It is well known that different levels of theory can have a considerable effect on the decomposition of the binding energy: second-order many-body perturbation (MP2) level that includes electron correlation generally will decrease the additive contribution relative to a Hartree–Fock (HF) calculation (18) but will increase the non-additive contribution. The DFT/B3LYP results here are considered to be comparable to those obtained by MP2.

As noted earlier, the open structure calculated for the mixed ionic trimers and shown in Fig. 5 can be viewed as a solvated proton. This behavior is also observed for the neat protonated dimers (25). The methanol protonated trimer in particular is a "magic" structure, as it can be regarded as a proton with a complete first-solvation shell (11, 26). Infrared spectroscopy reveals that the free and hydrogen-bonded OH stretching frequencies of the neat cluster ions blue-shift with increasing N (22, 24). The mixed protonated ions are expected to exhibit a similar spectroscopic signature.

Soft X-ray excited colour-centre luminescence and XANES studies of calcium oxide[1]

J.Y. Peter Ko, Franziskus Heigl, Yun Mui Yiu, Xing-Tai Zhou, Tom Regier, Robert I.R. Blyth, and Tsun-Kong Sham

Abstract: In this study, we show that colour centres can be produced by irradiating calcium oxide with soft X-rays from a synchrotron radiation source. Using the X-ray excited optical luminescence (XEOL) technique, two colour centres, F-centre, and F^+-centre can be identified. These colour centres emit photons at characteristic wavelengths. In addition, by performing time-resolved XEOL (TRXEOL), we are able to reveal timing and decay characteristics of the colour centres. We also present X-ray absorption near-edge structure (XANES) spectra collected across oxygen K-edge, calcium $L_{3,2}$-edge, and calcium K-edge. Experimental results are compared with density functional theory (DFT) calculations.

Key words: calcium oxide, colour centre, synchrotron, X-ray excited optical luminescence, X-ray absorption near-edge structure.

Résumé : Dans ce travail, on démontre qu'on peut produire des centres colorés par irradiation de l'oxyde de calcium avec des rayons X doux obtenus à partir d'une source de radiation de synchroton. Faisant appel à la technique de la luminescence optique excitée par les rayons X (LOEX), on a pu identifier deux centres colorés, le centre-F et le centre-F^+. Ces centres colorés émettent des photons à des longueurs d'onde caractéristiques. De plus, en faisant appel à la technique LOEX en temps résolu (LOEXTR), il a été possible de déterminer les caractéristiques de décroissance des centres colorés. On rapporte aussi les données obtenues par spectroscopie de la structure fine d'absorption des rayons X près du seuil (« XANES ») recueillis à la périphérie K de l'oxygène, $L_{3,2}$ du calcium et K du calcium. On a comparé les résultats expérimentaux avec ceux des calculs d'après la méthode de théorie de la densité fonctionnelle (TDF).

Mots-clés : oxyde de calcium, centre coloré, synchrotron, luminescence optique excitée par les rayons X, spectroscopie de la structure fine d'absorption des rayons X près du seuil.

[Traduit par la Rédaction]

Introduction

Luminescence from oxygen vacancies in calcium oxide has been a subject of considerable interest, both experimentally (1–4) and theoretically (5, 6). Such vacancies lead to the creation of defect states in wide gap oxides and can result in colouration. These vacancy-induced colour centres are referred to as F-centres. Oxygen can be removed from rock-salt structure of calcium oxide (band gap = 6.9 eV) by means of irradiation. The vacancies can be filled with either one electron (F^+-centre) or two electrons (F-centre). These colour centres are produced by either particle bombardment or additive colouration. Depending on the conditions under which the colour centres are formed, optical properties can vary (1). Some of the primary defects become stable and their number increases with radiation dose, thus changing the crystal features. The nature of the radiation source and the method of colour centre production (e.g., radiation vs. thermal process) can affect the relative population of F^+-centres vs. F-centres. It is also important to note that radiation damage can be non-uniform because of a non-uniform concentration of impurities within the crystal and the penetration depth of the radiation (7). Synchrotron radiation, with its full tunability in the soft X-ray region, provides a new

probe for colour-centre study by being able to tune the excitation energy across the absorption edges of elements of interest, such as Ca $L_{3,2}$- and O K-edges. This capability allows for the study of the production of colour centres as well as their luminescence properties.

In this study, we show colour-centre luminescence induced by synchrotron radiation in the soft X-ray region. Radiation damage of crystals is a typical process in which the energy of the intrinsic electronic excitation is converted into lattice defects (i.e., oxygen vacancies) (7). With soft X-rays, one phenomenon is photon-stimulated desorption, in which O^+ ions from the oxide surface can be desorbed as the X-ray is tuned across the O K-edge. This process results from the creation of the O 1s core hole, with subsequent Auger decay and coulomb explosion (two inner valence holes for example). The creation of the oxygen core hole is most efficient at the O K-edge resonance (1s → p transition). Thus, soft X-ray excitation will induce colour centres, and subsequently, energy transfer from X-ray absorption to these centres can lead to luminescence, which in turn will be used to monitor the absorption across the edge. This is sometimes known as optical X-ray absorption near-edge structure (XANES). Here, we present X-ray excited optical luminescence (XEOL) and XANES results of calcium oxide at the Ca $L_{3,2}$- and O K-edges, using total electron yield and luminescence yield detection schemes.

XEOL is an X-ray photon-in/optical photon-out technique in which the optical luminescence excited by tunable X-rays from synchrotron radiation is monitored with an optical spectrometer (8). XEOL deals with the measurement of specific optical de-excitation channels associated with the energy redistribution by a system upon the absorption of an energetic photon. Optical luminescence allows for the system to dissipate the excess energy from a highly excited state (e.g., with a core hole). It can be produced by direct excitation as well as secondary processes in which energetic electrons (photoelectron and Auger electrons for example) thermalize in the solid, producing more secondary electrons and holes. Fig. 1 shows a schematic of the XEOL process in both the energy (Fig. 1*a*) and time domains (Fig. 1*b*), starting from the excitation of a system by an incoming X-ray (Fig. 1*a*, left panel) to the relaxation process (Fig. 1*a*, right panel).

Time-resolved XEOL (TRXEOL) measurements has also been performed, where the lifetime of optical luminescence, which can range from nanoseconds to hundreds of nanoseconds, is studied (9). Also, luminescence within a certain time window after excitation can be used for time-gated XEOL and time-gated photoluminescence yield (PLY) XANES. This method takes advantage of the time structure of a synchrotron storage ring in which electrons are bunched by the radio frequency (RF) cavity, and as a result the emitted light is pulsed, the length of which is much shorter than the time gap between consecutive bunches (10). At the Canadian Light Source (CLS) where this experiment was conducted, the pulse width is ~60 ps, and the repetition rate is 570 ns in a single-bunch mode (11). Figure 1*b* shows a schematic of the TRXEOL process and a synchrotron storage ring with electron bunches. The emitted light pulses are monochromatized to desired excitation energies. Upon absorption, the energy of the excited state is transferred to primary de-excitation channels, such as Auger and X-ray fluorescence (fast), and secondary de-excitation processes, such as thermalization of electrons and holes and XEOL (slow). Within the XEOL time domain, the decay time can span from picoseconds to microseconds. Thus, TRXEOL can be used to study the luminescence properties of a broad variety of light emitting systems, including semiconductor nanostructures, organic light emitting device (OLED) materials, and soft matters.

Fig. 1. Schematic of (*a*) XEOL, showing the excitation and the recombination of holes and electrons leading to optical photon hv_{op} and fluorescent X-rays, hv_f, (*b*) TRXEOL, showing synchrotron radiation from a storage ring, electron bunches, the excitation light pulse (green), and the luminescence (red); the decay curve (stop–start) as well as the time-gated emission are shown in the inset.

XANES probes the local structure and bonding of an atom in a chemical environment by monitoring the atomic absorption coefficient modified by the molecular potential. As the photon energy approaches the threshold, a new excitation channel is switched on and transitions from core to bound, quasi-bound, and continuum states take place. A sharp resonance called whiteline is often observed at the onset of the threshold; it arises from the dipole transition from the core to high densities of unoccupied states, e.g., from 1s to p character at the bottom of the conduction band in ionic and semiconductor solids and to the LUMO in molecules. XANES is an element-specific method, sensitive to oxidation states and coordination chemistry. The detail of XANES is determined by the chemical environment (e.g., crystal field, density of unoccupied states, and the orientation of the specimen with respect to the polarization of the photon).

For light-emitting materials, three different channels can be used in measurements: (*i*) total electron yield (TEY), (*ii*) total fluorescence yield (FLY), and (*iii*) photoluminescence yield (PLY). TEY refers to the total electron yield upon excitation and is generally proportional to the absorption coefficient in a uniform specimen and is surface-sensitive. FLY refers to X-ray fluorescence yield and is bulk-sensitive. PLY refers to optical photon yield; either total (zero order) or partial (selected wavelength) yield (time-gated or ungated) can be used to monitor absorption edges.

© 2007 NRC Canada

In the measurements reported here, the probing depth of PLY is comparable to FLY and is more bulk sensitive than TEY.

Experimental

CaO powder was purchased from Alfa Aesar (Ward Hill, Massachusettes, USA, 99.95% purity, <10 μm particle size). All XEOL and TRXEOL measurements, with the exception of XANES at calcium K-edge, were performed on the spherically grating monochromator (SGM) beamline (undulator energy range: 200–2000 eV, resolution $E/\Delta E$: >5000) at the CLS (operation energy: 2.9 GeV). Operating current for our measurement was 250 mA at injection; a current up to 15 mA was used for the single-bunch measurement. XANES measurements at the calcium K-edge was performed on the double crystal monochromator (DCM) beamline (energy range: 1500–4500 eV, resolution $E/\Delta E$: ~2000) at Canadian Synchrotron Radiation Facility (CSRF) at the Synchrotron Radiation Center (SRC), University of Wisconsin-Madison. Luminescence was measured with a monochromator (JY-100) and a photomultiplier tube (PMT) (Hamamatsu R943–02), which has a range of 160 nm to 930 nm. The sample was prepared by spreading the powdered compound on a piece of double-sided carbon tape on a steel disk (diameter ~1 cm). The steel disk was mounted onto a sample holder. For the colour-centre study, the sample was irradiated at oxygen K-edge, 542 eV, for 1 h, and XEOL measurements were made at a 10 min intervals. The tape was checked to ensure no light-emitting impurity was present. At the set parameter, the flux was approximately 5×10^{10} photons/(s mA). For X-ray absorption measurements, oxygen K-edge and calcium $L_{3,2}$-edge XANES spectra were obtained on the same beamline. TEY, FLY, and PLY were obtained simultaneously using specimen current, a channel plate detector, and the JY-100 described earlier, respectively. For all experiments, the incoming monochromatic beam, I_0, was measured using a gold mesh detector upstream of the sample chamber. Photon flux was calibrated with a silicon photodiode. All experiments were performed at room temperature and under high vacuum conditions.

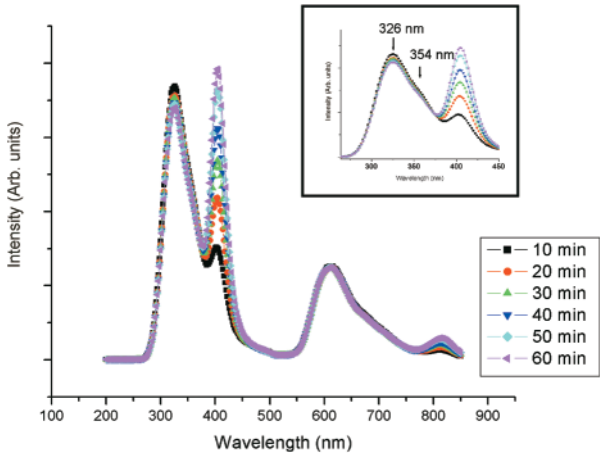
Results and discussions

XEOL and TRXEOL

XEOL spectra of CaO powder with excitation energy at the oxygen K-edge (542 eV) collected at various time intervals are shown in Fig. 2. The inset shows the spectral range from 250 to 450 nm to highlight the features of interest. All spectra have been normalized to the intensity of the incoming monochromatic photon flux (I_o).

Four peaks can be clearly distinguished at 326, 404, 607, and 808 nm. By performing Gaussian peak fits, shoulder peaks were found at 354 and 652 nm. The peak at 808 nm is the second order of 404 nm; the same can be said for the peak at 652 nm (second order of 326 nm). The peaks at 326 (3.8 eV) and 404 nm (3.1 eV) are attributed to emissions from F^+-centres and F-centres, respectively. At the early stage of irradiation, the number of F^+-centres dominate, although there are also some contributions from F-centres as well. As the sample is irradiated longer, more F-centres appear, causing the relative intensity of the peak at 404 nm to increase. This increase in intensity can be attributed to the creation of new vacancy sites and the conversion of previously created F^+-centres to F-centres. The evidence for the latter was observed previously by Pogatshnik (1), where continuously exposing a sample of calcium oxide under UV light in the region of absorption of the F^+-centre (325 nm) led to photo-conversion of F^+-centres to F-centres.

Fig. 2. XEOL spectra of CaO irradiated by synchrotron radiation at the oxygen K-edge (542 eV) at given time intervals. Inset: close-up view of spectral range from 250 to 450 nm.



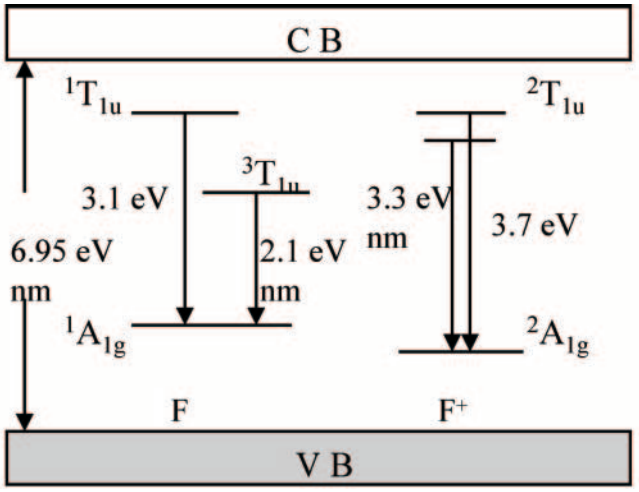


Fig. 3. Schematic for CaO F^+-centre and F-centre emission; arrows indicate possible routes for XEOL. The energy separations are experimental values given in ref. 6.

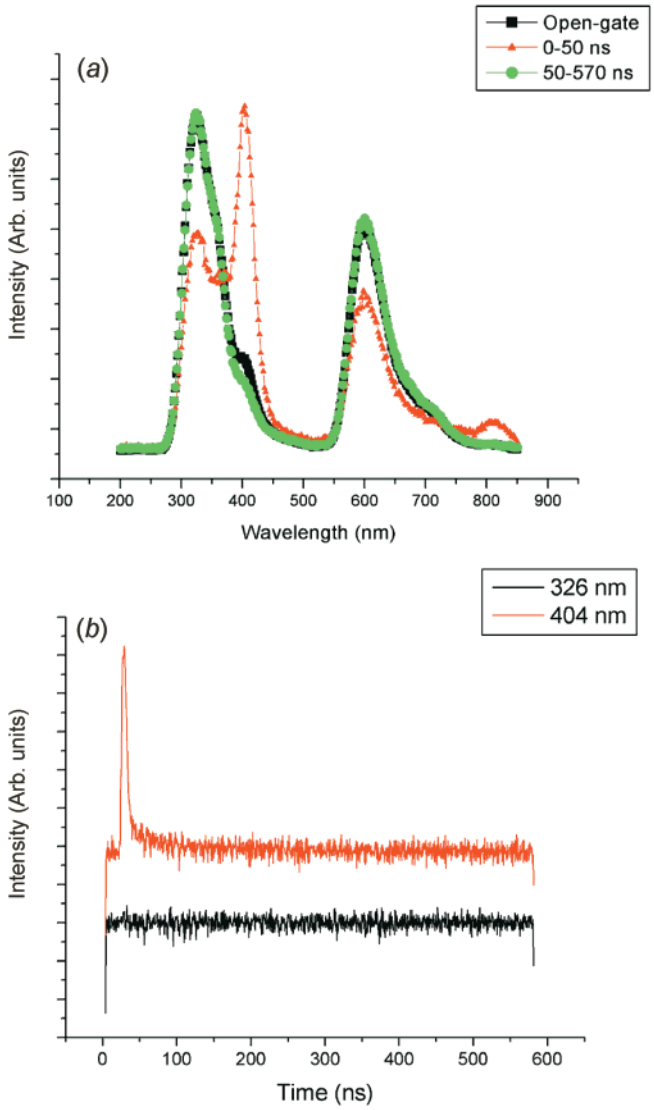
A schematic energy diagram of CaO colour centers based on previous experimental and theoretical evidence is illustrated Fig. 3. From Fig. 3, we see that F-centers (oxygen vacancy replaced with two electrons) show absorption and emission features at longer wavelengths than the F^+-centers (one electron, unpaired, magnetic). The values are from previous experiments (6). Theory also yields similar results. The origins of these emissions are more or less understood as illustrated. De-excitation from a singlet or triplet in the case of F-centres and from doublet to doublet in the case of the F^+-centres produce the optical emissions. In some cases,

© 2007 NRC Canada

intersystem crossing is involved, leading to slower decays (7).



Returning to Fig. 2, the 326 nm (3.8 eV) and 404 nm (3.07 eV) emissions are the $^2T_{1u}(x, z) \rightarrow {}^2A_{1g}$ (F^+) and the triplet $^1T_{1u} \rightarrow {}^1A_{1g}$ (F) transitions, respectively, according to Carrasco et al. (6). The emission at 354 nm (3.5 eV) and 607 nm (2.04 eV) are attributed to fluorescence from the self-absorption of photons emitted from F^+-centres (326 nm) and F-centres (404 nm), respectively, which also closely agree with theoretical and experimental values reported by Carrasco et al. for the $^2T_{1u}(y) \rightarrow {}^2A_{1g}$ (F^+) and $^3T_{1u} \rightarrow {}^1A_{1g}$ (F) transition (6). The latter transitions involve intersystem crossing and have time implication (slow) as confirmed by time-resolved measurements discussed later. It should be mentioned that the XEOL experiment excited at the Ca L-edge (see later) is dominated by F^+-centres and does not produce F-centres as dramatically as that at the oxygen edge. Thus, the time-dependent F-centre production observed in Fig. 2 with excitations at the O K-edge is likely tied to the large absorption coefficient at the O K-edge, enhancing photon stimulated desorption (desorbing O^+ ion following the creation of oxygen core hole), producing surface defects; also, very little luminescence was observed with excitations at the Ca K-edge in a recent measurement; these issues will be addressed elsewhere.

TRXEOL was performed on a new spot of the specimen at three different time windows: open-gate (0–570 ns), fast (0–50 ns), and slow (50–570 ns). The resulting spectra are shown in Fig. 4*a*. At first glance, the F-centre emission (404 nm) is dominant at the fast time window, whereas the F^+-centre emission (354 nm) is more intense at the slow time window, and there is only a very small contribution due to F-centre emission (404 nm). Close examination reveals that the 326 nm channel, which is near the 354 nm channel, is also fast. The results indicate that the F-centre $^1T_{1u} \rightarrow {}^1A_{1g}$ and F^+-centre $^2T_{1u}(x,z) \rightarrow {}^2A_{1g}$ emissions are narrower and decay much faster than the $^3T_{1u} \rightarrow {}^1A_{1g}$ (F) and $^2T_{1u}(y) \rightarrow {}^2A_{1g}$ (F^+) channels. This is expected, as noted earlier, since the slow pathway involves intersystem crossing. Another interesting observation is that at open-gate, the relative intensity of the luminescence of F^+-centres (326 nm) is much greater than that of F-centres (404 nm), which is another indication that there are more F^+-centres present initially. Timing results (Fig. 4*b*) show the decay behaviour at the two main emission wavelengths, 326 and 404 nm. The curve shows much faster decay characteristics at the F-centre emission (404 nm), compared with the F^+-centre emission (326 nm), although, the proximity of the much slower 354 nm emission has undoubtedly interfered with the measurement, as we can see from Fig. 4*a* that the 326 nm emission is faster than the nearby 354 nm emission. The fast decay for the 404 nm emission appears to be comparable to the time-resolution of the PMT. More detailed analysis awaits further investigation.

XANES

It is also interesting to investigate the O K-edge and Ca $L_{3,2}$-edge XANES with photoluminescence yield. Figure 5 shows the XANES spectra (TEY spectrum and PLY spectra at 326 nm, 404 nm, and zero-order) of calcium oxide around the oxygen K-edge. All spectra have been normalized to I_o.

Fig. 4. (*a*) TRXEOL spectra of CaO at three different time windows: open-gate (0–570 ns), fast (0–50 ns), and slow (50–570 ns); (*b*) plots showing decay behaviour at 326 and 404 nm.

