Résumé : Dans ce travail, on présente les résultats de la première étude cinétique d'un pesticide organophosphoreux contenant une liaison P=S, le Diazinon (**1**), dans la région acide modérément concentrée. L'analyse des produits (RMN du ^{31}P) montrent que la réaction ne se produit qu'au centre réactionnel comportant le P. Le profile de la réactivité en fonction de l'acidité (k_{obs} vs. molarité de H_2SO_4) s'apparente à une courbe dans laquelle la pente initiale légèrement vers le bas (molarité allant de 1 à environ 5) est suivie par une courbe beaucoup plus prononcée vers le haut (molarité allant d'environ 5 à 14). Utilisant des traitements impliquant la méthode de l'acidité en excès (*X*), on a trouvé que les possibilités mécanistiques A-1 et A-2 ne s'appliquent pas à l'ensemble de la plage d'acidité. On propose donc un nouveau mécanisme pour la région supérieure d'acidité (valeur de *X* d'environ 2 à 6). Ce mécanisme implique transfert de proton à la liaison P=S à partir de l'ion hydronium avec un transfert concomitant de proton de l'eau qui permet de transférer d'une façon efficace l'hydroxyde au centre P dans un processus apparenté au mécanisme A-S_E2. Un mécanisme putatif A-2 dans cette région est supplanté par la variante A-S_E2 proposée lorsque les arrangements cycliques conduisent à un transfert de proton couplé à une attaque nucléophile impliquant de l'eau. Ceci correspond au premier rapport d'un transfert de proton cinétiquement limitant au niveau de la fonctionnalité P=S dans l'hydrolyse acide de cette classe de neutroxines organophosphorées. La décomposition du diazinon est 600 000 fois plus rapide lorsqu'on passe d'un milieu impliquant une solution aqueuse neutre au milieu plus acide étudié (*X* d'environ 6).

Mots-clés : hydrolyse d'esters phosphorothioates, catalyse acide, transfert de proton cinétiquement limitant au P=S, analyse par excès d'acidité, mécanisme nouveau, une variante du mécanisme A-S_E2.

Scheme 1. Major reaction pathways of organophosphorothioate insecticides, where the protons in parentheses may or may not be present depending on the acidity of the medium.

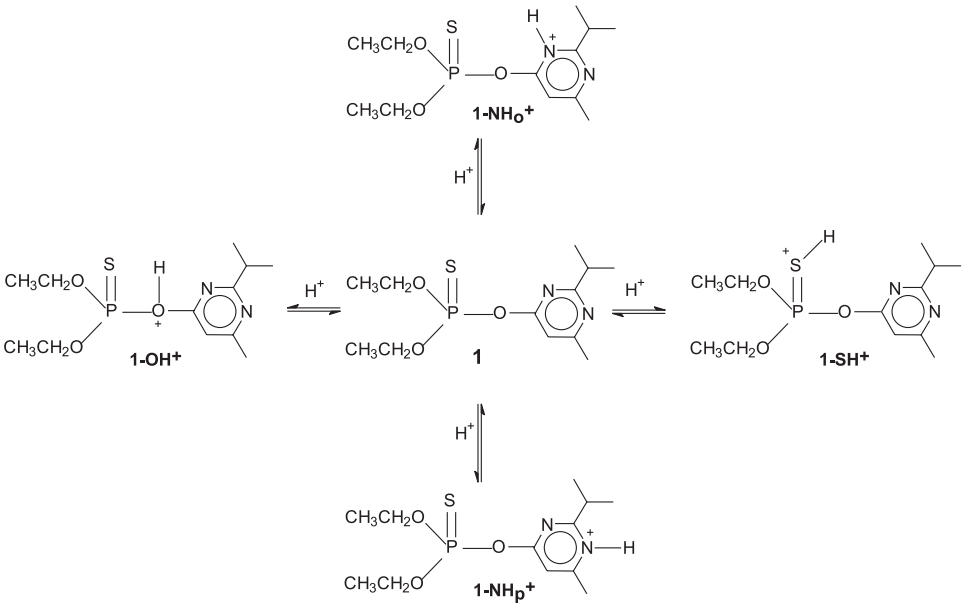
Introduction

Diazinon (**1**) is a member of a class of organophosphorothioate insecticides whose mechanism of action is acetylcholinesterase inhibition (1). In principle, such esters may exhibit two main pathways of reaction in neutral or alkaline aqueous solution, as shown in Scheme 1, where hydroxide is taken to be the dominant nucleophilic species under alkaline environmental conditions (2, 3). As shown, the dichotomy of attack involves C or P centres. On the aliphatic carbons (R = CH_3 or CH_2CH_3, typically) an S_N2(C) displacement occurs to give the corresponding organophosphorothioate anion and the alcohol. Attack at phosphorus in a presumably S_N2(P) mechanism (4) produces the aryloxide as a leaving group and the organophosphorothioic acid or its conjugate base (Scheme 1).

1

We, among other groups (5–7), have been engaged in the study of the degradation pathways and reactivities of a number of organophosphorus neurotoxins. In the case of fenitrothion (Scheme 1, R = CH_3, Ar = 3-methyl-4-nitrophenyl) with alkali metal ethoxides in ethanol, we dissected the pathways and found that S_N2(P) was dominant, S_N2(C) also contributed significantly, while the S_NAr attack on the aromatic ring constituted ca. 7% of the reaction (8). More recently (9), the regioselectivity of nucleophilic attack on fenitrothion was used to infer the location and orientation of fenitrothion in cationic micellar (9*a*) α-nucleophilic (9, 10) systems. These studies have highlighted the importance of the medium on pathways of reaction for these neurotoxins.

The research on Diazinon **1** (Scheme 1, R = CH_2CH_3, Ar = 2-isopropyl-6-methyl-pyrimidin-4-yl) for the most part has involved environmental studies, as it is an insecticide that has been applied for agricultural, silvicultural, and horticultural control of various insects (11). Most of these studies have focused on the half-life for disappearance of this insecticide in nonsterilized natural waters at various temperatures. Product analyses have emphasized biological breakdown rather than abiotic hydrolysis. In summary, few studies have examined the hydrolysis of **1** to fully elucidate reaction pathways of degradation in pure sterile water. However, a study by Ku et al. (12) involved the analysis of the products arising from hydrolysis under the pH range 2 to 9 and found 2-isopropyl-6-methylpyrimidin-4-ol (**2**) and *O*,*O*-dimethylphosphorothioate (or its conjugate acid) (**3**) as the only products.



One theme of our program of research has been the effect of reaction media on the reactivity and pathways of organic substrates (13), while the effect of acidic media (e.g., moderately concentrated sulfuric acid solutions) form a sub-theme (14). A third area of study in our group is environmental chemistry and the study of pesticide decomposition mechanisms (8, 9, 15). Our study of Diazinon **1** falls under this rubric. Our initial finding of a rate increase in the low pH region (16*a*) has now led to a study of the behaviour of **1** over a wide range of sulfuric acid solutions (H_2SO4 1–14 mol/L). Unlike previous work on organophosphorothioate ester degradation in alkaline media, the much weaker nucleophile H_2O will operate here. In this regard, attack at the aliphatic carbon could become more favourable here, since H_2O, as a softer nucleophile, would be expected to prefer attack at the softer carbon site (17).

In acidic media, the potential for catalysis would open up new and potentially faster pathways for decomposition. We note that the practical utility of acid hydrolysis of Diazinon formulations (that may also contain other bioactive agents) was examined by Dennis et al. (18) and emphasized the need for a mechanistic evaluation of such acidic systems. Scheme 2 highlights the multiplicity of protonation sites. Protonation of **1** on the aryloxy oxygen, giving rise to **1**-OH^+, would enhance the reaction by providing a better leaving group following the attack at phosphorus. Alternatively, protonation of the ring nitrogens of the pyrimidinyl moiety of **1** to give **1**-NH_o^+ or **1**-NH_p^+ would also produce a better leaving group and so may enhance the reaction. Protonation at P=S to give **1**-SH^+ would increase P electrophilicity, enhancing the attack by nucleophiles at phosphorus. Catalysis in moderately acidic media could be due to any one of these protonations or through the interplay of several simultaneously.

In this paper we report the acidity-rate constant profile for **1** in 1–14 mol/L sulfuric acid. The results will be discussed in terms of the excess acidity analysis, modes of acid catalysis, and potential mechanistic changeover (19, 20). The interesting rate-excess acidity profile has led us to propose a new variant of the A-S_E2 mechanism in the higher acidity medium in which rate-limiting proton transfer to the sulfur

of the P=S ester bond may occur in a concerted fashion with nucleophilic attack on the phosphorus centre.

Experimental

Materials and instruments

Common solvents and reagents (e.g., 95%–98% H_2SO_4, 99.8% D_2O, 85% H_3PO_4, and dimethyl sulfoxide-d_6) were purchased in the highest purity available and used without further treatment. Diazinon **1** was either obtained from Chem Services Inc. (99.5%) and used as obtained or synthesized as outlined later. *O*,*O*-diethylphosphorothioic acid **3** and triethyl thiophosphate were prepared in our laboratories and purified prior to use by column chromatography as described previously (16). Other reagents were purchased commercially but purified before use (vide infra).

Routine NMR spectra were recorded using a Bruker 300 MHz Avance spectrometer. For NMR spectrometric product analyses or kinetic studies, a Bruker 500 MHz Avance instrument was used. Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. For UV–vis spectrophotometric measurements and for kinetic runs, the following instruments were used: Varian CARY 3, Hewlett-Packard 8452A, or PerkinElmer Lambda-20. Temperature was maintained at 25 °C with a Peltier effect device in the case of the CARY 3 or with a circulating water bath in the case of the other spectrophotometers.

Diazinon (1)

Synthesis

Diazinon was synthesized by a method modified from Gysin and Margot (21). First, a weighed quantity of **2** (5.0 g; 0.033 mol) was reacted with KOH (1.9 g; 0.034 mol) in hot absolute ethanol to generate the potassium salt of **2**. Excess ethanol was removed at reduced pressure (rotovap), and then benzene (70 mL) was added. The solution was distilled to azeotropically remove water; residual benzene was removed using a rotovap. Dry acetone (100 mL) was then added. To this solution was added diethyl chlorothiophosphate (6.20 mL; 0.039 mol), and the mixture was heated at ~35 °C for 2 days under nitrogen. The solution was cooled and filtered through Celite® to remove KCl. The solvent was distilled from the filtrate (rotovap) to give an oil that was purified by column chromatography using methylene chloride as eluent. Two fractions were recovered, the starting material and crude **1**. When dried, the crude **1** was found to contain a white solid impurity (possibly unmodified **2**). The crude sample was dissolved in hexanes (40 mL) and purified by extraction with H_2O (4 × 20 mL). The hexanes layer was dried with anhydr. $MgSO_4$ and filtered to remove the drying agent. The solvent was removed using a rotovap and dried further overnight under reduced pressure and at ambient temperature. The final product was obtained in 50% yield and its purity was verified by ^1H, ^{31}P, and ^{13}C NMR (*J*-modulated and DEPT) spectroscopy. All spectra were consistent with that of Diazinon and contained no peaks ascribable to impurities. ^1H NMR ($CDCl_3$, ppm) δ: 6.64 (s), 4.33 (d of q, $J_{H\text{-}H}$ = 7.1 Hz, $J_{H\text{-}P}$ = 11.2 Hz), 3.10 (sept, $J_{H\text{-}Hf}$ = 6.9 Hz), 2.47(s), 1.37 (t, $J_{H\text{-}H}$ = 7.1 Hz) and 1.30 (d, $J_{H\text{-}H}$ = 6.9 Hz). ^{31}P NMR δ: 61.5 (s). ^{13}C NMR δ: 176 (s), 170 (s), 165 (d, $J_{C\text{-}P}$ = 4.6 Hz), 107 (d, $J_{C\text{-}P}$ = 6.4 Hz), 65.6 (d, $J_{C\text{-}P}$ = 5.1 Hz), 37.7 (s), 24.5 (s), 21.8 (s), 16.2 (d, $J_{C\text{-}P}$ = 8.0 Hz).

*p**K**a Values for the conjugate acids of 1 (1-NH$_p^+$, 1-NH$_o^+$, 1-SH$^+$) and models*

Attempts were made to determine pK_a values for the conjugate acids of Diazinon (Scheme 2, **1**-NH_p^+, **1**-NH_o^+, **1**-SH^+) and of 2-isopropyl-6-methyl-4-pyrimidinol **2** using ^1H (side chain and ring protons), ^{31}P NMR, as well as UV–vis spectrophotometric measurements (λ = 230, 254, and 260 nm). Generally, the methods yielded the same average values for the macroscopic acidity constants. These determinations involved recording spectra of **1** in a series of H_2SO_4 solutions (1–18 or 1–14 mol/L), and relevant chemical shifts

© 2007 NRC Canada

(or λ_{max} values) were plotted against the $-H_0$ acidity function for the acid solutions; H_0 is anchored to the aqueous pH scale. From these titration curves (fitted using the Origin® 7.0 program) the macroscopic pK_a value for **1**-NH_p^+ and (or) **1**-NH_o^+ (= 2.40) was determined and found to be similar to that for the same site in the product 2-isopropyl-6-methyl-4-pyrimidinol measured in the same way (i.e., pK_a = 2.84), which is also similar to that reported for the same site in 2,6-dimethyl-4-pyrimidinol (3.06) (22). These studies also set a limit for the pK_a ascribable to diprotonation at –7.3; higher acidity solutions led to the rapid decomposition of **1** and precluded a more precise assessment. A comparable ^{31}P NMR titration of *O*,*O*-diethyl phosphorothioic acid **3** yields a value for pK_a of the conjugate acid (S-site) of –5.14.

Purification of solvents and reagents and preparation of stock solutions

2-Isopropyl-6-methyl-4-pyrimidinol (2)

Commercial **2** (Sigma-Aldrich, 99%) was recrystallized from either acetone or ethanol to remove a fine black solid impurity. Melting point 172–173.5 °C (lit. value 172–175 °C (23)). The ^{1}H NMR spectrum (300 MHz) contained no extraneous peaks; (D_2O, ppm) δ: 6.09 (s, 1H, ring H-3), 4.72 (sept, 1H, *J* = 7.0 Hz, CH of 2-isopropyl), 2.19 (s, 2H, 6-CH_3), 1.19 (d, 6H, *J* = 7.0 Hz, CH_3 of 2-isopropyl). Exchange of the OH proton with solvent precludes its observation.

Stock solutions

In general, all stock solutions were prepared in volumetric flasks sealed with rubber septa or, alternatively, with a glass stopper and Parafilm®. Aqueous solutions were prepared with distilled, deionized, and degassed water (9). All stock solutions were stored in a refrigerator.

Sulfuric acid solutions

In each case, the calculated required amount of purified water was first transferred to the volumetric flask, and then the H_2SO_4 solutions were made up by mass. In general, the flasks were cooled in an ice bath and the calculated amount of concentrated (ca. 98%) H_2SO_4 was weighed and slowly added. The acid solutions were titrated against NaOH that had been standardized against anhydrous potassium hydrogen phthalate.

Diazinon (1)

An aliquot (15 μL) of **1** was dissolved in purified 1,4-dioxane (5 mL) to give the stock solution (1.10×10^{-2} mol/L). The 1,4-dioxane was purified prior to use by standard methods (24) and stored until use under nitrogen at low temperature (ca. –10 °C, freezer).

UV–vis spectrophotometric kinetic studies of the decomposition of 1 in acidic media

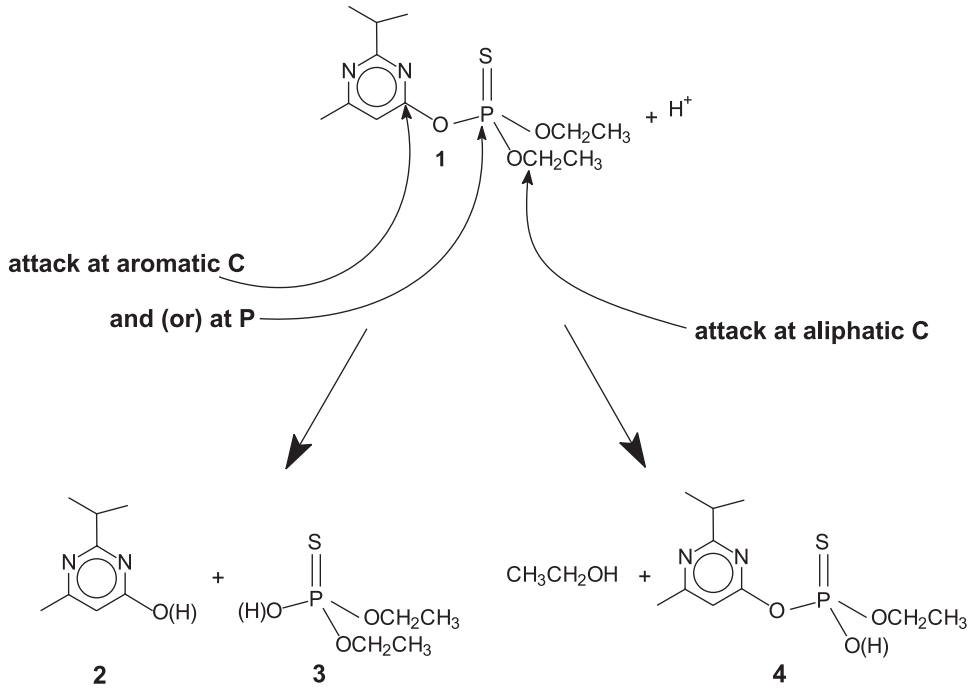
All kinetic runs were carried out under pseudo first-order conditions with the concentration of acid in large excess relative to Diazinon **1**. For experiments that used the stock solution of **1** in 1,4-dioxane, an aliquot (20 μL) of the stock solution was injected (via 25 μL gas-tight syringe) into the quartz UV cuvettes containing the sulfuric acid solution (2.50 mL added by pipette) with an initial (time = 0) concentration of **1** of 8.73×10^{-5} mol/L. The monitoring of this reaction solution spectrophotometrically revealed two processes, an initial fast process followed by a slow one; these were ascribed, respectively, to decomposition of the dioxane and of the substrate **1**. The rate data, however, could be readily dissected to yield the separate rate constants (25). The latter were validated by preparation of reaction solutions (in large volume) free of dioxane and the kinetic results here showed good agreement with those for the slower process.

In either case the rate of appearance of product **2** was followed at 230 nm, the approximate wavelength of maximum absorbance for **2** (or protonated derivatives), under acidic conditions (increased to 234 nm at higher acid concentrations). Reactions were monitored for at least three half-lives and the absorbance at infinite time (A_∞) noted at 10 $t_{1/2}$. Plots of $\log(A_\infty - A_t)$ vs. *t*, using suitable spectrophotometric data as described earlier for systems in which dioxane was present, afforded the pseudo first-order rate constants k_{obs} reported herein.

^{31}P NMR spectrometric studies of the decomposition of 1 in acidic media

Kinetic studies

The reaction was initiated by addition of 4 μL of Diazinon (no solvent) to 1 mL of sulfuric acid solution (4.9–9.5 mol/L) in an NMR tube containing a sealed capillary tube that contained either 5% (*v*/*v*) trimethyl phosphate in DMSO-d_6 or 20% (*v*/*v*) 85% phosphoric acid in D_2O; these capillaries served as external chemical shift standards and supplied the needed lock signal. Spectrometric parameters were optimized (e.g., suitable relaxation delays are given in ref. 26) as previously reported (9). After placement of the tube in the probe of the NMR (at 25 °C), spectra were acquired at regular intervals and the rate constant determined on the basis of the integral of the ^{31}P NMR signal for Diazinon and that of the product signal (normalized versus trimethyl phosphate or phosphoric acid). The plot of natural log (signal area) vs. time yielded the rate constant k_{obs} according to a first-order treatment,



$$[1] \quad \ln(\text{Integral } \mathbf{1}_{initial} - \text{Integral } \mathbf{2}_{time}) = -k_{obs}t + \text{constant}$$

Product analysis

NMR tubes were prepared as outlined for the kinetic experiments. Each tube contained a concentration of sulfuric acid (ranging from 1 to 17 mol/L). The reaction was initiated by injection of 4 μL of **1**. The lower acidity tubes (1–13 mol/L) were set aside to permit reaction for 48 h, while the reaction was allowed for 20 min for the higher acidity (14–17 mol/L) samples. Once the reaction was deemed complete, a ^{31}P NMR spectrum was obtained. Only one product peak was observed; its identity was confirmed as *O*,*O*-diethylphosphorothioic acid **3** through spiking the tubes with authentic compound and re-recording the ^{31}P spectrum.

Scheme 3. Pathways of Diazinon hydrolysis under acidic conditions, where attack at aromatic carbon and (or) phosphorus contrasts with attack at aliphatic carbon.

Results

Acid-catalyzed hydrolysis of Diazinon 1 — UV–vis kinetic study.

Rate data for the hydrolysis of Diazinon in 1–14 mol/L H_2SO_4 solutions were determined spectrophotometrically by following the production of the pyrimidinol leaving group **2** (Scheme 3). The observed rate constants k_{obs} at 25 °C were calculated through application of eq. [2],

$$[2] \qquad \log (A_\infty - A_t) = -k_{obs}t + \text{constant}$$

where A_t is the absorbance at time t and A_∞ at infinite time (i.e., 10 $t_{1/2}$). The pseudo first-order rate constants for the decomposition of **1** at each sulfuric acid concentration and corresponding excess acidity X are given in Table 1.

^{31}P NMR study — Kinetics and product identification.

The reaction was also studied by ^{31}P NMR spectrometry, a method that provides simultaneous rate and product identification data. The pseudo first-order rate constants k_{obs}, in the H_2SO_4 range 4.9–9.5 mol/L, were calculated from the integration of the peak area of **1** or its P-containing product according to eq. [1] (see Experimental section).

The rate data obtained from ^{31}P NMR spectrometry (Table 1) were in good agreement with results using UV–vis spectrophotometry. ^{31}P NMR spectrometry also demonstrated that the only phosphorus-containing product of Diazinon hydrolysis is *O*,*O*-diethylphosphorothioic acid **3** (Scheme 3).

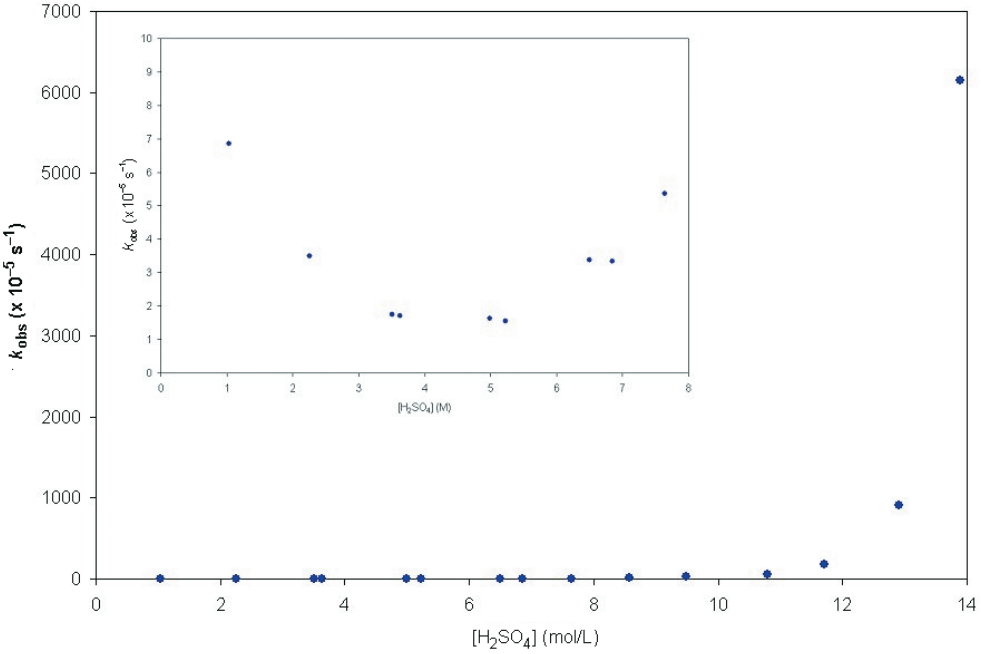
Discussion

Overview

The rate constants determined for the decomposition of **1** in moderately acidic media (Table 1, UV–vis determinations) were plotted as k_{obs} vs. the concentration of sulfuric acid (mol/L) (Fig. 1) and also plotted as log k_{obs} vs. the excess acidity function X, as the appropriate measure of the acidity of the medium (19, 27, 28) (Fig. 2). While the full scale plot in Fig. 1 (1 – ca. 14 mol/L) appears almost flat until about 11 mol/L where the curve swings upward, an enlargement (Fig. 1 inset) of the lower acidity region (1–8 mol/L) more clearly shows the initial decline in rate with

© 2007 NRC Canada

Fig. 1. Plot of pseudo first-order rate constants k_{obs} vs. sulfuric acid concentration (mol/L) for the hydrolysis of **1**. The enlarged inset of the concentration region from ca. 1 to 8 mol/L shows the initial decline and subsequent rise in reactivity with sulfuric acid concentration.



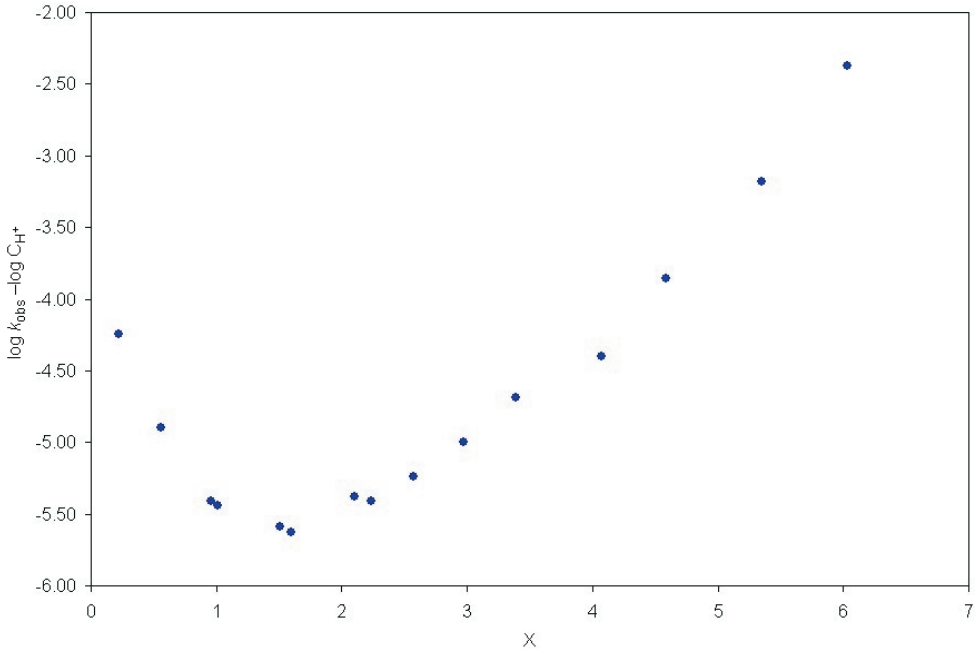


Fig. 2. Rate-excess acidity plot (log k_{obs} – log concentration of H^+ vs. X) for the hydrolysis of **1**.

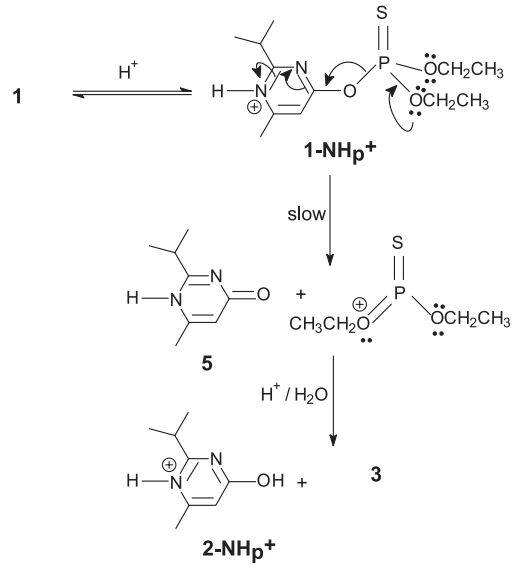
increasing sulfuric acid concentration (1–5 mol/L), with the sharper increase commencing at a concentration of about 5 mol/L. The profile in Fig. 2 highlights this interesting initial decline in rate with increasing sulfuric acid concentration (X = 0–1.6). Note, however, that even the lowest reaction rate determined (k_{obs} = 1.52 × 10^{-5} s^{-1} corresponding to X ~ 1.6) is 150-fold greater than the rate previously reported at pH 7.0 (k_{obs} = 1 × 10^{-7} s^{-1} (29)). From X = 1.6 onward, the rate rises more steeply; a rate constant of 6.15 × 10^{-2} s^{-1} is attained at X ~ 6, the most acidic solution studied (13.9 mol/L H_2SO_4), i.e., an acceleration of the rate of decomposition by a factor of 600 000 as compared with that found at pH 7.0. These results, and especially the initial decline in rate constant with acidity and later steep rise in reactivity, suggest the intervention of more than one mechanism over this acid range.

As noted earlier, Diazinon contains several sites for potential protonation and these are identified in Scheme 2 as **1**-OH^+, **1**-SH^+, and **1**-NH_o^+ and **1**-NH_p^+ for the ortho- and para-nitrogens, respectively. By considering suitable model

© 2007 NRC Canada

compounds (e.g., pyrimidinol derivatives (30)), protonation of one of the ring nitrogens would plausibly be expected for monoprotonation. It is then also plausible to expect the formation of **1**-NH_p^+ to be favoured over the formation of the isomeric **1**-NH_o^+. (Also see the Experimental section where NMR and spectrophotometric titrations yielded a macroscopic pK_a of 2.40 for **1**-NH_p^+ and **1**-NH_o^+ and a limiting composite pK_a of –7.3 for diprotonation). Henceforth, therefore, in the acid media examined, **1**-NH_p^+ is taken as the starting species for further reaction.

Reaction pathways



For the hydrolysis of Diazinon, three possible reaction sites can be envisioned; these include an attack at phosphorus as well as an attack at carbon, as outlined in Scheme 3. Attack at the aliphatic carbon of **1** would produce ethanol and de-ethyl Diazinon (**4**) as products; however, ^{31}P NMR spectrometry did not detect any **4**, and hence this pathway will not be considered further. This leaves the possibilities of attack at the aromatic carbon and (or) at phosphorus.

Considering first the S_NAr pathway, we note that generally two or more strongly electron-withdrawing substituents, such as nitro groups in the aromatic ring, are required for this route to be favoured. For example, in the case of the reaction of methyl 2,4-dinitrophenyl phosphate monoanion with amines, where nucleophilic attack at phosphorus is electrostatically suppressed, the reaction follows the S_NAr path (31). Differences in the reactivity of comparable P=S esters, as compared with this P=O example, would be expected to have little effect on this result (32). In contrast, with fenitrothion (Scheme 1, R = CH_3, Ar = 3-methyl-4-nitrophenyl) reacting with ethoxide, where the aryl ring of the leaving group is activated with only a single nitro group and where P-attack is not suppressed, ethanolysis via S_NAr occurs to a small (ca. 7%) extent, and P-attack is the dominant route (8). Thus, considering that a ring nitrogen is normally less effective in promoting S_NAr displacement compared with NO_2 (33), albeit recognizing that an unprotonated N is less activating than protonated N, it is reasonable to conclude that the reaction of Diazinon should proceed preferentially via P-attack rather than by S_NAr. Further discussion will, therefore, focus on reaction of **1** at the P-site.

Mechanisms of acid catalysis

In acidic media, reactions are most commonly catalyzed via mechanisms classified according to types A-1, A-2, or A-S_E2 (19, 27, 28*a*, 34–36). An A-1 process involves a unimolecular rate-determining step, where fast equilibrium protonation of the substrate S results in the formation of a reactive intermediate SH^+. In the current system, protonation facilitates the departure of the leaving group and SH^+ decomposes unimolecularly, and so here the A-1 pathway would involve the unimolecular breakdown of **1**-NH_p^+ with the formation of a metaphosphate-like intermediate, stabilized by resonance, that reacts further with water to give **3** (Scheme 4). On the other hand, in the A-2 mechanism fast equilibrium protonation of the substrate enhances the attack

Scheme 4. A-1 type mechanism for hydrolysis of Diazinon.

of a nucleophile in the bimolecular rate-determining step. Here, the rate-determining attack of water on the monoprotonated substrate 1-NH_p^+ with concomitant P–O bond scission leads to a protonated form **3**-H^+ that equilibrates to give **3** as the final product (Scheme 5). In contrast, *rate-limiting protonation* leading to the SH^+ intermediate that then decomposes in a separate fast step comprises the A-S_E2 pathway. A variant of this mechanism is proposed below.

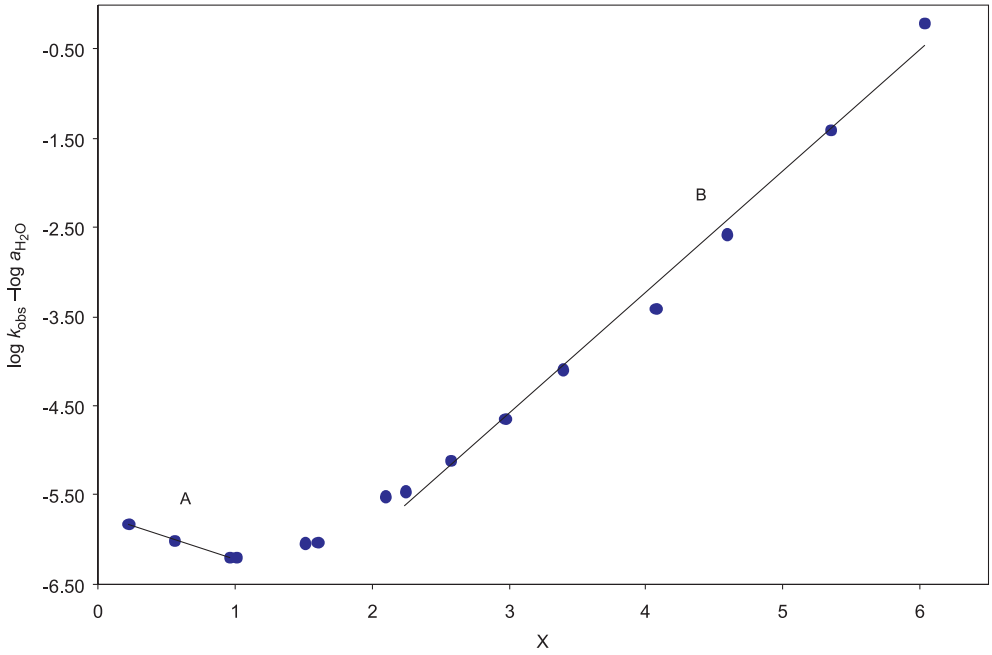
The excess acidity treatment affords insight into the mechanistic pathways of acid catalysis.

A-1 process

For an A-1 mechanism (Scheme 4), the appropriate excess acidity relationship is expressed in eq. [3], where it is assumed that any diprotonation over the range of H_2SO_4 studied will be negligible (19),

$$[3] \qquad \log k_{obs} - \log C_{H^+} = \log[k/K_{SH_2^{++}}] + m^{\ddagger}m^{*}X$$

However, as Fig. S4 (Supplementary material) shows, the resultant plot, instead of being linear with positive slope, displays strong curvature with a broad minimum (at values of *X* between 1 and 2), thus ruling out this mechanism as the sole process involved in the current system throughout the range of acidity studied.[3] The plot could be described as a "broad upward parabola".



A-2 process

A-2 mechanistic types have been observed in a number of systems involving phosphorus-containing substrates (36–38). In an A-2 process one or more molecules of water may be involved in a rate-determining step that occurs after rapid equilibrium protonation of the substrate (19). Scheme 5 shows the case where a single molecule of water acts as nucleophile. For an A-2 mechanism, any general excess acidity plot (i.e., one obtained from an equation similar to eq. [3]) should yield a downward arc that achieves a maxi-

Fig. 3. Rate-excess acidity plot for the hydrolysis of **1** showing a possible mechanistic switch from an A-2 process (line A) at lower X values to an A-1 (or A-S_E2 variant) process (line B) at higher X values. The equations of the lines are given in the text.

Scheme 5. A-2 type mechanism for hydrolysis of Diazinon.

mum near the point where the acidity of the medium would have fully converted the substrate to its protonated form. The decrease in rate that occurs with increasing acidity reflects the decreasing activity of water (a_{H_2O}) at higher acid concentrations.

The kinetic data were treated using eq [4], which involves one water as nucleophile (i.e., Nu = H_2O), and eq. [5], which involves two waters, neither of which however, yielded linear plots (Figs. S5 and S6; see Supplemental Data).[3]

$$[4] \quad \log k_{obs} - \log C_{H^+} - \log a_{Nu} = \log[k/K_{SH_2^{++}}] + m^{\ddagger}m^{*}X$$

$$[5] \quad \log k_{obs} - \log C_{H^+} - 2\log a_{Nu} = \log[k/K_{SH_2^{++}}] + m^{\ddagger}m^{*}X$$

However, even though the entire data do not fit either a single A-1 or A-2 mechanism, it is plausible that there is a change in mechanism when the plot switches from a decrease in rate with increasing acid concentration to an increase in rate with increasing acid concentration.

Switch from an A-2 to an A-1 process

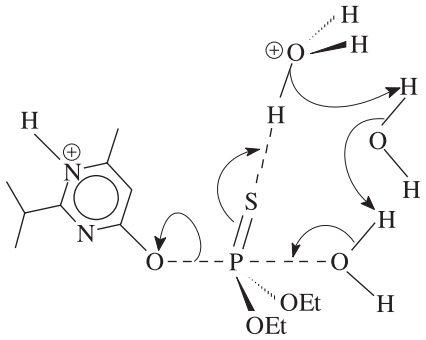
Based on the pK_a values found for Diazinon (2.40 for **1**-NH_p^+ and **1**-NH_o^+ and –7.3 as a limit for diprotonation), it was presumed (vide supra) that Diazinon was protonated at all values of X studied and that **1**-NH_p^+ was, therefore, the starting species for any further discussion. It follows then, that instead of finding a full downward arc, as expected for an A-2 process, the region of the rate-excess acidity profile bounded by $X = 0$ to about $X = 2$ represents the portion of the expected A-2 process where the rate declines as a function of the decreasing amount of free water present. In effect, the expected A-2 arc is truncated so that only the downward portion is seen. An empirical straight line, using one molecule of water as the simplest case (Fig. 3), was fit to the data ($X = 0$ to ca. 1), and for the limited number of points involved the fit is good ($r^2 = 0.998$). The equation of the line is,

$$[6] \quad \log k_{obs} - \log a_{H_2O} = -0.493X - 5.721$$

Similarly, the region defined by $X = 2$ to about 6 yields an empirical straight line treatment (Fig. 3) where the fit is also good ($r^2 = 0.992$) and the equation of the line is,

$$[7] \quad \log k_{obs} - \log a_{H_2O} = 1.366X - 8.688$$

This second line could represent an A-1 mechanism, and therefore overall there would be a switch from an A-2 to an A-1 type mechanism. Such changeovers are far from unprec-



© 2007 NRC Canada

edented and are found for a number of esters, thiobenzoate, and thionobenzoate esters, among other systems (19, 27). However, there is a paucity of examples of acid catalysis of the breakdown of P=S pesticides with structures clearly analogous to **1** (36) in the higher acidity (*X* ca. 2–6) region, and hence, comparison to related systems cannot be made. Moreover, it is difficult to envisage the mechanism of A-1 *catalysis* with increasing acidity, since with **1** the initial N-protonation of the ring is already complete in the dilute acid region. In short, while it is apparent that the A-2 mechanism should become less effective as the concentration of free water declines, it is not apparent that the A-1 mechanism should lead to catalysis as the acidity of the medium increases.

A concerted rate-limiting proton transfer to S with nucleophilic attack at P — An A-S_E2 variant mechanism

An essential part of the reactivity of Diazinon must be associated with the P=S moiety (32). However, it is noteworthy that neither the A-2 nor A-1 mechanisms involve protonation of P=S, even though these mechanisms do not explain the kinetic behaviour throughout the full acidity range.

As a variant of the A-S_E2 class, a mechanism can be proposed where rate-limiting proton transfer to the P=S function occurs in a cyclic array involving hydronium ion as proton donor to S but as proton acceptor from water, which effectively delivers hydroxide to P. A transition state structure for this A-S_E2 variant mechanism is illustrated in structure **6**, where the dotted lines indicate partial bond formation and rupture. In this structure, a bridging water molecule is included as has often been found in such acid-catalysed hydrolyses.[4] To our knowledge, this would be the first instance in which rate-limiting proton transfer to S in a molecule containing the P=S functionality has been proposed.

6

On the other hand, a comparison can be made with the pertinent studies of Cox and Yates (39) on the hydrolytic decomposition of a range of three sets of SC=O and OC=S substrates: four thiobenzoic acids (Ar-CO-SH), eight ethyl thiobenzoates (Ar-CO-SCH_2CH_3), and eight ethyl thionobenzoates (Ar-CS-OCH_2CH_3) in aqueous sulfuric acid media. In general, all of these substrates exhibited two (or more) mechanisms of decomposition. For example, with the parent ethyl thiobenzoate three mechanistic regions could be defined: (*i*) an A-2 mechanism involving two water molecules (*X* ca. 1–2), (*ii*) an A-S_E2 region where hydronium ion was found to be the proton source (*X* ca. 2.5–4) that switches over to (*iii*) an A-S_E2 mechanism where the proton source was assigned to undissociated sulfuric acid (*X* ca. 5–10). In contrast to the behaviour of ethyl benzoate that follows an A-2 mechanism that changes over to an A-1 pathway at about *X* = 6 with acylium ion formation, all of these S-containing substrates exhibit mechanistic changeover at significantly lower acidities (ca. *X* = 2–3) (39). Note that the mechanistic switch (A-2 → A-S_E2) suggested here for Diazinon also occurs at an excess acidity value (*X*) of about 2. Cox and Yates (39) concluded "that proton transfer to sulfur in involved in the slow step of the reaction at least some of the time, for all three types of sulfur-containing substrate in the study" This conclusion may also extend to **1** in moderately acidic sulfuric acid media.

Returning to the Diazinon – aq. H_2SO_4 system, in a (hypothetical) A-2 mechanism involving protonation at S, the pK_a of the P=S group is a dominant consideration. Such protonation in the current system corresponds to protonation at S of the monoprotonated substrate, **1**-NH_p^+, i.e., diprotonation overall. In our estimate (see the Experimental section), the lower limit for the pK_a for diprotonation is –7.3. Therefore, the acidity in our study should be insufficient to produce diprotonation. Note as well that *O*,*O*-diethyl thiophosphoric acid, a model for protonation at P=S, was found to have a pK_a of –5.14. Unfortunately, Diazinon undergoes rapid degradation in media with higher acidities.

An important aspect concerning the proposed (A-S_E2) mechanism, which is to be emphasized, is that the concerted nature of the process makes it accessible in a lower acid region compared to the A-2 mechanism discussed above. In this acid region (*X* = 2–6), although a_{H_2O} continues to decline, this is more than compensated for by the increasing acidity, as evidenced by the sharp upward curve of the rate-excess acidity profile.

Since P=S is a defining feature of a large class of pesticides in use, and the proposed mechanism is directly tied to this structural feature, a broad avenue is opened for the study of the general behaviour of these biocides in acid media.

Conclusions

Whereas in pesticides the lowered hydrolytic activity of P=S triesters relative to their P=O analogues confers lowered mammalian toxicity on these biocides (1), this lowered reactivity opens up the possibility of other routes of reaction. In the current case, we propose that acid catalysis occurs via the less common A-S_E2 type rather than the traditional A-2 or A-1 paths outlined (Schemes 4 and 5). Therefore, in simple ester or amide hydrolysis in acid, the A-2 or changeover of A-2 to A-1 mechanisms (19, 27) are supplanted in Diazinon hydrolysis by the concerted variant of the A-S_E2 process involving partial rate-determining proton transfer to P=S from hydronium ion with concomitant proton transfer from water and effective attack of hydroxide at the P centre

[4] We thank a referee for drawing our attention to this point. The current treatment does not permit definitive assignment of the number of water molecules involved in the transition state.

(structure **6**). In nature, for example in enzymatic processes (e.g., chymotrypsin), rate-determining proton transfers involving relays, in which proton transfer is central to the catalysis are the norm.

Acknowledgements

Financial support of this work was provided by the Natural Sciences and Engineering Research Council of Canada (to EB) and PGS A and PGS B scholarships (to DC) are gratefully acknowledged. Thanks are also extended to the sponsors of the Pestcon Scholarship (granted to DC) administered by the Chemical Institute of Canada, which assisted these studies in pesticide chemistry. Support of the Sir Wilfred Grenfell College Principal's Research Fund (to JMD) is also noted. Helpful comments of the referees are cheerfully acknowledged.

A reinterpretation of the unusual barochromism of azulene

Masami Okamoto, Satoshi Hirayama, and Ronald P. Steer

Abstract: The UV–vis spectra of azulene in methylcyclohexane and acetonitrile solution at room temperature have been measured as a function of applied pressure in the 0.1–600 MPa range. The solvatochromic shifts are normal, but the barochromic shifts are unusual (hypsochromic shift in the S_1–S_0 absorption bands vs. normal bathochromic shifts in its S_2–S_0 and S_3–S_0 absorption bands). An analytical relationship between the barochromic shift and the differences in the polarizabilities and dipole moments of the two radiatively coupled electronic states has been derived. The unusual barochromism of azulene has been reinterpreted in terms of differences in the polarizabilities of azulene in its ground and excited states and the dominance of dispersive interactions in barochromism.

Key words: barochromism, solvatochromism, azulene, polarizability, dipole moment.

Résumé : On a mesuré les spectres UV-vis de l'azulène en solutions dans le méthylcyclohexane et l'acétonitrile, à la température ambiante, en fonction de la pression appliquée de 0,1 à 600 Mpa. Les déplacements solvatochromes sont normaux, mais les déplacements barochromes sont inhabituels (déplacement hypsochrome des bandes d'absorption S_1–S_0 par rapport aux déplacements bathochromes des bandes d'absorption S_2–S_0 et S_3–S_0). On a développé une relation analytique entre le déplacement barochrome et les différences dans les polarisabilités et les moments dipolaires de deux états électroniques couplés d'une façon radiative. On a réinterprété la barochromie inhabituelle de l'azulène en fonction de différences dans les polarisabilités de l'azulène dans des états fondamental et excité et de la dominance d'interactions dispersives dans la barochromie.

Mots-clés : barochromie, solvatochromie, azulène, polarisabilité, moment dipolaire.

[Traduit par la Rédaction]

Introduction

The spectroscopic and photophysical properties of azulene continue to elicit interest because this nonalternant aromatic hydrocarbon provides one of only a few chromophores that fluoresce strongly from a second excited singlet state, S_2 (2^1A_1 in C_{2v} symmetry) (1). The lifetimes of this excited state are determined primarily by its rate of radiationless relaxation to lower electronic states. For azulene and many of its simply substituted derivatives, S_2–S_1 internal conversion is the dominant relaxation path, and the rate of this process follows the energy gap law of radiationless transition theory (2). Thus, the S_2 radiationless decay rates of these compounds vary directly with their Franck-Condon factors, $F = < \chi(s_2)|\chi(s_1) >^2$, which in turn are proportional to exp–[ΔE] when the electronic energy gap, $\Delta E = E(S_2) - E(S_1)$, is sufficiently large. In fluid solution, azulene's electronic energy gap can be tuned by solvatochromism (3), by choice of substituent (3, 4), and by the application of large hydrostatic pressures (5) (barochromism).

The overall effects of the application of a high pressure on the electronic spectrum of azulene have been known (6, 7) for many years; the S_1–S_0 transition in the visible undergoes an unusual blue shift with increasing pressure whereas the S_2–S_0 transition in the near UV undergoes a red shift. The result is a net decrease in ΔE with increasing pressure and an exponential increase in S_2's rate of radiationless decay (5). Although both the S_1–S_0 the S_2–S_0 spectra of azulene have been extensively studied in recent years (8, 9), the barochromic effects on them have received no attention. In fact, the original explanation for the observed barochromism (7), involving differences in the electric dipole moments of azulene in its ground and excited singlet states, has remained unchallenged for many years and has been propagated in the review literature (10, 11).

Recently, we carefully remeasured the effects of applying high hydrostatic pressures on the UV–vis spectra of azulene in solution, and in light of recent additional measurements of its excited state properties (vide infra) offer a reinterpretation of the observed barochromism.

Experimental section

Azulene (Fig. 1, C_s structure and coordinate axis system) was obtained from Sigma-Aldrich, and spectroscopic grade methylcyclohexane and acetonitrile solvents were obtained from Dojin Pure Chemicals Co. All were used as received.

Fig. 1. Azulene (C_s structure).

The absorption spectra were taken on a Shimadzu UV 260 spectrophotometer. Data were acquired digitally every 0.05 or 0.10 nm, usually at a spectral resolution of 2 nm. Several spectra were also taken at the substantially higher resolution of 0.2 nm; they exhibited small changes in the widths and apparent relative absorbances of resolved bands but no significant differences in the wavenumbers of band maxima, which were extracted manually from the data files. The differences in the spectra at the two resolutions are illustrated in the Supplementary Information for this paper.[2]

The high pressure cell was made of SUS 316 stainless steel, was fitted with sapphire windows, and had an optical path length of 0.6 cm and an aperture of 0.5 cm. The spectra were measured separately in the S_1–S_0, S_2–S_0, and $S_{3,4}$–S_0 ranges, using solution concentrations that gave a convenient absorbance in the wavelength range of interest. No evidence of solute aggregation was observed at any pressure in any of these solutions. The spectrum of the solvent alone was also measured separately and was deemed independent of pressure up to at least 600 MPa. The pressure was measured using a calibrated Manganin wire. Details may be found in ref. (12). All measurements were taken at a room temperature of 22 °C.

Results and discussion

The S_1–S_0 and S_2–S_0 spectra of azulene in methylcyclohexane as a function of pressure in the 0.1 to 600 MPa range are shown in Figs. 2a and 2b. All the resolved and partly resolved features in the S_1–S_0 spectrum exhibit blue shifts with increasing pressure in both solvents, whereas those in the S_2–S_0 spectrum exhibit red shifts, in qualitative agreement with the original measurements by Robertson and King (6). Graphs of the wavenumbers of the maxima of the origin bands of the S_1–S_0 and S_2–S_0 transitions in methylcyclohexane vs. pressure in this range are shown in Fig. 3.

Drickamer and co-workers (7) have shown that at much higher pressures the wavenumbers of the S_1–S_0 bands reach a maximum (near 6 000 MPa in azulene crystals) and then decrease quite rapidly with further increases in pressure. A hint of nonlinearity in the graphs of transition energy vs. pressure is evident in the present work (Fig. 3). Nevertheless, in the 0.1 to 600 MPa pressure range explored here, only a marginal statistical improvement is obtained when a second order polynomial is used to fit the data compared with a linear function. We therefore use the data from the linear fits: the slopes ($d\bar{\nu}_{u,0}/P$) of such plots and the observed intercepts ($\bar{\nu}_0$) for all the resolved features in the spectra in methylcyclohexane are given in Table 1.

The spectra as a function of applied pressure in acetonitrile (Fig. 2*c* shows the S_1–S_0 spectra) are not well-resolved and yield graphs qualitatively similar to those in Fig. 3 but with slopes and intercepts with large statistical error. The intrinsic broadening of the spectra in the polar solvent, not the spectral resolution employed, prevents the extraction of statistically meaningful barochromic data. Nevertheless, both the expected "normal" solvatochromic blue shift (of the singlet–singlet absorption systems) at any given pressure and the unusual barochromic shift of the S_1–S_0 origin are observed qualitatively in the polar solvent.

The apparent absorbances (and half-widths) of all resolvable bands increase with increasing pressure, albeit by different relative amounts for different features in the spectrum. The largest increase in absorbance is due to the increasing density of the solution (and hence molar concentration of the solute). The remaining small differences in the absorbances and half-widths of different features in the spectrum are real and are not due to increases in the molar absorptivity with increasing refractive index (13). However, these small changes cannot readily be quantified at the spectral resolution employed ($\Delta\lambda$ = 2.0 or 0.2 nm), given the fact that almost all of the observed vibrational structure in these spectra results from the overlap of several bands that are completely unresolved in solution at room temperature. Values of $\bar{\nu}_0$ (Table 1) are obtained by extrapolation of the data such as those in Fig. 3 to P = 0. However, owing to broadening in solution and the effects of band overlap these values will not correspond exactly to the wavenumbers of the same bands in the electronic spectra of the isolated molecule (8, 9).

The magnitudes of the measured slopes of the wavenumber vs. pressure plots (Table 1, $\bar{\nu}_{n,0}/dP$) for all of the vibronic bands in both the S_1–S_0 and S_2–S_0 systems may also be determined in part by the effects of overlapping transitions, so we ascribe significance only to the sign and range of values of these quantities. However, the lowest energy bands in both absorption systems are quite well-resolved from the rest of the spectrum at all pressures up to 600 MPa. We therefore ascribe significance to both the sign and magnitude of their barochromic slopes, despite the fact that these "origin" bands will actually consist of the true inhomogeneously broadened 0–0 transition overlapped by a number of weaker, hot, sequence bands ($\Delta v = v'' - v' = 0$, $v'' = 1, 2, 3, \ldots$). In both electronic band systems, the totally symmetric vibrations (a_1 in C_{2v}) are most active (8, 9), and the most intense of these weaker, hot, sequence bands are expected to be those of lowest frequency. The lowest frequency a_1 vibration in the ground state of azulene is $\bar{\nu}_{17}$ =

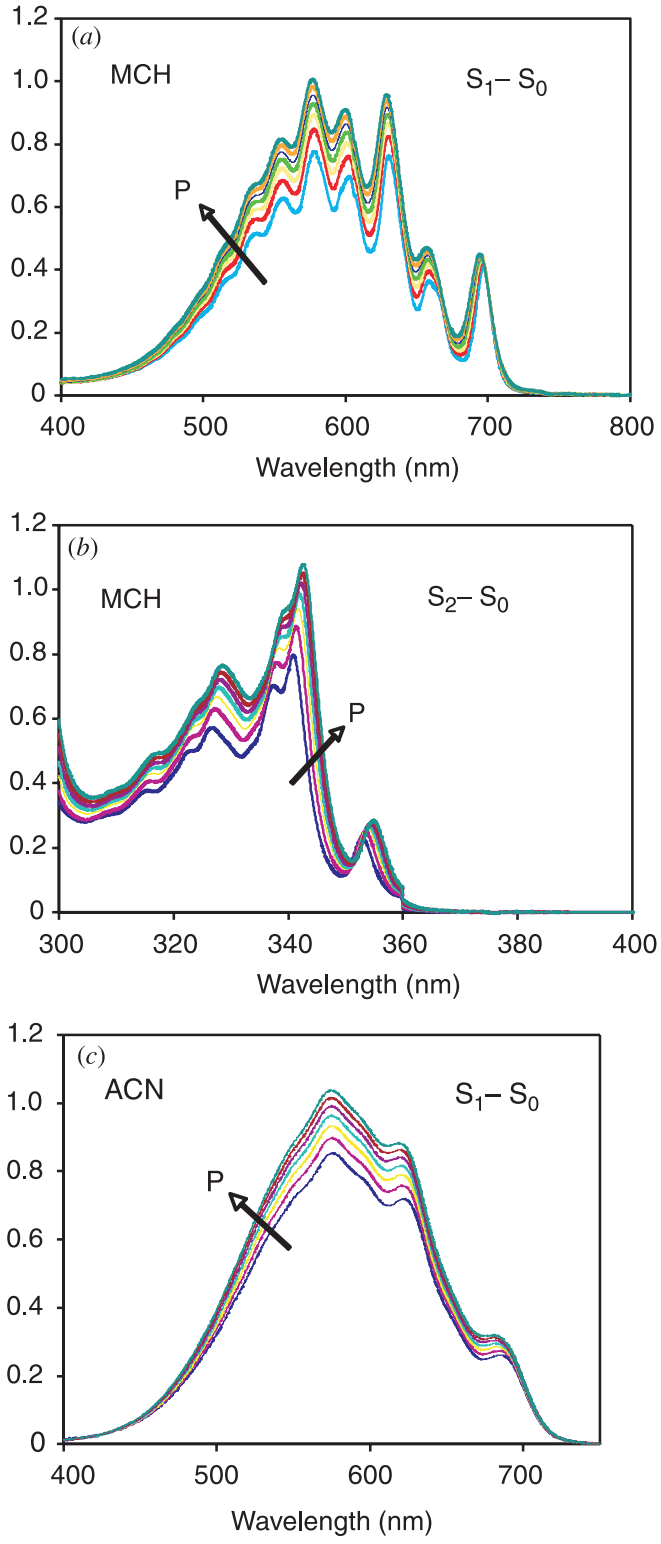

Fig. 2. (*a*) Visible (S_1–S_0) and (*b*) UV (S_2–S_0) spectra of azulene in methylcyclohexane, and (*c*) S_1–S_0 spectra of azulene in acetonitrile as a function of pressure. Apparent absorbance increases with increasing pressure in the 0.1 to 600 MPa range for methycyclohexane and in the 0.1 to 300 MPa range for acetonitrile. The discontinuity in the S_2–S_0 spectra near 360 nm is due to a change of excitation source in the spectrophotometer. The S_2–S_0 spectra in acetonitrile also exhibit no fully resolved vibrational features at any pressure.

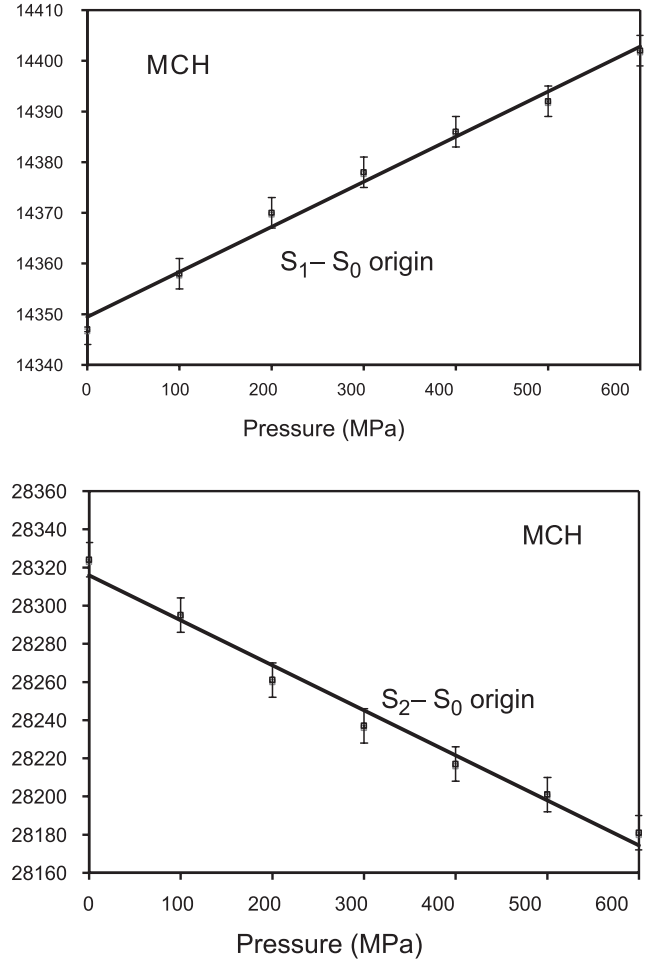

401 cm^{-1} ($\bar{\nu}_{16}$ = 680 cm^{-1}) (14), so if the relative intensity of the $\Delta v_{17} = 0$ sequence band is determined primarily by the thermal population of $v''_{17} = 1$, the intensity of this strongest sequence band should be only about 15% of that of the origin band itself. Note particularly that in methylcyclohexane, the observed ratio of $d\bar{\nu}_{n,0}/dP$ for the origin band of the S_2–S_0 system to that of the origin of the S_1–S_0 system is $R_{obs} = (d\bar{\nu}_{2,0}/dP)/(d\bar{\nu}_{1,0}/dP) = -2.9 \pm 0.3$, and that this ratio is almost independent of pressure in this pressure range. If a second-order polynomial in P is used to fit the data in Fig. 3, the ratio of the first-order pressure coefficients yields a value of R_{obs} within 10% of this value.

We now seek an explanation for these effects. The "anomalous" blue barochromic shift of the S_1–S_0 system of azulene (as distinct from the "normal" red shift seen in the S_2–S_0 spectrum) was originally ascribed to differences in the magnitudes of the dipole moments in its excited states compared with the ground state (6, 7, 10, 11). However, Baumann's accurate measurements (15), recently confirmed by high-level ab initio calculations (16–18), show that in nonpolar cyclohexane solution the dipole moments of azulene in its S_1 and S_2 states are both smaller in magnitude (and are both opposite in direction) compared with that in its ground state. Baumann's data (15) are reproduced in Table 2. In nonpolar solvents at modest applied pressures, such as those used here, the relative barochromic shift of the S_2–S_0 and S_1–S_0 origin bands originating solely in changes in the molecule's static electric dipole moments may be estimated from the ratio of the differences in the squares of the dipole moments in each pair of radiatively coupled states (19, 20), i.e., $R_{dipole} = (\mu^2_{S_2} - \mu^2_{S_0})/(\mu^2_{S_1} - \mu^2_{S_0}) = +1.3$. Thus, both the magnitude and sign of R_{obs} are inconsistent with a dominant solute electric dipole – solvent induced dipole origin of the barochromism in nonpolar solvents.

Baumann also provides experimental data for the ground and excited state polarizabilities of azulene in cyclohexane (15). These data (Table 2) suggest that the observed barochromism is due primarily to differences in azulene's polarizabilities in its S_0, S_1, and S_2 states. If the relative barochromic shift of the S_2–S_0 and S_1–S_0 origin bands at these modest applied pressures were due solely to changes in the molecule's polarizability, then to a good approximation $R_{obs} \approx R_{pol} = (\alpha_{S_2} - \alpha_{S_0})/(\alpha_{S_1} - \alpha_{S_0})$, i.e., the ratio of the differences in the frequency-weighted polarizabilites of each pair of radiatively coupled states (20). While Baumann (15) provides experimental data on all three of the polarizability tensor components for both S_0 and S_1, he is only able to obtain an accurate value of the z (long axis, largest) component, a_z, of that tensor for S_2. Nevertheless, it is clear that for each measured tensor component in the three states, $\alpha_i(S_2) > \alpha_i(S_0) > \alpha_i(S_1)$, ($i = x, y, z$), so the sign of R_{obs} may be accounted for by the fact that the polarizability of S_1 is smaller than that of S_0, whereas the polarizability of S_2 is greater than that of S_0. In fact, using the z (largest) component of the polarizability tensor in each state as representative of the full molecular polarizability results in $R_{pol,z} = (\alpha_{S_2,z} - \alpha_{S_0,z})/(\alpha_{S_1,z} - \alpha_{S_0,z}) = -2.6$. The reasonable

Fig. 3. $\bar{\nu}_{u,l}$ (solution) vs. pressure for the origin bands of azulene in methylcyclohexane. Errors are ±1.5, data channels (±3 cm^{-1} at 700 nm and 0.1 nm per channel; ±8 cm^{-1} at 350 nm and 0.05 nm per channel), representing the average error in selecting the channel of maximum intensity.

agreement between the magnitude of $R_{pol,z}$ and R_{obs} must be considered fortuitous given the errors in the tensor components quoted by Baumann, the errors in the measured barochromic slopes, and the approximations made in the above analysis. Nevertheless, both sign and magnitude agree and it is therefore tempting to ascribe the observed barochromism of azulene mainly to differences in its ground and excited state polarizabilities and not to differences in its dipole moments. This may be surprising, since the solvatochromism of azulene *at constant pressure* is "normal" (i.e., a blue shift in more polar solvents) in all of its visible and near UV absorption systems. We explore the source of this apparent discrepancy in the following section.

A comprehensive, quantitative analysis of the solvatochromism and barochromism of all three UV–vis absorption systems of azulene starts with the theory of solvatochromism of Bayliss and McRae (19, 20). Using second-order perturbation theory and the point dipole approximation, McRae (19) has derived a general four-term expression for the electronic transition energies of a solute embedded in a solvent continuum that is characterized by its refractive index, n, and its dielectric constant, D. Each of the four terms represents a

[a]Assignments of the S_1–S_0 bands are from ref. 8. Only the wavenumbers are given for the S_2–S_0 bands, which are vibronically tangled (9).

Table 2. Dipole moments and polarizabilities of azulene in its S_0, S_1, and S_2 states (from ref. 15).

		Polarizability (× 10^{-40} $CV^{-1}m^2$)[a]			
State	μ(× 10^{-30} Cm)[b]	α_x	α_y	α_z	α^c_{av}
S_0	3.31	6.4	19	26.4	17.3
S_1	–1.88	–1.9[d]	16.2	23.9	12.7
S_2	–1.16	—	—	33.0	—

Note: Conversion factors are: 1 D = 3.336 × 10^{-30} Cm; 1 $Å^3$ = 1.113 × 10^{-40} $CV^{-1}m^2$.

[a]Based on an ellipsoidal model.

[b]Colinear with the z axis. Positive values of μ are for the dipole pointing from the five-member ring (δ–) to the seven-member ring (δ+) (cf. Fig. 1).

[c]$\alpha_{av} = 1/3\mathrm{Tr}\{\alpha_i\}$

[d]With large error.

contribution to the solvatochromism resulting from dispersive and static dipole interactions. Simplifying to isolate the dipole moment and polarizability of the solute and retain the solvent continuum parameters, we obtain eq. [1] for the solvent shift of the electronic transition energy,

$$[1]\qquad \Delta\bar{\nu}_{u,l} = \bar{\nu}_{u,l}(\text{solution}) - \bar{\nu}_{u,l}(\text{gas})$$
$$= -Q(\alpha_u - \alpha_l)f_1 - R(\mu_u^2 - \mu_l^2)f_1 - S\mu_l(\mu_u - \mu_l)f_2 - T\mu_l^2(\alpha_u - \alpha_l)f_2^2$$

where $f_1 = (n^2 - 1)/(2n^2 + 1)$, $f_2 = (D - 1)/(D + 2) - (n^2 - 1)/(n^2 + 2)$, l and u designate lower and upper states respectively, and Q, R, S, and T are all positive constants. The derivation of the first term in eq. [1] from the expressions given by McRae (19) is not obvious and is therefore included in the Supplementary material for this paper.[2]

Thus, assuming that the polarizabilities and dipole moments of the solute are independent of pressure (a good assumption in the low hydrostatic pressure regime employed here),

© 2007 NRC Canada

$$[2]\quad d\Delta\bar{\nu}_{u,l}/dP = d\bar{\nu}_{u,l}(\text{solution})/dP$$
$$= -Q(\alpha_u - \alpha_l)df_1/dP - R(\mu_u^2 - \mu_l^2)df_1/dP$$
$$- S\mu_l(\mu_u - \mu_l)df_2/dP - 2f_2T\mu_l^2(\alpha_u - \alpha_l)df_2/dP$$

at constant temperature, where $df_1/dP = 6n/(2n^2 + 1)^2\, dn/dP \geq 0$ and $df_2/dP = [3/(D+2)^2]_n^2\,(\partial D/\partial P)_n^2 - [3/(n^2+2)^2]_D\,(\partial n^2/\partial P)_D$, a term that may be either positive or negative.

For nonpolar solvents, $f_2 \approx 0$, and only the first two terms in eqs. [1] and [2] are of importance. For sufficiently polar solvents, $D >> n$ and $df_2/dP \approx -6n/(n^2 + 2)^2(\partial n/\partial P)_D < 0$. Thus, the results for azulene's barochromism in nonpolar methylcyclohexane are consistent with the dominance of dispersion, the first term in eqs. [1] and [2], with a smaller contribution from dipole-induced dipole interactions, the second term. At constant pressure, the blue shift resulting from replacing a nonpolar solvent by a polar one is consistent with the dominant influence of term three in eq. [1], which contributes to an increase in both the S_1–S_0 and S_2–S_0 transition energies in azulene since both excited state dipole moments are opposite in sign (and smaller in magnitude) compared with the ground state. Term two in eq. [1] is expected to make a slightly smaller blue shift contribution to the solvatochromism in acetonitrile than in methylcyclohexane due to its smaller refractive index, and the term four makes no significant contribution. Finally, the fact that the S_1–S_0 transition of azulene retains its unusual barochromic behaviour in acetonitrile reflects the fact that dispersive interactions dominate the pressure-induced frequency shifts even in this polar solvent. Note that (*i*) df_1/dP is always positive in solution, (*ii*) df_2/dP is negative when $D >> n$, (*iii*) both df_1/dP and df_2/dP are functions of only n when $D >> n$, and (*iv*) df_2/dP is ca. 1.5 times larger in magnitude than df_1/dP for acetonitrile. Thus term three in eq. [2] represents a red barochromic shift that partially offsets the dominant (term one) dispersion-induced blue shift for the S_1–S_0 transition and that augments the dispersion-induced red barochromic shift of the S_2–S_0 transition. Unfortunately, the intrinsic broadening of the spectra in acetonitile precludes analysis that would further quantify these interactions.

Using the above analysis, one should be able to predict the polarizability of the S_3 state from its measured barochromism and the polarizabilities of the lower electronic states. Using the measured values of $d\bar{\nu}_{n,0}/dP$ (Table 1) and the experimentally measured polarizabilities of the ground, S_1 and S_2 states (Table 2 of ref. 15), one calculates $\alpha_z(S_3) = 28 \times 10^{-40}$ $CV^{-1}m^2$ ignoring dipolar contributions, a value that is only slightly larger than that of the ground state.

These results can be compared with the solvatochromic measurements of Renge (21) who recognized that changes in azulene's polarizability are primarily responsible for its solvatochromism in n-alkanes. Renge determined that $\Delta\alpha_{av} = 1/3\text{Tr}\{\Delta\alpha\} = (0\pm2) \times 10^{-40}$ $CV^{-1}m^2$, $(4.5\pm2) \times 10^{-40}$ $CV^{-1}m^2$, and $(3.8\pm2) \times 10^{-40}$ $CV^{-1}m^2$ for the S_1–S_0, S_2–S_0, and S_3–S_0 transitions, respectively, but based this on a rather limited $\bar{\nu}_{1,0}$ vs. $f(n^2)$ correlation for azulene's S_1–S_0 solvatochromism and used uncorrected (gas phase) values of the ground (and by extension excited) state dipole moments in his analysis (21). Renge's data are nevertheless consistent with the foregoing analysis when error limits and corrections are taken into account.

The hypsochromic barochromism of the S_1–S_0 absorption system of azulene is unusual and therefore of importance in testing theories of the effects of intermolecular interactions on molecular spectra. The preceding analysis supports recent models of the solvatochromism, barochromism, and thermochromism of polyatomic chromophores embedded in condensed media in which dispersive interactions are prominent (22–24). Unfortunately, the present state of both multireference CI and TDDFT calculations seems to preclude a definitive ab initio computation of the polarizabilities of a molecule the size of azulene, particularly in states such as S_1 and S_2, which are strongly coupled with still higher singlet states (9). It would, however, be interesting to ask if the Lennard–Jones potential model recently proposed by Renge (25) can reproduce the unusual barochromism of azulene at very high pressures (in excess of 6 000 MPa), where repulsive interactions at hard sphere intermolecular separations are expected to dominate.

Conclusions

The barochromism of azulene in fluid solution at room temperature has been re-examined. The unusual hypsochromic shift of the S_1–S_0 band system with increasing pressure, compared with the normal bathochromic shifts of the S_2–S_0 and S_3–S_0 band systems, is properly ascribed mainly to a decrease in the polarizability of the molecule in its S_1 state. This work illustrates the value of barochromism in obtaining experimental values of excited state polarizabilities and in testing theories of solvatochromic, barochromic, and thermochromic effects.

Zinc oxide as a new, highly efficient, green, and reusable catalyst for microwave-assisted Michael addition of sulfonamides to α,β-unsaturated esters in ionic liquids

Abdolkarim Zare, Alireza Hasaninejad, Ahmad Reza Moosavi Zare, Abolfath Parhami, Hashem Sharghi, and Ali Khalafi-Nezhad

Abstract: A simple, clean, and efficient procedure for the green synthesis of some *N*-alkyl derivatives of sulfonamides is described. Microwave-assisted Michael addition of sulfonamides to α,β-unsaturated esters, in the presence of catalytic amount of zinc oxide (ZnO) in 1-butyl-3-methylimidazolium bromide ([bmim]Br), affords the title compounds in high yields and short reaction times.

Key words: zinc oxide, green chemistry, microwave, Michael addition, sulfonamide, ionic liquid.

Résumé : On décrit une méthode simple, propre et efficace pour la synthèse verte de quelques dérivés *N*-alkyles des sulfonamides. L'addition de Michael assistée par micro-ondes de sulfonamides sur des esters α,β-insaturés, en présence d'une quantité catalytique d'oxyde de zinc (ZnO) dans le bromure de 1-butyl-3-méthylimidazolium ([bmim]Br) conduit à la formation des produits mentionnés dans le titre, avec des rendements élevés et de courts temps de réaction.

Mots-clés : oxyde de zinc, chimie verte, micro-onde, addition de Michael, sulfonamide, liquide ionique.

[Traduit par la Rédaction]

Introduction

Currently, ionic liquids are the subject of considerable interest as benign reaction media in organic synthesis because of their unique properties, such as non-volatility, non-flammability, recyclability, and ability to dissolve a wide range of materials (1). During the past decade, a variety of ionic liquids have been demonstrated as efficient and practical alternatives to organic solvents for many important organic transformations (1). Catalytic activity has been also reported for these green solvents (2). Together with the substitution of common molecular solvents, non-conventional activation methods, mainly microwave irradiation (MWI), have emerged as powerful techniques to reduce reaction times and to enhance reaction rates (3). As part of our drive to avoid the use of volatile organic solvents in reactions (4), we have initiated a program to explore the use of ionic liquids as efficient reaction media for useful organic transformations at room temperature.

N-Alkyl derivatives of sulfonamides are important because they have various biological activities, including their antidepressant, psychostimulant, analgesic, anti-ulcer, antiemetic, and anti-inflammatory properties (5). These compounds can be prepared via aza-conjugate addition of sulfonamides to α,β-unsaturated compounds (6). Michael reaction of sulfonamides with α,β-unsaturated esters also affords protected β-amino acids. This class of compounds (β-amino acids) are essential components in many bioactive compounds and drugs scaffolds, such as β-peptides (7), imeriamine (hypoglycemic and antiketogenic agent, Fig. 1) (8), vitamin B_3 (Fig. 1) (9), cryptophycin (antitumor) (10), and TAN-1057 A (antibiotic) (11). Indeed, to the best of our knowledge, there are only a few reports of Michael addition of sulfonamides. Reitz et. al have used alumina to carry out this reaction (6). However, in their report, the reaction times are long, and the yields are moderate. Moreover, they applied more reactive α,β-unsaturated ketones.

In aza-conjugate reactions, the nucleophilic nitrogen is usually among the powerful nucleophiles, such as amines (12), which, if used in the reaction, can lead to side products, e.g., amides via nucleophilic attack of amine to carbonyl group of α,β-unsaturated esters (12*a*). Furthermore, 1,2- and 1,4-condensation of a β-amino residue to α,β-unsaturated esters caused polymerization or tar formation (12*a*). Moreover, some procedures often require a large excess of reagents (12*b*). Therefore, in this context, using sulfonamides instead of amines in Michael reaction with

α,β-unsaturated esters seems to be more favorable, since lower nucleophilicity of nitrogen leads to less side reactions.

Recently, mineral oxides have proved to be useful to chemists both in the laboratory and in the industry because of the good activation of adsorbed compounds, reaction rate enhancement, selectivity, easier workup, recyclability of the supports, and the eco-friendly reaction conditions (13, 14). Zinc oxide (ZnO) is certainly one of the most interesting of these oxides because it has surface properties that can accomodate rich organic reactions (14). Zinc oxide is an inexpensive, moisture stable, reusable, commercially available, and environmentally benign catalyst. This catalyst has been used in several transformations, such as Beckmann rearrangement (14*a*), Friedel–Crafts acylation (14*b*), benzylic oxidation (14*c*), conversion of oximes to nitriles (14*d*), synthesis of cyclic ureas (14*e*), and acylation of alcohols and amines (14*f*, 14*g*).

Herein, we report a clean, facile, and rapid method for Michael addition of sulfonamides to α,β-unsaturated esters in the presence of catalytic amount of zinc oxide in [bmim]Br under MWI (Scheme 1). In this method, *N*,*N*-dialkyl sulfonamides formed together with the N-alkylated products in very low yields.

Results and discussion

To optimize reaction conditions, Michael addition of benzenesulfonamide to *n*-butyl acrylate was studied as a model reaction to provide compounds **1b** and **2b** (Scheme 1). First, the efficiency of several ionic liquids, including [bmim]Br, [bmim]Cl, [bmim]BF_4, and [bmim]PF_6, was investigated in the presence of ZnO (20 mol%) under MWI (300 W, max. 110 °C). Interestingly, all examined ionic liquids afforded almost similar yields and reaction times. However, [bmim]Br was applied as solvent for all reactions because the preparation of this ionic liquid was easy, compared with other ionic liquids.

In another study, the influence of various inorganic and organic basic catalysts on the model reaction was studied. The results are summarized in Table 1. Clearly, higher selectivity in shorter reaction time was attained when ZnO was used. Therefore, ZnO was the catalyst of choice in all reactions. Moreover, the effect of using different amounts of ZnO was investigated (Table 1). The optimum amount of ZnO was found to be 20 mol%.

Table 1. The effect of different basic catalysts on Michael addition of benzenesulfonamide (2 mmol) with *n*-butyl acrylate (2.2 mmol) in [bmim]Br (2 g) under MW conditions (300 W, max. 110 °C).

		Yield[a] (%)

[a]Isolated yield.

To select the appropriate MW power, conjugate addition of benzenesulfonamide to *n*-butyl acrylate was examined at different MW powers (100–600 W), with controlled temperature (max. 110 °C), in the presence of ZnO, and in [bmim]Br. The best results were observed at 300 W.

To compare the efficiency of the ionic liquid with that of the conventional solvents, the model reaction was examined in various conventional solvents. Thus, a mixture of benzenesulfonamide (2 mmol), ZnO (0.4 mmol), and *n*-butyl acrylate (2.2 mmol) was irradiated in a MW oven (300 W, max. 110 °C) in different solvents (5 mL) (Table 2). Clearly, conventional solvents exhibited lower selectivities and longer reaction times compared with [bmim]Br. Therefore, the ionic-liquid-accelerated method is more efficient.

The capability and efficiency of MW heating, compared with conventional heating, on Michael reaction was also investigated. For this purpose, compounds **1b** and **2b** as well as **1g** and **2g** were prepared via Michael reaction between benzenesulfonamide and α,β-unsaturated esters in the presence of ZnO in [bmim]Br under thermal conditions (110 °C) (Table 3). As Table 3 demonstrates, MW conditions gave better results compared with thermal conditions. This can be attributed to the efficient performance of the reactions with more polar transition state relative to the ground state under MWI (3*a*–3*c*).

[a]Isolated yield.

After optimizing the reaction conditions, Michael addition of sulfonamides was examined with structurally diverse α,β-unsaturated esters. The results are depicted in Table 4. The reactions proceeded efficiently, and the desired Michael adducts were obtained in high yields.

To study the structural influence of the alkoxy groups (–OR) of α,β-unsaturated esters (Michael acceptors) on the reaction, we have investigated the reaction of benzenesulfonamide with esters containing sterically hindered alkoxy groups. The results showed that the bulkiness of the alkoxy group had no significant effect on the yields, the selectivities, and the reaction times (Table 4, entries 1–6). The structural effect of α,β-unsaturated esters on Michael-addition reaction was also studied. Lower yields of the products and longer reaction times were observed when benzenesulfonamide was added to sterically hindered α,β-unsaturated esters (ethyl methacrylate and ethyl crotonate) (Table 4, entries 7 and 8). However, in these cases, the selectivity increased. Interestingly, the reaction of benzenesulfonamide as well as naphthalene-2-sulfonamide with ethyl crotonate afforded only the monoalkylated product (Table 4, entries 8 and 10). When 4-methylbenzenesulfonamide was used instead of benzenesulfonamide, the yields decreased (Table 4, entries 2 and 9).

The interesting behavior of [bmim]Br–ZnO system lies in the fact that it can be re-used after simple washing with Et_2O, thus rendering the process more economic. The yields of compounds **1b** and **2b** (model compounds) in the second, third, fourth, and fifth uses of the [bmim]Br/ZnO were almost as high as in the first use.

In conclusion, we have introduced a highly efficient catalyst for ionic-liquid-accelerated Michael addition of sulfonamides with α,β-unsaturated esters under MWI. The promising points for the presented methodology are high conversion, ease of handling and low cost of the catalyst, cleaner reaction profile, and short reaction times, which makes it a useful and attractive process for the rapid synthesis of *N*-alkyl sulfonamides as biologically interesting compounds.

Experimental

All chemicals were purchased from Merck or Fluka chemical companies. The progress of the reactions was followed with TLC using silica gel SILG/UV 254 plates. Silica gel 60, 0.063–0.200 mm (70–230 mesh ASTM) was used for column chromatography. All reactions were carried out using CEM MARS 5^{TM} MW oven. IR spectra were run on a Shimadzu FTIR-8300 spectrophotometer; ν_{max} values are reported in cm^{-1}. The ^1H NMR (250 MHz) and ^{13}C NMR (62.5 MHz) were run on a Bruker AVANCE DPX-250 FTNMR spectrometer. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus. Microanalyses were performed on a PerkinElmer 240-B microanalyzer. Melting points were recorded on a Büchi B-545 apparatus in open capillary tubes and are uncorrected.

General procedure for the preparation of compounds 1b and 2b

To a mixture of benzenesulfonamide (0.31 g, 2 mmol), well-ground ZnO (0.033 g, 0.4 mmol), and *n*-butyl acrylate (0.28 g, 2.2 mmol) in a MW vessel was added [bmim]Br (2 g) and mixed carefully. The resulting mixture was irradiated in a MW oven at 300 W for 5 min. The oven was programmed to give a maximum internal temperature of 110 °C. Afterward, the reaction mixture was cooled to room temperature and was extracted with Et_2O (3 × 25 mL). The organic extracts were then combined. After the removal of the solvent, the crude product was purified by column chromatography on silica gel with EtOAc–*n*-hexane (1:3) to give **1b** and **2b** as colorless oils. After isolating the products and evaporating the remainder Et_2O in ionic liquid, the ionic liquid containing the catalyst ZnO ([bmim]Br–ZnO) was used for the next run under identical reaction conditions.

C_9H_9O], 392 [$M^+ - C_6H_5SO_2$]. Anal. calcd. for $C_{30}H_{31}NO_6S$: C 67.52, H 5.86, N 2.62; found: C 67.40, H 5.71, N 2.78.

Ethyl 2-methyl-3-(phenylsulfonamido)propanoate (1g)

Pale yellow oil; isolated yield: 0.421 g (78%). IR (neat, cm^{-1}): 3283, 3034, 2966, 1732, 1447, 1328. ^1H NMR ($CDCl_3$, ppm) δ: 1.17–1.26 (complex, 6H, $2CH_3$), 2.73 (m, 1H, O=CC*H*), 3.14–3.20 (complex, 2H, O=CCH(CH_3)CH_2), 4.12 (q, 2H, *J* = 7.0 Hz, OCH_2), 5.65 (s, 1H, N*H*), 7.55–7.64 (complex, 3H, H_3–H_5 of the aromatic ring), 7.93 (m, 2H, H_2 and H_6 of the aromatic ring). ^{13}C NMR ($CDCl_3$) δ: 14.0, 14.7, 39.6, 45.4, 60.8, 126.8, 129.1, 132.5, 139.9, 174.7. MS *m*/*z*: 271 [M^+]. Anal. calcd. for $C_{12}H_{17}NO_4S$: C 53.12, H 6.32, N 5.16; found: C 53.31, H 6.57, N 5.01.

Compound 2g

Pale yellow oil; isolated yield: 0.048 g (6%). IR (neat, cm^{-1}): 3042, 2982, 1732, 1447, 1316. ^1H NMR ($CDCl_3$, ppm) δ: 1.09–1.19 (complex, 12H, $4CH_3$), 2.78 (m, 2H, 2O=CC*H*), 3.22–3.27 (complex, 4H, 2O=CCH(CH_3)CH_2), 4.03 (q, 4H, *J* = 7.0 Hz, 2OCH_2), 7.44–7.53 (complex, 3H, H_3–H_5 of the aromatic ring), 7.75 (m, 2H, H_2 and H_6 of the aromatic ring). ^{13}C NMR ($CDCl_3$) δ: 14.1, 15.3, 39.2, 52.4, 60.7, 127.3, 129.1, 132.7, 139.0, 174.7. MS *m*/*z*: 385 [M^+]. Anal. calcd. for $C_{18}H_{27}NO_6S$: C 56.08, H 7.06, N 3.63; found: C 55.80, H 7.23, N 3.77.

Ethyl 3-(phenylsulfonamido)butanoate (1h)

Pale yellow solid; isolated yield: 0.394 g (73%); mp 60–62 °C. IR (KBr, cm^{-1}): 3285, 3044, 2953, 1732, 1447, 1329. ^1H NMR ($CDCl_3$, ppm) δ: 1.14–1.23 (complex, 6H, $2CH_3$), 2.38–2.43 (complex, 2H, O=CCH_2), 3.68 (m, 1H, O=CCH_2C*H*), 4.04 (q, 2H, *J* = 7.1 Hz, OCH_2), 5.39 (s, 1H, N*H*), 7.49–7.59 (complex, 3H, H_3–H_5 of the aromatic ring), 7.89 (m, 2H, H_2 and H_6 of the aromatic ring). ^{13}C NMR ($CDCl_3$) δ: 14.0, 21.0, 40.7, 46.6, 60.7, 126.9, 129.0, 132.5, 140.9, 171.1. MS *m*/*z*: 271 [M^+]. Anal. calcd. for $C_{12}H_{17}NO_4S$: C 53.12, H 6.32, N 5.16; found: C 53.30, H 6.19, N 5.31.

Butyl 3-(4-methylphenylsulfonamido)propanoate (1i)

Pale yellow oil; isolated yield: 0.460 g (77%). IR (neat, cm^{-1}): 3286, 3044, 2960, 1732, 1330. ^1H NMR ($CDCl_3$, ppm) δ: 0.89 (t, 3H, *J* = 6.8 Hz, $CH_2(CH_2)_2CH_3$), 1.33 (m, 2H, CH_3CH_2), 1.56 (m, 2H, $CH_3CH_2CH_2$), 2.40 (s, 3H, ArCH_3), 2.51 (t, 2H, *J* = 5.3 Hz, O=CCH_2), 3.16 (t, 2H, *J* = 5.3 Hz, O=CCH_2CH_2), 4.04 (t, 2H, *J* = 7.0 Hz, OCH_2), 5.76 (s, 1H, N*H*), 7.33 (d, 2H, *J* = 7.9 Hz, H_3 and H_5 of the aromatic ring), 7.72 (d, 2H, *J* = 7.9 Hz, H_2 and H_6 of the aromatic ring). ^{13}C NMR ($CDCl_3$) δ: 13.5, 18.9, 21.3, 30.3, 34.1, 38.7, 64.5, 126.9, 129.6, 135.8, 143.2, 172.7. Radical-mediated cyclization reactions leading to spiro and [6,6]-fused heterocycles

K.C. Majumdar, P. Debnath, A.K. Pal, S.K. Chattopadhyay, and A. Biswas

Abstract: Regiochemical study of $^{n}Bu_3SnH$–AIBN-mediated aryl-radical cyclization of different 3-(2-bromophenylsulfenylmethyl)coumarins, 3-(2-bromophenylsulfonyl-methyl)coumarins, and 6-[(2-bromophenoxy)methyl]-4-methoxypyran-2-ones have been investigated with the formation of different [6,6]-fused and spirocylic heterocycles. The sulfides and ethers were prepared from 3-chloromethyl coumarin and 6-(bromomethyl)-4-methoxy pyran-2-one with different 2-bromothiophenol and 2-bromophenols under classical alkylation condition. The corresponding sulfones were prepared by oxidation of the sulfides with *m*-CPBA.

Key words: aryl-radical cyclization, coumarin and pyrone derivatives, 5-exo-trig, 5-endo-trig, $^{n}Bu_3SnH$, sulfur heterocycles.

Résumé : On a effectué des réactions de cyclisation radicalaires aryliques, catalysées par le Bu_3SnH–AIBN, de diverses 3-(2-bromophénylsulfénylméthyl)coumarines, de 3-(2-bromophénylsulfonylméthyl)coumarines et de 6-[(2-bromophénoxy)méthyl]–4-méthoxypyran-2-ones et on a étudié leur régiochimie par rapport à la formation d'hétérocycles divers spirocycliques ou à fusion [6,6]. On a préparé les sulfures et les éthers de la 3-chlorométhylcoumarine et de la 6-(6-bromométhyl)-4-méthoxypyran-2-one à l'aide de divers 2-bromothiophénols et de 2-bromophénols, dans des conditions d'alkylation classique. Les sulfones correspondantes ont été préparées par oxydation des sulfures à l'aide d'acide *m*-chloroperbenzoïque.

Mots-clés : cyclisation radicalaire arylique, dérivés de la coumarine et des pyrones, 5-exo-trig, 6-endo-trig, Bu_3SnH, hétérocycles sulfurés.

[Traduit par la Rédaction]

Introduction

Recently, free-radical cyclizations have been regarded as a versatile route for the construction of carbocycles as well as heterocycles (1). In particular, the synthesis of sulfur heterocycles by radical pathway presents a major challenge in organic synthesis. A survey of the literature revealed a few reports on the preparation of sulfur heterocycles by free-radical pathways, which include the cyclizations where the sulfur functionality either constitute the part of the hexenyl chain (2) or is placed outside (3) the 5-hexenyl system. Intramolecular homolytic substitution by an alkyl or aryl radical at the sulfur atom in the alkyl sulfides and sulfoxides have also been widely acceptable for the construction of sulfur heterocycles (4). To the best of our knowledge, no reports on the construction of benzothiophene and benzothiopyran heterocycles by free-radical methodology, employing 2-bromothiophenol as aryl-radical precursor, are available in literature.

We previously reported the synthesis of several novel five- and six-membered sulfur heterocycles by the application of sigmatropic rearrangement (5). Recently, we were successful in synthesizing quinolone-annulated (6) [6,6]-fused sulfur heterocycles by $^{n}Bu_3SnH$-mediated radical cyclization where small amount of β-scission (6, 7) product was formed along with 5-endo cyclization. It has been recognized that a stereoelectronically favored 5-exo cyclization is generally preferred over a 5-endo ring closure in those system, having an alkenic bond at the 5 position relative to the radical center. This regiochemical preference can be altered by the attachment of a suitable stabilizing group to the acceptor double bond (8). An extensive investigation by Della and Graney (2*f*) on the 5-hexenyl radical, where the sulfur functionality is in the α position to the radical center, revealed a dramatic effect on the regiochemistry of radical cyclization. Therefore, we studied the radical cyclization of 3-(2-bromo phenylsulfenylmethyl)coumarins, 3-(2-bromophenylsulfinyl methyl)coumarins, and 3-(2-bromophenylsulfonyl methyl)-coumarins. Here, we report the results of our investigation.

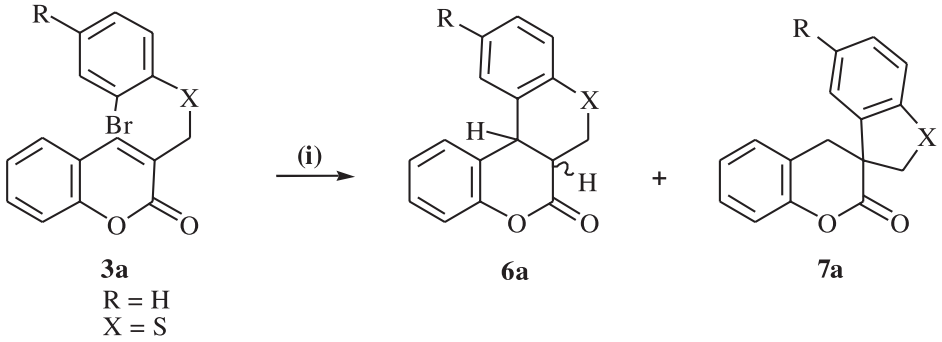
Results and discussion



The precursors 3-(2-bromophenylsulfenylmethyl)coumarins (**3a**–**3c**) were prepared in 82%–95% yield by treating 3-chloromethyl coumarin (**1**) with 2-bromothiophenol (**2**) in refluxing acetone (dry) in the presence of anhyd. potassium carbonate for 8 h (Scheme 1). The corresponding sulfones **4a**–**4c** and sulfoxide **5a** were synthesized in 85%–94% and 86% yields, respectively, from the sulfides **3a**–**3c** by the oxidation with *m*-CPBA (Scheme 1). Compounds **3a**–**3c** and

Scheme 1. Reagents and conditions: (*i*) anhyd. K_2CO_3, dry acetone, 8 h, and reflux; (*ii*) *m*-CPBA (1 equiv.), CH_2CL_2, 0 °C, and 1 h; (*iii*) *m*-CPBA (excess), CH_2Cl_2, and 0 °C to reflux.

Scheme 2. Reagents and conditions: (*i*) $^nBu_3SnH$, AIBN, toluene, N_2, 55–60 °C, and 1 h.

4a–**4c** were characterized by elemental analysis and spectroscopic data.

We initiated our study on the radical cyclization with the sulfide **3a**. Compound **3a**, when heated for 1 h at 55–60 °C with $^nBu_3SnH$ in dry degassed toluene in the presence of a catalytic amount of AIBN, afforded the two cyclized products **6a** and **7a** in 72% and 20% yield, respectively (Scheme 2).

Similarly, other sulfides **3b**–**3c** were treated to give the cyclic products **6b**–**6c** and **7b** in 85%–88% and 5% yields, respectively (Table 1). Sulfones **4a**–**4c**, when subjected to radical cyclization under similar conditions as the previously described, furnished the spirocyclic compounds **8a**–**8c** in 76%–85% yield, exclusively (Table 1), instead of the expected 5-endo cyclized product **9** (Scheme 3). The structure of the compounds **6a**–**6c**, **7a**–**7b**, and **8a**–**8c** were established from their elemental analysis and spectroscopic data. We observed that compounds **3** and **4**, when subjected to radical cyclization under refluxing conditions, underwent extensive decomposition without giving any cyclized products. To extend the scope of this reaction, we also attempted a similar radical reaction with 3-(2-bromophenylsulfinylmethyl)coumarins (**5a**), employing similar reaction condition. Unfortunately, we were unable to obtain any cyclized products, as the starting material decomposed under the reaction conditions.

The mechanistic rationalization for the formation of products **6a**–**6c** and **7a**–**7b** can be explained by assuming a 5-endo followed by a 5-exo cyclization of the aryl radical onto the double bond of a coumarin moiety, as depicted in Scheme 3. An alternative pathway, via 5-exo cyclization followed by neophyl rearrangement (9), has also been considered for the formation of products **6a**–**6c**. In the case of phenylsulfonylmethyl congener **4a**–**4c**, the generated aryl radicals undergo 5-exo cyclization exclusively to produce the spirocylic products **8a**–**8c**. However, 5-exo cyclization with subsequent neophyl rearrangement pathway is highly unlikely with the present system. The stability and nonnucleophilicity (10) of the intermediate benzylic radical, attributed to the excellent overlapping (11) of a p orbital of the radical center with the adjacent aromatic π system, might prevent further attack, and hence, the production of the intermediate cyclohexadienyl radical **11**.

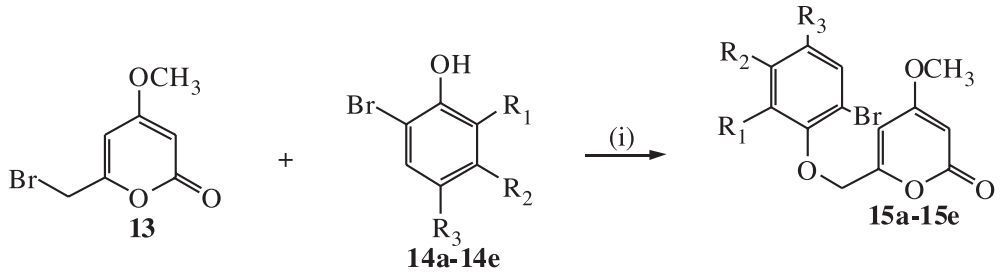
Scheme 3.

rived from benzo[1]pyran-2-ones afforded a mixture of [6,6]-fused and (or) spiro heterocycles, we wanted to examine the radical cyclization of the substrates containing pyran-2-one moiety. For this purpose, 6-[(2-bromophenoxy)methyl]-4-methoxypyran-2-ones (**15a**–**15e**) were synthesized in 77%–89% yields from 6-(bromomethyl)-4-methoxy pyran-2-one (**13**) and 2-bromophenols (**14a**–**14e**) (Scheme 4). Substrates **15a**–**15e** were characterized from their spectral data.



We then carried out the ^{n}Bu$_3$SnCl-mediated cyclization of compound **15a**. We applied the optimal reaction conditions used earlier (12), i.e., ^{n}Bu$_3$SnCl, Na(CN)BH$_3$, AIBN, in dry toluene, and under nitrogen atmosphere at 80 °C for 5 h. Surprisingly, intramolecular cyclization occurred to give only 11% of the cyclized product **16a**, and 76% of the starting material **15a** was recovered. However, changing the solvent, reagents, and raising the temperature of this reaction improved the yield. The best result was achieved by carrying out the reaction in toluene at 110 °C and using ^{n}Bu$_3$SnH instead of ^{n}Bu$_3$SnCl, which furnished **16a** in 79% yield. Similarly, compounds **15b**–**15e** afforded **16b**–**16e** in 68%–76% yields (Scheme 5).

The exclusive formation of five-membered spiro heterocycles **16a**–**16e** from **15a**–**15e** may easily be explained by the generation of the aryl radical **17** followed by a 5-exo-trig cyclization to give the allyl-radical intermediate **18**, which in turn abstracts the hydrogen from ^{n}Bu$_3$SnH to afford the spiro heterocycles **16a**–**16e**. The exclusive formation of five-membered heterocyclic compounds **16a**–**16e** from the substrates **15a**–**15e** may be attributed to the stability of the intermediate allylic radical **18.** There are precedents of Michael-type addition of a radical to the substrates containing Michael acceptors, giving Michael-type addition products; otherwise, α-*oxo* radical would be expected (13) (Scheme 6).

Although a stereoelectronically favored 5-exo-trig ring

closure is preferred for α-sulfenyl-5-hexenyl and α-sulfonyl-5-hexenylsystem, a significant amount of 5-endo-trig product is also formed, because of the longer C–S bond (8), to facilitate the easier approach of the radical center to accommodate the 5-endo transition state. This is quite evident for compounds **3a**–**3c** where products **6a**–**6c** were formed predominantly along with a small amount of the 5-membered products **7a**–**7b**. The stabilization of the intermediate tertiary radical **12** by the adjacent carbonyl group may also be responsible for the formation of the 5-endo product. However, this longer C–S bond for the facile 5-endo ring closure will no longer hold for the sulfones **4a**–**4c**. The presence of the two oxygen atoms attached to sulfur may be expected to favor the stereoelectronically favored 5-exo attack with the formation of highly stable spiro heterocyclic radical intermediate, which, by abstracting H-radicals, produces spirocyclic compounds **8a**–**8c** in excellent yield. However, in the case of compound **15**, the stabilization of the radical intermediate **18** by extended conjugation with the enone part might be responsible for the exclusive formation of the spiro product.

Interestingly, we found that the ratios of the spirocyclic to [6,6]-fused products from compounds **3a**–**3c** were different, depending on the group attached to the thiophenol. However, this ratio is increased by the presence of an activating group attached to the thiophenol moiety. With the *p*-ethyl-substituted phenylsulfenyl precursor, the [6,6]-fused product was produced exclusively. In contrast, this substituent effect on the mode of ring closure was completely absent for the precursors **4** and also from compound **15**. The explanation of the effect of the activating substituent, attached to the thiophenol moiety, is quite unknown. However, this study revealed that the choice of suitable precursors can be utilized for the selective formation of spirocyclic or [6,6]-fused sulfur heterocycles.

Conclusion

In summary, we have described $^{n}Bu_3SnH$-mediated mild and efficient synthesis of coumarin and pyrone-annulated heterocycles. All the reactions were clean with moderate to good yield. The use of 2-bromothiophenol provides an easy access to benzothiophene as well as benzothiopyran derivatives, which are of synthetic utility in organic synthesis.

Experimental

Melting points were determined in an open capillary and are uncorrected. IR spectra were recorded on a PerkinElmer L120–000A spectrometer (ν_{max} in cm^{-1}) using KBr discs. UV-absorption spectra were recorded in EtOH on a Shimadzu UV-2401PC spectrophotometer (λ_{max} in nm). ^1H NMR (300 MHz, 400 MHz, and 500 MHz) and ^{13}C NMR (75.5 MHz and 125 MHz) spectra were recorded on a Bruker DPX-300, Varian-400 MHz FTNMR, and Bruker DPX-500 spectrometer in $CDCl_3$ (chemical shifts in δ) with TMS as internal standard. Silica gel (60–120 mesh; Spectrochem, India) was used for chromatographic separation. Silica gel G (E-Merck, India) was used for TLC. Petroleum ether refers to the fraction boiling between 60 °C and 80 °C.

General procedure for the preparation of 3-(2-bromophenylsulfenylmethyl)coumarins

To a solution of 3-chloromethylcoumarin (**1**) (1 g, 5.15 mmol) in dry acetone (100 mL), 2-bromothiophenol (**2a**–**2c**) (5.15 mmol) and anhyd. potassium carbonate (2 g) were added, and the reaction mixture was refluxed for 8 h. The reaction mixture was then cooled, filtered, and the solvent was removed. The residual mass was extracted with CH_2Cl_2 (3 × 15 mL). The organic layer was washed with 5% Na_2CO_3 solution (2 × 10 mL), then with water (3 × 10 mL), and finally with brine (10 mL). After the removal of the solvent, the residue was subjected to column chromatography over silica gel. Elution of the column with 25% ethyl acetate in petroleum ether afforded 3-(2-bromophenylsulfenylmethyl)coumarins (**3a**–**3c**). All compounds were recrystalized from chloroform – petroleum ether (60–80 °C).

Compound 3a

Yield: 82%. Colourless crystalline solid; mp 100 °C. IR (KBr) ν_{max} (cm^{-1}): 1715, 1604, 743. ^1H NMR (400 MHz, $CDCl_3$) δ: 4.07 (s, 2H, $-SCH_2$), 7.02–7.07 (m, 1H, ArH), 7.18–7.25 (m, 3H, ArH), 7.31 (d, 1H, *J* = 8.28 Hz, ArH), 7.36 (d, 1H, *J* = 7.5 Hz, ArH), 7.47–7.51 (m, 1H, ArH), 7.54 (d, 1H, *J* = 7.87 Hz, ArH), 7.57 (s, 1H, =CH). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 33.2, 116.9, 119.4, 124.6, 124.9, 125.3, 128.1, 128.2, 128.4, 130.5, 131.8, 133.6, 136.6, 140.5, 153.6, 161.4. General procedure for the radical-cyclization reactions

A suspension of the compounds **3a**–**3c** and **4a**–**4c** (0.430 mmol), $^nBu_3SnH$ (0.174 mL, 0.648 mmol), and AIBN (20 mg) in dry degassed toluene (10 mL) was stirred at 55–60 °C for 1 h under N_2. The solvent was removed under reduced pressure. Water (10 mL) was added to the residue, and the mixture was extracted with CH_2Cl_2 (3 × 10 mL). The organic layer was washed with water (2 × 10 mL) and brine (10 mL) and dried (Na_2SO_4). Evaporation of the solvent furnished a crude material, which was then subjected to column chromatography over silica gel. The column was eluted with 8% and 25% ethyl acetate in petroleum ether to give the cyclized products **6a**–**6c**, **7a**, **7b**, and **8a–8c**. All compounds were recrystalized from chloroform – petrolium ether (60–80 °C).

Compounds 6c

Yield: 88%. Colourless crystalline solid; mp 192 °C. IR (KBr) ν_{max} (cm^{-1}): 1763, 1612, 1140.^1H NMR (400 MHz, $CDCl_3$) δ: 1.09 (t, 3H, *J* = 7.8 Hz, $–CH_2CH_3$), 2.49 (q, 2H, *J* = 7.5 Hz, $–CH_2CH_3$), 3.08 (dd, 1H, *J* = 6.0 and 12.6 Hz, $–SCHH_a$), 3.26–3.32 (m, 1H, $–C–H_c$), 3.49 (dd, 1H, *J* = 5.7 and 13.7 Hz, $–SCHH_b$), 4.34 (d, 1H, *J* = 5.12 Hz, $–C–H_d$), 6.69 (s, 1H, ArH), 7.03–7.20 (m, 5H, ArH), 7.32–7.38 (m, 1H, ArH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 15.90, 25.11, 28.75, 39.62, 40.36, 117.59, 125.0, 125.31, 128.09, 128.20, 129.39, 129.54, 129.67, 130.20, 131.69, 141.88, 150.99, 169.17. MS *m*/*z*: 296 [M^+]. Anal. calcd. for $C_{18}H_{16}O_2S$: C 72.97, H 5.41; found: C 73.11, H 5.36.

Compound 7a

Yield: 20%. Colourless crystalline solid; mp 126 °C. IR (KBr) ν_{max} (cm^{-1}): 1759, 1458, 1143. ^1H NMR (400 MHz, $CDCl_3$) δ: 3.13 (d, 1H, *J* = 11.52 Hz, –SCH), 3.21 (d, 1H, *J* = 16.12 Hz, ArCH), 3.26 (d, 1H, *J* = 16.08 Hz, ArCH), 3.88 (d, 1H, *J* = 11.48 Hz, –SCH), 6.97–7.03 (m, 2H, ArH), 7.09–7.15 (m, 3H, ArH), 7.17–7.22 (m, 2H, ArH), 7.30–7.34 (m, 1H, ArH). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 34.6, 40.7, 55.9, 116.5, 121.1, 122.8, 124.6, 124.8, 124.9, 128.8, 128.9, 129.1, 139.0, 140.5, 151.4, 169.3. MS *m*/*z*: 268 [M^+]. Anal. calcd. for $C_{16}H_{12}O_2S$: C 71.64, H 4.48; found: C 71.86, H 4.60.

Compound 7b

Yield: 5%. Colourless crystalline solid; mp 108 °C. IR (KBr) ν_{max} (cm^{-1}): 1766, 1457, 1167. ^1H NMR (400 MHz, $CDCl_3$) δ: 2.22 (s, 3H, $ArCH_3$), 3.12 (d, 1H, *J* = 11.4 Hz, –SCH), 3.20 (d, 1H, *J* = 16.32 Hz, ArCH), 3.24 (d, 1H, *J* = 16.4 Hz, ArCH), 3.79 (d, 1H, *J* = 11.40 Hz, –SCH), 6.84 (s, 1H, ArH), 6.98–7.0 (m, 1H, ArH), 7.07–7.16 (m, 4H, ArH), 7.29–7.33 (m, 1H, ArH). MS *m*/*z*: 282 [M^+]. Anal. calcd. for $C_{17}H_{14}O_2S$: C 72.34, H 4.96; found: C 72.18, H 5.10.

Compound 8a

Yield: 76%. Colourless crystalline solid; mp 120 °C. IR (KBr) ν_{max} (cm^{-1}): 1756, 1310, 1149. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.42 (d, 1H, *J* = 13.4 Hz, $–SO_2CH$), 3.43 (d, 1H, *J* = 16.17 Hz, ArCH), 3.49 (d, 1H, *J* = 16.2 Hz, ArCH), 4.00 (d, 1H, *J* = 13.4 Hz, $–SO_2CH$), 7.17–7.23 (m, 4H, ArH), 7.36–7.41 (m, 1H, ArH), 7.55–7.61 (m, 2H, ArH), 7.78–7.80 (m, 1H, ArH). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 37.6, 48.15, 58.0, 117.2, 122.3, 125.9, 126.5, 129.5, 129.9, 130.7, 131.0, 134.5, 137.7, 138.6, 151.5, 167.3. MS *m*/*z*: 300 [M^+]. Anal. calcd. for $C_{16}H_{12}O_4S$: C 64.00, H 4.00; found: C 64.21, H 4.08.

Compound 8b

Yield: 78%. Colourless crystalline solid; mp 92–93 °C. IR (KBr) ν_{max} (cm^{-1}): 1756, 1310, 1149. ^1H NMR (500 MHz,

© 2007 NRC Canada

$CDCl_3$) δ: 2.36 (s, 3H, $ArCH_3$), 3.38 (d, 1H, *J* = 13.08 Hz, –SO_2CH), 3.43 (d, 1H, *J* = 15.97 Hz, ArCH), 3.50 (d, 1H, *J* = 16.02 Hz, ArCH), 3.90 (d, 1H, *J* = 13.32 Hz, –SO_2CH), 6.83(s, 1H, ArH), 7.18–7.38 (m, 5H, ArH), 7.65–7.66 (m, 1H, ArH). MS *m/z*: 314 [M^+]. Anal. calcd. for $C_{17}H_{14}O_2S$: C 64.97, H 4.46; found: C 65.19, H 4.55.

Compound 8c

Yield: 85%. Colourless crystalline solid; mp 78 °C. IR (KBr) ν_{max} (cm^{-1}): 1766, 1302, 1121. ^1H NMR (500 MHz, $CDCl_3$) δ: 1.09 (t, 3H, *J* = 7.6 and 15.0 Hz, –CH_2CH_3), 2.60 (q, 2H, *J* = 7.5 and 14.8 Hz, –CH_2CH_3), 3.39 (d, 1H, *J* = 13.4 Hz, –SO_2CH), 3.40 (d, 1H, *J* = 16.17 Hz, ArCH), 3.46 (d, 1H, *J* = 16.2 Hz, ArCH), 3.99 (d, 1H, *J* = 13.38 Hz, –SO_2CH), 6.97 (s, 1H, ArH), 7.16–7.20 (m, 3H, ArH), 7.36–7.39 (m, 2H, ArH), 7.66–7.68 (m, 1H, ArH). MS *m/z*: 328 [M^+]. Anal. calcd. for $C_{18}H_{16}O_4S$: C 65.85, H 4.88; found: C 65.99, H 4.98.

General procedure for the preparation of 15a–15e

6-(Bromomethyl)-4-methyl-2*H*-pyran-2-one (**13**) (1.05 g, 4.82 mmol) and different *o*-bromophenols (**14a–14e**) (4.82 mmol) were refluxed in dry acetone (100 mL) in the presence of anhyd. potassium carbonate (3 g) for 3–4 h. The reaction mixture was then cooled, filtered, and the solvent was removed. Residual mass was extracted with CH_2Cl_2 (3 × 50 mL), and the extract was washed with water (3 × 30 mL) and then with brine (30 mL) and dried (Na_2SO_4). The residual mass after the removal of the solvent was subjected to column chromatography over silica gel (60–120 mesh). The column was eluted with petroleum ether – chloroform (1:9) to give compounds **15a**–**15e**. Attempts to recrystallize the products from different solvents, such as methanol, chloroform – petroleum ether (60–80 °C), benzene – petroleum ether (60–80 °C), acetonitrile–methanol, failed to give any crystalline compounds. All compounds were found to be amorphous in nature and hence white as paper.

Compound 15a

Yield: 82%. White amorphous solid; mp 117 °C. IR (KBr) ν_{max} (cm^{-1}): 2951, 1740, 1259, 1033. ^1H NMR ($CDCl_3$, 300 MHz) δ: 3.83 (s, 3H), 4.85 (d, *J* = 0.90 Hz, 2H), 5.47 (d, *J* = 2.25 Hz, 1H), 6.33–6.35 (m, 1H), 6.87–6.94 (m, 2H), 7.28–7.31(m, 1H), 7.56 (dd, *J* = 1.59 and 7.83 Hz, 1H). MS *m/z*: 310, 312 [M^+]. Anal. calcd. for $C_{13}H_{11}BrO_4$: C 50.18, H 3.56; found: C 50.43, H 3.63.

Compound 15b

Yield: 85%. White amorphous solid; mp 109–110 °C. IR (KBr) ν_{max} (cm^{-1}): 2920, 1732, 1260, 1049. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.29 (s, 3H), 3.83 (s, 3H), 4.64 (s, 2H), 5.49 (d, *J* = 1.88 Hz, 1H), 6.29 (s, 1H), 7.24–7.53 (m, 3H). MS *m/z*: 324, 326 [M^+]. Anal. calcd. for $C_{14}H_{13}BrO_4$: C 51.71, H 4.03; found: C 51.66, H 4.21.

Compound 15c

Yield: 81%. White amorphous solid; mp 121 °C. IR (KBr) ν_{max} (cm^{-1}): 2920, 1730, 1260, 1033. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.54 (s, 3H), 3.82 (s, 3H), 4.73 (s, 2H), 5.49 (d, *J* = 2.04 Hz, 1H), 6.37 (t, *J* = 0.94 Hz, 1H), 6.94 (d, *J* = 8.21 Hz, 1H), 7.39 (d, *J* = 8.16 Hz, 1H), 7.75 (s, 1H). MS *m/z*: 324, 326 [M^+]. Anal. calcd. for $C_{14}H_{13}BrO_4$: C 51.71, H 4.03; found: C 51.88, H 4.12.

Compound 15d

Yield: 77%. White amorphous solid; mp 126 °C. IR (KBr) ν_{max} (cm^{-1}): 2920, 1733, 1259, 1035. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.25 (s, 3H), 2.27 (s, 3H), 3.83 (s, 3H), 4.63 (d, *J* = 0.94 Hz, 2H), 5.49 (d, *J* = 2.44 Hz, 1H), 6.32–6.34 (m, 1H), 6.93 (s, 1H), 7.05 (s, 1H). MS *m/z*: 338, 340 [M^+]. Anal. calcd. for $C_{15}H_{15}BrO_4$: C 53.12, H 4.46; found: C 52.90, H 4.52.

Compound 15e

Yield: 89%. White amorphous solid; mp 132 °C. IR (KBr) ν_{max} (cm^{-1}): 2921, 1733, 1259, 1053. ^1H NMR ($CDCl_3$, 300 MHz) δ: 3.75 (s, 3H), 3.81 (s, 3H), 4.77 (s, 2H), 5.45 (d, *J* = 2.0 Hz, 1H), 6.30 (s, 1H), 6.78–6.85 (m, 2H), 7.11 (d, *J* = 2.68 Hz, 1H). MS *m/z*: 340, 342[M^+]. Anal. calcd. for $C_{14}H_{13}BrO_5$: C 49.29, H 3.84; found: C 49.38, H 3.70.

General procedure for the radical cyclization of compound 15a–15e

The appropriate compound **15a**–**15e** (0.32 mmol) was dissolved in dry toluene (10 mL), and the solution was purged with nitrogen for 30 min. AIBN (26 mg) and $^nBu_3SnH$ (0.104 mL, 0.38 mmol) were added, and the reaction mixture was refluxed for 3–4 h under nitrogen atmosphere. The reaction mixture was allowed to cool down to room temperature, and the solvent was removed under reduced pressure. Water (10 mL) was added to the residual mass, and the mixture was extracted with CH_2Cl_2 (3 × 10 mL). The CH_2Cl_2 solution was stirred with 10% KF solution (10 mL) for 1 h. The organic phase was washed with water (2 × 20 mL) and then brine (1 × 20 mL) and dried (Na_2SO_4). The solvent was distilled off, and the crude solid was purified by column chromatography over silica gel (230–400 mesh). Elution of the column with petroleum ether – ethyl acetate (4:1) gave pure solids **16a**–**16e**. Attempts to recrystallize the products from different solvents, such as methanol, chloroform – petroleum ether (60–80 °C), benzene – petroleum ether (60–80 °C), and acetonitrile–methanol, failed to give any crystalline compounds. All compounds were found to be amorphous in nature and hence white as paper

Compound 16a

Yield: 79%. White amorphous solid; mp 152–154 °C. IR (KBr) ν_{max} (cm^{-1}): 2998, 1697, 1261, 1015. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.78 (d, *J* = 17.18 Hz, 1H), 3.05 (d, *J* = 17.19 Hz, 1H), 3.83 (s, 3H), 4.37 (d, *J* = 10.6 Hz, 1H), 4.71 (d, *J* = 10.60 Hz, 1H), 5.30 (s, 1H), 6.87–7.38 (m, 4H). ^{13}C NMR (125 MHz) δ: 36.5, 56.8, 81.4, 85.7, 91.3, 111.5, 121.6, 124.3, 126.8, 132.1, 160.9, 165.8, 171.5. MS *m/z*: 232 [M^+]. Anal. calcd. for $C_{13}H_{12}O_4$: C 67.23, H 5.21; found: C 67.45, H 5.08.

Compound 16b

Yield: 74%. White amorphous solid; mp 147 °C. IR (KBr) ν_{max} (cm^{-1}): 2922, 1714, 1238, 1060. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.19 (s, 3H), 2.78 (d, *J* = 17.18 Hz, 1H), 2.98 (d, *J* = 17.23 Hz, 1H), 3.82 (s, 3H), 4.36 (d, *J* = 10.72 Hz, 1H), 4.72 (d, *J* = 10.74 Hz, 1H), 5.29 (s, 1H), 7.19–7.29 (m,

3H). MS *m*/*z*: 246 [M^+]. Anal. calcd. for $C_{14}H_{14}O_4$: C 68.28, H 5.73; found: C 68.11, H 5.62.

Compound 16c

Yield: 68%. White amorphous solid; mp 162 °C. IR (KBr) ν_{max} (cm^{-1}): 2920, 1720, 1240, 1035. ^1H NMR ($CDCl_3$, 500 MHz) δ: 2.33 (s, 3H), 2.77 (d, *J* = 17.16 Hz, 1H), 3.03 (d, *J* = 17.18 Hz, 1H), 3.83 (s, 3H), 4.36 (d, *J* = 10.58 Hz, 1H), 4.67 (d, *J* = 10.66 Hz, 1H), 5.29 (s, 1H), 6.69–6.75 (m, 2H), 7.24 (s, 1H). MS *m*/*z*: 246 [M^+]. Anal. calcd. for $C_{14}H_{14}O_4$: C 68.28, H 5.73; found: C 68.55, H 5.65.

Compound 16d

Yield: 71%. White amorphous solid; mp 143–144 °C. IR (KBr) ν_{max} (cm^{-1}): 2928, 1716, 1230, 1025. ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.17 (s, 3H), 2.24 (s, 3H), 2.74 (d, *J* = 17.22 Hz, 1H), 3.03 (d, *J* = 17.21 Hz, 1H), 3.82 (s, 3H), 4.33 (d, *J* = 10.60 Hz, 1H), 4.68 (d, *J* = 10.64 Hz, 1H), 5.28 (s, 1H), 6.92 (s, 1H), 6.97 (s, 1H). MS *m*/*z*: 260 [M^+]. Anal. calcd. for $C_{15}H_{16}O_4$: C 69.22, H 6.20; found: C 69.07, H 6.43.

Compound 16e

Yield: 76%. White amorphous solid; mp 166–167 °C. IR (KBr) ν_{max} (cm^{-1}): 2922, 1717, 1266, 1026. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.76 (d, *J* = 17.18 Hz, 1H), 3.03 (d, *J* = 17.18 Hz, 1H), 3.74 (s, 3H), 3.82 (s, 3H), 4.36 (d, *J* = 10.52 Hz, 1H), 4.68 (d, *J* = 10.51 Hz, 1H), 5.28 (s, 1H), 6.78–6.90 (m, 3H). MS *m*/*z*: 262 [M^+]. Anal. calcd. for $C_{14}H_{14}O_5$: C 64.12, H 5.38; found: C 64.03, H 5.43.

OBITUARY / NÉCROLOGIE

Professor Nick J. Taylor

Memoriam Nick J. Taylor 1944–2006

Nicholas (Nick) J. Taylor, MCIC, passed away suddenly in his home in Drumbo, Ontario on November 23, 2006, at the age of 61. He is survived by his brothers, Ronald and David, and their families. The University of Waterloo and the larger chemical community have lost an accomplished crystallographer, a mentor and teacher to numerous undergraduate and graduate students, a gentleman in the true sense of that word, and a close friend.

Nick was born in Purley, Surrey, UK on December 12, 1944, and completed his formal education at Whyteleafe Primary School (1950–1956), followed by a scholarship to Caterham School (1956–1961), and on passing the O-Level examinations, completed A-level examinations at Croydon Technical College (1961–1964) in Pure Mathematics, Applied Mathematics, Physics and Chemistry, and the S-level examination in Chemistry. He completed B. Sc. and Ph. D. degrees at the University of Surrey, graduating in 1971.

His Ph. D. research was in the area of phosphorus halide and metal halide chemistry, featuring both main-group and transition-metal halides, under the supervision of Professor Joseph I. Bullock. Nick was initially trained by Frederick W. Parrett, and his first paper is co-authored with Dr. Parrett, who had since moved to Royal Military College in Kingston,

Nécrologie Nick J. Taylor 1944–2006

Nicholas (Nick) J. Taylor, MCIC, est décédé subitement à son domicile de Drumbo (Ontario), le 23 novembre 2006, à l'âge de 61 ans. Il laisse dans le deuil ses frères, Ronald et David, ainsi que leurs familles. L'Université de Waterloo et le milieu élargi de la chimie perdent un cristallographe accompli, professeur et mentor de nombreux étudiants au baccalauréat et aux études supérieures, un « gentleman » au sens propre du terme et un ami très cher.

Nick est né à Purley (Surrey), au R.-U., le 12 décembre 1944. Il a amorcé sa formation scolaire à l'école primaire de Whyteleafe (1950-1956), puis a obtenu une bourse d'études pour entreprendre ses études secondaires à l'école de Caterham (1956-1961), jusqu'aux examens du niveau O. Par la suite, il a poursuivi ses études au collège de Croydon (1961-1964) jusqu'aux examens du niveau A en mathématiques pures, mathématiques appliquées, physique et chimie, et a aussi réussi l'examen du niveau S en chimie. L'Université de Surrey lui a d'abord décerné un B.Sc., puis un Ph.D. en 1971.

Ses recherches de doctorat, sous la direction du professeur Joseph I. Bullock, portaient sur la chimie des halogénures de phosphore et de métaux, particulièrement les halogénures des métaux des groupes principaux et de transition. Nick a fait ses premières armes avec Frederick W. Parrett. Il a aussi cosigné

Ontario. That paper (F.W. Parrett and N.J. Taylor, J. Inorg. Nucl. Chem. **32**, 2458 (1970)) is concerned with the IR spectra of polyhalide ions. It is interesting to note that many years later Nick collected, solved, and refined a number of structures of ammonium poly-iodide salts in collaboration with Professor Donald E. Irish. Regrettably, this work is currently unpublished because of the premature deaths of both chemists.

Nick moved to Royal Military College in 1971 and worked briefly as a post-doctoral fellow with Professor Parrett before moving to the University of Waterloo to work with Professor Arthur J. Carty (FCIC, FRS), initially as a post-doctoral fellow in 1973. Nick was appointed as a permanent staff member in 1981 and was Adjunct Professor of Chemistry and manager of the department's X-ray crystallographic facility until his untimely death.

In our early days at the University of Waterloo, X-ray diffraction data were collected on an aging Syntex $P2_1$ instrument (purchased in 1978), and at one point, before our arrival, punch cards had to be laboriously collated and read into the University's mainframe computer prior to solution and refinement! One of us still has a glossy 8½ × 11 inch print of the first structure Nick collected on our behalf (S. Collins, B.A. Kuntz, N.J. Taylor, and D.G. Ward. J. Organomet. Chem. **342**, 21 (1988)).

Of these early days his ex-wife Lynda remarks, "I remember Nick babysitting the old X-ray machine a lot in the early years of our marriage; we would walk into the Chemistry Department in all wind and weather to check that all was well when he was collecting data. On one occasion, late at night, we went in when a blizzard was blowing, and by the time we arrived at the door to the Chemistry Department, we looked like characters out of a scene in Dr. Zhivago".

A Nicolet-Siemens P4 diffractometer, along with much updated computing equipment, were purchased in the late 1980s and early 1990s, and a modern Apex 3000 CCD-based instrument was acquired in 2000. So a majority of the structures Nick collected, solved, and refined were obtained on conventional 4-circle instruments.

Nick was *personally responsible* for the collection, solution, and refinement of over 1300 structures during his tenure at Waterloo and is a co-author on 289 refereed journal publications. In an age of modern instruments where a data set can now be collected and a structure obtained in a matter of hours, his legacy may seem inconsequential. However, he was one of Canada's more prolific and accomplished crystallographers, especially given that he had neither a research group nor independent grant funding for much of his career. Many chemists may also be unaware that Nick was a largely self-taught crystallographer, having received no advanced training in the subject prior to moving to Waterloo.

Further, those of us who worked with him, and this includes a host of undergraduate, graduate students, and faculty at Waterloo, as well as other chemists and crystallographers from around the world, will remember Nick as being meticulous and a true craftsman. He was never satisfied with simply obtaining a structure, he always strived for the best result possible. Indeed, his care and attention to detail resulted in structural data from "old" diffractometers with esd values that rival those for many structures collected on modern CCD-equipped systems.

In a 20+ year association with Nick, we only encountered a couple of problems that were insoluble due to disorder, or "indifferent", or incommensurate crystals. In these cases, students were encouraged to try again, often under the direct tutelage of Nick as to the proper techniques for single

sa première publication avec M. Parrett, qui était alors au Collège militaire royal de Kingston (Ontario). L'article en question (F.W. Parrett et N.J. Taylor, J. Inorg. Nucl. Chem. **32**, 2458 (1970)) portait sur le spectre IR d'ions polyhalogénures. Il est intéressant de noter que, plusieurs années plus tard, Nick a recueilli, élucidé et affiné plusieurs structures de sels de polyiodure d'ammonium en collaboration avec le professeur Donald E. Irish. Malheureusement, ces travaux n'ont jamais été publiés à cause du décès prématuré des deux chimistes.

Nick s'est joint au Collège militaire royal en 1971, où il a brièvement occupé un poste de chercheur postdoctoral dans le groupe du professeur Parrett, avant de se joindre à celui du professeur Arthur J. Carty (FCIC, FRS), d'abord comme chercheur postdoctoral, à l'Université de Waterloo, en 1973. En 1981, Nick est devenu membre permanent du personnel; il a été nommé professeur adjoint et a occupé le poste de directeur du service de radiocristallographie jusqu'à son décès prématuré.

A nos débuts à l'Université de Waterloo, les données obtenues par diffraction des rayons X étaient recueillies sur un vieux diffractomètre Syntex $P2_1$ (acheté en 1978), et, quelque temps avant notre arrivée, des cartes poinçonnées devaient être laborieusement colligées et soumises à l'ordinateur central de l'Université avant que l'on puisse élucider et affiner les données! Un de nous possède encore une photo glacée de la première structure que Nick a recueillie pour lui (S. Collins, B.A. Kuntz, N.J. Taylor et D.G. Ward. J. Organomet. Chem. **342**, 21 (1988)).

Au sujet de cette époque, Lynda, son ex-épouse, raconte : « Je me souviens qu'au début de notre mariage, Nick prenait grand soin de cette machine. Beau temps, mauvais temps, nous allions à l'Université pour nous assurer que la cueillette des données se passait bien. A l'une de ces occasions, tard la nuit, nous nous y sommes rendus en pleine tempête de neige; lorsque nous sommes enfin parvenus au département de chimie, nous avions l'air de deux personnages sortis d'une scène de *Docteur Jivago*. »

Un diffractomètre Nicolet-Siemens P4 et de l'équipement informatique plus à jour ont été acquis à la fin des années 1980 et au début des années 1990. De plus, un détecteur bidimensionnel CCD Apex 3000 a été acheté en 2000. Ainsi, la majorité des structures recueillies, élucidées et affinées par Nick l'ont été sur un instrument traditionnel à quatre cercles.

Nick a été personnellement responsable de recueillir, d'élucider et d'affiner plus de 1300 structures à Waterloo. Il est coauteur de 289 articles dans des publications à comité de lecture. A l'âge de l'instrumentation moderne où un ensemble de données peut être recueilli et une structure obtenue en quelques heures, son œuvre peut sembler sans conséquence. Il a cependant été l'un des cristallographes canadiens les plus prolifiques et les plus accomplis, surtout si l'on considère que, pour une bonne partie de sa carrière, il n'a ni dirigé de groupe de recherche ni obtenu de subventions indépendantes. De nombreux chimistes ignorent probablement que Nick était un cristallographe autodidacte et qu'il n'avait reçu aucune formation avancée dans le domaine de la cristallographie avant d'arriver à Waterloo.

De plus, ceux qui ont travaillé avec lui, y compris un grand nombre d'étudiants au baccalauréat et aux études supérieures, et les professeurs de Waterloo, ainsi que d'autres chimistes et cristallographes du monde entier, se souviendront que Nick était très méticuleux et un véritable artisan. La simple obtention d'une structure ne le satisfaisait jamais; il s'efforçait toujours d'obtenir le meilleur résultat possible. En effet, il a réussi à soutirer de « vieux » diffractomètres des données structurales dont les valeurs d'écarts-types rivalisaient avec

crystal growth. It is gratifying that a number of these students, who now hold faculty appointments in Canada, continued to collaborate with Nick.

Nick had passions other than crystallography. He was an avid gardener (of both fruits and vegetables) and horticulturist (his day, hosta, and true lilies grace the gardens of friends and the University of Waterloo). In addition, he played the violin *con brio* and was a collector of vintage wines and ports. Finally, Nick had a deep interest in the natural world that dated back to his childhood, collecting fossil ammonites and other “ites” while on holiday along the seacoast between Cornwall and Dorset. It is there, amongst the wind and waves off Dodman Point in Cornwall, that Nick J. Taylor will find peace. We will all sorely miss him.

Scott Collins and Todd B. Marder (MCIC, FRSC-UK)y of Toronto.)

celles de plusieurs structures recueillies sur des détecteurs bidimensionnels CCD modernes.

En plus de 20 ans de collaboration avec Nick, nous n’avons croisé que quelques problèmes insolubles en raison du désordre ou de cristaux incommensurables, ou indiscernables. Dans ces cas, les étudiants étaient encouragés à essayer de nouveau, souvent sous la tutelle de Nick, pour apprendre les meilleures techniques de croissance d’un monocristal. Il est d’intérêt de constater que plusieurs de ces étudiants, maintenant professeurs dans des universités canadiennes, ont continué à collaborer avec Nick par la suite.

Nick avait d’autres passions que la cristallographie. Il cultivait fruits et légumes avec ferveur, et était un horticulteur de talent; encore aujourd’hui, ses hémérocalles, ses hostas et ses lis ornent les jardins de ses amis et de l’Université de Waterloo. De plus, il jouait du violon avec brio et collectionnait les grands vins et les portos. Enfin, Nick, ayant développé un vif intérêt pour la nature dès son enfance, collectionnait les fossiles (ammonites et autres « ites »), lorsqu’en vacances, il séjournait sur les côtes de Cornouailles et du Dorset. C’est à cet endroit, dans le vent et les vagues de Dodman Point en Cornouailles, que Nick J. Taylor reposera. Il nous manquera beaucoup.

The mechanism and kinetics of the HCO + HONO → HCHO + NO_2 reaction — A DFT study

Xiaomin Sun, Zhengting Cai, Dachang Feng, Wenshang Bian, Qing'an Qiao, and Wenxing Wang

Abstract: The hydrogen-transfer reaction of HCO + HNO_2 → HCHO + NO_2 has been studied using both the density function theory (DFT) and high-level ab initio method. Three complete reaction paths have been located for the transfer reaction. Geometry optimization and frequency calculation have been performed at the B3LYP/6–311++G** level. QCISD(T) and G3B3 methods have been used to verify the single-point energy. On the basis of the ab initio data, the rate constants have been deduced over a temperature range of 300–3000 K using the transition-state theory and canonical variational transition-state theory with small-curvature tunneling effect. The calculated rate constants have been compared with the previous reported values.

Key words: density function theory, reaction mechanism, variational transition-state theory, rate constant.

Résumé : Faisant appel à la théorie de la densité fonctionnelle et à des calculs ab initio de haut niveau, on a étudié la réaction de transfert d'hydrogène du HCO + HNO_2 → HCHO + NO_2. On a décelé trois voies réactionnelles complètes pour la réaction de transfert. On a effectué l'optimisation de la géométrie et le calcul de la fréquence au niveau B3LYP/6-311++G**. On a utilisé les méthodes QCISD(T) et G3B3 pour vérifier l'énergie du point unique. Sur la base des données obtenues par les calculs ab initio, on a dérivé les constantes de vitesse pour les températures allant de 300 à 3000 K; pour ce faire, on a utilisé la théorie de l'état de transition et la théorie de l'état de transition à variations canoniques modifiées par une faible courbure d'effet tunnel. On a comparé les constantes de vitesse calculées avec les valeurs rapportées antérieurement.

Mots-clés : théorie de la densité fonctionnelle, mécanisme réactionnel, théorie de l'état de transition variationnel, constante de vitesse.

[Traduit par la Rédaction]

Introduction

In the combustion of hydrocarbons and nitramine propellants, the reactions of CH_2O and NO_x can generate many reactive species, such as HCO, HNO, HONO, HNOH, and so forth (1–3). Moreover, the consequent reactions of HCO with HNO, HONO, and HNOH may play a significant role in the overall kinetics of these chemical systems. The reaction of HNO_2 with HCO has been studied by several groups in both experimental and theoretical calculations. In 1991, Tsang and Herron (4) investigated the kinetics of the reaction, and by combining the results from other work (5, 6) for the reverse reaction, they reported the rate constants of the HCO + HNO_2 → HCHO + NO_2 reaction.

Thus, $k(T) = 2.0 \times 10^{-21} T^{2.37} \exp(-1940/T)$ cm^3 molecule^{-1} s^{-1}; 300 K < T < 1000 K with an uncertainty factor of five. In 1996, to elucidate the mechanism and the kinetics of the forward reaction theoretically, Feng (7) first reported the transition-state (TS) and the intrinsic-reaction coordinates (IRC) with the ab initio UHF/6–31G method and the computed thermal rate constants, involving the tunneling effect, by calculating the microcanonical probability fluxes at the TS. On the basis of the agreement between the theoretical and experimental data, the results were excellent and cited in a textbook (8). However, Veszpremi also pointed out some drawbacks of Feng's study. First, the results, including the geometries and the energies, were derived at a relatively low level of theory with a modest basis set that excluded the polarization and diffuse functions. Second, the spin contamination should be verified to stay at a negligible level during the calculation. Also, it should be pointed out that the reaction path reported by Feng was not the fastest reaction path. Recently, Xu and Lin (9, 10) reported the kinetics and mechanisms of the title reaction on G2M level. Among the mentioned studies, there are still some aspects that are worth discussing. For example, the reaction mechanism is not uniform, the previously reported temperature dependency of the total rate constants is disputed, and large discrepancy exists

Fig 1. Geometry parameters of stationary points along three reaction paths at the B3LYP/6-311++G** level.

between the experimental and theoretical results in wider temperature range. It is necessary to perform the mechanism and kinetics studies.

In this paper, the mechanism for the reaction of HNO_2 (including trans- and cis-) with HCO was revealed. Next, kinetic calculations were carried out. Several important features of this study include (*i*) performing the density functional theory (DFT) calculations for the minimum energy paths (MEP) to obtain potential energy information, (*ii*) studying the kinetic nature in the temperature range from 300 to 3000 K using interpolated canonical variational transition-state theory (CVT) and the centrifugal-dominant, small-curvature tunneling approximation (SCT), including information at the reactants, intermediates, transition-states, products, and extra points along the MEP, (*iii*) fitting the non-Arrhenius expression, and (*iv*) comparing the calculated rate constants with the previous results.

Computation methods

For systems with a multiplicity > 1, the spin contamination is one of the aspects that should be considered. In DFT calculations, it is less common to find any significant spin contamination. In addition, recent developments in DFT (11) enabled the modification and improvement of the performance in geometrical optimizations and vibrational-frequency calculations. For hydrogen-bonded systems, it has long been recognized that the basis sets should include diffuse and polarization functions. Thus, combining B3LYP method (12) with 6–311++G** basis set should give satisfactory results.

The geometries of the reactants, intermediates, transition states, and products have been optimized at the B3LYP/6–311++G** level. To determine the nature of the stationary points, the zero-point energy (ZPE), and the thermal contribution to the free energy of activation, we have calculated the vibrational frequencies at the same level. An IRC calculation confirmed that the transition state connects the designated intermediates. At the B3LYP/6–311++G** level, a gradient step size of 0.02 amu bohr^2 was used to obtain the MEP in mass-weighted Cartesian coordinates. Then, we computed both the force-constant matrices of the stationary points and selected non-stationary points near the transition state along the MEP. The geometrical parameters and the frequencies of various species can be determined satisfactorily at the B3LYP/6–311++G** level. The single-point energies obtained at the QCISD(T)/6–311++G** level are chosen for the kinetic calculations. All ab initio calculations have been carried out using GAUSSIAN 03 programs (13) on SGI workstation.

The initial information obtained from the ab initio calculations allowed us to calculate the rate constants, including the tunneling effects. POLYRATE 9.3 program was used to perform all the kinetic calculations (14). Classical calculations were used for the rotational partition functions, and the vibrational modes were treated as quantum-mechanical separable harmonic oscillators. The centrifugal-dominant SCT

© 2007 NRC Canada

correction method was used in our calculations of the rate constants. The total rate constants are obtained as the sum of the calculated rate constants for the three reaction paths.

Results and discussion

Figure 1 shows the optimized geometries of the reactants, intermediates, transition states, and products. The rotational constants and vibrational frequencies of the reactants, products, intermediates, and transition states are listed in Table 1. The hyperfine coupling constants of the intermediates are listed in Table 2. The energies of the stationary points obtained with different methods are summarized in Table 3 and Table 4. The total forward rate constants obtained from different methods are listed in Table 5. The potential energy profile of the HCO + HNO_2 → HCHO + NO_2 system is drawn in Fig. 2. Figure 3 shows the classical potential energy, the ZPE curves, and vibrationally adiabatic potential energy as functions of s on the ^2A potential energy surface. The changes of the generalized normal-mode vibrational frequencies as functions of s are drawn in Fig. 4. Finally, the forward rate constants, including theoretical and previous results, are shown in Fig. 5.

Reaction mechanism

The reaction path

For the title reaction, three product paths on the doublet electronic-state potential energy surface have been identified from the calculations (shown in Fig. 2).

[1] HCO + *trans*-HNO_2 → IM1 → TS1 → IM4 → HCHO + NO_2

[2] HCO + *trans*-HNO_2 → IM1 → TS2 → IM3 → HCHO + NO_2

[3] HCO + *cis*-HNO_2 → IM2 → TS3 → IM4 → HCHO + NO_2

where IM is the intermediate, IM1 and IM2 are the precomplexes, and IM3 and IM4 are the post-complexes. All reactants have planar structures. It should be noted that the reactant HNO_2 has two isomers, i.e., *trans*-HNO_2 and *cis*-HNO_2. The former is more stable than the latter because the former has a lower energy, which can be explained by the stereo effect. In the optimization process, reactants first form a prior complex with low energy, which is a barrierless process. Then, the complex crosses a potential barrier and turns into the other complex. Finally, the products formed after the second complex are decomposed into two particles. There are three reaction paths, which have the similar processes, namely, path 1, path 2, and path 3. Path 3 is chosen to discuss its reaction mechanism because it has the lowest barrier. For convenience, the atoms are labeled according to the sequence of H3O2N1O4 and H7C6O5.

The whole path 3 includes HCO, *cis*-HNO_2, IM2, TS3, IM4, HCHO, and NO_2. The reaction process can be described as follows: first, when planar reactants, i.e., HCO and *cis*-HNO_2, approach each other, the H-bond complex IM2 is formed directly, then the energy decreases, and the potential well comes into being. Then, the H-bond between O7–H1 breaks

up, and the HCO encircles another bond between C2 and H4 and approaches *cis*-HNO_2, simultaneously. Subsequently, the transition state is formed. After the system crosses the potential barrier, another five-membered complex (IM4) comes into being as HCO continues to approach *cis*-HNO_2. If (IM4) yields to be clockwise, then its mirror-image conformer appears to be anticlockwise. There are two kinds of isomers in the potential well of the IM4. Thus, the detailed reaction paths become obvious.

Next, the transition states are considered; a more detailed analysis is performed for the transition states. As mentioned previously, the hydrogen-transfer reaction of HCO with HNO_2 proceeds over three potential energy surfaces (PESs), corresponding to the three paths, namely, surface 1, 2, and 3, respectively. At the B3LYP/6–311++G** level, three transition states were located, whose geometrical structures are shown in Fig. 1. The transition states are denoted as TS1, TS2, and TS3. The transition states were different both in energy and in the orientation angle of O–C–H. The C atom of HCO group abstracts the H atoms of HNO_2 from the *trans*-position of the O atom via TS1 or TS2. The breaking N–H bonds are elongated by 35.8% and 39.2%, while the forming C–H bonds in the corresponding transition states are longer than the equilibrium value of 1.107 Å by 12.9% and 11.8%. According to Hammond's postulate (15), these two transition states are product-like, and the H-transfer reaction from HNO_2 to HCO molecule occurs via later transition states. Nevertheless, the reaction still has a high barrier and a high exothermicity. For the TS3, the breaking N–H bonds in the *cis*-HNO_2 molecule are elongated by 25.6%, while the forming C–H bonds in the corresponding transition states are longer than the equilibrium value of 1.107 Å by 23.8%. This reaction path has a lower barrier and a higher exothermicity.

As shown in Table 1, at the B3LYP/6–311++G** level, three transition states have one, and only one, imaginary frequency. The values of the imaginary frequencies are large, which implies that the quantum tunneling effect may be significant and may play an important role in the calculation of the rate constants.

To prove that a particular transition state connects two specific intermediates or products, the intrinsic-reaction coordinate calculation is needed to relocate the minimal-energy reaction path from a transition state down to the nearest local minima in the forward and reverse directions.

The role of intermediates

Recently, several evidences (16, 17) indicated that the intermediates (IM) played an important role in the ground-state reaction dynamics even though these complexes occur at considerably larger internuclear distances than those of the transition states. Accordingly, many works are performed concerning the issue (18).

In this paper, four intermediates are found, whose formations change the topological properties of the PES. Therefore, attention should be paid to them.

The geometries of the intermediates are fully optimized, and the optimized parameters are listed in Fig. 1. Obviously, IM1 and IM2 have similar structures, which are composed of the HCO radical with the HONO molecule (t*rans*- and *cis*-). The H3—C6 distances are 2.214 Å in IM1 and IM2 . However, IM3 and IM4 compose the HCHO and NO_2 groups. The N1—O5 distance in IM3 is 2.987 Å, and the O2—H3 distance in IM4 is 2.593 Å. All the intermediates are weakly bonded complexes. The main difference is that IM1 and IM2 have the reactant-like structures, while IM3 and IM4 have the product-like ones.

The harmonic vibrational frequencies of the intermediates are shown in Table 1. Taking IM1 for example, the vibrational mode of highest frequency, 3548.8 cm^{-1}, corresponds to the H3–O2 stretching mode. This value is slightly smaller than that of the free *trans*-HONO molecule (3763.5 cm^{-1}). This result means that H3–O2 bond becomes weaker in the IM1 formation. In addition, the intermolecular stretching mode between the HCO radial and *trans*-HONO molecule is calculated to be 150.3 cm^{-1}, which is significantly small because of the weak interaction. This result implies that the structure of IM1 may be easily deformed by the thermal activation. Similar analysis can also be applied to the other intermediates.

By using the optimized structures, the hyperfine coupling constants (HFCCs) are calculated at B3LYP/6–311++G** level (19). The results are listed in Table 2 together with Mülliken atomic-spin densities on the atoms in parentheses. Taking the IM1 for example, the O2, H3, O4, and O5 atoms have negative HFCCs; whereas N1, C6, and H7 atoms have positive ones. A simple Mülliken spin densities calculation shows that the unpaired electron is mainly located on the HCO radical, especially on the C atom (spin densities on the carbon atom is calculated to be 0.507). The HFCCs of IM2 has the same trend as those of IM1. However, the HFCCs of IM3 and IM4 are very different from those of IM1 and IM2. In IM3, the O2, O4, and O5 atoms have negative HFCCs; whereas N1, H3, C6, and H7 atoms have positive ones. In IM4, the O2, O4, O5, and C6 atoms have negative HFCCs; whereas N1, H3, and H7 atoms have positive ones. Mülliken spin densities suggest that, both in IM3 and IM4, the unpaired electron is mainly located on the NO_2 molecule, espe-

cially on the N atom. The reliability of the HFCCs is expected to be verified by the experimental results, such as ESR and FTIR methods combined with the matrix-isolation technique. Other properties of the intermediates, such as the trajectory calculation, time-dependence of HFCC, and temperature-dependence of HFCCs, will be studied in the future.

Energy

Tables 3 and 4 summarize the potential energies at various theory levels, including HF, B3LYP, G3B3 (20), MP_n (n = 2, 3, and 4), QCISD, and QCISD(T). The energies are calculated by taking the zero of energy at the reactants (HCO + *trans*-HONO). From Tables 3 and 4, all the reaction paths have a double-well structure as a whole. The depth of the first well ranges from 0.32 kcal/mol to 5.46 kcal/mol, while the second well locates from 0.68 kcal/mol to 2.46 kcal/mol, measured by taking the zero of energy of NO_2 + H_2O. Although the potential-barrier values are different for the three reaction paths at the same computational level, the values for the same reaction path have the same trend obtained at the HF, B3LYP, and G3B3 levels. The effect of basis set on the potential barrier can be observed from our B3LYP result with two different basis sets, namely, 6–31G and 6–311++G**. The barrier height increases by 3.88 and 3.98 kcal/mol with the increase in basis sets at the B3LYP level for paths 1 and 2, respectively, while for path 3, the barrier height decreases by 1.20 kcal/mol. After comparison, the potential barriers and the reaction enthalpy, calculated at the QCISD(T)/6–311++G** level, are adopted for the following kinetic calculations.

The barrier of path 2, reported by Feng (7), is 11.53 kcal/mol. As for Lin's result (9), the barriers are 19.5 and 10.90 kcal/mol for paths 2 and path 3, respectively. Neither of them reported path 1. According to our calculations, the barriers are 22.28, 21.54, and 13.18 kcal/mol for paths 1, 2, and 3, respectively.

Kinetic calculations

Reaction path properties

The reaction kinetics for the three paths has been calculated independently. The three paths have similar features, and further discussion will refer only to path 3. The MEP is calculated at the B3LYP/6–311++G** level, and the energies along the IRC are calculated at the QCISD(T)/6–311++G** level. Figure 3 shows the changes of the classical potential energy V_{MEP} and the ground-state vibrational adiabatic potential energy V_a^G with the reaction coordinate s on path 3. From $s = -\infty$ to –10.0 amu bohr^2, the potential curves decrease very slowly. From s = –10.0 to –2.0 amu bohr^2, the curves increase gradually, and from s = –2.0 to 2.0 amu bohr^2, the curves increase and decrease quickly on passing the transition state. The V_{MEP} and V_a^G curves are similar in shape. The ZPE, which is the difference between V_a^G and V_{MEP}, is also shown in Fig. 3. The zero-point energy curve is almost unchanged as s varies except from s = –1.0 to 1.0 amu bohr^2 where a gentle valley appears. To analyze this behavior in detail, we have shown the variation of the generalized normal-mode vibrational frequencies of the hydrogen-transfer reaction in Fig. 4. When $s = -\infty$, the frequencies are associated with the reactants HCO and HNO_2, while in the positive

limit of *s*, the frequencies are associated with the products HCHO and NO_2. The frequency of mode 1, which connects the frequency of O–H stretching vibration in HNO_2 with the frequency of the C–H stretching vibration in HCHO, drops sharply from $s = -1.0$ to $s = +1.0$ amu $bohr^2$; this behavior is similar to that found in other hydrogen-transfer reactions (21–24). If changes in other frequencies were small, this drop could cause a considerable fall in the zero-point energy near the transition state. The four lowest harmonic frequencies corresponding to free rotations and translations of the reactants evolve to vibrations at about $s = 0.0$ amu $bohr^2$, and they present a maximum near the saddle point. The behavior of these four lowest frequencies compensates for the fall in the zero-point energy caused by modes 1, 3, and 4. Therefore, there is only a slight change in the zero-point energy with *s*, and the ground-state vibrational adiabatic potential energy V_a^G curve is similar in shape to the classical potential energy V_{MEP} curve.

Rate constants

As mentioned previously, the title reaction has three paths to the products. However, the barriers of path 1 and path 2 are higher than that of path 3. The barrier for path 3 can be interpreted as follows: The reactants, HCO and *cis*-HONO, have planar structures. The dihedral angel between the planes of the two reactants in TS3 is 106.88°. The distance between H7 and O4 is 3.230 Å, which is shorter than 3.281 Å in IM2, suggesting the formation of a hydrogen-bond. It is the hydrogen-bond that stabilizes the structure of TS3, i.e., lowers the barrier of path 3. In addition, path 3 has an equivalent path because the HCO has two permutations with *cis*-HONO to form two transition states that are mirror images. Thus, the total rate constant is $k_1 + k_2 + 2k_3$.

The TST and CVT with a SCT, which have been successfully applied to several analogous reactions (25–27), are effective methods to calculate the rate constants. In this paper, these methods are used to study the title reaction over a wide temperature range of 300–3000 K. To calculate the rate constants, 30 points near the transition state along the MEP were selected; 15 points on the reactants side and 15 points on the products side. Figure 5 shows the total rate constant vs. the temperature for the reaction of HCO with HNO_2. For comparison, the previous values, TST rate constants, and the CVT rate constants with the small curvature tunneling (SCT) correction are also shown in Fig. 5. All the values of $k_1 + k_2 + 2k_3$ obtained from various methods are listed in Table 5. The rate constants of each path are listed in the supplementary data.[2] The calculated rate constants have several important features: (*i*) The rate constants of TST and CVT are nearly the same over the temperature range of 300–3000 K, which enables us to conclude that the variational effect is small for

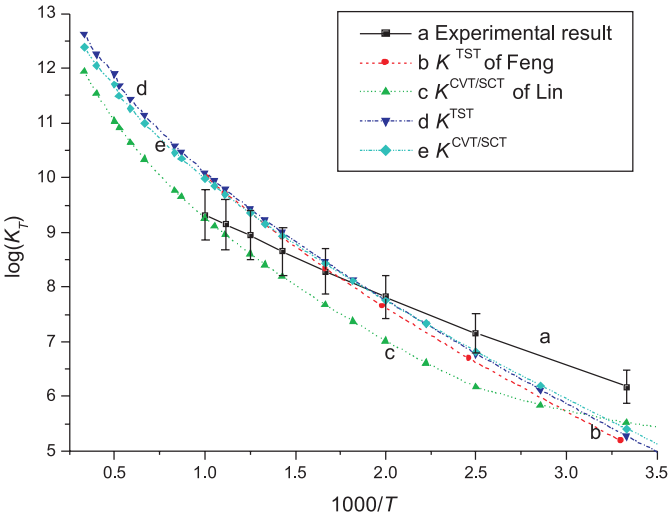
this reaction. (*ii*) When computing reaction rate constants for reactions involving hydrogen-atom transfer, tunneling effects must be taken into account. In the present case, the CVT/SCT rate constants are larger than the CVT ones over the temperature range of 300–3000 K; for example, at 300 K, the CVT rate constant is 3.06×10^{-19} cm^3 molecule^{-1} s^{-1}, while the CVT/SCT rate constant is 4.20×10^{-19} cm^3 molecule^{-1} s^{-1}. The latter is 1.37 × the former. The higher the temperature is, the less the ratio is, which means that the SCT correction plays an important role for the calculation of the rate constants only in the low-temperature range. For TST and CVT/ZCT, the same trend is observed. Another phenomenon is that the CVT/SCT rate constants are asymptotic to the rate constants of TST and CVT/ZCT in the high-temperature range. (*iii*) Comparing the calculated rate constants with the previous values for the title reaction, the CVT/SCT rate constants agree with experimental values for a wide temperature range. Therefore, the CVT/SCT method is a good choice to calculate accurate rate constants for the title reaction. (*iv*) Obviously, a non-Arrhenius behavior is exhibited by the calculated rate constants. The rate constants of the title reaction are fitted by two three-parameter formulas over the temperature range of 300–3000 K and given in units of cm^3 molecule^{-1} s^{-1} as follows:

$$k(T) = 4.58 \times 10^{-23.15}\ T^{2.55}\exp(-2369.25/T)$$



where 300 K < T < 3000 K for TST rate constants, and

$$k(T) = 2.59 \times 10^{-22.68}\ T^{2.34}\exp(-2247.56/T)$$

where 300 K < T < 3000 K for CVT/SCT rate constants.

Conclusion

In this paper, we have studied the reaction of HNO_2 with HCO at the QCISD(T)//B3LYP/6–311++G** level and TST (CVT) with the SCT approximation. Rate constants were reported over the temperature range of 300–3000 K. The structure of reaction paths includes the reactants, the prior-complex, the transition state, the post-complex, and the product. The complexes should not be ignored, as they are helpful to show the complete topological structure of the PES. The modified mechanism is more detailed and integrated. For this H-atom transfer reaction, three paths are calculated, and path 3 is verified to be the fastest. The reasonable interpretation is that the formation of a hydrogen bond in TS3 stabilizes the structure, i.e., lowers the barrier of path 3, which leads to $k_3 >> k_1$ (or k_2). The total forward rate constants are $k_1 + k_2 + 2k_3$ because path 3 has an equivalent path. A typical non-Arrhenius behavior is exhibited by the calculated rate constants. The calculated CVT/SCT rate constants agree with the limited previous reports.

Structures of the 2:1 adducts of benzyne with 2-methylanisole and benzene

Christopher O. Bender, René T. Boeré, Peter W. Dibble, and Ryan T. McKay

Abstract: The 2:1 adduct of benzyne with 2-methylanisole is shown to have the bisbenzotricyclic structure 6,6a,11,11a-tetrahydro-5-methoxy-6-methyl-5,6,11-metheno-5*H*-benzo[*a*]fluorene by a single-crystal X-ray diffraction study ($C_{20}H_{18}O$: *Pca*2$_1$, a = 15.0497(17), b = 9.87783(11), c = 9.6846(11); Z = 4; 1672 data points, R_1 = 0.0325). This structure is compared to an unpublished crystal structure of the parent hydrocarbon 6,6a,11,11a-tetrahydro-5,6,11-metheno-5*H*-benzo[*a*]fluorene, $C_{18}H_{14}$. Both structures have also been computed by DFT methods at the B3LYP/6–311(d,p) level of theory. Bond distances and angles between the solid-state measurements and gas-phase calculations are found to agree well; average deviations are well below 1%. The ^{1}H NMR spectra show surprisingly small $^3J_{HH}$ couplings in the central tricyclic cage, but can be assigned using 2D spectroscopy.

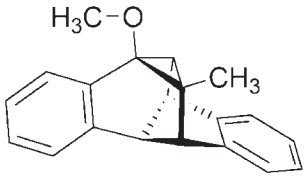
Key words: Hydrocarbon cages, strained rings, cyclopropane, X-ray crystallography, NMR.

Résumé : Faisant appel à la diffraction des rayons X par un cristal unique, on a montré que l'adduit 2:1 de benzyne sur le 2-méthylanisole possède la structure 6,6a,11,11a-tétrahydro-5-méthoxy-6-méthyl-5,6,11-méthéno-5*H*-benzo[*a*]fluorène [$C_{2o}H_{18}O$: *Pca*2$_1$, a = 15,04997(17), b = 9,8778(11) et c = 9,6846(11); Z = 4; 1672 données; R_1 = 0,325). On compare cette structure à une structure cristalline non publiée de l'hydrocarbure fondamental 6,6a,11,11a-tétrahydro-5,6,11-méthéno-5*H*-benzo[*a*]fluorène, $C_{18}H_{14}$. On a aussi calculé les deux structures par des méthodes de la théorie de la fonctionnelle de densité au niveau B3LYP/6-311(d,p) de la théorie. On a trouvé que les distances et les angles de liaison des mesures de l'état solide et des calculs en phase gazeuse concordent bien; les déviations moyennes sont bien en dessous de 1%. Les spectres RMN du ^{1}H présentent des couplages $^3J_{HH}$ qui sont très faibles dans la cage tricyclique centrale, mais qui peuvent être attribués en faisant appel à la spectroscopie 2D.

Mots-clés : cages d'hydrocarbures, cycles tendus, cyclopropane, diffraction des rayons X, RMN.

[Traduit par la Rédaction]

Introduction



Compound **1** is obtained as a major side-product in the preparation of 2-methyl-1-methoxy-4-hydro-1,4-ethenonaphthalene from the reaction of benzyne in neat 2-methylanisole (1). The structure of **1** is not readily deduced from the spectroscopic data; therefore, a single-crystal X-ray diffraction study was initiated. In this paper, we report the structure of **1**, 6,6a,11,11a-tetrahydro-5-methoxy-6-methyl-5,6,11-metheno-5*H*-benzo[*a*]fluorene and compare it to that reported for the parent hydrocarbon **2**, 6,6a,11,11a-tetrahydro-5,6,11-metheno-5*H*-benzo[*a*]fluorene. Since the initial reports of the synthesis of **2** (2, 3), it has been of interest for the preparation of benzannelated annulenes (4–6). Although the structure of **2** has also been determined by X-ray crystallography (7),[4] the details are neither in the open literature nor in the Cambridge Crystallographic Database. Therefore, we report here the derived geometric parameters of **1** and **2**, as well as a comparison between those common to both structures. In view of the unique structure of the central tricyclic cage common to both **1** and **2**, which also contains a highly strained 3-membered ring, we have computed the structure using hybrid DFT methods at the B3LYP/6–311(d,p) level of theory. There is excellent agreement between the calculated gas-phase and the measured solid-state geometries.

Experimental

Compound **1** was prepared as reported in ref. 1. Its high-resolution mass spectrum (EI, 70 eV) is consistent with the proposed formula, displaying only five high-intensity peaks

 doi:10.1139/V07-058 © 2007 NRC Canada

as follows: 274.1356 (calcd. for $C_{20}H_{18}O^+$ 274.1358, 81%); 259 ($C_{19}H_{15}O^+$, 100%); 244 ($C_{18}H_{12}O^+$, 64%); 228 ($C_{18}H_{12}^+$, 74%); and 215 ($C_{17}H_{11}^+$, 70%). Significantly, there is no peak resulting from a retro Diels–Alder process. NMR data (^{1}H, ^{13}C, ^{1}H–^{1}H COSY, HMBC, and HSQC experiments) of **1** were collected on a Bruker AVANCE-II spectrometer operating at 300.13 MHz for ^{1}H and 75.41 MHz for ^{13}C and are reported w.r.t. the $CHCl_3$ (^{1}H: 7.29 ppm) and $CDCl_3$ (^{13}C: 77.23 ppm) resonances. ^{1}H: δ 1.07 (s, 3H), 1.29 (t, J = 1.3 Hz, 1H), 2.44 (s, 1H), 2.75 (s, 1H), 2.93 (s, 1H), 3.55 (s, 3), 7.04–7.26 (m, 7H), 7.5–9 (d, J = 8.0 Hz, 1H). Selective decoupling at 2.93 and 2.75 ppm collapsed the 1.29 ppm triplet to a doublet, while decoupling the singlet at 2.44 ppm had no effect. Irradiation of the singlet at 2.93 ppm sharpened the signal at 2.44 ppm. ^{13}C: δ 10.92, 35.05, 38.41, 44.52, 49.82, 56.95, 57.76, 74.97, 121.80, 121.88, 123.24, 124.71, 124.83, 125.03, 125.29, 126.57, 135.28, 136.00, 149.34, 149.54.

Details of the crystal and the structure determination of **1** are summarized in Table 1. The space-group determination was problematic. Statistics favored *Pbcm*, but we were unable to solve the structure in this space group. The second choice $Pca2_1$, No. 29, is a polar non-centrosymmetric space group. The structure was solved by direct methods using SHELXS (8), expanded using Fourier techniques, and refined with SHELXL (9). Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using a riding model. Neutral atomic-scattering factors were taken from the International Tables (10). Selected bond distances and angles are presented in Table 2, and an exhaustive listing is provided in the Supplementary Materials.[5] A thermal ellipsoids plot showing the structure of **1** and the atom-numbering sequence used for both **1** and **2** throughout the discussion is presented in Fig. 1. Since all H atoms are placed by geometry, their positions are only approximate. The approximate shortest contacts in the structure are between C3 and H7 (2.73 Å), C4A and H6A (2.88 Å), C3 and H10 (2.88 Å), and C9 and H3 (2.86 Å), all just slightly shorter than the sums of the van der Waals radii of C and H (2.90 Å).

The starting point for the DFT calculations was the crystal geometry of **1**, imported via Mercury 1.4.1 (11) into GaussView (12). Calculations were performed in the Gaussian 98W suite of programs (13), and the converged minimum structures were confirmed by frequency calculations, which report no imaginary frequencies.

Results and Discussion

The structure of **1** is depicted in Fig. 1 (one enantiomer). The central tricylic structure consists of two cyclohexane rings in twist-boat conformations that share four adjacent atoms along one "side" of the boat. One end of each boat participates in a fused cyclopentane ring, which itself is in an envelope conformation; the other end is bridged on the non-fused side by a single bond, thereby creating a cyclopropane ring. Angles within the six-membered rings deviate considerably from the ideal tetrahedral angle (avg. deviation = 7 ± 2°) mostly to expanded values, while in the five-membered ring, the angles are highly compressed (avg. deviation = 8 ± 5°). The cyclopropane ring is close to ideal (avg. angles = 60.0 ± 0.7°).

The crystal structure of **2** was determined many years ago by photographic methods (7), but it is only available in a

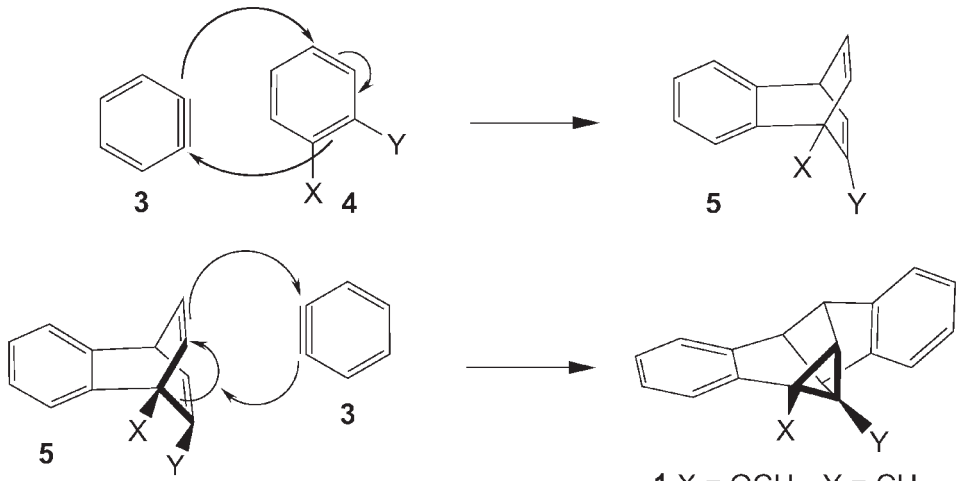
Ph.D. thesis (14). In Table 2, we compare bond lengths and angles for this structure with those that we obtained for **1**. As expected, the more-recent structure determination is more precise: the average value of the standard deviations in bond distances is 0.18% in **1** and 0.31% in **2**, while for bond angles, these values are 0.14% and 0.32%, respectively (15). While significant, the small absolute differences speak to good precision for the older structure. The largest deviation between the two X-ray structures is in the C6—C12 cyclopropane-ring bond, which in **2** is 0.09 Å shorter than in **1** (1.9% deviation). Only three other bond distances deviate by more than 1%: C6B—C7, C4A—C5, and C4A—C11B. Similarly, only six internal bond angles differ between the two X-ray structures by more than one percent, and these are all angles associated with atoms of the central cage (C5, C6, C6A, C11A, and C12).

The structures of **1** and **2** are due to Diels–Alder addition of benzyne to a benzene derivative (Scheme 1). The first step is a 1,4-cycloaddition to give a benzobarrelene **5**; it is well-known that tetrahalobenzynes react with toluene to give adducts in which the non-bridgehead product predominates; whereas in the addition to anisole, the bridgehead adducts predominate (16, 17). The proposed intermediate **5** (X = OCH_3, Y = CH_3) is therefore the expected product from the addition of benzyne, **3**, to 2-methylanisole, **4** (X = OCH_3, Y = CH_3). Subsequent 1,3-cycloaddition by a second molecule of benzyne to the 3,5 carbon atoms gives the observed products (Scheme 1).



The closest-related structure to **1** and **2** in the Cambridge Database is that of dimethyl-1-cyano-1,1a,2,8,8a,8b-hexahydro-2,3,8-methanetriylcyclopropa[*a*]fluorene-3,3a-dicarboxylate (**6**) (18, 19). This molecule shares the same

Scheme 1. Proposed mechanism for the synthesis of **1** and **2**.

central-cage structure, the "horizontal" fused benzo group, and a single substituent on the C6 atom of the cyclopropane ring.

There is notable agreement among the three X-ray structures (**1**, **2**, and **6**) that contain the same strained central carbon cage. The greatest variance is found within the fused cyclopropane rings. To further characterize this unusual strained cage structure, we have performed full structure optimizations using modern DFT methods. The geometrical results of these calculations are also included in Table 2. The normalized average deviations between calculated bond distances from the gas-phase theoretical and the solid-state experimental structure determinations is 0.41% for **1** and 0.72% for **2**. For the bond angles, these values are 0.44% and 0.35%, respectively. The computed structure of **2** adopts

[a]Taken from ref. 6 (^{1}H in CD_2Cl_2, ^{13}C in $CDCl_3$); quart: 151.0, 151.0, 136.5, 135.5; tert: 126.8, 125.8, 125.6, 124.9, 124.5, 122.0.

[b]Compare with 2.8 ppm for the bridgehead position in norbornene.

[c]Compare with 42 ppm in norbornene.

[d]Compare with 49 ppm in norbornene.

C_s symmetry naturally; the computed structure of **1** has a remarkably similar orientation of the flexible O1–C14 methoxy substituent groups to that found in the solid-state structure, though the angles associated with this group had the largest normalized deviation in the case of **1**. In contrast to the good agreement to the DFT calculations, the geometry reported for **2** obtained from a Consistent Valence Force Field contains deviations as high as 6% among the seven internal bond distances listed for comparison (normalized avg. deviation = 2.7%) (4).

The NMR spectra of **2** are consistent with the structure determined from the X-ray diffraction study. Taken as a whole, the 1D and 2D NMR experiments support the assignments in Table 3.

Diastereoselective formation of 18-membered ring BINOL-hydrogen phosphonate dimers — Quasi-covalent hydrogen bonds?

Hossein A. Dabbagh, Nader Noroozi-Pesyan, Ali R. Najafi-Chermahini, Brian O. Patrick, and Brian R. James

Abstract: Diastereoselective syntheses of the unusual dimers, 4-heptyl-2-(2′-hydroxy-binaphthyl)hydrogen phosphonate (**5**) and the cyclohexyl analogue (**7**), are achieved by hydrolysis of 4-(3,5-dioxa-4-phosphacyclohepta[2,1-α;3,4-α′]-dinaphthalene-4-yloxy)heptane (**4**) and the cyclohexane analogue (**6**), respectively. Two out of eight possible pairs of monomers units are involved in the stereoselective formation of the dimer **5a** of configuration $BINOL_R$-P_S:$BINOL_R$-P_S; this is determined by X-ray crystallographic data, which reveal a centrosymmetric, 18-membered ring structure with C_i symmetry, consisting of two monomers strongly hydrogen-bonded between the oxygen of P=O units and hydroxyl hydrogen atoms. Mass spectrometric, melting point, and thermal decomposition point data, as well as NMR data, support the presence of strong, quasi-covalent hydrogen bonds. Computational analysis suggests that the diastereoselectivity is controlled by molecularly constrained geometry of the monomer. Compound **7**, although not characterized crystallographically, appears to be analogous to **5**.

Key words: 18-membered ring, phosphonate dimer, diastereoselectivity, hydrogen-bonds, computational analysis.

Résumé : On a réalisé les synthèses diastéréosélectives des dimères inhabituels du phosphonate acide de 4-heptyl-2-(2N-hydroxybinaphtyle) (**5**) et de son analogue cyclohexyle (**7**) par le biais de l'hydrolyse respectivement du 4-(3,5-dioxa-4-phosphacycloheptane[2.1-α;3,4-α′]dinaphtalène-4-yloxy)heptane (**4**) et de son analogue cyclohexane (**6**). Deux des huit paires possibles d'unités monomères sont impliquées dans la formation stéréosélective du dimère **5a** de configuration $BINOL_R$-P_S:$BINOL_S$-P_R; cette conclusion est basée sur des données de diffraction des rayons X qui mettent en évidence l'existence d'une structure cyclique centrosymétrique à 18 chaînons de symétrie C_i, formée de deux monomères reliés fortement par une liaison hydrogène entre l'oxygène des unités P=O et les atomes d'hydrogène des hydroxyles. Les données de spectrométrie de masse, de point de fusion et de point de décomposition thermique ainsi que les données de la RMN sont en accord avec la présence de liaisons hydrogènes fortes et de nature pratiquement covalentes. Une analyse par des calculs théoriques suggère que la diastéréosélectivité est contrôlée par la géométrie fixée d'une façon moléculaire du monomère. Même si le composé **7** n'a pasété caractérisé d'une façon cristallographique, il semble être analogue au composé **5**.

Mots-clés : cycle à 18 chaînons, dimère de phosphonate, diastéréosélectivité, liaisons hydrogènes, analyse par des calculs théoriques.

[Traduit par la Rédaction]

Introduction

During studies aimed at developing new chiral phosphine ligands based on the binaphthol backbone, we accidentally discovered a dimeric structure maintained by two exceptionally strong hydrogen bonds, and this work is described here.

Hydrogen bonding plays a key role in biology and chemistry and remains a topic of intense current interest, as judged by an enormous continuing amount of literature. A few selected recent articles exemplify the general scope of the topic, ranging from the role of H bonding in: weak interactions in the gas phase (1), supramolecular assemblies (2), helical structures (3), promoting catalytic enantioselective reactions (4), molecular rotors (5), through to measurement of H-bond acidity of organics (6). Important consequences of both inter- and intra-molecular H bonding have long been recognized in the physiochemical behavior of DNA and RNA (7), while H bonding within phosphorus systems, of

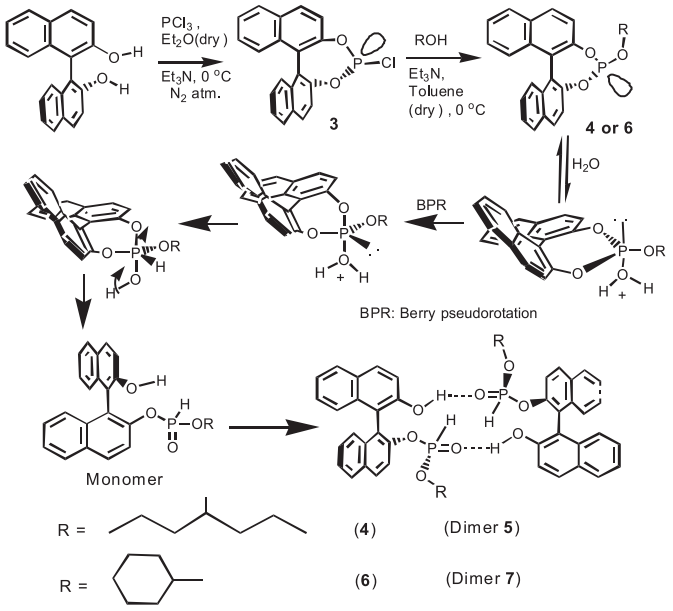
Table 1. Classification of hydrogen bonds within P-containing systems.

Linkages	Bond distance [range, donor---H---acceptor] (Å)	Strength
P-O-H---O-P	2.39–2.50	Very strong
P-OH---O-P	2.50–2.70	Strong
P-O-H---O-C	2.41–2.82	Strong
P-H---OH_2	2.56–3.15	Moderate
P-O---H-N	2.65–3.10	Moderate
C-O-H---O=P[a]	2.70	Strong



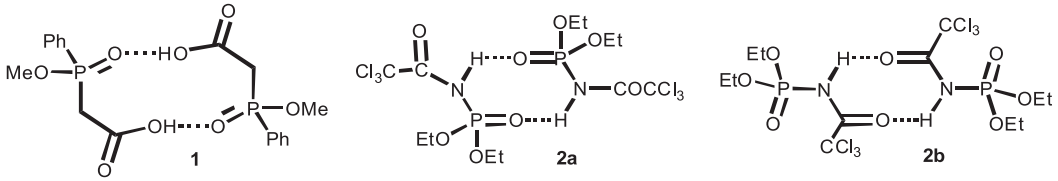
Note: Data taken from from refs. 8*a*, 10*b*, 10*f*, and 11*a*.
[a]Determined by an X-ray crystallographic study of **5a** (see Scheme 2 and Fig. 1).

relevance to our paper, is also well documented (8). Some contributions from our collaborative group have also demonstrated the importance of hydrogen bonding in determining the structure, conformation, energy, and reactivity properties of a molecule (9).

The factors determining the strength of a hydrogen bond, other than electronegativities of the donor and acceptor atoms, remain of interest. Homonuclear linear O---H---O bonds are well understood and display a practically continuous range of O---H---O distances from 2.36 to 3.69 Å: the upper value is the sum of the van der Waals radii and not a physical limit of the hydrogen-bond interaction that has been qualitatively defined as very strong (<2.50 Å), strong (2.41–2.82 Å), medium (2.56–3.15 Å), or weak (>3.15 Å); see Table 1 (8*a*, 10, 11). The strongest hydrogen bonds are seen in homonuclear linear or nearly linear systems with an O–H–O angle > 165°; the energies of bent O–H–O systems have been evaluated computationally and are 90%, 60%, and 10% of the linear system value for angles of 165°, 149°, and 110°, respectively (10*b*, 11*a*). A unified hydrogen bond theory has been presented in which O---H---O bonds are divided into five classes: negative charge-assisted $[–O---H---O–]^-$ (a strong H bond); positive charge-assisted $[=O---H---O=]^+$ (strong); resonance-assisted [-O–H---O=] (strong), where the two oxygens are connected by a π-conjugated system of variable length, including cases where the oxygens are attached to P or As atoms; polarization-assisted [---O(R)–H---O(R)H---] (moderate); and isolated H bonds [-O-H---O(R)(R)] (weak) (11*a*). Of note, a recently reported variable-temperature X-ray crystallographic and DFT computational study of the N-H---O/N---H-O tautomeric competition in 1-(arylazo)-2-naphthol has led to a transition-state hydrogen bond theory (12).

Our current work, based on designing chiral phosphines, prompted us to synthesize 4-(3,5-dioxa-4-phosphacyclohepta[2,1-α;3,4-α′]-dinaphthalene-4-yloxy)heptane (**4**) and the corresponding cyclohexane analogue (**6**) (see Scheme 1). During the attempted purification of **4** and **6**, we discovered their hydrolysis products, which proved to be the dimeric

Scheme 1. Formation of the dimeric phosphonates.



structures, 4-heptyl-2-(2′-hydroxybinaphthyl)hydrogen phosphonate (**5a**) and the cyclohexyl analogue (**7a**) (the "**a**" label refers to a particular stereoisomer of these dimers — see later). The 18-membered ring structure of these dimeric compounds is maintained by the presence of two strong hydrogen bonds, as discussed later (see Scheme 1).

Results and discussion

Prior to a discussion of compounds **5a** and **7a** and their unusual structures, it is best to introduce some general comments about H bonding in phosphorus compounds. The degree of such bonding, which is seen in the solid, liquid, and solution states, varies depending on the solvent, temperature, and the nature of the substituent group on the P atom. Most phosphorus acids form dimers with strong H bonds within a 6- to 10-membered ring (8*a*), although the esters $(RO)PO(OH)_2$ (R = 3-methylhexyl or *n*-octyl) are polymers containing intermolecular H bonding (8_a). Relevant to our paper, aryl H-phosphonates have been synthesized and characterized by ^{31}P NMR spectroscopy (13).

Dimeric centrosymmetric ring structures are quite common within phosphorus chemistry: **1** and **2** exemplify 12- and 8-membered ring structures, respectively (8*a*), and according to spectroscopic evidence, esters of (trichloroacetyl)amidophosphoric acid exist as **2a** rather than **2b**, which suggests that the H bond in N-H---O=P is more stable than that in N-H–O=C (8*a*).

Although lower oxy-acids of phosphorus were initially

© 2007 NRC Canada

thought to exist primarily in tautomeric forms in which the central atom was trivalent, it is now well-established that the majority of such compounds prefer structures that incorporate formally pentavalent phosphorus (8*a*, 14). A detailed analysis of bond and contact distances has suggested that when the O---O interaction is decreased from 2.80 to 2.40 Å, the H bond is transferred from a symmetrical O---H---O electrostatic interaction to a covalent unsymmetrical O–H---O bond (10*b*, 11*a*).

Synthesis of the BINOL phosphonates and solution NMR characterization (Scheme 1)

Hydrolysis of the phosphate esters 4-(3,5-dioxa-4-phosphacyclohepta[2,1-α;3,4-α′]-dinaphthalene-4-yloxy)heptane (**4**) and the cyclohexane analogue (**6**) produced what initially are the respective monomers, 4-heptyl-2-(2′-hydroxybinaphthyl)hydrogen phosphonate (**5m**) and the 4-cyclohexyl analogue (**7m**). The monomers, being chiral at phosphorus coupled with the axial chirality of the BINOL moiety, can exist theoretically in four possible configurations ($BINOL_R$-P_R, $BINOL_R$-P_S, $BINOL_S$-P_S, $BINOL_R$-P_S). Of interest, both precursor monomers appear to dimerize selectively with their mirror images to form the 18-membered ring dimers; certainly, the structurally characterized **5a** (see later) has the configuration $BINOL_R$-P_S:$BINOL_R$-P_S, maintained by two strong hydrogen bonds, while a second stereoisomer seen in solution (**5b**, see later) could be the $BINOL_R$-P_R:$BINOL_S$-P_S form. The analogous system based on **7** is considered from NMR data to behave similarly.

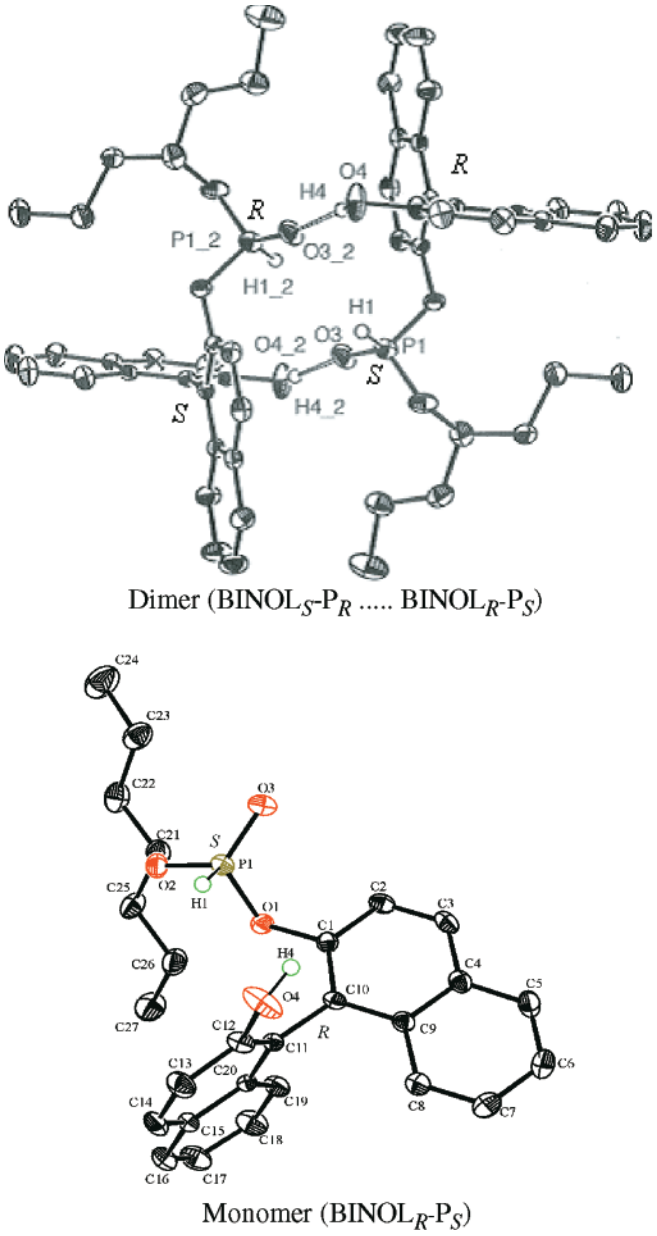
The necessary precursor reagent 4-chloro-3,5-dioxa-4-phosphacyclohepta[2,1-α;3,4-α′]-dinaphthalene (**3**) was prepared by reaction of PCl_3 with 2,2′-dihydroxy-1,1′-binaphthyl (BINOL) in dry Et_2O under an N_2 atmosphere, using procedures from the literature (15). This chloro compound was used without purification in the next step for the production of the phosphate esters **4** and **6** by treatment with the appropriate alcohol, 4-heptanol, or cyclohexanol, respectively. The esters were isolated in 70%–80% yields as yellow powders. The heptyl ester **4** was characterized in solution by ^1H NMR (with signals assigned for the methyl, methylene, and methyne protons of the heptyl group and the 12 binaphthyl protons) and a $^{31}P\{^1H\}$ singlet at δ 146. The corresponding cyclohexyl analogue **6** similarly showed three sets of ^1H signals for the 10 methylene protons, the single CH proton, and binaphthyl protons, as well as a $^{31}P\{^1H\}$ singlet at δ 150.

The remarkable hydrolysis products from **4** and **6** were accidentally synthesized by leaving acetone solutions of the esters in air at ambient temperatures for several days. After work-up procedures and purification by recrystallization, the respective yellow solid products 4-heptyl-2-(2′-hydroxybinaphthyl)hydrogen phosphonate (**5**) and the cyclohexyl analogue (**7**) were isolated as dimeric forms, based on NMR and MS data and an X-ray analysis of **5a**.

Analysis of crude samples of **5** by solution ^1H, $^1H\{^{31}P\}$, ^{31}P, and $^{31}P\{^1H\}$ NMR spectroscopy (see Experimental section) showed two major components **5a** and **5b**, two minor components **5c** and **5d**, and a trace amount of an unknown compound **5x** (Figs. S1–S8).[2] The ^{31}P NMR spectrum of pure **5a** (grown as a single crystal from a cyclohexane-CH_2Cl_2 solution of crude **5**) is a doublet of doublets centered at δ 3.80 because of coupling to two protons ($^1J_{PH}$ = 707, $^3J_{PH}$ = 10.7 Hz), as confirmed by a ^1H-decoupled spectrum that generates a $^{31}P\{^1H\}$ singlet; the $^1J_{PH}$ value is in the expected range (16). The ^1H NMR spectrum for **5a**, showing signals for the heptyl and binaphthyl protons, is consistent with the solid-state structure described later; the PH proton of **5a** is seen as a doublet at δ 6.65 ($^1J_{PH}$ = 703 Hz), which collapses to a singlet in the $^1H\{^{31}P\}$ spectrum. A $^{13}C\{^1H\}$ NMR spectrum of **5a** shows 27 signals corresponding to the number of binaphthyl and heptyl carbon atoms (20 and 7, respectively). Although **5a** was the only compound isolated in a pure state, it was not difficult (e.g., from the relative peak heights of the doublet of doublet patterns seen in the $^{31}P\{^1H\}$ spectra and relative intensities of the various ^1H resonances) to determine the NMR assignments (from data for mixtures) associated with what are possibly other stereoisomers (i.e., **5b**, **5c**, and **5d**, see later); similar reasoning allowed for the determination of resonances associated with each of **7a**–**7d**.

The NMR spectra of **5b** are similar to those of **5a**, and similar data are seen for **5c**, but for this species the ^{31}P shift is centered at δ 8.80; **5d** is characterized by just a doublet centered at δ 5.45 in the ^{31}P spectrum with a $^1J_{PH}$ value of 720 Hz. The structure of **5a** was elucidated by X-ray crystallography, while relevant EI and ES mass spectrometric data were also measured (see later).

The cyclohexyl-2-(2′-hydroxybinaphthyl)hydrogen phosphonate (**7**), like **5**, was isolated as a pale yellow solid. ^{31}P, $^{31}P\{^1H\}$, ^1H, and $^1H\{^{31}P\}$ NMR analysis revealed again the presence of two major components, **7a** (40%) and **7b** (38%), and two minor components, **7c** (18%) and **7d** (4%); Figs. S9 and S10.[2] Unfortunately, we were unsuccessful in obtaining any crystals of **7** suitable for X-ray analysis. However, the NMR data correspond closely to those measured for the **5a**–**5d** mixture (after allowance for the replacing of the 4-heptyl by a cyclohexyl moiety), and the structure of **7a** is likely to be analogous to that of **5a** but with a different R group (Scheme 1).



X-ray structure of 5a

The X-ray crystallographic analysis of **5a** reveals the essential monomer structure **5m** shown in Fig. 1 (see also Scheme 1), while the unit cell reveals two such monomer units interacting strongly via two hydrogen bonds between phosphonate P=O moieties and the OH groups of the BINOL; an overall centrosymmetric dimer structure for **5a** is seen with an 18-membered ring with C_i symmetry (Fig. 1

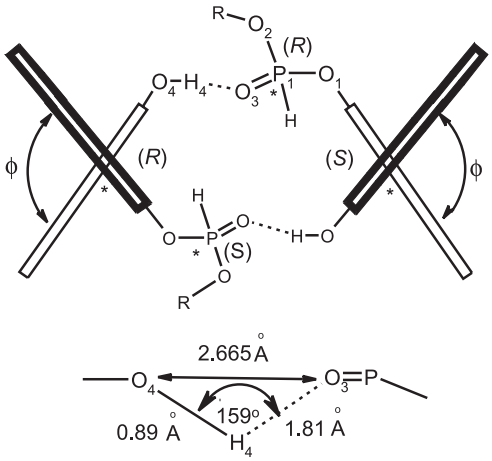

Fig. 1. Molecular structure of dimer **5a** (top) and monomer **5m** (bottom).

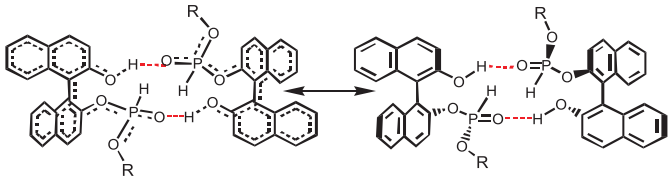
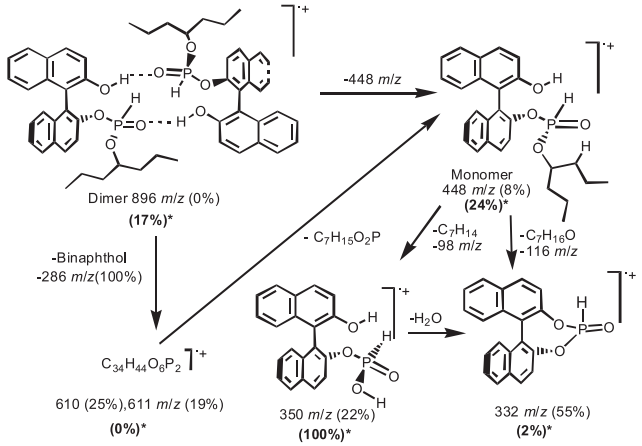


and Schemes 2 and 3). The torsion angles between the two BINOL rings are ~96°, favoring the *s*-transoid conformation. One of the BINOL units in the dimer structure necessarily has *R* axial symmetry and the other unit has *S* symmetry.

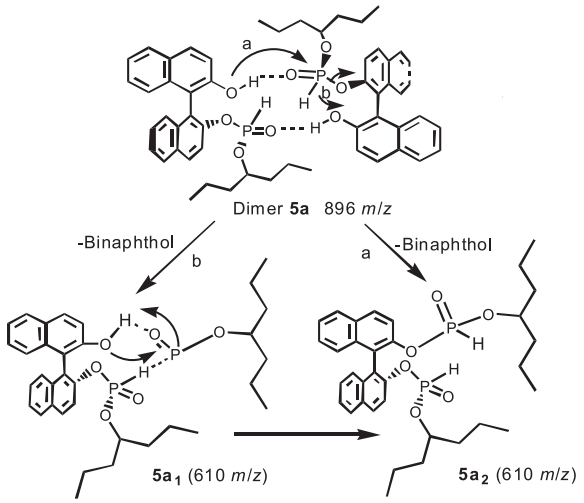
As expected, the P=O bond is some 0.1 Å shorter than the P–O bonds in the binaphthyl and heptyl groups, which are 1.58 and 1.55 Å, respectively. Within the hydrogen bonds, the distance between the hydroxyl-H and the acceptor-O atom is 1.81(2) Å, while the bond length for the hydroxyl group is 0.89(2) Å, and the O–H---O bond angle is 159°; the distance between the oxygens of the O---H-O moiety is ~2.70 Å, implying the presence of a strong hydrogen bond within this P=O---H-O-C system (Scheme 2 and Table 1). The strength of hydrogen bonding in the dimer may result from contributions of resonance-assisted and (or) polarization-assisted hydrogen bonds (see Introduction and Table 1),



Scheme 2. Diagram showing hydrogen bonding within the dimer.

Scheme 3. Diagram showing resonance-assisted hydrogen bonding.

Scheme 4. Summary of the mass spectral data. Values in parentheses are the % base peak from EI. Values in boldface marked with asterisks (*) are the % base peak from TOF MS Electron Spray (ES$^+$).



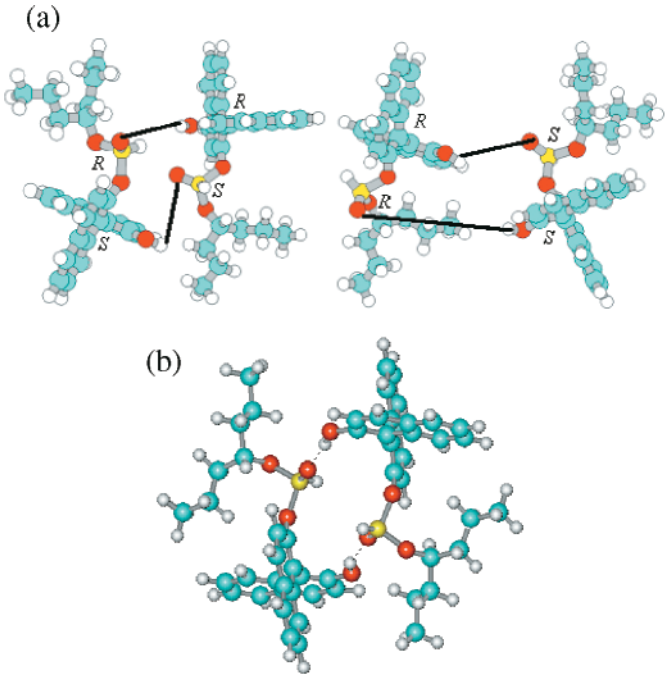
while the deviation from linearity of the O–H---O angle likely allows for a decrease in strain energy of the dimer structure (Scheme 3). More information supporting the presence of strong hydrogen bonds in **5a** was gleaned from mass spectrometric data.

Mass spectroscopic analysis

Positive ion electrospray mass spectral data for a solution of **5a** in CH_3OH–$CHCl_3$ showed molecular ions of *m/z* values around 897 corresponding to the dimer formulation M_2^+, 449 corresponding to the monomer M^+, and a 100% base peak at 350 corresponding to [BINOL + PO_2H]. Electron

© 2007 NRC Canada

Scheme 5. Plausible pathways for fragmentation of dimer 5a.

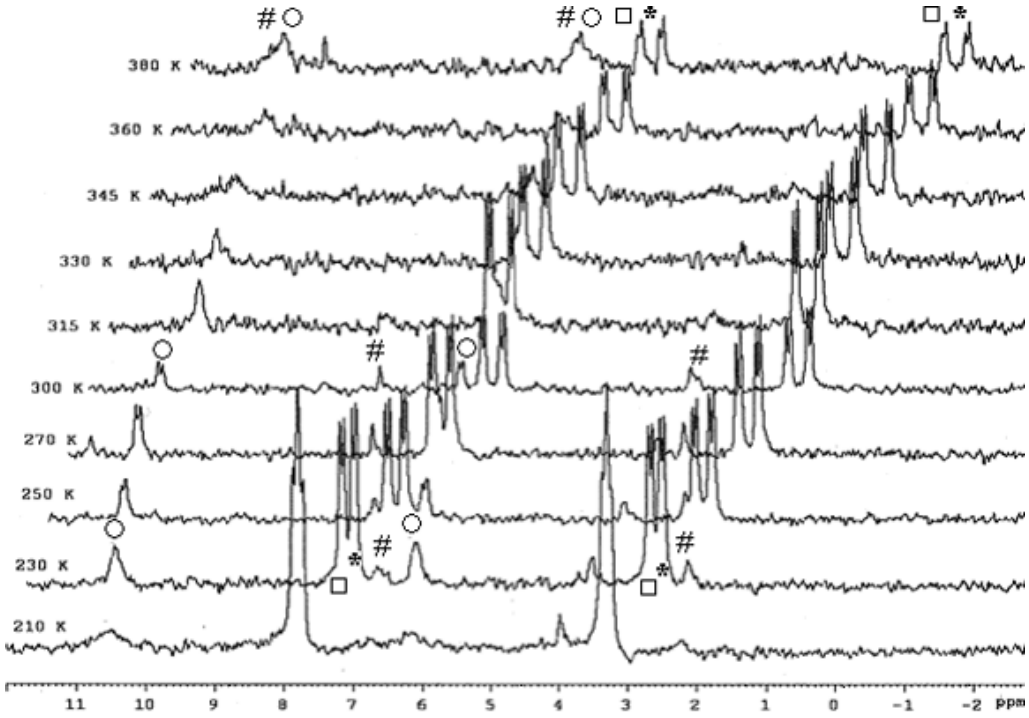


impact MS data did not show M_2^+ and instead revealed a 610/611 fragment (not detected by the ES analysis), a peak for M^+, the 350 peak, a peak at 332, and a 100% base peak at 286 for binaphthol. Scheme 4 summarizes these MS data and the formulations that correspond to the *m/z* values.

The percent abundance in the EI spectrum of the M^+ 448 peak is only about a fifth that of the 610/611 fragment, implying that cleavage of one P–O_{BINOL} bond and one [O–H---O] H-bond to form the 610/611 fragment takes preference over cleavage of the two H bonds to form the monomer; this suggests that the hydrogen bonding is strong (as indicated by the O---H---O structural data) and indeed even implies strength comparable to that of a P–O bond (at least under the EI conditions!). The reverse situation pertains to ES conditions where the monomer is formed exclusively (with the 350/332 fragments) from the dimer with respect to the 610/611 fragment; presumably, methanol breaks down most of the dimer structure by hydrogen-bond formation and prevents the intramolecular rearrangement required to produce the 610 fragment (Scheme 4).

Plausible mechanisms for the conversion of dimer **5a** to fragment 610 *m/z* (depicted by structures **5a$_1$** and **5a$_2$**) are outlined in Scheme 5 and involve direct loss of binaphthol from the dimer to give **5a$_1$** (step b), rearrangement of **5a$_1$** to **5a$_2$**, or direct nucleophilic attack by a binaphthol oxygen of one monomer at the phosphorus of the second monomer to give **5a$_2$** again with loss of binaphthol (step a). The facts that (*i*) the 610 fragment is not seen in the ES-MS, (*ii*) the polar methanol solvent does not break up completely the hydrogen bonds of the dimer, and (*iii*) judging by the sharp melting point at 144 to 145 °C (the hydrogen bonds likely remain intact at this temperature) are all consistent with the [O---H---O=P] hydrogen bond of the dimer being as strong as the P-O_{BINOL} bond. The loss of BINOL would then release strain to give **5a$_1$**, which could rearrange to **5a$_2$**. Justification of the direct rearrangement of the dimer **5a$_1$** to **5a$_2$** rearrangement is less obvious: a direct intramolecular nucleophilic attack by an oxygen of a BINOL hydroxyl group is unlikely because methanol is a better nucleophile and should interact more readily with the dimer to breakup the H bonds. However, the strength of H bonds between methanol and

Fig. 2. (*a*) Computer-generated minimum configuration of monomers **5m** using the HF/STO-3G program. Black lines (——) indicate hypothetical points of interactions to form dimers **5a** (left) and **5b** (right). (*b*) Computer-generated minimum configuration of dimer **5a** ($BINOL_R$-P_S---$BINOL_S$-P_R). Dotted lines show computed H bonds.



monomer is considered to be less than that of the H bonding in the dimer (judging by the observation of the M_2^+ ion). As evidenced by the high melting point, the boiling point (~180 °C in air), and thermal stability up to 250 °C (clear liquid at boiling point temperature with no color change), the stability of the dimer that results from the strong ("quasi-covalent") H bonds is remarkable. Liquid dimer, when cooled to room temperature (RT), re-melts again at 144 to 145 °C; when the dimer is placed under vacuum in a sealed capillary tube, decomposition becomes apparent at ~260 °C, with darkening of the color. A $CDCl_3$ solution of the dimer slowly decomposes in air (likely via hydrolysis) at RT to an unknown mixture as shown by ^{31}P NMR spectroscopy (Fig. S11).[2]

Diastereoselectivity of the dimer formation

Monomer **5m** has a chiral P center and axial chirality within the BINOL unit, while the dimer correspondingly has twice as many chiral moieties. The X-ray data of **5a** show the presence of the diastereomers $BINOL_S$-P_R:$BINOL_R$-P_S (meso form), and the NMR data of the crystal dissolved in $CDCl_3$ are consistent with the same structure. The solution NMR spectra of the crude sample show that the major component corresponds to **5a**; seen also are very similar resonances for the other major component (**5b**) and those of two minor ones (**5c** and **5d**), which have the same ^1H and ^{31}P NMR patterns as **5a** and **5b**, but as noted earlier the ^{31}P shifts are about 4 and 1 ppm downfield, respectively, from those of **5a** and **5b** (Figs. S1-S5).[2]

© 2007 NRC Canada

Fig. 3. Variable temperature ^{31}P NMR spectra of crude mixture of 4-n-heptyl-2-(2′-hydroxybinaphthyl)hydrogen phosphonate **5a** (*), **5b** (□), **5c** (○), and **5d** (#) in $CDCl_3$.

Computational analysis of the molecular geometry of the monomers predicts that only two enantiomeric pairs of these, with configurations $BINOL_R$-P_S:$BINOL_R$-P_S and $BINOL_R$-P_R:$BINOL_S$-P_S, have the appropriate geometry to interact and form the dimers (see Figs. 2, S12 and S13).[2] The first combination ($BINOL_R$-P_S:$BINOL_R$-P_S) is that found experimentally for **5a**, while the non-isolated **5b** is most likely of the $BINOL_R$-P_R:$BINOL_S$-P_S configuration. Other double combinations of monomers via hydrogen bonding to form the six other diastereomers are not possible because the monomers do not have the appropriate configurations, as seen in Fig. S12.[2]

Variable temperature ^{31}P NMR data from 210–380 K (Fig. 3) indicate that the chemical shifts of the major components (**5a** and **5b**) do not vary much with temperature, while those of the minor components (**5c** and **5d**) do. The NMR behavior is reversible, and the original ratio of isomers was seen on cooling the solution to 230 K; the data are qualitatively consistent with reversible conversion of dimers to monomers with increasing temperature, and so speculatively **5c** and **5d** might be monomeric diastereomers.

NMR and MS data on the mixture of major species **7a** and **7b** and minor species **7c** and **7d**, in which the 4-heptyl group of **5** has been replaced by cyclohexyl, suggest behavior similar to that found for the 4-heptyl system.

Conclusions

The dimer 4-heptyl-2-(2′-hydroxybinaphthyl)hydrogen phosphonate, accidentally synthesized by hydrolysis of 4-(3,5-dioxa-4-phosphacyclohepta[2,1-α;3,4-α′]-dinaphthalene-4-yloxy)heptane at RT, is a centrosymmetric 18-membered ring structure consisting of monomers, strongly hydrogen bonded via two P=O---H–O moieties; a corresponding cyclohexyl analogue appears to behave similarly. Racemic BINOL was used as a precursor reagent, but only two out of the eight possible diastereomeric dimers are formed from the racemic mixture of monomers. The diastereoselective formation of the H-bonded dimers is controlled by molecularly constrained geometry of the monomer.

Experimental

The various NMR spectra were recorded at RT (~20 °C) in $CDCl_3$ solution (unless stated otherwise) on Varian 90 MHz or Bruker AV 300 or 400 MHz instruments; singlet (s), doublet (d), triplet (t), multiplet (m), quintet (quin), broad (br); *J* values are given in Hz. FT-IR spectra (KBr, reported in cm^{-1}) were obtained on a Shimadzu IR-470 instrument. MS data (stated as *m*/*z* values) were acquired on Kratos Concept IIHQ LSIMS or Bruker Esquire ESI instruments. The computational analyses were performed using HyperChem pro 6.0, with PM3 calculations optimized by Polak-Ribiere algorithms. The PM3 optimized geometries were then taken for further optimization with the HF/STO-3G basis set. Racemic 1,1′-bi-2-naphthol (BINOL) was either purchased or prepared by a reported method (17).

X-ray crystallographic analysis of 5a

Measurements were made at –100 °C on a Rigaku ADSC CCD area detector with graphite monochromated Mo Kα radiation (λ = 0.710 60 Å). The final unit-cell parameters were based on 7004 reflections with 2θ = 4.2°–55.7°. The data were collected and processed using the d*TREK program (18). The structure was solved by direct methods (19) and

expanded using Fourier techniques (20). The non H atoms were refined anisotropically, while the H atoms were included but not refined. Some of the crystallographic data are given in Table 2, while selected bond lengths and angles are given in Tables 3 and 4, respectively.

4-Chloro-3,5-dioxa-4-phosphacyclohepta-[2,1-α;3,4-α′]-dinaphthalene (3)

In a 250 mL, two-necked flask, maintained at ~0 °C and equipped with a magnetic stirrer, freshly redistilled PCl_3 (1.5 mL, 17.2 mmol) was dissolved in 50 mL of dry Et_2O under N_2. To this solution was added BINOL (3.67 g, 13 mmol) in 100 mL of dry Et_2O, followed by Et_3N (4.3 mL, 14.9 mmol) dropwise, and the solution was stirred for 20 h at ~0 °C. The reaction mixture was then filtered, and the residue was washed with 5 mL of dry Et_2O; solvent was evaporated under vacuum from the filtrate to yield a yellow solid. IR: 3500 (m), 3100 (m), 1620 (s), 1590 (s), 1500 (s), 1210 (s), 960 (s), 820 (s), 750 (s). ^{1}H NMR (CCl_4) δ: 7.3–7.7 (m, 8H), 8.0–8.3 (m, 4H). ^{31}P NMR ($CDCl_3$) δ: (s, 178.8). Compound **3** was used without further purification for the synthesis of **4**.

4-(3,5-Dioxa-4-phosphacyclohepta[2,1-α;3,4-α′]-dinaphthalene-4-yloxy)heptane (4)

Under conditions used for the preceding synthesis, to compound **3** (1.50 g, 4.3 mmol) dissolved in 20 mL dry toluene was added 4-heptanol (0.50 g, 4.3 mmol). To this solution at 0 °C, Et_3N (2.5 mL, 8.6 mmol) was added dropwise, and the mixture was stirred for 48 h, with the reaction progress being monitored by TLC. The white solid $[Et_3NH]^+Cl^-$ was removed by filtration, and the filtrate evaporated to dryness to give a light yellow solid, which was then washed through a silica gel column using cyclohexane – ethyl acetate (9:1); the fraction containing **4** was evaporated to dryness and the solid residue was recrystallized from the same solvent mixture to yield pure **4** in 80% yield. Melting point 124–126 °C. IR: 3050 (w), 2900 (m), 2850 (m), 1620, (m), 1580 (s), 1500 (s), 1375 (s), 1320 (s), 1060 (m), 950 (s), 930 (s), 820 (s), 750 (s), 695 (m), 640 (m), 550 (m). ^{1}H NMR δ: 0.8–1.7 (m, 6H, C*H*$_3$; and 8H, C*H*$_2$), 4.1–4.5 (m, 1H, C*H*), 7.2–8.2 (m, 12H, binaphthyl). ^{31}P{^{1}H} δ: (s, 146.0).

4-*n*-Heptyl-2-(2′-hydroxybinaphthyl)-hydrogen-phosphonate (5)

The compound was prepared by allowing compound **4** to stand in air at ambient temperature for days, either in the solid state or in acetone solution. A mixture of species is formed but one, labeled **5a**, was isolated as pale yellow crys-

Electrocatalytic hydrogenation of octyl aldehyde over Pd catalysts

Ciprian M. Cirtiu and Hugues Ménard

Abstract: The electrocatalytic hydrogenation (ECH) of octyl aldehyde (octanal) to octyl alcohol (octan-1-ol) was investigated using commercial Pd/alumina catalysts in aqueous ethanol. The influence of different parameters, such as catalyst support, current intensity, polarity of solvent, supporting electrolyte, and octanal concentration, on the electrocatalytic hydrogenation of octanal was studied.

Key words: octanal, octan-1-ol, Pd/alumina catalyst, electrocatalytic hydrogenation.

Résumé : L'hydrogénation électrocatalytique de l'aldéhyde d'octyl (octanal) à l'alcool d'octyl (octan-1-ol) a été étudiée en utilisant des catalyseurs commerciaux de Pd/alumine en éthanol aqueux. L'influence de différents paramètres, tels que le support catalytique, l'intensité de courant, la polarité du solvant, l'électrolyte support et la concentration en octanal, sur l'hydrogénation électrocatalytique de l'octanal, a été étudiée.

Mots-clés : octanal, octan-1-ol, catalyseur Pd/alumine, hydrogénation électrocatalytique.

Introduction

It is confirmed in the literature (1) that electrocatalytic hydrogenation (ECH) can form the basis of unusually selective electrosynthetic reactions. As demonstrated recently (2), ECH can be a very efficient alternative to the catalytic hydrogenation (CH) of organic compounds. Electrochemical generation of adsorbed hydrogen provides an interesting means to hydrogenate organic compounds. The development of various specific electrodes, which allowed for selective hydrogenation of different classes of organic compounds (3), has improved the ECH technique.

To our knowledge, there are no studies on the ECH of octanal using palladium catalysts. It is well known that palladium catalysts are usually not active for the CH of saturated aliphatic aldehydes (4, 5). However, palladium catalysts are the most active for the CH of aromatic aldehydes under mild conditions. Ruthenium catalysts are very efficient for the hydrogenation of saturated aliphatic aldehydes (4). A promoting effect of stannous chloride has been observed with supported ruthenium and platinum catalysts in the hydrogenation of heptanal (6). Octan-1-ol is obtained in very high yields by the reduction of octanal via BINOL-Zr complex (7).

The difficulty to hydrogenate octanal comes from the stability of the C=O group, which is thermodynamically more stable, in comparison with the C=C group. The development of selective and efficient catalysts is an important requirement for the implementation of ECH in the pharmaceutical and chemical industries. In the ECH mechanism over supported catalysts, adsorption of target molecules onto the inorganic matrix that supported the metallic nanoaggregates represents a crucial step, as demonstrated recently (8). The adsorption, and implicitly the ECH efficiency, can be enhanced by the functionalization of the catalyst matrix.

In the present work, parameters that affect the ECH efficiency, including catalyst support, current intensity, water percentage, supporting electrolyte, and octanal concentration, are studied to obtain preliminary results. This study was motivated by the results obtained previously for the ECH of organic compounds, such as cyclohexanone and benzophenone, which are known to be difficult or completely non-hydrogenable over Pd catalysts.

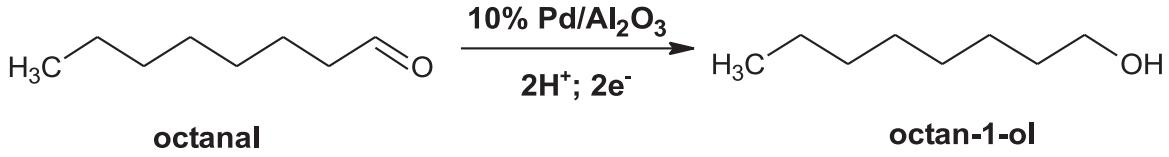
Experimental

Chemicals



Octanal and octan-1-ol (both from Aldrich) were of 99% grade of purity and were used as received. Ethyl alcohol (anhyd.) and high purity water (from a Milli-Q® unit) were used to prepare the solutions. Reticulated vitreous carbon (RVC) (100 pores per inch) (1 inch = 25.4 mm) purchased from Electrolytica Inc. was used as cathode; commercial 10% (*w*/*w*) Pd/alumina powder (reduced, Aldrich) and finely divided Pd (1.1–2.0 μm APS, Alpha Aesar) were used as catalysts in the present study. Glacial acetic acid (HPLC grade, Caledon), butyric (99%, Aldrich), and NaOH solution (10 mol/L) were used for the preparation of the electrolyte solutions.

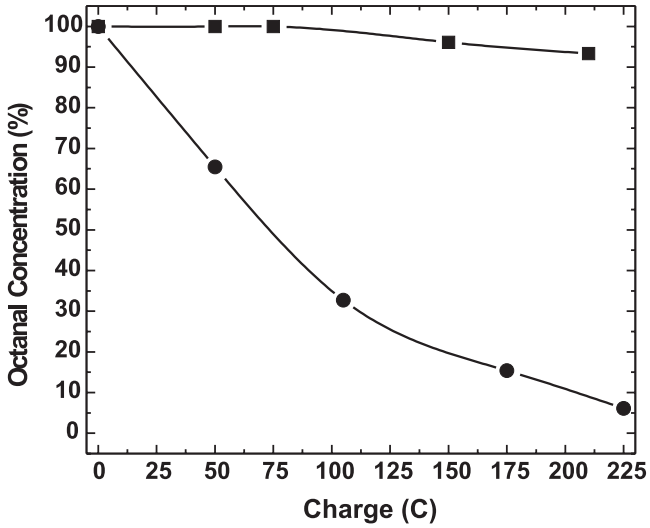
ECH procedure

All the electrolyses were conducted at ambient pressure and temperature in a two-compartment electrochemical reactor (9). The compartment of the cathode was filled with

 doi:10.1139/V07-059 © 2007 NRC Canada

Scheme 1. Reaction scheme for the electrocatalytic hydrogenation of octanal to octan-1-ol.

30 mL of 0.25 mol/L supporting electrolyte (acetate or butyrate buffer solution) in aq. ethanol (variable compositions of H_2O + CH_3CH_2OH). The pH was previously adjusted to 5 with 10 mol/L NaOH. The catalyst (200 mg of 10% Pd/alumina or finely divided Pd) was added to the cathodic compartment solution and dynamically circulated through the RVC cathode. The anodic compartment was filled with 1 mol/L solution of acid buffer in water. All the electrolyses were carried out under galvanostatic conditions (I = 10 mA or 20 mA) using an Agilent galvanostat/potentiostat (6634 B model). The RVC cathode was polarized under an applied constant current (10 or 20 mA); the corresponding charge being equal to 15 °C. The coulometer was reset after polarization; octanal was added in the cathodic compartment (2.6 or 5.2 mmol/L final concentration, depending on the experimental conditions), and 0.5 mL aliquot of mixed solution was immediately removed as reference sample (0 °C) and treated as described in the next section.



Products analyses

The progress of the reaction was monitored by GC. Quantitative analyses were performed on an Agilent 6890 Series chromatograph, equipped with an FID detector and HP-Innowax (crosslinked polyethylene glycol) capillary column (50 m × 0.22 mm × 0.4 μm). Aliquots of 0.5 mL were withdrawn from the electrochemical reactor at different times of electrolysis and were treated as follows: sample was filtered on Millex-HN syringe-driven filter (0.45 μm, Millipore); at 0.4 mL of filtered solution, 0.1 mL external standard (cyclohexanol) was added, and the mixture was injected in the GC. The conversion percentages presented in this study are determined from the GC yields. Both octanal and octan-1-ol were determined by GC. Kinetic curves, represented as relative concentrations vs. charge consumed, are reproducible with a standard deviation of ±3.1%.

Results and discussion

Adsorbed hydrogen is generated at the palladium surface by the electrochemical reduction of water. The brief electrical contact between the RVC cathode and the Pd/alumina particles, or finely divided Pd particles, is enough to charge the metallic aggregates and to produce the atomic hydrogen, which is implied in the hydrogenation process (10). The ECH efficiency, defined as the amount of transformed target species vs. the cumulative charge passed, is determined by the competition among the hydrogenation of the unsaturated compound (Scheme 1), hydrogen evolution, and, in some cases, the direct reduction of the substrate on the electrode surface. Figure 1 presents the remaining fraction of octanal for the ECH over 10% Pd/alumina and finely divided Pd catalysts under identical experimental conditions. Clearly, the supported catalyst is much more effective (nearly 100% conversion) than the non-supported. The same effect was observed in the ECH and CH of other organic compounds (2, 8, 11). The poor yield of hydrogenation using finely divided Pd catalyst is explained by the absence of the adsorption sites located on the catalyst support (alumina in the case of Pd/alumina catalyst) where the organic target molecule is adsorbed (8).

Fig. 1. ECH of octanal (5.2 mmol/L) over finely divided Pd (■) and 10% Pd/alumina (●) catalysts. Supporting electrolyte: 0.25 mol/L acetate buffer solution (pH 5) in aq. ethanol (50% H_2O *v*/*v*); I = 10 mA.

The relative rates of these processes are not only affected by the adsorption of target species, but also by the current intensity, the polarity of solvent, or the electrolyte nature, as discussed further. We have verified the influence of current intensity on the ECH of octanal over Pd/alumina catalyst in acidic aq. ethanol. One expects to have a decrease in the ECH efficiency because hydrogen evolution reactions are favored. As observed in Fig. 2, the higher the current intensity, the lower the ECH efficiency, which indicates that concurrent hydrogen evolution is more significant for a current intensity of 20 mA. In addition to the kinetic aspect, the current intensity influences the cell flow, by the formation of many cavities of hydrogen gas, as observed experimentally at high intensity of current. To limit the current loss, associated with the hydrogen-evolution reaction, the current must be adjusted to optimize the ECH reaction, while preserving a suitable reaction time; this is why all the reactions were carried out using a current intensity of 10 mA.

Another parameter, which can affect the ECH process, is the supporting electrolyte. It was demonstrated earlier that the acid used as supporting electrolyte intervenes in the ECH process by the change in the surface properties of the catalyst matrix (8), i.e., by fixation at the alumina surface. This

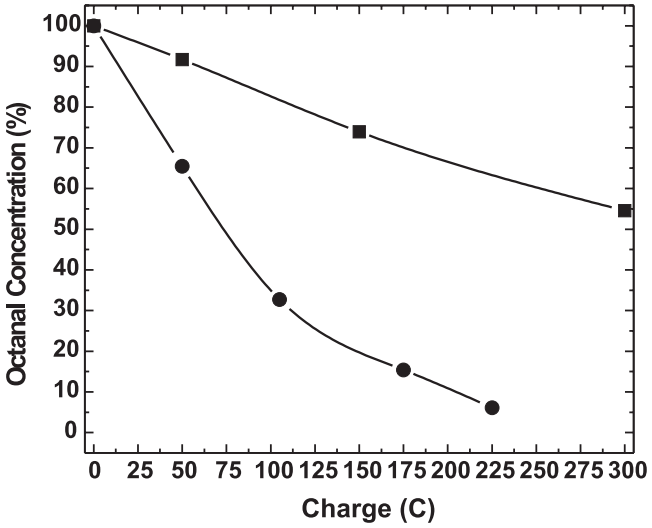
Fig. 2. ECH of octanal (5.2 mmol/L) over 10% Pd/alumina catalyst for different current intensities: (●) I = 10 mA and (■) I = 20 mA. Supporting electrolyte: 0.25 mol/L acetate buffer solution (pH 5) in aq. ethanol (50% H_2O *v*/*v*).



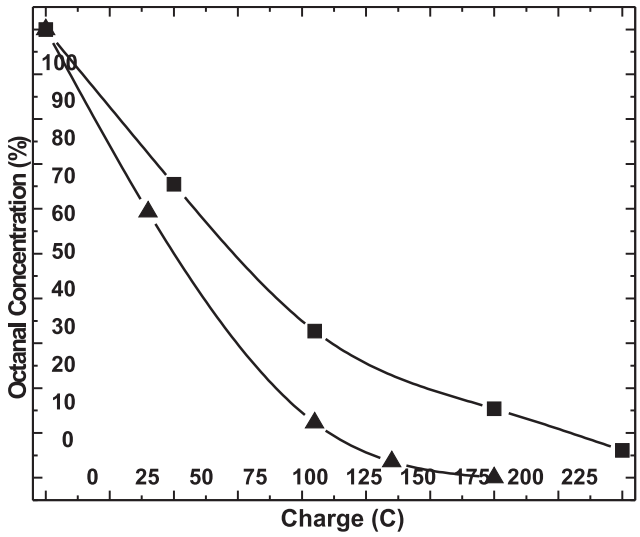


Fig. 3. ECH of octanal (5.2 mmol/L) over 10% Pd/alumina catalyst. Supporting electrolyte: 0.25 mol/L of (■) acetate buffer solution (pH 5) and (▲) butyrate buffer solution (pH 5) in aq. ethanol (50% H_2O *v*/*v*); I = 10 mA.

modification of the surface can affect the adsorption properties, and implicitly the process efficiency, because the adsorption is a key step in the ECH mechanism. Figure 3 presents the depletion curves for the octanal hydrogenation with two aliphatic carboxylic acids used as supporting electrolytes. These results are interpreted while being based on the principle of "in situ functionalized materials" introduced by our group (8). One observes a different behavior when the butyrate replaced the acetate. The nature of adsorption sites onto the catalyst matrix changes because of the carboxylate, which fixes on alumina. The polar surface of the alumina is transformed in a less polar surface by the acetate, which adsorbs onto the alumina via the carboxylate function. When the butyrate replaced the acetate, the alumina surface became less polar, increasing in this way the adsorption capacity. The polarity of solvent can also affect the adsorption equilibrium; this is why different water–ethanol mixtures were tested for the ECH of octanal over 10% Pd/alumina catalyst using acetate as the modifier of the alumina surface. The lower-polarity (ethanol-rich) solutions can reduce the adsorption of the target molecule onto the functionalized alumina and affect in this way the ECH efficiency (Table 1).

It is clear from Table 1 (entries 1–3) that as the ethanol concentration increases, the hydrogenation of octanal becomes less efficient. Again, we suggest that this behavior is principally due to the adsorption phenomena, which modulates the ECH process.

St. Pierre et al. observed a similar effect in their study of the ECH of cyclohexanone with nickel supported on functionalized-silica catalysts (12).

