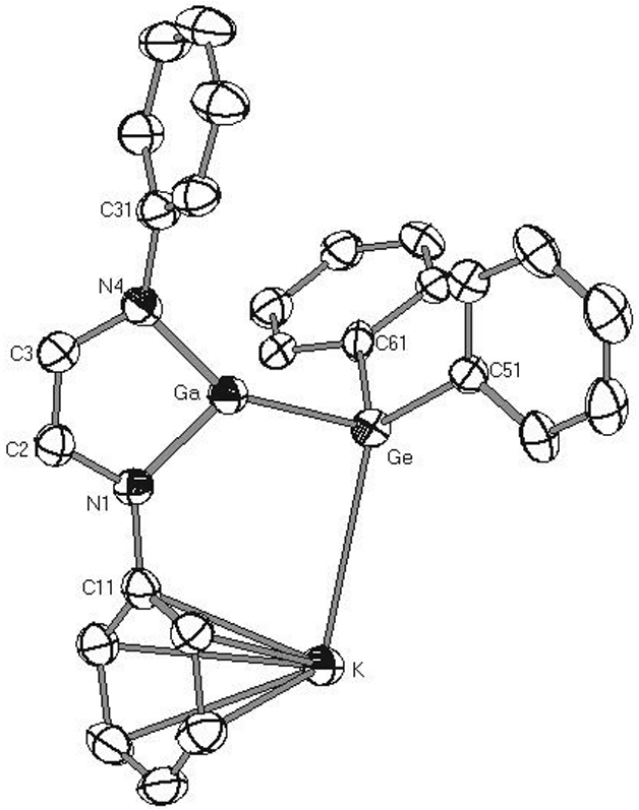
Scheme 1.

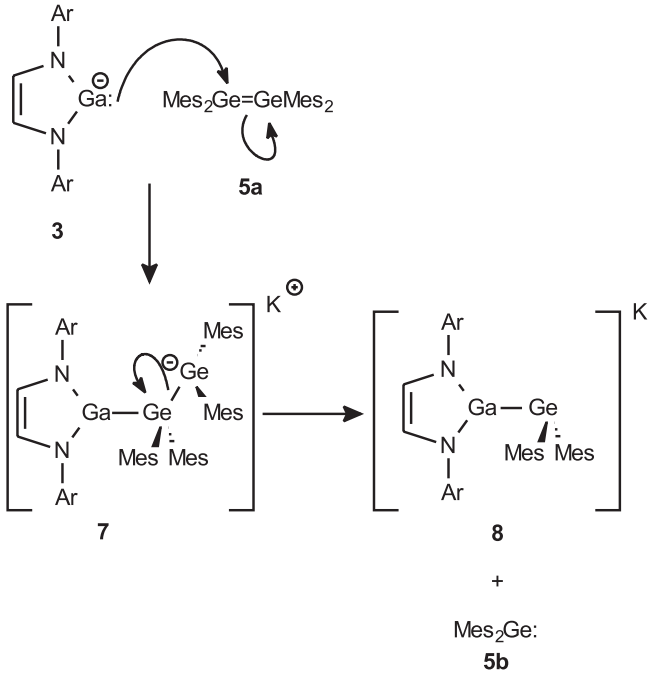


Scheme 2.

bridges between the aromatic diisopropylphenyl group of one molecule and the aromatic ring of the mesityl group of a second molecule (not shown in Fig. 1). The metrics of the $\{N(Ar)CH\}_2$ backbone are typical of those found in other gallium NHC complexes, i.e, the N—Ga bond length (average is 1.886 Å) is significantly shorter, and the N–Ga–N bond angle is larger (85.8(2)°), compared with the uncomplexed anionic gallium NHC (approximately 2.01 Å and 82°, respectively). The Ga—Ge bond length in **8** is 2.4600(8) Å, which is typical of other gallium–germanium single bonds,[3] but shorter than that found in **4**. The longer Ga—Ge bond length in **4** (2.5396(8) Å) was attributed to the increased steric congestion around the germanium centre (5). The geometry about the germanium in **8** is pyramidal, and the Ga–Ge–Mes bond angles are more acute (99.01(16) Å and 102.85(15) Å) than expected, given the steric bulk. Also, the K–Ge–C51–C61 fragment is close to planar (sum of the angles is 355.5°). These features are consistent with the previous report, suggesting that the germanium centre can be described as sp^2-hybridized with the gallium donating

Fig. 1. Thermal ellipsoid plot (50% probability surface) of **8**. Isopropyl groups, methyl groups, and hydrogens have been omitted for clarity. Selected bond lengths (Å): Ge—Ga = 2.4600(8), Ge—K = 3.3987(15), Ge—C(51) = 2.021(6), Ge—C(61) = 2.030(6), Ga—N(1) = 1.887(5), Ga—N(4) = 1.884(5), N(1)—C(2) = 1.392(7), N(4)—C(3) = 1.378(7), C(2)—C(3) = 1.323(7), N(1)—C(31) = 1.439(7), N(4)—C(11) = 1.4306(7); and angles (°): Ga–Ge–C(51) = 99.01(16), Ga–Ge–C(61) = 102.85(15), Ga–Ge–K = 90.02(3), C(51)–Ge–K = 119.28(17), C(61)–Ge–K = 126.97(16), C(51)–Ge–C(61) = 109.2(2), N(1)–Ga–N(4) = 85.8(2), Ge–Ga–N(4) = 149.47(15), Ge–Ga–N(1) = 123.88(14), Ga–N(4)–C(3) = 110.1(4), Ga–N(1)–C(2) = 110.7(4), N(4)–C(3)–C(2) = 116.9(6), N(1)–C(2)–C(3) = 116.5(6), Ga–N(1)–C(11) = 129.7(4), Ga–N(4)–C(31) = 129.6(4).

into the empty p orbital on the germanium (5), as in a base-stabilized germylene.



Unlike digermene **1a**, digermene **5a** does not dissociate to the corresponding germylene in solution. Thus, we do not believe that the major pathway to compound **8** is by the direct reaction of the germylene with the gallium NHC **3**. We propose that the addition of **3** to digermene **5a** initially yields the germyl potassium **7**, which then eliminates the transient dimesitylgermylene **5b** (Scheme 3).

Germylene **5b** can then dimerize to give **5a** (7), react with a molecule of **3** to form **8**, or insert into the double bond of **5a**, resulting in the formation of cyclotrigermane **6** (Scheme 4) (8). Because digermene **5a** is generated by the photolysis of cyclotrigermane **6**, the observation of the cyclotrigermane in the product mixture may also be attributed to incomplete photolysis. However, careful examination of the ^{1}H NMR

[3] A survey of the Cambridge Crystallographic Database revealed a Ga—Ge single-bond length average of 2.46 Å.

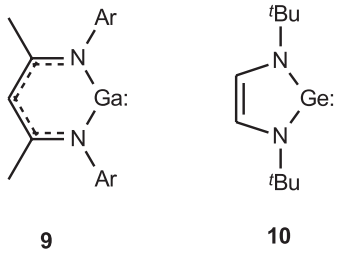
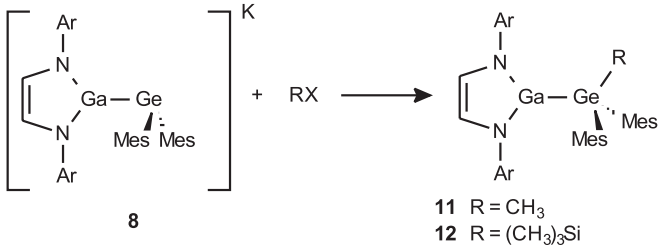
Scheme 4.



Ar = 2,6-diisopropylphenyl

spectrum of the solution of **5a** prior to the addition of **3** revealed the complete absence of cyclotrigermane **6**. Thus, the amount of cyclotrigermane present must be less than 5% (the assumed lower detection limit of the NMR experiment). This is much less than the 10% generated during the reaction of **5a** with **3.**



A similar mechanism has been proposed to explain the results of the addition of Grignard reagents to tetramesityldigermene **5a** (9). The nucleophilic addition of RMgX to the digermene resulted in the formation of a germyl Grignard reagent, which underwent subsequent elimination of MesMgX to give a germylene. Our results show that direct addition of **3** to digermenes is possible, and the reaction of **3** with a digermene does not require prior dissociation to a germylene.

Chart 1.

Ar = 2,6-diisopropylphenyl

Scheme 5.

RX = CH_3I
or
$(CH_3)_3SiCl$

Ar = 2,6-diisopropylphenyl

We have also investigated the reactivity of two additional NHC analogues towards **5a**. The neutral gallium(I) HC[MeC(2,6-*i*-$Pr_2C_6H_3$)N]$_2$Ga (**9**) (10) and the germanium NHC analogue Ge{N(*t*-Bu)C(H)}$_2$ (**10**) (11) (Chart 1) were added to a solution of digermene **5a**. However, in both cases, no reaction was observed, likely because of the decreased nucleophilicity of these compounds.

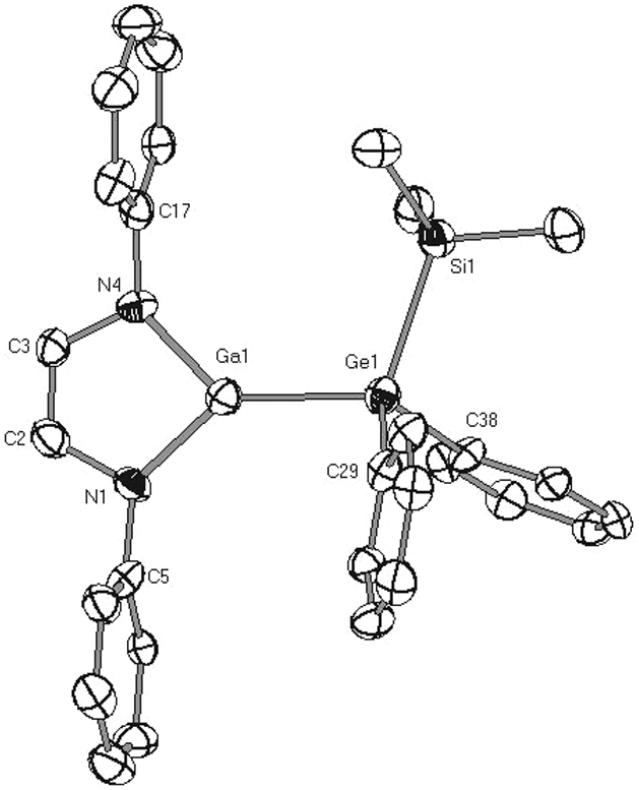
Salt-elimination reactions of 8

To explore the reactivity of **8**, both CH_3I and $(CH_3)_3SiCl$ were added to the new complex (Scheme 5). The addition of CH_3I to a solution of **8** dissolved in THF resulted in the instantaneous formation of a white precipitate. Analysis of the reaction mixture by ^{1}H NMR spectroscopy revealed the quantitative conversion of **8** to a new species **11**. The product was unambiguously identified by mass spectrometry and NMR spectroscopy. The EI mass spectrum of **11** revealed the highest-mass ion at *m/z* 772, with the expected isotopic distribution corresponding to the molecular ion of methylated **8**. The ^{1}H–^{13}C gHMBC spectrum of **11** showed a correlation between the signal at 0.77 ppm in the ^{1}H dimension, assigned to the Ge–CH_3 group, and the signal at 136.20 ppm in the ^{13}C dimension, assigned to the *ipso*-mesityl carbon. All signals in the ^{1}H and ^{13}C NMR spectra of **11** were entirely consistent with the proposed structure.

© 2007 NRC Canada

The addition of $(CH_3)_3SiCl$ to a THF solution of **8** resulted in the rapid change in colour of the solution from orange to yellow. NMR spectroscopic analysis (^1H, ^{13}C, and ^{29}Si) of the solid, isolated after solvent removal, was consistent with the formation of the trimethylsilyl adduct of **8**. Yellow crystals of **12** were grown from a solution of toluene and acetonitrile at –30 °C and analyzed by X-ray diffraction. Compound **12** crystallizes with two distinct molecules in the asymmetric unit. Although chemically identical, they differ structurally by the orientation of the mesityl substituents and the length of the gallium–germanium bond. The difference in the Ga—Ge bond length (2.4082(9) Å vs. 2.4312(10) Å) is most likely because of the increased steric demands caused by the rotation of one of the mesityl substituents. Only one of the molecules from the unit cell is presented in Fig. 2.

The structure of **12** is similar to that of **8** except the potassium has been replaced with $(CH_3)_3Si$. The metrics of the *N*-heterocyclic backbone are essentially unchanged from **8**. The geometry about the germanium is now a distorted tetrahedron. The Ga–Ge–*ipso*-C angles have increased from 99.01(16)° and 102.85(15)° in **8** to 103.31(12)° and 113.63(11)° in **12**. Interestingly, the Ga—Ge bond length has decreased from 2.4600(8) Å in **8** to 2.4312(10) Å in **12** despite the added steric bulk of the $(CH_3)_3Si$ group. In the initial report on the synthesis of **4**, the orbital contribution from germanium to the gallium–germanium bond was described as being mostly p in character because of the lack of change in hybridization (5). We believe that in the $(CH_3)_3Si$ adduct **1**, the orbital contribution from germanium is more sp^3 in character, resulting in a contraction of the gallium–germanium bond.



Conclusions

In summary, the addition of the gallium NHC analogue **3** to the solution stable digermene **5a** resulted in the formation of complex **8**. The molecular structure of **8** was determined and found to be similar to the previously reported gallium NHC complex **4** (5). The formation of **8** from **5a** demonstrates that the gallium NHC analogue **3** is able to add directly to digermenes and cause subsequent cleavage of the germanium–germanium bond. Dissociation of digermenes into germylenes is not a prerequisite for a reaction to occur with **3**. The gallium(I) compound **9** and the germanium NHC analogue **10** have both been found to be unreactive towards digermene **5a**, presumably because they are less nucleophilic than **3**.

Finally, the anionic complex **8** was derivatized with CH_3I and $(CH_3)_3SiCl$, forming compounds **11** and **12**, respectively. The molecular structure of the $(CH_3)_3Si$ adduct **12** was determined and the Ga—Ge bond length decreased, compared with the parent compound **8**. This is consistent with the bonding model proposed for gallium NHC base-stabilized germylenes (5).

We are continuing our research on the synthesis of gallium–germanium ring systems. Other methods are now being explored, including salt eliminations. We will report on our subsequent findings in due course.

Fig. 2. Thermal ellipsoid plot (50% probability surface) of **12**. Isopropyl groups, methyl groups, and hydrogens have been omitted for clarity. Selected bond lengths (Å): Ge(1)—Ga(1) = 2.4311(10), Ge(1)—Si(1) = 2.4162(19), Ge(1)—C(29) = 2.011(3), Ge(1)—C(38) = 2.026(3), Ga(1)—N(1) = 1.881(5), Ga(1)—N(4) = 1.862(4), N(1)—C(2) = 1.389(7), N(4)—C(3) = 1.392(7), C(2)—C(3) = 1.335(8), N(1)—C(5) = 1.428(5), N(4)—C(17) = 1.437(5); and angles (°): Ga(1)–Ge(1)–Si(1) = 107.65(5), Ga(1)–Ge(1)–C(29) = 103.31(12), Ga(1)–Ge(1)–C(38) = 113.63(11), Si(1)–Ge(1)–C(29) = 125.33(13), Si(1)–Ge(1)–C(38) = 99.15(13), C(29)–Ge(1)–C(38) = 108.13(16), Ge(1)–Ga(1)–N(1) = 137.68(15), Ge(1)–Ga(1)–N(4) = 134.19(17), Ga(1)–N(1)–C(2) = 108.4(4), Ga(1)–N(4)–C(3) = 109.1(4), N(1)–Ga–N(4) = 88.1(2), N(1)–C(2)–C(3) = 117.3(6), N(4)–C(3)–C(2) = 117.0(6), Ga(1)–N(1)–C(5) = 131.3(4), Ga(1)–N(4)–C(17) = 130.5(4).

Experimental

All manipulations were carried out under a dry N_2 environment at room temperature in a glovebox. Solvents were dried by passing through an alumina column and were subsequently degassed. $KGa\{N(Ar)CH\}_2$ was synthesized following the literature procedure (2). All other chemicals were purchased from commercial sources and used without further purification. NMR chemical shifts are reported in ppm with coupling constants in hertz. All spectra were acquired using C_6D_6 as the solvent. ^1H NMR spectra were referenced to residual C_6D_5H (7.15 ppm). ^{13}C spectra were referenced to the ^{13}C central transition (128.0 ppm) of C_6D_6. ^{13}C signals were unambiguously assigned using ^1H–^{13}C gHSQC and ^1H–^{13}C gHMBC spectroscopy. ^{29}Si chemical shifts were obtained using ^1H–^{29}Si gHMBC spectroscopy and refer-

enced externally to $(CH_3)_4Si$ (0.0 ppm). The purity of all compounds was determined by ^1H NMR spectroscopy (see supplementary data).[4] Melting points were determined under a N_2 atmosphere and are uncorrected.

Preparation of $KMes_2GeGa\{[N(Ar)CH]_2\}$ (8)

To a yellow solution of Mes_4Ge_2 (**5a**) (0.161 mmol, from the photolysis of 100 mg of Mes_6Ge_3 (**6**)) dissolved in THF (5 mL) was added a red THF (2 mL) solution of $KGa\{N(Ar)CH\}_2$ (**3**) (0.32 mmol, 0.16 g) to give a dark red solution. After 5 min, the colour of the solution changed to orange. The solvent was removed under vacuum, yielding an orange residue. The residue was taken up in hexanes, and a centrifuge was used to remove the suspended salts. The yellow precipitate was collected and washed with hexanes repeatedly. Compound **8** was collected, as a yellow powder, in 60% yield (0.15 g, 0.19 mmol); mp 98 °C dec. ^1H NMR: 1.02 (d, $^3J_{HH}$ = 6 Hz, 12 H, *i*-Pr CH_3), 1.23 (d, $^3J_{HH}$ = 6 Hz, 12 H, *i*-Pr CH_3), 2.15 (s, 6 H, *p*-Mes–CH_3), 2.21 (s, 12 H, *o*-Mes–CH_3), 3.58 (sept, $^3J_{HH}$ = 7 Hz, 4 H, *i*-Pr CH), 6.30 (s, 2 H, C_2H_2), 6.67 (s, 4 H, *m*-Mes–H), 7.01 (s, 6 H, *m*,*p*-Ar–H). $^{13}C\{^1H\}$NMR: 20.96 (*p*-Mes–CH_3), 24.40 (*i*-Pr–CH_3), 25.56 (*i*-Pr–CH_3), 27.04 (*o*-Mes–CH_3), 28.30 (*i*-Pr–CH), 121.40 (C_2H_2), 122.86 (*m*-Ar–CH), 124.86 (*p*-Ar–CH), 128.28 (*m*-Mes–CH), 134.36 (*p*-Mes–C), 143.14 (*o*-Mes–C), 147.02 (*o*-Ar–C), 148.47 (*i*-Ar–C), 150.83 (*i*-Mes–C). ESIMS (negative ion) *m*/*z* (%): 376 ($[\{N(Ar)CH\}_2]^-$, 100).

Preparation of $MeMes_2GeGa\{[N(Ar)CH]_2\}$ (11)

Excess methyl iodide (0.1 mL) was added to an orange THF (5 mL) solution of **8** (0.16 mmol, 130 mg). A white precipitate formed instantly, and the solution turned yellow. The solvent was removed under vacuum, and the residue was extracted with hexanes. The suspended salts were removed by centrifugation, yielding a yellow hexanes solution. The solvent was removed under vacuum to give **11**, as a yellow powder, in a yield of 97% (0.12 g, 0.155 mmol). ^1H NMR: 0.77 (s, 3 H, CH_3–Ge), 1.13 (d, $^3J_{HH}$ = 7 Hz, 12 H, *i*-Pr CH_3), 1.26 (d, 12 H, $^3J_{HH}$ = 6 Hz, *i*-Pr CH_3), 2.02 (s, 6 H, *p*-Mes–CH_3), 2.15 (s, 12 H, *o*-Mes–CH_3), 3.57 (sept, 4 H, $^3J_{HH}$ = 7 Hz, *i*-Pr CH), 6.32 (s, 2 H, C_2H_2), 6.57 (s, 4 H, *m*-Mes–H), 7.13–7.20 (m, 6 H, *m*,*p*-Ar–H). $^{13}C\{^1H\}$NMR: 5.35 (Ge–Me), 20.84 (*p*-Mes–CH_3), 23.84 ($CH(CH_3)_2$), 24.58 (*o*-Mes–CH_3), 25.98 ($CH(CH_3)_2$), 28.68 ($CH(CH_3)_2$), 121.94 (C_2H_2), 123.30 (*m*-Ar–CH), 125.96 (*p*-Ar–CH), 129.54 (*m*-Mes–CH), 136.20 (*i*-Mes–C), 138.22 (*p*-Mes–C), 142.22 (*o*-Mes–C), 145.63 (*o*-Ar–C), 145.70 (*i*-Ar–*C*); EIMS *m*/*z* (%): 772 ($[M]^+$, 50), 564 ($[M^+$ – GeMesMe], 70), 445 ($[Ga\{N(Ar)CH\}_2]^+$, 30), 327 ($[GeMes_2Me]^+$, 100). HR-EIMS: calcd. for $C_{45}H_{61}{}^{69}Ga^{74}GeN_2$ 772.331; found: 772.328.

Preparation of $(CH_3)_3SiMes_2GeGa\{[N(Ar)CH]_2\}$ (12)

Excess $(CH_3)_3SiCl$ (50 µL, 0.39 mmol) was added to an orange THF solution (2 mL) of **8** (100 mg, 0.12 mmol). The colour of the solution immediately turned yellow, and the solution was stirred for 5 min. The solvent was removed under vacuum, yielding a yellow residue. The residue was taken up in hexanes (5 mL), and the suspended solids were removed by centrifugation. The hexanes were removed under vacuum, leaving behind a yellow-orange residue of essentially pure **12** with a yield of 67% (0.07 g, 0.08 mmol); mp 190–192 °C. ^1H NMR: –0.01 (s, 9 H, $Si(CH_3)_3$), 1.14 (d, $^3J_{HH}$ = 7 Hz, 12 H, *i*-Pr CH_3), 1.27 (d, $^3J_{HH}$ = 7 Hz, 12 H, *i*-Pr CH_3), 2.05 (s, 6 H, *p*-Mes–CH_3), 2.08 (s, 12 H, *o*-Mes–CH_3), 3.53 (sept, $^3J_{HH}$ = 7 Hz, 2 H, *i*-Pr–CH), 6.31 (s, 2 H, C_2H_2), 6.82 (s, 4 H, *m*-Mes–CH), 7.12–7.21 (m, 6 H, *m*,*p*-Ar–CH). $^{13}C\{^1H\}$NMR: 1.36, 14.34, 20.85, 23.37, 26.29, 26.52, 28.85, 122.58, 123.31, 125.88, 129.15, 136.58, 137.45, 142.37, 145.80, 146.42. ^{29}Si NMR: –2.3. EIMS *m*/*z* (%): 830 ($[M]^+$, 58), 564 ($[M^+ – (CH_3)_3SiGeMes$, 21), 445 ($[M^+ – (CH_3)_3SiGeMes_2]$, 43), 385 ($[(CH_3)_3SiGeMes_2]$, 100).

Crystal structure determinations[5]

Crystals of **8**·(2 toluene) were grown from a concentrated toluene solution. A flat, yellow needle was mounted on a glass fibre stored at –30 °C. Crystallographic parameters are given in Table 1. Data were collected at low temperature (–123 °C) on a Nonius Kappa-CCD area detector diffractometer with COLLECT (Nonius B.V., Delft, The Netherlands, 1999). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out, using HKL2000 DENZO-SMN (12). The absorption correction was applied, using HKL2000 DENZO-SMN (SCALEPACK).

The SHELXTL/PC V6.14 for Windows NT (Bruker AXS, Madison, Wisconsin) suite of programs was used to solve the structure by direct methods. Subsequent difference Fourier syntheses allowed the remaining atoms to be located. The molecule was well ordered and consisted of two Ga–Ge moieties linked by a K atom. The K atom produced a dimer by forming an interaction with the two different aromatic rings. The toluene molecules of solvation were also well ordered. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen-atom positions were calculated geometrically and were included as riding on their respective carbon atoms.

The largest-residue electron-density peak (0.756 e/Å^3) was associated with the Ga–Ge bond. Full-matrix least-squares refinement on F^2 gave R_1 = 7.09 for 2σ data and wR_2 = 18.17 for all data (GoF = 1.023).

Crystals of **12**·(2.5 toluene) were grown from a concentrated toluene–acetonitrile solution at –30 °C. Crystallographic parameters are given in Table 1. A yellow plate was mounted on a glass fibre. Data were collected at low temperature (–123 °C) on a Nonius Kappa-CCD area detector diffractometer with COLLECT (Nonius B.V., Delft, The Netherlands, 1999). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement

Maximum and minimum transmission	0.9710 and 0.4236	0.9580 and 0.5694
Refinement method	Full-matrix least-squares on F^2	Full-matrix least-squares on F^2
Data/restraints/parameters	9398/8/559	17669/1/989
Goodness-of-fit F^2	1.033	0.950
Final *R* indices [$I > 2\sigma(I)$]	R_1 = 0.0687, wR_2 = 0.1451	R_1 = 0.0663, wR_2 = 0.1185
R indices (all data)	R_1 = 0.1515, wR_2 = 0.1729	R_1 = 0.1849, wR_2 = 0.1516
Largest diff. peak and hole (e Å^{-3})	0.756 and –0.573	0.745 and –0.649

and data reduction were carried out, using HKL2000 DENZO-SMN (12). The absorption correction was applied, using HKL2000 DENZO-SMN (SCALEPACK).

The SHELXTL/PC V6.14 for Windows NT (Bruker AXS, Madison, Wisconsin) suite of programs was used to solve the structure by direct methods. Subsequent difference Fourier syntheses allowed the remaining atoms to be located. There were two distinct molecules in the asymmetric unit. They are chemically identical but crystallographically different because of the orientation of the mesitylene groups. There were three toluene molecules of solvation, and one was located on a symmetry site and refined at 0.5 occupancy. All of the non-hydrogen atoms, except the 0.5 occupancy toluene molecule, were refined with anisotropic thermal parameters. The hydrogen-atom positions were calculated geometrically and were included as riding on their respective carbon atoms.

The largest-residue electron-density peak (0.745 e/Å^3) was associated with the 0.5 occupancy toluene molecule. Full-matrix least-squares refinement on F^2 gave R_1 = 6.63 for 2σ data and wR_2 = 15.16 for all data (GoF = 0.950).

The data were weak but no data were discarded in the final refinement. The 0.5 occupancy toluene was poorly defined, and it is the portion of the solution responsible for the Alert level A's or B's in the IUCR checkCIF program.

Ruthenium(III) acetylacetonate [$Ru(acac)_3$] — An efficient recyclable catalyst for the acetylation of phenols, alcohols, and amines under neat conditions

Ravi Varala, Aayesha Nasreen, and Srinivas R. Adapa

Abstract: A catalytic amount of ruthenium(III) acetylacetonate (2 mol%) [$Ru(acac)_3$] enables solvent-free acetylation of phenols, alcohols, and amines at ambient temperature in good to excellent yields. Furthermore, the catalyst could be recovered and reused at least three times without a significant loss in yields.

Key words: acetylation, protecting groups, ruthenium(III) acetylacetonate, phenols, alcohols, amines.

Résumé : L'utilisation d'une quantité catalytique d'acétylacétonate de ruthénium(III) (2 mol %) [$Ru(acac)_3$] permet de réaliser l'acétylation, sans solvant, de phénols, d'alcools et d'amines à la température ambiante, avec des rendements allant de bons à excellents. De plus, il est possible de récupérer le catalyseur et de le réutiliser au moins trois fois sans diminution significative des rendements.

Mots-clés : acétylation, groupes protecteurs, acétylacétonate de ruthénium(III), phénols, alcools, amines.

[Traduit par la Rédaction]

Introduction

Acetylation of phenol, alcohol, and amine functionalities is one of the most frequently used transformations in organic synthesis (1). Among the various protecting groups used for the hydroxyl function, acetyl is the most common because it is easy to introduce, stable in acidic reaction conditions, and easily removable by mild alkaline hydrolysis. In general, this can be achieved by treating alcohols with acid anhydrides or acid chlorides in the presence of stoichiometric amounts of amine bases such as tertiary amines (2), 4-(dimethylamino)pyridine (DMAP), 4-(1-pyrrolidino)pyridine (PPY) (3), and Bu_3P (4). Acylation of alcohols can also be achieved under an acid-catalyzed condition by treating alcohols with acid anhydrides in presence of several protic acids (5) and by using various metal salts as Lewis acids (6).

Certain reported methodologies suffer from one or more of the following disadvantages (5, 6): (*i*) potential health hazard (DMAP is highly toxic (e.g., intravenous LD_{50} in the rat is 56 mg/kg), and Bu_3P is flammable (flash point is 37 °C)); (*ii*) difficult handling (Bu_3P undergoes aerial oxidation, and triflates are moisture sensitive); (*iii*) high cost of the catalysts (e.g., triflates); (*iv*) special efforts required to prepare the catalysts ($Bi(OTf)_3$, Nafion-H, yttria–zirconia, and $AlPW_{12}O_{40}$); (*v*) lack of atom economy (use of excess of acetylating agents); (*vi*) stringent reaction conditions and the requirement of prolonged reaction times; (*vii*) in many cases, the reported acylation methodologies are applicable to only alcohols and are not suitable for acid-sensitive substrates; and (*viii*) in addition, the metal triflates may involve competitive side reactions (e.g., dehydration and rearrangement) with acid-sensitive substrates because of the large negative $H_\circ$ value of TfOH. Furthermore, the use of large amounts of acylating agents and activators should be avoided to promote green chemistry and atom efficiency.

Despite a number of precedents, a catalytically efficient practical alternative that can be used under milder and cost-effective conditions for this very important transformation is highly desirable, and there is still scope for further improvement. Another promising approach to environment-friendly chemistry is to minimize or completely eliminate the use of harmful organic solvents in organic syntheses. This is because organic reactions run under solvent-free conditions are advantageous because of their enhanced selectivity, effi-

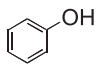
Scheme 1.

ciency, ease of manipulation, cleaner product formation, and the avoidance of toxic or volatile solvents (7). Thus, a paradigm shift from using solvents toward solvent-free reactions not only simplifies organic synthesis but also improves process conditions for large-scale synthesis.[2]

Recently, we have reported [$Ru(acac)_3$] as an efficient Lewis acid (LA) catalyst for chemoselective tetrahydropyranylation (THP) of alcohols and phenols under solvent-free conditions (8).

Results and discussion



In a continuation of our recent efforts to develop new synthetic routes for carbon–carbon and carbon–heteroatom bond formation and heterocycles (9), we herein present our preliminary results using an efficient recyclable [$Ru(acac)_3$]-catalyzed solvent-free acetylation of hydroxy and amine functions (Scheme 1). The procedure, based on the Lewis acid catalytic activity of the [$Ru(acac)_3$], represents an environmentally benign alternative to current chemical processes that use water-intolerant Lewis acids.

Initially, we have screened a few available acetylacetonates, such as [$VO(acac)_2$], [$Pd(acac)_2$], [$Ru(acac)_3$], and [$Co(acac)_3$], for the model reaction between aniline (1 mmol) and acetyl chloride (1.1 mmol) under neat conditions at ambient temperature. Among the catalysts tested, [$Ru(acac)_3$] proved to be the most efficient LA catalyst in terms of yields and reaction time (the corresponding acetylated product was obtained in 5 min with quantitative isolated yield >99%). An optimum concentration of 2 mol% of [$Ru(acac)_3$] is sufficient to afford the acetylated product in an excellent yield. While optimizing the acylating agent, several features that deserved comment are shown in Table 1.

In case of alcohols and phenols (Table 1, entries 1 and 2), acetic anhydride was preferred over the corresponding acid chloride or acetic acid. It is significant to note that acetyl chloride was preferred over acetic anhydride with the acetylation reaction of amines (Table 1, entry 3). This is in complete contrast with the observations reported by Yadav et al. (6*c*). This clearly demonstrates that the acetylation reaction behaviour is completely dependent on the chosen catalyst. Acetylation of amines, using acetic acid at ambient temperature, with our catalyst did not give acetylated product.

The direct condensation of acetic acid with alcohols is generally avoided because the equilibrium between the substrates and the products require the elimination of water from the reaction mixture, using a dehydrant or azeotropically, to shift the equilibrium in favor of the product.

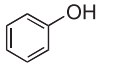
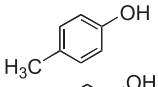
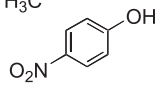
[a]Isolated yields with reused catalyst (recovered catalyst 99%, 99%, and 98% respectively).

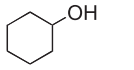
Intrigued by the observations in hand, we have studied the scope and the generality of this process for a wide range of aromatic and aliphatic phenols, alcohols and amines.

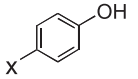
One of the important features of the present developed protocol for the formation of acetylated products is that absolute anhydrous conditions are not required. The reactions are clean and devoid of unwanted products and gave the corresponding acetylated products in moderate to excellent yields. Very importantly, this protocol allowed us to adopt a simple work-up procedure by employing ether to dissolve the organic material not the catalyst, which could be easily removed by filtration. The recovered catalyst is oven dried at 60 °C for 2 h and then reused for the model reaction without significant loss of yield for at least three cycles (Table 2; Table 3, entry 27).

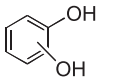


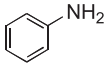


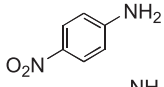


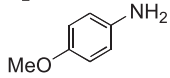


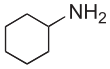


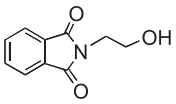


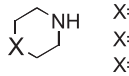


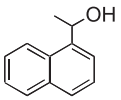


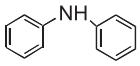


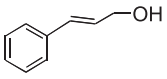


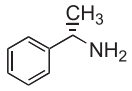


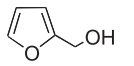












As evident from Table 3, the described methodology illustrates a fine acetylation procedure that has wide applicability, extending the scope to alkyl (1°, 2°, and 3°), allyl, propargylic, aryl, and benzylic alcohols (Table 3, entries 1–36).

Under optimized reaction conditions, secondary and tertiary alcohols do not experience any competitive dehydration (Table 3, entries 3, 4, and 12). Acid-sensitive functionalities, such as allylic and propargylic substrates (Table 3, entries 5–8 and 14), are tolerated, and no rearrangement took place for those substrates. Chiral alcohols and amines (Table 3, entries 9 and 36) were easily acetylated with complete retention of

[2] Exothermicity of a large-scale reaction should be controlled by maintaining the temperature and using an appropriate solvent, if necessary.

the optical purity. Steric factors played vital role in affecting acetylation (Table 3, entries 34 and 35), and the reaction completion took longer times with moderate yields.

Next, the scope of the present methodology was extended to other anhydrides and acid chlorides to test the efficacy of the catalyst, and the results are quite satisfactory. From Table 4, solid anhydrides, such as benzoic, maleic, succinic, and phthalic anhydrides, also reacted well in the acylation reaction with the model substrates chosen.

The present [Ru(acac)$_3$]-catalyzed acetylation may probably follow the mechanism depicted in Scheme 2: For alcohols and phenols, initially, electrophilic activation by [Ru(acac)$_3$] for possible coordination to both carbonyl oxygen atoms of the anhydride **2** to form a six-membered transition state, and then nucleophilic attack by the alcohol **1** to give the desired acetylated product **3**. For amines, [Ru(acac)$_3$] first activates the acyl halide **4** and then polarizes it on the nucleophilic amine **5** to form the corresponding acetylated product **6** and regenerates back.

The efficiency and generality of the present [Ru(acac)$_3$]-catalyzed protocol can be realized at a glance by comparing our results for the chosen model substrates with those of

some recently developed procedures (as shown in Table 5). The reactions have been compared with respect to the reaction times, mol% of the catalyst used, and the yields.

Conclusion

In summary, we have developed a mild, efficient, and highly selective methodology for the acetylation of alcohols using [Ru(acac)$_3$] as LA catalyst (2 mol%). Notable features of the protocol are clean and simple solvent-free reaction conditions, non-aqueous workup, and the use of recyclable and environmentally benign catalyst. This work widens the scope of using transition-metal salts and complexes in organic synthesis because of the nontoxic nature of the catalyst. We believe that this protocol will be a valuable addition to acetylation-related modern synthetic methodologies.

Typical experimental procedure

The hydroxy or amine compound (Table 3, entries 1–36; 1.0 mmol), acylating agent (1.1 mmol), [Ru(acac)$_3$] (2 mol%) were placed, successively, in a flask under neat conditions at room temperature. After stirring, the reaction mixture was treated with Et_2O (2 × 5 mL), and the catalyst was removed by filtration. The filtrate extracts were concentrated under reduced pressure, and the crude product was then purified by silica-gel chromatography (hexane – ethyl acetate). All the obtained acylated products were characterized by IR,

Fluoride detection based on fluorescence enhancement of thioureido naphthalene derivative

Sourav Chakraborty and Matthew A. Tarr

Abstract: A novel thioureido naphthalene derivative was synthesized and characterized. The compound proved itself as an effective fluoride sensor with respect to selectivity and sensitivity. In acetonitrile, the fluorescence intensity increased by 40-fold with the addition of 5 equiv. of fluoride. Fluorescence intensity did not substantially change with other halides, suggesting that the thioureido protons interact strongly with fluoride but not with other halides. The enhanced fluorescence is due to increased quantum efficiency of the fluoride complex.

Key words: fluoride sensing, thioureido compound, fluorescence.

Résumé : On a synthétisé et caractérisé un nouveau dérivé thiouréidonaphtalène. Le composé s'avère être efficace pour détecter l'ion fluorure tant par rapport à la sélectivité que qu'à la sensibilité. Dans l'acétonitrile, l'intensité de la fluorescence est multipliée par quarante lorsqu'on ajoute cinq équivalents de fluorure. L'intensité de la fluorescence ne subit pas de modification substantielle avec les autres halogénures, ce qui suggère que les protons thiouréido interagissent fortement avec l'ion fluorure mais pas avec les autres halogénures. L'augmentation de la fluorescence résulte d'une augmentation de l'efficacité quantique du complexe du fluorure.

Mots-clés : détection de l'ion fluorure, composé thiouréido, fluorescence.

[Traduit par la Rédaction]

Introduction

Anions play various important roles in biological and environmental processes in nature (1–6). Although considerable attention has been focused on the selective detection of anions using visible colorimetric sensors (7–19), less progress has been made with the more-powerful technique of fluorescence. Fluoride sensing is important, since fluoride plays crucial roles in dental caries (20) and other medical issues such as osteoporosis (21). Excess fluoride, however, causes fluorosis (22–25), a type of fluoride toxicity that is typically related to an increase in bone density. The important consequences of elevated and depleted fluoride concentration make effective fluoride sensing an important tool. Although a series of fluoride-sensor compounds have already been reported (7, 9, 12, 13, 15, 17, 18, 26–41) by several researchers, there remains a strong practical impetus to improve the detection at micromolar to submicromolar (29) levels. In addition, past research mainly focused on urea-based sensors (26–28, 30), while the whole new vista of novel thiourea-based sensors (12, 15, 35, 36, 40, 41) was largely unexplored.

Results and Discussion

We, therefore, synthesized and characterized 1,8-bis(phenylthioureido)naphthalene as a fluorescent probe for fluoride detection, as well as a chromogenic fluoride sensor. The structure of compound **1** was confirmed by ^{1}H and ^{13}C NMR and mass spectral analysis (Fig. 1).[2] In the presence of fluoride, this compound shows a new fluorescence peak (with λ_{max} = 447.5 nm), as shown in Fig. 2. Chloride, bromide, or iodide addition did not cause any change in the fluorescence intensity or shape.[2]

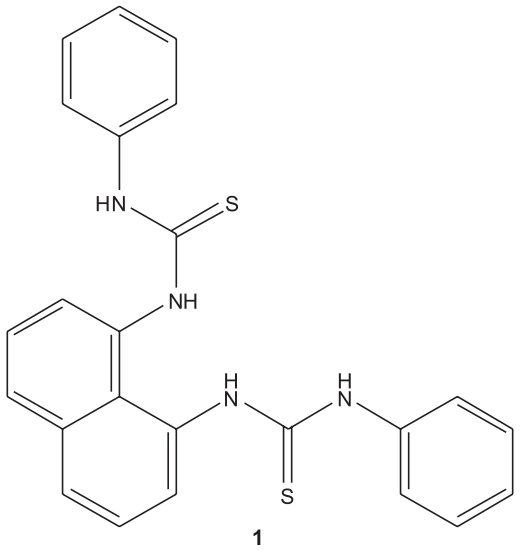
Compound 1.



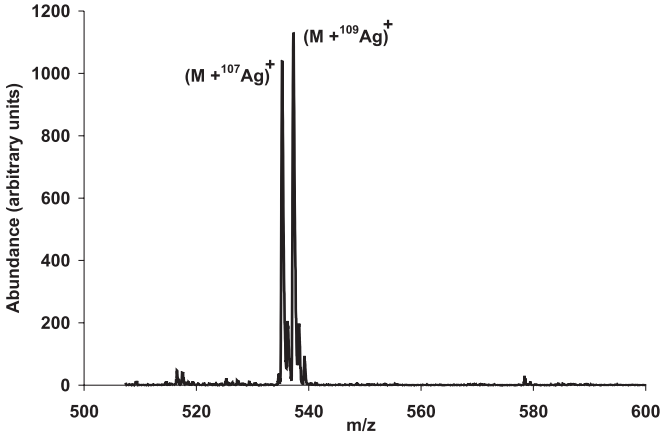


Fig 1. MALDI mass spectrum of 1,8-bis(phenylthioureido)naphthalene (Ag adduct). Mass of compound **1** is 428 amu.

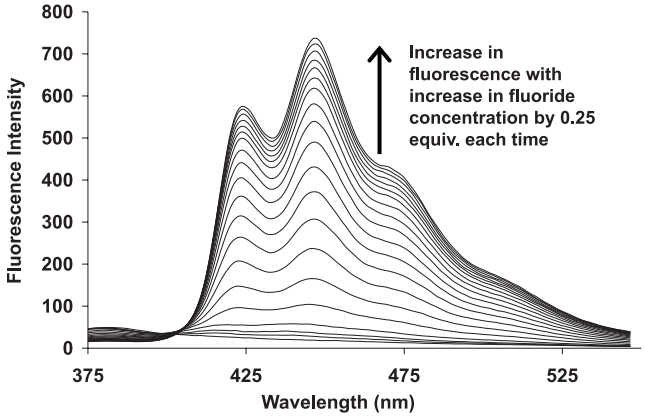
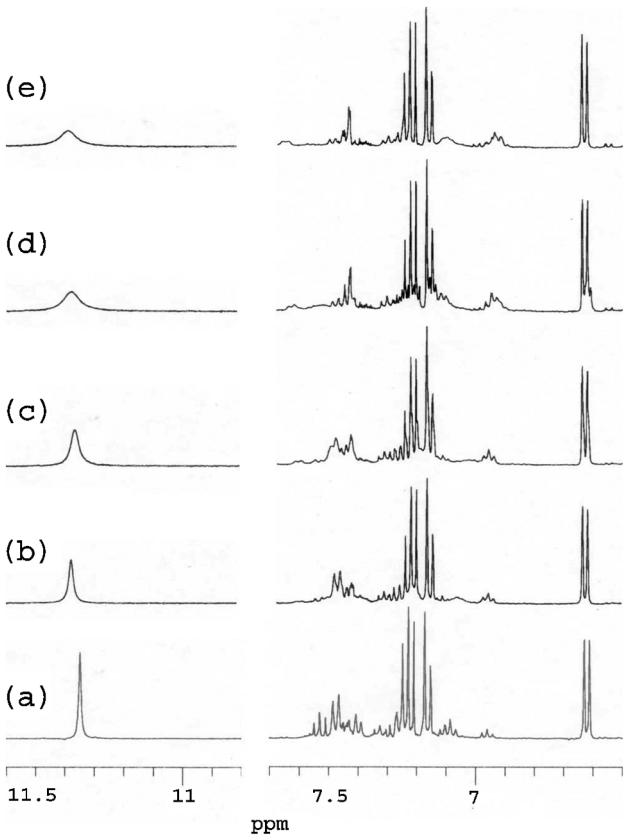
A fluorescence response to acetate and dihydrogenphosphate has been observed, although the response to fluoride is substantially higher than that for these other anions. The fluorescence response to 9 equiv. of dihydrogenphosphate is approximately equal to that observed for 1 equiv. of fluoride. Similarly, 9 equiv. of acetate yielded a fluorescence signal that was approximately equal to the addition of 2 equiv. of fluoride.[2] Separate experiments showed that even in the presence of 1 mmol/L acetate or 1 mmol/L dihydrogenphosphate, compound **1** still showed enhanced fluorescence with the addition of 0.25 equiv. of fluoride. While some interfering signals may result from the presence of these anions, the response to fluoride is not inhibited by their presence.

A titration experiment (^{1}H NMR) showed substantial changes upon the addition of fluoride. The thioureido proton signal decreased rapidly and broadened with the addition of fluoride (Fig. 3). No significant changes in the aromatic proton signals were apparent. The observed changes in the thioureido ^{1}H NMR signal suggest strong H-bonding between thioureido protons and fluoride ions, with exchange on the NMR time scale. Because of its small size and high charge density, the fluoride ion had a much stronger interaction with the thioureido protons than the other halides, resulting in the selective fluorescence enhancement by fluoride.

Fig 2. Fluorescence spectra on the addition of fluoride to compound **1** in acetonitrile. Initial concentration of the compound is 50 μmol/L. Fluoride was added in 12.5 μmol/L increments. Excitation wavelength = 345 nm, emission maximum = 447.5 nm.





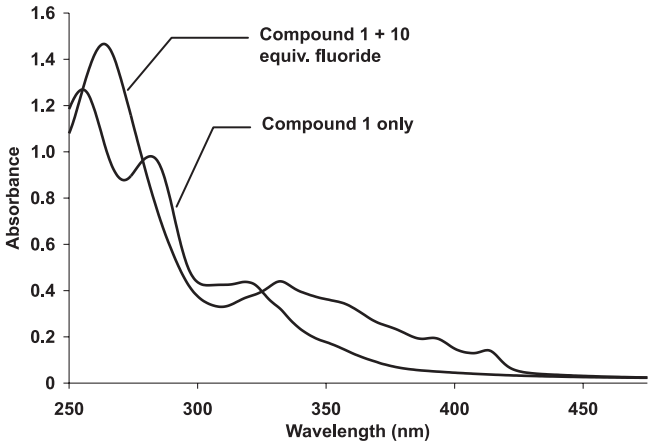


Fig 3. Partial ^{1}H NMR (400 MHz) of compound **1** (5 mmol/L) in DMSO-d_6 upon the addition of tetrabutylammonium fluoride: (*a*) 0 μmol/L, (*b*) 10 μmol/L, (*c*) 20 μmol/L, (*d*) 30 μmol/L, and (*e*) 40 μmol/L

Fluorescence intensity increased significantly with the addition of fluoride, while other halides showed little or no

Fig 4. Absorbance of compound **1** (50 μmol/L), before and after the addition of 500 μmol/L of fluoride.

change. An approximate 40-fold enhancement in fluorescence intensity at 447.5 nm was observed in the presence of 5 equiv. of fluoride (50 μmol/L compound **1**, 250 μmol/L F^-). Furthermore, the addition of only 0.25 equiv. of fluoride (12.5 μmol/L F^-) resulted in an approximate 1.5-fold increase in fluorescence intensity at 447.5 nm, indicating that detection limits in the low- to sub-micromolar range are possible. UV–vis absorbance spectra (Fig. 4) were acquired to determine if compound **1** can also behave as a chromogenic sensor. After the addition of 10 equiv. of tetrabutylammonium fluoride, a bathochromic shift in the absorbance spectrum was clearly observed. With the presence of fluoride, the absorbance extended into the visible region, indicating that the detection of fluoride could be carried out colorimetrically, perhaps even with the naked eye. However, superior detection limits exist using fluorescence methods.

The data in Fig. 4 indicate an approximate doubling in the absorbance at 345 nm upon the addition of excess fluoride. Fluorescence data (Fig. 2) illustrate an approximate 40-fold enhancement near saturation (the point where all compound **1** molecules are bound to fluoride). Since fluorescence at low concentration is proportional to absorbance, these data indicate that only a small portion of the fluorescence enhancement can be accounted for by the increased absorbance. Consequently, we can conclude that the fluoride complex has a larger quantum yield than the unbound **1**. Based on the absorbance and fluorescence data, the enhancement in quantum yield is estimated to be 20-fold. This observation agrees with previous reports that suggested improved planarity (28) and lack of relaxation via twisted conformations (42, 43), as possible mechanisms for enhanced fluorescence in ureido derivatives.

In summary, a novel thiourea-based sensor molecule, 1,8-bis(phenylthioureido)naphthalene, was synthesized and characterized. The compound showed fluorescent enhancement in the presence of fluoride. This response was selective for fluoride, with chloride, bromide, and iodide producing little or no response. The large enhancements in fluorescence (40-fold observed in this study) suggest that this molecule may provide improved analytical characteristics over previously described molecules, especially since many other studies have reported molecules that exhibit either fluorescence quenching in the presence of fluoride (14) or show only changes in absorbance (15, 26, 30, 31). Compound **1** may also be advantageous, since its fluoride complex can be excited in the visible region.

The potential practical applications of compound **1** appear to be versatile and include fiber optic and nanometric sensors for fluoride. Current work focuses on immobilizing compound **1** on a solid support such as a fiber optic or nanoparticles for the detection of fluoride in aqueous media.

Experimental section

All starting materials were purchased and used without further purification. ^1H and ^{13}C NMR were recorded on a 400 MHz spectrometer, operating at 9.4 T. NMR experiments were carried out in DMSO-d_6 with 0.05% (*v*/*v*) TMS. Mass spectra were acquired with a MALDI-TOF mass spectrometer. Fluorescence experiments were carried out in acetonitrile solution, with excitation wavelength of 345 nm and emission range of 375–550 nm with 7.5 nm slit widths. UV–vis absorbance experiments were carried out with quartz cuvettes (path length is 1 cm).

2.39 mmol of 1,8-diaminonaphthalene was dissolved in 20 mL of dry THF. Two drops of triethylamine was added, and this mixture was then added dropwise over 1 h to 32.5 mmol of phenylisothiocyanate, which was dissolved in 20 mL of THF. The system was kept in a nitrogen atmosphere. The mixture was stirred at room temperature for 24 h. The progress of the reaction was monitored by TLC (eluent: 4% acetonitrile in chloroform). The mixture of the compounds was purified by column chromatography (eluent: 4% acetonitrile in chloroform). The yield was approximately 20–22%.

Selected data for compound 1

Mp 135–137 °C dec. ^1H NMR (DMSO-d_6) δ 11.43 (s, 2H), 7.53 (d, J = 7.8 Hz, 2H), 7.46 (t, J = 7.8 Hz, 2H), 7.28 (t, J = 7.8 Hz, 4H), 7.21 (d, J = 7.9 Hz, 4H), 7.13 (t, J = 7.9 Hz, 2H), 6.67 (d, J = 7.8 Hz, 2H), two additional thioureido protons were not observed because of exchange. ^{13}C NMR (100 MHz, DMSO-d_6) δ 173.7 (q), 140.6 (q), 136.1 (q), 134.8 (q), 129.6 (2 × CH), 129.1 (CH), 122.6 (CH), 119.9 (CH), 119.0 (2 × CH), 116.9 (q), 105.4 (CH). MALDI-MS showed the silver adducts (^{107}Ag, ^{109}Ag) at m/z = 535, 537 amu, corresponding to the expected molar mass of 428 amu.

Acknowledgment

We extend our heartiest thanks to Dr. Vicki Colvin, Dr. James Tour, and Rice University for providing lab and office space following Hurricane Katrina. We also acknowledge the contributions of Dr. Alexander (Sandy) Yates, for MALDI-TOF experiments at Rice University, and Goutam Biswas, for his help in interpreting the NMR spectra. This project was supported by the Louisiana Board of Regents Health Excellence Fund (HEF(2001–06)-08).

Synthesis and enhanced neuroprotective activity of C60-based ebselen derivatives

Xu-Feng Liu, Wen-Chao Guan, and Weng-Shan Ke

Abstract: A C_{60}-based ebselen derivative 4 was synthesized through the cycloaddition of C_{60} with the azide (**3**) containing the ebselen component. It was obtained in a four-step synthesis starting from 2-(chloroseleno)benzoyl chloride and 2-(2-aminoethoxy)ethanol in 53% yield (based on consumed C_{60}). Its structure was characterized by ^{1}H NMR, ^{13}C NMR, IR, UV, and FAB-MS. To verify that the C_{60}-based ebselen derivative **4** had enhanced antioxidative and neuroprotective activity, the C_{60} derivative **5** and the ebselen derivative **6** were selected to treat cortical neuronal cells using the same procedures as with the C_{60}-based ebselen derivative **4**. The cellular viability of different derivative treatment groups was estimated by LDH leakage assay and MTT assay. At the same final concentration (30 μmol/L), the results showed that the antioxidative and protective potencies of the C_{60}-based ebselen derivative **4** (MTT (OD) 0.340 ± 0.035, LDH release (UL^{-1}) 4.80 ± 0.16) against H_2O_2-mediated neuronal injury have an advantage over those of C_{60} derivative **5** (MTT (OD) 0.297 ± 0.036, LDH release (UL^{-1}) 5.37 ± 0.31) and ebselen derivative **6** (MTT (OD) 0.267 ± 0.027, LDH release (UL^{-1}) 5.85 ± 0.26). Correspondingly, the GPX activity of **4** (1.62 U/μmol) was higher than that of **5** (0.77 U/μmol) and **6** (1.24 U/μmol). These findings demonstrate that the incorporation of two components with similar biological activity (C_{60} component and ebselen component) may be a desirable way of obtaining a new and more biologically effective C_{60}-based compound.

Key words: fullerene, ebselen derivative, azide, neuroprotective activity, cellular viability.

Résumé : On a réalisé la synthèse du dérivé **4** de l'ebsélène à base de C_{60} en procédant à la cycloaddition du C_{60} sur l'azide (**3**) qui contient une composante d'ebsélène qui a été obtenu en quatre étapes à partir du chlorure de 2-(chlorosélénо)benzoyle et de 2-(2-aminoéthoxy)éthanol, avec un rendement de 53% sur la base de la quantité de C_{60} utilisé. On a caractérisé sa structure par spectroscopies RMN du ^{1}H et du ^{13}C, par infrarouge, ultraviolet et spectrométrie de masse avec bombardement rapide. Dans le but de vérifier l'augmentation de l'activité antioxydante et neuroprotective du dérivé **4** de l'ebsélène à base de C_{60}, son activité a été comparé à celles du dérivé en C_{60} 5 et du dérivé de l'ebsélène **6** pour le traitement d'une cellule corticoneuronale, en utilisant les mêmes techniques. La viabilité cellulaire des groupes traités par divers dérivés a été évaluée par une combinaison de l'évaluation de l'émission de lactase déshydrogénase (LDH) et du clivage du bromure de 3-(4,5-diméthylthiazol-2-yl)-2,5-diphényltétrazolium (MTT). Les résultats montrent que, à la même concentration finale (30 μmol/L), les pouvoirs antioxydant et protecteur du dérivé **4** de l'ebsélène à base de C_{60}, (MTT (OD) 0,340 ± 0,035, émission de LDH (UL^{-1}) 4,80 ± 0,16) contre les dommages neuronaux provoqués par le H_2O_2 sont plus grands que ceux apportés par le dérivé en C_{60} (**5**), (MTT (OD) 0,297 ± 0,036, émission de LDH (UL^{-1}) 5,37 ± 0,31) et ceux apportés par le dérivé de l'ebsélène (**6**), (MTT (OD) 0,267 ± 0,027, émission de LDH (UL^{-1}) 5,85 ± 0,26). D'une façon correspondante, l'activité GPX du composé **4** (1,62 U/mmole) est supérieure à celles du composé **5** (0,77 U/mmole) et du composé **6** (1,24 U/mmole). Ces observations démontrent que l'incorporation de deux composants ayant des activités biologiques semblables (le composant en C_{60} et le composant de l'ebsélène) peut s'avérer être une façon désirable d'obtenir un composé à base de C_{60} qui soit biologiquement plus actif.

Mots-clés : fullerène, dérivé de l'ebsélène, azide, activité neuroprotective, viabilité cellulaire.

Introduction

Research in modern medical science (1) has suggested that free radicals are associated with a number of neurodegenerative diseases such as Parkinson's disease, Huntington's disease, and Alzheimer's dementia. Some reactive oxygen species (ROS), including superoxide ($O_2^{\cdot-}$) and hydroxyl (·OH) radicals and the nonradical molecules H_2O_2,

are believed to be major contributors to oxidative damage in neurodegenerative diseases. Reactive oxygen species produced during oxidative stress may cause various kinds of biological damage such as lipid peroxidation, protein oxidation and cross-linking, and lead to neuronal cell death (2). In light of a link between active oxygen species and neurodegenerative conditions, the development of chemopreventive agents with antioxidative activity is a recognized approach against neurological injury caused by ROS.

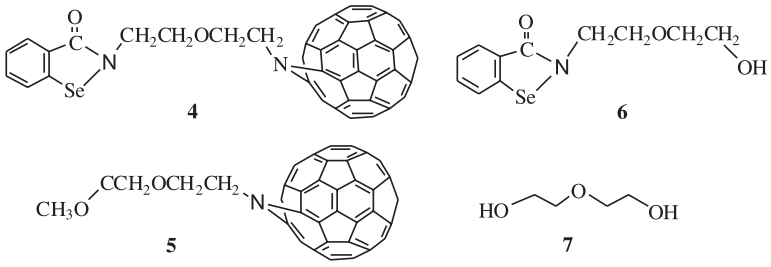
C_{60} fullerenes, owing to their electronic structure as an electron-poor polyolefine, are highly reactive with various organic radicals (3) and have drawn considerable attention in the area of antioxidant research. An electron paramagnetic resonance analysis has shown that C_{60} derivatives, such as carboxyfullerenes, fullerenols, and Hexa(sulfobutyl)fullerenes, have excellent capabilities to scavenge deleterious reactive oxygen species (4). In addition, neuroprotective effects of water-soluble C_{60} derivatives on oxidative injuries have also been extensively studied in several cell cultures and animal models of CNS damage. For example, carboxyfullerenes were confirmed to prevent apoptotic injury of cultured cortical neurons evoked by *N*-methyl-D-aspartate and β-amyloid peptide (5) and to inhibit iron-induced oxidative stress in rat brains (6). The same carboxyfullerenes were also reportedly able to inhibit cerebellar granule cell apoptosis (7) possibly via reducing the generation of ROS. Other fullerene derivatives, such as fullerenol, hexasulfobutylated C_{60} (FC4S), C_{60}(glucosamine)$_6$, have also been shown to possess neuroprotective potency related to their antioxidative property. Fullerenol was demonstrated to be a powerful scavenger for the free radicals induced by ischemia–reperfusion injury of the small intestine (8). Hexasulfobutylated C_{60} (FC4S) could be employed to be a free radical remover in biological systems (9). Recently, C_{60}(glucosamine)$_6$ has been found to prevent renal ischemia–reperfusion-induced apoptosis formation and superoxide generation (10). All these results demonstrate that fullerene and its derivatives possess an antioxidative activity and may be useful for neuroprotective agents in several acute or chonic neurodegenerative diseases.

On the other hand, ebselen and its analogues have been shown to possess glutathione (GSH) peroxidase-like activity and may act as an antioxidants and free radical scavengers (11). Recently, ebselen and its analogues were reported to have a neuroprotective effect against brain ischemic insults and glutamate-induced neurotoxicity (12). More recently, ebselen and its derivatives were demonstrated to have neuroprotective effects on laboratory rat spinal cord injuries (13). All the biological effects afforded by ebselen and its analogues are obviously related to their antioxidative properties and free radical scavenger activities.

In view of the described antioxidative and neuroprotective properties of C_{60} and ebselen derivatives, it is expected that the covalent attachment of a biologically active ebselen component to [60]fullerene may lead to the formation of a new C_{60}-based ebselen derivative possessing better antioxidative and neuroprotective properties than either of the parent C_{60} or ebselen. In this paper we report the synthesis of the new C_{60}-based ebselen derivative **4** by a cycloaddition reaction between C_{60} and ebselenyl azide, which contains a solubilizing ethyleneglycol chain. We also report on the neuroprotection of **4** against hydrogen peroxide induced neuronal insults in cortical cell cultures.

Scheme 1. Synthesis of the C_{60}-based ebselen derivative **4**.

Results and discussion



Synthesis and spectroscopic properties of C_{60}-based ebselen derivative 4

The preparation of the C_{60}-based ebselen derivatives **4** was carried out in four steps as depicted in Scheme 1. The chloride **1** was prepared by reacting 2-(2-aminoethoxy)ethanol and thionyl chloride ($SOCl_2$) under identical conditions to those used in ref. 14. The obtained chloride **1** was reacted with 2-(chloroseleno)benzoyl chloride, prepared in a four-step synthesis starting from anthanilic acid (15) in dry $CHCl_3$ in a molar ratio of 1.5:1 in presence of Et_3N. The reaction mixture was concentrated and purified by flash chomatography (silica gel, eluent 3:1 ethyl acetate – petroleum) to give the ebselen derivative **2** in 73% yield. Reaction (16) of ebselen derivative **2** with sodium azide (NaN_3) in a molar ratio of 1:3 in dry dimethylformamide (DMF) resulted in the desired azide **3** in 80% yield. Cycloaddition (17) of the azide **3** with C_{60} in an equimolar ratio in refluxing chlorobenzene under a nitrogen atmosphere gave the target compound **4** in a 53% yield (based on consumed C_{60}) after purification by flash chomatography eluting with toluene, followed by a toluene–$CHCl_3$ mixture (4:1).

The spectroscopic data for compound **4** are in agreement with the proposed structure. The ^{13}C NMR spectrum (150 MHz, $CDCl_3$) of compound **4** exhibits four aliphatic carbon peaks between 41.53 and 71.13 ppm and one carbonyl peak at 166.52 ppm. The peaks between 126.95 and 134.22 are assigned to the phenylene carbons of the ebselen moiety. There are 31 peaks between 133.51 and 147.90 ppm, and the signal at around 80.0 ppm corresponding to the bridgehead carbons is not observed. These data indicate that the C_{60} moiety of compound **4** has C_s symmetry with an annulene structure of monosubstituted C_{60} azafulleroid (17). In the ^1H NMR spectrum (600 MHz, $CDCl_3$) of compound **4**, two triplets (7.67, J = 7.3 Hz and 7.45, J = 7.3 Hz) and

© 2007 NRC Canada

Fig. 1. Compounds **4**, **5**, **6**, and **7** used in this study.

two doublets (8.05, J = 7.4 Hz and 7.87, J = 7.1 Hz) are attributed to phenyl protons. The resonances of methylene protons of the ethylene glycol chain are detected as four triplets (4.13, J = 6.3 Hz; 3.81, J = 6.3 Hz; 3.68, J = 6.7 Hz; 2.81, J = 6.7 Hz) that are similar to those of the starting azide with a small downfield shift due to the influence of the carbon sphere (17, 18). The IR spectrum of compound **4** shows characteristic bands of the fullerene moiety at 1430, 1035, and 528 cm^{-1} and an absorption of C=O at 1610 and 1567 cm^{-1}. The UV–vis spectrum of compound **4** displays typical absorptions due to the fullerene skeleton at 330, 268, and 258 nm, while the absorption at 420nm, characteristic of aziridinofullerenes, is absent, further confirming that compound **4** possesses an open annulene structure.

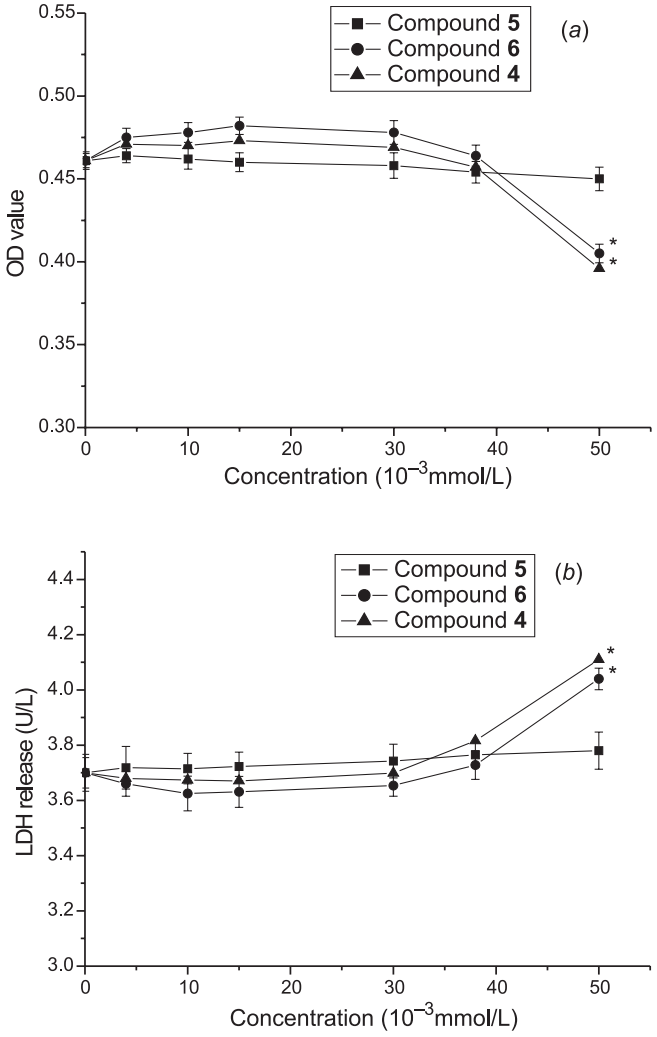
Cytotoxicity determination

The cytotoxicities of the C_{60}-based ebselen derivative **4**, the C_{60} derivative **5** (Fig. 1), and the ebselen derivative **6** (Fig. 1) in cortical neuronal cells were evaluated and determined based on their concentration-dependent effects on cell growth (MTT test) (Fig. 2*a*) and LDH leakage (Fig. 2*b*).

Results in Fig. 2*a* show that compound **5** in the concentration range of 0~50 μmol/L did not manifest cytotoxic effects. Compounds **4** and **6**, at concentrations ranging from 1 to 30 μmol/L, were able to slightly stimulate cell growth. However, when their concentrations were higher than 38 μmol/L, cell growth was significantly inhibited. In parallel with the results of the MTT test, cells treated with compound **4**, **5**, or **6** at concentrations of 1~30 μmol/L for 24 h did not show an obvious increase in LDH leakage (Fig. 2*b*). When cells were treated with compound **4** or **6** at concentrations higher than 38 μmol/L, a significant increase in LDH activity in the medium was observed. These cytotoxicity tests show that compounds **4**, **5**, and **6** at a concentration of up to 30 μmol/L have no toxic effect on cortical neurons. We thus decided to use 30 μmol/L in all subsequent experiments.

Effects of C_{60} derivative 5, ebselen derivative 6, and C_{60}-based ebselen derivative 4 on cellular viability and LDH release

To verify the enhanced neuroprotective activity of compound **4**, compounds **5**, **6**, and **7** (Fig. 1) were also used to treat cortical neuronal cells according to the same procedures as **4**.



Cell viability and cell damage were estimated by MTT assay and LDH leakage assay, respectively. The measurement results of LDH release and MTT (OD) are shown in Fig. 3. Compared with the control group, the treatmeant of cortical culture with H_2O_2 (150 μmol/L) for 2 h caused a decrease of MTT (OD) from 0.463 ± 0.024 to 0.220 ± 0.016 ($P < 0.01$) and an increase of LDH content in the extracellular media from 3.69 ± 0.16 to 7.93 ± 0.20 ($P < 0.01$), indicating H_2O_2-induced neuronal injury. Compound **4**, **5**, or **6** alone at a concentration of 30 μmol/L did not cause obvious changes in the MTT (OD) value and LDH release (compared with control group) (Fig. 3). However, they were effectively able to attenuate the H_2O_2-mediated increase of LDH release and the decrease of the MTT (OD) value (Fig. 3). MTT (OD) was elevated from 0.220 ± 0.016 (H_2O_2 alone) to 0.297 ± 0.036 (**5**), 0.267 ± 0.027 (**6**), 0.340 ± 0.035 (**4**) ($P < 0.01$) (Fig. 3*a*), and LDH release was reduced from 7.93 ± 0.20 (H_2O_2 alone) to 5.37 ± 0.31 (**5**), 5.85 ± 0.26 (**6**), 4.80 ± 0.16 (**4**) ($P < 0.01$) (Fig. 3*b*). Furthermore, compound **7** alone (30 μmol/L) did not modify the MTT (OD) value and LDH release (compared with the control group), indicating that the linker ($CH_2CH_2OCH_2CH_2$) in compounds **4**, **5**, and **6** has no influence on their neuroprotective activities.

Cellular viability in compounds **4** + H_2O_2 group (MTT (OD) 0.340 ± 0.035) was higher than that of compound **5** + H_2O_2 group (0.297 ± 0.036) or compound **6** + H_2O_2 group (0.267 ± 0.027). The LDH release (4.80 ± 0.16 UL^{-1}) for **4** was consistently lower than that of compound **5** + H_2O_2 group (5.37 ± 0.31) or compound **6** + H_2O_2 group (5.85 ± 0.26). These results indicate that the antioxidative and protective potency of C_{60}-based ebselen derivative **4** against H_2O_2-mediated neuronal injury show an advantage over those of the C_{60} derivative **5** and the ebselen derivative **6**.

However, the neuroprotective potency of compound **4** was marginally higher than those of the parent compounds **5** and **6** by 10%–20%. This is plausibly explained by the fact that the antioxidant capabilities of fullerene derivatives are influenced by various complex factors. First, the antioxidative activities of fullerene derivatives derive from their scavenging action on active oxygen radicals (·OH, O_2^{-}·), and the scavenging mechanism may be due to the electron-poor polyolefine bonds of the C_{60} moiety, which are highly reactive toward the addtition of radicals. Thus, the integrity of the conjugated bonds in the C_{60} cage (addition number), the electronegativity of adduct groups, and the steric hindrance of adduct groups against the attack of free radicals would all influence the antioxidant capabilities of fullerene derivatives. Besides, characteristics of fullerene derivatives, such as their amphipathic nature, solubility, and aggregation, are also not negligible. Another important influencing factor could be the special molecular mechanism responsible for the

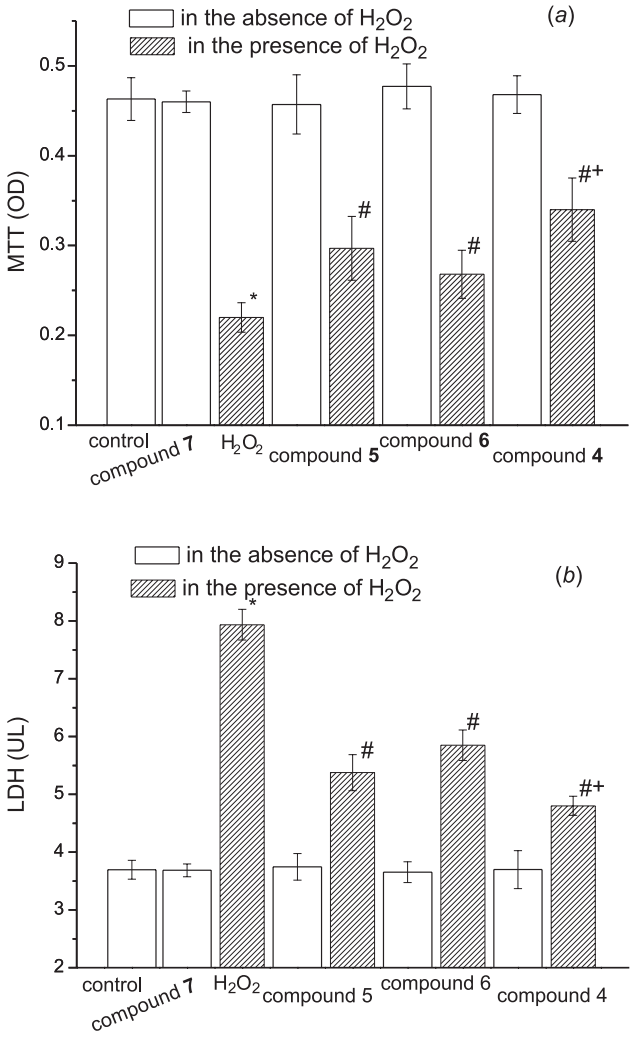
Fig. 2. Dose-dependent effects of compounds **4**, **5**, and **6** on the (*a*) neuronal cell growth (MTT test) and (*b*) LDH leakage. Values are mean ± SD of 4 experiments. *$P < 0.05$ compared with the control (one-way ANOVA with Newman–Keuls test).

neuroprotective effects produced by these compounds. Different mechanisms influence discrepancies in neuroprotective efficacy. In conclusion, the antioxidant capabilities of fullerene derivatives are ultimately determined by the combined effects of all the aforementioned factors.

GPX-like activity of compounds 4, 5, and 6



GPX activities were measured by a coupled enzymatic assay as described in a subsequent section, "Measurement of the GPX activity of compounds 4, 5, and 6". The decrease of NADPH absorption at 366 nm is a measure of GSH peroxidase activity (eqs. 1 and 2).

$$[1] \quad 2GSH + H_2O_2 \xrightarrow[\text{peroxidase}]{GSH} GSSG + 2H_2O$$

$$[2] \quad GSSG + NADPH + H^+ \xrightarrow[\text{reductase}]{GSH} 2GSH + NADP^+$$

The GPX-like activities of compounds **4**, **5**, or **6** in the catalyzed reduction of H_2O_2 are listed in Table 1. Experiments revealed that compounds **4**, **5**, and **6** all displayed

Fig. 3. (*a*) MTT (OD) of cortical neurons treated with compound **4**, **5**, **6**, or **7** in the presence or absence of H_2O_2. (*b*) LDH release of cortical neurons treated with compound **4**, **5**, **6**, or **7** in the presence or absence of H_2O_2. Values are mean ± SD of 8 experiments. Statistical comparisons were made using one-way ANOVA followed by a Newman–Keuls test as post hoc analysis. Differences were accepted as significant at $P < 0.05$ and $P < 0.01$, $P < 0.01$ (*) vs. control, $P < 0.01$ (#) vs. H_2O_2 group, $P < 0.05$ (+) vs. compound **5** with H_2O_2 or **6** with an H_2O_2 group.

GPX-like activities, and the catalytic action of compounds **4** and **6** was superior to that of ebselen. Furthermore, the GPX activity of compound **4** (1.62 U/μmol) was found to be higher than those of compounds **5** (0.77 U/μmol) and **6** (1.24 U/μmol).

Conclusions

The present work describes the synthesis of a C_{60}-based ebselen derivative that contains an ethyleneglycol chain between the fullerene and the biologically active ebselen component. The C_{60}-based ebselen derivative showed stronger neuroprotective potency than either of the parent C_{60} derivative or ebselen derivative alone. This enhanced neuroprotective potency can be reasonably attributed to both an

Activity (U/μmol)	0.99 (19)	0.77	1.24	1.62

improvement of its free radical scavenging capabilities and an improvement of its GPX-like activities. From this encouraging result it can be concluded that through selecting appropriate antioxidative components and introducing them to [60]fullerenes, we can obtain a new C_{60}-based antioxidant with better antioxidative ability, and that this is also an effective strategy for designing and synthesizing C_{60}-based antioxidants.

Experimental

Reagents and instruments

C_{60} (99% purity) was prepared by the Institute of Fullerenes of Wuhan University. All solvents and reagents were dried using standard procedures prior to use. All other commercially available compounds were used as received. Melting points were determined with a Digital Melting Point Apparatus (WRS-IB). Column chromatography was performed on silica gel (200–300 mesh). IR spectra were obtained on a Spectrum One PerkinElmer spectrometer in pellets with KBr. UV spectra were recorded on PerkinElmer λ 17 instrument. ^{1}H and ^{13}C NMR spetra were recorded on a Varian INOVA 600NMR instrument in CDCl3 at 600 and 150 MHz. Mass spectra and high-resolution mass spectra were performed on a JMS XS05H instrument.

An 18-day old Wister rat fetus was provided by the Experimental Animal Center of Tongji Medical College, Huazhong University of Science & Technology (China). D-Hanks, trypsinase, and DMEM were purchased from Gibco Co. (USA). Fetal calf serum (FCS), cytarabine hydrochlride, sodium azide, and potassium phosphate were purchased from Tianjin Biochemical Factory (China). Poly-L-lysine, DMSO, MTT, NADPH, GSH, and GSH reductase were obtained from Sigma-Aldrich Chemical Co. (USA). An LDH assay kit was obtained from Beijing Chemical Kit Company (China). Spectrophotometric measurements were made using a Konton UV-922 spectrophotometer. The optical density of each well was measured at 550 nm using an enzyme-linked analyzer (Bio-Rad550, USA).

Chemistry

2-(2-Chloroethoxy)ethylamine hydrochloride (1)

According to the procedure described in ref. 14, diethylene glycolamine (1.89 g, 18 mmol) was converted into the chloride **1** (1.79 mg, 80%) as a white solid. IR (KBr, cm^{-1}) ν: 3050 (N-H), 2920 (C-H), 1210 (C-N), 1110 (C-O-C), 750 (C-Cl). ^{1}H NMR (600 MHz, DCl_3) δ: 7.60 (3H, b, NH_3^+), 4.08 (2H, t, J = 6.8 Hz, OCH_2), 3.62 (2H, t, J = 6.4 Hz, OCH_2), 3.49–3.53 (4H, m, $ClCH_2$, NCH_2).

2-(2-(2-Chloroethoxy)ethyl)benzo[d][1,2]selenazol-3(2H)-one (2)

To a solution of **1** (747.6 mg, 6 mmol) and triethylamine (1.2 g, 12 mmol) in dry chloroform (50 mL) was added dropwise a solution of 2-(chloroseleno)benzoyl chloride (1.02 g, 4 mmol) in dry chloroform (40 mL) at 5~10 °C under stirring. The mixture was slowly warmed to 40 °C and stirred for 10 h. The resultant mixture was cooled and washed with 5% $NaHCO_3$ (2 × 50 mL), a saturated aq. solution of NaCl (2 × 50 mL), and was then evaporated to dryness. The residue was chromatographed on silica gel and eluted with 3:1 ethyl acetate – petroleum to give the ebselen derivative **2** (889 mg, 73%) as a pale yellow solid. TLC R_f 0.56 (ethyl acetate – petroleum ether 3:1); mp 110.4–111.3 °C. IR (KBr, cm^{-1}) ν: 3050 (C-H_{Ar}), 615, 1570 (amide C=O), 1280 (amide C-N), 1174 (C-O-C), 760 (C-Cl). ^{1}H NMR (600 MHz, $CDCl_3$) δ: 8.03 (1H, d, J = 7.5 Hz, ArH), 7.88 (1H, d, J = 7.0 Hz, ArH), 7.65 (1H, t, J = 7.2 Hz, ArH), 7.42 (1H, t, J = 7.2 Hz, ArH), 4.08 (2H, t, J = 6.2 Hz, NCH_2), 3.65~3.62 (4H, m, CH_2OCH_2), 3.53 (2H, t, J = 7.0 Hz, $ClCH_2$). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 166.52 (amide C=O), 134.35 (phenylene C), 132.58, 132.04, 129.22, 127.84, 127.0 5 (phenylene C), 70.16 (CH_2O), 69.12 (OCH_2), 43.52 (CH_2Cl), 40.22 (NCH_2).

2-(2-(2-Azidoethoxy)ethyl)benzo[d][1,2]selenazol-3(2H)-one (3)

To the obtained ebselen derivative **2** (762 mg, 2.5 mmol) dissolved in dry dimethylformamide (DMF) (80 mL) was added sodium azide (487.5 mg, 7.5 mmol). The mixture was warmed to 65 °C and stired for 12 h. The unreacted NaN_3 was removed by filtration, and DMF was distilled under reduced pressure. The yellow residue was washed with water, centrifuged, and then dried to constant weight at 80 °C in vacuo. The obtained yellow solid (622.4 mg, 80%) was used for the next reaction without further purification. Melting point ~130 °C decomp. IR (KBr, cm^{-1}) ν: 3055 (C-H_{Ar}), 2135 (N_3), 1620, 1573 (amide C=O), 1276 (amide C-N), 1170 (C-O-C). ^{1}H NMR (600 MHz, $CDCl_3$) δ: 8.02 (1H, d, J = 7.6 Hz, ArH), 7.86 (1H, d, J = 7.2 Hz, ArH), 7.67 (1H, t, J = 7.2 Hz, ArH), 7.41 (1H, t, J = 7.3 Hz, ArH), 4.06 (2H, t, J = 6.2 Hz, NCH_2), 3.65 (2H, t, J = 6.2 Hz, CH_2O), 3.50 (2H, t, J = 7.2 Hz, OCH_2), 1.92 (2H, t, J = 7.2 Hz, N_3CH_2). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 166.50 (amide C=O), 134.37 (phenylene C), 132.56, 132.02, 129.20, 127.84, 127.03 (phenylene C), 70.20 (CH_2O), 69.35 (OCH_2), 48.26 (CH_2N_3), 40.12 (NCH_2).

Reaction of C_{60} with azide 3 to give 4

C_{60} (250 mg, 0.345 mmol) was dissolved in 200 mL of chlorobenzene. Under nitrogen atmosphere the solution was heated at reflux and the azide **3** (107.4 mg, 0.345 mmol) in chlorobenzene (6 mL) was added dropwise. Heating was then continued for 8 h. The solution was concentrated and the crude residue chromatographed on a column with silica gel to give 95 mg of C_{60} (elution with toluene) and 114.5 mg (53% based on consumed C_{60}) of the monoaddition product **4** as a brown black solid (elution with a toluene–$CHCl_3$ mixture 4:1). UV–vis ($CDCl_3$) λ (nm): 330, 268, 258, 213. IR (KBr, cm^{-1}) ν: 3045 (C-H_{Ar}), 1610, 1567 (amide C=O), 1430 (C_{60}), 1275 (amide C-N), 1184 (C-O-C), 1035 (C_{60}), 753 (C-Cl), 528 (C_{60}). ^{1}H NMR (600 MHz, $CDCl_3$) δ: 8.05 (1H, d,

Preparation of ebselen derivative 6

Following the procedure described in ref. 20, diethylene glycolamine (1.456 g, 13.86 mmol) was reacted with 2-(chloroseleno)benzoyl chloride gave ebselon derivative **1** (2.5 g, 63%) as white needles; mp 116.7–117.5 °C. IR (KBr, cm^{-1}) ν: 3630 (O-H), 3048 (C-H_{Ar}), 1610, 1573 (amide C=O), 1283 (amide C-N), 1170 (C-O-C). ^1H NMR (600 MHz, $CDCl_3$) δ: 8.00 (1H, d, *J* = 7.6 Hz, ArH), 7.86 (1H, d, *J* = 7.1 Hz, ArH), 7.63 (1H, t, *J* = 7.3 Hz, ArH), 7.43 (1H, t, *J* = 7.3 Hz, ArH), 4.92 (1H, s, OH), 4.10 (2H, t, *J* = 6.2 Hz, NCH_2), 3.77~3.64 (4H, m, CH_2OCH_2), 3.54 (2H, t, *J* = 6.2 Hz, CH_2OH). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 166.55 (amide C=O), 134.33 (phenylene C), 132.54, 132.08, 129.20, 127.85, 127.00 (phenylene C), 72.26 (CH_2O), 69.23 (CH_2O), 61.52 (CH_2OH), 39.20 (NCH2).

Preparation of the C_{60} derivative 5

According to the procedure described in ref. 18, the reaction of l-azido-3,6-dioxoheptane (59.5 mg, 0.41 mmol) with fullerene (C_{60}) (300 mg, 0.42 mmol) gave the C_{60} derivative **5** (125.7 mg, 54% based on unrecovered C_{60}) as a purple solid. IR (KBr, cm^{-1}) ν: 2935, 1640, 1275, 1184 (C-O-C), 1030 (C_{60}), 528 (C_{60}). ^1H NMR (600 MHz, $CDCl_3$) δ: 4.01~3.94 (4H, m, OCH_2CH_2O), 3.76 (2H, t, *J* = 6.7 Hz, OCH_2), 3.52 (3H, s, OCH_3), 2.96 (2H, t, *J* = 6.7 Hz, NCH_2). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 147.83 (2), 147.02 (2), 145.07 (2), 144.75 (2), 144.71 (2), 144.55 (2), 144.46 (2), 144.32 (2), 144.26 (2), 144.15 (2), 143.80 (2), 143.68 (1), 143.48 (2), 143.41(1), 143.36 (2), 143.16 (2), 143.05 (2), 142.87 (2), 142.72 (2), 142.58 (2), 142.53 (2), 140.83 (2), 140.68 (2), 139.18 (2), 138.41 (1), 137.91 (1), 137.64 (2), 137.21 (2), 137.17 (2), 136.17 (2), 135.67 (2), 133.57 (2) (32 C_{60} sp^2 carbons), 71.63 (CH_2O), 70.05, 69.63 (CH_3O), 60.13, 58.87 (CH_2N). MS (FAB, NBA) *m/z*: 838 (M^+ + H), 735 ($C_{60}NH^+$), 720 (C_{60}).

Biological activity

Primary cortical neuronal cultures

Primary cultures of rat cortical neurons were established using a modification of previous methods (21), which are briefly outlined here. Cortical tissue from an 18-day old Wistar rat fetus was dissociated and put in D-Hanks with trypsinase (0.125%) to be digested for 20 min at 37 °C. The trypsinase was removed and the dissociated neurons were washed with DMEM–FCS (10%), and filtrated through a 200-order stainless steel sieve. After centrifugation at 4000*g* for 10 min, the cells were gently resuspended in DMEM–FCS (10%). The cell suspensions were vaccinated to poly-L-lysine (0.01) coated 96-well plates at the density of 1×10^5 cells per well. All cells were incubated in a DMEM culture medium containing 10% FCS, penicillin (100 U/mL), and streptomycin 100 μg/mL) at 37 °C in a 95% air – 5% CO_2 humidified culture box. On the 3rd day of vaccination, cytarabine (the terminal concentration 10 μmol/L) was added to the culture medium to prevent proliferation of nonneuronal cells.

On the 10th day of culture the neural cells could be used for the experiment and were randomly divided into different groups: control group, H_2O_2-injured group, compound-treated groups in the absence of H_2O_2 (compound **4**, **5**, **6**, and **7**), and compound-treated groups in the presence of H_2O_2 (compound **4** + H_2O_2, **5** + H_2O_2, and **6** + H_2O_2).

Cytotoxicity assessment of compounds 4, 5, and 6

The cytotoxicity of compounds **4**, **5**, and **6** was measured using MTT assay and LDH leakage assay prior to investigating their neuroprotective effects on H_2O_2-damaged cortical neuronal cells. Cells were cultured at the density of 1×10^5 cells per well in a DMEM culture medium containing FCS (10%), penicillin (100 U/mL), and streptomycin (100 μg/mL). When cells were attached to the bottom of the culture plates, the culture medium was replaced by the fresh DMEM culture medium containing the compound (**4**, **5**, or **6**) at diverse final concentrations from 0 to 50 μmol/L. After 24 h of incubation, cell viability and LDH leakage were determined by the MTT assay and LDH leakage assay, respectively. The MTT assay is based on the ability of viable mitochondria to convert MTT, a soluble tetrazolium salt, into an insoluble formazan precipitate, which is dissolved in dimethyl sulfoxide and quantified by spectrophotometry (22). LDH leakage assay is based on the ability of the LDH released in the culture medium to transform NAD to NADH. The increase of NADH is quantified by spectrophotometry. The activity unit of LDH is defined as the amount of LDH that produces 1 μmol NADH per min from NAD^+. The activity is expressed in U/L of the extracellular medium.

Culture treatments

Compounds **4**, **5**, and **6** were dissolved in DMSO, diluted with sterile water to prepare their stock solutions (10 mmol/L), and maintained at 4 °C. At the time of the change in medium, stock solutions were further diluted and applied to the cultures.

Oxidative injury (23) of the group was induced by adding H_2O_2 (final concentration 150 μmol/L) to the serum-free DMEM culture medium containing DMSO (0.2%) supplement and incubating at 37 °C for 2 h. After that treatment, the culture medium was replaced with fresh serum-free DMEM and the cells were cultured continuously for 24 h in a culture box. For compound-treated groups in the absence of H_2O_2, the neuronal cells were cultured with serum-free DMEM containing compound **4**, **5**, **6**, or **7** (final concentration 30 μmol/L) at 37 °C for 24 h. For compound **4**, **5**, or **6** in H_2O_2-treated groups, cortical neuronal cultures were pretreated with compound **4**, **5**, or **6** (final concentration

© 2007 NRC Canada

30 μmol/L) for 2 h, followed by exposure to H_2O_2 (150 μmol/L) for another 2 h. Afterwards, the cell cultures received the same treatmeant as the H_2O_2-injured groups. Control cells were not subjected to H_2O_2 and the various compounds, but were cultured in a serum-free DMEM medium supplemented with DMSO (0.2%) for 24 h.

Measurement of cell activity (24)

Cell viability was determined by measuring the mitochondrial dehydrogenase activity (MDHA) using reduction of MTT. After the culture treatments described earlier, an MTT solution (final concentration 0.5 mg/mL) was added to each well, and the cells were cultured at 37 °C for 4 h. After removal of the medium, formazan crystals produced by MDHA in viable cells were dissolved with dimethyl sulfoxide (200 μL). The value of opical density of each well was measured at 550 nm using an enzyme-linked analyzer.

Determination of (LDH) release (25)

Cellular damage was evaluated by measuring the release of lactate dehydrogenase (LDH) into the culture medium. LDH content in the extracellular medium was determined using the LDH assay kit according to the kit instructions.

Measurement of the GPX activity of compounds 4, 5, and 6

GPX activities of compounds **4**, **5**, and **6** were measured according to the method of Wilson et al. (19). The test mixture contained EDTA (1 mmol/L), sodium azide (1 mmol/L), GSH (1 mmol/L), NADPH (0.25 mmol/L), GSH reductase (1 U), DMSO (0.2%), and the test compound (30 μmol/L) in potassium phosphate buffer (50 mmol/L, pH 7.4). The reaction was carried out at 37 °C and was initiated by the addition of hydroperoxide (0.5 mmol/L). The rate of NADPH oxidation was followed over a 3 min period by monitoring the decrease of NADPH UV absorption at 366 nm (ε 3.5 × 10^3 $mol^{-1}Lcm^{-1}$). The rate of nonenzymatic reaction was determined in a mixture without a test compound (blank). The net rate of enzymatic oxidation of NADPH was used to calculate enzyme activity (1 μmol of NADPH consumed per minute). The activity is expressed in U/μmol of enzyme mimic.

Acyl transfer from carboxylate, carbonate, and thiocarbonate esters to enzymatic and nonenzymatic thiolates

Christian Gravel, Danielle Lapierre, Judith Labelle, and Jeffrey W. Keillor

Abstract: Transglutaminases (EC 2.3.2.13) (TGases) catalyze calcium-dependent acyl transfer reactions between peptide-bound glutamine residues as acyl donors and peptide-bound lysine residues as acyl acceptors, resulting in the formation of intermolecular ε-(γ-glutamyl)lysine crosslinks. The mechanistic details of its "ping-pong" transamidation reaction remain unknown. In particular, few studies have been published probing the nucleophilicity of TGase using acyl-donor substrates of varied electrophilicity. Herein we report the synthesis of activated esters of carbonates, carbamates, and thiocarbonates and their reactions with simple thiols, as a nonenzymatic point of reference, and with the catalytic cysteine residue of guinea pig liver TGase. Our kinetic results show that the simple substitution of a side chain methylene unit by oxygen or sulphur had a surprising effect on both substrate affinity and acylation reactivity. Furthermore, they provide unexpected insight into the importance of a side chain heteroatom for conferring affinity for tissue TGase as well as revealing an interesting class of irreversible inhibitors.

Key words: enzyme kinetics, enzyme inhibition, transglutaminase, acyl-transfer reactions, carbamate, thiocarbonate, carbonate.

Résumé : Les transglutaminases (EC 2.3.2.13) (TGases) catalysent, avec dépendance au calcium, le transfert d'un groupement acyle entre les résidus glutamine d'une première protéine et les résidus lysine d'une seconde protéine. Ceci résulte en la formation de réticulation intermoléculaire du type ε-(γ-glutamyl)lysine. Les détails mécanistiques de sa réaction de transamidation de type « ping-pong » restent inconnus. En particulier, peu d'études explorant la nucléophilie de la TGase à l'aide de substrats donneurs d'électrophilie variable ont été publiées. Dans cet article, nous rapportons la synthèse des esters activés des carbonates, carbamates et thiocarbonates ainsi que leurs réactions avec des thiols simples, comme point de référence non-enzymatique, et avec la cystéine catalytique de la TGase de foie de cobaye. Nos résultats cinétiques démontrent que la substitution simple d'un groupement méthylène par un oxygène ou par un soufre a un effet surprenant sur l'affinité de substrat ainsi que sur la réactivité d'acylation. De plus, ils permettent un aperçu inattendu de l'importance de la présence d'un hétéroatome dans la chaîne latérale pour conférer l'affinité pour la TGase tissulaire et révèlent une classe d'inhibiteurs irréversibles intéressants.

Mots-clés : cinétique enzymatique, inhibition d'enzyme, transglutaminase, transfert de groupement acyle, carbamate, thiocarbonate, carbonate.

Introduction

Transglutaminases (EC 2.3.2.13) (TGases) belong to a class of enzymes known as aminoacyltransferases that catalyze calcium-dependent acyl transfer reactions between peptide-bound glutamine residues as acyl donors and peptide-bound lysine residues as acyl acceptors, resulting in the formation of intermolecular ε-(γ-glutamyl)lysine crosslinks (1). TGases form a family of related enzymes found in plasma, tissues, and extracellular media in all vertebrates. One of the best known TGases is the well-characterized human plasma coagulation enzyme Factor XIIIa, activated by thrombin from its tetrameric zymogen during the coagulation process (2, 3). Other types of TGase known to date include the keratinocyte TGase (type I) (4), two epidermal TGases (types III and V), a TGase localized in the prostate (type IV) (5, 6), and the ubiquitous tissue TGase (type II), the focus of our research interest. Guinea pig liver tissue TGase (gTGase) was chosen as a model of the human enzyme for this work because it is 88% homologous (7) to the human tissue TGase (hTGase) and is readily purified in its recombinant His-tagged form (8). gTGase is a monomeric protein comprising 690 amino acids with a calculated molecular weight of 78.7 kDa. It is not glycosylated (1) although it possesses six potential *N*-glycosylation sites and contains 17 cysteine residues, none of which are comprised in disulfide bonds (9). One of these acts as the catalytic nucleophile, in a Cys-His-Asp triad reminiscent of that of the cysteine proteases. Comparison of the amino acid sequence of gTGase with those of the only TGases for which X-ray structures are

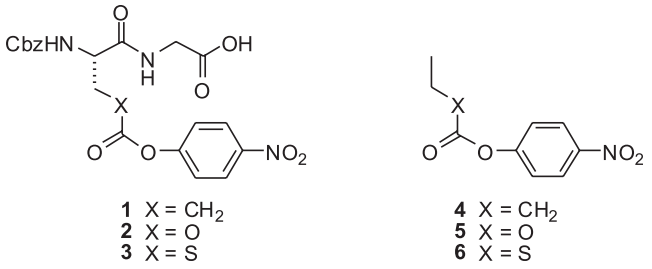
available — Factor XIIIa (10), human epidermal Tgase (eTGase) (11), human tissue TGase (hTGase) (12), and a fish tissue TGase (fTGase) (13) — indicates that the catalytic triad of gTGase would be composed of Cys-276, His-334, and Asp-358. The catalytic acyl-transfer reaction is known to proceed through a modified "ping-pong" mechanism (14) that is yet to be completely understood despite the involvement of TGase in critical processes such as the stabilization of extracellular matrices, formation of cross-linked cell envelopes, cell-matrix assembly, wound healing, and cellular adhesive processes (1). TGase has been implicated in important physiological disorders, such as amyloid protein aggregation leading to Alzheimer's disease (15), thrombosis, arteriosclerosis (16), autoimmune gluten intolerance (Celiac disease) (17, 18), cataract development (19), and Hb-Koln disease (2). TGase has also been implicated in neurodegenerative diseases related to an increase in transamidated (20) polyglutamine-containing peptide, leading to aggregation in neural tissues such as Huntington's disease (21). In the ping-pong mechanism, the acyl donor substrate undergoes nucleophilic attack by the active site thiolate, followed by the release of an equivalent of ammonia. The thiolester acyl enzyme intermediate thus obtained then undergoes a second nucleophilic attack by the acyl acceptor substrate, typically a primary amine, leading to the formation of a new isopeptidic compound and the regeneration of the free enzyme. These steps are facilitated by the presence of a general acid–base catalyst, His-334 (22). Water can also compete weakly as an acyl acceptor during the deacylation step, resulting in the net hydrolysis of the initial acyl-donor amide.



While a significant amount of data is available regarding the specificity and reactivity of various glutamine substrates (23, 24), far fewer studies have been published probing the nucleophilicity of TGase using acyl-donor substrates of varied electrophilicity. In addressing this paucity of data we carried out kinetic studies with nonenzymatic thiols to provide a point of reference. The thermal decomposition of such esters (25) and their susceptibility to nucleophilic attack by phenolate, secondary acyclic amines, and pyridines have been reported (26, 27, 28), but kinetic studies concerning the acylation of simple thiols by carboxylate-, carbonate-, carbamate-, and thiocarbamate-esters are also relatively few (29, 30). Herein we report on the reaction of the activated esters of carbonates, carbamates, and thiocarbonates with simple thiols and the catalytic cysteine residue of gTGase.

Results and discussion

Design and synthesis of acyl-donor reactants

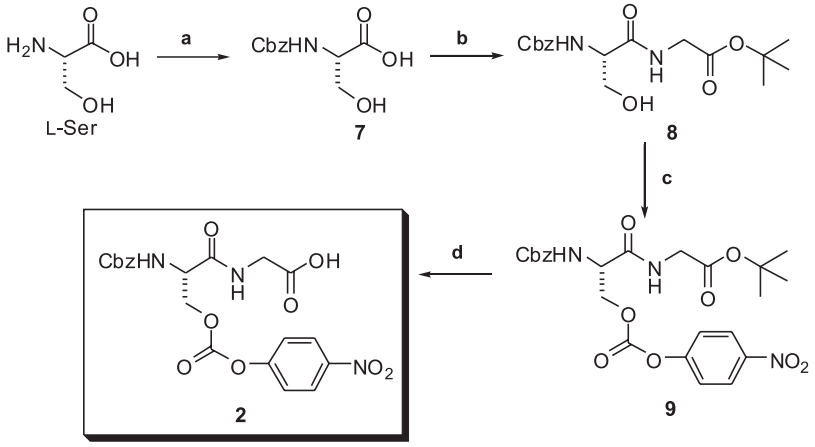
Compounds **1**, **2**, and **3** (see Fig. 1) were designed to bear the essential structural elements required for recognition by TGase as an acyl-donor substrate, i.e., a hydrophobic, planar moiety on the *N*α of the glutamine residue, a central amino acid having L configuration (31), and at least two methylene units in its side chain (asparagine not being recognized as a substrate) (22, 32, 33). The C-terminal glycine residue is not absolutely required but improves binding by an order of magnitude probably by distancing the terminal negative charge from the carboxylate of the central amino acid (33). Compounds **4**, **5**, and **6** (Fig. 1) were chosen as simplified

Fig. 1. Acyl-donor reactants studied herein.

functional models because of their commercial availability or synthetic accessibility as well as their resemblance to the reactive side chains of **1**, **2**, and **3**. Although it may have been interesting to study the acylation TGase from *p*-nitrophenyl carbamates (e.g., X = NH in Fig. 1), we confirmed that these molecules undergo a rapid elimination reaction in water releasing *p*-nitrophenolate and generating the corresponding isocyanate (34, 35, 36, 37), making their kinetic study impossible.

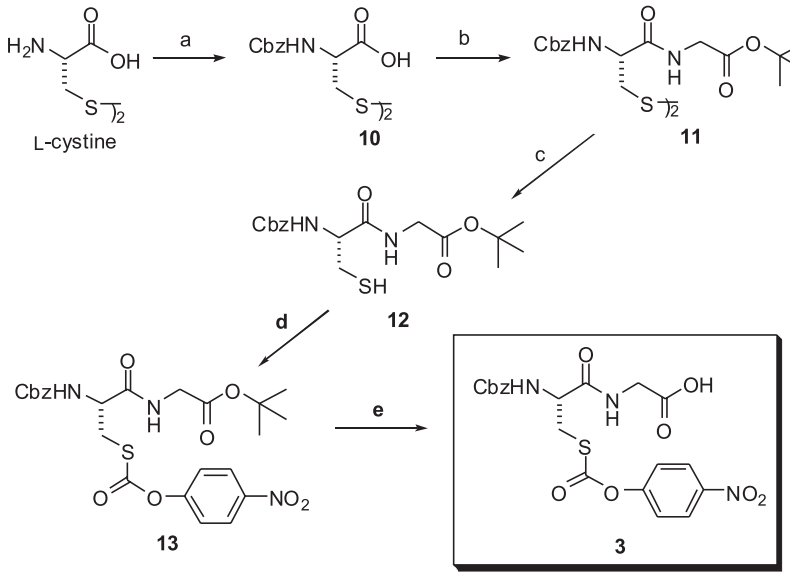
Compound **1** was synthesized as described previously (22). Compounds **2** and **3** were synthesized according to the pathways shown in Schemes 1 and 2, respectively. These synthetic routes are both straightforward, consisting of an initial protection of the amino groups of either serine (for compound **2**) or cystine (for compound **3**) with benzyl chloroformate (Cbz–Cl), followed by peptide coupling using TBTU as a coupling agent and subsequent introduction of the *p*-nitrophenoxycarbonyl moiety. In the case of compound **3**, a reduction step was required prior to side chain functionalization. Finally, deprotection of the *tert*-butyl ester provided the desired compounds **2** and **3** in modest unoptimized yields (34% and 40% overall isolated yields, respectively) but in quantities sufficient for subsequent kinetic studies.

Compound **4** is commercially available (Sigma-Aldrich) and compounds **5** and **6** were obtained by following known protocols (38, 39) in which *p*-nitrophenolate reacts with ethyl chloroformate and ethyl thiochloroformate with yields of 77% and 94%, respectively (Scheme 3).



Nonenzymatic kinetics

The reactions of ester **4**, carbonate **5**, and thiocarbonate **6** with either ethanethiol or cysteamine were followed spectrophotometrically by monitoring the increase in absorbance at 410 nm due to released *p*-nitrophenol. Under pseudo first-order conditions with thiol concentrations over 10-fold higher than those of compounds **4**–**6**, reaction kinetics were found to be clean first-order over at least five half-lives, allowing the determination of pseudo first-order rate constants (k_{obs}) by fitting the absorbance data to a simple mono-exponential equation (see Experimental section). The variation of k_{obs} as a function of thiol concentration provided the second order rate constants (k_2) for each of the thiolysis reactions studied. Figure 2 shows a representative example.



Second-order rate constants were thus obtained using either cysteamine or ethanethiol as nucleophiles at both pH 7 and 8. The results, shown in Table 1, demonstrate the greater reactivity of both thiols at higher pH, consistent with the thiolate being the active nucleophile. Also shown in bold in Table 1 are second-order rate constants normalized for the

6 X = S

fraction of thiolate present at each pH, based on literature values for the corresponding pK_a values (34, 35). This normalization generates similar values at each pH, within experimental error, for most of the compounds studied.

It is also clear from Table 1 that ester **4** reacts most rapidly with both thiols, followed by thiocarbonate **6** and (or) carbonate **5**. This trend in their relative reactivity most likely reflects their relative electrophilicity and a rate-limiting step involving nucleophilic attack by thiolate. In support of this supposition of relative electrophilicity, the ^{13}C chemical shifts of the side chain carbonyl groups of compounds **4**–**6**, indicative of their relative deshielding or electron density, are noted to be 172, 170, and 153 ppm, respectively, following the same general trend as their reactivity. The decreased electrophilicity of derivatives **5** and **6** compared with **4** suggests that resonance stabilization of the carbonyl group through electron donation from an adjacent heteroatom is more important than electron withdrawal through inductive effects.

It is also instructive to compare the relative reactivity of cysteamine and ethanethiol. It is evident from Table 1 that

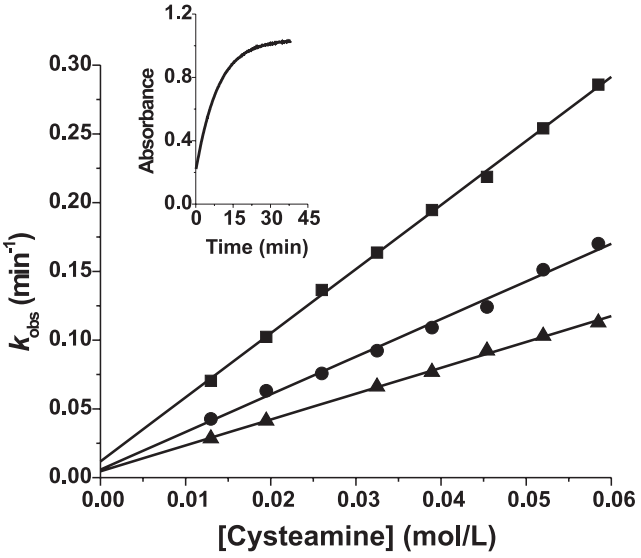
Fig. 2. Determination of second order rate constants for the thiolysis of ester **4** (squares), carbonate **5** (triangles) and thiocarbonate **6** (circles) upon reaction with cysteamine (35 °C, pH = 7.0). Inset: typical mono-exponential reaction from which k_{obs} was measured.



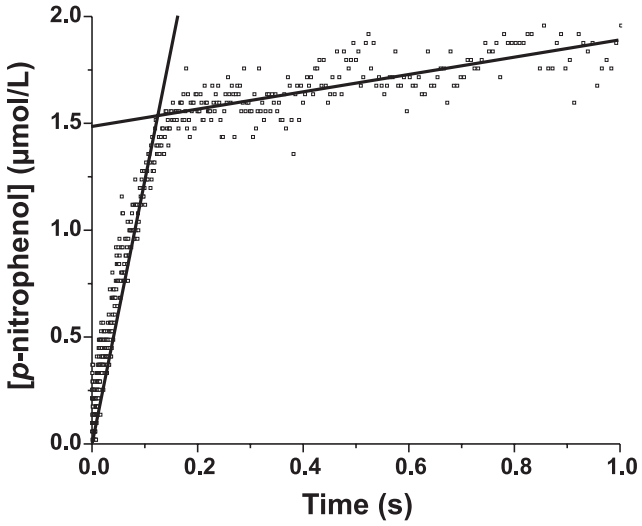


Fig. 3. Acylation of 2.2 μmol/L of gTGase by 198 μM of ester **1** at 25 °C and pH 7.0 (0.1 mol/L MOPS). (See Experimental for background correction.).

while the presence of a pendant ammonium group serves to decrease the pK_a of the thiol group of cysteamine, it does not further accelerate the reaction of the thiolate form significantly above that of ethanethiol. As has been noted previously, a pendant ammonium group can assist in the thiolysis of amides by acting as an intramolecular general acid protonating an amine leaving group (42). However, it has also been noted that this role is not required for a leaving group such as *p*-nitrophenolate (42, 43), also present in compounds **1**–**6**, whose departure does not require protonation.

Enzymatic kinetics

Compounds **1**–**3** were tested as substrates for recombinant gTGase and found to display similar kinetic behaviour during the first second of reaction. As shown in Fig. 3, rapid release of *p*-nitrophenol corresponding roughly to one equivalent of enzyme (0–0.1 s) was followed by slower turnover (0.1–1.0 s). The pre-steady state "burst" is consistent with the rapid acylation of gTGase by compounds **1**–**3**, leading to the corresponding acyl-enzyme featured in the ping-pong mechanism of Fig. 4. The initial rates of this burst phase were measured as a function of substrate concentration and fitted according to the hyperbolic Michaelis–Menten equation (see Experimental section) as shown in Fig. 5. The kinetic parameters obtained in this fashion are shown in Table 2.

At first glance, it is evident that the kinetic parameters measured for ester **1** and carbonate **2** are similar. Insofar as the K_M values reflect enzyme affinity for the substrate, it is not surprising that this parameter would be similar for the analogous compounds **1** and **2**. Moreover, the slight decrease in the acylation rate constant (k_{acyl}) on passing from the ester to the carbonate is to be expected for the reasons outlined earlier in the discussion of compounds **4** and **5**. Namely, the carbonate ester is presumably less electrophilic than the carboxylate ester as a result of resonance stabilization from the adjacent oxygen atom and therefore less susceptible to nucleophilic attack by the active site thiolate.

However, there is a reversal of this apparent trend on consideration of the kinetic parameters obtained for thiocarbonate **3**. The replacement of the γ-methylene unit of **1** by a sulfur atom in **3** leads to a ~20-fold decrease in the K_M and an increase in the value of k_{acyl}, suggesting a significant increase in affinity. The acylation rate constant itself increases by a factor of ~2.5, resulting in a combined ~50-fold increase in the efficiency of the enzymatic reaction (re-

flected in k_{acyl}/K_M). These results go against expectations based on the reactivity of models **4**–**6** in solution. Based on the earlier discussion for thiocarbonate **6**, substrate analogue **3** was expected to be *less* reactive than ester **1** owing to its lower electrophilicity due to carbonyl-stabilizing resonance forms but *more* reactive than carbonate **2** because of the reduced resonance stabilization from carbon–sulfur orbital overlap. Clearly, other forces are at play in the enzymatic reactions of **1**–**3** that take place in a constrained, hydrophobic, and functionalized active site, compared with the model reactions of **4**–**6** that take place in free aqueous solvent.

Among these interactions are those that result in the activation of the bound substrate. Many enzymes that catalyze acyl-transfer reactions from amide groups, for example, are thought to twist the amide out of its normally planar geometry, thereby decreasing resonance stabilization and activating the carbonyl toward nucleophilic attack (43, 44). Such torsion may also be present in the Michaelis complexes formed upon binding compounds **1**–**3**. Further, one may suppose that the larger sulphur atom of thiocarbonate **3** would render it more susceptible to steric distortion, easily reducing carbon–sulphur orbital overlap and subsequently the importance of resonance stabilization. At the limit, the sulphur atom of thiocarbonate **3** would only exert an electron-withdrawing inductive effect, effectively making it a better acylating agent than the ester **1**.

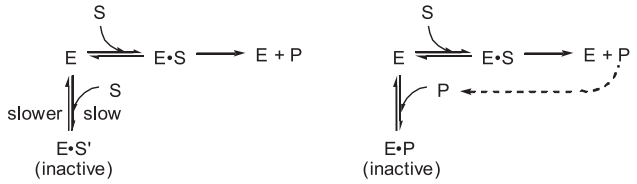
Alternatively, the sulphur atom in the side chain of **3** may simply allow for better placement of the reactive carbonyl in

© 2007 NRC Canada

Fig. 6. Acylation of 2.0 μM of gTGase by 3.10 mM of carbonate **2** showing : **A**) initial burst and turnover; **B**) turnover and final loss of activity. (See Experimental.)

the enzyme active site. It is known that the active site of gTGase is located at the bottom of a relatively long and narrow well, allowing the enzyme to react with glutamine residues but not with asparagines (32). The introduction of a sulphur atom in the place of a methylene unit would subtly affect the bond lengths and bond angles of the side chain effectively increasing its length (45), more easily placing the acyl group within the trajectory of the active site nucleophile. Consistent with this hypothesis, we have noted that many of the irreversible glutamine-analogue gTGase inhibitors that we have synthesized in the past show greater efficiency with increasing side chain length (46, 47).

Finally, while our understanding of detailed interactions leading to substrate affinity is grossly limited by the lack of any ligand-bound crystal structure, our modelling of tissue Tgase (48) allows us to speculate why the enzyme shows increased affinity for the thiocarbonate **3**. It is known that two tryptophan residues (Trp-240 and Trp-331) and one histidine residue (His-300) form the walls of the tunnel leading the side chain to the active site. Sulphur, being a highly polarizable atom, may form favourable interactions with the faces of these aromatic residues leading to tighter binding (lower K_M), while positioning the carbonyl group to react more rapidly with the active-site thiol (higher k_{acyl}).

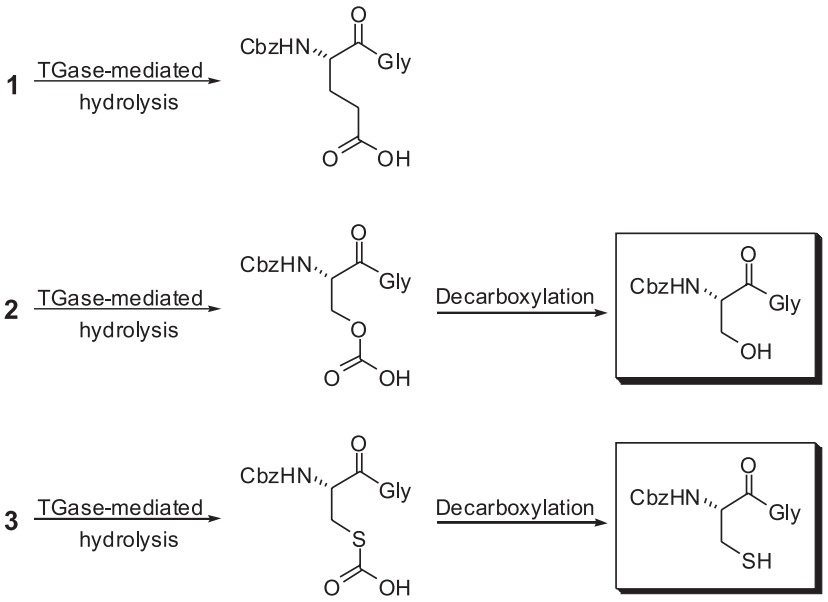


Inhibition kinetics

Upon closer examination of the stopped-flow traces obtained for the reaction of compounds **2** and **3** with gTGase, it was noted that over a longer time scale (up to 40 s) the slope of the "slow phase" levelled off in a nearly complete loss of activity (Fig. 6). This behaviour was not observed for ester **1**, where all of the ester substrate was consumed during the slow phase.

Knowing the final concentration of *p*-nitrophenol released prior to apparent inactivation by compounds **2** and **3** (Fig. 6*B*) allows us to estimate that the enzyme turns over ~7 times with carbonate **2** and ~4 times with thiocarbonate **3**. Apparently, all three compounds **1**–**3** initiate rapid acylation (burst phase), followed by the slower catalytic turnover of the respective acyl-enzyme (second phase). However in the case of carbonate **2** and thiocarbonate **3**, a competing event takes place that does not occur with ester **1**, leading to inhibition of the enzyme.

To characterize the inhibition, a competition experiment was carried out between ester **1** (used as the substrate) and thiocarbonate **3** (used as an inhibitor). This experiment revealed that the presence of **1** was able to temporarily protect the enzyme from inactivation by **3**, suggesting strongly that both compounds are bound in the same site. However even in the presence of ester **1**, the enzyme was still slowly inactivated by thiocarbonate **3** leading to a loss of about 50% of activity after 5 min when using 20 μmol/L of **1** (1 K_M) and 100 μmol/L of **3**. Interestingly, even after a long period (>30 min) of incubation with 100 μmol/L of thiocarbonate **3**, the addition of an aliquot of ester **1** revealed that some residual activity remained suggesting that the inactivation may be reversible. However, mass spectroscopy experiments confirmed that upon incubation with thiocarbonate **3**, the mass of gTGase increased by the expected mass of the acyl portion (see Experimental section).



Scheme 4. Two hypotheses for observed time-dependent inactivation by carbonate **2** and thiocarbonate **3**. (***A***) Two alternate binding modes or binding sites and (***B***) product inhibition.

These observations led us to formulate two hypotheses regarding the inactivation mechanisms of carbonate **2** and thiocarbonate **3**. The first possibility is that both compounds **2** and **3** could have two different binding modes, one of which would lead to typical substrate-like behaviour resulting in normal turnover as for **1** (i.e., the second phase of the stopped-flow traces, Fig. 6*A*). However, an alternate binding mode for both **2** and **3** having a slow k_{on} and an even slower k_{off} would slowly lead to a tightly bound inactive form of the enzyme (see Scheme 4*A*). This binding mode could be related to the presence of a heteroatom on the side chain of **2** and **3** in the place of the methylene group of compound **1**. Examination of our tissue TGase model (48) shows that at least four gTGase residues (Trp-240, His-304, Tyr-518, and Asn-519) present a polarized hydrogen atom within <5 Å of the side chain heteroatom. The formation of a strong dipole–dipole interaction with the sulphur atom of **3**, or even a hydrogen bond with the oxygen atom of **2**, may provide the driving force for adopting an alternative tight binding mode within the active site that leads to inhibition.

© 2007 NRC Canada

Scheme 5. Difference in final product obtained after TGase-mediated hydrolysis of compounds **1**–**3** followed by subsequent decarboxylation for compounds **2** and **3**.

Alternatively, this different binding mode could very well be related to a different binding site, such as for example the GTP binding site, that is known to modulate the enzyme's activity through allosteric effects (12). Recently, Case and Stein (49) reported TGase inhibitors that bind either directly in this GTP binding site or in a site that regulates GTP binding. Their results also demonstrate the possibility of inhibition through the differential interaction of a given inhibitor with different conformational states of the enzyme. This further supports our hypothesis that our inhibitors may be bound by TGase at more than one site. Furthermore, putative binding at a different site could lead to acyl transfer to an adjacent nucleophile, which may explain the minor peak observed by mass spectrometry that corresponds to a doubly acylated enzyme (see Experimental section).

The second possibility is that the released product of the hydrolysis step could act as an inhibitor. Inhibition by this product would be time-dependent as its concentration increases during the catalytic turnover of its parent compound (see Scheme 4*B*). In potential support of this hypothesis, the reaction products formed after catalytic hydrolysis of **2** and **3** may undergo further spontaneous decarboxylation leading to the final products Cbz-Ser-Gly and Cbz-Cys-Gly, respectively. For example, a rate constant of 0.4 s^{-1} was recently measured under physiologically relevant reaction conditions for the decarboxylation of monoalkyl carbonate salt (50); presumably, the decarboxylation of a monoalkyl thiocarbonate would be even faster. These decarboxylation products would differ substantially from the reaction product of **1** (Scheme 5). This may explain why ester **1** showed no time-dependent inhibitory effect whatsoever.

To test this hypothesis, simple inactivation experiments were carried out in the presence of Cbz-Ser-Gly, the ultimate decarboxylated product deriving from the hydrolysis of compound **2**. No inhibition was observed, even in the presence of up to 10 mmol/L of Cbz-Ser-Gly. While this result does not strictly rule out the possibility that the hydrolysed substrate may act as an inhibitor prior to expected decarboxylation, it leads us to favour the differential binding mode hypothesis (Scheme 4*A*) as an explanation of the observed inhibition.

Conclusions

A series of gTGase substrate analogues was prepared in which the electrophilicity of the reactive carbonyl was varied by the presence of adjacent heteroatoms. Kinetic studies with model compounds provided a nonenzymatic reference for the expected rate dependence. However, the simple substitution of a side chain methylene unit by oxygen or sulphur had a surprising, counter-intuitive effect on both substrate affinity and acylation reactivity. This kinetic characterization served to illustrate the challenges associated with studying free-energy relationships in enzymatic reactions. It also provided unexpected insight into structural elements important for conferring affinity for tissue TGase as well as revealing an interesting class of irreversible inhibitors. Further work is underway to exploit these compounds as mechanistic probes and to explore their in vivo utility as inhibitors.

Materials and methods

Synthesis

General

All commercial reagents were used without further purification. Dichloromethane and tetrahydrofuran (THF) were dried using a GlassContour system (Irvine, California) column. Dry acetonitrile was bought from EM Science and used without distillation. *p*-Nitrophenyl butanoate (**4**) was purchased from Sigma-Aldrich and used without further purification. Melting points were uncorrected. Water was purified using a Millipore BioCell system.

Ethyl* p-*nitrophenyl carbonate (5)

To a suspension of sodium *p*-nitrophenolate (20 mmol) in 20 mL of anhydrous acetonitrile, a solution of ethyl chloroformate (29 mmol) in 10 mL of acetonitrile was added dropwise at 0 °C under nitrogen atmosphere. The mixture was stirred for 30 min at 0 °C and then for 3 h at room temperature (RT). Solvent was then evaporated under reduced pressure and the solid obtained was washed with dichloromethane to give 3.2 g (77%) of product as a white powder. R_f 0.74 (100% EtOAc), mp 67 to 68 °C. IR (KBr) ν: 3119, 2918, 1756, 1617, 1597, 1518, 1351, 1304, 1281. ^{1}H NMR (DMSO-d_6, 400 MHz, ppm) δ: 1.30 (3H, t, J = 7.1 Hz), 4.29 (2H, q, J = 7.1 Hz), 7.55 (2H, d, J = 9.2 Hz), 8.31 (2H, d, J = 9.2 Hz). ^{13}C NMR (DMSO-d_6, 100 MHz, ppm) δ: 14.77, 66.11, 123.50, 126.25, 145.97, 152.86, 156.17. HRMS calcd. for $C_9H_9NO_5$: 211.048 073; found: 211.048 034. Anal. calcd. for $C_9H_9NO_5$: C 51.19, H 4.30, N 6.63; found: C 51.21, H 4.50, N 6.37.

Ethyl* p-*nitrophenyl thiocarbonate (6)

To a suspension of *p*-nitrophenol (9 mmol) and pyridine (9 mmol) in 15 mL of anhydrous dichloromethane, a solution of ethyl thiochloroformate (9 mmol) in 4 mL of dichloromethane was added dropwise at 0 °C under nitrogen atmosphere. The mixture was stirred for 15 min at 0 °C and then left overnight at RT. The mixture was then extracted with 30 mL of distilled water and the organic layer was washed with 30 mL of NaOH (0.5 mol/L), 30 mL of satd. NaCl, and again with 30 mL of distilled water before being dried over $MgSO_4$ and passed through a silica gel plug using 100% $CHCl_3$ as eluant. Evaporation under reduced pressure provided 1.87 g (93.5%) of product as a white powder. R_f 0.58 (100% $CHCl_3$), mp 60 to 61 °C. IR (KBr) ν: 3084, 2973, 2936, 1708, 1621, 1590, 1532, 1490, 1347, 1098. ^{1}H NMR (DMSO-d_6, 300 MHz, ppm) δ: 1.30 (3H, t, J = 7.3 Hz), 2.97 (2H, q, J = 7.3 Hz), 7.53 (2H, d, J = 9.2 Hz), 8.30 (2H, d, J = 9.2 Hz). ^{13}C NMR (DMSO-d_6, 100 MHz, ppm) δ: 15.54, 26.32, 123.72, 126.33, 146.14, 155.98, 170.01. HRMS calcd. for $C_9H_9NO_4S$: 227.025 230; found: 227.024 816. Anal. calcd. for $C_9H_9NO_4S$: C 47.57, H 3.99, N 6.16, S 14.11; found: C 47.45, H 3.86, N 6.09, S 13.64.

N-*Benzyloxycarbonyl-*L*-serine (7)*

Sodium bicarbonate (6.3 mmol) was dissolved in 6 mL of distilled water and L-serine (0.95 mmol) was added to the solution. Once the solution was completely dissolved, benzyl chloroformate (0.63 mmol) was added dropwise at 0 °C and the mixture was stirred for 2 h at 0 °C and then overnight at RT. The aqueous phase was washed with Et_2O (4 × 5 mL) and then acidified to pH 1 with concd. HCl and extracted with EtOAc (4 × 10 mL). The combined organic layers were then washed with water, dried over $MgSO_4$, and concentrated to provide 88 mg (58%) of product as a white solid. R_f 0.054 (hexanes–EtOAc 70:30), mp 116 to 117 °C (lit. value (51) 117–119 °C). $[\alpha]_D^{20}$ +5.52° (c 1.81, HOAc) (lit. value (51) 5.8 ± 0.5° (c 2.7, HOAc)). IR (KBr) ν: 3443–2555, 3319, 3029, 2940, 1748, 1690, 1535, 1478, 1248, 1060. ^{1}H NMR (CD_3OD, 300 MHz, ppm) δ: 3.84 (1H, dd, J = 4.0 and 11.3 Hz), 3.90 (1H, dd, J = 4.9 and 11.4 Hz), 4.28 (1H, t, J = 4.4 Hz), 5.12 (2H, s), 7.29–7.39 (5H, m). ^{13}C NMR (CD_3OD, 75 MHz, ppm) δ: 56.71, 62.08, 66.71, 127.87, 128.46, 137.14, 157.60, 172.75. HRMS calc. for $C_{11}H_{13}NO_5$: 240.087 20; found: 240.088 53. Anal. calc. for $C_{11}H_{13}NO_5$: C 55.23, H 5.48, N 5.86; found: C 55.10, H 5.90, N 5.84.

N-*Benzyloxycarbonyl-*L*-serinylglycine* tert-*butyl ester (8)*

To a solution of *N*-Cbz-L-serine (**7**) (1.3 mmol) in 13 mL of anhydrous acetonitrile, diisopropylethylamine (DIEA) (5.2 mmol) was added dropwise at RT under nitrogen atmosphere, and the solution was left to stir for 5 min before glycine *tert*-butyl ester (2.6 mmol) was added. Once the solution was completely dissolved, TBTU (2.6 mmol) was added and the mixture was stirred overnight. A 50 mL aliquot of EtOAc was then added to the mixture and the organic phase was washed with saturated NaCl (2 × 15 mL), HCl (0.1 mol/L, 15 mL), 5% $NaHCO_3$ (15 mL), and again with satd. NaCl (15 mL) before being dried over $MgSO_4$, filtered, and concentrated in vacuo. The crude product was purified by flash chromatography on silica gel using 60:39:1 EtOAc–hexanes–HOAc as the eluant to provide 0.66 g (94%) of product as a white solid. R_f 0.33 (hexanes–EtOAc 30:70), mp 67–70 °C. $[\alpha]_D^{20}$ –7.71° (c 1.75, $CHCl_3$). IR (KBr) ν: 3379, 3094, 2982, 2894, 1737, 1690, 1659, 1554, 1520, 1466, 1456, 1339, 1062. ^{1}H NMR ($CDCl_3$, 300 MHz, ppm) δ: 1.47 (9H, s), 3.06 (1H, s), 3.70 (1H, dd, J = 11 and 5.4 Hz), 3.95 (2H, d, J = 5.5 Hz), 4.13 (1H, m), 4.28 (1H, m), 5.15 (2H, s), 7.30–7.42 (5H, m). ^{13}C NMR ($CDCl_3$, 75 MHz, ppm) δ: 28.37, 42.50, 63.26, 67.47, 82.79, 128.41, 128.52, 128.89, 136.57, 156.99, 169.58, 171.69. HRMS calcd. for $C_{17}H_{24}N_2O_6$: 353.171 26; found: 353.172 30. Anal. calcd. for $C_{17}H_{24}N_2O_6$: C 57.94, H 6.86, N 7.95; found: C 57.78, H 7.33, N 8.00.

N-*Benzyloxycarbonyl*-O-(p-*nitrophenoxycarbonyl*)-*L*-*serinylglycine* tert-*butyl ester (9)*

To a solution of *N*-Cbz-L-SerGly *tert*-butyl ester (**8**) (1.6 mmol) dissolved in 5 mL of anhydrous acetonitrile, pyridine (7.9 mmol) was added dropwise under nitrogen. The solution was stirred for a few minutes and was then placed in an ice bath. At 0 °C, *p*-nitrophenyl chloroformate (1.6 mmol) was then added and the bath removed while the mixture was stirred for 3 h. A 20 mL volume of EtOAc was added and the organic layer was washed with HCl (3 mmol/L, 3 × 10 mL), dried over $MgSO_4$, filtered, and concentrated in vacuo. The crude product was purified by flash chromatography on silica gel using 30:70 EtOAc–hexanes as the eluant. A 0.51 g (63%) quantity of the product was obtained as a white powder that could be recrystallized from CH_2Cl_2–hexanes. R_f 0.37 (hexanes–EtOAc 60:40), mp 52–54 °C. $[\alpha]_D^{20}$ +6.87° (c 1.50, $CHCl_3$). N-*Benzyloxycarbonyl*-L-*cystine (10)*

To 1.44 g (5.94 mmol) of L-cystine in 175 mL of water was added 5 g (60 mmol) of $NaHCO_3$ and the mixture was cooled to 0 °C. A 1.70 mL volume (13.0 mmol) of benzyl chloroformate was added dropwise and the biphasic solution was stirred vigorously overnight. After acidification to pH 3 using 6N HCl, the aqueous phase was extracted with 3 × 150 mL EtOAc and the extract was concentrated in vacuo to give 3.38 g (99%) of a clear oil. R_f 0.05 (50:50 EtOAc–hexanes). ^{1}H NMR (CD_3OD, 300 MHz, ppm) δ: 2.98 (1H, dd, J = 9.1 and 13.9 Hz), 3.25 (1H, dd, J = 4.3 and 13.9 Hz), 4.51 (1H, dd, J = 4.3 and 9.1 Hz), 5.07 (2H, s), 7.27 (5H, m). ^{13}C NMR (CD_3OD, 75 MHz, ppm) δ: 41.18, 54.71, 67.81, 128.84, 129.03, 129.51, 139.09, 158.54, 174.02.

N-*Benzyloxycarbonyl*-L-*cystinylglycine* tert-*butyl ester (11)*

A 3.38-g (6.6 mmol) portion of *N*-benzyloxycarbonyl-L-cystine (**10**) and 5.76 mL (33 mmol) of DIEA were dissolved in 120 mL of anhydrous acetonitrile. To this solution was added 2.76 g (17 mmol) of glycine *tert*-butyl ester hydrochloride and 6.36 g (20 mmol) of TBTU. The mixture was stirred overnight. The next day, 120 mL of EtOAc was added and the organic phase was washed with 3 × 120 mL satd. NaCl, 100 mL 1N NaOH, and 100 mL H_2O. After concentration in vacuo and purification by silica gel chromatography (15 cm × 2.5 cm, 33% EtOAc–toluene), 2.91g (60%) of a white solid was obtained. R_f 0.43 (50:50 EtOAc–hexanes). ^{1}H NMR ($CDCl_3$, 300 MHz, ppm) δ: 1.42 (9H, s), 2.87 (1H, dd, J = 11 and 15 Hz), 3.10 (1H, dd, J = 15 and 4 Hz), 3.77 (1H, dd, J = 18 and 5 Hz), 4.00 (1H, dd, J = 18 and 5 Hz), 5.10 (1H, m), 5.16 (2H, s), 5.8 (1H, d, J = 9 Hz), 7.31 (5H, m), 7.95 (1H, t, J = 5 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz, ppm) δ: 27.90, 41.93, 46.04, 55.10, 67.15, 81.98, 127.50, 127.97, 128.37, 136.30, 156.87, 168.27, 170.02. HRMS calcd. for $C_{34}H_{46}N_4O_{10}S_2$ + H: 735.272 81; found: 735.272 07.

N-*Benzyloxycarbonyl*-L-*cysteinylglycine* tert-*butyl ester (12)*

A 100-mg (0.136 mmol) portion of *N*-benzyloxycarbonyl-L-cystinylglycine *tert*-butyl ester (**11**) and 100 mg (2.6 mmol) of sodium borohydride were dissolved in a mixture of 2 mL of ethanol and 2 mL of $CHCl_3$. The mixture was shaken for 30 min at RT. Then, 5 mL of $CHCl_3$ was added and the organic phase was washed with HCl (10 mL, 1 mol/L) and then concentrated in vacuo. If necessary, the product can then be purified by silica gel chromatography using 30:70 EtOAc–hexanes as eluant. To avoid oxidation, the last step was carried out immediately. R_f 0.50 (50:50 EtOAc–hexanes). ^{1}H NMR ($CDCl_3$, 300 MHz, ppm) δ: 1.17 (3H, s), 1.42 (1H, dd, J = 8.4 and 11.4 Hz), 2.58 (1H, ddd, J = 15.2, 11.4, and 6.6 Hz), 2.97 (1H, ddd, J = 15.2, 8.4, and 5.1 Hz), 3.87 (2H, d, J = 6.2 Hz), 4.50 (1H, m), 5.19 (2H, s), 6.04 (1H, d, J = 9.2 Hz), 7.11 (1H, t, J = 6.2 Hz), 7.61 (5H, m). ^{13}C NMR ($CDCl_3$, 75 MHz, ppm) δ: 27.91, 41.92, 46.14, 55.12, 67.02, 81.95, 127.80, 127.92, 128.74, 136.25, 156.92, 168.32, 170.06.

N-Benzyloxycarbonyl*-S-*(*p-*nitrophenyloxycarbonyl)-*L-*cysteinylglycine* tert-*butyl ester (13)

First, 110 mg (0.3 mmol) of *N*-benzyloxycarbonyl-L-cysteinylglycine *tert*-butyl ester (**12**) and 104 µL of DIEA were dissolved in 0.5 mL of $CHCl_3$ at 0 °C. Then, 60 mg (0.3 mmol) of *p*-nitrophenyl chloroformate dissolved in 0.5 mL of $CHCl_3$ was added at 0 °C and the mixture was shaken for 15 min. The mixture was then purified by silica gel chromatography using 1:2 EtOAc–hexanes. The product was obtained as 68 mg (68%) of a yellow solid. R_f 0.50 (1:1 EtOAc–hexanes). ^{1}H NMR ($CHCl_3$, 300 MHz, ppm) δ: 1.18 (3H, s), 3.19 (1H, dd, J = 6.4 and 13.5 Hz), 3.37 (1H, dd, J = 4.1 and 13.5 Hz), 3.88 (2H, d, J = 4.0 Hz), 4.70 (1H, dd, J = 4.1 and 6.4 Hz), 5.23 (1H, d, J = 13.2 Hz), 5.27 (1H, d, J = 13.2 Hz), 5.80 (1H, d), 6.95 (1H, t), 7.56 (2H, d, J = 10.5 Hz), 7.62 (5H, m), 8.58 (2H, d, J = 10.5). ^{13}C NMR ($CDCl_3$, 75 MHz, ppm) δ: 28.2, 28.5, 43.3, 53.2, 65.2, 122.2, 124.8, 127.2, 127.3, 127.8, 136.6, 145.1, 155.1, 155.4, 167.3, 168.0, 169.9.

N-*Benzyloxycarbonyl*-S-*(*p-*nitrophenyloxycarbonyl)-*L-*cysteinylglycine (3)

To 34 mg (64 µmol) of *N*-benzyloxycarbonyl-*S*-(*p*-nitrophenoxycarbonyl)-L-cysteinylglycine *tert*-butyl ester (**13**) dissolved in 2 mL of chloroform was added 500 µL (6.5 mmol) of TFA at 0 °C. The solution was stirred for 1 h and then evaporated in vacuo. The product thus obtained was used without further purification. R_f 0.12 (50:50 EtOAc–hexanes). ^{1}H NMR ($CHCl_3$, 400 MHz, ppm) δ: 3.10 (1H, dd, J = 6.3 and 13.6 Hz), 3.26 (1H, dd, J = 4.1 and 13.6 Hz), 4.05 (2H, d, J = 3.8 Hz), 4.82 (1H, dd, J = 4.1 and 6.3 Hz), 5.23 (1H, d, J = 13.1 Hz), 5.27 (1H, d, J = 13.1 Hz), 6.30 (1H, d, J = 8.1 Hz), 7.56 (2H, d, J = 10.5 Hz), 7.62 (5H, m), 7.87

(1H, t), 8.58 (2H, d, J = 10.5). ^{13}C NMR ($CDCl_3$, 75 MHz, ppm) δ: 28.0, 43.3, 53.2, 65.1, 122.2, 124.9, 127.2, 127.3, 127.8, 136.4, 145.0, 155.2, 155.4, 167.3, 168.0, 171.7. HRMS calcd, for $C_{20}H_{19}N_3O_9S$ + H: 478.091 48; found: 478.092 51.

TGase expression and purification

TGase was obtained according to a previously published procedure developed in the group (8). Enzyme activity was determined using the hydroxamate assay (52).

Pre-equilibrium kinetics

A buffer solution containing MOPS (110 mmol/L), $CaCl_2$ (3.3 mmol/L), and EDTA (55 mmol/L) was adjusted to pH 7.0. The enzymatic solution was prepared by dissolving approximately 1.5 mg of lyophilized gTGase in 6 mL of buffer solution. Protein concentration was measured using the D_C Protein Assay from BioRad (Mississauga, Ontario) and verified to be approximately 0.25 mg/mL in all cases. Stock substrate solutions were prepared by dissolving a known quantity of compound **1**, **2**, or **3** into dry, degassed acetonitrile. All pre-equilibrium kinetic data were collected using a SX.18MV stopped-flow reaction analyser from Applied Photophysics (London, UK). Measurements for the single mixing stopped-flow method were taken at an absorption wavelength of 410 nm. The injection syringes were of 2.5 mL volume for the enzyme solutions and of 0.25 mL volume for the substrate solution, ensuring a 1:10 mixing ratio resulting in final concentrations of 100 mnol for MOPS, 3 mmol/L for $CaCl_2$, 50 μmol/L for EDTA, and 10% acetonitrile. The optical path within the cell was 10 mm. The temperature was kept at 25 °C using an Isotemp 1016P bath from Fisher Scientific. All kinetic runs were corrected for background absorption from the buffer and substrate solutions. Pre-steady state and initial steady state rates were measured by linear regression over time ranges up to and from the obvious inflection point to give a linear correlation of at least R^2 = 0.99. Finally, all runs were corrected for nonenzymatic background hydrolysis by subtracting from each the final slope of the value obtained in the control experiments in which no TGase was used. Ensuing Michaelis–Menten plots were fit to the standard hyperbolic equation. All linear and nonlinear regression was performed using Microcal™ Origin® 6.0 software from Microcal Software, Inc.

Nonenzymatic hydrolysis kinetics

All measurements were made using a UV–vis Cary Varian 100 Bio spectrophotometer and disposable polystyrene cells. Final conditions in each cuvette were MOPS (0.1 mol/L, pH 7), μ = 0.2 mol/L (KCl) and a variable quantity of either ethanethiol or cysteamine, ranging from 10 to 60 mmol/L. Reactions were initiated by adding 50 μL of a DMF solution of acyl-transfer reactant to 950 μL of buffered thiol solution, resulting in an initial reactant concn. of 0.13 mmol/L. The release of *p*-nitrophenol was followed at 410 nm and absorbance data were fitted to a monoexponential equation ($Abs_t = Abs_\infty(1 - \exp[-k_{obs}t])$). The extinction coefficient for *p*-nitrophenolate at 25 °C and pH 7 was determined experimentally to be 8040 $(mol/L)^{-1}$ cm^{-1} (22). Correction for background hydrolysis was obtained by simultaneously running control experiments in absence of nucleophile in a second cell, while using the dual beam function of the instrument.

Mass spectroscopy

A solution of TGase (5 μmol/L), **3** (25 mmol/L), $CaCl_2$ (3 mmol/L), and EDTA (50 μmol/L) in Tris buffer (0.1 mol/L, pH = 7.0) was incubated for 15 min at 25 °C. Aliquots were withdrawn and injected on an Agilent HPLC-MS (1100 series, MSD TOF) equipped with a Poroshell 300SP-C8 column and running a 0.35 mL/min flow rate acetonitrile gradient (0 min, 20%; 6 min, 100%; 7 min, 100%; 7.2 min, 20%; 12 min, 20%). Protein was detected after 4.74 min and deconvolution showed a m/z ratio of 78 890 Da for the inhibitor-free sample of His-tagged enzyme. For the sample obtained after incubation in the presence of inhibitor, m/z ratios of 79 229 Da (major) and 79 568 Da (minor) were found, consistent with the expected mass increase due to addition of the acyl moiety of **3**.

Acknowledgments

This work was supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada. CG and DL thank NSERC for postgraduate scholarships, and CG and JL thank the Fonds Québecois de Recherche sur la Nature et les Technologies (FQRNT) for postgraduate scholarships.

Comparison study of live cells by atomic force microscopy, confocal microscopy, and scanning electrochemical microscopy

Xiaocui Zhao, Nils O. Petersen, and Zhifeng Ding

Abstract: In this report, three kinds of scanning probe microscopy techniques, atomic force microscopy (AFM), confocal microscopy (CM), and scanning electrochemical microscopy (SECM), were used to study live cells in the physiological environment. Two model cell lines, CV-1 and COS-7, were studied. Time-lapse images were obtained with both contact and tapping mode AFM techniques. Cells were more easily scratched or moved by contact mode AFM than by tapping mode AFM. Detailed surface structures such as filamentous structures on the cell membrane can be obtained and easily discerned with tapping mode AFM. The toxicity of ferrocenemethanol (Fc) on live cells was studied by CM in reflection mode by recording the time-lapse images of controlled live cells and live cells with different Fc concentrations. No significant change in the morphology of cells was caused by Fc. Cells were imaged by SECM with Fc as the mediator at a biased potential of 0.35 V (vs. Ag/AgCl with a saturated KCl solution). Cells did not change visibly within 1 h, which indicated that SECM was a noninvasive technique and thus has a unique advantage for the study of soft cells, since the electrode scanned above the cells instead of in contact with them. Reactive oxygen species (ROS) generated by the cells were detected and images based on these chemical species were obtained. It is demonstrated that SECM can provide not only the topographical images but also the images related to the chemical or biochemical species released by the live cells.

Key words: live cells, atomic force microscopy, confocal microscopy, scanning electrochemical microscopy.

Résumé : Dans ce travail, on a utilisé trois techniques de microscopie avec sonde à balayage, la microscopie de force atomique (MFA), la microscopie confocale (MC) et la microscopie à balayage électrochimique (MBEC), pour étudier des cellules vivantes dans un environnement physiologique. Dans ces expériences, on a étudié deux lignées de cellules modèles, CV-1 et COS-7. On a obtenu des images par les techniques de MFA en modes de contact ainsi que de percussion. Les cellules peuvent être plus facilement rayées ou déplacées par le mode de contact de la MFA que par le mode de percussion de la MFA. En utilisant le mode de percussion de la MFA, on peut obtenir et facilement discerner des structures superficielles détaillées, telles des structures filamenteuses sur la membrane cellulaire. On a étudié la toxicité du ferrocèneméthanol (Fc) sur des cellules vivantes en faisant appel à la MC en mode de réflexion en enregistrant des images accélérées de cellules vivantes contrôlées et de cellules vivantes avec diverses concentrations de Fc. Le Fc n'a pas provoqué de changements dans la morphologie des cellules. On a obtenu des images de cellules à l'aide de la MBEC en présence de Fc à un potentiel polarisé de 0,35 V (vs. Ag/AgCl avec une solution saturée de KCl). Les cellules ne présentent pas de changements visibles après une heure, ce qui indique que la MBEC n'est pas une technique invasive et qu'elle présente un avantage unique pour l'étude des cellules molles puisque l'électrode effectue son balayage au-dessus des cellules plutôt que de les toucher. On a détecté que des espèces réactives à l'oxygène (EOR) sont générées par les cellules et on a obtenu des images sur la base de ces espèces chimiques. On a démontré que la MBEC peut non seulement fournir des images topographiques, mais aussi des images reliées aux espèces chimiques ou biochimiques qui sont générées par les cellules vivantes.