On the TEY XANES, the edge jump is at ~537 eV and there is a sharp resonance at 542 eV. Also seen is a broad peak at 548 eV with shoulders on either side. The edge jump and beyond is attributed to the 1s → 2p transition, mapping the unoccupied densities of states. The sharp peak is likely due to localized states, such as OH on the surface. On the PLY, the edge jumps are negative (i.e., inverted spectra), which is similar to observations made by Bianconi et al. (12) and Naftel et al. (13) with calcium fluoride. This is due to saturation (total absorption, sometimes known as the thickness effect) (14). At total absorption (all photons are absorbed), the attenuation length of the X-ray, which is approximately 300 nm at the O K-edge, is much smaller than the sample thickness. Below the edge, the X-ray beam can penetrate much deeper into the sample, irradiating more atoms. At these energies, although all photons are absorbed, the core electrons are not excited. At the absorption edge, core electrons are excited to previously unoccupied levels turning on Auger and fluorescence channels near the surface. Through

Fig. 5. Oxygen K-edge XANES spectra of calcium oxide showing the TEY spectrum and PLY spectra at 326 nm, 404 nm, and zero-order.

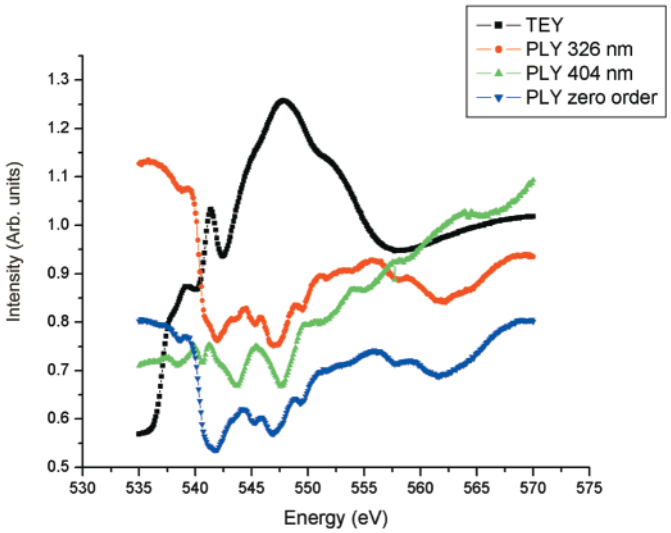

Fig. 6. Calcium $L_{3,2}$-edge XANES spectra of calcium oxide showing the TEY spectrum and PLY spectra at 326 nm, 404 nm, and zero-order.

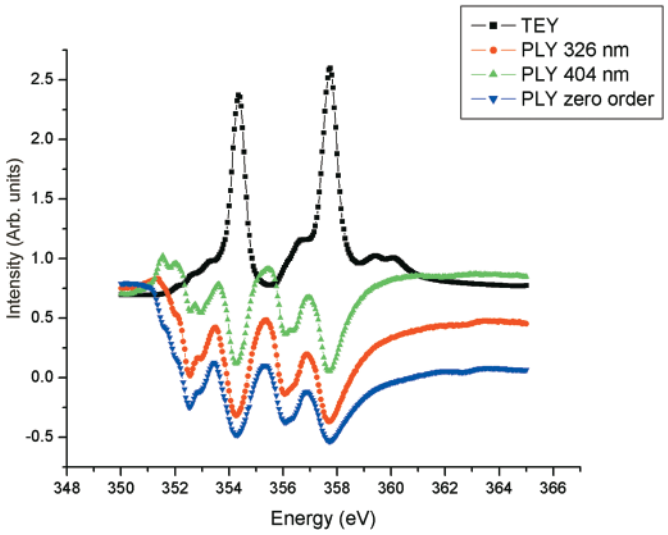

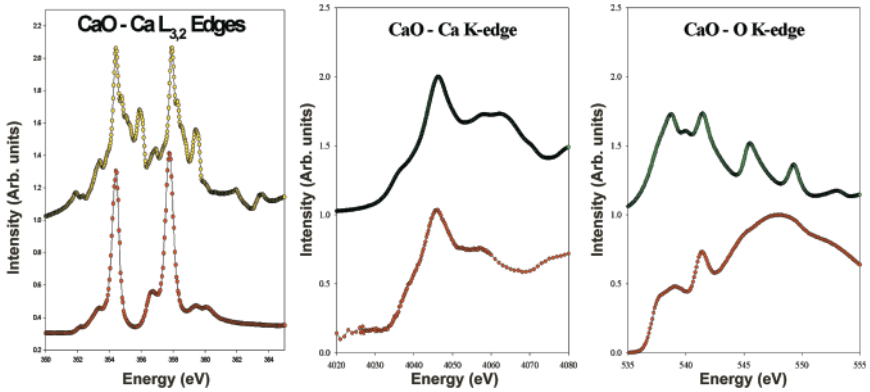

Fig. 7. Comparison of calculated XANES (top) with experiment (bottom) at the Ca $L_{3,2}$–edge (left), Ca K-edge (middle), and O K-edge (right) of CaO. Linewidths used in the convolution are from left to right, 0.1 eV, 5 eV, and 1 eV, respectively.

these channels, the excess energy can be carried by fluorescence X-rays and Auger electrons without contribution to the energy transfer to the medium (conversion to optical channel). In other words, Auger electrons and fluorescence X-rays can leave the sample without being reabsorbed. This reduces the efficiency of optical photons being produced per photon absorbed (i.e., reduced quantum yield, an inversion). In addition to inversion, the spectral features also vary depending on the yield. Although the details of the features are complex and will not be addressed here, one can see that the F-centre emission exhibits a different pattern than that of the F^+-centre.

Figure 6 shows XANES spectra (TEY spectrum and PLY spectra at 326 nm, 404 nm, and zero-order) of calcium oxide around calcium $L_{3,2}$-edge. Two sharp peaks can be seen at 354 and 358 eV. The peaks are due to excitation from core $2p^63d^0$ to $2p^53d^1$ or $2p^54s^1$ (more accurately, densities of states containing these characters) dipole transitions. (15). Smaller peaks that precede the main peaks are sensitive to the symmetry of atoms surrounding the Ca^{2+} ion in the first coordination sphere (16). They also have predominantly triplet characteristics and arise from spin-orbit coupling and Coulombic repulsion (17). The PLY-XANES features at the Ca $L_{3,2}$-edge bear considerable similarity to the TEY, compared with the O K-edge PLY-XANES. Again, the F-centre (404 nm) yield shows an interesting pre-edge feature between 351 and 352 eV, not observed in F^+-centre luminescence, suggesting a delay in the turn-on of the inversion.

XANES from DFT calculations

We have also conducted DFT calculations for the densities of states of CaO and corresponding XANES at the Ca $L_{3,2}$–edge,and Ca and O K-edge using the WIEN code, which solves the Kohn–Sham equation (18–20). These calculations employed the CaO lattice parameter of the rock-salt structure. Figure 7 compares the calculated XANES with experiment. The calculated spectra are broadened with a constant energy window so that the whiteline has about the same width as that of the experiment. It is interesting to note that although these calculations show reasonable agreement with experiment for CaF_2 (13) and at the Ca K-edge for CaO, the higher energy regions (post-whiteline) in the calculated

© 2007 NRC Canada

spectra for the shallower core levels, Ca $L_{3,2}$ and O K-edge of CaO, appear to be spiky and overemphasized. The whiteline and pre-edge features are in reasonable agreement however. The spiky features are due to high densities of l+1 states and should smooth out with an energy-dependent lifetime broadening, which increases significantly above the threshold (21). More details of these comparisons will be discussed elsewhere.

Conclusions

We have shown that luminescence centres (F^+-centre and F-centre) of calcium oxide can be created effectively by irradiating the sample with synchrotron radiation at the O K-edge. At the earlier stage of irradiation there are more F^+-centres, but continuing exposure converts some of these previously created F^+-centres to F-centres. We also observed that these colour centers can effectively convert the excess energy into optical channels. Moreover, using the TRXEOL technique we were able to identify timing characteristics of the colour-centre emissions; that is, that F-centre emission is a faster process than the F^+-centre emission. Experimental XANES and DFT calculations are in reasonable agreement.

Cross-linking organic semiconducting molecules by preferential C-H cleavage via "chemistry with a tiny hammer"[1]

W.M. Lau, Z. Zheng, Y.H. Wang, Y. Luo, L. Xi, K.W. Wong, and K.Y. Wong

Abstract: In the context of collision-induced dissociation in chemistry and kinematics in physics, we have determined that a beam of hyperthermal protons can be used as tiny hammers to preferentially break the C-H bonds of hydrocarbon precursor molecules adsorbed on a conductive substrate with little damage to other chemical bonds. The activated molecules are thereby converted to a cross-linked molecular network, with its chemical properties tailored by the preservation of the chemical functional groups of the precursors and with its physical properties tuned by the degree of cross-linking. This "chemistry with a tiny hammer" process is adopted to induce inter-chain cross-linking of the semiconducting molecular chains in poly (3,4-ethylenedioxythiophene) molecular films and to raise the electrical conductivity and stability of the molecular films. The results exemplify the unusual reaction design of this process as well as its application in electronic and optoelectronic device fabrication. The application is particularly attractive because the process does not require any chemical additives or catalysts other than a beam of protons, and it needs no thermal budget.

Key words: organic semiconductor, polymeric semiconductor, cross-linking, polymer, collision, dissociative collision, molecular electronics, device fabrication.

Résumé : On a démontré que, dans le contexte d'une dissociation induite par une collision en chimie et de la cinématique en physique, un faisceau de protons hyperthermiques peut être utilisé comme un petit marteau pour briser préférentiellement les liaisons C-H de molécules d'hydrocarbures précurseurs adsorbés sur un substrat conducteur, avec un minimum de dommage aux autres liaisons chimiques. Les molécules activées sont ainsi transformées en un réseau moléculaire réticulé dont les propriétés chimiques sont déterminées par la conservation des groupes fonctionnels chimiques des précurseurs alors que ses propriétés physiques sont ajustées par le degré de réticulation. On a adopté ce processus de chimie avec un minuscule marteau pour induire des réticulations interchaînes de chaînes moléculaires semiconductrices dans des films moléculaires de poly(3,4-éthylènedioxythiophène) et augmenter la conductivité électrique ainsi que la stabilité des films moléculaires. Les résultats obtenus mettent en relief le caractère inhabituel de la réaction impliquée dans ce processus ainsi que ses possibilités d'application dans la fabrication de dispositifs électroniques ou optoélectroniques. L'application est particulièrement intéressante en raison du fait que le processus ne requiert aucun additif ou catalyseur chimique, à l'exception d'un faisceau de photons et ne nécessite aucun budget thermique.

Mots-clés : semiconducteur organique, semiconducteur polymère, réticulation, polymère, collision, collision dissociative, électronique moléculaire, fabrication de dispositifs.

Introduction

Polythiophene and its derivatives have drawn much attention in recent materials research because of their potential applications in many electronic and optoelectronic devices, such as photodiodes, polymeric light emitting diodes, and electrochemical actuators (1). The molecular structure is relatively simple, with the thiophene monomers queuing like a long tape with their π units lying on the tape plane. Holes are typically injected electrochemically to convert these materials into p-type semiconductors, and the charged states are balanced with negatively charged chemical additives equiva-

Fig. 1. The molecular schematic structure of PEDT and PSS.

lent to the negatively charged p-type dopants in an inorganic semiconductor (such as B^- in p-Si). Among all polythiophenes, poly(3,4-ethylenedioxythiophene) (commonly referred as PEDT), mixed with poly(styrene sulphonate) (commonly referred as PSS) as its "dopant", has received worldwide acceptance as a practical conductive polymer because it possesses good optical and electrical properties and also high processibility in the conventional aqueous form (2–6). The basic molecular structures of PEDT and PSS are shown in Fig. 1. Various PEDT:PSS products with their PEDT/PSS molar ratio, amounts of chemical additives, and physical properties optimized for specific applications are commercially available and comprehensively reviewed (3,7). In general, the ultimate properties of any PEDT:PSS molecular film very much depend on the experimental conditions during preparation, in addition to the choice of a specific PEDT:PSS product (3, 7). For example, the as-deposited molecular film is typically required to be thermally cured in the temperature range of 50–300 °C for it to show the best performance in film stability and electrical conductivity (3, 7, 8). However, the molecular film is also known to be susceptible to degradation by environmental factors like oxygen, moisture, heat, light, and mechanical stress (2–11). Immediately, one sees that the effects of thermal energy are particularly interesting (9–11). On the one hand, excessive input of thermal energy can cause undesirable phase separation, drive oxidation, and compositional degradation and induce undesirable diffusion of materials in the relevant device structure. On the other hand, appropriate thermal treatments are known to drive the residual solvent and impurities out, improve structuring ordering and inter-chain charge transport, and even induce additional cross-linking in the presence of appropriate additives. However, because of the hygroscopic nature of many polymeric semiconductors, particularly PEDT:PSS, some of the improvement in conductivity gained by thermal annealing can be lost very quickly in air (8). In short, it is desirable to develop alternative post-deposition processes to improve the stability and electrical conductivity of the molecular film, particularly dry chemical processes that are compatible to device fabrication and that thus ideally require no thermal budget and no chemical additives.

This article reports on our trials to explore if cross-linking the PEDT molecules in the PEDT:PSS molecular film with a nonthermally driven method can improve its stability and electrical conductivity. Briefly, we adopt the kinematics-driven method (12–14) of using hyperthermal proton bombardment of organic precursor molecules adsorbed on a conductive substrate to preferentially cleave C-H bonds and thereby cross-link the precursors to a stable molecular network. Unlike the typical design considerations of chemical reactions in which chemical additives and catalysts are added to reduce the reaction energy barrier and thermal energy is used to drive the reaction, the design strategy of this kinematics-driven method employs hydrogen projectiles like tiny hammers to preferentially break C-H bonds of the organic precursors, and the reaction is driven by the kinematic energy transfer in the collision (15). Therefore, by nature the method imposes little risks in chemical contamination and virtually no thermal budget. Thus, it is attractive in the development of new fabrication processes for the production of organic electronic and optoelectronic devices.

Explanation of the new cross-linking method using hyperthermal protons

The kinematics-driven method for cross-linking adsorbed organic precursor molecules with hyperthermal proton bombardment is rather unusual in comparison to the conventional synthetic chemistry. The basic physics and chemistry of this method have already been shown elsewhere recently (12–14). Briefly, in the simplest embodiment a high vacuum reactor is used to facilitate the irradiation of the organic precursor molecules adsorbed on a conductive substrate with a beam of protons such that no other undesirable surface contamination reactions including oxidation occur. The kinetic energy of the protons is a reaction variable, but is assumed to be 10 eV in this explanatory example. When such a proton travels to about 0.5 nm from the surface, the probability of electron tunneling from the valence band below the Fermi level of the conductive substrate (including the valence band of the adsorbed molecular film) to the empty 1s level of the proton is very high. Hence, prior to any direct atomic interactions between the proton and the atoms or molecular moieties on the substrate, the proton is converted to an atomic hydrogen projectile with a kinetic energy of 10 eV.[3] Under the first-order approximation of hard-sphere binary collision (16), a projectile colliding head-on with a target transfers its kinetic energy most effectively, with the energy transfer frac-

[3] This clarification is important because the electronic energy carried by a proton amounts to 13.6 eV and is thus significantly higher than the projectile kinetic energy in most of our hyperthermal proton bombardment experiments described in Refs. 12–14 and in this present article. The validity of the expectation of surface neutralization prior to any collision induced dissociation of molecules on the surface is supported by the large and consistent group of experimental data (Refs. 12–14) that shows the observed reaction outcomes from the collision induced dissociation of molecules on the surface are critically dependent on the kinetic energy of the projectile. The optimum energy for cross-linking acrylic acid molecular units with no damage of the COOH group (Ref. 14) was found to be ~5–6 eV, which is much less than 13.6 eV.

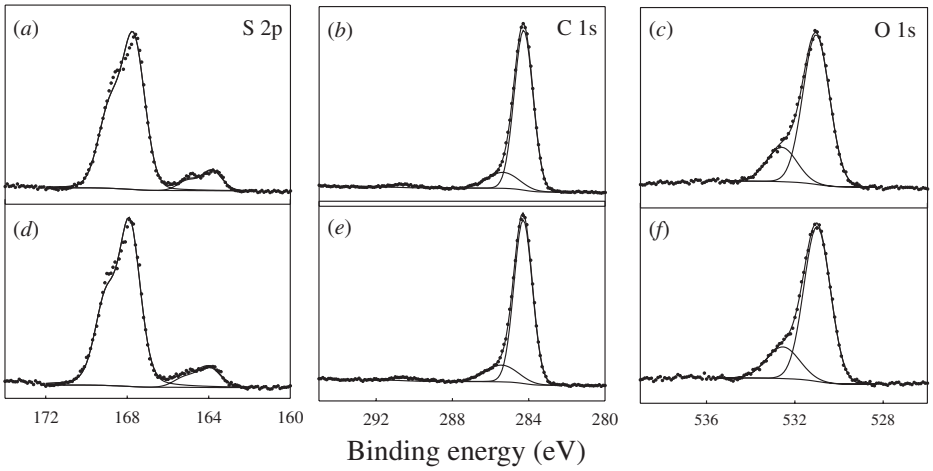
© 2007 NRC Canada

tion equal to $4M_pM_t/(M_p + M_t)^2$, where M_p and M_t are the mass of the projectile and target, respectively. Hence, a hydrogen projectile having a kinetic energy of 10 eV can transfer virtually all of its kinetic energy to its collision partner in a head-on collsion if this partner is also a hydrogen atom, but the maximum energy transfer amounts to only 2.8 eV if the partner is a carbon atom. The maximum energy transfer to the collision partner further reduces when the partner is heavier than carbon. Since the bond energy of C-H, C-C, and most other bonds in an organic molecule are typically about 3–5 eV, the collision can break C-H but not other bonds. As such, chemical selectivity can be derived from the nature of the kinematics and chemistry and by controlling the proton energy. In addition, this collision approach of breaking C-H bonds also attractively offers a high reaction yield. The collision cross-section for a projectile energy of 10 eV is typically a few $Å^2$ (16, 17). In comparison, although atomic hydrogen at room temperature (average kinetic energy of about 0.04 eV) is known to cause hydrogen abstraction, which can lead to the cleavage of a C-H bond, the reaction cross-section (18) is merely ~0.05 $Å^2$.

With this kinematics-driven method, precursor molecules such as dotriacontane (12), polyisoprene (13), docosanoic acid (14), and poly(acrylic acid)oligomer (14) have previously been deposited on a substrate such as a silicon wafer and treated with protons at 1–50 eV. The preferential C-H cleavage induced by the proton bombardment produces carbon radicals, and the recombination of them leads to cross-linking of the precursors. The evidence of collision-induced cross-linking has been proven by spectroscopic data, including photoemission evidence of a rising density of branching carbon with increasing proton fluence and secondary ion mass spectrometric evidence of the formation of such branching hydrocarbon chains. In addition, the relative degree of cross-linking has also been estimated by measuring the solubility of the molecular film in an organic solvent because the virgin film is soluble and the solubility decreases because of cross-linking. Indeed, the solubility decreases with increasing proton fluence. Further, the expectation that insufficient proton energy will compromise the C-H cleavage yield and excessive proton energy will lead to C-C bond breakage has also been confirmed by studying the reaction system as a function of the incident proton energy. The optimal proton energy for cross-linking simple saturated hydrocarbon molecules, such as dotriacontane ($CH_3(CH_2)_{30}CH_3$), is indeed around 10 eV, and when the proton energy is raised to 15–50 eV some C-C cleavage becomes detectable (12). At 50 eV, the reactivity of C-H cleavage is high such that a low fluence of less than 1×10^{16} cm^{-2} is enough to cross-link the molecules to the extent that the film is no longer soluble in hexane; yet the chemical selectivity is compromised such that even at this low fluence C-C bond cleavage is no longer negligible, and a loss of about 1 nm in molecular film thickness is evident. Since in the course of our research on cross-linking adsorbed hydrocarbon molecules we have found that most straight chain saturated hydrocarbon molecules with a carbon chain length shorter than 32 carbon atoms readily desorb in ultrahigh vacuum, the material loss induced by proton bombardment at 15–50 eV is likely due to C-C cleavage and fragment desorption. If we assume that one C-C cleavage is enough to lead to fragment desorption, we can estimate from the fluence dependence of molecular film loss that about 100 protons at 50 eV are required to cause one C-C cleavage with the result of fragment desorption. In comparison, from the fluence requirement for cross-linking the adsorbed molecules such that the molecular film becomes insoluble in hexane, we have also estimated that on average 10 protons are required to induce enough C-H cleavage to lead to the degree of cross-linking required for making the molecular film insoluble in hexane (12).