The effect of concentration on the ECH of octanal can be observed by comparing entries 1 and 4 in Table 1. As expected, the ECH is more efficient by increasing the octanal concentration. For a higher concentration of octanal than that used in the present study, one can expect to have an increase in the ECH efficiency, but a very concentrated solution of octanal must be avoided because of the low solubility of octanal in solutions rich in water.

Table 1. Remaining fraction of octanal after 200 °C.

Entry	Ethanol (%)	Octanal (%)
1	50	41
2	65	52
3	80	72
4	50	11[a]

Note: Experimental conditions: supporting electrolyte: 0.25 mol/L acetate buffer solution (pH 5); solvent: ethanol–water; I = 10 mA; octanal concentration: 2.6 mmol/L.
[a]Octanal concentration: 5.2 mmol/L.

Conclusion

The present work demonstrates that octanal can be hydrogenated to octan-1-ol over Pd/alumina catalyst. Effectively, the catalyst matrix plays an important role in the ECH process of octanal, but other parameters, such as current intensity, the polarity of solvent (water concentration), supporting electrolyte, and substrate concentration, also affect the process. These results show that ECH provides a good tool for the hydrogenation of saturated aliphatic aldehydes in mild conditions without the necessity of high pressure and temperature or hydrogen supply.

One-pot multicomponent synthesis of β-acetamidoketones catalysed by *p*TSA[1]

Biswanath Das, Kongara Ravinder Reddy, Yallamalla Srinivas, and Rathod Aravind Kumar

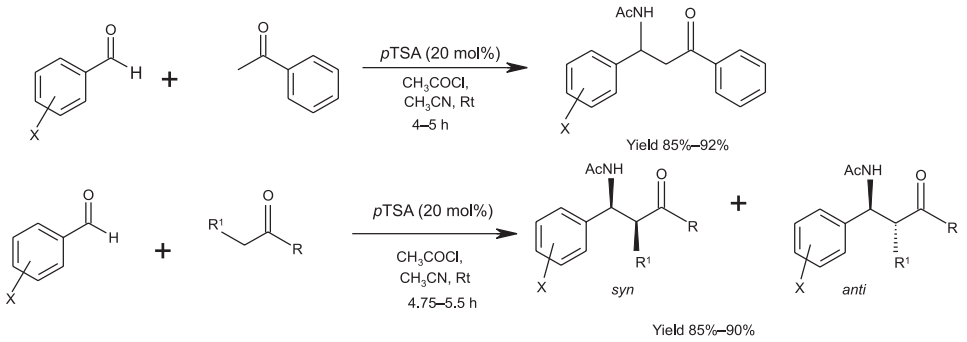
Abstract: A catalytic amount of *p*TSA has been found to be effective to carry out a one-pot three-component coupling of aromatic aldehydes, enolizable ketones or ketoesters, and acetonitrile in the presence of acetyl chloride to afford β-acetamidoketones in high yields. Short reaction times and inexpensive catalyst are main advantages of this protocol.

Key words: β-acetamidoketone, *p*TSA, multicomponent reaction, diastereoselectivity.

Résumé : On a trouvé qu'une quantité catalytique d'acide *p*-toluènesulfonique suffit pour effectuer une réaction monotope à trois composants qui permet d'effectuer le couplage d'aldéhydes aromatiques, de cétones ou de cétoesters énolisables et d'acétonitrile et d'acétonitrile, en présence de chlorure d'acétyle, et obtenir des β-acétamidocétones avec des rendements élevés. Des temps de réaction courts et un catalyseur peu coûteux sont les avantages de principaux de ce protocole.

Mots-clés : β-acétamidocétone, acide *p*-toluènesulfonique, réaction à plusieurs réactifs, diastéréosélectivité.

[Traduit par la Rédaction]



Introduction

Synthesis of β-acetamidoketones has attracted much attention in organic synthesis because of their multifunctional nature and the existence of their skeletons in various biologically important molecules (1). They act as building blocks for the preparation of compounds like 1,3 amino alcohols (2) and fragments of the natural nucleoside peptide antibiotics such as nikkomycins and neopolyoxins (3). Previously, Iqbal and co-workers (4) achieved the synthesis of β-acetamidoketones through a multicomponent reaction applying Lewis acids, $CoCl_2$, polyaniline $Co(OAc)_2$, and Montmorrilonite K-10 clay. Recently, other methods have also been reported involving $Sc(OTf)_3$, $ZrOCl_2$, BiOCl, or I_2 (5). However, most of the methods require expensive catalysts, long reaction times, or high temperature. The catalytic activity of a protic acid in the preparation of β-acetamidoketones has not yet been fully explored.

Results and discussion

In continuation of our studies (6) directed towards the development of useful synthetic methodologies, we recently found that *para* toluene sulfonic acid can efficiently catalyse the one-pot coupling of aromatic aldehydes, enolizabe ketones or ketoesters, and acetonitrile in the presence of acetyl

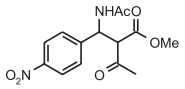
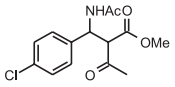
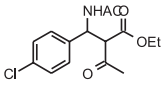
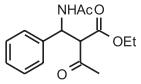
chloride to afford β-acetamidoketones at room temperature in high yields (Scheme 1).

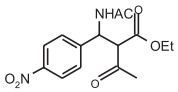
A variety of aromatic aldehydes were converted into the corresponding β-acetamidoketones following the above procedure in the presence of 20 mol% of *p*TSA. The conversion afforded the desired products within 4–5.5 h (Table 1).





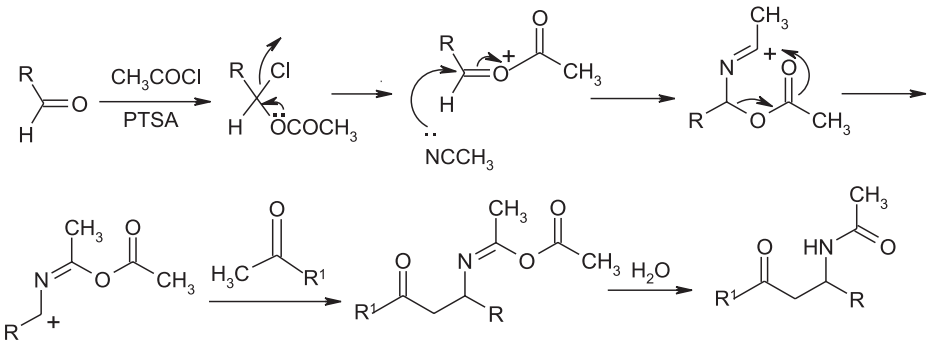






The aromatic aldehydes containing both electron-donating and electron-withdrawing groups worked well. The reaction with propiophenones (Table 1, entries g–j) or ketoesters (Table 1, entries k–o) is diastereoselective. In such cases, anti and syn products were formed. The amount of these anti and syn products was determined by ^{1}H NMR spectra. The coupling constant between H-2 and H-3 is 7–9 Hz for an anti isomer, while 2–5 Hz for a syn isomer (4). In most of the cases, an anti isomer was found to be major. Several functional groups, such as NO_2, alkyl, halogen, and ether, were compatible under the present reaction conditions (Table 1). The structures of the products were settled from spectral (^{1}H NMR and MS) data. The possible mechanism of the reaction is given (4) in the accompanying diagram following Table 1.

Conclusion



In conclusion, we have demonstrated an alternative and simple method for the synthesis of β-acetamidoketones using an organic Brønsted acid, *p*TSA, for the first time. The application of an inexpensive catalyst, high yields, short reaction times, and mild reaction conditions are the main ad-

vantages of this protocol. We feel that the method will find practical application in the synthesis of β-acetamidoketones.

Experimental

To a mixture of an aldehyde (1 mmol), a ketone or ketoester (1mmol), and AcCl (1 mmol) in MeCN (5 ml), *p*TSA (20 mol%) was added. The mixture was stirred at room temperature and the reaction was monitored by TLC. After completion, the mixture was poured on water and extracted with ethyl acetate (3 × 20 ml). The extract was dried over Na_2SO_4, and the solvent was concentrated under reduced pressure. The residue was subjected to column chromatography (SiO_2; hexane – ethyl acetate) to afford the pure β-acetamidoketone.

When ketoesters were used, the reaction was conducted under N_2 atmoshere. The analytical data of some representative products are given in the following.

Synthesis and characterization of intramolecularly coordinated alanes with new sterically demanding trisyl-based ligands

Clinton L. Lund, Olimpiu Stanga, J. Wilson Quail, and Jens Müller

Abstract: Five new intramolecularly coordinated aluminum species, whose molecular structures have been elucidated in solution by NMR spectroscopy and in the solid state by single crystal X-ray analysis, are described. All species are equipped with a trisyl-based ligand with a pyridyl donor group [Pytsi stands for -C(SiMe$_3$)$_2$SiMe$_2$(2-C$_5$H$_4$N)]. While the compound (Pytsi)AlMeCl was accessible either from Li(THF)(Pytsi) and MeAlCl$_2$ or from (Pytsi)AlCl$_2$ and LiMe, the *tert*-butyl derivative (Pytsi)Al*t*BuCl could only be obtained from Li(THF)(Pytsi) and *t*BuAlCl$_2$. Attempted synthesis of (Pytsi)Al*t*BuCl from (Pytsi)AlCl$_2$ and Li*t*Bu or from (Pytsi)AlCl$_2$ and *t*BuMgCl failed. Three other compounds (**3**–**5**) were synthesized and can be described as derivatives of (Pytsi)AlMe$_2$ with additional groups in the ortho position of the pyridyl group. Compound **3** carried a Me group in the ortho position, while compounds **4** and **5** were equipped with Ph and 2,6-diisopropylphenyl moieties, respectively.

Key words: aluminum, trisyl ligands, methyl alanes.

Résumé : On décrit cinq nouvelles espèces d'aluminium à coordination intramoléculaire dont on a déterminé les structures en solution par RMN et à l'état solide par diffraction des rayons X. Toutes les espèces incluent un ligand à base d'un groupe trisyle comportant un groupe donneur pyridyle [Pytsi = -C(SiMe$_3$)$_2$SiMe$_2$(2-C$_5$H$_4$N)]. Alors que le composé (Pytsi)AlMeCl est accessible à partir du Li(THF)(Pytsi) et du MeAlCl$_2$ ou du (Pytsi)AlCl$_2$ et du LiMe, le dérivé *tert*-butylé n'est disponible que par la réaction du Li(THF)(Pytsi) et du *t*-BuAlCl$_2$. On n'a pas pu réaliser la synthèse du (Pytsi)Al*t*-BuCl à partir du (Pytsi)AlCl$_2$ et du Li*t*-Bu ou par réaction du (Pytsi)AlCl$_2$ et du *t*-BuMgCl. On a réalisé la synthèse de trois autres composés (**3**–**5**) qui peuvent être décrits comme des dérivés du (Pytsi)AlMe qui comportent des groupes additionnels en position ortho du groupe pyridyle. Le composé **3** porte un groupe méthyle en position ortho alors que les composés **4** et **5** portent respectivement des groupes phényle et 2,3-diisopropylphényle.

Introduction

Group 13 element compounds EX$_3$ are textbook examples of Lewis acids. Usually, the electronic needs of the heavier group members Al, Ga, and In cannot be satisfied intramolecularly through π bonds and, hence, oligomers are found throughout their structural chemistry. By employing ligands that are equipped with donor groups, Lewis acid–base adducts are formed intramolecularly and oligomers can be prevented. One of the most commonly used intramolecularly coordinating ligands is the "one-armed" phenyl ligand (Fig. 1, Ar′). For example, employing the Ar′ ligand gives access to well-defined, monomeric aluminium halides (1). Azides of the heavier group 13 elements are usually oligomers (2), however, the application of Ar′ and Pr′ (Fig. 1), respectively, allowed for the preparation of the first monomeric aluminum azides (3–5). The use of the Pr′ ligand usually results in species of higher volatility than those equipped with Ar′ ligands and respective Al, Ga, and In azides had been employed as single-source precursors for chemical vapor deposition (CVD) of nitrides (2, 6).

The tris(trimethylsilyl)methyl ligand, commonly referred to as the trisyl ligand, is a widely used sterically demanding ligand with electron-donor properties provided by three silyl groups (β silyl effect) (7). Eaborn and co-workers (8) developed a series of trisyl-based ligands in which one of the methyl groups is formally replaced by a substituent with σ donor abilities. Modifications included ligands of the type -C(SiMe$_3$)$_2$(SiMe$_2$R) with R being MeO (7), Ph$_2$P (7), CH$_2$PPh$_2$ (7), Me$_2$N (Fig. 1, Me$_2$Ntsi) (7), and 2-C$_5$H$_4$N (Fig. 1, Pytsi). Recently, we had shown that Pytsi and Me$_2$Ntsi (Fig. 1) stabilized alanes and gallanes can be used for the preparation of [1]metallacyclophanes such as [1]ferrocenophanes (9–11), [1]chromarenophanes (11), and [1]vanadarenophanes (11). The type of intramolecularly co-

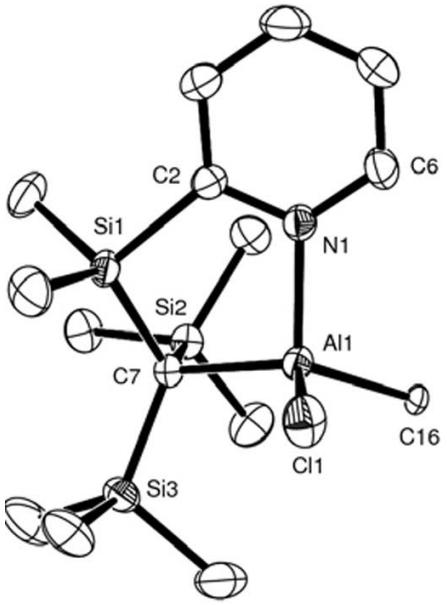
Fig. 1. Intramolecularly coordinating ligands.

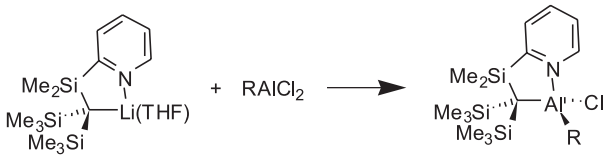
ordinating ligand is of crucial importance for getting strained organometallic species: a change from the sterically demanding Pytsi and MeNtsi, respectively, to the slimmer Ar′ ligand (Fig. 1) resulted in unstrained [1.1]ferrocenophanes (12, 13).

Because of the bulkiness and the β silyl effect, trisyl-type ligands might be ideal to stabilize low-coordinated Lewis-acid metal complexes. Starting with this working hypothesis, we set out to explore cationic aluminum species equipped with the Pytsi ligand. Cationic low-coordinated aluminum compounds are potential catalysts or initiators for olefin polymerizations (14–19). Recently, we described the synthesis of a saltlike compound [(Pytsi)AlMe][$MeB(C_6F_5)_3$] (19). This species was obtained by a methyl abstraction reaction from (Pytsi)$AlMe_2$ with the perfluorinated borane $B(C_6F_5)_3$, however, this compound slowly decomposed in toluene at ambient temperature. We planned to increase its stability by shielding the Al centre more effectively with sterically demanding groups, either attached to aluminum directly or attached to the backbone of the chelating ligand.



In this paper, we describe the synthesis and characterization of new alanes equipped with trisyl-based intramolecularly coordinating ligands.

Results and discussion

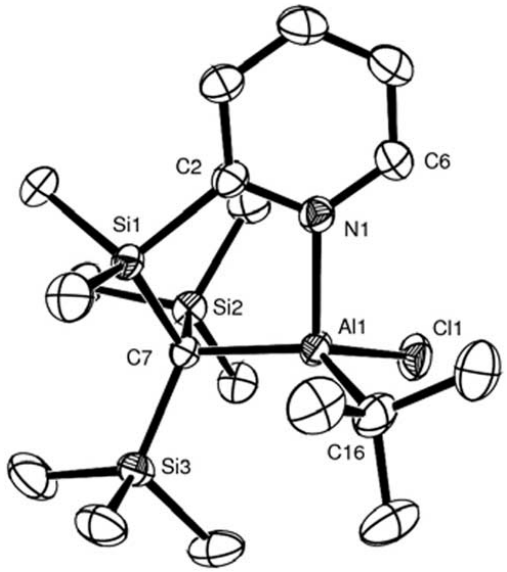


Cations are commonly synthesized through halide abstraction reactions from suitable halogen containing precursors. Often, silver salts of weakly coordinating anions are employed (20). Against this background, we intended to prepare precursor species of the type (Pytsi)AlClR. First, we prepared (Pytsi)AlClMe (**1**) from Li(THF)(Pytsi) and $MeAlCl_2$ (eq. [1]). A similar route had been previously employed for Ar′AlClMe (1). Compound **1** can also be synthesized by a substitution reaction from (Pytsi)$AlCl_2$ and LiMe. Both routes to species **1** work comparably well (see Experimental section). In accordance with the known synthesis of Ar′AlCl*t*Bu (1), we attempted the synthesis of (Pytsi)AlCl*t*Bu (**2**) from (Pytsi)$AlCl_2$ (21) and Li*t*Bu in Et_2O or with *t*BuMgCl in Et_2O. Both reactions proved unsuccessful. In the case of Li*t*Bu, a very rich ^1H NMR spectrum hinted at complex reactions and showed that the target compound **2** had not been formed. In the case of the Grignard reagent, no reaction happened at all. However, the target molecule **2** was accessible in a moderate isolated yield of 54% by reacting Li(THF)(Pytsi) with *t*Bu$AlCl_2$ (eq. [1]).

Compounds **1** and **2** are asymmetric species as revealed by NMR spectroscopy. For example, for both compounds the $SiMe_2$ and the two $SiMe_3$ moieties give rise to two singlets, each in ^1H NMR as well as in $^{13}C\{^1H\}$ NMR spectra. Compounds **1** and **2**, respectively, crystallize in the monoclinic space group $P\ 2_1/c$. Figs. 2 and 3 depict their molecular structures, and Table 1 shows their structural parameters.

Fig. 2. Molecular structure of **1** with thermal ellipsoids at the 50% probability level. H atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Al1–N1 = 1.962(2), Al–Cl1 = 2.1813(9), Al1–C7 = 2.008(2), Al1–C16 = 1.978(2), N1–Al1–Cl1 = 98.98(7), N1–Al1–C16 = 109.28(9), N1–Al1-C7 = 98.34(9), C7–Al1–Cl1 = 113.42(7), C7–Al1–C16 = 125.37(10), Cl1–Al1–C16 = 107.68(7).

[1]



R = Me (**1**)
*t*Bu (**2**)

Expectedly, the molecular structures are very similar. The Al atoms are four-fold coordinated by two C atoms, one Cl atom, and one N atom with nearly identical bond lengths (Figs. 2 and 3). The major difference between **1** and **2** is due to a different folding of the five-membered ring. For both compounds, the five-membered ring adopts an envelope conformation with C7 being the tip of the envelope. However, because of the stereogenic Al centre two different folding directions of C7 are possible. While in compound **1** C7 is folded away from the Cl atom, in compound **2** C7 is folded towards the Cl atom. The conformer found for **2** places the *t*Bu group in an axial position and allows a maximum distance towards the two neighbouring $SiMe_3$ groups, indicating that steric factors play the major role in finding a particular isomer.

As mentioned in the introduction, we attempted to shield the Al centre more effectively with sterically demanding groups. Therefore, we synthesized derivatives of (Pytsi)$AlMe_2$ (19, 21) in which the ortho position of the pyridine ring carries a Me (**3**), Ph (**4**), or Dipp group (**5**) (Dipp = 2,6-diisopropylphenyl). As illustrated in Scheme 1,

Fig. 3. Molecular structure of **2** with thermal ellipsoids at the 50% probability level. H atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Al1–N1 = 1.9765(14), Al–Cl1 = 2.1787(6), Al1–C7 = 2.0340(15), Al1–C16 = 2.0077(18), N1–Al1–Cl1 = 103.92(4), N1–Al1–C16 = 103.92(7), N1–Al1–C7 = 96.43(6), C7–Al1–Cl1 = 115.31(5), C7–Al1–C16 = 127.95(7), Cl1–Al1–C16 = 105.48(6).

compounds **3**–**5** have been prepared similarly as the known (Pytsi)$AlMe_2$ (19, 21). Of course, the methyl group in the 6 position of the pyridine ring is too small to sterically protect the aluminum atom. However, compound **3** was the first test case to determine if a small change to the pyridyl group has an influence on the synthesis of the respective dimethyl alane.

The preparation of **3**–**5** differs mainly in the way we synthesized the ortho-lithiated pyridine (Scheme 1). In all cases the ortho-lithiated pyridine derivative was prepared in situ. However, for compounds **3** and **4**, we generated it from a respective bromopyridine and LiBu. For compound **5**, we first used a nickel catalyst cross-coupling of a Grignard reagent (22, 23) followed by a selective deprotonation in the ortho position, a method that had been previously applied to other phenylpyridine derivatives (24) (Scheme 2).

The dimethylalanes **3**–**5** were isolated in moderate to good yields of 51% to 86% as crystalline colorless solids. All three compounds reveal patterns in their ^1H and ^{13}C NMR spectra that are consistent with time-averaged C_s symmetrical species. The most noteworthy feature in all the spectra is the appearance of the two isopropyl groups of the Dipp ligand of compound **5**. They show two doublets for the Me groups (δ 0.82 and 1.34) and one multiplet for the CH group (δ 2.40) in the ^1H NMR spectrum and two singlets for the Me groups and one singlet for the CH groups in the $^{13}C\{^1H\}$ NMR spectrum. This shows that both isopropyl groups are chemically equivalent, but the methyl groups are nonequivalent for each isopropyl group. As already mentioned above, the NMR spectra can be rationalized by assuming compound **5** is a time-averaged C_s symmetrical species; e.g., the $SiMe_3$ and the $AlMe_2$ moieties each give rise to one singlet. All facts combined prove that the Dipp ligand is oriented perpendicular to the pyridiyl moiety and is not rotating rapidly on the NMR time scale.

The molecular structures of compounds **3**–**5** were determined with single crystal X-ray analysis (Figs. 4–6 and Table 1). All species exhibit an envelope conformation of the five-membered heterocycle with C7 being the tip of the envelope. In all compounds, aluminum is tetrahedrally surrounded by a set of three C atoms and one N atom with very similar bond lengths and angles (Figs. 4–6). For example, the Al–N bond lengths are found in the narrow range between 2.0393(16) and 2.0587(15) Å, even though these donor bonds are expected to be the most flexible bonds in the molecules. A similar but slightly shorter Al–N bond was found for (Pytsi)$AlEt_2$ (Al-N = 2.0034(18) Å) (19). Reliable bond lengths and angles are not available for the closely related dimethylalane (Pytsi)$AlMe_2$, because it is disordered about a plane of symmetry that bisects the molecule along the Si_2C plane in the $C(SiMe_3)_2$ group (19). In both halves of the molecule the Me_2Al- and the Me_2Si moieties on one side and the two halves of the pyridine ring on the other side have similar sizes and shapes, which makes the disordering understandable (19). Both halves of (Pytsi)$AlMe_2$ can be made dissimilar by either changing the alkyl groups at aluminum or adding a substituent to the pyridyl moiety; neither (Pytsi)$AlEt_2$ (19) nor compound **3** are disordered in the crystal lattice.

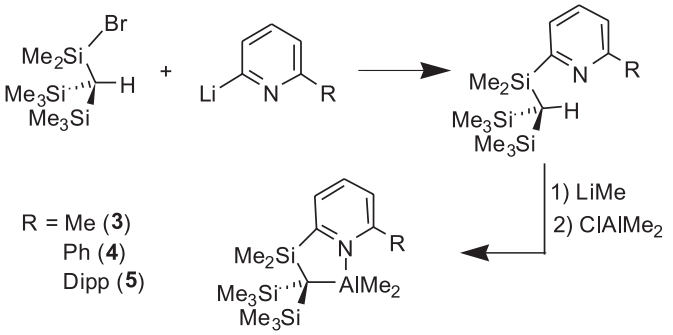
Conclusion

We synthesized five new intramolecularly coordinated aluminum species, whose molecular structures have been elucidated in solution by NMR spectroscopy and in the solid state by single crystal X-ray analysis. All species **1**–**5** are equipped with a trisyl-based ligand with a pyridyl donor group (Fig. 1, Pytsi). While the monomethyl compound (Pytsi)AlMeCl (**1**) is accessible either from Li(THF)(Pytsi) and $MeAlCl_2$ (eq. [1]) or from (Pytsi)$AlCl_2$ and LiMe, the *tert*-butyl derivative (Pytsi)Al*t*BuCl (**2**) could only be obtained from Li(THF)(Pytsi) and *t*Bu$AlCl_2$ (eq. [1]). The latter result is in contrast to the synthesis of the related species Ar′Al*t*BuCl (Fig. 1, Ar′), which was synthesized from Ar′$AlCl_2$ and Li*t*Bu (1). The different substitution behavior of (Pytsi)$AlCl_2$ and Ar′$AlCl_2$ towards Li*t*Bu can be interpreted as being due to the higher steric demand of Pytsi compared with Ar′ (Fig. 1).

Compounds **3**–**5** can all be described as derivatives of (Pytsi)$AlMe_2$ with additional groups in the ortho position of the pyridyl group. From the molecular structures of the Ph-substituted compound **4** (Fig. 5) and the 2,6-diisopropylphenyl derivative **5** (Fig. 6) one gets the impression that the aromatic group in the ortho position of the pyridyl ring might serve as a shield to help protect the Al atom and, consequently, we intend to employ these species as precursors for cationic aluminum compounds.

Experimental

General procedures



All manipulations were carried out using standard Schlenk techniques. Solvents were dried using a Braun Solvent Purification System and stored under nitrogen over 4 Å

Chloro{[dimethyl(pyrid-2-yl)silyl]bis(trimethylsilyl)methyl}methylaluminum (1)

Route 1: A solution of $MeAlCl_2$ (4.2 mL, 1.0 mol/L in hexane, 4.2 mmol) was added to a solution of Li(THF)(Pytsi) (1.577 g, 4.220 mmol) in hexane at –78 °C. After stirring for 20 min, the reaction mixture was allowed to warm to ambient temperature and stirred for 16 h. The solid was filtered off, extracted with Et_2O (3 × 10 mL), the combined organic extracts were reduced in volume to 10 mL, and crystallization at ca. –30 °C resulted in colorless crystals of **1** (1.395 g, 88%).

Route 2: LiMe (4.4 mL, 0.93 mol/L, 4.1 mmol) was added to (Pytsi)$AlCl_2$ (1.625 g, 4.140 mmol) in Et_2O (50 mL) at –78 °C. The slurry was stirred for 30 min at –78 °C, allowed to warm to ambient temperature, and stirred for 16 h. The white solid was filtered off and the product extracted with Et_2O (3 × 10 mL). The combined extracts were reduced in volume to 20 mL and kept at –30 °C to give colorless crystals of **1** (1.257 g, 82%).

[Dimethyl(6-methylpyrid-2-yl)silyl]bis(trimethylsilyl)methane

LiBu (15.0 mL, 2.7 mol/L in hexane, 40.5 mmol) was added dropwise to a solution of 2-bromo-6-methylpyridine (8.796 g, 37.12 mmol) in Et$_2$O (30 mL) at –78 °C to give a dark red solution. The solution was stirred for 20 min before being added to a cold solution (–78 °C) of HC(SiMe$_3$)$_2$(SiMe$_2$Br) (11.751 g, 39.505 mmol) in Et$_2$O (100 mL), which gave a brown solution. The cold bath was removed and the reaction mixture was stirred for 16 h. After the solvent was removed in vacuum, a dark-brown oil remained, which was transferred onto a dry silica column. The product was eluted with ethyl acetate and a subsequent flask-to-flask condensation under inert gas atmosphere yielded a light yellow oil [bp 82–84 °C, 10^{-3} mbar (1 bar = 100 kPa), 8.920 g, 77%]. ^{1}H NMR (500 MHz) δ: 0.10 (s, 18H, SiMe$_3$), 0.46 (s, 6H, SiMe$_2$), 2.43 (s, 3H, o-Me), 6.64 (d, 1H, H-5), 7.06 (pst, 1H, H-4), 7.11 (d, 1H, H-3). ^{13}C NMR (125.8 MHz) δ: 1.5 (SiMe$_2$), 3.4 (SiMe$_3$), 24.8 (CH$_3$), 121.8 (C-5), 125.7 (C-3), 134.0 (C-4), 158.0 (*ipso*-C-6), 169.2 (*ipso*-C-2).

{[Dimethyl(6-methylpyrid-2-yl)silyl]bis(trimethylsilyl)methyl}dimethylaluminum (3)

LiMe (6.6 mL, 1.0 mol/L in THF–cumene, 6.6 mmol) was added dropwise to [dimethyl(6-methylpyrid-2-yl)silyl]bis(trimethylsilyl)methane (1.866 g, 6.026 mmol) in THF (30 mL) at ambient temperature to give a red solution. Gas was given off immediately. After 1 h of stirring, the solvent was removed in vacuum to leave an oily residue behind, which was dissolved in hexane (20 mL). The solution was cooled to –78 °C and Me$_2$AlCl (6.6 mL, 1.0 mol/L in hexane, 6.6 mmol) was added dropwise over 10 min. The cold bath was removed and the reaction mixture stirred for 16 h at ambient temperature. Removal of all volatiles from the solution in high vacuum gave a white solid, which was extracted with hexane (3 × 15 mL). The combined organic fractions were separated from the solid remains by filtration. The organic phase was concentrated to 20 mL and kept at –30 °C to give light yellow crystalline plates of **3** (1.132 g, 51%). ^{1}H NMR (500 MHz) δ: –0.17 (s, 6H, AlMe$_2$), 0.29 (s, 18H, SiMe$_3$), 0.42 (s, 6H, SiMe$_2$), 2.26 (s, 3H, Me), 6.22 (d, 1H, H-5), 6.78 (pst, 1H, H-4), 6.88 (d, 1H, H-3). ^{13}C NMR (125.8 MHz) δ: –1.9 (AlMe$_2$), 4.5 (SiMe$_2$), 6.4 (SiMe$_3$), 23.0 (CH$_3$), 125.3 (C-5), 126.3 (C-3), 138.1 (C-4), 157.4 (*ipso*-C-6), 173.8 (*ipso*-C-2). ^{27}Al NMR (130.3 MHz) δ: 174.3 ($w_{1/2}$ = 2750 Hz). MS (70 eV) *m*/*z* (%): 350 (100) [M$^+$ – CH$_3$], 278 (37) [M$^+$ – Al – 4CH$_3$], 262 (15) [C$_{12}$H$_{20}$NSi$_3^+$]. Anal. calcd. for C$_{17}$H$_{36}$AlNSi$_3$ (365.713): C 55.83, H 9.92, N 3.83; found: C 55.16, H 10.57, N 3.63.

[Dimethyl(6-phenylpyrid-2-yl)silyl]bis(trimethylsilyl)methane

LiBu (2.2 mL, 2.8 mol/L in hexane, 6.2 mmol) was added dropwise to a stirring solution of 2-bromo-6-phenylpyridine (1.321 g, 5.643 mmol) in Et$_2$O (15 mL) at –78 °C. The resulting red solution was stirred for 20 min before a cold solution (–78 °C) of CH(Me$_3$Si)$_2$(SiMe$_2$Br) (1.712g, 5.755 mmol) in Et$_2$O (15 mL) was added. The cold bath was removed and the reaction mixture stirred overnight. The red-brown liquid phase was separated from the solids by filtration. Removal of all volatiles at ambient temperature in high vacuum from the liquid phase gave a red oil. The product was collected as a golden yellow oil by a flask-to-flask condensation (bp 145–150 °C, 10^{-3} mbar, 1.339 g, 64%). The fraction collected at 65–95 °C was discarded. ^{1}H NMR (500 MHz) δ: 0.11 (s, 18H, SiMe$_3$), 0.17 (s, 1H, CH), 0.52 (s, 6H, SiMe$_2$), 7.17(m, 2H, Py H-4, Ph H-5), 7.21 (d, 1H, Py, H-3 or H-5), 7.27 (t, 2H, Ph, H-3, H-4), 7.30 (d, 1H, Py, H-5 or H-3) 8.17 (d, 2H, Ph, H-2, H-6). ^{13}C NMR (125.8 MHz) δ: 1.4 (SiMe$_2$), 1.7 (CH), 3.3 (SiMe$_3$), 119.1 (Py, C-3 or C-5), 127.1 (Py, C-3 or C-5), 127.2 (Ph, C-2, C-6), 128.8 (Ph, C-3, C-5), 129.0 (Py, C-4), 134.6 (Ph, C-4), 140.3 (Ph, *ipso*-C), 156.7 (Py, *ipso*-C-6), 169.8 (Py, *ipso*-C-2).

{[Dimethyl(6-phenylpyrid-2-yl)silyl]bis(trimethylsilyl)methyl}dimethylaluminum (4)

LiMe (4.0 mL, 1.0 mol/L in THF–cumene, 4.0 mmol) was added dropwise to a stirring solution of [dimethyl(6-phenylpyrid-2-yl)silyl]bis(trimethylsilyl)methane (1.339 g, 3.602 mmol) in THF (30 mL) at ambient temperature resulting in the formation of gas and a red solution. After 1 h of stirring at ambient temperature, the red solution was cooled to 0 °C and Me$_2$AlCl (5.0 mL, 1.0 mol/L in hexane, 5.0 mmol) was added dropwise to give a clear brown solution that was stirred for 16 h at ambient temperature. Removal of all volatiles in high vacuum at ambient temperature yielded a light brown solid. The solid was extracted with ether (3 × 20 mL), and the solvent was removed to give a light brown solid, which was subsequently sublimed (140 °C, 10^{-3} mbar) to give a white solid (1.171 g, 76%). Crystallization from diethyl ether at –30 °C yielded colorless crystals of **4** (1.095 g, 71%). ^{1}H NMR (500 MHz) δ: –0.58 (s, 6H, AlMe$_2$), 0.26 (s, 18H, SiMe$_3$), 0.51 (s, 6H, SiMe$_2$), 6.62 (d, 1H, H-5), 6.90 (pst, 1H, H-4), 7.05 (d, 1H, H-3), 7.10–7.11 (m, 3H, Ph), 7.20–7.22 (m, 2H, Ph). ^{13}C NMR

(125.8 MHz) δ: –2.3 ($AlMe_2$, br), 4.7 ($SiMe_2$), 6.3 ($SiMe_3$), 125.7, (C-5), 127.7 (C-3), 128.4 (Ph), 129.1 (Ph) 129.7 (Ph, *ipso*-C), 138.0 (C-4), 160.3 (*ipso*-C-6), 174.8 (*ipso*-C-2). ^{27}Al NMR (130.3 MHz) δ: 182 ($w_{1/2}$ = 4500 Hz). MS (70 eV) *m/z* (%): 412 (100) [$M^+ - CH_3$], 340 (24) [$M^+ - Al - 4CH_3$], 217 (16). Anal. calcd. for $C_{22}H_{38}AlNSi_3$ (422.804): C 61.77, H 8.95, N 3.27; found: C 61.09, H 8.88, N 3.18.

2-(2,6-Diisopropylphenyl)pyridine

Bromo-2,6-diisopropylbenzene (6.115 g, 25.36 mmol) in THF (10 mL) was added to Mg turnings (0.740 g, 30.45 mmol) in THF (20 mL) in a flask equipped with reflux condenser. Heat was used to start the Grignard reaction. The mixture was refluxed for 24 h before being added to a mixture of P*t*Bu_3 (0.1472 g, 0.7376 mmol), $Ni(acac)_2$ (0.1684 g, 0.6555 mmol), and 2-bromopyridine (3.388 g, 21.44 mmol) in THF (100 mL) cooled to 0 °C, which resulted in a brown solution. The solution refluxed for 24 h and was subsequently poured into dilute HCl (200 mL; 0 °C). The organic phase was discarded and the aqueous phase was extracted with Et_2O (2 × 50 mL) and the Et_2O phase was discarded. K_2CO_3 was added to the aqueous phase until the evolution of CO_2 ceased during which the color of the solution went from brown to yellow. The aqueous phase was extracted with dichloromethane (3 × 150 mL) followed by the removal of volatiles in high vacuum from the combined organic phases to leave a brown oil behind. Flask-to-flask condensation under high vacuum at 120–125 °C yielded a viscous yellow oil (2.467 g, 48%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.06 (6 H, d, $HC(CH_3)CH_3$), 1.10 (d, 6 H, $HC(CH_3)CH_3$), 2.46 (m, 2H, $HC(CH_3)CH_3$), 7.19 (d, 1H, Ph), 7.25 (m, 2H, Py H-4, H-3), 7.33 (pst, 1H, Ph), 7.71 (pst, 1H, Py H-5), 8.70 (d, 1H, Py H-6). ^{13}C NMR (125.8 MHz, $CDCl_3$) δ: 23.9 ($HC(CH_3)CH_3$), 24.2 ($HC(CH_3)CH_3$), 30.3 (2 $HC(CH_3)CH_3$), 121.5 (Py, C-3 or C-4), 122.6 (Ph, C-3, C-5), 124.9 (Py, C-4 or C-3), 128.5 (Ph, C-4), 135.6 (Py, C-5), 138.6 (Ph, C-1), 146.4 (Py, *ipso*-C-6), 149.3 (Ph, C-2, C-6), 160.0 (Py, *ipso*-C-2).

{[6-(2,6-Diisopropylphenyl)pyrid-2yl]dimethylsilyl}bis(trimethylsilyl)methane

LiBu (22.0 mL, 2.87 mol/L in hexane, 63.1 mmol) was added dropwise to a solution of 2-dimethylaminoethanol (2.802 g, 31.43 mmol) in hexane (30 mL) cooled to 0 °C, and the resulting yellow solution was stirred for an additional 30 min. 2-(2,6-Diisopropylphenyl)pyridine (2.499 g, 10.44 mmol) in hexane (30 mL) was added and the color of the reaction mixture changed immediately to red. After 1 h of stirring at 0 °C, the mixture was cooled to –78 °C and $HC(SiMe_3)_2(SiMe_2Br)$ (11.355 g, 38.17 mmol) in hexane (30 mL) was added dropwise. The mixture was kept at –78 °C for 1 h before the cold bath was removed and stirring was continued for 16 h at ambient temperature. Deionized H_2O (100 mL) was added, and the aqueous phase was extracted with Et_2O (3 × 100 mL). The combined extracts were dried over $MgSO_4$, filtered, and the volatiles from the organic phase were subsequently removed in vacuum. Flask-to-flask condensation of the orange oil at high vacuum gave two fractions. The fraction at 85–125 °C was discarded. The product was received as an oil (bp 135–140 °C, 10^{-3} mbar, 3.214 g, 68%), which turned into a light yellow solid upon cooling to ambient temperature. ^{1}H NMR (500 MHz) δ: 0.10 (s, 18H, $SiMe_3$), 0.21 (s, 1H, CH), 0.47 (s, 6H, $SiMe_2$), 1.12 (d, 6H, $CH(CH_3)CH_3$), 1.23 (d, 6H, $CH(CH_3)CH_3$), 2.72 (m, 2H, $CH(CH_3)CH_3$, 6.92 (d, 1H, Py, H-3 or H-5), 7.12 (pst, 1H, Ph, H-4), 7.20 (m, 3H, Ph H-3, H-5, Py H-3 or H-5), 7.30 (pst, 1H, Py H-4). ^{13}C NMR (125.8 MHz) δ: 0.8 (CH), 1.3 ($SiMe_2$), 3.3 (2 $SiMe_3$), 23.9 ($HC(CH_3)CH_3$), 25.0 ($HC(CH_3)CH_3$), 30.7 ($HC(CH_3)CH_3$), 122.9 (Ph, 3-C, 5-C), 123.6 (Py, C-3 or C-5), 126.2 (Py, C-5 or C-3), 128.8 (Ph, C-4), 133.6 (Py, C-4), 140.2 (Ph, *ipso*-C-1), 146.7 (Ph, *ipso*-C-2, *ipso*-C-6), 160.3 (Py, *ipso*-C-6), 169.9 (Py, *ipso*-C-2).

{{[6-(2,6-Diisopropylphenyl)pyrid-2yl]dimethylsilyl}bis(trimethylsilyl)methyl}dimethylaluminum (5)

LiMe (2.6 mL, 1.0 mol/L in THF–cumene) was added dropwise to {[6-(2,6-diisopropylphenyl)pyrid-2yl]dimethylsilyl}bis(trimethylsilyl)methane (0.984, 2.158 mmol) in THF (20 mL). The solution was stirred for 4 h during which the solution turned brown and gas evolved. Subsequently, the flask was cooled to –78 °C and Me_2AlCl (2.6 mL, 1.0 mol/L in hexanes) was added dropwise. The cold bath was removed and the reaction mixture stirred overnight. After removal of volatiles from the clear yellow solution a yellow solid remained, which was extracted with ether (10 mL), the extract was filtered and volatiles were removed in vacuum from the filtrate to give a light yellow solid. The solid was dissolved in warm hexane (10 mL) and kept at –30 °C to give colorless crystals of **5** (0.953 g, 86%). ^{1}H NMR (500 MHz) δ: –0.62 (s, 6H, $AlMe_2$), 0.31 (s, 18H, $SiMe_3$), 0.50 (s, 6H, $SiMe_2$), 0.82 (d, 6H, $HC(CH_3)CH_3$), 1.34 (d, 6H, $HC(CH_3)CH_3$), 2.40 (m, 2H, $HC(CH_3)CH_3$), 6.91 (t, 1H, Py, H-4,), 6.96 (d, 1H, Py, H-3 or H-5), 7.08 (d, H, Py, H-5 or H-3), 7.11 (d, 2H, Ph, H-3, H-5), 7.26 (pst, 1H, Ph, H-4). ^{13}C NMR (125.8 MHz) δ: –2.5 ($AlMe_2$), 4.7 ($SiMe_2$), 6.5 (2 $SiMe_3$), 22.2 ($HC(CH_3)CH_3$), 26.4 ($HC(CH_3)CH_3$), 30.9 ($HC(CH_3)CH_3$), 123.1 (Ph, C-3, C-5), 127.8 (Py, C-3 or C-5), 128.3 (Py, C-5 or C-3), 130.7 (Ph, C-4), 134.9 (Ph, C-1), 136.7 (Py, C-4), 147.3 (Ph, C-2, C-6), 159.5 (Py, C-6), 175.5 (Py, C-2). ^{27}Al NMR δ: 179 ($w_{1/2}$ = 4300 Hz). A new microwave-assisted synthetic approach to novel pyrimido[4,5-*d*]pyrimidines

Mazaahir Kidwai, Priya, Shweta Rastogi, and Kavita Singhal

Abstract: An environmentally benign approach for the synthesis of novel 7-substituted 5-aryl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-diones, using mineral supports for their catalytic role and as energy transfer media, is described. The methodology eliminates the usage of solvent during the reaction. The rate enhancement and high yield is attributed to the coupling of solvent-free conditions with microwaves. Further, the role of various supports is studied during the reaction and it is concluded that a MW-assisted basic alumina catalysed reaction is the best in terms of catalysis as well as reaction time and yield.

Key words: microwave (MW) irradiation, SBT, pyrimido[4,5-*d*]pyrimidines, alumina, environmentally benign.

Résumé : On a mis au point une approche environnementalement bénigne à la synthèse de nouvelles 5-aryl-1*H*-pyrimido[4,5-d]pyrimidine-2,4-diones substituées en position 7 dans laquelle on utilise un support minéral joue aussi un rôle catalytique par le biais d'un milieu à transfert d'énergie. La méthodologie élimine l'utilisation d'un solvant pour la réaction. L'augmentation de la vitesse de réaction ainsi que son rendement élevé sont attribués au couplage de conditions sans solvant et de microondes. De plus, on a étudié le rôle de divers supports dans les réactions et on en conclut que la meilleures est la réaction catalysée par l'alumine basique, assistée par les microondes en termes de catalyse, de temps de réaction et de rendement.

Mots-clés : irradiation par microonde (MO), pyrimido[4,5-*d*]pyrimidines, alumine, environnementalement bénigne.

[Traduit par la Rédaction]

Introduction

An important class of annulated uracils with biological significance, as they have a connection with purine-pteridine systems (1), is associated with pyrimido[4,5-*d*]pyrimidines. Various derivatives of this scaffold have remained in high demand as they can be used for different biological activities in bronchodilators (2), vasodilators (3) and in antiallergic (2, 4), antihypertensive (5), and anticancer agents. Recently, pyrimido[4,5-*d*]pyrimidine analogues of folic acid have been found to provide antitumour activity (6). Further, its derivatives also display a wider range of pharmacological inhibitory properties; e.g., 5-phosphoribosyl-1-pyrophosphate synthetase (7), dihydrofolate reductase (8), and the tyrosine kinase domain of epidermal growth factor receptor (9) have been fully demonstrated. The derivatives of the barbituric acid constitute an important class of hypnotic, sedative, and anaesthetic compounds (10). Arylidene barbituric acids or chalcones of barbituric acid are useful intermediates in the synthesis of derivatives (11), heterocyclic compounds(12) and behave as electrically neutral Lewis acids (13). Recently, they were studied as nonlinear optical materials (14).

Motivated by the aforementioned findings and in continuation of our ongoing studies (15) on versatile heterocycles of pharmacological and biological importance, it was thought worthwhile to design the synthesis of novel derivatives that can be envisaged as the new lead compounds.

In the present communication, aiming at the preparation of 7-substituted 5-aryl-2-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-diones, we investigated, for the first time, a three-component condensation of heterocyclic chalcones of barbituric acid **1** with SBT and heterocyclic amines **3** as base. Moreover, the versatility of different solid supports was investigated under microwaves for this synthetic approach. The methodology utilizes facile and rapid one-pot condensation of barbituric acid, aromatic aldehydes, SBT (S-benzyl thiouronium chloride), and heterocyclic amines. The development of MW-assisted solid phase synthesis (16) has added a new dimension to organic synthesis, because high-yielding protocols offer the benefits of greater selectivity and experimental ease. A paradigm shift away from using solvent in organic functional group transformations, leading to environmentally benign solvent-free synthesis of novel pyrimidopyrimidines under MWs, is explored.

Results and discussion

A different approach to the synthesis of novel pyrimido[4,5-*d*]pyrimidine derivatives **4a**–**4l** with high pharmaceutical activity is sought. Thus, we contemplate an environmentally benign strategy in which the requisite moiety may be constructed by using the functionality in the chalcones of barbituric acid **1**, SBT, and heterocyclic base **3**.

 doi:10.1139/V07-065 © 2007 NRC Canada

Until now, the literature reports of the synthesis of such a skeleton involve phenyl isocyanate (17), 4-chlorophenyl diazonium chloride (18), and $POCl_3$ (19). But these procedures are tedious and require hazardous chemicals with catalyst loading that contaminated the final product. To obtain the desired product with high purity and optimized timing successfully, we describe herein a MW-assisted one-pot solid support synthesis. Different experimental trials were carried out to standardize the reaction under microwave irradiation. To the chalcones of barbituric acid **1** were added SBT and heterocyclic secondary amine **3** (morpholine–piperidine–pyrrolidine) adsorbed over basic alumina and irradiated under MW (Scheme 1, method C).

The products **4a**–**4l** were obtained in 70%–85% yield within 4–5 min of irradiation (Table 1.) Choosing an optimal solvent for adsorption is the primary requirement for successful synthesis. Thus, various reagents were tried, such as acetone, ethanol, acetic acid, and DMF. On the basis of solubility, the best solvent system was found to be a 1:1 mixture of ethanol and THF (tetrahydrofuran). The initial attempt to synthesize the products **4a**–**4l** consisted of two steps: (Step 1) the S-benzyl derivative **2** was prepared by irradiating chalcones **1** and SBT loaded over basic alumina under MW, followed by an elution and evaporation; (Step 2) this intermediate **2** obtained was then again adsorbed with secondary amines **3** over basic alumina and irradiated under MW to afford products **4a**–**4l**. The yield obtained by this two-step procedure was quite low, 40%–50%. The isolation of the intermediate **2** and its re-employment as a reactant or substrate for target moiety synthesis led to yield losses, as compared with one-pot MW-assisted solid support synthesis (method C). On other hand, a neat reaction with the same substrates was attempted but found to be unsuccessful. The α,β-unsaturated ketones **1**, possessing high melting points (>220 °C), could not be melted even after prolonged irradiation by microwaves; being in salt form, SBT could not be reacted because of the absence of solvent, thus charring occurred after a few minutes.

The role of base was also explored, and the reactions were attempted over different solid supports using basic alumina and neutral alumina under MW irradiation. It was observed that the amount of base required in the case of basic alumina was just ~0.1 mL, instead of 0.5–0.8 mL as was required in neutral alumina with comparable yields (Table 1). It was also found that the increase in the amount of solid support enhanced the product yields to a certain extent, but that further increase in the amount of solid support resulted in the reduction of product yields (Fig. 1).

As a solid support plays the role of energy transfer medium, increases in its amount results in more energy transfer to the reactant molecules, leading to a significant improvement in reactivity. Increase in solid support provides more active reagent sites and enhanced collision rates between reactants because of either the reduced dimensionality on solid reaction sites or a boost in their local concentration, due to trapping in the interstitial spaces of microporous solids. Further increase in the solid support decreases the concentration of reactants per unit surface area of solid support and thus reduces the collision frequency leading to a decrease in the yields (Fig. 1).

Furthermore, the characteristics of surface adsorption on the solid support result in the binding of the product to the solid support and, hence, in the incomplete elution of the product. After a certain point, the adsorption of product on a solid support dominates over its role as energy transfer medium, which results in incomplete elution and leads to lower yields. The compounds **4a**–**4l** were also synthesized classically by refluxing α,β-unsaturated ketones **1** with SBT and heterocyclic secondary amines **3** in ethanol and THF for 12–18 h (method A). The yield is poor compared with the one-pot synthesis (Table 1). One-pot synthesis over solid support not only reduces the reaction time of 12–18 h in method A to few minutes in methods B and C, but also act as a catalyst and energy transfer medium. In the mechanistic approach, SBT, being highly reactive in its salt form, attacks at the carbonyl moiety next to the arylidene part of the chalcone of barbituric acid **1** and leads to the formation of an imine system. As soon as this imine system forms, it facilitates the displacement of electron density towards the NH group of SBT, and the NH again attacks at the arylidene carbon. After cyclisation, the S-benzyl derivative **2** forms as an intermediate. The S-benzyl group, as substituent at position C_2, was found to perform an important role in the formation of the nucleus of pyrimido[4,5-*d*]pyrimidines. This is attributed to the requirement of basic conditions for nucleophilic displacement, since the secondary amine has a lone pair to attack, so that displacement takes place and S-benzyl is a good leaving group in furnishing an unstable intermediate, which finally results in our target moiety **4**. Had primary amine been the attacking species, the reaction would have been sluggish because of the lower basicity in the latter case. The structure of the novel compounds **4a**–**4l** was established on the basis of spectroscopic data and elemental analysis. The synthesized derivatives **4a**–**4l** are low melting crystalline light-yellow substances. Their IR spectra contain characteristic absorption bands of stretching vibrations of the C=N group at 1590–1620 cm^{-1}. The stretching vibrations of alkyl groups and alicyclic C–H bonds give rise to absorption in the region of 2960–2870 cm^{-1}, and those of the C–H bonds in the aromatic ring appear at 3060–3030 cm^{-1}. In the IR spectra of compounds **4a, 4d, 4g**, and **4j** the bands of the fragment C–O–C are observed in the region 1080–1200 cm^{-1}. Also, the ^1H NMR spectrum showed the absence of the singlet of the arylidene proton of chalcone at δ: 8.2–8.5. Apart from IR and ^1H NMR, CHN analysis and mass spectra also supported the proposed product. The chemical shifts of the ^{13}C NMR spectra are in accordance with the desired synthesized product.

Conclusion

The proposed methodology provides an facile, practical, convenient, and environmentally benign one-pot synthesis of bioactive pyrimido[4,5-*d*]pyrimidines. The MW-assisted procedure is modified in such a way that one-pot condensation is the best methodology in view of the fact that the excess of base used in conventional neutral alumina procedure is eliminated by using basic alumina. However, basic alumina further catalysed the reaction, in comparison with neutral alumina, further reducing the reaction time with comparable

yields, and thus emerged as the best solid support. These results also illustrate that the heterocyclic chalcones of barbituric acid **1** are useful substrates for the generation of an array of fused nitrogen heterocycles with two points of diversity, and SBT derivatives as good intermediates for nucleophilic displacement.

Experimental

MW irradiation was carried out on a Kenstar-OM 9925E MW Oven (800 W, 2450 MHz). The temperature of the reaction mixture was measured with a noncontact mini-Gun type IR thermometer (model 8868). IR spectra were recorded on a PerkinElmer FTIR-1710 spectrometer using KBr pellets. ^{1}H NMR spectra were obtained on a Bruker Avance Spectrospin 300 (300 MHz) using TMS as internal standard and chemical shifts are in δ. Elemental analysis was performed on a Heraeus CHN-Rapid analyzer. The melting points (uncorrected) were determined on a Thomas Hoover Melting point apparatus. ^{13}C NMR spectra were recorded at 300 MHz on a Bruker Topsin Spectrometer (300 MHz). Mass spectra were recorded on a TOF MS. All reactants

were purchased from Sigma-Aldrich and Lanchester and used without further purification. Solvents used in reaction are double distilled using vaccum distillation.

General procedure for the synthesis of 7-substituted 5-aryl-1*H*-pyrimido-[4,5-*d*]pyrimidine-2,4-diones (4a–4l)

Method A — Conventional solution phase

A mixture of chalcone **1** (0.01 mol), SBT (0.25 mol), morpholine–piperidine–pyrrolidine (0.76 mol) in 1:1 mixture of THF and ethanol (20 mL) refluxed for 10–18 h. The progress of the reaction was monitored by TLC (Merk TLC: mean particle size 10–12 μm; particle size distribution 5–20 μm; layer thickness 250 μm; plate height 30 μm). The product was evaporated in vacuo to leave an oily residue, which was triturated with methanol and recrystallized from an ethanol and benzene mixture.

Method B — One pot solid support MW (neutral alumina)

To the solution of chalcone **1** (0.02 mol), SBT (0.25 mol), and morpholine–piperidine–pyrrolidine (0.76 mol, 7–8 mL) in a mixture of THF and ethanol, neutral alumina (15 g) (Aldrich: 150 mesh; 58 Å; surface area 55 m^2/g; pH of aqueous suspension is 7.0 ± 0.5) was added with stirring and air dried. It was then placed in an alumina bath used as heat sink and subjected to MW intermittently. The progress of the reaction was monitored by TLC examination. Upon completion of the reaction, the product was eluted from dichloromethane. Recovering the solvent under reduced pressure gave the required products (**4a**–**4l**), which were then recrystallized from an ethanol and benzene mixture.

Method C — One pot solid support MW (basic alumina)

To the solution of chalcone **1** (0.02 mol), SBT (0.25 mol), and morpholine–piperidine–pyrrolidine (0.04 mol) basic alumina (Aldrich: 150 mesh; 58 Å; surface area 55 m^2/g; pH of aqueous suspension 8.5 ± 0.5) was added with stirring and air dried. The rest of the experimental procedure is same as described earlier in method B.

7-Morpholin-4-yl-5-phenyl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4a)

The recrystalization solvent was an ethanol and benzene mixture (1:1 *v*/*v*). Melting point 80–82 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1595. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.81 (t, 4H, CH_2OCH_2), 3.62 (t, 4H, CH_2NCH_2), 6.51–8.01 (m, 5H, Ar-H), 11.06 (s, 1H, NH), 11.10 (s, 1H, NH). ^{13}C NMR (300 MHz, $CDCl_3$) δ: C2 170.33, C4 170.31, C5 170.72, C7 162.72, C9 177.91, $C_1$0 112.52, C2 55.91, $C_{3'}$ 76.52, $C_{5'}$ 76.53, $C_{6'}$ 55.91, $C_{1''}$ 136.91, $C_{2''}$ 127.20, $C_{3''}$ 129.08, $C_{4''}$ 128.51, $C_{5''}$ 129.08, $C_{6''}$ 127.20. HRMS: M^+ 325.5. Anal. calcd. for $C_{16}H_{15}N_5O_3$: C 59.07, H 4.61, N 21.50; found: C 59.06, H 4.62, N 21.51.

5-Phenyl-7-piperidin-1-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4b)

Melting point 67–69 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1594. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.61 (m, 6H, 3′,4′,5′-CH_2), 2.92 (t, 4H, CH_2NCH_2), 7.31–8.22 (m, 5H, Ar-H), 10.90 (s, 1H, NH), 10.99 (s, 1H, NH). HRMS: M^+ 323.0. Anal. calcd. for $C_{17}H_{17}N_5O_2$: C 63.15, H 5.26, N 21.60; found: C 63.17, H 5.25, N 21.63.

5-Phenyl-7-pyrrolidin-1-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4c)

Melting point 60–62 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1610. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.01 (t, 4H, 3′,4′-CH_2), 3.71 (t, 4H, CH_2NCH_2), 6.92–8.21 (m, 5H, Ar-H), 10.92 (s, 1H, NH), 11.06 (s, 1H, NH). HRMS: M^+ 309.72. Anal. calcd. for $C_{16}H_{15}N_5O_2$: C 62.13, H 4.85, N 22.65; found: C 62.14, H 4.86, N 22.63.

5-(4-Methoxy-phenyl)-7-morpholin-4-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4d)

Melting point 75–77 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1598. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.91 (t, 4H, CH_2OCH_2), 3.63 (t, 4H, CH_2NCH_2), 3.94 (s, 3H, OCH_3), 7.04 (2H, d, *J* = 7.3 Hz, Ar-H), 7.49 (2H, d, *J* = 7.2 Hz, Ar-H), 10.89 (s, 1H, NH), 11.13 (s, 1H, NH). HRMS: M^+ 355.80. Anal. calcd. for $C_{17}H_{17}N_5O_4$: C 57.46, H 4.78, N 19.70; found: C 57.45, H 4.79, N 19.71.

5-(4-Methoxymethyl-phenyl)-7-piperidin-1-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4e)

Recrystalization solvent was an ethanol and benzene mixture (1:1 *v*/*v*). Melting point 70–73 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1599. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.71 (m, 6H, 3′,4′,5′-CH_2), 2.93 (t, 4H, CH_2NCH_2), 3.84 (s, 3H, OCH_3), 6.94 (2H, d, *J* = 7.3 Hz, Ar-H), 7.78 (2H, d, *J* = 7.2 Hz, Ar-H), 10.79 (s, 1H, NH), 11.03 (s, 1H, NH). ^{13}C NMR (300 MHz, $CDCl_3$) δ: C2 169.33, C4 168.39, C5 170.12, C7 162.41, C9 178.99, $C_1$0 112.12, $C_{2'}$ 51.13, $C_{3'}$ 22.17, $C_{4'}$ 23.16, $C_{5'}$ 22.17, $C_{6'}$ 51.13, $C_{1''}$ 135.53, $C_{2''}$ 126.97, $C_{3''}$ 128.42, $C_{4''}$ 117.32, $C_{5''}$ 128.42, $C_{6''}$ 126.52, $C_{7''}$ 51.47. HRMS: M^+ 352.7. Anal. calcd. for $C_{18}H_{19}N_5O_3$: C 61.18, H 5.38, N 19.83; found: C 61.16, H 5.38, N 19.84.

5-(4-Methoxymethyl-phenyl)-7-pyrrolidin-1-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4f)

Recrystalization solvent was an ethanol and benzene mixture (1:1 *v*/*v*). Melting point 64–66 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1600. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.01 (t, 4H, 3′,4′-CH_2), 3.71 (t, 4H, CH_2NCH_2), 3.81 (s, 3H, OCH_3), 6.87 (d, 2H, *J* = 7.3 Hz, Ar-H), 7.69 (d, 2H, *J* = 7.2 Hz, Ar-H), 10.67 (s, 1H, NH), 11.02 (s, 1H, NH). HRMS: M^+ 339.0. Anal. calcd. for $C_{17}H_{17}N_5O_3$: C 60.17, H 5.01, N 20.64; found: C 60.16, H 5.01, N 20.64.

5-Benzo[1,3]dioxol-4-yl-7-morpholin-4-yl-1*H*-pyrimido[4,5-*d*]pyrimidine-2,4-dione (4g)

Melting point 71–73 °C. IR (KBr, C=N, cm^{-1}) ν_{max}: 1598. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.86 (t, 4H, CH_2OCH_2), 3.26 (t, 4H, CH_2NCH_2), 5.94 (s, 2H, OCH_2O), 6.82 (1H, *J* = 8.0 Hz, Ar-H), 6.89 (1H, d, *J* = 8.0 Hz, Ar-H), 7.12 (s, 1H, Ar-H), 10.72 (s, 1H, NH), 11.14 (s, 1H, NH). HRMS: M^+ 369.0. Anal. calcd. for $C_{17}H_{15}N_5O_5$: C 55.28, H 4.06, N 18.90; found: C 55.27, H 4.05, N 18.88.

EFGShield — A program for parsing and summarizing the results of electric field gradient and nuclear magnetic shielding tensor calculations

Samyuktha Adiga, Dominic Aebi, and David L. Bryce

Abstract: A computer program (EFGShield) is described that simplifies and summarizes the output from electric field gradient (EFG) and nuclear magnetic shielding tensor calculations performed independently using existing quantum chemical software. In addition to summarizing tensor magnitudes according to conventions commonly used by solid-state NMR spectroscopists, the program provides Euler angles relating the orientations of the EFG and shielding tensor principal axis systems (PAS). An atomic coordinate file is generated that also contains dummy atoms representing the orientations of the EFG and shielding tensor PASs in the molecular framework. We demonstrate the functionality of the program using calculations of the chlorine EFG and shielding tensors for strontium chloride dihydrate and calcium chloride dihydrate. Several models of the chloride environment in these compounds are tested, including those where point charges are used to represent the extended three-dimensional lattices within the self-consistent charge field perturbation approach. The results highlight both the shortcomings and successes of traditional localized orbital-based basis sets in the description of the NMR properties of extended systems. We anticipate that EFGShield will be a useful tool for spectroscopists using quantum chemical software to aid in the interpretation of experimental data.

Key words: quantum chemical calculations, computer program, electric field gradient tensor, quadrupolar coupling constant, nuclear magnetic shielding tensor, Euler angles, alkaline earth chloride hydrates.

Résumé : On a mis au point un logiciel (« EFGShield ») qui simplifie et résume les résultats de calculs de gradient de champ électrique (GCE) et de tenseur de blindage magnétique nucléaire effectués d'une façon indépendante à l'aide d'un programme existant de chimie quantique. En plus de résumer les amplitudes des tenseurs en fonction des conventions généralement utilisées par les spectroscopistes de RMN, le programme fournit aussi les angles de Euler qui permettent de relier les orientations du GCE avec les systèmes d'axes principaux (SAP) du tenseur de blindage. Un fichier de coordonnées est généré qui contient aussi les atomes fictifs qui représentent les orientations des SAP du GCE et le tenseur de blindage par rapport au squelette moléculaire. On a effectué une démonstration de la fonctionnalité du programme à l'aide de calculs du GCE et des tenseurs de blindage du chlore du dihydrate du chlorure de strontium et du dihydrate du chlorure de calcium. On a évalué plusieurs modèles d'environnement du chlore dans ces composés, y compris ceux dans lesquels on utilise les charges ponctuelles pour représenter les réseaux tridimensionnels étendus à l'intérieur d'une approche autocohérente à la perturbation de champ de charge. Les résultats mettent en évidence les défauts et les qualités des ensembles de base traditionnels découlant d'orbitales localisées dans la description des propriétés RMN de systèmes étendus. On prévoit que le programme EFGShield sera un outil utile pour les spectroscopistes qui utilisent des logiciels de chimie quantique pour les aider dans l'interprétation de données expérimentales.

Mots-clés : calculs de chimie quantique, logiciel, tenseur du gradient de champ électrique, constante de couplage quadripolaire, tenseur de blindage magnétique nucléaire, angles de Euler, hydrates de chlorures de métaux alcalino-terreux.

[Traduit par la Rédaction]

Introduction

Solid-state nuclear magnetic resonance (SSNMR) spectroscopy is a useful and versatile technique for the characterization of diverse materials of chemical and biochemical interest. Much information is available on molecular structure and dynamics through the orientation-dependent chemical shift interaction and, for nuclei with spins greater than 1/2, the quadrupolar interaction. It is becoming increasingly popular to use quantum chemistry to aid in the interpretation of these experimentally accessible quantities. There are many different quantum chemistry software packages available that may be used to calculate NMR properties including the Gaussian suite of programs (1), the Amsterdam Density Functional (ADF) Program (2), CASTEP (3–5), and Dalton (6), among others.

While these programs generally provide complete descriptions of computed electric field gradient (EFG) and nuclear magnetic shielding ($\boldsymbol{\sigma}$) tensors (i.e., the complete 3 × 3 matrices that include all tensor components), we have found it convenient in our laboratory to develop a program to further treat the raw output from quantum chemical packages. For example, Gaussian 03 does not directly provide quadrupolar coupling constants, quadrupolar asymmetry parameters, or a set of Euler angles to describe the relative orientations of the EFG and shielding tensors. However, it is precisely these parameters, among others, that are required to properly simulate SSNMR spectra of quadrupolar nuclei in powdered solids (7). In cases where one is analyzing computational output for a large series of calculations, e.g., the results of a basis set study, it is convenient to have an automated analysis tool such as the one described herein.

As an example of the utility of the program, we address a question of interest concerning the NMR properties of solids that consist of extended interconnected networks of ions, rather than molecular crystals that consist of an ordered collection of essentially isolated molecular units. How well can traditional orbital-based basis sets describe the EFG and shielding tensors of nuclei in such systems? The chlorine NMR interaction tensors in the alkaline earth chlorides $SrCl_2 \cdot 2H_2O$ and $CaCl_2 \cdot 2H_2O$ are studied in the present work and the results of a series of quantum chemical calculations using various models of the chloride ion environment are analyzed using EFGShield. Comparisons to experimental data (8) and the results of plane-wave pseudopotential based calculations of the chlorine EFG and shielding tensors (8) are made in an effort to determine the usefulness of the orbital-based approach.

Tensor conventions

We briefly present the definitions and conventions used in the discussion of the EFG and shielding tensor magnitudes and orientations.

The electric field gradient tensor and quadrupolar parameters.

In an arbitrary molecule-fixed axis system the EFG tensor, $\boldsymbol{V}$, may be written in Cartesian form as,

$$[1] \qquad \boldsymbol{V} = \begin{bmatrix} V_{xx} & V_{xy} & V_{xz} \\ V_{yx} & V_{yy} & V_{yz} \\ V_{zx} & V_{zy} & V_{zz} \end{bmatrix}$$

The EFG tensor is symmetric, meaning that $V_{\alpha\beta} = V_{\beta\alpha}$ ($\{\alpha,\beta\} \in \{x, y, z\}$). Diagonalization of the tensor, so that it is expressed in its principal axis system (PAS), yields three eigenvalues (or principal components) and three corresponding eigenvectors that describe the orientation of the PAS relative to the initial molecule-fixed axis system. The principal components are denoted and ordered as follows,

$$[2] \qquad |V_{33}| \geq |V_{22}| \geq |V_{11}|$$

Since the trace of the EFG tensor is zero ($V_{33} + V_{22} + V_{11} = 0$), there are only two independent principal components. The asymmetry of the EFG tensor is described by the following asymmetry parameter,

$$[3] \qquad \eta_Q = (V_{11} - V_{22}) / V_{33}$$

In SSNMR experiments, one observes the result of an interaction between the EFG at a particular nucleus and the nuclear electric quadrupole moment (Q) specific to the nuclide under observation. The nucleus must be quadrupolar ($I > 1/2$) to possess a nonzero ground-state quadrupole moment. The nuclear quadrupolar coupling constant (C_Q) involves a product of the largest principal component of the EFG tensor and Q,

$$[4] \qquad C_Q = eV_{33}Q/h$$

Here, e, is the fundamental electronic charge, $1.602176487 \times 10^{-19}$ C; Q is the nuclear electric quadrupole moment specific to the nucleus of interest; h is Planck's constant, $6.62606896 \times 10^{-34}$ J s. Currently, all nuclear electric quadrupole moments used in EFGShield are from the 2001 collection of Pyykkö (9). All fundamental constants are the most up-to-date values from the National Institute of Standards and Technology (10). The following formula shows more explicitly how the value of C_Q (in MHz) is calculated from the value of V_{33} in Gaussian 03 (which is in atomic units, au) within EFGShield,

$$\begin{aligned} [5] \qquad C_Q[\text{MHz}] = {} & (1.602176487 \times 10^{-19}\ \text{C})(-V_{33}\ [\text{au}]) \\ & \times (Q\ [\text{fm}^2])(9.71736166 \times 10^{21}\ \text{JC}^{-1}\text{m}^{-2}\text{au}^{-1}) \\ & \times (10^{-6}\ \text{MHz Hz}^{-1})(10^{-30}\ \text{m}^2\text{fm}^{-2}) \\ & / (6.62606896 \times 10^{-34}\ \text{Js}) \end{aligned}$$

where the three additional values are included for unit conversions. A negative sign is included in front of the value of V_{33} obtained from Gaussian because an opposite sign convention is used in this program. This opposite sign convention has been noted previously in the literature (11, 12) and is most easily recognized by comparing experimental quadrupolar coupling constants for nuclei in diatomic molecules obtained from molecular beam or high-resolution microwave spectroscopy (where the experimental sign is available) to those calculated using Gaussian (11, 13).

Sometimes, the Greek symbol "χ" or "QCC" is also used to denote the quadrupolar coupling constant. For most quadrupolar nuclei typically observed in SSNMR experiments, C_Q is on the order of MHz.

The nuclear magnetic shielding tensor

The nuclear magnetic shielding tensor may be expressed in an arbitrary molecule-fixed axis system as follows, with up to nine independent elements (14, 15):

$$[6] \qquad \boldsymbol{\sigma} = \begin{bmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz} \end{bmatrix}$$

The shielding tensor is in principle antisymmetric, meaning that $\sigma_{\alpha\beta}$ is not in general equal to $\sigma_{\beta\alpha}$ ($\{\alpha,\beta\} \in \{x, y, z\}$). The symmetric ($\boldsymbol{\sigma}^{\text{sym}}$) and antisymmetric ($\boldsymbol{\sigma}^{\text{antisym}}$) parts of the tensor may be separated as follows:

© 2007 NRC Canada

$$[7]\qquad \boldsymbol{\sigma}^{\mathrm{sym}} = \frac{1}{2}(\boldsymbol{\sigma} + \boldsymbol{\sigma}^{\mathrm{t}})$$

$$= \begin{bmatrix} \sigma_{xx} & \left(\frac{\sigma_{xy}+\sigma_{yx}}{2}\right) & \left(\frac{\sigma_{xz}+\sigma_{zx}}{2}\right) \\ \left(\frac{\sigma_{yx}+\sigma_{xy}}{2}\right) & \sigma_{yy} & \left(\frac{\sigma_{yz}+\sigma_{zy}}{2}\right) \\ \left(\frac{\sigma_{zx}+\sigma_{xz}}{2}\right) & \left(\frac{\sigma_{zy}+\sigma_{yz}}{2}\right) & \sigma_{zz} \end{bmatrix}$$

$$[8]\qquad \boldsymbol{\sigma}^{\mathrm{antisym}} = \frac{1}{2}(\boldsymbol{\sigma} - \boldsymbol{\sigma}^{\mathrm{t}})$$

$$= \begin{bmatrix} 0 & \left(\frac{\sigma_{xy}-\sigma_{yx}}{2}\right) & \left(\frac{\sigma_{xz}-\sigma_{zx}}{2}\right) \\ -\left(\frac{\sigma_{xy}-\sigma_{yx}}{2}\right) & 0 & \left(\frac{\sigma_{yz}-\sigma_{zy}}{2}\right) \\ -\left(\frac{\sigma_{xz}-\sigma_{zx}}{2}\right) & -\left(\frac{\sigma_{yz}-\sigma_{zy}}{2}\right) & 0 \end{bmatrix}$$

where the superscript "t" denotes the transpose. The symmetric part of the tensor is therefore characterized by up to six independent quantities and the antisymmetric part is characterized by up to three independent variables (14). The symmetric part of the tensor is of paramount interest since the antisymmetric part does not influence NMR spectra to first order (16).

When the symmetric part of the shielding tensor is diagonalized, three eigenvalues and three eigenvectors are obtained. The eigenvalues are labelled and ordered as follows: $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$; they are unitless but since they are typically on the order of 10^{-6}, these shielding values are normally expressed in ppm. The eigenvectors describe the orientation of the PAS in the molecule-fixed axis system.

The isotropic shielding constant is given by,

$$[9]\qquad \sigma_{\mathrm{iso}} = \left(\frac{1}{3}\right)(\sigma_{11} + \sigma_{22} + \sigma_{33})$$

The anisotropy and asymmetry of the symmetric part of the shielding tensor may be conveniently described by the span (Ω) and the skew (κ), respectively,

$$[10]\qquad \Omega = \sigma_{33} - \sigma_{11}$$

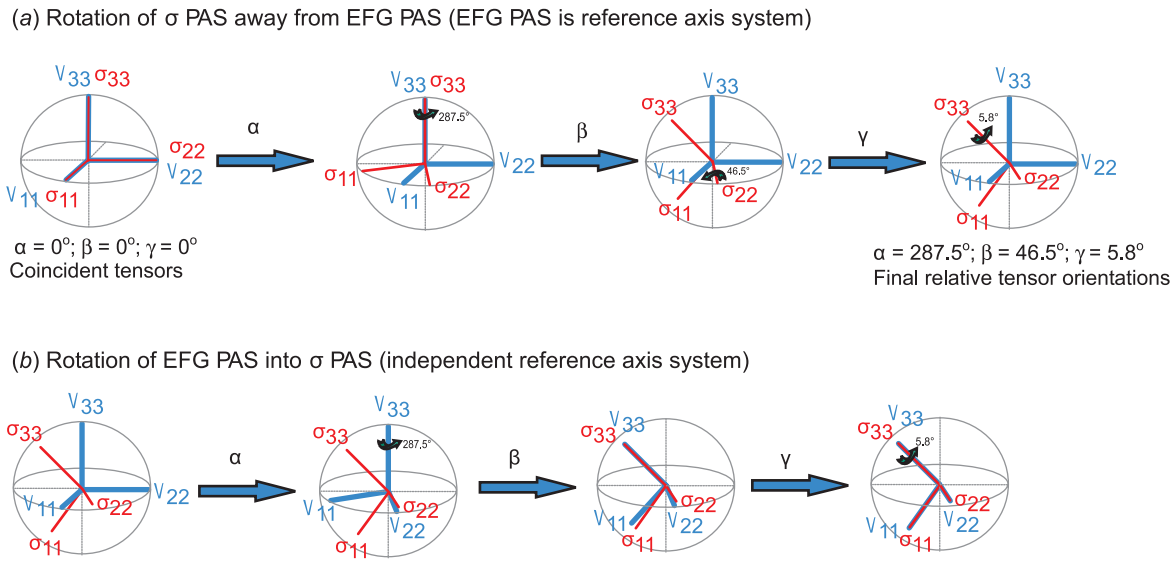
$$[11]\qquad \kappa = \frac{3(\sigma_{\mathrm{iso}} - \sigma_{22})}{\Omega}$$

This is the "Maryland convention" (17) and has also been referred to as the "Halifax convention" (18). Although these are the preferred representations, the reader should be aware that there are alternative descriptions of the anisotropy and asymmetry of the shielding tensor in use (14, 16, 19). We refer the reader to Eichele's webpage (20) and WSOLIDS software (21) for descriptions and tools for converting between different sets of conventions.

Euler angles

Diagonalization of the EFG and shielding tensors provides two sets of eigenvectors: one which relates the EFG PAS to the molecule-fixed axis system and one which relates the shielding tensor PAS to the molecule-fixed axis system. The relationship between the two PASs may be expressed by a series of three Euler angles α, β, and γ. Here, we adhere to the convention used by Eichele (20, 21) and Arfken (22), among others. We choose the EFG PAS to be the reference coordinate system. The two tensors are considered to be "coincident" when the following three pairs of axes lie in the same direction (see Fig. 1): (*i*) V_{33} and σ_{33}, (*ii*) V_{22} and σ_{22}, (*iii*) V_{11} and σ_{11}. Therefore, starting with coincident tensor PASs, the angles α, β, and γ describe the rotations of the shielding tensor PAS away from the EFG reference PAS (see Fig. 1*a*). (Starting with the final relative tensor orientations, an equivalent use of the same Euler angles describes the rotations of the EFG PAS required to bring it into coincidence with the shielding tensor PAS (see Fig. 1*b*).) Using the first description, starting with coincident tensors, the sequential rotations are as follows: rotation of the shielding tensor PAS by an angle α about the σ_{33} direction, followed by rotation of β about the new direction of σ_{22}, followed by rotation of γ about the new direction of σ_{33}. The angle β may always be easily visualized as the angle between the largest components of the two tensors, i.e., V_{33} and σ_{33}. All rotations are counterclockwise, i.e., mathematically positive. Further discussion of how the Euler angles are determined is presented later.

Description of the program



The program is currently compatible with output generated from Gaussian 03 (1) using the "NMR" and "Prop" keywords to calculate nuclear magnetic shielding and EFG tensors, respectively. EFGShield was written using C and is compiled to run under the Windows XP operating system. G03 output files generated either from Windows or Linux/Unix versions of Gaussian will work with EFGShield; the file needs to be in a "plain text" (ANSI encoding) format beforehand (this can be accomplished using MS Wordpad, for example).

EFGShield takes as input the entire G03 output file and then asks the user to indicate the "Center number" of the atom of interest. For example, if one is interested in the EFG and shielding tensor properties of atom No. 6 in the G03 output, then "6" is entered. EFGShield then automatically parses the G03 output to find the full EFG tensor and the full shielding tensor for the atom of interest (see Fig. 2). A summary of the results for atom number 6 is subsequently displayed instantaneously on the screen (Fig. 2). Additionally, a more detailed summary of the results is appended to the source file (see Fig. 3). Finally, an *xyz* molecular coordinate file is also created, with the two PASs centred on the chosen atom.

The EFG tensor is diagonalized to yield the EFG tensor eigenvalues and eigenvectors. Quadrupolar coupling constants are determined for the one or two most abundant quadrupolar isotopes of the atom chosen (depending on whether more than one quadrupolar isotope exists). The shielding tensor is symmetrized and then diagonalized to

© 2007 NRC Canada

Fig. 1. Depiction of the conventions used for the Euler angles α, β, and γ in the present work. (*a*) This series of rotations shows the rotation of the shielding tensor PAS away from the EFG PAS; the EFG PAS is used as the reference axis system. In this example, the first rotation is by α = 287.5° counterclockwise about σ_{33}; the second rotation is by β = 46.5° counterclockwise about the new direction of σ_{22}; the final rotation is by γ = 5.8° counterclockwise about the final direction of σ_{33}. The orientations depicted on the far right of part (*a*) are therefore described by the Euler angles α = 287.5°, β = 46.5°, γ = 5.8°. (*b*) Alternatively, the same set of angles may be used to rotate the EFG PAS into coincidence with the shielding tensor PAS. In this case the orientations depicted at the far left of part (*b*) are described by the Euler angles α = 287.5°, β = 46.5°, γ = 5.8° (the same orientations and same angles as in part (*a*)). The rotations depicted (successively about V_{33}, the new direction of V_{22}, and the final direction of V_{33}) will result in the coincidence of the tensors shown at the far right.

generate the shielding tensor eigenvalues and eigenvectors. The Jacobi routine from *Numerical Recipes* (23) is used to perform the diagonalizations. Eigenvectors are reported with respect to the Gaussian "Standard Orientation" axis system. Similarly, antisymmetric components of the shielding tensor are reported with respect to this axis system.

The next step is to ensure the right-handedness of the set of three eigenvectors corresponding to a particular PAS. This is done by finding the cross product between, for example, the eigenvectors corresponding to V_{11} and V_{22} in the case of the EFG tensor and requiring the eigenvector corresponding to V_{33} to lie along the resulting cross product vector. More specifically, let us define the components of the eigenvectors corresponding to the three principal components of the EFG tensor as follows:

[12] eigenvector for $V_{11} = (V_{11}x,\ V_{11}y,\ V_{11}z)$

eigenvector for $V_{22} = (V_{22}x,\ V_{22}y,\ V_{22}z)$

eigenvector for $V_{33} = (V_{33}x,\ V_{33}y,\ V_{33}z)$

where x, y, and z refer to the Gaussian "Standard Orientation" axis system. The cross product between the eigenvectors for V_{11} and V_{22} is calculated as follows:

$$[13]\quad (V_{11}x,\ V_{11}y,\ V_{11}z) \times (V_{22}x,\ V_{22}y,\ V_{22}z) = (V_{11}yV_{22}z - V_{11}zV_{22}y,\ V_{11}zV_{22}x - V_{11}xV_{22}z,\ V_{11}xV_{22}y - V_{11}yV_{22}x)$$

We then take the dot product of this resulting vector with the eigenvector corresponding to V_{33},

$$[14]\quad \text{dot product} = ((V_{11}yV_{22}z - V_{11}zV_{22}y)(V_{33}x) + (V_{11}zV_{22}x - V_{11}xV_{22}z)(V_{33}y) + (V_{11}xV_{22}y - V_{11}yV_{22}x)(V_{33}z))$$

If the dot product is unity then the EFG PAS is already right-handed. If the dot product is –1 then the EFG PAS is left-handed. We correct this latter situation by inverting the direction of the eigenvector corresponding to V_{33} (i.e., $V_{33}x$, $V_{33}y$, and $V_{33}z$ are replaced by $-V_{33}x$, $-V_{33}y$, and $-V_{33}z$). The same check of right-handedness is performed for the shielding tensor.

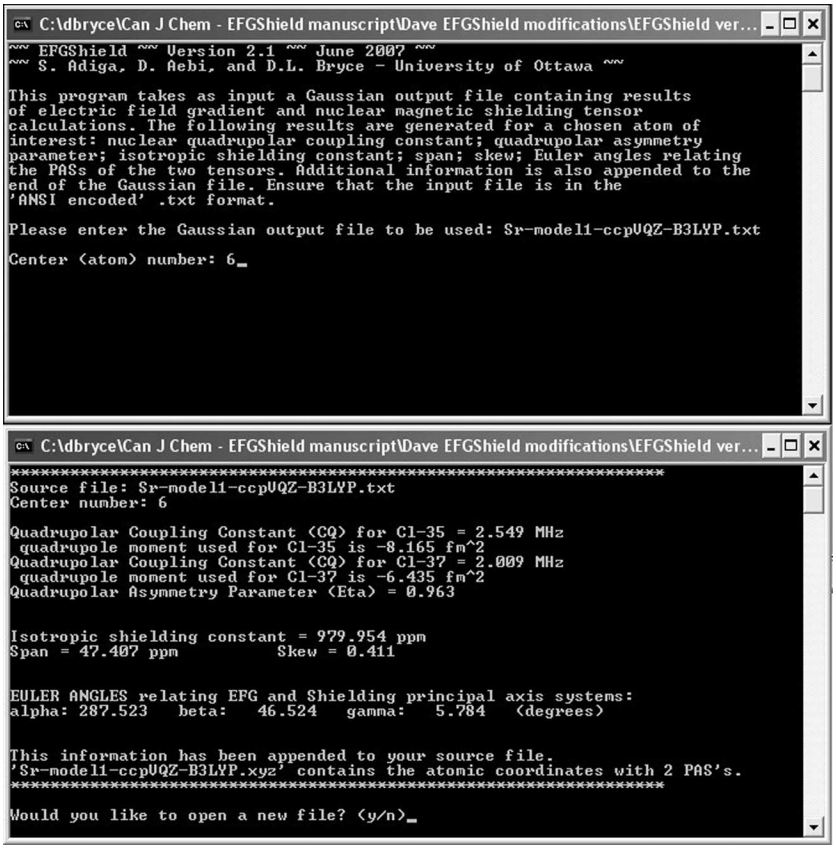
The Euler angles relating the two PASs are determined as follows. β is found by simply calculating the positive angle between the eigenvectors corresponding to V_{33} and σ_{33}. This is accomplished using a dot product operation. If the resulting value of β is greater than 90° then the signs of the components of the eigenvectors corresponding to σ_{33} and σ_{22} are inverted so that β will always be less than or equal to 90° and so that a right-handed coordinate system is maintained. α is found by calculating the angle between the V_{11} eigenvector and the projection of the σ_{33} eigenvector onto the plane comprising the eigenvectors corresponding to V_{11} and V_{22}. More explicitly, the projection vector (proj(x), proj(y), proj(z)) is calculated as follows:

$$[15]\quad \text{proj}(x) = \sigma_{33}x - (V_{33}x)\{(V_{33}x)(\sigma_{33}x) + (V_{33}y)(\sigma_{33}y) + (V_{33}z)(\sigma_{33}z)\}$$

$$\text{proj}(y) = \sigma_{33}y - (V_{33}y)\{(V_{33}x)(\sigma_{33}x) + (V_{33}y)(\sigma_{33}y) + (V_{33}z)(\sigma_{33}z)\}$$

© 2007 NRC Canada

Fig. 2. Top: Image of the introductory EFGShield screen. Users are asked to input a filename and a center number. Bottom: EFGShield's "results" screen, which provides quadrupolar and shielding tensor information for the chosen atomic center of interest. The example shown here is from a B3LYP/cc-pVQZ calculation using model 1 for strontium chloride dihydrate.



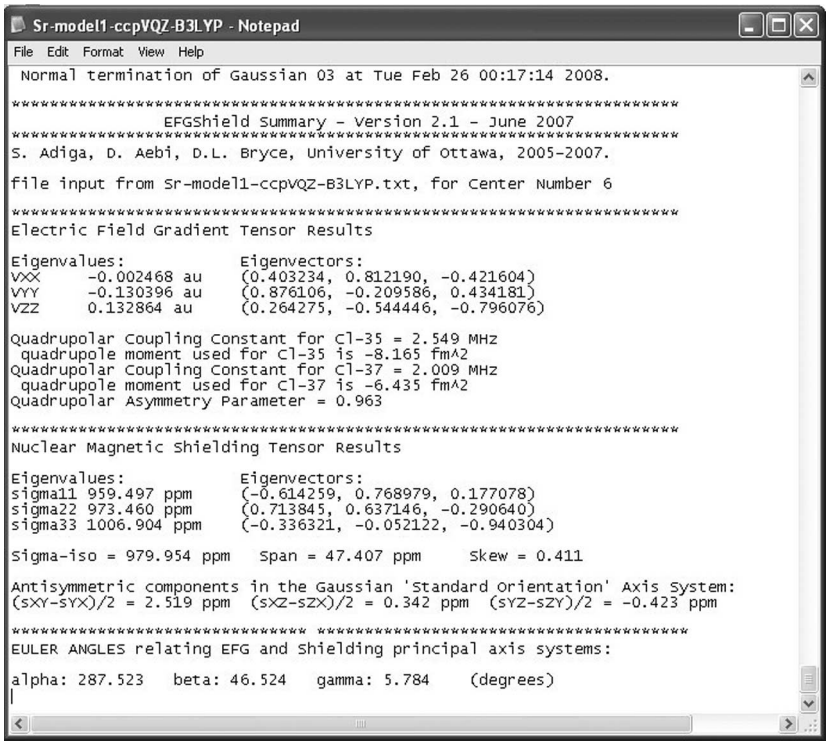


Fig. 3. An "EFGShield Summary" is appended to the end of the Gaussian source file. The example shown here is from a B3LYP/cc-pVQZ calculation using model 1 for strontium chloride dihydrate.

© 2007 NRC Canada

$$\text{proj}(z) = \sigma_{33}z - (V_{33}z)\{(V_{33}x)(\sigma_{33}x) + (V_{33}y)(\sigma_{33}y) + (V_{33}z)(\sigma_{33}z)\}$$

and the angle is then found between this projection vector and the eigenvector corresponding to V_{11} using a dot product operation. To ensure that the value obtained conforms with the convention that α should represent a counterclockwise rotation away from the direction of the V_{11} eigenvector, a check is made to determine whether the angle between the projection vector (eq. [15]) and the V_{22} eigenvector is greater than or less than 90°. If this angle is greater than 90°, then the value of α is replaced with $360° - \alpha$.

The final angle to be found is γ. The components of the vector representing the node line formed by the intersection of the plane defined by the V_{11} and V_{22} eigenvectors and the plane defined by the σ_{11} and σ_{22} eigenvectors is determined as follows:

$$\text{node}(x) = \det\begin{bmatrix} V_{33}y & V_{33}z \\ \sigma_{33}y & \sigma_{33}z \end{bmatrix}$$

$$\text{node}(y) = -\det\begin{bmatrix} V_{33}x & V_{33}z \\ \sigma_{33}x & \sigma_{33}z \end{bmatrix} \quad [16]$$

$$\text{node}(z) = \det\begin{bmatrix} V_{33}x & V_{33}y \\ \sigma_{33}x & \sigma_{33}y \end{bmatrix}$$

The value of γ is calculated as the positive angle between this node line vector and the eigenvector corresponding to σ_{22}. As in the case of α, a check is made to ensure that γ describes a counterclockwise rotation away from the node line. This is done by checking whether the angle between σ_{11} and the node line is greater than 90°, if this is the case then the value of γ is replaced with $360° - \gamma$.

In practice, if the two tensors are coincident then the Euler angles are immediately set to 0, 0, 0 and the above manipulations are skipped.

After finding the Euler angles, the lengths of the unit eigenvectors are uniformly scaled up by a factor of eight to prevent undue overlap of the dummy atoms with actual atoms during subsequent visualization. The resulting *xyz* file is readily opened with existing software, e.g., gOpenMol (24), RasMol (25), or the Chime (26) plug-in, to visualize the tensor orientations in the molecular frame.

Examples and Results

We consider EFG and shielding tensor calculations performed with Gaussian 03 (1) on the chlorine nuclei in calcium chloride dihydrate and strontium chloride dihydrate. The goal of these calculations is to explore the capability of orbital-based quantum chemical calculations in the prediction of NMR properties for systems that are inherently comprised of extended three-dimensional ionic networks in the solid state. EFGShield was used for the rapid and convenient analysis of the calculations performed on these systems. Precise experimental values for the magnitudes and relative orientations of the EFG and chemical shift tensors were recently reported from solid-state $^{35/37}$Cl NMR studies (8).

The results of both B3LYP and RHF calculations with a range of basis sets are summarized in Tables 1 and 2. Several models of the chloride environment in $SrCl_2{\cdot}2H_2O$ and $CaCl_2{\cdot}2H_2O$ were constructed based on their known diffraction structures (27, 28). For $SrCl_2{\cdot}2H_2O$, model 1 consisted simply of a chloride ion coordinated to three water molecules and five Sr^{2+} cations that are within 5 Å of the chloride ion (see Fig. 4). No additional point charges were included in model 1; this model therefore completely neglects the effects of the lattice beyond 5 Å. Model 2 consisted of the same atoms as model 1, plus seven additional point charges in the locations of the seven closest chloride ions in the surrounding lattice. Model 3 expanded on model 2 by adding point charges representative of Sr^{2+} and Cl^- ions out to a distance of 6 Å from the central chloride ion; this represents the addition of two new point charges representing Sr^{2+} and three additional point charges representing chloride ions. Model 4 consists again of the same fifteen central atoms used in model 1, with point charges representative of Sr^{2+} and Cl^- added out to a distance of 10 Å from the central chloride ion. In total there are 68 point charges representing chloride ions and 29 point charges representing strontium ions included in model 4. Models 1 and 4 are depicted in Figs. 4*a* and 4*b*. For all calculations on $SrCl_2{\cdot}2H_2O$, the five strontium cations closest to the central chloride ion were treated with the 3–21G* basis set.

For calculations on $CaCl_2{\cdot}2H_2O$, model 1 was the minimal model with no point charges. In addition to the central chloride ion, this model consists of two nearest-neighbour calcium ions and two water molecules to which the Cl^- ion is hydrogen-bonded. Model 2 included point charges out to 10 Å from the central chloride ion: 32 point charges representing Ca^{2+} and 68 point charges representing Cl^-. The two models are depicted in Figs. 4*c* and 4*d*.

In cases where point charges were used as part of the model, the self-consistent charge field perturbation (SC-CFP) procedure detailed by Zhang et al. (29) was employed. Briefly, this procedure involves an iterative series of quantum chemical calculations where the values assigned to point charges modeling the lattice are adjusted to the value obtained for the central chloride ion from the quantum chemical calculation. The iteration proceeds until the calculated charge on the central chloride ion matches (within 0.01*e*) that assigned to the point charges. Typically this required three to six iterations.

The chlorine NMR interaction tensor results obtained for strontium chloride dihydrate (Table 1) indicate both strengths and weaknesses of the calculations in reproducing the experimental solid-state NMR data. One weakness is an overestimation of $C_Q(^{35}\text{Cl})$ for most methods used and for all models used. The best agreement with the experimental value of $C_Q(^{35}\text{Cl}) = \pm(1.41 \pm 0.02)$ MHz is –2.06 MHz, which was obtained from an RHF/6–311++G(3df, 3pd) calculation on model 1. This result is comparable to the value of –2.00 MHz obtained from plane-wave pseudopotential calculations (8). Unfortunately, however, the agreement with experiment seen in Table 1 worsens as the model used for the calculations is enlarged in an attempt to incorporate more of the effects of the surrounding crystal lattice (models 2–4). This result showcases the difficulties in building a model for the lattice that properly reproduces the EFG at the central chloride ion of interest. The results for $C_Q(^{35}\text{Cl})$ using the largest model are all more than 100% in excess of

the experimental value. The calculations reproduce the value of η_Q with some consistency regardless of the model used; many of the results are within the experimental range of 0.80 ± 0.10.

Another strength of the calculations is in the prediction of the span of the CS tensor for $SrCl_2{\cdot}2H_2O$. Again, many results for the various models are within error of the experimental value of 41 ± 10 ppm. However, a systematic improvement with basis set size or with the size of the model used is not evident. The calculations fail dramatically in the calculation of the chlorine isotropic chemical shifts, and again no systematic improvement with the size of the model is seen. The largest calculated chemical shift, 60.3 ppm for a B3LYP/6–311++G(3df, 3pd) calculation on model 2, is not close to the experimental value of 142.1 ± 1.0 ppm. The chronic overestimation of the shielding constant by these calculations is in direct contrast to the results of plane-wave pseudopotential calculations, where the shielding constants were found to be significantly underestimated (8). An example of the tensor orientation information for model 1 of $SrCl_2{\cdot}2H_2O$ is presented in Fig. 5 (B3LYP/cc-pVQZ). Opening the *xyz* file generated by EFGShield using a program such as gOpenMol(24) provides an image of the molecule and the tensor orientations.

The results for calcium chloride dihydrate (Table 2) confirm the conclusions reached on the basis of the strontium chloride dihydrate data. In this case, however, the strengths and weaknesses of the calculations are emphasized even more. The quadrupolar asymmetry parameter is well-reproduced by most of the calculations. The relative tensor orientations are in outstanding agreement with experiment, despite the lack of a symmetry element requiring such orientations. However, the experimental value of $C_Q(^{35}Cl)$ is strongly overestimated as is the span of the CS tensor. This is true regardless of the model used. Interestingly, the magnitude of $C_Q(^{35}Cl)$ decreases by several MHz as a result of the inclusion of point charges out to 10 Å (model 2). Nevertheless the smallest calculated value, 9.24 MHz (RHF/6–311++G(3df, 3pd) on model 2), is still greater than 100% in excess of the experimental value of ±(4.26 ± 0.03) MHz. For comparison, our previous plane-wave calculations provided a value of 6.69 MHz (8).

Concluding Remarks

We anticipate that EFGShield will be useful to solid-state NMR spectroscopists seeking to use quantum chemical calculations to help with the interpretation of experimental spectra, particularly in the case of quadrupolar nucleus NMR in static powdered samples. The examples presented herein demonstrate the functionality of the program.

For strontium chloride dihydrate and calcium chloride dihydrate, local orbital-based quantum chemical calculations have difficulty in reproducing much of the experimental chlorine SSNMR data, despite the inclusion of point charges to model the extended crystal lattice. However, it has been shown that some parameters obtained from the calculations, such as the quadrupolar asymmetry parameter and the Euler angles describing the relative orientations of the EFG and shielding tensors, may be useful in the fitting and interpretation of experimental spectra. Clearly, theoretical models that

Isolation and characterization of an unusually stable formamidinium-containing macrotricyclic complex of lithium ion formed during the synthesis of 14-thia-1,4,8,11-tetraaza-bicyclo[9,5,3]nonadecane

Tosha M. Barclay, Alexander McAuley, and S. Subramanian

Abstract: Using 1,3-bis(chloroacetamido)propane (**5**) as the common intermediate, an efficient route is described to the stepwise syntheses of 1-thia-4,8-diazacyclodecane, [10]aneN_2S (**8**), and the pentadentate macrobicycle 17-thia-1,4,8,11-tetraazabicyclo[9,5,3]-nonadecane (**11**). During the investigation of the condensation of (**5**) with (**8**), with Li_2CO_3 used as a base the Li^+ cation is carried over as the complex of the dioxo intermediate (**10**) and survives further reduction. Prolonged contact of these complexes with $CHCl_3$ during cyclisation and extraction (in the presence of Li_2CO_3 and NaOH, respectively), leads to the formation of the complex cation $[Li(\mathbf{4})]^{2+}$ as a byproduct in which the cationic macrocycle (**4**), containing a formamidinium ring, is formed through bridging of the 1,11-nitrogens in the macrobicycle (**11**) by a -CH= group that is derived from $CHCl_3$. This renders the cavity in (**4**) too small for the inclusion of transition metal ions. Reaction of the lithium cation $[Li(\mathbf{4})]^{2+}$ with $PdCl_2$ yielded the trimetallic salt $[(Li(\mathbf{4})]\text{-}PdCl_2\text{-}[(Li(\mathbf{4})])](ClO_4)_4$ in which two $[Li(\mathbf{4})]^{2+}$ ions are bridged by a $PdCl_2$ unit through coordination of the pendant thioether donors. A crystal structure of this trimetallic salt confirms the formation of $[Li(\mathbf{4})]^{2+}$. In contrast, if triethylamine is used as a base during the cyclisation reaction leading to the formation of (**11**) and contact with aqueous NaOH and $CHCl_3$ during its isolation is minimized, the formation of (**4**) is prevented and the yield of (**11**) improved.

Key words: macrobicycle synthesis, lithium, formamidinium, paaladium, complex.

Résumé : Utilisant le 1,3-bis(chloroacétamido)propane (**5**) comme intermédiaire commun, on a réalisé une synthèse efficace des synthèses par étape du 1-thia-4,8-diazacyclodécane, du [10]aneN_2S (**8**) et du macrobicyle pentadentate 17-thia-1,4,8,11-tétraazabicyclo[9.5.3]nonadécane (**11**). Au cours de l'étude de la condensation du produit **5** avec le produit **8**, en utilisant le Li_2CO_3 comme base, le cation Li^+ est entraîné sous la forme de complexe de l'intermédiaire dioxo (**10**) et il survit à une réduction ultérieure. Un contact prolongé de ces complexes avec le $CHCl_3$ pendant la cyclisation et l'extraction (en présence respectivement de Li_2CO_3 et de NaOH) conduit à la formation d'un sous-produit, le cation complexe $[Li(\mathbf{4})]^{2+}$, un macrocycle cationique (**4**) qui contient un cycle formamidinium formé par le biais d'un pontage des atomes d'azote 1,11 du macrobicyle **11** avec un groupe "-CH=" dérivé du $CHCl_3$. Cette cyclisation rend la cavité du produit **4** trop petite pour l'inclusion d'ions de métaux de transition. La réaction du cation complexe $[Li(\mathbf{4})]^{2+}$ avec le $PdCl_2$ conduit à la formation du sel trimétallique $[Li(\mathbf{4})\text{-}PdCl_2\text{-}[Li(\mathbf{4})](ClO_4)_4$ dans lequel deux ions $[Li(\mathbf{4})]^{2+}$ sont réunis par un pont de coordination du $PdCl_2$ avec les groupes thioéthers donneurs latéraux. Une étude de la structure cristalline de ce sel trimétallique confirme la formation du $[Li(\mathbf{4})]^{2+}$. Toutefois, si on utilise de la triéthylamine comme base dans la réaction de cyclisation, il y a formation du composé **11** alors que si on minimise le contact avec le NaOH aqueux ou le $CHCl_3$ lors de l'isolation des produits, il est possible d'éliminer la formation du composé **4** et d'améliorer le rendement en produit **11**.

Mots-clés : synthèse de macrobicycles, lithium, formamidinium, palladium, complexe.

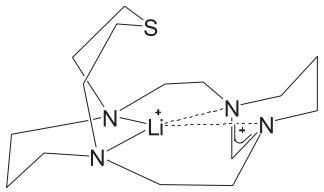
Introduction

The macrocyclic ligand, cyclam (1,4,8,11-tetraazacyclotetradecane), has been used extensively as a fundamental framework from which new ligand structures have been derived (1). This should not be surprising considering the extraordinarily high thermodynamic stability and kinetic inertness of cyclam and cyclam-based complexes of a wide range of metal ions (2) and also the extensive chemistry developed during the past decade for selective functionalization of such macrocycles (3). As a result, such derivatives

 doi:10.1139/V07-066 © 2007 NRC Canada

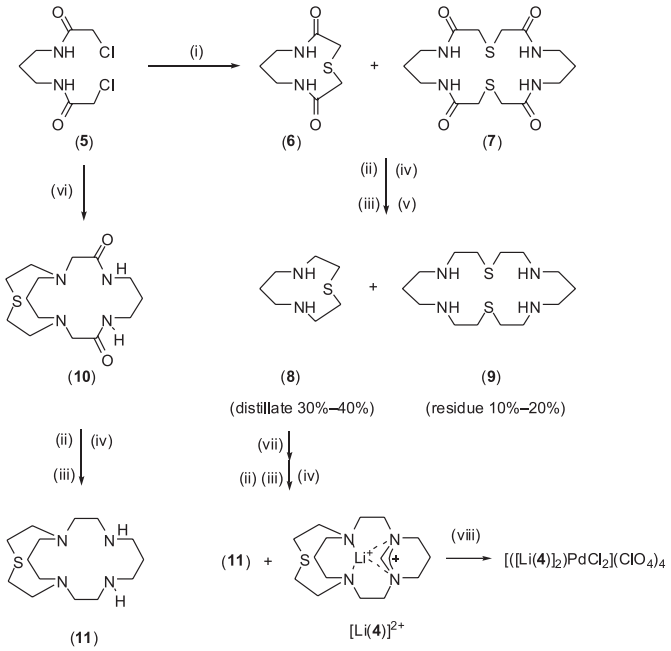
have been used extensively in supramolecular chemistry (4) and also in diagnostic and pharmaceutical applications (5). In this laboratory, efforts have been directed towards the synthesis of three isomeric macrobicyclic ligands, (**1**), (**2**), and (**3**). Each of these ligands (a [9]ane, a [10]ane, and a hemicryptate structure, respectively) is incorporated into a cyclam frame with an ether (-O-) (6), a secondary amine (-NH-) (7), or a thioether (-S-) (8) donor in one of the axial positions. The objective of these investigations is to study the effect of structure on the kinetics of substitution on the only axial site available in the penta-coordinate complexes of these ligands (9). Also, these macrobicycles may act as precursors to fully developed hexa-coordinate cryptate ligands.



The syntheses of the macrobicycles and their complexes have been reported from this laboratory for (**1**) (6–8*a*), (**2**) (8*b*), and (**3**) (9) with, in the case of (**1**) and (**2**), use being made of the precursors 1,4-diaza-7X-cyclononane, [9]aneN_2X and 1,5-diaza-8X-cyclodecane, [10]aneN_2X, respectively, where X = O or S. Access to a series of [9]aneX_3 ligands (X = O, NH, and S or a combination of these donors) is well-documented (10). However, the corresponding [10]aneX_3 analogues were prepared by a procedure developed by Richman and Atkins (11), where harsh conditions are associated with the removal of tosyl protecting groups causing cleavage in the ether and thioether systems leading to low yields (12). A recent report from this laboratory described the synthesis and structure of a Ni(II) complex of (**11**) (8*b*) in which (**8**) and (**11**) were prepared from different reagents. To prepare reasonable quantities of (**11**), an efficient route to (**8**) is required. This paper describes a procedure that uses 1,3-bis(chloroacetamido)propane (**5**), as a common intermediate, in the syntheses of both (**8**) and (**11**).

(**1**) (**2**) (**3**)

X = O, NH, S



Also presented in this report are details of the formation of the unusual cationic complex, $[Li(\mathbf{4})]^{2+}$ that is formed under some conditions as a major by-product during the synthesis and isolation of (**11**). The $[Li(\mathbf{4})]^{2+}$ ion has been isolated as a Pd(II) bridged species and the single crystal X-ray structure of the trimetallic species is reported here.

Experimental

NMR spectra were obtained on a Bruker AMX360 or AC300 high-field spectrometer using $CDCl_3$ for the final macrocylic ligands and DMSO-d_6 for the precursor oxo species. Mass spectra were recorded on a Finnegan 330 GC-MS instrument either by methane chemical ionization or using a low-energy electron impact method for the ligands and on a Kratos Concept instrument by FAB or LSIMS method for the complexes. 1,2-Diaminoethane (anhydr.), 1,3-diaminopropane, triethylamine, chloroacetyl chloride, and $Na_2S{\cdot}9H_2O$ purchased from Sigma-Aldrich Chemical Co. were used without further purification. 1,2-Bis(chloroacetamido)ethane and 1,3-bis(chloro-acetamido)propane (**5**) were prepared by a method similar to that described by Bradshaw and co-workers (13) and were purified by recrystallization from hot dry acetonitrile at 60 °C and dried under vacuum.

Scheme 1. Reaction conditions: (*i*) Na_2S (1:1 *v*/*v*), aq. CH_3CN; (*ii*) BH_3–THF (1 mol/L); (*iii*) HCl (3 mol/L); (*iv*) NaOH (3 mol/L); (*v*) Kruegler distillation to separate (**8**); (*vi*) (**8**)–Et_3N–CH_3CN; (vii) (**5**)–Li_2CO_3–CH_3CN–$CHCl_3$; (viii) $PdCl_2$–CH_3CN–$HClO_4$.

Caution! Perchlorate salts of organic ligand-containing transition metal complexes are potentially explosive. Use sintered funnels for filtration and vacuum techniques for drying samples. Prepare and handle only small quantities.

In Scheme 1 it is seen that a common intermediate (**5**) is used in the syntheses of both the precursor macrocycle (**8**) and the final macrobicycle (**11**).

3,9-Dioxo-1-thia-4,8-diazacyclodecane (6) and 3,9,13,19-tetraoxo-1,11-dithia-4,8,14,18-tetraazaeicosane (7)

To a dry colorless powder of 1,3-bis(chloroacetamido)propane (**5**) (65.0 g, 0.28 mol) placed in a 5 L round-bottomed flask, 2.5 L of a mixture of acetone–water (1:1 *v*/*v*) was added and the mixture was refluxed under nitrogen yielding a clear solution. To minimize photolytic hydrolysis of (**5**), the glass vessel was covered with aluminum foil. A solution of 98% pure $Na_2S{\cdot}9H_2O$ (70 g, 0.30 mol) in 0.5 L of water was added very quickly through a dropping funnel and the mixture (pH 11.0) was refluxed for 40 h. Acetone was re-

© 2007 NRC Canada

moved under vacuum in a rotary evaporator. After reduction of the aqueous solution to about 300 mL, the solution was neutralized with HCl to pH 7, and the resulting crystalline colorless powder was filtered under suction. This solid was found not to be hygroscopic although it retained large amounts of water. It was dried in a vacuum oven at 80 °C for at least 24 h. The filtrate was further concentrated and any colorless precipitate that formed was recovered. This process was repeated until about 47 g of the product was recovered. Yield 88% (based on **6**). ^{1}H NMR δ: 1.62 (m, 2H, C-CH_2-C), 3.08 (d of t, 4H, N-CH_2), 3.18 (s, 4H, CO-CH_2-S), 3.3 (broad, NH). ^{13}C NMR δ: 28.2 (C-CH_2-C), 36.4 (N-CH_2), 39.9 (S-CH_2), 171.7 (C=O). MS (CH_4 CI): 189 (M + 1), 217 (M + 29), 229 (M + 41). A second set of ^{13}C NMR peaks at 27.8, 35.8, 37,2, and 171.6 was also observed and assigned to the dimeric species 3,9,13,19-tetraoxo-1,11-dithia-4,8,14,18-tetraazaeicosane (**7**).

1-Thia-4,7-diazacyclodecane (8) and 1,11-dithia-4,8,14,18-tetraazaeicosane (9)

A vacuum-oven dried mixture of compounds (**6**) and (**7**) (24 g, 120 mmol based on (**8**)) was ground to a fine powder and charged into a 1 L round-bottomed flask. Under N_2, 350 mL of BH_3·THF (1 mol/L) was added under gentle stirring and subsequent heating to a gentle reflux for 24 h. The reaction mixture was cooled to room temperature. While vigorously stirring the mixture, the excess reductant was decomposed by the slow addition of methanol. Removal of the volatile solvents and addition of an aqueous solution with HCl (3 mol/L) was followed by reflux for 1 h. After cooling the solution and concentration to dryness, the residual solids were dissolved in about 300 mL of water and transferred to a 1 L beaker. The solution was made strongly basic (to about 3 mol/L) with solid NaOH while cooling in an ice bath. This basic solution was extracted with six aliquots of $CHCl_3$ (50 mL) at room temperature. The $CHCl_3$ extracts were dried and concentrated under vacuum, yielding a viscous oil (12.3 g, 78 mmol based on (**8**)). Using a Kugelrohr apparatus, the oil was distilled at 20 mmHg (1 mmHg (0 °C) = 133.322 4 Pa) pressure at 60–70 °C. This yielded 5.5 g (34 mmol, 28%) of a pale yellow oil that was identified to be pure (**8**). ^{1}H NMR δ: 1.60 (m, 2H, C-CH_2-C), 2.71 (d of t, 4H, S-CH_2), 2.89 (m, 8H, CH_2-N-CH_2), 3.1 (broad, NH). ^{13}C NMR δ: 28.6 (C-CH_2-C), 35.3 (S-CH_2), 48.3 and 49.8 (N-CH_2). MS (CH_4 CI): 161 (M + 1), 189 (M + 29), 201 (M + 41).

The remaining 14.3 g of dark brown residue was identified as impure (**9**). ^{1}H NMR δ: 1.67 (m, 2H, C-CH_2-C), 2.71 (d of t, 4H, S-CH_2), 2.76 (m, 8H, CH_2-N-CH_2), 3.3 (broad, NH). ^{13}C NMR δ: 29.4 (C-CH_2-C), 32.8 (S-CH_2), 47.9 and 48.7 (N-CH_2). MS (CH_4 CI): 321 (M + 1), 349 (M + 29), 361 (M + 41).

14-Thia-1,4,8,11-tetraazabicyclo[9,5,3]-nonadecane-3,9-dione (10)

To a solution of (**5**) (2.96 g, 13 mmol) in 500 mL of dry acetonitrile was added distilled [10]aneN_2S (**8**) (1.66 g, 10.4 mmol) in 50 mL of dry acetonitrile. This clear solution was added to a refluxing mixture of 2.5 L of anhydrous acetonitrile and 10 mL of Et_3N at the rate of 60 mL/min under a N_2 atmosphere. After completion of addition, the reaction mixture was refluxed for a period of 20 h. Most of the acetonitrile was distilled off in a rotary evaporator yielding a viscous oil that was extracted with acetone. An acetone insoluble fraction that consisted mostly of $[Et_3NH]^+Cl^-$ was filtered off. The acetone extracts were concentrated to obtain a colorless solid (2.0 g, 6.4 mmol). Yield 57% based on (**8**). ^{1}H NMR δ: 1.67 (m, 2H, C-CH_2-C), 2.71 (d of t, 4H, S-CH_2), 2.76 (m, 8H, CH_2-N-CH_2), 3.3 (broad, NH). ^{13}C NMR δ: 29.4 (C-CH_2-C), 32.8 (S-CH_2), 47.9 and 48.7 (N-CH_2), 169.1 (C=O). MS (CH_4 CI): 321 (M + 1), 349 (M + 29), 361 (M + 41).

14-Thia-1,4,8,11-tetraazabicyclo-[9,5,3]-nonadecane (11)

Crude, powdered, and vacuum dried bicyclic diamide (**10**) (2.20 g, 6.9 mmol) was placed in a 1 L round-bottomed flask into which 400 mL of THF·BH_3 (1 mol/L) was siphoned. The reaction mixture was gently stirred and refluxed for 24 h under N_2. The mixture was cooled and transferred to a 2 L beaker, and while stirring, methanol was added dropwise to decompose excess borane. After a HCl (3 mol/L) work-up, the solution was concentrated to dryness on a rotary evaporator. The resulting mass was suspended in 150 mL of water and a solution of NaOH (10 mol/L) was added a little at a time until a clear solution of pH 13 was obtained. This solution was extracted with 5 × 60 mL of $CHCl_3$, the combined extracts were dried over anhydr. Na_2SO_4, and concentrated to dryness. Traces of solvents were removed under vacuum to get a viscous oil (1.0 g, 3.5 mmol) of the ligand. Yield 51%.

Purification of (11)

Though ligand (**8**) prepared by the preceding method was pure, traces of impurities could be removed only by forming a Cu(II) complex and separating the pure cation $[Cu(\mathbf{11})]^{2+}$ from the impurities on a Sephadex CM C-25 cation exchange column. In a typical procedure, (**11**) (1.0 g, 3.5 mmol) in 25 mL of ethanol was added to a solution of $CuCl_2$·$2H_2O$ (0.6 g, 3.5 mmol) in 25 mL of water. The solution was refluxed for 2 h, diluted with 150 mL of distilled water, and loaded onto a sephadex CM C-25 column (10 cm × 50 cm) fitted with a medium frit, and eluted with a NaCl (0.1 mol/L) solution. Traces of initial impurities were collected with 500 mL of NaCl (0.1 mol/L) and discarded. The main fraction containing $[Cu(\mathbf{11})]^{2+}$ was collected as a single band with 300 mL of NaCl (0.15 mol/L). This fraction was concentrated to about 100 mL, treated with 25 mL of a 10% solution of Na_2S·$9H_2O$, and refluxed for 1 h. The precipitated CuS was filtered under gravity and the ligand was extracted with three 25 mL aliquots of $CHCl_3$. The $CHCl_3$ extracts were collected, dried with anhydr. Na_2SO_4, and evaporated to dryness. Traces of solvents were removed under vacuum. The resulting oily product crystallized into a waxy solid. Recovered yield 0.9 g. ^{1}H NMR δ: 1.60 and 1.67 (m, 2H each, C-CH_2-C), 2.41 (d of t, 4H, S-CH_2), 2.62 (broad multiplet, 16H, CH_2-N-CH_2), 2.98 (broad, 2HNH). ^{13}C NMR δ: 27.9 and 28.3 (-CH_2-CH_2-CH_2-), 30.3 (-S-CH_2-), 47.6 and 48.1 (-CH_2-CH_2-CH_2-), 55.8, 55.9, and 56.7 (-N-CH_2). MS (CH_4 CI): 287 (M + 1), 315 (M + 29), 327 (M + 41). FAB MS showed a very clean peak at 287.2 (M + 1).

[[Li(4)]-$PdCl_2$-[Li(4)]]$(ClO_4)_2$

To Li_2CO_3 (1.0 g, 13.5 mmol) and NaI (1.25 g, 8.3 mmol) in a 5 L three-necked round-bottomed flask was added 2 L of reagent grade acetonitrile. Upon refluxing this mixture, solutions of distilled [10]aneN_2S (**8**) (0.98 g, 6.1 mmol) dissolved in 500 mL of $CHCl_3$–CH_3CN (1:1 *v*/*v*) and (**5**) (1.39 g, 6.1 mmol) in 20% aq. CH_3CN were added separately and simultaneously using pressure equalized dropping funnels. The rate of addition was maintained at about 50 mL/h and the reaction mixture was maintained under an atmosphere of N_2. After 48 h of refluxing, insoluble materials, mostly of unused Li_2CO_3 and NaCl, were filtered off and the reaction mixture concentrated to obtain 2.5 g of a colorless solid, which was soluble only in water. This solid was dried in a vacuum oven and reduced with 150 mL of BH_3–THF using a procedure similar to that described earlier for the preparation of (**11**). After acid hydrolysis and basification, the product was extracted with $CHCl_3$ in a continuous liquid–liquid extractor to yield 1.2 g of a plastic hygroscopic solid.

To a solution of 100 mg dissolved in 2 mL of $CHCl_3$ was added under reflux a solution of $PdCl_2$ (62 mg, 0.35 mmol) in 25 mL of CH_3CN. The reaction mixture was refluxed for 48 h. Some Pd black that formed was removed by gravity filtration and to the clear filtrate, $HClO_4$ (1 mL, 1.0 mol/L) was added from which the trimetallic product crystallized (60 mg, 0.05 mmol). MS by use of a solution of the complex in CH_3CN–H_2O (8:2 *v*/*v*), two prominent peaks were observed in LSIMS (*m*/*e* = 454.1 (100%) for $[C_{30}H_{54}N_8S_2Li_2PdCl_2O_8]^{2+}$ and *m*/*e* = 297.1 (55%) for $[C_{15}H_{29}N_4S]^+$ ion) confirm the existence of both the trimetallic ion and the lithium-containing macrocycle (**4**).

X-Ray crystal structure determination

Single crystals of $[(Li(\mathbf{4}))_2PdCl_2](ClO_4)_2 \cdot H_2O$ were obtained by vapor diffusion or layering of Et_2O into solutions of the complex in CH_3CN. Data were collected on a Smart 1000 CCD area detector diffractometer with graphite-monochromated Mo Kα (λ = 0.710 73 Å) radiation. The cell parameters were determined from a nonlinear least-squares fit of the data. The data were corrected for absorption by the SADABS method (14). The structures was solved by direct methods by use of the SHELX 97 program (15), and refined by full-matrix least-squares on F^2 by use of all reflections. Hydrogen atom positions were initially determined by geometry and refined by a riding model. Non-hydrogen atoms were refined with anisotropic displacement parameters. Crystal structure parameters for $[(Li(\mathbf{4}))_2\ PdCl_2](ClO_4)_4 \cdot H_2O$ is presented in Table 1 and selected bond lengths and angles are listed in Table 2.

Discussion

Formation of the formamidinium complex

The formation of the formamidinium moiety within both triaza (16) and cyclam (3, 16*c*) rings has been observed previously. Such a configuration has been prepared in $CHCl_3$ and used in the selective functionalization of cyclam (3*b*). Under the prolonged exposure to strongly alkaline conditions used in this as well as the previous study (8*b*), $CHCl_3$ is known to form the dichlorocarbene $:CCl_2$ through the loss of HCl. As shown in scheme 1, in macrocycles containing 1,3-diaminopropane moieties, insertion of the dichlorocarbene into an N–H bond followed by elimination of HCl can lead to the formation of a $>N^+{=}CH{-}NH:$ functional group. The formation of the formamidinium moiety also reduces the 14-membered macrocyclic cavity to a 12-membered ring that is asymmetric and too small to permit incorporation of a transition metal ion (Scheme 2). However, a small cation such as Li^+ is retained within a thermodynamically stable complex. Relatively recently, we reported the structure of an encapsulated Li^+ complex in the macrotricyclic ligand [9]aneN_4S_2 that is derived from the 14-membered cyclam unit (8*c*). The presence of Li^+ during the preparation of this ligand led to its incorporation into [9]aneN_4S_2, and attempts to replace the Li^+ by transition metal ions have not been successful. It would appear that once present within the dioxo precursor (**10**), the Li^+ ion is held sufficient strongly to withstand the reduction process.

Structure of [[Li(4)]-$Pd(Cl)_2$-[Li(4)]]$(ClO_4)_4 \cdot H_2O$ [2]

An ORTEP diagram of the complex cation is presented in Fig. 1. The interesting aspects of this structure are the confirmation of the formamidinium group within the macrocyclic ring and the binding of the Li^+ ion.

The introduction of the formamidinium ring introduces an asymmetry into the macrocycle and that is reflected in the following two features: (*i*) the introduction of a conformational rigidity to the cyclam framework that renders the resulting 12-membered macrocycle a powerful chelating agent for Li^+ ion and (*ii*) this in turn forces the thioether donor to coordinate in an exodentate fashion. As seen in Fig. 1, the Li^+ is four coordinate, situated within bonding distances to the four nitrogens of the macrocycle, while the pendant thioether, in an exodentate fashion, coordinates to the square planar Pd(II) center.

Structural and molecular aspects of the coordination chemistry of Li^+ ion have been reviewed (17*a*). In an open frame formamidinium complex in which Li^+ adopts tetrahedral geometry, Li–N distances vary between 2.0 and 2.3 Å (17*b*). The Li–N distances in the trimetallic species described here can be divided into two distinct types. The bond distances Li–N1 (1.853(9)) and Li–N4 (1.839(9)) associated with the free-standing tertiary N donors of the "1,3-diaminopropane" moiety are substantially shorter than the Li–N2 (2.143(10)) and Li–N3 (2.214(9)) distances associated with the formamidinium ring nitrogens. An important aspect to note is that owing to the presence a single positive charge and its delocalization over the two nitrogen atoms, the formamidinium nitrogens might be described effectively

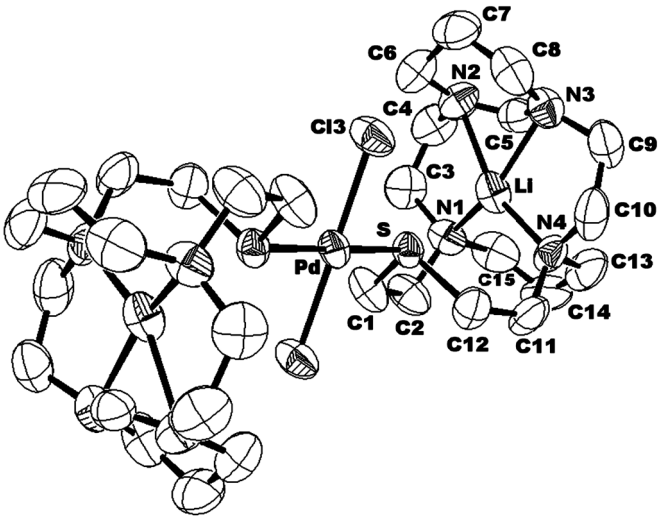
as 1e$^-$ electron donors, while the free-standing tertiary nitrogens provide regular lone pairs. The presence of an asymmetric 12-membered macrocycle is also reflected in a comparison with the regular 14-membered macrocycle (Li–N 2.080(3)) (8*c*). Also, within the small penta aza-[5,5,5]-cryptate (18) that selectively incorporates Li^+ ions, there is no distinction between two axial tertiary Li–N distances (Li–N(1) 2.008(13) and Li–N(3) 2.037(13)) and the three equatorial nitrogens (Li–N(2) 2.083(12), Li–N(5) 2.015(11), and Li–N(4) 2.056(11)) one of which is a secondary nitrogen. Again, the difference with the current system is the presence of a delocalized double bond within the formamidinium ring. In contrast to the current investigation, a nickel(II) complex of a formamidinium-containing cyclam ring (16*c*) has been described. In the nickel(II) complex, only one formamidinium and two secondary nitrogens are coordinated the metal centre. This again illustrates how the presence of a formamidinium ring influences coordination geometry within such macrocycles.

Synthesis



Generally, procedures reported for the formation of thioether macrocycles involve the reaction of a dithiolate anion with an appropriate α,ω-disubstituted halide (19). The use of Na_2S to form thioether macrocycles is relatively rare (8*c*). In the procedure presented here, an aqueous solution of

sodium sulfide is used in the intramolecular cyclisation of the chloroacetamido groups in (**5**) to form the precursor [10]aneN_2S (**8**). Under moderately dilute conditions (0.1 mol/L) and in a large batch, again a mixture of cyclic amides (**6**) and (**7**) were formed in good yields. However, no attempt was made to separate these amides (8*b*). The crude product was reduced directly to a mixture of [10]aneN_2S (**8**) and [20]aneN_4S_2 (**9**). The yield of this mixture varied within 60%–75%. In a subsequent microdistillation under vacuum, (**8**) was distilled off a clear pale yellow liquid and (**9**) was recovered from the residue. The fact that (**8**) can be obtained by a simple distillation, both in high purity and in large quantities makes this procedure more attractive.

In the modified procedure reported here for the macrocycle (**11**), the alkali metal carbonates used were replaced with triethylamine. The advantages of using Et_3N as a base are threefold: (*i*) the absence of alkali metal ions eliminates formation of complexes of cyclic diamide intermediate (**10**) and thus facilitates its separation from the reaction mixture; (*ii*) the nearly identical boiling points of acetonitrile and triethylamine results in most of the base being in the vapor phase while making available sufficient amounts in the liquid as the reaction progressed; and (*iii*) triethylamine hydrochloride, being highly insoluble in an acetone–acetonitrile mixture, is easily removed during the isolation of (**10**). Another advantage of the modified procedure are the shorter reaction times (less than 20 h) and the absence of chloroform during the cyclisation reaction of (**8**) with (**5**).

Scheme 2. Formation of formamidinium ring from $CHCl_3$ in the presence of NaOH.

While developing simpler routes to [10]aneN_2S (**8**) attempts were also made to synthesize the macrocycle [9]aneN_2S using the reaction of 1,2-bis(chloroacetamido)ethane with aq. Na_2S. However, only an insoluble polymeric species was isolated. The difference in the reactivities of 1,2-bis(chloroacetamido)ethane and 1,3-bis(chloroacetamio)propane (**5**) may arise from their conformation. 1,3-Disubstituted propanes in general tend to be adopted by a "w" conformation, in contrast to transoid conformations generally found in most 1,2-disubstituted ethanes in which the reactive groups are oriented in an unfavorable direction for cyclisation to be successful (20).

Summary

In summary, in the synthesis of bi- and tri-macrocycles of this type, the use of tertiary amines instead of alkali metal carbonates appears to eliminate many of the problems normally encountered. In particular, the tendency of the oxo derivatives such as (**10**) to complex alkali metal ions is a significant factor. Many of these macrocycles are also strong Lewis bases in weakly polar nonhydroxylic solvents such as $CHCl_3$. Prolonged contact and heating leads to the formation of formamidinium ring with chelation of small metal ions like Li^+.

Fluorescence quenching of gramicidin D in model membranes by halothane

Anna Carnini, Trinh T. Nguyen, and David T. Cramb

Abstract: Inhaled anesthetics were introduced in surgery over a century ago. To this day, the molecular mechanism of anesthetic action remains largely unknown. However, ion-channels of neuronal membranes are believed to be the most-likely molecular targets of inhaled anesthetics. In the study presented here, we investigated the interaction of a simplified ion-channel system, gramicidin, with halothane, a small haloalkane inhaled anesthetic in various environments. Fluorescence-quenching experiments of gramicidin D in dioleoylphosphatidylcholine (DOPC) large unilamellar vesicles (LUVS) have shown that halothane can directly interact with the ion channel (K_{SV} = 66 M^{-1}). Halothane quenched the fluorescence from tryptophan residues located at the lipid bilayer – aqueous interfaces as well as those tryptophans located deeper in the bilayer. Quenching data from gramicidin D in sodium dodecyl sulfide (SDS) micelles revealed that the tryptophan residues located at the micelle–solvent interface were preferentially quenched by halothane (K_{SV} = 22 M^{-1}). In 1-octanol, fluorescence quenching was observed, but with a lower K_{SV} value (K_{SV} = 6 M^{-1}) than in DOPC LUVS and SDS micelles. Taken together, these results indicate that halothane interactions with gramicidin, mediated by a lipid bilayer, are the strongest, and that the mechanism of anesthetic action may also be lipid-mediated.

Key words: anesthetics, lipid bilayer, membrane protein, fluorescence quenching.

Résumé : Les anesthésiants absorbés par inhalation ont été introduits en chirurgie il y a plus de cent ans. À ce jour, le mécanisme moléculaire de l'action anesthésique demeure toujours largement inconnu. Toutefois, on croit généralement que les membranes neuronales à canaux ioniques sont les cibles moléculaires les plus probables des anesthésiants absorbés par inhalation. Dans l'étude présentée ici, on a étudié l'interaction d'un système à canal ionique simplifié, la gramicidine, avec l'halothane, une petite molécule d'alcane halogéné utilisée comme anesthésiant dans divers environnements. Des expériences de piégeage de la fluorescence de la gramicidine D dans de grosses vésicules unilamellaires (GVUL) de dioléoylphosphatidylcholine (DOPC) ont permis de montrer que l'halothane peut interagir directement avec le canal ionique (K_{SV} = 66 M^{-1}). L'halothane permet de piéger la fluorescence des résidus de tryptophane situés aux interfaces de la bicouche lipide – eau ainsi que celles des tryptophanes situés dans des portions plus profondes de la bicouche. Les données du piégeage de la gramicidine D dans des micelles de dodécylsulfure de sodium (DSS) révèlent que les résidus de tryptophane situés à l'interface micelle–solvant sont piégés d'une façon préférentielle par l'halothane (K_{SV} = 22 M^{-1}). Dans le 1-octanol, on a observé du piégeage; toutefois la valeur de K_{SV} (K_{SV} = 6 M^{-1}) est beaucoup plus faible que celles observées dans les micelles de GVUL DOPC ou de DSS. Considérés dans leur ensemble, ces résultats suggèrent que les plus fortes interactions sont celles de l'halothane avec la gramicidine qui sont catalysées par une bicouche lipidique et que le mécanisme de l'action anesthésique pourrait aussi être catalysé par les lipides.

Mots-clés : anesthésiques, bicouche lipidique, membrane de protéine, piégeage de la fluorescence.

Introduction

Inhaled anesthetics were introduced in surgery over a century ago. To this day, the molecular mechanism of anesthetic action remains elusive. At the beginning of the twentieth century, Overton and Meyer noted a strong correlation between oil solubility of general anesthetics and their anesthetic potency (1, 2) (Overton–Meyer correlation). As a result of the Overton–Meyer correlation, it was hypothesized that inhaled anesthetics exert their action by targeting the lipid matrix of neuronal cell membranes (3).

In recent years, a protein-mediated mechanism of general anesthesia has been favored over the solely lipid-mediated mechanism. Ion channels of neuronal membranes are believed to be the most-likely molecular targets of inhaled anesthetics (4, 5). Emerging evidence suggests that anesthetics

might also interact directly with G-protein-coupled receptors (GPCRs) (6, 7). However, a specific receptor for general anesthetics has yet to be identified.

A molecular understanding of the mechanism of anesthesia will require detailed structural information regarding anesthetic–protein complexes. This presents a challenge when working with membrane proteins, since structural information is scarce. To overcome this problem, novel approaches have included using well-defined water-soluble model systems, such as synthetic four α-helix bundles (8) and the naturally occurring serum albumin proteins. These studies have indicated that inhaled anesthetics bind to pre-existing hydrophobic cavities or defects found within water-soluble protein model systems. Within these cavities, dipole – induced dipole interactions between anesthetics and hydrophobic side chains, such as tryptophan and phenylalanine, have been found to further stabilize and increase binding affinities (9, 10). The current consensus is that inhaled anesthetics interact with proteins via weak hydrogen and van der Waals bonding. Recent work by Liu et al. has shown that in the case of ferritin, a natural 4-helix bundle containing protein, weak polar interactions can in fact confer significant anesthetic selectivity (11).

Despite the significant insights into inhaled anesthetic – protein interactions obtained from water-soluble protein studies, the structural requirements for optimal anesthetic binding in membrane proteins is unclear. In the study presented here, we investigate the interaction of a simplified ion-channel system, gramicidin, with halothane, a small haloalkane-inhaled anesthetic. Halothane, although seldom used in clinical work today, is frequently used in veterinary medicine and in drug–protein binding studies. Gramicidin is a well-characterized small polypeptide composed of alternating D- and L-amino acids (12, 13). Gramicidin D is a mixture of three main isoforms, with the sequence of the most abundant (~85%) gramicidin A being HCO–L-Val_1–Gly_2–L-Ala_3–D-Leu_4–L-Ala_5–D-Val_6–L-Val_7–D-Val_8–L-Trp_9–D-Leu_{10}–L-Trp_{11}–D-Leu_{12}–L-Trp_{13}–D-Leu_{14}–L-Trp_{15}–$NHCH_2CH_2OH$. The lower-abundance isoforms, gramicidin B and C, differ at residue 11 (Trp_{11}(gA):Phe_{11}(gB):Tyr_{11}(gC) is 85:15:5 mol%, respectively). Gramicidin's secondary structure is solvent-dependent (14, 15). In lipid bilayers, gramicidin forms dimeric ion channels by the association of two right-handed, single stranded beta-helical monomers, each of which spans a single-bilayer leaflet (16). In organic solvents, gramicidin can adopt a variety of conformers: monomer or left-handed and right-handed double helices. In SDS micelles, gramicidin has been shown to adopt the single-stranded beta-helical monomer conformation (17). The structures of gramicidin are depicted in Fig. 1, which also includes a space-filling model of halothane for comparison. Gramicidin has been previously used as a model in anesthetic – ion-channel studies using NMR (17), photoaffinity (18) labeling, and molecular dynamics simulations (19, 20).

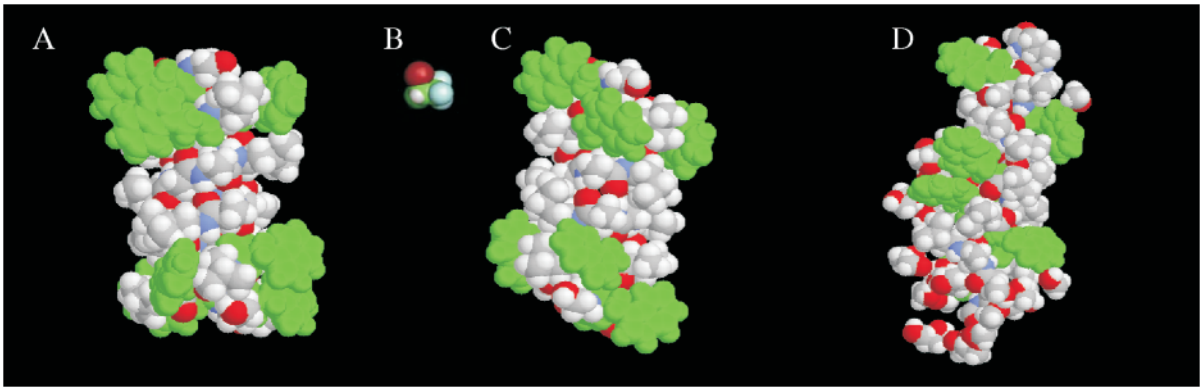
Presently, we have investigated the gramicidin-inhaled anesthetic interaction in a DOPC lipid bilayer in sodium dodecyl sulphate (SDS) micelles and in octanol by steady-state fluorescence quenching. Fluorescence-quenching experiments have been previously used to determine the binding of halothane to serum albumin (21). Halothane quenching of aromatic side chains (tryptophan, tyrosine, and phenylalanine) fluorescence is thought to occur as a result of an increase in intersystem crossing, which arises by spin–orbit coupling between the excited singlet state of the aromatic ring and the heavy atoms of chlorine and bromine (22). Our results indicate that the strongest interaction between gramicidin and halothane occurs in the lipid-bilayer environment. This suggests that although anesthetics may directly bind with membrane proteins, it is likely they do so mediated by lipids in the cell membrane.

Materials and methodology

1,2-Dioleoyl-sn-3-glycero-3-phosphocholine (DOPC) was purchased from Avanti Polar Lipids (Alabaster, AL). 2-Bromo-2-chloro-1,1,1-trifluoroethane (Halothane) 99% (0.01% thymol), sodium dodecyl sulfate (SDS), and gramicidin D were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). All reagents were used as delivered. Ultrapure water was used in the preparation of buffers and aqueous solutions using a Mega Pure™ System ACS (Corning, NY).

Preparation of gramicidin-containing large unilamellar DOPC vesicles (LUVS) and SDS micelles

Solutions of large unilamellar vesicles (LUVS) were prepared from a chloroform lipid stock (2.5 mg/mL). An appropriate aliquot of chloroform–lipid stock was transferred to a 10 mL volumetric flask to give a final lipid concentration of 0.1 mmol/L (0.25 mg/mL lipid). Stock solutions of gramicidin D were prepared in methanol (1 mmol/L final concentration). An aliquot of the protein stock was mixed with an aliquot of the lipid–chloroform stock. The organic solvents were evaporated using nitrogen. The final gramicidin concentration was 1 μmol/L, giving a DOPC:gramicidin molar ratio of 100:1. The lipid – gramicidin D film was resuspended in 10 mmol/L phosphate buffer (pH = 7.0) by stirring for 1 h. Under very similar conditions, gramicidin was found to adopt a right-handed, single-stranded beta-helical conformation (23). Large unilamellar vesicles were prepared by sonication using a sonicator bath (Laboratory Supplies Co, Inc.) followed by extrusion through a 100 nm polycarbonate membrane using an Avanti MiniExtruder. Alternatively, DOPC LUVS were prepared using a probe sonicator. The lipid solutions were kept on ice to prevent overheating because of the sonication energy. The solutions were sonicated in 10 s pulses to a total of five sonication cycles at which point the lipid solution was clear.



SDS micelles were prepared by dissolving the detergent in ultrapure water to a final concentration of 80 mmol/L. Solutions were allowed to stir for 1.5 h and then sonicated up to 30 min. Aliquots of gramicidin stock in methanol were added to a volumetric flask, and the organic solvent was evaporated with nitrogen gas. The protein film was resuspended with the micelle solution by stirring for an hour and sonicating for 5 min.

Acquisition of spectra and fluorescence-quenching analysis

The four tryptophan residues that gramicidin contains are the only fluorescent moieties in the polypeptide. Fluorescence experiments were performed using a Cary-Eclipse fluorimeter. Protein emission spectra were collected by exciting samples

with 280 nm, and emission and excitation slit widths were set at 5 nm. Fluorescence-quenching data for 1-octanol solution was analyzed using the Stern–Volmer equation

$$[1] \qquad F_0/F = 1 + K_{SV}[Q]$$

where F_0 and F are the integrated fluorescence intensities of the main tryptophan fluorescence peak in the absence and presence, respectively, of the quencher, Q; and K_{SV} is the Stern–Volmer quenching constant.

Fluorescence-quenching data in LUV and micelle media were analyzed using a modified Stern–Volmer equation, which accounts for the partitioning of halothane into the LUVs and micelles (24)

$$[2] \qquad \frac{F_0}{F} = \left(1 + \frac{K_{SV}K_{part}[Q]_{tot}}{1 + K_{part}\gamma_L[L]}\right)$$

where K_{part} is the water–lipid partition constant, $[Q]_{tot}$ is the total quencher concentration for the entire solution, $[L]$ is the lipid (or surfactant) concentration, and γ_L is the partial molar volume of the lipid (or surfactant).

Results

Since a large amount of evidence suggests a protein-mediated mechanism of general anesthesia, we investigated the interaction of halothane with the peptide ion channel, gramicidin, within bilayers and bilayer-mimetic environments. This was done to ascertain the effect of the local environment on halothane–gramicidin interactions. In previous work, we examined the location of inhaled anesthetic in a fluorescently labeled DOPC lipid bilayer (25). We found that halothane locates on the acyl chain side, near the headgroup region of the bilayer (25). Therefore, we might anticipate a heterogeneous distribution of halothane around gramicidin in bilayer environments.

Fluorescence quenching in DOPC unilamellar vesicles

The quenching of gramicidin D by halothane in a lipid bilayer was studied using DOPC LUVS (50 nm radius). Analysis of the emission spectra indicated that halothane preferentially quenches the long-wavelength-emitting tryptophans. Figure 2 shows the emission spectrum of tryptophan in the presence of halothane over a range of concentrations (0.1 mmol/L to 20 mmol/L). A large fraction of the accessible tryptophan residues is extensively quenched at halothane concentrations as low as 0.1 mmol/L. At 10 mmol/L halothane, the fluorescent signal was almost entirely quenched. The emission maximum of tryptophan in DOPC LUV occurred at 335 nm, indicative of a partial hydrophobic-residue environment. The quenching of tryptophan in DOPC LUVS resulted in a shift of the λ_{max} to longer wavelengths. Normalization of the spectra shows that the λ_{max} shifted by 20 nm to longer wavelengths (335 nm to 355 nm) (inset of Fig. 2). The small feature at 450 nm is likely a halogenated photoproduct. The integrated emission intensities of the λ_{max} feature were plotted vs. the quencher concentration (Fig. 3) and analyzed according to eq. [2]. From the value of the slope, the Stern–Volmer constant, K_{SV}, was calculated to be 66 M^{-1}.

Fluorescence quenching in SDS micelles

Since the LUV work showed that direct quenching of the ion channel by halothane is possible, we decided to investigate the direct halothane–peptide interaction in SDS micelles. Halothane concentrations ranged from 0.1 mmol/L to 20 mmol/L. The emission spectrum of gramicidin D in the presence of halothane at different concentrations is shown in Fig. 4. The emission maximum of gramicidin occurred at 334 nm in the absence of halothane. At 20 mmol/L halothane concentration, 56% of tryptophan emission was quenched. Quenching of the fluorescence by higher halothane concentrations was accompanied by a significant shift of the emission maximum to shorter wavelengths. Normalization of the emission spectra, as shown in the inset of Fig. 4, revealed that greatest effects on the position of the

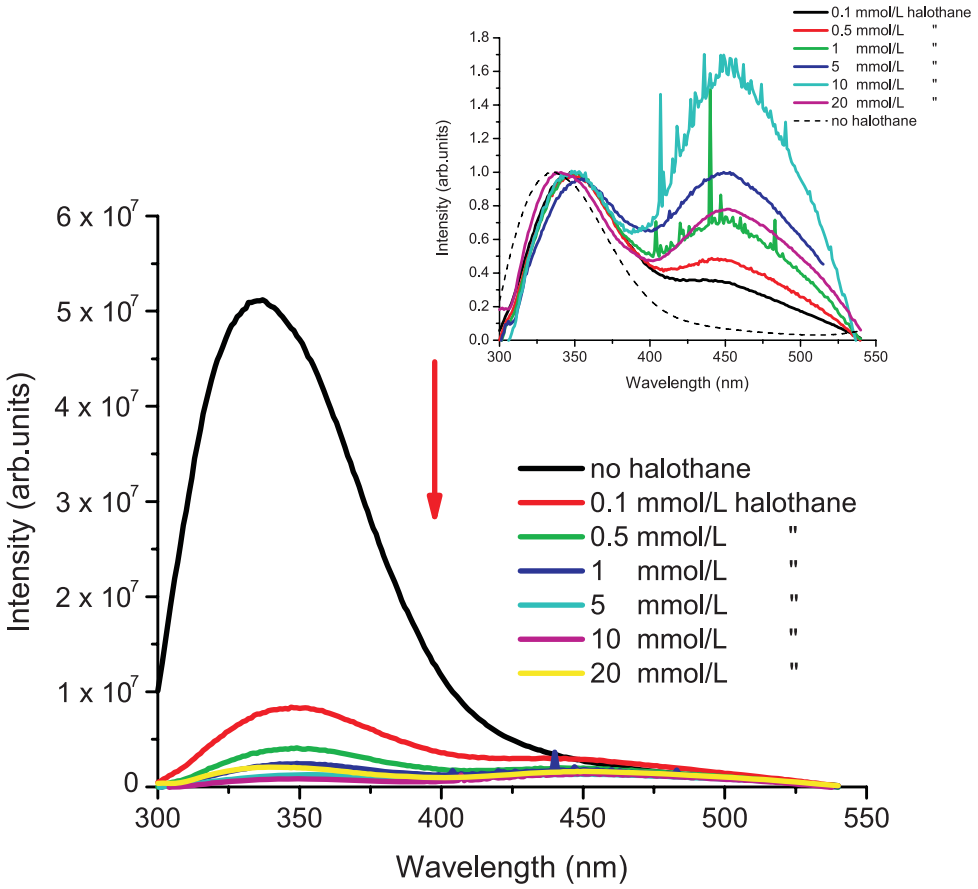
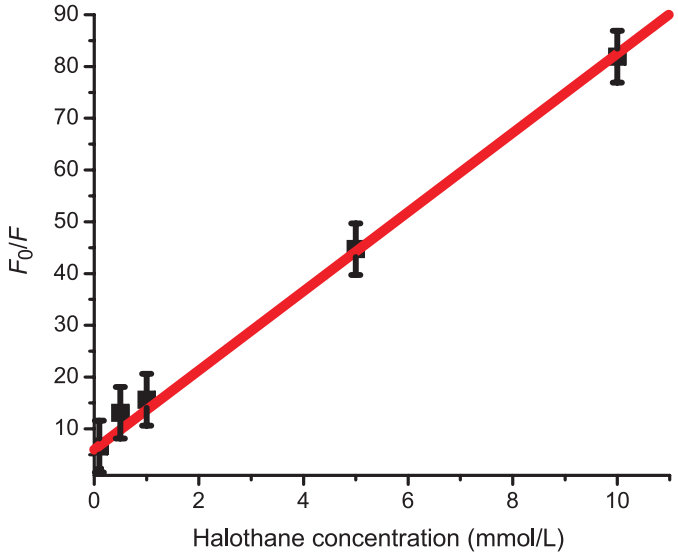
Fig. 2. Quenching of gramicidin D by halothane present at different concentrations in DOPC LUVs. The tryptophan λ_{max} in DOPC LUVs was at 335 nm in the absence of the anesthetic (λ_{ex} = 280 nm). Halothane was used at 0.1, 0.5, 1, 10, and 20 mmol/L. The normalized spectra are shown in the inset. Note the shift in λ_{max} to longer wavelengths. The prominent shoulder at ~450 nm is likely a photoproduct.





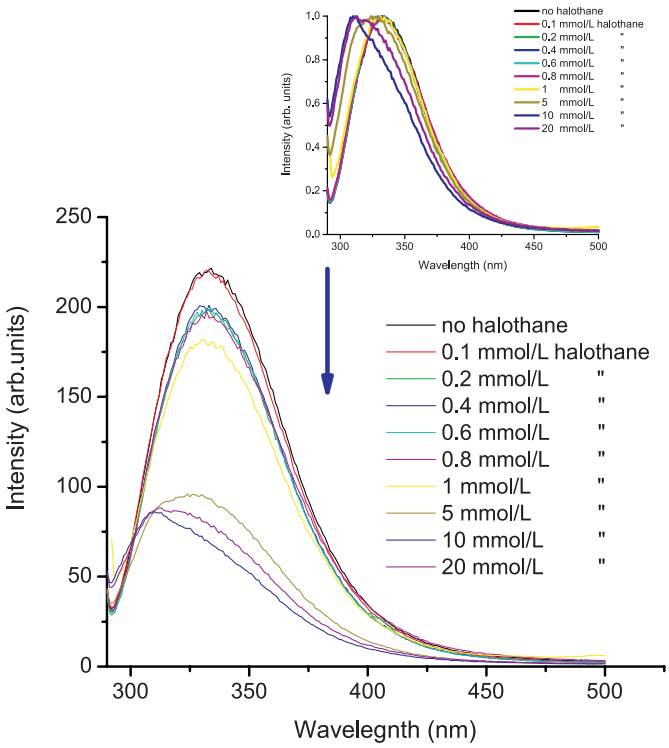


Fig. 3. Stern–Volmer plot for the quenching of gramicidin in DOPC LUVS. The calculated K_{SV} was 66 M^{-1}, using eq. [2].

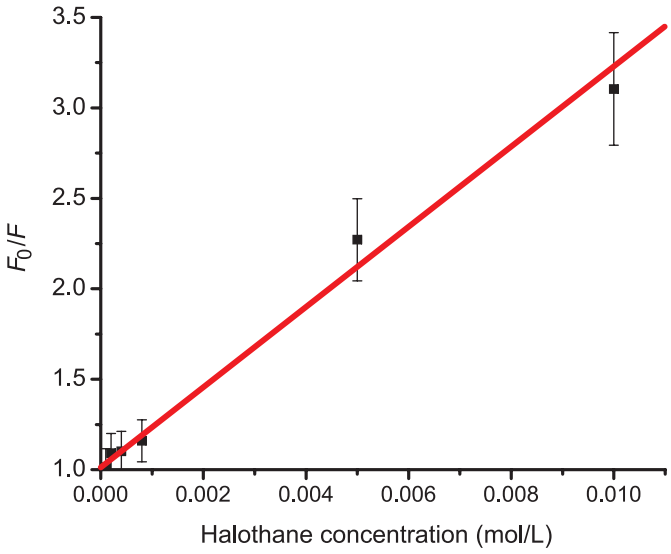
Fig. 4. Quenching of gramicidin D in SDS micelles. The tryptophan λ_{max} in SDS micelles was 334 nm in the absence of the anesthetic (λ_{ex} = 280 nm). The normalized spectra are shown in the inset. Note the large blue shift of λ_{max} from 334 nm to 312 nm at higher halothane concentrations.



λ_{max} was observed at 10 mmol/L and higher halothane concentration. At these concentrations, λ_{max} shifted 22 nm to shorter wavelength (334 nm to 312 nm) because of an increased influence of the SDS micelle CH Raman-scattering peak (26). At 5 mmol/L halothane, λ_{max} shifted only 5 nm to shorter wavelengths, whereas at lower concentrations (0.1 mmol/L to 1 mmol/L), the emission maximum remained unchanged at 334 nm. Similar to the study in LUVS, the Stern–Volmer plot was linear (Fig. 5). The K_{SV} calculated using eq. [2] was 22 M^{-1}.

Quenching of gramicidin D in octanol

To ascertain if conformation can affect halothane–gramicidin interactions, we investigated halothane quenching in 1-octanol. Gramicidin can be present in different conformers, depending on the organic solvent used (14). An equilibrium mixture of both parallel and antiparallel double helices is present in octanol, and above the dimerization constant for gramicidin, the predominant conformer is expected to be the left-handed antiparallel double helix (14). In our 1-octanol study, gramicidin concentration was below the peptide-dimerization constant (2 μmol/L). As a result, gramicidin monomers were almost exclusively present in solution.

Figure 6 shows the emission spectrum of gramicidin D in 1-octanol in the presence of 0.2 mol/L to 1.2 mol/L halothane. Quenching of the emission maximum at 340 nm increased with increasing halothane concentration. A blue-shifted peak in octanol appears after halothane is added as evidenced by an additional feature at 0.2 mol/L halothane

Fig. 5. Stern–Volmer plot for the quenching of gramicidin in SDS micelles. The calculated K_{SV} from eq. [2] was 22 M^{-1}.

(Fig. 6). By 0.4 mol/L halothane, the emission spectrum has shifted entirely over to the feature at 310 nm, which then decreases in intensity with increasing halothane. This feature is Raman-scattering peak for OH stretch (3300 cm^{-1}) of 1-octanol (26, 27), which was revealed as the fluorescence of tryptophan was quenched. Plotting of the integrated emission intensity vs. quencher concentrations yielded a linear Stern–Volmer plot with a K_{SV} value of 6 M^{-1} determined using eq. [1] (Fig. 7).

Discussion

To elucidate some of the molecular details of anesthetic – membrane protein interactions, we studied the halothane-induced quenching of tryptophan fluorescence in gramicidin. Gramicidin has been shown to create an ion channel through the association of two monomers, each of which spans one leaflet in a lipid bilayer. Each of the four tryptophan residues per monomer has a unique orientation in the lipid bilayer as indicated by several studies (28–31) (see Fig. 1). Tryptophan at position 9 is buried deepest in the membrane, and the remaining three tryptophan residues are located closer to the lipid – aqueous phase interface. The quenching experiments in LUV environments revealed that most tryptophans were equally accessible to halothane, independent of the anesthetic concentrations used, otherwise a sublinear Stern–Volmer plot would result. This suggests that the lipid bilayer mediates anesthetic–gramicidin interactions. The quenching was accompanied by a slight shift of λ_{max} to longer wavelengths. This shift may be the result of halothane increasing the net polarity within the bilayer such that the remaining unquenched tryptophans experience a slightly more-polar environment.

The previous observations agree with findings from recent molecular-dynamics-simulations studies of the gramicidin–halothane system in a fully hydrated DMPC bilayer (20). In this study, Tang et al. showed that halothane targeted the anchoring residues at the channel–lipid interface. Halothane molecules (6 out of 10) were found to migrate towards the

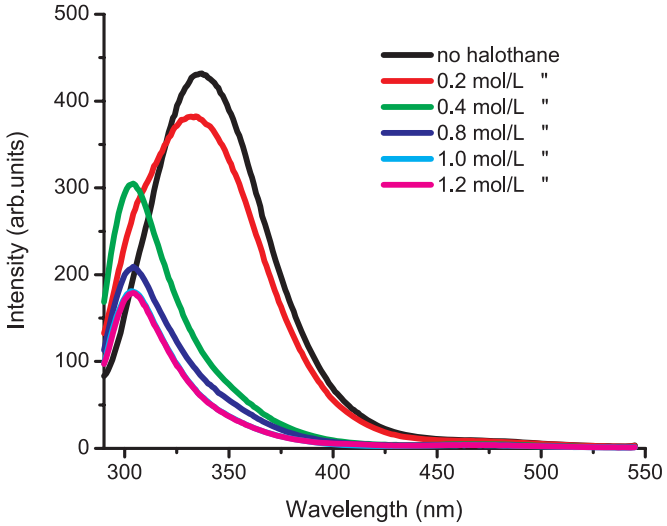
Fig. 6. Quenching of gramicidin D in 1-octanol. The tryptophan λ_{max} in 1-octanol was 337 nm in the absence of the anesthetic (λ_{ex} = 280 nm). Halothane was used at 0.1, 0.2, 0.4, 0.8, 1, and 1.2 mol/L.



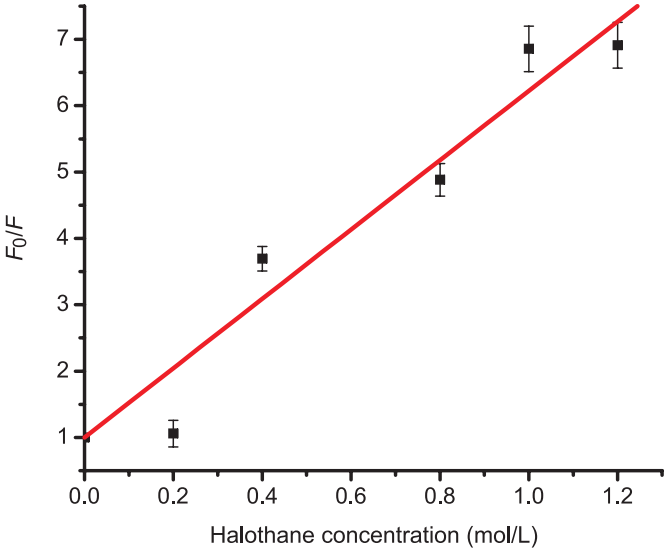


Fig. 7. Stern–Volmer plot for the quenching of gramicidin in 1-octanol. The calculated K_{SV} from eq. [1] was 6 M^{-1}.

membrane interface. It has been previously shown that this interaction requires gramicidin to be in the channel conformation promoted by the lipid environment (18, 32, 33). Tang et al. (18) found that tryptophan 9 and 15 create an amphiphilic pocket in the space between the side chain and lipid headgroups. Such an amphiphilic pocket is an optimal binding site for the slightly polar anesthetic molecule, halothane.

Since we saw evidence of a direct peptide–anesthetic interaction, we were compelled to investigate the halothane–gramicidin system in SDS micelles. As in the case of DOPC LUVS, halothane was found to interact with tryptophan when brought in close proximity in SDS micelles, as indicated by tryptophan fluorescence quenching. Preferential partitioning of halothane at the solvent–micelle interface has been previously reported (25), which suggests that there may be a selective quenching of the tryptophans. Indeed, there appears to be enhanced quenching of the red portion of fluorescence spectrum at lower halothane concentrations in Fig. 3.

Significantly, Tang et al. observed a similar tryptophan-residue arrangement in SDS micelles (18). Moreover, our observation that the preferred interaction between halothane and the tryptophans in gramicidin occurs near the micelle–solvent interface region is corroborated by earlier studies by others (34, 35). Using ^{19}F NMR, Yoshida et al. (34) showed that halothane interacted with SDS micelles at the interfacial region. A later study by Yoshino et al. (35), using the ^{19}F NMR, ^{1}H NMR, and NOE, further confirmed that halothane interacted with the hydrophilic moieties of the SDS micelles.

The quenching of gramicidin in octanol also resulted in a blue shift of the emission maximum. However, in this case the blue-shifted peak arises from Raman scattering.

To gain further insight into the anesthetic binding affinity to gramicidin in its ion channel, we analyzed the quenching data using Stern–Volmer plots. In DOPC LUVS, the Stern–Volmer plot revealed a linear relationship between halothane concentration and the amount of fluorescence quenching. From the slope, the K_{SV} value for the anesthetic–peptide interaction was determined to be 66 M^{-1}. The Stern–Volmer plot for the SDS experiments was also linear. In SDS micelles, the K_{SV} value was found to be 22 M^{-1}.

The presence of the lipid bilayer increased the interaction of halothane by approximately 3-fold (66 M^{-1} in DOPC LUVS vs. 22 M^{-1} in SDS micelles). This increased quenching may lay in different accessibilities of the tryptophans to halothane in the different environments (lipid bilayer vs. micelle).

In organic solvents, gramicidin is present in its non-channel conformation. The different conformation of gramicidin did not prevent halothane quenching from occurring. In the case of 1-octanol, relatively high halothane concentrations (0.1 mol/L to 1.2 mol/L) were required to see an effect on tryptophan emission. The K_{SV} value in 1-octanol is 6 M^{-1}, which is one order of magnitude lower than the value obtained in DOPC LUVs.

The Stern–Volmer quenching constants measured in the current study are similar to those measured for halothane interactions with plasma membrane Ca^{2+}-ATPase (36). However, in contrast to the study by Lopez and Kosk-Kosicka (36), we observe a 3-fold difference between lipid and detergent environments. The fact that the lowest K_{SV} was observed in octanol, which also has the lowest viscosity (η_{oct} = 0.07 P vs. η_{DOPC} = 0.8 P; 1 P = 1 dyn s/cm^2 = 0.1 Pa s), suggests that the quenching is not collisional. Interestingly, the quenching of gramicidin in POPC liposomes by acrylamide produced a K_{SV} of 0.95 M^{-1} (28). Because acrylamide is an aqueous quencher, it is not expected to partition significantly into the bilayer. Thus, the quenching from the study of Rawat et al. (28) was suggested to be collisional, and therefore the Stern–Volmer constant may not be directly comparable to the one determined in the present study.

The value of K_{SV} for halothane–gramicidin interactions in DOPC found in the present work suggests a free energy of binding $\Delta G_{association} \leq -10$ kJ/mol, which is in the range of

© 2007 NRC Canada

van der Waals bonding. The differences between the K_{SV}'s measured here for different environments should reflect the changes in free energy between free and bound halothane in DOPC vs. SDS vs. octanol.

Conclusions

Fluorescence-quenching experiments of gramicidin D in DOPC LUVS have shown that halothane can directly interact with gramicidin. Halothane quenched the fluorescence from tryptophan residues located at the lipid bilayer – aqueous interfaces as good as those located deeper in the bilayer. The partition of halothane in the vesicles may cause an increase in the local polarity as shown by the shift in the tryptophan emission maximum to longer wavelengths. SDS-quenching data revealed that the tryptophan residues located at the micelle–solvent interface were preferentially quenched by halothane. Tryptophan residues located deeper in the bilayer remained partly inaccessible to halothane. The effect of the non-channel conformation on halothane binding to the peptide was investigated in 1-octanol. In 1-octanol, higher anesthetic concentrations were required to detect changes in tryptophan fluorescence emission. Fluorescence quenching was observed, but with a lower K_{SV} value than in DOPC LUVS and SDS micelles.

Taken together, our data suggest that halothane can interact more strongly with gramicidin in the conformation promoted by the lipid bilayer. In turn, this suggests that the lipid matrix may be an important determinant in creating the optimal motif for inhaled-anesthetics binding to other membrane proteins.

Synthesis, characterization, and crystal structures of novel oligomeric Zn(II) and Cd(II) complexes with *N,N′*-dimethyl-2,2′-biimidazole

Letitia M. Gruia, Fernande D. Rochon, and André L. Beauchamp

Abstract: Zn(II) and Cd(II) complexes with *N,N′*-dimethyl-2,2′-biimidazole (Me_2biim) were synthesized and characterized by IR spectroscopy and by X-ray crystallographic methods. The reaction of zinc perchlorate with Me_2biim produced the dinuclear compound $[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)](ClO_4)_4$, containing two monodentate and three bridging Me_2biim ligands bonded to Zn atoms in a distorted tetrahedral environment. A related neutral $(NO_3)_2Cd(\mu\text{-}Me_2biim)_3Cd(NO_3)_2$ complex, containing only bridging Me_2biim ligands, was also synthesized, in which the distorted octahedral coordination of each Cd atom is completed by one monodentate and one bidentate nitrato ligand. Two ionic trinuclear Cd compounds were also obtained, which include two sets of three bridging Me_2biim ligands connecting a central Cd atom to two terminal Cd centers. An extra Me_2biim ligand is chelated to each terminal metal, and the sixth coordination site is occupied by water molecules in the symmetric $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(H_2O)(Me_2biim)](ClO_4)_6$ complex, whereas the aqua ligand is replaced by methanol at one of the terminal units in the non-symmetric $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(CH_3OH)(Me_2biim)](ClO_4)_6$ compound. In the chelating ligands, dihedral angles of ~38° between the two imidazole rings reduce repulsion between the *N*-methyl groups, but considerable strain remains, as evidenced from one of the Cd–N bonds being much longer than the other. In the various compounds, dihedral angles of 60–80° are found between the imidazole rings in the bridging ligands, and intramolecular inter-ligand π–π stacking contributes to stabilization.

Key words: zinc, cadmium, dimethylbiimidazole, crystal structure, dinuclear, trinuclear.

Résumé : Des complexes de Zn(II) et Cd(II) avec le *N,N′*-diméthyl-2,2′-biimidazole (Me_2biim) ont été synthétisés et caractérisés par spectroscopie IR et par diffraction des rayons X. La réaction du perchlorate de zinc avec Me_2biim conduit au composé dinucléaire $[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)](ClO_4)_4$, qui renferme deux ligands Me_2biim monodentates et trois pontants, définissant un environnement tétraédrique déformé autour du métal. Dans le composé neutre analogue $(NO_3)_2Cd(\mu\text{-}Me_2biim)_3Cd(NO_3)_2$ comportant seulement des ligands Me_2biim pontants, la coordination octaédrique déformée de chacun des atomes de Cd est complétée par deux ligands nitrato, l'un monodentate, l'autre bidentate. Deux composés ioniques trinucléaires de Cd ont aussi été obtenus. Ils renferment deux séries de trois ligands Me_2biim pontants reliant un atome de Cd central à deux atomes de Cd terminaux. Un ligand Me_2biim additionnel est chélaté à chacun des atomes terminaux. Le sixième site de coordination est occupé par des molécules d'eau dans le complexe symétrique $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(H_2O)(Me_2biim)](ClO_4)_6$, alors que le ligand aqua est remplacé par le méthanol pour l'un des motifs terminaux dans le composé non-symétrique $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(CH_3OH)(Me_2biim)](ClO_4)_6$. Dans les ligands chélatants, des angles dièdres de ~38° entre les cycles imidazoles diminuent la répulsion entre les groupements *N*-méthyles, mais la présence d'une liaison Cd-N beaucoup plus longue que l'autre indique qu'il reste beaucoup de tension dans le chélate. Dans les différents composés, les angles dièdres entre les cycles imidazole dans les ligands pontants sont de 60–80° et des interactions inter-ligand intramoléculaires de type « π–π stacking » contribuent à la stabilization.

Mots-clés : zinc, cadmium, diméthylbiimidazole, structure cristallographique, dinucléaire, trinucléaire.

Introduction

Imidazole is an aromatic moiety that can be protonated or deprotonated without losing its aromaticity, and the connection of two such units in 2,2′-biimidazole (H_2biim, Chart 1) opens a variety of possible protonation patterns and chelating and (or) bridging coordination modes. Because of this broad versatility, this ligand has received much attention in recent years for eventual applications, such as electron transport materials (1), molecular arrays with desirable topology (2), systems with interesting catalytic properties (3, 4), polymers with good thermal stability (5), and anticancer agents (6).

Chart 1. Syn conformation shown.

H_2biim **Me_2biim**

The 2,2′-biimidazole molecule has the anti conformation in the solid state, forming one-dimensional hydrogen-bonded ribbons with extensive inter-chain π–π stacking (7). It can coordinate to metals as a non-deprotonated, mono-deprotonated or bi-deprotonated ligand (8). In the neutral form, it usually binds in a chelating fashion, which imposes a syn conformation and appreciable strain to the metal complex, since the "bite" angle is ~75° (9). In these compounds, H_2biim remains planar, which maximizes aromaticity, and it forms numerous hydrogen bonds with its environment, which contribute to the stabilization of these systems. Occasionally, H_2biim binds as a bridging ligand, for instance in $[Zn_2(\mu\text{-}H_2biim)(H_2biim)_4](ClO_4)_4$ (10), despite the fact that the imidazole rings are no longer coplanar (dihedral angle ≈ 50°).

The chemistry of the *N*,*N*′-dimethyl derivative (Me_2biim) is very different. The free molecule exists as the anti conformer (11), and in the syn conformation required for chelate formation, steric hindrance between the methyl groups forces the two imidazole rings out of planarity. This characteristic reduces its chelating ability, but promotes a bridging role. In the literature, Me_2biim was reported to act as a chelating bidentate ligand in the mononuclear $PtI_2(Me_2biim)$, $PtCl_4(Me_2biim)$, and $SnMe_2Br_2(Me_2biim)$ complexes (12–14), but as a bridging ligand in $\{OReCl_2\}_2(\mu\text{–}O)(\mu\text{–}Me_2biim)_2$ (15), $\{PtBr(DMSO)\}_2(\mu\text{-}Me_2biim)$ (16), $[Ag(\mu\text{-}Me_2biim)]NO_3$ (17), $[\{Cu(H_2O)\}_2(\mu\text{-}Me_2biim)_4](NO_3)_4$ (18), and $[\{Cu(H_2O)\}_2(\mu\text{-}Me_2biim)_4](ClO_4)_4$ (19).

We recently described the synthesis and crystal structures of various Zn(II) and Cd(II) compounds with H_2biim (9). These two metal centers were selected because they cannot be readily oxidized or reduced; they are devoid of ligand-field effects, and their plastic coordination spheres can adjust to a certain extent to the coordinating preferences of the ligands. All these H_2biim complexes contained chelated ligands and were stabilized by an elaborate hydrogen-bonding system, but no appreciable π–π stacking was observed. This study was extended to Me_2biim, and several Zn(II) and Cd(II) di- or trinuclear compounds were prepared, containing both bridging and terminal monodentate or bidentate Me_2biim ligands. While this work was in progress, Sang and Xu (20) reported on various Cd(II) and Zn(II) compounds of different compositions with the same ligand.

Experimental section

The zinc and cadmium salts (Aldrich), the solvents, and all other chemicals were used as received. Me_2biim was synthesized following the method of Mohanty et al. (21), by methylation of 2,2-biimidazole obtained as described by Fieselmann et al. (22).

The IR spectra were recorded from 4000 to 300 cm^{-1} on a PerkinElmer 783 spectrophotometer as KBr or CsI pellets. Elemental analyses were performed in the Laboratoire d'analyse élémentaire de l'Université de Montréal. Mass spectra for the Zn compounds were recorded in the FAB^+ mode in nitrobenzyl alcohol at the Centre régional de spectrométrie de masse de l'Université de Montréal. Mononuclear and dinuclear fragments were distinguished from isotope distribution. The most intense component is due to the ^{64}Zn isotopomer for monomeric fragments; whereas two peaks of comparable heights corresponding to $^{64}Zn^{66}Zn$ and $^{64}Zn^{68}Zn/^{66}Zn^{66}Zn$ are observed for dinuclear species. Good mass spectra were not obtained for the Cd compounds.[2]

$[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)](ClO_4)_4\cdot 1/2H_2O$ (1)

The zinc salt and the ligand were reacted in a 1:2 molar ratio. Accordingly, $Zn(ClO_4)_2\cdot 6H_2O$ (37.2 mg; 0.10 mmol) was dissolved in 10 mL of water, and Me_2biim (32.4 mg; 0.20 mmol) was added while stirring. The reaction was stopped after 3 h, and the clear solution was evaporated under reduced pressure to a volume of 2 mL, from which colorless crystals deposited upon standing at room temperature for one week. Anal. calcd. for $Zn_2Cl_4O_{16}N_{20}C_{40}H_{50}\cdot 1/2H_2O$: C 35.63, H 3.81, N 20.77; found: C 35.32, H 3.83, N 20.61. FAB^+-MS: m/z = 487 $[^{64}Zn(Me_2biim)_2(ClO_4)]^+$.

$[(H_2O)Zn(\mu\text{-}Me_2biim)_3Zn(H_2O)](NO_3)_4\cdot H_2O$ (2)

$Zn(NO_3)_2\cdot 6H_2O$ (29.7 mg; 0.10 mmol) was dissolved in 10 mL of methanol, and Me_2biim (32.4 mg; 0.20 mmol) was added while stirring. After 3 h, the reaction was stopped, and the clear solution was concentrated to 2 mL and kept in a refrigerator. Colorless crystals deposited after 48 h. Anal. calcd. for $Zn_2N_{16}C_{24}H_{34}O_{14}$: C 31.98, H 3.80, N 24.86; found: C 32.38, H 3.88, N 25.11. FAB^+-MS: m/z = 802/804 (36%) $[Zn_2(Me_2biim)_3(NO_3)_3]^+$; 640/642 (30%) $[Zn_2(Me_2biim)_2(NO_3)_3]^+$; 450 (55%) $[Zn(Me_2biim)_2(NO_3)]^+$; 288 (100%) $[Zn(Me_2biim)(NO_3)]^+$. The preparation of this compound by a slightly different method was recently reported (20).

$(NO_3)_2Cd(\mu\text{-}Me_2biim)_3Cd(NO_3)_2$ (3)

$Cd(NO_3)_2\cdot 4H_2O$ (30.8 mg; 0.10 mmol) was dissolved in 2.5 mL of methanol, and Me_2biim (32.4 mg; 0.20 mmol) was added while stirring. After 2 h, the clear solution was left in a refrigerator. A homogeneous sample of colorless crystals deposited after 24 h. The composition was obtained from the X-ray diffraction study.

$[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(H_2O)(Me_2biim)](ClO_4)_6$ (4)

$Cd(ClO_4)_2\cdot 6H_2O$ (41.9 mg; 0.10 mmol) was dissolved in 5 mL of water, and Me_2biim (32.4 mg; 0.20 mmol) was added while stirring. The reaction was stopped 3 h later.

[2] Safety note: Although no problems were encountered, perchlorate salts of cadmium and zinc with organic ligands and solvents are potentially explosive and should be handled only in small quantities.

Colorless crystals deposited after one week at room temperature. Anal. calcd. for $Cd_3Cl_6O_{26}N_{32}C_{64}H_{84}$: C 33.90, H 3.73, N 19.77; found: C 33.69, H 3.60, N 19.55.

[$(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(CH_3OH)(Me_2biim)](ClO_4)_6$ (5)

The cadmium salt and Me_2biim were reacted in a 1:4 molar ratio. Accordingly, $Cd(ClO_4)_2{\cdot}6H_2O$ (104.8 mg; 0.25 mmol) was dissolved in a mixture of 8 mL methanol and 1 mL water. Me_2biim (162 mg; 1.00 mmol) was added while stirring. The clear solution was then transferred into a Teflon autoclave and heated at 115 °C for 12 h. The solution obtained after gradual cooling was kept in a refrigerator, and the crystals were collected after 24 h.

Crystallographic measurements and structure determination

Diffraction intensities for crystals **1**, **3**, and **5** were measured on a Bruker SMART diffractometer with a CCD 2K area detector controlled by the SMART software (23). The graphite-monochromatized Cu Kα radiation was used. Sets of 30 oscillation frames of 0.3° over a range of 9° were recorded in four regions of the reciprocal space, from which the reduced cell was determined by least-squares refinement. The data were collected at room temperature, using a narrow-frame method with scan widths of 0.30° in ω, exposure times being 5 s/frame for **1**, 10 s/frame for **3**, and 8 s/frame for **5**. Frames were recorded for different orientations of the crystal and detector so as to cover at least 95% of the reciprocal sphere. The first 101 frames were remeasured at the end of the data collection to monitor instrument and crystal stability. The data were integrated using SAINT (24), and the intensities were corrected for the Lorentz effect, polarization, and air absorption. A SADABS (25) absorption correction was applied based on the entire data sets. For crystal **5**, two data sets were measured, and redundant reflections were averaged.

For crystal **4**, an Enraf-Nonius CAD-4 diffractometer operating with graphite-monochromatized Cu Kα radiation was used, under the control of the CAD-4 software (26). The reduced cell was initially determined from 25 spots located on a preliminary rotation photograph and centered in the detector aperture. Accurate cell parameters were then determined from the positions of 25 high-angle reflections centered with the SETANG and DETTH procedures. The intensities were recorded at room temperature over the whole sphere by ω/2θ scan, and five standard reflections were measured every hour. An absorption correction based on the crystal geometry was applied using NRCVAX (27). The data were finally corrected for the effects of Lorentz and polarization and averaged.

All structures were solved by direct methods and refined on F^2 by full-matrix least squares. The SHELXTL system (28) was used for all calculations. Unless otherwise stated, all non-hydrogen atoms were refined anisotropically. Hydrogens were added to the model at idealized positions with standard C—, N—, O—H distances. Their isotropic displacement factors U_{iso} were adjusted to 20%–50% above the U_{eq} value for the bonded atom. At the end of the refinement, the VOID routine of PLATON (29) was used to check for the presence of unoccupied space in the structure. Individual details for each structure are given later. The crystal data are summarized in Table 1.[3]

For crystal **3**, the 2/*m* Laue symmetry and the systematic absences (*hkl*, $h + k \neq 2n$; *h0l*, $l \neq 2n$) were consistent with space groups *Cc* and *C*2/*c*. The structure was solved in the centric *C*2/*c* space group. Direct methods revealed the presence of two structural motifs per asymmetric unit; each consisting of a pair of Cd atoms bridged by three Me_2biim ligands. Peaks were found in the Δ*F* map for two well-defined nitrate ions (centered on N3, N4, N5, and N6) bonded to one of the Cd atoms in each motif. The nitrates close to the second Cd atom (centered on N1, N2, N7, and N8) were disordered, and they were described by two or three orientations. The ordered part of the structure was refined anisotropically. Constraints were applied to the nitrates in the refinement to maintain reasonable thermal parameters, to retain a planar structure, and to link the occupancies of nitrates belonging to the same local structural pattern. In the last cycles, the nitrates were refined anisotropically, except those with low occupancies (centered on N1′, N1″, N2′, N7′, and N8′).

Compounds **4** and **5** are isomorphous. Space group $P2_1/c$ was determined unambiguously from the 2/*m* Laue symmetry and systematic absences (*0k0*, $k \neq 2n$; *h0l*, $l \neq 2n$). Structure resolution raised no particular problems in both cases. In compound **4**, obtained from water, the sixth coordination site on each of the two terminal Cd atoms is occupied by an aqua ligand. In **5**, which was prepared from a 8:1 methanol–water solution, the water bonded to one of the terminal Cd atoms is replaced by a methanol ligand. In both cases, some of the ClO_4^- ions show high thermal motion. Attempts were made to use multiple disordered orientations to describe them, but this did not result in a significant improvement. The non-disordered model was retained, but constraints (DFIX) were applied to keep the Cl—O bond lengths and the intra-ionic O···O contacts close to the ideal values.

Compound **1** was found to be triclinic from the Laue symmetry, and resolution took place normally in the centric $P\bar{1}$ space group. No particular problems were encountered with the cationic part of the structure, but the four ClO_4^- ions were severely disordered. They were described by means of three orientations, using constraints as mentioned previously to maintain the tetrahedral geometry and to keep the occupancies normalized to unity. The Δ*F* map finally revealed a peak of 2.5 e/Å^3, suitably positioned to be a lattice water molecule, whose occupancy refined to 0.50. The atoms in the ClO_4^- ions and water molecule were refined

Results and discussion

Synthesis

The reaction between $Zn(ClO_4)_2{\cdot}6H_2O$ and Me_2biim in water in a 1:2 proportion produced colorless crystals, which were identified by X-ray diffraction as the dinuclear compound $[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)](ClO_4)_4{\cdot}1/2H_2O$ (**1**), containing three bridging Me_2biim ligands and a terminal monodentate Me_2biim ligand on each Zn atom. When the reaction was performed with $Zn(NO_3)_2{\cdot}6H_2O$ in wet methanol, the dinuclear compound $[(H_2O)Zn(\mu\text{-}Me_2biim)_3Zn(H_2O)](NO_3)_4{\cdot}H_2O$ (**2**) was isolated. Complex **2** contains only bridging Me_2biim ligands; the terminal monodentate Me_2biim ligands of **1** being replaced by aqua ligands. The crystal structure of **2** has been reported recently (20). These compounds were characterized by elemental analysis and by mass spectrometry. In the FAB$^+$ mass spectrum of the aqua species (**2**), peaks corresponding to the $[Zn_2(Me_2biim)_3(NO_3)_3]^+$ and $[Zn_2(Me_2biim)_2(NO_3)_3]^+$ species suggest that the dinuclear framework is rather robust, stabilized by nitrate ions, which have displaced the aqua ligands. For complex **1**, only the mononuclear fragment $[Zn(Me_2biim)_2(ClO_4)]^+$ was detected, perhaps because the dinuclear unit is not efficiently stabilized by the poor donor perchlorate ion.

The reaction of 2 equiv. of Me_2biim with $Cd(NO_3)_2{\cdot}4H_2O$ in methanol produced a neutral dinuclear compound, identified as $\{Cd(NO_3)_2\}_2(\mu\text{-}Me_2biim)_3$ (**3**), in which all Me_2biim ligands are bridging. A similar reaction with $Cd(ClO_4)_2{\cdot}6H_2O$ in water produced colorless crystals of the trinuclear species $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(H_2O)(Me_2biim)](ClO_4)_6$ (**4**), containing a central Cd atom bonded to six bridging Me_2biim ligands. In addition, each terminal Cd atom is bonded to a chelated Me_2biim ligand and to an aqua ligand. When the same reaction is performed in a methanol–water mixture with a Cd:Me_2biim proportion of 1:4, an unsymmetrical trinuclear compound $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(CH_3OH)(Me_2biim)](ClO_4)_6$ (**5**) is isolated. Similar trinuclear frameworks were observed in crystals of a different perchlorate salt reported recently (20).

All reactions of the Zn(II) and Cd(II) salts with Me_2biim produced oligomeric species containing bridging ligands. In this respect, the dimethylated ligand differs strikingly from H_2biim, which produced monomers containing chelated bidentate ligands only. A major difference between these two ligands is the much greater solubility of Me_2biim, which makes it possible to run the reactions directly with the metal salts under relatively mild conditions. In contrast, many H_2biim complexes had to be synthesized using the silver(I)-assisted transmetallation route involving the intermediate silver complex $[Ag(H_2biim)](NO_3)$ (30).

The five oligomeric Zn(II) and Cd(II) compounds with Me_2biim were characterized by IR spectroscopy and by X-ray crystallography.

IR spectroscopy

The IR spectra (4000–300 cm^{-1}) of free Me_2biim and its complexes were recorded in the solid state, and the frequencies are provided in the Supplementary data (Table S-1).[3] The approximate assignments proposed are based on earlier studies by Perchard and Novak (31–33) on *N*-methylimidazole and its metal complexes.

The spectra of the perchlorate complexes **1**, **4**, and **5** show the characteristic features for the free anion: very strong and broad ν_3 band at ~1090 cm^{-1} and less intense sharp peak for ν_4 at 624 cm^{-1} (10, 34, 35). The ν_1 and ν_2 vibrations are not observed in IR spectroscopy. The free NO_3^- anions in $[(H_2O)Zn(\mu\text{-}Me_2biim)_3Zn(H_2O)](NO_3)_4$ (**2**) give rise to the usual very strong ν_3 absorption at 1391 cm^{-1}, together with a weaker ν_2 band at 827 cm^{-1} (35). The ν_4 vibration is probably hidden by the strong band of Me_2biim at 737 cm^{-1}. In the complex $Cd(NO_3)_2(\mu\text{-}Me_2biim)_3Cd(NO_3)_2$ (**3**), all nitrato units are coordinated, one monodentate and one bidentate. Although the coordination state can sometimes be identified from vibrational spectra, the bands observed here at 1384 and 830 cm^{-1} do not differ from those of a free nitrate anion.

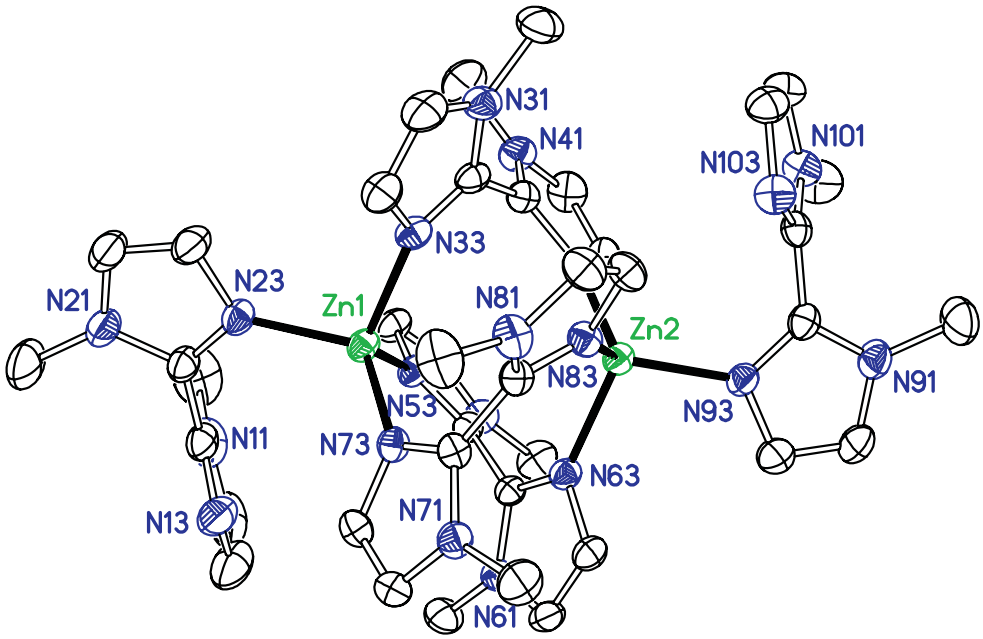
The presence of aqua ligands and water molecules was detected by the characteristic OH stretching mode. While the relatively high ν(O–H) frequency (3621 and 3552 cm^{-1}) observed for **1** indicates that this solvent is not coordinated, the lower ν(O–H) frequency (3480 cm^{-1}) observed in compound **2** confirms the coordination of the molecule and its involvement in hydrogen bonding (8). The aqua ligands in the $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(L')(Me_2biim)](ClO_4)_6$ compounds with $L' = H_2O$ (**4**) or CH_3OH (**5**) also give a ν(O–H) band at relatively low frequency (3424 cm^{-1}). The presence of methanol can usually be detected by a characteristic band at 1030 cm^{-1} (9), but it is masked here by the very strong ν_3 band of the ClO_4^- ion.

The Me_2biim bands undergo various displacements, intensity variations, and splittings upon coordination, but most of these changes are relatively small. More significant modifications in two regions may be useful as a diagnostic for the coordination of the imidazole ring, although they cannot discriminate between the bidentate-chelating, bidentate-bridging, and monodentate binding modes. As noted by Perchard and Novak for the complexation of 1-methylimidazole (32), the highest-frequency ring mode occurring at 1511 cm^{-1} in the free ligand is shifted by 15–26 cm^{-1} to higher frequency in the complexes. These authors also noted that another ring mode at ~910 cm^{-1} is displaced by +45 cm^{-1}. The corresponding vibration is found here at 917 cm^{-1} in free Me_2biim and in the 935–970 cm^{-1} range for the complexes. The weak peak at 918 cm^{-1} for complex **1** would be consistent with the presence of an uncoordinated imidazole ring in the monodentate ligand, although it might also origin from a weak ν_4 vibration of ClO_4^- (35).

Owing to the lack of absorption in the 600–400 cm^{-1} range for uncoordinated Me_2biim, absorptions occurring between 400 and 495 cm^{-1} may be assumed to result from metal coordination. Similar vibrations were found at 420 and 490 cm^{-1} for Zn and Cd complexes of H_2biim (9). However, they are probably not due to metal–ligand vibrations, since the ν(M–N) and ν(M–O) modes are expected to show at lower frequency. For instance, the Zn–N bands were reported at ~225 cm^{-1} for $ZnCl_2(py)_2$ (36, 37), 255 and 239 cm^{-1} for $ZnCl_2(imidazole)_2$ (38), 259 and 244 cm^{-1} for $ZnCl_2(1\text{-methylimidazole})_2$ (33), and 271 cm^{-1} for $[Zn(imidazole)_4]^{2+}$ (39). Our bands between 400 and 500 cm^{-1} are believed to result from low-frequency ligand modes involving mainly torsion and (or) deformation motions about the central C2–C2′ bond, whose energy would be raised in the constrained arrangement resulting from the closure of the chelate ring and the anchoring to the metal atoms in the bridging ligand. These modes might involve some motion of the metal, but this contribution is probably modest, since the frequencies are not sensitive to the replacement of Zn by Cd in the complexes.

Crystal structures

Crystal **1** consists of discrete $[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)]^{4+}$ ions (Fig. 1) separated by perchlorate anions. The dinuclear cation contains a $Zn(\mu\text{-}Me_2biim)_3Zn$ skeleton, in which three ligands form bridges between the two Zn atoms. An extra Me_2biim ligand is coordinated in a monodentate fashion to each metallic center. There is no binding contact around the free nitrogen atom of the non-bridging ligands. The Zn···Zn separation of 3.88 Å is too large for any significant interaction to take place directly between the metal centers.



The coordination geometry around each Zn atom is best described as distorted tetrahedral, with the metal atoms exclusively N-coordinated. Selected bond lengths and angles are listed in Table 2. The Zn—N bond lengths are between 1.993(4) and 2.020(4) Å, and there is no difference between the monodentate and bridging distances. They compare well with those found in the tetrahedral $ZnCl_2(imidazole)_2$ complex (1.995(11) and 2.020(11) Å) (40), and they are definitely shorter than those noted for the four-coordinate $ZnCl_2(biimidazole)$ molecule (2.064(3) Å) (9). The $N3_{br}$–Zn–$N3_{br}$ angles (105.1(2)–113.0(2)°) for the bridging ligands are all close to the ideal value. With the terminal monodentate ligands, two of the $N3_t$–Zn–$N3_{br}$ angles vary between 99.8(2)° and 105.0(2)°, while the third one is ~121°. The latter large angles (N23–Zn1–N73 and N83–Zn2–N93) are next to the uncoordinated imidazole ring.

The Me_2biim molecules are not planar; the imidazole rings being rotated with respect to one another about the C2–C2′ bond as a result of steric hindrance between the *N*-methyl groups. For the bridging ligands, the dihedral angle is ~66°, similar to those observed in $\{OReCl_2\}_2(\mu\text{-}O)(\mu\text{-}Me_2biim)_2$ (~62°) (15) and $[(H_2O)Zn(\mu\text{-}Me_2biim)_3Zn(H_2O)](NO_3)_4$ (67–76°) (20). In the terminal ligands, the angles are ~72° and ~57°, respectively. In this conformation, the two Me groups are far apart, and steric hindrance between the uncoordinated imidazole ring and the bridging ligands is minimized.

The bond distances observed in the imidazole moiety and the intra-ring angles are normal, and no appreciable differences are noted between the bonded and the non-coordinated rings. In contrast with chelates of non-methylated biimidazole, where ring closure reduces the C2′–C2–N3 angle ~15° below C2′–C2–N1, these angles in **1** show no appreciable differences for both the bridging and non-bridging ligands. The internal angles Zn–N3–C2 (avg. 131.1(3)°) are systematically larger than the external angles Zn–N3–C4 (avg. 122.4(3)°) for the bridging ligands, as reported for

Fig. 1. ORTEP drawing of the $[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)]^{4+}$ cation (**1**). Ellipsoids correspond to 30% probability. Hydrogen atoms are omitted for clarity.

$\{OReCl_2\}_2(\mu\text{-}O)(\mu\text{-}Me_2biim)_2$ (15) and $[(H_2O)Zn(\mu\text{-}Me_2biim)_3Zn(H_2O)](NO_3)_4$ (20). For the terminal monodentate ligands, the difference is much smaller; the average angle being 128.1(3)° for Zn–N3–C2 and 125.4(4)° for Zn–N3–C4.

The conformation of the bridging ligands makes it possible for one ring of each ligand to be parallel to and facing a ring in another ligand (Fig. 1). The ring–ring distances of ~3.3 Å, slightly smaller than the van der Walls distance for aromatic rings, suggest the presence of significant π–π interactions, which undoubtedly reinforce the structural integrity of the $Zn(\mu\text{-}Me_2biim)_3Zn$ unit.

A view of the unit cell is provided in the Supplementary data (Fig. S-1).[3] The complex cations are seen to pack as well-separated entities, surrounded by ClO_4^- counterions.

Compound **3** consists of the neutral dinuclear species $(NO_3)_2Cd(\mu\text{-}Me_2biim)_3Cd(NO_3)_2$ (Fig. 2), in which the two Cd atoms are bridged by three Me_2biim ligands. This framework, observed before in the dinuclear zinc compound, has not been reported so far for cadmium. Furthermore, in this case, the metal is six-coordinated, two nitrato ligands forming altogether three Cd–O bonds with each Cd atom. The asymmetric unit includes two independent molecules, but their stereochemistry and overall structures are very similar. Two of the four independent nitrato ligands in each molecule are disordered over two or three positions. However, these various local arrangements always correspond to one monodentate and one bidentate nitrate. Two of the three local structures for the Cd1/Cd2 molecule are represented in Fig. 2. They differ by the arrangement of the nitrato ligands attached to Cd2 (right-hand side of the figure): in **a** (32% occupancy), the bidentate nitrates are on the same side of the Cd–Cd axis, whereas in **b** (45% occupancy), they are on opposite sides. The third local structure (23% occupancy) is similar to **b** with the monodentate nitrate adopting a slightly different orientation.

The coordination geometry around the Cd(II) centers can be described as a very distorted octahedron. Details of the coordination sphere are given in Table 3 for the most-abundant local structures; the other components of the disorder are showing very similar structural features. Most of the Cd—N bond lengths are between 2.251(5) and 2.325(5) Å (mean = 2.287 Å), which compares well with the values found in biimidazole compounds (9). There is no obvious explanation for the greater distance (2.372(4) Å) found for one of the Cd—N bonds, and this may be an artifact created by the disorder. The shortest Cd—O distances correspond well with the Cd—O(nitrate) bond of 2.381(6) Å found in one of the biimidazole complexes (9), but they cover a broad range attaining 2.592(4) Å.

The angles around the metal show large deviations from the ideal octahedral values. The N–Cd–N bond angles are systematically greater than 90°, ranging from 93.1(2)° to 104.5(2)°. This is consistent with the small steric requirement of the nitrato ligands across the metal center. The trans bond angles range from 134.1(2) to 173.2(4)°, which is not unexpected considering the very small bite angle (~51°) of the bidentate nitrate.

Certain structural features of the bridging ligands noted in compound **1** are again observed here. However, the strain at the ring junction, as measured by the difference between the C2′–C2–N1 and the C2′–C2–N3 angles, is somewhat greater (~4.9°) than for the Zn compound (<1°), although definitely less than for chelated Cd-biimidazole compounds (~7°) (9). The internal Cd–N3–C2 angles are, on average, ~10° greater than the external Cd–N3–C4 angles, compared with ~8.7° for the Zn compound. Again, the two imidazole rings are not coplanar; the dihedral angle being ~80°, which is ~15° greater than for the Zn compound **1**. The Cd···Cd separation of 4.83 Å is ~1 Å greater than the Zn···Zn distance in **1**.

A simplified representation of the dinuclear molecule with the nitrates removed is presented in Fig. 3. Clearly, each of

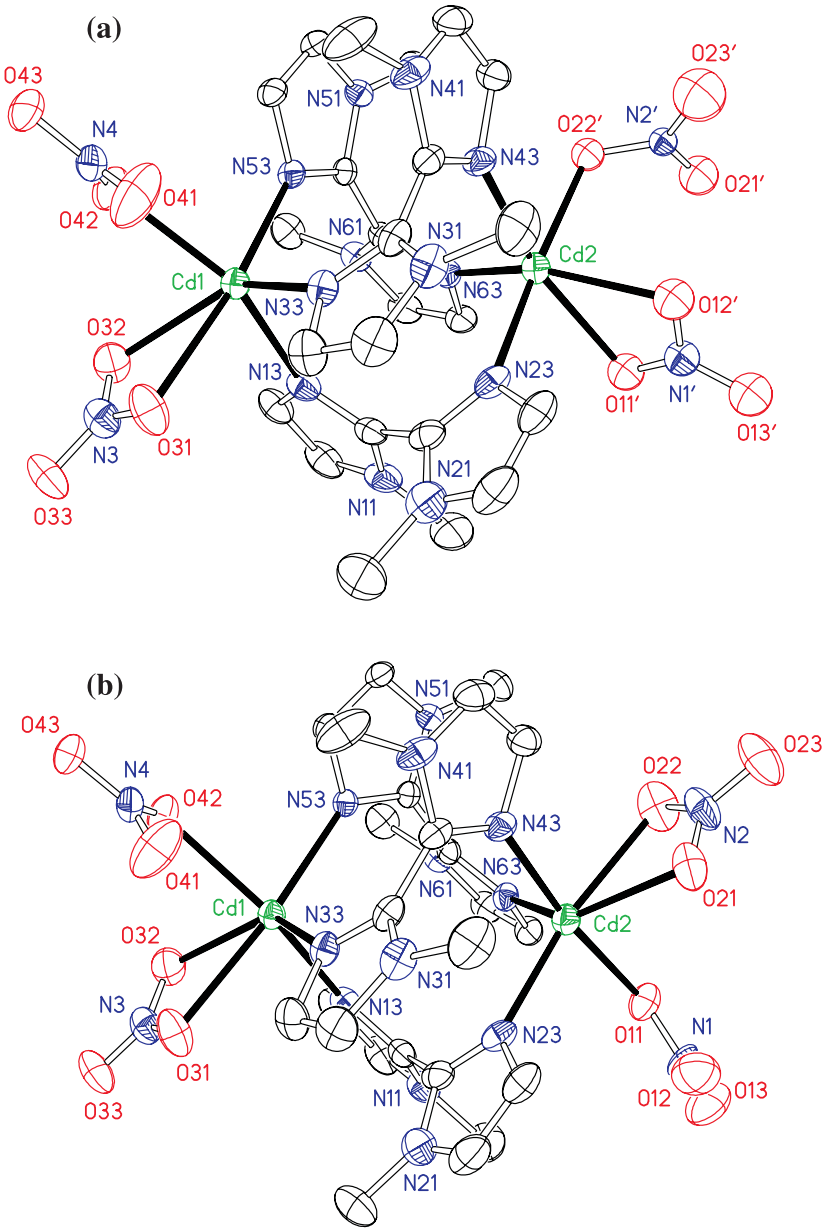
the imidazole rings is parallel to a similar ring in an adjacent ligand, and the overlap is fairly large. The average ring–ring distance (~3.3 Å), smaller than the sum of the van der Walls thickness of an aromatic ring, is indicative of appreciable π–π stacking interactions.

Views of the unit cell provided in the Supplementary data (Figs. S-2 and S-3) show that the molecules crystallize as layers parallel to the *ac* plane.[3] Any given layer contains well-separated molecules of symmetry-equivalent molecules; layers of Cd1/Cd2 molecules are alternating with layers of Cd3/Cd4 molecules in the direction of the *b* axis.



Crystals **4** and **5** are isostructural, consisting of discrete perchlorate anions and trinuclear cations [(Me_2biim)(L)Cd(μ-Me_2biim)$_3$Cd(μ-Me_2biim)$_3$Cd(L′)(Me_2biim)]$^{6+}$. Figure 4 shows the symmetric diaqua cation **4** (L = L′ = H_2O), whereas the aqua–methanol cation **5** (L = H_2O, L′ = CH_3OH) is illustrated in Fig. 5.

A crystal recently studied by Sang and Xu (20) was found to contain, in the same unit cell, the diaqua cation **4**, together with a related bisperchlorato (L = L′ = ClO_4^-) species, both lying on crystallographic inversion centers. In the present case, the cations do not possess crystallographic symmetry, but the trinuclear units are approximately centrosymmetric. They consist of two sets of three bridging ligands connecting the central Cd_c atom with terminal Cd_t atoms. Each Cd_t atom forms extra bonds to one water–methanol ligand and a chelating bidentate Me_2biim ligand. In both of our compounds, one of the $Cd_c\cdots Cd_t$ separations (4.79 Å) is the same as in the dinuclear complex **3**, while the other is somewhat greater (5.02 Å). The three Cd atoms are approximately collinear, with Cd1–Cd2–Cd3 angles of 178.32(2)° for **4** and 177.43(1)° for **5**. In the mixed diaqua–diperchlorato crystals (20), symmetry imposed that the three Cd atoms be perfectly collinear and that the $Cd_c\cdots Cd_t$ distances (~4.94 Å) be equal.

The three metal centers are six-coordinated. The selected distances and angles for **4** and **5**, given in Table 4, are in good agreement with those reported by Sang and Xu (20). The coordination around the central Cd2 atom includes six nitrogen atoms, belonging to six bridging Me_2biim ligands. In the two crystals, the Cd2—N bond distances vary between 2.373(4) and 2.432(4) Å (avg. 2.404 Å). Departure from the octahedral angles is small, the cis N–Cd2–N angles ranging from 86.0(2)° to 94.1(2)°, and trans angles from

Fig. 2. ORTEP drawings of $(NO_3)_2Cd(\mu\text{-}Me_2biim)_3Cd(NO_3)_2$ (**3**). Ellipsoids correspond to 30% probability, and hydrogens are omitted for clarity. The two represented local structures differ by the orientation on the nitrato ligands N1 and N2 (right-hand side).

176.0(2)° to 178.6(2)°. The less regular octahedra around the two terminal Cd_t atoms include five nitrogen atoms from three bridging and one chelated Me_2biim ligands. The sixth position is occupied by an aqua ligand in the symmetric crystal **4** and by an aqua ligand on Cd1 and a methanol ligand on Cd3 in the non-symmetric compound **5**. The two O-bonded ligands in **4** and **5** point in opposite directions, as clearly shown in Figs. 4 and 5.

Each bridging ligand is bonded to two Cd atoms. The Cd_t—N_{br} bond distances with the bridging ligands (2.245(6)–2.315(6) Å, mean = 2.282 Å) are ~0.12 Å shorter than those around the central Cd2 atom, whereas the N_{br}–Cd_t–N_{br} angles (mean = 102.2°) are substantially above 90°. This clearly reflects the less-crowded environment of the terminal Cd atoms, where much less space is occupied by the small H_2O–MeOH and the chelated Me_2biim ligands. The Cd—N_{ch} bonds with chelated Me_2biim are less uniform: each ligand forms one short bond (2.316(6)–2.337(5) Å), while the second bond is longer and covers a broader range (2.435(6)–2.572(7) Å). The long Cd—N_{ch} bonds does not lie close to the plane of the imidazole ring, as evidenced from the Cd-to-plane distance averaging 1.45 Å, compared with 0.60 Å for the short bond.

The Cd—OH_2 bonds in **4** are 2.503(6) and 2.567(8) Å, while in crystal **5**, the Cd—O(H)CH_3 bond (2.552(7) Å) is longer than the Cd—OH_2 bond (2.485(4) Å). These bonds are appreciably longer than the typical distance of 2.318 Å for a Cd—OH_2 bond (41).

The N_{ch}–Cd–N_{ch} bite angles in the chelate rings are ~72°, a value similar to those found in the Zn(II) and Cd(II) com-

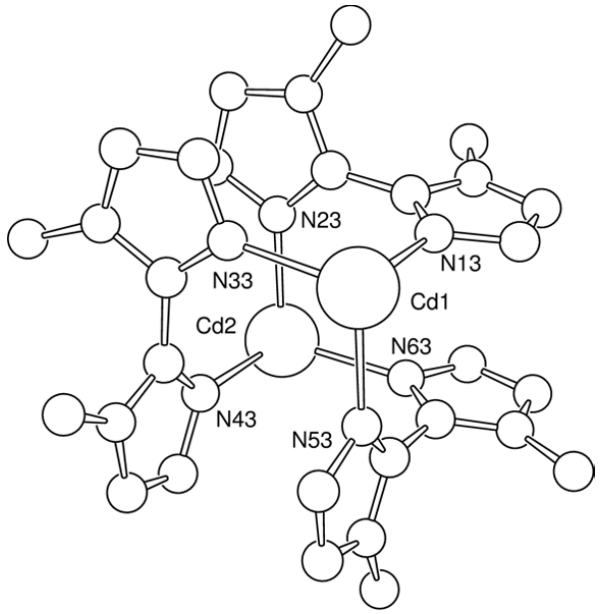
[a]For the most abundant disordered pattern (45% about Cd2 and 58% about Cd4).



plexes with H_2biim (9, 42). This small angle, the small size of the O-bonded ligand, and the steric constraints imposed by the bridging ligands result in important distortions of the octahedral coordination around the two terminal Cd atoms: the trans angles around Cd1 and Cd3 vary between 154.6(2)° and 168.7(3)°.

The dihedral angles between the two imidazole rings in the bridging ligands are ~70°, a value similar to those observed for the Zn compounds **1** (~66°) and **2** (67° and 76°) (20), although slightly smaller than the one found in the Cd crystal **3** (80°). In this conformation, no methyl–methyl repulsion remains. On the other hand, in the chelated Me_2biim ligands, steric hindrance between the methyl groups twists the molecule by 32–46° about the C2–C2′ inter-ring bond and brings the two imidazole rings out of the plane. This angle is probably a good compromise to minimize the methyl–methyl interactions, while preserving some π connection between the two aromatic imidazole rings (43). A similar twisting of 28° is observed in $SnMe_2Br_2(Me_2biim)$ (12).

Even when they are bridging, the Me_2biim ligands are appreciably distorted. The internal and external Cd–N–C angles show large differences. Details are provided in the Supplementary data (Table S-2).[3] Although they differed by only 4° in the *oxo*-rhenium compound $[\{ORECl_2\}_2(\mu\text{-}O)(\mu\text{-}biimMe_2)_2]$ (15), very large differences are noted in the present Cd complex. The effect is particularly large around the central Cd2 atom, where the Cd2–N3–C2 angles are ~20° larger than Cd2–N3–C4 (mean values: 137.2° vs. 116.7°). The difference remains large for the terminal units (131° vs. 122°). Furthermore, the Cd—N bond is usually displaced

significantly from the plane of the imidazole ring about all three Cd centers. The Cd-to-plane distances average 0.27 Å and may reach 0.50 Å. The distortion at ring junction is less important than in chelates, since the internal and external angles at C2 differ by ~9° for the non-bridging ligands and by only ~3° for the bridging ligands. Thus, the presence of chelated ligands in the molecule introduces important strain in the structure of these trinuclear compounds. On the other hand, many intramolecular π–π stacking interactions of the type shown in Fig. 3 are found between the imidazole rings with an average distance of ~3.2 Å between the ring centers.

Six perchlorate ions are incorporated in the lattice and held by Coulomb forces and hydrogen bonds to the aqua and methanol ligands. A packing diagram is available in the Supplementary data (Fig. S-4).[3]

Discussion

The coordination of Me_2biim with Zn(II) and Cd(II) differs strikingly from the behavior observed for the same metal centers with H_2biim (9, 44). This can be ascribed to two main factors:

(*i*) coordinated H_2biim participates in extended intermolecular hydrogen bonding, whereas coordinated bidentate Me_2biim is unable to form hydrogen bonds; (*ii*) the *N*-methyl groups of Me_2biim rotate the imidazole rings out of the plane, which changes the relative orientation of the *N*-donor lone pairs and leads to different structural preferences.

In the solid state, free H_2biim molecules in the anti conformation are connected into infinite ribbons by pairs of complementary N–H···N bonds (7). Further cohesion via π–π stacking between parallel ribbons results in very low solubility. As a consequence, long reaction times and vigorous conditions have to be used to produce a reaction with the undissolved ligand. In contrast, since Me_2biim is unable to form hydrogen bonds with itself, it dissolves in usual solvents, and reactions can be run in homogeneous media under much milder conditions.

Unsubstituted H_2biim usually acts as a chelating agent in monomeric species, where it is forced into the syn arrangement. The two imidazole rings are coplanar, and the resonance between the two aromatic π systems is maintained. These complexes participate in elaborate hydrogen-bonding systems, where the two N–H groups form strong hydrogen bonds with anions or solvent molecules, which is an important stabilizing factor in the structure of the metal complexes. In contrast, because of the proximity of the two N–Me groups, the two imidazole rings of Me_2biim are twisted out of the plane, and the ligand prefers to bridge two metal centers, although chelate formation remains possible.

In an undistorted H_2biim molecule acting as a bidentate chelating ligand, the vectors along the idealized lone pairs would meet at 4.9 Å from the N3 donors (Chart 2). To favor metal coordination, the five-membered rings are displaced in the ligand plane, so as to bring the N3 donors closer to each other. In a variety of complexes, this displacement reduces the θ angles at the connecting C2–C2′ bond from 125° to ~117°. Then, the metal atoms are found to bind at normal M—N distances, but the M—N vector deviates by ~13° from the idealized lone-pair direction (ϕ ~115°, ϕ′ ~140°).

To form chelates, Me_2biim, which exists as the anti conformer in the solid state (11), has to adopt a conformation on the syn side. Therefore, repulsion between the methyl groups becomes a crucial factor. In an undistorted Me_2biim molecule with a perfectly planar syn arrangement, the C_{Me}—C_{Me} distance would be extremely short (2.13 Å). The distances of 3.30–3.36 Å observed in the polymeric $[Ag(Me_2biim)]NO_3$ complex (17) can be regarded as a "normal" intramolecular Me–Me contact, since the helical structure of the chain likely leaves enough freedom for any severe local strain to be relieved. The slightly smaller distances of ~3.22 Å found in other non-chelate compounds, namely, the tetra-bridged $[Cu_2(\mu\text{-}Me_2biim)_4]^{4+}$ complex (18) and $\{PtBr(DMSO)\}_2(\mu\text{-}Me_2biim)$ (16), probably represent the lower limit for this contact.

Reduction of Me–Me repulsion can be achieved via two main structural parameters: the θ angles (C2′–C2–N3) at the ring junction and the dihedral angle between the imidazole rings. Inspection of an idealized Me_2biim molecule reveals that the contact limit of 3.20 Å occurs at a dihedral angle of 57° for the ideal θ angle (126°), but the dihedral angle is 33° when θ is 117°. Even the latter case represents a large departure from coplanarity, but the structure of $SnBr_2Me_2(Me_2biim)$ (12) suggests that it remains acceptable, since the dihedral angle in this compound is 27° for θ values of 115°. In this typical chelated ligand, some direct Me–Me repulsion is absorbed by a displacement of the methyl groups away from each other; the C2–N1–Me angles becoming 8° greater than C5–N1–Me. On the other hand, non-coplanarity implies that the M–N3 bond cannot lie in the plane of the ring. The Sn-to-plane distances observed are quite large (0.37 and 0.94 Å), which corresponds to angles of 9° and 22°, respectively, between the Sn–N bond and the imidazole plane. Nevertheless, this departure from ideality does not seem to be very energy costly, since the Sn—N bond lengths are normal. Qualitatively similar features are

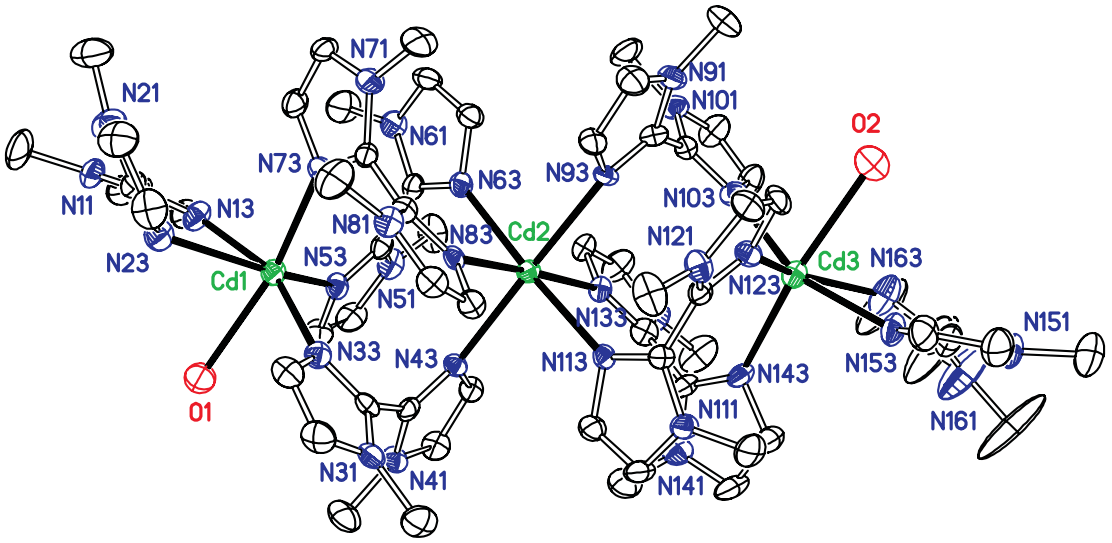
Fig. 4. ORTEP drawing of the $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(H_2O)(Me_2biim)]^{6+}$ cation (**4**). Ellipsoids correspond to 30% probability. Hydrogen atoms are omitted for clarity.



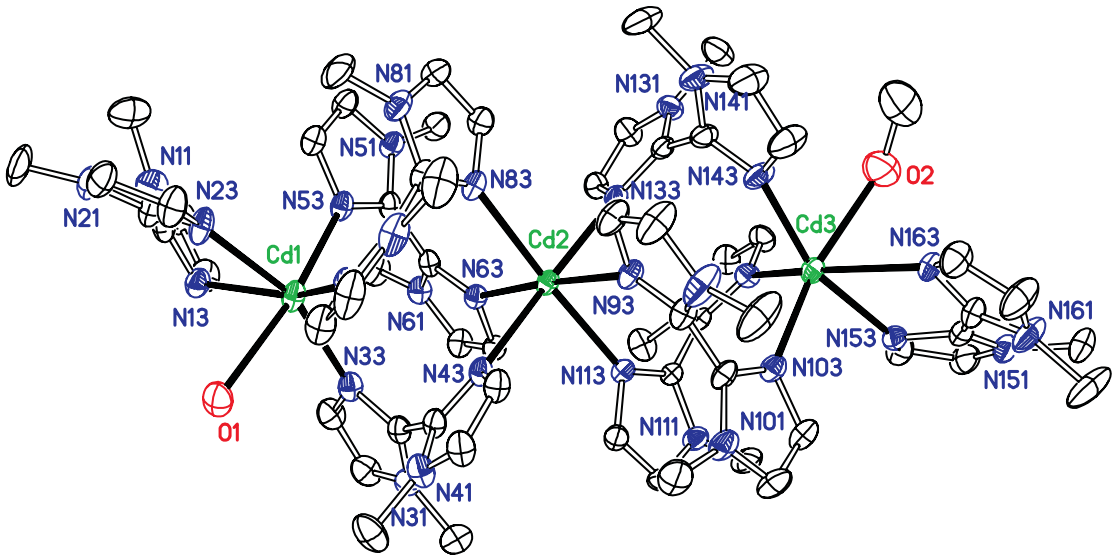


Fig. 5. ORTEP drawing of the $[(Me_2biim)(H_2O)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(CH_3OH)(Me_2biim)]^{6+}$ cation (5). Ellipsoids correspond to 30% probability. Hydrogen atoms are omitted for clarity.

observed for the chelating ligands bound to the terminal metal atoms of the $[Cd_3(Me_2biim)_8LL']^{6+}$ units described before and those reported by Sang and Xu (20). The θ angles (117–123°) are comparable, whereas the dihedral angles (21–44°) and the Cd-to-plane distances (0.54–1.33 Å) tend to be somewhat greater. For one of the rings in a terminal ligand of **4** and **5**, the Cd-to-plane distance reaches 1.74 Å. However, in this case, the Cd—N bond becomes 0.24 Å longer than the other. Surprisingly, chelating ligands were reported to be almost planar in $PtI_2(Me_2biim)$ and $PtCl_4(Me_2biim)$ (dihedral angles of 2° and 11°, respectively) (13, 14). A dihedral angle similar to that of $SnBr_2Me_2(Me_2biim)$ is expected, since the θ angles in the Pt compounds are also 115°. A possible explanation would be that in the presence of the very electron-rich Pt and halogen atoms, it may be difficult for X-ray diffraction to distinguish between a flat Me_2biim ligand and two puckered conformations averaged by disorder across the $PtX_2(Me_2biim)$ plane.

For dihedral angles greater than ~50°, methyl–methyl repulsion is no longer a significant factor. Extended polymeric chains are anticipated to develop when the conformation changes from syn to anti, and this type of structures is indeed observed for $[CdX_2(Me_2biim)]_n$ complexes (X = Cl, Br, I) (20), where the N3–C2–C2′–N3′ torsion angles range from 90° to 112°. Below 90°, small di- or trinuclear species are obtained, in which pairs of metal atoms are bridged by up to four ligands. On the basis of the structural data available at the moment, this is the preferred binding mode for Me_2biim, which has been observed in discrete dinuclear species with Cu(II), Zn(II), Cd(II), Re(V), and Pt(II) and trinuclear units with Cd(II). In all these compounds, the absence of direct repulsion between the N–Me groups is reflected by the fact

that the C2–N1–Me and C5–N1–Me angles differ by ≤2°. The average metal-to-plane distance of 0.21 Å is still relatively small, although values as high as 0.50 Å are occasionally found. In the bridging ligands, the θ angles (128–138°) are systematically *greater* than the ideal 126° value. This slightly larger angle is not expected to weaken the metal–N3 bond appreciably, since the same angle is systematically *decreased* by the same amount in H_2biim complexes. The larger angle contributes to reduce steric hindrance around the metal center by displacing the C5-bonded hydrogen away from the other ligands.

Optimal adjustment of the structural parameters of Me_2biim results in a coordination environment close to tetrahedral around the Zn(II) center in $[(Me_2biim)Zn(\mu\text{-}Me_2biim)_3Zn(Me_2biim)]^{4+}$. Although Zn(II) can reach five- and six-coordination with H_2biim (9, 10), only four-coordination is found with Me_2biim. Apparently, the constraints imposed by the bridging ligands make it difficult for a fifth ligand to bind to the relatively small Zn center, since otherwise, the terminal Me_2biim ligand would have been chelating bidentate, as found for the Cd trinuclear compounds. The N_{br}–Zn–N_{br} angles within the dinuclear framework are all close to the ideal 109.5° value. The angles involving the terminal ligand average 109.2°, but one N_t–Zn–N_{br} angle (~121°) is greater than the other two (102° and 105°) because of the particular steric requirement of the imidazole ring. Similar features were found in $[(H_2O)Zn(\mu\text{-}Me_2biim)_3Zn(OH_2)]^{4+}$, although the terminal angles are closer to 109.5° (104/116/117° pattern) because the terminal aqua ligand is sterically less demanding.

The larger Cd(II) atom shows a preference for six-coordination. In the $[Cd(\mu\text{-}Me_2biim)_3Cd]^{4+}$ unit, the torsion angles between the imidazole rings are greater than those of the corresponding Zn frameworks (~80° vs. ~65°). Some steric hindrance is suggested by the N–Cd–N angles being all greater than 90° (93–105°), but this could be simply due to the small space required by one bidentate and one monodentate terminal nitrate, since in the trinuclear $[(Me_2biim)Cd(\mu\text{-}Me_2biim)_3Cd(\mu\text{-}Me_2biim)_3Cd(Me_2biim)]^{6+}$ framework, the N–Cd–N angles around the central Cd atom lie between 86° and 94°. At the terminal Cd atoms, the N–Cd–N angles are all greater than 90° (100–105°). The for-

Chart 2.

mation of a dinuclear unit with nitrates, but not with perchlorates, may be related to the better donating ability of the nitrate, which can efficiently close the ends of the molecule at the dinuclear stage. It would be more difficult for perchlorates to play a similar role, because they are bigger and poorer donors, especially in a bidentate role. It can be speculated that in the perchlorate system, the Lewis acidity of the Cd center is better satisfied by introducing extra Me_2biim ligands and extending the chain. Why the chain does not extend beyond the trinuclear stage may be related to the fact that greater steric crowding about the central metal is achieved at the expense of some structural accommodation around the terminal metal atoms, so it may become difficult for two consecutive CdN_6 centers to coexist.

Interestingly, the imidazole rings in all di- and trinuclear units participate in intramolecular π–π stacking between the bridging ligands. These interactions are particularly clear in the Cd compounds. The loss of aromaticity because of the large torsion angles in the bridging ligands is likely balanced by these π–π interactions.

Conclusion

The di- and trinuclear frameworks observed in the present work are particularly interesting, since they consist of tube-like species, containing two or three metal centers maintained at an unbonded, but not very large distance, where the surface of the tubes consist of non-polar groups and the ends are polar. Stable units were produced with three Me_2biim ligands bridging triangular faces of octahedra or tetrahedra, as well as four ligands bridging square planes (with Cu(II)). Since most metal centers can adopt at least one of these coordination geometries, it may be anticipated that a variety of metal atoms can be similarly encapsulated by Me_2biim to develop materials in which a fairly large, but controlled metal—metal distance would be desirable.

Synthesis and characterization of bis(ferrocenylcarboxylato)telluranes

Prakash C. Srivastava, Sangeeta Bajpai, Rajesh Kumar, Shikha Srivastava, Vikas Singh, Shrinkhala Dwivedi, and Ray J. Butcher

Abstract: A convenient route to the synthesis of the first bis(ferrocenyl carboxylato) telluranes has been developed. Reactions of 1,1,2,3,4,5,6-heptahydro-1,1-(dihydroxo)tellurane and 1,1,2,3,4,5-hexahydro-1,1-(dihydroxo)tellurophene with ferrocene carboxylic acid give 1,1,2,3,4,5,6-heptahydro-1,1-bis(ferrocenyl carboxylato)tellurane (**3**) and 1,1,2,3,4,5,-hexahydro-1,1-bis(ferrocenyl carboxylato)tellurophene (**5**), respectively. The X-ray structure of **3** shows that it contains a tellurium heterocycle ($C_5H_{10}Te$), present in a chair conformation, sandwiched between two ferrocene units with carboxylate groups acting as spacers. Compound **3** also exhibits modest second harmonic generation (SHG) efficiency. The electrochemical studies of **3** and **5** through cyclic voltammetry show only one oxidation wave, indicating the presence of independent redox centers leading to reversible single-step two-electron redox systems.

Key words: tellurane, ferrocenylcarboxylate, SHG efficiency, electrochemistry.