Mots-clés : cellules vivantes, microscopie de force atomique, microscopie confocale, microscopie à balayage électrochimique.

Introduction

The study of single live cells has received increasing attention recently. Among the many analytical methods, atomic force microscopy (AFM), confocal microscopy (CM), and scanning electrochemical microscopy (SECM) have become more and more important to study living cells under physiological conditions and can provide a lot of structural and related functional information (1–3). AFM can image the morphology of living cells because of its high

spatial resolution. The other major application of AFM is real time monitoring of morphological changes of live cells in response to intracellular and extracellular stimuli (4–7). CM provides optical information for focal planes inside cells without the use of fluorescent probes. However, AFM and CM cannot provide the desired chemical and biochemical information in cell metabolism processes, such as redox species moving across cell membranes or cell respiration. In contrast, the electrochemical method is now widely used to directly determine species, such as reactive oxygen species (ROS) (8–18) or nitric oxide (19, 20), released from cells by using a well-positioned ultramicroelectrode (UME) or a chemically modified UME. There are a couple of reasons for this. First, the electrode at a biased potential close to living cells can monitor the immediate ROS flux from the cells by recording the corresponding current under physiological conditions without disturbing the biological mechanisms. Second, different types of ROS species can be identified by the amperometry method at different electrode potentials (18). Therefore, high selectivity can be obtained during the detection process. To position the electrode well and get images based on the detected chemical and biochemical information, the SECM technique has been developed (21). SECM involves the measurement of electrochemically active species with an UME when it is positioned above or moved across the cell surface. Since the electrochemical current is proportional to the concentration of a redox species in solution, any change in the chemical activities disturbs the electrochemical response of the electrode. This perturbation provides information on cellular functions and cellular topographies. More recently, SECM has become an important tool to study live cells because it can provide chemical or biochemical information about their metabolism (22–33). It has been used for measuring photosynthetic electron transport (22) and effects induced by cadmium (29) in single guard cells; for monitoring the oxygen consumption of single bovine embryos (23); for studying the toxicity of menadione on hepatocytes and detection of efflux of thiodione from isolated cells after menadione-induced oxidative stress (24); for imaging and real time detection of morphological changes of neuron cells before and after exposure to nerve growth factor (25); for high-resolution imaging of model neurons obtained with constant distance mode SECM (26); and for investigating the pathway of transmembrane charge transfer in nonmetastatic and metastatic human breast cells (27) and in bacteria (28). Our group has previously shown that SECM can be used to study the effect of Cd induced stress on single stomata in Brassica juncea (29). We found that plants treated with $CdCl_2$ (0.20 mmol/L) had lower stomatal density and larger stoma size compared with control plants, and that oxygen evolution above individual stomatal complexes in Cd-treated plants was lower than that from control plants.

In this report, time-lapse cell images were obtained with AFM, CM, and SECM. ROS profiles were mapped above COS-7 live cells, which are redox species released by living cells and include hydrogen peroxide, hydroxyl radicals, and superoxide anions. ROS are generated within the cells as by-products of biological oxidations and of cellular respiration (34). We demonstrated that SECM can provide not only topographical but also chemical information in contrast to AFM and CM.

Experimental section

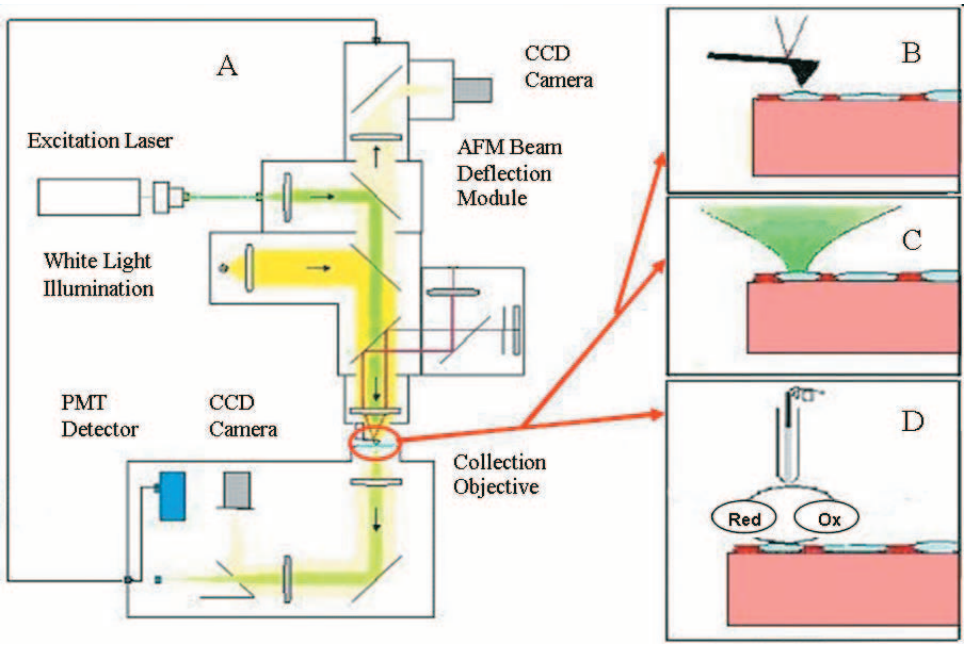
Chemicals

Ferrocenemethanol (Fc, 97%, Sigma-Aldrich, Mississauga, Ontario) stock solution was prepared at a concentration of 0.90 mmol/L. Culture media, serum, antibiotics, and glutamine were purchased from Gibco (Invitrogen Canada Inc., Burlington, Ontario). Deionized water (Milli-Q, Millipore, Bedford, Massachusetts, 18.2 MΩ resistivity) was used to prepare all aqueous solutions.

Cell culture

CV-1 and COS-7 cells (American Type Culture Collection, ATCC, Manassas, Virginia) (35) were used in the experiments. Both CV-1 and COS-7 cells were cultured in Eagle Minimum Essential Medium (EMEM) (Gibco) with 10% fetal bovin serum (FBS) (Gibco), 100 U/mL penicillin G, and streptomycin (Gibco), 2 mmol/L glutamine (Gibco) at 37 °C in a humidified atmosphere with 5% CO_2. One day before each experiment, cells were subcultured onto a Petri dish with a transparent glass bottom (MatTek Corporation, Ashland, USA). Before AFM and CM experiments, the red growth media was replaced with transparent Opti-MEMI media (modified EMEM media without phenol red) (Gibco) with 10 mmol/L Hepes buffer solution (Gibco) to see the cells clearly under the inverted microscopy. For SECM experiments, Opti-MEMI medium was used as the medium with 0.45 mmol/L ferrocenemethanol.

Experimental setup



All AFM, CM, and SECM images were recorded by the same instrument, an Alpha-SNOM (WITec, Ulm, Germany), which uses a closed loop scanning system.

The experimental setup for AFM is shown in Figs. 1A and 1B. Both contact mode and tapping mode AFM were used to image cells in the culture media. Silicon nitride cantilevers with a spring constant of 0.20 N/m were used in the experiments for contact mode and tapping mode AFM imaging. In tapping mode AFM, the AC mode end cap was used, which constrained a piezo transducer to oscillate the cantilever at its mechanical resonance. The oscillation amplitude of the cantilever was used as a feedback signal to measure topographic variations of the sample. This resulted in a topography image. Another type of image, a phase image, was also recorded by monitoring the phase between excitation (the free cantilever oscillation) and cantilever motion. Before scanning, a resonance frequency was selected automatically by performing a frequency sweep in the desired range. A resonant frequency of about 26 kHz with amplitude of 0.20 V was obtained in the cell culture medium by applying a 0.20 V potential to a piezo transducer for cantilever oscillation. The resolution in the Z direction of AFM is 4 Å. The lateral resolution depends on the AFM tip used in the experiment. For example, if the tip radius of curvature is about 5 nm, the lateral resolution of AFM will be about 10 nm.

The experimental setup for CM is shown in Figs. 1A and 1C. Reflection confocal images were obtained using the same instrument with a 488 nm Argon laser (Coherent Inc., Santa Clara, California) as the light source. The illumination power of the laser was adjusted to about 2 mW. The laser

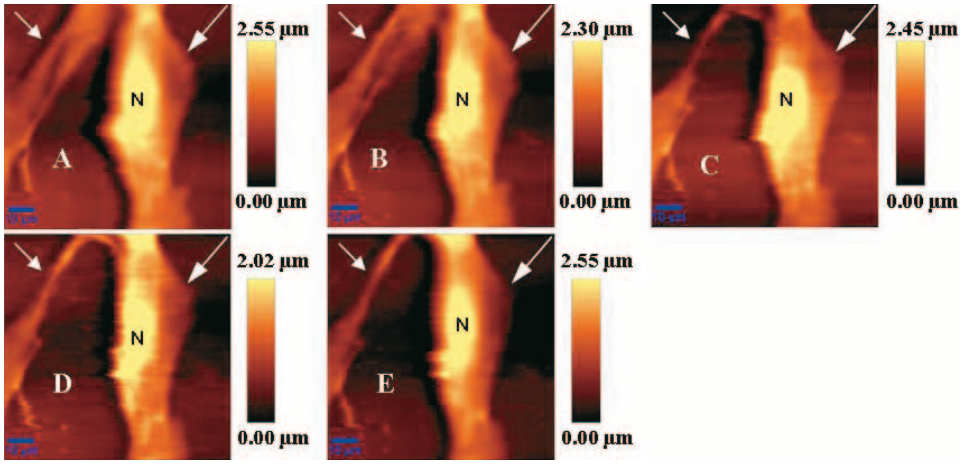
beam was fed into the CM with a 4 µm diameter optical fibre. The reflected light from the cells was collected by a multi-mode optical fibre with a diameter of 50 µm, which served as a pinhole for CM, and was then transmitted to a photomultiplier tube (PMT, Hamamatsu, Japan). Different optical density filters were used to attenuate the laser intensity and to keep minimal laser intensity on the cells to avoid unnecessary photobleaching. The reflective light intensity was kept under 1000 counts to prevent the photobleaching effect and enhance the sensitivity of CM. To obtain high-resolution images, we used a 60× water immersion objective lens (Nikon, Mississauga, Canada) with a numerical aperture of 1 and a long working distance of 2 mm. In every experiment, focal planes of cells were selected in the middle plane through the cells. The lateral resolution for CM is about 200 nm and the vertical resolution is about 500 nm.

The SECM instrument was modified from Alpha-SNOM by replacing the objective with an electrode holder and a custom-made Pt (2.0 µm diameter) electrode (29, 36) (Fig. 1, A and D). The electrochemical signal (current signal) was fed into one data acquisition channel of the Alpha-SNOM instrument. All the electrochemical experiments were performed with an electrochemical analyser (CH 832a, CH Instruments, Austin, Texas). The electrochemical system consisted of two electrodes. A 2.0 µm Pt was used as the working electrode and a Ag/AgCl electrode, with a saturated KCl solution, was used as both the reference and the counter electrode. In the experiments, the SECM electrode was brought closer to the cells and positioned at a desired height with a certain applied potential while the current was monitored. The probe approach curve (current vs. distance curve) was then plotted. At a fixed height, the working electrode was scanned in a plane with an applied potential by moving the scanning stage. Constant height SECM images can be obtained by recording current vs. lateral coordinates in the scanning plane. The scanning area can be repeatedly scanned because of the closed loop system. For SECM, the resolution is about 2 µm because a 2.0 µm diameter electrode is used in the experiment. The whole scanning process (the movement of scanning stage and the plot of image) was controlled by the WITec software adapted from CM mode.

Results and discussion



Contact mode and tapping mode AFM images of CV-1 live cells

Figure 2 shows time-lapse cell images taken within a 1 h period with contact mode AFM. The same scanning region was scanned repeatedly with the closed loop scanning system. In the image, a nucleus (labelled N) and two branches (labelled with arrows) were observed (Fig. 2A). As AFM scanning continued, the right branch (large arrow) became fuzzy (Fig. 2B), and cells began to shrink in size (Fig. 2C). The left branch (small arrow) became narrower and shrunk significantly, as can be seen from the connection between the branch and the nuclus (Fig. 2D). At the end, the left branch became a line and the height of this branch increased in the last scan (Fig. 2E) because of the injuries to the cell membranes that resulted in a rounding of the cell. The cell body became smaller and smaller. From the height level bars beside the topography images, we determined that the height of the cells changed from 2.02 µm to 2.55 µm. This evidence supported the fact that the cells were becoming rounded.

Using contact mode AFM, we can clearly see the cell membrane and nuclei (Fig. 2) under physiological conditions. However, cells were easily injured by the AFM tip because the tip was in physical contact with the cells (1). The spring constant of the cantilever used in the experiments was

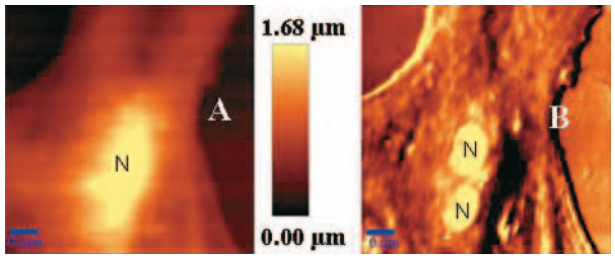
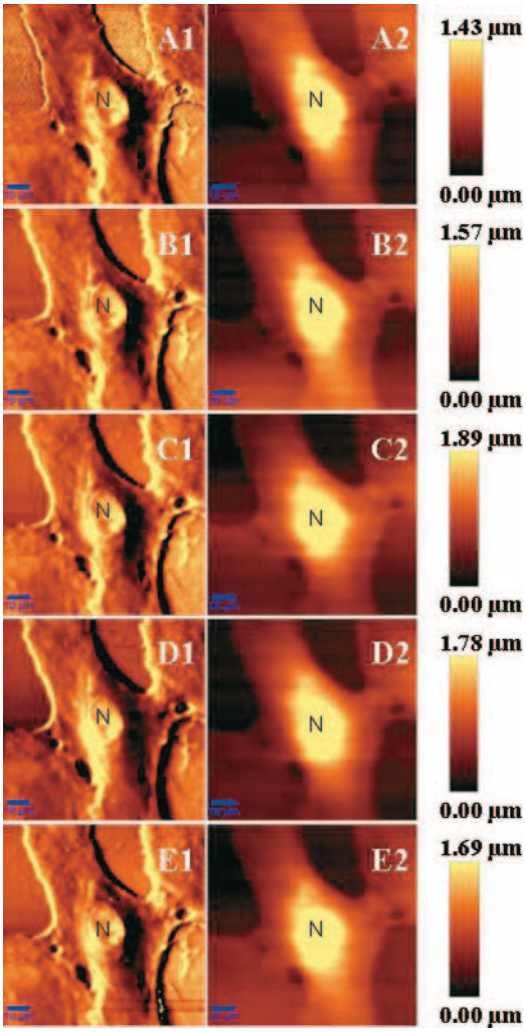
Fig. 2. Time-lapse contact mode AFM images of CV-1 cells. Images were obtained (A) 20 min, (B) 30 min, (C) 40 min, (C) 50 min (D), and (E) 60 min after cells were taken out of the incubator. The scale bars in the images represent 10 μm. The scan rate is 1 s/line (256 lines/image). The acquisition time for every image is about 5 min. N, large arrow, and small arrow indicate the nucleus, right branch, and left branch, respectively.



0.20 N/m. However, the average spring constant of cells is 0.0020 N/m (37, 38), which is one hundredth of that of our cantilever. When the tip scans over the soft cells, plasma membranes may be deformed or the tip might penetrate through the membrane (39). This may cause irreversible injury to the cell that eventually leads to cell death. The injured cell may become vulnerable and loosely attached to the substrate. You et al. (40) studied the disruptive effect of the cantilever tip on cell morphology using AV 12 and SK-N-SH cells, and they found that the extracellular matrix could be removed and the adhesion ability of cells could be degraded after several scans. In this way cells were injured, rounded up, and decreased in size (40). A less harmful imaging method should be used to image soft cells.

Tapping mode AFM, in which the tip is intermittently in contact with cells, was applied to image soft cells under physiological conditions. Both a topography image (Fig. 3A) and a phase image (Fig. 3B) were recorded. Two bright zones corresponding to the nucleus areas (N) surrounded by relatively flat membranes are shown (Fig. 3B). Long filamentous structures (bundles of stress fibers) or cytoskeleton elements, which were heterogeneous in distribution and organization over the cell membranes, can be easily seen (Fig. 3B). However, the filamentous structures of the cells were not detectable in topography images (Fig. 3A) because of the height of the cell (1.68 μm), which contributed to a large contrast between the high nucleus and flat membrane. The two nuclei cannot be distinguished either. Only one large nuclear area (N) can be seen in the topography image. The filamentous structures of the CV-1 cells were also imaged based on deflection signals and could not be revealed in images based on amplitude signals with tapping mode AFM (41). This phenomenon has been explained as resulting from the higher sensitivity of deflection signals to local stiffness of cells because the stiffness of cytoskeleton elements was higher than that of the plasma membrane of cells (41).



Time-lapse images of CV-1 cells were also recorded with tapping mode AFM. The same scanning region was repeatedly scanned with the closed loop scanning system. The images on the left side panels are phase images (Fig. 4, A1–E1). The images on the right side panels are topography images (Fig. 4, A2–E2) of the same areas. One nucleus (N) and the boundaries of three cells were obviously apparent in the phase images. As can be seen from Fig. 4, the images were almost the same except for a slight change in the cell–cell boundary within a 1 h scanning period. Cell–cell interaction was not disrupted and cells were not moved by the tip, in contrast to what happened in contact mode AFM. This is because in tapping mode AFM the tip was in contact with the cells only for a short time and then lifted up. Therefore, the lateral forces were drastically reduced and this mode was much more suitable for imaging live cells. It is important to note that the image A1 in Fig. 4 seemed obscure just after scanning over the nucleus. Cellular materials such as cellular debris, metabolic products, or cellular secretion, may be adsorbed at the apex of the scanning tip resulting in a slightly lower resolution (1). The vertical movements of cells also can be measured from the topography images (Fig. 4, A2–E2). The highest part of the cells was 1.43 μm in the first image (Fig. 4, A2). In the following scan, the cells moved up and the height was 1.57 μm (Fig. 4, B2). The cells continued to move up in the next two runs and the heights were 1.78 (Fig. 4, C2) and 1.89 μm (Fig. 4, D2), respectively. In the last scan, the cells moved down and the height of the cells

Fig. 4. Time-lapse tapping mode AFM images of CV-1 cells. Images were obtained (A1) and (A2) 20 min, (B1) and (B2) 30min, (C1) and (C2) 40 min, (D1) and (D2) 50 min, and (E1) and (E2) 60 min after cells were taken from the incubator. The scale bars in the images represent 10 µm. The scan rate is 1 s/line (256 lines/ image). The acquisition time for every image is about 5 min. N indicates the nucleus area.

decreased to 1.69 µm (Fig. 4, E2). During the cell movement process, the total change in height was 0.31 µm. This submicro movement can be accurately detected by AFM. The advantages of AFM, i.e., spatial high resolution and high sensitivity, were again demonstrated here.

Reflection CM images of COS-7 cells

In our experiments, the external surface changes of unstained live cells within a 1 h period were visualized by CM in reflection mode. The same area was repeatedly imaged, using the closed loop scanning stage. As can be seen from Fig. 5, the membrane and nucleus of an individual COS-7 cell were clearly imaged. The morphology of the cell did not change dramatically. Small changes at the cell edge might be due to the slow movement of the cell. We can conclude that cells can survive and are still healthy under weak laser illumination.

The toxicity of ferrocenemethanol (a widely used redox mediator in electrochemistry) on live cells was studied with CM. After one image of a cell was recorded (Fig. 6A), a certain amount of ferrocenemethanol was added to the Petri dish and was well mixed with the culture medium by using a micropipette. Time-lapse images were recorded in the same region as for images without ferrocenemethanol. Images of cells were obtained with dosages of ferrocenemethanol at different concentrations ranging from 1 to 450 µmol/L. Figure 6 shows cell images using 450 µmol/L of ferrocenemethanol. As seen in the images, there was almost no change in the shape or size of cells indicating that ferrocenemethanol caused almost no morphology changes. To confirm this conclusion, cells were split among a dozen petri dishes with the same density. Half of these cells were used as control cells. The other half were cultured in the culture medium for one day and the culture medium was replaced with ferrocenemethanol at various concentrations. The cells were then incubated overnight. The number of cells was counted and the shapes of cells were observed under the 60× objective. The number of cells detected after ferrocenemethanol treatment was almost the same as the number of control cells. The shapes of cells treated with ferrocenemethanol were similar to those of the control cells.

One of the advantages of CM, using fluorescence as the detection signal, is the ability to take optical slices through a three dimensional specimen, e.g., cells or tissues, and produce an image containing information from each of the focal planes (3, 42). Without labelling, a single COS-7 cell was imaged at different focus planes using reflection CM. By putting these focus planes together, a three-dimensional image of the cell was obtained that contained all the information from all the focus planes of the cell. Normally, COS-7 cells are about 5 µm in height, while CV-1 cells are just 2 µm high. Some cell lines are even higher. For example, PC12 cells are about 7 µm in height (43). To acquire focal plane images from the top and bottom of the cell, a total depth of 7 µm was scanned in our experiments by recording 15 stack images with a 500 nm depth difference between two successive images. As seen in Fig. 7, different images from different focal planes of the cell were obtained. Image 1 of Fig. 7 is from the highest focal plane through the cell. The edge of the cell can be clearly seen and the nucleus is shown in the brightest region. In sequence, the objective was moved 500 nm down to obtain image 2 in Fig. 7 as the second highest focal plane through the cell. In this image, the size and shape of the cell was the same as that in image 1, but the nuclear region became less bright and more obvious. In the following runs, the nuclear region became darker and was easily discerned in the images. Finally, by putting all 15 images together, a three-dimensional image of the cell can be obtained (Fig. 7, image 16).

Cyclic voltammetry and SECM approach curve to live cells

Cyclic voltammetry (CV) was carried out using a 2.0 µm diameter Pt electrode as a working electrode and a Ag/AgCl electrode as both reference and counter electrode. A detailed fabrication of the ultramicroelectrodes (UME) (2.0 µm Pt) was described previously (29, 36). A solution of 0.90 mmol/L ferrocenemethanol was used to test the electro-

Fig. 5. Time-lapse images of COS-7 cells with confocal microscopy within 1 hour. Integration time, 0.005 s; Pixel, 256 56. Images were obtained (A) 11 min; (B) 20 min; (C) 29 min; (D) 38 min; (E) 54 min and (F) 61 min after cells were taken from the incubator. The scale bars in the images represent 9 µm. The acquisition time for every image is about 6 min.

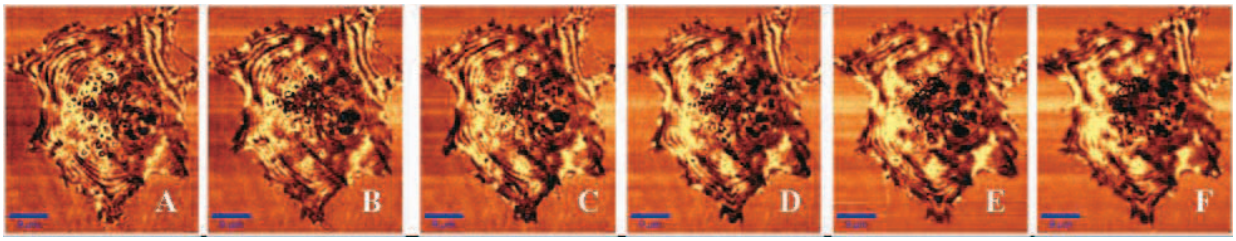

Fig. 6. Cell images of COS-7 cells with confocal microscopy (A) before adding ferrocenemethanol, (B) 9 min, (C) 17 min, (D) 32 min, and (E) 62 min after adding 450 µmol/L ferrocenemethanol. The scale bars in the images represent 8 µm. Integration time: 0.005 s; pixels: 256 × 256. The acquisition time for every image is about 6 min.

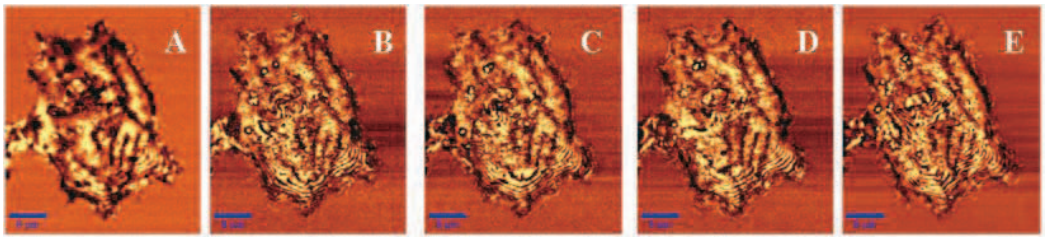

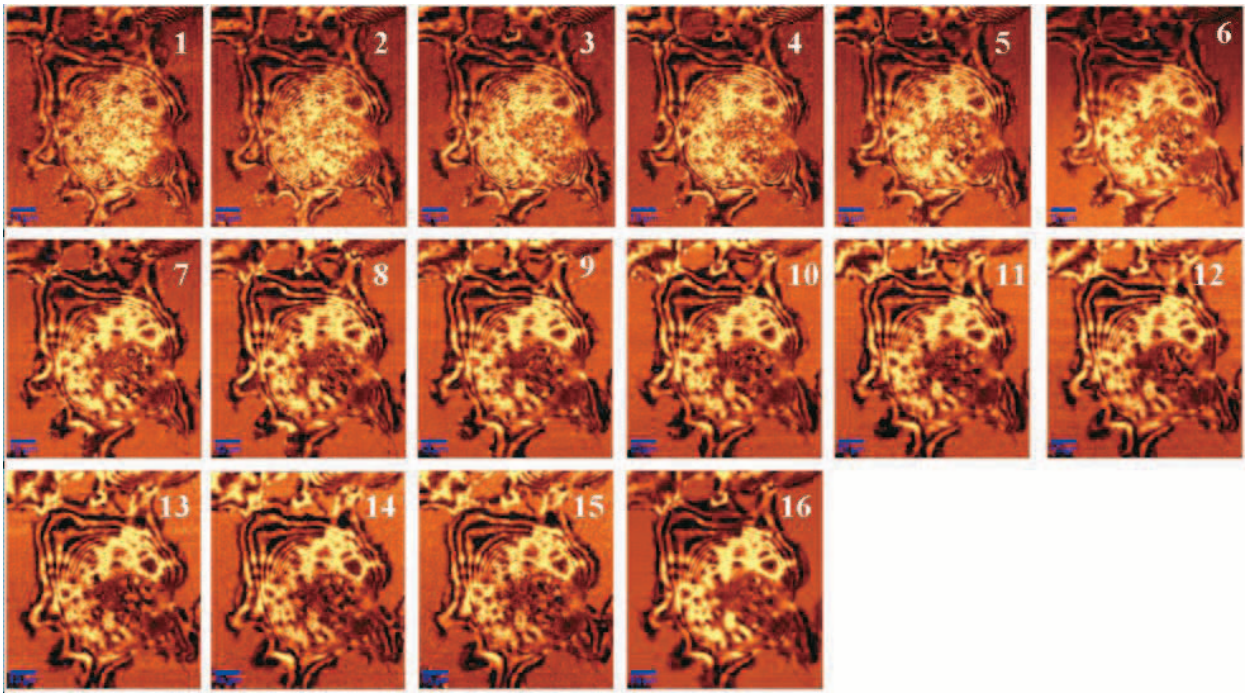

Fig. 7. Stack of 15 images (1–15) of COS-7 cells using confocal microscopy with a depth of 500 nm between consecutive images and a three-dimensional image (image 16) formed by overlapping 15 images (from image 1 to image 15) together. The scale bars in the images represent 10 µm. Integration time: 0.005 s; pixels: 128 × 128. The acquisition time for every image is about 1 min.

chemical behaviour of the electrode (Fig. 8A). A steady state current of 0.29 nA was obtained. The effective radius, a, (36) of the electrode can be calculated with this steady state current by using eq. [1],

$$[1] \qquad a = i_{T,\infty}/4nFDC^0$$

where $i_{T,\infty}$ is the steady state current of the electrode, n is the number of electrons transferred, F is Faraday constant, D, and C^0 are the diffusion coefficient and concentration of ferrocenemethanol. The diffusion coefficient used was 7.8×10^{-6} cm^2/s (44). The calculated value of the electrode radius was 1.1 µm, which was very close to the value of 1.0 µm in the specification that the manufacturer provided to us (Goodfellow Corporation, Devon, Pennsylvania).

After positioning the working electrode above the nucleus of one cell, the electrode with a biased potential of 0.35 V

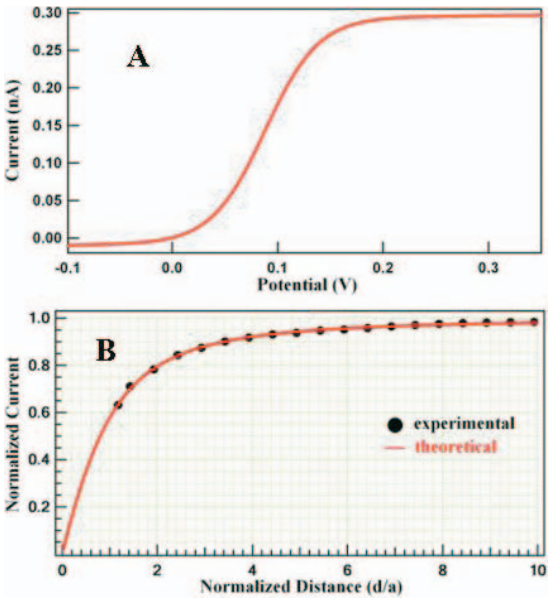
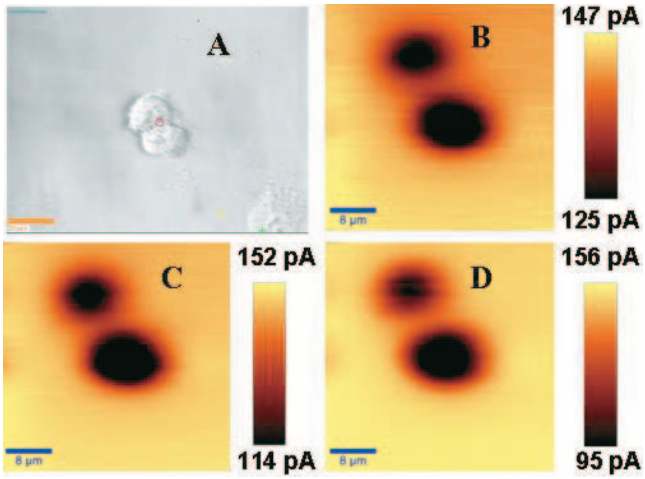
Fig. 8. (A) Cyclic voltammogram (scan rate 0.01 V/s) and (B) probe approach curve to a cell nucleus in 0.90 mmol/L ferrocenemethanol solution with a 2.0 µm diameter electrode for RG = 5.





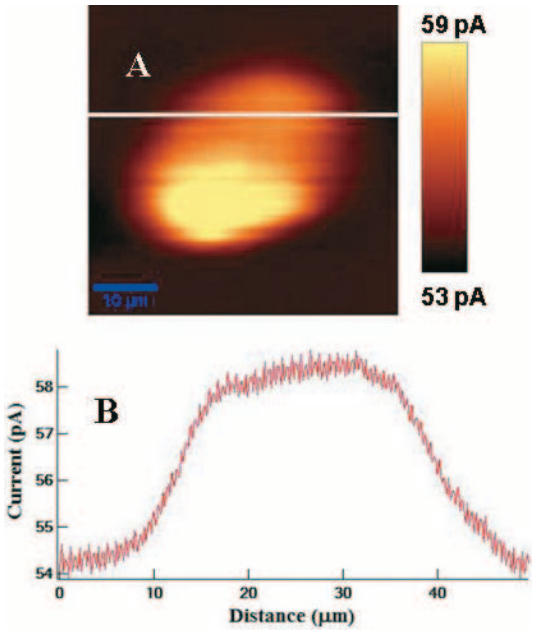


Fig. 9. (A) Optical picture of COS-7 cells subsequently imaged by SECM. Time-lapse SECM images (40 µm × 40 µm) of COS-7 cells after (B) 28 min, (C) 41 min, and (D) 54 min after cells were moved from an incubator with a 2.0 µm diameter electrode for RG = 5 at a biased potential of 0.35 V (vs. Ag/AgCl). Ferrocenemethanol concentration was 0.45 mmol/L. The distance between the electrode and the cell is about 2.0 µm (normalized current = 0.8). The scale bars in the images represent 8 µm. Integration time at each image pixel: 0.01 s; pixels: 256 × 256. The acquisition time for every image is about 12 min.

was slowly moved downward and the diffusion-limiting current of ferrocenemethanol oxidation was monitored. When the electrode was far from the cells, a constant current was obtained because of the hemispherical diffusion of ferrocenemethanol at a constant concentration of 0.90 mmol/L. The current decreased as the electrode was moved toward the cell because the hemispherical diffusion of ferrocenemethanol from solution to the electrode was partially blocked by the cell and so-called negative feedback was obtained. The electrode was stopped until the normalized current (the ratio of actual tip current, i_T, to the steady state current when the electrode is far away from the cell, $i_{T,\infty}$) was about 0.60. A theoretical probe approach curve (PAC) was plotted with the experimental one (Fig. 8B) (45), and the two matched very well. When the electrode was stopped at a normalized current of about 0.8 or 0.6, the distance between the electrode and cells was about 2.0 or 1.2 µm, which can be read from the theoretical PAC (36, 45).

Fig. 10. (A) SECM image at a biased potential of –0.80 V (vs. Ag/AgCl) with a 2.0 µm diameter electrode for RG = 5. The distance between the electrode and the cell is about 1.7 µm (normalized current = 0.75). The scale bars in the images represent 10 µm. Integration time at each image pixel: 0.01 s; pixels: 256×256. The acquisition time for every image is about 12 min. (B) Trace obtained by plotting a white horizontal line in image A.

Time-lapse SECM images

Cell topographies at different times were also recorded with SECM within a 1 h period using ferrocenemethanol (0.45 mmol/L) as the mediator. First, the cells of interest were located with the aid of an objective (Fig. 9A). The electrode was positioned above one cell and was moved toward the cell until the distance between the electrode and the cell nucleus was about 2.0 µm (normalized current = 0.8) with a biased potential of 0.35 V applied to the probe. With this biased potential, cells were scanned slowly (integration time at each image pixel is 0.01 s). The acquisition time for every image is about 12 min with 256 × 256 pixels. Since the cells blocked the ferrocenemethanol diffusing to the electrode, oxidization current decreased while the electrode was scanned over the cell and the negative feedback was obtained. Two cells were shown as two holes in the images.

© 2007 NRC Canada

Dark areas represented low current and bright areas corresponded to high current (Figs. 9B, 9C, and 9D). Nuclei (dark area) and part of the membranes (brown area) can be seen. Within 1 h the cell did not change because the tip scanned above the cells without touching them, which demonstrated that SECM was a noninvasive technique and had a unique advantage for study of soft cells.

Detection of ROS released by cells with SECM

At normal concentrations, ROS are essential to cells because of the important functions that they perform. However at elevated concentrations, ROS are harmful because they can damage key macromolecules, such as nucleic acids, proteins, and lipids, and ultimately cause cell death (34). Arbaults et al. (13) detected the immediate burst of ROS using amperometric detection with a platinized carbon fiber microelectrode by puncturing the cell cytoplasmic membrane with the microelectrode. Matsue's group also detected ROS release with electrochemical methods and the chemiluminescence method using phorbol myristate acetate (PMA) differentiated cells (14).

In our experiments, the working electrode was positioned about 1.7 μm (normalized current of 0.75) above the nucleus of the living COS-7 cells using oxygen as the mediator with a biased potential of –0.80 V, at which O_2 is reduced (eq. [2]).

$$[2] \qquad O_2 + 4e^- + 2H_2O \rightarrow 4OH^- \qquad \text{(eq. [2])}$$

At the same height, the electrode was scanned above the cell. A more negative feedback should be obtained if there were no species released by the living cells for the following two reasons (29): (*i*) cell respiration consumed O_2 and contributed to a lower concentration of O_2; (*ii*) the O_2 diffusion blockage also resulted in the decreased concentration of O_2. However, a positive feedback was observed and cells were shown as bumps instead of holes in the SECM image (Fig. 10A) as a result of increased current (Fig. 10B). ROS should have been generated by cells and diffused to the tip surface and reduced at the tip, which resulted in the increased current. ROS, such as superoxide ($O_2^{\cdot-}$), hydroxyl radicals ($OH^{\cdot-}$), and hydrogen peroxide are easier to reduce than oxygen. They were all reduced at the applied potential –0.80 V. The current observed represents the total concentrations of these species. Further study of this aspect is in progress in our lab. Note that Amatore's group (18) observed the ROS release from macrophages through the oxidation of these species. It also can be seen from image 10A and curve 10B that the current monitored above the cell nucleus is more positive than the current recorded above cell membranes. A higher concentration of ROS would contribute to a higher current. Two factors may contribute to this observation. First, as is well-known, the cell nucleus is higher than the cell membrane. Therefore, the distance between the electrode and cell nucleus is smaller than the distance between the electrode and cell membranes with the constant height SECM method. ROS are very active and if the electrode is not close enough to the cells some radicals such as hydroxyl or superoxide anion radicals can react with chemicals in the solution before diffusing to the surface of the electrode and will not be detected, giving a relatively low current. However when the electrode is closer to the cells, the ROS generated by cells can easily diffuse to the electrode and be monitored by the electrode. Another reason may be that the region near the nucleus of the cell may release more ROS than the membrane region.

Conclusions

We have used both contact and tapping mode AFM to image the topography of living cells. Nuclei and flat membranes can be readily identified by contact mode AFM under physiological conditions. However, cells were easily damaged or moved by the tip with time because the cells are a hundred times softer than the cantilever. Using nondestructive tapping mode AFM, high-resolution images were obtained. It was possible to image subcellular structures, e.g., filamentous structures and cytoskeletal structures. Cells were less damaged, but image clarity deteriorated with time as a result of debris on the cantilever tip from cellular material (1). The time-lapse images of living cells revealed that the tapping mode was more suitable for imaging live cells than contact mode. However, AFM provided only topographic information, not information about biochemical and biological reactions taken place in the cells (1).

With CM, the detailed structure and shape of cells were observed. There were few changes of cell shapes beyond slight movements of cell edges. Time-lapse images changed slightly as a result of water evaporation. Cell morphology changed very little with ferrocenemethanol treatment over several hours, indicating that ferrocenemethanol does not cause much change in cell morphology. Its use as a redox mediator in the subsequent SECM experiments may therefore be acceptable. One of the advantages of CM, the optical slicing of the cells, was demonstrated by scanning 15 images taken at different heights of the cell, with a 500 nm height difference between two adjacent focal planes. A three-dimensional image was reconstructed from the images obtained at these different focal planes.

Real time changes in cell morphology were imaged and monitored by constant height mode SECM with ferrocenemethanol as the mediator. The nucleus and membrane were visible when the tip was lowered until a normalized current of 0.8 was obtained. Cell morphology did not change with time because the tip was scanned above the cells without touching them. ROS generated by the cells were detected and images based on this chemical signal were obtained. The advantage of SECM, such as providing images based on chemical or biochemical information (detection of species released or consumed by the cells, respiration and photosynthesis, and transmembrane electron transfer) about cells was clearly demonstrated.

Zirconium(IV) chloride-catalyzed synthesis of 1,5-benzodiazepine derivatives

K. Srinivasa Reddy, Ch. Venkateshwar Reddy, M. Mahesh, K. Rosi Reddy, P.V.K. Raju, and V.V. Narayana Reddy

Abstract: Zirconium tetrachloride efficiently catalyzes the cyclocondensation reaction of *o*-phenylenediamine and a ketone in refluxing 1,2-dichloroethane to afford the corresponding 2,3-dihydro-1*H*-1,5-benzodiazepine in high yield. The formation of specific regioisomers and their structural elucidation are reported for the first time.

Key words: zirconium tetrachloride, *o*-phenylenediamines, ketones, 1,5-benzodiazepines, ^{1}H NMR, regioisomers.

Résumé : Le tétrachlorure de zirconium catalyse d'une façon efficace la réaction de cyclocondensation de l'*o*-phénylènediamine avec les cétones, dans du 1,2-dichloroéthane au reflux, pour conduire à la formation des 2,3-dihydro-1*H*-1,5-benzodiazépines, avec un rendement élevé. On rapporte pour la première fois la formation de régioisomères spécifiques ainsi que l'élucidation de leurs structures.

Mots-clés : tétrachlorure de zirconium, *o*-phénylènediamines, cétones, 1,5-benzodiazépines, RMN du ^{1}H, régioisomères.

[Traduit par la Rédaction]

Introduction

Benzodiazepines are important pharmaceutical compounds that are frequently used as prescribed drugs for combating central nervous system (CNS)-related diseases mainly because of their anticonvulsant, hypnotic, and other properties (1, 2). They are also used as intermediates in the manufacture of commercially important cationic dyes for acrylic fibers (3) and also used as starting materials for the preparation of fused ring compounds such as triazolo- (4), oxadiazolo- (5), oxazino- (6), or furano-benzodiazepines (7). More interestingly, the related diazapines showed unusual and novel pharmacological activity as HIV-1 reverse transcriptase inhibitors, as evidenced by niverperin (8). Because of their versatile biological activity and commercial utility, the synthesis of these compounds has acquired greater attention in synthetic organic chemistry and led to the development of new synthetic strategies. Generally, these compounds are prepared by cyclocondensation of *o*-phenylenediamine with α,β-unsaturated carbonyl compounds (9), β-haloketones (10), or ketones, involving combinations of Lewis acids and transition-metal salts like BF_3-etherate (11), $NaBH_4$ (12), polyphosphoric acid or (SiO_2) (13), $MgO/POCl_3$ (14), $Yb(OTf)_3$ (15), and Al_2O_3/P_2O_5 under microwave conditions (16). However, many of these methods suffer from drawbacks, such as drastic reaction conditions, cumbersome workup procedures, low yields, and co-occurrence of several side reactions. Therefore, there is still a need to develop new catalytic methods for the synthesis of these biologically active compounds.

Recently, zirconium(IV) chloride has received considerable attention as an efficient Lewis acid catalyst for various organic transformations such as Biginelli's reaction (17), electrophilic amination of activated arenes (18), thioacetylation of acetals, (19) deoxygenation of heterocyclic-*N*-oxides (20), reduction of nitro-compounds (21), and conversion of carbonyl compounds to 1,3-oxathiolanes (22). To continue our interest in zirconium(IV) chloride as a catalyst for novel synthetic methodologies (17, 23), we envisaged its use and effect in the cyclocondensation of ketones with *o*-phenylenediamine.

Results and discussion

In this paper, we wish to present the results of a facile one-pot method for the synthesis of 1,5-benzodiazepines catalysed by $ZrCl_4$,and also to report, for the first time, the unequivocal structure elucidation of the regioisomers formed in this reaction. Typically, 5 mmols of *o*-phenylenediamine were reacted with 10 mmols of ketone in 1,2-dichloroethane under refluxing condition for 30–180 min (Scheme 1). The cyclocondensation is catalyzed by 10 mol% of $ZrCl_4$ to afford the corresponding 1,5-benzodiazepine derivatives in good to excellent yields. The effects of different solvents such as acetonitrile, tetrahydrofuran, ethanol, dichloromethane, and 1,2-dichloroethane on the yield of 1,5-benzodiazepine in presence of 10 mol% of catalyst was studied, and it was observed that 1,2-dichloroethane was the solvent of choice in terms of yield and reaction time. Regarding the optimum quantity of the catalyst, it was found that 10 mol% of $ZrCl_4$ is necessary to promote the reaction. However, no reaction was observed in the absence of the catalyst,

even after prolonged reaction time (>18 h), under the present reaction conditions.

Optimizing the reaction conditions, we extended this procedure to a number of 1,5-bezodiazepine derivatives, using $ZrCl_4$ (10 mol%) in 1,2-dichloroethane at reflux temperature. The results summarized in Table 1 indicate the scope and generality of the reaction with respect to the examples described therein. As shown in Table 1, the reaction of acetone with *o*-phenylenediamine in the presence of $ZrCl_4$ afforded 2,2,4-trimethyl-2,3-dihydro-1*H*-benzodiazepine (Table 1, entry 7) in 96% yield. Acetophenone reacted with *o*-phenylenediamine under similar reaction conditions to yield 2-methyl-2,4-diphenyl-2,3-dihydro-1,5-bezodiazepine (Table 1, entry 1) in 90% yield. The cyclocondensation of *o*-phenylenediamine with *para*-substituted acetophenones and aliphatic ketones afforded the corresponding 1,5-benzodiazepine derivatives in good yields (88%–97%), indicating that the substitution on a ketone substrate has little effect on the yield (Table 1, **3a–i**). The cyclocondensation reaction may be proceeding via an intramolecular imine–enamine cyclization, promoted by $ZrCl_4$, as depicted in Scheme 2 (13). It may be presumed that the carbonyl group of the ketone coordinates with $ZrCl_4$, forming a complex **C** (17) for which we have no evidence, yet its formulation seems reasonable. The amine of *o*-phenylenediamine attacks the carbonyl group of the ketone, giving the intermediate dimine **A**. Then, 1,3-shift of the hydrogen attached to the methyl group occurs to form an isomeric enamine **B**, which on cyclization affords the seven-membered ring.

4-Substituted *o*-phenelenediamines were reacted with acetone, as well as acetophenone, to give the corresponding 1,5-benzodiazapine derivatives. Although the formation of 7- or 8-substituted 1,5-benzodiazepines from the corresponding 4-substituted *o*-phenylenediamines (e.g., 4-chloro, 4-nitro, 4-methyl, and 4-benzoyl) and acetone, acetophenone, or cyclohexanone was previously reported, the structure confirmation of the products has not been reported, and there exists ambiguity of the regioisomers (24). Similar to this is the case of the formation of a mixture of regioisomers in the ratio of 60:40, corresponding to 7- and 8- substituted 1,5-benzodiazapine derivatives obtained from 4-chloro and 4-benzoyl *o*-phenolenediamines and acetone (25). At this point, it is noteworthy to mention that the $ZrCl_4$-catalyzed reaction between 4-nitro, 4-methoxy *o*-phenylenediamine and the acetophenone derivative led to the formation of specific regioisomer in good yields (**3m–q**). The formation of regioisomers is in accordance with the mechanism (Scheme 2) proposed by Jung and co-workers (13), in which the intramolecular imine–enamine cyclization is favored by the presence of an electron-withdrawing group (NO_2) *para* to imine moiety, and *para* to enamine moiety in case of an electron-donating group (OCH_3). The intermediate formed in this reaction does not require the activation of amino-functionality, and as a result, the electronic nature of the substituent may not have significant effect on the yield; however, it affected the nature of cyclization, leading to the formation of specific regioisomers. We report detailed structural elucidation of the regioisomers (**3m–q**), using ^{1}H NMR spectroscopic data and the chemical shifts of the diagnostic protons along with the coupling constants, in Table 2 for the first time.

In 2-methyl-7-nitro-2,4-di(4′-chlorophenyl)-2,3-dihydro-1*H*-1,5-benz-odiazepine (**3n**, Fig. 1*a*), the *meta* coupled doublet at δ 8.18 ppm (J = 2.4 Hz) is assigned to a proton (6-H) *ortho* to the imine nitrogen of benzodiazepines, which is in the downfield region compared with the *ortho* coupled doublet at δ 6.76 ppm (9-H) (J = 9.0 Hz), which is *ortho* to the amine nitrogen. The *ortho* and *meta* coupled doublet of doublet at δ 7.89 ppm (J = 9.0 and 2.4 Hz) is assigned to 8-H.

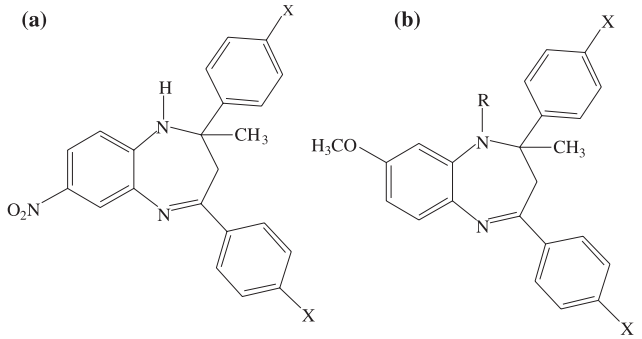
[a]Merged with the ab quartet of other aromatic protons.

The same analogy is applicable to 2-methyl-7-nitro-2,4-diphenyl-2,3-dihydro-1*H*-1,5-benzodiazepine (**3m**) and 2-methyl-7-nitro-2,4-di(4′-bromophenyl)-2,3-dihydro-1*H*-1,5-benzodiazepine (**3o**). However, in case of methoxy substituted benzodiazepines, namely 2-methyl-8-methoxy-2,4-diphenyl-2,3-dihydro-1*H*-1,5-benzodiazepine (**3p**) and 2-methyl-8-methoxy-2,4-di(4′-chlorophenyl)-2,3-dihydro-1*H*-1,5-benzodiazepine (**3q**) (Table 1), the *meta* coupled doublet (9-H) at δ 6.28 ppm (*J* = 2.2 Hz) is in the most shielded region, and the *ortho*-coupled proton (6-H) signal is merged with the other aromatic-proton signals in the region of δ 7.1–7.2 ppm. The doublet of doublet at δ 6.52 ppm (7-H) with a coupling constant of 8.7 and 2.2 Hz, respectively, is assigned to *ortho* and *meta* couplings of 6-H and 9-H protons. This clearly indicates that the shielded proton in this derivative is *ortho* to the amine nitrogen. Therefore, structure **3p** has been assigned for the methoxy-substituted benzodiazapine derivative (Fig. 1*b*). This is further confirmed by converting compound **3p** into its *N*-methyl derivative (1,2-dimethyl-2,4-diphenyl-2,3-dihydro-1*H*-1,5-benzodiazepin-8-yl methyl ether (**3r**)) using dimethyl sulfate under phase transfer catalysis (PTC) conditions (26). The ^{1}H NMR spectrum of the methylated compound **3r** (Fig. 1*b*) revealed the presence of a *meta*-coupled doublet at δ 6.76 ppm (*J* = 3.0 Hz), *ortho*-coupled doublet at δ 6.90 ppm (*J* = 9.0 Hz), and doublet of doublet at δ 6.68 ppm (*J* = 9.0 and 3.0 Hz) that are assigned to 9-H, 6-H, and 7-H, respectively.

To the best of our knowledge, 2-methyl-8-methoxy-2,4-di(4′-chlorophenyl)-2,3-dihydro-1*H*-1,5-benzodiazepine (**3q**) is reported for the first time, and the structures of the regioisomers have been unequivocally assigned, based on IR, NMR, and mass spectral data, and finally confirmed by X-ray crystallographic analysis.[2]

In conclusion, the results reveal that $ZrCl_4$ has proved to be an effective catalyst for the synthesis of 2,3-dihydro-1*H*-1,5-benzodiazepines. This protocol offers several advantages, such as selectivity, high yields, shorter reaction times, and simple workup procedure. Moreover, the interesting outcome of the present study is the isolation of the specific regioisomers **3m**–**q** in high yields, and their structures have been unequivocally characterized by spectroscopic data for the first time.



Experimental

NMR, spectra were recorded on Gemini 200, 300, and 400 MHz and Avance 600 spectrometers in $CDCl_3$, using TMS as internal standard. IR spectra were recorded on a

Nicolet 740 FTIR spectrometer, and Mass spectra were recorded on a VG Micro Mass 7070H. The melting points were determined in open glass capillaries on a Metler FP 51 melting point apparatus and are uncorrected. All reactions were carried out using reagent-grade solvents, and the reagents were purchased from local suppliers except $ZrCl_4$, which was purchased from Merck Limited, Mumbai.

General procedure for the $ZrCl_4$-catalyzed synthesis of 1,5-benzodiazepines (3)

A mixture, containing *o*-phenylenediamine (5 mmol), ketone (10 mmol), and $ZrCl_4$ (10 mol%) in 1,2-dichloroethane (15 mL), was refluxed for an appropriate period of time, as mentioned in Table 1. After completion of the reaction, as indicated by TLC, the reaction mixture was cooled to room temperature and washed with water (3 × 10 mL). The organic layer was dried over anhyd. Na_2SO_4, and the solvent was removed under reduced pressure. The crude mixture was purified by column chromatography on silica gel (100–200 mesh), using hexane – ethyl acetate (98:2) as an eluent to afford the pure products.

Triazene derivatives of (1,*x*)-diazacycloalkanes. Part VIII. Synthesis and characterization of a series of 1,4-di[2-aryl-1-diazenyl]-2-methylpiperazines[1]

Naomi Hunter, Reid Tingley, Brad Peori, and Keith Vaughan

Abstract: A series of 1,4-di-[2-aryl-1-diazenyl]-2-methylpiperazines (**4a**–**n**) have been synthesized by the reaction of 2-methylpiperazine with 2 equiv. of the appropriate diazonium salt. The products have been characterized by IR and NMR spectroscopy, and the molecular composition has been verified by HR-EIMS, with accurate mass measurement of the molecular ion. The presence of a chiral centre at C_2 of the piperazine ring in the bistriazene **4** creates a multitude of diastereotopic protons in the methylene groups of the piperazine ring, as evidenced by the complexity of the NMR spectra, which nevertheless can be fully assigned in some cases, such as the tolyl- (**4h**) and phenyl- (**4j**) derivatives. These two compounds also show a discrimination between the two *N*-arydiazenyl groups, as evidenced by the doubling of several aromatic-carbon signals in the ^{13}C NMR spectra. The assignment of the proton and carbon signals in **4h** and **4j** has been aided by the use of 2D NMR spectroscopy. A DEPT spectrum of **4j** clearly discriminates the methylene carbons and also indicates the methine carbons of the piperazine ring. COSY spectra provide clear information about the interactions between diastereotopic protons; when these results are combined with the results of HSQC spectroscopy, the proton and carbon signals can be fully correlated, leading to an unequivocal assignment of the proton and carbon atoms of the piperazine ring. The HSQC spectrum of **4j** also gives a complete correlation of the aromatic-proton and -carbon signals. These results compare favorably with the previously reported assignments of proton and carbon signals for triazenes of type **1** and bistriazenes of type **3**.

Key words: triazene, bistriazene, piperazine, 2-methylpiperazine, diastereotopic protons, diazonium coupling, 2D NMR, COSY, DEPT, HSQC.

Résumé : On a effectué la synthèse d'une série de 1,4-di-[2-aryldiaz-2-ényl]-2-méthylpipérazines (**4 a**–**n**) en procédant à la réaction de la 2-méthylpipérazine avec deux équivalents du sel de diazonium approprié. On a caractérisé les produits par spectroscopies IR et RMN et on a vérifié la composition moléculaire par spectrométrie de masse à haute résolution, avec ionisation électronique et mesure précise de la masse de l'ion moléculaire. La présence d'un centre chiral au niveau du C_2 du noyau pipérazine du bistriazène **4** crée une multitude de protons diastéréotopes dans les groupes méthylènes du noyau pipérazine qui sont détectés dans le spectre RMN qu'on a toutefois pu complètement attribuer dans quelques cas, tel ceux des dérivés tolyle (**4h**) et phényle (**4j**). Ces deux composés montrent aussi une discrimination entre les deux groupes *N*-aryldiazényles qui est détectée par le dédoublage de plusieurs signaux de carbones aromatiques dans le spectre RMN du ^{13}C. L'attribution des signaux des protons et de plusieurs signaux de carbones dans les composés **4h** et **4j** a été rendue possible par l'utilisation de la spectroscopie RMN en 2D. Un spectre « DEPT » du composé **4j** permet de distinguer les carbones méthyléniques et permet aussi d'identifier les carbones méthines du noyau pipérazine. Les spectres « COSY » fournissent aussi des informations claires concernant les interactions entre les protons diastéréotopes; quand on combine ces résultats avec les résultats de la spectroscopie « HSQC », on peut établir une corrélation totale des protons et des atomes de carbone qui conduit à une attribution sans équivoque des protons et des atomes de carbone du noyau pipérazine. Le spectre « HSQC » du composé **4j** permet aussi d'avoir une corrélation complète des signaux des protons et des atomes de carbone. Ces résultats se comparent favorablement avec les attributions des signaux des protons et des atomes de carbone rapportés antérieurement pour les triazènes du type **1** et les bistriazènes du type **3**.

Mots-clés : triazène, bistriazène, pipérazine, 2-méthylpipérazine, protons diastéréomères, couplage de diazonium, RMN-2D, « COSY », « DEPT », « HSQC ».

Introduction

In Part I of this series (1), the diazonium coupling reaction of 1-methylpiperazine was explored to synthesize the 4-methyl-1-(2-aryldiazen-1-yl-)piperazines (**1**) (see Chart 1). In the process of characterizing these triazenes by NMR spectroscopy, the chemical-shift parameters of the protons and carbons in the piperazine ring were clearly established and verified by some classical 2D NMR work. These data were used to advantage in characterizing the 4-methyl-1-[aryldiazenyl]-homopiperazines (**2a**), which have been described, along with the 1,4-di-(2-aryldiazen-1-yl)diazepanes (**2b**), in Part II of this series (2). The bistriazenes (**2b**) were obtained by the reaction of the homopiperazine with the diazonium salt in a 1:2 molar proportion. This bis(diazotization) strategy was subsequently explored with piperazine itself, and the synthesis of a series of 1,4-di-(2-aryldiazen-1-yl-)piperazines (**3**) was described in Part III of this series (3). The bistriazenes of type **3** were characterized by a range of spectroscopic techniques, and the data were compared with some previously published work (4), in which several of the bis(aryldiazenyl)piperazines had already been described.

The potential biological activity of triazene derivatives of piperazine has been studied by several groups. Butkus and co-workers investigated a series of aminoazobenzene sulfonic acids, such as **1a**, for their potential anti-inflammatory activity (5). A series of sulfonamides **1b** were

© 2007 NRC Canada

prepared by Lalezari and Afgahi (6) as potential anti-tumour agents, and the nitro derivatives **1c** and **3** (Ar = *p*-nitrophenyl) were prepared and investigated for their phytotoxic activity (7).

The work described in this paper is a logical extension of our previous study (3) of the synthesis of the symmetrical bistriazenes of series **3** to the unsymmetrical bistriazene series **4**, in which a methyl substituent is introduced at position 2 of the piperazine ring. In characterizing the series of bistriazenes (**3**), we observed that the eight protons of the piperazine ring occur as a single peak. The equivalence of all eight methylene protons in **3** is a little surprising in view of the potential for variation in chemical shift from either (*i*) axial vs. equatorial proton environment, (*ii*) *syn* or *anti* orientation of the *N*-aryldiazenyl groups, or (*iii*) a combination of both of these. We concluded that the dynamic effects in molecules of type **3** must be occurring faster than the NMR time-frame.

The introduction of asymmetry in the piperazine ring, as in structure **4**, might have some interesting consequences. In principle, the aryldiazenyl groups in **4** are in different environments; an interesting challenge is to see if high-field NMR can resolve these aryl groups. Furthermore, the C_2 carbon in **4** is a stereocenter, creating the situation where the methylene hydrogens at C_3, C_5, and C_6 become diastereotopic. Thus, the resolution and interpretation of the NMR spectra of the bistriazenes of type **4** have the potential of being an interesting and non-trivial exercise. These considerations prompted us to explore the effect of introducing a methyl substituent into the piperazine ring of the 1,4-bis(aryldiazenyl)piperazine system, and this paper reports the synthesis and characterization of a series of 1,4-di[2-aryl-1-diazenyl]-2-methylpiperazines (**4a**–**n**), with an in-depth analysis of the NMR spectra of these novel compounds.

Experimental

All reagents were reagent-grade materials, purchased from Sigma-Aldrich Canada Ltd., and were used without further purification. Melting points were determined on a Fisher–Johns melting-point apparatus and are uncorrected. IR spectra were obtained using Nujol mulls with a Bruker Vector 22 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained using either Bruker 400 MHz and 500 MHz spectrometers at the Atlantic Region Magnetic Resonance Center (ARMRC) at Dalhousie University, Halifax, NS or the ANASAZI 60 MHz EFT spectrometer at Saint Mary's University. Chemical shifts were recorded in $CDCl_3$ or d_6-DMSO solutions at 20 °C (as specified), and are relative to TMS as internal standard. Accurate mass measurements were obtained on a CEC 21–110B mass spectrometer, operated at a mass resolution of 8000 (10% valley) by computer-controlled peak matching to appropriate PFK reference ions. Spectra were obtained using electron ionization at 70 V and a source temperature of 175 °C, with samples being introduced by means of a heatable quartz probe. The standard deviation of mass measurement is ±0.0008 amu, which is an average of 3.6 ppm over the mass range of 100 to 300 amu.

1,4-Di-[2-aryl-1-diazenyl]-2-methylpiperazines (4a–n)

General procedure

The aromatic primary amine (0.01 mol) was dissolved in 12 mL of 3 mol/L hydrochloric acid by heating, if necessary, and the resulting solution was cooled in an ice/salt bath to 0 °C. The solution was diazotized with a solution of sodium nitrite (0.76 g) in water (3 mL) while maintaining the temperature below 5 °C, and then stirred for a further 0.5 h in the cold. A solution of 2-methylpiperazine (0.5 g), dissolved in water (10 mL), was added slowly to the mixture. After stirring for a further 0.5 h, the mixture was further neutralized with saturated sodium carbonate solution, and then stirred until precipitation was deemed to be complete (1–3 h). The solid product was filtered under suction, dried, and recrystallized from an appropriate solvent to give compounds **4a**–**n**.

1,4-Di-[2-(p-cyanophenyl)-1-diazenyl]-2-methylpiperazine (4a)

Yield 46%; yellow prisms; from DMSO; mp 187–189 °C. IR (nujol, cm^{-1}) ν_{max}: 2221 (CN), 849 (OOP). ^{1}H NMR (60 MHz, $CDCl_3$) δ: 1.46 (3H, d, J = 6.7 Hz, methyl at C_2), 4.12 (6H, br m, ring CH_2's), 4.50 (1H, br m, CH at C_2), 7.52 (4H, d, J = 8.6 Hz, arom.), 7.64 (4H, d, J = 8.7 Hz, arom.). HR-MS *m/z*: calcd. for $C_{19}H_{18}N_8$: 358.1654; found: 358.1649 (EI).

1,4-Di-[2-(p-nitrophenyl)-1-diazenyl]-2-methylpiperazine (4b)

Yield 37%; red prisms; from DMSO; mp 200 °C. IR (nujol, cm^{-1}) ν_{max}: 1509 (NO_2), 1377 (NO_2), 849 (OOP). ^{1}H NMR (60 MHz, $CDCl_3$) δ: 1.49 (3H, d, J = 6.5 Hz, methyl at C_2), 4.16 (6H, m, ring CH_2's), 4.48 (1H, m, CH at C_2), 7.54 (4H, d, J = 8.8 Hz, arom.), 8.23 (4H, d, J = 9.1 Hz, arom.). HR-MS *m/z*: calcd. for $C_{17}H_{18}N_8O_4$: 398.1451; found: 398.1455 (EI).

Methyl 4-[2-(4-{2-[4-(methoxycarbonyl)phenyl]-1-diazenyl}-3-methylpiperazino)-1-diazenyl]benzoate (4c)

Yield 90%; pale-yellow needles; from ethanol; mp 146–148 °C. IR (nujol, cm^{-1}) ν_{max}: 1716 (C=O), 859 (OOP). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.46 (3H, d, J = 6.5 Hz, methyl at C_2), 3.91 (6H, s, O–Me × 2), 4.05 (2H, br, H_b × 2), 4.12 (3H, br m, H_d, H_e, and H_f), 4.25 (1H, br, H_c), 4.61 (1H, m, CH at C_2, H_a), 7.50 (4H, dd, J = 3.5 and 8.5 Hz, arom.), 8.04 (4H, dd, J = 1.0 and 8.5 Hz, arom.). HR-MS *m/z*: calcd. for $C_{21}H_{24}N_6O_4$: 424.1859; found: 424.1849 (EI).

Ethyl 4-[2-(4-{2-[4-(ethoxycarbonyl)phenyl]-1-diazenyl}-3-methylpiperazino)-1-diazenyl]benzoate (4d)

yield 30%; yellow needles; from ethanol; mp 103–104 °C. IR (nujol, cm^{-1}) ν_{max}: 1704 (C=O), 857 (OOP). ^{1}H NMR (60 MHz, $CDCl_3$) δ: 1.39 (9H, m, methyl at C_2 + methyl protons of the ester groups), 4.07 (6H, m, ring CH_2's), 4.37 (5H, m, CH at C_2 + methylene protons of the ester groups), 7.49 (4H, d, J = 9 Hz, arom.), 8.06 (4H, d, J = 9 Hz, arom.). HR-MS *m/z*: calcd. for $C_{23}H_{28}N_6O_4$: 452.2172; found: 452.2169 (EI).

© 2007 NRC Canada

1,4-Di-[2-(p-acetylphenyl)-1-diazenyl]-2-methylpiperazine (4e)

Yield 26%; amorphous brown powder; from ethanol – ethyl acetate; mp 184 °C. IR (nujol, cm^{-1}) ν_{max}: 1672 (C=O), 846 (OOP). ^1H NMR (60 MHz, $CDCl_3$) δ: 1.41 (3H, d, J = 6.4 Hz, methyl at C_2), 2.53 (6H, s, acetyl Me), 4.04 (6H, m, ring CH_2's), 4.40 (1H, m, CH at C_2), 7.45 (4H, d, J = 8.5 Hz, arom.), 7.93 (4H, d, J = 8.7 Hz, arom.). HR-MS *m/z*: calcd. for $C_{21}H_{24}N_6O_2$: 358.1654; found: 358.1649 (EI).

1,4-Di-[2-(p-carboxamidophenyl)-1-diazenyl]-2-methylpiperazine (4f)

Yield 49%; yellow prisms; from ethanol–DMSO; mp 267–270 °C. IR (nujol, cm^{-1}) ν_{max}: 3383 (NH), 3191 (NH), 1653 (C=O), 856 (OOP). ^1H NMR (60 MHz, d_6-DMSO) δ: 1.34 (3H, d, J = 6.4 Hz, methyl at C_2), 4.10 (6H, br m, ring CH_2's), 4.57 (1H, br m, CH at C_2), 7.44 (4H, d, J = 8.3 Hz, arom.), 7.92 (4H, d, J = 8.5 Hz, arom.). HR-MS *m/z* (%): 247 ($[M - ArN_2]^+$, 1), 121 ($[Ar]^+$, 100), 105 ($[C_6H_4CHO]^+$, 12.5).

1,4-Di-[2-(p-sulfonamidophenyl)-1-diazenyl]-2-methylpiperazine (4g)

Yield 83%; brown prisms; from ethanol; mp 187–190 °C. IR (nujol, cm^{-1}) ν_{max}: 3336 (NH), 3227 (NH), 839 (OOP). ^1H NMR (60 MHz, d_6-DMSO) δ: 1.37 (3H, d, J = 6.4 Hz, methyl at C_2), 4.12 (6H, br, ring CH_2's), 4.60 (1H, br m, CH at C_2), 7.31 (4H, br, NH_2 × 2), 7.51 (4H, d, J = 8.7 Hz, arom.), 7.84 (4H, d, J = 8.6 Hz, arom.). HR-MS *m/z* (%): 283 ($[M - ArN_2]^+$, 13), 184 ($[ArN_2]^+$, 2), 157 ($[C_6H_4SO_2NH]^+$, 61), 77 ($[C_6H_5]^+$, 100).

1,4-Di-[2-(p-tolyl)-1-diazenyl]-2-methylpiperazine (4h)

Yield 55%; deep-pink prisms; from ethanol–water; mp 78–80 °C. IR (nujol, cm^{-1}) ν_{max}: 821 (OOP). ^1H NMR (500 MHz, $CDCl_3$) δ: 1.42 (3H, d, J = 6.7 Hz, methyl at C_2), 2.35 (6H, s, tolyl Me), 3.77 (1H, m, H_c), 3.92 (2H, d, J = 4.7 Hz, H_b), 3.96 (1H, m, H_f), 4.04 (1H, m, H_e), 4.13 (1H, m, H_d), 4.45 (1H, br m, H_a), 7.16 (4H, d, J = 8.1 Hz, arom.), 7.36 (4H, dd, J = 2.1 and 8.3 Hz, arom.). ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 15.95 (Me at C_2), 21.1 (tolyl Me), 42.3, 45.7, 53.6, 120.6/120.7, 129.5, 136.1/136.2, 147.9/148.1. HR-MS *m/z*: calcd. for $C_{19}H_{24}N_6$: 336.2062; found: 336.2071 (EI).

1,4-Di-[2-(p-bromophenyl)-1-diazenyl]-2-methylpiperazine (4i)

Yield 90%; small white prisms; from ethanol; mp 129–131 °C. IR (nujol, cm^{-1}) ν_{max}: 829 (OOP). ^1H NMR (500 MHz, $CDCl_3$) δ: 1.43 (3H, d, J = 6.5 Hz, methyl at C_2), 3.81 (1H, br m, H_c), 3.96 (2H, two overlapping broad singlets, H_b), 4.01 (1H, t, J = 5.3 Hz, H_f), 4.07 (1H, septet, J = 4.3 Hz, H_e), 4.17 (1H, br m, H_d), 4.51 (1H, br, CH at C_2), 7.34 (4H, dd, J = 3.5 and 8.5 Hz, arom.), 7.47 (4H, dd, J = 1.5 and 8.5 Hz, arom.). HR-MS *m/z*: calcd. for $C_{17}H_{18}N_6Br_2$: 463.9959; found: 463.9970 (EI).

1,4-Di-[2-(phenyl)-1-diazenyl]-2-methylpiperazine (4j)

Yield 84%; pale-yellow prisms; from hexanes; mp 54–57 °C. IR (nujol, cm^{-1}) ν_{max}: 762 and 691 (OOP). ^1H NMR (500 MHz, $CDCl_3$) δ: 1.44 (3H, d, J = 6.7 Hz, methyl at C_2), 3.81 (1H, m, H_c), 3.96 (2H, d, J = 4.5 Hz, H_b), 4.00 (1H, m, H_f), 4.08 (1H, m, H_e), 4.17 (1H, m, H_d), 4.51 (1H, br m, CH at C_2), 7.20 (2H, m, arom.), 7.36 (4H, t, J = 7.5 Hz, arom.), 7.46 (4H, d, J = 8.4 Hz, arom.). ^{13}C NMR (125.8 MHz, 323 K, $CDCl_3$) δ: 16.0 (Me at C_2), 42.5 (CH_2), 45.2 (CH_2), 53.0 (CH_2), 53.8 (CH), 120.9, 126.4/126.5, 128.9, 150.3/150.5. HR-MS *m/z*: calcd. for $C_{17}H_{20}N_6$: 308.1749; found: 308.1750 (EI).

1,4-Di-[2-(o-cyanophenyl)-1-diazenyl]-2-methylpiperazine (4k)

Yield 71%; pale-orange wafers; from ethanol; mp 130–131 °C. IR (nujol, cm^{-1}) ν_{max}: 2223 (CN), 767 and 722 (OOP). ^1H NMR (400 MHz, $CDCl_3$) δ: 1.50 (3H, br, methyl at C_2), 4.07 (2H, br, ring CH_2), 4.23 (4H, br m, ring CH_2's), 4.45 (1H, br m, CH at C_2), 7.23 (2H, t, J = 7.4 Hz, arom.), 7.53 (2H, t, J = 7.8 Hz), 7.60 (2H, t, J = 8.5 Hz, arom.), 7.64 (2H, d, J = 7.7 Hz, arom.). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 16.0 (vbr, Me at C_2), 44.0, 50.0, 56.0, 108.1 (CN), 117.6/117.7, 125.9, 126.0, 133.2, 152.2, 152.5 (arom.). HR-MS *m/z*: calcd. for $C_{19}H_{18}N_8$: 358.1654; found: 358.1648 (EI).

1,4-Di-[2-(o-nitrophenyl)-1-diazenyl]-2-methylpiperazine (4l)

Yield 68%; yellow prisms; from ethanol, mp 99–100 °C. IR (nujol, cm^{-1}) ν_{max}: 1528 (NO_2), 1377 (NO_2), 854 (OOP). ^1H NMR (400 MHz, $CDCl_3$) δ: 1.44 (3H, br, methyl at C_2), 4.09 (6H, br m, ring CH_2's), 4.45 (1H, vbr, CH at C_2), 7.24–7.30 (2H, m, arom.), 7.49–7.54 (4H, m, arom.), 7.70–7.73 (2H, dd, J = 3.9 and 8.6 Hz, arom.). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 16.0 (w, Me at C_2), 119.8/120.0, 123.9, 125.8/125.9, 132.3/132.4, 143.1/143.3, 145.2. HR-MS *m/z*: calcd. for $C_{17}H_{18}N_8O_4$: 398.1451; found: 398.1441 (EI).

1,4-Di-[2-(o-chlorophenyl)-1-diazenyl]-2-methylpiperazine (4m)

Yield 53%; yellow needles; from water, mp 87–88 °C. IR (nujol, cm^{-1}) ν_{max}: 721 (OOP). ^1H NMR (500 MHz, $CDCl_3$) δ: 1.46 (3H, d, J = 6.5 Hz, methyl at C_2), 3.91 (1H, br, H_b), 4.04 (2H, br, H_e and H_b'), 4.13 (2H, m, H_c and H_d), 4.28 (1H, br, H_f), 4.61 (1H, br, CH at C_2), 7.12 (2H, tt, J = 1.8 and 7.7 Hz, arom.), 7.23 (2H, tt, J = 1.8 and 7.7 Hz), 7.41 (2H, dd, J = 1.5 and 8.0 Hz, arom.), 7.45 (2H, dt, J = 1.5 and 8.1 Hz, arom.). ^{13}C NMR (125.77 MHz, $CDCl_3$) δ: 15.9 (w, Me at C_2), 118.7, 126.9/127.0, 127.13/127.15, 129.8/129.9, 130.2, 146.5/146.7. HR-MS *m/z*: calcd. for $C_{17}H_{18}N_6Cl_2$: 376.0970; found: 376.0982 (EI).

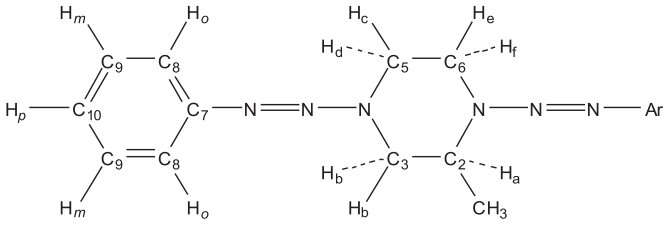
1,4-Di-[2-(3-pyridyl)-1-diazenyl]-2-methylpiperazine (4n)

Yield 57%; oil. IR (nujol, cm^{-1}) ν_{max}: 702 and 798 (OOP). ^1H NMR (60 MHz, $CDCl_3$) δ: 1.45 (3H, d, J = 6.5 Hz, methyl at C_2), 4.07 (6H, m, ring CH_2's), 4.50 (1H, m, CH at C_2), 7.2–7.5 (2H, m, arom.), 7.7–7.95 (2H, m, arom.), 8.43 (2H, dd, J = 1.6 and 4.7 Hz, arom.), 8.74 (2H, dd, J = 0.9 and 2.5 Hz, arom.).

Results and discussion

The target molecules, 1,4-di-[2-(3-aryl)-1-diazenyl]-2-methylpiperazine (**4a**–**n**), were synthesized by reacting 1 equiv. of 2-methylpiperazine with 2 equiv. of the appropri-

© 2007 NRC Canada



ate diazonium salt. The products are stable, crystalline solids, with the exception of the 3-pyridyl derivative (**4n**), which is an oil. The yields, which are variable in the range from poor (26%) to excellent (98%), depend on the nature and position of the aryl substituent. The yield is generally lower for electron-withdrawing substituents, but is higher if the substituent is in the *ortho* position, e.g., compare **4k** with **4a**. The products were first characterized by IR spectroscopy to confirm the presence of the aryl substituent, as indicated by the detection of bands from either carbonyl, nitrile, nitro, or NH groups, and the OOP bending vibration, characteristic of the substitution pattern. The molecular composition of each compound was established by HR-EI mass spectrometry with accurate mass measurement of the molecular ion, except for the cases of compounds **4f**, **4g**, and **4n**, which did not show molecular ions in the mass spectra. However, the mass spectrum of the amide **4f** contained peaks corresponding to fragments including the $[M - ArN_2]^+$ fragment at *m*/*z* 247. The analogous fragment is observed at *m*/*z* 283 in the mass spectrum of the sulfonamide **4g**.

Supporting evidence for the structures of the compounds **4a**–**n** was obtained from ^{1}H NMR analysis, which proved to be as complex and challenging as we could have expected. The aromatic protons give rise to the predictable pattern of an AA′BB′ system in the *p*-disubstituted benzenes (**4a**–**i**) or the complex pattern of an *o*-substituted benzene (**4k**–**m**), an unsubstituted benzene (**4j**), or a 3-pyridyl ring (**4n**). In most cases, the difference in the aryl groups, arising from the presence of the C_2 methyl substituents, is not detectable; the proton spectra give the appearance of indistinguishable aryl groups, and in many instances, the ^{13}C NMR spectra contain a single set of signals. However, several ^{13}C NMR spectra show doubling of many of the carbon signals, which we interpret as resolving the carbon signals of the two aryl groups. In the unsubstituted phenyl derivative (**4j**), two of the carbon signals are doubled, whereas in the *p*-tolyl compound (**4h**), three of the four carbon signals are doubled. In the *o*-cyanophenyl compound (**4k**), there is some doubling of the carbon signals, but in the *o*-nitrophenyl derivative, at least four of the six carbon signals are doubled. A similar observation is made in the ^{13}C NMR spectrum of the *o*-chlorophenyl analogue (**4m**).

The 2-methyl substituent on the piperazine ring consistently gives rise to a three-proton doublet in the range of 1.3–1.5 ppm, with a coupling constant of ~6.5 Hz, arising from the splitting by the adjacent CH proton at C_2, which itself is clearly observed in all spectra at 4.4–4.6 ppm, either as a complex multiplet or a broad hump. The resolution of the signals of the six methylene hydrogen atoms of the piperazine ring is variable, depending on the nature of the substituent in the phenyl ring. Those compounds with a strong electron-withdrawing group (**4a**–**g**, **4k**, **4l**, and **4n**) afford a proton spectrum with almost no resolution of the methylene protons, and these spectra show a broad six-proton multiplet at ~4.1 ppm. In compounds **4c** and **4m**, the methylene protons are partially resolved, whereas compounds **4h**, **4i**, and **4j** show complete resolution.

The ^{1}H NMR spectrum of the *p*-tolyl derivative **4h** also shows some details (for the key to the proton and carbon labels in this compound, see Fig. 1). The aromatic protons are clearly resolved. A six-proton singlet at 2.35 ppm is readily

Fig. 1. The key to the proton and carbon labels in **4h**.

assigned to the protons of the tolyl methyl groups. The doublet of the C_2 methyl is clearly resolved at 1.42 ppm, and H_a at C_2 is observed as a broad multiplet at 4.45 ppm. Four of the ring methylene hydrogens are observed as multiplets at 3.77, 3.96, 4.04, and 4.13 ppm. The remaining two methylene protons appear as two lines at 3.91 and 3.92 ppm. In the ^{13}C NMR spectrum of **4h**, the methyl carbon attached to C_2 is observed at 16.0 ppm, compared with the tolyl methyl carbon at 21.7 ppm. Three of the four carbons of the piperazine ring are observed at 42.3, 45.7, and 53.6 ppm. The assignment of these signals to specific protons and carbons of the piperazine ring is facilitated by 2D NMR.

The COSY spectrum of compound **4h** is reproduced in Fig. 2, which shows that the protons at 3.77 and 4.13 ppm are stongly coupled together, indicating that these protons are attached to the same carbon atom. Other proton–proton interactions are observed between 3.96 and 4.04 ppm, 3.96 with 3.77 ppm, and 4.45 with both 3.92 and 3.77 ppm. The final piece of the puzzle, with respect to the assignment of the protons in **4h**, is the HSQC spectrum shown in Fig. 3. First, the proton signal of H_a at 4.45 ppm correlates with the carbon signal at 53.6 ppm, which is assigned to C_2. Second, the 3.96 and 4.04 ppm proton signals, assigned to H_e and H_f, respectively, correlate with the carbon signal at 42.3 ppm, which we thereby assign to C_6. The H_c and H_d protons at 3.77 and 4.13 ppm, respectively, correlate with the C_5 carbon signal at 45.7 ppm. The final piece of information in Fig. 3 is a bonus, which is the correlation of the 3.91–3.92 ppm proton signals with a carbon signal at 53.0, which is very clear in the HSQC spectrum but was not picked out from the ^{13}C NMR spectrum of **4h**. This carbon signal must, therefore, be assigned to C_3, and the 3.91–3.92 signals are assigned to the H_b protons. Thus, a complete assignment of the proton and carbon signals of compound **4h** has been achieved.

Further evidence for these NMR correlations is provided by the series of NMR spectra obtained from the phenyl derivative **4j**. Figure 4 shows the ^{1}H NMR spectrum of **4j**. The details of resolution of the five aromatic protons of the phenyl ring are remarkable. The signals from the piperazine ring protons are equally impressive and very similar to those of the *p*-tolyl derivative (**4h**) in the range of 3.75–4.50 ppm. The H_c signal at 3.81 ppm has an apparent multiplicity of a septet, but in reality there are eight lines, i.e., a doublet of doublets of doublets, because of the coupling of the H_c proton to protons H_d, H_e, and H_f, with the two central lines overlapping. The signal of H_e at 4.08 ppm has a similar septet appearance; it is coupled to H_c, H_d, and H_f. Figure 5 shows stacked spectra of a VT NMR experiment in the range of 3.7–4.7 ppm for compound **4j**. The resolution of the piperazine ring protons disappears at low temperature, indi-

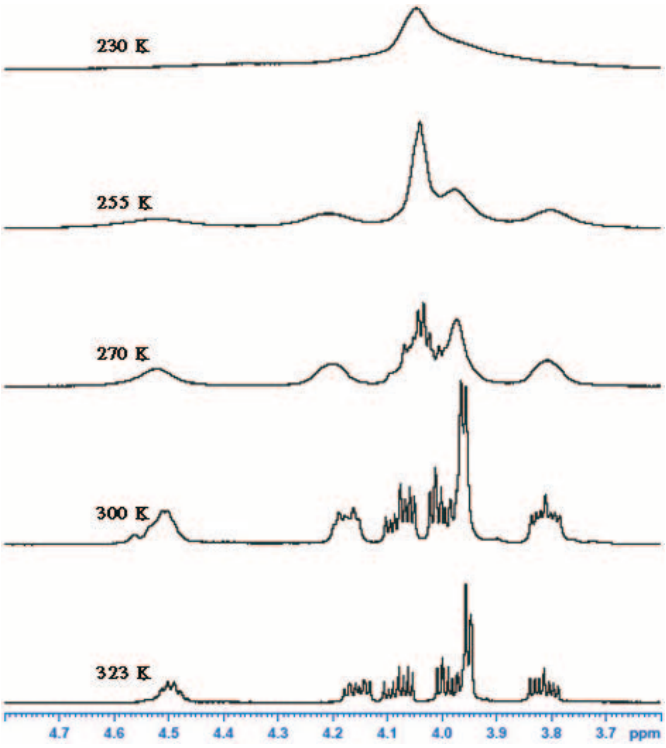

Fig. 6. HSQC NMR spectrum of 1,4-di-[2-(phenyl)-1-diazenyl]-2-methylpiperazine (**4j**) in $CDCl_3$ at 323 K.

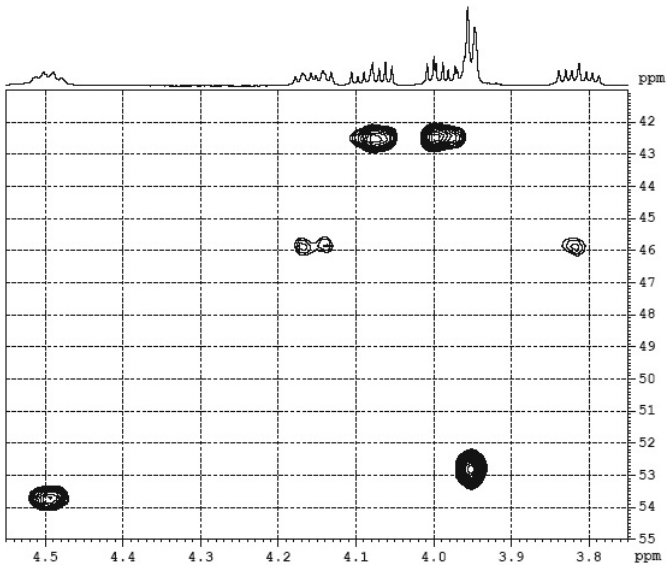

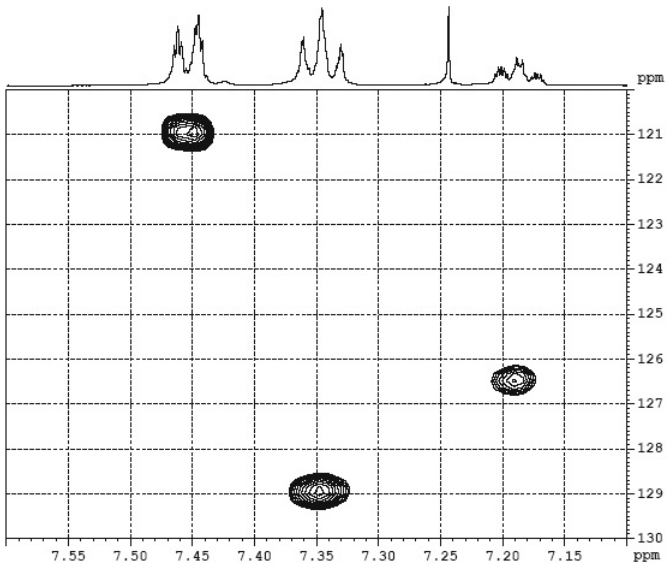

Fig. 7. The aromatic region of the HSQC NMR spectrum of 1,4-di-[2-(phenyl)-1-diazenyl]-2-methylpiperazine (**4j**) in $CDCl_3$ at 323 K.

cating that the various dynamic equilibria are occurring very quickly at ambient temperature. Moreover, it would appear that the broadening of the signals as the temperature is lowered is due to the freezing out of the conformational equilibria of the piperazine ring. The DEPT ^{13}C NMR spectrum of **4j** shows that the signal at 53.8 ppm is a methine carbon (C_2), and those at 42.5 and 53.0 ppm are methylene carbons. The HSQC spectrum of the piperazine ring proton region of **4j**, shown in Fig. 6, provides unequivocal assignment of the protons and carbon atoms in that compound. The 4.00 and 4.08 ppm signals are assigned to H_e and H_f, attached to the 42.5 ppm carbon (C_6), respectively. The 3.81 and 4.17 ppm signals are assigned to H_c and H_d, which are attached to the 45.9 ppm carbon (C_5), respectively, whereas the 4.51 ppm signal is assigned to the methine proton H_a, attached to C_2 (53.8 ppm). The remaining proton signal at 3.96 ppm is assigned to H_b, attached to C_3 (53.0 ppm). The final piece of the puzzle is the HSQC spectrum of the aromatic region of **4j** (Fig. 7), which shows the correlation between the aromatic proton signals and the carbon signals (Fig. 1). Based on the integration, the one-proton signal at 7.20 ppm is assigned to the *para* proton, H_p; the HSQC evidence shows that this proton is bonded to the 126.4 ppm carbon (C_{10}). The 7.36 ppm proton signal is a two-proton triplet, so this is assigned to the *meta* hydrogens, H_m, which correlates with the 128.9 ppm signal of C_9. The *ortho* hydrogens must, therefore, be assigned to the two-proton doublet at 7.46 ppm, which correlates with the 120.9 ppm carbon signal of C_8. This leaves the 150.3 ppm carbon signal to be assigned to the *ipso* carbon (C_7).

Finally, it is necessary to compare these results and conclusions with the previously observed and assigned NMR parameters for the triazenes of types **1** (1) and **3** (3). In the symmetrical bistriazenes of type **3**, the methylene groups of the piperazine ring give rise to a proton signal at ~4.1 ppm, which compares with the chemical shift assigned to the methylene protons in **4a**–**n** in the range of 3.8–4.1 ppm. The methylene carbon signals in **3** occur at ~46–47 ppm, compared with the observed signal at ~46 ppm, assigned to the C_5 carbon of compounds **4j** and **4h**. The analogous carbon in the piperazine ring of the compounds of type **1** occurs at ~47 ppm, and the analogous methylene protons of structure **1** give rise to proton signals at ~3.9 ppm. So, there is considerable agreement in the NMR parameters among these compounds, but the bottom line is the extraordinary degree of

© 2007 NRC Canada

complexity in the spectra of compounds of series **4** because of the introduction of a chiral centre at C_2.

Conclusion

This paper is part VIII in a series that describes the synthesis of a variety of triazenes and bistriazenes of the general classification, 1-aryldiazenyl-(1,*x*)-diazacycloalkanes, described by the general structure **5** (see Chart 1), where $m = 1$ or 2 and $n = 2–5$. Previously, we reported new triazenes derived from piperazine ($m = n = 2$) (1, 3), homopiperazine ($m = 2$, $n = 3$) (2), imidazolidine ($m = 1$, $n = 2$) (8), and hexahydropyrimidine ($m = 1$, $n = 3$) (9). The new piperazines of series **4** fit to the general structure **5**, where $m = 2$ and $n = 2$. Future work in this field of chemistry will endeavour to further extend the family of 1,4-di-(2-aryl-1-diazenyl)piperazines by preparing derivatives with multiple substituents in the piperazine ring.

Silica-supported $ZnCl_2$ — A highly active and reusable heterogeneous catalyst for the one-pot synthesis of dihydropyrimidinones–thiones

Raman Gupta, Monika Gupta, Satya Paul, and Rajive Gupta

Abstract: A novel silica-supported zinc chloride catalyst was prepared and investigated for the Biginelli reaction. The key features of the catalyst include rapid reaction with 100% conversion of aldehyde, good catalyst recyclability, and high stability under the reaction conditions (passes hot filtration test successfully). A low catalyst loading (12 mol% of $ZnCl_2$) was required to achieve a quantitative reaction. Other catalysts such as SiO_2–$AlCl_2$, SiO_2–$AlCl_2$–$ZnCl_2$ were also prepared and their activity was compared with SiO_2–$ZnCl_2$ for the Biginelli reaction.

Key words: silica gel, zinc chloride, Biginelli compounds, heterogeneous catalysis, reusability.

Résumé : On a préparé un nouveau catalyseur de chlorure de zinc supporté par du gel de silice et on a étudié son utilité dans la réaction de Biginelli. Le catalyseur est caractérisé par une vitesse de réaction rapide avec une conversion de l'aldéhyde à 100%, une bonne facilité de récupération du catalyseur et une grande stabilité dans les conditions de la réaction puisqu'il passe avec succès le test de la filtration à chaud. La charge de catalyseur nécessaire pour obtenir une réaction quantitative est faible (12 moles% de $ZnCl_2$) est faible. On a aussi préparé d'autres catalyseurs, tel le SiO_2–$AlCl_2$, SiO_2–$AlCl_2$–$ZnCl_2$ et on a comparé leur activité avec celle du SiO_2–$ZnCl_2$ pour la réaction de Biginelli.

Mots-clés : gel de silice, chlorure de zinc, composés de Biginelli, catalyse hétérogène, possibilité de réutilisation.

Introduction

Green chemistry, the design of chemical products and processes that reduce or eliminate the use and generation of hazardous substances (1), is an overreaching approach that is applicable to all aspects of chemistry. From feedstock to solvents, synthesis, and processing, green chemistry actively seeks ways to produce materials in a way that is more benign to human health and the environment (2). The area of catalysis is sometimes referred to as a "fundamental pillar" of green chemistry (3).

The development of heterogeneous catalysts for fine chemical synthesis has become a major area of research recently, as the potential advantages of these materials (simplified recovery and reusability and the potential for incorporation in continuous reactors and microreactors) over homogeneous systems can make a major impact on the environmental performance of a synthesis (3, 4). The majority of these novel catalysts are based on silicas, primarily since silica displays many advantageous properties such as excellent stability (chemical and thermal), high surface area, good accessibility, and catalytic materials can be robustly anchored onto its surface to provide catalytic centres (5).

Zinc chloride, an inexpensive and easily available Lewis acid catalyst, has been widely used in organic synthesis. However, it suffers from the serious drawback of being highly hygroscopic in nature so that it always needs to be fused prior to use and requires highly anhydrous conditions; it also produces exogenous wastes. These issues make the work-up process cumbersome.

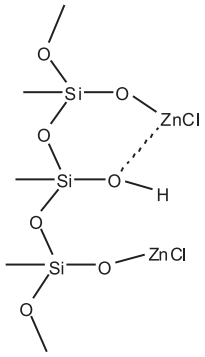
Pyrimidinones and their derivatives are medicinally important as calcium channel blockers and also are antiviral, antibacterial, antihypertensive, and α-1a-antagonists (6). The betzelladine alkaloids containing the dihydropyrimidine core unit are particularly notable, as they were recently found to be potent HIV gp-120-CD_4 inhibitors (7).

The Biginelli reaction, which was discovered more than a century ago (8), is one of the most important reactions in the synthesis of dihydropyrimidinones (DHPMs). The classical Biginelli reaction of an aldehyde, β-ketoester, and urea or thiourea requires strongly acidic conditions. Low to moderate yields are usually obtained, in particular when substituted aromatic or aliphatic aldehydes are employed. Recently, many methods for preparing DHPMs have been developed, and the Biginelli reaction has gained particular importance for ongoing research programs (9). However, many of these methods have drawbacks such as long reaction times, low product yields, harsh reaction conditions, the use of stiochiometric reagents, difficulties in work-up, the use of toxic and inflammable solvents, and incompatibility with other functional groups in the molecules. Therefore, there is a need to develop a heterogeneous catalyst for the synthesis of Biginelli compounds that is mild, reusable, eas-

 doi:10.1139/V07-018 © 2007 NRC Canada

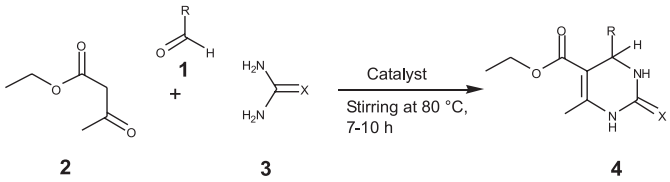
ily separable, compatible with acid sensitive functional groups, and cost-effective.

Keeping in view the biological importance of Biginelli compounds and that of heterogeneous catalysis in academia and industry, we wish to report here the application of heterogeneous catalysis to the synthesis of Biginelli compounds using reusable silica-supported zinc chloride (12 mol% of Zn as determined by atomic absorption spectrophotometer). Recently, $ZnCl_2$ has been reported for the synthesis of Biginelli compounds (10).



Results and discussion

Silica-supported zinc chloride was prepared by refluxing $ZnCl_2$ (3 g) with activated K100 silica gel (10 g) in sodium dried toluene for 10 h; at this temperature, some of the $ZnCl_2$ may react with the surface hydroxyl groups to create highly acidic species chemically bonded to the support. After separation of the catalyst by filtration under reduced pressure, it was dried at 110 °C for 12 h and stored in a desiccator. It could be used for several months. The proposed structure of the catalyst in which $ZnCl_2$ reacted with the surface hydroxyl groups of the silica gel is shown in Fig. 1. The other catalysts, SiO_2–$AlCl_2$ (11) (anhydr. $AlCl_3$ 3 g, SiO_2 10 g) and SiO_2–$AlCl_2$–$ZnCl_2$ ($AlCl_3$ 1.5 g, $ZnCl_2$ 1.5 g, SiO_2 10 g) were prepared by a similar procedure and stored in a desiccator. The stability of these catalysts was determined by thermogravimetric analysis (TGA). For SiO_2–$ZnCl_2$, the initial weight loss at 80 °C followed by 95-150 °C and 285-310 °C may be due to the loss of residual solvent and HCl, which may have formed during the reaction of $ZnCl_2$ with silica gel. Up to 310 °C, there is no possibility of loss of physiosorbed and chemisorbed $ZnCl_2$ from the surface of silica gel, so it is safe to carry out the reaction at 80 °C.



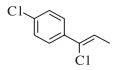
To optimize the reaction conditions, the reaction of 4-methoxybenzaldehyde, ethyl acetoacetate, and urea was selected as the model to examine the effects of catalyst (5–20 mol%), different solvents (methylene chloride, toluene, and acetonitrile), and reagents at different temperatures (RT, 50, 80, and 100 °C). The reactions were monitored by TLC and all yields reported in Tables 1 and 2 are isolated yields. The best conditions employ 0.12:1:1:1 mole ratios of catalyst (12 mol% of Zn, 0.2 g), 4-methoxybenzaldehyde, ethyl acetoacetate, and urea at 80 °C for 7 h using acetonitrile as the solvent.

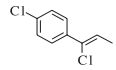
Using optimized conditions, the reactions of various aromatic–heterocyclic aldehydes, ethyl acetoacetate, and urea or thiourea were investigated (Scheme 1). It was found that all the reactions proceeded smoothly to give the corresponding 3,4-dihydropyrimidin-2-(1*H*)-ones–thiones in high yields (Table 1). Cinnamaldehyde, which showed poor yield in the absence of catalyst and 81% yield in the presence of very expensive lanthanide triflate (12), gave the corresponding pyrimidinones–thiones **4g** and **4p** in 85% and 87% isolated yields. Both aromatic aldehydes bearing electron-donating groups such as 4-OMe (**4b**, 92%) and electron-withdrawing groups such as 4-NO_2 (**4d**, 91%) gave excellent yields. More importantly, 2-furfuraldehyde, which normally gives low yield of products (9*c*, 13) afforded the desired products in 86% (**4f**) and 82% (**4o**) yields in 8.5 and 8 h, respectively. 2-

Figure 1. Probable structure of covalently anchored silica-supported zinc chloride.

Scheme 1.

Chloro-3-formylquinolines gave low yield of products (**4i** 20%, **4r** 32%). The mildness of the procedure makes this procedure very selective as the chlorine atoms in **4h**, **4i**, **4q**, and **4r** remain unaffected under the reaction conditions. The results are summarized in Table 1, which clearly indicates the generality and scope of the reaction with respect to various aromatic, heterocyclic, and unsaturated aldehydes.





The activity of the catalyst SiO_2–$ZnCl_2$ was also compared with unsupported anhydr. $ZnCl_2$ (0.0408 g, 12 mol%), $AlCl_3$ (0.0399 g, 12 mol%), and other silica supported catalysts SiO_2–$AlCl_2$ (0.185 g, 12 mol% of Al) and SiO_2–$AlCl_2$–$ZnCl_2$ (0.2 g, 5.5 mol% of Zn, 7.5 mol% of Al) taking 4-methoxybenzaldehyde, ethyl acetoacetate, and urea to give 3,4-dihydropyrimidinone **4b** as the model reaction, using acetonitrile as solvent and 80 °C as the reaction temperature. The results are summarized in Table 2. Among all catalysts, SiO_2–$ZnCl_2$ was found to be the most active, stable, and reusable catalyst.

To verify whether the reaction was catalyzed by SiO_2-$ZnCl_2$ or by the silica gel used for preparing the catalyst, we carried out the reaction (in the case of product **4b**) using activated silica gel (0.2 g) under similar conditions as with SiO_2-$ZnCl_2$. It was found that **4b** was formed in 23% yield (based on ^{1}H NMR) in 7 h. This clearly indicates that the reaction was catalyzed by SiO_2-$ZnCl_2$.

When using a supported metal catalyst, two important issues need to be addressed to qualify this to be a purely heterogeneous catalyst. One is the possibility that some active metal migrates from the solid to the liquid phase and that this leached metal salt would become responsible for a significant part of the catalytic activity. To rule out the contribution of the homogeneous catalysis in the results shown in Table 1, the reaction of 4-methoxybenzaldehyde, ethyl acetoacetate, and urea was carried out in the presence of SiO_2–$ZnCl_2$ until the conversion was 30% (^{1}H NMR yield, after 1 h), and at that point the solid was filtered off at the

reaction temperature. The liquid was then transferred to another flask and the reaction was continued for the remaining time, but no further significant formation of product was observed. This indicates that no active species was present in the supernatant and that the observed catalysis is purely heterogeneous. The second important point concerning heterogeneous catalysis is the deactivation and reusability of the catalyst. To test this, a series of 4 consecutive runs of the reaction of 4-methoxybenzaldehyde, ethyl acetoacetate, and urea with SiO_2–$ZnCl_2$ was carried out (1st use: 92% isolated yield after 7 h; 2nd use: 85% isolated yield after 8.5 h; 3rd use: 78% isolated yield after 12 h; 4th use: 67% isolated yield after 16 h). These results demonstrate that there is a decrease in the activity of the catalyst after every use. This may be due to either the deactivation of active centres resulting from complexation with both starting materials and products or microscopic changes in the structure of the catalyst. However, AAS analysis after the 4th use indicates that there is no change in the amount of Zn from the fresh to the 4th use of the catalyst.

Experimental

General

Silica gel (K100, 0.063–0.200 mm) was purchased from Merck (Germany) and anhydrous zinc chloride was purchased from Merck (India) and fused prior to use. All melting points were determined on a Perfit melting point apparatus and are uncorrected. ^{1}H NMR spectra were registered on a Bruker DPX-200 NMR spectrometer (200 MHz) in $CDCl_3$ – $CDCl_3$ + DMSO-d_6 using tetramethylsilane as internal standard. The IR spectra were recorded using KBr disc on PerkinElmer FTIR spectrophotometer. Mass spectral data were recorded on Jeol JMS D-300 mass spectrometer at 70 ev. Thermal analysis was carried out on DTG-60 Shimadzu thermal analyzer with heating rate of 10 °C/sec and the amount of metal content was determined on a double beam atomic absorption spectrophotometer GBC 932 AB (manufactured in Australia). The catalyst was stirred in dil. HCl for 10 h and the resulting filtrate was subjected to atomic absorption spectrophotometric analysis. Elemental analysis was carried out on Leco-CHNS-932 elemental analyzer manufactured by Leco corporation (USA).

Preparation of activated silica

K100 silica gel (10 g) was added to a round-bottomed

© 2007 NRC Canada

flask (250 mL) containing a 1:1 mixture of conc. HCl and distilled water (100 mL). The reaction mixture was refluxed in an oil bath for 24 h. On cooling, silica gel was filtered off and washed with excess distilled water until the washings were neutral. It was dried in an oven at 110 °C for 15 h.

General procedure for the preparation of silica-supported zinc chloride

To a mixture of anhydrous zinc chloride (3 g) and activated silica (10g, K100) in a round-bottomed flask (100 mL), sodium dried toluene (60 mL) was added and the reaction mixture was refluxed for 10 h. SiO_2–$ZnCl_2$ was obtained as a free-flowing powder after filteration under reduced pressure and dried at 110 °C for 12 h. It was stored in a desiccator and could be used for several months without loss of activity.

General procedure for the preparation of 3,4-dihydropyrimidinones–thiones

To a mixture of aldehyde **1** (2.5 mmol), ethyl acetoacetate **2** (2.5 mmol), and urea or thiourea **3** (2.5 mmol) in a round-bottomed flask (100 mL), acetonitrile (15 mL) was added. The reaction mixture was stirred at RT for 5 min and then the catalyst SiO_2–$ZnCl_2$ (200 mg, 12 mol% of Zn) was added and the stirring was continued at 80 °C in an oil bath for an appropriate time (Table 1). After completion of the reaction (monitored by TLC), the reaction mixture was filtered off. The product was obtained after removal of the solvent under reduced pressure and crystallization from EtOAc – petroleum ether. The residue was washed with acetonitrile followed by methylene chloride and dried at 110 °C for 5 h. It could be used further for carrying out the reaction.

The structures of the products were confirmed by IR, ^{1}H NMR, and mass spectral data, and comparison with authentic samples prepared according to the literature methods.

Spectral data of selected compounds

Ethyl 6-methyl-4-(4-methoxyphenyl)-3,4-dihydropyrimidin-2(1H)-one-5-carboxylate (4b)

IR (KBr, cm^{-1}) ν_{max}: 3390, 3243, 3106, 2958, 1706, 1651, 1278, 1088. ^{1}H NMR (DMSO-d_6) δ 1.01–1.20 (t, 3H, J = 7 Hz, CH_2CH_3), 2.30 (s, 3H, CH_3), 3.80 (s, 3H, OCH_3), 3.90–4.20 (q, 2H, J = 7 Hz, CH_2CH_3), 5.60 (s, 1H, C4-H), 6.80–6.90 (d, 2H, J = 7.2 Hz, ArH), 7.15–7.25 (d, 2H, J = 7.2 Hz, ArH), 7.65 (bs, 1H, NH), 9.17 (bs, 1H, NH). m/z: 290 (M^+).

Conclusion

In conclusion, we have developed a mild, simple, cost-effective, and green procedure for the synthesis of dihydropyrimidinones using reusable SiO_2–$ZnCl_2$ under het-

© 2007 NRC Canada

erogeneous catalysis conditions. Moreover, the mild reaction conditions, high yield of products, ease of work-up, compatibility with various functional groups, and the ecologically clean procedure, will make the present method a useful and important addition to the current methodologies for the Biginelli synthesis.

1D and 2D NMR investigations of the micelle-formation process in 8-phenyloctanoate micelles

Josette M. Landry, D. Gerrard Marangoni, Michael D. Lumsden, and Robert Berno

Abstract: The micellization process of sodium 8-phenyloctanoate in a deuterated aqueous solution was studied, using ^{1}H NMR spectroscopy and two-dimensional (2D) nuclear Overhauser enhancement spectroscopy (NOESY). ^{1}H NMR spectra, acquired for the sodium 8-phenyloctanoate before and after the critical micelle concentration (CMC) value, showed that large chemical-shift changes were observed for both the aromatic proton peaks and the peaks for the methylene protons near the terminal phenyl group. The plots for the methylene protons near the headgroup do not show these large chemical-shift changes. These observations support the view that the terminal phenyl ring of the surfactant is primarily located in the micellar interior. The 2D NOESY experiments show significant cross-peaks, between the phenyl protons and the methylene protons of the surfactant, that substantiate the conclusions on those drawn from NMR aromatic solute induced shift (ASIS) experiments on the same and similar systems. All these observations are consistent with the Gruen model of the micelle and previous NMR NOESY experiments for other surfactant systems.

Key words: surfactants, micelles, NMR, NOESY.

Résumé : Faisant appel à la spectroscopie RMN du proton et à la spectroscopie RMN du proton bidimensionnelle avec effet Overhauser nucléaire (« NOESY »), on a étudié le processus de micellisation du 8-phényloctanoate de sodium dans une solution aqueuse deutérée; les données acquises pour le 8-phényloctanoate de sodium avant et après la valeur de la concentration micellaire critique (CMC) mettent en mettent en évidence l'apparition de changements importants dans les déplacements chimiques des pics des protons aromatiques ainsi que des pics des protons des groupes méthylènes proches des groupes phényles terminaux. Les courbes des protons des groupes méthylènes adjacents des groupes carboxyles ne présentent pas ce genre de changements importants de leurs déplacements chimiques. Ces observations sont en accord avec les vues selon lesquelles le noyau aromatique terminal d'un agent de surface est situé principalement dans la phase micellaire intérieure. Les expériences de « NOESY » bidimensionnelles montrent l'existence de croisements importants de pics entre les protons aromatiques du groupe phényle et les protons des groupes méthylènes de l'agent de surface, ce qui corrobore les conclusions qui avaient étaient déduites d'expériences de RMN sur le déplacement induit de solutés aromatiques sur les mêmes systèmes et d'autres apparentés. Toutes ces observations sont en accord avec le modèle de Gruen de la micelle et avec les expériences de RMN « NOESY » pour d'autres systèmes d'agents de surface.

Mots-clés : agents de surface, micelles, RMN, « NOESY ».

Introduction

Surfactant molecules contain a hydrophobic part (tail) and hydrophilic part (head). They are typically organic-based and have specific properties that make them useful for a wide variety of applications. A very important property is that they lower the surface tension of a solvent (1–4). They are also able to act as emulsion agents to bring immiscible phases together (5–8). Surfactant molecules will aggregate to form micelles above a certain concentration, referred to as the critical micelle concentration or CMC value. The CMC value is detected by plotting a physicochemical property like conductivity measurements, viscosity measurements, NMR chemical shift or relaxation rates, or surface tension measurements and observing the "break" or inflection point in the property vs. concentration plot.

It has been demonstrated in the past two decades that NMR studies of surfactant solutions can provide a wealth of information on the conformations of surfactant molecules (9, 10). ^{13}C NMR chemical shifts provide information on the conformations of the chains that are comprising the micelles (11–14). ^{13}C relaxation-rate measurements, as a function of the magnetic field strength, have demonstrated that the motions of the surfactant carbons near the headgroups tend to be more restricted, while those near the end of the alkyl chain are essentially isotropic (15–17). NMR ring-current shift measurements of phenyl groups, attached to surfactant

Fig. 1. Typical NMR spectrum for the sodium 8-phenyloctanoate system.

chains, have been used to examine the structure of phenyl-containing surfactants and the locations of aromatic and non-aromatic solubilizates in the interior of surfactant micelles (18–21).

Two-dimensional nuclear Overhauser enhancement spectroscopy (NOESY) provides significant information on the intra- and inter-molecular proximity of protons in a number of systems. NOESY experiments give spectra that correlate protons that are within a spatial proximity of 0.5 nm. It is extensively used in the determination of the conformations of nucleic acids, proteins, and membranes (22). In the case of micellar systems, the NOE cross-peaks are indicative of intra- and inter-molecular protons that are close enough in space to have dipolar interactions (23–25). It has been shown in the literature that these cross-peaks correlate extremely well with other experiments used to probe the structure of micelles and mixed micelles, such as luminescence probing and aromatic solute-induced shifts. NOESY experiments are preferable because of the noninvasive nature of the technique.

Surfactant molecules, containing an aromatic ring, can provide a convenient group that can be monitored for aromatic ring-current shifts. Gao et al. examined the micellization process of the sodium 10-phenyldecanoate system and found that large upfield shifts were observed for the aromatic protons and the methylene protons near the terminal phenyl group, while the shifts of protons, attached to the methylene protons near the headgroup, were very small (20). From this, it was proposed that the terminal phenyl group is, on average, located in the micellar interior. In this paper, we will examine the ^{1}H chemical shifts of the sodium 8-phenyldecanoate system, as a function of the surfactant concentration. The NMR ring-current effects will be used to determine the average location of the phenyl groups in the micelle interior. These ring-current shifts will be correlated with the results from the 2D NOESY NMR experiments. These techniques provide conclusive evidence of the average location of the aromatic groups in the micelle interior, and will be used to show that the aromatic rings do, indeed, sample the entire micelle interior.

Experimental

Sodium 8-phenyloctanoic acid (FW = 220.31 g/mol) was purchased from Lancaster (97% pure). A bulk solution of sodium 8-phenyloctanoate (0.1 mol/L) was made up by transferring the acid in D_2O and adding NaOD dropwise until it was completely dissolved. A slight excess of a base was used to prevent hydrolysis, which resulted in the appearance of turbidity in the NMR tube. The solution was sonicated, and the final pD was adjusted to a value between 10 and 11. D_2O was purchased from both Sigma-Aldrich and Norell and was 99.9% pure. Samples of different concentrations were made up in the NMR tubes directly by pipetting appropriate amounts of a stock surfactant solution and D_2O, respectively.

The 1D NMR spectra (^{1}H) for the ω-phenyloctanoate surfactant system were obtained on a Bruker AC-200 at St. Francis Xavier University, operating at 200.13 MHz, for protons and a Bruker AVANCE-500 at the Atlantic Region Magnetic Resonance Centre (ARMRC) at Dalhousie University. A typical ^{1}H spectrum for the ω-phenyloctanoate system is given in Fig. 1. The ^{1}H spectra were referenced to the HOD peak, which was assigned a value of $\delta = 4.71$ ppm. The 2D experiments (COSY and NOESY) were performed on the AVANCE-500 spectrometer at the ARMRC. The mixing times and the delay times for the NOESY experiments were estimated from the spin–lattice relaxation times of the surfactant, determined in separate experiments. In all cases, we used an acquisition delay of ~$3 \times T_1$ and a mixing time of ~$1 \times T_1$ to obtain the NOESY spectra. For the COSY experiments, the data were zero-filled once and multiplied by a sine-bell window in both dimensions prior to the 2D Fourier transform. In the gradient NOESY experiments, 128 transients of either 2 or 4 scans (8 scans in the water-suppression experiments) over 512 × 128 complex data points were acquired. All acquisitions were done in phase-sensitive mode, with and without the saturation of the water resonance at ~4.7 ppm. The data were zero-filled twice in t_1 and multiplied by a squared sine-bell function in both dimensions before the 2D Fourier transform.

Results and discussion

The proton resonances on the hydrocarbon chain were assigned using standard COSY techniques. The sodium ω-phenyloctanoate surfactant protons are numbered consecutively from the carboxylate group. ^{1}H NMR chemical shifts were determined as a function of the inverse surfactant concentration. The averaged CMC value for the sodium ω-phenyloctanote systems was found to be 0.055 ± 0.002 mol/L from the breaks in the ^{1}H chemical shifts vs. inverse surfactant concentration plot. The difference in the Gibbs energy of micellization between the sodium ω-phenyloctanoate and the sodium ω-phenyldecanoate surfactant yields a Gibbs energy of transfer, of the CH_2 group into the micelle, of –3.2 kJ/mole, which agrees with the Gibbs transfer energies/CH_2 for a number of conventional monomeric anionic and cationic surfactants (26). The aggregation number of the surfactant has been estimated from the ^{1}H chemical shifts as a function of the inverse surfactant concentrations, as we have done previously using

© 2007 NRC Canada

^{13}C chemical shifts (27). The average aggregation number from the ^{1}H chemical shifts was 25 ± 2, suggesting that these micelles are small and likely hydrated in the micelles palisade layer region. It should be noted that this value of 25 is virtually the same as that obtained by Gao et al. for the 10-carbon surfactant of the same family (20). The aggregation numbers, obtained from the application of a mass-action model to the ^{13}C chemical shifts, are likely to be smaller than those obtained from luminescence-probing experiments and light scattering, as has been discussed in the literature by Söderman and Guering (28). We will now turn our attention to discussing the locations of the phenyl groups inside the micelles, as deduced by ^{1}H NMR ring-current shift measurements.

^{1}H NMR chemical-shift differences for the sodium ω-phenyloctanoate resonances are presented in Figs. 2–4. In this paper, we define the chemical-shift difference as follows:

$$[1] \qquad \Delta\delta = \delta(\text{aq}) - \delta(\text{obs})$$

Hence, a low frequency shift is defined as having a positive value of Δδ. When we examine the plots of the observed chemical shifts for the 8-phenyloctanoate system, we clearly see that the protons on or near the terminal benzene ring undergo significant low-frequency shifts upon micelle formation (i.e., they are characterized by large, positive Δδ values). In Figs. 2–4, we also observe that these large low-frequency shifts, leading up to and at the CMC of the surfactant, are much larger than the observed ^{1}H chemical shifts for surfactant systems like sodium dodecylsulfate (SDS) or dodecyltrimethylammonium bromide (DTAB). In fact, the chemical-shift changes of the CH_2 protons near the terminal phenyl group upon micelle formation range between 0.25 and 0.40 ppm on the 200 MHz spectrometer, and are comparable to the observed Δδ values for some ^{13}C resonances upon micelle formation (27).

For protons, the chemical shifts are dominated by the diamagnetic-shielding term, which is primarily influenced by the reduction in the electron density around the ^{1}H nucleus because of the electronegativity of bonded atoms. The ring-current effect arises from the strong anisotropy in the magnetic susceptibility, attributed to the produced ring current when the applied field, perpendicular to the magnetic plane, induces the circulation of the π electrons around the ring. With a proton attached to the ring a deshielding occurs, whereas protons above and below the ring should experience an enhancement in the local shielding, and hence, a decreased chemical shift. The fact that we only observe decreased resonance frequencies for the ω-phenyloctanoate protons is consistent with the presence of a neighbouring-group effect from the aromatic rings. Our results for the ω-phenyloctanoate are in excellent agreement with the results of Gao et al. and Nagakawa et al. (29). We note that, on average, we observed large ring-current shifts for protons attached to C7, C8, C*m*, C*o*, and C*p* upon micellization, but small shifts were observed for the protons at C2 and C3. If the phenyl group was located, on average, near the micelle interior, we would expect to see significant shifts for the C7, C8, C*m*, C*o*, and C*p* protons, but small shifts for the protons near the micelle surface (the C2 and C3 protons). These observations are also consistent with the line-broadening of the

ω-phenyldecanoate proton resonances by $Mn^{2+}(D_2O)^{6+}$, observed by Stark et al. (30).

The use of aromatic ring-current induced shifts has been criticized in the literature (31). Hence, it is instructive to consider another NMR technique with which the spatial arrangements of the hydrocarbon chains can be deduced in a noninvasive manner. 2D NOESY experiments have been shown to provide excellent insights into the nature of the micelle-formation process, solubilization in mixed micelles, and the formation of polymer–surfactant complexes. In case of the ω-phenyloctanoate system, we have obtained the NOESY spectra for the surfactant in micellar form at two concentrations: one at ~2 × the CMC of the surfactant and one at ~1/3 of the CMC value of the surfactant (Fig. 5). In case of the spectrum at 0.090 mol/L (Fig. 5*a*), it is clear that significant cross-peaks, which indicate the proximity of the protons between the neighbouring surfactant molecules, occur in the NOESY experiments. These cross-peaks are completely absent in the spectrum at the lower (<CMC) concentration. The spectrum at the higher concentration exhibits cross-peaks, indicative of through-space dipole–dipole coupling between protons either on adjacent surfactant molecules or even on the same molecule. The cross-peaks indicate the spatial proximity of the protons on adjacent surfactant molecules or the protons on the same surfactant molecule within a distance of 5 Å (22). In fact, we observe substantial chain–proton correlations between the protons in the micelle headgroups region and protons on the end of the chain, which would indicate that the surfactant chain is certainly bent back towards the surface of the micelles, as has been discussed previously (20). Examining the phenyl resonances at around 7.1 to 7.2 ppm, we observe the existence of cross-peaks between the phenyl resonances and the remaining chain protons in the surfactant. Apparently, the correlation between the phenyl protons and the protons near the headgroups of the surfactant is quite significant, indicating that the benzene rings are capable of bending back and interacting with the protons near the surfactant headgroups. The picture that emerges from these NOESY experiments is that the phenyl groups are indeed not buried in the interior of the surfactant micelles, but there is a significant amount of chain motion and bending within the hydrocarbons core of the micelles, which is in excellent agreement with the results of both ^{13}C NMR relaxation-rate measurements (15–17) and ^{13}C NMR chemical-shift measurements (11–13).

We have also obtained the NOESY spectrum for the same system at a slightly higher concentration (0.10 mol/L) using a solvent-suppression technique known as excitation sculpting to remove the water peaks from the spectra. The spectrum is presented in Fig. 6. Clearly, the cross-peaks that existed at 0.090 mol/L do exist at the higher surfactant concentration (~2 × the CMC of the surfactant). In this case, we

© 2007 NRC Canada

again observe cross-peaks between the benzene protons (δ = 7.2 ppm) and all the surfactant chain protons. This is consistent with the phenyl rings being able to sample the entire micellar interior, and this is again in excellent agreement with the ASIS experiments of Gao et al. for benzene in SDS micelles (21). Gao et al. concluded that phenyl rings are distributed rather uniformly throughout the interior of ω-phenyldecanoate micelles. In our NOESY experiments, the cross-peak volume between the phenyl protons and the C7 and C8 appears to be larger than that of the phenyl protons with C2 and C3, which is in excellent agreement with ASIS experiments. Hence, these observations seem to support the notion that the phenyl rings are primarily located in the micellar core, but they do bend back towards the micellar surface, as predicted by the Gruen model (32).

Summary and conclusion

The ^{1}H NMR chemical shifts and the NOESY spectra for ω-phenyloctanoate have been determined for the concentration range above and below the CMC of the surfactant. The ^{1}H chemical differences after micelle formation are substantially larger for the protons near the benzene rings in the chain. These shifts are consistent with the phenyl rings, attached to the end of the surfactant chain, bending back towards the micellar surface, which agrees with the previous work of Gao et al. on the ω-phenyldecanoate system. The 2D NOESY spectra, obtained for the same system, seem to bear out the hypothesis that the benzene ring is not anchored in the micellar interior but is in rapid exchange throughout the micellar interior.

Asymmetric organocatalytic direct aldol reactions of cyclohexanone with aldehydes in brine

Wen-Ping Huang, Jia-Rong Chen, Xin-Yong Li, Yi-Ju Cao, and Wen-Jing Xiao

Abstract: Organocatalytic asymmetric direct aldol reactions in brine with high diastereo- and enantioselectivities, using a readily available bifunctional amide catalyst, were developed.

Key words: aldol reaction, organocatalyst, asymmetric catalysis, water.

Résumé : Opérant dans de la saumure et faisant appel à un amide bifonctionnel facilement disponible comme catalyseur organique, on a développé des réactions aldoliques directes et asymétriques qui se produisent avec des diastéréo- et énantiosélectivités élevées.

Mots-clés : réaction aldolique, catalyse organique, catalyse asymétrique, eau.

[Traduit par la Rédaction]

Introduction

Water, the essential medium for the construction of chemical bonds in life, was widely accepted as "a contaminant in organic synthesis". Unless water is used as a reactant, the use of water was usually avoided in reaction systems. Nevertheless, Breslow and co-workers investigated Diels–Alder reactions in water in 1980s, and it was found that water could remarkably increase the reaction rate and selectivities (1). Since then, there has been considerable efforts to develop organic reactions, using water as an additive or a solvent instead of conventional organic solvents, with respect to environmental concerns, safety, and cost (2, 3). In contrast, there have been relatively few investigations using brine as the reaction media (4), although the reaction efficiency in brine may be superior to that in water. Herein, we report organocatalytic direct aldol reactions of cyclohexanone with aldehydes in brine, using our bifunctional organocatalyst **4e**. The reactions afforded the desired products in high yields and in excellent diastereo- and enantioselectivities.

Organocatalysis, primarily because of the operational simplicity, the cheap catalyst, and the potential industrial applications, has received renewed attention and became the focus of intensive research endeavor (5). In 2000, almost three decades after the first report of enantioselective proline-catalyzed intramolecular aldol reaction presented by Eder et al. (6*a*) and Hajos and Parrish (6*b*), List and co-workers described fundamental work on proline-catalyzed asymmetric intermolecular aldol reactions of ketones and aldehydes (7). After that, there has been a large amount of research activities in this field (8), which has resulted in the development of asymmetric organocatalysis. Although water as an additive has a certain positive effect on organocatalytic aldol reactions (9), the use of a large amount of water or aqueous buffer as solvent has been found to be detrimental in some cases (10). Recently, studies by Mase and co-workers (11*a*), Hayashi and co-workers (11*b*, 11*c*), Dziedzic and co-workers (11*d*), and Wu and co-workers (11*e*) revealed the possibility to carry out enantioselective direct aldol reactions in water, along or together with organic solvents, by the design and use of new organocatalysts (Scheme 1). Part of our ongoing project aimed at developing readily available bifunctional organocatalysts of broad utility to chemical transformations and with industrial potential (8*j*, 9*d*). Thus, we were interested in applying our artificial bifunctional amine catalysts **3** and **4** to aldol reactions in brine.

Results and discussion

The efficiency of our bifunctional catalysts was first evaluated with the direct asymmetric aldol reaction in water. Reaction of 4-nitrobenzaldehyde with cyclohexanone was performed in the presence of 20 mol% of catalyst **3** and 20 mol% of acetic acid (HOAc) (co-catalyst) at room temperature in 1 mL of water, and the aldol product **7a** (Fig. 1) was afforded in 89% yield, with 88% enantiomeric excess (ee) and a diastereomeric ratio (dr) of 92:8 (Table 1, entry 1). Encouraged by this result, we further examined the catalytic efficiency of the chiral amides **4a–e** in the presence of various acid additives (12). Notably, all the reactions with bifunctional catalysts **3** and **4a–e** proceed smoothly with good diastereo- and enantioselectivities, and **4e** shows the best catalytic activity with HOAc as the co-catalyst (Table 1, entries 1–10). Lowering the temperature to 0 °C further im-

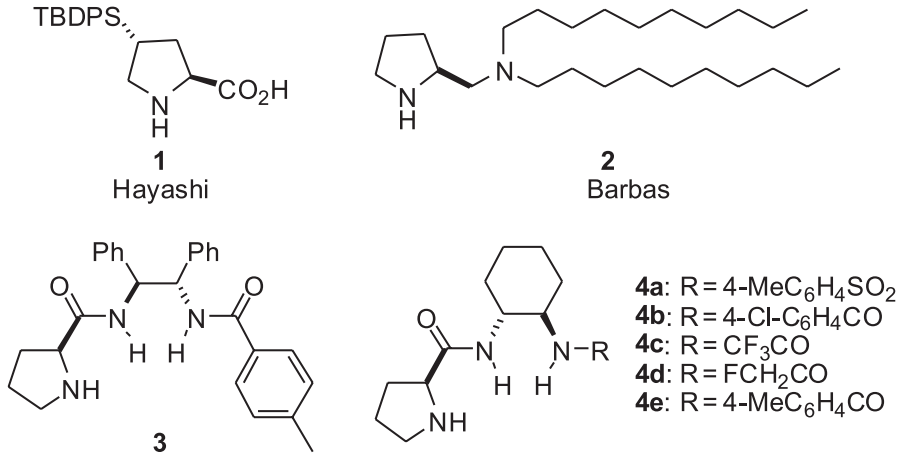

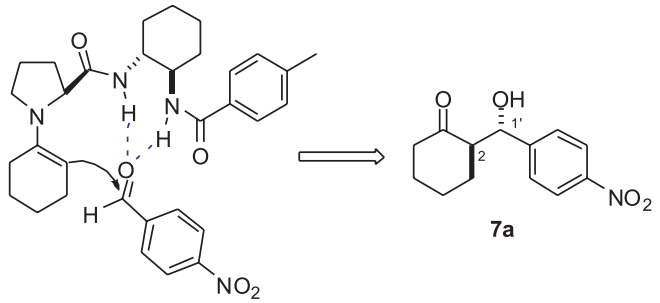

Fig. 1. Proposed transition state.

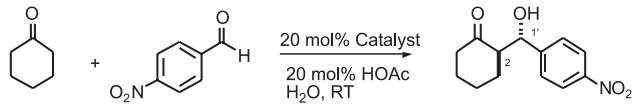

proves the dr from 89:11 to 92:8, although the product suffered a slight decrease of ee (Table 1, entry 11). The use of brine as solvent was remarkable in our catalytic system, and diasteroselectivity reached 95:5 (Table 1, entry 12). Therefore, brine was chosen as the solvent for further optimization. The chiral amide – acid combinations were also evaluated in different ratios, and the best ratio of catalyst **4e** to HOAc was 1:2 (Table 1, entries 12–15). The superior levels of asymmetric induction and efficiency, exhibited by the amide **4e** – HOAc in brine affording the aldol adduct **7a** in 92% yield with 93% ee and 95:5 dr, prompted us to select these catalytic conditions for further investigation (Table 1, entry 14).

Using these optimized conditions, reactions of cyclohexanone with various aldehydes, catalyzed by **4e** in brine, were then examined. As summarized in Table 2, the aromatic aldehydes **6a**–**i** reacted well with **5**, and the aldol adducts **7a**–**i** formed in high yields with high diastereo- and enantioselectivities (Table 2, entries 1 and 4–11). The only exception is the case of benzaldehyde, in which the ee was 83%, and the dr was 85:15 (Table 2, entry 12). Heteroaromatic aldehydes, such as **6k**, could also be successfully employed in this reaction with a lower yield of 43% (Table 2, entry 13). Notably, the reaction can still proceed well with little loss in selectivity even when the catalyst loading was reduced to 5 mol%, or only 2 equiv. of ketone was used (Table 2, entries 2 and 3).

The scope of this class of aldol reactions was also extended to a series of other ketone donors (Table 3). The reaction with the water-miscible ketone **6m** affords the aldol

adduct in good yield with high diastereo- and enantioselectivity, while moderate results were obtained with acetone as donor (Table 3, entries 1, 2). Significantly, the reaction preferentially occurred at the C3 position of butanone. To our surprise, although the reaction of cyclopentanone afforded the *syn*-diastrereomer as maojor product with 55% ee, the ee for the *anti*-adduct is still up to 92% (Table 3, entry 3).

Interestingly, the absolute configuration of the major aldol adduct **7a** was determined to be (2*R*,1*S*) by ^{1}H NMR spectroscopic analysis and comparison of HPLC retention time with literatures (11). Thus, we proposed that **4e**–HOAc catalyzed a *Si*-face of enamine attack on *Si*-face of the arylaldehyde. Notably, this result showed completely different transition-state model from the previously proposed L-proline-based aldol transition state (13) and recent Barbas and Hayashi's experiments (11). This unusual π-facial differentiation of enamine may be affected by the two-hydrogen-bond bearing chiral diaminocyclohexane backbone. Further studies on the mechanism are underway.

We have also found that this process is appropriate for gram-scale reactions, eventhough the catalyst loading is only 5 mol%, and water is 5500 mol%. The diastereo- and stereoselectivities are excellent (see eq. [1]). From a green-chemistry perspective, this is the real organocatalyzed aldol reaction in water (In Hayashi's catalytic system, 300 mol% water was used as solvent (11*b*)).

[1]

Experimental section

General methods

Unless otherwise noted, commercial reagents were used as received. Hexane and ethyl acetate, for flash column chromatography, were distilled before use. Flash column chromatography was performed using 200–300 mesh silica gel. ^{1}H NMR spectra were recorded on Varian Mercury 400 (400 MHz) spectrophotometers. Chemical shifts are reported in ppm from the solvent resonance, as the internal standard ($CDCl_3$: 7.26 ppm). Data are reported as follows: chemical shift, multiplicity (s = single, d = doublet, t = triplet, q = quartet, br = broad, and m = multiplet), coupling constants (Hz), and integration. ^{13}C NMR spectra were recorded on Varian Mercury 400 (100 MHz) spectrophotometers with complete proton decoupling ($CDCl_3$: 77.0 ppm). Chiral HPLC was performed on Agilent 1100 series with chiral columns (Chirapak AS, AD, OD, and OJ columns; Daicel Chemical Ind. Ltd.). Catalysts **3** and **4** were prepared by the previously described methods (8*j*).

Typical procedure for aldol reaction using the bifunctional catalyst 4e–HOAc in brine (Table 1, entry 14)

To a mixture of catalyst **4e** (33 mg, 0.10 mmol), cyclohexanone (0.26 mL, 2.5 mmol), and brine (1 mL), acetic acid (11.6 μL, 0.20 mmol) was added at 0 °C. The reac-

© 2007 NRC Canada

tion mixture was stirred for 10 min in a closed system, and then *p*-nitrobenzaldehyde (76 mg, 0.5 mmol) was added. The reaction mixture was stirred for 7 h, then the reaction was quenched by the addition of saturated ammonium chloride solution and extracted three times with ethyl acetate (3 mL). The mixture of combined organic phases was stirred over anhydr. $MgSO_4$, filtered, and concentrated to give pure aldol adduct **7a**, as white solid, through column chromatography on silica gel (hexane – ethyl acetate (3:1)). The enantiomeric excess (ee) of **7a** was determined by chiral-phase HPLC analysis.

2-[Hydroxy-(4-nitro-phenyl)-methyl]-cyclohexanone (7a)

2-[Hydroxy-(2,4-dichloro-phenyl)-methyl]-cyclohexanone (7i)

Yield: 88%; *anti:syn* (99:1). *Anti*-diastereomer: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.53–2.11 (m, 6H), 2.33–2.48 (m, 2H), 2.61–2.64 (m, 1H), 4.09 (d, J = 4.0 Hz, 1H), 5.28 (d, J = 8.0 Hz, 1H), 7.27–7.35 (d, J = 8.0 Hz, 2H), 7.49 (d, J = 8.8 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 24.8, 27.7, 30.3, 42.6, 57.5, 70.0, 127.5, 128.8, 129.2, 133.4, 133.7, 137.8, 215.0. HPLC (Chiralcel OD-H, Hexane–*i*-PrOH (90:10), 0.5 mL/min, 220 nm, 20 °C): t_R = 14.9 min (major) and t_R = 18.4 min (minor), ee: 94%. *Syn*-diastereomer: HPLC (Chiralcel OD-H, Hexane–*i*-PrOH (90:10), 0.5 mL/min, 220 nm, 20 °C): t_R = 10.8 min and t_R = 11.4 min.

2-(Hydroxy-phenyl-methyl)-cyclohexanone (7j)

Yield: 72%; *anti:syn* (85:15). *Anti*-diastereomer: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.25–2.10 (m, 6H), 2.32–2.49 (m, 2H), 2.58–2.65 (m, 1H), 4.78 (d, J = 6.0 Hz, 1H), 7.29–7.36 (m, 5H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 24.7, 27.8, 30.8, 42.6, 57.4, 74.7, 127.0, 127.9, 128.3, 140.9, 215.5. HPLC (Chiralcel OD-H, Hexane–*i*-PrOH (90:10), 1.0 mL/min, 220 nm, 20 °C): t_R = 18.2 min (major) and t_R = 26.5 min (minor), ee: 83% *Syn*-diastereomer: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.48–2.10 (m, 6H), 2.32–2.47 (m, 2H), 2.57–2.62 (m, 1H), 5.39 (d, J = 2.4 Hz, 1H), 7.23–7.35 (m, 5H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 24.8, 26.0, 27.9, 42.6, 57.1, 70.6, 125.7, 126.9, 128.1, 141.4, 214.8. HPLC (Chiralcel OD-H, Hexane–*i*-PrOH (90:10), 1.0 mL/min, 220 nm, 20 °C): t_R = 14.7 min and t_R = 16.2 min.

2-(Furan-2-yl-hydroxy-methyl)-cyclohexanone (7k)

Yield: 43%; *anti/syn* (89:11). *Anti*-diastereomer: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.30–2.10 (m, 6H), 2.34–2.46 (m, 2H), 2.88–2.90 (m, 1H), 3.90 (d, J = 3.6 Hz, 1H), 4.81 (d, J = 8.4 Hz, 1H), 6.26 (d, J = 3.2 Hz, 1H), 6.30 (q, J = 2.8 Hz, 1H), 7.36 (d, J = 1.2 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 24.6, 27.7, 30.5, 42.5, 54.8, 68.1, 107.9, 110.0, 142.2, 153.5, 214.9. HPLC (Chiralcel AD-H, Hexane–*i*-PrOH (95:5), 1.0 mL/min, 220 nm, 20 °C): t_R = 25.8 min (major) and t_R = 28.6 min (minor), ee: 86%. *Syn*-diastereomer: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.61–2.10 (m, 6H), 2.34–2.45 (m, 2H), 2.78–2.82 (m, 1H), 3.11 (d, J = 4.8 Hz, 1H), 5.26 (t, J = 3.6 Hz, 1H), 6.26 (d, J = 2.8 Hz, 1H), 6.30 (q, J = 2.8 Hz, 1H), 7.33 (d, J = 1.6 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 24.7, 27.2, 27.5, 42.4, 54.5, 66.5, 106.5, 110.2, 141.4, 154.6, 213.6. HPLC (Chiralcel AD-H, Hexane–*i*-PrOH (95:5), 1.0 mL/min, 220 nm, 20 °C): t_R = 17.8 min and t_R = 19.5 min.

4-Hydroxy-3-methyl-4-(4-nitro-phenyl)-butan-2-one (7m)

Yield: 55%; *anti/syn* (97:3). *Anti*-diastereomer: ^{1}H NMR (400 MHz, $CDCl_3$, δ): 1.01 (d, J = 7.6 Hz, 3H), 2.21 (s, 3H), 2.87–2.94 (m, 1H), 3.34 (d, J = 4.8 Hz, 1H), 4.87 (d, J = 8.0 Hz, 1H), 7.51 (d, J = 8.4 Hz, 2H), 8.21 (d, J = 8.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 14.1, 29.7, 53.2, 75.4, 123.7, 127.5, 147.5, 149.3, 212.8. HPLC (Chiralcel AS-H, Hexane–*i*-PrOH (93:7), 1.0 mL/min, 254 nm, 20 °C): t_R = 51.1 min (major) and t_R = 75.9 min (minor). *Syn*-diastereomer: HPLC (Chiralcel AS-H, Hexane–*i*-PrOH (93:7), 1.0 mL/min, 254 nm, 20 °C): t_R = 47.6 min and t_R = 66.8 min.[2]

Conclusions

In summary, we have developed an organocatalytic asymmetric direct aldol reaction in brine with high diastereo- and enantioselectivities, using a readily available bifunctional amide catalyst. From a green-chemistry view, employing brine or water as the reaction medium is environment-friendly and safe, regardless of performing the reaction under truly aqueous conditions or not (14). Further studies that focus on the application of this catalyst system to other types of transformations are under investigation in our laboratory.

Monte Carlo simulation study of the effects of acidity and LET on the primary free-radical and molecular yields of water radiolysis — Application to the Fricke dosimeter

Narongchai Autsavapromporn, Jintana Meesungnoen, Ianik Plante, and Jean-Paul Jay-Gerin

Abstract: Monte Carlo simulations are used to investigate the effects of acidity (pH) on the primary yields of various chemical species produced in the radiolysis of de-aerated aqueous sulfuric acid solutions over the range from neutral solution to 0.4 mol/L H_2SO_4. The effects of the quality of radiation, measured in terms of linear energy transfer (LET), have also been studied for LET varying from ~0.3 to 15 keV/μm at ambient temperature. Our results show that an increase in acidity ($1 < pH < 4$) leads to an increase in the yield $G_{e^-_{aq}+H\cdot}$ of the "reducing" free radicals (hydrated electron and H• atom) and a slight increase in $G_{\cdot OH}$ and $G_{H_2O_2}$, while there is a slight decrease in G_{H_2}. At $pH < 1$, •OH radicals react with HSO_4^- anions to form $SO_4^{\cdot-}$ radicals, resulting in a steep decrease in $G_{\cdot OH}$. By contrast, in the range of pH from ~4 to 7, the calculated yield values are independent of sulfuric acid concentration. In both neutral water and 0.4 mol/L H_2SO_4 (pH 0.46) solutions, the primary molecular yields increase upon increasing LET to ~15 keV/μm with a concomitant decrease in those of free radicals. As an exception, $G_{H\cdot}$ at first increases with LET, reaching a maximum near 6.5 keV/μm before decreasing steeply at higher LET. The results obtained are generally in good agreement with available experimental data over the whole acidity and LET ranges studied. Finally, as an application, we have simulated the radiation-induced oxidation of ferrous sulfate solutions in aerated aq. 0.4 mol/L H_2SO_4 (Fricke dosimeter) as a function of time up to ~50 s and addressed the effects of LET on the resulting ferric ion yield at 25 °C. The production of Fe^{3+} ions is highly sensitive to free-radical yields, especially H• atoms (via formation of $HO_2^{\bullet}$), resulting in a marked decline of $G(Fe^{3+})$ with increasing LET. The general trend of the observed variation of $G(Fe^{3+})$ with radiation quality is well reproduced by our computed Fe^{3+} ion yield values.

Key words: liquid water, acidic (H_2SO_4) aqueous solutions, radiolysis, free-radical and molecular yields, linear energy transfer (LET), Fricke dosimeter, Monte Carlo simulations.

Résumé : À l'aide de calculs de simulation Monte Carlo, nous avons étudié l'influence de l'acidité (pH) sur les rendements primaires des diverses espèces chimiques produites lors de la radiolyse de solutions aqueuses désaérées d'acide sulfurique dans la gamme de concentrations ~0–0.4 mol/L en H_2SO_4. L'influence de la qualité du rayonnement, décrite en termes de transfert d'énergie linéique (TEL), a aussi été étudiée pour des valeurs de TEL entre ~0,3 et 15 keV/μm à la température ambiante. Nos résultats montrent que, pour des irradiations avec des rayonnements de faible TEL, une augmentation en acidité ($1 < pH < 4$) conduit à une augmentation du rendement $G_{e^-_{aq}+H\cdot}$ de l'entité réductrice radicalaire (électron hydraté et atome H˙) et à un faible accroissement de $G_{\cdot OH}$ et $G_{H_2O_2}$, alors que G_{H_2} diminue légèrement. À $pH < 1$, les radicaux •OH réagissent avec les anions HSO_4^- pour former les radicaux $SO_4^{\cdot-}$, entraînant une diminution marquée de $G_{\cdot OH}$. En revanche, pour des pH entre ~4 et 7, les valeurs des rendements calculées sont indépendantes de la concentration en acide sulfurique. Autant pour l'eau liquide neutre que pour les solutions H_2SO_4 0,4 mol/L (pH 0,46), les rendements primaires moléculaires augmentent avec le TEL alors que ceux des espèces radicalaires diminuent de façon concomitante. Le cas de $G_{H\cdot}$ est singulier, puisqu'il augmente initialement avec le TEL, atteint un maximum à ~6,5 keV/μm, puis décroît rapidement à TEL plus élevé. Les résultats obtenus s'accordent bien avec les données expérimentales disponibles dans la littérature pour toute la gamme d'acidité et de TEL considérée. À titre d'application, nous avons enfin simulé l'oxydation radio-induite des ions ferreux en milieu H_2SO_4 0,4 mol/L aéré (dosimètre de Fricke) en fonction du temps jusqu'à ~50 s et étudié l'influence du TEL sur le rendement d'apparition des

ions ferriques à 25 °C. La production des ions Fe^{3+} est très sensible à la valeur des rendements radicalaires, en particulier les atomes H• (via la formation de HO_2•), résultant en une décroissance marquée de $G(Fe^{3+})$ lorsque le TEL augmente. L'allure générale de la variation expérimentale de $G(Fe^{3+})$ avec la qualité du rayonnement utilisé est bien reproduite par nos valeurs calculées des rendements d'ions Fe^{3+}.

Introduction

A large fraction of radiation chemistry has been concerned with studies of water and its solutions[2] mainly because of the unique importance of water, particularly in biological systems (living cells are composed of about 70%–85% water by weight) and also in various domains of nuclear science and technology, such as water-cooled nuclear power reactors (where water is used both as neutron moderator and as the heat transport medium). A good summary of the present status of aqueous radiation chemistry is given in refs. 1–4.