In summary, the expected preferential cleavage of C-H bonds induced by proton bombardment of adsorbed saturated hydrocarbon molecules in the energy range of 1–50 eV has already been verified experimentally. The experimental results indicate that the probability of C-H cleavage rises with increasing proton bombardment energy in this energy range. Although C-C bond cleavage is evident when the bombardment energy is raised to 15–50 eV, the probability of C-C cleavage relative to C-H cleavage is low because most of the collisions are not head-on and the amounts of kinetic energy transfer to a carbon target atom in most of these cases are still not enough for C-C cleavage. For cross-linking adsorbed saturated hydrocarbon molecules with this "chemistry with a tiny hammer" approach, the bombardment energy of ~10 eV seems to give the best combination of chemical reactivity and selectivity (12).

The results of proton bombardment of a molecular film of hydrocarbon molecules containing carboxylic acid functionality show another interesting feature of the new reaction approach because if the kinematics can drive C-H cleavage, it should also drive O-H cleavage (14). If so, the original chemical functionality of the precursor molecules can no longer be preserved and the technological impact is compromised. It turns out that the O-H bond is stronger than the C-H bond; hence, the O-H cleavage yield should drop more than the C-H cleavage yield when the proton energy is lowered. Indeed this has been proven experimentally (14); using a proton energy of around 6 eV with proper fluence control, molecular films of docosanoic acid and poly(acrylic acid)oligomer have been effectively cross-linked with little damage to the carboxylic acid functionality.



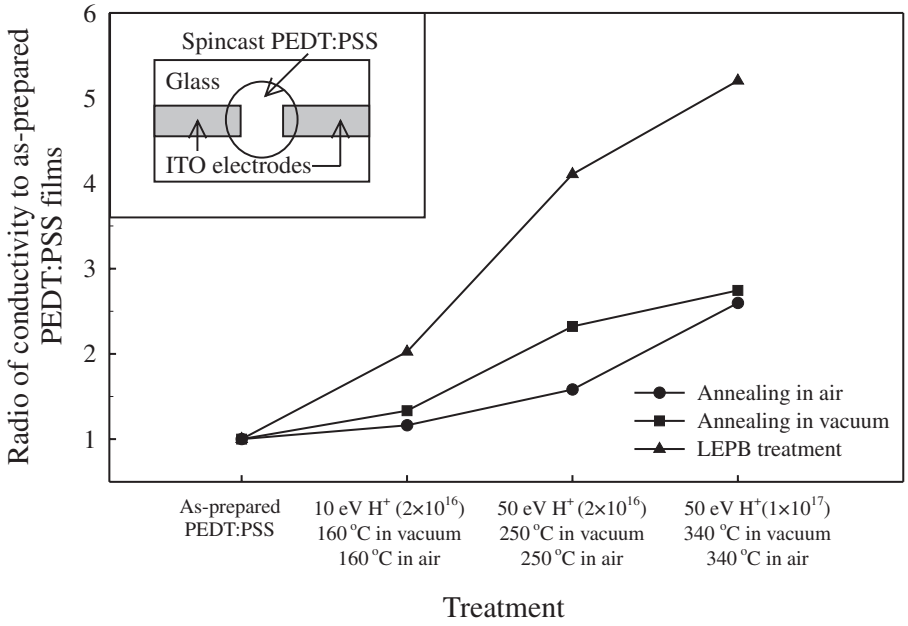
Therefore, with the kinematics-driven method one conducts chemistry with hyperthermal atomic hydrogen as a tiny hammer to preferentially break C-H bonds. Unlike the design of conventional chemical reactions, the design of reactions in this chemistry with a tiny hammer approach does not employ chemical additives, catalysts, and thermal energy to drive the reaction forward. Instead, it uses a beam of protons as the reagent and the proton kinetic energy as the main driving force. The design takes advantage of the ease in precisely controlling the proton fluence and the high collision cross-section. The magic of chemistry is enhanced by these attributes that are common to physicists but uncommon to synthetic chemists

Results and discussion on hyperthermal proton bombardment of PEDT

To test if the chemistry with a tiny hammer is effective in cross-linking the molecules in a PEDT:PSS film, one should track the solubility of the molecular film because it should decrease as a function of proton energy and fluence, as the

© 2007 NRC Canada

Fig. 2. (*a–c*) XPS S 2p, C 1s, and O 1s of the as-prepared PEDT:PSS film; (*d–f*): XPS S 2p, C 1s, and O 1s of the same film after the proton bombardment at 10 eV and a fluence of 2.0×10^{16} cm^{-2}.



solubility qualitatively reflects the degree of cross-linking. In fact, we have verified this experimentally. Briefly, the as-prepared PEDT:PSS films (~50 nm in thickness, measured by standard profilometry) can be completely removed by dissolution in de-ionized water. For PEDT:PSS films bombarded with hyperthermal protons, the film solubility decreases with increasing fluence for the same bombardment energy. It also decreases with increasing proton energy for the same fluence. For example, for the bombardment with 50 eV protons to a fluence of $2x10^{16}$ cm^{-2}, the average residual film thickness surviving the dissolution test amounts to 80% of the original film thickness. Hence, this implies that most of the molecules in the film have become cross-linked to the extent that they are no longer soluble in water. The bombardment with 10 eV protons can also yield the same results but the fluence has to be about 10 times higher. The correlation between proton bombardment and decrease in solubility, together with no undesirable chemical functionality change as shown later, suggests that the proposed chemistry with a tiny hammer approach to preferentially break C-H bonds and cross-link molecules is indeed applicable to the present work on hyperthermal proton bombardment of PEDT:PSS films. By controlling the degree of cross-linking with the bombardment conditions, the film solubility and stability can be adjusted and improved with no requirement of any thermal treatments.

The core value of the hyperthermal proton bombardment method is its chemical selectivity of breaking C-H bonds and thereby inducing chain cross-linking without compromising the desirable chemical functionalities of the precursor molecules. For the hyperthermal proton bombardment of the PEDT:PSS film, this is demonstrated by the results of chemical state analysis with XPS. Figures 2*a*–2*c* show the XPS C 1s, S 2p, and O 1s spectra of the as-prepared PEDT:PSS film on Au. The spectral features are consistent with the XPS data in the literature (9). Among them, the S 2p spectra are particularly informative. The convoluted doublet at the low binding energy end (163.9 eV) is attributed to the S $2p_{3/2}$ and S $2p_{1/2}$ spectral peaks of the sulfide of PEDT and that at the high-binding energy end to the sulphate of PSS. The latter is about 10 times more intense than the former because (*i*) the as-received PEDT:PSS solution mixture has a PEDT:PSS mixing molar ratio of about 1:4.5 for the optimal solubility and conductivity of the material, (*ii*) the PEDT:PSS film is granular because the as-received PEDT:PSS product comprises of pre-mixed PEDT:PSS gel particulates in an aqueous solution with the hydrophilic PSS orienting towards the particulate surface, and (*iii*) during film formation, the grain surfaces are enriched with PSS. Following this interpretation, we can also assign the small spectral components in the C 1s and O 1s spectra to the carbon atoms and oxygen atoms of the PEDT units and the intense components to those of the PSS units. A comparison of these chemical state data before and after the proton bombardment clearly shows that although the bombardment is effective in breaking C-H bonds and cross-linking the precursors, the overall chemical functionality properties are intact. In fact, the spectral data in Figs. 2*d*–2*f* are commonly found from the films bombarded by protons with a fluence up to $1x10^{17}$ cm^{-2}, no matter whether the energy is 10 or 50 eV. Further, by checking the characteristic energy loss spectral intensity of C 1s at ~292 eV, we have also found no change in the basic π nature of the molecules in the PEDT:PSS film, as any significant damage of the π nature will lead to a decrease of this π–π^* interband energy loss intensity. In this context it is relevant to note that if the protons are replaced with inert gas ions, the kinematics favoring preferential C-H cleavage is replaced with indiscriminating bond cleavage because of the relatively high mass of the inert gas projectiles. For example, it has been shown that by bombarding the same sample with 100 eV Ar^+ to the fluence of $1x10^{17}$ cm^{-2}, the PSS spectral component drops and the PEDT spectral component rises to the extent that the two spectral components have similar spectral intensities (19). Hence, unlike proton bombardment at 10–50 eV, the bombardment of the PEDT:PSS sample with a "heavy and indiscriminating hammer" like 100 eV Ar^+ can cause significant damage of the molecular chains and subsequent molecular fragment desorption. Therefore, we infer that the chemical functionalities of PEDT:PSS survive well in the proton bombardment experiments, and no significant degradation of the molecular chain and its chemical functionality is induced.

In addition to increasing film stability, the common prac-

© 2007 NRC Canada

Fig. 3. Ratio of conductivity of the PEDT:PSS film after different treatments to that of the as-prepared PEDT:PSS film (LEPB means low energy proton bombardment; the lines are drawn to aid readers in following the trends and bear no scientific content; the fluence is always measured as number of ions per cm^2). Inset: schematics of the electrical conductivitiy measurements.

tice of thermal curing as-deposited PEDT:PSS also improves the electrical conductivity of the film. Thus, the main goal of this work is to determine if the hyperthermal proton bombardment treatments can also improve the film conductivity. In this analysis, the current–voltage characteristics of a strip of PEDT:PSS deposited across two electrodes are measured and the analysis is applied to films before and after proton bombardment with different bombardment conditions. The analysis is also repeated for films before and after the common thermal curing treatments. The results are schematically summarized in Fig. 3 and clearly show that the hyperthermal proton bombardment is more effective than the common thermal curing treatments in increasing film conductivity. The observed evidence of raising the electrical conductivity by proton bombardment implies that the chemistry with a tiny hammer has induced some inter-molecular cross-linking of PEDT, since intermolecular cross-linking of PSS molecules and intermolecular cross-linking of PSS and PEDT should not increase the electrical conductivity of the molecular film.

To explain how the chemistry with a tiny hammer can effectively increase the electrical conductivity of the PEDT:PSS molecular film, we resort to the origin of electrical conductivity of the film. The basic conducting element is the polythiophene chain. When holes are injected to the π-conjugated polythiophene chain and stabilized by the PSS dopant unit, the holes can travel along the π-conjugated molecular "tape" with the planar arrangement of each pair of adjacent thiophene units spanning across the width of the tape. Holes from one conductor tape jump to another conductor tape when the two tapes are closely spaced, with their π–π system effectively overlapped at the "tape–tape" crossing point. Ideally, stacking the molecular tapes in an ordered fashion enhances the conductivity, but in many practical systems such as the PEDT:PSS molecular films in this study, its "crystallinity" is known to be weak mainly because it is difficult to accommodate the PSS chains in a crystalline stack of the polythiophene molecules (3, 8, 10, 20). Hence, in the following discussion, the PEDT molecules are assumed to be randomly packed, with many "tape–tape" crossing points having their separations affected by the thermally driven molecular motions in the film.

The main difference between the PEDT chain and the basic polythiophene chain can be simplified to merely widening the molecular tape of the polythiophene chain with an U-shape ethylenedioxy side branch for each thiophene unit (as shown in Fig. 1). This side branch depletes the remaining two C-H bonds of each thiophene unit, and because of this the conjugated backbone has no C-H bonds at all and cannot interact with the low energy proton projectiles (actually atomic hydrogen projectiles, as explained earlier) when the kinematics is not violent enough to break the strong bonds in the conjugated backbone. Experimentally, we find that proton bombardment at 10–50 eV is effective in improving the stability and electrical conductivity of PEDT, with no detectable undesirable effects such as materials loss even with a fluence up to $1x10^{17}$ cm^{-2}. This is not inconsistent with the hyperthermal proton bombardment of a film of adsorbed dotriacontane ($CH_3(CH_2)_{30}CH_3$, film thickness of 11nm). The C-C bond in this straight-chain hydrocarbon molecule is much weaker than the conjugated carbon bonds in the polythiophene units. Since the probability of C-C bond cleavage in dotriacontane has been found (12) to be much lower than that of C-H bond cleavage for proton projectiles with kinetic energy at 10–50 eV, the probability of damaging the conjugated carbon bonds should be even lower.

With the preceding clarification, we postulate several pathways that can lead to the observed increase in electrical conductivity. Further computational and experimental studies are underway to examine the validity of such postula-

© 2007 NRC Canada

tions. Nevertheless, the postulated pathways are summarized as follows:

(*i*) During the cascade collision process, some of the incident proton kinetic energy is dissipated to the PEDT molecules and this promotes molecular diffusion towards energy minimization with more intermolecular π–π overlapping. The effect is similar to enhancing molecule ordering by thermal annealing (8, 10).

(*ii*) Time-of-flight laser-induced ion mass spectrometry has been used to show (3) that the PEDT molecules in the commercially available PEDT:PSS product used in this study are actually relatively small and have not more than ~10 monomer units. If this is true and the head and tail thiophene units are terminated by C-H bonds, these C-H bonds can be cleaved during the hyperthermal proton bombardment. A pathway is thus created for cross-linking small PEDT molecules to larger PEDT molecules with longer conjugated lengths. Intuitively, we judge that the chance of having this rather special cross-linking condition is low. Since this pathway should lead to a significant increase in the average conjugation length and thus to an observable red shift of the optical absorption, we have begun to examine the effects of proton bombardment on the optical properties. Our preliminary results indeed indicate no observable red shift, which implies this cross-linking pathway being unimportant.

(*iii*) The chemistry with a tiny hammer approach can break the C-H bonds of the "ethylenedioxy" side branch and can thereby enable another cross-linking pathway. In the following discussion, we postulate that in the granular PEDT:PSS films studied in this work, each grain contains nominally flat molecular tapes randomly tangling together, with some of them having inter-chain separations as close as the van der Waals bond distance. By chance, inter-chain π–π overlapping may happen, and as explained earlier, electrical conductivity is induced. Thermally driven molecular motions may compromise such π–π overlapping and limit the electrical conductivity. Harnessing the chemistry with a tiny hammer to break C-H bonds without breaking other bonds can lock some of these casual inter-chain junctions by covalently cross-linking the ethylenedioxy side branches of the two nearby ethylenedioxy–thiophene units. Such a lock can thus secure the inter-chain π–π overlapping. This cross-linking reaction can then lead to the observed decrease in solubility and increase in electrical conductivity of the bombarded film. Computational modeling of such inter-chain π–π overlapping is expected to give a more detailed picture of this proposed pathway. In addition, experimental measurements of the proposed bonding changes of some of the ethylenedioxy side chains with NMR and secondary ion mass spectrometry are also informative. These studies are indeed underway in our research group.

Conclusion

In summary, the chemistry with a tiny hammer approach of using hyperthermal proton bombardment to induce preferential C-H cleavage and cross-link adsorbed organic precursors is shown to be applicable to the technologically important PEDT-based molecular films. Proton bombardment in a wide energy window of 10–50 eV is found to be effective in increasing both stability and electrical conductivity. There may be several plausible reaction pathways leading to these observed desirable effects, and further computational modeling and experimental studies are underway to examine the effectiveness of each individual reaction channel. In general, the film improvement method is attractive in that it does not use any chemical additives and catalysts other than protons in a dry process, and it does not require any thermal budget. It is conceivable that the method is applicable to the fabrication of other organic semiconductor films and devices.

Experimental

The PEDT:PSS (Baytron P AI 4083) stocks used in this report were purchased from Bayer AG (7). The PEDT:PSS molar mixing ratio is ~1:4.5. As-received PEDT-PSS was spin-cast on Au/Si substrates. The XPS analysis was conducted with a Kratos AXIS-HS spectrometer equipped with a monochromatic Al Kα source. For the current–voltage measurements of electrical conductivity, PEDT:PSS was spin-cast on patterned ITO electrodes on glass and the film conductivity was characterized with a Keithley 236 source measurement unit. Hyperthermal proton bombardment was performed with a mass-resolved low-energy ion beam system. Both the instrument and the basic hyperthermal ion bombardment process have already been described elsewhere (21). The PEDT-PSS film on an Au/Si substrate was bombarded with 10 and 50 eV proton beams at fluences up to 1×10^{17} cm^{-2}. The film solubility analysis was conducted by rinsing the film sample in de-ionized water for one minute and the change in film thickness was measured by a standard profilometer. For comparison, the film conductivity and solubility of PEDT:PSS films annealed in both air and ultrahigh vacuum (base pressure ~10^{-9} torr; 1 torr = 133.322 4 Pa) were also measured.

Examining the structural changes in $Fe_2(CO)_9$ under high external pressures by Raman spectroscopy[1]

Muhieddine Safa, Zhaohui Dong, Yang Song, and Yining Huang

Abstract: Pressure-induced structural changes in di-iron nonacarbonyl [$Fe_2(CO)_9$] were examined by in situ Raman spectroscopy with the aid of a diamond anvil cell. Our results indicate that $Fe_2(CO)_9$ undergoes a pressure-induced phase transformation at about 0.9 GPa. Upon further compression, another structural transformation is identified at 7 GPa. In the low-pressure phase below 0.9 GPa, the π back-bonding between metal and carbonyl increases with increasing pressure. In the high-pressure phase above 7 GPa, the combination of high-pressure and laser irradiation induces a change in structure from $Fe_2(CO)_9$ to $Fe_2(CO)_8$. $Fe_2(CO)_8$ appears to adopt a structure with C_{2v} rather than D_{3d} or D_{2h} symmetry. The metal–metal bond is gradually weakened under high pressures, and $Fe_2(CO)_8$ eventually decomposes by breaking the Fe–Fe bond when compressed up to 17.7 GPa.

Key words: metal carbonyl, Raman spectroscopy, high pressure, diamond anvil cell.

Résumé : Faisant appel à la spectroscopie Raman in situ avec l'aide d'une cellule à matrice de diamant, on a étudié les changements structuraux induits par la pression dans le difernonacarbonyle, [$Fe_2(CO)_9$]. Les résultats obtenus indiquent que le $Fe_2(CO)_9$ subit une transformation de phase induite par la pression à environ 0,9 GPa. Par compression subséquente, on a identifié une autre transformation structurale à 7 GPa. Dans la phase à basse pression, en dessous de 0,9 GPa, la liaison en retour π entre le métal et les carbonyles augmente avec une augmentation de pression. Dans la phase à haute pression, au-dessus de 7 GPa, une combinaison de pression élevée et une irradiation au laser induit un changement dans la structure de $Fe_2(CO)_9$ à $Fe_2(CO)_8$. Le $Fe_2(CO)_8$ semble adopter une structure de symétrie C_{2v} plutôt que les symétries D_{3d} ou D_{2h}. La liaison métal–métal s'affaiblit graduellement sous des pressions élevées et le $Fe_2(CO)_8$ se décompose éventuellement par bris de la liaison Fe–Fe lorsqu'on atteint une pression de 17,7 GPa.

Mots-clés : métal carbonyle, spectroscopie Raman, pression élevée, cellule à matrice de diamant.

Introduction

Vibrational spectroscopy has long been the method of choice for the characterization of organometallic compounds because it provides invaluable information on the molecular geometry, crystal structures of the solid complexes, and the nature of the bonding interactions in these compounds. Using external pressure as an independent variable to explore the change in molecular geometry and phase behavior of organometallic carbonyls is quite important, since many of the transition metal carbonyls exhibit interesting changes in both molecular and crystal structures under high external pressures (1, 2), but these changes often do not occur upon lowering temperatures.

The high-pressure studies are usually performed with the aid of diamond anvil cells (DACs). Coupling of a DAC to a Raman spectrometer provides an extremely useful approach to examine the metal carbonyls under pressures because the spectra in the CO stretching region (~2000 cm^{-1}) are very sensitive to the change of molecular geometry and crystal structure. The pressure dependences ($d\nu/dP$) of the ν(CO) and ν(M–CO) modes of transition-metal carbonyls provide the information regarding the π back-bonding between metals and the carbonyl groups. The corresponding IR spectroscopy is much less useful, since the strong diamond adsorption completely masks the ν(CO) region (3).

The structures of binuclear transition-metal carbonyls, such as $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$ and $MnRe(CO)_{10}$ have been examined by Raman spectroscopy under high pressures (4, 5). A second-order phase transition was detected, but more interestingly, the molecular geometry changed from the staggered structure (D_{4d}) to an eclipsed configuration (D_{4h}) in each case.

Tri-μ-carbonyl(hexacarbonyl)di-iron(0), $Fe_2(CO)_9$, was one of the earliest known metal carbonyls and remains to be one of the best-known examples for binuclear transition-metal carbonyls. This complex is an important reagent for organic synthesis and is a catalyst as well. The crystal struc-

ture has been determined by single-crystal X-ray diffraction (6, 7). The unit cell adopts a space group of $P6_3/m$ with two molecules per unit cell residing at C_{3h} sites and a molecular symmetry of D_{3h} (Fig. 1). The vibrational spectra of $Fe_2(CO)_9$ at ambient pressure and low temperature have been assigned (8–10). The low-temperature Raman studies indicated that there is no phase transition occurring at temperatures as low as 15 K (8). In addition, $Fe_2(CO)_9$ exhibits interesting photochemistry. The early study of Poliakoff and Turner showed that this complex undergoes the CO disassociation under irradiation (11, 12). $Fe_2(CO)_8$ was captured as a key product at very low temperature in matrixes. Structures of di-iron carbonyls with different stoichiometry [$Fe_2(CO)_x$] together with their bonding natures between the two irons have been extensively characterized by Xie et al. (13) using various computational approaches. Very recently, the photochemistry of $Fe_2(CO)_9$ was further examined by Bertini et al. (14) using time-dependent DFT theory.