Résumé : On a mis au point une méthode pratique de synthèse des premiers bis(ferrocénylcarboxylato)telluranes. La réaction du 1,1,2,3,4,5,6-heptahydro-1,1-(dihydroxo)tellurane et du 1,1,2,3,4,5-hexahydro-1,1-(dihydroxo)tellurophène avec l'acide carboxylique du ferrocène conduit respectivement à la formation de 1,1,2,3,4,5,6-heptahydro-1,1-bis(ferrocénylcarboxylato)tellurane (**3**) et de 1,1,2,3,4,5-hexahydro-1,1-bis(ferrocénylcarboxylato)tellurophène (**5**). La structure du composé **3** telle que déterminée par diffraction des rayons X montre qu'elle contient un hétérocycle de tellure ($C_5H_{10}Te$) qui est présent sous une conformation chaise et qui est pris en sandwich entre deux unités de ferrocène auxquelles il est retenu par des groupes carboxylates agissant comme cales. Le composé **3** possède aussi une faible efficacité dans la génération de la deuxième harmonique (GDH). Les études électrochimiques des composés **3** et **5** réalisées par le biais de voltampérométrie cyclique ne présentent qu'une seule vague d'oxydation, ce qui indique la présence de centres redox indépendants qui conduisent à des systèmes redox à deux électrons impliquant une seule étape réversible.

Mots-clés : tellurane, ferrocénylcarboxylate, efficacité dans la génération de la deuxième harmonique, électrochimie.

[Traduit par la Rédaction]

Introduction

Bridged ferrocenes containing main group (13–16) (p-block) elements are known and generally exist as polymers or oligomers (1–9). Ferrocene derivatives containing boron bridges have been synthesized by the reaction of dilithiated ferrocene and bis(dimethylboryl) ferrocene or bis(trimethylstannyl) ferrocene with $PhBCl_2$ (1, 2). A multinuclear ferrocene derivative with aluminium substitution has been synthesized by the reaction between dilithiated ferrocene with $AlEt_2Cl$ (3). The reaction of 1,1′-bis(trichlorostannyl) ferrocene with Me_3Ga results in the formation of 1,1′-digallyl ferrocene (4). Ring-opening polymerization (ROP) of main group element bridged [1]- and [2]-ferrocenophanes by thermal or anionic methods results in high molecular weight polymers containing ferrocene groups alternating with either boron, carbon, silicon, germanium, tin, or phosphorous atoms (5–7). A hexa-ferrocene unit on a tin–oxygen cluster has been synthesized by the reaction of *n*-butylstannonic acid with ferrocene monocarboxylic acid (8). A chalcogen (sulphur) bridged polymer has been synthesized by the reaction of trithia ferrocenophanes with Bu_3P (9). The interactions between main group elements and transition elements of the periodic table lead to useful precursors for ceramics, electronic materials, and catalysts (10, 11); if the transition metal containing entities are metallocenes (particularly ferrocenes), such combinations exhibit novel electrical, optical, chemical, and magnetic characteristics (12, 13). These include redox active materials for modification of electrodes (14) or materials that can function as multi-electron redox systems (15), biosensors (16*a*, 16*b*), or variable refractive index sensor materials (16*c*, 16*d*). The extent of interaction between ferrocene groups is largely dependent on the nature of the bridge linking the adjacent

ferrocene centers (14). However, since polymers are often less well-defined the investigations are best carried out with di- or tri-nuclear model compounds, but such species are often very difficult to prepare and crystallize for X-ray diffraction studies (17, 18). On the other hand, organotelluriums are useful precursors for semiconductors, tellurite glasses, and optoelectronic materials (19–21).

In view of the above, our work is directed to the synthesis of bis(ferrocenyl carboxylato) telluranes by a convenient route in which the complex **3** corresponds to new structural type where a cyclic tellurane ($C_5H_{10}Te$) is (formally) sandwiched between ferrocenes separated by carboxylate spacer groups. We also present preliminary results of their second harmonic generation (SHG) efficiency and electrochemistry.

Experimental

All manipulations were carried out at room temperature. The reagents were obtained from commercial sources and used as received unless otherwise noted. Benzene was dried over $CaCl_2$ and distilled before use. $C_5H_{10}TeI_2$ and $C_4H_8TeI_2$ were prepared according to literature methods (22, 23). ^{1}H NMR spectra were recorded on a Bruker WM 400 (400 MHz.) FT NMR spectrometer in $CDCl_3$ using TMS as an internal standard. Elemental analyses were performed on an Heraeus Carlo Erba 1108 elemental analyser. Cyclic voltammetry (CV) was performed with a CH-1660 scanning potentiostat–galvanostat interfaced to a desktop computer using the EG & G model 270 software package. Cyclic voltammograms of telluranes **3** and **5** were obtained by using a platinum working electrode, a platinum coil counter electrode and as Ag/AgCl (non-aq.) reference electrode. The scan rate was 100 mV/s and full IR compensation was employed in all measurements. Tetraethyl ammonium perchlorate (0.1 mol/L) in acetonitrile was used as supporting electrolyte and the sample concentration was in the order of 10^{-4} mol/L. Cyclic voltammetric studies were carried out at the IIT Bombay and SHG efficiency was measured at IISc, Bangalore.

Preparation of $C_5H_{10}Te(OH)_2$ (1) and $C_4H_8Te(OH)_2$ (4)

To 1,1,2,3,4,5,6-heptahydro-1,1-diiodo tellurane (1.00 g, 2.214 mmol), was added freshly prepared silver hydroxide (0.554 g, 4.432 mmol) in a mortar and ground with a small amount of deionized water to make a thin paste. This was ground for 45 min more, upon which the reddish brown crystals of 1,1,2,3,4,5,6-heptahydro-1,1-diiodo tellurane disappeared. The paste was filtered with hot water. The filtrate was $C_5H_{10}Te(OH)_2$ (**1**) (in situ). Compound **4** was similarly prepared using $C_4H_8TeI_2$ (1.00 g, 2.285 mmol) and silver hydroxide (0.571 g, 4.568 mmol) and the filtrate was $C_4H_8Te(OH)_2$ (**4**) (in situ).

Reaction of 1 with $HOOCC_5H_4FeC_5H_5$

A mixture of ~0.252 g (1.088 mmol) of $C_5H_{10}Te(OH)$**2 1** (in situ) and $HOOCC_5H_4FeC_5H_5$ (**2**) (0.500 g, 2.1753 mmol) in benzene (500 mL) was heated under reflux for 7 h using a Dean–Stark apparatus to remove the water formed in the reaction by azeotropic distillation. The mixture was filtered and reduced (~10 mL) to afford orange-yellow crystals, which were shown to be $C_5H_{10}Te(OCOC_5H_4FeC_5H_5)_2$ (**3**). Yield 0.686 g (96%), mp 194 °C. ^{1}H NMR ($CDCl_3$) δ: 4.21 (s, 10H, C_5H_5), 4.75–4.35 (m, 8H, C_5H_4), 3.21 (t, 4H, CH_2Te), 2.02–1.83 (m, 6H, CH_2C). Anal. calcd. for $Fe_2TeC_{27}H_{28}O_4$: C 49.4, H 4.3, Te 19.5; found: C 49.4, H 4.2, Te 19.5.

Reaction of 4 with $HOOCC_5H_4FeC_5H_5$

Using a procedure similar to that described earlier, the reaction of **4** (~0.173 g, 0.796 mmol) (in situ) with $HOOCC_5H_4FeC_5H$**5 2** (0.344 g, 1.496 mmol) in benzene gave $C_4H_8Te(OCOC_5H_4FeC_5H_5)_2$ (**5**). Yield 0.486 g (95%), mp 200 °C. ^{1}H NMR ($CDCl_3$) δ: 4.22 (s, 10H, C_5H_5), 4.75–4.31 (m, 8H, C_5H_4), 3.31 (t, 4H, CH_2Te), 2.72 (m, 4H, CH_2C). Anal. calcd. for $Fe_2TeC_{26}H_{26}O_4$: C 48.6, H 4.0, Te 19.9; found: C 48.6, H 4.0, Te 19.8.

Crystal structure determination

The orange-yellow crystal of **3** was mounted on a Bruker SMART CCD diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The data were corrected for Lorentz, polarization, and absorption effects. The structure was solved by the routine heavy atom method SHELXS-97 (24) and Fourier methods. Non-hydrogen atoms were refined anisotropically by full-matrix least-squares using the SHELXL-97 program (24) with hydrogen atoms in idealized positions. A summary of crystallographic parameters is presented in Table 1 (24).[2]

Results and discussion

1,1,2,3,4,5,6-heptahydro-1,1-bis(ferrocenyl carboxylato) tellurane (**3**) was synthesized by the reaction of 1,1,2,3,4,5,6-heptahydro-1,1-(dihydroxo)tellurane **1** with ferrocene monocarboxylic acid **2** in (1:2) stoichiometry in benzene, which yielded orange crystals of 1,1,2,3,4,5,6-heptahydro-1,1-bis(ferrocenyl carboxylato) tellurane (**3**). 1,1,2,3,4,5-Hexahydro-1,1-bis(ferrocenyl carboxylato) tellurophene (**5**) was similarly prepared by the reaction of 1,1,2,3,4,5-hexahydro-1,1-(dihydroxo) tellurophene **4** with **2** in benzene in 1:2 molar ratio (eq. [1], Fc = Ferrocenyl). The products (**3** and **5**) were obtained in nearly quantitative yields.

Fig 1. Structure of $C_5H_{10}Te$ $(OCOFc)_2$ (**3**).

Compound **3** contains two ferrocene units and the tellurium heterocycle [1,1,2,3,4,5,6-heptahydro tellurane, $C_5H_{10}Te$] is sandwiched between these, with carboxylate groups acting as spacers (Fig 1; Table 2). The $C_5H_{10}Te$ ring has a chair conformation in which part of the ring is flattened and a part is considerably puckered (25). Of the five methylene groups, two methylene carbon atoms of the C_5H_{10} group are bonded to Te(IV) atoms with bond lengths Te–C(1) = 2.124(3) Å and Te–C(5) = 2.134(3) Å. The coordination geometry formed by the four closest atoms C(1), C(5), O(1A), and O(1B) is approximately trigonal bipyramidal with the oxygen atoms of the unidentate ferrocenecarboxylate groups in the apical positions [Te–O(1A) = 2.145(2) Å, Te–O(1B) = 2.175(2) Å] and the two methylene carbon at-

oms in the equatorial plane [$\cdots$ C(1)–Te –C(5) = 97.56(11)°]. The fifth coordination position in the equatorial plane is apparently occupied by a stereochemically active electron pair. The O(1B)–Te –O(1A) angle of 163.43(8)° deviates considerably from linearity, with oxygen atoms pushed away from the equatorial tellurium lone pair (25, 26). In the unit cell diagram (withheld for sake of brevity) of **3**, no intermolecular interactions are seen between the molecules of **3**, in contrast to other organotellurium carboxylates (26) where a variety of supramolecular associations are present because of Te$\cdots$O secondary bonds formed through the intermolecular interactions between Te and O of the carboxylate groups.

To our knowledge, **3** and **5** are the first ferrocenyl carboxylato tellurium derivatives and their properties are noteworthy: they are virtually inert towards hydrolysis, even in boiling water, and they do not undergo any change until 194 °C. Their NLO (nonlinear optical) and electrochemical properties are being reported for the first time in this investigation.

Table 3. Second harmonic generation (SHG) data for bis(ferrocenyl carboxylato) telluranes.

Complex	SHG effciency[a]
$C_5H_{10}Te(OCOFc)_2$	0.13
$C_4H_8Te(OCOFc)_2$	0.018
$[N{\equiv}W(OCMe_3)_3]n$[29]	0.20
KH_2PO_4(KDP)[28]	0.16

[a]Efficiency (urea = 1) of unsized powders (λ_{ex} = 1064 nm).

Determination of the relative efficiency of second harmonic generation (SHG) using the Kurtz and Perry method (27) shows that 1,1,2,3,4,5,6-heptahydro-1,1-bis(ferrocenyl carboxylato) tellurane **3** is 0.13 times as efficient as urea. This is comparable to the SHG efficiency of potassium dihydrogen phosphate (KDP) (28) (Table 3). The SHG efficiency of **3** is also comparable to the tungsten nitrido $[N{\equiv}W(OCMe_3)_3]_n$ polymer (29) (Table 3). The SHG efficiency of **3** is modest in view of the fact that **3** should, in principle, possess large molecular hyperpolarisability (β) as it contains ferrocene units that are necessarily electrochemically charge–transfer active in nature. The closest analogue to complex **3** is 2-dicyanomethylene-1,3-bis(ferrocenylmethyl)-1,3-diazolidine, which also shows a SHG signal by the Kurtz powder technique with low efficiency (30).

The SHG efficiency of 1,1,2,3,4,5-hexahydro-1,1-bis(ferrocenylcarboxylato) tellurophene **5** is only 0.018 times as that of urea (Table 3), which is much lower than the SHG efficiency of **3.** In spite of our repeated efforts, we have not been able to grow the crystals of **5** for X-ray diffraction studies, and because of the absence of crystal structure data for **5** it is very difficult to comment on the large difference in SHG efficiency values of **3** and **5**. The irradiation of laser light for the evaluation of SHG efficiency through $C_5H_{10}TeI_2$ and $C_4H_8TeI_2$ resulted in their decomposition. This observation, coupled with SHG efficiencies of **3** and **5**, indicates that the attachment of FcCOO groups in place of iodide groups to $C_5H_{10}Te$ or C_4H_8Te heterocycles, probably confers stability to these tellurium heterocycles with respect to irradiation of laser light.

Cyclic voltammetric studies on **3** and **5** show a single quasi-reversible peak with an $E_{1/2}$ value of 0.27 V for **3** and 0.29 V for **5** (vs. Ag/AgCl). A representative cyclic voltammogram of **3** is reproduced in Fig. 2. Comparison of the $E_{1/2}$ value with those of some biferrocene molecules with different spacer groups is shown in Table 4. In biferrocene [A] (31), two oxidation waves are present [$E_{1/2}$ = 0.46 V and $E_{1/2}$ = 0.80 V and ΔE = 0.34 V (vs. Ag/AgCl)] as oxidation of the first ferrocenyl moiety makes subsequent removal of an electron more difficult. Similarly in bridged ferrocenes containing S(9), [P, Ge, Sn] (17*b*), and Si_n [n = 1, 2, 3] (31, 17*b*) bridges, two oxidation waves are observed because of electronic communication between ferrocene units. However, the presence of $(\text{-}CH_2\text{-})_n$ (n > 1) (17*b*) and $(SiMe_2)_n$ (n = 6) [D] (Table 4) (31) units serve as insulating units

Fig 2. Cyclic voltammogram of $C_5H_{10}Te(OCOFc)_2$ (**3**).

and only one oxidation wave is detected because of little interaction between the two ferrocene groups. Similarly, in the present investigation when a ferrocene group is separated from another ferrocene group by the spacer group [-C(=O)O-Te(R_2)-O-C(=O), R_2 = C_5H_{10}, C_4H_8], the spacer groups act as insulating units and only one oxidation wave is detected. The results are consistent with the earlier conclusions that noninteracting electroactive centers will involve as many electrons as there are centers and will yield a voltammetric wave with a slope matching to that of the corresponding molecule with a single electroactive center (14, 15). The current study opens routes to a convenient method of synthesis of ferrocenylcarboxylato telluranes with independent redox centers and leads to fully reversible single-step two-electron redox systems. Further efforts are directed towards (*i*) the attachment of different tellurium heterocycles, (*ii*) the incorporation of different (spacer) groups in the system, and (*iii*) extension of this chemistry to other transition metallocene carboxylates and investigation of their electrochemical and NLO properties.

Conclusions

We have synthesized the first organotellurium derivatives (**3** and **5**) containing ferrocene carboxylate groups. The structure of $C_5H_{10}Te(OCOFc)_2$ (**3**) has been confirmed by X-ray diffraction and it corresponds to a new structural type. The relative SHG efficiency of **3** is modest. The electrochemical measurements of **3** and **5** reveal them to be fully reversible single-step two-electron redox systems.

Self-assembled coating for modification of the electro-osmotic flow in nonaqueous capillary electrophoresis using formamide

Abebaw G. Diress and Charles A. Lucy

Abstract: The use of pure nonaqueous solvents in capillary electrophoresis (CE) can alter the separation selectivity and enhance the solubility of hydrophobic compounds and enables the use of higher voltages. However, control of the electro-osmotic flow (EOF) is essential. In this work, we report the use of self-assembled coatings for EOF modification and elimination of analyte adsorptions onto silica capillaries in pure formamide. Bilayer capillary coatings derived from the double chain cationic surfactant dimethyldioctadecylammonium bromide ($2C_{18}$DAB) reverses the EOF in buffers such as acetate, formate, and phosphate. Reversed EOF of $>1.1 \times 10^{-4}$ cm^2/Vs enables the separation of the pharmaceutical drugs propranolol, metoprolol, chloroquine, and chloropheniramine in less than 5 min with efficiencies of 0.2–0.5 million plates/m (66 000 to 165 000 plates). Chemical and physical factors affecting the coating stability and their influence on separation speed and efficiency of the cationic drugs in formamide are also investigated.

Key words: capillary electrophoresis, cationic surfactants, electro-osmotic flow, formamide, nonaqueous solvents.

Résumé : L'utilisation de solvants non aqueux purs dans l'électrophorèse capillaire (EC) peut altérer la sélectivité des séparations et augmenter la solubilité des composés hydrophobes et elle peut aussi permettre d'utiliser des voltages plus élevés. Toutefois, il est essentiel de contrôler l'écoulement électroosmotique (EEO). Dans ce travail, on a utilisé des enduits auto assemblés pour modifier l'écoulement électroosmotique et pour éliminer les adsorptions d'analyse sur les capillaires de silice dans le formamide pur. Des enduits capillaires à double couche dérivés d'une double chaîne de l'agent de surface, bromure de diméthyldioctadécylammonium ($2C_{18}$DAB) permet de renverser l'écoulement électrostatique dans des tampons, tels ceux de l'acétate, du formiate ou du phosphate. Des EEO inversés de $>1.1\times 10^{-4}$ cm^2/Vs permettent d'effectuer la séparation de médicaments tels, le propranolol, le métoprolol, la chloroquine et la chlorophéniramine en moins de 5 min avec des efficacités allant de 0.2–0.5 million plateaux/m (66 000 à 165 000 plateaux). On a aussi examiné les facteurs chimiques et physiques qui affectent la stabilité des enduits et leur influence sur la vitesse et l'efficacité de séparation des médicaments cationiques

Mots-clés : électrophorèse capillaire, agents de surface cationiques, écoulement électroosmotique, formamide, solvants non aqueux.

[Traduit par la Rédaction]

Introduction

Electrophoresis is the migration of ions under an applied electric field (E). The simplest expression for the velocity of this migration (ν) is given in eq. [1],

$$[1] \qquad \nu = \mu_e E = \frac{q}{6\pi\eta r_s} E$$

where μ_e is the electrophoretic mobility, which is directly related to the charge of the ion (q) and inversely related to the solvent viscosity (η) and the Stokes radius of the ion (r_s). In capillary electrophoresis (CE) the use of narrow (10–100 μm) capillaries enables electric fields of 100–500 V/cm to be applied, which results in rapid electrophoretic separations. However to achieve separation, the mobility of two ions must be different. Mobility differences between analytes may be intrinsic or can result from adjustment of (*i*) the charge of the ion (e.g., through acid–base equilibria or ionic screening (1)), (*ii*) the size of the ion (e.g., through complexation (2–4)), or (*iii*) the solvation of the ion by using mixed organic–water media. Advantages asserted for organic–water media over pure aqueous systems include altering the electrophoretic mobility (and thus possibly selectivity) of analytes, increased solubility of hydrophobic analytes, and the ability to use higher separation voltages and (or) high BGE ionic strengths because of lower electric current compared with water (5–8). The validity of these and other more speculative claims (e.g., increased efficiency) have recently been critically evaluated (9).

A wide range of solvents have been used in nonaqueous CE including methanol, ethanol, butanol, acetonitrile, nitromethane, and mixtures of two or more of these solvents (8, 10, 11). Formamide (FA) is one of the few organic sol-

vents possessing a dielectric constant greater than that of water (109.5 vs. 78.5). This property makes ion pairing of analyte ions with buffer counter-ions negligible, whereas ion pairing is often observed in low dielectric organic solvents such as acetonitrile (5, 11). FA also has a 3-dimensional hydrogen-bonded structure that is even more pronounced than that of water. Sahota and Khaledi (12) reported the first investigation of FA as a CE medium in 1994. Since then, FA or FA–aqueous buffers have been used for CE separations of enantiomers (13, 14), for control of the electro-osmotic flow (EOF) (15), as a solvent in MEKC (16–19), and for other applications (15, 20, 21). However, the potential of FA as a pure or mixed solvent in CE has not been fully achieved because of a lack of understanding of the influence of the solvent on mobility, low absorbance detection sensitivity since FA has a UV cut-off of 275 nm, and the slow EOF and mobilities in FA due to its high viscosity (3.3 cP). Recently, Porras and Kenndler (21) addressed the first issue in their thorough investigation of intrinsic mobilities, ionic strength, and pH on mobilities in FA. They also addressed the issue of detection by employing both indirect UV detection and contactless conductivity detection (21). However, they observed EOF values of only $+(0.8–1.5) \times 10^{-4}$ cm^2/Vs (21), approximately a factor of five lower than in aqueous buffers. Coupled with the low mobilities observed in FA (21), long analysis time would be expected, particularly under counter-EOF conditions where highest resolution is achieved. In this paper we focus on the control and modification of the EOF in buffers containing formamide. Double-chained cationic surfactants are employed to reverse the EOF. The reversed EOF conditions enable counter-EOF separations of basic analytes, which have previously only been studied under co-EOF conditions (12, 13).

Results and discussion

Both the migration time and resolution depend upon the apparent mobility (μ_a), which is directly dependent on the mobility of the electro-osmotic flow (μ_{eof}).

$$[2] \qquad \mu_a = \mu_e + \mu_{eof}$$

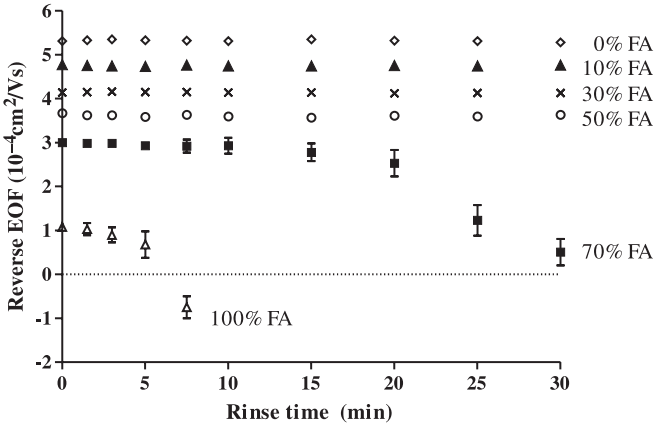
where μ_e is the electrophoretic mobility of the analyte as defined in eq. [1]. In general, most analytes separated by CE possess an electrophoretic mobility smaller than the EOF mobility (μ_{eof} is typically $+(2–8) \times 10^{-4}$ cm^2/(Vs) in aqueous buffers). This allows for the simultaneous determination of both positively and negatively charged species when the detector is placed at the cathodic (negative) end of the capillary. In this case, cations migrate in the same direction as the EOF (co-EOF) and anions migrate opposite to the direction of the EOF (counter-EOF). The greatest separation speed is achieved under co-EOF separation conditions, while greatest resolution is achieved using counter-EOF conditions. Thus, EOF plays a key role in electrophoretic separations (22).

The magnitude of the EOF mobility is expressed by the von Smoluchowski equation,

$$[3] \qquad \mu_{eof} = -\frac{\varepsilon\zeta}{\eta}$$

where ε and η are the dielectric constant and viscosity of the solvent and ζ is the zeta potential of the capillary surface. The zeta potential is the potential at the plane of shear and is a function of the surface charge and the ionic strength of the buffer. The EOF can be adjusted by alteration of the dielectric constant or viscosity (23, 24), but most often the focus is on controlling the surface charge of the capillary. Approaches include control of the deprotonation of silanols on the capillary surface, covalent coatings (25), and dynamic adsorption (ion exchange) of strongly retained cations (22). Dynamic coatings are attractive relative to covalently bonded polymer coatings because of their simplicity, versatility, and low cost.

Surfactants are a flexible and effective means of suppressing (26) or reversing (27) the EOF. Indeed, rapid and high efficiency separations of inorganic anions was made possible by reversal of the EOF using tetradecyltrimethylammonium bromide (TTAB) (28). EOF reversal by cationic surfactants involves the self-assembly of poly-cationic aggregates that adsorb onto the capillary surface. Single-tailed cationic surfactants such as TTAB form spherical micelles in water, which adsorb to reverse the EOF (27, 29). However, the surfactant must be in the electrolyte to maintain the EOF. Double-chain surfactants such as didodecyldimethylammonium bromide (DDAB or $2C_{12}$DAB) self-assemble to form vesicles in water, which adsorb onto the capillary as a bilayer (29). Bilayer coatings are much more effective at preventing protein adsorption and are sufficiently stable that the surfactant does not need to be present in the separation buffer (30). The use of long-chained dimethyldioctadecylammonium bromide ($2C_{18}$DAB) enhances the stability of the bilayer such that 60 replicate runs could be performed over 12 days using aqueous buffers that did not contain surfactant (31).



We have shown that long-chained two-tailed surfactants form bilayer coatings that are stable for a number of runs in buffers containing up to 60% *v*/*v* of organic solvents such as methanol, acetonitrile, ethanol, propanol, and butanol (32). As a continuation of that work, our interest in this study was to evaluate whether these long doubly chained surfactants could be used in buffers prepared in pure formamide (FA). Duval and Warr (33) observed that the single-chained surfactant tetradecyltrimethyl ammonium chloride (TTAC) formed similar micellar aggregates in FA as in pure water. This similarity in aggregation behavior is believed to be due to the combined effect of the high dielectric constant of FA and the hydrogen-bonding nature of the amide proton (34–36). However, there have been no studies of two-tailed surfactants in mixed FA–water or pure FA solvent systems.

Bilayer stability in formamide–water media

In Fig. 1 the stability of the coating was assessed by monitoring the electro-osmotic flow mobility (μ_{eof}) as the capillary was rinsed with surfactant-free buffer with varying amounts of FA (37, 38). Surfactant coatings were formed simply by rinsing the capillary with a 1.0 mmol/L aqueous surfactant solution for 10 min, followed by a brief rinse with a surfactant-free electrophoretic buffer to remove any nonsorbed surfactant. Both the initial value of the EOF and the coating stability depend on the volume fraction of FA in the separation buffer. The magnitude of the initial EOF (at zero

Fig. 1. Coating stability of $2C_{18}$DAB in formamide–aqueous phosphate buffers. 0% FA (◇), 10% FA (▲), 30% FA (×), 50% FA (○), 70% FA (■), 100% (△). Experimental conditions are: 25 mmol/L sodium phosphate buffer at pH 7.0; applied voltage –20 kV; capillary 37 cm × 50 μm i.d. (28.5 cm to the detector); neutral marker 0.5 mmol/L mesityl oxide at 254 nm; temperature 25 °C. The coating was prepared by rinsing the capillary with 1.0 mmol/L $2C_{18}$DAB prepared in water for 10 min at 93.8 kPa. The time on the *x*-axis represents the duration for which the coating is then subjected to a high-pressure (93.8 kPa) rinse of buffer not containing surfactant. The capillary was regenerated by rinsing with 1 mol/L NaOH and recoated with $2C_{18}$DAB solution prior to another rinse with separation buffer without surfactant. Error bars indicate the standard deviation of at least three runs. For points with no error bars the standard deviation is smaller than the symbol.

time) decreases as the amount of FA is increased. This is due in part to a decrease in the dielectric constant to viscosity ratio (i.e., lower ϵ/η value, Table 1). Both ϵ and η increase with increasing percentage of FA, with ϵ reaching a maximum value at ~65% and slightly decreasing thereafter, but the overall ϵ/η ratio decreases (39). Rearrangement of eq. [3] allows estimation of the ζ, which is constant at –68 ± 2 mV between 0% and 70% but then decreases by about half in pure FA.

In buffers containing 0%–50% FA (Fig. 1), the $2C_{18}$DAB coating displays a constant EOF value (%RSD < 0.8%) with no noticeable drift over 30 min of continuous rinsing with the surfactant-free buffer. The results in pure aqueous buffer are consistent with those observed previously (31), which allowed protein separations to be performed for 12 days in aqueous buffers without the need to regenerate the coating. In 70% FA (■ in Fig. 1), the EOF remains constant for 15 min of rinsing ($RSD_{0–15\ min}$ = 1.2%) and thereafter decreases rapidly, indicating degradation of the $2C_{18}$DAB coating. In 100% FA, a small reversed EOF of 1.22×10^{-4} cm^2/Vs is obtained with no rinsing (t = 0), but the EOF decreases rapidly, generating a normal EOF after only a 5 min rinse (~6 capillary volumes).

The $2C_{18}$DAB degradation behavior observed in 70% and 100% FA (Fig. 1) differs from that observed previously in aqueous solutions (30). In aqueous solution, the $2C_{12}$DAB bilayer degradation follows first order kinetics such that the EOF decreases exponentially to a residual EOF value. The more drastic behavior in Fig. 1 may be due to a collapse of the bilayer structure because of the lower zeta potential. A similar dramatic decrease in EOF to that in Fig. 1 has been observed for double-chain surfactants in high ionic strength aqueous solutions where the zeta potential was substantially lowered (31). Valkó et al. (40) reported that under unbuffered conditions the zeta potential of fused silica was a factor of two lower in formamide than in water, although others have seen essentially no change in zeta potential under similar conditions (18). The zeta potential of the fused silica might be lowered further by a change in the true pH of our buffer upon addition of FA. Alternately, the dramatic decrease in EOF at high %FA might be due to an increased value of the critical micelle concentration (cmc) with increasing concentrations of FA There are no literature cmc values for double-chain surfactants in FA or in FA–water mixtures. However, the cmc for single-chain surfactants increase significantly in formamide relative to the value in water (41, 42).

Effect of surfactant concentration on EOF

In aqueous buffers the EOF has been observed to be unaffected by low concentrations of cationic surfactant. The EOF undergoes a rapid transition to the reversed direction at a surfactant concentration near the cmc in the bulk solution or the critical surfactant aggregation concentration (csac) at the capillary surface (27, 43–45). Figure 2 shows that in pure FA $2C_{18}$DAB reverses the EOF, and that increased concentrations of surfactant gradually increase the magnitude of the EOF. This behavior is similar to our previous observations of C_{16}TAB in MeOH–water under conditions where the zeta potential of the capillary was low (45).

Effects of capillary size and buffer type

Capillary diameter significantly affects the stability of bilayer coatings (30, 46). Figure 3 shows the coating stability for 25 μm and 50 μm internal diameter $2C_{18}$DAB-coated capillaries in formamide. The 25 μm capillary was coated with 1.0 mmol/L surfactant solution for 25 min (compared with 10 min rinse for the 50 μm capillary) to ensure that same volume of surfactant solution had passed through both capillaries. As expected, both capillaries display the same initial reversed EOF (~1.12×10^{-4} cm^2/Vs) indicating that similar bilayers are produced. However, the coating shows poorer stability with the wider capillary. The larger volume-to-surface ratio of the wider capillary shifts the adsorption–desorption equilibrium towards desorption of more surfactant from the surface (30). Hence, the degradation in the bilayer structure results in the reduction of the EOF. This is similar to the bilayer degradation observed when the coating is subjected to longer rinsing times (e.g., longer than 20 min flushing in 70% FA buffer in Fig. 1).

The nature and concentration of the buffer influences the stability of surfactant coatings (30, 47). Aqueous acetate and formate buffers yield significantly lower stability surfactant coatings than phosphate buffer (30, 48). This is because the weaker attraction of acetate and formate to the surfactant head groups increases the electrostatic repulsion between the charged head groups, which results in a higher cmc and consequently a less stable bilayer. Hence, the coating stability was also examined in two other common buffers, ammonium acetate (NH_4Ac) and ammonium formate (NH_4Fo) buffers

[b]Initial EOF values obtained without rinsing the coatings with the electrophoretic buffer. All other experimental conditions are as described in Fig. 1.

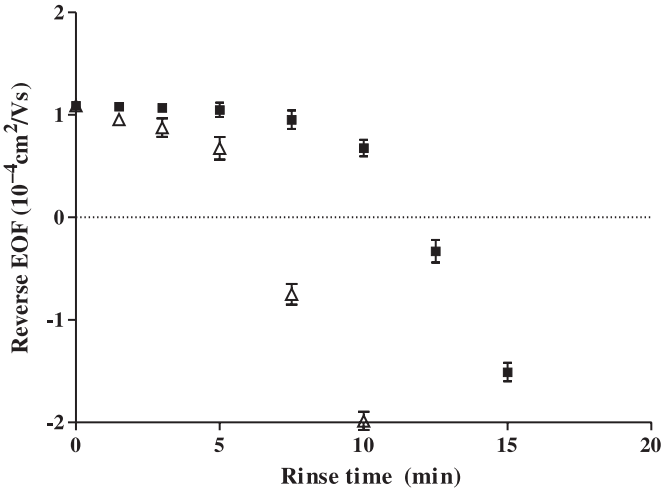

Fig. 2. Effect of $2C_{18}$DAB concentration on the reversed EOF mobility in formamide. Experimental conditions are: buffer 25 mmol/L sodium phosphate buffer (pH 7.0) prepared in formamide; applied voltage –20 kV; capillary 37 cm × 50 µm i.d. (28.5 cm to the detector); neutral marker 0.5 mmol/L mesityl oxide at 254 nm; temperature 25.0 °C. All the $2C_{18}$DAB solutions were prepared in formamide. All other conditions are as described in Fig. 1. Error bars indicate the standard deviation of at least three runs.

prepared in FA at pH 4.0. Under the conditions studied (0.1–2.0 mmol/L surfactant; 25 and 50 mmol/L ammonium acetate and ammonium formate in FA) reversed EOF was not achieved after rinsing of the capillary to remove non-sorbed surfactant. Instead, partially suppressed normal EOF (4.31×10^{-4} and 4.85×10^{-4} cm^2/Vs for 25 mmol/L NH_4Fo and NH_4Ac, respectively) was observed, indicating some surfactant adsorption but no bilayer formation. Complete removal of the surfactant (indicated by a return of the EOF to ~8.0×10^{-4} cm^2/Vs was achieved by flushing the capillary with 1.0 mmol/L NaOH followed by FA. Thus, $2C_{18}$DAB was ineffective as a semipermanent coating in FA in the presence of acetate or formate buffers.

However, when 1.0 mmol/L $2C_{18}$DAB was added to acetate or formate separation buffers as a dynamic additive, a strongly reversed EOF was obtained (Table 2). Also, over the surfactant concentration range studied, the magnitude of the EOF was independent of the surfactant concentration kept in the separation buffer. The magnitude of the reversed

Fig. 3. Effect of capillary i.d. on the stability of a double-chain surfactant coating in nonaqueous solvent: 25 µm i.d. (■); 50 µm i.d. (△). Experimental conditions are: 25 mmol/L sodium phosphate buffer (pH 7.0) and 1.0 mmol/L C_{18}DAB surfactant both prepared in formamide. All other conditions are as described in Fig. 1. Error bars indicate the standard deviation of at least three

EOF decreases as the buffer concentrations are increased, consistent with the expected inverse dependence on the ionic strength (21).

Separations of basic drugs in nonaqueous buffers

The utility of the coating in the presence of nonaqueous solvent was investigated by analyzing cationic drugs. Figure 4 shows the separation of four basic drugs (propranolol, metoprolol, chloroquine, and chloropheniramine) in sodium phosphate buffer prepared in pure formamide. There was no difference in the coating stability at pH 3.0 and pH 7.0, so a lower pH was used for the separation in Fig. 4 to ensure that all the drugs were positively charged. With the bare capillary (Fig. 4*a*), both separation efficiency (N < 150 000 plates/m) and migration time reproducibility (%RSD = 3.2–4.4) are poor. The peaks also are severely tailed (the asymmetry factor B/A ranges from 0.86 to 1.4) because of strong interactions between the positively charged analytes and the negatively charged wall.

Figure 4*b* shows the analogous separation in FA using a $2C_{18}$DAB-coated capillary. The separation was obtained with no surfactant in the separation buffer as the $2C_{18}$DAB

Note: Experimental conditions: applied voltage –15 kV; capillary 37 cm × 50 μm (28.5 cm to the detector); 1.0 mmol/L $2C_{18}$DAB was maintained in the pH 4.0 separation buffer; neutral marker 1.0 mmol/L mesityl oxide dissolved in formamide; 25.0 °C.

Fig. 4. Electropherogram of basic drugs in FA using (*a*) bare silica capillary and (*b*) $2C_{18}$DAB-coated capillary. Experimental conditions are: buffer 25 mmol/L sodium phosphate at pH 3.0 prepared in FA, detection at 210 nm; in (*a*) bare silica capillary 40.5 cm (32 cm to the detection window); applied voltage +20 kV; sample concentration 0.5 mmol/L; in (*b*) $2C_{18}$DAB coated capillary 33 cm (24.5 cm to the detection window); applied voltage –25 kV; 1.0 mmol/L $2C_{18}$DAB, sample concentration 0.5 mmol/L (except metoprolol 0.25 mmol/L). Peaks are (1) chloropheniramine, (2) metoprolol, (3) propranolol, and (4) chloroquine.

coating has good stability in phosphate buffers. The migration order is reversed relative to Fig. *4a* because the $2C_{18}$DAB-coating generates a strong reversed EOF. Peak efficiencies range from 0.2–0.5 million plates/m (66 000 to 165 000 plates) with no tailing (B/A = 0.98–1.1), indicating that analyte adsorption onto the capillary wall has been eliminated. Migration time and peak area reproducibilities on the $2C_{18}$DAB-coated capillary (rinsed with 1.0 mmol/L surfactant for 10 min at 93.8 kPa) in FA without regeneration are <0.8% and <3.5% RSD, respectively, for 5 replicate injections. The coating was regenerated after every five runs, as performance declined gradually with further runs.

One drawback with FA is its high UV absorbance. As a consequence, high analyte concentrations had to be used in Fig. 4. Other detection techniques such as electrochemistry or mass spectroscopy could be employed to improve the detection sensitivity. Nonetheless, the $2C_{18}$DAB bilayer coating is promising for rapid and efficient separation of cationic drugs in pure FA. FA would be suitable for the analysis of substances with low aqueous solubility and for separation that cannot be achieved in aqueous buffers. As shown in this study, however, appropriate choice of the capillary diameter, buffer type and content of FA are essential to achieve the desired result.

Conclusions

The double-chained surfactant dimethyldioctadecylammonium bromide ($2C_{18}$DAB) has been demonstrated to be a noncovalent coating for EOF modification and elimination of analyte adsorptions in pure formamide. The coating is generated simply by rinsing the capillary with a 1.0 mmol/L $2C_{18}$DAB in formamide. High efficiencies and migration time reproducibility of <0.8% RSD are achieved over 5 replicate injections without the regeneration of the coating. This is the first demonstration of the ability to reverse EOF and eliminate analyte adsorption using buffer additives in pure FA.

Experimental section

Apparatus

All capillary electrophoresis experiments were performed on an Agilent HP 3DCE instrument (Agilent Technologies, Palo Alto, California, USA) equipped with an on-column diode array UV absorbance detector. Data acquisition (20 Hz) and control were performed using ChemStation software (Agilent Technologies) on an HP personal computer. Untreated fused silica capillaries (Polymicro Technologies, Phoenix, Arizona, USA) with an inner diameter of 25 or 50 μm, an outer diameter of 365 μm, and a total length of 37 cm (effective length of 28.5 cm to the detector) were used. The polyimide coating at the detection window and at both ends of the capillary was removed by burning to avoid capillary blockage because of swelling of the polyimide

coating in organic solvents (49). In all experiments, the capillary cassette was thermostatted at 25.0 °C with forced-air cooling

Chemicals and reagents

All chemicals were reagent grade or better and were used without further purification. All solutions were prepared with Nanopure 18 MΩ water (Barnstead, Chicago, Illinois, USA). Phosphate buffers were prepared from sodium salts of orthophosphate (BDH, Darmstadt, Germany) and adjusted to the desired pH with reagent grade sodium hydroxide (BDH). Ammonium formate and acetate buffers were prepared from ammonium formate salt (BDH) and ammonium acetate (BDH), respectively. Buffers were prepared by dilution of a 1.0 mol/L stock buffer solution. The pH meter was calibrated with aqueous standards solutions immediately prior to use. For 10%–70% (*v*/*v*) formamide, the required amount of buffer and required volume of formamide (FA; Fisher, Fair Lawn, USA) were added before final dilution with Nanopure water. For 100% FA, the calculated amounts of reagents to make the buffers at specified pH were dissolved in FA and no pH adjustment was made. A 1.0 mmol/L mesityl oxide (Sigma-Aldrich, Milwaukee, Wisconsin, USA), dissolved in the solvent being studied, was used as the neutral EOF marker. The cationic surfactant dimethyldioctadecylammonium bromide ($2C_{18}$DAB) was used as received from Sigma-Aldrich. The $2C_{18}$DAB solutions in water or FA were prepared by a 30 min sonication of the buffer–surfactant mixture at a temperature of 50 °C, which is well above the chain melting temperature (32). Then the solutions were cooled to room temperature (24 °C) with stirring for 15 min. This sonication–stirring cycle was repeated until a clear solution was obtained. Typically, no more than three cycles were needed. The drugs propranolol, metoprolol, chlorpheniramine, and chloroquine were a gift from Pars Minoo pharmaceutical company (Tehran, Iran) and were of >99.98% purity.

EOF measurements

To avoid hysteresis effects, fresh capillaries were used with each new buffer system. New capillaries were rinsed under high pressure (93.8 kPa) with 1 mol/L NaOH for 10 min and then with distilled water for 5 min. For buffers prepared in pure FA, the capillary was rinsed for 5 min with pure FA instead of distilled water. After the preconditioning steps, the capillary was rinsed at high pressure (93.8 kPa) for 10 min with surfactant solution to coat the capillary. Then the excess surfactant was flushed out from the capillary using a 3 min high-pressure (93.8 kPa) rinse with the separation buffer.

To measure the EOF, the neutral marker (1 mmol/L mesityl oxide in water or FA) was injected into the capillary using hydrodynamic injection for 2 s at 5.0 kPa. The electroosmotic flow (μ_{eof}) was calculated from the migration time using,

$$[4] \qquad \mu_{eof} = \frac{L_t L_d}{t_{eof} V}$$

where L_t and L_d are the total length of the capillary (37.0 cm) and the capillary length to the detector (28.5 cm), respectively, t_{eof} is the migration time of the neutral EOF marker (in seconds), and V is the applied voltage (in volts). All the voltages used herein were experimentally verified to be within the linear region of the Ohm's plot. In all experiments, the EO*F* values were the average of three or more measurements. In cases where the observed EOF are slow (less than 2×10^{-4} cm^2/Vs) the pressure-mediated three injections technique developed by Williams and Vigh was employed (50).

Coating stability studies

The coating stabilities were examined using two techniques as described previously (30, 32). In the first method, hydrodynamic rinsing, the stability of the surfactant coatings was indirectly evaluated by monitoring the EOF as a function of high-pressure rinsing time with the separation (electrophoretic) buffer. In this procedure, the coated capillary was flushed with the electrophoretic buffer (in the absence of surfactant) at a constant pressure (93.4 kPa) for an initial period of 3 min. A neutral marker (1 mmol/L mesityl oxide) was injected and the EOF was measured as described earlier. The coating was then regenerated first by rinsing with aq. 1 mol/L NaOH at high pressure (93.8 kPa) for 5 min, followed by distilled H_2O for 5 min at 93.8 kPa and then with 1.0 mmol/L aqueous surfactant solution for 10 min at 93.8 kPa. For buffers prepared in pure FA, the capillary was rinsed for 5 min with pure FA instead of distilled water, and 1.0 mmol/L surfactant dissolved in FA was used for coating. Then, the capillary was subjected to a longer rinsing time with the electrophoretic buffer (e.g., 5 min) and the EOF was again determined as described earlier. This flushing–regeneration procedure was successively repeated for rinsing times up to 30 min at 93.8 kPa. The stability of the coating (i.e., the EOF) was then evaluated by plotting the values of EOF obtained vs. the high-pressure rinsing times.

In the second method, the stability of the coatings was assessed based on separation of basic drugs. These repetitive electrophoretic runs were carried out to test the long-term reproducibility and the capillary coating performance.

Separation of basic drugs

A 5.0 mmol/L stock solution of the drug samples propranolol, metoprolol, chloroquine, and chlorpheniramine, were prepared in Nanopure water or pure FA and stored at 6 °C. The chiral drugs were analyzed as racemic mixtures. The sample solutions were filtered through a 0.2 μm polypropylene membrane filter (Whatman) prior to injection. The final sample solutions were prepared from the stock solutions by diluting to concentrations of 1.0 and 0.25 mmol/L with the separation buffer. For the drug separations, a fresh capillary was flushed first with aq. 1 mol/L NaOH for 15 min at 93.8 kPa, followed by water or FA for 5 min at 93.8 kPa. Then the capillary was coated by rinsing for 10 min with 1.0 mmol/L $2C_{18}$DAB solution (prepared in water or FA) followed by a 3 min rinse at 93.8 kPa with the electrophoretic buffer to remove the excess surfactant from the capillary. A mixture of the drugs was injected for 2.0 s at 5.0 kPa. Detection for the drugs was performed using the direct UV mode at 210 nm. The peak asymmetry factor (B/A) was determined from the ratio of the width of the right half (B) over left half (A) of the analyte peak at 10% of its maxi-

© 2007 NRC Canada

mum height. B/A value equal to 1 corresponds to a symmetrical peak, greater than 1 is a tailing peak, and less than 1 is a fronting peak. The efficiencies were computed using the peak width at baseline.

The chemistry of the processes involved in the production of lanthanide titanates by the polymerized-complex method

Dimitr S. Todorovsky, Miroslava M. Getsova, Maria M. Milanova, Masato Kakihana, Nikolina L. Petrova, Michail G. Arnaudov, and Venelin G. Enchev

Abstract: The composition, some spectral characteristics, and thermal decomposition of solid lanthanide–titanium (lanthanide (Ln) = Y, La, Ce) and lanthanide–titanium citrates (CA) and tartrates (TA) have been studied. The complexes have been prepared in ethylene glycol medium at conditions modeling those of the polymerized-complex method applied for $Ln_2Ti_2O_7$ preparation. Special attention has been paid to the chemical nature of the bimetallic products as well as to the factors influencing the deprotonation of the alcoholic OH groups of the acidic ligands. The results contribute to further elucidation of the complexation and thermal decomposition processes involved in the polymerized-complex method.

Key words: inorganic compounds, sol–gel chemistry, infrared spectroscopy, nuclear magnetic resonance, thermogravimetric analysis (TGA).

Résumé : On a étudié la composition, quelques caractéristiques spectrales et la décomposition thermique de dérivés solides lanthanide–titane (lanthanide (Ln) = Y, La, Ce) et de citrates et tartrates de lanthanide–titane. On a préparé les complexes dans de l'éthylèneglycol, dans des conditions qui imitent celles de la méthode du complexe polymérisé appliquée à la préparation du $Ln_2Ti_2O_7$. On a porté une attention particulière à la nature chimique des produits bimétalliques ainsi qu'aux facteurs qui influencent la déprotonation des groupes OH alcooliques des ligands acidiques. Les résultats contribuent à une meilleure compréhension des processus de complexation et de décomposition thermique impliqués dans la méthode du complexe polymérisé.

Mots-clés : composés inorganiques, chimie gel–sol, spectroscopie infrarouge, résonance magnétique nucléaire, analyse thermogravimétrique (ATG).

Introduction

The polymerized-complex method (PCM) is widely used for the preparation of a number of multicomponent materials, including $Ln_2Ti_2O_7$ (Ln = lanthanide) (1, 2), which are highly effective ferroelectrics (Ln = La, Nd) or ionic conductors (Ln = Y). The PCM is based on the Pechini reaction (3), and its general nature is well-known: the formation of polymeric resin as a result of polyesterification between a metal complex of hydroxopolycarboxylic acid (preferably citric acid, CA) and a polyvalent alcohol (most often ethylene glycol, EG). The main advantage of the method is a homogeneous distribution of the metal ions in the resin formed. The limited ions mobility as well as the close contact between them ensure an insignificant segregation and favor the complete interaction leading to the production (at relatively low temperature) of homogeneous phase, fine dispersive material with a perfect crystal structure. The understanding of the processes involved (especially of the metal-complexes formation) is pointed out (3) as a key function for the successful use of this method.

Data on the processes involved as well as on the chemical nature of the formed intermediates, especially in the preparation of titanates, are given in the literature (1–16). The formation of a mixed-metal complex in the EG solution is supposed to be one of the main factors, which ensures the mixing of the different metal ions at the atomic level. The proofs of its existence are indirect (1–12), obtained by the study of the solutions containing a significant excess of CA and EG. Some other important problems cannot be considered as fully solved, i.e., (*i*) the reasons for the distinguished (1, 2, 10, 12, 16) deprotonation of the CA alcoholic OH group proceeding along with the complexation process at surprisingly low pH, even in some cases in the presence of

protonated COOH groups; (*ii*) the significant decrease (in comparison with the solid-state reactions) of the temperature and the time needed for a perfect final product obtaining is either due to the formation of mixed-metal precursors or due to the proper homogenization of the highly dispersive individual carbonates and (or) oxides formed at the pyrolysis.

It is rather difficult to solve the problems mentioned (and to look deeper inside the mechanism of the processes) via studying the real systems obtained in the course of the PCM. The great excess of CA and EG in the solutions or in the polyesters resins makes systems rather complicated and impedes a detailed investigation. Our approach of isolating the complexes formed and their study offers new possibilities in solving these problems. The need of investigations on the isolated complexes was pointed out by Kakihana et al. (2). Few previous papers reported results obtained following this approach. La–, Y–, Ti(IV)–, La–Ti–, and Y–Ti–citrates (CA) (17–19) and La–, Ti–, and La–Ti–tartrates (TA) (20), formed in the course of PCM, were isolated after relatively short heating at 40–135 °C of the EG–, CA–, or TA–Ln(III) and (or) Ti(IV) systems. Their composition, some spectral characteristics, morphology, and thermochemical behavior (17, 18, 20–22) were studied. The interaction between EG and CA in the temperature interval 40–120 °C was elucidated (23). Some results on Ce(III or IV)– and Ce(III or IV)–Ti(IV) complexes were reported in the literature (24, 25); more details are published elsewhere (26, 27). These results reveal different aspects of the studied processes and systems.

In the present paper, the results are generalized in an attempt to build up a complete picture of the chemistry of the processes involved in PCM. Direct proofs, both for the heterometalic nature of the complexes formed in the course of the PCM and on the chemistry of the processes involved in their thermal decomposition, are obtained. The results could be of assistance for (*i*) the processes of mechanism clarification in other similar citric or tartaric systems. The importance of the citrate systems and particularly of Ti–citrates is recently considerably increased, mainly because of the Ti expanded applications in ceramic materials, alloys, and composites in medical technologies (28–30); (*ii*) the understanding of the nature of the complexes formed in non-aqueous systems.

Experimental

Materials

$Ln(NO_3)_3{\cdot}6H_2O$, $(NH_4)_2Ce(NO_3)_6$, anhyd. citric acid, (D,L)-tartaric acid, ethylene glycol, Ti-tetraisopropilate (Merck), and acetone of extra pure grade were used. The exact content of Ln in the respectie nitrates was determined complexometrically.

Synthesis of the complexes

The citric complexes were synthesized under conditions close to the ones used in the PCM application for the preparation of $La_2Ti_2O_7$ (1). To the EG solution of CA, metal source(s) was (were) added with stirring at temperatures below 40 °C. The molar ratio EG:CA:metal(s) was adjusted, modeling the one used at $Ln_2Ti_2O_7$ preparation, by the PCM ($EG:CA:Ti^{4+}:Ln^{3+}$ = 40:10:1:1) (1, 2) and accounting for (*i*) the number of COOH in the acid (CA or TA) molecule; (*ii*) the overall charge of the cation(s) (mono- or bimetallic complex preparation in the system). In all of the synthetic procedures, the molar ratio of COOH:overall electrical charge of the cation(s) was kept constant. Thus, the EG:(CA or TA):Ti^{4+}:Ln^{3+} molar ratios at citrates preparation were set up as follows: Ln(III)–Ti(IV), 40:10:1:1; Ln(III), 40:10:2.3; Ti(IV), 40:10:1.7. However, at the preparation of the Ce(IV) and Ce(IV)–Ti(IV) complexes, the relative content of Ce^{4+} was kept the same as of Ln^{3+} to evaluate the effect of the lanthanide oxidation state on the complex composition. At tartrates preparation, the molar ratios were 40:15:1:1.1 for Ln(III)–Ti(IV), 40:15:1.1 for Ln(III), and 40:15:1.7 for Ti(IV).

Preparing the solutions, precautions were taken to prevent the Ti^{4+} hydrolysis. The typical synthetic procedure was performed as follows (for the preparation of La(III)–Ti(IV)–citrate complex): To 124.14 g (2 mol) EG, 96.06 g (0.5 mol) anhyd. CA was added. After complete dissolution, 14.21 g (0.05 mol) Ti-tetraisopropilate and 21.64 g (0.05 mol) $La(NO_3)_3{\cdot}6H_2O$ were added with stirring until clear solution was obtained. The system was agitated in thermostatically heated vessel for 30 min at 120 °C. Such heating conditions ensure the complex(es) formation, but are insufficient for polyesterification processing taking place at the PCM at much longer times. To study the complexes formation, in some experiments the heating conditions (time and temperature) were varied, later mentioned in the proper places in the text. After cooling down to room temperature, acetone as desalting agent was added in a volume of 10 times as much as the solution itself. After the separation of the precipitates obtained, they were soaked for 24 h in fresh acetone and then filtered, washed again with acetone, dried at room temperature, and stored in tightly closed vessels. No differences in the complexes compositions were found if ethanol was used as a desalting agent, but the yield was lower.

Similar citrates and tartrates were also synthesized in water medium (17, 22), mainly to test some spectral and thermogravimetric-data interpretations.

Analysis

By common organic analysis methods, the C, H, N, and Cl contents in the separated compounds were determined. The contents of Ln and Ti were determined by an ICP-AES in solutions, obtained after melting of ~0.5 g of the sample with ~10 g of $KHSO_4$ and dissolving the melt in H_2SO_4 (5%). The analytical lines, 323.657 nm (Ti), 408.672 nm (La), 360 nm (Y), and 413.38 nm (Ce), were singled out based on earlier results (31).

IR spectra in the range 400–4000 cm^{-1} were recorded by a Bomem–Michelson 100 FTIR or Specord IR75 (Carl–Zeis) spectrometers in KBr pellets. ^{13}C and ^{1}H NMR spectra of the complex D_2O solutions were taken using a Bruker 250 MHz spectrometer. ^{13}C cross polarization (CP) magic angle spinning (MAS) spectra of the solids were recorded on a Bruker MSL-300 instrument at 75.5 MHz; the samples were spun at 8.4 kHz in 4 mm ZrO_2 rotor.

SEM analysis of the samples coated with gold was carried out on a JOEL JSM-5300 instrument, and energy dispersive X-ray microanalysis was performed by a JOEL Superprobe 733 microanalyzer with 25 kV accelerating voltage. X-ray photoelectron spectroscopy studies were performed in an

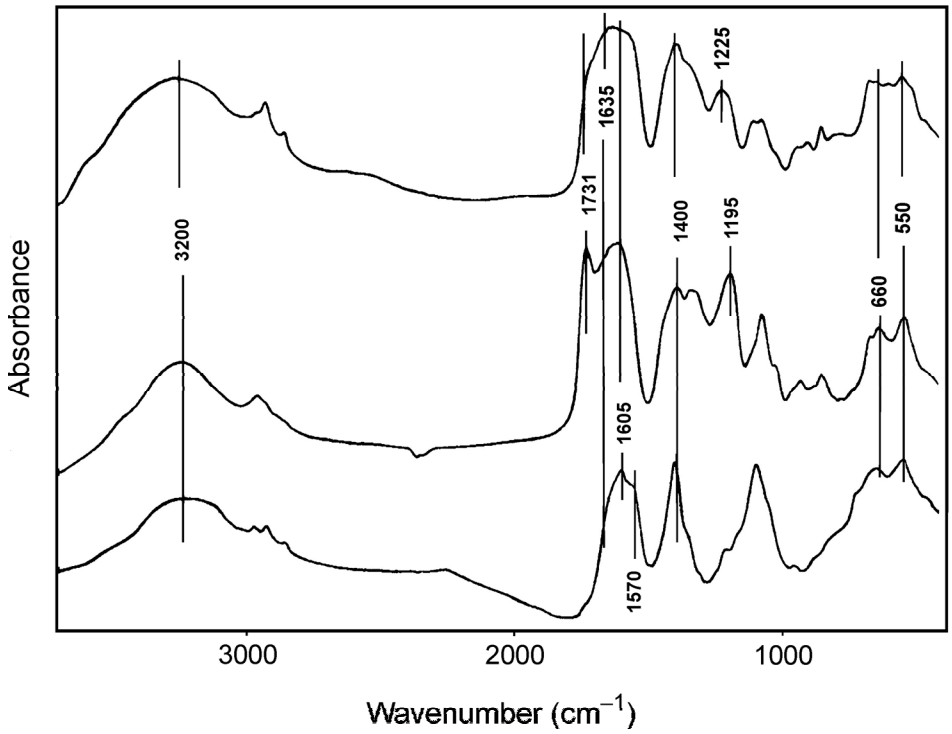
Escalab II electron spectrometer using Mg Kα radiation with energy of 1253.6 eV. All binding energies were referenced to the C1s photoelectron peak of CH_2 species at 285 eV.

DTA, DTG, and TG curves were recorded by a Paulik–Paulic–Erdey (MOM, Hungary) derivatograph in synthetic corundum crucible in static air at heating rate of 5 or 10 K min^{-1}. X-ray powder diffractograms were taken by a TUR-M62 (Germany) diffractometer at Cu Kα, 30 kV, 20 mA, at a scan rate of 0.03°/2 s. In some cases, the exact position of the peaks was determined using Lorenzian curve fit of the experimental data. The relative error in the determination of the interplanar distances was in the limits of 0.1%–0.03%.



Results and discussion

Composition and spectral characteristics of the complexes

The composition of the isolated products varies in narrow limits from one preparation to another, mainly because of the variation of the degree of the ligand esterification. On the basis of elemental-composition data, thermogravimetrically determined water content, and spectral data, complexes may be described by the formulae reported in Table 1. The data for Ti–, Y–, La–, Y–Ti–, La–Ti–citrates and tartrates are taken from the literature (17, 18, 20). The esterification degree, the relative amount of EG bonded as adduct, and the esterification mode of EG (with one or with both OH groups) are derived from the intensity ratios of the proton signals of the CH_2 groups in EG and CH in TA in the ^1H NMR spectra of the samples in D_2O solution. These data are reported only for the complexes that are satisfactory soluble and stable in D_2O. Some of the Ce(IV)-containing complexes suffer hydrolysis, and a precipitate enriched with Ce (in comparison with the initial complex) is formed shortly after dissolution. The yields of the synthetic procedures were estimated (on the basis of the masses of the metals introduced in the starting solution) as a ratio between the real mass of the obtained product and the mass expected according to the proposed formula. The yields vary in rather wide

interval from ~95% to 35%, obviously depending on the solubility of the products in EG–acetone mixture.

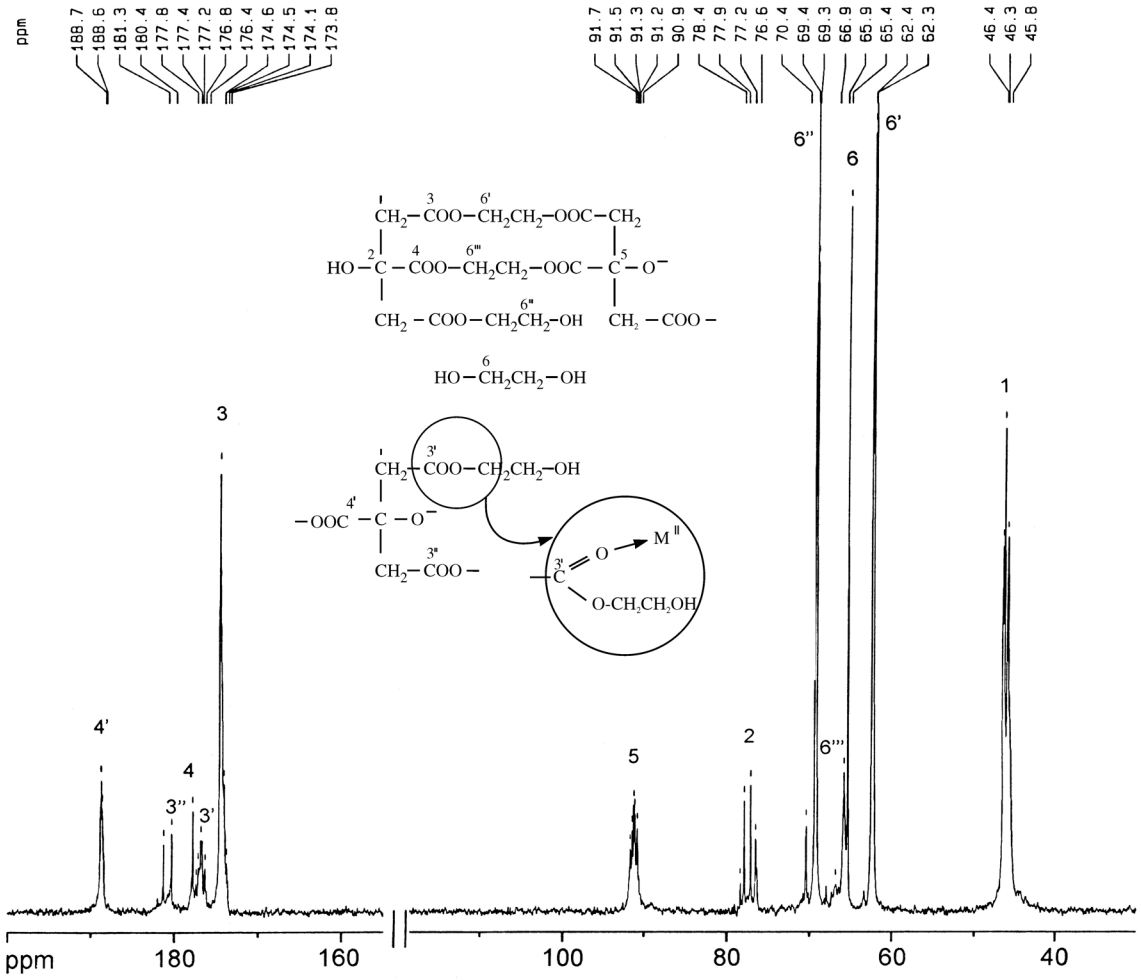
The spectral data confirm the formulae proposed in Table 1:

(*i*) The presence of H_2O in all of the prepared complexes is proved by the broad absorption bands at 3400–3200 cm^{-1} and 1635 cm^{-1} in the IR spectra (Fig. 1), and by the TG analysis. Non-dissociated OH groups of the citric ligands and from EG, bonded as adduct with CA, also contribute to 3400–3200 cm^{-1} band intensity. The presence of H_2O is also confirmed by the ^{1}H NMR spectra taken in C_2HCl_3.

(*ii*) A well-defined shoulder at 1040 cm^{-1}, belonging to ν(C–OH) of EG (23), in the IR spectra of the samples (Fig. 1) as well as the peaks at 65.5 ppm in the ^{13}C (Fig. 2) and at 3.6 ppm in the ^{1}H NMR spectra (Fig. 3) are associated with CH_2 groups of EG bonded as adduct.

(*iii*) The presence of resonance signals at 62 and 70 ppm in the ^{13}C (Fig. 2) and at 3.8 and 4.2 ppm in the ^{1}H (Fig. 3) NMR spectra, assigned to OCH_2 and $HOCH_2$ groups of EG, proves the formation of esters. The interpretation of the ^{1}H spectra was confirmed by a ^{13}C–^{1}H HMQC analysis. The difference in the intensity of the signals in the ^{1}H spectrum shows the presence of double-esterified EG and permits its relative content in the complex to be calculated. In some of the spectra, a signal at 4.35 ppm is also registered. Its association with the ^{13}C shifts of the EG urged us to assign it to the CH_2 from EG bonded as ester with the COOH belonging to the central C atom in CA. The spectrum simulation confirmed such an interpretation (18).

The IR spectral data also contribute to the elucidation of the interaction between the EG and the CA.



Our spectral study shows that the mixing of the compounds even at room temperature affects the bands of δ(O–H) at 1400 cm^{-1}, ν(C–O) at 1200 cm^{-1}, and the ones of C=O stretching vibration in CA. Applying the curve deconvolution and subtraction of the IR spectra by the so-called stepwise reduction procedure (32), it is possible to overcome the strong overlapping of the bands. In this way, it was shown that the band caused by the ν(O–H) in the CA alcoholic OH group is practically not disturbed, suggesting that, most probably, the latter does not take part in the association. In the same time, the 1750–1700 cm^{-1} spectral range clearly shows the differences between the C=O stretching vibration in the free COOH (1710 cm^{-1}), adducts (1725 cm^{-1}), and in the ester groups (1750 cm^{-1}), and permits the two types of bonding to be distinguished.

The ν(C–O) from the ester (1195 cm^{-1}) and from the adduct (1225 cm^{-1}) contribute to the band appearance around 1200 cm^{-1}.

(*iv*) The complexation is proved by bands of $\nu_{as}(COO^-)$ appearing around 1600 cm^{-1} (1605 cm^{-1} in La–Ti–citrate; 1600 cm^{-1} in the Y, Y–Ti, and Ce complexes; 1631–1605 cm^{-1} in Ce–Ti; 1630 and 1545 cm^{-1} in Ti ones) and $\nu_s(COO^-)$ around 1400 cm^{-1} (1400 cm^{-1} for La–Ti; 1437 cm^{-1} for Y and Y–Ti; 1390–1385 cm^{-1} and 1440–1380 cm^{-1} for Ce; 1450–1317 cm^{-1} for Ce–Ti; and 1385 cm^{-1} for Ti one). The shift of $\upsilon\gamma_{as}$ bands to the higher frequencies compared with those of the sodium citrate (1591 cm^{-1}) suggests that COO^- groups coordinate to the metal ions as monodentate ligands. The difference $(\nu_{as} - \nu_s)$ confirms such assumption,

© 2007 NRC Canada

Fig. 2. ^{13}C NMR spectrum of La–Ti–citric complex obtained at 120 °C (LaTiCit120).

which agrees with the observation in the literature (28) for Ti–citrates prepared in aqueous medium. However, the shoulder observed near 1575 cm^{-1} in some Ce–Ti–citrates might be assigned to a terminal carboxylate group from the bridging ligand (27).

Monodentate coordination can be accepted for Ti–Tar and La–Ti–Tar (Tar denotes tetraionized tartrate) ($\nu_{as}(COO^-)$ at 1630 cm^{-1}, $\nu_{as}(COO^-)$ at 1392 cm^{-1}, respectively). Ionic bonds are probable for La–Tar ($\nu_{as}(COO^-)$ = 1595 cm^{-1}). This difference is confirmed by the positions of the peaks for COO^- groups in the solid state ^{13}C NMR spectra near 181 and 183 ppm and is probably due to the fact that in La–Tar, each ligand is coordinated only via one of its COO^- groups, and the other one is protonated or esterified (20).

(*v*) The presence of citric and tartaric ligands with deprotonated alcoholic OH groups is confirmed by the shift at 85–91 ppm (1, 2, 18) in ^{13}C NMR spectra. The comparison of the solid-state ^{13}C NMR spectra with those taken in D_2O solution (20) leads to the conclusion that Ti–tartrate undergoes some reconstruction in D_2O solution with recovery of the initial protonated alcoholic OH group. Similar effect is observed for the citric complexes of the other easily hydrolyzed ion – Ce (IV) (27).

Actually, most of the isolated products are mixtures of complexes that are principally analogous to the ones formed in water medium (33) and differing by the esterification and deprotonation degree of the COOH and OH groups of the ligands. For example, the sample, labeled as LaCit40 (Table 1), most probably represents [3LaHCit + $La_2(HCitH)(HCitROH)_2$]·0.5HOROH·15H_2O, where HCit and Cit denote triionized and tetraionized citrates, respectively, and R–C_2H_4 group in EG. (The composition of some of the citric compounds is represented in Table 2).Variable degrees of protonation among the bound citrates within the same complex and within different species were reported by Kefalas et al. (28) and also by Collins et al. (30). Nevertheless, the presentation mode used in Table 1 (accounting for the overall composition of the formed precipitates) is useful for the analysis of the factors influencing the composition of the products. Some main characteristics of the complexes are listed in Table 3, and these data may be useful for some discussion.

As the elemental, IR, and TG analyses show that the complexes are isolated as hydrates with molar ratio H_2O:Cit ≈ 2 ± 0.5 and H_2O:Tar ≈ 1 ± 0.5. The only significant deviation (Ce3(Cl)Cit80) is probably due to the very low number of citric ligands and the necessity for the coordination satu-

ration of the Ce^{3+} to be reached. As a rule, the water relative content decreases with the increase of the temperature and time of heating (Table 3, column 10).

The presence of the ester-bonded EG in the samples prepared at 40 °C (Table 3, column 6) is a little bit unexpected from the point of view of the common notion for the temperature range (> 80–100 °C) in which the esterification is taking place. This fact is in coincidence with the earlier observation (1, 2) and proves a catalytic effect of the studied metal ions on the esterification. This effect could be observed in the IR spectra by the decrease of the intensity of the band at 1040 cm^{-1} corresponding to ν_{as}(C–O) in the EG (Fig. 4). As can be expected, the relative content of the esters in the isolated complexes quite sharply increases with the temperature of the synthesis (Table 3, column 6–8). The only exception is the Ce-complex, produced from $CeCl_3$.

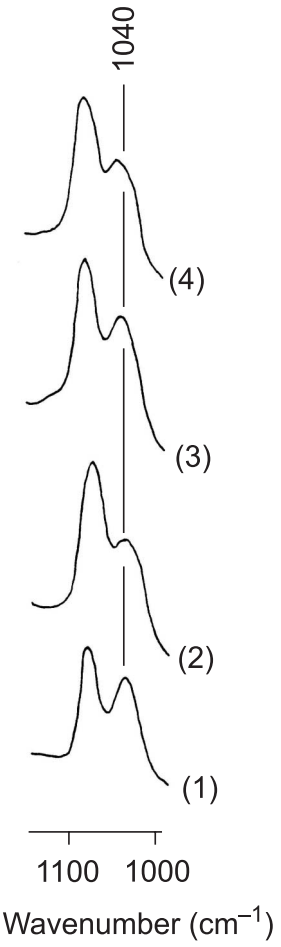
[a]See Table 1.
[b]*L*: number of ligands; L_H: number of ligands with protonated COOH groups; L^-: number of ligands with deprotonated alcoholic OH groups; Z_L: average charge of the ligands; R = CH_2CH_2.
[c]C: calculated according to the formulae proposed in Table 1; F: experimentally found.
[d]$Ce(NO_3)_3$ is used as a starting material.
[e]$CeCl_3$ is used as a starting material.

Obviously, the starting compound has a greatest catalytic effect on the esterification process, a high esterification degree is reached at relatively low heating temperature, and its further increase with the temperature increasing is impossible.

At lower heating temperature (40 °C), the esterification degree increases with the increase of heating time from 15 to 30 min. At higher temperature (120 °C), the degree of esterification is still established in the first 15 minutes of heating.

The ^{1}H NMR spectra analysis (18) suggests that at 120 °C (particularly at longer heating time), the EG can interact with both of its OH groups bridging the citrate ligand (Table 3, column 7). IR spectral data show that the TA interacts with the EG much weaker than the CA (20). Accordingly, the tartaric-complexes esterification degree is significantly lower than that of the citrate ones, but double EG esterification is also possible (Table 3, columns 6–8).



Generally, the studied complexes composition (Table 3) depends on the nature of the metal ion(s) (oxidation state, ionic radii, coordination number, and catalytic activity on the esterification), the nature of the acid (size of the molecule, dissociation and esterification ability, and number of COOH groups), and the synthetic conditions (heating temperature and time). No difference in the complexes composition was found using different desalting agents (17).

The experimental data suggest that four main concurrent processes determinate the composition of the complexes formed at lower temperatures (40 °C): dissociation of the acids, adduct formation, complexation, and esterification; mainly, the latter two are of significant importance at elevated temperatures (100–120 °C) when the deprotonation of all COOH groups has already happened. The steric limitations are of primary importance in determining bimetallic products composition all over the temperature range studied. No more than three citric and (at conditions applied by us) 3.5 tartaric ligands can be coordinated to Ln(III or IV) and Ti(IV) ions. This observation is in line with the ones for solid Ba–Ti–citrate (5, 16) and La–Ti–citrate existing in solution (2), prepared by the Pechini's method as well as for Ti(IV)–citrates, obtained in aqueous medium (28–30).

It is hard to distinguish the effect of every one of the listed processes and factors. The higher average charge of the ligands in LaCit40 in comparison with YCit40 is due to both higher catalytic activity of Y^{3+} (leading to higher lig-

Fig. 4. IR spectra in the range 1100–1000 cm^{-1} of ethylene glycol solutions of (*a*) CA, (*b*) CA–La^{3+}, (*c*) CA–Ti^{4+}, and (*d*) CA–La^{3+}–Ti^{4+}; heated for 30 min at 120 °C.

ands esterification degree; Table 3, column 8) and the stronger basicity of La^{3+} (contributing to the higher deprotonation degree; Table 3, column 5). The smaller ionic radii of Ce^{4+} compared with that of La^{3+} might be a factor, but not the only one determining the smaller ligand number in Ce4TiCit100 complex.

The experiments on the La–Ti–CA–EG system at different heating temperatures and times reveal the growth of the complexes. The progress of the esterification degree with the increase of the temperature and time of synthesis forces all of the COOH groups to take part in the esterification or complexation processes. After consumption of all of the available COOH groups, only oligomerization takes place without further principal reconstruction of the complexes.

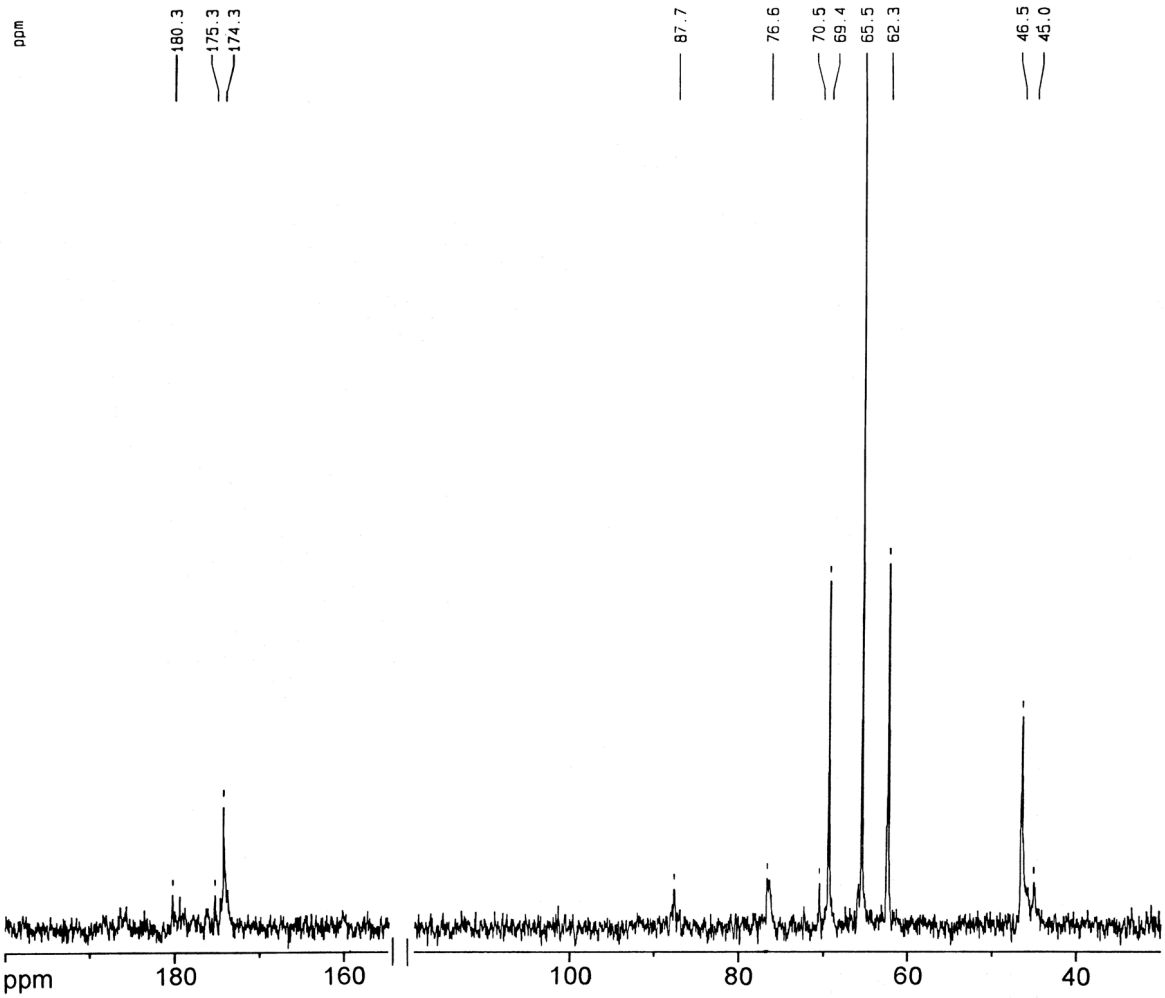
Our results suggest that namely the esterification is the most important factor determining the complexes composition. The data in Tables 1 and 3 contain a number of facts supporting this supposition: the almost equal esterification degree in YCit120 and LaCit120 leads to similar composition of the complexes; the similarity in the esterification caused by Ti^{4+} and La^{3+} at 40 °C leads to similar main characteristics of the respective complexes (accounting for the difference in the ions oxidation state); the weaker esterification of the TA in comparison with the CA causes smaller ligand number in TiTar120 than in TiCit120 (Table 3, column 2) in spite of the smaller size of the TA and the different number of COOH groups.

Chemical nature of the bimetallic complexes

Two main experimental evidences for the suggested mixed-metal nature of the bimetallic complexes are reported in the literature (10): (*i*) The IR spectra of the complexes existing in the bimetallic solutions do not result from simple superposition of the respective individual complexes spectra; (*ii*) the shift at 91 ppm in ^{13}C NMR spectra appears in bimetallic systems only.

It was established (Fig. 5, Table 3), however, that deprotonation of the alcoholic OH group is not a unique feature of the bimetallic systems (the same process takes place in the Ti–citric or tartaric–EG (19, 20) and aq. Ti–citric (28, 30) systems). On the other hand, the formation of mixed-metal Y–Fe(III) complexes is not accompanied with the deprotonation of the alcoholic group (34). This peculiarity is not specific for Ti–citrates. The same effect has been observed in Y–Zr–citrates (35) and is very probable in La–Mn ones (36). Nevertheless, the parallel study of mono- and bimetallic products, taken by us, provided a number of proves for mixed-metal nature of the latter ones:

(*i*) The detailed analysis of the IR spectra for the positions of $\nu_{as}(COO^-)$ and $\nu_{as}(COO^-)$ confirms the mentioned assertion (10) and shows that monodentate bridging exists in the LaCit120 ($\nu_{as}(COO^-)$ = 1600 cm^{-1}, $\nu_{as}(COO^-)$ = 1380 cm^{-1}); the frequency of the asymmetric vibration is in agreement with the expected intermediate ionic-coordination nature of the Ln complexes and of LaTiCit120 ($\nu_{as}(COO^-)$ = 1638 cm^{-1}, $\nu_{as}(COO^-)$ = 1383 cm^{-1}). Bridging type of bonding presents in TiCit120 ($\nu_{as}(COO^-)$ = 1635 and 1549 cm^{-1}, $\nu_{as}(COO^-)$ = 1380 cm^{-1}) as well (22).



(*ii*) The data in Table 3 concerning some of the main characteristics of the complexes exclude the possibility that the bimetallic products could be mixtures of the individual complexes. Indeed, the average charge and the esterification degree of the ligands and the relative content of the ligands with deprotonated alcoholic OH groups in the bimetallic products cannot be derived by averaging the respective values of the individual complexes (compare for example average charge of the ligands for TiCit120, LaCit120, and LaTiCit120 and similar tartaric systems; the esterification degree of the same type of complexes, synthesized at 40 °C; the relative content of the ligand with deprotonated alcoholic OH groups).

(*iii*) The ^{13}C solid-state NMR spectrum of the bimetallic LaTiCit120 (19) and of LaTiTar120 (20) cannot be represented as a simple superposition of the spectra of the monometallic complexes.

(*iv*) Analogous conclusion could be drawn from the analysis of electronic absorption spectra (19). The broad weak band near 33 500 cm^{-1} observed in the spectrum of La–citric complex does not appear in the bimetallic-complex spectrum, while the band at 44 000 cm^{-1} in the spectrum of TiCit120 is keeping its position. The latter fact suggests that, in the bimetallic product,

© 2007 NRC Canada

Fig. 5. ^{13}C NMR spectrum of Ti–citric complex obtained at 120 °C (TiCit120).

Ti(IV) preserves its coordination like in the individual complex.

(*v*) XPS analysis (19) shows that the covalence of the COO–M^{n+} bonds in the LaTiCit120 is higher than in both La- and Ti-monometallic complexes. Some partial charge transfer from ligands to Ti^{4+} ions is registered by the shift of Ti 2p3/2 lines to a lower binding energy for LaTiCit120 relative to TiCit120. Such a shift is not observed in a La 3d doublet position.

(*vi*) Even the morphology of the individual and mixed-metal complexes is rather different: aggregates of spherical particles with a size of 200–500 nm (LaCit120) and 500–800 nm (TiCit120) are typical for monometallic complexes, but blocks of few micrometers are formed in LaTiCit120 with uniform distribution of the both metals (the content of La and Ti is 50.18 and 49.82 mole% (relatively to the sum of the metals) as the energy dispersive X-ray microanalysis shows (19).

Deprotonation of the alcoholic OH group

Recently, formation of Ti(IV)–citrates by the coordination via deprotonated OH^- group was reported by several authors (28–30). All of the isolated compounds had been produced in aqueous medium at pH = 2 ($MMg_{1/2}[Ti(CitH_2)_3]\cdot 6H_2O$, M = K^+ or NH_4^+ (29)), pH = 6 (28) or pH = 7–8 ($(Na_8[Cit)_3]\cdot 17H_2O$ (30)).

However, the capability of the metals to decrease the pKa of bound ligands could not be the only reason for the deprotonation of the citric OH^- group, taking place at conditions applied in the present and earlier (1, 2, 10, 12) studies, when the complexation is taking place along and in competition with the esterification.

The results reported in the present paper lead to some additional elucidation of this process.

As it was already mentioned, our data show that all mixed-metal citrates, studied by us, can be satisfactory described as complexes with three ligands. It may be supposed that the steric factor is in charge of this limitation. The number of the ligands in the individual complexes is L < 3. If bimetallic complexes are formed, the increased total charge of the complexing agents can be "compensated" by (*i*) an increase of the ligand number, keeping the steric limitations; (*ii*) an increase of the COOH deprotonation degree; (*iii*) a decrease of the ligands esterification degree; (*iv*) deprotonation of the alcoholic OH groups.

According to our data, in all of the studied bimetallic citric systems, the ligand number reaches its upper limit. The YTiCit40 formation, for example, becomes possible only with the esterification-degree decrease (in comparison with

© 2007 NRC Canada

the individual systems), i.e., at 40 °C, the complexation is more advantageous than the esterification. At 120 °C, however, the esterification takes place rather intensively, and all of the COOH groups are fully exhausted by either esterification or complexation. In such conditions, the complex formation becomes possible only on behalf of the coordination through C–O$^-$. Higher esterification degree in LaTiCit120 (in comparison with YTiCit120) leads to higher portion of the ligand with deprotonated alcoholic OH groups. The increase in the complexing-agents charge at substitution of Ln(III) with Ce(IV), along with the relatively high esterification degree of the ligands, causes deprotonation of all of the OH groups available.

On the other hand, in spite of the lower number of COOH and higher number of alcoholic H groups in TA (compared with the CA), the deprotonation degree of the OH groups in the formed complex is lower because of higher ligand number (because of the smaller ligand size and smaller steric hindrance) and, mainly, lower esterification degree.

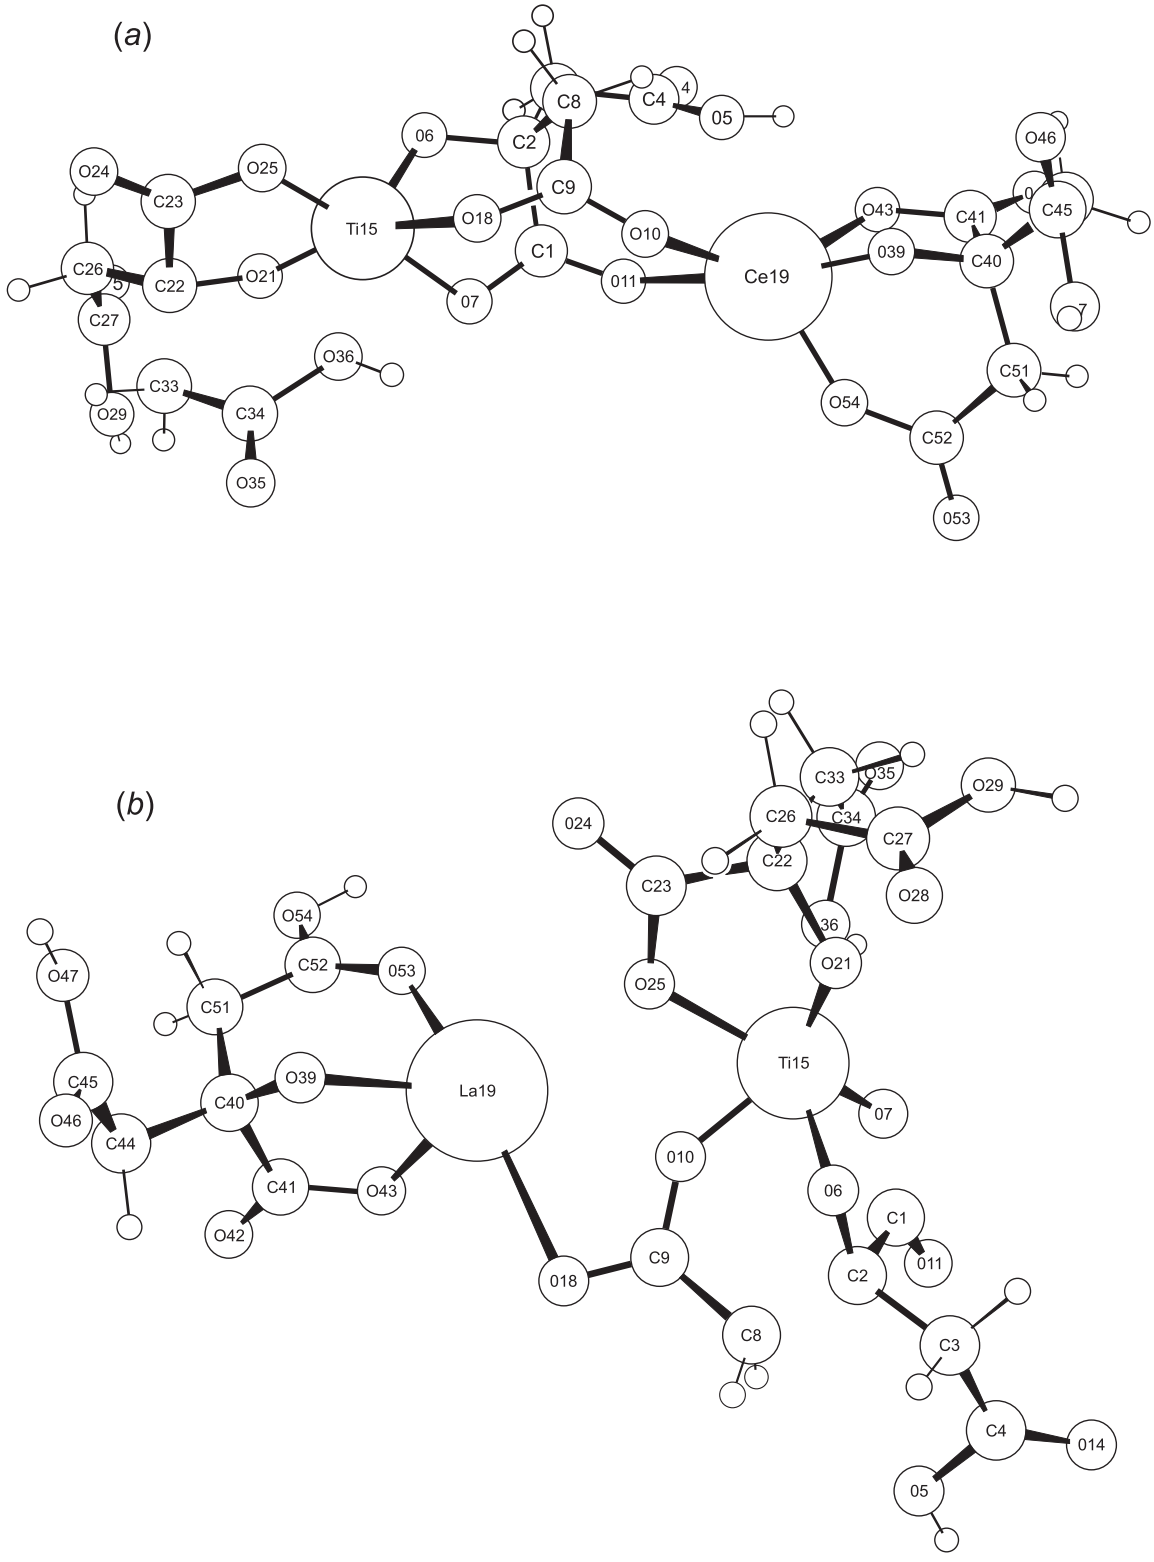
Our attempt for computer simulation of the complex formation, although not fully successful, shows that in some conditions the complexation via OH deprotonation leads to a sharp decrease of the system energy. This was particularly shown in the case of Ti complex, prepared at 40 °C, in which a trace of ligands with deprotonated OH group exist in spite of the relatively low esterification degree and the presence of COOH groups. The results for LaTiCit40 (Table 3) are similar: the ^{13}C NMR spectra (17) definitely show the presence of deprotonated alcoholic groups in spite of the COOH groups present. These results are consistent with the recent ones for Ti–citrates obtained at higher pH values (28–30). It is established that protonated COOH groups take part in strong hydrogen-bonding interactions between themselves or with lattice water molecules. It may be supposed that in EG systems studied in the present work, the adduct-bonded EG will block these groups and, in this way, impede their participation in the complexation process. Probably, the same COOH···EG interaction exists also in YTiCit40, but the lower esterification degree excludes the OH groups participation in the complexation via deprotonation (Table 3).

Based on indirect data and other assumptions, it had been evaluated (2) that Y–Ti–citrate existing in solution contains 2.5 ligands with deprotonated and 0.5 ligand with protonated alcoholic OH$^-$ groups, i.e., L$^-$/L = 0.83. Our results for the solid YTiCit120 (0.60) and for LaTiCit120 (0.80) (Table 3, column 5) are quite close to the evaluation made in (2).

The difference concerning Y–Ti–citrate could be explained with much-longer heating time (several hours) applied in (2) compared with this work (30 min). Lower portion of deprotonated OH$^-$ groups is observed in our experiments at lower heating temperature (LaTiCit40/15 and LaTiCit40, Table 3), but it may be expressed in Y–Ti systems at higher temperature also because of lower catalytic efficiency of these metals to esterification and, respectively, the necessity of longer heating time for the complex to reach its final chemical form.

Structure of the complexes

X-ray amorphous products were obtained at the experimental conditions applied in this study. The only exception was the complex $NH_4Ce4TiCit100$ (27), but even for this compound, the attempt to grow single crystal, suitable for X- ray study, failed. That is why high resolution solid state NMR and IR spectral analysis were used for evaluation of the complexes structure (19, 27).



The main experimental facts lying in the base of the hypothesis were (*i*) according to the thermogravimetric analysis data, one water molecule is coordinated to one of the metal ions in each structural units, (*ii*) as it was mentioned previously, IR spectrum proves the monodentate coordination of COO$^-$ groups in the mixed-metal complex, (*iii*) in the ^{13}C solid state NMR spectrum of the bimetallic complex, signals for ionized and esterified terminal and central COOH groups are observed. Shifting of the hydroxyl–carbon signals in the spectra of the individual and bimetallic citrates (74–76 ppm) in comparison with citric acid (72.3 ppm) suggests the coordination of La(III) with alcoholic group and of Ti(IV) with C–O$^-$ (19). Thus, the interpretation of the spectrum leads to the assumption that five- and six-membered rings are formed in the mixed-metal complex with the participation of terminal or central COO$^-$ and alcoholic or alkoxy groups.

The structure optimization of the LaTiCit120 and $NH_4Ce_4TiCit100$ complexes, shown in Fig. 6, was performed at ab initio level. Geometric structures were optimized at Hartree–Fock level without any symmetry constrains. The calculations were carried out with the Stewens–Basch–Krauss–Jasien effective core potentials and their concomitant basis set (CEP-31G) for all the atoms using GAUSSIAN 03 quantum-chemistry program package. On the basis of the experimental data, the scheme of bonding in La–Ti and Ce(IV)–Ti bimetallic complexes can be proposed (Fig. 6) (19, 27) with the following main peculiarities: (*i*) The carboxylic groups of the ligands are monodentate-coordinated to the metal ions. (*ii*) The Ln^{n+} and Ti^{4+} ions are joined together by bridging carboxyl groups of the citric ligands. (*iii*) The central COO$^-$ and alkoxide groups are coordinated to the metal ions, forming five-membered chelate ring. (*iv*) In the case of the La–Ti–citrate, in contrast to the Ce–Ti one, where alcoholic OH groups also exist, the latter are coordinated only to La^{3+} ions. (*v*) Terminal COOH groups (esterificated or deprotonated) together with alkoxide alcoholic OH group form six-membered chelate ring. (*vi*) As it was mentioned, the TG results prove the presence of a molecule of water, coordinated to the metal ions. In spite of that, the metal ions coordination saturation is reached, probably by intermolecular interaction with the participation of the esterificated terminal COOH groups.

Similar six-membered rings are accepted in the amorphous structure isolated from alkaline water solution $BaTi(C_6H_6O_7)_3{\cdot}4H_2O$ (where with $C_6H_6O_7$ is labeled doubly ionized citric ligand with deprotonated alcoholic OH group and one terminal COOH group) (16). In contrast to our results and the X-ray data for other Fe– and Ni–citrates (37, 38), the authors (16) assert that the central COOH group does not participate in the coordination. The assertion is based on the analysis of the Raman spectrum of the Ba–Ti complex and the existence of a resonance in the solid-state ^{13}C NMR spectrum near 188 ppm, assigned to the non-coordinated central COOH group. Protonated COOH groups do not exist in the discussed La–Ti and Ce–Ti

Fig. 6. Ab initio calculated structures of (*a*) Ce–Ti–citric and (*b*) La–Ti–citric complexes.

mixed-metal complexes, and this may be the reason for the difference in the structures. However, the detailed structural studies based on ^{13}C NMR (29) and X-ray diffractometry (28) undoubtly proved the possibility for the citrate groups to chelate to the Ti^{4+} through their negatively charged α-carbonyl oxygen atoms.

Thermal decomposition of the complexes

A number of papers dealing mainly with the synthetic aspects of the PCM report also some data on the thermochemical behavior of the polyester-resins precursors of the prepared compounds, including $Ln_2Ti_2O_7$ (1, 2). Hennings and Mayr (5) studied the thermal decomposition

© 2007 NRC Canada

of Ba–Ti–citrate in details; some thermochemical data are given about Li–Co–, NH_4–Li–Co– (39), and Li–Ni– (40) citrates; all of these complexes are prepared in water solution. The study of Ln–, Ti–, and bimetallic Ln–Ti–citrates and –tartrates prepared in EG medium (17, 21, 22, 27) permits the scheme of the thermochemical processes to be proposed. Some water-prepared compounds were also investigated aiming to compare the behavior of the two types of complexes.

The decomposition of EG-containing citrates proceeds in few stages:

(*i*) Dehydration (from 50 °C to 170–190 °C), taking place usually in two steps (as in Ba–Ti–citrate (5)). Usually only ~1 mol H_2O/mol (approximately ¼ from water found in the complexes) is stronger bounded, probably coordinated.

(*ii*) Intramolecular dehydration (from 170–190 °C to 200–215 °C) leads to a formation of a C=C double bond, i.e., to partial transformation of the citrates to aconitates/ $CH_2(COOH)C(COOH)=CH(COOH)$ aconitic acid and of tartrates to derivatives of the hydroxomaleinic acid. The process is common for all of the citric complexes (5, 6, 16, 37).

(*iii*) Separation of the EG bonded as adduct and as ester (from 200–215 °C to approximately 300 °C) proceeds stepwisely. The separation of the main part of the adduct-bonded EG takes place up to 235 °C; the decomposition of the esters of the type $–COO(CH_2)_2OH$ up to 250–280 °C. As a rule, the destruction of bridge-type esters $^{-}COO(CH_2)_2OOC^{-}$ proceeds simultaneously with the decarboxylation of the COOH groups (existing or formed as a result of deesterification). The higher temperature of a decomposition of the later type of esters explains the higher thermal stability of the polyester resins (6) (comparing with the complexes) in which they are dominant.

(*iv*) The decarboxylation of the citrates is completed at 320–355 °C and leads to transformation of the aconitates to itaconates ($CH_2(COOH)C(COOH)=CH_2$, itaconic acid), observed in other complexes (5, 6, 16). However, we did not find evidences for the formation of the itaconic anhydride reported in the literature (5). The decarboxylation of the TA COOH groups proceeds simultaneously with the deesterification and is completed at ~315 °C.

(*v*) It is hard to determine the nature of the few steps in which the complete destruction of the organic skeleton (from 320–380 °C to 420–520 °C) proceeds. Clearly, one of the reaction products is residual carbon. The nature of the formed metal-containing compound(s) is one of the main problems discussed in the literature (4–8, 12) for the Ba(Sr)–Ti–citrates. The assumption of Hennings and Mayr (5) for the destruction of the complex to $BaCO_3$ and TiO_2, taking part further in a solid-state reaction (enhanced by their high dispersity and intimate mixing), is not confirmed in the following works. The formation of $Ba_2Ti_2O_5CO_3$ is accepted (7) and thermodynamical consideration, IR spectra, and X-ray data (7) support this proposition. TiO_2 was not found in the residue obtained in the systems studied by us (22). The IR spectra confirm the presence of CO_3^{2-} or, more likely, oxycarbonate ions. In the same time at 485 °C, $LaTi[CH_2(O)CH(O)CH_3]_{1.5}[CH_2(O)C(O)=CH_2]_{0.5}[CH_2(O)C(O)OCH_3]$ is formed as intermediate. In the 485–535 °C temperature interval, the latter is destroyed to oxycarbonate. Judging from the experimentally found mass loss in this stage (22), it has to be accepted that X-ray amorphous $La_2Ti_2O_5(CO_3)_2$ is formed in the bimetallic system (but not $La_2Ti_2O_6CO_3$ as could be expected, comparing with the cited results for Ba–Ti system. Such intermediates formed are responsible for the higher temperatures of obtaining final products in lanthanide or Ln–Ti–systems, comparing with the pure Ti–citrate. In the IR spectrum of the intermediate, obtained after heating of the tartrates up to 480 °C, a band at 656 cm^{-1} is observed (20). This absorption maximum is rather close to the characteristic one (640 cm^{-1}) for the TiO_2 (anatase). This fact suggests that the mixed-metal compound is decomposed, and monometallic compounds (most probably $La_2(CO_3)_3$ and TiO_2) are formed.

(*vi*) The burning of the residual carbon starts at 420–520 °C and is completed at about 750 °C. The mass loss found for this stage (20) suggests that in the same temperature region, carbonate, obtained from the tartrate, transforms into $La_2O_2CO_3$. The possibility for such a transformation is proved in the literature (41).

(*vii*) The decomposition of the citrate-originated mixed-metal oxycarbonates proceeds at 750–850 °C. The stage can be better distinguished in samples with lower carbon content (water-prepared or with a lower degree of esterification) (22). As a difference, an exothermic (clearly observed on TG and DTG curves) process takes place around 750 °C in the residue obtained after tartaric-complex heating and leads to $La_2Ti_2O_7$ formation, quite likely as a result of solid-state reaction between TiO_2 and $Ln_2(CO_3)_3$ (20).

(*viii*) The heating changes the bonding nature (20). According to the IR data above 200 °C along with the dominating monodentate coordinated COO^{-} groups, bridging type of coordination exists. In the intermediate, obtained at 350 °C, the carboxylate groups are ionic-bonded with metal ions.

(*ix*) The final products of the individual citrates and tartrates heating are oxides; the bimetallic complexes heating (excluding Ce–Ti–citrates) leads to phase-homogeneous $Ln_2Ti_2O_7$ (17, 23). A good crystal structure from mixed-metal citric complexes is reached at times (4 h for Ln=La, 5 h for Ln=Y) and temperatures (750 °C and 850 °C, respectively) close to the ones of PCM (1, 2) and rather lower in comparison with the solid-state reactions (1100 °C (1)). Longer heating time (up to 8 h) is needed to obtain $La_2Ti_2O_7$ with perfect crystal structure if tartaric complexes are used as a starting material (20).

Conclusion

Some important details of the processes happening in Ln–Ti–CA(TA)–EG systems, leading to a more-precise picture of the complexation, esterification, and thermal decomposition of the complexes formed, are reported. The main factors

© 2007 NRC Canada

governing the composition of the Ln–Ti–citrate and tartrate complexes are determined. The data reported prove the mixed-metal nature of the bimetallic citrates and tartrates produced in the studied systems. One of the peculiarities of the complexation process, coordination via deprotonated CA or TA alcoholic OH group, seems to be an energetically advantageous way of complexation at high esterification degree of the ligands. EG, bonded as adduct to COOH groups, may prevent the latter ones to take part in the complexation (at relatively low temperature of synthesis) via deprotonation.

A difference in the final stages of the thermal decomposition of La–Ti–citrates and tartrates is observed. The final product of the burning, $La_2Ti_2O_7$, is a result of La–Ti–oxocarbonate decomposition in the case of the citrates, and of solid-state reaction between La–oxocarbonate and TiO_2 in the case of the tartrate.

The studied complexes can be used as precursors for the production of the respective materials instead of the polyester resin used in the common PCM. Such an approach ensures a decrease of the organic-components relative content in the precursor, keeping the principal advantages of the PCM: mixing the metals at atomic level. The EG solution of complexes was successfully used for the production of thin films of Y_2O_3, CeO_2, and La_2TiO_7.

Acknowledgments

Solid-state NMR analysis was done by Professor I. Wawer (The Medical University of Warsaw).

Substituent effects in the intramolecular photoredox reactions of benzophenones in aqueous solution

Nikola Basarić, Devin Mitchell, and Peter Wan

Abstract: A number of α-hydroxy-3-benzylbenzophenones **7**–**11** have been synthesized for the purpose of studying the effect of a phenyl substituent on the intramolecular photoredox reaction of 3-(hydroxymethyl)benzophenone (**5**) discovered in our laboratory. This latter compound was found to undergo a unimolecular (formal) intramolecular redox reaction upon photolysis in aqueous acid that results in clean reduction of the benzophenone ketone (to secondary alcohol) and oxidation of the alcohol to aldehyde. Three of the phenyl-substituted compounds with simple phenyl (**7**), *p*-methylphenyl (**8**), and *p*-methoxyphenyl (**9**) were found to undergo the acid-catalyzed intramolecular photoredox reaction with the observation that **9** also undergoes a residual photoredox reaction that is not acid-mediated and may involve initial photoinduced electron transfer, which is supported by LFP data. The *m*-methoxyphenyl (**10**) compound did not undergo the reaction. The trend in observed relative reactivity may be partially rationalized by examining changes in molecular orbital coefficients observed in the calculated HOMOs and LUMOs. The photoredox reaction has also been applied twice in succession in a single compound **11**, demonstrating that the photoredox reaction may be useful for sequential photoredox reactions in a multifunctional compound.

Key words: intramolecular photoredox, acid catalysis, meta effect, benzophenone photochemistry.

Résumé : On a synthétisé un certain nombre de α-hydroxy-3-benzylbenzophénones (**7**–**11**) pour pouvoir étudier l'effet d'un substituant phényle sur la réaction de photoredox intramoléculaire de la 3-(hydroxyméthyl)benzophénone (**5**) qui a été découverte dans notre laboratoire. On a trouvé que lorsque ce dernier composé en solution acide aqueuse est soumis à une photolyse, il subit une réaction redox intramoléculaire qui conduit à une réduction propre du groupement carbonyle de la benzophénone en alcool secondaire avec oxydation concomitante de l'alcool en aldéhyde. On a observé que, en solution aqueuse acidulée, trois des composés substitués par un groupe phényle, soit le dérivé phényle non substitué (**7**), le *p*-méthylphényle (**8**) et le *p*-méthoxyphényle (**9**), subissent la réaction photoredox intramoléculaire qui est accompagnée dans le cas du produit **9** d'une réaction photoredox résiduelle qui n'est pas catalysée par les acides et qui peut impliquer un transfert initial d'électron qui est photoinduit et cette hypothèse est supporter par des données de « LPF ». Le composé méthoxyphényle (**10**) ne subit pas la réaction. La tendance dans les réactivités relatives observées peut être partiellement expliquée par un examen des changements dans les coefficients d'orbitales moléculaires qui sont observés dans les valeurs calculées des orbitales moléculaires HO et BV. On a aussi appliqué la réaction photoredox deux fois en succession à un composé unique, **11**; ce résultat démontre que la réaction photoredox pourrait être utile pour des réactions photoredox séquentielles dans un composé multifonctionnel.

Mots-clés : photoredox intramoléculaire, catalyse acide, effet méta, photochimie des benzophénones.

Introduction

The photochemistry and photophysics of benzophenone (**1**) and its derivatives have been studied for over a century (1, 2). Indeed, benzophenone photoreduction was one of the first photoreactions described in the literature (3). Despite the many studies on this reaction, it was not until about 60 years later that the mechanism was shown to proceed via the triplet excited state (4, 5). Although many studies have examined benzophenone (**1**) photoreduction in various organic solvents, fewer studies have examined its photochemical and photophysical behavior in aqueous solution. It is known that the benzophenone triplet excited state is quenched by acid. This was first reported by Ledger and Porter (6) who noted that the phosphorescence of benzophenone (**1**) was quenched by added protons, although the detailed mechanism was not understood at that time. Initially, it was thought that the quenching was due to the formation of the protonated triplet **2** (protonation at the carbonyl) and Wyatt and co-workers (7, 8) assigned a pK_a of 1.5 ± 0.1 for the protonated triplet excited state using Förster cycle analysis. That is, the benzophenone triplet is more basic by sev-

eral orders of magnitude (at the carbonyl oxygen) compared with the ground state ($pK_a(S_o) = -5.7$ (7)). In a recent study, Wirz and co-workers (9) established that protonation (at the carbonyl) of triplet benzophenone results in an overall *photohydration* reaction, to give water-adducts **3** and **4** with a preference for **3**, i.e., hydration at the meta position (eq. [1]). This reaction was unexpected and has probably missed detection in the past because of the instability of the hydration products, which readily revert back to **1**. In addition, Wirz and co-workers (9) assigned a pK_a of –0.4 for the protonated triplet excited state; thus, the triplet is somewhat less basic than originally estimated by Wyatt and co-workers (7, 8).

[1] 

The mechanism (9) of photohydration presumably involves initial protonation of the carbonyl oxygen of triplet excited benzophenone, to generate an excited triplet state conjugate acid that has its positive charge significantly delocalized to the ortho and meta positions of the benzene ring (e.g., as shown in eq. [2]), as would be anticipated based on the Zimmerman "ortho-meta" effect for benzene ring site activation in photochemical reactions (10, 11). Attack by water at these sites of positive charge would lead to the observed hydration products, which upon deactivation to their ground states would not be expected to be long-lived and would readily return to benzophenone (**1**) by dehydration (and re-aromatization).

[2] 

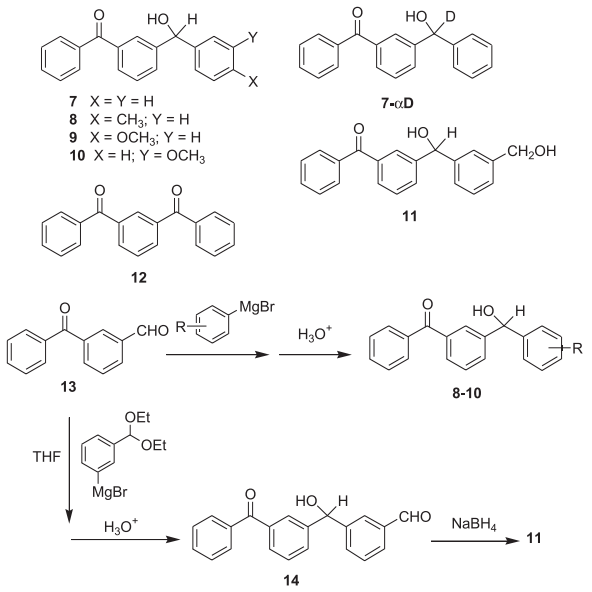
Although the described acid-catalyzed photohydration of benzophenone itself reported by Wirz and co-workers (9) gave no isolable *stable* product, it seemed reasonable to assume that the protonation of triplet excited benzophenone (**1**) might lead to other acid-catalyzed chemistry still to be discovered considering the known range and diversity of chemistry for ground state carbonyl compounds that are acid-catalyzed. Indeed, Wirz and co-workers (9) reported the acid-catalyzed photohydrolysis of *m*-fluoroacetophenones and benzophenones to give the corresponding phenols as proceeding via a protonated triplet. We recently reported two photochemical reactions of benzophenones that require acid-catalysis and appear to require prior protonation (at carbonyl) of triplet benzophenone: (*i*) photochemical deuterium exchange of the meta-substituted methyl group of 3-methylbenzophenone and 3-methylacetophenone (12) in deuterated aqueous acid and (*ii*) formal intramolecular redox reaction of some 3-(hydroxymethyl)benzophenones (13) (e.g., eq. [3] with the parent 3-(hydroxymethyl)benzophenone (**5**)). Notably, all the para isomers studied in these reactions were unreactive; the ortho isomers were not studied because of complications that would arise from the known competing intramolecular hydrogen abstraction pathway.

[3] 

In our view, the intramolecular photoredox chemistry of benzophenones deserves further study. Under appropriate dilution and at pH < 3, the reaction was found to be clean with very high quantum yield (eq. [3], $\Phi = 0.6$ at pH 2) (13). The reaction is mediated by water and acid and is unimolecular in substrate: the reaction becomes cleaner on dilution. At high substrate concentrations ($>10^{-5}$ mol/L), bimolecular (via bimolecular hydrogen abstraction, carbonyl abstracting the benzylic hydrogens of the benzyl alcohol) reactions compete giving rise to oligomeric and polymeric products. Photoproduct **6** does not itself undergo a photoredox reaction to give **5**, indicating that not all aromatic carbonyl chromophores can mediate the chemistry and that the question of photoredox reversibility would be an interesting issue to address in other compounds. Moreover, the reaction itself may be viewed as a formal transfer of electrons through the meta positions of the benzene ring, which cannot be accomplished in the ground state. In this paper we report the details of a study that addresses two aspects: (*i*) the structural and electronic effects on the photoredox reaction as ascertained by placing a phenyl and substituted phenyl groups at the benzyl alcohol carbon of **5** (i.e., α-hydroxy-3-benzylbenzophenones **7**–**10**) and (*ii*) the possibility that the photoredox reaction can be induced twice (one after another) in the same substrate on extended photolysis, by studying model compound **11**.

Results and discussion

Materials



Whereas α-hydroxybenzylbenzophenones **7** and **7-αD** were readily synthesized by $NaBH_4$ ($NaBD_4$) reduction of commercially available 3-benzoylbenzophenone (**12**), **8**–**11** were synthesized according to the reactions outlined in Scheme 1, all starting from 3-formylbenzophenone (**13**). Compounds **8**–**10** were made by the reaction of **13** with the appropriate Grignard reagent with isolated yields in the 14%–80% range. The synthesis of **11** required the intermediate aldehyde **14**, which was readily made by the reaction of **13** with the Grignard reagent derived from commercially available 3-bromobenzaldehyde diethyl acetal (Sigma-Aldrich). This step proceeded in about 20% isolated yield. The subsequent $NaBH_4$ reduction gave the desired benzophenone diol **11** in 50%.

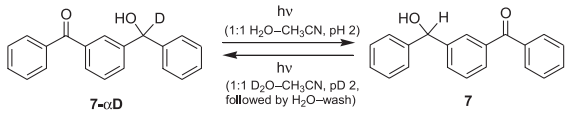
UV–vis and product studies

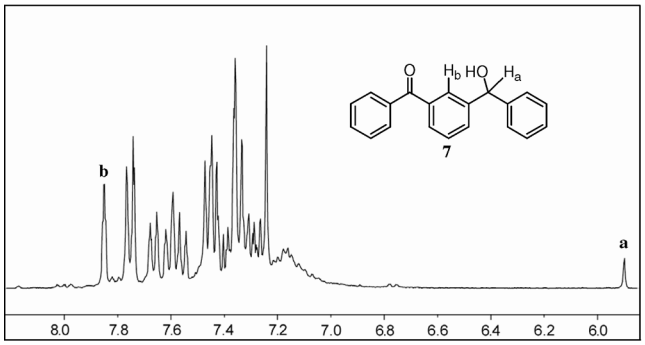
In view of the previous finding for the photoredox chemistry of **5** (13) in which higher substrate concentrations increased the proportion of side products because of a bimolecular hydrogen abstraction pathway, photolysis runs were carried out at the most dilute substrate concentrations deemed practical for NMR analysis. Most runs were carried out at 10^{-4} mol/L (10 mg in 400 mL, 1:1 H_2O–CH_3CN, pH 7 and 2, Rayonet RPR 100 reactor, 300 nm lamps, argon

© 2007 NRC Canada

Scheme 1.

purged), and some selected runs were carried out 10^{-5} mol/L (2 mg in 600 mL). Product studies were initially carried out with compounds **7** and **7-αD**. The anticipated photoredox chemistry for these compounds (in aqueous acid solution) would give no observable changes in their UV–vis as the reaction would only interchange the benzophenone ketone and benzhydrol alcohol moieties (with no overall change in molecular structure). To follow the reaction, photolyses of **7** (**7-αD**) were carried out in acidic D_2O (H_2O) and after work-up, NMR spectra were recorded. Photolysis (10^{-4} mol/L) of **7-αD** in 1:1 H_2O–CH_3CN (pH 2, argon purged) resulted in formation of the methine peak at δ 5.9 as would be expected on formation of **7** (≅20% yield) (eq. [4]). The reaction shown interconverts the ketone and alcohol carbons. Although this was not proven in the case of **7** (or **7-αD**), the same reaction for the phenyl-substituted compounds **8** and **10** (vide infra) conclusively shows that the reaction does interchange the carbons concerned. Accompanying the reaction was the formation of broad aromatic signals in the δ 7–7.3 region, indicative of oligomeric material resulting from photoreduction of the benzophenone moiety (Fig. 1) and a trace of the simple photooxidation product **12** (this is the major product when photolyzed with an oxygen or air purge). This oligomeric material proved to be intractable and appears to be a mixture of products. Photolysis at 10^{-5} mol/L gave a cleaner product mixture although the broad peaks observed at δ 7–7.3 could not be completely eliminated. In comparison, the photoredox reaction of **5** under these conditions (i.e., at 10^{-5} mol/L or lower) were exceptionally clean (13). As expected, photolysis of **7** in D_2O–CH_3CN (pD 2) (after H_2O wash before NMR analysis) showed the loss of the methine peak at δ 5.9 with essentially no change in the aromatic region except for growth of broad δ 7–7.3 region due to the formation of oligomers. Thus, **7**





[4] 

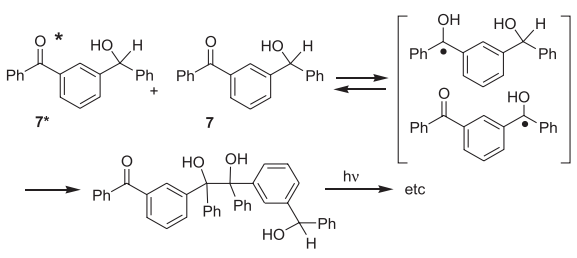


Fig. 1. Product mixture observed after photolysis of **7-αD** (10^{-4} mol/L) in 1:1 H_2O–CH_3CN (pH 2) for 2 min at 300 nm. Formation of **7** was determined by observation of a methine peak at δ 5.9 (H_a). Relative ratios of **7** and **7-αD** were calculated by using the H_b proton at δ 7.85 common to both compounds.

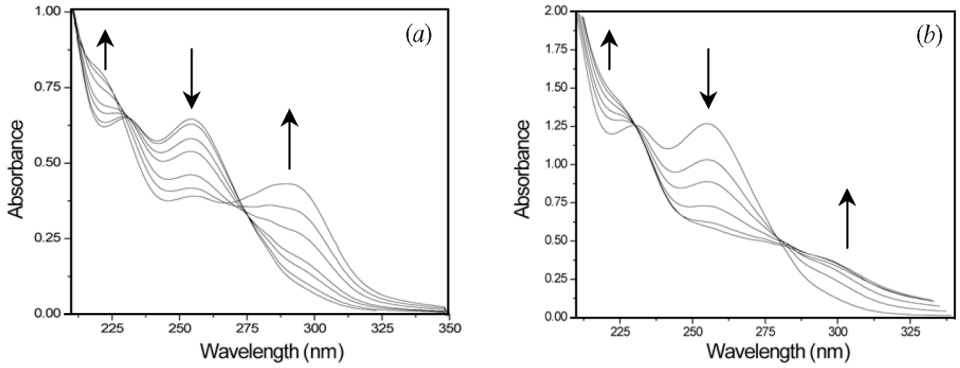
and **7-αD** are photochemically interconvertible (eq. [4]). Noteworthy was the fact that photolysis of **7** or **7-αD** in neat CH_3CN or in 1:1 H_2O–CH_3CN above pH 3 did not result in the photoredox reaction shown in eq. [4]; only the broad signals in δ 7–7.3 were observed.



The photoredox reaction of **5** was found to be exceptionally efficient with Φ = 0.6 at pH 2 (13). Using the reaction of **5** as a secondary reference, we have estimated a quantum yield of reaction for **7-αD** to be about 0.3 at pH 2, which further confirms the general high reactivity of these compounds in acid.

As will be shown, all of the photoredox reactions for the phenyl-substituted systems studied in this work (**7**–**11**), regardless of their relative efficiency with respect to the photoredox reaction itself, are accompanied by the formation of oligomeric material as already discussed for **7** and **7-αD**. This is in contrast to what was observed for **5** in which the reaction was exceptionally clean at 10^{-5} mol/L. We believe that the competing reaction(s) are bimolecular in nature and probably involve the triplet benzophenone-like ketone abstracting hydrogen from the benzylic hydrogens of another substrate. In the case of the phenyl-substituted compounds **7**–**11**, the hydrogen to be abstracted is of the benzhydrol type and hence even *more* prone to this reaction. A possible reaction sequence initiated by intermolecular hydrogen abstraction is shown in eq. [5]. Note that in this mechanism one would anticipate a mixture of products in which the benzophenone moiety would suffer "reduction", consistent with the observed NMR (aromatic signals only in the δ 7–7.3 region). This offers a reasonable explanation for the observed concentration-dependent formation of oligomeric products for all of these compounds.

[5]

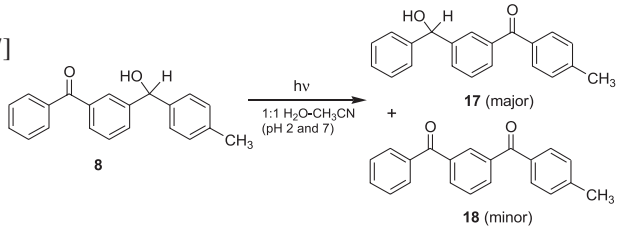
Fig. 2. UV–vis traces observed on the photolysis of **9** in 1:1 H_2O–CH_3CN at (*a*) pH 2 and (*b*) pH 7, purged with N_2, at 300 nm. Traces were taken after initial irradiation of 1 min followed by increasing photolysis times of up to 20 min.

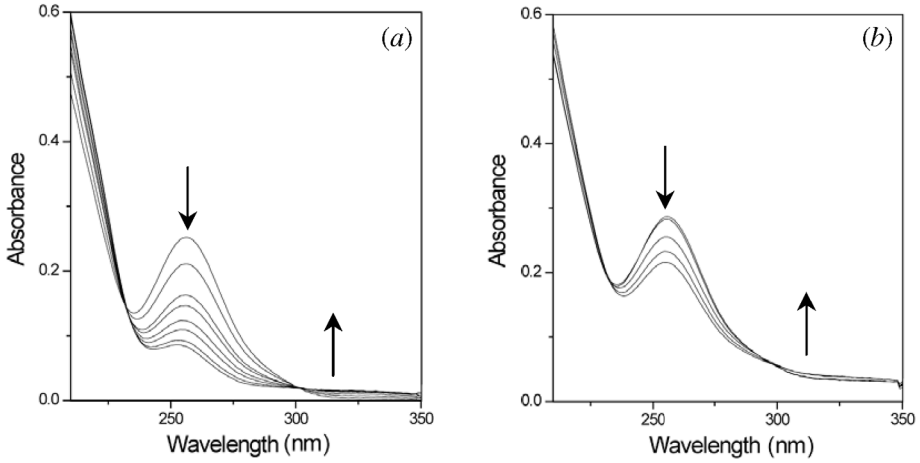


The anticipated photoredox reactions for the methoxy-substituted derivatives **9** and **10** were studied next since reaction would result in significant UV–vis changes. Photolysis of the meta-isomer **10** (pH 2 and 7) resulted in only the loss of substrate and the formation of oligmeric material as noted above for **7**, with no evidence of photoredox reaction. On the other hand, photolysis of the para-isomer **9** resulted in the expected photoredox reaction (eq. [6]) giving **15** (major) and **16** (minor). Notably, at 10^{-5} mol/L substrate, the reaction was much cleaner than **7**, with reaction being observed at pH 7 ($\Phi \cong 0.007$) *and* pH 2 ($\Phi \cong 0.02$), although the quantum yields are both much lower than for **5** and **7**. UV–vis traces carried out for **9** were informative (Fig. 2): photolysis in pH 2 resulted in the formation of a band at 290 nm that is assignable to the expected photoredox product **15**; at pH 7 a much lower yield of this product was observed. Both spectral traces show competing decomposition of the substrate, which is more pronounced at pH 7. Interestingly, **15** was found to be photoinert; that is, the photoredox reaction for **9** (eq. [6]) is not photoreversible. A possible reason for this is provided later.

[6]

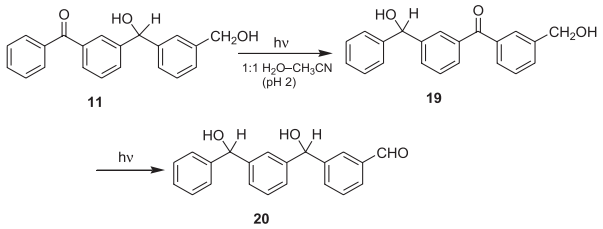
The last compound studied in this series was the *p*-methyl-substituted derivative **8**. The intramolecular photoredox reaction was observed at pH 2 (eq. [7]), but it was observed that this compound gave the highest proportion of oligomeric products compared with the other reactive systems discussed so far. Even at 10^{-5} mol/L, low conversion runs gave 10%–20% of the oligomeric products (estimated by comparing the intensity of the signal corresponding to the entire methyl proton region at δ 2.2–2.6 and the sum of the intensities at δ 2.31 and 2.42 corresponding to **8** and **17**, respectively). This is consistent with the greater availability of abstractable benzylic hydrogens (total of 4) in this molecule and the earlier proposal (eq. [5]) that the main competing reaction is due to bimolecular hydrogen abstraction by the benzophenone ketone of another substrate. To further test this assertion, we have carried out the photolysis of **8** in the presence of added naphthalene (a known efficient triplet quencher of benzophenone (1)) at pH 2. The presence of 10^{-4} mol/L naphthalene resulted in a much less efficient reaction and longer photolysis times (up to ten fold) were required, consistent with triplet state reactivity of the benzophenone chromophore of **8**. However, the photoredox reaction was much cleaner and could be taken to almost completion with formation of up to 20%–30% oliogomeric materials as estimated by NMR. This was a significant improvement over runs without added naphthalene. The results are consistent with a photoredox reaction that is unimolecular in substrate (although requiring water and acid mediation) and a competing reaction that is bimolecular in substrate. The addition of naphthalene reduces the lifetime of the reactive triplet state and hence all photochemical pathways. Noteworthy is the finding that in this case, the proportion of bimolecular pathway is retarded more than the unimolecular photoredox pathway, although we do not completely understand why this is so.

[7]



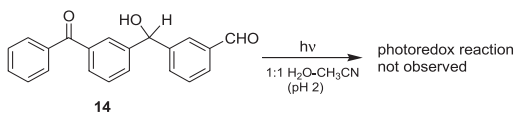
The photoredox product **17** could not be completely separated from substrate **8** using chromatography. The best that could be achieved was a mixture consisting of 92% **17** and 8% **8** from photolysis in the presence of added naphthalene. Subsequent photolysis of this mixture at pH 2 (300 nm) resulted in no observable change in the ratio of these compounds. Although in principle **17** could undergo the photoredox reaction returning to **8**, this result suggests that the return is very inefficient, and that at this photolysis wavelength the photostationary state has already been attained.

Compound **11** was designed with two oxidizable benzylic alcohol moieties. The idea was that this compound might undergo two photoredox reactions in succession, first forming **19** and then **20** as shown in eq. [8]. Initial studies by UV–vis (Fig. 3) spectra show that photolysis of **11** in acid



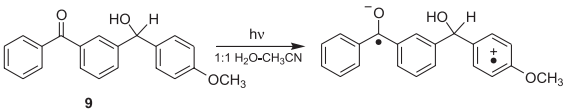
© 2007 NRC Canada

Fig. 3. UV–vis traces of the photolysis of **11** in 1:1 H_2O–CH_3CN at 300 nm at (*a*) pH 2 and (*b*) pH 7, purged with N_2. Traces were taken after 1 min of photolysis in each run, with latter runs requiring 2 min photolysis to produce noticeable spectral change.



(pH 2) resulted in significantly greater loss of the benzophenone chromphore absorption vs. runs in pH 7, consistent with the acid-catalyzed photoredox reaction. Since **11** and **19** have essentially the same benzophenone chromophore, it was not possible to follow their interconversion using UV–vis. The UV–vis traces are consistent with the eventual formation of **20**, which lacks the benzophenone moiety. Photolysis of **11** at pH 7 gave **14** (up to 10% yield) and oligomeric material. Compound **14** was also observed in all runs carried out in acid (pH 2). Its observation at pH 7 suggests that it is formed via some residual oxidation pathway because of traces of oxygen in the irradiated solution. Interestingly, **14** was found to be photoinert with respect to the photoredox reaction (eq. [9]), as was also the case for the m-methoxyphenyl derivative **10** (vide supra). In addition to **14**, photolysis of **11** in acid (pH 2) did give *both* **19** and **20** shown in eq. [8], although the yield of **20** was always higher than **19** even at the lowest conversions that we were able to conveniently carry out. Thus **19** could not be isolated in pure form and its presence was indicated by NMR assignment of product mixtures that were enriched in **19** by chromatography. It is clear that the reaction scheme shown in eq. [8] can be achieved, in that the end product is formed. Our data suggests that **19** is more reactive than **11** and preferentially undergoes a photoredox reaction to give **20**, although additional studies are warranted to show this in a direct way.

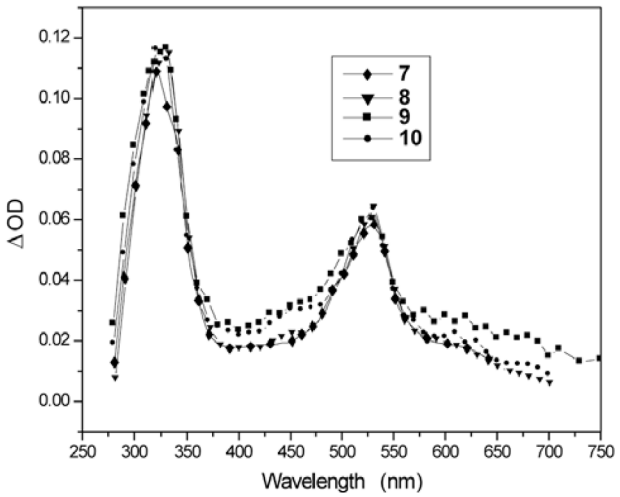
[8]



[9]

Nanosecond laser flash photolysis (LFP) studies

LFP studies were carried out using a Nd-Yag laser at 266 nm (pulse width ≅ 20 ns). Based on our initial LFP studies of the photoredox chemistry of **5** (13), transients assignable to reactive intermediates other than the reactive triplet state were not anticipated. Indeed, LFP of **7** and **8** gave the typical triplet state absorption expected for the benzophenone chromophore with maxima at 325 and 525 nm for **7** and **8** (Fig. 4) (9, 13). However, closer analysis of the spectra observed for both of the methoxyphenyl-substituted compounds **9** and **10** show that in addition to the triplet state signal, bands at ≅450 and >600 nm were also observed superimposed on the triplet signal. Shizuka and co-workers (14) have shown that benzophenone radical anion (450 nm) and methoxybenzene radical cations (630 nm) are produced from electron transfer from methoxybenzenes to triplet excited benzophenone. That the same signals were observed for **9** and **10** under dilute conditions and that the triplet signal itself was the dominant one indicate that intramolecular electron transfer from the methoxybenzene to the triplet excited benzophenone is a competing channel for these two compounds (eq. [10]).



[10]

With respect to the triplet absorption signal itself, the following general findings apply: (*i*) apparent lifetimes were sensitive to oxygen and acid (pH < 3). For **9** the apparent triplet lifetime was 5.2 μs at pH 7 and was reduced to 220 ns at pH 2; for **10** the lifetime was 5.3 μs at pH 7 and 660 ns at pH 2. The addition of oxygen (1 atm; 1 atm = 101.325 kPa) to all samples reduced triplet lifetimes to <100 ns in all cases; (*ii*) most decays could not be fitted to first-order decays and typically required a sum of two first-order decays, especially at pH 7 where there is no quenching of the triplet by acid. This is consistent with competitive pseudo first-order decays (including hydrogen abstraction) pathways. In addition, the benzophenone ketyl absorbs at 545 nm (15) and this overlaps with the 525 nm band of the triplet, mak-

Fig. 4. Triplet absorption spectra of **7**, **8**, **9**, and **10** detected by LFP (Nd-YAG, λ_{ex} = 266 nm) in 1:1 H_2O–CH_3CN (pH 7, N_2 purged) immediately after the laser pulse (≅20 ns).

ing kinetic analysis even more complex. The competition of bimolecular pathways of triplet decay can best be documented for **8** at pH 7 where dilution of the solution induced significantly longer triplet lifetimes: the apparent lifetime at 8.8×10^{-5} mol/L was 2.2 μs whereas at 1.4×10^{-5} mol/L it was 9.1 μs. In view of these complexities, LFP data was used only to infer that the triplet excited state is the reactive state and that it is subject to acid quenching, consistent with photoprotonation at the benzophenone carbonyl (vide supra).

Mechanisms of reaction

As discussed in the Introduction section, the protonation of the oxygen of triplet excited benzophenone in aqueous solution is an important primary photochemical pathway in acid (pH < 3). The more basic carbonyl oxygen in the triplet excited state implies considerable charge transfer from the benzene rings on electronic excitation that is probably enhanced in aqueous solution. Perhaps surprising is the fact that the triplet excited state also retains its ability to abstract hydrogen, as evidenced by the competing hydrogen abstraction pathway observed in this work.

We have carried out simple HOMO and LUMO (Chem 3D, MOPAC/AM1) calculations of the compounds studied in this work to gain possible insights into their relative reactivity. To our pleasant surprise, the experimental observations we have made can be rationalized by the results of these calculations. Shown in Fig. 5 are the calculated HOMOs and LUMOs for the unsubstituted phenyl derivative **7**. The excited state (singlet or triplet) may be viewed in the simplest approximation as attained by promoting an electron from the HOMO to the LUMO. Thus, there would be charge migration from two of the benzene rings (the benzophenone benzene ring with the attached PhCH(OH) group and the benzene ring of the attached Ph(CH)OH itself) to the benzophenone carbonyl and the other benzophenone benzene ring. One would therefore predict the increased basicity of the carbonyl oxygen. Subsequent protonation of the ketone oxygen would give rise to the conjugate acid, which one could argue would retain the electronic distribution of its precursor. A closer examination of Fig. 5 would predict that the benzene ring carbon bearing the PhCH(OH) substituent would be expected to bear most of positive charge in the (redistributed) electronic structure of the excited state (compared with the initial ground state). This is shown in Scheme 2 in which protonation of triplet **7** would give rise to a conjugate acid (carbocation) that may be represented by structures **21a** and **21b**. These predictions are also consistent with the mechanism of photohydration of benzophenone reported by Wirz and co-workers (9). In the case of the photohydration reaction (9), water would attack the carbocation of structure **21b**. This may indeed occur, leading to a product that would eventually return to substrate. However, another possible pathway that is not available in the parent benzophenone studied by Wirz and co-workers (9) is the deprotonation pathway leading to the double enol intermediate **22**. This is perhaps a pathway that initially seems unusual, but one can quickly see that ketonization of this double enol leads back to substrate or to a formal intramolecular redox product that was indeed observed for most of these compounds. Oxygen is expected to trap biradicals of the type **22** leading to the oxidized product **12**, although other mechanisms for photooxidation (photooxygenation) are not excluded.

HOMO and LUMO calculations for the *p*-methylphenyl derivative **8** gave similar results. However, this was not the case for the methoxy-substituted derivatives **9** and **10**. As shown in Fig. 6 for compound **9**, examination of the HOMO and LUMO characteristics would imply that electronic excitation of this compound would transfer charge from only the methoxybenzene ring to *both* of the benzene rings of the benzophenone. This is consistent with the photoinduced single electron transfer to form the benzophenone radical anion and methoxyphenyl radical cation that was inferred in the LFP results for this compound (and **10**). A residual formal photoredox pathway was observed for this compound at pH 7 and pH 2. Indeed, initial photoinduced electron transfer can lead to such a reaction (Scheme 3), and we believe that it is the pathway taken at pH 7. At lower pH, one would still expect protonation of the benzophenone carbonyl, and this may lead to an overall photoredox pathway as well, which is consistent with the higher quantum yield for this reaction at lower pH. The question remains as to why the *m*-methoxy-substituted compound **10** did not undergo photoredox reaction at any pH. Clearly in this case the photoinduced electron transfer appears to take place for **10** as indicated by the LFP data. We believe the explanation lies in the electronic structure of the radical cation shown in Scheme 3. A meta-substituted methoxy group (instead of the para-substituted methoxy group shown) would cause the cation and radical to be more localized at benzene positions that are ortho and para to the methoxy group (for resonance stabilization). This will have the effect of reducing the degree of positive charge that would be localized at the benzene ring carbon adjacent to the Ar(HO)CH moiety. This in term will reduce the acidity of the CH proton of the Ar(HO)CH group and hence the overall efficiency of the formal redox reaction. A similar argument may also be used to explain why photoredox chemistry was not observed when **10** is photoprotonated at pH 2.

Finally, we have also carried out HOMO and LUMO calculations for the photoredox product **15**. As noted earlier, this compound did not undergo the photoredox chemistry

Scheme 2.

Scheme 3.

that would have returned it back to **9**. As shown in Fig. 7, electronic excitation of this compound would result in charge migration from the benzophenone benzene ring substituted with the methoxy group to the carbonyl and the other adjacent benzophenone benzene ring. Although this would make the benzophenone carbonyl more basic (hence photoprotonated by acid), it does not predict that the Ph(HO)CH moiety would be activated with respect to deprotonation, as would be required for the photoredox reaction to proceed and that was predicted in similar HOMO and LUMO calculations for **7** and **8**. Thus, it would appear that simple low level HOMO and LUMO calculations offer a useful parallel study for the intramolecular photoredox chemistry of the benzophenones studied in this work, and we will be applying similar theoretical studies on related chemistry that can arise from acid–base chemistry of electronically excited states of other aromatic compounds.

Experimental section

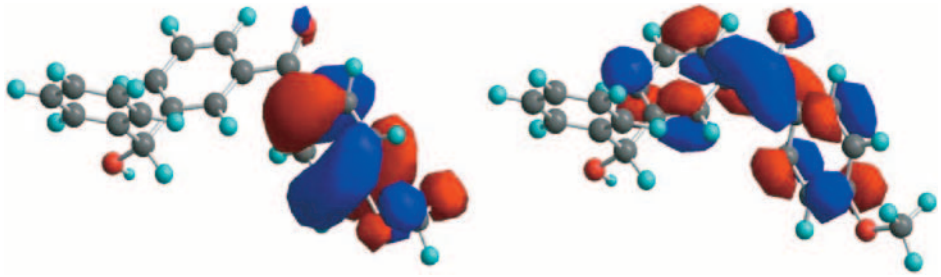
Instrumentation

^{1}H NMR spectra were recorded on Bruker 300 or 500 MHz instruments. Mass spectra were obtained on a Kratos Concept H instrument. UV–vis spectra were recorded on a Varian Cary 5 instrument. Preparative photolyses were performed using a Rayonet RPR 100 photochemical reactor equipped with 300 nm lamps.

Common laboratory reagents

All solvents used for synthesis (ACS grade) were purchased from Sigma-Aldrich and used as received unless otherwise noted. HPLC grade acetonitrile and distilled water were used in photolyses in mixed H_2O–CH_3CN solutions. D_2O and $CDCl_3$ were purchased from Cambridge Isotope laboratory and D_2SO_4 was obtained from Sigma-Aldrich. Preparative TLC was carried out on 20 cm × 20 cm silica gel GF Uniplates (Analtech).

Materials



All readily available organic and inorganic reagents required in the synthesis reported below were purchased from Sigma-Aldrich and used as received.

α-*D*-α-Hydroxy-3-benzylbenzophenone (7-αD)

3-Benzoylbenzophenone (0.30 g, 1.1 mmol) was dissolved in 60 mL of 2-propanol and sodium borodeuteride (0.024 g, 0.56 mmol) in 25 mL of 2-propanol was added slowly with stirring at room temperature (RT). The solution was then refluxed for 45 min, cooled and quenched with 100 mL of

H_2O. Upon extraction with 100 mL of CH_2Cl_2 and removal of the organic solvent, a yellow oil was obtained. Pure **7-αD** was obtained via preparative TLC using 1:24 ether–CH_2Cl_2 to give 0.25 g (oil 50%) of material. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.84 (t, 2H, 1.8 Hz), 7.74 (dd, 2H, 8.2 Hz and 1.4 Hz), 7.65 (dt, 1H, 7.6 Hz and 1.5 Hz), 7.60 (dt, 1H, 7.7 Hz and 1.6 Hz), 7.56 (tt, 1H, 7.5 and 1.3 Hz), 7.46–7.40 (m, 3H), 7.37–7.35 (m, 2H), 7.34–7.31 (m, 2H), 7.28–7.24 (m, 1H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 196.9 (s), 144.4 (s), 143.6 (s), 137.8 (s), 137.6 (s), 132.7 (s), 130.6 (s), 130.3 (s), 129.5 (s), 128.8 (s), 128.6 (s), 128.4 (s), 128.2 (s), 128.0 (s), 126.7 (s). EIMS *m/z*: 289 (M^+, 40), 273 (40), 209 (80), 196 (35), 184 (100), 166 (40), 152 (20). HRMS calcd. for $C_{20}H_{15}DO_2$: 289.1212; found 289.1206.

α-Hydroxy-3-benzylbenzophenone (7)

This compound was prepared the same as the preceding except that sodium borohydride was used. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.84 (t, 2H, 1.8 Hz), 7.74 (dd, 2H, 8.2 Hz and 1.4 Hz), 7.65 (dt, 1H, 7.6 Hz and 1.5 Hz), 7.60 (dt, 1H, 7.7 Hz and 1.6 Hz), 7.56 (tt, 1H, 7.5 and 1.3 Hz), 7.46–7.40 (m, 3H), 7.37–7.35 (m, 2H), 7.34–7.31 (m, 2H), 7.28–7.24 (m, 1H). 5.90 (s, 1H), OH signal too broad for detection. ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.8 (s), 144.4 (s), 143.7 (s), 137.9 (s), 137.7 (s), 132.7 (s), 130.7 (s), 130.3 (s), 129.5 (s), 128.9 (s), 128.7 (s), 128.5 (s), 128.3 (s), 128.1 (s), 126.8 (s). EIMS *m/z:* 288 (M^+, 15), 272 (10), 209 (30), 195 (10), 183 (50), 105 (100), 77 (60). HRMS calcd. for $C_{20}H_{16}O_2$: 288.1150; found 288.1152.

3-Formylbenzophenone

3-Methylbenzophenone (9.1 mL, 51 mmol) was combined with 2.5 equiv. of *N*-bromosuccinimide (22.8 g, 128 mmol) and benzoyl peroxide (0.11 g, 0.80 mmol) in 100 mL benzene. The reaction mixture was refluxed overnight for 17 h under N_2. After the mixture cooled, it was washed twice with 50 mL of distilled H_2O, dried with anhydr. $MgSO_4$, filtered, and the solvent removed in vacuo. The crude 3-(dibromomethyl)benzophenone was then combined with 5 equiv. of $CaCO_3$ (25.8 g, 258 mmol) in 300 mL 1:1 H_2O–dioxane and refluxed overnight for 17 h. After the reaction mixture had cooled, the solvent was removed under vacuum. Subsequently, 200 mL of CH_2Cl_2 and ~400 mL of 1 mol/L HCl was added with stirring to dissolve the solid. The organic phase was separated and the aqueous phase extracted twice with 100 mL of CH_2Cl_2. The organic fractions were combined and washed twice with 200 mL satd. $NaHCO_3$. The organic fraction was dried with anhydr. $MgSO_4$, filtered, and the solvent removed. Pure white crystals were obtained after chromatography (silica gel, 1:1 ether–hexanes), to yield 2 g (35%) of 3-formylbenzophenone (16). ^{1}H NMR (300MHz, $CDCl_3$) δ: 10.08 (s, 1H), 8.27 (s, 1H), 8.12–8.05 (m, 2H), 7.82–7.78 (m, 2H), 7.69–7.58 (m, 2H), 7.53–7.48 (m, 2H). This material was used without further treatment in the synthesis of **8–10** and **14**.

General procedure for the preparation of benzophenone derivatives 8–10 and 14

For the preparation of the Grignard reagents, 1.2 equiv. of magnesium turnings were reacted with 1.1 equiv. of the corresponding bromobenzene derivative dissolved in dry THF. The Grignard reagents were prepared in the following way. Magnesium turnings and ≅10 mL of dry THF were placed in a dry three-necked flask equipped with a nitrogen inlet, a dropping funnel, and a condenser. The corresponding bromobenzene derivative was dissolved in dry THF and placed in the dropping funnel. Several drops were added to the flask from the dropping funnel. The reaction was initiated by the addition of a crystal of iodine followed by heating. After initiation of the reaction, the remaining solution in the dropping funnel was added slowly to the reaction mixture over 45 min, while the reaction mixture was maintained at ≅40 °C. After the addition was completed, the reaction mixture was heated at reflux for one additional hour. The reaction was cooled to RT and cannulated to the dropping funnel for the next step. In the next reaction, a dry three-necked flask was equipped with a nitrogen inlet, a septum, and a dropping funnel. In this flask was placed a solution of 1 equiv. of 3-formylbenzophenone dissolved in THF. The solution was cooled to –78 °C. The prepared Grignard reagent was added slowly over the period of 2 h to the cooled solution, taking care that the temperature of the reaction mixture remained at –78 °C. After the addition of the reagent, the mixture was stirred for an additional 2 h at –78 °C and allowed to slowly reach RT overnight. The next day water was added to the reaction mixture followed by the addition of 1 mol/L HCl. The reaction mixture was extracted twice with diethyl ether, the organic fraction washed with water and dried over anhydr. $MgSO_4$. The solvent was then evaporated and the residue purified on a column of silica gel using CH_2Cl_2 as the initial eluent followed with CH_2Cl_2–EtOAc mixtures of increasing polarity (up to 20% of EtOAc).

α-*Hydroxy-3-(4′-methylbenzyl)benzophenone (8)*

Starting from 1.2 g (5.7 mmol) of 3-formylbenzophenone and 4-bromotoluene, the reaction furnished 400 mg (23%) of the product, a colorless oil. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 3434, 1656. ^{1}H NMR ($CDCl_3$,

300 MHz) δ: 7.83 (s, 1H), 7.74 (d, 2H, *J* = 7.4 Hz), 7.64 (d, 1H, *J* = 7.4 Hz), 7.52–7.61 (m, 2H,), 7.43 (dd, 2H, *J* = 7.4 Hz, *J* = 7.7 Hz), 7.39 (t, 1H, *J* = 7.7 Hz), 7.23 (d, 2H, *J* = 8.0 Hz), 7.12 (d, 2H, *J* = 8.0 Hz), 5.82 (s, 1H), 2.65 (br s, 1H), 2.31 (s, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.9 (s), 144.6 (s), 140.8 (s), 137.7 (s), 137.7 (s), 137.6 (s), 132.6 (d), 130.6 (d), 130.2 (d), 129.5 (d), 129.3 (d), 128.5 (d), 128.4 (d), 128.1 (d), 126.7 (d), 75.8 (d), 21.3 (q). EIMS *m/z*: 303 (M^+, 10), 302 (M^+, 45), 287 (20), 209 (30), 183 (50), 119 (50), 105 (100), 91 (30), 77 (70). HRMS calcd. for $C_{21}H_{18}O_2$: 302.1307; found 302.1306.

α-Hydroxy-3-(4′-methoxybenzyl)benzophenone (9)

Starting from 2.1 g (10 mmol) of 3-formylbenzophenone and 4-bromoanisole, the reaction furnished 460 mg (14%) of the product, a colorless oil. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 3446, 1653. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.82 (s, 1H), 7.74 (d, 2H, *J* = 7.5 Hz), 7.64 (dd, 1H, *J* = 1.4 Hz, *J* = 7.4 Hz), 7.52–7.61 (m, 2H), 7.44 (dd, 2H, *J* = 7.5 Hz, *J* = 8.1 Hz), 7.41 (t, 1H, *J* = 8.1 Hz), 7.22 (d, 2H, *J* = 8.8 Hz), 6.84 (d, 2H, *J* = 8.8 Hz), 5.83 (s, 1H), 3.76 (s, 3H), 2.50 (br s, 1H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.9 (s), 159.4 (s), 144.6 (s), 137.8 (s), 137.7 (s), 136.0 (s), 132.7 (d), 130.5 (d), 130.3 (d), 129.4 (d), 128.5 (d), 128.5 (d), 128.1 (d), 128.1 (d), 114.2 (d), 75.6 (d), 55.5 (q). EIMS *m/z*: 319 (M^+, 10), 318 (M^+, 60), 182 (40), 137 (50), 105 (100), 86 (75), 77 (88), 69 (100). HRMS calcd. for $C_{21}H_{18}O_3$: 318.1256; found 318.1255.

α-Hydroxy-3-(3′-methoxybenzyl)benzophenone (10)

Starting from 2.65 g (12.6 mmol) of 3-formylbenzophenone and 3-bromoaniosle, the reaction furnished 3.2 g (80%) of the product, a colorless oil. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 3435, 1656. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.83 (s, 1H), 7.74 (d, 2H, *J* = 8.1 Hz), 7.64 (d, 1H, *J* = 7.4 Hz), 7.52–7.61 (m, 2H), 7.43 (dd, 2H, *J* = 7.7 Hz, *J* = 8.1 Hz), 7.41 (t, 1H, *J* = 7.7 Hz), 7.23 (dd, 1H, *J* = 8.1 Hz, *J* = 8.3 Hz), 6.90–6.95 (m, 2H), 6.78 (d, 1H, J = 8.3 Hz), 5.83 (s, 1H), 3.76 (s, 3H), 2.50 (br s, 1H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.8 (s), 160.0 (s), 145.3 (s), 144.3 (s), 137.8 (s), 137.6 (s), 132.7 (d), 130.6 (d), 130.3 (d), 129.9 (d), 129.5 (d), 128.6 (d), 128.5 (d), 128.2 (d), 119.0 (d), 113.4 (d), 112.3 (d), 75.9 (d), 55.4 (q). EIMS *m/z*: 319 (M^+, 25), 318 (M^+, 100), 209 (25), 183 (40), 109 (55), 105 (78), 77 (60). HRMS calcd. for $C_{21}H_{18}O_3$: 318.1256; found 318.1254.

α-Hydroxy-3-(3′-formylbenzyl)benzophenone (14)

Starting from 2.0 g (9.5 mmol) of 3-formylbenzophenone, 255 mg of Mg (10.5 mmol), and 2.71 g of 3-bromobenzaldehyde diethyl acetal (10.5 mmol) (Sigma-Aldrich), the reaction furnished 560 mg (19%) of the product, a colorless oil. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 3434, 1695, 1653. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 9.98 (s, 1H), 7.91 (s, 1H), 7.84 (s, 1H), 7.78 (d, 1H, *J* = 7.8 Hz), 7.74 (d, 2H, *J* = 8.1 Hz), 7.63–7.70 (m, 2H), 7.53–7.62 (m, 2H), 7.50 (t, 1H, *J* = 7.6 Hz), 7.44 (dd, 1H, *J* = 7.6 Hz, *J* = 8.1 Hz), 7.40–7.48 (m, 1H), 5.98 (s, 1H), 2.10 (br s, 1H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.7 (s), 192.4 (d), 144.8 (s), 143.9 (s), 138.2 (s), 137.5 (s), 136.9 (s), 132.8 (d), 132.7 (d), 130.7 (d), 130.3 (d), 129.9 (d), 129.6 (d), 129.4 (d), 128.9 (d), 128.5 (d), 128.2 (d), 127.7 (d), 75.5 (d). EIMS *m/z*: 317 (M^+, 5), 316 (M^+, 20), 270 (25), 239 (30), 212 (25), 183 (70), 165 (15), 135 (20), 122 (20), 105 (100), 77 (85). HRMS calcd. for $C_{21}H_{16}O_3$: 316.1099; found 316.1097.

α-Hydroxy-3-[3′-(hydroxymethyl)benzyl]benzophenone (11)

The aldehyde **14** (450 mg, 1.4 mmol) was dissolved in 30 mL of MeOH and cooled under ice. To this solution was added a solution of $NaBH_4$ (40 mg, 1 mmol) in 10 mL of MeOH. The reaction mixture was stirred at 0 °C for 15 min and quenched by the addition of 50 mL of saturated ammonium chloride. Extractions with CH_2Cl_2 were carried out and the collected extracts were dried over anhydr. $MgSO_4$. After evaporation of the solvent, the residue was chromatographed on silica using CH_2Cl_2 as the initial eluent followed with CH_2Cl_2–EtOAc mixtures of increasing polarity (up to 30% of EtOAc). The product was obtained as a colorless oil, 215 mg, yield 48%. IR (neat, NaCl plates, cm^{-1}) ν: 3390, 1651. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.85 (s, 1H), 7.75 (d, 2H, *J* = 7.4 Hz), 7.66 (d, 1H, *J* = 7.8 Hz), 7.53–7.63 (m, 2H), 7.45 (dd, 1H, *J* = 7.4 Hz, *J* = 7.6 Hz), 7.43 (t, 1H, *J* = 7.6 Hz), 7.39 (s, 1H), 7.25–7.35 (m, 3H), 5.91 (s, 1H), 4.67 (s, 2H), 2.57 (br s, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 197.0 (s), 144.4 (s), 144.0 (s), 141.6 (s), 137.8 (s), 137.6 (s), 132.8 (d), 130.7 (d), 130.3 (d), 129.5 (d), 129.0 (d), 128.6 (d), 128.5 (d), 128.2 (d), 126.6 (d), 126.0 (d), 125.2 (d), 75.9 (d), 65.2 (t). EIMS *m/z*: 319 (M^+, 5), 318 (M^+, 20), 209 (38), 183 (35), 135 (28), 105 (100), 77 (50). HRMS calcd. for $C_{21}H_{18}O_3$: 318.1256; found 318.1254.

General photolysis procedure

A 10 mg sample of the benzophenone derivative was dissolved in 400 mL of 1:1 CH_3CN–H_2O and placed in a 600 mL quartz tube, which was continuously cooled with a cold finger to ~15 °C. The pH of the water portion was adjusted by the addition of H_2SO_4. The solution was purged with argon and irradiated at 300 nm in a Rayonet RPR 100 photochemical reactor using 2 or 16 lamps for different times (1–30 min). After irradiation, the solution was neutralized by the addition of $NaHCO_3$ and extracted using CH_2Cl_2. The combined extracts were dried over $MgSO_4$ and the solvent was evaporated. After evaporation of the solvent, photolysis mixtures were analyzed by NMR and (or) chromatographed on a thin layer of silica using CH_2Cl_2–EtOAc as eluent to separate photoproducts.

Photolysis of α-hydroxy-3-(4′-methylbenzyl)benzophenone (8)

A solution of **8** (10 mg in 400 mL, pH 2) was photolyzed (300 nm, 2 lamps) in a quartz tube for up to 20 min. After work-up the residue was chromatographed on prep. TLC to give **18** and a mixture of **8** and **17** (maximum isolated yield of **17** was 20%). The highest content of **17** (92%) was obtained on photolysis in the presence of naphthalene. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 3434, 1652. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.82 (dd, 1H, *J* = 1.7 Hz, *J* = 1.9 Hz), 7.66 (d, 2H, *J* = 8.1 Hz), 7.64 (ddd, 1H, *J* = 1.2 Hz, *J* = 1.6 Hz, *J* = 7.5 Hz), 7.58 (ddd, 1H, *J* = 1.1 Hz, *J* = 1.6 Hz, *J* = 7.7 Hz), 7.41 (t, 1H, *J*= 7.7 Hz), 7.37 (d, 2H, *J* = 8.5 Hz), 7.33 (dd, 2H, *J* = 7.7 Hz, *J* = 8.5 Hz), 7.25–7.28 (m, 1H), 7.24 (d, 2H, *J* = 8.1 Hz), 5.89 (s, 1H), 2.42 (s, 3H),

2.35 (br s, 1H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 196.5 (s), 144.3 (s), 143.7 (s), 143.5 (s), 138.3 (s), 135.0 (s), 130.5 (d), 130.4 (d), 129.4 (d), 129.2 (d), 128.9 (d), 128.6 (d), 128.1 (d), 128.1 (d), 126.8 (d), 76.2 (d), 21.9 (q). EIMS *m/z*: 303 (M^+, 10), 302 (M^+, 30), 279 (10), 223 (15), 212 (40), 197 (50), 165 (20), 149 (30), 133 (50), 119 (60), 105 (100), 91 (30), 77 (70). HRMS calcd. for $C_{21}H_{18}O_2$: 302.1307; found 302.1307.

The oxidized product **18** was also isolated from the preparative TLC as a colorless oil. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 1659. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 8.13 (dd, 1H, *J* = 1.8 Hz, *J* = 1.7 Hz), 7.96–8.00 (m, 2H), 7.79 (dd, 2H, *J* = 1.7 Hz, *J* = 8.0 Hz), 7.70 (d, 2H, *J* = 8.1 Hz), 7.59 (dt, 1H, *J* = 1.7 Hz, *J* = 7.7 Hz), 7.58 (ddd, *J* = 1.5 Hz, *J* = 7.0 Hz, *J* = 7.5 Hz), 7.47 (dd, 2H, *J* = 7.7 Hz, *J* = 8.0 Hz), 7.26 (d, 2H, *J* = 8.1 Hz), 2.41 (s, 3H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 196.1 (s), 195.8 (s), 144.0 (s), 138.4 (s), 138.0 (s), 137.3 (s), 134.5 (s), 133.6 (d), 133.5 (d), 133.1 (d), 131.3 (d), 130.5 (d), 130.3 (d), 129.4 (d), 128.7 (d), 21.9 (q). EIMS *m/z*: 301 (M^+, 10), 300 (M^+, 60), 279 (10), 223 (15), 209 (10), 167 (20), 149 (35), 119 (100), 105 (50), 91 (30), 77 (30). HRMS calcd. for $C_{21}H_{16}O_2$: 300.1150; found 300.1152.

Photolysis of 8 in the presence of naphthalene

A 400 mL of the CH_3CN–H_2O solution (pH 2) containing 10 mg of **8** and 50 mg of naphthalene was purged with argon and irradiated for 1 h at 300 nm (16 lamps). After irradiation, extractions with CH_2Cl_2 were carried out. The collected extracts were dried over anhydr. $MgSO_4$ and the solvent evaporated. The residue obtained from 3 photolyses was chromatographed on a prep. TLC (silica gel; CH_2Cl_2–EtOAc (2.5%)). The following fractions were isolated: ~10 mg of **18** and ~ 7 mg of the mixture containing 92% of **17** and 8% of the starting material **8**.

Photolysis of α-hydroxy-3-(4′-methoxybenzyl)benzophenone (9)

A solution of **9** (10 mg in 400 mL, pH 2) was photolyzed (300 nm, 16 lamps) in a quartz tube for up to 10 min. After work-up the residue was chromatographed on prep. TLC to give pure **15** as a colorless oil (maximum isolated yield of **15** was 40%–50%). IR (neat, NaCl plates, cm^{-1}) ν: 3429, 1646. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 7.77 (s, 1H), 7.76 (d, 2H, *J* = 8.8 Hz), 7.60 (d, 1H, *J* = 7.5 Hz), 7.57 (d, 1H, *J* = 8.1 Hz), 7.22–7.44 (m, 6H), 6.92 (d, 2H, *J* = 8.8 Hz), 5.86 (s, 1H), 3.86 (s, 3H), 2.76 (br s, 1H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 195.7 (s), 163.4 (s), 144.3 (s), 143.7 (s), 138.5 (s), 132.8 (d), 130.3 (s), 130.2 (d), 129.1 (d), 128.8 (d), 128.5 (d), 128.0 (d), 126.7 (d), 113.7 (d), 76.1 (d), 55.7 (q). EIMS *m/z*: 319 (M^+, 10), 318 (M^+, 60), 279 (15), 256 (15), 239 (15), 213 (50), 165 (20), 149 (70), 135 (100), 121 (30), 105 (100), 97 (30), 77 (87). HRMS calcd. for $C_{21}H_{18}O_3$: 318.1256; found 318.1257.

The oxidized product **16** was also isolated as a colorless oil. IR (neat from CH_2Cl_2 solution, salt plates, cm^{-1}) ν: 1654. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 8.10 (s, 1H), 7.97 (d, 1H, *J* = 7.2 Hz), 7.95 (d, 1H, *J* = 7.5 Hz), 7.76–7.84 (m, 4H), 7.54–7.62 (m, 2H), 7.47 (dd, 2H, *J* = 7.0 Hz, *J* = 7.8 Hz), 6.94 (d, 2H, *J* = 8.8 Hz), 3.86 (s, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 196.2 (s), 196.1 (s), 163.8 (s), 138.7 (s), 137.9 (s), 137.2 (s), 133.4 (d), 133.2 (d), 133.0 (d), 132.8 (d), 131.1 (d), 130.3 (d), 129.8 (s), 128.7 (d), 114.0 (d), 55.8 (q). EIMS *m/z*: 317 (M^+, 5), 316 (M^+, 20), 279 (30), 212 (25), 167 (40), 149 (100), 135 (95), 105 (30), 77 (35). HRMS calcd. for $C_{21}H_{16}O_3$: 316.1099; found 316.1101.

Photolysis of α-hydroxy-3-[4′-(hydroxymethyl)benzyl]benzophenone (11)

A solution of **11** (10 mg in 400 mL, pH 2) was photolyzed at 300 nm for up to 15 min. After work-up, the residue was separated by prep. TLC. The main product was **20** (maximum isolated yield 5%–10%) as a mixture of diastereomers (colorless oil). IR (neat, NaCl plates, cm^{-1}) ν: 3402, 1694. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 9.96 (s, 1H), 9.95 (s, 1H), 7.86 (2d, 2H, *J* = 1.8 Hz), 7.76 (2dd, 2H, *J* = 1.4 Hz, *J* = 7.7 Hz), 7.62 (2dd, 2H, *J* = 1.8 Hz, *J* = 7.6 Hz), 7.47 (2dd, 2H, *J* = 7.6 Hz, *J* = 7.7 Hz), 7.42–7.45 (m, 2H), 7.12–7.34 (m, 16H), 5.87 (s, 2H), 5.81 (s, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 192.5 (d), 145.0 (s), 144.6 (s), 144.6 (s), 143.8 (s), 143.8 (s), 143.7 (s), 143.7 (s), 136.8 (s), 132.7 (d), 129.4 (d), 129.2 (d), 129.1 (d), 128.8 (d), 128.0 (d), 127.9 (d), 127.9 (d), 127.9 (d), 126.8 (d), 126.8 (d), 126.5 (d), 126.4 (d), 126.1 (d), 126.0 (d), 125.0 (d), 76.4 (d), 76.3 (d), 75.9 (d), 75.9 (d). EIMS *m/z*: 319 (M^+, 7), 318 (M^+, 35), 239 (30), 211 (20), 183 (20), 167 (30), 133 (20), 105 (100), 77 (45). HRMS calcd. for $C_{21}H_{18}O_3$: 318.1256; found 318.1254.

Also found were **14** (identified by comparison to an authentic sample made above) and a trace amount of **19** was detected in the photomixture, which could not be purified. ^{1}H NMR of an enriched TLC fraction assignable to **19** is as follows: ($CDCl_3$, 500 MHz) δ: 7.83 (s, 1H), 7.73 (s, 1H), 7.67 (d, 2H, *J* = 7.4 Hz), 7.62 (d, 1H, *J* = 7.7 Hz), 7.58 (d, 1H, *J* = 7.4 Hz), 7.40–7.48 (m, 2H), 7.24–7.40 (m, 5H), 5.90 (s, 1H), 4.73 (s, 2H).

Nanosecond laser flash photolysis (LFP)

All LFP studies were conducted at the University of Victoria LFP facility employing a Nd-YAG laser with a pulse width of 20 ns and excitation wavelength of 266 nm. Flow cells (0.7 cm) were used and solutions were purged with nitrogen or oxygen for 30 min prior to measurements. Optical densities at 266 nm were ~0.1–0.7.

Thermal and microwave assisted synthesis of *N*-aroylamino acridinediones

T. Josephrajan and V.T. Ramakrishnan

Abstract: A series of *N*-aroylamino acridinediones (**3a**–**3d** and **6a**–**6e**) have been synthesized from tetraketones (**1** and **4**) and benzoic hydrazides (**2a**–**2d** and **5a**–**5e**) under thermal and microwave irradiation conditions with solid supports.

Key words: acridine, hydrazide, microwave irradiation.

Résumé : On a réalisé la synthèse d'une série de *N*-aroylaminoacridinediones (**3a**–**3d** et **6a**–**6e**) à partir des tétracétones (**1** et **4**) et d'hydrazides benzoïques (**2a**–**2d** et **5a**–**5e**) sur des supports solides et en faisant appel à des conditions thermiques ou d'irradiation aux microondes.

Mots-clés : acridine, hydrazide, irradiation aux microondes.

[Traduit par la Rédaction]

Introduction

The acridinedione ring is a important heterocyclic unit present in many biologically active compounds (1*a*, 1*b*). These 1,4-dihydropyridines are structurally similar to the NADH molecule, which acts as a coenzyme in biological systems and plays a crucial role in brain-targeted chemical delivery systems (1*c*, 2). The importance of the acridinedione ring system as a DNA intercalator (3) and as a laser dye has been established in our earlier reports (4). Recently, by using nanosecond laser flash photolysis, Lindqvist et al. studied (5) the radical intermediates involved in the oxidation of the 1,4-dihydropyridine derivative of AZT as related to AIDS dementia. These dyes operate in the blue-green region and they have a lasing properties that is comparable to that of the well-known standard coumarin-102. Acridinedione dyes have been reported as very good photoinitiators for the photo polymerization of acrylates and methacrylates (6) and are used as photosensitizers in onium salt decomposition (7).

Results and discussion

In continuation of our studies on the synthesis of acridinediones (8), we were interested to synthesize *N*-aroylamino acridinediones by using acid hydrazides. The acid hydrazides are a prominent structural motif found in numerous pharmaceutically active compounds (9). They have been found to possess a wide spectrum of medicinal activities such as anti-tubercular, antibacterial, and anti-fungal activities. Sugimoto et al. (10) reported the anti-acetylcholinesterase activity of a series of *N*-aroylamino compounds.

The exploitation of microwave irradiation for enhancing the rate of organic reactions has been gaining more importance in recent years (11). Recently, Suarez et al. (12) reported the microwave-assisted synthesis of acridinediones. However, there is no report in the literature for the synthesis of *N*-aroylamino acridinediones. We report herein the synthesis of various acridinediones from acid hydrazides and tetraketones under microwave irradiation as well as by a conventional method using P_2O_5 in ethanol under refluxing conditions.

The reaction of methylene bis(cyclohexane-1,3-dione) (**1**) and benzoic hydrazide (**2a**) in ethanol, with a catalytic amount of P_2O_5 under microwave irradiation, afforded the 10-(benzoylamino)-3,4,6,7,9,10-hexahydro-1,8(2H,5H) acridinedione (**3a**) in 85% yield. The reaction was completed in 5 min. However, conventional heating of the above reaction mixture required 35 h to give the product **3a** in 80% yield. In the above lines, microwave-assisted synthesis was also extended to other substrates **3b**–**3d** (Scheme 1, Table 1). In all cases, the reaction was completed in 4 to 5 min, affording the product in good yields. We also extended our study for the reaction of methylene bisdimedone **4** with various hydrazides **5a**–**5e**, which afforded the corresponding acridinediones **6a**–**6e** in good yields, as shown in Scheme 2 and Table 2.

The solvent-free "green" approach involves the exposure of neat reactants to microwave irradiation with the use of supported reagents or catalysts that are of mineral origin. Clay minerals, alumina, and supported reagents are commonly employed to synthesize a wide range of compounds. Hence, we have carried out the above synthesis in the presence of montmorrilonite K-10 clay with microwave irradiation. In this condition, the reaction required about 15–17 min to give the respective product with a slight increase in the yield. The results are presented in Tables 1 and 2. Thus, microwave irradiation assisted synthesis of

acridinedione systems has been found to be highly efficient for the synthesis of multifunctional acridinediones.

The IR spectrum of these compounds showed characteristic peaks around 1650 and 1380 cm^{-1} for the vinylogous amide and amide carbonyl groups. In the ^1H NMR spectrum of **3a**, the C-3 and C-6 methylene protons appeared as a multiplet at δ 1.80–2.10; the C-2, C-4, C-5, C-7, and C-9 methylene protons appeared in the range δ 2.30–3.30 as a multiplet; the aryl protons resonated at δ 7.50–7.70 as a multiplet; the NH proton appeared as a singlet at δ 10.90. The signals in the ^{13}C NMR spectrum at δ 167.0 and 197.7 indicate the presence of an amide (ArCONH) and keto group, respectively; the C-4a and C-9a carbons appeared at δ 155.6 and 111.4. In the X-ray crystal structure of compounds **3a** (13), **3d** (13), and **3b** (14), the central ring adopts boat conformation (14). However, in the tetramethyl-substituted acridine **6d** (15), the central ring is nearly planar. In all of the cases the outer rings adopts sofa conformation. The absorption and fluorescence spectra of the acridinedione dyes **3a**–**3d** and **6c** in different solvents show the absorption maximum around 370 nm. Fluorescence lifetime of the dyes varies with substituents on the nitrogen atom and with the solvents. These dyes are more polar in the excited state than in the ground state (4).

Experimental

Melting points were determined using a Toshniwal melting point apparatus in an open capillary tube and are uncorrected. IR spectra were recorded in Nicolet Impact 400 FT-IR spectrophotometer. ^1H NMR and ^{13}C NMR spectra were recorded on Jeol GSX (400 MHz), Bruker DPX (200 MHz), and Varian EM 390 (90 MHz) spectrometers, using TMS as internal standard. GC-MS data were obtained from a Jeol-DX-303 spectrometer. Microanalyses were performed on a PerkinElmer 240B element analyzer. Microwave reactions were performed using a Kenstar microwave oven (800 W).

The hydrazides **2** were prepared from the esters of the corresponding acids by treatment with hydrazine hydrate. The tetraketones **1** and **4** were prepared from cyclohexane-1,3-dione and dimedone, respectively, on treatment with formaldehyde (12).

General procedure for 10-(benzoylamino)-3,4,6,7,9,10-hexahydro-1,8(2*H*,5*H*)acridinedione (3a)

Method A

To a solution of 2,2′-methylene-bis(cyclohexane-1,3-dione) (**1**) (1.0 g, 4.2 mmol) and benzoic hydrazide (0.58 g, 4.2 mmol) in ethanol (40 mL), a catalytic amount of P_2O_5 was added and the mixture refluxed on a steam bath for 35 h. The reaction mixture was concentrated and poured into ice; the yellow solid was filtered, dried, and crystallized from a mixture of chloroform and ethanol (1:1) to obtain the title compound **3a** (1.25 g, 88%).

Method B

To a solution of 2,2′-methylene-bis(cyclohexane-1,3-dione) (**1**) (0.1 g, 0.42 mmol) and benzoic hydrazide (0.058 g, 0.42 mmol) in ethanol (10 mL), a catalytic amount of P_2O_5 was added and was irradiated in a microwave oven (75–78 °C) for 5 min. The reaction mixture was concentrated and poured into ice; the yellow solid obtained was filtered, dried, and crystallized from a mixture of chloroform and ethanol (1:1) to obtain the title compound **3a** (0.12 g, 85%).

Method C

A homogenized mixture of 2,2′-methylene-bis(cyclohexane-1,3-dione) (**1**) (0.1 g, 0.42 mmol) benzoic hydrazide (0.058 g, 0.42 mmol) and montmorillonite K-10 clay (0.1 g) was irradiated in a microwave oven (60–65 °C) for 17 min. The resulting product was dissolved in a methanol–chloroform mixture and the clay was filtered off. The solvent was distilled off and the product **3a** isolated and crystallized (0.13 g, 93%).

10-(Benzoylamino)-3,4,6,7,9,10-hexahydro-1,8(2*H*,5*H*) acridinedione (3a)

Brown solid; yield 88%; mp 138–140 °C. IR (KBr, cm^{-1}) 3506, 1658, 1625, 1587, 1386. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.80–2.10 (m, 4H, C_3 and C_6-CH_2), 2.30–3.30 (m, 10H, C_2, C_4, C_5, C_7, and C_9-CH_2), 7.50–7.70 (m, 3H, Ar-H), 8.00 (d, 2H, J = 8 Hz, Ar-H), 10.90 (s, 1H, NH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 18.7, 20.9, 24.6, 36.1, 111.4, 127.7, 129.0, 130.5, 133.1, 155.6, 167.0, 197.7. MS *m*/*z* (%): 366 (M^+, 0.1), 216 (5.7), 215 (12), 198 (0.4), 187 (25.4), 159 (4.6), 131 (13.6), 121 (25), 105 (51.3), 103 (11.4), 77 (100). Anal. calcd. for $C_{20}H_{20}N_2O_3$ (%): C 71.41, H 5.99, N 8.33; found: C 71.44, H 6.04, N 8.38.

10-(4-Hydroxybenzoylamino)-3,4,6,7,9,10-hexahydro-1,8(2*H*,5*H*)acridinedione (3b)

Pale yellow solid; yield 81%; mp 268–270 °C. IR (KBr, cm^{-1}) 3519, 3159, 1640, 1622, 1579, 1386. ^{1}H NMR (400 MHz, $CDCl_3$-DMSO-d_6) δ: 1.80–1.95 (m, 4H, C_3 and C_6-CH_2), 2.19–2.60 (m, 8H, C_2, C_4, C_5, and C_7- CH_2), 2.85 and 2.98 (2d, 2H, J = 20 Hz, C_9-CH_2), 6.90 (d, 2H, J = 8 Hz, Ar-H), 7.80 (d, 2H, J = 8 Hz, Ar-H), 10.30 (br s, 1H, Ar-OH), 11.00 (s, 1H, NH). MS *m*/*z* (%): 352 (M^+, 15), 306 (2), 216 (6), 215 (8), 198 (4), 187 (97), 159 (16), 137 (34), 121 (51), 93 (18). Anal. calcd. for $C_{20}H_{20}N_2O_4$ (%): C 68.17, H 5.72, N 7.95; found: C 68.22, H 5.77, N 7.96.

10-(4-Methylbenzoylamino)-3,4,6,7,9,10-hexahydro-1,8(2*H*,5*H*)acridinedione (3c)

Greenish yellow solid; yield 86%; mp 148–150 °C. IR (KBr, cm^{-1}) 3450, 1681, 1624, 1577, 1384. ^{1}H NMR (90 MHz, $CDCl_3$-DMSO-d_6) δ: 1.80–2.10 (m, 7H, C_3, C_6-CH_2 and Ar-CH_3), 2.20–2.40 (m, 8H, C_2, C_4, C_5 and C_7-CH_2), 3.00 (br s, 2H, C_9-CH_2), 7.30 (d, 2H, J = 8 Hz, Ar-H), 7.80 (d, 2H, J = 8 Hz, Ar-H), 9.50 (s, 1H, NH). ^{13}C NMR (100.4 MHz, $CDCl_3$-DMSO-d_6) δ: 18.3, 20.7, 21.3, 24.2, 35.8, 111.2, 127.5, 129.1, 154.3, 166.7, 196.5. MS *m*/*z* (%): 350 (M^+, 18.3), 293 (6.1), 216 (100), 215 (97.9), 214 (90.4), 187 (93.5), 135 (51.8), 119 (100), 91 (73.4). Anal. calcd. for $C_{21}H_{22}N_2O_3$ (%): C 71.98, H 6.33, N 7.99; found: C 72.01, H 6.38, N 8.03.

10-(4-Methoxybenzoylamino)-3,4,6,7,9,10-hexahydro-1,8(2*H*,5*H*)acridinedione (3d)

Pale brown solid; yield 81%; mp 228–230 °C. IR (KBr, cm^{-1}) 3471, 1654, 1614, 1585, 1388. ^{1}H NMR (90 MHz, $CDCl_3$) δ: 2.01 (m, 4H, C_3 and C_6-CH_2), 2.33 (m, 8H, C_2, C_4, C_5, and C_7- CH_2), 3.11 (m, 2H, C_9-CH_2), 3.86 (s, 3H, OCH_3), 7.01 (d, 2H, J = 8 Hz, Ar-H), 7.90 (d, 2H, J = 8 Hz, Ar-H). ^{13}C NMR (50 MHz, $CDCl_3$-DMSO-d_6) δ: 18.7, 20.8, 24.53, 36.0, 55.6, 111.2, 114.2, 122.5, 129.7, 155.8, 163.4, 166.6, 197.7. MS *m*/*z* (%): 216 (0.32), 215 (1.9), 187 (9.8), 159 (3.2), 151 (8.1), 135 (29.6), 107 (9.4), 104 (10), 103 (16.8), 77 (76.5). A comparison of the energetic and topological properties of weak interactions in molecular organic crystals

David J. Wolstenholme and T. Stanley Cameron

Abstract: Several molecular organic crystals [tetraphenylphosphonium squarate, bianthrone, and bis(benzophenone) azine] have been analyzed topologically following a multipole refinement of each compound. This has resulted in the complete characterization of all the weak interactions present in these systems (C-H···O, C-H···C, and C-H$^{\delta+}$···$^{\delta+}$H-C). Correlations have been found to exist between the energetic and topological properties for each type of interaction. The coexistence of the three types of interactions provides a unique opportunity to examine their energetic differences and similarities. This examination can also be used to help understand the complex nature of C-H$^{\delta+}$···$^{\delta+}$H-C type interactions, in particular those characterized as H–H bonds. All this leads to a better understanding of the role H–H bonds play in molecular organic crystals compared with other weak interactions such as hydrogen bonds and van der Waals interactions.

Key words: energetics, multipole refinement, H–H bonds, hydrogen bonds.

Résumé : Faisant appel pour chaque composé à une méthode de raffinement multipolaire, on a fait une analyse topologie de plusieurs cristaux moléculaires organiques, dont le squarate de tétraphénylphosphonium, la bianthrone et la bis(benzophénone)azine. Ces analyses ont permis de faire une caractérisation complète de toutes les interactions faibles qui sont présentes dans ces systèmes, telles C-H···O, C-H···C et C-H$^{\delta+}$···$^{\delta+}$H-C. On a trouvé qu'il existe des corrélations entre les énergies et les propriétés topologiques de chaque type d'interaction. La coexistence de ces trois types d'interaction fournit une opportunité unique d'examiner les similarités et les différences dans les énergies. Cet examen peut aussi être utilisé pour mieux comprendre la nature complexe des interactions du type C-H$^{\delta+}$···$^{\delta+}$H-C, en particulier celles caractérisées par des liaisons H–H. Tout ceci conduit à une meilleure compréhension du rôle des liaisons H–H dans les cristaux moléculaires organiques par comparaison avec d'autres interactions faibles, telles les liaisons hydrogènes traditionnelles et les interactions de van der Waals.

Mots-clés : énergie, raffinement multipolaire, liaisons H–H, liaisons hydrogènes.

[Traduit par la Rédaction]

Introduction

The study of hydrogen bonds and other weak interactions in molecular organic crystals has been a key area of research in organic chemistry. This is a result of the important role these interactions play in solid-state chemical processes (1, 2). Until recently, only classical strong hydrogen bonds (O-H···O, N-H···O, and N-H···N) were studied in any great detail. However, over the past 20 years weaker C-H···O and C-H···N interactions have gained considerable attention (3–6). These types of weak interactions have been shown to play an important role in the formation and stability of molecular organic crystals lacking stronger intermolecular interactions (3). During the early 1990s a new type of weak interaction of the form C-H$^{\delta+}$···$^{\delta-}$H-M, where M represents a transition metal, was discovered (7). These interactions were shown to possess properties similar to those of weak to moderately strong hydrogen bonds and were classified as dihydrogen bonds. Since that time, a number of experimental and theoretical studies have been conducted on the topology and energetics of these weak interactions (8, 9). This in turn has lead to experimental and theoretical studies of interactions containing two hydrogen atoms of similar charge (C-H$^{\delta+}$···$^{\delta+}$H-C and C-H$^{\delta-}$···$^{\delta-}$H-C) (10–15). Early studies performed by Cioslowski and Mixon proposed that these types of interactions were best classified as classical nonbonding steric interactions (16). However, an overwhelming number of experimental (17–26) and theoretical (27–36) studies have provided evidence for a bonding interaction between the two hydrogen atoms in this class of H–H interaction. These H–H interactions were initially believed to be dihydrogen bonds, however, observations made by Matta et al. (10, 14) have shown that the electronic properties of the two hydrogen atoms in these interactions differ significantly from those of dihydrogen bonds (or hydrogen bonds in general). Therefore, this new category of weak interactions was given the name H–H bonds.

The experimental examination of the electron density in molecular organic crystals commonly uses the atoms in molecules (AIM) methodology, particularly when intermolecular interactions (hydrogen bonds or van der Waals interactions) are involved (37–39). The AIM theory states that in a bound equilibrium molecular state, the nuclei of the bonded atoms are linked by a line in which the electron density is a maximum with respect to any neighboring lines, which is referred to as a bond path (BP) (40). Along this BP, the minimum in the electron density represents a (3, –1) critical point that can be thought of as the gateway between two bonded atoms. According to the quantum theory of atoms in molecules (QTAM), both the BP and BCP are considered essential for a bond to exist between two atoms (40). Thus, the interpretation of BCP properties provides useful information about the nature of chemical bonding in weak interactions.

Several properties of the electron density at the BCP can be used to characterize and understand these weak interactions. The rho value, $\rho(r_{cp})$, represents the amount of electron density accumulated at the critical point between the two bonded atoms. In the case of an open-shell interaction (covalent bonds) $\rho(r_{cp})$ values are greater than 0.5 eÅ^{-3}, whereas in closed-shell interactions (hydrogen bonds or van der Waals interactions) $\rho(r_{cp})$ values are generally less than 0.5 eÅ^{-3}. The Laplacian, $\nabla^2\rho(r_{cp})$, contains a wealth of information with respect to the charge concentration accumulated in any particular type of bond. If the $\nabla^2\rho(r_{cp})$ value > 0, the charge concentration is locally depleted at the BCP, as occurs in closed-shell interactions. If the $\nabla^2\rho(r_{cp})$ value < 0, then the charge concentration is locally concentrated at the BCP, which is typical of a covalent bond (41). Additional parameters used to characterize weak interactions are the potential energy density, $V(r_{cp})$, and the kinetic energy density, $G(r_{cp})$ (42). Both the potential and kinetic energy densities can be calculated for closed-shell interactions using Abramov's approximations as follows:

$$[1] \qquad G(r_{cp}) = (3/10)(3\pi^2)^{2/3}\ \rho^{5/3}(r_{cp}) + (1/6)\ \nabla^2\rho(r_{cp})$$

$$[2] \qquad V(r_{cp}) = (\hbar^2/4m)\ \nabla^2\rho(r_{cp}) - 2G(r_{cp})$$

These equations show that closed-shell interactions are dominated by a local excess in the kinetic energy and open-shell interactions are dominated by a lowering of the potential energy (14). It should also be noted that the bond energies for closed-shell interactions can be approximated from their potential energy density through the following relationship (37),

$$[3] \qquad \text{Bond energy} = (1/2)\ V(r_{cp})$$

These bond energy estimates have been shown to be in very good agreement with Hartree–Fock calculations for interactions in the medium range from the atomic nuclei, which falls in the region of weak interactions (42).

This study evaluates 50 weak intra- and inter-molecular interactions examined experimentally using X-ray crystallographic charge density studies. These interactions range from C-H···O hydrogen bonds to H–H bonds as found in three molecular crystals: (tetraphenylphosphonium squarate [TPS], bianthrone [BIAN], and bis(benzophenone) azine [AZINE]) (Figure 1). With these 50 interactions a series of correlations have been obtained between the energetic and topological properties of the electron density for each type of interaction. Analysis of these results has led to a better understanding of the electronic and energetic nature of C-H$^{\delta+}\cdots^{\delta+}$H-C interactions and how they relate to other weak interactions.

Experimental

The three organic crystals (TPS, BIAN, and AZINE) were all found to be colorless prisms. They were each mounted on the end of a Lindemann glass capillary, since a tube has a greater resistance to vibration than a fiber of the same cross-section. The low-temperature high-resolution single crystal X-ray diffraction data were collected on a Rigaku RAPID area detector [TPS] and a Saturn 70 CCD diffractometer [BIAN and AZINE] using Mo Kα radiation (6, 15). The crystallographic details of the refinement can be found in Table 1. The details of the collection and treatment of the crystals in order to obtain high resolution, large redundancy, and better completeness in all three of the data sets have been explained in detail elsewhere (6, 15). The CIF files are available in the Supplementary data.[2]

Multipole refinement

Charge density studies require high-resolution X-ray data obtained at low temperature. The electron density used to topologically evaluate the electron distribution in a crystal can be obtained through the multipole expansion method, which incorporates the Hanson–Coppens model (43). Where ρ_{core} and $\rho_{valence}$ are spherically averaged Hartree–Fock core and valence densities, $d_{lm\pm}$ represents the spherical harmonic angular functions, R_l is the radial function, κ and κ′ are the expansion–contraction parameters, and P_v and $P_{lm\pm}$ represent the population parameters.

$$[4] \qquad \rho(\boldsymbol{r}) = P_c\rho_{core}(\boldsymbol{r}) + P_v\kappa\rho_{valence}(\kappa\boldsymbol{r}) + \sum_{1=0}^{I_{max}}\kappa'^3\rho_{valence}(\kappa\boldsymbol{r})\sum_{m=0}^{I_{max}}P_{lm\pm}d_{lm\pm}(\theta,\phi)$$

The multipole refinement of the three molecules was carried out with the XDLSM module, which is incorporated in the XD software package (44). Any residual bonding density not modeled in the conventional spherical refinement was taken into account in the multipole refinement. The scattering factors used throughout the three multipole refinements were those derived by Clementi and Raimondi for all atoms (45). The least-squares refinements involved the minimization of

the $\sum w(|F_o| - K|F_c|)^2$ function for all reflections with $I > 3\sigma(I)$. Only a general procedure for the multipole refinement of the three compounds will be presented here, since a more detailed description has been included in our previous work (6, 15). Initially, the positional, thermal parameters, and the scale factor were refined to make sure the data was transferred from the conventional spherical refinement to the XD program correctly. This was followed by a high-order refinement (sin θ/λ ≥ 0.6 or 0.7 Å) to obtain accurate positional and thermal parameters for the heavy atoms. Next, a low-order refinement (sin θ/λ ≤ 0.6 or 0.7 Å) was carried out to obtain initial positions and accurate isotropic thermal parameters for the hydrogen atoms. The bond lengths involving the hydrogen atoms were fixed to the distance reported from accurate neutron diffraction data of similar compounds (C_{ar}-H = 1.08 Å) since neutron diffraction data was not available for these compounds (46, 47). The next step in the refinements involved releasing the monopole, dipole, quadrupole, octapole, and, if necessary, the hexadecapole populations with all the heavy atom κ parameters in a stepwise manner. This was followed by a single κ′ term for each of the chemically unique heavy atoms in each structure being refined. Finally, all parameters were combined and refined except the κ′ parameters. This procedure was then cycled through until convergence was achieved. Throughout the multipole refinement, the κ and κ′ parameters for the hydrogen atoms in all three compounds were left fixed at the default XDLSM value of 1.2. The XDPROP module incorporated into the XD package was then used to evaluate the topological properties of the electron density for all three

compounds (44). The quality of the refinements can be seen in the static deformation maps of the three compounds, examples of which are shown in Fig. 2. All static, residual, dynamic, and deformation maps were produced using the XDGRAPH option in the XD package (44).

Results and discussion

In previous publications, we have reported a large set of experimental data in which the topological properties of 16 C-H···O interactions (13 TPS and 3 BIAN), 22 C-H···C interactions (11 TPS, 7 BIAN, and 4 AZINE), and 12 C-H$^{\delta+}$···$^{\delta+}$H-C interactions (3 TPS, 4 BIAN, and 5 AZINE) were characterized as either hydrogen bonds, H–H bonds or van der Waals interactions (6, 15). The TPS structure was shown to contain seven weak hydrogen bonds (5 C-H···O and 2 C-H···C), 2 H–H bonds, and 18 van der Waals interactions. Similarly, the BIAN structure was shown to contain 2 C-H···O hydrogen bonds, one H–H bond, and 11 van der Waals interactions. Finally, the AZINE study showed that the crystal contained 2 unique H–H bonds and 10 unique van der Waals interactions. It should be noted that there are two types of interactions classified as C-H···C interactions. The first type (C-H···C$_\pi$) involves a bond path starting off in the direction of a "carbon–carbon" π system then terminating at a carbon acceptor (Fig. 3*a*). The second type (C-H···C) involves a bond path directly from a hydrogen donor to a carbon acceptor (Fig. 3*b*). These two types of C-H···C interaction are grouped together for this study since they possess similar topological and energetic properties. A large variety of interactions are therefore available to study correlations between the energetic and topological properties of the electron density for the three types of weak interactions. The relevant topological values for the H–H interactions can be found in Table 2.

The pioneering work on the topological and energetic correlations of weak interactions has been carried out by Espinosa et al. (37–39). These studies focused on the correlations of weak interactions of the form C-H···O, C-H···N, and C-H···C.

Recently, these types of correlations have been extended to a variety of theoretical dihydrogen bonds (48). However, experimental energetic correlations of H–H interactions, in particular C-H$^{\delta+}$···$^{\delta+}$H-C interactions, have not been investigated in much detail. This subclass of weak interactions has also been found to produce similar correlations between the properties of the electron density at the BCP and the energetic properties. These correlations can be used to understand the electronic and energetic nature of C-H$^{\delta+}$···$^{\delta+}$H-C interactions and H–H bonds, as well as provide insight into the energetic similarities or differences of these interactions from other weak interactions.

According to the second criterion proposed for hydrogen bonding by Koch and Popelier (49, 50), there must be a certain accumulation of electron density at the BCP for an interaction to be considered a hydrogen bond. This has recently been applied to interactions of the form C-H$^{\delta+}$···$^{\delta+}$H-C to characterize them as H–H bonds (15). Thus, a reasonable place to begin looking for correlations between the bond energies and the properties of the electron density is with a correlation involving $\rho(r_{cp})$. Figure 4 shows the correlations between the electron density at the BCP and the bond energies for the C-H$^{\delta+}$···$^{\delta+}$H-C, C-H···C, and C-H···O interactions. It is clear that the bond energies increase in a linear fashion as $\rho(r_{cp})$ increases for all three types of interactions. It can also be observed that the H–H correlation is almost identical to that of the C-H···O correlation. This indicates that the H–H interactions and C-H···O interactions accumulate similar amounts of electron denity when the interactions are of similar energy. This may indicate that they adopt similar roles in the crystal packing of small organic molecules. Interestingly, only the H–H interactions classified as H–H bonds fall in the same region as the C-H···O interactions. This would seem to further indicate that H–H bonds are uniquely different from other forms of C-H$^{\delta+}$···$^{\delta+}$H-C interactions. In addition, it can be seen that the bond energies increase at a slower rate for C-H···C interactions than they do for the other two types of interactions. This seems to be consistent with the fact that C-H···C interactions are usually weaker than interactions of the C-H···O type and are generally classified as van der Waals interactions. These correlations also indicate that at a certain point the C-H$^{\delta+}$···$^{\delta+}$H-C interactions start to become stronger than C-H···C interactions. The point at which the C-H$^{\delta+}$···$^{\delta+}$H-C interactions start to become stronger then the C-H···C interactions is where the H–H interactions begin to be classified as H–H bonds. This progression from C-H$^{\delta+}$···$^{\delta+}$H-C interactions in the van der Waals region (same region as C-H···C interactions) to the

[a]H–H interactions that are classified as H–H bonds

H–H bonding region (similar to weak C-H···O hydrogen bonds) seems to indicate a change in the way the two positively charged hydrogen atoms interact. This provides further evidence of a bonding interaction occurring between the two positive hydrogen atoms.

A recent theoretical study on a wide range of dihydrogen bonds has shown a similar linear fit between $\rho(r_{cp})$ and the bond energies as the C-H$^{\delta+}$···$^{\delta+}$H-C interactions in the three crystals of interest (48). These authors conclude that there is no actual clear separation between hydrogen bonds and dihydrogen bonds when comparing $\rho(r_{cp})$ values, consistent with the observations made for H–H interactions involving two positively charged atoms. This provides further support for the energetic and topological nature of H–H interactions, compared with other weak interactions.

The third Koch and Popelier criterion (49, 50) requires that a certain amount of charge depletion must occur at the BCP for an interaction to be classified as a hydrogen bond. This criterion has also been successfully used to distinguish between H–H bonds and van der Waals interactions of the form C-H$^{\delta+}$···$^{\delta+}$H-C (15). Figure 5 shows the correlations between the Laplacian of the electron density at the BCP, $\nabla^2\rho(r_{cp})$, and the bond energy for the three types of interactions present in the compounds of interest. The bond ener-

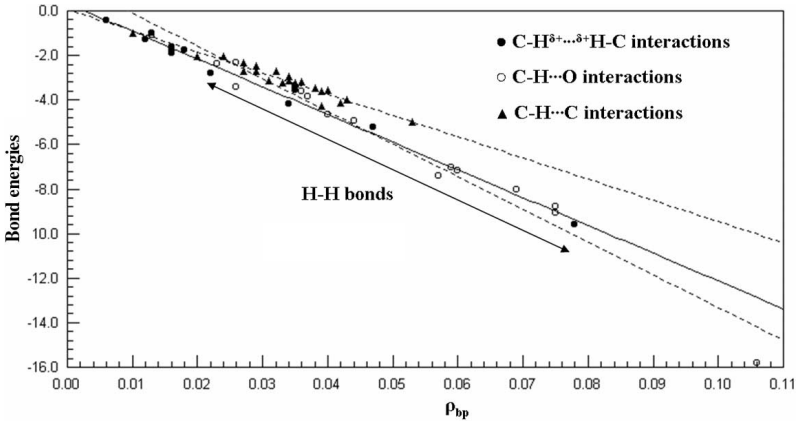
The dashed lines represent the fitting of the C-H···C and C-H···O interactions ($R^2 = 0.94$ and 0.97, respectively). The solid line represents the fitting of the C-H$^{\delta+}$···$^{\delta+}$H-C interactions ($R^2 = 0.99$).



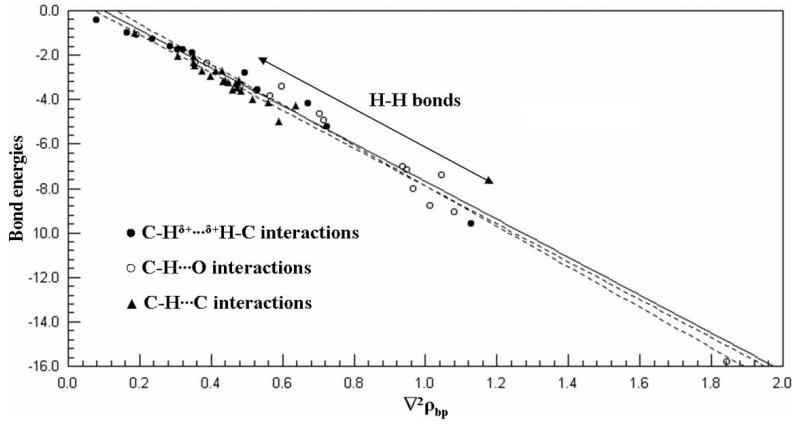


Fig. 5. Linear dependence of the bond energy [kJ mol^{-1} bohr^{-3}] on the $\nabla^2\rho_{cp}$ at the BCP [eÅ^{-5}] ($y = ax + b$) for all the weak interactions of TPS, BIAN, and AZINE. The dashed lines represent the fitting of the C-H···C and C-H···O interactions ($R^2 = 0.92$ and 0.98, respectively). The solid line represents the fitting of the C-H$^{\delta+}$···$^{\delta+}$H-C interactions ($R^2 = 0.99$).

gies associated with all three types of interactions increase in a linear fashion with increasing $\nabla^2\rho(r_{cp})$ values. Unlike the correlation between the bond energy and $\rho(r_{cp})$, the $\nabla^2\rho(r_{cp})$ correlations for each of the three types of interactions show almost identical fits. Previous studies of the correlation between $\nabla^2\rho(r_{cp})$ and R_{ij} (interaction length) have shown that depletion of the charge density for C-H$^{\delta+}$···$^{\delta+}$H-C interactions is less than that for other weak interactions of similar R_{ij} values (15). Since no difference between the $\nabla^2\rho(r_{cp})$ and bond energy correlations is observed for each type of interaction, this seems to indicate that the strength of an interaction is an important factor in the amount of charge density accumulated or depleted in a bond. This seems reasonable since the overlap in R_{ij} values falls in the weaker portion for H–H interactions and in the stronger portion of the C-H···C and C-H···O interactions. It should also be noted that theoretical results on dihydrogen bonds show no significant difference from hydrogen bonds (48).

Correlations between interaction lengths, R_{ij}, and the other properties of the electron density at the BCP are not part of Koch and Popelier's criteria for hydrogen bonding (49, 50). However, they are still commonly used to distinguish between hydrogen bonds, H–H bonds, and van der Waals interactions (4, 5, 15). It has previously been shown that correlations exist between the internuclear distance (the direct distance between two atoms) and the bond energies for C-H$^{\delta+}$···$^{\delta+}$H-C interactions (9). However, the experimental correlations between R_{ij} and the bond energies have yet to be investigated in any great detail for interactions of this form.

Figure 6 shows the exponential correlations ($y = a\exp(bx)$) between the bond energies and the R_{ij} values for all three types of interactions. It can be seen that the bond energies for each type of interaction increase as the R_{ij} values decrease. The C-H···O and C-H···C interactions appear to follow almost the same exponential curve, with the only difference being in the R^2 values. In the case of the C-H···O interactions the R^2 value is 88.6% and for the C-H···C interactions it is 66.2%, which appears to show a trend in the data but no clear correlation. The C-H···C interactions follow the same curve as the C-H···O interactions for the larger R_{ij} values and possess similar R^2 values. However the lack of interactions below 2.7 Å for the C-H···C interactions gives rise to a poor exponential fit, while the inclusion of points below 2.7 Å for the C-H···O interactions gives rise to a rea-

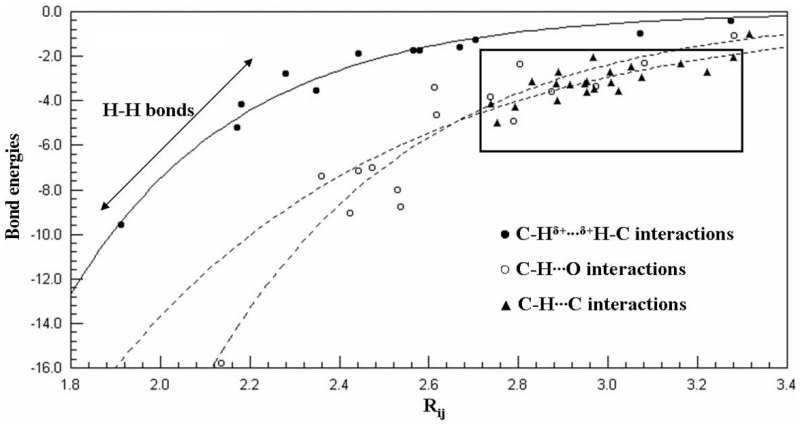

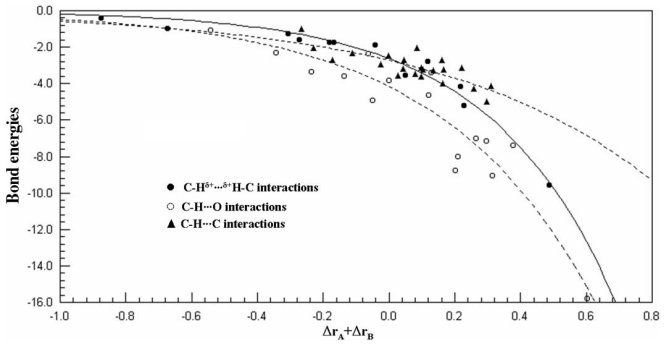

Fig. 7. Exponential dependence of the bond energy [kJ mol^{-1} bohr^{-3}] on the ($\Delta r_A + \Delta r_B$) [Å] ($y = a \exp(bx)$) for all the weak interactions of TPS, BIAN, and AZINE. The dashed lines represent the fitting of the C-H···O interactions ($R^2 = 0.89$) and the C-H···C interactions ($R^2 = 0.66$). The solid line represents the fitting of the C-H$^{\delta+}$···$^{\delta+}$H-C interactions ($R^2 = 0.97$).

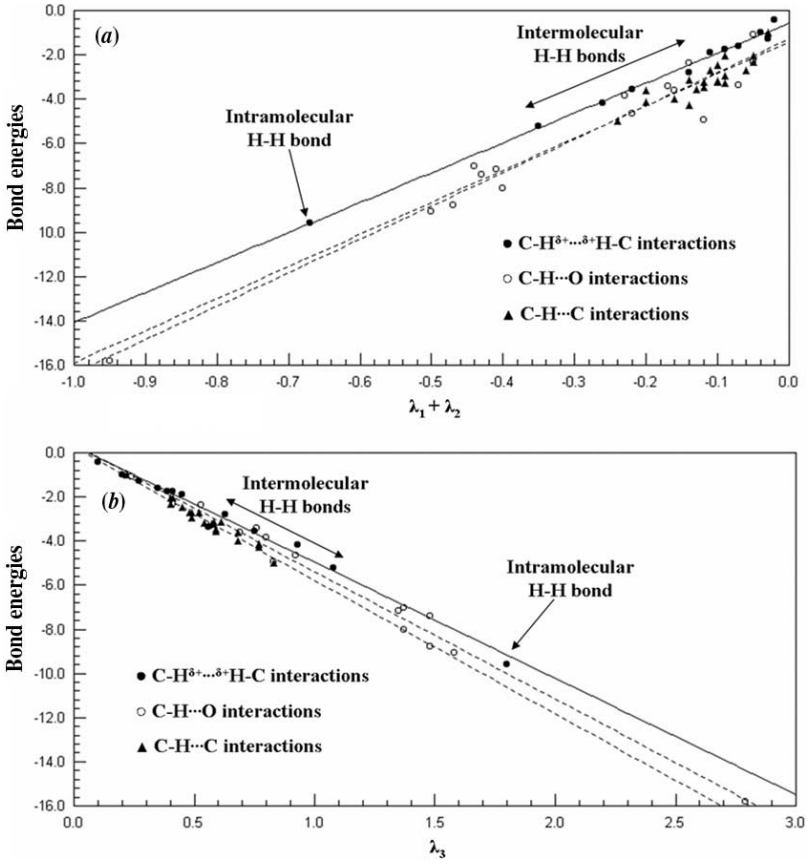

sonable exponential fit (Fig. 6). The lack of C-H···C interactions below 2.7 Å is a direct result of the weak nature of this type of interaction.

A comparison of the correlations between the bond energies and R_{ij} for the C-H$^{\delta+}$···$^{\delta+}$H-C interactions and the other types of weak interactions further demonstrates the fact that the H–H interactions are part of a different population (15). It is clear from Fig. 6 that C-H$^{\delta+}$···$^{\delta+}$H-C interactions require smaller R_{ij} values to obtain similar bond energies to those of C-H···O and C-H···C interactions. This can be attributed to the smaller size of the donor and acceptor atoms involved in C-H$^{\delta+}$···$^{\delta+}$H-C interactions, where the other types of weak interactions involve larger heteroatoms such as oxygen or carbon. Again, the theoretical results for dihydrogen bonds involving intermolecular distances show similar exponential trends as those observed in the R_{ij} correlations for the above interactions (48). Interestingly, the theoretical results extend to shorter intermolecular distances for the H–H interactions but still maintain the expected exponential fit.

The fourth Koch and Popelier criterion for hydrogen bonding (the mutual penetration of the two atoms concerned) is crucial for the characterization of weak hydrogen bonds (49, 50). This criterion has also been shown to be essential for the characterization of H–H bonds (15). Thus, it is important to establish correlations between the mutual penetration values ($\Delta r_H + \Delta r_A$) and the bond energies when looking at the nature of the three interactions of interest. This type of correlation is also important in comparing the energetic differences between H–H bonds and hydrogen bonds. In this work, the nonbonding radius for carbon is taken as 1.85 Å, oxygen as 1.54 Å, and hydrogen as 1.2 Å (51, 52). Figure 7 shows the exponential dependence of the bond energies on the $\Delta r_H + \Delta r_B$ values for all three types of interactions. These correlations show that the bond energies for each type of interaction increase as the $\Delta r_H + \Delta r_B$ values increase. Again, all three types of interactions appear to fit different exponential curves. A direct comparison between the C-H$^{\delta+}$···$^{\delta+}$H-C correlation and the C-H···C correlation cannot be made because of the poor fit made by the C-H···C type interactions. However, it appears that the bond energies increase at a faster rate for the C-H$^{\delta+}$···$^{\delta+}$H-C interactions than for the C-H···C interactions. This seems to indicate that at a certain point the C-H$^{\delta+}$···$^{\delta+}$H-C interactions will require less penetration to achieve bond energies similar to those of C-H···C interactions. One of the possible reasons for the C-H···C interactions possessing a poor exponential goodness of fit (R^2 value) could be the lack of points in the higher mutual penetration area of the plot, a direct reflection of their weak nature. The opposite trend is observed between the C-H$^{\delta+}$···$^{\delta+}$H-C correlation and the C-H···O correlation, where the C-H···O bond energies increase at a faster rate than those of the C-H$^{\delta+}$···$^{\delta+}$H-C interactions. This justifies the idea that

The dashed lines represent the fitting of the C-H···C and C-H···O interactions ($R^2 = 0.96$ and 0.99, respectively). The solid line represents the fitting of the C-H$^{\delta+}$···$^{\delta+}$H-C interactions ($R^2 = 0.99$).

H–H bonds fit somewhere between C-H···O and C-H···C hydrogen bonds in the hierarchy of weak interactions.

Linear correlations can be observed between the bond energies and the sum of the negative curvatures ($\lambda_1 + \lambda_2$) and the positive curvature (λ_3) for the three types of weak interactions. Figures 8*a* and 8*b* show that intermolecular H–H bonds tend to possess bond energies similar to C-H···C interactions and intramolecular H–H bonds tend to fall in the middle region of the C-H···O hydrogen bonds. This shows that the geometry of a crystalline compound plays a significant role in the formation and strengths of H–H bonds. These two linear relationships show that H–H bonds require larger λ_1, λ_2, and λ_3 values than C-H···O and C-H···C hydrogen bonds of equivalent bond energies. This is not the case for H–H interactions classified as van der Waals interactions, which have similar curvatures to those of other van der Waals interactions.

It has previously been shown that $V(r_{cp})$ and $G(r_{cp})$ are related to the deconvoluted contributions of the concentration or depletion of electrons at the BCP for hydrogen bonds, since they represent the pressures exerted on the atomic basins on the electrons around the BCP and vice versa (37, 38). It has also been found that the energy densities are intrinsically related to the curvatures of the electron density at the BCP in a linear fashion. This has also been observed for the three types of weak interactions of interest in this study (see Supplementary data).[2] Thus, $\lambda_1 + \lambda_2$ and λ_3 can be used to measure directly the amount of deconvoluted concentration and depletion of electrons at the BCP for weak interactions either along or perpendicular to the bond path. The values of both the positive and negative curvatures of the electron density for the H–H bonds are significantly larger then those of the corresponding C-H···C and C- H···O interactions of similar energy. In this way, H–H bonds lead to a thinner topological overlap to obtain similar energies. This is a result of an increase in the repulsive $G(r_{cp})$ magnitude along the bond path, which increases λ_3 and depletes the electron density to the atomic basin. A larger repulsive $G(r_{cp})$ magnitude would be expected for H–H bonds, since they involve two positively charged atoms, which will result in greater repulsion between the two atoms. The larger $\lambda_1 + \lambda_2$ values [or $V(r_{cp})$] for H–H bonds indicates a greater concentration contribution perpendicular to the bond path than that of C-H···C and C-H···O interactions of similar energy.

Conclusion

The use of high-resolution X-ray data for the topological

study of three organic molecules has led to investigations of a series of correlations between the bond energies and several properties of the electron density at the BCP for C-H$^{\delta+}$...$^{\delta+}$H-C, C-H···C, and C-H···O interactions. It has been shown that the bond energies for H–H bonds fall within the range of weak to moderate hydrogen bonds depending on the geometry present in the crystalline state. This study has also shown that a comparison of $\rho(r_{cp})$ values between the three types of interactions leads to a progression of H–H interactions that are van der Waals in nature to H–H bonds. The curvatures at the BCP for H–H bonds have also been shown to have thinner topological overlap than other weak interactions of similar energy. These correlations have helped to show that the bond energies associated with H–H bonds have a wide range and are comparable to those of weak hydrogen bonds. Finally, this study has led to a better understanding of how the energetic properties of C-H$^{\delta+}$...$^{\delta+}$H-C interactions play a significant role in the formation and stability of molecular organic crystals.

X-Ray structures and binding properties of molecular clips based on diethoxycarbonyl glycoluril

Bao H. Zhou, Li P. Cao, Guo D. Yin, M. Gao, and An X. Wu

Abstract: The crystal structures of two molecular clips derived from diethoxycarbonyl glycoluril were reported. Their unique binding behavior towards hydroquinone, which is different from Nolte's clips (high affinity for resorcinol), has been characterized through ^{1}H NMR and IR. Job-plot analyses provide good evidence of a 1:1 stoichiometry for the complexes.

Key words: crystal structure, molecular clips, binding properties

Résumé : On a déterminé les structures cristallines de deux clips moléculaires dérivés du diéthyoxycarbonylglycouril. Faisant appel à la spectroscopie IR et à la RMN du ^{1}H, on a caractérisé leur comportement de liaison unique vis-à-vis de l'hydroquinone qui est différent de celui des clips de Nolte qui ont une grande affinité pour le résorcinol. De plus, une analyse à l'aide de courbes de Job permet d'obtenir de bonnes indications à l'effet que la stoechiométrie de ces complexes est 1:1.

Mots-clés : structure cristalline, clips moléculaires, propriétés de fixation.

[Traduit par la Rédaction]

Introduction

The design and synthesis of host molecules for the binding of neutral guests continues to be an area of great interest in supramolecular chemistry (1–3). Research in Nolte's laboratory has for some time been focused on the development of receptors derived from the concave molecule diphenylglycoluril (4–8), which show high affinity for resorcinol by means of hydrogen bonding between the hydroxyl groups of the guest and the urea carbonyl groups of the host and by π–π stacking interactions between the guest and the host side walls. In addition, similar clips synthesized by Chen and coworkers (9) also showed high affinity for resorcinol but no conspicuous complexation with hydroquinone.

Here, we report the crystal structures of two molecular clips (Figs. 1, 2) derived from diethoxycarbonyl glycoluril with larger cavities compared with Nolte's 3U clip. In addition, their unique binding behavior towards hydroquinone has been investigated.

Results and discussion

According to the general procedure in our laboratory, we synthesized two clips **4U-CC** and **4U-(±)CT** (for the complexation studies, the racemate was used) (10–12) and obtained their crystal structures. Both molecular clips can self-associate into the dimer (Fig. 3) in the crystal but as monomer in the solution of $CDCl_3$, which has been verified by the crystallographic study and ^{1}H NMR analysis (10). In the self-associated dimer, the cavity of one monomer is filled by one of the two aromatic side walls of its dimeric partner and vice versa.

In X-ray single-crystal structure, either from the centroid distance of the side walls or from the height of the cavity, both revealed that the two molecular clips have larger cavities than those of Nolte's 3U clips (4–8) (Fig. 2, Table 1). In addition, the distances of the oxygen atoms O10···O11 or O4···O5, as hydrogen-binding sites on the two clips, are longer than that of Nolte's 3U clip. We assumed that larger clips such as **4U-CC** and **4U-(±)CT** might be as optimal synthetic receptors for different guests from Nolte's 3U clip.

With the aid of ^{1}H NMR, the binding properties of the two molecular clips were studied, and it was found that addition of hydroquinone to the solution of **4U-CC** or **4U-(±)CT** caused the NMR signals of the aromatic protons of the guest and the signals of the cavity-wall protons of the host to shift upfield (Fig. 4, Table 2), whereas the proton signals of the OH groups moved downfield (the Figures of

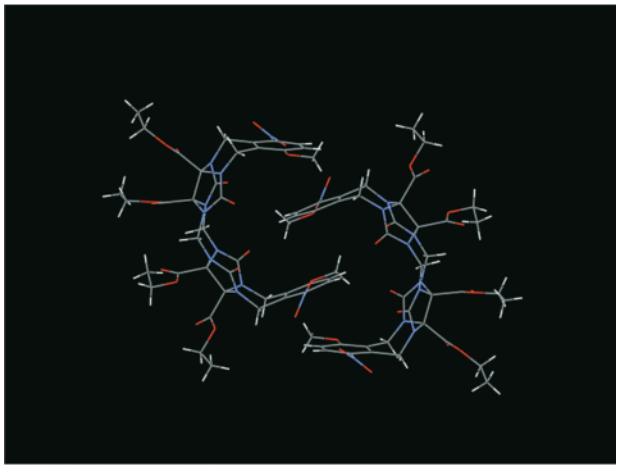
Table 1. Selected parameters from the X-ray crystal structures of **4U-CC**, **4U-(±)CT**, and Nolte's 3U clip.

Compound	=O···O= distance (Å)	Ar···Ar centroid distance (Å)	The height of the cavity (Å)
4U-CC	5.910(O11···O10) 5.793(O4···O5) 3.352(O4···O10) 3.384(O11···O5)	7.58	6.33
4U-(±)CT	5.753(O11···O10) 5.757(O4···O5) 3.729(O4···O10) 3.347(O11···O5)	7.58	6.07
Nolte's clip[a]	5.509	6.68	4.65

[a]As representative examples.

Fig. 3. X-ray structures showing dimers of **4U-CC** and **4U-(±)CT**.



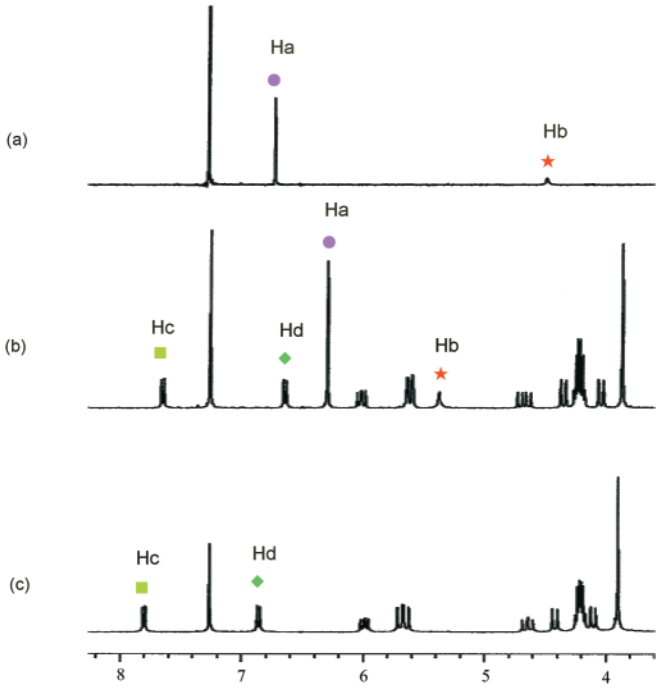


Fig. 4. Partial ^{1}H NMR spectra (400 MHz, $CDCl_3$, 298K) of (*a*) free guest hydroquinone, (*b*) the mixture of host **4U-CC** and guest hydroquinone (1:1), and (*c*) free host **4U-CC**.

complexes **4U-(±)CT** and hydroquinone have been deposited as Supplementary data).[2] These shifts indicate that complexes are formed, involving hydrogen bonds between the OH groups of the guest and the carbonyl groups of the host. Furthermore, they suggest that the aromatic moiety of the guest is wedged between the walls of the cavity. Only one signal was observed for the free and bound forms of the host and guest, implying that the exchange process is fast on the NMR time-scale.

Infrared spectroscopy was also used to investigate hydrogen bonding between hosts and guests (Fig. 5). The host carbonyl stretching vibration band is influenced by hydrogen bonding. IR spectra of compounds **4U-CC** mixed with hydroquinone shows that ν(C=O) splits into two bands (1760 and 1726 cm^{-1}) and **4U-(±)CT** mixed with hydroquinone shows that ν(C=O)

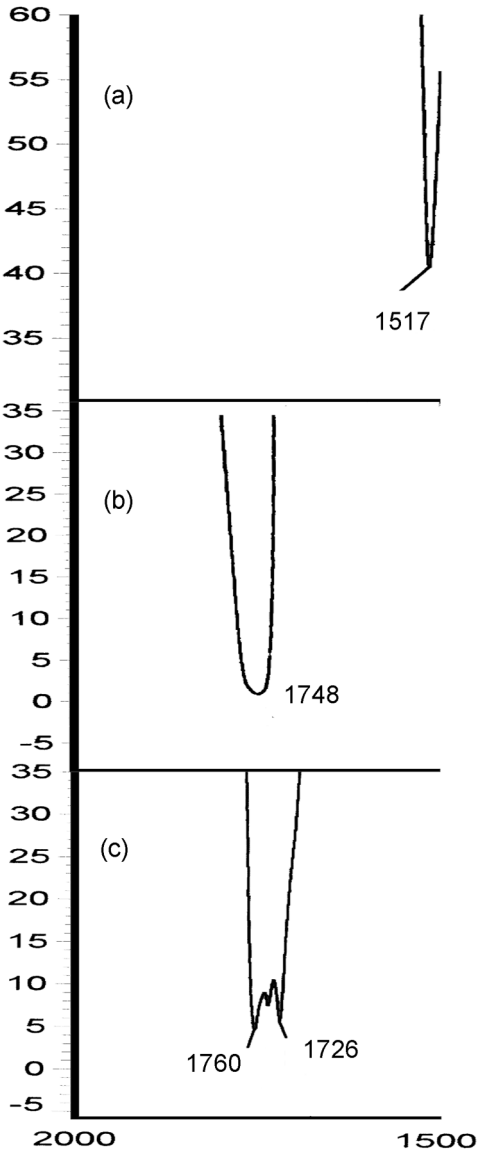
Free **4U-(±)CT**					7.816	6.895		
4U-(±)CT-hydroquinone	6.103	5.843	0.612	1.367	7.603	6.598	0.213	0.397

Fig. 5. IR spectra of (*a*) hydroquinone, (*b*) **4U-CC**, and (*c*) a mixture of hydroquinone and **4U-CC**.



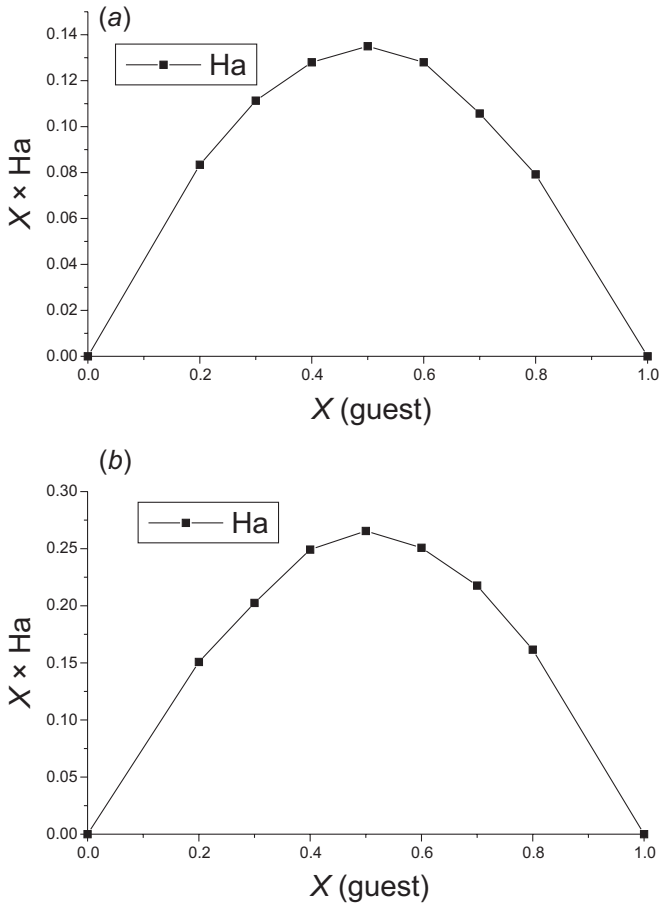


Fig. 6. Job-plot analysis of the stoichiometry between (*a*) **4U-CC** and hydroquinone and (*b*) **4U-(±)CT** and hydroquinone at 25 °C in $CDCl_3$.