The radiolysis of pure liquid water (in the absence of oxygen) by low-LET (linear energy transfer or energy loss per unit track length, -dE/dx) radiation such as ^{60}Co γ-rays, fast electrons, or high-energy protons, can be described under ordinary irradiation conditions by the following *global* equation, written for an absorbed energy of 100 eV (1),

$$[1]\quad G_{-H_2O}H_2O \rightsquigarrow G_{e^-_{aq}}e^-_{aq} + G_{OH^-}OH^- + G_{H^+}H^+ + G_{H\cdot}H\cdot + G_{H_2}H_2 + G_{\cdot OH}\cdot OH + G_{H_2O_2}H_2O_2 + G_{HO_2\cdot/O_2\cdot^-}HO_2\cdot/O_2\cdot^- + \ldots$$

where the coefficients G_X are the so-called "primary" free-radical and molecular yields ("long-time" or "escape" yields) representing the numbers of the various radiolytic species X (e^-_{aq}, OH^-, H^+, H•, H_2, •OH, H_2O_2, HO_2•/O_2•$^-$, …) that remain throughout the bulk of the solution after spur expansion owing to diffusion.[3] At ambient temperature, this spur expansion is essentially complete on the microsecond time scale after the initial energy deposition. At this time, the species that have diffusively escaped from spur or track reactions become homogeneously distributed in the bulk of the solution and available to react with added solutes (treated as spatially homogeneous) at moderate concentrations. At this stage, G_{-H_2O} denotes the corresponding yield for net water decomposition. For ^{60}Co γ-radiation and neutral water at ambient temperature (LET ~0.3 keV/μm, pH 7), the values of the primary yields are (3),

$$[2]\quad \begin{array}{lll} G_{e^-_{aq}} = 2.50 & G_{H\cdot} = 0.56 & G_{H_2} = 0.45 \\ G_{\cdot OH} = 2.50 & G_{H_2O_2} = 0.70 & G_{HO_2\cdot/O_2\cdot^-} = 0.02 \\ G_{-H_2O} = 3.94 & & \end{array}$$

These values, including the contribution of hydroperoxyl/superoxide anion radicals (HO_2•/O_2•$^-$, pK_a = 4.8, is a minor radiolytic product and can be usually omitted in the case of low-LET radiation)[4] are connected by the equations:

$$[3]\quad G_{e^-_{aq}} + G_{OH^-} = G_{H^+}$$

$$[4]\quad G_{e^-_{aq}} + G_{H\cdot} + 2G_{H_2} = G_{\cdot OH} + 2G_{H_2O_2} + 3G_{HO_2\cdot/O_2\cdot^-}$$

$$G_{-H_2O} = G_{e^-_{aq}} + G_{H\cdot} + 2G_{H_2} - G_{HO_2\cdot/O_2\cdot^-} = G_{\cdot OH} + 2G_{H_2O_2} + 2G_{HO_2\cdot/O_2\cdot^-}$$

expressing the charge conservation (electroneutrality) and material balance of eq. [1], respectively.[5] Examination of the material balance eq. [4] normally serves as a stringent criterion for a consistent set of G values.

For ^{60}Co γ-irradiated 0.4 mol/L sulfuric acid aqueous solutions at room temperature (pH 0.46), representative values of the primary free-radical and molecular product yields are (e.g., see ref. 5):

$$[5]\quad \begin{array}{lll} G_{e^-_{aq}+H\cdot} = 3.66 & G_{H_2} = 0.40 & \\ G_{\cdot OH} = 2.84 & G_{H_2O_2} = 0.78 & \\ G_{HO_2\cdot/O_2\cdot^-} = 0.02 & G_{-H_2O} = 4.44 & \end{array}$$

In fact, radiolysis experiments concerning acidic solutions were carried out before those for neutral solutions [the most commonly used acid was H_2SO_4 in 0.4 mol/L aqueous solutions, although a few other acids such as HCl, $HClO_4$, and $(COOH)_2$ were also employed in radiation yield determina-

[2] In fact, experiments showing that water is decomposed by the action of dissolved radium salts were carried out shortly after Henri Becquerel's discovery of radioactivity (1896). One reviewer of this paper pointed out that Sir William Ramsay [J. Chem. Soc. Trans. **91**, 931 (1907)] was the first to systematically perform a series of complete experiments relating to the action of radium "emanation" on water. His article entitled, "The chemical action of the radium emanation. Part I. Action on distilled water", was published in 1907, precisely a century ago. A historical account of the radiation chemistry of water is given in ref. 1 and refs. cited therein.

[3] The symbol G with the formula of the species as subscript is used here to represent the "primary" yield of species X. Note that, following convention, the symbol G(X) with the formula of the product in parentheses denotes the experimental 100-eV yield of the "final" product X. Throughout this paper, values of G are expressed in units of molecules per 100 eV of absorbed energy; for conversion into SI units, 1 molec./100 eV ≈ 0.10364 μmol/J.

[4] The production of HO_2•/O_2•$^-$ is significant only in high-LET radiation tracks (e.g., see ref. 3).

[5] Equations [3] and [4] can readily be derived by writing that, at any time, the total (algebraic) charge of the transient species and stable products formed in the decomposition of water should be zero and the total number of H• atoms in the transients and products considered should be equal to twice the number of O atoms.

tions at low pH] for historical reasons related to the early development of the standard aerated ferrous sulfate (Fricke) dosimeter (6). One of the reasons that dictated the choice of sulfuric acid came from the fact that the dominant anion HSO_4^- was then considered to not intervene in the course of the radiolysis. The concentration of 0.4 mol/L H_2SO_4 was originally selected to provide the same mass absorption for X-rays in the dosimeter solution as in air (7). At such a high concentration of H_2SO_4, the H^+ ions very rapidly scavenge most, if not all, of the e_{aq}^- radicals in the spurs/tracks to form $H^\cdot$ atoms (5, 8–10):

$$[6] \qquad e_{aq}^- + H^+ \rightarrow H^\cdot$$

with a bimolecular rate constant $k_6 \approx 1.12 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1} (value corrected to take into account the effects of ionic strength at this acid concentration; see later) (11–15). The total primary yield of the reducing radicals e_{aq}^- and $H^\cdot$ may then be represented by the sum $G_{e_{aq}^- + H^\cdot} = G_{e_{aq}^-} + G_{H^\cdot}$.

A great many experimental and theoretical studies have shown that the yields in the radiolysis of water and aqueous solutions are highly dependent on the distances separating the primary products from each other along the track of the ionizing radiation. The distribution of separations, commonly referred to as the "track structure" (e.g., see ref. 3), is largely determined by the geometry of the physical energy loss events, or in other words by the quality of the radiation. An often used specifier of beam quality is the LET. The most evident effect of increasing the LET of the radiation is to give lower free-radical and higher molecular primary yields (3, 16–20). This behavior is explained by the increased intervention of radical–radical reactions as the local concentration of radicals within the track increases. In fact, as the LET increases, the initially isolated "spherical" spurs change to a situation in which the spurs overlap to form continuous "cylindrical" tracks consisting of a "core" of intense ionization and electronic excitation surrounded by a region composed of the tracks of knocked-out secondary electrons (δ-rays) called the "penumbra" (21–23). This should permit fewer free radicals to escape combination and recombination reactions during the expansion of the tracks and, in turn, the formation of more molecular products.

One of the best studied systems in radiation chemistry is the aerated dilute solution of ferrous sulfate in aq. 0.4 mol/L H_2SO_4, which is referred to as the "Fricke dosimeter" after Hugo Fricke who first published accounts of its properties in 1927–1929 (6). The chemistry of this system is based on the oxidation of ferrous ions to ferric ions by the oxidizing species $HO_2^\cdot$ (bearing in mind the rapid conversion of e_{aq}^- and $H^\cdot$ to $HO_2^\cdot$ at low pH and in the presence of oxygen), $^\cdot OH$, and H_2O_2 that are produced in the radiolytic decomposition of water (see later) (2, 7, 16, 24). From this mechanism, the yield of Fe^{3+} ions can be expressed in terms of the primary free-radical and molecular yields, given earlier, by the following stoichiometric equation (2, 24):

$$[7] \qquad G(Fe^{3+}) = 3(G_{e_{aq}^- + H^\cdot} + G_{HO_2^\cdot}) + G_{^\cdot OH} + 2G_{H_2O_2}$$

This relationship, which has been confirmed by experiment, shows that the production of Fe^{3+} ions is highly sensitive to factors that alter the free-radical yields, especially the yield of $H^\cdot$ atoms. In particular, $G(Fe^{3+})$ depends on the type of the radiation used. Data by a number of different authors have shown that $G(Fe^{3+})$ steadily decreases with increasing LET, this dependence reflecting the lower yields of radicals that escape the high-LET track as compared with low-LET radiolysis (e.g., see refs. 7, 11, 16, and 25–33). The Fricke dosimeter is a widely used liquid chemical dosimeter because of the accuracy, reproducibility, and linearity of its response as a function of dose (with care, Fricke dosimetry is capable of 0.1% precision for ^{60}Co γ-rays and high-energy X-rays and electrons) (33). In fact, its well-established characteristics are a standard in radiation–chemical work for comparison of yields under various conditions, both for experimental observations and for theoretical calculations.

For years, it has repeatedly been underlined that the problem of the influence of pH on the primary free-radical and molecular yields of water radiolysis is not yet totally resolved, especially at extreme values of pH where a certain confusion still exists (5, 10, 31). To gain further insights into our understanding of the effects of varying acidity and LET in the radiation chemistry of water, in the present study we have performed Monte Carlo simulations of the radiolysis of aq. H_2SO_4 solutions (over the range from neutral solution to 0.4 mol/L H_2SO_4) to calculate the variations of $G_{e_{aq}^- + H^\cdot}$, $G_{^\cdot OH}$, G_{H_2}, and $G_{H_2O_2}$ with pH for different values of the LET varying from ~0.3 to 15 keV/μm. This is followed, as an application, by a Monte Carlo study of the radiolytic oxidation of Fe^{2+} to Fe^{3+} ions in the Fricke dosimeter as a function of time (up to ~50 s) to address the influence of the radiation quality on the ferric ion yield. The results in each case are tested against the available experimental data.

This paper deals only with results at 25 °C. The main features of our simulation approach are presented in the next section, followed by the results and their discussion. Conclusions are drawn in the final section.

Monte Carlo simulations

Monte Carlo simulation techniques are used to model the complex succession of events that are generated in liquid water and sulfuric acid aqueous solutions under irradiation. The detailed description and implementation of our Monte Carlo code IONLYS-IRT that simulates the nonhomogeneous distribution of reactive species initially produced by the energy deposition by the incident radiation and by all the secondary electrons that it has generated (i.e., the radiation track structure) and the subsequent chemical reactions of these species with each other and with available solutes has been given previously (see ref. 34 and the refs. therein). In brief, the IONLYS simulation program models, on an event by event basis, all of the events of the early physical ($<10^{-15}$ s) and physicochemical ($\sim 10^{-15}$–10^{-12} s) stages in the track development. The complex spatial distribution of reactants at the end of the physicochemical stage, which is provided as an output of the IONLYS program, is then used directly as the starting point for the subsequent nonhomogeneous chemical stage ($\sim 10^{-12}$–10^{-6} s). This third and final stage, during which the individual reactive species diffuse randomly and react with one another (or with the environment) until all spur or track processes are complete, is covered by our IRT program. This program employs the "independent reaction times" (IRT) method (35, 36), a computer efficient stochastic simulation technique that is used to

© 2007 NRC Canada

simulate reaction times without following the trajectories of the diffusing species. The IRT method relies on the approximation that the reaction time of each pair of reactants is independent of the presence of other reactants in the system. Within the framework of this approach, the competition between the reactions is simply described via a sorting out of the stochastically sampled reaction times of each potentially reactive pair. The IRT simulation technique also allows one (as is the case in this study) to include in a simple way pseudo first-order reactions of the radiolytic products with various scavengers that are homogeneously distributed in the medium. The ability of our IRT program to give accurate time-dependent chemical yields has been well validated by comparison with a full step-by-step Monte Carlo simulation, which does follow the reactant trajectories in detail (37).

To reproduce the effects of fast electron or ^{60}Co γ-radiolysis, we use short (~100 μm) segments of 300 MeV proton tracks, over which the LET value obtained in the simulations is nearly constant[6] and equal to ~0.3 keV/μm at 25 °C. The number of proton histories (~150) is chosen so as to ensure only small statistical fluctuations when calculating average yields while keeping acceptable computer time limits. We should note that the use of high-energy protons as primary particles was more appropriate here than that of electrons since we wanted to study track segments over which the LET is essentially constant. In fact, a proton that has the same LET as an electron must also have an energy ~2000 times larger, and consequently its LET is much less affected by a given series of energy depositions (11, 36).

The reaction scheme and reaction parameters, as well as the diffusion coefficients of reactive species used in our IRT program for the radiolysis of pure liquid water, are taken from Tables 1 and 2 of ref. 36. Only slight adjustments were made in some reaction rate constants and diffusion coefficients to take account of the latest data available from the literature.

Modeling the effects of acidity

To simulate the radiolysis of water under acidic conditions, we have used aqueous solutions of sulfuric acid of various concentrations in the range ~0–0.4 mol/L (i.e., at different pH values between ~7 to 0.46). As discussed earlier, much experimental and theoretical work has been done over many decades on the radiation chemistry of aq. H_2SO_4 solutions (especially, in 0.4 mol/L sulfuric acid), at least in part because of the fact that sulfuric acid was widely employed in the early development of the Fricke and other chemical dosimeters (custom then dictated its continued usage) (38). For aq. H_2SO_4 (a diprotic acid) we have:

$$[8] \qquad H_2SO_4 \underset{pK_{a1}}{\overset{H^+}{\rightleftarrows}} HSO_4^- \underset{pK_{a2}}{\overset{H^+}{\rightleftarrows}} SO_4^{2-}$$

Table 1. Reactions added to the pure water reaction scheme to simulate the radiolysis of de-aerated aq. H_2SO_4 solutions, at 25 °C.

Reaction	k ((mol/L)$^{-1}$ s^{-1})
$H^{\cdot} + SO_4^{\cdot-} \rightarrow HSO_4^-$	1.0×10^{10} [a]
$H^{\cdot} + S_2O_8^{2-} \rightarrow SO_4^{\cdot-} + HSO_4^-$	2.5×10^{7} [b]
$^{\cdot}OH + HSO_4^- \rightarrow H_2O + SO_4^{\cdot-}$	1.5×10^{5} [c]
$e_{aq}^- + S_2O_8^{2-} \rightarrow SO_4^{\cdot-} + SO_4^{2-}$	1.2×10^{10} [b]
$H_2O_2 + SO_4^{\cdot-} \rightarrow HO_2^{\cdot} + HSO_4^-$	1.2×10^{7} [d]
$OH^- + SO_4^{\cdot-} \rightarrow {}^{\cdot}OH + SO_4^{2-}$	8.3×10^{7} [d]
$SO_4^{\cdot-} + SO_4^{\cdot-} \rightarrow S_2O_8^{2-}$	4.4×10^{8} [d]

Note: The rate constants given here for the reactions between ions are at ionic strength equal to zero.

[d]Ref. 43.

with $pK_{a1} \approx -3$ and $pK_{a2} = 1.987$ at 25 °C (39, 40). Hence, H_2SO_4 is virtually completely dissociated when dissolved in water above pH ≈ 0, and the solution contains mainly H^+, HSO_4^-, and a certain amount of SO_4^{2-}.[7] The concentration of each species changes as the total acid concentration changes.

We summarize in the following the model assumptions and procedures we have used to carry out the Monte Carlo simulations of the radiolysis of aq. H_2SO_4 solutions with IONLYS-IRT (some of the details of our computational modeling have already been given in refs. 11 and 41). As noted before, the effects of the background concentrations of H^+ in solutions were added to the IRT program as pseudo first-order reactions. We also supplemented the pure water reaction scheme to include the reactions listed in Table 1, which account for the species present in irradiated sulfuric acid solutions. At high acidities, a certain proportion of the $^{\cdot}OH$ radicals react with hydrogen sulfate (or bisulfate) ions[8] to form the sulfate radical $SO_4^{\cdot-}$ according to (e.g., see refs. 14, 42, and 44–46):

$$[9] \qquad {}^{\cdot}OH + HSO_4^- \rightarrow H_2O + SO_4^{\cdot-}$$

The importance of $SO_4^{\cdot-}$ (or equivalently, its protonated form $HSO_4^{\cdot}$, although no pK_a value has been determined) as an intermediate in the radiolysis of aq. H_2SO_4 solutions at low pH has long been recognized. However, the value of the rate constant (k_9) for reaction [9] is not well established, and the data reported thus far in the literature span a range of about an order of magnitude ($1.3–15 \times 10^5$ (mol/L)$^{-1}$ s^{-1}) (14, 42, 44, 45). In view of such uncertainty, instead of choosing, somewhat arbitrarily, a particular value of k_9 among those already published, we have selected $k_9 = 1.5 \times 10^5$ (mol/L)$^{-1}$ s^{-1} in this study by adjusting this parameter so as to match, at low LET, the experimental (47–50) and simulated values of $G_{\cdot OH}$ in the region of pH < 1–2. Concomitantly, the $SO_4^{\cdot-}$ escape yields calculated using this value of k_9 are also found, in this acid range, to be less than the

[6] Such an analysis thus gives the track segment yields at a well-defined LET (e.g., see ref. 3).
[7] In this work, the dissociation of HSO_4^- is simply treated for the entire range of pH studied as a weak-acid problem in dilute aqueous solutions. Under these conditions, the concentrations of H^+ ($F + x$), HSO_4^- ($F - x$), and SO_4^{2-} (x) are readily determined, at equilibrium, by solving the quadratic equation, $K_{a2} = [H^+]\,[SO_4^{2-}]/[HSO_4^-] = (F + x)\,(x)/(F - x)$, where F and K_{a2} are the considered concentration of H_2SO_4 and its second acid dissociation constant ($K_{a2} = 10^{-pK_{a2}} \approx 0.0103$), respectively.
[8] Contrary to the hydrogen sulfate ion HSO_4^-, the sulfate ion, SO_4^{2-} has been reported to be unreactive toward $^{\cdot}OH$.

© 2007 NRC Canada

$G_{SO_4^{\bullet-}}$ values measured experimentally (42, 48, 50). This observation is consistent with the fact that there are two distinct formation processes of the $SO_4^{\bullet-}$ radical (for a review see ref. 51), the indirect process via $^{\bullet}OH$ radical attack on HSO_4^- according to reaction [9] (which we have considered) and the direct action of radiation on the sulfuric acid anions (which we have not considered in our simulations; see later). Unfortunately, a more quantitative comparison between modeling and experiment is difficult to offer at this stage, as the experimental discrimination between the two contributing components of $G_{SO_4^{\bullet-}}$ has not been clearly elucidated yet. The diffusion coefficients of HSO_4^-, $SO_4^{\bullet-}$, SO_4^{2-}, and $S_2O_8^{2-}$, employed in the Monte Carlo simulations are taken to be (in units of 10^{-9} m^2 s^{-1}) 1.385 (for both HSO_4^- and $SO_4^{\bullet-}$), 1.065, and 1.145, respectively (52).

In addition, we have introduced in the IRT program the effects due to the ionic strength of the solutions (e.g., see ref. 53) for reaction [6] and for the recombination of the proton with the hydroxyl ion (11, 34):

[10] $OH^- + H^+ \rightarrow H_2O$

as well as for all reactions between ions [except for the peculiar bimolecular self-recombination of hydrated electrons for which there is no evidence of any ionic strength effect (54)], including those given in Table 1. To relate rate constant and ionic strength of the solution, we used the following equation, obtained from the Brönsted–Bjerrum model of ionic reactions and the extended Debye–Hükel theory of ionic solutions (55, 56):

$$[11] \qquad \log\left(\frac{k}{k_o}\right) = 1.02\, Z_a Z_b \left(\frac{I^{1/2}}{1+I^{1/2}}\right) - 2bI$$

where k is the rate constant at ionic strength I, k_0 is the rate constant in the limit of zero ionic strength (i.e., at infinite dilution), Z_a and Z_b are the algebraic numbers of charges on the reactants (positive for cations and negative for anions), and b is a parameter taken as ($0.15\, Z_a Z_b$) in this study. I is defined as (57):

$$[12] \qquad I = \frac{1}{2}\sum_i Z_i^2 C_i$$

where Z_i is the charge number of the ith ion and C_i is its molar concentration. The sum extends over all ionic species present in the solution. According to eq. [11], the rate constant will increase, decrease, or remain the same with increasing ionic strength, depending on whether the reactants have the same sign, opposite signs, or whether one reactant is neutral. For example, in 0.4 mol/L H_2SO_4 solutions, the rate constants for reactions [6] and [10], corrected for these effects, are $k_6 \approx 1.12 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1} (see earlier) and $k_{10} \approx 5.97 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1} (instead of 2.11×10^{10} and 11.3×10^{10} $(mol/L)^{-1}$ s^{-1} in neutral water at 25 °C, respectively) (11–15, 36).

Finally, in our simulations the direct action of ionizing radiation on the sulfuric acid anions (mainly HSO_4^-) is neglected, which is a reasonably good approximation over the range of sulfuric acid concentration studied (up to ~0.4 mol/L). In fact, in 0.4 mol/L H_2SO_4 (pH 0.46), only about 3.5% of the total energy expended in the solution is initially absorbed by direct action on HSO_4^- (rather than on H_2O) (assuming that the energy absorbed by each component is proportional to its electron fraction) (58). However, at higher acid concentrations this effect can no longer be neglected (42, 48, 50, 59).

Modeling the effects of radiation quality (LET)

The influence of the quality of the radiation (or LET) on the yields of the radiolytic species produced in neutral water and in aq. 0.4 mol/L sulfuric acid solutions at 25 °C has been investigated by performing a series of simulations with protons of various initial energies and therefore various LET. In this study, we limit ourselves to the incident proton energy range ~300–2.1 MeV, corresponding to LET values between ~0.3 and 15 keV/μm (11, 60, 61).

As mentioned earlier, the calculations are performed by simulating short (~20–100 μm) proton track segments over which the energy and LET of the proton are well-defined and remain essentially constant. Typically, about 5000 to 35 000 reactive chemical species are generated in the chemical development of such simulated track segments (depending on the LET). Statistically, the kinetics of ~30–150 different proton tracks (depending on the proton energy) are usually simulated to obtain computed averages of chemical yields for comparison with experiment.

Simulations of the Fricke dosimeter

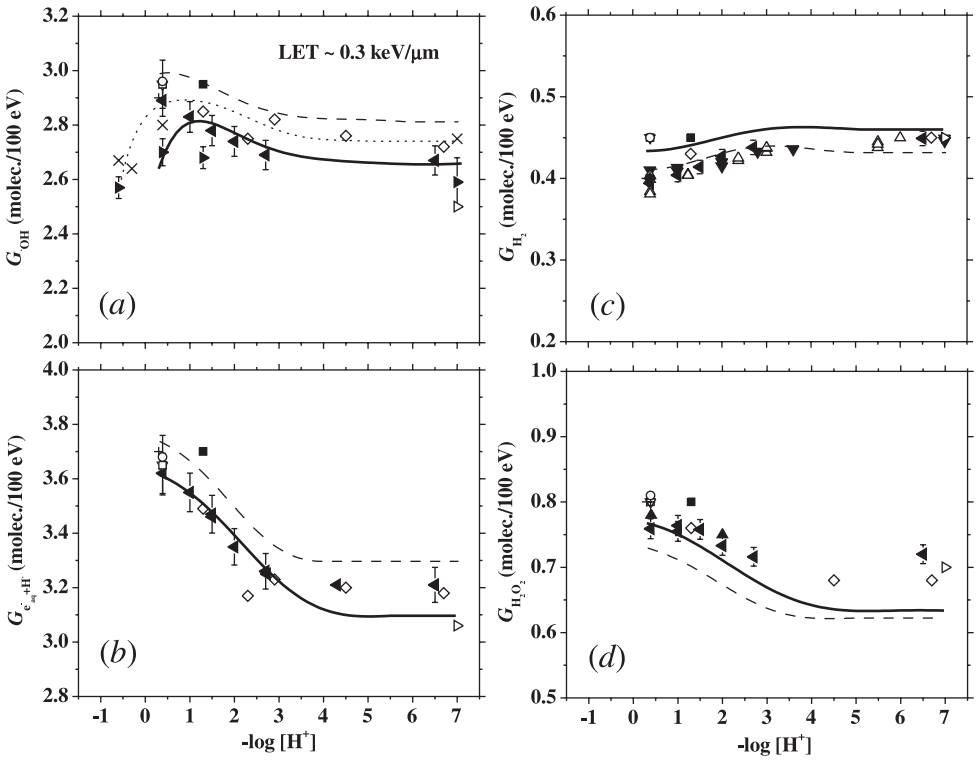
To stochastically model the chemistry of the ferrous–sulfate Fricke dosimeter, we have added to the IRT program the reactions of Fe^{2+} ions with the oxidizing species $HO_2^{\bullet}$, $^{\bullet}OH$, and H_2O_2 that are formed in the water of the irradiated solution under aerated conditions. The mechanism for the radiolytic oxidation of Fe^{2+} ions to Fe^{3+} is well-understood and the rate constants of the individual reactions taking place are known. The reaction scheme is as follows (2, 7, 14–16, 24, 36, 62–64):

[6] $e_{aq}^- + H^+ \rightarrow H^{\bullet}$
$k_6 \approx 1.12 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1}
pK_a ($H^{\bullet}/e_{aq}^-$) = 9.59

[13] $H^{\bullet} + O_2 \rightarrow HO_2^{\bullet}$
$k_{13} = 2.1 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1}

[14] $Fe^{2+} + {}^{\bullet}OH \rightarrow Fe^{3+} + OH^-$
$k_{14} = 3.4 \times 10^{8}$ $(mol/L)^{-1}$ s^{-1}

[15] $Fe^{2+} + HO_2^{\bullet} \rightarrow Fe^{3+} + HO_2^-$
$k_{15} = 7.9 \times 10^{5}$ $(mol/L)^{-1}$ s^{-1}



[16] $HO_2^- + H^+ \rightarrow H_2O_2$
$k_{16} \approx 2.66 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1}
pK_a (H_2O_2/HO_2^-) = 11.62

[17] $Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$
$k_{17} = 52$ $(mol/L)^{-1}$ s^{-1}

[10] $OH^- + H^+ \rightarrow H_2O$
$k_{10} \approx 5.97 \times 10^{10}$ $(mol/L)^{-1}$ s^{-1}
pK_a (H_2O/OH^-) = 13.999

Fig. 1. Variations of the primary free-radical and molecular yields (in molec./100 eV) of the radiolysis of de-aerated aq. H_2SO_4 solutions by 300 MeV incident protons (LET ~0.3 keV/μm) as a function of –log [H^+] over the sulfuric acid concentration range 0–0.4 mol/L at 25 °C. The solid and broken lines represent the results of our Monte Carlo simulations for (*a*) $G_{\cdot OH}$, (*b*) $G_{e^-_{aq}+H^\cdot}$, (*c*) G_{H_2}, and (*d*) $G_{H_2O_2}$, obtained at 10^{-6} and 10^{-7} s after the initial energy deposition, respectively. The calculations were performed with k_9 = 1.5×10^5 $(mol/L)^{-1}$ s^{-1} (see text); this value of k_9 was adjusted to match the experimental and simulated values of $G_{\cdot OH}$ in the region of pH < 1–2. This is shown in (*a*) where the curve of $G_{\cdot OH}$ vs. –log [H^+] calculated at 2.5×10^{-7} s is also presented for H_2SO_4 concentrations up to ~4 mol/L (dotted line), for the sake of comparison. Note that in solutions greater than 0.4 mol/L sulfuric acid, the measured $G_{\cdot OH}$ data were corrected to account for the direct action of radiation on HSO_4^- anions according to a procedure given in ref. 48 based on the formula $(G_{\cdot OH})^0 = G_{\cdot OH}/E_w$, where $(G_{\cdot OH})^0$ is the *G*-value for ·OH production that results from energy absorption by water and E_w denotes the electron fraction of water. Experimental data: ref. 3 (▷), refs. 8 and 69 (△), refs. 10 and 47 (◇), ref. 48 (▶), ref. 49 (◀), ref. 50 (×), refs. 66 and 67 (□), ref. 68 (○), ref. 70 (▼), ref. 71 (▽), ref. 72 (●), refs. 73 and 74 (+), ref. 75 (■), and ref. 76 (▲). For conversion of yield values into SI units, 1 molec./100 eV ≈ 0.10364 μmol/J.

As we can see, each H· atom forms a hydroperoxyl radical, and each of these radicals oxidizes three Fe^{2+} ions, one by reaction [15] and two by the reaction sequence [16], [17], and [14]. Each ·OH radical oxidizes one Fe^{2+} ion, and each molecule of H_2O_2 oxidizes two Fe^{2+} ions. Summing all sources of Fe^{3+} ions, the yield of ferric ions in an aerated solution $G(Fe^{3+})$ is related to the escape yields of the free radicals and molecular species of water radiolysis by eq. [7].

Note that the values of k_6, k_{10}, and k_{16} shown earlier and used in the simulations have been corrected using eqs. [11] and [12] for the effects due to the ionic strength in the case (under study here) of a solution made of 0.4 mol/L H_2SO_4 and 5 mmol/L $FeSO_4$. Note also that, as we have mentioned above, for solutions of 0.4 mol/L in H_2SO_4 there is a small amount of ·OH radicals that react with HSO_4^- to form $SO_4^{\cdot-}$ (reaction [9]). However, the overall ferric ion yield remains the same as given by eq. [7] since the sulfate radical reacts with Fe^{2+} in the same way as ·OH (24, 43):

[18] $SO_4^{\cdot-} + Fe^{2+} \rightarrow Fe^{3+} + SO_4^{2-}$

$k_{18} \approx 2.79 \times 10^8$ $(mol/L)^{-1}$ s^{-1}.

Under normal irradiation conditions, the radical concentrations are low compared with the background concentrations of acid, Fe^{2+} ions, and oxygen (~2.5×10^{-4} mol/L) in solution, and the reactions were treated in the IRT program as pseudo first-order (see earlier). In modeling the Fricke dosimeter, the slowest component of the kinetics of Fe^{3+} formation is due to the Fenton-type reaction [17] (65). For example, in the case of 5 mmol/L $FeSO_4$ solutions considered here, this reaction takes several seconds to go to completion, which increases signficantly the computer time usually chosen for modeling the radiolysis of water (typically ~1 μs). In this work, the time evolution of $G(Fe^{3+})$ has been followed until ~50 s.

Results and discussion

The effects of acidity on the primary free-radical and molecular yields

Figure 1 displays our calculated values of $G_{\cdot OH}$, $G_{e^-_{aq}+H^\cdot}$, G_{H_2}, and $G_{H_2O_2}$ for the radiolysis of air-free aqueous sulfuric acid solutions at 25 °C as a function of –log [H^+] in the range from neutral solution to 0.4 mol/L H_2SO_4, using 300 MeV

© 2007 NRC Canada

incident protons (LET ~0.3 keV/μm). Available experimental data (3, 8, 10, 47–50, 66–76) are also included for comparison. Our results show that an increase in acidity (1 < pH < 4) leads to an increase in $G_{e^-_{aq}+H^\cdot}$ and slight increases in $G_{^\cdot OH}$ and $G_{H_2O_2}$, while there is a slight decrease in G_{H_2}. At pH < 1, $G_{^\cdot OH}$ diminishes steeply. By contrast, in the range of pH from ~4 to 7, the calculated yield values are constant and independent of sulfuric acid concentration. As can be seen from Fig. 1, the computed primary yield values are generally in good agreement with the experimental values over the whole acidity range studied.

As the direct action of radiation on the sulfuric acid anions has been ignored in our simulations, the "initial" yields of the radiolytic species arising from the radiolysis of pure water can be regarded as essentially independent of the H_2SO_4 concentration. Hence, the variation of the yields of those species with acid concentration only results from the various chemical reactions that contribute to their formation or decay, while the spurs expand by diffusion. To gain further insight into the effects of acidity on $G_{^\cdot OH}$, $G_{e^-_{aq}+H^\cdot}$, G_{H_2}, and $G_{H_2O_2}$, it is thus of interest to examine the unfolding of those various reactions that lead to the different primary yields shown in Fig. 1. This can readily be done with our Monte Carlo simulations, which enable us to determine quantitatively the time dependence of each reaction. Table 2 summarizes the major spur/track reactions that are involved in the primary yields of water decomposition products. The importance of these reactions can be quantified by the yield variations ΔG that they cause over the time interval of nonhomogeneous track chemistry (~10^{-12}–10^{-6} s). Figures 2 and 3 compare, for pure neutral water and 0.4 mol/L H_2SO_4 (pH 0.46) aqueous solutions, respectively, the time profiles of the extents ΔG of each of these reactions, calculated from our simulations for low-LET radiolysis.

Table 2. Most important spur/track reactions inferred from our Monte Carlo simulations of the nonhomogeneous chemical stage in the low-LET radiolysis of de-aerated neutral liquid water and aqueous sulfuric acid solutions at 25 °C and in the time interval ~10^{-12}–10^{-6} s.

[R8]	${}^\cdot OH + {}^\cdot OH \rightarrow H_2O_2$
[R9] (or [9])	${}^\cdot OH + HSO_4^- \rightarrow H_2O + SO_4^{\cdot -}$
[R10]	$H^\cdot + H^\cdot \rightarrow H_2$

[a]Reaction symbols used in the text.

The hydroxyl radical

The hydroxyl radical is the main oxidizing radical formed when aqueous sulfuric acid solutions are irradiated. As can be seen in Fig. 1*a*, our calculated values of $G_{^\cdot OH}$ are independent of pH over the range ~4–7, slightly increase at pH < 4 to reach a weakly pronounced maximum around pH 1, and then fall steeply as the pH is further reduced below 1. From Fig. 2*a*, it is seen that in neutral water ${}^\cdot OH$ is produced mainly by reaction [R4], whereas its decay is dominated by reactions [R8], [R5], [R7], and [R6] (in order of decreasing importance). In contrast, in 0.4 mol/L H_2SO_4 solutions (see Fig. 3*a*), the formation of ${}^\cdot OH$ due to reaction [R4] is decreased by almost 100% because of the occurrence of the very rapid reaction [6] of the H^+ ions, which at this acid concentration capture most, if not all, of the e^-_{aq} radicals in the spurs. For the same reason, the removal of ${}^\cdot OH$ due to reaction [R5] is also significantly decreased at low pH in favor of reaction [R7]. Finally, as discussed above, there is a decrease of ${}^\cdot OH$ caused by reaction [9].

The reducing free-radical species e^-_{aq} and $H^\cdot$

As shown in Fig. 1*b*, the effect of increasing –log [H^+] from ~0.4 to 7 is to reduce our calculated values of $G_{e^-_{aq}+H^\cdot}$ (= $G_{e^-_{aq}} + G_{H^\cdot}$) from ~3.7 to 3.1 molec./100 eV (that is by less than 20%), which is in good agreement with experiment. In the pH range ~4–7, $G_{e^-_{aq}+H^\cdot}$ is independent of acid concentration. From Figs. 2*b* and 2*c*, it is seen that in neutral water the decay of the e^-_{aq} yield up to ~10^{-6} s is mainly due to the reactions [R5] and [R1] (or [6]) of e^-_{aq} with ${}^\cdot OH$ radicals and H^+ ions. In 0.4 mol/L H_2SO_4 solutions, however, it clearly appears from Fig. 3*b* that reaction [R1] largely dominates the decay of e^-_{aq}, which is rapidly converted in the spurs into the hydrogen atom. This reaction occurs mostly at early times (<10^{-9} s).

As for the $H^\cdot$ atom, Figs. 2*c* and 3*c* show that in both neutral water and 0.4 mol/L sulfuric acid solutions reaction [R7] is responsible for most of its decay, while its production takes place mainly through the occurrence of reaction [R1].

Molecular hydrogen

As is well established, G_{H_2} slightly decreases with increasing acidity (8, 10, 47, 49, 59, 69, 70, 72–74; see also ref. 5). As one can see from Fig. 1*c*, our calculations reproduce such a decrease in G_{H_2} at pH < 4, in agreement with experiment. In the range of pH ~4–7, G_{H_2} is independent of acidity. The measured microsecond yield value, G_{H_2} = 0.45 molec./100 eV at pH 7, is also well reproduced by our simulations.

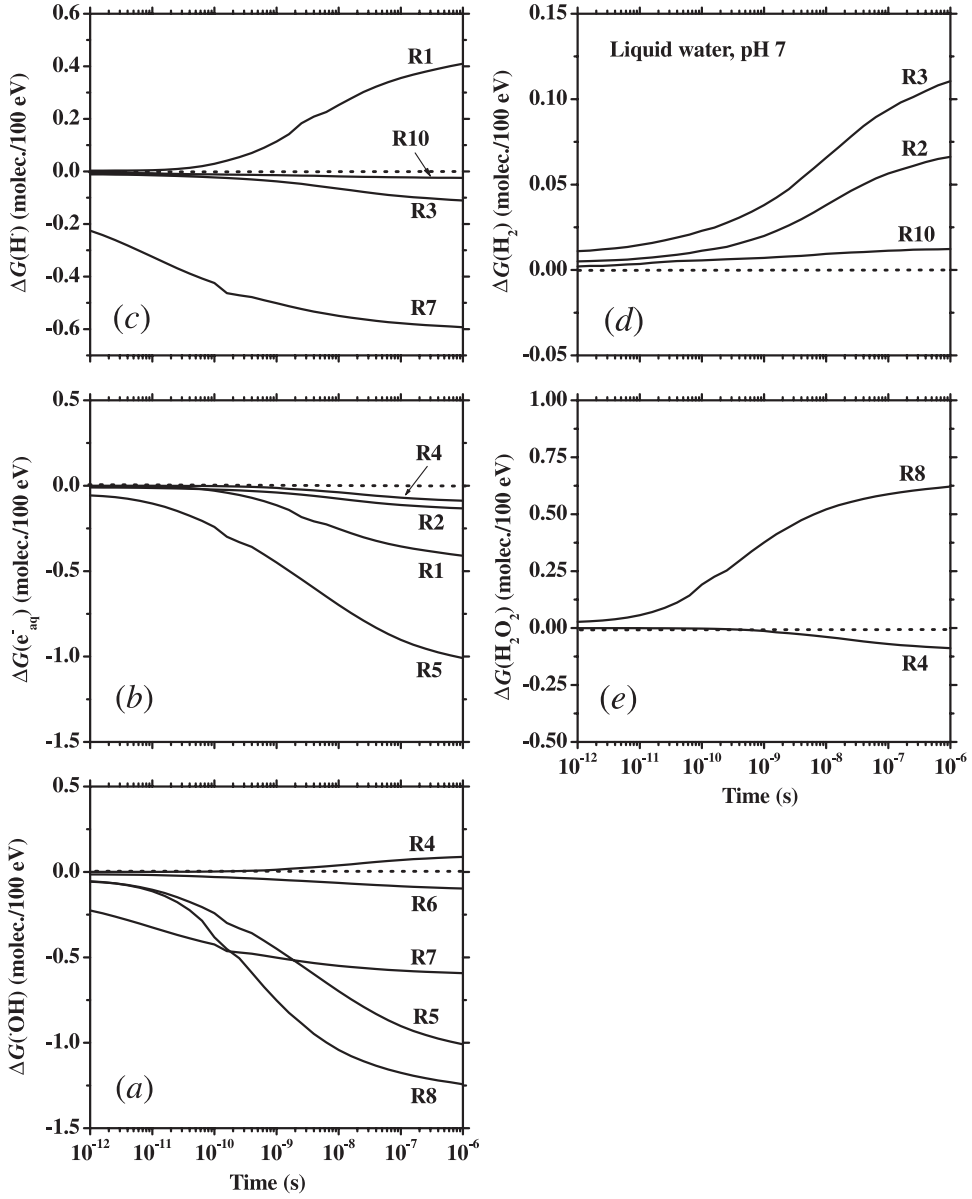

Figure 2*d* shows that in neutral water the production of H_2 is predominantly due to reactions [R3] and [R2] (in order of decreasing importance). By contrast, as the acidity increases reaction [R10] occurs to an increasing extent in the spurs. As it clearly appears from Fig. 3*d*, reactions [R2] and [R3] are only of minor importance in 0.4 mol/L H_2SO_4 solutions, and the production of H_2 under such acidic conditions can be almost entirely attributed to reaction [R10].

Hydrogen peroxide

As is shown in Fig. 1*d*, our calculated values of $G_{H_2O_2}$ remain unaffected by changes of pH in the range ~4–7 and increase as –log [H^+] is decreased from ~4 to 0.4, in good agreement with experiment. It has long been established from modeling and experimental studies that the main precursor of the molecular yield of H_2O_2 is ${}^\cdot OH$ through the spur reaction [R8] of ${}^\cdot OH$ with itself. The importance of this reaction is quantified in Figs. 2*e* and 3*e*. As can be seen, there is clear evidence that the combination reaction of ${}^\cdot OH$

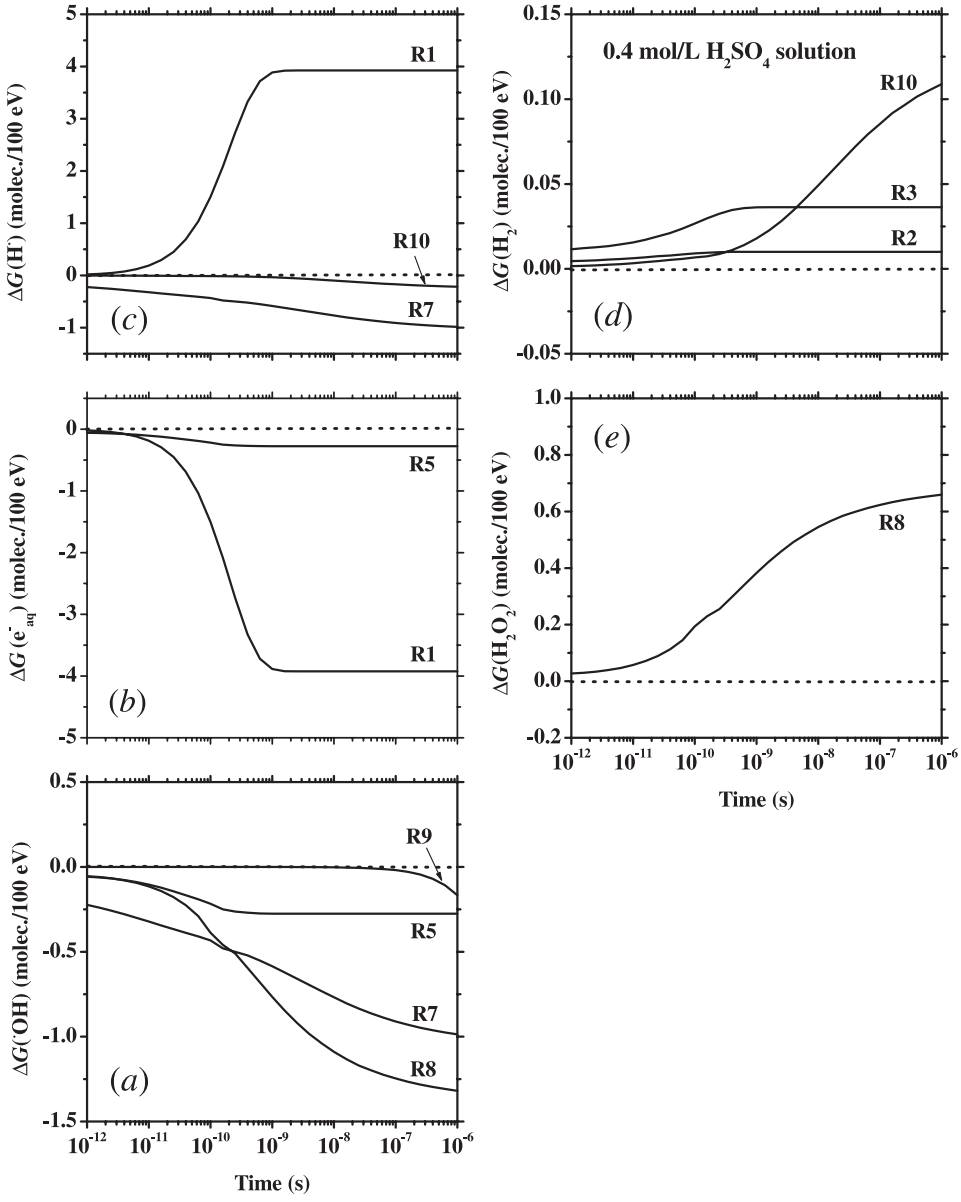
Fig. 2. Time dependence of the extents ΔG (in molec./100 eV) of the main spur/intratrack reactions that are involved in the formation and decay of (*a*) $^{\cdot}OH$, (*b*) e^-_{aq}, (*c*) $H^{\cdot}$, (*d*) H_2, and (*e*) H_2O_2 (see text and Table 2), calculated from our Monte Carlo simulations of the radiolysis of de-aerated liquid water by ~300 MeV protons (LET ~0.3 keV/μm) at neutral pH, 25 °C, and in the interval 10^{-12}–10^{-6} s. Note that the initial yields of $^{\cdot}OH$, e^-_{aq}, $H^{\cdot}$, H_2, and H_2O_2, calculated at the end of the physicochemical stage, are ~5.43, 4.26, 0.97, 0.28, and 0.11 molec./100 eV, respectively.

radicals is the major source of primary hydrogen peroxide both in neutral water and in 0.4 mol/L H_2SO_4 solutions. Figure 2*e* also shows that in neutral water the decay of H_2O_2 is dominated by the back reaction [R4]. In contrast to this situation, in 0.4 mol/L H_2SO_4 solutions the removal of H_2O_2 due to the occurrence of reaction [R4] is decreased by almost 100%.



Proposed interpretation of the effects of acidity on the primary free-radical and molecular yields

As can be seen in Figs. 1*a*–1*d*, the values of the primary free-radical and molecular product yields do not change in the range ~4 < pH < 7. This can easily be explained if we consider, as mentioned earlier, that the main effects of acidity on the primary yields of the radiolysis of aqueous solutions at low pH are attributed to the presence of H^+ ions, which can rapidly scavenge hydrated electrons through reaction [6] (or [R1]). At pH 4 for example, one has a H^+ concentration of 10^{-4} mol/L and a scavenging power, defined as the product k_6 [H^+] (e.g., see ref. 20), of ~2.05×10^6 s^{-1}. Hence, the time scale over which reaction [6] occurs, measured by the reciprocal of the scavenging power, is ~5×10^{-7} s. Therefore, the addition of 10^{-4} mol/L H^+ ions will contribute only very little to the scavenging of e^-_{aq} in the spurs. Under such conditions, a change of pH from 7 to ~4 has, indeed, no effect on either radical or molecular primary yields.

At pH < 4, the concentration of H^+ ions is high enough to be able to convert the e^-_{aq} radicals in the spurs or tracks into $H^{\cdot}$ atoms, interfering to some extent with the back reactions

Fig. 3. Time dependence of the extents ΔG (in molec./100 eV) of the main spur/intratrack reactions that contribute to the formation and decay of (*a*) $^{\cdot}OH$, (*b*) e^-_{aq}, (*c*) $H^{\cdot}$, (*d*) H_2, and (*e*) H_2O_2 (see text and Table 2), calculated from our Monte Carlo simulations of the radiolysis of de-aerated 0.4 mol/L H_2SO_4 aqueous solutions by ~300 MeV protons (LET ~0.3 keV/μm) at 25 °C and in the interval 10^{-12}–10^{-6} s. The initial yields of $^{\cdot}OH$, e^-_{aq}, $H^{\cdot}$, H_2, and H_2O_2, calculated at the end of the physicochemical stage, are as in the legend of Fig. 2.

forming water (see Figs. 3*b* and 3*c*). According to Hayon (69, 77) and as clearly shown in Fig. 2*b* from our simulations, these electrons in neutral solution would have predominantly combined, in the absence of other electron-accepting solutes with which they could react, with $^{\cdot}OH$ to form water:

[R5] $\quad e^-_{aq} + {}^{\cdot}OH \rightarrow OH^-$

$$k_{R5} = 2.95 \times 10^{10}\ (\text{mol/L})^{-1}\ \text{s}^{-1} \quad (15)$$

The $H^{\cdot}$ atoms, on the contrary, react less efficiently than e^-_{aq} with $^{\cdot}OH$ in the spurs:

[R7] $\quad H^{\cdot} + {}^{\cdot}OH \rightarrow H_2O$

$$k_{R7} = 1.55 \times 10^{10}\ (\text{mol/L})^{-1}\ \text{s}^{-1} \quad (15)$$

This reduction in reactivity is also the result of $H^{\cdot}$ having a larger diffusion coefficient (7.0×10^{-9} m^2 s^{-1}) than e^-_{aq} (4.9×10^{-9} m^2 s^{-1}) (4, 15, 78). The effect of acid is thus to decrease in the spur time scale the importance of the back reaction [R5]. The conversion of e^-_{aq} to $H^{\cdot}$ in the spurs in acidic solution, and the subsequent "protection" of the $^{\cdot}OH$ radicals against the action of hydrated electrons (69, 77, 79) lead to the following consequences:

(*i*) Since the reducing free-radical entities are less reactive while the spurs expand, owing to the intervention of reaction [R7], $G_{e^-_{aq}+H^{\cdot}}$ increases on going from neutral to acidic solutions, as observed experimentally (Fig. 1*b*).

(*ii*) At low pH this mechanism tends to increase $G_{^{\cdot}OH}$. This is clearly seen in Fig. 1*a* where $G_{^{\cdot}OH}$ slightly increases at pH < 4.

© 2007 NRC Canada

(*iii*) Due to the dimerization of the ·OH radicals, $G_{H_2O_2}$ also increases with increasing acidity up to 0.4 mol/L H_2SO_4, in good agreement with experiment (Fig. 1*d*). At higher sulfuric acid concentrations, however, our simulations predict (data not shown) that $G_{H_2O_2}$ should diminish owing to the removal of ·OH radicals due to the increased intervention of reaction [9] (or [R9]) (see Fig. 1*a*). Unfortunately, there is at present no experimental or theoretical data available in the literature with which to compare our results.

(*iv*) The yield of molecular hydrogen is gradually lowered below pH 4 (Fig. 1*c*). This is explained by the fact that as the acidity progressively increases, the contribution of the self reaction of the H· atom:

$$[R10] \quad H^{\cdot} + H^{\cdot} \rightarrow H_2$$

$$k_{R10} = 5.03 \times 10^9 \text{ (mol/L)}^{-1} \text{ s}^{-1} \quad (15)$$

becomes more important. As can be seen in Fig. 3*d*, this reaction is the dominant chemical route for producing H_2 in 0.4 mol/L H_2SO_4 solutions. Under neutral conditions (see Fig. 2*d*), reaction [R10] is only of minor importance, and the production of H_2 can be almost entirely attributed to reaction [R3]:

$$[R3] \quad e^-_{aq} + H^{\cdot} (+ H_2O) \rightarrow H_2 + OH^-$$

$$k_{R3} = 2.5 \times 10^{10} \text{ (mol/L)}^{-1} \text{ s}^{-1} \quad (80)$$

and to a lesser extent reaction [R2]. Since reaction [R10] is less efficient than reaction [R3], conversion of the e^-_{aq} to H· atoms leads to a lowering of G_{H_2} at low pH.

(*v*) Finally, the yield of decomposition of water G_{-H_2O} increases as the pH decreases below ~4, in order of course, to maintain the material balance in eq. [4].

Overall, our present Monte Carlo calculations generally agree well with experiment (see Fig. 1). Results clearly show that the primary free-radical and molecular yields of the radiolysis of aqueous solutions are influenced by the addition of H^+ ions, especially at high sulfuric acid concentrations. However, in accord with a previous conclusion by Draganić and Draganić (10), there is no strong dependence of those yields on pH.

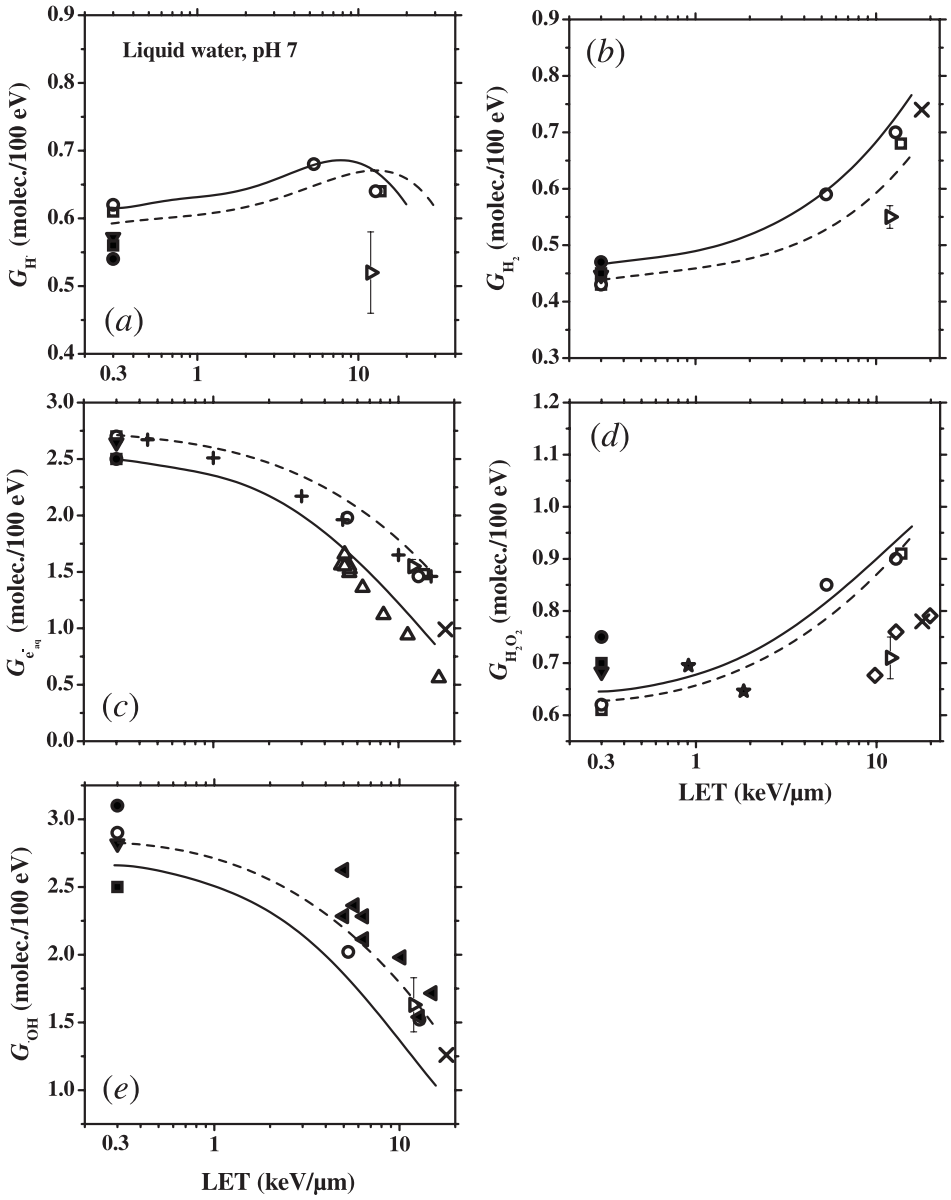
The effect of LET on the primary free-radical and molecular yields of the radiolysis of neutral liquid water and aq. 0.4 mol/L H_2SO_4 solutions

Figures 4 and 5 show the variations of our computed primary free-radical and molecular yields as a function of LET over the range ~0.3–15 keV/μm for de-aerated neutral liquid water and aq. 0.4 mol/L H_2SO_4 solutions, respectively, at 25 °C. For the sake of comparison, available experimental data for various radiation types and different authors (3, 8, 20, 48, 49, 66–76, 81–100) are also included in the figures. Overall, our computed results are in good agreement with the measured yields. In both neutral water and acidic solutions it is seen that, in general, the primary yields of molecular products increase with increasing LET at the expense of those of free radicals. These variations in radical and molecular yields reflect the effect of changing conditions on the extent of radical–radical reactions within spurs/tracks; as mentioned earlier, high LET favors high reaction rates for radicals within the dense columnar regions of tracks. We should notice, however, the peculiar behavior of $G_{H^{\cdot}}$ in neutral water. In fact, unlike the other radical yields our calculated $G_{H^{\cdot}}$ values exhibit a slight maximum near 6.5 keV/μm before decreasing at higher LET (Fig. 4*a*). The origin of this maximum was discussed in detail previously (101). In essence, this variation of $G_{H^{\cdot}}$ as a function of LET does not arise from a change in the initial yield of H· atoms (i.e., at the end of the physicochemical stage), which is nearly constant over the LET range studied, but rather from the various reactions that are involved in their production and decay in the time interval of nonhomogeneous spur/track chemistry (see Table 2). As one can see from Figs. 2*c* and 4*a*, our calculations, which confirm the results previously obtained by Meesungnoen et al. (101), show that the overall effect of LET on $G_{H^{\cdot}}$ is dominated by reaction [R1] (or [6]) up to the maximum of $G_{H^{\cdot}}$ at ~6.5 keV/μm and by reactions [R7], [R3], and [R10] (in order of decreasing importance) at higher LET.

Together with the yields obtained at 10^{-6} s (Figs. 4 and 5, solid lines), we also show our primary free-radical and molecular yield values calculated at 10^{-7} s after irradiation (Figs. 4 and 5, broken lines). Such a comparison is given as a means to estimate the sensitivity of our computed escape yields with regards to the uncertainty in assigning a value for the time (generally quoted ~10^{-6}–10^{-7} s in the literature) marking the end of the nonhomogeneous radiation chemical stage (that is, when the expanding spurs and tracks overlap, or equivalently, when the species are considered to be homogeneously distributed in the solution). As can be seen from Figs. 4 and 5, the differences found between these two sets of yield values at 10^{-6} and 10^{-7} s depend strongly on the particular species and LET. For low-LET radiation, these differences are of the order of a few percent only (but never exceed ~10%) suggesting that at ~10^{-7} s after the ionizing event, the intratrack reactions in fast electron or γ-radiolysis are already nearly complete. By contrast, there are considerably more reactions of species in high-LET tracks than in the spurs produced by fast electrons. In fact, the differences observed in yield values at 10^{-6} and 10^{-7} s become more important with increasing LET (e.g., they amount to ~30%–40% at ~15 keV/μm for the particular case of e^-_{aq} and ·OH, compared with ~3%–10% at ~0.3 keV/μm). These differences reflect the changes in the nature of the track structure; at high LET, the species will not escape as they diffuse along the axis of the cylindrical track and will continue to react among themselves to longer times (in the absence of solutes) (e.g., see refs. 102 and 103).

The material balance eq. [4] for reducing (e^-_{aq}, H· and H_2) and oxidizing (·OH, H_2O_2, and $HO_2^{\cdot}/O_2^{\cdot-}$) species is found to be satisfied throughout the range of LET studied for both neutral water and acidic solutions:

(*i*) For neutral water we have (at 10^{-6} s) for ^{60}Co γ radiation (LET ~ 0.3 keV/μm):



$$G_{red} = G_{e^-_{aq}} + G_{H^{\cdot}} + 2G_{H_2} = 4.05 \pm 0.04, \text{ and}$$

$$G_{ox} = G_{\cdot OH} + 2G_{H_2O_2} + 3G_{HO_2^{\cdot}/O_2^{\cdot-}} = 3.99 \pm 0.05$$

in good agreement with the experimental value of ~3.94 molec./100 eV given in eq. [2]; for a LET of ~12.8 keV/μm, our calculated primary yields are: G_{red} =

Fig. 4. Variations of the primary free-radical and molecular yields (in molec./100 eV) of the radiolysis of de-aerated neutral liquid water at 25 °C as a function of LET over the range ~0.3–15 keV/μm (up to ~20 keV/μm for the primary yield of H· atoms). The solid and broken curves represent the results of our Monte Carlo simulations for (*a*) $G_{H\cdot}$, (*b*) G_{H_2}, (*c*) $G_{e^-_{aq}}$, (*d*) $G_{H_2O_2}$, and (*e*) $G_{\cdot OH}$ at 10^{-6} and 10^{-7} s, respectively. Experimental data: ref. 3 (■), ref. 20 (data taken from the line marked "selected" in Fig. 7.7.1, which is a fit of experimental yields from different authors at various LET) (+), ref. 81 (▷), ref. 82 (▼), ref. 83 (□), ref. 84 (○), ref. 85 (△), ref. 86 (◀), ref. 87 (◇), ref. 88 (★), ref. 89 (×), and ref. 90 (●). LET values used here for the various types of radiation considered correspond to dose-average LET values, taken from ref. 60.

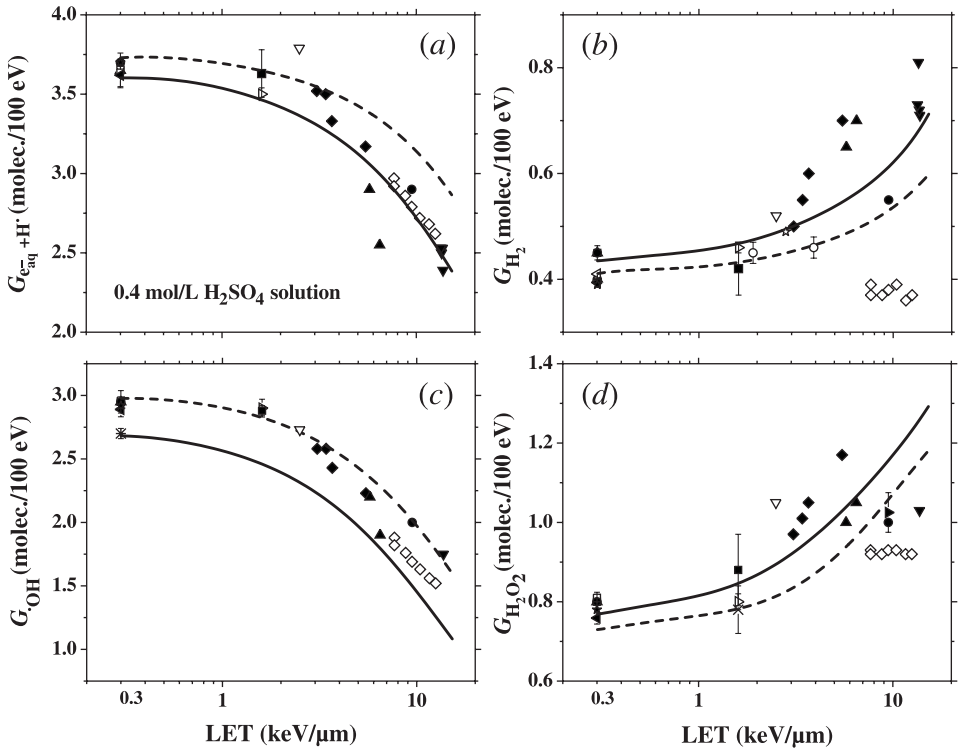
3.14 ± 0.04 and G_{ox} = 3.10 ± 0.03, which compare well with the values of ~3.09 and 3.05 molec./100 eV deduced for this LET from the room temperature yield data reported by Elliot et al. (15, 81), respectively.

(*ii*) For 0.4 mol/L H_2SO_4 solutions, we have similarly (at 10^{-6} s) for ^{60}Co γ radiation:

$G_{red} = G_{e^-_{aq}+H\cdot} + 2G_{H_2}$ = 4.47 ± 0.04, and

G_{ox} = 4.26 ± 0.07

in good accord with the experimental value of ~4.44 molec./100 eV given in eq. [5]; for a LET of ~13.7 keV/μm, we find G_{red} = 3.84 ± 0.03 and G_{ox} = 3.73 ± 0.04, which compare satisfactorily with the values of ~3.81 and ~3.98 molec./100 eV reported by Barr and Schuler (71) and Schuler and Allen (91) for 18 MeV deuterons, respectively.



The effect of LET on the chemistry and the yield of the Fricke dosimeter

Kinetics of Fe^{3+} formation

As an application and also as a test of the reliability of our primary yields, Monte Carlo simulations were used to study

© 2007 NRC Canada

Fig. 5. Variations of the primary free-radical and molecular yields (in molec./100 eV) of the radiolysis of de-aerated 0.4 mol/L H_2SO_4 aq. solutions (pH 0.46) at 25 °C as a function of LET over the range ~0.3–15 keV/μm. The solid and broken curves represent the results of our Monte Carlo simulations for (*a*) $G_{e^-_{aq}+H^\cdot}$, (*b*) G_{H_2}, (*c*) $G_{\cdot OH}$, and (*d*) $G_{H_2O_2}$ at 10^{-6} and 10^{-7} s, respectively. Experimental data: refs. 8 and 69 (△), ref. 48 (✳), ref. 49 (◀), refs. 66 and 67 (▲), refs. 66, 68, and 92 (□), ref. 70 (◁), refs. 71 and 91 (▼), ref. 72 (○), refs. 73 and 74 (+), ref. 75 (in 0.05 mol/L H_2SO_4) (●), ref. 76 (★), ref. 93 (◆), ref. 94 (×), ref. 95 (▷), ref. 96 (▽), ref. 97 (◇), ref. 98 (■), ref. 99 (▶), and ref. 100 (☆). Dose-average LET values used here for the various radiations considered are taken from ref. 60.

the LET dependence of the oxidation of ferrous ions in the radiolysis of air-saturated solutions of 5 mmol/L $FeSO_4$ in aq. 0.4 mol/L H_2SO_4 (the ferrous-sulfate Fricke dosimeter).[9,10] As described earlier, the mechanism of this chemical system, well-understood in terms of oxidation of Fe^{2+} ions to Fe^{3+} by $H^\cdot$ atoms (via production of $HO_2^\cdot$), $^\cdot OH$ radicals, and H_2O_2, includes the sequence of reactions [6] and [13]–[17]. Figure 6 shows the kinetics of Fe^{3+} formation as obtained from our simulations for 300 MeV irradiating protons (LET ~ 0.3 keV/μm) at ambient temperature. As can be seen from this figure, $G(Fe^{3+})$ is time dependent as a result of the differences in the lifetimes of the reactions making up the radiolysis mechanism (2, 105, 106). The fastest reaction of Fe^{2+} ions is with $^\cdot OH$ radicals. It is completed on a microsecond time scale. The oxidation of Fe^{2+} by $HO_2^\cdot$ is slower and requires a few milliseconds for completion. The slowest component in the formation of Fe^{3+} is due to Fe^{2+} oxidation by H_2O_2 (both the molecular product yield and that formed by reaction [16]). This latter reaction takes place at times longer than ~0.1 s and is completed by about 30 s.

The accepted value of the ferric ion yield in the Fricke dosimeter, obtained for ^{60}Co γ-rays, high-energy X-rays, or fast electrons, is $G(Fe^{3+})$ = 15.6 ± 0.2 molec./100 eV (e.g., see refs. 7, 25, 28, and 107–110) at 25 °C. Under the same low-LET conditions, our computed value of $G(Fe^{3+})$ at ~50 s is found to be equal to ~15.7 molec./100 eV (Fig. 6), in very good agreement with the standard value.

Variation of G(Fe³⁺) with LET

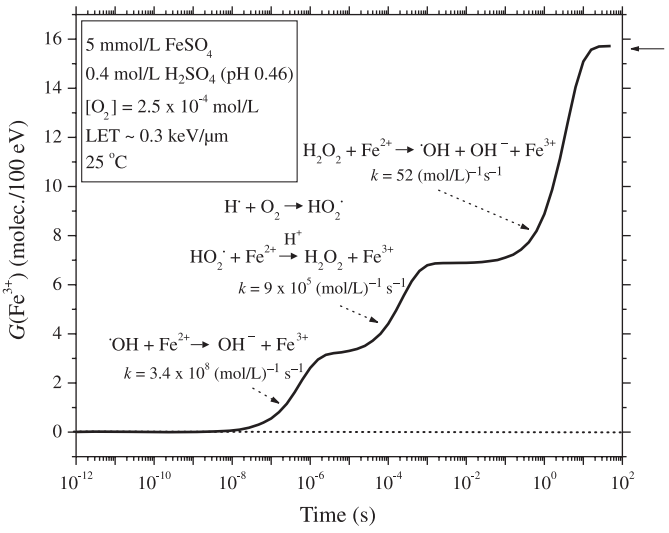


Figure 7 shows the values of $G(Fe^{3+})$ calculated from our Monte Carlo simulations of the radiolysis of aerated solutions of 5 mmol/L $FeSO_4$ in aq. 0.4 mol/L H_2SO_4 as a function of LET over the range ~0.3–15 keV/μm at 25 °C. It is seen that as the LET increases the yield diminishes. Our computed values are compared with experimental data of ferric ion yields vs. LET obtained by a number of different workers (26, 28, 33, 67, 72, 81, 91, 95, 108, 109, 111–123) using a variety of methods for radiations of different energies. Despite the relatively large uncertainties of the reported measurements, there is a good agreement between theory and experiment. Also shown in the figure are the curves of $G(Fe^{3+})$ vs. LET calculated at two different times chosen for the completion of spur/track processes (namely, 10^{-7} and 10^{-6} s after the energy deposition event) on the basis of the

[9] Note that the commonly used Fricke solution typically contains 1 mmol/L $FeSO_4$ and is saturated with air. The "super-Fricke" dosimeter, saturated with oxygen and containing 10 mmol/L ferrous sulfate, is seldom used. See ref. 30.

[10] A preliminary report of this work has been presented at the 48th Annual Meeting of the Japanese Society of Radiation Chemistry, Osaka, Japan, October 12–14, 2005. See ref. 104.

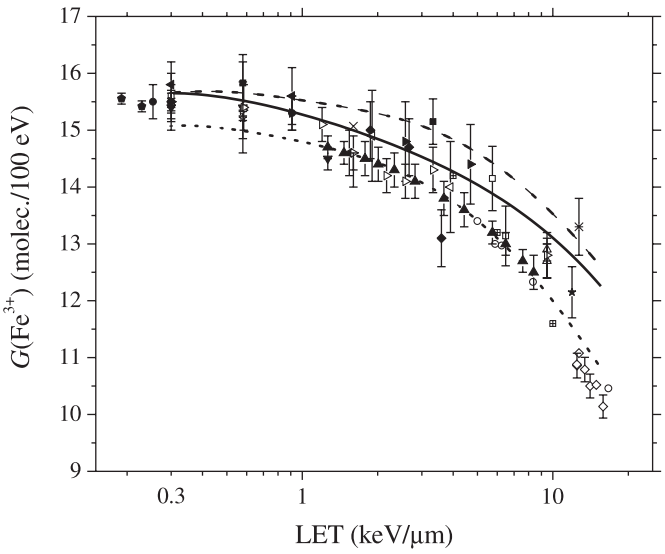
Fig. 6. Time evolution of $G(Fe^{3+})$ (in molec./100 eV) in the radiolysis of air-saturated solution of 5 mmol/L $FeSO_4$ in aq. 0.4 mol/L H_2SO_4 at 25 °C. The concentration of dissolved oxygen used in the calculations is ~2.5×10^{-4} mol/L. The solid line shows our simulated kinetics of Fe^{3+} ion formation. The arrow on the right of the figure shows the accepted value (15.6 molec./100 eV) of the yield of the Fricke dosimeter for ^{60}Co γ-rays and fast electrons.



values of G(primary yields) using eq. [7]. As can be seen, the values of $G(Fe^{3+})$ obtained from our Monte Carlo simulations are found to lie between the two curves of the yields obtained from eq. [7] at 10^{-7} and 10^{-6} s, over the whole LET range considered.

This dependence of $G(Fe^{3+})$ on LET results from the fact that the production of ferric ions in the Fricke system is most sensitive to radical yields; indeed, according to eq. [7], the lower the yield of radicals which escape the radiation track, the lower the Fricke G-value. Since increasing LET has the effect of reducing the free-radical product yields from water (see Fig. 5), it follows that $G(Fe^{3+})$ also decreases as the LET increases.

Conclusions

In this study, we have used Monte Carlo simulations to investigate the influence of acidity (pH) on the primary yields of the various chemical species produced in the radiolysis of de-aerated aqueous sulfuric acid solutions over the range of H_2SO_4 concentrations ~0–0.4 mol/L. The effects of the quality of radiation, a measure of which is its LET, has also been studied for LET varying from ~0.3 to 15 keV/μm at ambient temperature. Our results show that an increase in acidity ($1 < pH < 4$) leads to an increase in the yields of the reducing radicals (e^-_{aq} and H· atom) and the oxidizing products (·OH radical and H_2O_2), while the yield of H_2 decreases. At $pH < 1$, ·OH radicals react with HSO_4^- anions to form $SO_4^{\cdot-}$ radicals, resulting in a marked decrease in $G_{\cdot OH}$. By contrast, at $pH > 4$, the yields are essentially independent of sulfuric acid concentration. In both neutral liquid water and 0.4 mol/L H_2SO_4 (pH ~ 0.46) solutions, the most evident effect of increasing LET is an increase in the primary yields of molecular products, accompanied by a corresponding decrease in those of free radicals. As an exception, $G_{H\cdot}$ at first increases vs. LET, then reaches a maximum near 6.5 keV/μm before decreasing steeply at higher LET. The results obtained are in generally good agreement with available experimental data over the whole acidity and LET ranges studied.

Fig. 7. Plot of the ferric ion yield $G(Fe^{3+})$ (in molec./100 eV) for aerated 0.4 mol/L H_2SO_4 aq. solution (Fricke dosimeter) at 25 °C against LET in the range ~0.3–15 keV/μm. The solid curve represents the values of $G(Fe^{3+})$ calculated from our Monte Carlo simulations. The broken and dotted lines correspond to the Fricke G-values calculated at 10^{-7} and 10^{-6} s, respectively, from eq. [7] based on G(primary products). Experimental data: ref. 26 (▲), ref. 28 (●), ref. 33 (⬟), ref. 67 (□), ref. 72 (◁), ref. 81(★), refs. 91, 108, and 121 (○), ref. 95 (×), refs. 109 and 122 (◀), ref. 111 (▼), ref. 112 (▽), ref. 113 (in 0.05 mol/L H_2SO_4) (▷), ref. 114 (in 0.05 mol/L H_2SO_4) (▶), ref. 115 [based on $G(Fe^{3+})$ = 15.6 molec./100 eV for ^{60}Co γ-rays] (■), ref. 116 (△), ref. 117 (◇), ref. 118 (in 0.05 mol/L H_2SO_4) (◆), ref. 119 (☆), ref. 120 (✳), and ref. 123 (⊞). Dose-average LET values used here for the various radiation types considered are taken from ref. 60. Note that, for X-rays, there are in certain cases insufficient experimental details for an estimate of the average energy of electrons resulting from photon absorption in the solution to be made. This results in some uncertainty in assigning an average LET value to the corresponding reported $G(Fe^{3+})$ results.

Finally, as an application, we have simulated the chemical development of the Fricke dosimeter (aerated solution of ferrous sulfate in aq. 0.4 mol/L H_2SO_4) as a function of time up to ~50 s and addressed the effects of LET on the resulting ferric ion yield at 25 °C. The production of Fe^{3+} ions is found to be highly sensitive to free-radical yields, especially H· atoms, and is strongly dependent on the quality of the radiation. Our calculated values of $G(Fe^{3+})$ agree very well with the experimental yields.

The good overall agreement between calculated and experimental yield values obtained for both neutral water and acidic solutions, as well as for the Fricke dosimeter, gives

strong support to the validity and consistency of the assumptions employed in this study.

Acknowledgments

One of the authors (NA) expresses his appreciation to Dr. Kashane Chalermwat, Dr. Nisa Chawapun, and Dr. Wisatre Kongcharoensuntorn for their support and continuous encouragement during the course of this study. JPJG thanks the Japan Society for the Promotion of Science for a 2005 JSPS Invitation Fellowship for Research in Japan, which allowed him to present preliminary results of this work as part of an invited talk at the 48th Annual Meeting of the Japanese Society of Radiation Chemistry, held in Osaka, Japan, on October 12–14, 2005. The financial assistance of the Natural Sciences and Engineering Research Council of Canada (under Grant No. 9020–04) is gratefully acknowledged.

REVIEW / SYNTHÈSE

The natural bite angle — Seen from a ligand's point of view[1]

Olaf Kühl

Abstract: The natural bite angle concept is examined using *N*,*N*′-bisphosphino urea ligands as rigid scaffolds. The ligand has an upper limit of about 95° for the observed bite angle in chelate complexes, but prefers a much lower one. The ligand can be described as possessing downward flexibility. The dependence of the bite angle on the P—P distance within the ligand and the M—P bond length is illustrated. The metal tries to force the ligand into its own preferred structure, whereas the ligand wants to achieve a short P—P distance. A truly rigid ligand such as the *N*,*N*′-bisphosphino urea family is thus seen to clearly discriminate between metal atoms according to their individual assertiveness, using the P—P distance in the complex as a measure. Although the natural bite angle concept is valid and helpful in determining the possible bite-angle range for ligands before it is actually synthesised, its practical applicability seems to be limited to those cases where the flexibility range of the ligand allows for only one metal-preferred bite angle to be realized.

Key words: natural bite angle, ligand effects, ligand design.

Résumé : On a examiné le concept de l'angle naturel de prise en utilisant des ligands de *N*,*N*′-bisphosphinourées comme échafauds rigides. La limite supérieure pour l'angle de prise observé du ligand dans des chélates complexes, toutefois, sa préférence se situe à une valeur de beaucoup inférieure. On peut dire que le ligand possède une flexibilité descendante. On illustre la dépendance de l'angle de prise sur la distance P—P dans le ligand et sur la longueur de la liaison M—P. Le métal tend à forcer le ligand à prendre sa structure préférée alors que le ligand tend à raccourcir la distance P—P. Il apparaît donc que des ligands vraiment rigides, tels ceux de la famille de la *N*,*N*′-bisphosphinourée, peuvent faire une discrimination entre des atomes métalliques suivant leurs propres préférences en utilisant la distance P—P dans le complexe comme mesure. Même si le concept d'angle naturel de prise est valide et peut être utile dans la détermination des limites probables de l'angle de prise de ligands avant même qu'ils soient synthétisés, la limite de son domaine d'application semble limité aux cas où la limite de flexibilité du ligand ne permet de réaliser qu'un seul angle de prise d'un métal.

Mots-clés : angle de prise naturel, effets de ligand, mise au point de ligand.

[Traduit par la Rédaction]

Introduction

For decades, ligand design and engineering have been at the core of research into new and improved transition-metal complexes for homogeneous catalysis (1). Ligand design methods are only meaningful if the reaction mechanism, the required properties of the metal, the ligand and the substrate, as well as the influence of reaction conditions are thoroughly understood. Because there are rather narrow limits for the choice of metal, temperature, and pressure, and the substrates are largely dictated by the target product, the main focus for the improvement of catalysts is often on the ligand (1).

The ligand frequently carries such useful information as electronic (2) and steric properties (3), chirality (4), symmetry, and hemilability (5). Methods to determine the electronic and steric properties of the ligands, using IR and NMR spectroscopy, electrochemical methods, thermodynamical data and cone angles, as well as theoretical calculations, were devised (6). The best known of these techniques are the steric and electronic parameters defined by Tolman for monodentate ligands (2, 3) that were later adapted for chelating ligands (7). The Tolman electronic parameter (TEP) is defined as the A_1 band of the νCO stretching vibration observed in the IR spectra of $[Ni(CO)_3L]$. The TEP value can be calculated from any other series of transition-

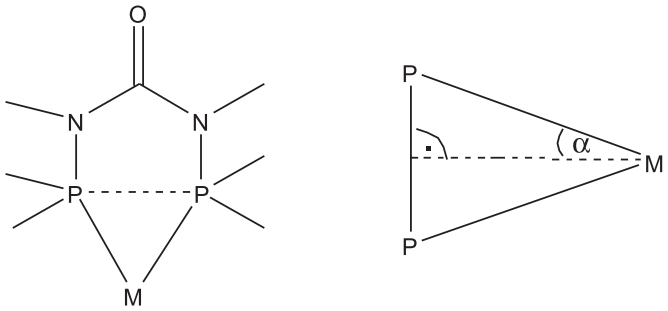
metal carbonyl complexes of phosphanes, and theoretical methods to calculate it are available (6). Arguably the best technique, but one that requires a large amount of experimental data, is the quantitative analysis of ligand effects (QALE), developed by Giering et al. (8–10).

The discovery that chelate ligands have beneficial properties that are not observed for monodentate ligands (4) led to the widespread use of chelate ligands in homogenous catalysis. This chelate effect had to be described in terms of electronic and (or) steric contributions. Rather obvious factors are increased complex stability with chelate coordination and the stronger influence of ligand chirality on the asymmetry of the catalyst, and thus the stereoselectivity of the reaction (4). The influence of the chelate ligand on the geometry of the metal, and therefore on crucial intermediates in the catalytic cycle, was discovered relatively late. The electronic influence of chelate ligands can be determined by calculating the TEP value using the Crabtree formula (7) or converting it from any other suitable carbonyl complex of the ligand (6).



The steric properties of a chelate ligand are only insufficiently represented by the adjusted Tolman cone angle. Therefore, a new parameter, the natural bite angle (1, 11, 12), was introduced.

The natural bite angle

The natural bite angle is defined as the angle formed by the two donor atoms of the chelate ligand and the metal atom under the condition that the metal atom exerts no influence on the ligand (1, 11, 12). In the solid state, the donor atoms in the free ligand are often unfavorably orientated for metal coordination, and hence, crystal structure determinations are not often helpful in measuring the natural bite angle. Instead, it can be calculated using molecular mechanics (MM). The procedure is rather simple and involves orientating the two donor atoms of the ligand (phosphorus in our case) towards an imaginary metal atom, assigning a fixed metal-to-donor-atom bond length and no force to the P–M–P angle (12) (see Fig. 1). The force field is used to calculate the distance between the two donor atoms, and thus the P–M–P angle known as the natural bite angle.

In this definition, the natural bite angle of a ligand depends only on two parameters: the M—P bond length and the P—P distance. The P—P distance is calculated by the molecular mechanics (MM) program used, but the M—P bond length must be chosen. Therefore, it is crucial to standardize the M—P values to make natural bite angles comparable in the literature. This amounts to choosing a specific metal as the standard and means that if another metal rather than the standard one is chosen, the natural bite angle has to be adjusted to the individual M—P bond length. The natural bite angle was introduced into the literature by Casey (11) and further developed by van Leeuwen (1, 12), using rhodium (I) catalysts as models. Both authors used different default values for the standard Rh—P bond (230 and 231.5 pm, respectively). Small as the difference of 1.5 pm may seem, it nonetheless translates to a difference of 0.6° in the resulting natural bite angle. The comparability of the two datasets is, therefore, somewhat compromised.

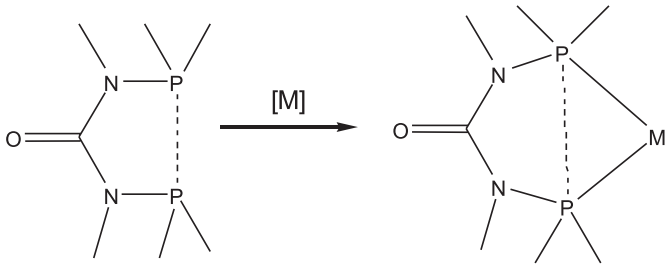
Fig. 1. Illustration of the definition of the natural bite angle taking a bisphosphino urea ligand as an example.

$$\alpha = 0.5\ \text{P–M–P}$$

$$\text{P–M–P} = 2\ \sin^{-1}\ (\text{P—P} / 2\ \text{M—P})$$

This becomes more important if different catalyst metals are considered. The M—P bond length of 231.5 pm lies in the middle of the range for typical M—P bond lengths: Mo(0), 245 pm (13, 14); Rh(I), 231.5 pm (12); Cu(I), 226 pm (15); Pd(II)/Pt(II), 220 pm (14, 16); Ni(0), 218 pm (17, 18). The difference of 27 pm in the range of M—P bond lengths translates into a natural bite angle spread of 12°. A statistical analysis performed by Dierkes and van Leeuwen (12) on the chelate ligands $Ph_2P(CH_2)_2PPh_2$ and $Ph_2P(CH_2)_3PPh_2$ shows that indeed most structurally determined bite angles of their complexes fall within a 10° range. This can be interpreted as an unchanged P—P distance and a dependence of the bite angle on the M—P bond length. Therefore, it might be better to report the P—P distance rather than the bite angle, since the bite angle is significantly influenced by the M—P bond length, and thus the choice of metal, when by definition it ought to be independent of it.

However, the mean values of the observed bite angles are 87° and 91°, respectively, and thus very close to the metal-preferred values for octahedral and square-planar metal complexes that dominate the literature.



The mathematical relationship between the P—P distance, the M—P bond length, and the P–M–P angle (the observed bite angle) means that the metal can attain the preferred bite angle by the adjustment of the M—P bond length, i.e., if the natural bite angle of the ligand is too large for a chelate complex to be formed, the P–M–P angle can be reduced by increasing the M—P bond length. A weaker coordination of the metal is then offset by a chelate bonding mode. More importantly, the flexibility of the M—P bond length increases the flexibility range of the natural bite angle that is defined as a 3 kcal/mol deviation in energy from the natural bite angle value (11, 12).

The phosphino urea ligand system

An experimentally verified natural bite angle of a diphosphane ligand requires a method that measures the P—P distance in a conformation suitable to chelate bonding to a metal, but in the absence of such metal. This can easiest be done when the ligand crystallizes in such a conformation, and thus the P—P distance can be measured by X-ray crystal structure determination.

© 2007 NRC Canada

Fig. 2. The widening of the ligand mouth (P—P distance increase) upon chelate coordination of the bisphosphino urea ligands.

In addition, the ligand backbone should be truly rigid, meaning that the metal has to use considerable force to open the mouth of the ligand (see Fig. 2), thereby increasing the P—P distance and the bite angle. Only then can the influence of the metal be determined, and more importantly, which metals are more assertive. Rigidity does not mean that the P—P distance cannot be increased at all, but rather that the resistance of the ligand is high enough to be able to distinguish between metals of equal geometrical preferences.

Bisphosphino ureas (19) contain the NC(O)N backbone that is characterised by its planarity, its short N—C bonds (138–140 pm), and a rather rigid N–C–N angle (118–121°) (14, 16, 20–24). The phosphorus atoms would be coplanar with the NC(O)N unit; however, the repulsion of the phosphorus atom lone pairs (PALP) that point towards each other results in a noticeable dislocation of the phosphorus atoms from the common plane in the free ligand (see Fig. 3) (17, 24).

In all structurally determined bisphosphino ureas, the phosphorus atoms face each other with the PALP pointing towards each other or towards an imaginary metal atom (20–22). They are pre-orientated for metal coordination, and the P—P distance, determined from their crystal structures, can be taken to calculate their natural bite angles.

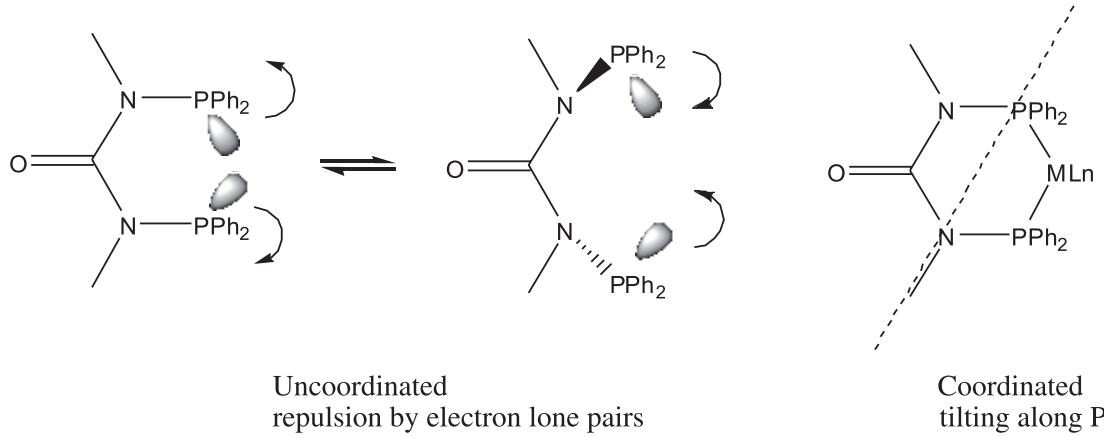
Chelate coordination to metals results in an unfavorable bond-lengths distribution with the urea backbone displaying short bond lengths (N—C is around 138–140 pm), and the metal giving rise to significantly longer M—P bond lengths (220–248 pm). Hence, to preserve the planarity of the ensuing metallacycle, the metal will have to force the ligand's mouth open, widening the N–C–N angle. However, the ligand effectively resists this, and instead, the metallacycle folds along the P—N vector (the line connecting the P and N atoms that are not bonded to each other), preserving the accustomed P—P distance even in the metal complex (16, 17, 24). Indeed, the value of the P—P distance in the metal complex can be taken as an indication of how assertive the metal is.

Flexibility of the ligand

The N–C–N unit in the bisphosphino urea backbone can be seen as a strong spring that causes the ligand to be very rigid as much as it prevents the P—P distance to increase largely. Indeed, the question of rigidity was identified early as a central issue in the understanding of the natural bite angle concept (1, 11, 12). As a measure of the flexibility of a chelate ligand, a bite angle range is calculated using molecular mechanics techniques encompassing all structures within 3 kcal/mol from the minimum (11). In many cases, that translates into a flexibility range of about 30–40° (12). That makes octahedral, square planar, tetrahedral, and even trigonal planar (trigonal bipyramidal) metal geometries easily accessible to the ligand. The observed bite angles for these flexible ligand systems will be metal-preferred rather than dependent on the natural bite angle of the ligand. Furthermore, there will be no effective discrimination between the ee and the ea coordination in trigonal-bipyramidal metal complexes (ee: equatorial–equatorial; ea: equatorial–axial). Consequently, no favorable product distribution in the rhodium-catalyzed hydroformylation of linear aldehydes can be expected, assuming that the bite angle of the ligand plays a central role in it.

Bisphosphino urea ligands were reacted with metal precursors, featuring metal-preferred bite angles ranging from 90° to 180°: 90° (octahedral) Cr(0), Mo(0), W(0) (13, 14, 20); 90° (square planar) Pd(II), Pt(II) (14, 16, 23); 90° (ea-trigonal bipyramidal) Fe(0) (20); 109.5° (tetrahedral) Ni(0) (17), Cu(I) (24); 120° (ee-trigonal bipyramidal) Fe(0) (20); and 180° (linear) Au(I) (14). With the exception of the trigonal bipyramidal geometry, all geometries have at least one structurally determined representative, enabling a detailed insight into the ligand preferences (see Fig. 4).

The experimentally determined P—P distances in the free bisphosphino urea ligands range from 280 to 308 pm (20–22) (see Fig. 5 and Table 1). These translate into uncommonly small natural bite angles (using 231.5 pm as the standard). If actually observed bite angles are considered, then it becomes soon apparent that any metal can force the mouth of these ligands open (see Fig. 2). In all metal complexes, the P—P distance is greater than that observed in the free ligand, ranging from 309.9 pm to 324.6 pm (see Table 2).



Geometry around the metal

From the observed bite angles ranging from 80.7° to 94.8°, the bisphosphino urea ligands only support metal-preferred bite angles of 90°. The exception is the copper(I) complex, which is distorted tetrahedral (24). However, for the copper(I) complex, the only evidence for chelation is in the solid state. In solution, the complex is labile, and the metallacycle opens as one of the phosphorus atoms dissociates from the copper atom. In fact, the compound displays dynamic behavior in solution even at low temperatures, probably via a fast dissociation–association mechanism (24). A similar Ni(0) complex, probably with a preferred tetrahedral geometry, shows similar dynamic behavior, although no crystal structure was reported (17).

If the preferred bite angle of the metal is further increased, the bisphosphino urea ligand will no longer act as a chelate ligand, but it will bridge two metal atoms in a κ^1 fashion. This is observed in the reactions of the ligand with $[Fe_2(CO)_9]$ (20) and [AuCl(tht)] (tht = tetrahydrothiophene) (14). Gold(I) complexes favor linear geometries with a P–Au–L angle of 180°, and it is no surprise that the rigid bisphosphino urea ligand will not accommodate such a large bite angle. Quite expectedly, it chooses to act as a bis-κ^1 ligand to two gold atoms instead.

© 2007 NRC Canada

Fig. 3. The structure of bisphosphino urea ligands in the free state (left) and in metal chelate complexes (right).

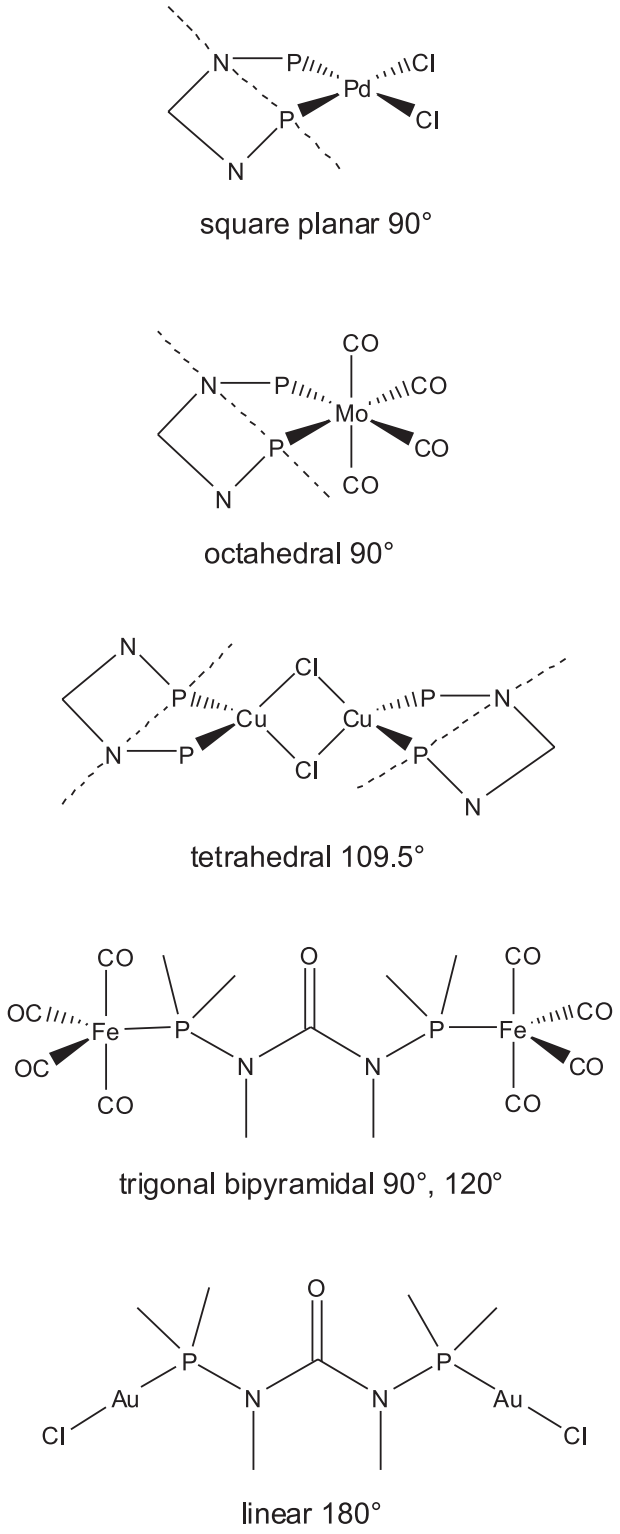
The case of the Fe(0) carbonyl complex is quite different as a trigonal-bipyramidal complex has two accessible bite angles: 120° for ee coordination and 90° for ea coordination. It is this choice for which the natural bite angle concept was developed using rhodium as the model atom.

From the previously mentioned arguments, it is understandable that the bisphosphino urea ligand will not occupy the ee sites, as the metal-preferred bite angle of 120° is certainly inaccessible for the rigid chelate ligand. However, the ea sites seem comparable to the situation in octahedral and square-planar complexes, where the metal-preferred bite angles are 90°. The answer can be found by carefully studying the reaction conditions employed. A suspension of $[Fe_2(CO)_9]$ in toluene was treated with $\{PhBu^tPN(Me)\}_2CO$ at room temperature. Under these conditions, the bisphosphino urea ligand can cleave the Fe—Fe bond but cannot displace a carbonyl ligand from the iron fragment. Heating would be needed for this reaction to occur. As a consequence, the two phosphorus atoms of the ligand react seperately with one $[Fe_2(CO)_9]$ molecule each until the iron complex is consumed. The question of suitable bite angles does not arise.

Another feature of bisphosphino urea ligands is clearly demonstrated by the reactions with the Ni(0) (17), Cu(I) (24), Fe(0) (20), and Au(I) (14) precursors. Despite their apparent steric crowdedness and their preference for nonbonding P—P contacts, they can evidently rotate freely around the P—N bond (see Fig. 6). Another interesting detail is supplied by the reaction between $\{PhBu^tPN(Me)\}_2CO$ and *cis*-$[W(CO)_4$(norbornadiene)] (20). The product is not the expected P,P′-chelate complex, but a P,O-chelate complex where the carbonyl oxygen atom is bound to the metal (see Fig. 7). Evidently, the steric congestion around the phosphorus atoms prevents the attack of the second phosphorus atom on tungsten, while the norbornadiene ligand is still bound to it in a κ^2 fashion (with one double bond) in the transition state. Instead, coordination of the less-crowded carbonyl group is preferred.

In the bisphosphino ureas, we find a rare case where the P—P distance in the free ligand can be determined from the crystal structure and proves to be smaller than the distance in any of their metal-chelate complexes. The very short P—P distances in the free ligand are far shorter than the sum of the van der Waals radii of phosphorus (25) and indicative of a positive interaction between the two phosphorus atoms. In principle, one of the phosphino groups can utilize its lone pair to act as a Lewis base towards the other phosphino group. This behavior is observed in related systems, resulting in a P—P bond and a five-membered ring system (6). This very short P—P distance has been identified as the cause why the natural bite angle of the free bisphosphino urea ligand could not be calculated by standard MM methods (17). In fact, the authors reported that the van der Waal's radius for phosphorus had to be significantly reduced to reproduce the natural bite angle of $\{Ph_2PN(Me)\}_2CO$.

Softness of the metal



In the metal complexes, the ligand apparently wants to maintain the short P—P distance but is opposed by the interplay of the metal-preferred bite angle and the M—P bond length. The combination of their optimal values produces a P—P distance that exceeds that of the free ligand. The increase of the P—P distance in the metal complex compared with the free ligand can therefore be seen in terms of the influence or the assertiveness of the metal, since the metal forces the mouth of the ligand open.

Looking at the respective metal atoms and their accompanying preferred bite angles, a trend manifests itself. The greatest P—P distances are found for the 3d and 4d elements: copper, molybdenum, and palladium, whereas the P—P distances in complexes of the 5d element platinum approach the values for the free ligands (309.9, 312.2, and 314.0 pm, respectively). It seems that the ligand is determined to attain its resting position (the free ligand status quo) regardless of the preferences of the metal. With the "softer" 5d element platinum, it almost achieves its goal; however, with the somewhat "sturdier" 3d and 4d elements, it has to make significant concessions.

The case of copper is quite different. The preferred geometry of copper(I) is tetrahedral, and thus, the copper atom wants to realize a larger bite angle (109.5°). As it cannot increase the P—P distance far enough, it has to settle for a short M—P bond length, and indeed, the observed Cu—P bond length of 223.5 pm is at the bottom end of the observed bond length range for Cu(I)—P in chelate complexes (15).

Fig. 4. The metal-coordination geometries observed in the complexes of bisphosphino urea ligands.

The copper complex is a special case in another context. The chelate bonding mode is only observed in the solid state and opens up in solution with accompanying Cu—P bond fissure. There is reason to believe that the stabilizing supramolecular π–π stacking interactions of the phenyl rings in the solid state are the cause for the feasibility of a distorted tetrahedral geometry around copper despite the two very acute bite angles of 93.2 (P–Cu–P) and 95.9° (Cl–Cu–Cl). The copper(I) complex effectively defines the upper limit of the bisphosphino urea ligand bite-angle range.

Fig. 5. The P—P distance in the free bisphosphino urea ligands. The resulting natural bite angles are 74.6°, 80.8°, and 83.4°, respectively (with 231.5 pm as standard M—P bond length).

Difficulties in molecular modelling (MM) calculations

The natural bite angle method will only fail when there are unforseen effects that significantly influence the P—P distance in the ligand. This is clearly the case for the bisphosphino urea ligands with exceptionally short P—P distances in the free ligands. These short P—P distances are due to attractive forces between the two phosphorus atoms that are not appreciated by the force fields of the standard MM programs. Consequently, erroneous P—P distances and natural bite angles are predicted by these programs in these cases (17).

The natural bite angle concept was based on a great deal of statistical evidence (12), and it may be beneficial to reflect on the validity of this evidence. By far, the majority of the chelate complexes of diphosphanes are either octahedral

or square-planar because most catalyst metals prefer square-planar geometries (Pt(II), Pd(II), Ir(I), Rh(I), and to some extent Ni(II)), whereas the popular group VI metals (W, Mo, and Cr) prefer an octahedral geometry. The most popular diphosphane ligands are 1,ω-diphosphino alkanes (12) that, with the exception of dppm (bis-diphenylphosphino methane), have natural bite angles in the vicinity of 90°. It is not surprising that a narrow distribution is observed when a perfect match between the natural bite angle of the ligand and the metal-preferred bite angle is its foundation.

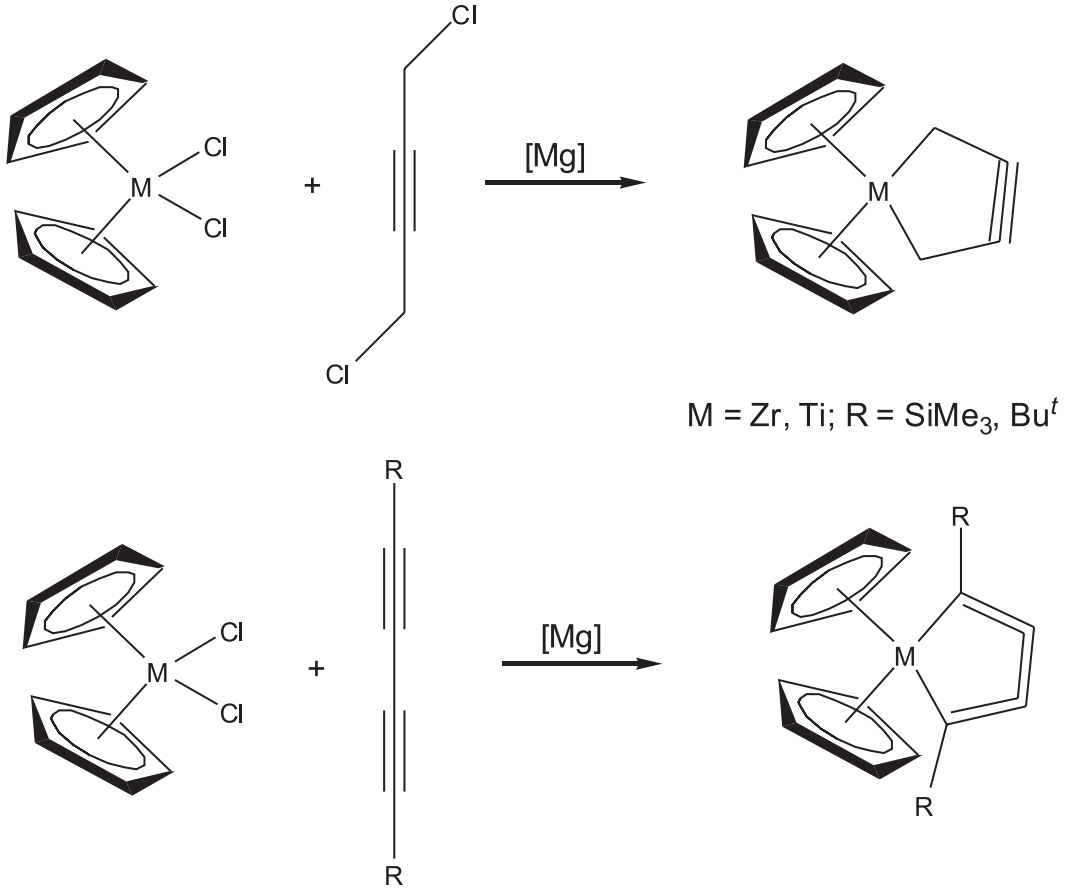
However, the natural bite angle concept might target the wrong parameter altogether. The only relevant parameter wholly determined by the ligand is the P—P distance in the free ligand, whereas the M—P bond length and the bite angle are dependent on the choice of the metal. It would therefore be better if the P—P distances were calculated and reported rather than the bite angles that rely on the standardized M—P bond lengths and are only valid for one specific metal atom.

The definition of the natural bite angle calls for a dummy atom that pulls the two phosphorus atoms of the ligand into the same direction, but the M—P bond length (and choice of metal) is left to the individual researcher. That would mean that natural bite angles were not standardized and confusing, if not completely useless. On the other hand, standardization to a specific bond length (normally 231.5 pm for Rh(I)) generates a false sense of validity for the standardized natural bite angle if applied to other metal complexes. A plain P—P distance would at least recognize the need to convert the value to the metal presently under consideration but lacks the appeal of a simple, ready-to-use value.

Upward and downward flexibility

It is not enough to average all data found in the literature. Instead, the rigidity of the ligand backbone has to be taken into account. It can be expected that a flexible ligand will adapt to the metal geometry presented to it. That is plainly seen in the available statistical evidence. But what happens if the ligand backbone strongly resists the geometry offered by the metal? Three cases can be differentiated: total rigidity, upward flexibility, and downward flexibility. Bisphosphino urea ligands display downward flexibility, meaning that they have an upper limit (about 324 pm or 95°) and strive towards the resting state of the free ligand (about 300 pm or 80°). Upward flexibility describes the opposite situation, and total rigidity means that the ligand does not yield either way.

Good examples for upward flexibility are the complexes formed in the reaction between metallocene dichlorides (M = Ti, Zr) and 1,4-dichlorobutin-2 or 1,4-disubstituted butadiins-1,3 with magnesium as the reducing agent (see Fig. 8). In both cases, the preferred bite angle of the ligand is 180°, although the orientation of the ligand-based orbitals used for binding to the metal would suggest a somewhat smaller angle. The ligand has to bend to coordinate to the metal in chelate fashion. It is very surprising that it tolerates a bite angle as low as 97–101° (26–28). The bite angle has to be so low because of the large Cp–M–Cp angle of about 130° that leaves no more space for a larger bite angle. As the ligand would clearly prefer a larger bite angle if it could be accommodated by the metal, the system can be taken as an example of upward flexibility even in the absence of a structurally determined example. The alternative for the ligand is the formation of a cyclopropene-ring system with the other two carbon atoms pending as a side chain (28).



Upward and downward flexibilities only make sense when there is a definite aim to achieve. The most important discrimination is between the ea and ee coordination in trigonal bipyramidal complexes. This is seen as a decisive factor in the product distribution of hydroformylation reactions (29–31). A flexible ligand (typical range is 30–40°) will not be able to discriminate between a metal-preferred bite angle of 90° (ea) and 120° (ee). However, a downward flexible ligand of, e.g., 105° will only realize ea coordination, whereas an upward flexible ligand of, e.g., 105° will only realize ee coordination. MM calculations can normally settle this issue, as they can calculate the natural bite angle and the flexibility range. It is then easy to determine which metal-preferred bite angles lie within this range.

Conclusions

The natural bite angle concept is far more complex than what is suggested by the simple geometrical equation that defines it. First, the natural bite angle was defined for rhodium(I) complexes (11, 12), meaning that the natural bite angle has to be adjusted for the different M—P bond lengths when other metals are considered. Second, the effective flexibility range of the ligand has to be taken into account when the natural bite angle is used to discriminate between two different metal-preferred bite angles, and third, the tolerance

Fig. 8. Formation of the metallocene but-2-yne and metallocene buta-1,2,3-triene complexes.

of the metal towards distortions in its coordination sphere needs to be considered.

Considering the rather large flexibility range of most ligands (30–40°) (12), the range of the observed M—P bond lengths for a given metal, and the tolerance for distortions displayed by most metal centres, it can be expected that only a select minority of chelate ligands will completely discriminate between two different metal-preferred bite angles such as the ones observed in a trigonal-bipyramidal complex. The majority of chelate ligands will simply populate both accessible bite angles to different degrees. In cases where this is decisive for the product formed, a more or less favorable product distribution will be the result.

The importance for the bite angle concept in ligand design lies not in the absolute value of the P—P distance but in its flexibility range and its application to a specific M—P bond length range. The ideal case is a chelate ligand displaying an upward or downward flexibility that is suitable only for one and not the other of two possible metal-preferred bite angles.

Interactions of platinum(II)-derivatized triplex-forming oligonucleotides with DNA[1]

Meghan A. Campbell, Tracey McGregor Mason, and Paul S. Miller

Abstract: Polypyrimidine oligonucleotides can bind to tracts of contiguous purines in double-stranded DNA to form triple-stranded complexes. The stability of the triplex is reduced significantly if the target purine tract is interrupted by a single pyrimidine. Previous studies have shown that incorporation of an N^4-aminoalkylcytosine into the triplex-forming oligonucleotide (TFO), opposite a single CG interruption, facilitates triplex formation. Examination of molecular models suggested that further modification of the amino group of the aminoalkyl arm might enable adduct formation with the N7 of the guanine of the CG interruption. To test this, we prepared 2′-deoxyribo-and 2′-*O*-methylribo-TFOs that contained cytosine (**C**), N^4-(2-aminoethyl)cytosine (**ae-C**), or diethylenetriamineplatinum(II) (**DPt-C**) or *cis*-aquodiammineplatinum(II) (**cPt-C**) derivatives of N^4-(2-aminoethyl)cytosine, positioned opposite a CG interruption of a polypurine tract found in the *pol* gene of HIV-1 proviral DNA. Although the **C**- and **ae-C**-derivatized deoxyribo-TFOs formed triplexes of modest stability and the **DPt-C**-modified TFO failed to form a triplex, the **C**- and **ae-C**-derivatized 2′-*O*-methylribo-TFOs formed remarkably stable triplexes (T_m = 57 °C). The **DPt-C**- and **cPt-C**-modified 2′-*O*-methylribo-TFOs also formed triplexes, although their stabilities were reduced (T_m = 33 °C), suggesting that the tethered platinum group may interfere sterically with TFO binding. Consistent with this hypothesis was the observation that triplex stability was restored (T_m = 57 °C) when the diethylenetriamineplatinum(II) group was tethered to the 5′-end of the 2′-*O*-methylribo-TFO via a 2-aminoethylcarbamate linkage. Taken together, these results suggest that 2′-*O*-methylribo-TFOs may be particularly useful in targeting purine tracts in DNA that have CG interruptions, and that further modification with platinum derivatives could lead to the design of TFOs that are capable of covalent binding to their target, thus increasing the effectiveness of the TFO.

Key words: triplex-forming oligonucleotide, TFO, cisplatin, interrupted polypurine tract.

Résumé : Les oligonucléotides de polypyrimidine peut se lier à des ensembles purines contiguës dans de l'ADN à double brin pour former des complexes à trois brins. La stabilité du complexe est réduite d'une façon significative si l'ensemble de purine cible est interrompue par une seule pyrimidine. Des études antérieures ont montré que l'incorporation d'une N^4-aminoalkylcytosine dans le l'oligonucléotide formant le triplex (OFT) vis-à-vis une seule interruption CG facilite la formation du triplex. L'examen de modèles moléculaires suggère qu'une autre modification du groupe amino de la chaîne aminoalkyle pourrait rendre possible une formation d'adduit avec le N7 de la guanine de l'interruption CG. Afin de vérifier cette hypothèse, on a préparé des 2′-désoxyribo- et 2′-*O*-méthylribo-OFT qui contenaient de la cytosine (**C**), N^4-(2-aminoéthyl)cytosine (**ae-C**) ou des dérivés du diéthylènetriamineplatine(II) (**DPt-C**) ou du *cis*-aquodiammineplatine(II) (**cPt-C**) à base de N^4-(2-aminoéthyl)cytosine qui ont été positionnés en face d'une interruption CG d'un ensemble de polypurines dans le gène *pol* de l'ADN du HIV-1 proviral. Même si désoxyribo-OFT modifié par la cytosine (**C**) et l'**ae-C** conduit à la formation de complexes ne présentant qu'une modeste stabilité et que le OFT modifié par le **DPt-C** ne conduit pas à la formation de triplex, le 2′-*O*-méthylribo-OFT modifié par **C** ou par **ae-C** conduit à la formation de triplex d'une stabilité remarquable (T_m = 57 °C). Les 2′-*O*-méthylribo-OFT modifiés par **DPt-C** et **cPt-C** forment aussi des triplex, même si leurs stabilités sont réduites (T_m = 33 °C), ce qui suggère que le groupe platine en laisse peut interférer stériquement avec la fixation du OFT. En accord avec cette hypothèse, on a observé que la stabilité du triplex est restaurée (T_m = 57 °C) lorsque le groupe diéthylènetriamineplatine(II) est mis en laisse à l'extrémité 5′ du 2′-*O*-méthylribo-OFT par le biais d'une liaison 2-aminoéthylcarbamate. L'ensemble de ces résultats suggère que les 2′-*O*-méthylribo-OFT sont particulièrement utiles pour cible des blocs de purine dans de l'ADN qui comportent des interruptions CG et que des modifications subséquentes avec des dérivés du platine pourraient conduire à la mise au point d'OFT capables de se lier d'une façon covalente à leur cible, ce qui aurait comme effet d'augmenter l'efficacité du OFT.

Mots-clés : oligonucléotide formant un triplex, OFT, cisplatine, ensemble de polypurine interrompu.

Introduction

Oligonucleotides can be designed to target and bind to polypurine tracts in double-stranded DNA through the formation of triple-stranded complexes (1–8). The bases of these so called triplex-forming oligonucleotides (TFOs) contact the target purine bases through the major groove of DNA. Two types of binding motifs, the pyrimidine-purine-pyrimidine motif and the purine-purine-pyrimidine motif, have been identified. In the former motif, bases of an all-pyrimidine TFO, whose backbone polarity is parallel to that of the purine tract, form Hoogsteen-type hydrogen bonds with adenine and guanine bases in the target strand. In the latter motif, bases of an all-purine TFO, whose backbone polarity is antiparallel to that of the purine tract, form reversed Hoogsteen-type hydrogen bonds with the purines of the target strand. In addition to these two motifs, a "mixed" motif has been described, in which T and G residues of the TFO bind to A and G residues, respectively, of the purine tract.

Triplex formation requires a tract of contiguous purine bases in the target strand. It has been know for some time that interruption of the purine tract of the target by a single pyrimidine can greatly reduce the stability of the triplex or eliminate its formation altogether (9–14). There have been a number of attempts to design or identify base analogs that can be incorporated into TFOs to "recognize" pyrimidine interruptions, and thus stabilize the resulting triplex (14–36). These efforts have met with varying degrees of success. We have previously reported that N^4-(2-aminopropyl)- and N^4-(2-acetamidopropyl)-modified cytosines targeted to a CG interruption can stabilize triplex formation when incorporated into deoxyribopyrimidine TFOs (17). The results suggested that the amino or acetamido groups of these modified bases could make contacts across the major groove with the guanine of the CG interruption. Recently McLaughlin and coworkers (37, 38) synthesized a deoxyribothymidine TFO carrying a 5′- platinum-modified alkyl group and demonstrated that this TFO could covalently bind to its target via the formation of a guanine–platinum adduct adjacent to the TFO binding site. This observation, coupled with our own, suggested that the modification of the aminoalkyl arm of an internal N^4-(aminoalkyl)cytosine residue with a reactive platinum group might create a TFO that could bind covalently to the guanine base of the CG interruption.

This report describes the syntheses of deoxyribonucleoside TFOs derivatized with platinated N^4-(2-aminoethyl)cytosine residues and the characterization of their interactions with a short DNA duplex, whose purine tract contains a single CG interruption. Similarly modified 2′-*O*-methylribonucleoside TFOs were also prepared, and their binding interactions with the DNA duplex were characterized. Although the platinated TFOs proved to have inferior binding capabilities, the unmodified 2′-*O*-methylribonucleoside TFOs showed remarkably high affinities for the DNA target.

Results and discussion

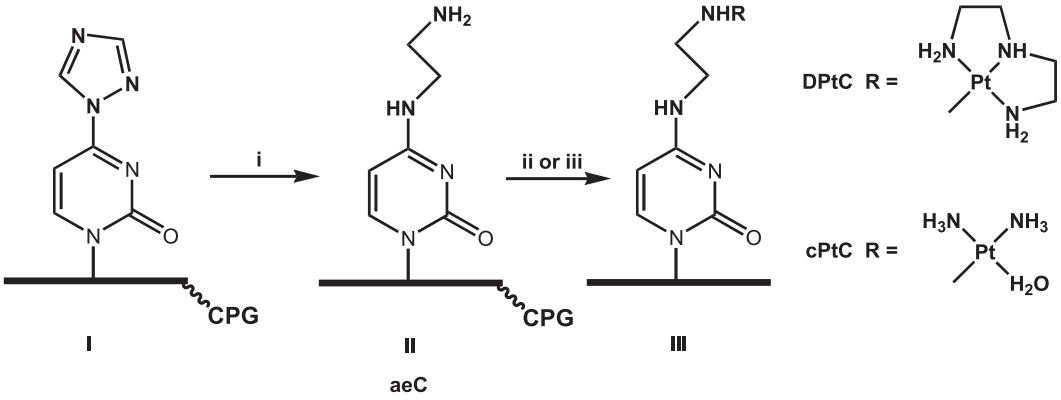
DNA targets and TFOs

Figure 1 shows the two DNA targets used in this study. The **DNA-1** target, where Y is G and Z is C, is 17 base pairs in length and consists of an uninterrupted purine tract. The **DNA-2** target, where Y is C and Z is G, contains a single pyrimidine interruption at position 12 of the duplex. The sequence of this second duplex corresponds to nucleotides 4899–4915, found in the coding region of the pol-1 gene of HIV-1 proviral DNA.

Fig. 1. General structure of TFO and its DNA target; C = 5-methylcytosine.

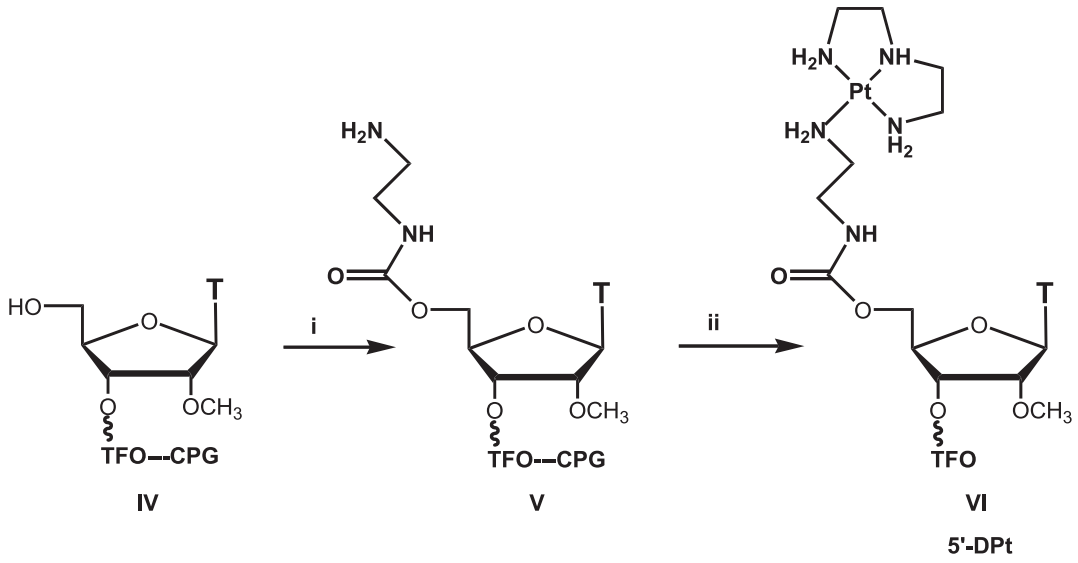
```
5'-TTCTTCTTTTCXTTTCT   TFO
5'-AAGAAGAAAAGYAAAGA | DNA TARGET
3'-TTCTTCTTTTCZTTTCT |
```

Also shown in Fig. 1 is the general sequence of the TFO, whose bases consist of thymine and 5-methylcytosine residues. The polarity of the TFO is the same as that of the purine strand of the target duplex. Base X is either a cytosine or modified cytosine base. The sequences of the TFOs are shown in Table 1, and the structures of the modified bases at X are shown in Schemes 1 and 2. TFOs with two different types of backbones were investigated: those consisting of deoxyribonucleotides, series **1** TFOs, and those consisting of 2′-*O*-methylribonucleotides, series **2** and **3** TFOs. In these internally modified TFOs, base X is positioned opposite the CG interruption in the **DNA-2** target. An additional 2′-*O*-methylribo-TFO, **4**, was prepared, in which the diethylenetriamineplatinum(II) [Pt(dien)] group was positioned at the 5′-end of the oligonucleotide. This 5′-modified TFO contains a deoxycytidine residue at position X.



Syntheses of platinum-modified TFOs

The oligonucleotides were synthesized on controlled-pore glass supports by automated oligonucleotide chemistry, using either protected deoxyribonucleoside-3′-*O*-bis(diisopropylamino)-β-cyanoethylphosphoramidites or protected 2′-*O*-methylribonucleoside-3′-*O*-bis(diisopropylamino)-β-cyanoethylphosphoramidites. For TFOs **1** and **3**, deoxycytidine was placed at position X, whereas 2′-*O*-methylcytidine was placed at position X in TFO **2**. The internally modified TFOs in series **1** and **3** were prepared as shown in Scheme 1. These oligonucleotides were prepared with 4-triazole-deoxyuridine residue incorporated at position X (structure **I**). The support-bound, protected oligonucleotide was then converted to the N^4-(2-aminoethyl)-C derivative, **II**, by treating the support with ethylenediamine. The aminoethyl derivatized oligonucleotide was released from the support and deprotected by treatment with ammonium hydroxide. The oligonucleotide was then purified by strong anion exchange (SAX)-HPLC. The aminoethyl group was converted to the Pt(dien) or the *cis*-chlorodiammineplatinum(II) derivative, **III**, by reacting the oligomer with chlorodiethylenetriamineplatinum (II) chloride, [Pt(dien)Cl]Cl, or *cis*-diamminedichloroplatinum(II) dichloride (*cis*-DDP), respectively. The platinum-derivatized TFOs were purified by SAX-HPLC.



TFO **4**, which contains a 5′-Pt(dien) group, was prepared as shown in Scheme 2. The oligonucleotide was synthesized with deoxycytidine incorporated at position X, and the 5′-terminal dimethoxytrityl group was removed to give oligonucleotide **IV**. The support-bound, protected oligonucleotide was converted to its 5′-(2-aminoethyl)carbamate derivative, **V**, by sequential treatment with carbonyldiimidazole and ethylenediamine. The derivatized oligonucleotide was

cleaved from the support and deprotected by treatment with ammonium hydroxide. Following purification by SAX-HPLC, the oligonucleotide was converted to the Pt(dien) derivative, **VI**, by reaction with [Pt(dien)Cl]Cl. Each of the oligonucleotides was characterized by MALDI-TOF mass spectrometry, as indicated in Table 1.

Triplex formation by deoxyribo-TFOs

The presence of a single pyrimidine interruption can adversely affect the stability of a triplex. This can be observed by comparing the thermal stability of the triplex formed between TFO **1** and **DNA-1**, which contains a contiguous purine tract, with that of the triplex formed between TFO **1** and **DNA-2**, which contains a CG interruption. As shown by the melting curves in Fig. 2, the **1/DNA-1** triplex displays a single transition, whose midpoint (T_m) is 63 °C, which corresponds to dissociation of all three strands. In contrast, the melting curve of the **1/DNA-2** triplex shows two transitions. The first transition at 34 °C corresponds to the dissociation of the TFO. The remaining duplex then melts at 63 °C, as signaled by the second transition. Although molecular models suggest that the cytosine at position X can be accommodated within the major groove of the triplex opposite the CG interruption, it seems unlikely that it forms any productive hydrogen-bond contacts with this base pair. The loss of hydrogen-bonding interactions could account for the 29 °C reduction in the stability of the triplex.

As shown in Table 2, replacement of the cytosine at X with N^4-(2-aminoethyl)cytosine, TFO **1-ae**, results in a small increase in the stability of the triplex formed with **DNA-2**. Molecular models suggest that the 2-aminoethyl arm of **1-ae** is too short to reach across the major groove and make contact with the guanine of the CG base pair of the target. However, the primary amino group of this arm would be expected to be protonated at pH 6.5. This protonation could reduce the overall charge repulsion between the phosphate backbone of the TFO and those of **DNA-2**, and thus help stabilize the triplex. Consistent with this hypothesis is the observation that the acetamido derivative of **1-ae**, which eliminates the positive charge of the 2-aminoethyl group, forms a triplex with **DNA-2**, whose T_m is approximately 2 °C less than that of the triplex formed by **1-ae**.[3]

Platinum(II) compounds, such as *cis*-DDP, react readily with the N7 of the guanines of the double-stranded DNA to

from intra- and interstrand platinum cross-links (39). Derivatization of the amino group of 2-aminoethyl arm of TFO **1-ae** with *cis*-DDP could position Pt near the guanine of the CG interruption, and thus enable covalent attachment of the TFO to the pyrimidine-rich strand of the DNA duplex. To determine if the guanine of an isolated CG interruption is accessible to platination, the triplex shown in Fig. 3 was prepared. This triplex is comprised of a 17-base pair duplex that consists of complementary strands of deoxyadenosine and thymidine residues. These AT base pairs are interrupted by a single internal CG base pair located 12 nucleotides in from the 5′-end of the deoxyadenosine strand. The TFO consists of thymidines and a single deoxycytidine, positioned opposite to the CG interruption. Triplex formation was confirmed by UV thermal denaturation analysis (data not shown). The 5′-end of the pyrimidine strand of the duplex was end labeled with ^{32}P-phosphate. The triplex was then incubated with [Pt(dien)Cl]Cl at 4 °C, which is 14 °C below the dissociation temperature of the TFO strand, and the products of the reaction were analyzed by denaturing polyacrylamide gel electrophoresis. As shown in Fig. 3, a new, slower migrating band appears in the gel, which corresponds to the N7-G platinum adduct of the labeled pyrimidine strand of the triplex. Thus, this experiment demonstrates that the N7-G of the CG interruption is accessible to platination through the major groove of the triplex.

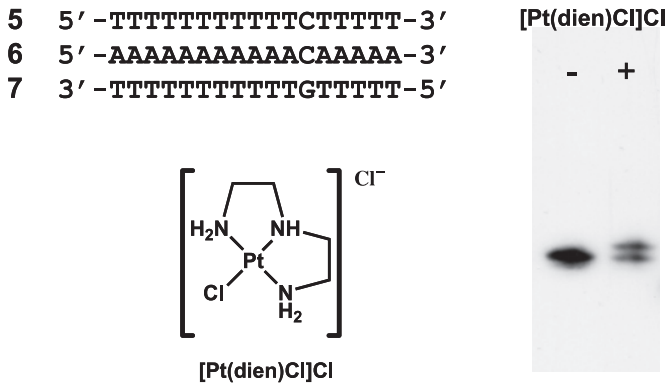
[b]Melting temperatures were determined at pH 6.5 in a buffer, containing 100 mmol/L 3-(*N*-morpholino)propanesulfonic acid, 100 mmol/L sodium acetate, and 2.5 mmol/L magnesium acetate.



A nonreactive Pt(dien) derivative, **1-DPt**, was prepared to determine the effect of the platinum group on triplex formation. As shown in Table 2, this modified TFO was unable to form a triplex with **DNA-2** under conditions where stable triplex formation was observed with the 2-aminoethyl-derivatized TFO, **1-ae**. Triplex formation was also assayed under conditions where increasing concentrations of **1-DPt** were incubated with **DNA-2**. Under these conditions, the TFO was present in 2- to 10-fold excess over the target duplex. Triplex formation was monitored by nondenaturing polyacrylamide gel electrophoresis, and as shown in Fig. 4, no triplex could be detected, even in the presence of a 10-fold excess of **1-DPt**. These results suggest that although free [Pt(dien)Cl]Cl can react with the guanine of the CG interruption, when tethered to a TFO, this platinum(II) group may sterically interfere with formation of the triplex. The observation that the acetamido derivative of **1-ae**, a less bulky modification, can from a triplex, whose T_m is 38 °C (data not shown), is consistent with this conjecture.

Triplex formation by 2′-*O*-methylribo-TFOs

The triplexes, formed by the deoxyribo-TFOs **1** and **1-ae** and **DNA-2**, have rather low thermal stabilities. Previous work, from our laboratory and others, has shown that TFOs that are comprised of 2′-*O*-methylribonucleosides often form significantly more stable triplexes with double-stranded DNA targets than those formed by the corresponding deoxyribo-TFOs (40–45). The reasons for this increase are not entirely clear. 2′-*O*-Methylribonucleosides exclusively adopt a 3′-endo conformation, which would be expected to preorganize the TFO in an A-form conformation that is compatible with the final A-like conformation of the triplex. In addition, the somewhat hydrophobic 2′-*O*-methyl groups of the nucleosides may contribute to the stacking interactions along the backbone of the TFO when it is engaged in triplex

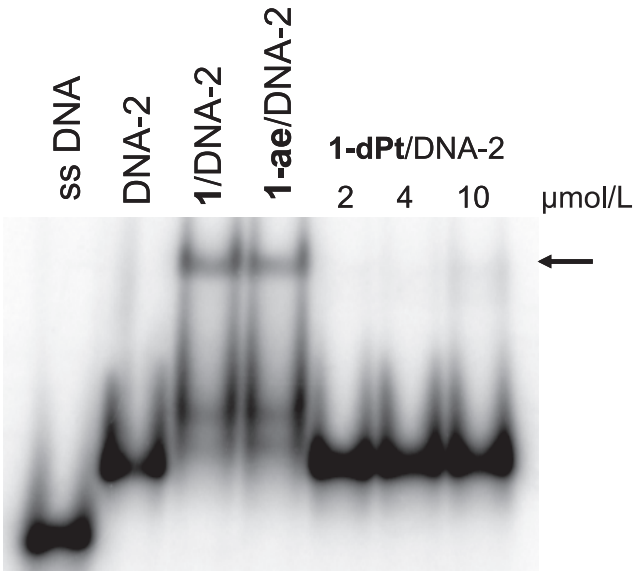
Fig. 3. Reaction of [Pt(dien)Cl]Cl with the triplex formed by oligonucleotides **5**, **6**, and [^{32}P]-**7**. The triplex was incubated in the presence or absence of [Pt(dien)Cl]Cl, and the reaction mixture was analyzed by denaturing polyacrylamide gel electrophoresis.



formation. Both of these factors may contribute to the overall triplex stability.

The 2′-*O*-methylribonucleotide analog of **1**, TFO **2**, was prepared, and its interactions with **DNA-1** and **DNA-2** were examined by thermal denaturation experiments. As shown in Table 2, the T_m of the triplex formed between TFO **2** and **DNA-1** is 15 °C higher than that of the corresponding triplex formed by TFO **1**. This result is consistent with the expectation that 2′-*O*-methylribo-TFOs form more stable triplexes than 2′-deoxyribo-TFOs. This increased stability carries over to the triplex formed between TFO **2** and the CG interrupted target **DNA-2**. Although the interruption decreases the stability as expected, this triplex still has a remarkably high T_m, 57 °C, which is 23 °C higher than that of the corresponding triplex formed by deoxyribo-TFO **1**. Interestingly, substitution of the 2′-*O*-methylcytidine at position X in **2** with deoxycytidine, TFO **3**, did not diminish the stability of the triplex. These results suggest that modification of TFOs with 2′-*O*-methylribonucleotides may be an effective way to address the problem of pyrimidine interruptions in triplex binding sites.

Like its deoxyribo counterpart, the N^4-(2-aminoethyl)cytosine derivative of TFO **3**, **3-ae**, formed a stable triplex with **DNA-2**, although in this case the modification reduced the T_m by 3 °C. Conversion to the Pt(dien) derivative, **3-DPt**, significantly reduced the T_m. Relocating the Pt(dien) group to the 5′-end of the TFO, as in TFO **4**, restored the T_m of the triplex to the same value as that of the triplex formed with unmodified TFO **3**. As was the case with the deoxyribo-TFO, this result is consistent with the idea that the somewhat bulky platinum group may sterically hinder the formation of the triplex.

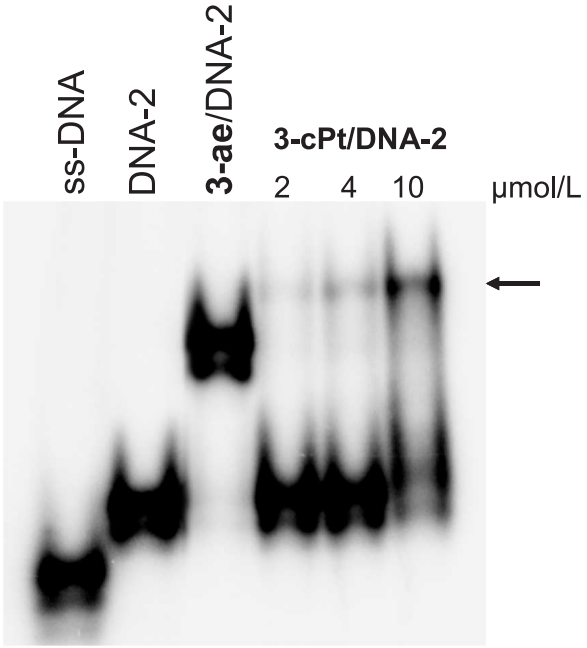
Although derivatization with the platinum group reduced triplex stability, the T_m of the **3-DPt/DNA-2** triplex, 33 °C, is sufficiently high to determine if platinum can react with the guanine of the CG interruption of **DNA-2**. To test this, the *cis*-chlorodiammineplatinum(II) derivative of TFO **3**, **3-cPt**, was prepared. Gel electrophoresis studies, carried out under nondenaturing conditions, showed that **3-cPt** forms a triplex with **DNA-2** (see Fig. 5). When electrophoresis was carried out under denaturing conditions, little or no covalent adduct was observed, even after prolonged incubation at

Fig. 4. Interactions of DNA duplex **DNA-2** with TFOs **1**, **1-ae**, or **1-DPt**. A 1 μmol/L solution of [^{32}P]-**DNA-2** was incubated with 2 μmol/L TFO **1** or 2 μmol/L TFO **1-ae** or 2, 4, or 10 μmol/L TFO **1-DPt**, and the solutions were analyzed by nondenaturing polyacrylamide gel electrophoresis. The left two lanes of the gel contain labeled single-stranded DNA and [^{32}P]-**DNA-2**, respectively. The position of the triplex is indicated by the arrow.

20 °C (data not shown). This result suggests that if the platinum group resides in the vicinity of the CG guanine, it may not be positioned properly for productive reaction to occur. It may be possible to remedy this situation by changing the length of the linker. Alternatively, the platinum-modified linker could be relocated to the 5′-end of the TFO, where, in analogy to the results of Sharma and McLaughlin (37, 38), it could react with the guanines outside the TFO binding site.

Conclusion

Polypurine-rich tracts are found throughout the human genome, particularly in the promoter regions of genes. Such tracts are potential target sites for therapeutic or diagnostic TFOs. Frequently, these tracts contain single pyrimidine interruptions. The ability to form stable triplexes with such sites could significantly expand the range of sequences that can be targeted by TFOs. Our results suggest that 2′-*O*-methylribo-TFOs may be particularly useful in targeting sites that have CG interruptions. Further modification with platinum derivatives, compounds that have already been shown to be effective therapeutic agents, could lead to the design of TFOs that are capable of covalent binding to their target, thus increasing the effectiveness of the TFO.



Experimental

Materials

Protected 2′-deoxy- and 2′-*O*-methylribonucleoside-3′-*O*-bis(diisopropylamino)-β-cyanoethylphosphoramidites and 2′-*O*-methyl-5-methyluridine-3′-*O*-bis(diisopropylamino)-β-cyanoethylphosphoramidite were purchased from Glen Research Inc., Sterling, VA. The base-protecting groups were

benzoyl (A,C) or isobutyryl (G). 5′ Nucleoside-derivatized controlled-pore glass supports, 4,5-dicyanoimidazole, 1-*H*-tetrazole or 5-ethylthiotetrazole, Cap Mix A, Cap Mix B, and oxidizing solution were also purchased from Glen Research Inc., Sterling, VA. 2′-*O*-Methyl-5-methyluridine-derivatized CPG was purchased form ChemGenes Corp., Ashland, MA. Phosphoramidite solutions were prepared using synthesis-grade acetonitrile (Fisher Scientific) that was dried and stored over calcium hydride. MALDI-TOF analysis was performed in the AB Mass Spectrometry/Proteomics Facility at The Johns Hopkins School of Medicine, with support from the National Center for Research Resources Shared Instrumentation, Grant 1S10-RR14702.

Synthesis of oligonucleotides

The oligonucleotides, whose sequences are shown in Fig. 1 and Table 1, were synthesized on an ABI DNA synthesizer (model 392 or 3400), using phosphoramidite chemistry and standard automated procedures. The phosphoramidite solutions were made to a concentration of 0.15 mol/L; 5-ethylthiotetrazole was used as the activating agent, and coupling times were 120 s for deoxyribonucleoside phosphoramidites and 450 s for 2′-*O*-methylribonucleoside phosphoramidites. The oligonucleotides were deprotected and removed from their supports by incubating the CPG in a solution containing 300 μL of concentrated ammonium hydroxide and 100 μL of 95% ethanol for 3.5 h at 55 °C. The supernatant from this reaction was evaporated and residue dissolved in 200 μL of 50% aq. acetonitrile. The oligonucleotides were purified by SAX-HPLC on a Dionex DNAPac PA 100-4 × 250 mm column (Dionex Corp., Sunnyvale, CA), using a 30 min linear gradient of 0 to 0.5 mol/L sodium chloride in a solution containing 100 mmol/L Tris, pH 7.8, and 10% acetonitrile at a flow rate of 1.0 mL/min. The oligonucleotide solutions were desalted on either a C-18 SEP PAK cartridge (Waters, Inc, Milford, MA) or a C-18 Clarity Tube (Phenomenex, Inc., Torrance, CA). The concentration of purified oligomers was determined from their UV absorbance at 260 nm, using calculated extinction coefficients based on nearest neighbor approximations (46). The compositions of the oligonucleotides were confirmed by MALDI-TOF mass spectrometry (see Table 1).

Preparation of 2-aminoethyl-modified TFOs

TFOs **1-ae** and **3-ae** were prepared by incubating the CPG support-bound, protected oligonucleotide with a 0.25 mol/L solution of ethylenediamine in dry pyridine for 30 min at room temperature. The CPG was then washed with dry acetonitrile, and the oligomers were deprotected and purified, as described above.

The 5′-(2-aminoethyl)carbamate derivative of **3** was prepared by incubating the detritylated CPG support-bound oligonucleotide with a 500 mmol/L solution of carbonyldiimidazole in dry acetonitrile for 4 h at room temperature. The CPG was washed with dry acetonitrile, dried under vacuum, and then incubated with a solution containing 750 mmol/L ethylenediamine and 350 mmol/L triethylamine in dry acetonitrile. The CPG was washed with dry acetonitrile, and the oligonucleotide was deprotected and purified, as described above.

Preparation of platinum-modified TFOs

Solutions of the platinum compounds were prepared as follows: [Pt(dien)Cl]Cl was prepared according to the method of Roat and Reedijk (47). A 1 mmol/L solution of this compound in water was prepared and stored in the dark at room temperature. A 5 mmol/L solution of *cis*-DDP (Sigma-Aldrich, Inc.) was incubated with 10 mmol/L silver nitrate overnight at 37 °C. The resulting precipitate was centrifuged, and the supernatant containing *cis*-diaminediaquoplatinum(II) dinitrate was stored in the dark at room temperature.

A 10 mmol/L solution of the aminoethyl-modified TFO in 500 μL of water was incubated with 100 μmol/L [Pt(dien)Cl]Cl or 100 μmol/L *cis*-diamminediaquoplatinum(II) dinitrate at 37 °C for 2–6 h. The platinated TFOs were purified by either SAX-HPLC or by HPLC on a 4.6 × 150 mm C-18 reversed-phase column, using a 30 min linear gradient of 0% to 52.5% methanol in 50 mmol/L Tris, pH 8.5, at a flow rate of 1.2 mL/min. The compositions of the platinum-modified TFOs were confirmed by MALDI-TOF mass spectrometry (see Table 1).

Reaction of a DNA triplex with [Pt(dien)Cl]Cl

The 5′-end of oligonucleotide **7** (see Fig. 3) was phosphorylated using polynucleotide kinase and γ-[^{32}P]-ATP, mixed with equivalent amounts of oligonucleotides **5** and **6**, and evaporated to dryness. The residue was dissolved in 28.2 μL of triplex buffer that contained 100 mmol/L 3-(*N*-morpholino)propanesulfonic acid (MOPS), pH 6.5, 100 mmol/L sodium acetate, and 2.5 mmol/L magnesium ac-

etate to a final concentration of 5.6 μmol/L of each strand. The solution was heated at 65 °C for 15 min, cooled slowly to room temperature, and incubated overnight at 4 °C. Aliquots (1.8 μL) of 10 mmol/L [Pt(dien)Cl]Cl or triplex buffer were added, and the solutions were incubated at 4 °C for 24 h. A 1 μL aliquot of each reaction mixture was denatured in 5 μL 90% formamide loading buffer and then electrophoresed on a 20% polyacrylamide gel run under denaturing conditions at 800 V. The gel was autoradiographed at –80 °C.

Thermal denaturation experiments

A solution of **DNA-1** or **DNA-2** and the TFO were prepared in 1 mL of triplex buffer, containing 100 mmol/L MOPS, pH 6.5, 100 mmol/L sodium acetate, and 2.5 mmol/L magnesium acetate such that the final concentration of each strand was 2 μmol/L. Each solution was heated to 90 °C for 10 min, allowed to cool slowly to room temperature, and stored overnight at 4 °C. The absorbance at 260 nm was monitored using a Cary 3E spectrophotometer, fitted with a thermoelectric cell holder at 0.25 °C intervals as the solution was heated from 5 °C to 80 °C at a rate of 0.4 °C/min. The melting temperature was determined by plotting the first derivative of the absorbance vs. temperature profile and is accurate to ±1 °C.

Interactions of TFOs with DNA as monitored by gel electrophoresis

The pyrimidine strand of **DNA-2** was phosphorylated, using polynucleotide kinase and γ-[^{32}P]-labeled ATP at a specific activity of 10 Ci/mmol. This labeled strand (50 pmol) was mixed with 50 pmol of its unlabeled complementary strand, and the solution was evaporated to dryness. The residue was dissolved in 35 μL of triplex buffer; the solution was heated to 90 °C for 10 min, and then slowly cooled to room temperature. Solutions containing 20, 40, or 100 pmol of the TFO were evaporated to dryness; the residues were each dissolved in 3 μL of triplex buffer; 7 μL aliquots of the labeled **DNA-2** were added, and the solutions were incubated overnight at 4 °C. A 2 μL aliquot of 50% glycerol was added to each sample, and the solutions loaded onto a 20% native polyacrylamide gel that was run at 100 V at 4 °C. The gel was dried and imaged using a Typhoon phosphorimager.

Reaction of 3-cPt with DNA-2

[^{32}P]-Labeled **DNA-2** (specific activity 100 Ci/mmol) was prepared as previously described. A solution containing 30 pmol of the labeled duplex was evaporated to dryness, and the residue was dissolved in 30 μL of triplex buffer. The duplex solution was heated to 90 °C for 10 min and cooled slowly to room temperature. Solutions containing 4, 10, or 20 pmol of **3-cPt** were evaporated to dryness; the residue was dissolved in 10 μL of the labeled duplex solution, and the reaction mixture was incubated at 20 °C for 24 or 72 h. Each reaction mixture was quenched with 10 μL of 90% formamide gel loading buffer. These samples were electrophoresed on a 20% denaturing polyacrylamide gel and run at 800 V. The gel was dried and imaged using a Typhoon phosphorimager.