In the present study, we have investigated the behavior of $Fe_2(CO)_9$ under high external pressures up to about 18 GPa. Particular attention was paid to the possible pressure-induced phase transition, the geometry change and the combining effect of laser irradiation and applying high pressure on the photochemical behavior of $Fe_2(CO)_9$.

Experimental

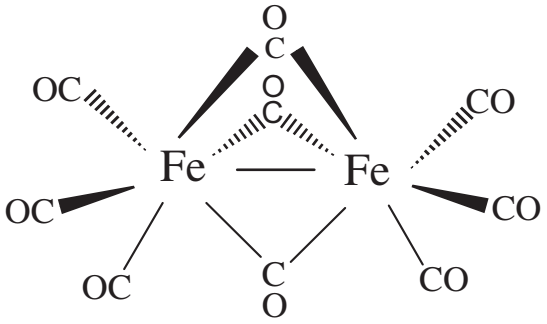
Polycrystalline powder of $Fe_2(CO)_9$ was purchased from Alfa Aesar Chemical Company (purity ≥99%) and was used without further purification. Raman spectra were recorded on a Renishaw Model 2000 Raman spectrometer equipped with a Leica microscope and a thermoelectronically cooled CCD detector. The 632.8 nm line of a HeNe laser was used as the excitation source with an average power of several milliwatts at the sample. The resolution achieved was typically 1 cm^{-1}. The sample and several tiny ruby chips were placed in a stainless steel gasket (250 μm in diameter and 70 μm thick) mounted between two opposing anvils of a symmetric piston-cylinder type DAC. The DAC was then mounted onto an X–Y stage, and the laser beam was focused on the sample via a 4X microscope objective. The pressure was calibrated by using the well-known ruby method (15). No pressure media were used. The uncertainty for pressure determination is estimated as 0.05 GPa.

Results

Raman spectra of $Fe_2(CO)_9$ at 0–7 GPa

The Raman spectrum of $Fe_2(CO)_9$ was collected at ambient pressure and room temperature before compression and is depicted in Fig. 2. The structure of $Fe_2(CO)_9$ at ambient pressure has been well-established and extensively characterized by X-ray diffraction and vibrational spectroscopy. Under factor group analysis (9), 18 modes are predicted to be Raman active and eight modes to be IR active, while 10 modes are both Raman and IR active out of a total of 54 vibrational modes. In general, the Raman active modes are observed in two spectral regions, i.e., 1800–2150 cm^{-1} and below 600 cm^{-1}, corresponding to the carbonyl stretching and iron–carbonyl cluster vibrations, respectively. Our Raman spectrum is consistent with previous vibrational studies (9) with the major characteristic modes being observed. The assignments of these modes are labeled in Fig. 2 and listed in Table 1 in comparison with previous observations. In the carbonyl stretching region, the peaks at 2107, 2013, and 1988 cm^{-1} are attributed to the terminal carbonyls

Fig. 1. Molecular structure of $Fe_2(CO)_9$.



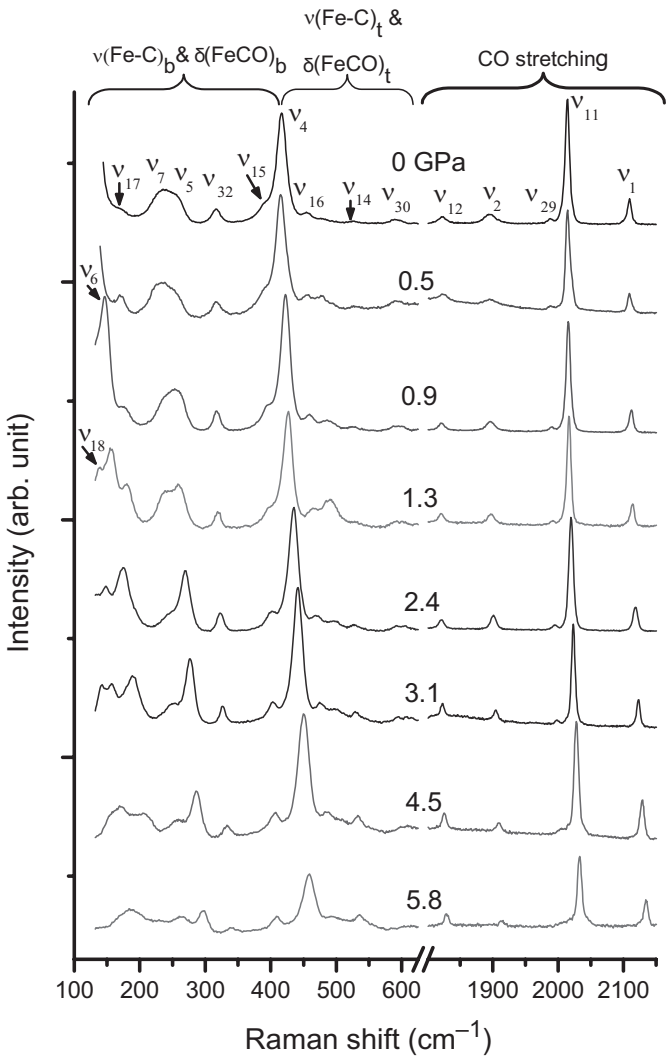


Fig. 2. Selective Raman spectra of $Fe_2(CO)_9$ on compression at 0–5.8 GPa in the spectral regions of 100–650 cm^{-1} and 1800–2150 cm^{-1}. The pressures in GPa are labeled for each spectrum. The assignments of the Raman modes are labeled on the top spectrum collected at ambient pressure. The spectra are normalized to the same scale and offset vertically for clarity.

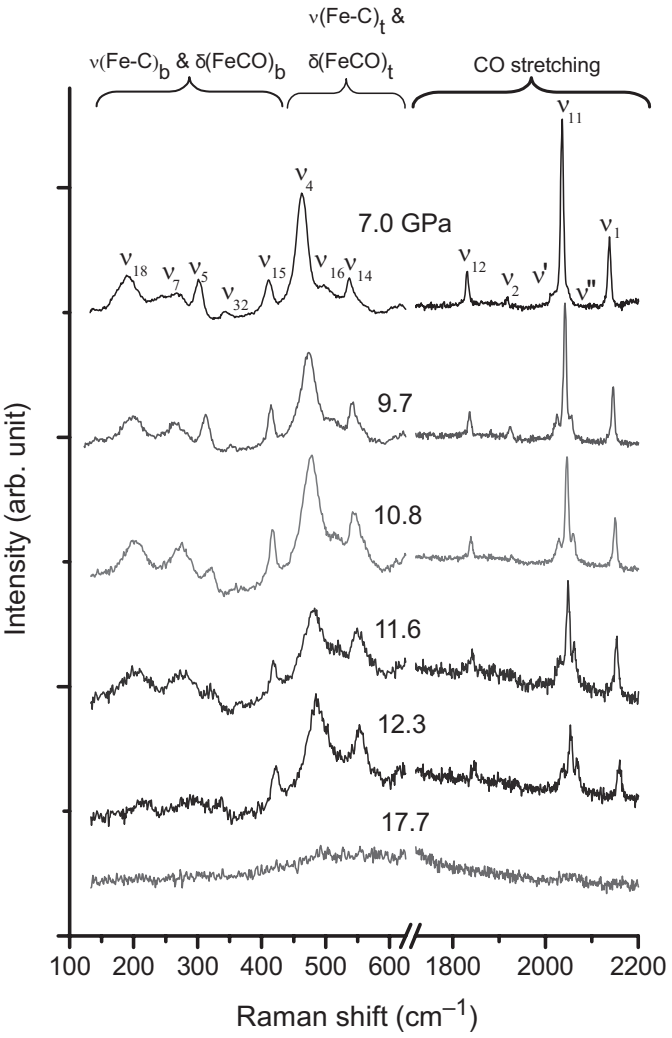
[b]First observed at 0.9 GPa.
[c]First observed at 1.3 GPa

$[\nu(CO)_t]$, while those at 1895 and 1824 cm^{-1} are associated with bridging carbonyls $[\nu(CO)_b]$. In the spectral region between 600 and 400 cm^{-1}, the vibrations are associated with the bending of the terminal carbonyls $[\delta(Fe–CO)_t]$ and the stretching between iron and terminal carbonyls $[\nu(Fe–C)_t]$. The modes below 400 cm^{-1} are due to the bending of bridging carbonyls $[\delta(Fe–CO)_b]$, the stretching between iron and bridging carbons $[\nu(Fe–C)_b]$, as well as some vibrations from iron-centred cluster $[\Delta Fe_2C_3]$ (9).



Upon compression, the Raman modes for carbonyl stretching shift to higher frequencies smoothly. The Raman intensities of these modes are relatively insensitive to pressure except for mode ν_{29}, a $\nu(CO)_t$ mode, the intensity of which decreases with pressure significantly. In the lower vibrational frequency region, the major Raman modes are found to shift to higher frequencies markedly. In addition, significant changes in Raman patterns are found in this region. For instance, ν_{15}, a very weak $\delta(FeCO)_b$ mode at 393 cm^{-1} at ambient pressure, becomes a resolvable shoulder of ν_4 mode at 0.9 GPa and is completely deconvoluted from ν_4 mode at 5.8 GPa. Furthermore, the ν_7 and ν_5 modes, which exhibit a broad convoluted peak at ambient pressure, become a resolvable doublet at 1.3 GPa, which further develops into two bands with strongly constrasting intensities. The most drastic changes of the Raman spectra are observed below 200 cm^{-1}. The ν_{17} mode is greatly enhanced by compression between 0.5–1.3 GPa but becomes indiscernible beyond 1.3 GPa. More interestingly, a new Raman mode, which is identified as ν_6 (Table 1), is observed at 0.9 GPa. This mode, which is not observable at lower pressures because of the use of an edge filter in the Raman spectrometer, shifts rapidly to higher frequency until 5.8 GPa when the intensity drops significantly. Other new modes observed include the ν_{18} mode at 138 cm^{-1} at 1.3 GPa and a band at 142 cm^{-1} at 3.1 GPa, which can be assigned as a mode associated with the iron-centred cluster vibration. These low-frequency modes become very weak with increasing pressure up to 5.8 GPa.

Raman spectra of $Fe_2(CO)_9$ at 7–17.7 GPa

Raman spectra of $Fe_2(CO)_9$ at 7–17.7 GPa are depicted in Fig. 3. At 7 GPa, eight Raman modes (ν_{18}, ν_7, ν_5, ν_{32}, ν_{15}, ν_4, ν_{16}, and ν_{14}) are observed in the low-wavenumber region below 600 cm^{-1}. These modes shift to higher wavenumbers with pressure, and their intensities decrease systematically. Concurrent to the weakening of Raman intensities, all bands become significantly broader with only three bands (ν_5, ν_4, and ν_{14}) identifiable at 12.3 GPa. When pressure is increased to 17.7 GPa, the Raman features in this region completely disappeared, indicating the destruction of the Fe–C cluster. The most striking change is observed in the carbonyl stretching region. A new peak at 2018 cm^{-1} is observed at 7.0 GPa, which develops into a relatively intense Raman mode with increasing pressure. When pressure is increased to 9.7 GPa, another new peak at 2056 cm^{-1} was observed all the way to 12.3 GPa. The intensities of these carbonyl stretching modes

Fig. 3. Selective Raman spectra of $Fe_2(CO)_9$ on compression at 7.0–17.7 GPa in the spectral regions 100–650 cm^{-1} and 1800–2200 cm^{-1}. The pressures in GPa are labeled for each spectrum. The assignments of the Raman modes are labeled on the top spectrum collected at 7.0 GPa. The spectra are normalized to the same scale and offset vertically for clarity.

are also reduced by compression with the ν_2 mode being completely unobservable at 11.6 GPa. Similar to the low frequency regions, the carbonyl stretching region exhibits absolutely no Raman feature at 17.7 GPa, indicating the compound has completely decomposed.

Pressure dependence of Raman modes of $Fe_2(CO)_9$

Figure 4 shows the Raman shifts of major modes in both the low-frequency region and the carbonyl stretching region as a function of pressure on compression. The pressure dependences $d\nu/dP$ are also listed in Table 2. As can be seen from the Fig. 4 and Table 2, below 0.9 GPa, all modes exhibit a positive linear dependence with pressure except for two modes, ν_{14} and ν_{12}, which have negative $d\nu/dP$ values. A distinct change in slope at 0.9 GPa is observed for almost all modes. In the region below 0.9 GPa, all modes follow a linear pressure dependence with larger $d\nu/dP$ values than those between 0.9 and 7 GPa, except for ν_{16}, ν_2, and ν_{11} modes, which exhibit larger $d\nu/dP$ values at the higher pressure region. Most significantly, the ν_{29}, ν_{16}, and ν_{32} modes are not observed beyond 7 GPa, while new modes in the carbonyl stretching region are observed above 7 GPa (Fig. 3), indicating a major phase or structural transition.

Discussion

Figure 4 illustrates that in the pressure region below 7 GPa, most of the Raman modes exhibit a distinct break in the slopes of the $\nu - P$ plots at around 0.9 GPa, suggesting that there is a pressure-induced phase transition. Since the discontinuities in Fig. 4 are not abrupt, and there is no change in the number of internal modes at the transition, the observed phase transformation is likely second-order. Previous vibrational studies showed no phase change occurring at low-temperature (8). Therefore, the new phase appears to only exist under high pressures.

In the low-pressure phase, three high-frequency bands at 2107, 2013, and 1988 cm^{-1} due to the terminal carbonyl stretching vibrations [$\nu(CO)_t$] steadily shifted to higher frequencies with increasing pressure. The band at 1895 cm^{-1} is almost pressure-insensitive, while the 1824 cm^{-1} band has a negative pressure-shift rate, i.e., it shifts to lower frequencies with increasing pressure. Both the 1895 and 1824 cm^{-1} bands are due to the bridging carbonyl stretching modes, [$\nu(CO)_b$]. Normally, all the internal modes shift gradually with increasing external pressure because of the anharmonicity of the potential function. Any unusual pressure behavior, such as very large, small, and even negative pressure dependence should be explained in terms of specific intra- and intermolecular interactions. The insensitivities and (or) negative pressure dependences of terminal $\nu(CO)_t$ modes have been reported in the previous high-pressure Raman studies on transition metal carbonyl complexes (16–18). Such observations were interpreted as the pressure-enhanced π back-bonding between the metal centre and the CO groups, i.e., the strengthening of the π back-bonding decreases the carbonyl bond order, which results in a constant or decreasing $\nu(CO)$ frequency. In the present case, the two bridging $\nu(CO)_b$ modes exhibit a very small and a negative pressure dependence, suggesting that in the low-pressure phase, the π back-bonding between iron and bridging carbonyl groups is particularly enhanced under external pressure. It is also worth noting that the broad peak centred at around 260 cm^{-1} exhibits a very prominent positive pressure dependence (41.5 cm^{-1}/GPa) in the low-pressure phase. This band has been previously assigned to the Fe–Fe stretching mode (8, 9). Thus, the very large pressure shift rate of the ν(Fe–Fe) mode implies that the metal–metal bond is significantly shortened by pressure.

All the results indicate that in the low-pressure phase, increasing pressure significantly affects the cluster involving two metal centres and three bridging CO groups [$(Fe_2C_3)_b$]. It appears that the bonding interactions responsible for holding the cluster together, such as metal–metal bond and the bonding between bridging CO and metal centres, are strengthened by pressure. Several binuclear transition-metal carbonyl complexes, such as $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, and $MnRe(CO)_{10}$, have been examined under high external pres-

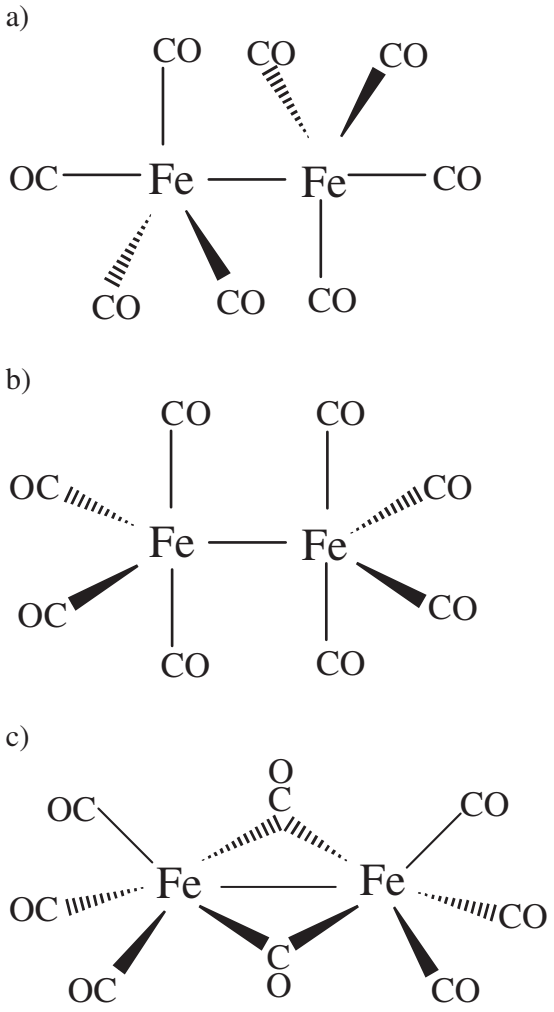
		$(d\nu/dP)_T$ (cm^{-1}/GPa)	
Raman modes	Frequency at ambient P (cm^{-1})	0–0.9 GPa	0.9–7.0 GPa
ν_{18}	138	—	10.7
ν_7	236	41.5	7.4
ν_{32}	316	5.5	5.0
ν_{15}	393	12.4	2.2
ν_4	415	19.4	6.3
ν_{16}	457	7.9	8.1
ν_{14}	529	–7.1	1.7
ν_{30}	594	10.3	3.8
ν_{12}	1824	–10.5	1.8
ν_2	1895	1.9	3.7
ν_{29}	1988	4.8	3.6
ν_{11}	2013	3.9	4.7
ν_1	2107	9.9	4.2



sure by Raman spectroscopy (4, 5). In each case, a change in molecular geometry from staggered (D_{4d}) to eclipsed (D_{4h}) configuration was observed. However, in the present case, the molecular geometry of $Fe_2(CO)_9$ remained as D_{3h}. Apparently, the pressure-strengthened interactions between metal centres and bridging carbonyl groups via π bonding prevents any rotation of $Fe(CO)_3$ fragment around Fe–Fe axis from changing to other configurations.

In the high-pressure phase (0.9–5.8 GPa), all the ν(CO) stretching modes are gradually shifting to the higher frequencies, including the two bands due to the bridging carbonyl groups. Overall, there is no major change in the appearance of the spectra in the ν(CO) region, indicating no change in the molecular geometry in this high-pressure phase. As shown in Fig. 2, in the low-frequency region, all the bands originating from the $(Fe_2C_3)_b$ cluster as well as all the $(Fe–CO)_b$ stretching and bending vibrations are gradually broadened with increasing pressure except for the ν_7 mode, which is mainly due to metal–metal bonding. All these results suggest that in the pressure range of 0.9–5.8 GPa, the $(Fe_2C_3)_b$ core is significantly distorted under pressure, while the $Fe(CO)_3$ groups involving terminal carbonyls are relatively unaffected.

When the pressure was increased to 7 GPa, some distinct changes were observed in the ν(CO) region. In particular, two new bands appeared at 2018 and 2056 cm^{-1} (Fig. 3). The appearance of these new bands in the ν(CO) region implies the formation of a new carbonyl species. The early work by Fletcher et al. showed that irradiation of $Fe_2(CO)_9$

© 2007 NRC Canada

Fig. 5. Proposed structures of $Fe_2(CO)_8$ with (*a*) D_{3d}, (*b*) D_{2h}, and (*c*) C_{2v} symmetries.

with UV light leads to the formation of $Fe_2(CO)_8$ at low temperature according to the following (11):

$$Fe_2(CO)_9 \rightarrow Fe_2(CO)_8 + CO$$

They were able to capture two $Fe_2(CO)_8$ isomers in matrices at 20 K: the CO bridged and unbridged $Fe_2(CO)_8$. The CO bridged isomer is a kinetic product and the unbridged compound is thermodynamically much more stable. The point groups of C_{2v} and D_{3d} were proposed for the CO bridged and unbridged $Fe_2(CO)_8$ species, respectively. The authors later established that the unbridged compound actually has D_{2h} symmetry (12). These symmetries are depicted in Fig. 5.