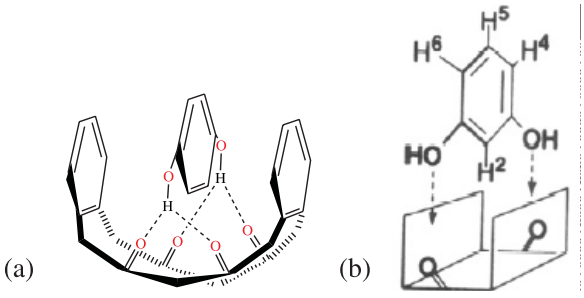
splits into two bands (1759 and 1737 cm^{-1}, Supplementary data).[2] This splitting indicates that the carbonyl groups of some hosts in the complexes are involved in hydrogen bonding. The Δν (24 and 22 cm^{-1}, respectively) values agree with values reported in the literature for hydrogen-bonded complexes of other urea derivatives with phenols (13).

Job-plot analyses (14, 15) were performed to determine the stoichiometry of the complexes **4U-CC** and hydroquinone as representative examples. The plot of the mole fraction *X* vs. the mole fraction multiplied by the complexation-induced ^{1}H NMR shift of the substrate shows a maximum at *X* = 0.5 (Fig. 6*a*). This provides good evidence of a 1:1 stoichiometry for the complexes, which is the same for the complex of **4U-(±)CT** and hydroquinone (Fig. 6*b*).



The results show that there exists hydrogen bonds and π–π stacking interactions in a binding process similar to Nolte's clips. But compared with Nolte's clip binding of resorcinol guest molecule, our molecular clips possess four oxygen atoms as binding sites, which strengthen the affinity for guests. According to the calculated distances of the oxygen atoms (Table 1), we assumed that our molecular clips might bind hydroquinone through bifurcated hydrogen bonds and π–π stacking interactions (Fig. 7)

Conclusion

The crystal structures of two clips derived from diethoxycarbonyl glycoluril have been presented. These molecules show high affinity for hydroquinone, which is different from Nolte's clips. In addition, the binding properties of the molecular clips with other guests were being investigated. The details will be reported later.

Experimental part

Crystal data for compounds **CC** and **(±)CT** are given in Table 3. Single crystals, suitable for X-ray crystallographic analyses, were obtained from a slow evaporation of the 1, 2-dichloroethane and methanol solutions. The crystal data of compounds were collected on Bruker SMART APEX CCD diffractometer. The SMART (version 5.628) program was used for collecting data frames, and SAINT Plus (version 6.45) was used for integration of the intensity of reflections and scaling. SADABS was used for absorption correction (16). Structures **CC** and **(±)CT** were solved by direct methods using the programs SHELXS-97 and refined by full matrix least-squares methods against F^2 with SHELXL-97 (17). During the refinement of the **(±)CT** structure, electron-density peaks were located so that they were believed to be highly disordered solvent molecules (possibly methanol). Attempts made to model the solvent molecule were not successful. The SQUEEZE option (18) in PLATON indicated there was a solvent cavity of volume 261.0 A^3 containing approximately 18 electrons. In the final cycles of refinement, this contribution to the electron density was removed from the observed data. All the hydrogen atoms were fixed at the calculated positions, and the positions of hydrogen atoms were refined by a riding model. All non-hydrogen atoms were refined with anisotropic displacement parameters.

Pyrazolo[3,4-*b*]pyridine in heterocyclic synthesis: synthesis of new pyrazolo[3,4-*b*]pyridines, imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridines, and pyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidines

Mohamed A.M. Gad-Elkareem, Azza M. Abdel-Fattah, and Mohamed A.A. Elneairy

Abstract: Pyrazolo[3,4-*b*]pyridine derivatives **7** and **9** were synthesized via the reaction of 3-amino-1*H*-pyrazolo-[3,4-*b*]pyridine derivative **2** with ω-bromoacetophenones. Reaction of **7** and **9** with Ac_2O afforded the imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridine derivative **8** and pyrazolo[3,4-*b*]pyridine derivative **10**, respectively. Reaction of **2** with chloroacetonitrile followed by DMF–DMA gave imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridines **4** and **5**, respectively. Acetylacetone and 1,1-dicyano-2,2-dimethylthioethene were reacted with **2** to afford the pyrido[2′,3′:3,4]pyrazolo-[1,5-*a*]-pyrimidines **11** and **14**, respectively. Also, **2** reacted with DMF–DMA to yield the formamidine **15**, which in turn, reacted with active methylene reagents, yielding the corresponding pyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidines **18** and **23a**–**23d**.

Key words: 1*H*-pyrazolo[3,4-*b*]pyridines, imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridines, pyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidines.

Résumé : On a réalisé la synthèse des dérivés pyrazolo[3,4-*b*]pyridines **7** et **9** par le biais d'une réaction de la 3-amino-1*H*-pyrazolo-[3,4-*b*]pyridine **2** avec des ω-bromoacétophénones. Les réactions de composés **7** et **9** avec l'anhydride acétique conduisent respectivement à la formation de la imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridine **8** et de la pyrazolo[3,4-*b*]pyridine **10**. La réaction du composé **2** avec le chloroacétonitrile, suivie d'un traitement avec du DMF et du DMA conduit à la formation respectivement des imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridines **4** et **5**. Les réactions de l'acétylacétone et du 1,1-dicyano-2,2-diméthylthioéthène avec le composé **2** conduisent respectivement à la formation des pyrido[2′,3′:3,4]pyrazolo-[1,5-*a*]pyrimidines, **11** et **14**. Le produit **2** réagit aussi avec le mélange DMF–DMA pour conduire à la formation d'une formamidine **15** qui réagit ensuite avec des réactifs portant des groupes méthylènes actifs pour conduire à la formation des [2′,3′:3,4]pyrazolo[1,5-*a*]pyrimides, **18** et **23a**–**23d**.

Mots-clés : 1*H*-pyrazolo[3,4-*b*]pyridines, imidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridines, pyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidines.

[Traduit par la Rédaction]

Introduction

1*H*-Pyrazolo[3,4-*b*]pyridines comprise a very interesting class of compounds because of their significant and versatile biological and pharmacological activities, such as antimalarial (1), antiproliferative (2), antimicrobial (3–5), inhibition of cyclin-dependent kinases (6), and cardiovascular (7–9), antiviral (10, 11), and antileishmanial (12) activities. Moreover, pyridopyrazolopyrimidines revealed antiproliferative activity (13) and are used as potent kinase inhibitors (14). In view of these reports and as a continuation of our pervious work (4, 5, 15–19) directed towards the synthesis of substituted condensed pyrazoles, we report a new and convenient method for the synthesis of such ring systems that are required in medicinal chemistry, utilizing 3-amino-1*H*-pyrazolo-[3,4-*b*]pyridine derivative **2**.

Results and discussion

Pyridine-2(1*H*)-thione derivative **1** reacted with hydrazine hydrate to afford the corresponding 3-amino-1*H*-pyrazolo[3,4-*b*]pyridine derivative **2** (20). The reactivity of compound **2** towards halo-reagents is studied in this paper. Thus, compound **2** reacted with chloroacetonitrile in potassium hydroxide – dimethyl formamide (DMF) solution to afford a reaction product **4**, which exhibited NH_2 (3454 and 3313 cm^{-1}) absorption bands in its IR spectrum with the absence of any absorption band due to C≡N function. The ^1H NMR spectrum of **4** revealed the singlet signal of two protons at δ = 3.91 ppm, assignable for NH_2, and a singlet signal of two protons at δ = 5.2 ppm characterized for CH_2. Based on the data obtained, the reaction product was formulated as 2-amino-3-hydroimidazo[1′,2′:1,5]pyrazolo[3,4-*b*]pyridine derivative **4**. The formation of **4** was assumed to

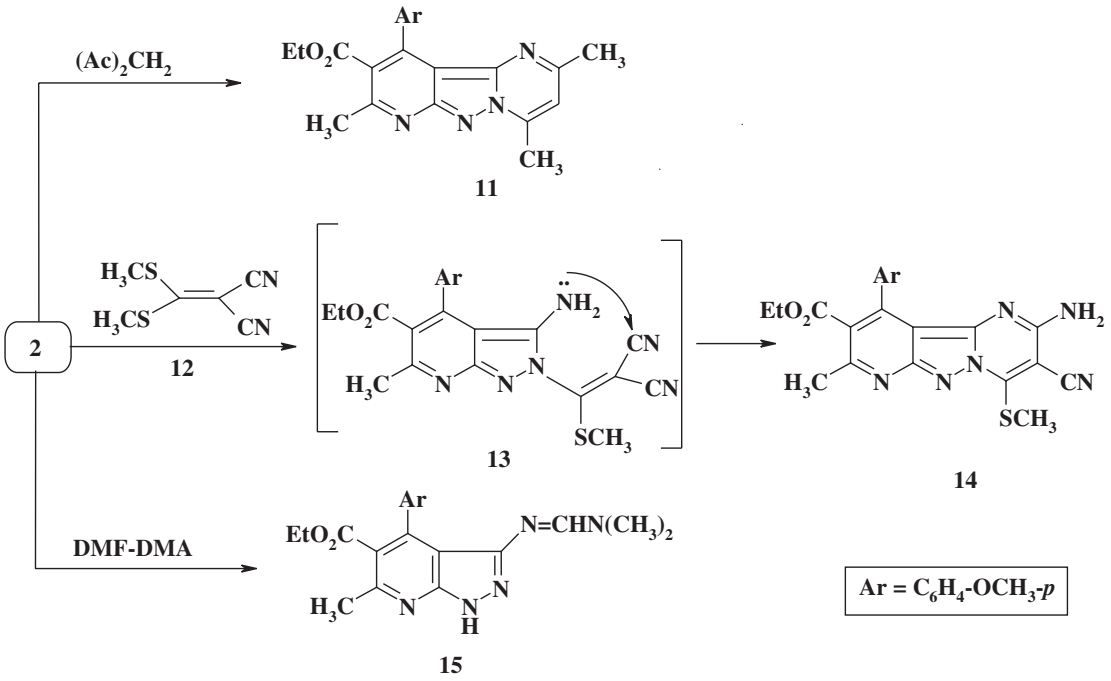
Scheme 1.

proceed via initial N-2 alkylation (21) of the ring nitrogen in compound **2** to give the non-isolable intermediate **3**, which underwent cyclization via addition of the amino group to the nitrile function to afford the final product, compound **4**. Condensation of **4** with dimethylformamide–dimethylacetal (DMF–DMA) in dry dioxane under reflux yielded the formamidine derivative **5**. The IR spectrum of compound **5** revealed the absence of the NH_2 group, and its ^1H NMR spectrum exhibited the absence of the signal due to the NH_2 group (at δ = 3.91 ppm in compound **4**) and the presence of the signals of $N(CH_3)_2$ at δ = 2.74 and 2.84 ppm and the signal of N=CH at δ = 7.70 ppm (cf. Scheme 1 and Experimental Section).



Also, compound **2** reacted with *p*-methyl-ω-bromoacetophenone (**6a**) under the same reaction conditions to give the *N*-2-alkyl product **7**. The IR spectrum of compound **7** showed the presence of the absorption bands of NH_2 and two carbonyl groups. Moreover, the ^1H NMR spectrum of compound **7** revealed the presence of NH_2 and CH_2 protons (cf. Scheme 1 and Experimental Section).

Reaction of compound **7** with acetic anhydride in glacial acetic acid under reflux afforded a reaction product **8** of the molecular formula $C_{28}H_{26}N_4O_4$. IR spectrum of **8** showed the disappearance of the absorption bands of NH_2 group, and its ^1H NMR spectrum revealed the absence of CH_2 and NH_2 protons, and instead, the signal of $C_{(3)}$–H of the imidazole moiety and $COCH_3$ was detected at δ = 7.28 and 2.42 ppm, respectively. Based on the data obtained, the reaction product was formulated as ethyl-1-acetyl-9-(4-methoxyphenyl)-7-methyl-2-(4-*p*-tolyl)-1*H*-imidazo-[1′,2′:1,5]pyrazolo[3,4-*b*]pyridine-8-carboxylate (**8**). The formation of **8** was assumed to proceed via the cyclization of **7** with the loss of water molecule followed by acetylation of the imidazole ring nitrogen (cf. Scheme 1 and Experimental Section).

On the other hand, compound **2** reacted with ω-bromoacetophenone (**6b**) to give the *N*-1-alkyl product **9**, which established on the basis of the elemental analysis, spectral data, and chemical evidence. Treatment of **9** with acetic anhydride in glacial acetic acid under reflux afforded the corresponding acetylation product ethyl-3-acetylamino-4-(4-methoxyphenyl)-6-methyl-2-(2-oxo-2-phenylethyl)-1*H*-pyrazolo[3,4-*b*]pyridine-5-carboxylate (**10**). The structure of **10** was established on the basis of the elemental and spectral data, which showed the presence of NH, CH_2, and three C=O groups. The failure of all the attempts to cyclize **10** as in case of **8** led to the conclusion that the alkylation first took place at N-1 at compound **2** (cf. Scheme 1 and Experimental Section).

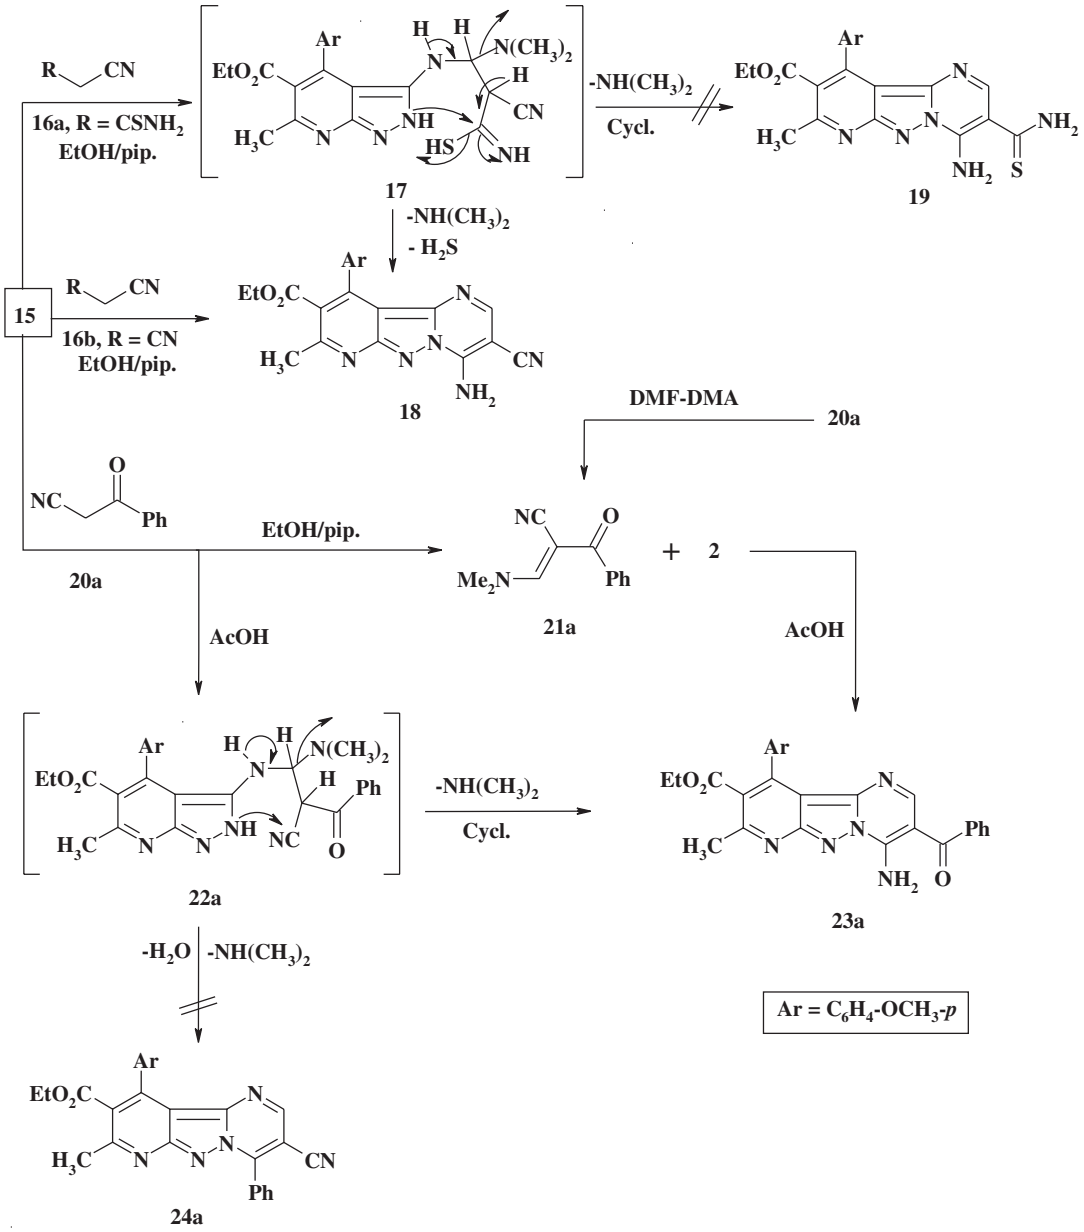
Scheme 2.

Condensation of compound **2** with acetyl acetone in glacial acetic acid (22) under reflux afforded the corresponding pyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivative **11**, its structure was confirmed by elemental analysis and spectral data, which showed the disappearance of NH and NH_2 protons, indicating their participation in the condensation process (cf. Scheme 2 and Experimental Section).

The reactivity of compound **2** towards ketene dithioacetal was also investigated; thus, 1,1-dicyano-2,2-dimethylthioethene (**12**) (23) reacted with compound **2** in dimethylformamide under reflux in the presence of potassium carbonate as a catalyst to afford the corresponding pyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivative **14**. The IR spectrum of compound **14** showed the presence of NH_2 (3444 and 3324 cm^{-1}) and C≡N (2214 cm^{-1}) groups. The ^1H NMR spectrum of compound **14** exhibited a signal at $\delta = 2.97$ ppm assignable to methylsulfanyl group. The formation of **14** was preceded via initial alkylation (21) at N-2 to give the non-isolable intermediate **13** and subsequent ring closure to yield the final product **14** (cf. Scheme 2 and Experimental Section).

Condensation of **2** with DMF–DMA in dry dioxane under reflux afforded the ethyl 3-{[(*N*,*N*-dimethylamino)methylene]amino}-4-(4-methoxyphenyl)-6-methyl-1*H*-pyrazolo-[3,4-*b*]pyridine-5-carboxylate (**15**). Structure **15** was inferred from its spectral data, elemental analysis, and chemical transformations. ^1H NMR spectrum of **15** confirmed the presence of CH_3 protons and disappearance of NH_2 protons, indicating that the condensation was carried out on the amino group not the methyl group (cf. Scheme 2 and Experimental Section).

The chemistry of the dimethylaminomethyleneaminopyrazole derivatives is now receiving considerable attention as one of the major routes to synthesize the biologically active pyrazolo[1,5-*a*]pyrimidines (24–26) and pyrimido-[2,3:4,3]pyrazolo[1,5-*a*]pyrimidines (27). Thus, treatment of dimethylaminomethyleneaminopyrazolo[3,4-*b*]pyridine derivative **15** with cyanothioacetamide (**16a**) in ethanol containing catalytic amount of piperidine afforded a condensation product via dimethylamine elimination. Two structures were considered for this reaction product: compounds **18** and **19**. Elemental analysis of this reaction product indicated the absence of sulfur; the IR spectrum showed the absorption band of C≡N (2223 cm^{-1}) group, and its ^1H NMR spectrum indicated the presence of only one NH_2 group at $\delta = 9.27$ ppm. Based on these data, structure **19** was excluded, and structure **18** could be readily established for the main reaction product (cf. Scheme 3 and Experimental Section).



The formation of compound **18** in this reaction product can be assumed to proceed via the formation of the non-isolable adduct **17**, followed by intramolecular cyclization involving the loss of one molecule of H_2S (28) (turned lead acetate paper into black during the reaction) and $HN(CH_3)_2$ to yield compound **18** (cf. Scheme 3).

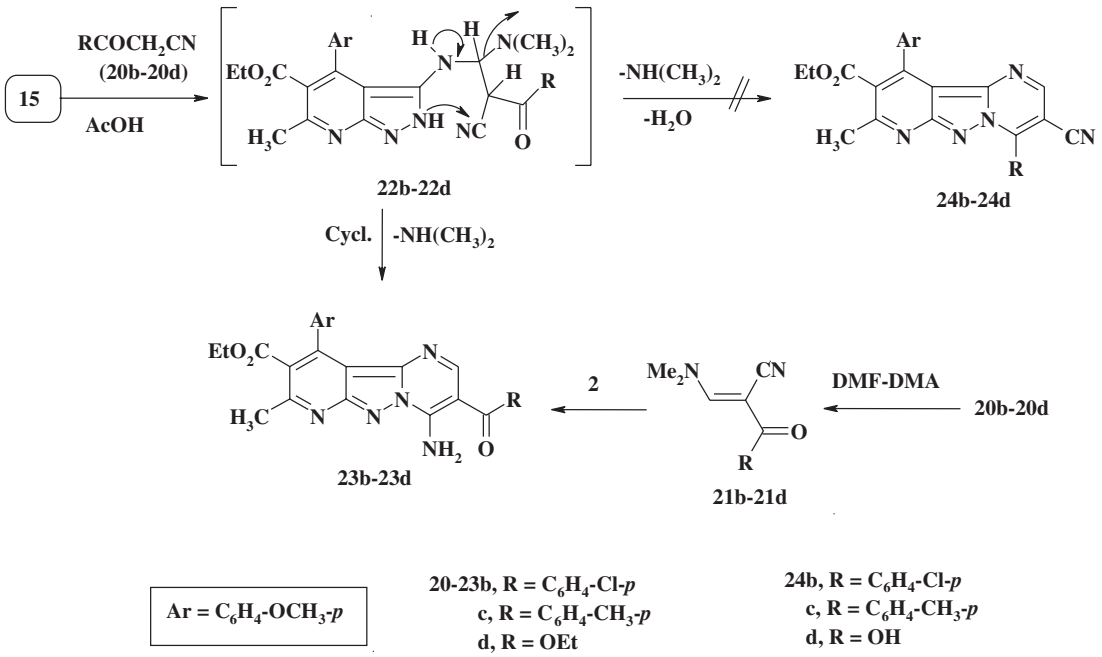
A solid evidence for the structure of compound **18** came from its authentic synthesis by the reaction of compound **15** with malononitrile (**16b**) under the same reaction conditions to afford one and the same reaction product **18**. Compound **18**, prepared via this route, was found to be completely identical in all aspects (mp, mixed mp, and TLC) with compound **18** prepared via the first route (cf. Scheme 3).

On the other hand, compound **15** reacted with benzoylacetonitrile (**20a**) in ethanol containing catalytic amount of piperidine under reflux to give 3-aminopyrazolo[3,4-*b*]pyridine derivative **2** (20) and 3-phenyl-2-[(*N*,*N*-dimethylamino)methylene]-3-oxopropanenitrile (**21a**) (25) instead of the addition product that would be expected by analogy with the earlier reports (24–27). The formation of compounds **2** and **21a** in this reaction is assumed to proceed via *N*,*N*-dimethylaminomethylene exchange under the

© 2007 NRC Canada

Scheme 3.

applied reaction conditions leading to the regeneration of the amino group (17, 29) and hence the formation of **2** (cf. Scheme 3).



The reaction of **15** with **20a** in glacial acetic acid under reflux afforded an addition product with dimethylamine elimination. Two structures seemed possible for this reaction product: **23a** and **24a**. The IR spectrum of the reaction product indicated the presence of absorption bands due to NH_2 (3369 and 3235 cm^{-1}) and COPh (1647 cm^{-1}) groups and the absence of any absorption band that might be attributed to the C≡N group. The ^1H NMR spectrum of the reaction product exhibited the signal of NH_2 protons at δ = 9.67 ppm (D_2O-exchangeable), and its ^{13}C NMR spectrum revealed the signal of C=O at δ = 195.78 ppm. Moreover, the mass spectrum of this reaction product showed the molecular ion peak M^+ at *m*/*z* = 481 (63.9%), corresponding to the molecular formula $C_{27}H_{23}N_5O_4$; also, the base peak in the spectrum was found at *m*/*z* = 105 (100%), which was attributed to the benzoyl radical ($PhCO^+$). Based on the data obtained, the reaction product was formulated as 4-amino-3-benzoylpyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivative **23a** rather than the possible alternative 3-cyano-4-phenylpyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivative **24a** (cf. Scheme 3 and Experimental Section).

The formation of compound **23a** proceeds via first the formation of the non-isolable adduct **22a** followed by the cyclization involving addition to the nitrile function group with the loss of one molecule of dimethylamine to afford compound **23a** rather than the loss of water molecule that gives compound **24a** as we would expect by analogy with the earlier reports (24–27) (cf. Scheme 3).

An unequivocal support for the structure of **23a** was achieved via its synthesis through other route, i.e., condensing **20a** with DMF–DMA and subsequent condensation of

© 2007 NRC Canada

Scheme 4.

the so-formed 3-phenyl-2-[(*N*,*N*-dimethylamino)methylene]-3-oxopropanenitrile (**21a**) (25) with **2** in glacial acetic acid to afford a product that is identical in all respects (mp, mixed mp, and spectral data) to compound **23a** (cf. Scheme 3).

Similarly, compound **15** reacted with aroylacetonitriles **20b**–**20c** and ethyl cyanoacetate (**20d**) in glacial acetic acid under reflux to yield the corresponding 4-amino-3-aroylpyrido[2′,3′:3,4]pyrazolo[1,5-*a*]-pyrimidine derivatives **23b** and **23c** and 4-amino-3-ethoxycarbonylpyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivative **23d,** respectively, instead of the 3-cyano-4-arylpyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivatives **24b** and **24c** and 3-cyano-4-hydroxypyrido[2′,3′:3,4]pyrazolo[1,5-*a*]pyrimidine derivative **24d** (cf. Scheme 4).

The reactions of **15** with **20b**–**20c** in this study did not take place as would have been expected by analogy with the earlier reports (24–27).

Also, the structure of compounds **23b**–**23d** was established on the basis of the elemental analysis and spectral data. A further support for the structure of **23b**–**23d** was achieved via its synthesis through other routes, i.e., via condensing **2** with **21b–21d** (25, 26) in glacial acetic acid to afford a product identical in all respects (mp, mixed mp, and spectral data) to those corresponding to compounds **23b**–**23d** (cf. Scheme 4).

Conclusion

The reaction of 3-amino-1*H*-pyrazolo[3,4-b]pyridine derivative **2** with ω-bromoacetophenones gave either N-1 or N-2 alkylation products, and the reaction of dimethylaminomethyleneaminopyrazolo[3,4-b]-pyridine derivative **15** with β-keto nitrile was found to be highly dependent on the reaction mediums whether it is a basic medium (ethanol–pipredine), which gave dimethylaminomethylene group exchange or acidic (acetic acid), which afforded addition followed by cyclocondensation reaction involving the nitrile function instead of loss of water molecule as would be expected by analogy with the earlier reports (24–27).

Experimental

Melting points were measured with a Gallenkamp apparatus and are uncorrected. IR spectra (KBr discs) were recorded on BRUKER Vector 22 FT-IR spectrophotometer. ^{1}H and ^{13}C NMR spectra were determined in DMSO-d_6 and $CDCl_3$ at 300 MHz on Varian Mercury VX spectrometer using TMS as an internal standard. Chemical shifts are expressed as δ ppm and *J* as Hz units. Mass spectra were recorded on GCMS-QP 1000 EX spectrometer at 70 eV. Elemental analyses were carried out at the Microanalytical Center of Cairo University. Compounds **1** (20), **2** (20), **12** (23), and **21a**–**21d** (25, 26) were prepared according to the literature procedures.

Reactions of compound 2 with halo-reagents

General procedure

A mixture of compound **2** (10 mmol) and each of chloroacetonitrile and compounds **6a** and **6b** (10 mmol) was stirred in DMF (30 mL) containing 10 mmoles of KOH at room temperature for 2 h. The reaction mixtures were poured on cold water and acidified with dilute HCl. The solid products obtained were collected by filtration and crystallized from ethanol to afford compounds **4**, **7**, and **9**, respectively.

Reaction of compounds 7 and 9 with acetic anhydride

A solution of each of compounds **7** and **9** (10 mmol) in glacial acetic acid (30 mL) was treated with acetic anhydride (5 mL) and heated under reflux for 6 h. The reaction mixture was then cooled and poured onto cold water. The solid products thus formed were filtered off and crystallized from ethanol to give compounds **8** and **10**, respectively.

Ethyl-1-acetyl-9-(4-methoxyphenyl)-7-methyl-2-(4-p-tolyl)-1H-imidazo[1′,2′:1,5]pyrazolo[3,4-b]pyridine-8-carboxylate (8)

Yellowish brown crystals (53%) from ethanol, mp 324–326 °C. IR υ (cm^{-1}): 1724 (ester C=O), 1676 (amide C=O). ^{1}H NMR ($CDCl_3$): δ 1.09 (t, J = 7.2 Hz, 3H, CH_2CH_3), 2.42 (s, 6H, CH_3-tolyl and $NCOCH_3$), 2.77 (s, 3H, CH_3, $C_{(7)}$), 3.97 (s, 3H, OCH_3), 4.17 (q, J = 7.2 Hz, 2H, CH_2CH_3), 7.09 (d, J = 8.4 Hz, 2H, Ar–H), 7.28 (s, 1H, $C_{(3)}$–H), 7.65–7.76 (m, 4H, Ar–H), 7.87 (d, J = 8.4 Hz, 2H, Ar–H). Anal. calcd. for $C_{28}H_{26}N_4O_4$ (482): C 69.71, H 5.39, N 11.62; found: C 69.40, H 5.11, N 11.91%.

Ethyl-3-acetylamino-4-(4-methoxyphenyl)-6-methyl-2-(2-oxo-2-phenyl-ethyl)-1H-pyrazolo[3,4-b]pyridine-5-carboxylate (10)

Yellow crystals (60%) from ethanol, mp 224–226 °C. IR υ (cm^{-1}): 3183 (NH), 1723 (ester C=O), 1698 (Ar. C=O), 1664 (amide C=O). ^{1}H NMR (DMSO-d_6): δ 0.97 (t, J = 7.0 Hz, 3H, CH_2CH_3), 1.54 (s, 3H, $COCH_3$), 2.55 (s, 3H, CH_3), 3.82 (s, 3H, OCH_3), 4.05 (q, J = 7.0 Hz, 2H, CH_2CH_3), 6.13 (s, 2H, CH_2, N–CH_2COPh), 7.0–726 (m, 4H, Ar–H), 7.59–7.75 (m, 3H, Ar–H), 8.12 (d, J = 7.25 Hz, 2H, Ar–H), 9.75 (s, 1H, NH). ^{13}C NMR (DMSO-d_6): δ 13.38 (CH_3CH_2), 22.89 (6-CH_3), 32.56 (CH_3CO), 53.09 (NCH_2COPh), 55.17 (OCH_3), 60.89 (OCH_2CH_3), 107.03 (C-3a), 123.66 (C-5), 138.29 (C-4), 142.79 (C-3), 154.81 (C-6 and C-8a), 159.49 (CO_2Et), 192.91 ($COCH_3$), 197.19 (COPh), 113.15, 126.06, 128.06, 128.84, 129.74, 132.06, 132.89, 159.49 (arom. C's). Anal. calcd. for $C_{27}H_{26}N_4O_5$ (486): C 66.66, H 5.34, N 11.52; found: C 66.92, H 5.20, N 11.22.

Ethyl-10-(4-methoxyphenyl)-2,4,8-trimethylpyrido-[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-9-carboxylate (11)

A mixture of compound **2** (10 mmol) and acetylacetone (10 mmol) in glacial acetic acid (30 mL) was heated under reflux for 3 h then cooled. The solid product thus formed was filtered off and crystallized from acetic acid to afford compound **11** as yellow crystals (58%), mp 168 °C. IR υ (cm^{-1}): 1721 (C=O), 1622 (C=N). ^{1}H NMR ($CDCl_3$): δ 1.07 (t, J = 7.02 Hz, 3H, CH_2CH_3), 2.61 (s, 3H, CH_3), 2.83 (s, 3H, CH_3), 2.94 (s, 3H, CH_3), 3.86 (s, 3H, OCH_3), 4.16 (q, J = 7.02 Hz, 2H, CH_2CH_3), 7.00 (d, J = 8.4 Hz, 2H, Ar–H), 7.15 (s, 1H, $C_{(3)}$–H), 7.56 (d, J = 8.4 Hz, 2H, Ar–H). Anal. calcd. for $C_{22}H_{22}N_4O_3$ (390): C 67.69, H 5.64, N 14.35; found: C 67.42, H 5.33, N 14.10

Ethyl-2-amino-3-cyano-10-(4-methoxyphenyl)-8-methyl-4-methylsulfanylpyrido[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-9-carboxylate (14)

A mixture of compound **2** (10 mmol) and compound **12** (10 mmol) in dimethylformamide (30 mL) containing 1.0 g of anhyd. potassium carbonate was heated under reflux for 5 h. The reaction mixture was then cooled, poured onto ice-cold water, and acidified with dilute HCl. The solid product obtained was filtered off and crystallized from ethanol to give compound **14** as brown crystals (55%), mp 201–202 °C. IR υ (cm^{-1}): 3445, 3335 (NH_2), 2214 (C≡N), 1718 (C=O), 1637 (C=N). ^{1}H NMR ($CDCl_3$): δ 1.05 (t, J = 7.2 Hz, 3H, CH_2CH_3), 2.76 (s, 3H, CH_3), 2.97 (s, 3H, SCH_3), 3.87 (s,

3H, OCH_3), 4.13 (q, *J* = 7.2 Hz, 2H, CH_2CH_3), 6.97–7.44 (m, 6H, Ar–H and NH_2). Anal. calcd. for $C_{22}H_{20}N_6O_3S$ (448): C 58.92, H 4.46, N 18.75, S 7.14; found: C 58.64, H 4.18, N 18.99, S 6.88.

Ethyl-3-{[(N,N-dimethylamino)methylene]amino}-4-(4-methoxyphenyl)-6-methyl-1H-pyrazolo[3,4-b]pyridine-5-carboxylate (15)

This compound was synthesized from compound **2** (10 mmol) and DMF–DMA (12 mmol) in a manner similar to that described for the preparation of compound **5**. It was crystallized from ethanol to give yellow crystals (76%), mp 174 °C. IR υ (cm^{-1}): 3195 (NH), 1734 (C=O). 1632 (C=N). ^1H NMR ($CDCl_3$): δ 0.99 (t, *J* = 7.2 Hz, 3H, CH_2CH_3), 2.72 (s, 3H, CH_3), 2.75 (s, 3H, CH_3, $N(CH_3)_2$), 2.80 (s, 3H, CH_3, $N(CH_3)_2$), 3.83 (s, 3H, OCH_3), 4.08 (q, *J* = 7.2 Hz, 2H, CH_2CH_3), 6.91 (d, *J* = 8.6 Hz, 2H, Ar–H), 7.38 (d, *J* = 8.6 Hz, 2H, Ar–H), 7.63 (s, 1H, N=CH), 11.74 (s, 1H, NH). Anal. calcd. for $C_{20}H_{23}N_5O_3$ (381): C 62.99, H 6.03, N 18.37; found: C 62.70, H 5.80, N 18.09.

Synthesis of ethyl-4-amino-3-cyano-10-(4-methoxyphenyl)-8-methylpyrido[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-9-carboxylate (18)

A mixture of compound **15** (10 mmol) and either of cyanothioacetamide (**16a**) or malononitrile (**16b**) (10 mmol) in ethanol (30 mL) containing 0.5 mL of triethylamine, as a catalyst, was heated under reflux for 2 h. The solid product obtained on hot was filtered off and crystallized from dioxane to give compound **18** as yellow crystals (67%), mp 309–310 °C. IR υ (cm^{-1}): 3427, 3391 (NH_2), 2223 (C≡N), 1722 (C=O), 1645 (C=N). ^1H NMR ($CDCl_3$): δ 1.08 (t, *J* = 7.2 Hz, 3H, CH_2CH_3), 2.86 (s, 3H, CH_3), 3.91 (s, 3H, OCH_3), 4.16 (q, *J* = 7.2 Hz, 2H, CH_2CH_3), 7.02 (d, *J* = 8.6 Hz, 2H, Ar–H), 7.51 (d, *J* = 8.6 Hz, 2H, Ar–H), 8.426 (s, 1H, $C_{(2)}$–H), 9.27 (br, 2H, NH_2). ^{13}C NMR (DMSO-d_6): δ 13.41 (CH_3CH_2), 24.07 (8-CH_3), 55.09 (OCH_3), 60.97 (OCH_2CH_3), 78.73 (C-3), 101.72 (C-10a), 113.23 (CN), 122.84 (C-9), 143.78 (C-10b), 144.90 (C-10), 149.29 (C-6a), 158.89 (C-8), 159.78 (C-2), 160.01 (C-4), 168.16 (CO), 114.93, 126.42, 130.26, 155.22 (arom. C's). Anal. calcd. for $C_{21}H_{18}N_6O_3$ (402): C 62.68, H 4.47, N 20.89; found: C 62.39, H 4.21, N 20.62.

Reaction of compound 15 with compounds 20a–20d and 2 with 21a–21d

General procedure

A mixture of compound **15** (10 mmol) and each of compounds **20a**–**20d** (10 mmol) in glacial acetic acid (30 mL) was heated under reflux for 3 h. The solid products obtained after cooling were filtered off and crystallized from the proper solvent to afford compounds **23a**–**23d**, respectively. Reaction of **2** with **21a**–**21d** was preceded in a similar manner to give the same reaction products **23a**–**23d**.

Ethyl-4-amino-3-benzoyl-10-(4-methoxyphenyl)-8-methylpyrido[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-9-carboxylate (23a)

This compound was formed as yellow crystals from acetic acid (68%), mp 297–298 °C. IR υ (cm^{-1}): 3369, 3235 (NH_2), 1714 (ester C=O), 1647 (PhC=O), 1622 (C=N). ^1H NMR ($CDCl_3$): δ 1.05 (t, *J* = 7.2 Hz, 3H, CH_2CH_3), 2.80 (s, 3H, CH_3), 3.85 (s, 3H, OCH_3), 4.12 (q, *J* = 7.2 Hz, 2H, CH_2CH_3), 7.25–7.57 (m, 9H, Ar–H), 8.62 (s, 1H, $C_{(2)}$–H), 9.67 (br, 2H, NH_2, lost after D_2O-exchange). ^{13}C NMR ($CDCl_3$): δ 13.80 (CH_3CH_2), 24.73 (8-CH_3), 55.20 (OCH_3), 61.41 (OCH_2CH_3), 102.55 (C-10a), 102.87 (C-3), 123.95 (C-9), 138.34 (C-10b), 143.98 (C-10), 145.91 (C-6a), 149.27 (C-2), 151.98 (C-8), 162.15 (C-4), 169.06 (CO_2Et), 195.78 (COPh), 113.44, 126.95, 128.51, 128.81, 130.61, 131.82, 160.31 (arom. C's). MS: (M^+) 481 (63.9%), 105 (100%). Anal. calcd. for $C_{27}H_{23}N_5O_4$ (481): C 67.36, H 4.78, N 14.55; found: C 67.06; H 4.45, N 14.30.

Ethyl-4-amino-3-(4-chlorobenzoyl)-10-(4-methoxyphenyl)-8-methylpyrido[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-9-carboxylate (23b)

Yellow crystals from acetic acid (65%,), mp 301–302 °C. IR υ (cm^{-1}): 3373, 3237 (NH_2), 1711 (ester C=O), 1648 (Ar. C=O), 1626 (C=N). ^1H NMR (DMSO-d_6): δ 1.02 (t, *J* = 7.25 Hz, 3H, CH_2CH_3), 2.65 (s, 3H, CH_3), 3.81 (s, 3H, OCH_3), 4.08 (q, *J* = 7.25 Hz, 2H, CH_2CH_3), 7.02–7.74 (m, 8H, Ar–H), 8.34 (s, 1H, $C_{(2)}$–H), 9.25 (br., 2H, NH_2). Anal. calcd. for $C_{27}H_{22}N_5O_4Cl$ (515.5): C 62.85, H 4.26, N 13.57, Cl 6.88; found: C 63.15, H 4.00, N 13.27, Cl 6.61.

Ethyl-4-amino-3-(4-methylbenzoyl)-10-(4-methoxyphenyl)-8-methylpyrido[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-9-carboxylate (23c)

Yellow crystals, (63%, dioxane), mp 317–318 °C. IR υ (cm^{-1}): 3376, 3238 (NH_2), 1713 (ester C=O), 1648 (Ar. C=O). ^1H NMR ($CDCl_3$): δ 1.05 (t, *J* = 7.2 Hz, 3H, CH_2CH_3), 2.44 (s, 3H, CH_3, aroyl), 2.82 (s, 3H, CH_3), 3.87 (s, 3H, OCH_3), 4.15 (q, *J* = 7.2 Hz, 2H, CH_2CH_3), 7.28 (d, *J* = 8.4 Hz, 2H, Ar–H), 7.53–7.59 (m, 6H, Ar–H), 8.66 (s, 1H, $C_{(2)}$–H), 9.46 (br., 2H, NH_2, lost after D_2O-exchange). Anal. calcd. for $C_{28}H_{25}N_5O_4$ (495): C 67.87, H 5.05, N 14.14; found: C 67.60, H 5.36, N 14.39.

Diethyl-4-amino-10-(4-methoxyphenyl)-8-methylpyrido-[2′,3′:3,4]pyrazolo[1,5-a]pyrimidine-3,9-dicarboxylate (23d)

Yellow crystals, (66%, dioxane), mp 258–259 °C. IR υ (cm^{-1}): 3402, 3284 (NH_2), 1715 (ester C=O, $C_{(9)}$), 1700 (ester C=O, $C_{(3)}$), 1642 (C=N). ^1H NMR ($CDCl_3$): δ 1.04 (t, *J* = 7.2 Hz, 3H, CH_2CH_3), 1.41 (t, *J* = 7.1 Hz, 3H, CH_2CH_3), 2.79 (s,3H, CH_3), 3.89 (s, 3H, OCH_3), 4.17 (q, *J* = 7.2 Hz, 2H, CH_2CH_3), 4.44 (q, *J* = 7.1 Hz, 2H, CH_2CH_3), 7.0 (d, *J* = 8.8 Hz, 2H, Ar-H), 7.52 (d, *J* = 8.8 Hz, 2H, Ar–H), 7.75 (br, 2H, NH_2), 8.88 (s, 1H, $C_{(2)}$–H). ^{13}C NMR (DMSO-d_6): δ 13.41 ($2CH_3CH_2$), 23.02 (8-CH_3), 55.16 (OCH_3), 60.53 ($2CH_2CH_3$), 101.43 (C-10a), 120.68 (C-3), 126.87 (C-9), 130.52 (C-10b), 147.81 (C-10), 151.38 (C-6a), 153.04 (C-2), 158.61 (C-8), 159.57 (C-4), 168.27 ($2CO_2Et$), 113.83, 129.39, 142.82, 154.46 (arom. C's). Anal. calcd. for $C_{23}H_{23}N_5O_5$ (449): C 61.46, H 5.12, N 15.59; found: C 61.72, H 5.39, N 15.88.

Chromatographic enantiomer separation and circular dichroism (CD) spectra of three 4-endosubstituted-3,6-diphenyl-3,6-phenylphosphorylcyclohexenes

Martin B. Hocking and Aga Z-Q. Khan

Abstract: Three enantiomeric pairs of Diels–Alder adducts of 2,5-diphenylphosphole-1-oxide have been resolved by elution of each of the enantiomers with 95% ethanol from a swollen microcrystalline triacetylcellulose stationary phase. The degree of separation achieved in each case was confirmed by comparing the absorbance maximum of the UV spectrum of each separated enantiomer with that of a similar concentration of the relevant racemic mixture. The circular dichroism (CD) spectrum of each of the separated enantiomers was recorded, and spectral parameters are listed.

Key words: enantiomer separations, three 4-endosubstituted phosphorus-bridged cyclohexenes (phosphanorbornenes), ethanol, microcrystalline triacetylcellulose.

Résumé : On a effectué la résolution de trois paires énantiomères d'adduits de Diels–Alder du 1-oxyde de 2,5-diphénylphosphole en faisant l'élution de chaque énantiomère à l'aide d'éthanol à 95% à partir d'une phase stationnaire formée de triacétylcellulose microcristalline gonflée. Le degré de séparation obtenu pour dans chaque cas a été confirmé en procédant à une comparaison du maximum d'absorbance dans le spectre UV de chaque énantiomère séparé avec celui à une concentration similaire du mélange racémique approprié. On a enregistré les spectres de DC de chacun des énantiomères séparés et on rapporte les paramètres spectraux.

Mots-clés : séparation d'énantiomères, trois cyclohexènes à pont de phosphore et substitués en position 4 endo (phosphanorbornènes), éthanol, triacétylcellulose microcristalline.

[Traduit par la Rédaction]

Introduction

A number of chiral drugs and pesticides are in commercial use as their racemic mixtures because of either the lack of a suitable stereospecific synthetic route to the respective enantiomers or the practical difficulties attached to the resolution of these materials on a large scale at the time of their development. Growing recognition of the important differences in the bioactivity of isolated enantiomers, compared with the activity of their racemic mixtures in the same applications, has spurred the development of viable stereospecific synthetic routes to individual enantiomers (1). Recently, difficulties with some enantiomer syntheses scale have stimulated the mastery of several racemate separation techniques on a preparative scale (2). In particular, enantiomer separations by chromatographic techniques using solvent elution from chiral stationary phases (CSPs) have been substantially refined (3). Among the available stationary phases, swollen microcrystalline triacetylcellulose (TAC) has been found to be among the most versatile of CSPs for both analytical and preparative separations (4, 5).

In connection with another synthetic project, we had prepared racemic mixtures of three phosphorus-containing heterocycles by the addition of the appropiate dienophile to 1,2,5-triphenylphosphole-1-oxide (6) (Chart 1).[2] In this paper, we examine the efficacy of a few of the resolution methods outlined here for the separation of these racemic mixtures (7–9).

Experimental section

Chromatographic separations

Thirty milligrams of each of compounds **1**–**3** was dissolved in ethanol (95%, 1 mL), and the solution was injected into the chromatographic system. This consisted of two 60 × 1.0 cm steel columns, packed with swollen microcrystalline triacetylcellulose (TAC) and connected in series. The eluate (mobile phase: 95% ethanol, flow rate 1 mL/min) was passed through an UV detector (LKB Uvicord, 224 nm) followed by a polarimeter detector (PerkinElmer 241 MC, 365 nm, Hg lamp) in series. The output from the detector was fed to a two-channel recorder (LKB Model 2210) to obtain the chromatogram. The eluate was collected after its passage through the polarimeter tube. Further experimental

details of the resolution methodology are given in the literature (10).

Circular dichroism (CD) spectral methods

The CD spectra of the first-eluted enantiomers (El) were recorded directly from the eluted chromatographic fractions containing them, using a JASCO Model J-500A spectropolarimeter. Concentrations were measured from their UV spectra obtained using a Cary Model 2290 spectrophotometer by comparing the absorbances of the resolved compounds at 261 nm with those of spectra recorded on solutions of the pure racemic compounds of about the same concentration in the same solvent.

Results and discussion

Resolutions achieved

After only a single pass through the resolution columns, initially all three compounds **1**–**3** were only poorly resolved, as evidenced by no resolved elution peaks in the continuous UV trace taken of the column effluent. Recycling improved the separation to give well-resolved samples after three cycles. Enantiomeric excesses were checked by recording their solution ^{1}H NMR spectra on a Varian Model XL-300 NMR spectrometer in the presence of the chiral-shift reagent "Pirkle's alcohol" (11), (+)-1-(9-anthryl)-2,2,2-trifluoroethanol (**4**). Spectra of racemic **1** with one equivalent of **4** in $CDC1_3$ showed two partly resolved triplets for the ester methyl group, whereas **2** and **3** showed two completely separated multiplets for 4-H. The ^{1}H NMR spectrum of the fully resolved **3** under the same conditions showed only one 4-H multiplet even when the plot gain was increased, indicating a 98%–99% optical purity. The less well-resolved ester **1** showed two overlapping methyl triplets with unequal intensities, and the cyano compound **2** showed two 4-H multiplets with unequal intensities. The measured ratios of enantiomers in the latter two samples were 0.73:0.27 and 0.67:0.33, respectively, corresponding to 46% and 34% enantiomeric excess for **1** and **2**. The evaluation was performed by calculation of theoretical NMR spectra and then adjusting the ratios to obtain the best fit with the experimental spectra.

A measure of the quantitative efficiency of the chromatograpic separation was obtained by substituting t_1, t_2, and t_0, which are the retention times of the first and second enantiomers eluted, and the non-retained reference (1,3,5-tri-*t*-butylbenzene), respectively, into eq. [1] and [2]. The capacity factors k_1' and k_2' were then used to obtain the selectivity factor α by substitution into eq. [3] (12).

$$[1] \qquad k_1' = \frac{t_1 - t_0}{t_0}$$

$$[2] \qquad k_2' = \frac{t_2 - t_0}{t_0}$$

$$[3] \qquad \alpha = \frac{k_2'}{k_1'}$$

The results are given in Table 1.

Other stationary phases tested

Attempts to resolve compounds **1**–**3** by elution with 60:35:5 *n*-hexane:dioxane:isopropanol or 50:50 hexane:dioxane on HIBAR (13) columns (from Alltech Associates Inc., Deerfield, Illinois) were fruitless. Likewise, using 75:25 or 50:50 *n*-hexane:dioxane on TRIM (14) columns (rigid macroporous particles prepared by suspension polymerization of trimethylolpropane trimethacrylate) were also unsuccessful.

The CD spectral parameters of the first-eluted enantiomers obtained as described in the Experimental Section are given in Table 2. The CD spectra of the second enantiomers were also recorded and were found to be mirror images of

© 2007 NRC Canada

the first enantiomers, which confirmed that no decomposition had occurred during the chromatography.

Because of the complexity of the chromophoric system, a detailed analysis of the CD spectra was not feasible. Without a substituent in the 4 position, the molecule is achiral with a plane of symmetry through the phosphorus atom bisecting the 1–2 and 4–5 bonds. Introduction of the 4-substituent creates a chiral center at C-4 and also renders the phosphorus atom stereogenic. However, ^{1}H NMR spectra of the various isolated chiral fractions showed no evidence of more than two enantiomers. Presumably, rates of interconversion of the two phosphorus substituents in each of these examples were sufficiently high to reduce the number of isolable enantiomers observed to two. The rotational strengths of the various electronic transitions in the molecule arise mainly by interaction through space between the transition moments in the individual chromophores. The CD bands of **3** are more intense than the bands of **1** and **2** because the 4-phenyl group has electronic transitions in the near UV region, which interact much more strongly with the transitions of the other phenyl groups in the same wavelength region than do the far-UV transitions of the ester and cyano groups.

Efficient preparation of chiral non-racemic sulfur compounds

Joannie Minville, Mélina Girardin, and Claude Spino

Abstract: *p*-Menthane-3-carboxaldehyde serves as an efficient chiral auxiliary in the preparation of chiral non-racemic *S*-alkylthiocarbamates or *S*-dithiocarbonates via the 3,3-sigmatropic rearrangement of the corresponding alkylthionocarbamates or xanthates. The transfer of chirality during rearrangement is complete, and the final products possess a chiral tertiary or quaternary carbon bearing sulfur. The rearranged products are then transformed into enantiopure cyclic or acyclic sulfur-containing products, depending on the means of clivage of the auxiliary. The synthesis of a potent MMP-13 inhibitor is presented.

Key words: 3,3-sigmatropic rearrangement, *p*-menthane-3-carboxaldehyde, *S*-alkylthiocarbamate, *S*-dithiocarbonate, alkylthionocarbamate, xanthate, ring-closing metathesis.

Résumé : Le *p*-menthane-3-carboxaldéhyde est un auxiliaire chiral efficace dans la préparation de *S*-alkylthiocarbamates ou de *S*-dithiocarbonates non chiraux par le biais d'un réarrangement sigmatropique-3,3 des alkylthionocarbamates ou des xanthates correspondants. Le transfert de chiralité durant ce réarrangement est total et les produits finaux possèdent un atome de carbone tertiaire ou quaternaire chiral portant un atome de soufre. Suivant les méthodes utilisées pour cliver l'auxiliaire, es produits réarrangés sont alors transformés en produits cycliques ou acycliques énantiopurs contenant du soufre. On rapporte la synthèse d'un puissant inhibiteur MMP-13.

Mots-clés : réarrangement sigmatropique-3,3, *p*-menthane-3-carboxaldéhyde, *S*-alkylthiocarbamate, *S*-dithiocarbonate, alkylthionocarbamate, xanthate, métathèse accompagnant une fermeture de cycle.

[Traduit par la Rédaction]

Introduction

Many natural and man-made products, containing a sulfur atom, have huge potential in medicinal chemistry (1). Figure 1 lists some examples. Montelukast **1** (singulair) is a potent antagonist of the cysteinyl leukotriene receptor and serves as a prophylactic, once-a-day, anti-asthma agent (2). Compound **3** is a potent inhibitor of phosphodiesterases (PDE4) at nanomolar concentrations (3). Natural products, containing a chiral sulfide moiety, include the fatty-acid synthetase inhibitors thiolactomycin **4** and thiotetromycin **5** (4), gliotoxin **6** (5), with antiviral, antibacterial, and immunosuppressive activities, and biotin **2** (6).

The construction of chiral C–O and C–N bonds has reached a higher level of sophistication than the making of chiral C–S bonds (7). In fact, chiral C–S bonds are often made by displacement of the corresponding chiral C–O bonds (8). When displacing a chiral allylic C–O bond, transposition may or may not occur. With Mitsunobu reactions, transposition is usually not observed (9), whereas 3,3-sigmatropic rearrangements provide products with a transposed double bond (10).

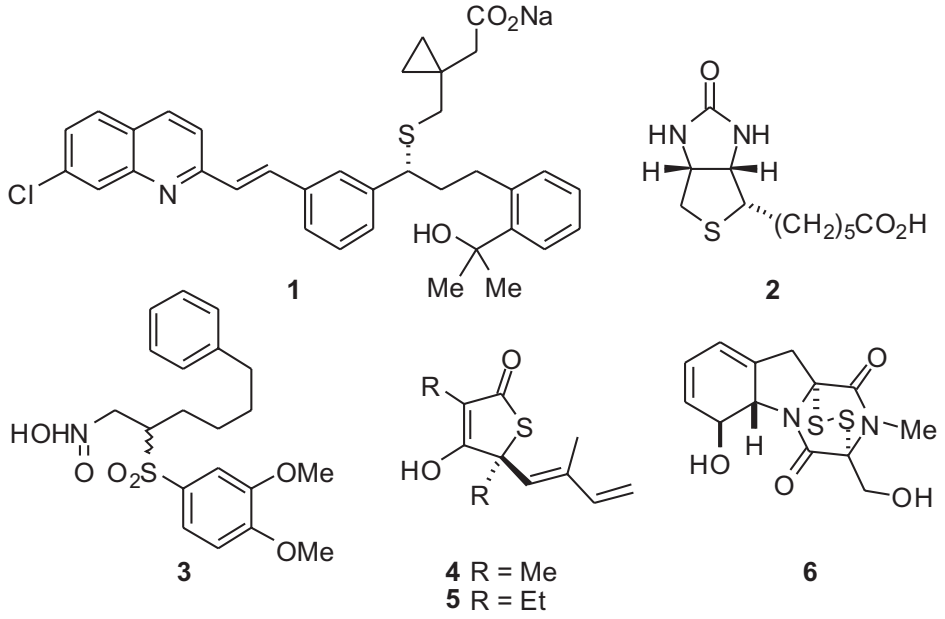
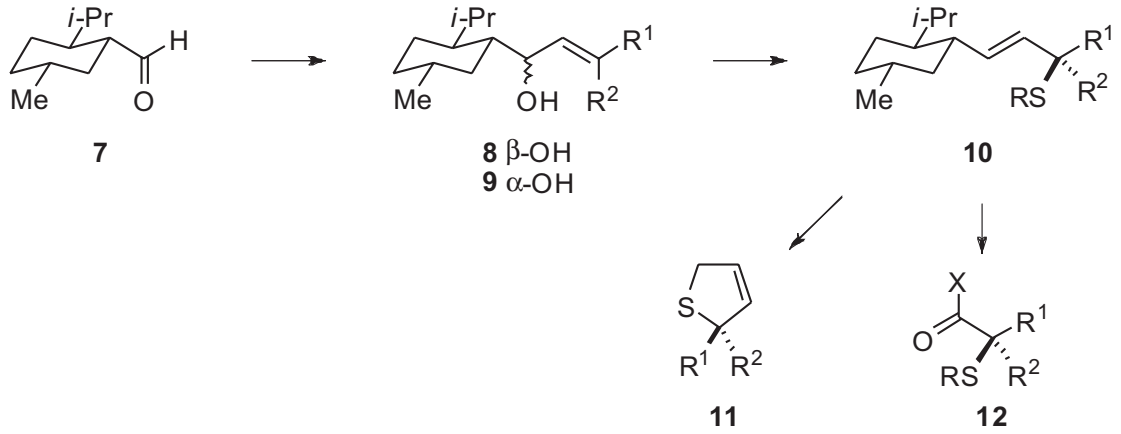
In that regard, we viewed our chiral scaffold derived from *p*-menthane-3-carboxaldehyde **7** as ideal to implement a methodology aimed at preparing chiral sulfur-containing compounds (Scheme 1) (11). First, the bulky menthyl moiety allows rearrangements reactions to occur at low temperatures (11*b*). Thus, the 3,3-sigmatropic rearrangement of allylic thionocarbamates (12, 13), phosphonothionates (12*b*), xanthates (14), or similar precursors should proceed smoothly to give the desired chiral C–S bond, even in the case of trisubstituted double bonds. Second, the chiral auxiliary is cleavable by two completely different methods, giving rise to cyclic or acyclic products. Last, either stereochemistry of the targeted chiral C–S bond can be selected by controlling the stereochemistry of the alcohol (both are easily obtained) and (or) the geometry of the alkene and (or) the absolute configuration of **7** (both enantiomers are readily available and inexpensive). This flexibility is a great asset for synthesis.



Results and discussion

Building the thiocarbamates and xanthates



Our strategy starts with the synthesis of allylic alcohols **8**, which were prepared by one of methods A, B, or C (Scheme 2). Method A involves the preparation of vinyl iodides **17** using Schwartz' hydrozirconation or hydroboration of the substituted acetylenes **13**. After submitting vinyl iodides **17** to a metal-halogen exchange using *t*-butyllithium, the resulting vinyllithiums **18a** were stereoselectively added to (–)-*p*-menthane-3-carboxaldehyde **7** in the presence of

Fig. 1. Biologically active sulfur-containing natural and unnatural products.

Scheme 1. Strategy to obtain chiral sulfur compounds.

trimethylaluminium (15). The major alcohols **8a**, **c**, **d**, and **f** result from the addition of the vinyllithiums to aldehyde **7** following Felkin–Ahn's model of stereoselectivity (16). Trimethylaluminium renders this addition highly stereoselective, and the Felkin adducts **8** were isolated essentially as a single isomer (52 to 200:1; Table 1, entries 1, 3, 4, and 6). Method B uses the stereoselective addition of vinylalanes **18b**, made from the zirconium-catalyzed carboalumination (17) of alkynes **13**, to aldehyde **7**. While this method is slightly less stereoselective than method A, it is nonetheless the excess trimethylaluminium used during the carbolumination process that provides this level of stereoselection (11 to 30:1; Table 1, entries 2, 7, and 8). Evaporation of the excess trimethylaluminium prior to addition to **7** leads to lower stereoselectivities. Method C involves the addition of lithium acetylides **14** to **7**. Propargyl alcohol **15**, isolated as a 2:1 mixture of diastereomers, was then converted to the desired allylic alcohol **8** using Red-Al. All mixtures of alcohols **8** and **9** were easily separated by flash chromatography, and the sequence was continued with isomerically pure alcohols as determined by GC or HPLC.

The minor diastereomer **9** (α-OH) could be prepared in sufficient quantities first by oxidizing the major isomer **8** to the corresponding enone **19** and then by reducing the latter using Super-Hydride™ (Scheme 3). This reduction is completely diastereoselective and gives **9** as the sole diastereomer (11*a*). Having access to both alcohols **8** and **9** in large quantities allowed us to measure the diastereoselectivities of the subsequent reactions. Moreover, both enantiomers of the final chiral sulfur compounds can be prepared from a single enantiomer of the chiral auxiliary **7** via alcohols **8** or **9**, since they lead to enantiomeric products after cleavage of the chiral auxiliary, respectively.

Starting from the allylic alcohols **8** or **9**, we procured the allylic thionocarbamates as intermediates (not shown), using *N*-phenylisothiocyanate as reagent to make them. They rearranged to the *S*-allylthiocarbamates **20** or **21**, respectively, upon acidification of the reaction mixture with PPTS (Table 2). The rearrangement does not proceed (or proceeds very slowly) while the allylthionocarbamates are still under basic conditions. However, once the solution is acidified, the rearrangement takes place within a few hours at 66 °C.

Many substrates underwent the rearrangement slowly at room temperature within several days. This sequence allowed us to prepare various *S*-allylthiocarbamates **20a**–**20h** and **21a**–**21h** in good to excellent yields with diastereomeric excesses (de) > 90%. We believe that the de of compound **21f** reported in Table 2, entry 12 is > 76%. The lower-than-expected value may be due to an impurity that co-elutes with the diastereomer of **21f**, and that we could neither identify nor remove. The structure of **20c** was confirmed by single crystal X-ray diffraction analysis, and it was consistent with a concerted rearrangement of **8c** via a chair-like transition state (TS) **20**-*E*-chair (Scheme 4).

The minor *S*-thiocarbamates in the rearrangement of the thionocarbamates derived from **8** or **9** do not come from a competing concerted transition state (18) but must instead be derived from ionic pathways competing with the concerted one. Indeed, a close look at the possible transition states (Scheme 4, only the chair-like TS are represented) (19) leads us to the conclusion that to attack the alkene face leading to the minor *S*-thiocarbamate, the thionocarbamate must maximize its $A^{1,3}$ strain, which would give a product having a *Z* double bond. There is no concerted pathway leading to **21** from **8** or to **20** from **9**. Ionic intermediates, on the other hand, would collapse to a mixture of **20** and **21** regardless of their origin.

One might wonder why we did not observe the formation of regioisomers **23** as a minor product if ionic intermediates are involved. However, it is our experience that the menthyl moiety is very efficient at preventing attack at the β position. For example, when alcohol **8g** is submitted to an acidic environment, some regioisomer **24g** was isolated as a mixture of diastereomers, but the recovered alcohol **8g** was diastereo-

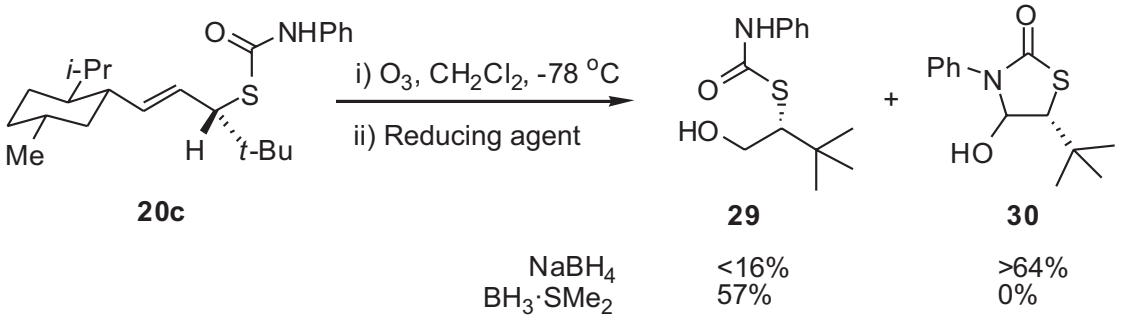
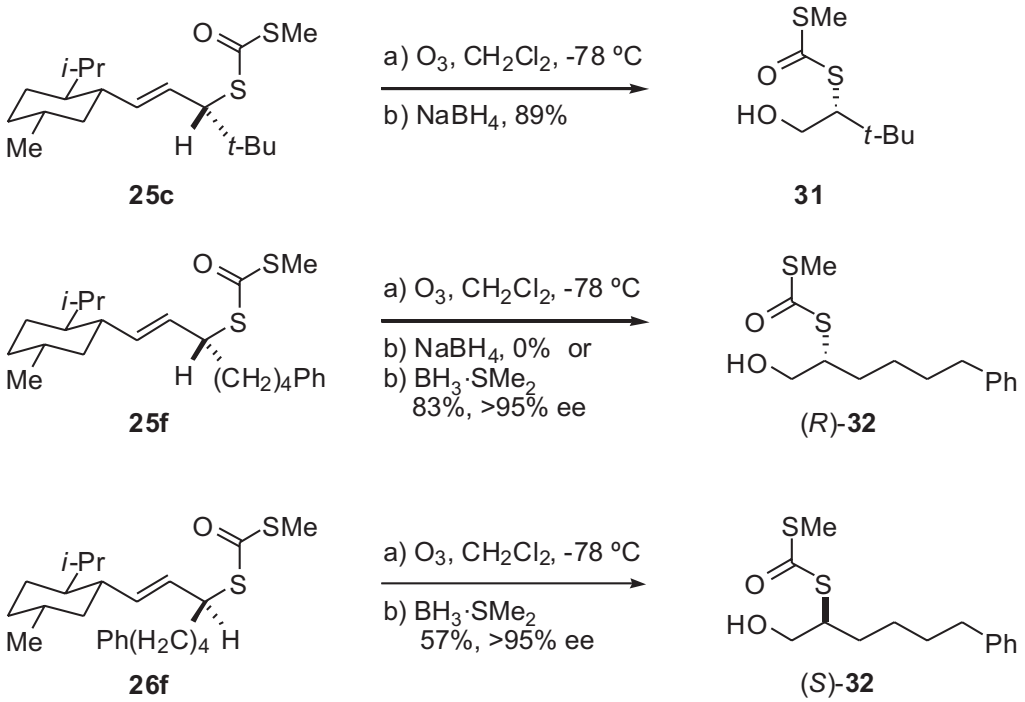
merically pure. This implies that the ionic intermediates collapsed exclusively to the regioisomer **24g**.

Our observation that the thionocarbamates (Scheme 4, X = H) rearrange much faster than the metallated thionocarbamates (X = Na) is in line with observations by Nakai and Zaim that electron donors (e.g., R_2N) at that position slowed the rearrangement, while an electron-withdrawing group such as Cl increased the reaction rate (18). Possibly, the proton sits exclusively on the nitrogen atom in the thionocarbamate, while the metal is perhaps on sulfur. According to Nakai and Ari-Izumi, a higher bond order for the thiocarbonyl is found in precursors that undergo fast reactions (18*a*).



Also, these authors found that substitution on the allylic fragment increased the reaction rate. Although we have not measured the actual rate constants of our reactions, we have qualitatively observed that the thionocarbamates derived from the trisubstituted allylic alcohols **8b**, g, h and **9b**, g, h rearranged substantially faster than the others. For example, the thionocarbamates derived from **8g** and **9g** rearranged in 53% and 67% yield, respectively, at room temperature in 24 h. The analogous thionocarbamates made from **8f** and **9f** did not rearrange after the same time at room temperature. Several days later, some rearrangement was observed for **8f** and **9f**, but the reaction had not reached completion. This same trend was observed for **8a** and **8c**.

Xanthates derived from alcohols **8** or **9** rearranged to allylic dithiocarbonates **25** or **26** (Table 3, entries 1–6). The reaction conditions and times were very similar to the ones used for the thionocarbamates. Table 3 reveals that yields and diastereoselectivities are also comparable. The main difference resides in the subsequent cleavage of the chiral auxiliary (see later).



We also tested the rearrangement on the imidazole variant of thionocarbamates because they are supposed to proceed at lower temperatures, which could be an advantage for some thermally unstable substrates (Scheme 5 and Table 3, entries 7–10) (20). Indeed, we obtained a 78% yield of **27c** from **8c** after stirring for 3 days at room temperature (Table 3, entry 7). However, while the rearrangements were somewhat faster than their *N*-phenyl carbamate analogs, it proved to be less general. For example, alcohols **8e** and **9e** yielded only elimi-

Scheme 7. Oxidative cleavage of *S*-thiocarbonates **25c**, **25f**, and **26f**.

nation and other decomposition products under those conditions.

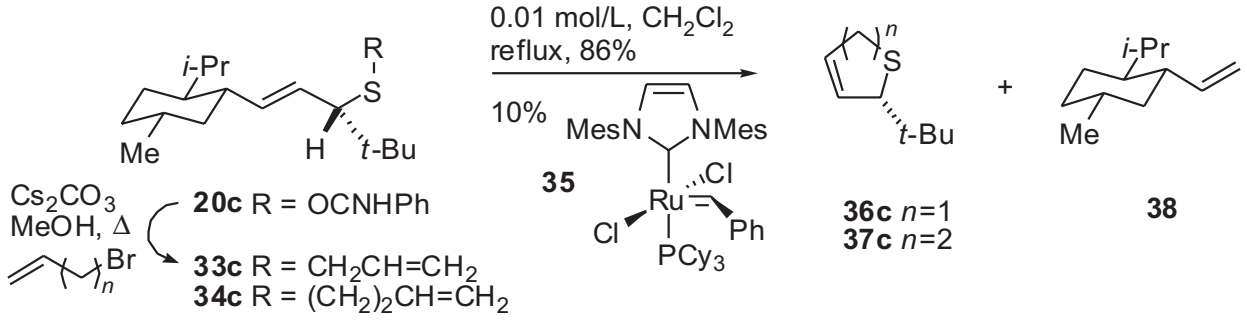
The low temperature at which all of these rearrangements take place is noteworthy and likely the result of the steric volume of the menthyl fragment (steric decompression).[2] Some thionocarbamates derived from **8** or **9** undergo rearrangement at room temperature, albeit rather slowly. Usually, such compounds require heating in excess of 100 °C for the rearrangement to take place. For example, Thomas and co-workers used, in their synthesis of thiotetronic acids, a xanthate to thiocarbonate rearrangement that occurred at 145 °C during distillation (10).

Cleaving the chiral auxiliary

Oxidative cleavage

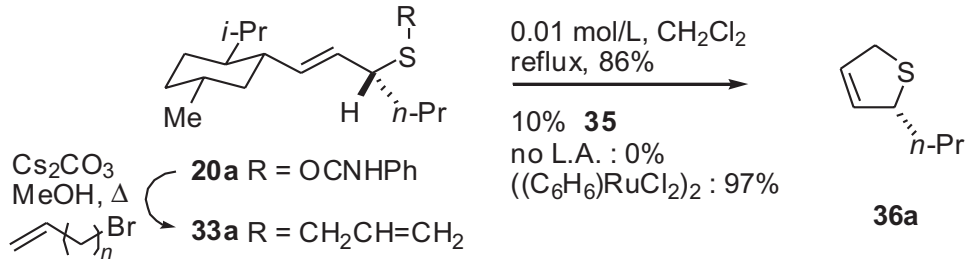
Cleavage of the auxiliary in *S*-thiocarbamate **20c** with ozone, the usual method by which we cleave this chiral auxiliary (11), resulted in the efficient conversion of the starting material. Indeed, a reductive work-up with $NaBH_4$ led to the formation of a mixture of the desired alcohol **29** and thiazolidinone **30** in 80% combined yield (Scheme 6). When $BH_3 \cdot SMe_2$ was used as the reducing agent, only alcohol **29** was formed in 57% yield. The Lemieux protocol ($OsO_4/NaIO_4$) or similar methodologies are less efficient and often lead to a mixture of products.

The yields of cleavage products were consistently better from *S*-thiocarbonates **25** or **26**. Here too, the use of $BH_3 \cdot SMe_2$ usually gives superior results, though sodium borohydride can give good yields of products (Scheme 7). This is the protecting group of choice for sulfur if oxidative cleavage is needed. We verified the stereochemical integrity of the alcohols **32** by making the Mosher ester derivatives on both enantiomers and found no racemization. Aldehydes can be prepared using dimethylsulfide as reducing agent but α-thioaldehydes are sensitive to racemization and must be used without purification, unless of course the α-position is dialkylated (see later).



Cleavage by ring-closing metathesis

We have recently discovered that it is possible to generate



[2] We have observed the same phenomenon for the Claisen rearrangement, see ref. 11.

Scheme 10. RCM cleavage of allylic sulfones **39a** and **39c**.

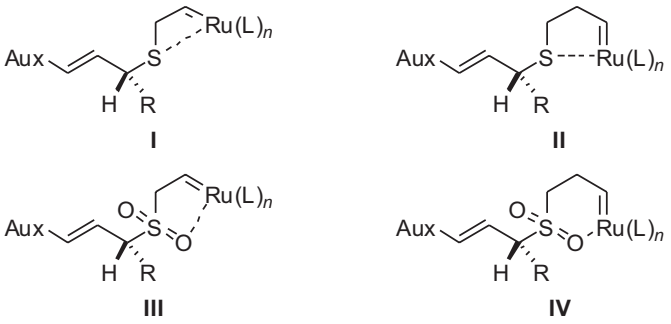
chiral nonracemic cycloalkenes by ring-closing metathesis (21) starting from dienes that still possess the menthyl moiety (22). To the best of our knowledge, this was the first example of a chiral auxiliary that could be cleaved by RCM. However, several heteroatoms, sulfur in particular (21, 23), may cause problems by coordinating to the metal center, and it was unclear at the onset if chiral *S*-heterocycles could be prepared by this method.

Thus, the carbamate functionality in **20c** was hydrolyzed and the resulting thiol alkylated in a one-pot procedure to give the precursor **33c** in 84% yield. To our delight, 2,5-dihydrothiophene (24) **36c** was obtained in 86% yield from **33c** using the Grubbs–Nolan catalyst **35** (25) (Scheme 8). It appeared that catalyst poisoning was not going to be a problem, or so we thought. Compound **38** is very conveniently recovered by evaporation and distillation. It can be converted back to the chiral auxiliary **7** by ozonolysis.

To our surprise, the very similar precursor **33a**, prepared in the same way from **20a**, gave no cyclic product under identical conditions (Scheme 9). Instead, some dimer (not shown) was isolated. We had to add an external Lewis acid to get the reaction to go (97% conversion by NMR).[3] A ruthenium(II) dimer was the Lewis acid that gave the best results.

3,6-Dihydrothiopyrans **37c** could not be prepared from of the corresponding precursors **34c**, after testing several solvents, catalysts, Lewis acids, and other additives (Scheme 8).

Sulfolenes **40a** and **40c** were efficiently prepared by RCM cleavage of **39a** and **39c**, respectively (Scheme 10). The low temperature used for RCM cleavage in this case was essential, since higher temperatures lead to the slow cheletropic extrusion of SO_2 in the sulfolene product to give the corresponding 1,3-dienes. Again, we were unable to prepare the analogous six-membered cyclic sulfones.



There seem to be several factors controlling the rate of RCM in our system. It is plausible that the formation of 3,6-dihydrothiopyrans **37** is prevented by the formation of a stable chelate **II** between sulfur and ruthenium (Fig. 2). The allylic sulfides do not form a stable chelate (cf. **I** in Fig. 2), and in those cases, poisoning of the catalyst probably occurs intermolecularly. In this case, bulky R groups such as *t*-Bu in **33c** or external Lewis acids are enough to allow the reaction to proceed.

We have shown previously that the formation of six-membered carbo- or *N*-heterocycles is kinetically less favored than the formation of the analogous five-membered rings (22). We suggest that under the reaction conditions and time used, the RCM reaction does not reach equilibrium and

[3] Isolated yield was low because of the high volatility of the product.

Fig. 2. Possible chelates in RCM of allylic sulfides and sulfones.

that the difference in efficiency of formation of dihydrothiophenes and dihydrothiopyrans is kinetically driven. We think that perhaps the longer C–S bond (>1.8 Å) hampers the ring-closing metathesis for six-membered ring formation and that poisoning of the catalyst is not the sole problem in this case, since a fair amount of dimer was isolated in each case.

Sulfones do form internal chelates with ruthenium, but the oxygen–ruthenium bond is weaker such that allylic sulfones (**III**, Fig. 2) undergo RCM fast enough, while homoallylic sulfones yield mostly dimer because of the slower rate of six-membered ring formation (**IV**, Fig. 2).

Synthesis of a potent MMP inhibitor

Several sulfonylhydroxamic acids are potent matrix metalloproteinase (MMP) inhibitors that have been studied in the clinic for the treatment of cancer and osteoarthritis (Fig. 3) (26). The overexpression of MMPs may result in the degradation of cartilage and may lead to medical conditions, such as osteoarthritis and rheumatoid arthritis. Compounds **41** and **43** are two highly selective inhibitors of MMP-13 in the nanomolar concentration (27) that may offer protection against cartilage degradation and potentially better treatment of osteoarthritis (28). Compounds **41** and **42** were previously prepared as racemic mixtures, but a small amount of **41** was resolved by preparative HPLC on a chiral column, and it was shown that (+)**–41** was 20 times as active as (–)**–41** (27). Their asymmetric synthesis thus becomes interesting.

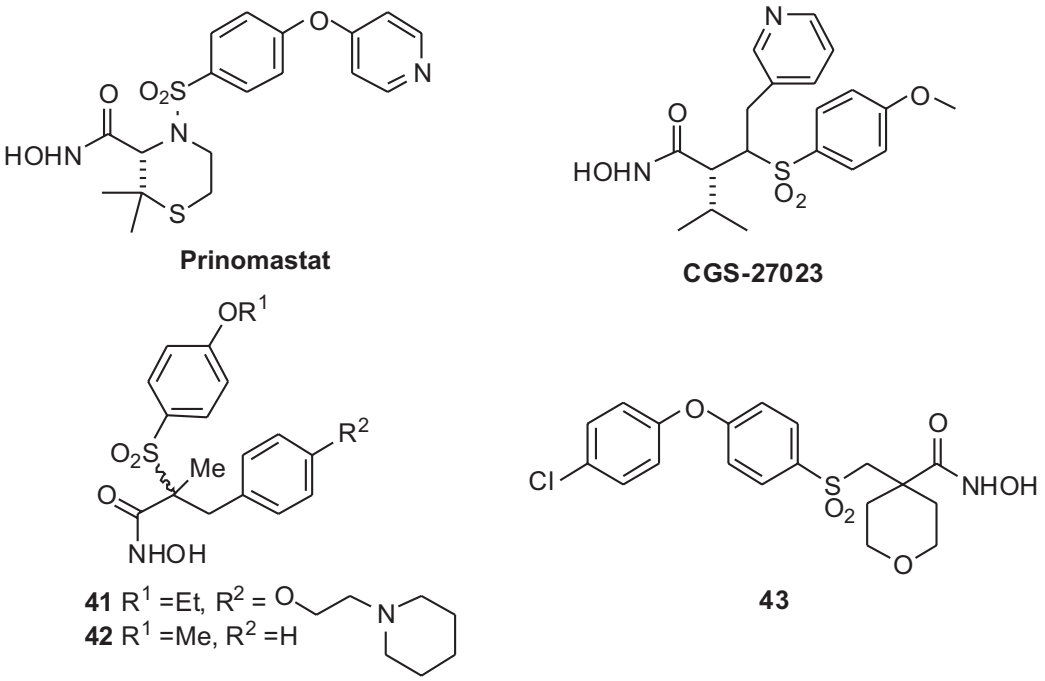
We synthesized **42** as shown in Scheme 11. Alcohol **8h** was easily prepared in two steps from the commercially available propynylbenzene **43**. The ratio of β- and α-alcohols **8h** and **9h** was excellent, and their chromatographic separation was easy. Diastereomerically pure alcohol **8h** was submitted to the rearrangement conditions to give **20h** in 88% yield as essentially a single diastereomer. The *S*-thiocarbamate function could be directly coupled to iodide **45** using Tamaru's allylsulfenylation conditions to give a good yield of **46** (29). The synthesis was continued by first oxidizing the sulfur in **46**, then oxidatively cleaving the chiral auxiliary with ozone. Acid **47** could be obtained directly in one step by treating **46** with ozone, but this procedure led to lower yield of **47** and many decomposition products. Alternatively, when dimethylsulfide was used in the ozonolysis work-up, the α-sulfonylaldehyde was obtained and could be purified. Its treatment with Jones' reagent gave **47** in 53% yield for the two steps. Carrying out the two previoulsy reported steps (27) completed the synthesis of **42** for a total of eight steps and 12% overall yield from **43**.

In conclusion, we have successfully extended our *p*-menthane-3-carboxaldehyde based methodology to include the formation of chiral sulfur-bearing tertiary and quaternary carbons. This methodoly is becoming highly versatile and compares favorably to methodologies based on the classical alkylation of chiral enolates (30). Furthermore, carbo-, *N*-hetero-, and *S*-heterocyclic compounds are now directly accessible using RCM without the need for an extra step to cleave the auxiliary.

Experimental[4]

General

Flash chromatography was performed using Merck silica gel (230–400 Mesh ASTM) with solvents distilled prior to use. NMR spectra were recorded on a Bruker AC-300 spectrometer (^{1}H NMR at 300 MHz, ^{13}C NMR at 75.5 MHz). Infrared spectra were recorded on a PerkinElmer 1600 FTIR spectrometer with a thin layer of the product on a NaCl disc. HPLC analyses were performed on a HP 1100 apparatus; GC analyses were performed on a Agilent 6890 series apparatus; GCMS analyses were performed on a HP 5890 serie II instrument (25 m length, 25μ OD, capillary Stabiliwax-DB5 column) coupled with a mass spectrometer (HP 5971). High-resolution spectrometry was performed on a ZAB-1F micromass spectrometer. Optical rotations $[\alpha]^{20}_{D}$ were measured on a PerkinElmer 343 polarimeter.



Alcohol 8f (method A)

Vinyliodide **17f** (5.50 g, 19.2 mmol) was dissolved in diethyl ether (70.0 mL), and the solution was cooled to –78 °C. A solution of *t*-BuLi in pentane (38.4 mmol) was added dropwise to the mixture. The reaction mixture was stirred at –78 °C for 30 min and then at RT for 1 h. It was again cooled to –78 °C before the addition of trimethylaluminium (2.0 mol/L in hexanes, 24.0 mL, 48.0 mmol) followed by a solution of (–)-*p*-menthane-3-carboxaldehyde **7** (2.70 g, 16.0 mmol) in diethyl ether (10.0 mL). The reaction mixture was stirred at –78 °C for 2 h and then at RT overnight. The reaction was quenched with an aqueous solution of sodium bicarbonate (100 mL) at 0 °C. The two phases were separated, and the aqueous phase was extracted with diethyl ether (3 × 100 mL). The combined organic portions were washed with brine, dried with anhyd. magnesium sulfate, and evaporated under reduced pressure. The crude product (**8f**:**9f** 52:1 by GC) was purified by flash chromatography on silica gel eluting with a mixture of hexanes/ethyl acetate (100: 0 to 95:5). A colorless oil was obtained (3.44 g, 55%).

Alcohol 8g (method B)

A flask containing a solution of *bis*(cyclopentadienyl)zirconium dichloride (129 mg, 0.44 mmol) in 6.3 mL of dichloromethane was put under vacuum and then filled with argon (3×). Trimethylaluminium (545 μL, 5.69 mmol) was added using a sass equipped with a syringe under an argon atmosphere. The solution was stirred 10 min at RT and then 5 min at 0 °C before the dropwise addition of hex-5-ynylbenzene (300 mg, 1.90 mmol). The mixture was stirred at RT overnight. A solution of (–)-*p*-menthane-3-carboxaldehyde **7** (246 mg, 1.46 mmol) in 4.9 mL of tetrahydrofuran was added dropwise to the reaction mixture at –78 °C. The reaction was warmed to RT and stirred overnight. A saturated aqueous solution of potassium carbonate was added dropwise until gas evolution stopped. The white precipitate was dissolved in a 1 N aq. solution of HCl. Then a 5 N aq. solution of HCl was added until the two layers were clear. The two phases were separated, and the aqueous layer was extracted three times with dichloromethane (50 mL). The organic layers were combined, washed with a saturated aqueous solution of sodium bicarbonate, dried over $MgSO_4$, filtered, and evaporated under reduced pressure. The crude compound was determined to be a mixture of the two diastereomers **8g** and **9g** in a ratio of 94:6 (88% de). The crude product was purified by flash chromatography on silica gel (100% hexanes to 5% EtOAc in hexanes). Two colorless oils were isolated (major diastereomer **8g**, 132 mg, 75%, >99% de by HPLC.; minor diastereomer **9g**, 12 mg, 7%, >99% de).

General procedure for the preparation of *S*-allylthiocarbamates

To a solution of the allylic alcohol **8** or **9** (0.198 mmol) in THF (2 mL) at 0 °C was added NaH 60% *w*/*w* in oil (15 mg, 0.372 mmol), and the mixture was stirred for 1 h at this temperature before the addition of phenylisothiocyanate (47 μL, 0.396 mmol). The reaction was heated to reflux and stirred for 3 h. It was then cooled down to RT before the addition of pyridinium *p*-toluenesulfonate (124 mg, 0.495 mmol) in THF (3.3 mL). The reaction was then heated to reflux for 2–3 h. Then, the reaction was stopped by the addition of water (5 mL) and Et_2O (5 mL). The two phases were separated, and the aqueous layer was extracted with Et_2O (3 × 10 mL). The combined organic layers were washed with brine, dried with anhyd. $MgSO_4$, and concentrated under reduced pressure. The crude product was purified by flash chromatography on silica gel (100% hexanes to 5% EtOAc in hexanes) to afford the desired product.

S-allylthiocarbamate 20c

Prepared following the general procedure for the synthesis of *S*-allylthiocarbamates. Reaction time after the addition of pyridinium *p*-toluenesulfonate: 2 h. Compound **20c** was isolated as a white solid (74 mg, 96%, 98% de by GC), mp 102–103 °C. ^1H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.41 (d, 2H, J = 8.3 Hz), 7.30 (t, 2H, J = 8.0 Hz), 7.11–7.07 (m, 2H), 5.50–5.47 (m, 2H), 3.97–3.94 (m, 1H), 1.91–1.78 (m, 2H), 1.70 (dm, 1H, J = 12.1 Hz), 1.62–1.53 (m, 2H), 1.36–1.21 (m, 1H), 1.01 (s, 9H), 0.98–0.78 (m, 4H), 0.85 (d, 3H, J = 7.2 Hz), 0.82 (d, 3H, J = 6.6 Hz), 0.70 (d, 3H, J = 7.2 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 165.1 (s), 138.1 (d), 137.9 (s), 129.0 (d), 127.0 (d), 124.1 (d), 119.5 (d), 59.9 (d), 47.0 (s), 44.9 (d), 42.9 (t), 35.1 (t), 34.4 (d), 32.5 (d), 28.2 (d), 27.9 (q), 23.9 (t), 22.5 (q), 21.4 (q), 15.1 (q). HRMS calcd. for $C_{31}H_{43}ONS$: 477.3065, found: 477.3056. $[\alpha]^{20}_D$ –37.0 (*c* = 1.30, $CHCl_3$).

S-allylthiocarbamate 20h

Prepared following the general procedure for the synthesis of *S*-allylthiocarbamates. Reaction time after the addition of pyridinium *p*-toluenesulfonate: 3 h. Compound **21h** was isolated as a colorless oil (77 mg, 88%, 99% de by HPLC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.44 (d, 2H, *J* = 8.3 Hz), 7.34 (d, 2H, *J* = 7.2 Hz), 7.35–7.22 (m, 4H), 7.15–7.09 (m, 2H), 5.82 (d, 1H, *J* = 15.4 Hz), 5.32 (dd, 1H, *J* = 15.4, 9.4 Hz), 3.35 (ABq, 2H), 2.01–1.90 (m, 1H), 1.76–1.57 (m, 4H), 1.61 (s, 3H), 1.46–1.30 (m, 1H), 1.08–0.78 (m, 4H), 0.86 (d, 3H, *J* = 6.6 Hz), 0.83 (d, 3H, *J* = 7.1 Hz), 0.74 (d, 3H, *J* = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 165.1 (s) 137.7 (s), 137.1 (s), 136.2 (d), 132.4 (d), 131.0 (d), 129.1 (d), 127.7 (d), 126.5 (d), 124.3 (d), 119.7 (d), 55.6 (s), 47.0 (d), 46.6 (t), 44.9 (d), 43.3 (t), 35.1 (t), 32.4 (d), 28.0 (d), 24.3 (q), 24.0 (t), 22.5 (q), 21.4 (q), 15.5 (q). IR (neat) ν (cm^{-1}): 3310, 3029, 2922, 1666, 1514, 1438, 1139. LRMS (*m*/*z*, relative intensity) 435 (M^+, 1), 344 (8), 283 (23), 145 (85), 84 (100). HRMS calcd. for $C_{28}H_{37}ONS$: 435.2596, found: 435.2593. $[\alpha]^{20}_D$ –49.2 (*c* = 1.03, $CHCl_3$).

S-allylthiocarbamate 21c

Prepared following the general procedure for the synthesis of *S*-allylthiocarbamates. Reaction time after the addition of pyridinium *p*-toluenesulfonate: 2 h. Compound **21c** was isolated as a colorless oil (77 mg, >99%, >99% de by GC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.40 (d, 2H, *J* = 7.7 Hz), 7.30 (t, 2H, *J* = 7.7 Hz), 7.08 (t, 1H, *J* = 7.7 Hz), 7.04 (s, 1H), 5.47–5.44 (m, 2H), 3.94–3.91 (m, 1H), 1.87–1.78 (m, 2H), 1.69 (d, 1H, *J* = 12.1 Hz), 1.61–1.54 (m, 2H), 1.38–1.26 (m, 1H), 1.01 (s, 9H), 0.98–0.80 (m, 4H), 0.86 (d, 3H, *J* = 6.6 Hz), 0.71 (d, 3H, *J* = 7.2 Hz), 0.62 (d, 3H, *J* = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 164.9 (s), 138.0 (s), 138.0 (d), 129.0 (d), 126.9 (d), 124.1 (d), 119.4 (d), 60.2 (d), 47.2 (s), 44.8 (d), 43.1 (t), 35.1 (t), 34.2 (d), 32.5 (d), 28.0 (d), 27.8 (q), 24.0 (t), 22.6 (q), 21.2 (q), 15.1 (q). IR (neat) ν (cm^{-1}): 3298, 2954, 2914, 2869, 1659, 1499, 1439, 1147, 749. LRMS (*m*/*z*, relative intensity) 387 (M^+, 12), 330 ($(M - C_4H_9)^+$, 8), 177 (71), 97 (100). HRMS calcd. for $C_{24}H_{37}ONS$: 387.2596, found: 387.2591. $[\alpha]^{20}_D$ –165.1 (*c* = 1.03, $CHCl_3$).

S-allylthiocarbamate 21g

Prepared following the general procedure for the synthesis of *S*-allylthiocarbamates. Reaction time after the addition of pyridinium *p*-toluenesulfonate: 3 h. Compound **21g** was isolated as a colorless oil (64 mg, 67%, 98% de by HPLC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.37 (d, 2H, *J* = 7.7 Hz), 7.32–7.24 (m, 4H), 7.18–7.14 (m, 3H), 7.08 (t, 1H, *J* = 7.7 Hz), 6.98 (br s, 1H), 5.62 (d, 1H, *J* = 15.7 Hz), 5.39 (dd, 1H, *J* = 15.7, 9.4 Hz), 2.61 (t, 2H, *J* = 7.7 Hz), 2.04–1.79 (m, 3H), 1.73–1.45 (m, 6H), 1.64 (s, 3H), 1.43–1.25 (m, 3H), 1.04–0.78 (m, 4H), 0.85 (d, 3H, *J* = 6.6 Hz), 0.81 (d, 3H, *J* = 7.2 Hz), 0.64 (d, 3H, *J* = 7.2 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 164.9 (s), 142.5 (s) 137.6 (s), 135.7 (d), 133.2 (d), 129.0 (d), 128.4 (d), 128.2 (d), 125.6 (d), 124.1 (d), 119.4 (d), 53.6 (s), 47.2 (d), 44.8 (d), 43.2 (t), 40.7 (t), 35.7 (t), 35.1 (t), 32.4 (d), 31.6 (t), 28.0 (d), 24.5 (q), 24.3 (t), 24.0 (t), 22.5 (q), 21.4 (q), 15.2 (q). IR (neat) ν (cm^{-1}): 3302, 2947, 2928, 2869, 1660, 1513, 1435, 1137, 749. LRMS (*m*/*z*, relative intensity) 477 (M^+, 1), 357 (1), 325 (95), 119 (100). HRMS calcd. for $C_{31}H_{43}ONS$: 477.3065, found: 477.3056. $[\alpha]^{20}_D$ –175.6 (*c* = 0.52, $CHCl_3$).

General procedure for the preparation of thiocarbonates

To a solution of the allylic alcohol **8** or **9** (0.099 mmol) in THF (1 mL) at 0 °C was added NaH 60% *w*/*w* in oil (7 mg, 0.198 mmol), and the mixture was stirred for 1 h at this temperature before the addition of carbon disulfide (24 μL, 0.396 mmol). The reaction was heated to reflux and stirred for 2 h. It was then cooled down to RT before the addition of methyl iodide (25 μL, 0.396 mmol) and was again heated to reflux for 45 min. Then, the reaction was stopped by the addition of water (5 mL) and Et_2O (5 mL). The two phases were separated, and the aqueous layer was extracted with Et_2O (3 × 10 mL). The combined organic layers were washed with brine, dried with anhyd. $MgSO_4$, and concentrated under reduced pressure. The crude product was purified by flash chromatography on silica gel (100% hexanes to 2% EtOAc in hexanes) to afford the desired product.

Thiocarbonate 25b

Prepared following the general procedure for the synthesis of thiocarbonates. Compound **25b** was isolated as a colorless oil (90 mg, 59%, >99% de by HPLC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.56 (d, 2H, *J* = 16.0 Hz), 5.34 (dd, 1H, *J* = 15.7, 9.1 Hz), 2.33 (s, 3H), 1.94–1.68 (m, 6H), 1.62–1.52 (m, 2H), 1.58 (s, 3H), 1.38–1.23 (m, 2H), 1.01–0.76 (m, 7H), 0.86 (d, 6H, *J* = 6.6 Hz), 0.67 (d, 3H, *J* = 7.1 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 188.7 (s), 135.7 (d), 132.4 (d), 58.0 (s), 47.1 (d), 44.9 (d), 43.1 (t), 35.1 (t), 32.4 (d), 30.9 (t), 28.2 (d), 24.5 (q), 24.0 (t), 22.5 (q), 21.4 (q), 18.0 (t), 15.2 (q), 14.4 (q), 12.8 (q). IR (neat) ν (cm^{-1}): 2955, 2927, 2871, 1641. LRMS (*m*/*z*, relative intensity) 343 (MH^+, 4), 250 (8), 235 (100). HRMS calcd. for $C_{19}H_{35}OS_2$ (MH^+): 343.2129, found: 343.2135. $[\alpha]^{20}_D$ –46.9 (*c* = 0.73, $CHCl_3$).

Thiocarbonate 25c

Prepared following the general procedure for the synthesis of thiocarbonates. Compound **25c** was isolated as a colorless oil (135 mg, 99%, >99% de by GC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.43–5.40 (m, 2H), 4.04–4.06 (m, 1H), 2.40 (s, 3H), 1.87–1.75 (m, 2H), 1.74–1.68 (m, 1H), 1.62–1.50 (m, 3H), 1.36–1.25 (m, 1H), 0.99–0.77 (m, 3H), 0.95 (s, 9H), 0.85 (d, 3H, J = 7.2 Hz), 0.84 (d, 3H, J = 6.6 Hz), 0.68 (d, 3H, J = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 188.8 (s), 138.7 (d), 126.1 (d), 59.8 (d), 47.0 (d), 44.9 (d), 42.8 (t), 35.1 (t), 34.4 (s), 32.4 (d), 28.3 (d), 27.7 (q), 23.9 (t), 22.5 (q), 21.4 (q), 15.0 (q), 13.1 (q). IR (neat) ν (cm^{-1}): 2956, 2927, 2869, 2360, 2340, 1646, 1366, 861. LRMS (*m/z*, relative intensity) 342 (M^+, 6), 267 (23), 235 (84), 177 (82), 97 (100). HRMS calcd. for $C_{19}H_{34}OS_2$: 342.2051, found: 342.2044. $[\alpha]^{20}_D$ +85.3 (c = 0.83, $CHCl_3$).

Thiocarbonate 26b

Prepared following the general procedure for the synthesis of thiocarbonates. Compound **26b** was isolated (60 mg, 39%, >96% de by HPLC) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.55 (d, 2H, J = 15.4 Hz), 5.35 (dd, 1H, J = 15.4, 9.4 Hz), 2.32 (s, 3H), 1.98–1.72 (m, 6H), 1.70–1.50 (m, 2H), 1.60 (s, 3H), 1.43–1.24 (m, 2H), 1.01–0.66 (m, 7H), 0.86 (d, 6H, J = 6.6 Hz), 0.66 (d, 3H, J = 7.2 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 188.6 (s), 135.7 (d), 132.5 (d), 58.0 (s), 47.2 (d), 44.8 (d), 43.3 (t), 35.1 (t), 32.4 (d), 30.9 (t), 28.0 (d), 24.3 (q), 24.0 (t), 22.5 (q), 21.4 (q), 18.0 (t), 15.2 (q), 14.3 (q), 12.7 (q). IR (neat) ν (cm^{-1}): 2955, 2927, 2871, 1642. LRMS (*m/z*, relative intensity) 343 (MH^+, 3), 250 (5), 235 (100). HRMS calcd. for $C_{19}H_{35}OS_2$ (MH^+): 343.2129, found: 343.2135. $[\alpha]^{20}_D$ –22.9 (c = 0.74, $CHCl_3$).

Thiocarbonate 26c

Prepared following the general procedure for the synthesis of thiocarbonates. Compound **26c** was isolated as a colorless oil (122 mg, 90%, 98% de by GC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.41–5.38 (m, 2H), 4.05 (dd, 1H, J = 5.5, 3.3 Hz), 2.38 (s, 3H), 1.95–1.75 (m, 2H), 1.73–1.60 (m, 1H), 1.58–1.51 (m, 3H), 1.36–1.28 (m, 1H), 0.99–0.78 (m, 9H), 0.96 (s, 9H), 0.65 (d, 3H, J = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 188.7 (s), 138.7 (d), 126.0 (d), 60.0 (d), 47.2 (d), 44.7 (d), 43.0 (t), 35.1 (t), 34.2 (s), 32.4 (d), 27.8 (d), 27.8 (q), 24.0 (t), 22.5 (q), 21.4 (q), 15.3 (q), 13.0 (q). IR (neat) ν (cm^{-1}): 2955, 2927, 2869, 1647. LRMS (*m/z*, relative intensity) 342 (M^+, 5), 235 (38), 177 (35), 97 (100). HRMS calcd. for $C_{19}H_{34}OS_2$: 342.2051, found: 342.2044. $[\alpha]^{20}_D$ –157.3 (c = 0.49, $CHCl_3$).

General procedure for the preparation of *S*-allylimidazoyl thiocarbonates

To a solution of the allylic alcohol (0.099 mmol) in acetonitrile (0.5 mL) was added thiocarbonyldiimidazole (53 mg, 0.297 mmol), and the mixture was stirred for 3 days at RT. Then, the reaction was stopped by the addition of water (5 mL) and Et_2O (5 mL). The two phases were separated, and the aqueous layer was extracted with Et_2O (3 × 10 mL). The combined organic layers were washed with brine, dried with anhyd. $MgSO_4$, and concentrated under reduced pressure. The crude product was purified by flash chromatography on silica gel (100% hexanes to 5% EtOAc in hexanes) to afford the desired product.

Imidazoyl thiocarbonate 27c

Prepared following the general procedure for the synthesis of imidazoyl thiocarbonates. Compound **27c** was isolated as a colorless oil (28 mg, 78% yield, 97% de by HPLC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 8.18 (s, 1H), 7.45 (s, 1H), 7.06 (s, 1H), 5.58–5.41 (m, 2H), 4.10 (d, 1H, J = 9.3 Hz), 1.91–1.66 (m, 3H), 1.60–1.45 (m, 2H), 1.34–1.23 (m, 2H), 1.02 (s, 9H), 1.01–0.62 (m, 3H), 0.84 (d, 3H, J = 7.2 Hz), 0.81 (d, 3H, J = 6.6 Hz), 0.68 (d, 3H, J = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 165.3 (s), 140.0 (d), 135.4 (d), 130.6 (d), 125.3 (d), 115.9 (d), 60.9 (d), 47.0 (d), 44.9 (d), 42.7 (t), 35.0 (t), 34.5 (s), 32.4 (d), 28.3 (d), 27.8 (q), 23.9 (t), 22.5 (q), 21.4 (q), 15.0 (q). IR (neat) ν (cm^{-1}): 3125, 2954, 2924, 1762, 1693. LRMS (*m/z*, relative intensity) 362 (M^+, 3), 306 (39), 107 (100). HRMS calcd. for $C_{21}H_{34}ON_2S$: 362.2392, found: 362.2386. $[\alpha]^{20}_D$ –47.3 (c = 0.64, $CHCl_3$).

Imidazoyl thiocarbonate 28c

Prepared following the general procedure for the synthesis of imidazoyl thiocarbonates. Compound **27c** was isolated as a colorless oil (17 mg, 42% yield, 99% de by HPLC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 8.20 (s, 1H), 7.48 (s, 1H), 7.08 (s, 1H), 5.58–5.41 (m, 2H), 4.10 (d, 1H, J = 9.3 Hz), 1.93–1.81 (m, 1H), 1.72–1.52 (m, 4H), 1.39–1.22 (m, 2H), 1.04 (s, 9H), 0.98–0.65 (m, 3H), 0.86 (d, 3H, J = 6.6 Hz), 0.76 (d, 3H, J = 7.2 Hz), 0.57 (d, 3H, J = 7.2 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 165.4 (s), 139.8 (d), 135.6 (d), 130.6 (d), 125.2 (d), 116.1 (d), 61.1 (d), 47.2 (d), 44.7 (d), 42.9 (t), 35.1 (t), 34.4 (s), 32.4 (d), 28.0 (d), 27.8 (q), 24.0 (t), 22.5 (q), 21.2 (q), 15.1 (q). IR (neat) ν (cm^{-1}): 2955, 2927, 2869, 1695, 1467. LRMS (*m/z*, relative intensity) 362 (M^+, 10), 306 (62), 95 (100). HRMS calcd. for $C_{21}H_{34}ON_2S$: 362.2392, found: 362.2386. $[\alpha]^{20}_D$ –98.8 (c = 1.42, $CHCl_3$).

Alcohol 31

Thiocarbonate **25c** (50 mg, 0.146 mmol) was solubilized in 4.9 mL of dichloromethane and Sudan III (1 mg) was added. The mixture was cooled down to –78 °C. Ozone was bubbled through the solution until the indicator color passed from red to pale pink or from red to violet. Then, dry nitrogen was bubbled through the solution for 5 min before sodium borohydride (55 mg, 1.459 mmol) was added. The mixture was stirred at –78 °C for 30 min and was slowly warmed to RT overnight. Then, the reaction was stopped by the addition of water (5 mL) and dichloromethane (5 mL). The two phases were separated, and the aqueous layer was extracted with dichloromethane (3 × 10 mL). The combined organic layers were washed with brine, dried with anhyd. $MgSO_4$, and concentrated under reduced pressure without heating. The crude product was purified by flash chromatography on silica gel (100% hexanes to 10% EtOAc in hexanes) to afford the desired product. Menthyl alcohol was also recovered in 80% yield. Compound **31** was isolated as a colorless oil (27 mg, 89%, 93% ee by HPLC). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 4.00 (dd, 1H, J = 11.3, 3.6 Hz), 3.72 (dd, 1H, J = 8.8, 3.9 Hz), 3.62 (dd, 1H, J = 11.6, 8.8 Hz), 2.44 (s, 3H), 1.90–1.50 (br s, 1H), 1.02 (s, 9H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 190.3 (s), 62.6 (t), 60.3 (d), 34.4 (s), 28.1 (q), 13.3 (q). IR (neat) ν (cm^{-1}): 3430,

Alcohol (R)-32

The substrate (68 mg, 0.239 mmol) was solubilized in 2.4 mL of dichloromethane. The mixture was cooled down to –78 °C. Ozone was bubbled through the solution until TLC showed completion. Nitrogen was then bubbled through the solution for 5 min before a borane-methylsulfide solution (2 mol/L in THF, 0.48 mL, 0.955 mmol) was slowly added. The mixture was stirred at –78 °C for 30 min and was slowly warmed to RT overnight. Then, the reaction was stopped by the addition of water (5 mL) and dichloromethane (5 mL). The two phases were separated, and the aqueous layer was extracted with dichloromethane (3 × 10 mL). The combined organic layers were washed with brine, dried with anhyd. $MgSO_4$, and concentrated under reduced pressure without heating. The crude product was purified by flash chromatography on silica gel (100% hexanes to 20% EtOAc in hexanes) to afford 56 mg of the desired product (83%) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.28 (m, 2H), 7.20–7.16 (m, 3H), 3.79–3.66 (m, 3H), 2.62 (t, 2H, *J* = 7.7 Hz), 2.43 (s, 3H), 1.97 (s, 1H), 1.84–1.72 (m, 1H), 1.70–1.37 (m, 5H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 190.2 (s), 142.3 (s), 128.3 (d), 125.7 (d), 65.4 (t), 48.9 (d), 35.7 (t), 31.1 (t), 30.5 (t), 26.6 (t), 13.3 (q) IR (neat) ν (cm^{-1}): 3600–3200 (br), 3025, 2931, 2857, 1644, 869. General procedure for the preparation of RCM precursors

The thiocarbamate (0.064 mmol) and the bromide (0.322 mmol) were solubilized in 1 mL of methanol, and cesium carbonate (0.322 mmol) was added. The mixture was stirred and heated overnight at 80 °C in a sealed tube. Water (5 mL) and diethyl ether (5 mL) were added to the reaction mixture. The two layers were separated, and the aqueous layer was extracted three times with diethyl ether. The combined organic layers were washed with brine, dried over anhyd. $MgSO_4$, filtered, and evaporated under reduced pressure. The crude product was purified by flash chromatography on silica gel (100% hexanes to 4% EtOAc in hexanes).

Sulfide 33c

Prepared following the general procedure for the synthesis of RCM precursors. Compound **33c** was isolated as a colorless oil (54 mg, 79% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.76 (dddd, 1H, *J* = 15.9, 10.6, 8.4, 5.7 Hz), 5.31 (dd, 1H, *J* = 15.9, 10.6 Hz), 5.12–5.04 (m, 3H), 3.07 (dd, 1H, *J* = 13.9, 5.7 Hz), 2.99 (dd, 1H, *J* = 13.9, 8.4 Hz), 2.83 (d, 1H, *J* = 9.9 Hz), 2.03–1.56 (m, 4H), 1.43–1.32 (m, 1H), 1.25–0.67 (m, 11H), 0.97 (s, 9H), 0.71 (d, 3H, *J* = 7.2 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 137.6 (d), 135.2, (d), 127.5 (d), 116.5 (t), 58.8 (d), 47.2 (d), 45.2 (d), 44.2 (t), 35.1 (t), 33.8 (t), 33.2 (s), 32.6 (d), 28.2 (q), 28.1 (d), 23.8 (t), 22.6 (q), 21.4 (q), 15.0 (q). IR (neat) ν (cm^{-1}): 2955, 2920, 2871, 1641, 1458, 1366, 971, 912. LRMS (*m/z*, relative intensity) 308 (M^+, 6), 267 ((M – C_3H_5)$^+$, 24), 257 ((M – C_4H_9)$^+$, 100), 177 (78), 97 (88). HRMS calcd. for $C_{20}H_{36}S$: 308.2538, found: 308.2543. $[\alpha]^{20}_D$ +9.6 (*c* = 1.31, $CHCl_3$).

Sulfide 34c

Prepared following the general procedure for the synthesis of RCM precursors. Compound **34c** was isolated as a colorless oil (54 mg, 75% yield.) ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.82 (ddt, 1H, *J* = 16.8, 10.3, 6.6 Hz), 5.31 (dd, 1H, *J* = 15.1, 10.3 Hz), 5.15–5.07 (m, 2H), 5.02–4.99 (m, 1H), 2.88 (d, 1H, *J* = 10.3 Hz), 2.48–2.38 (m, 2H), 2.36–2.21 (m, 2H), 1.98–1.80 (m, 2H), 1.74–1.70 (m, 1H), 1.65–1.56 (m, 3H), 1.40–1.25 (m, 1H), 0.98–0.77 (m, 3H), 0.97 (s, 9H), 0.87 (d, 3H, *J* = 7.2 Hz), 0.86 (d, 3H, *J* = 6.6 Hz), 0.71 (d, 3H, *J* = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 137.3 (d), 137.1, (d), 127.6 (d), 115.5 (t), 60.1 (d), 47.2 (d), 45.0 (d), 44.0 (s), 35.1 (t), 34.0 (t), 33.8 (q), 32.5 (d), 29.8 (t), 28.2 (d), 28.0 (q), 23.9 (t), 22.5 (q), 21.4 (t), 15.0 (q). LRMS (*m/z*, relative intensity) 322 (M^+, 25), 265 (95), 205 (69), 177 (72), 127 (100). HRMS calcd. for $C_{21}H_{38}S$: 322.2694, found: 322.2705. $[\alpha]^{20}_D$ –12.3 (*c* = 0.86, $CHCl_3$).

(S)-2-tert-Butyl-2,5-dihydrothiophene 36c

A solution of sulfide **33c** (92 mg, 0.30 mmol) in dichloromethane (30 mL, 0.01 mol/L), was brought to reflux and then degassed by passing a stream of argon for 15 min while refluxing. The Grubbs–Nolan catalyst **35** (25 mg, 10 mol%) was quickly added while the solution was still under reflux. The resulting pale pink solution was refluxed for 18 h. It was cooled to room temperature, and volatiles were removed under reduced pressure without heating. Analysis of the crude reaction mixture showed complete conversion to **36c** and auxiliary by-product **38**. The crude product was purified by flash chromatography on silica gel (100% pentane) to afford the desired product **36c** (36 mg, 85%) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.86 (tt, 1H, *J* = 6.6, 2.2 Hz), 5.77 (tt, 1H, *J* = 6.6, 2.2 Hz), 4.12 (br s, 1H), 3.64 (br s, 2H), 0.94 (s, 9H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 130.9 (d), 128.9 (d), 68.0 (d), 38.4 (t), 35.5 (s), 27.1 (q). IR (neat) ν (cm^{-1}): 2956, 2868, 1712, 1691, 1463. LRMS (*m/z*, relative intensity) 142 (M^+, 20), 85 (100), 77 (10). HRMS calcd. for $C_8H_{14}S$: 142.0816, found: 142.0814. $[\alpha]^{20}_D$ –43.1 (*c* = 1.23, $CHCl_3$).

Sulfone 39c

The allylic sulfide **33c** (192 mg, 0.622 mmol) was solubilized in 3 mL of dichloromethane, and *m*-chloroperbenzoic acid (215 mg, 1.24 mmol) was added to the solution. The mixture was stirred for 10 min at RT and was then cooled to 0 °C before the addition 5 mL of a saturated aqueous solution of $NaHCO_3$ and 5 mL of dichloromethane. The two layers were separated. The aqueous layer was extracted with dichloromethane (3 × 5 mL). The combined organic layers were washed with brine, dried over anhyd. $MgSO_4$, filtered, and evaporated under reduced pressure. The crude product was purified by flash chromatography on silica gel (5% to 10% EtOAc in hexanes). The desired product was isolated as a white solid (163 mg, 77%), mp 107–108 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 5.88 (dddd, 1H, *J* = 16.0, 10.3, 9.0, 6.1 Hz), 5.60 (dd, 1H, *J* = 15.1, 10.3 Hz), 5.49–5.31 (m, 3H), 3.85 (dd, 1H, *J* = 13.8, 9.0 Hz), 3.41 (dd, 1H, *J* = 13.8, 6.1 Hz), 3.32 (d, 1H, *J* =

10.5 Hz), 2.11–2.00 (m, 1H), 1.76–1.59 (m, 4H), 1.43–1.17 (m, 1H), 1.14 (s, 9H), 1.05–0.78 (m, 4H), 0.86 (d, 3H, J = 6.1 Hz), 0.85 (d, 3H, J = 7.7 Hz), 0.69 (d, 3H, J = 6.6 Hz). IR (CHCl3) ν (cm^{-1}): 3028, 2957, 1310, 1126. LRMS (*m/z*, relative intensity) 358 (MNH_4^+, 30), 235 (100), 97 (70). HRMS calcd. for $C_{20}H_{40}NO_2S$ (MNH_4^+): 358.2780, found: 358.2784. $[\alpha]^{20}_D$ –73.5 (c = 0.73, $CHCl_3$).

Sulfolene 40c

A solution of **39c** (50 mg, 0.15 mmol) in dichloromethane (147 mL, 0.001 mol/L) was brought to reflux and then degassed by passing a stream of argon for 15 min while refluxing. The Grubbs–Nolan catalyst **35** (12 mg, 10 mol%) was quickly added while the solution was still under reflux. The resulting pale pink solution was refluxed for 18 h. It was cooled to room temperature, and volatiles were removed under reduced pressure without heating. Analysis of the crude reaction mixture showed complete conversion to **40c** and auxiliary by-product **38**. The crude product was purified by flash chromatography on silica gel (100% hexanes to 30% EtOAc in hexanes) to afford the desired product **40c** (21 mg, 84%) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 6.17–6.06 (m, 2H), 3.75–3.56 (m, 2H), 3.55–3.53 (m, 1H), 1.18 (s, 9H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 129.1 (d), 124.0 (d), 74.4 (d), 56.4 (t), 34.5 (s), 27.1 (q). IR (neat) ν (cm^{-1}): 2963, 2868, 1298, 1245, 1109. LRMS (*m/z*, relative intensity) 192 (MNH_4^+, 40), 175 (MH^+, 5), 110 (100), 96 (95). HRMS calcd. for $C_8H_{15}SO_2$ (MH^+): 175.0793, found: 175.0790. $[\alpha]^{20}_D$ –15.2 (c = 1.96, $CHCl_3$).

Sulfonylhydroxamic acid 42

Carboxylic acid **47** (45 mg, 0.135 mmol) was dissolved in dichloromethane (20 mL), and one drop of *N,N*-dimethylformamide was added. The mixture was cooled to 0 °C, and oxalyl chloride (151 μL, 1.73 mmol) was added dropwise. The reaction mixture was stirred at 0 °C for 1 h. The solution was concentrated under reduced pressure, and the residue was taken up in dichloromethane (2 mL).

In a separate flask, the hydrochloride salt of hydroxylamine (435 mg, 6.26 mmol) was dissolved in a 5:1 mixture of tetrahydrofuran and water (6.2 mL), and it was cooled to 0 °C. Triethylamine (1.1 mL, 7.9 mmol) was added dropwise, and the reaction mixture was stirred 1 h at 0 °C.

The acyl chloride solution previously prepared was added to the hydroxylamine solution at 0 °C. The resulting mixture was stirred 2 h, then water (10 mL) and chloroform (10 mL) were added. The two phases were separated, and the aqueous phase was extracted with chloroform (3 × 10 mL). The combined organic phases were washed with brine, dried over anhyd. magnesium sulfate, and concentrated under reduced pressure. Flash chromatography on silica gel, eluting with ethyl acetate, gave a white solid (31 mg, 65%), mp 48–51 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 9.72 (br s, 1H), 7.77 (d, 2H, J = 8.5 Hz), 7.23–7.22 (m, 3H), 7.13–7.11 (m, 2H), 7.02 (d, 2H, J = 8.5 Hz), 3.88 (s, 3H), 3.58 (d, 1H, J = 13.8 Hz), 3.10 (d, 1H, J = 13.8 Hz), 1.65 (br s, 1H), 1.35 (s, 3H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 164.8 (s), 164.5 (s), 133.5 (s), 132.4 (d), 130.3 (d), 128.6 (d), 127.6 (d), 125.7 (s), 114.5 (d), 71.6 (s), 55.7 (q), 38.7 (t), 16.1 (q). IR (CHCl3) ν (cm^{-1}): 3650–3500 (br), 3500–3175 (br), 3028, 2934, 2845, 1656, 1595, 1141. LRMS (*m/z*, relative intensity) 349 (M^+, 3), 285 (20), 155 (100). HRMS calcd. for $C_{17}H_{19}NO_5S$ (M^+): 349.0984, found: 349.0990. $[\alpha]^{20}_D$ –12.9 (c = 1.80, $CHCl_3$).

Arylsulfide 46

Thiocarbamate **20h** (94 mg, 0.22 mmol) and the aryl iodide **45** (66 mg, 0.28 mmol) were dissolved in toluene (1.0 mL). Cesium carbonate (91 mg, 0.28 mmol) and triphenylphosphine (17 mg, 0.065 mmol) were added, and argon was bubbled through the solution for 5 min prior to the addition of $Pd(PPh_3)_4$ (25 mg, 0.022 mmol). The reaction mixture was stirred and heated to reflux temperature overnight. The mixture was filtered through Celite®, and the filtrate was concentrated under reduced pressure. The crude product was purified by flash chromatography on silica gel (100% hexanes to 10% EtOAc in hexanes). A colorless oil was isolated (66 mg, 72%). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.39 (d, 2H, J = 8.5 Hz), 7.24–7.11 (m, 5H), 6.81 (d, 2H, J = 8.5 Hz), 5.56 (d, 1H, J = 15.5 Hz), 4.62 (dd, 1H, J = 15.5, 9.1 Hz), 3.80 (s, 3H), 3.03 (d, 1H, J = 12.9 Hz), 2.87 (d, 1H, J = 12.9 Hz), 1.92–1.81 (m, 1H), 1.67 (br d, 1H, J = 12.1 Hz), 1.54–1.21 (m, 4H), 1.18 (s, 3H), 1.07–0.51 (m, 4H), 0.84 (d, 3H, J = 6.6 Hz), 0.72 (d, 3H, J = 6.6 Hz), 0.68 (d, 3H, J = 6.6 Hz). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ (ppm): 160.2 (s), 139.2 (d), 137.4 (s), 134.9 (d), 133.7 (d), 130.6 (d), 127.5 (d), 126.2 (d), 122.9 (s), 113.7 (d), 55.2 (q), 54.1 (s), 48.0 (t), 47.0 (d), 44.7 (d), 43.0 (t), 35.0 (t), 32.4 (d), 27.7 (d), 23.9 (t), 23.6 (q), 22.5 (q), 21.4 (q), 15.5 (q). IR (neat) ν (cm^{-1}): 2953, 2923, 1588, 1493, 1246. LRMS (*m/z*, relative intensity) 422 (M^+, 1), 283 (18), 145 (100). HRMS calcd. for $C_{28}H_{38}OS$: 422.2643, found: 422.2637. $[\alpha]^{20}_D$ –42.2 (c = 1.45, $CHCl_3$).

Carboxylic acid 47

Arylsulfide **46** was treated as per the preparation of sulfone **39c**. A white solid was obtained after chromatography (834 mg, 85%), mp 137–138 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.76 (d, 2H, J = 8.8 Hz), 7.26–7.18 (m, 3H), 7.11–7.08 (m, 2H), 6.95 (d, 2H, J = 8.8 Hz), 5.73 (d, 1H, J = 15.8 Hz), 4.81 (dd, 1H, J = 15.8, 9.3 Hz), 3.86 (s, 3H), 3.34 (d, 1H, J = 12.9 Hz), 3.23 (d, 1H, J = 12.9 Hz), 2.02–1.90 (m, 1H), 1.67 (br d, 1H, J = 12.6 Hz), 1.55–1.19 (m, 4H), 1.16 (s, 3H), 0.84 (d, 3H, J = 6.6 Hz), 0.80–0.47 (m, 4H), 0.68 (d, 3H, J = 6.0 Hz), 0.66 (d, 3H, J = 6.0 Hz). IR ($CHCl_3$) ν (cm^{-1}): 2922, 1595, 1497, 1458, 1289. LRMS (*m/z*, relative intensity) 455 (MH^+, 1), 437 (8), 283 (100), 145 (85). HRMS calcd. for $C_{28}H_{39}O_3S$ (MH^+): 455.2620, found: 455.2622. $[\alpha]^{20}_D$ –75.9 (c = 0.69, $CHCl_3$).

The resulting sulfone (35 mg, 0.079 mmol) was solubilized in dichloromethane (1.0 mL). The mixture was cooled down to –50 °C, then ozone was bubbled through the solution for 4 h. Nitrogen was then bubbled through the solution for 10 min before Jones' reagent was added dropwise until the orange color persisted. The reaction mixture was stirred for 60 min at RT. Then, 2-propanol was added dropwise until the solution became blue-green. The mixture was concentrated under reduced pressure, and the resulting solids were dissolved in a minimum amount of water (1 mL). Dichloromethane (1 mL) was added, and the two phases were separated. The aqueous layer was extracted

© 2007 NRC Canada

with dichloromethane (3 × 1 mL). The combined organic fractions were washed with brine, dried over anhyd. magnesium sulfate, and concentrated under reduced pressure. The crude product was purified by flash chromatography on silica gel (10% methanol in dichloromethane). A colorless oil was isolated (13 mg, 51%). ^{1}H NMR (300 MHz, CD_3OD) δ (ppm): 7.89–7.85 (m, 2H), 7.19 (br s, 5H), 7.11 (d, 2H, J = 9.3 Hz), 3.90 (s, 3H), 3.72 (d, 1H, J = 12.6 Hz), 2.86 (d, 1H, J = 12.7 Hz), 1.24 (s, 3H). IR (neat) ν (cm^{-1}): 3700–3100 (br), 2925, 2851, 1709, 1595, 1265, 1141. LRMS (*m/z*, relative intensity) 335 (MH^+, 5), 317 (10), 163 (70), 91 (100). HRMS calcd. for $C_{17}H_{19}O_5S$ (MH^+): 335.0953, found: 335.0946. $[\alpha]^{20}_D$ –17.7 (*c* = 0.56, $CHCl_3$).

Comparative studies of univariate and multivariate optimizations for manganese determination in antihypertensive drugs by electrothermal atomic absorption spectrometry

Josianne Nicácio Silveira, Paulo Celso Pereira Lara, Michelle Batista Dias, Clésia Cristina Nascentes, Cynthia Demicheli, and José Bento Borba da Silva

Abstract: Comparative studies using the univariate and multivariate optimizations (factorial design) were undertaken to determine manganese in antihypertensive drugs by electrothermal atomic absorption spectrometry (ET AAS). For the univariate method, the optimum pyrolysis and atomization temperatures were 500 and 2200 °C, and for multivariate analysis, the temperatures were 500 and 2400 °C, respectively. No differences were observed between the methods with respect to the slopes of the calibration curves, recoveries, results for certified urine samples for the two levels, and the averages of the intra- and inter-assay coefficients of variation (CV) using Student *t* and *F* tests as a statistical tool ($P < 0.05$). Calibration was performed by matrix matching. All other studies were made using the optimized multivariate conditions. The characteristic mass was of 0.68 ± 0.17 pg (the recommended mass is 0.60 pg). The limits of detection and quantification were 0.23 and 0.77 μg L^{-1}, respectively. Intra- and inter-assay studies on the drug spiked with 0.5, 1.0, and 1.5 μg L^{-1} of Mn yielded mean results of 3.6 ± 1.9% and 9.6 ± 2.2%, respectively. For the intra-assay evaluation, seven samples of each concentration were evaluated for Mn on the same day, whereas, for the inter-assay study, these solutions were analyzed in three replicates during three consecutive days. Recovery studies on the drug spiked with three levels of Mn ($n = 7$ for each level) furnished results between 101.4 ± 17.2% and 106.6 ± 7.5%. The results of a certified urine sample analysis (two levels of Mn) agreed at a 95% level of confidence. Forty eight antihypertensive drug samples were analyzed, and the drug contents varied between 2.9 ng and 1.9 μg $capsule^{-1}$.

Key words: manganese, antihypertensive drugs, electrothermal atomic absorption spectrometry, multivariate optimization.

Résumé : Afin de déterminer le manganèse dans les médicaments hypertensifs par spectrométrie d'absorption atomique électrothermique (SAA ET), on a effectué des études comparatives en faisant appel à des optimisations à une et à plusieurs variables (modèle factoriel). Pour la méthode à une variable, les températures optimales pour la pyrolyse et l'atomisation sont de 500 et 2200 °C alors que pour l'analyse à plusieurs variables, elles sont respectivement de 500 et 2400 °C. On n'a observé aucune différence entre les méthodes en ce qui a trait aux pentes des courbes de calibration, aux résultats pour des échantillons certifiés d'urine pour deux niveaux et pour les moyennes des coefficients de variation (CV) intra- et inter-essais en utilisant les tests de Student *t* et *F* comme outil statistique ($P < 0,05$). On a effectué la calibration en procédant par appariement de matrice. Toutes les autres études ont été réalisées en utilisant des conditions à variables multiples optimisées. La masse caractéristique était de 0,68 ± 0,17 pg (la masse recommandée est de 0,60 pg). Les limites de détection et de quantification sont respectivement de 0,23 et 0,77 μg L^{-1}. Les études intra- et inter-essais effectuées sur le médicament fortifié dans lequel on a ajouté 0,5, 1,0 et 1,5 μg L^{-1} de manganèse ont conduit à des résultats moyens respectifs de 3,6 ± 1,9% et 9,6 ± 2,2%. Pour l'évaluation intra-essai, on a évalué le même jour la quantité de manganèse de sept échantillons de chaque concentration, alors que pour l'évaluation intra-essai on a analysé trois duplicata de ces solutions durant trois jours consécutifs. Les études de récupération sur le médicament fortifié à trois niveaux de manganèse ($n = 7$ pour chaque niveau) ont conduit à des résultats entre 101,4 ± 17,2% et 106,6 ± 7,5%. Les résultats pour l'analyse d'un échantillon certifié d'urine (deux niveaux de manganèse) correspondent au niveau de 95% de confiance. On a analysé quarante-huit échantillons de médicament hypertensif et le contenu de ces médicaments en manganèse varie de 2,9 à 1,9 μg par capsule.

Introduction

Manganese is an essential element for humans and animals. It is largely distributed as particles in the earth's crust, in water, and in the atmosphere (1). Normal human blood and urine levels are 2–8 μg dL^{-1} and 0.1–0.8 μg dL^{-1}, respectively, (2). Individuals exposed to high levels of manganese can suffer deterioration of neurological functions, beginning with unspecific symptoms and neurological signals (3).

The Recommended Daily Ingestion (RDI) of manganese is 5.0 mg for normal adults and from 2.0 to 5.0 mg for pregnant and lactating women. Certain groups of the population in general are more extensively exposed to manganese through some foods, from living close to industrial areas, by occupational exposure, and from other sources such as medicines (3).

According to Flores et al. (4), the control of heavy metals in the most-diverse samples (biological tissues, water, soil, foods, and so forth) is currently a relevant subject, principally for evaluating the degree of exposure and possible consequences for the human health. In this respect, control of contamination in medicines is of vital importance, since such contamination may constitute a public health problem. Quality control is necessary to prevent eventual risk of intoxication by contaminants in medicines and for the control of medicines where this type of element is present as the main constituent or as an adjuvant.

Electrothermal atomic absorption spectrometry (ET AAS) can be employed for the direct analysis of liquid samples and slurries with the advantages of low time consumption and a simple pre-treatment process with reduced contamination problems (5). Frequently, the optimization of experimental conditions for ET AAS determinations (chemical modifiers, pyrolysis time, pyrolysis and atomization temperatures) requires a large number of experiments in addition to being time-consuming and expensive. Moreover, the interactions between optimized variables are not evaluated. Multivariate optimization would seem to be a more adequate approach when many variables are involved. Factorial design (6, 7) is a good and simple statistical tool that can be used to verify the effects of variables and their interactions based on a small number of experiments.

Choudhary et al. (8) has studied multi-mineral pharmaceutical formulations of twelve drugs produced in Pakistan to determine calcium, copper, iron, magnesium, manganese, potassium, and zinc contents by AAS. In another work (9), Acar determined lead, chromium, manganese, and zinc as slurries of botanical and other biological samples by ET AAS, using tungsten-containing chemical modifiers.

In the present work, a factorial design was employed to optimize experimental conditions for the direct determination of manganese in antihypertensive drugs by electrothermal atomic absorption spectrometry. The results were compared with those of conventional pyrolysis- and atomization-temperature curves (univariate method).

Experimental

Instrumentation

All measurements were performed on a Varian (Victoria, Australia) SpectrAA Z-220 atomic absorption spectrometer equipped with a graphite furnace, an autosampler (PSD – 31–972), and the Polarized Zeeman Background correction procedure. The atomic signal was measured in peak-height mode. A single element, hollow cathode lamp for Mn from IST (Imaging & Sensing Technology, Horseheads, NY, WL 22936, serial No. 12774) was used as the light source; it was operated at 15.0 mA with a spectral band-pass of 0.2 nm at 279.5 nm. Unless otherwise specified, the conditions recommended by the manufacturer were employed. Argon (99.999%) from Air Liquide® (Contagem, MG, Brazil) was used as the purge gas. Graphite-coated pyrolytic tubes without a platform (Varian, part No. 63–100012–00) were employed throughout this work.

Reagents and solutions

All of the solutions were prepared using deionized water from a Milli-Q system (Millipore, Bedford, MA, USA). Nitric acid (65% *w*/*w*, Suprapur®, Merck, Darmstadt, Germany, part No. 1.00441.0250) was used. The calibration solutions were prepared from a stock manganese solution containing 1000 ± 0.002 mg L^{-1} (Titrisol–Merck) in 5% *v*/*v* HNO_3. The final solutions contained 0.4% *v*/*v* HNO_3. In all of the studies, a standard solution of 1000 mg L^{-1} tungsten (Titrisol–Merck) was used for the graphite-tube treatment.

Plastic bottles, autosampler cups, and glassware materials were cleaned by soaking in 20% (*v*/*v*) HNO_3 for 1 day, rinsing many times with Milli-Q water, and drying. The autosampler washing solution, containing 0.1% (*v*/*v*) Triton X–100 (Merck) plus 0.2% (*v*/*v*) nitric acid, was used to avoid analyte adsorption onto the surface of the container, to avoid clogging the autosampler pipette, and to improve the dispersion of sample solution onto the platform.

Sampling and sample treatment

Samples (capsules) were obtained from 20 manipulation pharmacies. Industrial samples (tablets) were obtained from a local drugstore. Two kinds of antihypertensive drugs were selected from those most consumed by patients in Belo Horizonte, MG, Brazil. The active principles of these two drugs were enalapril maleate and anlodipine besilate. Since different pharmacies use different excipients, a capsule (reference sample A) was produced that contained all the excipients and the two active pharmaceutical ingredients, as used and sold in the manipulation pharmacies that participated in this project.

The sample capsules or tablets were weighed in a tube with a threaded cover, and 300 μL of concentrated nitric acid

[a]N = graphite tube without modifier; Y = graphite tube with modifier.

was added with subsequent stirring for one minute, followed by the addition of 2.5 mL of Milli-Q water with one more minute of stirring. The volume of the solution was increased quantitatively to 25.0 mL with water, resulting in a homogeneous slurry.

Graphite-tube treatment

The graphite tubes were treated with a permanent W modifier. The treatment with 520 μg of tungsten was accomplished by applying 40 μL of the solution of the metal ion (1.0 g L^{-1}) onto the tube and submitting it to a furnace temperature program 13 times, with 13 injections of 40 μL of Milli-Q water to cleanse the tube (10) after each temperature program.

Optimization

The reference sample (A) spiked with 3.0 μg/L of Mn in 1.2% HNO_3 was employed to obtain the most appropriate temperatures for both methods (uni- and multivariate). The volume of sample introduced into the graphite tube was 22 μL for both methods.

Univariate optimization

In the conventional method, the pyrolysis- and atomization-temperature curves were obtained independently. To obtain the pyrolysis-temperature curve, the atomization temperature used was that recommended by the manufacturer, and measurements were obtained between 500 °C and 1000 °C (at intervals of 100 °C). These studies were performed without the use of a modifier. Previous results for the determination of manganese in human urine and serum by ET AAS with comparison of several modifiers indicated that the the best results were obtained without the use of a modifier (11). The pyrolysis temperature utilized to obtain the atomization-temperature curve was the one that gave the best results in the previous study (500 °C), varying of 100 °C between 1900 °C and 2400 °C. Sensitivity, absorption-pulse forms, background absorption, and the lowest-atomization temperature (to increase the lifetime of the graphite tube) were criteria for selection of the best conditions. Matrix-matching calibration curves and analytical characteristics were obtained under the optimized conditions.

Multivariate optimization

A factorial design (2^3 plus two center points) was performed to determine the optimal experimental conditions and to evaluate the influence of and the interaction between the factors studied. The minimum and maximum levels for pyrolysis and atomization temperatures were chosen according to the information furnished by the manufacturer. No modifier was used (11). The selection of tungsten was based on the wide use of that modifier for analytes with a tendency to be refractory. The variables studied were pyrolysis temperatures (500 °C and 1500 °C), atomization temperatures (2000 °C and 2400 °C), and the use or non-use of a permanent modifier (W). The factorial design is presented in Table 1. The Mn absorbance (n = 3) was analyzed using the Statgraphics Plus software that supplies the best condition of Mn determination. The highest-absorbance signal was selected, and the background was corrected, showing a good removal from the matrix. Matrix-matching calibration curves and analytical characteristics were obtained using the optimized conditions.

Results and discussion

Determination of the temperature program by the univariate and multivariate methods

The results obtained for the pyrolysis- and atomization-temperature curves using the conventional method are presented in Fig. 1, while the time for pyrolysis is presented in Fig. 2. The highest-sensitivity and the lowest-background signals were obtained with a pyrolysis temperature of 500 °C and an atomization temperature of 2200 °C.

The results obtained using the multivariate method are shown in Figs. 3 and 4. The Pareto chart (Fig. 3) presents the variables that have a significant effect on the response obtained at a 95% significance level. The effects of the variables (modifier and pyrolysis temperature) were statistically significant. The effect of the atomization temperature was not significant. On the other hand, the atomization temperature of 2400 °C was more effective than that of 2000 °C for the determination of manganese (Fig. 4, main-effects plot) in spite of the fact that no statistically significant difference between 2000 °C and 2400 °C was observed. For that reason,

Fig. 1. Pyrolysis- and atomization-temperature curves obtained for manganese in reference sample A, using the conditions optimized by the univariate method.

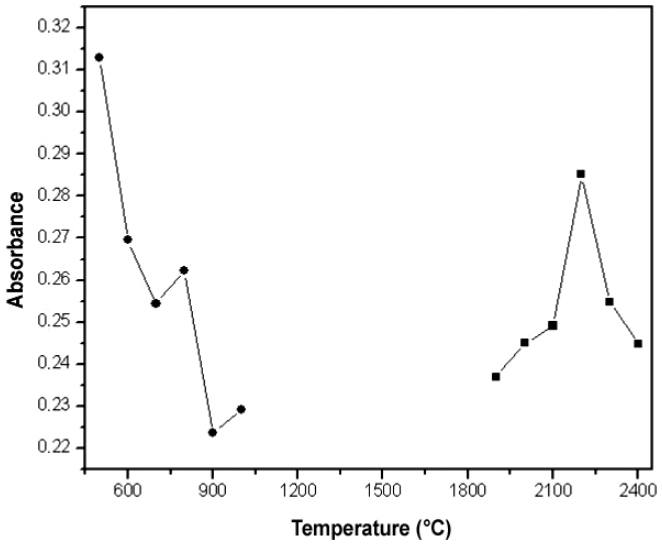

Fig. 2. Pyrolysis-time curve for manganese in reference sample A, using univariate optimization.

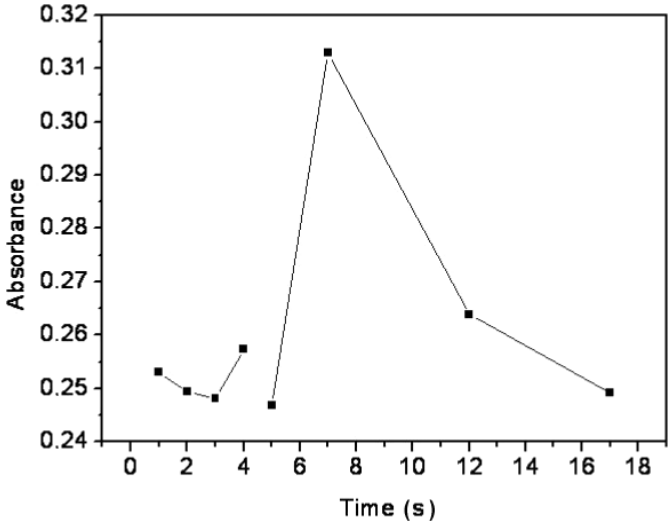

Fig. 3. Pareto chart showing the results of the factorial design (multivariate method) for the variables pyrolysis and atomization temperatures, modifier, and their interactions for Mn determination in reference sample A by ET AAS.

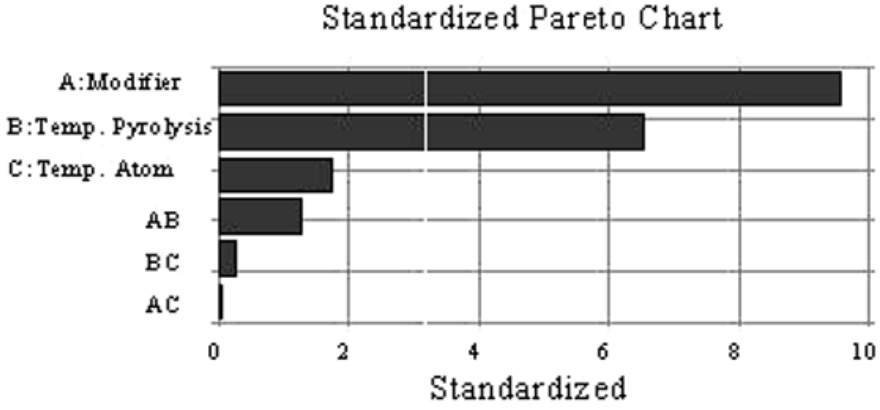

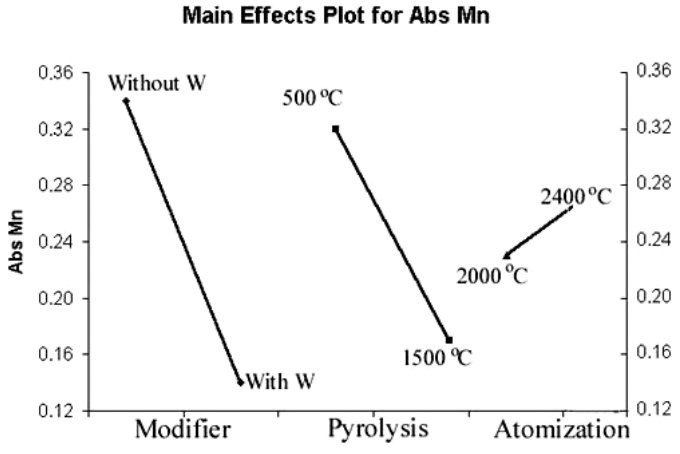

Fig. 4. Main-effects plot showing the results of the factorial design (multivariate method) of the variables pyrolysis and atomization temperatures and modifier for manganese in reference sample A.

2400 °C was chosen as the atomization temperature, and this temperature should not significantly reduce the life-time of the graphite furnace. According to the absorbance results, the pyrolysis temperature of 500 °C was better than that of 1500 °C. In the estimated response surface (Fig. 5) obtained with the Mn absorbance data, there is a tendency for a low pyrolysis temperature in combination with the highest atomization temperature. Under these conditions (500 and 2400 °C), the background was around 0.16 absorbance units. The optimal conditions obtained by the conventional and multivariate methods were very similar, since the best atomization temperature was 2200 °C for the univariate method and, in the multivariate optimization, the best analytical signal was obtained at an atomization temperature of 2400 °C. The results show that the multivariate method presents advantages because of the smaller number of experiments. The temperature program for manganese determination obtained after optimization of the analytical conditions is shown in Table 2.

Mean recovery (%)	106.3 ± 8.7	104.1 ± 2.6

[a]CV is the coefficient of variation.

Analytical figures of merit

Optimized conditions obtained by conventional and multivariate procedures were employed to determine the analytical characteristics presented in Table 3.

The limit of detection (LOD, μg L^{-1}) was calculated using the equation: LOD = 3 × $S_{0.5}/b$, where $S_{0.5}$ is the standard deviation for 10 measurements of the first point of the matrix-matching calibration curve, and b is the slope of the calibration curve, whereas the limit of quantification was calculated using the equation: LOQ = 10 × $S_{0.5}/b$.

The accuracy of the method was evaluated by the use of certified urine samples (Bio-Rad Laboratories, Lyphochek® Urine Metals Control level 1 – 69081 and level 2 – 69082, Irvine, CA, USA) with two manganese concentration levels and through recovery studies on the drugs.

Sample A (reference sample), spiked with 0.5, 1.0, and 1.5 μg L^{-1} of Mn, was used for the recovery study, which was performed in seven replicates and read in triplicate.

The precision was evaluated through intra- and inter-assay studies. The intra-assay variation coefficient was calculated using the standard deviation of the 0.5, 1.0, and 1.5 μg L^{-1} concentrations of Mn added to the reference sample (A), divided by the average of the respective concentrations, and multiplied by 100. These analyses were performed separately in seven replicates on the same day and read in triplicate. To calculate the inter-assay variation coefficient, the same procedure was repeated with three replicates of the sample and read in triplicates on three different days.

The optimized conditions obtained by conventional and multivariate procedures were employed to determine the analytical characteristics presented in Table 3. No differences were found between the methods concerning the slopes of the calibration curves, recoveries, and certified urine samples for the two levels and the average of the CV's for the intra- and inter-assays ($P < 0.05$) when statistical tools (Student F and t tests) were employed.

Considering that the multivariate procedure simultaneously evaluates all the variables studied and requires a smaller number of experiments for the development of a method, thereby requiring less time and expense, this procedure was adopted for determining Mn in the samples. Seven matrix-matching calibration curves were constructed by applying the temperature program presented in Table 2. All calibration curves were constructed in the range between 0.5 and 4.0 μg L^{-1} of Mn (Fig. 6) and presented an $R^2 > 0.99$. The results for uni- and multivariate methods were very similar, as is shown Table 3.

The recoveries and deviations ($n = 7$) for the spiked samples are presented in Table 4. The recovery values obtained were nearly 100%; a result that shows the high degree of accuracy of both methods.

The accuracy was also evaluated in a study performed using certified urine samples (Table 5). For both methods, the

Fig. 6. Absorption signal for manganese in reference sample A spiked with 4.0 μg L^{-1} of manganese (last point of the matrix-matching calibration curve).

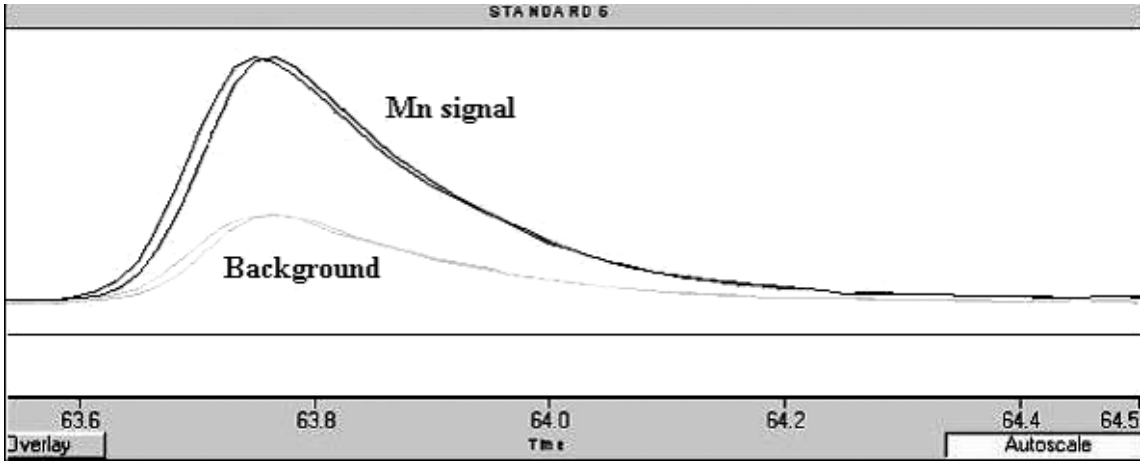

Table 4. Recovery of Mn in antihypertensive drugs by conventional and multivariate methods (n = 7).

Concentration of Mn (μg L^{-1})	Recovery (univariate method) (%)	Recovery (multivariate method) (%)
0.5	116.3 ± 9.7	101.4 ± 17.2
1.0	101.0 ± 4.5	106.6 ± 7.5
1.5	101.6 ± 1.3	104.2 ± 6.8

Table 5. Certified and determined values (μg L^{-1}) for Mn in the urine sample (n = 7).

	Certified	Univariate	Multivariate
Level 1	5.9–8.9	7.4 ± 1.0	7.7 ± 1.2
Level 2	15.9–23.8	21.4 ± 2.5	21.3 ± 0.6

Table 6. Intra- and inter-assay studies of the precision.

	CV intra (%, n = 7)		CV inter (%, n = 3)	
Concentration of Manganese (μg L^{-1})	Univariate	Multivariate	Univariate	Multivariate
0.5	3.4	3.4	2.8	7.2
1.0	3.5	5.6	10.6	11.5
1.5	1.3	1.8	6.3	10.0
Average	2.8 ± 1.3	3.6 ± 1.9	6.5 ± 3.9	9.6 ± 2.2

results obtained for both Mn concentration levels were in agreement with the certified values. This result again demonstrates the accuracy of the proposed methods.

The averages of the intra-assay variation coefficients (Table 6) were 2.8 ± 1.3% and 3.6 ± 1.9% for the conventional and multivariate methods, respectively. The averages of the inter-assay variation coefficients were 6.5 ± 3.9% and 9.6 ± 2.2%, respectively, thus demonstrating the high precision of both methods.

Determination of manganese in antihypertensive drugs

Manganese concentration in different antihypertensive drugs was determined using the experimental conditions optimized by the multivariate method and matrix-matching calibration curves.

The manganese levels of 48 antihypertensive drugs were analyzed, and the levels encountered varied from 2.9 ± 0.6 to 1921.7 ± 211.4 ng $capsule^{-1}$ or $tablet^{-1}$. The highest manganese levels were found in the tablets and in the amlodipine besilate. The levels of manganese in the medicines analyzed are not worrisome, since the oral absorption is low, being 3% to 5% of the ingested dose with rapid elimination ($t_{1/2}$ of 37 days). Thus, in agreement with the Brazilian legislation, the average RDI is 5 mg. On the other hand, because of the inherent toxicity of each metal, the development of methods that are specific and sensitive for their determination in medicines is still necessary for quality control.

Conclusions

The factorial design is a simple procedure for evaluating ET AAS conditions for manganese determination in antihypertensive drugs with a reduced number of experiments. The results indicate that there are no significant differences between the figures of merits obtained by the two methods. The manganese levels in the analyzed samples varied from 2.9 ± 0.6 to 1921.7 ± 211.4 ng $capsule^{-1}$ or $tablet^{-1}$. The highest manganese levels were found in the tablets and in the anlodipine besilate.

The simplicity of the method of preparation and of the set of instrumental and analytical conditions resulted in a rapid,

precise, and accurate determination of manganese in antihypertensive-drug samples.

The levels of manganese in the medicines analyzed are not worrisome. However, the proposed method was simple, fast, specific, and sensitive, which is advantageous when compared with the tests based on the reaction with the sulfide ion proposed by the pharmacopeias in general. The proposed method can be applied to the investigation of other medicines of continuous use.

Glycosides from the North Atlantic sea cucumber *Cucumaria frondosa* V — Structures of five new minor trisulfated triterpene oligoglycosides, frondosides A_7-1, A_7-2, A_7-3, A_7-4, and isofrondoside C

Alexandra S. Silchenko, Sergey A. Avilov, Anatoly I. Kalinovsky, Pavel S. Dmitrenok, Vladimir I. Kalinin, Jeffrey Morre, Max L. Deinzer, Carl Woodward, and Peter D. Collin

Abstract: Seven highly polar trisulfated triterpene glycosides belonging to the frondoside A_7 group have been isolated from the North Atlantic sea cucumber *Cucumaria frondosa*. The structures of five new glycosides, frondosides A_7-1 (**1**), A_7-2 (**2**), A_7-3 (**3**), A_7-4 (**4**), and isofrondoside C (**5**) were elucidated, three of which contained lanostane aglycons without a lactone-ring. Three pairs of the glycosides proved to be isomers by virture of the positions of double bonds in the aglycons nuclei; two pairs of the glycosides differed from each other by the character of the oxygen functionality at C-22. The results from these studies provided the basis for postulating the biosynthetic pathways of norlanostane glycosides in the sea cucumber.

Key words: Cucumaria frondosa, sea cucumbers, frondosides, triterpene glycosides.

Résumé : Au départ de concombres de mer, *Cucumaria frondosa*, du nord l'Atlantique, on a isolé plusieurs glycosides de triterpène trisulfatés très polaires qui appartiennent au groupe frondoside A_7. On a élucidé les structures de cinq nouveaux glycosides, les frondosides A_7-1 (**1**), A-2 (**2**), A_7-3 (**3**), A_7-4 (**4**) et l'isofrondoside C (**5**), dont trois contiennent des aglycones de lanostane sans noyau lactonique. Trois paires de glycosides sont des isomères de position de doubles liaisons dans les noyaux des aglycones; les deux autres paires de glycosides diffèrent l'un de l'autre par le caractère de la fonctionnalité oxygène en C-22. Les résultats de ces études fournissent les bases nécessaires pour postuler les voies de biosynthèse des glycosides du norlanostane dans les concombres de mer.

Mots-clés : Cucumaria frondosa, concombres de mer, frondosides, glycosides de triterpène.

[Traduit par la Rédaction]

Introduction

Our investigations on the triterpene glycosides from the North Atlantic sea cucumber *Cucumaria frondosa* (1–4) have continued and the structures of highly polar trisulfated glycosides are being presented. Structurally, these glycosides are diverse with different aglycon moieties, including holostane and nonholostane skeleton systems with shortened and unshortened side chains. These compounds contain identical trisulfated pentaoside-branched carbohydrate chains, and they are refered to the A_7 group by analogy with cucumariosides of the A_7 group from *C. japonica* (5).

In spite of the predominance of these trisulfated glycosides, which distinguish them from the mono- and disulfated glycosides in *C. frondosa*, this compound class has not been thoroughly investigated to date because of the very complicated multicomponent composition. Moreover, the presence of three polar sulfate groups affects the chromatographic behaviour of the glycosides, thus complicating the isolation of the individual components by HPLC. There are some good examples in the literature that demonstrate the difficulties in the isolation procedure of trisulfated glycosides. Frondoside F, a trisulfated pentaoside obtained from *C. frondosa* (6), has a saturated polycyclic nucleus in the aglycon moiety and an 18(22)-lactone instead of the more common 18(20)-lactone. These structural features for sea cucumber glycosides have not been reported before. However, experimental data in the paper by Yayli (6) raise many questions including the absence of a quasi-molecular ion in the FAB mass spectrum, the absence of any correla-

tion between protons at C-8 and C-9 in the ^{1}H-^{1}H-COSY spectrum, and the absence of graphic explanation of the NOESY data. A simple explanation could be that the investigator was working with a complicated mixture of glycosides having both 7(8) and 9(11) double bonds. As a result, not all the signals of the constituents were accumulated and indicated in the ^{13}C NMR spectrum (7). In other cases, the investigation of trisulfated glycosides were carried out only after the desulfation of the corresponding fraction and isolation of the desulfated derivatives (2). Only the use of modern isolation techniques and modified HPLC conditions have allowed us to isolate the pure natural substances belonging to this group of glycosides.

The sea cucumber *C. frondosa* was collected in the Gulf of Maine, Penobscot Bay, Maine, USA. The fraction of trisulfated frondosides (glycosides belonging to the frondoside A_7 group) (5) observed to be homogeneous by TLC was obtained from the ethanolic extract of the organism after column chromatography on polychrom-1 (powdered Teflon) and silica gel. Further separation of this fraction by HPLC yielded 10 individual glycosides, five of which were previously unreported. These are named here as frondosides A_7-1 (**1**), A_7-2 (**2**), A_7-3 (**3**), A_7-4 (**4**), and isofrondoside C (**5**).

Results and Discussion

Three of the glycosides were identified on the basis of NMR data as known frondoside C (**7**), which had been isolated earlier from *C. frondosa* (2), koreoside A (**8**) from *C. koraiensis* (8), and isokoreoside A (**9**) from *C. conicospermium* (9). Frondoside C (**7**) and isokoreoside A (**9**) were isolated as native substances, in contradistinction to earlier works (refs. 2 and 9), where the structures of the natural products, **7** and **9**, were elucidated on the basis of their desulfated derivatives. The spectra of these desulfated derivatives were compared with the spectra of the corresponding nonseparable fractions of thisulfated glycosides with identical carbohydrate chains to determine the number and positions of sulfate groups.

The signals of the carbohydrate moieties in the NMR spectra of all the isolated glycosides **1**–**5** and **7**–**9** of the frondoside A_7 group were identical. The corresponding data are discussed here only for one of these glycosides, namely for frondoside A_7-1 (**1**) (Table 1). The presence of five anomeric carbon signals at 102.2–105.2 ppm in the ^{13}C NMR spectrum of frondoside A_7-1 (**1**) and the corresponding doublets at 4.96–5.29 ppm (J = 7.0–8.0 Hz) of the anomeric protons in the ^{1}H NMR spectrum were consistent

with those of a pentasaccharide chain with β-configuration for the glycosidic linkages (10). Positions of interglycosidic bonds were elucidated by the analysis of HMBC spectra of frondoside A_7-1 (**1**) with correlations found between H-1 of the first xylose residue and C-3 of the aglycon, H-1 of quinovose and C-2 of the first xylose, H-1 of the glucose residue and C-4 of quinovose, H-1 of terminal 3-O-methyl glucose and C-3 of glucose, and between H-1 of the terminal xylose residue and H-2 of quinovose. Analogous correlations were revealed in the NOESY spectrum that confirmed the sequence of monosaccharide units in carbohydrate moieties of glycosides belonging to the frondoside A_7 group.

To confirm the presence of three sulfate groups in the carbohydrate moieties of all the isolated substances, isofrondoside C (**5**) was desulfated to give a derivative **6**. The sugar resonances in the NMR spectrum of **6** were compared with those of isofrondoside C (**5**) (Tables 1 and 2). Because of α- and β-effects of the sulfate group, the C-4 and C-5 signals of the first xylose residue in the ^{13}C NMR spectrum of **5** were shifted downfield by 6.8 ppm and upfield by 2.5 ppm, respectively, in comparison to these signals in the spectrum of desulfated derivative **6**. The same effects were observed for the C-5 (3.1 ppm upfield) and C-6 (5.5 ppm downfield) signals of the glucose residue and C-5 (2.68 ppm

upfield) and C-6 (4.99 ppm downfield) signals of the 3-O-methyl glucose residue in the ^{13}C NMR spectrum of **5** in comparison with that of **6**. These data indicated the presence of three sulfate groups attached to C-4 of the first xylose residue and to C-6 of glucose and 3-O-methyl glucose residues in the studied glycosides. The NMR resonances of carbons of the carbohydrate parts of glycosides **1**–**5** and **7**–**9** were found to be identical to those of the cucumariosides A_7-1, A_7-2, and A_7-3 from *C. japonica* (5), which confirms the identity of carbohydrate chains of these substances.

The HR ESI MS (negative ion mode) of the frondoside A_7-1 (**1**) exhibited a pseudomolecular ion peak $[M_{3Na} - Na]^-$ at *m/z* 1499.4215, which compared with that calculated for $C_{59}H_{89}O_{35}S_3Na_2$ of 1499.4142. Thus, the molecular formula of frondoside A_7-1 (**1**) is $C_{59}H_{89}O_{35}S_3Na_3$.

The MALDI TOF MS (positive ion mode) of glycoside **1** exhibited a pseudomolecular ion peak $[M_{3Na} + Na]^+$ at *m/z* 1545, which confirmed the molecular formula $C_{59}H_{89}O_{35}S_3Na_3$ and the fragment ion peaks at *m/z* 1443 $[M_{3Na} - SO_3Na + Na + H]^+$ and 1341 $[M_{3Na} - 2SO_3Na + Na + 2H]^+$. These latter peaks correspond to elimination of sulfate groups and confirm the structure of carbohydrate chain of **1**.

The signals of the aglycon of frondoside A_7-1 (**1**) were assigned by extensive NMR spectroscopic studies (^1H, ^{13}C, HSQC, HMBC, COSY, NOESY, TOCSY) (Table 3) to be similar with those of the known frondoside A_2-1 from *C. frondosa* (3), which contains a holostane aglycon with a 7(8) double bond, a keto-group at the C-16 position, and a 24(25) double bond in the side chain that confirms the identity of the aglycons in these saponins. The correlation between H-19 and H-9 in the NOESY spectrum of **1** indicated a β-configuration for H-9. Hence, the structure of frondoside A_7-1 (**1**) is 3-*O*-{6-*O*-sodium sulfate-3-*O*-methyl-β-D-glucopyranosyl-(1→3)-6-*O*-sodium sulfate-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β-hydroxy-16-oxo-9β-holosta-7,24-diene.

The HR ESI MS (negative ion mode) of the frondoside A_7-2 (**2**) exhibited a pseudomolecular ion peak $[M_{3Na} - Na]^-$ at *m/z* 1485.4450, which calculated as 1485.4350 *m/z* for

$C_{59}H_{91}O_{34}S_3Na_2$ and allowed the determination of the molecular formula of frondoside A_7-2 (**2**) as $C_{59}H_{91}O_{34}S_3Na_3$.

The positive ion mode MALDI TOF MS of the frondoside A_7-2 (**2**) exhibited a pseudomolecular ion peak at *m/z* 1531 $[M_{3Na} + Na]^+$ that corresponded to the molecular formula and the fragment ion peaks at *m/z* 1429 and 1327 analogous to those of frondoside A_7-1 (**1**). The ion peak at *m/z* 1195 observed in the spectrum of frondoside A_7-2 (**2**) was due to the loss of two sulfate groups along with the terminal xylose residue.

The NMR spectra of the aglycon moiety of frondoside A_7-2 (**2**) were found to be very similar to the spectra of frondoside A_2-4 from *C. frondosa* (4), indicating that the same holostane aglycons were present with 7(8) and 24(25) double bonds and no functionality at C-16 (Table 4). Indeed, the high-field signal of 24.4 ppm for C-16 observed in the ^{13}C NMR spectrum of frondoside A_7-2 (**2**) corresponded to two protons in the HSQC spectrum (signals at 1.87 (m, H – 16″) and 2.11 (m, H – 16″) ppm). Moreover, the signals of the isolated spin system CH_2(15)-CH_2(16)-CH(17) were observed in the COSY spectrum of frondoside A_7-2 (**2**), corroborating the aglycon structure of **2** (Table 4). The correlation between H-19 and H-9 in the NOESY spectrum of **2** confirmed the β-configuration for H-9. Hence, frondoside A_7-2 (**2**) is 3-*O*-{6-*O*-sodium sulfate-3-*O*-methyl-β-D-glucopyranosyl-(1→3)-6-*O*-sodium sulfate-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β-hydroxy-9β-holosta-7,24-diene.

The HR ESI MS (negative ion mode) of frondoside A_7-3 (**3**) exhibited a pseudomolecular ion peak $[M_{3Na} - Na]^-$ at *m/z* 1489.4768 that calculated as 1489.4662 *m/z* for $C_{59}H_{95}O_{34}S_3Na_2$ and allowed the assignment of the molecular formula for frondoside A_7-3 (**3**) as $C_{59}H_{95}O_{34}S_3Na_3$.

The MALDI TOF MS (positive ion mode) of frondoside A_7-3 (**3**) exhibited a pseudomolecular ion peak $[M_{3Na} + Na]^+$ at *m/z* 1535 that also corresponded to the molecular formula $C_{59}H_{95}O_{34}S_3Na_3$. In the MALDI TOF MS (negative ion mode) of glycoside **3,** ion peaks at *m/z* 1387 and 1285 were due to the elimination of two sulfate groups.

The signals of the polycyclic nucleus of the aglycon part in the NMR spectra of frondoside A_7-3 (**3**) were similar to those of frondoside C from *C. frondosa* (2), which has the nonholostane aglycon without a lactone. The ^{13}C NMR spectrum shows signals at 148.7 (C-9) and 114.9 (C-11) ppm, and the ^{1}H NMR spectrum shows a multiplet at 5.33 (H-11) ppm for the 9(11) double bond (Table 5). The signals for the tertiary carbon at 123.1 (C-24) ppm and quaternary carbon

at 132.1 (C-25) ppm were indicative of a 24(25) double bond in the side chain of glycoside **3**. However, in comparison with frondoside C (2) the signals of C-22 and H-22 of frondoside A_7-3 (**3**) were shifted upfield (δ_C 77.0 ppm and δ_H 2.88 ppm), and signals for an O-acetic group were absent. These data indicated the presence of a tertiary carbon (C-22) bearing a hydroxyl group (Table 5). The asymmetric center at C-20 in frondoside A_7-3 (**3**) was determined as the R configuration by analogy with frondoside C and confirmed by the presence of the cross peaks H-21/H-12 and H-22/H-16 in the NOESY spectrum of **3**. The asymmetric center at C-22 was deduced as the R, the most probable from the C-20 and C-22 signals in the ^{13}C NMR spectrum of glycoside **3** on the basis of a comparison of this spectrum with that of model substances where the signals of C-20 and C-22 were characteristic for R,R-configuration at C-20 and C-22, which had the same values of chemical shifts and differed by 2 ppm from each other in the case of R,S-configuration (11). Hence the structure of frondoside A_7-3 was determined to be 3-*O*-{6-*O*-sodium sulfate-3-*O*-methyl-β-D-glucopyranosyl-(1→3)-6-*O*-sodium sulfate-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β,20(*R*),22(*R*)-trihydroxylanosta-9,24-diene.

The HR ESI MS (negative ion mode) of the frondoside A_7-4 (**4**) exhibited a pseudomolecular ion peak $[M_{3Na} - Na]^-$ at *m/z* 1489.4851, which calculated as 1489.4662 *m/z* for $C_{59}H_{95}O_{34}S_3Na_2$. The molecular formula of frondoside A_7-4 (**4**) was determined to be $C_{59}H_{95}O_{34}S_3Na_3$.

The MALDI TOF MS (positive ion mode) of the frondoside A_7-4 (**4**) exhibited a pseudomolecular ion peak at *m/z* 1535 $[M_{3Na} + Na]^+$ that also was consistent with the molecular formula $C_{59}H_{95}O_{34}S_3Na_3$. In the MALDI TOF MS (negative ion mode), fragment ion peaks at *m/z* 1387 and 1285 corresponding to sequentual elimination of two sulfate groups were observed.

The NMR spectra of the aglycon part of frondoside A_7-4 (**4**) clearly indicates that this substance is an isomer of frondoside A_7-3 (**3**) by the double bond position in the aglycon nucleus (Table 6). Indeed, the signals at 122.1 (C-7) and 149.1 (C-8) ppm in the ^{13}C NMR spectrum are characteristic of a 7(8) double bond in **4**. The comparison of the ^{13}C NMR spectra of frondosides A_7-4 (**4**) and A_7-3 (**3**) showed similar side chains signals that indicated that their side chains have 24(25) double bond and a hydroxyl group at C-22. The presence of the cross-peaks H-9/H-18 and H-9/H-19 in the NOESY spectrum of **4** indicated a β-configuration of H-9 and showed that the C ring in the aglycon was

largely in the "boat" conformation. The boat conformation for the C ring in holostane-type aglycons was observed earlier by X-ray analysis (12). Hence the structure of frondoside A_7-4 (**4**) was elucidated as 3-*O*-{6-*O*-sodium sulfate-3-*O*-methyl-β-D-glucopyranosyl-(1→3)-6-*O*-sodium sulfate-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β,20(*R*),22(*R*)-trihydroxy-9β-lanosta-7,24-diene.

The HR ESI MS (negative ion mode) of the isofrondoside C (**5**) exhibited a pseudomolecular ion peak $[M_{3Na} - Na]^-$ at *m/z* 1531.4817. The calculated mass for $C_{61}H_{97}O_{35}S_3Na_2$ is 1531.4766 from which the molecular formula of isofrondoside C (**5**) $C_{61}H_{97}O_{35}S_3Na_3$ was established.

The MALDI TOF MS (positive ion mode) of the isofrondoside C (**5**) exhibited a pseudomolecular ion peak at *m/z* 1577 $[M_{3Na} + Na]^+$ that confirmed the molecular formula $C_{61}H_{97}O_{35}S_3Na_3$. In the MALDI TOF MS (negative ion mode) the ion peaks at *m/z* 1429 and 1327 corresponded to the sequential elimination of two sulfate groups.

The structure of glycoside **5** was deduced on the basis of NMR data of its desulfated derivative **6** (Table 7). The NMR spectra of **6** showed signals characteristic of the lanostane aglycon containing a 7(8) double bond (25.0 (CH_3-18), 121.4 (C-7), and 148.9 (C-8) ppm in ^{13}C NMR spectrum). The signals of the acetate group at C-22 (79.5 (C-22), 170.5 ($OCOCH_3$), and 21.0 ($OCOCH_3$) ppm in ^{13}C NMR spectrum) and 24(25) double bond (signals at 122.1 (C-24) and 133.1 (C-25) ppm) in the side chain were also detected. The correlation between H-19 and H-9 in the NOESY spectrum of **5** yielded evidence for a β-configuration of H-9. Thus, the new glycoside **5** is an isomer of the known frondoside C (**7**) by the position of the double bond in the aglycon nucleus. The aglycon structure was confirmed by the corresponding HMBC and NOESY correlations (Table 2). The 20*R*,22*R* configurations for the hydroxy group at C-20 and the acetoxy group at C-22 in **5** were suggested as most probable by the almost coincident corresponding carbon chemical shifts of **6** and the known 2β,3β,22(*R*)-triacetoxy-14α,20(*R*),25-trihydroxy-5β-cholest-7(8)-en-6-one (13). Hence, the structure of isofrondoside C (**5**) was deduced as 3-*O*-{6-*O*-sodium sulfate-3-*O*-methyl-β-D-glucopyranosyl-(1→3)-6-*O*-sodium sulfate-β-D-glucopyranosyl-(1→4)-[β-D-xylopyranosyl-(1→2)]-β-D-quinovopyranosyl-(1→2)-4-*O*-sodium sulfate-β-D-xylopyranosyl}-3β,20(*R*)-dihydroxy-22(*R*)-acetoxy-9β-lanosta-7,24-diene.

In most cases, sea cucumbers have been reported to accumulate glycosides with one type of polycyclic system for the aglycons that contain either the 7(8) or 9(11) double bond.

There are only four known species of sea cucumbers that contain both glycosides with the 7(8) and 9(11) double bond simultaneously. These are, *C. conicospermium* (9), *Pentacta australis* (14), *Neothyonidium magnum* (15, 16), *Psolus fabricii* (17–19). However, only two pairs of glycosides from *C. conicospermium* were isomeric by such double bond positions. Thus, when compared with other sea cucumbers it is very unusual that *C. frondosa* contains three pairs of isomers, i.e., frondosides A_7-3 (**3**) and A_7-4 (**4**), and frondoside C (**7**) and isofrondoside C (**5**), koreoside A (**8**) and

© 2007 NRC Canada

isokoreoside A (**9**), that differ only in the positions of the double bonds in the polycyclic systems of their aglycons.

Moreover, there are two pairs of glycosides in *C. frondosa* that differ in the character of the oxygen function at C-22 in the aglycon side chains. Actually, hydroxyl groups in frondosides A_7-3 (**3**) and A_7-4 (**4**) are replaced by the O-acetate groups in frondoside C (**7**) and isofrondoside C (**5**). Probably, the biosynthetic pathway from lanostane (no lactone ring) glycosides with unshortened side chains to non-lanostane glycosides with shortened side chains occurs through the introduction of a hydroxyl or acetate group at C-22 that is followed by the cleavage of a side chain. Such a biosynthetic pathway of biosynthesis is evident because of the presence of substances with shortened side chains in the aglycon, such as koreoside A (**8**) and isokoreoside A (**9**) in the fraction of trisulfated glycosides of *C. frondosa*. The analogous biosynthetic transformations are known for the biogenesis of steroid hormones from cholesterol in vertebrates (20).

The quantitative content of the main components of the glycosidic fraction in some body parts of *C. frondosa* collected in March 2003 in the Gulf of Maine was investigated (Table 7). The integumental epithelium of the sea cucumbers, the body walls with epithelium, and the buccal tentacles with calcareous ring were extracted separately, Then, the glycoside fractions were obtained from each extract by column chromatography on Teflon and silica gel.

The spawning season of *C. frondosa* near the eastern shore of the US and Canada is during April and May (21). The quantitative predominance of trisulfated glycosides (of the A_7 group) collected in March (46%–58% from glycosidic fraction of *C. frondosa*) for all investigated parts of the organism, when compared with the content of monosulfated glycosides (13%–25%, frondosides A, A_1 and glycosides belonging to the A_2 group) and disulfated glycosides (22%–29%, glycosides of A_3 and A_6 groups) (Table 7), could be explained by the accumulation of this group of substances before spawning as regulators of the pubescence process in the population. Therefore, the biological role of monosulfated and trisulfated glycosides could be different. The hemolytic activity of the glycosides correlated with their toxicity (22). Monosulfated frondosides show high hemolytic activity and probably provide a biochemical defense mechanism towards predators. However, the hemolytic activity of trisulfated glycosides is much less than that of the monosulfated ones (22). It was reported earlier that triterpene glycosides of sea cucumbers perform a hormonelike function and may regulate the process of oocyte maturation in the sea cucumber population (23). So, it is likely that just trisulfated glycosides perform a hormonelike regulatory function in the organism of *C. frondosa*. However, to confirm this point it seems to be necessary to carry out investigations on seasonal variations of the different groups of the saponins in different organs and tissues of *C. frondosa*.

Experimental section

General experimental procedures

All melting points were determined with a Kofler Thermogenerate apparatus. Specific rotation was measured on a PerkinElmer 343 polarimeter. NMR spectra were recorded on a DRX-500 Bruker spectrometer at 500.12 and 125.67 MHz for ^1H and ^{13}C, respectively, in C_5D_5N–D_2O (4:1) with TMS as an internal reference ($\delta = 0$). The HMBC experiments were optimized on the long-range coupling constant $J = 8$ Hz, and the mixing time in the NOESY experiments was 350 ms. The MALDI TOF MS (positive and negative ion modes) were recorded using a Bruker mass spectrometer, model BIFLEX III with impulse extraction of ions, on an α-cyano-4-hydroxycinnamic acid matrix. The ESI MS (negative ion mode) measurements were performed on a ESI TOF (LCT, Micromass, Altrincham, UK) mass spectrometer fitted with a standard two-spray source. HPLC was performed using an Agilent 1100 chromatograph equipped with a differential refractometer on a Zorbax ODS and Diasphere-110 C_8 columns.

Animal material

The sea cucumber *C. frondosa* (family Cucumariidae, order Dendrochirotida) was collected in Penobscot Bay (Gulf of Maine, Maine, USA) in September 2000 by commercial dragging. Taxonomic identification was carried out by Dr. E.N. Gudimova. A voucher specimen is on a deposit in the collection of the Murmansk Marine Biological Institute of the Kolsky Scientific Center of the Russian Academy of Sciences, Murmansk, Russia.

Extraction and isolation of the subfraction of trisulfated glycosides

Body walls of the sea cucumbers were separated, cut very small, lyophilized to dryness, and extracted twice with hot ethanol (dry weight of the residue was 943 g). The combined extracts were concentrated to dryness and chromatographed on a polychrom-1 column (powdered Teflon, Biolar, Latvia) previously loaded in EtOH and washed by water to remove inorganic salts and polar impurities. The fraction containing glycosides was eluted with 50% acetone. This fraction was chromatographed on silica gel columns eluted with a $CHCl_3$–EtOH–H_2O (100:125:25) solvent system to obtain a TLC homogenous crude subfraction of trisulfated glycosides belonging to the A_7 group (1942 mg).

Isolation of glycosides 1–5 and 7–9

The fraction of trisulfated frondosides (1942 mg) was submitted for HPLC (followed by desalting on a Teflon column as described previously) on a Zorbax ODS (10 × 250) [mobile phase MeOH–water–($Na_2HPO_4 \cdot 12H_2O$ (358 mg) + $NaH_2PO_4 \cdot 2H_2O$ (156 mg) in 100 mL of water) (59:38:3)] column to give the subfractions **I**–**V** that were subsequently chromatographed on a Diasphere-110 C_8 (4 × 250) column. The different ratios of the solvents MeOH–H_2O–[$Na_2HPO_4 \cdot 12H_2O$ (358 mg) + $NaH_2PO_4 \cdot 2H_2O$ (156 mg) in 100 mL of water] were used as mobile phase. Ratio 40:57:3 for subfraction **I**. Ratio 42:54:4 for subfraction **II** to obtain 8 mg of koreoside A (**8**), mp 250 °C, $[\alpha]_D^{20}$ –48° (*c* 0.1, pyridine) and 6 mg of isokoreoside A (**9**), mp 238 °C, $[\alpha]_D^{20}$ –64° (*c* 0.1, pyridine). Ratio 45:53:2 for subfraction **III** to give 3 mg of frondoside A_7-1 (**1**), mp 213–215 °C, $[\alpha]_D^{20}$ –11° (*c* 0.1, pyridine). See Tables 1 and 3 for NMR data. MALDI TOF MS (positive ion mode) *m*/*z*: 1545 ($C_{59}H_{89}O_{35}S_3Na_4$ $[M_{3Na} + Na]^+$, 1), 1443 ([$M_{3Na} - SO_3Na$ +

Desulfation of isofrondoside C (5).

Glycoside **5** (10 mg) was dissolved in a mixture of pyridine–dioxane (1:1) and refluxed for 1 h. The obtained mixture was concentrated in vacuo. The residue was chromatographed on a Si gel column with $CHCl_3$–EtOH–H_2O (100:50:4) to give the desulfated derivative **6**: 7 mg, mp 224 °C, $[\alpha]_D^{20}$ –36° (*c* 0.1, pyridine); see Table 2 for NMR data.

Determination of the quantitative content of different groups of frondosides in some parts of *C. frondosa*

Sea cucumbers were collected in the Penobscot Bay (Gulf of Maine, Maine, USA) in March 2003 and were disintegrated into body wall and integumentary epithelium, integumentary epithelium, and buccal tentacles with the calcareous ring. The freeze-dried parts of the sea cucumbers were extracted twice with hot ethanol. The combined extracts of corresponding parts were concentrated to dryness and chromatographed on a polychrom-1 column (powdered Teflon, Biolar, Latvia) as described earlier to give the summarized fractions of triterpene glycosides. These fractions were chromatographed on silica gel columns with a $CHCl_3$–EtOH–H_2O (100:75:10, 100:100:17, and 100:125:25) solvent system to obtain frondoside A_1 and frondoside A (as individual substances), the subfractions of monosulfated frondosides that belongs to the A_2 group, disulfated frondosides that belong to the A_3/A_6 group, and trisulfated frondosides that belongs to A_7 group in different ratios for each part (Table 7).

PERSPECTIVE / PERSPECTIVE

The Canadian Synchrotron Radiation Facility (CSRF) in Madison — Twenty-five years of soft X-ray research[1]

G. Michael Bancroft

Abstract: The first beamline at the Canadian Synchrotron Radiation Facility (CSRF) was established with NSERC funding in 1982 at the Tantalus synchrotron outside Madison, Wisconsin, after many years of work at the University of Western Ontario to establish a synchrotron facility in Canada. The CSRF facility expanded to three very productive soft X-ray beamlines over the next twenty years. The planning, funding, and construction of the three beamlines is outlined; and the dedicated work of the scientists who set up the laboratory, along with those who conducted important research there, are described. CSRF has produced over 500 publications in many different scientific areas from 11 different Canadian Universities. One of the CSRF beamlines, and several CSRF personnel have been transferred to the Canadian Light Source in Saskatoon, and CSRF will formally close in March, 2008.

Keywords: CSRF at the University of Wisconsin Madison, synchrotron radiation, soft X-ray research, materials science.

Resume : Le premier faisceau lumineux de l'Institut canadien du rayonnement synchrotron (ICRS) a été établi en 1982, avec le support financier du CRSNG, en marge du synchrotron Tantalus à l'extérieur de Madison, Wisconsin, après plusieurs années de travaux à l'Université de Western Ontario dans le but de créer un synchrotron au Canada. Sur une période de vingt ans, l'ICRS a été l'objet d'expansions qui ont porté à trois le nombre des faisceaux très productifs de rayons X doux. La planification, le financement et la construction des trois faisceaux sont décrite dans ce travail et on décrit le travail dévoué des scientifiques qui ont mis le laboratoire sur pieds ainsi que celui des personnes qui y ont réalisé d'importants travaux de recherches. L'ICRS a produit plus de 500 publications dans divers domaines scientifiques; ils provenaient de chercheurs attachés à onze universités canadiennes différentes. L'un des faisceaux de l'ICRS et plusieurs membres du personnel de l'ICRS ont été transférés au Centre canadien de rayonnement synchrotron [Canadian Light Source (CLS)] à Saskatoon et l'ICRS sera formellement fermé en mars 2008.

Mots-clés : ICRS à l'Université de Wisconsin Madison, rayonnement synchrotron, recherches avec des rayons X doux, science des matériaux.

Introduction

The Canadian Synchrotron Radiation Facility (CSRF) began operation with one soft X-ray beamline in 1982 at the low-energy 240 MeV Tantalus synchrotron at the University of Wisconsin outside Madison, Wisconsin. CSRF was then transferred to the "new" second generation 1 GeV Aladdin synchrotron in January 1986, after Aladdin had been delayed for over three years because of technical problems. Three soft X-ray CSRF beamlines were funded by Canadian organizations between 1979 and 1995, and several hundred Canadian scientists, along with many international scientists, have routinely and successfully used these Canadian facilities since 1983. The CSRF facility has produced over 50 Ph.D. and M.Sc. theses from 11 different Canadian Universities and well over 500 publications in refereed journals. The total capital and operating funding has been incredibly small for such a productive facility. Two of the three CSRF beamlines have been duplicated at the third generation Canadian Light Source (CLS) in Saskatoon with great improvements in intensity and resolution. The newest CSRF beamline was transferred to CLS in 2004 and modified for greatly enhanced performance at the CLS. The third CSRF beamline will be duplicated at the CLS within a year. Several of the CSRF employees are now employed at the CLS and many of the students, postdoctoral fellows (postdocs), and faculty that did a lot of their research at CSRF are now CLS users. Funding for the CSRF from the Natural Sciences

and Engineering Research Council of Canada (NSERC) and the National Research Council (NRC) terminates on March 31, 2008, and CSRF will formally cease operations on March 31, 2008.

T.K. Sham approached me to suggest that it might be interesting to write an article on the history of the CSRF in this issue of Canadian Journal of Chemistry. CSRF history is dominated by: first, excellent cooperation and teamwork from a large number of very talented Canadian faculty, post-doctoral fellows, and students from a number of Canadian universities; second, a remarkable international collaboration and cooperation from the Synchrotron Radiation Centre (SRC) outside Madison, Wisconsin; and third, a number of good decisions (with a significant amount of luck!) on the selection of CSRF beamline equipment and beamline personnel. These three characteristics, along with excellent support from NSERC and NRC after 1988, enabled CSRF to be a very cost-effective, world-class, soft X-ray synchrotron facility for over 20 years. Before looking at the CSRF history, it is important to review first my early scientific history that led me to synchrotron radiation (SR) studies, and second, the history of SR in Canada in the 1970s before CSRF was formed.

My early road to "see the light"

I arrived in the Department of Chemistry at UWO in July 1970 to continue a strong research program using Mössbauer spectroscopy that began in 1964 as a Ph.D. student at the University of Cambridge (1). In 1969, I attended an inorganic chemistry Faraday Society discussion in Cambridge and presented a paper on the use of Mössbauer spectra for obtaining bonding and structure in Fe(II) low-spin compounds (2). This meeting also featured papers on the use of photoelectron spectroscopy for studying bonding and structure in inorganic compounds in the gas and solid phases (3). I became very interested in this new spectroscopic area and after setting up my Mössbauer program at UWO in 1970 and 1971, I began to plan for a photoelectron spectrometer, a McPherson ESCA 36 (ESCA = electron spectroscopy for chemical analyses) to perform both UPS (UV photoelectron spectroscopy) and XPS (X-ray photoelectron spectroscopy) on gases and solids. This spectroscopy had been developed in the 1960s mainly by groups at Uppsala University in Sweden (4) and Oxford University in England (5).

In early 1972, I proposed to my department head, Howard Clark, that I would like to apply for a photoelectron spectrometer at UWO. I was not even aware of synchrotron radiation (SR) at the time! Howard Clark strongly supported a $140 000CAN application (a very large grant at the time) to NRC in October 1972, sent me to a photoelectron workshop in Cardiff, Wales, in the summer of 1972, and did a substantial amount of the grant writing. He suggested that the operating funds (including a technician's salary) for the facility would come from income from contracts with private industry and also suggested that we get support from other interested universities to strengthen the application. It is important to emphasize that he was not directly interested in the technique and was not on the application. Such support from senior administration is not common! I received support from the Universities of Windsor and Toronto for the southwestern Ontario ESCA facility, the grant was awarded in March 1973, and the McPherson ESCA 36 spectrometer was working very long hours with full-time technician Bob Lazier in early 1974. This same versatile (but non-UHV) spectrometer was purchased by other groups in Canada (e.g., R.G. Cavell in Alberta and N.S. McIntyre at AECL, Pinawa) at about the same time. The UWO instrument supported a very diverse program of investigation using UV and X-ray photons on gases, solids, and surfaces: from the observation and characterization of a new effect in the spectra, ligand field splitting; to determining the order of molecular orbitals and chemical shifts in organic, inorganic, and organometallic molecules; to the absorption of metals on minerals; to applied industrial surface science with support from a number of steel companies.

Fortuitously, Bill McGowan, the first Director of the Centre for Chemical Physics (CCP) at UWO, initiated the Canadian SR effort just as I began planning for the photoelectron purchase in 1972. Gerhard Herzberg and several of his close NRC spectroscopic colleagues (along with Ed Rowe, the Director of the Madison, Wisconsin, Tantalus SR facility) attended the first Canadian workshop organized by Bill McGowan on the uses of synchrotron radiation (SR) at UWO in October 1972. At this workshop, I realized the power of SR to improve the resolution of photoelectron spectra and to change the photon energy to vary cross-sections. Dr. McGowan pushed extremely hard for a Canadian synchrotron in the period 1972–1977. For example, he applied in July 1973 to the NRC for a feasibility study for a Canadian SR source. As there were *no* known Canadian users at the time (very limited international SR work at Stanford, Tantalus, Cornell, and several European sites had only begun in about 1969), that request (and later requests, see later) was rejected. In January 1975, Dr. McGowan hosted a CCP SR workshop to consider a design from Roger Servranckx of the University of Saskatchewan for a Canadian low-energy synchrotron, and Dr. McGowan suggested a possible site for the synchrotron at the University of Western Ontario to the UWO senior administration.

Canadian scientists began to use synchrotron radiation in the USA in 1974. Probably, the first Canadian user was Daryl Crozier from Simon Fraser University who set up a beamline at the Stanford synchrotron in 1974 for high-energy EXAFS studies. In late 1974, I made an application to Ed Rowe and the Tantalus synchrotron at the University of Wisconsin Physical Sciences Laboratory to obtain photoelectron spectra of volatile organometallics. For one week in March 1975, I went to Madison with my new Ph.D. graduate T.K. Sham to collaborate with Dean Eastman from IBM, who was very well-known for recent SR photoemission studies of semiconductors. He had a UHV photoemission system and was extremely flexible and helpful in obtaining spectra of organometallic films by subliming my volatile compounds onto metal substrates to avoid charging problems. This one week of *very* intense work changed my career! I decided to do part of my sabbatical (July 1975 to January 1976) working with Dean Eastman and postdoc Wolfgang Gudat, and I was greatly encouraged by Eastman and Rowe to spend at least six months at Tantalus studying the valence band and core level spectra of organometallics. I was able to do some good science in that six months (6), but

© 2007 NRC Canada

in addition I learned a lot about synchrotron beamlines and had good discussions with the optics group at Tantalus, especially Charlie Pruett.

In September 1975, Dr. McGowan submitted a very large proposal entitled, *A National Laboratory for SR Studies* to Paul Redhead, the Director of the Physics Division at the NRC. Paul Redhead chaired an ad-hoc NRC committee on SR, and that committee met in June, August, and October of 1976. I spent the second six months of my sabbatical at Siegbahn's lab in Uppsala, Sweden, using his new monochromatic X-ray spectrometer for high resolution core level studies of volatile gases (7), and I returned to Ottawa from Sweden for the first two meetings. The Canadian chemists on that committee were Camille Sandorfy, Chris Brion, and me. Bill McGowan also organized the first very large international SR workshop at Laval University in June 1976. There were 55 attendees at this workshop, with just 11 Canadian scientists. A 624 page report on the many uses of SR was submitted to Paul Redhead's ad-hoc committee. There was still very little Canadian involvement at this time, but it was obvious even then to nearly all the committee members that SR research was going to be very important for Canadian science, and that Canada should be a major player in SR research along with all the other G7 countries that already had SR facilities (8, 9). However, because there were still very few Canadian users, and Canada is averse to taking "risks", this proposal was turned down.

The Beginning of CSRF

It was apparent that establishing a Canadian synchrotron was years away, so the next best thing was to construct a beamline or beamlines at a facility in the USA. As the new Director of the Centre for Chemical Physics at UWO, I headed up a $541 000CAN application (co-applicants were Bill McGowan and Bill Ware, both from UWO) to NRC in October 1977 for the Canadian Synchrotron Radiation Facility (CSRF) to construct one Canadian soft X-ray beamline and three endstations for the existing Tantalus and newly designed Aladdin SR sources at the University of Wisconsin in Madison. I had a very cordial invitation from Ed Rowe (including a 100% use of a SR port on Aladdin at *no* charge in perpetuity!), great technical support at UWO from postdocs Raj Gupta and Leighton Coarsworth, and excellent scientific and technical support from Ed Rowe and Charlie Pruett from Tantalus.

In July 1978, the newly created NSERC awarded $320 000CAN in capital for the Canadian Synchrotron Radiation Facility in Madison, a soft X-ray beamline ($200 000CAN), and two endstations (my photoelectron spectroscopy and Bill McGowan's X-ray microscopy of cells). The visiting committee, chaired by Boris Stoicheff from the University of Toronto, complimented the UWO group for their initiative "on behalf of researchers in Canada" and went on to say that, "their persistent efforts during the last several years to stimulate interest in and acquire funding for a Canadian Synchrotron Facility have led to the current unique opportunity for Canadian science". It is interesting to contrast the cost of this beamline with present more sophisticated beamline costs, at all third generation synchrotrons including CLS, of several million dollars! Not enough capital money was awarded to do the job and it was necessary to arrange multiple sources of funding with concomitant huge amounts of time and effort. With strong support from Dean John Bancroft, I was able to obtain $100 000CAN from the UWO Academic Development Fund and another $40 000CAN from NSERC in the next year to complete the two experimental endstations.

I was appointed the Scientific Director of CSRF (and I continued until 1999), and Norman Sherman was also appointed the NRC manager for close to two decades. But who was paying the operating costs for CSRF? NRC was "to own, staff, and manage the facility" (from NSERC President Gordon McNabb's letter of July 7, 1978). This sounded very promising, but then NRC allotted $5 000CAN annually to own, operate, and maintain the equipment!! After months of correspondence with both NRC and NSERC, the $5 000CAN was not increased. (It is important to note that, as I show later, both NRC and NSERC became very supportive of CSRF financially and scientifically, and that NRC personnel, such as Norman Sherman and later Arthur Carty and Walter Davidson, were enormously helpful). This small operating contribution created enormous problems for me and for the development of CSRF. Fortunately and again coincidentally, UWO (with John Bancroft, George Connell, and Howard Baldwin being enormously helpful) scraped together enough funding by 1980, mostly through the newly announced UWO 2nd Century Fund (a fund which was launched well after the UWO Centenary in 1977), mainly to hire Kim Tan in January 1980 for most of five years as the CSRF Operations Manager based in Madison. Kim Tan did his Ph.D. work with Bill McKonkey at the University of Windsor and a postdoc with Chris Brion in EELS at UBC. He had no synchrotron experience, but had a lot of spectroscopic experience in high vacuum conditions, and more importantly an excellent attitude. He was the only CSRF employee at CSRF from 1980 till 1987 and was the glue that held things together, especially in the first 10 years.

All the initial purchases were funneled through the NRC, with Norman Sherman guiding them and in constant contact with me. We ordered the beamline momochromator from Baker Engineering, a company near Madison in Evansville, Wisconsin, that was marketing a unique soft X-ray monochromator (so-called "Grasshopper" monochromator) that had been designed and built by Neil Lien and Charlie Pruett of the Physical Sciences Laboratory and Fred Brown, a physicist from the University of Illinois (10). Neil Lien joined Baker Engineering, and our monochromator was the first one that Baker made and the fourth that had been manufactured; it was labeled Mark IV. This monochromator was state-of-the-art in the energy region from 20 eV to 200 eV, and it had proven to be easy to use, rugged, and dependable at the Tantalus ring. This $200 000CAN beamline is still working routinely as I write in 2007!!

Kim Tan worked closely with Baker Manufacturing in Evansville, Wisconsin, (with excellent cooperation and collaboration with the monochromator designers Charlie Pruett, Fred Brown, and Niel Lien) in assembling the soft X-ray Grasshopper monochromator; in one year the monochromator was successfully tested at Tantalus (Fig. 1), the first publication appeared in 1982 (11), and the beamline plus XPS was working routinely at Tantalus by January, 1983 (12).

Fig. 1. The official opening ceremony of the first CSRF beamline (the Grazing incidence "Grasshopper" beamline) at the Tantalus synchrotron in October 1983. From left to right: Norman Sherman (NRC, the CSRF Manager), Bill McGowan (Professor, UWO), Brian Yates (graduate student, UWO), Ed Rowe (Tantalus Director, Physical Sciences Laboratory), Brenda Addison (graduate student, UWO), Mike Bancroft (CSRF Scientific Director, UWO), and Kim Tan (CSRF Operations Manager, UWO).

However, we needed Aladdin to get the best results. Aladdin was significantly delayed so that my first graduate student, Brian Yates (now at CLS), had to use Tantalus for all his excellent gas phase Ph.D. results [e.g., (13)]. Doug Shinozaki and Bill McGowan also had a very strong program on soft X-ray microscopy of biological specimens on Tantalus (14). Very fortunately, Seppo and Helena Aksela, sponsored by the Centre for Chemical Physics in 1984, wanted to begin synchrotron studies of the rare gas atoms, and our beamline was as good as any in the world at the time for these studies. Seppo doggedly recorded most of the initial resonance Auger spectra of atoms at the CSRF on Tantalus, and these spectra were interpreted by Helena (15). The resulting series of papers on Ne, Ar, Kr, and Xe are widely cited and formed the basis for their much higher resolution studies in the 1990s on higher intensity synchrotron beamlines. With seven publications in 1984 and 1985 and 16 publications in 1986 (see the publication list in the Supplementary data), the CSRF facility was taking off, and operating money from NSERC and NRC increased greatly.[3] NSERC introduced infrastructure grants in 1983, and Norman Sherman strongly supported increased funding from the NRC. The NSERC and NRC grants of $32 000CAN and $16 000CAN allotted in April 1984 came closer to paying Kim Tan's salary and maintenance costs; by 1987–1988, NSERC and NRC were contributing $82 000CAN and $35 000CAN, and UWO funding was no longer required. Remember that we were paying *nothing* for the use of Aladdin, and Kim Tan was very skillful in accessing technical help from the Aladdin facility for reasonable fees. This saga to gain reasonable operating funding again illustrates the difficulty of getting anything really novel started in Canada — or outside Canada in this case. Exchange rate issues (the US dollar has varied from $1.10CAN to $1.60CAN over the years!) have made budgets very difficult, and long term visa and healthcare issues for employees have been problematic. Fortunately, Norman Sherman at the NRC and the UWO Dean's office were always helpful.

Travel to Madison was a problem, especially in the first 10 years. It took 6–8 h by plane (via Toronto and Chicago) until regular flights from London to Detroit began. I was in Madison at least 4 times a year from 1980 to 1998 and I always enjoyed these trips for the exciting science with dedicated, talented, students and postdocs, and rather few problems at CSRF. I especially enjoyed the rural farm atmosphere (cows, tobacco, and corn) surrounding the SRC, the residence 12 miles from Madison near Stoughton, and the easy country walk to and from SRC and the residence.

CSRF on Aladdin — Towards three beamlines

Aladdin was supposed to be operational in 1982, but multiple problems seriously delayed the commissioning of this new second generation 1 GeV ring. Indeed by 1985, there was considerable concern that the funding would collapse for Aladdin, and that the Canadian program could not reach its potential on Tantalus. Fortunately by late 1985, most of

Fig. 2. The official opening ceremony for the second CSRF beamline (the Double Crystal Monochromator (DCM) beamline) in 1990. From left to right (front row): Fred Middleton (Physical Sciences Laboratory (PSL)), Jim Taylor (Director, Synchrotron Radiation Centre, University of Wisconsin), Norman Sherman, Kim Tan, John Hicks (PSL), T.K. Sham (Professor, UWO), Jing-Ming Chen (CSRF postdoc), and Masoud Kasrai (Senior scientist, UWO); (back row): Bing Xing Yang (CSRF beamline manager), M. Bissen (SRC), Dan Wallace (SRC), Tim Sailor (PSL), Mike Bancroft, Bengt Olsson (UWO postdoc), Leon Silverling (SRC), Brian Yates (UWO research scientist), Ron Cavell (Professor, University of Alberta), and Glen Caldwell (Vice-President Research, UWO).

Aladdin's problems were solved, and reasonable electron currents could be stored with good lifetimes. We decided to transfer the CSRF beamline to Aladdin (with Ed Rowe still promising us 100% use in perpetuity!) in early 1986 — one of the first beamlines installed on Aladdin. This switch to Aladdin opened up a lot of new science for CSRF users on the Grasshopper beamline because the Aladdin X-ray intensity was much higher than on Tantalus over a broader energy range from 10 to 4 keV. The Grasshopper beamline became useful up to over 300 eV on Aladdin, but most importantly the higher energies could be available using other higher energy monochromators (see later). Many new users became involved on the Grasshopper beamline (see refs. cited in ref. 16), and the scientific program expanded greatly from the two initial programs of Mike Bancroft and Bill McGowan/Doug Shinozaki, mainly to absorption studies (XANES) of gases and solids of all kinds along with high resolution XPS studies of gases and solids. Ron Cavell very generously gave the CSRF one of his ESCA 36 XPS instruments, which was extensively modified by John Bozek and Jeff Cutler for the highest resolution gas phase XPS and Auger studies on a second generation synchrotron; John Bozek and Tolek Tylisczczak (courtesy of Adam Hitchcock) did most of the hardware and software development to scan the Grasshopper monochromator for XANES studies.

With the higher energies available from Aladdin, I planned in 1987 (after becoming Chair of Chemistry at UWO) for a new beamline to cover the energy range from 1.5 keV to 4 keV. Fortuitously again, the Ontario Centre for Materials Research (OCMR) was formed in 1987, and I submitted a $2.1CAN million application to the OCMR for this beamline (cost of about $500 000CAN), endstations for solid-state spectroscopy, and several five-year appointments — a new Professor in my Department and a postdoc for the beamline. My former excellent Ph.D. student, T.K Sham, was hired (after 11 years at Brookhaven National Laboratory doing synchrotron research) to design the beamline at CSRF in 1987 in expectation of the grant. The grant was successful, T.K. Sham was hired as an Associate Professor in Chemistry at UWO, and B.X. Yang from Brookhaven was hired as a postdoc to construct the beamline in 1988. The monochromator ($210 000US) was built by the local PSL group headed by Fred Middleton, and Bing Xing Yang did a remarkable job (with some help in 1989 from the PSL group, Jin-Min Chen, and a postdoc Bengt Olsson) to get the whole beamline working in less than 18 months (Fig. 2) (17). It is interesting to note that Baker Engineering also bid on our monochromator, and apparently their design at Brookhaven National Lab never worked well! In contrast, the unique PSL DCM has worked routinely for almost 20 years! Another hire in my group in 1987 also made a fundamental difference to the CSRF effort. A former colleague from the University of Cambridge in 1964–1968, Masoud Kasrai, became a Senior Chemical Physics Fellow at UWO in early 1987, and he has spent the last 20 years at UWO researching at CSRF for many weeks every year, helping un-

Fig. 3. The official opening of the third CSRF beamline (the Spherical Grating Monochromator (SGM) beamline) in 1999. From left to right: Ron Cavell, Brian Yates (CSRF beamline manager), Nils Petersen (Vice-President Research, UWO), Walter Davidson (NRC, the CSRF Manager), T.K. Sham, Mike Bancroft, Kim Tan, and Jim Taylor. The SGM was shipped to CLS in 2004 for the CLS SGM beamline.

selfishly in many ways with the many students and postdocs in my group and other UWO groups. The two dedicated SR appointments at UWO, T.K. Sham and Masoud Kasrai, became absolutely critical to the ensuing success of CSRF. The productivity of CSRF increased enormously at that point. For example, as shown in ref. 18, over 40 scientists from over 10 Canadian laboratories and universities did experiments at CSRF from 1990 to 19992, and the productivity of the facility increased dramatically to over 30 papers per year in 1992 in a wide variety of scientific areas (see ref. 18, Table 4). We were guaranteed 80% of the beamtime on the DCM, and users came from the following Canadian organizations: the Universities of Alberta, British Columbia, Carleton, Laval, McMaster, Simon Fraser, Toronto, Waterloo, and Western Ontario; also from AECL, CANMET, ESSO, INRS, and NRC. Foreign users came from: Oulu and Turku, Finland, SRC in Madison, and Brookhaven National Laboratory. The research interests of this group varied widely: development of new techniques such as soft X-ray SAXS, EXAFS in liquids from photoconductivity measurements, X-ray excited optical luminescence (XEOL), and soft X-ray fluorescence detection; radiation damage of polymers, reflectivity of muti-layer mirrors, XANES and EXAFS studies of a huge range of gases, solids, and surfaces — semiconductors, coals, glasses, multi-layers, metallo-proteins, tribofilms; and high-resolution XPS–Auger measurements of simple molecules and organometallics.

The funding for the facility from NSERC and NRC was now stable and adequate; (e.g., in 1993–1994 the amounts received were $173 000CAN and $50 000CAN, respectively); as is the international norm, there were *no* user charges of any kind to use the two beamlines.

The intermediate energy range from 300 to 1500 eV was still lacking at CSRF, and I applied to NSERC for $1.4CAN million in 1992 for a third beamline using a so-called spherical grating monochromator (SGM) to give CSRF high resolution capabilities between 250 and 700 eV. The funding was obtained in 1994, my first SR graduate student Brian Yates was hired to construct the beamline, and the entire beamline was ordered from Baker Engineering in 1995. Again, Brian did a marvelous job, mostly on his own. The beamline was somewhat delayed at the Baker end, but it began working to specifications in 1998 for general users (19) (Fig. 3). This beamline enabled very high-resolution studies at the C, N, and O K-edges. Adam Hitchcock donated his photo-ionization chamber for coincidence measurements, and this was used by Adam and John Neville.

Under the direction of Walter Davidson (of NRC) and T.K. Sham since 1999, the Grasshopper and DCM beamlines are still working well at CSRF. The SGM was shipped to the Canadian Light Source in 2004 and forms the basis for a very fine third generation line (the beam team leader is T.K. Sham at UWO) that is working as well as any in the world. It is hoped that the Grasshopper beamline will be shipped to CLS as a museum piece, and that the DCM line will remain at the SRC for general use. The DCM replacement at CLS (again headed by T.K. Sham) should be ready for use by the end of 2007.

Conclusions

After the usual difficult "teething period" from 1980 to 1984, CSRF became a very successful SR facility in the soft X-ray region, with a small fraction of the funds required by most international SR facilities. Several hundred researchers

have used CSRF over the 25 years; over 50 Ph.D. and M.Sc. theses (Table 1) have been produced with at least 7 still expected, and over 500 papers have been published (please see the Supplementary material for the complete list).[3] The *total* capital cost for the three beamlines and all endstations was just over $3CAN million, and the *total* operating cost from 1980 to 1999 was $2.6CAN million. Since 1999, under the direction of T.K. Sham and Walter Davidson, the operating costs (from NSERC and NRC) have been over $2CAN million (over $400 000 per year for several years, but decreasing as CLS comes on stream) as the success of the facility became well-known. As expected, the initial use of the facility was dominated by UWO users, but a quick perusal of the CSRF theses and publications shows that users from 10 other Canadian universities and organizations contributed over 50% of the theses since 1993. Not only are the quantity of CSRF publications remarkable for the amount of money spent, but the high quality of these publications is indicated by the large number of citations for many of them.

But probably most importantly, the CSRF provided first SR training and experience for a lot of present CLS employees (mostly in beamline design and construction) and CLS users. For example, former CSRF employees now employed at CLS include Kim Tan, Brian Yates, and Yongfeng Hu. Other CLS employees, Ian Coulthard, Jeff Cutler, Detong Jiang (now at the University of Guelph) did their Ph.D. or postdoctoral work at CSRF, and Emil Hallin from the Saskatchewan Accelerator Group was introduced to SR beamlines at CSRF. Many faculty members who are strong users of CLS did their first SR research at CLS. For example, Stephen Urquhart and John Tse, at the University of Saskatchewan, did a lot of research at CSRF, and other Canadian faculty such as Adam Hitchcock, Ron Cavell, T.K. Sham, and Grant Henderson did most of their initial SR work at CSRF. And, of course T.K. Sham — the most productive of any Canadian SR researcher — did an enormous amount of his SR work at CSRF from 1987 until recently. The first publications from the CLS from the two replacement CSRF beamlines originated mostly from the above group of outstanding researchers.

It is extremely pleasing for me to see CLS become an excellent international SR facility and to see that the former CSRF users are critical to the CLS development. Many of the papers referred to here come from the above group of people. Finally, I have to thank again the enormous number of talented students, postdocs, senior scientists, and faculty, who have put great effort into the success of the remote CSRF facility. And all of us must thank the SRC staff and management at the Aladdin synchrotron for their outstanding cooperation. Certainly, this must be a model for international cooperation of all kinds.

Chemical vapor deposition of nickel-group metals on multiwall carbon nanotubes[1]

Maoqi Feng and Richard J. Puddephatt

Abstract: Chemical vapor deposition (CVD) of Ni, Pd, and Pt films and of Ni/Pd and Pd/Pt bimetallic films on multiwall carbon nanotubes (MWCNTs) can be effected at low temperature if the nanotubes are pretreated by CVD of titanium carbide. In the absence of the pretreatment, the CVD leads to formation of isolated nanoparticles of the nickel-group metals. The metallized MWCNTs are curved or kinked, as a result of the interaction with the metal. Preliminary oxidation of the carbon nanotubes allows easier metallization, and the bending of the metallated nanotubes is not observed in this case.

Key words: Chemical vapor deposition, platinum, palladium, nickel, carbon, nanotube.

Résumé : Si on opère avec des nanotubes qui ont été prétraités par un dépôt de vapeur chimique (DVC) de carbure de titane, on peut effectuer à basse température des dépôts de vapeurs chimiques de films de Ni, Pd et Pd et de films bimétalliques de Ni/Pd et Pd/Pt sur des nanotubes de carbone à parois multiples (NCPM). En l'absence d'un prétraitement, le DVC conduit à la formation de nanoparticules isolées du métal du groupe du nickel. Les NCPM métallisées sont recourbées ou déviées en raison de l'interaction avec le métal. Une oxydation préliminaire des nanotubes de carbone facilite la métallisation et, dans ce cas, on n'observe pas de courbure dans les nanotubes métallisés.

Mots-clés : dépôt de vapeur chimique, platine, palladium, nickel, carbone, nanotube.

[Traduit par la Rédaction]

Introduction

The surface metallization of inorganic and organic materials has relevance in areas such as geochemistry and nanoelectronics, so it is an active area of research (1, 2). For example, there has been much interest in the use of chemical vapor deposition (CVD) to form thin films of transition metals (3), including nickel (4), palladium (5), and platinum (6), on metals, semiconductors, and insulating materials. The metallization of carbon nanotubes to give a hybrid material for potential applications in electronic devices or catalysis is rapidly developing; however, although transition-metal nanoparticles are often used as catalysts for forming carbon nanotubes (7), the use of CVD as a method of metallizing carbon nanotubes has been neglected (8, 9). Instead, carbon nanotubes are usually coated by solution methods, such as electroless deposition, or by metal evaporation–sputtering methods (8, 9). In all coating methods, it is important to recognize that most late transition metals bind only weakly to the nanotube surface; hence, metal deposition tends to give isolated nanoparticles, which are often located at defect sites of the nanotube. One method that has been successful in coating nanotubes with metals by electron-beam evaporation is to apply a preliminary coating of titanium, which forms a stable carbide at the interface, so it gives a continuous and uniform coating (9). Subsequent evaporation of other metals onto the titanium-coated carbon nanotubes can then give uniform metal coatings (9). This article reports the metallization of multiwall carbon nanotubes (MWCNT's) with the metals nickel, palladium, and platinum or with the bimetallics Ni/Pd and Pd/Pt by CVD techniques. Because direct deposition of the metals led to the formation of isolated metal nanoparticles, a new method was developed in which preliminary CVD of titanium carbide was carried out to give a continuous coating, followed by CVD of the nickel-group metal. An unexpected discovery was that the CVD on the MWCNT can lead to the bending of the carbon nanotube. We have previously reported the low-temperature CVD of palladium and platinum on organic materials, including deposition on polystyrene beads to give macroporous films of the metal (10).

Results and discussion

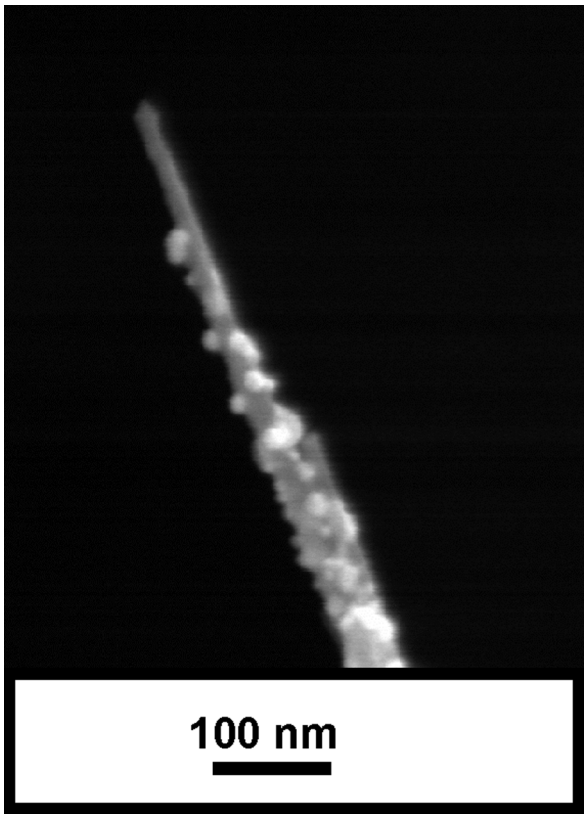
Direct deposition experiments

The atmospheric-pressure CVD experiments were conducted by using a hot-wall CVD apparatus (10) with the multiwall carbon nanotubes supported on the surface of a silicon wafer and using hydrogen as the carrier gas. Initial experiments were carried out to deposit nickel, using the precursor [$Ni(Cp)_2$]; palladium, using the precursor [$Pd(hfac)_2$]; and platinum, using the precursor [$Pt(COD)Me_2$], with the

 doi:10.1139/V07-014 © 2007 NRC Canada

precursor warmed to 60 °C and the substrate heated to 200–250 °C. CVD of bimetallic alloys Ni/Pd and Pd/Pt was carried out by using equimolar amounts of the appropriate precursors. The metallized MWCNT's were then structurally characterized by imaging, SEM or TEM, and the composition of the film was studied by XPS and XRD.

The metallic phases were characterized by the binding energies of Pt $4f_{7/2}$ at ~71.2 eV, Pd $3d_{5/2}$ at 335 eV, and Ni $2p_{3/2}$ at 853 eV, with only minor variations as a function of film thickness and alloy formation. It has previously been shown that the metals are formed in high purity by CVD on silicon or glass by using hydrogen as a carrier gas (6). In the present experiments, CVD was carried out on carbon nanotubes, and XPS analysis always showed the presence of carbon. For example, a sample of carbon nanotubes coated with palladium was analyzed as (atom%): Pd, 35; C, 65 atom%, but the composition varied across the sample. It is shown later by SEM or TEM imaging that the nanotubes are not evenly coated by the direct CVD route, so it is clear that much of the detected carbon is the nanotube substrate (and graphitic impurity in the commercial samples of MWCNT). The composition of the Ni/Pd and Pd/Pt alloys, formed by CVD, was determined by XPS analysis to be Ni:Pd ≈ 1:1 and Pd:Pt ≈ 3:1, which reflects the relative ease of decomposition of the two precursors in an individual CVD experiment. The nickel-coated MWCNT samples gave significant oxygen analysis (Table 1), although NiO was not detected by XRD analysis. It is likely that the nickel surface is oxidized during storage and transfer, prior to XPS analysis.



SEM examination of the metallized carbon nanotubes showed the presence of isolated metal nanoparticles in all cases. For example, Fig. 1 shows an SEM image of a carbon nanotube coated with nickel, and Fig. 2 shows a TEM image of a carbon nanotube coated with palladium. They are representative of similar images obtained for nanotubes coated with nickel, palladium, or platinum or with Ni/Pd or Pd/Pt alloys. Clearly, there is no continuous coating, but isolated nanoparticles of nickel or palladium are formed, with average diameter of ~20 nm. This structure arises because the nucleation rate is low, and growth at the forming metal surface is fast, while the metal – carbon nanotube interactions are relatively weak. The autocatalysis of the CVD of nickel, palladium, and platinum by the reactive metal surface is well documented (5, 6).

Pre-coating with titanium carbide

Titanium carbide can be formed at high temperature (>800 °C) by the reaction of titanium atoms with carbon nanotubes, and it has been used to connect individual nanotubes (11). In the present work, titanium carbide was deposited by CVD at 400 °C on carbon nanotubes, using $[Cp_2TiCl_2]$ as a precursor (12). The film formed this way was analyzed by XPS and XRD. The Ti $2p_{3/2}$ peak for TiC was broad with components from 455–459 eV, whereas crystalline TiC is reported at 455.1 eV and TiO_2 (anatase or rutile) at 459 eV (13). The data are similar to those reported for partially oxidized TiC(O) films, for which components with Ti $2p_{3/2}$ = 456 and 458 eV were observed (13). In confirmation, an O 1s peak at 530 eV was observed, close to the literature values for TiO_2 of 529.7–529.9 eV. The C 1s peak was dominated by the peak for the carbon nanotubes at 284.5 eV, but there was a lower-energy peak at ~283.5 eV, close to the value reported for carbide in Ti–O–C films at 283.45 eV (13). Finally, XRD analysis confirmed the presence of a crystalline TiC phase (13). XPS analysis gave (atom%) Ti:C:O (49:40:11). Thus, the thin films are identified as partially oxidized TiC.

An unexpected feature of the images obtained by SEM or TEM was that many of the TiC-coated carbon nanotubes were curved or kinked, whereas all of the uncoated nanotubes were linear. Figure 3 shows a TEM image of one such curved nanotube. The deposition of titanium carbide on fullerenes has been shown to cause surface reconstruction (9, 14), while the bending of carbon nanotubes may be

caused by replacement of carbon hexagons by pentagons (14), so it is possible that the bending observed in Fig. 3 arises as a result of surface reconstruction of the carbon nanotube, caused by the deposition of titanium carbide.

Nickel-group elements were deposited on the titanium carbide-coated carbon nanotubes by CVD, as previously described; however, under these conditions, the coatings were continuous and more even. Qualitatively, the deposition of nickel-group metals was faster on the TiC-coated nanotubes because the induction period for nucleation on the carbon surface of the pure nanotube was no longer present. Thus, it is shown that TiC is an effective intermediate layer because it can interact strongly with both the carbon nanotube substrate and the nickel-group metal. Figure 4 shows an SEM image of a carbon nanotube coated first with TiC and then with Pd/Pt alloy. Comparing with Fig. 1, it is clear that the metal coating is more continuous and even, with no isolated metal nanoparticles.

Some typical analytical data by EDX for the continuous nickel-group coatings obtained are listed in Table 1. In samples with thicker coatings, the TiC buffer layer was not detected, but the samples always contained residual carbon impurity in the range of 15–21 atom%. It is not obvious whether the carbon impurity arises from the substrate, from carbon in the ligands used, or from a combination of both. The samples containing Ni or Ni/Pd coatings also gave significant oxygen content, indicating partial oxidation of the surface nickel. XPS binding energies showed that Ni, Pd, and Pt coatings contained the elements in the metallic state.

Fig. 3. A TEM image of a MWCNT coated with TiC, showing the curvature induced by the CVD process.

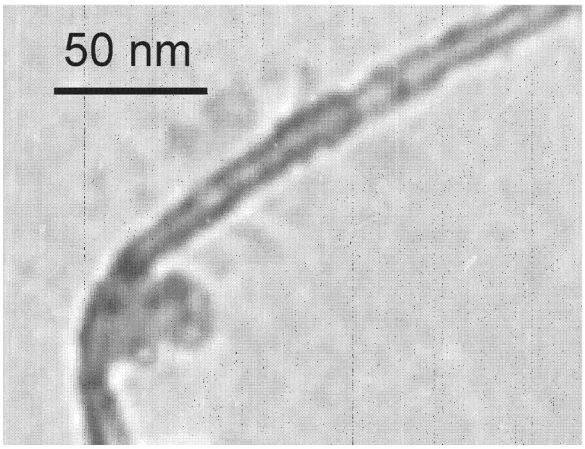

Fig. 4. An SEM image of a carbon nanotube coated first with TiC and then with Pd/Pt alloy. The background material arises from a graphitic impurity in the carbon nanotubes.

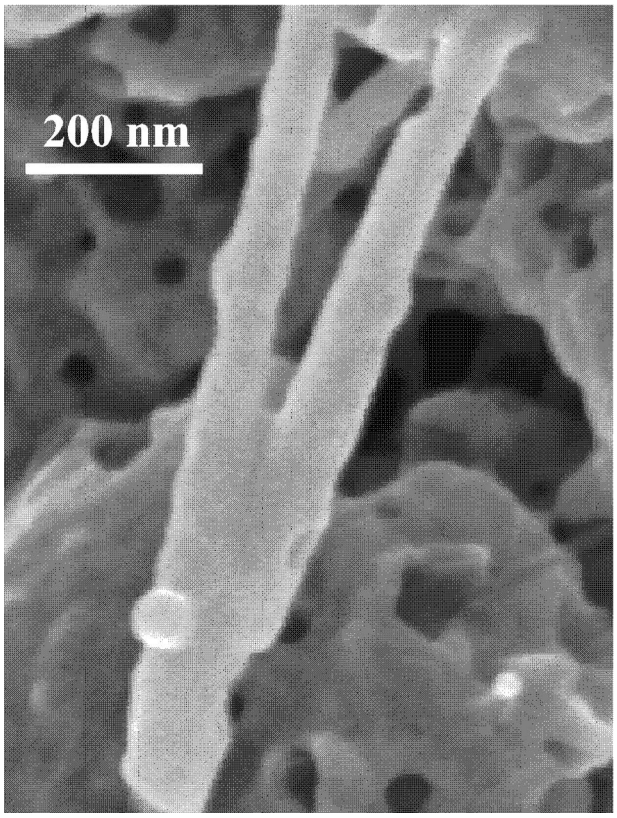

Figure 5 shows TEM images of nanotubes coated with TiC and then with a nickel-group metal. Figure 5(*a*) shows a nanotube coated with TiC and then with a thin coat of nickel. The kink in the nanotube and the even coating of the nanotube with nickel are obvious features. Less obvious is the presence of a helical appearance along the nanotube. Figure 5*b* shows CVD-coated nanotubes first with TiC and then with a thicker coating of Ni/Pd alloy. The apparent helical structure is now very pronounced and appears to arise

from multiple bends of the coated nanotubes. The metallic coating is again uniform and continuous along the length of the nanotube. These images further show that the problem of forming disconnected particles of Ni, Pd, Pt, and Ni/Pd or Pd/Pt bimetallic alloys by direct CVD onto the MWCNTs (Fig. 2) is overcome by precoating the nanotubes with TiC (Figs. 4, 5), which forms a strong interaction with the MWCNTs and gives a high nucleation rate for subsequent metal deposition.

Pre-oxidation of the carbon nanotubes

Oxidation of carbon nanotubes by nitric acid is known to introduce carboxylic acid, carbonyl, and hydroxyl groups at the surface, and these functional groups can act as nucleation centres in the deposition of metals, such as silver, gold, and platinum from solution (15).

CVD onto the oxidized carbon nanotubes, using $[Cp_2TiCl_2]$ as a precursor, gave a mixture of TiC and TiO_2 in a ratio of roughly 1:3, as determined by XRD and XPS analyses. XRD peaks for TiO_2 are broadened, indicating the formation of small particles, and the average particle size is estimated to be about 6 nm, as calculated from the Scherrer equation (16). The much greater degree of oxidation of titanium to form TiO_2 on the oxidized compared with the untreated carbon nanotubes indicates that the oxophilic titanium abstracts oxygen atoms from the oxygen-containing functional groups on the nanotube walls. Nevertheless, it is possible to deposit nickel-group metals by CVD to give continuous coatings on these treated nanotubes, and the compositions for thick films are very similar to those for films on unoxidized carbon nanotubes (Table 1). However, no bending or kinking of the coated nanotubes was observed by SEM or TEM imaging, in contrast to the observations with unoxidized carbon nanotubes described earlier. Figure 6 shows a TEM image of a bundle of oxidized carbon nanotubes coated first with TiC/TiO_2 and then with palladium, showing that the nanotubes remained linear.

The uniform coating of the oxidized carbon nanotubes with TiC/TiO_2 suggested that it might be possible to coat the nanotubes with a pure metal oxide (15, 17). This hypothesis was tested by CVD of zirconium dioxide, using $[Zr(DPM)_4]$ as a precursor (DPM = dipivaloylmethanate). Zirconia formed a continuous coating on the oxidized carbon nanotubes (Fig. 7*a*), and it was identified by XRD (Fig. 8). Further coating with nickel gave a continuous film (though with some visible imperfections) rather than isolated nanoparticles (Fig. 7*b*). A thick film gave the composition (atom%) of Ni:C:O (62:19:19), similar to that obtained for direct deposition on the oxidized carbon nanotubes. Again, no bending or kinking of the oxidized carbon nanotubes was observed as a result of the CVD-coating processes.