An approach for the synthesis of duplexes containing N^3T-butyl-N^3T interstrand cross-links via a bisphosphoramidite strategy[1]

Christopher James Wilds, Ernest Palus, and Anne Marietta Noronha

Abstract: DNA duplexes containing an interstrand cross-link have been synthesized utilizing a bis-3′-*O*-phosphoramidite deoxythymidine dimer where the N^3 atoms are bridged by a butyl linker. With this approach sufficient quantities of high purity cross-linked duplexes are obtained that will enable various biochemical and structural studies to aid in research directed towards understanding the mechanism of interstrand cross-linked DNA repair. This methodology has advantages over a previously reported method to synthesize cross-linked DNA duplexes involving a monophosphoramidite of the same cross-linked thymidine dimer including circumventing the use of costly 5′-*O*-deoxyphosphoramidites in the assembly of the cross-linked duplex by solid-phase synthesis. This strategy can be employed to produce cross-linked duplexes in which the lesions are engineered to have a directly opposed (**1**–**1**) or staggered (**1**–**2** or **2**–**1**) orientations. Biophysical studies of duplexes containing this N^3T-butyl-N^3T cross-link in staggered **1**–**2** and **2**–**1** orientations reveal that both duplexes have a higher T_m than a non-cross-linked duplex suggesting that these linkages do not result in the destabilization of duplex DNA. Circular dichroism spectra of the **1**–**2** and **2**–**1** cross-linked duplexes exhibit minor differences from B-form structure, which correlates with molecular modeling studies.

Key words: chemically modified oligonucleotides, interstrand cross-link, DNA adduct, DNA repair.

Résumé : Faisant appel à un dimère bis-3-*O*-phosphoramidite de désoxythymidine dans lequel les atomes en N^3 sont attachés par un lien butyle, on a réalisé la synthèse de duplex d'ADN contenant une réticulation entre brins. Avec cette approche, il a été possible d'obtenir des quantités suffisantes de duplex réticulés de grande pureté qui permettront de réaliser diverses études biochimiques et structurales qui aideront dans les études orientées vers la compréhension du mécanisme de réparation de l'ADN réticulée entre les brins. Pour la synthèse de duplex d'ADN réticulés impliquant un monophosphoramidite du même dimère de thymidine réticulée, cette méthodologie présente plusieurs avantages par rapport à une méthode proposée antérieurement, dont celui d'éviter dans l'assemblage du duplex réticulé par la synthèse en phase solide l'utilisation des 5'-*O*-désoxyphosphoramidites de coût élevé. Cette stratégie peut être utilisée pour produire des duplex réticulés dans lesquels les lésions sont construites de façon à présenter des orientations qui soient opposées (**1**–**1**) ou décalées (**1**–**2** ou **2**–**1**). Les études biophysiques des duplex contenant la réticulation N^3T-butyl-N^3T dans les orientations décalées **1**–**2** et **2**–**1** révèlent que ce deux duplex présentent du T_m dont la valeur est supérieure à celle du duplex non réticulé, ce qui suggère que ces liaisons ne résultent pas d'une déstabilisation du duplex de l'ADN. Les spectres de dichroïsme circulaire des duplex réticulés en **1**–**2** et en **2**–**1** présentent des différences mineures par rapport à celui de la structure de forme B, ce qui est en bon accord avec les études de modélisation moléculaire.

Mots-clés : oligonucléotides modifiés chimiquement, réticulation entre les brins, adduit d'ADN, réparation d'ADN.

Introduction

The role that covalent DNA lesions play in cancer chemotherapy needs no introduction. Interstrand cross-links (ICL) exert their therapeutic effect on cancer cells by preventing DNA strand separation and normal mitosis and ultimately lead to apoptosis, thus halting the process of cell proliferation. However, the development of resistance to the effects of antitumor agents is often due to enhanced repair of interstrand cross-links (1–5). Although a number of repair pathways including homologous recombination and nucleotide excision repair have been implicated in cross-link repair in bacteria and mammalian cells (1), an understanding of the molecular mechanisms that are involved is lacking. Since development of resistance is one of the primary reasons for treatment failure, understanding how to alter the signaling of repair enzymes should allow chemotherapeutic agents to effectively stop the spread of cancer cells.

To correlate the structures of ICL and their repair, a number of groups have focused on methods to produce larger

amounts of DNA duplexes containing well-defined lesions or mimics thereof. An attractive approach to produce cross-linked duplexes involves de novo synthesis of cross-linked phosphoramidites and solid-phase synthesis (6–11) over the more traditional route of treating duplex DNA with an excess of bifunctional alkylating agent to produce the ICL (12). The latter method not only suffers from poor yields, but in addition produces numerous monoalkylated and other side products that must be separated from the desired cross-linked product.

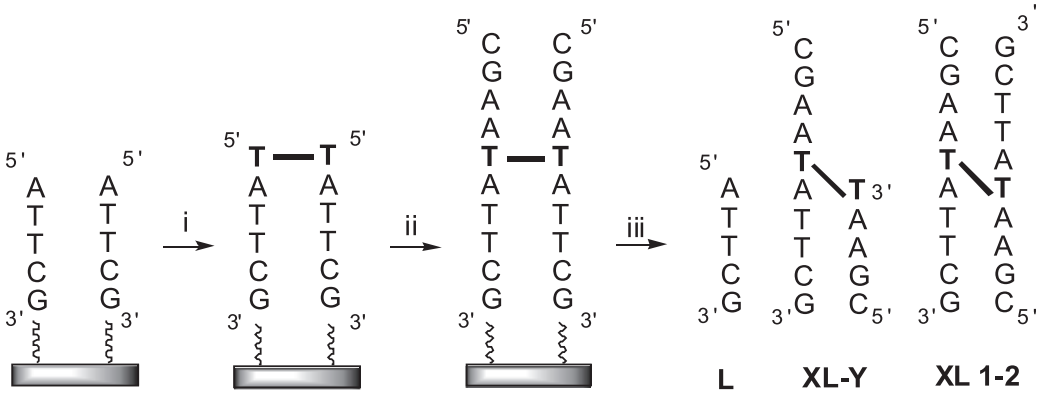
We recently described the synthesis and characterization of short DNA duplexes that contain directly opposed N^3T-alkyl-N^3T interstrand cross-links using a phosphoramidite reagent to introduce them in DNA by solid-phase oligonucleotide synthesis (13). This methodology has allowed the solid-phase syntheses of a number of cross-linked duplexes of well-defined structure that have been engineered to contain an ICL between a mismatched TT base-pair (13). In fact, this particular ICL is of considerable interest because it shares similarities to the interstrand cross-links produced by the reaction of duplex DNA with bifunctional alkylators such as bischloroethylnitrosourea, which forms a N^1G-ethyl-N^3C cross-link in sequences containing GC base pairs (14) or busulfan, which links the N^7 atoms of two deoxyguanosines with a butyl linker in duplex DNA (15).

Although thymine is not the major base alkylated by agents such as dimethylnitrosamine and *N*-methyl-*N*-nitrosourea (16), it is the most photochemically reactive base (17). Exposure to UV radiation in sunlight results in the formation of cis-syn pyrimidine photodimers, a cause of skin cancer (18, 19). Intercalation of psoralen at 5′-d(TA) sites followed by absorption of long wavelength UV irradiation results in [2 + 2] photocycloaddition at the 3,4 or 4′,5′ double bonds of psoralen and the 5,6 double bond of thymidine producing an interstrand cross-link (20, 21).

The use of bisphosphoramidites in oligonucleotide chemistry to produce branched oligonucleotide structures has been well studied and documented by many groups, especially those of Ogilvie and Damha (22–24). As part of our investigation on the synthesis and properties of interstrand cross-linked DNA we have developed a modified synthesis

Scheme 1. Chemical synthesis of bisphosphoramidite **3**.

of this N^3T-butyl-N^3T cross-link via a bisphosphoramidite strategy that allows for the production of larger amounts of material fairly easily. In this report we describe the syntheses of short DNA duplexes that contain N^3T-butyl-N^3T interstrand cross-links and discuss some of their physical properties.



Results

Syntheses and characterization of cross-linked duplexes

The structure of the N^3T-butyl-N^3T interstrand cross-linked adduct and the cross-linked duplexes (**XL 1–2** and **XL 2–1**) are shown in Fig. 1. The cross-linked duplexes (**XL 1–2** and **XL 2–1**) are similar to sequences that contain a N^3T-ethyl-N^3T cross-link, which enables comparison of the effects of a two and four carbon linkage between the *N3* atoms of deoxythymidine in cross-linked DNA (25). The approach to construct these duplexes requires the synthesis of bisphosphoramidite **3** according to the methodology shown in Scheme 1. Starting from 1-{N^3-[5′-*O*-(dimethoxytrityl)-3′-*O*-(*tert*-butyldimethylsilyl)-2′-deoxythymidylyl]}-4-{N^3-[5′-*O*-dimethoxytrityl)-2′-deoxythymidylyl]}butane **1**, the synthesis of which was previously reported, the 3′-*O*-TBDMS group was removed with TBAF to form the symmetrical dimer **2** that was then phosphitylated to produce the cross-linked bisphosphoramidite **3** in good yield. The molecular

Scheme 2. Methodology to construct the cross-linked duplex **XL 1–2** via solid-phase synthesis. (*i*) Coupling of bisphosphoramidite **3**, (*ii*) chain extension with 3′-*O*-deoxyphosphoramidites, and (*iii*) cleavage from the solid support and deprotection using NH_4OH–ethanol (3:1).

weight obtained for this compound was in agreement with the expected value and the ^{31}P NMR spectra contained two peaks at 153.6 and 153.7 ppm, in the region diagnostic of a phosphoramidite.

The solid-phase synthetic strategy used to prepare the cross-linked duplexes is illustrated in Scheme 2 for the sequence **XL 1–2**. All syntheses were carried out on a 1 µmol scale with the first nucleoside attached via the 3′-OH group to a controlled pore glass (CPG) solid support with a loading of 64 µmol/g. Cross-linked duplex assembly begins with commercially available 3′-*O*-deoxyphosphoramidites. The N^3T-butyl-N^3T bisphosphoramidite **3** is coupled simultaneously to the 5′-ends of two oligonucleotide chains attached to the solid support. A chain extension around the 5′ ends of the cross-linked site with 3′-*O*-deoxyphosphoramidites completes the synthesis of the cross-linked duplex. Unlike our previous strategy to synthesize N^3T-alkyl-N^3T interstrand cross-linked DNA duplexes (13, 26), this strategy did not require removal of a TBDMS protecting group at one of the 3′ alcohol functionalities of the N^3T-butyl-N^3T dimer while the cross-linked dimer was still attached to the solid support. This was accomplished by removal of the support from the oligonucleotide synthesizer and treatment with TBAF solution (1 mol/L in THF) for 30 min, before being returned to the oligonucleotide synthesizer for chain extension to complete the synthesis of the cross-linked duplex. The current methodology overcomes problems previously encountered with the removal of the TBDMS group prior to extension of the final arm of the duplex, such as variable efficiency in the desilyation encountered in the synthesis of both N^4T-alkyl-N^4T and N^4C-alkyl-N^4C cross-linked duplexes (13, 27). Lower yields of cross-linked duplexes were observed with longer exposure times to TBAF, presumably due to cleavage of the oligonucleotide from the solid support (28). Another benefit of this methodology is that a lower concentration of bisphosphoramidite **3**, specifically 0.03 mol/L as opposed to 0.15 mol/L, is used in cross-linked oligonucleotide assembly. The lower concentration of bisphosphoramidite **3** in the coupling reaction to the oligonucleotide attached to the solid-support promotes the synthesis of branched molecules, such as the desired cross-linked product and **XL**-**Y** type failure sequences over linear counterparts such as **L** (see Scheme 2). The synthesis of longer cross-linked duplexes should not present any additional limitations to those that are also encountered in the synthesis of linear oligonucleotides. Finally, expensive 5′-*O*-deoxyphosphoramidites are not required for such syntheses, permitting correct polarity within the chains of the duplex but at a reduced cost.

The cross-linked oligomers were cleaved from the solid support and deprotected with a mixture of concentrated ammonium hydroxide – ethanol (3:1) at 55 °C for 4 h and analyzed by both strong anion exchange (SAX) HPLC and polyacrylamide gel electrophoresis (PAGE). The analysis of the crude and purified products for the synthesis of **XL 1–2** via PAGE is shown in Fig. 2. The crude deprotection products are shown in lane 2 with two major products visible having mobilities similar to a 16- and 20-mer. Purification of the cross-linked duplexes were performed by SAX HPLC using a sodium chloride gradient (0–0.5 mol/L) over 30 min in a buffer that contained 100 mmol/L Tris-HCl and 10% acetonitrile. The major side product in these syntheses was the deprotected form of **XL**-**Y**, which resulted from the coupling of only one phosphoramidite moiety to a linear CPG bound oligomer. The nucleoside composition of this side product was confirmed by nuclease digest followed by reversed-phase HPLC analysis. This is formed in favor over the linear uncoupled sequence (Scheme 2, designated **L**). The duplexes **XL 1–2** and **XL 2–1**, whose retention times are shown in Table 1, eluted as single peaks and were obtained in approximately 15% yield after desalting, compared with less than 10% by previously reported methods (13).

Duplexes **XL 1–2** and **XL 2–1** were digested with a combination of snake venom phosphodiesterase and calf intestinal phosphatase and analyzed by C-18 reversed phase HPLC. As shown in Table 1, each duplex was hydrolyzed to its component deoxynucleosides and the N^3T-butyl-N^3T dimer in ratios consistent with the composition of each particular duplex. In addition to this characterization, each duplex was analysed by MALDI TOF mass spectrometry. As shown in Table 1, the experimentally determined molecular weights were in agreement with calculated values.

Thermal denaturation (T_m) and circular dichroism (CD) studies

Results of UV thermal denaturation (T_m) experiments are shown in Fig. 3. Both duplexes **XL 1–2** and **XL 2–1** exhibit

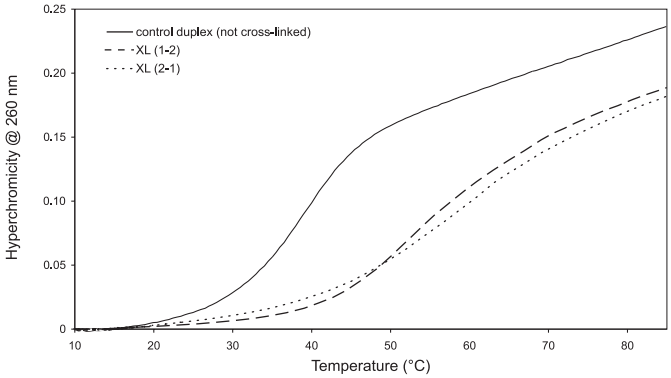

Fig. 2. Polyacrylamide gel electrophoresis (20%, PAGE) analysis of cross-linked duplex **XL 1–2**. (Lane 1) Control 10mer, (lane 2) crude cross-linked duplex **XL 1–2**, and (lane 3) SAX HPLC purified **XL 1–2**.

a sigmoidal denaturation profile with T_m values of 53 and 55 °C, respectively. In comparison, the non-cross-linked control duplex (5′-dCGAAATTTCG)$_2$ gave a T_m of 37 °C.

The circular dichroism (CD) spectra of these duplexes are shown in Fig. 4. All three duplexes exhibit features typical of a B-form duplex. In the case of cross-linked duplex **XL 2–1** the peaks have a higher amplitude, a characteristic of DNA duplex that contain uninterrupted AT-rich tracts that have increased intrastrand base stacking (19). Molecular models that have been geometry-optimized using an Amber force field for the **XL 1–2** and **XL 2–1** cross-linked duplexes, as well as their non-cross-linked counterparts, suggest that when the cross-link is in the **1–2** orientation there is a greater distortion induced in the duplex than in the **2–1** orientation (Fig. 5*b* and 5*d*). Molecular models generated using an Amber force field for non-cross-linked B-form duplexes have a distance of 2.9 Å between the *N3* atom of deoxythymidine and the N1 atom of deoxyadenosine when

Fig. 3. Hyperchromicity (A_{260}) vs. temperature profiles of non-cross-linked control duplex (5′-dCGAAATTTCG)$_2$ (solid line), cross-linked duplexes **XL 1–2** (broken line), and **XL 2–1** (dotted line). Solutions contained cross-linked duplex (2 μmol/L) and control duplexes (2.25 μmol/L) in sodium chloride (90 mmol/L), sodium phosphate (10 mmol/L), and ethylenediaminetetraacetate buffer (1 mmol/L) at pH 7.0 were heated at 0.5 °C/min.

base-paired. For the **XL 1–2** and **XL 2–1** cross-linked duplexes this distance increases to 4.1 and 4.2 Å, respectively. The distance in B-form DNA between the O4 atom of deoxythymidine and the N6 atom of deoxyadenosine is 2.9 Å. For the **XL 1–2** and **XL 2–1** cross-linked duplexes this distance increases to 5.4 and 3.0 Å, respectively, suggesting that in the latter case the two atoms are close enough to form a hydrogen bond. The cross-linked site of each AT base pair for the **XL 1–2** cross-link has the adenine bases displaced vertically along the helical axis. For the **XL 2–1** duplexes, the adenine bases exhibit some twist.

These results illustrate some differences from studies of cross-linked oligonucleotides containing a N^3T-ethyl-N^3T cross-link in **1–2** and **2–1** orientations. Both ethyl cross-linked duplexes were stabilized relative to the non-cross-linked duplex, however the **2–1** duplex was more stable by 24 °C, compared with 6 °C for the **1–2** duplex. The **2–1** and **1–2** N^3T-butyl-N^3T duplexes were both significantly stabilized relative to the non-cross-linked control by 18 and 16 °C, respectively. Although neither NMR or X-ray struc-

[a]Experiments were carried out in buffer containing sodium chloride (90 mmol/L), sodium phosphate (10 mmol/L), and ethylenediaminetetraacetate buffer (1 mmol/L) at pH 7.0. The concentration of each duplex was ~2.25 μmol/L.

Fig. 4. Circular dichroism spectra of non-cross-linked control duplex (5′-dCGAAATTTCG)$_2$ (solid line), cross-linked duplexes **XL 1–2** (broken line), and **XL 2–1** (dotted line). Solutions contained cross-linked duplexes (2 μmol/L) and control duplex (2.25 μmol/L) in sodium chloride (90 mmol/L), sodium phosphate (10 mmol/L), and ethylenediaminetetraacetate buffer (1 mmol/L) at pH 7.0. Spectra were recorded at 10 °C.

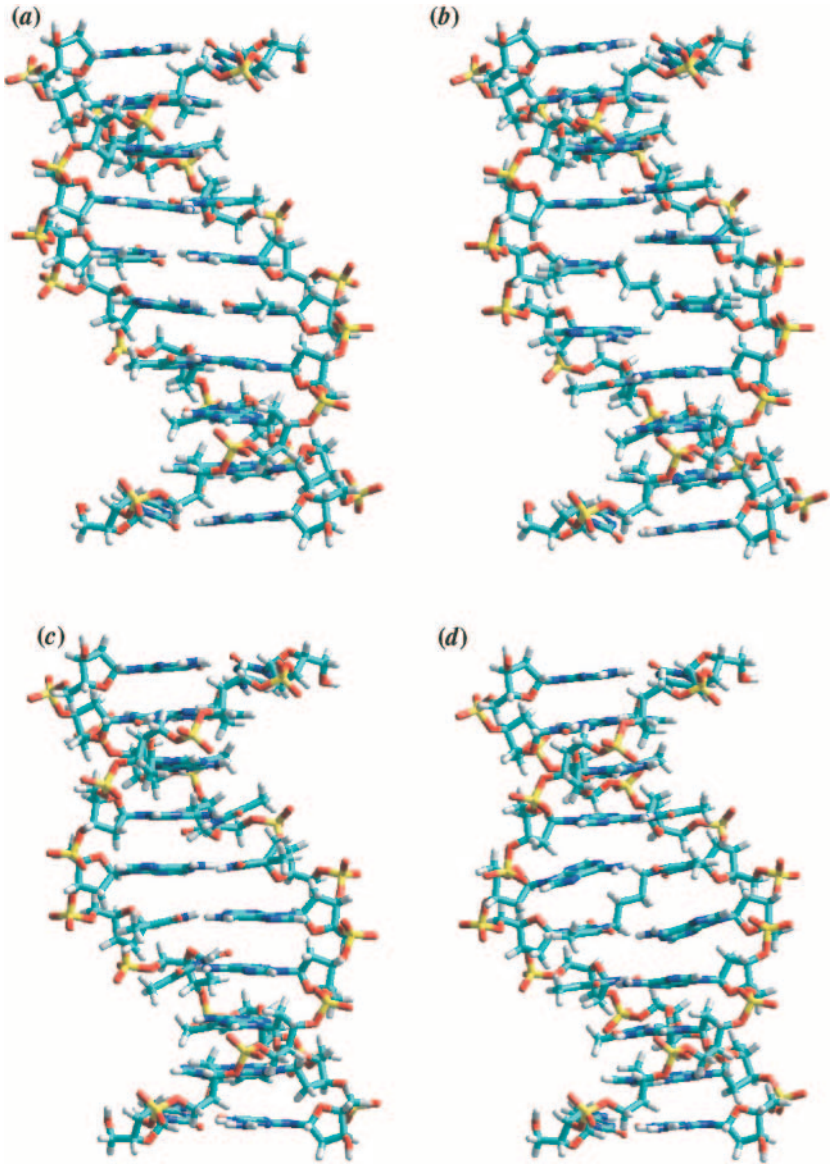
tures are available for the **1–2** or **2–1** cross-links, the solution structure of an undecamer containing a mispair aligned N^3T-ethyl-N^3T interstrand cross-link suggest that it is well-accomodated between the minor and major grooves, maintaining interstrand stacking with flanking bases (30). In the case of mispair-aligned N^3T-butyl-N^3T undecamers, the solution structure showed a dramatic widening of the major groove and large propeller twisting for the mispair (31). Duplexes containing the N^3T-ethyl-N^3T cross-link in both **1–2** and **2–1** orientations with complementary 3′-overhanging ends were synthesized and their ability to undergo self-ligation with T4 DNA ligase was investigated (25). The **2–1** cross-linked N^3T-ethyl-N^3T duplex underwent rapid self-ligation, whereas no multimeric products were observed for the duplex **1–2** under identical conditions suggesting some structural deformation preventing multimerization of the **1–2** sequence. The similar thermal stability of both **XL 1–2** and **XL 2–1** N^3T-butyl-N^3T sequences, as opposed to the differing stability of the N^3T-ethyl-N^3T cross-links, may be due to the additional flexibility of the butyl vs. ethyl linkage between the bases allowing the former to be better accommodated into a B-form duplex in either orientation.

This current study provides a simplified means for the production of N^3T-alkyl-N^3T interstrand cross-links that may be synthesized with either **1–1**, **1–2**, or **2–1** staggered orientations. The differing properties of these cross-linked duplexes provides a means to synthesize molecules that cause differing levels of distortions within DNA that should allow for progress in the elucidation of repair pathways of interstrand cross-linked DNA.

Experimental section

General

Compound **1**, namely 1-{N^3-[5′-O-(dimethoxytrityl)-3′-*O*-(tert-butyldimethylsilyl)-2′-deoxythymidylyl]}-4-{N^3-[5′-*O*-(dimethoxytrityl)-2′-deoxythymidylyl]}butane was prepared as previously described (13). 5′-*O*-Dimethoxytrityldeoxyribonucleoside-3′-*O*-(β-cyanoethyl-*N*,*N*′-diisopropyl) phosphoramidites and protected deoxyribonucleoside-controlled pore glass (CPG) supports were purchased from Proligo, Inc. (Boulder, Colorado). All solid phase oligonucleotide syntheses were carried out with 500 Å pore size controlled pore glass solid support with a nucleoside loading of 64 μmol/g. All other chemicals and solvents were purchased from Sigma-Aldrich Chemical Company (Milwaukee, Wisconsin) and used as is. Strong anion exchange (SAX) HPLC was carried out using a Dionex DNA PAC PA-100 column (0.4 cm × 25 cm) purchased from Dionex Corp. (Sunnyvale, California) on a Waters Breeze HPLC system. Reversed phase HPLC was carried out using a Symmetry C-18 5 μm column (0.46 cm × 15 cm) purchased from Waters Inc. (Milford, Massachusetts). The columns were monitored at 260 nm for analytical runs or 290 nm for preparative runs. Denaturing polyacrylamide gel electrophoresis was carried out on 20 cm × 20 cm × 0.75 cm gels containing 20% acrylamide and 7 mol/L urea in TBE (89 mmol/L Tris, 89 mmol/L boric acid, and 0.2 mmol/L ethylenediaminetetraacetate buffered at pH 8.0). The running buffer was TBE. Oligonucleotides were detected by UV shadowing. MALDI-TOF mass spectra for oligonucleotides were conducted at the Johns Hopkins University Mass Spectrometry Facility using a Voyager DE-STR MALDI-TOF instrument. ESI mass spectra for small molecules were collected at the Department of Chemistry at McGill University using a Kratos MS25RFA mass spectrometer. NMR spectra of nucleosides were collected using a Varian INOVA 300 MHz NMR spectrometer.



Chemical synthesis

1-{N^3-[5′-O-(Dimethoxytrityl)-2′-deoxythymidylyl]}-4-{N^3-[5′-O-(dimethoxytrityl)-2′-deoxy thymidylyl]} butane 2

To a stirred solution of nucleoside **1** (250 mg, 0.198 mmol) in tetrahydrofuran (1 mL) was added tetrabutylammonium fluoride (1 mol/L in THF, 0.219 mL, 0.219 mmol). The reaction was allowed to proceed at room temperature (RT) for 30 min. The solvent was removed in vacuo. The crude was taken up in dichloromethane (25 mL), extracted twice with sodium bicarbonate (3%, 25 mL), then dried over sodium sulfate. The crude was filtered, evaporated to dryness, and purified by flash column chromatography using a 4:1 ethyl acetate – hexanes solvent system to yield compound **2** as a colorless foam (215 mg, 95.2%). R_f (SiO_2) 0.175 (hexanes – ethyl acetate, 1:4). ^{1}H NMR (300 MHz, d_6-DMSO, ppm) δ: 1.50–1.54 (10H, -CH_2-CH_2- and C5-CH_3),

2.19–2.37 (4 H, H2′ and H2″), 3.20–3.32 (4H, H5′ and H5″), 3.78 (12H, -OCH_3), 3.80–3.87 (4H, -CH_2-N^3-), 3.94–3.97 (2H, H4′), 4.34–4.41 (2H, H3′), 6.29 (2H, H1′), 6.92–7.45 (26 H, DMT), 7.62 (2H, H6). ESI-MS calcd.: 1142.5 [M + Na^+]; found: 1165.3.

1-{N^3-[5′-O-(Dimethoxytrityl)-3′-O-(β-cyanoethyl-N,N′-diisopropyl)phosphoramidite]}-2′-deoxythymidylyl]}-4-{N^3-[5′-O-(dimethoxytrityl)-2′-deoxythymidylyl-3′-O-(β-cyanoethyl-N,N′-diisopropyl)phosphoramidite]}butane 3

To a stirred solution of nucleoside **2** (200 mg, 0.175 mmol) in THF (0.8 mL) was added diisopropylethylamine (0.080 mg, 0.61 mmol) followed by *N*,*N*-diisopropylamino cyanoethyl phosphonamidic chloride (196 uL, 0.52 mmol). The reaction was stirred at RT for 2 h. Upon completion, the reaction was quenched by the addition of dichloromethane (25 mL) and the solution was extracted with sodium bicarbonate (3%, 25 mL). The organic layer was dried over sodium sulfate, filtered, and evaporated. The product, a colorless powder, was precipitated from hexanes (0.220 g, 81.5%). R_f (SiO_2) 0.76 (hexanes – ethyl acetate, 1:4). ^{31}P NMR (161.8 MHz, d_6-acetone, ppm) δ: 153.6, 153.7. ESI-MS calcd.: 1542.7 [M + Na^+]; found: 1565.2.

Oligonucleotide synthesis and purification

The cross-linked duplexes, whose sequences are shown in Fig. 1, were assembled using an Applied Biosystems Model 3400 synthesizer according to standard cyanoethyl-phosphoramidite chemistry protocols (6). Long chain alkylamine controlled pore glass (LCAA-CPG) was used as the solid support. The nucleoside phosphoramidites were diluted in anhydrous acetonitrile at a concentration of 0.15 mol/L for the 3′-phosphoramidites or 0.03 mol/L for the cross-linked bisphosphoramidite **3**. Assembly of the se-

© 2007 NRC Canada

quences was carried out as follows: (*a*) detritylation with 3% trichloroacetic acid in dichloromethane; (*b*) nucleoside phosphoramidite coupling time of 2 min for commercial phosphoramidites and 30 min for the cross-linked bisphosphoramidite; (*c*) capping with 1:1 *v*/*v* of acetic anhydride–2,6,lutidine–tetrahydrofuran 1:1:8 (*v*/*v*/*v*, solution A) and 1-methyl-1-*H*-imidazole–tetrahydrofuran 16:84 (*w*/*v*, solution B); (*d*) oxidation with 0.02 mol/L iodine in tetrahydrofuran–water–pyridine, 2.5:2:1. The 5′-terminal trityl groups were removed on the synthesizer. The oligomer-derivatized CPG was transferred from the reaction column to screw-capped microfuge tubes fitted with teflon lined caps and the protecting groups were removed by treatment with 1 mL of concentrated ammonium hydroxide – ethanol (3:1) for 4 h at 55 °C. The cross-linked duplexes were purified by SAX HPLC with a 30 mL linear gradient of sodium chloride in a buffer that contained 100 mmol/L Tris (pH 7.8) in 10% acetonitrile at a flow rate of 1.0 mL/min. The purified oligomers were then desalted using C-18 SEP PAK cartridges (Waters Inc.) as previously described (13).

Nuclease digestion and MALDI-TOF mass spectrometry

The cross-linked oligomers (0.2 A_{260} unit) were characterized by digestion with a combination of snake venom phosphodiesterase (0.28 unit) and calf intestinal phosphatase (5 units) in a buffer containing Tris (pH 8.1, 10 mmol/L) and magnesium chloride (2 mmol/L) as previously described (13). The resulting mixture of nucleosides was analyzed by reversed phase HPLC and the ratio of nucleosides determined. The results are given in Table 1. The molecular weights of each cross-linked oligomer were determined by MALDI-TOF mass spectrometry using an Applied Biosystems Voyager DE-STR and the results are shown in Table 1.

UV thermal denaturation studies

Molar extinction coefficients for the oligonucleotides and cross-linked duplexes were calculated from those of the mononucleotides and dinucleotides according to nearest-neighbour approximations (units = 10^4 $(mol/L\ cm)^{-1}$) (7). Non-cross-linked duplexes were prepared by mixing equimolar amounts of the interacting strands and lyophilizing the resulting mixture to dryness. The resulting pellet was then redissolved in sodium chloride (90 mmol/L), sodium phosphate (10 mmol/L), and EDTA buffer (1 mmol/L) at pH 7.0, to give a final concentration of 2.25 μmol/L in each strand. The cross-linked duplexes were dissolved in 1 mL of the described buffer to give a final concentration of 2 μmol/L. The solutions were then heated to 80 °C for 15 min on a sand bath, cooled slowly to RT, and stored at 4 °C overnight before measurements. Prior to the thermal run, samples were degassed by placing them in a Speed Vac concentrator for 2 min. Denaturation curves were acquired at 260 nm at a rate of heating of 0.5 °C/min. using a Varian CARY 300 spectrophotometer fitted with a 12-sample thermostated cell block and a temperature controller. The data were analysed in accordance with the convention of Puglisi and Tinoco and transferred to Microsoft Excel for analysis.

Circular dichroism (CD) spectroscopy

Circular dichroism spectra were obtained on a Jasco J-700 spectropolarimeter equipped with a NESLAB RTE-111 circulating bath. Samples were allowed to equilibrate for 5–10 min at 5 °C in sodium chloride (90 mmol/L), sodium phosphate (10 mmol/L), and EDTA (1 mmol/L) at pH 7.0 to a final concentration of 2 μmol/L in each strand for the cross-linked duplexes and 2.25 μmol/L for the control duplex. Each spectrum was an average of 5 scans. Spectra were collected at a rate of 100 nm/min with a bandwidth of 1 nm and sampling wavelength of 0.2 nm using fused quartz cells (Hellma, 165-QS). The CD spectra were recorded from 350 to 200 nm at 10 °C. The molar ellipticity was calculated from the equation $[\theta] = \theta/Cl$, where θ is the relative ellipticity (mdeg), C is the molar concentration of oligonucleotides (moles/L), and l is the path length of the cell (cm). The data were processed on a PC computer using Windows™-based software supplied by the manufacturer (Jasco, Inc.) and transferred into Microsoft Excel for presentation.

Molecular modeling studies

Molecular models of 10-bp duplexes (5′-dCGAATATTCG)$_2$ and (d-CGAAATTTCG)$_2$ as well as duplexes containing a N^3T-butyl-N^3T interstrand cross-link linking deoxythymidine at the underlined sites (d-CGAA$\underline{T}$ATTCG)$_2$ (**XL 1–2**) and (d-CGAAA$\underline{T}$TTCG)$_2$ (**XL 2–1**) were built using HyperChem molecular modeling software. All duplexes were geometry-optimized using the AMBER forcefield.

Commercialization of automated RNA synthesis — Twenty years on[1]

Gerald Zon

Abstract: Following the introduction of the first successful automated DNA synthesizer by Applied Biosystems Inc. (ABI) in 1983, the company was in a position to consider the commercialization of additional chemistries to enable the automated synthesis of RNA oligonucleotides or other analogs. This retrospective account provides a personal view of how ABI collaborated with Professor Kelvin K. Ogilvie in 1986 to commercialize automated RNA synthesis, using the 2′-*O*-alkylsilyl-protected monomers that he pioneered. The influence of end-user scientific applications on this decision-making process is highlighted, together with the influence of such applications on subsequent commoditization of RNA. Hopefully, these perspectives will provide chemists with further appreciation of the sometime complex and unpredictable interplay between academically interesting chemistry and evolving scientific applications that influence commercialization, and vice versa.

Key words: RNA, synthesis, automated, 2′-*O*-alkylsilyl phosphoramidite, siRNA.

Résumé : À la suite de l'introduction avec succès du premier appareil de synthèse automatique de l'ADN par Applied Biosystems Inc, (ABI), en 1983, la compagnie était en excellente position pour faire la commercialisation des méthodes chimiques additionnelles nécessaires aux synthèses automatiques d'oligonucléotides de l'ARN et d'autres analogues. Cette revue rétrospective fournit une vue personnelle de la façon dont ABI a collaboré avec le professeur Kelvin K. Ogilvie en 1986 pour commercialiser des synthèses automatiques d'ARN à l'aide des monomères protégés par les groupes 2′-*O*-alkylsilyles qu'il avait développé. On met en évidence l'influence des applications scientifiques des usagers sur cette décision ainsi que l'influence de telles applications sur la commercialisation subséquente d'ARN. Il est à espérer que ces perspectives permettront aux chimistes de mieux comprendre les relations souvent complexes et imprévisibles entre de la chimie académiquement intéressante et les applications scientifiques en évolution qui influencent la commercialisation et vice versa.

Mots-clés : ARN, synthèse, automation, 2′-*O*-alkylsilyle phosphoramidite, siARN.

[Traduit par la Rédaction]

Introduction

After the long trip from Applied Biosystems Inc. (ABI) in Foster City, California, to Montréal, Quebec, my business colleague, Elaine Heron, and I were quite tired and glad to check-in to our hotel near McGill University late one night in November 1986. Just that week, I had moved from the National Institutes of Health (NIH) to join ABI, a fledgling biotechnology company, and so the excitement of meeting Professor Kelvin K. Ogilvie the next morning to discuss the possibility of commercializing automated RNA synthesis kept me awake. I had read Ogilvie's papers on the use of 2′-*O*-alkylsilyl nucleoside monomers for automated RNA assembly and looked forward to meeting him and discussing the use of these reagents with ABI's DNA synthesizer, an instrument that had been successfully introduced three years earlier. The context of this eventual milestone in the commercialization of RNA synthesis is the subject of this personalized account. The intent is to provide chemists with insights on how corporate "biotechnology tool" providers such as ABI must find a balance between introducing interesting new chemistry per se and supporting their customer's scientific applications. Many businesses seek the so-called "killer applications" for products, i.e., applications that are widely pursued by many customers. In the early 1980s, following the dawn of recombinant DNA techniques and molecular genetics, killer applications, such as DNA hybridization probes and DNA sequencing primers, were clearly evident. However, in 1986, the circumstances were quite different for synthetic RNA. Although there were a few biophysical or biochemical studies that needed synthetic RNA, there was no widely recognized killer application. ABI's inclination to commercialize automated RNA synthesis at that time was, therefore, predicated on the hope that scientists would find a killer application for synthetic RNA, if enabling technology was made available, hopefully sooner rather than later to avoid carrying an unprofitable product line. Although, important new uses for synthetic RNA, such as synthetic ribozymes and RNA aptamers, eventually did evolve, this did not occur until many years later. The hoped-

 doi:10.1139/V07-005 © 2007 NRC Canada

for killer application did not occur until relatively recently with the advent of RNA interference (RNAi) methodology, a discovery for which Andrew Z. Fire and Craig C. Mello were awarded the Nobel Prize in Physiology or Medicine in 2006. During the ensuing 20 years, various improvements in automated RNA synthesis yield, scale, and throughput have been reported by scientists and engineers at ABI, and elsewhere, some of whom are contributors to, or cited in this Special Issue to honor Professor Ogilvie. What follows is a brief retrospective on the beginnings of commercial automated synthesis of RNA.

The DNA prelude to RNA

During 1981, there were a number of independent circumstances that would ultimately converge some seven years later and lead to the commercialization of automated RNA synthesis by ABI in 1988. From a personal perspective, in 1981, I was using Vega Biotechnologies Inc. (VBI) peptide-synthesis equipment at NIH to manually synthesize a pool of mixed-base oligodeoxynucleotides by the phosphotriester method for use as degenerate hybridization probes by my colleagues. The months it took to make and purify just this one pool of probes was quite discouraging. It was, therefore, with real interest that I read Ogilvie's 1981 article in *Science* (1) entitled "Automated Synthesis of Gene Fragments", wherein a 14-mer was made in just 6.5 h! In addition to this stunning automation of DNA synthesis, I was quite familiar with trivalent organophosphorus chemistry and thought that the described use of methylchlorophosphite monomers offered not only the efficiencies that were described but also provided chemical flexibility for modified internucleotide linkages. Moreover, successful extension to RNA was indicated by the last sentence of this publication (1) that referred to a manuscript in preparation demonstrating that "this basic procedure also applies to the synthesis of RNA sequences". The co-authors of this publication (1) were at Bio Logicals Inc. (BLI), a Canadian company in Toronto. Detailed descriptions by Bender and Ogilvie of automated solid-phase synthesis of DNA and RNA, using blocked phosphodichloridites such as $MeOPCl_2$, were also published in 1981 in a patent application by BLI (2). In this methodology, the synthesis of RNA took advantage of extensive earlier work by Ogilvie and co-workers (3) on nucleoside monomers having 2′-blocking groups such as the *tert*-butyldimethylsilyl group. However, the initial focus was on DNA synthesis, as evident in a January 23, 1981 *New York Times* article (4), which reported that genes could be made by machine. A rapid, automated assembly of DNA had been demonstrated the previous day at the Chemists' Club in New York city by scientists from BLI and Ogilvie, who was a member of the firm's scientific advisory board.

Two other significant events, relating to DNA and RNA synthesis, also occurred during 1981. The first was the publication of a patent application (5), describing the work by Caruthers and Matteucci on inorganic (e.g., silica) solid-phase synthesis of DNA or RNA that featured the coupling of protected nucleoside 3′-methylphosphomonotetrazolide that was made in situ from the corresponding monochlorodite. Secondly, Beaucage and Caruthers (6) published a communication, describing deoxynucleoside 3′-phosphoramidites as a new class of key intermediates for DNA synthesis. The phosphoramidites had great utility because they were sufficiently stable for easy handling and prolonged storage, yet they were precursors for the virtually instantaneous and in situ generation of reactive phosphotetrazolides within a flow-through column of solid support. Consequently, it was possible to bypass the great instability of both phosphochloridites and phosphotetrazolides when in solution. 1981 was also the year in which ABI began operation. ABI started as a company that intended to commercialize protein sequencers, DNA synthesizers, and other automated systems, as the "picks and shovels for the biotechnology gold rush", to quote Sam Eletr, co-founder and first CEO. The first protein sequencers that were introduced later that year featured proprietary "zero-dead-volume" valves. Two years later, these same valves would also be beneficially utilized in ABI's DNA synthesizer to minimize wasted reagents and solvents, and thus offer more favorable economics. In 1983, the immediate goal was to use phosphoramidite chemistry to provide a fast and reliable "push button" DNA synthesis system. ABI's initial business strategy was to meet the great demand for synthetic DNA, for use as hybridization probes and sequencing primers, in recombinant DNA technology and academic research. This meant focusing ABI's resources on introducing a synthesizer that would initially provide DNA, but would still be compatible with future reagents for synthesizing other types of oligonucleotides, such as RNA or other modifications. However, as indicated later in this article, several scientifically driven market factors arose and needed to be evaluated. This caused ABI to focus on the automated synthesis of DNA-based oligonucleotide analogs before proceeding with RNA synthesis.

Chemistry options and applications

Although a number of companies, such as ABI, Beckman, Biosearch, BLI, Systec, and VBI, were offering automated systems for the synthesis of DNA in 1982–1983 (7), commercialization of automated RNA synthesis remained on the horizon. Instead, much attention was focused on improving the efficiency of DNA synthesis. For example, Adams and co-workers at Monsanto (8) reported outstanding results for the manual synthesis of a 51-mer, using sterically hindered (e.g., *N,N*-diisopropyl-)3′-phosphoramidites (6), in conjunction with a long-chain linker to controlled-pore glass vs. silica (5), and detritylation with protic acids vs. $ZnBr_2$ (5), and these modifications were soon being evaluated for automated synthesis. In addition, there were several issues related to coupling performance and controversial DNA quality, user preferences (e.g., faster time-to-DNA and "no thiophenol!"), and the question of whether to use *O*-methyl (6, 9, 10) or *O*-(β-cyanoethyl) (11) phosphate protection to settle. While these and other chemistry and engineering issues were being addressed at ABI to define and introduce its initial automated DNA synthesizer, the company was also contemplating what the next-generation chemistry would be. One potentially large market opportunity was the synthesis of sequence-specific inhibitors of gene expression. At ABI, the methylphosphonate (P–Me) class of DNA analogs, originally envisioned by Ts'o and Miller at The Johns Hopkins

© 2007 NRC Canada

University, was pursued by William Efcavitch, who prepared methylphosphonamidites for solid-phase synthesis. I agreed with this view of P–Me analogs and was keen on extending the scope of phosphoramidite chemistry to produce oligonucleotide analogs with modified phosphotriester (RO–P) or phosphorothioate (P–S) internucleotide linkages. These novel compounds would be more resistant to enzymatic degradation and suitable for use in antisense applications. Providing these novel chemistries and a larger-scale instrumentation for their synthesis thus became a large part of ABI's commercialization interests during 1983–1986. Finally, hydrogen phosphonate (H–phos) chemistry (12) for the synthesis of DNA or RNA (12*a*), and P–S or other analogs (12*b*), had to be carefully evaluated in view of the possibility that this alternative chain-assembly chemistry might provide significant advantages over phosphoramidite chemistry. The potential advantages of H–phos synthesis were widely touted by many leading nucleic acid chemists, who were contacted by ABI in 1986. However, such advantages did not materialize in extensive work at ABI or elsewhere. ABI, therefore, discounted H–phos chemistry, as a commercially viable, generally applicable alternative for chain-assembly, and focused attention on the use of phosphoramidite methodology for DNA and RNA synthesis.

While automated DNA synthesis was maturing, Ogilvie and his McGill group continued to refine their RNA synthesis protocols. Ogilvie's published work in this period indicated the benefits of transitioning from the initial phosphochloridite approach (13) to the adoption of *N,N*-diisopropyl phosphoramidite reagents (8–10). The sometimes controversial issue about potential 2′–3′ linkage rearrangement, using 2′-*O*-alkylsilyl vs. 2′-*O*-tetrahydropyranyl protection, and trade-offs regarding compatibility or not of these groups, respectively, during acid-catalyzed deprotection of the 5′-*O*-di(or mono)methoxytrityl moiety (11, 14), was also being resolved in favour of the 2′-*O*-alkylsilyl protecting groups.

A decision by ABI to launch automated RNA synthesis with 2′-alkylsilyl monomers

With all of the previously mentioned background information, our meeting with Ogilvie in November 1986 was aimed at the technical evaluation of the current status of RNA synthesis in his laboratory as a basis for possible commercialization by ABI. During the course of the discussion, I was pleasantly surprised and truly impressed by the progress that had been made by Richard T. Pon, who had recently finished his graduate studies, and by Nassim Usman and Masad J. Damha, who were in the midst of their graduate work. All of the major chemistry issues, particularly hypothetical linkage rearrangement, were discussed in detail and fully addressed. Moreover, Ogilvie shared with us his intent to synthesize, sequence, and functionally characterize a relatively long tRNA analog. We indicated the importance of this goal to ABI from the standpoint of providing the scientific community with compelling data for the quality of synthetic RNA. ABI had previously used analogous DNA-cloning and -sequencing results to ensure customers of the high quality of the synthetic DNA and address concerns of a few, who were skeptical of the quality of DNA that could be made so easily. By the end of the day, Elaine Heron and I were prepared to support a collaboration aimed at demonstrating that Ogilvie's monomers for RNA synthesis would be successful. That confidence was predicated in large part on our seeing Ogilvie's promising preliminary results, obtained with 2′-*O*-alkylsilyl-protected phosphoramidites using a BLI synthesizer, as were subsequently reported (14). We provided an ABI DNA synthesizer for his continuation of that work and to transition his chemistry to the widely used ABI instrument platform. This investment was a relatively low-risk proposition, given the progress already demonstrated, and subsequent work with this system led to the desired result: a landmark publication by Ogilvie and co-workers (15) in 1988 describing the synthesis, sequencing, and functional activity of a 77-mer $tRNA^{fmet}$ analog, prepared using 2′-*O*-alkylsilyl RNA phosphoramidites.

That year, ABI introduced automated RNA synthesis to its extensive base of DNA synthesis customers with the release of detailed protocols prepared by Alex Andrus (*ABI User Bulletin*, No. 47. April 18, 1988). At that time, 2′-*O*-alkylsilyl *N,N*-diisopropyl phosphoramidite monomers and solid supports were available from Peninsula Laboratories Inc. in Belmont, California, where they were commercialized by one of Ogilvie's former students, Taifeng Wu. As described elsewhere (16), follow-up work by ABI scientists and collaborators included the introduction of base-labile groups for fast deprotection of nucleobases, a reagent and protocol for improved desilylation, synthesis scale-up, use of polystyrene as a solid support, and the introduction of a new reagent for sulfurization that could be applied to RNA.

Postscript

Following these beginnings of commercial RNA synthesis, other academic and corporate researchers have continued to make significant contributions to the field. Particularly, noteworthy developments include the new 2′-*O*-triisopropylsilyloxymethyl (TOM) (17) and 2′-*O*-bis(2-acetoxyethoxy)methyl (ACE) (18) protecting groups, which have become well established. Other new 2′-protecting groups are also being developed, e.g., 2′-*O*-(*t*-butyl)dithiomethyl (DTM) (19), but their long-term popularity remains to be determined. On the other hand, RNA synthesis using Ogilvie's original 2′-*O*-*t*-butyldimethylsilyl protection is still widely employed by commercial suppliers (20) even though over 20 years have lapsed since its first use with phosphoramidite chemistry.

While these kinds of chemistry improvements were not surprising, it is probably true that very few, if any, persons anticipated two major changes related to automated RNA synthesis that were driven from the perspective of scientific applications, i.e., customer demand. First was the transition of customers from "make RNA" to "buy RNA", which also applied to DNA, and represents true commoditization of RNA and DNA. That shift, from customers making their own RNA or DNA to buying it from a commercial supplier or core lab, was enabled by the evolution of a service industry that used largely ABI, and eventually other, synthesizers to make and sell RNA or DNA to thousands of customers worldwide, on a daily basis, for a myriad of uses. Many types of biological applications in this marketplace require

© 2007 NRC Canada

only relatively small quantities of each sequence but need large numbers of different sequences relatively quickly and at a relatively low price. These requirements have been enabled by the development of small-scale, high-throughput synthesizers such as the MerMade-384 that can produce RNA or DNA in four 96-well plates (see www.Bioautomation.com). The second unanticipated change was the advent of RNAi methodology, which uses synthetic short-interfering RNA (siRNA) to very efficiently silence gene expression. This technology has provided the long-awaited killer application for RNA synthesis, and very large numbers of synthetic RNAs are now routinely produced. This widespread usage of synthetic siRNA is evidenced by 3261 citations in *Chem. Abstr.*, indexed to the search term siRNA, during the year 2005, of which 576 were also indexed to the search terms synthesis or synthetic. Remarkably, 157 (27%) of these reports are patents. The relatively huge demand for synthetic siRNA in RNAi applications has provided a compelling economic incentive for academic or corporate chemists to continue to develop faster, better, and cheaper methods for the preparation of siRNA, and chemically modified analogs thereof, for basic and applied research. One market survey estimated that in 2006 ~15 000 research labs would have performed RNAi studies with synthetic siRNA, having a market value of ~$100 million,[2] while another survey projects that the market value of siRNA technology will grow to ~$250 million in 2009.[3] Like past pursuit of antisense oligonucleotide therapeutics, which fueled the development of kilogram-scale DNA synthesis and purification, the current pursuit of therapeutic applications of siRNA and its analogs has refueled efforts to extend such manufacturing technology to similarly large quantities of RNA-based compounds.

Significant investments in siRNA therapeutics are also reflected in the October 30, 2006 announcement by Merck & Co. Inc. that it intends to acquire Sirna Therapeutics Inc. for $1.1 billion. It is truly exciting to imagine what may be written in 2016 in an article that could be entitled "Commercialization of automated RNA synthesis — Thirty years on".

Characterization of pH3DZ1 — An RNA-cleaving deoxyribozyme with optimal activity at pH 3[1]

Md. Monsur Ali, Srinivas A. Kandadai, and Yingfu Li

Abstract: We previously described a cis-acting RNA-cleaving deoxyribozyme known as pH3DZ1 that exhibits optimal catalytic activity at pH 3.0 (Zhongjie Liu, Shirley H. Mei, John D. Brennan, and Yingfu Li. J. Am. Chem. Soc. **125**, 7539 (2003)). This DNA catalyst was made of a 99-nucleotide (nt) catalytic domain covalently linked to a 23-nt DNA–RNA chimeric substrate containing a single ribonucleotide as the cleavage site. In the present work, we conducted an extensive sequence examination of this deoxyribozyme via nucleotide truncation and reselection experiments, with a goal to minimize its size and identify the nucleotides that are crucial to its catalytic function. A trans-acting deoxyribozyme that can process an external substrate was also successfully designed. Stretches of 30 and 17 nucleotides from the 5′ and 3′ ends of the trans catalyst, respectively, were found to be completely dispensable; in contrast, few nucleotides could be deleted internally without producing a detrimental effect. The reselection experiment led to the discovery of 7 and 5 absolutely conserved nucleotides located at the 5′ and 3′ ends of the minimized catalyst, respectively, separated by a 31-nt element in which 14 highly conserved nucleotides were scattered among 17 variable nucleotides. The shortened deoxyribozyme and the original catalyst showed a similar pH profile with the optimal activity at pH 3; however, the minimized deoxyribozyme still exhibited strong catalytic activity at pH 2.5, while the full-length catalyst was barely active at this pH. Finally, it was found that this deoxyribozyme generated two cleavage fragments, one with 2′,3′-cyclic phosphate and the other with 5′-OH.

Key words: DNA, deoxyribozyme, RNA cleavage, in vitro selection, catalysis.

Résumé : Dans un travail antérieur (Zhongjie Liu, Shirley H. Mei, John D. Brennan, and Yingfu Li. J. Am. Chem. Soc. **125**, 7539 (2003)), on a décrit un désoxyribozyme connu sous le nom de code pH3DZ1, qui est capable de cliver l'ARN, qui agit d'une façon cis et dont l'activité catalytique est optimale à un pH de 3,0; ce catalyseur d'ADN a été fait en liant le domaine catalytique 99-nucléotide (nt) à un substrat chimérique 23-nt ADN–ARN ne contenant qu'un seul ribonucléotide comme site de clivage. Dans le travail présenté maintenant, on a fait appel à des expériences de tronquage et de resélection pour effectuer un examen extensif de la séquence de ce désoxyribozyme dans le but de minimiser sa taille et d'identifier les nucléotides qui sont cruciaux à son fonctionnement catalytique. On a aussi développé avec succès un désoxyribozyme agissant de façon *trans* qui peut traiter un substrat extérieur. On a identifié des blocs respectivement de 30 et de 17 nucléotides des extrémités 5′ et 3′ du catalyseur trans dont on peut se dispenser complètement; par opposition à cette situation, il n'y a que peu de nucléotides internes qui peuvent être éliminés sans produire des effets néfastes. L'expérience de resélection a permis de découvrir des blocs de 7 et 5 nucléotides absolument nécessaires qui sont situés respectivement aux extrémités 5′ et 3′ du catalyseur minimisé et qui sont séparés par un élément de 31-nt dans lequel 14 des nucléotides à conserver sont éparpillés parmi les 17 nucléotides variables. Le désoxyribozyme raccourci et le catalyseur original présentent tous les deux des profiles de pH semblables, avec une activité optimale à un pH de 3; toutefois, le désoxyribozyme raccourci présentait encore une forte activité catalytique à un pH de 2,5 alors que le catalyseur global était pratiquement inactif à ce pH. Enfin, on a trouvé que ce désoxyribozyme génère deux fragments de clivage, un avec un phosphate 2′,3′,-cyclique et l'autre avec un 5′-OH.

Mots-clés : ADN, désoxyribozyme, clivage d'ARN, sélection in vitro, catalyse.

Introduction

Although DNA is best known as the material that stores the genetic information of all living organisms on earth, in recent years it has also been widely explored as a synthetic material in diverse applications ranging from the design of biosensors (1–6), to the construction of nanodevices (7–11), and to the creation of catalysts (12–18).

The first catalytic DNA was reported in 1994 (19), and since then hundreds of DNA sequences with catalytic abili-

ties have been isolated from random-sequence DNA pools using a well-established laboratory technique known as "in vitro selection" (20, 21). Commonly known as deoxyribozymes and even simply DNAzymes, DNA catalysts have been obtained to catalyze diverse chemical reactions including cleavage and ligation of DNA or RNA (22–41), 5′-phosphorylation and 5′-adenylation of DNA (42–44), porphyrin metallation (45), and thymine dimer repair (46). From a theoretical perspective, DNA catalysts offer an important platform for the fundamental examination of inherent catalytic capabilities of nucleic acids. From a practical point of view, DNA catalysts have great potential to be exploited as desirable molecular tools for innovative chemical and biological applications.

Aiming to investigate the fundamental catalytic capability of DNA and to obtain DNA catalysts that can function under harsh chemical conditions, we recently carried out in vitro selection experiments to derive self-cleaving deoxyribozymes that were active in a highly acidic environment (34). The effort led to the isolation of several unusual DNA catalysts with optimal catalytic activity at a defined acidity that precisely reflected the pH value specifically set during the in vitro selection experiment (such as pH 3, 4, 5, or 6). The deoxyribozyme that was active at the most acidic condition was named pH3DZ1, which was derived under pH 3.0 as the constant solution acidity and expectedly exhibited the optimal activity at this pH (34).

The major goal of the present study was to conduct a comprehensive analysis of the sequence requirement of pH3DZ1 in an effort to minimize its size and identify the nucleotides that are most crucial to its catalytic function.

Results

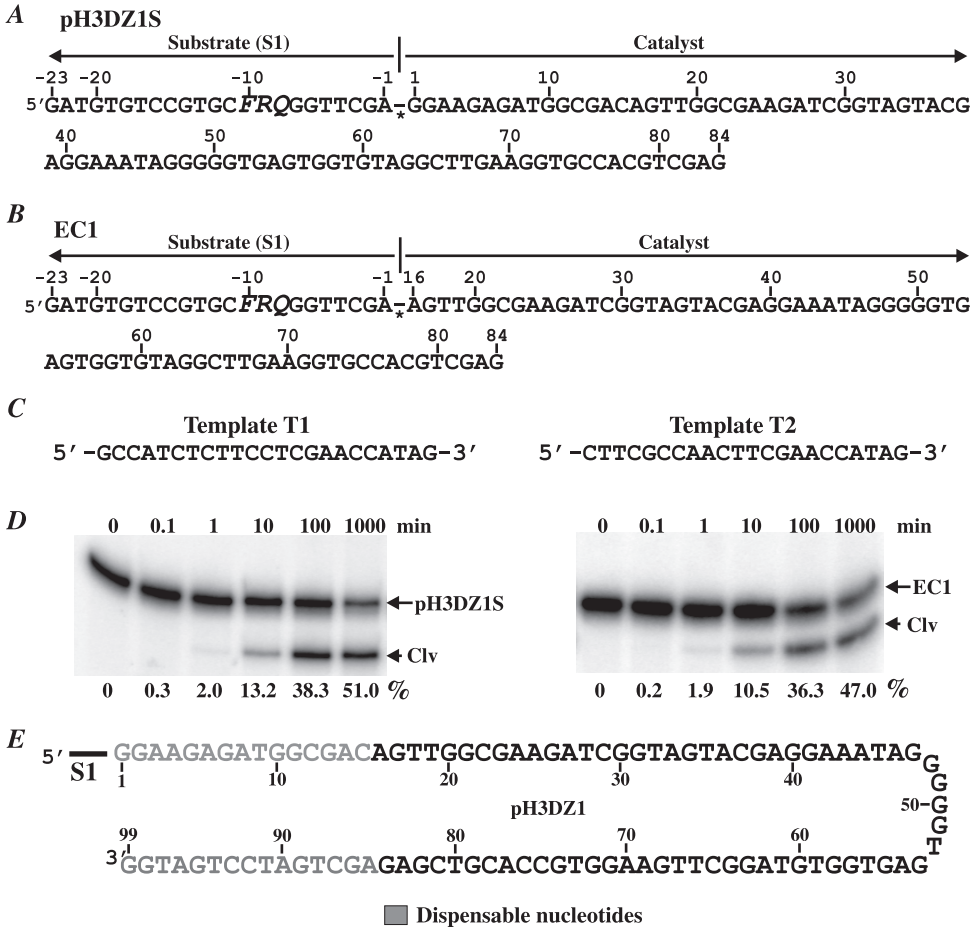
Removal of the two primer-binding sequence elements from pH3DZ1

pH3DZ1 was originally isolated from a random-sequence DNA library by in vitro selection while the pH of the reaction mixture was maintained at 3.0 (34). The full-length pH3DZ1 is a 122-nucleotide (122-nt) cis-acting catalyst cleaving a covalently attached DNA–RNA chimeric substrate that has a single ribonucleotide as the cleavage site. It was shown previously that the last 15 nucleotides of pH3DZ1, which were used as the 3′ primer binding arm for a polymerase chain reaction (PCR) amplification during the in vitro selection, could be removed without affecting the catalyst activity (34). This shortened deoxyribozyme, named pH3DZ1S, was used as the reference sequence in this report (Fig. 1*A*).

For description convenience, we divide the sequence of pH3DZ1S into two sequence elements (Fig. 1*A*): a 23-nt "substrate" domain (Fig. 1*A*, numbered –1 to –23 in the 3′-5′ direction) and an 84-nt "catalyst" domain (numbered 1 to 84 in the 5′-3′ direction). It should be noted that the substrate domain contains three special nucleotides abbreviated as R, F, and Q. R denotes adenine ribonucleotide, the only ribonucleotide in the otherwise all-DNA sequence. F and Q denote a fluorescein-labeled thymine deoxyribonucleotide (fluorescein-dT) and a DABCYL-labeled thymine deoxyribonucleotide (DABCYL-dT), respectively. Such modifications were intended for the future exploration of pH3DZ1 as a potential biosensor because the catalytic activity is directly linked to the generation of a fluorescence signal.

The 15 nucleotides at the 5′-end of the catalyst domain within pH3DZ1S (Fig. 1*A*, G_1-A_{15}) were used as the 5′ primer-binding arm for the PCR amplification step during the original in vitro selection experiment. To assess whether this sequence element could be removed, we designed a shortened sequence EC1 (Fig. 1*B*). To compare the catalytic activity of EC1 to pH3DZ1S, we constructed radioactive cis-acting deoxyribozymes using the following procedure: the substrate S1 and the two catalysts were produced separately by automated DNA synthesis and purified by preparative denaturing (urea, 8 mol/L) polyacrylamide gel electrophoresis (denaturing PAGE); each catalyst was phosphorylated at the 5′-end using γ-^{32}P[ATP] and T4 polynucleotide kinase; each phosphorylated catalyst was joined to the substrate by DNA ligation with T4 DNA ligase in the presence of a template oligonucleotide (Fig. 1*C*; T1 for pH3DZ1S ligation; T2 for EC1 ligation) followed by purification by denaturing PAGE. This procedure produced the ^{32}P-labeled pH3DZ1S and EC1 with the ^{32}P-phosphodiester bond (Fig. 1*A*, indicated with "*") linking the substrate domain to the catalyst domain. Upon RNA cleavage, the 3′-cleavage fragment (Fig. 1*D*, designated as "clv") would be radioactive and can be detected by autoradiography.

The activities of pH3DZ1S and EC1 were assessed in a time-course study and the data are given in Fig. 1*D*. The two deoxyribozymes had almost identical time-course profiles. A small amount of cleavage (~2%) was observed after 1 min incubation; when the reaction time was progressively increased, the percentage of cleaved product was also increased; at 1000 min reaction time, about 50% of the cis-acting catalyst was cleaved. The data in Fig. 1*D* indicate that none of the 30 nucleotides located in the two primer-binding arms were recruited as the catalytically important nucleotides during in vitro selection. We term these residues as "dispensable nucleotides", which are shown as gray letters in Fig. 1*E* and subsequent figures.



Engineering a trans-acting deoxyribozyme

Both pH3DZ1S and EC1 are cis-acting catalysts that cleave the substrate covalently attached to the catalyst. As described earlier, the process of making these cis-acting constructs was time-consuming and expensive. To expedite the sequence assessment process, we sought to derive a trans-acting (i.e., bimolecular) system where a deoxyribozyme can cleave a substrate provided as a separate molecule.

Almost all cis-acting RNA-cleaving deoxyribozymes derived by in vitro selection to perform catalysis under neutral conditions can be relatively easily converted into trans-acting deoxyribozymes because these deoxyribozymes typically use two Watson–Crick helical binding arms to recognize their substrates (47). pH3DZ1 was not expected to adopt the same strategy simply because the Watson–Crick base pairings would not apply to a DNA catalyst that functions in a highly acidic environment (because N1 of adenosine and N3 of cytosine are protonated at low pH (13)). Indeed, our attempts to identify Watson–Crick binding arms in pH3DZ1 were not successful (data not shown).

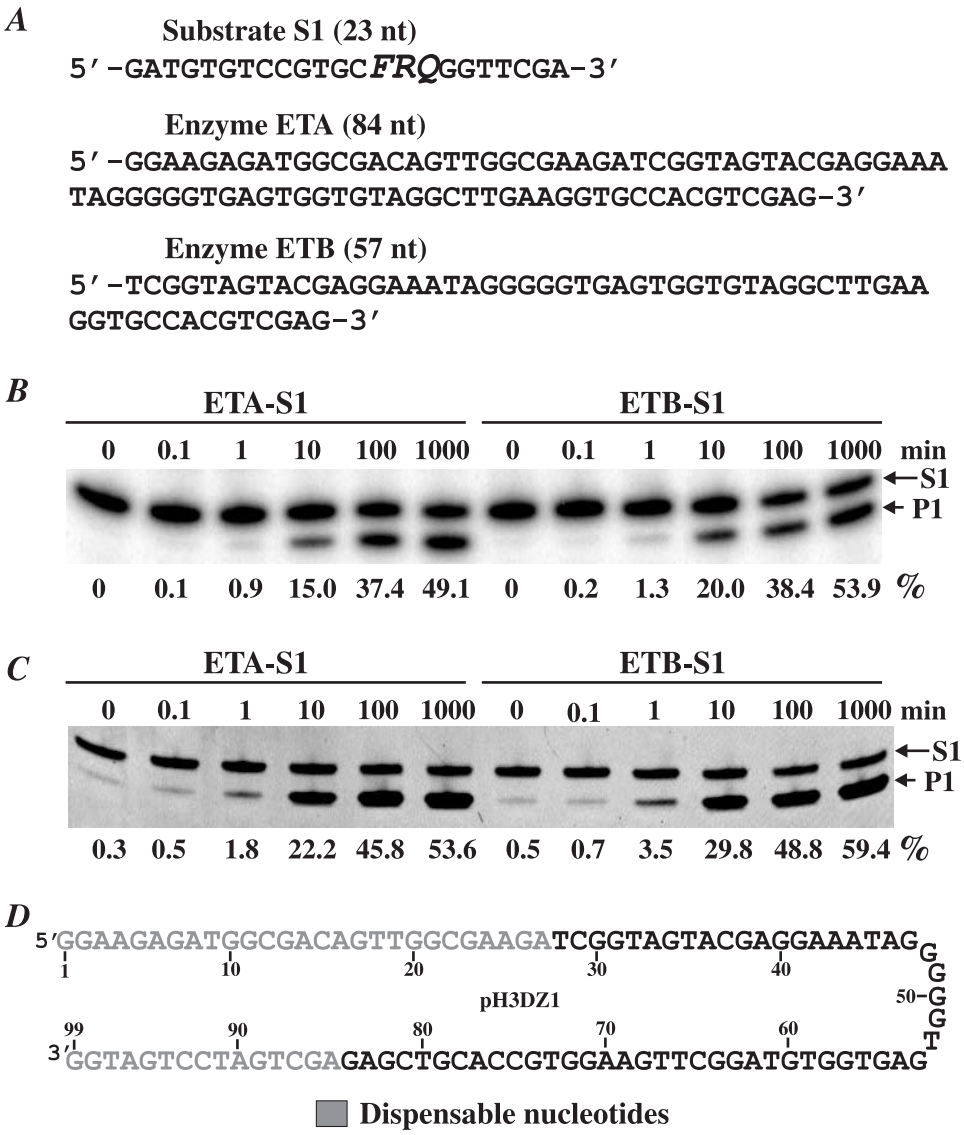
Fig. 1. Examination of the relevance of the original primer-binding sites to the catalytic activity of pH3DZ1. (*A*) The sequence of pH3DZ1S in which the 3′ primer-binding site of pH3DZ1 (5′ AGCTGATCCTGATGG3′) is deleted. This cis-acting catalyst is divided into two sequence elements, the substrate (S1) domain numbered –1 to –23 in the 3′-5′ direction and the catalyst domain numbered 1 to 84 in the 5′-3′ direction. F denotes fluorescein-deoxythymidine, R denotes riboadenosine, and Q denotes DABCYL-deoxythymidine. The symbol "*" indicates the ^{32}P-labeled phosphodiester linkage for the assay shown in (*D*). (*B*) The sequence of EC1 is a shortened version of pH3DZ1, where both of the original primer-binding sites are removed. (*C*) The sequences of T1 and T2 templates used for ligating S1 to the relevant catalyst in (*A*) and (*B*), respectively. (*D*) The cleavage activity of pH3DZ1S (image on left) and EC1 (image on right). The numbers above and below each image are the reaction time points (in minutes) and percentages of cleavage, respectively. "Clv" on the side of each image denotes the relevant cleavage product that can be detected by autoradiography. (E) The sequence of pH3DZ1 with dispensable nucleotides indicated in gray.

The finding that the constant 15-nt segment between G_1 and A_{15} is dispensable seems to suggest that we might be able to design a trans-acting catalyst simply by breaking pH3DZ1S into two separate molecules right at the substrate–catalyst junction. This manipulation indeed resulted in a fully functional bimolecular assembly made of ETA (84 nt) as the enzyme and S1 (23 nt) as the substrate (Fig. 2, panels *A* and *B*). Using the same time-course assay that was used for pH3DZ1S and EC1, we found that ETA exhibited a cleavage activity that was very similar to the two cis-acting deoxyribozymes (comparing Fig. 1*D* with Fig. 2*B*). It should be noted that the trans systems were assessed under the following single-turnover condition: S1 = 0.5 μmol/L and ETA= 25 μmol/L (S1–ETA 1:50).



Interestingly, we further found that 27 nucleotides from the 5′-end of ETA could be completely removed; the resultant catalyst, named ETB (its sequence is given in Fig. 2*A*), was as active as ETA in processing S1 (Fig. 2*B*). Based on this observation, ETB was adopted as the reference deoxyribozyme for the subsequent sequence truncation experiments to be detailed in the next section.

Up to this point, the activity of the deoxyribozyme constructs was assessed using radioactive (via ^{32}P-label) deoxyribozyme–substrate constructs and autoradiography (phosphorimaging). Since the substrate sequence also contains the fluorescein label, the activity of the deoxyribozymes can also be followed with fluorescence imaging (fluorimaging) (35). Therefore, we also performed the fluorescence scan of the same time-course gel shown in Fig. 2*B* and the result is shown in Fig. 2*C*.

Because the substrate S1 also has a DABCYL quencher placed two nucleotides away from the fluorescein, the substrate would have a low level of fluorescence due to fluorescence quenching. The cleaved product P1, however, would

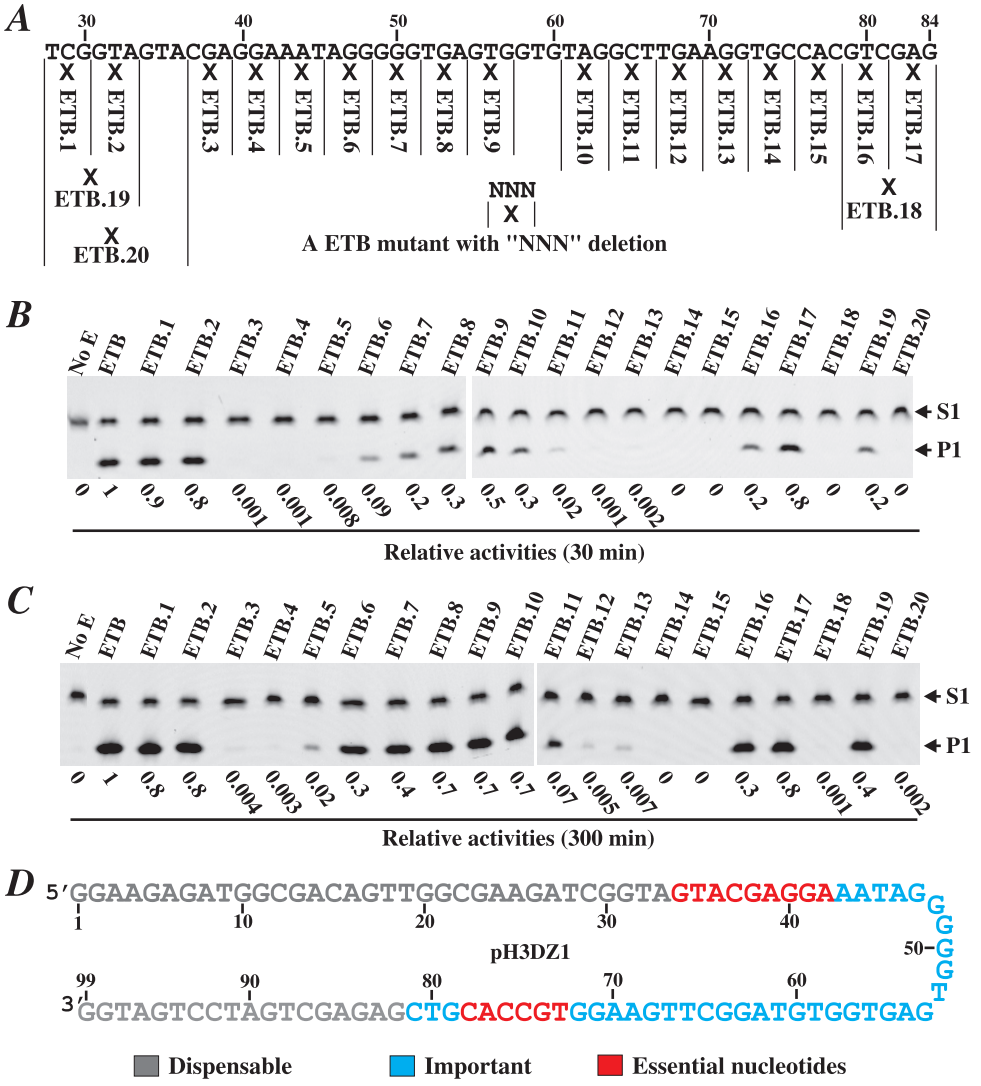
Fig. 2. Design of trans-acting deoxyribozymes. (*A*) The sequence of trans-acting deoxyribozyme systems. S1 is the external substrate for the two fully active trans-acting pH3DZ1 constructs denoted ETA (84 nt) and ETB (57 nt). ETB has the same sequence as ETA except that the 27 nucleotides located at the 5′ end of ETA are deleted. (*B*) and (*C*) The cleavage activity of ETA and ETB towards S1. The numbers above and below each image are the reaction time points (in minutes) and percentages of cleavage, respectively. S1 was labeled with 5′-^{32}P-phosphate. "P1" on the side of each image denotes the 5′-cleavage fragment that can be detected by phosphorimaging (*B*) and fluorimaging (*C*). The percent cleavage in (*B*) and (*C*) was calculated by eqs. [2] and [1] described in the text, respectively. (*D*) The sequence of pH3DZ1 with dispensable nucleotides indicated in gray.

produce an enhanced fluorescence. It was previously found that the cleavage of such substrates could generate an approximately 6-fold increase of fluorescence in the PAGE-based assay (48, 49). Indeed, we noticed that scanning the cleavage gel by fluorimaging provided much more sensitive visual results for low cleavage activity. Using the 1 min incubation of ETA-S1 as an example, in the phosphorimaging scan the cleavage product band was barely visible (Fig. 2*B*, lane 3), while in the fluorimaging scan the product band was much more evident (Fig. 2*C*, lane 3). Because of this observation, we chose to assess the cleavage activity of deoxyribozyme constructs by fluorimaging in the remaining experiments.



We calculated the cleavage percentages based on the fluorescence intensity for both ETA–S1 and ETB–S1 and compared the values to those derived by radioactivity assessment. The data are given in Fig. 2*C*. Since the cleavage product was about 6-fold more fluorescent than the substrate, we computed the cleavage percentage from fluorimaging using eq. [1],

$$[1] \quad \text{Percent cleavage} = 100\% \times (F_{\text{product}} / 6) / [F_{\text{substrate}} + (F_{\text{product}} / 6)]$$

where F_{product} and $F_{\text{substrate}}$ represent the fluorescence intensity of the cleaved product P1 and uncleaved substrate S1, respectively. In comparison, the cleavage percentage from phosphorimaging was calculated using eq. [2],

Fig. 3. Deletion mutants of deoxyribozyme ETB. (*A*) The sequence of ETB and its deletion mutants with specified nucleotides truncated. For example, ETB.13 is an ETB mutant with the deletion of $A_{70}G_{71}G_{72}$. Most of the ETB mutants carry a 3-nt deletion except for ETB.18 (6-nt deletion), ETB.19 (6-nt deletion), and ETB.20 (9-nt deletion). (*B*) and (*C*) The fluorimage of the cleavage activity of the truncated trans-acting mutants towards S1 at 30 min and 300 min, respectively. "S1" and "P1" on the side of each image denote the substrate and its 5′-cleavage fragment. The activity of each mutant deoxyribozyme is normalized in reference to ETB using eq. [2] described in the text. (*D*) The sequence of pH3DZ1 with component nucleotides categorized as "dispensable", "important", and "essential" according to the truncation data to this point.

[2] Percent cleavage = 100%

$$\times R_{product} / (R_{substrate} + R_{product})$$

where $R_{product}$ and $R_{substrate}$ are the radioactivity of the cleaved product and uncleaved substrate, respectively.

We found that the cleavage activities computed by both methods are largely in agreement with each other. For example, for the 10 and 100 min time points, 15.0% and 37.4% cleavage were observed for ETA–S1 by the phosphorimaging method, while 22.2% and 45.8% cleavage were registered by the fluorimaging method.

We briefly examined the turnover ability of the trans-acting ETB. When ETB (0.1 µmol/L) was mixed with S1 (10 µmol/L) under our standard reaction conditions, 1, 4, 9, and 17 turnovers were observed after the mixture was incubated for 0.5, 2, 4, and 8 h, respectively. This finding indicates that ETB is a "true" enzyme and is capable of ~2 turnovers per hour. The full kinetic characterization of trans-acting ETB will be the subject of a future investigation and the results will be reported elsewhere.

Finally, Fig. 2*D* provides an update on the nucleotide dispensability in the sequence of pH3DZ1 (comparing Figs. 1*E* and 2*D*).

Assessing truncation mutants of ETB

We next synthesized and assessed a series of truncation mutants of ETB by making sequential 3-nt deletions starting from T_{28} and ending at G_{84} (ETB.1 to ETB.17). Two 6-nt (ETB.18 and ETB.19) and one 9-nt (ETB.20) deletion mutants were also examined. Figure 3*A* illustrates the deletion

© 2007 NRC Canada

map. The cleavage activity of the examined mutants (revealed by fluorimaging) is provided in Figs. 3*B* and 3*C*. It should be noted that each deoxyribozyme was assessed in two reaction time points, a 30 min reaction (Fig. 3*B*, a time point designed to reveal mutants with a strong activity) and a 300 min incubation (Fig. 3*C*, to test for weakly active mutants). To provide a quantitative comparison of the activity of the mutant deoxyribozymes, we normalized the activity of each mutant against ETB using eq. [3],

$$[3] \quad \text{Relative activity} = \%\ \text{cleavage of a mutant} / \%\ \text{cleavage of ETB}$$

where % cleavage is calculated by eq. [1]. The calculated data are given at the bottom of the PAGE gels in Figs. 3*B* and 3*C*.

The results presented in Fig. 3 reveal some important information about the sequence requirements of pH3DZ1. First, two sequence elements, those between G_{34} and T_{45} and those between T_{67} and C_{78}, are extremely critical to the function of pH3DZ1, as the deletion of any 3 sequential nucleotides in these regions resulted in mutant deoxyribozymes that were either completely inactive (ETB.3, ETB.4, ETB.14, and ETB.15) or barely active (ETB.5, ETB.12, and ETB.13). Second, the sequence element covering T_{46}–T_{66} is highly important; truncation of any 3-nt element in this region produced mutant deoxyribozymes with either medium activity (ETB.7, ETB.8, ETB.9, and ETB.10) or severely reduced activity (ETB.6 and ET.11).

Moreover, the findings that ETB.16 (3-nt deletion), ETB.17 (3-nt deletion), and ETB.18 (6-nt deletion covering nucleotide deletions of both ETB.17 and ETB.18) were weakly active, strongly active, and completely inactive, respectively, point to the following: (*i*) the $G_{82}A_{83}G_{84}$ motif is dispensable, (*ii*) the $G_{79}T_{80}C_{81}$ motif plays an important role for catalysis, and (*iii*) more importantly, G_{79} is a critical residue. The last point in particular can be justified by comparing the reduced activity of ETB.16 (we speculate that the critical role of G_{79} in this mutant was fulfilled by G_{82}) and the loss of activity of ETB.18 (in which both G_{79} and G_{82} are absent).

Finally, comparing the activities of the four mutant deoxyribozymes with various nucleotides truncated from the 5′-end (i.e., ETB.1 and ETB.2 having two sequential 3-nt deletions; ETB.19 with a 6-nt truncation that covers both ETB.1 and ETB.2; and ETB.20 with three additional nucleotides removed beyond ETB.19) led to the following comments: (*i*) the $T_{28}C_{29}G_{30}$ sequence element is dispensable (revealed by the strong activity of ETB.1), (*ii*) only one of the two tandem GTA elements located near the 5′-end ($G_{31}T_{32}A_{33}$ and $G_{34}T_{35}A_{36}$) is required for the function of pH3DZ1 (revealed by the strong activity of ETB.2 and the loss of activity of ETB.20), and (*iii*) at least one nucleotide needs to be retained prior to $G_{34}T_{35}A_{36}$ for the full activity of the deoxyribozyme (revealed by the medium activity of ETB.19).

Figure 3*D* provides an updated summary of nucleotide requirements for the function of pH3DZ1 (where dispensable, important, and essential nucleotides are colored gray, light-blue, and red, respectively) after taking into consideration the sequence truncation results.

In vitro selection experiment to further identify the functionally essential nucleotides

The truncation experiments discussed earlier indicate that the minimized deoxyribozyme ETB.2 contains all of the catalytically important or essential nucleotides. To assess the importance of individual nucleotides within the shortened deoxyribozyme, we conducted a reselection experiment using a mutant deoxyribozyme library synthesized based on the sequence of ETB.2. The sequences of all DNA molecules used for reselection are shown in Fig. 4*A*. The library sequence is denoted L1 in which the nucleotides corresponding to G_{31}–G_{84} of the original pH3DZ1 were partially mutagenized (76% of the original nucleotide and 24% of the equal mixture of other three nucleotides at each relevant position, following a previous protocol (50)) during chemical synthesis of the library. However, new constant regions were added to this catalytic motif as primer binding arms for the purpose of avoiding the cross-contamination by the original pH3DZ1.

The reselection scheme is depicted in Fig. 4*B*, which is similar to that used for the original selection (34). Briefly, each selection cycle consists of eight steps. In step I, 87-nt DNA L1 is ligated to the 17-nt substrate S2. The ligated 104-nt DNA is purified by PAGE (step II) and then allowed to self-cleave in the selection–assay buffer (step III). The 89-nt cleavage fragment is isolated by PAGE (step IV) and amplified by PCR using primers P1 and P2 (step V). The resulting 105-bp PCR product is used as the template for second PCR using primers P2 and P3 for the introduction of a ribonucleotide linkage embedded in front of the L1 sequence (step VI). After treatment with NaOH to cleave the ribonucleotide linkage (step VII), the 87-nt cleavage fragment is purified by PAGE, phosphorylated at the 5′-end (step VIII), and used to initiate the next selection cycle.

We chose to use a relatively long reaction time (5 h) for the purpose of identifying catalytically essential nucleotides. The progress of the selection is shown in Fig. 4*C*. Although there was no detectable cleavage activity from the initial library (generation 0 or G0), 8% and 22% of the molecules in G1 and G2 were found to self-cleave, respectively. Surprisingly, the activity of G3 (12% cleavage) was lower than that of G2, and we attribute this abnormality to some unidentified experimental errors. By G4 and G5, the cleavage activity was observed to reach saturation at ~40%. Because of this, G5 was cloned and 31 clones were successfully sequenced.

Figure 5*A* lists the sequences of these deoxyribozyme mutants (the primer-binding arms are omitted for clarity) along with a variation index (V.I.) chart compiled according to a previously published protocol (51). Briefly, the V.I. value for each random position was derived as follows: the observed mutation rate at each position / 0.24 (the mutation rate of the starting library). A V.I. value of 0 indicates that the base of the given nucleotide is absolutely conserved in all of the sequenced clones. If the base of a given nucleotide is not specifically involved in catalysis, the V.I. value is expected to be close to 1. Bases with V.I. values significantly smaller

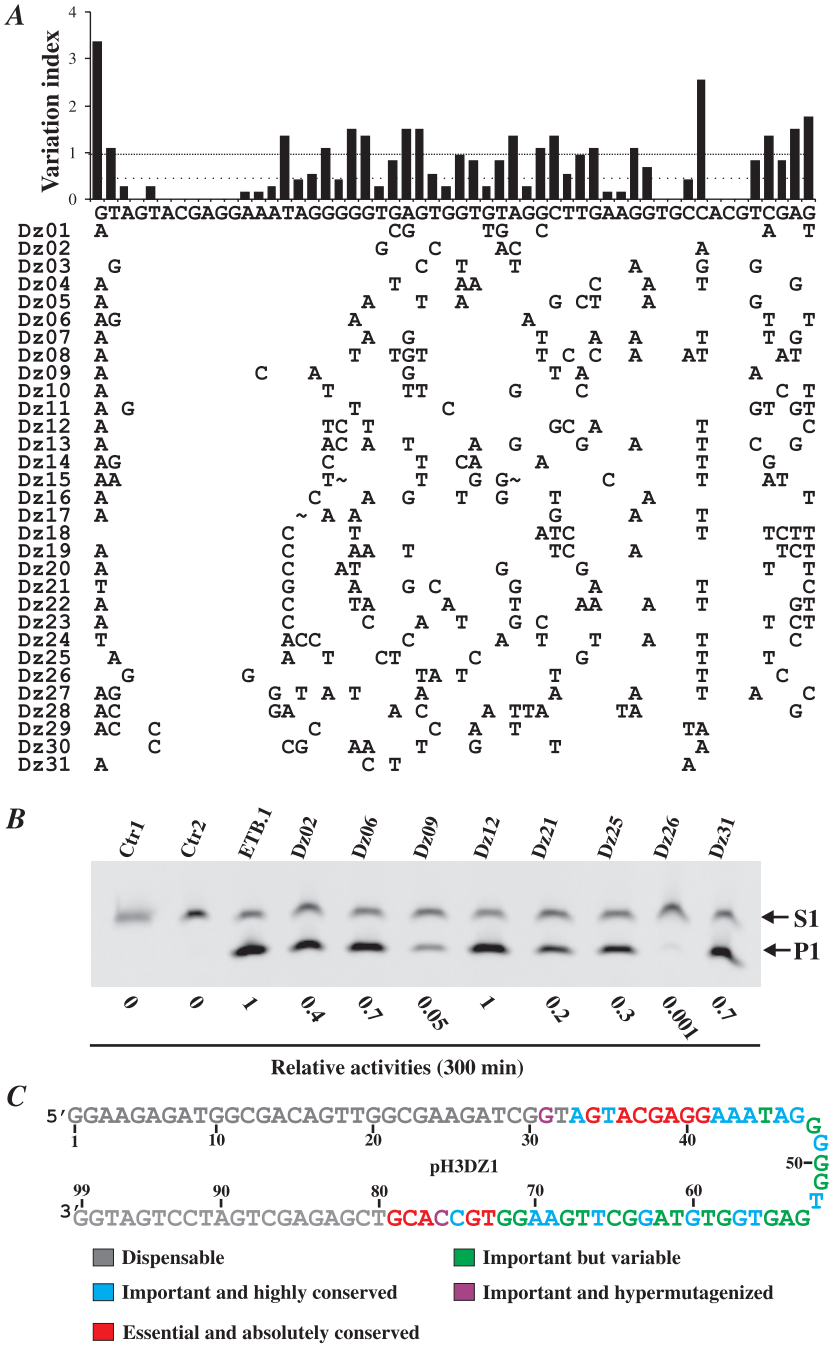
C



than 1 (such as 0.5 marked on the variation index chart) are taken as important residues for catalysis. V.I. values larger than 1 could mean that the base(s) observed in the selected mutants may offer a selective advantage over the original base (51).

The data in Fig. 5*A* reveal that 12 nucleotides within pH3DZ1 are absolutely conserved (red nucleotides in Fig. 5*C*) and they are G_{34}, A_{36}, C_{37}, G_{38}, A_{39}, G_{40}, G_{41}, T_{73}, G_{74}, A_{77}, C_{78}, and G_{79}. In addition, the following seventeen nucleotides are highly conserved (with V.I. values at 0.5 or smaller; Fig. 5*C*, light-blue nucleotides): A_{33}, T_{35}, A_{42}, A_{43}, A_{44}, A_{46}, G_{47}, G_{49}, T_{52}, T_{56}, G_{57}, G_{60}, G_{63}, T_{66}, A_{69}, A_{70}, and C_{75}. Two nucleotides, G_{31} and C_{76}, (Fig. 5*C*, purple nucleotides), exhibit V.I. values significantly larger than 1. Inter-

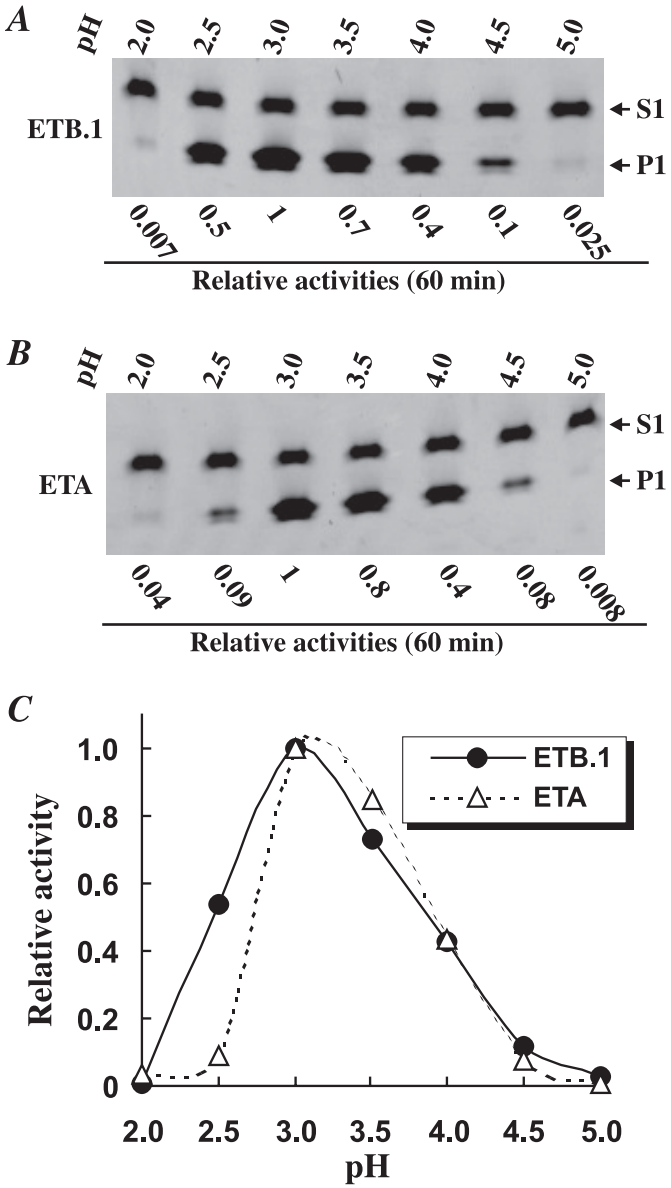
Fig. 5. Mutant deoxyribozymes isolated from reselection. (*A*) Sequence analysis of the terminal pool. The variation index (V.I.) was complied upon sequencing 31 clones from the G5 population. The V.I. was calculated by dividing the observed mutation rate at each position by 0.24 (the mutation rate of the starting library). The wild-type sequence is shown at the bottom of V.I. chart (the constant nucleotides are omitted for clarity). The two dotted lines indicate V.I. values of 1 and 0.5, respectively. The actual mutations in each deoxyribozyme (named Dz01–Dz31) are listed; the missing letters in each sequence indicate that no mutation was observed in those locations and "~" indicates a deletion at this location. (*B*) The fluorescent image of the cleavage activity of 8 deoxyribozymes randomly chosen from (*A*), where Ctr1 is the reaction mixture at 0 min and Ctr2 is the substrate only incubated in the reaction buffer without enzyme for the same time period as the test samples. (*C*) The sequence of pH3DZ1 with component nucleotides now categorized as "dispensable", "important but variable", "important and highly conserved", "important and hypermutagenized", and "essential and absolutely conserved" according to both the truncation and reselection data.



estingly, G_{31} was almost exclusively mutated to A while C_{76} predominately mutated to T (Fig. 5*A*).

The above observations are consistent with the sequence truncation data discussed earlier (see Fig. 3). For example, the absolutely conserved nucleotides fall precisely within the two crucial sequence elements between G_{34} and T_{45} and between T_{67} and C_{78}, identified through the examination of truncation mutants. Not surprisingly, the reselection experi-

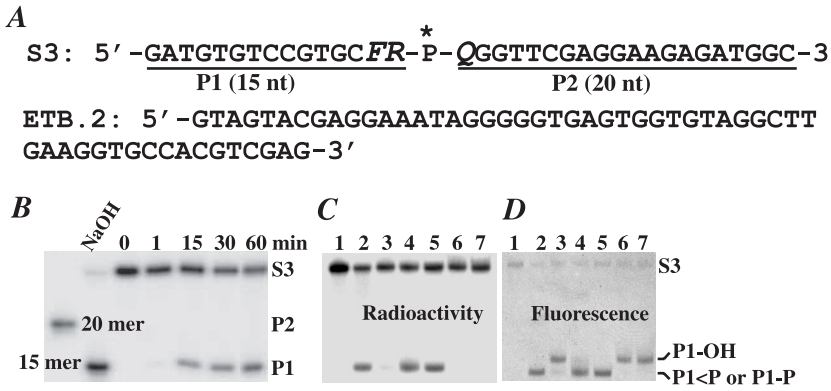
Fig. 6. Comparison of pH profiles of full-size and truncated trans-acting pH3DZ1. (*A*) and (*B*) are pH-dependent cleavage activities of ETB.1 and ETA towards S1, respectively. S1 and ETB.1 or ETA were incubated under a given pH for 60 min and the cleavage products were analyzed by denaturing PAGE. "S1" and "P1" on the side of each image denote the substrate and its 5′-cleavage fragment, both of which can be detected by fluorimaging. The activity of each deoxyribozyme is normalized in reference to its activity at pH 3.0 following eq. [1] in the text. (*C*) The pH profile of ETB.1 and ETA. The relative activity of each deoxyribozyme is plotted against pH of the solution.

ment verifies the postulated essentiality of G_{79}. Likewise, the same experiment identified A_{33} as a highly conserved nucleotide, confirming our speculation that at least one nucleotide preceding G_{34} must be retained to maintain the full activity of the deoxyribozyme. Moreover, the finding that 14 nucleotides within the T_{46}–T_{66} sequence element are highly conserved substantiates the importance of this central element revealed by the truncation experiments presented in Fig. 3.

To demonstrate that the selected deoxyribozyme variants are catalytically active, we assessed the activity of the eight clones randomly chosen from the sequences listed in Fig. 5*A*. These mutant deoxyribozymes were chemically synthesized without the two primer-binding arms, incubated with the substrate S1 for 300 min (the duration time for reselection), analyzed by PAGE, which was scanned by fluorimaging (Fig. 5*B*). By normalizing the activities of these mutant deoxyribozymes against ETB.1, we found that three of these mutants (Dz06, Dz12, and Dz31) have a strong activity (with a relative activity between 0.7 and 1), three other mutants (Dz02, Dz21, and Dz25) have a medium activity (relative activity between 0.2 and 0.4), one mutant (Dz09) has a weak activity (relative activity of 0.05), and one mutant (Dz26) is barely active (relative activity of 0.001). The very weak activity of Dz26 could be rationalized by the mutational data as this mutant had two mutations occur to the extremely conserved nucleotides (i.e., A_{32} to G, A_{42} to G; their V.I. values are much smaller than 0.5); in contrast, the other more active mutants had maximally one such mutation.

Comparison of pH dependences of full-length and truncated *trans*-deoxyribozymes



An experiment was carried out to compare pH profiles of the full-length *trans*-deoxyribozyme ETA and its shortened version ETB.1. Each deoxyribozyme was assessed for the cleavage activity towards S1 within 60 min under solution conditions with variable acidity, analyzed by denaturing PAGE, and scanned for fluorescence (Fig. 6; panel *A* for ETB.1; panel *B* for ETA). The activity of each deoxyribozyme at chosen pH points was normalized against their activity at pH 3.0, and the derived values (given under the PAGE gels in Figs. 6*A* and 6*B*) were then plotted in Fig. 6*C*. We found that the profile of ETA was almost identical to that of the cis-acting full-length pH3DZ1 (34). The pH dependences of ETA and ETB.1 were also quite similar: both deoxyribozymes had the highest activity at pH 3.0 and showed a progressive decrease in activity when the pH of the solution was raised from 3.0 to 5.0; both were almost inactive when the pH was increased to 5.0 or decreased to 2.0. However, there was one significant difference in that ETB.1 retained a substantial activity at pH 2.5, whereas ETA was only weakly active at this pH. The precise reasons for this deviation are not clear to us at the moment; however, we speculate that the 45 nucleotides removed from the 5′-end of ETA might contain nucleotides (or a sequence element) that exhibit inhibitory effects towards the function of the catalytic core at pH 2.5.

Characterization of cleavage products

To characterize the cleavage products produced by pH3DZ1, we followed a previously published protocol that utilizes a specially labeled substrate containing ^{32}P-labeled phosphodiester linkage at the cleavage site that permits the tracing of the transfer of the phosphorous atom from the substrate to the cleavage products (52). The substrate (denoted S3) was produced by ligating a matching 5′-^{32}P-labeled oligonucleotide to a relevant 3′-ribo-terminated

© 2007 NRC Canada

Fig. 7. Characterization of the products of pH3DZ1-mediated RNA-cleavage. (*A*) Sequences of substrate S3 with ^{32}P-labeled phosphodiester linkage (denoted by **P***) at the cleavage site and the trans-acting deoxyribozyme ETB.2. (*B*) Tracing phosphoester transfer. S3 was first incubated with ETB.2 for 0, l, 15, 30, and 60 min; the resultant reaction mixtures were then analyzed by 10% denaturing PAGE. Upon cleavage, S3 was converted into a visible (radioactive) 5′-cleavage fragment P1 (15 nt) and invisible (nonradioactive) 3′-cleavage fragment P2 (20 nt). The first lane shows 5′-^{32}P-labeled P2; the second lane shows the cleavage product produced when S3 was reacted with NaOH (0.25 mol/L) for 10 min at 90 °C. (*C*) and (*D*) Determination of the chemical nature of the phosphate at the end of P1 by enzymatic digestion. P1 was further found to contain a 2′,3′-cyclic phosphate terminus using T4 polynucleotide kinase (PNK), calf intestine alkaline phosphatase (CIAP), and 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNPase). Lane 1: S3 alone; lane 2: S3 incubated with ETB.2 for 60 min; lanes 3–7: S3 incubated with ETB.2 (60 min) followed by PNK (lane 3), CIAP (lane 4), CNPase (lane 5), first CNPase then PNK (lane 6), first CNPase then CIAP (lane 7). Each reaction mixture was analyzed on 10% denaturing PAGE. The images in (*C*) and (*D*) were taken from the same gel using phosphorimaging and fluoroimaging

oligonucleotide; this produced S3 with ^{32}P-labeled phosphodiester linkage right at the cleavage junction (Fig. 7, marked with "*"). When S3 was incubated with ETB.2 for various time points, only one cleavage product was observed on the autoradiograph (Fig. 7*B*). Since the visible cleavage fragment had the same gel mobility as the 15-nt DNA ladder (but not the 20-nt DNA ladder), we can conclude that the 5′-cleavage fragment (P1) acquired a terminal phosphate at the 3′-end, while the 3′-cleavage fragment (P2) had an unphosphorylated 5′-hydroxyl group.

We next examined whether the terminal phosphate of P1 was in the form of a 2′,3′-cyclic phosphate or a 2′- and (or) 3′-monophosphate through treatment of three protein enzymes: T4 polynucleotide kinase (T4 PNK, which has both 2′,3′-cyclic nucleotide 3′-phosphodiesterase activity and 2′- and 3′-phosphatase activity), calf intestine alkaline phosphatase (CIAP, which has 2′- and 3′-phosphatase activity but does not have 2′,3′-cyclic phosphodiesterase activity), and 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNPase, which has the ability to hydrolyze 2′,3′-cyclic phosphate solely to 2′-phosphate) (52). When the ETB.2–S3 reaction mixture (Fig. 7*C*, lane 2) was incubated with PNK (Fig. 7*C*, lane 3), P1 lost its radioactivity; when incubated with CIAP (Fig. 7*C*, lane 4), P1 retained its radioactivity. These two observations strongly suggest that P1 has a 2′,3′-cyclic phosphate. When the same reaction mixture was first treated with CNPase and then further treated with either CIAP (Fig. 7*C*, lane 6) or PNK (Fig. 7*C*, lane 7), the radioactivity of P1 was lost (note that the radioactivity of P1 remained unchanged when it was treated with CNPase alone; Fig. 7*C*, lane 5). The fluorescence scan of the same gel (Fig. 7*D*) further verified the loss of the terminal phosphate from P1 after the digestion with PNK (Fig. 7*C*, lane 3), CNPase–CIAP (Fig. 7*C*, lane 6), and CNPase–PNK (Fig. 7*C*, lane 7): the dephosphorylated P1 was expected to migrate relatively slower because of the loss of the negative charges associated with the phosphate group. From these analyses, we conclude that the cleavage of S3 by ETB.2 produces a 5′-cleavage fragment with a 2′,3′-cyclic phosphate and a 3′-cleavage fragment with a 5′-OH. It is interesting to note that the same products are found for all naturally occurring self-cleaving ribozymes and all man-made RNA-cleaving nucleic acid enzymes (47, 52).

Discussion

Most artificial nucleic acid enzymes (ribozymes and deoxyribozymes) were derived to perform catalysis at neutral pH. However, several ribozymes and deoxyribozymes that can catalyze chemical transformations in acidic environments have also been reported. These include a self-cleaving ribozyme (53), an RNA-cleaving deoxyribozyme (34, 50), and an RNA-ligating ribozyme (54, 55) that perform their catalytic functions at pH 4; an RNA-cleaving deoxyribozyme with optimal activity at pH 4.8 (34); an RNA-ligating ribozyme that operates at pH 5.8 (56); and an RNA-cleaving deoxyribozyme with best activity at pH 6 (34, 48). The existence of this array ribozymes and deoxyribozymes that are functional at low pH strongly indicates that the catalytic power of nucleic acids is not lost in acidic environments. Among these acidic nucleic acid enzymes, pH3DZ1 is the only catalyst that can still perform catalysis in a highly acidic environment at pH 3.

pH3DZ1 was originally isolated from a random-sequence DNA pool as a cis-acting deoxyribozyme to carry out the reaction of cleaving a covalently attached chimeric RNA–DNA substrate at a single RNA linkage in a highly acidic solution (pH 3.0) (34). In the present work, we have converted pH3DZ1 from a cis-acting catalyst into a trans-acting deoxyribozyme that is capable of cleaving an external substrate. Through comprehensive sequence truncations, we have reduced the size of the trans catalyst from 99 nt to 51 nt, with the removal of 30 and 18 residues from the 5′ and

© 2007 NRC Canada

3′ ends of the catalyst, respectively. Internal nucleotide truncation experiments showed that the minimized trans catalyst contains two essential short sequence elements flanking a larger central sequence motif. This central element appears to play important (but not essential) roles in the catalytic function of pH3DZ1, based on the observation that deleting as few as 3 nucleotides anywhere in this region severely reduced the activity of the trans catalyst.

A reselection experiment was subsequently performed, which led to the identification of 12 absolutely conserved, 17 highly conserved, and 2 hyper-mutated nucleotides. Not surprisingly, all absolutely conserved nucleotides are distributed in the two essential sequence elements, with 7 nt at the 5′ end of the minimized catalyst and 5 nt at the 3′ end. The reselection experiment also revealed that the central sequence element contained 14 of the 17 highly conserved nucleotides, which explains why each 3-nt deletion within this region caused significant reduction in the activity of the deoxyribozyme.

It is reasonable to speculate that many (if not all) of the absolutely conserved nucleotides at the two ends of the minimized catalyst are involved both in the construction of the catalytic site and in the catalyst–substrate recognition, and the substrate-binding and (or) catalytic roles rendered by these essential nucleotides also require the additional support provided by the nucleotides in the central sequence element. The precise structure of pH3DZ1 can only be revealed by high-resolution techniques including NMR and X-ray crystallography, which will be the subject of future experimentation.

Many RNA-cleaving deoxyribozymes that cleave a standard RNA substrate or an RNA–DNA chimeric substrate under neutral pH have been isolated from random-sequence DNA pools by in vitro selection experiments (19, 28–39, 41, 57–65). The optimized pH3DZ1 is different from the known neutral pH-functional RNA-cleaving deoxyribozymes such as 10–23 and 8–17 in the following aspects. First, neutral deoxyribozymes are relatively small in size. Both 10–23 and 8–17 are made of less than 30 nucleotides, roughly half of which were used as the catalytic core and the other half as two substrate-binding arms (30, 37). The minimized pH3DZ1 is about twice as large, requiring ~50 nucleotides for the full catalytic activity. Second, the neutral RNA-cleaving deoxyribozymes whose secondary structures have been characterized interact with their substrates through the formation of two short Watson–Crick helices. Because of extensive protonation at the N1 atom of adenosine and the N3 atom of cytosine (both of which are hydrogen-bonding sites in Watson–Crick base pairs) at pH 3, DNA is not expected to adopt Watson–Crick interactions in this highly acidic environment. We speculate that the lack of simple yet effective Watson–Crick interactions might be the key reason behind the increased size of pH3DZ1, because pH3DZ1 may require a large number of nucleotides for the formation of more complex tertiary structure.

The two unique properties associated with pH3DZ1, its optimal activity in highly acidic solutions and its synchronized catalysis-signaling capability, may offer an opportunity for creating unique molecular sensors for unconventional applications. It is conceivable that the in vitro selection approach could be utilized again to select low pH-functional allosteric deoxyribozymes from random-sequence pools with a built-in minimized pH3DZ1 sequence. Such molecular sensors might be useful for detecting organic molecules soluble only in highly acidic aqueous solutions, for monitoring chemical (or enzymatic) reactions that can only be carried out in acidic environment, or for analyzing biological samples under highly acidic conditions for the purpose of inactivating nucleases. We are currently testing these ideas and will report our findings in future publications.

Materials and methods

All the DNA oligonucleotides used in this study were synthesized by automated DNA–RNA synthesis (W.M. Keck Oligonucleotide Synthesis Facility, Yale University, New Haven, Connecticut, and Integrated DNA Technologies) following the standard phosphoramidite chemistry. The partially randomized DNA library used for reselection was synthesized using the following mixture of the four standard phosphoramidites (produced by manual mixing): 76% of the wild-type nucleotide and 8% of each of the remaining 3 nucleotides using a protocol described previously (50). Before use, DNA oligonucleotides were purified by 10% denaturing (8 mol/L urea) PAGE. The triisopropylsilyloxymethyl (TOM) group of the DNA–RNA chimeric substrate was removed following the previously reported method (35). Radioactive nucleotides ([γ-^{32}P]ATP and [α-^{32}P]dGTP) were purchased from GE Healthcare. T4 DNA ligase, T4 polynucleotide kinase (PNK), and deoxynucleoside 5′-triphosphates (dNTPs) were purchased from MBI Fermentas. All other chemical reagents were purchased from Sigma-Aldrich and used without further purification.

All catalytic assays and reselection experiments were conducted in the selection–assay buffer containing citric acid (50 mmol/L), NaCl (500 mmol/L), with the acidity of the solution adjusted to pH 3.0 at 25 °C. The 2× stop solution contained EDTA (80 mmol/L, pH 8.0, 25 °C), urea (16 mol/L), Tris (180 mmol/L), boric acid (180 mmol/L), sucrose (20% *w*/*v*), xylene cyanol (0.05%) and bromophenol blue (0.05%). The DNA phosphorylation and ligation reactions were performed according to the manufacturer protocols.

Assessing activity of cis-acting deoxyribozymes

For cleavage reactions involving cis-acting deoxyribozymes, the deoxyribozymes were first ligated with the 23-nt substrate (its sequence is given in Fig. 1*A*) following the previously reported protocol (35). The ligated construct was then purified by 10% PAGE. This deoxyribozyme (1 pmol in 2.5 μL H_2O) was heated at 90 °C for 30 s and then cooled to room temperature (RT) for 5 min. The cleavage reaction was started with the addition of 2.5 μL of 2× selection–assay buffer at RT. The final DNA concentration was set at ~0.2 μmol/L. An aliquot of the reaction mixture was withdrawn at 0.1, 1, 10, 100, and 1000 min and quenched with the 2 × stop solution. Cleavage products were analyzed by 10% denaturing PAGE and product yields were determined by quantitating product bands using Typhoon and ImageQuant software (Molecular Dynamics).

© 2007 NRC Canada

Assessing activity of trans-acting deoxyribozymes

For cleavage reactions involving trans-acting deoxyribozymes under single-turnover conditions, 2.5 pmol of each substrate (S1) was mixed with 75 pmol of a relevant deoxyribozyme (the volume was adjusted to 2.5 μL with double distilled water), heated to 90 °C for 30 s and cooled to RT for 5 min. Then, 2.5 μL of 2× selection–assay buffer was added to initiate the cleavage reaction at RT. After the time period as indicated in the relevant figures, the reaction was stopped by adding the 2× stop solution. The cleaved products were analyzed by 10% denaturing PAGE and the product yields were visualized using Typhoon 9200 and quantitated using ImageQuant software. It should be noted that Typhoon 9200 was used for both phosphorimage and fluorimage in this study.

Reselection of pH3DZ1 mutants

A partially randomized DNA library was used to carry out the reselection according to the previously reported protocol (35) with some variations (all the DNA sequences are listed in Fig. 4*A*). Briefly, 500 pmol of gel-purified library (L1) was phosphorylated at the 5′-end with 20 μCi of [γ-^{32}P]ATP and PNK and then ligated with the substrate S2. In the first round of reselection, 100 pmol of ligated DNA in 50 μL of water was heated at 90 °C for 30 s and cooled to RT for 5 min. After addition of 50 μL of the 2× selection–assay buffer and incubation for 5 h at RT, the reaction was quenched by EDTA (pH 8.0) to a final concentration of 30 mmol/L. The cleavage fragment was isolated by 10% denaturing PAGE, amplified by PCR, and then made into single-stranded DNA, all according to the previous protocol (35). Subsequent rounds of reselection were carried out in a similar way. The DNA population after the sixth round was cloned by TA cloning technique and the plasmids from ~30 clones were sequenced, again following the previously published protocol (35).

Determination of pH profiles

The RNA cleavage activity of trans-acting deoxyribozyme ETA and ETB.1 (sequences given in Figs. 2 and 3) was assessed in solutions with pH of 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, and 5.0 (pH of each final mixture). The reaction mixture containing 2.5 pmol of substrate S1 (5′-^{32}P labeled) and 75 pmol of deoxyribozyme was heated to 90 °C for 30 s and cooled to RT for 5 min. The cleavage reaction was initiated with the addition of 2.5 μL of the 2× selection–assay buffer. After incubation at RT for 30 min, the reaction was stopped by adding the 2× stop solution. The products were analyzed by 10% denaturing PAGE. The bands were visualized by Typhoon 9200 and quantified by ImageQuant software.

Characterization of cleavage products

Preparation of substrate (S3)

Five hundred pmol of P2 was radiolabeled at the 5′-end with γ-^{32}P[ATP] and covalently ligated to P1 following the reported method (52). This ligated 35-nt substrate (sequence shown in Fig. 7) was purified by 10% denaturing PAGE.

Determination of cleavage products by enzymatic digestion

S3 (0.5 μmol/L) was allowed to cleave in the presence of ETB.2 (15 μmol/L, 60 μL reaction volume) for 1 h under the same selection–assay condition as described earlier. The cleaved products were isolated by ethanol precipitation (four times) and the pellet was resuspended in 24 μL of deionized water. One μL of this DNA solution was used for each enzymatic probing reaction that involved PNK, CIAP, CNPase, CNPase–PNK, and CNPase–CIAP, respectively. Both PNK- and CIAP-mediated reactions were carried out at 37 °C for 1 h in a 10 μL reaction mixture containing 10 units of either PNK or CIAP in a reaction buffer supplied by the manufacturer. The CNPase-mediated hydrolysis of 2′,3′-cyclic phosphate was conducted at 37 °C for 1 h in a 6 μL mixture containing ~5.0 units of CNPase, Tris–HCl (50 mmol/L, pH 7.5 at 25 °C), NaCl (50 mmol/L), DTT (1 mmol/L), and glycerol (10%). To this reaction mixture, PNK (or CIAP) buffer was added, followed by the addition of PNK (or CIAP); the final reaction volume reached 10 μL. Each mixture was incubated at 37 °C for another hour. Following the inactivation of the concerned enzyme at 90 °C for 2 min, the DNA fragments in the mixture were separated by 10% denaturing PAGE and analyzed using Typhoon 9200 and ImageQuant software.

Ion-tagged synthesis of an oligoribonucleotide pentamer — The continuing versatility of TBDMS chemistry[1]

Robert A. Donga, Tak-Hang Chan, and Masad J. Damha

Abstract: An oligoribonucleotide has been synthesized in solution, using an ionic-liquid-based soluble tag at a scale several hundred times that of a standard solid-phase synthesis approach. Ogilvie's 2′-TBDMS strategy was adopted, and because of the resultant increase in lipophilicity, it allowed an easier purification of the growing oligomer compared with the previously observed for DNA, which does not require 2′ protection. The procedure is illustrated by the synthesis of the pentaribonucleotide sequence AGAUC, corresponding to a segment of the $tRNA^{fMet}$ from *E. coli.*

Key words: solution-phase RNA synthesis, ionic-liquid tag.

Résumé : Nous avons réalisé la synthèse d'un oligoribonucléotide en solution en utilisant un support soluble à base d'un liquide ionique dont la quantité correspond à plusieurs centaines de fois celle qui serait utilisée dans une approche basée sur une synthèse en phase solide normale. On a adopté la stratégie 2′-TBDMS d'Ogilvie et on a trouvé que, en raison de son caractère lipophile, la purification de l'oligomère croissant se fait beaucoup plus facilement que ce qui a été observé avec l'ADN qui ne requiert pas de protection en 2′. La méthode est illustrée par la synthèse de la séquence du pentaribonulcléotide AGAUC qui correspond à un segment de la $t\text{-}ARN^{fMet}$ du *E. coli*.

Mots-clés : synthèse d'ARN en solution, traceur ionique liquide.

[Traduit par la Rédaction]

Introduction

Since it was first introduced by Ogilvie and co-workers in 1974 (1), the *tert*-butyl dimethylsilyl (TBDMS) group has become the standard 2′-protecting group in both solid- and solution-phase oligomerizations of ribonucleotides (2). Along with the phosphoramidite approach (3) to ribonucleoside coupling, the TBDMS group remains one of the most widely used 2′-protecting groups for commercially available ribo-phosphoramidites. With the advent of RNAi and an increasing number of RNA-based therapeutics progressing toward clinical development (4), the TBDMS approach will continue to be an important resource as more commercially viable processes are developed for the large-scale synthesis of oligoribonucleotides.

However, the limitation in RNA chemistry, thus far, has been the cost-efficient preparation of oligomers at a sufficiently large scale. A solid-phase approach to large-scale DNA and RNA synthesis is expensive because of the cost of the solid supports and the need for a large excess of phosphoramidite compared with what is usually required in a solution-phase approach (5). A conventional solution-phase approach, where the 3′-terminal nucleoside is not linked to a support but simply protected at the 3′ position (and 2′ for RNA), is intrinsically arduous because of the necessity of chromatographic purification after each coupling cycle. An alternative approach, developed by Bonara et al. (6), uses a soluble polyethylene glycol tag for DNA solution-phase synthesis. In an effort to improve this strategy, which requires an energy-intensive cooling step during purification, and to adapt it to use in RNA, we have been exploring the utility of ionic liquids as soluble supports in oligonucleotide synthesis (7). Herein, we report the preparation of a pentaribonucleotide in solution, requiring only simple precipitations at ambient temperature for purification during the chain-extension cycles. The process retains the versatile TBDMS group as the 2′-protecting group. The pentaribonucleotide was prepared on a 1 g scale and was assembled in 32 h (an average of 8 h per coupling cycle).

Discussion

The sequence of the selected pentaribonucleotide represents base positions 45 to 49 of an unpaired coil region of *N*-formyl methionine tRNA from *E. coli*. It was selected primarily because it contains all four common ribonucleosides. It is also a sequence that has been previously synthesized in solution by Damha using the phosphite triester approach (8), which required several weeks to achieve. The latter compound serves as a good reference standard for the pentaribonucleotide made by the process described here.

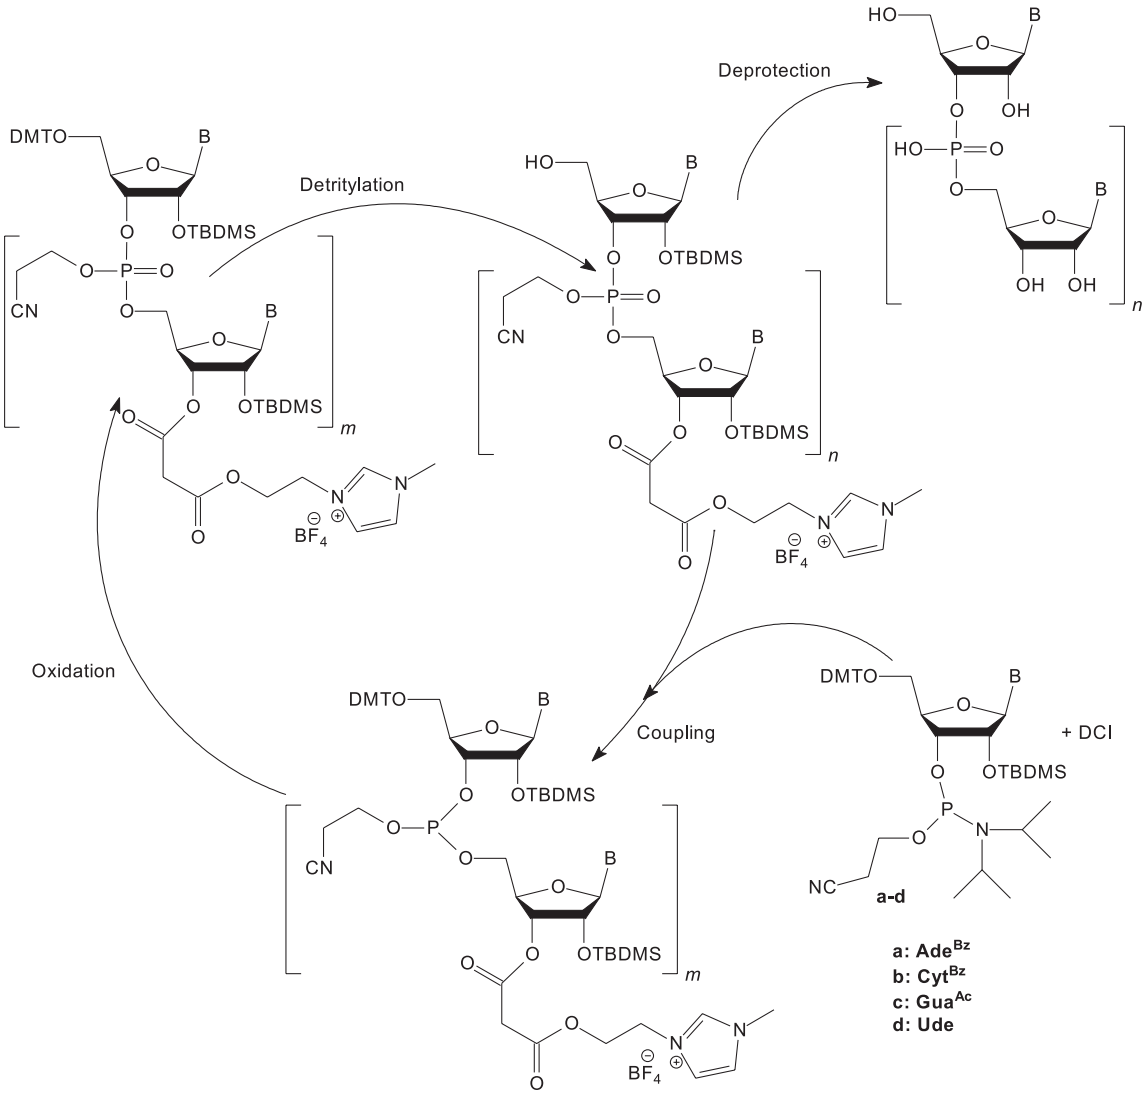
Scheme 1. Nucleoside succinylation.

a: Succinic anhydride, 4-dimethylaminopyridine, and anhydrous acetonitrile

Scheme 2. Coupling of ionic tag.



a: *O*-(benzotriazol-l-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium tetrafluoroborate, triethylamine, and anhydrous acetonitrile

Synthesis began with the attachment of the 3′-cytidine to the ionic ethyl-methyl-imidazolium tag through a succinyl linker. Thus, *N*-benzoyl-2′-*tert*-butyldimethylsilyl-5′-dimethoxytrityl-cytidine was reacted with succinic anhydride in the presence of 4-dimethylaminopyridine (DMAP). The presence of the base, DMAP, caused the 2′-TBDMS protecting group to isomerize, yielding a statistical mixture of 2′-TBDMS- and 3′-TBDMS-protected cytidine with no alteration of the other protecting groups (Scheme 1). However, this isomerization is inconsequential, since the 2′/3′-silyl group and the 3′/2′-succinyl linker of this terminal nucleoside will be removed to release the required 2′- and 3′-OH groups during the final deprotection step of the desired full-length pentamer. In addition, it would be expected that the solubility properties of the two regioisomers, an important consideration for the purification steps, would be very similar. Succinylation at the free 3′- or 2′-hydroxyl group provided the 2′/3′-succinylated nucleoside along with some unreacted nucleoside. This crude mixture was then esterified with the free hydroxyl group of the ionic tag (Scheme 2). In our previous work (7), dicyclohexylcarbodiimide (DCC) was used as the condensing reagent, but long reaction times were required (3–7 d), and the yield of the desired succinate ester was only 65%–85%. An alternative coupling reagent, *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU), proved to be more suitable for this reaction. In addition, its counterion, tetrafluoroborate, matched that of the ionic liquid employed as the tag. Thus, the succinylated nucleoside **1** and TBTU were first mixed in the solid state, followed by the addition of the ionic liquid [3-(2′-hydroxyethyl)-1-methylimidazolium tetrafluoroborate], triethylamine, and finally the solvent. The reaction was complete in less than 90 min, yielding the desired product **2** and a small amount of nucleoside dimer; the latter formed by the reaction of **2** with a small amount of 5′-DMT rC^{NBz} TBDMS that was carried forward from the succinylation step. At this point, a water–chloroform extraction was performed to remove any excess ionic liquid, the excess coupling reagent, and the resulting tetramethylurea by-product of the reaction, leaving a mixture of nucleoside dimer and the desired product **2**. The ion-tagged nucleoside **2** was easily separated from the dimer and any other remaining impurities by two simple precipitations. In our previous work on DNA oligomers (7), the preferred precipitation medium consisted of a mixture of ethyl acetate and diethyl ether. This yielded purer precipitates than diethyl ether alone by effectively solubilizing the undesired by-products while generating the desired tagged oligomer as a finely divided precipitate. However, when this media was used here, it was found that the nucleoside **2** was slightly soluble, resulting in a loss of the desired product and collapse of the precipitate into a slightly impure waxy solid. Therefore, the system was changed to neat diethyl ether as this was found to restore the desired properties of the precipitation medium with no appreciable loss of the tagged materials.

The synthesis cycle (Scheme 3) requires the removal of the DMT group at the 5′-terminus of the growing oligonucleotide chain. Generally, this is achieved by treatment with trifluoroacetic acid in dichloromethane. In our earlier work on DNA, this step was often problematic, especially for removing the DMT group from the nucleoside unit directly linked to the ionic tag. We ascribe the slower rate of DMT cleavage to the proximal imidazolium ion, which makes protonation of the O5′ rate limiting. A similar phenomenon is generally invoked to explain the slower rate of esterification of glycine (NH_3^+–CH_2–COOH), relative to propanoic acid under acidic conditions (9). Consistent with this notion, the rate of detritylation increases as the site of

Scheme 3. Oligoribonucleotide coupling cycle (illustrated as one regioisomer).

protonation is spatially removed from the positively charged ion tag (i.e., rate of detritylation of trimer > monomer; see later). Alternate detritylation methods employing Lewis acids, such as zinc bromide, were tested and found to be somewhat successful, but Lewis acids were more difficult to remove via precipitation. Thymine and cytosine, and to a greater extent adenine and guanine, are sensitive to acid-mediated depyrimidation/depurination (10), rendering the application of stronger acids troublesome in DNA synthesis. Because of the inductive effects of 2′-OH groups, RNA is not as prone to acid-mediated depurination; therefore, a stronger acid may be employed in the detritylation step. Thus, *p*-toluenesulphonic acid was selected as the detritylation reagent, as it was found that a single treatment was sufficient to achieve complete detritylation of the first nucleoside. Weaker acids, such as trifluoroacetic acid, required multiple treatments and longer reaction times to achieve the same result.

With the 5′ position of the 3′-nucleoside deblocked, the oligomerization cycle could begin (Scheme 3). The nucleoside **3** was mixed with 1.66 equiv. of ribouridine (2′-TBDMS-protected) 3′-cyanoethylphosphoramidite, using 4,5-dicyanoimidazole (DCI) as the activator (0.06 mol/L in anhyd. acetonitrile). After 2 h of stirring, excess *tert*-butanol (approximately 6 equiv.) was added to quench the excess phosphoramidite and to enhance the solubility of the resulting nucleoside 3′-(*tert*-butyl-2-cyanoethyl) phosphite triester by-product in the precipitation medium. The intermediate UpC dimer was isolated and purified by adding the reaction mixture dropwise to stirred diethyl ether. The resultant fine precipitate was filtered over celite and recovered from the filter by dissolving in acetone.

Once purified, the intermediate UpC phosphite triester was redissolved in anhydr. acetonitrile, and a capping step was performed using acetic anhydride and DMAP. In our DNA synthesis (7), oxidation of the intermediate phosphite triester to the phosphate was achieved using iodine as the oxidant. This procedure necessitated a difficult extraction to remove the generated salts but precluded the need for a capping step, since any unreacted oligomer would be removed with the aq. phase. The difficulty of the extraction (because of the formation of strong emulsions) outweighed the advan-

tage of the removal of the capping step, especially since the capping step overcomes the undesirable O6 extension sometimes observed for guanosine (11). Thus, in the present protocol for RNA, the capping step was reinstated, and the oxidation procedure was changed to employ a reagent that would not require extractions. *tert*-Butylhydroperoxide (6 mol/L) in decane was chosen and found to completely oxidize the phosphite triester in less than 15 min. A further advantage is that it could easily be removed, together with its by-product *tert*-butanol, since it was completely soluble in the precipitation medium. At this point, it was observed by mass spectroscopy that the original tetrafluoroborate counteranion of the tag had been exchanged for dicyanoimidazolide, an effect that was not observed in our previous work on DNA synthesis. Indeed, anion exchange occurred several times during the synthesis cycles, alternating between dicyanoimidazolide and *p*-toluenesulphonate, but this did not appear to adversely affect the solubility properties of the intermediate di (UpC), tri (ApUpC), tetra (GpApUpC), and pentanucleotides (ApGpApUpC), isolated during and after each coupling step (see later). It had been previously observed in other experiments (data not shown) that the solubility properties of these types of molecules were adversely affected when exchanges occurred for halides; thus, the identity of the counterion is of importance, since a change in solubility can have a dramatic impact on the quality and yield of the synthesis cycle. Therefore, this must be taken into account during the design of the oligomerization cycle such that if anion exchanges occur, the resulting ion-paired molecule maintains an acceptable level of solubility in the solvents used for synthesis and recovery, while also maintaining its insolubility in the precipitation medium.

Chain extension proceeded as previously outlined, but it was found that the yields exceeded 100% after the detritylation steps, as determined by the weight of the product (Table 1). This was due to the incomplete removal of *p*-toluenesulphonic acid, which subsequently interfered with the next coupling steps (e.g., premature detritylation following the next coupling step). Once this effect was realized, the detritylating reagent was substituted with the volatile trifluoroacetic acid, which could be more readily removed during the precipitation step or afterwards, by evaporation if necessary. Again, this approach necessitated two acid treatments per detritylation step, but no further premature detritylation was observed at the coupling stage, and precipitations alone were sufficient to remove the acid. Thus, while it has been found that weaker acids may be used for the detritylation step of the oligomerization cycle shortly after the initial nucleoside is deprotected, multiple treatments are still required so it would be advantageous to use stronger acids if their complete removal could be assured.

One of the advantages of solution-phase over solid-phase synthesis of oligomers is the capacity to directly monitor chain elongation by various means, including mass spectrometry (MS). Indeed, ion-tagged oligomers are especially amenable to this technique, since the molecules contain permanent positive charges. This means that ion-tagged molecules only need to have their solutions nebulized in an electrospray ionization (ESI) source to give very strong MS signals. Indeed, when using an octopole analyzer, short oligomers provided excellent results. Long oligomers quickly exceed the upper limits of the mass detector; however, in these cases multiple charging occurred more readily, pulling the analyte back into an observable window (Fig. 1). This is noticed by comparing the mass spectrum for longer oligomers to that of UpC (Fig. 2). For the dimer, the ion tag creates a high-energy barrier to protonation and likewise to formation of these adducts. As the chain length increases, the site of protonation is spatially removed from the positively charged ion tag, and adducts are readily observed. Using this technique, the identities of all post-detritylation compounds were confirmed by HR-ESIMS (Table 2).

Finally, the pentamer **11** was deprotected to the free nucleotide in parallel with a sample of the original sequence **8**, made by the original solution-phase approach (8). This consisted of treatment of 1–2 mg of each detritylated (but otherwise fully protected oligomer) with 1 mL of 40% (*v*/*v*) aq. methylamine and incubating at 60 °C for 20 min. The resultant solution was cooled to –78 °C and dried under vacuum. The resultant solid was treated with 300 µL of 1.5:0.75:1 (*v*/*v*/*v*) triethylamine trihydrofluoride – 1-methyl-2-pyrrolidinone – triethylamine solution and incubated for 90 min at 60 °C (12). The reaction mixture was then cooled to ambient temperature and 1 mL of anhyd. ethanol was added. The samples were mixed and cooled at –78 °C for 30 min, resulting in precipitates. The samples were then centrifuged at 14000 r/min at 4 °C for 30 min, and the supernatant was removed. The precipitates were washed

with 200 μL of –78 °C ethanol, and then the residual solvent was removed under vacuum. The precipitates were dissolved in 1 mL of autoclaved, deionized water and loaded onto Waters® Sep-Pak™ C_{18} cartridges for desalting. The cartridges were rinsed with water, and then the desired products were eluted with 1:1:1 (*v*/*v*/*v*) water–methanol–acetonitrile. The solvent was removed under vacuum to yield the crude, deprotected AGAUC pentamers.

The identity and purity of the pentamers were assessed using a triethylammonium acetate ion-pairing reverse-phase

Fig. 3. HPLC chromatogram of the co-injection of **11** and solution-phase synthesized standard.

HPLC analysis on a Phenomenex® Clarity™ semipreparatory-scale column. The samples were injected individually, and the major peaks in the chromatograms were collected and analyzed by low resolution ESIMS in the negative mode. The major ion found in both cases corresponded exactly to the expected mass of the fully deprotected AGAUC pentamers missing a single proton (1551 daltons). The two samples were also co-injected at a 1:1 ratio in the HPLC column and found to overlap perfectly (Fig. 3). As a final test to show that the deprotected compounds were identical, they were analyzed side by side, co-loaded on a 24% polyacrylamide gel, and electrophoresed (data not shown). In all cases, single bands with the same electrophoretic mobility were found, showing that indeed the synthesis using the ionic tag yielded, after deprotection, an identical compound to that of the standard solution-phase-derived molecule.

Conclusion

In summary, a functional method has been developed to rapidly synthesize oligoribonucleotides in solution and in excellent yields. The method utilizes simple precipitations as the sole purification method during chain elongation and is amenable to scales several hundred times that of a standard solid-phase synthesis. Although 5′-detritylation continues to pose a challenge, the presence of the lypophilic TBDMS group greatly enhances the solubility of the phosphoramidite monomers in the medium used for the precipitation-based purifications. Thus, the purification of RNA using this approach is superior to that of DNA, as observed in our previous work (7). We believe that the soluble ionic tag we have developed, in conjunction with Ogilvie's RNA method, enable the synthesis of short RNA oligomers as rapidly as DNA. We will further explore the limits of this method with target sequences corresponding to those of short interfering RNA (19–23 nucleotides).

Experimental

N-benzoyl-2′/3′-*tert*-butyldimethylsilyl-3′/2′-succinyl-5′-dimethoxytrityl-cytidine (1)

N-benzoyl-2′-*tert*-butyldimethylsilyl-5′-dimethoxytrityl-cytidine (1 g, 1.31 mmol) was mixed with succinic anhydride (0.39 g, 3.93 mmol) and 4-dimethylaminopyridine (0.16 g, 1.34 mmol), and the mixture was dissolved in 30 mL of dry acetonitrile. The reaction was stirred for 4 d at room temperature, and the progress was determined by TLC (9:1 dichloromethane–methanol), which showed the disappearance of the starting material and the appearance of two products (2′-3′ isomerization of the TBDMS-protecting group). The solvent was removed under vacuum, and the resulting solid was taken up in chloroform and extracted with water. The organic layer was dried with anhyd. sodium sulphate, filtered, and the solvent was removed under vacuum. The resulting crude product (1.1 g,

© 2007 NRC Canada

97%) was used without further purification. $C_{47}H_{54}N_3O_{11}Si^+$ (low resolution ESIMS) calculated: 864.3; found: 863.9.

N-benzoyl-2′/3′-*tert*-butyldimethylsilyl-3′/2′-(1-succinyl-4-[3-(2″-oxyethyl)-1″-methylimidazolium tetrafluoroborate])-5′-dimethoxytrityl-cytidine (2)

Compound **1** (1.1 g, 1.31 mmol) was mixed with TBTU (0.5 g, 1.58 mmol), 3-(2′-hydroxyethyl)-1-methylimidazolium tetrafluoroborate (0.34 g, 1.58 mmol) and triethylamine (0.4 mL, 2.62 mmol). The mixture was dissolved in 20 mL dry acetonitrile and stirred for 90 min. The solvent was then removed under vacuum, and the resulting oil was taken up in chloroform and extracted with water. The organic layer was dried over sodium sulphate. The solvent was removed under vacuum, and the resulting solid was dissolved in 5 mL of acetone. The solution was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether, taken up in acetone, and precipitated again. The solid was filtered off, rinsed, and collected from the filter by dissolution in acetone (1.01 g, 73%) and was used without further purification. $C_{53}H_{62}N_5O_{11}Si^+$ (low resolution ESIMS) calculated: 972.4; found: 972.3, tetrafluoroborate counterion by ESIMS.

N-benzoyl-2′/3′-*tert*-butyldimethylsilyl-3′/2′-(1-succinyl-4-[3-(2″-oxyethyl)-1″-methylimidazolium *p*-toluenesulphonate])-cytidine (3)

Compound **2** (0.69 g, 0.65 mmol) was dissolved in 10 mL of 0.1 mol/L *p*-toluenesulphonic acid solution in acetonitrile and stirred for 10 min. Methanol (5 mL) was added to quench the trityl cation, and the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether, taken up in acetone, and precipitated again. The solid was filtered off, rinsed, and collected from the filter by dissolution in acetone (0.51 g, 93%) and was used without further purification. $C_{32}H_{44}N_5O_9Si^{+1}$ (HR-ESIMS) required: 670.29069; found: 670.29028, *p*-toluenesulphonate counterion by ESIMS.

5′-DMT-rU-(2′-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as dicyanoimidazolide salt) (4)

Compound **3** (0.44 g, 0.53 mmol) was mixed with 2-*tert*-butyldimethylsilyl-5-dimethoxytrityl-uridine-3-cyanoethyl-phosphoramidite (0.75 g, 0.88 mmol) and dicyanoimidazole (0.14 g, 1.2 mmol), and the mixture was dissolved in 20 mL of dry acetonitrile. The reaction mixture was stirred for 2 h, and then 0.5 mL of *tert*-butanol was added. The mixture was stirred a further 15 min and was then precipitated from diethyl ether as with previous compounds. The precipitate was isolated from the filter by dissolving in acetone and then removing the solvent under vacuum. The resulting solid was dissolved in 5 mL of dry acetonitrile and 250 μL each of a 17.5% (*v*/*v*) solution of acetic anhydride in anhyd. acetonitrile and saturated dimethylaminopyridine in 25% (*v*/*v*) anhyd. pyridine – acetonitrile. This reaction mixture was stirred for 10 min, and then 0.5 mL of 6 mol/L *tert*-butylhydroperoxide in decane was added. After a further 10 min of stirring, the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether, and collected from the filter by dissolution in acetone (0.77 g, 93%) and was used without further purification. $C_{71}H_{90}N_8O_{19}PSi_2^+$ (low resolution ESIMS) calculated: 1445.6; found: 1446.0, dicyanoimidazolide counterion by ESIMS.

5′-HO-rU-(2′-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as *p*-toluenesulphonate salt) (5)

Compound **4** (0.77 g, 0.49 mmol) was dissolved in 10 mL of 0.1 mol/L *p*-toluenesulphonic acid solution in acetonitrile and stirred for 10 min. Methanol (5 mL) was added to quench the trityl cation, and the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether, taken up in acetone, and precipitated again. The solid was filtered off, rinsed and collected from the filter by dissolution in acetone (0.68 g, 0.65 g theoretical yield, excess thought to be residual salts), dried under vacuum, and was used without further purification. ^{31}P NMR (ppm): 0.082 to –0.513. $C_{50}H_{73}N_8O_{17}Si_2P^{+2}$ (HR-ESIMS) required: 572.21727; found: 572.21795, *p*-toluenesulphonate counterion by ESIMS.

5′-DMT-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rU-(2′-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as dicyanoimidazolide salt) (6)

Compound **5** (0.60 g, 0.46 mmol) was mixed with *N*-benzoyl-2′-*tert*-butyldimethylsilyl-5′-dimethoxytrityl-adenosine (1.65 g, 1.67 mmol) and dicyanoimidazole (0.12 g, 1.0 mmol), and the mixture was dissolved in 10 mL of dry acetonitrile. Upon addition of solvent, the solution turned pale orange, indicating that the excess mass appreciated in the previous step was likely *p*-toluenesulphonic acid, causing some detritylation of the incoming phosphoramidite. The reaction was stirred for 1 h, and then 0.5 mL of *tert*-butanol was added. The mixture was stirred a further 15 min and was then precipitated from diethyl ether, as with previous compounds. The precipitate was isolated from the filter by dissolving in acetone and then removing the solvent under vacuum. The resulting solid was dissolved in 5 mL of dry acetonitrile and 250 μL each of a 17.5% (*v*/*v*) solution of acetic anhydride in anhyd. acetonitrile and saturated dimethylaminopyridine in 25% (*v*/*v*) anhyd. pyridine – acetonitrile. This reaction mixture was stirred for 10 min, and then 0.5 mL of 6 mol/L *tert*-butylhydroperoxide in decane was added. After a further 10 min of stirring, the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether, collected from the filter by dissolution in acetone (0.89 g, 91%), and was used without further purification. $C_{97}H_{123}N_{14}O_{26}P_2Si_3Na^{2+}$ (low resolution ESIMS) calculated: 1034.4; found: 1034.5, dicyanoimidazolide counterion by ESIMS.

5′-HO-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rU-(2-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as *p*-toluenesulphonate salt) (7)

Compound **6** (0.89 g, 0.41 mmol) was dissolved in 5 mL of 0.1 mol/L *p*-toluenesulphonic acid solution in acetonitrile and stirred for 10 min. Methanol (1 mL) was added to quench the trityl cation, and the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided

precipitate. The precipitate was filtered off, rinsed with diethyl ether, dissolved off the filter with acetone, and dried under vacuum. TLC analysis indicated that detritylation was incomplete, so the solid was dissolved in a further 5 mL of 0.1 mol/L *p*-toluenesulphonic acid solution in acetonitrile and stirred for 10 min. Methanol (1 mL) was again added to quench the trityl cation, and the reaction mixture was precipitated as before. The precipitate was filtered off, rinsed with diethyl ether, and collected off the filter by dissolution in acetone. The solution was concentrated under reduced pressure to an approximate volume of 5 mL and was again precipitated from diethyl ether. The solid was filtered off, rinsed with diethyl ether and collected from the filter by dissolution in acetone (0.81 g, 0.79 g theoretical yield, excess thought to be residual salts), dried under vacuum, and was used without further purification. ^{31}P NMR (ppm): 0.510 to –0.508. $C_{76}H_{106}N_{14}O_{24}Si_3P_2^{+2}$ (HR-ESIMS) required: 872.31268; found: 872.31383, *p*-toluenesulphonate counterion by ESIMS.

5′-DMT-rG-(*N*-Ac, 2′-TBDMS)-3′-5′-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rU-(2′-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as *p*-toluenesulphonate salt) (8)

Compound **7** (0.71 g, 0.37 mmol) was mixed with *N*-acetyl-2′-*tert*-butyldimethylsilyl-5′-dimethoxytrityl-guanosine (0.72 g, 0.77 mmol) and dicyanoimidazole (0.10 g, 0.84 mmol), and the mixture was dissolved in 7 mL of dry acetonitrile. Upon addition of the solvent, the solution turned slightly orange, indicating that the excess mass appreciated in the previous step was likely *p*-toluenesulphonic acid, causing some detritylation of the incoming phosphoramidite. The reaction was stirred for 1 h, and then 0.5 mL of *tert*-butanol was added. The mixture was stirred a further 15 min and was then precipitated from diethyl ether, as with previous compounds. The precipitate was isolated from the filter by dissolving in acetone and then removing the solvent under vacuum. The resulting solid was dissolved in 5 mL of dry acetonitrile and 250 µL each of a 17.5% (*v*/*v*) solution of acetic anhydride in anhyd. acetonitrile and saturated dimethylaminopyridine in 25% (*v*/*v*) anhyd. pyridine – acetonitrile. This reaction mixture was stirred for 10 min, and then 0.5 mL of 6 mol/L *tert*-butylhydroperoxide in decane was added. After a further 10 min of stirring, the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether and collected from the filter by dissolution in acetone (1.02 g, 99%), and was used without further purification. Low resolution MS indicated that no anion exchange occurred in this cycle (i.e., counterion remained *p*-toluenesulphonate). $C_{118}H_{154}N_{20}O_{34}P_3Si_4Na^{2+}$ (low resolution ESIMS) calculated: 1311.5; found: 1311.7, *p*-toluenesulphonate counterion by ESIMS.

5′-HO-rG-(*N*-Ac, 2′-TBDMS)-3′-5′-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rU-(2′-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as *p*-toluenesulphonate salt) (9)[3]

Compound 8 (1.02 g, 0.37 mmol) was dissolved in 5 mL of 3% (*v*/*v*) trifluoroacetic acid in acetonitrile (~0.4 mol/L) and stirred for 10 min. Acetone (1 mL) was added to facilitate precipitation, and the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether, dissolved off the filter with acetone, and dried under vacuum. The solid was redissolved in trifluoroacetic acid solution and stirred for 10 min. Acetone (1 mL) was again added, and the reaction mixture was precipitated as before. The precipitate was filtered off, rinsed with diethyl ether, and collected off the filter by dissolution in acetone. The solution was concentrated under reduced pressure to an approximate volume of 10 mL and was again precipitated from diethyl ether. The solid was filtered off, rinsed with diethyl ether and collected from the filter by dissolution in acetone (0.82 g, 91%), dried under vacuum, and was used without further purification. ^{31}P NMR (ppm): 0.637 to –0.466. $C_{97}H_{137}N_{20}O_{32}Si_4P_3^{+2}$ (HR-ESIMS) required: 1149.39748; found: 1149.39934, *p*-toluenesulphonate counterion by ESIMS.