The work by Butler and co-workers showed that photolysis of $Fe_2(CO)_9$ can also occur during the acquisition of Raman spectra (8). In the present study, the appearance of additional ν(CO) bands suggest that $Fe_2(CO)_8$ is also formed by laser irradiation and stabilized by high external pressure. In particular, the frequencies of these new bands (2018 and 2056 cm^{-1}) are closer to those observed in the bridged $Fe_2(CO)_8$ (2022 and 2055 cm^{-1}) rather than the two high-frequency peaks of the unabridged isomer at 2006 and 2038 cm^{-1} (11). Therefore, the observations of five terminal $\nu(CO)_t$ and two bridging $\nu(CO)_b$ bands are consistent with C_{2v} symmetry (19). We also noticed that the intensity of the $\nu(CO)_b$ band, initially observed at 1895 cm^{-1}, quickly decreased with increasing pressure and is almost depleted completely at 12.6 GPa. It appears that $Fe_2(CO)_8$ may undergo further decomposition by losing one of the two bridging carbonyl groups.

In the low-frequency region, starting from 5.8 GPa, all the vibrations associated with $(Fe_2C_3)_b$ core, including the ν_7(Fe–Fe) mode, become gradually broadened with increasing pressure. At 12.3 GPa, all the previously mentioned bands become extremely broad. All these results suggest that the decomposition begins by breaking the $(Fe_2C_3)_b$ core, while the $Fe(CO)_3$ terminal groups are relatively unaffected in the beginning. Although peak broadening could be induced by structural amorphization or pressure gradients, the irreversible transformation and reasonably sharp ruby profiles rule out these possibilities and suggest that the transformation is chemical in nature. At 17.7 GPa, no Raman bands were observed, indicating that all the metal carbonyl species have completely decomposed.

Conclusions

In the present work, we have examined the behavior of $Fe_2(CO)_9$ under high external pressures. In the low-pressure range of 0–0.9 GPa, the pressure enhances the π back-bonding between the bridging CO ligands and the metal centres. The bonding interactions involving $(Fe_2C_3)_b$ cluster were strengthened upon compression in this pressure range. In the intermediate pressure region of 0.9–7 GPa, the molecular geometry remains as D_{3h}, but the $(Fe_2C_3)_b$ core undergoes distortion with increasing pressure. Above 7 GPa, gradual decomposition induced by the combination of pressure and laser irritation starts to be observed. $Fe_2(CO)_8$ with C_{2v} symmetry was identified as a product. This species at ambient pressure is very unstable and can only be captured at very low temperature in matrices. Apparently, this CO bridged compound is stabilized by high pressure. At higher pressure, further decomposition of $Fe_2(CO)_8$ was detected through losing a bridging CO group.

Solvation and electronic structures of M^+L_n, with $M^+ = Mg^+$ and Ca^+, L = H_2O, CH_3OH, and NH_3, and n = 1–6[1]

Ka Wai Chan, Young Wu, and Zhi-Feng Liu

Abstract: The solvation clusters $M^+(L)_n$, with a singly charged alkaline earth cation Mg^+ or Ca^+ as the solute and with water, methanol, or ammonia as the solvent, are studied systematically in the size range n = 1–6, to compare the variations in the solvation interactions. For clusters with $n \leq 3$, the energies and structural values are compared in details, with both the MP2 and B3LYP methods. For clusters with $n \geq 4$, the solute–solvent and solvent–solvent interaction energies are calculated to explain the relative stability among various isomeric structures, and the contrast in both solvent and electron distribution among these cluster series. Thermal stabilities for these clusters are also examined by ab initio molecular dynamics simulations at finite temperature.

Key words: solvation clusters, ab initio calculations, solute–solvent interactions, size-dependent effects.

Résumé : Afin de pouvoir comparer les variations dans leurs interactions de solvatation, on a effectué une étude systématique des agrégats de solvatation $M^+(L)_n$ (n = 1–6) comportant, comme soluté, un cation alcalino-–terreux avec une seule charge, tel le Mg^+ ou le Ca^+, et de l'eau, du méthanol ou de l'ammoniac comme solvant. Utilisant les méthodes MP2 et B3LYP, on a pu comparer en détails les valeurs structurales ainsi que celles des énergies pour les agrégats dans lesquels $n \leq 3$. Pour les agrégats dans lesquels $n \geq 4$, on a calculé les énergies d'interaction soluté–solvant et solvant–solvant afin de pouvoir expliquer la stabilité relative entre les diverses structures isomères ainsi que le contraste tant dans la distribution de solvant que la distribution électronique entre les diverses séries d'agrégats. On a aussi évalué les stabilités thermiques de ces agrégats en faisant appel à des simulations de dynamique moléculaire ab initio à la température ambiante.

Mots-clés : agrégats de solvatation, calculs ab initio, interactions soluté–solvant, effets reliés à la taille.

[Traduit par la Rédaction]

Introduction

Singly charged alkaline earth cations such as Mg^+ and Ca^+ are interesting solutes in the study of solvation clusters that have provided considerable insights into solvation interactions (1–3). First, they are open shell species with a singly occupied molecular orbital (SOMO), which could reside either on the metal ion or in the solvation shells (in an orbital detached from the metal ion), depending on the solvation environment. Then, there are of course the solvent–solvent and ion–solvent interactions, with the ion either being in +1 or +2 states, again depending on the solvation environment (4–8). Furthermore, these species could only be studied as clusters, since they are unstable in solutions, and thus they provide a fairly unique medium to probe the complex interactions among the three components, electron, cation, and solvents. And finally, it is now well-understood that these interactions lead to rich variations in both the geometrical and electronic structures and also to reactivities that can be controlled by varying the cluster size. Electronically, these ions are isoelectronic to alkali atoms, and spectroscopically, electronic excitations and photo-induced fragmentation have been studied extensively over the years (1, 3). For the ground state, the most interesting observation is the size-dependent reactivity of these clusters. In the case of $Mg^+(H_2O)_n$ and $Ca^+(H_2O)_n$, it is the loss of hydrogen atom and the formation of metal hydroxide (9–11). In the case of $Mg^+(CH_3OH)_n$ and $Ca^+(CH_3OH)_n$, both the hydrogen loss and the methyl loss channels are accessible (12, 13). Hydrogen loss has also been observed in the case of $Mg^+(NH_3)_n$, although the reaction rate is lower (14). More interestingly, these reactions are only observed when the size is within a certain range (typically around 6–18), and such size-dependent reactivities have been studied extensively, both by experiments and theory. In the case of $Mg^+(H_2O)_n$, the switch-on around 6 and switch-off around 18 are now understood to be related to the detachment of the SOMO from the metal orbital into the solvation shell, and the position of this solvated electron relative to the metal ion (4, 5). All these works have demonstrated the intricate links between electron solvation, ion solvation, and chemical reactivity, and have provided interesting examples in which much insights into solvation are gained by detailed studies on solvation clusters.

The solvation environment in these clusters is also dependent on the identity of the metal ion and the solvent molecules. The difference in the ionic radius between Mg^+ and Ca^+ affects both the strength of ion–solvent interaction and the steric ef-

fects around the first solvation shell. Similarly, as the solvent molecule is changed from water, to methanol, or to ammonia, the ion–solvent, solvent–solvent, and electron–solvent interactions are altered, producing interesting variations in the solvation environment. Although these clusters have been studied individually before, a systematic comparison on the structures and reactivities of these clusters should provide a better understanding on the interplay of these factors. In this paper, we take a first step in this direction by a theoretical study on the $M^+(L)_n$, with M^+ being Mg^+ or Ca^+, L being H_2O, CH_3OH, or NH_3, and n between 1 and 6. Ab initio and density functional theory (DFT) methods are employed in our calculations, and the attention will be focused on the geometrical and electronic structures and their variations across these cluster series, which are the foundation for understanding the structures and reactivities in larger clusters.

Computational details

The energy calculations and the structure optimizations are all performed using the Gaussian 98 Package (15). Two basis sets, 6-31+G** and 6-311+G**, are tested. It is well-understood that diffuse orbitals are needed to account for the solvation around the SOMO. Most of these structures are examined at two levels, MP2 and B3LYP. As discussed later, $Ca^+(L)_3$ is found to be a very difficult case, with its optimized structure being very sensitive to the choice of method and the basis set. As a result, $Ca^+(H_2O)_3$ is treated as a special case and studied extensively using CISD, QCISD, and MP4 for post-Hartree–Fock treatment. As these clusters are radicals, the electron densities are spin-polarized. The calculated $< S^2 >$ values show no problem with spin contamination. All energies include corrections for the basis set superposition error (BSSE), using the counterpoise method (16, 17).

To gauge the strength of solvation interactions, two energetic quantities are calculated. The first is $BE[M^+/L_n]$, with M^+ being the metal ion, and L is the neutral solvent, as defined by

$$BE[M^+/L] = E[M^+] + E[(L)_n] - E[M^+(L)_n]$$

which calculates the difference between the energy of the cluster $M^+(L)_n$, and the energy sum of an isolated metal ion M^+ and a solvent cluster $(L)_n$ taking the same geometry as $M^+(L)_n$ but with the metal ion removed. $BE[M^+/(L)_n]$ measures the solute–solvent interaction energy. The other quantity, $BE[(L)_n]$ measures the solvent–solvent interaction energy, as defined by,

$$BE[(L)_n] = n \times E[L] - E[(L)_n]$$

where L is an isolated solvent molecule, and $(L)_n$ is the same as defined above.

To gauge the extent of electron detachment from the metal ion, we follow the method previously used by Tsurusawa and Iwata (18) to calculate the SOMO centroid, $R\{e^-\}$. The space around a cluster is first divided into small cubic cells with a uniform length of δr, and each cubic cell is labeled by an index ijk to indicate its position, $\mathbf{r}_{ijk} = (x_i, y_j, z_k)$. The SOMO centroid is then calculated by

$$R\{e^-\} = \sum \rho(\mathbf{r}_{ijk})\mathbf{r}_{ijk},$$

where $\rho(\mathbf{r}_{ijk})$ is the electron density due to the SOMO. The difference between the SOMO centroid and the metal position, $R[\{e^-\} - M]$, measures the deviation of the SOMO center from the metal ion. The other quantity calculated is the SOMO extent measure (SEM), also introduced by Tsurusawa and Iwata, which is the volume that contained half the electron on the SOMO. It is calculated by first ranking the density in each cubic cell over the entire grid, and the cell volume is added from the highest density value to the lower ones until the total charge $\sum \rho(\mathbf{r}_{ijk})\Delta V_{ijk}$ is over 0.5. ΔV_{ijk} are the volume elements, which are then added together to produce the SEM that indicates the spacial extent of SOMO.

One of the interesting aspects of solvation clusters is their thermal stability, since their potential energy surfaces are usually flat with many minima and low transition barriers. At finite temperature, the most stable structure may not be the most abundant because of the entropy effects, which has recently been demonstrated in the case of hydrated sulfate clusters (19–21). Ab initio molecular dynamics (AIMD) is the best way to examine this kind of effect, since quality empirical potential surfaces are usually not available to describe the metal ion and solvent interactions. For that purpose, we use the Vienna Ab initio Simulation Package (VASP) (22–25). A cluster is put in a periodic cubic box with a length of 15 Å in order to minimize the interaction between their neighboring images. The electronic wave function is expanded in a planewave basis set with a cutoff energy at 273.9 eV for water and methanol clusters and at 250 eV for ammonia clusters, while the core area is described by PAW pseudopotentials (26). The exchange correlation functional is PW91 (27), while the electron densities are spin-polarized. A constant background charge is subtracted to neutralize the charge on the cluster ion. Only the Γ point is used in the k-space sampling. The AIMD simulations are performed at 300 K as controlled by a Nóse–Hoover thermostat (28, 29) for a total of 10 000 time steps, each of 0.4 fs for the Ca^+ clusters and 0.5 fs for the Mg^+ clusters.

Results and discussion

Interaction energy for $n = 1$–3

For the solvation clusters studied in this report, the two most commonly used methods have been MP2 and DFT/B3LYP (6, 30). Because of the rapid increase in computational cost with the number of water molecules, MP2 is the only affordable post-Hartree–Fock treatment for a cluster with a few water molecules (4, 5, 7, 8). For the same reason, density functional theory based methods are the only choices when n reaches beyond 10. For the basis set, it is generally understood that diffuse functions are needed to describe the solvated electron on the SOMO. In previous studies, we have identified DFT calculations (B3LYP or BPW91) with a basis set of 6-31+G** as the best compromise between computational accuracy and cost in the specific cases of $Mg^+(H_2O)_n$ and $Na(H_2O)_n$ (5, 31). In this study, detailed comparisons are also made for $n = 1$–3 for all the solvated Mg^+ and Ca^+ clusters at four specific levels, MP2/6-31+G**, MP2/6-311+G**, B3LYP/6-31+G**, and B3LYP/6-311+G**, as listed in Tables 1, 2, 3, and 4.

For the Mg^+ clusters with one solvent molecule, the agreement between MP2 and B3LYP results is quite decent. For the interaction energy between Mg^+ and solvent, the difference is around 2 kcal/mol (1 cal = 4.184 J) with slightly higher B3LYP values. The difference in the optimized geometry parameters is fairly small, as listed in Table 1. And the two basis sets

also produced fairly small differences in either the energy or the geometric parameters. The same is observed as the number of solvents is increased to 2 and 3, as listed in Tables 2 and 3. The difference in the ion–solvent interaction energy between MP2 and B3LYP is usually under 3 kcal/mol. The agreement is also excellent for the solvent–solvent interaction energy, which is usually positive or just slightly below zero, indicating that the ion–solvent interaction is much more important than the solvent–solvent interaction. For the geometry parameters, only the O-Mg-O and N-Mg-N angles show an appreciable difference around 4°. These comparisons indicate that similar to $Na(H_2O)_n$ and $Mg^+(H_2O)_n$, B3LYP/6-31+G** should

be an excellent choice for the study on $Mg^+(CH_3OH)_n$ and $Mg^+(NH_3)_n$ clusters.

For the Ca^+ clusters, the agreements among various levels are less satisfactory than those for the Mg^+ clusters, as shown in Tables 1, 2, and 4. Again, the B3LYP method produces larger solute–solvent interaction energy. For $n = 1$, the difference is around 5 kcal/mol, while for $n = 2$ and 3, the difference could reach around 10 kcal/mol. Basis set is also an important factor, especially for the B3LYP method, with the difference between B3LYP/6-31+G** and B3LYP/6-311+G** values also reaching 10 kcal/mol for $n = 2$ and 3. For MP2 calculations, the change in basis set produces a change of around 4 kcal/mol for the solute–solvent interaction energy. It is also interesting to notice that the B3LYP/6-31+G** results are actually in good agreement with the MP2 results in all cases, which indicates that B3LYP/6-31+G** is a better choice for the study of Ca^+ clusters than B3LYP/6-311+G**. The agreement among various methods is better for the solvent–solvent interaction energies, which are small in their values as the dominant interactions in these clusters are again the solute–solvent interactions. Finally, it should be noted that larger fluctuations are also observed in the optimized bond distances, with difference reaching around 1 Å in some cases, which are more sensitive to the choice of basis set (6-31+G** versus 6-311+G**), rather than the choice of methods (MP2 versus B3LYP).

The structure of Ca^+L_3

While the structural parameters for cluster series are in good agreement with previous findings (4–8), the structures for Ca^+L_3 have turned out to be sensitive to the calculation levels. Previously, Watanabe and Iwata identified a planar D_{3h} structure **Ca^+-W-3a** (30), as shown in Fig. 1, as the most stable for $n = 3$ at the MP2 and MP4 levels with a basis set of 6-31G*, which is reproduced in our calculations at the B3LYP/6-311+G** level. However, when the basis set is 6-31+G** and 6-311+G**, the MP2 optimized structure is changed to **Ca^+-W-3b**, in which the three oxygen atoms are in the same plane, and all three water molecules are squeezed to one side of the plane, opposite to the SOMO, with C_{2v} symmetry. Such a structure was identified before at the Hartree–Fock level (32). The D_{3h} **Ca^+-W-3a** is also predicted as the most stable structure when other functionals (BLYP and PW91) with a basis set of 6-311+G** are used. But when the basis set is lowered to B3LYP/6-31+G**, an imaginary frequency is found for **Ca^+-W-3a** and the most stable structure becomes **Ca^+-W-3c**, which is pyramidal.

[b]From Ref. 34.

In their study on $Ca^+(H_2O)_n$, Watanabe and Iwata identified the importance of d orbitals on the Ca atom in the solute–solvent interactions that made the structures of $Ca^+(H_2O)_n$ distinct from the structures of $Mg^+(H_2O)_n$ (30). Our results further show that in the case of $Ca^+(L)_3$, the p orbitals could also play an important role. The relative importance of p and d orbitals is very sensitive to the calculation level, and so are the optimized structures. As shown in Table 5, the DFT methods (with B3LYP, BLYP, and PW91 functionals) all produce the planar D_{3h} **Ca^+-W-3a** as the most stable structure, when triple zeta basis sets are used, while optimization by either MP2 or CISD method leads to the planar C_{2v} **Ca^+-W-3b**. Single point energy calculations performed at the MP4, CCSD, and QCISD levels using the geometry optimized at MP2/6-311+G(3df, 3pd)

© 2007 NRC Canada

also indicate that **Ca^+-W-3b** is more stable. Nonetheless, the energy difference between these two structures is small, typically below 1 kcal/mol, and at each level there is only one stable structure among **Ca^+-W-3a** and **Ca^+-W-3b**, with the other one containing imaginary frequencies. The plot for the SOMO indicates another interesting difference between these structures. In **Ca^+-W-3a**, SOMO takes the shape of a d_{z^2} orbital and indicates sd hybridization. In contrast, the SOMO in **Ca^+-W-3b** stays on the opposite of the three water molecules and indicates sp hybridization. Therefore, while sd hybridization is preferred in DFT calculations, sp hybridization is preferred in post-Hartree–Fock calculations.

Since there is no known experimental geometry for $Ca^+(H_2O)_3$, it is difficult to conclude which structure, **Ca^+-W-3a** or **Ca^+-W-3b**, is more stable. But the small energy difference indicates that water molecules can easily move within the coordination plane. Not only 3d orbitals, but also 4p orbitals can participate in the hybridization to form the SOMO, and the two types of hybridization have comparable effects on the total energy. Therefore, as water molecules move around the coordination plane, the SOMO could change from one type of hybridization into another, with only a small energy cost. It underlies the fact that the optimized structure is very sensitive to the method and basis set used.

Experimental stepwise solvation energy is known for both $Ca^+(H_2O)_n$ and $Mg^+(H_2O)_n$ for $n = 1$–3 (33, 34). As listed in Table 6, the B3LYP/6-311+G** results are in better agreement with experiment than the MP2 results. For $Mg^+(H_2O)_n$, the MP2 results are only slightly better. Similar discrepancies between DFT and post-Hartree–Fock results are also found for both $Ca^+(CH_3OH)_3$ and $Ca^+(NH_3)_3$.

Structures and energies for $n = 4$–6

As shown in our previous study on $Mg^+(H_2O)_n$ (4), the cluster structures for $n > 3$ can be roughly characterized by the number of solvent molecules in the first solvation shell, which varies from 3 to 6. The relative stabilities among these structures are determined by factors such as ion–solvent and solvent–solvent interactions. At finite temperature, entropy could also be an important factor.

In the case of $Mg^+(H_2O)_n$, it was found that the energy difference among these structures were small. This conclusion is corroborated by calculations at the B3LYP level, as shown in Table 7. The energy difference is typically within 5 kcal/mol. However, the solute–solvent and solvent–solvent interaction energies vary considerably among these structures. Using $n = 6$ as an example, when there are 6 water molecules in the first shell (**Mg^+-W6-6**), the solute–solvent interaction energy is the strongest among 4 isomers at an exothermic 151.7 kcal/mol. At the same time, the solvent–solvent interaction between water molecules are endothermic, at −31.2 kcal/mol, indicating repulsion among water molecules. In contrast, when the Mg^+ coordination number is reduced to 3, as in **Mg^+-W6-3**, the solute–solvent interaction energy is only 115.8 kcal/mol, while the solvent–solvent interaction energy is at a much more favorable 4.9 kcal/mol. Therefore, the cluster structure could either favor the solute–solvent interaction, albeit with a considerable increase in solvent–solvent repulsion, or favor the solvent–solvent interaction at a cost to the solute–solvent interaction. As the solvent is changed from water to methanol or ammonia, and the solute is changed from Mg^+ to Ca^+, the relative importance of these interactions are changed too, producing interesting variations in the relative stability among isomer structures.

Table 7. Relative energies (in kcal/mol with BSSE and ZPE corrections), relative Gibbs energies (at 298 K and in kcal/mol), solute–solvent interactions, $BE[Mg^+/(H_2O)_n]$ (in kcal/mol), solvent and solvent interactions, and $BE[(H_2O)_n]$ (in kcal/mol) in $Mg^+(H_2O)_n$, for $n = 5$ and 6 at B3LYP/6-311+G**.