Conclusions

The deposition of the transition metals Ni, Pd, and Pt, and of the alloys Ni/Pd and Pd/Pt, on MWCNTs by CVD, using a buffer layer of TiC, provides a viable method for the metallization of carbon nanotubes, with potential uses as nanowires etc. The unusual bending of the MWCNTs, observed during CVD, is caused by the interaction of

the MWCNTs with the adsorbate. Thus, although a detailed explanation is not possible at this stage, it appears likely that adsorbate-induced reconstruction of the nanotube surface occurs, and that the distortions are amplified by the subsequent epitaxial growth of the metal films.

Experimental

The precursors used for CVD of TiC, Ni, Pd, and Pt were $[Cp_2TiCl_2]$, $[Ni(Cp)_2]$, $[Pd(hfac)_2]$ and $[Pt(COD)Me_2]$. $[Cp_2TiCl_2]$ and $[Ni(Cp)_2]$ (Cp = η-C_5H_5) were commercial samples (Aldrich, Strem), and $[Pd(hfac)_2]$ (hfac = hexafluoroacetylacetonate) and $[Pt(COD)Me_2]$ (COD = 1,5-cyclooctadiene) were prepared as described previously {$[Pd(hfac)_2]$, $[Pt(COD)Me_2]$} (5, 6). Multiwall carbon nanotubes (MWCNT, 7–12 nm outer diameter, 0.5–10 μm long) were purchased from Alfa Aesar in the form of a suspension in toluene. The substrates for CVD were prepared by adding a drop of the MWCNT suspension in toluene to a section of silicon wafer (1 cm in diameter), followed by evaporation of the solvent at 60 °C.

CVD was conducted at atmospheric pressure by using a horizontal glass hot-wall CVD apparatus (10). The carrier gas was ultra-high purity H_2 at a flow rate of 100 mL min^{-1}. The precursor was heated to 60 °C to give a suitable rate of evaporation in the carrier-gas stream. The substrate was heated as follows: deposition of TiC at 400 °C, Ni at 200 °C, Pd or Pt (or alloys of these elements) at 250 °C. Under these conditions, a typical CVD experiment was complete in 2 h. After the deposition, the silicon wafer was removed from the reactor, and the metallized MWCNTs were removed from the silicon surface and stored in vacuum for further analysis. For CVD of alloy materials, a mixture of $[Ni(Cp)_2]$–$[Pd(hfac)_2]$ or $[Pd(hfac)_2]$–$[Pt(COD)Me_2]$ was used for the deposition of Ni/Pd or Pd/Pt, respectively.

XPS spectra were recorded by using a SSL SSX-100 small-spot XPS surface-analysis instrument with a monochromatized Mg Kα X-ray source (1253.6 eV); binding energies were reproducible to within 0.1 eV. X-ray diffraction (XRD) profiles were measured using a Rigaku diffractometer with Co Kα radiation (wavelength = 1.790210 Å) at 40 kV and 40 mA, operating over a $2° < 2\theta < 82°$ angular range. TiC was identified by comparison to standard data from the Joint Committee for Powder Diffraction Studies (JCPDF) card 32–1383. SEM images were obtained using a Hitachi S-4500 scanning electron microscope. TEM images were obtained using a Philips EM300 transmission electron microscope system, operating at 80 keV.

Precipitation of gold by the reaction of aqueous gold(III) chloride with cyanobacteria at 25–80 °C — Studied by X-ray absorption spectroscopy[1]

Maggy F. Lengke, Bruce Ravel, Michael E. Fleet, Gregory Wanger, Robert A. Gordon, and Gordon Southam

Abstract: The mechanisms of gold precipitation by the interaction of cyanobacteria (*Plectonema boryanum* UTEX 485) and gold(III) chloride aqueous solutions (7.6 mmol/L final gold) have been studied at 25, 60, and 80 °C, using both laboratory and real-time synchrotron radiation absorption spectroscopy experiments. Addition of aqueous gold(III) chloride to the cyanobacterial culture initially promoted the precipitation of amorphous gold(I) sulfide at the cell walls and finally caused the formation of octahedral (111) platelets (<1 to 6 μm) of gold metal near cell surfaces and in solutions. X-ray absorption spectroscopy results confirmed that the reduction mechanism of gold(III) chloride to elemental gold by cyanobacteria involves the formation of an intermediate Au(I) species, gold(I) sulfide, with sulfur originating from cyanobacterial proteins, presumably cysteine or methionine. Although the bioreduction of gold(III) chloride to gold(I) sulfide was relatively rapid at all temperatures, the reaction rate increased with the increase in temperature. At the completion of the experiments, elemental gold was the major species present at all temperatures.

Key words: gold, X-ray absorption spectroscopy (XAS), cyanobacteria, transmission electron microscopy (TEM), precipitation, biosynthesis.

Résumé : Opérant à 25, 60 et 80 °C et faisant appel à des expériences tant de laboratoire que de spectroscopie d'absorption de rayonnement d'un synchrotron en temps réel, on a étudié les mécanismes de précipitation de l'or par l'interaction de la cyanobactérie (*Plectonema boryanum* UTEX 485) et de solutions (7,6 mmol/L finale d'or) aqueuses de chlorure d'or(III). L'addition de la solution aqueuse de chlorure d'or(III) à la culture cyanobactérienne provoque initialement une précipitation de sulfure d'or(I) amorphe sur les surfaces de la cellule et ultérieurement la formation de plaquettes (<1 à 6 μm) octaédriques (111) d'or métallique près des surfaces de la cellule et dans les solutions. Les résultas de la spectroscopie d'absorption de rayons X confirment que le mécanisme de réduction du chlorure d'or(III) en or élémentaire par la cyanobactérie implique la formation d'une espèce intermédiaire Au(I), le sulfure d'or(I), dans lequel le soufre provient de la cystéine ou de la méthionine des protéines de la cyanobactérie. Même si la bioréduction du chlorure d'or(III) en sulfure d'or(I) se fait relativement rapidement à toutes les températures, la vitesse de réaction augmente avec une augmentation de la température. Quelle que soit la température, à la fin des expériences, l'or élémentaire est l'espèce principale.

Mots-clés : or, spectroscopie d'absorption des rayons X (SAX), cyanobactérie, microscopie électronique en transmission (MET), précipitation, biosynthèse.

Table 1. Starting proportions for the cyanobacterial experiments at 25, 60, and 80 °C at The University of Western Ontario (UWO) and Argonne National Laboratory (APS).

Final Au (mmol/L)	Mixture	Total volume (mL)
Laboratory experiments at UWO		
7.6 mmol/L	20 mL of 26.6 mmol/L Au + 50 mL of cyanobacteria	70
XAS experiments at APS		
7.6 mmol/L	0.2 mL of 26.6 mmol/L Au + 0.5 mL of cyanobacteria	0.7

Note: Stock solutions contained ~20 mg/mL cyanobacteria (dry weight).

Introduction

Gold particles have many important applications in industry and nanotechnology. Therefore, it is essential to find simple and effective methods to synthesize gold particles, and it is also important to develop clean, nontoxic, and environment-friendly procedures. Consequently, biological processes that lead to the formation of gold particles are appealing as possible environment-friendly nanofactories.

Biological methods using organisms, such as bacteria and cyanobacteria, for the synthesis of gold particles are relatively new areas that are currently being explored (1–9). A number of laboratory experiments have been conducted to understand the interaction of gold with bacteria (e.g., *Bacillus subtilis* 168, Fe(III)-reducing bacteria, magnetotactic cocci, *Lactobacillus* sp., *Arthrobacter tumescens* IAM 1447, *Bacillus subtilis* IAM 1026, *Brevibacterium helovolum* IAM 1637, *Corynebacterium equi* IAM 1038, *Deinococcus proteolyticus* IAM 1214, *Escherichia coli* IAM 1264, *Pseudomonas maltophilia* IAM 1554, *Zooglea ramigera* IAM 12136) and cyanobacteria (e.g., *Plectonema terebrans*, *Plectonema boryanum* UTEX 485), using gold(III) chloride ($AuCl_4^-$) (1–9). Studies by Southam and Beveridge (2, 3) demonstrated the formation of metallic octahedral gold, possibly by organic sulfur and phosphate compounds from bacteria. Similarly, Lengke et al. (8, 9) observed the precipitation of metallic octahedral gold by the reaction with *Plectonema boryanum* UTEX 485 at pH 1.9–2.2 and at 25–200 °C and investigated the mechanisms of gold precipitation by X-ray absorption spectroscopy (XAS) at 25 °C. XAS results indicated that the interaction of cyanobacteria with gold(III) chloride initially promoted the precipitation of gold(I) sulfide and finally caused the formation of metallic octahedral gold. Fe(III)-reducing bacteria reduced gold(III) chloride prior to, or simultaneously with, the adsorption of gold onto the cell surfaces at pH 7.0, and the reactions involved the hydrogenase enzyme from these bacteria (4). The formation of gold by magnetotactic cocci was observed inside granules containing phosphorus, sulfur, and iron, and it was suggested that the sulfur-containing component of the granules is much more important in gold reduction than the phosphorus-containing component (7). Gold has also been observed within the cells of *Lactobacillus* sp., but the mechanisms of gold reduction were not discussed (5). The precipitation of gold by other bacteria (e.g., *Bacillus subtilis*, *Escherichia coli* IAM 1264, *Pseudomonas maltophilia* IAM 1554) at pH 1–6 and the precipitation of gold on the sheaths of *Plectonema terebrans* were hypothesized to take place through adsorption on the cells, although the precise mechanisms were poorly understood (1, 6).

Biosynthesis of gold particles by the reaction of aqueous gold(III) chloride ($AuCl_4^-$) with bacteria and cyanobacteria have been intensively studied (1–9); however, only one study has investigated the mechanisms of gold precipitation using cyanobacteria at 25 °C (9). Therefore, the goal of this study was to elucidate the mechanisms of gold precipitation using gold(III) chloride ($AuCl_4^-$) and cyanobacteria at 25–80 °C and to determine whether the mechanisms at 25 °C and higher temperatures are similar. This study was conducted using a combination of laboratory-based cyanobacterial experiments, supported by transmission electron microscopy (TEM), and real-time experiments by XAS. X-ray absorption near edge structure (XANES) provides information on the changes in oxidation state and coordination chemistry of gold during bioreduction, which is required to understand the chemical mechanisms of gold precipitation by cyanobacteria.

Experimental

Cyanobacterial cultures

The filamentous cyanobacterium, *Plectonema boryanum* UTEX 485 (obtained from the culture collection at the University of Texas at Austin, Texas, USA), was grown in batch cultures in BG-11 medium (10) and buffered with 10 mmol/L *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) at a control temperature of 29 °C under ambient CO_2 conditions. The pH of the medium was adjusted to 8.0 using 1 mol/L NaOH solution. Before experimentation, the culture was transferred (20% (*v*/*v*) of inoculum), and grown for 6–8 weeks to reach stationary "growth" phase. It was then centrifuged and washed three times with sterile distilled, deionized water to remove salts and trace metals from the medium.

Laboratory-based cyanobacterial and abiotic experiments

The cyanobacterial experiments were conducted at The University of Western Ontario (UWO) to examine the role of cyanobacteria in the bioaccumulation of gold from aqueous solutions of gold(III) chloride [$HAuCl_4 \cdot 3H_2O$; Alfa Aesar Company, Ward Hill, Massachusetts, USA]. To initiate the experiments, gold solutions (7.6 mmol/L final gold; Table 1) were added to a washed cyanobacterial culture (~20 mg/mL dry weight). The experiments were conducted at 25 °C for 48 h, and 60 and 80 °C for 24 h. pH, E_h, total gold, sulfur, phosphorus, and cyanobacterial populations were measured with time. All experiments were conducted in duplicate. Because there was no significant variation between duplicates for the first six experiments, triplicate experiments were

© 2007 NRC Canada

unnecessary. Abiotic control experiments, consisting of 7.6 mmol/L gold, were conducted using $AuCl_4^-$ solutions without the cyanobacteria.

Bacterial viability and total bacterial counts

The effects of $AuCl_4^-$ solution on the cyanobacteria were monitored during the course of the cyanobacterial experiments by determining bacterial viability using the LIVE/DEAD® BacLight™ bacterial viability kit (L-7007; Molecular Probes, Inc., Eugene, Oregon, USA). When viewed with a fluorescence microscope, viable bacteria, stained with the LIVE/DEAD® BacLight™ reagents, appear green, whereas dead bacteria appear red. The total number of bacteria in the cultures was determined by the direct counting method using a Petroff–Hauser counting chamber and a phase-contrast light microscope (Nikon Labophot microscope).

Chemical analyses

The pH and E_h were monitored using a Denver Instrument Basic pH/ORP/temperature meter. The pH electrode was calibrated using buffer solutions 4, 7, and 10 with analytical uncertainties in the pH measurements of ±0.05 pH unit. The E_h was measured using an ORP electrode and calibrated using ZoBell's solution (11).

Total gold, sulfur, and phosphorus concentrations were measured over the course of the experiments with a PerkinElmer 3300-DV inductively coupled plasma optical emission spectrometer (ICP-OES). The uncertainty in measured gold, sulfur, and phosphorus is ~5%, with detection limits of 0.25 μmol/L, 0.03 mmol/L, and 0.02 mmol/L for gold, sulfur, and phosphorus, respectively.

Transmission electron microscopy (TEM)

Unstained whole sample mounts of cyanobacteria and gold particles from the experiments were examined with a Phillips CM-10 transmission electron microscope (TEM), operated at 80 kV, and a Phillips EM400T transmission electron microscope (TEM) with energy dispersive X-ray spectrometer (EDS), operated at 100 kV. The whole mounts were prepared by floating Formvar carbon-coated 200 mesh copper grids on a drop of culture for several minutes to allow the bacteria and any fine-grained particles to attach to the grid. Selected-area electron-diffraction (SAED) patterns of the precipitated solids were obtained by TEM from unstained whole mounts to ascertain the crystallinity of the solids.

X-ray Absorption Spectroscopy (XAS)

XAS data collection

All XAS measurements were performed at the Pacific Northwest Consortium (PNC/XOR) bending magnet beamline, 20-BM, at the Advanced Photon Source, Argonne National Laboratory, Argonne, Illinois, USA. The Au-L_3 edge XAS measurements were collected using a Si(111) double-crystal monochromator under standard conditions of 7.0 GeV and 102 mA beam current. The energy of each scan was calibrated to the inflection of the Au-foil edge (11919 eV).

All XAS measurements for the cyanobacterial samples were conducted under in situ and real-time reaction conditions. Cyanobacterial samples contained a mixture of gold(III) chloride solution and cyanobacteria (7.6 mmol/L final gold; Table 1) and were prepared in an acid-resistant Teflon fluid cell (3.5 cm × 1 cm × 0.5 cm) with Teflon-coated Kapton film windows. XAS measurements were recorded in transmission mode at 25 °C and in fluorescence mode at 60 and 80 °C, and at intervals that were up to approximately 40 h at 25 °C and 60 min at 60 and 80 °C.

Model compounds, namely, gold(III) chloride ($HAuCl_4 \cdot 3H_2O$), gold(III) thiocyanate ($KAu(SCN)_4$), gold(I) chloride (AuCl), gold(I) cyanide (AuCN), gold(I) thiosulfate ($Na_3Au(S_2O_3)_2 \cdot 2H_2O$), gold(I) sulfide ($Au_2S$), gold(I) thiomalate ($NaO_2CCH_2CH(SAu)CO_2Na.xH_2O$), gold(I) chloro(triphenylphosphine) ($C_{18}H_{15}AuClP$), and gold foil (Au), were measured in the solid form in transmission mode. All model compounds contained a purity of at least 99.9% and were acquired from either Alfa Aesar Company, Ward Hill, Massachusetts, USA or Sigma-Aldrich Inc., St. Louis, Missouri, USA. The model compounds, except for gold foil, were ground and mixed with boron nitride and then pressed as a pellet prior to the measurement to achieve an edge step near unity in transmission. XAS spectra for all standards other than the gold foil and gold(I) sulfide were also collected in solution in transmission mode. The liquids were prepared from the solid compounds and diluted with distilled, deionized water without pH adjustment. Gold(III) hydroxide was prepared, as a model compound, by diluting solid gold(III) chloride with distilled, deionized water, and the pH of the solution was adjusted to pH 11 using NaOH. These model compounds were chosen as reference because they represent the most stable oxidation states of gold, Au(0), Au(I), and Au(III), and were used to qualitatively illustrate the environment expected to be found in the cyanobacterial samples.

Transmission spectra were collected from the cyanobacterial samples and model compounds, using 1 atm (1 atm = 101.325 kPa) nitrogen-gas-filled ionization chambers. A reference spectrum was measured for each sample using a third-ionization chamber and gold foil. The spectra were monitored for radiation-induced chemical effects, but none were found in any sample.

XAS data analysis

XAS data were processed using the ATHENA program (12, 13). Individual scans were calibrated and aligned using the reference gold foil spectrum, then averaged to improve signal quality. XANES spectra were analyzed by fitting with linear combinations of standard spectra. XANES spectra for both the standards and the cyanobacterial samples were normalized and then corrected before analysis to remove variation in the shape of the background. Normalization is done by regressing polynomials to the data regions before and after the edge step. The pre-edge line is subtracted from the data to place the baseline at 0. The post-edge line is extrapolated back to the edge energy of 11919 eV. The difference between the pre- and post-edge lines at 11919 eV is the "edge step". The pre-edge-subtracted data are normalized by dividing by this step height at each energy interval. A background correction is made by subtracting the slope of the

© 2007 NRC Canada

pre-edge line from the post-edge polynomial and then subtracting this difference function from the normalized data. This has the effect of flattening the XANES spectra such that the oscillatory fine structure oscillates about unity. With flattened spectra, the linear combination analysis does not require any additional terms to account for the different background shapes of the standards and data.

Results

Cyanobacterial and abiotic experiments

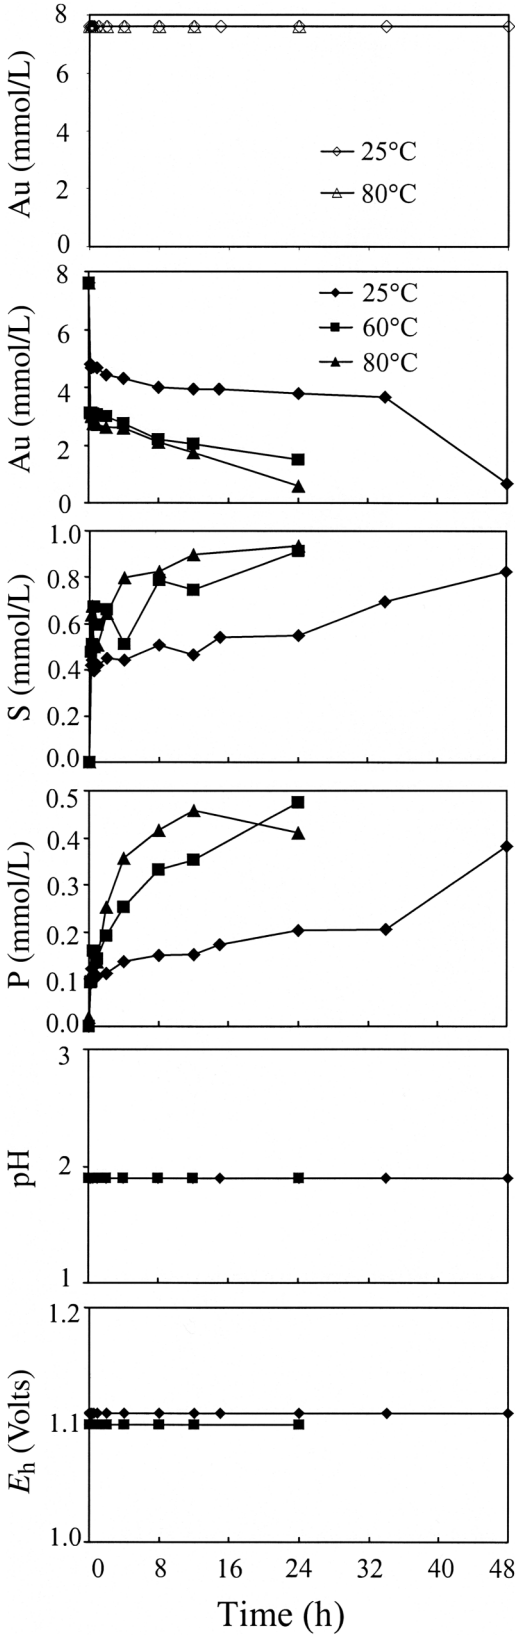
At 25 °C

Upon the addition of gold(III) chloride (7.6 mmol/L final gold) to the cyanobacterial culture, the soluble gold concentration significantly decreased after 48 h at 25 °C (Fig. 1). Total soluble sulfur and phosphorus concentrations increased from 0.00 to ~0.82 mmol/L and ~0.38 mmol/L, respectively, after 48 h (Fig. 1). The pH and E_h values were relatively constant at ~1.9 and ~1.11 V, respectively. All cyanobacteria were killed within several minutes upon the addition of gold(III) chloride, with concomitant change in color of the cyanobacteria from green to brown, while the solution color remained yellow until the end of the experiments.

At 60 °C

The soluble gold concentration decreased with the increase in reaction time (Fig. 1). Total soluble sulfur and phosphorus concentrations increased from 0.00 to ~0.91 mmol/L and to ~0.47 mmol/L, respectively, after 24 h (Fig. 1). The pH and E_h values were relatively constant at ~1.9 and ~1.10 V, respectively. Cyanobacteria were killed within several minutes. Development of a brown color on cyanobacteria was taken as macroscopic evidence of gold precipitation.

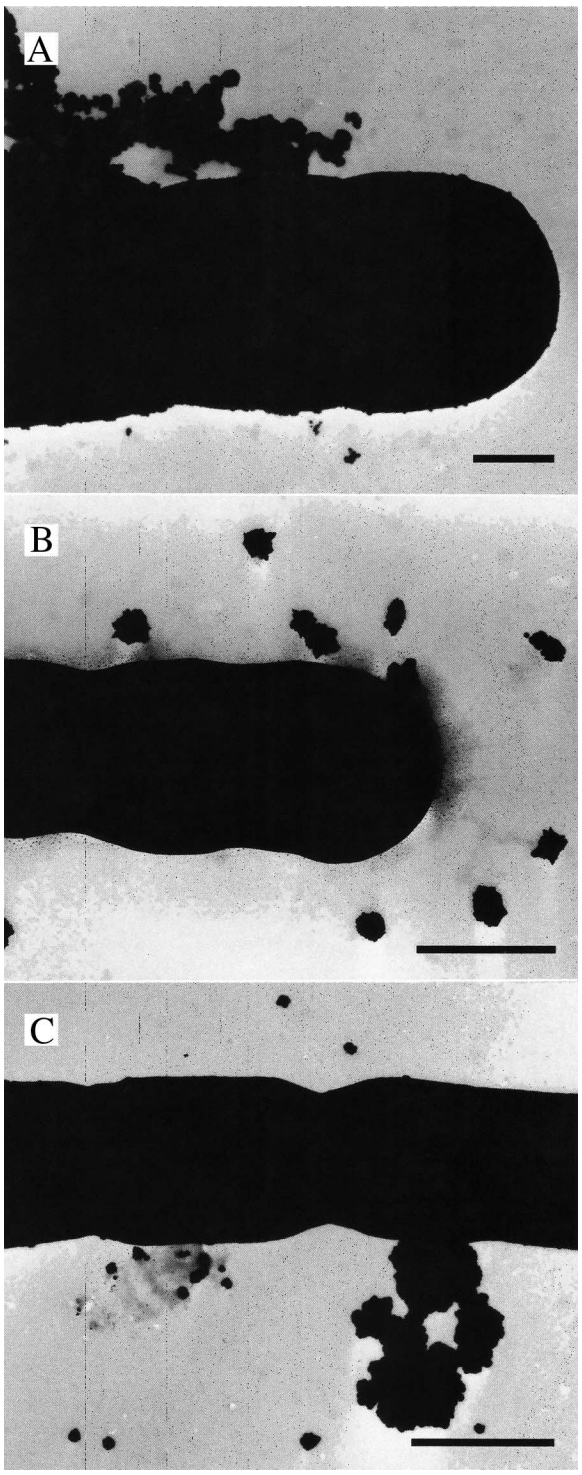
At 80 °C



The soluble gold concentration decreased with the increase in reaction time by about 7 mmol/L (Fig. 1). During the course of experiments, total soluble sulfur and phosphorus concentrations increased gradually from 0.00 to ~0.93 mmol/L and ~0.41 mmol/L, respectively (Fig. 1). The pH and E_h values were relatively constant at ~1.9 and ~1.10 V, respectively. All cyanobacteria were killed within several minutes at 80 °C, with concomitant change in color of the cyanobacteria from green to brown, while the solution color became light-yellow at the end of the experiments.

For abiotic experiments using aq. $AuCl_4^-$ at 25, 60, and 80 °C, total soluble gold concentrations were relatively constant (Fig. 1), and pH and E_h values also remained relatively constant until the end of experiments.

TEM



TEM observations on products of cyanobacteria – gold(III) chloride experiments at 25, 60, and 80 °C are presented in Figs. 2 and 3. Addition of gold(III) chloride to the cyanobacteria resulted in the precipitation of nanoparticles at the cell surfaces and at the cell wall – solution interface within several minutes (Fig. 2). These early formed nanoparticles were amorphous to electron diffraction (data not shown) and by TEM–EDS, gold was associated with sul-

Fig. 2. TEM micrographs of whole mounts of cyanobacterial cells cultured in the presence of gold(III) chloride at 2 h at UWO: (A) precipitation of nanoparticles of gold at cell boundary at 2 h at 25 °C, (B) precipitation of nanoparticles of gold in the vicinity of the cell at 60 °C, (C) precipitation of nanoparticles at cell boundary and near the cell at 80 °C. Scale bars in A, B, and C are 0.5, 1.0, and 0.3 μm, respectively.

fur, phosphorus, and nitrogen. After several minutes, the dead cyanobacteria released cytoplasmic material around the cells, causing further precipitation of gold nanoparticles,

Fig. 3. TEM micrographs and the corresponding TEM–SAED diffraction patterns of whole mounts of nanoparticles of gold metal in the cyanobacteria – gold(III) chloride system at 60 °C and 24 h: (A) octahedral gold, and (B) TEM–SAED twinned diffraction pattern consistent with crystalline gold metal. Scale bar in A is 1.5 μm.

which were characterized by TEM–SAED and TEM–EDS as gold metal. Initially, these second-generation gold nanoparticles were anhedral in shape, but ultimately octahedral shapes with sizes ranging from <1 to 6 μm were formed (Fig. 3A). TEM–SAED patterns were consistent with octahedral gold(111) crystals (Fig. 3B).

XAS

XANES spectra of model compounds

XANES spectra of the model compounds, gold(III) chloride, gold(III) hydroxide, gold(III) thiocyanate, gold(I) chloride, gold(I) cyanide, gold(I) thiosulfate, gold(I) sulfide, gold(I) thiomalate, gold(I) chloro(triphenylphosphine), and gold foil, are presented in Figs. 4 and 5. The absorption edge of gold(III) and gold(I) compounds shifts to lower energy compared with the gold foil. The unusual edge shift for Au(III) is readily attributed to the low-energy dipole-allowed 2p to 5d transition, which is allowed for the d^8 species and forbidden for d^{10} Au(0) (14). Oxidation states of gold are determined from the position and appearance of the intense

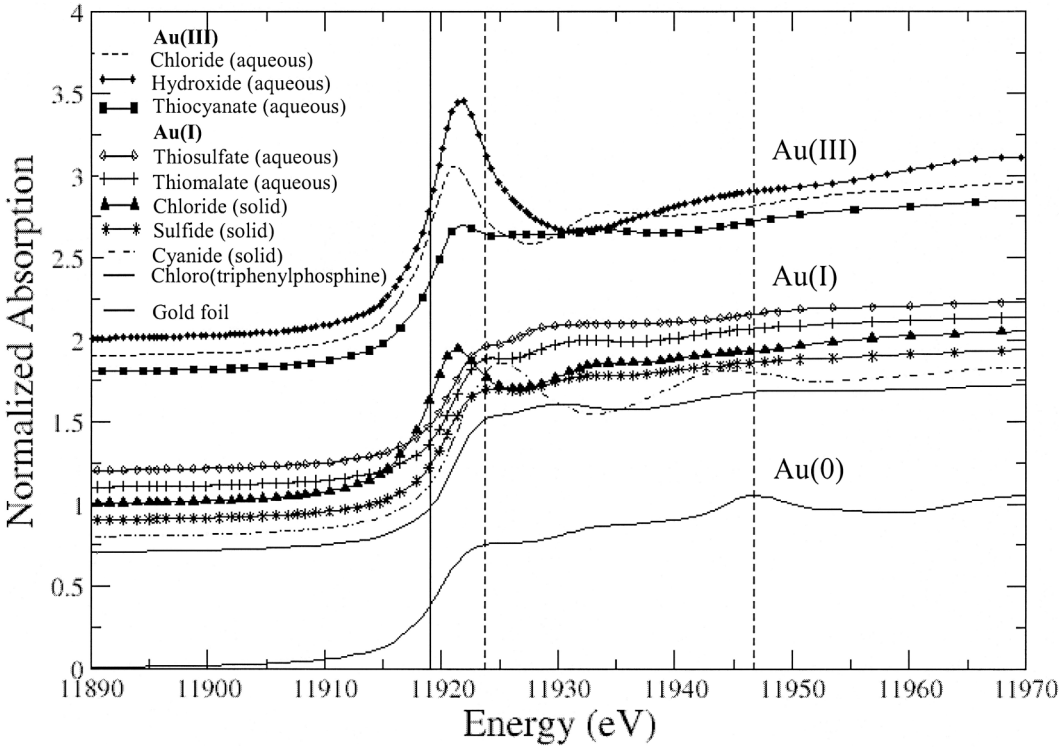
Fig. 4. XANES Au-L_3 edge spectra of the gold model compounds measured in the solid and aqueous forms. The vertical solid line indicates the tabulated edge energy, 11919 eV. The vertical dashed lines mark distinctive features of the gold foil and gold(I) sulfide spectra, indicative of the presence of those species in the LC–XANES fitting.



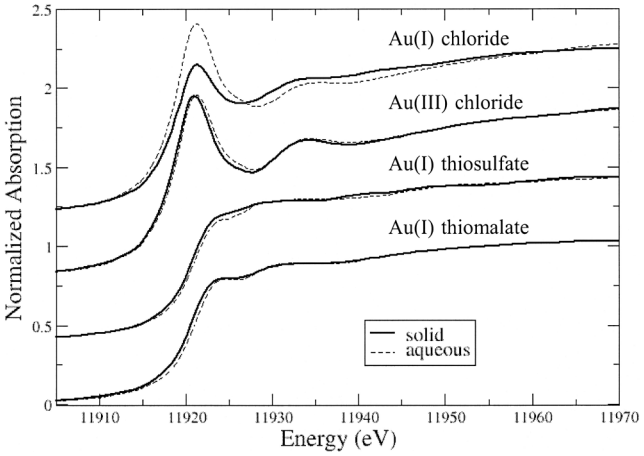


Fig. 5. Comparison of XANES Au-L_3 edge spectra of the gold(I) chloride, gold(III) chloride, gold(I) thiosulfate, and gold(I) thiomalate model compounds measured in the solid form and in solution. Gold(I) chloride clearly disproportionates in solution.

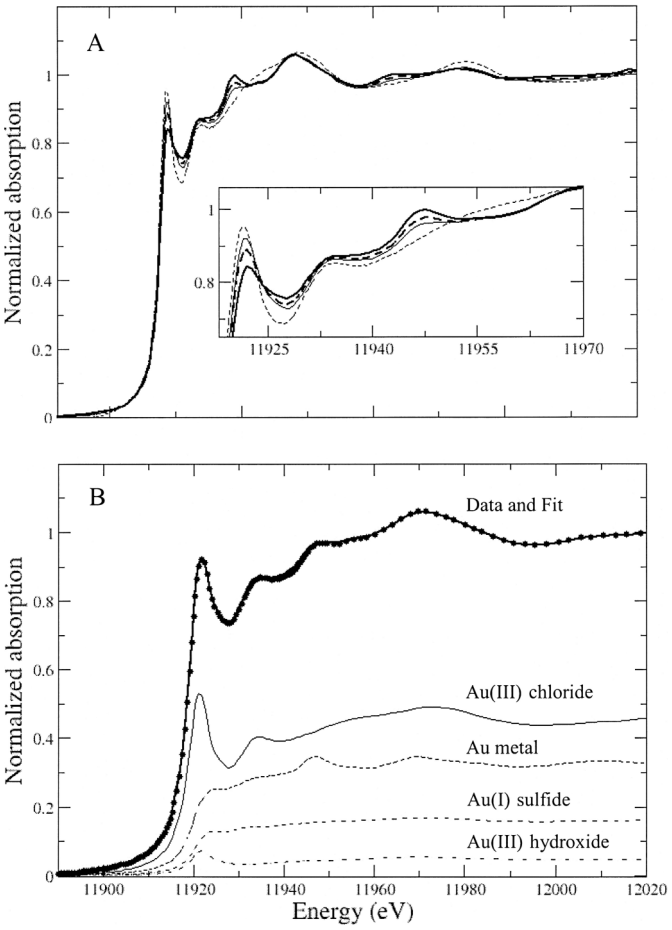

and sharp Au-L_3 edge feature (15). The white-line feature appears at approximately 11921 eV for Au(III) (e.g., gold(III) chloride, gold(III) hydroxide, and gold(III) thiocyanate), but it shifts to higher photon energy with the decreasing oxidation state of gold, as presented in Fig. 4. The white-line feature should only be observed in Au(III) because of the unfilled final-state 5d orbital in the electron configuration of gold (Table 2). However, some Au(I) compounds (e.g., gold(I) chloride and gold(I) cyanide) show a white-line feature with less intensity because of the incorporation of electrons from the closed 5d orbital in chemical bonding (15). The possible incorporation of d electrons from the closed d^{10} subshell for chemical bonding suggests that the electron configuration of Au(I) is $5d^{10-\delta}6s^{\delta}$ (15,16). In a linear 2-fold coordination such as gold(I) cyanide, it has been proposed that hybridization between the 5d and 6s orbitals leads to a valence-electron distribution of $5d^{10-\delta}6s^{\delta}$. This implies the presence of unoccupied d states above the Fermi level, similar to the electron configuration in Au(III) compounds. The occurrence of an edge peak confirms the presence of the vacancies in the 5d valence level. In case of Au(0), the 5d orbital is filled, and no electrons can be added (Table 2); therefore, the white line is absent. For gold foil, the post-edge XANES peaks at approximately 11947 eV are characteristic of Au(0) (Fig. 4). Thus, the white-line feature and its intensity were used for the determination of the oxidation state of gold. The Au-L_3 XANES spectra for the solutions of the selected model compounds (gold(III) chloride, gold(I) thiosulfate, and gold(I) thiomalate) show similar spectra to the solids, confirming that the Au atoms remain complexed in aqueous solution (Fig. 5). We observed no changes in energy shifts of the edge position for measurements in solutions compared with corresponding solids.

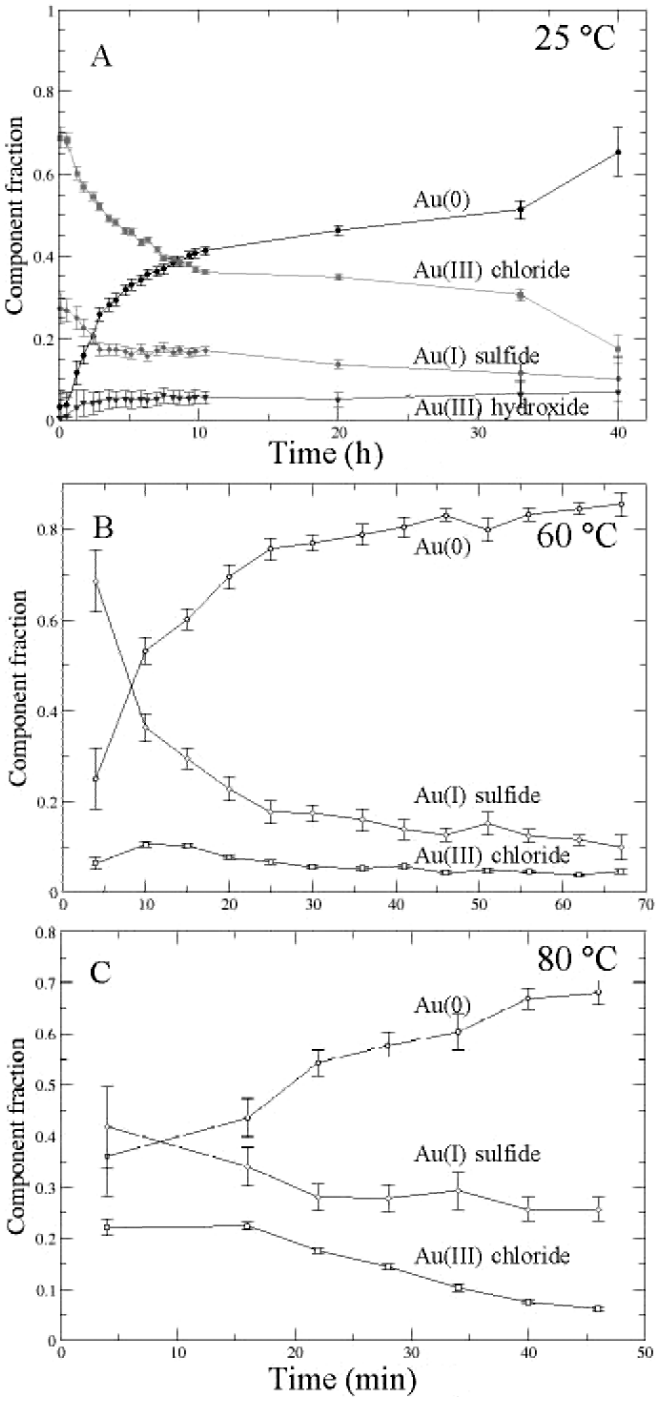
Fig. 6. (A) Evolution of the XANES Au-L_3 edge spectral shift from the beginning to the end of the cyanobacterial experiments at 7.6 mmol/L final gold; thin dashed line, thin solid line, thick dashed line, and thin solid line are measurements after at 10 min, 2 h and 40 min, 8 h and 15 min, and 40 h, respectively. The inset shows the details of the main XANES features. (B) Example of an LC–XANES fit at 5 h and 12 min. The weighted components are displayed below the fit.

However, the spectrum of gold(I) chloride in solution is not similar to the solid, indicating that gold(I) chloride is unstable in solution (Fig. 5). At 25 °C and high concentration, gold(I) chloride disproportionates to a mixture of gold(III) chloride and gold metal (17), via the following reaction:

[1] $3AuCl_2^- \leftrightarrow 2Au_{(s)} + AuCl_4^- + 2\ Cl^-$



XANES spectra of cyanobacterial samples

XANES spectra and the results of linear-combination fits (LC–XANES) for the cyanobacteria that reacted with gold(III) chloride (7.6 mmol/L final gold) at 25, 60, and 80 °C are presented in Figs. 6 and 7.

At 25 °C

The in situ, real-time experiments were conducted on the cyanobacterial samples at 25 °C for approximately 40 h. During the course of experiments, the spectra showed significant change from the first to the last scans; therefore, an average of every five scans was used for data analysis. The

Fig. 7. Evolution of gold oxidation states and species with time at 7.6 mmol/L final gold in solution, deduced from LC–XANES fits: (A) 25 °C, (B) 60 °C, and (C) 80 °C.

evolution of the data from the beginning to the completion of experiments is shown in Fig. 6A. With the increase in reaction time, the Au-L_3 edge position moved to higher energy, the white line intensity became smaller, and the peak at 11947 eV became higher (Fig. 6A), indicating progressive change in the oxidation state from Au(III) to Au(0). Four model compounds, namely, gold foil (Au), gold(III) chloride, gold(I) sulfide, and gold(III) hydroxide, showed the best match in the (linear-combination) LC–XANES fits

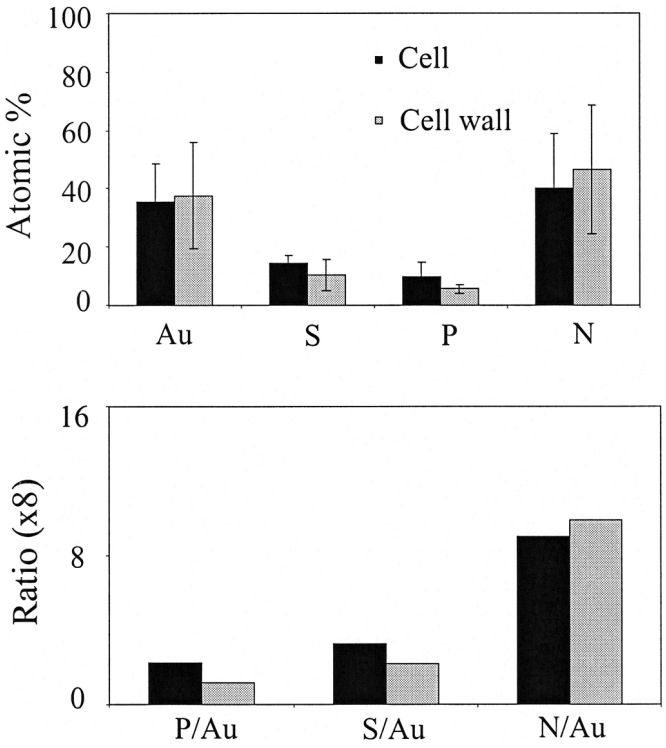
© 2007 NRC Canada

(Fig. 6B). The results of the fits as a function of time are presented in Fig. 7A. Gold(III) chloride and gold(I) sulfide decreased as gold(0) increased with time. Data reduction indicated that trace gold(III) hydroxide consistently improved the fits, although the pH was very low (pH 1.9). The presence of gold(III) hydroxide in the sample was attributed to the replacement of Cl^- by O-containing ligands during the hydration of gold(III) chloride because the XAS measurements for cyanobacterial samples were conducted in aqueous solution in the presence of unreduced gold(III) chloride.

At 60 °C

The in situ, real-time experiments were conducted on a cyanobacterial sample at 60 °C for approximately 68 min. During the course of experiments, changes in spectra were observed; therefore, an average of every five scans was used for data analysis. Three model compound, namely, gold foil (Au), gold(III) chloride, and gold(I) sulfide, showed the best match in the LC–XANES fits. The proportion of gold(III) chloride decreased sharply after the addition of cyanobacteria within the first 4 min, and then remained constant for the duration of the experiment. Gold(I) sulfide decreased in proportion to the increase in gold(0), i.e., gold(I) sulfide and gold(0) distributions were inversely correlated.

At 80 °C



The in situ, real-time experiments were conducted on the cyanobacterial sample at 80 °C for approximately 47 min. During the course of experiments, the spectra showed change from the first to the last scans; therefore, an average of every five scans was used for data analysis. Three model compounds, namely, gold foil (Au), gold(III) chloride and gold(I) sulfide, showed the best match in the LC–XANES fits. As in the 60 °C experiments, gold(III) chloride decreased sharply after the addition of cyanobacteria within the first 4 min, and then slightly decreased until the end of the experiments. Also, gold(I) sulfide and gold(0) showed linear changes with time and were inversely correlated (Fig. 7C).

Discussion

Based on the results of the laboratory cyanobacterial experiments, total gold concentrations decreased significantly at all three temperatures (25, 60, and 80 °C) after the addition of gold(III) chloride to the cyanobacterial culture, whereas total soluble sulfur and phosphorus concentrations increased with time until the completion of the experiments (Fig. 1). The TEM–EDS for the cyanobacterial samples at 25 °C after 2 h reaction time showed the association of gold with sulfur, phosphorus, and nitrogen in the cyanobacterial cells and at the cell walls (Fig. 8). This suggests that sulfur, phosphorus, nitrogen, and gold were involved in the formation of gold nanoparticles precipitated in the early stages of the experiments.

LC–XANES fits confirm that elemental gold was present as a major phase at the completion of all experiments, and that gold(III) chloride was present as a major component in the 25 °C experiments. Gold(III) chloride could undergo ligand-exchange reactions with the O-containing ligands in the 25 °C experiments. However, at 60 and 80 °C, gold(III) chloride was largely reduced by the cyanobacteria, and the

Fig. 8. Histograms of the normalized contents of gold, sulfur, phosphorus, and nitrogen (atomic weight %) by TEM–EDS in the reacted cyanobacterial cells and cell walls, with corresponding ratios of P:Au, S:Au, and N:Au, at 7.6 mmol/L final gold in solution and 25 °C.

binding occurred via a ligand-exchange mechanism, forming gold(I) sulfide by a very fast reaction (Fig. 7). The only source of sulfur in the experimental vessels for the formation of gold(I) sulfide was organic sulfur from the cyanobacteria. Thus, sulfur from cyanobacteria was released to the bulk solutions, and immediately bound with the reduced gold, forming gold(I) sulfide. The fast reduction of Au(III) to Au(I) and the fast release of organic sulfur from the dying and dead cyanobacteria at the higher temperatures investigated (60 and 80 °C) resulted in the presence of gold(I) sulfide as a major phase at the initial stage in the reaction. The reduction of gold(I) sulfide to elemental gold was slower at 25 °C than at 60 and 80 °C. This reduction step was also somewhat slower at 80 °C than at 60 °C, presumably reflecting the increase in stability of aq. gold(I) sulfide at the higher temperature (18, 19).

We noted that the mechanisms for the interaction of bacteria and cyanobacteria with gold(III) chloride have not been investigated in detail in previous studies (1–7). The present XAS results show that Au(III) was reduced to Au(I) bound as gold(I) sulfide, with the sulfide being of organic (cyanobacterial) origin, in a very fast reaction (within minutes). Within the cyanobacteria, sulfur presumably was present as cysteine or methionine groups of the outer membrane or periplasmic proteins (20). These proteins also contain phosphorus and nitrogen, and this may explain the indirect relationship between nitrogen and gold (TEM–EDS results). As soft acids, gold(III) and gold(I) ions readily form com-

© 2007 NRC Canada

plexes with non-polar soft bases such as sulfur and phosphorus. Therefore, the interaction of a gold cation with sulfur would be expected. The reduction of Au(I) to Au(0) was a slower process than the formation of gold(I) sulfide, and occurred after most of the gold(III) chloride had been consumed by the reaction with the cyanobacterial culture (Fig. 7). Thus, we deduce that the steps for the bioaccumulation of gold from gold(III) chloride solution by cyanobacteria are

[2] gold(III) chloride ($AuCl_4^-$) $\rightarrow$

gold(I) sulfide (Au_2S) $\rightarrow$ gold(0) (Au)

Acknowledgment

We thank Dr. Marianna Krol for providing the cyanobacterial cultures and access to the incubation chamber, Ronald Smith for his help during TEM analysis, and Dr. Steve Heald, Dr. Mahalingam Balasubramanian, and Michael Pape for their technical assistance during XAS measurements. We thank Dr. TK Sham and two anonymous reviewers for their constructive comments. Experiments at the PNC/XOR facilities, Advanced Photon Source, Argonne National Laboratory, and research at these facilities were supported by the United States Department of Energy–Basic Energy Sciences, a major facilities access grant from the Natural Sciences and Engineering Research Council of Canada (NSERC), the University of Washington, Simon Fraser University, the Pacific Northwest National Laboratory, and the Advanced Photon Source. Use of the Advanced Photon Source was also supported by the United States Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357. Support for synchrotron efforts was also provided by the United States Department of Energy, Office of Science, Biological and Environmental Research, Environmental Remediation Science Program. The research at The University of Western Ontario was supported in part by the National Science Foundation LExEn Program and NSERC Discovery Grants to G. Southam and M. E. Fleet.

Synthesis and characterization of fluorinated phosphonium ionic liquids[1]

Jocelyn J. Tindale, Chris Na, Michael C. Jennings, and Paul J. Ragogna

Abstract: A wide variety of phosphonium ionic liquids containing fluorous ponytails R_{fn} (R_{fn} = $-(CF_2)_{n-1}CF_3$; n = 4, 6, 10) are synthesized by the reaction of R_{fn}-$(CH_2)_2$-I with trialkylphosphines (R_3P; R = Me, ^{n}Bu, ^{n}Oct). The efficacy of multiple metathetical routes to anion exchange have been investigated, thus the corresponding BF_4^-, PF_6^-, tosylate (OTs^-) and triflate (OTf^-) derivatives have also been prepared. All compounds have been comprehensively characterized by multinuclear NMR spectroscopy, ESI-MS, DSC, and TGA/SDTA, and in the case of $[Me_3PCH_2CH_2R_{f4}][I]$ by single crystal X-ray diffraction. These materials range from high melting solids (e.g., $[Me_3P(CH_2)_2R_{f4}][I]$ T_m = 195 °C) to very low melting liquids (e.g., $[^nOct_3P(CH_2)_2R_{f4}][OTf]$ T_g = –64 °C), and they all have high thermal decomposition points (295 to 394 °C). Incorporation of the more weakly coordinating BF_4^- and PF_6^- yielded a significant increase in the melting point of the materials, in contrast to OTf^- and OTs^- derivatives, which all exhibited significantly depressed melting points.

Key words: phosphonium ionic liquids, alternative solvents, fluorine, phosphorus, fluorous ponytails.

Résumé : On a réalisé la synthèse d'une grande variété de liquides ioniques du phosphonium portant des queux de cheval fluorées [R_{fn} = $-(CF_2)_{n-1}CF_3$; n = 4, 6, 10] en faisant réagir des R_{fn}-$(CH_2)_2$-I avec des trialkylphosphines (R_3P; R = méthyle, butyle, octyle). On a étudié l'efficacité des voies de métathèses multiples conduisant à un échange d'anion; pour cette raison, on a aussi préparé les dérivés BF_4^-, PF_6^-, tosylate (OTs^-) et triflate (OTf^-). Tous les composés ont été caractérisés par spectroscopie RMN multinucléaire, par spectrométrie de masse avec ionisation par électronébulisation, par analyse calorimétrique différentielle et par analyse thermogravimétrie et analyse thermique simultanée et, dans le cas du cristal $[Me_3PCH_2CH_2R_{f4}][I]$, par diffraction des rayons X par un cristal unique. Au point de vue physique, ces produits varient de solides à points de fusion élevés pour des composés comme le $[Me_3P(CH_2)_2R_{f4}][I]$ (T_m = 195 °C) à liquides à points de fusion très faibles des composés comme le $[octyl_3P(CH_2)_2R_{f4}][OTf]$, ($T_g$ = –64 °C); ils ont toutefois tous des points de décomposition thermique élevés (295 à 394 °C). L'incorporation des anions plus faiblement coordinants BF_4^- et PF_6^- conduit à une augmentation substantielle dans les points de fusion de ces matériaux; ce résultat est en opposition avec ce qui est observé avec les dérivés OTf^- et OTs^- qui présentent tous des diminutions significatives des points de fusion.

Mots-clés : liquides ioniques du phosphonium, solvants alternatifs, fluor, phosphore, queux de cheval fluorées.

[Traduit par la Rédaction]

Introduction

"Reduce, reuse, and recycle" waste are considered cornerstone ideas for living "green" (1). This philosophy is becoming increasingly more important in terms of developing cleaner processes for chemical synthesis and manufacturing (2). Many synthetic methods and chemical reactions are carried out in the solution phase, which is considered to be one of the most difficult areas for developing a more environmentally benign process. The identification of ionic liquids as ideal media in which to perform a vast array of solution phase chemistry has been a crucial development for overcoming the difficulties associated with making this area of chemistry "greener".

Ionic liquids possess remarkable properties, which make them ideal candidates as alternative solvents for synthesis (3), catalysis (4), and chemical separations (5) (e.g., negligible vapor pressure, high thermal stability, large liquid range) (6–12). In addition to these more familiar applications, ionic liquids have been reported as highly versatile media for use as electrolytes in various electrochemical devices such as solar cells (13, 14) and lithium batteries (11), as electrochemical capacitors (15), matrices for MALDI mass spectrometry (16, 17), surfactants (18), electropolishing agents (13), phase

Fig. 1. Common cations in ionic liquids.

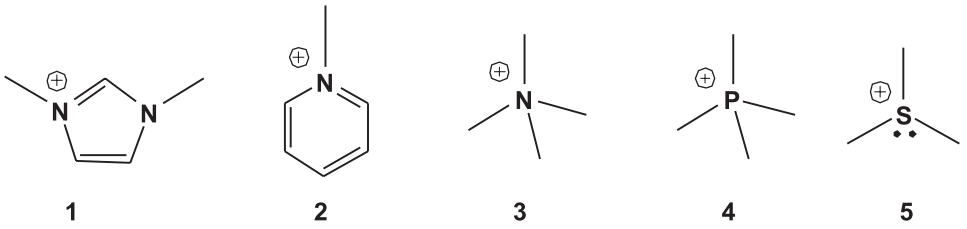

Fig. 2. Ionic liquids featuring unusual functionalities.

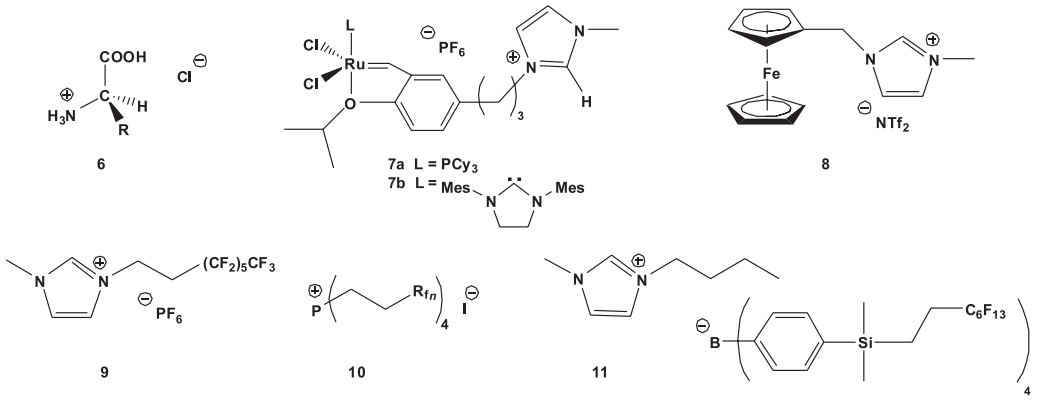

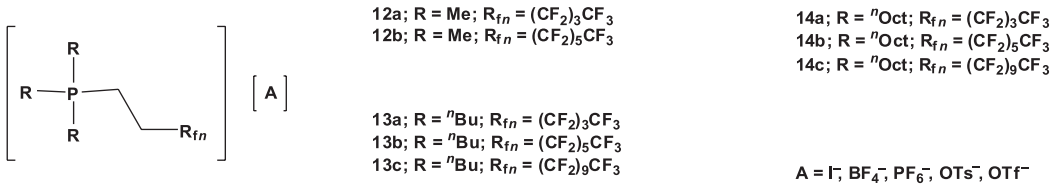

Fig. 3. Numbering scheme for the ionic liquids containing one fluorous chain. Compound numbers refer to the composition of the phosphonium cation.

transfer catalysis (19), and as highly resilient media in radiation intensive environments (20). The overwhelming majority of these ionic liquids employ nitrogen-based cations (**1**–**3**), while there have been limited reports on the use of phosphonium or sulphonium ionic liquids (**4**, **5**, Fig. 1).

Despite their greater thermal stability, propensity for forming multiphasic systems, increased resilience in basic environments, and demonstrated utility in a variety of catalytic and other synthetic applications, reports on the development of new phosphonium ionic liquids are relatively uncommon (19, 21–27).

Incorporating unusual but potentially useful functionalities into the cation or anion pair can impart these materials with attractive properties not observed in more conventional systems. For example, ammonium-based systems derived from natural amino acids generate biodegradable, chiral-solvent media **6** (28). Other functionalities integrated into the ionic liquid frameworks include catalytically active organometallic complexes (e.g., **7**), such as the Grubbs generation I (**7a**) and generation II catalysts (**7b**) or ferrocenyl substituents that are tethered to an imidazolium cation (**8**). These materials proved to be highly effective in ring-closing olefin metathesis (RCM) or as novel media for the study of electron transfer dynamics, respectively (Fig. 2) (29–33). However, these substituents can limit the environmental compatibility of the end materials.

Ionic liquids integrated with perfluoroalkyl chains, also referred to as fluorous ponytails (R_{fn} = $-(CF_2)_{n-1}CF_3$) (**9**, **10**), have shown excellent utility as surfactants or as a solvents for phase transfer catalysis (18, 19, 34–37). Systems containing heavily fluorinated anions paired with imidazolium cations (**11**) have displayed temperature dependent solvent miscibilities similar to those observed for highly fluorinated organic solvents (34) and will likely have applications in fluorous biphasic catalysis (38, 39) as a nonvolatile fluorous phase, a distinct advantage over current technologies.

In this context, we report the synthesis and characterization of a wide range of phosphonium ionic liquids that contain a diverse array of highly fluorinated alkyl chains as a component of the cation (Fig. 3). In all cases, the products are air stable, hygroscopic, exhibit high decomposition points, are soluble in a variety of polar organic or fluorinated solvents (acetone, CH_2Cl_2, α,α,α-trifluorotoluene), have wide liquid ranges, and are a promising new alternative solvent media.

Experimental section

General

Trialkylphosphines ($^nBu_3P$, $^nOct_3P$) were donated by Cytec Corporation and distilled prior to use (0.01 torr, 1 torr = 133.322 4 Pa; 80 and 160 °C, respectively). Sodium

 doi:10.1139/V07-035 © 2007 NRC Canada

hexafluorophosphate, AgOTs, $NaBF_4$, HBF_4, HPF_6, HOTs, NaOTs (Sigma-Aldrich), and TMS-OTf (Alfa Aesar) were used as received. Fluorinated alkyl iodides (Fluorous Technologies Inc.) were used without further purification, except for $CF_3(CF_2)_9CH_2CH_2I$, which was sublimed prior to use (0.05 mmHg, 1 mmHg = 133.322 4 Pa; –20 °C cold finger). The purity of all reagents was assessed by multinuclear NMR spectroscopy (^1H, $^{19}F\{^1H\}$, $^{31}P\{^1H\}$) where appropriate, and they were stored in a nitrogen-filled MBraun Labmaster 130 glove box. Solvents were obtained from Caledon Laboratories and dried using an Innovative Technologies Inc. Controlled Atmospheres Solvent Purification System, which utilizes dual-alumina columns. The dried solvents were collected under vacuum and stored under a nitrogen or argon atmosphere in Strauss flasks or stored in the drybox over 4 Å molecular sieves. Deuterated solvents were dried by stirring for a minimum of 2 days over CaH_2, then vacuum distilled and stored over 4 Å molecular sieves in the drybox. Solution ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on either a Varian INOVA 400 MHz, a Varian INOVA 600 MHz, or a Varian Mercury 400 MHz spectrometer (^1H: 400.09, 599.49, and 400.1 MHz, respectively; ^{31}P: 161.82, 242.67, and 161.96 MHz, respectively). Proton decoupled ^{19}F NMR spectra were recorded on either a Varian INOVA 400 MHz or Varian Mercury 400 MHz spectrometer (376.15 MHz, 376.46 MHz, respectively).

All samples for ^1H NMR spectroscopy were referenced to the residual protons in the solvent relative to $(CH_3)_4Si$ (δ (ppm): chloroform-*d* 7.26; pyridine-d_5 8.71; 7.55, 7.20; acetonitrile-d_3 1.94; acetone-d_6 2.05). Phosphorus-31 chemical shifts were reported relative to an external standard (85% H_3PO_4, 0.00 ppm) and ^{19}F NMR data were referenced to an external standard ($CF_3(C_6H_5)$, –63.9 ppm) relative to $CFCl_3$, 0.00 ppm. Mass spectrometry measurements were recorded in positive and negative ion modes using an electrospray ionization Micromass LCT spectrometer. Melting and glass transition points were determined using differential scanning calorimetry (DSC) on a DSC 822e Mettler Toledo instrument. A 0.005–0.010 g sample was heated at a rate of 10 °C/min over a temperature range of –70 to 120 °C. Ionic liquids that were liquid at room temperature (RT) were cooled to –70 °C for 15 min, followed by increasing the heating rate to 10 °C/min until reaching 120 °C. The decomposition temperatures were determined using thermal gravimetric analysis (TGA) on a TGA/SDTA 851e Mettler Toledo instrument. A 0.005–0.010 g sample was heated at a rate of 10 °C/min over a temperature range of 100 to 600 °C. Decomposition temperatures were confirmed by DSC, in that no exotherm indicative of a decomposition with zero mass loss was observed below the decomposition points noted. Single crystal X-ray diffraction data were collected on a Nonius Kappa CCD area detector using Mo K_α radiation (λ = 0.710 73 Å). Single crystals of [**12a**][I] were successfully grown via vapour diffusion of Et_2O into a CH_2Cl_2 solution of the salt, yielding colourless needles of sufficient quality for X-ray diffraction analysis. They were selected under oil, mounted on a glass fiber, and then placed in a cold stream of N_2. Structures were solved by direct methods and refined using full-matrix least-squares on F^2. Representative samples were tested for their water content by Karl Fischer titration on a 684 KF coulometer by Metrohm.

Crystal data for [12a][I]

$C_9H_{13}F_9I_1P_1$, M = 450.06 g mol^{-1}, Rhombohedral, $R3$, a = 19.6596(6) Å, c = 21.4939(9) Å, V = 7194.4(4) Å^3, T = 150(2) K, Z = 18, D_c = 1.870, measured reflections = 23 068, unique 2827, refined parameters 237, $R[I > 2\sigma I]$ = 0.0446, $wR_2(F^2)$ = 0.1236, R_1 (all data) = 0.0571, wR_2 (all data) 0.1307.

General procedure for the synthesis of $[R_3P(CH_2)_2R_{fn}]$[I] reactions involving ^{n}Bu$_3$P or ^{n}Oct$_3$P

A vial (27.7 × 57 mm, 4 dr.) was charged with $I(CH_2)_2R_{fn}$, where n = 4, 6, 10 (2.72 mmol), R_3P where R = n-C_4H_9, n-C_8H_{17} (2.47 mmol), and a Teflon stir bar. The neat reaction mixture was stirred at RT for 48 h. The residual reagents were removed in vacuo (0.05 mmHg, 100 °C) resulting in viscous liquids or waxy solids [**13**][I] and [**14**][I].

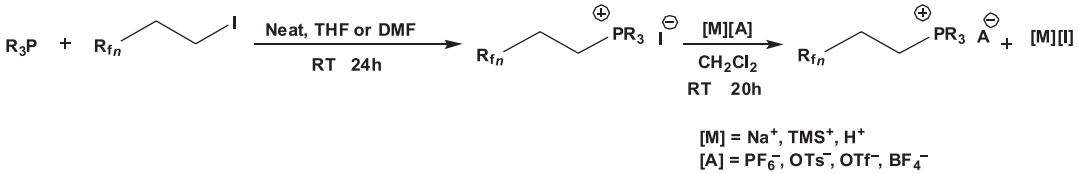
Variations to the general procedure — Reactions involving $(CH_3)_3P$

These were carried out in THF (5 mL) and were stirred for 42 h at RT. An off-white solid precipitated from the reaction mixture, which was filtered and the residual solvent removed in vacuo to give [**12**][I].

General procedure for [13–14][A] salts (A = PF_6^-, BF_4^-, OTs^-) via the parent Brønstead acids

A vial was charged with [**13–14**][I] (0.433 mmol) in CH_2Cl_2 (5 mL). The solution was stirred vigorously and the respective Brønstead acid (0.866 mmol) required to give the desired ionic liquid was dissolved in distilled water (2 mL) and added dropwise. The mixture was stirred for 20 h. The resulting mixture was washed with cold distilled water (4 × 5 mL), and after each wash the aqueous layer was tested with a 10% solution of $AgNO_3$ to confirm the absence of I^- (21). The dichloromethane fraction was dried with $MgSO_4$, and the volatiles were removed in vacuo (0.05 mmHg, 115 °C) for 20 h to give colourless to slightly yellow viscous liquids or solids.

General procedure for [13–14][A] salts via sodium salts (A = PF_6^-, BF_4^-, OTs^-)



The required phosphonium iodide (0.250 g) and sodium salt (30% mol excess) in CH_2Cl_2 (5 mL) were stirred vigorously (24 h, RT). The NaI precipitate was filtered and the organic fraction was extracted with water (4 × 5 mL). A 10% solution of $AgNO_3$ was added to each aqueous phase to confirm the absence of I^-. The dichloromethane fraction was dried with $MgSO_4$ to remove residual water. Volatiles were removed in vacuo (0.05 mmHg, 115 °C) for 20 h to give colourless to slightly yellow viscous liquids or solids.

General procedure for [13–14][OTf] salts via trimethylsilyl triflate (Me_3Si-OTf)

The required phosphonium iodide (0.250 g) in CH_2Cl_2 (4 mL) and trimethlsilyl triflate (30% mol excess) in CH_2Cl_2 (1 mL) were stirred vigorously under nitrogen (24 h, RT). The resulting Me_3Si-I was removed in vacuo (0.05 mmHg, 115 °C) yielding viscous liquids, tacky solids, or in the case of [**14c**][OTf], a waxy solid.

Scheme 1.

Procedure for [(14c][OTs] salt via AgOTs

[**14c**][I] (0.182 g, 0.174 mmol) in CH_2Cl_2 (5 mL) was added to AgOTs (0.073 g, 0.261 mmol) and stirred for 4 days at RT. The resulting solid was centrifuged and the supernatant was filtered through Celite. The solvent was removed in vacuo resulting in a yellow viscous liquid. The liquid was redissolved in acetone and filtered through Celite until a colourless liquid remained and all traces of AgI were removed. The volatiles were removed in vacuo to give a colourless, viscous liquid. Upon standing for elongated periods (5 days), the material formed a colourless, waxy solid, [**14c**][OTs].

Multinuclear NMR spectroscopy

The $^{31}P\{^1H\}$ NMR spectra of the trimethyl phosphonium series [**12**][I] all exhibited a singlet at δ 29.6 ppm. The *n*-butyl (**13**) and *n*-octyl (**14**) substituted series displayed chemical shifts further downfield at δ 35.2 ppm. Proton NMR spectra were identical for all the *n*-butyl and *n*-octyl phosphonium series (**13**–**14**) except in the case of those containing OTs^- anions, for which the aryl and methyl resonances were observed for that anion. Therefore, proton NMR data for [**13a**][I] and [**14a**][I] only are listed in the following section. The $^{19}F\{^1H\}$ NMR spectra for each fluorous chain (**a**–**c**) are identical, and therefore only one example of each R_{fn} chain is reported.[3]

[13a][I]

^1H NMR ($CDCl_3$, ppm) δ: 0.98 (t, 9H, J = 6.8, CH_3), 1.55 (m, 12H, $CH_2CH_2CH_3$), 2.61–2.54 (m, 8H, PCH_2 CH_2CF_2, $PCH_2(CH_2)CH_3$), 2.76–2.72 (m, 2H, PCH_2CH_2). $^{19}F\{^1H\}$ NMR ($CDCl_3$, ppm) δ: –81.5 (t, 3F, J = 9.4, CF_3), –115.0 (m, 2F), –123.9 (m, 2F), –126.5 (m, 2F).

[13b][I]

$^{19}F\{^1H\}$ NMR ($CDCl_3$, ppm) δ: –81.4 (t, 3F, J = 9.4, CF_3), –114.8 (m, 2F), –122.4 (m, 2F), –123.0 (m, 2F), –123.4 (m, 2F), –126.7 (m, 2F).

[13c][I]

$^{19}F\{^1H\}$ NMR ($CDCl_3$, ppm) δ: –81.18 to –81.30 (t, 3F, J = 9.4 Hz, CF_3), –114.5 (m, 2F), –122.3 (m, 10F), –122.9 (m, 2F), –123.2 (m, 2F), –126.6 (m, 2F).

[14a][I]

^1H NMR ($CDCl_3$, ppm) δ: 0.87 (t, 9H, J = 6.8 Hz, CH_3), 1.33–1.19 (m, 24H, $(CH_2)_3(CH_2)_4CH_3)_3$), 1.58–1.43 (m, 12H $(CH_2(CH_2)_2(CH_2)_4CH_3)_3$), 2.62–2.50 (m, 8H, $PCH_2CH_2CF_2$ and $PCH_2(CH_2)_6CH_3$), 2.85–2.76 (m, 2H, PCH_2CH_2).

Results and discussion

Synthesis

The synthesis of the phosphonium ionic liquids involves the quaternization of an alkyl phosphine by a haloalkane in a S_N2 reaction (Scheme 1). A mixture of neat R_3P (R = ^{n}Bu, ^{n}Oct) and I-$(CH_2)_2R_{fn}$ at RT was slowly converted (48 h) to form viscous liquids or solids at RT. Phosphorus-31 NMR spectra of the resulting material indicated that there was complete consumption of the alkyl phosphine (δ (ppm): ^{n}Bu$_3$P = –32, ^{n}Oct = –35) to the quantitative formation of a single phosphorus-containing product with a chemical shift consistent with that of a phosphonium cation, 35 ppm (cf. ^{n}Bu$_4$P$^+$ δ = 32) (40). Excess I-$(CH_2)_2R_{fn}$ was removed in vacuo and the resulting material was purified, if necessary, by precipitation from concentrated CH_2Cl_2 solutions using *n*-hexane or by washing with *n*-pentane. Reaction times can be reduced to as little as 12 h by heating the neat mixtures to 80 °C or by adding polar solvents (THF, DMF; 10 mL) and heating to 60 to 80 °C; however, the resulting material was found to be of inferior purity.

It has been well-established that ionic liquids can be "tuned" to achieve a target property (e.g., viscosity, melting point, hydrophobicity, or hydrophilicity) by way of pairing different anions with a given cation. This is readily achieved via metathetical routes, using the appropriate Ag^+, Na^+, or Li^+ salts or Brønstead acids (Scheme 1). A facile anion exchange reaction with the sodium salts of PF_6^-, BF_4^-, OTs^- (OTs^- = tosylate; tolylsulphonate) or with the corresponding Brønstead acids HPF_6, HBF_4, HOTs or with trimethylsilyl (TMS) derivates TMS-OTf (OTf = triflate; trifluoromethanesulphonate) have provided access to a range of fluorinated phosphonium salts with varying anions.

Anion exchange reactions carried out by salt metathesis using Ag^+ salts of the desired anion ([A^-], where A = PF_6^-, BF_4^-, OTs^-, OTf^-) were successful; however, there was significant contamination of the resulting ionic liquid with [Ag][I], which could not be removed. A substantial quantity of [Ag][I] remained in the isolated ionic liquid, which would subsequently turn black upon exposure to light, in which the contamination is a consequence of its very low solubility in water (K_{sp} ([Ag][I]) = 8.51×10^{-17}) (41). Extraction of the CH_2Cl_2 solutions with distilled H_2O was found to be an integral step in ensuring that the resulting ionic liquids remain

free of the metathesis by-products (see later). Removing the residual [Ag][I] from the ionic liquid is possible via successive filtrations of a solution of the contaminated product through tightly packed Celite or silica gel columns. However, this is much more labour intensive and will reduce the overall yields appreciably.

Subsequent methodologies for anion exchange involving Brønstead acids, sodium salts, or trimethylsilyl derivatives were considerably more successful. A stoichiometric excess of an aqueous solution of a Brønstead acid containing the desired anion was added to a CH_2Cl_2 solution of the $[R_3PCH_2CH_2R_{fn}][I]$ forming a two-phase system, which was vigorously stirred for 24 h. Similarly, the corresponding sodium salt was added to a mixture of $[R_3PCH_2CH_2R_{fn}][I]$ in CH_2Cl_2 and stirred for 24 h. The sodium salt approach resulted in a NaI precipitate, which was filtered, and the CH_2Cl_2 solutions were extracted with water to remove any remaining NaI. Workup for the Brønstead acid method involved the separation of the organic layer followed by extraction with H_2O, which gave the desired $[R_3PCH_2CH_2R_{fn}][A]$ product in good yields. For all anion exchange methodologies, the absence of residual halide was confirmed by testing the aqueous wash layers with $AgNO_3$ (21). All materials that were subjected to an aqueous wash were dried at 100 °C for a minimum of 12 h.

Anion exchange via the sodium salts was more facile than using the corresponding Brønstead acid approach given that the precipitation and filtration of NaI removed the bulk of the unwanted metathesis by-product. Further extraction of any remaining NaI with water yielded a highly pure product (solubility of NaI = 1.84 g/mL in cold water) (42). Overall, the TMS-I elimination method (from the reaction of [**13–14**][I] with TMS-OTf) gave products with the greatest yields and purity, as minimal reaction workup was required. Identification of all phosphonium ionic liquid derivatives was confirmed by multinuclear NMR spectroscopy and ESI-MS. In all ESI mass spectra the free cation $[M^+ - A]$ and complex ions $[M_2A^+]$ (A = I^-, PF_6^-, BF_4^-, OTs^-, OTf^-) were positively identified (Table 1) and the absence of remaining phosphonium iodide or NaI were confirmed in both the positive and negative ion mode spectra.

Table 2. Karl–Fischer titration data for selected ionic liquid samples.

Sample	Run 1 av value (mmol/L)[a]	Run 2 av value (mmol/L)[b]
[**13a**][BF_4]	5.403	1.000
[**13b**][OTf]	1.204	0.574
[**14b**][PF_6]	0.500	0.700
[**14b**][Ts]	15.529	3.218
[**14b**][I]	14.592	4.030

[a]Test perfomed on samples that were exposed to the open atmosphere for several months.
[b]Values obtained from samples immediately after drying.

Contamination of the resulting ionic liquids by water is often an issue, given their hygroscopic nature, and this is an especially important consideration as moisture can degrade those derivatives that have BF_4^- or PF_6^- counteranions. After

the synthesis, work-up, and drying of the material in vacuo, representative samples, which had been stored in the open air for several weeks after the initial drying process, were selected for Karl–Fischer titrations. The first KF analysis revealed relatively high water content in the range of 0.50 mmol/L ([**14b**][PF_6]) to 15.52 mmol/L ([**14b**][OTs]; Table 2, Run 1). Subsequently, the samples were dried in vacuo at 100 °C and re-analyzed, showing minimal water content (Table 2, Run 2). Multinuclear NMR analysis of these same samples did not indicate decomposition of the material upon sitting in the open atmosphere; however, they should be considered hygroscopic and stored in a dry environment, as the samples slowly take on water from the air.

Differential scanning calorimetry and thermogravimetric analysis

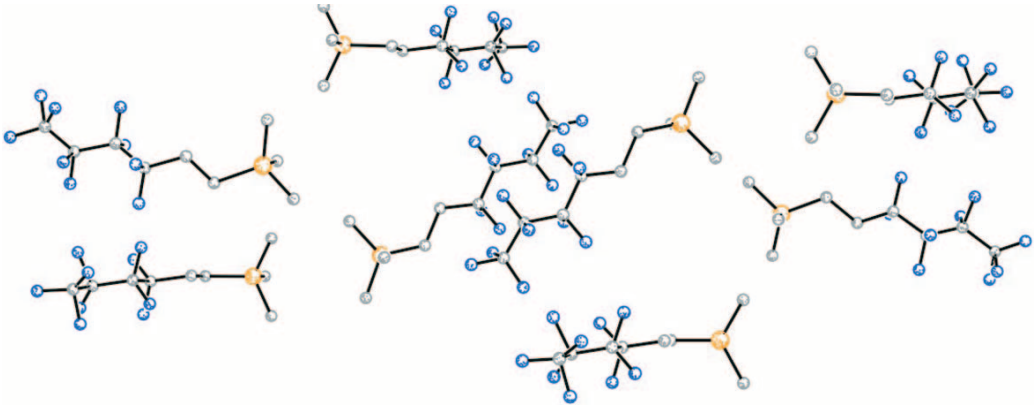
Critical to the classification of a material with a distinct cation–anion pair as an ionic liquid, is a characteristic melting point at or below 100 °C. The melting points (or glass transition temperatures) for compounds **12**–**14** were determined by differential scanning calorimetry (DSC). A vast majority of the ionic liquids were found to be low melting solids or viscous liquids and the melting–glass transition temperatures were observed over a wide temperature range (e.g., [**14a**][OTs]: –64 °C; [**12a**][I]: 195 °C) (Table 3).

Samples that were solids at RT displayed distinct melting peaks; conversely, products that were liquids at RT did not have observable melting curves, but rather exhibited glass transition signals at considerably lower temperatures (–64 to –25 °C). In the case of [**14a**][OTf] no melting or glass transition signals were observed despite many attempts at varying the conditions for obtaining a DSC trace. This is attributed to the melting–glass transition points being lower than –70 °C, which is outside of the range of our current instrumentation.

As expected, compounds [**12**][I] are high melting point solids as a result of the small size of the parent phosphine (PMe_3), which allows for efficient cation–anion packing arrangements. In general, as the alkyl chain length is increased (Me < ^{n}Bu < ^{n}Oct) along the iodide series, the melting points decrease. However, the melting point increases with increasing R_{fn} chain length for both the [**13**][I] and [**14**][I], which is attributed to the ordering of the cations into fluorophilic and fluorophobic regions.

The anion exchange products exhibit an interesting melting and glass transition temperature trend. The more weakly coordinating anions are expected to lower the melting points of the ionic liquids (7). However, this was not observed for the anion exchange products of the cations [**13**] or [**14**] paired with BF_4^- or PF_6^-. These clearly demonstrate that the melting point actually increases in comparison to the iodide analogues despite comparable anion sizes (I^- = 2.2 Å; BF_4^- = 2.2 Å; PF_6^- = 2.4 Å) (7). In contrast, the triflate and tosylate anions lowered the melting point of the ionic liquids substantially because of a combination of a large increase in anion size, charge delocalization, and the reduction in symmetry.

The negligible vapor pressures of phosphonium ionic liquids imply that they remain intact and stable upon heating until the upper thermal limit is obtained, at which point they primarily decompose through elimination pathways. The decomposition temperatures recorded were obtained at the onset of decomposition where 2% mass loss had occurred (Table 2). The decomposition temperatures measured in a dynamic heating environment are higher than those reported for nitrogen based ionic liquids and are in the range or slightly higher than those reported for other nonfluorinated systems (43).



For [**12**–**14**][I], the decomposition temperatures increased with increasing length of the R_{fn} chain as the longer fluorous chains may increase steric hindrance, therefore promoting fluorophilic interactions and imposing higher decomposition points. In general, the stability of the ionic liquid is inversely proportional to the tendency to form stable R_{fn}-A decomposition products, and therefore the decomposition temperatures for the [**13**–**14**][A] series were higher for the more weakly coordinating anions OTf^- and OTs^- than they were for the smaller BF_4^- and PF_6^-, following the expected trends (7).

X-ray crystallography

By definition ionic liquids are low melting point salts; thus, obtaining solid-state structures by way of X-ray diffraction methodologies is not common. This presents difficulties in identifying the dominant interactions in bulk

Fig. 4. A section of the solid-state packing arrangement of [**12a**][I]. Ball and stick drawings have been used and iodide anions have been removed for clarity.

samples of these materials. In this regard, salts that contain cation **13** and **14** are generally liquids or soft waxes at RT, precluding the growth of crystalline materials suitable for X-ray diffraction studies. However, high melting point model compounds of **13** or **14** can be generated by using PMe_3 as the parent phosphine rather than $^{n}Bu_3P$ or $^{n}Oct_3P$. Single crystals of [**12a**][I] (Fig. 4) of sufficient quality for X-ray diffraction analysis were obtained. All other $[Me_3PCH_2CH_2R_{fn}][I]$ samples did not yield single crystals under similar conditions, only microcrystalline powders.

The solid-state structure of [**12a**][I] reveals the expected phosphonium cation with a distorted tetrahedral bonding arrangement about phosphorus with standard $P–C_{Methyl}$ single bond lengths for a trimethylphosphonium cation (1.766(6)–1.780(7) Å) as well as consistent $P–CH_2CH_2R_{fn}$ bond lengths, which are slightly longer (1.802(6) Å; relative to nonfluorinated alkyl C–P bonds) (44–48). The structure is best described as ionic, since the closest cation–anion interaction is an I···H contact at 2.917 Å. The most striking feature of the structure is the packing arrangement for the cation revealing a "head to head" (fluorophobic) and "tail to tail" (fluorophilic) arrangement, where the fluorous ponytails are associated with one another as are the methyl groups on phosphorus. This arrangement is imposed by the long fluorous chains and has previously been observed in highly fluorinated phosphines or in the solid-state structures of partially fluorinated compounds (49). In a bulk sample, it is likely that these are the dominant intermolecular interactions and have a strong influence on the physical properties of these materials.

Conclusions

Phosphonium ionic liquids containing fluorinated ponytails and varying degrees of fluorine content have been synthesized and comprehensively characterized. Efficient anion exchange can be achieved using metathetical routes; however, silver metathesis reagents should be avoided because of significant contamination of the residual AgI byproduct. Trimethylsilyl reagents were preferred as the metathesis was facile and the resulting ionic liquids were obtained in high yield and purity with a minimal workup. Investigating the properties of the series of compounds **12–14** demonstrated that varying the length of alkyl and fluorous chains in the cation influenced the melting and decomposition parameters of the ionic liquids. Increasing the alkyl chain length decreased the melting point, while increasing the length of the fluorous chains resulted in higher melting temperatures. The electron-withdrawing fluorous chains increased the stability of the ionic liquid, as did incorporating weakly coordinating anions.

Steady-state photolysis of dimesitylbis(trimethylsilyl)germane[1]

Krysten L. Hurni and Kim M. Baines

Abstract: The photolysis of dimesitylbis(trimethylsilyl)germane (**3**) in hexanes or THF, at low temperature, has been investigated as a potential method for the preparative-scale synthesis of tetramesityldigermene (**5**). A product mixture, consisting of hexamethyldisilane, mesitylene, 2-trimethylsilylmesitylene (**7**), a new germacyclobutene (**8**), and an unidentified polymer, was obtained. No evidence for the formation of tetramesityldigermene (**5**) was observed.

Key words: diaryldisilylgermane, digermene, germylene, germacyclobutene, photolysis.

Résumé : On a étudié la photolyse du dimésitylbis(triméthylsilyl)germane (**3**) dans les hexanes ou le THF, à de faibles températures, comme méthode potentielle de la synthèse à l'échelle préparative de tétramésityldigermène (**5**). On a obtenu un mélange de produits formé d'hexaméthyldisilane, de mésitylène, de 2-triméthylsilylmésitylène (**7**), d'un nouveau germacyclobutène (**8**) et d'un polymère non identifié. On n'a observé aucune formation du tétramésityldigermène (**5**).

Mots-clés : diaryldisilylgermane, digermène, germylène, germacyclobutène, photolyse.

[Traduit par la rédaction]

Introduction

Since the synthesis of the first solid digermene 30 years ago by Lappert et al. (1), followed six years later by the preparation of the first solution-stable digermene by Masamune et al. (2), several methods for the preparation of digermenes have been realized (3). These heavier alkene analogues are important not only because they are useful substrates for the preparation of a variety of organogermanium compounds, but also because they are the molecular analogues of the germanium dimers found on the Ge(100)-2 × 1 surface (3*i*). For some time, our research group has been extensively engaged in the study of the reactivity of digermenes (4). This, and the interest in the emerging applications of digermene chemistry (3*i*, 5), have continuously driven a need for the development of efficient routes for the preparation of digermenes.

In almost every review on digermene chemistry published since 1990, the preparation of tetraaryldigermenes by the irradiation of a diarylbis(trimethylsilyl)germane has been described as one of the primary methods for the synthesis of digermenes (Scheme 1) (3*a*–3*f*, 3*h*). An analogous method is frequently employed in the preparative-scale synthesis of a variety of disilenes (3*b*, 3*e*, 6); however, in the case of tetraaryldigermenes, the photolyses have, in general, only been carried out in a matrix at low temperature on an analytical scale. The presence of the digermene under these conditions has been inferred by the observation of appropriate signals by UV–vis or NMR spectroscopy (7*a*–7*e*). On one occasion, the photolysis of bis(2,4,6-triisopropylphenyl)bis(trimethylsilyl)germane was carried out at room temperature in solution for the subsequent preparation of an adduct of tetrakis(2,4,6-triisopropylphenyl)digermene; however, the adduct was isolated in very low yield (7*f*). The irradiation of diphenylbis(trimethylsilyl)germane (**1**) in solution at room temperature has been investigated, primarily as a source of diphenylgermylene (**2**) for kinetic studies (8); the synthesis of tetraphenyldigermene was not the goal of these studies. Although the generation of diphenylgermylene (**2**) was shown to be the primary reaction pathway followed in the steady-state photolysis of germane **1** at room temperature, the occurrence of other minor reaction pathways was noted (8*b*–8*c*). Similarly, dimesitylbis(trimethylsilyl)germane (**3**) has been investigated as a photochemical precursor of dimesitylgermylene (**4**) for solution-state kinetic studies (9). Both dimesitylgermylene (**4**) and tetramesityldigermene (**5**) were readily detected by UV–vis spectroscopy; however, the weakness of the absorptions precluded the use of germane **3** as an effective source of germylene **4** for kinetic measurements. To date, the viability of using the irradiation

Scheme 2.

of diarylbis(trimethylsilyl)germanes as a means for the preparation of practical quantities of a digermene has not been demonstrated.

Many of our studies on the reactivity of digermenes employ tetramesityldigermene (**5**) as the prototypical digermene (4). We generate digermene **5** either by thermolysis or by photolysis of hexamesitylcyclotrigermane (**6**) (10). A disadvantage of this method is the concomitant formation of an equivalent of dimesitylgermylene (**4**). In general, germylene **4** and digermene **5** are trapped during the course of the reaction, and the two products are separated by chromatography (Scheme 2) (4*c*). The irradiation of germane **3** as a possible route to tetramesityldigermene (**5**) is particularly attractive, since hexamethyldisilane is a volatile, relatively inert coproduct, which could easily be removed in vacuo from digermene **5** (or the products derived from it) at the end of the procedure. The formation of **5** could be determined either directly, using UV–vis or NMR spectroscopy, or indirectly, by the reaction with a well-known trapping reagent (e.g., methanol). We now report on the results of our investigations of this reaction on a preparative scale.

Results

A colourless solution of **3** was photolyzed (254 nm) at –70 °C for 24 h.[3] The product mixture obtained after removal of the solvent was quite complex. Similar results were obtained when either hexanes or THF were used as the solvent for the photolysis. In the early stages of the photolysis, the colourless solution became yellow and, by the end of the photolysis, the colour of the solution was orange. The crude product mixture was separated by preparative TLC. Five products were isolated, and four were unambiguously identified as mesitylene, 2-trimethylsilylmesitylene (**7**), germacyclobutene **8**, and hexamethyldisilane. An uncharacterized germanium-containing polymer was also obtained (Scheme 3). The relative ratios of the products were determined by GC analysis of the reaction mixture before exposure to air and are given in Table 1. A GC–MS of the headspace gas revealed no additional volatile products. Because of the difficulties encountered during the separation of and loss by evaporation of several products, we were unable to determine the isolated yields.[4] Hexamethyldisilane was identified as a component of the product mixture (prior to its removal in vacuo) by comparison of its ^{1}H chemical shift with that of an authentic sample. The relative amount of hexamethyldisilane could not be determined by GC, since it eluted with the solvent in the gas chromatogram; however, it

Scheme 3.

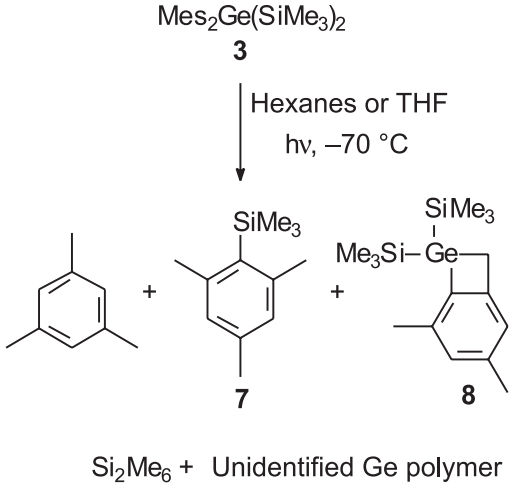

Table 1. Relative ratios of volatile products formed by irradiation of **3** for different time periods, as determined by GC.

Time (h)	Mesitylene	**7**	**8**	**10**	**11**	**3**
0.5[a]	12	2	14	n/a	n/a	72
1[a]	19	3	22	n/a	n/a	54
3[a]	37	7	44	n/a	n/a	12

[a]Irradiation (254 nm) of **3** at –70 °C in hexanes.
[b]Irradiation (254 nm) of **3** at –70 °C in hexanes in the presence of 2,3-dimethylbutadiene.
[c]Germane **3** and germacyclopentene **10** initially co-elute in the gas chromatogram. Together, they account for 76%.

[3] Previous work from this laboratory has shown that tetramesityldigermene (**5**) rearranges to (trimesitylgermyl)mesitylgermylene between –70 °C and room temperature (4*a*, 4*b*, 4*e*).
[4] Mesitylene and hexamethyldisilane partially evaporate under ambient conditions. Complete loss of mesitylene occurs upon chromatography. 2-Trimethylsilylmesitylene (**7**) slowly evaporates after extended periods in vacuo.

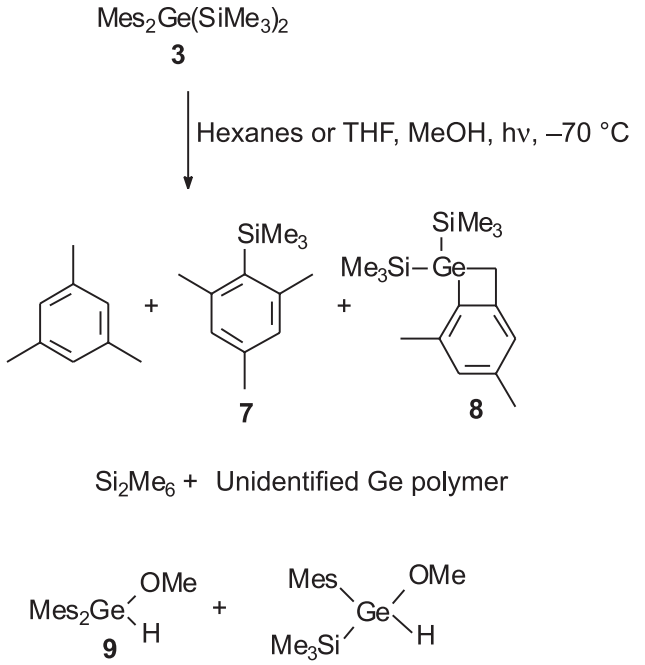
could be determined by ^{1}H NMR spectroscopy prior to removal of the solvent.[5] Mesitylene was identified in the crude product mixture by ^{1}H NMR spectroscopy and by comparison of the GC retention time with that of an authentic sample. Compounds **7** and **8** could not be completely separated.

An authentic sample of 2-trimethylsilylmesitylene (**7**) was prepared by treatment of bromomesitylene with BuLi, followed by the addition of trimethylsilyl chloride, a variation on the published procedure (11). Thus, **7** was unambiguously identified in the mixture by comparison of the ^{1}H NMR spectroscopic data and of the GC retention time with that of the prepared authentic sample.



The ^{1}H NMR spectrum of germacyclobutene **8** contained six signals: a singlet at 0.23 ppm assigned to two equivalent trimethylsilyl groups, two singlets (6.85 and 6.70 ppm) assigned to two aryl-*H*'s, and three singlets at 2.19, 2.23, and 2.52 ppm, which were consistent with the presence of two CH_3–Ar groups and a CH_2 group, respectively. Clearly, the mesityl group is no longer symmetric. The ^{1}H–^{29}Si *g*HMBC spectrum of **8** displayed a correlation between the signal assigned to the trimethylsilyl groups in the ^{29}Si dimension and the signal assigned to the CH_2 group in the ^{1}H dimension. The highest-mass ion was located at *m*/*z* 338 in the mass spectrum of **8**. Moreover, the precise mass of *m*/*z* 338 agrees well with the calculated mass of **8**. The structure of **8** is completely consistent with the spectroscopic data.

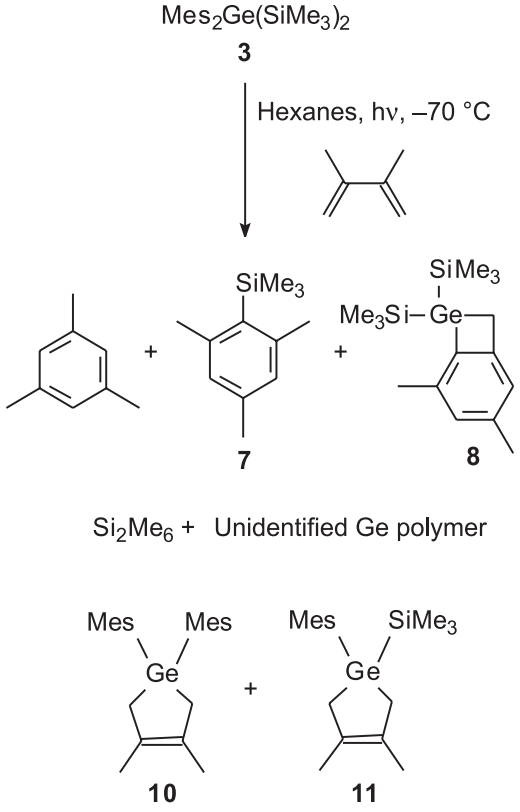
The relative amount of germacyclobutene **8** in the product mixture varied greatly depending on the length of the irradiation time. The photolysis of germane **3** was monitored hourly by GC; a steady increase in the relative amounts of mesitylene, **7**, and **8** was observed as **3** was consumed, up to a given time period. Interestingly, prolonged irradiation of the sample (24 h) led to a reduction in the relative amount of **8** and an increase in the relative amount of mesitylene (Table 1). Photolysis of a mixture of **7** and **8**, isolated from the reaction mixture, showed complete loss of germacyclobutene **8** by ^{1}H NMR spectroscopy and the appearance of mesitylene by GC, while **7** remained unchanged. Thus, germacyclobutene **8** is photolytically unstable and decomposes to produce mesitylene and other unidentified, nonvolatile products.

A yellow solid precipitated from the crude product mixture (exposed to air) upon the addition of methanol. The signals in the ^{1}H NMR spectrum of this solid were very broad. The chemical shifts of the signals were consistent with the presence of both mesityl groups and trimethylsilyl groups. The same material was also isolated by chromatography from the product mixture in yields of 10–20 wt%. Elemental analysis of the solid by Energy Dispersive X-ray analysis (EDX) confirmed the presence of germanium and silicon in the sample. These observations are consistent with the formation of a polymer, which has been tentatively assigned the structure $(GeR_2)_n$ (R = Mes, Me_3Si).

Photolysis of germane **3** at 10 °C produced the same products in approximately the same ratios. Mes_2GeH_2 was also identified in trace amounts based on a comparison of the GC retention time and the ^{1}H NMR chemical shifts with those of an authentic sample (12).

Scheme 4.

The addition of methanol to the reaction solution (prior to exposure to the ambient atmosphere) at low temperature or at room temperature led to the production of trace amounts of dimesitylmethoxygermane (**9**), identified by comparison of the ^{1}H chemical shifts with the published data (13). No evidence for the formation of the methanol adduct of digermene **5**, ($Mes_2Ge(OMe)GeHMes_2$), and hence, no evidence for the formation of digermene **5** was observed. Co-photolysis of germane **3** with methanol also produced methoxygermane **9** in low yield in addition to mesitylmethoxy(trimethylsilyl)germane, identified by GC–MS analysis (Scheme 4).



In an attempt to trap any transient germylenes, germane **3** was co-photolyzed with 2,3-dimethylbutadiene, a well-known and efficient trapping agent for germylenes (8*b*, 14, 15). The solution remained clear and colourless throughout the entire irradiation. The resulting product mixture contained both 1,1-dimesityl-3,4-dimethyl-1-germacyclopent-3-ene (**10**) and 1-mesityl-3,4-dimethyl-1-(trimethylsilyl)-1-germacyclopent-3-ene (**11**) in addition to the previously observed products (Scheme 5). There was also a noticeable increase in the relative amount of **7** produced under these conditions (Table 1).

Germacyclopentene **10** was identified by comparison of the GC retention time and the ^{1}H NMR chemical shifts with those of an authentic sample (4*b*, 16). Germacyclopentene **11** was characterized by NMR spectroscopy and mass spectrometry as part of a mixture of **11** with trace amounts of **7** and **8**. The most diagnostic feature of the ^{1}H NMR spectrum of **11** is the two sets of doublets at 1.90 and 2.23 ppm, as-

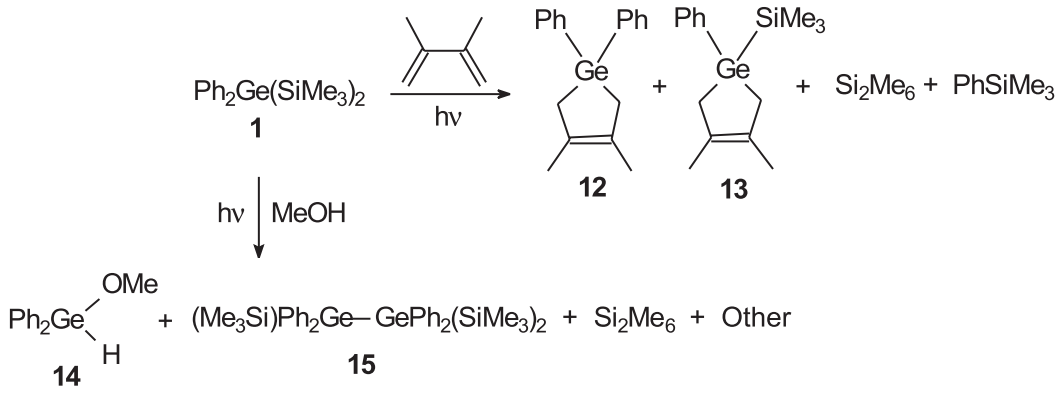
Scheme 5.

signed to the non-equivalent ^{1}H's of the CH_2 groups. A correlation was observed between these two signals in the ^{1}H dimension of the ^{13}C–^{1}H *g*HSQC spectrum of **11** and one signal in the ^{13}C dimension at 27.59 ppm. The ^{1}H–^{1}H *g*COSY spectrum of **11** revealed a correlation between the signals assigned to the CH_2 groups and the signal assigned to equivalent methyl groups, consistent with the structure of **11**. The mass spectrum of one component of the crude product mixture (separated by GC) exhibited a highest-mass ion at *m*/*z* 347, corresponding to the molecular ion of **11**. Furthermore, the precise mass determination of *m*/*z* 347 agrees with the calculated precise mass of **11**.

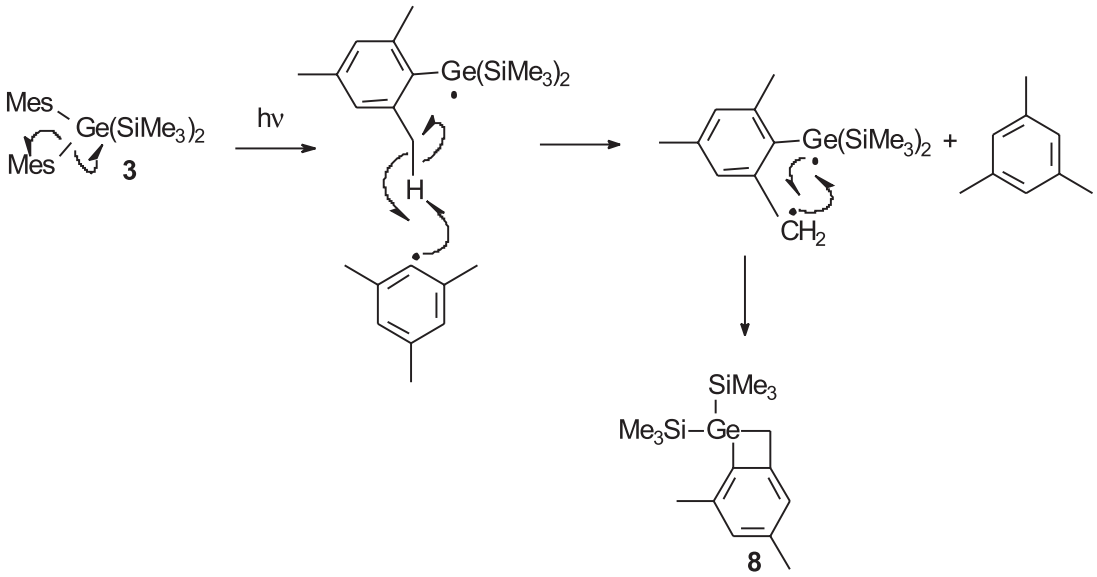
Discussion

Clearly, a quick evaluation of the results shows that germane **3** is not a clean source of germylene **4**, and thus, is not a viable precursor for the preparation of digermene **5**. The results can be better understood if we consider the previous report of the steady-state irradiation of the corresponding phenyl derivative, diphenylbis(trimethylsilyl)germane (**1**) (8*c*). Co-photolysis of **1** with 2,3-dimethylbutadiene resulted in the formation of germacyclopentenes **12** (major product) and **13** (minor product) in addition to hexamethyldisilane and trimethylsilylbenzene (Scheme 6) (8*c*). The products are believed to be formed by extrusion of either diphenylgermylene (**2**) or phenyl(trimethylsilyl)germylene, with the concomitant formation of the disilane or arylsilane, respectively, followed by addition of the germylene to the diene (8*c*). Examination of the structures of the products formed during the photolyses of both **1** and **3** in the presence of the diene reveals many similarities. The structures of compounds **10** and **11** are analogous to those of compounds **12** and **13**. Hexamethyldisilane and an aryltrimethylsilane were observed in both reactions. Although the formation of mesitylene is observed during the irradiation of **3**, benzene was not reported as a product of the photolysis of **1**. Not surprisingly, an analogous compound to germacyclobutene **8** was not formed during the photolysis of **1**. Since dienes are known triplet quenchers, and thus, may suppress radical formation (8*c*), the co-photolysis of germane **1** with methanol was also examined. The formation of both methoxydiphenylgermane (**14**) and 1,1,2,2-tetraphenylbis(trimethylsilyl)digermane (**15**) was observed under these conditions in addition to other unidentified products (Scheme 6). Germane **14** was believed to be formed by the insertion of germylene **2** into the OH bond of methanol. On the other hand, the formation of digermane **15** was rationalized by the coupling of two $Ph_2(Me_3Si)Ge$ radicals, which result from the homolysis of a Ge–Si bond (8*c*). An analogous digermane was not observed by ^{1}H NMR spectroscopy or GC–MS upon the photolysis of germane **3** in the presence of methanol. The photolysis of germane **1** in the absence of a trapping agent was not examined.



On the basis of the relative amounts of hexamethyldisilane and **7** formed, the extrusion of a germylene from **3** appears to be a minor reaction pathway. We propose a radical-based mechanism to explain the formation of germacyclobutene **8** from the irradiation of dimesitylbis(trimethylsilyl)germane (**3**). Homolysis of the Ge–Mes bond produces a germyl and a mesityl radical. Abstraction of a benzylic hydrogen by the mesityl radical results in the formation of a benzylic radical and mesitylene. Germacyclobutene **8** is reasonably formed by ring closure of the resulting 1,4-biradical (Scheme 7). We note that, at low conversions, mesitylene and **8** are formed in approximately equal amounts, consistent with this proposal (Table 1). To provide some evidence for the proposed mechanism, **3** was irradiated for 5 h in THF-d_8. After irradiation, THF-d_8 was removed and replaced with C_6H_6. A signal at 6.71 ppm, which we attribute to 1,3,5-$(CH_3)_3C_6H_2D$, was observed in the ^{2}H NMR spectrum of the product. The formation of the deuterated mesitylene is consistent with a cage-escaped mesityl radical, which, at least to some extent, abstracts a deuterium from the solvent. We acknowledge that the mesityl radical may result from homolysis of the Ge–Mes bond of **3** or during the secondary photolysis of **8**.

On the other hand, homolysis of the Ge–Si bond could produce a trimethylsilyl and a germyl radical. By following a similar reaction pathway, the formation of germylenes **4** and **16** in addition to **7** and hexamethyldisilane can be accounted for. However, the formation of hexamethyldisilane and **7** by concerted elimination of **4** or **16** is also plausible (Scheme 8) and, perhaps, more likely given that the relative amount of **7** increased when 2,3-dimethylbutadiene was used as a trapping agent.



Photolysis of germane **3** in the presence of either 2,3-dimethylbutadiene or methanol gives **10** and **11** or **9**, respectively. This provides convincing evidence for the formation of germylenes **4** and **16** during the reaction. In the absence of a germylene trap, the germylenes may indeed couple to produce digermenes. However, under the given reaction con-

Scheme 8.

ditions, any digermenes formed apparently polymerize, yielding a germanium-based polymer.

Clearly, our results indicate that the steady-state photolysis of germane **3** in solution is not a feasible route for the preparation of synthetic quantities of digermene **5**. The results were somewhat surprising, given the commonly held belief that the photolysis of diarylbis(trimethylsilyl)germanes is a useful method for the preparation of tetraaryldigermenes. However, our results appear reasonable, given that the observed products of the steady-state solution photolyses of diphenylbis(trimethylsilyl)germane (**1**) demonstrated that cleavage of the germanium–phenyl bond was occurring, at least to some extent, during irradiation, since products, formally derived from phenyl(trimethylsilyl)germylene, were isolated (8*b*, 8*c*). Previous studies of the photolysis of dimesitylbis(trimethylsilyl)germane (**3**), in which both dimesitylgermylene (**4**) and tetramesityldigermene (**5**) were characterized by UV–vis spectroscopy, showed no evidence for the formation of additional products or alternate reaction pathways (7*b*–7*e*, 9). It is unlikely that the absorptions originally assigned to the germylene **4** and digermene **5** are erroneous, as has been shown in the diphenyl case (8*c*, 15), since the assignments for the mesityl system, both in a matrix and in solution, have been corroborated in at least three independent studies (7*b*–7*d*, 9, 17). Possibly, at the low conversions used in the previous experiments, the absorptions of potential radical species could not be observed and (or) are too weak to be observed.

The low yields of germacyclopentenes **10** and **11** obtained

© 2007 NRC Canada

during the photolysis of **3** in the presence of 2,3-dimethylbutadiene are most likely due to secondary photolysis of the germacyclopentene rings (17). However, even at low conversion, the irradiation still yields only relatively low ratios of **10** and **11** (Table 1). Unfortunately, there are few reagents that are known to react quickly with dimesitylgermylene (**4**) under photolytic conditions to give a stable product, and thus, we were limited in our selection of germylene trapping agents.

In summary, the steady-state irradiation of germane **3** in solution is not a feasible route for the preparation of practical quantities of tetramesityldigermene (**5**), contrary to what may be expected based on the numerous reviews written on digermene chemistry (3). Thus, for tetramesityldigermene (**5**), the thermolysis or photolysis of hexamesitylcyclotrigermane (**6**) continues to be the best method for the preparation of this useful digermene. We are continuing our search for alternate large-scale, practical syntheses of tetramesityldigermene (**5**).

Experimental

General details

Unless otherwise indicated, all reactions were carried out in flame-dried glassware under an inert atmosphere of argon using a dual manifold vacuum line or prepared under a nitrogen atmosphere using an MBraun Labmaster 130 glovebox. THF and hexanes were purged with nitrogen and then passed through an alumina column (Innovative Technology Inc., Newburyport, Massachusetts) prior to use. Trimethylsilyl chloride was distilled from calcium hydride prior to use. 2,3-Dimethylbutadiene, BuLi, and 1-bromo-2,4,6-trimethylbenzene were purchased from the Aldrich Chemical Co. and used without further purification. Chromatography was carried out on conventional silica-gel preparative plates. Dimesitylbis(trimethylsilyl)germane (**3**) was prepared according to the previously reported procedure (7*d*).

NMR spectra were recorded on a Varian Mecury 400, a Varian Inova 400, or a Varian Inova 600 NMR spectrometer. The standards used were as follows: residual C_6D_5H (7.15 ppm) for ^{1}H NMR spectra, C_6D_6 central transition (128.00 ppm) for ^{13}C NMR spectra, and Me_4Si as an external standard (0.00 ppm) for ^{29}Si spectra. Mass spectra were recorded on a Finnegan MAT model 8400 mass spectrometer with an ionizing voltage of 70 eV (reported in mass-to-charge units (*m*/*z*) with ion identity and intensity relative to the base peak in parentheses). GC analyses were performed on a polydimethylsiloxane column using an Agilent 6850 Series GC. Photolyses were performed at 254 nm using a Rayonet Photochemical Reactor (Southern New England Co.) typically equipped with 10 bulbs. Samples were cooled by circulating methanol through a vacuum-jacketed quartz immersion well using an Endocal model ULT–70 low-temperature external bath circulator.

Photolysis of dimesitylbis(trimethylsilyl)germane (3)

A clear, colourless solution of germane **3** (100 mg, 0.219 mmol), dissolved in hexanes or THF (8 mL), was placed in a quartz Schlenk tube fitted with a septum. The solution was photolyzed at –70 °C for 24 h; the colour of the solution changed from light yellow to deep orange during the photolysis and reverted to yellow when the solution was warmed to room temperature. Gas chromatograms of both the reaction mixture and the headspace gas were recorded prior to exposure to the ambient atmosphere. In some reactions, methanol was added to the solution either at room temperature or in the cold (dry ice – acetone bath). The solvent was removed by rotary evaporation, yielding a yellow oil. Hexamethyldisilane and mesitylene were removed in vacuo. The resulting crude mixture was purified by preparative TLC (silica gel; hexanes) to give a polymer as a yellow solid and a liquid mixture of **7** (11) and **8**.[5]

Co-photolysis of dimesitylbis(trimethylsilyl)germane (3) with 2,3-dimethylbutadiene

A clear, colourless solution of germane **3** (100 mg, 0.219 mmol) and 2,3-dimethylbutadiene (0.1 mL, excess), dissolved in hexanes (8 mL), was irradiated at –70 °C for 24 h. The solution remained clear and colourless throughout the irradiation. The solvent was removed by rotary evaporation to yield a clear, slightly yellow liquid. The crude product mixture was separated by chromatography (silica gel; hexanes) to give a polymer, germacyclopentene **10**, and a mixture of **7**, **8**, and **11**.[5] Compounds **7**, **8**, and **11** were further separated from the mixture using preparative TLC (silica gel; hexanes). Compound **7** was removed under high vacuum to give **11**, which remained contaminated with small amounts of **8**.

1-Mesityl-3,4-dimethyl-1-(trimethylsilyl)-1-germacyclopent-3-ene (11)

The chemical characterization of tribofilms using XANES — Interaction of nanosize calcium-containing detergents with zinc dialkyldithiophosphate[1]

L.G. Yu, E.S. Yamaguchi, M. Kasrai, and G.M. Bancroft

Abstract: A Plint friction and wear tester was used to investigate the effect of several calcium-containing detergents on the tribological and tribochemical performance of a zinc dialkyldithiophosphate (ZDDP) lubricating oil additive in a low-sulfur base stock, 100N. Thus, the friction and wear behavior of a steel-on-steel contact lubricated by 100N oil containing ZDDP alone and ZDDP–detergent mixtures at 100 °C was evaluated in a pin-on-disc configuration. The wear scar width of the upper steel pins was determined using an optical microscope, while the tribofilms formed on the lower steel discs were analyzed using X-ray absorption near edge structure (XANES) spectroscopy and X-ray photoelectron spectroscopy (XPS). At the same time, the thermal-oxidation films of the oil blends containing different additives were also prepared on the same steel discs and analyzed using XANES spectroscopy for comparative studies. It was found that in simple formulations the three kinds of calcium-containing detergents improved the friction-reducing and antiwear abilities of the 100N base stock. This was related to the individual tribochemical reactions and the deposition (in one case) of nanosized $CaCO_3$ on the rubbing steel surface, indicating that the calcium-containing detergent had a synergistic antiwear performance with the ZDDP tested in the present work. Moreover, the calcium-containing detergents contributed to retarding the thermo-oxidation and friction-induced decomposition of ZDDP in 100N oil and influenced the composition and thickness of the tribofilms, which could be dependent on the molecular structures of the detergents and directly related to the tribochemistry of ZDDPs in mineral oil. The rubbing of the steel–steel pair at 100 °C was more beneficial for the deposition of nanosized calcium carbonate on the steel surface than heating at 150 °C. The calcium-containing detergents alone in the base stock also experienced tribochemical reactions, leading to obvious changes in the oxidation state of S in the corresponding tribofilms. Therefore, it was supposed that the tribochemical reactions of the ZDDP and detergents together with the deposition of nanosized $CaCO_3$ on the rubbing steel surfaces accounted for the good antiwear performance of the blended oils.

Key words: ZDDP, detergent, thermal film, tribofilm, tribochemistry, XANES, XPS.

Résumé : On a utilisé une friction de Pling et un appareil permettant d'évaluer la durée de vie pour étudier l'effet de plusieurs détergents contenant du calcium sur la performance tribologique et tribochimique d'un dithiophosphate dialkyle et de zinc (DPDZ), un additif d'huile de lubrification dans une base ne contenant que de faibles quantités de soufre, 100N. Opérant à 100 °C et faisant appel à une configuration avec pointe sur un disque, on a évalué les comportements de friction et d'usure sur un contact acier sur acier lubrifié avec de l'huile 100N ne contenant que du DPDZ ou des mélanges de DPDZ et de détersif. On a déterminé la largeur de la cicatrice d'usure des pointes d'acier de la partie supérieure en faisant appel à la microscopie optique, alors qu'on a analysé les tribofilms formés sur les disques d'acier inférieurs en procédant à des analyses de spectroscopie d'absorption des rayons X à la périphérie de la surface (« XANES ») ainsi que par spectroscopie photoélectronique des rayons X (SPX). En même temps, on a aussi préparé des films d'oxydation thermique de mélanges d'huile contenant divers additifs sur les mêmes disques d'acier et, à des fins d'études comparatives, on les a analysés par spectroscopie « XANES ». On a trouvé que dans les formulations simples, les trois types de détersifs contenant du calcium augmentent les capacités de réduction de la friction et de l'usure de l'huile de base 100N. Ces qualités sont reliées aux réactions tribochimiques individuelles et, dans un cas, au dépôt sur la surface de friction de l'acier, de $CaCO_3$ de taille nano ce qui indique que, dans le présent travail, le détersif contenant du calcium possède une performance antifriction synergique avec le DPDZ. De plus, les détersifs contenant du calcium contribuent au retardement de la thermooxydation et de la décomposition induite par la friction

du DPDZ dans l'huile 100N et qu'ils influencent l'épaisseur des tribofilms qui pourraient dépendre des structures moléculaires des détersifs et être reliés directement à la tribochimie du DPDZ dans l'huile minérale. Un frottement d'une paire acier–acier, à 100 °C, est plus bénéfique au dépôt sur la surface de l'acier de carbonate de calcium de taille nano qu'un chauffage à 150 °C. Les détersifs ne contenant que du calcium dans l'huile de base donnent aussi lieu à des réactions tribochimiques qui conduisent à des changements évidents dans l'état d'oxydation du S dans les tribofilms correspondants. On suppose donc que les réactions tribochimiques du DPDZ et des détersifs ainsi que le dépôt de $CaCO_3$ de taille nano sur des surfaces frottées d'acier permettent d'expliquer la bonne performance antiusure des huiles d'assemblage.

Mots-clés : DPDZ, détersif, film thermique, tribofilm, tribochimie, « XANES », SPX.

Introduction

As the most important multifunctional commercial additives for engine oils, zinc dialkyldithiophosphates (ZDDPs) have been successfully used for over five decades and found to be very effective for antioxidation performance and wear control (1, 2). It has been found that the performance of ZDDPs is closely related to their degradation on metallic surfaces and the subsequent formation of tribofilms thereon (3, 4). Moreover, some dispersants and detergents have been found to exhibit significant effects on the tribological and tribochemical properties of ZDDPs as engine oil additives, which could be attributed to their synergistic and (or) antagonistic effects with ZDDPs (5–8). No doubt, the proper combination of ZDDPs with certain detergents is crucial in keeping the engine clean by preventing the deposition of harmful carbon, lacquer, and sludge. This is why the mutual interactions among ZDDPs and various detergents and dispersants have been highlighted in many studies (6–9).

In the past, researchers have reported that several overbased detergents were able to provide substantial wear protection (7, 8, 10–12), which could be due to the accumulation of calcium carbonate on the metal surface. Willermet et al. (13, 14) reported that the introduction of an overbased detergent led to changes in the composition and chain length of the polyphosphate in the antiwear film derived from ZDDP-containing engine oil. For instance, in the absence of overbased detergents the tribofilms derived from ZDDPs consist of zinc polyphosphate, while in their presence polyphosphate reacts with the metallic cation to produce a lower average phosphate chain length. Recent studies by Kasrai et al. (15, 16) using X-ray absorption near edge structure (XANES) spectroscopy have supported these findings.

Dispersants and detergents may differ from each other regarding their effect on the tribological behavior of ZDDPs, and thus some of the reported results contradict each other. For example, Shirahama and Hirata (17) reported that the introduction of an overbased sulphonate to a ZDDP-containing blend was harmful to the antiwear properties of the tribofilm; this is perhaps because the overbasing component of the sulphonate acts to retard the decomposition of ZDDP that may be the rate-determining step of the antiwear action of ZDDP. On the contrary, Rounds (18) found that overbased sulphonate contributed significantly to the antiwear performance of ZDDP-derived antiwear films, which may be related to the formation of a pastelike structure of residual hydroxide from the detergent in the contact zone. In our previous work, we found that overbased calcium and magnesium sulphonate detergents acted to retard the formation of ZDDP-derived tribofilms under sliding conditions, and that the antiwear film formed from ZDDP-detergents was not simply the mixture of the films formed separately (19). In the study of the effects of various succinic anhydride or polyamine dispersants on the tribological behavior of ZDDPs-derived tribofilms, we also found that mono polyisobutylene succinic anhydride or polyamine, bis polyisobutylene succinic anhydride or polyamine, and polyisobutylene succinic anhydride or pentaerythritol dispersants had little effect on the antiwear performance of ZDDPs, though they did enhance the thermal-oxidative and tribochemical decomposition of ZDDPs (20, 21). However, borated polyisobutylene succinic anhydride or polyamine dispersant alone was capable of significantly increasing the antiwear performance of a mineral base stock. It has been suggested that the retardation of the decomposition of ZDDPs by the overbased calcium and magnesium sulphonate detergents may be related to the competitive adsorption of the degraded products of ZDDPs and to the deposition of the detergent nanocores on the sliding metal surfaces (11, 12). This suggestion may be studied by X-ray photoelectron (XPS) and XANES spectroscopy (22, 23). Thus, we introduced three types of calcium-containing detergents into blends containing a commercial secondary alkyl ZDDP and investigated the effect of the detergents on the tribological behavior and tribochemistry of the ZDDP-derived tribofilms.

There is another important reason for this study. Secondary alkyl ZDDPs have been found to give better wear performance than the primary or aryl ZDDPs, and since the establishment of the GF-3 specification level for automotive engine oils, the amount of allowable phosphorus in the engine oil has steadily decreased from 0.1 wt% phosphorus in GF-3 oils to perhaps 0.05 wt% phosphorus allowed for GF-5 oils. The reason for this is that although phosphorus, particularly the phosphorus delivered by ZDDP, has been the predominant antiwear agent in fully formulated lubricants for decades, studies have suggested that phosphorus may poison catalytic converters used on gasoline-fueled engines to reduce exhaust emissions of unburned hydrocarbons and oxides of nitrogen (24–26). As the environmental regulations governing tailpipe emissions have tightened, the allowable concentration of phosphorus in engine oils has been significantly reduced. Further reductions in the phosphorus content of engine oil require studies such as this one at low levels of phosphorus.

Even though we have been discussing the gasoline engine

© 2007 NRC Canada

oil side of the automotive market, changes are also occurring for diesel engine lubricating oils. Although it is not conclusively proven that phosphorus in diesel engine lubricating oils is detrimental to the emission system, developers of these oils must meet strict new emission standards, new fuel economy standards, and achieve extended drain. Formulators for diesel engine oils have been asked to protect the environment by delivering long drain oils that give good emission control and therefore contain lower levels of sulfated ash, phosphorus, and sulfur, while providing fuel economy.

These trends are not just taking place in the United States. Actually, since 1970 the European Union has been trying to reduce pollutant levels, and the newest Euro IV standard for heavy duty trucks and bus engines requires an approximate 60% reduction in NO_x and a 97% mass reduction in particulates compared with the original Euro I (27). This means that the engine formulations have to be compatible with the aftertreatment system of a diesel engine, and this is a significant change. It requires a reduction in phosphorus, sulfated ash, and sulfur. With regard to phosphorus, more phosphorus is thought to deactivate the catalyst and give rise to increased emissions, which is not favored. With regard to sulfated ash, blockage of the diesel particulate filter and the continuously regenerating trap (CRT) may occur. This can give rise to fuel economy reductions because of increased backpressure on the engine, and may result in greater cost to manufacture. With regard to sulfur, increased levels may give rise to the blockage of the NO_x storage sites, and this leads to increased emissions. It can also give rise to increased sulfate particles affecting the diesel oxidation catalyst, the CRT, selective catalytic reduction, and the catalyzed diesel particulate filter. This can yield increased cost and size of the aftertreatment system. Finally, an increase in sulfur may give rise to a fuel economy penalty because there is a desensitization of the catalytic conversion affecting the $DeNO_x$ traps and selective catalytic reduction. These same kinds of concerns are being voiced around the world, including India (28) and Japan (29). The low level of phosphorus that we used in our tested oil blends addresses these concerns.

Experimental details

Materials and preparation of various oil blends

The oil blends containing secondary alkyl ZDDP with an average alkyl chain length of 4.5, referred to as ZDDP, and (or) various Ca-containing detergents were prepared at the laboratories of Chevron Oronite in Richmond, California, using low-sulfur Chevron 100N as the base stock. The physico-chemical properties of the 100N base stock are given in Table 1, while the constituents of the various oil blends are listed in Table 2.

Table 1. Physico-chemical properties of 100N base stock.

Items	Properties
Density (g/cm^3)	0.859
Viscosity at 40 °C (m^2/s)	1.99×10^{-5}
Viscosity at 100 °C (m^2/s)	4.03×10^{-6}
Viscosity index	97
Pour point (°C)	–9
Sulfur content (wt%)	0.002

Preparation of thermal films and tribofilms of various oil blends

A silicone oil bath was used to prepare thermal-oxidative films (referred to as thermal films) of various oil blends. Thus, the AISI 52100 steel coupons of a size ϕ 19 mm × 4 mm in thickness (HRC 60–64, polished to a mirror finish using 3 μm diamond paste) were separately immersed in 60 mL of each oil blend in 100 mL glass bottles and sealed and heated in the silicone oil bath at 150 °C for 6 h to allow for the formation of the thermal films. After heating, the steel coupons were removed and gently wiped using tissue paper to remove any residual oil on the surface.

A Plint friction and wear tester was used to evaluate the friction-reducing and antiwear performance of the oil blends on a steel–steel contact. The details about the friction and wear tests have been provided elsewhere (30). Briefly, a pin (ϕ 6.2 mm × 11 mm, HRC 60–64) made of AISI 52100 steel was driven by a motor to reciprocate over the steel coupon in a pin-on-disc configuration. The lubrication of the frictional pair was realized by introducing about 30 mL of an oil blend into the steel coupon holder of the Plint machine before commencing the friction and wear test. The sliding friction and wear tests were carried out at a frequency of 25 Hz, stroke of 7 mm, load of 220 N, and temperature of 100 °C, for a duration of 1 h. The friction coefficient was automatically recorded using a sensor connected to a desktop computer. At the end of each sliding test, both the upper steel pin and lower steel coupon were ultrasonically cleaned in hexane for about 5 min and allowed to dry in atmosphere. The wear scar widths of the cleaned upper steel pins were measured using a Nikon® digital camera, while the lower steel coupons were used for the XANES analysis and (or) XPS analysis. Three repeated sliding friction and wear tests were conducted for each oil blend, and the averaged friction coefficients and wear scar widths of the three tests, with rel-

ative errors of ±10% and ±5%, respectively, are reported in this article.

XANES detection methods and analysis

Background

Total electron yield (TEY) has been used to investigate the L-edge XANES of low-Z elements (<300 eV, X-ray region) in thin films, including tribofilms, for many years. On the other hand, the fluorescent yield (FY) method has been the detection technique chosen for K-edge XANES for soft and hard X-ray regions (>1000 eV). During the early work in this area, the FY detection method was developed for very soft X-ray (<300 eV) detection (31). It should be pointed out that the FY yield for this region is at least four orders of magnitude smaller than that for the Auger yield (TEY). Thus, the background noise of the detector must be extremely low to detect the FY yield.

The sampling depth of the TEY and FY detection modes was also investigated using carefully prepared SiO_2-coated Si samples with various thicknesses of SiO_2 (32). It was found that TEY probes the topmost surface information to a film depth of about 5 nm (L-edge) or 50 nm (K-edge), while FY gives the subsurface and bulk film information to a depth of about 500 Å (L-edge) or several microns (K-edge). Therefore, the combination of these detecting modes is a powerful nondestructive technique to differentiate the surface and bulk chemical features of the thermal films and tribofilms prepared from various oil blends (30). As a result of these developments, it was shown for the first time that tribofilms generated from ZDDP on steel are multilayer films (33).

Data acquisition

The P and S K-edge and P, S, and Ca L-edge XANES spectra of the thermal films and tribofilms were recorded using a InSb double-crystal monochromator (DCM) beamline and a Grasshopper grating beamline from the Canadian Synchrotron Radiation Facility (CSRF) situated on the 1 GeV Aladdin storage ring at the University of Wisconsin (Madison, Wisconsin). Both the total electron yield (TEY) and fluorescence yield (FY) raw data were collected for the thermal film and tribofilm made from each oil blend; the photon resolution for the P and S K-edge data on the DCM beamline was about 0.9 eV and that for the P and S L-edge data on the Grasshopper grating beamline was about 0.2 eV. The XANES raw data were processed using a Ban software to remove a linear background and calibrated with respect to the data of carefully selected model compounds with known XANES chemical features.

DLS analysis

Dynamic light scattering (DLS) studies of the oil blends were carried out at 60 °C to determine the size of detergent molecules in suspension because of their high viscosities. A Brookhaven Instruments 90 Plus particle size analyzer, with a 35 mW laser and avalanche photodiode (APD) detector, was used. Analyses for each sample were repeated in triplicate. Figure 1 shows the size distributions of the three Ca detergents and Table 3 lists the effective size of each detergent. In the homodyne photocount autocorrelation method, the scattered light autocorrelation function is compared by

Fig. 1. Particle size distribution of detergents I, II, and III.

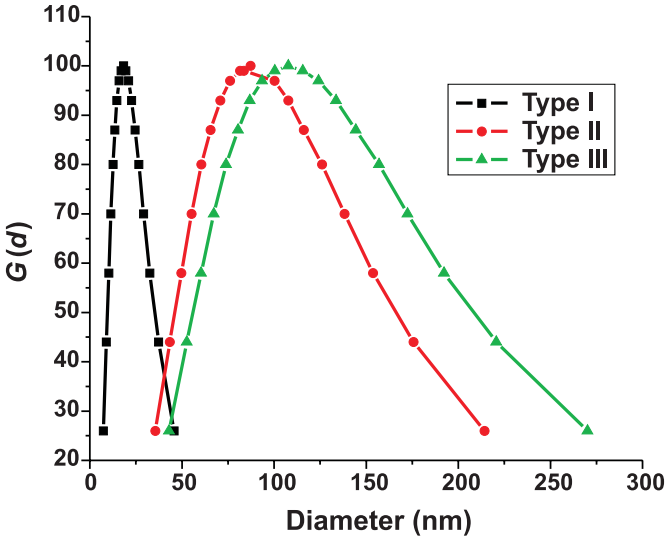

Table 3. Effective diameters of Ca detergents measured by DLS.

Detergent	Viscosity (60 °C) cP	Effective diameter (nm)	Polydispersity
Type I	11.45	18.3	0.364
Type II	10.59	87.3	0.346
Type III	10.57	107.7	0.367

signal-averaging within a digital correlator. The intensity autocorrelation function $I_2(t)$ can be related, for the case of Gaussian statistics (34), to the scattered electric field correlation function $I_1(t)$ as follows,

$$[1] \qquad I_2(t) = \langle I(0)I(t)\rangle = |I_1(0)|^2 + \beta|I_1(t)|^2$$

where β is the detector efficiency. For the simple case of a translationally diffusing particle, $I_1(t)$ is a single exponential decay involving the translational diffusion coefficient D_t,

$$[2] \qquad I_1(t) = A\ \exp[-q^2 D_t]$$

where $q = (4\pi\,\eta_D/\lambda_0)\ \sin(\theta/2)$ is the scattering magnitude at the scattering angle θ, for light of wavelength λ_0 in vacuum, scattered in a medium of index of refraction, η_D.

If there is a distribution of sizes there will be more than one relaxation, each with its own rate, $\Gamma = q^2 D_t$. In that case, $I_1(t)$ can be written as an integral over a relaxation rate distribution function $g(\Gamma)$,

$$[3] \qquad I_1(t) = \int g(\Gamma)\ \exp[-\Gamma t]\ d\Gamma$$

and the problem of determining $g(\Gamma)$ is that of inverting a Laplace transform. This can be done by CONTIN, a computer program developed specifically for DLS by Provencher (35). CONTIN yields $g(\Gamma)$, average values of Γ, and standard deviations that are a measure of the polydispersity. Typically a spherical particle model is used with this method. The effective diameters increase as the TBN number varies from 140 to 250 (see Table 2). The effect of the size of the detergents will be discussed below.

Results and discussion

Friction-reducing and antiwear performance of various oil blends

Figure 2 shows the friction coefficients for various oil blends. ZDDP and the calcium-containing detergents were all able to improve the friction-reducing ability of the 100N base stock to some extent. Moreover, the introduction of the calcium-containing detergents to the base stock had some effects on the friction-reducing ability of ZDDP. The steady-state friction coefficients for the base oil (oil blend No. 1), the oil blend containing ZDDP alone (oil blend No. 2), or calcium detergent III alone (oil blend No. 8), and the one containing both ZDDP and calcium detergent III (oil blend No. 5) were all about 0.10, with the difference being within the relative error (±10%) for the measurement of the friction coefficient. However, it was likely that the calcium-containing detergents I and II were able to decrease the friction coefficient of the base oil from ~0.1 to ~0.08 (compare the friction coefficients for oil blends Nos. 3 and 6 with that of No. 1, or those for Nos. 4 and 7 with that of No. 1). The ability of the calcium-containing detergents to decrease friction was greatest for calcium detergent II.

Looking at Fig. 1 and Table 3, we notice that detergent types I and II are smaller in size than detergent type III. In particular, detergent type I has the smallest particle size (but the highest particle concentration). Detergent type II has an intermediate particle size, and detergent type III has the largest particles and the greatest polydispersity. At this stage we cannot explain how the sizes in this range can affect the friction behavior of the detergent.

Figure 3 shows the wear scar widths (WSW) of the upper steel pins lubricated with various oil blends. It is obvious that the base stock gave much larger wear scar width and high wear of the steel pin in the steel–steel contact. In comparison, ZDDP alone and ZDDP combined with each of the three types of calcium detergent additives were very effective in decreasing the wear scar width of the upper steel pin, indicating that they could be good antiwear additives for the steel–steel sliding contact. In particular, the oil blend containing ZDDP alone registered a steel pin wear scar width of 0.165 mm, which is much smaller than that for the base oil and in good agreement with what has been reported elsewhere (18). Furthermore, the blends with ZDDP and each of the three calcium-containing detergents (blends Nos. 3–5) recorded a steel pin wear scar width smaller than that for the blend containing ZDDP alone, indicating that the calcium detergents were beneficial for improving the tribological behavior of ZDDPs. In fact, oil blend No. 5 shows synergistic behavior for antiwear performance. Moreover, it is interesting to note that each of the three calcium detergents alone in the base stock also gave good antiwear protection for the steel–steel contact, indicating that these Ca-type detergents themselves could be promising multifunctional additives for low-sulfur mineral oil. Again, tribofilm generated from detergent type III (no ZDDP) with larger particle size has relatively larger WSW compared with types I and II. Further work is necessary to correlate the structure of these calcium-containing detergents with their effects on the tribochemistry of the tribofilms derived from ZDDPs, especially in full formulations rather than these simple ones.

Film thickness

The relative thickness of thermal films and tribofilms generated from different blends was measured using XANES spectroscopy. We have shown in the past that the intensity of the P K-edge XANES spectra can be used to measure the average thickness of the major phosphate component of ZDDP-derived antiwear films (21). The peak intensity of the FY K-edge spectra is a direct measure of surface coverage (mass thickness) and can be used to monitor the film thickness of the tribofilms (36). Figure 4 shows the relative film thickness for thermal films and tribofilms. It is seen that the oil blend containing ZDDP alone forms a relatively thick thermal film and tribofilm on the steel surface. However, in-

corporation of the Ca-detergent in the blend prevented the formation of a thick thermal films. This is also the case for tribofilm but to a lesser extent.

XPS profiling using Ar^+ sputtering was used to investigate the elemental composition and thickness of tribofilms. The elemental composition of tribofilms Nos. 2–5 and No. 8 are summarized in Table 4. It is very interesting to note that the Ca concentration in tribofilms Nos. 3–5 qualitatively increases as the total base number (TBN) increases from 140 to 250 in the blends. At the same time the proportion of Zn decreases. This suggests that Zn is replaced by Ca in the tribofilms, in agreement with the data in the literature (13, 15). As an example, the Ar^+ sputtering results for tribofilms No. 2 (ZDDP alone) and No. 5 (ZDDP plus detergent III) are presented in Fig. 5. Also, the Ca concentrations for tribofilms No. 5 and No. 8 (detergent III alone) are plotted in Fig. 5. It is obvious that the relative concentration of Zn, P, and S in the tribofilm blended with the Ca detergent is lower than that of No. 2 tribofilm. The sputtering rate has been calibrated using a film of SiO_2 and found to be ~50 Å/60 s. Using this calibration, the films are over 50 nm thick. After 480 s sputtering, the Fe 2p signal increased markedly (not shown), suggesting that the substrate is becoming exposed and we were approaching the maximum film thickness. Another interesting observation is the measurement of Ca in tribofilms No. 5 and No. 8. The film generated from detergent alone is also quite thick and that is why these detergents show such a good antiwear protection (see Fig. 3).

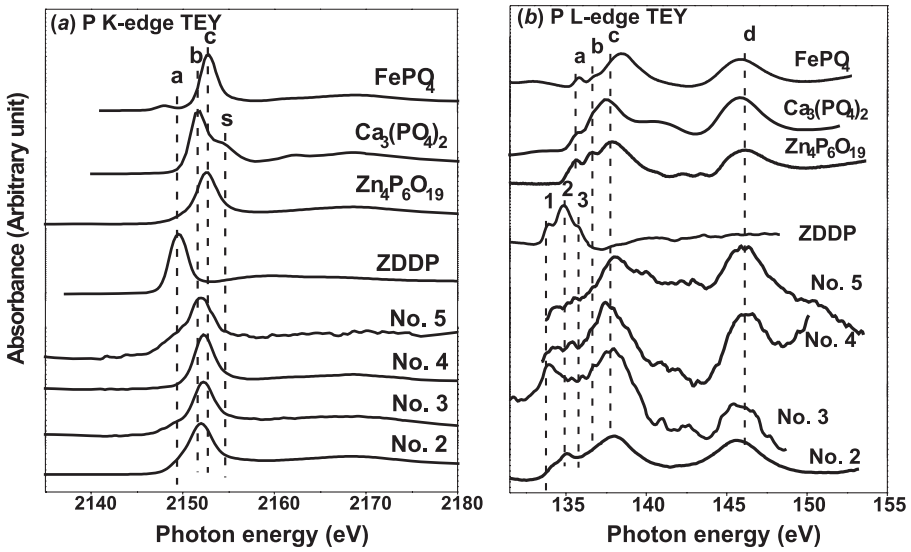
XANES analysis of the thermal films

Fig. 6*a* shows the P K-edge TEY XANES spectra of thermal films made from various oil blends listed in Table 2. The spectra of relevant model compounds are also included in Fig. 6*a*. The P K-edge XANES spectrum of ZDDP in oil (ZDDP) is shifted by ~3 eV to lower energy compared with that of the polyphosphate. The thermal films spectra align very closely with that of polyphosphate, indicating that the ZDDP has been thermally oxidized to a phosphate at 150 °C. The presence of Ca detergents in blends Nos. 3–5 has significantly retarded the oxidation rate of ZDDP, as discussed earlier, in conjunction with the film thickness (Fig. 4). A close inspection of Fig. 6*a* indicates the presence of a broad shoulder (peak a) on the low energy side of the spectrum for No. 5, corresponding to unreacted ZDDP. Another interesting finding in Fig. 6*a* is the absence of a shoulder S, corresponding to $Ca_3(PO_4)_2$ in the spectra for Nos. 3–5 (15, 16, 37). This indicates that the Ca in the detergents does not exchange with Zn in Zn phosphate, and as a result no appreciable amount of Zn–Ca phosphate forms under thermal conditions (see below for tribofilms). The FY XANES spectra, sampling the bulk of the thermal films, were also recorded (not shown). The spectra for Nos. 3–5 were noisy and weak, an indication that the films were very thin (see Fig. 4), with less decomposition of ZDDP to phosphate.

The P L-edge XANES spectra of model compounds and thermal films are presented in Fig. 6*b*. The spectrum of ZDDP in oil is distinct from those of phosphate model com-

© 2007 NRC Canada

Fig. 6. (*a*) P K-edge and (*b*) L-edge XANES spectra of model compounds and thermal films made from various oil blends.



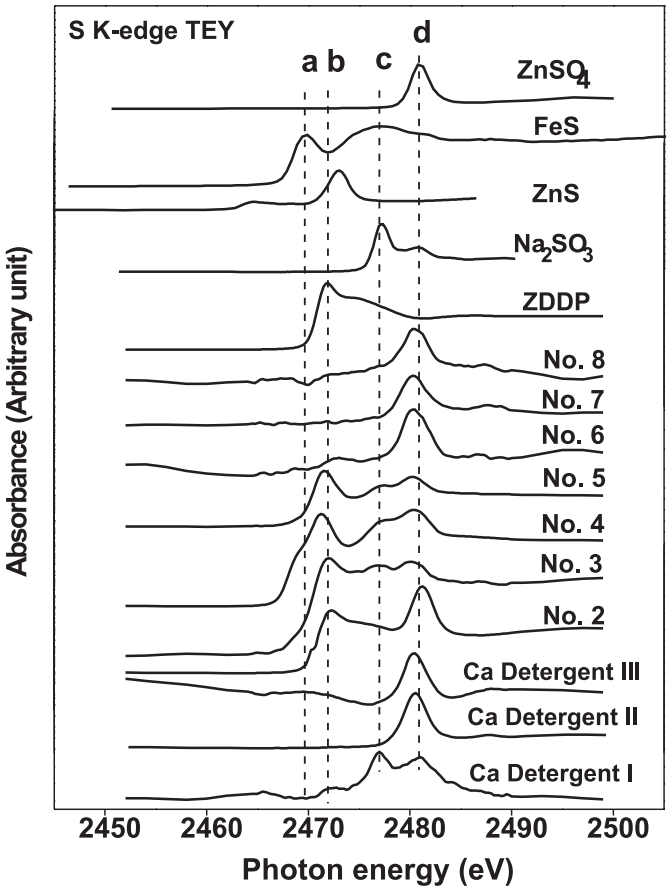


Fig. 7. S K-edge TEY XANES spectra of model compounds and thermal films made from various oil blends.

pounds and is shifted to the lower energies, compared with the phosphate spectrum. Thermal film spectrum of No. 2 shows the characteristic peaks a–d corresponding to a polyphosphate. The spectra of Nos. 3–5 also correspond to a phosphate. However, since the spectra are noisy no detailed information regarding the nature of the phosphates can be derived from the spectra. Therefore, it is concluded that heating of the AISI 52100 steel coupons at 150 °C in the base oil containing the calcium-containing detergents (oil blends Nos. 3–5) and ZDDP led to the formation of a very thin film of phosphate, compared with that of ZDDP alone in base oil.

The sulfur composition of thermal films was investigated using S K-edge and L-edge XANES spectroscopy. Figure 7 shows S K-edge XANES spectra of the thermal films and model compounds, representing sulfur in different oxidation states. The spectra of Ca detergents II and III in oil show a peak corresponding to a sulfate (peak d), whereas detergent I shows peaks corresponding to sulfide (peak b), sulfite (peak c), and sulfate (peak d). Thermal films derived from blends No. 3–5, containing detergents and ZDDP, all show the presence of sulfide (peak b), sulfite (peak c), and sulfate (peak d). However, thermal film generated from ZDDP alone, No. 2, shows no sulfite. Careful inspection of the spectrum for No. 4 shows a shoulder corresponding to a FeS species, which is not found in the other thermal films. This blend contains detergent II and ZDDP. It is not clear how FeS is formed under thermal conditions. Formation of FeS is generally associated with tribofilms generated under extreme pressure (EP) conditions (23).

Thermal films generated from detergents I to III, spectra for Nos. 6–8, show only sulfate (peak d). The FY spectra probing the bulk of the films were also recorded (not shown). They were generally noisy, an indication that the films were very thin. The sulfur L-edge XANES spectra (not shown) were noisy and did provide additional information. From these data, it is clear that sulfur is susceptible to oxidation under thermal film formation conditions. This can partly be due to the length of time (~6 h) that is required to generate the films and the fact that the film is exposed to air in oil at 150 °C (see the later discussion of tribofilms).

XANES analysis of the tribofilms of various oil blends

Figure 8*a* shows the P K-edge XANES spectra of the tribofilms for various oil blends along with the spectra of relevant model compounds. The main peak b of the

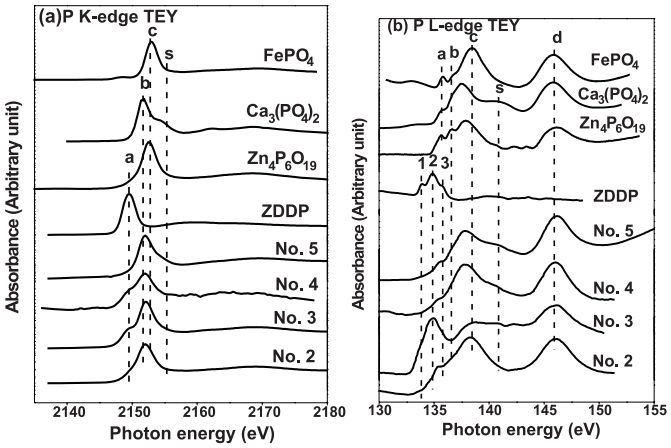
Fig. 8. (*a*) P K-edge and (*b*) L-edge XANES spectra of model compounds and tribofilms made from various oil blends.



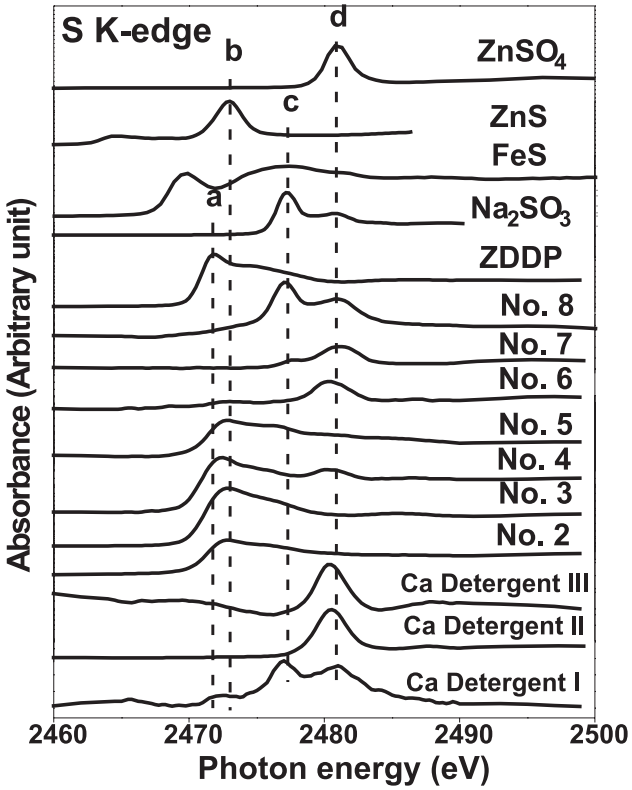


Fig. 9. S K-edge TEY XANES spectra of model compounds and tribofilms made from various oil blends.

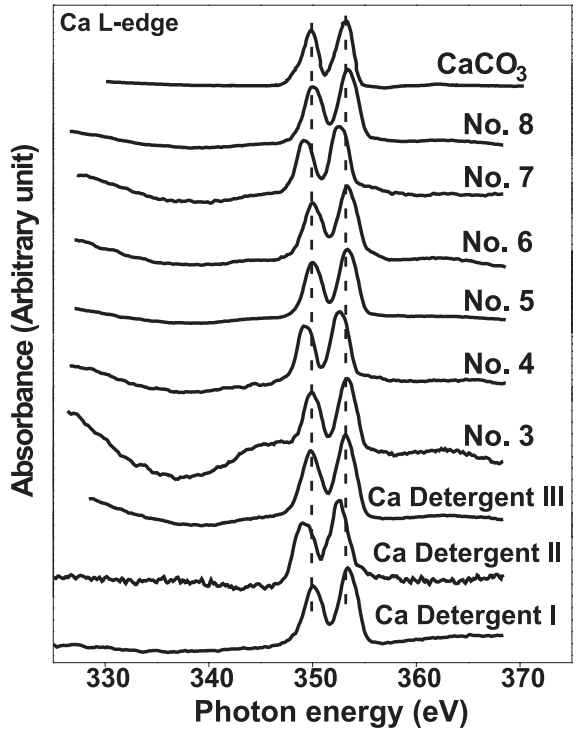

tribofilms aligns closely with that of Zn and Ca phosphate, but is shifted ~1 eV to lower energy compared with that of Fe phosphate (peak c). Peak a of ZDDP aligns very closely with that of the shoulder in the spectra for No. 3 and No. 4, indicating the presence of unreacted ZDDP in these films, generated from Ca detergents and ZDDP. Spectra for No. 5 and No. 2 do not show the shoulder.

The corresponding P L-edge XANES spectra of model compounds and tribofilms are presented in Fig. 8*b*. The spectral features for No. 2 (ZDDP alone) are very similar to those of Zn polyphosphate, whereas the spectral features of the Fe and Ca phosphates are shifted to higher and lower energies compared with Zn phosphate, respectively. The addition of detergents I, II, and III to ZDDP changed the spectral features of the polyphosphates in the tribofilms. First, the ratio of intensity of peaks a/c (0.54) for spectrum No. 2 (ZDDP alone) dropped to 0.3 for the spectra of Nos. 4 and 5 (ZDDP plus detergents). Nicholls et al. (38) provided a calibration curve assigning the a/c and b/c ratios to the number of phosphorous atoms in different polyphosphate glasses. The P L-edge spectra of short chain polyphosphates with 10 or fewer P atoms in a polyphosphate glass exhibit an a/c ratio of ~0.44 or less. Medium chain polyphosphates, which have between 10 and 25 P atoms in each chain in the polyphosphate glass network, exhibit an a/c ratio between ~0.44 and ~0.60. Long chain species, characterized by 25 or more P atoms in the polyphosphate chain, show an a/c ratio of ~0.60 or greater. Thus, the addition of detergents has reduced the polyphosphate chain length from medium to short. Second, peak c of spectra Nos. 4 and 5 shifted to lower energy, approaching that of Ca phosphate. The broad peak s of Ca phosphate is quite apparent in spectra of Nos. 3–5, whereas it is not present in spectrum of No. 2. This is a strong indication that Ca has incorporated into Zn polyphosphate to form Ca–Zn phosphate. This is in good agreement with previous results (14, 15, 32). As noticed in conjunction with P K-edge spectra (Fig. 8*a*), there is a peak or shoulder in the spectra of Nos. 3–5, corresponding to peak 2 of ZDDP. This peak is especially very strong in spectrum of No. 3. These data confirm the observations from the P K-edge data that, along with phosphate, some undecomposed ZDDP is present in the tribofilms. This was also observed in the case of thermal film formation. This information, and the observation that films generated from combination of ZDDP and Ca detergents are thin, strongly suggests that the detergents interact with ZDDP and retard the decomposition of ZDDP to phosphates (17). However, as was shown in Fig. 3, the interaction is a synergistic one and generally improves the antiwear performance of ZDDP. However, detergent size has no significant effect. In the past, we have investigated the effects of Ca sulfonate, phenate, and salicylate detergents in combination with ZDDP. In general the effect has been antagonistic (15, 16, 37). Here we notice that detergent type III (larger size) behaves differently. The spectra of No. 5 in Fig. 8 (K-edge and L-edge) for a film generated from detergent III and ZDDP do not show the shoulder corresponding to unreacted ZDDP. It seems the composition of these particular detergents plays an important role in providing superior antiwear function and friction-reducing performance.

The sulfur composition of tribofilms was investigated using S K-edge and L-edge XANES spectroscopy. Figure. 9 shows the S K-edge XANES spectra of tribofilms and model compounds along with those of detergents in oil. As was shown earlier, the spectra of Ca detergents II and III in oil show a peak corresponding to a sulfate (peak d), whereas detergent I shows peaks corresponding to sulfide (peak b), sulfite (peak c), and sulfate (peak d). Tribofilms generated

© 2007 NRC Canada

Fig. 10. Ca L-edge TEY XANES spectra of model compounds and tribofilms made from various oil blends.

directly from the detergents (no ZDDP), spectra of Nos. 6–8, show sulfite (S^{4+}) and sulfate (S^{6+}) features. The film generated from ZDDP alone, spectrum of No. 2, shows peak b corresponding to ZnS with a broad shoulder corresponding to unreacted ZDDP. The spectra of Nos. 3–5, for films generated from ZDDP in combination with detergent I to III, have a broad peak encompassing unreacted ZDDP (peak a) and ZnS (peak b). In contrast to thermal films (Fig. 7), there is little or no oxidized form of sulfur in the tribofilms.

S L-edge XANES spectra of the tribofilms were also recorded (not shown). The results support the S K-edge findings indicating that the topmost surface chemistry of S is very similar to the near surface and the bulk.

Calcium was also present in both the thermal films and tribofilms. As an example, the Ca L-edge XANES spectra of tribofilms along with those of $CaCO_3$ and detergents in oil are presented in Fig. 10. As is obvious from Fig. 10, the spectral features of tribofilms and detergents in oil align very closely with those of $CaCO_3$. However, close inspection of the spectra clearly shows that the doublet feature in the spectrum of detergent II (in oil) is shifted to lower energy by ~0.5 eV, compared with those of detergents I and III. This indicates that, most likely, the counter ion of Ca^{2+} in detergent II is different from that in detergents I and III. Overall, calcium can be present in the tribofilm as $CaCO_3$, Ca phosphate, and undecomposed detergents. It is very interesting to find that both in thermal films and tribofilms, calcium is present and becomes an integral part of the film. As was shown in Fig. 3, the antiwear properties of the three detergents, regardless of differences in their composition, are very similar.

Conclusions

The effects of three kinds of calcium-containing detergents on the tribological and tribochemical features of a ZDDP additive in 100N base stock was investigated using XANES spectroscopy and XPS. The main conclusions are given in the following.

The three kinds of calcium-containing detergents tested in the present work were all able to improve the friction-reducing performance of the 100N base stock (calcium detergent II was the most effective.) In base stock alone, these calcium-containing detergents gave good antiwear protection for the steel–steel contact, which was dependent on the tribochemical reactions of the detergents themselves.

The mixtures of ZDDP with each of the three types of calcium-containing detergents as additives in 100N oil were more effective in reducing wear of the steel–steel contact than ZDDP alone. These Ca detergents showed synergistic antiwear performance with the ZDDP tested in the present work.

Heating of the AISI 52100 steel coupons in various oil blends at 150 °C only led to the formation of very thin thermal-oxidation films containing Zn phosphate, sulfate, and small amounts of calcium. The calcium-containing detergents contributed to retarding the thermo-oxidation decomposition of ZDDP in 100N oil, which could be dependent on the molecular structures of the detergents and directly related to the tribochemistry of ZDDPs in mineral oil. The reduction of the thickness can also partially be due to the cleaning action of the detergent.

Much more Ca was detected by XANES in the tribofilms as compared with the thermal films, which indicates that the rubbing of the lubricated steel–steel pair enhances formation of tribofilms containing Ca.

The calcium-containing detergents influenced the composition and thickness of the tribofilms. The reciprocating sliding of the steel pin-on-disc pair at 100 °C was more effective than heating at 150 °C to induce the decomposition of ZDDP, leading to incorporation of the active sulfur originating from ZDDP and (or) other additives into the tribofilm.

Each of the three calcium-containing detergents, alone, also produced tribochemical reactions, leading to changes in the oxidation state of S in the corresponding tribofilms. The deposition of nanosized $CaCO_3$ onto the rubbing steel surfaces may account for the good antiwear performance of this oil blend.

Canadian Light Source — Optical Metrology Facility[1]

Brian W. Yates and Dylan G. Maxwell

Abstract: The Canadian Light Source Optical Metrology Facility serves as a support facility and provides metrological services required by the synchrotron beamlines. The Facility consists of three state-of-the-art instruments: a Micromap 570 surface profiler, an Ocean Optics long trace profilometer, and a Zygo Verifire AT Fizeau interferometer. These three complementary measurement systems permit a complete analysis of the synchrotron beamline optical components. The systems will be discussed in detail, noting synchrotron and industrial applications where possible.

Key words: optics, metrology, surface roughness, slope error, tribology.

Résumé : Le laboratoire de métrologie optique de la source canadienne de lumière sert de support et fournit les services requis par les faisceaux linéaires du synchrotron. Le laboratoire consiste en trois appareils ultramodernes, un profileur de surface Micromap 570, un profilomètre à long tracé Ocean Optics et un interféromètre Zygo Verifire AT Fizeau. Ces trois systèmes de mesure complémentaires permettent de faire une analyse complète des composantes d'un faisceau optique du synchrotron. On discute des systèmes en détail et, lorsqu'on en a noté, on discute aussi des applications industrielles ou celles du synchrotron.

Mots-clés : optique, métrologie, aspérités d'une surface, erreur sur la pente, tribologie.

Introduction

The Canadian Light Source (CLS) is the Canadian national synchrotron science facility (1), operating on the University of Saskatchewan campus in Saskatoon, Saskatchewan. The CLS is operated as a not-for-profit corporation wholly owned by the University of Saskatchewan. The facility was constructed with a $173CAN million capital budget starting in 1999 and operations began in early February 2004. The facility is a third generation 2.9 GeV synchrotron light source that produces a high intensity light source of infrared, visible, ultraviolet, and both soft and hard X-ray radiation. The CLS currently has seven operational scientific beamlines and a further seven beamlines in the early stages of construction. The beamlines provide multidisciplinary support in the areas of advanced materials, earth and environmental science, life sciences, and industrial science. Canadian researchers in such diverse areas as chemistry, physics, geology, materials science, soils science, surface science, biochemistry, and engineering can submit scientific proposals and apply for beam time at the CLS.

The Optical Metrology Facility (OMF) is a support facility at the CLS that determines the required optical specifications through SHADOW ray-tracing modeling (2, 3) and measures the quality of the optical components prior to beamline installation. However, the OMF has a broader mandate to support scientific researchers or "users" at the CLS and, where possible, researchers across Canada. Therefore, this paper has been written to inform the Canadian scientific community what instrumentation and capabilities are available.

Typical surface parameters measured by the OMF instruments are surface roughness (surface finish), radius of curvature (flatness), height and slope errors, and power spectral density (PSD). Removal of the desired best-fit theoretical figure (e.g., plane, cylinder) from the raw surface height yields the height error and differentiation generates the slope error. A large slope error will result in an undesirable experimental focus, where photon flux, brightness, and spot size have been compromised. Slope error, surface roughness, and mirror coating quality determines the photon flux density, focus characteristics, and photon energy range delivered to the beamline experimental station. Since all measurement methods use visible light, these techniques are noncontact and nondestructive. In general, the surfaces being measured need to be somewhat reflective. Uncoated glass optics with about 4% reflectivity are still suitable for measurement. We have developed tools within the OMF (metrological, software) to improve our understanding of the interplay that these parameters have on the overall focus quality and to deliver optical components to the beamlines that meet or exceed their design specifications.

Optical Metrology Facility

All OMF instruments are housed in a 27 m^2 Class 10 000 clean room with four HEPA units. The metrological instru-

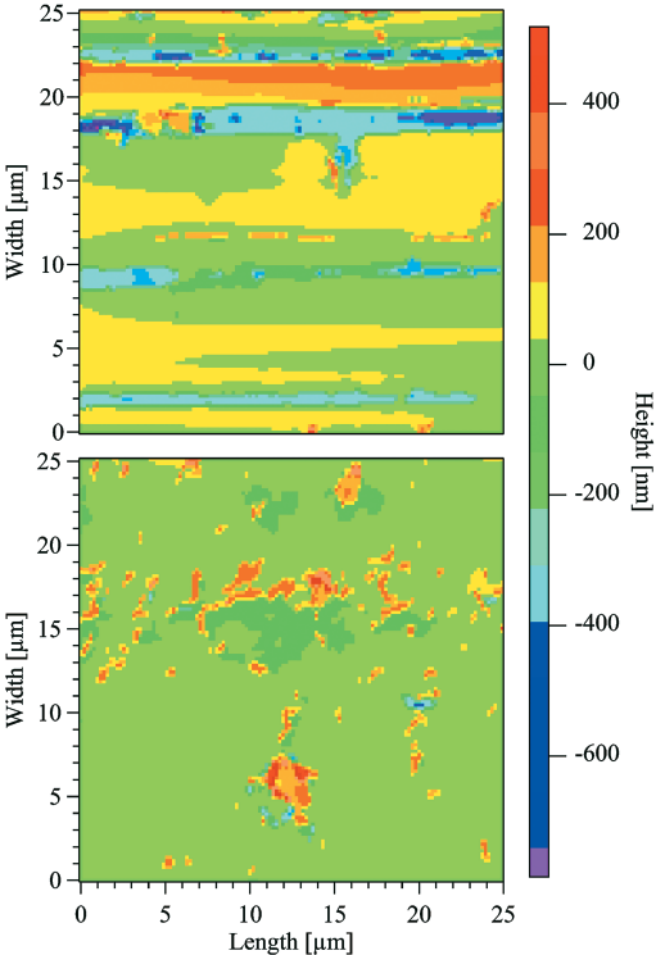
[b]Height range is dependent on the mode used — smooth, wave, or focus.
[c]Zoom feature ranges from (1–6)X. Numbers shown reflect the highest zoom factor of 6X.

ments are mounted on vibration isolation tables (Technical Manufacturing Corporation, 780 Series) with pneumatic isolation legs to minimize vibrational effects. Plastic curtains and bellows are used, when required, to minimize air turbulence effects. The temperature in the room is maintained at 23.0±0.2 °C, since temperature changes are extremely critical for metrological measurements. The Micromap 570 surface profiler from Micromap Corporation primarily measures the surface roughness of test optics. The Long Trace Profilometer (LTP) from Ocean Optics Inc. measures the slope error for a one-dimensional line profile and radius of curvature. Finally, a Verifire AT Fizeau interferometer from Zygo Corporation measures the height error map for a surface and radius of curvature. See Fig. 1 for a view of the OMF scientific instrumentation currently available and Table 1 for a summary of their measurement ranges and limitations for surface slope and height errors. Basic metrological equipment such as light sources, optical and micromechanical components, precision height gage, laboratory grade gage and angle blocks, beam profiler, and various NIST-traceable standards are available for routine testing and experiments by users.

Micro-roughness measurements



The Micromap 570 surface profiler is a microscope-based instrument that utilizes visible light interferometry (520 nm, white) to measure the surface roughness of reflective optical surfaces. A CCD detector (9.8 μm pixel pitch) mounted on the microscope is used to measure an area on the surface (<1 mm^2, which is dependent on the microscope objective used) with a height resolution of approximately 0.01 nm. Four different objectives are currently available, 5X, 10X, 20X, and 50X, which enables one to cover a wide range of spatial sampling periods (0.0002–1.25 mm) or spatial frequencies (0.0004–2.5 $μm^{-1}$). The electronic noise floor contribution, which limits the achievable surface roughness, has been characterized by measuring calibrated fused silica super smooth mirrors from General Optics (Cat. No. GO-FS100–1R) of ~0.03 nm root-mean-square (RMS) surface roughness. Surface roughness down to 0.03 nm RMS can be routinely measured with some signal averaging.

Three measurement modes are available in the distributed software — smooth phase mode (interferometry phase measurement), wave mode (white light interferometry phase scan), and focus mode (interferometry focus scan). Smooth phase mode is ideal for very smooth surfaces (0.02–100 nm RMS roughness) but is limited to a maximum height measurement of 4 μm (objective focus depth dependent). Wave mode is ideal for smooth surfaces with heights and steps < 5 μm. Focus mode is ideal for rough surface textures with heights and steps > 5 μm (maximum height measurement of 150 μm).

The surface height map shown in the bottom portion of Fig. 2 is for an antiwear film, produced using a four-ball extreme pressure wear machine. In this device a ball is rotated in contact with 3 test spherical balls that are held stationary. The contact surfaces are covered with test lubricant, the central ball is rotated and a load applied, and then a timed test is performed. The map was taken using a 50X objective on an antiwear film and shows the following surface amplitude parameters: 63.12 nm RMS surface roughness (Sq), 32.86 nm

© 2007 NRC Canada

Fig. 2. Surface height maps measured with the Micromap 570 surface profiler using a 50X objective. The bottom map is for an antiwear film with surface amplitude parameters of 63.12 nm RMS surface roughness (Sq), 32.86 nm arithmetical mean deviation (Sa), and 1.013 μm peak-to-valley (St). The top map is outside the wear track region with 131.5 nm RMS Sq, 88.73 nm Sa, and 1.299 μm St.

arithmetical mean deviation (Sa), and 1.013 μm peak-to-valley (St). For comparison purposes, a nearby section outside the wear track region is shown in the top portion of Fig. 2. The unworn surface height map is less homogenous, showing the following surface amplitude parameters: 131.5 nm RMS Sq, 88.73 nm Sa, and 1.299 μm St. A significant reduction in surface roughness and arithmetic mean deviation has occurred in the wear process that produces these antiwear films.

Most modern automotive oils contain many additives, antiwear agents, anti-oxidants, detergents, and dispersants. The most popular antiwear agent is zinc dialkyldithiophosphate (ZDDP). ZDDP decomposes on the hot metal engine surfaces to generate very thin inhomogeneous antiwear films (~100 nm thickness). The chemistry of antiwear films has been studied extensively with conventional XPS surface techniques and using synchrotron sources on the phosphorus L-edge and K-edge XANES, using total electron yield (TEY) and fluorescence yield (FY) (4–6). TEY and FY techniques are well-suited to study these antiwear films since their analysis depths match well. L-edge TEY has an analysis depth of ~5 nm making it surface sensitive, while FY has an analysis depth of ~70 nm making it a bulk measurement technique. Combined with the energy tunability of synchrotron beamlines via crystal or grating diffraction, TEY and FY make very powerful probes into the antiwear film surface chemistry and tribology. The operational variable line spacing plane grating monochromator (VLS-PGM) beamline at the CLS is particularly well suited for phosphorus L-edge studies (at ~135 eV binding energy) because of the high undulator photon flux and very high resolving power (up to 30 000). The soft X-ray microcharacterization beamline (SXRMB) currently under construction at the CLS, which will be commissioned in early 2008, should provide access to the low-Z K-edges of elements like phosphorus and sulphur. The SXRMB beamline will utilize a bending magnet source and a double crystal monochromator, which will use InSb-111 and Si-111 crystal pairs for diffraction to access the photon energy range of ~1.8–10 keV. In addition, antiwear films can be measured for surface amplitude parameters in the CLS OMF using the Micromap 570 surface profiler to gain insight into their tribology.

Height and Slope Error Measurements

The long trace profilometer measures the slope and curvature of optical surfaces along one dimension using a zero path-difference interferometer. Our LTP IV is an improved version of the original LTP (7) and now incorporates a precision linear air bearing and aluminum beam from New Way. Two "folding" mirrors and a reference planar mirror in the optical system have been replaced with super smooth silicon mirrors from General Optics (custom folding mirrors, <0.1 nm RMS roughness and <2 μrad RMS slope error, Cat. No. GO-S100–1). A 3 mW class IIIa solid state laser source (λ = 635 nm) with circular beam source and 0.7 mrad beam divergence from Edmund Industrial Optics (Cat. No. F54–024) is used to probe the test optic. The CLS LTP can measure reflective optical surfaces up to 1.5 meters in length, covering the range of spatial samplings from 2–1500 mm and spatial frequencies of 0.00033–0.25 mm^{-1}. Surfaces of virtually any shape can be measured in situ, as long as the surface slope change is within the ±5 mrad acceptance angle of the LTP optical system. Our current LTP measurement floor is ~0.45 μrad RMS in slope and 10 nm RMS in height (Table 1), being limited by air turbulence and thermal drift during measurement.

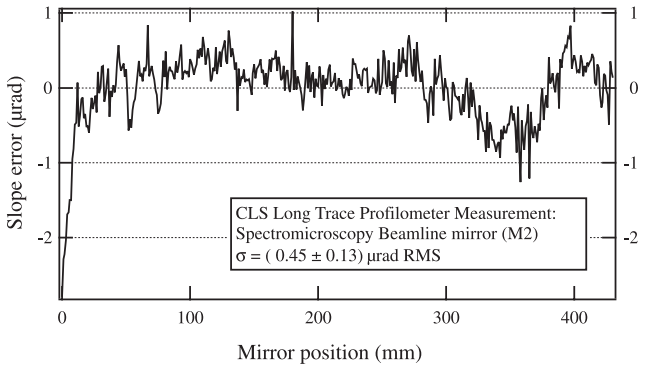
Figure 3 shows the LTP signal averaged slope error profile of the CLS spectromicroscopy beamline M2 planar mirror. In this case the desired figure is planar, so the slope error of 0.45 ± 0.13 μrad RMS represents a very slight deviation from "flat". Slope error represents the difference in slope between the surface and the desired figure (e.g., plane, cylinder). In this case the planar mirror, which is a critical component in the plane grating monochromator design for this beamline, met the stringent design goal of 0.5 μrad RMS slope error.

The Verifire AT Fizeau interferometer measures the deviation of height of a test reflective surface from a reference surface, typically a reference flat. It accomplishes this using phase shifting interferometry and a collimated HeNe laser

© 2007 NRC Canada

beam (λ = 632.8 nm) of 150 mm diameter. Three dimensional surface height maps of optical surfaces up to 150 mm in diameter can be measured at normal incidence or up to 1500 mm in grazing incidence using a new optics tip and tilt stage designed at the CLS. The radius of curvature and slope error can be calculated from the measured surface height map. A variable zoom feature allows a particular region to be enlarged by up to six times magnification. The spatial period measured depends on the zoom factor and number of pixels used, the grazing incidence angle, and the test optic length (L). A typical normal incidence spatial period range without zoom is about 0.3–L mm.

A grazing incidence measurement on a far IR beamline M3 planar mirror, in so-called "double pass" mode, is shown in Fig. 4. A collimated HeNe laser beam is output from the Fizeau interferometer through a reference transmission flat (Fig. 4, left side), reflected off the M3 mirror under test on a tip and tilt stage (Fig. 4, right side), and then reflected back with a return flat (top right) to the detector in the interferometer. Double pass refers to the fact that the collimated beam is reflected twice off the test mirror. The transmission and return flats form an optical cavity. Our custom optical cavity purchased from Zygo Corporation is approximately λ/50 in quality, so flatness measurements to ~12.7 nm are certainly possible with this instrument.



Software Development

Software has been developed to provide advanced analysis functionality beyond that of the control and analysis commercial instrumentation software provided by the vendors. The core functionality includes support for signal averaging, error analysis, curve fitting, and PSD for both profile (1D) (8) and surface (2D) data (9). Signal averaging is frequently beneficial for reducing noise but requires multiple surface height map measurements to be collected and analyzed. The software was developed in C/C++ using the ROOT data analysis framework (10) from CERN.

A data window can be applied to select the desired analysis region of the measured optic. Both height and slope maps are supported and conversions allowed. The software is designed to handle multiple measurements so that a surface uncertainty map can be computed from the variation amongst unique permutations of the original sample measurements. Averaging these measurements generates a mean surface map. A best-fit polynomial to remove piston, tilt, power, and twist can be applied to the data, if desired. The uncertainties in the fitted parameters are calculated from the best-fit differences of the surface with and without the surface uncertainty map. The radius of curvature with uncertainty is calculated from certain fitted parameters and their respective uncertainties. Mean and RMS values of the maps are calculated with their estimated uncertainties. These results are formatted so that they can be combined to generate a comprehensive report.

An example of the output from the software can be seen in Fig. 5. The average of several successive surface height map measurements on the Fizeau interferometer of a Kirkpatrick-Baez (KB) mirror is shown in the center left of Fig. 5, with the best-fit polynomial approximation to a sphere removed. The lower left histogram shows the residuals binned according to height. The surface height uncertainty map is shown in the center right, while the corresponding height uncertainty distribution is displayed in the lower right histogram. The histograms are helpful in visualizing the measurement distributions and showing how closely they follow normal or gaussian statistics. The upper right box shows the radius of curvature and fitted parameter results with their respective errors. This particular KB mirror has a height error of 0.0115 ± 0.0002 μm and a radius of curvature of 42.61 ± 0.6 km, which is considered optically flat for all intents and purposes.

Fig. 3. LTP slope error measurement results for the CLS spectromicroscopy beamline planar mirror (M2), showing a signal averaged slope error of 0.45 ± 0.13 μrad RMS.

Summary

The CLS Optical Metrology Facility is fully operational and all instrumentation is performing well within their design specifications. To reduce the LTP measurement noise floor even further, we are currently studying how to optimize the room temperature feedback control system for temperature derivative instead of temperature bandpass. Replacement of the LTP aluminum beam with a ceramic beam from Coorstek Inc. is also being considered. A ceramic beam would have a substantially better flatness of ~4 μrad, higher stiffness, lower coefficient of thermal expansion, and lower thermal conductivity.

Considerable effort has been spent to build a complete state of the art metrology laboratory that is capable of performing a complete analysis of synchrotron beamline optical components. This is required to deliver synchrotron beamlines that meet or exceed their design specifications with respect to photon flux intensity, density and distribution, brightness, photon energy range and resolution, and focal size.

In the future we look forward to expanding our support to scientific users and their research programs within the CLS and afar, including industrial research like the tribology example shown in this paper.

High-resolution gas phase P L-edge photoabsorption spectra of PF_5[1]

Y.F. Hu, L. Zuin, and R. Püttner

Abstract: High-resolution photoabsorption spectra of P 2s and 2p levels of PF_5 are reported. Fine structure, due to spin-orbit and ligand field splittings together with strong vibrational progression, is resolved in the Rydberg region of the P 2p spectrum. A ligand field splitting of 31 meV for the $2p_{3/2}$ orbital is obtained from the fit of the Rydberg transitions. The Franck–Condon fit analysis revealed that the vibrational progression of the higher Rydberg states is different from that of the valence-Rydberg mixed 4s state. In particular, we derived a decrease in P–F bond distances of 12 and 28 pm for the 4s valence-Rydberg mixed state and the high nl Rydberg states, respectively. The natural linewidths of the P 2p levels were determined to be 55 meV.

Key words: PF_5, Rydberg state, vibrational, ligand field splitting, photoabsorption.

Résumé : On a déterminé les spectres photoélectroniques à haute résolution des niveaux 2s et 2p du phosphore dans le PF_5. Dans la région de Rydberg du spectre 2p du phosphore, on a résolu la structure fine qui résulte de couplages spin-orbite et couplages de champ avec une progression vibrationnelle importante. Faisant appel à un ajustement des transitions de Rydberg, on a déterminé que le couplage du champ de ligand de l'orbitale $2p_{3/2}$ est de 31 meV. Une analyse de l'ajustement de Franck–Condon révèle que la progression vibrationnelle des états de Rydberg les plus élevés est différente de celle de l'état 4s de valence de Rydberg mixte. On a, en particulier, mis en évidence des diminutions respectives de 12 et 28 ppm dans les distances des liaisons P–F de l'état 4s de valence de Rydberg mixte et les états élevés nl de Rydberg. On a déterminé que les largeurs de raies naturelles des niveaux 2p du phosphore sont de 55 meV.

Mots-clés : PF_5, état de Rydberg, vibrationnel, dédoublement de champ de ligand, photoabsorption.

Introduction

Excitations of the 2p inner shell of gas phase molecules containing second-row elements such as Si, P, S, and Cl have been traditionally studied by electron energy loss spectroscopy (EELS) (1) with resolutions between 50 meV and 1 eV. Recent developments in soft X-ray beamlines has made it possible to record high-resolution photoabsorption spectra of these molecules using synchrotron radiation. This high resolution of ~30 meV has previously been used to resolve fine features such as vibrational structure and ligand field splitting (also called molecular field splitting) in SiF_4 (2, 3), SiH_4 (4), $SiCl_4$ (5), H_2S (6), SO_2 (7), and HCl (8).

For L-edge of P-containing molecules such as PF_5, several studies of modest resolution (50–200 meV) have been carried out to determine general assignment and oscillation strength (9, 10), to study quasi-isotropic fragmentation of PF_5 (11), and to investigate ligand field splitting in the P continuum 3d orbitals (12). In this study, high-resolution photoabsorption spectra of P L-edge of PF_5 are recorded using the newly commissioned VLS-PGM beamline at the Canadian Light Source (13). An improved photon resolution (15 meV at P 2p or a resolving power of >10 000) and signal to noise ratio allowed us to resolve many more Rydberg transitions. Furthermore, vibrational fine structures due to P–F stretching are resolved in these Rydberg transitions. Vibrational progression fit revealed that the higher Rydberg states exhibit a shorter P–F bond distance upon the 2p excitation than the valence-Rydberg mixed 4s states. A ligand field splitting of 31 meV on the $2p_{3/2}$ level was obtained from the fit.

Experimental

The spectra were recorded with the VLS-PGM beamline at the Canadian Light Source (CLS) (13). The beamline employs a 185 mm PPM undulator, and three variable line-spacing plane gratings are used to cover the photon energy of 5.2–250 eV. A 10 μm slit was used for both entrance and exit slits. With these conditions, a resolving power of >10 000 is expected (14) and achieved (13) over the entire

 doi:10.1139/V07-055 © 2007 NRC Canada

range, with a maximum resolving power of ~50 000 reached at 30 eV photon energy (13). The energy scale was calibrated against Kr 3d and Ar 2p lines.

A double ionization gas cell (10 cm active path length in each chamber) was used for the photoabsorption measurements. The PF_5 gas was commercially available (research grade) and used without further purification. Typical gas pressures of a few mbar (1 bar = 100 kPa) were used in the gas cell. A 0.2 μm carbon window was used between the gas cell and the differentially pumped section to protect the UHV of the beamline. PF_5 is vulnerable to hydrolysis, therefore, the sample introduction line and the gas cell were flushed several times to passivate internal surfaces until no feature due to OPF_3 was detectable.

Results and Discussion

Overview of P 2s and 2p regions

The photoabsorption spectrum of PF_5 in the P 2p and 2s regions is shown in Fig. 1. The general features of the spectrum are in good agreement with those of previous studies (9–12). This spectrum can be divided into four regions: the broad feature in the 2p pre-edge (peaks 1 to 4 shown in the insert); the 2p pre-edge Rydberg region with many sharp structures; the 2p post-edge region (between 145 and 165 eV); and the 2s pre-edge region. Assignments of broad features, with exception of the 2p Rydberg region, are well established (9–12), and they are only discussed briefly here. Peaks 1 and 2 are assigned to transitions to the σ* (a_1') valence type antibonding orbitals from the P 2p spin-orbit components, while peaks 3 and 4 are the spin-orbit components of 2p → σ* (e′) transitions. Three broad and intense resonances (peaks 5, 6, and 7 in Fig. 1) are observed in the 2p post-edge region. They are due to transitions from 2p to the P 3d continuum orbitals, which are split by 3d ligand field splitting with an energy order of: $3d_{xz,\ yz}$ (e″) < $3d_{x^2-y^2,\ xy}$ (e′) < $3d_{z^2}$ (a_1'). Peaks 8 and 9 at 197.39 and 201.76 eV, respectively, are due to transitions of 2s to valence antibonding σ* orbitals (9). Peak positions and assignments of the above broad features are given in Table 1. The Rydberg region (between 141.5 and 145 eV) is very complex with many sharp peaks, and a number of new features are resolved. The assignment of the Rydberg states will be discussed in the next section.

Rydberg region

Figure 2 displays the Rydberg region of PF_5 below the P 2p ionization threshold. This spectrum reveals a rich fine structure that is due to the spin-orbit and ligand field splittings of the P 2p level superimposed by strong vibrational progressions. The solid line through the data points represents the results of a fit analysis, which will be described in detail later. For a basic understanding of the spectrum and the performed fit analysis, we first want to summarize the main results.

Due to the spin-orbit and ligand field splittings, Rydberg series converge towards three different P 2p ionization thresholds. The assignment of the resonances is given by the vertical bar diagrams below the spectrum. It is dominated by the 2p → 4s excitations, which exhibit a vibrational fine structure as shown by the subspectrum around 141.7 eV.

Fig. 1. Overview photoabsorption spectrum of P 2s and 2p levels of PF_5. The broad features are labeled as peaks 1–9. Their energies and assignments are given in Table 1. The sharp features between 141.5 and 150 eV belong to the 2p Rydberg transitions. The details are shown in Fig. 2 and discussed in the text.

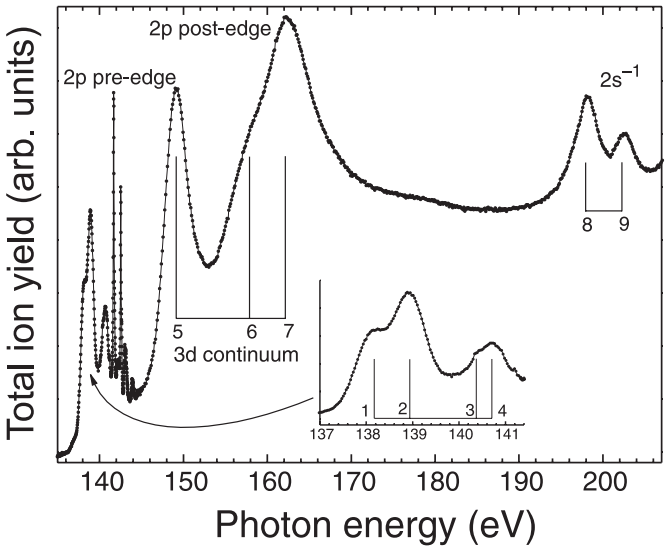

Table 1. Peak energies and assignments of broad features in the P 2s and 2p excitations of PF_5.

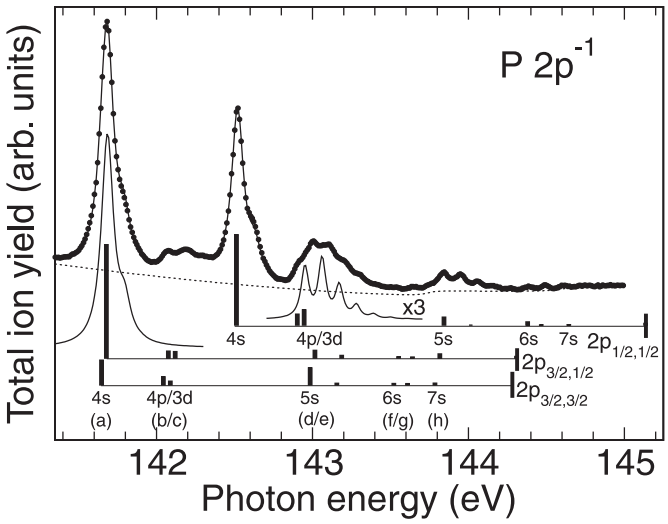
Peak	Energy (eV)	Assignment
2p Pre-edge		
1	138.17	$2p_{3/2} \rightarrow (9a_1')^*$
2	138.95	$2p_{1/2} \rightarrow (9a_1')^*$
3	140.40	$2p_{3/2} \rightarrow (7e'')^*$
4	140.72	$2p_{1/2} \rightarrow (7e'')^*$
2p Post-edge		
5	149.12	$2p \rightarrow 3d_{xz,\ yz}$ (e″)
6	157.48	$2p \rightarrow 3d_{x^2-y^2,\ xy}$ (e′)
7	162.16	$2p \rightarrow 3d_{z^2}$ (a_1')
2s Pre-edge		
8	198.09	$2s \rightarrow \sigma^*$ (e′)
9	202.51	$2s \rightarrow \sigma^*$ (a_2'')

This subspectrum is different from that at about 143 eV, which represents the excitations to the higher Rydberg states. This difference in the vibrational progressions is due to the mixed valence-Rydberg character of the 4s orbital, while all higher nl orbitals show a pure Rydberg character. Such a mixed valence-Rydberg character for the lowest Rydberg states was observed for similar molecules such as SiF_4 (2, 3) or SiH_4/SiD_4 (4) and resulted in a vibrational progression different from that for the higher Rydberg states.



Altogether, eight different 2p → nl Rydberg transitions (as indicated with letters *a* to *h* under the $2p_{3/2,3/2}$ level in Fig. 2) were obtained from the fit analysis. Their energy positions and quantum defects are given in Table 2. Based on the assumption of an almost constant quantum defect for a nl Rydberg series, these transitions can be distinguished into two different groups of series. This also allows us to derive the energy positions of the corresponding ionization thresh-

Fig. 2. Details of the P 2p Rydberg region. The solid line through the data points represents the results of the fit. The background is represented by the dotted line. The three vertical-bar diagrams in the lower part of the figure represent the energy positions and intensities of Rydberg transitions converging towards the spin-orbit and ligand field split P 2p ionization thresholds. The assignments of the Rydberg transitions (*a* to *h* in brackets) is given in Table 2. The solid subspectra show the vibrational progressions used in the fit analysis. Note that the intensity of the subspectrum indicating the vibrational progressions used for the higher nl Rydberg transitions ($2p_{1/2,1/2}$ → transition *c*) is multiplied by a factor of three.

olds. One series (transitions *a, d, f*, and *h*) results in a quantum defect δ≈1.75 and can be readily assigned to the ns Rydberg series since (*i*) the lowest transition shows a valence-Rydberg mixing, which is typical for low ns states and (*ii*) this quantum defect value is similar to that of the 2p → 4s excitations in SiF_4 (2) and $SiCl_4$ (5). Moreover, the transitions *b, c, e*, and *g* give rise to two more Rydberg series due the small splitting between transitions *b* and *c* of 44 meV. They exhibit a quantum defect of ≈1.50 (≈0.50) by assuming that the lowest state of this series has a 4p (3d) character. A quantum defect value of ≈1.50 for np levels agrees well with the results obtained for tetrahedral SiX_4 molecules (2–5). In addition, considerable contributions of the 2p → np(e′) Rydberg excitations were calculated by different groups (11, 12), so that such an assignment is reasonable. In principle, under the trigonal bipyramidal geometry of PF_5 there exist two different np Rydberg series, namely, np(a_2'') and np(e′). However, excitations of the np(a_2'') Rydberg orbitals from the 2p levels are forbidden by dipole selection rules, so that 2p → np transitions alone cannot explain the observed splitting between transitions *b* and *c*.

The nd levels can split into the sublevels nd(e″), nd(e′), and nd(a_1'). In contrast to the np levels, transitions to all three sublevels are allowed by dipole selection rules, as also seen in the 3d splitting in the continuum of the 2p post-edge region. Such a splitting of the different 3d sublevels was observed in the tetrahedral molecules $SiCl_4$ (5) and $Si(CH_3)_4$ (3) and may explain the observed splitting. However, this leads to a quantum defect of ≈0.50, i.e., a value considerable higher than those observed for nd Rydberg transitions of different SiX_4 molecules (2–5). Nevertheless, at least one of the two series under discussion has to have nd character since (*i*) the ns series is clearly identified and (*ii*) the dipole-allowed np(e′) series alone does not explain the experimental findings. It is, however, at present unclear if the second and third series are caused by both 2p → np(e′) and 2p → nd Rydberg transitions or by 2p → nd transitions alone with an observable splitting between the 2p → 3d transitions of different symmetry.

The vibrational fine structure displayed by the subspectra is due to a change of the P–F equilibrium distance upon core excitation. Although PF_5 possesses 12 vibrational modes (15), the vibrational fine structure for the higher Rydberg states can be described by one mode only. This mode could be identified as the symmetric stretching mode and can be understood by a similar change of all bond distances. To extract detailed information on the change of the bond distance, a Franck–Condon fit analysis was performed by calculating the Franck–Condon factors on the assumption of Morse potentials for the ground and the excited states. For this, an algorithm described by Halman and Laulich (16) as well as Ory et al. (17) was used. To describe the ground-state potential energy curve, equilibrium distances and vibrational energy were taken from the literature (15, 18). We used the same potential energy curve and linewidth for all excited states with the exception of the 4s state because of the observed valence-Rydberg mixing. In addition, the same values of spin-orbit and ligand field splittings were assumed for all transitions. The background is represented by the dotted subspectrum and was described by a quadratic function as well as two arctan functions to simulate the unresolved Rydberg states directly below the ionization thresholds. In

© 2007 NRC Canada

addition, two broad Gaussians were applied to account for the broad structures at ≈141 and ≈148 eV (Fig. 1, peaks 4 and 5). Finally, the spectrum was convoluted with a Gaussian of 15 meV to simulate the experimental resolution.

As stated earlier, the fit result shown in Fig. 2 is represented by the solid lines through the data points. The energy positions of the $v''= 0 \rightarrow v'= 0$ transitions, as well as the intensities, are represented by the vertical-bar diagram. The energy positions are also summarized in Table 2 together with their quantum defects and assignments. The ionization energies derived from the assignment and the Rydberg formula are also given. From the fit, we obtained a splitting between the $2p_{3/2,3/2}$ and $2p_{3/2,1/2}$ as well as $2p_{1/2,1/2}$ ionization thresholds of 31(5) and 858(3) meV, respectively. Fits without a ligand field splitting of the $2p_{3/2,3/2}$ level were also performed. However, they resulted in about 35% higher values for χ^2 so that we see evidence for a ligand field splitting in the order of 30 meV.

The very small ligand field splitting in PF_5 is consistent with the small nuclear quadrupole splittings (QS) observed (and predicted by the partial quadrupole splitting method) from Mössbauer spectra on analogous trigonal pyramidal species. For example, the QS on the isostructural $SnCl_5^-$ species are very small or not resolvable (19). Since the QS is proportional to the ligand field splitting at core levels (20), we expect that the ligand field splitting on the Sn, Sb, or P core levels of isostructural species, such as PF_5, will also be very small. It has been reported that the QS on species such as SnF_3^- are about 4 to 5 times that of the QS on $SnCl_5^-$ (21). By a similar proportion, this 31 meV of ligand field splitting on the $2p_{3/2}$ level of PF_5 compares very favorably with a P $2p_{3/2}$ splitting of 146 meV reported for PF_3 (22).

The vibrational progression for the higher Rydberg states exhibits six vibrational substates and we obtained from this progression an increase of the vibrational energy from 101.2 to 110.0(1.0) meV as well as a decrease of the P–F bond distances by 28(2) pm. In addition, a natural linewidth of 55(3) meV is derived from the fit of all higher Rydberg states with the inclusion of the ligand field splitting and a 15 meV photon width. For the fits without ligand field splitting, this value was much larger, 76(3) meV. The vibrational progression for the 4s states with mixed valence-Rydberg character turned out to be much shorter, and we obtained a vibrational energy of 115(2) meV, a decrease of the bond distance by 12(2) pm and a linewidth of 91(3) meV. A vibrational progression based on these parameters describes the spectrum quite well. Nevertheless, these values have to be considered with caution since it is well-known from SiF_4 (2, 3) and SiH_4/SiD_4 (3, 4) that an admixing can lead to considerable excitations of bending modes. Therefore, we conjecture that the decrease in the bond distance essentially describes the actual change upon excitation. However, the higher vibrational energy and in particular the much larger linewidth are only ways of describing the unresolved vibrational modes.

Summary

With the improved photon resolution and signal to noise ratio on the VLS-PGM beamline at CLS, we were able to resolve many new transitions in the P 2p Rydberg region of PF_5. These vibrationally resolved Rydberg states were assigned to excitations from three spin-orbit and ligand field split 2p core levels. A ligand field splitting of 31 meV for the P $2p_{3/2}$ core levels is determined from the fit analysis. The 4s Rydberg state, which has mixed valence-Rydberg character, was shown to have a vibrational progression that is different from that of the pure, higher nl Rydberg states.

Sophisticated calculations are necessary to assign the additional splittings observed in transitions 2 and 3, as it is still unclear which transition ($2p \rightarrow np(e')$, $nd(e'')$, $nd(e')$, or $nd(a'_1)$) contribute significantly to the higher nl Rydberg region of the P 2p spectrum. It would be interesting to apply this high resolution (<15 meV for P 2p levels) to other P-containing molecules for more experimental data.

Acknowledgement

The research described in this work was performed at the Canadian Light Source (CLS), which is supported by Natural Sciences and Engineering Research Council of Canada (NSERC), National Research Council (NRC), Canadian Institutes of Health Research (CIHR), and the University of Saskatchewan. We thank the CLS staff for the operation of the ring and help with the PGM beamline. We thank Mike Bancroft for his continuous support and fruitful discussions on the P 2p ligand field splitting.

Condensation of silicon nanowires from silicon monoxide by thermal evaporation — An X-ray absorption spectroscopy investigation[1]

P.-S. G. Kim, Y.-H. Tang, T.-K. Sham, and S.T. Lee

Abstract: We report a Si K-edge X-ray absorption fine structures (XAFS) study of silicon monoxide (SiO), the starting material for silicon nanowire preparation, its silicon nanowires, and the residue after the preparation of the starting material. The silicon nanowires were condensed onto three different substrates, (*i*) the wall of the furnace quartz tube, (*ii*) a porous silicon substrate, and (*iii*) a Si(100) silicon wafer. It was found that the Si K-edge XAFS of SiO exhibits identifiable spectral features characteristic of Si in 0 and 4 oxidation states as well as in intermediate oxidation states, while the SiO residue primarily shows features of Si(0) and Si(4). The XAFS suggest that SiO is not exactly a simple mixture of Si and SiO_2. The silicon nanowires produced by the process exhibit morphology and luminescence property variations that depend on the nature of the substrate. X-ray excited optical luminescence (XEOL) at the O K-edge suggests an efficient energy transfer to the optical decay channel. The results and their implications are discussed.

Key words: silicon nanowires, thermal evaporation, silicon monoxide, X-ray absorption fine structures, X-ray excited optical luminescence.

Résumé : On a étudié les structures fines d'absorption des rayons X par le silicium à la périphérie K (SFAX) de monoxyde de silicium (SiO), le produit de départ dans la préparation de nanofils de silicium, de son résidu après la préparation et des produits. Les nanofils sont condensés de silicium sur trois substrats différents: (*i*) la surface du tube de quartz de la fournaise, (*ii*) le substrat de silicium poreux et (*iii*) une pastille de Si(100). On a trouvé que les SFAX par le silicium à la périphérie K du SiO présentent les caractéristiques spectrales du silicium dans les états d'oxydation 0 et 4 de même que celles des états d'oxydation intermédiaires alors que le résidu de SiO ne présente que les caractéristiques des états d'oxydation du Si(O) et du Si(4). Les SFAX suggèrent que le SiO n'est pas un simple mélange de Si et de SiO_2. Les nanofils produits par la méthode de préparation présentent une morphologie et des variations de la propriété de luminescence qui dépendent de la nature du substrat. La luminescence optique excitée des rayons X (LOEX) de l'oxygène à la périphérie K suggère qu'il existe un transfert efficace d'énergie vers la voie de désactivation optique. On discute de ces résultats et de leurs implications.

Mots-clés : nanofils de silicium, évaporation thermique, monoxyde de silicium, structures fines d'absorption des rayons X, luminescence optique excitée des rayons X.

Introduction

It is well-established that Si nanowires can be prepared by a number of methods, varying from laser ablation (1, 2), thermal evaporation with or without catalysts (3), and solution chemistry (4). The size, crystal orientation, and morphology vary somewhat depending on the preparation conditions, although all silicon nanowires are inevitably capped with a layer of silicon oxide. Of considerable interest is the thermal evaporation technique using silicon monoxide (SiO) as a starting material. It is generally believed that group IV element monoxides such as CO, SiO, and GeO are good sources for the preparation of elemental nanostructures through disproportionation of MO (M = C, Si, Ge) (3),

$$[1] \qquad 2MO \rightarrow M + MO_2$$

In this study, we tracked the starting material, SiO, its residue, and the products — a Si nanowire web grown on the wall of a quartz furnace tube and two Si nanowire thin films condensed on different substrates, a Si(100) wafer and a po-

Fig. 1. A schematic of the double furnace set up for the experiment (1 Torr = 133.322 4 Pa).

rous silicon film prepared on a silicon wafer — using X-ray absorption fine structure spectroscopy (XAFS) at the Si K-edge. The Si(100) and porous silicon substrate provide a nearly atomically flat and a nanostructure substrate surface morphology of the same element, respectively. Emphasis is placed on the identification of characteristic spectral features of Si and silicon oxide in different oxidation states. XEOL (X-ray excited optical luminescence) with excitation energies at the O K-edge was also used to characterize the optical properties of these Si nanowires (5, 6).

Experimental Procedures

The preparation of silicon nanowires was carried out using a double tube-furnace system, shown in Fig. 1. The reaction took place inside a quartz tube inserted into the furnace. This system provides additional temperature control for the condensation of the products. The starting material SiO was obtained commercially (Alfa, 99.5%). XRD analysis shows that it is amorphous. Several grams of the starting material were placed at one end of the quartz tube reactor set at a high temperature (Fig. 1, furnace to the left, set at 1000 °C). The substrates, an n-type Si(100) wafer and a porous silicon film prepared on a n-type Si wafer (etched electrochemically in HF at 100mA/cm^2 for 20 min) (7, 8) were placed in the middle of the second furnace set at a lower temperature (800 °C). Argon was used as a carrier gas, which flowed through the pre-evacuated tube at a pressure of 740 torr and a rate of 50 sccm during the experiment (1 Torr = 133.322 4Pa). The process was allowed to proceed under these conditions for 20 h, then the furnaces were cooled to room temperature. A brownish ring on the quartz tube and a yellowish brown film on both substrates were clearly visible. SEM images (scanning electron microscopy), recorded at Surface Science Western, and TEM images (transmission electron microscopy), recorded at the Brockhouse Institute of Materials Science of McMaster University, are shown in Fig. 2. They clearly reveal the formation of nanowires with substrate-dependent morphology. The presence of Si and oxygen was revealed by EDX.

The nanowire web condensed on the quartz wall, henceforth denoted SiNW I, is free-standing upon removal from the wall of the quartz tube. The nanowires are relatively short (~1 μm). Silicon nanowires deposited on the Si(100) wafer, henceforth denoted SiNW II, are encapsulated with a thick oxide coating and have an average diameter of >100 nm. Silicon nanowires condensed on porous silicon, henceforth denoted SiNW III, are ~50 nm in diameter on average, typical of most silicon nanowires reported in the literature (3). They are short (~1 μm) and thin (~50 nm), compared with the thick nanowire (>100 nm) on Si(100), denoted SiNW II, while the nanowires condensed on porous silicon, a nanostructured substrate, SiNW III, is the thinnest (<50 nm). After the evaporation process, a significant amount of residue remained and the residue appeared noticeably darker than the brownish starting material. The specimens of interest for XAFS and related studies are summarized in Table 1.

Si K-edge XAFS of SiO, the silicon nanowires film condensed on the three different substrates, the residue of the starting material (henceforth denoted SiO-residue), as well as the three standards, were recorded in total electron yield (TEY) and fluorescence yield (FLY) at the DCM beamline of the Canadian Synchrotron Radiation Facility (CSRF) at the Synchrotron Radiation Center, University of Wisconsin, Madison (800 MeV, ~250 mA injection current). XEOL data, excited with photon energy above the oxygen K-edge, were collected at the CSRF SGM beamline using a JY 100 monochromator equipped with a Hamamutsu photon multiplier as reported previously (9). In all measurements, the substrate's contribution to the TEY is negligible since the thickness of the specimen is larger than the absorption length of Si at the Si K-edge (1.3 μm) and the O K-edge (0.5 μm) (10).

Results and Discussion

Si K-edge XAFS of SiO and its residue

Figure 3*a* shows the Si K-edge XANES (X-ray absorption near edge structure) of SiO, the starting material in the Si nanowire synthesis, in both TEY and FLY together with the

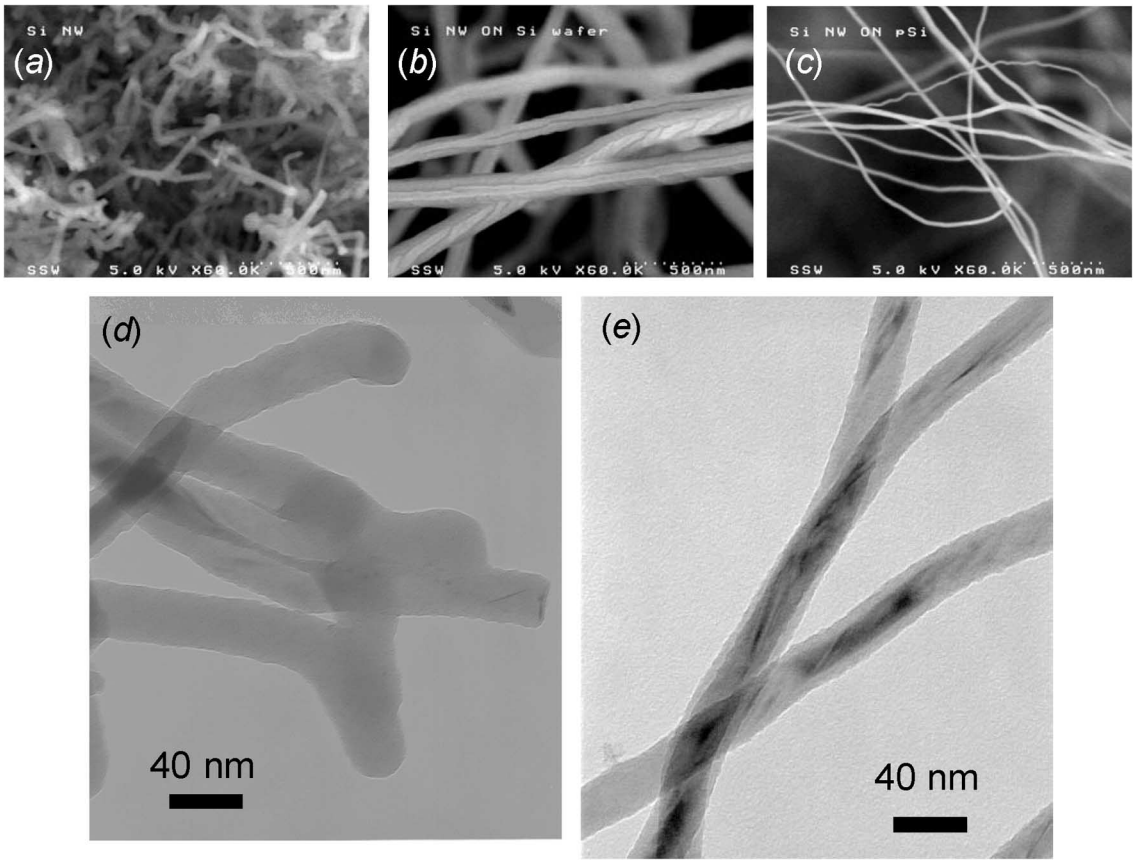
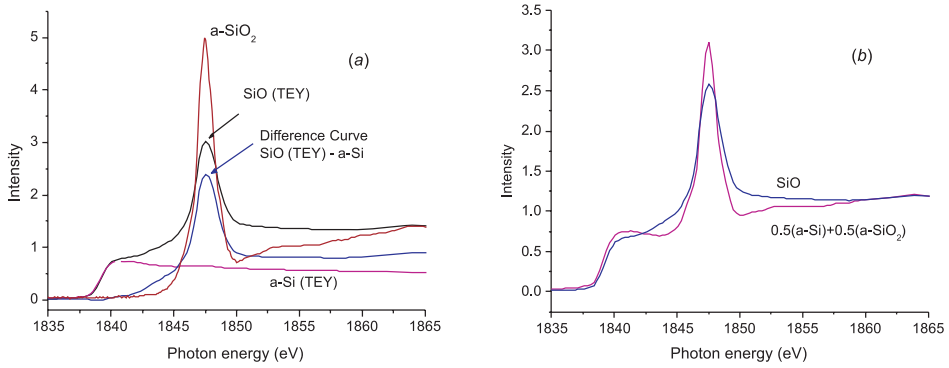
Fig. 2. SEM images of the products from left to right, (*a*) SiNW I, silicon nanowire condensed on the quartz tube, (*b*) SiNW II, silicon nanowire thin films on a Si(100) wafer, and (*c*) SiNW III, silicon nanowire on a porous silicon substrate. Transmission electron microscope images of (*d*) free-standing SiNW I and (*e*) SiNW III (on a porous silicon substrate) show similar results as SEM (obtained with a Philips CM12 operating at the accelerating voltage of 120 KV).





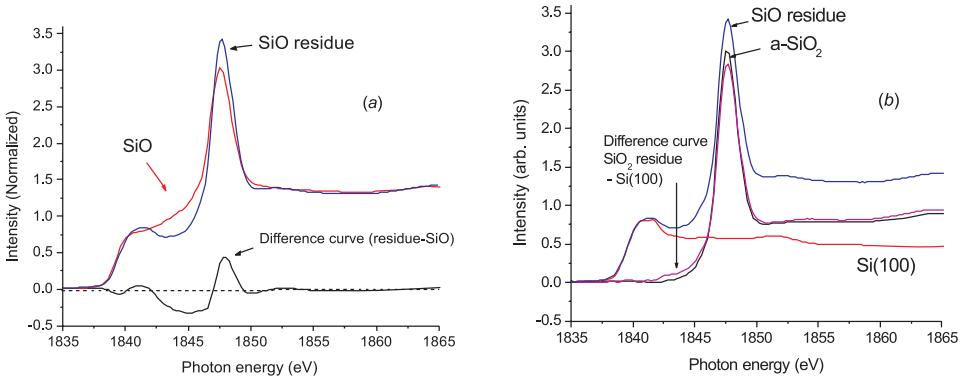


Fig. 3. (*a*) Si K-edge XANES of SiO together with that of amorphous Si and amorphous SiO_2 in TEY; the difference curve between SiO and amorphous Si (normalized to the elemental white line) is also shown. (*b*) A comparison of SiO XANES with a synthesized XANES of 0.5(a-Si) + 0.5(a-SiO_2).

XANES of amorphous Si (a-Si) and amorphous SiO_2 (a-SiO_2) recorded in TEY. The latter two specimens serve as a standard for elemental Si(0) and dioxide Si(4) material with no significant long-range order, respectively. We see from Fig. 3*a* that the resonance characteristics of elemental silicon Si(0) and silicon dioxide Si(4+) are clearly noticeable at 1841 and 1848 eV, respectively, in a-Si and a-SiO_2. The 1841 eV peak arises from the elemental Si 1s to conduction band (p character) dipole transition and is blurred compared with the well-known doublet (band structure) feature of crystalline Si (11). The 1848 eV peak arises from the Si 1s to t_2 transition in a tetrahedral "SiO_4" local environment. These features are clearly present in the SiO XANES, although there is a noticeable broadening. This observation indicates that in SiO, there exists tetrahedral "$SiSi_4$" and "SiO_4" bonding locally with no significant long-range order. Perhaps the most interesting region is the absorption coefficient between 1841 and 1845 eV. This region exhibits con-

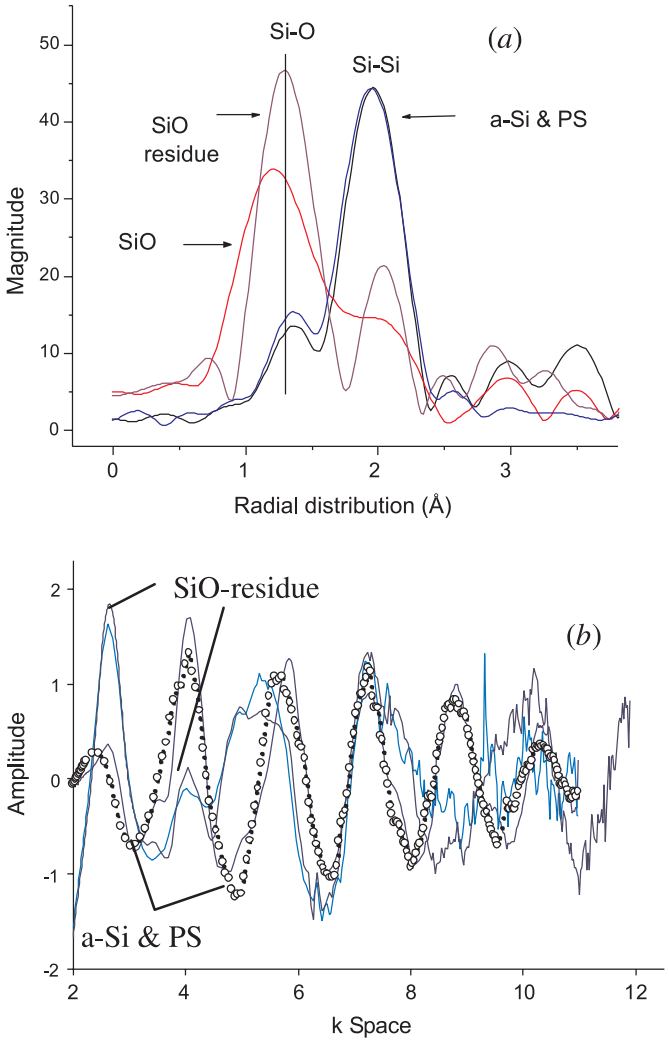
Fig. 4. (*a*) Si K-edge XANES of SiO, its residue recorded in TEY, and the difference spectrum. (*b*) Si K-edge XANES of SiO residue, Si(100), and their difference curve; the Si XANES of a-SiO_2 is also shown.

siderable and continuous absorption intensity between the Si(0) and Si(4) white line indicating the existence of a combination of tetrahedral "Si_xSiO_y" (where x + y = 4 or less) bonding environments locally with Si in the intermediate oxidation states (e.g., 1–3). It has been shown in a study of the Si/SiO_2 interface from a thin film of silicon oxide grown on a silicon substrate that all oxidation states (0 to 4) can exist in the Si/SiO_2 interface where the dioxide is often the dominant oxide component (12). The difference curve between the normalized XANES (TEY) of SiO and amorphous Si (at the elemental Si K-edge, 1841 eV) is also shown in Fig. 3*a*. It clearly reveals the continuous region of absorption intensity between 1842 and 1847 eV. This feature is absent in the a-SiO_2 spectrum. Fig. 3*b* displays a comparison of the SiO XANES with the stoichiometric sum of the a-Si and a-SiO_2 XANES. It is apparent from Fig. 3*b* that SiO is not exactly a mixture of Si and SiO_2. The above observations provide convincing evidence for the presence of intermediate oxidation states of Si in SiO, most probably forming a random network of Si-Si and Si-O bonds.

Figure 4*a* compares the Si K-edge XANES of SiO with its residue in some detail. It shows the XANES recorded in TEY and normalized to unit edge jump, together with the difference spectrum. The white lines, characteristic of the elemental Si (1841 eV) and the Si dioxide (1848 eV) and associated features for the SiO-residue, sharpen noticeably at the expense of the intensity between the two peaks for the starting material; i.e., the absorption features of Si, characteristic of the intermediate oxidation states of Si seen in SiO as shown in the 1842–1847 eV region of the difference curve, decreased markedly in the SiO-residue. This is accompanied by an increase in the intensity of the SiO_2 white line.

Figure 4*b* compares the XANES of the SiO-residue with that of a Si(100) wafer of which the white line associated with elemental Si(0) is scaled to the same height as that for the SiO- residue so that the difference curve will remove the elemental Si contribution to SiO. The difference curve is very similar to that of a-SiO_2, although the oxide resonance is less intense and there is still some residue in the 1842–1847 eV region. These observations are consistent with the notion that SiO has undergone disproportionation to form Si and SiO_2.



It is interesting to note that the structure of SiO is still being debated. For example, Yasatitis and Kaplow (13) first reported X-ray diffraction results of SiO and suggested that SiO assumed a phase of its own, while others believe that SiO disproportionates into Si and SiO_2. More recently, Holt et al. (14) reported X-ray diffraction results using synchrotron radiation. They showed that the radial pair distribution function is similar to that of a mixture of Si and SiO_2 but did not elaborate pending further analysis.

Let us now revisit the structure of SiO from the EXAFS (extended X-ray absorption fine structures) perspective. The XAFS spectrum is conveniently divided into two regions, (*i*) the XANES region, the first ~50 eV above the edge where bound-to-bound and bound-to-quasi-bound transitions take place and (*ii*) the EXAFS region that appears as oscillations and extends as much as 1 keV above the threshold. EXAFS arises from the modulation of the absorption coefficient at the absorbing atom by the interference of the outgoing and the backscattered photoelectron wave (by neighboring atoms). EXAFS is often denoted by $\chi(k)$, where $k = 0.513\ (E - E_0)^{1/2}$ ($Å^{-1}$), is the wave vector and E and E_0 are the photon energy above and at the threshold, respectively. $\chi(k) = A(k)\Phi(k)$, where the amplitude term $A(k)$ contains information about the coordination number, the bond length of the neighboring atom, and the dynamic behavior (Debye–Waller factor). $\Phi(k)$ is the phase function containing information about the phase shifts of the absorbing and backscattering atom and the bond length. EXAFS can be analyzed with Fourier transform (FT) and curve fitting. FT separates the amplitude and phase and yields the phase modified radial distribution of atomic shells around the absorbing atom. FT was used in our analysis. A fully quantitative analysis is not reported here because the presence of a distribution of elemental silicon wires of difference sizes and surface silicon oxide in these systems will hamper the accuracy of the analysis.

Figure 5*a* and 5*b* shows the FT of the Si K-edge EXAFS and the EXAFS of SiO, SiO-residue, porous silicon (PS), and a-Si (Δk ~ 2.7–12 $Å^{-1}$ with k^2 weighting), respectively. PS and a-Si are used as references because they do not exhibit significant long-range order. From the FT, we see that SiO exhibits two main peaks at 1.29 and 2.08 Å, followed by a couple of weak peaks at 2.84 and 3.32 Å. These peaks are significantly broad compared with that of the SiO residue and a-Si in spite of the fact that similar data length (~2.7 – ~11 $Å^{-1}$) was used in the analysis (Fig. 5*b*). This indicates that there is a distribution of Si–O and Si–Si dis-

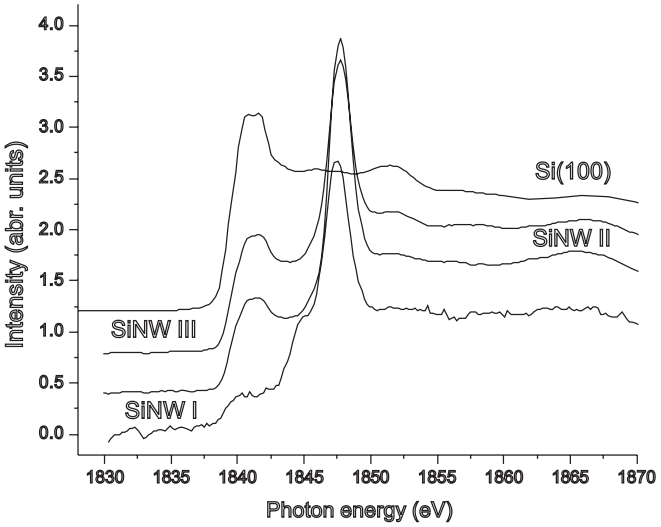

Fig. 5. (*a*) Fourier Transform of the Si K-edge EXAFS (k^2 weighted) of SiO, its residue, porous silicon, and amorphous silicon. The vertical line marks the position of the first Si-O shell in a-SiO_2 (not shown) and the first Si–Si shell in a-Si and PS, which also show the presence of surface oxide. (*b*) The corresponding EXAFS, the open circles represent amorphous silicon; porous siliocn shows similar patterns while SiO and SiO-residue exhibit closely related oscillations as noted.

tances in SiO. The two main peaks correspond to the first shell Si–O and Si–Si interatomic distances in SiO after the usual phase correction (add ~0.3 Å). It is interesting to note that after phase correction, these peak positions, especially the first two peaks, compare favorably with the X-ray diffraction results of SiO of which the radial distribution curve shows peaks at 1.6, 2.41, 3.2, and 3.6 Å (14). The first two peaks in the SiO FT were attributed to the first shell Si–O and Si–Si interatomic distances. Another interesting feature is that the EXAFS Si–Si interatomic distance in SiO, as observed in the FT, deviates towards longer interatomic distance slightly from that in PS and a-Si. This observation supports the notion that SiO is not exactly a mixture of Si and SiO (13).

The FT of the EXAFS of the SiO-residue displays similar radial distribution as that of SiO, except that the first two

Fig. 6. Normalized Si K-edge XANES for SiO residue and the three Si nanowire specimens, SiNW I (quartz), SiNW II (Si wafer), and SiNW III (PS).

peaks in the FT sharpen considerably, consistent with the XANES results. This suggests that the SiO-residue exhibits a higher degree of order and produces more Si(4+) sites upon heating. The Si–O distance in the SiO-residue is similar to that of SiO_2 (not shown for clarity and marked by a vertical line) in the FT, supporting the notion that disproportionation has taken place, although we cannot rule out the presence of unreacted SiO in the residue since a comparison of Fig. 3*b* and Fig. 4*b* indicates that the XANES of SiO-residue, though very similar to, is still not exactly the sum of SiO_2 and Si.

Si K-edge XAFS of SiNW condensed on various substrates

Figure 6 shows the Si K-edge XANES for the three types of Si nanowires collected from the Si nanowire web on the quartz tube (SiNW I) and the two thin films on the Si wafer and porous silicon substrate (SiNW II and SiNW III, respectively) (Table 1). The features are similar to those recorded previously (5–9, 15). All spectra have been normalized to unity edge jump at 1880 eV so that we can compare the relative element and oxide content in these SiNWs by comparing their relative edge jump (5). The absorption at 1880 eV is flat and the absorption coefficient between this energy and the photon energy just below the edge can be used to represent the total edge jump of all Si components (Si in the core of the nanowire and the encapsulating Si oxide) (9, 15). From Fig. 6, we see that the elemental white line at 1841 eV is the least intense in the SINW I specimen (the SiNW removed from the quartz tube) followed by that of SiNW III (the SiNW on porous silicon) and then SiNW II (the SiNW on Si(100)). The silicon oxide to silicon ratio (relative edge jump) estimated from Fig. 6 shows the trend SiNW I > SiNW II > SiNW III, as expected since the shorter and thinner wires have a relatively large surface area of oxides (11). In addition, a significant suboxide feature is observed at 1845 eV in SiNW I, which is not seen in the other samples. This feature is reminiscent of similar features observed in

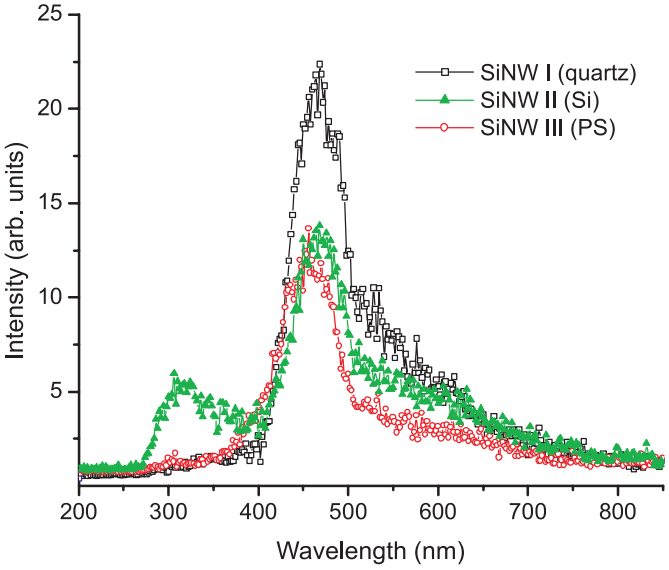
Table 1. Summary of specimens for XAFS and related investigations.

Specimens	Description
SiO	Commercially obtained powder (Alfa, 99.95%)
SiO-residue	Residue of the starting material
SiNW I	Silicon nanowire removed from the quartz tube, free-standing
SiNW II	Silicon nanowire condensed on the surface of a Si(100) wafer
SiNW III	Silicon nanowire condensed on the surface of a porous silicon film (~10 μm) prepared from a n-type Si(100) wafer. (Refs. 7, 8)
a-Si	Amorphous silicon film prepared by IMS, NRC
a-SiO_2	Amorphous silicon dioxide film prepared by IMS, NRC
PS	p-Type porous silicon (20 mA, 20 min) (Ref. 11)
Si(100)	HF refreshed n-Si(100) wafer with a resistivity of ~ 1–10 Ωcm

SiNW chains with oxide nodules (6) and may be associated with the oxygen from quartz as an oxygen source. This is likely due to the short length morphology of the wires with oxide nodules at the tip (Fig. 2). The Si K-edge feature for Si(0) is most blurred in SiNW I, indicating that it is likely to contain a wider distribution of small Si nanostrucutes with a relatively large Si/SiO_2 interface (5–9, 15).



It is worthwhile to comment on the dependence of the morphology on the substrate. It should be noted that no catalyst, such as Au nanoparticles, was used. The quartz surface could be a source of oxygen and be responsible for the relatively high oxide content and the presence of nodules in SiNW I. HF-refreshed Si(100) is a relatively flat surface and the substrate as well as Si from SiO can both serve as the Si source for the growth, leading to thicker wires in SiNW II. Porous silicon is itself a nanosubstrate. Thus, silicon nanowire grown on PS (SiNW III) is expected to be the thinnest, as is observed.

It is generally recognized that as-prepared silicon nanowire is encapsulated by a thick oxide layer with a somewhat rugged Si-oxide interface. It is not too surprising, judging from the SEM (Fig. 2), that the thick SiNW II (diameter of the order of ~10^2 nm) has the least fraction of oxygen since the oxide layer does not thicken dramatically as the size of the nanowire increases, and that the SiNW II is significantly thicker than SiNW I and SiNW III (diameter on the order of ~10 nm), which is significantly longer than SiNW and is without oxide nodules.