5′-DMT-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rG-(*N*-Ac, 2′-TBDMS)-3′-5′-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rU-(2-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as *p*-toluenesulphonate salt) (10)

Compound **9** (0.71 g, 0.29 mmol) was mixed with *N*-benzoyl-2-*tert*-butyldimethylsilyl-5′-dimethoxytrityl-adenosine (0.72 g, 0.77 mmol) and dicyanoimidazole (0.08 g, 0.65 mmol), and the mixture was dissolved in 7 mL of dry acetonitrile. No colour change was observed upon solvent addition this time. The reaction mixture was stirred for 2 h, and then 0.5 mL of *tert*-butanol was added. The mixture was stirred a further 15 min and was then precipitated from diethyl ether, as with previous compounds. The precipitate was isolated from the filter by dissolving in acetone and then removing the solvent under vacuum. The resulting solid was dissolved in 5 mL of dry acetonitrile and 250 µL each of a 17.5% (*v*/*v*) solution of acetic anhydride in anhyd. acetonitrile and saturated dimethylaminopyridine in 25% (*v*/*v*) anhyd. pyridine – acetonitrile. This reaction mixture was stirred for 10 min, and then 0.5 mL of 6 mol/L *tert*-butylhydroperoxide in decane was added. After a further 10 min of stirring, 1 mL of acetone was added, and the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with diethyl ether and collected from the filter by dissolution in acetone (0.92 g, 95%), and was used without further purification. $C_{144}H_{187}N_{26}O_{41}P_4Si_5Na^{2+}$ (low resolution ESIMS) calculated: 1611.6; found: 1611.8, *p*-toluenesulphonate counterion by ESIMS.

5′-HO-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rG-(*N*-Ac, 2′-TBDMS)-3′-5′-rA-(*N*-Bz, 2′-TBDMS)-3′-5′-rU-(2′-TBDMS)-3′-5′-rC-(*N*-Bz)-2′/3′-TBDMS-Succ-IL (as *p*-toluenesulphonate salt) (11)

Compound **10** (0.92 g, 0.27 mmol) was dissolved in 5 mL of 3% (*v*/*v*) trifluoroacetic acid in acetonitrile (~0.4 mol/L) and stirred for 10 min. Acetone (1 mL) was added to facilitate precipitation, and the reaction mixture was added dropwise to stirred diethyl ether, resulting in a finely divided precipitate. The precipitate was filtered off, rinsed with di-

[3] Because of the residual *p*-toluenesulphonic acid observed carrying over in the previous two coupling cycles, it was decided that a volatile acid would be used for subsequent detritylations.

Synthesis and structure of fluoroindole nucleosides[1]

Jelena Božilović, Jan W. Bats, and Joachim W. Engels

Abstract: Chemically modified bases are frequently used to stabilize nucleic acids, to study the driving forces for nucleic acid structure formation, and to tune DNA and RNA hybridization conditions. Nucleoside analogues are chemical means to investigate hydrogen bonds, base stacking, and solvation as the three predominant forces that are responsible for the stability of nucleic acids. To obtain deeper insight into the contributions of these interactions to RNA stability, we decided to synthesize some novel nucleic acid analogues where the nucleobases are replaced by fluoroindoles. Fluorinated indoles can be compared with fluorinated benzimidazoles to determine the role of nitrogen in five-membered ring systems. The synthesis of fluoroindole ribonucleosides as well as the X-ray crystal structures of all synthesized fluoroindole ribonucleosides are reported here. These compounds could also be building blocks for a variety of biologically active RNA analogues.

Key words: indoles, nucleosides, crystal structure, glycosilation, indole-synthesis.

Résumé : Des bases chimiquement modifiées sont souvent utilisées pour stabiliser les acides nucléiques, pour étudier la force motrice pour la formation de la structure d'acides nucléiques et pour ajuster les conditions d'hybridation de l'ADN et de l'ARN. Les analogues de nucléosides sont des méthodes chimiques d'étudier les liaisons hydrogènes, l'empilement des bases et la solvatation comme les trois forces prédominantes, responsables de la stabilité des acides nucléiques. Afin de mieux évaluer les contributions de ces interactions à la stabilité de l'ARN, on a effectuer la synthèse de nouveaux analogues de l'acide nucléique dans lesquels les nucléobases sont remplacées par de fluoroindoles. On peut comparer les fluoroindoles aux benzimidazoles fluorés pour déterminer le rôle de l'azote dans le système cyclique à cinq chaînons. On rapporte la synthèse des ribonucléosides de fluoroindoles ainsi que les structures déterminées par diffraction des rayons X de tous les ribonucléosides de fluoroindoles. Ces composés pourraient aussi être utilisés dans la synthèse d'une variété d'analogues de l'ARN biologiquement actifs.

Mots-clés : indoles, nucléosides, structure cristalline, glycosilation, synthèse de l'indole.

[Traduit par la Rédaction]

Introduction

A series of fluorobenzimidazole nucleosides has been synthesized earlier and we reported the stabilizing contribution of a C–F···H–C bond (1, 2). The inability of fluorine to compete with stronger hydrogen bond acceptors, such as oxygen and nitrogen, is due to its low polarizability and contracted lone pairs. The fluorobenzimidazole analogues investigated so far all show very similar properties. Indole structure is present in a variety of natural compounds, such as amino acids, alkaloids, etc. The position of fluorine as shown by the dipole moments (Fig. 1) has a greater influence on charge distribution for fluoroindoles than for fluorobenzimidazoles. Thus, we decided to synthesize and evaluate a similar pattern of substitution on fluoroindoles (Fig. 1). To the best of our knowledge, the ribofluoro–indole compounds have not been synthesized and evaluated, though some deoxy compounds have recently been under investigation. The thermodynamic and spectroscopic studies give no information on the fine structure and conformational dynamics of fluorobenzimidazole-containing RNA. Such information would be a valuable comparison to determine the influence of nitrogen in the five-membered ring. As the charge distribution and dipole moments between those two classes of compounds differ significantly, we also expected to observe differences in RNA oligonucleotide stability as a result of containing those building blocks. Here we report strategies for the synthesis (3) of fluoroindole building blocks and the X-ray crystal structures of all synthesized fluoroindole ribonucleosides.

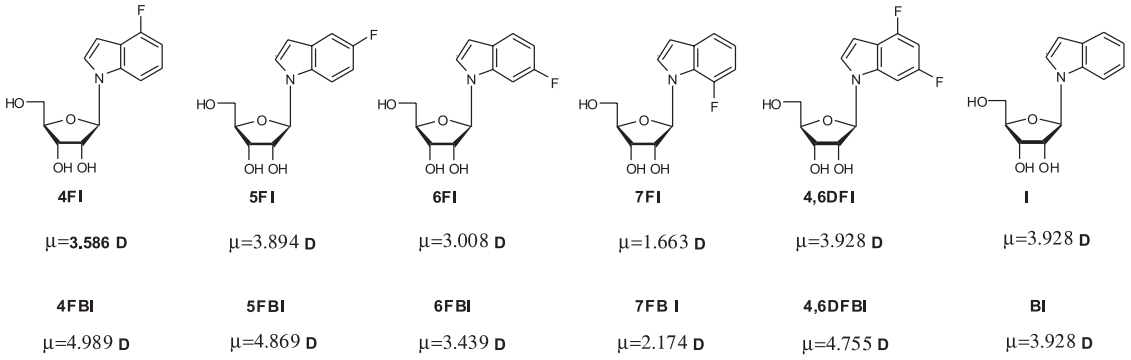
Synthesis

The synthesis of fluoroindoles (which are not commercially available) was achieved very efficiently in a four-step procedure (4) as shown in Fig. 2. Methyl azidoacetate, an in-

 doi:10.1139/V07-020 © 2007 NRC Canada

Fig. 1. Synthesized fluoroindoles (4FBI, 5FBI, etc. are abbreviations for substituted fluorobenzimidazoles).



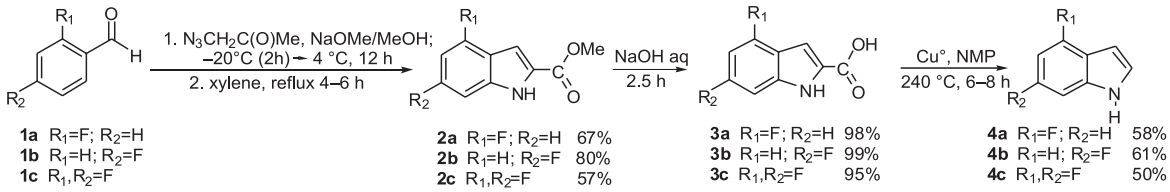


Fig. 2. Synthesis of fluoroindoles.

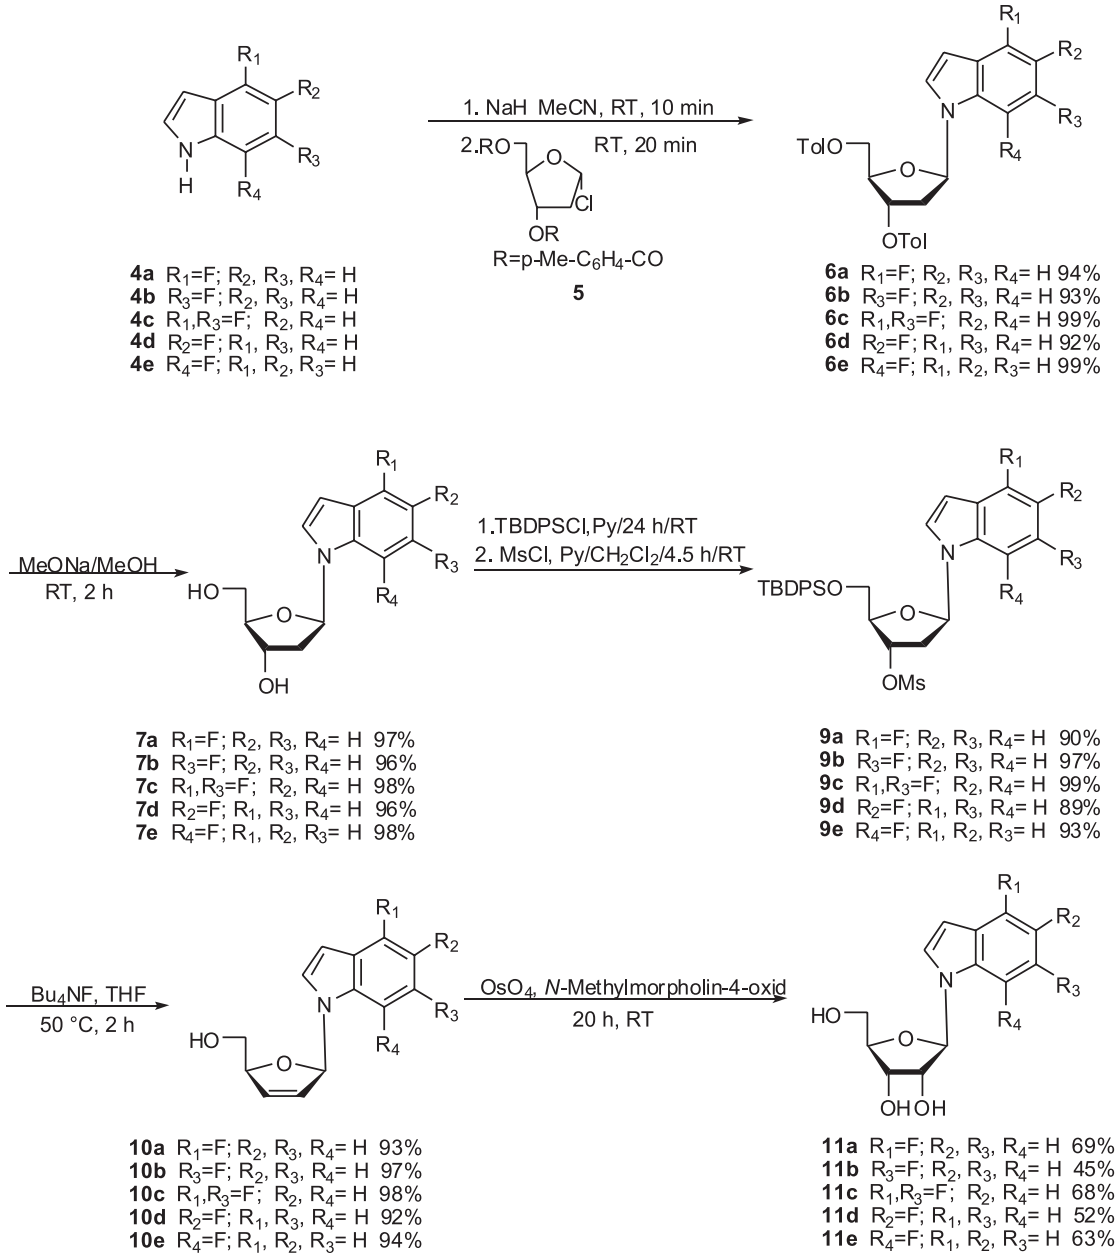
termediate in indole synthesis, was synthesized by a literature procedure (5). The prolonged reaction time and lower temperature improved the literature procedures (**2a**–**2c**). After hydrolysis of the methyl ester the decarboxylation followed, during which the main problem lies in the very high temperature at which the reaction occurs. Prolonging the reaction time does not lead to higher yields.

The direct synthesis of ribonucleosides was tried with 5-*O*-*tert*-butyldimethylsilyl-2,3-*O*-isopropylidene-α-D-ribofuranosyl chloride as the ribofuranosyl donor and a base for deprotonation of indole. Reaction conditions were varied: solvents (CH_3CN, THF, toluene), bases (NaH, TDA1–KOH), temperatures (RT to 70 °C), and reaction times (30 min to 19 h). When CH_3CN was used as a solvent and TDA1–KOH as a base, we obtained yields below 5% and separation of the obtained products was difficult to achieve (6). The Vorbrueggen method, though varying the time (2, 4, 8, and 12 h, reflux), gave no product. As can be seen, a variety of conditions and bases were tried but they did not result in a successful ribonucleoside synthesis.

As none of the direct glycosilations tried was successful, we decided to first synthesize the deoxy derivative and then the ribo derivative thereof, as shown in Fig 3. For glycosilation, we used the protected chlorodeoxyribose derivative (7). The deoxy derivative was obtained in very high yield. The key point is that the glycosilation reaction is very fast and that therefore only the β isomer is obtained (isomerization of the sugar **5** does not take place because of the fast reaction time). After deprotection, the 5′-OH is protected again with TBDPS-Cl and 3′-OH with MsCl. Deprotection of 5′-OH and elimination of OMs is accomplished in a one-step procedure. All yields reported are very good (more than 90%) except for the dihydroxilation with OsO_4 for which the yields vary from 45%–70% (based on **10a**–**10e**). However, the overall yields are between 27% and 46%. Despite the formally "long way" of synthesis, all procedures are worked out as routine and the overall yields are satisfactory.

Crystal structures of fluoroindoles



The crystal structures of 5FI, 6FI, and 4,6DFI are isomorphous and have the orthorhombic space group $P2_12_12_1$. The structures 4FI and 7FI are monoclinic with space groups $P2_1$ and $C2$, respectively. The five-membered furanose ring has a conformation between a *C*2-exo, *C*3-endo half chair, and a *C*3-endo envelope in four of the five compounds. A *C*2-endo, *C*3-exo half chair is found for 4FI. The fluoroindole groups are essentially planar and adopt anti orientations about the glycosyl bond. The O4′–C1′–N–C7 torsion angles are –99.8, –86.2, –79.8, –171.0, and –85.8 ° for 4FI, 5FI, 6FI, 7FI, and 4,6DFI, respectively. The outlying value for 7FI may result from an intramolecular C–H···F interaction between the 7-fluoro atom and the H2′ atom (distance F···H = 2.51 Å).

The crystal packings of all five structures show layers of molecules connected by intermolecular O–H···O hydrogen bonds. The packing in 4FI is shown in Fig. 4. Layers of molecules are found parallel to the [0 0 1] plane. Molecules within each layer are not only connected by hydrogen bonding between the hydroxyl groups but are also connected by weak C–H···O and C(furanose)–H···π(indole) interactions. There is no hydrogen bonding between neighboring layers. Instead, the indole groups of neighboring layers are connected by C(indole)–H···π(indole) contacts. The shortest H···C distance is 2.79 Å The 4-fluoro atom is of minor importance for the crystal stabilization. The shortest intermolecular H···F distance is 2.69 Å.

The crystal packing in 6FI is shown in Fig. 5. A similar packing is found in the isomorphous 5FI and 4,6DFI structures. Again, layers of molecules are found parallel to the [0 0 1] plane. Molecules within a layer are connected by three O–H···O hydrogen bonds, three weak intermolecular C–H···O contacts, and a weak intermolecular C(furanosyl)–H···π(indole) interaction. The fluoroindole units of neighboring layers show intermolecular C(indole)–H···F contacts

© 2007 NRC Canada

Fig. 3. Efficient synthesis of fluoroindole nucleosides.

with H···F distances of 2.40 Å and C–H–F angles of 155 °. There also is an additional C(indole)–H···π(indole) interaction with H···C distances of 2.71 and 2.72 Å.

In the isomorphous 5FI structure, a similar C(indole)–H···F contact occurs with a H···F distance of 2.46 Å and a C–H–F angle of 146 °. The isomorphism of the 5-fluoro and the 6-fluoro compounds may seem surprising but can easily be understood as a C(6)–F(6)···H(5)–C(5) contact occurring in 6FI and a related C(6)–H(6)···F(5)–C(5) contact in 5FI, with only the fluorine position reversed. A similar packing is also observed for 4,6DFI. Here, only the 6-fluoro atom is involved in an intermolecular C–H···F contact (H···F distance 2.39 Å, C–H–F angle 155 °), while the 4-fluoro atom is not involved in any short contacts.

A somewhat different packing pattern is found for 7FI. This structure contains bilayers of molecules parallel to the [0 0 1] plane. The molecules in each bilayer are connected by three intermolecular O–H···O hydrogen bonds, a weak intermolecular C(furanose)–H···π(indole) interaction, and an intermolecular C–H···F contact (H···F distance 2.30 Å, C–H–F angle 124 °). Neighboring bilayers are connected by C(indole)–H···π(indole) contacts only, with a shortest H···C distance of 2.84 Å.

Thus the conclusion of this work is that all five compounds form two-dimensional networks of hydrogen-bonded molecules. The indole units point away from the layers. The packing between the layers is governed by a competition of weak C–H···π and C–H···F interactions and thus depend on the substitution pattern of the fluorine containing indole units. Similar results were found for a series of fluorine-substituted 1-(β-D-ribofuranosyl)phenyls (8).

Unfortunately it is impossible to compare in depth the

crystal structures of fluoroindoles and fluorobenzimidazoles because the only known crystal structure of fluorobenzimidazole is that of 1′,2′-dideoxy,3′,5′-dihydroxy-1′-(4-fluoro-6-methylbenzimidazole)-β-D-ribofuranose. There are, however, some similarities between fluoroindoles and this compound. Intermolecular C–H···F contacts also play a dominant role in the packing of the the crystal structure of 1′,2′-dideoxy,3′,5′-dihydroxy-1′-(4-fluoro-6-methylbenzimidazole)-β-D-ribofuranose (9). The molecules in this structure are connected into bilayers by O–H···O, O–H···N, C–H···O, and C–H···N hydrogen bonds. Neighboring bilayers are connected by three different C–H···F interactions with H···F distances between 2.51 and 2.59 Å.

Experimental section

Crystal structure analyses of 4FI, 5FI, 6FI, 7FI, and 4,6DFI

The compounds were crystallized from methanol or methanol–water. Single crystals were measured on a Siemens SMART 1K CCD diffractometer with Mo Kα radiation. Details of the measurements and the crystal data are given in Table 1. Empirical absorption corrections were made. Equivalent reflections, including Friedel opposites, were merged. The structures were determined by direct methods and refined by least-squares against all measured F^2 values. H atoms were either taken from a difference synthesis and refined or they were geometrically positioned and were constrained. Crystallographic data in cif format for the compounds 4FI, 5FI, 6FI, 7FI, and 4,6DFI can be found in the Supplementary Data.[3]

General

The anhydrous solvents, for example, methanol, acetonitrile, pyridine, CH_2Cl_2, and THF, were obtained from Fluka and used without further purification. Flash column chromatography was performed on (FC) silica gel (40–63 μm) from Merck, TLC on silica gel 60 F_{254} plates from Merck, NMR on a Bruker-AM250 and Bruker-AMX400 (^{1}H, ^{13}C, ^{19}F) spectrometers (δ in ppm, J in Hz), MS on a PerSeptive Biosystems MALDI-TOF spectrometer and Fisons VG platform II (ESI = electrospray-ionization).

General procedure for the preparation of methyl indole-2-carboxylates (8a–8c)

To a solution of MeONa (28.6 mL, 5.4 mol/L MeONa in MeOH) in MeOH (60ml) at –20 °C was added a solution of benzaldehyde (33 mmol) and methyl azidoacetate (135 mmol) in MeOH (34 mL) dropwise over 30 min. The mixture was stirred for 3 h at –20 °C and overnight at 4 °C. The heterogenous mixture was then poured over ice, allowed

to warm to 5–10 °C, filtered, and the precipitate was washed with water. The solid was immediately dissolved in xylenes (100 mL) and the solution was washed with brine and dried over $MgSO_4$. The resulting solution was added dropwise to a flask of xylenes (200 mL) at reflux and the solution was held at reflux until TLC indicated the reaction was complete (3–6 h). The mixture was concentrated to dryness. The residue was purified by flash column chromatography (CH_2Cl_2).

Methyl-4-fluorindol-carboxylate (2a)

This compound was obtained from **1a** as a white solid in 66.7% yield. TLC (CH_2Cl_2). R_f 0.63. ^{1}H NMR (250 MHz, DMSO-d_6, ppm) δ: 12.29 (s, 1H, NH), 7.35 (m, 2H, 6H, 7H), 7.17 (s, 1H, 3H), 6.86 (m, 1H, 5H), 3.92 (s, 3H, OCH_3). ^{13}C NMR (62.9 MHz, DMSO-d_6) δ: 163.18 (C=O), 162.11 (C2), 159.38 (C6), 138.03 (C8), 128.55 (C9), 124. 36 (C7), 110.43 (C5), 108.75 (C3), 98.60 (C4), 52.47 (OCH_3). ESI-MS: 193.8 $[M + H]^+$.

Methyl-6-fluorindol-carboxylate (2b)

This compound was obtained from **1b** as a white solid in 80% yield. TLC (CH_2Cl_2). R_f 0.68. ^{1}H NMR (250 MHz, DMSO-d_6, ppm) δ: 11.99 (s, 1H, NH,), 7.69 (dd, 1H, J = 5.52 Hz, J = 8.82 Hz, 7H), 7.16 (m, 2H, 3H, 4H), 6.96 (m, 1H, 5H), 3.87 (s, 3H, OCH_3). ^{13}C NMR (62.9 MHz, DMSO-d_6, ppm) δ: 163.18 (C=O), 162.11 (C2), 159.38 (C6), 138.03 (C8), 128.55 (C9), 124. 36 (C7), 110.43 (C5), 108.75 (C3), 98.60 (C4), 52.47 (OCH_3). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –117,22 (m, 1F, 6F). ESI-MS: 191.6 $[M + H]^+$.

Methyl-4,6-difluorindol-carboxylate (2c)

This compound was obtained from **1c** as a white solid in 73% yield. TLC (CH_2Cl_2). R_f 0.49. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 12.36 (s, 1H, NH), 7.16 (m, 1H, 7H), 7.04 (m, 1H, 3H), 6.92 (ddd, 1H, J = 2.0 Hz, J' = 8.3 Hz, J'' = 8.3 Hz, 5H), 3.89 (s, 3H, OCH_3). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –116.65 (m, 1F, 6F), –114.20 (m, 1F, 4F). ESI-MS: 209.6 $[M - H]^-$. EI anal. calcd.: C 56.88, H 3.34, N 6.63; found: C 57.04, H 3.41, N 6.48.

General procedure for the preparation of indole-2-carboxylic acids (9a–9c)

Methyl indole-2-carboxylates (21.6 mmol) were added to a solution of aq. 2 mol/L NaOH (350 mL). The mixture was stirred at reflux for 1–2 h. The solution was cooled and neutralized with concd. HCl. The resulting precipitate was collected by filtration, washed with water, and dried under vacuum to obtain indole-2-carboxylic acid.

4-Fluorindole-2-carboxylic acid (3a)

This compound was obtained from **2a** as a white solid in 98% yield. ^{1}H NMR (250 MHz, DMSO-d_6, ppm) δ: 12.09 (s, 1H, NH), 7.29–7.19 (m, 2H, 6H, 7H), 7.95 (m, 1H, 3H), 3.39 (bs, 1H, COOH). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –120.77 (m, 1F, 4F). ESI-MS: 177.6 $[M - H]^-$.

6-Fluorindole-2-carboxylic acid (3b)

This compound was obtained from **2b** as a white solid in 99% yield. TLC (CH_2Cl_2–MeOH 95:5). R_f 0.33. ^{1}H NMR (250 MHz, DMSO-d_6, ppm) δ: 12.97 (bs, 1H, COOH), 11.80 (s, 1H, NH), 7.66 (dd, 1H, J = 8.8 Hz, J' = 5.5 Hz, 4H), 7.12 (m, 2H, 3H, 7H), 6.51 (ddd, 1H, J = 8.8 Hz, J' = 9.7 Hz, J'' = 2.5 Hz, 5H). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –117.86 (m, 1F, 6F). ESI-MS: 179.2 $[M + H]^+$.

© 2007 NRC Canada

4,6-Difluorindole-2-carboxylic acid (3c)

This compound was obtained from **2c** as a white solid in 99% yield. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 8.25 (bs, 1H, NH), 7.10 (s, 1H, 3H), 7.02 (dd, 1H, J = 9.4 Hz, J = 1.3 Hz, 7H), 6.91 (m, 1H, 5H), 3.42 (bs, 1H, COOH). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –116.91 (m, 1F, 6F), –114.82 (m, 1F, 4F). ESI-MS: 197.9 $[M + H]^+$.

General procedure for the preparation of fluorinated indoles (4a–4c)

The indole-2-carboxylic acid (12.5 mmol), copper powder (50 mmol), and *N*-methylpyrrolidinon (200 mL) were heated at reflux. A continuous stream of argon bubbled slowly through the reaction mixture via a metal tube, while maintaining reflux for 6–12 h. The mixture was cooled, filtered through Celite, and the filter cake was washed with ether. The filtrate and ether were diluted with water (500 mL) and extracted four times with ether. The organic extract was washed with water and brine, dried with $MgSO_4$, and concentrated to dryness. The residue was purified by flash column chromatography (CH_2Cl_2).

4-Fluoroindole (4a)

This compound was obtained from **3a** as white crystals in 58% yield. TLC (*n*-hexan–EtOAc 85:15). R_f 0.40. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 11.41 (bs 1H, NH), 7.39 (m, 1H, 2H), 7.23 (m, 1H, 7H), 7.05 (m, 1H, 6H), 6.76 (m, 1H, 5H), 6.49 (d, 1H, 3H). ESI-MS: 133.7 $[M - H]^-$. EI anal. calcd.: C 71.10, H 4.48, N 10.36; found: C 71.38, H 4.64, N 10.44.

6-Fluoroindole (4b)

This compound was obtained from **3b** as white crystals in 61% yield. TLC (*n*-hexan–EtOAc 85:15). R_f 0.38. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.12 (bs 1H, NH), 7.59 (d, 1H, J = 3.3 Hz, 2H), 7.18 (dd, 1H, J = 8.7 Hz, J' = 5.6 Hz, 4H), 7.07 (dd, 1H, J = 2.2 Hz, J' = 10.2 Hz, 7H), 6.90 (ddd, 1H, J = 8.7 Hz, J' = 2.2 Hz, J'' = 10.1 Hz, 5H), 6.54 (d, 1H, J = 3.3 Hz, 3H). ^{19}F NMR (235.4 MHz, $CDCl_3$, ppm) δ: –121.83 (m, 1F, 6F). ESI-MS: 121.8 $[M + H]^+$. EI anal. calcd.: C 71.11, H 4.44, N 10.37; found: C 71.20, H 4.42, N 10.50.

4,6-Difluoroindole (4c)

This compound was obtained from **3c** as white crystals in 50% yield. TLC (*n*-hexan–EtOAc 85:15). R_f 0.43. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.35 (d, 1H, J = 2.6 Hz, 2H), 7.04 (dd, 1H, J = 2.1 Hz, J' = 9.6 Hz, 7H), 6.77 (m, 1H, 5H), 6.45 (d, 1H, J = 2.0 Hz, 3H), 3.46 (bs, 1H, NH). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 159.60 (C4), 157.22 (C6), 137.85 (C5), 126.67 (C8), 122.98 (C3), 116.78 (C9), 109.91 (C7), 97.32 (C2). ESI-MS: 152.2 $[M - H]^-$.

General procedure for the preparation of 1-[2′-desoxy-3′,5′-bis-*O*-(4-methylbenzoyl)-β-D-*erythro*-pentofuranosyl]-indoles (6a–6e)

To a solution of indole (6.2 mmol) in 80 mL of CH_3CN was added NaH (9.7 mmol) at room temperature (RT). The resulting solution was stirred at RT for 10 min. 3,5-Bis-*O*-(4-methylbenzoyl)-D-*erythro*-pentofuranosyl-α-chloride (7.4 mmol) was then added and stirring was continued for 20 min. The reaction was quenched by adding Dowex-80 and the resulting mixture was filtered and concentrated to dryness. The residue was purified by flash column chromatography (hexane–EtOAc 85:15).

1-[2′-Desoxy-3′,5′-bis-O-(4-methylbenzoyl)-β-D-erythro-pentofuranosyl]-4-fluoroindole (6a)

This compound was obtained from **4c** as a white foam in 94% yield. TLC (hexane–EtOAc 85:15). R_f 0.29. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.95 (m, 4H, H_{Ar}), 7.45 (d, 1H, J = 3.4 Hz, 2H), 7.32–7.06 (m, 6H, H_{Ar}), 6.82 (m, 1H, 5H), 6.66 (d, 1H, J = 3.4 Hz, 3H), 6.45 (pt, 1H, J = 5.6 Hz, J' = 6.7 Hz, 1′H), 5.72 (m, 1H, 3′H), 4.76 (m, 2H, 5′H), 4.62 (m, 1H, 4′H), 2.89 (m, 1H, 2′H_β), 2.70 (m, 1H, 2′H_α), 2.47 (s, 3H, Ar-CH_3), 2.44 (s, 3H, Ar-CH_3). ^{19}F NMR (235.4 MHz, $CDCl_3$, ppm) δ: –121,79 (m, 1F, 4F). ESI-MS: 510.0 $[M + Na]^+$. EI anal. calc.: C 71.46, H 5.34, N 2.87; found: C 71.19, H 5.49, N 3.03.

1-[2′-Desoxy-3′,5′-bis-O-(4-methylbenzoyl)-β-D-erythro-pentofuranosyl]-6-fluoroindole (6b)

This compound was obtained from **4b** as a white foam in 94% yield. TLC (hexane–EtOAc 85:15). R_f 0.30. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.05 (d, 2H, J = 8.2 Hz, *o*-Tol-H), 7.96 (d, 2H, J = 8.2 Hz, *o′*-Tol-H), 7.59 (d, 1H, J = 3.3 Hz, 2H), 7.37 (dd, 1H, J = 10.2 Hz, J' = 2.1 Hz, 7H), 7.30 (d, 2H, J = 8.0 Hz, *m*-Tol-H), 7.26 (d, 2H, J = 8.0 Hz, *m′*-Tol-H), 6.93 (ddd, 1H, J = 8.8 Hz, J' = 2.1 Hz, J'' = 10.1 Hz, 5H), 6.59 (d, 1H, J = 3.3 Hz, 3H), 6.41 (pt, 1H, $J_{1'H2'H\beta}$ = 6.0 Hz, $J_{1'H,\,2'H\alpha}$ = 7.2 Hz, 1′H), 5.74 (m, 1H, 3′H), 4.67 (m, 2H, 5′H), 4.61 (m, 1H, 4′H), 2.88 (m, 1H, 2′H_β), 2.69 (m, 1H, 2′H_α), 2.49 (s, 3H, Ar-CH_3), 2.45 (s, 3H, Ar-CH_3). ESI-MS: 488.8 $[M + H]^+$. EI anal. calcd.: C 71.46, H 5.34, N 2.87; found C 71.42, H 5.53, N 3.08.

1-[2′-Desoxy-3′,5′-bis-O-(4-methylbenzoyl)-β-D-erythro-pentofuranosyl]-4,6-difluoroindole (6c)

This compound was obtained from **4c** as a white foam in 99% yield. TLC (hexane–EtOAc 85:15). R_f 0.33. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 8.00 (d, 2H, J = 8.2 Hz, *o*-Tol-H), 7.86 (d, 2H, J = 8.2 Hz, *o-′*Tol-H), 7.63 (d, 1H, J = 3.5 Hz, 2H), 7.53 (dd, 1H, J = 9.6 Hz, J' = 1.7 Hz, 7H), 7.50 (d, 2H, J = 1.6 Hz, *m*-Tol-H), 7.37 (d, 2H, J = 8.2 Hz, *m′*-Tol-H), (ddd, 1H, J = 1.7 Hz, J' = 9.4 Hz, J'' = 9.4 Hz, 5H), 6.59 (m, 2H, 1′H, 3H), 6.12 (m, 1H, 4′H), 4.55 (m, 2H, 3′H, 5′H), 2.94 (m, 1H, 2′H_β), 2.70 (m, 1H, 2′H_α), 2.41 (s, 3H, Ar-CH_3), 2.37 (s, 3H, Ar-CH_3). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –119.00 (m, 1F, 6F), –118.01 (m, 1F, 4F). ESI-MS: 527.9 $[M + Na]^+$.

1-[2′-Desoxy-3′,5′-bis-O-(4-methylbenzoyl)-β-D-erythro-pentofuranosyl]-5-fluoroindole (6d)

This compound was obtained from **4c** as a white foam in 92% yield. TLC (hexane–EtOAc 85:15). R_f 0.35. ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.00 (d, 2H, J = 8.0 Hz, Tol-H), 7.91 (d, 2H, J = 8.0 Hz, Tol-H), 7.86 (m, 2H, H_{Ar}), 7.37 (m, 5H, H_{Ar}), 6.92 (ddd, 1H, J = 8.9 Hz, J = 11.0 Hz, J = 2.1 Hz, 6H), 6.59 (pt, 1H, $J_{1'H2'H\beta}$ = 6.1 Hz, $J_{1'H,2'H\alpha}$ = 6.8 Hz, 1′H), 6.53 (d, 1H, J = 3.1 Hz, 2H), 5.71 (m, 1H, 3′H), 4.61 (m, 1H, 4′H), 4.52 (m, 2H, 5′H), 2.95 (m, 1H, 2′H_β), 2.70 (m, 1H, 2′H_α), 2.46 (s, 3H, Ar-CH_3), 2.39 (s, 3H, Ar-CH_3). ^{19}F NMR (235.4 MHz, $CDCl_3$, ppm) δ: –124.11 (m, 1F, 5F). ESI-MS: 509.8 [M + Na]$^+$. EI anal. calcd.: C 71.45, H 5.38, N 2.87, found: C 71.22, H 5.50, N 2.65.

1-[2′-Desoxy-3′,5′-bis*-O-*(4-methylbenzoyl)*-β-*D*-erythro-*pentofuranosyl]-7-fluoroindole (6e)

This compound was obtained from **4b** as a white foam in 99% yield. TLC (hexane–EtOAc 85:15). R_f 0.39. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.96 (m, 2H, H_{Ar}), 7.86 (m, 2H, H_{Ar}), 7.69 (d, 1H, J = 3.3 Hz, 2H), 7.43–7.30 (m, 5H, H_{Ar}), 7.04 (m, 2H, H_{Ar}), 6.70 (pt, 1H, $J_{1'H2'Hβ}$ = 6.6 Hz, $J_{1'H,2'Hα}$ = 7.6 Hz, 1′H), 6.63 (d, 1H, J = 3.3 Hz, 3H), 5.69 (m, 1H, 3′H), 4.57–4.46 (m, 3H, 5′H, 4′H), 2.96 (m, 1H, 2′$H_β$), 2.74 (m, 1H, 2′$H_α$), 2.37 (s, 3H, Ar-CH_3), 2.35 (s, 3H, Ar-CH_3). ^{19}F NMR (282.3 MHz, DMSO-d_6, ppm) δ: –132.04 (m, 1F, 7F). ESI-MS: 505.1 [M + NH_4]$^+$. EI anal. calcd: C 71.46, H 5.34, N 2.87; found: C 71.35, H 5.39, N 2.68.

General procedure for the preparation of 1-[2′-desoxy-β-D-*erythro*-pentofuranosyl]-indoles (7a–7e)

A mixture of 1-[2′-desoxy-3′,5′-bis-*O*-(4-methylbenzoyl)-β-D-*erythro*-pentofuranosyl]-indole (5.8 mmol) and 6.9 mL 5.4 mol/L MeONa in MeOH (37.2 mmol) in MeOH (200 mL) was stirred at RT for 2 h. The reaction was quenched by adding Dowex-80 and the resulting mixture was filtered and concentrated with silica gel to dryness. The residue was purified by flash column chromatography (hexane–EtOAc 1:2).

1-(2′-Desoxy*-β-*D*-erythro-*pentofuranosyl)-4-fluoroindole (7a)

This compound was obtained from **6a** as a white solid in 97% yield. TLC (CH_2Cl_2–MeOH 9:1). R_f 0.57. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.64 (d, 1H, J = 3.4 Hz, 2H), 7.43 (d, 1H, J = 8.2 Hz, 7H), 7.12 (m, 1H, 6H), 6.83 (m, 1H, 5H), 6.57 (d, 1H, J = 3.4 Hz, 3H), 6.37 (pt, 1H, $J_{1'H,2'Hβ}$ = 6.2 Hz, $J_{1'H,2'Hα}$ = 7.6 Hz, 1′H), 5.29 (d, 1H, J = 4.1 Hz, 3′OH), 4.89 (t, 1H, J = 5.4 Hz, 5′OH), 4.35 (m, 1H, 3′H), 3.82 (m, 1H, 4′H), 3.53 (m, 2H, 5′H), 2.47 (m, 1H, 2′$H_β$), 2.41 (m, 1H, 2$H_α$). ^{13}C NMR (400 MHz, DMSO-d_6, ppm) δ: 138.28 (d, J = 44.8 Hz, C4), 125.92 (C2), 122.21 (C6), 119.15 (C_{Ar}), 117.05 (C_{Ar}), 106.96 (C7), 104.33 (C5), 99.13 (C3), 87.08 (C4′), 84.71 (C1′), 70.64 (C3′), 61.76 (C5′), 40.13 (C2′). ESI-MS: 252.0 [M + H]$^+$. EI anal. calcd.: C 62.14, H 5.62, N 5.57; found: C 62.33, H 5.80, N 5.35.

1-(2′-Desoxy*-β-*D*-erythro-pentofuranosyl)-6-fluoroindole (7b)

This compound was obtained from **6b** as a white solid in 96% yield. TLC (CH_2Cl_2–MeOH 9:1). R_f 0.57. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.59 (d, 1H, J = 3.3 Hz, 2H), 7.52 (dd, 1H, J = 8.7 Hz, J' = 5.6 Hz, 4H), 7.47 (m, 1H, 7H), 6.90 (ddd, 1H, J = 8.7 Hz, J' = 2.2 Hz, J'' = 10.1 Hz, 5H), 6.51 (d, 1H, J = 3.3 Hz, 3H), 6.33 (pt, 1H, $J_{1'H,2'Hβ}$ = 6.4 Hz, $J_{1'H,2'Hα}$ = 7.2 Hz, 1′H), 5.26 (d, 1H, J = 4.2 Hz, 3′OH), 4.89 (t, 1H, J = 5.3 Hz, 5′OH), 4.35 (m, 1H, 3′H), 3.81 (m, 1H, 4′H), 3.53 (m, 2H, 5′H), 2.47 (m, 1H, 2′$H_β$), 2.21 (m, 1H, 2$H_α$). ^{19}F NMR (235.4 MHz, DMSO-d_6, ppm) δ: –120.84 (m, 1F, 6F). ESI-MS: 249.9 [M – H]$^-$.

1-(2′-Desoxy*-β-*D*-erythro-*pentofuranosyl)-4,6-difluoroindole (7c)

This compound was obtained from **6c** as a white solid in 98% yield. TLC (hexane–EtOAc 1:2). R_f 0.17. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.56–7.29 (m, 12H, H_{Ar}), 6.86 (ddd, 1H, J = 1.9 Hz, J' = 10.3 Hz, J'' = 10.2 Hz, 5H), 6.47 (d, 1H, J = 3.4 Hz, 3H), 6.34 (pt, 1H, $J_{1'H,2'Hβ}$ = 6.4 Hz, $J_{1'H,2'Hα}$ = 6.5 Hz, 1′H), 5.35 (d, 1H, J = 4.6 Hz, 3′OH), 4.43 (m, 1H, 3′H), 3.89 (m, 1H, 4′H), 3.72 (m, 2H, 5′H), 2.49 (m, 1H, 2′$H_β$), 2.30 (m, 1H, 2′$H_α$), 2.05 (s, 9H, *t*-Bu). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 155.7 (d, J = 50.6 Hz, C4), 154.8 (d, J = 62.2 Hz, C6), 141.5 (C8), 137.5 (C_{Ar}), 135.8 (C_{Ar}), 135.6 (C_{Ar}), 135.2 (C_{Ar}), 133.0 (C_{Ar}), 132.2 (C_{Ar}), 129.8 (C_{Ar}), 128.5 (C_{Ar}), 128.2 (C_{Ar}), 128.1 (C_{Ar}), 127.9 (C_{Ar}), 127.5 (C_{Ar}), 126.9 (C2), 111.2 (C9), 103.1 (C3), 95.7 (C5), 93.6 (C7), 83.5 (C1′), 83.3 (C4′), 65.3 (C3′), 64.2 (C5′), 36.0 (C2′), 25.73 (Si$C(CH_3)_3$), 20.5 (SiC(CH_3)$_3$). 19.5 (SiC(CH_3)$_3$), 14.5 (SiC(CH_3)$_3$). ESI-MS: 505.8 [M – H]$^-$.

1-(2′-Desoxy*-β-*D*-erythro-*pentofuranosyl)-5-fluoroindole (7d)

This compound was obtained from **6d** as a white foam in 96% yield. TLC (CH_2Cl_2–MeOH 9:1). R_f 0.56. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.90 (d, 1H, J = 3.2 Hz, 2H), 7.71 (m, 1H, 7H), 7.35 (m, 1H, 4H), 7.03 (ddd, 1H, J = 8.7 Hz, J' = 2.1Hz, J = 10.2 Hz, 6H), 6.54 (d, 1H, J = 3.2 Hz, 3H), 6.40 (pt, 1H, $J_{1'H,2'Hβ}$ = 6.3 Hz, $J_{1'H,2'Hα}$ = 6.9 Hz, 1′H), 5.32 (d, 1H, J = 4.1 Hz, 3′OH), 4.92 (t, 1H, J = 5.2 Hz, 5′OH), 4.40 (m, 1H, 3′H), 3.86 (m, 1H, 4′H), 3.57 (m, 2H, 5′H), 2.57 (m, 1H, 2′$H_β$), 2.28 (m, 1H, 2$H_α$). ^{19}F NMR (282.3 MHz, DMSO-d_6, ppm) δ: –124.53 (m, 1F, 5F). ESI-MS: 249.8 [M – H]$^-$. EI anal. calcd: C 62.14, H 5.62, N 5.57; found: C 62.32, H 5.78, N 5.45.

1-(2′-Desoxy*-β-*D*-erythro-*pentofuranosyl)-7-fluoroindole (7e)

This compound was obtained from **6d** as a white foam in 98% yield. TLC (CH_2Cl_2–MeOH 9:1). R_f 0.63. ^{1}H NMR (300 MHz, DMSO-d_6, ppm) δ: 7.73 (d, 1H, J = 3.2 Hz, 2H), 7.40 (m, 1H, H_{Ar}), 6.97 (m, 2H, H_{Ar}), 6.51 (m, 2H, 3H, 1′H), 5.31 (d, 1H, J = 4.2 Hz, 3′OH), 4.85 (t, 1H, J = 5.6 Hz, 5′OH), 4.31 (m, 1H, 3′H), 3.72 (m, 1H, 4′H), 3.53 (m, 2H, 5′H), 2.40 (m, 1H, 2′$H_β$), 2.37 (m, 1H, 2$H_α$). ^{13}C NMR (300 MHz, DMSO-d_6, ppm) δ: 132.50 (d, J = 45.0 Hz, C7), 132.40 (C2), 126.42 (C_{Ar}), 123.05 (C_{Ar}), 122.93 (C_{Ar}), 119.97 (C_{Ar}), 119.80 (C_{Ar}), 116.80 (C_{Ar}), 87.10 (C4′), 86.07 (C1′), 70.71 (C3′), 61.83 (C5′), 60.47 (C2′). ^{19}F NMR (282.3 MHz, DMSO-d_6, ppm) δ: –132.23 (m, 1F, 7F). ESI-MS: 250.0 [M – H]$^-$.

General procedure for the preparation of 1-(2′-desoxy-5′-*O*-*tert*-buthyldiphenylsilyl-β-D-*erythro*-pentofuranosyl)-indoles (13a–13f)

To a solution of 1-[2′-desoxy-3′,5′-bis-*O*-(4-methylbenzoyl)-β-D-*erythro*-pentofuranosyl]-indole (3.75 mmol) in pyridine (20 mL) at 0 °C was added dropwise *tert*-butyldiphenylsilylchloride (4.3 mmol) in 30 min. The mixture was stirred at RT for 24 h and concentrated with silica gel to dryness. The residue was purified by flash column chromatography (hexane–EtOAc 4:1).

1-(2′-Desoxy-5′-*O*-*tert*-buthyldiphenylsilyl-β-D-*erythro*-pentofuranosyl)-4-fluoroindole (8a)

This compound was obtained from **7a** as a white solid in 87% yield. TLC (CH_2Cl_2–MeOH 99:1). R_f 0.51. ^{1}H NMR (400 MHz, DMSO-d_6 ppm) δ 7.59 (m, 4H, H_{Ar}), 7.52 (d, 1H, J = 3.4 Hz, 2H), 7.39 (m, 13H, H_{Ar}), 7.08 (m, 1H, 6H), 6.83 (m, 1H, 5H), 6.50 (d, 1H, J = 3.4 Hz, 3H), 6.41 (pt, 1H,

*1-(2′-Desoxy-5′-*O*-tert-buthyldimethylsisyl-3′-*O*-mesyl-β-D-erythro-pentofuranosyl)-7-fluorindole (9e)*

This compound was obtained from **8e** as a white foam in 93% yield. TLC (*n*-hexan–EtOAc 4:1). R_f = 0.36. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.64–7.59 (m, 5H, H_{Ar}), 7.49–7.31 (m, 7H, H_{Ar}), 7.10–6.98 (m, 2H, H_{Ar}), 6.61 (pt, 1H, $J_{1'H,2'H\beta}$ = 7.1 Hz, $J_{1'H,2'H\alpha}$ = 6.6 Hz, 1′H), 6.53 (m, 1H, H_{Ar}), 5.46 (m, 1H, 3′H), 4.27 (m, 1H, 4′H), 3.74 (m, 2H, 5′H), 3.30 (s, 3H, SCH_3), 2.93 (m, 1H, 2′H_β), 2.81 (m, 1H, 2′Hα), 1.00 (s, 9H, *t*-Bu). ^{19}F NMR (282.3 MHz, DMSO-d_6, ppm) δ: –132.56 (m, 1F, 7F). ESI-MS: 567.9 $[M + H]^+$.

General procedure for the preparation of 1-(2′,3′-didesoxy-β-D-*glycero*-pent-2-enofuranosyl)indoles (10a–10e)

To a solution of compound 14 (2.8 mmol) in THF (50 mL) was added Bu_4NF (1 mol/L solution in THF, 10.4 mL). The mixture was stirred at 50 °C for 2 h (Ar atmosphere) and concentrated to dryness. The residue was purified by flash column chromatography (1st $CHCl_3$–MeOH 95:5; 2nd $CHCl_3$–MeOH 98:2).

1-(2′,3′-Didesoxy-β-D-glycero-pent-2-enofuranosyl)-4-fluoroindole (10a)

This compound was obtained from **9a** as a white solid in 93% yield. TLC ($CHCl_3$–MeOH 95:5). R_f 0.47. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.75 (d, 1H, J = 4.0 Hz, 2H), 7.59 (d, 1H, J = 4.6 Hz, 1′H), 7.22 (m, 2H, 6H, 7H), 6.91 (m, 1H, 5H), 6.61 (d, 1H, J = 4.0 Hz, 3H), 6.55 (m, 1H, 3′H), 6.21 (m, 1H, 2′H), 4.93 (t, 1H, J = 5.7 Hz, 5′OH), 4.87 (m, 1H, 4′H), 3.67 (m, 2H, 5′H). ^{19}F NMR (282.3 MHz, DMSO-d_6, ppm) δ: –122.40 (m, 1F, 4F). ESI-MS: 233.8 $[M + H]^+$.

1-(2′,3′-Didesoxy-β-D-glycero-pent-2-enofuranosyl)-6-fluoroindole (10b)

This compound was obtained from **9b** as a white solid in 97% yield. TLC ($CHCl_3$–MeOH 95:5). R_f 0.51. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.55 (m, 2H, 2H, 7H), 7.37 (d, 1H, J = 3.4 Hz, 1′H), 7.03 (m, 1H, 4H), 6.91 (ddd, 1H, J = 8.6 Hz, J' = 2.2 Hz, J'' = 9.9 Hz, 5H), 6.49 (m, 2H, 3H, 3′H), 6.13 (m, 1H, 2′H), 4.86 (t, 1H, J = 5.6 Hz, 5′OH), 4.78 (m, 1H, 4′H), 3.52 (m, 2H, 5′H). ^{19}F NMR (250.1 MHz, DMSO-d_6, ppm) δ: –120.88 (m, 1F, 6F). ESI-MS: 233.9 [M + H]+). EI anal. calcd.: C 66.94, H 5.19, N 6.01; found: C 66.85, H 5.34, N 6.12.

1-(2′,3′-Didesoxy-β-D-glycero-pent-2-enofuranosyl)-4,6-fluoroindole (10c)

This compound was obtained from **9c** as a white solid in 99% yield. TLC ($CHCl_3$–MeOH 95:5). R_f 0.52. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.51 (dd, 1H, J = 1.8 Hz, 7H), 7.43 (d, 1H, J = 3.4 Hz, 2H), 7.03 (d, 1H, J = 1.3 Hz, 1′H), 6.89 (ddd, 1H, J = 1.8 Hz, J' = 10.3 Hz, J'' = 10.2 Hz, 5H), 6.56 (d, 1H, J = 3.4 Hz, 3H), 6.48 (m, 1H, 2′H), 6.13 (m, 1H, 2′H), 6.13 (m, 1H, 3′H), 4.87 (t, 1H, J = 5.4 Hz, 5′OH), 4.81 (m, 1H, 4′H), 3.51 (m, 2H, 5′H). ^{19}F NMR (235.4 DMSO-d_6, ppm) δ: –119.17 (m, 1F, 6F), –118.37 (m, 1F, 4F). ESI-MS: 251.9 $[M + H]^+$.

1-(2′,3′-Didesoxy-β-D-glycero-pent-2-enofuranosyl)-5-fluoroindole (10d)

This compound was obtained from **9d** as a white solid in 93% yield. TLC ($CHCl_3$–MeOH 95:5). R_f 0.46. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.70 (m, 1H, 6H), 7.42 (d, 1H, J = 3.6 Hz, 1′H), 7.33 (m, 1H, 2H), 7.03 (m, 2H, 7H, 3′H), 6.52 (m, 2H, 4H, 2′H), 6.15 (d, 1H, J = 3.1 Hz, 3H), 4.86 (t, 1H, J = 5.4 Hz, 5′OH), 4.80 (m, 1H, 4′H), 3.55 (m, 2H, 5′H). ^{19}F NMR (282.3 MHz, DMSO-d_6, ppm) δ: –124.44 (m, 1F, 5F). ESI-MS: 233.7 $[M + H]^+$. EI anal. calcd.: C 66.94, H 5.19, N 6.01; found: C 66.80, H 5.49, N 5.83.

1-(2′,3′-Didesoxy-β-D-glycero-pent-2-enofuranosyl)-7-fluoroindole (10e)

This compound was obtained from **9e** as a white solid in 93% yield. TLC ($CHCl_3$–MeOH 95:5). R_f 0.51. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.52 (m, 2H, 2H,6H), 7.40 (d, 1H, J = 3.4 Hz, 1′H), 7.03 (m, 1H, 4H), 6.91 (m, 1H, 5H), 6.50 (m, 2H, 3H,3′H), 6.13 (m, 1H, 2′H), 4.86 (t, 1H, J = 5.6 Hz, 5′OH), 4.78 (m, 1H, 4′H), 3.52 (m, 2H, 5′H). ^{19}F NMR (250.1 MHz, DMSO-d_6, ppm) δ: –120.88 (m, 1F, 6F). ESI-MS: 233.9 $[M + H]^+$. EI anal. calcd.: C 66.94, H 5.19, N 6.01; found: C 66.85, H 5.24, N 6.18.

General procedure for the preparation of 1′-desoxy-1′-(indolyl)-β-D-ribofuranose (16a–16f)

Compound 15 (4.4 mmol) and *N*-methyl-morpholine oxide (11.9 mmol) were dissolved in 50 mL of acetone–water (8:1) and OsO_4 (5.5 mL, 2.5% in 2-methyl-2-propanol) was added. The mixture was stirred at RT for 20 h, 10% $Na_2S_2O_4$ (15 mL) was then added and stirring was continued for 15 min. The mixture was treated with water (100 mL) and extraced with EtOAc (2 × 150 mL). The combined extracts were washed with brine, dried over $MgSO_4$, and concentrated to dryness. The residue was purified by flash column chromatography (hexane–EtOAc 1:2).

1′-Desoxy-1′-(4-fluoroindolyl)-β-D-ribofuranose (11a)

This compound was obtained from **10a** as white crystals in 69% yield. TLC (CH_2Cl_2–MeOH 95:5). R_f 0.21. ^{1}H NMR (400 MHz, DMSO-d_6, ppm) δ: 7.66 (d, 1H, J = 3.4 Hz, 2H), 7.42 (d, 1H, J = 8.3 Hz, 7H), 7.12 (m, 1H, 6H), 6.84 (m, 1H, 5H), 6.58 (d, 1H, J = 3.3 Hz, 3H), 5.88 (d, 1H, J = 6.1 Hz, 1′H), 5.34 (d, 1H, J = 5.4 Hz, 2′OH), 5.14 (s, 1H, 3′OH), 5.02 (t, 1H, J = 5.6 Hz, 5′OH), 4.26 (d, 1H, J = 5.0 Hz, 2′H), 4.08 (m, 1H, 3′H), 3.93 (m, 1H, 4′H), 3.61 (m, 2H, 5′H). ^{19}F NMR (250.4 MHz, DMSO-d_6, ppm) δ: –122.53 (m, 1F, 4F). ESI-MS: 265.7 $[M - H]^-$.

1′-Desoxy-1′-(6-fluoroindolyl)-β-D-ribofuranose (11b)

This compound was obtained from **10b** as white crystals in 45% yield. TLC (CH_2Cl_2–MeOH 95:5). R_f 0.21. ^{1}H NMR (250 MHz, DMSO-d_6, ppm) δ: 7.58 (d, 1H, J = 3.4 Hz, 2H), 7.53 (dd, 1H, J = 8.6 Hz, J' = 5.6 Hz, 4H), 7.46 (dd, 1H, J =

High-quality oligo-RNA synthesis using the new 2′-*O*-TEM protecting group by selectively quenching the addition of *p*-tolyl vinyl sulphone to exocyclic amino functions[1]

Chuanzheng Zhou, Wimal Pathmasiri, Dmytro Honcharenko, Subhrangsu Chatterjee, Jharna Barman, and Jyoti Chattopadhyaya

Abstract: During the F^--promoted deprotection of the oligo–RNA, synthesized using our 2′-*O*-(4-tolylsulfonyl)ethoxymethyl (2′-*O*-TEM) group [Org. Biomol. Chem. **5**, 333 (2007)], *p*-tolyl vinyl sulphone (TVS) is formed as a by-product. The TVS formed has been shown to react with the exocyclic amino functions of adenosine (A), guanosine (G), and cytidine (C) of the fully deprotected oligo–RNA to give undesirable adducts, which are then purified by HPLC and unambiguously characterized by ^{1}H, ^{13}C Heteronuclear Multiple Bond Correlation (HMBC) NMR and mass spectroscopic analysis. The relative nucleophilic reactivities of the nucleobases toward TVS have been found to be the following: N^6–A > N^4–C > N^2–G > > N^3–U. This reactivity of TVS toward RNA nucleobases to give various Michael adducts could, however, be suppressed by using various amines as scavengers. Among all these amines, morpholine and piperidine are the most efficient scavenger for TVS, which gave highly pure oligo–RNA even in the crude form and can be used directly in RNA chemical biology studies.

Key words: RNA synthesis, RNA alkylation, *p*-tolyl vinyl sulphone, Michael addition.

Résumé : Au cours de la déprotection sous l'influence de l'ion fluorure de l'oligo–ARN synthétisé à l'aide de notre groupe protecteur 2′-*O*-(4-tolylsulfonyl)éthoxyméthyl (2′-*O*-TEM) [Org. Biomol. Chem. **5**, 333 (2007)], il y a formation de la *p*-tolyl vinyl sulfone (TVS) comme sous-produit. Il a été montré que la TVS réagit avec les fonctions aminées exocycliques de l'adénosine (A), de la guanosine (G) et de la cytidine (C) de l'oligo-ARN complètement déprotégé pour conduire à la formation de produits indésirables qui ont été purifiés et caractérisés sans ambiguïté par spectrométrie de masse et par corrélation des liaisons multiples hétéronucléaires (CLMH) des spectres RMN du ^{1}H et du ^{13}C. On a établi que les réactivités nucléophiles relatives des nucléobases vis-à-vis de la TVS sont dans l'ordre suivant: N^6–A > N^4–C > N^2–G > > N^3–U. En utilizant diverses amines comme pièges, il serait toutefois possible d'éliminer cette réactivité de la TVS vis-à-vis des nucléobases pour conduire à divers adduits de Michael. Parmi ces amines, la morpholine et la pipéridine sont les pièges les plus efficaces pour la TVS; leur utilization conduit, même dans le produit brut, à la formation d'oligo–ARN très pur qui peut être utilizé dans des études de chimie biologique de l'ARN

Mots-clés : synthèse d'ARN, alkylation d'ARN, *p*-tolyl vinyl sulfone, addition de Michael.

[Traduit par la Rédaction]

Introduction

The discovery of RNA interference (RNAi) (1) and especially the finding that small interfering RNA (siRNA) (2) can induce degradation of the target RNA have highlighted the need for facile chemical synthesis of oligo–RNA sequences (e.g., a synthetic 21 mer siRNA) (2) and have thereby stimulated work on the development of new methodology for the chemical synthesis of RNA (3–7). Recently, we have developed a new RNA synthesis strategy based on protecting 2′-OH with a 2-(4-tolylsulfonyl)ethoxymethyl (2′-*O*-TEM) (8) group and showed its successful use in the solid-phase synthesis of at least 12 different oligo–RNAs of varying sizes (14–38 mer long) and sequences (8). The main advantages of this 2′-*O*-TEM group based RNA synthesis strategy (8) are (*i*) the low coupling time (120s), (*ii*) high

Scheme 1. Mechanism of deprotection of the 2′-*O*-TEM group and the adduct formation with tolyl vinyl sulfone (**1**).

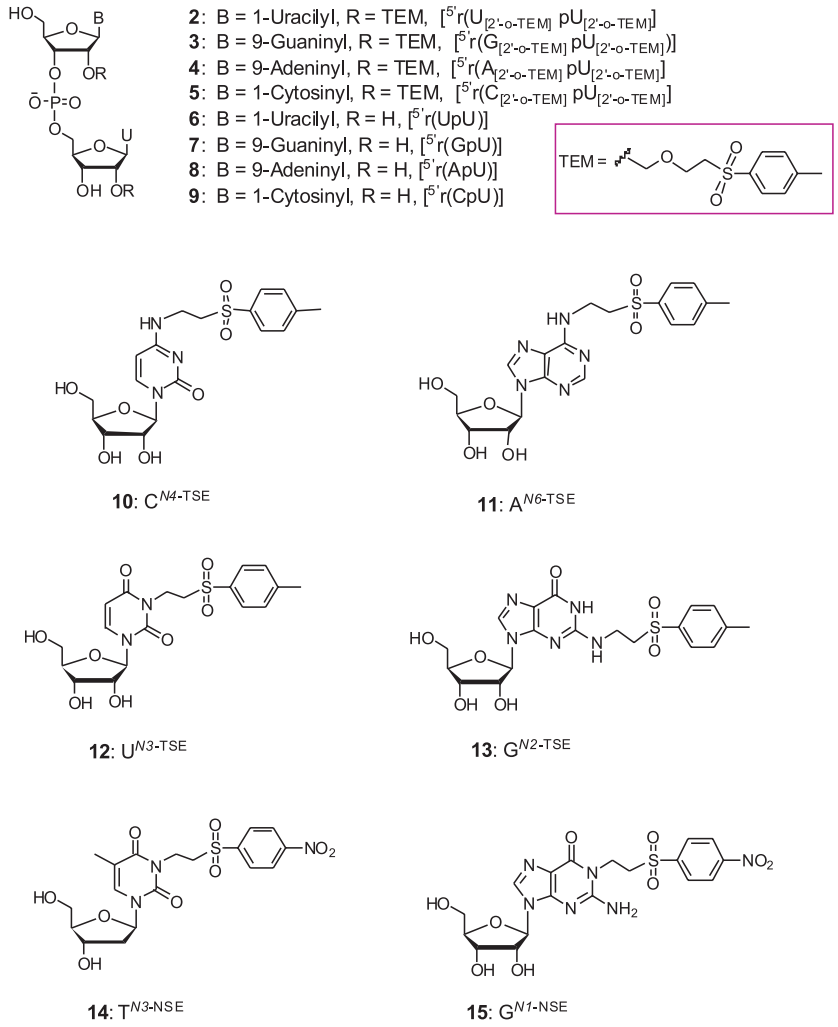
stepwise coupling yield (97%–99%), leading to (*iii*) the crude RNA, obtained after a simple deprotection step. The crude form RNA was sufficiently pure for chemical biology research without the need for any additional purification steps.

The 2′-*O*-TEM group is stable upon ammonia treatment and can be quickly cleaved by 1 mol/L tetrabutylammonium fluoride (TBAF) in THF through F^--promoted β elimination (Scheme 1). But the by-product *p*-tolyl vinyl sulphone (TVS) (**1**), which is generated during deprotection, attacks the nucleophilic sites of nucleobases of the oligo–RNA to form some undesirable side products that somewhat reduce the purity of the oligo–RNA. To obtain clean oligo–RNA at the end of the synthesis, we had earlier employed a mixture of 10% (*v*/*v*) *n*-propylamine and 1% (*v*/*v*) bis(2-mercaptoethyl)ether in 1 mol/L TBAF–THF as a scavenger for TVS during the deprotection of the 2′-*O*-TEM group. Clearly, we wanted to find other neutral alternative(s) to this scavenger because bis(2-mercaptoethyl)ether has a foul odour and it can also deactivate many enzymes, even in trace amounts (ppm).

Earlier work (8) has excluded N^3 of 1-uracilyl as a reactive centre for the side product formation. To this point, the potential nucleophilic sites have been known to be N^1 of 9-adeninyl (9, 10), N^7 and N^1 of 9-guaninyl (11, 12), and N^3 of 1-cytosinyl (13, 14). In this study, through isolation of the pure adducts formed with TVS and by identifying them unambiguously by MS and NMR, we have unexpectedly found that N^2 of 9-guaninyl, N^4 of 1-cytosinyl, and especially N^6 of 9-adeninyl are the reactive nucleophilic sites for adduct formation with TVS, and more powerful scavengers were therefore developed.

Results and discussion

Deprotection of the 2′-*O*-TEM group from dimeric RNAs



It was known (8) that when deprotecting with 1 mol/L TBAF–THF, pure poly-U can be easily obtained as the sole product, hence the lactam function of 1-uracilyl and the internucleotidic phosphate backbone are not amenable to adduct formation with TVS. We anticipated that the possible nucleobases that could potentially be involved in the adduct formation with TVS are 9-guaninyl, 9-adeninyl, and 1-cytosinyl moieties in oligo–RNA. Keeping this in mind, four dimeric ribonucleotides, $^{5'}r(U_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**2**), $^{5'}r(G_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**3**), $^{5'}r(A_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**4**), $^{5'}r(C_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**5**), (Scheme 2), were synthesized. They were treated with 1 mol/L TBAF–THF for 4 h at RT, then the reaction mixtures were analyzed by reverse phase HPLC (RP-HPLC). The RP-HPLC profiles are shown in Fig. 1.

As expected, $^{5'}r(U_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**2**) upon treatment with 1 mol/L TBAF–THF gave a single product (Fig. 1*A*, R_T = 5.89 min), which proved to be the desired product $^{5'}r(UpU)$ (**6**) by MALDI-TOF MS (*m*/*z* calcd.: 551.10 $[MH]^+$; found: 551.11). Treatment of $^{5'}r(G_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**3**) with 1 mol/L TBAF–THF also gave the desired product $^{5'}r(GpU)$ (**7**). (Fig. 1*B*, R_T = 6.56 min, *m*/*z* calcd.: 590.12 $[MH]^+$; found: 590.11). We therefore could safely exclude 1-uracilyl and 9-guaninyl aglycons as substrates for adduct formation with TVS.

The RP-HPLC analysis of the reaction of $^{5'}r(C_{[2'\text{-}o\text{-TEM}]}\ pU_{[2'\text{-}o\text{-TEM}]})$ (**5**) is shown in Fig. 1*C*. The product with R_T = 4.75 min was proved by MS to be the fully deprotected product $^{5'}r(CpU)$ (**9**) (*m*/*z* calcd.: 550.12 $[M]^-$; found: 550.12). However, the peak appearing at 18.43 min (Fig. 1*C*) was the major product, which was analyzed by MS (*m*/*z* found: 730.32 $[M]^-$). This suggested that this product was formed by the reaction of one molecule of PVS with $^{5'}r(CpU)$ (**9**). This major product was separated and its base composition was analyzed by digesting it with mixture of phosphodiesterase I and shrimp alkaline phosphatase (see experimental section). The digestion mixture was applied to RP-HPLC analysis. As shown in the Fig. 1*C* inset, the digestion gave two products. One appears at 4.06 min, corresponding to uridine. The second peak appears at 17.01 min. It was probably formed by the addition of TVS to cytidine and clearly needed further characterization (represented by **X** in Fig. 1*C*).

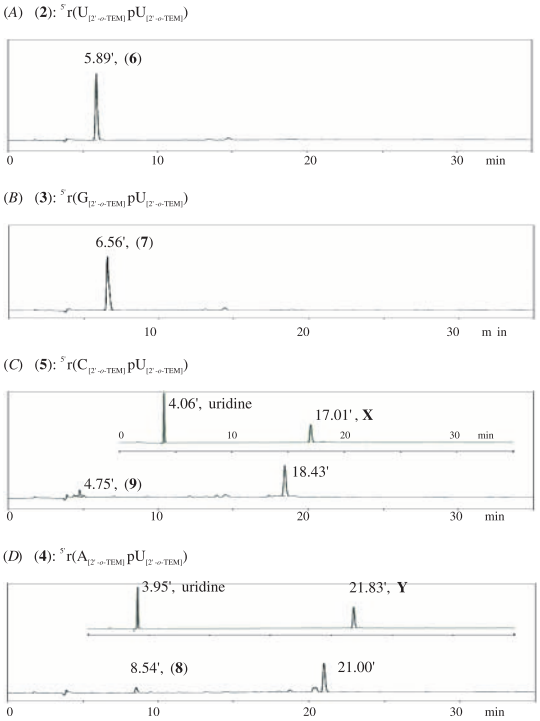
Scheme 2. **10**: N^4-(4-tolylsulfonylethyl)cytidine ($C^{N4\text{-}TSE}$); **11**: N^6-(4-tolylsulfonylethyl)adenosine ($A^{N6\text{-}TSE}$); **12**: N^3-(4-tolylsulfonylethyl)uridine ($U^{N3\text{-}TSE}$); **13**: N^2-(4-tolylsulfonylethyl)guanosine ($G^{N2\text{-}TSE}$); **14**: N^3-(4-nitrophenylsulfonylethyl)thymidine ($T^{N3\text{-}NSE}$); **15**: N^1-(4-nitrophenylsulfonylethyl)guanosine ($G^{N1\text{-}NSE}$).

Dimer $^{5'}r(A_{[2'\text{-}o\text{-}TEM]}\ pU_{[2'\text{-}o\text{-}TEM]})$ (**4**) was treated with 1 mol/L TBAF–THF and gave a very small amount of the desired product $^{5'}r(ApU)$ (**8**) (Fig. 1*D*, R_T = 8.54 min, *m*/*z* calcd.: 572.41[M]$^-$; found: 572.31). The predominant reaction product (*m*/*z* found: 754.34 [M]$^-$) appears at 21.00 min. Base composition analysis of this major product by enzymatic digestion, as described earlier, gave uridine (Fig. 1*D* inset, R_T = 3.95 min) and another product (Fig. 1*D*, represented by Y, R_T = 21.83 min). This result suggested that both the cytidine and adenosine were reactive toward adduct formation with TVS.



Characterization of TVS adducts with aglycones of RNA

To determine the chemical nature of the adducts (**X** and **Y** in the HPLC elution profile in Figs. 1*C* and 1*D*), either cytidine or adenosine was treated with 3 equiv. of TVS at RT in 1 mol/L TBAF–THF for 24 h. The major product of the reaction between cytidine and TVS was separated by silica gel chromatography. This compound showed $[MH]^+$ at *m*/*z* 426.17, which suggested that it was an unimolecular adduct of TVS and cytidine. The chemical shift of β-C ($\delta_{\beta\text{-}C}$, 34.69 ppm, see Fig. 2 and Table 1) (12) suggested that the TVS is attached to the N atom, and the potential site could be either N^4 or N^3 of cytidine. The assignment of the covalent binding site of TVS could easily be achieved by ^1H, ^{13}C Heteronuclear Multiple Bond Correlation (HMBC) NMR experiment (12). As shown in Fig. 2*A*, the β-H shows a strong cross peak with C4 (shown by red line) but no cross-correlation with the C2, which strongly supports the explanation that the TVS has been formed as an adduct to N^4 of cytidine to give N^4-(4-tolylsulfonylethyl)cytidine ($C^{N4\text{-}TSE}$, **10**).

The reaction between adenosine and TVS gave a major product with $[MH]^+$ at *m*/*z* 450.18, which also indicated that a unimolecular adduct had formed between TVS and adenosine. Two unambiguous NMR proofs were used to confirm that TVS is indeed covalently bonded to the N^6 of adenosine to give product N^6-(4-tolylsulfonylethyl)adenosine ($A^{N6\text{-}TSE}$, **11**): (*i*) in the ^1H,^{13}C HMBC spectrum (Fig. 2*B*), the HN^6 shows cross coupling with C5, C6, and β-C, and (*ii*) more direct proof is the fact that the HN^6 of adenosine shows a strong cross peak with β-H (Fig. S2.1) in the ^1H, ^1H

Fig. 1. RP-HPLC analysis of the reaction products upon treatment of compounds **2–5** with 1 mol/L TBAF–THF at RT for 4 h. The products (R_T = 18.43 min in *C* and R_T = 21.00 min in *B* were digested respectively by mixture of phosphodiesterase and alkaline phosphatase. HPLC analysis of the digestion reaction is shown in the inset. RP-HPLC conditions: 0′→10′→35′, A →A–B 9:1, *v*/*v*→A–B 2:8, RT, flow rate 1 mL/min. Buffer A: 0.1 mol/L TEAA in H_2O–CH_3CN (*v*/*v*, 95:5). Buffer B: 0.1 mol/L TEAA in H_2O–CH_3CN (*v*/*v* 50:50).

COSY NMR spectrum, thereby confirming that the N^6 of adenosine has undergone a conjugate Michael addition to TVS.[3]

Co-injection of compound **10** with **X** on RP-HPLC has also shown that they are the same compound. In the same way, **Y** was shown to be compound **11** (Fig. S5.1 and S5.2).[3]

It has been reported that thymidine and guanosine can react with with acrylonitrile or phenylvinyl sulfone in the presence of a base such as tetra-*n*-butylammonium hydroxide (12), TBAF–THF (15), or ammonia (16, 17). These α,β-unsaturated compounds were adducted to the N^3 of thymidine (12, 15–17) and the N^1 of guanosine (12), respectively. Here, we have also studied the reaction between uridine or guanosine with TVS in 1 mol/L TBAF–THF. As reported (12), TVS is adducted to the N^3 of uridine (NMR spectra shown in Figs. 2*C* and S3) to give the product N^3-(4-tolylsulfonylethyl)uridine ($U^{N3\text{-}TSE}$, **12**).[3] For guanosine, the predominant product was proved to be N^2-(4-tolylsulfonylethyl)guanosine ($G^{N2\text{-}TSE}$, **13**) in an unambiguous manner by NMR and not $G^{N1\text{-}TSE}$, as earlier believed (12). Thus, (*i*) the imino proton is present ($\delta_{N1\text{-}H}$ = 10.94 ppm, see Fig. S4.1) in the ^1H NMR spectrum of **13**; (*ii*) the $\delta_{\beta\text{-}C}$ and $\delta_{\beta\text{-}H}$ (see Table 1) in **13** are much different than in compound N^1-(4-nitrophenylsulfonylethyl)guanosine ($G^{N1\text{-}NSE}$, **15**, Scheme 2) (12); (*iii*) in the ^1H,^{13}C HMBC spectrum (Fig. 2*D*), β-*H* shows a strong cross peak with C2 but none with C5, C6, or C8 in **13**.[3]

The Michael addition between the α,β-unsaturated compound, such as acrylonitrile with DNA or RNA under different conditions, leads to cyanoethylation of nucleobases, which has been studied extensively. Because of the natural electronic structure of nucleobases (18), the cyanoethylation generally occurs at N^3 of uridine (19) and cytidine (9), N^1 of adenosine (9, 20), N^7, and N^1 of guanosine (9, 12). Though cyanoethylation at N^6 of adenosine (20) was also observed, it was in fact obtained by Dimroth rearrangement (21) of N^1 of cyanoethylated adenosine in the presence of a strong base such as aqueous sodium hydroxide. Alkylation of nucleosides with other reagents such as diazomethane and dimethyl sulfate also occurs at the ring nitrogen atom such as N^7 and N^1 of purine (10, 11) and N^3 of pyrimidine (11, 14).

The present unexpected findings may have important applications in directly alkylating exocyclic amines of nucleosides as probes to determine the structure and (or) function of a nucleic acid (22, 23). Many methods have been developed for the alkylation of exocyclic amino groups (24–26), but these methods (24–26) are multi-step reactions and are time-consuming and laborious. To our knowledge, no direct alkylation method has been developed until now. The present finding that TVS can indeed be added selectively to an exocyclic amino of cytidine, adenosine, and guanosine provides an easier way to the direct alkylation of exocyclic amino groups of nucleobases if they exist as a part of a non-hydrogen-bonded loop or hairpin structure in the RNA scaffolds. Moreover, the phenyl moiety of TVS is relatively easy to derivatize for fluorescence detection purposes. Alternatively, by attaching other functional groups to the phenyl moiety, such as some specific cross-linking agents, we can conveniently introduce various functional groups to the non-hydrogen-bonded exocyclic amino of the nucleobases to map the folding in the RNA scaffolds by estimating spatial proximities.

Relative nucleophilic reactivities of the exocyclic amino groups of RNA toward TVS

Earlier we showed that in dimeric RNAs neither uridine nor guanosine participates in the adduct formation with TVS. Subsequently we showed that all of the four monomeric ribonucleosides are found to react with TVS. This apparent contradiction may be explained by comparing the nucleophilic reactivities of different ribonucleoside aglycons in an oligo–RNA toward TVS. We therefore chose a tetrameric RNA, 5′r(UpApCpG) (**16**, Scheme 3), for a model study; 0.5 OD (12.5 μmol) of **16** was treated with 0, 1/4, 1/2, 1, 2, 4, and 20 equiv. of TVS, respectively, in 1 mol/L TBAF–THF (total reaction volume 40 μL) at RT for 24 h. The aliquots of the reactions were analyzed by RP-HPLC (Fig. 3). The maldi-tof MS spectra showed that each of the

three products **17** (*m/z* found: 1406.23 $[MH]^+$), **18** (*m/z* found: 1406.23 $[MH]^+$), and **19** (*m/z* found: 1406.26 $[MH]^+$) has only one molecule of TVS attached, thereby suggesting that the products **17**, **18**, and **19** are isomeric in nature. Furthermore, base composition analysis of these products by enzyme digestion showed that **17** is $^{5'}$r(UpApCpG$^{N2\text{-TSE}}$), **18** is $^{5'}$r(UpAp$C^{N4\text{-TSE}}$ pG), and **19** is $^{5'}$r(Up$A^{N6\text{-TSE}}$ pCpG) (see Fig. 4).

The yields of the three products in the reactions between $^{5'}$r(UpApCpG) (**16**) and different stoichiometries of TVS are listed in Table 2. In the presence of a limited amount of TVS, (1/4, 1/2 equiv.), only N^6 of adenosine was alkylated to give $^{5'}$r(Up$A^{N6\text{-TSE}}$ pCpG) (**19**). With the increase in concentration of TVS (1 or 2 equiv.), N^4 of cytidine was also alkylated to give $^{5'}$r(UpAp$C^{N4\text{-TSE}}$ pG) (**18**). By increasing the amount of TVS further to 20 equiv., a small amount of product by the alkylation of N^2 of guanosine was also observed to give $^{5'}$r(UpApCpG$^{N2\text{-TSE}}$) (**17**). This proves that the alkylation tendency of ribonucleotide by TVS in oligo–RNA in 1 mol/L TBAF–THF follows the sequence, N^6 – A > N^4 – C > N^2 – G > > N^3 – U. By controlling the concentration of TVS, selective alkylation of N^6 of adenosine, or both N^6 of adenosine and N^4 of cytidine, or all the exocyclic amino functions of ribonucleobases is possible. Since all the exocyclic amino functions participate in H-bond formation in the tertiary structure of nucleic acid, their selective alkylation by TVS gives the possibility of identifying those nucleobases that are not hydrogen bonded, and thus TVS can be used as a chemical probe for the structure and function of the nucleic acid.

Morpholine and piperidine as scavenger for TVS to avoid adduct formation

In the 2′-*O*-TEM group based solid-phase RNA synthesis (8), a mixture of 10% *n*-propylamine and 1% bis(2-mercaptoethyl) ether was used as the scavenger for TVS. Two disadvantages of employing bis(2-mercaptoethyl)ether as the deprotecting agent are its foul odour and its ability, in trace amounts, to possibly cause enzyme deactivatation in biological assays. In this study we wanted to use an appropriate amine as the sole scavenger to examine if the quality of the crude RNA could be further improved.

The Michael addition of amine to TVS (27–29) has shown that primary amines are notably less reactive than secondary amines because the former binds to two moles of solvent through H-bonds, compared with the latter that binds only to one mole of the solvent. It was also shown (27–29) that large differences in the basicity of amines has relatively little effect on the reactivity. Thus morpholine (pK_a = 8.4) is about one seventh as reactive as piperidine (pK_a = 11.1), but the former is > 100 times less basic. In our case, the ideal amine should have better nucleophilicity toward TVS than the exocyclic amino groups of the nucleobases of RNA, and at the same time the basicity of the amine cannot compromise any oligo–RNA chain cleavage. Keeping this in mind, several types of amines with very different pK_a values were se-

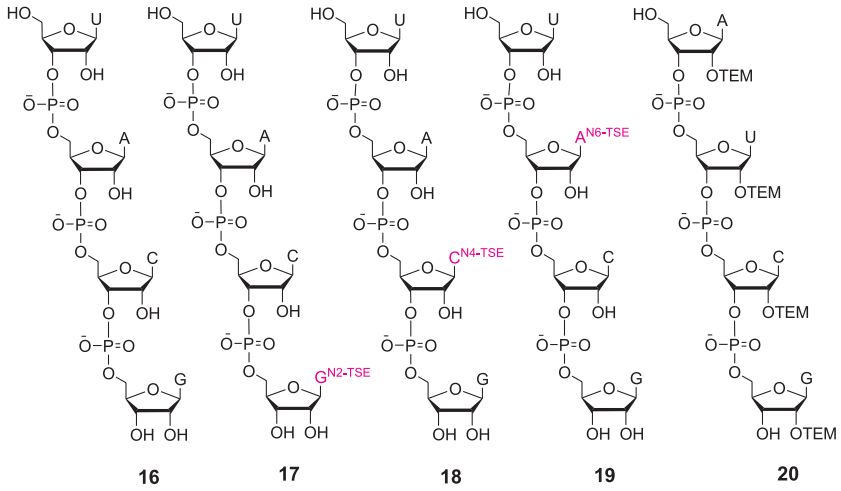
Scheme 3.



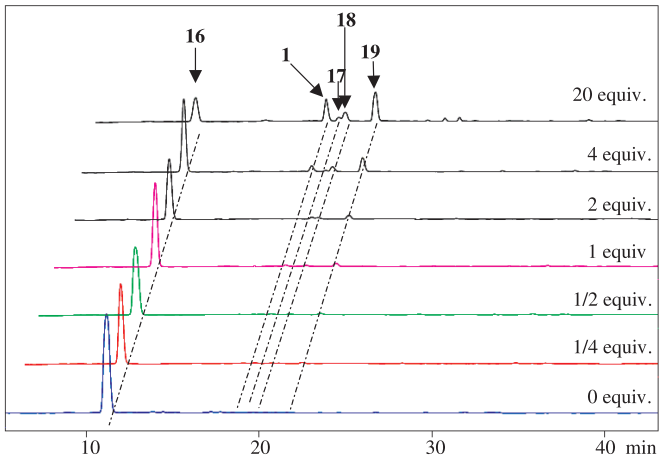


Fig. 3. RP-HPLC analysis of the reactions between $^{5'}$r(UpApCpG) (**16**) (0.5 OD, 12.5 µmol) with 0, 1/4, 1/2, 1, 2, 4, and 20 equiv. of TVS in 1 mol/L TBAF–THF at RT for 24 h. Each reaction has the same total volume of 40 µL. RP-HPLC conditions: 0′→10′→42′, A→A–B 9:1 →B, RT, flow rate 1 mL/min. Buffer A: 0.1 mol/L TEAA in H_2O–CH_3CN (*v*/*v*, 95:5). Buffer B: 0.1 mol/L TEAA in H_2O–CH_3CN (*v*/*v* 50:50).

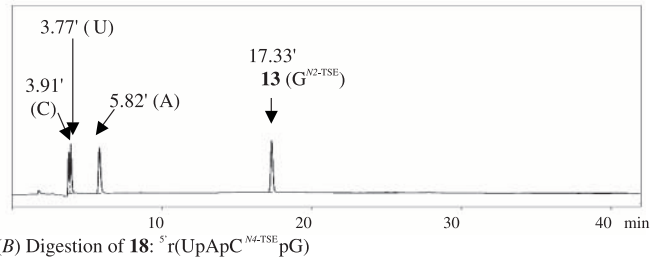

lected to test their abilities as scavengers of TVS in 1 mol/L TBAF–THF solution. The $^{5'}$r(A$_{[2'\text{-}o\text{-TEM}]}$ pU$_{[2'\text{-}o\text{-TEM}]}$ pC$_{[2'\text{-}o\text{-TEM}]}$ pG$_{[2'\text{-}o\text{-TEM}]}$ (**20**, Scheme 3) was used as the model compound and was treated with 1 mol/L TBAF–THF containing 10% (*v*/*v*) of different amines at RT for 24 h, and the reaction mixtures were analyzed by RP-HPLC (Fig. S7).[3] The percentage of chain cleavage product and side products formed through the reaction of TVS to oligo–RNA were obtained by integrating the HPLC profile (see Fig. S7) and they are given in Table 3.[3]

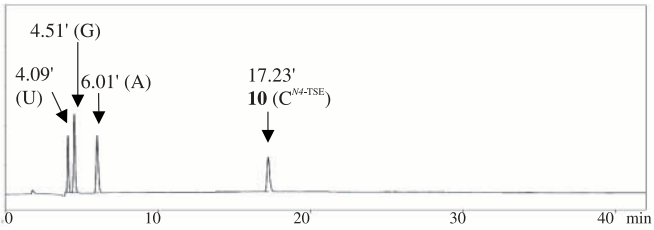

Table 3 shows that a primary or secondary amine, such as *n*-propylamine, piperidine, or morpholine, when used alone can scavenge TVS more efficiently than the standard deprotection condition (8) [a mixture of *n*-propylamine and bis(2-mercaptoethyl)ether] employed earlier for the deprotection of the 2′-*O*-TEM group. Among these amines, the morpholine and piperidine are especially attractive.

Fig. 4. The compounds **17**, **18**, and **19** were digested by a mixture of phosphodiesterase and alkaline phosphatase. The HPLC profiles of digestion mixture are shown in (*A*) **17**, (*B*) **18**, and (*C*) **19.** RP-HPLC conditions: 0′→10′→42′, A→A–B 9:1, *v*/*v* →B, RT, flow rate 1 mL/min. Buffer A: 0.1 mol/L TEAA in H_2O–CH_3CN (*v*/*v*, 95:5). Buffer B: 0.1 mol/L TEAA in H_2O–CH_3CN (*v*/*v* 50:50). Abbreviations are A = adenosine, G = guanosine, C = cytidine, U = uridine, $A^{N6\text{-TSE}}$ = N^6-(4-tolylsulfonylethyl)adenosine, $C^{N4\text{-TSE}}$ = N^4-(4-tolylsulfonylethyl)cytidine, $G^{N2\text{-TSE}}$ = N^2-(4-tolylsulfonylethyl)guanosine.

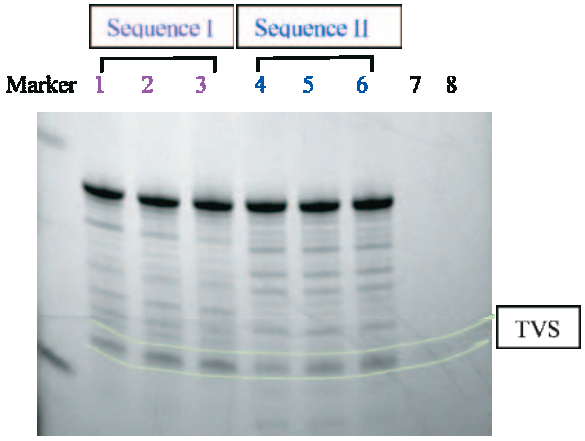
Amine[a]	pK_a[c]	Oligo–RNA chain cleavage (%)	TVS adduct with oligo–RNA (%)
Standard condition[b]	—	9.1	17.0
n-Propylamine	10.71	1.6	8.1
Piperidine	11.12	8.3	0
Morpholine	8.33	0	7.2



[a]Deprotection reagents: a solution of 10% (*v*/*v*) of each amine in 1 mol/L TBAF–THF, RT, 24 h.
[b]A mixture of 10% *n*-propylamine and 1% bis(2-mercaptoethyl)ether in 1 mol/L TBAF–THF (8).
[c]The pK_a values are taken from Perrin (30).

Morpholine, benefiting form its lower pK_a (8.4), does not cause any chain cleavage but allows the addition of TVS to oligo–RNA to some extent (7.2%) in 1 mol/L TBAF–THF solution. On the other hand, piperidine can completely quench the reaction between TVS and oligo–RNA, but it leads to a small amount (8.3%) of chain cleavage (Table 3).

To examine the potential of morpholine and piperidine as candidates as scavengers of the undesirable byproduct TVS, we have deprotected two 21-mer RNAs using 1 mol/L TBAF–THF, containing either a mixture of *n*-propylamine and bis(2-mercaptoethyl)ether (8), piperidine, or morpholine. Thus, two 21-mer RNAs were synthesized on a solid support with the 2′-*O*-TEM group using our published procedure (8) (sequence I: 5′-GAC GUA AAC GGC CUC AAG UUC; sequence II: 5′-ACU UGU GGC CGU UUA CGU CGC). After treatment with 25% NH_3–MeOH for 20 h at RT and then for 4 h at 40 °C, they were divided into three parts and incubated with (*a*) the standard deprotecting reagent (8) (1 mol/L TBAF–THF containing 10% *n*-propylamine and 1% bis(2-mercaptoethyl) ether), (*b*) 1 mol/L TBAF–THF containing 10% of piperidine, or (*c*) 1 mol/L TBAF–THF containing 10% of morpholine at RT for 20 h. After evaporation of the volatile materials, the products were first passed through a Sep-Pak® Plus (C18, reverse phase) (31) column to remove hydrophilic matter such as excess of F^-, and then NAP^{TM}-10 (Sephadex G25) column (32) to separate the smaller molecules from the larger ones on the basis of size (thus, the full-size oligo–RNA elutes from the truncated sequences and hydrophobic protecting group residues) to give the crude products, which are of high purity and can be used directly for various biological experiments. These crude products were analyzed by 20% denatured PAGE and gel picture obtained by UV–visualization (Fig. 5).

As shown in Fig. 5, all three deprotecting conditions give highly pure crude RNA. Use of morpholine or piperidine,

Fig. 5. 20% denatured PAGE picture of crude RNAs obtained from the deprotection of RNA sequence I (5′-GAC GUA AAC GGC CUC AAG UUC) and RNA sequence II (5′-ACU UGU GGC CGU UUA CGU CGC) with different 2′-*O*-TEM deprotecting conditions. The 2′-*O*-TEM group was deprotected with 1 mol/L TBAF–THF containing different scavengers at RT for 20 h. Lanes 1 and 4: 10% *n*-propylamine and 1% bis(2-mercaptoethyl)ether. Lanes 2 and 5: 10% piperidine. Lanes 3 and 6: 10% morphholine. Marker, upper band: xylene cyanol blue; bottom band: bromophenol blue. Gel picture obtained by UV–vis (254 nm) showing all UV absorbing compounds both nucleic acids (full product and n-1 failure sequences) as well as the cleaved protecting groups. Note that the noncharged TVS (**1**) (λ_{max} = 233 nm) also runs on the gel and is visible by 254 nm light shadowing if in high concentration (Fig. S8).[3] The bands between dashed lines correspond to TVS. Lanes 7 and 8 were run together as a control. Lane 7 product obtained by incubating compound TVS with 1 mol/L TBAF–TMF. Lane 8 product obtained by incubating compound TVS with 1 mol/L TBAF–TMF containing 10% morpholine.

© 2007 NRC Canada

however, gives only a very minor improvement of RNA purity (~84%) compared with that of the standard condition (8) (~82%) [a mixture of *n*-propylamine and bis(2-mercaptoethyl)ether], which is in contrast to the result obtained from the deprotection of the tetrameric RNA (**20**) (see Table 3) with the above three reagents.

Conclusion

In this study, we found that N^6 of adenosine, N^4 of cytidine, and N^2 of guanosine, just as N^3 of thymidine (12), can be alkylated by the α,β-unsaturated compound TVS in 1 mol/L TBAF–THF solution through Michael addition. In oligo–RNA, their nucleophilicities toward TVS are different: N^6 – A > N^4 – C > N^2 – G >> N^3 – U. Hence, by controlling the concentration of TVS, selective alkylation of these nucleophilic sites can be easily achieved. This discovery not only provides a new approach for the alkylation of non-hydrogen-bonded exocyclic amino groups of nucleobases in RNA, but also provides a new strategy for the potential application of the reagent TVS as a chemical probe for detecting the structure and (or) the function of nucleic acid. To avoid adduct formation and chain cleavage during deprotection of 2′-*O*-TEM group with 1 mol/L TBAF–THF, both morpholine and piperidine have been proved to be good scavengers of TVS, which can give high quality crude RNA, bypassing the practical problems of employing the mixture of *n*-propylamine and bis(2-mercaptoethyl)ether (8).

Experimental section

General experimental methods

Chromatographic separations were performed on Merck G60 silica gel. Thin layer chromatography (TLC) was performed on Merck pre-coated silica gel 60 F_{254} glass-backed plates. ^{1}H NMR spectra were recorded at 270.1 MHz and 500 MHz, respectively. ^{13}C NMR spectra were recorded at 67.9 MHz, 125.7 MHz, and 150.9 MHz, respectively. Chemical shifts are reported in ppm (δ scale). Reversed-phase (RP) HPLC: Kromasil 100, C18, 5μ, 100*4.6 mm. Flow 1 mL/min at RT, UV detector with detecting wavelength of 260 nm. Buffer A: 0.1 mol/L TEAA in H_2O–CH_3CN (95:5). Buffer B: 0.1 mol/L TEAA in H_2O–CH_3CN (50:50). Polyacrylamide gel electrophoresis (PAGE): 20% acrylamide (acrylamide/bisacrylamide 29:1), 7 mol/L urea, TBE buffer.

Oligoribonucleotide synthesis

Oligo–RNAs **2–5** and **20** were synthesized through our published procedure (8). After the completion of the automated solid-phase synthesis, the solid supports were treated with 25% NH_3–MeOH at RT overnight, filtered, and purified by HPLC. Oligo–RNA **14** was synthesized by a TBDMS approach according to reported procedure (33) and purified by HPLC. Their structural integrity were verified by MALDI-TOF MS: (**2**) calcd. 974.92 $[MH]^+$, found 975.29; (**3**) calcd. 1013.94 $[MH]^+$, found 1014.24; (**4**) calcd. 997.95 $[MH]^+$, found 998.25. (**5**) cal. 973.94 $[MH]^+$, found 974.29; (**20**) calcd. 2071.85 $[MH]^+$, found 2070.15; (**14**) calcd. 1224.21 $[MH]^+$, found 1224.19.

The 21-mer RNAs, sequence I and sequence II, were synthesized according to our published procedure (8). After completion of the synthesis, the solid supports were treated with 25% NH_3–MeOH at RT for 20 h and then at 40 °C for 4 h. After filtration, each sample was separated into three parts and the volatile materials were evaporated. The residues were co-evaporated with dry methanol twice and dried in vacuum. Then they were treated with 1 mol/L TBAF–THF (dried over 4 Å molecular sieves overnight) containing different scavengers at RT for 20 h. After evaporation of the volatile matter, the residues were diluted with double-distilled water and applied to a NAP-10 column (Amersham Pharmacia Biotech, Sweden). Loading volume is 1 mL and elution was done with 1.2 mL of double-distilled water. The collected fractions were subjected to Sep-Pak® Plus C18 cartridges (Waters) according to manufacturer instructions, to give the crude products. The crude RNAs were subjected to 20% denatured PAGE analysis without any purification step.

General procedure of reaction between ribonucleosides with *p*-tolyl vinyl sulphone (1)

Ribonucleoside (1 mmol) was dissolved in dry 1 mol/L TBAF–THF (5ml) and *p*-tolyl vinyl sulphone **1** (3 mmol for adenosine, cytidine, uridine and 1 mmol for guaonsine) was added. The reaction was stirred at RT for 24 h and analyzed by HPLC. Then the reaction mixture was evaporated to dryness. The residue was diluted with dichloromethane (DCM) and washed with satd. $NaHCO_3$ and dried over $MgSO_4$. The major product was obtained by short column chromatography.

N^4-(4-tolylsulfonylethyl) cytidine (10) ($C^{N4\text{-}TSE}$)

HPLC analysis of the reaction mixture showed that 38.6% of the cytidine was transformed into product **10** and 38.3% of the cytidine was unreacted. CC (DCM, MeOH from 2% to 10%). ^{1}H NMR (270 MHz, $CDCl_3$ + CD_3OD) δ: 2.45 (s, 3H, Ph*Me*), 3.46 (t, *J* = 5.8 Hz, 2H, SO_2CH_2), 3.75–3.96 (m, 4H, $SO_2CH_2CH_2$, 5′,5″-*H*), 4.09 (broad, 1H, 4′-*H*), 4.18 (broad, 2H, 2′3′-*H*), 5.69 (d, *J* = 1.5 Hz, 1H, 1′-*H*), 5.76 (d, *J* = 7.4 Hz, 1H, 5-*H*), 7.37 (d, *J* = 7.7 Hz, 2H, ph*H*), 7.77 (d, *J* = 8.3 Hz, 2H, ph*H*), 7.87 (d, *J* = 7.4 Hz, 1H, 6-*H*). ^{13}C NMR (67.9 MHz, $CDCl_3$ + CD_3OD) δ: 23.94 (Ph*Me*), 34.69 ($SO_2CH_2CH_2$) 54.79 ($SO_2CH_2CH_2$), 60.88 (5′-C), 69.31 (3′-C), 74.94 (2′-C), 84.88 (4′-C), 92.53 (1′-C), 95.81 (5-C), 127.98 (ph), 130.24 (ph), 136.10 (ph), 141.11 (C6), 145.47 (ph), 157.21 (2-C), 164,05 (C4). MALDI-TOF MS: calcd.: 426.13 $[MH]^+$; found: 426.17.

N^6-(4-tolylsulfonylethyl) adenosine (11) ($A^{N6\text{-}TSE}$)

HPLC analysis of the reaction mixture showed that 35.6% of the adenosine was transformed into product **11** and 56.8% of the adenosine was unreacted. CC (DCM, Acetone from 20% to 50%). ^{1}H NMR (270 MHz, $CDCl_3$ + CD_3OD) δ: 2.36 (s, 3H, Ph*Me*), 3.50 (t, 2H, SO_2CH_2), 3.69 (t, 1H, 5′-*H*), 3.84–4.01 (m, 3H, 5″-*H*, $SO_2CH_2CH_2$), 4.26 (broad, 1H, 4′-*H*), 4.44 (broad, 1H, 3′-*H*), 5.50 (broad, 1H, 2′-O*H*), 5.84 (d, *J* = 6.7 Hz, 1H, 1′-H), 6.62 (broad, 1H, 5′-O*H*), 6.97 (t, *J* = 6.1 Hz, 1H, N^6H), 7.25 (d, *J* = 7.9 Hz, 2H, ph*H*), 7.74 (d, *J* = 8.2 Hz, 2H, ph*H*), 7.90 (s, 1H, 8-*H*), 8.03 (s, 1H, 2-*H*). ^{13}C NMR (67.9 MHz, $CDCl_3$ + CD_3OD) δ: 21.60 (Ph*Me*), 34.65 ($SO_2CH_2CH_2$) 54.91 ($SO_2CH_2CH_2$), 62.99 (5′-C), 72.37 (3′-C), 74.01 (2′-C), 87.45 (4′-C), 90.86 (1′-

C), 120.46 (5-C), 127.90 (ph), 130.00 (ph), 135.95 (ph), 140.67 (8-C), 145.07 (ph), 147.49 (4-C), 152.06 (2-C), 154.08 (6-C). MALDI-TOF MS: calcd.: 450.14 $[MH]^+$; found: 450.19.

N^3-(4-tolylsulfonylethyl) uridine (12) ($U^{N3\text{-}TSE}$)

HPLC analysis of the reaction mixture showed that 57.2% of the uridine was transformed to product **12** and 34.1% of the uridine was unreacted. CC (DCM, MeOH from 5% to 7%). ^{1}H NMR (270 MHz, $CDCl_3$ + CD_3OD) δ: 2.39 (s, 3H, Ph*Me*), 3.42 (t, *J* = 7.0 Hz, 2H, SO_2CH_2), 3.76 (dd, *J* = 12.2 Hz, 2H, 5′,5″-*H*), 3.99 (d, *J* = 1.5 Hz, 1H, 4′-*H*), 4.10–4.21 (m, 4H, 2′, 3′, -*H*, $SO_2CH_2CH_2$), 5.65 (d, *J* = 8.1 Hz, 1H, 5-*H*), 5.72 (d, *J* = 2.3 Hz, 1H, 1-*H*), 7.32 (d, *J* = 7.8 Hz, 2H, ph*H*), 7.74 (d, *J* = 8.2 Hz, 2H, ph*H*), 7.85 (d, *J* = 8.1 Hz, 1H, 6-*H*). ^{13}C NMR (67.9 MHz, $CDCl_3$ + CD_3OD) δ: 23.88 (Ph*Me*), 34.95 ($SO_2CH_2CH_2$) 52.56 ($SO_2CH_2CH_2$), 60.95 (5′-C), 69.41 (3′-C), 74.73 (2′-C), 85.16 (4′-C), 91.13 (1′-C), 101.40 (5-C), 128.04 (ph), 130.11 (ph), 135.67 (ph), 139.81 (6-C), 145.36 (ph), 150.92 (2-C), 162.60 (4-C). MALDI-TOF MS: calcd.: 427.11 $[MH]^+$; found: 427.15.

N^2-(4-tolylsulfonylethyl) guanosine (13) ($G^{N2\text{-}TSE}$)

HPLC analysis of the reaction mixture showed that 50.3% of the guanosine was transformed to product **13** and 23.8% of the guanosine was unreacted. The product **13** was too polar to purify by silica gel column chromatography, hence preparative HPLC was used to purify a small amount of product **13** for NMR and MS analysis. ^{1}H NMR (270 MHz, DMSO-d_6) δ: 2.38 (s, 3H, Ph*Me*), 3.51–3.60 (m, 6H, SO_2CH_2, $SO_2CH_2CH_2$, 5′,5″-*H*), 3.99 (t, *J* = 1.5 Hz, 1H, 4′-*H*), 4.11 (t, 1H, 3′-*H*), 4.47 (t, *J* = 5.3 Hz, 1H, 2′-*H*), 5.68 (d, *J* = 5.8 Hz, 1H, 1′-*H*), 6.88 (br., 1H, N^2H), 7.42 (d, *J* = 7.9 Hz, 2H, ph*H*), 7.77 (d, *J* = 8.2 Hz, 2H, ph*H*), 7.93 (s, 1H, 8-*H*), 10.94 (br., 1H, N^1H). ^{13}C NMR (67.9 MHz, DMSO-d_6) δ: 21.64 (Ph*Me*), 34.95 ($SO_2CH_2CH_2$) 54.11 ($SO_2CH_2CH_2$), 62.11 (5′-C), 70.99 (3′-C), 74.27 (2′-C), 85.87 (4′-C), 87.21 (1′-C), 117.70 (5-C), 128.17 (ph), 130.43 (ph), 136.46 (8-C), 136.70 (ph), 144.96 (ph), 151.06 (4-C), 152.89 (2-C), 157.67 (6-C). MALDI-TOF MS: calcd.: 466.23 $[MH]^+$; found: 466.13.

Base composition analysis

Shrimp alkaline phosphatase and phosphodiesterase I (*Crotalus adamanteus* venom) were purchased from Amersham Pharmacia Biotech, Sweden. A reaction mixture containing 20 mmol/L Tris-HCl (pH 8.0), 10 mmol/L $MgCl_2$, shrimp alkaline phosphatase (0.5 unit), and phosphodiesterase I (*Crotalus adamanteus* venom) (0.4 unit) was added to oligoribonucleotide (0.1 OD unit at 260 nm) with a total reaction volume of 30 µL. The reaction mixture was incubated at 37 °C for 12 h and subjected to HPLC analysis directly.

Hydrophilic modifications in peptide nucleic acid — Synthesis and properties of PNA possessing 5-hydroxymethyluracil and 5-hydroxymethylcytosine[1]

Robert H.E. Hudson, Yuhong Liu, and Filip Wojciechowski

Abstract: We have investigated the chemistry for the incorporation of C5-hydroxymethyl-uracil and -cytosine in peptide nucleic acid (PNA) and the subsequent effect of this modification on PNA hybridization behavior. Largely based on literature precedent, we prepared a peptide nucleic acid monomer, possessing 5-hydroxymethyuracil, which was compatible with Fmoc-based oligopeptide synthesis. An improved, large-scale synthesis of 5-hydroxymethylcytosine was developed, as a starting point for the synthesis of a monomer containing this nucleobase. In each case, the hydroxyl group was blocked as a *t*-butyldiphenylsilyl ether, and the exocyclic amino group of cytosine was additionally blocked with the benzoyl-group. The modified monomers were incorporated into isolated positions in the oligomer sequence using standard protocols. The modified oligomers showed that the 5-hydroxymethyl group is compatible with triplex and duplex formation.

Key words: peptide nucleic acid, hydroxymethyluracil, hydroxymethylcytosine, modified nucleobase, hybridization.

Résumé : On a étudié la chimie de l'incorporation d'un C5-hydroxyméthyl-uracile et d'une -cytosine dans un acide nucléique peptidique (ANP) ainsi que l'effet de cette modification sur le comportement d'hybridisation de l'ANP. En se basant principalement sur les précédents trouvés dans la littérature, on a préparé un acide nucléique peptidique monomère possédant un groupe 5-hydroxyméthyluracile qui était compatible avec une synthèse d'oligopeptide basée sur l'utilisation d'un groupe Fmoc. On a développé une synthèse à grande échelle améliorée de la 5-hydroxyméthylcytosine qui a été utilisée comme point de départ pour la synthèse d'un monomère contenant cette nucléobase. Dans chaque cas, le groupe hydroxyle a été bloqué par un éther *t*-butyldiphénylsilyle et on a de plus bloqué le groupe amino exocyclique de la cytosine à l'aide d'un groupe benzoyle. On a incorporé les monomères modifiés dans des positions isolées de la séquence de l'oligomère en faisant appel aux protocoles habituels. Les oligomères modifiés ont permis de montrer que le groupe 5-hydroxyméthyle est compatible avec la formation d'un triplex et d'un duplex.

Mots-clés : acide nucléique peptidique, hydroxyméthyluracile, hydroxyméthylcytosine, nucléobase modifiée, hybridisation.

[Traduit par la Rédaction]

Introduction

Ready access to synthetic oligonucleotides has enabled much of the tremendous progress witnessed in molecular biology, forensics, diagnostics, and related areas over the past couple of decades. Some applications of oligonucleotides, especially in hostile environments containing DNA or RNA degrading enzymes, require structural modifications to resist degradation. Out of endeavors to make robust oligonucleotide analogs, peptide nucleic acid (PNA) was born (1). PNA is an oligonucleotide mimic based on a polyamide repeat unit. It exhibits very tight and specific binding to complementary nucleic acids and continues to be of interest for both in vitro diagnostic applications and in vivo therapeutic use (2).

Although the original design of PNA "works" quite well (see Fig. 1), possessing excellent hybridization affinity and selectivity, often-cited limitations are its poor water solubility, poor ability to remain in solution and a tendency to be adsorbed onto surfaces, sequence-dependent aggregation, and a general difficulty in penetrating cellular membranes. These biophysical properties are related in various degrees to the non-ionic structure of PNA. Judicious chemical modifications can improve these biophysical properties while maintaining the highly desirable hybridization properties. For example, the aqueous solubility of PNA is improved by the attachment of a cationic amino acid, such as lysine, to one or both ends of the oligomer (3). Alternatively, introduction of charged (guanidinium) groups along the backbone structure improves the aqueous solubility and also facilitates cellular-membrane penetration (4). Another strategy to improve the solubility of PNA is to introduce hydrophilic nucleobase replacements (5).

The modular nature of PNA is particularly amenable to structural variation, and this has led to the synthesis of a wide variety of modified PNAs. We have chosen to investi-

Fig. 1. Structures of DNA and PNA.

gate nucleobase modifications as a way to introduce additional functionality, which may be distributed throughout the PNA oligomer without changing the *N*-2-aminoethylglycine backbone structure. Our approach, as reported herein, was to make a conservative structural modification that added hydrophilic character, which was synthetically accessible and would be sterically tolerated in a duplex or triplex structure. The 5-hydroxymethyl modification of pyrimidines (Fig. 2) fulfilled these requirements.

The 5-hydroxymethyl modification constitutes a relatively minor structural change to the nucleobases, representing the replacement of a hydrogen on 5-methyluracil (thymine) or 5-methylcytosine by a hydroxyl. The resulting 5-substituent is placed in the major groove and is expected to be sterically well tolerated (6). Other advantages are that the chemistry is accessible and starts with inexpensive reagents, and substitution does not produce a new stereocenter and thereby avoids problems of enantiomeric purity in the product.

Experimental

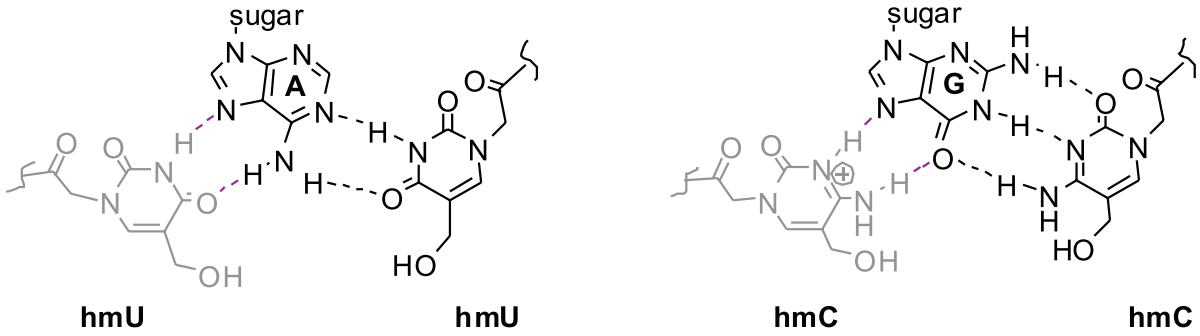
General

All reagents and solvents were obtained from common commercial sources and used without further purification, unless indicated. Anhydrous solvents were prepared by passing the reagent-grade solvent through columns of activated alumina (Innovative Technologies). Chromatography was carried out using silica gel 60 (particle size 0.063–0.200 mm; Merck). TLC was carried out on plastic sheets, silica gel 60 F_{254}, layer thickness of 0.2 mm (Merck). NMR spectra were recorded on Mercury 400 (400.1 MHz for ^{1}H; 100.6 MHz for ^{13}C) and Inova 400 spectrometers. Chemical shift values, reported in ppm, were referenced by the spectrometer to the residual proton in the deuterated solvents used to record the spectra. Resonances, attributed to conformers due to restricted rotation around amide bonds (i.e., rotamers), are reported as major (ma) and minor (mi) in the ^{1}H and ^{13}C NMR spectra. Assignments are shown for selected resonances that have been unambiguously identified by the use of 2D NMR correlation experiments. Multiplicity of signals are indicated where appropriate (s: single, d: doublet, t: triplet, q: quartet, m: mulitplet, br: broad, v: very). Melting points were determined on a Gallenkamp melting-point apparatus and are reported uncorrected.

5-Hydroxymethyluracil (1)

The synthesis of 5-hmU followed our previously reported method (7). Specifically, triethylamine (42 mL, 300 mmol) was added to a suspension of uracil (22.4 g, 200 mmol) and paraformaldehyde (18.0 g, 600 mmol) in water (600 mL). The mixture turned into a clear solution after heating to 60 °C. The solution was stirred at 60 °C overnight after which time the water was removed under vacuum until the volume reached 60 mL. To this residue, 60 mL of ethanol (95%) was added, and the resultant solution was left to stand at room temperature for 30 min. Once a precipitate formed, the mixture was placed in the refrigerator at 4 °C for several hours, a white solid was collected by filtration, and was washed with cold ethanol. The filtrate was cooled to –20 °C, and a second crop of **1** was collected. Further crops were yielded by reducing the volume of the filtrate by one half and diluting with an equal volume of 95% ethanol, followed by cooling to –20 °C. White solid; 26.1 g (92%); mp (from ethanol) 360 °C dec (lit. 300 °C dec.) (13). TLC ($CHCl_3$–CH_3OH, 4:1): R_f 0.16. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 11.04 (s, 1H, NH), 10.69 (d, J = 5.20 Hz, 1H, NH), 7.22 (d, J = 5.20 Hz, 1H, H6), 4.85 (t, J = 5.60 Hz, 1H, OH), 4.09 (d, J = 4.80 Hz, 2H, –CH_2–). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 163.6, 151.2, 138.0, 112.6, 55.8. HR-MS (EI) calcd. for $C_5H_6O_3N_2$: 142.0378; found: 142.0376.

Ethyl(5-hydroxymethyluracil-1-yl)acetate (2)



To a suspension of 5-hydroxymethyluracil (22.4 g, 158 mmol) and K_2CO_3 (21.8 g, 158 mmol) in DMF (475 mL) was added ethyl bromoacetate (98%, 28.3 g, 166 mmol). The reaction mixture was stirred overnight after which time the K_2CO_3 was removed by filtration, and the DMF was removed under vacuum, thus yielding a white solid. The solid was washed with H_2O (180 mL) by stirring the slurry for approximately 2 h. The first crop of **2** (21.4 g) was obtained by filtration and drying. Further crops were recovered from the filtrate by reducing its volume. White solid; 82% (29.5 g); mp 178–180 °C. TLC ($CHCl_3$ – CH_3OH, 4:1): R_f 0.46. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 11.42 (s, NH), 7.53 (s, 1H, H6), 5.07 (t, J = 5.60 Hz, 1H, OH), 4.54 (s, 2H, –CH_2–), 4.13 (m, 4H, overlapping –OCH_2–), 1.21 (t, J = 7.20 Hz, 3H, –CH_3). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 168.1, 163.0, 150.7, 141.7, 113.4, 61.2, 55.9, 48.8, 14.2. HR-MS (EI) calcd. for $C_9H_{12}O_5N_2$: 228.0746; found: 228.0748.

Ethyl[5-(*t*-butyldiphenylsilanyloxymethyl)uracil-1-yl]acetate (3)

To a solution of ethyl(5-hydroxymethyluracil-1-yl)acetate (5.01 g, 22 mmol) and imidazole (3.29 g, 48 mmol) in DMF (110 mL) was added *tert*-butyldiphenylchlorosilane (TBDPS-Cl, 98%, 6.64 g, 23.7 mmol) with stirring. The solution was stirred overnight after which time the reaction was stopped by adding 5% $NaHCO_3$ in H_2O (11 mL). The solvents were removed under vacuum to give a white solid.

Fig. 2. (*a*) Expected base-pairing of adenine (A, DNA strand) with 5-hydroxymethyluracil-containing PNA in duplex formation (black) and triplex formation (black and grey). (*b*) Expected base-pairing between guanine (G, DNA strand) with 5-hydroxymethylcytosine-containing PNA in duplex formation (black) and triplex formation (black and grey).

This material was dissolved in dichloromethane (250 mL), washed with H_2O (100 mL × 3), and the organic phase was separated and dried over sodium sulfate. The crude product was obtained after removing the dicholormethane by vacuum and was subsequently purified by trituration with hexanes to remove the silanol byproduct (TBDPS-OH; R_f 0.96; ethyl acetate–DCM, 1:2). The yield was 99% (10.2 g); mp 168–170 °C. TLC (ethyl acetate – DCM, 1:2): R_f 0.71. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 11.52 (s, NH), 7.65–7.67 (m, 4H, Ar–H), 7.62 (s, 1H, C6–H), 7.43–7.48 (m, 6H, Ar–H), 4.59 (s, 2H, N–CH_2–), 4.36 (s, 2H, O–CH_2Ar), 4.16 (q, J = 7.20 Hz, 2H, O–CH_2–), 1.21 (t, J = 7.20 Hz, 3H, C–CH_3), 1.00 (s, 9H, SiC–CH_3). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 168.3 (C7), 163.0 (C2), 150.8 (C1), 142.6 (C4), 135.2 (C13), 132.7 (C12), 130.0 (C15), 128.0 (C14), 112.0 (C3), 61.3 (C8) 58.9 (C5), 48.9 (C6), 26.7 (C11), 18.9 (C10), 14.1 (C9). HR-MS (EI) calcd. for $C_{25}H_{30}O_5N_2Si$: $[M + H]^+$, 467.2002; found: 467.1994.

[5-(*t*-butyldiphenylsilanyloxymethyl)uracil-1-yl]acetic acid (4)

To a solution of ethyl[5-(*t*-butyldiphenylsilanyloxymethyl)uracil-1-yl]acetate (10.6 g, 22.7 mmol) in THF (204 mL) and H_2O (22 mL) at 0 °C was added 2.5 mol/L NaOH (47 mL, 6 equiv.). The mixture was stirred at 0 °C for 20 min, then 1 mol/L HCl (170 mL) was added to stop the reaction. The aqueous phase was extracted with ethyl acetate four times (400 mL × 1, 100 mL × 3). The ethyl acetate phase was washed with H_2O (100 mL × 2) and then dried over sodium sulfate. The solvent was removed under vacuum to yield the title compound: white solid; 8.2 g, 96%; mp 169–170 °C. TLC (ethyl acetate – DCM, 1:2): R_f 0.71. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 13.14 (br s, 1H, COOH), 11.47 (s, 1H, NH), 7.65–7.67 (m, 4H, Ar), 7.62 (s, 1H, C6–H), 7.41–7.50 (m, 6H, Ar), 4.49 (s, 2H, N–CH_2–), 4.35 (s, 2H, O–CH_2–), 1.00 (s, 9H, –CH_3). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 169.8, 163.0, 150.9, 142.8, 135.2, 132.8, 130.0, 128.0, 111.8, 58.9, 48.8, 26.7, 18.9. MS (ESI) calcd. for $[C_{23}H_{26}O_5N_2Si + Na]^+$: 461.15; found: 461.1.

Methyl(*N*-(2-((9H-fluoren-9-yl)methoxy)carbonyl)aminoethylglycinate hydrochloride (5)

To a suspension of methyl 2-aminoethylglycinate dihydrochloride (6.0 g, 20.8 mmol) and Fmoc-*N*-hydroxysuccinimide (10.8 g, 1.1 equiv.) in dioxane (100 mL) was added aq. $NaHCO_3$ (3 equiv., 7.4 g/120 mL) with rapid stirring for 50 min. The reaction mixture was diluted with 400 mL H_2O, which produced an instant white precipitate that redissolved on the addition of DCM (350 mL). This aqueous phase was extracted with DCM (2 × 300 mL), and then the DCM phase was dried over sodium sulfate, acidified with Et_2O – HCl (5 mol/L), and cooled in the freezer overnight. The desired product was collected by filtration: white solid; 7.0 g, 61%; mp 110–113 °C. Further product can be obtained by reducing the volume of the filtrate. TLC (CH_3COOEt – CH_3OH, 95:5; visualized with UV and 0.3% ninhydrin (purple)): R_f 0.24. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 9.44 (br s, 2H, H_2N^+), 7.90 (d, J = 7.20 Hz, 2H, Ar), 7.70 (d, J = 7.20 Hz, 2H, Ar), 7.58 (t, J = 5.60 Hz, CONH), 7.42 (t, J = 7.20 Hz, 2H, Ar), 7.33 (t, J = 7.60 Hz, 2H, Ar), 4.33 (d, J = 6.80 Hz, 2H, –CH_2–O), 4.23 (t, J = 6.80 Hz, 1H, Ar_2–CH–), 4.00 (s, 2H, N–CH_2–), 3.74 (s, 3H, O–CH_3), 3.33 (overlapping with water, –CH_2–CH_2–), 3.02 (t, J = 6.00 Hz, 1.8H, ma, –CH_2–CH_2–), 2.90 (mi, 0.2H). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 167.1, 156.3, 143.9, 140.8, 127.7, 127.2, 125.3, 120.2, 65.7, 52.7, 46.7, 46.6, 46.5, 36.6. MS (EI) calcd. for $[C_{20}H_{22}O_4N_2HCl – HCl]^+$: 354.16; found: 354.1.

Byproducts identified as dibenzofulvene: R_f 0.96 (ethyl acetate – methanol, 95:5), and 2-oxo-3-*N*-(Fmoc)piperazine: R_f 0.42 ($CHCl_3$ – CH_3OH – CH_3COOH, 90:8:2). Mp 172–174 °C.

Methyl(2-(((9H-fluoren-9-yl)methoxy)carbonyl)aminoethyl)glycinate (6)

The hydrochloride salt of the title compound (3.0 g, 7.8 mmol) was suspended in dichloromethane (350 mL) and shaken against a saturated aq. $NaHCO_3$ solution (150 mL × 3) to liberate the free base. The phases were separated, and the combined aqueous phases were back-extracted with dichloromethane (100 mL × 3). The organic phase was dried over sodium sulfate, and the solvent was removed under vacuum to yield the free base as a white wax-like product: 2.70 g (99%); mp 76–78 °C. TLC (ethyl acetate – methanol, 95:5; visualized by UV and 0.3% ninhydrin (purple)): R_f 0.30. ^{1}H NMR (400.1 MHz, $CDCl_3$, ppm) δ: 7.76 (d, J = 7.60 Hz, 2H, Ar), 7.61 (d, J = 7.60 Hz, 2H, Ar), 7.40 (t, J = 7.60 Hz, 2H, Ar), 7.32 (t, J = 7.20 Hz, 2H, Ar), 5.36 (br, ma, CONH), 5.12 (br, mi, CONH), 4.40 (d, J = 7.20 Hz, 2H, –CH_2–O), 4.22 (t, J = 6.80 Hz, 1H, Ar_2–CH–), 3.73 (s, 3H,

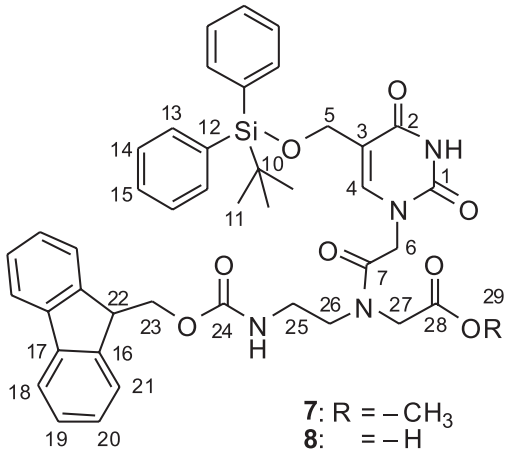
O–CH_3), 3.42 (s, 2H, N–CH_2–C(O)), 3.27 (q, J = 5.60 Hz, ma, CONH–CH_2–), 3.17 (mi, CONH–CH_2–), 2.75 (t, J = 5.60 Hz, ma, –CH_2–N), 2.62 (mi, –CH_2–N). ^{13}C NMR (100.6 MHz, $CDCl_3$, ppm) δ: 173.1, 156.7, 144.2, 141.5, 127.8, 127.2, 125.2, 120.1, 40.8, 66.7, 52.0, 50.4, 48.8, 47.4. HR-MS (EI) calcd. for $C_{20}H_{22}O_4N_2$: 354.1580; found: 354.1581.



Fmoc hmU-OMe (7)

To a suspension of methyl(2-(((9H-fluoren-9-yl)methoxy)carbonyl)aminoethyl)glycinate (**6**) (1.61 g, 4.5 mmol) and the nucleobase acetic acid derivative **4** (3.18 g, 7.3 mmol) in DMF (45 mL) was added 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride (EDC, 1.39 g, 7.3 mmol) in two portions within 0.5 h. The mixture was stirred for 16 h at room temperature, and then the reaction mixture was diluted with dichloromethane (1000 mL). This solution was washed with 0.05 mol/L HCl (200 mL × 4), saturated $NaHCO_3$ (200 mL × 3), and H_2O (450 mL × 7), respectively. The organic layer was separated and dried over Na_2SO_4, and the solvent was removed under vacuum at room temperature. The crude product (white foam) was purified by gradient column chromatography (DCM, ethyl acetate, ethyl acetate – methanol (95:5), respectively) to yield the title compound as a white foam (Fig. 3): 3.10 g, 88% yield. TLC (ethyl acetate – methanol, 95:5; visualized by UV and 0.3% ninhydrin (purple)): R_f 0.63. ^{1}H NMR (400.1 MHz, $CDCl_3$, ppm) δ: 7.19–7.77 (m, overapping 19H, Ar), 6.06 (br t, ma, backbone NH) and 5.45 (br t, mi, backbone NH), 4.51–4.54 (br s, overlap H5 and its rotamer), 4.51–4.54 (br s, ma, H6) and 4.37–4.44 (overlap, mi, H6), 4.37–4.44 (overlap, H23 and its rotamer), 4.17–4.20 (m, H22), 4.17–4.20 (mi, H27) and 4.07 (s, ma, H27),[3] 3.74 (s, ma, H29) and 3.78 (s, mi, H29), 3.57 (br s, ma, 1.6 H, H26) and 2.88 (br s, mi, 0.4 H, H26), 3.45 (br m, ma, H25) and 3.38 (br m, mi, H25), 1.08 (s, ma, H11) and 1.09 (s, mi, H11). ^{13}C NMR (100.6 MHz, $CDCl_3$, ppm) δ: 170.1 (C28), 167.3 (C7), 162.7 (C2), 157.0 (C24), 151.2 (C1), 144.0 (C16), 141.4 (C17), 141.2 (C4), 135.7 (C13), 133.0 (C12), 130.0 (C15), 128.0 (C14), 127.8 (C19), 127.2 (C20), 125.2 (C21), 120.1 (C18), 114.2 (C3), 66.9 (C23), 59.1 (C5), 53.0 (r), 52.6 (C29), 50.5 (r), 49.0 (C27), 48.9 (C26), 48.6 (r), 48.5 (C6), 47.3 (C22), 39.2 (r), 39.6 (C25), 27.1 (C11), 19.4 (C10). HR-MS (ESI-TOF) calcd. for $[C_{43}H_{46}O_8N_4Si + Na]^+$: 797.2983; found: 797.3022.

Fmoc-hmU-OH (8)

The ester precursor to the PNA monomer acid (2.93 g, 3.78 mmol) was dissolved in THF (32 mL), and then H_2O (21 mL) was added to produce a turbid mixture. The mixture was cooled to 0 °C, and 2.5 mol/L NaOH (12 mL, 8 equiv.) was added. The mixture was stirred for 5 min at 0 °C during which time the mixture cleared to produce a homogeneous solution. The reaction was stopped by addition to a separatory funnel containing a mixture of ethyl acetate (400 mL) and 0.3 mol/L HCl (200 mL). The acidic aqueous phase was extracted by ethyl acetate (150 mL × 3). The ethyl acetate washes were combined (~850 mL), washed with H_2O (100 mL × 3), and dried over Na_2SO_4. The ethyl acetate was removed under vacuum at room temperature to yield an off-white (yellowish) foam (Fig. 3). The product was purified by column chromatography using a gradient of solvents (DCM; DCM–methanol (90:10), (85:15), and (78:22); respectively) to give the title compound as an off-white solid: 2.60 g, 90%; mp 216–21s7 °C. TLC ($CHCl_3$ – CH_3OH – CH_3COOH, 90:8:2; visualized with UV and 0.3% ninhydrin (grey)): R_f 0.08. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 11.39 (br s, uracil NH) and 11.36 (br s, uracil NH), 7.29–7.88 (overlapping signals, 18H Ar, backbone NH), 4.75 (s, mi, 0.2H, H6) and 4.56 (s, ma, 1.8H, H6), 4.23–4.35 (m, overlap, 2H, H5) and (r, H23), 4.17–4.20 (m, overlap, H23, H22), 3.95 (s, 2H, H27),[3] 3.44 (br m, mi, H26) and 3.38 (br m, ma, H26), 3.36 (br m, mi, H25) and 3.16 (br m, ma, H25), 0.98 (s, 9H, H11). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 171.5 (C28), 166.9 (C7), 163.0 (C2), 156.2 (C24), 150.9 (C1), 143.9 (C16), 143.3 (C4), 140.7 (C17), 135.2 (C13), 132.8 (C12), 129.9 (C15), 128.0 (C14), 127.6 (C19), 127.1 (C20), 125.3 (C21), 120.1 (C18), 111.4 (C3), 65.6 (C23), 58.9 (C5), 51.4 (r), 48.5 (C27), 48.1 (C6), 47.6 (r), 46.9 (C26), 46.7 (C22), 38.7 (r), 38.0 (C25), 26.7 (C11), 18.8 (C10). HR-MS (ESI-TOF) calcd. for $[C_{42}H_{44}O_8N_4Si + Na]^+$: 783.28261; found: 783.2841.

Fig. 3. Structure of the 5-hydroxymethyluracil (hmU) PNA monomer ester (R = –CH_3) and acid (R = –H), defining the arbitrary numbering system used in NMR signal assignments.

5-Hydroxymethylcytosine (9)

Triethylamine (16.5 mL, 118 mmol) was added to a suspension of cytosine (5.27 g, 47.4 mmol) and paraformaldehyde (3.28 g, 109 mmol) in water (140 mL). The mixture was stirred and heated under reflux for 72 h. After 24 h and 32 h of reaction, a second and third portion of paraformaldehyde (1.14 g, 38.0 mmol) and (0.57 g, 19.0 mmol) was added, respectively. After completion of the reaction, the volatile components (water and triethylamine) were removed under vacuum to give a dark-coloured residue (12.8 g), which represented greater than 100% theoretical yield. This residue was dissolved to produce a clear solution by heating with 35 mL of 95% ethanol and 18–24 mL H_2O, depending on solubility. The solution was left at room tem-

[3] Variable position (3.85 – 4.20 ppm), depending on the protonation state of the carboxylic acid.

© 2007 NRC Canada

perature for a short time during which a precipitate formed. Further precipitation was induced by cooling to 4 °C. The first crop of 5-hydroxymethylcytosine, 4.2 g (5-hmC, yellow solid, purity ≈ 90% (wt%), 7%–8% (wt%) cytosine, as determined by ^{1}H NMR spectroscopy) was collected by filtration and washed three times with 20 mL of 95% ethanol. This first crop represents 57% chemical yield of **9** from cytosine. Reduction in the volume of the filtrate gave subsequent crops of 5-hmC. The later crops contained proportionally more cytosine and other unidentified compounds. Nonetheless, these impure fractions of 5-hmC were suitable for further use. The total yield of 5-hmC calculated from all recovered fractions, based on determining the purity by ^{1}H NMR spectroscopy, was 85%. This experiment was repeated many times and proved to be reproducible. Mp 300 °C dec. TLC (*t*-butyl alcohol – methyl ethyl ketone – H_2O – NH_4OH, 4:3:2:1): R_f 0.32, compared with R_f 0.46 for cytosine. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 10.60 (v br, ring NH), 7.28 (s, 1H, C6–H), 7.10 (br, NH_2), 6.54 (br, NH_2), 4.99 (v br, OH), 4.16 (s, 2H, O–CH_2–Ar). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 165.6, 157.0, 140.8, 104.9, 57.1. HR-MS (EI) calcd. for $[C_5H_7O_2N_3 + H]^+$: 142.0616; found; 142.0620.

Ethyl(5-hydroxymethylcytosin-1-yl)acetate (10)

To a suspension of crude 5-hydroxymethylcytosine (**9**) (8.97 g, 68% (wt%), 43 mmol) and K_2CO_3 (5.97 g, 43.2 mmol) in dry DMF (140 mL), was added ethyl bromoacetate (5.6 mL, 98% pure, 47.5 mmol). The reaction mixture was stirred overnight, and a dark-coloured oil was obtained after removal of the K_2CO_3 by filtration through a pad of Celite and evaporation of DMF under vacuum. Ethyl acetate (120 mL) was added to triturate the residue, which was sonicated (often 1–2 h, sometimes up to 5 h), and then a brown solid was isolated by filtration. The solid crude product was washed with a small amount of ethyl acetate (50 mL × 3). All of the mass was accounted for in the crude material, which was found to contain the desired product (**10**, 60% (wt%)) along with the dialkylated byproduct (19% (wt%)), some unreacted starting material **9** (~20% (wt%); R_f 0.06; DCM – CH_3OH, 4:1), and small amounts of unidentified compounds, as estimated by examination of ^{1}H NMR spectra. The crude material was suitable for the next reaction. The title compound **10** could also be purified by solvent gradient silica-gel column chromatography (DCM; DCM – CH_3OH (90:10), (85:15), and (80:20); respectively). Mp 175–177 °C, as isolated from chromatography. TLC (DCM – CH_3OH, 4:1): R_f 0.25. ^{1}H NMR (399.8 MHz, DMSO-d_6, ppm) δ: 7.54 (s, 1H, C6–H), 7.33 (br s, NH_2), 6.62 (br s, NH_2), 5.11 (t, J = 5.20 Hz, OH), 4.45 (s, 2H, –CH_2–N), 4.17 (d, J = 5.20 Hz, 2H, O–CH_2–Ar), 4.11 (q, J = 7.20 Hz, 2H, O–CH_2–), 1.19 (t, J = 7.20 Hz, 3H, –CH_3). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 168.8, 165.0, 155.7, 144.2, 105.7, 60.9, 57.1, 50.0, 14.1. HR-MS (EI) calcd. for $[C_9H_{13}O_4N_3]^+$: 227.0906; found: 227.0905.

Identified byproduct: *N*1,*N*4-bisalkylated nucleobase: ethyl(*N*4-(2-ethoxy-2-oxoethyl)-5-(hydroxymethylcytosin-1yl)acetate. TLC (DCM – CH_3OH, 4:1): R_f 0.52. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 7.88 (s, 1H, C6–H), 5.44 (t, J = 5.2, –OH), 4.72 (s, 2H, N1–CH_2–), 4.32 (d, J = 5.3, 2H, O–CH_2–Ar), 4.29 (s, 2H, N4–CH_2–), 4.16 (q, J = 7.1, 4H, 2 × –CH_2–), 1.22 (t, J = 7.2, 6H, 2 × –CH_3). ^{13}C NMR (100.6 MHz, DMSO-d_6, ppm) δ: 185.2, 170.9, 167.9, 145.9, 144.6, 108.8, 61.6, 61.5, 56.1, 49.7, 49.0, 14.1.

Ethyl[5-(*t*-butyldiphenylsilanyloxymethyl)cytosin-1-yl]acetate (11)

Crude ethyl(5-hydroxymethylcytosin-1-yl)acetate (**10**), which contained 5-hmC, was used as the starting material for this transformation. As a byproduct, 5-(*t*-butyldiphenylsilanyloxymethyl)cytosine was obtained, which could be alkylated by ethyl bromoacetate to give the title compound, as a supplementary route to the following one.

As an example, a particularly impure sample was utilized. To a solution of crude ethyl(5-hydroxymethylcytosin-1-yl)acetate (**10**) (5.08 g, 48% (wt%), ~11 mmol) and imidazole (3.66 g, 54 mmol) in DMF (115 mL) was added TBDPS-Cl (8 mL, 27.0 mmol) with stirring. The solution was stirred overnight, and then a saturated solution of $NaHCO_3$ (10 mL) was added to stop the reaction. The DMF and H_2O were removed under vacuum to yield a dark-brown oil, which was dissolved in ethyl acetate (300 mL) and washed with H_2O (150 mL × 4). Unreacted starting materials (**9** and **10**), as well as dialkylated hmC, were removed by the aqueous washes. Compound **9** was recovered by back-extraction with ethyl acetate, the efficacy of which was monitored by TLC. The ethyl acetate phase was dried over Na_2SO_4, and the solvent was removed under vacuum to yield compound **9** along with silylated 5-hmC. The title compound **11** was isolated as a slightly orange solid, 40% yield, by flash column chromatography, using a gradient of solvents (hexane, ethyl acetate, and ethyl acetate – methanol (96:4) for **9**; ethyl acetate – methanol (75:25) for 5-(*t*-butyldiphenylsilanyloxymethyl)cytosine). Mp 183–185 °C, as isolated from chromatography. TLC (ethyl acetate – methanol, 95:5) R_f 0.18. ^{1}H NMR (400.1 MHz, $CDCl_3$, ppm) δ: 7.64 (d, J = 8.00 Hz, 4H, Ar), 7.38–7.48 (m, 6H, Ar), 6.48 (s, 1H, C6–H), 4.42 (s, 2H, SiO–CH_2–Ar), 4.31 (s, 2H, –CH_2–N), 4.19 (q, J = 6.40 Hz, 2H, –O–CH_2–), 1.26 (t, J = 6.40 Hz, 3H, –CH_3), 1.04 (s, 9H, SiC–CH_3). ^{13}C NMR (100.6 MHz, $CDCl_3$, ppm) δ: 143.6, 168.2, 166.0, 156.2, 135.8, 132.7, 130.3, 128.1, 105.0, 62.0, 61.4, 50.2, 27.0, 19.3, 14.3. HR-MS (EI) calcd. for $[C_{25}H_{31}O_4N_3Si + H]^+$: 466.2162; found: 466.2155.

Identified byproduct: 5-(*t*-butyldiphenylsilanyloxymethyl)cytosine; white solid. TLC (ethyl acetate – methanol, 95:5): R_f 0. ^{1}H NMR (400.1 MHz, DMSO-d_6, ppm) δ: 7.63 (d, J = 6.00 Hz, 4H, Ar), 7.42–7.50 (m, 6H, Ar), 7.10 (s, 1H, C6–H), 4.46 (s, 2H, SiO–CH_2–Ar), 1.00 (s, 9H, SiC–CH_3). Ethyl[4-benzoyl-5-(*t*-butyldiphenylsilanyloxymethyl)cytosin-1-yl]acetate (12)

To a solution of ethyl[5-(*t*-butyldiphenylsilanyloxymethyl)cytosin-1-yl]acetate (3.42 g, 7.3 mmol) in anhyd. pyridine (35 mL) was added benzoyl chloride (1 mL, 8.0 mmol) with stirring. The solution was stirred overnight, ethyl acetate (300 mL) was added, and the solution was washed with 1 mol/L HCl (200 mL × 2) to remove most of

© 2007 NRC Canada

the pyridine.[4] The ethyl acetate phase was subsequently washed with 0.02 mol/L HCl (200 mL × 3) and then water (200 mL × 3) to remove traces pyridine. The acidic aqueous phase was back-extracted by ethyl acetate (200 mL). The ethyl acetate phases were combined and dried over Na_2SO_4. The crude product had the appearance of an orange oil after removal of the solvent. Column chromatography (hexane, hexane–EtOAc (95:5) and (92:8) for **12**; EtOAc – CH_3OH (95:5) to recover **11**; R_f 0.04 (EtOAc – DCM, 1:6) was used to purify the crude material. White solid; 92% (4.16 g, after column-chromatography purification); mp 130–132 °C. TLC (EtOAc – DCM, 1:6): R_f 0.76. ^{1}H NMR (400.1 MHz, $CDCl_3$, ppm) δ: 13.19 (s, 1H, NH), 8.03 (d, J = 7.20 Hz, 2H, Ar), 7.63 (d, J = 6.40 Hz, 4H, Ar), 7.28–7.40 (m, 10H, Ar and C6–H), 4.70 (s, 2H, O–CH_2–Ar), 4.43 (s, 2H, N–CH_2–), 4.20 (q, J = 7.20 Hz, 2H, O–CH_2–), 1.24 (t, J = 7.20 Hz, 3H, –CH_3), 1.04 (s, 9H, –Si–CCH_3). ^{13}C NMR (100.6 MHz, $CDCl_3$, ppm) δ: 179.6, 167.2, 158.2, 148.5, 141.3, 136.8, 135.6, 133.0, 132.6, 130.2, 130.0, 128.2, 128.1, 115.2, 62.4, 59.4, 49.9, 27.0, 19.5, 14.3. [4-*N*-Benzoyl-5-(*t*-butyldiphenylsilanyloxymethyl)cytosin-1-yl]acetic acid (13)

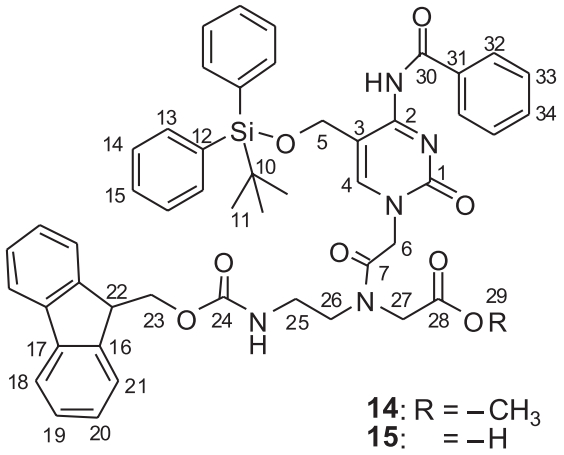
To a solution of **12** (2.78 g, 4.88 mmol) in THF (55 mL) and H_2O (14 mL) at 4 °C was added 2.5 mol/L NaOH (16 mL, 8 equiv.). The mixture was stirred at 0 °C for 15 min, and the reaction was stopped by decanting into a separation funnel containing ethyl acetate (280 mL) and 0.25 mol/L HCl (190 mL) in which the reaction mixture was acidified, and **13** was obtained. The ethyl acetate phase was washed with H_2O (140 mL × 2). The aqueous phase was extracted with ethyl acetate (280 mL × 2). The ethyl acetate phases were combined and washed with H_2O (400 mL), dried over Na_2SO_4, and the solvent was removed under vacuum to yield the title compound as a white foam: 2.74 g (99% yield). TLC (ethyl acetate – DCM, 1:6; same eluent used for **12**): R_f 0. ^{1}H NMR (400.1 MHz, $CDCl_3$, ppm) δ: 8.06 (d, J = 7.20 Hz, 2H, Ar), 7.68 (m, 4H, Ar), 7.34–7.49 (m, 10H, Ar and C6–H), 4.73 (s, 2H, O–CH_2–Ar), 4.54 (s, 2H, –CH_2–N), 1.09 (s, 9H, SiC–CH_3). ^{13}C NMR (100.6 MHz, $CDCl_3$, ppm) δ: 177.7, 170.8, 158.7, 149.6, 142.8, 136.2, 135.7, 132.9, 132.8, 130.2, 129.8, 128.4, 128.1, 114.5, 59.6, 50.5, 27.1, 19.5. HR-MS (ESI-TOF, positive ion mode) calcd. for $[C_{30}H_{31}O_5N_3Si + H]^+$: 542.2111; found: 542.2091.