	Relative energy	Relative Gibbs energy	$BE[Mg^+/(H_2O)_n]$	$BE[(H_2O)_n]$
Mg^+-W5-5	0.0	0.0	127.4	−21.8
Mg^+-W5-4	2.1	1.9	114.5	−8.8
Mg^+-W5-3	1.3	3.0	109.5	−1.3
Mg^+-W6-6	0.0	0.0	151.7	−31.2
Mg^+-W6-5	3.8	3.4	138.7	−20.0
Mg^+-W6-4	4.7	6.0	127.7	−7.7
Mg^+-W6-3	4.8	5.8	115.8	4.9

When water is replaced by methanol as the solvent molecule, the change is obvious but small. The solute–solvent interaction is larger for Mg^+–CH_3OH than for Mg^+–H_2O, which has already been noted above for the smaller clusters. At the same time, there is also an increase in the solvent–solvent repulsion, as indicated in Table 8, because of the presence of the methyl group in methanol. The balance of these two factors leaves the structures of $Mg^+(CH_3OH)_5$ and $Mg^+(CH_3OH)_6$ quite similar to their hydrated counterpart, in that as the number of solvent varies in the first shell, the energy does not change much.

More appreciable changes are observed when the solvent molecules are ammonia, as listed in Table 9. Again, both the solute–solvent interaction and solvent–solvent repulsion are stronger, and as compared to water the increase is larger for ammonia than for methanol for both types of interactions, as indicated in Table 8. However, in the case of ammonia, the increase in solute–solvent interaction is larger than the increase in solvent–solvent repulsion. Therefore, structures with high number of solvents in the first shell are energetically favored for $Mg^+(NH_3)_n$, with $n = 5$ and 6.

When the solute Mg^+ is replaced by Ca^+, both the solute–solvent interaction and solvent–solvent repulsion decrease for all three solvents, as shown in Tables 10–12, largely because of the larger ion radius for Ca^+. Not surprisingly, structures with high number of solvents in the first shell are favored for $Ca^+(NH_3)_5$ and $Ca^+(NH_3)_6$. And the same is also true when either water or methanol is the solvent. This is largely because of the fact that the decrease in solvent–solvent repulsion is more substantial, and higher direct coordination around Ca^+, which increases the solute–solvent interaction, is energetically less costly as the solvent–solvent repulsion does not increase to the same extent as in $Mg^+(H_2O)_n$.

Electronic structures for $n = 4$–6

The most interesting feature in the electronic structures of these three cluster series is the electron on the singly occupied molecular orbital (SOMO). It is now well-understood that as the number of solvent molecules increases, this electron is eventually detached from the metal atom and solvated by solvent molecules to form an electron-ion pair, which contributes to the size-dependent reactivities in these clusters.

It turns out that the shape and extent of SOMO for the hydrated clusters are quite similar to those for the methanol clusters but in sharp contrast to the ammonia clusters. The contrasts are illustrated in Fig. 2 and by two numbers listed in Tables 7–12, which were previously used by Tsurusawa and Iwata (18) to indicate the detachment of SOMO from the metal ion in hydrated sodium clusters $Na(H_2O)_n$. The first number R[{e^-}–M^+] is the distance between the geometric center of SOMO and the metal ion. The second number is the SEM, which measures the spatial extent of the SOMO. Both quantities have been defined in the previous section on computational details.

In **Mg^+-M6-3**, a $Mg^+(CH_3OH)_6$ cluster with only three methanol molecules in the first shell, the Mg^+ ion is on the surface of the cluster, while the SOMO is largely situated on the Mg, as reflected by an R[{e^-}–Mg^+] distance of only 0.82 Å. As the number of methanol molecules increases in the first shell, the R[{e^-}–Mg^+] value increases to 2.06 Å in **Mg^+-M6-6**, in which all six methanol molecules are directly coordinated with the metal ion. The SEM value also doubled. As shown in Fig. 2, the electron is now detached from the metal and localized on one side of the cluster, which is a typical example of the electron–ion pair.

The SOMO in **Mg^+-A6-3**, a $Mg^+(NH_3)_6$ cluster with three ammonia molecules in the first shell, is quite similar to the SOMO in its methanol counterpart, **Mg^+-M6-3**. The Mg^+ ion is on the cluster surface and so is SOMO situated on the ion, producing comparable R[{e^-}–Mg^+] and SEM numbers. As discussed earlier in the ammonia clusters, a high coordination number around the metal ion is energetically more favorable, and the most stable isomer at $n = 6$ is the one with all six ammonia molecules in the first solvation shell, as in **Mg^+-A6-6**. Its SOMO is in sharp contrast with that in its methanol counterpart, **Mg^+-M6-6**. The SEM for **Mg^+-A6-6** is 135.9 Å^3, compared with a mere 25.8 Å^3 in **Mg^+-M6-6**. The R[{e^-}–Mg^+] value for 0.0 Åcompared with a value of 2.06 Å for **Mg^+-M6-6**. The electron is actually detached from the metal ion, notwithstanding a zero value for R[{e^-}–Mg^+]. As illustrated in Fig. 2, the electron is completely delocalized among the six ammonia molecules, which accounts for the large SEM value, and at the same time produces a geometric center that coincides with the position of the metal ion. Such a contrast has been observed before, in the comparison between $Na(H_2O)_n$ and $Na(NH_3)_n$ clusters (35). It can be understood as due to the difference in dipole moment. The larger dipole moments in water and methanol produce stronger solvation interaction around the electron, which

Fig. 2. The SOMO for a number of methanol (M) and ammonia (A) clusters with six solvent molecules. For structures with 3 solvent molecules in the first shell, the SOMO shapes are similar. For structures with all six solvent molecules in the first shell, there is a sharp contrast between the methanol and the ammonia clusters.

makes it possible to be localized by a few solvent molecules within the cluster. While the dipole moment for ammonia is smaller, the interaction between ammonia and the metal ion is stronger. The cluster structure is geared toward maximizing the metal–ammonia interaction, while the electron is less well solvated and is delocalized over all the ammonia molecules.

Thermal stability

In our previous study on $Mg^+(H_2O)_n$ and hydrated sulfate clusters $SO_4^{2-}(H_2O)_n$, it was found that structures with large numbers of water molecules in direct coordination with the solute ion could lose water molecules to outer solvation shells during AIMD simulations at finite temperature (5, 20). This is due to the entropy effect, since upon heating the inner solvation shell could be too crowded for the thermal motion of solvent molecules. It is natural to ask if the same could happen for the clusters studied in this report.

Shown in Fig. 3 is the time evolution of the coordination number around the metal ion for six clusters containing six solvent molecules at 300 K. The coordination number is obtained with a cutoff distance of 2.5 Å for Mg^+–O, 2.8 Å for Mg^+–N, and 2.7 Å for Ca^+–O, as obtained from the calculated radial

distribution plots. Fluctuations in the coordination number indicate loose solvation shells with solvent molecules crossing solvation shells during the simulation. It is observed only for the two Ca clusters. In the case of **Ca^+-M6-3**, a $Ca^+(CH_3OH)_6$ cluster with only three methanol molecules in the first shell, the coordination number is increased to 4 after 2 ps, which is in agreement with the energetic data in Table 11 with **Ca^+-M6-3** being the least stable isomer in terms of both the relative energy and the relative Gibbs free energy. In the case of **Ca^+-M6-6**, a $Ca^+(CH_3OH)_6$ cluster with all six solvent CH_3OH molecules in the first shell, there is a short period of time when the coordination number is decreased to 5. It indicates some flexibility in the solvation shell, although **Ca^+-M6-6** is the most stable structure at $n = 6$.

In contrast, the other four Mg clusters, **Mg^+-M6-6** and **Mg^+-M6-3** for $Mg^+(CH_3OH)_6$, and **Mg^+-A6-6** and **Mg^+-A6-3** for $Mg^+(NH_3)_6$, are more rigid, and the coordination number does not change during the simulation. This is not surprising in the case of $Mg^+(CH_3OH)_6$, since energy and free energy differences among its various isomers, as listed in Table 8, are fairly small. But it is somewhat surprising that **Mg^+-A6-3** does not go through any changes during the simulation, since it is considerably less stable than the other isomers and high coordination number should be favored for the ammonia solvated cluster. The possible explanation is that with the Mg^+–NH_3 interaction being relatively strong, the solvation structure is more rigid and shifting an NH_3 solvent between solvation shells is kinetically more difficult.

Conclusion

By a systematic comparison of the solvated Mg^+ and Ca^+ clusters with $n \leq 6$, we find that the solvation interactions produced by the three types of solvent molecules, water, methanol, and ammonia, vary in interesting and important ways. While in terms of solute–solvent interactions, CH_3OH is slightly stronger than H_2O, the repulsion among CH_3OH molecules is also slightly stronger. As a consequence, the geometrical and electronic structures for the methanol-solvated clusters are quite similar to their counterparts for the hydrated clusters. As a solvent molecule, ammonia stands in contrast to water and methanol. Despite the repulsion between ammonia molecules, the solute–ammonia interaction is much stronger for ammonia than for either water or methanol, and therefore ammonia molecules tend to squeeze into the first solvation shell. Furthermore, because of the smaller dipole moment on ammonia, the electron on the SOMO is delocalized among solvent ammonia molecules once it is detached from the metal ion at high coordination number. This is again in sharp contrast with the water and methanol clusters in which the detached electron is localized among a subset of solvent molecules. How such contrasts would affect the structures as cluster size grows over 6, in terms of geometry, electron solvation, and reactivity, should be interesting subjects for further studies.

Acknowledgment

Calculations reported in this paper were performed on the computer clusters operated by the Department of Chemistry, the Chinese University of Hong Kong (CUHK), supported by a Special Equipment Grant, and on the SGI Origin 2000, at the Information Technology Services Center (ITSC), CUHK. We thank Mr. Ka Fai Woo at the Department of Chemistry and Mr. Frank Ng at ITSC, for technical support. We gratefully acknowledge the financial support provided by the Hong Kong SAR Government through the Project CUHK 401604P. One of the authors (ZFL) would like to acknowledge his indebtness to Professor G. Mike Bancroft for his guidance and advice that have deeply influenced his academic career. This paper is dedicated to Professor Bancroft on the occasion of his 65th birthday.

Remarkable two-step, four-electron oxidative addition reactions at phosphorus [P(I)–P(V)] in terminal electrophilic phosphinidene complexes[1]

Todd W. Graham, Konstantin A. Udachin, Marek Z. Zgierski, and Arthur J. Carty

Abstract: The reactivity of the terminal phosphinidene complex $[Re(CO)_5\{\eta^1\text{-}P(N^iPr_2)\}]AlCl_4$ towards the oxidants S_8 and Me_3SnN_3 has been investigated. These result in unprecedented four-electron oxidative addition reactions, affording complexes containing the P(V) ligands η^1-P(=S)(Cl)(N^iPr_2) and η^1-P(=NR)(Cl)(N^iPr_2), respectively. DFT calculations support the proposed mechanism.

Key words: electrophilic phosphinidene, low coordinate phosphorus, rhenium, oxidative addition, P(I) ligand.

Résumé : On a étudié la réactivité de phosphinidènes terminaux $[Re(CO)_5\{\eta^1\text{-}P(N^iPr_2\}]AlCl_4$ vis-à-vis des oxydants S_8 et Me_3SnN_3. Ces interactions donnent lieu à des réactions d'addition oxydantes à quatre électrons inconnues jusqu'à maintenant qui conduisent à la formation de complexes comportant respectivement les ligands P(V) η^1-P(=S)(Cl)(N^iPr_2} et η^1-P(=NR)(Cl)(N^iPr_2}. Des calculs selon la théorie de la fonctionnelle de la densité sont en accord avec le mécanisme proposé.

Mots-clés : phosphinidène électrophile, phosphore à faible coordination, rhénium, addition oxydante, ligand P(I).

[Traduit par la Rédaction]

Introduction

Over the years since the isolation and structural characterization of the first terminal, cationic, electrophilic phosphinidene complex of molybdenum in 2001 (1*a*), it has become clear that an extensive range of these phosphinidene-based analogues of Fischer carbenes can be synthesized. Examples of $[L_nM(=PNR_2)]$ complexes with metals from groups VI (1), VII (2), VIII (1*b*, 3), IX (4), and X (5) have been described, and a comprehensive picture of bonding and reactivity in these molecules is beginning to emerge, which complements an extensive reaction manifold already established for transient (6*a*, 6*b*) and nucleophilic (6*c*, 7) phosphinidenes. The bonding in terminal, electrophilic phosphinidene complexes consists primarily of a σ donor interaction from one phosphorus lone pair to the metal center with weak π back donation from the metal into the vacant p orbital on phosphorus. The electrophilicity of the phosphorus is partially alleviated by π donation from the NR_2 group. Structurally, these bonding interactions are typically manifested in slightly shortened M–P bonds, planar geometries at the nitrogen substituents, and short P–N bonds (1*b*, 2–4). Accordingly, aminophosphinidene ligands (P–NR_2) are regarded as isoelectronic to CO, with phosphorus in the +1 oxidation state. Chemically, as expected from the bonding model, such complexes undergo facile nucleophilic addition at the P(I) center forming adducts with Lewis bases (2, 8), in contrast to nucleophilic phosphinidene complexes such as $[Cp^*Ir(PPh_3)(=PMes^*)]$ (9), which react with electrophilic reagents.

The oxidative addition reaction is a key step in many important organometallic transformations (10). It typically proceeds via an addition of a reagent X–Y to a metal complex [M], resulting in the formation of a new complex of the form [M](X)(Y) and in a change of the oxidation state of the metal from $(n)^+$ to $(n + 2)^+$. Many of the reactions with terminal aminophosphinidene complexes we have previously described have resulted in conversion of the P(I) ligand to P(III); for example, conversion to a coordinated phosphaalkene ($R_2NP=CR_2$) or phosphaimine ($R_2NP=N\text{-}N=CPh_2$) ligand (3*b*). We have also observed reactions in which activated X–H bonds (X = SiR_3, OR, or $C_6H_4N_2Ph$) oxidatively add to the P(I) ligand, affording coordinated functionalized phosphines ($P(H)(X)NR_2$) (2, 11).

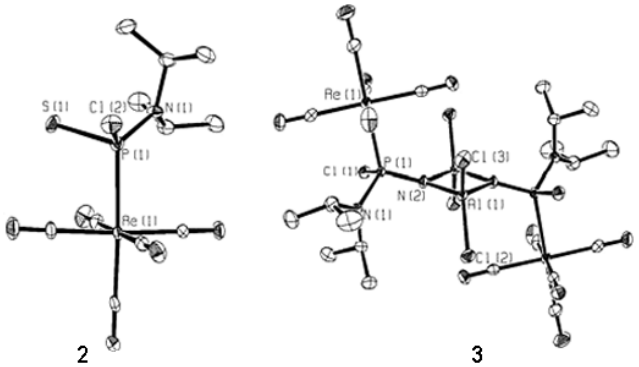
Scheme 1.



We now wish to report a new and unprecedented type of oxidative addition reaction, which results in the conversion of a P(I) center in cationic $[Re(CO)_5\{\eta^1\text{-}P(N^iPr_2)\}]AlCl_4$ (**1**) to a P(V) ligand in neutral $[Re(CO)_5\{\eta^1\text{-}P(=S)(Cl)(N^iPr_2)\}]$ (**2**) via reaction with S_8. A similar four-electron oxidative addition occurs on reaction of **1** with Me_3SnN_3 affording the novel neutral dimer $[Re(CO)_5\{P(Cl)(N^iPr_2)=N(AlCl_2)\}]_2$ (**3**).

Results and discussion

The complex $[Re(CO)_5\{\eta^1\text{-}P(N^iPr_2)\}]AlCl_4$ (**1**) (2), prepared by halide abstraction from $[Re(CO)_5\{\eta^1\text{-}P(Cl)N^iPr_2\}]$ (**4**) by $AlCl_3$, reacts smoothly with S_8 in dichloromethane, precipitating $AlCl_3$ and affording a quantitative yield of the new compound $[Re(CO)_5\{\eta^1\text{-}P(=S)(Cl)(N^iPr_2)\}]$ (**2**) (Scheme 1), which displays a ^{31}P NMR resonance at δ 100 (see Experimental Section), sharply upfield of that in **1** (δ 956). The ^1H NMR spectrum of **2** shows only resonances due to the ^{i}Pr groups. A single crystal X-ray analysis[3] (Fig. 1) revealed that a new one-electron donor P(V) ligand $P(=S)(Cl)N^iPr_2$ is coordinated to a typical square-pyramidal $Re(CO)_5$ fragment. The Re(1)—P(1) bond length of 2.4972(8) Å is significantly longer than the corresponding Re—P distance in the precursor phosphinidene complex **1** (2) (2.446(3) Å). The P(1)—S(1) separation of 2.181(1) Å is considerably longer than the short P=S separation of Ph_3P=S (1.950(3) Å) (12), which may be attributed to competitive π bonding to phosphorus from the sulfur atom and the nitrogen lone pair of the N^iPr_2 substituent. In agreement with this, the P(1)—N(1) bond length (1.661(3) Å) indicates substantial residual π character (4). While oxidation of R_3P to form R_3P=S is a well-known reaction (13), the direct conversion of P(I) to P(V) is a new reaction pathway for coordinated phosphorus ligands. Complex **2** is likely formed from the intermediate complex **A** (Scheme 1) via oxidative sulfuration; the highly electrophilic phosphorus center in **A** then

reacts with chloride ion to form the product. Although we have not been able to observe intermediate **A**, DFT analyses (14) of the cations **1**, **A**, and the neutral product **2** support the proposed mechanism. The energy of intermediate **A** formed by adding sulfur to the phosphinidene cation **1** lies 5.45 eV below the sum of the energies of **1** and atomic S, thus **A** is an energetically stable species. However, addition of chloride ion to **A** provides an additional stabilization energy of 5.82 eV. There is therefore a strong driving force for

[3] X-ray data for **2**: FW 524.91; orthorhombic; *Pna*2(1); a = 24.342(1) Å; b = 7.6634(7) Å; c = 9.2297(8) Å; T = 125(2) K; V = 1721.7(3) Å^3; Z = 4; D_{calcd} = 2.025 Mg/m^3; 4709 independent reflections ($R_{(int)}$ = 0.0234); GOF = 1.150; R_1 = 0.0184; wR_2 = 0.0458.

the oxidation from P(I) in **1** to P(V) in **2**. The minimized geometry of **2** matches the major features of the X-ray data with the HOMO being a localized 3p orbital on the sulfur atom. The LUMO of **A** is centered on phosphorus, which also bears a positive charge (+0.52 e (Mulliken)), consistent with nucleophilic attack by Cl^- at this atom. Experimental and calculated (DFT) P—S and P—N bond lengths in **2** confirm that the ground state has substantial contributions from the mesomeric form **2b** (Scheme 1). Synthetically, we have found that **2** can also be generated directly from the neutral terminal chlorophosphido complex $[Re(CO)_5\{\eta^1\text{-}P(Cl)N^iPr_2\}]$ (**4**) and S_8, although the reaction is qualitatively much slower than with complex **1**. ^{31}P NMR spectroscopy of solutions of **1** showed no indication of the presence of any of the phosphide complex **4**, and exhaustive pentane extractions of solid complex **1** afforded no trace of highly soluble **4**. While we cannot completely eliminate the possibility of trace amounts of **4** in equilibrium with **1**, we believe the experimental evidence coupled with the DFT calculations favor the intermediacy of **A** in the oxidative conversion of **1** to **2**.

By contrast, the reaction of **1** with ^{t}BuSH affords the new P(III) complex $[Re(CO)_5\{P(N^iPr_2)(H)(S^tBu)\}]AlCl_4$ (**5**), which results from oxidative addition of the S–H bond to the P(I) ligand. This compound has been fully characterized (see Experimental Section) and displays a ^{31}P NMR resonance at δ –11. The ^1H NMR spectrum of **5** shows the expected ^{t}Bu and ^{i}Pr resonances, in addition to a characteristic P–H signal at δ 8.62 with a large $^1J_{PH}$ of 424 Hz.

The reaction of **1** with Me_3SnN_3 readily affords the new complex $[Re(CO)_5\{P(Cl)(N^iPr_2)=N(AlCl_2)\}]_2$ (**3**) (Scheme 1). The ^{31}P NMR spectrum of the product shows a high-field resonance at δ 81 (cf. δ 100 in **2**), and the ^1H NMR spectrum shows only the presence of ^{i}Pr signals (see Experimental Section). The X-ray analysis[4] confirms that in the centrosymmetric structure, the rhenium and phosphorus ligand environments in **3** are closely related to those in **2**, with a one electron P(V) fragment coordinated to each octahedral rhenium center in the dimeric molecule. The P–N(2) bonds of the two equivalent P(V) ligands are bound to two $AlCl_2$ units forming an $N_2Al_2Cl_4$ bridge between $[Re(CO)_5\{P(Cl)(N^iPr_2)\}]$ entities. The P(1)—Cl(1) (2.1298(9) Å) and P(1)—N(1) (1.660(2) Å) distances are typical, and the P=N separation (1.600(2) Å) is as expected for an R_3P=N ligand (15). The μ-$AlCl_2$ fragments have an average Al—Cl separation of 2.147 Å and average N—Al distances of 1.855 Å. By analogy with compound **2**, **3** likely forms by initial conversion to the extremely electrophilic intermediate **B**. Nucleophilic attack of the RN nitrogen in **B** on $AlCl_4^-$ forms **C**; subsequent chloride attack on phosphorus with concomitant elimination of RCl and dimerization forms compound **3**.