XEOL studies of SiNW

Figure 7 shows the XEOL recorded for the three different SiNW specimens with excitation photon energy above the oxygen K-edge (550 eV). The XEOL from SiNW I and SiNW III are very similar to other silicon nanowires, such as oxide-capped silicon nanowire or an alternate Si nanoparticle-silicon oxide chain (5, 6). The emissions at ~460 nm, ~530 nm, and ~630 nm have been attributed to silicon oxide, small nanocrystallites in the nanowire and Si-oxide interface (5, 6). The position of the maximum intensity and branching ratio (peak intensity/total intensity) vary somewhat, reflecting the variation in morphology. The SiNW/Si II specimen exhibits an intense feature at ~310 nm, which is characteristic of emissions from defects of silicon oxide glass (16). It is not absolutely clear at present whether or not this silicon dioxide glass structure is part of the encapsulating oxide on the thick nanowire, since similar emissions in this region are significantly less noticeable from the free-standing SiNW I and SiNW III. This indicates that the morphology and structure of the oxide layer on SiNW II is different from that of the other two SiNW specimens. Returning to the SEM and TEM, we clearly see the unusual textures of the very thick wires in SiNW II. These structures are clearly related to this luminescence in the UV, although the exact details require further investigation.

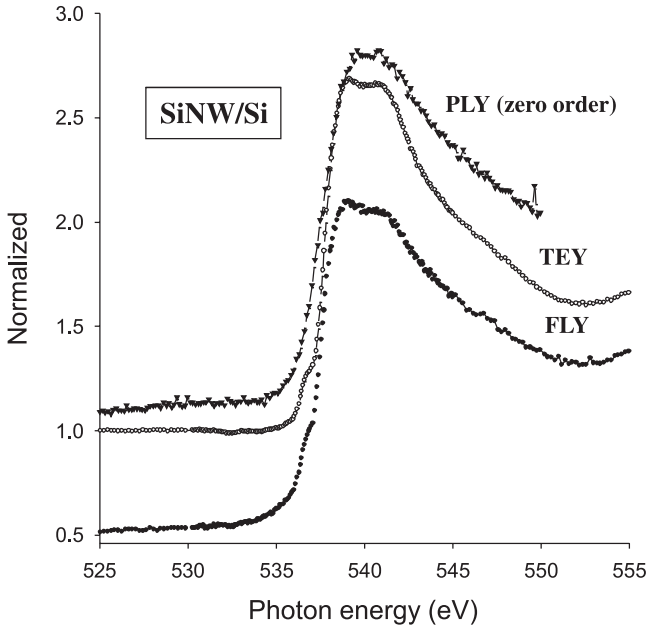


Fig. 7. XEOL of the three Si nanowire samples excited at 550 eV (photon energy).

The corresponding O K-edge XANES in TEY, FLY, and PLY (photoluminescence in zero order) for SiNW III (on a Si wafer substrate) is shown in Fig. 8. The O K-edge spectra recorded at selected wavelengths (~300 nm, 460 nm, 600 nm) are similar, albeit with lower count rates. Similar results are also obtained for the other SiNW samples (not shown). The most noticeable feature in Fig. 8 is the positive edge jump when the absorption is monitored with PLY. This observation indicates that the luminescence is associated with electronic states involving oxygen (17). In other words, the luminescence yield from the specimen with excitation photon energies across the O K-edge tracks the absorption coefficient. Thus the X-ray energy absorbed by oxygen is effectively transferred to the optical decay channel. It must be

© 2007 NRC Canada

Fig. 8. O K-edge XANES of SiNW II (on Si wafer) recorded in TEY, FLY, and PLY (zero order).

noted that neither SiO nor its residue exhibits any detectable XEOL.

Conclusion

We have reported a study of SiO in which we tracked SiO, the starting material in the preparation of silicon nanowires, its residue, SiO-residue, and its products (Si nanowires) deposited on different substrates with X-ray absorption spectroscopy at the Si K-edge and X-ray excited optical luminescence at the O K-edge. We found that despite the similarity, SiO is not exactly a mixture of Si and SiO_2. The chemical reaction leading to the formation of Si nanowire is almost certainly a disproportionation reaction of SiO. The products are silicon oxide encapsulated silicon nanowires with morphology and optical property variations as characterized by SEM, XAFS, and XEOL. While thick Si nanowires with a distinct glassy silicon oxide emission features are formed on a nearly atomic flat Si(100) surface, Si nanowires removed from the quartz tube and deposited on a nanostructured porous silicon surface exhibit typical emission features.

Characterization of the influence of fission product doping on the anodic reactivity of uranium dioxide[1]

Heming He, Peter G. Keech, Michael E. Broczkowski, James J. Noël, and David W. Shoesmith

Abstract: The influence of fission product doping on the structure, composition, and electrochemical reactivity of uranium dioxide has been studied using X-ray diffractometry (XRD), scanning electron microscopy (SEM/EDX), Raman spectroscopy, and X-ray photoelectron spectroscopy (XPS). Experiments were conducted on SIMFUEL specimens with simulated burn-ups (increasing doping levels) of 1.5, 3.0, and 6.0 atom%. As the dopant level increased, the lattice contracted, suggesting the dominant formation of dopant-oxygen vacancy clusters. The smaller than expected lattice contraction can be attributed to the segregation of Zr (one of eleven added dopants) to ABO_3 perovskite-type phases that SEM/EDX shows also contain Ba, Ce, and possibly some U. Raman spectroscopy shows that doping leads to a loss of cubic symmetry, possibly associated with tetragonal distortions. Raman mapping confirms this loss of cubic symmetry and suggests the specimen is not uniformly doped. Electrochemical experiments show that these distortions lead to a decrease in the oxidative dissolution rate of the UO_2 with increased doping density.

Key words: UO_2, X-ray diffraction, electrochemistry, Raman spectroscopy, nuclear fission products.

Résumé : Faisant appel à la diffraction des rayons X (DRX), à la microscopie électronique à balayage (MEB), à la spectroscopie Raman et la spectroscopie photoélectronique des rayons X (SPX), on a étudié l'influence du dopage du produit de fission sur la structure, la composition et la réactivité électrochimique du dioxyde d'uranium. Les expériences ont été réalisées sur des spécimens de SIMFUEL comportant des épuisements simulés (avec augmentation des niveaux de dopage) de 1,5, 3,0 et 6,0 atom%. Une augmentation du niveau de dopant provoque une contraction du réseau cristallin ce qui suggère la formation dominante d'agrégats de dopants et de lacunes d'oxygène. Le fait que la contraction du réseau cristallin soit plus faible que prévu peut être attribué à la ségrégation du Zr (un des onze dopants ajoutés) aux phases ABO_3 de type perovskite pour lesquelles la microscopie électronique à balayage démontre aussi la présence de BA, de Ce et éventuellement d'uranium. La spectroscopie Raman montre que le dopage conduit à une perte de la symétrie cubique qui peut être associée à des distorsions tétragonales. La cartographie Raman permet de confirmer la perte de la symétrie cubique et suggère que le spécimen n'est pas dopé d'une façon homogène. Des expériences électrochimiques montrent que ces distorsions conduisent à une diminution du taux de dissolution oxydante du UO_2 avec une augmentation de la densité du dopage.

Mots-clés : UO_2, diffraction des rayons X, spectroscopie Raman, produits de fission nucléaire.

[Traduit par la Rédaction)

Introduction

A key issue in determining the corrosion performance of nuclear fuel under permanent disposal conditions is the influence of in-reactor burn-up (the amount of thermal energy generated per unit mass of uranium dioxide) on fuel corrosion and dissolution rates leading to the release of radionuclides to groundwater. Fuel burn-up leads to complex and significant changes in the properties of the fuel (1–3) and the extent of burn-up changes with reactor type. For light water reactors (LWR), burn-up is typically in the range 35–45 GWd/MTU, compared with 6 to 12 (average ~8) GWd/MTU for CANDU reactor fuel. However, there is an on-going trend to higher burn-ups (3–6).

Subtle changes in fuel density occur as fabrication sintering porosity is eliminated, and the generation of fission gas bubbles expands the lattice and interlink to form grain boundary tunnels (3, 7). At higher linear power ratings, UO_2 grain growth becomes an important process, and thermal stresses cause cracking of the fuel matrix (3). Collision cascades initiated by fission and alpha recoil events create a large number of atomic defects, but the final defect number is limited through thermal reannealing (8). Inhomogeneity arises at both microscopic and macroscopic levels because of temperature and neutron flux gradients within the fuel as

well as through the segregation of fission products that are insoluble in the UO_2 matrix (1, 3). The influence of neutron irradiation was discussed by Spino and Papaiannou (9) and refs. cited therein. Transmission electron microscopy (TEM) has shown that lattice damage is manifested as an increase in dislocation density and increases with increasing burn-up up to ~40 GWd/MTU. This gives rise to a dislocation cell structure leading to grain subdivision in the outer rim of LWR fuel.

These physical effects are not easily reproduced in nonradioactive analogues of spent UO_2. However, the chemical effects of nonvolatile fission products and actinides, which introduce dopants at substitutional and defect sites in the uraninite structure, can be reproduced in simulated spent fuels (i.e., SIMFUEL) (10–12). For these materials, if the free energy of a fission product oxide (conveniently expressed as an electrochemical potential) is more negative than the oxidation potential of the fuel then it is stabilized as an oxide; otherwise, it will be present as a stable element (metal). In the case of Mo, these potentials are close and it can exist in either oxide or elemental forms. Whether or not a specific fission product that is stable as an oxide remains in solid solution or separates into a distinct precipitate can be determined by its compatibility with the face-centered cubic UO_2 matrix. In many cases, fission products can divide between a range of structures, but an abundance of evidence exists to show that actinides and lanthanides remain in solid solution, with UO_2 (13, 14) substituting for U in the fluorite lattice. The chemical composition and microstructure of nuclear fuel have been studied extensively (1, 3, 15–17) and will only be summarized here.

Elements stable in metallic form (Mo, Ru, Pd, Tc, Rh) tend to congregate in alloy precipitates, generally referred to as ε-particles.

Fission products, which are stable as oxides but incompatible with the UO_2 matrix (Rb, Cs, Ba, Zr, Nb, Mo, Te, Sr), separate into precipitates sometimes referred to as grey phases. These phases tend to have the general composition ABO_3 and to adopt a cubic perovskite-type structure with Ba, Sr, and Cs in the A sites and Zr, Mo, U, Pu, and rare earths in the B sites (1).

Elements that remain as substitutional ions within the fuel matrix include the actinides: Np, Pu, Am, and Cm; the rare earths elements (REE): La, Ce, Pr, Nd, Pm, Sm, Eu, Gd, and Y; and Sr, Zr, Ba, Te, and Nb within the limits of their solubility in the UO_2 and to the extent that they have not precipitated in perovskite-type oxides.

Two fission products are worth special mention: Mo, which can be present in both metallic and oxide forms and hence helps to maintain the fuel close to stoichiometry; Zr, which tends to distribute between perovskite-type phases and the fuel matrix, within which it exerts a major influence on lattice dimensions (18).

Despite the fact many of the elements created during fission are of lower oxidation state than U^{IV}, the excess oxygen created is almost completely neutralized by oxidation of elemental Mo and reaction with the inner Zr-cladding surface (19, 20). The approximate change in CANDU fuel stoichiometry has been calculated to be from $UO_{2.000}$ to $UO_{2.007}$ (21), and O/M measurements confirm the absence of significant fuel oxidation in both low (22) and high (23) burn-up LWR fuel. This slight increase in degree of nonstoichiometry, coupled to the substitution of U^{IV} by trivalent or divalent ions, leads to a substantial decrease in electrical resistivity (24–26).

Considerable evidence exists to show that the fission product and actinide–lanthanide doping of the fuel associated with burn-up exerts a significant effect on the air oxidation of fuel (27–30). These studies, as well as studies on the impure natural form of UO_2 (uraninite) (31) show that both the mechanism of oxidation of UO_2 to U_3O_8 and its rate are influenced by the presence of dopants and impurities. A prominent feature of doped UO_2 is the enhanced kinetic stability of the cubic fluorite structure (compared with that of undoped UO_2) with respect to U_3O_8 formation; oxidation experiments on doped UO_2 show that it retains this structure to higher temperatures and for longer times than the undoped material (27), clearly demonstrating a retardation of the oxidation kinetics.

The analysis of X-ray diffraction (XRD) patterns for partially oxidized samples shows that the oxidation of pure UO_2 (or lightly doped UO_2) proceeds via U_3O_7,

$$[1] \qquad UO_2 \rightarrow U_3O_7 \rightarrow U_3O_8$$

whereas UO_2 doped with larger amounts of dopants (such as Gd) proceeds via U_4O_9,

$$[2] \qquad UO_2 \rightarrow U_4O_9 \rightarrow U_3O_8$$

These observations are supported by studies with SIMFUELs (10, 29), LWR fuels (highly doped and following the reaction path [2] (32)) and CANDU fuels (lightly doped and following reaction path [1] (33)). In addition, the studies of Cobos et al. (29) on specimens with simulated burn-ups covering the whole range up to 200 GWd/MTU also suggest that the kinetics of the transformation, $UO_2 \rightarrow U_4O_9$, are slightly retarded as the dopant concentration increases. This effect is virtually negligible for simulated burn-ups below ~25 GWd/MTU (i.e., over the burn-up range anticipated for CANDU fuels).

Weight gain measurements show that the oxidation of doped UO_2 proceeds to a stoichiometry of $UO_{2.4}$ despite XRD evidence demonstrating the retention of the cubic fluorite structure and the peak broadening and shifts characteristic of U_4O_9 ($UO_{2.25}$) (27, 29). A similar stabilization of U_4O_{9+y} has been observed for UO_2 doped with Pu (34) or Th (35). While the reasons for this retained stability of the fluorite phase remain uncertain, it has been suggested that the dopants may disrupt the defect cluster ordering that is thought to be responsible for the tetragonal distortion of the U_3O_7 lattice (30).

Our previous studies show that under oxidizing aqueous conditions, the corrosion of UO_2 proceeds via a surface oxidation step prior to destruction of the lattice and the release of soluble U^{VI}. In the neutral to slightly alkaline conditions anticipated for waste repository groundwater, dissolved uranium then reprecipitates to form corrosion product deposits,

$$[3] \qquad UO_2 \rightarrow UO_{2+x} \rightarrow {UO_2}^{2+} \rightarrow UO_3 \cdot yH_2O$$

While schoepite formation is observed under laboratory conditions, more complex depositions are anticipated under disposal conditions.

© 2007 NRC Canada

Based on the evidence for air oxidation, one might anticipate an influence of lattice doping on the corrosion process, which involves a similar reaction sequence. In this paper we have studied this possibility using a range of simulated spent fuels (SIMFUELs) ranging from 1.5 atom% burn-up (14 GWd/MTU, typical of normal CANDU fuel), to 3.0 atom% (28 GWd/MTU, representing a reasonable high burn-up CANDU fuel), and 6.0 atom% (56 GWd/MTU, corresponding to a high burn-up LWR fuel). Changes in structure and composition have been analyzed by X-ray diffractometry (XRD), Raman spectroscopy, and X-ray photoelectron spectroscopy (XPS); subsequently, the oxidative reactivity has been determined electrochemically.

Experimental

Fuel specimens and electrode preparation

The three electrodes used in this study were made with 1.5, 3, 6 atom% SIMFUEL pellets, fabricated at Chalk River Laboratories, Ontario, and consist of natural UO_2 doped with nonradioactive fission products (Ba, Ce, La, Mo, Sr, Y, Zr, Rh, Pd, Ru, Nd) to replicate the chemical effects of a CANDU reactor irradiation to the corresponding burn-up (10).

The electrical resistivities (l) of the SIMFUEL specimens are compared with that of an almost stoichiometric pure UO_2 ($UO_{2.001}$) in Table 1. These values are obtained using the current interrupt method during electrochemical experiments as described elsewhere (36). Lattice substitution of U^{IV} by lower valent species causes the expected enhancement in conductivity in the 1.5 and 3 atom% SIMFUELS. However, the 6 atom% SIMFUEL has a considerably higher resistivity than the less heavily doped materials. One possibility is that this material contains a degree of substoichiometry as a consequence of over reduction during sintering. The high concentration of lower-valence lattice substituents may have facilitated O^{2-} loss from the UO_2 matrix, which would partly offset their contribution to the conductivity (37).

Electrodes of these materials were prepared using methodology described elsewhere (38). Prior to use, an electrode was polished (wet) with 600 grit SiC paper, rinsed with distilled deionized water (18MΩcm) and re-polished (wet) with 1200 grit SiC paper. Before immersion into the electrochemical cell, the electrode was ultrasonically cleaned with distilled deionized water for 5 min to remove any polishing particles from the fuel surface.

SIMFUEL characterization

X-ray diffraction

X-ray diffraction patterns were recorded over the 2θ range, 20° to 80°, using Co Kα radiation from a Rigaku Rotafex X-ray diffractometer operating at 40 kV and 40 mA. A scanning step of 0.02° and a scanning rate of 0.2° min^{-1} were used. The diffractometer was calibrated using a standard Si sample. The peaks in the XRD patterns were fitted using Pearson VII functions, and the parameters obtained were employed to determine the cell parameters.

Table 1. Resistivities of various uranium dioxide specimens.

Material	Resistivity (Ωcm)	Gwd (MTU)
$UO_{2.001}$	982	0
1.5 atom% SIMFUEL	182	14
3.0 atom% SIMFUEL	81	28
6.0 atom% SIMFUEL	1120	56

Raman spectroscopy

Raman microspectrometric measurements were carried out with a Renishaw 1000 confocal Raman spectrometer (Renishaw PLC., UK). Raman backscattering was excited with a 632.8 nm excitation wavelength helium–neon laser operating at 50% power to avoid oxidation of the UO_2 sample surface during the measurements. When focused on regions subsequently identified as the perovskite-type grey phases, an operating power of 100% was used and multiple scans were performed to ensure maximum sensitivity. Individual spectra were obtained for an exposure of 45 s over the wavenumber range from 120 to 1400 cm^{-1}. The laser was focused onto the sample using 50× uncoated objective lenses, at a sample spot size of ~1 μm. The Raman spectrometer was calibrated using a Si single crystal, and the correct shift was maintained for all samples.

Raman maps were obtained with the same micro Raman spectrometer. The SIMFUEL samples were mounted on a computer-controlled automated *xy* translation stage with 0.1 μm resolution and 1 μm reproducibility. Mapping was performed point-by-point using 2 μm steps over a 40 μm linear region; spectra were acquired for 45 s at each step. To ensure ideal laser focusing on the rough specimens, an autofocusing system with a 50× magnification in the Z (XX) configuration, was used. This system employed a high-precision piezo translator and feedback signal to automatically track and adjust the laser beam focus on the sample. More than 20 individual Raman spectra were collected under nondestructive conditions at room temperature for each SIMFUEL specimen. Individual spectra were then used to obtain an averaged Raman spectrum.

The Raman images were generated via the same HeNe laser (λ = 632.8 nm) beam and a CCD detector with 2–4 cm^{-1} resolution. Three images centered at 450, 570, and 1150 cm^{-1} were accumulated with (121 × 121) pixels. Typically, images were acquired with one accumulation of 600 s. To avoid damage, a laser power less than 200 μW was used to record images. The absence of laser damage was verified by careful comparison of optical images recorded before and after Raman map collection.

Energy dispersive X-ray results (EDX) and elemental imaging

A Hitachi S-4500 field emission scanning electron microscope (SEM) with an energy dispersive X-ray (EDX) analysis system was used to collect images. A high electron beam voltage of 30 kV was used, resulting in a spatial resolution of <2 nm. Micrographs were recorded at various magnifications (100–5000X). EDX mapping was performed to identify the size, distribution, number density, and elemental composition of regions or particles on the surface; EDX was again performed on an individual particle to determine elemental composition.

© 2007 NRC Canada

X-ray photoelectron spectroscopy (XPS)

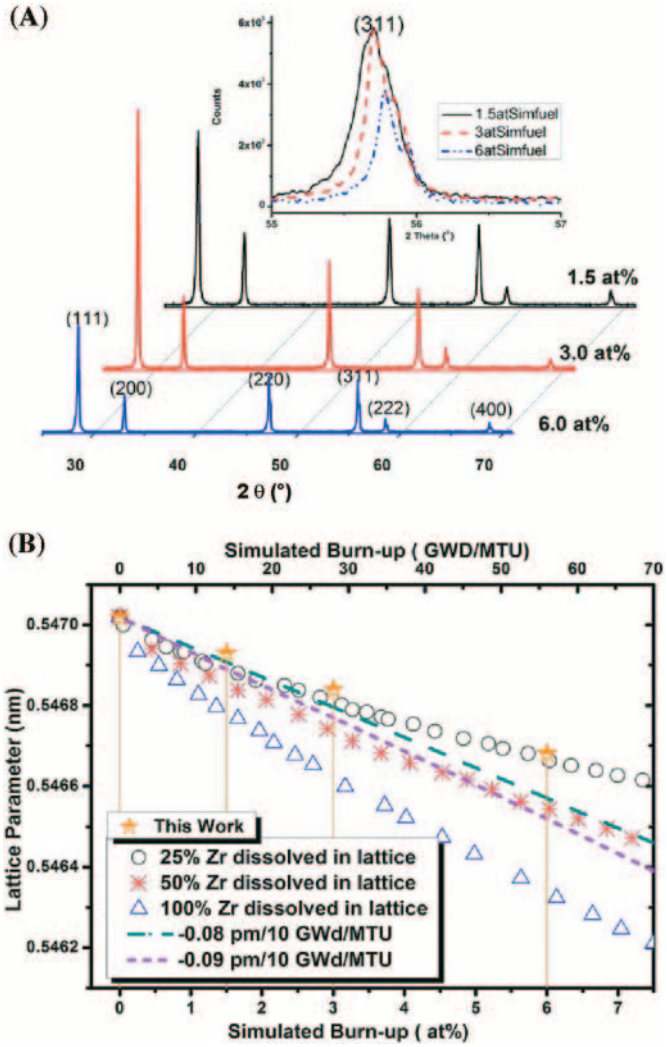
An SSX-100 spectrometer was used to record XPS spectra. Spectra were excited using Al Kα radiation to bombard the surface with high energy monochromatic X-rays ($h\nu$ = 1486.6 eV). The instrument work function was set to give a value of 84.00 ± 0.05 eV for the binding energy of the Au ($4f_{7/2}$) line of metallic gold. The spectrometer was calibrated such that the energy difference between the Cu ($2p_{3/2}$) and Cu ($3p_{1/2}$) lines of copper metal was 875.5 ± 0.1 eV. The position of the C (1s) line at 285.0 eV was recorded and used, when necessary, to correct for surface charging. The U ($4f_{7/2}$) peaks, satellites associated with U ($4f_{5/2}$) band region, and the valence band region of the UO_2 spectrum were recorded. The procedure used to analyze these regions involved a fitting routine that was 70% Gaussian and 30% Lorentzian with a Shirley background correction. A detailed description of the procedure and spectral fitting methods has been published elsewhere (39).

Electrochemical experiments

Solutions

All experiments were conducted in 0.1 mol/L NaCl (pH 9.5) solutions, prepared with distilled deionized water (resistivity of 18.2MΩcm), purified using a Millipore milli-Q-plus unit to remove organic and inorganic impurities, and subsequently passed through Milli-Q-plus ion exchange columns. All chemicals were reagent grade and purchased from Fisher Scientific.

Electrochemical cell and equipment



All experiments were conducted in a standard three-electrode, three-compartment cell. The counter electrode was made of Pt foil spot-welded to a Pt wire. All potentials were measured and are quoted against a saturated calomel reference electrode (SCE). All electrochemical experiments were performed with a Solartron 1287 potentiostat controlled by Corrware Version 2.9 Software. Working electrodes were cathodically cleaned at a potential of –1.2 V for 5 min prior to recording voltammograms at a scan rate of 10 mV s^{-1}.

Results and discussion

X-ray diffraction

The XRD patterns of the three simulated UO_2 fuel specimens with burn-ups of 1.5, 3.0, and 6.0 atom% are given in Fig. 1A. (Please note the use of at% for atom% in all figures.) The similarity in patterns shows that the UO_2 fluorite structure, a cubic arrangement of O^{2-} ions with a U^{4+} cation at alternating cubic body-centered positions, is retained in all specimens. Inspection of the insert in Fig. 1A shows that the position of the fluorite (311) peaks for the SIMFUEL specimens differed slightly. These peaks shifted to higher 2θ values with increased simulated burn-up, which is indicative of a decrease in the lattice parameter and hence, the unit cell volume.

Fig. 1. (A) X-ray diffraction patterns of SIMFUELs with different burnup (atom%). (B) Variation of the lattice parameter for UO_2 with percentage of simulated atomic burn-up for sintered SIMFUEL samples. The dashed and short dashed lines are from Kleykamp (42, 43). The three different symbols (○, ✶, △) show the influence of various Zr contents (18).

The effect of fission product dissolution into the UO_2 lattice is shown in Fig. 1B as a function of simulated burn-up, which gives the measured lattice parameter for each SIMFUEL as well as the value for undoped UO_2 of 0.547 02 nm (29, 40). The results show a close to linear decrease in UO_2 lattice constant with an increase in simulated burn-up, which is in approximate agreement with Vegard law[3] (41) and consistent with fission product and actinide dissolution in the UO_2 matrix to form a solid solution. This trend is also consistent with available literature data, which are also summarized in Fig. 1B. Spino and Papaioannou (9) measured an average lattice contraction of 0.087 pm/10GWd/MTU based on measurements over the burn-up range 0–70 GWd/MTU. A similar trend of 0.08–0.09 pm/10GWd/MTU was obtained by Kleykamp (dashed

[3] Vegard's law is an approximate empirical rule, which holds that a linear relation exists, at constant temperature, between the crystal lattice constant of an alloy and the concentrations of the constituent elements.

line and short dashed line in Fig. 1B) for irradiated LWR-fuels (42) and also for FBR-fuels (43).

The influence of dopants on the UO_2 lattice parameter varies depending on their identity. Tsuji et al. (44) showed that the lattice parameter decreased on doping with Pu but increased on doping with Th and La. Kapoor et al. (45) observed a linear reduction in lattice parameter with increasing Gd content, despite Gd^{3+} having the same ionic radius as U^{4+}. According to Park and co-workers (46, 47), Gd^{3+} is effectively negatively charged (in a U^{IV} lattice) and is neutralized by the creation of an oxygen vacancy. As the dopant concentration increases, Gd^{3+} attracts these vacancies to form dopant-vacancy clusters leading to lattice contraction. This appears to be the dominant mechanism in spent and simulated spent fuels.

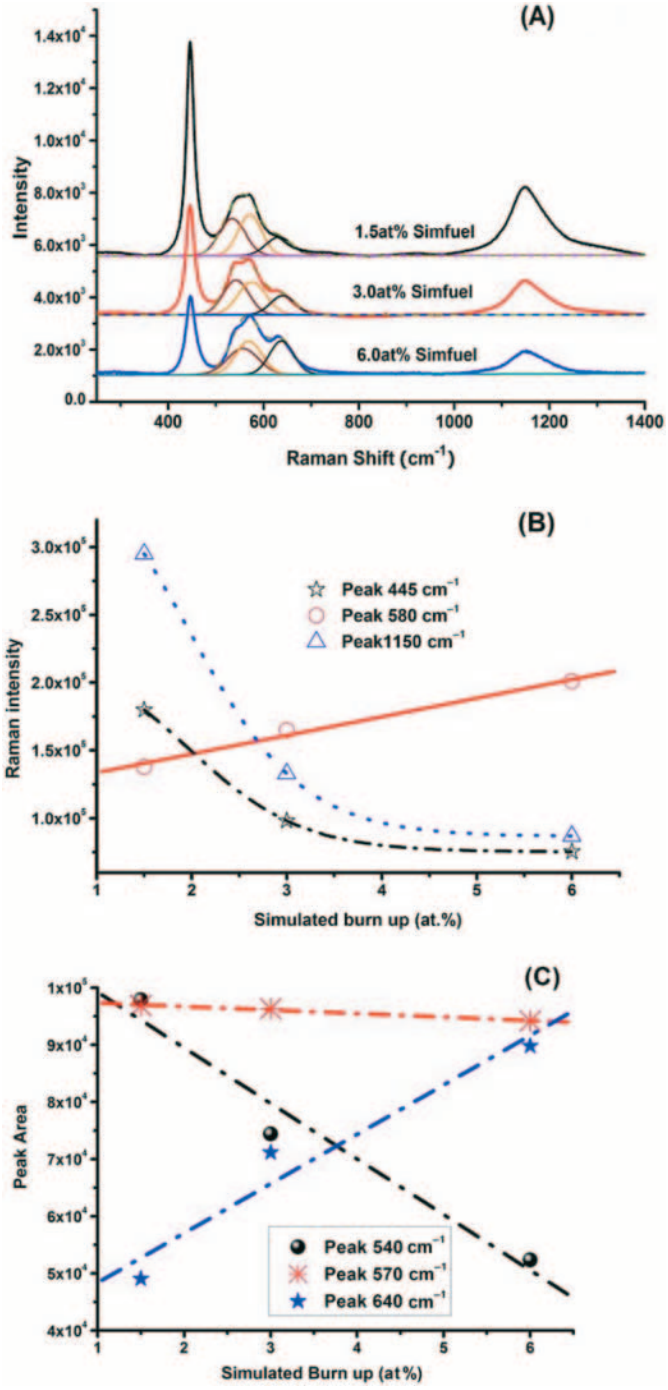

Figure 1B also shows the influence of various Zr contents on the lattice constant, as reviewed by Kleykamp (18). As mentioned earlier, Zr is shared between the UO_2 lattice and the so called grey-phase perovskite (ABO_3). The effective ionic radii of U^{4+} and Zr^{4+} are 114.0 (45) and 84 pm (48), respectively, and because of this significant size differential Zr largely controls the lattice dimension of SIMFUEL and spent fuel. The smaller than expected decrease in lattice parameter with simulated burn-up for our specimens may be attributable to the distribution of Zr, which appears to agree well with the data of Kleykamp if 25% of the Zr is assumed dissolved in the UO_2 lattice (18). Based on an analysis of the composition of grey-phase precipitates in irradiated fuels (1) and on phase equilibrium studies in the system BaO-UO_2-ZrO_2-MoO_2 (49), Kleykamp proposed a maximum of 25% dissolution of Zr in the fuel matrix, the rest being precipitated in the perovskite phase (18). Our data suggests the SIMFUEL UO_2 matrices are only lightly Zr-doped, suggesting major segregation of Zr to an ABO_3 perovskite phase.

Raman spectroscopy

Group theory predicts that UO_2, which possesses a fluorite structure with a space group O_h ($Fm3m$), will possess one Raman active mode (T_{2g}) (50). Consequently, stoichiometric UO_2 should possess a single fundamental vibrational stretch at around 450 cm^{-1}. This peak is triply degenerate (T) with a symmetric (g) stretching mode arising as a result of the fluorite structure (51, 52). A similar vibration at 460 ± 5 cm^{-1} has been reported for other oxides with the fluorite structure (CeO_2, ThO_2) (53). In addition, a broad peak near 1150 cm^{-1} has been observed (54) and attributed to a crystal electric field transition, probably $\Gamma_5 \rightarrow \Gamma_3$. The intensity of this peak was found to increase with a temperature decrease (200 to 5 K), which was taken to be confirmation that it was attributable to electronic scattering (55). These authors claimed this peak could be taken as a fingerprint for a quasi-perfect fluorite lattice, since its intensity decreased as the degree of nonstoichiometry of UO_2 increased, finally disappearing as UO_{2+x} approached $UO_{2.1}$. Experimentally, a very broad peak between 500 and 700 cm^{-1} has been observed and attributed to UO_2 lattice damage, possibly because of the presence of defects leading to a breakdown in selection rules (51). Senanayake et al. (51) showed the presence of two peaks at 578 and 640 cm^{-1} in this region.

Figure 2A shows averaged Raman spectra for the three SIMFUELs obtained by point-by-point (2 μm per step)

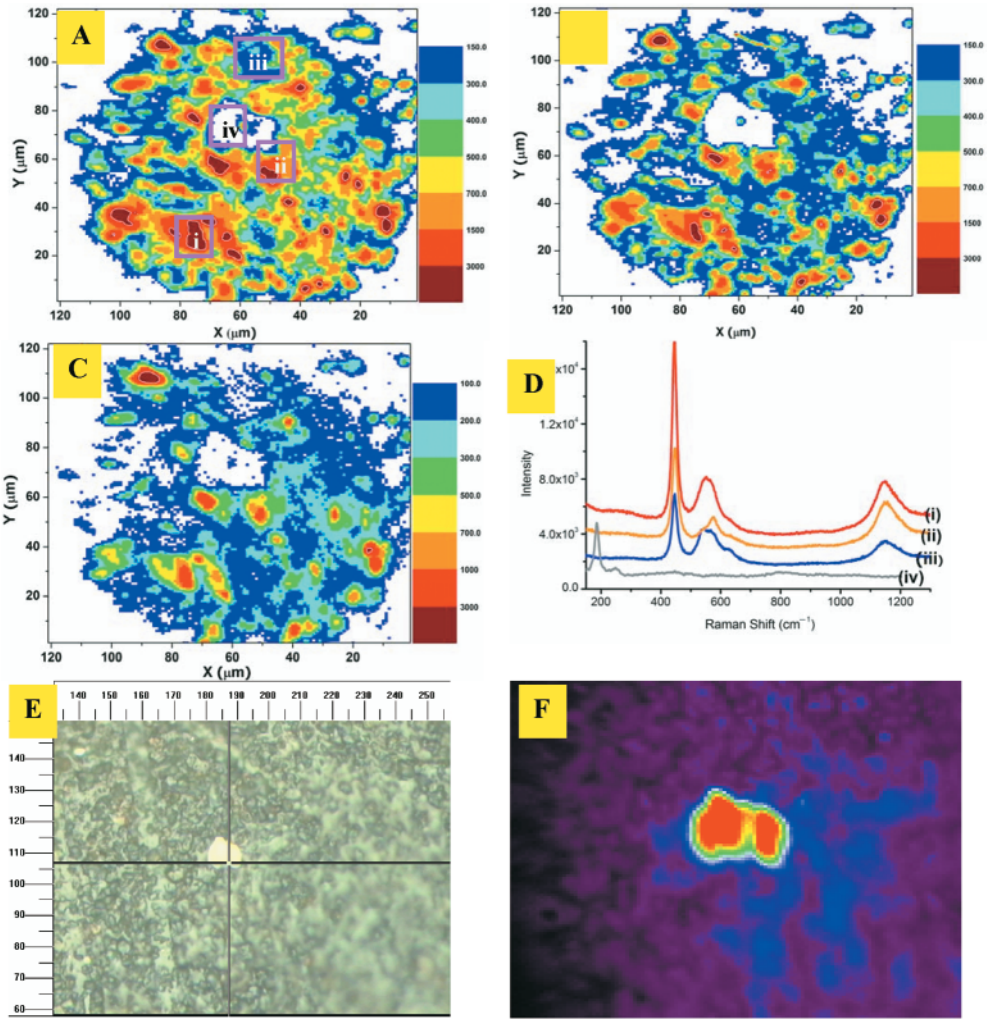

Fig. 2. (A) Averaged Raman spectra for the three different SIMFUELs. (B) Change in intensity of Raman peaks as a function of simulated burn-up. (C) Peak areas calculated from the Raman peaks in the region 500–700 cm^{-1}.

Raman mapping over a 40 μm linear region. All three of the expected spectral features are observed. The characteristic fundamental T_{2g} stretching mode shifts only marginally from 445 to 447 cm^{-1} with increasing simulated burn-up from 1.5 to 6.0 atom%. This shift could be due to the increased concentration of fission products in solid solution with UO_2. Irrespective of whether this shift is significant, both this peak and that at 1140–1150 cm^{-1} show very similar

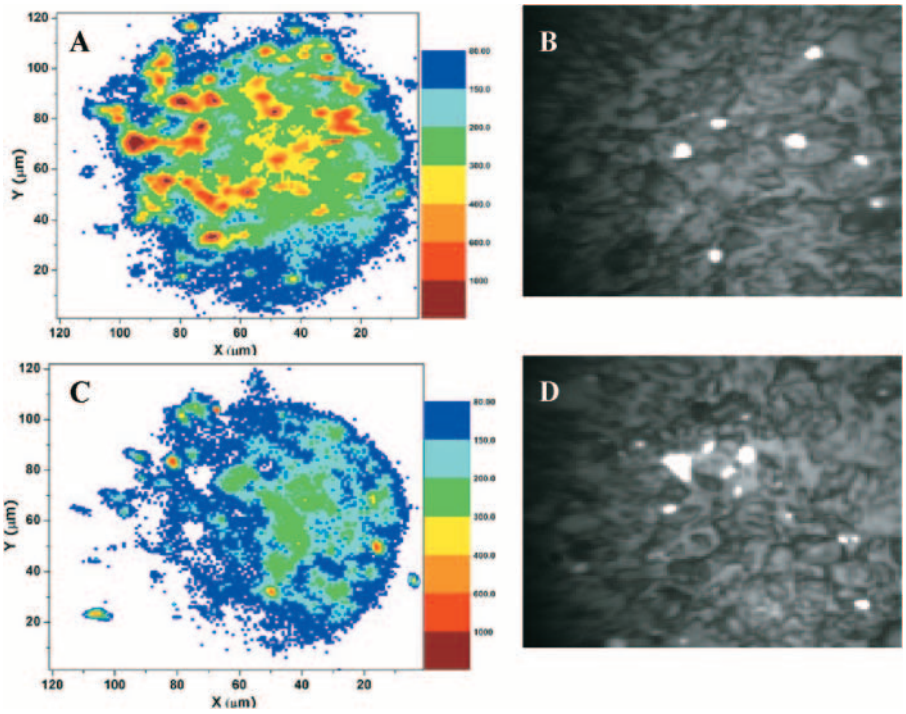
Fig. 3. Raman imaging of polished 1.5 atom% SIMFUEL: (A) Raman image with the color intensity set for the 450 cm^{-1} fundamental vibration; (B) Raman image for 580 cm^{-1}; (C) Raman image for 1150 cm^{-1}; (D) individual Raman spectra taken at the locations noted on the Raman imaging map (A); (E) optical image of the same area of the surface; (F) white light image.

decreases in intensity with increased doping (Fig. 2B). These decreases are accompanied by a small, but significant, increase in the intensity of the broad peak in the range 500 to 700 cm^{-1}. That the changes in these peaks occur in concert eliminates the possibility that they can be attributed to artifacts (such as variations in surface roughness). Previous deconvolutions of the spectra in this region (51) yielded peaks at 578 and 640 cm^{-1}, but Fig. 2A clearly shows the presence of three peaks, as indicated by the deconvolutions shown at 540, 570, and 640 cm^{-1}. Estimates of the area associated with these peaks are plotted in Fig. 2C and show a decrease in area of the 540 cm^{-1} peak accompanied by an increase in area associated with the 640 cm^{-1} peak as the degree of doping increases. By contrast, the area associated with the peak at 570 cm^{-1} is independent of doping level.



The loss in intensity of the fundamental U–O stretch and the crystal field transition accompanied by the increased relative importance of the broad band associated with lattice damage are clearly attributable to the lattice distortions caused by fission product doping. The subtle changes in the peaks at 540 and 670 cm^{-1} (as shown in Fig. 2C) suggest a consistent influence of doping on the rearranged (damaged) fluorite structure. The distortions of the ideal cubic UO_2 fluorite structure to a tetragonal or even orthorhombic structure because of doping are consistent with the lattice contractions observed by XRD and would be expected to decrease the intensities of the peaks at 445 and 1150 cm^{-1} associated with the perfect lattice. The consistent changes in the two peaks associated with the damaged region suggest a regular change in the nature of the defect clusters formed by the dopants and the oxygen vacancies. The origin of the peak at 540 cm^{-1}, which has not been reported by other researchers, remains unknown, but one possibility is that it is attributable to the perovskite structure (ABO_3) formed by the separation of dopants such as Ba, Sr, Zr, Mo in the so-called grey phase. Evidence exists to show that a cubic perovskite structure can exhibit a peak in this wavelength region (53).

Raman imaging

Figures 3A–3C show the relative Raman intensities for three distinct wavelengths as a function of location within an area (121 × 121 μm) of the surface of a 1.5 atom% SIMFUEL specimen. The three wavelengths chosen are those at which the three distinct spectral features are located

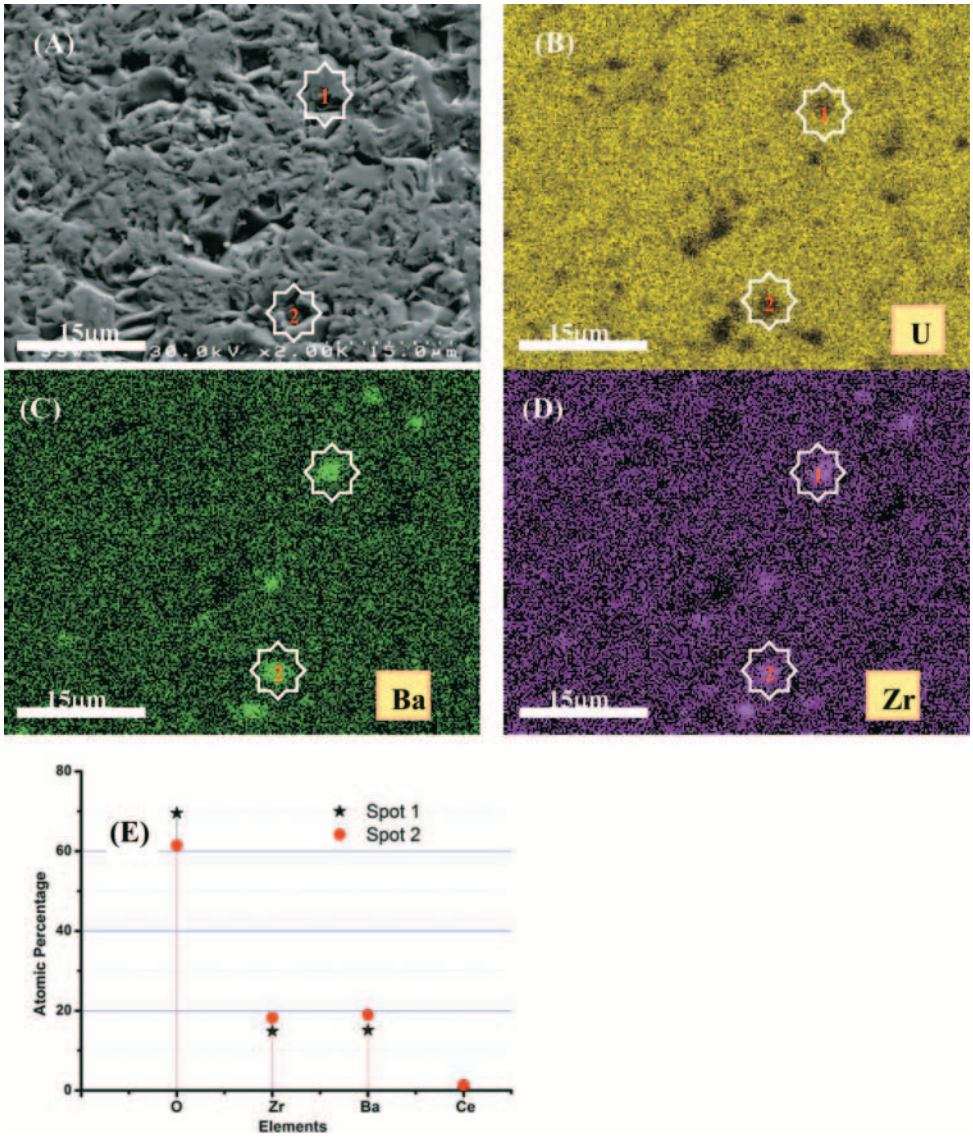
Fig. 4. Raman images obtained on 3.0 atom% (A) and (C) 6.0 atom% SIMFUELs with the colour intensity set for the 450 cm^{-1} fundamental vibration. White light images of the same area of the surface obtained on (B) 3.0 atom% and (D) 6.0 atom% SIMFUELs.

in Fig. 2A (450, 580, 1150 cm^{-1}). Figure 3D shows individual spectra taken at the labeled locations in Fig. 3A, while Fig. 3E shows an optical image of the same area of the surface.

The spectrum recorded at location (*i*) shows that the peak intensities associated with a perfect fluorite lattice (450 and 1150 cm^{-1}) are large compared with that for the peak associated with lattice damage (550 cm^{-1}). Comparison to Fig. 2A indicates that this can be associated with a light doping of this area of the surface. The spectra for the orange and blue sections, labeled (*ii*) and (*iii*) respectively in Fig. 3C, show a decreasing prominence of the peaks at 450 and 1150 cm^{-1} and the splitting of the wide band in the region 500 to 700 cm^{-1}, with an increasing prominence of the peak at 640 cm^{-1}. Comparison to the spectra for the three SIMFUELs in Fig. 2A shows these changes are an indication of increased doping (and therefore, distortion of the cubic lattice structure). Given that the UO_2 grain size in these materials is in the range 8–15 μm (29), the distribution of colour in the Raman image suggests that the SIMFUEL may comprise a network of individual grains with different degrees of doping.

The colour contrast in the white light images Figs. 4B and 4D give some indication of the surface roughness, and comparison to the spectral images shows this contrast does not match the colour distribution, indicating that the differences in Raman features cannot simply be attributable to intensity variations due to differences in surface topography. This indicates that the spectral contrast is primarily associated with the non-uniform doping of the SIMFUEL. Figures 4A and 4C show intensities for the O–U fundamental vibrational stretch (450 cm^{-1}) for the 3 and 6 atom% SIMFUEL specimens, respectively. Comparison of the relative intensities in these maps to the intensity shown for the 1.5 atom% SIMFUEL specimen (Fig. 3A) confirms the destruction of the perfect fluorite lattice as the doping level increases, as implied by the average spectra in Fig. 2A.



Recalling that the rate and extent of surface oxidation under dry air conditions is influenced by the degree of burn-up, the above observations raise the possibility that the corrosion rates of the surfaces will also vary with degree of doping of the surface region. A second possibility is that variations in degree of doping will also introduce the possibility of the separation of anodes and cathodes on the corroding surface, with the more heavily doped areas of the surface being capable of the sustaining higher cathodic reduction rates (of O_2 and H_2O_2).

The spectrum associated with location (*iv*) (Fig. 3A) did not show spectral features characteristic of doped UO_2, with only a weak band at 189 cm^{-1} being observed. The distinctness of this feature is clearly apparent in the optical image in Fig. 3E and the white light (as opposed to laser) image in Fig. 3F. This area is about 10 μm in size making it too large to be an ϵ-particle, which SEM analyses show to be ≤1 μm.[4] A possibility is that it is a perovskite phase, ABO_3, formed during the sintering process. The cubic perovskite structure would give rise to the optical vibrational modes described as $3F_{1\mu} + F_{2\mu}$. The $F_{1\mu}$ modes are IR active, while the $F_{2\mu}$ mode is silent since there are no Raman-active vibrational modes, so this structure or a slight distortion of it should not

Fig. 5. SEM/EDX analyses of a polished 6.0 atom% SIMFUEL specimen. (A) SEM image; (B), (C), and (D) EDX element maps for U, Ba, and Zr, respectively, recorded separately in the same surface region showing the distribution of these different components; (E) EDX spot analysis taken at the locations labelled on the SEM image.

generate a Raman spectrum (53). However, highly nonstoichiometric $BaCe_xZr_{1-x}O_3$ (x = 0.6, 0.8) formed at high pressures, which has a highly distorted perovskite structure, did show a broad band around 200 cm^{-1} (56), i.e., in the range where a band (at 189 cm^{-1}) is observed in our spectra.

Energy dispersive X-ray results (EDX) and elemental imaging

The SEM image in Fig. 5A is a representative example of a polished specimen surface. With the exception of physical defects, there are no defined features in the SEM image. Figures 5B–5D show the U, Ba, and Zr distribution in the surface of 6.0 atom% SIMFUEL, as measured by EDX analysis. A distinguishable attenuation in the U map is observed at locations where bright spots appear for Ba and Zr. This is consistent with the expected formation of perovskite-type oxide precipitates with the chemical form ABO_3 The approximate composition of this phase can be obtained from EDX spot analyses (Fig. 5E), which yield a ratio of Ba–(Zr + Ce)–O of ~1:1:3. It is noteworthy that the O content is higher than expected for the ABO_3 stoichiometry, suggesting the phase may also contain U (57).

X-ray photoelectron spectroscopy

XPS was used to characterize the influence of doping on surface composition. The binding energies of the U4$f_{7/2}$ and U4$f_{5/2}$ peaks are positioned at 379.5 and 390.5 eV (1.5% and 3%), and 379.7 and 390.7 eV (6%), respectively (as shown in Table 2). These positions are comparable to those obtained by others (58) on UO_2 (111) single crystals. The slight shift in the U4f peaks for 6% SIMFUEL is attributable to peak broadening towards the high-binding energy side. The FWHM increases from 2.0 to 2.05 to 2.12 with increasing burn-up, consistent with an increase in multiple oxidation states in the fuel surface.

Table 2. Comparison between the XPS core level parameter values on SIMFUEL specimens with different degrees of simulated burn-up.

	Binding energy (B.E.) (eV)					
SIMFUEL	U $4f_{7/2}$	FWLM	Satellite	U $4f_{5/2}$	FWLM	Satellite
1.5 atom%	379.5	2.00	6.7	390.5	2.00	6.7
3.0 atom%	379.5	2.05	6.7	390.5	2.05	6.7
6.0 atom%	379.7	2.12	6.9	390.7	2.12	6.9

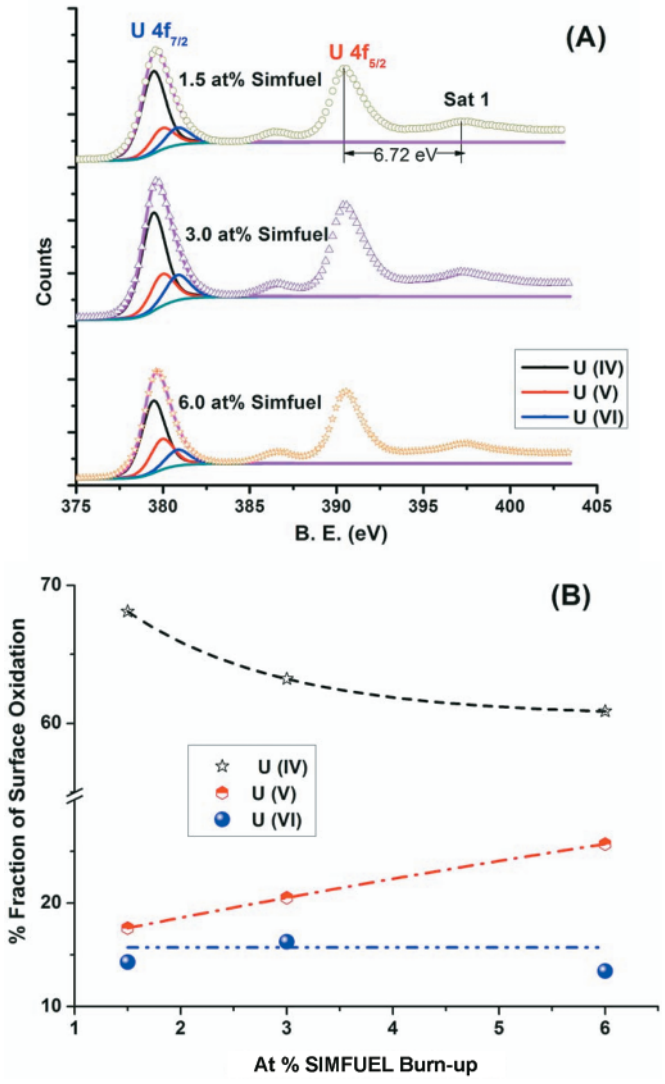

Fig. 6. (A) U $4f_{5/2}$ and U $4f_{7/2}$ regions of the XPS spectra recorded on 1.5, 3.0, and 6.0 atom% burn-up SIMFUELs; (B) relative fractions of all three oxidation states as a function of burn-up.

This change in surface composition is confirmed by the peak deconvolutions shown in Figs. 6A and 6B. The procedure used in peak fitting is described elsewhere (39). The position of the satellite peaks (Fig. 6A) at 6.7 eV (1.5 and 3%) and 6.9 eV (6%) are consistent with the 7 eV expected for reduced UO_2. While the peak deconvolutions (Fig. 6B) show U^{IV} remains the dominant oxidation state, increased doping leads to a measurable increase in the U^V content at the expense of U^{IV}. The U^{VI} content of the surface is independent of the degree of doping and almost certainly arises from air oxidation (on transfer of the specimens from the polishing pad to the vacuum chamber of the XPS spectrometer). An increase in U^V content is to be expected as the level of RE^{3+} cation doping increases.

Our previous studies suggest that an increase in the U^V content of the surface will lead to an increased density of the donor–acceptor sites utilized in cathodic reactions, such as the reduction of O_2 (59) and H_2O_2 (60). Since these two oxidants are the primary products of the alpha radiolysis of water, catalysis of their reduction could increase the fuel corrosion rate. In the case of H_2O_2, rapid chemical oxidation of the surface appears able to create catalytic donor states (U^V states), and hence, we might expect their variation due to the RE^{3+} doping to be relatively insignificant in catalyzing H_2O_2 reduction. However, this may not be the case for other cathodic processes, in particular O_2 reduction.

Electrochemistry

Figures 7A and 7B show voltammograms recorded in unbuffered and borate buffered solutions for the three SIMFUEL specimens. As discussed in detail previously (39), oxidation of UO_2 occurs in two stages. In region 1 (up to 0.2 V vs. SCE), the surface of UO_2 is oxidized to UO_{2+x}, a process that involves injection of O^{2-} into the vacant sites in the fluorite lattice accompanied by the creation of U^V states. In region 2, (>0.2 V vs. SCE), further oxidation of this thin surface layer to the U^{VI} state and its dissolution as UO_2^{2+} occurs. In the neutral to alkaline solution employed in our experiments, UO_2^{2+} has limited solubility and accumulates on the fuel surface as a $UO_3{\cdot}yH_2O$ deposit. The cathodic peak in region 3 on the reverse scan is due to the reduction of this anodically formed dual layer (UO_{2+x} / $UO_3{\cdot}yH_2O$). In unbuffered solution, however, anodic dissolution can lead to the development of locally acidified conditions (due to UO_2^{2+} hydrolysis) in the asperities in the rough electrode surface (Fig. 5A). In buffered solution, this acidification would be expected to be at least partially avoided.

The similarity in the anodic oxidation sequence,

$$[4] \qquad UO_2 \rightarrow UO_{2+x}\ (UO_3{\cdot}yH_20)$$

to that observed under dry air conditions (reaction sequences [1] and [2]) is worth noting. In both cases, the first stage involves modification of the UO_2 fluorite lattice by the incorporation of interstitial O^{2-}, while the second stage involves lattice destruction by recrystallization (in air) or dissolution and redeposition (in aqueous solution). Inspection of Figs. 7A and 7B shows the anodic currents in both region 1 ($UO_2 \rightarrow UO_{2+x}$) and region 2 ($UO_2 \rightarrow UO_2^{2+}$ / $UO_3{\cdot}yH_2O$) decrease as the extent of simulated doping is increased, sug-

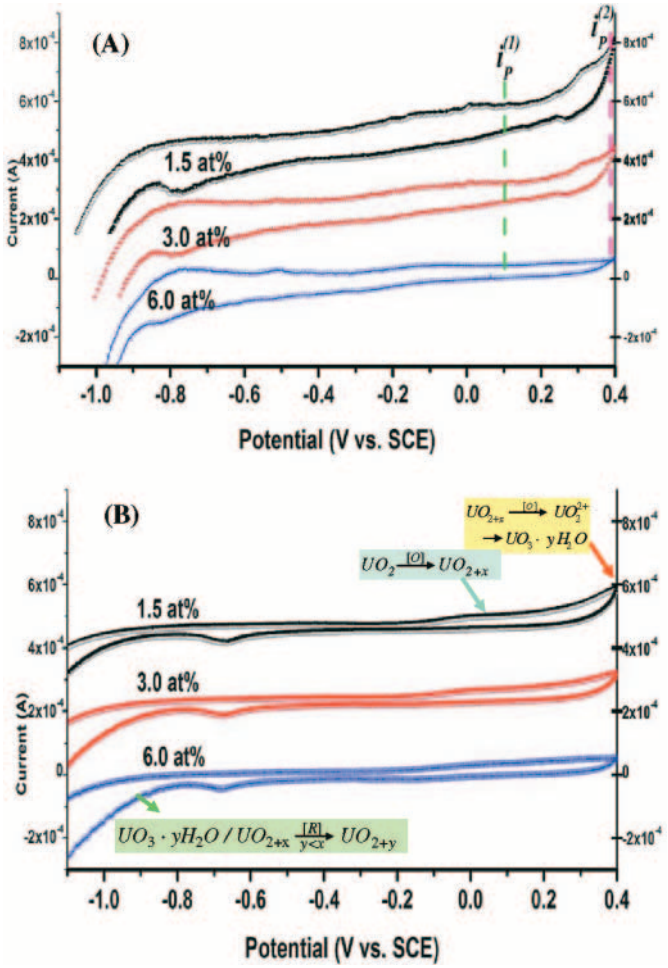
Fig. 7. Voltammograms recorded on 1.5, 3.0, and 6.0 atom% burn-up SIMFUELs at room temperature in (A) 0.1 mol/L NaCl at pH 9.5 and in (B) borate buffered solution of 0.1 mol/L NaCl at pH 9.5.



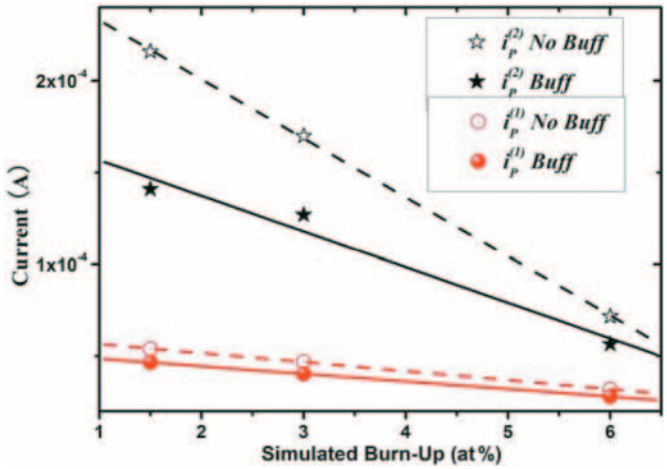


Fig. 8. Current densities for oxidation ($UO_2 \rightarrow UO_{2+x}$, $i_p^{(1)}$) and dissolution ($UO_{2+x} \rightarrow UO_2^{2+}$, $i_p^{(2)}$) in buffered and unbuffered solutions as a function of simulated burn-up (data taken from Fig. 7).

gesting a similar influence of lattice doping on oxidation under aqueous conditions as observed for air oxidation.

To emphasize this influence, we have plotted the currents at 0.1 V (representative of region 1) and 0.4 V (vs. SCE, representative of region 2) for all three SIMFUEL specimens in Fig. 8. At 0.1 V the decrease in current with increase in simulated burn-up is small and effectively independent of solution buffering. This indicates a measurable but marginal influence of doping on the surface modification of the UO_2 fluorite lattice, consistent with the minor influence of doping on the first stage of the air-oxidation process (at these burn-up levels). The lack of any effect of buffering is not surprising, considering the negligible solution pH change caused by the conversion of a thin surface layer to UO_{2+x}.

By contrast, the influence of doping on the anodic destruction by conversion of UO_2 to U^{VI} followed by dissolution is much more marked, similar to the second (recrystallization) stage of the air oxidation process. As expected, the presence of a buffer decreases the current for dissolution of all SIMFUEL specimens (at 0.4 V vs. SCE), and this effect becomes less prominent as the extent of doping is increased. The very small influence of buffering on the anodic dissolution current for 6 atom% SIMFUEL reinforces the argument that doping to this level stabilizes the fluorite surface against anodic oxidation and (or) dissolution, thereby preventing the formation of soluble and hydrolysable UO_2^{2+}.

By analogy to the air oxidation behaviour, it can be speculated that doping stabilizes the UO_{2+x} fluorite structure against further oxidation to produce soluble species by interfering with the defect cluster ordering that would lead to destabilizing tetragonal distortions. Our XRD data demonstrate that the primary influence of dopants is to induce the lattice contraction indicative of the formation of dopant vacancy clusters. It is possible that this retards anodic oxidation at high doping levels by reducing the number-density of available vacancy sites for O^{2-} incorporation, the first step in the anodic oxidation and (or) dissolution process.

Summary and conclusions

The addition of fission product dopants to UO_2 to simulate the influence of in-reactor burn-up leads to a contraction of the fluorite lattice, which is expected if dopant-vacancy (RE^{III}-O^{V}) clustering occurs.

EDX mapping demonstrates the presence in the matrix of ABO_3 perovskite particles containing primarily Ba and Zr, but also a small amount of Ce, and possibly U. The segregation of Zr to such particles accounts for the smaller than expected measured lattice contraction.

Raman spectroscopy confirms that the fluorite lattice structure is significantly disturbed as the doping level is increased. The spectral responses due to the fundamental O–U stretch and a crystal electric field transition, indicative of a cubic fluorite lattice, decrease in intensity with increasing doping level, while responses indicating a damaged lattice increase. Raman imaging at the wavenumbers associated with these responses shows that doping of the matrix is non-uniform, with some grains being more heavily doped than others.

XPS indicates an increase in U^{V} concentration, at the expense of U^{IV}, with increased doping.

© 2007 NRC Canada

Voltammetric experiments show that the currents, due to oxidation first of the fluorite lattice to UO_{2+x} and then to dissolved UO_2^{2+} and deposited $UO_3{\cdot}yH_2O$, are suppressed as the extent of doping increases. This suppression is particularly marked for the 6 atom% SIMFUEL and is consistent with the influence of doping on the air oxidation of SIMFUELs and spent fuels. This affect is tentatively assigned to the formation of dopant-vacancy clusters that stabilize the fluorite lattice against the formation of destabilizing tetragonal distortions and reduce the availability of oxygen vacancies which facilitate oxidation and then dissolution.

Pulsed-field ionization electron spectroscopy and molecular structures of copper-(pyridine)$_n$ (n = 1, 2) complexes[1]

Xu Wang, Bradford R. Sohnlein, Shenggang Li, Jason F. Fuller, and Dong-Sheng Yang

Abstract: Cu-(pyridine)$_n$ (n = 1, 2) complexes are prepared in a pulsed laser ablation cluster source and identified using laser photoionization time-of-flight mass spectrometry. High-resolution electron spectra of these complexes are obtained using pulsed-field ionization zero electron kinetic energy (ZEKE) photoelectron spectroscopy. Metal-pyridine and pyridine-based vibrational modes are identified by comparing the ZEKE spectra with previous spectroscopic studies of isolated pyridine, pyridine adsorbed on metal surfaces, and other Cu complexes. Ground electronic states and molecular structures are determined by comparing the ZEKE spectra with ab initio and multidimensional Franck–Condon factor calculations. Metal-pyridine bond energies of the neutral complexes are derived from the measured ionization energies and thermochemical relations. The mono-ligand complex has C_{2v} symmetry in both the neutral and ionized forms, whereas the di-ligand complex has an eclipsed pyridine configuration with D_{2h} and C_2 symmetries for the ion and neutral species, respectively. Although both the mono- and di-pyridine Cu complexes are formed by Cu binding to nitrogen atoms, important binding differences are found between these two complexes.

Key words: pulsed-field ionization, ZEKE, photoelectron, ab initio, copper-pyridine complexes.

Résumé : On a préparé des complexes de Cu(pyridine)$_n$ (n = 1, 2) dans une source d'agrégat avec ablation au laser pulsé et on les a identifiés par spectrométrie de masse à temps d'envol avec une photoionisation au laser. On a déterminé les spectres électroniques à haute résolution de ces complexes en faisant appel à la spectroscopie photoélectronique à l'aide d'une ionisation à champ pulsé avec une énergie cinétique électronique égale à zéro (ECEZ). On a identifié les modes vibrationnels du complexe métal-pyridine et ceux à base de pyridine en comparant leurs spectres à ECEZ avec ceux d'études spectroscopiques antérieures de la pyridine seule et de la pyridine adsorbée sur des surfaces métalliques ainsi que ceux d'autres complexes du Cu. On a déterminé les états électroniques fondamentaux et les structures moléculaires en comparant les spectres ECEZ avec des calculs ab initio et des calculs du facteur de Franck–Condon multidimensionnels. On a évalué les énergies de la liaison métal-pyridine de complexes neutres à partir d'énergies d'ionisation mesurées et de relations thermochimiques. Le complexe monocoordonné possède une symétrie C_{2v} tant dans ses formes neutres qu'ionisées alors que le complexe dicoordonné comporte une configuration avec une pyridine éclipsée de symétries D_{2h} et C_2 respectivement pour les espèces ioniques et neutres. Même si les complexes du cuivre comportant un ou deux molécules de pyridine se forment par la fixation du cuivre aux atomes d'azote, on a trouvé qu'il existe d'importantes différences dans les liaisons de ces deux complexes.

Mots-clés : ionisation à champ pulsé, ECEZ, photoélectron, ab initio, complexes du cuivre avec la pyridine.

Introduction

Pyridine (C_5H_5N) is the best-known heterocyclic aromatic nitrogen ligand, and its coordination chemistry has been extensively studied in condensed phases (1). The majority of pyridine compounds use the nitrogen electron pair to bind with metal ions in a monodentate mode (1), although aromatic ring coordination is also possible (2). Similar to the condensed-phase coordination chemistry, studies of pyridine adsorption on metal surfaces (3–10) and binding to individ-

ual metal atoms or ions (11–18) have shown both nitrogen and ring binding modes.

Studies of pyridine adsorption on copper surfaces have been reported using surfaced-enhanced Raman spectroscopy (3, 7), reflection-adsorption IR spectroscopy (4), photoelectron diffraction (5), temperature programmed desorption, low energy electron diffraction and electron stimulated desorption ion angular distribution (6), photoelectron spectroscopy (8, 9), and near edge X-ray absorption fine structure analysis (10). In these studies, a number of possible adsorption geometries of pyridine were considered on a metal surface. These geometries included vertical absorption via the N lone-pair electrons, tilted adsorption via both the lone-pair electrons of the N atom and the π electrons of the aromatic ring, flat adsorption via the π electrons, and edge on adsorption through the N and C atoms. Pyridine was found to adsorb on Cu (110) via the nitrogen lone pair orbital. At low coverage, the ring plane of pyridine was perpendicular to the surface; at high coverage, it was tilted away from the surface normal. In the gas phase, the most stable structures of pyridine association complexes with a neutral Cu atom (12, 16), small Cu clusters (18), or a Cu^+ ion (16) were predicted to be formed by metal σ interactions with the nitrogen lone-pair electrons by density functional theory (DFT) or ab initio calculations. The bond dissociation energy of Cu^+-pyridine was determined by photodissociation spectroscopy (274 kJ mol^{-1}) (12) and collision-induced dissociation (CID) [246 (10) kJ mol^{-1}] (11), and that of Cu^+-$(pyridine)_2$ was determined by ion-ligand exchange equilibrium measurements [495 (25) kJ mol^{-1}] (15). The ligand field spectra of Cu^{2+}-$(pyridine)_n$ (n = 4–7) were recorded in the UV region, which indicated d–d transitions in these doubly charged complexes (17, 19). In spite of these experimental and computational studies, very little gas-phase electronic-vibrational spectroscopy has been reported for metal complexes with one or more pyridine molecules, except for a recent study of Cu-pyridine (14). Such spectroscopic measurements should provide direct evidence about the structures and bonding for these interesting systems.

In this work, we report pulsed-field ionization zero electron kinetic energy (ZEKE) photoelectron spectroscopy of Cu-$(pyridine)_n$ (n = 1, 2). The ZEKE spectrum of Cu-pyridine exhibits a number of new features compared with a previous study (14), which allows the identification of additional copper-pyridine and pyridine-based vibrations. The spectrum of Cu-$(pyridine)_2$ is reported for the first time. From this spectrum, the ionization and bond energies of the bis(pyridine) complex are determined. By comparing the spectra of the mono and bis(pyridine) complexes, interesting bonding differences are revealed in these two complexes.

Experimental and computational methods

The experimental setup has been described in a previous publication (20). Copper-$(pyridine)_{1,2}$ complexes were prepared by reactions of copper atoms with the vapor of pyridine (99.9+%, Sigma-Aldrich) in molecular beams. The metal atoms were produced by pulsed laser vaporization of a copper rod (99.9%, Alfa Aesar) with the second harmonic output of a Nd:YAG laser (532 nm, ~3 mJ, Quanta-Ray GCR-3) in the presence of He or Ar carrier gas (ultra high purity, Scott-Gross) at ~50 psi. The carrier gas was delivered by a home-made piezoelectric pulsed valve (21). The metal rod was translated and rotated by a motor-driven mechanism to ensure that each laser pulse ablated a fresh surface. At room temperature, vapor of the ligand was introduced downstream of the ablation by a stainless steel capillary to a small reaction chamber (~1.5 mL), where the pyridine molecules interacted with the metal atoms entrained in the carrier gas.

The copper complexes in the molecular beams were identified by photoionization time-of-flight mass spectrometry. Ionization was carried out by a frequency-doubled dye laser (Lumonics, HD-500), pumped by a XeCl excimer laser (308 nm; Lumonics PM-884). The production of Cu-$(pyridine)_{1,2}$ complexes was maximized by optimizing the timing and power of the vaporization and photoionization lasers, the amount of the ligand vapor, and the backing pressure of the carrier gas. Prior to ZEKE experiments, ionization thresholds of the complexes were measured by recording the ion signals as a function of laser wavelength. ZEKE electrons were produced by phototexcitation of neutral molecules to high-lying Rydberg states, followed by a ~3 μs delayed, pulsed electric field ionization (1.2 V cm^{-1}, 100 ns) of these Rydberg states. A small dc field of ~0.08 V cm^{-1} was applied to help separate ZEKE from kinetic electrons produced by direct photoionization. The pulsed electric field was generated by a delay pulsed generator (Stanford Research System DG535). The ZEKE spectra were recorded by scanning the photoexcitation laser while monitoring the intensity of the ZEKE signal. The ion and electron signals were detected by a dual microchannel plate detector (Galileo), amplified by a preamplifier (Stanford Research System SR445), averaged by a gated integrator (Stanford Research System SR250), and recorded in a laboratory computer. Laser wavelengths were calibrated against titanium or vanadium atomic transitions (22). Field-dependent measurements were not performed because of the limited size of the ZEKE signal.

Calculations of molecular geometries and vibrational frequencies were carried out using the second-order Møller–Plesset (MP2) perturbation theory method and 6–311+G(d,p) basis implemented in the GAUSSIAN 03 program (23). Single-point energy calculations using the MP2 optimized geometries were performed with the coupled cluster CCSD(T) method with correlation-consistent aug-cc-pVDZ basis for H, C, and N, and aug-cc-pVDZ-PP basis for Cu (24). These single-point energy calculations were performed using the MOLPRO 2006.1 program (25). Multidimensional Franck–Condon (FC) factors were computed from the theoretical equilibrium geometries, harmonic frequencies, and normal modes of the neutral and ionic complexes (26). The Duschinsky effect (27) was considered to account for normal mode differences between the neutral molecule and ion in the FC calculations. Spectral broadening was simulated by giving each line a Lorentzian line shape with the linewidth of the experimental spectrum. Boltzmann distributions were used to simulate spectra at specific temperatures.

Results and discussion

Cu-pyridine

Figure 1*a* shows the ZEKE spectrum of Cu-pyridine

© 2007 NRC Canada

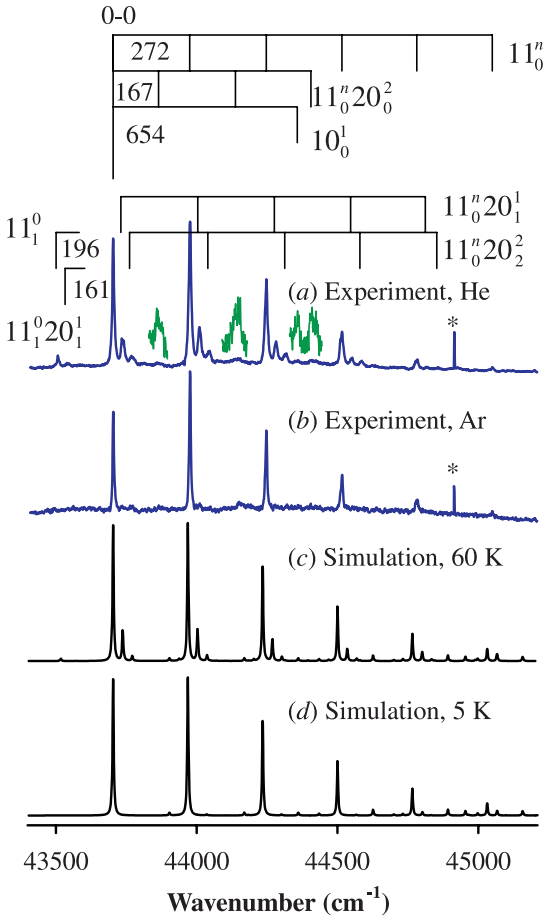

Fig. 1. Experimental ZEKE spectra of Cu-pyridine seeded in (*a*) He, (*b*) Ar, simulations at (*c*) 60 K, and at (*d*) 5 K. The peak with an asterisk is the Cu $^4D^0_{1/2} \leftarrow {}^2S_{1/2}$ atomic transition. Vertical expansions are made in (*a*) to show clearly the $11^n_0\,20^n_0$ and 10^1_0 weak peaks.

seeded in He carrier gas. Major peaks in this spectrum have a spectral linewidth (full width at half maximum) of 7 cm^{-1}. Compared to the spectrum recently recorded by Miyawaki and Sugawara (14), this spectrum shows a number of additional weak transitions and a significantly narrower linewidth. The first strong peak appears at 43 703 (5) cm^{-1}, and corresponds to the 0–0 transition between the zero vibrational levels of the ground electronic states of the neutral and ionized complexes. Above the 0–0 transition, the spectrum displays a major vibrational progression (11^n_0) with five 272 cm^{-1} intervals; a weak signal at 167 cm^{-1} and its combination with two 272 cm^{-1} intervals ($11^n_0\,20^2_0$), and an additional weak peak at 654 cm^{-1} (10^n_0). On the higher energy side of the first five members of the major progression, the spectrum exhibits two peaks separated by 34 cm^{-1} ($11^n_0 20^1_1$, $11^n_0 20^2_2$). Below the 0–0 transition, the spectrum shows two small peaks (11^0_1, $11^0_1 20^1_1$) with the lower energy peak at 196 cm^{-1} from the band origin. In contrast to all these peaks, a peak at 44 915 cm^{-1} has a much narrower linewidth and is easily assigned to be the Cu $^4D^0_{1/2} \leftarrow {}^2S_{1/2}$ atomic transition (22).

The 272 cm^{-1} intervals in the major vibrational progression are very close to the Cu$^+$-diazine stretching frequencies of Cu$^+$-pyrazine (265 cm^{-1}), Cu$^+$-pyrimidine (270 cm^{-1}), and Cu$^+$-pyridazine (273 cm^{-1}) observed in the ZEKE spectra of Cu-diazines (28). It is also comparable to the Cu-pyridine stretching frequency of 244 cm^{-1} measured in the Raman spectrum of pyridine adsorbed on aqueous Cu colloids (Table 1) (3). Thus, the main progression is assigned to the transitions from the zero vibrational level of the neutral complex to excited levels of the Cu$^+$-pyridine stretch in the ionized complex (11^n_0). The 654 cm^{-1} spacing is comparable to the frequency of the pyridine ring inplane asymmetric deformation mode in the gas phase (ν_{6a}, 601 cm^{-1}) (29–31), liquid (618 cm^{-1}) (32), or on the Cu colloid (632 cm^{-1}) (3) and electrode (633 cm^{-1}) (7) surfaces (Table 1). This vibration can thus be assigned to the same vibrational mode in the Cu$^+$-pyridine complex (ν_{10}^+). The blue shift of this pyridine deformation mode is induced by the metal-pyridine interaction, and the extent of such shifts has been found to correlate with the metal-pyridine binding strength (7, 16, 18). The weak peaks below the band origin and on the higher energy side of the major progression disappear when He is replaced by Ar as a carrier gas, as shown in Fig. 1*b*. This observation indicates that the weak peaks are due to the transitions from excited vibrational levels of the neutral complex. Because the supersonic expansion of the heavier Ar gas provide a more efficient cooling than does the lighter He gas, metal complexes seeded in Ar have lower vibrational temperatures than those seeded in He. The use of different carrier gases has been employed to identify the vibrational hot bands in the ZEKE spectra of other metal complexes (28, 33). In addition to the disappearance of the vibrational hot bands, the spectral linewidth is reduced from 7 cm^{-1} in Fig. 2*a* to 5 cm^{-1} in Fig. 1*b*. In PFI-ZEKE experiments, the intrinsic spectral linewidth is determined by the linewidth of the laser used for photoexcitation and the magnitude of the electric pulse used for ionization. The spectral linewidth of the laser is only 0.08 cm^{-1}, and the spectral broadening from the electric field is no more than 1–2 cm^{-1}. The additional spectral broadening measured in Figs. 1*a* and 1*b* is due to the unresolved rotational envelope resulting from the transitions of excited rotational levels (28, 33). The narrower linewidth in Fig. 1*b* vs. 1*a* is due to fewer rotational populations for the molecules seeded in Ar than in He.

For detailed spectral assignments, we will compare the experimental measurements with theoretical calculations. In calculating the geometry of Cu-pyridine, we considered both σ and π structures formed by Cu binding to the nitrogen atom and the six-membered π ring, respectively. However, no minimum energy π structure was found for either neutral or ionic species. Table 2 lists the electronic energies, equilibrium geometries, and harmonic frequencies of the σ structure from the MP2/6–311+G(d,p) calculations. These calculations yield a C_{2v} structure with the metal atom being coplanar to the aromatic ring. The Cu–N distance is predicted to be 2.005 Å and is fairly close to those of the Cu-diazine complexes (2.000–2.021 Å) calculated by the same method and basis (28). The geometry of pyridine shows very little change upon coordination, similar to those of diazine molecules in the Cu-diazine complexes. Upon ionization, the Cu$^+$–N distance (1.889 Å) is shrunk because of the reduced Pauli electron repulsion between Cu 4s^1 and N lone-pair electrons and to the additional charge–dipole attraction in the ionized species. Figures 1*c* and 1*d* show the spectral

[a]Labels in parentheses are based on a correlation with the vibrational modes of benzene (29).
[b]The gas phase and liquid values of the free ligand are taken from references (30) and (32), respectively.
[c]The values of pyridine adsorbed on Cu(110), Cu colloid, and Cu electrode surfaces are taken from refs. 4, 3, and 7, respectively.
[d]This work. All values are from the ZEKE spectrum of Cu-$(pyridine)_2$, except for 294 and 654 cm^{-1} that are measured from the ZEKE spectrum of Cu-pyridine.

Fig. 2. Experimental ZEKE spectrum (*a*) seeded in He, (*b*) simulations of eclipsed, and (*c*) staggered structures at 80 K.

simulations of the $^1A_1 \leftarrow {}^2A_1$ transition obtained by using the equilibrium geometries, harmonic frequencies, and force fields of the neutral and ionic states at two different temperatures. In these simulations, the calculated vibrational frequencies are not scaled, while the 0–0 transition energies are shifted to the measured value for easier comparison of the experimental and theoretical spectra. The simulation in Fig. 1*c* was carried out at the vibrational temperature of 60 K and is compared with the experimental spectrum recorded with He carrier, whereas the simulation in Fig. 1*d* was performed at 5 K and is compared with the experimental spectrum with Ar carrier. These simulations are in excellent agreement with the experimental spectra, and thus the spectral assignments based on these comparisons are straightforward. The 272 cm^{-1} progression is due to excitations of the Cu^+-pyridine stretching mode (ν_{11}^+), and the 654 cm^{-1} interval arises from the excitation of the pyridine ring in-plane deformation (ν_{10}^+). Both of these assignments are consistent with those obtained from the comparison of the ZEKE spectrum of Cu-pyridine with the ZEKE spectra of Cu-diazines (28), IR spectra of the free ligand (29–31), and the Raman spectra of pyridine adsorbed on a copper electrode (7). The 167 cm^{-1} interval is assigned to an overtone transition of the Cu^+-pyridine out-of-plane bend (ν_{20}^+). Since this vibrational mode has a b_1 representation, only transitions with $\Delta v = \pm 2, \pm 4, \ldots$ are possible. Thus, the frequency of the Cu^+-pyridine out-of-plane bend is 84 cm^{-1}. All other transitions present in Fig. 1*a*, but not in Fig. 1*b*, are due to either the Cu-pyridine stretching (ν_{11}) or the Cu-pyridine out-of-plane bending (ν_{20}) excitations in the neutral complex. The frequency of the neutral Cu-pyridine stretch, 196 cm^{-1}, is measured from the lowest energy peak (11_1^0), and that of the neutral Cu-pyridine out-of-plane bend, 49 cm^{-1}, is derived from the sequence transitions ($11_1^0 20_1^1$, $11_0^n 20_1^1$, and $11_0^n 20_2^2$), and the ionic Cu^+-pyridine out-of-plane bend (11_0^n). A complete assignment of all the transitions is given in Table 3.

The assignment of the Cu^+–Cu-pyridine stretch vibrations is consistent with a recent ZEKE study by Miyawaki and Sugawara (14). For the sequence transitions, however, our assignment is different. In the previous study, the sequence transitions were attributed to the excitations of the Cu-pyridine in-plane bend (b_2), and the assignment was made

Table 2. Electronic energies, bond lengths, bond angles, and vibrational frequencies of the neutral and ionized Cu-pyridine complexes from MP2/6–311+G(d,p) calculations.

Bond lengths (Å)	Bond angles (°)	Vibrational frequencies (cm^{-1})
$^2A_1$ (C_{2v}), E_e = –1886.875 29 (a.u.)		
Cu–N = 2.005	∠Cu–N–C = 120.9	a_1: 3243, 3222, 3213, 1643, 1508, 1241, 1088, 1047, 1027, 630, 186
N–C = 1.350	∠N–C–C = 122.7	a_2: 938, 878, 361
C–C = 1.396 / 1.397	∠C–C–C = 119.0 / 119.0	b_1: 927, 908, 723, 565, 377, 66
	∠C–N–C = 118.2	b_2: 3237, 3216, 1615, 1481, 1399, 1381, 1178, 1086, 655, 130
$^1A_1$ (C_{2v}), E_e = –1886.690 29 (a.u.)		
Cu–N = 1.899	∠Cu–N–C = 120.7	a_1: 3255, 3239, 3231, 1659, 1517, 1251, 1098, 1063, 1029, 658, 266
N–C = 1.358	∠N–C–C = 122.1	a_2: 943, 878, 368
C–C = 1.393 / 1.397	∠C–C–C = 119.3 / 118.6	b_1: 955, 913, 731, 581, 380, 100
	∠C–N–C = 118.6	b_2: 3252, 3234, 1616, 1496, 1399, 1390, 1191, 1099, 652, 166

Note: The bond lengths (Å) and angles (°) of the free ligand from the MP2/6–311+G(d,p) calculations: N–C = 1.344, C–C = 1.399, 1.397; ∠N–C–C = 123.9, ∠C–C–C = 118.6, 118.3, ∠C–N–C = 116.8.

by comparing the experimental 34 cm^{-1} intervals with B3LYP calculated frequency differences between the ionic and neutral in-plane and out-of-plane bending modes, respectively. Since these metal-ligand bending modes have very low frequencies, the prediction of their values often has relatively large errors and is sensitive to theoretical methods and basis sets. Thus, spectral assignment solely based on the frequency comparison may be tentative as pointed by Miyawaki and Sugawara. Moreover, the observation of the weak transitions ($11_0^n 20_0^2$ and 10_0^1) in our measurements yield three additional vibrational frequencies (ν_{20}^+ = 84 cm^{-1}, ν_{20} = 49 cm^{-1}, and ν_{10}^+ = 654 cm^{-1}), which were not reported in the previous study.

Cu-(pyridine)$_2$

Figure 2*a* presents the ZEKE spectrum of Cu-(pyridine)$_2$ seeded in He carrier gas. This spectrum displays remarkable differences from that of Cu-pyridine. First, the 0–0 transition is shifted to 29 917 cm^{-1}, 13 590 cm^{-1} lower than that of the mono-pyridine complex. Second, the linewidth of each band in the ZEKE spectrum of the Cu-(pyridine)$_2$ complex (~40 cm^{-1} with He and ~27 cm^{-1} with Ar) is much broader than that of the mono-pyridine complex (~7 and 5 cm^{-1} with He and Ar, respectively). Third, many more different vibrational intervals are identified in the spectrum of the di-ligand complex, which include 194, 658, 1023, 1089, 1225, and 1626 cm^{-1}.

The measured vibrational intervals can be assigned by comparing them with the ZEKE spectrum of Cu-pyridine and vibrational frequencies of free pyridine (29) or pyridine absorbed on metal surfaces (4, 7). The 194 cm^{-1} intervals are due to excitations of the pyridine-Cu^+-pyridine stretch mode. This stretching frequency is smaller than that the corresponding stretching mode of the mono-pyridine complex (272 cm^{-1}) as a result of the heavier mass of the di-pyridine complex. The 658 cm^{-1} spacing is almost the same as the frequency of the in-plane ring deformation (654 cm^{-1}) measured for Cu^+-pyridine and thus is assigned to the same pyridine vibrational mode of Cu^+-(pyridine)$_2$. Other vibrational intervals (1023, 1089, 1225, and 1626 cm^{-1}) are compared with the vibrational frequencies of free and absorbed pyridine in Table 1. From this comparison, the 1023, 1089, 1225, and 1626 cm^{-1} intervals are attributed to the symmetric ring breath, in-plane C–H bends, and C–C/C–N stretch, respectively. These pyridine-based vibrational frequencies are slightly larger than those of pyridine in the gas phase, but similar to those of pyridine absorbed on Cu (110) (4) and electrode surfaces (7).

Although the vibrational assignment is straightforward, the identification of the involved electronic transition and molecular structure of this di-ligand complex requires theoretical calculations. In our calculations, the formation of a π structure by Cu binding to one of the pyridine rings was excluded since such a structure was not found for Cu-pyridine. However, the σ structure formed by Cu binding to the nitrogen atom of each pyridine molecule may be in an eclipsed or a staggered configuration, as shown in Fig. 3. The optimized geometries, energies, and vibrational frequencies of both configurations are listed in Table 4. According to the MP2/6–311+G(d,p) calculations, the staggered structure has a lower energy than the eclipsed structure in both the neutral and ionic forms. For the eclipsed structure, a $^2B_{3u}$ neutral state is located in D_{2h} molecular symmetry. The $^2B_{3u}$ state of the eclipsed Cu-(pyridine)$_2$ has significantly shorter Cu–N distances (1.838 Å) than that of the $^2A_1$ state of Cu-pyridine (2.005 Å). Ionization of the $^2B_{3u}$ state yields the ^1A_g state also in D_{2h}. In contrast to the mono-pyridine species where the ionized form has a shorter Cu–N distance, the ionized di-pyridine complex has a longer Cu–N bond (1.862 Å) than the neutral species. Vibrational frequency calculations of both the $^2B_{3u}$ and ^1A_g states reported a small imaginary frequency for a pyridine ring torsion mode in the neutral (27*i* cm^{-1}) and ionized (21*i* cm^{-1}) species, respectively. Additional calculations without symmetry constraints (C_1 point group) still yielded a small imaginary frequency (<30i cm^{-1}) for both the neutral and ionic states. Such small imaginary frequencies are likely due to numerical errors in the calculations, and thus these two states are considered local minima. In contrast to the eclipsed configuration, the staggered structure of the neutral complex has a lower molecular symmetry (C_2), presumably because of Jahn–Teller distortion. A ^2B electronic state is predicted for the C_2 staggered structure. In

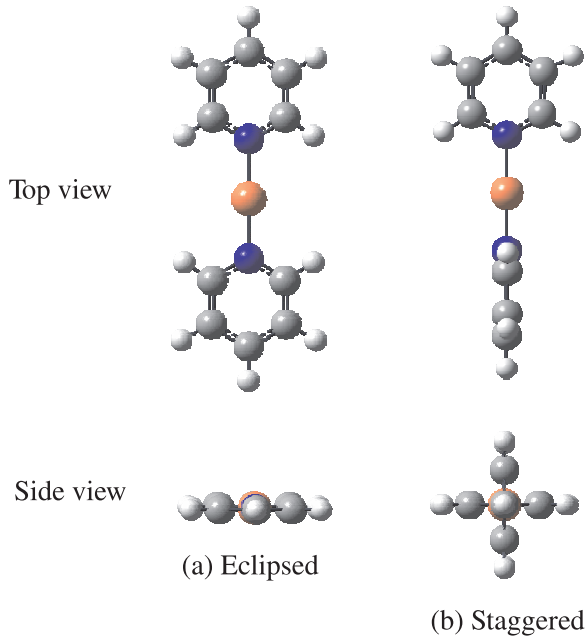

Fig. 3. (*a*) Eclipsed and (*b*) staggered structures of Cu-(pyridine)$_2$. In the web version Cu is shown in red, N in blue, C in grey, and H in white. In the print version Cu is shown in dark grey, N in black, C in light grey, and H in white.

this state, the two Cu–N bond lengths (1.863 and 1.813 Å) are not the same, but their average is identical to the Cu–N distance (1.838 cm^{-1}) of the eclipsed $^2B_{3u}$ state. Ionization of the ^2B state yields a $^1A_1$ ion state in D_{2d} symmetry, and the Cu^+–N distance (1.861 Å) is almost the same as one of the Cu–N bonds in the neutral complex. The ion has a higher molecular symmetry because Jahn–Teller distortion does not exist in a singlet electronic state.

Figures 2*b* and 2*c* show the simulations of the ^1A_g (D_{2h}) ← $^2B_{3u}$ (D_{2h}) transition of the eclipsed structure and the $^1A_1$ (D_{2d}) ← ^2B (C_2) transition of the staggered structure. Again, the calculated frequencies in these simulations are not scaled, but the 0–0 transition energies are shifted to the experimental value for simplicity. Compared to the experimental spectrum, the simulation of the $^1A_1$ (D_{2d}) ← ^2B (C_2) transition of the staggered structure considerably overestimates the intensities of the 1225 and 1626 cm^{-1} peaks, but underestimates the intensity of the 1023 cm^{-1} peak. These peaks are marked with asterisks in Fig. 2*c*. On the other hand, the simulation of the ^1A_g (D_{2h}) ← $^2B_{3u}$ (D_{2h}) transition of the eclipsed structure reproduces the experimental spectrum quite well. Therefore, the observed ZEKE spectrum is attributed to ionization of the eclipsed D_{2h} structure. Spectral assignments derived from the simulation of the eclipsed D_{2h} structure are the same as those from spectral comparisons of Cu-(pyridine)$_2$, Cu-pyridine, free pyridine, and surface-adsorbed pyridine discussed earlier. These assignments are listed in Table 3, where ν_{11}^+ represents for the symmetric pyridine-Cu^+-pyridine stretch, ν_8^+ in-plane pyridine ring deformation, ν_9^+ ring breath, ν_6^+ and ν_7^+ in-plane C–H bends, and ν_4^+ C–C/C–N stretch in the ^1A_g ion state. From the theoretical vibrational analysis, the pyridine-Cu^+-pyridine stretching mode in this di-ligand complex displays different motions from the Cu^+-pyridine stretch in the mono-ligand species. The metal-ligand stretch of the di-ligand complex is largely characterized by the movement of two pyridine molecules along the N–Cu^+–N axis, while that of the mono-ligand species is described by a large Cu^+ displacement. In addition to these ion modes, the spectral simulation indicates that the broad linewidth in the experimental spectrum contains unresolved sequence transitions involving the pyridine ring torsion (ν_{63}) and bending (ν_{56}) modes.

As noted previously, although the ^2B (C_2) state of the staggered structure is predicted to be lower in energy than the $^2B_{3u}$ state of the eclipsed structure, the simulation of the ^1A_g (D_{2h}) ← $^2B_{3u}$ (D_{2h}) transition of the eclipsed structure shows a better match with the experimental spectrum. In attempt to obtain better energies, we carried out CCSD(T) single-point energy calculations at the MP2 optimized geometries of the ^2B (C_2) and $^2B_{3u}$ (D_{2h}) states. However, these higher-level calculations yielded the same energy order for the two electronic states as the MP2 calculations, although the energy difference between these two states was reduced from 46 kJ mol^{-1} (MP2) to 17 kJ mol^{-1} [CCSD(T)]. We also performed calculations for the eclipsed and staggered structures using B3P86 and B3LYP methods. Like

[a]Two pyridine rings in the ^2B state of the staggered configuration of Cu-(pyridine)$_2$ are not equivalent becasue of Jahn–Teller distorted low molecular symmetry. Thus, the carbon and nitrogen atoms in these two rings are differentiated with single primes.

MP2, the simulations of the ^1A_g (D_{2h}) ← $^2B_{3u}$ (D_{2h}) transition of the eclipsed structure from these density functional methods are in good agreement with the experimental spectrum. However, both the B3P86 and B3LYP calculations failed to locate any staggered structure for the neutral complex. The failure of finding a neutral staggered configuration by the density functional theory may also suggest that the eclipsed structure is more stable, as indicated by the ZEKE measurements.

Comparison of experiment and theory

Table 5 summarizes the ZEKE spectroscopic measurements for the Cu-(pyridine)$_{1,2}$ complexes, along with the values from the MP2 and CCSD(T) calculations. The bond dissociation energies of Cu^+-pyridine were previously measured as 274 kJ mol^{-1} by photodissociation (12) and 246(10) kJ mol^{-1} by CID (11). Although the uncertainty of the photodissociation value was unknown, bond dissociation energies from such measurements are normally considered as the upper limit. Moreover, the bond dissociation energy of Cu^+-pyrimidine was measured to be 250(10) kJ mol^{-1} with CID (34). From the viewpoint of electrostatic interactions, the Cu^+ bonding with pyridine and pyrimidine should be comparable since these two ligands have similar electric dipole moments (pyridine, 2.215 D; pyrimidine, 2.334 D) (35). Based on the above considerations, the CID value of the dissociation energy of Cu^+-pyridine is used in Table 4. The dissociation energy of Cu^+-(pyridine)$_2$ is taken from a

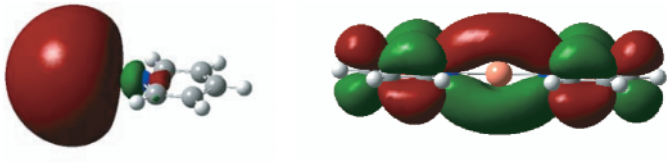
Note: D_0^+ (Cu^+-pyridine → Cu^+ + pyridine) is from ref. 11 with an uncertainty of 10 kJ mol^{-1}; D_0^+ [Cu^+-(pyridine)$_2$ → Cu^+ + 2 pyridine] is from ref. 15 with an uncertainty of 25 kJ mol^{-1}. D_0 (Cu-pyridine→ Cu + pyridine) and D_0 [Cu-(pyridine)$_2$ → Cu + 2 pyridine] are obtained by using the thermodynamic relation discussed in the text.

previous ion-ligand exchange equilibrium measurement (15). The dissociation energies of the mono- and di-pyridine neutral complexes are obtained using the thermochemical relationship: AIE(M – L_{n-1}) – AIE(M – L_n) = D_0^+(M – L_n) – D_0(M – L_n), where D_0^+ and D_0 are the bond energies of M^+ – L_n and M – L_n, respectively, and AIE(M – L_{n-1}) and AIE(M – L_n) are the adiabatic ionization energies of M – L_{n-1} and M – L_n, respectively.



The calculated vibrational frequencies are in very good agreement with those determined experimentally, although slightly larger errors are presented for the low-frequency Cu^+/Cu-pyridine out-of-plane bending modes. However, the agreements between MP2 and ZEKE are very poor for the ionization and dissociation energies of the di-ligand complex. The major reason for this poor agreement was due to the spin contamination of the $^2B_{3u}$ state from a higher energy quartet state. Although it has no significantly adverse effect on the geometry (as indicated by the high quality of simulation in Fig. 2*b*), the spin contamination has considerably raised the total energy of the $^2B_{3u}$ state. As a result, the ionization and dissociation energies of Cu-(pyridine)$_2$ were predicted to be too low compared with the experimental values. In fact, the predicted dissociation energy for Cu-(pyridine)$_2$ → Cu^+ + 2 pyridine was even smaller than that of Cu-pyridine → Cu + pyridine. Apparently, the MP2 calculations for the Cu-(pyridine)$_2$ dissociation energy were wrong. To improve the MP2 values, we carried out single-point energy calculations using the CCSD(T) method for the ^1A_g and $^2B_{3u}$ states of the di-ligand complex. The ionization energy of the $^2B_{3u}$ state from the CCSD(T) calculations is now closer to the experimental value, although it is still low. The dissociation energy of the $^2B_{3u}$ state is inline with the value derived from the thermochemical relation, while the dissociation energy of the ^1A_g state is somewhat overestimated. As a further computational effort, we also calculated ionization and dissociation energies of the mono-ligand species using the CCSD(T) method. The ionization energy of the $^2A_1$ state from the CCSD(T) prediction is in excellent match with the value from the ZEKE measurement, while the dissociation energies of both the $^2A_1$ and $^1A_1$ states are too large compared with the experimental values. Since the CCSD(T) calculations reproduce well the precisely measured ionization energy for the mono-ligand species, we are puzzled by the relatively large differences between the theoretical and experimental dissociation energies of both the $^2A_1$ and $^1A_1$ states, especially the dissociation energy of the $^2A_1$ state. More experimental and computational studies are needed to resolve this discrepancy. Experimentally, more precise measurements for the ion bond energies will definitely be valuable, as these measurements will also reduce the uncertainties of the neutral dissociation energies derived from the thermochemical cycle. Computationally, larger and better basis sets may improve the predictions.

Metal-ligand binding in the mono- and di-pyridine complexes

Although pyridine can function as a σ donor through the nitrogen lone pair or a π donor or acceptor through occupied or empty π orbitals, the formation of the Cu-pyridine σ structure can be described by dative binding from the nitrogen lone pair to Cu 4s or 4pσ orbital. However, this dative bonding is impeded by Pauli electron repulsion between the nitrogen lone pair and Cu $4s^1$ electrons. To reduce the electron repulsion, s-pσ polarization may occur to polarize electron density away to the opposite side of the Cu atom and from pyridine, allowing the ligand to experience a larger effective nuclear charge (11, 36). This s-pσ polarization mechanism is evident from the atomic orbital compositions and electron density map of the highest occupied molecular orbital (HOMO) of Cu-pyridine (Fig. 4*a*), where the electron density is not spherical. However, because of the large energy difference between the Cu 4s and 4p orbitals

© 2007 NRC Canada

Fig. 4. Electron densities of the (*a*) highest occupied molecular orbitals of the Cu-pyridine $^2A_1$ state and (*b*) the Cu-(pyridine)$_2$ $^2B_{3u}$ state from the MP2/6–311+G(d,p) calculations.

(a) Cu-pyridine, $^2A_1$ (b) Cu-(pyridine)$_2$, $^2B_{3u}$

(~3.78 eV) (22), the s-pσ polarization mechanism is not expected to be effective. As a result, the Cu-pyridine bond energy (23 kJ mol^{-1}) is relative small. Ionization of Cu-pyridine removes the Cu 4s-based electron from the HOMO and thus the electron repulsion between Cu 4s and nitrogen lone pair. The removal of this Pauli repulsion greatly enhances the metal-ligand σ dative binding. Moreover, the removal of the Cu-based electron creates a charge–dipole attraction between Cu^+ and pyridine, further increasing the metal-ligand binding. The metal-ligand bond energy of the ionized complex is measured to be about 10 times stronger than that of the corresponding neutral species. Due to the increased ion bonding, the ionization energy of the Cu-pyridine complex (5.4185 eV) is red shifted compared with that of the metal atom (7.7264 eV) (35).

One might think that the binding mechanism between Cu and pyridine in the di-pyridine complex should be similar to that of the mono-ligand species. It is true that the di-pyridine complex is also formed by Cu binding with nitrogen atoms. However, its bond energy is measured to be almost five times stronger than that of the mono-ligand species. This large binding difference cannot be rationalized by the nitrogen lone-pair donation and Pauli repulsion discussed earlier. Although the nitrogen σ donation increases with the number of pyridine molecules, Pauli repulsion is expected to increase as well since the s-pσ polarization mechanism is not operative in the linear Cu-(pyridine)$_2$ complex. Consequently, the dissociation energy of Cu-(pyridine)$_2$ → Cu + 2 pyridine should not be more than twice as that of Cu-pyridine → Cu + pyridine. Thus, there must be additional factors contributing to the larger than expected difference between the mono- and di-ligand bond energies. The major contribution is the significant π bonding in this σ complex. Instead of the largely Cu 4s electron density in the $^2A_1$ HOMO of the mono-pyridine complex, the $^2B_{3u}$ HOMO of the di-pyridine complex consists of the bonding interaction between the Cu 4pπ and nitrogen 2pπ electrons (Fig. 4). This π-bonding interaction reduces the Cu–N distances and thus enhances the pyridine-Cu-pyridine bonding. The Cu–N distances of the Cu-(pyridine)$_2$ $^2B_{3u}$ state are predicted to be 1.838 Å, 0.169 Å shorter than that of the Cu-pyridine $^2A_1$ state (2.005 Å). Ionization of the Cu-(pyridine)$_2$ $^2B_{3u}$ state removes the π-bonding electron and thus increases the Cu–N distances. Like the mono-ligand complex, the ion bond dissociation energy of Cu^+-(pyridine)$_2$ (495 kJ mol^{-1}) is also larger than that of the neutral species (107 kJ mol^{-1}), because of the additional charge–dipole attraction and reduced Pauli repulsion.

Conclusion

Vibrationally resolved ZEKE spectra are reported for the Cu-(pyridine)$_n$ (n = 1,2) complexes. The ZEKE spectrum of the mono-pyridine complex exhibits a narrower linewidth and additional vibrational transitions compared with a previously reported ZEKE spectrum, whereas the ZEKE spectrum of the di-ligand complex is first studied in this work. The ionization energy of the mono-ligand complex is much lower than that of Cu atom, and the ionization energy of the di-ligand complex is further reduced compared with that of the mono-ligand species. These ionization energy shifts are the result of stronger metal-ligand bonding in the ion than in the neutral complex, and the increased ion binding is due to the additional charge–dipole interaction and reduced electron repulsion in the ion. The ion bond energy of the di-ligand complex is about two times stronger than that of the mono-ligand species, whereas the difference of the corresponding neutral bond energies is increased to five times. Copper binds to a single pyridine molecule in a planar C_{2v} structure and to two pyridine molecules in an eclipsed configuration, both through the nitrogen atoms. In addition to the Cu–N σ bonding in the mono- and di-ligand species, important π binding between the Cu and N pπ orbitals greatly enhances the metal-ligand bonding in the di-ligand complex. In comparing the experimental measurements with the theoretical calculations, we find that the geometries and vibrational frequencies predicted by the MP2 calculations are very good for both the mono- and di-ligand species, but the ionization and dissociation energies of the di-ligand neutral complex are underestimated because of the spin contamination in the $^2B_{3u}$ state. The CCSD(T) calculations improve the ionization energies for both the mono- and di-ligand complexes but overestimate the their bond energies, except for the neutral Cu-(pyridine)$_2$ complex.

Dipole oscillator strength distributions, properties, and dispersion energies for ethylene, propene, and 1-butene[1]

A. Kumar, B.L. Jhanwar, and W. Meath

Abstract: A recommended isotropic dipole oscillator strength distribution (DOSD) has been constructed for the ethylene molecule through the use of quantum mechanical constraint techniques and experimental dipole oscillator strength (DOS) data; the DOS data employed are recent experimental results not available at the time of the original constrained DOSD analysis of this molecule. The constraints are furnished by molar refractivity data and the Thomas–Reiche–Kuhn sum rule. The DOSD is used to evaluate a variety of isotropic dipole oscillator strength sums, logarithmic dipole oscillator strength sums, and mean excitation energies for ethylene. Pseudo-DOSDs for this molecule, and for propene and 1–butene, which are based on an earlier constrained DOSD analysis for these molecules, are developed. They are used to obtain reliable results for the isotropic dipole–dipole dispersion-energy coefficients C_6, for the interactions of the alkenes with each other and with 47 other species, and the triple-dipole dispersion-energy coefficients C_9 for interactions involving any triple of molecules taken from ethylene, propene, and 1–butene.

Key words: alkenes, dipole properties, pseudo-states, dipole–dipole and triple-dipole dispersion energies, long-range additive, non-additive interaction energies.

Résumé : Faisant appel à des techniques de contrainte de mécanique quantique et des données expérimentales de force d'un oscillateur dipolaire (FOD), on a développé une distribution de la force d'un oscillateur dipolaire isotrope (DFOD) recommandée pour la molécule d'éthylène; les données de force d'un oscillateur dipolaire utilisées sont des résultats expérimentaux récents qui n'étaient pas disponibles lors de l'analyse originale contrainte de la DFOD de cette molécule. Les contraintes sont fournies par les données de réfractivité molaire et la règle des sommes de Thomas–Reiche–Kuhn. On utilise la DFOD pour évaluer des sommes de forces d'oscillateurs dipolaires isotropes, des sommes logarithmiques de force d'oscillateur dipolaire et des énergies d'excitation moyenne de l'éthylène. On a développé des valeurs pseudo-DFOD pour cette molécule, pour le propène et le but-1-ène qui sont basées sur une analyse antérieure de ces molécules par une méthode contrainte de type DFOD. Les résultats obtenus sont utilisés pour obtenir des résultats fiables pour les coefficients C_6 de l'énergie de dispersion dipôle–dipôle isotrope, pour les interactions des alcènes les uns avec les autres et avec 47 autres espèces ainsi que pour les coefficients C_9 d'énergie de dispersion triple-dipôle pour les interactions impliquant tout triplet de molécules impliquant de l'éthylène, du propène et du but-1-ène.

Mots-clés : alcènes, propriétés dipolaires, pseudo états, énergies de dispersion dipôle–dipôle et triple-dipôle, énergies d'interaction additives, non-additives à longue portée.

[Traduit par la Rédaction]

Introduction

One of the purposes of this work is to assess the reliability of the results for a wide variety of the isotropic dipole properties of the ground-state ethylene, propene, and 1-butene molecules evaluated previously (1) by using the constrained dipole oscillator strength distribution (DOSD) technique (2–7). The original constrained DOSD calculations (1) were based on the then rather sparse and disjointed (as a function of photon energy) experimental dipole oscillator strength

(DOS) data for these alkenes, which were drawn from the work of several different experimental groups. Our new calculations for ethylene are based on much more recent, extensive, and reliable experimental DOS data (8). They can be used to directly check the reliability of the original DOSD calculations for this molecule and, in conjunction with a recent study (9) for methanol, ethanol, and propan-1-ol, which involves analogous input DOS data sets for these molecules, to indirectly assess the reliability of the analogous results for propene and 1-butene. We also present new reliable results for the isotropic dipole–dipole dispersion energies for the interaction of the three alkenes with each other and with a variety of other species. Discrete pseudo-state representations (10, 11) of the recommended constrained dipole oscillator strength distributions for the alkenes are constructed, which are useful for the efficient evaluation (10–12) of the dipolar dispersion energies, particularly the triple-double dispersion energies, for interactions involving these molecules; explicit reliable results for the triple-dipole dispersion-energy coefficients are included for all triples of the alkene molecules.

The relationship between molecular dipole oscillator strength distributions (DOSDs) and the isotropic dipole properties of molecules, and the dipole–dipole and the triple-dipole dispersion energies for interactions involving molecules, is well known (2, 13–19). The molecular dipole properties explicitly considered here are the dipole oscillator strength sums S_k, the logarithmic dipole sums L_k, the mean excitation energies I_k, and the molar refractivity R_λ as a function of wavelength λ. The properties S_k, L_k, and I_k, which depend on the value of the index k, and the dipolar dispersion energies find application in many research areas (2, 13–16, 20–32).

A quantum mechanical constraint technique (2–7) is used to construct the DOSDs for ethylene from a base of experimental dipole oscillator strength input data (1, 8) using constraints comprised of the molar refractivity (1, 33, 34) of the molecule for two well-separated wavelengths and the Thomas–Reiche–Kuhn sum rule (14, 35) for the DOSD. Specific results for integrated dipole oscillator strengths for ethylene, over various energy regions, are computed. Recommended values for the dipole sums, S_k, k = –10(2) – 4(1) – 3(½) 0, 1, 2; the logarithmic dipole sums L_k and mean excitation energies I_k, k = –2(1) 2; and the molar refractivities of the molecule are tabulated; those for propene and 1-butane can be found in the literature (1). A ten pseudo-state representation of the recommended DOSD for each of the three alkenes is also constructed and tabulated, and these are used to evaluate the results for the dipole–dipole dispersion-energy coefficients for a variety of interactions involving these molecules, and the triple-dipole dispersion-energy coefficients for the interaction of any combination of the three alkenes. The estimated uncertainties in our results for the dipole properties and dispersion energies, and a comparison with literature values, are included in the discussion. The values obtained from the constrained DOSD approach, either the original (1) or the present calculations, are either the only values or the only reliable values available for most of the dipole molecular properties considered in this paper. The results for the dispersion energies obtained herein are generally the only available reliable values for the interactions considered in this paper.

Relationship between DOSDs and dipole properties and dispersion energies

The differential dipole oscillator strength distribution (DOSD) for a molecule is the differential dipole oscillator strength df/dE as a function of photon energy E from the electronic absorption threshold E_0 for the molecule to very high photon energies. Generally, the dipole properties and dispersion-energy coefficients evaluated using DOSDs are isotropic results, since only orientationally averaged input dipole oscillator strengths are available over the required wide range of photon energies. In some instances (36–40), i.e., CO, H_2, N_2, NO, and O_2, sufficient anisotropic constraints are available to permit the construction of anisotropic DOSDs and hence the evaluation of anisotropic molecular properties.

A variety of important isotropic molecular properties can be evaluated as integrals whose integrands involve the isotropic DOSD weighted by simple functions of the photon energy. These include the dipole oscillator strength sums S_k, the logarithmic dipole sums L_k, and the mean excitation energies I_k, defined by

$$[1] \qquad S_k = \int_{E_0}^{\infty} (E / E_H)^k (df / dE)\, dE$$

$$[2] \qquad L_k = \int_{E_0}^{\infty} (E / E_H)^k (df / dE) \ln(E / E_H)\, dE$$

$$[3] \qquad I_k = E_H \exp(L_k / S_k)$$

where $E_H \approx 4.35975 \times 10^{-18}$ J (≈ 27.21 eV) is the Hartree of energy (2, 13, 14). The index k can take on various integer and half-integer values, and each choice defines a different dipole property via eqs. [1–3]. For example, the straggling (I_1 and S_1), stopping (I_0), and the total (I_{-1}, S_{-1}) inelastic scattering cross-sections of fast charged particles in matter (13, 20, 21); S_2 and I_2 determine (2, 13, 14) charge densities at the nucleus and Lamb shifts, while S_{-1}, S_{-3}, $S_{-3/2}$, S_{-2}, and L_{-2} can be used to obtain estimates for the dipole–dipole dispersion energies between molecules (10, 15, 22, 23). An important property, which is involved as a constraint in the construction of DOSDs, is the molar refractivity R_λ of a dilute molecular gas. It is related (2, 14–16) to the refractive index $n(\lambda)$ of the gas at wavelength λ and to an integral involving the DOSD

$$[4] \qquad R_\lambda = (1 / \rho)[(n^2(\lambda) - 1) / (n^2(\lambda) + 2)]$$

$$= (4\pi / 3) N_A (E_H)^2 a_0^3 \int_{E_0}^{\infty} (df / dE)(E^2 - (hc / \lambda)^2)^{-1} dE$$

$$= (4\pi / 3) N_A \alpha(\lambda)$$

where $a_0 \approx 5.29177 \times 10^{-11}$ m = Bohr, ρ is the molar density of the gas, h is Planck's constant, N_A is Avogadro's constant, c is the speed of light, and $\alpha(\lambda)$ is the wavelength-dependent electronic dipole polarizability of the molecule. The static dipole polarizability is $\alpha_d = \alpha(\lambda = \infty) = a_0^3 S_{-2}$. The S_k, k = –4, –6, –8, … are other moments of the DOSD that occur in the Cauchy expansion of $\alpha(\lambda)$.

The dipole–dipole dispersion energy is the dominant interaction energy at long range for interactions of spherically symmetric systems including freely tumbling molecules. Its importance lies in its use for representing long-range interactions between two atoms or molecules and in constructing potential-energy models that are valid for all intermolecular distances (24–30). The orientationally averaged dipole–dipole dispersion energy (16, 17) for the interaction of molecules A and B is given by $-C_6(\mathrm{A,B})R^{-6}_{\mathrm{AB}}$ where R_{AB} is the distance between species A and B and $C_6(\mathrm{A,B})$ is the dipole–dipole dispersion-energy coefficient for the interaction

$$[5]\qquad C_6 = E_{\mathrm{H}}a_0^6(3/2)\int_{E_0(A)}^{\infty} dE(\mathrm{A})\int_{E_0(B)}^{\infty} dE(B) \times \frac{[df(\mathrm{A})/dE(\mathrm{A})][df(\mathrm{B})/dE(\mathrm{B})](E_{\mathrm{H}})^3}{E(\mathrm{A})E(\mathrm{B})[E(\mathrm{A})+E(\mathrm{B})]}$$

where $E(\mathrm{A})$, $\mathrm{d}f(\mathrm{A})/dE(\mathrm{A})$, and $E_0(\mathrm{A})$ are the excitation energy, the differential dipole oscillator strength, and the electronic absorption threshold for molecule A, respectively.

Analogously, the triple-dipole dispersion energy gives the dominant non-additive interaction energy for an assembly of well-separated spherical or "tumbling" species and can be used to help model non-additive effects for other molecular configurations as well (26, 31, 32). For the interaction of three molecules A, B, and C, the triple-dipole dispersion energy is given by (16, 18, 19)

$$[6]\qquad W^{(3)} = (3\cos\theta_{\mathrm{A}}\cos\theta_{\mathrm{B}}\cos\theta_{\mathrm{C}}+1) \times C_9(\mathrm{A,B,C})R^{-3}_{\mathrm{AB}}R^{-3}_{\mathrm{BC}}R^{-3}_{\mathrm{AC}}$$

where θ_{A} is the angle between R_{AB} and R_{AC}. In terms of the original continuous DOSDs for the interacting molecules A, B, and C, the triple-dipole dispersion-energy coefficient C_9 for "tumbling" molecules is given by

$$[7]\qquad C_9(\mathrm{A,B,C}) = E_{\mathrm{H}}a_0^9(3/2)\int_{E_0(\mathrm{A})}^{\infty}\int_{E_0(\mathrm{B})}^{\infty}\int_{E_0(\mathrm{C})}^{\infty} dE(\mathrm{A})dE(\mathrm{B})dE(\mathrm{C}) \times \frac{[df(\mathrm{A})/dE(\mathrm{A})][df(\mathrm{B})/dE(\mathrm{B})][df(\mathrm{C})/dE(\mathrm{C})]}{E(\mathrm{A})E(\mathrm{B})E(\mathrm{C})} \times \frac{[E(\mathrm{A})+E(\mathrm{B})+E(\mathrm{C})](E_{\mathrm{H}})^5}{[E(\mathrm{A})+E(\mathrm{B})][E(\mathrm{B})+E(\mathrm{C})][E(\mathrm{C})+E(\mathrm{A})]}$$

Clearly, many important molecular properties and dispersion interaction energies can be evaluated if molecular dipole oscillator strength distributions (DOSDs) are available. The basic procedure used here for constructing molecular dipole oscillator strength distributions has been discussed in detail in the literature (2, 6, 7). Briefly, the initial DOS input data is divided, from the UV-absorption threshold E_0 to very large values of the photon energy, into N_0 energy intervals as suggested by the structure of the input DOS data and by the photon-energy regions associated with the individual sources of the DOS data. The number of different initial DOSDs that can be obtained by taking all possible combinations of the input DOS data is given by $N_D = \prod_{j=1}^{N_0} N_j$ *where* N_j is the number of independent sources of DOS data used for the j^{th} input spectral region (41). Each of the initial DOSDs considered is modified by requiring satisfaction of the constraints via application of a constrained least-squares technique (2, 6, 7). The input initial oscillator strength database, $(\mathrm{d}f/\mathrm{d}E)_{\mathrm{initial}}$ vs. E, for each spectral region i, is modified via

$$[8]\qquad (df/dE)^i_{\mathrm{constrained}} = (1+a_i)(df/dE)^i_{\mathrm{initial}}, \quad i = 1,2,\ldots,N_0$$

so that the total constrained DOSD satisfies the imposed constraints through the choice of the a_i. The degree of modification of the initial DOSD data required to satisfy the constraints can be represented by the standard deviation (STD) defined by

$$[9]\qquad \mathrm{STD} = [\sum_{i=1}^{N_0}(a_i-\bar{a})^2/N_0]^{1/2}$$

where $\bar{a}$ is the average of all the a_i values (6, 41). The recommended DOSD is represented by a set of data points E_j and $(\mathrm{d}f/\mathrm{d}E)_j$, for $j = 1, 2, \ldots, N_p >> N_0$, and a set of interpolating functions to connect the points. For very high photon energies, $E \geq 10^8$ eV, $(\mathrm{d}f/\mathrm{d}E)$ is represented by the Born dipole formula (35) $AE^{-2.5}$. The dipole properties of molecules are readily evaluated (2) using such a representation of DOSDs.

Construction of the DOSD for ethylene

The experimental dipole oscillator strength (DOS) data used by Jhanwar, Meath, and MacDonald (1) for constructing the original constrained DOSDs for ethylene, propene, and 1-butene have been reviewed by these authors. Generally, relatively few sources of DOS data were available at that time, the experimental DOS data were sparse as a function of photon energy and from a variety of sources, and no direct experimental data was available for $E > 70$ eV for ethylene, for $E > 27$ eV for propene, and for $E > 24$ eV for 1-butene. We base our new constrained DOSD calculations for ethylene on the extensive DOS data of Cooper, Olney, and Brion (8), which are available from the electronic absorption threshold to 200 eV; both high- and low-resolution measurements are available for $E \leq 50$ eV, while for higher photon energies, only low-resolution measurements were made. Analogous experimental studies have unfortunately not been carried out for propene and 1-butene, and so, for these molecules, our recommended DOSD results remain those of the earlier work (1). For ethylene, these more-recent DOS results are part of an extensive collection of experimental DOS data from the same laboratory that in the past has produced DOS data for other molecules that have proved to be very reliable in the sense that the modifications in the data induced by our constraint procedures have often been less than or on the order of the estimated experimental errors of ≈ 5% (to 10%) (see for example, refs. 9, 42–49).

For higher photon energies, for which the recent experimental DOS data are not available, we use, as input DOS values for ethylene, the recommended values of Jhanwar et

© 2007 NRC Canada

al. (1). These were originally based on additivity rules and then modified by the constraints imposed on the overall initial DOS data collection. For large photon energies, the modifications were generally quite small (1).

Following earlier work (1), the constraints for constructing the DOSDs for ethylene are provided by the Thomas–Reiche–Kuhn sum rule $S_0 = 16$ and by experimental molar-refractivity data. The molar-refractivity constraints are obtained by using refractive-index data for ethylene, measured by Watson and Ramaswamy (33) and Friberg (34) as normalized to Watson and Ramaswamy's value at 5462 Å. The results at two well-separated wavelengths, namely, $R(\lambda = 6440\ \text{Å}) = 10.6362\ \text{cm}^3\ \text{mol}^{-1}$ and $R(\lambda = 2302\ \text{Å}) = 13.7115\ \text{cm}^3\ \text{mol}^{-1}$, are employed as constraints. The percentage difference between these two values of R_λ, namely, $\Delta R_\lambda = 200(R_{\lambda 2} - R_{\lambda 1})/(R_{\lambda 1} + R_{\lambda 2}) = 25.3\%$, is very much larger than the expected experimental error in the refractive-index data, and hence, the least-squares constraint procedure can be used with confidence with this refractivity data to construct the DOSDs for ethylene (41, 50).

The following DOSDs have been constructed for ethylene: (*i*) DOSD1: 6.02 – 50.0 eV (high-resolution data of Cooper et al. (8)), 50.0 – 200.0 eV (low-resolution data of Cooper et al. (8)), 200 eV – ∞ (recommended DOSD of Jhanwar et al. (1)); STD = 2.11. (*ii*) DOSD2: as in DOSD1 except the high-resolution data are replaced by the low-resolution data; STD = 5.14.

DOSD1, with the smallest STD for the input data considered here, is chosen as the recommended DOSD for ethylene. The integrated dipole oscillator strengths for the recommended DOSD, together with those calculated from the initial DOS data used to construct the DOSDs for ethylene, are given in Table 1 together with the corresponding integrated oscillator strengths from the original (1) recommended DOSD for ethylene. The approach used here removes errors in the initial DOSD data in a global sense and is capable of yielding reliable dipole molecular properties and very reasonable integrated oscillator strengths. It does not necessarily lead to constrained DOSDs that are accurate on a point-by-point basis (51).

The integrated oscillator strengths evaluated using the initial high-resolution DOS data of Cooper et al. (8) are higher than our recommended integrated oscillator strengths for $6.02\ \text{eV} \le E \le 20.7\ \text{eV}$ and are lower than our results for $20.7\ \text{eV} \le E \le 50\ \text{eV}$. The maximum modification in the high-resolution data induced by our fitting procedure is about 6.5% in the 6.8–8.0 eV energy region; generally, the modifications in the initial input data in the other energy regions is much smaller than this except for 12.3–18.0 eV where it is 4.7%. Generally, the integrated DOSs obtained from the unmodified experimentral high-resolution DOS data (8) agree with our recommended results to within the estimated experimental error.

The initial low-resolution integrated DOSs are significantly different from the recommended results, and with the integrated DOS's obtained from the unmodified high-resolution data, for $E \le 12.3$ eV. The low-resolution integrated DOS is high from 6.02 to 6.8 eV, and the disagreements with the recommended (initial high-resolution) results are 13.7% (19.0%), –6.5 (–5.0), –26.5 (–25.8), 4.0 (6.4), –12.1 (–11.7), –18.4 (–17.1), and 13.1% (13.8%) for the energy regions 6.8–8.0 eV, 8.0–8.6 eV, 8.6–9.0 eV, 9.0–10.4 eV, 10.4–10.7 eV, 10.7–11.8 eV, and 11.8–12.3 eV, respectively. For higher excitation energies, the agreement between the various integrated oscillator strengths is within 5% except for the 26.7–35.0 eV and the 35.0 eV–50 eV energy regions where the low-resolution result is 6.7% and 5.1% and 9.7% and 7.9% lower than the recommended and high-resolution values, respectively.

The discrepancies between our integrated oscillator strengths and those corresponding to the original (1) DOSD for ethylene are often less than 5% and generally less than 10% with the exception of the 8.0–8.6 eV, 8.6–9.0 eV, and the 20.7–26.7 eV energy intervals where the original integrated DOSs are 12.7, 28.7, and 12.4% lower than our recommended results, respectively, and the 70.0–100.0 eV and the 100.0–200.0 eV energy regions where the original results are 15.2 and 21.8% higher than the new results.

A number of sources of DOS data for ethylene were involved in the construction of the original (1) constrained DOSD for this molecule, and these and other DOSs, and associated integrated DOSs, for the molecule have been discussed extensively earlier (see for example, refs. 1 and 8 and papers cited therein).

Relatively recently, Berkowitz (52) has updated his earlier (53) discussion and compilation of the photoabsorption cross sections for a variety of gaseous atoms and molecules including ethylene. As pointed out by Berkowitz (52), there are several sources of DOS data, in addition to Cooper et al. (8), that were not available at the time of the construction of the original (1) constrained DOSD for ethylene. Those of particular interest in his analysis (52), in addition to Cooper et al. (8), are the measurements of Holland et al. (54) and Kempgens et al. (55) in the energy regions 10.513 eV to 24.8 eV and 284 eV to 340 eV, respectively. Berkowitz presents integrated oscillator strengths for ethylene over different energy intervals than used in Table 1, and so to compare with his results, we have calculated integrated DOSs for our recommended DOSD over appropriate energy regions. Our results are 7.785(–1), 6.189, 4.624, 6.034(–1), 1.287(–1), 8.451(–1), 2.691, 1.364(–1), and 3.448(–3) for the energy regions 6.62–10.513 eV, 10.513–24.8 eV, 24.8–80.0 eV, 80.0–200.0 eV, 200–285 eV, 285–340 eV, 340–1740 eV, 1740–10^4 eV, and 10^4–∞ eV, respectively. Berkowitz's corresponding results, using his raw experimental DOS input, differ from our results by –6.9%, –0.5%, –5.8%, 14.0%, 39.8%, 19.9%, –2.2%, 2.7%, and –7.2%, respectively. He adjusted the experimental data in the 6.62–10.513 eV and the 10.513–24.8 eV regions to obtain good agreement with the experimental result (see next section) for S_{-2} and the Thomas–Reiche–Kuhn sum rule; the corresponding adjusted integrated DOSs in these regions differ by 0.6% and 1.5%, respectively, with our constrained DOSD results. As we shall see in the next section, the dipole sums obtained by Berkowitz agree very well with those obtained by our constrained DOSD approach even though the integrated DOSs in some energy regions differ appreciably. This arises for two reasons: the relevant energy regions do not contribute significantly to the sums or the discrepancies in the DOSs tend to cancel in the calculation of the dipole sums, since they can vary in sign as E changes. Finally, we point out that our DOSs for ethylene begin with an absorption threshold of

6.02 eV relative to that of 6.62 eV used in ref. 52. The oscillator strength from 6.02 to 6.62 eV is only 1.856(–4) and has no effect on the dipole properties considered by Berkowitz (52).

Dipole properties

Results for the molar refractivity of ethylene evaluated using our recommended DOSD are listed in Table 2 for a variety of wavelengths between 2302 Å and 6709 Å where they are compared with the experimental results of Watson and Ramaswamy (33), Friberg (34), and Lowery (56); for common wavelengths, the agreement between the results from the various sources is excellent as is the agreement with the molar refractivity results evaluated from the original (1) DOSD for ethylene.

The results for the dipole properties of ethylene, namely, the S_k, $k = -10(2) - 4(1) - 3(1/2)\ 0, 1, 2$; and the logarithmic dipole sums L_k and mean excitation energies I_k, $k = -2(1)\ 2$, evaluated using both the constrained and unconstrained ethylene DOSD1, are compared for common properties, with the literature results of Olney et al. (57) in Table 3. Olney et al. (57) computed the dipole properties by employing the photoabsorption spectrum of Cooper et al. (8); the calculations were based on the high-resolution data, augmented by the low-resolution data as needed. In order to obtain absolute values of the DOSs for ethylene, the original experimental data of Cooper et al. (8) were normalized using the valence-shell TKR (VTKR) sum rule (58). Using the normalized data of Cooper et al., Olney et al. obtained $S_{-2} = 28.26$ and then renormalized the distribution of Cooper et al. by satisfying the experimental result $S_{-2} = 27.79$ (59). It is this renormalized distribution that was used to evaluate the dipole properties of ethylene listed in Olney et al. (57). The dipole properties S_k and L_k, corresponding to the absolute scale of the original normalized DOS data of Cooper et al. (8), can be obtained from those of Olney et al. (57) by multiplying the latter by the factor 1.0169, which is the ratio of the S_{-2} evaluated from the Cooper et al. data to that finally used by Olney et al.; the mean excitation energies are unaffected by this normalization procedure.

For the dipole properties S_k, the results of Olney et al. (57) are lower than our values by 2.5% for $k = -1$ and are higher by about 0.3, 1.3, 1.9, 2.7, 3.2, and 3.6% for $k = -2(-1) -10$. For L_{-1} and L_{-2}, they are 13.5% and 2.4% lower than our recommended results. The differences between the two sets of values for common properties are less than the (rather large) uncertainties estimated by Olney et al. Results for S_k with $k = -5/2, -3/2, -1/2, k \geq 0$, and L_k and I_k with $k \geq 0$, are not available in Olney et al. (57); those for I_{-1} and I_{-2}, which can be calculated from their corresponding results for the analogous S_k and L_k sums via eq. [3], are 6.0% and 1.4% lower than our recommended values. For $k \approx 0$ and $k > 0$, the original DOS data of Copper et al. (8), and hence the DOS results of Olney et al. (57), will lead to poor values for the dipole properties unless extended to higher photon energies and constrained to both refractivity data and the full TRK sum rule $S_0 = 16$. For example, the S_0's evaluated from the unconstrained DOSD1 and DOSD2 are 15.98 and 15.75, respectively; using the Cooper et al. data (8) (i.e., up to 200 eV only) yields 12.27 and 12.04, respectively. Using the original DOS data in this way requires an extension of this data to very high photon energies as illustrated in the construction of the DOSDi, $i = 1, 2$.

The values of the dipole properties evaluated using the original (1) recommended DOSD for ethylene are also included in Table 3. The agreement with our new results is ex-

[a]Used as constraints in constructing the DOSD.

cellent; to within about 1%, and often to significantly less than 1%, except for S_{-10} where the older result is about 2% higher than our current recommended result.

This table also includes the dipole properties of the molecule obtained using the unconstrained DOSD1. The unconstrained dipole sums S_k are less than the recommended results by 1%, 1.6%, and (only) 0.1% for k = 2, 1, and 0, respectively. For $k < 0$, they are systematically greater than the recommended values by from 0.8% to 5.3% as k decreases from $k = -0.5$ to $k = -10$ in agreement with the greater values of the integrated oscillator strengths for the input DOS data relative to the recommended integrated DOSs for low excitation energies ($E \leq 20.7$ eV); the dipole sum S_k for negative k are dominated by the low-energy part of the DOSD, more so as k decreases (41, 60–62). The unconstrained results for the L_k are less than the recommended results by 0.9%, 1.7%, 4.0%, 4.7%, and 3.8% for $k = 2(-1) -2$, respectively, and the unconstrained average energies I_k agree with the recommended values to within about 1% except for I_0 where the discrepancy is 2.3%.

The results for the dipole properties of ethylene developed here and in the original alkene paper (1), and those for propene and 1-butane obtained earlier by Jhanwar et al. (1), are the most reliable compilation of such properties for these alkenes. References to other literature results for some of these properties have been given previously and other relevant literature can be found in these references. A discussion of a selection of more-recent work follows.

Hohm (59) has determined values of the frequency-dependent dipole polarizability of ethylene and propene by measuring accurate values of the refractive index of these molecules over a limited range of wavelengths relative to those in Table 2. The corresponding molar refractivities (see eq. [4]) for ethylene and propene are higher and lower than the results evaluated from our recommended DOSDs for these molecules by only a maximum of 0.4% and 0.25%, respectively. For the wavelengths 6329.9, 6119.71, 5940.96, 5435.16, and 3251.3 Å, the DOSD results are 10.6465, 10.6680, 10.6881, 10.7531, and 11.6342 cm^3 mol^{-1} for ethylene, respectively, and 15.6571, 15.6873, 15.7156, 15.8129, and 17.0459 cm^3 mol^{-1} for propene, respectively.

Hohm has extracted the dipole sums S_k, $k = -2$, -4, -6, and -8 by fitting a Cauchy series to his frequency-dependent polarizability data. For ethylene, the sums so obtained are 0.3%, 1.7%, and 1.7% higher, and 11.5% lower; and for propene, they are 0.3% lower, 0.5% and 5.1% higher, and 9.0% lower, than the recommended DOSD results of this paper and Jhanwar et al.(1). The larger discrepancies as k decreases, given the excellent agreement for the refractivity data, are probably due to difficulties in fitting the Cauchy series to polarizability data over a limited wavelength range; see for example the discussion in Hohm (59). The evaluation of the dipole sums using the DOSD approach involves no such fitting procedure.

As discussed in the previous section, Berkowitz (52) has analyzed the experimental DOSs for the ethylene molecule. He has evaluated the dipole sums S_k, $k = -2(1)$ 2, using both raw and adjusted experimental DOS data and the value of the S_{-2} used in the adjustment is that due to Holm (59) just discussed. The results obtained for the dipole sums S_k, $k = -2$

to 2, respectively, differ from our constrained DOSD results of Table 3 by –3.2%, –2.52%, –0.6%, 1.6%, and –1.6% and by only 0.2%, –0.1%, 0.5%, 1.8%, and –1.6% for the raw vs. the adjusted DOS input, respectively.

Time-dependent Hartree–Fock (TDHF) results for the ethylene S_k, k = –2, –4, and –6, are available from Spackman (63); he employed an 6–31G(+sd +sp) basis set and an ELP (electrical properties) basis set of Liu and Dykstra (64). The ab initio results are 1.7% lower and 4.8% and 16.1% higher for the 6–31G(+sd +sp) basis and 0.5%, 13.3%, and 34.3% higher for the ELP basis set than our recommended results, which are very similar to those of Jhanwar et al. (1) used in the analysis of Spackman (63). Generally, the ELP basis seems to perform better in the calculation of dipole sums and ethylene is one of the exceptions pointed out by Spackman (63).

About a year after Spackman's paper, Maroulis (65) carried out a study of basis set and electron correlation effects in the ab initio calculation of the dipole polarizability (and hyperpolarizability) of ethylene using the self-consistent field and many body-perturbation theory methods. Eight basis sets were discussed/investigated beginning with that due to Dunning (66) and perturbation theory through fourth order, including contributions from single, double, triple, and quadruple substitutions from the zeroth order function were considered. The Hatree–Fock limit of S_{-2} (the dipole polarizability in units of a_0^3) was estimated to be 28.36 ± 0.14, while the best estimate, including correlation effects, was 27.29 ± 0.12, which is within about 1.5% of the then, and the current, recommended result of 27.70. Reference 65 has a nice discussion of the then available theoretical and experimental results for the dipole polarizability of ethylene.

Dalskov and Sauer (67) have evaluated the ethylene dipole sums S_k, k = –2, –4, and –6, using the random phase approximation (RPA), the second-order polarization propagator approximation (SOPPA), the SOPPA with coupled cluster singles and doubles amplitudes (SOPPA(CCSD)), and the coupled cluster singles and doubles linear response function method (CCSDLR); two basis sets were investigated, Sadlej's (68, 69) medium-sized polarization basis set (basis set I) and Dunning's (70) correlation consistent valence triple ζ basis set augmented by two diffuse polarization functions for all angular momenta in the basis added in an even tempered fashion (71, 72) (basis set II). For the first three ab initio methods, the dipole sums were directly evaluated using the approach discussed by Fowler et al. (73), while a Cauchy fit to the frequency-dependent polarizability was used in the case of the CCSDLR calculation.

The discrepancies of the ab initio results with respect to our recommended values for basis set I (and II) are 2.2%, 2.3%, –0.8%, and –0.6% (2.9%, 1.6%, –0.6%, and –0.6%), 15.7%, 13.5%, 6.7%, and –2.4% (15.5%, 9.2%, 4.9%, and –4.7%) and 35.2%, 26.4%, 16.1%, and –6.6% (36.0%, 19.7%, 13.9%, and –9.7%) for S_{-2}, S_{-4}, and S_{-6}, respectively,

© 2007 NRC Canada

in the order RPA through CCSDLR. These results are more or less in agreement with the trend discussed in Dalskov and Sauer (67) that the accuracy of these ab initio approaches increases in the order RPA to CCSDLR. Generally, the dipole sums are more difficult to compute as k decreases. Dalskov and Sauer also computed the frequency-dependent dipolar polarizability of ethylene using basis set II and the CCSDLR method over a limited wavelength range (five values from 6329.9 to 3251.3 Å). Their corresponding results vary from being 0.7% to 1.5% lower than those evaluated from our recommended DOSD, as the λ decreases; the agreement is well within the estimated errors (67) in their calculations.

The ethylene dipole sums S_k, $k = -2$ and -4, have also been evaluated by Caillie and Amos (74) using the self-consistent field (SCF) approach and two variants of density functional theory (DFT), namely, the local density approximation (LDA) and a gradient corrected functional (BLYP); basis sets (see earlier) developed by Sadlej (68, 69) and Woon and Dunning (71, 72) were investigated. The dipole sum S_{-2} was calculated directly, while S_{-4} was determined by a Cauchy fit of the relevant frequency-dependent polarizability through terms varying as λ^{-4}. The ab initio results are all greater than our recommended values; for the Sadlej (Woon and Dunning), basis sets by 2.3%, 5.1%, and 3.6% (2.9%, 5.0%, and 3.8%), and 15.5%, 17.8%, and 17.0% (15.5%, 15.6%, and 15.6%) for S_{-2} and S_{-4}, respectively, in the order: SCF, LDA, BLYP. The DFT results show no improvement relative to the SCF results and, as in the case of the ab initio methods employed by Dalskov and Sauer (67), the more sophisticated basis set shows little improvement over the results obtained from the Sadlej basis.

A recent discussion of the mean excitation energies for the stopping power of some 32 atoms and molecules can be found in Kamakura et al. (75). This includes the evaluation of I_0 for these species using, as a basis, the analysis of the relevant oscillator-strength spectra recently given by Berkowitz (52). A detailed comparison with a variety of literature values of I_0 for the atoms and molecules considered is included in Kamakura et al. (75). Their result for I_0 for ethylene is 51.3 eV, which is 2.3% higher than our recommended result; the older recommended DOSD result of Jhanwar et al. (1), referred to in ref. 75, is 0.5% lower than our recommended result.

The discussion (76) of the radiation interaction parameters (S_k, L_k, I_k, $k = 1,0, -1$, $S_{1/2}$), and their additivity for the alkenes based on the results of ref. 1, is not significantly affected by the results of the current work.

The ab initio quantum mechanically calculated results (63, 65, 67, 74) for the dipole properties discussed earlier do not include vibrational averaging effects, which are included, for example, in the experimentally based results of Hohm (59) and in the DOSD values for these properties. As emphasized, for example, by Russell and Spackman (77), the sizes of these effects are often reasonably small, and so high-quality electronic property calculations are generally required initially before vibrational effects are considered within the ab initio treatment used in the calculation. Ab initio calculations of such properties are complicated by several factors: (*i*) the selection of the nuclear geometry of the molecule (equilibrium or vibrationally averaged geometries, experimental or calculated geometries, calculated geometries that have been calculated previously or those that are consistent with the theoretical approach used in the property evaluation), (*ii*) the choice of the ab inito method, (*iii*) the choice of the basis set used to carry out the calculation, and (*iv*) whether or not vibrational averging effects are included in the calculation. Each of these factors can introduce error into the final ab initio result for the property.

The molecular property most studied in the context of the last paragraph is the polarizability of molecules. For example, two studies (78, 79) indicate that the effects of vibrational averaging on the isotropic dipole polarizabilities of the first-row hydrides CH_4, NH_3, H_2O, and HF varies from being 4%–5.5% to 1.5% higher than the unaveraged values; a study (77) of the second-row hydrides shows similar results. As might be expected, molecules with a number of hydrogen atoms bonded to a common atom show the largest vibrational averaging effect as does H_2 itself. Results for S_{-2}, as a function of the bond length of H_2, are available in the literature (80, 81), and for example, the result at the vibrationally averaged bond length $r_0 = 1.449\ a_0$ is 4% higher than at the equilibrium bond length $r_e = 1.40\ a_0$. Limited results for some of the other dipole properties of H_2, as a function of bond length, are also available in ref. 82.

Vibrational averaging effects, when available for the molecule of interest, have been used from time to time to help reconcile ab initio and constrained DOSD results for molecular properties (see for example, refs. 37, 42, 48). Also, it is relevant to point out that the effects of molecular geometry, including vibrational averaging, can be relatively more significant in the evaluation of the (intrinsically smaller) anisotropy of molecular properties than it is for the isotropic properties of particular interest in this paper (37, 77–82).

Dispersion-energy coefficients

The dipole dispersion-energy coefficients are generally most conveniently evaluated by using discrete representations (pseudo-DOSDs) of the recommended constrained DOSDs for the interacting species (10, 11). This representation of the original DOSD of the molecule is particularly useful for the efficient evaluation of the triple-double dispersion energy, which is given (eq. [7]) in terms of a triple integral involving the original continuous DOSDs of the interacting species (11, 12). The pseudo-DOSD for a given molecule is determined from known values of the dipole sums S_k by requiring

$$[10] \qquad S_k = \sum_{i=1}^{n} (E_i / E_H)^k f_i \quad , k = 2,1,0, -1, -2, \ldots, 3-2n$$

The values of $2n$ dipole sums generate n pseudo-dipole (excitation energy oscillator strength) pairs (E_i, f_i). The ten pseudo-state representation of the constrained DOSD 1 for ethylene is given in Table 4. It is more than adequate for evaluating the dipole–dipole and the triple-dipole dispersion-energy coefficients, for interactions involving the ethylene molecule, to well within the accuracy (≤1% for dipole–dipole, ≤1%–2% for triple-dipole) generally expected (10–12) from using the original constrained DOSD. We have also computed the pseudo-DOSDs for propene and 1-butene using the S_k determined from the recommended DOSDs for

Note: Numbers in parentheses indicate a power of ten.

these molecules constructed by Jhanwar et al. (1); they can be found in Tables 5 and 6.

The discretized version of eq. [7], useable for the evaluation of the dipole–dipole dispersion-energy coefficient C_6 by employing the pseudo-DOSDs of the interacting species, is given by (10, 14)

$$[11] \quad C_6(\mathrm{A},\mathrm{B}) = E_H a_0^6 (3/2) \sum_{i=1}^{n_A} \sum_{j=1}^{n_B} \frac{f_i(\mathrm{A}) f_j(\mathrm{B}) (E_H)^3}{E_i(\mathrm{A}) E_j(\mathrm{B}) [E_i(\mathrm{A}) + E_j(\mathrm{B})]}$$

The results for the C_6 coefficients obtained from this result for the interaction of ethylene, propene, and 1-butane with themselves and with some 47 other atoms and molecules, can be found (units of $E_H a_0^6$) in Tables 7, 8, and 9, respectively. In these calculations, the alkene molecules are represented by the pseudo-states listed in Tables 4, 5, and 6, and the pseudo-states for the other species can be found in the literature (6, 7, 9, 10, 12, 42, 46–49, 51, and refs. cited therein). The uncertainties are ≈1%.

The pseudo-DOSD expression for the triple-dipole interaction energy coefficient C_9 is (11, 14)

$$[12] \quad C_9(\mathrm{A},\mathrm{B},\mathrm{C}) = E_H a_0^9 (3/2) \sum_{i=1}^{n_A} \sum_{j=1}^{n_B} \sum_{k=1}^{n_C} \frac{f_i(\mathrm{A}) f_j(\mathrm{B}) f_k(\mathrm{C})}{E_i(\mathrm{A}) E_j(\mathrm{B}) E_k(\mathrm{C})} \times \frac{[E_i(\mathrm{A}) + E_j(\mathrm{B}) + E_k(\mathrm{C})](E_H)^5}{[E_i(\mathrm{A}) + E_j(\mathrm{B})][E_j(\mathrm{B}) + E_k(\mathrm{C})][E_k(\mathrm{C}) + E_i(\mathrm{A})]}$$

Using the pseudo-states given in Tables 4–6, the triple-double dispersion-energy coefficients for the interaction of any three alkenes taken from ethylene, propene, and 1-butene can be evaluated with an estimated error of less than 2%. The results are given, in units of $E_H a_0^9$, in Table 10. The C_9 coefficients for all the interactions involving the alkenes and any of the other species occurring in the earlier tables can be evaluated by using the pseudo-states for the species referred to previously.

Olney et al. (57) have evaluated two dipole–dipole dispersion-energy coefficients using their DOSs for He, Ne, and C_2H_4 and obtained $C_6(\mathrm{He}-C_2H_4) = 19.92$ and $C_6(\mathrm{Ne}-C_2H_4) = 39.96$, which are 0.7% and 1.7% lower than our results.

Spackman (83) has carried out time-dependent Hartree–Fock (TDHF) calculations for C_6 and C_9, for the dimers and trimers, respectively, of ethylene, propene, and 1-butene, using a 6–31G(+sd +sp) basis set. His results of 285.4, 596.9, 1037.92, 5555.2, 16418.7, and 37286.5, respectively, are 4.9%, 9.8%, 8.2% and 6.6%, 15.2% and 13.0% lower than our recommended results. As thoroughly discussed by Spackman (63, 83, 84), who has used many of our previous constrained DOSD results for C_6 and C_9 for a variety of molecules to assess the situation, this level of TDHF calculation cannot be expected to give accurate results for these dispersion-energy coefficients.

Spackman has discussed the systematics of the deviations of 6–31G(+sd +sp) TDHF results of the dispersion-energy coefficients from the constrained DOSD values and suggested how to correct the TDHF results to obtain values that are generally much closer to the DOSD results if the static dipole polarizabilities of the interacting species are known both at the 6–31G(+sd +sp) TDHF level of approximation and reliably (for example, experimentally or through a constrained DOSD analysis). His equations for the predicted values, written for the interaction of like molecules, have the form

$$[13] \quad C_{6,\mathrm{pre}} = c[\alpha_{d,\mathrm{exp}} / \alpha_{d,\mathrm{TDHF}}]^a C_{6,\mathrm{TDHF}}$$

and

[14] $$C_{9,\mathrm{pre}} = d\,[\alpha_{d,\mathrm{exp}} / \alpha_{d,\mathrm{TDHF}}]^b C_{9,\mathrm{TDHF}}$$

where in Spackman's work, the parameters a, b, c, and d are $a = 2$, $b = 3$, $c = 0.9435$, and $d = 0.9283$. Using Spackman's results (63, 83) for $\alpha_{d,\mathrm{TDHF}}$, $C_{6,\mathrm{TDHF}}$, and $C_{9,\mathrm{TDHF}}$, and our recommended values of S_{-2} as $\alpha_{d,\mathrm{exp}}$, one obtains $C_{6,\mathrm{pre}}$ = 278.4, 639.5, and 1100.0 and $C_{9,\mathrm{pre}}$ = 5421.4, 18440.5, and 41206.8 for the like interactions involving ethylene, propene, and 1-butene; these results differ from our recommended results by –7.3%, –3.4%, and –2.7% (avg. = –4.4%), and –8.8%, –4.7%, and –3.8% (avg. = –5.8%), respectively. The improvement relative to the TDHF values is very good except for ethylene where the correction factors multiplying the TDHF results are less than unity.

More recently, Cybulski and Haley (85) have discussed several new approximations for calculating the dispersion-energy coefficients C_6 and C_9, which are based on eqs. [13] and [14] for the interaction of like species. They developed several schemes using our literature DOSD results to determine the parameters a, b, c, and d and tested their approach against our accurate DOSD results for some fourteen interactions involving rare gases, HF, N_2, CO, H_2O, and normal

alkanes. Their approximations have been set up using higher level basis set values for the input TDHF quantities than Spackman's scheme, which is designed for the use of 6–31G(+sd +sp) TDHF results for the input polarizabilities and dispersion-energy coefficients; the TDHF input from refs. 63, 83, and 85, for common molecules are significantly different. Thus, as discussed previously (9), the approximations of Cybulski and Haley, which yield an improvement on the Spackman scheme for the fourteen test interactions, do not necessarily improve the situation for other interactions (partly depending on the nature of the TDHF input).

The alkene ab initio results (83) for the dipole–dipole dispersion-energy coefficients do not contain vibrational averaging effects. Also, all the problems discussed at the end of the last section regarding the ab initio calculation of molecular properties apply to the calculation of the C_6 coefficients as well; various approximations (15, 16) for C_6 indicate that this coefficient qualitatively behaves as the product of the dipole polarizabilities of the two interacting molecules. Results for C_6 for the H_2–H_2 interaction, and for the interaction of H_2 with all the rare gases (R_g), as a function of the H_2 bond length are available in the literature (80–82). For example, the increase in C_6 due to increasing the H_2 bond length from $r_e = 1.40\ a_0$ to $r_0 = 1.449\ a_0$ is about 6% for the H_2–H_2 interaction and about 2.8% to 3.2% for the H_2–R_g interactions. In general, the bond length dependence of the dispersion-energy coefficients, the higher-order coefficients as well as C_6, is important as input for the construction of multi-dimensional potential-energy surfaces that reflect the relevant vibrational motions in a molecular complex, see for example ref. 86 and citations therein.

Discussion and conclusions

Estimates for the uncertainties in our recommended values for molecular dipole properties, evaluated using the constrained dipole oscillator distribution approach, are based on methods developed and used previously (2, 6, 7, 21, 41). The recommended results are compared with those obtained from alternative DOSDs satisfying the same constraints (i.e., DOSD1 and DOSD2 for ethylene in this paper and the various DOSDs considered for all three alkenes in ref. 1). For the properties that depend significantly (21, 41, 50, 60, 61) on energy regions of the DOSD that dominate the constraints used in constructing the DOSDs, that is the S_k, L_k, and I_k for $-6 \le k \le 0$ or 1, the estimated errors are ≤ 1%−2%. The uncertainties will increase, relatively slowly, as k decreases for $k < -6$ because local errors in the DOSD for small photon energies are magnified for these properties (21, 50, 60, 61); they can be as high as 10% to 15% for S_{-10}. These error estimates assume reliable values (errors of a few tenths of a percent) for the molar refractivities used as constraints. For $k \ge 1$, and particularly for $k = 2$, the estimated errors in the dipole properties are related to errors in the high-energy input data used in the construction of the DOSD and generally can be on the order of several percent. These error estimates apply for the three alkene molecules considered in this work and in ref. 1. Because of the analysis of

© 2007 NRC Canada

Berkowitz (52), which includes consideration of relatively recent high-energy DOS data for ethylene, and the agreement between his and our results for S_2 and S_1, we estimate the errors in our recommended results for the S_k, L_k, and I_k, $k = 1, 2$, to be 1%–2% for this molecule.

As indicated earlier, part of motivation for this work was to verify the reliability of the results for the dipole properties of the alkenes obtained in the original (1) constrained DOSD analysis for these molecules. That work was carried out in the early 1980s and was based on the then available DOS data for the molecules, which, as discussed earlier in the present paper, were sparse, from various experimental groups, with no direct experimental DOS data being available for photon energies greater than 50 eV for ethylene, 27 eV for propene, and 24 eV for 1-butene (in ref. 1, the higher-energy DOSs were obtained via mixture rules with ethylene playing a relevant role for propene and 1-butene). The constrained DOSD analysis in the current paper for ethylene, which is based on extensive experimental DOS data from a single experimental group (8), indicates that the results for the properties of these molecules obtained originally are indeed reliable and that the present recommended values for ethylene offer only a marginal improvement. Similarly, the values of the dipole properties of ethylene for $k \leq 1$ obtained by Olney et al. (57), which were obtained in 1997 by using the same experimental molecular DOS database as used in the present paper (with no extension beyond 200 eV using mixture rules) and an energy-independent normalization approach, offer little improvement relative to the original (1) evaluation of these properties. This indicates the power of the constraint procedure used in our work, namely, the reproduction of experimental molar refractivity data and the satisfaction of the full Thomas–Reiche–Kuhn sum rule ($S_0 = N$). The use of both of these constraints normalizes the complete DOSD, from small to very large E, in a smooth, continuous, and energy-dependent manner. Energy-independent normalization (8, 57, 87) and (or) no extension of the DOS database to very high photon energies can lead to difficulties in determining reliable values of atomic and molecular dipole properties even from extensive experimental DOS data sets; this has been discussed in the literature (see for example, refs. 9, 47, 49, and some of the citations therein) and is also illustrated by the discussion of the dipole properties of ethylene given earlier here.

The results for the dipole–dipole and the triple-dipole dispersion energies for the interactions considered in this paper are new and are apparently (essentially) the only reliable values available for these alkenes. They represent prototype interactions involving prototypical molecules containing the alkene group and therefore should be of considerable interest. The estimated errors for the C_6 and C_9 results given in this paper are 1% and 2%, respectively.

Accurate DOSD values of C_6 for important prototype interactions furnish useful checks of other methods for evaluating dispersion-energy coefficients, for example, empirical, non-empirical, ab initio quantum mechanical, and Padé approximant approaches (10, 11, 15, 28, 29, 51, 83, 88–93). In this context, it is relevant to point out that in the construction of potential-energy models (24–30) (mentioned briefly previously), it is necessary to include the dispersion energy to at least terms that vary as R^{-10} at long range. The terms varying as powers of R^{-1} higher than R^{-6} are not accessible by DOSD techniques due to the lack of (experimental) higher multipole (than dipole) oscillator strengths. The method of choice for determining these higher-order dispersion energies is via ab initio quantum mechanical methods analogous to those used for the dipole–dipole case. The reliability of these methods for these energies can be checked indirectly via the checks on the dipole–dipole dispersion energy referred to earlier, since the ab initio calculation of the higher-order terms is not easier than for the dipole–dipole dispersion energy. In any event, as pointed out earlier, the dipole–dipole dispersion energy is the lead or dominant dispersion energy, and the success of the potential-energy models depends (26, 61) on a reliable value of the coefficient C_6.

The pseudo-DOSDs employed in this work to calculate the dipole–dipole and the triple-double dispersion-energy coefficients form a concise representation of the original recommended DOSDs for the alkene molecules, which are continuous functions of the excitation energy from the UV-absorption threshold to many thousands of eV. They give reliable results for the dispersion-energy coefficients and a variety of other molecular properties through the use of discretized analogues of the usual expressions for these properties (10–12). We emphasize that more than ten pseudo-states are needed to reliably evaluate some of these properties,[3] for example, the logarithmic dipole sums L_k for "larger" values of k, which have significant negative and positive contributions (41, 49).

Acknowledgements

The authors wish to thank C.E. Brion, G. Cooper, and T.N. Olney for making their dipole oscillator strengths for ethylene available to us. This research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada (NSERC).

Chemical forms of calcium in Ca,Zn- and Ca,Cd-containing grains excreted by tobacco trichomes[1]

Géraldine Sarret, Marie-Pierre Isaure, Matthew A. Marcus, Emiko Harada, Yong-Eui Choi, Sébastien Pairis, Sirine Fakra, and Alain Manceau

Abstract: Tobacco (*Nicotiana tabacum* L. cv. Xanthi) plants exposed to toxic levels of zinc and cadmium excrete metals through their leaf trichomes (epidermal hairs) as Zn,Ca- and Cd,Ca-containing grains. Little is known about the nature and formation mechanism of these precipitates. The chemical, crystalline, and noncrystalline compositions of individual grains produced by tobacco were studied by scanning electron microscopy coupled with energy dispersive X-ray analysis (SEM-EDX), micro-X-ray diffraction (μXRD), and calcium K-edge micro X-ray absorption near edge structure (μXANES) spectroscopy. Zinc is predominantly incorporated in calcite and cadmium in calcite and vaterite. Aragonite, which occurs occasionally, does not seem to contain trace metals. In addition to being precipitated in its three possible polymorphic forms, calcite, aragonite, and vaterite, calcium is also speciated as amorphous $CaCO_3$ and possibly organic Ca in some grains. Most often, a particular grain consists of two or more crystalline and noncrystalline phases. The observed variability of intra- and inter-grain elemental and phase composition suggests that this biomineralization process is not constrained by biological factors but instead results from thermodynamically and kinetically controlled reactions. This study illustrates the potential of laterally resolved X-ray synchrotron radiation techniques (μXRD and μXANES) to study biomineralization and metal immobilization processes in plants.

Key words: biomineralization, detoxification, micro-XANES, micro-XRD.

Résumé : Lorsque des plants de tabac (*Nicotiana tabacum* L. cv. Xanthi) sont exposés à des niveaux toxiques de zinc et de cadmium, ils excrètent des métaux par les trichomes (poils épidermiques) de leurs feuilles qu'on retrouve sous la forme de grains contenant du Zn,Ca et du Cd,Ca. On connaît peu de choses sur la nature et le mécanisme de formation de ces précipités. On a étudié les compositions chimiques cristallines et non cristallines de grains individuels produits par le tabac en faisant appel à la microscopie électronique à balayage couplée à l'analyse des rayons X en dispersion d'énergie (MEB-XDE), à la diffraction micro des rayons X (μDRX) et à la micro spectroscopie d'absorption X de type XANES (μXANES) au seuil *K* du calcium. Le zinc est principalement incorporé dans la calcite et le cadmium dans la calcite et la vatérite. L'aragonite qu'on rencontre occasionnellement ne semble pas contenir de traces de métaux. En plus d'être précipité sous ses trois polymorphes possibles, calcite, aragonite et vatérite, le calcium se trouve aussi sous la forme de $CaCO_3$ amorphe et possiblement sous la forme de Ca organique dans certains grains. Le plus souvent, un grain est formé d'au moins deux phases cristallines et non cristallines. La variabilité tant intra- qu'intergrains en terme de composition élémentaire et de nature des phases suggère que ce processus de biominéralisation n'est pas contraint par des facteurs biologiques, mais qu'il résulte plutôt de réactions sous contrôle thermodynamique et cinétique. Cette étude illustre le potentiel des techniques de rayonnement X synchrotron résolues latéralement (μDRX et μXANES) dans l'étude des processus de biominéralisation et d'immobilisation des métaux dans les plantes.

Mots-clés : biominéralisation, détoxification, spectroscopie d'absorption micro-X de type XANES (μXANES), diffraction micro des rayons X (μDRX).

Introduction

Recently, a novel original mechanism of Zn and Cd detoxification was described in tobacco (*Nicotiana tabacum* L. cv. Xanthi). Tobacco exposed to Cd excreted Cd,Ca-containing grains through leaf trichomes (1, 2), and a similar excretion of Zn,Ca-containing grains was observed under Zn exposure (3). Trichomes are specialized epidermal structures. In tobacco, they are glandular and excrete various organic substances including nicotine and resins. This detoxification process may have implications in human health, since smoking is one of the principal routes of exposure to heavy metals, and also in phytoremediation as tobacco is a candidate species for phytoextraction.

The morphology, elemental composition, mineralogy, as well as Zn and Cd speciation in the grains were investigated by scanning electron microscopy coupled with energy dispersive X-ray analysis (SEM-EDX), micro-X-ray fluorescence (μXRF), micro-X-ray diffraction (μXRD), Zn K-edge micro extended X-ray absorption fine structure (μEXAFS) (3), and Cd L_{III} edge micro X-ray absorption near edge structure (μXANES) spectroscopy (Isaure et al., manuscript in preparation). Calcium was always the major component. μXRD analyses revealed the presence of calcite and less frequently vaterite and aragonite, two other $CaCO_3$ polymorphs. Calcium oxalate mono- and di-hydrate were occasionally found. Calcite and vaterite were substituted by cations, probably Zn, Cd, and possibly Mn and Mg. Zn μEXAFS confirmed the occurrence of Zn-substituted calcite and evidenced Zn associations with other phases including organic compounds, silica, and phosphate (3). Cd μXANES showed that cadmium was a Ca substituent in calcite and vaterite and (or) sorbed on the surface of these minerals (Isaure et al., manuscript in preparation).

The mechanism of formation of these grains remains unclear. Biogenic minerals may result from a controlled biomineralization process leading to well-defined minerals and shapes. They may also be biologically induced, which means that an organism promotes the precipitation but does not control the crystallization process (4). In the present case, grains could result from the exudation of a liquid containing the various metals and substances and the precipitation of the various solid phases because of water evaporation. Alternatively, they might be formed intracellularly and excreted thereafter as suggested by Choi and Harada (5). The purpose of this study is to better characterize the structure and composition of the grains. Grains excreted by tobacco, under various Zn, Cd, and Ca exposure conditions, were investigated by SEM-EDX, μXRD, and Ca K-edge μXANES spectroscopy. Results of these complementary approaches are compared, and a hypothesis for the formation of the grains is proposed in light of these data.

Experimental

Materials

Plant culture and grain collection procedures have been described previously (3). Briefly, tobacco plants were grown in hydroponic conditions and exposed for 5 weeks to Zn or Cd, with or without a supplement of Ca (Table 1). A control condition with Ca only was also tested. Then, grains were

© 2007 NRC Canada

collected by washing the leaves in ultrapure water and centrifugating the suspension. Several Ca-containing reference compounds were used for the Ca XANES data analysis. Calcite, vaterite, and Cd-containing vaterite were synthesized at room temperature (RT) according to a modified protocol of Paquette and Reeder (6, 7). Briefly, an aqueous solution (500 mL) containing 10 mmol/L $CaCl_2$ and 1.8 mol/L NH_4Cl was placed in a glass reactor, an EPPENDORF tube containing solid ammonium carbonate was allowed to float at the surface of the solution, and the reactor was closed and kept unstirred. NH_4Cl was used as a background electrolyte to provide a high ionic strength. Initial pH was 4.9. The decomposition of ammonium carbonate produces NH_3(g) and CO_2(g), which dissolve into the solution simultaneously increasing pH and alkalinity. The supersaturation of the solution induces the formation and growth of $CaCO_3$ crystals. Continuous sublimation of NH_3(g) buffers the solution around pH = 7.9. After 13 days, the reactor contained rhombohedral crystals and spherical particles attached to the surface of the glass. The two types of particles were separated and characterized by XRD. Rhombohedral crystals corresponded to calcite and spherical particles to vaterite. For the synthesis of Cd-containing vaterite, the same procedure was used except that after 13 days, when crystal size amounted to 150–200 μm in diameter, the $CaCl_2$–NH_4Cl solution was progressively doped with 0.1 mol/L $CdCl_2$ to a total concentration of 100 μmol/L Cd to incorporate Cd as a Ca substituent in vaterite (6, 7). The progressive addition of $CdCl_2$ kept the solution undersaturated with respect to otavite ($CdCO_3$). After 7 days, the particles were collected and separated. Spherical particles were identified as Cd-containing vaterite by XRD and μXRF. The Cd content was 1–20 ppm based on μXRF analysis.

Aragonite was a natural specimen. The XANES spectrum for synthetic amorphous $CaCO_3$ was provided by Y. Politi (8). Ca oxalate monohydrate (whewellite) was purchased from Sigma-Aldrich. A solution containing 0.5 mol/L $Ca(NO_3)_2$ at pH 2.6 was used as a reference for aq. Ca^{2+}. The phase purity of all crystalline samples was checked by XRD prior to XANES analysis.

Electron microscopy

The morphology and the chemical composition of the grains were studied by SEM-EDX using a Jeol-JSM 840A equipped with a Kevex Si(Li) detector. The chamber pressure was 10^{-6}–10^{-5} torr (1 torr = 133.322 4 Pa), and the accelerating voltage was 20 kV. Grains were mounted on kapton tape or on carbon tape, then fixed on carbon stubs and coated with carbon. Images were taken at a magnification of 500 to 10 000. EDX spectra were recorded on prominent spots of the grains to optimize the detection.

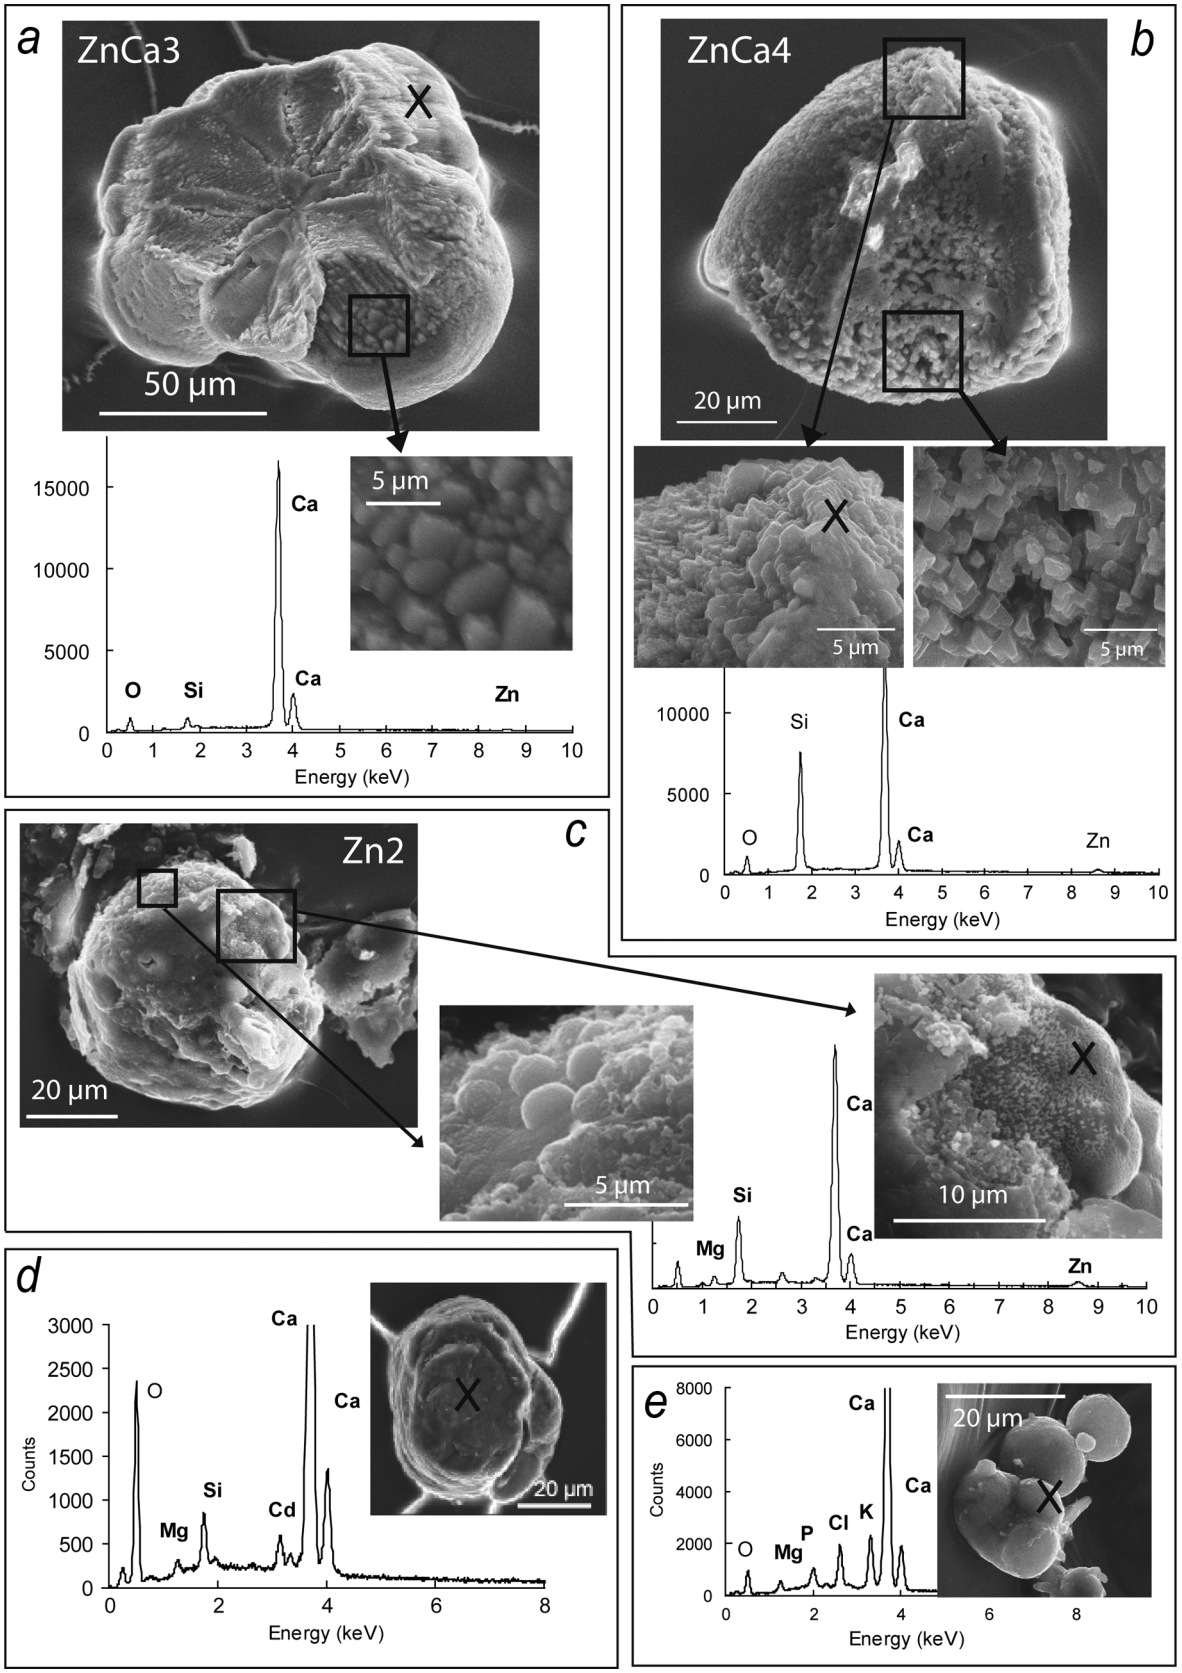
μXRF, μXRD, and μXANES

The μXRF, μXRD, and Ca K-edge μXANES measurements were performed on beamline 10.3.2 of the Advanced Light Source (ALS, Berkeley, California) (9). The grains were spread on kapton tape and analyzed at RT and pressure. First, each grain was mapped by μXRF. Then, μXANES and μXRD data were recorded on the Zn-richest region for the Zn and Zn + Ca treatments, on the Cd-richest region for the Cd and Cd + Ca treatment, and on the Ca-richest region for the Ca treatment. μXRF data were collected at 10 keV with a beam size of 5 × 5 μm. The same X-ray spot size was used for Ca μXANES. Fluorescence X-ray yield was measured with a 7-element Ge solid-state detector. The spectra were recorded between 3900 to 4400 eV. μXRD patterns were recorded at an incident energy of 17 keV with a beam size of 16 × 7 μm. More experimental details are given in (3). Ca XANES reference spectra were recorded at RT on beamline ID21 at the European Synchrotron Radiation Facility (ESRF, Grenoble, France). Each spectrum is the average of two to three spectra, each about 15 min long.

XRD and XANES data treatment

The XRD data treatment was performed as described previously (3). Briefly, after calibration with alumina, two-dimensional XRD patterns were integrated to one-dimensional patterns for peak assignment. For substituted calcite crystals the unit cell parameters *a* and *c* were refined, and the stoichiometry of the substituent was estimated from these two parameters using the Vegard law (10) with calcite, smithsonite ($ZnCO_3$), and otavite ($CdCO_3$) as end members for the Ca-Zn and Ca-Cd solid solutions. This approach cannot be used for substituted vaterite because of the absence of a $CdCO_3$ structural analogue of vaterite.

XANES spectra were processed using WinXAS (11). All spectra were energy-calibrated with respect to calcite (the inflection point for this reference was set to 4042.6 eV). The collected scans were averaged; the background was subtracted and normalized using linear (pre-edge) or cubic (post-edge) polynomials. XANES spectra were then fitted by linear combinations using calcite, aragonite, vaterite, Cd-containing vaterite, amorphous $CaCO_3$, aq. Ca^{2+}, and Ca oxalate monohydrate reference spectra. The quality of the fits was quantified by the normalized sum-squares residuals $NSS = \sum(\mu_{experimental} - \mu_{fit})^2 / \sum(\mu_{experimental})^2 \times 100$, in the 4000–4150 eV range, where μ is the normalized absorbance. An energy shift of ±0.5 eV maximum and a correction of slope were allowed to account for the energy resolution of the monochromator and for possible inconsistencies in data processing. For some spectra, linear combination (LC) fitting did not provide satisfactory results, and over-absorption effects were suspected based on the comparison of these spectra with the standards. Therefore, each spectrum was fitted with and without a correction of over-absorption using a simple model (12). This model assumes that the smooth part of the resonant absorption is a constant fraction of the nonresonant background (which is a reasonable assumption in the XANES region), and that the sample is infinitely thick, i.e., totally absorbs the incident beam (which is probably true considering the energy range and the size and global composition of the grains). The equation used is,



$$[1] \qquad y_{experimental} = (1 + a) / (1 + a y_{corrected})$$

where *y* is the normalized resonant absorbance (which equals 0 below the edge and oscillates around 1 above the edge) and $a = \mu_{resonant} / (\mu_{nonresonant} + \mu_{fluorescence})$, where $\mu_{resonant}$, $\mu_{nonresonant}$, and $\mu_{fluorescence}$ are the three components of the absorbance μ.

Equation [1] can be solved as,

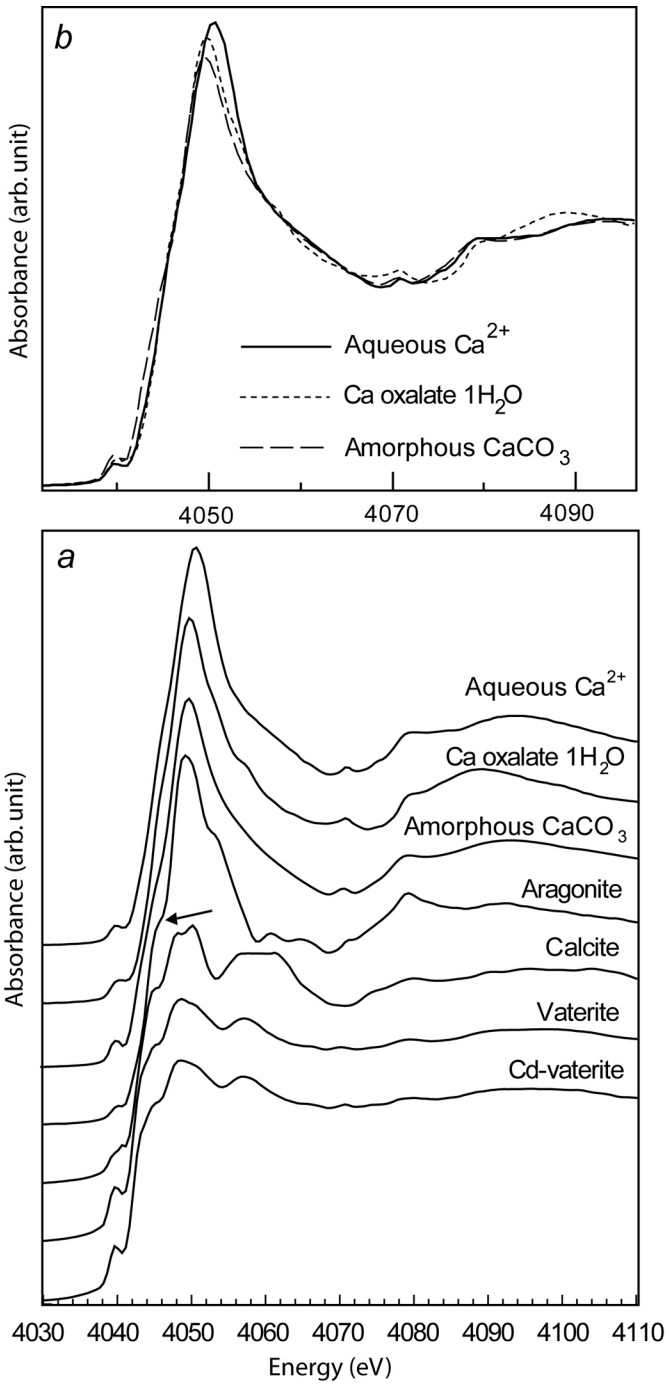
Fig. 2. (*a*) μXRF spectrum and (*b*) one- and two-dimensional μXRD patterns for grains ZnCa5 and Zn3. All XRD peaks were attributed to substituted calcite. The positions of three peaks for pure calcite are indicated by arrows.

[2] $$y_{corrected} = y_{experimental} / (1 + a(1 - y_{experimental}))$$

The over-absorption parameter *a* equals 0 in the absence of an over-absorption effect and increases with this effect. Because of the sample heterogeneity, the precise composition of the sample is not known, so *a* is an adjusted parameter.

Results

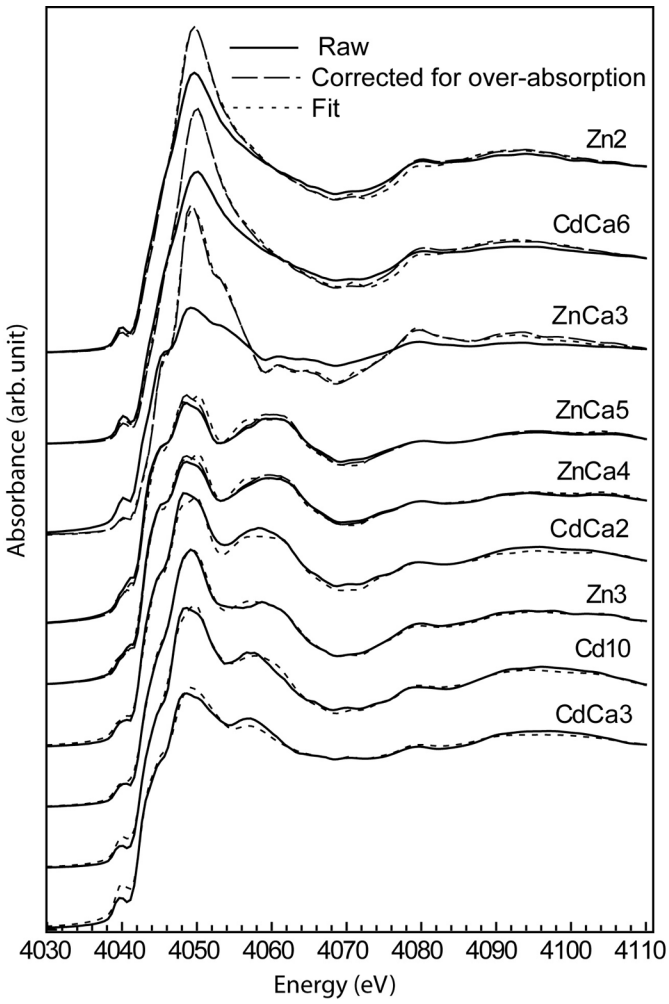
The morphology of the grains as observed by SEM varied considerably. The grains varied from 10 to 150 μm in diameter. Each grain is an aggregate of different types of particles. The first type is composed of micro-faceted crystallites (insets in Figs. 1*a* and 1*b*), and the second type is composed of globular structures of various sizes (from 2 to 50 μm, see Figs. 1*c*–1*e*). Some grains such as Zn2 (Fig. 1*c*) seem visually less crystalline. The elemental composition of the grains varies from one grain to another and within the same grain. Ca was always the major component regardless of the plant metal treatment conditions. Minor elements include Mg, Si, P, Cl, K, and Zn or Cd depending on the plant treatment (Fig. 1). The high Si peaks observed in Figs. 1*a*–1*d* are attributed to kapton tape on which the grains were mounted. Silicon is not detected in the grain presented in Fig. 1*e* (mounted on carbon tape). However, Si was found in small amounts in some grains (not presented in this study), as was Mn.



Our previous study using μXRD (3) showed that grain ZnCa3 contained substituted calcite and aragonite, grain ZnCa4 contained substituted calcite, and grain Zn2 did not contain crystalline phases. The two-dimensional μXRD patterns for grains ZnCa5 and Zn3 show that the Bragg reflections for these two grains consist of small arcs of Debye–Scherrer rings, indicating that the grains are composed of micrometer size mosaic crystals (Fig. 2*b*). All reflections correspond to substituted calcite, and the major Ca substituent is Zn, based on μXRF (Fig. 2*a*). Note that although Ca is the major element, the Ca Kα peak has a low intensity relative to the Zn Kα peak due to air absorption and the lower fluorescence yield of Ca vs. Zn. The refined unit cell parameters *a* and *c* for grains ZnCa5 and Zn3 were 4.97 and 16.97 Å and 4.95 and 16.83 Å, respectively, compared with 4.9896 and 17.0610 Å for pure calcite. The calculated formulae using the Vegard law were $Ca_{0.95}Zn_{0.05}CO_3$ and $Ca_{0.89}Zn_{0.11}CO_3$, respectively. The difference in the Zn stoichiometry coefficient obtained using parameters *a* and *c* was ±0.01. The μXRD results for the Cd-containing grains will be presented separately together with Cd L_{III}-XANES data (Isaure et al., manuscript in preparation). Briefly, the grains CdCa2 and Cd10 contain micrometer-sized crystals of substituted calcite and finer (nanometer-sized) crystals of substituted vaterite. Grain CdCa3 contains nanocrystals of substituted vaterite only. Finally, no crystalline phases were detected in grain CdCa6. For Cd-substituted calcite, the Vegard law provides an imprecise estimation of Cd stoichiometry because the contrast in ionic radius between Cd and Ca is small (0.95 Å for Cd^{2+} and 1.00 Å for Ca^{2+} compared with 0.74 Å for Zn^{2+}) (13). For instance, the substitution rate for grain CdCa2 could be anywhere between 30% and 80%. It was not possible to calculate the stoichiometry of Cd in vaterite because of the absence of a Cd end member (see the Experimental section).

Since calcium is the major element in the grains, Ca K-edge μXANES spectroscopy was then performed to get some insight on the composition of the grains and test for the presence of amorphous Ca phases. Fig. 3*a* shows the XANES spectra for several Ca reference compounds. The four $CaCO_3$ species (calcite, vaterite, aragonite, and amorphous $CaCO_3$ (ACC)) have clearly distinct spectra, which enables their identification (14, 15). However, Ca XANES has no sensitivity to substitutional impurities, as seen for instance for low Cd-containing vaterite (Cd content lower than 1%, as estimated by μXRF) and pure vaterite, exhibiting nearly identical spectra. The spectra for aq. Ca^{2+}, Ca oxalate monohydrate, and ACC share some similarities. However, the lower part of the edge is shifted to lower energy for the ACC spectrum, and the maximum of the white line (zero value of the first derivative) increases from 4049.5 (ACC) to 4049.9 eV (Ca oxalate monohydrate), and to 4050.5 eV (aq. Ca^{2+}, Fig. 3*b*). The aragonite spectrum is distinct from the three previous spectra in displaying a shoulder at 4046 eV (arrow in Fig. 3) and a minimum between 4060 and 4070 eV.

Fig. 4 shows the Ca μXANES spectra for the grains. They were fitted by LC using the standard spectra presented earlier, and the results are presented in Table 2. The ZnCa3 spectrum presents strong similarities with the aragonite



© 2007 NRC Canada

Fig. 3. (*a*) Ca K-edge XANES spectra for the reference compounds used in the linear combination fits and (*b*) enlargement of the main peaks for aq. Ca2+, Ca oxalate monohydrate, and ACC.

spectrum but with markedly lower amplitude. The drop in amplitude suggests some over-absorption effect (12) due to a high Ca content of the analyzed spot. The fit without over-absorption correction (see the Materials section) did not provide a satisfactory result (*NSS* = 0.065% with 68% vaterite and 25% aragonite). Introducing an over-absorption correction greatly improved the fit (Fig. 4, *NSS* = 0.014% with aragonite as the only component). The over-absorption

Fig. 4. Ca K-edge μXANES spectra for the tobacco grains and corresponding linear combination fits. Five spectra (Zn2, CdCa6, ZnCa3, ZnCa5, and ZnCa4) were corrected for over-absorption.

parameter *a* value found (1.38) corresponds to a very strong over-absorption effect. The fit was not improved significantly by introducing a second component (*NSS* decreased by less than 10%). Thus, the spot analyzed by μXANES likely contains aragonite as the sole Ca species.

The grains ZnCa4 and ZnCa5 were fitted with 98% calcite. The fit was slightly improved with a correction for over-absorption (*NSS* = 0.015% and 0.021%, compared with 0.020% and 0.035%, respectively), and the proportions were unchanged. Adding a second component did not significantly improve the fits (*NSS* decreased by less than 10%).

For grains Zn2 and CdCa6, fits without over-absorption correction were not satisfactory (*NSS* = 0.048% and 0.091%, respectively, for two-component fits). Fair one-component fits with over-absorption correction were obtained with ACC (*NSS* = 0.021% and 0.024%, respectively), but the match was not optimal for the first oscillation (around 4080 eV). Ca oxalate monohydrate and aq. Ca^{2+} provided weaker fits (*NSS* = 0.086% and 0.053% for Zn2, and 0.076% and 0.043% for CdCa6, respectively). Adding a second component did improve the reproduction of the first oscillation. Several fits of equivalent qualities were obtained with ACC

[a]Coefficient of over-absorption.

[b]Residual between fit and experimental data $NSS = \sum(\mu_{experimental} - \mu_{fit})^2 / \sum(\mu_{experimental})^2 \times 100$ in the 4000–4150 eV range, where μ is the normalized absorbance.

[c]Fit shown in Fig. 4. The error bars on the percentages correspond to the variation needed to increase *NSS* by 20%.

as a major component (about 80% and 70% of total Ca) and various species as secondary components. *NSS* values were more than doubled if ACC was excluded (Table 2 and Fig. 1 in the Supplementary information).[3] Therefore, grains Zn2 and CdCa6 likely contain ACC as major species and an additional species whose nature remains unknown.

For the other grains (Zn3, CdCa2, CdCa3, and Cd10), over-absorption correction did not improve the fits. Calcite was the major form in grains Zn3 and CdCa2, and fits of equivalent quality were obtained with ACC, aq. Ca^{2+}, and Ca oxalate monohydrate as minor species. Aqueous Ca^{2+} is unlikely in solid-state material. ACC and Ca oxalate monohydrate are more likely. In the absence of reference spectra for Ca bound to organic ligands other than oxalate, this latter compound may be considered as a proxy for Ca bound to organic compounds in general. Therefore, this pool is referred to as organic Ca and (or) ACC in Table 3. Vaterite was found in grains CdCa3 and Cd10. For this latter grain only, no satisfactory fit was obtained with two components (*NSS* = 0.046%), so a third component was introduced. Again, a contribution of organic Ca and (or) ACC was found in grains CdCa3 and Cd10.

The speciation of Ca was then compared with the mineralogy and morphology of the grains (Table 3). The percentages were rounded to the nearest ten for clarity. Except for two grains, ZnCa3 and CdCa2, the same crystalline species were identified by μXRD and Ca μXANES. Zn-substituted calcite and Cd-substituted vaterite were identified by μXRD in grains ZnCa3 and CdCa2, respectively, but not by Ca μXANES spectroscopy. This difference likely results from the larger beam size and higher penetration depth of X-rays in μXRD measurements relative to μXANES (16 × 7 μm vs. 5 × 5 μm and a few tens of μm at 17 keV vs. a few μm at 4 keV). Thus, μXRD probes a different material volume than Ca μXANES, even when conducted on the same spot.

Discussion and conclusion

Results showed that besides crystalline calcium carbonates (calcite, vaterite, and aragonite), the tobacco grains contained ACC as well. Whewellite (Ca oxalate monohydrate) did show up in some XANES fits, but its presence could not be firmly attested. Ca oxalate mono- and dehydrate have several XRD peaks in common with calcite but several peaks at distinct positions as well. These two minerals were positively identified by μXRD in other tobacco grains based on the presence of these specific peaks (3). In the present

	Zn3	70% calcite, 30% organic Ca, and (or) ACC	Zn-subst. calcite ($Ca_{0.89}Zn_{0.11}CO_3$)	Not observed
Cd + Ca	CdCa2	90% calcite, 10% organic Ca, and (or) ACC	Cd-subst. calcite, Cd-subst. vaterite	Not observed
	CdCa3	80% vaterite, 20% organic Ca, and (or) ACC	Cd-subst. vaterite	Rounded
	CdCa6	70% ACC, 30% undetermined	No diffraction peaks	Not observed
Cd	Cd10	30% calcite, 40% vaterite, 30% organic Ca, and (or) ACC	Cd-subst. calcite, Cd-subst. vaterite	Rounded and faceted

Note: The error bar on the percentages varies from 5% to 15% depending on the species (see Table 2).

study, no such peaks were found on the XRD patterns. However, it is still possible that coarse crystals of Ca oxalate mono- or dehydrate are present but produce nonspecific peaks only, or that Bragg conditions were not met for these coarse crystals. Therefore, the presence of Ca oxalate mono- and dehydrate cannot be ruled out. Other undetermined organic ligands may also complex Ca. In addition, mixed mineral and organic Ca compounds such as organic matter containing calcite (16) may occur.

The Ca μXANES analysis showed that strong over-absorption effects may take place and decrease dramatically the amplitude of the spectra. We show that this effect is far from negligible when identifying and quantifying Ca species. For instance, for grain ZnCa3, the uncorrected spectrum was fitted by 68% vaterite and 25% aragonite, and the corrected spectrum was fitted with 100% aragonite. Note that the LC fit without over-absorption correction was relatively bad, which alerted us on the possibility of an over-absorption effect.

In the environment, ACC is thermodynamically unstable and rapidly transforms into vaterite and then calcite (17). However, it is found as a stable compound in plants (e.g., cystoliths) and animals (e.g., cuticle of crustaceans, spicules of ascidiae, granules in molluscs) (18). ACC is probably stabilized by proteins, magnesium, and phosphorus in these organisms (18). In our case, Mg and P were found in the grains.

Biologically controlled biomineralization leads to well-defined mineral species and shapes. Here, the variety of morphologies and of $CaCO_3$ crystal structures, and their coexistence with amorphous and possibly organic forms, supports the hypothesis of a biologically induced (as opposed to biologically controlled) biomineralization. This study illustrates the potential of microfocused X-ray techniques to study biomineralization processes, and strategies of metals immobilization developed by plants to cope with metal toxicity.

Acknowledgements

We acknowledge the ALS (Berkeley, California) and the ESRF (Grenoble, France) for the provision of beamtime. We are grateful to Jean Susini and the staff of beamline ID21 at the ESRF for their technical support during the experiment. The operations of the Advanced Light Source at Lawrence Berkeley National Laboratory are supported by the Director, Office of Science, Office of Basic Energy Sciences, Materials Sciences Division, of the US Department of Energy under Contract No. DE-AC02–05CH11231. We acknowledge Y. Politi and S. Weiner for sharing the ACC Ca XANES spectrum, and two anonymous reviewers.

Formation of group 12 [Zn, Cd] mixed-chalcogen nanoparticles from the reagent Me_3Si-SeS-$SiMe_3$[1]

Elizabeth A. Turner, Harald Rösner, Yining Huang, and John F. Corrigan

Abstract: Mixed-chalcogen metal chalcogenide nanoparticles (MSe_xS_{1-x}; M = Zn, Cd) have been synthesized using Me_3Si-SeS-$SiMe_3$ as a delivery source of Se^{2-} and S^{2-} to the metal core. This method demonstrates the ease with which mixed-chalcogen particles can be fabricated at low temperature using colloidal techniques. Reaction with Me_3Si-SeS-$SiMe_3$ occurs via a redox pathway resulting in Se–S bond cleavage and ultimately contributing to the non-equivalent Se:S ratio observed in the isolated particles. Subsequent thermolysis of $ZnSe_{0.57}S_{0.43}$ and $CdSe_{0.28}S_{0.72}$ in hexadecylamine gives rise to controlled particle growth while maintaining the observed stoichiometry. Particles are characterized by EDX, TEM, and powder X-ray diffraction analysis in conjunction with UV–vis absorption and photoluminescence (PL) spectroscopy.

Key words: nanoparticles, semiconductors, mixed-chalcogen, quantum confinement, Group 12.

Résumé : On a effectué la synthèse de nanoparticules mixtes comportant un chalcogène et un chalcogénure métallique ($MeSe_xS_{1-x}$; M = Zn, Cd) en utilisant le Me_3Si-SeS-$SiMe_3$ comme source pouvant livrer les groupes Se^{2-} et S^{2-} au métal central. On a fait une démonstration de cette méthode par la facilité avec laquelle des particules de chalcogènes mixtes peuvent être fabriqués à basse température en faisant appel à des techniques colloïdales. La réaction avec le Me_3Si-SeS-$SiMe_3$ se produit par une voie réactionnelle redox qui provoque un clivage de la liaison Se-S et qui contribue éventuellement au rapport non équivalent de Se:S qui est observé dans les particules qui ont été isolées. Une thermolyse subséquente du $ZnSe_{0.57}S_{0,43}$ et du $CdSe_{0.28}S_{0.72}$ dans l'hexadécylamine conduit à une croissance contrôlée des particules tout en maintenant la stoechiométrie observée. On a caractérisé les particules par le biais de la diffraction des rayons X par des poudres et les techniques « EDX » et « TEM » en relation avec les spectres d'absorption UV–vis et la spectroscopie de photoluminescence (PL).

Mots-clés : nanoparticules, semiconducteurs, chalcogènes mixtes, confinement quantique, groupe 12.

[Traduit par la Rédaction]

Introduction

Metal-chalcogenides (ME; M = Zn, Cd, Hg; E = S, Se, Te; or M_2E; M = Cu, Ag) have been of tremendous interest over the past several decades (1). In particular, an extensive amount of research has surrounded both the synthesis (2) and characterization (3) of group 12–16 nanomaterials. Upon constricting the dimensions of a given material to the nanometer-size regime, quantum confinement effects predominate such that electronic, physical, and optical properties become size specific (4). Ultimately, for semiconductors, these phenomena give rise to an increase in band gap energy from that of the bulk material, where the band gap becomes tunable to a desired particle size. As a result, group 12–16 nanomaterials have found potential applications in the fabrication of new devices such as LEDs, photovoltaic, and photoelectrochemical devices (5). The control of particle size and the efficient delivery of chalcogen (E^{2-}) to the metal core, however, are two challenging aspects of nanomaterial synthesis. One means of managing these two synthetic obstacles is through the use of trimethylsilyl-chalcogenide reagents as an easily handled chalcogen source in conjunction with passivating the metal core with long alkyl chain amine (phosphine) ligands, thereby preventing possible aggregation (6).

One of the pioneering methods in controlling particle size is what is commonly referred to as the controlled arrested precipitation method from colloidal solutions where dilute aqueous mixtures of M^{2+} and E^{2-} species are combined together (7). This method was further extended into what is considered to be one of the most notable advances in the formation of discrete nanoparticles, the TOP or TOPO (trioctylphosphine or trioctylphosphine oxide) pyrolysis method. The rapid injection of sources of both M^{2+} and E^{2-} species into a hot coordinating solvent facilitates the development of nanoparticles (8). An extension of this method has been to inject metal clusters, where the metal-chalcogen bond is already prepositioned, into a hot hexadecylamine (HDA) solution (9). By increasing the reaction temperature,

particles are found to grow via Ostwald ripening (10) where the more soluble smaller particles grow in an effort to form larger particles (11). The large surface area to volume ratio of the smaller particles promotes the number of energetically less stable surface molecules, and larger particles having a greater volume to surface area ratio are of a lower energy state and thus preferentially form at the expense of smaller particles (12).

Manipulating particle size is one means of dictating their physical properties. An additional degree of freedom can be gained by substituting some metal (or chalcogen) atoms with another metal (or chalcogen), thus forming ternary MM′E (or MME′; M ≠ M′ and E ≠ E′) materials. These materials exhibit physical properties whose energies are intermediate between those of ME and M′E (or ME′). Recent studies have focused on the synthesis and characterization of group 12–12′–16 nanoclusters and nanoparticles through the use of trimethylsilyl-chalcogenide reagents (13). The formation of 12–16–16′ nanomaterials, however, remains relatively unexplored (vide infra).

Only a few known examples exist where discrete quantum dots, rather than thin films, of mixed-chalcogen cadmium materials have been synthesized. Quantum dots and tetrapod nanocrystals of $CdSe_xTe_{1-x}$ (14) have been synthesized from cadmium salts and stock solutions of selenium and tellurium using either TOP, TOPO, or stearic acid as surface stabilizing ligands. Homogeneously alloyed zinc-blende $CdSe_xS_{1-x}$ (15) nanocrystals have also been prepared from cadmium oxide, oleic acid, and stock solutions of elemental sulfur and selenium, added in varying proportions. Discrete particles were observed using transmission electron microscopy (TEM) and chemical homogeneity was demonstrated by powder X-ray diffraction (PXRD). By changing the ratio S:Se, the photophysical properties could be altered such that an increasing selenium content leads to a shift to lower energy of the excitonic transition, as observed in the absorption spectra. The majority of reports on mixed-chalcogen ternary alloys, however, involve the preparation of $CdSe_xS_{1-x}$ thin films typically on glass, quartz, GaAs, and silicon. A typical procedure involves the mixture of CdS and CdSe powders combined in a desired ratio (16). Other methods employ $CdCl_2$, thiourea and sodium selenosulfate as precursors (17), while the elemental forms of cadmium, sulfur, and selenium can also be combined with a desired stoichiometry in a glass melt (18). An extension to this synthesis involves the use of elemental sulfur and selenium with cadmium salts (19), while other procedures use a combination of metal salts with various chalcogen precursors (i.e., H_2E and $CS(NH_2)_2$) (20). Regardless of the choice of reagents, the methods involve specialized techniques such as chemical bath deposition, molecular beam epitaxy, or pulsed laser ablation, all of which require extremely high temperatures. The deposited materials typically have nanometer dimensions, where examples of nanowires and nanoribbons have been formed on a Si[111] substrate (21).

Herein we report the synthesis of MSe_xS_{1-x} (M = Zn, Cd) nanoparticles formed from the reagent $Me_3Si\text{-}SeS\text{-}SiMe_3$. The highly reactive nature of this reagent allows for the facile low temperature delivery of both sulfur and selenium to the corresponding metal acetate. The resulting nanoparticles are easily formed in solution at room temperature (RT). Subsequent thermolysis of the zinc and cadmium mixed-chalcogen nanoparticles in hot hexadecylamine is found to provide controlled particle growth. The resulting nanoparticles are analyzed by UV–vis absorption and PL spectroscopy, in addition to TEM, powder X-ray diffraction, and EDX analysis.

Experimental

Materials

All synthetic procedures and manipulations were performed under an inert nitrogen atmosphere using standard Schlenk techniques and gloveboxes, unless otherwise noted. Toluene, pentane, and hexanes (all from Caledon) were dried and collected using an MBraun MB-SPS solvent purification system with tandem activated alumina – activated copper redox catalyst (22). Dichloromethane (EMD) was dried and distilled over P_2O_5. Anhydrous methanol was purchased from Caledon. Cadmium acetate dihydrate (98%), anhydrous zinc acetate (99.99%), *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), *n*-butyl lithium in hexanes (1.6 mol/L), tri(*n*-butyl)phosphine, and hexadecylamine (HDA) were purchased from Sigma-Aldrich. Sulfur (99%) was purchased from EM Science. Cadmium acetate dihydrate was dried under vacuum (10^{-3} torr; 1 torr = 133.322 4 Pa) at 130 °C and stored under inert conditions. TMEDA was dried and distilled over a lump of sodium and stored under inert conditions. The reagent $Se(SiMe_3)_2$ was prepared according to literature procedures (13*c*, 23).

Synthesis of TMEDA Li^+ $^-SeSiMe_3$

In a Schlenk tube with no stir bar, $(SiMe_3)_2Se$ (0.15 mL, 0.7 mmol) and TMEDA (0.1 mL, 0.7 mmol) were added to tetrahydrofuran (10 mL) and cooled to 0 °C, producing a light brown solution. *n*-Butyl lithium (0.44 mL, 0.7 mmol) was added to the reaction, upon which the solution immediately became colourless, and the reaction was kept at 0 °C for 30 min with periodic mixing via agitation. A stir bar was then added to the solution and the reaction was warmed to RT with stirring. The solvent was removed under vacuum (10^{-3} torr for one hour) producing a colourless oil. The anion was used immediately in the subsequent chalcogen insertion as the product has limited stability at RT. ^1H NMR (C_7D_8, 203K) δ: 0.72 (s, $Si(CH_3)_3$), 1.64 (br s, CH_2), 2.11 (s, CH_3). $^{13}C\{^1H\}$ (C_7D_8, 203 K) δ: 8.41 ($Si(CH_3)_3$), 47.08 (CH_2), 56.11 (CH_3). ^{29}Si NMR (C_7D_8, 203 K) δ: 1.1. ^{77}Se NMR (C_7D_8, 203 K) δ: –520.

Synthesis of TMEDA Li^+ $^-SSeSiMe_3$

In a Schlenk tube, sulfur (0.023 g, 0.7 mmol) was suspended in pentane (10 mL) and cooled to -78 °C. Toluene (5 mL) was added to the lithio trimethylsilyl selenolate anion (0.7 mmol) and the solution was cooled to –78 °C. The anion solution was rapidly added to the sulfur suspension at –78 °C upon which a slightly yellow solution developed. The reaction was removed from the cold bath until a bright yellow cloudy solution resulted. The solution was then immediately cooled again to –78 °C and allowed to stir for an additional 20 min. The product was used in situ as removal of the solvent leads to product decomposition; in addition, the lithio trimethylsilyl selenothiolate anion must be used

immediately as it quite reactive to both air and elevated temperatures. ^{1}H NMR (C_7D_8, 203 K) δ: 0.31 (s, Si(CH_3)$_3$), 1.58 (br s, CH_2), 2.12 (s, CH_3). ^{13}C{^{1}H} (C_7D_8, 203 K) δ: 1.22 (Si(CH_3)$_3$), 48.55 (CH_2), 56.00 (CH_3). ^{29}Si NMR (C_7D_8, 203K) δ: 15.3. ^{77}Se NMR (C_7D_8, 203 K) δ: –96.

Synthesis of Me_3Si-SeS-$SiMe_3$

An excess of chlorotrimethylsilane (0.2 mL, 1.4 mmol) was added to lithio trimethylsilyl selenothiolate anion (0.7 mmol) at –78 °C. The reaction was allowed to gradually warm to RT upon which the cloudy solution went through a clear bright yellow stage followed by the development of a cloudy yellow suspension. Upon achieving this stage the reaction was immediately cooled to –78 °C and kept cold until further use. The product cannot be isolated as removal of the solvent leads to rapid decomposition. Furthermore, the generated lithium chloride must be added to subsequent reactions as filtration of the solution also leads to decomposition. The product is exceptionally reactive to air and has only short-term stability at RT. ^{1}H NMR (C_7D_8, C_5D_{12}, 218 K) δ: 0.26 (SSi(CH_3)$_3$), 0.34 (SeSi(CH_3)$_3$). ^{13}C{^{1}H} NMR (C_7D_8, C_5D_{12}, 218 K) δ: 1.27 (SeSi(CH_3)$_3$), 3.86 (Si(CH_3)$_3$). ^{29}Si NMR (C_7D_8, C_5D_{12}, 218 K) δ: 15.9 (Se*Si*(CH_3)$_3$), 16.4 (S*Si*(CH_3)$_3$). ^{77}Se NMR (C_7D_8, C_5D_{12}, 218 K) δ: –100.

Synthesis of $CdSe_xS_{1-x}$ nanoparticles

Anhydrous cadmium acetate (0.320 g, 1.4 mol) was solubilized with 2.2 equiv. of tri(*n*-butyl)phosphine (0.76 mL, 3.05 mol) in toluene (30 mL), producing a turbid solution. After stirring at RT for 1 h, a solution of Me_3Si-SeS-$SiMe_3$ (1.4 mol) was added and the reaction was stirred at RT overnight, resulting in the precipitation of a pale yellow solid. The solid was isolated via removal of the mother liquor, followed by washing (3 × 10 mL methanol), sonication for 15 min at 45 °C, and centrifugation. The resulting solid was dried under vacuum (10^{-3} torr) for 1 h.

Synthesis of $ZnSe_xS_{1-x}$ nanoparticles

Anhydrous zinc acetate (0.255 g, 1.4 mol) was solubilized with 2.2 equiv. of tri(*n*-butyl)phosphine (0.76 mL, 3.05 mol) in CH_2Cl_2 (10 mL). After stirring at RT for one hour, Me_3Si-SeS-$SiMe_3$ (1.4 mol) was added and the reaction was stirred at RT overnight. A resulting white solid precipitated from solution and was isolated via removal of the mother liquor and washing with hexanes (3 × 15 mL), followed by drying under vacuum (10^{-3} torr) for 1 h.

Thermolysis of MSe_xS_{1-x} in hexadecylamine

To the obtained MSe_xS_{1-x} [M = Zn, Cd] nanoparticles, hexadecylamine (HDA; 20 g, 82.8 mmol) was added to the flask and heated to 60 °C, until all of the HDA had melted. The solution was then degassed under vacuum (10^{-3} torr) for 20 min. The mixture was then heated to 240 °C, where at specified temperature intervals an aliquot was taken. At each temperature the reaction was annealed for 15 min, an aliquot was taken, washed with anhydrous methanol (15 mL) thus precipitating the resulting particles, centrifuged at 45 °C, and washed again with methanol. The obtained solids were dried under vacuum (10^{-3} torr) for 15 min and stored in a glovebox.

Characterization

Solution ^{1}H, ^{13}C{^{1}H}, and ^{77}Se NMR spectra were recorded on a Varian Inova 400 spectrometer with an operating frequency of 399.76, 100.53, and 76.24 MHz respectively. ^{29}Si NMR spectra were obtained indirectly as gradient heteronuclear multibond coupling (g-HMBC) experiments to proton ($J_{Si–H}$ = 6 Hz). ^{1}H and ^{13}C{^{1}H} NMR spectra were referenced internally to the respective deuterated solvent as well as externally to TMS, ^{29}Si NMR spectra were referenced to silicon grease (–20 ppm), and ^{77}Se NMR spectra were referenced externally to $PhSeSiMe_3$ (+85.6 ppm) (24). Powder X-ray diffraction (PXRD) patterns were obtained using a Rigaku diffractometer with a Co Kα radiation source (λ = 1.799260 Å). UV–vis absorption spectra for $ZnSe_xS_{1-x}$ nanoparticles were recorded on an Ocean Optics SD2000 UV–vis fiber optic spectrometer equipped with a Mini-D2T light source and a UV2/OFLV-4 detector. The spectra were obtained as a mineral oil mull between two quartz plates. UV–vis absorption spectra of the $CdSe_xS_{1-x}$ nanoparticle series were recorded on a Varian Cary 100 UV–vis absorption spectrometer. The spectra were obtained in a CH_2Cl_2 solution. Luminescence measurements were obtained using a Photo Technology International fluorimeter equipped with an LPS 220B lamp power supply and an 814 photomultiplier detection system. Energy dispersive X-ray (EDX) analyses were carried out by Dr. Brian Hart at Surface Science Western (UWO). A Quartz Xone EDX analysis system coupled to a Leo 440 SEM equipped with a Gresham light element detector was used to obtain semiquantitative analysis of Zn, Cd, S, and Se. Analyses were carried out using a 20 kV electron beam rastered over 100 μm × 100 μm areas and repeated to ensure reproducibility. Samples for high-resolution transmission electron microscopy (HR-TEM) were obtained by dispersing the solid in CH_2Cl_2 and dropping these dilute suspensions on gold-plated grids, allowing the excess solvent to evaporate. TEM investigations were performed in a Philips Tecnai F20 ST operated at 200 kV. The TEM was equipped with an EDAX Energy-Dispersive X-ray SiLi detector with a S-UTW (super ultra-thin window). EDX analyses were carried out in the STEM mode with a HAADF (high angle annular dark field) detector using a nanometer-sized probe (1 nm spot size for the presented measurements). Use of an analytic double tilt holder (Philips) was made. High-resolution micrographs were taken with a 1K × 1K CCD camera and analyzed with the software package Digital Micrographs (Version 3.7.4, Gatan Company) to perform fast Fourier Transformations (FFT).

Results and discussion

Synthesis of mixed-chalcogen nanoparticles

Trimethylsilyl-chalcogen reagents ($RESiMe_3$, $E(SiMe_3)_2$; R = alkyl, aryl, ferrocenyl) are valuable in the formation of structurally characterized nanoclusters (25) and nanoparticles (26). The reactive pendant trimethylsilyl moiety allows for the facile and homogeneous delivery of either chalcogenolate (RE^-) or chalcogenide (E^{2-}) bonding interactions to a metal salt via the generation and elimination of the corresponding trimethylsilane (27). Although the synthesis of binary and ternary mercury chalcogenides has been a syn-

© 2007 NRC Canada

thetically challenging area (28), one recent example involves the formation of $HgSe_xS_{1-x}$ particles from both $S(SiMe_3)_2$ and $Se(SiMe_3)_2$ and mercury acetate, using TOP in a phase separation method, to control particle growth (29). Particles varying in size from 2 to 3 nm were formed.

Traditional trimethylsilyl-chalcogenide reagents (i.e., $E(SiMe_3)_2$; E = S, Se, Te) are well-known and extensively used in synthesis, however, there is recent interest in synthesizing silylated-chalcogen reagents containing two chalcogen elements, whereby both E^{2-} and E'^{2-} are supplied to the metal core. Recently we have communicated the synthesis and characterization of the first mixed-chalcogen silylated reagent $Me_3Si\text{-}SeS\text{-}SiMe_3$ and demonstrated its use in the formation of a $[Cu_{84}Se_{15}S_{27}(PEt_2Ph)_{24}]$ cluster (30).

Bis(trimethylsilyl)selenosulfide $[Me_3Si\text{-}SeS\text{-}SiMe_3]$ is a highly reactive reagent, for which both exposure to atmosphere and elevated temperatures leads to rapid decomposition. In addition, the reagent cannot be isolated and can only be synthesized in dilute solutions. Lithium chloride generated in the formation of $Me_3Si\text{-}SeS\text{-}SiMe_3$ cannot be removed via filtration and must be carried forward in subsequent syntheses. Although $Me_3Si\text{-}SeS\text{-}SiMe_3$ is not a storable precursor, its low temperature stability is ideal for the generation of MSe_xS_{1-x} (M = Zn, Cd) nanoparticles at RT vs. the typically explored high temperature methods.

$CdSe_xS_{1-x}$ nanoparticles

Given the sensitivity of $Me_3Si\text{-}SeS\text{-}SiMe_3$, cadmium acetate $[Cd(OAc)_2]$ can only be introduced in a select number of solvents. The addition of $Me_3Si\text{-}SeS\text{-}SiMe_3$ at RT to a toluene solution of $(P^nBu_3)_2Cd(OAc)_2$ results in the immediate consumption of $Me_3Si\text{-}SeS\text{-}SiMe_3$, as noted by the disappearance of the yellow colour associated with the selenosulfide, in conjunction with the complete solubilization of $Cd(OAc)_2$. This reactivity is then followed by the precipitation of a colourless solid from solution, which gradually develops into a pale yellow colour after stirring overnight. The resulting solid is easily isolated where washing with anhydrous methanol effectively removes any LiCl. Isolated particles were characterized by HR-TEM, however, given their poor solubility a UV–vis absorption spectrum could not be obtained.

To investigate the growth of the resulting $CdSe_xS_{1-x}$ nanoparticles in a coordinating solvent, the solid was added to a hot (60 °C) solution of hexadecylamine (HDA) and heated to 240 °C. Upon increasing the temperature, the sample colour changes from pale yellow to an intense red (Supplementary data, Fig. S1).[4] At specified temperature intervals the sample is annealed (where upon there is no corresponding change in colour) and an aliquot is taken. The resulting nanoparticles are isolated by precipitating from solution using anhydrous methanol.

Lyothermal growth of the nanoparticles results in an increase in particle size without altering the chemical composition (i.e., the ratio between Cd:Se:S). EDX (energy dispersive X-ray) analysis was performed on three separate areas of each sample, where the overall ratio was determined by calculating the average based on the atomic percentages for the corresponding elements. Table 1 clearly demonstrates the nondeviating stoichiometry beginning with the as-synthesized particles and those obtained through thermolysis in HDA. The ratio between Se and S in the isolated particles is not 1:1 although a stoichiometrically precise reagent is used in the synthesis. The reactivity of $Me_3Si\text{-}SeS\text{-}SiMe_3$ however, is expected to occur with Se–S bond cleavage as has previously been established with the synthesis of a $[Cu_{84}Se_{27}S_{15}(PEt_2Ph)_{24}]$ cluster (30). It is necessary to note that the stoichiometry is reproducible and is a reflection of the isolated particles.

The growth in particle size is surveyed using HR-TEM microscopy. Shown in Fig. 1 are the HR-TEM images for as-synthesized, 180 °C, 210 °C, and 240 °C lyothermally grown particles. At 180 °C the particles are found to be ~3.5 nm in diameter, while an increase in thermolysis temperature to 240 °C leads to particles of ~9 nm in diameter. The *d* spacing, as determined by TEM (3.54 Å), is relatively consistent with the *d* spacing associated with the (1 1 1) reflection in the powder X-ray diffraction pattern (3.40 Å).

The photophysical properties of the obtained nanoparticles were analyzed using UV–vis absorption and photoluminescence (PL) spectroscopy. The UV–vis absorption spectra of the thermolysed samples (Fig. 2) distinctly display a red shift in absorption maximum upon increasing thermolysis temperature. At a thermolysis temperature of 160 °C, the absorption maximum is observed at 445 nm (2.79 eV) and shifts by over 100 nm to lower energy upon increasing the thermolysis temperature to 240 °C (560 nm; 2.21 eV). This shift in absorption maximum is consistent with an increase in particle size upon increasing thermolysis temperature. The observed absorption maxima are consistent with what has previously been reported for $CdSe_xS_{1-x}$ having a similar stoichiometry and particle size (15).

The low- and high-energy PL spectra for this series is shown in Fig. 3, where the spectra were obtained by irradiating samples at 468 nm. As is illustrated in Fig. 3*a*, the emission maximum shifts from 488 nm (2.54 eV) to 590 nm (2.10 eV) upon increasing thermolysis temperature and is associated with band-edge emission. At lower energy, two types of emission are observed (Fig. 3*b*) that, although normalized in the figure, are found to increase in intensity (relative to the high energy emission) as the thermolysis temperature is raised. The emission observed at lower energy is much broader in comparison to the sharp band-edge emission and results from deep-trap emission coinciding with nanoparticle defects. The appearance of both band-edge and deep-trap emission is not uncommon for $CdSe_xS_{1-x}$ systems, although several reported examples have developed techniques thereby eliminating deep-trap emission (16–21). One method is to prolong the thermal annealing time, thus forcing defects within the nanoparticle to move to the surface creating a defect-free nanoparticle core. This was investigated for the sample prepared at 230 °C, where, rather than annealing for 15 min, the thermolysis temperature was held for 4 h. Based on the PL spectrum (not shown) after 4 h,

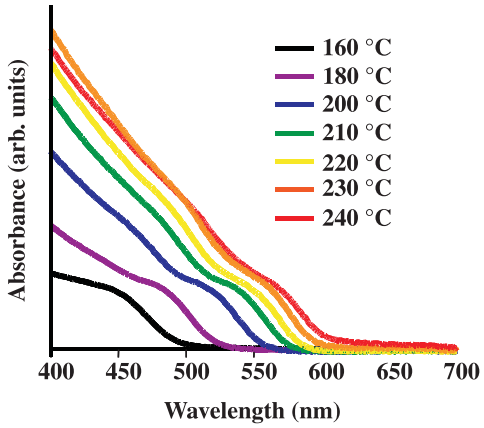
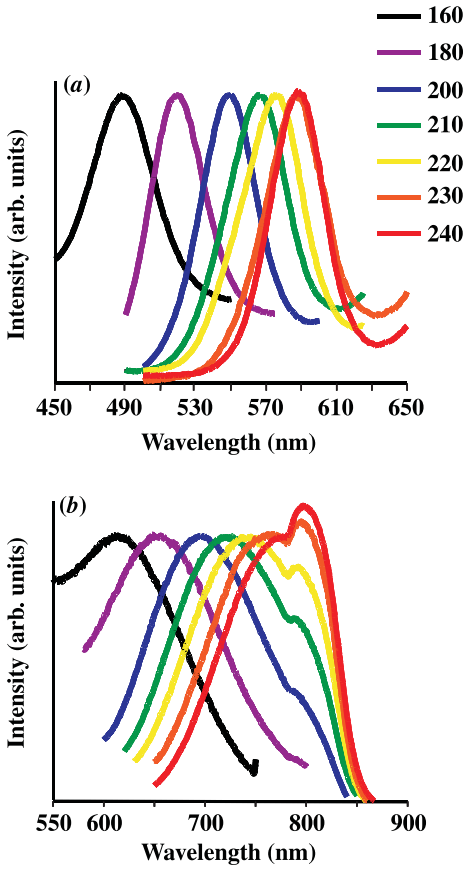
prolonged annealing times minimized the low energy emission but did not all together eliminate it.

Spectroscopically, the two types of deep-trap emission behave differently. The higher energy emission maximum is red-shifted upon increasing thermolysis temperature from 620 nm (2.00 eV) at 160 °C to 770 nm (1.61 eV) at 240 °C. The lower energy emission however only begins to appear at 200 °C and remains relatively unaltered in peak position upon increasing thermolysis temperature (~790 nm; 1.57 eV). Conversely, the intensity of this low energy emission greatly increases upon raising the thermolysis temperature, where at 240 °C this is the predominant emission observed. Photoluminescence excitation (PLE) measurements confirm the single species nature of the observed emission (Fig. S2).[4] Previous work with CdS and CdSe nanocrystals have described a similar spectroscopic behaviour where the higher energy emission is associated with shallow traps, while the lower energy emission results from deep traps (7*c*, 31).

The powder X-ray diffraction (PXRD) patterns for $CdSe_xS_{1-x}$ (Fig. 4) thermolysed at 200 °C, 220 °C, and 240 °C display two important features. First, the relative

Fig. 2. UV–vis absorption spectra of thermolysed $CdSe_xS_{1-x}$ nanoparticle series. The spectra have been normalized for clarity.





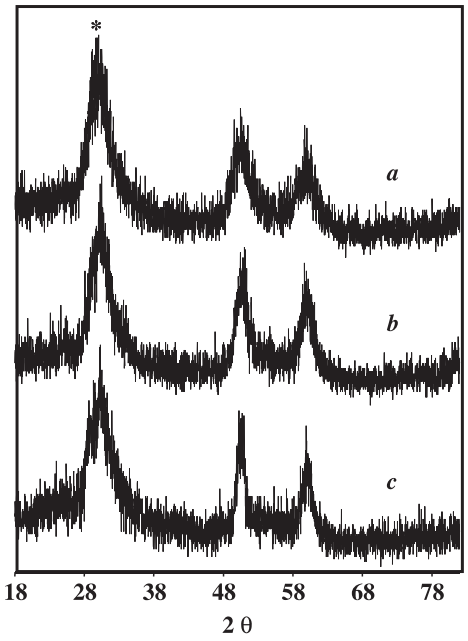


Fig. 3. Photoluminescence spectra of the $CdSe_xS_{1-x}$ thermolysis series at (*a*) high energy and (*b*) low energy. Excitation at 468 nm. The spectra have been normalized for clarity.

peak positions remain unchanged with increasing thermolysis temperature, which is consistent with the chemical composition remaining unaltered. Second, the diffraction peaks become sharper as the thermolysis temperature is raised, consistent with the observed particle growth. The observed PXRD pattern is characteristic of the cubic phases of CdS and CdSe (32). Thus using the (1 1 1) reflection, the lattice parameter *a* can be calculated using eq. [1]. From

Fig. 4. Powder X-ray diffraction patterns of $CdSe_xS_{1-x}$ samples thermolysed at (*a*) 200 °C, (*b*) 220 °C, and (*c*) 240 °C. Asterisk (*) Denotes (1 1 1) reflection.

each PXRD pattern the *d* spacing of (1 1 1) is found to be 3.40 Å and *a* is calculated to be 5.89 Å, where the corresponding lattice parameters for CdS and CdSe are 5.818 and 6.077 Å, respectively (33).

$$[1] \qquad \frac{1}{d^2} = \frac{h^2 + k^2 + l^2}{a^2} = \frac{3}{a^2}$$

Using Vegard's rule (34), which assumes a linear dependence of composition on lattice parameter, the stoichiometry of the obtained $CdSe_xS_{1-x}$ nanoparticle system can be determined using eq. [2],

$$[2] \qquad a(x) = x \cdot a_{CdSe} + (1 - x)a_{CdS}$$

Based on eq. [2], *x* is calculated to be 0.28 (i.e., $CdSe_{0.28}S_{0.72}$), which is similar to what is observed via EDX analysis.