Fmoc hmC-OMe (14)

Compound **13** (3.83 g, 7.1 mmol) and hydroxybenzotriazole (HOBt, 1.03 g, 7.6 mmol) were dissolved in anhyd. DMF (39 mL). The solution was cooled to 0 °C. After adding *N*,*N*′-dicyclohexylcarbodiiimide (DCC, 1.58 g, 7.6 mmol) in one portion, the mixture was taken off the ice and stirred at room temperature for 1 h during which time a thick white precipitate of dicyclohexylurea (DCU) was formed. Methyl(2-(((9H-fluoren-9-yl)methoxy)carbonyl)aminoethyl)glycinate (2.52 g, 7.1 mmol) was added, and the mixture was stirred overnight. The precipitated DCU was filtered out by passing the solution through a pad of Celite. The filtrate was diluted with DCM (450 mL) and washed with acidic water twice (H_2O, 250 mL; 1 mol/L HCl, 6 mL) to remove the unreacted backbone submonomer, then washed with $NaHCO_3$ (satd. 250 mL × 2) and H_2O (300 mL × 3), respectively. All aqueous phases were back-extracted with DCM. The combined organic phases were dried over Na_2SO_4, and the solvent was removed under vacuum (RT). The crude product (yellow oil) was purified by column chromatography (hexane, hexane – ethyl acetate (80:20), (60:40), and (10:90) for the title compound, whereas ethyl acetate – methanol (98:2) and (95:5) was used to recover the backbone). White solid; 3.61 g, (58%); mp 125–126.5 °C (softens at 92 °C). TLC (ethyl acetate – methanol, 95:5; visualized with UV and 0.3% ninhydrin (green)): R_f 0.62. ^{1}H NMR (400.1 MHz, $CDCl_3$, ppm) δ: 13.26 (v br, NH), 8.13 (d, J = 7.20 Hz, 2H, H32), 7.29–7.74 (m, 22H, aromatic protons), 6.06 (br t, ma, backbone NH) and 5.48 (br t, J = 4.80 Hz, mi, backbone NH), 4.77 (s, 2H, H5), 4.64 (s, ma, H6) and 4.52 (s, mi, H6), 4.47 (d, J = 6.80 Hz, ma, H23) and 4.40 (d, J = 7.20 Hz, mi, H23), 4.22–4.25 (m, 1H, H22), 4.09 (s, ma, H27) and 4.22–4.25 (m, mi, H27), 3.73 (s, ma, H29) and 3.79 (mi H29), 3.73 (br, ma, H26) and 2.95 (br, mi H26), 3.46 (br, ma, H25) and 3.41 (br, mi H25), 1.15 (s, mi, H11) and 1.13 (s, ma, H11). ^{13}C NMR (100.6 MHz, $CDCl_3$, ppm) δ: 179.3 (C30), 169.9 (C28), 166.9 (C7), 158.5 (C2), 156.9 (C24), 148.5 (C1), 143.8 (C16), 142.8 (C4), 141.2 (C17), 136.7 (C31), 135.5 (C13), 133.0 (C12), 132.4 (C34), 130.0 (C15), 129.8 (C32), 128.1 (C33), 127.9 (C14), 127.7 (C19), 127.1 (C20), 125.1 (C21), 119.9 (C18), 114.2 (C3), 66.7 (C23), 59.3 (C5), 52.4 (ma, C29) and 52.9 (mi, C29), 48.9 (ma, C6) and 49.1 (mi, C6), 48.8 (ma, C27) and 50.3 (mi, C27), 48.7 (C26), 47.2 (C22), 39.0 (mi, C25) and 39.4 (ma, C25), 26.9 (C11), 19.3 (C10). HR-MS (ESI-TOF) calcd. for $[C_{50}H_{51}O_8N_5Si + Na]^+$: 900.3405; found: 900.3430.



Fmoc-hmC-OH (15)

Compound **14** (3.40 g, 3.9 mmol) (Fig. 4) was dissolved in THF (42 mL) and H_2O (11 mL). The solution was cooled to 4 °C in an ice-bath, and then 2.5 mol/L NaOH (12.1 mL, 8 equiv.) was added. The solution was stirred for 5 min at 4 °C, and then the reaction was stopped by decanting it into a separation funnel containing ethyl acetate (500 mL) and acidified water (36 mL of 1 mol/L HCl and 200 mL of H_2O). The ethyl acetate phase was washed with H_2O (200 mL × 2). The aqueous phase was extracted with ethyl acetate (150 mL × 2). The organic phase was separated and dried over Na_2SO_4. The solvent was removed under vacuum (RT). The crude product (off-white solid, 3.7 g) was purified by flash column chromatography (hexane, hexane – ethyl acetate (50:50), ethyl acetate, and ethyl acetate – methanol (95:5), (80:20), and (75:25)). White solid; 2.95 g (90%); mp 186–187 °C, as isolated from chromatography (softens at 130 °C). TLC (EtOAc – CH_3OH, 95:5; visualized with UV and 0.3% ninhydrin (green)): R_f 0.04. ^{1}H NMR (400.1 MHz,

[4] Caution: care must be taken in the amount of HCl used, which should be calculated based on complete neutralization of pyridine; excess acid removed the *N*4-Bz group.

Synthesis of PNA oligomers

PNA oligomers were synthesized on a 5 μmol scale using the standard FastMoc module on an Applied Biosystems 433A synthesizer employing a NovaSyn TGR (Rink amide) resin. The hexameric PNA (**P1**) was synthesized using the Rink amide resin with a loading of 0.23 mmol/g. Oligomers (**P2**–**P5**) were prepared on a Rink amide resin preloaded with lysine (approximate loading: 0.065 mmol/g).

Resin cleavage and deprotection

To the resin bound oligomer (**P1**–**P5**) was added an ice-cold solution of TFA (950 μL) and triethylsilane (25 μL). The resin was agitated for 2 h. After filtration, TFA was removed with a stream of nitrogen, and the oligomer was precipitated, as a white solid, with cold diethyl ether (15 mL). Under these conditions, the TBDPS protecting group is also removed.

Oligomer **P4**, which contains an hmC residue, was additionally treated with concentrated aq. ammonia (1 mL, 55 °C for 12 h). The solution was dried under reduced pressure to give an off-white solid.

Oligomer purification

The crude, solid oligomers were dissolved in aq. TFA (0.1%), filtered, and purified by RP-HPLC, using a 250 mm × 4.6 mm, C18-bonded phase, 300 Å pore, and 5 μm particle-size column.

Characterization of PNAs

Mass spectral analysis of oligomers was performed at the UWO Biological Mass Spectrometry Laboratory. Electrospray ionization time-of-flight mass spectrometry (ESI-TOF MS) was performed with mass calibration provided by myoglobin (M^+ = 16951.49 Da, average mass) or histatin 5 (M^+ = 3036.33 Da, monoisotopic mass) (see Table 1).

Binding analysis

Poly(riboadenylic acid) (poly(rA)) was purchased from Sigma (Milwaukee, WI). Mixed sequence oligonucleotides were synthesized and purified by standard methods or purchased from the University Core DNA Services (Calgary, AB). Thermal denaturation of PNA:NA complexes (~2 μmol/L in nucleobases) was measured at 260 nm with a temperature ramp of 0.5 °C/min under ionic conditions (150 mmol/L NaCl, 10 mmol/L Na_2HPO_4, and 0.1 mmol/L EDTA at pH 7.0). A minimum of two independent samples were run many times, and the T_m was estimated by determining the maximum in the first derivative of the denaturation curve. The error associated with the T_m values is ±0.5 °C.

Results and discussion

The goal of this work was to achieve the synthesis of 5-hydroxymethyl-derivatized uracil and cytosine PNA monomers, incorporate these modified bases into PNA, and study their impact on hybridization. As a starting point, we were interested in a scalable and straightforward approach to the synthesis of the monomers. Key considerations were on the preparation of the 5-hydromethyluracil and -cytosine and subsequently the use of an appropriate protecting-group strategy for the hydroxyl functional group.

5-Hydroxymethyluracil-containing PNA

The synthesis of 5-hydroxymethyluracil monomer (hmU), suitable for Fmoc-based peptide chemistry, is outlined in Scheme 1. We took the approach of preparing the appropriate (pyrimidin-1-yl)acetic acid ester derivative, which would be condensed with the methyl[*N*-2-(Fmoc-amino)ethyl]glycinate "backbone" submonomer in a convergent fashion, which we have previously reported (8). The synthesis starts with the inexpensive uracil and a one-step hydroxymethylation. Despite the potential biological importance of 5-hydroxymethyluracil and nucleoside derivatives thereof (9–12),[5]

[5] 5-hmU is a component of bacteriophage DNA, as well, there exists hmU specific binding proteins. The DNA of the dinoflagellate *Gyrodinium cohnii* contains 5-hmU. Glycosylated hmU is found in *Typanosoma Brucei*, the causative organism of African sleeping sickness. 5hmU is caused by oxidative damage to DNA

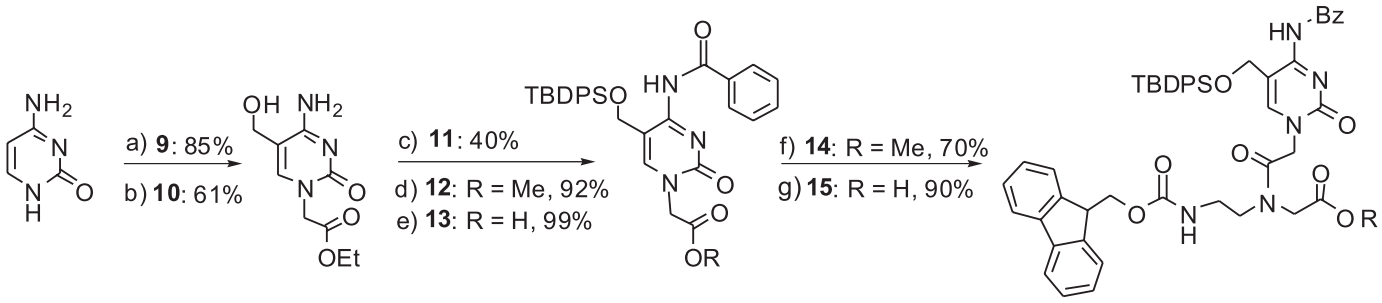
there exist but a few synthetic routes to the modified nucleobase. Hydroxymethyluracil has been prepared by the reaction of uracil with paraformaldehyde in water, using an inorganic base (13, 14). However, we wished to avoid the potential problem of separating the nucleobase from inorganic salts and were inspired by the report of triethylamine-catalyzed hydroxymethylation of the deoxynucleoside (15). The reaction of paraformaldehyde with uracil in aq. NEt_3 (0.5 mol/L) proceeds smoothly overnight, and the product conveniently crystallizes from the reaction solvent.



As with uracil, thymine, and related derivatives, we next proceeded to the alkylation of the nucleobase with ethyl bromoacetate in anhyd. DMF with K_2CO_3 (16), suspecting that we would achieve the desired chemoselectivity, based on the pKa differences between the 5-hydroxyl group and the lactam/imide groups of the heterocycle. We observed complete selectivity for N-alkylation and recovered the desired N1-derivative in good yield. The only byproduct that we were able to identify from this reaction was the *N*1,*N*3-bisalkylated nucleobase.

Next, we chose a silyl ether as the masking group for the 5-hydroxy functionality for ease of installation and removal as well as orthogonality to the Fmoc- group and the methyl ester of the backbone. Initially, we prepared the *t*-butyldimethylsilyl ether, but this proved not robust enough in model studies; thus, we turned to the *t*-butyldiphenylsilyl ether. This group was stable to alkyl ester hydrolysis (0.43 mol/L NaOH, THF – H_2O, 0 °C, >40 min), Fmoc-removal (30% piperidine in DMF, 40 min), and normal workup conditions (pH 1–12), yet was completely and rapidly removed by treatment with TFA. After settling on a hydroxyl-protecting group, standard transformations yielded the hmU monomer **8** with some noteworthy points. The condensation of the backbone submonomer **6** with the modified nucleobases **4** was mediated by the use of the carbodiimide reagent EDC without the use of additional base or additives. As well, the best yield and least elimination of the Fmoc-group were obtained when the acid component was used in excess (1.6 equiv.) relative to the backbone submonomer free base. In this instance, the isolated yields of **7** were reliably high (88%) with a minimal loss of the base-labile Fmoc-group (<4%).

The penultimate step, the saponification of the monomer ester (**7**), was also carefully done to avoid loss of the Fmoc-

Scheme 2. Reagents and conditions: (*a*) $(HCHO)_n$, 0.75 mol/L Et_3N, H_2O, 3 d, 95 °C; (*b*) K_2CO_3, DMF, $BrCH_2CO_2Et$, 24 h; (*c*) TBDPS-Cl, imidazole, DMF, 16 h; (*d*) BzCl, pyridine; (*e*) 0.46 mol/L NaOH, 15 min, 4 °C; (*f*) **6**, DCC, HOBT, DMF; (*g*) (*i*) 0.46 mol/L NaOH, 0 °C, 5 min; (*ii*) H^+.

group. The reaction conditions (8 equiv. of NaOH, 0.46 mol/L, 5 min) were optimized to give complete hydrolysis, while minimizing concomitant removal of the Fmoc-group. Nonetheless, some Fmoc- groups were lost (4%–8%), yet the final monomer was recovered in 90% yield from column chromatography. The optimized conditions for the condensation and hydrolysis reactions were then used for the synthesis of the hmC monomer **15**.

5-Hydroxymethylcytosine-containing PNA

Although 5-hydroxymethylcytosine has been known for some time in the context of a modified base found in the DNA of the *Escherichia coli* T-even bacteriophages (17) and in the nucleoside antibiotic mildiomycin (18), there has been no report of its synthesis from cytosine, via hydroxymethylation, until quite recently. Aside from isolation from these natural sources, early syntheses are based on multistep de novo heterocycle formation (19).

Our initial attempts to produce hmC under similar conditions of reaction to those used for the synthesis of hmU were unproductive. During this period of time, Abdel-Rahman and El Ashry reported a small-scale (1 mmol) hydroxymethylation of cytosine with paraformaldehyde in 0.5 N KOH solution under microwave irradiation (20). Our attempts to repeat this synthesis failed. However the report of the reaction of 2-deoxycytosine monophosphate with paraformaldehyde in the presence of 5 mol/L KOH (75 °C, 4 d) (12% yield) (21) motivated our further efforts on the direct hydroxymethylation of cytosine. Although the reaction of cytosine in aq. KOH with paraformaldehyde failed miserably, hmC was formed in good chemical yield (~85%) when triethylamine was employed along with higher reaction temperature and longer reaction time. We found that a molar excess of paraformaldehyde was necessary for the reaction to proceed in good chemical yields, but the addition must be made portion-wise during the course of the reaction. For instance, addition of greater than 3 equiv. of paraformaldehyde at the beginning of the reaction causes the formation of undesired and unidentified byproducts and made the recovery of hmC by recrystallization unfeasible. The reaction completely fails to give the desired product at 10 equiv. of paraformaldehyde. To overcome these problems, the amount of paraformaldehyde was carefully controlled and added in several portions during the reaction ($(HCHO)_n$ – cytosine (mol) 3.5:1), Scheme 2. The hmC is recovered from the reaction solution by crystallization. Although later crops are significantly contaminated with unreacted cytosine (up to approximately 20% (wt%)), they are still suitable for use in the next step.

The next necessary transformations are installation of nucleobase-protecting groups and alkylation. For cytosine, either of two routes may be used: N4-protection followed by N1-alkylation in the presence of either K_2CO_3 or NaH (22, 23); or the reverse, N1-alkylation in the presence of NaH and then protection of the exocyclic amino group (24). Both routes were attempted and gave identical yields; thus, the alkylation was simply performed in DMF with K_2CO_3, as was done with 5-hydroxymethyluracil.

Following alkylation, the nuclebase was protected, first by silylation of the hydroxyl group and then benzoylation of the exocyclic amino group. The silylation step gave a poor yield, likely by interference by the adjacent amino group, which could not be improved even by use of an excess TBDPS-Cl (2 equiv.). The remaining transformation to yield the hmC PNA monomer **15** proceeded without incident.

Synthesis and hybridization properties of PNA containing C5-hydroxymethylpyrimidines

The hmU and hmC PNA monomers were used for both automated and manual PNA-oligomer synthesis. Initially, standard conditions were employed (resin loading 0.23 mmol/g), and this was suitable for the incorporation of hmU in isolated positions (**P1**) by automated methods. However, upon attempts to prepare contiguously modified oligomers by manual methods, the synthesis failed after 5 or 6 residues. Although these oligomers were identified by mass spectrometry, they were inseparable, and further sequence elongation was not possible. Therefore, we turned to lower-loading resin (0.06 mmol/g), which did not resolve this problem. However, the lower-loading resin was subsequently used to prepare singly modified oligomers **P2**–**P4**, which allowed us to evaluate the effect of the hmU or hmC substitution for T or C, respectively.

The oligomers were examined for their ability to bind complementary nucleic acids (Table 2). The poly(hmU/T) hexamer was used for triplex formation with poly(rA), wherein two strands of PNA bind to the RNA strand, thus giving each complex a total of six modifications. Compared with the unmodified oligomer, there was a slight drop in T_m (–1.5 °C) per insert. Interestingly, the same modest T_m drop

was observed in the singly modified duplexes (**P4** and **P5**), regardless of the identity of the nucleobase. These investigations represent the first study of the effect of 5-hydroxymethylpyrimidines on complex stability in either DNA or analogs. Previous studies have focused on the glycosylated derivatives (25), wherein only the diaminoglycoside conjugate was stabilizing towards duplex formation (26, 27). Relevant studies to 5-hydroxymethylcytosine have been focused on the interaction between oligonucleotides bearing this modification and enzymes and have not included T_m measurements (28, 29).

In summary, we have described a convenient, large-scale synthesis of 5-hydroxymethylcytosine and 5-hydroxymethyluracil and the transformation of these modified nucleobases in monomers compatible with PNA synthesis. The modifications were placed in isolated positions in sequences capable of either triplex formation or duplex formation. Dense functionalization of PNA oligomers was not achieved, likely because of the hydrophobic/steric nature of the protected hmU and hmC monomers. A single modification had a small negative impact on the stability of the complex, independent of the particular nucleobase, and multiple substitutions had an additive effect. Overall, the substitution of a hmU or hmC for T or C, respectively, is tolerated in both the context of a duplex or a triplex, within the sequences examined. Further investigation on the optimization of the protecting-group strategy and oligomerization chemistry is needed to fully evaluate this modification and its impact on the biophysical properties of PNA.

Kinetic characterization of a cis- and trans-acting M^{2+}-independent DNAzyme that depends on synthetic RNaseA-like functionality — Burst-phase kinetics from the coalescence of two active DNAzyme folds[1]

Richard Ting, Jason M. Thomas, and David M. Perrin

Abstract: This work describes the kinetics of the DNAzyme 9_{25}-11, a combinatorially selected, M^{2+}-independent ribophosphodiesterase that is covalently modified with both cationic amines and imidazoles. At 13 °C, cis- and trans-cleaving constructs of 9_{25}-11 demonstrate the highest rate constants reported to date for any M^{2+}-independent nucleic acid catalyst, investigated at physiological ionic strength and pH 7.5 (0.3 min^{-1} for self cleavage and 0.2 min^{-1} for intermolecular cleavage). In contrast to the cis-cleaving species, single-turnover experiments with the trans-cleaving species exhibit biphasic cleavage data, suggesting the presence of two conformations of the catalyst–substrate complex. Pulse–chase experiments demonstrate that both complexes lead to substrate cleavage. Under multiple-turnover conditions, the higher rate constant appears in a burst phase that decays to a slower steady state exhibiting a rate constant of 0.0077 min^{-1}, a value approximating that of the slow-cleaving phase seen in single-turnover experiments. Slow product release is excluded as the source of the burst phase. An integrated rate equation is derived to describe burst-phase kinetics based on the funneling of the initial population of fast-cleaving conformation into a steady-state population composed largely of the slow-cleaving conformation.

Key words: RNase mimics, DNAzymes, ribozymes, kinetics, RNA cleavage.

Résumé : Dans ce travail, on décrit la cinétique de la 9_{25},11-ADNzyme, une ribophosphodiestérase M^{2+}-indépendante qui a été sélectionnée d'une façon combinatoire et qui a été modifiée d'une façon covalente avec des amines cationiques ainsi que des imidazoles. À 13 °C, de tous les catalyseurs d'acide nucléique, l'entité 9_{25},11 de clivage cis- et trans- présente la constante de vitesse la plus élevée pour une activité M^{2+}-indépendante, à force ionique physiologique et à un pH de 7,5 (0,3 min^{-1} pour l'autoclivage et de 0,2 min^{-1} pour le clivage intermoléculaire). Par opposition à ce qui est observé avec des espèces à clivage cis-, des expériences à simple rotation avec des espèces à clivage trans- fournissent des données relatives à un clivage biphasique ce qui suggère la présence de deux conformations du complexe catalyseur substrat. Des expériences de recherche de pulsation démontrent que les deux complexes conduisent à un clivage du substrat. Dans des conditions impliquant plusieurs rotations, il semble que la constante de vitesse la plus élevée soit dans une phase explosive qui ralentit vers un état stationnaire plus lent dont la constante de vitesse est 0,0077 min^{-1}, une valeur qui se rapproche de celle de la phase lente du clivage observé dans les expériences à rotation unique. Une libération lente de produit est exclue comme source de la phase explosive. On a dérivé une équation de vitesse intégrée pour décrire la cinétique de la phase explosive; elle est basée sur une orientation de la population initiale de la conformation à clivage rapide dans une population d'état stationnaire formée en grande partie de la conformation à clivage lent.

Mots-clés : imitation de la RNase, ADNzymes, ribozymes, cinétique, clivage de l'ARN.

Introduction

The discovery of catalytic RNA, and combinatorial methods for the in vitro selection of unnatural nucleic acid catalysts (ribozymes and DNAzymes) (1), have intrigued chemists and biologists alike. Following the identification of any catalyst, be it re-engineered from a naturally occurring ribozyme or from a combinatorially selected species, conditions for characterization are often chosen to push the envelope of catalysis (e.g., a high k_{cat} or M^{2+}-independence), even if such conditions are not absolutely physiologically applicable. For instance, naturally occurring ribozymes and

their unnatural variants have been studied at high concentrations of di- and mono-valent metal cations (e.g., 10–400 mmol/L Mg^{2+}, or 800 mmol/L NH_4Cl and 100 mmol/L Mg^{2+}, or 4 mol/L LiCl) (2–7). In a similar vein, two combinatorially selected DNAzymes have been found to exhibit impressive k_{cat} values in the order of 10 min^{-1} in the presence of 10 mmol/L Mn^{2+} or 100 μmol/L Pb^{2+} (8, 9). Generally in these cases, the most important rate constant is taken to be that of chemistry, which is most readily identified under single-turnover conditions. Nevertheless, to fully evaluate a catalyst's potential, it should also be characterized under multiple-turnover conditions where very high values of k_{cat} may not be expressed because of the slow product release (e.g., HH16, RNaseP, VS) (5, 7, 10–12) that results from the conditions chosen to favor k_{cat}.

Our interest in catalytic nucleic acids involves synthetically incorporating protein-like functionalities to increase k_{cat} values for M^{2+}-independent RNA cleavage (13). The impetus for this comes from the fact that numerous investigations of naturally occurring ribozymes have addressed the question of M^{2+}-independence (2–4, 14–24). Furthermore, several combinatorial selections have identified DNAzymes that can operate without Mg^{2+}, thus underscoring a general interest in M^{2+}-independent activity (25–27). These studies identified self-cleaving species with k_{obs} values in the order of 10^{-3} min^{-1}. With few exceptions (6), when nucleic acid catalysts are evaluated under physiological ionic strength where M^{2+} is minimally present (e.g., 0.2 mmol/L Mg^{2+} and 150 mmol/L monovalent M^+), k_{cat} values for intermolecular cleavage are low and turnover remains quite elusive. In light of the fact that intracellular levels of M^{2+} (28–31) may limit the in vivo activity of such catalysts, recent reviews (32–34) have further highlighted the potential utility of M^{2+}-independent ribonucleases as research tools and therapeutics. Moreover, the importance of turnover with regards to therapeutic development has also been noted (35). At physiological pH and submolar concentrations of M^+ (absence of an M^{2+}, polyamine, or histamine) (36), turnover by an unmodified nucleic acid catalyst has yet to be observed.

Using the combinatorial selection methods developed early on (37–39), we and others have discovered DNAzymes with protein-like cationic amines and imidazoles that can cleave RNA in the absence of a M^{2+}, as does RNaseA (13, 40–43). We now seek to quantify the catalytic advantages that synthetically modified nucleosides may impart under conditions where unmodified nucleic acid catalysts have been found to be catalytically deficient. It is under these somewhat more stringent conditions that we may properly gauge the advantage that modified nucleotides will bring.

Recently, we reported on the general kinetic properties of the modified DNAzyme 9_{25}-11t, which catalyzed ribophosphodiester hydrolysis in the absence of an M^{2+} at 24 °C (k_{cat} of 0.03 min^{-1}) (13). Previous studies on M^{2+}-dependent ribozymes and DNAzymes employed conditions that deviate drastically from physiological, but enhance rate constants for cleavage. Herein, we identify conditions that favor a significantly higher k_{cat} value with respect to M^{2+}-independent RNA hydrolysis; in the case of 9_{25}-11, the change in conditions involves simply lowering the temperature from 24 °C to 13 °C, a temperature that deviates from most physiological applications. At 13 °C, the rate constants for both intramolecular cleavage, $k_{self\text{-}cleave}$, and single-turnover intermolecular cleavage, $k_{cat\ STR}$, increase by approximately an order of magnitude. These observations demonstrate the highest rate constants to date for any nucleic acid catalyst evaluated at submolar ionic strength and pH in the absence of M^{2+}.

In the case of intermolecular cleavage, the higher rate constant observed under single-turnover conditions is manifested in a burst phase that precedes a slow steady-state rate under multiple-turnover conditions. After excluding slow product release, we developed a fully integrated kinetic framework that involved dynamic partitioning of an active-catalyst conformation into a less active one to account for the observed burst phase. Fersht (44) and others (45) have discussed conformational partitioning and hysteretic behavior as explanations for a burst phase. To explain the observed burst phase, we developed an alternative model that differs from other hystereses (see later), and this model may apply to any catalyst displaying similar kinetic behavior, irrespective of its composition.

Materials and methods

Enzymes and chemicals

Enzymes, ^{32}P-labeled nucleotides, reagents, and buffers were purchased from commercial sources (NEB, Roche, Amersham-USB, PerkinElmer, and Fermentas). 5-aminoallyl-deoxyuridine, 8-histaminyl-deoxyadenosine phosphoramidites, and triphosphates were synthesized as previously described (40, 46).

Oligonucleotides

S1, 5′-GCGTGCC**rC**GTCTGTT-3′; 3D2, 5′-GCGTGCC**rC**-GTCTG-3′; 3A2, 5′-GCGTGCC**rC**GTCTGTTGG-3′; 5D2, 5′-GTGCC**rC**GTCTGTT-3′; S1-OMe, the non-cleavable substrate analogue containing a 2′-*O*-methyl cytosine ribonucleotide in place of the ribocytidine of S1; pre-$P_{5'}$, the chemical precursor to the 5′-cleavage product of S1, 5′-GCGTGCC**rC**p-3′ (where p is a 3′-phosphate); $P_{3'}$, the 3′-cleavage product of S1, 5′-GTCTGTT-3′; and the trans-cleaving catalyst 9_{25}-11t (where the letter "t" denotes trans-cleaving), 5′-CCAACAG**UUCUCAU**CCG**UAGUGAA**GGC-ACGC-3′ (where **U** = 5-aminoallyldeoxyuridine and **A** = 8-histaminyldeoxyadenosine) were synthesized using standard automated solid-phase methods. The cis-cleaving sequence, 9_{25}-11c (where the letter "c" denotes cis-cleaving), was synthesized using Sequenase 2.0, as previously described (40). All labeled and unlabeled oligonucleotides were purified by 7 mol/L urea (D-PAGE) gels, ethanol precipitated, desalted on a G-25 spin column, and stored in water at –20 °C prior to use. The 5′-cleavage product of S1 possessing a 2′,3′-cyclic phosphate, $P_{5'}$, was synthesized according to literature precedent (10, 13, 47) and verified by MALDI-TOF analysis: $[M - H]^-$ *m/z* (predicted): 2462.4; *m/z* (experimental): 2460.6.

Oligonucleotide labeling

Substrates S1, 3D2, 3A2, 5D2, S1-OMe, and the 5′-cleavage product, $P_{5'}$, were 5′ end labeled with T4 polynucleotide kinase lacking 3′-phosphatase activity (Fermentas).

© 2007 NRC Canada

Sequenase 2.0 was used to extend 3D2 against a complementary template by two nucleotides ([α-^{32}P] TTP) to give 3′-^{32}P labeled S1. To generate 3′-^{32}P labeled $P_{3'}$, 3′-^{32}P labeled S1 was treated with NaOH and then gel-purified to give 3′-^{32}P labeled $P_{3'}$.

Kinetic experiments

The procedures used are generally adapted from literature precedents (10, 11, 48, 49). Self-cleavage experiments were performed as previously described (50). Kinetic experiments with the trans-cleaving species, 9_{25}-11t, were performed under mineral oil in a Julabo F-10 temperature-controlled water bath. Substrate, catalyst, and chase solutions were buffered in CB200 (50 mmol/L Tris HCl pH 7.5, 1 mmol/L EDTA, and 200 mmol/L NaCl), unless specified otherwise, where CB200 refers to cleavage buffer with 200 mmol/L NaCl. Multiple independent data sets were collected for all experiments. Autoradiography data were generated using Molecular Dynamics phosphor screens and a Molecular Dynamics Typhoon 9200 phosphorimager and were quantified with ImageQuant v5.2. Volumes were corrected for background using ImageQuant v5.2 histogram peak correction. The kinetic constants reported in this text result from least-square fits of data using SigmaPlot 2001 v7.101. Errors associated with the constants are the standard errors generated from these fits.

Single-turnover (STR) kinetics, determination of $k_{obs\ STR}$

Cleavage reactions in trans were initiated by mixing equal volumes of 9_{25}-11t at increasing concentrations (5–1500 nmol/L) and trace radiochemical quantities of the labeled substrate S1 (<1 nmol/L) in CB200 (buffer) at 13 °C. Aliquots were removed at various time points, quenched with formamide solution, and resolved by 7 mol/L urea denaturing 20% 29:1 monomer/bis(polyacrylamide) gel electrophoresis (20% D-PAGE). First-order rate constants, $k_{obs\ STR}$, were obtained by fitting data to the single-exponential eq. [1]

$$[1] \qquad [P]_t = [P]_\infty(1 - e^{-k_{obs\ STR}t})$$

where $[P]_t$, and $[P]_\infty$ are the fractions of substrate cleaved at time t and at the end point, respectively. Rate constants for biphasic curves were obtained by fitting data to the following double-exponential equation

$$[2] \qquad [P]_t = [P_{fast}]_\infty(1 - e^{-k_{obs\ fast\ STR}t}) + [P_{slow}]_\infty(1 - e^{-k_{obs\ slow\ STR}t})$$

where the subscripts "fast" and "slow" identify the constants that describe fast and slow phases, respectively.

Determination of the maximum first-order rate constant ($k_{cat\ STR}$) and the catalyst concentration at which the rate is half-maximal ($K_{M\ STR}$) under single-turnover conditions

For each of the fast- and slow-cleaving phases, $k_{cat\ STR}$ and $K_{M\ STR}$ were determined by plotting $k_{obs\ STR}$ against total 9_{25}-11t concentration, $[E_t]$, using the hyperbolic equation

$$[3] \qquad k_{obs\ STR} = \frac{k_{cat\ STR}[E_t]}{K_{M\ STR}[E_t]}$$

Pulse–chase cleavage experiments to determine the dissociation rate constants for S1 ($k_{-1\ fast}$ and $k_{-1\ slow}$)

Pulse–chase cleavage experiments followed literature precedents (48, 49). The chase was initiated typically 3 min after the pulse by the addition of unlabeled S1 in CB200 in 50-fold excess over the catalyst. Data corrected for cleavage prior to the chase (49) were fit to eq. [2] to obtain the rate constants $k_{chase\ fast}$ and $k_{chase\ slow}$. The S1 dissociation rate constant, k_{-1}, was determined from k_{chase}, according to eq. [4] (49)

$$[4] \qquad k_{-1} = k_{chase} - k_{cat\ STR}$$

Pulse–chase native gel shift assays used for determining the dissociation rate constants for an S1 substrate analogue ($k_{-1\ fast\ S1\text{-}OMe}$ and $k_{-1\ fast\ S1\text{-}OMe}$)

Aliquots of 9_{25}-11t (0.5 μmol/L) and trace radiochemical quantities of 5′-^{32}P labeled S1-OMe were equilibrated in CB200 at 13 °C overnight. The chase was initiated by the addition of unlabeled S1 in 100-fold excess over the catalyst. The reactions were stopped by placing the tubes on ice and adding a 1/10 of the volume of ice-cold loading solution (70% sucrose, 0.01% bromophenol blue, and 0.01% xylene cyanol in CB200). In a 4 °C cold room, samples were loaded on a pre-cooled native gel run at 4 °C and 3 W (~50 mA) with CB200 as the running buffer under peristaltic circulation. The first-order dissociation rate constants, $k_{-1\ fast\ S1\text{-}OMe}$ and $k_{-1\ slow\ S1\text{-}OMe}$, were obtained by fitting biphasic data to the double-exponential equation

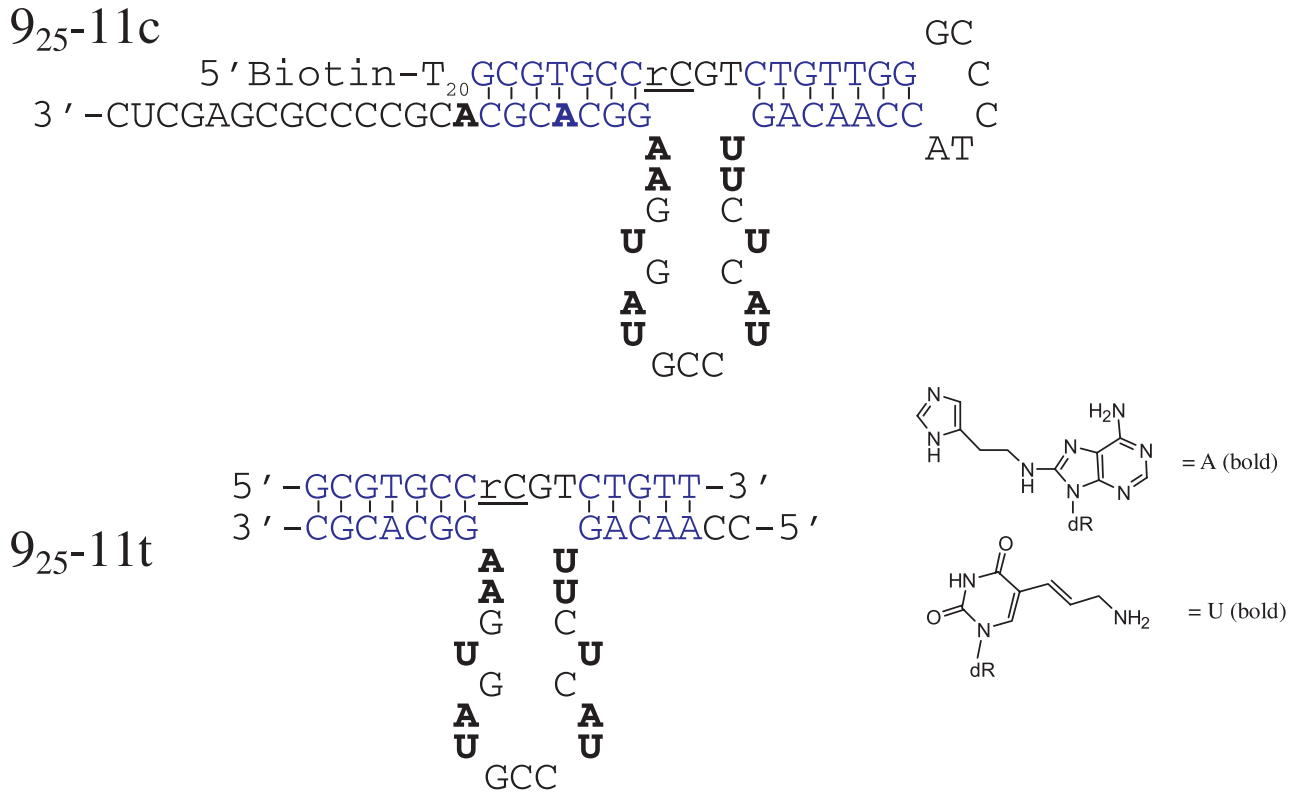
$$[5] \qquad f = f_o + f_{\infty\ fast}(1 - e^{-k_{-1\ fast\ SI\text{-}OME}t}) + f_{\infty\ slow}(1 - e^{-k_{-1\ slow\ SI\text{-}OME}t})$$

where $f_{\infty\ fast}$ and $f_{\infty\ slow}$ are the respective maximum fractions of bound substrate analogue that dissociates in the fast- or slow-dissociating phases, and f_o is the fraction of S1-OMe that was not bound to 9_{25}-11t at $t = 0$.

Native gel shift assays used for determining the dissociation rate constant of product oligonucleotides

Product-dissociation constants for 9_{25}-11t were measured as described earlier for $k_{-1\ S1\text{-}OMe}$, using 5′-^{32}P labeled $P_{5'}$ or 3′-^{32}P labeled $P_{3'}$. These experiments were carried out with each product in the absence or presence of the other at 50 μmol/L.

Multiple-turnover (MTR) kinetics using denaturing PAGE analysis



Multiple-turnover experiments were performed at a ratio of [S]/[E] ≥ 15 in CB200 at 13 °C. Cleavage was quantified according to protocols detailed for the single-turnover experiments. For steady-state analysis, multiple-turnover kinetic data following the burst phase were fit to the equation

$$[6] \qquad P = k_{obs\ MTR}\ t + P_o$$

where P_o is the amplitude of the burst phase. Values of $k_{obs\ MTR}$ obtained at different enzyme concentrations were

Figure 1. The sequences of 9_{25}-11c, prepared by templated enzymatic polymerization of synthetic monomer triphosphates, and 9_{25}-11t, synthetically prepared on the solid phase. Substrate S1 is shown hybridized to 9_{25}-11t. Emboldened **A** and **U** represent the modified nucleotides shown at right. The rC indicates the target ribophosphodiester bond. Predicted Watson–Crick pairs are indicated by a dash between blue-colored complementary bases.

plotted vs. total catalyst concentration, $[E_t]$, according to the following equation

[7] $$k_{\text{obs MTR}} = [E_t]\ k_{\text{cat steady state MTR}}$$

To obtain values for the burst-phase constants, multiple-turnover data were fit to the equation

[8] $$P = C(1 - e^{-k_{\text{burst}}t}) + k_{\text{obs MTR}}t$$

The initial rate of product formation was determined by linear regression of the cleavage data obtained at early time points (up to 12 min). A first-order rate constant was obtained by dividing the initial rate by the total catalyst concentration multiplied by the 0.35 fraction to reflect the fraction of the catalyst initially present in the fast-cleaving conformation as determined by the amplitudes for each phase (see Results and Discussion sections for the rationale of attributing this value).

Native PAGE analysis of multiple-turnover kinetics – An attempt to observe a product–catalyst complex

Multiple-turnover experiments were performed using 5′-^{32}P labeled S1 and 3′-^{32}P labeled S1. Reaction concentrations were 1 µmol/L for 9_{25}-11t and 10 or 15 µmol/L for the substrate, S1. Aliquots were removed and quenched in formamide loading solution (for D-PAGE) or added to 1/10 of the volume ice-cold native gel loading solution. Resolution by D-PAGE and native PAGE at 4 °C was performed as described earlier.

Error analysis

Variance from week to week was found to be as high as 30%, and up to 30% when the resynthesis of catalyst 9_{25}-11t is considered. Others have reported the same for unmodified ribozymes (7, 10, 48, 49). For the self-cleaving sequence 9_{25}-11c, errors from day to day were generally lower (~ 10%–20%), and variance seemed to depend on the freshness of both the Sequenase used to synthesize 9_{25}-11c and the dGTPα^{32}P used for internal labeling. To control for such error, all self-cleavage measurements were conducted on the same day for the six temperatures noted.

Attempts at ligation

Ligation reactions under single-turnover and external-equilibrium-shift conditions were performed at 13 °C as previously described (13).

Results

The unimolecularity of the enzymatically prepared self-cleaving species, 9_{25}-11c (where the letter "c" denotes cis-cleaving), allowed us to estimate a chemical-cleavage rate constant without having to entertain the complicating effects of enzyme–substrate association and dissociation. Once this was investigated, we turned our attention to catalysis in trans with 9_{25}-11t (where the letter "t" denotes trans-cleaving), a synthetic trans-cleaving derivative of 9_{25}-11c that was evaluated under single- and multiple-turnover conditions. Figure 1 shows the two synthetically modified nucleosides, the self-

cleaving species (9_{25}-11c), and the trans-cleaving species (9_{25}-11t) with its substrate S1. All rate constants measured at 13 °C are listed in Table 1. A full kinetic scheme that lists representative values from this table is given in the Supplementary data.[3]

The maximum rate constant for the self-cleavage of 9_{25}-11c ($k_{\text{obs STR}}$) is observed at ~13 °C

Previously, a value of 0.044 min^{-1} had been reported for $k_{\text{self-cleavage}}$ for 9_{25}-11c at 37 °C (40). As part of an initial study to see if varying several conditions (e.g., concentration of M^{2+}, buffer, ionic strength, temperature, and so forth) would cause an increase in the value of the observed self-cleavage rate constant, $k_{\text{self-cleave}}$, the kinetics of 9_{25}-11c was investigated as a function of temperature. Plots of the self-cleaved fraction vs. time at which it approached 70% cleavage at all temperatures, were monophasic, and fit to eq. [1] (Fig. 2A). Of the temperatures surveyed, the cleavage rate constant appears to be maximal at ~13 °C with a $k_{\text{self-cleave}}$ of 0.28 ± 0.02 min^{-1} (Fig. 2B). Although this rate constant varied linearly with sodium concentration between 20 and 200 mmol/L NaCl, no increase was observed at higher ionic strength (e.g., 0.2–1 mol/L NaCl). Furthermore, $[Mg^{2+}]$ up to 5 mmol/L had little effect (data not shown). As variation in the values of the self-cleavage rate constant could be as high as 20% from day to day, all self-cleavage reactions were performed on the same day using six different temperature baths to minimize error and ensure internal consistency.

To probe whether a folding step was rate-limiting at 13 °C (51, 52), pre-folding was attempted by preincubation of 9_{25}-11c under various conditions known to suppress cleavage activity followed by sudden restoration of permissive conditions (see Supplementary data) (52).[3] No conditions could be found to permit prefolding such that a faster cleav-

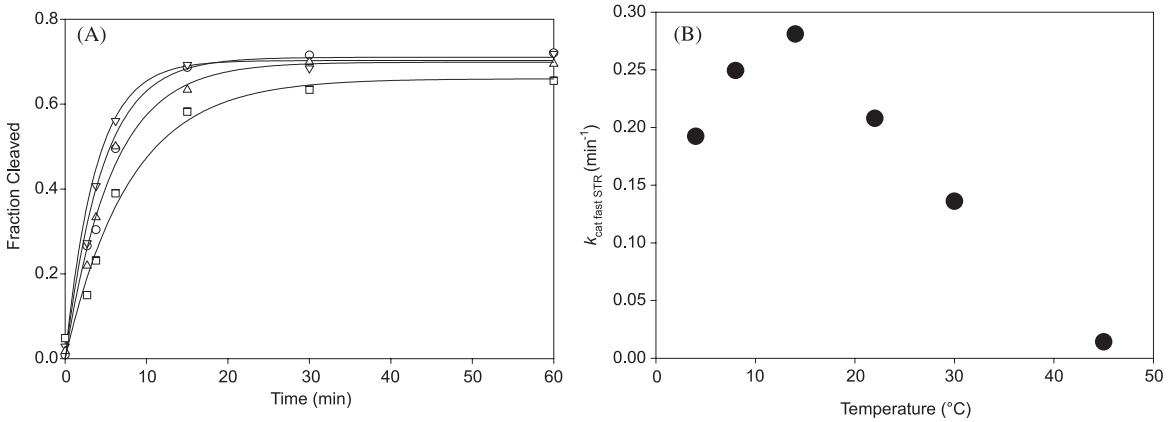
Figure 2. (A) Time courses for the cleavage of the cis-cleaving sequence, 9_{25}-11c, at different temperatures in CB200 buffer. Radiochemical amounts of 9_{25}-11c were incubated in CB200 at (○) 8 °C, (▽) 13 °C, (△) 22 °C, and (□) 30 °C (4 °C and 45 °C are not shown). Data were fit to the single-exponential eq. [1]. R^2 were greater than 0.983; the mean R^2 value is 0.989. (B) Observed cleavage rates, $k_{\text{self-cleave}}$, obtained from single-exponential fits were plotted against temperature demonstrating an optimal rate constant, $k_{\text{self-cleave}}$, of 0.28 min^{-1} at 13 °C.



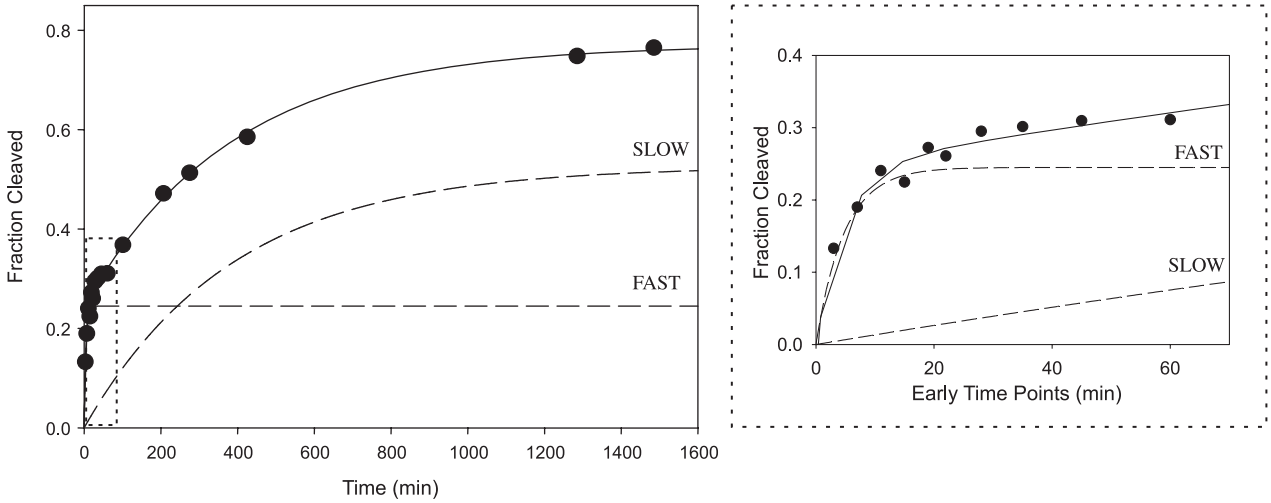


Figure 3. Single-turnover data for the cleavage substrate S1 by the trans-cleaving catalyst 9_{25}-11t at 13 °C in CB200. Dashed lines display theoretical S1 cleavage traces of the individual phases.[4]

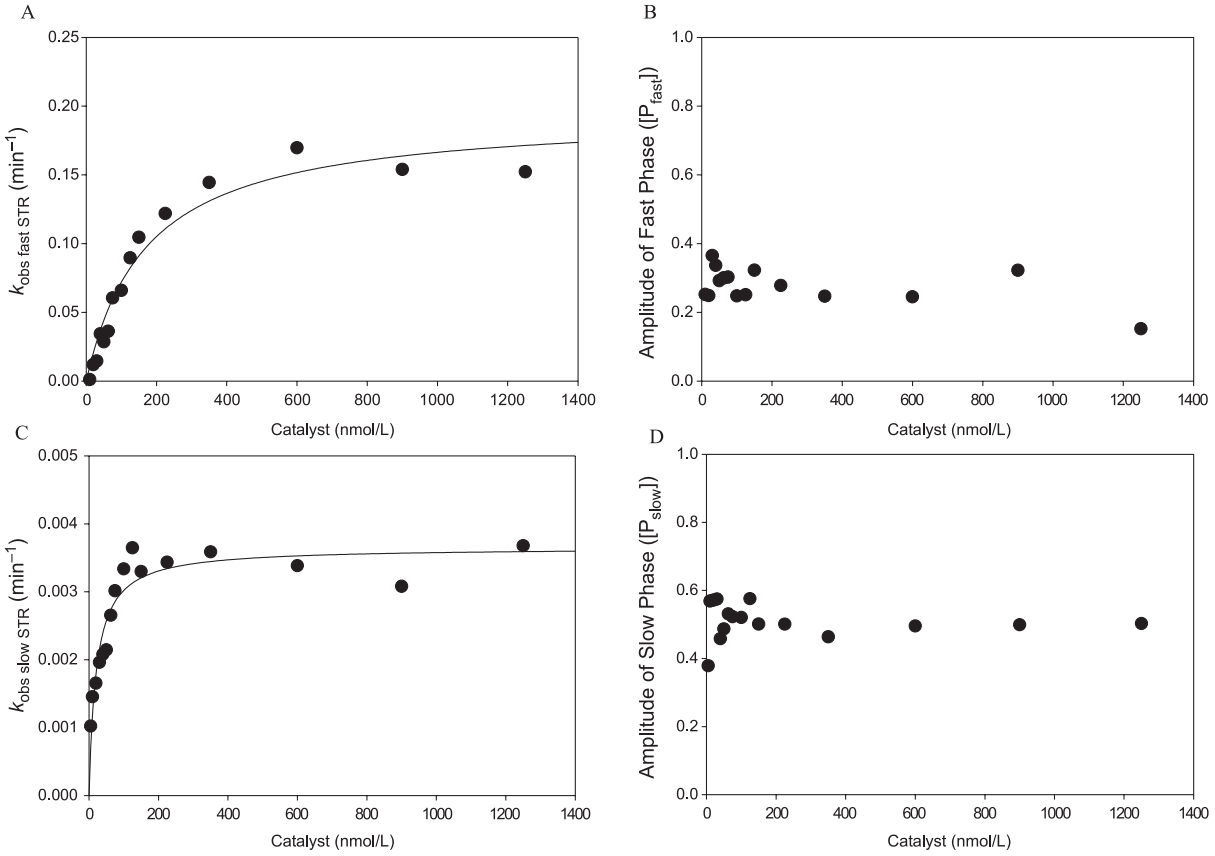
age rate could be identified. Given the comparatively small size of the catalytic motif and the fact that neither sigmoidal nor lag-phase kinetics were observed, the chemical step for self-cleavage was assumed to be rate-limiting not folding.

Single-turnover cleavage of S1 by 9_{25}-11t at 13 °C displays biphasic kinetics



The rate constant for 9_{25}-11c self-cleavage provided a benchmark for evaluating intermolecular catalysis by the trans-cleaving construct, 9_{25}-11t. Trans-cleavage was initially examined under single-turnover conditions with S1 at 13 °C. These data could not be fit to a single-exponential function given by eq. [1]. Instead, data were fit to a double-exponential function given by eq. [2] (Fig. 3). For all catalyst concentrations, ~35% of the substrate is cleaved in the fast phase, while ~65% of the substrate is cleaved in the slow phase. Generally, percentages are normalized to the maximum amount of substrate cleaved (Figs. 4B and 4D).

For each phase, a value of $k_{\text{cat STR}}$ and a value of the pseudo-Michaelis constant, $K_{\text{M STR}}$, were obtained by fitting $k_{\text{obs fast STR}}$ or $k_{\text{obs slow STR}}$ to a hyperbolic plot against total catalyst concentration (eq. [3]). The values so determined for $K_{\text{M fast STR}}$ and $k_{\text{cat fast STR}}$ were 170 ± 30 nmol/L and 0.20± 0.01 min^{-1}, and for $K_{\text{M slow STR}}$ and $k_{\text{cat slow STR}}$, the values were 21 ± 4 nmol/L and 0.0036 ± 0.0001 min^{-1}, respectively (Figs. 4A and 4C). Based on these values, the ratio of k_{cat}

[4] Data were fit to the double-exponential eq. [2]. The cleavage reaction was performed with 900 nmol/L catalyst and <1 nmol/L substrate S1 in CB200 at 13 °C. Fitting data to the double-exponential eq. [2] gives 0.996 for R^2 at 13 °C (graph at right details the early-time points enclosed in the colored box). Fitting data to a single-exponential gives an R^2 value of 0.704. The observed rate constant for the fast-cleavage phase, $k_{\text{obs fast STR}}$, is 0.21 ± 0.02 min^{-1} (fast-phase amplitude is 25 ± 0.7%). The observed rate constant for the slow-cleavage phase, $k_{\text{obs slow STR}}$, is 0.0026 ± 0.0002 min^{-1} (slow-phase amplitude is 53 ± 1%).

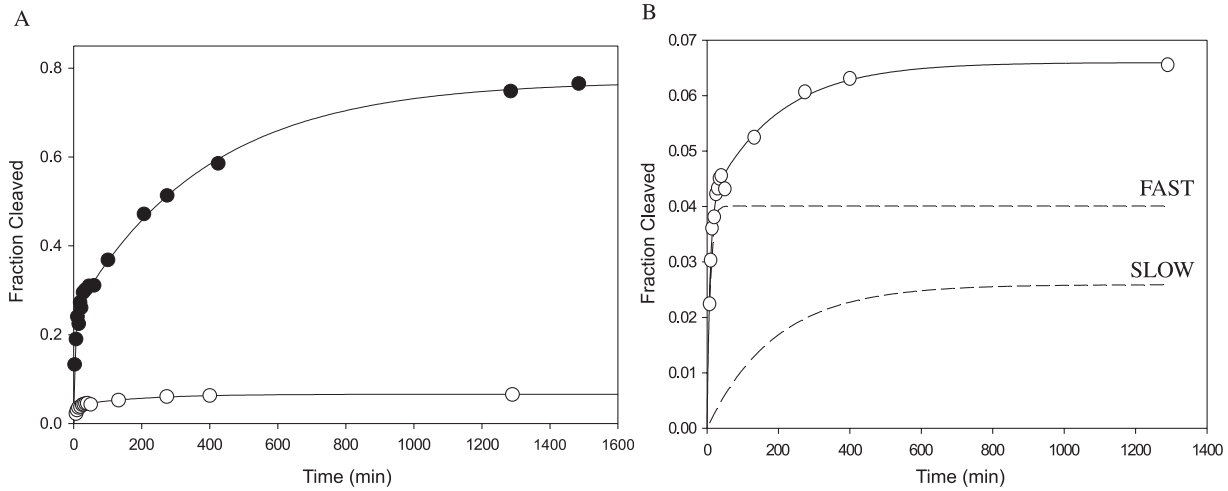
Figure 4. Effect of 9_{25}-11t concentration on the fast- and slow-phase rate constants and phase amplitudes in single-turnover experiments at 13 °C in CB200. Observed rate constants at different catalyst concentrations, $k_{obs\ fast\ STR}$, were obtained by fitting substrate cleavage data to the double-exponential eq. [2]. The values $k_{obs\ fast\ STR}$ and $k_{obs\ slow\ STR}$ at various 9_{25}-11t concentrations were fit separately to eq. [3]. (A) Effect of 9_{25}-11t concentration on $k_{obs\ fast\ STR}$: the maximum first-order fast-rate constant, $k_{cat\ fast\ STR}$, is 0.20 ± 0.01 min^{-1}, and the catalyst concentration at which the reaction rate is half-maximum for the fast phase, $K_{M\ fast\ STR}$, is 170 ± 30 nmol/L (R^2 is 0.952). (B) Effect of 9_{25}-11t concentration on the fast-phase amplitude. The fraction of substrate cleaved through the fast-cleavage rate constant (not normalized for the extent of cleavage), $[P_{fast}]_\infty$, is 28%. (C) Effect of 9_{25}-11t concentration on $k_{obs\ slow\ STR}$ ($k_{cat\ slow\ STR}$ is 0.0036 ± 0.0001 min^{-1}, and $K_{M\ slow\ STR}$ is 21 ± 4 nmol/L, and R^2 is 0.892). (D) Effect of 9_{25}-11t concentration on the slow-phase amplitude.[5]

$_{STR}/K_{M\ STR}$ for the more active conformation is calculated to be ~1.2 × 10^6 $(mol/L)^{-1}$ min^{-1}. The observation of the fast phase suggests that a significant fraction of 9_{25}-11t displays a $k_{cat\ STR}$ value comparable to $k_{self\text{-}cleave}$ for 9_{25}-11c.

Investigating the nature of the biphase

The number of studies addressing either biphasic kinetics, catalytic heterogeneity, or both in catalytic RNA has become rather extensive (5, 7, 48, 52–54). However, fewer examples of such have been identified with DNAzymes. In addition, only a few studies have characterized synthetically modified DNAzymes (13, 40–43). For these reasons, elucidating the origin of the biphasic nature of 9_{25}-11t was pursued. Four reasonable explanations could account for the observed biphasic single-turnover kinetics: (*i*) the presence of synthetic impurities arising from the solid-phase synthesis of 9_{25}-11t, (*ii*) catalyst dimerization or aggregation (55, 56), (*iii*) the existence of a significant reverse reaction (ligation) rate (5), or (*iv*) the presence of kinetically inactive folds (48, 57).



The presence of synthetic impurities is unlikely given the following observations: (*i*) two independent syntheses of 9_{25}-11t and at least three different purifications of each (six purifications in total) all resulted in functional catalysts that exhibited nearly identical biphasic kinetics at 13 °C, (*ii*) single-turnover kinetics at 24 °C were homogeneous and monophasic (13), suggesting that heterogeneity is not an intrinsic quality of the synthetic preparation, but rather dependent on low temperature, and (*iii*) single-turnover kinetics with alternate substrates 3D2 and 5D2 at 13 °C were monophasic (see Supplementary data, pp. S2–S3).[3]

Dimerization–aggregation has been seen in hammerhead variants (55, 56) and is certainly plausible for 9_{25}-11t, given its high degree of autocomplementarity that affords the pos-

[5] The average value of $[P_{slow}]_\infty$ is 52%. The relative invariance of $[P_{fast}]_\infty$ and $[P_{slow}]_\infty$ as a function of catalyst concentration suggests that these fractions are independent of the catalyst concentration. Catalyst concentrations ranged from 5 nmol/L to 1500 nmol/L.

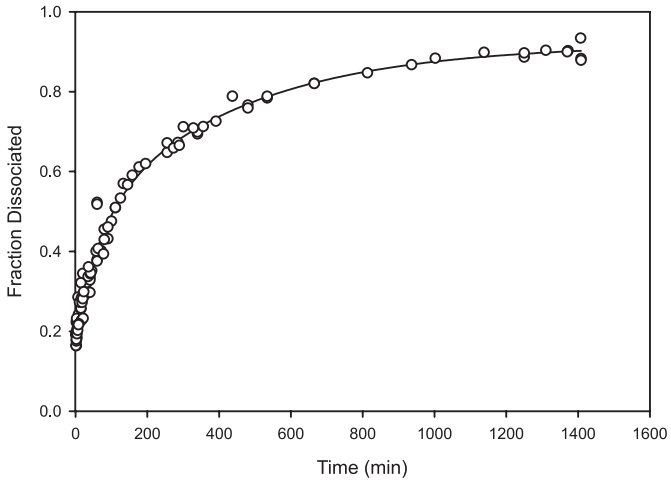

Figure 5. Determination of substrate-dissociation rate constants for substrate S1 by pulse–chase cleavage assay with 9_{25}-11t in CB200 13 °C. (A) 900 nmol/L Catalyst was incubated with <1 nmol/L S1 (●), or 112 nmol/L catalyst and <1 nmol/L S1 were challenged with 50 µmol/L of excess unlabeled S1 for 3 min (○).[6] (B) Rescaling the fraction-cleaved axis for the chased reaction clearly shows biphasic behavior. Dotted lines indicate the constituent curves for the fast and slow phases.

sibility that kinetically favored hairpins are in competition with thermodynamically favored dimers. That possibility was excluded based on (*i*) the absence of any observable high-molecular-weight aggregates in native gel retardation analysis of 9_{25}-11t, (*ii*) the invariance of the single-turnover amplitudes for each phase with catalyst concentration (Figs. 4B and 4D), and (*iii*) the observation that the multiple-turnover steady-state S1 cleavage rate increased linearly with increasing catalyst concentration over a range of 50 nmol/L to 1 µmol/L catalyst (see later). Finally, a significant reverse-reaction (ligation) rate could have explained biphasic kinetics, as has been described for the VS ribozyme (5). This was experimentally excluded for 9_{25}-11t; at 13 °C, no ligation could be detected.

Excluding the first three explanations, conformational heterogeneity was investigated as the origin of the biphase. This explanation was elaborated by Esteban et al., who employed pulse–chase kinetic assays under single-turnover conditions to demonstrate that biphasic kinetics, observed for the hairpin ribozyme, were due to the presence of one active and one essentially inactive catalyst–substrate conformation (48). Some important differences emerged between 9_{25}-11t and the hairpin ribozyme; in contrast to the monophasic curves obtained for the hairpin ribozyme (48) in pulse–chase experiments, the curves obtained for 9_{25}-11t remain distinctly biphasic (Fig. 5). This suggests that each of the two ES complexes can lead to substrate cleavage. Two first-order rate constants were observed in the pulse–chase experiment: $k_{\text{chase fast}} = 0.23\ \text{min}^{-1}$ and $k_{\text{chase slow}} = 0.0041\ \text{min}^{-1}$. Using eq. [4] and the respective values of $k_{\text{cat STR}}$, we calculated

Figure 6. Pulse–chase analysis by native gel electrophoresis to determine the first-order rate constant for the dissociation of the 2′-OMe substrate analogue (S1-OMe) from 9_{25}-11t at 13 °C in CB200.[7]

two values for substrate S1 dissociation constants: $k_{-1\ \text{fast}}$ is 0.03 min^{-1} and $k_{-1\ \text{slow}}$ is 0.0005 min^{-1} (Fig. 5).

To corroborate these dissociation constants, pulse–chase native gel shift assays were performed with a nonhydrolyzable substrate analog (S1-OMe). These data were also biphasic, and rate constants could be calculated from eq. [5] (Fig. 6): $k_{-1\ \text{fast S1-OMe}}$ was 0.014 ± 0.004 min^{-1} with an amplitude for the fast phase of 26 ± 7%, and $k_{-1\ \text{slow S1-OMe}}$ was

[6] Data for the unchased reaction were fit to eq. [2], giving 0.21 min^{-1} for $k_{\text{obs fast STR}}$ and 0.0026 min^{-1} for $k_{\text{obs slow STR}}$ (R^2 is 0.996). Data for the chased reaction were fit to eq. [2], giving 0.233 min^{-1} for $k_{\text{chase fast}}$ and 0.0041 min^{-1} for $k_{\text{chase slow}}$ (R^2 is 0.981). These values were treated according to eq. [4] to give the substrate dissociation rate constants, $k_{-1\ \text{fast}}$ and $k_{-1\ \text{slow}}$.

[7] A trace of 5′-^{32}P labeled S1-OMe was incubated with 9_{25}-11t (1 µmol/L) in CB200. The chase was commenced by the addition of an equal volume of 100 µmol/L unlabeled substrate in CB200. Aliquots were taken at various times, added to 1/10 of the volume of 70% sucrose (held in an ice bath) to halt further dissociation, and then quickly loaded onto 20% native PAGE gels run at 4 °C. The fraction of S1-OMe dissociated was plotted vs. time. The data were fit to a double-exponential eq. [5], which returned the following dissociation rate constants and phase amplitudes: $k_{-1\ \text{fast S1-OMe}} = 0.014 \pm 0.004\ \text{min}^{-1}$, $k_{-1\ \text{slow S1-OMe}} = 0.0023 \pm 0.0005\ \text{min}^{-1}$, amplitude fast = 27 ± 7%, and amplitude slow = 46 ± 6%.

© 2007 NRC Canada

0.0023 ± 0.0005 min^{-1} with a slow-phase amplitude of 46 ± 6%. Despite the structural difference imparted by the 2′-OMe substitution, these dissociation constants are consistent with those observed for substrate S1 in the kinetic pulse–chase experiments. Likewise, the amplitudes agree with those observed in single-turnover cleavage experiments.

Attempts to restore monophasic kinetics

In an attempt to simplify the study of 9_{25}-11t under conditions where $k_{cat\ STR}$ is optimal, we tried to find conditions that would not involve multiple conformations of the E or ES complex with different activities, as had been done for the group I intron ribozyme (52). Thus, 9_{25}-11t was subjected to various treatments (58) in the hope of attaining well-behaved kinetics (see Supplementary data, p. S4).[3] Despite numerous treatments, biphasic kinetics persisted under single-turnover conditions. Moreover, the relative amplitudes and $k_{cat\ STR}$ values of the two phases did not change significantly.

Monophasic kinetics were observed with substrates containing fewer bases at either the 5′ or the 3′ terminus (sequences are given in the Supplementary data)[3]: substrate 5D2 was truncated by two bases at the 5′ terminus, whereas substrate 3D2 was truncated by two bases at the 3′ terminus. Nevertheless, the values for $k_{cat\ STR}$ obtained with these substrates, $k_{cat\ 5D2\ STR}$ and $k_{cat\ 3D2\ STR}$, were both lower than the value of $k_{cat\ fast\ STR}$ observed with S1. The third substrate, 3A2, contained two additional complementary bases at the 3′ terminus and displayed biphasic kinetics that gave lower values for $k_{cat\ STR\ fast}$ and $k_{cat\ STR\ slow}$ as well as a reduced extent of cleavage (see Supplementary data, Figs. S1–S3).[3] Despite biphasic kinetics, substrate S1 was retained for continued investigation because the experimental value of $k_{cat\ fast\ STR}$ was higher than the values obtained with other substrates. As with other DNAzymes that give different and even biphasic kinetics when reconfigured to cleave alternative substrates (59), 9_{25}-11t appears to be especially sensitive to substrate length.

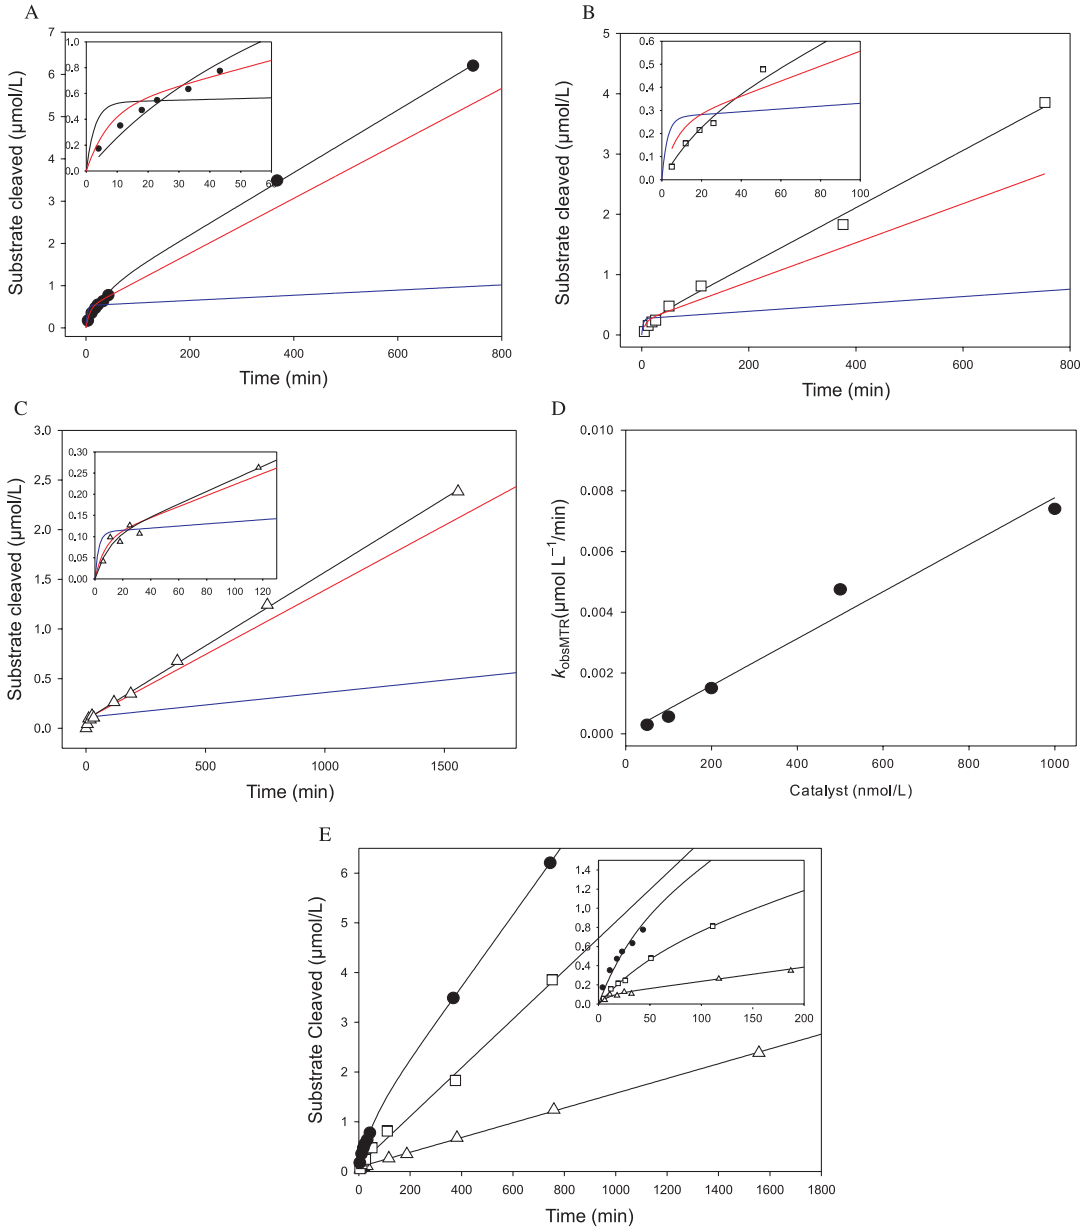
Multiple-turnover cleavage of S1 by 9_{25}-11t at 13 °C

Multiple-turnover experiments were conducted at 13 °C with a saturating concentration of substrate S1 and various catalyst concentrations. Substrate cleavage as a function of time was linear following a clearly evident burst phase at initial-time points (Fig. 7A–7C). When the steady-state multiple-turnover rate constant was plotted against enzyme concentration (see eqs. [6] and [7]), the value of $k_{cat\ steady\ state\ MTR}$ was found to be 0.0077 ± 0.0007 min^{-1} (Fig. 7D). This value is similar (within a factor of two) to that of $k_{cat\ slow\ STR}$ (0.0036 ± 0.0001 min^{-1}) observed in the single-turnover experiments with S1, suggesting that the steady-state phase represents turnover by a catalyst population that exists largely as the slow-cleaving conformation.

The initial rate of product formation at the outset of the burst phase was calculated by the method of initial rates (44), for which we made two assumptions: (*i*) the slow-cleaving conformation of the catalyst contributed negligibly to catalysis at early-time points and (*ii*) the initial rate of product formation in the burst phase reflected an effective catalyst concentration that was corrected to reflect the fraction of catalyst that is in the fast conformation in single-turnover experiments (i.e., 1 μmol/L × 0.35). By this analysis, the initial first-order rate constant was found to be 0.10 ± 0.03 min^{-1}, which is close (within a factor of two) to the value of the first-order rate constant ($k_{cat\ fast\ STR} = 0.2 \pm 0.01$ min^{-1}), extracted for the fast phase under the single-turnover conditions. It remained important to identify the basis for the slow steady-state rate. Since slow product release commonly explains burst-phase kinetics, and because that would certainly have been consistent with the reduction in temperature from 24 °C to 13 °C, we next investigated this possibility.

Slow product release does not account for the burst phase

To address slow product release, we attempted to measure the dissociation rate constants for both $P_{5'}$ and $P_{3'}$. The rate of product dissociation at 13 °C was too high to be effectively measured by native PAGE assays; more than 95% of the electrophoretically separable, radioactive complex had already dissociated within 0.5 min of the addition of the chase (data not shown). These results are qualitatively meaningful in that they show that the product-dissociation rate constants are much higher than either $k_{cat\ fast\ STR}$ or $k_{cat\ slow\ STR}$. Product inhibition was also evaluated under multiple-turnover conditions: addition of one or both products at 50 μmol/L prior to the addition of substrate S1 at 15 μmol/L produced no effect on the burst phase (data not shown), suggesting that the catalyst's affinity for product is also quite low.



Although these experimental results suggest that product release is not rate-limiting, a *caveat* associated with the experimental basis of these experiments must be entertained: directly following cleavage, 9_{25}-11t might retain one or both products in a distinct complex that undergoes a slow conformational change before releasing product. By such reasoning, the free catalyst used in either experiment may not bind products, with the same affinity as a catalyst–product complex, on its descent from the transition state in a conformationally coupled step that could explain slow product release. If that were the case, any measurement of product- dissociation rate constants obtained by incubating free catalyst with product would provide misleading values. To further address this concern, we examined multiple-turnover kinetics by native PAGE in the hope of observing a trapped catalyst–product complex.

Native PAGE analysis of multiple-turnover provides additional evidence against slow product release

If the steady-state rate constant were to reflect slow product release rather than chemistry, then $k_{cat\ steady\ state\ MTR}$ would actually represent a product-dissociation constant. Consequently, the half-life for either the $EP_{5'}$ or the $EP_{3'}$ complex, would be ~90 min, and at least one of these complexes would be observable by native PAGE gel retardation experiments. Multiple-turnover reactions were initiated for varying times at 13 °C, stopped by placing on ice, and immediately analyzed by native PAGE at 4 °C. The experiment was performed for both 3′- and 5′-labeled S1 to investigate and ultimately exclude slow product release. While a steady-state level of ES complex was observed, no EP complex could be observed (3′ or 5′ product). Multiple-turnover cleav-

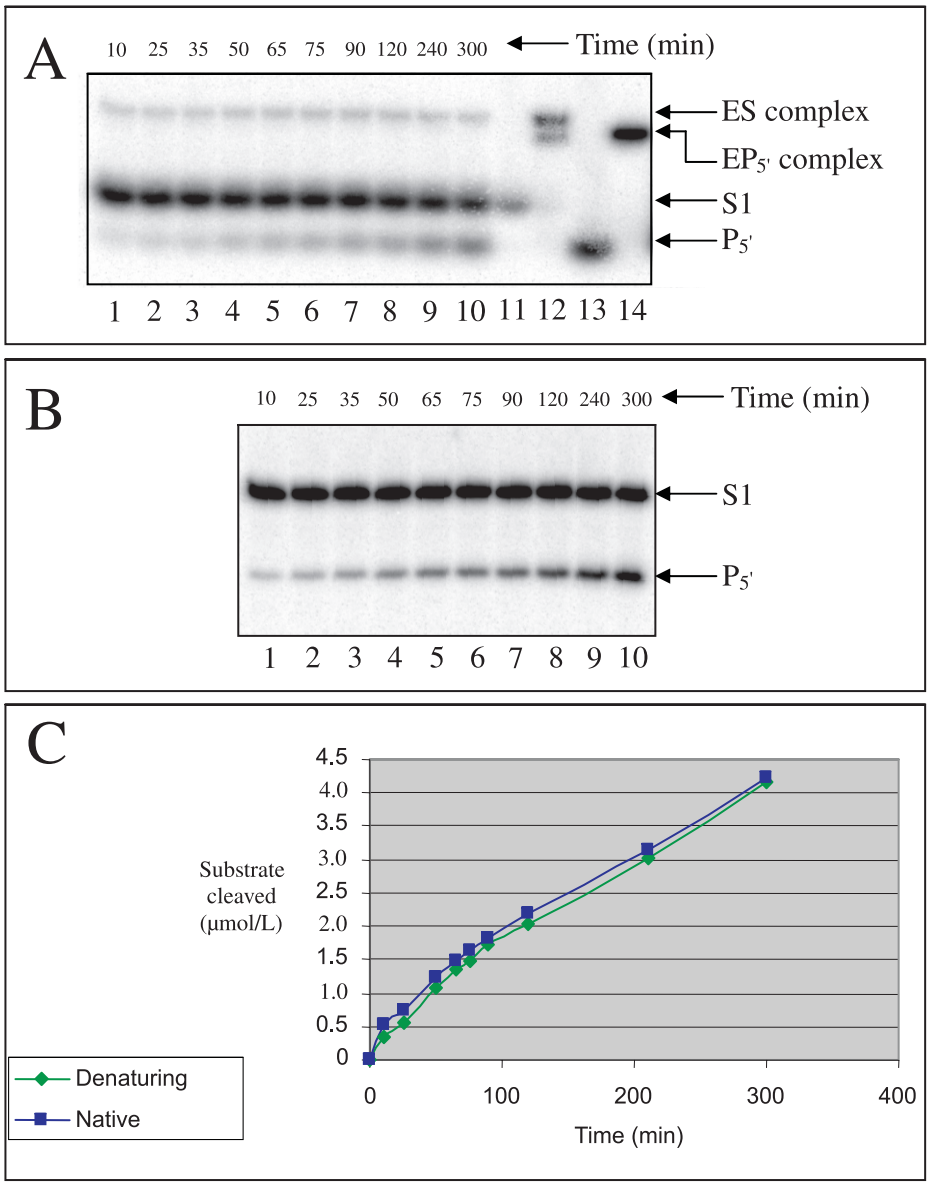
Figure 7. Multiple-turnover cleavage of substrate S1 by 9_{25}-11t at 13 °C in CB200. Cleavage reactions were peformed with varying concentrations of catalyst, 15 µmol/L unlabeled S1, and <1 nmol/L 5′-labeled S1 in CB200 at 13 °C. Cleavage was allowed to proceed until a maximum of 20% of the substrate was cleaved. (A) 1000 nmol/L Catalyst. (B) 500 nmol/L Catalyst. (C) 200 nmol/L Catalyst. Black traces are the result of fitting data to eq. [8]; red traces are predicted by eq. [17] for the model shown in Scheme 2B (using $k_{cat\ fast}$ = 0.2 min^{-1}, $k_{cat\ slow}$ = 0.0036 min^{-1}, $k_{-1\ fast}$ = 0.014 min^{-1}, $k_{-1\ slow}$ = 0.0023 min^{-1}, fraction$_{fast}$ = 0.35, fraction$_{slow}$ = 0.65, and $[ES_{fast}]_o = 0.35 \times [E_t]$); and blue traces are predicted by eq. [17] for the model shown in Scheme 2C (using $k_{cat\ fast}$ = 0.2 min^{-1}, $k_{cat\ slow}$ = 0, k_i = 0.37 min^{-1}, k_{-i} = 0.0036 min^{-1}, and $[ES_{fast}]_o = [E_t]$). (D) Determination of the first-order steady-state rate constant, $k_{cat\ steady\ state\ MTR}$, by linear-regression analysis of $k_{obs\ MTR}$ vs. 9_{25}-11t concentration (according to eq. [7]; $k_{cat\ steady\ state\ MTR}$ is 0.0077 ± 0.0007 min^{-1} and the intercept is 0.000 ± 0.0003 µmol/L min^{-1}; R^2 is 0.975). (E) Compiled multiple-turnover data at all catalyst concentrations clearly displaying the burst nature of the 9_{25}-11t system. (●) 1000 nmol/L; (□) 500, 200, and 100 nmol/L; (○) 50 nmol/L 9_{25}-11t.



age of 5′-labeled S1, as observed by native PAGE, is shown in Fig. 8A. Aliquots from the same cleavage reaction were also analyzed by denaturing PAGE, shown in Fig. 8B. Plots of the appearance of product over time, as observed by native and denaturing PAGE, both showed a burst phase and overlap closely (see Fig. 8C), indicating that no product is retained in an $EP_{5'}$ complex. The same result was obtained with the 3′-labeled substrate (see Supplementary data, Fig. S5).[3]

To verify that this native PAGE multiple-turnover technique effectively detects slow product release at a rate comparable to the steady-state rate observed for 9_{25}-11t, this technique was applied to the hammerhead ribozyme (variant HH16), which indeed displayed burst-phase kinetics attributed to slow product release under multiple-turnover conditions (10, 11). Analysis of the HH16 multiple-turnover reaction by denaturing PAGE clearly demonstrated burst-

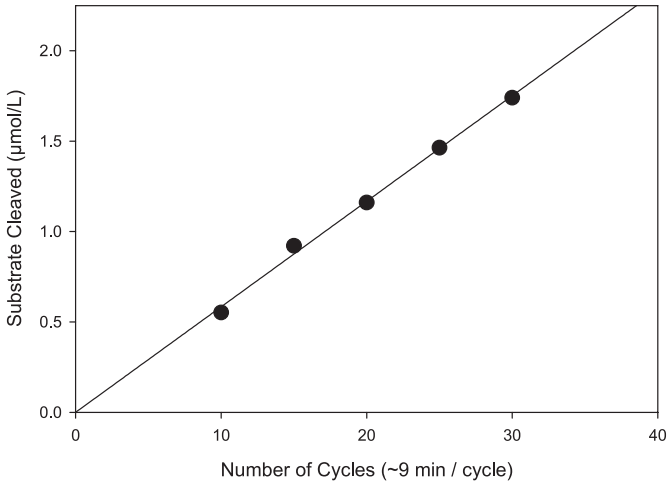
Figure 8. Native PAGE analysis of multiple-turnover cleavage of substrate S1 by 9_{25}-11t at 13 °C in CB200. (A) Lanes 1–10: time course for multiple-turnover reaction (1 µmol/L catalyst, 15 µmol/L S1, in CB200 at 13 °C) as observed by native PAGE at 4 °C. Control lanes reveal electrophoretic mobilities of: uncleaved S1 (lane 11), ES1 complex (lane 12) (some $EP_{5'}$ complex is also visible), $P_{5'}$ (lane 13), $EP_{5'}$ complex (lane 14). The reaction lanes show a small, steady-state amount of ES1, and no observable $EP_{5'}$. (B) The same time course (lanes 1–10) for the same reaction as in (A) run on a denaturing PAGE gel. (C) Plots of substrate cleaved vs. time for both the native and denaturing gels.[8]

phase kinetics, whereas analysis by native PAGE showed a completely linear appearance of free product over time ($k_{\text{steady state}} \approx 0.005$ min^{-1}) because of the retention of products in an $EP_{5'}$ complex (see Supplementary data, Fig. S6).[3]



Temperature cycling enhances the rate of multiple turnover and demonstrates catalyst stability

Thermal cycling of the cleavage reaction was used to overcome the multiple-turnover limitations, associated with burst-phase kinetics, by taking advantage of both the optimum temperature for the single-turnover cleavage at 13 °C and the optimum temperature previously identified for steady-state multiple-turnover at 24 °C (13). By cycling the temperature (15 s at 13 °C, 7 min at 24 °C, and 15 s at 95 °C), we obtained an apparent first-order rate constant $k_{\text{obs thermocycle MTR}}$, of 0.064 ± 0.002 min^{-1} (Fig. 9). Notably, this rate constant is a composite that comprises all reaction steps during the temperature cycling. Although this value is only 30% of the fastest initial rate observed for 9_{25}-11t, it represents a 20-fold improvement over the steady-state multiple-turnover rate at 13 °C, and a modest improvement over the previously reported steady-state rate at 24 °C (13).

[8] Production of the unbound product, as observed in the native gel, matches the production observed by denaturing gel, indicating that the burst phase is not due to slow release of the 5′ product.

Figure 9. The effect of temperature cycling on the multiple-turnover rate of S1 substrate cleavage by 9_{25}-11t at 13 °C in CB200.[9]

The overall rate is increased, presumably by restoring the faster burst-phase rate with each thermal cycle. Qualitatively, this experiment also demonstrates that the synthetic modifications are thermally stable over a wide temperature range, underscoring the resilience of the catalyst and its chemical modifications.

Discussion

On the choice of conditions for characterization

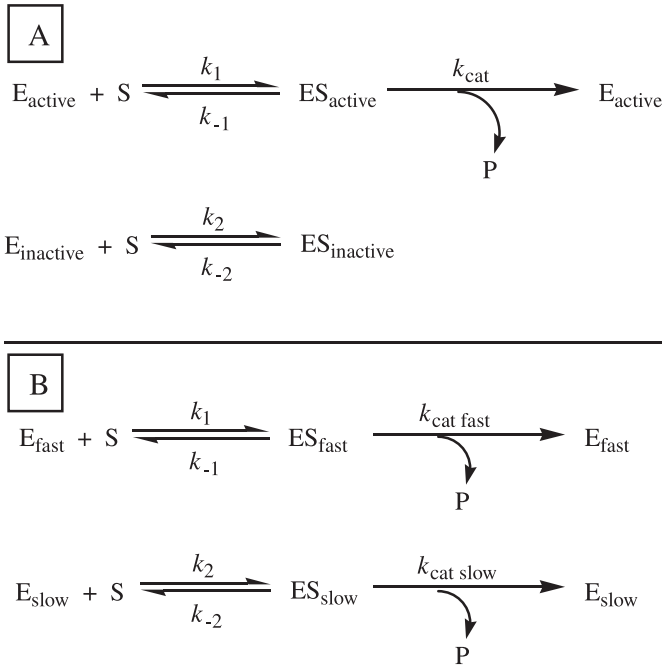
Following the discovery of any catalyst, one is at liberty to choose meaningful conditions for characterization. As 9_{25}-11 is the first DNAzyme to present two synthetic functionalities that are characteristic of protein enzymes, we contend that it is important to report on conditions where k_{cat} values are increased substantially, even if those conditions deviate from physiological relevance. Following our initial report of self-cleavage at 37 °C (40), we have now found that 9_{25}-11c exhibits a substantially increased rate constant for self-cleavage, $k_{self\text{-}cleave}$ (~0.3 min^{-1}) at 13 °C. This value falls within an order of magnitude of a hypothetical upper limit for selecting DNAzymes using a biotin–avidin self-cleavage system (40), and is to date, the highest value reported for M^{2+}-independent and co-factor independent self-cleavage at pH 7.5 and physiological ionic strength seen in any nucleic acid catalyst (RNA or DNA).

We then questioned whether a value similar to $k_{self\text{-}cleave}$ could be observed with 9_{25}-11t at 13 °C under both single- and multiple-turnover conditions. It was important to examine this because the re-engineering of a self-cleaving species for catalytic turnover often leads to a significant reduction in the value of the observed cleavage rate constant. Within a somewhat complicated biphasic regime at 13 °C, we identified a cleavage rate constant, $k_{cat\ fast\ STR}$, in the engineered synthetic species 9_{25}-11t, which compares quite favorably with 9_{25}-11c, the enzymatically prepared self-cleaving progenitor. Identifying maximal rates in both cis- and trans-cleaving species examines the limitations of nucleic acid catalysts and suggests the potential advantages imparted by the inclusion of modified nucleotides in selection.

Summary of experimental findings

In general, biphasic kinetics under single-turnover conditions are common to ribozymes or DNAzymes; however, the reasons for that may be quite diverse. In developing a kinetic model, we first excluded catalyst missynthesis, aggregation, and ligation as origins of the biphasic kinetics. Thus, the most likely explanation was the presence of two or more DNAzyme folds. The characterization of biphasic single-turnover kinetics at 13 °C for 9_{25}-11t reveals that a minor fraction of the population of 9_{25}-11t displays an increased cleavage rate constant similar in value to that observed for 9_{25}-11c at 13 °C. Furthermore, we find that under multiple-turnover conditions at 13 °C, the elevated cleavage rate constant is expressed in a pre-steady-state burst phase.

With regard to developing a kinetic model for the cleavage of S1 by 9_{25}-11t at 13 °C, one of the most salient experimental observations is the persistence of biphasic kinetics in the pulse–chase single-turnover cleavage assay. This observation indicates that two conformations of the ES complex are formed, and that both can lead to substrate cleavage. It is this observation that clearly differentiates the kinetic model for 9_{25}-11t from that for the hairpin constructs previously described by Esteban et al. (48) (Scheme 1A) where pulse–chase single-turnover cleavage experiments exhibited monophasic behavior.



The fully elaborated kinetic model for cleavage of S1 by 9_{25}-11t at 13 °C must also explain the observation of burst-phase kinetics under multiple-turnover conditions. We first examined the most common ascription of burst-phase kinetics, namely, slow product release, which a priori would have been consistent with the reduction in temperature (25) that allowed for an apparent increase in $k_{cat\ STR}$. Pulse–chase native PAGE assays demonstrated that product-dissociation rates are too fast to be measured by this method. In addition, we added back one or both products at 50 µmol/L prior to the start of multiple-turnover assays and found no effect on the burst phase. Most conclusively, no catalyst–product complex could be observed by native PAGE analysis of multiple-turnover reactions using 5′- and 3′-^{32}P labeled substrates. Based on these results, slow product release was excluded as the source of the burst phase at 13 °C for 9_{25}-11t.

Irreversible chemical inactivation of the catalyst was also considered as an explanation for burst-phase kinetics. However, temperature cycling with excess S1 gave a higher turnover rate than could be achieved at any single temperature. This experiment suggests that the collapse of the initial burst-phase rate to the steady-state rate is not due to the permanent inactivation of the catalyst. Rather, it demonstrates that the faster initial rate can be restored, which suggests a

[9] 100 nmol/L Catalyst, 15 µmol/L unlabeled S1, and <1 nmol/L 5′-labeled S1 was incubated in buffer CB200 at 13 °C. The reaction was placed into a PCR temperature cycler programmed as follows: 13 °C for 15 s, 22 °C for 7 min, and 95 °C for 15 s. With temperature-ramping time included, the time for one cycle was ~9 min. Aliquots were removed for analysis after every five cycles. Data were fit to a linear equation: $k_{obs\ thermocycle\ MTR}$ is 0.58 ± 0.02 $cycle^{-1}$ or 0.064 ± 0.002 min^{-1} for the 9 min cycle (R^2 is 0.996). The linearity of the graph indicates that the catalyst is not deactivated upon heating. A control reaction done with only labeled substrate in CB200 showed a negligible amount of cleavage during the temperature program.

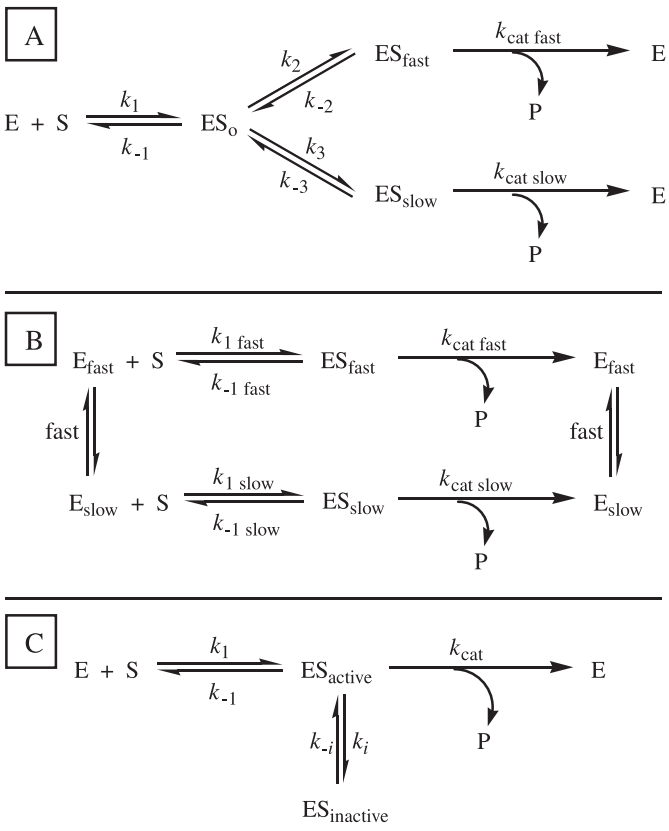
Scheme 1.



conformational partition as a source of the burst phase in the absence of slow product release. An alternative explanation for the burst phase must therefore be considered based on conformational partitioning (see later). At this point, the model shown in Scheme 1B can be excluded. Although it can explain biphasic pulse–chase kinetics, it does not predict burst-phase multiple-turnover kinetics in the absence of slow product release for the following reason: E_{fast} and E_{slow} (as well as ES_{fast} and ES_{slow}) cannot interconvert, so the ratio of ES_{fast} to ES_{slow} remains constant. The overall multiple-turnover rate is simply the sum of two independent linear rates.

Evaluation of kinetic models that are qualitatively consistent with the data

Three similar kinetic models that are qualitatively consistent with the data are shown in Scheme 2. Each can explain biphasic single-turnover and pulse–chase kinetics ($k_{fast} \neq k_{slow}$). Each model can also explain burst-phase kinetics under multiple-turnover conditions: because both the slow and inactive ES complexes cleave and (or) dissociate the substrate much more slowly than the more active ES complex, the concentration of the former increases (and the latter decreases) until a steady state is achieved.

The first model (scheme 2A) involves partitioning of unstructured free catalyst by competing association/folding pathways. In this model, the ratio of the association/folding rate constants (k_1) for each phase should reflect the observed partition ratio in single-turnover experiments. Using the constants $K_{M\ STR}$, k_{-1}, and $k_{cat\ STR}$, determined for the fast and slow phase experimentally, the apparent association constants, $k_{1\ fast}$ and $k_{1\ slow}$, are calculated to be 1.4×10^6 $(mol/L)^{-1}$ min^{-1} and 2.0×10^5 $(mol/L)^{-1}$ min^{-1}, respectively.

Scheme 2.

In contrast, the observed partition ratio in single-turnover experiments favors cleavage through the slow phase by a wide margin. Clearly, this model can be excluded because it is not quantitatively consistent with the data obtained from single-turnover experiments.

A closely related model (Scheme 2B) appears to be consistent with all of the kinetic data. This model presupposes the existence of preformed conformations of the fast- and slow-cleaving catalyst that equilibrate rapidly relative to the rate of substrate association. The consequences of this model parallel those of the previous model (Scheme 2A) with the exception that the observed single-turnover partition ratio can now be rationalized as the ratio of pseudo-first-order association rate constants in a Curtin–Hammett analysis (eq. [9]).

$$[9] \qquad \frac{[E_{fast}]k_{on\,fast}}{[E_{slow}]k_{on\,slow}} = \frac{[P_{fast}]_\infty}{[P_{slow}]_\infty}$$

According to this model, a small, fast-cleaving fraction (e.g., 5%) of the total free catalyst can bind the substrate at a significantly faster rate than the much more plentiful, slow-cleaving conformation to skew the partition observed under single-turnover conditions more in favor of the fast phase.[10]

[10]It should be noted that eq. [9] applies under single-turnover conditions whether or not the unbound catalyst conformations are equilibrating because the binding of trace substrate does not appreciably alter the unbound-catalyst populations. Under multiple-turnover conditions, eq. [9] only applies when the unbound-catalyst conformations are rapidly equilibrating, that is, where substrate association is described by a Curtin–Hammett-type regime.

Scheme 3.

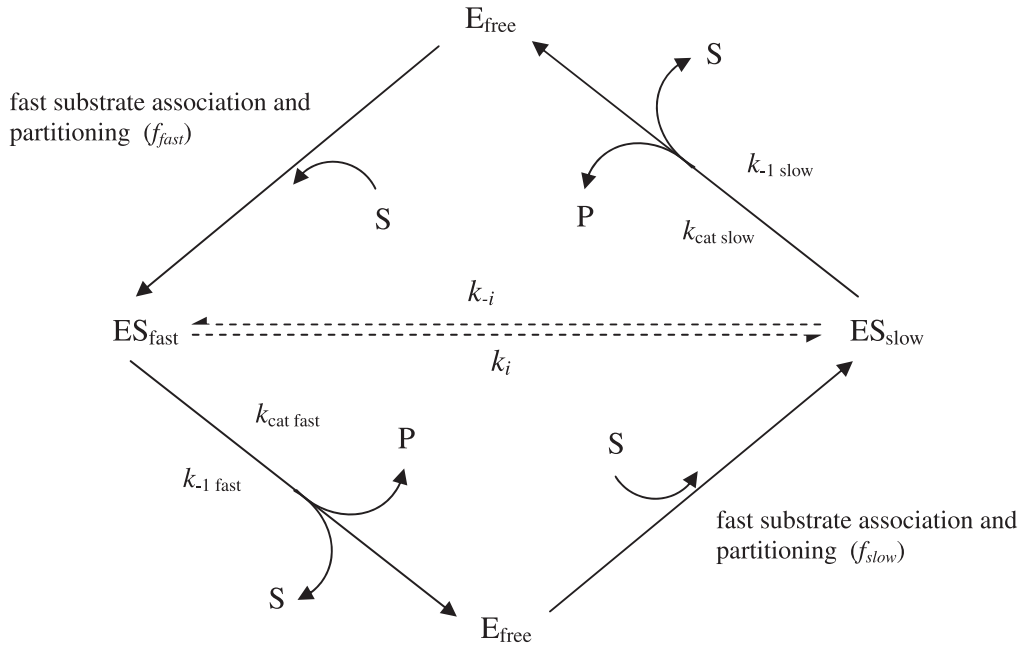

Table 2. Multiple-turnover rate constants for the cleavage reaction with noted concentrations of 9_{25}-11t and 15 μmol/L S1 in CB200 at 13 °C.

Data source	Burst amplitude (C) (μmol/L)	Burst decay (k_{burst}) (min^{-1})	Steady state ($k_{obs\ MTR}$) (μmol/L min^{-1})
1000 nmol/L 9_{25}-11t			
Experimental data	0.7±0.2	0.03±0.01	0.0074±0.0002
Scheme 2B simulation	0.47	0.14	0.0065
Scheme 2C simulation	0.53	0.37	0.0012
500 nmol/L 9_{25}-11t			
Experimental data	0.20±0.09	0.05±0.05	0.0048±0.0002
Scheme 2B simulation	0.23	0.14	0.0032
Scheme 2C simulation	0.27	0.37	0.00062
200 nmol/L 9_{25}-11t			
Experimental data	0.09±0.01	0.10±0.05	0.0015±0.0001
Scheme 2B simulation	0.093	0.14	0.0013
Scheme 2C simulation	0.11	0.37	0.00025

Note: Rate constants obtained by fitting multiple-turnover data (see Fig. 7) to eq. [8] are compared with rate constants predicted by simulation of kinetic models shown in Schemes 2B and 2C (see text for full description of simulations).

To test the validity of this model quantitatively, eqs. [10A–10C] were derived based on Scheme 3 to describe the time-dependent appearance of product (see Supplementary data, pp. S8–S9).[3] Scheme 3 describes the pathways for the interconversion of ES_{fast} and ES_{slow} via E_{Free}; the dotted lines connote an assumption that the substrate-bound forms do not readily interconvert.

$$[10A]\quad P(t) = (k_{cat\ slow STR}) - k_{cat\ fast STR}) \times \left(\frac{[k_{-i}[E_t] - (k_i + k_i)[ES_{fast}]_o]}{(k_{-i} + k_i)^2}\right)(1 - e^{-(k_{-1} + k_i)t}) + \left[k_{cat\ slow STR} + (k_{cat\ fast STR} - k_{cat\ slow STR}\left(\frac{k_{-i}}{k_{-i} + k_i}\right)\right][E_t]t$$

where

$$[10B]\quad k_i = (k_{cat\ fast\ STR} + k_{-1\ fast})f_{slow}$$

$$[10C]\quad k_{-i} = (k_{cat\ slow\ STR} + k_{-1\ slow})f_{fast}$$

Given the number of variables in eq. [10A], we were unable to obtain least-squares fits for multiple-turnover data. Instead, multiple-turnover simulations were performed by substituting rate constants determined from single-turnover and pulse–chase experiments into eqs. [10A–10C] (specifically $k_{cat\ fast\ STR}$ = 0.2 min^{-1}, $k_{cat\ slow\ STR}$ = 0.0036 min^{-1}, $k_{-1\ fast}$ = 0.014 min^{-1}, $k_{-1\ slow}$ = 0.0023 min^{-1}, $fraction_{fast}$ = 0.35, $fraction_{slow}$ = 0.65, $[ES_{fast}]_o = 0.35 \times [E_t]$). The simulations for this model closely resemble the experimental multiple-turnover data (see red-colored traces in Fig. 7).

Data from multiple-turnover experiments were also fit to eq. [8], allowing comparison of the experimental and simu-

© 2007 NRC Canada

lated values of the burst amplitude (C), the burst-decay constant (k_{burst}), and the steady-state rate constant ($k_{cat\ steady\ state\ MTR}$) (see Table 2). This simulation closely reproduced the experimental steady-state rate constant. However, with regards to the burst-phase constants, the agreement between simulation and experiment was within only an order of magnitude. Equation [10A] predicts that k_{burst} should be invariant with catalyst concentration. When the data were fit to eq. [8], k_{burst} was not well-determined, i.e., the values varied from 0.03 to 0.1 min^{-1} with no regular dependence on catalyst concentration (eq. [10A] predicts a value of 0.14 min^{-1} for all catalyst concentrations). The low level of substrate cleaved during the burst phase (especially at low catalyst concentrations) made quantitation by phosphorimaged autoradiography difficult, casting doubt on the accuracy of the burst-decay and amplitude constants obtained from fitting data to eq. [8].

Another closely related kinetic model, shown in Scheme 2C, involves partitioning between an active and an inactive ES complex following the initial formation of the active complex upon substrate binding. In this case, the normalized fraction of the substrate cleaved in the slow phase in single-turnover experiments is given by the following equation that is based on the two competing pathways for the decomposition of ES_{active}

$$[11] \quad f_{slow} = \frac{k_i}{k_i + k_{cat\ fast\ STR}}$$

where k_i is the rate constant as defined in Scheme 2C for the conversion of the ES_{active} into the $ES_{inactive}$. Using eq. [11] and the experimentally determined $k_{cat\ fast\ STR}$ and f_{slow} values, one can calculate the value of k_i to be 0.37 min^{-1}. In this model, the slow-cleaving phase would result from the slow isomerization of the inactive ES complex to the active one; therefore, k_{-i} is assumed to be equal to the measured value of $k_{cat\ slow\ STR}$ (0.0036 min^{-1}).

A multiple-turnover simulation was performed for this model as well (see Table 2 and blue traces in Fig. 7). In this case, eq. [10A] still applies where $k_{cat\ fast\ STR}$ = 0.2 min^{-1}, $k_{cat\ slow\ STR}$ = 0, and $[ES_{fast}]_o = [E_t]$, and eqs. [10B] and [10C] are replaced with the values k_i = 0.37 min^{-1} and k_{-i} = 0.0036 min^{-1}. As shown in Fig. 7 and Table 2, the steady-state rate is significantly underestimated by this model; the burst (exponential)-decay constant (k_{burst} is approximately equal to 0.37 min^{-1}, i.e., the sum of $k_{-i} + k_i$) is overestimated, more so by this model (Scheme 2C) than by the previous model (Scheme 2B). Thus, the model that seems to be most congruent with the data is that shown in Scheme 2B.

Concluding remarks: relevance to (*i*) other nucleic acid catalysts and (*ii*) kinetics of protein catalysts that exhibit burst-phase absent slow product release

(*i*) Whereas irregular kinetics have been characterized for group I intron, hairpin, and HDV ribozymes (48, 52, 54), these kinetics have not been thoroughly examined for DNAzymes. This study of the irregular kinetics of 9_{25}-11t may prove pertinent to DNAzymes and biocatalysts in general, and the discussion of possible kinetic models may prove useful to those confronted with biphasic kinetics. For instance, in contrast to initial reports on the 10–23 DNAzyme that described a catalytically perfect activity limited by chemistry and not product release (8), a recent report has now described biphasic kinetics under single-turnover conditions at 10 mmol/L Mg^{2+} for a 10–23 sequence that targeted an 18-nucleotide subsequence of the mRNA of the vanilloid receptor subtype (59). Although no explanation for this observation was provided, several factors may contribute to this observation, including target mRNA accessibility and folding. Biphasic kinetics and substrate-dependent k_{cat} values would limit the generality of reconfiguring a selected catalytic motif to cleave any given target sequence.

In this report, we have investigated some of the properties and limitations of this catalyst at lower temperature. Of note is a significantly higher rate constant for M^{2+}-independent RNA hydrolysis at 13 °C than the value that was initially reported for either of 9_{25}-11t or 9_{25}-11c at higher temperature (13, 40, 60). Although the enhanced cleavage rate displayed by 9_{25}-11c is expressed by a minor fraction of 9_{25}-11t, this finding extends the apparent rate enhancement for this modified DNAzyme by another order of magnitude over its unmodified counterparts selected under similar conditions (26, 27). The identification of a faster rate in case of 9_{25}-11c and 9_{25}-11t would also suggest that higher rate constants may be realized at physiological temperature in future selections, particularly if the low-temperature optimum is due to particular aspects of the initial selection.[11] This work should help focus efforts at using new chemistries and more stringent reselection conditions in the hope of overcoming the limitations of biphasic kinetics and a low-temperature optimum, thereby more fully exploiting the advantage provided by modified nucleotides.

(*ii*) With regards to protein catalysts, slow product release, accompanied by a conformational change is often found to explain burst-phase kinetics. This is the case for the ATP Sulfurylase-GTPase (61). In the context of an exonuclease-deficient mutant of T7 DNA polymerase, a burst phase was explained not entirely by product release but by conformational partitioning on the template DNA (62). Finally, two acyl–enzyme intermediates with different rate constants for product hydrolysis have been observed for a mutant β-lactamase to explain a burst phase (63). The phenomenon of a two different substrate-bound enzymes that interconvert slowly yet appreciably over the time period during which multiple turnover is measured has been termed "enzyme hysteresis" and has been reviewed in 1970 (45). In the model we present here to explain the observed burst for 9_{25}-11t, we do not need to invoke a slow partition between substrate-bound forms, but rather a fast interconversion between two conformations of the free catalyst that are locked into place by substrate binding. In that regard, for the case where two distinctly active

[11]This is a reasonable recollection of the ambient temperature in a drafty lab, in Paris during February when the first four rounds of selection were conducted: Feb 9, 15, 18, and 24 of the year 2000. By the fourth round, detectable activity appeared with little increase observed in generations 5–9.

© 2007 NRC Canada

and interconvertable conformations of the free catalyst can provide for burst-phase kinetics, to the best of our knowledge, there is no precedent for a formal treatment thereof. To that end, the equations developed herein not only fit the data accumulated for 9_{25}-11t, but may apply to any catalyst that exhibits biphasic kinetics under single-turnover conditions and burst-phase kinetics under multiple-turnover in the absence of slow product release.

ABOUT THE AUTHOR

Kelvin K. Ogilvie, C.M., Ph.D., D.Sc., H.Col., F.C.I.C., was (1993-2003) president and vice-chancellor of Acadia University in Wolfville, Nova Scotia where he led the development and implementation of the acclaimed Acadia Advantage Program, which was recognized by, and incorporated into, the Permanent Collection of the Smithsonian Institute in Washington, DC in 1999. He is a leading expert in biotechnology, bioorganic chemistry, and genetic engineering. His scientific accomplishments include the development of the "Gene Machine", an automated process for the manufacture of DNA. He is the inventor of Ganciclovir, a drug used worldwide to fight infections that occur when one's immune system is weakened. Both of these achievements were recognized in 2000 as "Milestones of Canadian Chemistry in the 20th Century" by the Canadian Society of Chemistry. He also developed a general method for the chemical synthesis of large RNA molecules, demonstrated by the first total chemical synthesis of a functional Transfer RNA (tRNA) molecule, which is still the basis for RNA synthesis worldwide. He has also written and spoken extensively on the challenges facing Canada as a nation, the role of the "knowledge" economy, postsecondary education, and entrepreneurship.

Dr. Ogilvie became a faculty member in the Department of Chemistry at the University of Manitoba in 1968. He moved to McGill University in 1974 and in 1984 was appointed founding Director, Office of Biotechnology, and Canadian Pacific Professor of Biotechnology at McGill. In 1987, he moved to Acadia University to serve as Vice-President (Academic) and Professor of Chemistry.

Dr. Ogilvie has served on numerous national and international organizations, including the Atomic Energy Control Board, the National Biotechnology Advisory Committee, the National Advisory Board for Science and Technology, and the Canadian eBusiness Initiative. He has served as scientific advisor to numerous technology companies and as a consultant and expert witness for international pharmaceutical and biotechnology companies. He is a widely sought-after speaker, has a number of patents, and his 150 scientific publications have received more than 5000 citations. He recently completed a three-year term as the initial Chair of the Premier's Advisory Council on Innovation (Nova Scotia), is currently AIMS Senior Fellow for Postsecondary Education, a member of the Board of Genome Canada, the Board of Governors of Quest University, and the Scientific Advisory Board of NRC's Institute of Marine Bioscience.

Dr. Ogilvie was named a Steacie Fellow in 1992, was admitted to the Order of Canada in 1991, and received the Manning Principal Award as Canada's outstanding contributor to innovation in 1992. He was identified as "a Canadian Who Made a Difference" in the 1988 Maclean's Honour Roll, has received three honourary degrees, the Queen Elizabeth Golden Jubilee Medal, the Commemorative Medal of the 125th Anniversary of the Confederation of Canada, and appeared as a mystery guest on "Front Page Challenge" (1988). He has also received the Buck-

À PROPOS DE L'AUTEUR

Kelvin K. Ogilvie, C.M., Ph.D., D.Sc., H.Col., MICC a été recteur et vice-chancelier de l'Université Acadia, à Wolfville (Nouvelle-Écosse), de 1993 à 2003, où il a dirigé l'élaboration et la mise en œuvre du programme Acadia Advantage - programme reconnu et prisé qui a été intégré à la Collection permanente du Smithsonian Institute de Washington D.C., en 1999. M. Ogilvie est une figure de proue de la biotechnologie, de la chimie bio-organique et du génie génétique. Parmi ses réalisations scientifiques figure la mise au point de la « machine à gènes », processus automatisé de fabrication d'ADN. Il a également inventé le ganciclovir, médicament utilisé d'un bout à l'autre de la planète pour combattre les infections chez les humains immunodéficients. En 2000, la Société canadienne de chimie a reconnu ces deux réalisations comme des « jalons de la chimie canadienne au XXe siècle ». M. Ogilvie a également mis au point une méthode générale de synthèse chimique de grandes molécules d'ARN, démontrée par la première synthèse chimique complète d'une molécule fonctionnelle d'ARN de transfert (ARNt), qui constitue encore aujourd'hui le fondement de la synthèse de l'ARN partout dans le monde. Il a également prononcé de nombreux discours et rédigé bon nombre d'articles sur les défis auxquels le Canada fait face en tant que pays, le rôle de l'économie du savoir, les études postsecondaires et l'entrepreneuriat.

M. Ogilvie est devenu professeur au Département de chimie de l'Université du Manitoba en 1968. Il s'est ensuite joint à l'Université McGill, en 1974. En 1984, il a été nommé directeur du Bureau de la biotechnologie et professeur titulaire de la chaire de biotechnologie du Canadien Pacifique à l'Université McGill. En 1987, il entre en fonction à l'Université Acadia à titre de vice-recteur (Affaires universitaires) et professeur de chimie.

M. Ogilvie a mis son expertise au service d'organismes nationaux et internationaux, y compris la Commission canadienne de sûreté nucléaire, le Comité consultatif national de la biotechnologie, le Conseil consultatif des sciences et de la technologie, et l'Initiative canadienne pour le commerce électronique. Il a également servi de conseiller scientifique auprès d'un grand nombre d'entreprises technologiques ainsi que d'expert-conseil et de témoin expert pour des sociétés pharmaceutiques et biotechnologiques internationales. M. Ogilvie est un conférencier très recherché. De plus, il est titulaire de nombreux brevets et auteur de 150 publications scientifiques qui ont fait l'objet de plus de 5 000 citations. Il a récemment terminé un mandat de trois ans à titre de premier président du Advisory Council on Innovation, qui exerce son rôle auprès du premier ministre de Nouvelle-Écosse. Il est actuellement agrégé supérieur de recherches en matière d'enseignement postsecondaire pour AIMS et membre du conseil de Génome Canada, du Conseil des gouverneurs de l'Université Quest et du Conseil scientifique consultatif de l'Institut des biosciences marines du CNRC.

M. Ogilvie a été nommé agrégé titulaire de la bourse Steacie en 1992, a été décoré de l'Ordre du Canada en 1991 et a reçu le prix Manning Principal en 1992 pour sa remarquable contribution à l'innovation au Canada. Il a été cité au tableau d'honneur du magazine Maclean's en 1988 comme Canadien « qui a su changer les choses ». Il est titulaire de

Whitney Medal of the ACS (1983). Dr. Ogilvie was named an Honourary Colonel in the Canadian Air Force and was an inaugural inductee into the Nova Scotia Discovery Centre Science and Technology Hall of Fame in 2002.

trois grades honorifiques, il a reçu la médaille du jubilé d'or de la Reine Élisabeth II et la médaille commémorative du 125e anniversaire de la Confédération du Canada, et il a même pris part à l'émission de télévision Front Page Challenge en tant qu'invité mystère (1988). En 1983, il a reçu la médaille Buck-Whitney de l'ACS. Enfin, M. Ogilvie a été nommé colonel honoraire à l'Aviation canadienne et est devenu un des premiers membres du Temple de la renommée pour la science et la technologie du Discovery Centre, en Nouvelle-Écosse, en 2002.

Étude DFT des réactions de cycloaddition de type Diels–Alder sur le 4-aza-6-nitrobenzofuroxane

Sameh Ayadi et Manef Abderrabba

Résumé : Dans ce travail, nous avons étudié théoriquement les réactions de Diels–Alder à demande inverse d'électrons entre le 4-aza-6-nitrobenzofuroxane **1** et les diénophiles de type **3a**–**3c**. Nous avons discuté de point de vue thermodynamique et orbitalaire la possibilité et la stéréosélectivité de ces réactions. Les états de transition de la réaction entre le 4-aza-6-nitrobenzofuroxane **1** et les diénophiles de type **3a**–**3c** ont été déterminés.

Mots-clés : Diels–Alder à demande inverse d'électrons (DADEI), méthode DFT, 4-aza-6-nitrobenzofuroxane.

Abstract: The purpose of this work is a theoretical study of Diels–Alder reactions between the 4-aza-6-nitrobenzofuroxan **1** with a series of dienophiles **3a**–**3c**. From a thermodynamic and orbital point of view, we discuss the reactivity and the stereoselectivty of these reactions. Activation barriers in the Diels–Alder reactions of compound **1** with a series of dienophiles **3a**–**3c** have been calculated and discussed.

Key words: inverse electron demand Diels–Alder (IEDDA), DFT method, 4-aza-6-nitrobenzofuroxane.

Introduction

Le 4-aza-6-nitrobenzofuroxane **1** est un électrophile puissant (1) analogue à celui de 4,6-dinitrobenzofuroxane DNBF **2** qui était considéré comme la référence en chimie hétérocyclique dans les processus d'addition ou de substitution nucléophile (1–3). Plusieurs travaux de recherche ont montré que le 4,6-dinitrobenzofuroxane est capable de réagir comme diénophile ou hétérodiénophile dans des réactions de cycloaddition de type Diels–Alder (1, 4–7).

Nous avons trouvé intéressant d'effectuer une étude théorique sur la possibilité et la stéréosélectivité des réactions de Diels–Alder à demande inverse d'électrons entre le 4-aza-6-nitrobenzofuroxane **1** et les diénophiles de type **3a**–**3c** tels que l'éthénol **3a**, le vinylamine **3b** et l'éther de méthyle **3c** (fig. 1).

Dans chaque cas, nous avons vérifié que ces réactions sont sous le contrôle des orbitales frontières, comme la plupart des réactions de Diels–Alder (6). Nous avons par la suite étudié de point de vue thermodynamique et cinétique la possiblité et la régiosélectivité des réactions de Diels–Alder entre le 4-aza-6-nitrobenzofuroxane **1** et les diénophiles de type **3a**–**3c**.

Les méthodes de calcul

Cette étude a été réalisée en utilisant le programme GAUSSIAN 98 (8). Les calculs ont été effectués au niveau DFT avec les bases standard 3-21G*, 6-31G* et 6-31G**. Nous avons utilisé la fonctionnelle B3-LYP dans laquelle l'énergie d'échange est calculée par la méthode de Becke à trois paramètres, et la corrélation est calculée par la méthode de Lee, Yang et Paar (9, 10). En effet il a été récemment établi que cette DFT était actuellement la plus performante pour ce type de système (11).

Résultats et discussion

Étude thermodynamique

Nous avons réalisé une étude thermodynamique sur la possibilité et la régiosélectivité de la réaction entre le 4-aza-6-nitrobenzofuroxane **1** et les diénophiles de type **3a**–**3c**, tels que l'éthénol **3a**, le vinylamine **3b** et l'éther de méthyle **3c** (fig. 2). En utilisant la méthode de calcul DFT/B3-LYP avec les bases standard 6-31G*, 6-31G** et 3-21G*, nous avons déterminé dans les conditions standard (298,15 °K et 1 atm; 1 atm = 100,325 kPa) les variations d'énergie réactionnelle ΔE_r, les variations d'enthalpie libre réactionnelle ΔG_r, les variations d'enthalpie réactionnelle ΔH_r et le ZPE qui correspond aux réactions (I) et (II) (tableau 1).

Comme le montre le tableau 1, les variations d'enthalpie libre réactionnelle ΔG_r sont toutes négatives, par conséquent les réactions sont possibles et favorisées thermodynamiquement. De plus, nous avons remarqué que les valeurs de la variation d'enthalpie libre réactionnelle ΔG_r qui correspond aux réactions (I) sont toujours supérieures en valeur absolue aux valeurs de la variation d'enthalpie libre réactionnelle qui correspond aux réactions (II). Ce qui nous a permis de dire

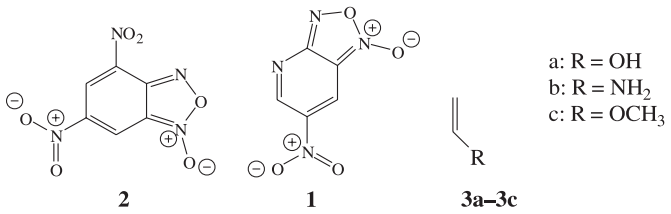

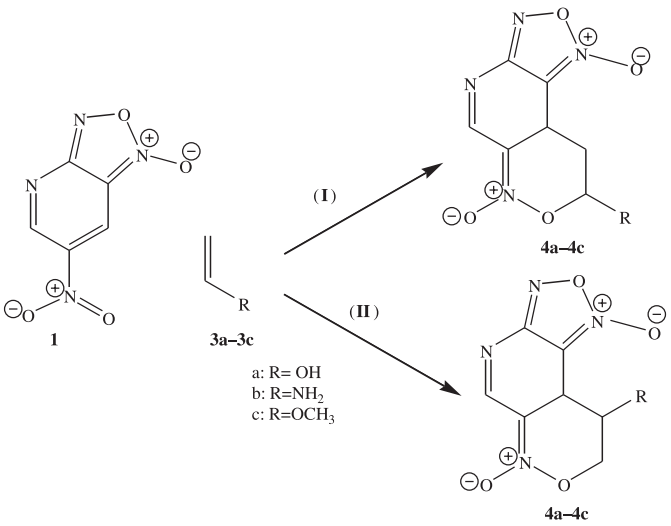

Fig. 2.

que les réactions (I) donnent toujours les produits majoritaires de la réaction.

Nous avons aussi remarqué que les valeurs de la variation de l'énergie ΔE_r qui correspond aux réactions (I) sont plus importantes que celles de la variation de l'énergie ΔE_r qui correspond aux réactions (II). Ce qui confirme de nouveau que les produits majoritaires de la réaction sont les régioisomères de type **4a**–**4c**.

Étude des orbitales frontières

En utilisant la méthode de calcul DFT/B3-LYP avec les bases standard 6-31G**, 6-31G* et 3-21G*, nous avons déterminé l'énergie de la LUMO et l'énergie de la HOMO de 4-aza-6-nitrobenzofuroxane **1** et l'énergie de la LUMO et la HOMO des diénophiles de type **3a**–**3c** (voir tableau 2).

Le diagramme orbitalaire des réactifs 4-aza-6-nitrobenzofuroxane **1** et l'éthénol **3a**, calculé au niveau DFT avec la fonctionnelle B3-LYP et la base standard 6–31G** est donné sur la figure 3.

Ce diagramme orbitalaire donne une bonne indication qualitative quant à la réactivité de notre système. L'interaction principale se produisant entre la LUMO de 4-aza-6-nitrobenzofuroxane **1** et la HOMO du diénophile (l'éthénol **3a**) démontre que notre système correspond bien à une réaction de Diels–Alder à demande inverse d'électrons (DADEI) (12–16). Dans le cas de l'interaction du 4-aza-6-nitrobenzofuroxane **1** avec le vinylamine **3b** et l'éther de méthyle **3c**, nous avons aussi trouvé une réaction de Diels–Alder à demande inverse d'électrons (DADEI), puisque l'interaction principale se produit entre la LUMO de l'hétérodiène de la molécule **1** et la HOMO de vinylamine **3b** et l'éther de méthyle **3c**. Comme le montre le tableau 2, la différence d'énergie HOMO–LUMO est plus petite dans le cas de la réaction du 4-aza-6-nitrobenzofuroxane **1** avec le vinylamine **3b** que dans le cas de la réaction de 4-aza-6-nitrobenzofuroxane **1** avec l'éthénol **3a** ou avec l'éther de méthyle **3c**; résultat attendu, car NH_2 est un meilleur donneur Π et un moins bon attracteur σ que OH, et la réaction devrait donc être plus facile.

L'examen des coefficients (2pz) des orbitales frontières au niveau DFT/B3-LYP de 4-aza-6-nitrobenzofuroxane **1** (fig. 4) montre que le coefficient de la LUMO de carbone C5 est toujours inférieur à celui du carbone C7, celui-ci paraît donc plus réactif. C'est-à-dire que l'addition d'une molécule de diénophile de type **3a**–**3c** sur le 4-aza-6-nitrobenzofuroxane **1** se fait en premier lieu sur le carbone C7.

Dans le but de déterminer la stéréoselectivité de la réaction entre le 4-aza-6-nitrobenzofuroxane **1** avec les diénophiles, tels que l'éthénol **3a**, le vinylamine **3b** et l'éther de méthyle **3c**, nous avons déterminé par la méthode DFT avec la fonctionnelle B3-LYP et les bases standards 6-31G**, 6-31G* et 3-21G* les coefficients (2pz) des orbitales frontières HOMO des diénophiles de type **3a**–**3c** et les coefficients (2pz) des LUMO du carbone C7 et de l'oxygène numéro 8 (O8) pour le 4-aza-6-nitrobenzofuroxane **1** (tableau 3).

L'examen des coefficients des orbitales frontières présentés sur la figure 5 montre que la réaction entre le 4-aza-6-

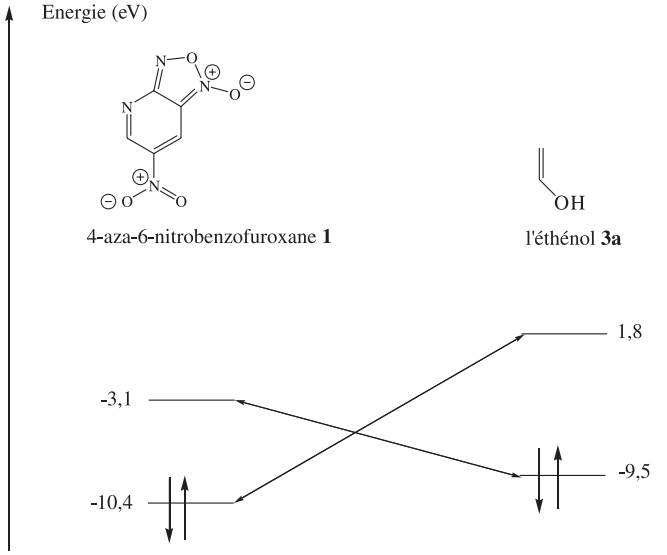

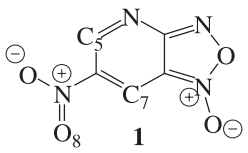

Fig. 4.

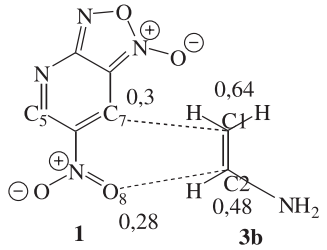
nitrobenzofuroxane **1** avec le vinylamine **3b** devrait être aussi plus stéréosélective que celle avec l'éthénol **3a**. Au niveau DFT/B3-LYP avec la base 3-21G*, les coefficients (2pz) de 4-aza-6-nitrobenzofuroxan deviennent respectivement 0,36 (C7) et 0,28 (O8), différence encore peu marquée. Au niveau DFT/B3-LYP avec la base 6-31G**, la différence est accentuée, favorisant la formation de la liaison (C7–C1) et la liaison (O8–C2) qui conduit à la formation du composé **4b**. Ce résultat est en accord avec le résultat trouvé par l'étude thermodynamique.

Calcul des états de transition

Dans le but d'étudier la régiosélectivité de la réaction entre le 4-aza-6-nitrobenzofuroxane **1** avec les diénophiles, tels que l'éthénol **3a**, le vinylamine **3b** et l'éther de méthyle **3c**, nous avons déterminé les états de transition pour la formation des composés de type **4a**–**4c** et **4′a**–**4′c** (fig. 2).

Les calculs théoriques montrent que la formation de régioisomère **4a** est favorisée par rapport au régioisomère **4′a**. En utilisant la méthode de calcul DFT/B3-LYP avec les bases standard 6-31G**, 6-31G* et 3-21G*, nous avons trouvé une grande énergie d'activation respectivement de 30,3; 36,4 et 32,5 kcal·mol^{-1} aux niveaux de calcul cités précédemment. Ces valeurs sont plus grandes que celles trouvées pour les états de transition conduisant à la formation des régioisomères **4a**; la formation du régioisomère **4′a** est improbable.



La comparaison des profils énergitiques des réactions conduisant respectivement aux régioisomères **4a** et **4′a** est donnée sur la figure 6.

Nous avons déterminé au niveau de calcul DFT/B3-LYP avec les bases standard 6-31G**, 6-31G* et 3-21G* les états de transition pour la formation des régioisomères **4b** et **4′b** ainsi que les états de transition pour la formation des régioisomères **4c** et **4′c** (tableau 4).

4′c (exo)		33,7	36,7

Dans le cas de la réaction du 4-aza-6-nitrobenzofuroxane **1** avec le vinylamine **3b**, l'état de transition apparaît plus proche des réactifs que pour l'énol **3a**. Comme le montre le tableau 4, l'énergie d'activation pour la formation de régioisomères **4′b** et **4′c** est plus importante que l'énergie d'activation pour la formation de régioisomères **4b** et **4c**. Ce qui explique de nouveau que la formation des régioismères **4b** et **4c** est favorisée par rapport à la formation des régioisomères **4′b** et **4′c**.

Fig. 7. Géométrie des états de transition de la formation des composés **4a** endo.

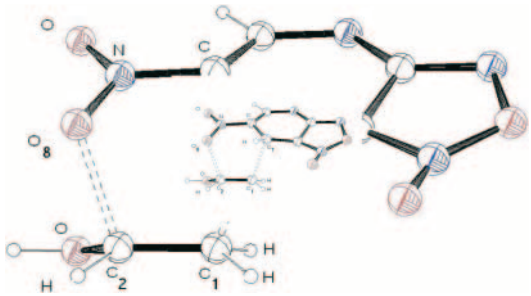

Tableau 5. Longueurs des liaisons en formation C–O et C–C dans l'état de transition pour la cycloaddition de la molécule **1** avec le diénophile **3a**–**3c** dans les approches endo (**4a)** et exo (**4a).**

	C–C	C–O	C–C	C–O
	(endo) **4a**		(exo) **4a**

DFT/6-31G*	2,03	2,32	2,18	2,31
DFT/3-21G*	2,02	2,41	2,17	2,51

Dans le but de déterminer la stéréospécificité de la réaction entre le 4-aza-6-nitrobenzofuroxane **1** avec les diénophiles **3a**–**3c**, nous avons déterminé les états de transition correspondant à l'addition concertée conduisant au composé **4** dans les deux approches endo et exo. Les énergies correspondantes sont reportées dans le tableau 4.

Les résultats montrent que la forme endo est favorisée par rapport à la forme exo. La géométrie des états de transition de **4a** endo est présentée sur la figure 7.

Si on compare les longueurs des liaisons en formation, on constate que la liaison C–C est plus courte que la liaison C–O, l'état de transition est donc caractéristique d'un mécanisme concerté asynchrone (17–20), d'autant plus que la valeur finale de la longueur C–O est plus petite que celle de la longueur C–C. Ces distances sont assez proches de celles trouvées pour les Diels sans hétéroatomes (de 2,2 à 2,3 Å; 1 Å = 1 nm) (tableau 5) (11).

Conclusion

Nous avons réalisé une étude théorique sur la possibilité et la stéréosélectivité des réactions de Diels–Alder à demande inverse d'électrons entre le 4-aza-6-nitrobrnzo-

© 2007 CNRC Canada

furoxane et les diénophiles **3a**–**3c**, tels que l'éthénol **3a**, le vinylamine **3b** et l'éther de méthyle **3c**. Les résultats de calculs théoriques par la méthode DFT avec la fonctionnelle B3-LYP et les bases standards 6-31G**, 6-31G* et 3-21G* montrent que ces réactions sont possibles théoriquement et, par conséquent, elles sont favorisées thermodynamiquement. Ces résultats de calculs montrent aussi que les produits majoritaires de la réaction sont les régioisomères de type **4a**–**4c**. Les calculs des états de transition montrent que le produit cinétique de la réaction sont les régioisomères de type **4a**–**4c** et en plus les régioismères endo sont favorisées par rapport aux régioisomères exo.

En conclusion, les calculs sembleraient indiquer que l'addition de vinylamine **3b** sur le 4-aza-6-nitrobenzofuroxane **1** devrait être plus facile et plus stéréosélective que l'addition de l'éthénol **3a**, ce qui présente évidemment un grand intérêt pour les expérimentateurs.

N-Bromosuccinimide (NBS) — Selective and effective catalyst for trimethylsilylation of alcohols and phenols using hexamethyldisilazane and their regeneration under mild and neutral reaction conditions

Ardeshir Khazaei, Amin Rostami, Ayeh Raiatzadeh, and Marjan Mahboubifar

Abstract: Structurally diverse alcohols and phenols were trimethylsilylated in a clean and efficient reaction with hexamethyldisilazane (HMDS) based on the use of a catalytic amount of *N*-bromosuccinimide under both dichloromethane and solvent-free conditions at room temperature. Deprotection of trimethylsilyl ethers was also be achieved efficiently in the presence of a catalytic amount of NBS in methanol at ambient temperature.

Key words: N-bromosuccinimide, solvent-free, alcohols, phenols, hexamethyldisilazane, trimethylsilyl ether, catalyst, detrimethylsilylation.

Résumé : Opérant à la température ambiante, on a effectué d'une façon propre et efficace la triméthylsilylation d'alcools et de phénols de structures différentes par réaction avec de l'hexaméthyldisilazane (HMDS), dans du dichlorométhane ou sans solvant, en présence d'une quantité catalytique de *N*-bromosuccinimide (NBS). La déprotection des éthers triméthylsilyles peut aussi se faire d'une façon efficace en présence d'une quantité catalytique de NBS, dans le méthanol, à la température ambiante.

Mots clés : N-bromosuccinimide, sans solvant, alcools, phénols, hexaméthyldisilazane, éther triméthylsilyle, catalyseur, détriméthylsilylation.

Introduction

The protection of hydroxy groups through the formation of silyl ethers has been extensively utilized in organic synthesis (1). Silyl ethers are easily prepared, show resistance to oxidation, have good thermal stability and low viscosity, and are easily recoverable from their parent compounds. Moreover, numerous silylating methods can be utilized today; among them, trimethylsilylation is one of the most often used. Generally, the formation of trimethylsilyl ethers is carried out by the treatment of alcohols with trimethylsilyl chlorides or trimethylsilyl triflates in the presence of a base (2), Li_2S (3), and sometimes a nonionic super base catalyst (4). However, some of these methods frequently suffer from drawbacks such as a lack of reactivity or a difficulty removing amine salts derived from the reaction during the silylation reaction. HMDS is a stable, cheap, and commercially available compound that can be used for the preparation of trimethylsilyl ethers from hydroxy compounds, giving ammonia as the only by-product. Even though the handling of this reagent is easy, its main drawback is its poor silylating ability; forceful conditions and long reaction times are required (5). Therefore, for the activation of HMDS a variety of catalysts have been reported such as $(CH_3)_3SiCl$ (6), $ZnCl_2$ (7), zirconium sulfophenyl phosphonate (8), montmorillonite K-10 (9), I_2 (10), $LiClO_4$ (11), $H_3PW_{12}O_{40}$ (12), $Al(OTf)_3$ (13), $CuSO_4{\cdot}5H_2O$ (14), KBr (15), and $LiClO_4$–SiO_2 (16). Although these methods produce good results in many instances, few of these catalysts can do both protection and deprotection of alcohols and phenols as trimethylsilyl ethers. Therefore, there is still a demand to develop new mild methods for the trimethylsilylation of hydroxyl compounds and their regeneration in the presence of inexpensive and benchtop catalysts.

Similar to protection, deprotection of the trimethylsilyl ethers constitutes an important process in the synthetic chemistry of polyfunctional molecules, including the total synthesis of natural products. Although several methods

have been reported for the deprotection of trimethylsilyl ethers (17), the development of mild, efficient, ecofriendly, and selective reagents for the deprotection of trimethylsilyl ethers continues to be desirable.

Solvent-free reactions have attracted considerable attention in chemical processes for different reasons. They are valuable due to environmental safety, economic viewpoint, easy workup, high yields of the products, and (usually) fast reaction times (18). This is why we tried to develop a solvent-free version of this new reaction.

Results and discussion

In continuation of our interest in the application of *N*-halo compounds (19) in organic synthesis, we have found that NBS is an inexpensive commercially available reagent that has been used as an effective catalyst for the acetalization of carbonyl compounds (20*a*, 20*b*), the conversion of aldehydes to 1,1-diacetates (20*c*), and the acylation of alcohols (20*d*) under mild and nearly neutral reaction conditions.

In this present work, the catalytic application of NBS has been investigated as a selective reagent for the efficient trimethylsilylation of a wide range of alcohols and phenols under both solution and solvent-free conditions as well as the desilylation of the corresponding TMS ethers in methanol (Scheme 1).

We first examined the effect of different ratios of ROH–HMDS–catalyst. The 1:2:0.01 ratio for alcohols and phenols gave the best results and produced trimethylsilyl ethers in quantitative yields. As shown in Table 1, using a mixture of HMDS (2 mmol) and a catalytic amount of NBS (0.01 mmol), primary (alkyl and benzylic), secondary (hindered and unhindered), and tertiary alcohols and a variety of phenols (with electron-withdrawing and electron-releasing groups) were transformed into the corresponding trimethylsilyl ethers in good to high yield under both dichloromethane (I) and solvent-free (II) conditions at room temperature (RT). We observed that amines and thiols were not converted to the corresponding silyl ethers under these reaction conditions, even after prolonged reaction times.

Because of the nearly neutral nature of the reaction medium, no elimination by-products were observed at all. Subsequently, we discovered that the desilylation of the trimethylsilyl ethers can be carried out to obtain the corresponding alcohols and phenols in good to excellent yields by using the same catalyst in methanol at RT (Scheme 1 and Table 2).

We used this procedure for the selective trimethylsilylation of *n*-octanol (as a model for primary alcohols) or 2-pentanol (as a model for secondary alcohols) in the presence of 1-adamantanol (as a model for tertiary alcohols). The only observed products were *n*-octyl trimethylsilyl ether or 2-pentyl trimethylsilyl ether in 100% conversion (Scheme 2).

Similarly, in a binary mixture of 4-methoxyphenol and

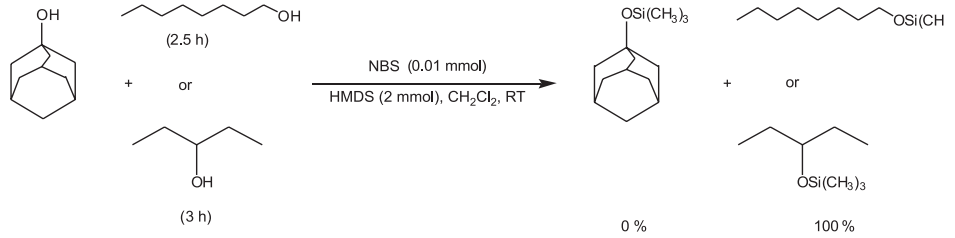
2,6-diisopropylphenol (as a model for hindered phenol), 4-methoxyphenol was completely converted to the corresponding silyl ether, while 0% conversion was observed for 2,6-diisopropylphenol (Scheme 3).

To assess the catalytic activity of NBS for trimethylsilylation, we compared our results for the trimethylsilylation of 1-naphtol with the best of the well-known procedures from the literature (Table 3). The advantages and the characteristic aspects of the described method in this communication, in comparison with other previously reported catalysts, are the following: a variety of phenols (6, 10, 12) can be trimethylsilylated in good to high yields (11, 14) at RT (12, 14). In addition, the catalyst NBS is inexpensive, has no sensitivity to moisture (11), does not require a large amount of catalyst (11), and no special efforts are required for the reaction (14).

On the basis of the previously reported mechanism for the application of I_2 for the trimethylsilylation of alcohols (10) and the catalytic application of NBS for the protection of carbonyl and hydroxyl functional groups (18), one explanation for this process is that NBS may act as a source for the formation of Br^+, which polarizes the Si–N bond in HMDS to produce the reactive silylating agent (as a Lewis acid). Therefore, the mechanism shown in Scheme 4 is proposed.

Conclusion

In summary, we have shown that NBS is an efficient and selective catalyst for the protection of a variety of alcohols and phenols as TMS ethers using HMDS and their deprotection under very mild conditions. The product yields are good to high and the procedure is easy and clean. Therefore, this procedure could be utilized in transformations that need mild reaction conditions.



Experimental

General procedure for the trimethyisilylation of alcohols and phenols using HMDS catalyzed with NBS in solution

Alcohols or phenols (1 mmol) were added to a mixture of HMDS (2 mmol) and NBS (0.01 mmol) in CH_2Cl_2 (7 mL), and the mixture was then stirred at RT for the specified time (Table 1). The progress was monitored by TLC. After completion of the reaction, water (10 mL) was added to destroy the extra amounts of HMDS for alcohols and 5% aq. NaOH (10 mL) for phenols, then the organic layer was separated and dried over anhydr. Na_2SO_4. The solvent was evaporated, and *n*-hexane (20 mL) was added to the residual mixture. Insoluble catalyst was removed by filtration. Evaporation of the *n*-hexane under reduced pressure gave pure product without further purification.

General procedure for the trimethyisilylation of alcohols and phenols using HMDS catalyzed with NBS under solvent-free conditions

Alcohols or phenols (1 mmol) were added to a mixture of HMDS (2 mmol) and NBS (0.01 mmol), and the mixture was then stirred at RT for the specified time (see Table 1). The progress was monitored by TLC. After completion of the reaction, water (10 mL) was added to destroy the extra amounts of HMDS for alcohols and 5% aq. NaOH (10 mL) for phenols. The trimethylsilyl ethers were then extracted with *n*-hexane (20 × 2 mL), and the organic layer was dried over anhydr. Na_2SO_4. Evaporation of the *n*-hexane under reduced pressure gave pure product without further purification.

General procedure for the deprotection of trimethylsilyl ethers catalyzed with NBS

NBS (0.2 mmol) was added to a mixture of TMS ethers (1 mmol) in MeOH (3 mL), and the mixture was then stirred at RT for the specified time (Table 2). The progress of the reaction was monitored by TLC. On completion of the reaction, methanol was removed under reduced pressure and the product was purified through a short column of silica gel to obtain pure alcohol or phenol.

Quinonoids from the barks of *Cratoxylum formosum* subsp. *pruniflorum*

Nawong Boonnak, Chatchanok Karalai, Suchada Chantrapromma, Chanita Ponglimanont, Akkharawit Kanjana-Opas, Kan Chantrapromma, and Hoong-Kun Fun

Abstract: A mixture of new bianthrones J (**1a** and **1b**) was isolated from the barks of *Cratoxylum formosum* subsp. *pruniflorum* together with six known quinonoids, namely bianthrone A_1 (**2**), vismones E (**3**) and D (**4**), 11-hydroxy-5-methoxy-2,2,9-trimethyl-2*H*-anthra[1,2-b]-pyran-7,12-dione (**5**), vismiaquinone (**6**), and 3-geranyloxy-6-methyl-1,8-dihydroxyanthraquinone (**7**). Their structures were assigned on the basis of spectroscopic methods. The antibacterial and cytotoxic activities of compounds **3** and **4** were also reported.

Key words: Cratoxylum formosum subsp. *pruniflorum*, bianthrone, vismone, anthraquinone, antibacterial activity, cytotoxicity.

Résumé : À partir de l'écorce de *Cratoxylum formosum* subsp. *pruniflorum* on a isolé de nouvelles bianthrones J (**1a** et **1b**) aux côtés de six quinonoïdes connues, soit la bianthrone A_1 (**2**), les vismones E (**3**) et D (**4**), la 11-hydroxy-5-méthoxy-2,2,9-triméthyl-2*H*-anthra[2,1-b]pyrane-7,12-dione (**5**), la vismiaquinone (**6**) et la 3-géranyloxy-6-méthyl-1,8-dihydroxyanthraquinone (**7**). On a attribué leurs structures sur la base de méthodes spectroscopiques. On a aussi déterminé les activités antibactériennes et cytotoxiques des composés **3** et **4**.

Mots-clés : Cratoxylum formosum subsp. *pruniflorum*, bianthrone, vismone; anthraquinone, activité antibactérienne, cytotoxicité.

[Traduit par la Rédaction]

Introduction

During the course of our investigation on the bioactive chemical components of plants belonging to the family Guttiferae, we have focused on *Cratoxylum formosum* subsp. *pruniflorum*, which is a shrub or small tree found widely in the northeastern part of Thailand. Decoction of the fresh or dried leaves from this plant has been used in traditional medicine as tonic, stomachic, and diuretic (1). This shrub produces various types of secondary metabolites including xanthones, triterpenoids, flavonoids, and anthraquinones (2–5). Some of these anthraquinones have been found to have cytotoxic and antiprotozoal activities (4, 6–7). We previously reported nine new xanthones and a new anthraquinone from the roots and barks of *C. formosum* subsp. *pruniflorum* (8). In continuation of our study, we describe herein the isolation and identification of a mixture of new bianthrones J (**1a** and **1b**) together with six known compounds (**2–7**). The antibacterial and cytotoxic activities of all the isolates were also evaluated.

Results and discussion

The crude CH_2Cl_2 and acetone extracts from the barks of *C. formosum* subsp. *pruniflorum* were fractionated by silica gel column chromatography to obtain a mixture of new bianthrones J (**1a** and **1b**) along with six known quinonoids (**2–7**).