These results, coupled with previous studies describing facile P=C, P=N, and P=S bond-forming reactions at both terminal (3*b*) and doubly bridging (16) phosphinidene complexes, illustrate the synthetic potential of electrophilic P(I) centres for the generation of new types of coordinated P(III) and P(V) ligands.

Conclusion

In conclusion, we have demonstrated for the first time that terminal electrophilic phosphinidene complexes can undergo two step, four-electron oxidative addition reactions leading to new types of coordinated P(V) ligand systems. We attribute the remarkable and unprecedented reactivity of the phosphinidene complexes to the low oxidation state (i.e., P(I)) and coordination number of the phosphinidene ligand, both of which favor oxidative addition. We note that main-group compounds, which contain phosphorus in low coordination environments (17), are known, and we anticipate exciting and complementary reactivity patterns to emerge.

Experimental[5]

General comments

All procedures were carried out using standard Schlenk techniques or in a glovebox under a nitrogen atmosphere. THF was distilled from Na/benzophenone. Dichloromethane and pentane were purified using solvent purification columns containing alumina (dichloromethane) or alumina and copper catalyst (pentane). $CDCl_3$ and CD_2Cl_2 were vacuum-distilled from $AlCl_3$ and then CaH_2. C_6D_6 was vacuum-distilled from Na/benzophenone. NMR spectra were recorded at 400.13 MHz (^1H), 161.98 MHz ($^{31}P\{^1H\}$), or 100.61 MHz ($^{13}C\{^1H\}$). $Cl_2PN^iPr_2$ (18) was prepared according to the literature procedures. $Re_2(CO)_{10}$ and $AlCl_3$ were obtained from Strem Chemicals. All other reagents were obtained from Aldrich and were used as received.

$[Re(CO)_5\{\eta^1\text{-}P(=S)(Cl)(N^iPr_2)\}]$ (2)

13 mg (0.0507 mmol) of S_8 was added to 250 mg (0.399 mmol) of $[Re(CO)_5\{P(N^iPr_2)\}]AlCl_4$, the mixture was stirred for 1 h, and then the solvent was removed in vacuo. The solid was dissolved in ~3 mL of THF and filtered, and then pentane was added dropwise until the solution became cloudy. Cooling to −45 °C overnight resulted in the formation of large crystals of $AlCl_3(THF)_2$, which were filtered off. This was repeated twice until all $AlCl_3(THF)_2$ was removed from the solution. On standing, compound **2** crystallized in 50% yield. Analytically pure compound **2** may also be prepared by adding 1/8 equiv. of S_8 to $[Re(CO)_5(P(Cl)N^iPr_2)]$ at −45 °C in THF and stirring for 2 h, followed by recrystallization from THF–pentane at −45 °C. Yield: 67%. ^1H NMR (δ, $CDCl_3$, 25 °C): 3.96 (sept., $^3J_{HH}$ = 6.7 Hz, 2H, C*H*$(CH_3)_2$); 1.61 (d, $^3J_{HH}$ =

Characterization of metallurgical-grade aluminas and their precursors by ^{27}Al NMR and XRD[1]

Linus M. Perander, Zoran D. Zujovic, Tania Groutso, Margaret M. Hyland, Mark E. Smith, Luke A. O'Dell, and James B. Metson

Abstract: The structure of metallurgical- or smelter-grade aluminas (MGAs) is complex and poorly understood. Ultra-high-field solid-state ^{27}Al NMR results on industrial as well as on laboratory-prepared aluminas are discussed in relation to XRD results. It is demonstrated that high-field NMR can effectively be used to quantify the proportion of the thermodynamically stable alpha-alumina phase in these materials. The results demonstrate that ^{27}Al NMR is a vital adjunct to XRD methods to quantify the transition alumina phases that invariably dominate the MGAs. The nature of the disorder in these materials, determined by ^{27}Al NMR, is also compared with literature data, such as XANES and EXAFS studies, on typical laboratory-prepared materials. The utility of ^{27}Al NMR studies to provide new insight into the structural complexity of metallurgical aluminas is shown.

Key words: solid-state magic-angle-spinning NMR, metallurgical-grade alumina, transition alumina, gamma-alumina, coordination number.

Résumé : La structure des alumines de qualité métallurgique (AQM) ou pour électrolyse est complexe et mal comprise. Opérant à champ élevé et à l'état solide, on a déterminé les spectres RMN du ^{27}Al d'alumines industrielles et d'autres préparées en laboratoire et on discute de ces spectres en relation avec les résultats obtenus par diffraction des rayons X (DRX). On a démontré que la RMN à champ élevé peut effectivement être utilisée pour quantifier la proportion de la phase thermodynamiquement stable d'alumine alpha qui est présente dans ces matériaux. Les résultats démontrent que la RMN du ^{27}Al est une addition absolument nécessaire aux méthodes de DRX pour quantifier les phases d'alumines de transition qui dominent invariablement les AQM. On a aussi comparé la nature du désordre dans ces matériaux, telle que déterminée par RMN du ^{27}Al, avec les résultats déjà publiés dans la littérature et obtenus par des études à l'aide de la spectroscopie d'absorption X de type XANES ou EXAFS sur des matériaux typiques préparés en laboratoire. On démontre donc l'utilité de la RMN du ^{27}Al à fournir de nouvelles indications sur la complexité structurale des alumines métallurgiques.

Mots-clés : RMN à l'état solide et à l'angle magique, alumine de qualité métallurgique, alumine de transition, alumine gamma, indice de coordination de l'aluminium.

[Traduit par la Rédaction]

Introduction

Over 50 million tonnes of metallurgical-grade alumina (MGA) is produced annually, largely as a raw material for the electrolytic production of aluminum. This material is produced almost exclusively by the Bayer process to a reasonably uniform specification across the industry, in terms of specific surface area, particle size and strength, residual hydrogen or moisture as well as impurity and alpha-alumina contents. The microstructure of this material is of considerable interest for a number of reasons; there has, for instance, been interest in the relationship between properties and the behavior of the alumina when used in gas scrubbing systems and when fed to the reduction cell (1, 2). Furthermore, this material can also provide insights into the complex relationship within the family of the so-called "transition aluminas" produced in the calcination of gibbsite $Al(OH)_3$ (3).

In the Bayer process, the calcination step plays an important role in the evolution of microstructural features that can be related to the properties and the performance of the MGA

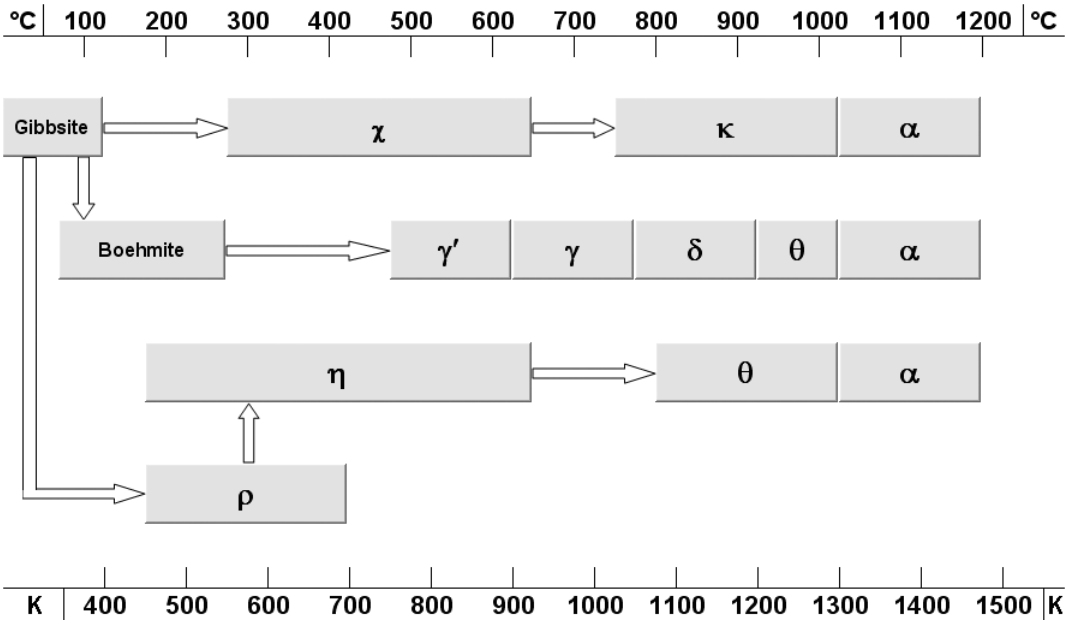
in the aluminum smelter. For the calcination step, production technology has progressively moved from rotary kilns to the more energy-efficient gas suspension or fluid-bed-type rapid-flash calciners, in some cases with capacity in excess of 4 000 tonnes per day (4). Due to the extended residence time, rotary kilns produce a more-homogenous and structurally ordered material. However, the literature and the understanding of the processes operating under flash-calcination conditions are lacking when compared, for example, with the typical gamma-aluminas widely used in catalysis.

The most-authoritative description of the interrelationship of the alumina phases or "forms" during calcination processes is that of Wefers and Misra (3). The speed of the modern calcination process, together with the variation of particle size, velocity, and residence time, produces a far-from-equilibrium phase distribution both between and within individual alumina grains. MGAs can thus be viewed as granular materials comprised of aggregates of intergrown alumina crystals; generally, with a crystallite size of 10–40 μm. Figure 1 shows a scanning electron micrograph of a typical assembly of MGA particles. The precipitation conditions of the precursor gibbsite are selected to maximize yield in the critical size range, thus causing the dominance of heavily intergrown aggregates.

The disorder and complexity of MGA is influenced by the calcination process as well as the gibbsite precipitation stage. The calcination strategy is governed first and foremost by the need to meet a specification for a specific surface area of 70–80 m^2g^{-1}, while maintaining a low residual-moisture content, necessary to limit HF generation when fed into the molten cryolite electrolyte in the reduction cell. Surface area is also critical for effective performance as a gas scrubbing medium and for optimal dissolution in the reduction cell. Surface area is maximized by controlling the transition sequence to limit maximum temperature and residence time. With increasing temperature, the phase sequence moves from the hexagonal gibbsite, $Al(OH)_3$, through the oxyhydroxide boehmite, AlOOH, into the cubic system represented by the spinel structured gamma-alumina (5) (Fig. 2). Neutron diffraction studies indicate that the face-centred cubic oxygen sublattice in the spinel-based transition aluminas tends to be highly ordered in these materials; however, the aluminum ions are quite disordered, leading to the broadened lines typical of their powder X-ray diffraction (XRD) patterns (6).

In gibbsite, aluminum atoms occupy two thirds of the octahedral positions, with hydroxyl groups octahedrally coordinated in double layers. This gives gibbsite a monoclinic symmetry (space group $P2_1/n$) with a hexagonal close packing of the hydroxyl groups. Upon heating, the hydroxyls are progressively lost through the structural channels formed in the gibbsite lattice by the formation of water by proton exchange between neighbouring hydroxyls (7–9). This is accompanied by the structural rearrangement of the crystal lattice, a pseudomorphic transformation (i.e., the original morphology of the parent gibbsite is retained) with little change in the external dimensions, and as a consequence, a large internal porosity develops. The long-range ordering in gibbsite or boehmite is lost, and an amorphous transition-alumina form, gamma-alumina, appears.

Fig. 1. Scanning electron micrograph of "typical" metallurgical-grade alumina particles.



Further heating results in the conversion to delta- and then to theta-alumina, which are also spinel-structured transition-alumina forms. Gamma-, delta- and theta-alumina all have a face-centred cubic packing of the oxygen anions with various amounts of aluminum cations in either the octahedral or tetrahedral interstices. The proportion of tetrahedral sites increases with temperature (10), having 25%–30% of the octahedral sites occupied for gamma-alumina and 50% for theta-alumina (11, 12), until the abrupt disappearance of tetrahedrally coordinated aluminum upon the formation of alpha-alumina (corundum), which marks the end of the transformation sequence. Alpha-alumina has a hexagonal close packing of the oxygen anions, and all of the octahedral aluminum sites are occupied (13).

The mix of "forms" and high levels of disorder in MGAs present significant challenges in understanding their structure with relation to the performance as a raw-material feed for the smelting process (14). The X-ray methods by which we might follow these phase transformations are constrained by the limited long-range order in these materials. Thus, methods, which do not rely on long-range crystallographic order, can provide new insights and improved understanding of these materials. Kato et al. have reported X-ray absorption near-edge studies (XANES) of the Al K-edge in transition aluminas (15). In the manner of NMR studies, this approach appears to provide significant insight into the occupancy of octahedral and tetrahedral sites, i.e., key to understanding the forms and transition points in the alumina samples examined. However, the XANES approach has yet to be applied to MGAs.

A new phase, described as gamma-prime-alumina (γ'-Al_2O_3) was introduced by Paglia et al., which significantly improved the fitting of diffraction data on aluminas from fluid-bed and gas-suspension calciners (16). Ashida et al. developed a model used for fitting XRD data to better accommodate the degree of structural disorder observed for MGAs

Fig. 2. Thermal-decomposition pathways of gibbsite, adapted from ref. 3.

by including the contribution of theta-alumina to the background (14). However, a significant challenge is the broad and diffuse diffraction patterns of amorphous transition alumina phases, making quantitative or structural determinations difficult.

Ingram-Jones et al. compared flash calcining with soak calcining of gibbsite in laboratory trials (17). They used XRD and ^{27}Al magic-angle spinning (MAS) NMR to examine the dehydroxylation sequence, as a function of both the calcination temperature and particle size. They suggested a cross-over of the calcination pathways shown in Fig. 2, where chi-alumina would transform into gamma-alumina for flash-calcined fine gibbsite particles (<0.5 μm) and partially for coarse (~14 μm) particles as well. The remainder of the coarse gibbsite would react via the previously discussed spinel-based (fcc) transformation sequence (i.e., boehmite – gamma – delta – theta alumina) before converting to alpha-alumina. Whittington et al. proposed a similar mechanism based on quantitative X-ray analysis of laboratory aluminas (18). The authors noted that the careful control of the calcination time allows the phase distribution (although perhaps not the degree of structural disorder) of both rotary kiln and fluid-bed-calcined aluminas to be reproduced in the laboratory. Interestingly, Ingram-Jones et al. also found the chi-alumina originating from soak and flash-calcined gibbsites to have different short-range structures.

Solid-state MAS NMR studies can provide significant insight into the occupancy of octahedral and tetrahedral sites (the chemical shifts being characteristic of the oxide (or hydroxide) coordination (AlO_n/$Al(OH)_n$)) (19), which is key to understanding the forms of alumina in the samples tested. ^{27}Al MAS NMR chemical-shift ranges for aluminum in different coordinations with oxygen (or hydroxyls) are typically –10 to 20 ppm for octahedrally coordinated aluminum (AlO_6), 30 to 40 ppm for pentahedrally coordinated aluminum (AlO_5), and 50 to 80 ppm for tetrahedrally coordinated aluminum (AlO_4) (19, 20). The variation in the reported ranges for the chemical shifts reflects the range of possible Al–O bond lengths and angles, and next-nearest-neighbour species. A recently published ^{27}Al NMR study of a sol–gel manufactured theta-alumina reported the NMR parameters of its two aluminum sites (21). Several ^{27}Al studies have made use of the high sensitivity and the relatively minor contribution of particle and crystallite size effects of this technique to explore the transition aluminas (10, 11, 20–25). Furthermore, MAS NMR has also been beneficial in settling some of the ambiguity concerning the onset temperatures of the transition reactions; since XRD relies on the development of nuclei of sufficient size or long-range order for the detection of the phase, the technique does not always give reliable onset-temperature data. However, NMR has not been frequently applied to MGAs because of the low spectral resolution caused by the co-existence of different transition aluminas and the influence of the second-order quadrupolar interaction causing significant spectral broadening. With higher magnetic fields now becoming available, some of these problems may be overcome (26).

This study examines the use of multiple-field ^{27}Al MAS NMR on samples formed from the reaction of model hydroxides and MGAs, as compared to XRD data. Solid-state MAS NMR spectra of quadrupolar nuclei, such as ^{27}Al (nuclear spin I = 5/2), are broadened by the second-order quadrupolar interaction, a mechanism characterized by the quadrupolar coupling constant C_Q, in MHz (26). This second-order quadrupole interaction dominates the usually observed central transition (26) and has an angular dependence that is only partially averaged by conventional MAS. The interaction scales inversely with the applied magnetic field, so that high magnetic fields are normally advantageous, and the magnetic-field dependence can also be used to constrain the fits. In disordered solids, a distribution in bond lengths and angles for a particular site leads to a distribution in C_Q, resulting in asymmetric, rather featureless spectral lineshapes with a tail on the low frequency side. Re-

© 2007 NRC Canada

cording the spectra from samples at multiple magnetic fields can greatly constrain the fitting even of featureless and overlapping lines. The distributions in C_Q in such materials can be simulated as a Gaussian around a central (mean) value, and the FWHM of this distribution can be used as a quantitative measure of the amount of disorder for a particular atomic site (27). In this study, three magnetic fields are applied, including 18.8 T. The aluminum-site distribution in two calcined samples and an MGA are compared using ^{27}Al MAS NMR and discussed in the context of the XRD data.

Experimental

Materials

Two Bayer gibbsites from different refineries but with very similar specifications (in terms of particle and crystallite size, morphology, and purity) were calcined in a fluid-bed-type reactor, with electrically controlled heating to ensure a uniform temperature distribution. The calcination time was 20 min, and the temperature was 1020 °C; X-ray analysis reveals that the disorder in the material is similar to that of an industrially calcined gibbsite, although the higher temperature and longer retention time than normally encountered in an industrial fluid-bed calciner produces a slightly more-crystalline material, indicated by the narrower and more-developed peaks in the X-ray diffractograms, Figs. 3–5.

XRD

X-ray diffractometry was performed on a Bruker D8 apparatus using Cu Kα X-rays, a 2θ range of 10–80°, a stepwidth of 0.02°, and a counting time of 10 s. To obtain quantitative information about the phase composition of the samples, subsequent Rietveld refinement of the X-ray diffractograms was performed using the FullProf software (28–30).

NMR

^{27}Al experiments were carried out using Varian Chemagnetics Infinity (8.45 T), Bruker Avance II (14.1 T), and Varian Infinity Plus (18.8 T) spectrometers. All MAS NMR experiments on Varian spectrometers were performed using the Spinsight program. The spectra at 8.45 T (^{27}Al Larmor frequency 93.81 MHz) were obtained with a 3.2 mm probe at 10 kHz spinning frequency. The pulse width used was 1 μs. ^{27}Al spectra at 14.1 T (^{27}Al Larmor frequency 156.37 MHz) were obtained with a 3.2 mm probe at 15 kHz spinning frequency using the TopSpin program. The pulse width was 2 μs. ^{27}Al spectra at 18.8 T (^{27}Al Larmor frequency 208.24 MHz) were recorded with a 2.5 mm probe at 25 kHz spinning frequency. The pulse width was 1 μs. These pulse lengths meant that the tip angle was in the linear-response regime (26). The repetition delay for all experiments was 5 s, which was sufficient to produce relaxed spectra. The spectra were referenced against YAG (Yttrium Aluminium Garnet) with the signal corresponding to the octahedrally coordinated aluminum site set to 0.7 ppm, so that chemical shifts reported are relative to the primary shift reference of 1 mol/L $[Al(H_2O)_6]^{3+}$ at 0 ppm. The QuadFit program was used to simulate the spectra and fit the peaks (31).

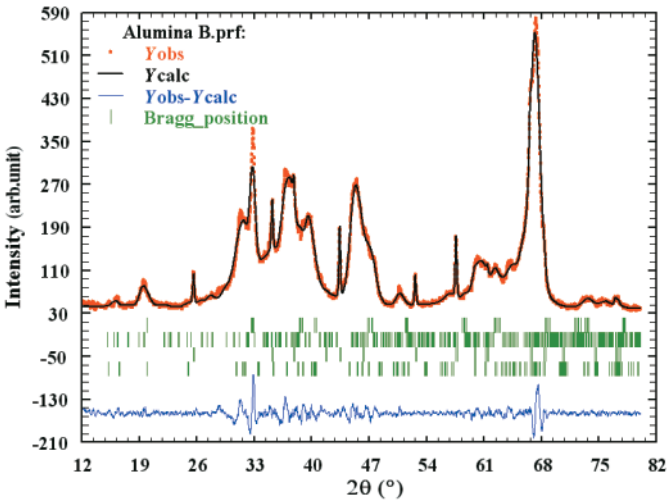
Results and discussion



In the last few decades, significant progress in the understanding of the complex structure and phase evolution of MGA has been made possible by advances in the fields of MAS NMR and improvements in structural modelling of diffraction data. However, quantitative measurements are still especially challenging, since the transformation reactions are continuous with several phases co-existing during the rapid heating encountered in modern calciners. Analyses of MGA show that the material is dominated by the poorly defined gamma phase(s); understanding the structure of these phases is key to understanding the properties of MGA. The relatively ill-defined and broad diffraction patterns are exemplified in Fig. 3, where the result from a Rietveld refinement on XRD data from a MGA is shown. In fact, even the structures of most transition aluminas are not fully understood (3,

Table 1. Results from the Rietveld refinement (quantitative phase analysis (%)) of the XRD data for the laboratory-prepared aluminas, A and B, used in this study and for an industrial fluid-bed-calcined MGA sample.