$ZnSe_xS_{1-x}$ nanoparticles

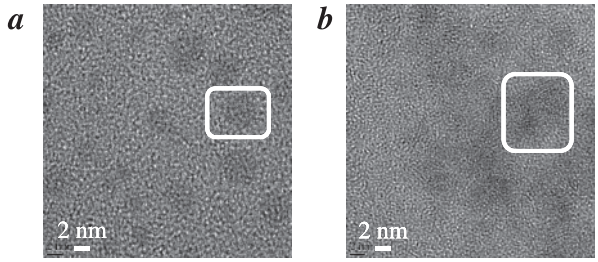
A handful of published examples have investigated the synthesis of $ZnSe_xS_{1-x}$ nanomaterials. $ZnSe_xS_{1-x}$ (where x = 0.05–0.08) is almost perfectly lattice-matched to GaAs and thus improves the blue-green response over the conventionally used ZnSe. Consequently, $ZnSe_xS_{1-x}$ is well-suited for fabricating optoelectronic devices (35). Much like its cadmium counterpart, $ZnSe_xS_{1-x}$ is formed as thin films on either glass or GaAs substrates. The synthesis typically involves the mixing of ZnS and ZnSe powders in a specified ratio (35, 36), although some procedures use dimethylzinc in the presence of gaseous H_2Se and H_2S (37) as well as $ZnCl_2$ with thiourea and selenourea (38). A variety of specialized techniques such as spray pyrolysis, atomic layer epitaxy, and close-space evaporation are used for thin film formation and thus require high operating temperatures. Using Me_3Si-SeS-$SiMe_3$, discrete nanoparticles of $ZnSe_xS_{1-x}$ can be produced.

As previously reported (30), the use of Me_3Si-SeS-$SiMe_3$ imposes limitations with regards to solvent choice and reaction conditions that must be considered when designing a chemical reaction. Employing similar conditions used in the formation of $CdSe_xS_{1-x}$, zinc acetate [$Zn(OAc)_2$] was solubilized in toluene with 2.2 equiv. of tri(*n*-butyl)phosphine. Toluene, however, does not effectively solubilize $Zn(OAc)_2$ and P*n*-Bu_3. As opposed to using phosphine-based ligands to coordinate to $Zn(OAc)_2$ in toluene, an amine ligand (triethylamine) was alternatively employed. Although this leads to the dissolution of $Zn(OAc)_2$, the addition of Me_3Si-SeS-$SiMe_3$ results in the formation of a brightly coloured red solid after a few hours of stirring, suggesting decomposition and the possible precipitation of elemental selenium. In contrast, tri(*n*-butyl)phosphine oxide is able to solubilize $Zn(OAc)_2$ in toluene, however, the addition of Me_3Si-SeS-$SiMe_3$ leads to the immediate formation of a red solid. This reactivity suggests an additional limitation of Me_3Si-SeS-$SiMe_3$ in which hard bases such as amines and oxides should be avoided, while soft bases such as phosphines are less reactive toward Me_3Si-SeS-$SiMe_3$.

An alternative solvent to toluene is to use dichloromethane to solubilize $Zn(OAc)_2$ and P*n*-Bu_3. The addition of Me_3Si-SeS-$SiMe_3$ causes the immediate consumption of the selenosulfide. Although a precipitate does not form initially, continued stirring overnight results in the formation of a white solid. The solid, however, is quite soluble in anhydrous methanol and thus LiCl cannot be removed at this stage and must be carried through to the thermolysis.

The obtained solid is added to a hot (60 °C) HDA solution and gradually heated to 240 °C. At specified temperature intervals the sample is annealed for 15 min, an aliquot is taken, precipitated out with anhydrous methanol, and isolated via centrifugation. By washing with methanol, LiCl is effectively removed from the sample as determined by EDX analysis. The increase in thermolysis temperature does not result in an associated colour change.

To ensure that the chemical composition remains unaltered during the thermolysis, the atomic ratio between zinc, selenium, and sulfur was determined from EDX analysis (Table 2). As is shown in Table 2, the ratio between zinc, selenium, and sulfur remains relatively unaltered throughout thermolysis, however, at 240 °C the quantity of both sulfur and selenium increases, although the ratio between the two elements is similar to what is observed at the lower thermolysis temperatures. The same ratio is not observed in the as-synthesized $ZnSe_xS_{1-x}$ largely because of the presence of chloride within the sample (from LiCl), which consequently affects the overall ratio calculated for the respective elements. Again, the ratio between selenium and sulfur is not 1:1, likely due to the expected Se–S bond cleavage and the presence of both phosphine sulfides and phosphine selenides in the reaction mixture. Phosphine sulfides and selenides are known to form from P*n*-Bu_3 with various chalcogen sources (39). Both sulfur and selenium are however, incorporated into the nanoparticles through the use of the Se–S reagent.



Particle size measurements were calculated based on HR-TEM images (Fig. 5). As can be seen, the particle size increases upon increasing thermolysis temperature. At 200 °C (Fig. 5*a*), individual particles of $ZnSe_xS_{1-x}$ are observed and

	Ratio as determined by EDX analysis		
	Zinc	Selenium	Sulfur
As-synthesized	1	0.47	0.36
190 °C	1	0.43	0.49
210 °C	1	0.40	0.44
220 °C	1	0.40	0.48
240 °C	1	0.52	0.59

Fig. 5. HR-TEM images of $ZnSe_xS_{1-x}$ particles thermolysed at (*a*) 200 °C and (*b*) 240 °C. Box outlines individual particles.

are ~4 nm in diameter. Upon increasing the thermolysis temperature to 240 °C, the particles grow to ~8 nm in diameter, however, it appears as though homogeneity is lost at elevated temperatures.

The spectroscopic properties of the obtained nanoparticles were analyzed using UV–vis absorption and PL spectroscopy. The UV–vis absorption spectra of the thermolysis series (Fig. 6) distinctly display a red-shift in absorption maximum with increasing the thermolysis temperature. At a thermolysis temperature of 190 °C, the absorption maximum is found at 305 nm (4.07 eV) and shifts 30 nm to lower energy with increasing the thermolysis temperature to 240 °C (335 nm, 3.70 eV). This shift in absorption maximum is consistent with an increase in particle size.

The PL spectra (obtained by irradiating between 310–320 nm) for the series $ZnSe_xS_{1-x}$ (Fig. 7) differs significantly from the PL spectra of the $CdSe_xS_{1-x}$ series in that one type of emission is observed, corresponding to band-edge emission. The emission maximum shifts from 342 nm (3.63 eV) at 200 °C to lower energy (362 nm, 3.42 eV) with increasing the thermolysis temperature to 240 °C. This red shift in emission maximum upon increasing thermolysis temperature confirms an increase in particle size. PLE measurements confirm the nature of the emitting species (Fig. S3).[4]

Much like the PXRD patterns for $CdSe_xS_{1-x}$, the PXRD patterns for $ZnSe_xS_{1-x}$ thermolysed at 190 °C, 210 °C, and 220 °C (Fig. 8) indicate a sharpening of diffraction peaks with increasing thermolysis temperature, in addition to consistent peak positions. Conversely, the obtained $ZnSe_xS_{1-x}$ nanoparticles display a characteristic hexagonal phase pattern as observed for ZnS and ZnSe (40). Thus, using the (0 0 2) reflection, the lattice parameter *c* can be calculated (double the associated *d* spacing, *d* = 3.2 Å). The obtained *c* parameter (6.4 Å) is found to be intermediate between the *c* parameters for ZnS (6.234 Å) and ZnSe (6.53 Å) (37), and

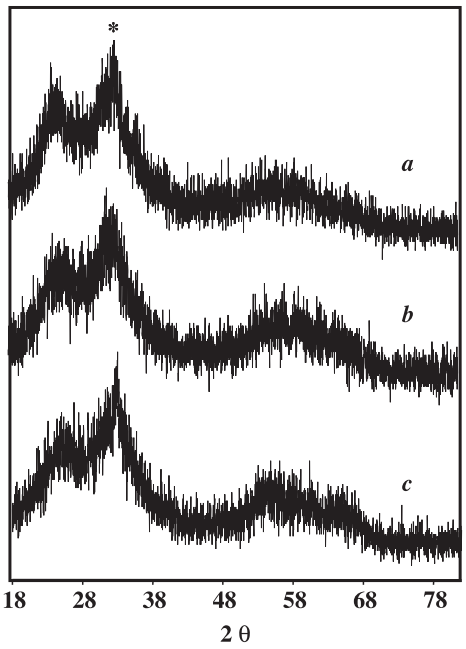
using Vegard's rule (eq. [2], substitute *a* for *c*), *x* is found to be an intermediate value.



It is noteworthy to mention that the observed stoichiometry in the zinc system varies significantly from the stoichiometry of the cadmium system, thus reflecting a differing reactivity between the two elements.

Conclusions

It has been demonstrated that $Me_3Si\text{-}SeS\text{-}SiMe_3$ is an effective delivery agent of both sulfur and selenium. As such, the reagent has found utility in the synthesis of mixed-chalcogen zinc and cadmium nanoparticles. $Me_3Si\text{-}SeS\text{-}SiMe_3$ serves as a reagent for the distribution of both chalcogen elements at low temperature vs. the conventional methods used for the formation of MSe_xS_{1-x} materials, which typically require two chalcogen reagents and relatively high temperatures. The resulting nanoparticles display a nonstoichiometric amount of both sulfur and selenium as the ensuing chemistry with the corresponding metal acetate leads to Se–S bond cleavage. Thermolysis of both zinc and cadmium nanoparticle species in hexadecylamine leads to controlled particle growth with increasing thermolysis tem-

perature, as has been noted by the red-shift in both the absorption and emission excitonic transition. An extension of this research will be to investigate the effectiveness of $Me_3Si\text{-}SeS\text{-}SiMe_3$ in the synthesis of $HgSe_xS_{1-x}$ nanoparticles.

Electronic structures of CdSe nanocrystals — An X-ray absorption near-edge structure (XANES) investigation[1]

Jigang Zhou, Xingtai Zhou, Xuhui Sun, Michael Murphy, Franziskus Heigl, Tsun-Kong Sham, and Zhifeng Ding

Abstract: CdSe nanocrystals (NCs), capped with trioctylphosphine oxide and 1-octadecanamine, have been synthesized with colloidal methods. Both UV–vis absorption and photoluminescence spectra show that the prepared nanostructures exhibit a quantum confinement effect. X-ray absorption near–edge structure (XANES) at Se K-edge recorded in fluorescence yield mode have been carried out on these NCs, with different size and capping ligands to gain insight into how their electronic structures are affected by the NC size and chemical properties of the ligands. The results indicate that XANES are sensitive to both the NC size and the nature of the capping ligands. The whiteline intensity in XANES spectra can be related to the photoluminescence properties of these NCs.

Key words: CdSe nanocrystals, capping ligands, X-ray absorption near-edge structure, UV–vis spectroscopy, photoluminescence.

Résumé : Faisant appel à des méthodes colloïdales, on a réalisé la synthèse de nanocristaux (NC) de CdSe portant des embouts d'oxyde de trioctylphosphine et d'octadécan-1-amine. Les spectres d'absorption UV-vis et les spectres de photoluminescence montrent que les nanostructures qui ont été préparées présentent un effet de confinement quantique. On a fait appel à la méthode des structures par absorption de rayons X auprès du seuil (XANES, ("X-ray absorption near edge structure") près du seuil K du Se en mode de fluorescence pour déterminer les structures de ces NC portant divers embouts de tailles différentes afin de pouvoir déterminer l'effet de la taille des NC et des propriétés chimiques des ligands sur leurs structures électroniques. Les résultats indiquent que les spectres de type XANES sont sensibles tant à la taille du NC qu'à la nature des ligands servant d'embouts. On peut relier l'intensité de la ligne blanche des spectres de type XANES avec les propriétés de photoluminescence de ces NC.

Mots clés : nanocristaux de CdSe, ligands servant d'embout, structure par absorption de rayons X auprès du seuil, spectroscopie UV–vis, photoluminescence.

Introduction

Direct band gap CdSe nanocrystals (NCs) exhibit size-tunable optical properties such as blue shifts in their UV–vis absorption and photoluminescence (PL) spectra with deceasing NC size. This behavior results from the quantum confinement of excitons in the NC to dimensions smaller than the exciton Bohr radius (10 nm in CdSe)(1). The confinement alters the band structure from bulk to molecular character, resulting in the opening of the band gap and ultimately the splitting of bands into discrete energy levels. This leads to a blue shift of the absorption and PL spectra with decreasing NC size. Applications of these CdSe nanostructures in biological imaging (2), novel sensors (3), and potential light emitting devices (4, 5) are anticipated and intensively pursued. A reliable green chemical route (6, 7) was also well-developed for synthesizing free standing CdSe NCs through arresting NCs during growth by the application of capping ligands. The size-dependent optical propeties have been utilized to demonstrate quantum confinement in NCs (1), to characterize NCs,(8), and to monitor NC growth in situ. Since NCs have a very large surface to volume ratio, NC properties are extremely surface sensitive. Surface capping ligands not only halt the growth of NCs and prevent their

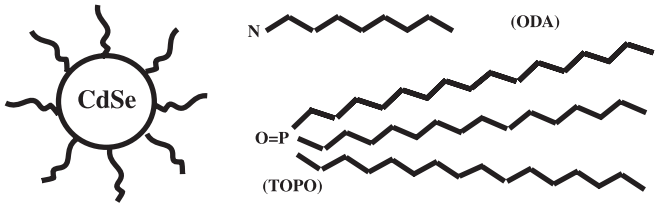
aggregation, but they also play a critical role in determining the properties of NCs. For instance, hydrophobicity, photochemistry, and optical performance are all dependent on surface capping. PL is believed to be sensitive to the NC size and type of capping ligands (6), because the electronic structure of CdSe NCs is altered by the two factors mentioned.

Although the understanding of the effects of NC size and ligand type on the PL of NCs is crucial to the synthesis and manipulation of these nanomaterials, detailed information on the relationship between electronic structures and ligand–NC interaction still remains scarce because of relatively limited analysis methods.

X-ray absorption near edge structures (XANES) refers to the modulation of the atomic absorption coefficient of a core level of an atom in a specific chemical environment in the region of ~50 eV above the threshold for core electron excitation. It encompasses bound to bound, bound to quasi-bound (virtual molecular orbital, multiple scattering state), and bound to continuum transitions. The absorption coefficient across an absorption edge is a function of (*i*) the dipole transition matrix element <i|r|f> (from the initial state <i|, e.g., Se 1s to the final state |f>, e.g., states with Se 4p character), which increases abruptly at the threshold (edge) and is modulated markedly by the molecular potential around the atom and (*ii*) the density of unoccupied electronic states of appropriate symmetry above the Fermi level in metals, in the conduction band in semiconductors and insulators, and in the LUMO in molecular systems. Thus, XANES is sensitive to the unoccupied electronic densities of states and the local structure. XANES is element specific and can also be sensitive to either the surface or the bulk of the specimen depending on the edge and the detection schemes.



XANES has been increasingly used to study electronic structure, chemical bonding, and surface chemistry of nanostructures (9–18). However, study on free standing NCs has not yet been widely reported. In this work, we report a study on the effects of the size of NCs and the type of capping ligands on the electronic structures of CdSe NCs, using Se K-edge XANES. The electronic structures are correlated to their PL properties.

Experimental section

Synthesis of CdSe NCs

CdSe NCs capped with trioctyl phosphine oxide (TOPO) or octadecanamine (ODA) were synthesized according to procedures reported by Peng and co-workers (6,7) and Bard and co-workers (19) with a modification of the temperature for the Se precursor injection and NC growth, described in the following. Briefly, for ODA capped NCs, 5.00 g of technical grade trioctylphosphine oxide (TOPO), 5.00 g of ODA, 2.00 g of ODE, and 0.10 g of cadmium acetate hydrate were placed into a three-necked round-bottomed flask, stirred and heated to ~140 °C. After degassing with argon for approximately 1 h at this temperature, the solution in the flask was heated to 280 °C. At this temperature, the heating mantle was immediately removed and a cold Se solution (prepared by mixing 0.16 g of Se powder, 4.00 g of trioctylphosphine (TOP), and 80 μL of toluene) was quickly injected into the reaction vessel through a rubber septum. The temperature dropped to ~250 °C after the injection. With continuous stirring, the temperature dropped to ~180 °C. At this point the flask was reheated slowly to 250 °C. Aliquots were taken out of the flask at 5 min time intervals and cooled to ~50 °C with tap water bath. In this way NCs with different sizes were obtained. After addition of 10 mL of $CHCl_3$, the solution was kept in the dark. The NCs were precipitated with a copious amount of methanol and collected by centrifugation and decantation. The precipitate was then dissolved in $CHCl_3$ and re-precipitated. This cycle was repeated three times to increase purity. The product, CdSe NCs, are capped with ODA and denoted as NCs(ODA).

For TOPO-capped CdSe NCs, 12.00 g of technical grade trioctylphosphine oxide (TOPO) was used to replace the mixture of 5 g of technical grade trioctylphosphine oxide (TOPO), 5.00 g of ODA, and 2.00 g of ODE in the NCs(ODA) synthesis. The solution in the flask was heated to 330 °C. At this temperature, the heating mantle was removed immediately and a cold Se solution (prepared by mixing 0.16 g of Se powder, 4.00 g of trioctylphosphine (TOP), and 80 μL of toluene) was quickly injected into the reaction vessel through a rubber septum. The mixed solution was allowed to cool down in the ambient. The purification procedure was the same as described previously. The purified CdSe NCs capped with TOPO are denoted as NCs(TOPO). The ligand passivated NCs are illustrated in the following schematic.

UV–vis absorption and PL spectra of NCs

UV–vis absorption spectra were measured on a Cary 300 Bio spectrometer (Varian, Mississauga, Ontario). The corresponding solvents were used as references. A PTI Flourimeter QM-7/2005 set with an excitation slit width of 0.5 mm and an emission slit width of 0.3 mm was used to excite the samples at 360 nm and to record their PL spectra. A quartz cuvette with a path length of 1.00 cm was used in the UV–vis absorption and PL experiments. Samples were prepared by dispersing NCs in chloroform. The spectra were normalized to the maximum absorption in the UV–vis absorption spectra or the maximum emission peak in the PL spectra for comparison.

XANES of CdSe NCs

The specimens were prepared by depositing a NC-containing solution onto a Si wafer to form a thin film. The solvent was then evaporated. Commercial CdSe powder (Sigma-Aldrich) was pressed into a carbon tape and used as a reference. The Se K-edge XANES spectra were obtained on the PNC-XOR BM line of the Advanced Photon Source (APS). Crystal Si 111 was used as the monochromator with a resolution (FWHM) of 1.5 eV at the Se K-edge. XANES spectra were recorded in X-ray fluorescence yield (FLY) mode using a multichannel solid-state detector (Canberra 12 element Ge solid state detector). A Rh-coated planar har-

© 2007 NRC Canada

monic rejection mirror was used to minimize this contribution of harmonics. Since FLY is collected over a thin sample and the count rate was kept below 50 000 cps/detector element to keep dead time below 10%, the nonlinearities from the detector are negligible. Data were then normalized to the incident photon flux. The incident was recorded by an ionization chamber. After background correction, the spectra at the Se K-edge are normalized to the edge jump, the difference in absorption coefficient just below and at a flat region above the edge (12 710 eV) for quantitative comparison.

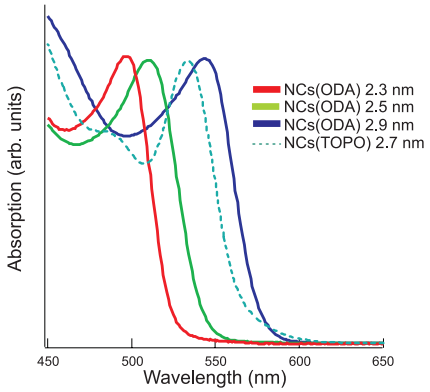
Results and discussions

UV–vis and photoluminescence spectroscopy

Figures 1 and 2 show the UV–vis absorption and PL spectra for the purified NCs(TOPO) (dashed line) and NCs(ODA) (solid line) of different sizes, respectively. It should be noted that the absorption peak in the UV–vis spectroscopy and the luminescent peak in the PL spectroscopy are associated with the electronic transition between the conduction band and the valence band. The peak positions can be therefore correlated to the energy separation of the band gap, since quantum confinement effect manifests itself in opening the CdSe NC band gap as the size of the NC decreases. According to the first UV–vis absorption peak position, the size of CdSe NC can be determined using previously established size calibration curves (1, 7). The NC diameters were then estimated from the first absorption peak wavelengths to be 2.3, 2.5, and 2.9 nm for NCs with the first absorption maximum at 498, 511, and 543 nm, respectively, according to sizing curves established by Peng and coworkers (8). As for the NCs(TOPO), the size is estimated to be 2.7 nm according to the first UV–vis absorption peak at 533 nm (8). It should also be noted that in situ UV–vis absorption spectra could be recorded during the synthesis and used to monitor the growth stage in terms of the size of NCs. These NCs also exhibit the size dependent emission peak wavelengths displayed in the PL spectra at longer wavelength as expected (Fig. 2). For instance, NCs(ODA) show emission maximum at 509, 543, and 578 nm corresponding to 2.3, 2.5, and 2.9 nm in diameter, respectively.

Furthermore, as previous reported (1, 6, 7, 20) the size distribution for one batch of NCs can be revealed from the full width at half-maximum (FWHM) in the PL spectrum, since the spectrum is a collective result contributed by individual NCs. The emission peaks in NCs(ODA) are very sharp. The FWHM for NCs with diameter of 2.3, 2.5, and 2.9 nm was only 73, 100, and 111 meV, respectively, which indicates that the size distribution was narrow and the deviation should be less than 10% for all batches. The evolution of size distribution during the growth process reported here is in good agreement with literature (7). The PL FWHM in NCs(TOPO) is 147 meV, indicating that the size distribution is slightly wider than that in NCs(ODA). Additionally, all PL spectra have a nonzero tail in the long wavelength region. This can be best seen in the spectrum of NCs(TOPO) and 2.3 nm NCs(ODA). This means that all samples have emission allowed surface defect related states. It has been extensively reported that primary amine (20), for instance ODA, can provide stronger surface passivation in NCs than TOPO. Thus, surface states that trap electrons, hence reduce

Fig. 1. UV–vis absorption spectra of the CdSe NCs dispersed in chloroform. The dashed line represents TOPO-capped CdSe NCs. The size is estimated to be 2.7 nm. Solid lines correspond to ODA-capped CdSe NCs. The sizes are estimated to be 2.3, 2.5, and 2.9 nm from left to right.



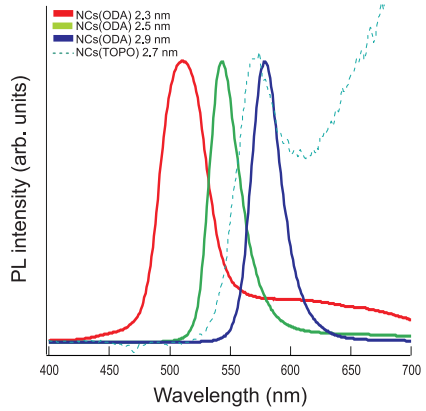


Fig. 2. PL spectra of the CdSe NCs dispersed in chloroform. The dashed line represents TOPO-capped CdSe NCs. Solid lines correspond to ODA-capped CdSe NCs as described in Fig. 1.

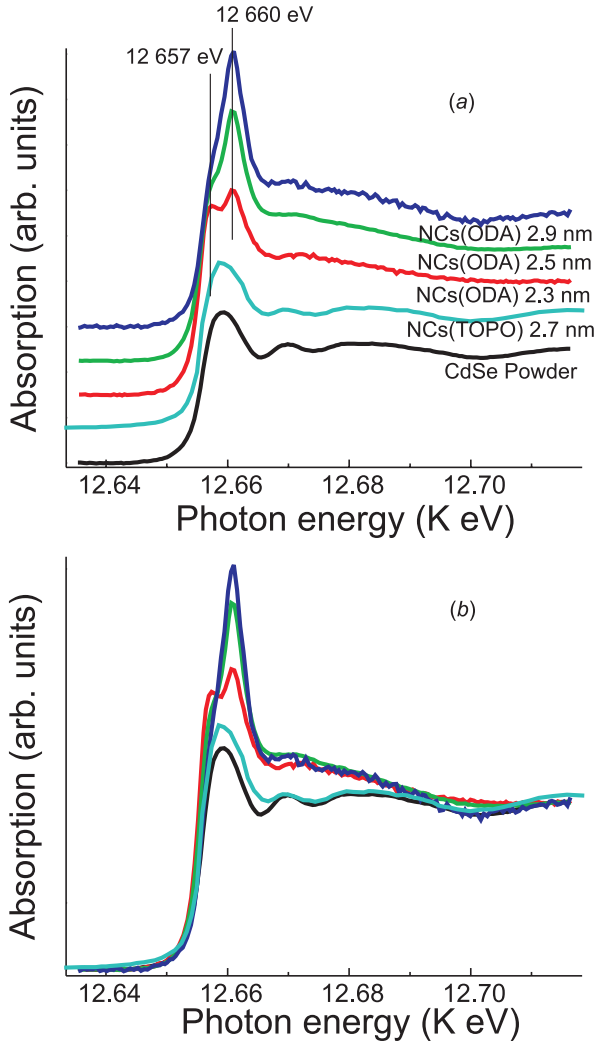

light emission, are quenched more significantly in NCs(ODA) than in NCs(TOPO). Consequently, NCs(ODA) exhibit much higher PL quantum yield than NCs(TOPO). This phenomenon can be understood considering the electron donation ability and structure effect of capping ligands. The amine group in ODA is a considerably better electron donor than the P=O group in TOPO. The linear structure in ODA also facilitates its passivation ability on the targeted NCs.

Interestingly, in contrast to the above generalization we observed that the relative surface states related emission from NCs(TOPO) is much stronger than in the similar-sized NCs(ODA), indicating that emission allowed surface defect related states, rather than traps, in NCs(TOPO) are more pronounced than those in NCs(ODA). Furthermore, the emission allowed surface defect related states in NCs(TOPO) are even more pronounced than in smaller-sized NCs(ODA), as seen in the PL spectra. All of these results allow us to propose that the strong amine–NC interaction induced surface reconstruction in NCs(TOPO) is very different

from that in NCs(ODA). This aspect will be addressed in the following section.

XANES spectroscopy

The Se K-edge XANES spectra of the NCs(ODA), NCs(TOPO), and CdSe powder are shown in Fig. 3. The photon energy is calibrated to the Se 1s to 4p transition of a Se film at 12 658 eV. The most noticeable feature is the identical appearance of the XANES for NCs(TOPO) and bulk CdSe confirming that the NC is crystalline and has the same Wurzite structure (18) as that of bulk CdSe. Se K-edge XANES probes the densities of unoccupied states of primarily Se 4p character as well as crystal structure, The 1s 4p dipole transition at the threshold often results in a sharp absorption peak known as the whiteline. The rising edge and the area under the whiteline are related to the formal charge at the Se site and the densities of states of 4p holes in the Se conduction band, respectively. Multiple scattering resonance features up to 50 eV beyond the whiteline are characteristic of the immediate vicinity of the absorbing atom in the crystal (12).

The Se K-edge XANES spectra of the NCs(ODA) are noticeably different from those of CdSe powder and NCs(TOPO). We can see from Fig. 3*a* that replacing the TOPO capping liagnd (weakly bonded P=O based ligand) with the ODA capping ligand (a strongly bonded amine based ligand) shifts the Se K-edge whiteline maximum to higher energy by 2 eV and exhibits more features. This result illustrates the chemical sensitivity of XANES. Close examination reveals that the whiteline splits into two bands at 12 657 and 12 660 eV. This is noticeably different from the single band seen in bulk CdSe and NCs(TOPO). We attribute the whiteline splitting in the XANES spectra to contributions from the surface and core of the NCs induced by strong ligand NC interaction.

Before we proceed further, let us consider for the moment how a ligand interacts with the surface of a CdSe NC, which contains both Cd and Se ions, and the fraction of atoms on the surface (21). In our preparation, although the synthesis of CdSe NCs is performed in a Se-rich environment (the molar ratio of Se to Cd in the precursor is about 10), the ligand–CdSe surface interaction is believed to favour the O-Cd (in TOPO-capped NCs) or the N-Cd (in ODA-capped NCs). As for the surface to bulk atom ratio in the NC, it has been estimated that approximately 1/3 of the atoms are on the surface for a ~3 nm NC.

We now return to the splitting of the whiteline in CdSe(ODA). We attribute the 12 657 and the 12 660 eV peak to surface and core contributions (henceforth denoted S and C), respectively. These assignments are based on the observation that the surface peak decreases in intensity as the size of the NC increases (surface to bulk atom ratio decreases); this is accompanied by the increase in the intensity of peak C. We envision that the strong amine–NC interaction screens the Cd^{2+} ion, considerably reducing its formal oxidation state. Charge neutrality requires corresponding charge depletion at the Se^{2-} site of the NC, giving rise to a 1s-4p shift (peak C) to higher energy. The shift of the surface peak S to lower energy results from amine–Se interaction on the surface. Finally the oscillation beyond 12 680 eV is blurred in NCs(ODA) compared with that in NCs(TOPO). Since it is well-documented (6) that the crystalline characteristic of NCs(ODA) is the same as that of NCs(TOPO), which favored the Wurzite structure, this feature must be also related to the surface reconstruction in NCs(ODA), resulting in a shell that is substantially different from the core, which maintains the crystal structure of bulk CdSe.

A close examination of the whitelines shown in Fig. 3*b* reveals an obvious increase in intensity in the CdSe NCs relative to that of CdSe powder. This is interesting since a more intense whiteline hints at a higher unoccupied density of states (DOS) of 4 p character in the conduction bands. Assuming no countervailing selection rule arguments (reasonable for a randomly oriented NC system), the more intense whiteline in Pt L_3 or M_3 edge is often observed and expected in Pt nanoparticles (PtNPs) supported on nano Si substrates relative to that of bulk Pt, which is due to PtNP–Si oxide interactions that withdraw d charges from Pt (16). The reduc-

© 2007 NRC Canada

tion of DOS of p character in Pt NPs-CNTs relative to that of CNTs has also been reported (22), which provided the evidence that charge redistribution transfer between the environment, the Pt NPs, to C 2p-derived states has occurred. Since the present system does not favor such charge redistribution between NCs and the environment, the intensity variation trend must relate to amine–NC interaction-induced rehybridization of Se s, p, and even d orbitals such that Se loses p charge in these amine-capped NCs. This observation is of considerable interest, although more details await further experimental and theoretical investigations.

The DOS increases from CdSe powder to NCs(TOPO), and NCs(ODA) may be explored further in connection with the intensity of the luminescence. It was reported that the PL quantum yield increased with the size of NCs until the diameter of NCs reached 3.3 nm, then the PL quantum yield decreased as the size of NCs increased during growth of the NCs (6). The size of NCs(ODA) in the present research are smaller than 3.3 nm, so the PL quantum yield for these NCs should increase with size. Therefore the PL quantum yield in those samples should increase from CdSe powder to NCs(TOPO) and then to NCs(ODA). The increase of PL quantum yield follows the same trend in the DOS increase. Our results indicate that surface state emission (PL) from NCs(TOPO) is the strongest, followed by the smallest NCs(ODA), then the large NCs(ODA). This trend also corelates with the DOS variation trend. It should be noticed, however, that this trend should be used with caution since we have taken into account the effect of both size and surface chemistry.

In conclusion, we have synthesized CdSe NCs capped with ODA or TOPO with controlled size. The UV–vis absorption and PL were used to characterize the NCs in terms of size and optical properties. XANES spectra at the Se K-edge were performed to probe the electronic structure, which is found to be dependent on capping ligand and size. This appears to be an emerging phenomenon of NCs with interesting implications (23). A correlation between the whiteline intensity in the XANES spectra and the optical emission intensity was observed. Finally, we have demonstrated that XANES is a very valuable tool to explore the surface and size effects on the electronic structure of CdSe NCs and have anticipated that XANES will be widely used in the characterization of nano systems.

High-resolution XANES S $L_{3,2}$ edge spectra collected from a series of iron-bearing sphalerite(Zn,Fe)S minerals[1]

Allen Pratt, Lucia Zuin, Y. Mui Yiu, and Sarah Harmer

Abstract: High-resolution S $L_{3,2}$-edge XANES spectra have been collected from a series of high-quality sphalerite samples. Each of the sphalerite samples examined has a characteristic iron concentration, and the range is from <0.01 to 14.79 wt% Fe. The structures of the S $L_{3,2}$-edges are investigated by comparing ab initio calculated spectra with experimentally measured S $L_{3,2}$-edge spectra collected from synthetic ZnS sphalerite. The theoretical and experimental data provide evidence that S 2p electron transitions to empty S 3s and S 3d states can occur across an energy range above the absorption edge. A chemical shift, associated with iron to sulphur bonds, is identified, and for the first time, a pre-edge feature associated with S–Fe bonding in sphalerite is observed.

Key words: XANES, zincblende, sphalerite, characteristic iron content, S L-edge structure, ab initio calculated spectra, density of states, pre-edge peak.

Résumé : On a mesuré les spectres d'absorption synchrotron à haute résolution de type « XANES » près du seuil $L_{3,2}$ d'une série d'échantillons d'excellente qualité de sphalérite. Chacun des échantillons de sphalérite examiné comporte une concentration caractéristique de fer qui se situe entre < 0,01% à 14,7% en poids de fer. On a étudié la structure des seuils $L_{3,2}$ des spectres synchrotron par comparaison de spectres calculés par une méthode ab initio avec les spectres d'absorption synchrotron près du seuil $L_{3,2}$ mesurés expérimentalement avec une sphalérite ZnS de synthèse. Les données théoriques et expérimentales permettent de montrer que les transitions synchrotron des électrons 2p vers les états synchrotrons vides 3s et 3d se produisent à travers une plage d'énergie qui est supérieure au seuil d'absorption. On a identifié le déplacement chimique qui est associé aux liaisons fer-soufre et on a observé pour la première fois la caractéristique pré-seuil associée à la liaison S–Fe de la sphalérite.

Mots-clés : « XANES », zincblende, sphalérite, contenu en fer caractéristique, structure synchrotron au seuil L, spectres calculés par des méthodes théoriques ab initio, pic pré-seuil.

[Traduit par la Rédaction]

Introduction

The results and interpretations presented in this study build on the foundational work conducted by Professor Bancroft's group on metal sulphides using the Canadian Synchrotron Radiation Facility (CSRF) Grasshopper beamline on the Aladdin Storage Ring (1*a*, 1*b*, 2, 3, 4). The focus mineral sulphide for this study is sphalerite, (Zn,Fe)S. Understanding sphalerite mineral chemistry is important because it is the primary source for virtually all of the world's zinc production. Over 7 000 000 tonnes of zinc each year originate from sulphide ores in which sphalerite (Zn,Fe)S is the dominant zinc mineral (5). The purpose of this study is to build on the work conducted previously by Professor Bancroft's group and use the high-resolution capabilities of the recently commissioned VLS-PGM beamline at the Canadian Light Source to investigate the fine structure in the S $L_{3,2}$-edge collected from a series of iron-bearing sphalerite samples. In this work, we interpret the experimental results through comparison with theoretical results obtained using ab initio modeling. The S $L_{3,2}$-edge was chosen to investigate because it has fine structures that are not found in the S K-edge (1*b*).

Sphalerite is in the cubic crystal system. Well-formed individual specimens commonly occur, and when found in natural settings, the most common crystal shape is the tetrahedron (6). The structure of sphalerite is similar to that of diamond with one half of the C atoms replaced by Zn and the other half by S. The Zn is tetrahedrally coordinated by four S atoms, and S is tetrahedrally coordinated by four Zn

atoms (7). Atoms in the sphalerite structure, it is also known as the zincblende structure, form tetrahedrally distributed orbitals of the hybrid sp^3 (8). The sphalerite structure is characterized by two interpenetrating face-centered cubic lattices, with the sulphur atoms being centered on the points of one lattice and zinc atoms on the other (Fig. 1) (7). Sphalerite nearly always contains Fe, substituting in part for Zn. The maximum iron content is about 26 wt%. The iron-rich varieties above 10 wt% Fe are referred to as marmatite, and the most iron-rich varieties are referred to as christophite (6).

In this research, X-ray absorption near-edge structure (XANES) S $L_{3,2}$-edge spectra, collected from a series of sphalerite specimens, are investigated through comparison with the theoretical S $L_{3,2}$-edge of ZnS sphalerite. The characteristic feature of each sphalerite specimen is its respective iron concentration. In this work, sphalerite iron concentrations range from <0.01 to 14.79 wt% Fe.

Fig. 1. Line drawing of sphalerite showing Zn and S coordination and the two characteristic interpenetrating face-centered cubic lattices; sulphur atoms are centered on the points of one lattice and zinc atoms on the other lattice. After Bloss (7).

Methods

XANES spectra were collected from a series of sphalerite samples that each had a characteristic iron concentration. Large crystals and coarse cleavages of sphalerite from Nacia, Chihuahua, Mexico (14.79 wt% Fe); Montaubon, Quebec, Canada (8.14 wt% Fe); Oklahoma, USA (0.19 wt% Fe); and a synthetic specimen (<0.01 wt% Fe) were used in these experiments. Mineralogical examination showed that all the samples were >98% sphalerite. Impurities were largely carbonate minerals and the sulphide mineral species, pyrite and chalcopyrite. Detailed characterizations of the materials used in this work are provided in Dutrizac et al. (5). For this work, small fragments of material were broken from each sphalerite sample. The fragments were examined with a hand lens and a stereo microscope to determine purity. Fragments with traces of other minerals were discarded.

The hand-picked mineral fragments were prepared for XANES analyses by further grinding the samples into a fine powder in an alumina mortar and pestle. Immediately following grinding, the powder was mounted to a metal disc with double-sided carbon tape and placed into the load lock of the XANES analytical chamber. Exposure to air was about 1 min.

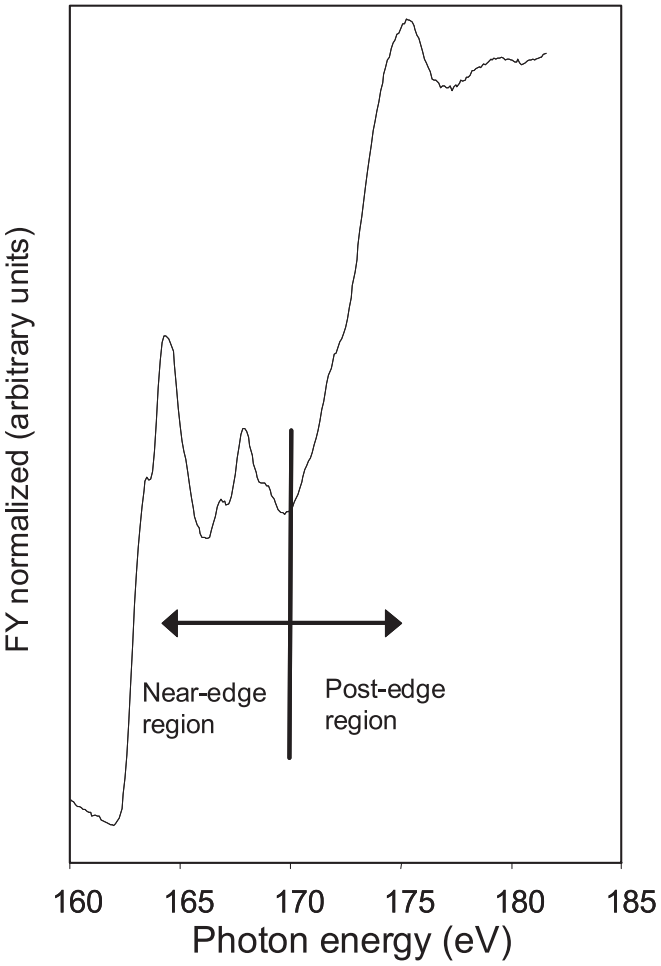
Sulphur $L_{3,2}$-edge XANES spectra were collected using the recently commissioned VLS-PGM beamline (9, 10) at the Canadian Light Source (CLS), University of Saskatchewan. The VLS-PGM beamline is Canada's replacement for the CSRF Grasshopper beamline at Aladdin. Three variable line-spacing plane gratings cover the photon energy region 5.2–250 eV. For this work, we used the high-energy grating, 98–250 eV, and 100 μm entrance and 100 μm exit slits. At the time these experiments were conducted, the beamline resolution for 100 μm slits was unknown. For 50 μm slits, the resolution was 117 meV. The resolution was determined from gas-phase measurements made at the Ar L-edge (10). Spectra were collected at room temperature simultaneously in fluorescence yield (FY) and total electron yield (TEY) modes. Detailed information on the detection system is provided in Kasrai et al. (1*a*). Only FY spectra are shown. FY detection was chosen for two reasons: (*i*) FY is the XANES L-edge data collection method with the highest spectral resolution (1*a*); (*ii*) the FY sampling depth is near 100 nm (1*b*), making the FY data collected more bulk-sensitive than surface-sensitive, and this allows for flexibility in the sample preparation. The S L-edge spectra were collected by monitoring the fluorescence yield using a microchannel plate (MCP) detector (1*a*). All the spectra were normalized with respect to the incident photon flux (I_0). I_0 was simultaneously recorded with the FY by monitoring the current emitted from a nickel mesh located downstream from the last refocusing mirror. The spectra presented here are the sum of five scans. The energy scale was calibrated using the four sharp peaks at 162.4, 163.5, 168, and 169.3 (±0.1) eV in the L-edge spectrum for pyrite (1*b*).

In this work, the theoretical structure of the S $L_{3,2}$-edge for ZnS sphalerite is determined using ab initio calculations. Comprehensive and complete details on the calculation are provided in Yiu et al. (11). Briefly, we have used the full potential linearized augmented plane wave (LAPW) method (11), based on the density functional theory (DFT) (12) with generalized gradient approximation (GGA) (13), to calculate the electronic structure of ZnS sphalerite. ZnS in general has four crystal structures, B1 (rocksalt) (14), B2 (CsCl structure) (15), B3 (zincblende structure), and B4 (Wurtzite) structures (16). The naturally occurring crystal, sphalerite, has the zincblende structure with space group $F\bar{4}3m$. It has cubic face-centred lattice with Zn at (0,0,0) and S at (1/4,1/4,1/4), and a lattice constant of 5.41 Å. The B1 and B2 structures of ZnS crystals are the high-pressure phases of these crystals. We model the sphalerite crystals where Zn and S atoms are quenched at the perfect crystal sites of the zincblende structure as shown in Fig. 1 with spatial symmetry of $F\bar{4}3m$. The eigen-states of these ZnS crystal systems have been evaluated self-consistently employing the Wien code (17). Ten thousand k points have been used in the calculation of the irreducible wedge of the Brillouin zone. The XANES spectra are determined using Fermi's golden rule and dipole matrix elements convoluted by the life-time and instrumentation broadenings.

The LAPW method is one of the most-accurate methods for performing electronic-structure calculations for crystals.

© 2007 NRC Canada

The LAPW method is a procedure for solving the Konh–Sham equations for the ground-state density and total energy of a many-electron system. The many-body system consists of non-overlapping atomic spheres and an interstitial region. The eigen function of the atomic sphere is a linear combination of the radial wave function and the spherical harmonics. In the interstitial region, the eigen function consists of plane wave expansions. Core states are treated fully relativistically.



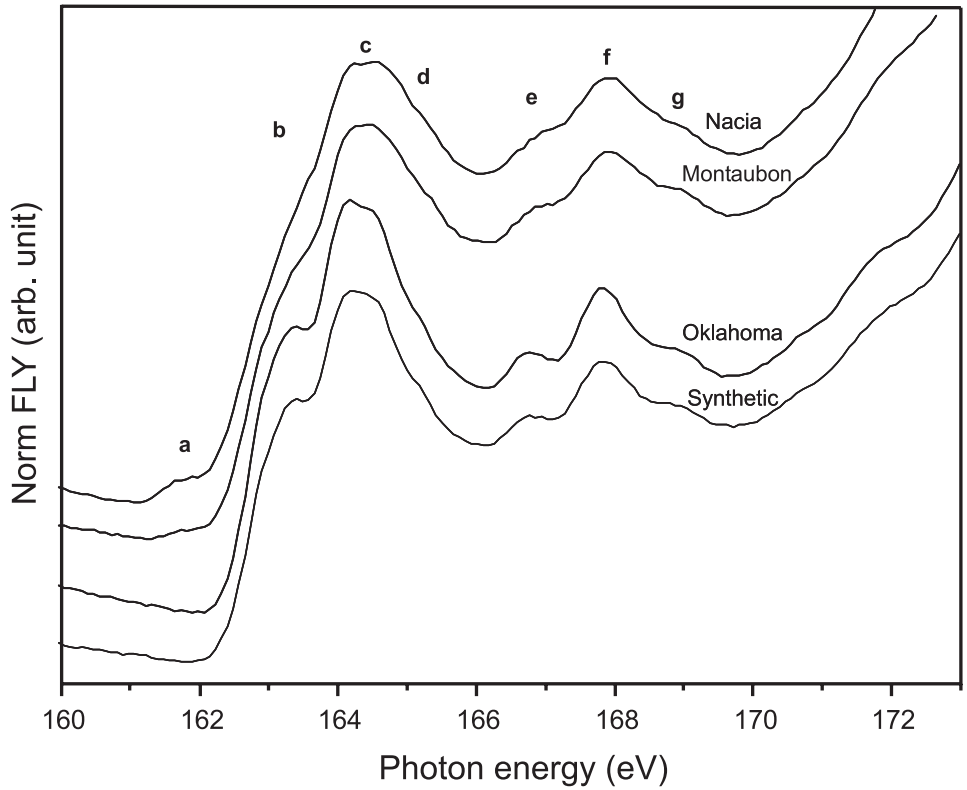
Results and discussion

The S $L_{3,2}$-edge XANES spectrum collected from a synthetic sphalerite sample is shown in Fig. 2. The S L-edge for sphalerite begins at 162.0 eV, and from the leading edge to about 170.0 eV, the XANES spectrum is made up of a series of sharp, well-defined peaks. Beyond 170.0 eV, there is a marked increase in background, and peak structures become diffuse. This dataset nicely shows that an S $L_{3,2}$-edge XANES spectrum can be divided into two basic regions: (*i*) the near-edge region and (*ii*) the post-edge region. The near-edge region is usually found in the first 15 eV above the onset position for absorption; the post-edge region is usually found 15 eV to about 50 eV above the initial absorption position (18). The near-edge region is sensitive to chemical shifts and has fine structure that is due to transitions to unoccupied electron orbitals in the conduction band (3, 4). The XANES post-edge region is sensitive via the multiple scattering of photons to the geometrical arrangement surrounding the absorbing atom (1*b*). Structures in the post-edge region are usually broad and not very well resolved. Following on the example set by Li et al. (2), the division between near- and post-edge regions for sphalerite S $L_{3,2}$-edge spectra is taken at 170 eV.

For all the spectra collected in this study, the post-edge features are very similar, in both position and intensity. This is expected because all the samples have the same crystal structure and tetrahedral coordination of sulphur. In all the spectra collected, there were no features in the post-edge region that could be attributed to oxidized sulphur species, such as sulphite or sulphate. This result shows that the FY XANES spectra examined in this study are representative of fresh sphalerite. Beam damage is not suspected in the data that were collected. No noticeable changes in the spectra were observed during acquisition, and spectra that were collected during two separate beamtime sessions match one another remarkably well.

The S $L_{3,2}$-near-edge XANES spectra acquired from the different sphalerite specimens examined are shown in Fig. 3. Sulphur in all the samples examined is in four-fold coordination, and the electronic configuration is fully occupied, $1s^2 2s^2 2p^6 3s^2 3p^4$ (8). The structure in the near-edge of the S $L_{3,2}$-edge XANES spectra is related to the electronic structure of the conduction band (4, 19, 20). The ab initio calculated S $L_{3,2}$-edges for ZnS sphalerite are shown in Figs. 4 and 5. The theoretical spectra were calculated using the density of states (DOS) for Zn and S in the zincblende structure. The calculated DOS data for sulphur are shown in Fig. 6. The theoretical S L-edge is constructed using L_3 and L_2 line separation of 1.1 eV (4) and an area ratio of 1:1. The calculated spectra as shown do not have a background, whereas the experimental spectra contain background contributions.

Fig. 2. Sulphur L-edge XANES of synthetic sphalerite.



The XANES edge in Fig. 4 was calculated with an intrinsic line broadening of 0.1 eV. Comparison with the experimental data for synthetic sphalerite shows remarkable agreement with regard to individual peak positions. The experimental XANES is however significantly broader than the calculated spectrum. This is in part due to self-absorption and vibrational broadening. The data were collected using FY mode on a relatively concentrated sample, and some self-absorption is expected to occur and broaden the resonance. Limitations in instrument resolution and signal processing electronics also will contribute to line broadening. Broadening will also occur as the lifetime of the core hole increases as a function of increasing photon energy. The calculations do not account for this phenomena; however, for this dataset, the change in photon energy is so small that broadening related to photon-energy-dependent core-hole lifetimes will not be significant.

To account for the broadening influences, a spectrum with a line broadening of 1.0 eV is calculated. Comparison of this calculated spectrum with the measured spectrum shows very reasonable agreement in the XANES structure. (Fig. 5). Most notable are the improvements in agreement in edge structure between experimental and theoretical data on the main-peak slopes near 163 eV and 165 eV (Fig 5, labels b

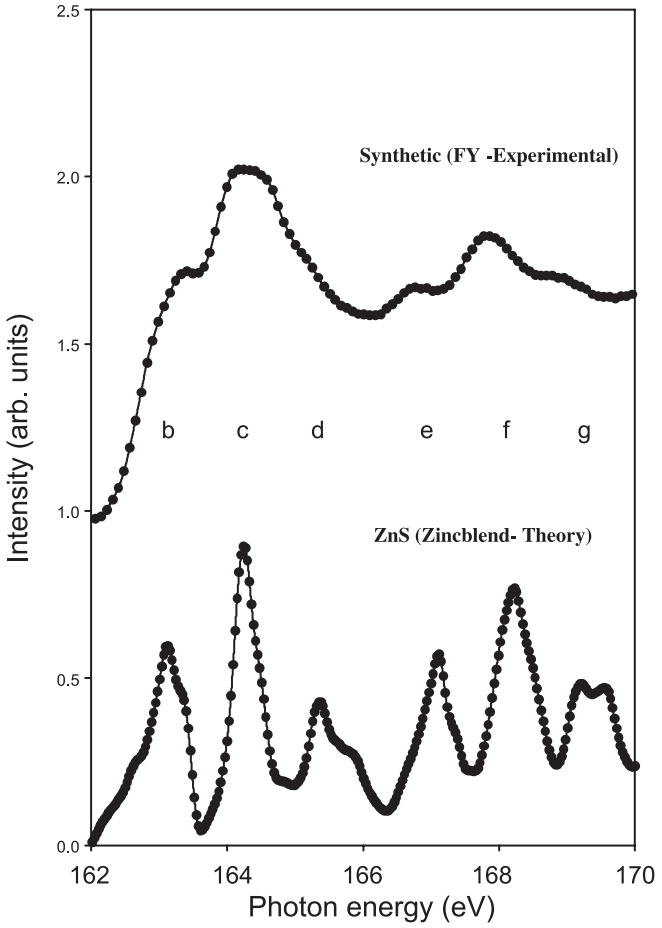
Fig. 3. Sulphur L-edge XANES of sphalerite samples from Nacia, Chihuahua, Mexico (14.79 wt% Fe); Montaubon, Quebec, Canada (8.14 wt% Fe); Oklahoma, USA (0.19 wt% Fe); and a synthetic specimen (<0.01 wt% Fe).

and d). There is also a considerable improvement in the structure of the two edges between 166 eV and 170 eV (Fig. 5).

We should point out that there is a limitation on the density functional theory. DFT tends to underestimate band gaps of semi-conductors, since it assumes that electron distributions have no singularity inside the crystals. By adding GGA, it corrects its limitation to a certain extent. From the density of state results as indicated in Fig. 6 with GGA, the calculated band gap of the ZnS crystal is 2.09 eV, whereas the experimental band gap is 3.70 eV (21). The ZnS crystals are one of the wide band gap materials.



The theoretical absorption edge is made up of six distinct peaks. These peaks are identified with the labels b, c, d, e, and f in Figs. 4 and 5. Each of these peaks has a unique structure, and this structure is due to the overlap and mixing of the L_3 and L_2 edges within each of the peaks. There is one exception, and it is the leading peak in the edge near 163 eV (label b). This peak is exclusively made up of contributions from the L_3 edge. The sharp peak identified by the label c is where the L_2 edge emerges. This peak contains contributions from the L_3 edge as well.

The S 2p electron transitions that contribute to S L-edge of sphalerite can be understood by comparing the calculated density of states, the theoretical, and experimental S $L_{3,2}$-edges. The electrical dipole transitions as modeled for the L_3- and L_2-edges only allow for ΔL (angular momentum quantum number) = ±1. The S L_3 absorption edge is from $2p_{3/2}$ electron transitions to the unoccupied states of d or s, and the L_2 absorption edge results from $2p_{1/2}$ electron transitions to the unoccupied states of d or s. Examination of the positions and intensities of the first DOS peaks near 3.3 eV above the Fermi level (Fig. 6) for S s and S d show S 2p electrons undergo transitions to both states (Fig. 6). Comparison of the DOS peak intensities for S s and S d shows that, at the initiation of absorption, it is the S 2p electron transitions to empty S 3s states that dominate. As the energy difference from the edge is increased, an increase in the S 2p electron transitions to empty S 3d states is observed. At 4.6 eV above the Fermi level, the DOS peaks for S s and S d have near equal intensities. From this point toward higher energies, the DOS data show that transitions to both empty S 3s and S 3d states occur, but it is the transitions to empty S 3d states that are dominant. These results show that S 2p electron transitions to empty S 3s and S 3d states occur across an energy range above the absorption edge.

With increased ferrous iron content, there is an increase in the broadness of the individual absorption contributions in the experimental XANES spectra (Fig. 3). The broadening is systematic and suggests that there is a chemical shift in line positions for S transitions that result from S atoms that are bonded with iron atoms. The broadening of the spectra as Fe content increases shows that the line positions for electron transitions associated with S atoms bonded with iron atoms occur at slightly different energies than the electron transitions that occur when S is bonded with Zn in the zincblende structure. For the Oklahoma sample (0.19 wt% Fe), the broadening is manifested by the decreased resolution of the peak at 163.3 eV. For the Montaubon sphalerite (8.14 wt% Fe), the broadening has been expanded to include the peaks at higher energies (labeled e, f, and g in Fig. 3). In the Nacia sample, which has the highest iron content (14.79 wt% Fe),

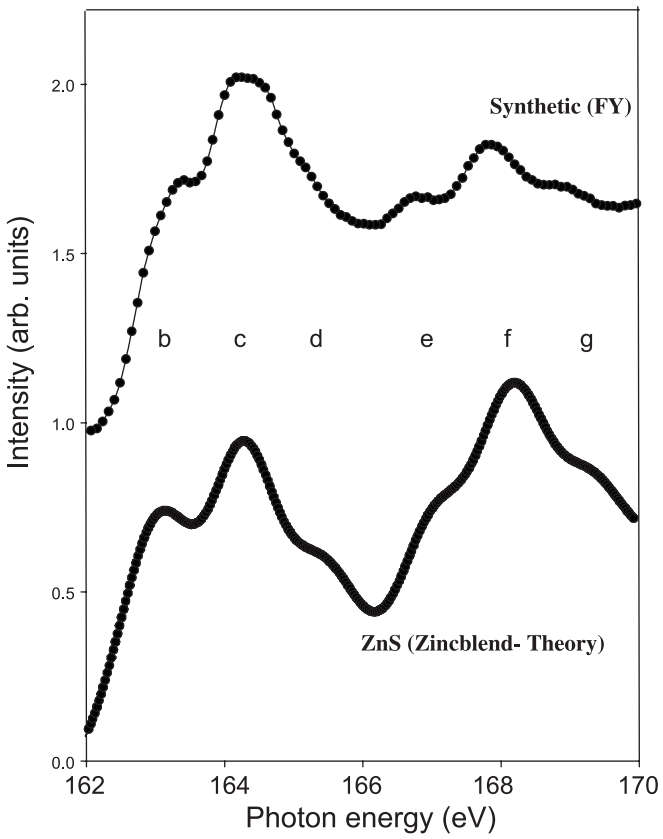

Fig. 4. Ab initio calculated L_3- and L_2-edges for ZnS sphalerite. For the theoretical spectrum, the line broadening was the natural linewidth of 0.1 eV. Peaks in the theoretical and experimental spectra are identified with the lowercase letters.

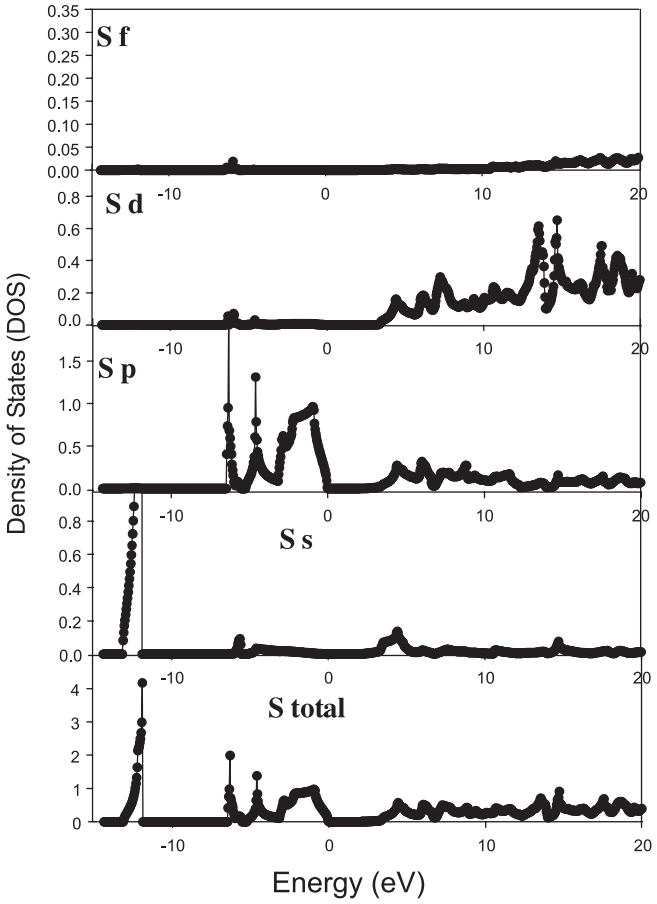
broadening from electron transitions related to Fe–S bonds has progressed to the extent that "all" individual edge contributions have become diffuse.

Examination of the XANES spectra collected from the sphalerite samples shows that the S L-edge data for the Montaubon and Nacia sphalerite contain a peak at the toe of the edge at 161.7 eV. This low-energy peak has a weak intensity, and it is identified with the label (a) in Fig 3. This peak is in the pre-edge region of the data, and this is the first time that a pre-edge peak has been observed for sphalerite. The peak is only observed in the sphalerite varieties with considerable iron concentrations, and empirically this suggests that it is associated with Fe–S bonding in sphalerite. It may be that the peak is simply the beginning of the L_3-edge for Fe–S bonds in sphalerite. This would indicate that there is a significant chemical shift (1.7 eV) for Fe–S bonds in sphalerite. Another and perhaps more likely possibility is that the peak results from S 2p electron transitions to hybridized Fe 3d – S 3p states. Optical microscopy and XANES studies have shown that this transition occurs in a variety of metal sulphide species (3, 12, 21, 22). If this is indeed the explanation for the pre-edge peak observed here, then this result indicates that there is a strong covalency in the S–Fe bond in sphalerite.

Fig. 5. Ab initio calculated L_3 and L_2 edges for ZnS sphalerite. The line broadening in theoretical spectrum is 1.0 eV. Peaks in the theoretical and experimental spectra are identified with the lowercase letters.

Conclusions



The S L-edge for sphalerite shows remarkable agreement between theory and experiment. Examination of the spectra through comparison with theoretical spectra and the calculated density of states for ZnS sphalerite shows that there is a mixing of S 2p electron transitions to empty 3s and 3d states over a range of energies above the absorption edge. Comparison of the S L-edge spectra collected from sphalerite with characteristic Fe concentrations shows that there is a chemical shift that is associated with transitions linked to Fe–S bonding. For the first time, a pre-edge feature associated with S–Fe bonding in sphalerite is observed.

Examination of the proposition that Cu(II) can be required for charge neutrality in a sulfide lattice — Cu in tetrahedrites and sphalerite[1]

Alan N. Buckley, William M. Skinner, Sarah L. Harmer, Allan Pring, Robert N. Lamb, Liang-Jen Fan, and Yaw-wen Yang

Abstract: Synchrotron XPS and Cu $L_{2,3}$-edge NEXAFS spectroscopic data for a natural tetrahedrite surface prepared by fracture under UHV were in accord with the composition of the mineral and its expected semiconductivity. The 2p binding energy for the 6-coordinate S atoms was found to be not detectably greater than that for the 4-coordinate S atoms, and surface species were not clearly discernible in either surface-optimized S 2p or Cu 2p spectra. The Cu 2p and Cu $L_{2,3}$-edge spectra indicated that all Cu in the mineral was indisputably Cu(I). The Cu $L_{2,3}$-edge spectra of relatively pure natural sphalerite treated with mildly acidic aqueous cupric solution revealed the presence of Cu(II) in the outermost layer of the fracture surfaces, but it was concluded that most of the Cu near the surface of the mineral was in formal oxidation state Cu(I), albeit with higher than normal d^9 character. The Cu(I) absorption peak was at an energy much lower than for the tetrahedrite absorption edge, but still consistent with Cu(I) in 4-fold coordination by S. The Cu(II) was consistent with Cu bonded both to S atoms in the outermost layer of the sphalerite and to O atoms in chemisorbed water. S 2p spectra determined at different photon energies revealed high binding energy components arising from oligosulfide-like environments in the outermost layers, but not necessarily in a completely restructured lattice and not in a Cu oligosulfide only. The data indicated some loss of Zn in addition to the Zn that had been replaced by Cu in the outermost layers of the sulfide lattice. The presence of these oligosulfide-like environments precluded the detection of S with formal oxidation state greater than (-II) that might have arisen only from Cu(I) in the S lattice. No evidence was obtained for the presence of Cu(II) in a sulfide lattice, but it was not possible to exclude the possibility of a very low concentration because of the presence of the Cu(II) bonded to both S and O at the surface of the treated sphalerite.

Key words: tetrahedrite, sphalerite, copper uptake, XPS, NEXAFS.

Résumé : Les données de spectroscopie photoélectronique aux rayons X par synchrotron et de spectroscopie d'absorption X de type « NEXAFS » près du seuil L_{23} du cuivre pour une surface de tétrahédrite naturelle préparée par fracture sous « UHV » sont en accord avec la composition du minerai et de sa semiconductivité attendue. On a trouvé que l'énergie de liaison 2p des atomes de soufre hexacoordinés n'est pas plus élevée que celle des atomes de soufre tétracoordonnés et que les espèces en surface ne peuvent pas être facilement discernées dans les spectres S 2p ou Cu 2p optimisés pour la surface. Les spectres Cu 2p et ceux près du seuil L_{23} du cuivre indiquent que tous les atomes de cuivre dans l'ensemble du minerai sont de type Cu(I), sans questionnement. Les spectres près du seuil L_{23} du cuivre d'une sphalérite naturelle relativement pure et traitée avec une solution cuprique aqueuse et faiblement acide mettent en évidence la présence de Cu(II) dans la couche externe des surfaces de fracture; on a toutefois conclu que la plupart des atomes de cuivre près de la surface du minerai se trouvent dans un état d'oxydation formel Cu(I) qui possède par ailleurs un caractère d^3 plus élevé que la normale. Le pic d'absorption du Cu(I) se situe à une énergie qui est de beaucoup inférieure à celle observée par absorption près du seuil de la tétrahédrite, mais qui est encore en accord avec un Cu(I) dans une coordination quaternaire avec le soufre. Le Cu(II) est en accord avec un atome de cuivre lié à des

atomes de soufre dans la couche extérieure de la sphalérite et à des atomes d'oxygène dans l'eau de chimisorption. Les spectres 2p du soufre déterminés à diverses énergies photoniques ont mis en évidence la présence de composants d'énergie de liaison plus élevée qui découlent d'environnements oligosulfurés dans les couches les plus externes, mais pas nécessairement dans un réseau complètement restructuré et pas seulement dans un oligosulfure de cuivre. Les données indiquent qu'il y a une certaine perte de zinc en plus de l'addition du zinc qui a été remplacé par le cuivre dans les couches les plus externes du réseau de sulfure. La présence de ces environnements de type oligosulfure ne permet pas la détection des atomes de soufre ayant un état d'oxydation formel plus grand que (-II) qui pourraient découler uniquement du Cu(I) dans des réseaux de soufre. On n'a pas pu obtenir de données pouvant permettre de confirmer la présence de Cu(II) dans le réseau de sulfure; il n'est toutefois pas possible d'exclure la possibilité de l'existence d'une très faible concentration en raison de la présence de Cu(II) lié tant à un atome de soufre qu'à un atome d'oxygène à la surface de la sphalérite traitée.

Introduction

The classical representation of tetrahedrite is $Cu_{12}Sb_4S_{13}$, but the tetrahedrite group minerals are more generally represented by $(Cu,Ag)_{10}(Cu,Fe,Zn)_2(Sb,As)_4S_{13}$. In each formula unit or half unit cell, the twelve univalent (Cu and Ag) or divalent atoms occupy 6 trigonal planar (^{III}M) sites and 6 tetrahedral (^{IV}M) sites (1). The trivalent atoms also occupy tetrahedral sites, but each is bonded to only 3 S atoms, resulting in a structural vacancy. Twelve of the 13 S atoms are 4-coordinate, whereas the other S atom is 6-coordinate and bonded to ^{III}M atoms. The coordination information can be summarized by $^{III}(Cu,Ag)_6{}^{IV}(Cu,Fe,Zn)_6{}^{III}(Sb,As)_4{}^{IV}S_{12}{}^{VI}S$, although there is some evidence for Fe, especially Fe(III), occupying trigonal sites (2).

The members of the tetrahedrite group of most interest in the present context are those in which the number of Cu atoms is greater than 10 minus the number of Ag atoms. There is general agreement that in natural tetrahedrites of this composition, the Ag preferentially occupies the univalent metal sites and the excess Cu is located in the divalent metal sites, but there is no consensus concerning the formal oxidation state of that Cu. Some consider either explicitly (e.g., 3) or implicitly (e.g., 4) that it is Cu(I), but others maintain that Cu in the divalent metal sites is Cu(II) (e.g., 5, 6), notwithstanding the reported antipathy of Cu(II) for tetrahedral coordination (7). Indeed, it has been argued that when tetrahedrite minerals are deficient in divalent metal atoms such as Fe or Zn, a minor Cu(II) component can be required for "charge neutrality" (6). Support for this hypothesis, which has been reiterated recently (8), was originally provided by the observation of an absorption peak near 931 eV in the total electron yield (TEY) Cu L_3-edge near-edge X-ray absorption fine structure (NEXAFS) spectra of synthetic and natural tetrahedrite samples prepared by grinding under acetone after being mixed with ultra pure graphite (6). For the four natural tetrahedrites studied in that investigation, the correlation between the expected Cu content in the divalent metal sites and the Cu(II) concentration indicated by NEXAFS spectroscopy was not strong. Furthermore, the corresponding fluorescence yield NEXAFS spectra were not determined, which raises the question as to whether the observed Cu(II) might have been associated with Cu-O surface oxidation products of the tetrahedrite specimens rather than Cu(II) in the sulfide lattice. Nevertheless, for synthetic $Cu_{12}Sb_4S_{13}$, electron paramagnetic resonance and related measurements were reported to be consistent with Cu(II) in the divalent metal sites (9). Instead of postulating the presence of Cu(II) for charge neutrality, Charnock et al. (2) proposed that for Fe-containing tetrahedrites in which copper is present in excess of 10 atoms per unit formula, compensation of the valence deficiency is by Fe(III). Fe K-edge extended X-ray absorption fine structure (EXAFS) and Mössbauer spectroscopic data for synthetic specimens were in agreement with that hypothesis, but for natural specimens the Fe was present mainly as Fe(II) in tetrahedral coordination.

Setting aside for the moment the origin of the small concentration of Cu(II) detected in some of the tetrahedrite samples, the proposition that Cu(II) can be required for "charge neutrality" is a contentious one, as it appears to be based on the assumption that the S in the sulfide lattice must remain as S(-II), despite the fact that it cannot have only this formal oxidation state in CuS, nor can the S be only S_2(-II) in CuS_2. In both cases, the deviation from typical S(-II) or S_2(-II) is evident in the S 2p spectra for these materials. As a more subtle example, it has been proposed (10) that djurleite, $Cu_{1.96}S$, can be represented by $Cu(I)_{62}Cu(II)S_{32}$. However, it is now widely accepted that Cu has a formal oxidation state of only Cu(I) in all copper-containing sulfides, including CuS and CuS_2 (11–19), except perhaps for tetrahedrite.

A corollary of the "Cu(II) for charge neutrality" hypothesis is that the Cu initially replacing Zn in the surface layers of sphalerite ("copper activation" of sphalerite for its recovery by flotation), must be present as Cu(II), notwithstanding the counsel by Pattrick et al. (18) that because copper chalcogenides are invariably Cu(I), the Cu incorporated into ZnS is likely to be reduced to Cu(I) with the concomitant oxidation of sulfide to form S^-–S^- bonds and, with increasing substitution of Zn with Cu, the formation of a covellite-like surface layer. However, if it is considered possible for some Cu(II) to be in tetrahedral sites in tetrahedrite, the question arises as to whether it might be possible for the Cu initially replacing Zn in sphalerite to be Cu(II). The Cu 2p spectra obtained in X-ray photoelectron spectroscopy (XPS) studies of the copper activation of sphalerite under conditions not conducive to the formation of $Cu(OH)_2$ have indicated that the Cu is present as Cu(I) regardless of the extent of uptake, although Cu 2p spectra are appreciably less sensitive than Cu L_3-edge spectra for the detection of Cu(II) (6,

© 2007 NRC Canada

20). In the corresponding S 2p spectra, there has been clear evidence for an increase in the formal oxidation state (to those less negative than -II) of some of the S after Cu uptake, but the observed S 2p binding energies have been too large to have arisen from a Cu(I) sulfide phase or S(-I) only (21). Heavily Cu-substituted surface layers would be expected to restructure, although it appears that Cu can be incorporated into an unreconstructed sphalerite lattice at least to a small extent. On the one hand there have been reports of supergene cuprian sphalerite with Cu content up to 10 atom% (22), while on the other hand attempts by Pattrick et al. (23) to substitute (in a silica tube at 600 °C) Cu into a sphalerite lattice without the concomitant introduction of indium produced sphalerite with only ~0.2 atom% Cu. In the latter case, the corresponding Cu $L_{2,3}$-edge spectra were reported to reveal the presence of some (but presumably not all) Cu(II) that was thought to be located in the ZnS lattice (23). It was concluded that Cu substitution at low concentrations can occur without the need for corresponding Zn vacancies, and it was proposed that the limit of Cu substitution is controlled by the aversion of Cu(II) for tetrahedral coordination in sulfides (23).

There is some, although perhaps not incontrovertible, evidence for the existence of Cu(II) in the wurtzite ZnS lattice. The IR emission centre in Cu-doped wurtzite ZnS is normally assigned to the substitution of Zn by Cu(II), whereas the green and blue centres are associated with Cu(I) at substitutional sites (24). There is stronger optical spectroscopic evidence for Cu(II) substituting for Zn at the ppm level in polymorphic (including cubic) crystalline ZnS (25).

Pattrick et al. (18) investigated the Cu activation of 2.5 × 8 cm^2 slabs of polycrystalline synthetic sphalerite and natural Fe-rich sphalerite by 0.5 mol dm^{-3} Cu^{2+} at pH 3.9 primarily by means of fluorescence reflection EXAFS (REFLEXAFS) spectroscopy. The large slabs of ZnS were polished to optical flatness in air, and the ~0.1° angle of incidence corresponded to a penetration depth of ≤5 nm. The Cu K-edge fluorescence REFLEXAFS data indicated that the Cu was bonded to 3 S atoms at 0.225 nm and one O atom at 0.207 nm, distances similar to those obtained by bulk EXAFS for pure ZnS powder similarly Cu-activated. It was reasoned (18) that these results, when averaged over the ~2 layers of Zn exchanged by Cu, suggested that the outermost Cu must be bonded to more than one O, as Cu below the surface would be expected to be fully bonded to S.

There has typically been at least one limitation in previous investigations of the interaction of sphalerite with cupric ions that has prevented a definitive conclusion concerning the possible existence of Cu(II) in the treated mineral. Most notably, Cu L_3-edge absorption spectra have usually not been obtained to complement Cu 2p photoelectron spectra, but other limitations have included the use of impure natural sphalerite, surfaces of relatively pure sphalerite that have been abraded, polished, or cleaved in air prior to treatment with the Cu-containing aqueous phase, treatment in Cu^{2+} solution of concentration in excess of 0.001 mol dm^{-3}, treatment for periods of at least 30 min, or treatment at a pH of ~9, which is of relevance to flotation but which may allow the adsorption of Cu-hydroxy species on the treated surfaces.

In this work, a tetrahedrite surface prepared by the fracture of a single piece specimen under ultra high vacuum (UHV) was characterized by partial electron yield (PEY) and total fluorescence yield (TFY) NEXAFS spectroscopy as well as synchrotron XPS (SXPS). Spectra from the tetrahedrite were sought not only to establish whether they were consistent with the mineral composition and structure, but also because a reference material containing Cu in trigonal planar and tetrahedral S environments was required to assist interpretation of the spectra from Cu-doped sphalerite. Relatively pure sphalerite samples were cleaved while immersed in aqueous solutions of cupric ions and subsequently characterized by SXPS and NEXAFS spectroscopy in such a way as to minimize exposure of the treated mineral surface to oxygen, and hence minimize any oxidative leaching of Zn from the Cu-treated surface or possible oxidation of Cu(I) in the sulfide lattice near the surface to a Cu(II) oxygen species. In both systems, the aim was to identify the source of any Cu(II) present, and to determine whether S of formal oxidation state more positive than (-II) was discernible.

Experimental details

Mineral specimens

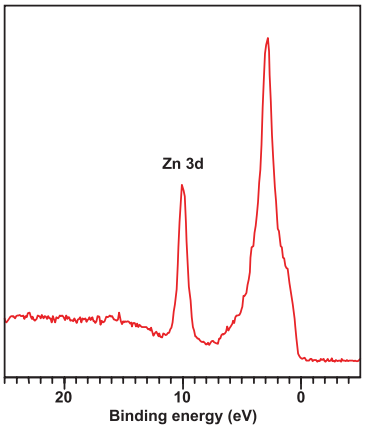
The tetrahedrite was a massive polycrystalline specimen from Casapalca, Peru. Specimens of approximate size 3 × 3 × 6 mm were mounted in a vice-like specimen holder, designed for use in the double-blade cleaving stage, attached to the rotary distribution chamber of the Australian Synchrotron Research Program (ASRP) soft X-ray spectroscopy endstation. Preliminary bulk analysis was carried out on the mineral specimen with an FEGSEM, and the tetrahedrite structure was confirmed by XRD. The bulk composition below the fracture surface characterized by SXPS was determined by electron microprobe analysis using a Cameca SX-51 instrument at the Adelaide Microscopy Centre, University of Adelaide. Operating conditions included an accelerating voltage of 20 kV and a beam current of 19.5 nA. Standards used were PbS (S), $CuFeS_2$ (Cu, Fe), ZnS (Zn), CoAsS (As), Ag_2Te (Ag), Sb_2S_3 (Sb), and Bi_2Se_3 (Bi). Apart from slightly low values for Fe and Zn, the analyses were found to be within the composition range reported for other tetrahedrite specimens from Casapalca, viz. $(Cu,Ag)_{10+x}(Fe,Zn)_{2\pm y}(Sb,As)_{4+z}S_{13}$ (26). The compositions of the 16 regions analysed varied by less than 2%. The sphalerite used in the investigation was a relatively pure (almost colourless) mineral specimen from Santander, Spain.

Interaction of aqueous cupric ions with sphalerite

Approximately 3 × 3 mm surfaces of the Santander sphalerite were prepared by fracture while under 10^{-3} mol dm^{-3} Cu sulfate solution at pH 2 or 5, and the fracture surfaces were left immersed for periods ranging from 1 to 5 min prior to being rinsed with water. Adjustment of pH was made with dilute hydrochloric acid. The specimen treatment and rinsing was carried out in a nitrogen-flushed glove box surrounding the introduction chamber of the ASRP endstation with nitrogen-saturated solution and water, respectively, and therefore would have taken place in no more than a low concentration of residual oxygen. The sphalerite specimens, with the treated fracture surface uppermost, were

© 2007 NRC Canada

mounted on a stainless steel specimen stub by means of double-sided conducting adhesive tape.



Spectroscopic measurements

The SXPS and NEXAFS spectroscopic measurements were carried out in the ASRP soft X-ray spectroscopy end-station while connected to beamline 24A at the NSRRC in Hsinchu, Taiwan. BL24A is a bending-magnet wide-range beamline incorporating a grating monochromator (27). With 25 μm slits and 400 L/mm grating, the resolution was 0.07 eV at a photon energy of 210 eV. The synchrotron was operated at 300 mA in continuous top-up mode. The ASRP end-station, constructed by OmniVac and PreVac, is equipped with a SPECS Phoibos 150 electron energy analyser and an OmniVac UHV-compatible partial yield detector based on a multichannel plate behind retarding grids. Electron analyser pass energies of 10 eV and 20 eV were used for S 2p and Cu 2p spectra, respectively. A Gammadata Scienta Flood Gun 300, operated at 3 eV energy and 0.05 mA emission, was used for specimen charge compensation only during determination of the tetrahedrite photoelectron spectra. Cu $L_{2,3}$-edge NEXAFS spectra are shown together with the absorption current monitored concomitantly by a Cu metal mesh in the beamline but unnormalized by the flux incident on a Au mesh also in the beamline. The NEXAFS spectroscopic analysis depths in PEY and TFY modes would be ~8 nm and >100 nm, respectively (28). Conventional XPS measurements were undertaken using monochromatised Al K_α X-rays in a Kratos Axis Ultra spectrometer.

Measurement of binding energies in SXPS

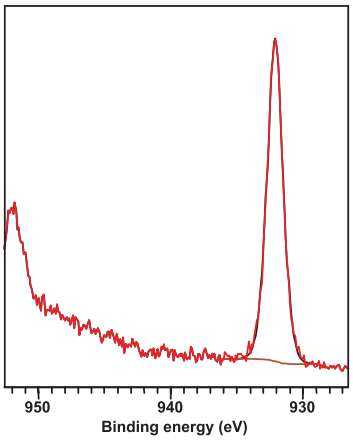
The measurement of photoelectron binding energies in SXPS can be complicated by uncertainties in the photon energy arising from any variation in the incidence of the synchrotron beam on the first optical element of the beamline. The situation is even more complicated when an electron flood gun has to be used for charge compensation with poorly conducting materials and when no reference peaks are available, such as when there is negligible carbon present at a fracture surface prepared under clean UHV conditions. Typically, a flood gun electron beam required to minimize photoelectron linewidths overcompensates for the positive charge established as a result of the photoemission, and hence renders the surface negative by a few eV. The degree of overcompensation can be different for different photon energies as charging can depend on the photon flux, and the flux normally varies as the monochromator grating and settings are changed. When the use of a flood gun was necessary in the investigation of a clean fracture surface in the present work, electron energies were measured relative to the top of the valence band. This is effectively the same as measuring the energies relative to the onset of photoemission at the same photon energy, as the top of the valence band is typically estimated by extrapolating the leading edge of the valence band peak to the baseline (29). The method is "calibrated" using a similar well-characterized reference material. Sphalerite is an appropriate reference material for the two systems studied in the present work, as Zn is present in tetrahedral sites in tetrahedrite, and some essentially unaltered sphalerite remains as a substrate within the depth analysed for Cu-treated sphalerite.

Fig. 1. Tetrahedrite Zn 3d and valence band spectrum determined at a photon energy of 210 eV.

Pure cubic ZnS fracture surfaces have been characterized by conventional XPS without a flood gun but with Au decoration for a binding energy reference (29) and a Zn 3d binding energy of 10.1 eV was determined. A S $2p_{3/2}$ binding energy of 161.6 eV was obtained for an Fe-containing mineral sphalerite with a flood gun using a magnetic confinement charge compensation system (30).

Fitting of core photoelectron spectra

The CasaXPS (version 2.0) software was used to fit photoelectron spectra. The constraints used in fitting S 2p spectra were a (3/2, 1/2) splitting of 1.19 eV, intensity ratio 2:1, and equal linewidths. Fitted parameters were not significantly different if a Gaussian–Lorentzian sum SGL(p) of lower Lorentzian character (smaller "p") rather than the more usual product, GL(p), was used to approximate the Voigt profile. However, SGL(10) or GL(50) usually gave slightly better fits at the leading edge compared with GL(30). The asymmetric lineshape proposed by Gelius (31, 32) of general form A(a,b,n)GL(p), where a, b, and n are parameters determining the shape of the tail contribution to the lineshape, was used for the Cu 2p spectra of Cu-treated sphalerite, typically A(0.35, 0.4, 0)GL(50).



Results

Tetrahedrite

The survey photoelectron spectrum determined at a photon energy of 1100 eV, for a tetrahedrite surface prepared by fracture under ~5 × 10^{-11} torr (1 torr = 133.322 4 Pa) and transferred to the analyser chamber without exposure to a higher pressure, was largely consistent with the electron microprobe analysis of the mineral, viz. $Cu_{10.07}Ag_{0.23}Zn_{1.40}Fe_{0.22}Sb_{2.76}As_{1.35}Bi_{0.01}S_{13}$. In particular, peaks from Cu, Zn, Sb, and S were clearly visible, Fe 2p peaks were barely evident, and Ag 3d peaks were not discernible at all. Peaks from As, such as the 3d at a binding energy near 43 eV, were not quite as intense as expected from the microprobe analysis. A flood gun was required to minimize the effect of charging, consequently photoelectron energies were determined relative to the onset of photoemission as described in the experimental details section. The need for a flood gun indicates that the mineral was a

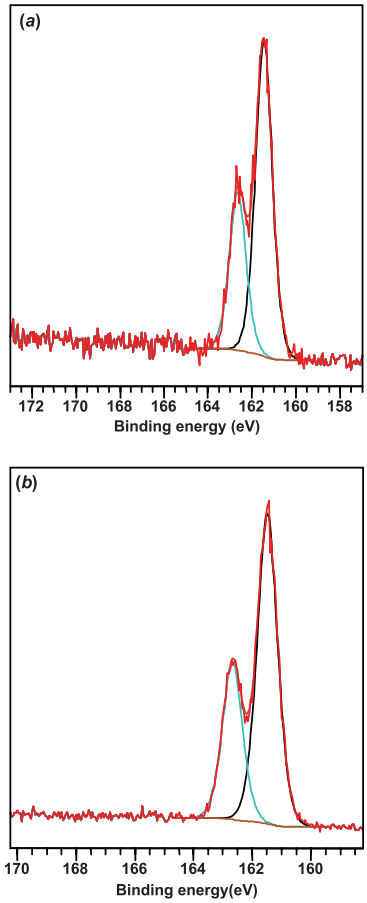
Fig. 2. Tetrahedrite Cu 2p spectrum determined at a photon energy of 1100 eV and fitted with a single symmetric $2p_{3/2}$ peak.



semiconductor with a substantial band gap rather than a conductor and hence with a total number of valence electrons per unit cell close to 208 (33), as expected from the composition, which predicts 207.8 per unit cell. Spectra in the valence region were determined at photon energies of 210 eV (Fig. 1), 400 eV, and 800 eV, and a quite steep valence band edge, estimated to be at a binding energy of ~0.8 ± 0.1 eV, was observed in each case. The Zn 3d binding energy was approximately 10.1 eV.

From the spectra for Cu-treated sphalerite (vide infra), it is expected that the valence band spectrum for tetrahedrite would be dominated by a Cu 3d peak at a binding energy ~7 eV lower than that for the Zn 3d. The valence band would also contain significant contributions from Sb (5p) and As (4p) as well as S, nevertheless, for relative intensity comparison purposes, the Cu 3d peak can be approximated by the relatively sharp central peak in the valence band. The estimated intensity of that peak, relative to the Zn 3d peak, was essentially the same at 800 eV as at 210 eV. In principle, an estimate of the Cu/Zn ratio can be obtained from the relative intensity of the two corresponding 3d peaks and a calculated photoionization cross section ratio at 800 or 210 eV; however, the Cu 3d peak intensity might have been systematically underestimated and the calculated cross sections for the 3d levels of Cu and Zn might not be very accurate, consequently it was preferable for this intensity ratio to be calibrated for tetrahedrite and used later for Cu-treated sphalerite. At a photon energy of 210 eV, the Cu 3d/Zn 3d cross section ratio was estimated to be 1:2.9, while at 800 eV a ratio of 1:2.6 was obtained. By comparison, the Cu 3d/Zn 3d cross section ratio at 1254 eV calculated by Scofield (34) was 1:1.36.

On the same energy reference basis, the Sb $3d_{5/2}$ binding energy was 529.6 eV, an energy also close to the value expected given the corresponding value of 530.1 eV observed for Sb_2S_3 (35). The Sb $3d_{5/2}$ linewidth at a photon energy of 800 eV was 0.94 eV compared with 0.72 eV observed (35) for Sb_2S_3 by means of conventional XPS with a magnetic confinement charge neutralization system. The slightly larger linewidth for tetrahedrite is more likely to have been due to a wider distribution of Sb environments in tetrahedrite compared with stibnite than to broadening arising from incomplete compensation by the flood gun of non-

Fig. 3. S 2p spectrum for a tetrahedrite fracture surface determined at a photon energy of (*a*) 210 eV and (*b*) 400 eV fitted with a single doublet in each case.

uniform charging (given the relatively narrow Cu 2p linewidth; vide infra). It is unlikely to have been due to a larger X-ray linewidth (0.25 eV) provided by the monochromator grating and slit settings used (1600 L/mm, 25/25 μm). The observed width of the Sb 3d peaks is of relevance for evaluating the observed widths of the Cu 2p and S 2p photoelectron peaks. There was no evidence for any O 1s intensity near the Sb $3d_{5/2}$ peak.

The $2p_{3/2}$ peak in the Cu 2p spectrum determined at a photon energy of 1100 eV (Fig. 2) was at a binding energy of 932 eV, close to values previously observed for Cu in other sulfide minerals (e.g., 36). The peak could be fitted with a single symmetrical component of Gaussian–Lorentzian lineshape and of linewidth 1.4 eV, which was at least as narrow as the corresponding peak for other sulfide minerals that had been characterized under the same experimental conditions and that were sufficiently conducting to not require charge compensation with a flood gun. The symmetrical nature of this peak is of considerable relevance in the interpretation of the Cu 2p spectrum from Cu-doped sphalerite (vide infra). As expected from the absence of a Cu $2p_{3/2}$ component between 933 and 934 eV that could have arisen from any Cu(II) present, excited final state satellites were not discernible. Thus, the Cu 2p spectrum was consistent with the presence of only Cu(I) in a sulfide of nonmetallic conductivity.

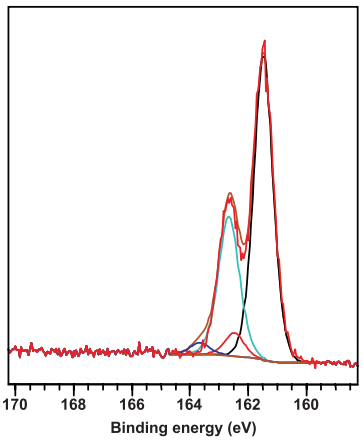
© 2007 NRC Canada

The S 2p spectrum determined at a photon energy of 210 eV is shown in Fig. 3*a*. The spectrum can be fitted with a single S 2p doublet with symmetrical Gaussian–Lorentzian components of width 0.9 eV and at a $2p_{3/2}$ binding energy of 161.5 eV. This observation is notable for two reasons. First, the absence of any indication of at least one additional doublet at a binding energy noticeably lower than that for the main doublet revealed that surface species (i.e., species expected when covalent bonds are broken on fracture or when the atoms in the outermost layers relax significantly following fracture) either had not been formed or were close in energy to the bulk states. A photon energy of 210 eV corresponds to the value of maximum surface sensitivity for S 2p photoelectrons, and the photon linewidth at 210 eV should have been sufficiently narrow to allow the resolution of surface species such as those observed for covellite (37). However, the 0.9 eV S $2p_{3/2}$ linewidth at a photon energy of 210 eV was broader than values observed for better conducting Cu sulfides under similar experimental conditions, including ~0.55 eV for covellite, ~0.6 eV for cubanite, and ~0.7 eV for bornite, therefore the formation of surface species cannot be precluded. Second, the absence of an additional doublet of intensity ~8% of that of the main doublet and at a binding energy at least 0.5 eV higher indicated that the two 6-coordinate S atoms in the tetrahedrite unit cell do not have a measurably higher binding energy than the 24 4-coordinate S atoms. On the basis of the binding energy difference deduced for 4- and 5-coordinate S in pentlandite (38), Schaufuß et al. (39) had postulated that a unit increase in S coordination would lead to an increase in S 2p binding energy of ~0.8 eV. Subsequently, a binding energy difference of at most 0.3 eV was determined for the 2- and 3-coordinate S atoms in stibnite (35), and a negligible binding energy difference was observed for the 5-coordinate S in millerite (β-NiS) and the 6-coordinate S in α-NiS (40). The negligible difference observed for the S atoms in tetrahedrite provides confirmation that a higher S coordination number does not necessarily lead to higher S core electron binding energies.

The S 2p spectrum observed at a photon energy of 400 eV is shown in Fig. 3*b*. As for the S 2p spectrum excited at 210 eV, the 400 eV spectrum could be fitted with a single doublet of symmetric components of width 0.8 eV. The slightly narrower linewidth of the doublet components in the 400 eV spectrum compared with the 210 eV spectrum (Fig. 3*a*) is not expected to have arisen from a better photon beam resolution. Rather, it is most probably because of a more effective compensation by the flood gun of less specimen surface charging produced by a photon flux that was lower at 400 eV (800 L/mm grating) than at 210 eV (400 L/mm grating), but the narrower linewidth could also have been the result of a contribution from surface species that was lower because of the greater analysis depth. The observed S $2p_{3/2}$ binding energy of 161.5 eV is within 0.1 eV of the value for chalcopyrite. Also, the S K-edge spectrum for a natural tetrahedrite was found to be quite similar to that for chalcopyrite (41).

To demonstrate that the tetrahedrite S 2p spectrum cannot be fitted satisfactorily with a second doublet arising from the 6-coordinate S of intensity 1/13th that of the principal (4-coordinate S) doublet and at a significantly higher binding energy, the spectrum in Fig. 3*b* was fitted with such a second doublet constrained to 1 eV higher binding energy from the principal doublet and with the same component line shape and width (Fig. 4). It can be seen from Fig. 4 that the best fit obtainable on this basis is inadequate. The best fit was also clearly inadequate for a shift of only 0.5 eV. These shifts should be compared with a shift of 1.6 eV that would correspond to an increase of S 2p binding energy of 0.8 eV per unit increase in S coordination number.

Fig. 4. S 2p spectrum shown in Fig. *3b* fitted with a second doublet of intensity 1/13th that of the principal doublet and shifted 1 eV to higher binding energy.



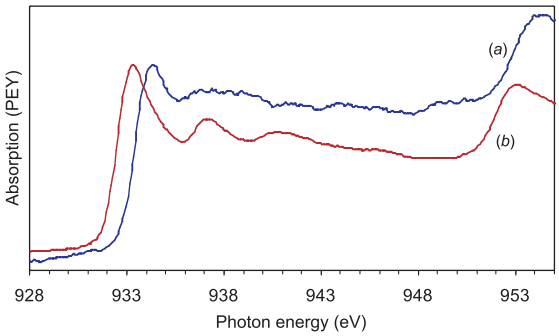


Fig. 5. PEY Cu $L_{2,3}$-edge NEXAFS spectrum for (*a*) a tetrahedrite and (*b*) Cu metal.

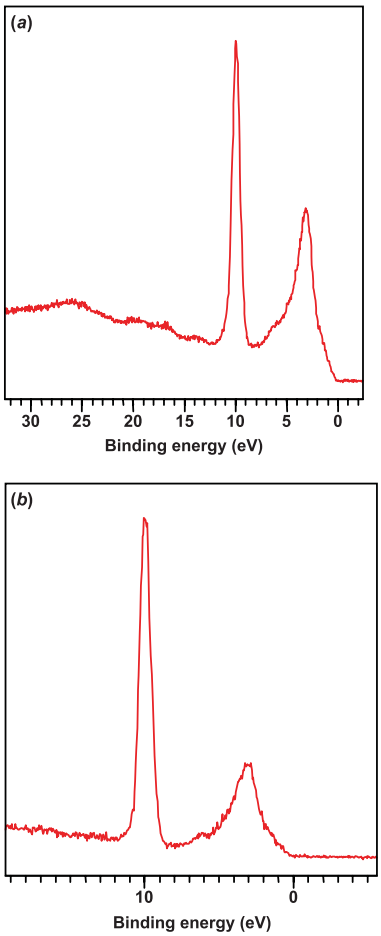
TFY and PEY Cu $L_{2,3}$-edge NEXAFS spectra were determined for the same tetrahedrite fracture surface. The NEXAFS spectra were obtained immediately after the photoelectron spectra that had been determined (at a photon energy of 1100 eV) using the same monochromator settings but using several different irradiated areas on the fracture surface to check for any sign of surface chemical degradation brought about by the photon beam. A representative PEY Cu $L_{2,3}$-edge NEXAFS spectrum is shown in Fig. 5 together with the spectrum from Cu metal determined concomitantly. The L_3 absorption edge was at 933.4 eV relative to the edge position for Cu metal of 932.6 eV. An absorption edge energy of 933.4 eV (peak energy of ~934.5 eV) is similar to that observed for chalcocite and ~1.9 eV higher than that for chalcopyrite (36). Thus, the absorption energy for tetrahedrite is in the "indisputably Cu(I)" region rather than being near the lower end of the Cu(I) range adjacent to that for Cu(II) (6). The TFY spectrum was essentially the same

© 2007 NRC Canada

as the PEY spectrum apart from an even flatter baseline before the absorption edge. It is important to note that despite the significant Cu + Ag excess (>10) and comparable Zn + Fe deficiency (<2) in the tetrahedrite investigated, viz. $(Cu,Ag)_{10.3}(Zn,Fe)_{1.6}(Sb,As,Bi)_{4.1}S_{13}$, there was no evidence for an absorption peak near 931.3 eV in the TFY spectrum that could have arisen from a small concentration of Cu(II) in the mineral's divalent metal sites. Even in the corresponding PEY spectrum (Fig. 5*a*), any absorption near 931 eV remained below noise level.

The Cu L_3 peak energy of 934.5 eV is in agreement with the values found by Pattrick et al. (6). In the tetrahedrite specimens they studied that did not contain Te (instead of Sb), the Cu(I) peak energies ranged from 934.0 to 934.6 eV, while the energy of the Cu(II) L_3 peak, when present, was in the slightly narrower range of 930.5 to 930.8 eV. For specimens that did not contain Ag, the Cu(I) range was 934.2 to 934.6 eV. They concluded that the L_3 peak energy for Cu in tetrahedral sites (934.0 eV) was smaller than that for Cu in the trigonal sites (~935 eV), consistent with a longer more ionic Cu–S bond in the former sites and a shorter (0.226 nm), stronger more covalent Cu–S bond in the latter sites. The absorption spectrum observed in the present work is in accord with the findings of Pattrick et al. (6), apart from the absence of a peak from Cu(II).



Interaction of sphalerite with mildly acidic aqueous cupric ions

Survey photoelectron spectra, determined at a photon energy of 1100 eV from Santander sphalerite fracture surfaces treated in Cu sulfate solution, revealed peaks from oxygen in addition to those from Zn, S, and Cu, notwithstanding preparation of the specimens in the nitrogen-flushed glove box surrounding the end-station load lock. More O was evident after 1 min treatment than 5 min, suggesting that the O might be associated with adsorbed water; treated surfaces are expected to become increasingly hydrophobic as a result of Cu incorporation (21, 42), and less water adsorption would be expected on a more hydrophobic surface. Indeed, each narrow scan O 1s spectrum determined at a photon energy of 800 eV consisted of a structureless symmetrical peak of width ~2 eV centred at a binding energy of ~532.5 eV, intimating that the probable source of the oxygen was chemisorbed water rather than Cu-O species such as hydroxide (43). The O 1s intensity was clearly lower, and the Cu 2p intensity obviously higher, towards the end of the specimen irradiation period than at the beginning of data collection, indicating that some O was lost from the surface during the measurements and that the Cu was below the oxygen-containing species. The survey spectra also revealed that a flood gun was not necessary to compensate for specimen charging, unlike the situation for the same sphalerite not treated with Cu.

The valence band and Zn 3d spectra determined at photon energies of 210, 400, and 800 eV were all consistent with a Zn 3d binding energy of 10.0 ± 0.1 eV. As for the tetrahedrite studied, this binding energy is close to the 10.1 eV determined for pure cubic ZnS by Ley et al. (29). The low kinetic energy band edge was not noticeably steeper at a photon energy of 210 than 400 eV; a steeper edge might have been expected if a Cu sulfide-like surface layer with high electrical conductivity had been produced. At a photon energy of 210 eV, the central peak in the valence band was noticeably more intense relative to that for the Zn 3d than at the higher photon energies (Fig. 6). This energy variation was much more pronounced than for tetrahedrite, therefore it must have reflected a higher concentration of Cu in the outermost layers rather than a change in the relative Zn and Cu 3d photoionization cross sections with energy. Changes in the concentration of Cu relative to Zn in the outermost layers can be monitored by the Cu 3d/Zn 3d intensity ratio in spectra determined at 210 eV, while changes in the depth analysed by ~790 eV electrons will be reflected in the Cu 3d/Zn 3d intensity ratio in spectra determined at 800 eV (Table 1). It is also possible to estimate Cu/Zn atomic ratios from the Cu 3d/Zn 3d intensity ratios. From the calibration of Zn 3d and estimated Cu 3d peak intensities carried out for tetrahedrite, the Cu/Zn ratio in the depth analysed by ~200 eV electrons after treatment with Cu for 1 min at pH 5 was 2:1. By contrast, the ratio in the depth analysed by ~790 eV electrons was 0.7:1.

Each narrow scan encompassing the Zn 3p, Cu 3p, and Cu $L_3M_{4,5}M_{4,5}$ peaks determined at a photon energy near 1010 eV also enabled an estimate of the Cu/Zn ratio within the depth analysed by electrons of kinetic energy ~925 eV to be made from the Cu 3p/Zn 3p intensity ratio (Table 1). For

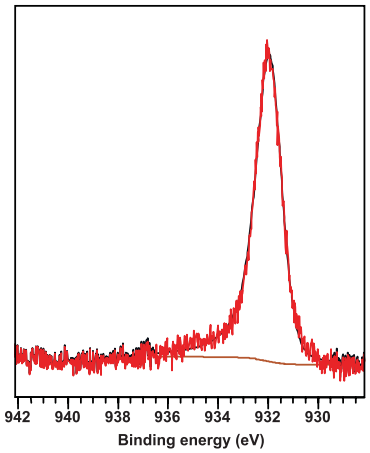
Fig. 7. Cu 2p spectrum for a Santander sphalerite surface treated with aq. Cu^{2+} for 1 min at pH 5 determined at a photon energy of 1100 eV and fitted with two components.



example, the Cu 3p/Zn 3p intensity ratio indicated a Cu/Zn ratio of ~0.5:1 within the surface layer analysed after interaction with aq. Cu^{2+} for 1 min at pH 5, based on calculated values of subshell photoionization cross sections (44) that predicted a Cu 3p/Zn 3p cross section ratio at 1010 eV of 0.88:1. This value is in reasonable agreement with the ratio estimated experimentally from the Cu 3d/Zn 3d intensity ratio at 800 eV.

The principal $2p_{3/2}$ component in the Cu 2p spectrum determined at a photon energy of 1100 eV, shown in Fig. 7 for a surface interacted with cupric ions for 1 min at pH 5, was at a binding energy of ~932.4 eV, close to values previously observed for Cu-activated sphalerite (e.g., 21, 45) and for Cu in other sulfide minerals (e.g., 36). The Cu $L_3M_{4,5}M_{4,5}$ Auger peak kinetic energy and the principal Cu $2p_{3/2}$ peak binding energy, i.e., the modified Auger parameter, was 1850.0 eV, close to the value of 1849.9 eV observed by Perry et al. (46) for presumably pure sphalerite but greater than the value of 1849.3 eV for two Fe-containing sphalerites (21). An Auger parameter of ~1850.0 is entirely consistent with Cu(I) in a sulfide lattice (21), but ~0.3 eV lower than that for covellite (CuS).

It is clear from Fig. 7 that the Cu $2p_{3/2}$ peak could not be fitted adequately with a single component. A better fit could be obtained by including a second minor component at a higher binding energy, however, if the linewidth of the second component was constrained to be no more than 10% greater than that of the principal component, the binding energy of the second component was ~2.3 eV higher than that for the principal component (Table 1). A Cu $2p_{3/2}$ binding energy of 934.8 eV is higher than values normally observed for Cu(I) species or even Cu(II) oxides but similar to values reported for Cu bonded to oxygen in Cu(II) hydroxide (43) and in other oxy-anions. There was no evidence for the excited final state satellites normally associated with Cu(II) species, however for a primary peak of such low intensity excited final state satellites might not be discernible. For the other specimens with the same linewidth constraint, the minor component was at a binding energy 1.85 ± 0.05 eV higher than that for the principal component, nevertheless a binding energy of 934.35 eV is still higher than values nor-

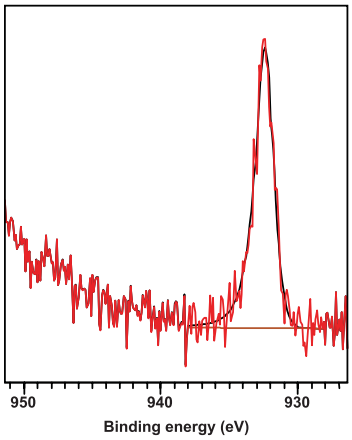
Fig. 8. Cu $2p_{3/2}$ spectrum from a cubanite fracture surface determined at a photon energy of 1025 eV and fitted with a single asymmetric peak.

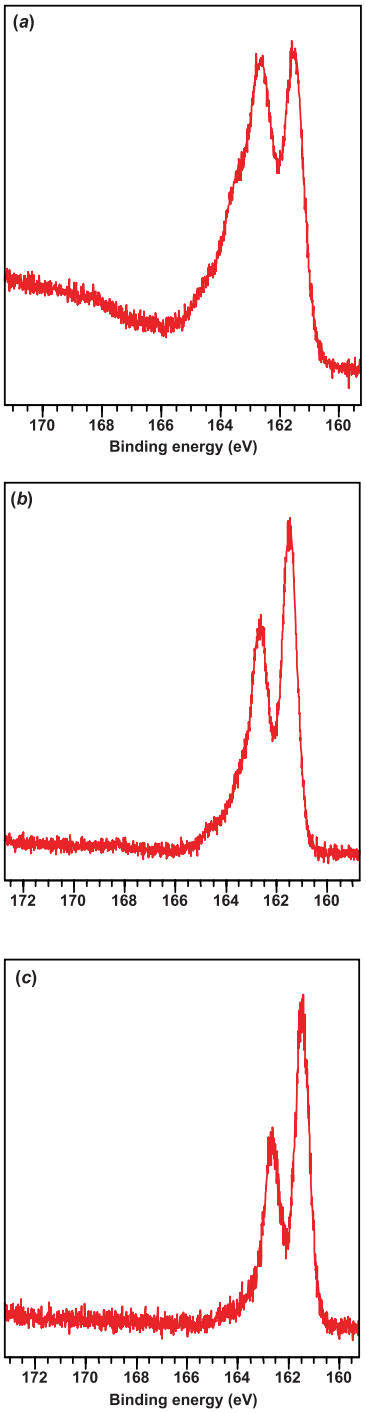


mally observed for Cu(I) species. The intensity of the fitted high binding energy Cu $2p_{3/2}$ component, constrained to have a linewidth no more than 10% greater than that of the principal component, was found to correlate poorly both with the intensity of the principal Cu $2p_{3/2}$ component and with the Cu 3d/S 2p intensity ratio determined at a photon energy of 210 eV.

When the width of the second component was constrained to be no greater than three times the width of the principal component, the best-fit parameters for the second component, which included a significantly lower shift and a higher intensity, suggested that the fit might have been specious. Kartio et al. (45) reported that they required a minor component (intensity ~8%) shifted 1.4 eV to higher binding energy from the principal component and of only slightly greater linewidth to fit the Cu $2p_{3/2}$ peak in their conventional XPS data for Cu activation of sphalerite for 1 h at pH 9. The lower intensity of the higher binding energy component observed by Kartio et al. could be explained by the different pH or by the lower surface sensitivity of the Cu 2p spectrum determined at 1487 eV compared with 1100 eV in the present work.

The Cu 2p spectrum in Fig. 7 resembles the corresponding spectrum from a fracture surface prepared under UHV of some Cu sulfide minerals such as cubanite or covellite determined at similar monochromator and analyser resolution. The Cu $2p_{3/2}$ peak for cubanite ($CuFe_2S_3$) is shown in Fig. 8 fitted with one asymmetric component of shape A(0.3,0.25,0)SGL(20). The Cu $L_{2,3}$-edge NEXAFS spectrum corresponding to the Cu 2p spectrum in Fig. 8 confirmed the expected absence of Cu(II). These observations raise the possibility that the shape of the Cu $2p_{3/2}$ peak from Cu-treated sphalerite arises from a physical effect rather than from the presence of high binding energy Cu environments, such as those in surface species, or with formal oxidation state Cu(II). In this regard it is important to recall that a surface sensitive Cu $2p_{3/2}$ spectrum from tetrahedrite displayed no such high binding energy component, and the corresponding surface optimized S 2p spectrum revealed no discernible low binding energy surface species. If the Cu $2p_{3/2}$ lineshape were to be the result of a physical effect such as a

Fig. 9. Fit to the Cu $2p_{3/2}$ peak in Fig. 7 with a single asymmetric component.



high electron density at the Fermi level, then the Cu $2p_{3/2}$ peak should be able to be fitted with a single asymmetric component. Such a fit is possible, and with the asymmetric lineshapes tried the fits were comparable with, but not better than, those with a higher binding energy component of unconstrained width. An example of a fit with a single asymmetric component of shape A(0.3,0.35,0)GL(50) is shown in Fig. 9. As noted earlier, however, a high electron density at the Fermi level for Cu atoms was not obvious from the shape of the leading edge of the valence band. In principle, surface species for a Cu-Zn-S layer formed by the incorporation of Cu might also be a possible explanation, but as discussed later, there was no evidence for any corresponding S 2p surface species. Another possible reason for the lineshape is a distribution of electronic environments that varies with depth, but this should not be applicable for cubanite or covellite surfaces prepared by fracture under UHV. No definitive explanation for the Cu $2p_{3/2}$ peak shape for the Cu-treated sphalerite can be offered at this stage.

The S 2p spectra for treated surfaces determined at a photon energy of 210 eV (Fig. 10*a*) can be fitted adequately with 3 doublets in the sulfide region (Fig. 11 and Table 2) and the presence of a low concentration of S-O species appeared to be evident from a broad peak near 168.3 eV in the spectrum for the surface treated with Cu^{2+} for 1 min at pH 5. The principal sulfide $2p_{3/2}$ peak was at 161.6 eV. There was no evidence for a S 2p component at a binding energy significantly lower than that for the principal substrate doublet and that might have arisen from identifiable surface species. The reliability of the fitted components was assessed by using different background and line shapes in fitting the same spectrum and by comparing data for spectra obtained at 210 eV near the start and near the end of the accumulation period for all photoelectron and NEXAFS spectra from each specimen (see Table 2 for representative examples). It was found that binding energy shifts and intensities for the fitted components were reproducible to within ±0.1 eV and ±10%, respectively, with significantly higher reproducibility usually observed for fits to the same spectrum on the same basis but starting with different initial parameter estimates. In particular, there was no major difference in the form of the spectra determined near the beginning and end of the specimen X-ray irradiation period, although the relative intensity of

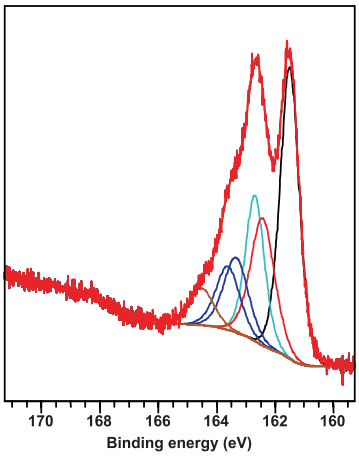

Fig. 10. S 2p spectrum from Santander sphalerite treated for 5 min with aq. Cu^{2+} at pH 2 determined at a photon energy of (*a*) 210 eV, (*b*) 400 eV, and (*c*) 800 eV.

peaks from some elements did change. For example, the S 2p intensity increased towards the end of the measurement period, most probably because of the loss of chemisorbed water from the surface.

As expected, the higher binding energy sulfide components were less obvious in the S 2p spectra obtained at 400 eV (Fig. 10*b*), as was the peak arising from the low concentration of S-O species for the surface treated for 1 min.

Fig. 11. S 2p spectrum in Fig. 1*0a* fitted with three doublet components.

The sulfide region of the 400 eV spectra could be fitted on essentially the same basis as the 210 eV spectra apart from a marginally (~0.1 eV) lower binding energy shift for the highest binding energy doublet. The higher binding energy sulfide components were even less evident in the S 2p spectra determined at 800 eV (Fig. 10*c*), and a peak arising from S-O species was not discernible, confirming that alteration to the sphalerite surface was limited to the outermost few atomic layers. The 800 eV S 2p spectra could be fitted on much the same basis as the 400 eV and 210 eV spectra (Table 2), apart from a further small decrease in the binding energy shift for the highest binding energy doublet.

As evident from Table 2, the S 2p spectra from fracture surfaces treated with Cu^{2+} for 1 and 5 min were broadly similar, although for the surface treated for 5 min at pH 2 there was slightly less higher binding energy sulfide intensity, and the background was flatter. A surface treated with Cu^{2+} for 5 min at pH 5 gave rise to a S 2p spectrum that displayed more high binding energy sulfide intensity than for 1 min interaction with Cu^{2+} solution, but the Cu/Zn ratio revealed by the Cu 3p/Zn 3p intensity ratio determined at a photon energy of 1010 eV was only ~0.3:1, and the Cu 3d/Zn 3d ratio was also lower. Therefore, the concentration of high binding energy sulfide evident in the S 2p spectrum does not appear to be directly related to the concentration of Cu relative to Zn in the surface layer. In the 210 eV S 2p spectrum for the specimen treated for 5 min at pH 5, the intensity of the 1.9 eV shifted component (32%) was greater than the unshifted (24%) with the intermediate about half the unshifted (Table 2). By contrast, for the surface treated for 1 min and for which the corresponding Cu/Zn ratio was 0.7:1, the 1.9 eV shifted S 2p component (14%) was relatively small compared with the unshifted (33%) and intermediate (20%). In particular, the intermediate binding energy sulfide intensity does not appear to be directly related to the Cu concentration, as it should be if a separate Cu oligosulfide phase were formed. It is possible that the concentration of high binding energy S is related to the degree of Zn deficiency which could arise after the initial Cu uptake.

The Cu $2p_{3/2}$ peak shapes near the baseline on the high binding energy side were similar for 1 and 5 min treatment

[a]Constrained to maximum value.
[b]Data estimated from figure.

Fig. 12. PEY Cu L_3-edge NEXAFS spectrum for (*a*, *b*) Santander sphalerite treated with aq. Cu^{2+} at pH 5 for 1 min (*a*) near the start, (*b*) towards the end of the measurement period, and (*c*) Cu metal.

with Cu^{2+}, and the intensity of any higher binding energy component was not obviously influenced by the Cu/Zn ratio in the outermost layers. These observations would be consistent with a physical explanation for the lineshape (such as a high Cu electron density at the Fermi level), but not with the presence of Cu(II) to compensate for loss of Zn. However, only the much greater sensitivity of Cu $L_{2,3}$-edge NEXAFS spectra towards Cu(II) can confirm or preclude the presence of very low concentrations of Cu(II).

Cu $L_{2,3}$-edge NEXAFS spectra were determined in PEY and TEY mode for each Cu-treated sphalerite fracture surface investigated. The slightly more surface sensitive PEY spectra were not significantly different from the corresponding TEY spectra. For the spectra determined soon after the beginning of the measurement period (and start of the irradiation by the X-ray beam), a peak at 930.7 eV, indisputably arising from Cu(II), dominated the spectrum (Fig. 12). A shoulder at ~931.7 eV was also evident, and as this absorption energy is slightly higher than the upper limit of 931.2 eV normally observed for Cu(II) (6, 7, 47, 48), the peak giving rise to the shoulder was probably part of a spectrum from Cu(I). The absorption edge, near 933.6 eV, of the main L_3 peak is consistent with the second part of a spectrum for Cu(I) but not with spectra observed for typical Cu(II) materials (49). Towards the end of the measurement period, the intensity of the Cu(II) peak at 930.7 eV was lower relative to the now resolved peak at 931.7 eV and the main absorption edge from Cu(I), indicating some photoreduction of Cu(II) to Cu(I) had occurred. The fact that the peak near 931.7 eV did not appear to exhibit photoreduction supports its assignment to Cu(I). The photoreduction behaviour was similar for surfaces treated with Cu^{2+} for 1 and 5 min, and there was no obvious dependence on the period between treatment and characterization that might have arisen from a slow conversion of Cu(II) to Cu(I) in the sulfide lattice.

Discussion

Tetrahedrite

Although Charnock et al. (2) cautioned that the delocalization of electrons in many sulfide structures means that assignment of formal oxidation states to the cations represents an over-simplification, they noted that quite different ^{57}Fe Mössbauer spectra were produced by different

© 2007 NRC Canada

tetrahedrite minerals. Also, Pattrick et al. (6) have established that tetrahedrites display different Cu $L_{2,3}$-edge NEXAFS spectra, therefore differences in formal oxidation states for Cu and Fe in the tetrahedrites are not merely semantic differences.

There have been very little XPS data published for tetrahedrite, and most of that information is for surfaces conditioned in alkaline solution. Most importantly for the present study, Mielczarski et al. (50) found that for a natural tetrahedrite immediately after treatment at pH 10, a significant concentration of Cu(II) hydroxide was present at the mineral surface, but Sb-O species were not evident. If the oxidation behaviour of the mineral were similar in air to aq. pH 10 solution, or even if Sb(V)-O as well as Cu(II)-O species were formed, then it would be possible for Cu(II) from surface oxidation of the specimen to be detected in PEY or TEY NEXAFS spectra. This might explain the observation of 2.9% Cu(II) in a finely divided natural tetrahedrite specimen of composition $Cu_{5.84}Ag_{4.22}Zn_{0.43}Fe_{1.59}Sb_{4.10}As_{0.13}S_{13}$ (i.e., with Cu + Ag only marginally greater than 10) by means of TEY NEXAFS spectroscopy (6). However, low-resolution Cu 2p spectra obtained (13) for both tetrahedrite and tennantite specimens, ground under nitrogen but transferred to the spectrometer in air, provided no evidence for the presence of Cu(II). Cu $2p_{3/2}$ and $Sb_{3/2}$ spectra reported (51) for tetrahedrite after 30 min grinding in a planetary mill in air indicated the presence of Cu(II) and Sb-O species at the altered surface, whereas before that treatment only Cu(I) (as well as some Sb-O species) had been evident.

XPS data available for the closely related mineral tennantite, $(Cu,Ag)_{10}(Fe,Zn)_2As_4S_{13}$, suggest a lower reactivity towards oxygen. The absence of Cu 2p excited final state satellites for a tennantite surface prepared by fracture in air, and minimal oxidation of such a surface after further exposure to air for 30 min, have been reported (52). Also, negligible Cu(II) species retained at the surface of tennantite conditioned at pH 10 or polarized in 0.1 mol/L HCl have been observed (50, 53). On the other hand, Cu $2p_{3/2}$ components within the binding energy range 933.9–936.2 eV attributed to Cu(II) were observed (54) at the surface of both natural and synthetic tennantite after it had been conditioned at pH 11.

It is perhaps surprising that no evidence for S 2p surface species was discernible for tetrahedrite. Sulfides of structure similar to sphalerite or wurtzite are expected to undergo considerable relaxation of surface atoms following fracture. For sphalerite, the relaxation involves movement of the outermost Zn and S atoms by up to 0.05 nm (55), and conventional XPS evidence for a S 2p surface state shifted by about –0.5 eV has been reported (30). The fitted S $2p_{3/2}$ linewidth was broader than for Cu sulfides of higher electrical conductivity (and for which charge compensation was not required), but any surface species must have had energies not markedly different from the bulk states, and (or) there was an equal concentration of states with energies higher and lower than the bulk states. A broad leading absorption peak observed in the S K-edge and L-edge NEXAFS spectra for minerals of composition $Cu_{11.06}Fe_{0.99}As_{0.18}Sb_{4.03}S_{13}$ and $Cu_{10.53}Fe_{0.94}As_{2.31}Sb_{1.78}S_{13}$ was attributed (56) to the presence of the 6-coordinate S and (or) the presence of minor Cu(II).

Cu-treated sphalerite

Taking into account the higher $L_{2,3}$ absorption cross-section for Cu(II) relative to Cu(I), and the fact that Cu(II) L_3-edge spectra, such as those for tenorite and azurite (49), usually consist largely of a single narrow peak, it is clear that most of the Cu at the surface of Cu-treated sphalerite was present as Cu(I), nevertheless some Cu(II) was undoubtedly also present. The question is, where was the Cu(II) located? Was it a low concentration of Cu(II) in the sphalerite lattice, or was it from one or more Cu(II)-O species present at the Cu-treated surface, or both? Although the O 1s spectra indicated that the O was probably present as chemisorbed water rather than a hydroxide, which probably would have been associated with Cu(II), the Cu(II) intensity appeared to correlate with the O 1s intensity. This suggests that the outermost layer of Cu may have been between the surface of the sulfide lattice and chemisorbed water. Such an arrangement would be consistent with the REFLEXAFS data of Pattrick et al. (18), who concluded that Cu at the surface of sphalerite was bonded to both S and O atoms. It is also consistent with the ease of removal of the Cu(II); the process may well be one of stimulated desorption of chemisorbed water rather than of simple photoreduction of Cu(II) to Cu(I). Loss of chemisorbed water from the surface would be consistent with the observed lowering of O 1s intensity during the course of the measurements. If this is indeed the case, then it effectively precludes any conclusion on whether a low concentration of Cu(II) can be present in the sulfide lattice.

Some apprehension has been expressed (57) about the accommodation of Cu(I) in the sphalerite lattice on the grounds of a larger ionic radius of Cu(I) compared with Zn(II) and a charge imbalance between Cu(I) and S(-II). Given that the Zn–S bond length (0.234 nm) in sphalerite is similar to tetrahedral Cu–S bond lengths (e.g., 0.234 nm in tetrahedrite, 0.232 nm in chalcopyrite), such that the tetrahedral covalent radii (the radii of relevance here) for Zn and Cu are considered to be 0.131 and 0.135 nm, respectively (58), size would not appear to constitute a problem. Furthermore, the covalent radii of Cu(I) and Fe(II) in tetrahedral S sites are similar, with relevant Fe–S bond lengths of ~0.231 nm (2), and Fe is accommodated easily within the sphalerite lattice therefore Cu(I) should also be easily accommodated. Moreover, there should be no requirement for the actual charge on the S atoms in the sulfide lattice to remain the same after replacement of Zn by Cu.

The remaining question is whether the Cu(I) that was present near the sphalerite surface was in a sphalerite S lattice essentially unchanged apart from the substitution of some Zn by Cu (and a concomitant decrease in the electron density on the S atoms around those Cu atoms) in a sphalerite S lattice containing some Zn vacancies as well as some Cu in Zn sites, or only in a phase restructured to a CuS-like phase (that could be subsequently oxidized to a Cu oligosulfide) similar to that proposed by Kartio et al. (45).

Although the Cu L-edge peak at 931.7 eV attributed to Cu(I) is at an energy slightly lower than the lower limit of

© 2007 NRC Canada

931.9 eV usually associated with Cu(I) and approaching the upper limit of 931.2 eV normally associated with Cu(II), the leading absorption peak energy for Cu(I) in tetrahedral coordination by S is not always as high as the edge peak energy observed for tetrahedrite (934.5 eV) where no "pre-edge" peak is observed. Low energy pre-edge peaks are observed for chalcopyrite (932.6 eV) and bornite (932.7 eV), therefore an even lower energy (931.7 eV) of the pre-edge peak for treated sphalerite is not by itself sufficient reason to rule out Cu in 4-fold coordination by S, but it does indicate a significant difference in electronic environment. In particular, a d^9 character for the Cu atoms larger than normally observed for Cu(I) but not as large as that normally observed for Cu(II) is indicated.

The interaction of aq. Cu^{2+} ions with the surface of sphalerite has been extensively investigated by means of bulk and surface techniques and the findings reviewed by Finkelstein (42). Three of those findings are highly relevant for interaction under weakly acidic conditions. First, the number of Cu^{2+} ions removed from solution by the mineral is the same, within experimental error, as the number of Zn^{2+} ions released to the solution (e.g., 59, 60). Accordingly, at least during the initial stage of the Cu^{2+} treatment and before any restructuring of the sphalerite surface layer to a Cu sulfide phase might occur, the ion exchange reaction [1] forming a metastable surface phase should be applicable (21),

$$[1] \qquad xCu^{2+} + ZnS \rightarrow xZn^{2+} + Zn_{1-x}Cu_xS$$

Second, Cu 2p photoelectron spectra and X-ray excited Cu $L_3M_{4,5}M_{4,5}$ Auger electron spectra determined by conventional XPS have been consistent with the presence of only Cu(I) in the sulfide lattice; no Cu(II) has been discernible (e.g., 21, 45, 46). However, it should be noted that in some nonsulfide systems, small concentrations of Cu(II) have been detected directly by Cu L_3-edge NEXAFS spectra and indirectly by ToF-SIMS when the presence of Cu(II) was not evident in the Cu 2p or Cu $L_3M_{4,5}M_{4,5}$ spectra (20). The observation of some Cu(II) at the surface after treatment in alkaline solutions has normally been attributed to adsorbed Cu(II) hydroxy species. Third, at least one S 2p component at a binding energy at least 0.8 eV higher than that for sphalerite has been observed for the Cu^{2+}-treated mineral, suggesting a formal oxidation state less negative than (-II) for this component.

It should be noted that the metastable surface phase representation $Zn_{1-x}Cu_xS$ implies no particular formal oxidation state for the Cu, just as the chemical formulae CuS and CuS_2 do not. What is implied is a formal oxidation state for S more positive than -II if the Cu is present as Cu(I) and therefore the possible presence of a S 2p component at a binding energy higher than that for sphalerite. It should also be emphasised that a formal oxidation state of S(–II) does not mean an *actual* charge of S^{-2}. Pauling (58) even considered that the actual charge on the S atoms in some metal sulfides might be positive.

The observation of at least one S $2p_{3/2}$ binding energy higher than that for sphalerite has usually been explained by the formation of a CuS-like phase (e.g., 45),

$$[2] \qquad Zn_{1-x}Cu_xS \rightarrow xCuS + (1-x)ZnS$$

As mentioned earlier, any CuS-like phase cannot be the same as covellite, as the Auger parameter is different, as is the high binding energy side of the Cu $2p_{3/2}$ peak. Alternatively, and notwithstanding the fact that the S 2p spectrum provides no evidence for the production of elemental sulfur, a Cu_2S-like phase plus elemental S has been proposed (e.g., 61),

$$[3] \qquad Zn_{1-x}Cu_xS \rightarrow 0.5xCu_2S + 0.5xS^0 + (1-x)ZnS$$

Kartio et al. (45) first resolved the high binding energy S 2p component into two components by determining spectra at 209 eV from Santander sphalerite surfaces wet-polished in air and treated with Cu^{2+} solution at pH 9.2 either in air or under nitrogen. They found that for the nitrogen-purged Cu^{2+} solution the surface Cu concentration relative to Zn and S was greater than for treatment in air, and that the component at +1.8 eV was less intense, but the +0.8 eV component was of comparable intensity, relative to the underlying sphalerite component. They proposed that the S 2p component at a binding energy ~0.8 eV higher than for sphalerite arose from the CuS-like activation product, and the component ~1.8 eV higher arose from oligosulfide. They correctly noted that the formation of a Cu oligosulfide phase requires oxidation following the Cu incorporation and cannot be the result of Cu incorporation alone. However, in an apparent contradiction of that understanding they suggested that the S^0 in eq. [3] could actually be part of a polysulfide chain.

Even if oligosulfide-like electronic environments were established within a modified sphalerite lattice rather than a restructured phase, loss of Zn that was not replaced by Cu would be involved, and that leaching would constitute an oxidation process,

$$[4] \qquad Zn_{1-x}Cu_xS \rightarrow Zn_{1-x-y}Cu_xS + yZn^{2+} + 2ye^-$$

It is expected that the oxidant associated with eq. [4] would be residual oxygen. If such a loss of Zn occurred in the cupric solution, it would not be in agreement with previous observations of the Cu uptake being the same as the Zn release, but if the additional Zn loss was only from the outermost few atomic layers, then it might not be detectable by measuring solution concentrations. It is also possible that Zn loss might occur when a treated sphalerite surface is washed with water after removal from the cupric solution.

If the S 2p component shifted by ~0.8 eV were to arise from a CuS-like Cu-activation product, then its intensity might be expected to be proportional to the concentration of Cu. Indeed, even if a Cu oligosulfide were the Cu-activation product, the component shifted by ~0.8 eV should correlate with the Cu concentration, as that binding energy would be expected to correspond to S atoms nearest the Cu atom of a Cu oligosulfide complex (62). A poor correlation was observed in the present study. The poor correlation could be explained by loss of Zn from the Cu-activated surface that is not replaced by Cu as in eq. [4]. Oligosulfide-like electronic environments could be associated with Zn or Cu atoms (i.e., could be considered part of a Zn or Cu oligosulfide) and could be created by Zn vacancies in a largely unrestructured sulfide lattice. This possibility would be more consistent with a surface layer sufficiently conducting to not need a

© 2007 NRC Canada

flood gun; a "molecular" Cu oligosulfide was found to charge even in conventional XPS (62).

Gerson et al. (57) proposed a model for a Cu-activated sphalerite surface that did not involve the formation of oligosulfide either in a reconstructed phase or in a largely unreconstructed S lattice containing vacancies. They postulated that the Cu atoms would have a distorted trigonal planar geometry (coordinated to 3 S atoms) in both surface and bulk sites where the S would have an "oxidation state" of approximately –1.5 in the former case and –0.5 in the latter, and thereby give rise to the two high binding energy S 2p components observed. However, although an interesting suggestion, their model is inconsistent with the similar binding energies observed for the S atoms associated with the trigonal planar and tetrahedral Cu sites in tetrahedrite, or with the poor correlation between the concentration of high binding energy S environments and the concentration of Cu in the treated sphalerite surface. On the available evidence, loss of some metal atoms from a sphalerite surface that are not replaced by Cu (i.e., oxidation of a Cu-treated surface) is the only plausible explanation for a S-enriched surface that could have oligosulfide-like electronic environments. It has yet to be established whether CuS-like "disulfide" environments can be produced *without* the concomitant formation of oligosulfide-like environments. A more definitive identification of the nature of the Cu-treated sphalerite surface and the mechanism by which it becomes S-rich should result from the research currently in progress by Harmer et al. on the treatment of Fe-containing sphalerites by aq. Cu^{2+}.

Conclusions

The Cu $L_{2,3}$-edge and Cu 2p spectra for a natural tetrahedrite surface prepared by fracture under UHV indicated that all Cu in the mineral was indisputably Cu(I), with no Cu(II) present for "charge neutrality". This was notwithstanding the fact that the mineral characterized had a significant excess of univalent metal atoms and a comparable deficiency in divalent metal atoms. The XPS data provided no evidence for different S or Cu core electron binding energies in tetrahedrite. In particular, the 2p binding energy for the 6-coordinate S atoms was found to be not detectably greater than that for the 4-coordinate S atoms, and there was no measurable difference in the 2p binding energies for the Cu atoms in trigonal planar and tetrahedral sites.

The Cu $L_{2,3}$-edge spectra of relatively pure natural sphalerite treated with mildly acidic aqueous cupric solution revealed the presence of Cu(II) that was consistent with Cu bonded both to S atoms in the outermost layer of the sphalerite and to O atoms in chemisorbed water. Most of the Cu near the surface of the mineral was in formal oxidation state Cu(I), albeit with higher than normal d^9 character. Surface-optimized S 2p spectra revealed high binding energy components from the outermost layers that were consistent with oligosulfide-like environments, but not necessarily in a completely restructured lattice and not in a Cu oligosulfide only. The presence of these oligosulfide-like environments precluded the detection of S with formal oxidation state greater than (-II) that might have arisen only from Cu(I) in the S lattice. The data were consistent with some loss of Zn in addition to the Zn that had been replaced by Cu in the outermost layers of the sulfide lattice. No evidence was obtained for the presence of Cu(II) in a sulfide lattice, but it was not possible to exclude the possibility of a very low concentration because of the presence of the Cu(II) bonded to both S and O at the surface of the treated sphalerite. Accordingly, no support was obtained for the proposition, nor irrefutable evidence for its indictment that Cu(II) can be required for charge neutrality in a sulfide lattice.

Acknowledgements

Access to synchrotron beam time was made possible by support from the Australian Synchrotron Research Program, which is funded by the Commonwealth of Australia under the Major National Research Facilities Program. Use of the Taiwan Light Source, assistance by personnel at the National Synchrotron Radiation Research Center in Hsinchu, electron microprobe analyses by Daniel Yoo-Hyun Sung, and helpful discussions with David French and Angus Netting are gratefully acknowledged.

High resolution O 1s XPS spectral, NMR, and thermodynamic evidence bearing on anionic silicate moieties (units) in $PbO-SiO_2$ and Na_2O-SiO_2 glasses[1]

H.W. Nesbitt and K.N. Dalby

Abstract: Recent technical advances in X-ray photoelectron spectroscopy (XPS) have largely overcome differential charging of insulator surfaces, with the result that O 1s linewidths for silicates can be routinely collected that are 50% to 100% narrower than had been previously obtainable. The bridging and nonbridging oxygen signals of glasses are well resolved and now can be accurately measured by XPS without resorting to ad hoc fitting procedures. All O 1s spectra of silicates collected so far are somewhat asymmetric to the high binding energy side of the peak, a characteristic due primarily to vibrational contributions in the ion state produced by photoemission (electronic excited state). This asymmetry must be considered if the proportion of bridging to nonbridging oxygen ratios are to be accurately determined from the XPS O 1s spectra of silicates. X-ray photoelectron spectroscopy (XPS) and nuclear magnetic resonance (NMR) experiments yield similar silicon-bridging oxygen (Si-**O**-Si) concentrations for $PbO-SiO_2$ glasses. The data are proof that the reaction, $2PbO + SiO_2 \Rightarrow Pb_2SiO_4$, does not go to completion (i.e., one or other reactant is not completely consumed). Instead, the data indicate that an equilibrium exists among these constituents, with the equilibrium constant for the reaction being near 15; ergo, some metal bridging oxygen (MBO or Pb-**O**-Pb), silicon bridging oxygen (BO or Si-**O**-Si), and nonbridging oxygen (NBO or M-**O**-Si) are present over the entire range of binary melt compositions. NMR and XPS spectroscopic techniques yield substantially different Si-**O**-Si concentrations in Na_2O-SiO_2 glasses of intermediate to high Na_2O content. XPS experiments indicate higher proportions of Si-**O**-Si in Na_2O-rich glasses than do the NMR studies. In spite of the different results, three independently collected sets of NMR experiments are similar and yield similar Si-**O**-Si concentrations. Five XPS experimental studies are likewise self-consistent (but different from the NMR studies). Comparison of data from the two spectroscopic techniques indicates that all experimental spectra are of good or reasonable quality, so that systematic experimental problems or the interpretation (i.e., fitting) of these spectra may be incorrect for one or both types of spectral data. Viscosity, conductivity, and the XPS data are consistent with (but not proof for) formation of an $Na_2Si_2O_5$ species in the Na_2O-SiO_2 glasses. The most comprehensive NMR study is, by contrast, consistent with the formation of an orthosilicate species (Na_4SiO_4). The NMR and XPS results cannot yet be reconciled and additional experimental studies are required to resolve and to understand better Na_2O-SiO_2 liquids and glasses.

Key words: XPS, high resolution, silicate glass, NMR.

Résumé : Les progrès techniques récents dans le domaine de la spectroscopie photoélectronique aux rayons X (SPX) ont permis d'éliminer des différences dans les charges des surfaces des isolants et il en résulte que des largeurs de raies 1s de l'oxygène de quelques silicates de 50% à 100% plus fines que celles obtenues antérieurement peuvent maintenant être recueillies d'une façon routinière pour les silicates. Les signaux des atomes d'oxygène qui servent ou qui ne servent pas de pont dans les verres sont maintenant bien résolus et il est alors possible de mesurer d'une façon précise les SPX sans avoir à utiliser des méthodes ad hoc d'ajustements. Tous les spectres 1s des atomes d'oxygène des silicates qui ont été recueillis jusqu'à maintenant sont quelque peu asymétriques et déplacés vers la partie de haute énergie de liaison du pic, une caractéristique qui est principalement due à des contributions de vibration dans l'état ionique produit lors de la photoémission (état électronique excité). On doit considérer cette émission si on veut déterminer avec précision la proportion des rapports des signaux des atomes d'oxygène qui servent ou qui ne servent pas de pont dans les verres à partir des spectres SPX 1s des atomes d'oxygènes des silicates. Des expériences de spectroscopie photoélectronique des rayons X (SPX) et de résonance magnétique nucléaire (RMN) ont permis de déterminer des concentrations similaires d'atomes d'oxygène servant de pont pour le silicium (Si-**O**-Si) de verres du

type PbO-SiO_2. Les données sont une preuve que la réaction 2Pbo + $SiO_2 \Rightarrow Pb_2SiO_4$ n'est pas complète (c'est-à-dire qu'un ou l'autre des réactifs n'est pas complètement utilizé). Les données montrent plutôt qu'il existe un équilibre entre ces constituants, avec une constante d'équilibre de pratiquement 15; en conséquence, sur l'ensemble des combinaisons binaires du produit fondu, on retrouve diverses entités impliquant, entre autre, des atomes d'oxygène liant des métaux (du type Pb-**O**-Pb), des atomes d'oxygène liant des atomes de silicium (du type Si-**O**-Si) et des atomes d'oxygène non liants (du type M-**O**-Si). Les techniques de RMN et de SPX conduisent à des concentrations substantiellement différentes de Si-**O**-Si dans les verres de Na_2O-SiO_2 contenant des quantités allant d'intermédiaires à élevées de Na_2O. Par comparaison avec les résultats obtenus par RMN, les expériences de SPX donnent des proportions supérieures de Si-**O**-Si dans les verres riches en Na_2O. Malgré les différences dans ces résultats, trois expériences indépendantes de RMN ont conduit à des ensembles de données similaires et ont conduit à des concentrations en Si-**O**-Si semblables. De la même manière, cinq expériences de SPX sont autocohérentes, mais différentes des études par RMN. Une comparaison des données obtenues par les deux techniques spectroscopiques indique que tous les spectres expérimentaux sont de qualité qui varie de bonne à raisonnable et qu'on doit en conclure que des problèmes expérimentaux systématiques ou des problèmes d'interprétation (telle l'ajustement) de ces spectres pourraient se présenter pour un ou chacun de ces types de données spectrales. La viscosité, la conductivité et les données de SPX sont en accord le fait, mais n'en sont pas une preuve, que dans les verres Na_2O-SiO_2 il y a formation d'une espèce $Na_2Si_2O_5$. L'étude RMN plus approfondie est, par ailleurs, en accord avec la formation d'une espèce orthosilicate (Na_4SiO_4). Les résultats de la RMN ou des SPX ne peuvent pas encore être réconciliés et des études expérimentales additionnelles s'imposent pour résoudre et comprendre mieux les liquides et les verres Na_2O-SiO_2.

Mots-clés : SPX, haute résolution, verre de silicate, RMN.

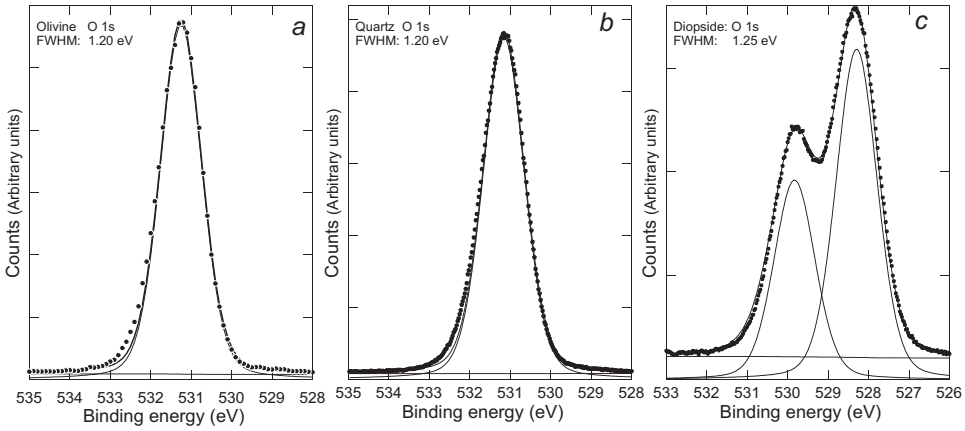
Introduction



It is a pleasure to contribute to a volume honouring Mike Bancroft's diverse contributions to the understanding of synthetic and natural compounds. His interests in insulators, and silicates particularly, derived from an early and productive encounter with Roger Burns, a postdoctoral fellow at Cambridge University. Mike's interest in natural materials, his enthusiasm and prodding, convinced the senior author to apply X-ray photoelectron spectroscopy to natural semiconductors and insulators in the late 1980s. Although Mike's early forays into XPS studies of insulators were frustrated by poor resolution resulting from surface charging, this interest was re-ignited with the advent of the magnetic confinement charge compensation system of the Kratos Ultra Axis instrument, first produced in the 1990s. With the acquisition of the instrument at *The* University *of* Western Ontario, Mike has been integral to our investigations into the spectroscopic properties of silicates. Here we report some recent findings. His experience of, insight into, and enthusiasm for XPS studies of gaseous and solid materials has had a major impact on the direction of our small group.

The bulk properties of silicate glasses and melts have been studied quantitatively since the early 1950s (1). The thermodynamic properties of silicate glasses have also been evaluated from many perspectives, yet only the last 20 years has seen the application of numerous spectroscopic techniques to silicate liquids and glasses, including Raman, IR, X-ray photoelectron spectroscopy (XPS), and nuclear magnetic resonance spectroscopy (NMR; 2–9). The vibrational spectroscopies (Raman and IR) yield broad signals requiring sophisticated fitting procedures to evaluate the various contributions to the spectra (e.g., 7). The XPS data provide a direct measure of the fraction of bridging oxygen (Si-**O**-Si) relative to total oxygen in liquids and glasses (8), and with appropriate care NMR (^{29}Si and ^{17}O) also provides the proportions of Si-**O**-Si and nonbridging oxygen (M-**O**-Si where M is a metal ion) in silicate liquids and glasses (e.g., 9). The evaluation of bridging and nonbridging abundances in glasses has, however, been hampered by broad O 1s linewidths. The breadth of these lines results either from the charging of surfaces or from the use of nonmonochromatic photon sources, which yield broad peaks. Recent advances in charge compensation incorporated into the Kratos Ultra Axis instrument have overcome charging problems, allowing the use of a monochromated Al Kα source. These advances have resulted in O 1s linewidths some 50% to 100% narrower than has been previously obtainable. The properties of the narrower O 1s spectra of silicates are evaluated here and are found to be asymmetric. The insight gained is used to interpret and accurately quantify measurements in PbO-SiO2 glasses and to interpret better the XPS results from previous studies. Here we compare XPS and NMR data from PbO-SiO_2 and Na_2O-SiO_2 glasses using a measure common to both techniques, the fraction of bridging oxygen (Si-**O**-Si) in silicate glasses. This measure is adopted because the fraction of Si-**O**-Si may be unambiguously evaluated over a wide range of compositions solely from the data collected by each technique.

Electrical conductivity measurements of alkali-, alkaline earth-, and Pb-silicate melts indicate 100% Faradaic yield (1). In the SiO_2-rich portion of these binary melts, conductance is unipolar with the cation transporting all charge, whereas in the metal oxide-rich portion O^{2-} may also contribute to charge transport (1*d*). Viscosity studies corroborate these findings (1*a*, 1*b*). An important conclusion drawn from these and more recent studies is that silicate melts (and glasses) are ionic and must be treated as ionic solutions (e.g., ref. 2). A second conclusion is that the anions of the melt or glass, which are composed of SiO_4 tetrahedra, are effectively immobile, and hence do not contribute to transport of charge; these anionic species, although charged negatively, are apparently too large to be appreciably mobile in melts or glasses. The investigations of Bockris et al. (1*a*–1*c*)

Fig. 1. (*a*) Illustrates the XPS O 1s XPS spectrum of olivine ($[Mg,Fe]_2SiO_4$); (*b*) illustrates the XPS XPS O 1s spectrum of alpha-quartz (SiO_2); (*c*) illustrates the XPS O 1s spectrum of pyroxene ($[Ca,Mg]_2Si_2O_6$). XPS data for (*a*) and (*b*) are from Zakaznova-Herzog et al. (15) and the spectrum for (*c*) is modified after Zakaznova-Herzog et al. (14). The spectra are fitted with a Shirley background (11) and a (80:20 Gaussian-Lorentzian) Voigt line shape (12). Dots represent experimental data, curve mimicing the data is the fit, and the symmetric curves are the peaks used in the fit. Binding Energies have not been corrected to a standard (typically C 1s) value.

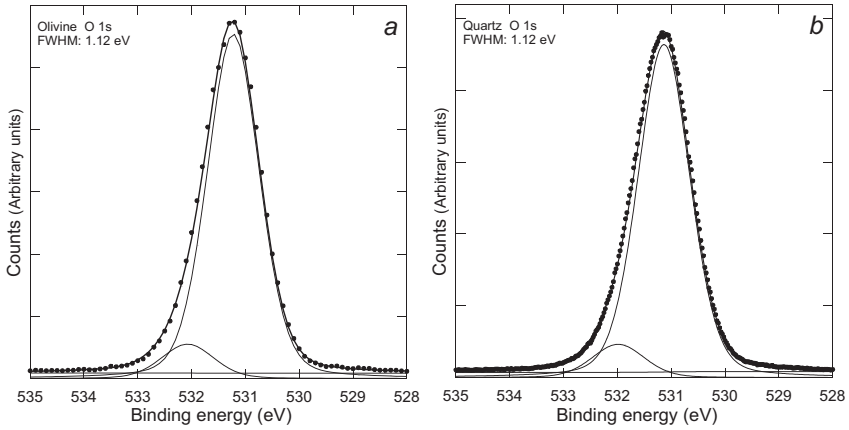
proposed that trimeric or tetrameric rings were the basic structures from which these largely immobile anionic species are constructed. The structural aspects of silicate liquids and glasses at the molecular level remain a major source of scientific interest and controversy. Throughout this communication the term "moiety" is used to represent a molecular unit or cluster in a glass or melt. The compositions of the moieties or units are stipulated as required for thermodynamic speciation calculations, but there is no implication of structure with regard to the moiety or the glass (melt).

Thermodynamic arguments have been constructed indicating that silicate-rich liquids are composed of discrete silicate anionic moieties, with their molar mass being dependent primarily on the number of SiO_4 tetrahedra in each moiety (3). Gotz and Masson (4) extracted four discrete anionic silicate species from PbO-SiO_2 glass (at the orthosilicate composition), and although the extraction technique (trimethylsilylation coupled with chromatography) is not quantitative, the study provides strong evidence for a suite of silicate species in silicate liquids and glasses. These efforts culminated in the application of polymer theory to metal oxide silicate liquids (5). The applicability of polymer theory was, however, questioned because silica tetrahedra tend to form networks rather than chains, and new thermodynamic approaches were developed to emphasize the ionic nature of silicate liquids and glasses and speciation within these liquids (6).

XPS O 1s signals of silicates

Linewidths and peak shapes

Previous O 1s and Si 2p XPS studies of insulating silicates have produced linewidths ranging from about 1.5 to 2.5 eV, as apparent from XPS studies cited herein. The lines are sufficiently broad that bridging and nonbridging oxygen signals are sometimes overlapped entirely or one is present as an indistinct shoulder on the other broad peak. The amount and accuracy of chemical state information gleaned from such spectra is consequently limited. Recent advances incorporated into the Kratos Ultra Axis XPS instrument has largely overcome differential charging, resulting in much narrower lines (10). The spectra of Fig. 1 are sufficiently narrow to identify asymmetry on the high binding side of these peaks. With the recognition of asymmetry, appropriate procedures for fitting O 1s spectra are evaluated so that accurate proportions of bridging and nonbridging oxygen abundances can be accurately evaluated, as now discussed.



Nesbitt et al. (10) demonstrated that the Si 2p linewidth of crystalline silicates (olivine and quartz) is determined by final state vibrational contributions so that neither inherent nor minimal instrumental linewidths can be achieved for Si 2p lines. The interpretation is consistent with the Si 2p linewidths for the gas phase analogue, tetramethoxysilane ($Si[OCH_3]_4$), where the vibrational contributions have been identified, yet the total Si 2p linewidth is 1.10 eV (10, 13). Nesbitt et al. (10) and Zakaznova-Herzog et al. (14) collected O 1s spectra for a number of crystalline silicates (Fig. 1) and obtained linewidths of about 1.2 eV. Like the Si 2p spectra, neither inherent nor instrumentally controlled O 1s linewidths could be approached and we propose that final state vibrational contributions control the widths of both Si 2p and O 1s lines in silicates.

Final state vibrational contributions also affect peak shape. Because photoemission causes a vertical (Frank–Condon) transition to an excited electronic state, affected peak shapes are controlled by the number of vibrational states accessed in the electronic excited state. The resulting suite of states accessed generally does not give rise to a symmetric spectral manifold because a greater number of high binding energy final states are more likely to be accessed than low binding energy states (e.g., 13). With the high resolution now achievable for insulating samples, the asymmetry of peaks is detectable.

The O 1s line shapes of olivine and quartz are somewhat asymmetric to the high binding energy side (Figs. 1*a*, 1*b*), and this may result from final state effects just as for Si 2p spectra. The asymmetry of the olivine (M_2SiO_4) and quartz (SiO_2) O 1s peaks were simulated by fitting a second peak to

© 2007 NRC Canada

Fig. 2. As for Fig. 1*a* and 1*b* except a second peak has been added to each spectrum to account for peak asymmetry. In both diagrams, the intensity, energy splitting and linewidth of the second peak are fixed by the properties of the respective main peak (see text for details).

the high binding energy side of each spectrum (Fig. 2) where (*i*) it has precisely the same FWHM as the lower energy major peak, (*ii*) it is located at 0.67 eV higher binding energy than the major peak maximum, and (*iii*) its intensity is 15.65% that of the major peak, thus demonstrating the extent of the asymmetry. The second peak is consequently entirely constrained by properties of the major peak. The good fit (Fig. 2) is an indication that the asymmetric characteristics are the same in both the quartz and olivine O 1s spectra and probably arise from the same process (i.e., effectively the same envelope of final state contributions). A more fundamental approach to fitting the O 1s spectra would be to identify the vibrational energy splittings and the properties of the potential energy curves of both ground and excited (electronic) states, so that an appropriate manifold of vibrational contributions could be calculated and used to fit the spectra.

O 1s signals in silicate minerals

Crystalline orthosilicates such as olivines (e.g., $[Mg,Fe]_2SiO_4$) consist of discrete SiO_4 tetrahedra with each apical oxygen bonded to a divalent cation (e.g., Mg; M-**O**-Si). These cations are octahedrally coordinated to six oxygen atoms of adjacent tetrahedra. The Mg–O bonds thus bind the individual tetrahedra and provide structural integrity to the mineral. There should consequently be only M-**O**-Si in olivines, and indeed high-resolution XPS spectra (10, 15) reveal only one type of oxygen (Fig. 1*a*).

Quartz (SiO_2) is composed solely of SiO_4 tetrahedra with each apical oxygen being a bridge to an adjacent tetrahedron (Si-**O**-Si bonding), producing a three-dimensional network. All oxygen atoms are of the Si-**O**-Si type, and as expected the high resolution XPS O 1s spectrum of quartz (Fig. 1*b*) demonstrates the presence of only one contribution (10).

Minerals of metasilicate composition (e.g., pyroxenes) are composed of infinite chains of tetrahedra where two of the four oxygen atoms of each tetrahedron are shared with an adjacent tetrahedra, and the remaining two oxygen atoms of each tetrahedron are typically bonded to alkaline earths or 3d metal cations (e.g., Mg, Ca, Fe); each tetrahedron consequently includes two bridging oxygen (Si-**O**-Si) and two nonbridging oxygen (M-**O**-Si) atoms. A high-resolution XPS O 1s spectrum of diopside ($CaMgSi_2O_6$) reveals two distinct peaks (Fig. 1*c*), the higher binding energy peak representing Si-**O**-Si and the lower energy peak M-**O**-Si. The Ca and Mg atoms have different coordination numbers, complicating the spectrum as explained by Zakaznova-Hertzog et al. (14).

O 1s signals in silicate glasses

The O 1s spectra of $PbO\text{-}SiO_2$ glasses (Fig. 3) display two distinct peaks, but as emphasized by Dalby et al. (8) these glasses include three types of oxygen, Si-**O**-Si (bridging oxygen), M-**O**-Si (nonbridging oxygen), and M-**O**-M (metal-bridging oxygen such as Na-**O**-Na or Pb-**O**-Pb). Dalby et al. (8) note that the lower binding energy peak is composite and includes the signal for the latter two types of oxygen (i.e., M-**O**-Si and M-**O**-M). The three types of oxygen may be found in binary liquids or glasses.

Mass balance considerations affecting oxygen species

Effect of compositional changes on types of oxygen

Viscosity and conductivity studies (1*a*–1*c*) and the NMR and XPS studies here surveyed indicate that the addition of metal oxide (MO, e.g., MgO, CaO, or PbO) to the SiO_2 liquid causes breakdown of the three-dimensional network through formation of M-**O**-Si according to

[1] $$1\text{M-}\mathbf{O}\text{-M} + 1\text{Si-}\mathbf{O}\text{-Si} \Rightarrow 2\text{M-}\mathbf{O}\text{-Si}$$

If reaction [1] proceeds to completion, then all oxygen would be as M-**O**-Si at the orthosilicate composition (e.g., M_2SiO_4); no Si-**O**-Si or M-**O**-M would be present at this composition. The olivine group of silicate minerals are orthosilicates and indeed all oxygen atoms are of the M-**O**-Si type. An alternative representation of reaction (1) is,

[2] $$2MO + SiO_2 \Rightarrow M_2SiO_4$$

One or both of the reactants of [2] are completely consumed if the reaction proceeds to completion. The abundances of M-**O**-Si, Si-**O**-Si, and M-**O**-M have been calculated assuming that the reaction goes to completion, and the results are plotted in Figs. 4*a* and 4*b*.

© 2007 NRC Canada

For monovalent metal oxides (e.g., Na_2O, K_2O), the concentration of M-**O**-Si may be calculated on the assumption that each metal atom produces one M-**O**-Si in silicate liquids and glasses. Reactions may be written that incorporate this constraint, an example being the formation of a disilicate moiety (i.e., $M_2O + 2SiO_2 \Rightarrow M_2Si_2O_5$). Where $M_2O = Na_2O$,

[3] $Na_2O + 2SiO_2 \Rightarrow Na_2Si_2O_5$

Reaction [3] is feasible in that the NMR study of Stebbins (9) noted that a glass of $Na_2Si_2O_5$ composition displayed a spectrum similar to its crystalline equivalent. Furthermore, Bockris et al. (1*a*–1*c*) and Bockris and Mellors (1*d*) propose an $Si_6O_{15}^{6-}$ anionic species in silicate liquids. All such double rings consist of two M-**O**-Si and three Si-**O**-Si per unit formula (i.e., $Na_6Si_6O_{15}$ or $Na_2Si_2O_5$). The proportions of Si-**O**-Si, Na-**O**-Si, and Na-**O**-Na in glass of the Na_2O-SiO_2 binary system have been calculated assuming that Rxn [3] goes to completion and the results are shown in Fig. 4*c*.

Experimental aspects of PbO-SiO_2 glasses

XPS O 1s studies

Dalby et al. (8)

The XPS O 1s spectra of four PbO-SiO_2 glasses range in composition from $X_{PbO} = 0.50$ to 0.667 and display two distinct contributions (Fig. 3). As for diopside (Fig. 1*c*), the high binding energy peak represents the Si-**O**-Si signal (8). The low binding energy peak may include an M-**O**-Si and an M-**O**-M contribution, where M = Pb, as argued by Dalby et al. (8). As evidence, Sorokina et al. (16) quote the O 1s binding energy of PbO (their Table 1) to be on the low binding energy side of the O 1s envelope of their PbO-SiO_2 glasses and a Pb-**O**-Pb signal is consequently expected to be associated with the low binding energy peak of O 1s spectra in PbO-SiO_2 glasses and to overlap with the M-**O**-Si contribution. The Si-**O**-Si contribution should be unaffected by the M-**O**-Si signal so that the fraction of oxygen present as Si-**O**-Si may be calculated whereas fractions of M-**O**-Si and M-**O**-M cannot.

The four spectra (Fig. 3) were fitted with all peaks having the same FWHM (1.25 eV). This constraint is different from that used by Dalby et al. (8) to demonstrate the insensitivity of the calculated fraction of Si-**O**-Si to different fitting constraints. The constraint used here yields Si-**O**-Si percentages of 20.2, 24.9, 36.5, and 41.1 whereas the constraints used by Dalby et al.(8) yielded 19.3, 26.0, 36.9, and 42.6. The resolution of the above referenced spectra is appreciably better than any O 1s spectra previously obtained and are consequently the most reliable so far obtained for PbO-SiO_2 glasses. The bridging oxygen fraction in the PbO-SiO_2 glasses derived from the Dalby et al. (8) data are plotted in Fig. 4.

Smets and Lommen (17)

These XPS O 1s spectra are of lower resolution than those collected by Dalby et al. (8). Smets and Lommen (17) assumed that there were two contributions to these spectra and without evidence assumed that the linewidths of the two contributions were equal. The latter assumption was confirmed by Dalby et al. (8). Their calculated fractions of Si-**O**-Si (Fig. 4*a*) are consistent with those of Dalby et al. (8). Smets and Lommen's (17) use of an achromatic rather than monochromatic source probably accounts for their obtaining reasonable peak shapes and peak areas for these insulating samples.

Gee et al. (18)

Gee et al. (18) collected XPS O 1s spectra using a monochromatized source with a flood gun to compensate for surface charging. Their calculated Si-**O**-Si fractions are plotted in Fig. 4*a*. Two results agree with the results of Smets and Lommen (17) and Dalby et al. (8; i.e., at $X_{PbO} = 0.5$ and 0.6) but the other data do not. The variability of the data may be related to ineffective charge compensation.

Sorokina et al. (16)

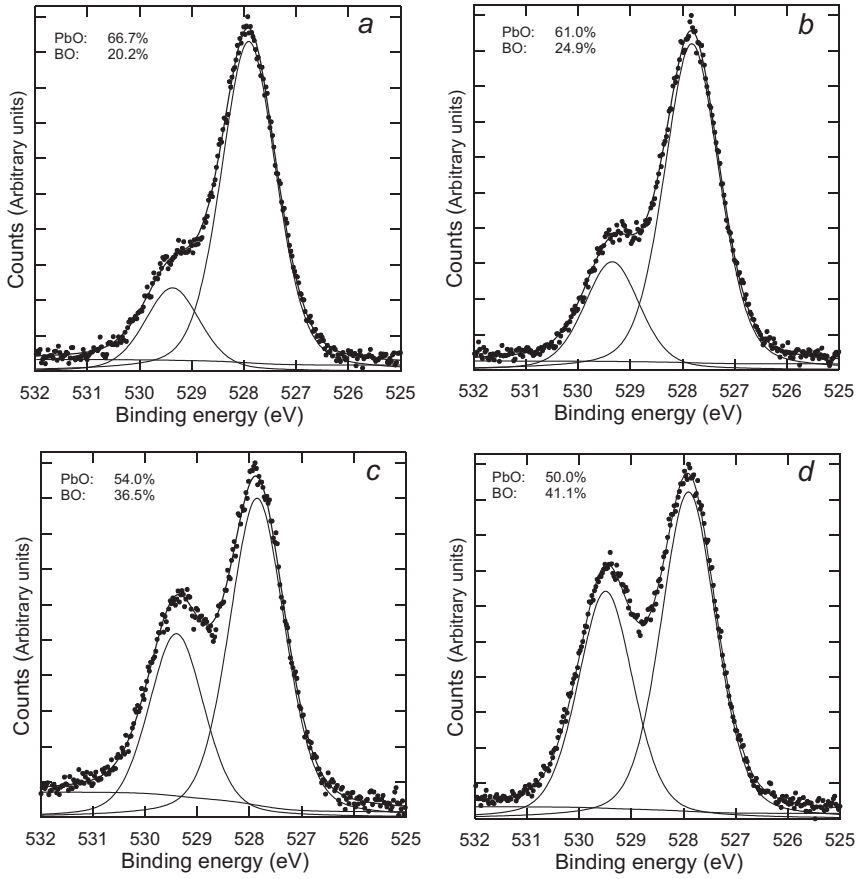
This study collected O 1s, Si 2p, and Pb 4f spectra from PbO-SiO_2 glasses. They illustrate fitted O 1s spectra, but there is ambiguity in the reporting of the calculated Si-**O**-Si fraction. As well, their data plot well above the other sets of data. They sputtered the surfaces and may have disrupted the surface. Dalby et al. (8), for example, observed very slow reduction of Pb to the metallic state in the near-surface promoted by the X-ray source.

Other XPS Studies

Wang and Zhang (19) collected the O 1s spectra from glasses ranging in composition from $X_{PbO} = 0.15$ to 0.70 and fitted their spectra with two peaks. The constraints on shape and width were not documented and the results are inconsistent with previously mentioned results. Shakhmin and Tyutikov (20) conducted an XPS study of PbO-SiO_2 glasses with a monochromated source and electron flood gun. Surfaces were exposed to the atmosphere prior to loading the samples into the spectrometer. The results are different from other results, perhaps because of contaminated surfaces or surface charging problems.

Summary of XPS O 1s spectral studies

The survey emphasizes the difficulty of obtaining consistent XPS O 1s results on insulators. The data of Dalby et al. (8) are the best resolved Si-**O**-Si signals of all studies reported and the lineshapes conform to the expected Gaussian–Lorentzian shape. These data are consequently taken as the most accurate of the XPS data. Smets and Lommen (17) assumed that the Si-**O**-Si and M-**O**-Si signals were of equal width when fitting their data, an assumption verified by the study of Dalby et al. (8). It is therefore not surprising that the two sets of data yield consistent results, and these are taken as the most reliable of the XPS data.



^{29}Si MAS-NMR studies

Fayon et al. (21)

The ^{29}Si MAS-NMR spectral studies report results from PbO-SiO_2 glasses ranging in composition from $X_{PbO} = 0.31$ to 0.73. From the reported distribution of Q species, the fraction of Si-**O**-Si were calculated and plotted in Fig. 4*b*. These data are consistent with the XPS results of Dalby et al. (8) and Smets and Lommen (17). The agreement between the NMR and XPS measurements provides confidence that the Si-**O**-Si content as a function of composition is known

© 2007 NRC Canada

Fig. 3. XPS O 1s spectra of PbO-SiO_2 glasses of compositions: (*a*) PbO:SiO_2 = 66.6:33.3; (*b*) PbO:SiO_2 = 61.0:39.0; (*c*)PbO:SiO_2 = 54.0:46.0; (*d*) PbO:SiO_2 = 50.0:50.0. All XPS data are from Dalby et al. (8) and all spectra were fitted with a Shirley background (34) and Voigt line shapes (35). The low binding energy peak represents NBO and the high binding energy peak BO in all diagrams. Peak widths are discussed in the text.

and that the deconvolution of NMR and XPS spectra is reasonable.

Shrikhande et al. (22)

The Q species distribution reported by this MAS-NMR study was used to calculate Si-**O**-Si concentrations (Fig. 4*b*). The calculated values for X_{PbO} = 0.50 and 0.60 conform to the data of Fayon et al. (21), the XPS data of Dalby et al. (8), and Smets and Lommen (17), but the high silica results (X_{PbO} = 0.125 and 0.25) plot appreciably lower than the trends established by the other studies. Apparently, the abundance of Q species high in Si-**O**-Si was underestimated during fitting of the high-silica glass spectra.

Takaishi et al. (23)

This study provides Q species distributions for three glasses rich in PbO (X_{PbO} = 0.50, 0.667, and 0.89). The Si-**O**-Si calculated for the two most siliceous compositions conforms to the other NMR data (Fig. 4*b*), but the sample richest in PbO is greatly divergent from the trend established by the other data.

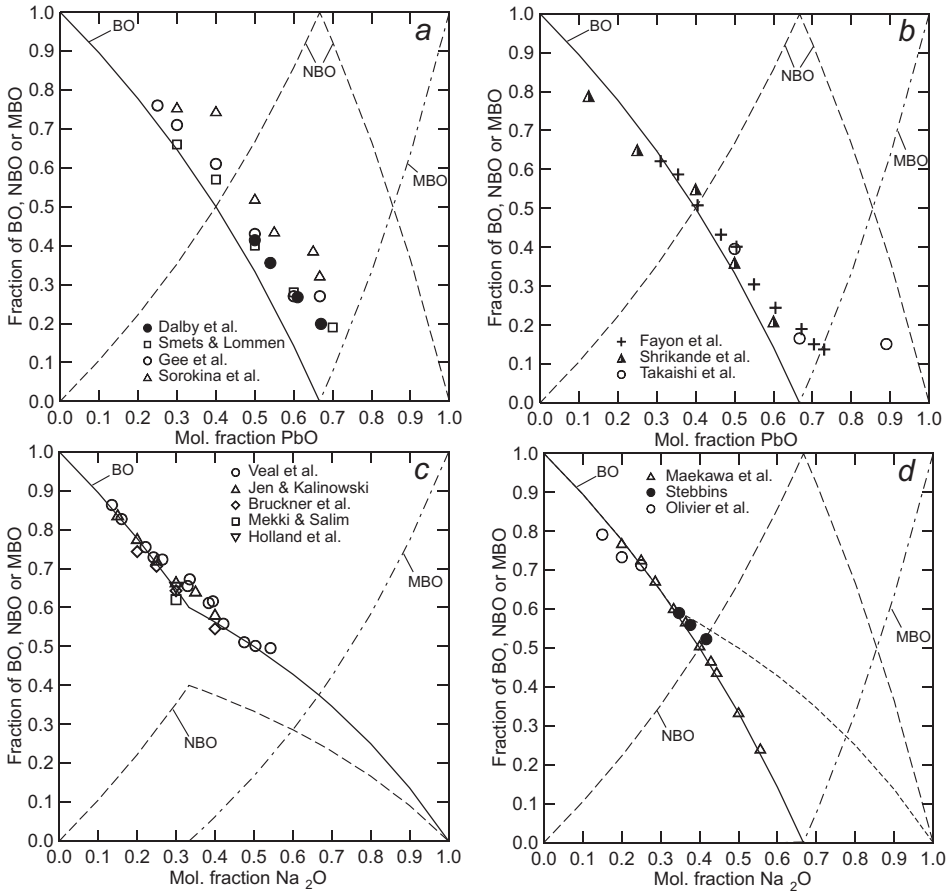
Summary of MAS-NMR spectral studies

The NMR data of Fayon et al. (21) are accepted as the most accurate NMR data available, in part because these and the XPS O 1s results are consistent. Nevertheless, there is a need to investigate ambiguities associated with both types of experiment to ensure that neither the NMR nor XPS technique has introduced systematic error related to the analytical technique or the fitting procedures.

Studies of Na_2O-SiO_2 glasses

XPS O 1s spectra

Veal et al. (24)



The O 1s spectra of a wide range of glasses are reported in graphical form. The fraction of Si-**O**-Si was calculated from their graphs and plotted in Fig. 4*c*. No information about instrumental equipment, conditions, or settings was provided. Veal et al. (24) noted that their data at high Na_2O content did not confirm the tenet that each Na atom produces a M-**O**-Si bond in the glass. As explanation, they offered that the Na-rich glasses may have become hydrated through absorption of water during preparation. Their sample preparation technique, however, should have removed any hydrated surface layer before analysis.

Jen and Kalinowski (25)

This study took precautions to ensure their glasses were not hydrated. They also used an achromatic source so that charging was minimized. As shown in Fig. 4*c*, their results

© 2007 NRC Canada

Fig 4. (*a*) Experimental XPS O 1s data for PbO-SiO_2 glasses. The curves for BO, NBO and MBO fractions are calculated assuming that the Pb_2SiO_4 moiety has formed in the glass and the reaction (Rxn 4) has gone to completion (see text for details). (*b*) Experimental NMR data for PbO-SiO_2 glasses. The BO, NBO and MBO curves calculated as in (4*a*). (*c*) Experimental XPS O 1s data for Na_2O-SiO_2 glasses. The curves for BO, NBO and MBO fractions are calculated assuming that a disilicate moiety ($Na_2Si_2O_5$) has formed in the glass and the reaction (Rxn 8) has gone to completion (see text for details). (*d*) Experimental NMR data for Na_2O-SiO_2 glasses. The curves for BO, NBO and MBO fractions are calculated assuming that an orthosilicate moiety (Na_2SiO_4) has formed in the glass and the reaction (Rxn 10) has gone to completion (see text for details). The short dashed curve is the BO content calculated assuming the disilicate reaction goes to completion (Rxn 8).

are consistent with those of Veal et al. (25). This careful study consequently demonstrates the reproducibility of the XPS results.

Bruckner et al. (26)

Bruckner et al. fractured their glasses in the vacuum of the XPS instrument ensuring that the surfaces analysed were not hydrated. They also used an achromatic source so that charging was minimized. The measured Si-**O**-Si contents (Fig. 4*c*) are consistent with the data of Veal et al. (26) and Jen and Kalinowski (25).

Other studies

Mekki and Salim (27) and Holland et al. (28) analysed the O 1s signal of Na_2O-SiO_2 glasses of the same composition (X_{Na2O} = 0.30) and obtained the same result (Fig. 4*c*). Mekki and Salim (27) used an achromatic source and their O 1s spectrum was reasonably resolved. Holland et al. (28) reported an identical abundance of Si-**O**-Si in glass of the same composition, but the quoted value may be that measured made by Mekki and Salim (27).

^{29}Si MAS-NMR spectra

Maekawa et al. (29)

Maekawa et al. conducted an ^{29}Si NMR study of Na_2O-SiO_2 glasses over the compositional range X_{Na2O} = 0.20 to 0.556. Calculated Si-**O**-Si fractions derived from reported Q species abundances conform to the XPS data at high silica contents (Fig. 4*d*), but plot below the XPS data at the low SiO_2 content (compare Figs. 4*c* and 4*d*).

Stebbins (9)

Stebbins reported NMR data for three compositions. He quotes the Si-**O**-Si fraction for the Q_4 species. Q_2 and Q_3 species abundances were here calculated from the Q_4 abundance and the equilibrium constants provided by Stebbins. The Si-**O**-Si fractions derived from the data of Stebbins (Fig. 4*d*) plot close to the NMR data of Maekawa et al. (29), but define a somewhat shallower trend. The data plot lower than the XPS data for similar compositions.

Olivier et al. (30)

Their NMR data provide Q-species distributions for three

© 2007 NRC Canada

highly siliceous glasses. The Q-species were used to calculate the fraction of Si-**O**-Si, and these are plotted on Fig. 4*d*. Two points plot below the trend defined by the Maekawa et al. (29) data, but the third does not.

Summary of NMR and XPS results

From the conformity of the five XPS experiments and three sets of NMR data, it is concluded that both types of experimental data are reproducible. There is, however, a serious disparity between the XPS and the NMR data in the compositional range between about X_{Na_2O} = 0.4 and 0.6, which must be explained.

Discussion

$PbO\text{-}SiO_2$ system

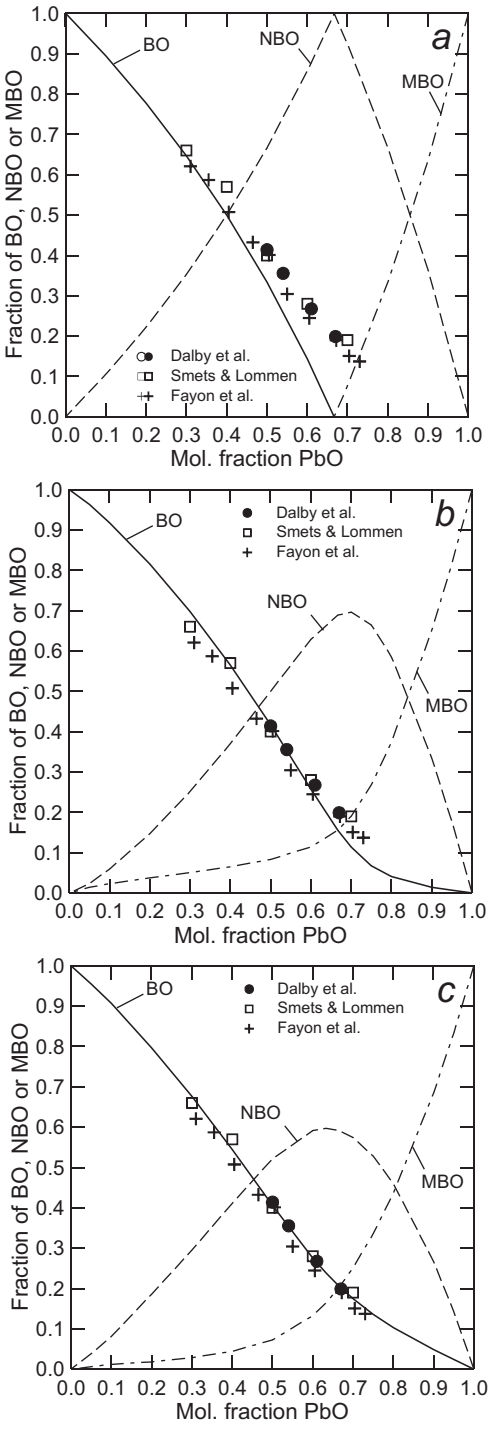
Mass balance constraint

The XPS data of Dalby et al. (8) and Smets and Lommen (17) and the NMR data of Fayon et al. (21) indicate that the measured Si-**O**-Si contents of these glasses are accurate to within a few percent of the calculated values (Fig. 5*a*). These Si-**O**-Si contents plot near or above the Si-**O**-Si content calculated assuming that Rxn [1], or its equivalent Rxn [2], goes to completion; consequently, the assumption that the reaction goes to completion may be reasonable in high silica glasses, but it is not reasonable in glasses of intermediate and high PbO content. A more realistic approach must be adopted if Si-**O**-Si, M-**O**-Si, and M-**O**-M contents are to be explained over the entire compositional range of this binary system.

Thermodynamic approach

The limitations of the mass balance arguments may be alleviated by appealing to thermodynamic considerations. If PbO = MO for Rxn [2],

$$[4] \qquad 2PbO + SiO_2 \Rightarrow Pb_2SiO_4$$



The associated mass action equation with equilibrium constant (K_4) is,

$$[5] \qquad K_4 = (Pb_2SiO_4) \,/\, [(PbO)^2(SiO_2)]$$

where the value of K_4 is infinite, the reaction necessarily goes to completion (one or both reactants is completely consumed), and the concentrations of Si-**O**-Si, M-**O**-Si, and M-**O**-M are those shown by the curves in Fig. 5*a*. If K_4 were finite the reaction would not go to completion, and both reactants then would be present at all binary compositions; that is, all three oxygen species, Si-**O**-Si, M-**O**-Si, and M-**O**-M, would be present over the entire compositional range of the binary. Takaishi et al. (23) provide X-ray and neutron diffraction results demonstrating the existence of M-**O**-M even at 50% SiO_2 (metasilicate composition), justifying the proposed thermodynamic approach to evaluate the distribution of oxygen species.

The most reliable XPS and NMR experimental data indicate greater Si-**O**-Si content than calculated (Fig. 5*a*); hence, the experimental data require K_4 to be finite. A K_4 value has been adopted that duplicates the Si-**O**-Si content in the experimental data at 50% SiO_2, and with this value the abundances of Si-**O**-Si, M-**O**-Si, and M-**O**-M for the entire range

Fig. 5. (*a*) Most reliable XPS O 1s and NMR experimental data for $PbO\text{-}SiO_2$ glasses. The BO, NBO and MBO curves are calculated as for Fig. 4*a* (K_4 = infinite value); (*b*) as for Fig. 5*a* except the BO, NBO and MBO curves were calculated with K_4 = 15 (rather than being infinite) so that Rxn (4) does *not* go to completion; (*c*) as for Fig. 5*a* except the BO, NBO and MBO curves were calculated assuming three distinct Si moieties were present in the glass, a network forming moiety represented by SiO_2, a metasilicate (ring) moiety ($PbSiO_3$) and an orthosilicate moiety (Pb_2SiO_4). See text for details of the calculation.

© 2007 NRC Canada

of composition have been calculated using eq. [5] (K_4 = 15.0) and plotted in Fig. 5*b*. Although a reasonable approximation to the experimental data, the trend of the calculated Si-**O**-Si content (Fig. 5*b*) is nevertheless somewhat steeper than that defined by the experimental measured Si-**O**-Si data at the extremities of composition. No K_4 value yields an appreciably better simulation of the data.

Multiple structures in liquids

There are several studies that indicate ring structures in silicate liquids and glasses (e.g., 8, 1*a*, 1*b*, 1*c*, 1*d*, 31, 32, 33, 34, 35). Bockris et al. (1*b*, 1*c*) proposed the basic anionic unit is $[Si_nO_{2n+3}]^{6-}$ or its neutral equivalent, $M_6Si_6O_9$, the normalized formula of which is $MSiO_3$. The evidence is based on viscosity, molar volume, expansivity, and measured Si-**O**-Si contents. The formation of $MSiO_3$ (metasilicate composition) may be written as,

[6] $PbO + SiO_2 \Rightarrow PbSiO_3$

where the associated mass action equation is,

[7] $K_6 = (PbSiO_3) / [(PbO)(SiO_2)]$

and K_6 is the equilibrium constant. Inclusion of an orthosilicate moiety (Rxn [2]) and a metasilicate moiety (Rxn [6]), with K_4 = 1.50 and K_6 = 4.00, duplicates the measured Si-**O**-Si content at 50% SiO_2 (Fig. 5*c*). The *K* values then were used to calculate Si-**O**-Si, M-**O**-Si, and M-**O**-M over the entire compositional range (Fig 5*c*). The calculations simulate well the Si-**O**-Si measurements.

The simulation includes three types of Si moieties, the orthosilicate moiety (SiO_4^{4-} or Pb_2SiO_4), the metasilicate ring moiety ($PbSiO_3$), and a three-dimensional network moiety represented in these calculations by SiO_2. Bockris et al. (1*a*–1*c*) also argue for a three-dimensional network structural entity in highly siliceous liquids, thus justifying the use of SiO_2 as the moiety representing the network species. This simple thermodynamic treatment requires a minimum of three Si moieties to reproduce the most reliable XPS and NMR experimental data. Although these calculations are consistent with the presence of three Si moieties in the glass, they nevertheless, cannot be taken as proof that these three moieties exist in the glass. Furthermore, if they exist, these liquids and glasses probably contain more than just these three moieties.

Na_2O-SiO_2 system

XPS and NMR experimental data yield similar Si-**O**-Si contents in Na_2O-SiO_2 glasses where the fraction SiO_2 is greater than about 0.66, but the two types of data diverge for glasses of lower SiO_2 content (Figs. 4*c* and 4*d*).

Interpreting XPS results

Brockris et al. (1*a*–1*d*) collected viscosity, volume, and conductivity data on the Na_2O-SiO_2 system and argued strongly for three-membered ring structures in these liquids. Stebbins (9) provided support for the argument by noting the similarity between NMR spectra of Na_2SiO_5 glass and crystals, the crystal having a double ring structure much as proposed by Bockris et al. (1*b*–1*d*). Single and double ring structures contain Q_2 and Q_3 species respectively, and these are the dominant species in the disilicate–metasilicate range of composition. If the disilicate ring structure $[Si_6O_{15}]^{6-}$ were to form in these liquids and noting that $Na_6Si_6O_{15}$ is equivalent to $Na_2Si_2O_5$ (if normalized) then,

[8] $Na_2O + 2SiO_2 \Rightarrow Na_2Si_2O_5$

where the associated mass action equation is,

[9] $K_8 = (Na_2Si_2O_5) / [(Na_2O)(SiO_2)^2]$

and K_8 is the equilibrium constant. The Si-**O**-Si, M-**O**-Si, and M-**O**-M abundances shown in Fig. 6*a* were calculated assuming that Rxn [8] goes to completion (one or both reactants are completely consumed). A K_8 value of 250 was then adopted so that the measured Si-**O**-Si content at $X_{Na_2O} = 0.3$ was reproduced (Fig. 6*b*). The K_8 value was then used to calculate the Si-**O**-Si, M-**O**-Si and M-**O**-M contents at all other compositions of the binary system. The comparison between the Si-**O**-Si XPS measurements and calculation is good, and calculated results are consistent with the existence of such a moiety in Na_2O-SiO_2 liquids (and glasses).

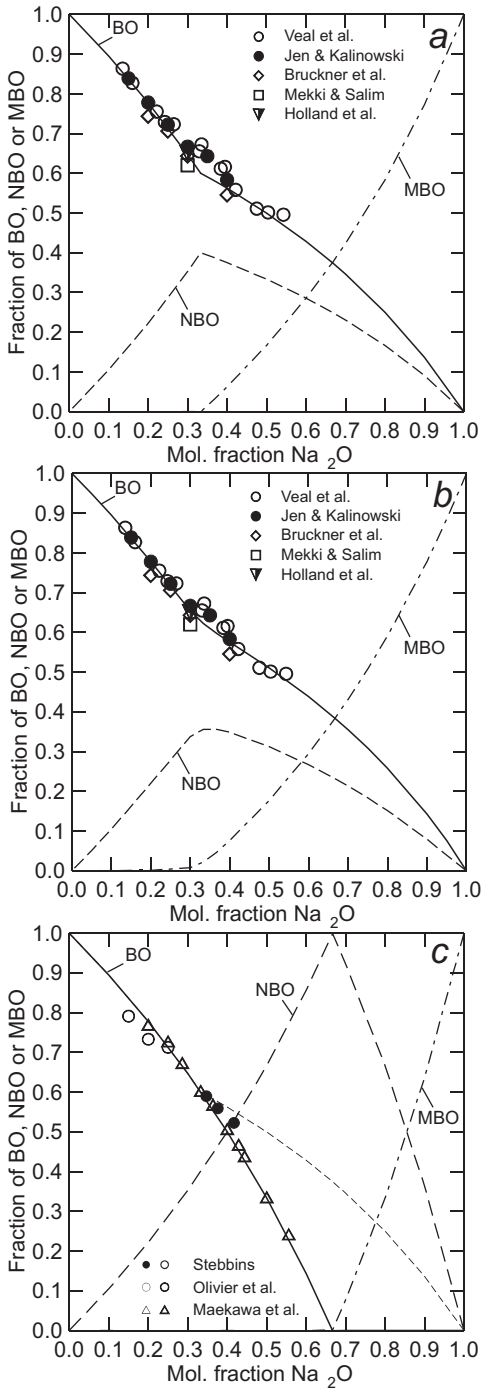
Interpreting NMR results

The NMR measurements of Maekawa et al. (29) are consistent with the studies of Stebbins (9) and Olivier et al. (30). Si-**O**-Si contents derived from these studies are also consistent with the XPS data for glasses with SiO_2 mol fractions greater than 0.66, indicating that the two techniques can yield the similar results for this binary system. Nevertheless, at lower SiO_2 contents the Maekawa et al. (29) NMR data are dramatically different from those obtained by XPS. The NMR data of Stebbins (9) plot between those of Maekawa et al. (29) and the XPS data (Figs. 4*c*, 4*d*). Indeed the Olivier et al. (30) and Stebbins (9) data, if combined, define a trend somewhat shallower than the Maekawa et al. (30) data (Fig. 6*c*). There is consequently no objective experimentally based means to determine which of the NMR or XPS data is correct.

An orthosilicate (Na_4SiO_4) may be proposed for the Na_2O-SiO_2 system in which Na_2O and SiO_2 react to form the moiety,

[10] $2Na_2O + SiO_2 \Rightarrow Na_4SiO_4$

where the associated mass action equation is,



[11] $K_{10} = (Na_4SiO_4) / [(Na_2O)^2(SiO_2)]$

and K_{10} is the equilibrium constant. Where Rxn [10] is assumed to go to completion (i.e., K_{10} has an infinite value) the abundances of Si-**O**-Si, M-**O**-Si, and M-**O**-M were calculated with the results shown as curves in Fig. 6*c*. The calculations mimic the data of Maekawa et al. (29). The implications are that K_{10} is very large, and that, in effect, the reaction has gone to completion in these glasses. The short dashed curve of Fig. 6d is the Si-**O**-Si content calculated assuming Rxn [8] goes to completion (as in Fig. 6*c*).

The Si-**O**-Si results of Stebbins (9) describe a shallower trend (Fig. 6d), and do not support an effectively infinite value for K_{10}. The presence of an orthosilicate moiety, at least in SiO_2-dominated liquids, is also inconsistent with the viscosity and conductivity data of Bockris et al. (1*a*–1*d*). Maekawa et al. (29) noted (p. 59) that their test for Q species assignments assumed the absence of free alkali oxide

Fig. 6. (*a*) XPS O 1s experimental data for Na_2O-SiO_2 glasses. The BO, NBO and MBO curves are calculated as for Fig. 4*c* (K_8 = infinite value); (*b*) as for Fig. 6*a* except the BO, NBO and MBO curves were calculated with K_8 = 250 so that Rxn (8) does *not* go to completion; (*c*) NMR experimental data for Na_2O-SiO_2 glasses. The BO, NBO and MBO curves were calculated assuming an orthosilicate moiety (Na_2SiO_4) formed in the glass and that Rxn (10) goes to completion (K_{10} = infinite value). The short dashed curve indicates BO concentrations if a disilicate species formed (K_8 = infinite value). See text for details of calculations.

ions (M_2O). They justified the assumption by stating that XPS and thermodynamic studies indicate the absence of free Na_2O (hence M-**O**-M) in glasses of the compositional range they studied. The XPS study to which they refer is that of Bruckner et al. (26) who also *assumed* that there was no M-**O**-M contribution to their XPS O 1s spectra, hence the Bruckner et al. (26) publication provides no justification for the assumption. The thermodynamic study to which they refer measured "Na_2O" activities, which were found to be very low in these SiO_2-dominated liquids. At low concentrations of Na_2O, however, activity coefficients may vary greatly from unity in compositions well removed from compositions where Raoult's Law behaviour pertains, so that this evidence for the assumption requires additional testing.

Conclusions

The most reliable XPS and NMR experimental studies of the PbO-SiO_2 glasses yield similar Si-**O**-Si concentrations. Many of the XPS O 1s measurements with poorly resolved peaks overestimate Si-**O**-Si contents of these glasses, whereas one of the NMR studies generally underestimates Si-**O**-Si contents. The most reliable XPS and NMR data proves the assumption that Rxn [4] goes to completion is invalid (i.e., every Pb atom is associated with two M-**O**-Si moieties in these glasses). A thermodynamic treatment, however, reproduces the experimental data.

The NMR and XPS experimental data yield dramatically different results in Na_2O-rich Na_2O-SiO_2 glasses. Five XPS studies are self-consistent but yield much greater Si-**O**-Si contents near the metasilicate composition than do the data from the most comprehensive NMR study. The XPS measurements are compatible with the formation of an $Na_2Si_2O_5$ moiety in the glasses with equilibrium constant of 250. The results of the comprehensive NMR study are consistent with the formation of a Na_2SiO_4 moiety in the solutions where the equilibrium constant has a large value. Additional detailed studies of Si-**O**-Si contents are required of this system to resolve the ambiguity and to understand better the Na_2O-SiO_2 system.

Acknowledgments

We thank V.P. Zakaznova-Herzog for providing the original XPS data for olivine and diopside and G.M. Bancroft for critical and insightful comment on these glass studies and for editing the first draft of the manuscript. The study was funded by the Natural Science and Engineering Research Council of Canada (NSERC). Surface Science Western at the University of Western Ontario, through M. Beisinger, provided exceptional technical support with the Kratos XPS for which we are very grateful.

Self-assembly of biomolecules at surfaces characterized by NEXAFS[1]

Xiaosong Liu, Fan Zheng, A. Jürgensen, V. Perez-Dieste, D.Y. Petrovykh, N.L. Abbott, and F.J. Himpsel

Abstract: Surface science has made great strides towards tailoring surface properties via self-assembly of nanoscale molecular adsorbates. It is now possible to functionalize surfaces with complex biomolecules such as DNA and proteins. This brief overview shows how NEXAFS (near edge X-ray absorption fine structure spectroscopy) can be used to characterize the assembly of biological molecules at surfaces in atom- and orbital-specific fashion. To illustrate the range of applications, we begin with simple self-assembled monolayers (SAMs), proceed to SAMs with customized terminal groups, and finish with DNA oligonucleotides and Ribonuclease A, a small protein containing 124 amino acids. The N 1s absorption edge is particularly useful for characterizing DNA and proteins because it selectively interrogates the π^* orbitals in nucleobases and the peptide bonds in proteins. Information about the orientation of molecular orbitals is obtained from the polarization dependence. Quantitative NEXAFS models explain the polarization dependence in terms of molecular orientation and structure.

Key words: NEXAFS, bio-interfaces, ribonuclease A, immobilization, orientation.

Résumé : La chimie des surfaces a fait de grands pas dans la direction de la possibilité d'ajuster les propriétés des surfaces par le biais d'autoassemblages d'adsorbats moléculaires à l'échelle nanométrique. Il est maintenant possible de fonctionnaliser des surfaces avec des biomolécules complexes, tels l'ADN et des protéines. Cette brève revue montre comment on peut appliquer la spectroscopie de la structure fine d'absorption des rayons X près du seuil ("NEXAFS") à la caractérisation d'assemblages de molécules biologiques liés à des surfaces de façon spécifiquement atomique et orbitalaire. Pour illustrer l'éventail des applications, on commence avec des monocouches autoassemblées simples (MAA) à partir desquelles on procède à des MAA portant des groupes terminaux personnalisés et on termine avec des oligonucléotides de l'ADN et la ribonucléase A, une petite protéine comportant 124 acides aminés. L'absorption 1s au seuil de l'azote est particulièrement utile pour caractériser l'ADN et les protéines parce qu'il permet d'interroger sélectivement les orbitales π^* des nucléobases et des liaisons peptidiques des protéines. Les informations relatives à l'orientation des orbitales moléculaires sont obtenues à partir de la dépendance de la polarisation. Des modèles quantitatifs de "NEXAFS" permettent d'expliquer la dépendance de la polarisation en fonction de l'orientation moléculaire et de la structure.

Mots-clés : NEXAFS, bio-interfaces, ribonucléase A, immobilisation, orientation.

Motivation

The functionalization of surfaces with biomolecules (1) is becoming a significant part of biochemistry and molecular biology, both of which traditionally have focused on phenomena occurring in bulk solution. Among the major drivers of this technology are DNA microarrays ("DNA chips") used for massively parallel analysis and synthesis of DNA (2), detection of proteins involved in signaling networks in cells ("protein chips") (3), as well as solid-state biosensors for rapid detection of pathogens in the field (4). For the study of protein activity and for achieving optimum sensitiv-

ity of immunoassays and protein sensors, it is important to control the orientation of proteins adsorbed on a surface (5). Consequently, the development of methods to assess the orientation of proteins on surfaces has been a focus of considerable research activity in recent years. Surface functionalization schemes, such as self-assembled monolayers (SAM) and phospholipid bilayers, make it possible to specifically immobilize proteins on surfaces, control their surface density, increase their orientational order, and prevent them from denaturing.

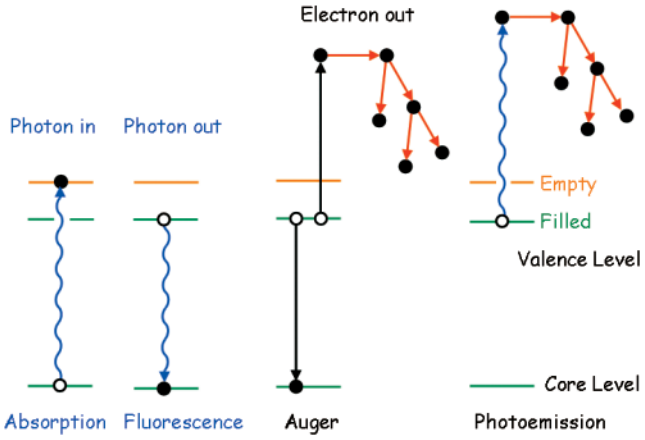
Biological activity of molecules in solution is typically measured using molecules labeled with tags that can be easily observed and (or) manipulated. These tags can be, for example, fluorescent, radioactive, chemiluminescent, magnetic, and electrochemical. However, in many cases labeled measurements can be difficult or even impossible for biomolecules immobilized on a surface. Surface analysis techniques such as ellipsometry, attenuated total reflection, quartz microbalance, and surface plasmon resonance can be used to measure the wet and dry mass uptake by biologically functionalized surfaces (1, 6). To understand the chemistry and structure of these surfaces, however, it is desirable to obtain element-specific and bond-specific information. This is where sophisticated techniques are required, such as FTIR (Fourier transform IR spectroscopy), XPS (X-ray photoelectron spectroscopy), and NEXAFS (near edge X-ray absorption fine structure spectroscopy) (1, 7, 8).

NEXAFS technique

NEXAFS measures optical dipole transitions from a core level to unoccupied valence orbitals, as shown in Figs. 1 and 2. The binding energy of the core level identifies a specific element and its charge, for example, neutral carbon and positively charged carbon in Fig. 2. The binding energy and its chemical shift can be measured independently by XPS. NEXAFS goes beyond XPS by identifying a specific σ* or π* orbital located at a particular atom (left side of Fig. 2, from ref. 9). Furthermore, the orientation of the orbital can be determined using optical dipole selection rules from the polarization dependence of the transition intensity. Accordingly, NEXAFS measurements require synchrotron radiation because there are no other tunable polarized light sources available in the soft X-ray regime. Typical elements in biomolecules, such as C, N, O, and S, exhibit simple s-to-p transitions, which are dipole-allowed if the electric field vector $\boldsymbol{E}$ of the incident X-rays is parallel to the transition dipole moment, which is perpendicular to the plane of peptide bond in proteins and perpendicular to the plane of the nucleotide bases in DNA. The observed intensity follows a $\cos^2\theta_E$ pattern around that axis. A measurement of the transition intensity makes it possible to determine the amount of certain bonds on a surface.

Usually, the optical absorption is measured indirectly by detecting decay products of the core hole, such as the total electron yield (TEY), the fluorescence yield (FY), or the Auger electron yield (Fig. 1). All of these decay products are proportional to the number of core holes created in the absorption process. The probing depth, however, varies. Electron detection is surface sensitive (typically 1–2 nm), while fluorescence detection probes deeper (typically

Fig. 1. Schematic of various methods to measure X-ray absorption via decay products of the core hole that is created in the absorption process. Detecting energy-selected fluorescence photons provides sensitivity to dilute species. Detecting Auger electrons, photoelectrons, and secondary electrons provides surface sensitivity.



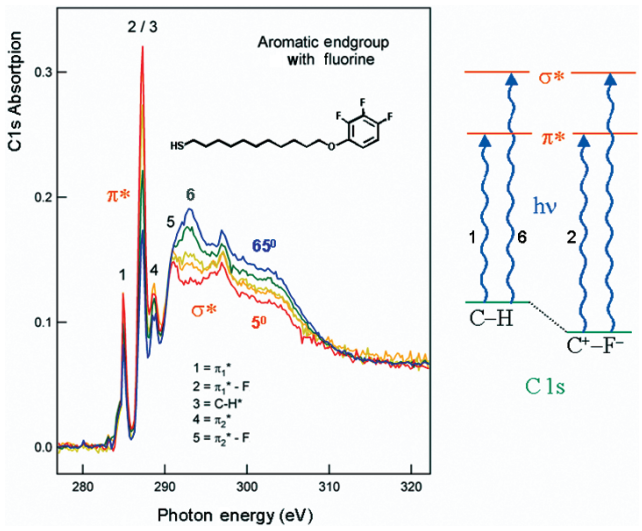


Fig. 2. Chemical selectivity of NEXAFS, demonstrated by a self-assembled monolayer of alkane chains with aromatic terminal groups (9). Transitions from the C 1s core level to unoccupied valence orbitals are observed. Specific atoms can be addressed by selecting the core level and by using its chemical shift to determine the oxidation state (here neutral C^0 in C-H versus C^{1+} in C-F). Specific valence orbitals are addressed via the final state, such as σ* and π*. The orientation of an orbital is obtained from its polarization dependence when changing the angle of incidence θ (measured from the surface normal).

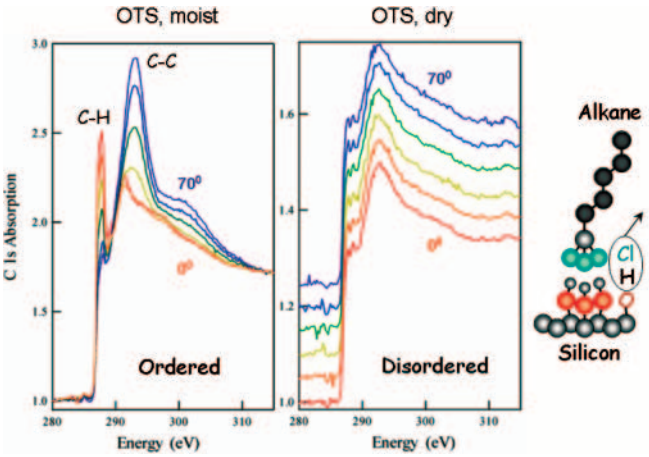

100 nm to several μm, depending on the absorption length at the photon energy of the emitted photons). By simultaneously measuring electron and fluorescence yield, it is possible to obtain a coarse depth profile of the sample.

Electron detection produces a much higher signal than fluorescence, since most of the core holes in the 100–1000 eV binding energy range decay by an Auger process. Fluorescence decay occurs 10^4–10^5 times less frequently. The decay of an Auger electron into multiple secondary electrons am-

Fig. 3. Functionalization of an oxidized silicon surface via siloxane chemistry (11). The coverage can be inferred from the height of the C 1s edge jump relative to the pre-edge background (which is normalized to 1). The orientation of the alkane chains is obtained from the polarization dependence. Both depend strongly on the preparation, with a dry environment leading to low coverage and random orientation.

plifies the signal further in the total electron yield mode (see Fig. 1). Nevertheless, fluorescence detection makes it possible to filter out photons characteristic of the substrate, thereby enhancing the signal-to-noise ratio for dilute systems, such as a fraction of a monolayer of DNA or protein immobilized at a surface. This trade-off between electron and photon detection will be demonstrated in the section on DNA and proteins. A channel plate with an Al filter is able to discriminate against a Si substrate, because Al absorbs the red-shifted Si fluorescence optimally ($Z_{Al} = Z_{Si} - 1$). Unfortunately, there is no good filter material to absorb C 1s fluorescence while transmitting the N 1s edge, which is of interest for DNA and proteins. In that case, a more sophisticated Si–Li detector or a multilayer band pass reflector is called for. Auger electron detection via an electron spectrometer allows some filtering as well. In Auger detection, however, the NEXAFS features are superimposed on the photoemission spectrum of the occupied valence orbitals sweeping through the fixed Auger energy window.

Self-assembled monolayers (SAMs)

Self-assembled monolayers of alkanes are widely used as the first step of chemically functionalizing surfaces. The two prevailing methods of attaching alkanes to a surface utilize thiol groups (on noble metals) or siloxanes (on oxidized silicon) (10). Figure 2 shows the NEXAFS spectrum of an alkanethiol on gold (10), and Fig. 3 of a siloxane on oxidized Si (OTS = octadecyltrichlorosilane) (11). The siloxane chemistry can be applied directly to a silicon wafer but requires stringent control over preparation conditions to achieve reproducible and well-defined surface functionalization. A well-ordered, densely packed SAM requires long soaking in solution (Fig. 3, left side), while quick drying in a nitrogen atmosphere produces a randomly oriented layer with much lower coverage (Fig. 3, right side).

The orientation of molecules in SAMs is inferred from the polarization dependence of NEXAFS. Rotating the sample changes the polar angle of incidence and therefore the angle θ of the electric field vector $\boldsymbol{E}$ with respect to the surface normal (for p-polarized light). The spectra on the left of Fig. 3 exhibit a strong θ-dependence, while the spectra on the right are identical to each other to the extent that they can only be distinguished by a vertical offset. On average, the C-H orbitals are oriented perpendicular to the alkane chain and the C-C orbitals parallel to it. Therefore, the intensity maximum of the C-H signal and the intensity minimum of the C-C orbital at $\theta = 90°$ both imply that the chains are, on average, oriented perpendicular to the surface. The fact that the intensity modulation is not quite 100% is usually taken as a sign that the chains are slightly tilted away from the normal (7), forming many domains with a well-defined polar tilt angle α but randomly distributed azimuthal tilt angles ϕ. Independent information from other techniques supports a tilted geometry for alkane-based SAMs. From the NEXAFS spectra alone, it is difficult to distinguish such a situation from a finite spread of tilt angles α around the surface normal. Examples are single-stranded DNA chains (section on DNA and proteins) and the orientation of the terminal group in Fig. 2 (10). These situations will be discussed more quantitatively in the quantitative analysis section.

The coverage can be estimated by normalizing the NEXAFS spectra to their pre-edge region, which is dominated by the substrate. While the spectra of ordered OTS on the left of Fig. 3 rise by 2 units (from 1 to 3), the spectra of disordered OTS on the right increase by only 0.5 units (from 1 to 1.5, see the red (bottom-most) spectrum with zero offset). Thus, the coverage is four times larger for ordered adsorption. At the highest possible coverage, the alkane chains come within a van der Waal's bond distance of each other and are forced to adopt a tilted geometry with dense packing.

Alkane-passivated surfaces can be further functionalized by adding specific terminal groups on top of a SAM. Two examples of functionalized SAMs are shown in Figs. 2 and 4 (from refs. 10 and 12, respectively). Spectroscopically, the terminal group can be distinguished from the supporting alkane chain by its valence orbital or its core level.

Particularly useful for selecting terminal groups are the sharp π^* orbitals, whose cross-section is large compared with the C-H or C-C orbitals of alkane chains. In Fig. 2, the π^* orbitals of the C=C-H groups in the phenyl group (Peak 1) appear below all the other orbitals. The π^* orbitals of the C=C-F groups in the fluorinated part of the phenyl group (Peak 2) overlap with the C-H orbitals of the alkane chain (Peak 3), but their higher cross section makes them dominant. This can be inferred from the π^* intensity ratio of Peaks 2 and 1, which should be 4:2 (counting =C-O- with =C-F) in this system.

In Fig. 4, the terminal group contains Fe, which can be probed selectively at the sharp Fe 2p absorption edge. The 3d transition metals are involved in many biological systems, such as enzymes and photosystems (12). Their sharpest edge is the 2p edge. It is ideal for probing the oxidation state from the multiplet structure induced by the interaction of the 2p core hole with the 3d valence electrons (13) as well as covalent bonding effects (14, 13). The 1s edges are much broader, but they are needed for probing highly dilute metallo-proteins in solution. The functionalization of alkane

chains by ferrocene in the 2+ and 3+ oxidation states allows for prototypical experiments that investigate electrochemical and photochemical switching of the oxidation state. The multiplet structure of Fe^{2+} and Fe^{3+} and their energy shift are obtained via reference spectra, using molecular ferrocene (14) and a Fe^{3+} mineral (Fig. 4*c*, top and bottom spectra). They compare well to the spectra of two SAMs with ferrocene terminal groups in the 2+ and 3+ oxidation states, which were prepared by electrochemical means (15) (Fig. 4*c*, spectra at the center). Irradiation with intense undulator radiation reduces Fe^{3+} back to Fe^{2+} and further (Fig. 4*b*).

DNA and proteins

Immobilization of DNA and proteins at surfaces is a fast-growing area of research. DNA microarrays are revolutionizing biotechnology by allowing the simultaneous identification of many DNA sequences. They are a critical component of advanced systems for medical diagnostic and pathogen detection. The full potential of chip-based sensors in genomics and proteomics can only be realized if the fragile biomolecules survive the attachment process intact. Furthermore, they must be properly oriented to perform their biological function, for example, binding to a complementary DNA strand in a DNA chip and to a specific protein in an immunosensor. The ability to characterize the chemistry and structure of biomolecules at surfaces facilitates the systematic and controlled development of future generations of DNA chips and protein biosensors.

Despite the complexity of biomolecules, NEXAFS is able to provide information about the attachment process and the orientation of immobilized DNA and proteins. The C 1s edge tends to be difficult to analyze because of the multitude of carbon atoms in different chemical environments. However, the N 1s edge singles out specific atoms and bond orbitals. For both DNA and proteins, the lowest unoccupied N valence orbital is a π*, as shown in Figs. 5 and 6. These orbitals are sharp and have a high cross section, which makes them easy to detect. In DNA, the N π* orbitals are located at the base pairs, and they are all oriented parallel to the axis of the double-helix in double-stranded DNA (Fig. 5*d*). In proteins, the N π* orbitals are located at the peptide bonds, which link amino acids into peptides and eventually proteins. This has been demonstrated very clearly in (16), where the N π* orbital is observed only when amino acids are linked together, not in individual amino acids. Fig. 6 shows this peptide bond as the first major peak at the N 1s absorption edge. It also includes the wave function of the peptide bond orbital, which extends over four atoms (Cα, C, N, O) and forces them into a planar arrangement. Even more selective are the absorption edges of minority elements in proteins. S is the most prominent example. It is only part of a few amino acids, such as cysteine, but these are important in cross-linking proteins and attaching them to a surface. Fig. 6 shows the S 1s edge spectrum. As a second row element, sulfur has little tendency towards π bonding. Therefore, the S 1s edge does not exhibit a π* orbital, only a σ*. However, it is sensitive to the formation of S-S crosslinks, for example between two cysteines (17).

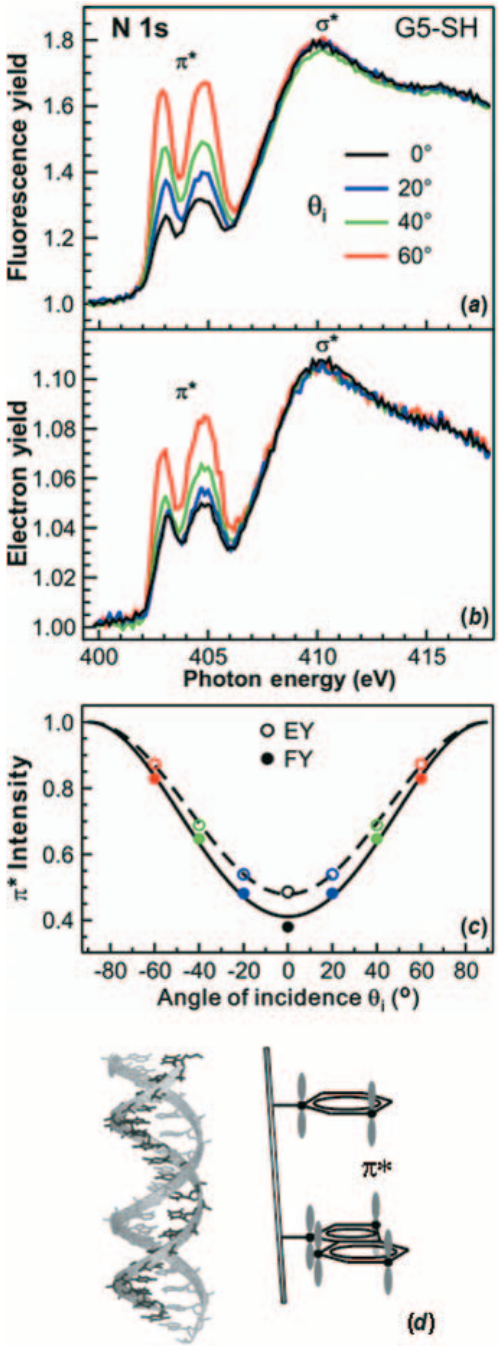

Fig. 4. Determination of the oxidation state of Fe in a self-assembled monolayer functionalized by a ferrocene terminal group (15). The multiplet structure of the Fe 2p to 3d transitions reveals the oxidation state. Spectra for molecular ferrocene (from

The information from NEXAFS becomes more and more selective by going from C to N, S, and other minority elements, such as transition metals in metallo-proteins (12, 13). NEXAFS of the 2p to 3d transitions of 3d transition metals provides very specific information about the oxidation state and spin state (see Fig. 4). The electron yield signal of dilute elements becomes swamped by background absorption from the C 1s core level, the C 2s, 2p valence orbitals, and the substrate. This problem is solved by fluorescence detection, where the background photons from the C 2s, 2p valence orbitals, and from the substrate can be filtered out. Figure 5 demonstrates the effect of a simple Al filter in front of a

Fig. 5. The π* orbitals of the nucleotide bases in DNA detected at the N 1s edge. The spectra in (*a*)–(*c*) are for single-stranded DNA consisting of 5 guanine nucleotides and attached to a gold surface via a thiol group (18). Fluorescence detection in (*a*) provides a much better signal to background ratio than electron detection in (*b*). The polarization dependence shows that the π* orbitals are oriented perpendicular to the surface (on average). Similar spectra are obtained for double-stranded DNA (19), where the π* orbitals of all base pairs point along the axis of the double helix, as indicated in (*d*).

channel plate detector. After normalizing the data to the pre-edge background, the electron yield in panel 5*b* provides a low signal-to-background ratio of 8%, which increases the noise substantially and makes a reliable background subtraction difficult. The filtered fluorescence measurement in panel 5*a* improves this ratio to 65%, i.e., signal and background become comparable. This ratio can be improved further by using an energy-dispersive Si-Li or Ge detector (not shown). However, it is difficult to maintain the large acceptance angle of a channel plate, and the maximum count rate suffers as the energy resolution of the detector is improved. Detector efficiency is a critical factor with biological samples because radiation damage imposes severe limits on the exposure time.

Fig. 6. Polarization-dependent NEXAFS of a protein (RNase A, from (21)). The N 1s edge reveals the π* orbital of the peptide bond that polymerizes amino acids into a protein (shaded in (*a*), and (*c*)). Despite the summation over 124 amino acids in RNase A, there is substantial polarization dependence at the N 1s and S 1s edges (see (*a*) and (*b*)). A parameter-free calculation is consistent with the data in (*f*). The polarization dependence can be enhanced by choosing a minority species, such as sulfur. The *y*-axis scales are same in panels (*a*) to (*d*). (*a*) and (*b*) are for oriented immobilization, (*c*) and (*d*) for random immobilization (21).

The orientation of DNA nucleobases can be determined from the polarization dependence of the N 1s NEXAFS spectra (18–20). At the C 1s edge, the polarization effects are averaged out because of the many inequivalent C atoms with nearly random bond orientations. Figures 5*a*–5*c* show the polarization dependence for single-stranded DNA oligomers consisting of 5 guanine nucleotides attached to a Au surface via a thiol bond (from ref. 18). Similar measurements have been made for double-stranded DNA (19). The maximum of the π* intensity occurs at grazing incidence, i.e., with the

© 2007 NRC Canada

electric field vector ***E*** perpendicular to the surface. The dipole selection rules lead to the conclusion that the π* orbitals of the bases are preferentially oriented perpendicular to the surface (parallel to ***E***). Therefore, the aromatic rings of the nucleobases are parallel to the surface. A more quantitative evaluation is shown in panel 5*c* for both electron and fluorescence detection. Since the fluorescence measurement is affected by an additional dipole selection rule in the emission process, one has to make sure that the detection geometry does not distort the polarization dependence. This can be achieved by having a large acceptance angle or by placing the detector near the magic angle, where the orientation dependence vanishes. For 100% orientation, one should observe a $\cos^2\theta_E$ dependence of the NEXAFS intensity according to the matrix element for a s to p dipole transition. Experimentally, the $\cos^2\theta_E$ modulation is only 60% of the maximum, which indicates only partial ordering. A quantitative analysis will by given in the section Quantitative analysis. The degree of orientation can be changed (18) by varying the length of the DNA segment, its base sequence, and the preparation conditions. The σ* orbitals generally have a much smaller polarization dependence than the π* orbitals, which can be explained by the fact that an aromatic ring contains σ* orbitals in many in-plane directions, while all the π* orbitals are parallel to each other and perpendicular to the plane.

Proteins are even more complex and less regular than DNA, and yet it has been possible to observe a polarization dependence in RNase A (21), a protein containing 124 amino acids and more than 10^3 atoms (not counting H). The π* orbital at the N 1s edge exhibits a 18% modulation between θ = 0° and 60°, while the S 1s edge is modulated by 41%. This follows the expectation that a less frequent element, such as S, experiences less averaging. The higher σ* orbitals have a much weaker polarization dependence than the π* orbitals, similar to the DNA results. As a further cross-check, RNase A can be immobilized by a different technique that gives random orientation (21). In that case the polarization dependence of the peptide band π* orbital is comparable to the experimental error of a few percent.

The polarization dependence at the N 1s edge is surprisingly strong in view of the 123 peptide bonds contributing to the spectrum. A purely random arrangement of these bonds within one protein molecule (together with perfect orientation of the molecules relative to each other) would give a modulation of $1/\sqrt{123} = 9\%$. Therefore, we have developed a program that sums the dipole matrix elements over all 123 peptide bonds using the atomic coordinates in the protein data base and a specific orientation of the molecules based on the immobilization method. (The protein is bound to the supporting SAM via a S–S bond to the cysteine at the 19th residue, and that bond is assumed to be perpendicular to the surface (21).) The calculated modulation (red curve in Fig. 6*f*) is surprisingly close to the experimental points (blue dots), and the remaining difference goes in the right direction. The data are modulated less than the calculation because the molecules are not perfectly oriented and the polarization of the synchrotron light is not perfect (93% in this experiment). A similar calculation can also be performed for the 12 sulfur atoms in RNase A, and it represents the data equally well. Thus, we conclude that RNase has substantial internal correlations between the orientations of the peptide bonds, which double the statistical polarization dependence. This is quite reasonable in view of the internal structure of proteins, which contain highly regular elements, such as the α-helix and the β-sheet. RNase A, for example, contains 22% α-helices and 46% β-sheets.

Quantitative analysis

NEXAFS has been mostly used for qualitative analysis of the chemical reactions that occur during the immobilization process of biomolecules at surfaces. However, quantitative NEXAFS analysis can be used for determining both coverage and orientation of molecules. Here we mainly address the orientational information that can be obtained from the polarization dependence of the NEXAFS signal. A widely used formula for the polarization dependence (7) assumes a layer of tilted molecules consisting of domains with perfect orientation within each domain. The domains all have the same polar tilt angle α, but a random-distribution of azimuthal angles φ. This leads to the formula,

$$[1] \qquad I(\theta) / I(0°) = 1 + P[(2/\sin^2\alpha) - 3]\sin^2\theta$$

where θ is the angle of incidence from the sample normal ($\theta = 90° - \theta_E$), α is the tilt angle of a p-orbital from normal, and *P* is the degree of polarization of the soft X-rays. These assumptions are reasonable for simple SAMs that are known to be nearly perfectly ordered. However, in more complex systems, such as SAMs with tailored terminal groups, DNA, or proteins, one encounters two phenomena that are not captured by eq. [1].

First, there can be more than a single angle determining the geometry of the system. A terminal group is often able to rotate around the bond that attaches it to the supporting alkane chain. An extreme case is the orientation of a protein at a surface, which requires three angles to be fully characterized. If one allows for different folding patterns, the number of variables increases rapidly.

Second, larger molecules may exhibit a distribution of bond angles instead of being perfectly oriented. That introduces a finite spread σ of the bond angles. Moreover, for a system that contains a distribution of bond orientations, the interpretation of a polarization-dependent measurement in terms of a unique angle, in general, will not result in a value close to the average of that distribution (18, 22, 23).

In all cases, one faces the dilemma that NEXAFS provides at best two experimental numbers for each orbital that characterize the polar and azimuthal polarization dependence of the peak height. Therefore, one needs to carefully select the free parameters when fitting the data and freeze the remaining variables by using other experiments or making judicious assumptions. For example, it makes little sense to assume a fixed polar tilt angle (as in eq. [1]) for characterizing the orientation of floppy molecules, such as single-stranded DNA (18). A more reasonable assumption is a distribution of tilt angles with an average orientation α_0 relative to the surface normal. Using a Gaussian distribution with standard deviation σ leads to the following polarization dependence (24),

© 2007 NRC Canada

[2] $I(\theta) / I(0°) = 1 + P[8z/(3z - 1 - 2\cos(2\alpha_0)) - 3]\sin^2\theta$, where $z = \exp(4\sigma^2)$

With this approach, the free parameter becomes σ, and the average angle α_0 needs to be obtained from symmetry arguments (e.g., $\alpha_0 = 0°$ for DNA (18, 19)), or from other measurements (e.g., X-ray diffraction of the bulk phase (24)).

Another situation occurs in proteins, where the π* signal at the N 1s edge contains contributions from many nitrogen atoms in peptide bonds with different orientations. In that case one needs to sum over the angular dependence of all individual orbitals. Each overall orientation (Θ, Φ) of the protein corresponds to a well-defined polarization dependence $I(\theta, \phi, \Theta, \Phi)$ with respect to the angle of incidence (θ, ϕ). The polarization dependence is calculated by summing over the individual contributions $I_n(\theta, \phi, \Theta, \Phi)$ from the *n*th peptide bond. Each of these follows a $\cos^2\theta_n$ law, where θ_n is the angle between the electric field vector $\boldsymbol{E}$ and the direction $\boldsymbol{e}_n^{\mathrm{N}}(\Theta, \Phi)$ of the π* orbital in the *n*th peptide bond. The vectors $\boldsymbol{e}_n^{\mathrm{N}}$ are obtained from the cross product of the vectors $\boldsymbol{r}_n^{\mathrm{CO}}$ and $\boldsymbol{r}_n^{\mathrm{CN}}$ that define the plane of the peptide bond (see Fig. 6*e*). They connect the carbon atom in the *n*th peptide bond with its neighboring oxygen and nitrogen atoms. For the S 1s edge, the unit vector $\boldsymbol{e}^{\mathrm{S}}{}_m$ connects the *m*th S atom with the adjacent C atom along a σ bond. The atomic coordinates are obtained from the protein databank available from www.pdb.org.

The overall orientation angle Θ of RNase in Figs. 6*a*, 6*b*, and 6*f* is determined by its attachment to the supporting SAM via a S–S bond to the cysteine at the 19th residue. Assuming that this S–S bond is perpendicular to the surface, one needs to rotate the coordinates in the protein data bank such that the vector $\boldsymbol{r}_{19}^{\mathrm{SH}}$ becomes parallel to the surface normal. This is achieved by calculating the transformation matrix for this rotation and applying it to all vectors $\boldsymbol{e}_n$. The azimuthal orientation Φ of the RNase molecules around the S–S bond is assumed to be random. That leads to an average over the azimuthal orientation Φ, which is equivalent to an average over the angle of incidence ϕ with fixed orientation Φ. This approach eliminates the angles Θ, Φ, and ϕ from the problem. The normalized polarization dependence of the NEXAFS signal $I(\theta)/I(0°)$ becomes a function of the angle of incidence θ from the surface normal, without adjustable parameters. For the N 1s and S 1s edges one obtains,

[3*a*]
$$\boldsymbol{e}_n^{\mathrm{N}} = \frac{\boldsymbol{r}_n^{\mathrm{CO}} \times \boldsymbol{r}_n^{\mathrm{CN}}}{\left|\boldsymbol{r}_n^{\mathrm{CO}} \times \boldsymbol{r}_n^{\mathrm{CN}}\right|}$$
$$\frac{I^{\mathrm{N}}(\theta)}{I^{\mathrm{N}}(0°)} = \frac{\int \sum_n [\boldsymbol{E}(\theta)\, \boldsymbol{e}_n^{\mathrm{N}}]^2 \, \mathrm{d}\phi}{\int \sum_n [\boldsymbol{E}(0°)\, \boldsymbol{e}_n^{\mathrm{N}}]^2 \, \mathrm{d}\phi}$$

[3*b*]
$$\boldsymbol{e}_m^{\mathrm{S}} = \frac{\boldsymbol{r}^{\mathrm{SC}}}{\left|\boldsymbol{r}_m^{\mathrm{SC}}\right|}$$
$$\frac{I^{\mathrm{S}}(\theta)}{I^{\mathrm{S}}(0°)} = \frac{\int \sum_m [\boldsymbol{E}(\theta)\, \boldsymbol{e}_m^{\mathrm{S}}]^2 \, \mathrm{d}\phi}{\int \sum_m [\boldsymbol{E}(0°)\, \boldsymbol{e}_m^{\mathrm{S}}]^2 \, \mathrm{d}\phi}$$

Applying these formulas to the N 1s and S 1s data of oriented RNase A in Fig. 6 gives the correct magnitude of the polarization dependence (see panel (*f*)). This calculation could be refined further by including the degree of polarization *P* and a distribution of orientation angles (compare eqs. [1] and [2]). Both would bring the calculation closer to the experimental values.

Apart from the polarization dependence, there are several other quantitative results that can be extracted from NEXAFS data of proteins. Spatially resolved spectromicroscopy (25, 26) maps the distribution of proteins in biological samples.[3] The spectrum of a protein can be modeled (27) by using reference spectra for individual amino acids (28) and taking the changes due to the formation of the peptide bond into account. For the determination of relative concentrations, it is useful to normalize the spectra to the edge jump between the pre-edge and the continuum absorption 20–30 eV above the edge. This normalization provides a signal proportional to the density of C, N, O, and S atoms.