A mixture of new bianthrones J (**1a** and **1b**) was obtained as a yellow-green powder. It showed a molecular ion peak at *m/z* 674.2864 $[M]^+$ in the HR EIMS (calcd. for *m/z* 674.2880), corresponding to a molecular formula $C_{42}H_{42}O_8$. Moreover, the bianthrones J also displayed a EIMS peak at *m/z* 338 $[M - 336]^+$ corresponding to the fragment ion of $C_{21}H_{22}O_4$, which was the same as that of 2-(3-methyl-1-butenyl)-1,8-dihydroxy-3-methoxy-6-methyl anthrone (9), a

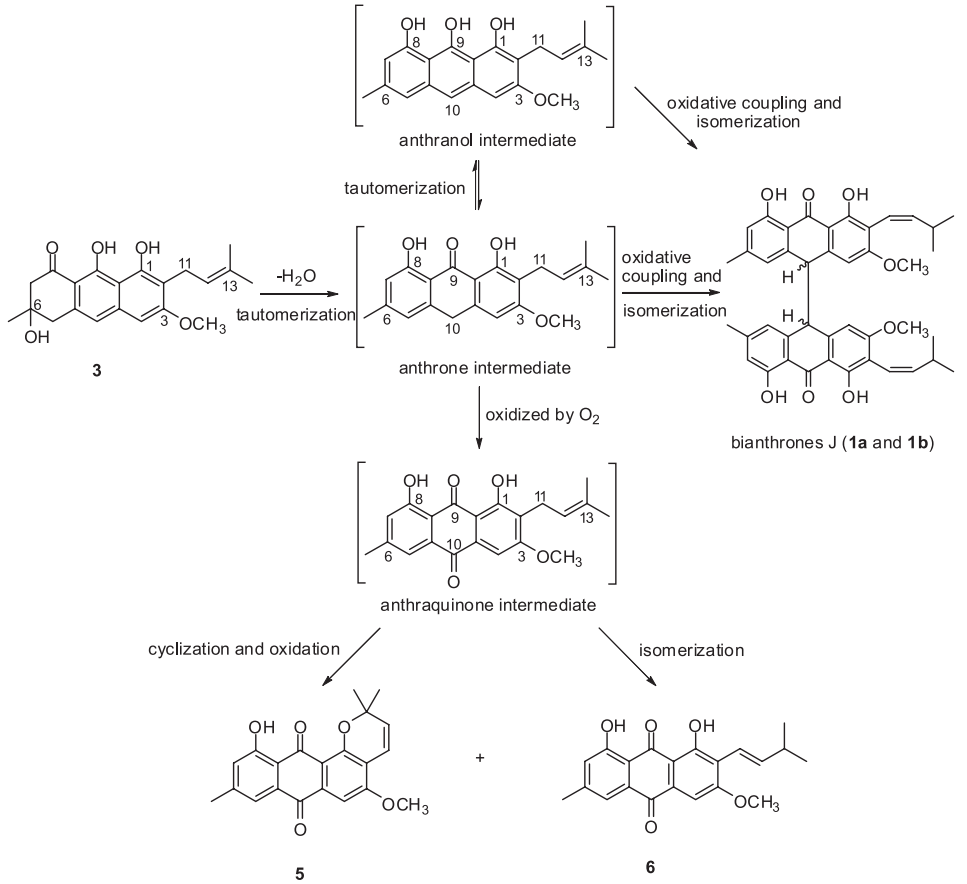
half structure of bianthrones J. The UV spectrum showed absorption bands at 273 and 360 nm. The IR absorption band at 1640 cm^{-1} indicated the presence of the conjugated carbonyl groups. These results suggested a bianthrone type. In this case, the bianthrones J were optically inactive (a mixture of (±) and meso forms). The ^1H and ^{13}C NMR spectral data (Table 1) showed two sets of the signals of (±) and meso forms that were similar to those of bivismiaquinone except for the appearance of the *cis*-olefinic protons of 3-methyl-1-butenyl groups at δ 6.53 (2H, dd, *J* = 0.7, 6.6 Hz, H-11/11′), 6.68 (2H, t, *J* = 6.6 Hz, H-12/12′), 6.47 (2H, dd, *J* = 0.7, 6.6 Hz, H-11/11′), and 6.63 (2H, t, *J* = 6.6 Hz, H-12/12′) instead of the corresponding *trans*-olefinic protons of bivismiaquinone (10) at δ 6.51 (2H, d, *J* = 16.2 Hz, H-11/11′), 6.66 (2H, dd, *J* = 6.6, 16.2 Hz, H-12/12′), 6.45 (2H, d, *J* = 16.2 Hz, H-11/11′), and 6.60 (2H, dd, *J* = 6.6, 16.2 Hz, H-12/12′). The olefinic protons signals at δ 6.68 and 6.63 were assigned to H-12 and H-12′ from HMBC correlation to δ_C 113.4 (C-2/2′), 115.6 (C-11/11′), and 33.1 (C-13/13′), whereas signals at δ 6.53 and 6.47 were assigned to H-11 and H-11′, as they exhibited correlations with δ_C 143.6 (C-12/12′) and 113.4 (C-2/2′). The two signals of 1,1′-OH at δ 12.63 and 12.68 showed HMBC correlation with δ_C 161.7 (C-1/1′), 113.4 (C-2/2′), 110.6 (C-9a/9′a) and 161.3 (C-1/1′), 113.4 (C-2/2′), 111.1 (C-9a/9′a), respectively, which confirmed the attachment of the 3-methyl-1-butenyl moiety at C-2 and C-2′. The locations of all substituents were confirmed by HMBC correlations as shown in Table 1. This mixture was designated as bianthrones J (**1a** and **1b**), a related geometrical isomer of bivismiaquinone, previously isolated from *Psorospermum febrifugum* (11).

The remaining known compounds were identified as bianthrone A_1 (**2**) (11, 12), vismone E (**3**) (13), vismone D (**4**) (13, 14), 11-hydroxy-5-methoxy-2,2,9-tri-methyl-2*H*-anthra[1,2-b]pyran-7,12-dione (**5**) (15), vismiaquinone (**6**) (16), and 3-geranyloxy-6-methyl-1,8-dihydroxyanthraquinone (**7**) (13) (see Fig. 1) by comparison of their spectral data with those published in the literature. Moreover, compounds **2–4** were isolated for the first time from this genus.



As previously reported (13), vismones with β-hydroxy carbonyl functionality are acid-sensitive under mild conditions, such as prolonged contact with SiO_2 during chromatographic purification. Those vismones with a C-6 hydroxyl group are easily dehydrated and further tautomerized to yield anthrone and anthranol intermediates, which are possibly further oxidized by O_2 to produce anthraquinones and bianthrones (17). We proposed that compound **3** was chemically transformed to an anthrone intermediate (Scheme 1),

Scheme 1. Plausible biogenetic pathway of the quinonoid compounds.

which was further oxidized at C-10 to form an anthraquinone skeleton. Subsequent cyclization followed by oxidation of the side chain of the anthraquinone intermediate yielded compound **5**, whereas compound **6** was generated by isomerization. Oxidative coupling of two molecules of anthrone or anthranol intermediate, followed by side chain isomerization, presumably produced bianthrones J (**1a** and **1b**). We also suggested that compounds **2** and **7** were de-

[a]Inactive.

rived from compound **4** by the similar pathway as shown in Scheme 1. Therefore, compound **3** should be a precursor of bianthrones J (**1a** and **1b**) and compounds **5** and **6**, while compound **4** is a precursor of compounds **2** and **7**.

The antibacterial and cytotoxic activities of compounds **3** and **4** are shown in Tables 2 and 3, respectively, in which compounds **3** and **4** showed potent antibacterial activities against *Streptococcus faecalis* and *Shigella sonnei*. Compound **4** also exhibited strong antibacterial activity against *Salmonella typhi*. In addition, compound **4** was highly active for cytotoxicity against all tested cell lines except for the HT-29 cell line, whereas compound **3** was moderately active against only the KB cell line. Bianthrones J (**1a** and **1b**) and compounds **2** and **5–7** were found to be inactive for both antibacterial and cytotoxic activities. From the plausible biosynthetic routes (Scheme 1) and biological activity results (Tables 2 and 3), we speculate that if the transformation processes of compound **3** to bianthrones J (**1a** and **1b**) and compounds **5** and **6**, and compound **4** to compounds **2** and **7**, are inhibited, it might be possible to obtain larger amounts of bioactive compounds **3** and **4**, which may be used as starting materials for partial synthesis or biotransformation to develop compounds with enhanced antibacterial and cytotoxic activities.

Experimental section

General experimental procedures

Melting points were determined on a Fisher-Johns melting point apparatus. Optical rotations were measured on a JASCO P-1020 digital polarimeter. UV and IR spectra were recorded on a SPECORD S 100 (Analytik Jena) and a PerkinElmer FTS FT-IR spectrophotometer, respectively. The ^1H and ^{13}C NMR spectra were recorded on a 500 MHz Varian UNITY INOVA and 300 MHz Bruker FT NMR Ultra Shield spectrometers in $CDCl_3$ or CD_3OD with TMS as the internal standard. Chemical shifts were reported in δ (ppm) and coupling constants (*J*) expressed in Hz. EI and HREI mass spectra were measured on a Kratos MS 25 RFA spectrometer. Quick column chromatography (QCC) and column chromatography (CC) were carried out on silica gel 60 F_{254} (Merck) and silica gel 100 (Merck), respectively.

Plant material

The barks of *C. formosum* subsp. *pruniflorum* were collected in May 2004 from Nong Khai Province in the northeastern part of Thailand. The voucher specimen (No. 0012677) has been deposited at Prince of Songkla University Herbarium, Biology Department, Faculty of Science, Prince of Songkla University, Thailand.

Extraction and isolation

The air-dried and finely chopped barks of *C. formosum* subsp. *pruniflorum* (4.0 kg) were successively extracted with CH_2Cl_2 and acetone (each 2 × 20 L, for 5 days) at room temperature. The crude extracts were evaporated to dryness under vacuum to afford CH_2Cl_2 (76.28 g) and acetone (21.74 g) extracts. The crude CH_2Cl_2 extract was subjected to QCC (column size: 12 × 16 cm) and eluted with increasing polarity of CH_2Cl_2 and acetone in hexane to afford 10 fractions (F1–F10). Fraction F2 (58.06 g) was separated by CC using a gradient of hexane–EtOAc to afford 8 subfractions (F2A–F2H). Subfraction F2C (120.02 mg) was further purified by CC with EtOAc–hexane (1:4 *v*/*v*) to give compound **7** (68.20 mg). The subfraction F2F was separated by CC with $CHCl_3$–hexane (3:7 *v*/*v*) to give 3 fractions (F2FA–F2FC) and the subfraction F2FB was further purified by prep TLC with $CHCl_3$–hexane (3:7 *v*/*v*) to yield compound **6** (3.30 mg). Subfractions F2G and F2H were each further separated by CC eluting with acetone–hexane (1:9 *v*/*v*) and CH_2Cl_2–hexane (2:3 *v*/*v*) to give compounds **2** (30.20 mg) and bianthrones J (**1a** and **1b**) (35.50 mg), respectively. The fraction F4 was fractionated by CC using EtOAc–hexane (3:7 *v*/*v*) as eluents to afford 7 fractions (F4A–F4G). The subfraction F4E was further purified by prep TLC with EtOAc–hexane (1:3 *v*/*v*) to give compound **4** (7.40 mg), while the subfraction F4F was purified by CC with EtOAc–hexane (1:4 *v*/*v*) to give compound **3** (15.20 mg). The acetone extract was subjected to QCC (column size: 12 × 16 cm) using a gradient of hexane with acetone to afford 12 fractions (FA1–FA12). The fraction FA2 (1.98 g) was further separated by CC with acetone–hexane (3:97 *v*/*v*) to give 6 fractions (FA2A–FA2F) and then the subfraction FA2B (422.00 mg) was purified by CC with acetone–hexane (1:19 *v*/*v*) to give compound **5** (3.00 mg).

Bioassays

Antibacterial assay

The isolated compounds from the barks of *C. formosum* subsp. *pruniflorum* were tested against the microorganisms *Bacillus substilis* (obtained from Department of Industrial Biotechnology, PSU), *Staphylococcus aureus* (TISTR517) (obtained from Microbial Resources Center (MIRCEN), Bangkok, Thailand), *S. faecalis*, *S. sonnei*, *S. typhi*, and *Pseudomonas aeruginosa*. The last four microorganisms were obtained from Department of Pharmacognosy and Botany, PSU. The antibacterial assay employed was the same as described in Boonsri et al. (18). Vancomycin, which was used as a standard, showed antibacterial activity of 75 µg/mL.

Cytotoxic assay

The procedure for cytotoxic assay was performed by the sulphorhodamine B (SRB) assay as described by Skehan et al. (19). In this study, four cancer cell lines obtained from the National Cancer Institute, Bangkok, Thailand, were used, MCF-7 (breast adenocarcinoma), KB (human oral cancer), HeLa (Human cervical cancer), and HT-29 (colon cancer). Camptothecin, which was used as a standard, showed cytotoxic activity in the range of 0.2–2.0 µg/mL.

Formation of monofluorophosphate from fluoride in phosphoric acid – water and phosphoric acid – sulfuric acid – water mixtures

Kenneth E. Newman, Raymond E. Ortlieb, Nicole Pawlik, and Jason Reedyk

Abstract: When dissolved in concentrated phosphoric acid, sodium fluoride reacts rapidly to form monofluorophosphate. In less concentrated acid, the reaction does not proceed to completion, and the reaction kinetics become very much slower. The equilibrium and rate constants for the reaction have been determined. In ternary mixtures of phosphoric acid, sulfuric acid, and water, the formation of monofluorophosphate is considerably enhanced, and the kinetics are rapid. The results are interpreted in terms of the very low water activity coefficients in strong-acid solutions.

Key words: monofluorophosphate, monofluorophosphoric acid, ^{19}F NMR, ^{31}P NMR, phosphoric acid, sulufric acid, equilibria, kinetics.

Résumé : Lorsqu'il est dissout dans de l'acide phosphorique concentré, le fluorure de sodium réagit rapidement pour former le monofluorophosphate. Dans de l'acide moins concentré, la réaction n'est pas complète et la cinétique de la réaction est ralentie. On a déterminé les constantes d'équilibre et de vitesse de la réaction. Dans des mélanges ternaires d'acide phosphorique, d'acide sulfurique et d'eau, la formation du monofluorophosphate est très accélérée et la cinétique est rapide. On interprète les résultats en fonction des très faibles coefficients d'activité de l'eau dans des solutions fortement acides.

Mots-clés : monofluorophosphate, acide monofluorophosphorique, RMN du ^{19}F, RMN du ^{31}P, acide phosphorique, acide sulfurique, équilibre, cinétique.

Introduction

Mono-, di-, and hexafluorophosphates, along with their corresponding acids, were first synthesized and characterized by Lange and co-workers in a series of papers starting in 1926 (1). As part of this extended study, they reported that sodium fluoride, when dissolved in concentrated phosphoric acid, gave a mixture of HF and monofluorophosphoric acid (MFP), H_2PO_3F.[2] The ratio of MFP to HF increased with increasing phosphoric acid concentration. The patent literature suggests that sodium monofluorophosphate (Na_2PO_2F) is commercially manufactured using very forcing conditions. For example, the 1993 patent of Swidersky et al. involves mixing H_3PO_4, NaOH, and NaF in stoichiometric amounts, together with a small amount of water, at temperatures between 150 and 400 °C (2). The anhydrous acid itself can be made under much less forcing conditions, namely room temperature reaction of anhydrous metaphosphoric acid (HPO_3) and gaseous hydrogen fluoride (3).

MFP salts find uses in the treatment of osteoporosis, control of corrosion (particularly in steel reinforcing in concrete), and as fungicides and bactericides. However, the major use of MFP salts is as anticaries agents in toothpastes. The hydrolysis of MFP to fluoride is extremely slow at near neutral pH values, although it is hydrolyzed readily by phosphatase enzymes, including those found in saliva (4). The addition of an acid has also been shown to significantly enhance the reaction rate (5).

Phosphoric acid is manufactured by the reaction of the ore (apatite), $Ca_5(PO_4)_3(OH)$, with concentrated sulfuric acid in the temperature range of 70–80 °C (the so-called "wet process") according to the simplified reaction [1] (6).

$$[1] \quad Ca_5(PO_4)_3(OH) + 5H_2SO_4 = 5CaSO_4(s) + 3H_3PO_4 + H_2O$$

The ore is invariably contaminated with fluoroapatite, $Ca_5(PO_4)_3(F)$, with the total fluoride content of the feedstock in the range of 3.5%–4%. The strongly acidic reaction conditions favor the formation of HF, which dissolves silica and silica-like impurity minerals in the ore. Products of this reaction are various fluorosilicates, including the volatile silicon

[2]Given the strongly acidic media of interest in this paper, the extent of protonation of monofluorophosphate will not always be obvious. Thus, we will refer to the species as MFP regardless of its form except where noted.

 doi:10.1139/V07-027 © 2007 NRC Canada

tetrafluoride (SiF_4), as well as hexafluorosilicic acid (H_2SiF_6) and (or) its salts. Phosphoric acid reactor vessels are thus typically scrubbed to remove the volatile HF and SiF_4. The other product of reaction [1], calcium sulfate (gypsum) is typically pumped as a slurry to tailings ponds; process water is also stored for recycle in storage ponds. These ponds are typically fairly acidic (pH < 2) with very high dissolved solids content, and with fluoride levels in the range of 0.35%–1.35% (7). Probably, the fluoride is mostly in the form of HF and SiF_6^{2-}, but the latter species may partially hydrolyze to SiF_4. Fugitive emissions of gaseous HF and SiF_4 from the ponds are thus of environmental concern.

The work reported here is the first part of an extended study to explore and understand in detail the chemistry and fate of the fluoride impurities as they pass through the "wet process" manufacture of phosphoric acid. The ready formation of MFP in phosphoric acid under benign conditions led us to focus initially on the conditions that determine its formation. Given the central role of sulfuric acid on the manufacturing process, its effect on MFP formation was clearly important to the study.

Experimental

NaF (Fisher, ACS grade), Na_2PO_3F (Alfa Aesar, >99%), H_3PO_4 (Aldrich, 100%), H_3PO_4 (Sigma, 85%, ACS), H_2SO_4 (95%–98%, ACS grade), and D_2O (Cambridge Isotope Laboratories, 99%) were used as received. All solutions were prepared by weight in polyethylene or Teflon containers and were typically 0.01 *m* total fluoride. Solutions typically contained 10%–15% D_2O, although a few solutions were prepared with 40%–50% D_2O. Some of the most-acidic solutions were prepared without D_2O and thus were run unlocked. NMR spectra were obtained with a Bruker 400 Avance NMR spectrometer using a Bruker ATMA multinuclear probe operating at 161.98 MHz for ^{31}P and 376.46 MHz for ^{19}F. All NMR spectra were run at 22.0 ± 0.1 °C. Samples were contained in 5 mm NMR tubes with polytetrafluoroethylene – fluorinated ethylene polypropylene copolymer (PTFE–FEP) liners (Wilmad LabGlass, NJ, USA).

Results

The ^{19}F NMR spectrum of a 0.01 *m* solution of NaF in 85%[3] H_3PO_4 solution consists of a doublet, centered at –75.1 ppm with a coupling constant of 937 Hz, and a somewhat broad peak at ~147 ppm. The ^{31}P NMR spectrum of a similar solution consists of a very large peak centered at ~0 ppm, a small doublet centred at –7.4 ppm with a coupling constant of 937 Hz, and another small peak at –12.8 ppm. The spectra are readily interpreted in terms of a mixture of MFP and HF. The doublet feature in each spectrum is due to $J_{12}(^{19}F–^{31}P)$ coupling in the MFP. The large peak at ~0 ppm in the ^{31}P spectrum is due to H_3PO_4, and the small peak at –12.8 ppm is due to a small amount of pyrophosphate ($P_2O_7^{4-}$). These assignments are consistent with literature values (8). It is worth noting that the ^{19}F chemical shifts of both MFP and HF and the MFP coupling constant show considerable variation, as the phosphoric acid concentration is varied from 5% to 85% H_3PO_4.

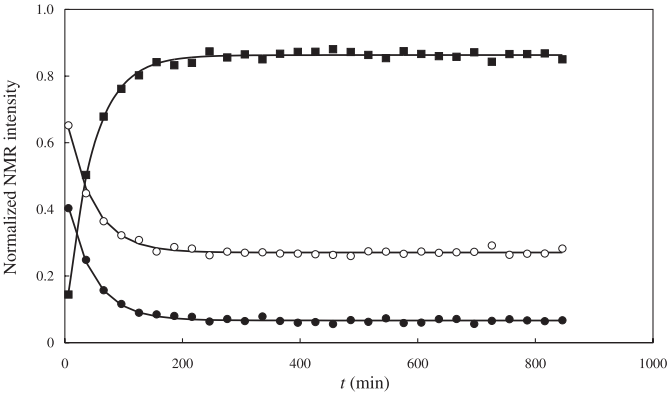

Fig. 1. Variation of normalized NMR intensities of each peak of the monofluorophosphate doublet (closed and open circles) and hydrogen fluoride (closed squares) for a 0.0078 *m* of sodium monfluorophosphate solution in a phosphoric acid – water mixture of the composition $x(H_3PO_4) = 0.254$. The D_2O/H_2O fraction was 0.41. For clarity, the data for the component of the MFP doublet represented by the open circles were displaced vertically by 0.2 units. The smooth curves are the fitted values, obtained as described in the text.

We may define α as the fraction of the fluorine-containing species in the form of MFP

$$[2] \qquad \alpha = \frac{c_{MFP}}{c_{MFP} + c_{HF}}$$

where c_i is the concentration (expressed as either molality or molarity). At 85% H_3PO_4, the value of α from the integration of the ^{19}F spectrum is 0.81. As the phosphoric acid concentration is decreased, not only does α decrease, but also the kinetics of interconversion of HF and MFP become surprisingly slow. The dependence of α on phosphoric acid concentration was thus determined as the infinite-time values obtained from a study of the kinetics of the reaction of 0.01 *m* Na_2MFP in aq. phosphoric acid solutions. Figure 1 shows a typical kinetic ^{19}F NMR run. The integrated NMR peak intensities were normalized by dividing through by the sum of the intensities. The normalized intensities were fitted to a first-order kinetic equation by a non-linear least-squares approach, using the "Solver" facility of Microsoft® Excel. Each NMR peak was fitted to a unique time-zero and time-infinity intensity, but with a common value for the rate constant. For H_3PO_4 compositions greater than 80% [$x(H_3PO_4) > 0.42$], the kinetics were too fast to measure by this NMR method, and thus, only the equilibrium values could be measured. For $x(H_3PO_4) < 0.04$, the infinity values for the MFP peaks were too small to be measured reliably and were thus constrained to zero. Although no extended study was performed, the kinetics do not appear to exhibit any strong isotope effects as the D_2O fraction is changed. Figure 2 shows the values of α as a function of $x(H_3PO_4)$. For the two points

[3] Throughout this work, "% *i*" refers to the weight% of solvent species *i*, calculated excluding the solutes. $x(i)$ refers to the mole fraction of solvent species *i*, calculated excluding the solutes.

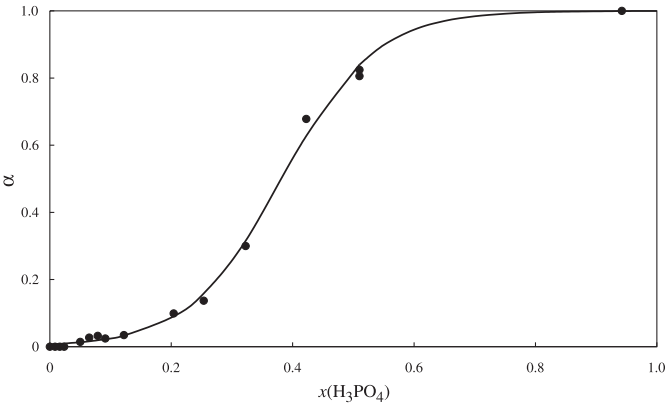
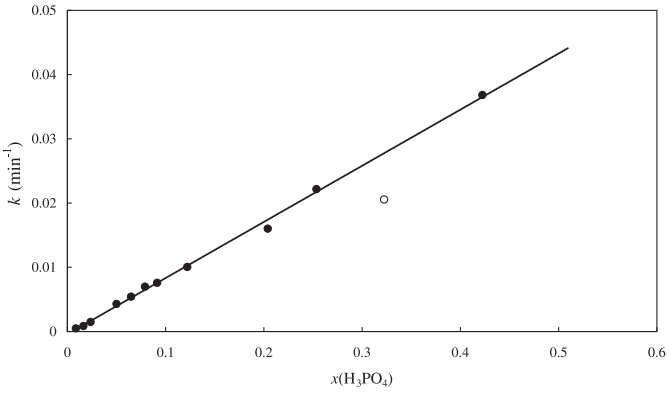
Fig. 2. Equilibrium fraction (α) of monofluorophosphate as a function of the mole fraction of H_3PO_4. ●: Experimental values; ——— : Fitted values (see Discussion for details).





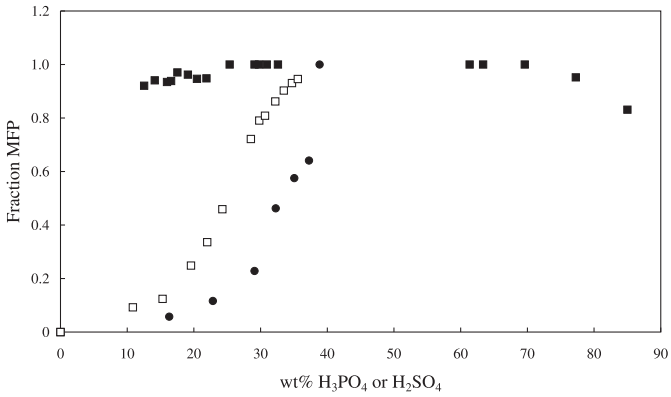


Fig. 3. Apparent first-order rate constants for the interconversion of HF and MFP as a function of the mole fraction of H_3PO_4. The line represents the best straight-line fit, excluding the open-circle data point.

in the figure at $x(H_3PO_4) \approx 0.51$, one was obtained using NaF as the initial reactant, the other using Na_2MFP. The origin of the smooth line through the data will be discussed later. Figure 3 shows the apparent first-order rate constants for the kinetics of formation of MFP as a function of $x(H_3PO_4)$. Quite remarkably, the values obtained were linear with $R^2 = 0.997$.[4]

For the phosphoric acid – sulfuric acid – water mixtures, it is more difficult to survey adequately the solvent composition range. In addition to the H_3PO_4 – H_2O binary mixtures (i.e., the 0% H_2SO_4 isopleth), measurements were also made along the following ternary diagram isopleths: ~43% phosphoric acid, 15% H_2O, and 50% H_2SO_4. The results are shown in Fig. 4. In the ~ 43% H_3PO_4 series, the weight

Fig. 4. Equilibrium fraction (α) of monofluorophosphate in H_3PO_4 – H_2SO_4 – H_2O mixtures. □: 15% H_2O, plotted vs. % H_2SO_4; ●: 50% H_2SO_4, plotted vs. % H_3PO_4; ■: ~ 43% H_3PO_4, plotted vs. % H_2SO_4 (see text for information on this series).

composition varied slightly (from 42.3 to 45.5), which accounts for the slightly scattered results. It is remarkable that sulfuric acid has such a large effect on MFP formation. For example, a H_3PO_4–H_2SO_4 – H_2O (42:38:20) mixture yields 100% MFP, whereas a H_3PO_4 – H_2O (42:58) mixture yields only 10% MFP. The results are even more dramatic in the low-water (15%) mixtures where a H_3PO_4 – H_2SO_4 – H_2O (20:60:15) mixture yields 100% MFP, whereas in a 20% H_3PO_4 solution in the absence of H_2SO_4, the yield is ~ 1%. The kinetics in the sulfuric acid solution were typically too fast to measure by our relatively slow NMR method.

Discussion

Formation of MFP in H_3PO_4 – H_2O mixtures

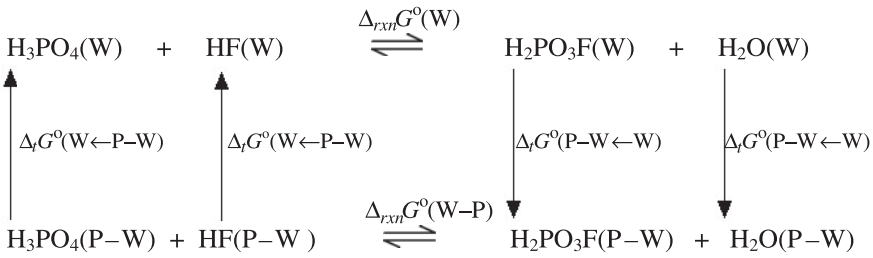
Theory

For the reaction of HF to give MFP, we can write

[3] $$H_3PO_4 + HF \rightleftharpoons H_2PO_3F + H_2O$$

In terms of the reaction conditions of interest here, both phosphoric acid and water are the predominant species (the solvent), whereas HF and MFP are considered solutes. We have written both of the reactants in their protonated forms because phosphoric acid is a weak acid in water and HF is even weaker. We have no reliable knowledge about the ionization state of MFP. Certainly, it is a stronger acid (in water) than phosphoric acid. However, in the strongly acidic solvents of interest here, we will assume that it is also protonated.

In general, an equilibrium constant is only a "constant" in any given solvent or solvent mixture. For example, in mixtures of ethanol–water, weak acids become considerably weaker as the alcohol content of the solvent increases. One approach to this problem is to define our equilibrium constant K(P–W) for reaction [3] in solvent mixture P–W as



[4] Most texts on error analysis give a definition for R, see for example ref. 9.

© 2007 NRC Canada

$$[4]\qquad K(\mathrm{P-W}) = \left[\frac{c(H_2PO_3F)}{c(HF)}\frac{\gamma(H_2PO_3F)}{\gamma(HF)}\frac{x(H_2O)}{x(H_3PO_4)}\right] = \left[\frac{\alpha}{1-\alpha}\frac{\gamma(H_2PO_3F)}{\gamma(HF)}\frac{x(H_2O)}{x(H_3PO_4)}\right]$$

where the γ terms are the conventional concentration-dependent activity coefficients, which can be ignored, providing the concentrations are low enough. This equilibrium constant changes when the solvent composition is changed because the standard chemical potentials of the reactants and products are solvent-dependent. This is often referred to as the "primary medium effect". One approach to this problem is to use "free energies of transfer". Thus, we can write, for the thermodynamic cycle involving reaction [3] in two different solvents, W and P–W

[5]

where Δ_tG^o(P–W ← W) are called the free energies of transfer of the species from solvent W (in this case, water) to the solvent mixture P–W. Straightforward analysis of the thermodynamic cycle allows us to write the standard free energy of reaction in solvent mixture P–W as

$$[6]\qquad \Delta_{rxn}G^o(\mathrm{P-W}) = \Delta_{rxn}G^o(\mathrm{W}) + \sum_{\text{products}}\Delta_tG^o(\mathrm{P-W} \leftarrow \mathrm{W}) - \sum_{\text{reactants}}\Delta_tG^o(\mathrm{P-W} \leftarrow \mathrm{W}) = -RT\ln K(\mathrm{P-W})$$

The great utility of this equation is that, in principle, the various free energy of transfer terms can be obtained for individual species by thermodynamic measurements such as vapor pressure or solubility. Thus, we can obtain the solvent-composition dependence of the equilibrium constant.

For the reaction of interest, it is not obvious how one would measure the free energy of transfer of HF from H_2O to H_3PO_4. Even if one could find a suitable experimental technique, HF reacts too rapidly in phosphoric acid. It is also not immediately obvious how one would measure this quantity for H_2PO_3F. However, for the purposes of this analysis, we wish to explore the crucial role of the free energy of transfer terms for the two-solvent components, i.e., H_2O and H_3PO_4. The free energy of transfer of species W from W to solvent mixture P–W can be written more formally as

$$[7]\qquad \Delta_tG^o[\mathrm{W(P-W)} \leftarrow \mathrm{W(W)}] = [\mu(\mathrm{W}) - RT\ln x_w]_{\mathrm{P-W}} - [\mu(\mathrm{W}) - RT\ln(x_w = 1)]_{\mathrm{W}}$$

The usual definition for activity coefficients in binary solvent mixtures is

$$[8]\qquad \mu(\mathrm{W}) = \mu^o(\mathrm{W}) + RT\ln x_w + RT\ln\gamma_w$$

with $\ln\gamma_w \to 1$, as $x_w \to 1$; thus, eq. [7] becomes (as we might expect)

$$[9]\qquad \Delta_tG^o[\mathrm{W(P-W)} \leftarrow \mathrm{W(W)}] = RT\ln\gamma_w$$

Applying a similar approach to eqs. [7] and [8] to the transfer of species P from W to a P–W mixture, we obtain

$$[10]\qquad \Delta_tG^o[\mathrm{P(P-W)} \leftarrow \mathrm{P(W)}] = [\mu(\mathrm{P}) - RT\ln x_p]_{\mathrm{P-W}} - [\mu(\mathrm{P}) - RT\ln(x_p = 0)]_{\mathrm{W}}$$

This equation yields

$$[11]\qquad \Delta_tG^o[\mathrm{P(P-W)} \leftarrow \mathrm{P(W)}] = RT\ln\gamma_P - RT\ln\gamma_P(0)$$

where $\gamma_P(0)$ is the limiting activity coefficient of P in pure W.

Solvent-activity coefficients are frequently expressed in terms of an equation of the form (10)

$$[12]\qquad \ln\gamma_w = Ax_p^2$$

and

$$[13]\qquad \ln\gamma_P = A(1 - x_P)^2$$

By combining eqs. [9], [11], [12], and [13], we readily obtain

$$[14]\qquad \Delta_tG^o[\mathrm{W(P-W)} \leftarrow \mathrm{W(W)}] - \Delta_tG^o[\mathrm{P(P-W)} \leftarrow \mathrm{P(W)}] = 2RT\,Ax_P$$

Combining eqs. [6] and [14] (ignoring contributions from free energy of transfer of the two solutes) we obtain

$$[15]\qquad \ln K(\mathrm{P-W}) = \ln K(\mathrm{W}) - 2Ax_P$$

predicting a linear dependence of ln K with phosphoric acid mole fraction.

Comparison with experiment

The values of K(P–W), obtained from the data in Fig. 2 using eq. [4], vary from 0.28 to 4.5 over the solvent composition range $x(H_3PO_4)$ = 0.049–0.51. A plot of ln(K) vs. $x(H_3PO_4)$ is predicted to be linear by eq. [15]. To see how well the values for α obey this prediction, they were fitted by a non-linear least-squares approach, using Microsoft® Excel Solver, to eq. [4] with the γ terms set to unity and with ln(K) as a linear function of $x(H_3PO_4)$. Thus, the two fitting parameters were the slope and intercept. Figure 2 shows a comparison between observed and calculated values of α. The large variation of K with solvent composition is the

© 2007 NRC Canada

cause of the sigmoid shape of Fig. 2. The values obtained for ln K(W) and 2A in eq. [15] were –2.7 and –8.5, respectively. No attempt was made to assess the uncertainties in these parameters because the data were obtained over a narrow range of x_p.

The activity coefficients of both W and P in phosphoric acid mixtures can be obtained from vapor-pressure measurements. The calculation is straightforward because, for this system, the vapor contains no phosphoric acid. The 20 °C vapour-pressure data (11) after conversion to water activity coefficients were fitted to eq. [12] to obtain a value of –10.7 for 2A.[5]

Thus, we conclude that the majority of the large increase in equilibrium constant for the formation of MFP, going from pure water to pure phosphoric acid, is due to the extreme thermodynamic non-ideality of the mixture. In particular, the reaction is strongly promoted by the low water activities, which manifest themselves in the negative value for A in eqs. [12] to [15]. However, the previously mentioned analysis has not included free energy of transfer terms for the two solutes. We also caution that experimental measurements on which the previously mentioned analysis was performed are not of the highest precision.

Formation of MFP in H_3PO_4 – H_2SO_4 – H_2O

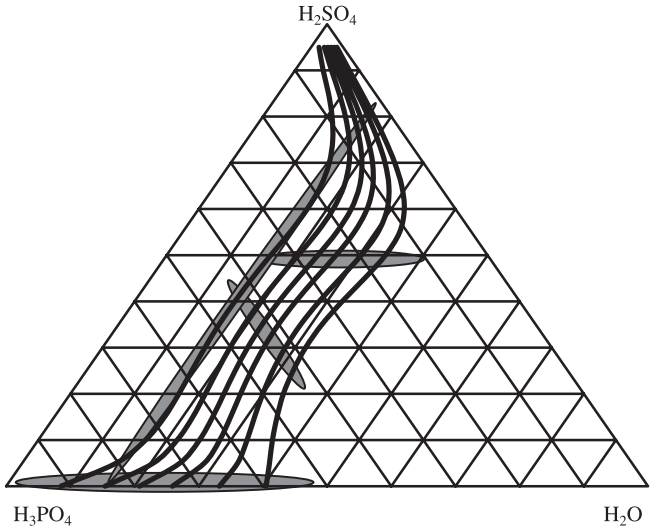
To obtain an analytical and graphical representation of the variation of α with solvent composition for the H_3PO_4 – H_2SO_4 – H_2O mixtures, the experimental values for α were fitted using a non-linear least-squares approach to equations of the form:

$$[16] \quad K_{app} = \frac{\alpha}{1-\alpha}\frac{x(H_2O)}{x(H_3PO_4)}$$

with

$$[17] \quad \ln K_{app} = P_1 w_P(1 + S_{11}w_S + S_{12}w_S^2) + P_2 w_P^2(1 + S_{21}w_S + S_{22}w_S^2)$$

and with w_P and w_S being the wt% of phosphoric and sulphuric acids in the ternary solvent mixture, respectively. The optimal values for the fitting parameters are shown in Table 1.



There is no particular theoretical reason for choosing the previously mentioned equations, which are simply convenient representations of the data. With the addition of extra terms, slightly improved fits can be obtained. Figure 5 shows the triangular contour plot from the fit. Whilst the accuracy of the fit may be doubtful in the solvent region that is low in both H_2O and H_3PO_4 (i.e., the H_2SO_4 apex), the form of the graph is unmistakable. Formation of MFP is determined most strongly by the water content of the solution: the lower the water content, the larger the formation of MFP. Quite remarkably, this is a much stronger determinant than the phosphoric acid content of the solution. Thus, we conclude that, as in the case of the binary solvent mixture H_3PO_4 – H_2O, the reaction is being driven by the strong ability of sulphuric acid to depress the thermodynamic activity of water. From the water-activity data for the simple binary mixture H_2SO_4 – H_2O (12), we obtain a value of –24.3 for 2A.[6] This is, of course, simply a manifestation of the strong dehydrating ability of this acid. This effect is used to advantage in many chemical processes such as the production of concentrated nitric acid (13). HNO_3 – H_2O mixtures form an azeotrope, and thus the acid cannot be concentrated by simple distillation. It is concentrated by extractive distillation using concentrated sulphuric acid. It is interesting to note that phosphoric acid has also been suggested as an extractive distillation agent to concentrate nitric acid. (14).

Table 1. Fitting parameters for the determination of α in H_3PO_4 – H_2SO_4 – H_2O mixtures from eqs. [11] and [12].

P_1	-9.298×10^{-2}
P_2	1.298×10^{-3}
S_{11}	1.189×10^{-1}
S_{12}	-2.473×10^{-3}
S_{21}	1.529×10^{-1}
S_{22}	-1.753×10^{-3}

Note: The fit included 65 data points (as shown in Figs. 2 and 4). The standard deviation between observed and calculated points is 0.04.

Fig. 5. A triangular graph that shows contour plot of the fraction α of MFP formed in H_3PO_4 – H_2SO_4 – H_2O mixtures (see text for details). Moving from left to right across the figure, the contours represent fractions of 0.95, 0.8, 0.6, 0,4, 0.2, and 0.1. The ellipses represent the composition regions where the measurements were taken.

Acknowledgements

We acknowledge helpful discussions with Mr. Ken Larlee of Agrium Inc. (Redwater, AB) and with all of the members

[5] Vapor-pressure data are probably not extensive enough to justify including higher-fitting terms to this equation. Including these terms does not make a significant difference to the results given here.

[6] To get a good fit, it is necessary to take into account that for the first deprotonation step, sulfuric acid is strong; thus, we define the mole fraction of water as $x_w = n_w/(n_w + 2n_s)$ where n is the number of moles of i, and i is water or sulfuric acid.

An efficient synthesis of carboxaldehyde derivatives of 4*H*-pyran-4-one

Reza Teimuri-mofrad and Fatemeh Abrishami

Abstract: We developed a general method for the synthesis of various 2-mono- and 2,6-di-carboxaldehyde substituted derivatives of 3,5-diphenyl-4*H*-pyran-4-one and 4*H*-pyran-4-one. 3,5-Diphenyl-6-methyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**4a**), 6-methyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**4b**), 3,5-diphenyl-4-oxo-4*H*-pyran-2,6-dicarboxaldehyde (**5a**), 4-oxo-4*H*-pyran-2,6-dicarboxaldehyde (**5b**), 3,5-diphenyl-6-hydroxymethyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**10a**), and 6-hydroxymethyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**10b**) were obtained from the corresponding di-, tri-, and tetra-bromo derivatives of 2,6-dimethyl-3,5-diphenyl-4*H*-pyran-4-one (**1a**) and 2,6-dimethyl-4*H*-pyran-4-one (**1b**) by treatment with silver acetate followed by hydrolysis. Compounds **4a** and **4b** were also obtained by the oxidation of **10a** and **10b** with barium manganate.

Key words: 4*H*-pyran-4-one, hydroxymethyl and carboxaldehyde derivatives, acetoxylation, hydrolysis, oxidation.

Résumé : On a développé une méthode de synthèse générale pour divers 2-mono- et 2,6-di-carboxaldéhydes dérivés de la 3,5-diphényl-4*H*-pyran-4-one et la 4*H*-pyran-4-one. On a ainsi préparé la 3,5-diphényl-6-méthyl-4-oxo-4*H*-pyrane-2-carboxaldéhyde (**4a**), la 6-méthyl-4-oxo-4*H*-pyrane-2-carboxaldéhyde (**4b**), la 3,5-diphényl-4-oxo-4*H*-pyrane-2,6-dicarboxaldéhyde (**5a**), la 4-oxo-4*H*-pyrane-2,6-dicarboxaldéhyde (**5b**), la 3,5-diphényl-6-hydroxyméthyl-4-oxo-4*H*-pyrane-2-carboxaldéhyde (**10a**) et la 6-hydroxyméthyl-4-oxo-4*H*-pyrane-2-carboxaldéhyde (**10b**) en soumettant les dérivés di-, tri- et tétra-bromés correspondants de la 2,6-diméthyl-3,5-diphényl-4*H*-pyran-4-one (**1a**) et de la 2,6-diméthyl-4*H*-pyran-4-one (**1b**) à un traitement par de l'acétate d'argent suivi par une hydrolyse. Les composés **4a** et **4b** ont aussi été obtenus par oxydation des produits **10a** et **10b** par le manganate de baryum.

Mots-clés : 4*H*-pyran-4-one, dérivés hydroxyméthyles et carboxaldéhydes, acétoxylation, hydrolyse, oxydation.

[Traduit par la Rédaction]

Introduction

4*H*-Pyran-4-one and its derivatives have been the subject of intensive research because of their importance in various applications and their widespread biological significance (1–3). They are widely distributed in nature (4–6), and consequently, have become accessible in laboratories by a variety of synthetic methods (7–9). These compounds are useful as fungicides, herbicides, and in the treatment of hypersensitivity conditions, such as asthma and allergies (10, 11).

Functionalized heterocycles are often used for the synthesis of the target organic compounds. Some 4*H*-pyran-4-ones, containing a carboxaldehyde group, may be prepared by the oxidation of hydroxymethyl group in derivatives of kojic acid (12–14) and by the formylation of pyrones in the presence of trifluoroacetic acid (15). Recently, Ghandi and co-workers prepared some mono- and di-carboxaldehyde derivatives of 4*H*-pyran-4-one, substituted at positions 2 and 6 by the condensation of mono- and dimethyl derivatives of 4*H*-pyran-4-one with benzaldehyde, followed by the oxidation of the corresponding mono- and di-styryl derivatives in the presence of osmium tetroxide and potassium periodate (Scheme 1) (16).

It is important to explore an efficient method for the synthesis of carboxaldehyde derivatives of 4*H*-pyran-4-ones because these compounds are potentially useful and carry out a wide range of reactions that would make them suitable for the synthesis of a number of 4*H*-pyran-4-one derivatives. For example, host macrocycles, such as azacrown ethers, could be obtained from their dicarboxaldehyde derivatives.

We report a novel method for the synthesis of mono- and di-carboxaldehyde derivatives of 4*H*-pyran-4-one, substituted at positions 2 and 6, from the acetoxylation and hydrolysis of the corresponding di-, tri-, and tetra-bromo derivatives of 4*H*-pyran-4-one.

Results and discussion

2-Dibromomethyl-6-methyl-4*H*-pyran-4-one (**6b**), 6-bromomethyl-2-dibromomethyl-4*H*-pyran-4-one (**7b**), 2,6-bis(dibromomethyl)-4*H*-pyran-4-one (**8b**), and 3,5-dibromo-2,6-bis(dibromomethyl)-4*H*-pyran-4-one (**8c**) were first prepared in 1997 by Lowe and co-workers through the bromination of 2,6-dimethyl-4*H*-pyran-4-one (**1b**) with 2.1 equiv. of *N*-bromosuccinimide in 10%, 3.1%, 3.4%, and 0.3% yields, respectively, (17). As a result, we tried to synthesize 2-dibromomethyl-3,5-diphenyl-6-methyl-4*H*-pyran-

Scheme 1. (*i*) PhCHO, NaOMe, 1,4-Dioxane; (*ii*) OsO_4, KIO_4.

4-one (**6a**), 6-bromomethyl-2-dibromomethyl-3,5-diphenyl-4*H*-pyran-4-one (**7a**), and 2,6-bis(dibromomethyl)-3,5-diphenyl-4*H*-pyran-4-one (**8a**) from 2,6-dimethyl-3,5-diphenyl-4*H*-pyran-4-one (**1a**) by means of Wohl–Ziegler bromination (18, 19). Bromination of **1a** with 5 equiv. of *N*-bromosuccinimide in the presence of dibenzoyl peroxide in tetrachloromethane produced a mixture of **6a**, **7a**, and **8a**, as major products, and other minor products. The crude product was chromatographed on silica gel and eluted with ethyl acetate – petroleum ether (1:9) to yield **8a**, **7a**, and **6a** as the first, second, and third fractions in 43%, 32%, and 17% yields, respectively. The mixture of other minor products was obtained as the fourth fraction (Scheme 2).

As a second result, we attempted to synthesize **6b**, **7b**, and **8b**, in accordance with Lowe and co-workers report (17), by means of Wohl–Ziegler bromination in the presence of excess *N*-bromosuccinimide. Since Lowe and co-workers were looking to obtain 2,6-bis(bromomethyl)-4*H*-pyran-4-one, they merely used 2.1 equiv. of *N*-bromosuccinimide, but they further got **6b**, **7b**, and **8b** as well. Therefore, to increase the yields of compounds **6b**, **7b**, and **8b**, we tried to use excess amount of *N*-bromosuccinimide, longer reaction time, and sun lamps during the reaction. Bromination of **1b** (20) with 8 equiv. of *N*-bromosuccinimide in presence of dibenzoyl peroxide in tetrachloromethane under radiation of IR lamps produced a mixture of **6b**, **7b**, and **8b**, as major products, and other minor products. The crude product was chromatographed on silica gel and eluted with ethyl acetate – petroleum ether (4:1). The first fraction was **8c** in 0.8% yield, which was produced from further bromination of the nuclear 4*H*-pyran-4-one positions in **8b** (17). The compounds **8b**, **7b**, and **6b** were obtained as the second, third, and fourth fractions in 31%, 23%, and 9% yields, respectively. Additionally, the mixture of other minor products was afforded as the fifth fraction (Scheme 2).

Treatment of **6a**, **7a**, and **8a** with silver acetate in refluxing glacial acetic acid, followed by the reaction with aq. acetic acid (21), produced 2-mono- and 2,6-di-carboxaldehyde derivatives of 3,5-diphenyl-4*H*-pyran-4-one, 6-methyl-3,5-diphenyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**4a**), 6-acethoxymethyl-3,5-diphenyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**9a**), and 3,5-diphenyl-4-oxo-4*H*-pyran-2,6-dicarboxaldehyde (**5a**) in 86%, 71%, and 75% yields, respectively. Under the same conditions, **6b**, **7b**, and **8b** produced 2-mono- and 2,6-di-carboxaldehyde derivatives of 4*H*-pyran-4-one, 6-methyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**4b**), 6-acethoxymethyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**9b**), and 4-oxo-4*H*-pyran-2,6-dicarboxaldehyde (**5b**) in 73%, 66%, and 70% yields, respectively.

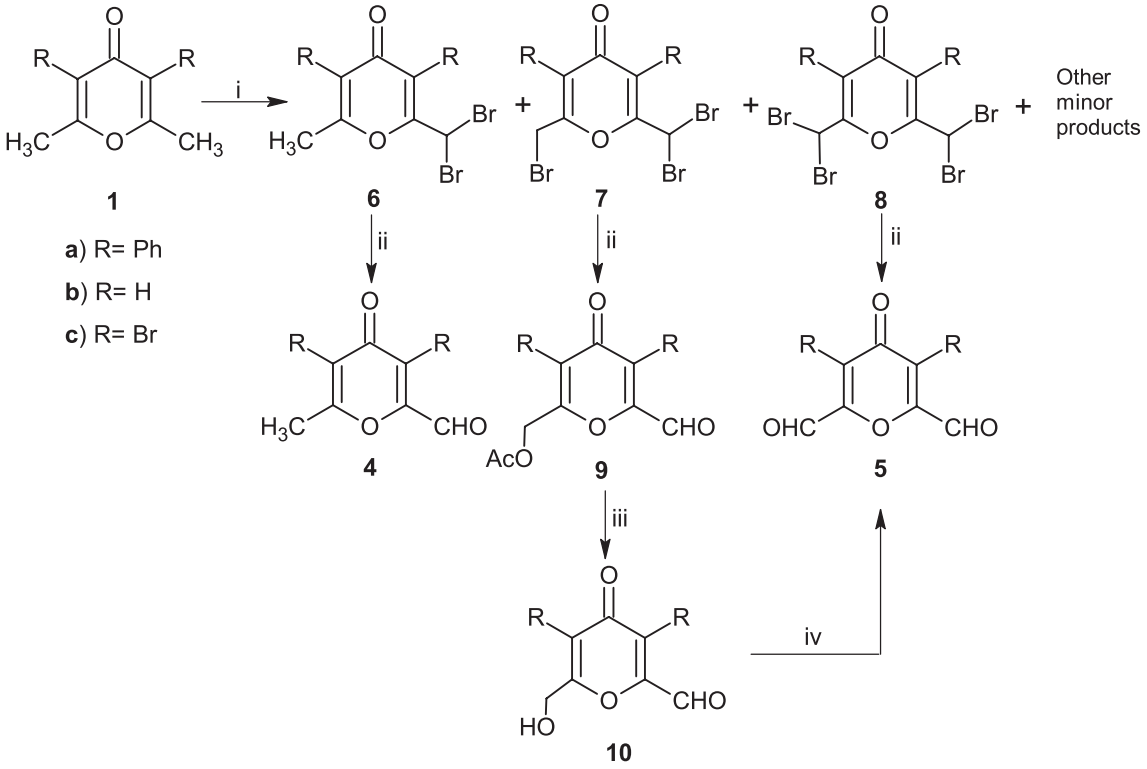
Acidic hydrolysis (hydrochloric acid, water, tetrahydrofuran) of **9a** and **9b** produced 3,5-diphenyl-6-hydroxymethyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**10a**) and 6-hydroxymethyl-4-oxo-4*H*-pyran-2-carboxaldehyde (**10b**) in 89% and 81% yields, respectively.

In addition, we decided to oxidize the monohydroxymethyl derivatives of 4*H*-pyran-4-one, **10a** and **10b**, to the corresponding dicarboxaldehyde derivatives, **5a** and **5b**, with barium manganate in dichloromethane and tetrahydrofuran at room temperature. Compounds **5a** and **5b** were obtained in 91% and 82% yields, respectively, (Scheme 2).

The data obtained from Mass spectrometry, IR, ^{1}H and ^{13}C NMR spectra, and elemental analyses are fully consistent with the proposed structures.

In conclusion, we developed a new efficient method for the preparation of mono- and di-carboxaldehyde derivatives of 3,5-diphenyl-4*H*-pyran-4-one and 4*H*-pyran-4-one, substituted at positions 2 and 6, resulting in the compounds **4a**, **4b**, **5a**, **5b**, **9a**, **9b**, **10a**, and **10b**. Our method offers some advantages over the previous one. For instance, it uses cheaper reagent and has higher total yields. Some of these compounds can be used as precursors to synthesize the host molecules. This work is now under investigation.

Experimental



Melting points were determined with an Electrothermal Instrument model 9100 and are uncorrected. IR spectra were run on a Shimadzu FTIR-4300 Spectrophotometer as KBr disks or as smears between salt plates. The ^{1}H and ^{13}C NMR spectra were recorded on a FT-NMR Bruker 300 MHz spectrometer. Chemical shifts (δ) were reported in ppm using TMS as internal standard. Mass spectra were recorded on a Shimadzu MS-QP 1100 EX mass spectrometer. Elemental analyses were performed on a Heareus, CHN-O-RAPID, analyzer.

Reaction of 1a with excessive *N*-bromosuccinimide — Synthesis of di-, tri-, and tetra-bromo derivatives 6a, 7a, and 8a

2,6-Dimethyl-3,5-diphenyl-4*H*-pyran-4-one (**1a**) was prepared according to a published procedure (18). A mixture of **1a** (5.52 g, 0.02 mol), *N*-bromosuccinimide (17.8 g, 0.1 mol), and dibenzoyl peroxide (0.4 g) in tetrachloromethane (60 mL) was refluxed for 96 h. After cooling, the reaction mixture was filtered. The filtrate was concentrated in vacuum, and then dichloromethane (150 mL) was added to the residue. The mixture was washed with several portions of satd. sodium hydrogen carbonate and then water (3 × 50 mL). The organic layer was dried over magnesium sulfate and concentrated in vacuum. The resulting solid was purified by column chromatography on silica gel with ethyl acetate – petroleum ether (1:9) as eluent. Compounds **6a, 7a**, and **8a** were obtained as major products in 0.4:0.74:1 molar ratio, respectively. Specific details are given for each compound.

Reaction of 1b with excessive *N*-bromosuccinimide — Synthesis of di-, tri- and tetra-bromo derivatives 6b, 7b, and 8b

2,6-Dimethyl-4*H*-pyran-4-one (**1b**) was prepared according to a published procedure (20). A mixture of **1b** (2.48 g, 0.02 mol), *N*-bromosuccinimide (28.48 g, 0.16 mol), and dibenzoyl peroxide (0.5 g) in tetrachloromethane (80 mL) was refluxed under the radiation of IR lamps for 96 h. After cooling, the reaction mixture was filtered. The filtrate was concentrated in vacuum, and then dichloromethane (180 mL) was added to the residue. The mixture was washed with several portions of satd. sodium hydrogen carbonate and then water (3 × 50 mL). The organic layer was dried over magnesium sulfate and concentrated in vacuum. The resulting solid was purified by column chromatography on silica gel with ethyl acetate – petroleum ether (4:1) as eluent. Compounds **6b**, **7b**, **8b**, and **8c** were obtained in 0.29:0.74:1:0.026 molar ratio, respectively. Specific details are given for each compound.

*2-Dibromomethyl-6-methyl-4*H*-pyran-4-one (6b)*

Light-yellow crystals (0.51 g, 9%); mp 131.2–132.8 °C (lit. 132 °C) (17). IR υ (cm^{-1}): 1248, 1655. ^1H NMR (DMSO-d_6): 2.36 (3H, s, $–CH_3$), 6.28 (1H, s, $–CHBr_2$), 6.37

Reaction of 6a, 7a, and 8a with silver acetate — Synthesis of 4a, 9a, and 5a

A mixture of **6a** (3 mmol), **7a** (2 mmol) or **8a** (1.5 mmol), and silver acetate (1.17 g, 6.9 mmol) in glacial acetic acid (20 mL) was refluxed for 16 h. After cooling, the mixture was filtered, and the precipitate was washed with dichloromethane (30 mL). Then, cold water (30 mL) was added to the filtrate, and the mixture was stirred and separated. The aqueous layer was extracted with dichloromethane (2 × 20 mL). The combined organic layer was washed with cold water (4 × 20 mL) and then concentrated in vacuum. A solution of acetic acid (20 mL) and water (20 mL) was added to the residue. The mixture was refluxed for 3 h and then concentrated in reduced pressure. Dichloromethane (30 mL) was added to the residue, and the mixture was washed with water (3 × 20 mL). Organic layer was dried over magnesium sulfate, and the solvent was evaporated in vacuum. Specific details are given for each compound.

3,5-Diphenyl-6-methyl-4-oxo-4*H*-pyran-2-carboxaldehyde (4a)

From 1.3 g of **6a**, pale-yellow crystals (0.75 g, 86%) were obtained; mp 188.6–189.7 °C (lit. 189.6 °C) (16). IR υ (cm^{-1}): 800, 980, 1260, 1640, 1700, 2820, 2920, 3010. ^{1}H NMR ($CDCl_3$): 2.40 (3H, s, –CH_3), 7.40 (10H, m, phenyl H), 9.80 (1H, s, –CHO). ^{13}C NMR ($CDCl_3$): 21.1 (–CH_3), 128.3, 128.6, 130.2, 132.0, and 133.0 (phenyl C), 134.5 (pyran C-5), 138.9 (pyran C-3), 149.0 (pyran C-6), 153.0 (pyran C-2), 183.9 (pyran C-4), 202.0 (–CHO). Reaction of 6b, 7b, and 8b with silver acetate — Synthesis of 4b, 9b, and 5b

A mixture of **6b** (1.5 mmol), **7b** (1 mmol) or **8b** (0.75 mmol), and silver acetate (0.585 g, 3.45 mmol) in glacial acetic acid (10 mL) was refluxed for 16 h. After cooling, the mixture was filtered, and the precipitate was washed with dichloromethane (40 mL). Then, cold water (20 mL) was added to the filtrate, and the mixture was stirred and separated. The aqueous layer was concentrated under reduced pressure, and the residue, after complete drying, was extracted with dichloromethane (3 × 20 mL). The combined organic layer was washed with cold aqueous solution of satd. sodium chloride (2 × 5 mL) and concentrated in vacuum. A solution of acetic acid (10 mL) and water (10 mL) was added to the residue. The mixture was refluxed for 4 h and then concentrated in reduced pressure. The residue, after complete drying, was extracted with acetone (3 × 10 mL). The combined organic solution was concentrated in vacuum after drying over sodium sulfate. Specific details are given for each compound.

6-Methyl-4-oxo-4*H*-pyran-2-carboxaldehyde (4b)

From 0.42 g of **6b**, white crystals (0.15 g, 73%) were obtained; mp 117.9–118.6 °C (lit. 118.4 °C) (16). IR υ (cm^{-1}): 1285, 1560, 1640, 1710, 2990. ^{1}H NMR ($CDCl_3$): 2.40 (3H, s, –CH_3), 6.30 (1H, s, pyran CH-3), 6.65 (1H, s, pyran CH-5), 9.65 (1H, s, –CHO). ^{13}C NMR ($CDCl_3$): 20.5 (–CH_3), 118.0 (pyran C-5), 121.5 (pyran C-3), 157.2 (pyran C-6), 168.0 (pyran C-2), 179.1 (pyran C-4), 187.0 (–CHO). 4-Oxo-4H-pyran-2,6-dicarboxaldehyde (5b)

From 0.33 g of **8b**, yellow oil (0.08 g, 70%) was obtained. IR υ (cm^{-1}): 1100, 1280, 1425, 1615, 1675, 1720, 3010. ^1H NMR (acetone-d_6): 7.05 (2H, s, pyran CH-3,-5), 9.75 (2H, s, –CHO). ^{13}C NMR (acetone-d_6): 123.5 (pyran C-3,-5), 168.0 (pyran C-2,-6), 181.0 (pyran C-4), 188.0 (–CHO). MS *m/z*: 152 [M^+]. Anal. calcd. for $C_7H_4O_4$ (152.105) %: C 55.28, H 2.65; found: C 55.19, H 2.73.

6-Acethoxymethyl-4-oxo-4H-pyran-2-carboxaldehyde (9b)

From 0.36 g of **7b**, colorless oil (0.13 g, 66%) was obtained. IR υ (cm^{-1}): 1635, 1705, 1750, 2990. ^1H NMR ($CDCl_3$): 2.10 (3H, s, $–OOCCH_3$), 4.90 (2H, s, $–CH_2O–$), 6.32 (1H, s, pyran CH-3), 6.62 (1H, s, pyran CH-5), 9.68 (1H, s, –CHO). ^{13}C NMR ($CDCl_3$): 20.0 ($–OOCCH_3$), 61.9 ($–CH_2OOC–$), 118.5 (pyran C-5), 122.1 (pyran C-3), 158.0 (pyran C-6), 167.2 (pyran C-2), 180.1 (pyran C-4), 188.2 (–CHO). MS *m/z*: 196 [M^+]. Anal. calcd. for $C_9H_8O_5$ (196.157) %: C 55.11, H 4.11; found: C 54.99, H 4.0.

3,5-Diphenyl-6-hydroxymethyl-4-oxo-4H-pyran-2-carboxaldehyde (10a)

A mixture of **9a** (0.435 g, 1.25 mmol), tetrahydrofuran (6 mL), water (3 mL), and concentrated hydrochloric acid (0.1 mL) was refluxed for 15 h. The mixture was concentrated under reduced pressure, and then water (5 mL) was added to the residue. The mixture was extracted with dichloromethane (3 × 10 mL), and the combined organic layer was washed with water (3 × 10 mL), dried over magnesium sulfate, and the solvent was distilled under reduced pressure. Pale-brown crystals (0.34 g, 89%) were obtained; mp 215.1–216.5 °C. IR υ (cm^{-1}): 1648, 1700, 3439 (br). ^1H NMR ($CDCl_3$): 2.60 (1H, br, $–CH_2OH$), 4.46 (2H, s, $–CH_2OH$), 7.25–7.50 (10H, m, phenyl H), 9.58(1H, s, –CHO). MS *m/z*: 306 [M^+]. Anal. calcd. for $C_{19}H_{14}O_4$ (306.316) %: C 74.50, H 4.61; found: C 73.91, H 4.71.

6-Hydroxymethyl-4-oxo-4H-pyran-2-carboxaldehyde (10b)

A mixture of **9b** (0.118 g, 0.6 mmol), tetrahydrofuran (3 mL), water (1.5 mL), and concentrated hydrochloric acid (0.05 mL) was refluxed for 15 h. The mixture was concentrated under reduced pressure and the residue, after complete drying, was extracted with acetone (3 × 10 mL). The combined organic solution was concentrated in vacuum after drying over magnesium sulfate. Colorless oil (0.075 g, 81%) was obtained. IR υ (cm^{-1}): 1642, 1705, 3450 (br). ^1H NMR (DMSO-d_6): 2.95 (1H, br, $–CH_2OH$), 4.49 (2H, s, $–CH_2OH$), 6.35 (1H, s, pyran CH-3), 6.68 (1H, s, pyran CH-5), 9.63 (1H, s, –CHO). MS *m/z*: 154 [M^+]. Anal. calcd. for $C_7H_6O_4$ (154.120) %: C 54.55, H 3.92; found: C 53.89, H 3.99.

Oxidation of 10a and 10b with barium manganate — Synthesis of 5a and 5b

The fine powder of barium manganate (0.84 g) was added immediately to a stirred solution of **10a** or **10b** (0.3 mmol) in dichloromethane–tetrahydrofuran (1:1) (6 mL). The mixture was stirred at room temperature for 2 h. Inorganic byproducts were removed by filtration of the reaction mixture through Celite. The Celite was washed with dichloromethane, and the latter solution was added to the previously obtained dichloromethane–tetrahydrofuran filtrate. Evaporation of dichloromethane–tetrahydrofuran in vacuum gave a pale-yellow residue. Specific details are given for each compound.

Compound 5a

From 0.092 g of **10a**, 0.09 g pale-yellow residue was obtained, which recrystallized from ethylacetate and petroleum ether. Pale-yellow crystals (0.083 g, 91%) were obtained; mp 195.7–197.1 °C (lit. 196.9 °C) (16). The physical and spectral properties were identical to that of **5a** reported earlier.

Compound 5b

From 0.046 g of **10b**, pale-yellow oil (0.037 g, 82%) was obtained. The physical and spectral properties were identical to that of **5b** reported earlier.

Solvent effects on the reactions of copper chlorides with $OP(NH\text{-}t\text{-}Bu)_3$ — Formation of the novel $[Cu_5Cl_{10}]^{5-}$ anion via in situ templation

Zhiyong Fu and Tristram Chivers

Abstract: X-ray structural investigations have shown that the products of the reaction of $CuCl_2{\cdot}2H_2O$ and $OP[NH\text{-}t\text{-}Bu]_3$ are markedly dependent on solvent and temperature. The polymeric ionic complex $[(t\text{-}BuNH_3)_2(Cu_3(OH)(H_2O)Cl_7)]_\infty$ (**1**), containing a trinuclear anionic repeating unit, is obtained from toluene at 80 °C, whereas the 2:1 adduct $Cu(t\text{-}BuNH_2)_2Cl_2$ (**4**) is formed at 150 °C. By contrast, a neutral tetranuclear cluster $Cu_4[PO(NH\text{-}t\text{-}Bu)_3]_4(\mu_4\text{-}O)Cl_6$ (**2**) or the one-dimensional chain $[Cu(Py)_2Cl_2]_\infty$ (**3**) is produced when the reaction is carried out in hexane or pyridine, respectively, at 80 °C. The reaction of a mixture of CuCl and $CuCl_2{\cdot}2H_2O$ (2:1 molar ratio) with $OP[NH\text{-}t\text{-}Bu]_3$ at 80 °C in toluene produces $[t\text{-}BuNH_3]_5[Cu_5Cl_{10}]$ (**5**), in which the anion is a pentanuclear cluster with both terminal and bridging chloride ions. The removal of the chloride ions from the reaction mixture by the addition of $AgNO_3$ yields the 2:1 adduct $Cu[OP(NH\text{-}t\text{-}Bu)_3]_2(NO_3)_2$ (**6**).

Key words: copper halides, templation, P–N compounds, cluster complexes, one-dimensional framework

Résumé : Des études par diffraction des rayons X ont montré que les produits obtenus par réaction du $CuCl_2{\cdot}2H_2O$ et le $OP[NH\text{-}t\text{-}Bu]_3$ dépendent fortement du solvant et de la température. Le complexe ionique polymère $[(t\text{-}BuNH_3)_2(Cu_3(OH)(H_2O)Cl_7]_4$ (**1**) contenant une maille élémentaire anionique trinucléaire est obtenu à partir du toluène à 80 °C alors que l'adduit 2:1 $Cu(t\text{-}BuNH_2)_2Cl_2$ (**4**) est le produit qui se forme à 150 °C. Par opposition à ces résultats, lorsqu'on effectue les réactions dans l'hexane ou la pyridine à 80 °C, ce sont respectivement un agrégat tétranucléaire neutre de formule $Cu_4[PO(NH\text{-}t\text{-}Bu)_3]_4(\mu_4\text{-}O)Cl_6$ (**2**) et la chaîne unidimensionnelle $[Cu(Py)_2Cl_2]_4$ (**3**) qui se forment. La réaction d'un mélange de CuCl et de $CuCl_2{\cdot}2H_2O$ (rapport molaire de 2:1) avec le $OP[NH\text{-}t\text{-}Bu]_3$, à 80 °C dans le toluène, conduit à la formation de $[t\text{-}BuNH_3]_5[Cu_5Cl_{10}]$ (**5**) dans lequel l'anion est un agrégat pentanucléaire dans lequel les anions terminaux et formant le pont sont des chlorures. L'élimination des ions chlorures du mélange réactionnel par addition de $AgNO_3$ conduit à la formation de l'adduit 2:1 $Cu[OP(NH\text{-}t\text{-}Bu)_3]_2(NO_3)_2$ (**6**).

Mots-clés : halogénures de cuivre, formation de maquette, composés P–N, complexes agrégés, squelette unidimensionnel.

Introduction

The direct addition of organic ammonium cations to a reaction mixture (known as templation) is a common technique for the syntheses of inorganic materials with new structural motifs in either hydrothermal or solvothermal processes (1, 2). A variety of factors including the length, structure, and conformation of the cation, as well as interactions with the counter-anions, play important roles in determining the structures and properties of the inorganic materials formed in this way (3–21). Although facile P–N bond cleavage is an impediment in the preparation of metal imidophosphates (22, 23), this liability provides an opportunity to generate novel inorganic compounds by an in situ templation approach (24–27). Recently, it has been demonstrated through the use of P–N compounds as sources of amines or organic ammonium cations that this strategy produces materials that are structurally different from those obtained by the direct templation method. Neeraj and Cheetham (24) obtained two new zinc phosphates, $[Me_2NH_2][Zn_3(PO_4)(HPO_4)_2]{\cdot}H_2O$ and $[(Me_2NH_2)(H_3O)][Zn_4(PO_4)_3(H_2O)]_2{\cdot}H_2O$, by using hexamethylphosphoramide $OP(NMe_2)_3$ as an in situ source of both amine and phosphoric acid under hydrothermal conditions at 180 °C. More recently, we have shown that *n*-propylimidodiphosphonic anhydride $[O(OH)P(\mu\text{-}O)PO(OH)(\mu\text{-}N\text{-}n\text{-}Pr)]_2{\cdot}2NH_2\text{-}n\text{-}Pr$, which contains an eight-membered $P_4N_2O_2$ ring, provides a source of phosphate under either hydrothermal or solvothermal conditions (25). The primary amine $n\text{-}PrNH_2$ or the alkylammonium cation $[n\text{-}PrNH_3]^+$ formed as a result of P–N bond cleavage may function as a pH controller or as a structure-directing agent, respectively, in the formation of zinc phosphates.

The application of in situ templation has also furnished novel results for copper halide systems (26, 27). For example, the concurrent release of the templating cation $[RNH_3]^+$ and chloride ions via in situ P–N and P–Cl bond cleavage in the precursors $Cl_3P{=}NR$ results in new copper chloride complexes, which cannot be produced by direct templation (26).

More significantly, the use of OP(NH-*t*-Bu)$_3$ as an in situ source of [*t*-BuNH$_3$]$^+$ generates the novel copper halide chain {[Cu$_3$(OH)(H$_2$O)Cl$_7$]$^{2-}$}$_\infty$ (**1**), which contains an antiferromagnetically coupled trinuclear fragment (27). Identification of the other products of this solvothermal process demonstrated that, in addition to providing a source of [*t*-BuNH$_3$]$^+$, the tris(alkylamido)phosphate OP(NH-*t*-Bu)$_3$ serves as a proton acceptor to adjust the pH value of the reaction medium (27).

These examples indicate that the use of P–N compounds as precursors for in situ templation is a potentially versatile method for the preparation of new inorganic materials. In hydrothermal processes it is well established that the formation of anionic networks is kinetically controlled and highly sensitive to reaction conditions (24). Thus, it can be anticipated that the variation of reaction conditions will affect the outcome of the in situ templation processes. Systematic studies of this new approach may provide insights into the reaction pathways. In this contribution we have investigated the influence of solvent and the addition of M$^+$ ions (M = Cu, Ag) on the outcome of the reaction of CuCl$_2$·2H$_2$O and OP(NH-*t*-Bu)$_3$. Six different copper complexes were obtained under a variety of solvothermal reaction conditions and their structures have been determined by X-ray crystallography.

Experimental section

Reagents and general procedures

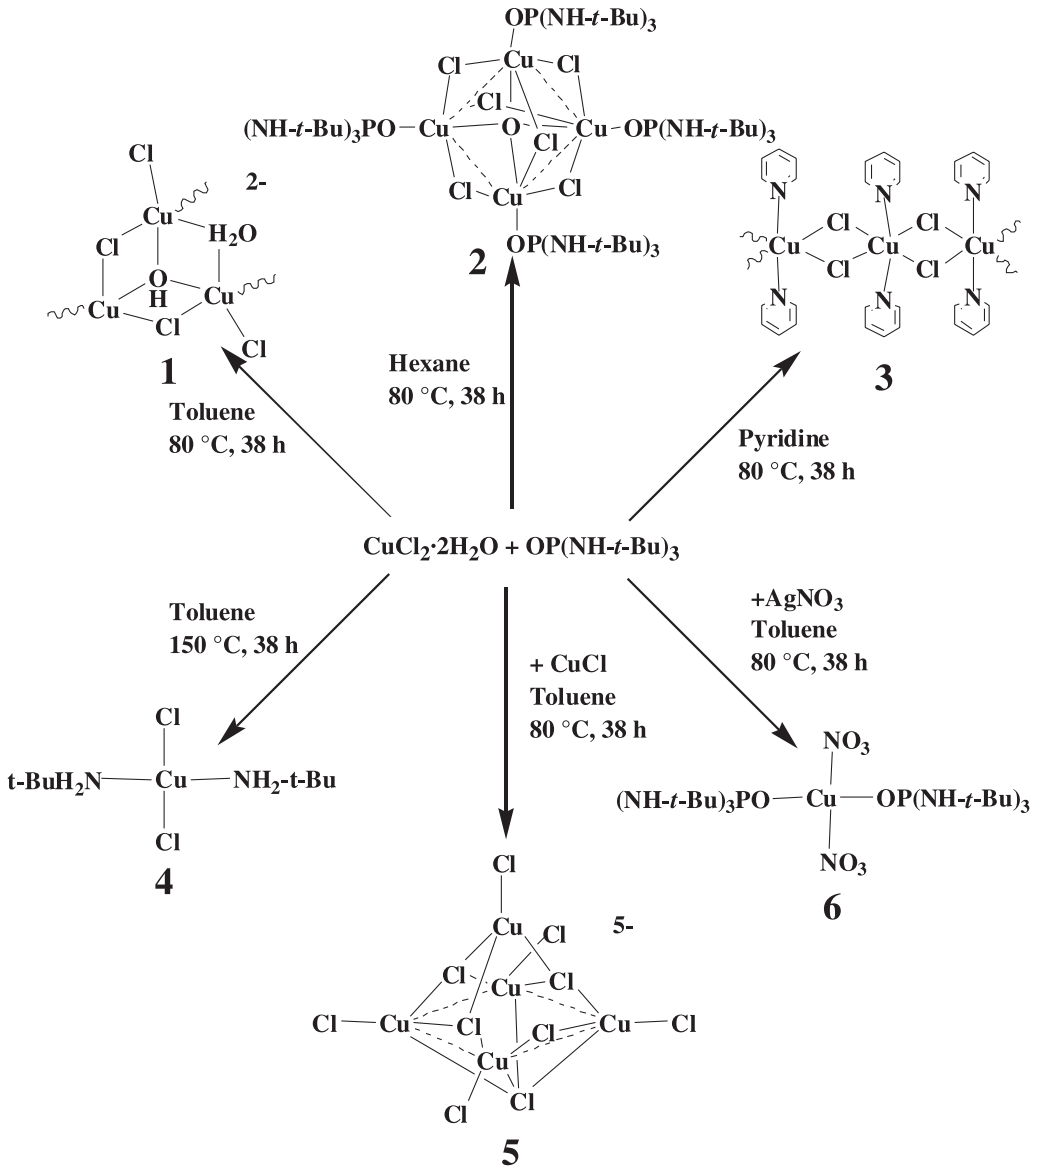
The reagent OP(NH-*t*-Bu)$_3$ was prepared according to the literature procedure (28). Toluene, hexane, pyridine, CuCl$_2$·2H$_2$O, and CuCl were used as received. IR spectra were recorded as NaCl pellets on a Nicolet Nexus 470 FTIR spectrometer in the range 4000–350 cm^{-1}. Elemental analyses were obtained with a Control Equipment Corporation model 440 instrument by the Analytical Services Laboratory, Department of Chemistry, University of Calgary and by the Analytical Services of Fujian Institute of Research on the Structure of Matter, China.

All syntheses were carried out in a sealed 23 mL polytetrafluoroethylene-lined Parr acid digestion vessel. The vessel was allowed to cool to room temperature upon completion of the reaction before isolation of the products.

Preparation of {[*t*-BuNH$_3$]$_2$[Cu$_3$(OH)(H$_2$O)Cl$_7$]}$_\infty$ (1)

A mixture of CuCl$_2$·2H$_2$O (0.170 g, 1.00 mmol) and OP[NH-*t*-Bu]$_3$ (0.263 g, 1.00 mmol) in toluene (10 mL) was heated at 80 °C for 38 h. Yellow platelike crystals of **1** were obtained (0.093 g, 45%). IR (cm^{-1}) ν: 3515 [O – H], 3123 [N – H]. Anal. calcd. for C$_8$H$_{27}$Cl$_7$Cu$_3$N$_2$O$_2$: C 15.45, H 4.38, N 4.50; found: C 16.12, H 4.10, N 4.86.

Preparation of Cu$_4$[PO(NH-*t*-Bu)$_3$]$_4$(μ$_4$-O)Cl$_6$ (2)



A mixture of CuCl$_2$·2H$_2$O (0.170 g, 1.00 mmol) and OP[NH-*t*-Bu]$_3$ (0.263 g, 1.00 mmol) in hexane (10 mL) was heated at 80 °C for 38 h. Yellow blocklike crystals of **2** were obtained (0.120 g, 31%). Anal. calcd. for C$_{48}$H$_{120}$Cl$_6$Cu$_4$N$_{12}$O$_5$P$_4$: C 37.53, H 7.87, N 10.94; found: C 37.93, H 7.62, N 10.51.

Preparation of [Cu(Py)$_2$Cl$_2$]$_\infty$ (3)

A mixture of CuCl$_2$·2H$_2$O (0.170 g, 1.00 mmol) and OP[NH-*t*-Bu]$_3$ (0.263 g, 1.00 mmol) in pyridine (10 mL) was heated at 80 °C for 38 h. Blue blocklike crystals of **3** were obtained (0.226 g, 77%). Anal. calcd. for

$C_{10}H_{10}Cl_2CuN_2$: C 41.04, H 3.44, N 9.57; found: C 41.52, H 3.26, N 10.05.

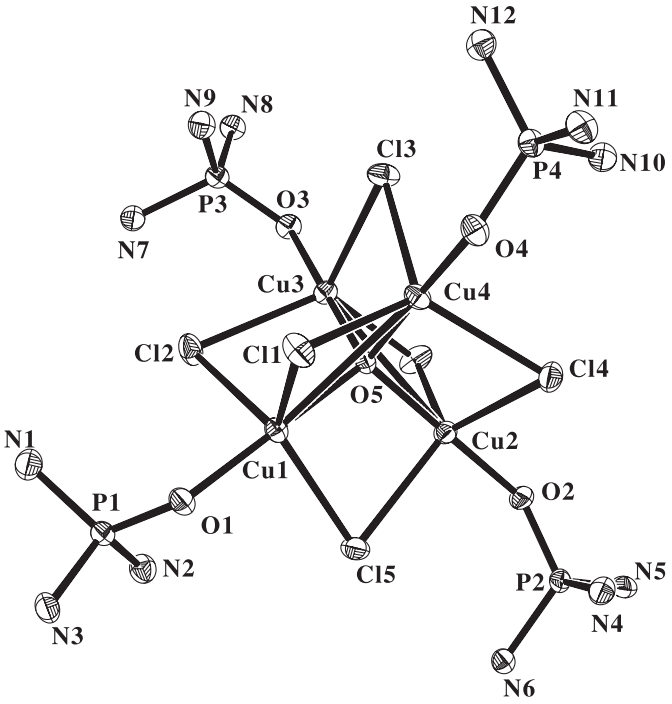
Preparation of $Cu(t\text{-}BuNH_2)_2Cl_2$ (4)

A mixture of $CuCl_2{\cdot}2H_2O$ (0.170 g, 1.00 mmol) and $OP[NH\text{-}t\text{-}Bu]_3$ (0.263 g, 1.00 mmol) in toluene (10 mL) was heated at 150 °C for 38 h. Blue blocklike crystals of **4** were obtained (0.207 g, 73%). Anal. calcd. for $C_8H_{22}Cl_2CuN_2$: C 34.23, H 7.90, N 9.98; found: C 34.39, H 7.96, N 9.85.

Preparation of $[t\text{-}BuNH_3]_5[Cu_5Cl_{10}]$ (5)

A mixture of $CuCl_2{\cdot}2H_2O$ (0.85 g, 0.500 mmol), CuCl (0.99 g, 1.00 mmol), and $OP[NH\text{-}t\text{-}Bu]_3$ (0.263 g, 1.00 mmol) in toluene (10 mL) was heated at 80 °C for 38 h. Colourless platelike crystals of **5** were obtained (0.090 g, 43%) by manual separation of **5** from the other products. Despite several attempts, satisfactory CHN analyses could not be obtained owing to the necessity to separate the crystals of **5** by hand. A few crystals of **1** were also isolated and identified by determination of unit cell dimensions.

Preparation of $Cu[OP(NH\text{-}t\text{-}Bu)_3]_2(NO_3)_2$ (6)



A mixture of $CuCl_2{\cdot}2H_2O$ (0.170 g, 1.00 mmol), $AgNO_3$ (0.340 g, 2.00 mmol), and $OP[NH\text{-}t\text{-}Bu]_3$ (0.263 g, 1.00 mmol) in toluene (10 mL) was heated to 80 °C for 38 h. Blue blocklike crystals of **6** were obtained (0.183 g, 51%). Anal. calcd. for $C_{24}H_{60}CuN_8O_8P_2$: C 40.36, H 8.47, N 15.69; found: C 39.97, H 8.31, N 15.47.

X-ray analyses

Suitable crystals of the complexes [**2**, yellow block (0.28 × 0.16 × 0.16 mm^3); **3**, blue block (0.20 × 0.16 × 0.16 mm^3) ; **4**, blue block (0.16 × 0.12 × 0.06 mm^3); **5**, colourless plate (0.24 × 0.1 × 0.06 mm^3); **6**, blue block (0.18 × 0.12 × 0.12 mm^3)] were selected, coated with oil (Paratone 8277, Exxon), and mounted on glass fibres. The measurements were made on a Nonius Kappa CCD diffractometer with

Fig. 1. Molecular structure of **2** (30% thermal ellipsoids); *tert*-butyl groups and hydrogen atoms attached to the nitrogen atoms have been omitted for clarity.

graphite-monochromated Mo Kα radiation. Data were collected at –100 °C, using the ω and ϕ scans to a maximum θ value of 25.03°, 25.02°, 25.01°, 25.03°, and 25.03° for **2**, **3**, **4**, **5**, and **6**, respectively. The unit cell parameters were calculated and refined from the full data sets. Crystal cell refinement and data reduction were carried out using the Nonius DENZO package. After data reduction, the data were corrected for absorption based on equivalent reflections using SCALEPACK (29). The structure was solved by direct methods (30) and refined by full-matrix least-squares methods with SHELXL-97 (31).

The Cu3 and Cl3 atoms in **5** were disordered over four positions with unequal site occupancy factors in an approximate ratio of 5.4:2:1.6:1; the Cl1 atom in **5** was disordered over two positions with unequal site occupancy factors in an approximate ratio of 9:1. All non-hydrogen atoms were treated anisotropically with the exception of the disordered atoms. All hydrogen atoms were included at geometrically idealized positions.

Crystallographic data for **2**, **4**, **5**, and **6** are summarized in Table 1.[3]

Results and discussion

In the solid state, tris(*tert*-butylamido)orthophosphate $OP(NH\text{-}t\text{-}Bu)_3$ adopts a one-dimensional chain structure in which individual molecules are connected by hydrogen bonds (28). Under solvothermal conditions with toluene as solvent this P–N compound does not decompose at 120 °C;

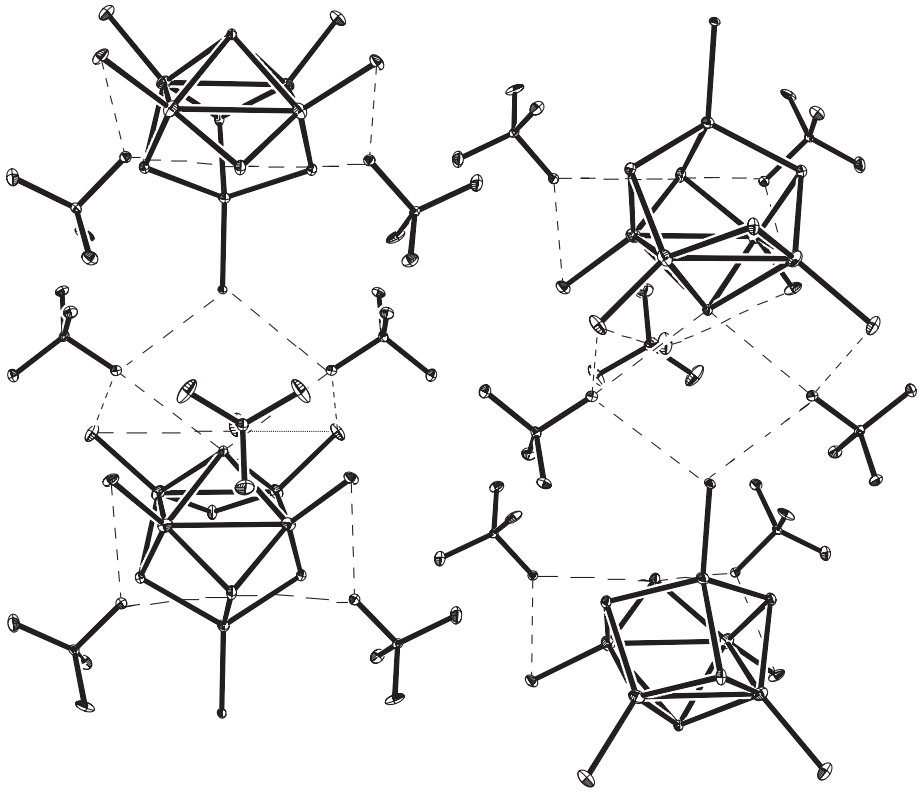
however, partial decomposition is observed upon heating at 150 °C for 38 h. The reaction of $CuCl_2 \cdot 2H_2O$ and OP(NH-*t*-Bu)$_3$ in a 1:1 molar ratio was carried out under different solvothermal conditions to evaluate the effect of (*i*) solvent and (*ii*) the addition of M^+ ions (M = Cu, Ag) on the nature of the products obtained. As indicated in Scheme 1, a variety of products are formed and their structures have been determined by single-crystal X-ray diffraction studies. Under certain conditions, P–N bond cleavage occurs with the release of *t*-BuNH$_2$ and the subsequent formation of [*t*-BuNH$_3$]$^+$ under the influence of HCl present in the reaction mixture. In other cases, the intact OP(NH-*t*-Bu)$_3$ ligand is observed in the reaction product.

Fig. 3. Molecular structure of the $[Cu_5Cl_{10}]^{5-}$ anion in **5** (30% thermal ellipsoids) showing the most important contributor to the disordered structure. Symmetry transformations used to generate equivalent atoms are $a = x, 3/2 - y, z$.

Effect of solvent



The reaction of $CuCl_2 \cdot 2H_2O$ and OP(NH-*t*-Bu)$_3$ in a 1:1 molar ratio was carried out in three different solvents, viz. toluene, hexane, and pyridine, under similar reaction conditions (80 °C, 38 h). In toluene, P–N bond cleavage takes place with the in situ formation of the templating cation [*t*-BuNH$_3$]$^+$, which directs the assembly of the copper halide chain $[Cu_3(\mu_3\text{-}OH)(\mu_2\text{-}H_2O)Cl_7]^{2-}\}_\infty$ (Scheme 1) (27). Interestingly, when the same reaction is carried out in toluene at 150 °C, the primary amine *t*-BuNH$_2$ formed by P–N bond cleavage is trapped by coordination to the Cu^{2+} centres to give the 2:1 adduct Cu(*t*-BuNH$_2$)$_2$Cl$_2$ (**4**), rather than by protons with the formation of [*t*-BuNH$_3$]$^+$.

By contrast, P–N bond scission is not observed when hexane is employed as the reaction medium. In this solvent at 80 °C, the major product is the oxo-centred tetranuclear cluster Cu$_4$[OP(NH-*t*-Bu)$_3$]$_4$(μ_4-O)Cl$_6$ (**2**), in which the four copper centres are each coordinated by an *O*-monodentate OP(NH-*t*-Bu)$_3$ ligand.

A third type of behaviour is observed when pyridine is used instead of a hydrocarbon solvent. In this case, the strongly coordinating solvent molecules replace the water ligands in $CuCl_2 \cdot 2H_2O$, resulting in the formation of the one-dimensional chain $[Cu(Py)_2Cl_2]_\infty$ (**3**). In this transformation the reagent OP(NH-*t*-Bu)$_3$ remains unchanged in the mother liquid as revealed by a ^{31}P NMR spectrum.

Fig. 4. Packing diagrams for **5** viewed along the [001] direction showing the most important contributor to the disordered structure; hydrogen atoms have been omitted for clarity.

Effect of the addition of M^+ (M = Cu, Ag)

No reaction takes place between cuprous chloride (CuCl) and OP(NH-*t*-Bu)$_3$ at 80 °C in toluene under solvothermal conditions owing to the insolubility of CuCl. However, the addition of CuCl (2 equiv.) to equimolar quantities of $CuCl_2 \cdot 2H_2O$ and OP(NH-*t*-Bu)$_3$ in toluene at 80 °C results in the production of the ion-separated salt [*t*-BuNH$_3$]$_5$[Cu_5Cl_{10}] (**5**), which contains a novel pentanuclear penta-anion (vide infra). Thus, the presence of CuCl has a significant influence on the outcome of the in situ templation process, cf. the formation of **1** in the absence of CuCl.

In view of the foregoing observation, the effect of the addition of 2 equiv. of Ag^+ (in the form of silver nitrate) on the reaction of $CuCl_2 \cdot 2H_2O$ and OP(NH-*t*-Bu)$_3$ in toluene at 80 °C was also investigated. In this case, P–N bond cleavage does not occur. Instead, the silver ions remove the chloride ligands from the copper centre via ion-exchange and intact OP(NH-*t*-Bu)$_3$ ligands are observed in the formation of the 2:1 adduct Cu[OP(NH-*t*-Bu)$_3$]$_2$(NO_3)$_2$ (**6**).

X-ray structures

The details of the X-ray structure of **1** were discussed in a preliminary communication (27). The structure of **2** is shown in Fig. 1, and selected metrical parameters are summarized in Table 2. It is a tetranuclear copper cluster similar to those reported for $Cu_4[(NCH_3)_2CHO]_4(\mu_4\text{-}O)Cl_6$, $Cu_4[C_6H_{12}N_4]_4(\mu_4\text{-}O)Cl_6$, $Cu_4[OP(C_6H_5)_3]_4(\mu_4\text{-}O)Cl_6$, and $Cu_4[OPEt_3]_4(\mu_4\text{-}O)Cl_6$ (32–34). In contrast to the observation of one linear and three bent Cu–O–P coordination linkages (Cu2–O2–P2 = 141.02(46)°) in the complex $Cu_4[OPEt_3]_4(\mu_4\text{-}O)Cl_6$ (34), all Cu–O–P connections in **2** are bent significantly (Cu–O–P = 130.1(3)°–136.7(3)°). The six Cl^- ions bridge (μ_2) the edges of the tetrahedron formed by the four copper ions. A single μ_4-O^{2-} ion is embedded in the centre of the tetrahedron. The propellerlike structure is comprised of three seco-cubes each of which has six unique Cu–Cl edges and shares three Cu–O edges with another seco-cube. Each copper atom exhibits distorted trigonal bipyramidal geometry with three chlorine atoms in the equatorial plane and two oxygen donors in the axial positions. The bond angles O–Cu–O are approximately linear (177.0(2)° to 179.44(19)°). The bond angles Cl–Cu–Cl vary from 112.25(8)° to 127.63 (8)°. The Cu—Cl distances, which lie in the range 2.3420(19)–2.5125(19) Å, and the Cu—O bond lengths (1.894(4)–1.915(4) Å) are similar to previously reported values for related tetranuclear copper halide clusters (32–34). As expected, the P—O distances in **2** (1.492(5) –1.502(5) Å) are slightly longer than that in the free ligand OP(NH^{t}Bu)$_3$ (1.474(3) Å) (28) as a result of coordination to the copper centres. The tetrahedron defined by the four copper atoms in **2** is more distorted than that in the complex $Cu_4[OPEt_3]_4(\mu_4\text{-}O)Cl_6$ and adopts approximately C_{2v} symmetry; the Cu—Cu distances have typical values ranging from 3.0319(12) to 3.172(2) Å.

X-ray quality blue crystals of **3** were grown from a pyridine solution and identified as the one-dimensional chain $[Cu(Py)_2Cl_2]_\infty$, with the two pyridine molecules in a trans arrangement, by comparison of the unit cell parameters with those of the published structure (35).

Note: The symmetry transformations used to generate equivalent atoms for **5** are $a = x, -y + 3/2, z$. Bond distances and angles are given for the most important contributors only.

(36), the 2:1 adduct Cu(*t*-BuNH$_2$)$_2$Cl$_2$ (**4**) adopts a distorted tetrahedral structure involving two neutral *t*-BuNH$_2$ ligands and two chloride ions (Cu1—N1 = 1.997(4) Å, Cu1—N2 = 2.003(4) Å, Cu1—Cl1 = 2.2569(15) Å, Cu1—Cl2 = 2.2449(15) Å) (Fig. 2). The preference for tetrahedral geometry (see Table 3) presumably reflects the need to minimize steric interactions between bulky *t*-BuNH$_2$ ligands.

The structure of [*t*-BuNH$_3$]$_5$[Cu$_5$Cl$_{10}$] (**5**) incorporates a pentanuclear penta-anion in which the five copper atoms form a square pyramid (Fig. 3); a search of the Cambridge structural data base indicates that this is the first example of the [Cu$_5$Cl$_{10}$]$^{5-}$ penta-anion. Selected bond lengths and angles for **5** are given in Table 4. Each copper centre is coordinated by a distorted tetrahedral arrangement of four Cl$^-$ ligands. The unique copper atom (Cu3) is connected to three μ_3-Cl bridges and one terminal chloride ligand (Cu3—Cl3 = 2.308(7) Å, Cu3—Cl7 = 2.368(3) Å, Cu3—Cl7a = 2.368(3) Å, Cu3—Cl9 = 2.553(6) Å). The bond angles Cl–Cu3–Cl range from 96.05(1)° to 127.9(2)°. By contrast, the copper centres located in the square plane interact with two

Fig. 5. Molecular structure of **6** (30% thermal ellipsoids); *tert*-butyl groups attached to nitrogen have been omitted for clarity.

μ_3-Cl bridges, one μ_4-Cl bridge, and one terminal chloride ligand (Cu–^{t}Cl = 2.2517(17)– 2.2824(19) Å (t = terminal), Cu—μ_3Cl = 2.3179(17)–2.4561(18)Å, Cu—μ_4Cl = 2.5033(17)–2.5775(17) Å). The distances between the copper centers (Cu–Cu) lie in the range of 2.9258(18) to 2.9612(13). The bond angles Cl–Cu–Cl vary from 98.90(6)° to 132.03(8)°. In contrast to the related pentanuclear copper chloride cluster Cu$_5$[(C$_3$H$_5$)$_2$O]$_2$Cl$_5$, which contains diallyl ether as well as chloride ligands (37), the [Cu$_5$Cl$_{10}$]$^{5-}$ unit in **5** is surrounded by five [*t*-BuNH$_3$]$^+$ cations, which engage in weak N···Cl interactions with the anion (3.20–3.30 Å) (Fig. 4). These anion–cation interactions may help to stabilize the penta-anionic cluster.

The monomeric compound **6** has a distorted square-planar structure formed by two [NO$_3$]$^-$ ions and two neutral OP(NH-*t*-Bu)$_3$ ligands (Cu—O = 1.900(3)–2.047(4) Å, and the angle O–Cu–O = 86.16(13)°–93.45(13)°) (Fig. 5). Other structural parameters are given in Table 3.

Conclusions

This study has shown that the reaction medium has an important effect on the outcome of the reaction of CuCl$_2$·2H$_2$O and OP(NH-*t*-Bu)$_3$ under solvothermal conditions. With toluene as the reaction medium, P–N bond cleavage occurs with the in situ formation of *t*-BuNH$_2$ or the templating agent [*t*-BuNH$_3$]$^+$, which directs the formation of copper halide clusters, whereas P–N bond cleavage is not observed in hexane under similar conditions. The production of the pentanuclear cluster [Cu$_5$Cl$_{10}$]$^{5-}$ upon addition of CuCl to this reaction mixture is noteworthy and suggests that other novel cluster aggregations may be formed by in situ templation under solvothermal conditions when two different metal salts are used.

Efficient regio- and stereo-selective cleavage of aziridines and epoxides using an ionic liquid as reagent and reaction medium

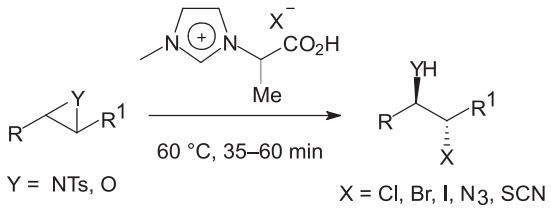
Brindaban C. Ranu, Laksmikanta Adak, and Subhash Banerjee

Abstract: Ionic liquids, containing a variety of functionalities such as halo, azido, and thiocyano, efficiently cleave aziridines and epoxides to the corresponding products in high yields. The cleavages are regio- and stereo-selective. The reactions are complete in 1 h at 60 °C and do not require any other catalyst or organic solvent. Thus, a convenient synthetic route to 1,2-haloamines, 1,2-azidoamines, 1,2-thiocyanoamines, 1,2-azidoalcohols, and 1,2-thiocyanoalcohols is developed.

Key words: aziridine, epoxide, ionic liquid, cleavage, regioselectivity, stereoselectivity

Résumé : Des liquides ioniques contenant diverses fonctions, telles halogéno, azido ou thiocyano, permettent de cliver efficacement les aziridines et les époxydes pour fournir les produits correspondants avec des rendements élevés. Les clivages sont régio- et stéréosélectifs. Les réactions sont complètes en moins d'une heure, à 60 °C, et elles ne nécessitent pas l'utilisation d'autres catalyseurs ou solvants organiques. On a donc développé une voie de synthèse commode pouvant conduire aux 1,2-halogénoamines, 1,2-azidoamines, 1,2-thiocyanoamines, 1,2-azidoalcools et 1,2-thiocyanoalcools.

Mots clés : aziridine, époxyde, liquide ionique, clivage, régiosélectivité et stéréosélectivité.



[Traduit par la Rédaction]

Introduction

Ionic liquids are attracting increasing attention in organic synthesis because of their unique advantages as reaction media (1), compared with organic solvents, and efficient promoters for a variety of reactions (2). However, the potential of ionic liquids as reagents has been less explored, and as a part of our activities in this area (3) we initiated an investigation to explore the utility of ionic liquids as efficient reagents (3*a*) for useful transformations.

Aziridines (4) and epoxides (5) are very useful synthetic intermediates. Because of their ring strain and high reactivity, their reactions with various nucleophiles lead to regio- and stereo-selective synthesis of various important synthons. Considerable progress towards the development of several procedures (6) has been achieved in the nucloephilic ring-opening reactions of aziridines and epoxides. The nucleophilic reagents involved in these procedures include tributylphosphine in H_2O (6*a*), $CeCl_3$ in CH_3CN (6*b*), NaN_3–$CeCl_3$ in CH_3CN (6*c*), Me_2SBr_2 in CH_3CN (6*d*), $LiClO_4$–NaX (where X = N_3, CN) in CH_3CN (6*e*), KSCN–sulfated zirconia in CH_3CN (6*f*), zinc halides in CH_2Cl_2 (6*g*), KSCN–$LiClO_4$ in CH_3CN (6*h*), KSCN–β-cyclodextrin in H_2O (6*i*), TBAX–β-cyclodextrin in H_2O (6*j*), $^nBu_4NF$–Me_3SiX in THF (6*k*), $TMSN_3$–$Sn(OTf)_2$ in benzene (6*l*), InX_3 in CH_3CN (6*m*), NaN_3 or KCN–SiO_2 in H_2O (6*n*), $TMSN_3$ in THF (6*o*), NaN_3 in ionic liquid H_2O (6*p*), activated DMF complexes (6*q*), NaX–$Ce(OTf)_4$ in micelle (6*r*), fluoride anion (6*s*), and aminosaccharides (6*t*) in the ionic liquid *N*-methylpyridinium tosylate, among others. However, most of these procedures involve a nucleophilic reagent (usually metal salts), an acid catalyst, and organic solvents like CH_3CN and CH_2Cl_2. We report here a new strategy for the cleavage of aziridines and epoxides with a variety of nucleophiles using a core ionic liquid, 1-(1-carboxy-ethyl)-3-methyl-3*H*-imidazolium derivative [PnMIm]X [where X = N_3, SCN, Cl, Br, I] without any additional reagent, catalyst, or organic solvent (Scheme 1).

Scheme 1.

Results and discussion

The general experimental procedure is very simple and convenient. A mixture of aziridine (or epoxide) and ionic liquid [PnMIm]X was heated at 60 °C for a certain period of time, as required to complete the reaction (TLC). The usual

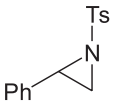
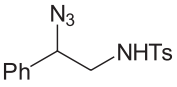
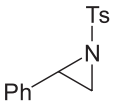
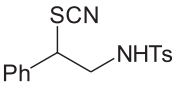
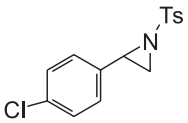
work-up and purification by column chromatography provided the product.

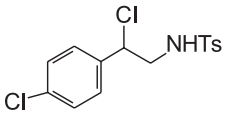


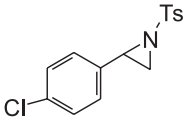


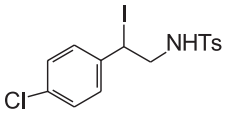


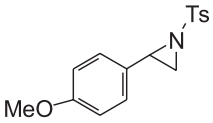


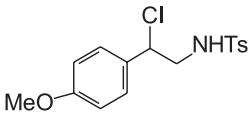


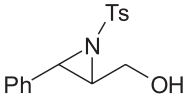


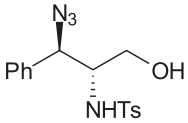


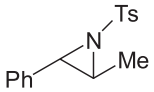


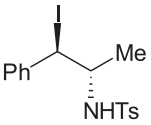


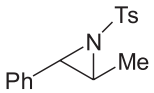


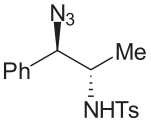


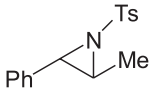


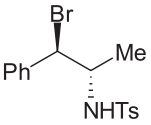












Several structurally diverse aziridines underwent cleavages by this procedure using a core ionic liquid [PnMIm]X (where X = Cl, Br, I, N_3, SCN) to provide the corresponding 2-chloro-, bromo-, iodo-, azido-, and thiocyano-amines. The results were summarized in Table 1. Both alkyl- and aryl-substituted aziridines participated in this reaction. The alkyl-substituted aziridines underwent nucleophilic attack at the less hindered (substituted) carbon atom (Table 1, entries 1 and 2), whereas in aryl-substituted aziridines nucleophiles attacked at the benzylic positions (Table 1, entries 8–23) because of their electronic factor. The cyclohexene azide provided trans isomers by this cleavage, as indicated by the ^{1}H NMR spectra of the corresponding amines (Table 1, entries 3–7). The disubstituted aziridines also furnished trans-functionalized amines (Table 1, entries 16–23).

The epoxides also underwent cleavages by this ionic liquid, producing 2-azido-, nitro-, and thiocyano-alcohols under this procedure. The cleavages by halo-bearing ionic liquids were reported earlier (3*a*). The reactions of alkyl- and aryl-substituted as well as cyclohexene epoxides proceeded smoothly. The results are reported in Table 2. The epoxide of an α,β-unsaturated ketone underwent nucleophilic attack at the α-carbon atom followed by subsequent dehydration to furnish the corresponding α-azido α,β-unsaturated ketone (Table 2, entry 9) under the reaction conditions.

In general, the reactions were very clean, fast, and high-

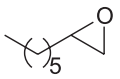
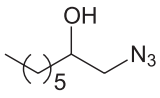
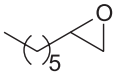
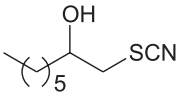
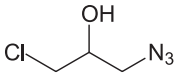
yielding. The cleavages of both aziridines and epoxides by this reagent were highly regioselective, affording a single product. The stereochemistry of products was determined as trans by the coupling constant (*J* value) of the hydrogens at the cleaved carbon atoms. It has been observed that nucleophilic attack occurred at the less-substituted carbon atoms of the alkyl-substituted terminal aziridines and epoxides, whereas aryl-substituted substrates underwent attack at the benzylic position, being dictated by the electronic factor. It may be anticipated that these cleavage reactions proceed through the usual S_N2 path as outlined in our earlier paper on epoxide cleavage (3*a*). Several functional groups, such as Cl, OMe, and OPh, remained unaffected during this reaction. The ionic liquids were easily prepared by substitution reaction of the core imidazolium bromide with the sodio-salt of the corresponding anion.

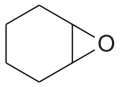


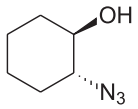


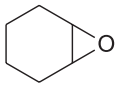


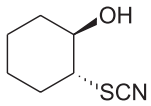


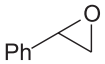


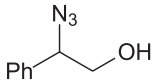


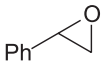


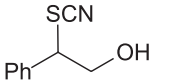


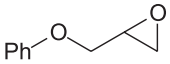


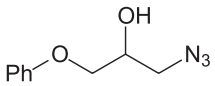


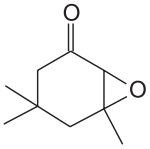


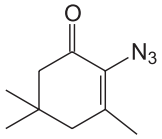












The products of this cleavage reaction, 2-azidoalcohols, 2-thiocyanoalcohol, 2-azido amines, 2-haloamines, and 2-thiocyanoamines are very useful intermediates and have wide applications in organic synthesis (7, 8).

Conclusion

In conclusion, the present procedure provides a novel and

general route to the cleavage of epoxides and aziridines by a variety of nucleophiles carried out by an inexpensive and easily accessible ionic liquid [PnMIm]X, which itself works as reagent, catalyst, and reaction medium. The other significant advantages offered by this method are operational simplicity, considerably fast reaction time (30–60 min), high isolated yields of products, general applicability to a wide variety of substrates, excellent regio- and stereo-selectivity, thus providing a better and practical alternative to the existing procedures (6). Moreover, this demonstrates the potential of ionic liquids as efficient reagents and shows promise for further useful applications.

Experimental

General

IR spectra were taken as thin films for liquid compounds and as KBr pellets for solids using a Shimadzu 8300 FTIR spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ and d_6-DMSO solution at 300 and 75 MHz, respectively (Bruker 300 DPX instrument).

General experimental procedure for the preparation of ionic liquid [PnMIm]x

2-Bromopropionic acid (3.06 g, 20 mmol) was added dropwise to a cooled (0–5 °C) solution of *N*-methylimidazole (1.64 g, 20 mmol) in dry acetonitrile (10 mL). The reaction mixture was then stirred for 12 h at room temperature (RT). The crude product, obtained by evaporation of solvent, was washed with Et_2O (2 × 5 mL) and dried under vacuum to provide the bromo ionic liquid, [PnMIm]Br, ready to be used for cleavage reactions.

The iodo and chloro analogues were prepared from the corresponding 2-iodopropionic acid and 2-chloropropionic acid following the same procedure.

General experimental procedure for the ring opening of aziridines. Representative procedure for the ring opening of 2-hexyl-1-(toluene-4-sulfonyl)-aziridine with [PnMIm]Cl (Table 1, entry 1)

A mixture of 2-hexyl-1-(toluene-4-sulfonyl)-aziridine (281 mg, 1 mmol) and [PnMIm]Cl (225 mg, 1.3 mmol) was heated at 60 °C with stirring for 50 min (TLC). The reaction mixture was quenched with saturated brine and extracted with ether (3 × 10 mL). Evaporation of ether left the crude product, which was purified by column chromatography over silica gel (hexanes–Et_2O 50:50) to provide the pure *N*-(1-chloromethyl-heptyl)-4-methyl-benzenesulfonamide as a colourless liquid (285 mg, 90%), whose spectroscopic data (IR, ^{1}H, and ^{13}C NMR) are in good agreement with those reported (6*q*).

This procedure was followed for the nucleophilic cleavage of all aziridines listed in Table 1. The known compounds (referenced in Table 1) were identified by the comparison of their spectroscopic data with those reported. The unknown compounds (Table 1, entries 15 and 17) were properly characterized by its spectroscopic data and elemental analysis.

N-*[2-Chloro-2-(4-methoxy-phenyl)-ethyl]-4-methyl-benzenesulf onamide (Table 1, entry 15)*

Colourless viscous liquid. IR (neat, cm^{-1}) ν: 3493, 3282, 2922, 1612, 1514, 1454, 1326, 1250, 1159. ^{1}H NMR δ: 2.38 (s, 3H), 2.97–3.24 (m, 2H), 3.76 (s, 3H), 4.74 (dd, J_1 = 3.72 Hz, J_2 = 8.64 Hz, 1H), 5.10 (t, J = 4.75 Hz, 1H), 6.85 (d, J = 8.64 Hz, 2H), 7.19 (d, J = 8.64 Hz, 2H), 7.29 (d, J = 7.98 Hz, 2H), 7.72 (d, J = 8.34 Hz, 2H). ^{13}C NMR δ: 21.9, 50.6, 55.7, 72.8, 114.4 (2C), 127.5 (2C), 127.5 (2C), 130.1 (2C), 133.3, 137.1, 143.9, 159.9. Anal. calcd. for $C_{16}H_{18}ClNO_3S$: C 56.55, H 5.34, N 4.12; found: C 56.48, H 5.25, N 4.01.

N-*(2-Iodo-1-methyl-2-phenyl-ethyl)-4-methyl-benzene sulfonamide (Table 1, entry 17)*

Colourless viscous liquid. IR (neat, cm^{-1}) ν: 3500, 3273, 1596, 1450, 1326, 1161, 1091. ^{1}H NMR δ: 1.13 (d, J = 6.54 Hz, 3H), 2.42 (s, 3H), 3.57–3.64 (m, 1H), 4.93 (d, J = 8.37 Hz, 1H), 5.05 (d, J = 5.73 Hz, 1H), 7.15–7.33 (m, 7H), 7.73 (d, J = 8.16 Hz, 2H). ^{13}C NMR δ: 19.9, 21.5, 38.5, 56.1, 127.0 (2C), 128.5 (2C), 129.0, 129.3 (2C), 129.7 (2C), 139.0, 139.3, 143.6. Anal. calcd. for $C_{16}H_{18}INO_2S$: C 46.27, H 4.37, N 3.37; found: C 46.16, H 4.29, N 3.28.

General experimental procedure for the ring opening of epoxides. Representative procedure for the ring opening of 2-hexyl-oxirane by [PnMIm]N_3 (Table 2, entry 1)

A mixture of 2-hexyl-oxirane (128 mg, 1 mmol) and [PnMIm]N_3 (256 mg, 1.3 mmol) was heated at 60 °C with stirring for 45 min (TLC). The reaction mixture was quenched with saturated brine and extracted with ether (3 × 10 mL). Evaporation of ether left the crude product, which was purified by column chromatography over silica gel (hexane–Et_2O 80:20) to provide the pure 1-azido-octan-2-ol

Synthesis and characterization of $[M(DMSO)_6][SnCl_6]$ complexes (M = Fe^{2+}, Co^{2+}, and Ni^{2+}) — An old mystery solved

Andrew P. White, Katherine N. Robertson, T. Stanley Cameron, Bernard V. Liengme, Daniel B. Leznoff, Simon Trudel, and Manuel A.S. Aquino

Abstract: The synthesis of an "unknown" Fe(II) complex originally reported in 1973 and formulated then as $[Fe(DMSO)_5Cl][SnCl_4]$ was thoroughly reproduced and the compound reformulated as the novel $[Fe(DMSO)_6][SnCl_6]$ double complex salt. Current elemental analysis and IR and Mössbauer spectroscopy matched the original 1973 data, and Raman spectroscopy and single crystal X-ray diffraction provided additional confirmation of our reformulation. $[Fe(DMSO)_6][SnCl_6]$ (**1**) crystallizes in the trigonal space group $R\bar{3}$ with octahedral $[Fe(DMSO)_6]^{2+}$ and $[SnCl_6]^{2-}$ complex ions with an Fe—O bond length of 2.121(3) Å. The same synthesis was extended to Co(II) and Ni(II) to generate the novel $[Co(DMSO)_6][SnCl_6]$ (**2**), which crystallizes in the triclinic space group $P\bar{1}$ with a Co—O bond length of 2.093(4)–2.113(5) Å, and $[Ni(DMSO)_6][SnCl_6]$ (**3**), which crystallized in the trigonal $R\bar{3}$ space group and has a Ni—O bond length of 2.062(2) Å. The Sn—Cl bond length in all three complexes ranged from 2.421(2) to 2.448(2) Å.

Key words: DMSO complexes of Fe(II), Co(II) and Ni(II), $SnCl_6^{2-}$ salts, IR, Raman and Mössbauer spectroscopy, X-ray crystal structures.

Résumé : La synthèse d'un complexe "inconnu" de Fe(II), qui avait originalement été rapportée en 1973 et pour lequel la formule $[Fe(DMSO)_5Cl][SnCl_4]$ avait alors été proposée, a été complètement reproduite et on peut maintenant lui attribuer la formule $[Fe(DMSO)_6][SnCl_6]$, un double sel complexe. Les données obtenues au cours de ce travail pour les analyses élémentaires, les spectres infrarouge et de Mössbauer correspondent à celles qui avaient été obtenues dans le travail original de 1973; on a par ailleurs déterminé le spectre Raman et la structure cristalline par diffraction des rayons X sur un cristal unique et ces données ont permis de confirmer notre reformulation. Le complexe $[Fe(DMSO)_6][SnCl_6]$ (**1**) cristallise dans le groupe d'espace trigonal $R\bar{3}$ avec un ion octaédrique $[Fe(DMSO)_6]^{2+}$ et des ions complexes $[SnCl_6]^{2-}$; la longueur de la distance Fe—O est de 2,121(3) Å. On a étendu cette synthèse au Co(II) et au Ni(II) pour générer la formation du complexe $[Co(DMSO)_6][SnCl_6]$ (**2**) qui cristallise dans le groupe d'espace triclinique $P\bar{1}$ avec une longueur de la liaison Co—O de 2,093(4)–2,113(5) Å et du complexe $[Ni(DMSO)_6][SnCl_6]$ (**3**) qui cristallise dans le groupe d'espace trigonal $R\bar{3}$ avec une longueur de la liaison Ni—O de 2,062(2) Å. La longueur de la liaison Sn—Cl dans les trois complexes est de 2,421(2)–2,448(2) Å.

Mots-clés : complexes du Fe(II), du Co(II) et du Ni(II) avec le DMSO, sels complexes du $SnCl_6^{2-}$, spectroscopie Raman et de Mössbauer, structures cristallines par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

A number of years ago Fred Wen, a Master's student of one of the authors (BVL), reported on a reaction involving $FeCl_2$, $SnCl_2$, and dimethylglyoximate anion ($dmgH^-$) in dimethylsulfoxide (DMSO) (1), while investigating the chemistry and spectroscopy (IR and Mössbauer) of Fe–Sn complexes. The red product of this reaction was reported to have the formulation $[Fe(DMSO)_5Cl][SnCl_3]$ and was reportedly only produced when $dmgH_2$ was present.

$$FeCl_2 + SnCl_2 \xrightarrow[DMSO]{dmgH_2} [Fe(DMSO)_5Cl][SnCl_3]$$

This formulation was consistent with the elemental analysis and IR spectroscopy performed at the time. However, while the ^{57}Fe Mössbauer spectrum did reveal a high-spin Fe(II) center to be present, the ^{119}Sn Mössbauer results pointed unequivocally to an oxidized Sn(IV) center, which was *not* consistent with the above formulation.

We report here a thorough re-investigation of this reaction, both in the presence and absence of $dmgH^-$ and compare our elemental analysis, IR, and ^{57}Fe Mössbauer results with those reported by Wen. In addition, we extend the synthetic method to include Co(II) and Ni(II) (along with the

Fe(II)) and report on the IR and Raman spectroscopy and the X-ray crystallography of all three complexes. We show them to have the formulation $[M(DMSO)_6][SnCl_6]$, where M = Fe(II) (**1**), M = Co(II) (**2**), and M = Ni(II) (**3**). These double complex salts have not been reported previously, and in fact there have been only a limited number of structures reported containing the $[M(DMSO)_6]^{2+}$ dication with these metal centers (2–10), with only one for M = Fe(II) (2) and two others, $[Co(DMSO)_6][CoCl_4]$ (4) and $[Ni(DMSO)_6][NiCl_4]$ (6), reported as double complex salts (neither of which contain two octahedra).

Experimental

Reagents

$FeCl_2{\cdot}4H_2O$, $CoCl_2{\cdot}6H_2O$, $NiCl_2{\cdot}6H_2O$, and $SnCl_2{\cdot}2H_2O$ (Sigma-Aldrich) were used as received. Dimethylsulfoxide and 2,2′-dimethoxypropane (Sigma-Aldrich) were used without further purification.

Synthesis

$[M(DMSO)_6][SnCl_6]$, M = Fe(II) (1), Co(II) (2), and Ni(II) (3)

Complexes **1**, **2**, and **3** were all prepared in a similar fashion. $FeCl_2{\cdot}4H_2O$ (**1**) (2.10 g, 10 mmol), $CoCl_2{\cdot}6H_2O$ (**2**) (2.50 g, 10 mmol), or $NiCl_2{\cdot}6H_2O$ (**3**) (2.50 g, 10 mmol) and $SnCl_2{\cdot}2H_2O$ (4.30 g, 20 mmol) were dissolved in 150–200 mL of dimethylsulfoxide (DMSO) at room temperature. The resulting solution was gravity filtered to yield a yellow-green (**1**), light purple (**2**), or yellow-green (**3**) solution. Ten milliliters of 2,2′-dimethoxypropane was then added and the solution was heated under Ar at 100–120 °C for 3 to 4 h until the solution changed to pale yellow (**1**), dark purple (**2**), or dark green (**3**). The solution was then allowed to cool and diethyl ether was added until a pale yellow (**1**), light blue (**2**), or light green (**3**) precipitate formed. The precipitate was vacuum filtered, washed with 20 mL of diethyl ether, and dried in vacuo. In all three cases, crystals could be grown by cooling and slow evaporation from hot DMSO solutions. Yields were 8.2 g (91%) for **1**, 8.3 g (92%) for **2**, and 7.9 g (87%) for **3**.

Physical Methods

IR spectra were run as KBr discs on a Bio-Rad FTS-175 spectrophotometer. Raman spectra were acquired on a Renishaw InVia Raman Microscope (Prospect Scientific, Toronto, Canada) equipped with a 514.5 nm laser, a 1800 l/mm grating, a CCD detector, and a 50 × 0.75 NA objective. Samples were deposited on glass slides and the laser power used on the sample was 5 mW. Mössbauer spectra were run at 80 K on a WEB Mössbauer spectroscopy system connected to a Janis Research variable temperature SHI-850 Cryostat and a closed cycle refrigerator. A ^{57}Co (in rhodium matrix) source was used with a source strength of ~40 mCi (1 Ci = 37 GBq). The detector was a Reuters–Stokes Kr–CO_2 proportional counter. Samples were loaded into a custom-made Teflon holder and the velocity scanned between 4 and –4 mm/s using a constant acceleration triangle waveform. The measured isomer shifts (δ) are relative to an Fe foil measured at 295 K in zero magnetic field. Fitting of the data was performed using WMOSS software. C, H, and Cl elemental analysis was performed by Canadian Microanalytical Service Ltd. (Delta, BC, Canada).

X-ray structure determinations for **1** and **3** were performed on a Rigaku AFC5R diffractometer with graphite monochromated Mo Kα radiation and a rotating anode generator, whereas **2** was analyzed using a Rigaku Saturn CCD area detector with graphite monochromated Mo Kα radiation. The crystal data and structure refinement parameters for all three complexes are given in Table 1. All structures were solved by direct methods (11) and expanded using Fourier techniques (12). For complexes **1** and **3** the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. They were placed in geometrically calculated positions and allowed to ride on the heavy atom to which they were bonded with U_{iso} equal to 1.5 × U_{eq} of the heavy atom. In complex **1** the dimethylsulfoxide (DMSO) ligands, of which only one was unique, were found to be disordered. The sulfur and carbon atoms of the ligand were split over two positions and the occupancy of each refined (Part 1 (A) 92.9% and Part 2 (B) 7.1%). The atomic displacement parameters of C1a/C1b and of C2a/C2b were restrained to be equal. A rigid bond restraint and a restraint for similar atomic displacements were applied to the entire molecule. Finally, restraints were applied to certain of the bond lengths and 1,3 distances in the cation. These restraints were applied to both part A and part B atoms. The C—S bond lengths were restrained to 1.73 (0.015) Å and the O—S bond lengths to 1.50 (0.01) Å. The distance between C1 and C2 atoms in both A and B was restrained to 2.64 (0.02) Å and the O1 to C distances were restrained to 2.60 (0.02) Å. For complex **2**, the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using a riding model, with U_{iso} of hydrogen equal to 1.2 × U_{eq} of the heavy atom to which each was bonded.

For all complexes the neutral atom scattering factors were taken from Cromer and Waber (13). Anomalous dispersion effects were included in F_{calc} (14); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (15). The values for the mass attenuation coefficients are those of Creagh and Hubbell (16). All calculations for complexes **1** and **3** were performed using the teXsan (17) crystallographic software package of Molecular Structure Corporation except for the refinement, which was performed using SHELXL-97 (18). All calculations on complex **2** were performed using the CrystalStructure (19, 20) crystallographic software package. ORTEP diagrams were prepared using ORTEP-3 (version 1.076) (21) and POV-Ray (version 3.6.0) (22).

Additional details are provided in the Supplementary data.[2]

Results and discussion

Synthesis

Since it is puzzling why Wen used $dmgH_2$ in his preparations, we have repeated his synthesis of the iron complex (as closely as possible) in the presence and absence of 30 mmol of $dmgH_2$. In both cases a product is formed. The colour of the crude product in the presence of the $dmgH^-$ is pink to red and in the absence of the $dmgH^-$ it is yellow. After recrystallization from hot DMSO *both* products appear yellow and crystalline and have the proposed formulation, $[Fe(DMSO)_6][SnCl_6]$ (**1**) (see more later). The small amount of red impurity, almost certainly due to $[Fe(dmgH)_2(DMSO)_2]$, is easily removed by recrystallization. In fact, the longer the heating in DMSO is allowed to proceed (>5 h) the fainter the red colour of the crude product. The presence of $[Fe(dmgH)_2(DMSO)_2]$ would not be unusual as numerous $[Fe(dmgH)_2L_2]$-type complexes (with L = pyridine, phosphines, CO, and isocyanides, for example) have been documented in the literature (23). When we undertake an identical reaction, using $CoCl_2$ as our starting material, we obtain a purple coloured crude product (with or without $dmgH^-$ present) that, upon recrystallization, yields a light blue crystalline product **2**. Only in the case of $NiCl_2$ as our starting reactant do we encounter two distinct products. With $dmgH^-$ present, only the bright red $Ni(dmgH)_2$ is formed. In the absence of $dmgH^-$, only **3** is formed.

Another significant feature of these reactions that should be noted is that the correct stoichiometric amount of chloride ion must be present, i.e., 2 equiv. from the 10 mmol $FeCl_2$ and 4 equiv. from the 20 mmol $SnCl_2$. If only 10 mmol of $SnCl_2$ is used, no significant amount of solid is produced. It is odd that Wen used 20 mmol of $SnCl_2$ in his reaction as his proposed formulation, $[Fe(DMSO)_5Cl][SnCl_3]$ only requires 4 equiv. of Cl^-.

Finally, the issue of the presence of Sn(IV) vs. Sn(II) that Wen noted and that contradicts his formulation needs to be addressed. Under the reaction conditions, which we have tried to reproduce closely, air has not been excluded rigorously. Even though the reaction heating is performed under an atmosphere of argon, the initial dissolution of reagents and the final workup (addition of diethylether) is not. In addition, none of the solvents have been degassed. These conditions are certainly enough to prevent the oxidation of the Fe(II) but not Sn(II), as it is very sensitive to even small amounts of O_2 in solution (24).

Table 2 compares the C, H, and Cl elemental analysis results for all three complexes obtained in this current work, with and without the addition of $dmgH^-$ for **1** and **2**, to those obtained by Wen (1).

It is clear that the elemental analyses for **1** and **2** are identical whether the synthetic procedure employed $dmgH^-$ or not. As mentioned earlier, complex **3** only forms in the absence of $dmgH^-$. Comparing the results for complex **1** to those of Wen we see reasonable agreement of the %C and

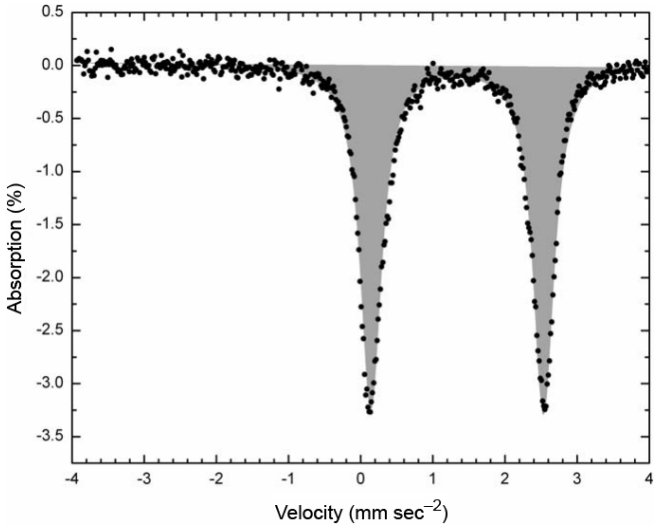
%H values but the %Cl of Wen's product is lower. As Wen provides no evidence that he recrystallized his crude product, the slight disparity in the elemental analysis values could be due to a small amount of $[Fe(dmgH)_2(DMSO)_2]$ impurity, which would substantially lower the %Cl and slightly raise the %C and %H. It should also be noted that even small amounts of DMSO of solvation would raise the %C and %H and lower the %Cl.

IR, Raman, and Mössbauer spectroscopy



The IR and Raman spectra for complexes synthesized in the presence or absence of $dmgH^-$ were identical (see Table S1 in the Supplementary material).[2] All three complexes show very similar IR and Raman spectra that are predominated by modes associated with the DMSO ligand (25). As well, the data for our complex **1** is essentially identical to the data for Wen's complex. Briefly, the major features are bands around 2900–3000 cm^{-1} due to ν_{as} and ν_s (C–H); δ_{as} and δ_s (C–H) at 1290–1440 cm^{-1}; a very strong ν (S=O) at 1005 cm^{-1} in the IR (very weak in the Raman); and ν_{as} and ν_s (C–S) in the range 670–720 cm^{-1}. A key feature of the IR spectra is the decrease in ν (S=O) of about 45 cm^{-1} in the complexes from that of free DMSO, which is indicative of binding through the oxygen (26).

The ^{57}Fe Mössbauer spectrum of complex **1**, determined at 80 K, is shown in Fig. 1. Fitting the data yielded an isomer shift (δ) of 1.34 mm s^{-1} vs. Fe foil and a quadropolar splitting (ΔE_q) of 2.39 mm s^{-1}. These parameters are consistent with a high-spin Fe(II) center (27) and are very similar to the values Wen determined for his complex. Wen's parameters were δ = 1.56 mm s^{-1} and ΔE_q = 2.12 mm s^{-1}, using nitroprusside as reference (instead of Fe foil). Using a correction of 0.26 mm s^{-1} for Fe foil vs.nitroprusside (27), our isomer shift value for complex **1** is δ = 1.60 mm s^{-1}. We have not been able to measure the ^{119}Sn Mössbauer spectrum; however, Wen's results pointed to an Sn(IV) center (δ = 0.47 mm s^{-1}, ΔE_q = 0 vs. SnO_2), which already contradicted his proposed formulation of $[Fe(DMSO)_5Cl][SnCl_3]$ (which would contain an Sn(II) center) and supports ours, $[Fe(DMSO)_6][SnCl_6]$, which contains an Sn(IV) center.

Structure of $[Fe(DMSO)_6][SnCl_6]$ (1)

Complex **1** crystallizes in an R-centered trigonal cell with a space group of $R\bar{3}$. The structure is shown in Fig. 2, crystal parameters in Table 1, and selected bond lengths and angles in Table 3. The structure consists of an octahedral $[Fe(DMSO)_6]^{2+}$ cation containing Fe(II) and an $[SnCl_6]^{2-}$ anion containing Sn(IV). As mentioned in the Experimental section, the DMSO ligands are disordered and the S and C atoms are averaged between two positions with 92.9% and 7.1% occupancy (see Fig. 2*A*). The bond angles for both ions are consistent with essentially undistorted octahedral coordination. There are no surprises in any of the bond lengths (ranging from 2.102(3) to 2.149(3) Å (2)), with the Fe—O bond length of 2.121(3) Å comparing well with the values seen in the only other complex containing $Fe(DMSO)_6^{2+}$ that we have been able to find that has been crystallographically characterized $[Fe(DMSO)_6][Cl_2Fe(MoS_4)]$.

Fig. 1. ^{57}Fe Mössbauer spectrum (with fitting) of $[Fe(DMSO)_6][SnCl_6]$ at 80 K.

Structure of $[Co(DMSO)_6][SnCl_6]$ (2)

Complex **2** crystallizes in a primitive triclinic cell with space group $P\bar{1}$. The structure is shown in Fig. 3, crystal parameters in Table 1, and selected bond lengths and angles in Table 3. As in **1** this complex consists of two essentially undistorted octahedra. Most bond lengths and angles are identical to those in **1** and the Co—O bond length is in the range 2.093(4)–2.113(5) Å. Three previous structures containing the $[Co(DMSO)_6]^{2+}$ cation have been reported, including $[Co(DMSO)_6](ClO_4)_2$·DMSO (3), $[Co(DMSO)_6](CoCl_4)$ (4), and $[Co(DMSO)_6]I_4$ (5), with Co—O bond lengths ranging from 2.083(2) to 2.113(4) Å.

Structure of $[Ni(DMSO)_6][SnCl_6]$ (3)

Complex **3** (similar to complex **1**) crystallizes in the R-centered trigonal cell with a space group of $R\bar{3}$, with no disorder of the DMSO ligands. The structure is shown in Fig. 4, crystal parameters in Table 1, and selected bond lengths and angles in Table 3. Its characteristics are very similar to those of **1** and **2**. A number of X-ray structures, which include the $[Ni(DMSO)_6]^{2+}$ cation, have been previously reported (6–10). The Ni—O bond length in our complex is 2.062(2) Å, which is close to the values seen, for example, in $[Ni(DMSO)_6]Cl_2$·DMSO (2.041(3)–2.085(3) Å) and $[Ni(DMSO)_6][NiCl_4]$ (2.059(3)–2.079(3) Å) (6).

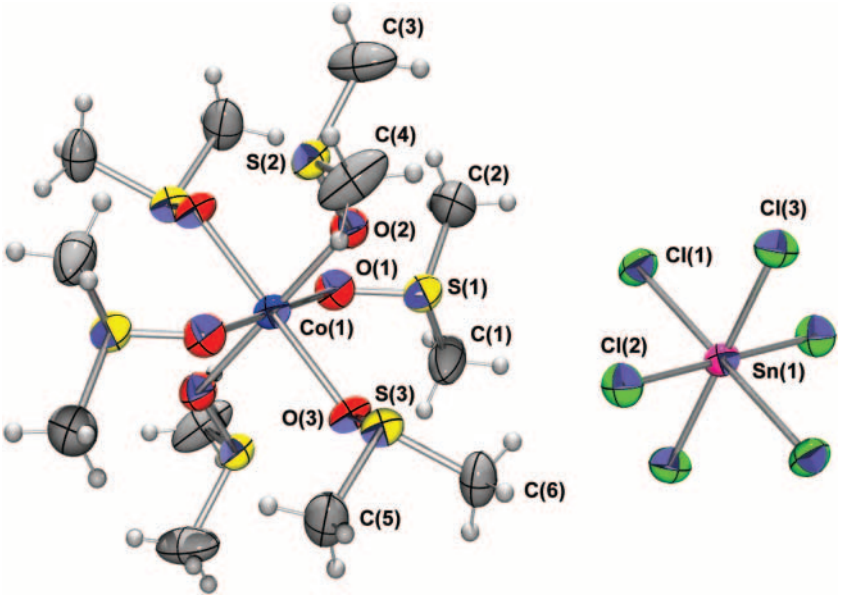
Fig. 3. Molecular structure of $[Co(DMSO)_6][SnCl_6]$ (**2**). The ellipsoids represent the 50% probability of finding the atom at that position.



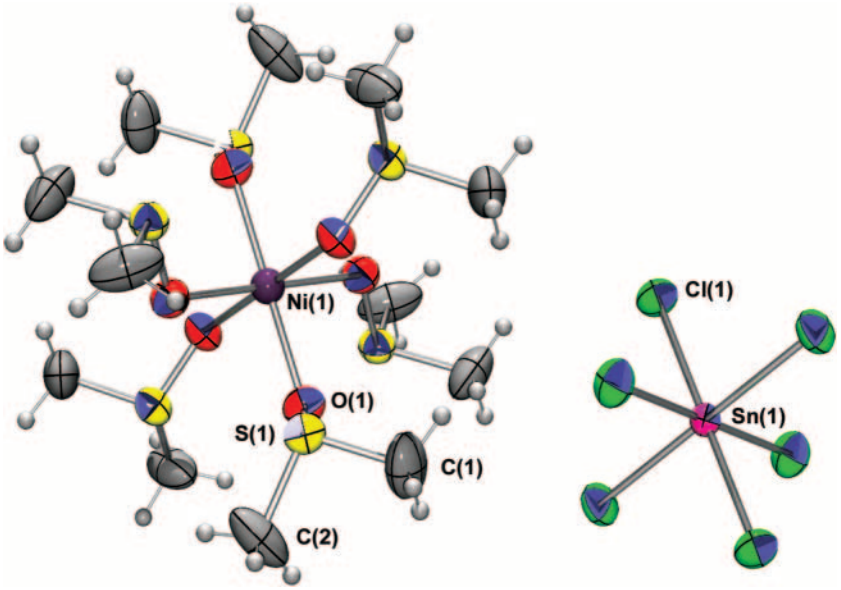


Fig. 4. Molecular structure of $[Ni(DMSO)_6][SnCl_6]$ (**3**). The ellipsoids represent the 50% probability of finding the atom at that position.

The Sn—Cl bond length for the three complexes ranges from 2.421(2) Å to 2.448(2) Å, typical of $SnCl_6^{2-}$ complexes (28), and the decrease in M—O bond length on going from Fe(II) to Co(II) to Ni(II) is consistent with the increase in effective nuclear charge and decrease in the ionic radii for octahedral (high-spin) ions, Fe(II) > Co(II) > Ni(II), as per the Irving–Williams series for first-row $[M(H_2O)_6]^{2+}$ complexes (29).

Conclusion

We have succeeded in reproducing Wen's synthesis of the unknown iron–tin complex both in the presence and absence of $dmgH^-$ and have shown that the same compound is produced in both cases. The original reddish colour Wen reported was most likely due to an $[Fe(dmgH)_2(DMSO)_2]$ impurity that is easily removed by recrystallization from hot DMSO. The elemental analysis (allowing for the $[Fe(dmgH)_2(DMSO)_2]$ impurity in Wen's sample) and IR and Mössbauer spectroscopy of our iron–tin complex match Wen's results very well. From the additional Raman data and the single crystal X-ray diffraction results, we conclude that the correct formulation for the complex is $[Fe(DMSO)_6][SnCl_6]$. We were able to extend the synthesis to include Co(II) and Ni(II) and the structures of both $[Co(DMSO)_6][SnCl_6]$ and $[Ni(DMSO)_6][SnCl_6]$ were also elucidated. None of the three complexes have been previously reported, and while the $[Co(DMSO)_6]^{2+}$ and

© 2007 NRC Canada

$[Ni(DMSO)_6]^{2+}$ ions have been reported in X-ray structures on a few occasions, surprisingly, ours is only the second reported structure containing the $[Fe(DMSO)_6]^{2+}$ complex ion.

The mystery of Wen's unknown iron–tin complex has therefore been solved and we hope this may encourage other researchers to re-investigate past experiments to clear up unsolved problems. We are currently trying to extend the synthesis even further to Cr(II) and Ru(II), as neither the $[Cr(DMSO)_6]^{2+}$ or $[Ru(DMSO)_6]^{2+}$ have been structurally characterized.

Improvement of hydrothermal stability of an ordered mesoporous molecular sieve via multistage recrystallization

Yong M. Luo, Zhao Y. Hou, Rong T. Li, and Xiao M. Zheng

Abstract: A highly ordered mesoporous aluminosilicate molecular sieve, designated as MSAMS-4, has been synthesized via multistage recrystallization. Hydrothermal-stability tests revealed that MSAMS-4 has retained a well-ordered hexagonal-symmetry mesostructure both after treatment with 100 °C water for 120 h and after steaming at 800 °C for 6 h.

Key words: aluminosilicates molecular sieves, mesoporous materials, multistage recrystallization, hydrothermal stability.

Résumé : Faisant appel à des recristallisations en plusieurs étapes, on a réalisé la synthèse d'un tamis moléculaire d'aluminosilicate mésoporeux fortement ordonné, dénommé MSAMS-4. Des essais de stabilité hydrothermique démontrent que le MSAMS-4 maintient sa mésostructure de symétrie hexagonale bien ordonnée après avoir été traité à 100 °C pendant 120 heures ou par de la vapeur d'eau à 800 °C pendant 6 heures.

Mots-clés : tamis moléculaires d'aluminosilicates, matériaux mésoporeux, recristallisation en plusieurs étapes, stabilité hydrothermique.

[Traduit par la Rédaction]

Introduction

The hydrothermal stability and the acidity of mesoporous molecular sieves are far lower than those of microporous aluminosilicate zeolites. This could be attributed to the amorphous nature of the mesopore walls, which severely hinders them from practical applications, e.g., acting as catalytic supports or catalysts in petroleum refining and fine-chemical synthesis (1–3). Therefore, many efforts have been focused on improving both the hydrothermal stability and the acidity of mesoporous molecular sieves (4–13). One might expect both to be improved if zeolite-like order could be introduced into the mesopore walls. The amorphous walls of the mesostructure could indeed be converted to a partially zeolitic product. For example, Kloetstra et al. reported the transformation of the walls of Al-HMS and Al-MCM-41 into partially zeolitic structures by ion-exchanging them with a microporous zeolites-structure template, such as TPA^+ (4). Hydrothermally stable mesoporous materials have been synthesized via the assembly of zeolite seeds of ZSM-5, BEA, TS-1, FAU, and so forth, using cetyltrimethylammonium bromide (CTAB) or $HO(CH_2CH_2O)_{20}(CH_2CH(CH_3)O)_{70}(CH_2CH_2O)_{20}H$ (P123) as a structure-directing agent (5–11).

Results and discussion

In this paper, we describe the synthesis of a highly ordered mesoporous aluminosilicate molecular sieve, designated as MSAMS-4, via multistage recrystallization, using ordered mesoporous SBA-15 and aluminosilicates sol–gel diluted solution. Its hydrothermal stability might be attributed to the synergistic effect of the thicker wall, the higher condensation of silanol groups, insertion of non-framework Al atoms, and the formation of zeolites-like subunits within the mesoporous framework.

Figure 1A illustrates the XRD patterns of MSAMS-4 before and after hydrothermal-stability tests. An intense (100) diffraction peak and three well-resolved higher-order (110), (200), and (210) peaks are observed for all three samples. Figure 1B provides the N_2 adsorption–desorption isotherms for MSAMS-4 before and after hydrothermal treatment, and the corresponding pore-size-distribution curves of them are

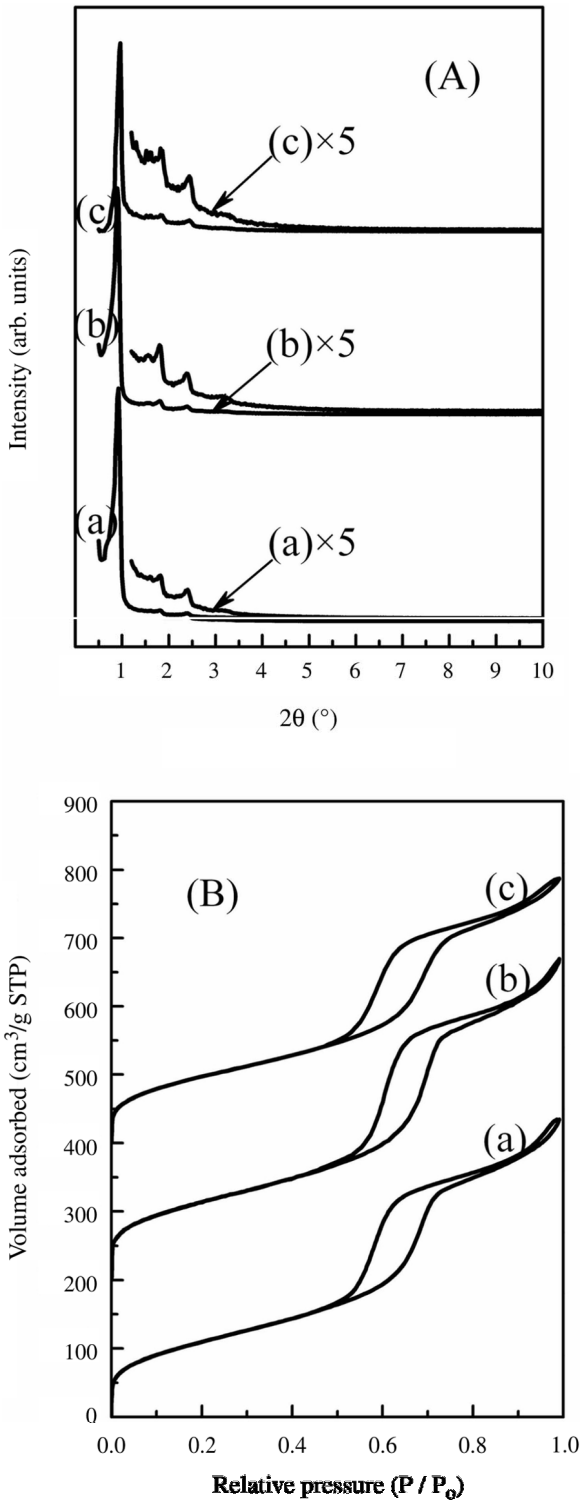
Fig. 1. (A) XRD patterns and (B) N_2-adsorption isotherms of MSAMS-4 before and after the hydrothermal-stability test: (*a*) before, (*b*) after treatment with 100 °C water for 120 h, and (*c*) after steaming at 800 °C for 6 h (20% H_2O in N_2 (*v*/*v*)). The isotherms of (*b*) and (*c*) are offset by 200 and 400 cm^3/g for clarity.



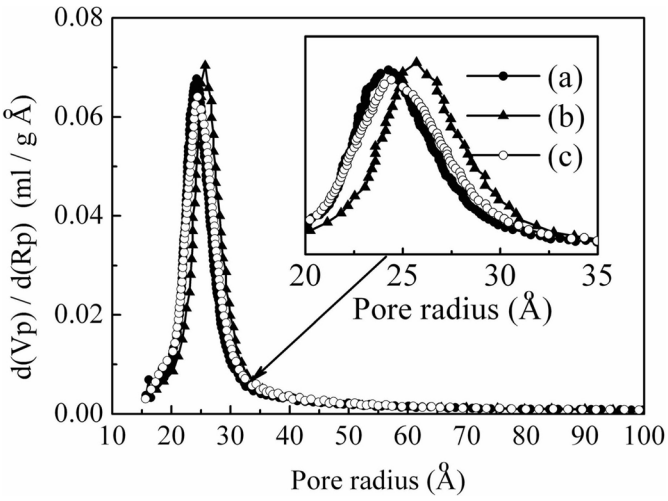


Fig. 2. BJH pore-size-distribution curves of MSAMS-4 before and after the hydrothermal-stability test: (*a*) before, (*b*) after treatment with 100 °C water for 120 h, and (*c*) after steaming at 800 °C for 6 h (20% H_2O in N_2 (*v*/*v*)).

presented as BJH plots in Fig. 2. All samples exhibit type IV isotherms with H_1 hysteresis loops, and a relatively narrow pore-size distribution is observed for each of them. In addition, no obvious changes for the specific surface area and micropore and mesopore volumes of MSAMS-4, before and after hydrothermal-stability tests, are observed (see Table S1 in supplementary data).[3] XRD and N_2 adsorption–desorption results indicate that MSAMS-4 maintained a perfect ordered mesostructure after the hydrothermal-stability tests.