Summary and outlook

In summary, we demonstrate how the element and orbital sensitivity of NEXAFS spectroscopy can be used to investigate the binding properties of biomolecules at surfaces. Simple alkane passivation layers serve as tutorial examples. The complexity is increased systematically by adding customized terminal groups. Eventually, DNA and proteins are tackled. The orientation of the immobilized protein is detected from the polarization dependence of the NEXAFS intensity. The results suggest that NEXAFS can be used to investigate fairly complex biomolecules at surfaces, such as DNA oligomers and proteins containing more than a hundred amino acids. The agreement between the results of complementary NEXAFS, XPS, and FTIR measurements (18) strongly suggests that these ex situ techniques capture salient properties of biomolecules as they are immobilized in solution. Such element-specific surface-sensitive diagnostic methods help to monitor and control the multistep immobilization process of biomolecules.

To have an impact on day-to-day biochemical research, it will be necessary to simplify the access to the required synchrotron light sources and the analysis of the results. Protein crystallography can serve as a model, where automation in sample handling and data processing has become routine. Even remote control data acquisition has become possible, as long as there is a synchrotron staff member available to load the samples. Due to the vacuum requirements for NEXAFS, the sample introduction becomes more complicated. However, it is possible to build sample cells with thin Si or Si_3N_4 windows that separate the sample atmosphere from the detector and the synchrotron, while transmitting enough light to operate in the fluorescence detection mode. In the "water window" between the C 1s and O 1s edges, the mean free path of soft X-rays is only a few μm in liquid water (4 μm at the N 1s edge). This length increases to 0.3 m in saturated water vapor (18 Torr at 100% humidity; 1 torr = 133.322 4 Pa). That makes sample handling much easier. In addition, the radiation damage from radicals created by

© 2007 NRC Canada

photodecomposition of the liquid water film between sample and window is avoided. Developing practical "wet" or "humid" sample cells is an important step in bringing NEXAFS closer to a mainstream analytical technique for surface biochemistry.

Looking farther into the future, one could go beyond self-assembled monolayers and consider more complex objects, such as phospholipid membranes, supported by molecular stilts (29). Like a cell wall, such a membrane may contain ion channels, photosynthetic centers, molecular motors, etc. Compared to a natural cell, this is a more controllable environment that can be used for selectively investigating a specific part of the incredibly complex cell machinery.

An O K-edge XANES study of calcium aluminates[1]

Grant S. Henderson, Daniel R. Neuville, and Laurent Cormier

Abstract: Oxygen K-edge XANES spectra of crystalline calcium aluminate phases exhibit features that are strongly influenced by orbital mixing between the O 2p antibonding states and Ca and Al orbitals. Specific peaks in the spectra are characteristic of the calcium coordination and can be assigned to Ca in nine-, eight-, seven-, and six-fold coordination. The Q speciation of the AlO_4 tetrahedra also influences the position of the peaks, and several peaks result from a mixture of Ca and Al interactions.

Key words: O K-edge XANES, calcium aluminates, coordination, Q species.

Résumé : Les spectres d'absorption X de type XANES « X-ray absorption near edge structure » près du seuil K de l'oxygène des phases cristallines d'aluminate de calcium présentent des caractéristiques qui sont fortement influencés par la combinaison des orbitales entre les états antiliants 2p de l'oxygène et les orbitales du calcium et de l'aluminium. Des pics spécifiques des spectres sont caractéristiques de la coordination du calcium et ils peuvent être attribués au calcium dans des états de nona-, octa-, hepta- et hexacoordinations. La spéciation Q du tétraèdre du AlO_4 influence aussi la position des pics et plusieurs d'entre eux correspondent à un mélange d'interactions du calcium et de l'aluminium.

Mots-clés : spectres XANES près du seuil K de l'oxygène, aluminates de calcium, coordination, espèces Q.

[Traduit par la Rédaction]

Introduction

In general, X-ray absorption studies of glass structure have focused on investigating the structural environment of the major cations making up the glass of interest. There have been very few studies that have investigated the oxygen environment. However, recent studies (1–2) have shown that the oxygen K-edge can be useful for probing glass structure. Oxygen K-edge XANES result from O 1s transitions to O 2p antibonding states mixed with cation orbitals (1–2, and refs. therein) and are sensitive to interactions with whatever is bound to the oxygen. The spectra are complex and also influenced by a number of factors other than the nature of the cation that is bound to the oxygen. These include whether or not oxygen is bridging or non-bridging, the coordination geometry of the cation, and the bond angles between the oxygen and surrounding cations (cf. (3)). Despite these complexities, the O K-edge XANES has proven useful for determining the coordination of Ti in Ti-silicate glasses (1) and of germanium in alkali germanate glasses (3) where determination of cation coordination can be problematic.

In glass systems that lack the long-range structure and translational symmetry typical of crystalline phases, analysis of XANES spectra requires the use of crystalline standards as a means to make logical assignments of the observed peaks in the spectra. One of the glass systems that are currently of interest to geologists is the calcium aluminosilicate (CAS) ternary. CAS glasses are important geologically and for commercial applications. This is because of their highly refractory nature and excellent optical and mechanical properties (cf. (4), and refs. therein). Furthermore, glasses in this system can be made by conventional melt-quenching techniques in a narrow range of compositions (60–70 mol% CaO) at very low wt% SiO_2 contents, contrary to alkali or Mg aluminosilicate glasses. Addition of small amounts of SiO_2 to CaO–Al_2O_3 (CA) glasses extends the glass-forming region and lowers the liquidus temperature (5), and the macroscopic properties are markedly changed with the introduction of silica, suggesting structural modification of these glasses. Here, we investigate, using O K-edge XANES, a series of calcium aluminate phases used as standards in the studies of the CAS system.

Experimental

The crystalline calcium aluminate phases $Ca_3Al_2O_6$ (C3A), $CaAl_2O_4$ (CA), and $CaAl_4O_7$ (CA2) (the C3A, CA, and CA2 terminology uses the standard notation for cements where C = CaO, A = Al_2O_3) were prepared by melting the appropriate quantities of Al_2O_3, $CaCO_3$, and SiO_2. Approximately 100 g of the stoichiometric mixtures of $CaCO_3$–Al_2O_3–SiO_2 (Rectapur from Merck) were ground for 1 h under alcohol in an agate mortar. The mixtures were heated slowly to decompose the carbonate and then heated up to 1900 K in covered Pt-alloy crucibles for a few hours in equilibrium with air. The samples were quenched in a few sec-

 doi:10.1139/V07-071 © 2007 NRC Canada

onds from high temperature by dipping the bottom of the platinum crucible into distilled water. The crushing, heating, and quenching were repeated four times for each sample and corresponds to heating the samples to 1950 K for 24 h. The crystals were then obtained by thermal treatment near the glass-transition temperatures. All crystals were characterized by X-ray diffraction, electron microprobe analysis (Camparis Center, Paris), and by Raman spectroscopy (JY64000, 514.5 Å). The experimental details of the characterization techniques are given in ref. 4.

The O K-edge spectra were recorded on the SGM beamline at the Canadian Light Source (CLS), University of Saskatoon. The beamline at CLS has three gratings with line spacings of 600, 1100, and 1700 lines/mm, which extend the photon region from 250 to 2000 eV. The energy resolution is approximately 0.05 eV at the O K-edge. The photon flux at 100 mA is 10^{12} photons/s, and the beam size is <1 mm (horizontal) × 100 μm (vertical) (6). The monochromator step size was varied between 0.05 and 0.1 eV to maximize the signal-to-noise ratio, and the scan rate was adjusted according to the step size, based on a scan rate of 0.858 eV min^{-1} for a step size of 0.1 eV. The spectra were collected simultaneously in both fluorescence yield (FY) and total electron yield (TEY) modes, with the latter measured by current yield. Incident photon energy was calibrated at the start of the experimental run using nitrogen (N_2). All samples were crushed, ground, and mounted on carbon tape immediately prior to analysis. The energy ranges of all spectra have been calibrated using the first sharp peak in the O K-edge spectrum of rutile TiO_2 at 531.1 eV. Peak positions are accurate to ±0.1 eV. A background subtraction has been applied using a Victoreen or polynomial function fitted to the pre-edge region. In addition, each spectrum has been normalized to the peak with maximum intensity and with the same intensity scale.

Crystalline calcium aluminates

The structure of $CaAl_2O_4$ (CA) has been determined by Horkner and Muller-Buschbaum (7). It is a tridymite-like structure with AlO_4 tetrahedra making up six-membered rings. Calcium atoms occupy cavities within the fully polymerized AlO_4 network. There are three Ca sites of which two have Ca in octahedral coordination, while the third has Ca bonded to nine oxygens. The AlO_4 tetrahedra are all fully interconnected (Q^4) (Q^n species where n = the number of bridging oxygens). $CaAl_4O_7$ (CA2) has a feldspar-like structure with calcium occupying large cavities within the interconnected AlO_4 tetrahedra (8). Calcium is in a seven-coodinated site, while the aluminium atoms are in tetrahedral sites. The AlO_4 tetrahedra are all Q^4 species, although one of the oxygen atoms is bound to three AlO_4 tetrahedra forming an oxygen tricluster. The structure of $Ca_3Al_2O_6$ (C3A) has been determined by Mondal and Jeffery (9). It consists of puckered six-membered rings of AlO_4 tetrahedra with Ca atoms occupying the holes between the rings. There are two types of slightly distorted AlO_4 tetrahedra that make up the rings; each type alternates around the ring and is a Q^2 species. There are six different Ca sites with three of them containing Ca in six-fold coordination and one each in seven-, eight-, and nine-fold coordination (9).

The O K-edge XANES spectra for the three calcium aluminates are shown in Fig. 1. The FY spectrum for CA (Fig. 1*a*) is comparable to that of Jiang (10); peaks *b*, *c/d*, and *e* of Fig. 1 are the equivalent peaks *a*, *b*, and *c* of Jiang (10) shown in the inset. However the XANES spectrum is of much higher resolution than the ELNES (Electron-loss near-edge spectroscopy) spectrum (10) and exhibits a number of additional peaks not observed in the ELNES spectrum (peak positions are given in Table 1).

The TEY and FY CA spectra are comparable. However, in the TEY spectrum the pre-edge peak (peak *a*) is increased in intensity, while the intensities of peaks *b* and *e* are reduced. In addition, the asymmetry in the FY spectrum at peaks *b′* and *c* is also less apparent. Jiang and Spence (11) assign the pre-edge peak, which is also observed in complex oxides, to π* O–O transitions induced by radiation damage from the incident beam. The reduced intensity of peak *b*, relative to peak *c*, is also attributed to beam damage (Jiang; personal communication), and the increased intensity of the pre-edge peak in the TEY spectrum would support this radiation-induced mechanism. Jiang (10) has carried out theoretical calculations, which show that peak *b*, *c/d*, and *e* are due to O 1s to O 2p antibonding states mixed with s, p, and d orbitals of the cation to which the O is bound. These results are similar to those of other studies involving the O K-edge (1–3, 12). For the $CaAl_2O_4$ phase, the transitions are dominated by states associated with the Ca. Jiang (10) assigns peak *b* to transitions involving oxygen and the nine-coordinated Ca site, and peaks *c* and *e* to oxygen and both calcium and aluminium sites. Furthermore, he suggests that peak *c* should show some asymmetry because of the presence of the two types of Ca sites: the nine-fold Ca site will be at lower energy than the six-fold Ca site. Figure 1 shows that peak *b* of ref. 10 actually consists of three peaks (labelled *b′*, *c*, and *d*). Following ref. 10, we can assign peak *b′* to transitions involving the nine-fold coordinated Ca site. We could then assign peak *c* to the six-fold Ca site and peak *d* to transitions involving Al. However, an assignment of peak *c* to transitions involving Al rather than Ca seems more likely. This is because the O K-edge spectrum of CA2 with increased Al content exhibits higher intensity for peak *c* relative to peak *d*; the latter being more intense in the C3A spectrum.

Peaks *f*, *g*, and *h* are not shown in the study of Jiang (10). However, Mizoguchi et al. (13) have used overlap population diagrams to assign peaks in ELNES and XANES spectra of MgO. Since the O K-edge XANES is dominated by transitions involving the oxygen and Ca, we can use the study of ref. 13 to help assign the higher-energy peaks of Fig. 1*a*. Following Mizoguchi et al. (13), it seems likely that peaks *g* and *h* arise from similar peaks observed in the O K-edge spectrum for MgO (see Fig. 7 of ref. 13). If so, then we can assign peak *g* to transitions of O 2p antibonding states mixed with Ca and Al p orbitals and peak *h* to similar transitions involving Ca and Al d states. The shoulder on peak *g* (peak *f*) may be due to transitions involving Ca and (or) Al orbitals.

The spectrum for CA2 is shown in Fig. 1*b*, and peak positions are given in Table 1. The spectrum is qualitatively similar to that of CA but with subtle differences. Peak *b* is shifted to higher energy by ~0.5 eV. The shift by ~0.5 eV to higher energy is consistent with the shift in energy calcu-

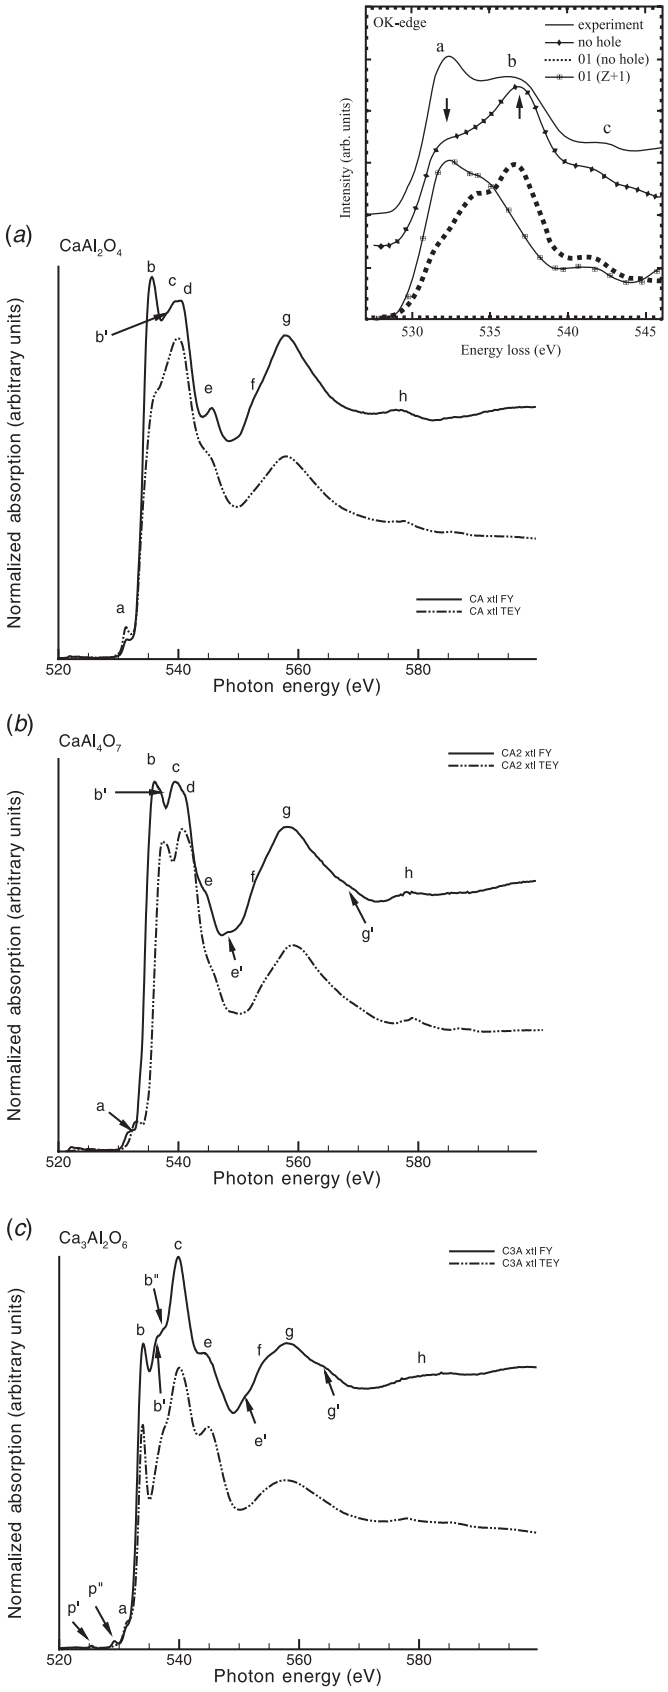

Fig. 1. O K-edge spectra of calcium aluminate phases: (*a*) CA ($CaAl_2O_4$), (*b*) CA2 ($CaAl_4O_7$), and (*c*) C3A ($Ca_3Al_2O_6$). Peak positions are given in Table 1.[3] The peaks *a*, *b,* and *c* in the inset are comparable to peaks *b*, *c/d*, and *e* of the CA spectrum.

lated by Jiang (10) for a change in coordination of Ca. As noted earlier, Ca is nine- and six-fold coordinated in CA but only seven-fold coordinated in CA2. The peak labelled *b′* at 537.0 eV is not equivalent to the peak *b′* (537.8 eV) observed in the CA spectrum. Its appearance, coupled with an increase in intensity of peak *c* relative to peak *d*, suggests that both peaks *b′* and *c* in the CA2 spectrum are due to interactions involving Al not Ca. Peak *e* has also moved to lower energy and been reduced in intensity, although a small weak peak *e′* is observed prior to peak *f*. Peaks *f*, *g*, and *h* are essentially unchanged except for the appearance of a weak shoulder *g′* on the high energy side of peak *g*. The TEY and FY spectra for CA2 are similar, but the pre-edge peak *a* is increased in intensity in the TEY spectrum as is peak *c* (relative to peaks *b* and *d*), while the intensity of peak *e* is greatly reduced in the TEY spectrum

The TEY and FY spectra for C3A are shown in Fig. 1*c* with peak positions given in Table 1. The FY spectrum exhibits three pre-edge features (peaks *a*, *p′*, and *p″*), and peak *b* has moved to lower energy and sharpened considerably (greatly reduced FWHM). Peak *c* has increased in intensity relative to peak *b* and has smaller shoulders labelled *b′* and *b″*. The TEY and FY are, like those of CA and CA2, qualitatively similar to each other. The TEY spectrum exhibits increased intensity of peaks *a*, *b*, and *e* relative to these peak in the FY spectrum. Furthermore, peak *b′* and *b″* appear to have merged into a broad shoulder, while the two pre-edge peaks labelled *p′* and *p″* have been reduced in intensity.

Discussion

The region between 533–543 eV in the crystalline calcium aluminate O K-edge XANES spectra is complex, consisting of at least six individual transitions due to mixing of the O 2p antibonding states with Ca and Al. More specifically, the complexity arises from the close proximity of peaks due to Al in tetrahedral coordination vs. those due to Ca in nine-, eight-, seven- and six-fold coordination. In addition, for C3A, there is a large proportion of Al in Q^2 species. This means that the Al—O bond distances will exhibit a much broader range than the other two phases because the Al—NBO distances will be shorter than the Al—BO distances, leading to broadening of any Al—O contributions. However, using the analysis of Jiang (10) combined with careful examination of the spectra, some preliminary assignments can be made concerning the origin of some of these peaks.

The C3A structure has six different Ca sites of which three are in relatively regular six-fold coordination, while the other three are in distorted seven-, eight-, and nine-fold coordination. The density of state (DOS) calculations of Jiang (10) indicate that the Ca total DOS occur between 0–11 eV of the edge, while those of Al become more important at en-

g	558.2	Ca/Al	557.9	Ca/Al	557.9	Ca/Al
g′	567.6	Ca/Al			564.7	Ca/Al
h	578.6	Ca/Al	576.6	Ca/Al	582.1	Ca/Al

ergies higher than 11 eV. Furthermore, the shorter Al—O bonds push the unoccupied Al DOS several eV above the unoccupied Ca DOS. As Jiang (10) points out, this causes the intensity of the O K-edge near the threshold region to be dominated by Ca–O interactions. Consequently, we can assign the sharp peak for C3A at 534.0 eV (*b*) and the sharp peak at 535.6 eV (*b*) in the CA spectrum to transitions involving the distorted nine-fold Ca sites. For CA2, the peak at 536.1 eV (peak *b*) can also be assigned to interactions involving Ca; more specifically to Ca in seven-fold coordination.

The peak associated with the nine-fold Ca site in C3A is at lower energy than the nine-fold Ca site in CA because the C3A structure is composed of Q^2 AlO_4 tetrahedra, while CA is exclusively Q^4 tetrahedra. Jiang (14) has shown that the presence of non-bridging oxygens (NBO) will also move the O 2p transition to lower energy relative to the one involving bridging oxygens (BO) by about 0.8 eV, which is in the order of the experimental difference of ~1.6 eV. The C3A FY spectra also have narrower peaks than the equivalent CA and CA2 spectra. The smaller widths of the peaks in the C3A spectrum could be due to the fact that the six-fold Ca sites in the C3A structure are relatively regular compared to CA or CA2 (7–9), and this has also been observed in recent Ca K-edge results (15).

A unique characteristic of the CA2 structure is the presence of oxygen atoms that are shared between three Q^4 aluminium atoms: oxygen "triclusters" (8). The triclusters must contribute to peaks involving Al; however, theoretical analysis of the individual O contributions to the peaks is required to understand the explicit contributions from such triclusters.

The other peak observed in all three spectra that is primarily due to O 2p interactions with Ca is the peak at 539.9 eV (peak *c*) in the C3A spectrum. This peak loses intensity relative to other peaks as the amount of Ca is reduced on going from C3A to CA2. However, analysis of its behavior is complicated by the close proximity of peaks due to Al interactions (see later).

The other peaks in the near-edge region of the spectrum (~535–540 eV) can be assigned to interactions with Al and (or) Ca. The peaks that are due primarily to interactions with Al clearly increase in intensity with the addition of Al_2O_3. In C3A, peaks at 536.5 and 537.4 eV (peaks *b′* and *b″*) are likely due to Al, as the relative intensity (compared with peak *c*) in this region is greatly reduced compared with CA and CA2. The C3A structure has Al atoms bonded to both non-bridging oxygens (NBOs) and bridging oxygens (BO). The Al—NBO bonds will be slightly shorter than the Al—BO bonds, and as a consequence, it is likely that the 2 peaks (*b′* and *b″*) are due to Al–NBO and Al–BO interactions, respectively. However, possible contributions to these peaks from the eight- and seven-fold Ca sites cannot be ruled out without a detailed theoretical analysis. For the CA and CA2 spectra, there is only a single peak in this region due to Al–BO interactions as neither of these structures contains NBOs. The observation of a single peak for CA and CA2, supports the previous assignment to Al interactions for C3A.

In both the CA and CA2 spectra, peaks *c* and *d* are a combination of Ca and Al interactions. As noted before, Jiang (10) assigns the peak at 537.8 eV (peak *b′*) in the CA spectrum to interaction with nine-fold Ca and peaks at 539.4 and 540.4 eV (peaks *c* and *d*) to interactions with Ca and Al, respectively. As we pointed out, the peak at 539.4 eV must be due to Al and not Ca, as it increases in intensity in the CA2 spectrum. For the C3A spectrum, there is also a peak due to Ca interactions in the same energy range (peak *c*). However, the peak due to Ca is shifted to higher energy by ~0.5 eV.

The higher-energy peaks (*e*, *f*, *g*, *h*, and so forth) cannot be unambiguously assigned at the present time without at least some initial theoretical analysis of the orbitals contributing to the mixing between the O 2p states and the cations, and any specific assignments would be highly speculative.

Finally, there are some notable differences between the TEY and FY spectra of the individual crystalline phases. The TEY spectra are more representative of the surface structure compared with the FY spectra. While there are no data for the sampling depths for FY and TEY electrons for the O K-edge, data for the Ti L-edge at 464 eV indicate that the TEY sampling depth is ~ 47 Å (16), and for the FY electrons, it will be significantly higher. We would expect the O K-edge sampling depths to be comparable if not slightly higher given that the study by Frazer et al. (16) used samples coated in Cr, which would further attenuate the sampling depth.

For C3A the TEY spectrum exhibits an increase in the rel-

© 2007 NRC Canada

ative intensity of peak *b*, a reduction in intensity of peak *c* and broadening of peaks *b′* to *c*. The increased intensity of peak *b* suggests that the distorted nine-fold Ca site is more prevalent at the surface. Furthermore, the broadening of the peaks may be related to increased contributions from NBOs, which will be in higher abundance at the surface. A point of interest is that peak *e* increases in intensity and evolves into a well-defined peak in the TEY spectra. This would suggest that the dominant interaction with this peak involves oxygens associated with the nine-fold Ca site.

The CA TEY spectrum exhibits a large reduction in the relative intensity of peak *b*, suggesting that the nine-fold Ca site is not in abundance at the surface. In addition, there is some loss of resolution for peak *e*. This supports the suggestion that interactions with oxygens bound to the higher coordinated Ca site in both the C3A and CA structures are primarily responsible for peak *e*.

The CA2 TEY spectrum, compared with the spectra of the other CA phases, shows much less variation compared with the FY spectrum. There is only a small loss of relative intensity of peak *b* accompanied by a similar loss of intensity in peak *e*. Again, this suggests that peak *e* is associated with interactions involving oxygens associated with the Ca site. However, unlike C3A and CA, the CA2 structure only has Ca in a seven-fold site (cf. nine-, eight-, seven-/six-fold for C3A and nine-/six-fold in CA); consequently, there is no interaction between Ca atoms in different coordination geometries and the oxygen atom, and consequently, there is no preference for one Ca site over another at the surface.

In summary, the O K-edge XANES spectra of crystalline calcium aluminates is complex. The details of the spectra are strongly influenced by the cations to which the oxygen atoms are bound. However, the intense peak in the near edge region can be assigned to interactions involving Ca as can a peak at around 539.9 eV. The exact position of the near-edge peak is influenced by the Q speciation of the Al tetrahedra. Peaks due to the presence of Al can also be assigned in a region between ~536–539.4 eV. A peak due to the presence of Ca is almost co-located with the one due to Al in this region; however, the Ca peak is ~0.5 eV higher in energy.

Pushing the limit of confocal polarized Raman microscopy[1]

François Lagugné-Labarthet

Abstract: Raman microscopy has emerged as a powerful technique to characterize anisotropic materials with submicrometer resolution. The use of polarized light allows one to obtain precise information about the local organization of the relevant molecular groups through the determination of the most probable distribution function. Such polarization analysis can be conducted under a confocal microscope, but caution must be exercised because of the use of objectives of high numerical value. The molecular orientation can be effectively correlated with the topography of the sample when atomic force microscopy experiments are conducted on the same object. In the present review paper, we present Raman imaging results that have been conducted on mesostructured polymer surfaces and on a single isolated semiconductor nanowire.

Key words: Raman spectroscopy, confocal microscopy, orientation parameters, azopolymers, nanowires.

Résumé : La spectroscopie Raman présente des avantages considérables pour identifier des systèmes moléculaires anisotropiques avec une résolution spatiale inférieure au micromètre. Les propriétés de polarisation de la lumière offrent en outre la possibilité de déterminer précisément l'orientation la plus probable des groupes moléculaires ainsi que de la fonction de distribution associée. De telles mesures peuvent être conduites avec un microscope confocal mais il est alors nécessaire de tenir compte de l'utilisation d un objectif a grande ouverture numérique. L'orientation moléculaire locale peut dès lors être corrélée à la topographie de surface grâce a des mesures annexes en microscopie a force atomique. Dans ce manuscript de revue nous reportons les résultats de notre groupe en imagerie Raman polarisée sur des films de polymères mésostructurés et sur des nanofils semiconducteurs isolés.

Mots-clés : spectroscopie Raman, microscopie confocale, paramètres d'orientation moléculaire, polymères azoïques, nanofils.

Introduction

The macroscopic properties of a material often depend on the degree of local organization and interactions of its elemental molecules. The electrical, mechanical, tribological, optical, and biological functions are strongly influenced not only by the composition of its intrinsic atomic composition, but also by the local orientation and interactions of the molecular arrangements. Such factors are of importance in surface science where the orientational properties of a single monolayer can determine the properties of the surface. For example, surface anisotropy is of great importance in the field of liquid crystal displays, where a rubbed polymer surface will induce an homogenous alignement of liquid crystal molecules deposited on its surface. This is also the case in materials science where the bulk anisotropic growth direction of a crystal will influence the optical and conductive properties of the final material.

In this context, it is important to precisely assess orientation information in organized systems and to give an accurate representation of the distribution of the anisotropic molecular entities. Vibrational spectroscopy plays an important role since it allows one to quantify the ordering of an anisotropic system at a molecular (vibrational) level. In uniaxial systems where the orientation of a molecule or a functional group is only determined by a single angle θ, polarized IR spectroscopy can provide relevant information through the measurement of the second-order parameter, $\langle P_2 \rangle = 1/2\ (3\ \cos^2\theta - 1)$ (1, 2). In Raman spectroscopy, both order parameters $\langle P_2 \rangle = 1/2\ (3\cos^2\theta - 1)$ and $\langle P_4 \rangle = 1/8\ (35\cos^4\theta - 30\cos^2\theta + 3)$ can be measured and then combined in a distribution function $f(\langle P_2 \rangle, \langle P_4 \rangle)$ to describe more accurately the orientation of active molecular groups (3, 4). These order parameters are determined by performing Raman polarized measurements where both input polarized and analyzer direction are properly selected.

Raman spectroscopy can also be combined with a confocal optical microscope, keeping the polarized flexibility. The spatial resolution of Raman measurements combined with a confocal microscope will be limited to the diffraction limit of light, $1.22\ \lambda$/N.A., where λ and N.A. are the excitation wavelength and the numerical aperture of the microscope objective, respectively. When the laser spot is tighly focussed, one must be careful with the polarized properties of the excitation laser beam and backscattered Raman signal, since the use of a high numerical aperture objective modifies the propagation path of the coupled light. Raman imaging

 doi:10.1139/V07-094 © 2007 NRC Canada

with high spatial resolution can be performed on isolated objects that are smaller than the wavelength. In such experiments great care must be taken with the positioning and scanning of the sample in low vibration environments and with high-precision and reproducible piezoelectric stages. Here again, polarized Raman imaging can be performed giving information on the molecular orientation or directions of the molecular vibrations.

In this paper we review two examples of our recent work emphasizing Raman imaging in confocal microscopy. The first example concerns the study of anisotropic azobenzene polymers. Polarized Raman measurements have been conducted to determine the local orientation of the side chain azobenzene chromophores on micrometer-scale diffraction gratings. The second example shows the imaging capability of a state-of-the-art Raman confocal microscope on a single gallium nitride nanowire.

Polarized Raman imaging of polymer mesostructures

Azobenzene polymers that are substituted in the 4-4′ positions with electron-donating (-NH_2) and electron-accepting (-NO_2) groups possess intense electronic transitions in the visible region. Under irradiation with a linearly and resonant polarized light, the azobenzene side chain chromophores undergo efficient trans–cis photoisomerization and angular reorientation from a $trans_{//}$ to a $trans_{\perp}$ isomer, where // and ⊥ refer to the parallel and perpendicular directions with respect to the polarization of the actinic field (5–7). This property leads to a birefringent–dichroic uniaxial material with preferential orientations of the chromophores perpendicular to the polarized direction of the polarized light (8, 9). In addition, it is also possible to modulate the surface of such azopolymer thin films upon irradiation with an interference pattern, leading to the formation of surface relief diffraction gratings with large diffraction efficiency (8, 10). In the present study, the authors have focused their attention on a grating with 25% efficiency that was holographically inscribed on an azopolymer thin film and then electrically poled using an intense DC field (11, 12). The surface relief amplitude of the grating was about 390 nm as measured by atomic force microscopy, which corresponds nearly to the initial thickness of the film. The poling experiment was conducted to generate nonlinear optical properties of the thin grating by creating a noncentrosymetric arrangement of the chromophores within the grating.

General methods and theoretical approach

The grating was first inscribed using the (p+p) polarized (where p indicates an in-plane polarized beam) configuration, which is known to be very efficient to lead to highly diffractive gratings (11, 13). In such a polarized configuration, the resulting optical field from the interference pattern is always polarized along the same direction, i.e., perpendicular to the grating grooves, which implies that the resulting molecular reorientation of the chromophores would always be in the same direction after $trans_{//}$–cis–$trans_{\perp}$ cycles. Assuming a uniaxial photoinduced reorientation of the rodlike molecules in the direction perpendicular to the actinic optical field, the azobenzene entities will have the same probability to orient in the in-plane (*Y*) and in the out-of-plane (*Z*) directions that are equivalent in the angular hole burning model (Fig. 1a) (14). For such a uniaxial orientation, the molecular orientation can be described by a unique angle θ between the molecular director and the reference axis, which in the present case is the out-of-plane direction (Fig. 1a, *Z*). In this work, the *Z* direction was chosen as the reference because an electrical poling field (3 KV) was also induced perpendicular to the thin film surface, i.e., along the *Z* direction (11, 15).

Assuming this uniaxial orientation and cylindrical symmetry (the molecules have a revolution symmetry along their long molecular axis), the angular distribution function $f(\theta)$ of the chromophores along the out-of-plane *Z* direction can be described on the basis of the Legendre polynomials using information entropy theory. In this general method, the distribution function is obtained by maximizing the information entropy, and the Lagrange method of undetermined multipliers leads to the normalized function, which includes the second ($\langle P_2 \rangle$) and fourth ($\langle P_4 \rangle$) order parameters.

$$[1] \qquad f(\theta) = \frac{\exp(\lambda_2 P_2(\cos\theta) + \lambda_4 P_4(\cos\theta))}{\int_{-1}^{+1} \exp(\lambda_2 P_2(\cos\theta) + \lambda_4 P_4(\cos\theta)) \mathrm{d}(\cos\theta)}$$

and where the coefficients $\langle P_2 \rangle$ and $\langle P_4 \rangle$ are given by,

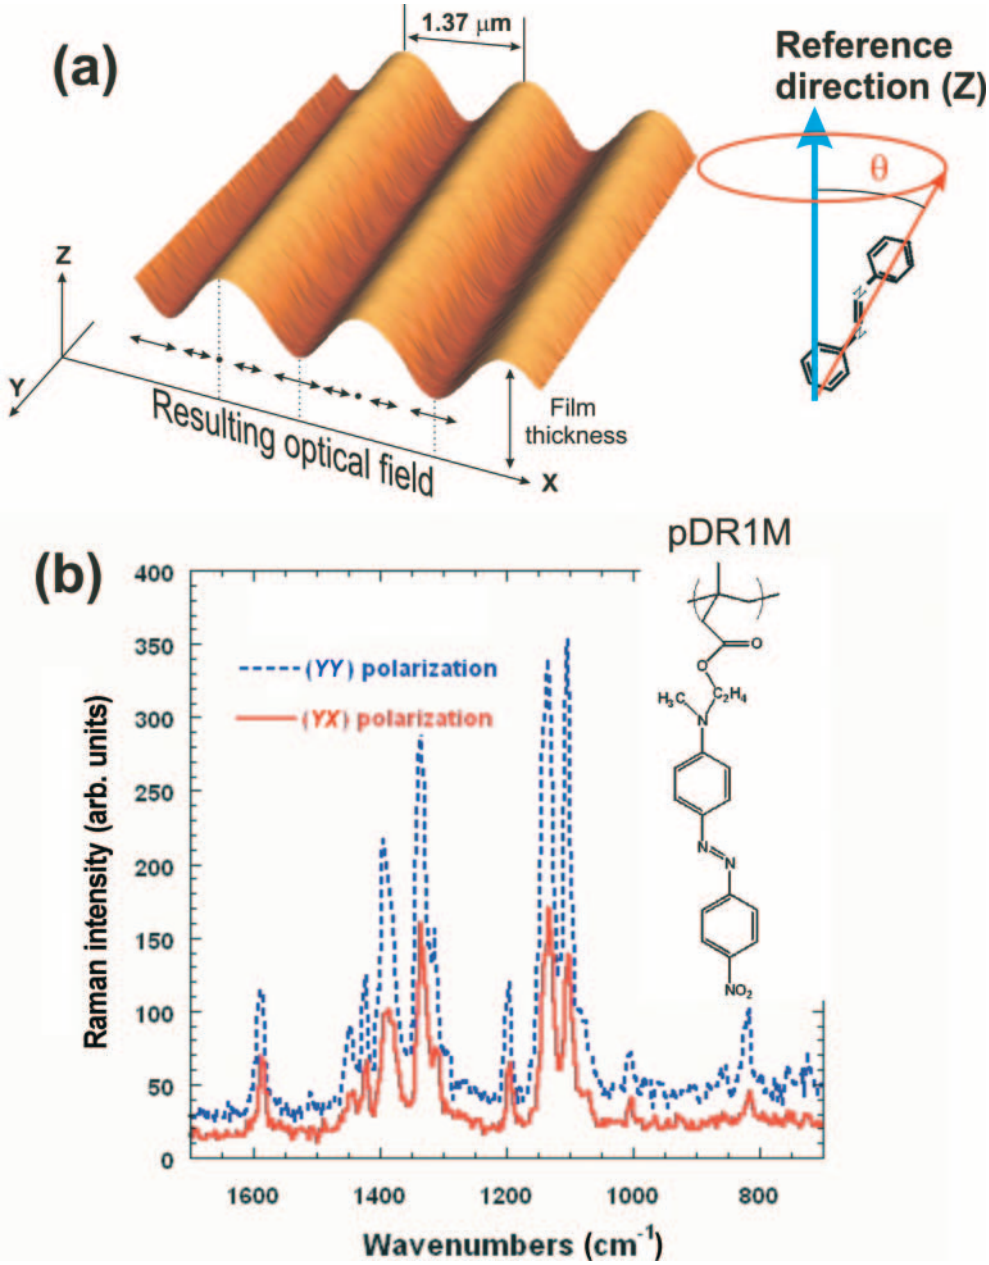
$$[2] \qquad \langle P_2 \rangle = \int_{-1}^{+1} P_2(\cos\theta) f(\theta) \mathrm{d}(\cos\theta)$$

$$\langle P_4 \rangle = \int_{-1}^{+1} P_4(\cos\theta) f(\theta) \mathrm{d}(\cos\theta)$$

with

$$[3] \qquad P_2(\cos\theta) = \frac{1}{2}(3\cos^2\theta - 1)$$

$$P_4(\cos\theta) = \frac{1}{8}(35\cos^4\theta - 30\cos^2\theta + 3)$$



The resulting distribution function can be derived knowing the experimental $\langle P_2 \rangle$ and $\langle P_4 \rangle$. The Lagrange multipliers λ_2 and λ_4 are numerically calculated using eqs. [1] and [2]. The normalized distribution function $f(\theta)$ can be determined for the various area of the gratings where $\langle P_2 \rangle$ and $\langle P_4 \rangle$ have been determined.

The theoretical expressions of polarized Raman intensities, taking into consideration the use of a large N.A. microscope objective, have been exhaustively detailed for gratings inscribed with a (p+p) interference pattern. We recall here the essential expressions to obtain $\langle P_2(\cos\theta) \rangle$ and $\langle P_4(\cos\theta) \rangle$. In previous studies, the two first even order parameters were determined relative to the actinic field polarization, which is along *X* for (p+p) interference pattern (16). However, to compare these parameters with nonlinear optical measurements, a common axis which corresponds to the *Z* or *Y* directions is selected as a proper reference (Fig. 1*a*).

The polarized Raman intensities depend on the average over all orientations in space (17),

Fig. 1. (a) Components of the incident optical field upon grating inscription using the (p+p) polarized configuration of the interfering beams and angular distribution of the azo chromophores relative to the reference direction. (b) Polarized *YY* and *YX* polarized Raman spectra of a pDR1M polymer thin film in the 700–1700 cm^{-1} spectral range.

[4] $$I_{ij} \propto I_0 \langle \alpha_{ij}^2 n_T \rangle$$

where *i*, *j* denote the input and analyzer polarized directions, respectively, and α_{ij} the molecular polarizability tensor elements, and where the quantities,

[5] $$\langle \alpha_{ij}^2 n_T \rangle = \int_0^{2\pi} d\psi \int_0^{2\pi} d\varphi \int_{-1}^{+1} n_T(\theta)[\mathbf{T}(\theta,\varphi,\psi)\vec{\alpha}\mathbf{T}^t(\theta,\varphi,\psi)]^2 d(\cos\theta)$$

are calculated using the normal **T** and transposed $\mathbf{T}^t$ classical Euler matrices. Since the integral involves only the angle θ, the averaged quantities $\langle \alpha_{ij}^2 \rangle$ can be expressed in terms of $\langle \cos^2 \theta \rangle$ and $\langle \cos^4 \theta \rangle$, thus $\langle P_2 \rangle$ and $\langle P_4 \rangle$. In the rigorous treatment, the use of a high N.A. objective must be taken into account. For the grating grooves oriented along the polarized direction of the input beam (along *Y*), we arrive in a first set of experiments with the general intensity equations,

[6] $$I_{YX} = [\langle \alpha_{YX}^2 \rangle A + \langle \alpha_{YZ}^2 \rangle B](2C_0 + C_2) + [\langle \alpha_{ZX}^2 \rangle A + \langle \alpha_{ZZ}^2 \rangle B](4C_1) + [\langle \alpha_{XX}^2 \rangle A + \langle \alpha_{XZ}^2 \rangle B]C_2$$

$$I_{YY} = [\langle \alpha_{YY}^2 \rangle A + \langle \alpha_{YZ}^2 \rangle B](2C_0 + C_2) + [\langle \alpha_{ZY}^2 \rangle A + \langle \alpha_{ZZ}^2 \rangle B](4C_1) + [\langle \alpha_{XY}^2 \rangle A + \langle \alpha_{XZ}^2 \rangle B]C_2$$

© 2007 NRC Canada

In the second set of experiments, the grating is rotated under the microscope with its grooves oriented in the perpendicular direction to the input polarized giving,

$$[7]\quad I_{XY} = [\langle\alpha^2_{XY}\rangle A + \langle\alpha^2_{XZ}\rangle B](2C_0 + C_2) + [\langle\alpha^2_{ZY}\rangle A + \langle\alpha^2_{ZZ}\rangle B](4C_1) + [\langle\alpha^2_{YY}\rangle A + \langle\alpha^2_{YZ}\rangle B]C_2$$

$$I_{XX} = [\langle\alpha^2_{XX}\rangle A + \langle\alpha^2_{XZ}\rangle B](2C_0 + C_2) + [\langle\alpha^2_{ZY}\rangle A + \langle\alpha^2_{ZZ}\rangle B](4C_1) + [\langle\alpha^2_{YX}\rangle A + \langle\alpha^2_{YZ}\rangle B]C_2$$

with

$$[8]\quad A = \pi^2 \int_0^{\theta_m} (\cos^2\theta + 1)\sin\theta\, d\theta = \pi^2\left(\frac{4}{3} - \cos\theta_m - \frac{1}{3}\cos^3\theta_m\right)$$

and

$$B = 2\pi^2\left(\frac{2}{3} - \cos\theta_m + \frac{1}{3}\cos^3\theta_m\right)$$

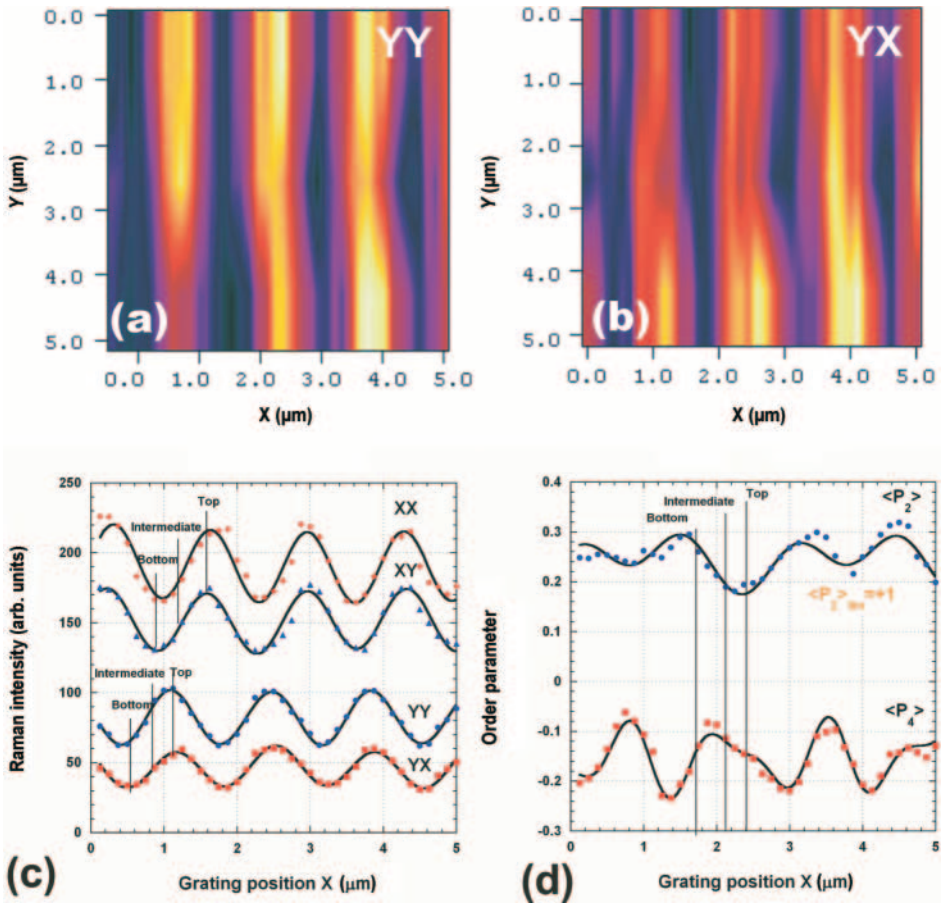
Here, the expressions A and B come from the integrations of the squares of the electric vector components over the scattering cone, and the constants $C_0 = 5.3825$, $C_1 = 0.1424$, and $C_2 = 5.10^{-4}$ are related to the focalization efficiency and are calculated via the integration of the incident electric field vector components over the effective irradiated volume (18). All these parameters are dependent on the angular semi-aperture of the objective ($\theta_m = 64.16°$ for the 100×, N.A. = 0.9 microscope objective) and the refractive index of the sample n ($n = 1.645$).

Finally, knowing the intensities I_{ij} in the different parts of the grating (δ) and their ratio $R_1(\delta) = I_{XY}/I_{XX}$, and $R_2(\delta) = I_{YX}/I_{YY}$, the two first even order parameters, namely $\langle P_2\rangle$ and $\langle P_4\rangle$, can be estimated.

From the Raman polarized spectra experimentally measured ($\lambda_{excitation} = 752.5$ nm) in the 700–1700 cm^{-1} spectral domain and shown in Fig. 1b, we integrate a particular vibrational mode whose orientation is well known. The $\upsilon_s NO_2$ mode is oriented along the long molecular axis of the trans-shaped azobenzene chromophore and is thus a good probe to estimate the orientation of the rod-shaped azobenzene chromophore. The other modes at 1104 cm^{-1} (υ-N, υ18a), 1134 and 1196 cm^{-1} (δCH ring, υ9a and υ9b), 1392 cm^{-1} (υN=N), and 1589 cm^{-1} (ωC=C, 8a and 8b) are also characteristic of the trans azobenzene chromophores, but their directions are less unidirectional than $\upsilon_s NO_2$. In the following we have arbitrarily selected the whole 1044–1180 cm^{-1} spectral range to calculate the polarized intensities I_{ij}, their ratios $R_1(\delta)$ and $R_2(\delta)$, and finally the order parameters $\langle P_2\rangle$ and $\langle P_4\rangle$. As illustrated in Figs. 2a and 2b, we have thus obtained the polarized Raman images over a (5 μm)^2 area for *YY* and *YX* polarizations, respectively. Under these conditions, the variations over several grating periods of the average polarized Raman intensities are plotted in Fig. 2c for the full set of input and output polarizations. The variation of the final order parameters $\langle P_2\rangle$ and $\langle P_4\rangle$ along the position on the grating are reported in Fig. 2d.

Discussion

First, the $\langle P_2\rangle$ order parameter varies from +0.228 (bottoms) to +0.266 (tops). As expected, these values are positive, but they denote an orientational ordering along the Z reference direction that is far from perfect. For a perfect alignment one should expect $\langle P_2\rangle = 1.0$, since θ would be 0. In contrast, the parameter $\langle P_4\rangle$ is always negative and varies markedly from –0.067 (bottoms) to –0.230 (tops); the influence of $\langle P_4\rangle$ is thus preponderant on the shape of the distribution function. Actually, using only the sets of $\langle P_2\rangle$ and $\langle P_4\rangle$, the polar distribution functions (Fig. 3) are asymmetric and display maxima at ±34° (bottoms), ±39° (intermediates), and ±42°(tops) with respect to the direction of reference. Also, the distribution function in the top regions is significantly narrower than in the bottom regions (the full width at half maximum, fwhm, varies from ±28° to ±60°); this probably indicates the existence of increasing force and pressure constraints during the peak relief formation and during the related chromophore diffusion mechanisms. Because of the large force gradients during the isomerization cycles and the angular reorientations, the chromophore orientation distributions appear significantly perturbed by the polymer migration from areas of high field intensity (that correspond to the bottoms of the grating) to area of lower field intensity (tops of the grating).



As a demonstration of high-resolution Raman confocal imaging on mesostructured polymer thin films, both atomic force microscopy surface topography and Raman images were conducted on superimposed surface relief gratings (Fig. 4). Raman measurements were recorded with a Labram HR 800 (Horiba, Jobin-Yvon) spectrometer combined with an inverted microscope (Olympus IX 71), and an X,Y Piezoelectric stage to position the sample for the best accuracy and repeatability. A 100× 0.9 NA microscope objective was used. A Raman spectrum (Fig. 4c) was recorded every 100 nm along the X and Y directions with an integration time of 5 s per spectrum ($\lambda_{excitation} = 752.5$ nm). The variation of the Raman signal was integrated over the 1060–1180 cm^{-1} spectral domain (Fig. 4d). It must be pointed out that details on the Raman profile are obtained with a spatial resolution better than $\lambda/2$.

Polarized Raman microscopy of single nanostructures

One-dimensional semiconductor nanowires of gallium nitride (GaN) are prime candidates for future nanoscale devices, such as blue laser and high-power and high-temperature electronics (19). Significant advances in nanostructure synthesis allows controlling not only the size but also the crystallographic orientations of the nanostructure by properly choosing the best substrate with matching lattice constants. GaN wires grown on a (100)-$LiAlO_2$ substrate have their [001] axis perpendicular to the growing direction and display a triangular cross-section, while wires grown on (111)-MgO have their growing axis along the [001] direction with an hexagonal Wurzite-type lattice (19). Consequently, it is of importance to measure the homogeneity and the composition of such nanowires at the individual scale and to correlate them with the dimensions and optical properties of these strongly anisotropic materials. In this context, trans-

mission electronic microscopy (TEM) and scanning electron microscopy together with electron diffraction play an important role to characterize individual nanowires with an unprecedented resolution. However, optical microscopy and spectroscopy are also able to play a key role in diagnostics that go far beyond visualizing the physical shape of nanoobjects. Molecular optical spectroscopy, such as Raman scattering, can be very helpful to probe the crystallinity, mechanical stress, temperature effects, the confinement of phonons modes, or the lattice dynamics in nanocrystals allowing to correlate the optical measurements with the anisotropy of the nanowire (20). In addition, these optical techniques can be easily implemented in synthesis reactors to monitor in situ and in real time the growing process of the nanoobjects. Raman confocal microscopy has a spatial resolution of roughly one third the excitation wavelength, which often limits its use for the characterization of aggregated bundles of nanowires. However, we have recently shown that polarized imaging of individual isolated nanowires is possible.

General methods

As reported by Lagugné-Labarthet and co-workers (20), a single [001] nanowire with a Wurtzite-like hexagonal cross-section was first cut and positioned on a microscope glass slide (Fig. 5). Atomic force microscopy (AFM) reveals a diameter of about 170 nm and a length of 41 μm. The Raman setup is based on an inverted microscope combined with a spectrometer (grating 600 grooves/mm, resolution 4 cm^{-1}). The sample is scanned with a piezoelectric stage with an intrinsic accuracy of 1 nm in the lateral directions. The light beam input excitation wavelength was fixed at $\lambda = 514.5$ nm from an Ar^+ ion laser and the input polarized was selected with a half-waveplate. Focussing on the sample was done with a 100× objective (NA = 0.90), and the Raman signal was collected under the backscattering geometry. A polarizer serves as an analyzer just in front of the entrance slit of the spectrometer. The laser intensity was fixed to 10 mW at the focal point. The depolarization ratios were checked with a reference sample of liquid CCl_4. The pinhole of the confocal microscope was closed to about 140 μm, which corresponded to a focal volume of about 1 μm^3, limiting significantly the background signal of the glass substrate. The detector was a liquid nitrogen cooled CCD camera and acquisition time was fixed to 1 s/spectrum in the imaging mode, while an acquisition time of 20 s/spectrum was used to record most spectra shown in the present work. Raman spectra under the polarized configurations $Y(ZZ)\bar{Y}$, $Y(XX)\bar{Y}$ and $Y(XZ)\bar{Y}$ are shown in Fig. 5. The nanowire was aligned so that the *Z* polarized direction matches the growing direc-

tion (i.e., the $\vec{c}$ axis) of the nanowire. Y and $\bar{Y}$ are the directions of the input excitation and the backscattered Raman signal, respectively.

Discussion

As reported by various authors for thin films (21, 22) and for bundles of nanowires (23), GaN that crystallizes in the hexagonal Wurtzite-type structure belongs to the space group C^4_{6v} and has two formula units per primitive cell. According to factor group analysis, the Raman active modes are $1A_1(x^2 + y^2, z^2) + 1E_1(xz, yz)) + 2E_2(x^2 - y^2, xy)$, while $2B_2$ modes are silent. Since GaN Wurtzite structure is noncentrosymmetric, both A_1 and E_1 modes can be split into longitudinal optical (LO) and transverse optical (TO) components. For a GaN single nanowire, four main signals are observed at 142, 530, 557, and 568 cm^{-1}, and they can be assigned to E_2(low), A_1(TO), E_1(TO), and E_2(high) symmetry type modes, respectively. In the $Y(XZ)\bar{Y}$ configuration, only E_1(TO) mode is expected, and the peak at 530 cm^{-1} (A_1 (TO)) denotes a polarization leak. The polarized spectra shown in Fig. 5 allow unambiguous assignments, which is in a good agreement with previous work on GaN thin films (23). Mapping of the nanowire was performed by recording step-spectra at every 200 nm with an integration time of 1s. Such a short acquisition time was required to rule out any thermal effects because of the high laser power. By intensity integration of the 509–552 cm^{-1} spectral domain around the A_1(TO) mode (530 cm^{-1}), the variations of the Raman signal over the full nanowire are investigated. The images shows an excellent lateral resolution better than 200 nm, with a reasonable acquisition time of about 1 h for a polarized image. For the $Y(ZZ)\bar{Y}$ polarized configuration, Fig. 6a shows that the signal is maximum on the straight portions of the nanowire, while it almost disappears on the bent portion of the nanowire. The geometric complementary image (Fig. 6b) is obtained by integration of the E_2 (high) mode at 568 cm^{-1}. In the $Y(XX)\bar{Y}$ polarized configuration, the opposite spectroscopic contrast is observed with a maximum signal of the 568 cm^{-1} mode in the straight portions of the wire, as observed in Fig. 6c, and a maximum signal for the A_1 mode in the horizontal part of the nanowire.

Under this scattering configuration, the optical longitudinal phonon modes were not observed. To complement these polarized spectra, nonpolarized spectra of the end face of an upright GaN nanowire grown on MgO were recorded. Actually, two nanowires stuck together can be seen on Fig. 7, along with the corresponding Raman image integrated over the most intense peak at 568 cm^{-1}. A totally similar spectrum was observed for a single nanowire, which excludes any coupling effects between the two nanowires. In addition to the phonon modes observed earlier, additional broader peaks are detected at 256, 318, 421, 660, and 731 cm^{-1}. The latter can be assigned to the LO type mode of A_1 symmetry (23). The origin of the peaks at 318 and 421 cm^{-1} arises from second-order Raman effects, providing information of the vibrational states over the Brillouin zone; they are assigned to overtone processes of acoustic phonons (24–26). As suggested in previous experimental and theoreti-

cal branch produces a peak in the phonon density of states around 250 cm^{-1} (24). It is noteworthy that this peak is observed only from the extremity of a single nanowire but never when the nanowire is flat on the surface. This allows us to conclude that finite-size effects, defects, and phonon confinement phenomena can only be observed at the end(s) of the nanowires. The broad peak at 660 cm^{-1} is observed for both the nanowire extremities and also for the $Y(ZZ)\bar{Y}$ polarization.

As reported by Liu et al. (23), this broad peak is presumably due to a defect state with an energy close to the A_1 (LO), or it can be tentatively assigned to the first overtone of a B_1 silent mode. Furthermore, Raman measurements were also performed on an isolated GaN nanowire grown using the chemical vapour transport synthetic approach (CVT). The wire has a cylindrical cross section with its $\vec{c}$ axis oriented perpendicular to the growing direction $[1\bar{1}0]$. Because of the cylindrical symmetry of the nanowire, the angular position of $\vec{c}$ relative to the substrate plane is not known (Fig. 8a). For $Y(XX+XZ)\bar{Y}$ spectra (Fig. 8c), the input polarization is along the growth direction and no analyzer was used. Only the two E_2 modes (low and high) can be observed at 143 and 568 cm^{-1}, respectively. With an orthogonal polarization input relative to the growth direction, $Y(ZZ+ZX)\bar{Y}$, only E_1 and E_2(high) at 559 and 568 cm^{-1}, respectively, can be observed. It is noteworthy that the A_1 (TO) mode is not clearly defined, and only a broad background can be observed in Fig. 8c. These observations exclude an orientation of the $\vec{c}$ axis in the direction perpendicular relative to the substrate plane (i.e., along the propagation direction of the probe beam) where A_1 mode should be observed along with E_2. Also, the $\vec{c}$ axis cannot be oriented along the substrate plane, as shown in Fig. 8a where A_1 mode should also be observed together with E_1. This is certainly due to a peculiar orientation of the $\vec{c}$ axis, which presumably has a tilted angle with respect to the substrate plane. Because of the $[1\bar{1}0]$ growing direction of this nanowire, the c axis is possibly tilted at an angle of about $\theta = \pm 45°$ relative to the substrate plane. In addition, one must point out that even for the [001] nanowire the A_1 mode is very weak compared with the intensity of the E_2 (high) mode (Fig. 5). This may be an additional source to account for the absent A_1 mode. For such a configuration, only the E_2 modes are expected to be the strongest ones. This emphasizes the tremendous advantage of Raman spectroscopy, allowing to assign not only the crystalline structure of an individual nanowire but also to determine the most probable orientation of its crystallographic axes.

The high spatial resolution of the modern Raman confocal instrument together with a piezoelectric stage demonstrates unambiguously the possibility to image the optical properties of nanoobjects with a resolution better than 200 nm,

keeping the full control of polarized analysis. With the help of a higher resolution spectrometer, stress-induced shifts and crystallinity modifications at various growing temperatures can be monitored for individual objects.

Summary

In this article, we reviewed two recent examples of polarized Raman measurements conducted by our group on meso and nanoscale objects. The analysis of the polarized measurements was applied to materials such as polymer thin films and inorganic nanostructures. The basis of the theoretical expressions of the polarized intensities as well as the order parameters and associated distribution functions were defined and developed for a given example. The use of a high numerical aperture is also taken into consideration for the microscopic polarized intensities. In the case of nanomaterials, Raman microscopy can provide useful information on the direction of the nanocrystal axes using polarized measurements.

Raman confocal microscopy, in conjunction with polarized analysis recordings, can lead to a better understanding of the optical, mechanical, or biological properties of a sample, emphasizing the importance of using polarized analysis combined with microscopy measurements.

Acknowlegments

The author is grateful to Jean-Luc Bruneel (CNRS, France) and David Talaga (CNRS france) for experimental assistance, and Peidong Yang (UC berkeley, USA) for the nanomaterial project and collaboration.

The contribution of XANES spectroscopy to tribology[1]

M. Nicholls, M.N. Najman, Z. Zhang, M. Kasrai, P.R. Norton, and P.U.P.A. Gilbert

Abstract: X-ray absorption near edge structure spectroscopy (XANES) analysis has been routinely used to study the complex chemical interactions between additives in engine oil and metallic surfaces during high-temperature and pressure reciprocating wear conditions. XANES analysis provides detailed chemical and structural information on the resultant antiwear and tribo films formed on metallic surfaces. The following review will illustrate how XANES analysis on the macro scale can provide the information required to elucidate complex film formation mechanisms, then describes the use of emerging XANES spectromicroscopy to such systems, and concludes by showing the complementary nature of the macro and micro scale spatially resolved XANES analysis; Professor Bancroft has utilized the combination of these to stay at the forefront of XANES research in the field of tribology and in spectroscopy science in general.

Key words: tribology, XANES, X-ray absorption near edge structure spectroscopy, metals, thiophosphates, spectromicroscopy, tribochemistry.

Résumé : L'analyse des spectres de la structure fine d'absorption des rayons X près du seuil (« XANES ») a été utilisée d'une façon routinière pour l'étude des interactions chimiques complexes entre les additifs des huiles à moteur et les surfaces métalliques, dans des conditions de températures et de pressions élevées qui provoquent des usures réciproques. Les analyses de type « XANES » permettent d'obtenir des informations chimiques et structurales détaillées sur les films anti usure/tribo résultants qui se forment sur les surfaces métalliques. La revue qui est présentée ici permettra d'illustrer comment les analyses de type « XANES » à l'échelle macro peuvent fournir l'information requise pour élucider les mécanismes complexes de formation de films et ensuite décrire l'utilisation de la spectromicroscopie de type « XANES » qui se développe à l'étude de tels systèmes avant de conclure en mettant en évidence la nature complémentaire des études de type « XANES » résolues dans l'espace aux échelles micro et macro; la combinaison qui a été utilisée par le professeur Bancroft pour lui permettre de demeurer à la tête des méthodes de type « XANES » dans le champ de la tribologie et dans le domaine de la spectroscopie en général.

Mots-clés : tribologie; « XANES », spectroscopie de la structure fine d'absorption des rayons X près du seuil, métaux, thiophosphates, spectromicroscopie, tribochimie.

[Traduit par la Rédaction]

Introduction

In 1966 the term tribology was coined by the newly formed Committee on Tribology of the British House of Commons. Tribology can be defined as the science and technology of interacting surfaces in relative motion and of related subjects and practices (1). It encompasses a wide variety of topics and is a truly interdisciplinary field of study. One of the core disciplines of tribology is chemistry, termed tribochemistry, and presents a most challenging approach to understanding the history of a rubbing contact, the dynamic nature of the contact, the protective film formation process, and attrition during wear. In one combination or another, a wide range of chemical and analytical techniques have been used to understand the tribochemistry of a system. These include X-ray photoelectron spectroscopy (XPS) (2–7), Auger electron spectroscopy (AES) (8–12), energy dispersive X-ray (EDX) analysis (13–15), IR spectroscopy (16–21), and transmission electron microscopy (TEM) (8, 22).

It is the formulation and study of engine oils and how they decompose in solution and between rubbing contacts that comprises a vast majority of the associated literature on how additives work. Until 1986, X-ray absorption spectroscopy (XAS) was an unexplored technique in the investigation of tribological contacts (23). X-Ray absorption spectroscopy probes the transition of electrons from core states and is particularly useful for low-Z elements (such as C, N, P, O, and S, common elements found in additive molecules). Spectra allow for the collection of a comprehensive

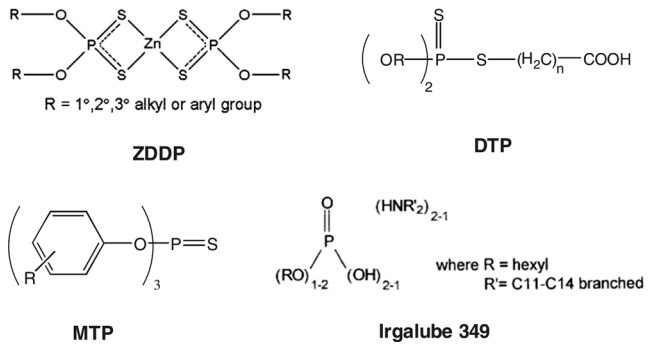
set of data that provide details on geometry, oxidation state, and quantum numbers of the absorbing atom. Chemical changes, which result from the additives breaking down or interacting during rubbing, are observed as changes in the absorption structures in the recorded spectra (24–26).

Advancements in the area of nanotechnology have demanded an improvement in the spatial resolution of many surface analytical techniques, and XAS is not impervious to these pressures. In fact, XAS has welcomed these advancements and has made some very significant strides towards providing spatially resolved chemical speciation to <100 nanometer spatial resolution (27–30). The first use of spatially resolved XAS, termed X-ray photoelectron emission spectromicroscopy (X-PEEM), was published on the reaction films formed from organo-molybdenum compounds in a tribo-contact in 1997 (31). As the technique evolved and improved, many other groups exploited it in the study of tribology (32–36).

The use of XAS, or more specifically X-ray absorption near edge structure (XANES) spectroscopy, and subsequently X-PEEM began to be embraced by the tribology community after a chance meeting at an Ontario Center for Materials Research (OCMR) meeting in 1990. At that meeting G.M. Bancroft and M. Kasrai from the University of Western Ontario (UWO) introduced XANES to a major lubricant manufacturer, Imperial Oil. At that time, Dr. Kim Fyfe from Imperial Oil was looking for a technique that could easily characterize the chemical form of phosphorus and sulfur. After a short explanation and introduction to the approach, which G.M. Bancroft and M. Kasrai were exploiting at that time to investigate the intricate and detailed chemistry of coals and bitumus materials, an almost 10-year relationship began between the UWO and Imperial Oil. This chance meeting has led to the co-authorship of 15 publications by the three researchers and allowed for the crossing of paths with two other very prominent researchers at Chevron, Dr. Elaine Yamaguchi and Ray Ryason in 1994. The collaboration with Chevron continues today with over 15 joint publications. This has established the UWO group as the leading world experts in the study of tribochemistry by XANES spectroscopy, with a total of 55 publications with associates over the last 15 years. At the root of these publications is the ability of XANES spectroscopy to elucidate the lubrication properties of antiwear additives, determine mechanisms by which certain oil additives perform, but also be able to explain their behavior at a fundamental chemical level.

Examples of the type of work performed over the last 15 years will be briefly discussed in this paper to demonstrate the usefulness of XANES in the study of tribochemistry. The first section will highlight the information XANES spectroscopy has provided about the macrochemistry of the tribofilms generated from dialkyl-dithiophosphates (and derivatives thereof) on steel surfaces, and how this information can be used to explain the growth and wear processes experienced in the rubbing contact. The second section will illustrate the more advanced, spatially resolved, microchemical characterization done with X-PEEM. The section will describe how this approach helps to identify the location and chemical speciation of an antiwear film formed on a high silicon content (~18%) aluminum–silicon alloy, which is beneficial to understanding the applicability of such an alloy in a combustion engine. The final section will demonstrate the value of combining XANES and X-PEEM results to comprehensively evaluate both the tribochemical make-up as well as topographical features of lubricious films generated from ashless phosphorus- and sulfur-containing additives. This introduction presents the wealth of information that XANES spectroscopy has provided to the tribology community, and clearly demonstrates how the group at the UWO has maintained their dominance in the field by exploiting its emerging capabilities.

Experimental



Sample preparation and film formation

The steel samples were manufactured from 52100 steel into square specimens 10 mm × 10 mm × 4 mm or 19 mm diameter discs. The composition of 52100 steel is ~1% C, 1.3%–1.6% Cr, and the remainder primarily Fe. The steel samples were polished with 3 μm diamond paste. The aluminum 390 (A390) material was wire electrode discharge machined to create 10 mm × 10 mm × 4 mm samples. The composition range of A390 is ~4%–5% Cu, 16%–18% Si, with small percentages of Mg, Fe, Zn, and Ti. The A390 samples were polished with 0.3 μm alumina and finished with 0.05 μm silica suspension. The reciprocating cylinders were manufactured from 52100 steel, 6 mm in diameter and 6 mm in length. The steel sample and pins were austenitized and quenched. Their hardness was >60 Rockwell C. The pins were used as is.

The antiwear films were formed in a reciprocating Plint wear tester (37) under boundary lubrication conditions with a cylinder-on-flat test geometry establishing a line contact. The test conditions consisted of rubbing times that varied between 10 s and 10 h, at varying temperatures 60–100 °C, with a frequency of 25 Hz, load between 60–220 N, and a 7 mm stroke length. Chemical structures of the additives used in this study are shown in Fig. 1. A ZDDP commercial concentrate was obtained from Imperial Oil Limited, Canada. The concentrate is a mixture of neutral and basic forms, consisting of 85% secondary (C-4) and 15% primary (C-8) alkyls. The concentrate was diluted using MCT-10 base oil to 1.2 mass% resulting in a phosphorus content of ~0.1% by weight. MCT-10 base oil is a mineral oil with a sulfur content of 0.12 mass%. Two different ashless thiophosphate additives were used. The first additive used was an ashless triaryl monothiophosphate and is referred to as MTP. The second additive used was an ashless dialkyldithiophosphate and is referred to as DTP. The lubricant formulation was achieved by dissolving the additive by weight in the low sulfur base stock. The concentrations used in this study were 0.5 wt% DTP and 1.5 wt% MTP, respectively. The antiwear films were stored as is with their oily protective layer. Before insertion into vacuum the samples were thoroughly rinsed in hexanes. The light hydrocarbon rinse has been found not to alter the antiwear film, which is very robust (38, 39). On the X-PEEM samples, a grid composed of indent marks was created using a Vickers hardness tester. This grid allowed for relocation of the same regions with the multiple techniques discussed below.

Surface imaging

Topographical imaging was performed using a Digital Instruments Nanoscope IIIa® atomic force microscope. Images were obtained in constant force mode to investigate the morphology and topography of the blank substrates, wear scars, and antiwear films after formation. A LEO-440 scanning electron microscope with a Quartz Xone Gresham light element detector was used to image the surfaces in field-emission and backscattering modes and to perform X-ray analysis.

XANES and X-PEEM analysis

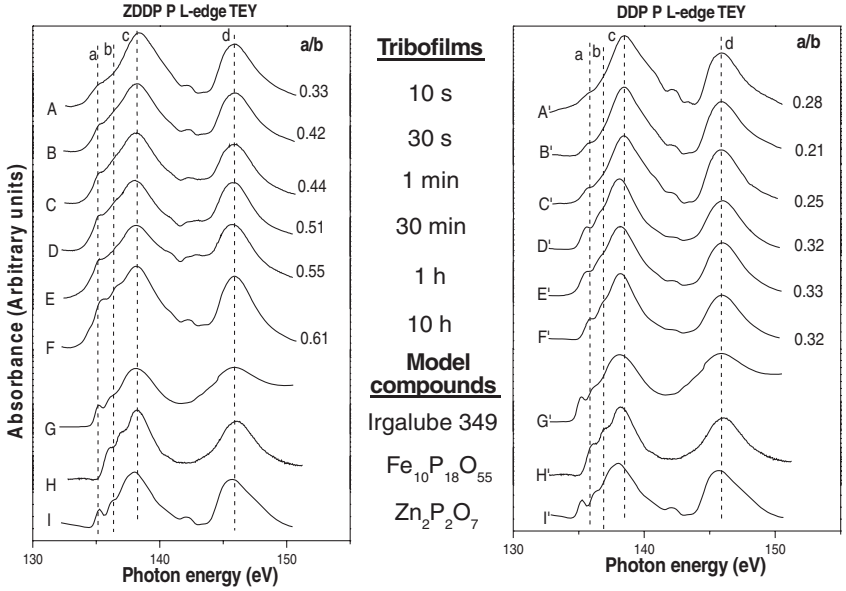
X-ray absorption spectra provide detailed information about the local environment and oxidation state of elements in a film or on a surface. XANES analysis employs the use of soft X-rays making it a nondestructive technique. XANES spectroscopy was performed at the Canadian Synchrotron Radiation Facility at the 1 GeV Aladdin storage ring, University of Wisconsin, Madison. The data were obtained using the Grasshopper beamline, which has a resolution of ~0.1 eV, and the double crystal monochromator (DCM) beamline with a photon resolution of ~0.9 eV. Spectra were recorded using the total electron yield (TEY) and fluorescence yield (FY) detection modes (details of which can be found elsewhere (40)), and represent the information from a surface several square millimetres in area. The sampling depths of the TEY and FY at the P K-edge are 50 nm and >800 nm, respectively (41), and the sampling depths of the TEY and FY at the P L-edge are 5 and 60 nm, respectively (41). These techniques are ideally suited for measuring antiwear films such as these, which are on the order of 50–100 nm thick. At least two individual scans were recorded for each specimen and digitally combined. The spectra were normalized against I_o, and a linear background was subtracted.

X-ray photoelectron emission spectromicroscopy was performed using the SPHINX (42) microscope (ELMITEC GmbH), with an optimum spatial resolution of 10 nm (42), installed on the 6m-TGM (toroidal grating monochromator) beamline at the 1 GeV Aladdin storage ring, University of Wisconsin, Madison, optimized to give ~0.1 eV resolution at the phosphorus L-edge (for details see refs. 32, 43, and 44). Image intensity in X-PEEM is proportional to the TEY, and the surface sensitivity was limited by the escape depth of the secondary electrons at the phosphorus L-edge (3–5 nm) (41, 43). For the phosphorus L-edge region, a "stack" consisting of 301 images were taken over an energy range of 130–160 eV with an energy spacing of ~0.1 eV. A 100 μm field of view was chosen for the selected areas with a resolution of ~200 nm per pixel. Typical areas examined were <10 μm^2. The images were combined to produce a three-dimensional data set or spectromicroscopy movie (29) that was analysed to extract detailed chemical information about the tribofilm using aXis2000 software (28, 45). The data analysis procedure and the obstacles overcome have been described elsewhere (28, 29, 45, 46). Briefly, the aXis2000 software enables the selection of a single pixel, or regions of interest of several pixels in size, from which XANES spectra are extracted. The resulting spectra are averaged over all the pixels contained in the region of interest. Thus, some spectra are the average of a few pixels (usually with poor signal-to-noise) or several tens or hundreds of pixels.

Contributing evidence to the usefulness of XANES in the study of tribolochemistry

As examples of the value of XANES to the study of tribology, this first section will highlight the information that XANES spectroscopy has provided about the macrochemistry of the tribofilms generated from dialkyldithiophosphates. The second section will illustrate the more advanced, spatially resolved, microchemical characterization done with X-PEEM. The final section will demonstrate the value of combining XANES and X-PEEM results to comprehensively evaluate both the tribochemical make-up as well as topographical features of lubricious films generated from ashless phosphorus- and sulfur-containing additives.

A. Study of the tribochemistry of ZDDP and DTP using XANES



XANES measurements have been found to be ideally suited to the chemical studies of these films. First, most of the important elements in these films (e.g., P and S) have suitable absorption peaks (e.g., P and S L- and K-edges) in the soft-X-ray energy region. Some of these provide better chemical resolution than other analytical techniques. Second, TEY and FY detection modes allow for nondestructive study of the chemical nature of the surface, the near surface region, and the bulk of the film.

Zinc dialkyldithiophosphate (ZDDP) has been used for many years as the most common and the best antiwear (AW) additive for engine lubricant formulations. ZDDP is contained in fully formulated combustion engine oils at less than 0.1 wt% phosphorus content. Current environmental regulations are driving research to develop other AW additives that contain less phosphorus, since this element poisons catalytic converters leading to increased NO_x exhaust emissions. Despite the wide use of ZDDP, the formation, composition, and function of sacrificial wear films produced from its decomposition products are only partially understood. However, it is now widely accepted that ZDDP tribofilms consist mainly of phosphates with some sulfides (47), and the average thickness of the films is less than 100 nm (39).

Sarin et al. (48) showed that ashless thiophosphates gave comparable antiwear and antioxidant properties to those of

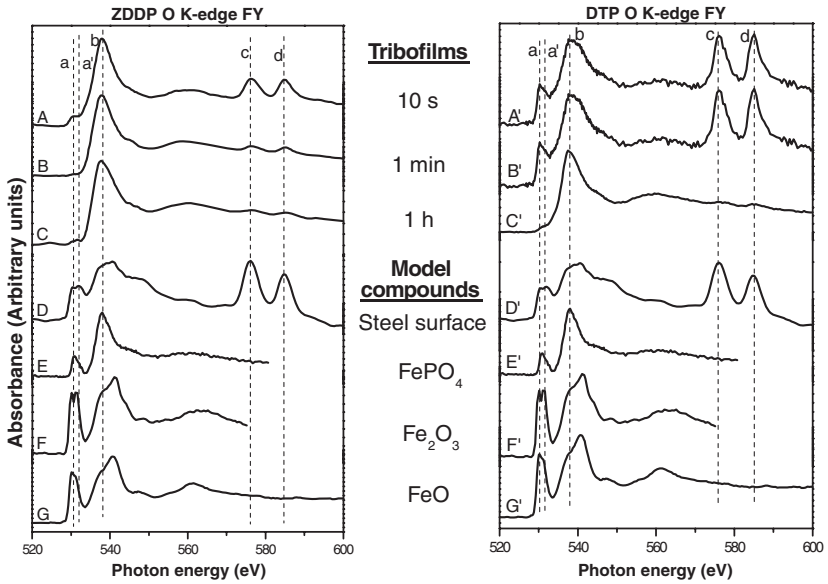
© 2007 NRC Canada

Fig. 2. Phosphorus L-edge XANES (in TEY mode) spectra of model compounds and tribofilms generated from 1 wt% ZDDP (left) and DTP (right) for different rubbing times.

ZDDP in bench tests. In contrast to the ZDDP film chemistry, XANES analysis showed that DTP gave short-chain polyphosphates throughout the film, and the sulphide formed was largely FeS (49). It was assumed that the cation in the phosphate glass was Fe^{2+}. This section will describe the use of XANES to the study of ZDDP and DTP tribofilm products and how the detailed chemical and structural data can be interpreted to theorize the decomposition and film formation mechanisms.

Results and discussion

Phosphorus characterization



Phosphorus L-edge XANES spectra of tribofilms generated from ZDDP and DTP at different rubbing times and model compounds are shown in Fig. 2. These spectra are characteristic of polyphosphate glasses observed in all of our previous studies of both ZDDP and DTP films (49–55). Comparing the ZDDP spectra in Fig. 2 (left), it can be seen that the peak positions in spectra A to F of the tribofilms generated at different rubbing times are highly similar to the positions for the model compound, zinc polyphosphate ($Zn_2P_2O_7$). In particular, the position of peak a in the tribofilms is much closer to peak a for Zn polyphosphate than for Fe polyphosphate or a phosphate ester, Irgalube 349. This indicates that the major cation in the surface of these films is Zn^{2+} rather than Fe^{2+} or Fe^{3+} and is consistent with our previous findings that films formed for long rubbing times have long-chain Zn polyphosphates at the surface and shorter-chain Zn polyphosphates (with some Fe) in their bulk (50–55). X-ray photoelectron spectroscopy (XPS) also showed that there is no Fe the in surface of the films (56). The peak located at ~142 eV is due to carbon contamination of the beamline optics and is a 2nd order carbon peak (32, 46). The intensity of peaks a or b relative to peak c has been used to indicate the phosphate chain length; an a/c of about 0.3 is representative of a short-chain polyphosphate, and an a/c of about 0.6 indicates a long-chain polyphosphate (57). The FY spectra of ZDDP films provide chemical information about the bulk and indicate that the chain length is shorter (a/c of <0.4) for the long rubbing time films, an a/c of ~0.6 from the surface sensitive TEY measurement as observed previously (e.g., see Figs. 2E, 2F). These spectra show the bi-layer nature of the ZDDP films having short-chain polyphosphates in the bulk and long-chain polyphosphates at the surface.

However, the present results on ZDDP antiwear films show, for the first time, that the polyphosphate chain length at the surface of these films increases with rubbing time. For spectrum A from the 10 s film, the ratio of intensity of peak a/c is 0.33, indicating a short-chain zinc polyphosphate. With increasing rubbing time, the a/c ratio of the spectra (A to F) increases. Thus, for the 10 h film (spectrum F), the a/c ratio is 0.61. Because the Zn/P ratio of 1:2 in ZDDP is much smaller than the Zn/P ratio in a short-chain polyphosphate (e.g., 1:1 in $Zn_2P_2O_7$), the initial formation of a short-chain polyphosphate indicates that substantial Fe must be present in these shorter rubbing time films. The availability of Fe (or Fe oxides) from the steel surface decreases as the film becomes thicker, and the chain length increases with relatively more Zn and less Fe in the surface of the films. Unfortunately, the position of peak a is not sensitive to the differences in the relative proportion of Fe and Zn in these films and therefore no direct evidence supports this.

The spectra of the DTP films (Fig. 2, right) are qualitatively similar to the ZDDP spectra — they are all characteristic of polyphosphates. However, there are two obvious differences. First, the position of peak a in all spectra aligns very well with peak a for $FePO_4$ rather than $Zn_2P_2O_7$, suggesting that, as expected, Fe is the predominant cation in these films (the shoulder in the ZDDP spectra), which appears just before peak a, is due to the presence of a small amount of unreacted ZDDP (50, 51). Second, the ratio a/c in all spectra is close to 0.3, indicating that all films contain short-chain polyphosphates as was found earlier by Najman

© 2007 NRC Canada

Fig. 3. Oxygen K-edge XANES spectra of model compounds and tribofilms generated from 1 wt% ZDDP (left) and DTP (right) for different rubbing times.

(55). It is not easy to rationalize why DTP gives short-chain polyphosphate, especially for the thick films, when the availability of cations for DTP has to be less than that for ZDDP. However, careful examination of spectra shows that position of peak c in spectra D′ to F′ (30 min to 10 h films) shifts slightly (~0.5 eV) to lower energy corresponding to zinc polyphosphate or Irgalube 349 spectrum G′. This suggests that in the absence of Fe as a cation, contaminant zinc and (or) an alkyl group are balancing the charge in these films. The alkyl group may originate from incomplete decomposition of DTP. Our recent studies on phosphate esters indicate that the P L-edge spectra of some of the organic phosphates are similar to those of metal phosphates (55).

Oxygen characterization and the role of Fe in the films

Oxygen K-edge FY XANES spectra of tribofilms generated from ZDDP and DTP at different rubbing times and model compounds are shown in the left and right panels of Fig. 3, respectively. The TEY spectra for all of these samples (not shown) are qualitatively similar. Spectra A (A′) to C (C′) are produced from tribofilms rubbed for 10 s, 1 min, and 1 h, respectively. Peaks c and d in some of these spectra originate from chromium L-edge XANES from a concentration of the 1% Cr in the 52100 steel surface oxide. This may indicate that the probing depth is greater than 500 Å and large enough to detect the steel surface in these very thin films; however, there could also be Cr incorporated into these phosphate films as suggested by XPS broad scans (not shown). Peak a is very weak in the ZDDP spectra (A and B) showing a rather small amount of Fe in these films. In contrast, the spectra A′ and B′ from the DTP films show a very intense peak a without any noticeable a′. This certainly indicates that there is appreciable Fe phosphate in these films, although there is still a contribution to these spectra from the surface Fe oxide. However, after one hour of rubbing (spectrum C′), peak a is very weak (although stronger than in the comparable ZDDP spectrum C), indicating rather little Fe is in the films. If Fe is the only cation (or even the predominant cation due to some Zn incorporation) in these phosphate films, the intensity of peak a should be much larger in spectrum C′. On the other hand, it was shown in Fig. 2 for 30 min to 10 h films, that contaminant zinc cations and alkyl groups may balance the charge for these phosphates. We cannot, at present, explain this apparent discrepancy.

Fe L-edge results for Fe characterization

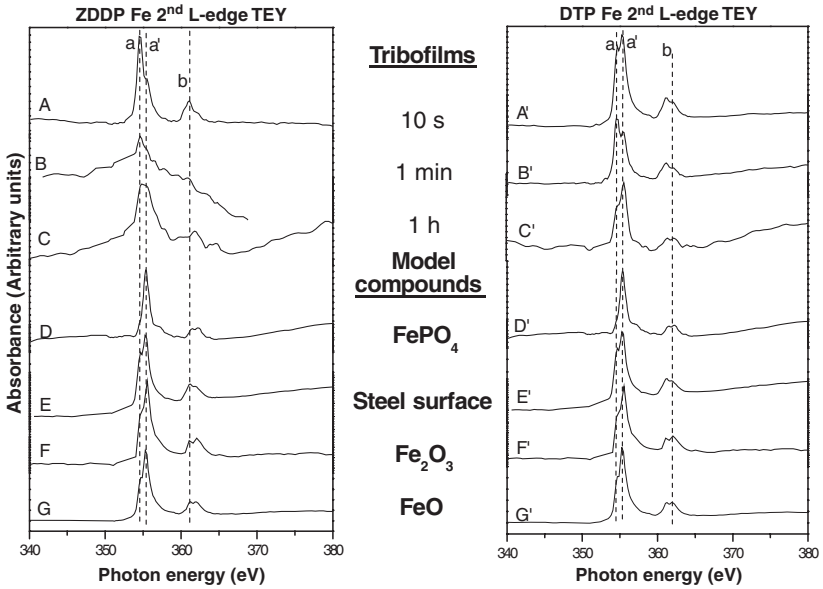
The iron L-edge spectra of the films and model compounds taken with second-order synchrotron light (24) are shown in Fig. 4 for the ZDDP films (left) and DTP films (right). As for the oxygen K-edge spectra, the $FePO_4$ spectrum (D) is appreciably different from those of the oxides: peak a is very narrow and not split as with the other three Fe standards (spectra E, F, and G). For ZDDP films, the 10 s film (A) shows mostly Fe oxides. However for the thicker 1 min and 1 h ZDDP films (B and C), the spectra are very weak, showing that there is very little Fe in the surface of these films. For the very thin DTP films (A′ and B′) and thick film (C′) the spectra are very similar to the Fe oxide from the steel surface. This is not surprising. As was shown in Fig. 6 of reference (56), the DTP films were very inhomogeneous and are composed of small pads compared to the ZDDP films. Furthermore, scratch marks are quite apparent in these films and obviously the Fe signal may originate from the substrate, although a contribution may also be given by the small amount of iron phosphate that can exist in the film.

Sulfur characterization

Sulfur K-edge XANES spectra of tribofilms generated from ZDDP and DTP at different rubbing time and model compounds are shown in Fig. 5. The spectra of the ZDDP films (spectra A, B, and C) are highly similar to the ZnS spectrum (with peak c dominating), as reported in our previous studies (58, 59). This indicates that the main chemical state of sulfur in the tribofilms generated from ZDDP at all rubbing times is ZnS. However, for the 10 sec film (spec-

© 2007 NRC Canada

Fig. 4. Fe L-edge XANES spectra (recorded with second-order light) of model compounds and tribofilms generated from 1 wt% ZDDP (left) and DTP (right) for different rubbing times.



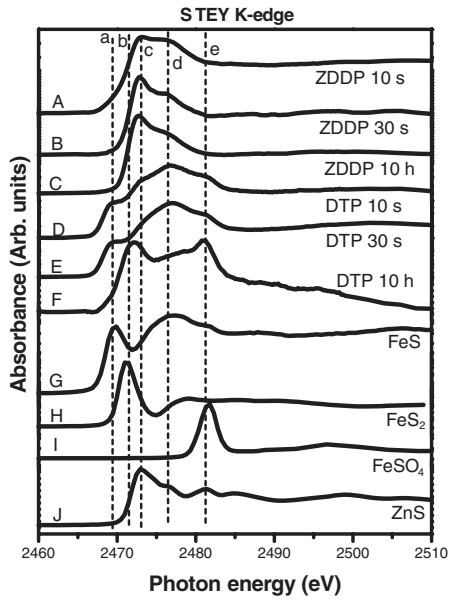


Fig. 5. Sulfur K-edge XANES spectra of model compounds and tribofilms generated from 1 wt% ZDDP and DTP for different rubbing times.

trum A) there are two shoulders, peaks a and d. These two shoulders correspond to the FeS spectrum (spectrum G). This result implies that there are two kinds of sulfides in the tribofilm generated from 10 sec rubbing. Zinc sulfide is the main chemical state of sulfur, but there is also some iron sulfide in the film. Because the concentration of iron sulfide is lower, there are only two shoulders in spectrum A, and this indicates that iron sulfide does exist in the tribofilm at the beginning of rubbing; and more importantly, Fe from the surface is immediately available for reaction with the sulfur and (or) phosphorus generated as the ZDDP decomposes. As rubbing continues, peak a disappears and the intensity of peak d decreases. This indicates that the amount of FeS in the film decreases relative to the amount of ZnS. In the thick films, there is probably only FeS right at the interface between the tribofilm and the steel surface. This is not unexpected from the principle of hard acids and soft bases as outlined by Martin and co-workers (60, 61). The soft base S^{2-} prefers to react with the borderline soft acid Zn^{2+} over the harder acid Fe^{2+} or Fe^{3+}. This principle can also be expressed by thermodynamic predictions. For example, consider the reactions,

[1] $$FeS + Zn^{2+} \rightarrow ZnS + Fe^{2+}$$

or

[2] $$FeS + ZnO \rightarrow FeO + ZnS$$

ΔG^0 is negative for these two reactions because of the very large negative ΔG_f^0 for ZnS (–201.3 kJ/mole) compared with FeS (–100.4 kJ/mole) (62). In the presence of a Zn species, FeS is expected to convert to ZnS. However, the majority of the zinc ends up in Zn polyphosphates rather than ZnS. The very large ΔH_f^0 values (ΔG_f^0 values are not available (62)) for the Zn phosphates (e.g., –2892 kJ/mole for $Zn_3(PO_4)_2$ and –4479 kJ/mole for $Zn_3P_4O_{13}$) indicate that the Zn phosphates are the thermodynamically stable zinc products in this complex system. For example, the ΔG value is –145 kJ for the following reaction,

[3] $$3ZnS + 2\ H_3PO_4 \rightarrow Zn_3(PO_4)_2 + 3H_2S$$

Indeed, the presence of Zn in the DTP films from a very minor zinc contamination shows that Zn phosphates are incredibly stable compounds. The XPS data shown elsewhere (56) support this discussion. In DTP films in the absence of Zn (or very small amount due to contamination), the sulfur proportion (~1%) is very low compared with that of ZDDP films (~8%).

For the DTP films, Najman (55) already reported that substantial FeS was present in these films after rubbing for greater than 5 min. The formation of FeS is much clearer in

the 10 s and 30 s films, as shown in Figs. 5D and 5E; indeed, FeS is the dominant sulfur species in these two spectra.[4] The presence of peak c in these spectra could be due to a small amount of ZnS from the contaminant Zn. The 10 h film shows the presence of sulfate (peak e) and some FeS and FeS_2, with perhaps a small amount of ZnS.

Sulfur K-edge XANES spectra of tribofilms generated from different concentrations of ZDDP were also investigated (not shown). The spectra of sulfur in the different concentration tribofilms are the same and align with zinc sulfide. This indicates that the concentration of ZDDP does not affect the formation of zinc sulfide in the tribofilm.

From the preceding discussion, it can be concluded that the tribofilm generated from ZDDP is a multilayer film. The mechanism of tribofilm formation for both ZDDP and DTP is given in more detail below.

A. ZDDP Mechanism

(Products entering solution are ignored.)
Stage 1. Physical and chemical adsorption.

[4] $Zn[(RO)_2PS_2]_2$ (solution) $\rightarrow Zn[(RO)_2PS_2]_2$ (ZDDP adsorbed)

Stage 2. Initial film formation (~10 nm) on the surface when cations are plentiful.

[5] $Zn(RO)_4P_2S_4 + O_2$ (in oil) + FeO $\rightarrow$ Zn/Fe phosphate (short-chain) + ZnS + FeS

Stage 3. Surface is covered with a thin film and Fe is not accessible from the substrate.

[6] $Zn(RO)_4P_2S_4 + O_2$ (in oil) $\rightarrow$ Zn phosphate (long-chain) + ZnS

In stage 2 based on ΔH_f^0 values, the proportion of FeS will be very small. In stage 3, Zn phosphate formation is preferred over ZnS formation.

Stage 4. Conversion of long-chain polyphosphate to short chain.

[7] Zn phosphate (long-chain) + $6H_2O \rightarrow$ Zn phosphate (short-chain) + $4H_3PO_4$

In stage 4, any water in the system can hydrolyze long-chain polyphosphates to short-chain (53, 63). As a result, the film becomes thicker, composed of short-chain Zn phosphate (with little Fe). We can think of a tri-layer film, with the top layer consisting of longer chain phosphates, a middle layer of predominantly short-chain phosphates, and an inorganic layer of ZnS and (or) FeS.

B. DTP Mechanism

(Products entering solution are ignored.)
Stage 1. Physical/chemical adsorption.

[8] $(RO)_2PSS\text{-}C_2H_4CO_2R$ (solution) $\rightarrow (RO)_2PSS\text{-}C_2H_4COOR$ (DTP adsorbed)

Stage 2. Initial film formation (~10 nm) on the surface when Fe are plentiful.

[9] $(RO)_2PSS\text{-}C_2H_4CO_2R + O_2$ (in oil) + FeO $\rightarrow$ Fe phosphate (short-chain) + FeS

Stage 3. Surface is covered with a thin film of Fe phosphate and no cation is accessible from the substrate.

[10] $(RO)_2PSS\text{-}C_2H_4CO_2R + O_2$ (in oil) + H_2O (in oil) $\rightarrow$ phosphate ester + alkyl sulphide

In stage 3, the alkyl sulphide will be dissolved in oil. However, it is difficult to see how the phosphate ester can remain on the surface.

Conclusions

The macro-scale XANES spectra yield much information about the film chemistry. The phosphorus L-edge spectra (along with the oxygen K-edge spectra and Fe L-edge spectra) have been used for the first time to give information on the role of Fe in the films. For ZDDP, a bi-layer phosphate film develops very quickly. Initially, the film is predominantly short-chain polyphosphate with Zn as the predominant cation, but the film develops to give predominantly long-chain Zn polyphosphate at the surface and a shorter chain polyphosphate with some Fe in the bulk. The average polyphosphate chain length increases with an increase in ZDDP concentration up to a certain point. For DTP, the polyphosphate film is of short-chain character throughout the test, with cations being Fe and alkyl groups. The proportion of alkyl groups is much higher on the surface. At this stage we cannot give a quantitative estimate of the proportion of Fe in the tribofilm. The Fe from the oxide and from solution must become available at the high local temperatures for the phosphate film formation, even for the relatively thick films. Some sulfur from the ZDDP reacts to form ZnS, but in addition the presence of FeS has been identified for the first time in the early films from both ZDDP and DTP.

This study demonstrates how XANES spectroscopy can provide detailed chemical information on complex heterogeneous tribofilms formed on steel. It goes further by illustrating how this information can be interpreted to elucidate complex film formation mechanism. A next step in understanding such complex systems would be able to spatially extract the same comprehensive information from discrete locations on a surface. Synchrotron spectromicroscopy has enabled the acquisition of chemical information on the submicron length scale (27, 29, 32, 44, 64) and opened up the ability to investigate, for the first time, the spatial distribution and chemical speciation of antiwear (AW) films.

[4] In the case of tribofilms, the formation of a pure compound is rarely observed. Typically, intermediate species are incorporated in the film as a result of incomplete chemical reactions. Thus, the use of the term dominant to indicate that the major sulfur component of the film, in this case, is FeS.

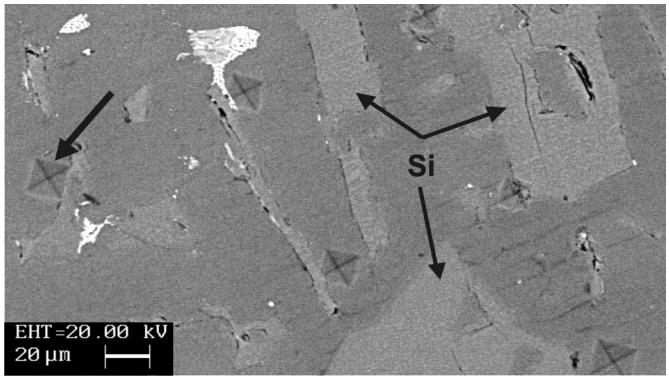
B. X-ray photoelectron emission spectroscopy of ZDDP films on Al–Si alloys

Not only are replacement additives for ZDDP being sought to reduce emissions, but automotive manufacturers are also envisioning weight savings by altering the design of the engine block to reduce fuel consumption and therefore also reduce emissions. Aluminum–silicon alloys with high silicon contents (>18%) are currently being investigated as cost effective replacements for cast iron components. The introduction of silicon improves the wear resistance of aluminium through the formation of separate hard phase silicon grains in the aluminum matrix. A long-standing question is the function of the silicon grains. It is generally thought, since very little research exists, that the grains, after honing and etching of the surface, act like riders that bear the load of the conforming surface (65–69). To date no suitable additive has been found which can effectively lubricate Al–Si alloys. It would be ideal if ZDDPs proved to be effective additives to reduce friction and wear of Al–Si alloys.



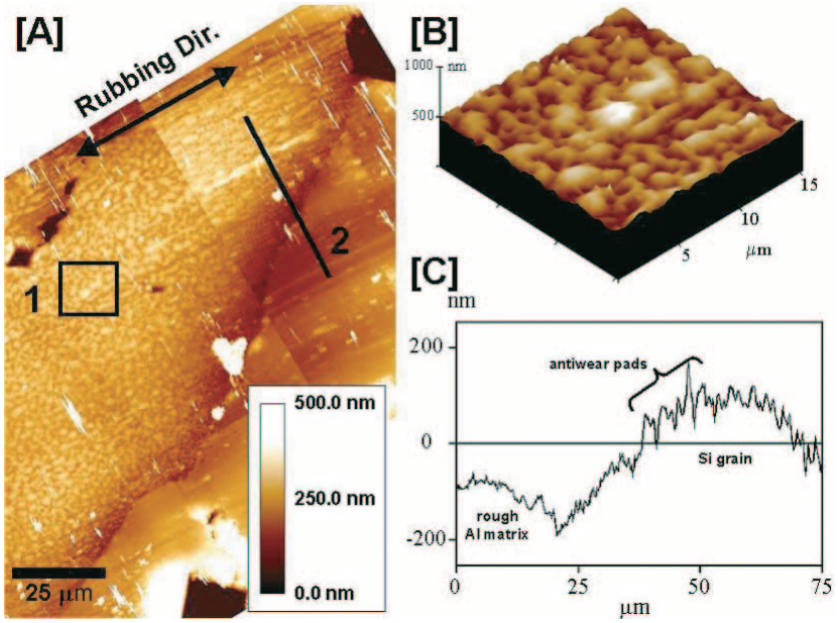
For the first time, the spatial localization,and chemical speciation of ZDDP AW films on high silicon content Al–Si alloys was performed using X-ray photoelectron emission spectromicroscopy (X-PEEM). The ability to spatially resolve features on a surface enables examination of the occurrence (or lack thereof) and location of ZDDP AW film formation under lubricated wear of a high-silicon content (~18%) Al–Si alloys.

Results and discussion

Fiducially placed indents were used to recognize and reanalyse specific areas of interest, using atomic force microscopy (AFM), X-PEEM, and secondary electron microscopy (SEM). These indents were made after the ZDDP AW films were formed on the Al–Si alloy. As was performed previously (70), SEM imaging and EDX elemental mapping were used to understand the heterogeneous nature of the alloy surface and was performed after X-PEEM analysis. A high-resolution SEM image is shown in Fig. 6. The diamond-shaped indents used to identify the regions of interest are clearly observed, as are the distinct grey features that have been identified by EDX as silicon grains (70). Light wisps and blotches are due to the difference in backscattering from the agglomeration of other elements such as iron, copper, and magnesium.

Once a particular silicon grain was pinpointed, the region was then examined by AFM. AFM imaging provides high-resolution topographic information and has been routinely used to observe the varying morphology of AW films (71–73). In this instance, AFM was used to investigate where (if any) ZDDP AW films formed. ZDDP antiwear films on steel have a heterogeneous topography composed of islands and valleys. The islands have been termed AW pads and are thought to act like a cushion preventing the two rubbing surfaces from coming into contact (44). Figure 7A is a mosaic of AFM images that show a large silicon grain running diagonally across the figure. The large "diamond-shaped" indents can also be observed at the top and bottom. In AFM images, objects with a higher elevation appear lighter. Careful examination of the silicon grain shows small, elevated islands, or ZDDP AW pads. The pads have an elongation that is in the direction of the rubbing experienced during the friction test. A 3D AFM image of the AW pads, boxed 1 in Fig. 7A, is shown in Fig. 7B. The padlike morphology can be clearly observed and is quite similar to those formed on steel under identical rubbing conditions (70). Again, the pads are thought to limit the contact between the two rubbing surfaces. Since AFM imaging provides 3D topographic information it is possible to extract useful height information about the surface. A cross-sectional profile along the line (marked 2) in Fig. 7A is shown in Fig. 7C. From this profile the height of the silicon grain can be measured to be ~100 nm; as well, the oscillations on the surface of the grain can be identified as the small AW pads.

Fig. 6. A secondary electron image (in backscattering mode) of the Al–Si surface. Vicker's indents can be identified in the image as well as the distinct silicon grains.



Advancements in X-ray photoelectron emission spectromicroscopy have made it possible to image surfaces similar to a secondary electron microscope. This gives the user the unique ability to distinguish small features on a surface (on a submicron scale), and then determine the chemical nature of the species present using X-ray absorption spectroscopy. This powerful combination of techniques has only become possible (at this resolution) in the last several years and has only been routinely used to analyse ZDDP AW films on steel recently (32, 44, 74). The imaging function of the X-PEEM was used to locate the same fiducial indents identified in with the AFM images. For comparative purposes, the AFM image is reintroduced in Fig. 8A with the X-PEEM image Fig. 8B (with the same orientation and scale as in the AFM image). The large indents can be observed, as well as the large AW pads (circled).

Using the X-PEEM analysis software, an image mask was generated to separate the ZDDP AW pads form all other features (details of the entire procedure can be found elsewhere (44)). Figure 9 shows the mask used to select only the large AW pads. The mask is used to extract and average the phosphorus L-edge spectra obtained from each pixel within the mask. The average spectrum using this procedure is labelled (D), shown in Fig. 10, and is compared with the model spectra from compounds with known oxidation state and elemental geometry around the phosphorus atom. Comparisons to unreacted ZDDP (A), a zinc polyphosphate glass (B), and a ZDDP AW film formed on steel, make interpretation of the film chemistry much easier. The spectrum from the unreacted ZDDP shows its characteristic triplet structure (51). The zinc polyphosphate has peaks a, b, and c that are shifted to higher energy from peaks 1, 2, and 3 of unreacted

© 2007 NRC Canada

Fig. 7. (A) A mosaic of AFM images showing a large silicon grain on the top of which patches of ZDDP antiwear film can be observed. The silicon grain runs diagonally through the image. (B) A 3D topographic image of the antiwear pads found within box 1. (C) A cross-sectional profile taken across 2.

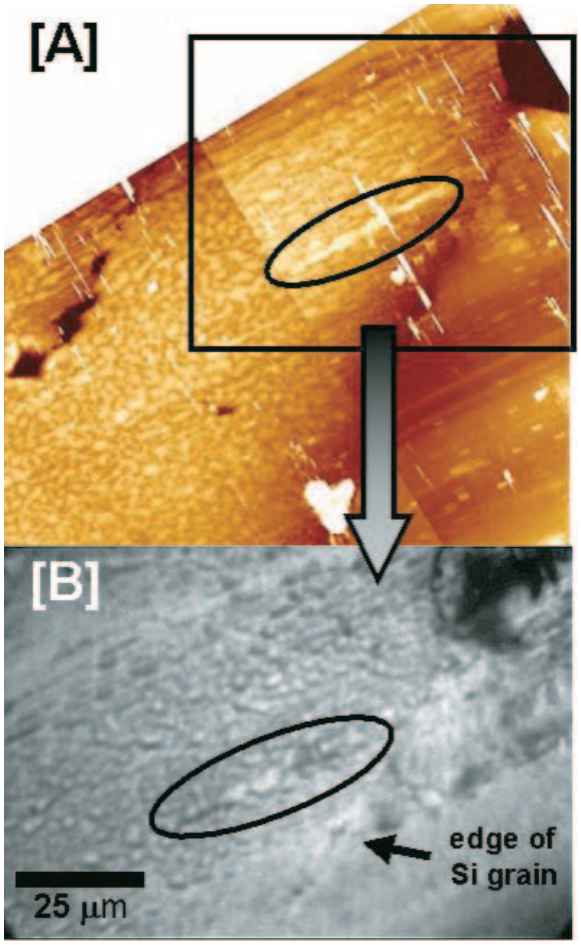
ZDDP. Peaks a and b are the 2p spin-orbit doublet, separated by 0.8 eV. They are assigned to the transitions of electrons from occupied $2p_{3/2}$ and $2p_{1/2}$ levels to unoccupied antibonding orbitals. Peak c is attributed to the transition of the 2p electrons to a p-like t_2* molecular orbital. As described previously, the ratio of the intensities of peaks a/b increase as the polyphosphate chain length increases (44, 57, 75). An *ideal* ZDDP AW film formed on 52100 steel (C) has a polyphosphate structure. Comparison of this spectrum (C) to that of the AW film formed on the Si grain (D) reveals that the AW film does have the characteristic polyphosphate structure as that formed by ZDDP on the steel surface.

In spectrum (D) the ratio is 0.65, and in spectrum (E) the ratio is 0.60. This indicates that the AW pads have a longer polyphosphate chain length than the off-pad areas (44, 57, 75). This would indicate that although the Al matrix is too soft to allow shear forces to reach a sufficient magnitude to decompose ZDDP, polyphosphates can form on the hard silicon grains and must transfer to the Al matrix. The shorter-chain polyphosphates as well as unreacted ZDDP were also found in regions off the silicon grains on the Al matrix (70). This is indicative of the sacrificial nature of ZDDP AW films as they form on steel. Spectrum (F) in Fig. 10 shows a small shoulder (labelled s) to the left of peak a that lines up well with unreacted ZDDP, indicating that ZDDP species are also located in the Al matrix.

These results show that X-PEEM is a powerful tool for the investigation of ZDDP AW action on Al–Si alloys. Topographic imaging has observed that the ZDDP antiwear films are formed of patches (termed antiwear pads), characterized as smooth plateaus between which valleys and *bare* surfaces have been found. X-PEEM analysis at the phosphorus L-edge identified polyphosphates in the ZDDP AW film. It was found that the antiwear pads were located on the hard silicon grains and were oriented in the direction of rubbing; furthermore, the AW pads had a slightly longer polyphosphate chain length than the lower (valley) and surrounding Al matrix regions. This indicates that not only does the ZDDP AW film formed on Al–Si alloys possess a similar polyphosphate structure to films formed on steel, but it also has the same sacrificial characteristic (whereby polyphosphate is transferred from the hard silicon grains to the softer Al matrix) that it does on steel surfaces.

Conclusions

The use of spatially resolved X-PEEM chemical analysis in combination with high-resolution topographic imaging have provided new insight into the location and structure of ZDDP AW films on Al–Si alloys. The combination of these techniques provides researchers with the unique ability to obtain useful data on the chemical nature and wear protection mechanisms of ZDDP, and thus provide insight into how new replacement additives need to function to perform as effectively as ZDDP.



The final section in this review will demonstrate the coupling of the powerful macro-scale XANES analysis (e.g., section A) with the unique X-PEEM ability of spatially resolving where the tribofilms have formed and determine their exact chemical make-up.

C. Investigating the microchemical properties of tribofilms generated from ashless thiophosphate additives

As shown above, XANES has focused primarily on the understanding of tribochemistry from reaction films generated from various types of ZDDPs. However, concerns over some of the potential environmental implications of using ZDDPs have created an increased interest in the understanding of how metal-free lubricant additives function (37, 48,

© 2007 NRC Canada

Fig. 8. The AFM image from Fig. 7 is re-introduced (A) for navigation, along with the (B) secondary electron X-PEEM image showing the silicon grain and antiwear pads. The large antiwear pads are circled in the AFM to aid in identification in the X-PEEM image.

76). As a result, only recently has XANES been extended to that family of additives. Various types of phosphate esters as well as organosulfur compounds, such as sulfurized esters and dialkyldithiocarbamates, have been studied using XANES with much success (77, 78).

This section discusses the complementary use of macroscale XANES and X-PEEM to investigate the microchemical properties of lubricious films generated from ashless thiophosphate oil additives under boundary lubrication. During reciprocating sliding, noticeable differences were seen between an ashless dithiophosphate additive (DTP) and a monothiophosphate additive (MTP). Wear scar width measurements of the pin revealed that the DTP additive at a concentration of 0.5 wt% in sulfur-free base oil provided statistically better wear protection than the MTP additive at a concentration of 1.5 wt%. Preliminary tribochemical film analysis using X-ray photoelectron spectroscopy (XPS) and conventional XANES revealed slight differences in the phosphorus concentration at the near surface, while the polyphosphate structure, from a macrochemical perspective, was relatively the same between the two additives — both the MTP and DTP additives generated a short-chain

Fig. 9. A mask showing the selection of the larger ZDDP antiwear pads only. Spectra were extracted from only these regions to produce the spectrum shown in Fig. 10D.

polyphosphate AW film (49, 79). Figure 11 displays the conventional macro XANES spectra (acquired from ~5mm^2 area) at the phosphorus L-edge for the tribochemical films generated from two ashless thiophosphate additives.

Results and discussion

The general topographical features of both MTP and DTP tribofilms were compared using both X-PEEM and AFM and are shown in Fig. 12. Based on the images, differences in the tribofilms are immediately apparent. For DTP, the 120 × 120 µm AFM image reveals a heterogeneous surface with elongated pads oriented in the sliding direction with widths between 2.5–5.0 µm as determined by X-PEEM. Conversely, the MTP tribofilm appears to be very homoge-

© 2007 NRC Canada

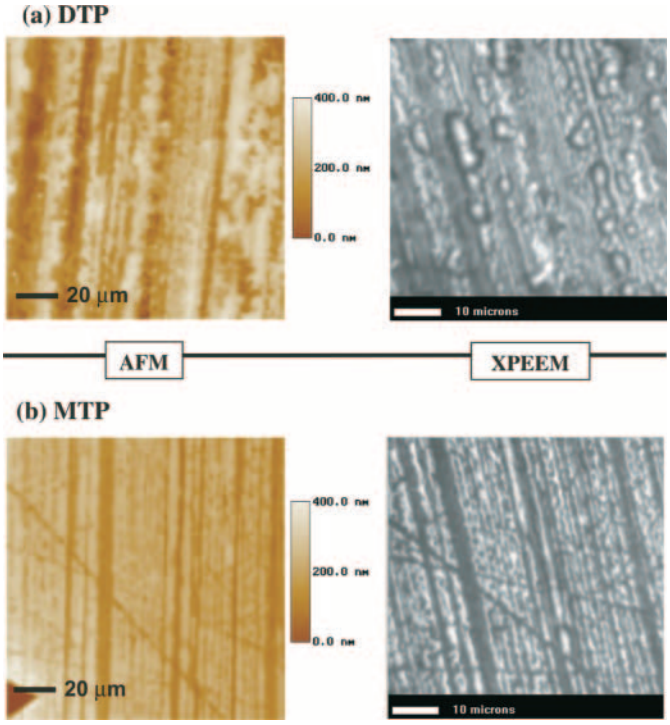
Fig. 11. Conventional P L-edge XANES spectra (from ~5 mm^2 area) of tribofilms generated from DTP and MTP in total electron yield (TEY) mode, compared with an iron polyphosphate model compound.

neous topographically, with thin elongated pads oriented in the sliding direction as well. Pad widths for the MTP tribofilm were estimated to be in the range of 1.5–2.0 μm.

Using X-PEEM analysis similar to that shown previously, the P L-edge region data showcase the properties of the AW films in a variety of ways. Figure 13b shows a "difference image" revealing the spatial distribution of polyphosphate from the DTP AW film excluding topographic information. The difference image technique subtracts two different spectral images along the phosphorus L-edge to show image contrast based on chemical and elemental properties. Figure 13a is a PEEM image of area of tribochemical film generated from the DTP additive taken at a photon energy of 137.2 eV. This on-peak image shows topography and chemistry combined. Figure 13b is a digital difference of two images, on-peak and off-peak, taken at 137.2 and 133.7 eV, respectively. Since the off-peak image contains only the topographic contribution, the difference image in Fig. 13b shows only the chemistry. Notice the presence of phosphorus on the surface of the tribofilm and its higher concentration (brighter pixels) where the pads are located. From the stack of difference images that can be created, one of the fascinating observations (not shown) is that the image intensity of the padlike structures begins to increase, eventually reaching a maximum intensity at the absorption edge.

As mentioned above, conventional XANES spectroscopy at the phosphorus L-edge samples an area on the order of several square millimetres, dimensions too large to provide any microchemical information (see Fig. 11 for example). On the SPHINX microscope,where the X-PEEM experiments were conducted with a field of view of 100 μm, in which each pixel represented an ~200 nm × 200 nm area, thereby enabling microchemical analyses. Figure 14 shows the X-PEEM image of an area where local XANES spectra

Fig. 12. Height mode atomic force microscope images and topographical PEEM image for the two AW films prepared: (a) DTP and (a) MTP.



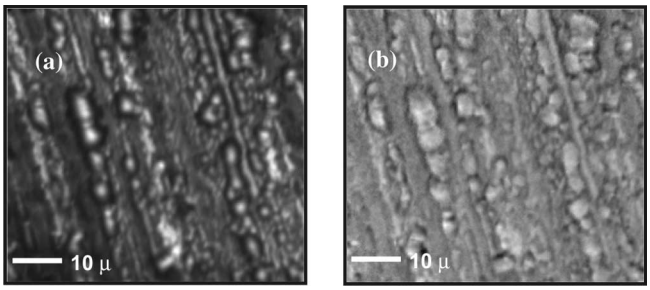


Fig. 13. (a) PEEM image of an area of tribochemical film generated from the DTP additive taken at a photon energy of 137.2 eV. This on-peak image shows topography and chemistry combined. (b) Digital difference of two images, on-peak and off-peak, taken at 137.2 and 133.7 eV, respectively. Since the off-peak image contains only the topographic contribution, the difference image in (b) shows only the chemistry.

at the phosphorus L-edge were taken within the wear scar for the DTP AW film, and can be compared with Fig. 11 that displays the conventional macro XANES spectra. XANES spectra were extracted from several different areas within the respective X-PEEM image and are indicated by the labelled areas. Several regions were analysed to determine notable differences in polyphosphate chain length from pad to pad. Prior work from our group has shown that for phosphorus L-edge XANES spectra, the intensity of peaks a and b relative to peak c correlate very well to polyphosphate chain length i.e., a higher ratio of a/c suggests longer-chain polyphosphates (57) (also see the example in Section A).

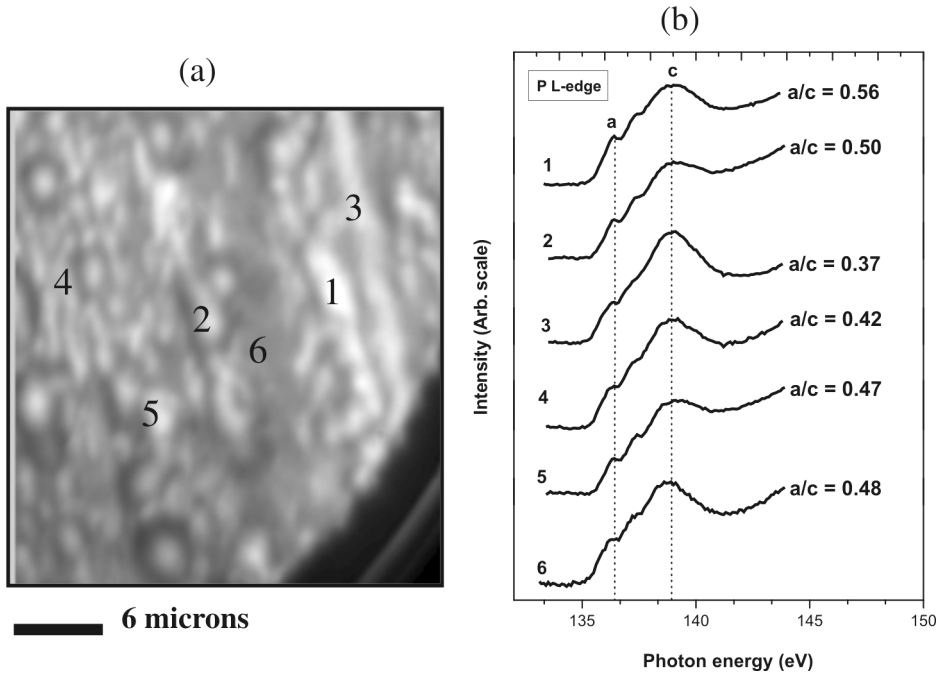
Fig. 14. Detailed microchemical analysis of a region within the wear scar of AW film of DTP. (a) PEEM image with labeled areas indicating where local P L-edge XANES spectra were extracted. (b) Corresponding P L-edge XANES spectra.



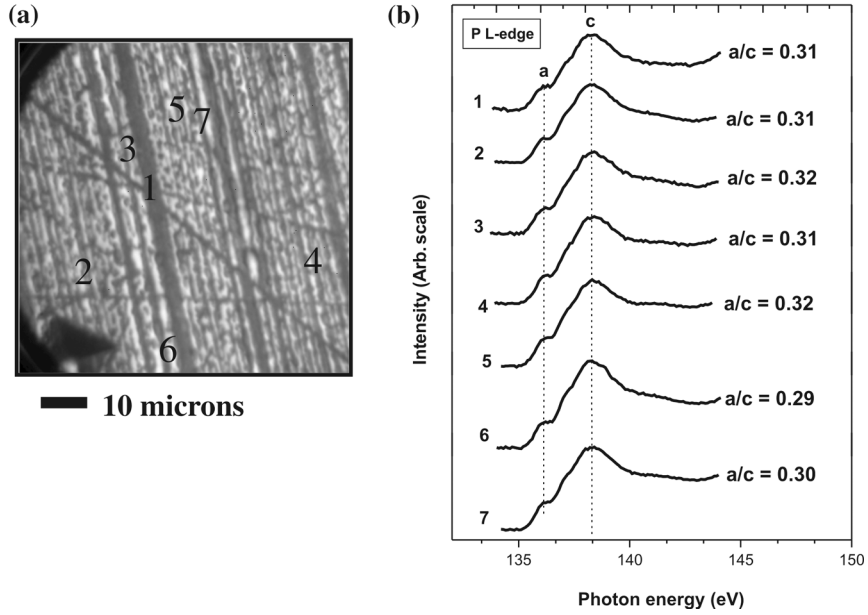


Fig. 15. Detailed microchemical analysis of a region within the wear scar for AW film of MTP. (a) PEEM image with labeled areas indicating where local P L-edge XANES spectra were extracted. (b) Corresponding P L-edge XANES spectra.

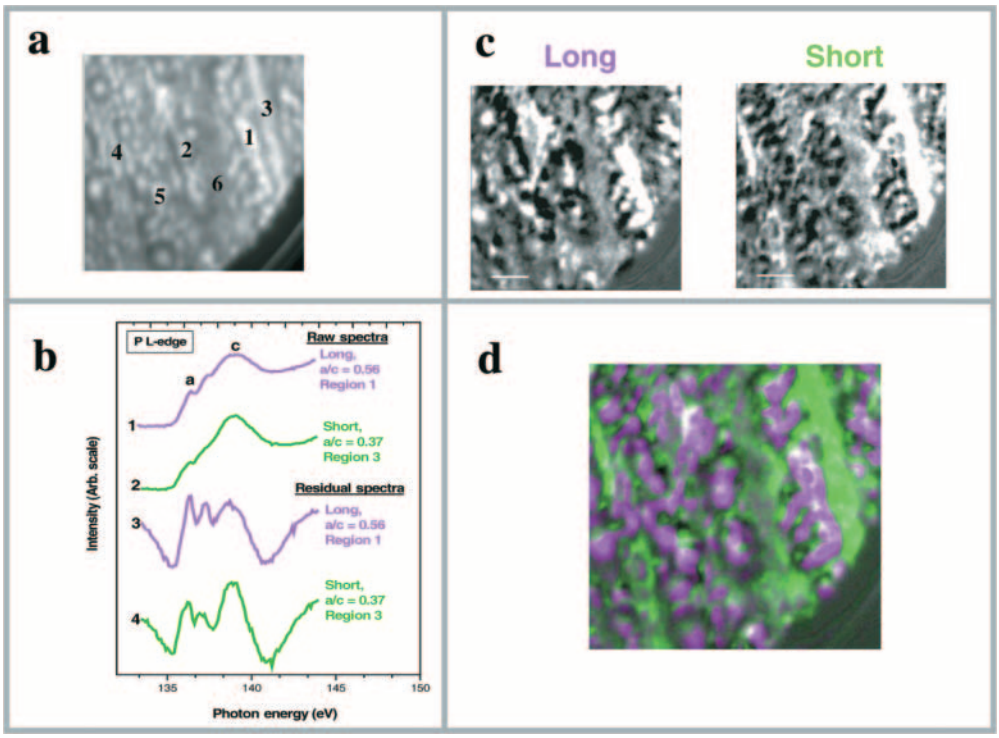

With this in mind, the a/c ratios of the different regions are shown beside the corresponding phosphorus L-edge spectra, 1–6, respectively. Looking at both the local XANES spectra and the corresponding ratios, it is clear that while the different regions do look similar to one another spectrally, there are variations in the microchemical properties of the DTP film, with local areas consisting of varying degrees of polyphosphate chain length.

Focusing on the microchemical properties of the MTP AW film, X-PEEM reveals differences when compared with DTP. The X-PEEM image of the MTP AW film in Fig. 15, along with the corresponding extracted spectra, clearly shows microchemical homogeneity throughout the analysed area of the film (again, these microchemical spectra can be compared with Fig. 11, which displays the conventional macro XANES spectra). Focusing on the a/c ratios, there is little or no change across individual pads. Several different areas were also investigated (not shown) with similar results, thus concluding that the AW pads that are developed during tribofilm formation are predominantly or almost completely

Fig. 16. Example of chemical mapping depicting polyphosphate chain length distribution within an area of AW film generated from DTP. (a) Topographical X-PEEM image displaying selected regions of interest. (b) Spectra 1 and 2 correspond to the raw P L-edge XANES spectra of regions 1 and 3 in (a). Spectra 3 and 4 correspond to residual P L-edge XANES spectra of regions 1 and 3 after a spline background was removed. (c) Derived quantitative chemical maps of the two components used. Spectra 3 and 4 were used as the components to generate the maps. (d) Color-coded composite map displaying polyphosphate chain length distribution. Areas of longer chain polyphosphates are colored in magenta, while green depicts areas of shorter chain polyphosphates.

short-chain polyphosphates. Recalling results obtained from conventional XANES, surprisingly, the polyphosphate chain length between the two AW films was similar (Fig. 11).

The ability to extract local XANES spectra at the submicron level clearly demonstrates the power of X-PEEM and how useful it is in the field of tribology. X-PEEM was able to discriminate between areas of different polyphosphate chain lengths within an AW film for the DTP additive on the basis of intensity ratio of peaks a to c in the phosphorus L-edge. Another advantage of X-PEEM is that the intensity of the peaks observed can also be used as individual components to obtain a chemical distribution map, of varying polyphosphate chain length, from the set of images collected. There are several references in the literature describing the use of quantitative analytical techniques to extract these types of maps from a wide range of materials including polymers and proteins (29, 30, 64). Briefly, a linear regression analysis was applied pixel-by-pixel to the acquired image sequence to derive the component maps. This allows for full spectral variation to be used in deriving the maps. Since the tribofilms studied are not comprised of one pure component but rather a mixture, no quantitative reference standards exist thus making the analysis semiquantitative (80).

Looking at a spatial distribution map of polyphosphate chain length for the DTP AW film in Fig. 16, different regions within the AW film are clearly differentiated visually. To generate the colour-coded map in Fig. 16d, a spline background was removed from the raw phosphorus L-edge XANES spectra, and the spectra depicting areas of both longer- and shorter-chain polyphosphates were used as individual components for the map. The individual components are shown in Fig. 16c. The more intense bright areas reveal concentrated areas of shorter- and longer-chain polyphosphate for each component, respectively. The phosphorus L-edge spectromicroscopy reveals that there are areas of long-chain polyphosphates that are segregated from areas of shorter-chain polyphosphates, and upon closer inspection there are regions where both types coexist (black in Fig. 16d). White regions are where there were difficulties fitting to either spectra (typically because of lack of signal). The consistency of the colour-coded map was evaluated spectroscopically in 19 different areas (data not shown). Here the a/c peak intensity values were extracted from the phosphorus L-edge XANES spectra and tested against the map to determine its validity. It was found that the microchemistry along the various selected areas of interest was in good agreement with the map.

Conclusions

In general, this in-depth analysis of the tribochemical films generated from ashless thiophosphate oil additives clearly demonstrates the powerful capabilities of the X-PEEM technique, a clear extension of the macro XANES information that was originally acquired at the phosphorus L-edge. With X-PEEM, high quality submicron XANES spec-

© 2007 NRC Canada

tra can be obtained with phenomenally high energy and spatial resolution. Coupling the power of this technique with other topographical imaging techniques such as AFM has created an entirely new and exciting way to evaluate tribochemical structure–performance relationships for lubricant additives.

Concluding remarks

Undoubtedly XANES analysis has provided tribologists with a wealth of knowledge over the last 20 years. This brief review illustrates how XANES can probe common elements in additives and provide unique information. The three examples described above take the science from its beginning: macro-scale XANES has provided detailed chemical and structural information on antiwear and tribo films on metallic surfaces with enough illumination that complex and theoretically sound reaction mechanisms could be proposed. The review then reveals the more recent advancements in the field of XANES spectromicroscopy, in which complex surfaces can be imaged with submicron resolution, which enables the user to extract detailed XANES spectra from small discrete features. The last example summarizes the previously described macro- and micro-scale XANES approaches by coupling the methods to provide a complementary and compelling combination to spatially resolve where the tribofilms have formed and to determine their exact chemical make-up.

With this we dedicate our sincere thanks to G.M. Bancroft, a great friend and mentor, for guiding us through our research and ushering us into the forefront of XANES research through its use in tribochemistry at metallic surfaces.

Acknowledgements

The authors would like to personally thank A.P. Hitchcock for his help with aXis2000 and useful discussions about the analysis of the X-PEEM data. The authors would also like to thank K. Tan, A. Jurgensen, and the staff of the Synchrotron Radiation Centre (SRC), University of Wisconsin, Madison, for their technical support. M.A.N. would personally like to thank Heather Bloomfield and Ross Davidson of Surface Science Western, The University of Western Ontario, for acquisition and discussion about the SEM results. We are grateful to the National Science Foundation for supporting the SRC under Award # DMR-0537588. Financial support was provided by General Motors of Canada Ltd. and the Natural Sciences and Engineering Research Council of Canada (NSERC).

Comparison of the distributions of bromine, lead, and zinc in tooth and bone from an ancient Peruvian burial site by X-ray fluorescence[1]

Ronald R. Martin, Steven J. Naftel, Andrew J. Nelson, and William D. Sapp III

Abstract: Synchrotron micro X-ray fluorescence was used to study the distribution of selected trace elements (Zn, Pb, and Br) in tooth and bone samples obtained from an individual from a pre-Columbian archaeological site (Cabur) located on the north coast of Peru. The results show that Zn, Pb, and Br are present in both the teeth and bone samples and that the Zn and Pb seem to be confined to similar regions (cementum and periostium), while Br shows a novel distribution with enrichment close to the Haversian canals and (or) in regions that appear to be Ca deficient.

Key words: teeth, bone, metals, XRF, Br, Zn, and Pb.

Résumé : On a fait appel à la fluorescence de micro rayons X (FRX) à synchrotron pour étudier la distribution d'éléments choisis (Zn, Pb et Br) qui sont présents à l'état de trace dans des échantillons de dents et d'os obtenus à partir des restes d'un individu retrouvé sur un site archéologique précolombien (Cabur) situé sur la côte Nord du Pérou. Les résultats montrent que le Zn, le Pb et le Br sont présents dans les échantillons d'os ainsi que de dents et que le Zn et le Pb semblent confiner dans des régions similaires (cementum et periostium) alors que le Br présente une distribution nouvelle comportant un enrichissement aux abords des canaux haversiens et/ou dans les régions qui apparaissent comme déficientes en calcium.

Mots-clés : dent, os, métaux, FRX, Br, Zn, Pb.

[Traduit par la Rédaction]

Introduction

Human teeth and bone constitute significant reservoirs of trace elements that are potentially indicative of diet, disease, and (or) environmental exposure (1). Bone is a complex tissue, approximately 35% organic (mainly collagen), while the remainder is mineral, principally bioapatite. The outer portion of most bone is dense and is termed compact bone. The structure of compact bone is formed around the cylindrical shaped osteons, or Haversian systems, oriented parallel to the long axis of the bone. The Haversian systems are the sites where remodeling of the bone occurs. Bone density decreases toward the center to yield spongy or trabecular bone (2). The outer surface of bone is covered by a fibrous membrane called the periostium. This term is also used to indicate the outside surface of the bone itself, while the term endostium indicates the center of the bone.

As noted in the preceding, bone is actively remodeled so that the turnover time for any metal deposited in bone represents a confounding factor in the interpretation of bone metal content. In addition, turnover is dependent on bone type. Lead (Pb^{2+}), thought to substitute for Ca^{2+} in calcium carbonate and hydroxyapatite in the mineralized component of bone and teeth (3), has a turnover rate estimated at 1% per year in cortical bone and 8% per year in trabecular bone (4).

Teeth are more robust than bone and are generally well preserved. However, tooth structure is such that the individual component tissues (enamel, dentine, cementum) of teeth have unique potentials as metal reservoirs. Enamel, the hardest structure in the human body, constitutes the tooth crown and is generally believed to be free of remodeling effects and is resistant to diagenesis. Naturally, much analytical effort has been directed at the enamel.

In mammals (and hence humans) there are two sets of dentition, which form at different times in an individual's life. Deciduous teeth begin formation within 14–19 weeks of fertilization and enamel mineralization is complete shortly after birth (5, 6). Thus, analysis of the metal content of deciduous enamel reveals details of a brief period in an individual's life. The permanent dentition is formed from early childhood to approximately 16 years of age. Therefore, analysis of the enamel of permanent teeth reveals details of a much longer period during an individual's development. The

permanent dentition enamel is often thought to preserve ingested lead (7).

Budd et al. (8) have used laser ablation inductively coupled plasma mass spectrometry (La_ICP/MS) and isotope dilution thermal ionization mass spectrometry (ID/TIMS) to study Pb distributions in cross-sections from ancient and modern teeth. Their results show enhanced Pb content in the outer 30 μm of the enamel. This effect is attributed to exposure to the oral cavity. They also showed the dentine to be enriched in Pb and concluded that enamel was indicative of metal exposure during crown formation if the outer layer was removed before analysis.

Cementum is a connective tissue that surrounds the tooth root in incremental, mineralized layers (9). These layers exhibit a seasonal growth pattern and potentially represent a chronological record of metal exposure throughout an individual's life; for this reason, the cementum is an especially promising tissue for trace metal analysis. Individual cementum ring structures vary in width depending on age, species, and location on the tooth root. In humans, the cementum is of the order of a few hundred micrometres across, with individual rings varying from about 5–20 μm in width (10).

Given the variation in metal content in different components of bones and teeth, meaningful analysis is ideally carried out using techniques that examine small regions (of the order of micrometres) with low detection limits so that the spatial distributions within each component might be resolved. Techniques that have been used include secondary ion mass spectroscopy (SIMS) (11), proton induced X-ray emission (PIXE) (12), and laser ablation inductively coupled plasma mass spectroscopy (La_ICP/MS) (8).

Perhaps the most promising technique for studying metal distributions in teeth and bone is provided by synchrotron radiation analysis (SRA) (13). In SRA, electrons circulating in a central accelerator ring (synchrotron) at relativistic velocities are used to generate electromagnetic radiation at wavelengths from the visible to high energy X-rays at intensities exceeding conventional sources by as much as eight orders of magnitude. In micro-SRA the X-rays produced by the synchrotron may be focused to a spot of the order of 1 μm × 1 μm, inducing element-specific X-ray fluorescence from the metals in a sample with detection limits in the ppb range. Analysis can be carried out under ambient conditions, avoiding artifacts introduced by high vacuum techniques, and, in principle at least, SRA is nondestructive. In addition, synchrotron X-ray microspectroscopy can provide chemical information including oxidation state, coordination number, bond length, X-ray diffraction information, and possible identification of nearest neighbor atoms using X-ray absorption near edge spectra (XANES) and extended X-ray absorption fine structure (EXAFS). Not surprisingly, SRA is widely applied to the study of the chemistry and structure of teeth and bone (14–23).

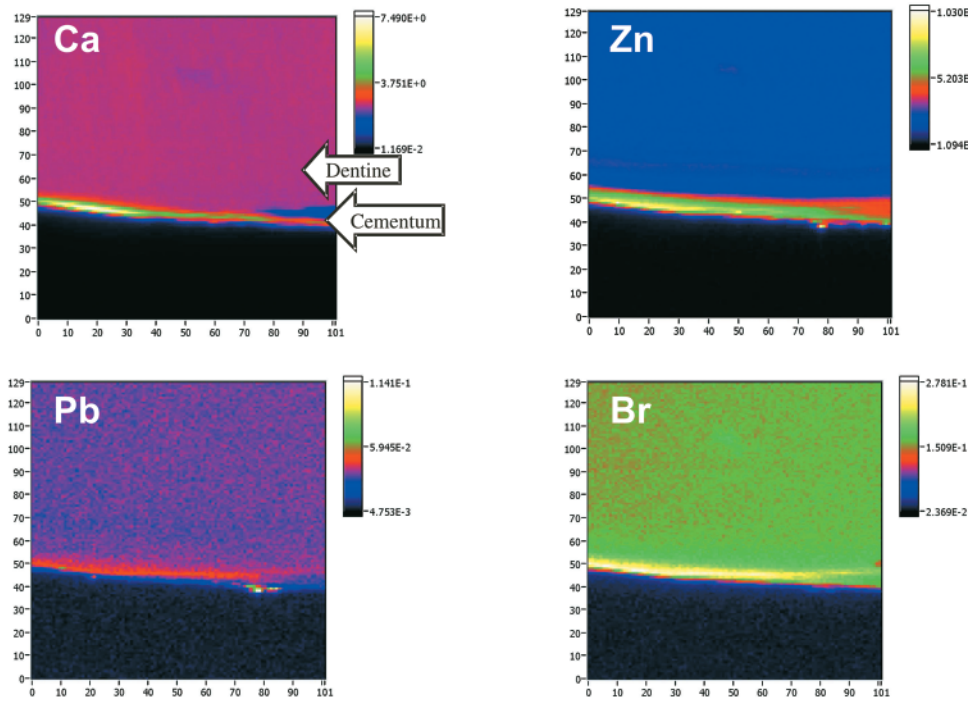
We have used synchrotron induced X-ray fluorescence to study the trace element distribution in the cementum rings of human teeth (24) showing Zn enrichment in this region, as well as variation in metal content across the ring system. Since diagenesis represents a significant confounding factor in the interpretation of metal distribution in teeth (25), we have also used the element distribution in the cementum ring system to establish criteria for distinguishing between endogenous (derived internally) and exogenous (derived externally) metals (26).

This study focused on four elements. Calcium was used as the best indicator of mineralization within the teeth. Zinc is present in the oral cavity (27), plays an important role in the formation of dental calculus (28), inhibits formation of hydroxyapatite (29), and is readily incorporated in calcium triphosphate (30), one of the mineral components of teeth. In addition, it is sufficiently enriched in the cementum that its X-ray fluorescence can be used to identify the cementum region (24, 26). Lead has been widely studied in anthropology (31), and it is possible that lead originated from pre-Columbian ore smelting (32). Finally, bromine, when present, is indicative of a marine diet (16).

The objectives of this preliminary study of the Cabur sample was limited to determining (*i*) if the X-ray fluorescence from both teeth and bone contained all four elements in the study, (*ii*) what similarities existed between the metal distributions in the teeth and bone, and (*iii*) what inferences might be drawn from the results.

Archaeological context

In this study we examine material from the Cabur site in northern Peru. This site is located in the Jequetepeque Valley on the north coast of Peru. It is the palace of a local lord that was constructed in about 1150 A.D. and was abandoned in 1532 A.D. The site documents the continuity of local power through three cultural phases, including the Chimu and Inka imperial occupations of the Jequetepeque Valley. Three burials, dating to the Chimu period (ca. 1400 A.D.), were excavated from the central part of the site. These burials were of young children who were buried at the same time and were probably sacrificed (33). One tooth and one rib section were selected from one of these individuals (B12-U1-E2). The tooth section was analyzed at both the Advanced Photon Source (APS) and the National Synchrotron Light Source (NSLS), while the bone section was only analyzed at NSLS. The tooth was a lower right first permanent molar, and the sex was undetermined (because of its young age), however a dental eruption age of approximately 12.2 years could be estimated using standard methods (34), while the suggested age from an analysis of the cementum annulations (35) was 15.2 years. Thus, a range of 10–15 years is a reasonable estimate for the age of this individual.



The goal, from the archaeological perspective, was to add information to the osteobiography being constructed for this individual. In this case the information consists of the history of their exposure to trace elements in their diet and environment. When placed in the full osteobiographic and archaeological context, this information has potential implications for our understanding of the organization of craft production, distribution of resources, dietary choices, and population movements among the pre-Columbian Peruvian population.

Experimental

The tooth and rib selected for this experiment were embedded in resin and sectioned with a low speed diamond saw, followed by polishing with diamond grit using isopropanol as lubricant. The final thickness of the samples

Fig. 1. Micro X-ray fluorescence elemental maps of the tooth cross-section obtained at PNC/XOR. The cementum and dentine are indicated. The *x*–*y* scale represents pixel numbers, and the actual image size is 500 μm × 640 μm. The colour scale refers to the XRF intensity normalized to I_0 in total counts/I_0.

was between 50 and 100 μm. The embedded samples were mounted in such a way that no other material was present in the X-ray beam during measurements. The approximate concentrations of the elements of interest (~10 ppm) are too low to cause self-absorption effects in these samples.

Micro X-ray fluorescence maps were collected at the PNC/XOR (Pacific Northwest Consortium – Collaborative Access Team) facility (36), beamline 20-ID-B, located at the APS, Argonne National Laboratory and at beamline X27A (37) located at the NSLS, Brookhaven National Laboratory.

At APS, the incident X-ray energy was selected at 16 200 eV using a Si(111) monochromator, and a pair of Kirkpatrick–Baez mirrors focused the beam to 5 μm × 5 μm. This beam struck the sample at an angle of 45° relative to the sample surface. Emitted fluorescence X-rays were monitored using a 13 element Ge detector placed at 90° relative to the incident X-rays to minimize interference from scattered X-rays. The sample was scanned in 5 μm steps for Ca Kα, Zn Kα, Br Kα, and Pb L emission lines simultaneously. Both the Pb Lα and Pb Lβ lines were monitored, as the As K α line overlaps the lead Lα line but not the Pb Lβ line. The signal was only attributed to Pb if both Lα and Lβ patterns were identical.

At NSLS, the experimental geometry was identical. The incident X-rays were selected at 15 000 eV using a Si(111) monochromator, and focused to 6 μm vertically × 20 μm horizontally. Emitted fluorescence X-rays were monitored using a 13 element Ge detector, which collected Ca Kα, Zn Kα, Br Kα, and Pb L simultaneously.

Results and discussion

Figure 1 shows the tooth distributions of Ca, Zn, Pb, and Br obtained using the APS 20-ID beamline. The images obtained for Ca and Zn are consistent with our observations of other teeth (24, 26). Lead is present in the dentine and enriched in the cementum. In addition, there is a single highly enriched lead inclusion at the surface of the tooth. It is difficult to interpret the lead signal unambiguously. The presence of lead in the dentine and in a narrow band in the cementum might be taken as evidence for lead ingestion, but without clear evidence of banding in the cementum (26) this assignment is uncertain. The local enrichment at the tooth surface might well represent soil lead or metals introduced at burial. However, reports of lead artifacts are very rare in the Andean archaeological record. One galena spindle whorl has been reported for the site of Pampa Grande (38) and isolated artifacts have been reported from the sites of Tucumé (Narvaez, personal communication) and Puruchuco (Cock, personal communication).

Bromine is enriched in the cementum and present within the dentine. This result is consistent with a marine diet. Naturally any analysis showing enriched bromine at the burial site would challenge this interpretation.

Figure 2 shows the results obtained at the National Synchrotron Light Source, beamline X27A. Note that this beamline has a lower photon flux (36, 37) and larger spot size than the APS 20-ID beamline, and that the images were obtained from a different area. The results are an excellent match with those obtained at APS with the exception that the width of the cementum system varies somewhat across the image (this is not a surprising result as cementum thickness varies with location on the tooth), and there is evidence of banding in the calcium and zinc images.

Lead is indicated in the cementum and dentine; as well, there is some local enrichment at the surface. The scale bar

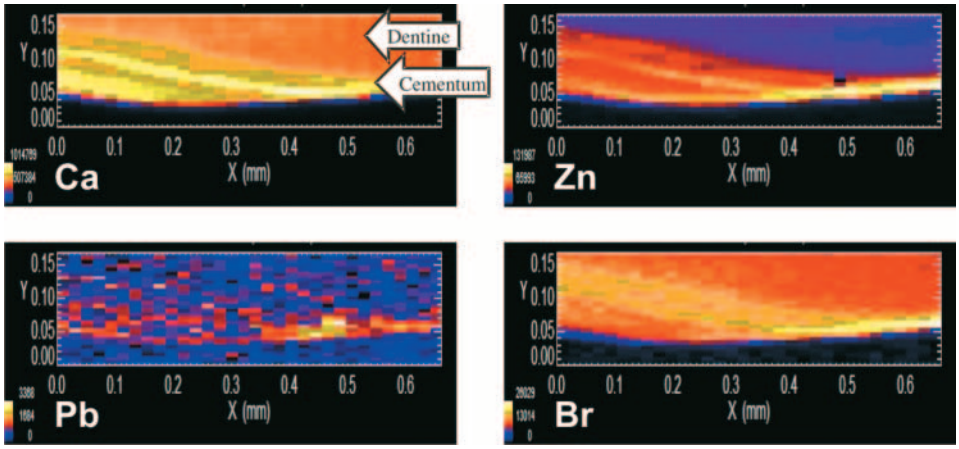
Fig. 2. Micro X-ray fluorescence elemental maps of the tooth cross-section taken on X27A. The cementum and dentine are indicated. The colour scale refers to the XRF intensity normalized to I_0 in total counts/I_0.



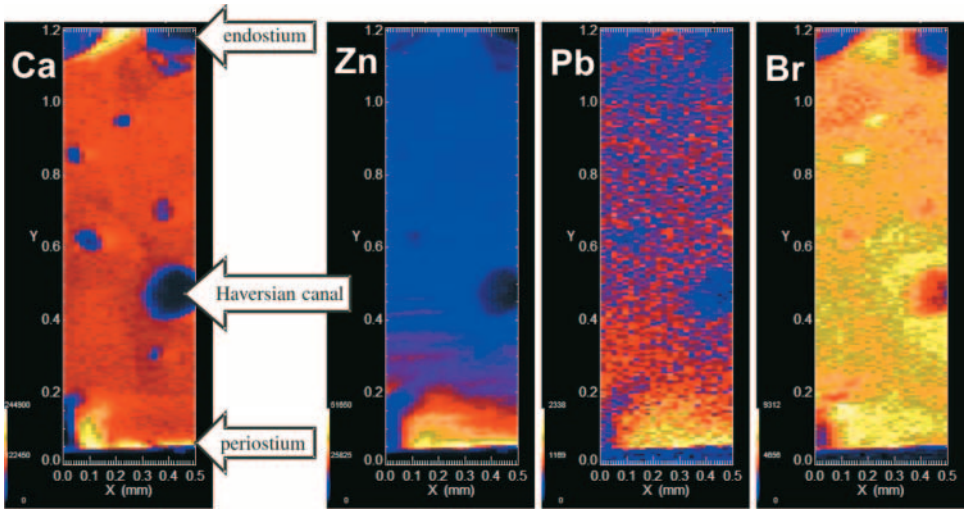


Fig. 3. Micro X-ray fluorescence elemental maps of the rib cross-section. The periostium, endostium, and a Haversian canal are indicated. The colour scale refers to the XRF intensity normalized to I_0 in total counts/I_0.

(see Fig. 2) suggests a 10-fold increase in the cementum relative to the dentine.

Bromine shows evidence for banding in the cementum; however, the interpretation of the results is virtually the same as for the previous area. Taken together, these similar results from different areas of the same tooth, obtained on synchrotron micro-beams with different spot sizes and photon fluxes, increases our confidence in the results.

Interpretation of the tooth data is rendered more difficult because of the young age of the individual. The youth of the individual means that the cementum region will be narrow and pronounced repeated banding would be unlikely.

Figure 3 shows the images obtained from the rib cross-section. The calcium image shows the mineralized portion of the bone with notable enrichment in the periostium, an observation consistent with the known distribution of bone density. There is also some enrichment in the endostium. The areas where calcium is absent are indicative of the Haversian canal systems through which blood vessels and nerves ramify in cortical bone, as well as representing regions where osteons are active. Haversian canals are not permanent at any site so that their distribution changes with time, older canals become mineralized while new ones develop in the process of remodeling. The widths of Haversian canals are indicative of an individual's age (39).

Zinc is enriched in the periostium. Lead is present in the periostium and the cortex. While diagenesis cannot be ruled out as an explanation for this pattern, when combined with the suggestive tooth data the argument for endogenous lead is strengthened. The lead distribution in the periostium is in general agreement with early lead–bone studies using synchrotron radiation (40).

Bromine reveals a complex pattern. It should be noted that bromine is enriched in both the periostium and endostium, where it exhibits the same pattern as calcium. There is also pronounced enrichment around the largest of the Haversian canals and around two of the remaining canals (y = ~0.9). The image appears to place Br within the canal. This is an experimental artifact resulting from the difference between the X-ray escape depths of Br Kα X-rays relative to Ca Kα X-rays (~0.4 mm and ~0.03 mm, respectively). As a result, the Br image is displaced and broadened relative to the Ca image (24). There is little or no bromine deposition near two of the remaining canals (y = ~0.6 and ~0.3). This distribu-

© 2007 NRC Canada

tion may have resulted if no bromine was present when the two bromine-free canals were active; if so, it may be possible to extract endogenous bromine chronologies (dietary shifts) from distribution patterns. This observation fits well with ongoing research on other samples from the Jequetepeque Valley that is using carbon, nitrogen and oxygen isotope analysis to examine patterns of mobility in pre-Columbian times (41).

In general, the results are similar to previous synchrotron microanalysis of bone (40).

Conclusions

Although carried out in different regions and on different beamlines, the depositional patterns in the tooth cross-sections are similar, exhibiting patterns for the individual elements observed in other samples. The distributions within the matching rib sample confirm the presence of all four elements in the bony skeleton.

The widely dispersed bromine signal in both tooth and bone may be ascribed with high confidence to a marine diet. Bromine exhibits a distribution pattern within the bone that suggests an intimate relationship with the Haversian canal system; this may be tentatively assigned to the depositional chronology of the element, which may indicate a significant dietary shift in the individual's lifetime.

Only one individual has been studied because of the difficulties encountered in obtaining well-documented samples from several individuals spread over several sites in Peru. Broad conclusions regarding the entire local population are not warranted at this time. Future work will include quantitative analysis of a significant number of individuals.

The lead signal may be indicative of widespread smelting using lead ores and coincident in time with the Cabur burials. The evidence that the lead is endogenous is strong, but in the absence of extensive banding in the cementum system must be tentative. Given the rarity of lead artifacts in the archaeological record, it is likely that any exposure to lead was the product of the pre-Columbian smelting of lead-bearing galena ore for silver. The deposition of lead in highland lake sediments during the Tiwanaku period has documented the ability of smelting products to spread over a wide area (32). No smelting site has yet been identified in the area of Cabur, but several other sites have been identified on the Peruvian north coast where smelting and (or) metal working took place (42, 43).

The enrichment of zinc in the cementum and in the outer layers of compact bone suggest that zinc may play a role in both tooth and bone mineralization.

The specific roles and (or) origins of the lead, zinc, and bromine will be the subject of future research using matched standards to quantify these species. Efforts will be undertaken to resolve their chemistry using XANES and EXAFS with model compounds.

Theoretical X-ray absorption investigation of the uniaxial compression of hexagonal graphite[1]

Dawn M. Shaw, Michael Odelius, and John S. Tse

Abstract: The X-ray absorption (XAS) and powder X-ray diffraction (XRD) spectra for the intermediate structures along uniaxial *c*-axis compression of hexagonal graphite are studied with the first-principles pseudopotential plane wave method. Comparison with experiment is made whenever results are available. A transformation from graphite to a new carbon phase was observed in the simulation. The new phase consists of alternating linkages of the graphite layers via the formation of C–C σ bonds. The calculated XAS and XRD reproduced most but not all of the features observed in a recent experiment. Comments are made on the reliability of the computational procedures to reproduce the XAS of these structures.

Key words: graphite, uniaxial compression, ab initio, and X-ray absorption spectroscopy.

Résumé : Faisant appel à la méthode des premiers principes du plan pseudopotentiel, on a étudié la possibilité d'utiliser les spectres d'absorption de rayons X (SAX) et diffraction de rayons X par des poudres (DRX) pour les structures intermédiaires le long de la compression de l'axe c uniaxial du graphite hexagonal. Chaque fois que des résultats sont disponibles, on fait une comparaison avec des données expérimentales. Dans la simulation, on a observé une transformation du graphite en une nouvelle phase de carbone. La nouvelle phase est formée de liaisons alternées de couches de graphite qui résultent de la formation de liaisons σ C–C. Les spectres SAX et DRX calculés reproduisent la plupart des caractéristiques qui ont été observées dans une expérience récente. On fait aussi des commentaires sur la fiabilité des méthodes de calcul pour reproduire les spectres SAX de ces structures.

Mots-clés : graphite, compression uniaxale, ab initio, spectroscopie d'absorption des rayons X.

Introduction

It is well known that carbon can participate in sp-, sp^2-, and sp^3-type bonds, and hence exists in a variety of forms. The conversion mechanism between various forms of carbon has long been a topic of interest (1). Much of the work, both theoretically (2–5) and experimentally (6–10), has largely been focused on the conversion of graphite to diamond. However, details on the direct conversion route from graphite to diamond are still unknown. This, in part, is due to the mixture of rhombohedral and hexagonal graphite in the samples used in the experiments (2). Theoretical calculations, on the other hand, are able to distinguish between the chemical behavior of rhombohedral and hexagonal graphite. For this reason, they have been able to provide insight into the different possible conversion pathways for the transformation from graphite to diamond. From the calculations, it is clear that, depending on whether the starting graphite structure is rhombohedral or hexagonal, the conversion route to diamond is different (2). Rhombohedral graphite is shown to transform directly to hexagonal diamond (2, 3) when it is compressed. On the other hand, hexagonal graphite transforms to a superhard phase (4, 5), which is not quench-recoverable at room temperature (10, 11). To convert this superhard phase to diamond, the crystal must be heated to provide energy for lateral motion between the puckered layers (10, 11), which facilitates the formation of interlayer C–C bonds. Very recently, an experimental investigation (10) has shown that this superhard form of graphite is structurally different from the more well-known hexagonal diamond. The formation of this new polymorphic phase has been characterized using inelastic X-ray scattering (IXS) and XRD experiments. IXS provides similar information to XAS but is applicable to in situ studies of materials in a diamond anvil cell.

A number of experimental (10, 12–18) and theoretical (10, 12, 13, 18–21) studies have focused on the assignment of the spectral features in the electronic spectra of graphite and diamond. The assignment of the transitions to higher-energy continuum states in the conduction band is less straightforward. For this reason, assignments for this region are often ambiguous. Lower-energy electronic transitions to the conduction band are well-characterized, but their exact nature is still being debated (14, 15, 17). Apart from the lack

of a detailed understanding, the electronic spectra are still indispensable for monitoring changes in the chemical bonding as graphite is compressed. As the graphite layers are compressed, some of the carbon will rehybridize from sp^2 to sp^3 with concomitant formation of C–C bonds between layers. As a result, significant changes in the electronic spectra are observed. These changes can be followed and provide evidence of sp^2-to-sp^3 transition of graphite under pressure.

In this study, the structures obtained from uniaxial compression of the *c* axis of hexagonal graphite are reported. Theoretical XAS and XRD patterns are computed, and comparison is made to experiment where possible. The present approach is reasonable, since in the XAS experiment (10), compression was performed in a diamond anvil cell without a hydrostatic medium. The sample preferentially aligned with the graphite layers perpendicular to the compression direction, and this is very similar to uniaxial compression.

Computational methods

The starting structure was constructed from the lattice coordinates of hexagonal graphite. An orthorhombic cell containing 3 × 2 × 2 unit cells was used. The resulting supercell consisted of four graphite layers with a total of 96 carbon atoms. The initial model had lattice constants $a = b = 2.456$ Å and $c = 6.696$ Å, corresponding to a density of 2.28 g cm^{-3}, which is close to the experimental value of 2.265 g cm^{-3} (11). It is noteworthy for subsequent discussion that the length of the "*c*" axis of the model is twice that of the experimental *c* axis of the initial structure. At ambient conditions, it is four times the interplanar graphite distance. Electronic structure calculations and geometry optimizations were performed with the pseudopotential plane wave method implemented in the Car Parrinello (CPMD) suite of programs (22). The Perdew–Burke–Enzerof (PBE) exchange–correlation functional (23) was used in the calculations. The core electrons for the carbon atoms were replaced with the Troullier–Martins pseudopotential (24). In the calculation of the XAS, a similar procedure was used to generate an appropriate pseudopotential representing the screened or unscreened core-hole states. Wave functions of the valence electrons were expanded in a plane-wave basis set with an energy cutoff of 70 Rydberg. The energy sampling was done for the Γ-point only. Although the calculations were performed using a single *k* point, it is expected that the larger supercell used here reduces the need for a larger set of *k* points (25). Geometry optimizations were performed using the preconditioned conjugate gradient (PCG) method. Convergence is achieved so that the largest contribution to the gradient of the nuclei was less than or equal to 0.001 Hartree/Bohr.

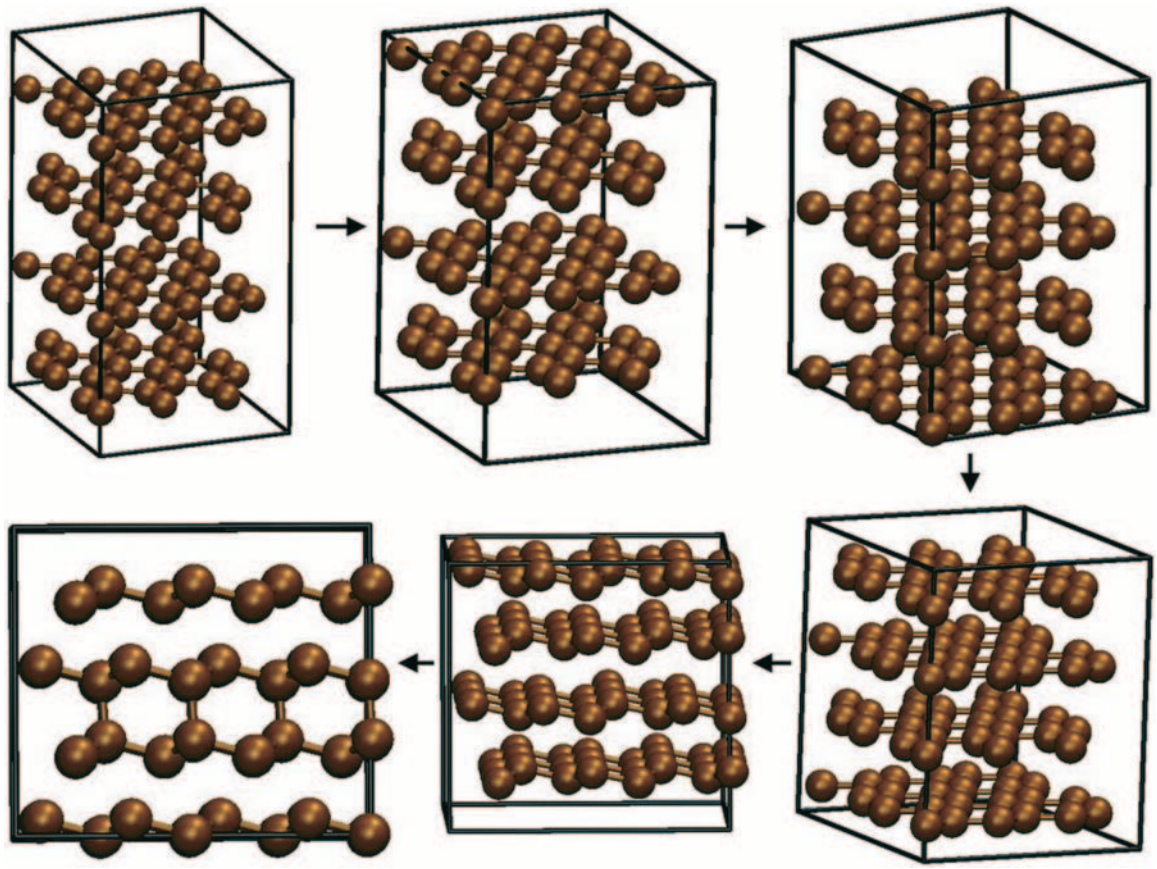
It has been shown in a previous XRD study (10) that the change in the *a* axis with uniaxial compression is quite small. Thus, the simulation was performed by gradually reducing the *c* axis of the model system by a selected amount. The atomic positions at each compression step were reoptimized with the cell axes fixed. This process was repeated until the interlayer distance was reduced to less than 2.0 Å. At this point, bonding between the carbon layers was observed, and no further compression was necessary. In total, five compressions were performed. Since the sample was not compressed hydrostatically, we chose not to estimate the applied pressure for each compression.

At each compression, once the structural relaxation had been achieved, the XAS for the intermediate structure was computed. In principle, the XAS intensities (oscillator strengths) should be computed individually for a large number of excitations from the core level to vacant valence, Rydberg, and continuum states. This procedure, however, is prohibitively expensive. An approximation, which may circumvent this problem, is to employ the transition potential method of Slater (26). Within this approximation, electron excitations are computed from wave functions of the initial and final states obtained from the transition-state potential. The transition matrix elements for the excitation from a 1s core orbital $|\phi_{1s}>$ to a final state $|\phi_f>$ with energy ω_f is given by

$$[1] \qquad I = \frac{2}{3}\omega_f \left| \langle \phi_{1s} | \bar{\mu} | \phi_f \rangle \right|^2$$

where μ is the dipole operator and *I* is the intensity of the transition. Spectra are then obtained from the eigenvalues and pseudo-wavefunctions projected onto a numerical basis containing the three functions ($\phi_{1s}x$, $\phi_{1s}y$, $\phi_{1s}z$). The resulting spectra are convoluted in a manner similar to that suggested in ref. 27. Namely, a set of Gaussian broadening functions with full width half maximum (FWHM) estimated from experiment were used to convolute the calculated excitation energies. In addition, an error function was used to mimic effects of the edge jump. To insure the quality of the wave function for the XAS, the cutoff was increased first from 70 to 90 and then to 110 Rydberg. At a 90 Rydberg cutoff, no significant change in the XAS was observed, indicating that convergence in the energy cutoff had been achieved.

Two approaches were used to approximate the final state in the calculations of the near-edge XAS spectra: the half (partially screened) core hole (HCH) (28) and full (unscreened) core hole (FCH). In the half core-hole approach, the wave function is obtained with half an electron removed from the core. Accordingly, a pseudopotential was generated with the same electron configuration. This approach is known to include relaxation effects up to second order and yield spectra in reasonable agreement with experiment (26, 28). The "transition-state" empty orbitals were used in the calculation of the XAS spectra. In the full core-hole approach, one electron is removed from the core. In this case, this is equivalent to an unscreened final core-hole state.



Powder XRD patterns at different stages of compression were generated from the corresponding optimized atomic positions with the program Mercury (29) at the experimental X-ray wavelength $\lambda = 0.331$ Å (10).

Results and discussion

Figure 1 shows the crystal structures obtained at different stages of compression. Arrows in the figure denote the direction of increasing uniaxial pressure. A transition from an sp^2-layered structure to a buckled structure is clearly observed at $c = 7.392$ Å (in the diagram, carbon atoms were connected when their distance was less than 1.5 Å). It is significant to note that interlayer C–C single bonds are observed only between alternate pairs of layers. This structure

Fig. 1. Structures obtained from uniaxial compression of the *c* axis of hexagonal graphite. The compression path follows the arrows shown in the figure, leading from hexagonal graphite to a form where there is significant bonding between alternate layers. Note that the "*c*" axis in the initial structure is twice that of the crystallographic *c* axis.

is clearly different from hexagonal diamond, where the C–C bonds linking adjacent layers are complete, forming a 3D network. This observation is in contrast with the experimental suggestion that the new high-pressure phase obtained at 23 GPa has a 3D structure (10), although details of the structure have not been characterized. Thus, the present theoretical calculations predict a new polymorph of carbon.

Powder XRD patterns corresponding to the intermediate structures are shown in Fig. 2. The predicted diffraction patterns are in reasonable agreement with experimental XRD patterns reported in refs. 8 and 10. Since the experiments may have included both the rhombohedral and hexagonal forms, an exact match to experiment is not possible. Furthermore, since the experimental sample undoubtedly has preferred orientation, a direct comparison of the calculation with the observed Bragg peak intensity is not appropriate.

In the calculation, as the *c* axis is reduced, some of the hexagonal-graphite diffraction peaks disappear. In addition, some weak peaks become more intense and new Bragg peaks appear in the region $8° < 2\theta < 9°$. This observation is indicative of the formation of a new structure different from the hexagonal graphite. Changes to the XRD initiate at c = 11.392 Å (the second compression step). However, significant changes are observed when $c < 10.192$ Å. As shown in Fig. 1, a definite buckling and the formation of interlayer C–C bonds starts to appear when $c = 8.992$ Å (in the fourth compression step). Changes in the calculated XRD patterns reflect the onset of the sp^2-to-sp^3 transition. A detailed examination of the calculated diffraction pattern shows that additional Bragg peaks started to appear at $2\theta \approx 14–16°$. This feature is associated with the shifting of the graphite layers against each other. At the third compression step, a new peak starts to emerge at $2\theta \approx 16.7°$ and becomes more prominent at the fourth compression step. This is due to the puckering of the graphitic layers. The final diffraction pattern shows an additional weak peak at $2\theta \approx 8.8°$, and it corresponds to the complete linking of the adjacent graphite layers. The theory reproduces the experimental results semiqualitatively. In the experiment, as the pressure increases, the [002] peak shifts to higher diffraction angle with decreasing intensity. A broad unresolved band of diffraction peaks starts to develop from $2\theta \approx 8–11°$ with an additional feature at $2\theta \approx 13.5°$. At the highest pressure (23.9 GPa), there appears to be a feature at 8.4° and broad peaks at 9–10° and 15–17°, indicating a mixture of crystalline materials.

Now, we turn to the discussion on the electronic structure associated with the structural changes. Figure 3 shows the powdered average XAS for structures obtained from uniaxial compression along the *c* axis using the HCH approach. The HCH approach is the generally accepted model and has been shown in a recent study to give XAS in almost quantitative agreement with experiment (28). When graphite is compressed, because of the linkage of the graphite layers to form

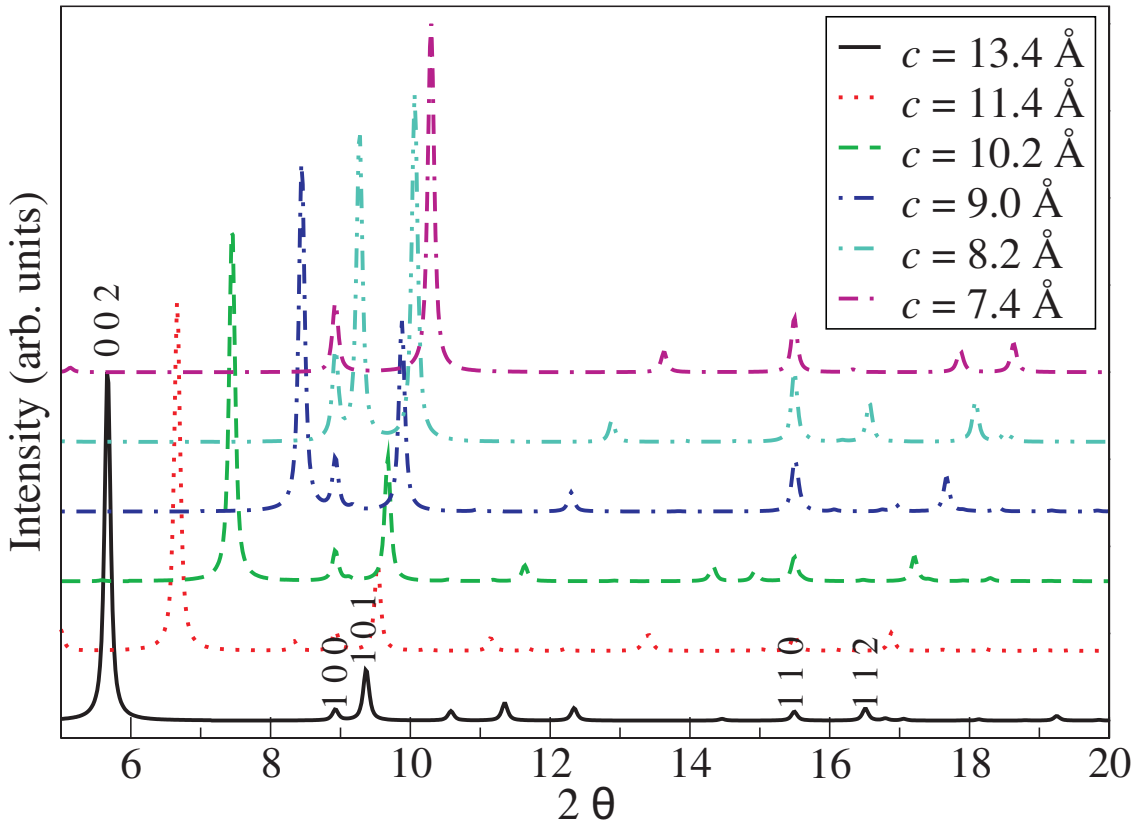
Fig. 2. Calculated powder XRD for structures obtained via uniaxial compression along the *c* axis. Note that the *c* axis of the simulation model is twice that of the crystallographic cell (see text).



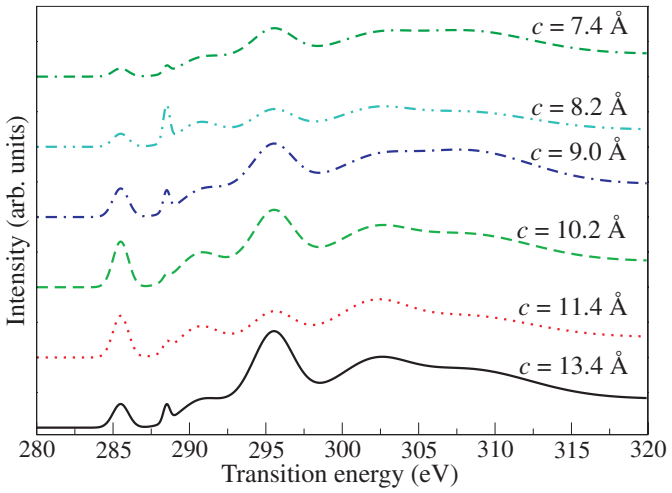


Fig. 3. Powdered average XAS for graphite structures computed via uniaxial compression along the *c* axis using the HCH approach.

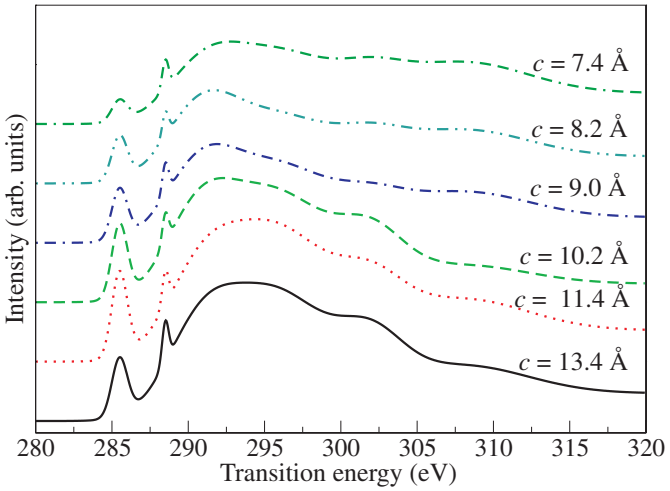
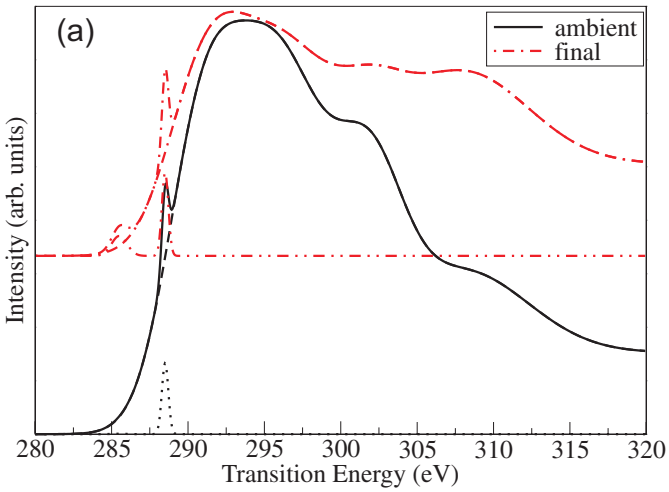


a three-dimensional structure, the intensity of the low-energy pre-edge peak, which is assigned to excitations into the π^* orbital, is expected to decrease gradually, and the intensity of the bands corresponding to the σ^* excitations should increase substantially, as shown in the vertical IXS spectra in ref. 10. This implies a reduction in the π bonding between carbon atoms in the layers with a concomitant increase in σ bonding between the layers. However, as shown in Fig. 3, as uniaxial pressure is applied, the theoretical spectra show an initial increase in the π^* peak, then a decrease as the *c* axis is further compressed. The intermediate structures corresponding to the compression are shown in Fig. 1. The initial increase in the π^* intensity can be traced back to the small shift between the graphite layers. However, the overall agreement of the theoretical XAS spectra computed with the HCH approximation with experiment is rather poor. In the experiment, the intensity of the π^* peak decreases monotonically with pressure. Moreover, the calculated intensity of the π^* to the σ^* bands are significantly underestimated.

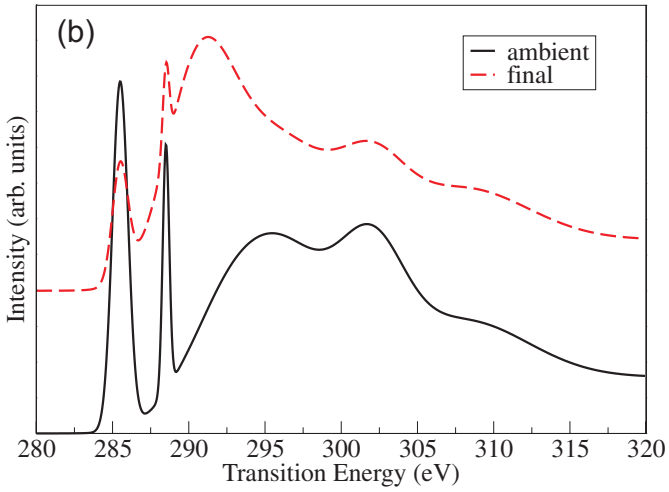
A possible cause for the discrepancy may be the improper description of the core-hole state. To this end, calculations of the XAS of uniaxially compressed graphite were repeated using the FCH approximation. Figure 4 shows the XAS obtained using the FCH approach. The spectra show a different trend as predicted by the HCH calculations. The most significant difference is on the computed relative intensity between the π^* and σ^* peaks. The FCH approach has improved the relative π^*/σ^* intensities significantly, and they are now in closer agreement with experiment. Moreover, the behavior of the π^* excitation with increasing compression is now in qualitative agreement with experiment. There is only a slight increase in the π^* intensity in the first compression step. This again is attributed to the relative shift of the graphite layers. However, with increasing compression, the π^* intensity decreases as observed in the experiment. The calculated XAS spectra are still not in quantitative agreement with experiment. The remaining discrepancy, apart from the assumptions made in the theoretical calculations,

© 2007 NRC Canada

Fig. 4. Powdered average XAS for graphite structures computed via uniaxial compression along the *c* axis using the FCH approach.



would be due to the fact that the experimental sample may be a mixed phase as commented earlier. Taken in all, there is a qualitative agreement between the FCH results and experiment.



To investigate details of the absorption spectra, polarization-dependent XAS spectra calculated with the FCH approximation are reported in Figs. 5*a* and 5*b*. Using polarized synchrotron radiation, it is possible to resolve contributions from the C_{1s} to π^* transition, which is perpendicular to the graphite plane (i.e., *z*-polarized), and the C_{1s} to σ^* transition, which is parallel to the graphite plane (i.e., *xy*-polarized). We can perform calculations in a similar manner, dividing the XAS into *c* (*z* axis, vertical) and *a*, *b* (*x*–*y* axis, horizontal) components.

At zero pressure, the *xy*-polarized XAS spectrum (Fig. 5*a*) shows a small but sharp pre-edge feature at 288.5 eV and several broad features at 293, 302, and 307 eV. The low-energy peak has been assigned to excitation into a π^* orbital (16). The intensity of this peak is very low in comparison to the σ^* contribution (see dashed line in Fig. 5*a*, where the π^* excitation below 290 eV is plotted separately). This is due to orbital mixing as a result of the lowering of the symmetry when a localized core hole is generated. The broad features are excitations into the σ^* continuum. There is no substantial change in the *xy*-polarized XAS profile when the graphite is compressed.

The *z*-polarized XAS spectrum (Fig. 5*b*) differs significantly from the *xy*-polarized spectrum. Two intense excitations are observed at 286 and 288.5 eV. This is followed by broad features at higher energy. The first sharp peak is undoubtedly assigned to the strong symmetry allowed $C_{1s} \rightarrow \pi^*$ excitation. The second sharp peak at 288.5 eV, which has energy close to the first sharp excitation in the *xy*-polarized spectrum can also be assigned to a π^* excitation (16). In contrast to the *xy*-polarized XAS, the intensity of the π^* excitation decreases substantially when graphite is compressed. This is not surprising. As commented before, this is the consequence of the loss of π bonding in graphite because of cross linkage of adjacent graphite layers under uniaxial pressure.

Fig. 5. Polarized XAS for graphite at ambient pressure and after the fifth (final) compression step, computed using the FCH. Polarization is (*a*) in the *xy* plane and (*b*) along the *z* axis. Note that the absolute magnitudes of the XAS intensities are not the same for both the ambient pressure and the compressed structures. The small peak assigned to the π^* excitation in the *xy*-polarized spectrum is separated from the plot and shown as a dashed line.

The results show that the FCH method may be more appropriate to describe the XAS for graphite. This would imply that the screening of the core hole is not very effective in this case, which is quite surprising for a system with extensively delocalized π electrons. The sensitivity of the calculated spectral features with the approximation for the core-hole state is puzzling and problematic. The HCH approach, which satisfies the Slater transition-state theory and partially accounts for core relaxation effects, should be more theoretically sound. In this case, a direct comparison between calculated and observed spectra of compressed graphite shows that apparently FCH is the preferred approximation for the calculation of the XAS spectra, at least qualitatively. A possible explanation is that dynamical screening effects may be important. Moreover, since energy-dependent self-energy effects are not included, the calculated peak positions and intensities are expected to deviate from experi-

© 2007 NRC Canada

ment. The theoretical reason behind this trend is under investigation.

Conclusions

In conclusion, theoretical XAS and XRD for the uniaxial compression of hexagonal graphite are presented and compared with experiment. The XRD are shown to be in reasonable agreement with experiment and clearly show that sp^2-to-sp^3 transition is achieved once the *c* axis value is reduced beyond roughly 7.2 Å. This corresponds to an interlayer spacing below 1.8 Å, which is close to the C–C single-bond length of 1.5 Å. This observation is supported by the reduction of the π^* and subsequent increase of the σ^* peaks in both the FCH and HCH computed XAS. In all cases, general features of the XAS, particularly in the pre-edge region, are reproduced, but quantitative agreement with the observed spectra has not been achieved. In the graphite system, the relative π^*/σ^* peak intensities in the XAS are not reproduced accurately with both the FCH and HCH approximations. Finally, although cross-linkage of the graphite layers under cold compression was observed in the theoretical calculations, we failed to achieve a completely three-dimensional network, which might otherwise explain the superhardness (10) of the new phase observed in the experiment. The reason for the lack of quantitative agreement with experiment is currently under investigation.

Geometries and energetics of methanol–ethanol clusters: a VUV laser/time-of-flight mass spectrometry and density functional theory study[1]

Y. Liu, S. Consta, F. Ogeer, Y.J. Shi, and R.H. Lipson

Abstract: Hydrogen-bonded clusters, formed above liquid methanol (Me) and ethanol (Et) mixtures of various compositions, were entrained in a supersonic jet and probed using 118 nm vacuum ultraviolet (VUV) laser single-photon ionization/time-of-flight mass spectrometry. The spectra are dominated by protonated cluster ions, formed by ionizing hydrogen-bonded Me_mEt_n neutrals, m = 0–4, n = 0–3, and $m + n$ = 2–5. The structures and energetics of the neutral and ionic species were investigated using both the all-atom optimized potential for liquid state, OPLS-AA, and the density functional (DFT) calculations. The energetic factors affecting the observed cluster distributions were examined. Calculations indicate that the large change in binding energy going from trimer to tetramer can be attributed more to pair-wise interactions than to cooperativity effects.

Key words: alcohol clusters, cluster formation, DFT calculations, mass spectrometry, vacuum ultraviolet laser.

Résumé : Les agrégats à liaisons hydrogènes qui se forment au-dessus de mélanges de méthanol (Me) et d'éthanol (Et) liquides de compositions diverses ont été entraînés dans un jet supersonique et on les a étudiés grâce à une combinaison de spectrométrie de masse à temps de vol et d'ionisation à simple photon produite par un laser ultraviolet sous vide (UVV), à 118nm. Les spectres sont dominés par les ions protonés, formés par l'ionisation des espèces neutres qui s'ionisent, Me_mEt_n dans lesquelles m = 0–4, n = 0–3 et $m + n$ = 2–5. On a étudié les structures et les énergies tant des espèces neutres qu'ioniques à l'aide d'une combinaison calculs de la théorie de densité fonctionnelle (TDF) et du potentiel optimisé de l'état liquide pour tous les atomes (POEL-TA). On a examiné les facteurs énergétiques qui affectent les distributions d'agrégats qui ont été observés. Les calculs indiquent que le grand changement d'énergie de liaison qui est observé en passant du trimère au tétramère peut être attribué plutôt à des interactions par paire qu'à des effets de coopération.

Mots-clés : agrégats d'alcools, formation d'agrégats, calculs selon la théorie de la densité fonctionnelle (TDF), spectrométrie de masse, laser UV sous vide.

[Traduit par la Rédaction]

Introduction

Alcohol clusters have attracted considerable experimental and theoretical attention (1–3), since they often serve as prototypical molecules to study molecular association through hydrogen bonding (H-bonding). Compared to water molecules that can form as many as four H-bonds, the alkyl group in an alcohol molecule limits the number of intermolecular H-bonds each hydroxyl group can form. The interplay between the formation of H-bonding and the steric repulsion between alkyl groups determine the structure and stability of alcohol clusters. For small alcohol clusters such as methanol (Me) or ethanol (Et), H-bonds play a key role in determining the most-stable structures (4), whereas the alkyl chains have a more pronounced effect in larger clusters, as shown in our earlier studies of butanols (5). Despite the extensive amount of research that has been done on neat alcohols (1–3), the number of studies on alcohol mixtures, specifically on their vapor cluster compositions, is quite limited. In this work, VUV laser/time-of-flight (TOF) mass spectrometry was used to probe Me–Et clusters formed in the vapor phase above their liquid mixtures. Their structures and energetics were investigated using both the all-atom optimized potential for liquid state, OPLS-AA (3), and the density functional (DFT) calculations.

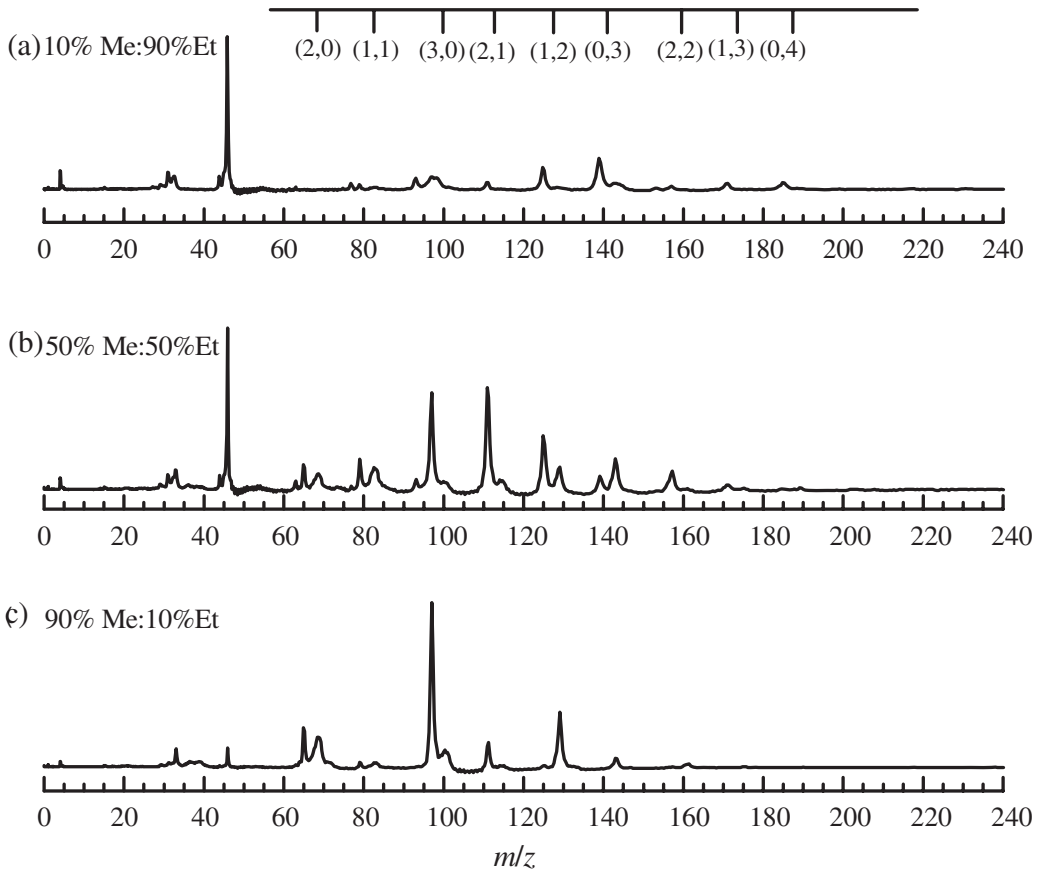
Fig. 1. A plot of the total vapor pressure of methanol–ethanol mixtures as a function of the mole fraction of ethanol (X_{Et}). The insert shows the deviation between the experimentally determined vapor pressures and those calculated using Raoult's Law.

molecules having different functional groups (7). In this work, ~10 mL of Me:Et liquids with different volume ratios ranging from 10%:90% to 90%:10% was placed in a stainless steel vial. After the vapor–liquid equilibrium was achieved, ~1 atm (1 atm = 101.325 kPa) of He carrier gas was passed through the liquid mixtures. The alcohol vapor entrained in the carrier gas was subsequently expanded as a supersonic jet into the ionization region of the mass spectrometer. As shown in Fig. 1, experimentally measured Me:Et vapor pressures as a function of the mole fraction of Et (8), X_{Et}, are very close to those predicted by Raoult's Law. The negative deviations from Raoult's law (the insert in Fig. 1), while expected for alcohol systems capable of hydrogen-bonding, are at most only ~0.5% of the total vapor pressure at $X_{Et} \approx 0.6$. Thus, it was felt that Raoult's Law could be reliably used to predict the vapor-phase compositions.

The jet was ionized by 118.2 nm VUV light generated by non-resonant third harmonic generation in a phase-matched Xe/Ar gas cell. The positively charged ions were extracted and dispersed in a linear time-of-flight mass spectrometer ($m/\Delta m \approx 500$). The ions were detected at the end of the 1 m flight tube by a microchannel plate (MCP) to produce a mass spectrum of m/z vs. ion intensity.



Experimental results

Typical TOF mass spectra of the Me:Et mixtures are shown in Fig. 2. Many more peaks are found in the region $m/z > 46$ (Et monomer) than in the spectra obtained using pure Me or pure Et (4). Peak assignments are listed in Table 1. The main observation is the presence of heterogeneous cluster ions formed from Me and Et, which can be represented by a general formula $HMeEt_n^+$ or (m, n) where m, n = 1–4, and $m + n \leq 5$. The homogenous Me and Et cluster ions are also present, and fit the general formula when either m or n is set to 0. The fragment ion at m/z = 77 is attributed to methyl loss from ethanol dimer to produce $[CH_2{=}OH^+{\cdots}HOC_2H_5]^+$. Most of the peaks have shoulders to slightly higher m/z, which are attributed to metastable decomposition leading to daughter fragment-ion formation inside the drift tube of the mass spectrometer.

The most-striking feature for all the TOF mass spectra of the Me:Et mixtures studied in this work is that the strongest features belong to the trimer ions of the protonated cluster. This agrees with the results obtained using neat alcohol vapors (4). The strongest peak centered at m/z = 139 in the sample with 10% Me can be assigned to Et_3H^+ clusters. In the sample with 50% Me, the dominant features at m/z = 97 and 111, correspond to Me_3H^+ and Me_2EtH^+ clusters, respectively. In the sample with 90% Me, the mass spectrum is dominated by the peak at m/z = 97, corresponding to Me_3H^+. It is interesting to note that the TOF mass spectrum of the 90% Et: 10% Me binary mixture exhibits more heterogeneous cluster ions than that of the 10% Et: 90% Me mixture, which suggests that Me has a higher tendency to self-associate in the gas-phase than Et.

Fig. 2. VUV laser mass spectra of methanol (Me) – ethanol (Et) vapor mixtures found in equilibrium with Me–Et liquid mixtures having volume ratios of (*a*) 10:90, (*b*) 50:50, and (*c*) 90:10. Raoult Law predicts the gas-phase molar percentage ratios to be approximately (*a*) 19:81, (*b*) 70:30, and (*c*) 95:5. The numbers in brackets are (*m*, *n*) values corresponding to the most abundant $Me_mEt_nH^+$ as described in the text.

Previous studies have shown that VUV ionization of neat Me and Et clusters yields a protonated species by the following reaction (9):

[1] $$R_n \xrightarrow{hv} R_{n-1}H^+ + RO^- \text{ or } RO^{\cdot} + e^-$$

where R denotes the alkyl chain. Similar reactions are assumed to hold for the mixed cluster as well:

[2] $$Me_mEt_n \xrightarrow{hv} Me_{m-1}Et_nH^+ + MeO^{\cdot} + e^-$$

$$Me_mEt_n \xrightarrow{hv} Me_{m-1}Et_nH^+ + EtO^{\cdot} + e^-$$

Equations [1] and [2] suggest that the probability of protonated (N – 1)-mer formation can be correlated to the abundance of the neutral N-mer. Such a correlation would be invalid for van der Waals clusters because, upon ionization, they lose monomer units uncontrollably by evaporation (10). Neutral alcohol clusters, however, differ in that hydrogen-bonding is ≥10 times stronger than van der Waals interactions. An ionized alcohol cluster can be viewed as a solvated proton surrounded by monomer units (11). Thus, the combination of evaporative cooling due to the loss of one ligand (eqs. [1] and [2]) and solvated proton–ligand polarization makes further ligand loss difficult. Although this effect will become less important with increasing neutral-cluster size, the ion intensities recorded by VUV laser/mass spectrometry should qualitatively correlate with the neutral-cluster distribution in the supersonic expansion. Moreover, our work on neat methanol (4), ethanol (4), and butanol (5) vapors showed that the cluster distributions are relatively unaffected by changes in the stagnation pressure of the carrier gas used to form the supersonic expansion. This observation is supported by the work of Jackson and co-workers (12) who obtained essentially identical neat-alcohol mass spectra to ours but using very different stagnation pressures. Together, the experimental results suggest that neutral tetramers are the most-abundant clusters prior to ionization.

These neat-alcohol cluster distributions were simulated previously using a Grand Canonical Monte Carlo scheme (4, 5), which established that the dominance of the tetramer could only be understood if the vapor introduced by this experimental method was supersaturated. While the exact level of supersaturation has not been established quantitatively in this work, the design of experimental arrangement used to deliver the gas into the system made such a scenario a distinct possibility.

Theoretical calculations

Density functional (DFT) calculations were carried out using GAUSSIAN-98 program (13). The hybrid density functional B3LYP (14) was used, since it has been shown to provide reliable results for hydrogen-bonded systems, including neat-alcohol clusters (15, 16). Since an accurate de-

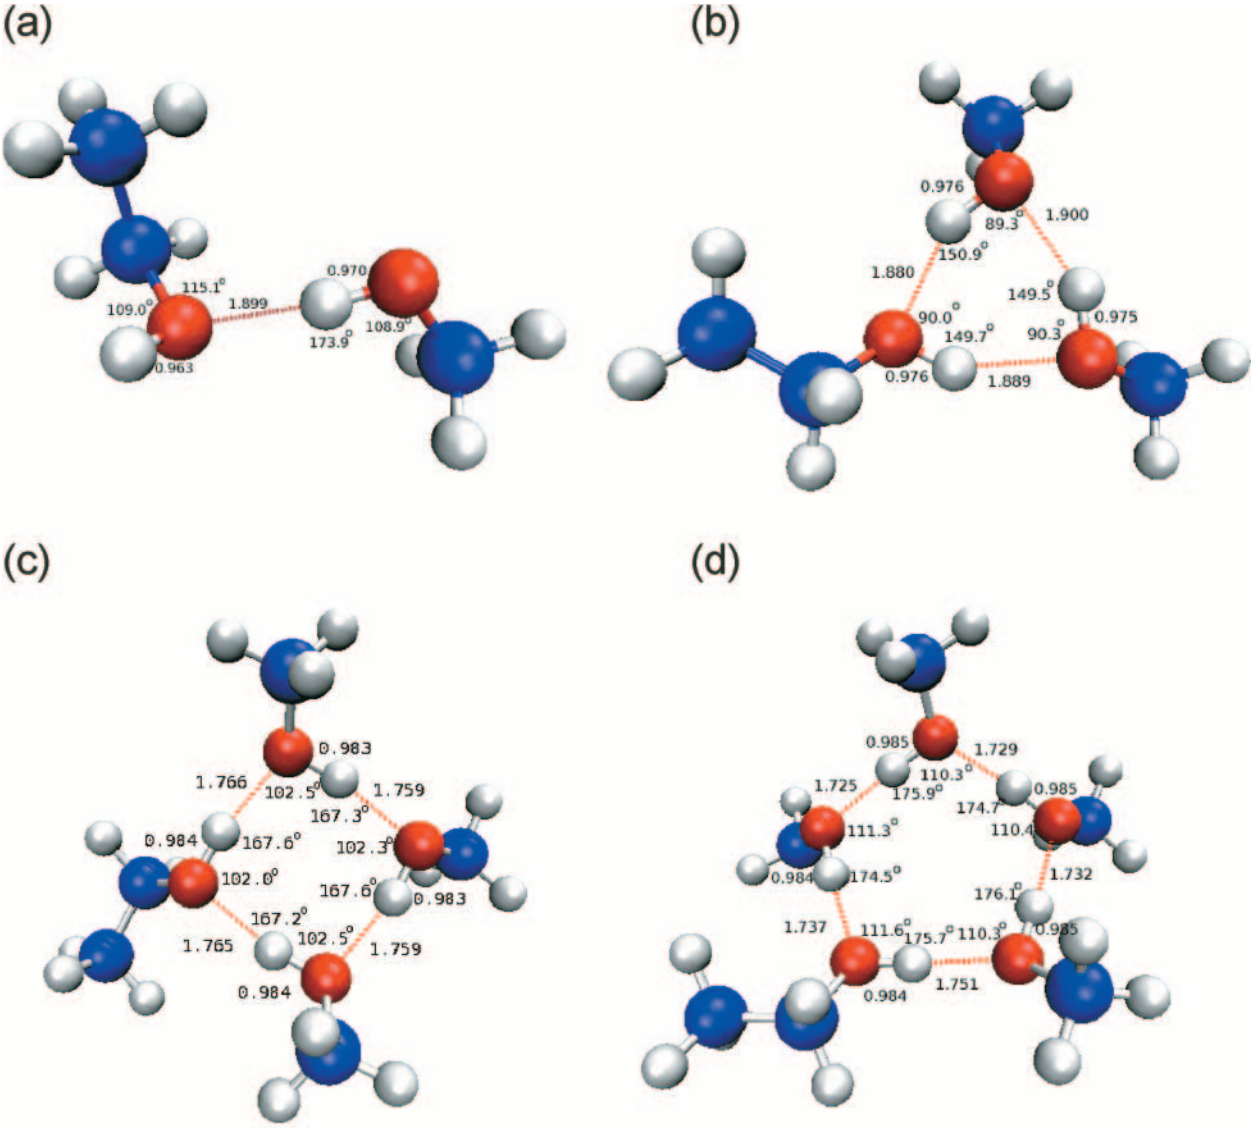
scription of H-bonds requires a highly flexible basis set, the 6–311++G(d, p) basis set was used for geometry optimization, followed by single-point energy (SPE) calculations using a larger basis set, 6–311++G(3df, 2p). The energies were corrected for zero-point energy (ZPE) and basis-set superposition error (BSSE) (17). Geometry optimizations were also done using the OPLS-AA force field. Comparison with the DFT results can provide an evaluation of the empirical potentials used in the OPLS-AA force field.

(a) Structures of Me_mEt_n (m = 0–4, n = 0–4, $m + n$ = 2–5) isomers

Alcohol clusters exhibit structural isomerism. For example, the ethanol monomer has a trans (t) and a gauche (g) conformation in which the trans isomer is slightly more stable than the gauche. Global minima on the potential energy surface (PES) for the structural isomers were found by first performing Molecular Dynamics (MD) simulations in a NVT ensemble at T = 100 K using the OPLS-AA force field. Several tens of local minima on the PES were then selected as the initial conformations for geometry optimizations using the OPLS-AA force field. The structures obtained were further optimized by DFT/B3LYP calculations. The optimized structures among the most-stable isomers are shown in Figs. 3*a*–3*d*. Except for the dimers, which form open structures, the most-stable structures for the trimers through to the pentamers are monocyclic rings in which each molecule has two H-bonds. The oxygen atoms in these structures act as both a proton donor and an acceptor. The number of H-bonds is a maximum in the cyclic trimer, which agrees reasonably with intuition. However, cyclic tetramers and pentamers in fact do not have the maximum number of H-bonds possible. For example, the monocyclic pentamer is more stable than the branched cyclic species even though one molecule in the branched cyclic structure has three H-bonds. It should be appreciated that another common feature of the monocyclic structures is that the alkyl groups are arranged to minimize steric hindrance. A similar behavior is found for water clusters (18).



Figures 4*a*–4*d* show the dependences of the nearest-neighbour O–O separations, the H-bonded O–H bond lengths, the covalent O–H bond lengths, and the OHO angles on cluster size. These values were calculated by taking averages over various mixture clusters. As the cluster size increases, the O–O distance ($r_{O–O}$) and the H-bond length ($r_{O–H}$) decrease, while the covalent O–H bond lengths ($r'_{O–H}$) increase slightly. These trends indicate that the monocyclic structures contract because of H-bond shortening as the cluster becomes larger. This structure change implies that H-bonding becomes stronger with the increasing cluster size, which is consistent with the trends of the average binding energies per molecule (see later). On the other hand, the O–O repulsions do not favor the contractions energetically. The interplay between H-bonding and O–O repulsion results in the tetramers and the pentamers having comparable $<E_b>$ and $<r_{O–O}>$. A similar trend was also found in our previous studies of the *n*-butanol and *iso*-butanol isomers, but not for *sec*-butanol and *tert*-butanol (5). Since the *sec*-butanol and *tert*-butanol have short and bulky alkyl chains, steric repulsion makes the O–O separations larger in the pentamers than in the tetramers. The structural changes in small alcohol clusters resemble those of water including a systematic contraction of the nearest-neighbour O–O separation with increasing cluster size, and a red shift of the H-bonded OH stretch frequency (19, 20).

The proton positions were located in this work by measuring the average OHO angle (Fig. 4*d*). In the dimers, the protons lay approximately along the O–O axes to form linear H-bonds. The trimer protons are so close in this cluster that repulsion forces them outward to off-axis positions. The deviations from the O–O axes reduce quickly however with the increasing cluster size, which is indicated by an increasing OHO angle going from the trimer to the pentamer. In the pentamer, the OHO angles are essentially restored to the values found for the dimer. This implies that in the pentamer, the proton–proton separations are sufficiently large that the repulsion between them has become negligible. Extrapolation of these trends suggests that even larger monocyclic structures should have very similar bond distances and average binding energies per molecule. Of course, it may be that these larger clusters would rather adopt more compact shapes, for example, bicyclic or cage-like structures.

Lastly, the cluster structures obtained from the OPLS-AA and the DFT calculations were compared. The OPLS-AA model underestimates cluster covalent O–H bond lengths by at least 0.01 although the trend is similar to that calculated by DFT (Fig. 4*c*). The OPLS-AA also underestimates the H-bond length and the nearest-neighbour O–O distance for the dimer. These deviations correlate with the overestimated OPLS-AA binding energies. Yet, except for the deviations mentioned earlier, the OPLS-AA model predicts the microscopic cluster structures almost as well as DFT.

Fig. 3. Optimized structures of Me_mEt_n (m = 0–4, n = 0–3, $m + n$ = 2–5) clusters found by DFT/B3LYP calculations: (*a*) dimers, (*b*) trimers, (*c*) tetramers, and (*d*) pentamers. The unit of bond length is Å, and the angles are in degrees.

(b) Structures of protonated clusters

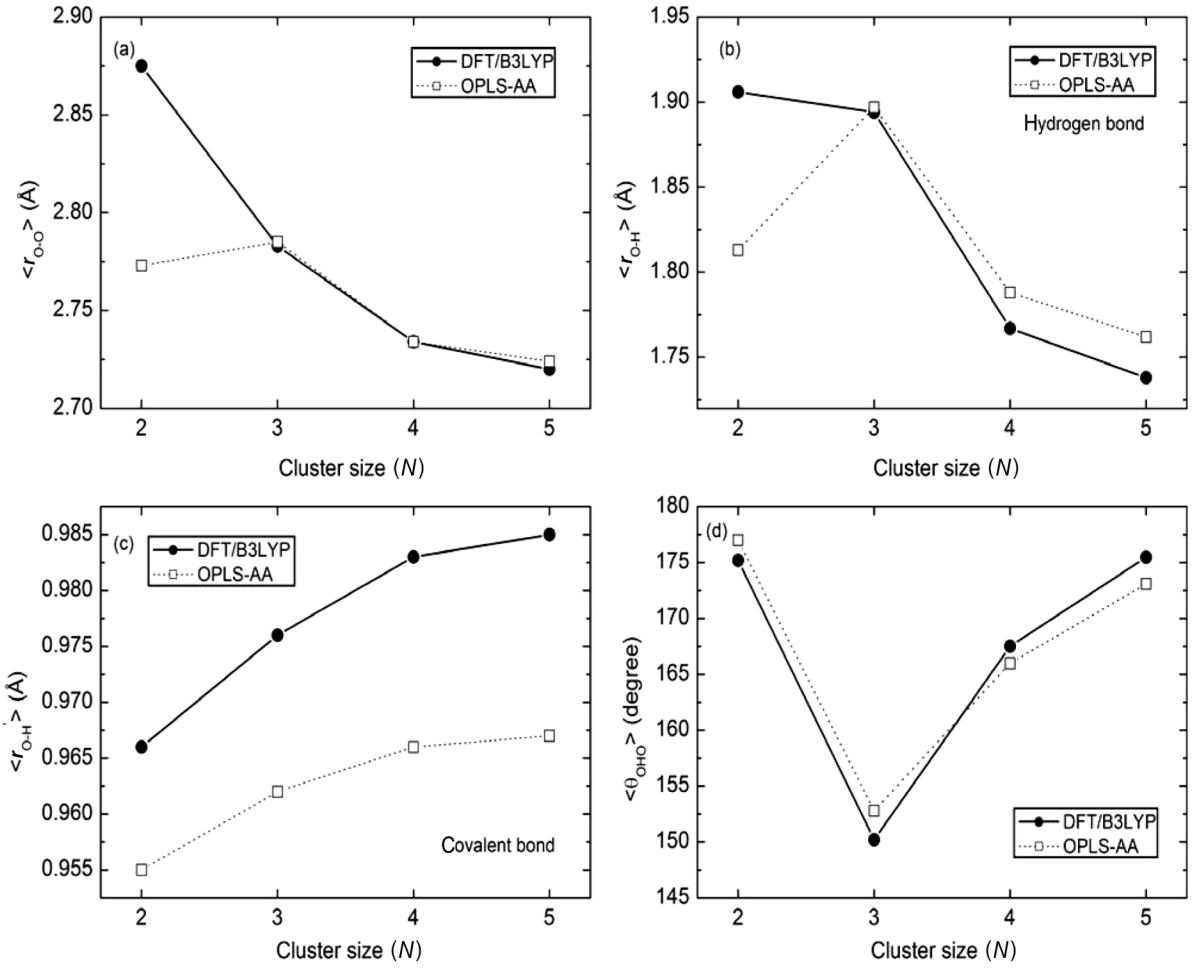
As noted earlier, the protonated trimer ions are the most dominant cluster ions detected by VUV laser mass spectrometry. The optimized structures for Me_3H^+, Et_3H^+, and Me_2EtH^+, respectively, are shown in Figs. 5*a*–5*d*. Unlike the neutral clusters, the protonated trimers form open structures that maximize the alkyl group separations and minimize proton–proton repulsions. The H-bonds are noticeably shorter than those in the neutral clusters, and the covalent O–H bonds are slightly stretched. As a result, the nearest-neighbour O–O distances are also contracted in the protonated clusters relative to their neutral counterparts.

Energetics of Me_mEt_n (m = 0–4, n = 0–4, $m + n$ = 2–5) isomers

The binding energy of a cluster, E_b', is defined as the difference between the total energy of the cluster and those of its isolated components:

$$[3] \quad E_b'[Me_mEt_n] = E_{tot}[Me_mEt_n] - mE_{tot}[Me] - nE_{tot}[Et]$$

where $E_{tot}[Me_mEt_n]$, $E_{tot}[Me]$, and $E_{tot}[Et]$ are the total energies of the mixed cluster, methanol monomer, and ethanol monomer, respectively. The binding energy per molecule can be calculated from $E_b[N_{(m+n)}] = E_b'[Me_mEt_n]/(m + n)$. For monocyclic clusters that have the same number of molecules and H-bonds (other than dimer), $E_b[N_{(m + n)}]$ represents the strength of a H-bond. The incremental binding energy is then defined as follows:



$$[4] \quad E_{ib}[N_{(m+n)}] = E_b[N_{(m+n)}] - E_b[N_{(m+n-1)}]$$

and is a measure of the change in the H-bond strength because of the addition of a monomer to the cluster.

The binding energy can be further understood in terms of many-body interactions. The binding energy of a Me_mEt_n binary cluster can be decomposed as follows (18):

© 2007 NRC Canada

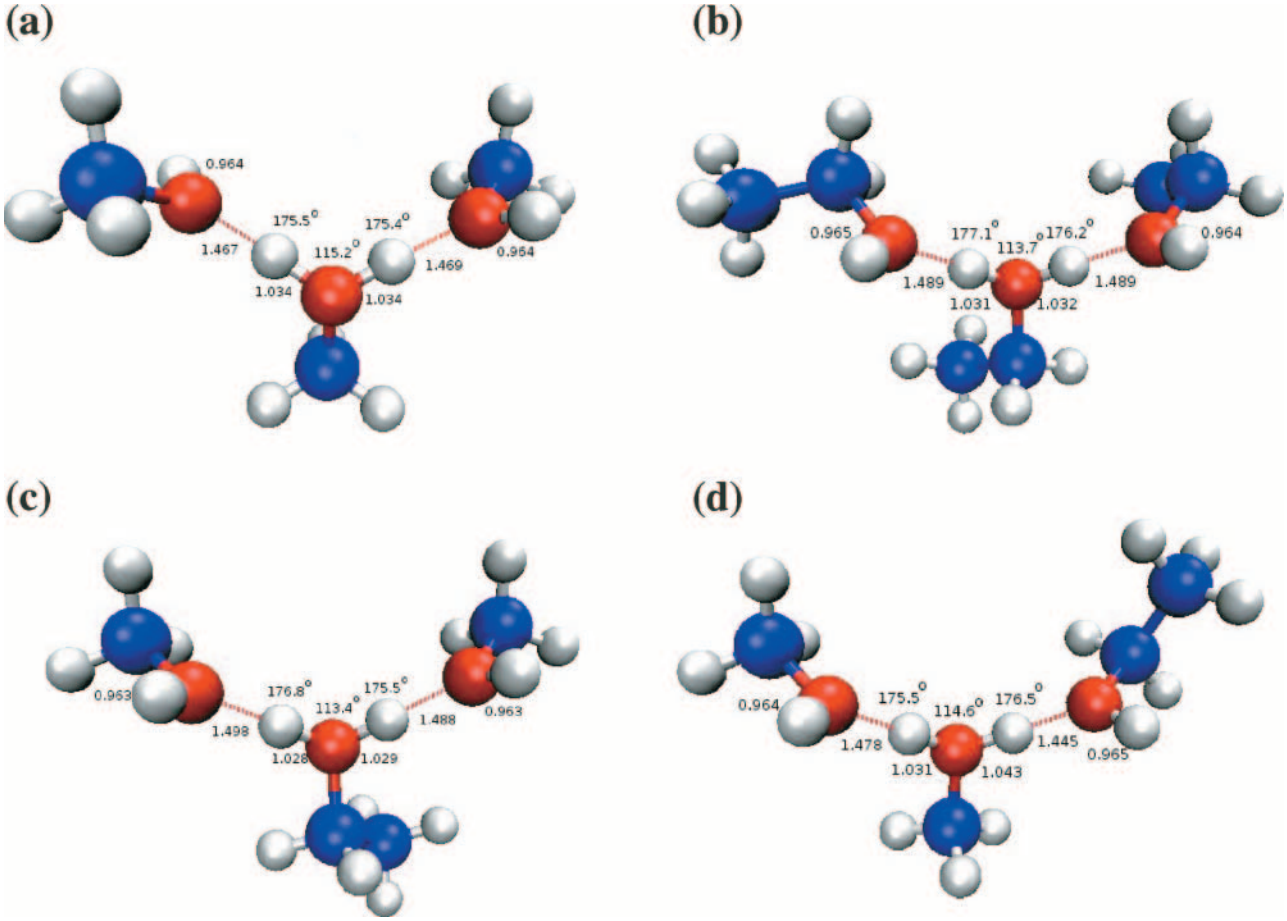
Fig. 4. (*a*) Average O–O distances, (*b*) average H-bond lengths, (*c*) average covalent O–H bond lengths, and (*d*) average OHO angles, as a function of cluster size calculated using the OPLS-AA model and by DFT.

$$[5]\quad E_b'[\mathrm{Me}_m\mathrm{Et}_n] \equiv \sum_{i=1}^{m+n} E(i) - mE_{\mathrm{tot}}(\mathrm{Me}) - nE_{\mathrm{tot}}(\mathrm{Et}) + \sum_{i=1}^{m+n-1}\sum_{j>1}^{m+n}\Delta^2 E(\mathrm{ij}) + \sum_{i=1}^{m+n-2}\sum_{j>1}^{m+n-1}\sum_{k>j}^{m+n}\Delta^3 E(\mathrm{ijk}) + \sum_{i=1}^{m+n-3}\sum_{j>l}^{m+n-2}\sum_{k>j}^{m+n-1}\sum_{l>k}^{m+n}\Delta^4 E(\mathrm{ijkl}) + \cdots + \Delta^{m+n}E(m,n)$$

where E(i), E(ij), E(ijk), and E(ijkl) are the total energies of the monomers, dimers, trimers, and tetramers within a given cluster, respectively. E_{tot}(Me) and E_{tot}(Et) are the total energies of an isolated methanol and ethanol molecule, respectively. The first three terms together are called the relaxation term, and it represents the energy required to change the geometry of the isolated monomers to that found in the cluster. The pair-wise two-body additive terms, three- and four-body non-additive terms are defined as (18):

$$[6]\quad \Delta^2 E(\mathrm{ij}) = E(\mathrm{ij}) - [E(\mathrm{i}) + E(\mathrm{j})]$$

$$[7]\quad \Delta^2 E(\mathrm{ijk}) = E(\mathrm{ijk}) - [E(\mathrm{i}) + E(\mathrm{j}) + E(\mathrm{k})] - [\Delta^2 E(\mathrm{ij}) + \Delta^2 E(\mathrm{ik}) + \Delta^2 E(\mathrm{jk})]$$



$$[8]\quad \Delta^4 E(\mathrm{ijkl}) = E(\mathrm{ijkl}) - [E(\mathrm{i}) + E(\mathrm{j}) + E(\mathrm{k}) + E(\mathrm{l})] - [\Delta^2 E(\mathrm{ij}) + \Delta^2 E(\mathrm{ik}) + \Delta^2 E(\mathrm{il})] - [\Delta^2 E(\mathrm{jk}) + \Delta^2 E(\mathrm{jl}) + \Delta^2 E(\mathrm{kl})] - [\Delta^3 E(\mathrm{ijk}) + \Delta^3 E(\mathrm{ijl}) + \Delta^3 E(\mathrm{ikl}) + \Delta^3 E(\mathrm{jkl})]$$

The cooperativity is defined as the sum of all non-additive terms with orders higher than the two-body term. The resultant binding energies were computed for $\mathrm{Me}_m\mathrm{Et}_n$ (m = 0–4, n = 0–4, $m + n$ = 2–5) isomers, and are listed in Table 2. Excellent agreement with the experimental values for pure methanol and ethanol dimers (21) were obtained when the binding energies were calculated after geometry optimizations that included corrections for ZPEs but not BSSE. Moreover, the calculated binding energy of methanol dimer differed by only 0.05 kcal/mol from the value obtained from MP2/VTZ(2df, 2p) and MP2/ESPB calculations (15). In general, the binding energies among various isomers are very similar, with energy variations typically <0.3 kcal/mol. The gauche mixed dimer was found to be slightly more stable than the trans species, while the opposite trend was observed for the mixed trimers.

The relative stability of the different clusters was determined by the energy calculations done using both the OPLS-AA and the DFT/B3LYP methods. Plots of the average binding energy/molecule, and the average incremental binding

Fig. 5. Optimized structures of the protonated clusters obtained by DFT/B3LYP calculations: (*a*) Me_3H^+, (*b*) Et_3H^+, (*c*) Me_2EtH^+, and (*d*) Me_2H^+Et. The unit of bond length is Å, and angles are given in degrees.

energy vs. cluster size are shown in Figs. 6*a* and 6*b*, respectively. The energies were averaged per cluster over the different isomers. The average incremental binding energy clearly maximizes at $N_{(m+n)} = 4$. Therefore, the large energy gain due to the formation of the tetramers should be associated with its abundance in the vapor, along with the supersaturation effect discussed before. A similar energy trend has been reported for neat methanol and water vapors (1, 2). It should be noted that methanol prefers to form larger clusters than water (1). This difference implies that entropy as well as energetics may also play a role in determining cluster-size distributions in alcohols.

The results obtained using the empirical force field were compared with those obtained by DFT. As shown in Fig. 6*b*, both the OPLS-AA and DFT calculations predict a similar trend in the size dependence of the incremental binding energy. Strikingly, the incremental binding energies for the tetramer obtained by the two different approaches agree remarkably well. As this value describes the relative stability of the trimers and tetramers, it is critical in understanding the exceptional stability of the tetramer. The OPLS-AA model generally overestimates the binding energy per molecule (Fig. 6*a*). The largest discrepancy is found for the dimer. This should translate into a large deviation of the computed dimer OH stretching modes from the experimental values (2). This disagreement, however, is not surprising because the OPLS-AA potential parameters were originally fitted to reproduce the properties of liquids. The origin of this error probably comes from an overestimation of the static dipole moment in the force field parameters (2). The OPLS-AA model describes the stability of large clusters better because, in the gas-phase, large clusters usually adopt cyclic structures, which closely resemble their liquid-phase counterparts. However, further comparisons with DFT show that the OPLS-AA model fails to predict the relative stabilities among the clusters of equal *N*, and the relative stability of the structural isomers associated with a given cluster composition. Here, the energy differences are generally very small, and this suggests therefore, that the OPLS-AA model is only qualitatively reliable for predicting the stability of clusters of different sizes. While the OPLS-AA model does describe the relative stability between trimers and tetramers well, significant differences between the calculated OPLS-AA and DFT energies exist. Careful tests should therefore be taken when using the OPLS-AA energies to describe the stability of the cluster.

Discussion and conclusions

VUV single-photon ionization and TOF mass spectrometry were used to detect gas-phase protonated methanol and ethanol cluster ions. Optimized structures for these neutral precursors have been calculated. Not surprisingly the most-stable neutral mixed clusters are monocyclic, similar to that

[a]Binding energy calculated after geometry optimization using B3LYP/6–311++G(d, p).
[b]Binding energy calculated after geometry optimization using B3LYP/6–311++G(d, p) followed by a single point energy calculation using B3LYP/6–311++G(3df, 2p).
[c]Experimental binding energies for pure methanol and ethanol dimers (23) lie between –3.20 to –3.50 kcal/mol, and –3.39 to –3.99 kcal/mol, respectively.

found for neat-alcohol clusters (4). These structures are also consistent with recent infrared studies that suggest that the OH groups of the monomers involved in neat methanol and ethanol clusters larger than the dimer are all involved in hydrogen bonding (22–24). The protonated trimer ions correspond to the most abundant species detected by VUV laser/time-of-flight mass spectrometry. The correlation shown in eq. [1] between a neutral N-mer and a protonated (N – 1)-mer ion suggests that the mixed alcohol tetramers are "magic" clusters. This conclusion holds for neat methanol and ethanol tetramers because these size clusters (with S_4 symmetry) are expected to exhibit a maximum hydrogen-bonding cooperativity effect, and a minimum ring strain (1, 2).

The neutral mixed cluster binding energies were decomposed into the terms representing the many-body interactions (see eqs. [5–8]) to understand the size-dependence trend found here for the incremental binding energy. Table 3. shows the average binding energies and their components calculated by DFT (without ZPE corrections) for the alcohol clusters ranging from the dimer to the pentamer. It can be seen again that the difference in the binding energies for the N-mer and (N – 1)-mer maximizes for the tetramer. Further examination shows that the differences in the pair-wise additive contributions have the same trend as the binding-energy differences, whereas the differences in the non-additive contributions, often termed cooperativity effects, does not exhibit this trend. This observation suggests that the large change in energy going from the trimer to the tetramer is mainly due to pair-wise interactions rather than higher-order cooperativity effects; that is, the tetramer stability is mainly a balance between the energy gained through attractive H-bonding vs. the repulsion between the oxygen atoms within the cluster.

It is instructive to compare the relative contributions of the pair-wise additive and non-additive terms, rather than their absolute values. Table 4. lists the percentage contribution of the many-body terms to the binding energy, which were averaged over various alcohol clusters, along with the corresponding values for water clusters taken from ref. 18. It can be seen that the repulsive contribution due to the relaxation term becomes more pronounced going from the dimer to the pentamer. This indicates that for the larger clusters, the individual monomers deform considerably relative to their isolated conformations. These deformations include the stretching of the covalent O–H bonds (Fig. 4*c*). The additive

Table 3. Average binding energies and their many-body components for Me_mEt_n (m = 0–4, n = 0–4, $m + n$ = 2–5) clusters (in kcal/mol). The binding energies E_{b2} correspond to those in Table 2 (without ZPE corrections). E_r is the relaxation term defined in eq. [5]. $< {}^nE >$ are the n-body terms defined in eqs. [5–8]. E_c corresponds to the non-additive terms. $< E_{b2} >$, $< {}^2E >$, and E_c are the differences of average binding energies, two-body terms, and non-additive terms, respectively. The positive signs for the relaxation terms denote repulsive contributions to the energy.

$m + n$	$<E_{b2}>$	E_r	$<\Delta^2E>$	$<\Delta^3E>$	$<\Delta^4E>$	$<\Delta^5E>$	E_c	$\Delta<E_{b2}>$	$\Delta<\Delta^2E>$	ΔE_c
2	–4.98	0.14	–5.12	—	—	—	—	–4.98	–5.12	—
3	–14.69	0.56	–12.15	–3.10	—	—	–3.10	–9.71	–7.03	–3.10
4	–26.45	1.43	–21.53	–3.89	–2.46	—	–6.53	–11.76	–9.38	–3.25
5	–33.06	2.44	–25.50	–7.63	–1.76	–0.61	–10.00	–6.61	–3.97	–3.65

Table 4. Percentage contribution of many-body terms to the binding energy of Me_mEt_n (m = 0–4, n = 0–4, $m + n$ = 2–5) clusters. The notations have the same meanings as those in Table 3. The negative sign indicates that the relaxation term has a repulsive contribution. The values in parenthesis are the corresponding values for $(H_2O)n$ (n = 2–5) clusters, which are taken from ref. 19.

$m + n$	Theory level	E_r	$< {}^2E >$	$< {}^3E >$	$< {}^4E >$	$< {}^5E >$	E_c
2	B3LYP(MP2)	–2.8 (–0.8)	102.8 (100.8)	—	—	—	—
3	B3LYP(MP2)	–3.8 (–2.7)	82.7 (85.1)	21.1 (17.6)	—	—	21.1 (17.6)

5	B3LYP(HF)	–7.4 (–1.4)	77.1 (78.9)	23.1 (20.4)	5.3 (2.1)	1.9 (0.01)	30.2 (22.51)

Fig. 6. (*a*) Average binding energy per molecule, $< E_b >$, and (*b*) average incremental binding energy, $< E_{ib} >$, as a function of cluster size obtained by DFT/B3LYP and OPLS-AA calculations.

contribution to the binding energy represented by the two-body term decreases, while the non-additive contribution increases with the increasing cluster size. The non-additive interactions (cooperativity) can contribute significantly (as high as 20%–30%) in both the alcohol and the water clusters. The four- and five-body terms also provide non-negligible contributions (7%–9%) in the alcohol clusters, whereas these contributions are less than 3% in the water clusters. In other words, the four- and five-body terms in the alcohol clusters contribute ~30% of the cooperativity effect in alcohol clusters. In the water clusters, however, the contributions from these high-order terms are less than 10%. This analysis shows that cooperativity effects in both alcohol and water clusters are significant. Nevertheless, the alcohol-cluster binding energies converge more slowly than those for water clusters. To capture the cooperativity effects in water clusters, it was deemed sufficient to consider terms up to and including three-body interactions to design a force field (18). The effect of even higher-order terms, such as the four-body interaction, must be included for alcohol clusters to obtain a similar accuracy.