From Fig. S1 (see Supplementary data),[3] the absorption branch of isotherm for MSAMS-4 shows the inflection point at a lower relative-pressure value than that of SBA-15, suggesting a smaller mean pore size for MSAMS-4. On the other hand, compared with SBA-15, no changes in the basal spacing (d_{100}) and linewidth are observed for MSAMS-4. The smaller pore size and the unchanged basal spacing indicate a thicker pore wall (~1.0 nm). In addition, the intensity ratio of the (200)/(110) diffraction peaks of MSAMS-4 is higher than that of SBA-15, indicating a thicker pore wall in case of the MSAMS-4 (14). The thicker MSAMS-4 pore wall might be attributed to the five-membered ring subunits, overgrowing within the channels of SBA-15 with the aid of microporous-zeolites structure template TEA^+, which are expected to provide significantly improved hydrothermal stability to MSAMS-4 (3).

Figure 3 exhibits a band centered at 960 cm^{-1}, observed for both MSAMS-4 and the parent SBA-15, which is characteristic of noncondensed silanol groups (15, 16). However, the intensity of the band for MSAMS-4 is much weaker than that for SBA-15, suggesting a higher condensation degree of the silanol groups in case of MASMS-4, which was further confirmed by ^{29}Si NMR. On the other hand, the band in the 550–600 cm^{-1} region, assigned to the characteristic vibration of five-membered ring subunits (17), is well-expressed in the spectrum of MSAMS-4, but not for the parent SBA-15. The

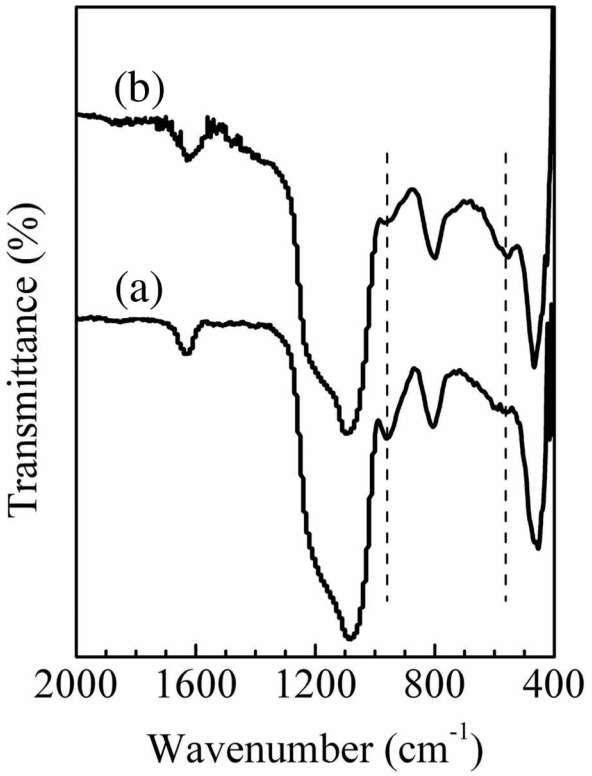

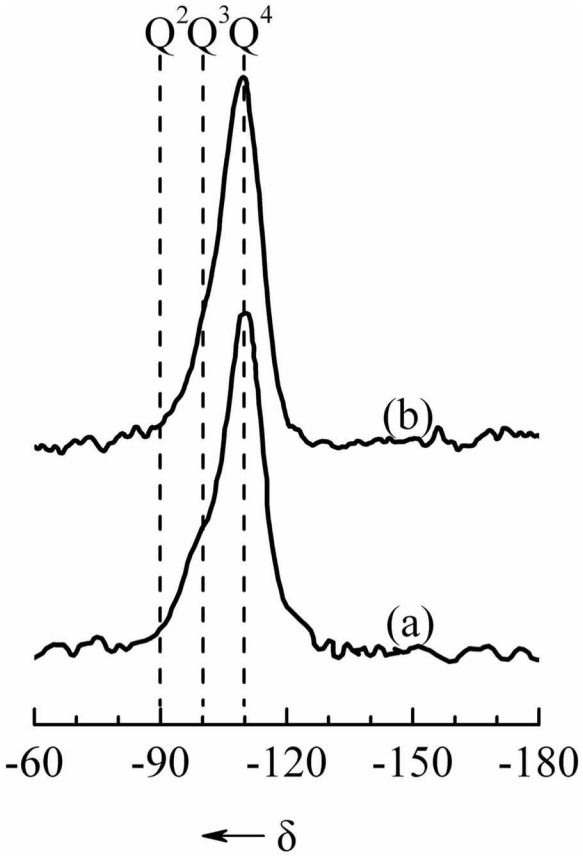

Fig. 4. ^{29}Si MAS NMR spectra of MSAMS-4: (*a*) as-synthesized and (*b*) calcined.

presence of this band indicates the formation of zeolite-like subunits, comprised of AlO_4 and SiO_4 tetrahedra, within the framework of the ordered mesoporous material, which should play an important role in improving its hydrothermal stability (6).

Generally, ordered mesoporous silicate materials show three ^{29}Si NMR resonances, centered at –110, –100, and –90 ppm, which might be attributed to $Si(OSi)_4$ (Q^4), $(HO)Si(OSi)_3$ (Q^3), and $(HO)_2Si(OSi)_2$ (Q^2) framework units, respectively. ^{29}Si MAS NMR spectra of the as-synthesized and calcined MSAMS-4 are presented in Fig. 4. Notably, the as-synthesized MSAMS-4 is primarily composed of fully condensed Q^4 silica units (δ = –110 ppm) and a smaller fraction of incomplete cross-linked Q^3 units (δ = –100 ppm). Normally, surfactant-containing silica mesostructures, whether assembled from ionic or neutral surfactants, exhibit Q^4/Q^3 ratios that are <2.0, and their calcined derivatives typically have values near 3.0 (1, 18). The Q^4/Q^3 ratio of the as-synthesized MSAMS-4 approximates 6.5, and the ratio does not change greatly after calcination, suggesting that the SiOH groups might be site-isolated and buried in the framework. Normally, the high degree of condensation of the silanol groups is responsible for significantly improving the hydrothermal stability of mesoporous molecular sieves (19).

^{27}Al MAS NMR spectrum of MSAMS-4 shows a single resonance centered near 55 ppm (Fig S2, see Supplementary data),[3] characteristic of tetrahedral aluminum centers. This ^{27}Al NMR result indicates that all the Al atoms of MSAMS-4 are incorporated into the framework via multistage recrystallization. This is likely because the octahedrally coordinated Al interacts with the silanol groups of SBA-15, which not only further reduces silanol-groups concentration, but it also acts to heal defect sites in the structure of the parent SBA-15 (20), thus stabilizing the structure.

Conclusions

In conclusion, we synthesized a highly ordered mesoporous molecular sieve, MSAMS-4, via multistage recrystallization. MSAMS-4 exhibits extraordinary stability both in 100 °C water and in high-temperature steam. Its hydrothermal stability may be attributed to the synergistic effect of the thicker wall, the higher condensation of silanol groups, insertion of non-framework Al atoms, and the formation of zeolites-like subunits within the mesoporous framework.

Experimental

Synthesis of MSAMS-4

The following general procedure, described in the literature (12, 13), was used to prepare MSAMS-4:

(*i*) SBA-15 was synthesized using P123, phosphomolybdic acid (HPMo), and tetraethyl orthosilicate (TEOS) as a structure-directing agent, a promoter, and a silica source, respectively. In a typical synthesis batch, 4.0 g of P123 was dissolved in 105 mL of distilled water with vigorous stirring at RT for 3 h, then the calculated amount of HPMo (0.64 g) was added into the solution to keep the molar ratio of Si/Mo at 12.4. After dissolv-

© 2007 NRC Canada

ing P123 and HPMo completely, 8.55 g of TEOS and 0.75 mL of concd. HCl (36 wt%) were added dropwise to the reaction mixture. The chemical composition of the reaction mixture was 4 g of P123 copolymer, 0.041 mol of TEOS, 0.00028 mol of HPMo, 0.0087 mol of HCl, and 5.83 mol of H_2O. Subsequently, the mixture was stirred at 38 °C for 20 h and then thermally treated at 96 °C for 6 h. The reaction products were filtered, washed, and dried at 45 °C for 48 h. Finally, the samples were calcined at 550 °C in air for 8 h.

(*ii*) 9.0 mmol tetraethylammonium bromide (TEA^+) was dissolved in 9.6 mL deionized water. Next, 21.6 mmol TEOS, 25 mL H_2O, and the calculated sodium aluminate ($NaAlO_2$) were added to the solution, and the solution was stirred at RT overnight. Then, the solution was diluted with denionized water to yield 150 mL aluminosilicate sol–gel diluted solution, and the final chemical composition of this solution was 1 mol of TEA^+, 0.06 mol of Al_2O_3, 2.6 mol of SiO_2, 0.06 mol of Na_2O, and 316 mol of H_2O.

(*iii*) the calcined SBA-15 (about 5 g) was added to the diluted solution, and the mixture was vigorously stirred at RT for 2 h. After that, the reaction product was crystallized at 110–130 °C for 12–36 h, followed by filteration, washing, and drying. Subsequently, the dried product was suspended in glycerol and crystallized at 130–150 °C for 24–48 h. Finally, the product was filtered, washed, dried, and calcined at 550 °C in air for 8 h.

Characterization of MSAMS-4

Powder XRD patterns were performed on a Rigaku D/max 2550PC diffractometer, operating at 40 kV and 300 mA and using Cu Kα radiation. BET surface area and N_2 adsorption–desorption isotherms were carried out on an Omnisorp-100CX apparatus at –196 °C. FTIR spectra of the samples in the form of KBr pellets were recorded by using a Nicolet 560 IR spectrometer. The ^{27}Al and ^{29}Si MAS NMR spectra were recorded on a Bruker DSX 300 spectrometer with spinning frequencies of 12 kHz and 4 kHz, respectively.

Intermolecular interactions and electronic properties in phosphino-(oligothiophene) palladium(II) and platinum(II) complexes

Tracey L. Stott, Michael O. Wolf, and Brian O. Patrick

Abstract: A series of Pt(II) and Pd(II) complexes containing diphenylphosphino-substituted oligothiophene ligands ranging from 1 to 3 thiophene rings in length have been prepared. Crystal structures of four of these complexes were determined via single X-ray crystal diffraction and the solid-state packing arrangements found to vary with both the metal and the thiophene-containing ligand. In some cases, π-stacking between thiophene rings are found for the oligothiophene ligands. Solution and solid-state absorption spectra of these complexes are reported.

Key words: oligothiophenes, metal complexes, structural properties, electronic spectra.

Résumé : On a préparé une série de complexes du Pt(II) et du Pd(II) contenant des ligands oligothiophènes substitués par des groupes diphénylphosphino dans lesquels le nombre de noyaux thiophènes varie de un à trois. On a déterminé les structures cristallines de quatre de ces complexes par diffraction des rayons X par un cristal unique et on a observé que les arrangements de l'empilement à l'état solide varient en fonction de la nature du métal ainsi que du ligand contenant le thiophène. Dans quelques cas, on a observé un empilement π pour les ligands oligothiophènes. On a aussi mesuré les spectres d'absorption en solution et à l'état solide de ces complexes.

Mots-clés : oligothiophènes, complexes métalliques, propriétés structurales, spectres électroniques.

Introduction

Conjugated oligomers are of significant interest for application in electroluminescent devices (1), solar cells (2), and field-effect transistors based on molecular materials (3). Solid-state packing and intermolecular interactions are known to influence the emission properties (4) and charge mobility (5) of these materials. In π-conjugated oligomers such as oligothiophenes, π-stacking (6, 7) has been shown to influence the charge mobility as well as the excitation and emission energy of the material (4, 8). The degree of conjugation may also be influenced by solid-state packing, and unsubstituted oligothiophenes adopt a planar, fully conjugated arrangement in the solid state (5).

The solid-state packing of conjugated oligomers, such as oligothiophenes, can be influenced by the use of different organic substituents (5, 9–12) or by a combination of electron-rich and electron-poor groups (13). A novel approach in controlling the solid-state packing is through the use of coordination chemistry where the conjugated groups are positioned as ligands on metal complexes giving a defined local geometrical arrangement, which may predispose the molecule towards specific packing arrangements. Intramolecular geometry may be controlled with coordination chemistry approaches; for example, our group has recently reported the use of pendant Ru(II) complexes to control the coplanarity of rings in a terthiophene derivative (14, 15). In the present work, we have selected palladium(II)- and platinum(II)-bis(phosphine) complexes to further explore these effects. These were chosen because they are readily synthesized, are stable in air, crystallize easily (16), and exist in both cis- and trans-substituted square planar geometries (16–22). Our group has previously reported the synthesis and characterization of several β-substituted phosphinothiophene palladium(II) complexes (23–25). The metal was found to affect both the electronic properties and the structure of the oligothiophene. Au(I) complexes of the α-phosphinothiophene ligands used here have also been reported (26).

Metal centers may create quenching sites within the crystal (27, 28) thus limiting the immediate utility of these materials for application in optoelectronic devices; however, these studies still allow exploration of solid-state effects. The crystal structures of a series of phosphinothiophene palladium(II) and platinum(II) complexes are reported in this paper. The effects of the metal geometry and the length of the thiophene ligand on the structure and electronic spectra are explored. Gray and co-workers (29) recently reported the third-order nonlinear optical behavior of one of the Pd com-

pounds ($Pd(PT_3)_2Cl_2$) and one of the Pt compounds ($Pt(PT_3)_2Cl_2$) described here; however, the solid-state structures of these complexes have not been reported.

Experimental

General

^1H and $^{31}P\{^1H\}$ NMR experiments were performed on either a Bruker AV-300 or a Bruker AV-400 spectrometer. Spectra were referenced to a residual solvent (^1H) or external 85% H_3PO_4 (^{31}P). Isomer ratios were determined from ^{31}P NMR spectra obtained with a delay time of 2 s. Electronic spectra were obtained on a Cary 5000 in HPLC grade CH_2Cl_2. Solid-state absorption spectra were obtained by drop casting the compound from a CH_2Cl_2 solution onto a quartz slide. Microanalyses were performed at UBC. Electrospray mass spectra were obtained by infusion of 10 μmol/L of a methanol solution at ~10 μL/min into the electrospray source of a Bruker Esquire ion trap mass spectrometer. The spectra were acquired in positive ion mode. MALDI-TOF mass spectra were obtained on a Bruker Biflex IV mass spectrometer. Samples were prepared from dichloromethane in a dithranol matrix. $PdCl_2$ and K_2PtCl_4 were purchased from Strem and used as received. THF was dried over Na and benzophenone and was distilled before use. CH_2Cl_2 was dried by passing over an alumina column. Acetonitrile was dried over 3 Å molecular sieves and was degassed by sparging with N_2 for 20 min. No special precautions for the exclusion of oxygen were taken during synthesis. The phosphine ligands 2-diphenylphosphinothiophene (PT), 2-diphenylphosphino-5,2′-bithiophene (PT_2) and 2-diphenylphosphino-5,2′:5′,2′′-terthiophene (PT_3) were prepared as described previously (30, 31).

Synthesis

$Pd(PT)_2Cl_2$ (1)

$PdCl_2$ (0.033 g, 0.19 mmol) was dissolved in an HCl–H_2O solution (0.2:3 *v*/*v*), which was then added dropwise to a solution of 0.10 g (0.39 mmol) PT dissolved in an ethanol–acetonitrile mixture (5:4 *v*/*v*). A yellow precipitate formed immediately, and the yellow slurry was stirred for 1 h. The solvent was then removed via rotary evaporation, and the resulting sticky material was dissolved in CH_2Cl_2 and acetone, then filtered, and a yellow powder was precipitated in hexanes. The product was recrystallized in hexanes–CH_2Cl_2, yielding an analytically pure product. Yield 80%. Anal. calcd. for $C_{32}H_{26}Cl_2P_2PdS_2$: C 53.83, H 3.67; found: C 53.67, H 3.67. ^1H NMR ($CDCl_3$) δ: 7.80 (m, 1H), 7.69–7.62 (m, 5H), 7.46–7.34 (m, 6H), 7.13 (m, 1H). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: 13.6 (s), 23.9 (s).

$Pd(PT_2)_2Cl_2$ (2)

$PdCl_2$ (0.025 g, 0.14 mmol) and PT_2 (0.10 g, 0.29 mmol) were mixed together in a 1:2 mixture of CH_3CN–CH_2Cl_2 for 3 h. The solvent was removed, and the resulting yellow powder was dissolved in CH_2Cl_2, gravity filtered, and precipitated with hexanes. The product was recrystallized in hexanes–CH_2Cl_2. Yield 40%. Anal. calcd. for $C_{40}H_{30}Cl_2P_2PdS_4$: C 54.71, H 3.44; found: C 54.31, H 3.58. ^1H NMR (CD_2Cl_2) δ: 7.73–7.66 (m, 5H), 7.47–7.38 (m, 6H), 7.31 (dd, J = 5.0, 1.2 Hz, 1H), 7.18 (dd, J = 1.2, 3.5 Hz, 2H), 6.98 (dd, J = 5.0, 3.6 Hz, 1H). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: 14.0 (s), 24.2 (s).

$Pd(PT_3)_2Cl_2$ (3)

Results obtained by using a different synthesis were previously reported by our group (24). $PdCl_2$ (0.021 g, 0.12 mmol) was dissolved in an HCl–H_2O solution (0.2:3 *v*/*v*). This was added dropwise to a solution of 0.10 g (0.23 mmol) of PT_3 in THF, and a yellow precipitate began to form almost immediately. The yellow slurry was stirred for 1 h, and the solvent was then removed via rotary evaporation. The resulting sticky material was dissolved in CH_2Cl_2, filtered, and precipitated in hexanes. The product, a bright yellow powder, was recrystallized in hexanes–CH_2Cl_2. Yield 86%. Anal. calcd. for $C_{48}H_{34}Cl_2P_2PdS_6$: C 55.30, H 3.29; found: C 55.06, H 3.29. ^1H NMR ($CDCl_3$) δ: 7.70–7.63 (m, 4H), 7.46–7.38 (m, 6H), 7.28–7.20 (m, 6H, includes $CHCl_3$), 7.18 (d, J = 3.6 Hz, 1H), 7.15 (d, J = 3.6 Hz, 1H), 7.08 (d, J = 3.6 Hz, 1H), 7.04 (d, J = 3.6 Hz, 1H), 6.99 (dd, J = 5.2, 3.6 Hz, 1H). $^{31}P\{^1H\}$ NMR (CD_2Cl_2) δ: 14.3 (s), 24.4 (s).

General procedure for the synthesis of $Pt(PT_n)_2Cl_2$ complexes

The appropriate ligand was dissolved in 50 mL of CH_2Cl_2 and stirred with a solution of 0.5 equiv. of K_2PtCl_4 in 10 mL of H_2O. The reaction was monitored both by the disappearance of the red color in the H_2O layer due to K_2PtCl_4 and by the disappearance of the ligand via TLC. When the reaction was complete the layers were separated, the organic layer was dried over $MgSO_4$ and gravity filtered, and the solvent was removed via rotary evaporation. A minimal amount of CH_2Cl_2 was added to dissolve the resulting solid, which was then precipitated in 300 mL hexanes. The resulting powder was collected via suction filtration and either dried under vacuum or recrystallized from CH_2Cl_2–hexanes to yield an analytically pure sample.

$Pt(PT)_2Cl_2$ (4).

Yield 67%. Anal. calcd. for $C_{32}H_{26}Cl_2P_2PtS_2$: C 47.89, H 3.27; found: C 47.78, H 3.57. ^1H NMR ($CDCl_3$) δ: 7.65–7.59 (m, 2H), 7.47–7.41 (m, 4H), 7.32–7.28 (m, 2H), 7.17–7.13 (m, 4H), 7.04–7.01 (m, 1H). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: 5.6 (s), $^1J_{P-Pt}$ = 3680 Hz. MS (MALDI-TOF) *m*/*z*: 766 (MW-Cl).

$Pt(PT_2)_2Cl_2$ (5)

Yield 73%. Anal. calcd. for $C_{40}H_{30}Cl_2P_2PtS_4$: C 49.69, H 3.13; found: C 49.72, H 3.39. ^1H NMR ($CDCl_3$) δ: 7.58–7.53 (m, 4H), 7.43–7.40 (dd, J = 7.7, 3.8 Hz, 1H), 7.36–7.32 (m, 2H), 7.24–7.19 (m, 6H, includes $CHCl_3$), 7.07 (dd, J = 3.6, 0.9 Hz, 1H), 7.01 (dd, J = 3.6, 1.1 Hz, 1H), 6.97 (dd, J = 5.1, 3.7 Hz, 1H). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: 5.1 (s), $^1J_{P-Pt}$ = 3690 Hz. MS (ESI) *m*/*z*: 931 (MW-Cl).

$Pt(PT_3)_2Cl_2$ (6).

Previously reported by Gray and co-workers (29). Yield 81%. Anal. calcd. for $C_{48}H_{34}Cl_2P_2PtS_6$: C 50.97, H 3.03; found: C 50.61, H 3.27. ^1H NMR (CD_2Cl_2) δ: 7.68–7.57 (m, 8H), 7.51–7.38 (m, 6H), 7.32–7.19 (m, 11H), 7.15 (dd, J =

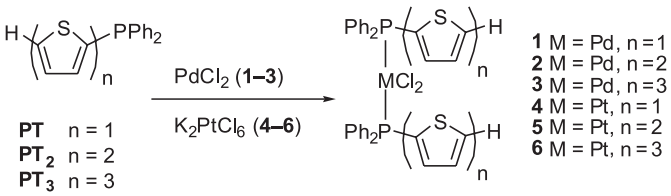
3.51, 1.1 Hz, 2H), 7.07–6.98 (m, 7H). $^{31}P\{^{1}H\}$ NMR (CD_2Cl_2) δ: 4.9 (s), $^{1}J_{P-Pt}$ = 3700 Hz. MS (ESI) *m/z*: 1095 (MW-Cl).

X-ray Crystallography

Suitable crystals of **2**, **3**, **5**, and **6** were mounted in oil on a glass fiber, and the data for each compound were collected at 173(1) K. The structures were solved using direct methods (32, 33) and refined using SHELXL-97 (34). All measurements were made on a Bruker X8 APEX diffractometer with graphite monochromated Mo Kα radiation. For each of the four structures, one terminal thiophene ring was disordered in two orientations. In each case, the disordered fragments were modeled using the simple restraints (SADI or SAME) found in SHELXL.



The data for **2** were collected to a maximum 2θ value of 55.8°. Data were collected in a series of ϕ and ω scans in 0.50° oscillations with 10.0 s exposures. Data were collected and integrated using the Bruker SAINT (35) software package and were corrected for absorption effects using the multiscan technique (SADABS) (36). The data were corrected for Lorentz and polarization effects. The material crystallizes with one half-molecule residing on an inversion center. One thiophene ring in the asymmetric unit is disordered and was modeled in two orientations. The atoms of the major disordered fragment were refined anisotropically, while the atoms of the minor fragment (with a relative population of approximately 0.23) were refined isotropically. Restraints were used to ensure the disordered thiophene fragments had reasonable geometries. All other nonhydrogen atoms were refined anisotropically. All hydrogen atoms were included in calculated positions but not refined.

The data for **3** were collected to a maximum 2θ value of 55.6°. Data were collected in a series of ϕ and ω scans in 0.50° oscillations with 10.0 s exposures. Data were collected and integrated using the Bruker SAINT (35) software package and were corrected for absorption effects using the multiscan technique (SADABS) (36). The data were corrected for Lorentz and polarization effects. All nonhydrogen atoms were refined anisotropically, while all hydrogen atoms were included in calculated positions but not refined. The terminal thiophene ring containing S(3) was disordered and modeled in two orientations with relative populations of 0.77 and 0.23 for the major and minor fragments, respectively.

The data for **5** were collected to a maximum 2θ value of 50.2°. Data were collected in a series of ϕ and ω scans in 0.50° oscillations with 20.0 s exposures. Data were collected and integrated using the Bruker SAINT (35) software package, were corrected for absorption effects using the multiscan technique (SADABS) (36), and were corrected for Lorentz and polarization effects. One thiophene ring is disordered in two orientations. All atoms except the two sulfur fragments and one carbon were refined anisotropically. All hydrogen atoms were included in calculated positions but not refined.

The data for **6** were collected to a maximum 2θ value of 52.8°. Data were collected in a series of ϕ and ω scans in 0.50° oscillations with 12.0 s exposures. Data were collected and integrated using the Bruker SAINT (35) software package. Data were corrected for absorption effects using the multiscan technique (SADABS) (36). The data were corrected for Lorentz and polarization effects. All nonhydrogen atoms were refined anisotropically. All hydrogen atoms were included in calculated positions but not refined. The thiophene ring containing S (6) was disordered and modeled in two orientations with the populations of the major and minor fragments refined to an approximate 2:1 ratio.

Scheme 1.

Results and discussion

Synthesis of complexes

The palladium complexes **1**–**3** were synthesized by one of two methods. The ligand and $PdCl_2$ were either stirred together in a mixture of CH_2Cl_2 and CH_3CN, or $PdCl_2$ was dissolved in dilute HCl and subsequently added dropwise to a solution of the ligand in an appropriate solvent (Scheme 1). The crude products were crystallized in CH_2Cl_2–hexanes to yield analytically pure materials in reasonable yields. Complex **1** has been reported previously (37, 38), and the synthesis and structure of **3** was previously communicated by our group (39). Palladium bis(phosphine) complexes of this type are known to exhibit cis–trans equilibria in solution (20), which can be observed by ^{31}P NMR spectroscopy. The ^{31}P NMR signals for the trans complexes are generally found at a lower chemical shift than those of the cis isomer (40–45). The ^{31}P NMR spectra of **1**–**3** in CD_2Cl_2, $CDCl_3$, and DMSO indicate that although both cis and trans isomers exist in solution, the trans isomer predominates in these solvents (as determined by integration of ^{31}P NMR spectra).

As a single species is desirable for solution characterization, we also chose to synthesize the more inert Pt (16, 46) analogs **4**–**6**. These were prepared by stirring together a solution of K_2PtCl_4 in H_2O and the appropriate ligand dissolved in CH_2Cl_2. The progress of the reaction was monitored by the disappearance of the dark red color of $[PtCl_4]^-$ in the water layer. The crude product obtained was either crystallized in CH_2Cl_2–hexanes or dried under vacuum. Complex **4** has been previously synthesized (37, 38, 47), and the synthesis of **6** was reported by Gray and coworkers (29).

The ^{195}Pt satellites in the ^{31}P NMR spectra of **4**–**6** may be used to determine the geometry at the metal (18, 48). Complexes **4** (δ 6), **5**(δ 5), and **6** (δ 6) have ^{195}Pt–^{31}P coupling constants of 3681, 3685, and 3700 Hz, respectively, which indicate that these are cis-substituted complexes. A second less intense peak was observed in the ^{31}P NMR spectra of analytically pure **6** at δ 11.5. This peak is assigned to the trans isomer, expected to appear downfield to the signal from the cis isomer (48). However, because of the low intensity, no ^{195}Pt satellites are observed for this signal. It may be

that the increased steric bulk of the terthienyl group results in the formation of some trans isomer.

Molecular solid-state structures

Four of the complexes have been characterized by single crystal X-ray diffraction and selected data is shown in Table 1.[2] Complex **3** was reported in a preliminary communication; however, comparisons are included here. The molecular structures of the four complexes are shown in Fig. 1.

All four complexes **2**, **3**, **5**, and **6** are close to a square planar geometry at the metal center. The largest distortion is observed in **5** where one of the Cl–Pt–P angles is 170.85(5)°. In the two Pd complexes the ligands are arranged in trans geometry, whereas the Pt complexes both exhibit cis geometry at the metal. The metal–Cl, metal–P, and P–C bond lengths are similar to those observed for other complexes of this type. The bond lengths in the thiophene rings range from 1.666(8) to 1.752(7) Å for the S–C bonds and from 1.332(8) to 1.519(10) Å for the C–C bonds. The arrangement and coplanarity of adjacent thiophene rings can be assessed by the S–C–C–S torsion angle. A syn coplanar arrangement is indicated by an S–C–C–S angle of 0°, while an anti coplanar arrangment gives an angle of 180°. Unsubstituted thiophene oligomers typically crystallize in a nearly completely anti coplanar arrangement (5). In all the structures here, adjacent thiophene rings are not completely coplanar (S–C–C–S angle is between 7.6(7)° and 175.40(14)°), and both syn and anti arrangements are found, sometimes within the same molecule. Table 2 summarizes these angles. The largest deviation from coplanarity between adjacent rings is found in **6** where rings containing S2 and S3 have an interannular angle of approximately 40°.

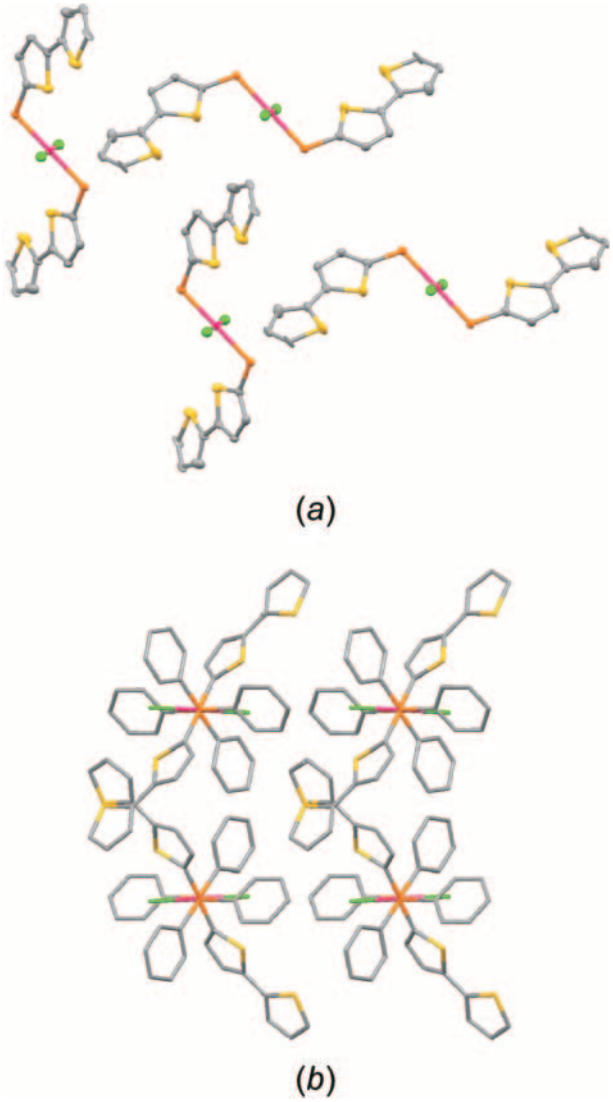

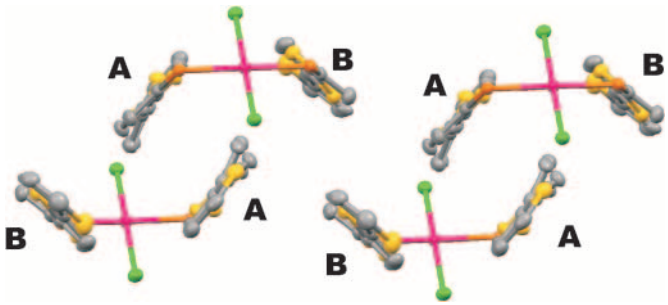

Fig. 3. Packing diagram for **3**, viewed down the long molecular axis of the terthienyl groups. Phenyl groups and hydrogen atoms are omitted for clarity.

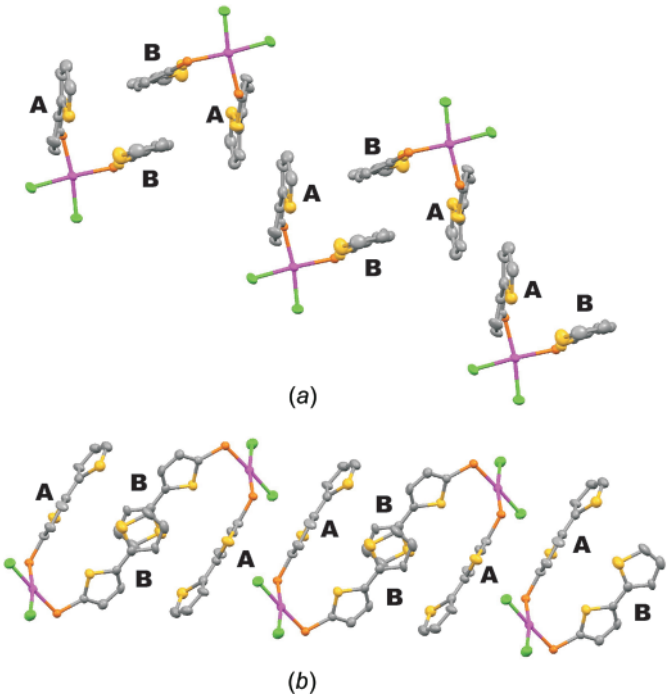
Solid-state packing of Pd complexes

Complex **2** crystallizes in the $P2_1/n$ point group. The bithienyl groups are arranged on opposite sides of the plane passing through the Pd, P, and Cl atoms (Fig. 2*a*). The bithiophene groups are arranged in interlocking stacks with adjacent bithienyl groups twisted relative to one another by approximately 90°. When the structure is examined looking down the *c* axis (Fig. 2*b*), it is apparent that the phenyl groups form a tube surrounding the bithienyl stacks, separating the stacks from each other. No π-stacking of thiophene rings is observed in this structure. Short S–S interactions are believed to be important in facilitating charge-transfer in the oligothiophenes (5), however here the shortest intermolecular S–S distance is ~5.6 Å, precluding any interactions between sulfur atoms.



Complex **3** was previously reported but the solid-state packing is discussed here for comparative purposes. This complex crystallizes in the $P2_1/n$ point group. In contrast to **2**, the terthienyl groups are oriented on the same side of the metal plane in this case. In the crystal lattice, the arrangement of the terthienyl groups may be examined by considering the crystallographically distinct terthienyl groups **A** and **B** (Fig. 3). Pairs of terthienyl groups **A** are arranged with interplanar distances, for the inner thiophene rings of the terthienyl groups, within the range of π-stacking (3.65 Å) (13, 49). The π orbital overlap between aromatic groups is greatest if they are arranged in a stack perpendicular to the molecular plane. The two **A** groups are slightly slipped relative to one another, with the slip greater along the short axis of the groups. The degree of slip along the long and short axis may be quantified via pitch and roll angles, as discussed for organic conjugated oligomers by Curtis et al. (13). The interactions between the other pair of coplanar terthienyl groups (**B** and **B**) are much weaker, since these groups are slipped much more substantially (large roll angle) relative to each other despite having little slip along the long axis (small pitch angle). Pairs of groups **A** and **B** are arranged face-to-edge, similar to the motif found in herringbone stacks of organic oligomers (13). The shortest S–S distance in the lattice is 4.13 Å, again too long for any significant S–S interactions in this structure (5).

Solid-state packing of Pt complexes

Complex **5** crystallizes in the $P2_1/c$ point group. The structure shows some similarities to that of the Pd terthienyl complex **3**. The bithienyl groups in **5** are also arranged on the same side of the plane containing the metal, and weak intermolecular π-stacking (3.76 Å) between the outer thienyl

Fig. 4. Packing diagram of **5** viewed (*a*) down the long molecular axis of the bithienyl groups and (*b*) down the short molecular axis of bithienyl groups **A**. Phenyl groups and hydrogen atoms are omitted for clarity.

rings in group **B** on adjacent molecules is observed (Fig. 4*a*). However, these groups show substantial slip along the long molecular axis (large pitch angle) relative to what is observed in **3** (Fig. 4*b*). The **A** groups are rather far apart in the structure and do not interact. Some intramolecular π-stacking of phenyl groups is observed (not shown), with a plane-to-plane distance between the centroids of the rings of 3.63 Å.

Complex **6** crystallizes in the $P2_1/n$ point group. The terthienyl groups (**A**) in this structure are arranged in an approximately coplanar fashion to each other with an intermolecular plane-to-plane distance (between the centroids of the rings) of 3.45 Å (Fig. 5). The rings are slightly slipped along both the long and short molecular axis. The other terthienyl groups (**B**) are arranged so that the edges of the pair of **A** groups point towards the plane of **B** with the **A** and **B** groups twisted 90° relative to each other. Thus in Fig. 5 the view is down the long axes of the two **A** groups, with the long axis of the **B** groups perpendicular to these. Intramolecular π-stacking is also observed between thienyl and phenyl rings (Fig. 6), with a plane-to-plane distance between the centroids of the rings of 3.52 Å.

Absorption spectra

The solution and solid-state absorption spectra of complexes **1–6** are shown in Figs. 7 and 8 respectively, and the data is summarized in Table 3. Although both cis and trans isomers are present in solutions of the Pd complexes **1–3**,

Fig. 5. Packing diagram of **6**. Phenyl groups and hydrogen atoms are omitted for clarity.

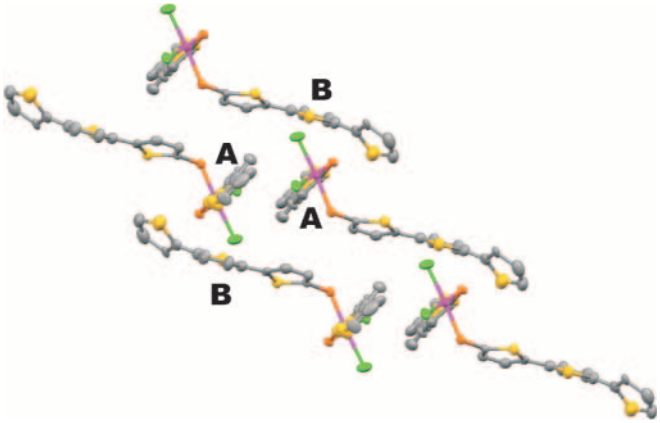

Fig. 6. Intramolecular stacking between phenyl ring and inner thiophene ring in group **B** of **6**. Hydrogen atoms are omitted for clarity.

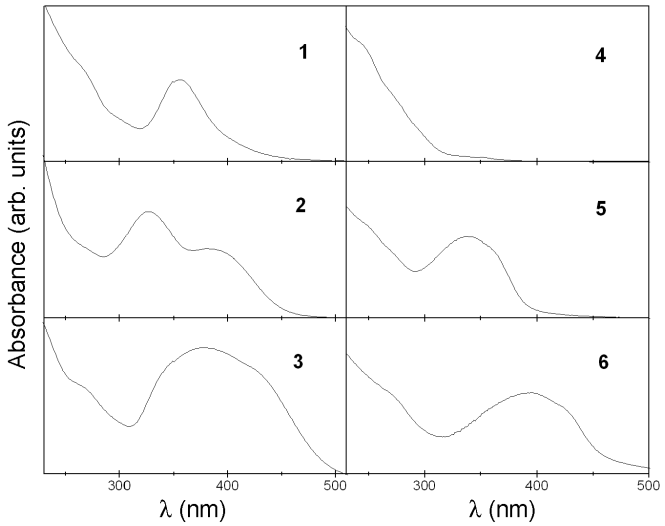
6	269 (sh), 2.1×10^4; 277 (sh), 1.6×10^4; 377, 5.8×10^4	270 (sh), 396

Fig. 8. Solid-state absorption spectra of palladium complexes **1–6**.



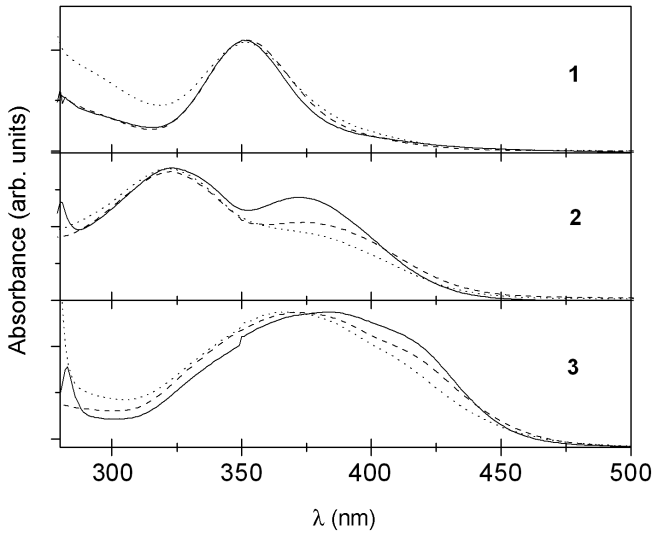


Fig. 9. Solution absorption spectra of palladium complexes **1**, **2**, and **3** in CH_3CN (dotted line), CH_2Cl_2 (broken line), and toluene (solid line).

the amount of cis is low in CH_2Cl_2 (ca. 5% as determined by integration of the ^{31}P NMR spectrum) and should not significantly affect the spectra. In the solution spectrum of **1**, there are shoulders between 250 and 300 nm and a distinct peak at 352 nm. The higher energy bands are assigned to n→π* and π→π* transitions of the ligands and are not substantially shifted from the spectra of the uncoordinated PT (31). The band at 352 nm is not seen in the spectra of PT or in the analogous gold (26) or platinum (**4**) complexes. A band at comparable energy and molar absorptivity is seen in the spectra of other dichlorobis(phosphine) palladium complexes (40, 50–55) and is usually assigned to a LMCT transition (Cl→Pd). The energy of charge transfer bands typically change with the polarity of the solvent (56); however, for **1** no significant shift was observed for this band when comparing the spectra in toluene, CH_2Cl_2, and CH_3CN (Fig. 9). In the solid state the band does shift slightly (3 nm).

Two overlapping bands can be seen in both the solution (322 nm and 374 nm) and solid-state (328 and 384 nm) absorption spectra of **2**. Presumably, one of these peaks is due to a π→π* transition in the bithienyl group and the other to a Cl→Pd charge transfer band, similar to that seen in the spectrum of **1**. The higher energy band is assigned as the π→π* transition, as it is very similar in energy to PT_2 (λ_{max} = 333 nm) (31). The Pd center appears to have little effect on the absorbance of the thiophene group. The lower energy band is assigned to the LMCT transition, which is shifted by 22 nm when compared with the spectrum of **1**. This indicates that the phosphinothiophene ligand has some influence on the LMCT transition. Although the shift is surprisingly large, it is known that there is a significant contribution from triphenylphosphine to the LMCT band of *trans*-dichlorobis(triphenylphosphine) palladium (II), as determined by resonance Raman spectroscopy (51). When the solution spectra for **2** taken in toluene, CH_2Cl_2, and CH_3CN are compared, (Fig. 9) a shift in energy and a change in the intensity of the lower energy band are observed.

The solution spectrum of **3** consists of a broad band at 372 nm with a shoulder at 415 nm. The peak is assigned to a terthiophene-based π→π* transition. As in the spectrum of **2**, it is very similar in energy to the ligand (λ_{max} = 374 nm), indicating little influence of the Pd center on the conjugated moiety. This has also been noted by Gray and co-workers (29). The solid-state spectrum of **3** appears much the same as the solution spectrum, but the peak broadens and shifts to lower energy (380 and 428 nm). These effects may be due to the π-stacking of the terthienyl groups observed in the crystal structure or to the increased planarity of the terthienyl groups in the solid state (57–60). As was seen in the β-substituted phosphinothiophene palladium(II) complexes previously reported (24), no distinct LMCT band is observed here. It is likely that this band overlaps with the terthienyl π→π* transition, which would also indicate some phosphinothiophene character in the LMCT. There appears to be a small decrease in the energy of the band, as the polarity of the solvent is increased and the shoulder at 415 nm becomes more prominent (Fig. 9). This may be due to conformational effects or, if the LMCT overlaps with the terthienyl π→π*

© 2007 NRC Canada

transition, it may be solvatochromism of the LMCT transition.

The spectra of platinum complexes **4**–**6** are dominated by the $\pi \rightarrow \pi^*$ transitions of the oligothiophene moieties. The spectra of these complexes in solution and in the solid state are very similar to those of the corresponding ligands, indicating little electronic effect of the metal center on the thienyl moiety. The shoulders in the spectra of **5** and **6** have been assigned to conformational effects (57, 60).

Conclusions

The series of palladium (II) and platinum (II) phosphinothiophene complexes reported here show interesting variation in their solid-state crystal structures. Although both cis and trans species are observed in the ^{31}P NMR spectra of the palladium complexes **1**–**3**, the isolated crystals of both **2** and **3** exhibit trans geometry exclusively. The platinum complexes **4**–**5** exist in solution only as the cis isomer, as evidenced by their respective ^{31}P–^{195}Pt coupling constants, while **6** appears to have a small amount of the trans isomer present. Only cis isomers are seen in the solid state.

We have focused on the intermolecular interactions between the oligothiophene groups and have found that in contrast to most organic oligothiophenes that pack in a herringbone fashion (5), these metal complexes adopt a variety of structures in the solid state depending on both the metal and the oligothiophene ligand. Interestingly, we find similarities in the structures of **3** and **5**, both of which pack with the oligothiophene groups interlocked and on the same side of the metal plane. The overlap between the terthienyl groups is greater in **3** and it is tempting to speculate that if the bithienyl groups in **5** were extended by one ring, the overlap would improve to give a structure similar to **3**. However, this is not observed and the Pt terthienyl complex **6** exhibits quite a different structure, although also one in which π-stacking between terthienyl groups is observed.

Synthesis, characterization, and reactivity of Pd(II) salicylaldimine complexes derived from aminophenols

Bennett J. Tardiff, Joshua C. Smith, Stephen J. Duffy, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Schiff bases, derived from the condensation of salicylaldehydes with 3- and 4-aminophenol, reacted with palladium(II) acetate to give the corresponding bis(*N*-arylsalicylaldiminato)palladium(II) complexes. These complexes have been found to be active catalysts for the Suzuki–Miyaura cross-coupling of aryl bromides and iodides with aryl boronic acids, using water as a solvent.

Key words: cross-coupling, green chemistry, palladium, salicylaldimines, Schiff base, Suzuki–Miyaura.

Résumé : Les bases de Schiff résultant de la condensation de salicylaldéhydes avec les 3- et 4-aminophénols réagissent avec l'acétate de palladium(II) pour conduire aux complexes correspondants bis(*N*-arylsalicylaldiminato)palladium(II). On a trouvé que ces complexes sont actifs dans les réactions de couplages croisés de Suzuki–Miyaura des bromures et des iodures d'aryles avec les acides arylboroniques, en présence d'eau comme solvant.

Mots-clés : couplage croisé, chimie verte, palladium, salicylaldimines, base de Schiff, Suzuki–Miyaura.

[Traduit par la Rédaction]

Introduction

The use of palladium complexes to catalyze the coupling of organoboron compounds with aryl or vinyl halides has become one of the most widely used tools in organic synthesis. The scope and utility of the Suzuki–Miyaura reaction have been the subject of several excellent reviews (1). Indeed, the Suzuki–Miyaura cross-coupling reaction has become an attractive route to generating biaryls, compounds with vast applications ranging from pharmaceutical chemistry to materials science. The use of boronic acids in this cross-coupling process is especially advantageous, as these compounds are relatively nontoxic and thermally, air-, and moisture-stable (2).

Numerous advances have been made to this reaction since its discovery. For instance, the use of aryl chlorides as substrates and the ability to conduct the reaction at low temperature and at low catalyst loading have greatly increased the versatility of the Suzuki–Miyaura cross-coupling reaction. Catalyst development has also played a significant role in improving this reaction (3), as traditional palladium complexes used to catalyze this transformation contained air-sensitive phosphine ligands. Recently, catalysts, containing *N*-heterocyclic carbenes (4), and "ligandless" systems (5), as well as heterogeneous systems (6), have also been employed. A considerable amount of research has also focused on designing water-soluble catalysts to provide a greener and more environmentally benign alternative to this reaction (4*i*, 7). In a recent elegant study by Hong et al., it was found that (*N*-arylsalicylaldiminato)palladium(II) complexes are active catalysts for the Suzuki–Miyaura cross-coupling reaction of a wide array of aryl bromides (8*a*). However, reactions were carried out in organic solvents (THF and toluene), and high yields were only achieved after long periods of time (days). Likewise, trinuclear triphenylphosphine Au(I) complexes with *N,N,O*-tridentate unsymmetrical Schiff base ligands catalyzed the Suzuki–Miyaura cross-coupling reaction to afford nonsymmetrical biaryls in good yields, whereas the Au(III) complexes gave only arylboronic homocoupling products (8*b*). As part of our ongoing investigation into designing new metal Schiff base complexes, we prepared several palladium complexes derived from salicylaldehydes and aminophenols and examined their ability to be used as catalysts for the green Suzuki–Miyaura cross-coupling reaction.

Experimental

General

Reagents and solvents used were purchased from Aldrich Chemicals. $Pd(OAc)_2$ was purchased from Precious Metals Online Ltd. (Melbourne, AU). NMR spectra were recorded on a JEOL JNM-GSX270 FT spectrometer or a Varian Mercury Plus 200 NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and are referenced to the residual solvent protons in the deuterated solvent at 270 and 200 MHz, respectively. ^{13}C NMR chemical shifts are referenced to the solvent carbon resonances as internal standards at 68 and 50 MHz, respectively, and are reported in ppm. Multiplicities are reported as singlet (s), doublet (d), triplet (t), multiplet (m), broad (br), and overlapping (ov). Infrared spectra were obtained using a Mattson Genesis II FTIR spectrometer. Melting points were determined using a Mel-Temp apparatus and are uncorrected. Microanalyses for C, H, and N were carried out at Guelph Chemical Laboratories (Guelph, ON). GC–MS analyses were conducted using a Varian Saturn 2000 MS, coupled to a CP-3800 GC. The GC was equipped with both the 1177 injection port with a CP-8410 liquid autoinjector connected to an SPB-1 (Supelco) fused-silica column (30 m × 0.25 mm i.d. × 0.25 μm) and the 1079 solid-injector chromatoprobe, attached to a 50 cm transfer line. The GC–MS spectrometer is controlled by the Saturn Workstation software, Version 5.51. Imines were prepared by established procedures (9).

X-ray crystallography

Crystals of **2b** were grown from a DMSO solution at 20 °C, **2e** from a saturated THF solution at 5 °C, and **2f** from a saturated CH_2Cl_2 solution at 5 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and exposure times of 10 s (**2b**), 30 s (**2e**), and 80 s (**2f**). The detector distances were 5 cm. The data were reduced (10*a*) and corrected for absorption (10*b*). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (10*c*). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically (**2b**) or included in calculated positions and refined using a riding model (**2e** and **2f**).

Complex 2a

Palladium(II) acetate (100 mg, 0.45 mmol) was added to a solution of 2-((*E*)-(3-hydroxyphenylimino)methyl)phenol (200 mg, 0.94 mmol) in EtOH (15 mL). The solution was heated at reflux for 2 h, at which point the solvent was removed under vacuum, leaving a brown powder, which was washed with Et_2O (3 × 5 mL). Yield: 170 mg (71%); mp 284–286 °C dec. IR (Nujol): 3433 (br, OH), 2933 (s), 2910 (s), 2856 (s), 1608 (w), 1538 (w), 1457 (w), 1376 (w), 1272 (w), 1145 (w), 846 (w). Spectroscopic NMR data (in DMSO-d_6): ^{1}H δ: 9.61 (br s, O*H*, 2H), 8.02 (s, N=C*H*, 2H), 7.43 (d, *J* = 7.4 Hz, Ar, 2H), 7.23–7.13 (ov m, Ar, 4H), 6.78–6.73 (ov m, Ar, 6H), 6.50 (t, *J* = 7.4 Hz, Ar, 2H), 6.02 (d, *J* = 8.4 Hz, Ar, 2H). ^{13}C{^{1}H} δ: 164.6, 163.7, 157.6, 150.6, 135.8, 135.6, 129.2, 120.7, 120.4, 115.8, 115.2, 113.8, 112.4. Anal. calcd. for $C_{26}H_{20}N_2O_4Pd$ (%): C 58.82, H 3.80, N 5.28; found: C 58.43, H 3.49, N 5.12.

Complex 2b

Palladium(II) acetate (100 mg, 0.45 mmol) was added to a solution of 2-((*E*)-(4-hydroxyphenylimino)methyl)phenol (200 mg, 0.94 mmol) in EtOH (15 mL). The mixture was heated at reflux for 2 h, at which point the solvent was removed under vacuum. The resulting brown solid was washed with Et_2O (3 × 5 mL). Yield: 155 mg (65%); mp 306 °C dec. IR (Nujol): 2919 (s), 2854 (s), 1606 (w), 1542 (w), 1462 (m), 1376 (m), 1178 (w), 842 (w), 759 (w). Spectroscopic NMR data (in DMSO-d_6): ^{1}H δ: 9.49 (br s, O*H*, 2H), 7.99 (s, N=C*H*, 2H), 7.42 (d, *J* = 7.4 Hz, Ar, 2H), 7.23–7.14 (ov m, Ar, 6H), 6.83–6.76 (ov m, Ar, 4H), 6.48 (t, *J* = 7.2 Hz, Ar, 2H), 6.06 (d, *J* = 8.4 Hz, Ar, 2H). ^{13}C{^{1}H} δ: 164.6, 163.7, 146.3, 141.3, 135.7, 135.3, 126.2, 120.8, 120.2, 115.1, 114.8. Anal. calcd. for $C_{34}H_{24}N_2O_4Pd$ (%): C 64.71, H 3.84, N 4.44; found: C 64.48, H 3.52, N 4.32.

Suzuki–Miyaura cross-coupling reactions

An aryl halide (1 mmol) and a boronic acid (1 mmol) were added to a solution of H_2O (10 mL), K_2CO_3 (276 mg, 2 mmol), and palladium complex (0.5 mol %). The solution was heated at reflux for 2 h. An organic extraction was performed using dichloromethane (2 × 10 mL), whereupon the solution was diluted by a factor of 100 and analyzed in duplicate using GC–MS spectroscopy.

Results and discussion

Salicylaldimines

Schiff bases are remarkable compounds that have been utilized extensively in organic syntheses (12). For instance, a recent report describes a highly diastereo- and enantioselective asymmetric aldol reaction of glycinate Schiff bases with aldehydes (12*a*). In this study, we have found that salicylaldehydes add to 3- and 4-aminophenol to give compounds having spectroscopic data consistent with the Schiff bases **1a**–**1f**. As expected, the proton, initially assigned to the aldehyde group, shifts from 10 to 9 ppm in the ^{1}H NMR spectra upon conversion to the imine functionality, and a resonance at ~160 ppm in the ^{13}C NMR spectra corresponds to the N=CH methine carbon. Likewise, formation of these compounds can be monitored by the diagnostic C=N stretching band in the IR spectra at ~1620 cm^{-1} (12*b*). Attempts to make the corresponding Schiff bases from 2-aminophenol led to products arising from a competing oxidative cyclization reaction (13).

Metal complexes

We have found that addition of **1a**–**1f** to $Pd(OAc)_2$ afforded bis(*N*-arylsalicylaldiminato)palladium(II) complexes (Scheme 1) in moderate yields (41%–71%). Complexes **2a**–**2f** have been characterized by a number of physical methods, including multinuclear NMR spectroscopy. A significant upfield shift in the ^{1}H NMR spectra is observed for the imine methine proton, from ~9 ppm to ~8 ppm, upon coordination of the ligand to the d^8 metal centre. The diagnostic

Selected bond lengths (Å) and angles (°) for **2b**: Pd—O(16) No. 1, 1.9842(13); Pd—O(16), 1.9843(13); Pd—N(8) No. 1, 2.0256(14); Pd—N(8), 2.0257(14); O(1)—C(2), 1.367(2); C(5)—N(8), 1.439(2); N(8)—C(9), 1.292(2); C(15)—O(16), 1.311(2); O(16) No. 1–Pd–O(16), 180.00(6); O(16) No. 1–Pd–N(8) No. 1, 90.89(5); O(16)–Pd–N(8) No. 1, 89.11(5); O(16) No. 1–Pd–N(8), 89.11(5); O(16)–Pd–N(8), 90.89(5); N(8) No. 1–Pd–N(8), 180.00(7); C(2)–O(1)–H(1), 111.8(19); O(1)–C(2)–C(3), 121.90(17); O(1)–C(2)–C(7), 118.57(17).

C=N stretching band in the FTIR spectra has also shifted from ~1620 cm^{-1} to ~1595 cm^{-1} upon coordination to the metal centre (14). Elemental analyses are also consistent with bis Schiff base formulation, and complex **2a** has also been characterized by a mass spectrometry IA-MALDI-TOF study (15), which showed an excellent match between simulated and observed isotope patterns (Fig. 1).

Complex **2b** has been characterized by a single-crystal X-ray diffraction study (Fig. 2). Crystallographic data are provided in Table 1.[3] The environment about Pd is square-planar, supplemented by hydrogen bonds of 2.679(2) Å, resulting in an octahedral environment and a two-dimensional network. DMSO molecules hydrogen bond at a distance of 1.93(3) Å and long S···O bonds of 3.2437(15) Å complete the formation of the two-dimensional sheets. The Pd—O and Pd—N distances of 1.9843(13) Å and 2.0257(14) Å, respectively, are similar to those seen in related complexes (8*a*, 9). Similar copper complexes have recently been reported to be active catalysts in the polymerization of norbornene (16).

Interestingly, the molecular structure of **2e** (Fig. 3) has also been characterized by a single-crystal X-ray diffraction study, and in this case, the metal lies in a distorted square-planar geometry with a cis-N_2O_2 donor set. The naphthyl groups are distorted from the $Pd(N,O)_2$ plane and result in a parallel alignment of the phenol groups. The C(6)—C(25) distance of 3.349(8) Å suggests that intramolecular arene–arene stacking may be important (17). While it is unclear at this time why these ligands lie in a cis configuration, this unusual arrangement has been observed recently in bulky bis(*N*-3,5-Bu^t-2-phenyl-(*R*)-salicylaldiminato)copper(II) complexes, where small changes in the substituents resulted in drastic changes in the molecular structure and in the corresponding redox properties (18). Attempts to obtain single crystals of the corresponding 4-hydroxyl derivative **2f** were complicated by crystal twinning and the deposition of very thin plates from solutions of **2f**. However, the preliminary structure of **2f** clearly shows the trans-arrangement of the ligands (Fig. 4). As these conformers are indistinguishable by NMR spectroscopy, further structural studies are therefore needed to understand the nature of these discrepancies.

Catalytic activity

As mentioned previously, Hong et al. found that cross-coupling reactions of aryl bromides and phenyl boronic acids could be catalyzed by $Pd(OAc)_2$ and 2-[1-(2,4,6-trimethylphenylimino)ethyl]phenol (HL) (8*a*). Reactions were carried out in organic solvents (THF and toluene) at

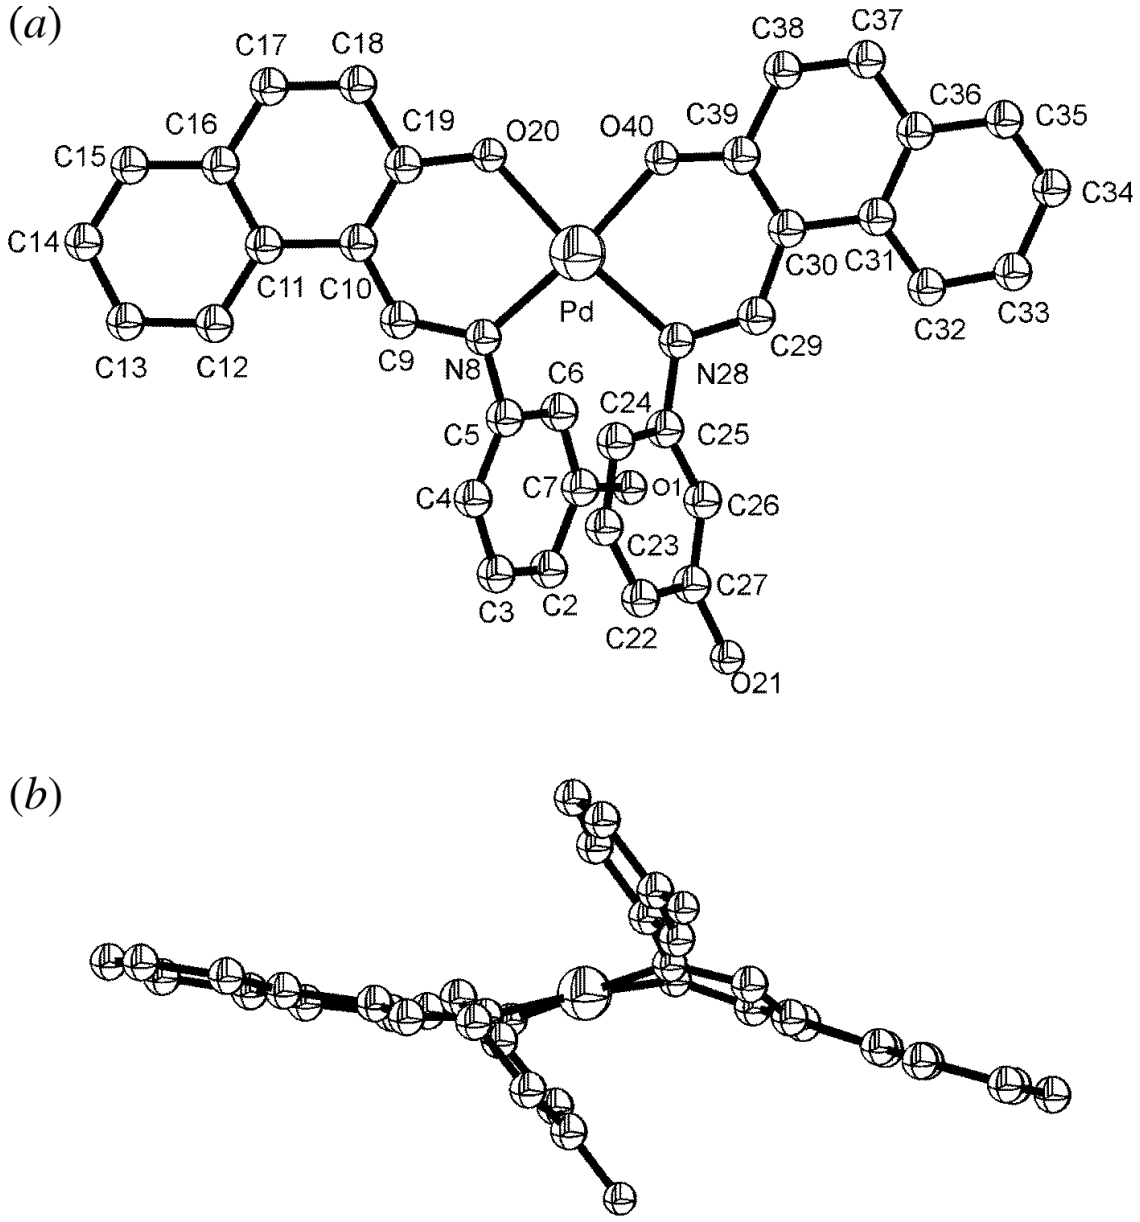
room temperature, and high yields of the desired products were only achieved after long periods of time (days). Interestingly, only one molar equivalent of the N,O-bidentate Schiff base ligand was used in this study, although the catalyst resting state appears to be the corresponding bis Schiff base compound PdL_2. Reduced catalytic activity was observed for reactions using this bis Schiff base compound, as the active catalyst precursor was believed to be the mono Schiff base compound PdL(OAc)(solvent). It is also possible that palladium nanoparticles, formed by the decomposition of the catalyst precursor during the reaction, are responsible for the observed catalytic activity in these systems (7*o*).

In this preliminary study, preformed complexes **2a**–**2f** were examined for their ability to catalyze the coupling of 4-iodotoluene and phenyl boronic acid in water. Reactions were conducted in air using 0.5 mol% catalyst loading and potassium carbonate at reflux. Remarkably, all reactions with these bis Schiff base complexes gave near-quantitative yield of the unsymmetrical biaryl cross-coupling product after only 2 h (Table 2, entry 1). Complex **2f** gave the most consistent results with minimal amount of catalyst decomposition; therefore, it was used in all the catalytic studies. While reactions with bromotoluene also gave high yields of the desired biaryl product (Table 2, entry 2), these catalysts failed to couple reactions with chlorotoluene (Table 2, entry 3). The electronic nature of the aryl group had little effect on activity, as both the methoxy- (Table 2, entry 4) and fluoro-substituted iodobenzene (Table 2, entry 5) derivatives gave excellent yields of the desired product. Reactions of 4-iodotoluene and naphthalboronic acid using 0.5 mol% of **2f** also gave near-quantitative yields of the corresponding cross-coupling product.

Conclusion



In summary, we have prepared a series of (*N*-arylsalicylaldiminato)palladium(II) complexes, derived from aminophenols, and examined their ability to catalyze the Suzuki–Miyaura cross-coupling reaction. Although no significant activity is observed with aryl chlorides, these complexes effectively catalyze the coupling of both aryl bromides and aryl iodides. Further work is needed to expand the scope of this reaction, the results of which will be published in due course.

Aqua-mediated one-pot synthesis and aromatization of pyrimido-fused 1,4-dihydropyridine derivatives using ammonium salts

Mazaahir Kidwai and Kavita Singhal

Abstract: Dipyrimidine-fused pyridine derivatives were synthesized using 1,3-diketone, aldehyde, different ammonium salts, and water, as the solvent. Aromatization was observed when ammonium nitrate was used as the source of nitrogen, and thus, dipyrimidine-fused pyridine derivatives were synthesized in one-pot synthetic procedure. This environmentally benign procedure leads to high yield of products (80%–90%) in a single step, with greater purity using water as the solvent.

Key words: water, aromatization, dipyrimidopyridine, ammonium salts.

Résumé : On a effectué les synthèses de dérivés de la dipyrimidine condensée à de la pyridine en utilisant une 1,3-dicétone, un aldéhyde, divers sels d'ammonium et de l'eau comme solvant. On observe l'aromatisation lorsqu'on utilise du nitrate d'ammonium comme source d'azote et dans de telles conditions les synthèses des dérivés de la dipyrimidine condensées à de la pyridine sont réalisées par une méthode monotope. Cette méthode environnementalement bénigne conduit à des rendements élevés (80 % à 90 %) de produits d'une grande pureté, en une seule étape et utilisant de l'eau comme solvant.

Mots-clés: eau, aromatisation, dipyrimidopyridine, sels d'ammonium.

[Traduit par la Rédaction]

Introduction

The use of toxic and volatile organic solvents has led to immense environmental deterioration. This entails a challenge for chemists to develop new alternatives that can meet the promises of green chemistry. One of the recent advances in this area where substantial progress has been made is the use of water as reaction medium (1). Various advantages offered by the use of water as the solvent, such as the increased rate of reaction (2), have been explained on the basis of its permanent dipole moment and its behavior as pseudo-organic solvent at elevated temperature. Hence, water has become an attractive medium for many organic reactions. Not only one can avoid the use of dry reactants and solvents, but also the use of water provides unique reactivity and selectivity.

Multicomponent one-pot synthetic protocols (3), such as Hantzsch reaction (4), and their products, 1,4-dihydropyridines (DHPs) (5), have attracted considerable attention because of their recognition as a core structure in calcium antagonists (6). In the case of the structure–activity relationship, the effect of substitution on the DHPs ring has been thoroughly studied (7), and its usefulness has led to recent developments. Furthermore, the scope of this pharmacophore, especially dipyrimidopyridines (DPPs) (8), which are structurally cyclized compounds of the amino analogues of the Hantzsch esters, has been increased by the identification of them as 5-deazaflavin derivatives (Fig. 1, **I**) (9). 5-Deazaflavins were considered to be $NAD(P)^+$ models (NAD: nicotinamide dinucleotide), which oxidize alcohols and exhibit efficient autorecycling oxidation in approximately 100% yield. Furthermore, one of the canonical forms has been regarded as model of the nicotinamide nucleotide-protected by annelation "masked NAD^+ analogue", i.e., as NAD-type redox catalysts (10) (Fig. 1, **II**). The fusion of the two pyrimidine rings (i.e., ureido and thioureido groups) to the pyridine nucleus improved the antiviral activity (11), and the products have also shown antibacterial activities (12).

Aromatization of 1,4-DHPs has also attracted considerable attention because of the reported in vivo studies (13) and their important role in the biomimetic oxidation reactions (14). Dihydropyridines are often produced in a synthetic sequence and need to be oxidized to pyridines. Many oxidizing agents, such as HNO_3, DDQ (15), ceric ammonium nitrate (16), $Mn(OAc)_3$ (17), $Bi(NO_3)_3{\cdot}5H_2O$ (18), $Cu(NO_3)_2$ (19), $RuCl_3/O_2$ (20), activated carbon/O_2 (21), I_2/MeOH (22), $FeCl_3$ (23), and Pd/C (24), have been documented for the aromatization of Hantzsch esters. Most of the existing methods suffer from drawbacks, including two steps, tedius workup, the use of hazardous organic solvents (e.g., dichloromethane, chloroform, and xylene), expensive complex catalysts under strong acidic conditions, and poor

5-Deazaflavins (**I**)

Dipyrimidopyridine Analogues (**II**)

yields. Therefore, developing a one-pot protocol, using water as the solvent, that could omit any harmful catalyst seems highly desirable.

In our endeavor to develop an environmentally benign protocol (25) and continuing our interest in nitrogen heterocycles with biopotentiality using aqueous-mediated synthetic methodologies (26), we attempted to synthesize dipyrimidine-fused pyridines in appreciable yields using barbituric acid or 2-thiobarbituric acid as alternates to β-ketoesters (27) in water. In this paper, water is used as a solvent together with the ammonium salts, ammonium acetate and ammonium nitrate, for a one-pot synthesis of dipyrimido-fused pyridines using Hantzsch reaction; most of the disadvantages in reported methods were resolved.

Results and discussion

Ammonium acetate as a nitrogen source

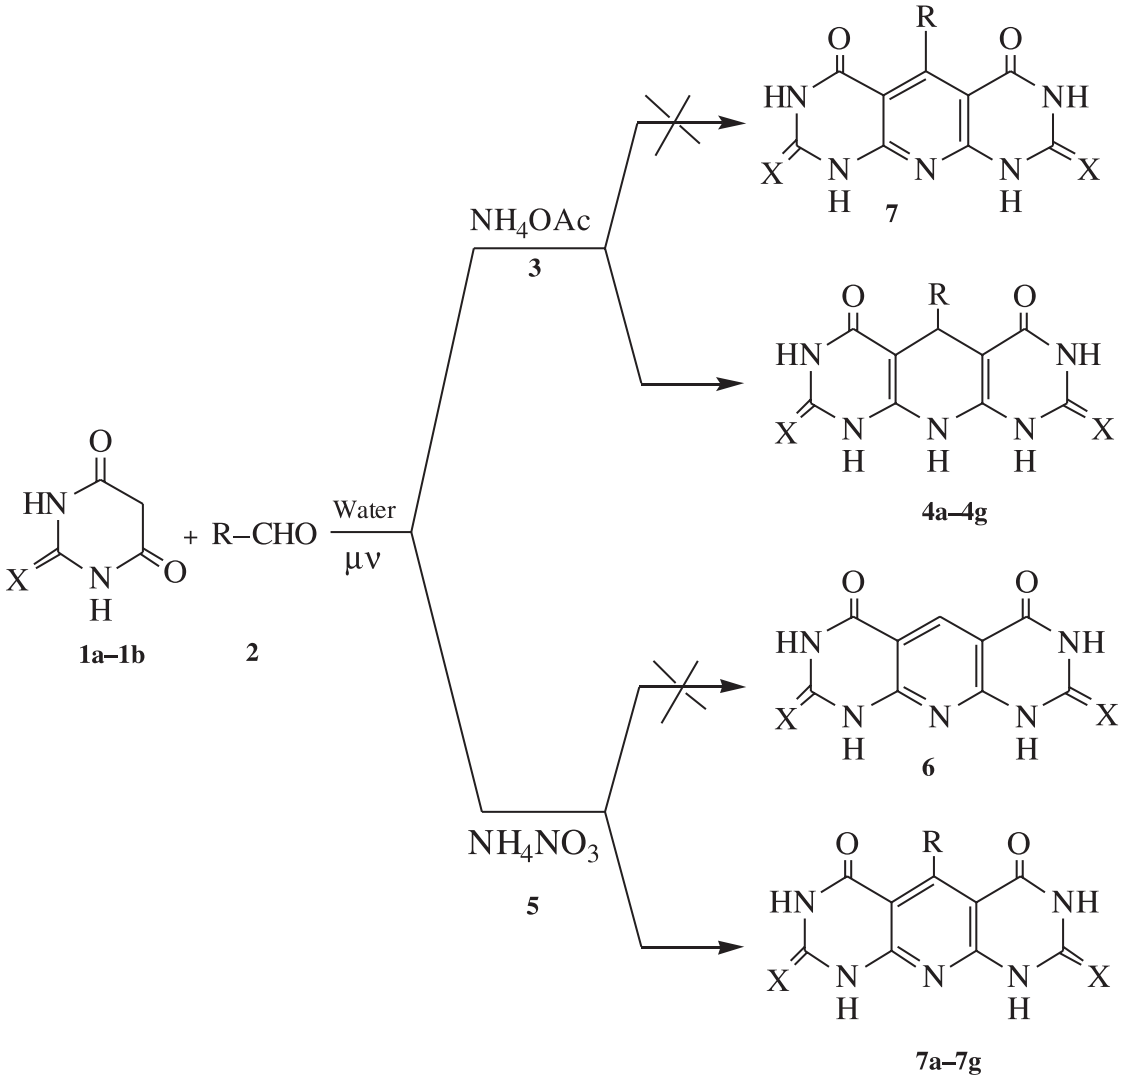
The choice of solvent has always been the biggest challenge facing the eco-efficient processes. In search for the optimal solvent, refluxing 1 mol of the aromatic or heteroaromatic aldehyde **2a**–**2e**, 2 mol of barbituric acid (BA) (**1a**) or 2-thiobarbituric acid (TBA) (**1b**), and 4 mol of ammonium acetate (**3**) in water would provide 5-aryl-3,5,7,9,10-pentahydro-(1*H*)-pyrimido[5′,4′:5,6]pyrido[2,3-*d*] pyrimidine-2,4,6,8-tetrone (**4a**–**4f**) or 5-thienyl-2,8-dithioxo-3,5,7,9,10-pentahydro-(1*H*)–pyrimido[5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-4,6-diones (**4g**) (Scheme 1) in synthetically advantageous manner (Table 1).

The process proved to be quite simple in all respects with easy workup. At the completion of the reaction, water-insoluble organic compounds crystallized out immediately. All products were identified using the spectroscopic data and elemental analysis.

Ammonium carbonate as a nitrogen source

To study the conditional aspects of Hantzsch reaction, we used different ammonium salts as alternative nitrogen sources to improve the catalyzing conditions. To achieve the target, the previously mentioned method was performed using ammonium carbonate in place of ammonium acetate. Because of the release of carbonate ions, the aqueous solution of ammonium carbonate becomes basic; thus, it expectedly solubilizes the barbituric acid (BA) or 2-thiobarbituric acid (TBA) completely, and the reaction proceeds faster. However, we were unsuccessful in restoring the product from the reaction mixture by acidification workup, and even the evaporation of water led to the contamination of the catalyst in the product. Thus, the use of ammonium carbonate is inconvenient, as the desired product cannot be isolated.

Ammonium nitrate as a nitrogen source



In another trial to standardize the reaction, we employed another ammonium salt, ammonium nitrate, which afforded the aromatized product using the similar optimized reaction conditions. Accordingly, 1 mol of the aromatic or heteroaromatic aldehydes **2a**–**2e** was treated with 2 mmol of BA or TBA in the presence of 4 mol of ammonium nitrate (**5**) in refluxing water (Scheme 1). On completion of the reaction, the solvent was removed using vacuum filtration. An 84%–90% yield of the aromatized product **7a**–**7g** was obtained and identified as 5-aryl-3,7,9-trihydro-(1*H*)-pyrimido-[5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-2,4,6,8-tetrone (**7a**–**7f**) or 5-thienyl-2,8-dithioxo-3,7,9-trihydro-(1*H*)-pyrimido [5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-4,6-dione (**7g**) from the mp, elemental analysis, and spectroscopic data. In ^{1}H NMR spectra, no signal for C_5–H was obtained, this suggested the aromatization of the dihydropyridine ring, and the appearance of the IR band at 1550 cm^{-1}, which was attributed to C=N, confirmed the final product. From the literature, the aromatization of 1,4-DHPs using reagents such as nitrous fumes and $KMNO_4$ resulted in either the dealkylated or the alkylated product or both. When ammonium nitrate was used, only alkylated pyridine ring derivatives (**7a**–**7g**) were isolated, and the nature of the isolated product was further confirmed by the presence of ^{1}H NMR spectral peaks in the aromatic region.

Owing to the green credentials of microwave irradiation (MWI) and utilizing the property of water as a polar solvent, the same reaction was performed under MWI. An Erlenmeyer flask, containing BA or TBA (2 mmol), aldehyde (1 mmol), ammonium nitrate (3 mmol), and the sufficient amount of water for making the slurry of reaction media, was subjected to MWI for the required time (Method D). Notably, there is a remarkable decrease in reaction time with the increased yields of products compared with the conventional methodology (Table 2).

To optimize the reaction temperature, the synthesis of **7e** was performed in water at temperatures ranging from 70 to 130 °C, at different MW powers, i.e., 400, 480, 560, 640, and 800 W. At low power (400 and 480 W), the time needed for the temperature to reach 100 °C was too long. Micro-

Scheme 1. Synthesis of dipyrimidopyridine.

wave irradiation at 560 W in 2 mL of water furnished the highest yield of 5-thienyl-3,7,9-trihydro-(*1H*)-pyrimido[5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-2,4,6,8-tetrone (**7e**) (Scheme 1), without evaporation of the solvent. Thus, a microwave power of 560 W was chosen as the optimal one. The ease of separation of dipyrimidopyridine derivatives from the reaction media is the foremost advantage of this process in aqueous media.

In the synthesis of Hantzsch esters using ammonium nitrate as catalyst, sometimes the reaction does not proceed or exhibit sluggish nature. Notably, we have examined the smooth oxidation using a mild oxidizing agent, ammonium nitrate, and this can be attributed to the fact that this particular system could become more susceptible to oxidation than the unfused pyridines.

Looking at the success of this approach in which no external catalyst was required, it was worthwhile to attempt the reaction in neat reaction conditions under MWI, i.e., omitting the solvent and the catalyst, but no proper results were obtained, as the absence of water lead to some charring on prolonged heating, thus emphasizing the importance of water, which acts as a solvent and provides a media for the transfer of energy. Despite the insolubility of the reactants, an example has been established for the condensation reaction in water.

Conclusion

In conclusion, we have explored the reactivity of various ammonium salts for the Hantzsch reaction. We have found ammonium nitrate to be the best and least expensive catalyst, acting as a nitrogen donor as well as an oxidizing agent in a one-pot protocol for the synthesis of dipyrimidopyridines. The present procedure is equally effective for both BA and TBA; thus, it can be adopted for the synthesis of a library of bioactive compounds in a greener way ensuring the atom economy. Furthermore, we have proved that water could be used as a suitable green solvent for MW-irradiated Hantzsch reaction, resulting in the desired products. The current procedure does not use an organic solvent or an external catalyst; thus, it could be established as a more-straightforward method to synthesize dipyrimido-fused pyridine derivatives. These results may stimulate interest among researchers involved in the industrial-scale reactions.

Experimental

Melting points were recorded on a Thomas Hoover melting-point apparatus and are uncorrected. IR spectra (Nujol) were recorded on a PerkinElmer FTIR-1710 spectrophotometer. ^{1}H NMR spectra were recorded on a Bruker Avance Spectrospin 300 (300 MHz) using TMS as internal standard. Elemental analysis was performed on a Heraeus CHN Rapid Analyser. The purity of compounds was checked on silica-gel-coated aluminium plates (Merck). A Kenstar microwave oven, model No. OM9925E (at 2450 MHz, 800W) was used for MWI. Temperature of the reaction mixture was measured through AZ, Mini Gun Type, non-contact IR Thermometer, model No. 8868. All reactants were purchased from Sigma-Aldrich and Lanchester and used without further purification.

General procedure for the synthesis of 5-aryl-3,5,7,9,10-pentahydro-1*H*-pyrimido [5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-2,4,6,8-tetrone (4a–4f) or 5-thienyl-2,8-dithioxo-3,5,7,9,10-pentahydro-1*H*–pyrimido[5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-4,6-diones (4g)

Method A (conventional heating)

To the mixture of barbituric acid (**1a**) or 2-thiobarbituric acid (**1b**) (2 mol), aromatic or heteroaromatic aldehydes (**2a**–**2e**) (1 mol), and 4 mol of ammonium acetate (**3**) was added 10 mL of water. The reaction mixture was refluxed for the appropriate time (as shown in Table 1) with constant stirring. The progress of the reaction was monitored by TLC. Upon completion of the reaction, the solid obtained was filtered and washed with water and ethanol.

Method B (microwave irradiation)

In an Erlenmeyer flask, barbituric acid (**1a**) or 2-thiobarbituric acid (**1b**) (2 mol), aromatic or heteroaromatic aldehydes (**2a**–**2e**) (1 mol), and ammonium acetate (**3**) (2 mol) were mixed with 2 mL of water. The reaction mixture was subjected to MWI for a specific time (Table 1). The progress of the reaction was monitored at 30 s intervals. Upon completion of the reaction, the mixture was cooled, filtered, washed with water, and dried.

Compound 4a

Curdy white solid; mp 210–212 °C. IR (Nujol, cm^{-1}) ν_{max}: 3484, 3121, 3068, 1740, 1695, 1655, 1630. ^{1}H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.28 (s, 1H, C_5–H), 6.81–7.02 (m, 4H, Ar–H), 10.21 (s, 3H, NH), 11.43 (s, 2H, NH). Anal. calcd. for $C_{15}H_{11}N_5O_5$: C 52.71, H 3.29, N 20.46; found: C 52.78, H 3.22, N 20.52.

Compound 4b

Yellow solid; mp 226–228 °C. IR (Nujol, cm^{-1}) ν_{max}: 3460, 3130, 3082, 1754, 1690, 1657, 1625. ^{1}H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 3.80 (s, 3H, OCH_3), 5.80 (s, 1H, C_5–H), 7.12 (d, 2H, J = 7.0 Hz, Ar–H), 7.16 (d, 2H, J = 7.0 Hz, Ar–H), 10.19 (s, 3H, NH), 11.45 (s, 2H, NH). Anal. calcd. for $C_{16}H_{13}N_5O_5$: C 54.64, H 3.57, N 19.42; found: C 54.59, H 3.62, N 19.29.

Compound 4c

Yellow solid; mp 165–168 °C. IR (Nujol, cm^{-1}) ν_{max}: 3472, 3120, 3036, 1736, 1678, 1657, 1615. ^{1}H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.81 (s, 1H, C_5–H), 7.12–7.26 (m, 5H, Ar–H), 10.21 (s, 3H, NH), 11.41 (s, 2H,

NH). Anal. calcd. for $C_{15}H_{11}N_5O_4$: C 55.38, H 3.38, N 21.53; found: C 55.51, H 3.33, N 21.40.

Compound 4d

Brown solid; mp 202–204 °C. IR (Nujol, cm^{-1}) ν_{max}: 3472, 3121, 3049, 1740, 1673, 1655, 1610. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.80 (s, 1H, C_5–H), 5.89 (s, 2H, OCH_2O), 6.72 (d, 1H, *J* = 8.0 Hz, Ar–H), 6.82 (d, 1H, *J* = 8.0 Hz, Ar–H), 7.10 (s, 1H, Ar–H), 10.24 (s, 3H, NH), 11.45 (s, 2H, NH). Anal. calcd. for $C_{16}H_{11}N_5O_6$: C 52.71, H 2.87, N 18.81; found: C 52.54, H 2.94, N 18.76.

Compound 4e

Brown solid; mp 164 °C dec. IR (Nujol, cm^{-1}) ν_{max}: 3478, 3124, 3062, 1746, 1682, 1654 1622. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.81 (s, 1H, C_5–H), 7.48–7.51 (t, 1H, thienyl), 8.10 (d, 1H, *J* = 3.1 Hz, thienyl), 8.31 (d, 1H, *J* = 4.5 Hz, thienyl), 10.20 (s, 3H, NH), 11.41 (s, 2H, NH). Anal. calcd. for $C_{13}H_9N_5O_4S$: C 47.10, H 2.82, N 21.04; found: C 47.12, H 2.71, N 21.14.

Compound 4f

Brown solid; mp 188–190 °C. IR (Nujol, cm^{-1}) ν_{max}: 3466, 3130, 3087, 1740, 1688, 1655, 1620. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.78 (s, 1H, C_5–H), 7.72–7.76 (m, 5H, Ar–H), 10.21 (s, 3H, NH), 11.40 (s, 2H, NH). Anal. calcd. for $C_{18}H_{11}N_6O_4Cl$: C 52.47, H 2.70, N 20.38; found C 52.61, H 2.67, N 20.46.

Compound 4g

Green solid; mp 276 °C dec. IR (Nujol, cm^{-1}) ν_{max}: 3472, 3121, 3076, 1754, 1695, 1662, 1610. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.81 (s, 1H, C_5–H), 7.51 (t, 1H, thienyl), 8.12 (d, 1H, *J* = 3.1 Hz, thienyl), 8.29 (d, 1H, *J* = 4.5 Hz, thienyl), 10.19 (s, 3H, NH), 11.43 (s, 2H, NH). Anal. calcd. for $C_{13}H_9N_5O_2S_3$: C 42.90, H 2.52, N 19.39; found C 42.97; H 2.47; N 19.28.

General Procedure for the synthesis of 5-aryl-3,7,9-trihydro-(1*H*)-pyrimido [5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-2,4,6,8-tetrone (7a–7f) or 5-thienyl-2,8-dithioxo-3,7,9-trihydro-(1*H*)-pyrimido[5′,4′:5,6]pyrido[2,3-*d*]pyrimidine-4,6-dione (7g)

Method C (conventional heating)

To the mixture of barbituric acid (**1a**) or 2-thiobarbituric acid (**1b**) (2 mol), aromatic or heteroaromatic aldehydes (**2a**–**2e**) (1 mol), and 4 mol of ammonium nitrate (**5**) was added 10 mL of water. The reaction mixture was refluxed for the appropriate time with constant stirring. The solid obtained was filtered and washed with water and ethanol.

Method D (microwave irradiation)

In an Erlenmeyer flask, barbituric acid (**1a**) or 2-thiobarbituric acid (**1b**) (2 mol), aromatic or heteroaromatic aldehydes (**2a**–**2e**) (1 mol), and ammonium nitrate (**5**) (3 mol) were mixed with 2–3 mL of water. The reaction mixture was subjected to MWI for a specific time (Table 1). The progress of the reaction was monitored at 30 s intervals. Upon completion of the reaction, the mixture was cooled, filtered, washed with water, and dried.

Compound 7a

Curdy white solid; mp > 320 °C. IR (Nujol, cm^{-1}) ν_{max}: 3354, 3272, 3193, 1723, 1672, 1614, 1536. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 6.84–7.11 (m, 4H, Ar–H), 10.21 (s, 2H, NH), 11.43 (s, 2H, NH). Anal. calcd. for $C_{15}H_9N_5O_5$: C 53.01, H 2.74, N 20.60; found: C 53.09, H 2.65, N 20.64.

Compound 7b

Yellow solid; mp 270–272 °C. IR (Nujol, cm^{-1}) ν_{max}: 3360, 3211, 3097, 1723, 1685, 1639, 1548. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 3.81 (s, 3H, OCH_3), 7.14 (d, 2H, *J* = 7.0 Hz, Ar–H), 7.20 (d, 2H, *J* = 7.0 Hz, Ar–H), 10.19 (s, 2H, NH), 11.47 (s, 2H, NH). Anal. calcd. for $C_{16}H_{11}N_5O_5$: C 54.87, H 3.11, N 19.54; found C 54.90, H 3.08, N 19.60.

Compound 7c

Curdy white solid; mp 202–204 °C. IR (Nujol, cm^{-1}) ν_{max}: 3218, 3200, 3082, 1730, 1671, 1614, 1549. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 7.21–7.34 (m, 5H, Ar–H), 10.20 (s, 2H, NH), 11.43 (s, 2H, NH). Anal. calcd. for $C_{15}H_9N_5O_4$: C 55.72, H 2.78, N 21.67; found: C 55.64, H 2.71, N 21.78.

Compound 7d

Yellow solid; mp 290–292 °C. IR (Nujol, cm^{-1}) ν_{max}: 3210, 3193, 3082, 1733, 1667, 1614, 1541. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 5.89 (s, 2H, OCH_2O), 6.71 (d, 1H, *J* = 8.0 Hz, Ar–H), 6.87 (d, 1H, *J* = 8.0 Hz, Ar–H), 7.14 (s, 1H, Ar–H), 10.24 (s, 2H, NH), 11.43 (s, 2H, NH). Anal. calcd. for $C_{16}H_9N_5O_6$: C 52.77, H 2.40, N 18.29; found: C 52.83, H 2.42, N 18.86.

Compound 7e

Yellow solid; mp 210–214 °C. IR (Nujol, cm^{-1}) ν_{max}: 3211, 3086, 1724, 1685, 1640, 1548. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 7.48 (t, 1H, thienyl), 8.18 (d, *J* = 3.1 Hz, 1H, thienyl), 8.42 (d, *J* = 4.5 Hz, 1H, thienyl), 10.21 (s, 2H, NH), 11.43 (s, 2H, NH). Anal. calcd. for $C_{13}H_7N_5O_4S$: C 47.38, H 2.18, N 21.32; found: C 47.41, H 2.21, N 21.27.

Compound 7f

Rust color solid; mp 210–213 °C. IR (Nujol, cm^{-1}) ν_{max}: 3348, 3204, 3080, 1736, 1680, 1628, 1540. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 7.76–7.84 (m, 5H, Ar–H), 10.19 (s, 2H, NH), 11.44 (s, 2H, NH). Anal. calcd. for $C_{18}H_9N_6O_4Cl$: C 52.79, H 2.14, N 20.54; found: C 52.87, H 2.20, N 20.56.

Compound 7g

Yellow solid; mp 276 °C dec. IR (Nujol, cm^{-1}) ν_{max}: 3352, 3228, 3092, 1728, 1692, 1634, 1552. ^1H NMR (300 MHz, $CDCl_3$ – TFA, TMS) δ: 7.48 (t, 1H, thienyl), 8.16 (d, *J* = 3.0 Hz, 1H, thienyl), 8.42 (d, *J* = 4.5 Hz, 1H, thienyl), 10.19 (s, 2H, NH), 11.40 (s, 2H, NH). Anal. calcd. for $C_{13}H_7N_5O_2S_3$: C 43.08, H 1.86, N 19.25; found: C 43.21, H 1.93, N 19.39.

OBITUARY / NÉCROLOGIE

Professor Keith Yates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/13/12
For personal use only.

In Memoriam KEITH YATES 1928–2006

Keith Yates has passed away at the age of 78. He had had a heart attack and stroke in May 2005, which left him mostly paralyzed, and then a second fatal heart attack on December 2, 2006. He died in Victoria, BC, not far from his home on Mayne Island and is survived by his wife of 53 years, June, and his three daughters Alison, Robyn, and Nicola. He never wanted to leave Mayne Island and he now rests there in the cemetery at St. Mary Magdalene.

He was born on October 22, 1928, in Preston in Lancashire, England, and was raised mostly in Blackpool. After World War II, he followed his parents to British Columbia and married June in 1953. He then began his studies in organic chemistry. A brief summary of his various degrees includes a B.A. from the University of British Columbia in 1956, an M.Sc. (1957), and a Ph.D. (1959), also from UBC (his supervisor was Ross Stewart, who survives him), with numerous scholarships and awards along the way. He then went to England to do postdoctoral research with R.P. Bell at Oxford University, and this work eventually led to being awarded an Oxford D. Phil. degree in 1961. Following this, he was appointed as an Assistant Professor at the University of Toronto in 1961, and rose through the ranks to full Professor in 1968. He remained there, apart from sabbati-

Nécrologie — KEITH YATES 1928–2006

Keith Yates est mort à l'âge de 78 ans. En mai 2005, il avait subi une crise cardiaque et un accident cérébrovasculaire qui l'avaient laissé pratiquement paralysé; une deuxième crise cardiaque, le 2 décembre 2006 lui a été fatale. Il est mort à Victoria, BC, près de sa résidence à Mayne Island; il laisse dans le deuil June, son épouse depuis 53 ans, ainsi que ses trois filles Alison, Robyn, and Nicola. Il n'a jamais voulu quitter Mayne Island et il repose maintenant en paix dans le cimetière de St. Mary Magdalene.

Il est né le 22 octobre 1928, à Preston dans le Lancashire, en Angleterre, et il a été élevé principalement à Blackpool. Après la deuxième guerre mondiale, il s'est déplacé avec sa famille vers la Colombie britannique où il s'est marié à June en 1953. Il a alors commencé ses études en chimie organique. Des études à l'Université de British Columbia lui ont permis d'obtenir successivement un B.A. (1956), un M.Sc. (1957), and un Ph.D. (1959) sous la supervision de Ross Stewart qui lui survit; dans ce processus, il a obtenu de nombreuses bourses et prix. Il est allé en Angleterre pour faire des travaux de recherches postdoctorales avec R.P. Bell à l'Université d'Oxford qui lui ont éventuellement permis d'obtenir en 1961 un D. Phil. d'Oxford. À son retour au Canada en 1961, il a été nommé assistant professeur à l'Université de Toronto in 1961 où il est

cals, until he retired (two years early) in 1991. During his distinguished research career (summarized in the following) he received numerous awards, among them the Syntex Award (1984) and the CIC Medal (1991), and he was appointed a Fellow of the Royal Society of Canada in 1984.

With Ross Stewart he began his long-term interest in aqueous acidic systems and the organic reactions that take place in them. He measured the basicities of amides, ketones, and other carbonyl compounds, using the techniques of the time, applied the Hammett equation to the results, and studied deuterium isotope effects in organic cations. (I will not cite references here as there would be just too many of them.) With R.P. Bell in Oxford he studied the details of the halogenations of carbonyl compounds in buffers, determining which reaction was significant at low and which at high halogen concentrations. Eventually he followed this with his own study of the acid-catalyzed process and of brominations in the presence of added salts. Later in Toronto, he studied many electrophilic brominations with his students and associates.

In Toronto he measured an acidity function for amides, HA, in aqueous sulfuric and hydrochloric acid media, having found that the Hammett H0 function did not work well for the determination of the basicities of carbonyl compounds (and thus showing the basicities that he had determined earlier with Ross Stewart were incorrect). He measured and extended the H0 function in aqueous perchloric acid solutions. His students also measured activity coefficients and water activities in some of these media. He determined several acidity functions in the 70% aqueous dimethyl sulfoxide medium. Eventually, the acidity function concept with a different function for each class of compounds was abandoned in favour of the simpler two-parameter excess acidity treatment, using just one function with a numerical value being used to express the class of compound involved.

He wrote seminal papers and reviews on ester hydrolysis in acid media; the mechanisms he proposed for some of these still stand up today. The hydrolyses of many other functional groups were also studied. He developed the transition state activity coefficient method to help distinguish between different mechanistic possibilities. Amide hydrolysis proved more difficult; when he began work it was still not clear whether amides protonated on oxygen or nitrogen. Oxygen protonation was eventually established, but several proposed hydrolysis mechanisms were subsequently found wanting. The actual experimental measurements withstood the test of time well, however, and form the basis of current mechanistic theories. The excess acidity treatment was also applied to kinetic measurements and proved invaluable in mechanistic determinations.

Later in his career he became interested in photochemistry, studying the photochemical oxidations of nitrobenzyl alcohols and the photohydrations of aromatic alkenes and alkynes, among many other reactions, showing that the course of several reactions in water is different from that in organic solvents. Many reactions were shown to involve intramolecular proton transfers. He determined some excited state dipole moments and polarizabilities, which was very difficult work.

He was always interested in theoretical calculations and published many papers using them over the years, as they became more and more accurate, on a wide variety of molecules and ions in collaboration with his friend and colleague Imre Csizmadia. He wrote a book entitled *Hückel Molecular Orbital Theory* in 1978 (while he was Depart-

devenu professeur titulaire en 1968. À part ses années sabbatiques, il est resté à Toronto pour toute sa carrière, jusqu'à sa retraite en 1991 prise avec deux années d'avance. Au cours de sa carrière exceptionnelle, résumée plus loin, il a reçu de nombreux prix, dont le Syntex Award (1984) et la médaille de l'Institut de chimie du Canada (1991); il a aussi été nommé Fellow de la Société Royale du Canada en 1984.

C'est avec Ross Stewart qu'a commencé son intérêt à long terme pour les systèmes acides aqueux et pour les réactions organiques qui s'y déroulent. Il a mesuré les basicités des amides, des cétones et d'autres composés carbonylés en faisant appel à des techniques de temps, il a appliqué les résultats à l'équation de Hammett et il a étudié les effets isotopiques du deutérium dans les cations organiques (Je ne présenterai pas ici de références car il y en aurait trop). Avec R.P. Bell à Oxford, il a étudié les détails des réactions d'halogénation des composés carbonylés dans des tampons et il a ainsi déterminé quelles sont les réactions significatives à des concentrations faibles et élevées d'halogène. Il a éventuellement poursuivi ces travaux par des études personnelles des processus acidocatalysés et des réactions de bromation en présence de sels additionnés. Plus tard, à Toronto, avec ses étudiants et ses associés, il a étudié plusieurs réactions de bromation électrophiles.

À Toronto, il a aussi mesuré une fonction d'acidité pour les amides, HA, dans des milieux aqueux d'acide sulfurique et d'acide chlorhydrique; il trouvé que la fonction H0 de Hammett ne fonctionne pas bien pour la détermination des basicités des composés carbonyles (et il a ainsi montré que les basicités qu'il avait déterminées antérieurement avec Ross Stewart étaient incorrectes). Il a mesuré et étendu le fonction H0 aux solutions en milieu acide perchlorique aqueux. Ses étudiants ont aussi mesuré les coefficients d'activité et les activités de l'eau dans un certain nombre de ces milieux. Il a déterminé plusieurs fonctions d'acidité dans un milieu aqueux à 70% de diméthylsulfoxyde. Éventuellement, le concept d'une fonction d'acidité comportant une fonction différente pour chaque classe composés a été abandonnée en faveur d'un traitement de l'excès d'acidité à deux paramètres beaucoup plus simple qui ne fait appel qu'à une seule fonction comportant une valeur numérique qui est utilisée pour exprimer la classe de composé impliqué.

Il a écrit plusieurs articles et revues fondamentales sur l'hydrolyse des esters en milieu acide; les mécanismes qu'il a proposé pour un certain nombre de ces cas sont encore reconnus aujourd'hui. Il a aussi étudié les hydrolyses de plusieurs autres groupes fonctionnels. Il a développé la méthode du coefficient d'activité dans l'état de transition qui permet de distinguer entre divers mécanismes possibles. L'hydrolyse des amides s'est avéré un sujet plus difficile; lorsqu'il a commencé à travailler sur ce sujet, il n'était pas clair si les amides se protonent sur l'oxygène ou sur l'azote. Il a éventuellement été établi que la protonation se fait sur l'oxygène, mais subséquemment plusieurs mécanismes se sont avérés incomplets. Toutefois, les valeurs expérimentales obtenues ont bien soutenu les assauts du temps et elles forment aujourd'hui la base des théories mécanistiques actuelles. Le traitement par l'excès d'acidité a aussi été appliqué aux mesures cinétiques et il s'est avéré d'une valeur inestimable dans les déterminations mécanistiques.

Plus tard dans sa carrière, il est devenu intéressé à la photochimie et il a été amené, en autre, à étudier les oxydations photochimiques des alcools nitrobenzyliques et les réactions de photohydratation d'alcènes et d'alcynes aromatiques; il a ainsi été amené à démontrer que le cours de plusieurs de ces réactions varie suivant la nature aqueuse ou organique du solvant utilisé. Il a été démontré que plusieurs réaction impliquent des

ment Chairman; being Chairman never slowed his research output in the slightest), and while now outdated it still surprises me that these simple calculations can give the same reactivity order for a series of molecules or ions as do the much more elaborate modern calculations. He also became interested in the (still neglected) principle of least nuclear motion, following a suggestion made by Ossie Tee. When he became interested in photochemistry he applied theoretical calculations to many excited state processes. The last thing he studied, by himself without any associates, was a simple approach to the application of Marcus theory to photochemical proton transfers, using an intersecting parabola model.

This necessarily brief and incomplete summary may help to show the incredibly wide-ranging scope of his interests. He was interested in all aspects of physical organic chemistry, among many other subjects, and contributed mightily to many of them. I do not have an accurate count, but he published well over 150 research papers as well as several review articles and book chapters.

The number of current or recently retired academics who were Keith's Ph.D. students, or post-doctoral fellows in his group, is phenomenal, being at least fourteen, which may be a Canadian record. For this reason alone his influence on Chemistry teaching and research was vast, not only in Canada but in at least four other countries. In no particular order these academics are (with their institution), Alan Hopkinson (York University, Toronto), Bob McClelland (Toronto), Jim Pincock (Dalhousie), Bob McDonald (Mount Saint Vincent University, Halifax), Linda Sweeting (Towson University, Maryland), Julie Altmann (Kings College and Imperial College, University of London), Jacques Périé (Université Paul Sabatier, Toulouse), Tom Modro (University of Pretoria, South Africa), Ossie Tee (Concordia), Steve Anderson (University of Wisconsin at Whitewater), Peter Wan (Victoria), Mary Boyd (now at Georgia Southern University), Paul Mezey (now at Memorial), and myself (Toronto). Some of the theoretical people were supervised jointly by Keith and by Imre Csizmadia. There are second-generation people too, Judy Bolton (now at the University of Illinois at Chicago), Bruce Lennox (McGill), and Fran Cozens (Dalhousie) who were all Bob McClelland's Ph.D. students; one of my former graduate teaching assistants has just been appointed to an academic post in California.

Keith was Chairman of the Department of Chemistry at the University of Toronto for two terms, 1974–1985, (with a sabbatical year between terms), and the Department was happier then than at anytime before or since. He had an open door policy; anyone could come and see him and say what they wanted. He would listen to everyone and then decide to do what he wanted to do anyway, but everyone was happy because he had listened to them.

Keith will be sorely missed, but I am sure that he will want to be remembered as the highly intelligent, fun-loving man that he was. He was a longtime supporter of this journal; he was the Physical Organic Editor for a time while he was Chairman. He published much of his best work here, and what would be a better memorial to him than to have it chosen as the journal of first choice for all current and future physical organic chemists.

Robin A. Cox

(The photograph is courtesy of the University of Toronto.)

transferts intramoléculaires de proton. Il a déterminé les moments dipolaires et les polarisabilités de quelques états excités, ce qui s'est avéré un travail très difficile.

Il a toujours été très intéressé par les calculs théoriques et, au cours de sa carrière, il a publié plusieurs articles faisant appel à cette méthode, principalement quand elle est devenue de plus en plus précise; ces travaux couvrant une grande variété de molécules et ions ont souvent été réalisés en collaboration avec son collègue et ami Imre Csizmadia. Il est l'auteur d'un livre intitulé Hückel Molecular Orbital Theory publié en 1978 (alors qu'il était directeur du Département de chimie; ces fonctions n'ont jamais ralenti ses activités de recherche); même si ce livre est maintenant désuet, il me surprend encore par le fait que ces calculs simples puissent, pour une série de molécules ou ions, conduire au même ordre de réactivité que les méthodes modernes beaucoup plus élaborées. Il a aussi développé un intérêt pour le principe (toujours négligé) du principe du mouvement nucléaire minimal qui avait été suggéré par Ossie Tee. Quand il a pris de l'intérêt pour la photochimie, il a appliqué les calculs théoriques à plusieures processus d'états excités. La dernière chose qu'il a étudié, seul et sans associé, a été une approche simple à l'application de la théorie de Marcus aux transferts photochimiques de protons qui faisait appel à un modèle de parabole à intersection.

Ce résumé nécessairement bref et incomplet devrait quand même permettre de démontrer l'étendue incroyable de ses intérêts scientifiques. Il a été intéressé, entre autre, par tous les aspects de la chimie organique physique, et il a grandement contribué à plusieurs d'entre eux. Je n'ai pas un total exact, mais il a publié plus de 150 articles de recherches ainsi que plusieurs articles de revue et de chapitres de livres.

Le nombre de professeurs d'université encore en fonction ou qui se sont retirés récemment qui ont été des élèves ou des chercheurs postdoctoraux dans le groupe de Keith est phénoménal, soit au moins quatorze, qui pourrait être un record canadien. Pour cette seule raison, son influence sur l'enseignement de la chimie et de la recherche a été énorme, non seulement au Canada, mais dans au moins quatre autres pays. Sans ordre particulier, ces professeurs d'université sont (avec leur institution): Alan Hopkinson (York University, Toronto), Bob McClelland (Toronto), Jim Pincock (Dalhousie), Bob McDonald (Mount Saint Vincent University, Halifax), Linda Sweeting (Towson University, Maryland), Julie Altmann (Kings College et Imperial College, University of London), Jacques Périé (Université Paul Sabatier, Toulouse), Tom Modro (University of Pretoria, South Africa), Ossie Tee (Concordia), Steve Anderson (University of Wisconsin à Whitewater), Peter Wan (Victoria), Mary Boyd (maintenant à Georgia Southern University), Paul Mezey (maintenant à Memorial), and moi (Toronto). Plusieurs des personnes impliquées en chimie théorique se trouvaient sous la direction conjointe de Keith et d'Imre Csizmadia. Il y a aussi des gens de deuxième génération, telle Judy Bolton (maintenant à l'Université d'Illinois à Chicago), Bruce Lennox (McGill), et Fran Cozens (Dalhousie) qui ont tous été des étudiants au Ph.D. de Bob McClelland; un de mes assistants a récemment été à un poste académique en Californie.

Keith a été directeur du Département de chimie de l'Université de Toronto pour deux termes, 1974–1985, (avec une année sabbatique entre les deux termes); cette période a été la plus heureuse pour le département. Il avait une politique de porte ouverte et chacun pouvait aller le voir pour lui dire ce qu'il pensait. Il écoutait tout le monde et décidait alors de faire malgré tout ce qu'il avait choisi de faire; tout le monde était toutefois heureux parce qu'il les avait écouté.

Keith sera grandement regretté, mais je suis certain qu'il voudrait qu'on se souvienne de lui comme l'homme qu'il était,

très intelligent, et qui aimait s'amuser. Il a été pendant longtemps défenseur de ce journal; il en a été l'éditeur de la section de chimie organique physique alors qu'il était directeur du département. Il a publié la plus grande partie de ses travaux dans ce journal; pour les praticiens actuels et futurs de la chimie organique physique, une façon appropriée d'honorer sa mémoire, serait de choisir régulièrement ce journal comme premier choix pour leurs publications.

Preparation of ABC triblock copolymers of *N*-alkyl substituted acrylamides by RAFT polymerization

Ya Cao and X.X. Zhu

Abstract: Reversible addition-fragmentation chain transfer (RAFT) polymerization of *N*-alkyl substituted acrylamides has been carried out by the use of a trithiocarbonate (2-dodecylsulfanylthiocarbonyl-sulfanyl-2-methyl propionic acid) as the RAFT reagent. The *N*-alkyl groups of the acrylamide monomers are important in the RAFT process. *N*-alkyl monosubstituted polyacrylamides are found to be active macro-chain transfer agents, while *N,N*-disubstituted monomers can react easily with them to form a sequent block. We have designed a synthetic pathway to successfully prepare ABC triblock copolymers of *N*-alkyl substituted acrylamides with low polydispersities (PDI < 1.20) by a three-step RAFT polymerization process.

Key words: block copolymers, RAFT polymerization, *N*-alkyl substituted acrylamides, thermosensitive polymers.

Résumé : Utilisant le trithiocarbonate de l'acide (2-dodécylsulfanylthiocarbonylsulfanyl-2-méthylpropionique) comme réactif TCAR, on a effectué la polymérisation par transfert de chaîne avec addition-fragmentation réversible (TCAR) d'acrylamides substitués par un groupe *N*-alkyle. Les groupes *N*-alkyles des monomères acrylamides sont important dans le processus TCAR. On a trouvé que les polyacrylamides portant un seul substituant *N*-alkyle sont actives comme agents de transfert de la chaîne macromoléculaire alors que les monomères *N,N*-disubstitués peuvent facilement réagir avec celles-ci pour former un bloc séquentiel. Faisant appel à un processus de polymérisation TCAR à trois étapes, on a mis au point une méthode de synthèse permettant de préparer avec succès des copolymères à trois blocs ABC d'acrylamides substitués par un groupe *N*-alkyle de faible polydispersité (PDI < 1,20).

Mots-clés : copolymères à bloc, polymérisation par transfert de chaîne avec addition-fragmentation réversible, acrylamides substitués par un groupe *N*-alkyle.

[Traduit par la Rédaction]

Introduction

Polymers based on *N*-alkyl substituted polyacrylamides possess interesting thermosensitive properties. They are soluble in water at low temperatures but become insoluble as the temperature rises above a certain lower critical solution temperature (LCST) (1). A great deal of interest has been focused on the preparation of complex thermosensitive polymers that exhibit temperature-tunable self-assembled morphologies with potential applications in nanotechnology, biomedicine, and membrane separations (2, 3). We have reported previously that the LCST of *N*-alkyl substituted acrylamide polymers can be easily tuned by a radical copolymerization of appropriate comonomers. These random copolymers exhibited only one LCST (1, 4), while diblock copolymers have been found to exhibit double thermosensitivity (5, 6). In more sophisticated systems, precise multiple transitions may be required. It is useful to make well-defined multiblock copolymers in which each block presents a different LCST and aggregates at a different temperature, thus forming a stepwise aggregation process with multiple thermosensitivity.

Recently, controlled radical polymerization has been applied to prepare polymers and block copolymers with well-defined structures and possible reactivation for further chain extension. Reversible addition-fragmentation chain transfer (RAFT) polymerization seems well-suited for polymerizing acrylamide derivatives (7, 8). To date, there have been several acrylamide derivatives synthesized via RAFT polymerization, including *N,N*-dimethylacrylamide (DMA) (9, 10), *N*-isopropylacrylamide (iPA) (11–15), *N*-*tert*-butylacrylamide (tBA) (16), acrylamide (AM) (17,18), *N*-acryloyl morpholine (19). Most reports focus only on the controlled polymerization of iPA and AM (8). RAFT copolymerization of different kinds of neutral acrylamide monomers still proves to be challenging (20). It is even more difficult to prepare ABC triblock copolymers by the RAFT technique. Extending polymerization time or using multiple synthesis steps would produce an increasing amount of dead polymers or cause the loss of chain transfer activity of macro-chain transfer agents (CTAs). To avoid this problem, some researchers used bifunctional CTAs to synthesize ABA triblock copolymers in two steps (20, 21) or PEO-based macro-CTAs as the first segment with subsequent chain extension with acrylamide monomers (22–24). However, to

prepare thermosensitive ABC triblock copolymers based totally on *N*-alkyl acrylamides, the above-mentioned approach is not applicable. To the best of our knowledge, the use of a three-step RAFT polymerization to synthesize ABC triblock copolymers of acrylamide derivatives has not been reported.

Here we report the first successful synthesis of ABC triblock copolymers based on *N*-alkyl acrylamides utilizing the RAFT polymerization technique. To facilitate this three-step synthesis, we chose to use a trithiocarbonate with a very high chain transfer efficiency as the RAFT reagent to reduce the reaction time. A difference in reactivity was found to exist among the *N*-alkyl substituted acrylamide monomers.

Experimental

Materials

All reagents were purchased from Sigma-Aldrich and used without further purification unless otherwise stated. 2,2-Azoisobutyronitrile (AIBN) was recrystallized from methanol. iPA was recrystallized from toluene–hexane (3:2, *v*/*v*). *N*,*N*-Dimethylacrylamide (DMA) was vacuum distilled prior to use. Other *N*-substituted acrylamide monomers (*N*,*N*-ethylmethylacrylamide, MEA; *N*,*N*-diethylacrylamide, DEA; *N*-*n*-propylacrylamide, nPA) were prepared from the corresponding alkylamines and acryloyl chloride according to a similar procedure reported by Shea et al. (25). A trithiocarbonate (2-dodecylsulfanylthiocarbonyl-sulfanyl-2-methyl propionic acid, DMP) was used as the RAFT reagent and was prepared according to a previously reported procedure (26).

General RAFT polymerization

With AIBN as an initiator and DMP as the RAFT reagent, all polymerizations were conducted in dimethyl sulfoxide (DMSO) at 70 or 80 °C in septasealed vials that were bubbled with nitrogen for 20 min before the reaction. The typical [DMP]/[AIBN] ratio was 5. Samples were periodically withdrawn from the reaction mixture for analyses.

Synthesis of macro-CTAs

nPA (13.2 g, 0.117 mol), DMP (0.284 g, 0.779 mmol), and AIBN (25.6 mg, 0.156 mmol) were added along with DMSO (30 mL) to a 100 mL flask. After purging with N_2 for 20 min, the copolymerization proceeded at 70 °C for 50 min and the product PnPA was purified by precipitation in warm water (conversion = 64.4%, M_n = 8100, PDI = 1.07).

RAFT copolymerization of the second block

With the macro-CTA as the RAFT reagent, the second block was added similarly. We describe here a typical procedure to add a block of iPA to a poly(*N*-*n*-propylacrylamide) (PnPA) macro-CTA derived from DMP. iPA (6.28 g, 0.056 mol), macro-CTA PnPA (3.0 g, 0.370 mmol), AIBN (9.14 mg, 0.056 mmol), and DMSO (40 mL) were added to a 100 mL round-bottomed flask equipped with a magnetic stir bar. The mixture was purged with N_2 for 20 min prior to being immersed in a preheated oil bath at 70 °C. The copolymerization was allowed to proceed for 45 min before termination by exposure to air. The product was then dialyzed and lyophilized (conversion = 85.8%, M_n = 20 900, PDI = 1.14).

Synthesis of the triblock copolymer P(nPA-*b*-iPA-*b*-MEA)

MEA (1.081 g, 9.57 mmol), P(nPA-*b*-iPA) (2.5 g, 0.120 mmol), and AIBN (3.94 mg, 0.024 mmol) were added along with 30 mL DMSO to a 100 mL flask. After purging with N_2 for 20 min, the copolymerization proceeded at 70 °C for 3 h and the products were isolated by dialysis and subsequent lyophilizaion (conversion = 92.3%, M_n = 30 900, PDI = 1.16).

Polymer Characterization

Average molecular weights and molecular weight distributions (PDI) were obtained by size exclusion chromatography (SEC) on a Waters 1525 system equipped with three Waters Styragel columns and a refractive index detector (Waters 2410). THF was used as the mobile phase (1.0 mL/min), and the system was calibrated with polystyrene standards. The NMR spectra of the monomers and polymers in $CDCl_3$ were recorded on a Bruker AV400 spectrometer operating at 400 MHz for protons. Monomer conversions were determined by comparing the integration of the NMR signals (5.0–6.5 ppm) of the protons of the vinyl group of the residual monomers with the integration of the characteristic NMR signals of the polymer. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry of the polymers was performed on an AutoFlex MALDI-TOF (Bruker Daltonics) equipped with a nitrogen laser (337 nm) and with an accelerating potential of 20 kV. Samples were prepared with 3-β-indole acrylic acid (IAA) as matrix

Results and discussion

RAFT homopolymerization of *N*-alkyl acrylamides

RAFT homopolymerization of several *N*-alkyl acrylamides including three *N*,*N*-disubstituted (DMA, MEA, and DEA) and two *N*-monosubstituted (iPA and nPA) acrylamides has been carried out easily in the presence of trithiocarbonate DMP as chain transfer agent in DMSO. The general synthetic scheme of the homopolymer and block copolymers is outlined in Fig. 1.

Figure 2*A* shows SEC chromatograms for the homopolymerization of DEA, indicating the good control of the RAFT polymerization with unimodal traces. The polydispersity indices of the polymers are mostly lower than 1.2 in most cases. The polymerization proceeded at very fast rates and the monomer conversion was greater than 90% within 1 h. In all cases, to keep the activity of polymer chains it is important to keep the reaction time relatively short (within 90 min in this case).

Shown in Fig. 2*B* are the respective M_n and PDI (M_w/M_n) values as a function of monomer conversion. For samples of relatively low molecular weight, the M_n determined by SEC agreed well with that determined by MALDI-TOF mass spectrometry and NMR, indicating the validity of the M_n values obtained by SEC. The PDI values throughout the polymerization are below 1.2 even at high conversions. The observed molecular weights are consistent with the theoretical values (calculated from the monomer to CTA molar ra-

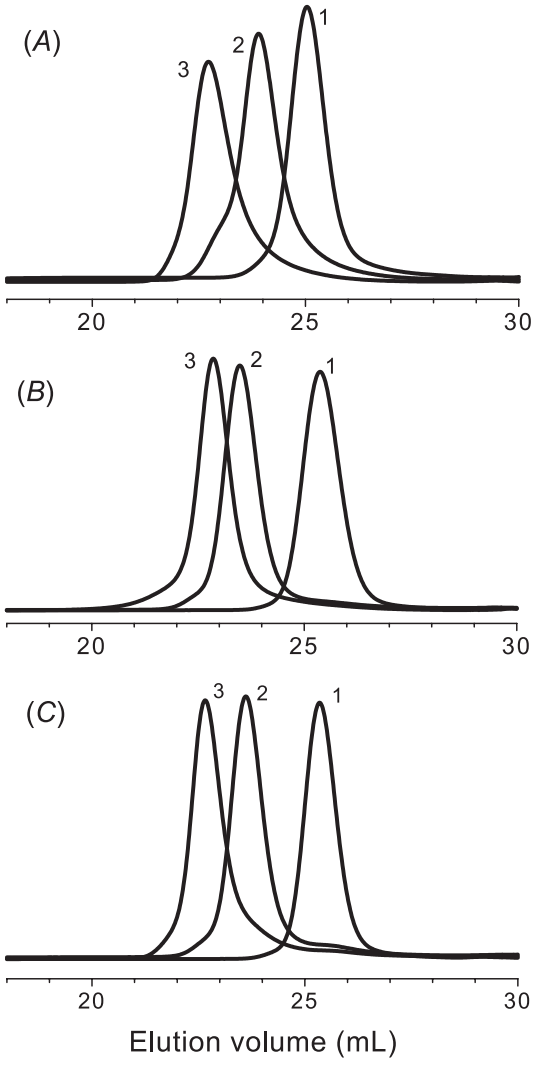
tio) initially, with a negative deviation at high conversions. According to the classic RAFT mechanism, this negative deviation of molecular weight may indicate there are other sources of radicals, such as initiator-derived chains (8). A decrease in the amount of AIBN and a lower reaction temperature helped very little to improve the negative deviation, indicating that there may be other causes for the loss of chain transfer activity of the propagating chains.

Several acrylamide derivatives can be synthesized similarly via RAFT polymerization. Data for the homopolymerization (Table 1) did not show any obvious retardation, and high conversion was obtained within a short time suggesting a high chain transfer efficiency of the RAFT reagent DMP.

© 2007 NRC Canada

In all cases, experimental molecular weights were lower than theoretically predicted. However, there is a good agreement between the theoretical and experimental molecular weights when conversions or the molar ratios of monomers to RAFT reagents are low (Table 1, PDMA1, PDEA1, PMEA, and PiPA1). In general, as shown in Table 1, higher temperatures can accelerate the RAFT polymerization process but also result in larger PDI values. Higher conversions can be achieved with longer reaction time but also lead to more polydisperse samples.

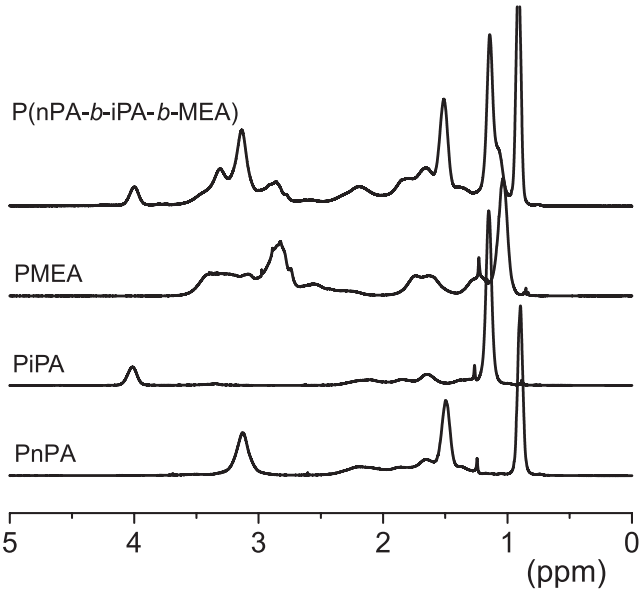
Preparation of ABC triblock copolymers



Diblock copolymers can be made by using the homopolymer as a macro-CTA to react with a second monomer. As shown in Fig. 3*A*, PiPA was used to add onto *N*-*n*-propylacrylamide to prepare the corresponding block copolymer. The copolymer P(iPA-*b*-nPA) exhibits a monomodal SEC trace. The clear shifts of the copolymer peaks (M_n = 17 200, PDI = 1.15 and M_n = 28 500, PDI = 1.17) away from the peak of the macro-CTA PiPA (M_n = 9600, PDI = 1.10) confirm the formation of block copolymers. We found that the use of the macro-CTA made of *N*-alkyl monosubstituted acylamide is a good choice and can easily chain-extend with other monomers, especially the *N,N*-disubstituted acrylamides, while the macro-CTAs made of some disubstituted acrylacrylamides may not chain-extend as easily (dead chains). This indicates that a reactivity difference exists among the acrylamide derivatives though they have similar chemical structures. Generally, macro-CTAs of PiPA and PnPA have high transfer constants and they are good leaving groups in the subsequent block copolymerization step. With this knowledge, we have designed a copolymerization pathway to synthesize ABC triblock copolymers. For a copolymer with multiple thermosensitivity, the cloud points of the homopolymer blocks should be taken into consideration. PnPA was used as the first block and macro-CTA to react with iPA to form a diblock copolymer P(nPA-*b*-iPA). ABC triblock copolymers were then synthesized by chain extension of with the macro-CTA P(nPA-*b*-iPA) with MEA or DMA (Figs. 3*B* and 3*C*). The SEC traces of diblock copolymers indicate that most of diblock macro-CTAs chain-extended with third comonomers to convert into the triblock copolymers. Even after three steps of RAFT polymerizations, the triblock copolymers obtained still had very low polydispersities (below 1.20).

Figure 4 shows the typical NMR spectra of some of the homopolymers obtained (PnPA, PiPA, PMEA) and of the triblock copolymer P(nPA-*b*-iPA-*b*-MEA). The characteristic peaks of the three homopolymers are all clearly found in the spectrum of the corresponding block copolymer at nearly the same chemical shift, confirming the chemical composition of the ABC block copolymers obtained.

Conclusions



RAFT polymerizations of several *N*-alkyl substituted acrylamides have been successfully carried out in the presence of a trithiocarbonate DMP as chain transfer agent. Selected homopolymers can be used as macro-CTAs to be subsequently chain-extended with other acrylamide-based monomers to form diblock copolymers. We found that the polymers of *N*-monosubstituted acylamides such as iPA and nPA are active macro-chain transfer agents, while *N,N*-disubstituted monomers react easily with them to form a sequent block. Further studies are needed to better understand the difference in their reactivities. ABC triblock copolymers were synthesized successfully. We believe that this method can be used in the preparation of other well-defined multiblock copolymers. The thermal properties of the copolymers are being studied and the triblock copolymer manifests a three-step aggregation process in water. The details of the variable temperature studies will appear in a forthcoming report.

Iodine-promoted Prins-cyclization of ketones — A facile synthesis of spirocyclic-4-iodo-tetrahydropyrans and 5,6-dihydro-2*H*-pyrans

J.S.Yadav, B.V. Subba Reddy, V. Hari Krishna, T. Swamy, and G.G.K.S. Narayana Kumar

Abstract: Homoallylic and homopropargylic alcohols undergo smooth coupling with ketones in the presence of molecular iodine at ambient temperature to produce spirocyclic-4-iodotetrahydropyrans and 5,6-dihydro-2*H*-pyrans, respectively, in high yields in a short reaction time with high selectivity. The use of molecular iodine makes this procedure quite simple, more convenient, and cost-effective.

Key words: Prins-cyclization, iodine, homopropargylic alcohol, spirocyclic-4-iodopyrans.

Résumé : Sous l'influence d'iode moléculaire, à la température ambiante, les alcools homoallyliques et homopropargyliques conduisent à un couplage en douceur avec les cétones pour conduire respectivement à la formation, avec des rendements élevés et une sélectivité élevée, de 4-iodotétrahydropyranes et de 5,6-dihydro-2*H*-pyranes spirocycliques après de temps de réactions courts. L'utilisation de l'iode moléculaire rend cette méthode très simple, plus commode et plus efficace au point de vue des coûts.

Mots-clés : cyclisation de Prins, iode, alcool homopropargylique, 4-iodopyranes spirocycliques.

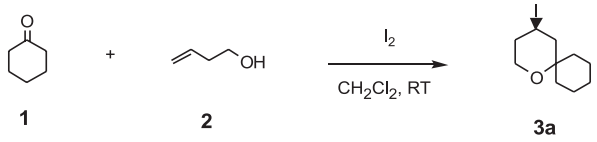
Introduction



The tetrahydropyran ring system is a core unit in a number of natural products such as avermectins, aplysiatoxins, oscillatoxins, latrunculins, talaromycins, and acutiphycins (1). In particular, spirocyclic-tetrahydropyran derivatives are found in various biologically active molecules. Generally, tetrahydropyran derivatives are prepared via Prins-cyclization using acid catalysis (2–4). Although a large number of methods are available for the Prins-cyclization of aldehydes, only a few procedures are reported for ketones (5–7). Therefore, the development of a simple and convenient method involving inexpensive and readily available reagents would extend the scope of the Prins-cyclization in natural product synthesis (8). Recently, molecular iodine has received considerable attention as an inexpensive, nontoxic, readily available catalyst for various organic transformations, affording the corresponding products with high selectivity in excellent yields (9). The mild Lewis acidity associated with iodine enhanced its usage in organic synthesis to perform several organic transformations using stoichiometric levels to catalytic amounts. Owing to advantages associated with this ecofriendly catalyst, molecular iodine has been explored as a powerful reagent for various organic transformations (10).

Results and discussion

In this article, we report an efficient and metal catalyst free Prins-cyclization for the rapid synthesis of spirocyclic-tetrahydropyrans from homoallylic alcohols and ketones using molecular iodine under neutral conditions. Accordingly, treatment of 3-buten-1-ol with cyclohexanone in the presence of molecular iodine at ambient temperature for 30 min gave the corresponding 4-iodotetrahydropyran in 96% yield (Scheme 1).

Similarly, various ketones such as cyclopentanone, cyclododecanone, acetone, 2-butanone, 3-pentanone, 2-hexanone, and 2-adamantanone underwent smooth coupling with 3-buten-1-ol to give the respective spirocyclic-4-iodotetrahydropyrans in excellent yields (Table 1, entries **b**–**h**). Encouraged by the results obtained with 3-buten-1-ol, we turned our attention to various substituted homoallylic alcohols. Interestingly, 1-phenyl-3-buten-1-ol reacted efficiently with cyclohexanone and cyclododecanone to produce 2,4,6-trisubstituted pyran derivatives (Table 1, entries **i** and **j**). Likewise, the coupling of 2-butanone with 1-nonen-4-ol

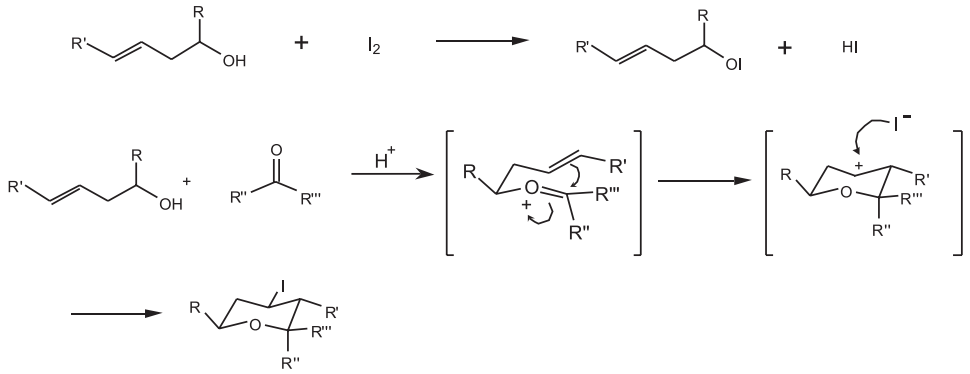
gave the corresponding trisubstituted pyran in 90% yield (Table 1, entry **k**). Furthermore, simple homopropargylic alcohol underwent smooth coupling with cyclohexanone to produce spirocyclic dihydropyran derivative **3l** (Scheme 2).



Similarly, 3-pentyn-1-ol also reacted well with several ketones such as cyclopentanone, cyclohexanone, cyclododecanone, and 3-pentanone to generate 2,3,4-trisubstituted pyran derivatives in high yields under similar conditions (Table 1, entries **m**–**p**). However, no reaction was observed in

Scheme 3.

the absence of a catalyst even after a long reaction time (12 h). As solvent, dichloromethane appeared to give the best result. In all cases, the reactions proceeded rapidly at room temperature under mild conditions. The reactions were clean and the products were obtained in excellent yields with high diastereoselectivity. Only a single isomer was obtained in each reaction, the structure of which was confirmed by ^{1}H NMR and also by comparison with authentic samples (6). The formation of the products may be further explained by hemi-acetal formation and subsequent Prins-type cyclization (Scheme 3).

Other iodide sources such as LiI, *t*-Bu_4NI, and NaI failed to produce the desired product. Cyclic ketones gave slightly higher yields when compared with acyclic ketones. As depicted in Table 1, a variety of ketones participated in Prins-cyclization under these reaction conditions. The scope and generality of this process is illustrated with respect to various ketones and homoallylic and homopropargylic alcohols, and the results are presented in Table 1.

In summary, we describe a rapid and efficient Prins-cyclization of ketones to produce spirocyclic-4-iodo-tetrahydropyrans in high yields with high selectivity. The use of inexpensive and readily available molecular iodine has made this procedure simple, convenient, and practical. In addition to its simplicity, efficiency, and milder reaction conditions, this method provides a rapid access for spirocyclic-4-iodo tetrahydropyran derivatives with diverse chemical structures.

Experimental

Melting points were recorded on Buchi R-535 apparatus and are uncorrected. IR spectra were recorded on a PerkinElmer FT-IR 240-c spectrophotometer using KBr optics. ^{1}H, ^{13}C NMR spectra were recorded on Gemini-200 spectrometer in $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on a Finnigan MAT 1020 mass spectrometer operating at 70 eV. TLC was monitored on 0.25 mm precoated silica gel plates (60F-254).

General procedure

A mixture of homoallylic alcohol (2 mmol), ketone (1 mmol), and iodine (1 mmol) in dichloromethane (5 mL) was stirred at 23 °C for a specified time (Table 1). After completion of the reaction as indicated by TLC, the reaction mixture was quenched with water and extracted with ether (2 × 10 mL). The combined organic layers were washed with aqueous sodium thiosulfate and brine and dried over anhydr. Na_2SO_4. The removal of solvent, followed by purification on silica gel (Merck, 100–200 mesh, ethyl acetate – hexane, 0.5:9.5), gave pure 4-iodotetrahydropyran. The products thus obtained were characterized by IR and NMR spectroscopy. The characterization data was found to be consistent with the authentic samples (6).

A solvent-free protocol for facile condensation of indoles with carbonyl compounds using silica chloride as a new, highly efficient, and mild catalyst

Alireza Hasaninejad, Abdolkarim Zare, Hashem Sharghi, Mohsen Shekouhy, Reza Khalifeh, Alireza Salimi Beni, and Ahmad Reza Moosavi Zare

Abstract: A simple and efficient solvent-free procedure for the preparation of bis(indolyl)methanes via electrophilic substitution reactions of indoles with aldehydes and ketones is described. The reactions took place in the presence of a catalytic amount of silica chloride at room temperature. The advantages of this method are high yields, short reaction times, low cost, and compliance with green-chemistry protocols.

Key words: silica chloride, indole, carbonyl compound, solvent-free, bis(indolyl)methane.

Résumé : On décrit une méthode très simple et efficace n'impliquant pas de solvant pour la préparation de bis(indolyl)méthanes qui s'effectue par le biais d'une réaction de substitution électrophile d'indoles avec des aldéhydes et des cétones, à la température ambiante, en présence d'une quantité catalytique de chlorure de silicium. Les avantages de cette méthode sont ses rendements élevés, ses courts temps de réaction, ses coûts peu élevés et leur appariement avec des protocoles de chimie verte.

Mots-clés : chlorure de silicium, indole, composés carbonylés, sans solvant, bis(indolyl)méthane.

[Traduit par la Rédaction]

Introduction

Indole derivatives are known for their vast applications in material sciences (1), agrochemicals (2), and pharmaceuticals (3). Among these compounds, the substrates including bis(indolyl)methane moieties, such as secondary metabolites (4) and marine-sponge alkaloids (5), are important classes of bioactive metabolites. Therefore, there is a great interest in the synthesis of this class of compounds. Electrophilic substitution reaction of indole with carbonyl compounds has been used as a useful route toward the synthesis of bis(indolyl)methanes. Different reagents and catalysts have been employed to accomplish this transformation, such as acetic acid (6*a*), $InCl_3$ (6*b*), $In(OTf)_3$ (6*c*), InF_3 (6*d*), $Dy(OTf)_3$ (6*e*), $Ln(OTf)_3$ (6*f*), $FeCl_3$ (6*g*), NBS (6*h*), $PPh_3{\cdot}HClO_4$ (TPP) (6*i*), trichloro-1,3,5-triazine (6*j*), $AlPW_{12}O_{40}$ (6*k*), $ZrOCl_2{\cdot}8H_2O$ (6*l*), and Ru(III) (6*m*). The synthesis of bis(indolyl)methanes in the absence of a catalyst has been also reported (6*n*). However, some of the reported methods are associated with the following drawbacks: (*i*) the use of expensive reagents (6*c*, 6*e*, 6*f*, 6*k*), (*ii*) long reaction times (6*a*, 6*b*, 6*d*), (*iii*) low yields (6*a*), and (*iv*) the use of an additional microwave oven (6*g*). Because of the wide range of biological, industrial, and synthetic applications of bis(indolyl)methanes, their preparation has received renewed interest.

Solvent-free organic reactions have been used as a useful technique in organic synthesis. Solid-state protocols often lead to shorter reaction times, higher yields, easier workup, compliance with green-chemistry protocols, and may enhance the regio- and stereo-selectivity of the reactions (7). Solvent-free condensation of indoles with carbonyl compounds is scarce in the literature (6*l*, 8). Having those aspects in mind and also in continuation of our previous studies to explore new applications of silica chloride (9), we report a new, clean, and efficient solvent-free method for the condensation of indoles with carbonyl compounds. The method involves the use of a catalytic amount of silica chloride under extremely mild conditions (Scheme 1).

Results and discussion

First, to optimize the reaction conditions, silica chloride was used as a catalyst for the condensation of indole (2.1 mmol) with benzaldehyde (1 mmol), as a model reac-

Scheme 1. Condensation of indole with benzaldehyde.

tion under solvent-free conditions (Scheme 1). Interestingly, the reaction proceeded efficiently at room temperature, and the desired bis(indolyl)methane was isolated in 93% yield after 10 min. The reaction was also examined in the presence of silica gel without using silica chloride. In these conditions, the reaction was unsuccessful, and 55% of the starting materials remained intact plus an undesired product, which has not been identified. Therefore, silica chloride was used as a catalyst for all reactions in the absence of solvent.

To compare the efficiency of the solvent-free vs. solution conditions, a model reaction was examined in several solvents, including CH_2Cl_2, $CHCl_3$, MeCN, THF, benzene, DMF, and DMSO. Thus, a mixture of indole (2.1 mmol), benzaldehyde (1 mmol), and silica chloride (0.5 g) in the appropriate solvent (10 mL) was stirred at room temperature for 4 h. Moderate yields of the product were obtained in these conditions; therefore, the solvent-free method is more efficient.

To investigate the capacity and efficiency of our catalyst, the condensation of indoles with a variety of aromatic and aliphatic aldehydes and ketones was carried out using this catalyst (Table 1). As Table 1 indicates, the reactions proceeded efficiently, and the desired products were obtained in good to excellent yields and in short reaction times.

Notably, the electronic properties of the aromatic ring of carbonyl compounds affected the results of the reaction. When an electron-withdrawing substituent, such as NO_2, was present on the aromatic ring, reaction times were decreased; however, the yields did not change significantly (Table 1, entries 2, 3, and 14). Electron-donating substituents (e.g., Me or OMe) had negligible effect on reaction times, but caused the reaction yields to decrease (Table 1, entries 6 and 7). Aliphatic aldehydes as well as ketones needed longer reaction times in comparison with aromatic aldehydes (Table 1, entries 10, 11, 12, and 15).

In conclusion, we have introduced a highly efficient catalyst for the condensation of indoles with aldehydes and ketones in the absence of solvent under mild reaction conditions. The promising points for the presented methodology are high conversion, ease of handling and low cost of the catalyst, cleaner reaction profile, and short reaction times, which make it a useful and attractive process for the rapid synthesis of substituted bis(indolyl)methanes.

Experimental

All chemicals were purchased from Merck or Fluka Chemical Companies. Silica chloride was prepared by the reaction of silica gel (item 7731 for TLC from Merck, Darmstadt, FRG) with thionyl chloride according to the literature procedure (10). ^{1}H NMR (250 MHz) and ^{13}C NMR (62.5 MHz) were run on a Bruker AVANCE DPX-250 FTNMR spectrometer. Melting points were recorded on a Büchi B-545 apparatus in open capillary tubes and are uncorrected.

General procedure for condensation of indole with benzaldehyde

To a mixture of indole (0.25 g, 2.1 mmol) and benzaldehyde (0.11 g, 1 mmol) was added silica chloride (0.5 g) and grinded at room temperature for 10 min. Afterward, the reaction mixture was suspended in acetone (20 mL) and filtered. The solvent was evaporated, and the crude product was purified by plate chromatography or recrystallization.

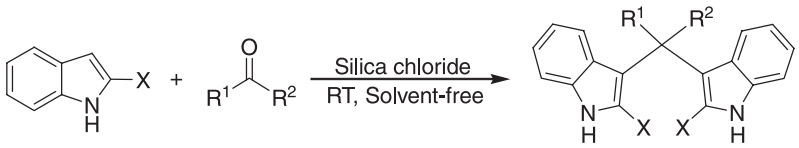
*3-((1*H*-Indol-3-yl)(phenyl)methyl)-1*H*-indole (1)*

Recrystallization from chloroform – petroleum ether (1:1) gave pink solid; yield: 0.301 g (93%); mp 140–142 °C (lit. 142–144 °C) (9). IR (KBr, cm^{-1}): 3402, 3051, 1618, 1600. ^{1}H NMR ($CDCl_3$, ppm) δ: 5.86 (s, 1H, ArCH), 6.66 (s, 2H), 7.11 (t, 2H, *J* = 6.9 Hz), 7.14–7.22 (m, 3H), 7.28–7.31 (m, 2H), 7.35–7.42 (m, 6H), 7.93 (br, 2H, NH). ^{13}C NMR ($CDCl_3$) δ: 31.6, 110.9, 111.9, 118.4, 119.5, 121.2, 124.0, 126.3, 127.1, 128.5, 128.6, 137.0, 145.2.

*3-((1*H*-Indol-3-yl)(4-nitrophenyl)methyl)-1*H*-indole (2)*

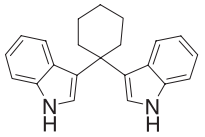
Recrystallization from EtOAc – petroleum ether (1:1) gave yellow needles; yield: 0.352 g (96%); mp 217–219 °C (lit. 220–222 °C) (6*c*). IR (KBr, cm^{-1}): 3423, 3051, 1593, 1510, 1458, 1337. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.01 (s, 1H, ArCH), 6.72 (s, 2H), 7.02–7.08 (m, 4H), 7.36 (d, 2H, *J* = 8.1 Hz), 7.41 (d, 2H, *J* = 8.1 Hz), 7.49 (d, 2H, *J* = 8.6 Hz), 8.05 (br, 2H, NH), 8.17 (d, 2H, *J* = 8.6 Hz).

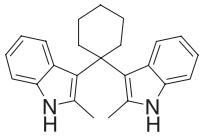
*3-((1*H*-Indol-3-yl)(3-nitrophenyl)methyl)-1*H*-indole (3)*



Recrystallization from EtOAc – petroleum ether (1:1) gave yellow solid; yield: 0.350 g (95%); mp 220–222 °C (lit. 221–223 °C) (11). IR (KBr, cm^{-1}): 3403, 3045, 2917, 1520, 1453, 1350. ^{1}H NMR ($CDCl_3$, ppm) δ: 6.23 (s, 1H, ArCH), 7.01 (t, 2H, *J* = 7.3 Hz), 7.06 (s, 2H), 7.22 (t, 2H, *J* = 7.0 Hz), 7.45 (d, 2H, *J* = 7.5 Hz), 7.53 (d, 2H, *J* = 8.0 Hz), 7.75 (m, 1H), 8.02 (d, 1H, *J* = 7.6 Hz), 8.26 (d, 1H, *J* = 7.7 Hz), 8.33 (s, 1H), 8.09 (s, 2H, NH).

*3-((4-Chlorophenyl)(1*H*-indol-3-yl)methyl)-1*H*-indole (4)*





Recrystallization from chloroform – petroleum ether (1:1) gave pink solid; yield: 0.328 g (92%); mp 78–80 °C (lit. 76–78 °C) (12). IR (KBr, cm^{-1}): 3412, 3056, 1483. ^{1}H NMR ($CDCl_3$, ppm) δ: 5.86 (s, 1H, ArCH), 6.65 (s, 2H), 6.85–7.96 (m, 12H), 8.00 (br, 2H, NH).

Concerted rate-limiting proton transfer to sulfur with nucleophilic attack at phosphorus — A new proposed mechanism for hydrolytic decomposition of the P=S pesticide, Diazinon, in moderately acidic sulfuric acid media

Doreen Churchill, Julian M. Dust, and Erwin Buncel

Abstract: We report herein the first kinetic study of a P=S containing organophosphorus pesticide, Diazinon (**1**), in the moderately concentrated acid region. Product analyses (^{31}P NMR) show that reaction occurs only at the P centre. The rate-acidity profile (k_{obs} vs. molarity of H_2SO_4) appears as a curve in which the initial slight downward trace (molarity = 1 to ca. 5) is followed by sharper upward curve (molarity ca. 5 to 14). Using treatments involving the excess acidity (*X*) method, the A-1 and A-2 mechanistic possibilities were found to be inoperative over the full acidity range. A novel mechanism is proposed for the higher acidity (*X* ca. 2–6) region. This mechanism involves proton transfer to P=S from hydronium ion with concomitant proton transfer from water, which effectively delivers hydroxide to the P centre in a variant of the A-S_E2 process. A putative A-2 mechanism in this region is supplanted by the proposed A-S_E2 variant where the cyclic array results in proton transfer being efficiently coupled with nucleophilic attack involving water. This constitutes the first report of rate-limiting proton transfer at the P=S functionality in acid hydrolysis of this class of organophosphorus neutroxins. A 600 000-fold acceleration in the decomposition of Diazinon is associated with the change of medium from neutral aqueous solution to the most acidic medium studied (*X* ca. 6).

Key words: phosphorothioate ester hydrolysis, acid catalysis, rate-limiting proton transfer at P=S, excess acidity analysis, new A-S_E2 variant mechanism.