Sample	Gamma-Al_2O_3	Gamma-prime-Al_2O_3	Total gamma-Al_2O_3	Theta-Al_2O_3	Alpha-Al_2O_3
A	28	42	70	22	8
B	26	45	71	25	4
MGA	32	44	76	22	2

Fig. 5. X-ray diffractogram and Rietveld refinement of XRD data for alumina B (calcined for 20 min at 1020 °C).

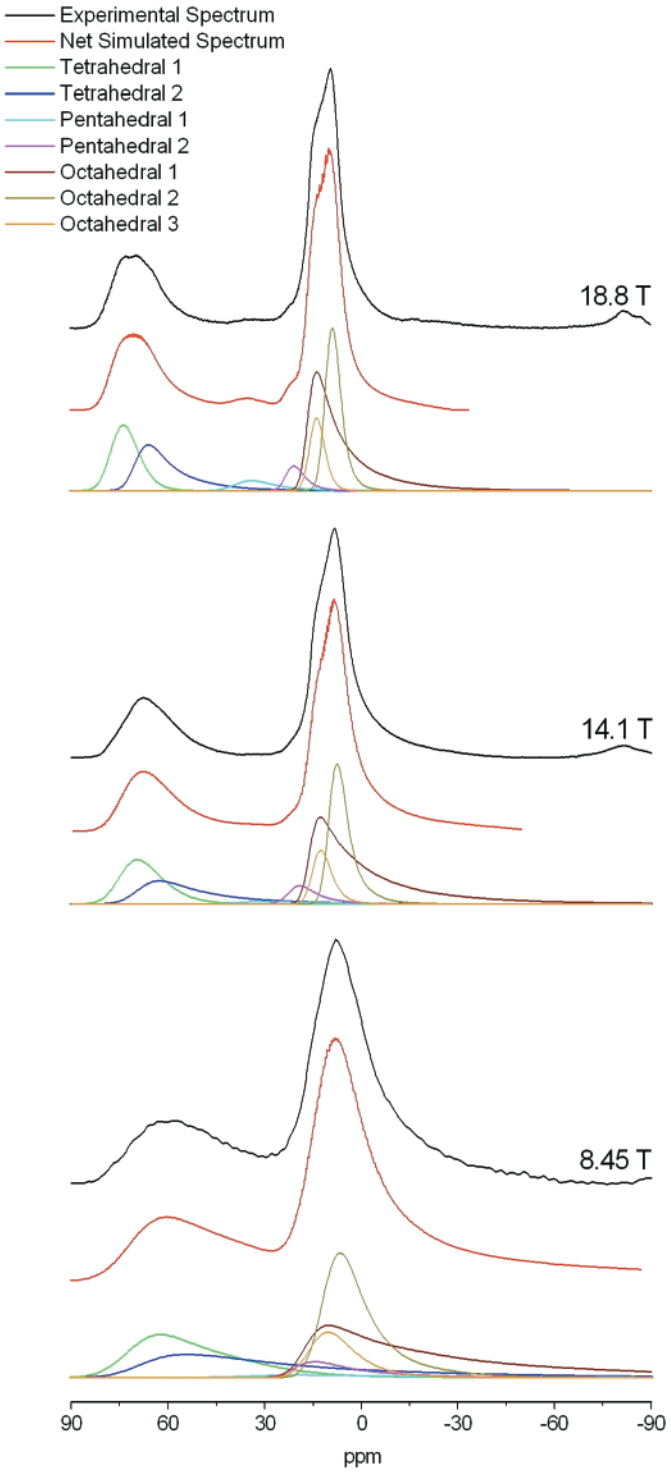
12, 32). The XRD technique is limited by the need for long-range ordering in the material. Supplementary information, as produced from ^{27}Al MAS NMR, can be very useful in better defining such systems.

In Figs. 3–5, the results from the XRD measurements and the Rietveld refinements for the MGA sample and alumina A and B are displayed. The numerical data from the quantitative phase analysis (using the Rietveld method) are listed in Table 1.

The ^{27}Al MAS NMR spectra obtained from alumina A at three fields are shown in Fig. 6, along with the individual simulated peaks for each aluminum environment. The NMR parameters and relative intensities of each site for both aluminas A and B are shown in Table 2. The ^{27}Al MAS NMR spectrum of the MGA sample is shown in Fig. 7. Integration of the various lineshapes revealed that this sample consists of a much-higher fraction of the gamma-alumina phase (see Table 3). The key to the robustness and uniqueness of these fits, despite significant spectral overlap, is that the same parameters are used to fit the spectra at all three fields. The ability to fit all three fields accurately with spurious parameters would be highly coincidental and is hence unlikely. Also, the positions (and parameters) of several peaks are not arbitrary, as they are largely determined by the known phases that are present in this sample (i.e., gamma-, theta-, and alpha-alumina).

This assignment of the peaks was made by comparison to the chemical-shift positions and NMR parameters previously reported for a sol–gel theta alumina and corundum (21). The chemical shifts and C_Q values for the theta phase are in good agreement with the published data, although the presence of a distribution in C_Q in the theta form present here suggests it is more disordered than the sol–gel formed sample (21, 26). This disorder appears to be present in the corundum phase too, which could explain why the C_Q value is slightly larger here than the commonly accepted value of 2.38 MHz (33).

The peaks at 71 and 16 ppm have much larger ΔC_Q, corresponding to a broader distribution of aluminum environments, as would be expected from a more disordered alumina phase. Hence, these peaks probably belong to the more-disordered gamma-alumina. Wefers et al. considered theta-alumina to be an intermediate between the low-temperature transition aluminas and the energetically favored alpha-alumina (3). Levin et al. showed that a disordering of the gamma phase is required to obtain the lattice parameters for theta-alumina (34). Furthermore, numerous XRD studies show that theta-alumina has narrower and more-developed peaks than gamma-alumina, also indicating a more-crystalline, or ordered structure (e.g., Stumpf et al. (35)). It is therefore assumed that gamma-alumina is more disordered than theta-alumina, and consequently that gamma-alumina has more asymmetric peaks (i.e., a broader distribution of C_Q) and larger mean C_Q.



The peak centred at a chemical shift of approximately 38 ppm indicates the presence of pentahedrally coordinated aluminum (AlO_5) in accordance with previously reported values for the chemical shift (20, 23, 36). The presence of penta-coordinated aluminum is consistent with the disordered nature of the MGAs and is thought to originate from more highly distorted (disordered) sites (components) in an X-ray amorphous part. More disordered or even amorphous aluminas, if present in significant quantities, limit the accuracy of XRD methods for quantitative phase measurements of MGAs. In gamma-alumina, penta-coordinated aluminum has also been speculated be present and would originate from aluminum at the external surface and be associated with the Lewis acidity and catalytic activity of the materials (24).

The only remaining question is the small peak at 23 ppm where ΔC_Q is only 4 MHz. This could be associated with a more "ordered" site within the disordered gamma or a small amount of penta-coordinated aluminum perhaps within the theta phase.

The distribution of aluminum cations between octahedral and tetrahedral positions for the transition aluminas has been investigated in several studies. Considering the ideal spinel structure as a basis for the gamma-alumina structure, the fraction of octahedral to tetrahedral aluminum is 0.67. The deformed spinel structures (usually represented as $Al_8^{\square}O_{12}$, where $\square$ represents a vacant Al), either with octahedral or tetrahedral cation vacancies, gives a theoretical fraction of octahedral aluminum of 0.63 and 0.75, for octahedral or tetrahedral vacancies, respectively. Based on the results in this

Fig. 6. Fitted ^{27}Al MAS NMR spectra of alumina A (calcined for 20 min at 1020 °C). The black line is the experimental spectrum, and the red line is the sum of the individual fitted curves.

study (Table 3), it cannot be unambiguously deduced whether octahedral or tetrahedral vacancies are favored. It is generally considered, and also experimentally supported, that aluminum would favor octahedral coordination in gamma-alumina under normal conditions (usually meaning that no hydrogen is included in the structure), leaving tetrahedral vacancies in the spinel-based framework (6, 24). A recent study, however, suggests a preferential distribution of aluminum over tetrahedral sites for gamma-alumina (37). In another study, conducted by Lee et al., the distribution of octahedral and tetrahedral aluminum in gamma and alpha alumina was examined using MAS NMR as well as quantum mechanical calculations; this reported a fraction of 0.7 ± 0.02 (11). It should be noted that in some of the earlier work, the lower magnetic-field strengths and lower MAS frequencies employed result in significant interference of the octahedral spinning sidebands with the peaks stemming from tetrahedrally and pentahedrally coordinated aluminum. This makes accurate quantification of the spectra very difficult. Another possible reason for the significant variation in the observed distribution of aluminum between different sites is the influence of different preparation techniques and precursor materials in the various studies.

Zhou et al. examined eta-, gamma-, and theta-aluminas using profile refinement of neutron diffraction data (6). They suggested that, in gamma-alumina, a fraction of the aluminum cations would also occupy non-spinel sites, aptly labelled as quasi-octahedral, as they lie so close to the octahedral aluminum sites; the distance being only 0.373 Å. They ascribe these sites mainly on the surface of the gamma-alumina where they also would contribute to the catalytic activity of the material. The occupation of non-spinel sites in gamma-alumina is supported in the study by Wolverton et al., who propose that not only surface sites would show this abnormal coordination but also atoms in the bulk (12). One possible explanation of the small 23 ppm peak observed here is that it is the quasi-octahedral aluminum resulting from a distorted gamma-alumina framework resulting from the incomplete transformation or complex-phase composition, which puts further stress on the structure. If the peak at 23 ppm is a quasi-octahedral site belonging to the gamma-alumina, this would correspond to 11% and 8% of the "octahedrally" coordinated aluminum atoms in alumina A and B, respectively. However, the deformed spinel-based crystal structure for gamma-alumina derived by Zhou et al. suggests that 25% of the aluminum atoms would be in quasi-octahedral coordination.

Theoretical and computational studies strongly indicate that cation vacancies in octahedral sites would be energetically favorable in gamma-alumina (12, 38). Krokidis et al. propose an equilibrium structure for gamma- alumina with 69%–75% of the aluminum ions in octahedral positions. The fractions of octahedrally coordinated aluminum (Table 3) show some agreement with this structure. However, the short heating times and the presence of theta- and alpha-alumina could distort the gamma-alumina structure, resulting in an incomplete lattice framework, and perhaps accounts for the AlO_5 observed. Data obtained on crystallographically pure, single phase systems cannot be directly compared to the data obtained for the structurally disordered systems represented by the samples used in this study. Nevertheless, important information on the coordination environment can be deduced from the results.

For the theta-alumina, the ideal structure would give a 50:50 distribution for aluminum over tetrahedral and octahedral sites (12). The experimental results for aluminas A, B,

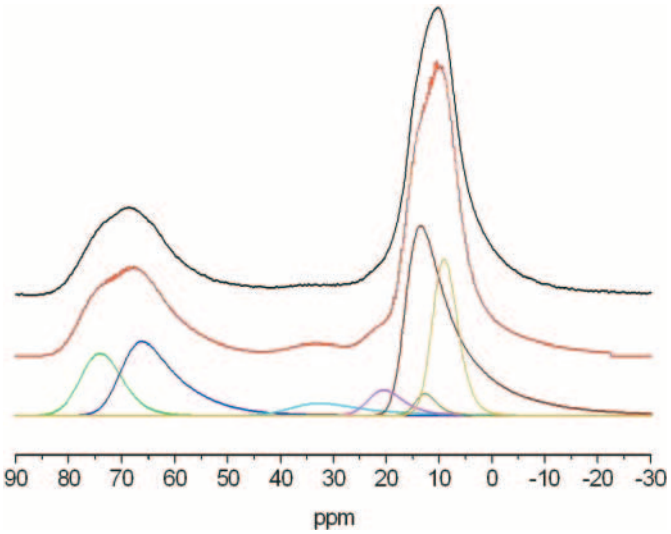
Table 2. Peak parameters used in the curve fitting of the NMR data, collected at 18.8 T, for alumina A (calcined for 20 min at 1020 °C) and the resulting peak intensities. The relative abundances are approximate, since the spinning sideband intensities were not included in the integration.

^{27}Al NMR Peak	Chemical Shift (±2 ppm)	Mean C_Q (±1 MHz)	ΔC_Q (±1 MHz)	Alumina A Intensity (%)	Alumina B Intensity (%)	Alumina Phase
Tet 1	77	5.5	3	15	20	Theta
Tet 2	71	8	6	15	12	Gamma
Pent 1	38	8	7	2	2	—[b]
Oct[a]	23	5	4	4	3	Gamma
Oct 1	16	7	9.5	33	37	Gamma
Oct 2	14	3.5	3	8	5	Alpha
Oct 3	10	3	3.5	23	22	Theta



[a]Possibly a quasi-octahedral peak (see discussion).
[b]Small quantity of AlO_5 from some amorphous component of gamma- or other transition alumina (such as the X-ray amorphous chi- or rho-alumina).

Table 3. Total intensities and fraction of octahedrally coordinated aluminum for the various transition alumina phases, for aluminas A and B and the MGA sample.

Sample	Total gamma-Al_2O_3 (±2%)	Total theta-Al_2O_3 (±2%)	Total alpha-Al_2O_3 (±2%)	Fraction of octahedral Al in gamma-Al_2O_3	Fraction of octahedral Al in theta-Al_2O_3
A	50	38	8	0.71	0.61
B	51	42	5	0.67	0.52
MGA	66	28	3	0.82	0.61

Note: The quasi-octahedral peak (at a chemical shift of 23 ppm) is included in the gamma-alumina.

Fig. 7. The ^{27}Al MAS NMR spectrum of MGA obtained at 18.8 T, with simulated peaks (same colors as Fig. 6).

and the MGA show some agreement with the ideal structure. The theta-alumina in alumina B appears to be very close to the ideal structure. In alumina A and the MGA, the complex-phase mixture and severe disorder in the material results in the lineshapes of the associated resonances showing much more disorder than in a crystalline alumina. The "theta" phase present in these two samples may actually be closer to the more-disordered delta-alumina phase, which would explain the lower tetrahedral to octahedral ratio.

Recently, a number of authors report on the use of various synchrotron radiation sources to investigate the transition aluminas and their transformation reactions (15, 39–42) as well as some aluminum-containing minerals and zeolites (43, 44). It seems that by examining the Al K-edge XANES or NEXAFS features, information on the coordination environment can be obtained. The methods clearly show some promise for analyzing disordered systems, such as MGAs. Quantification is made in a similar manner as with the NMR results in this study; i.e., by curve fitting of the obtained spectrum. The results generally give a distribution of octahedral and tetrahedral aluminum closer to unity regardless of the calcination temperature (15, 40), which does not agree well with NMR data nor has there been any report of pentahedrally coordinated aluminum for which there is strong experimental evidence in this and other studies.

It is clear that there still exists considerable ambiguity over several issues relating to the transition aluminas, the variations in structure that occur, and the accurate characterization of these structures. The true structure and the distribution of aluminum cations and vacancies for some of the transition aluminas remain yet to be discovered (3, 32). Another outstanding question is the location of the residual hydroxyl groups, initially thought to be located on the exterior of the alumina structure and at grain boundaries. In gas-suspension or fluid-bed calcined MGAs, the very high heating rates are expected to result in a far more random distribution. Computational studies indicate that for the formation of cubic spinel-based transition alumina forms, protons may have a stabilizing effect on the structure (45), but contradictory results are obtained in neutron diffraction studies (6, 12). It has also been suggested that hydrogen would be present as water from the decomposition reactions of gibbsite and boehmite and located within the amorphous structure (3, 46).

© 2007 NRC Canada

The MGAs must be viewed as a kinetically "frozen" material in which the different phases exist not in a simple binary mixture, but in a continuum of evolving and disappearing phases. Local variations between particles and even within particles further contribute to difficulties and uncertainties with interpreting the data. The structural domains transcend both short-range nanostructures and longer-range ordering; a combination of techniques such as MAS NMR and XAS with XRD will be necessary for a more-complete understanding of these important materials.

Conclusions

It has been shown that ^{27}Al MAS NMR spectroscopy can be used to quantify the distribution of aluminum between different sites in the component phases of MGAs. The use of multiple applied magnetic fields, and especially the availability of higher magnetic fields, is crucial to constrain the simulations. The results also clearly demonstrate that the complementary information obtainable by XRD significantly aids quantification. Amorphous aluminas, if present in significant quantities, can however limit the accuracy of XRD methods for quantitative phase measurements of MGAs. An NMR peak at 23 ppm was detected and could be due to aluminum in a quasi-octahedral coordination, relating to a distorted gamma-alumina form. In conclusion, ^{27}Al MAS NMR has been shown to be an extremely useful part of experimental methodologies to examine the commercially significant and structurally interesting transition aluminas and their precursors.

Characterization of the conformational changes in recombinant human metallothioneins using ESI-MS and molecular modeling[1]

Jayna Chan, Zuyun Huang, Ian Watt, Peter Kille, and Martin J. Stillman

Abstract: Electrospray ionization mass spectrometry (ESI-MS) data and molecular modeling calculations were used to gain mechanistic, conformational, and domain-specific information from the acid-induced demetallation reactions of human metallothionein. The recombinant proteins studied were the single α- and β-rhMT-1a domains and the βα- and αβ-rhMT-1a two-domain species, based on the human metallothionein 1a sequence. Complete molecular models (MM3/MD) for all the fully metallated and demetallated species using a modified force field are reported for the first time. Basic residues that contribute to the ESI-MS charge states are identified from the molecular models. Demetallation took place under equilibrium conditions within a narrow pH range. For the two-domain proteins, these results support a demetallation mechanism involving the initial complete demetallation of one domain followed by the other for both βα-rhMT and αβ-rhMT. Based on the stability of the separate domains, the β domain is predicted to demetallate first in the two-domain rhMTs. Both the α domain and the β domain were observed to bind an excess of one Cd^{2+} ion. The metallated rhMT structures were shown to have very stable conformations, but only when fully metallated. Two or more conformations were observed at low pH in the ESI-MS data, which are interpreted as arising from the presence of structure, as opposed to a random coil, in the apo-rhMT. This is the first report of the existence of a structure in the two-domain metal-free apo-MT proteins. Only at extremely low pH does the structure open fully to give the highest charge distribution, which is associated with a random coil. Pre-existing structural features in the apo-MT would explain why the metallation reactions occur so rapidly.

Key words: recombinant human metallothionein-1 (rhMT1), electrospray ionization mass spectrometry (ESI-MS), circular dichroism (CD), molecular mechanics/molecular dynamics (MM3/MD).

Résumé : On a utilisé des données de spectrométrie de masse avec ionisation par électronébulisation (SM-IEN) et des calculs théoriques de modélisation moléculaire pour obtenir des informations mécanistiques, conformationnelles et spécifiques au domaine relatifs aux réactions de démétallation induites par des acides de métallothionéines humaines. Les protéines recombinantes étudiées sont les espèces α- et β-rhMT-1a, à un domaine, et les espèces βα- et αβ-rhMT-1a à deux domaines sur la base de la séquence 1a de la métallothionéine humaine. Faisant appel à un champ de forme modifié, on a pu définir pour la première fois les modèles moléculaires complets (MM3/MD) de toutes les espèces métallées et démétallées. Sur la base des modèles moléculaires, on a identifié les résidus basiques qui contribuent aux états chargés de SM-IEN. La démétallation se produit sur une très faible plage de pH. Pour les protéines à deux domaines, ces résultats sont en accord avec un mécanisme de démétallation impliquant une démétallation complète d'un domaine suivie par l'autre pour le βα-rhMT et le αβ-rhMT. Sur la base de la stabilité de chacun des domaines pris séparément, on peut prédire que des rhMT à deux domaines, le domaine β sera le premier à subir une démétallation. On a observé que le domaine α ainsi que le domaine β se lient tous les deux à un excès d'ion Cd^{2+}. On a démontré que les structures rhMT démétallées sont dans des conformations très stables, mais uniquement lorsqu'elles sont complètement démétallées. Dans les données de SM-IEN du apo-rhMT à faible pH, on a observé la présence d'au moins deux conformations qui a été interprétée en fonction de la présence d'une structure par opposition à la pelote statistique. Ceci constitue le premier rapport de l'existence d'une structure dans protéines apo-MT à deux domaines et privées de métal. La structure ne s'ouvre complètement qu'à des valeurs extrêmement faibles du pH et elle conduit alors à la

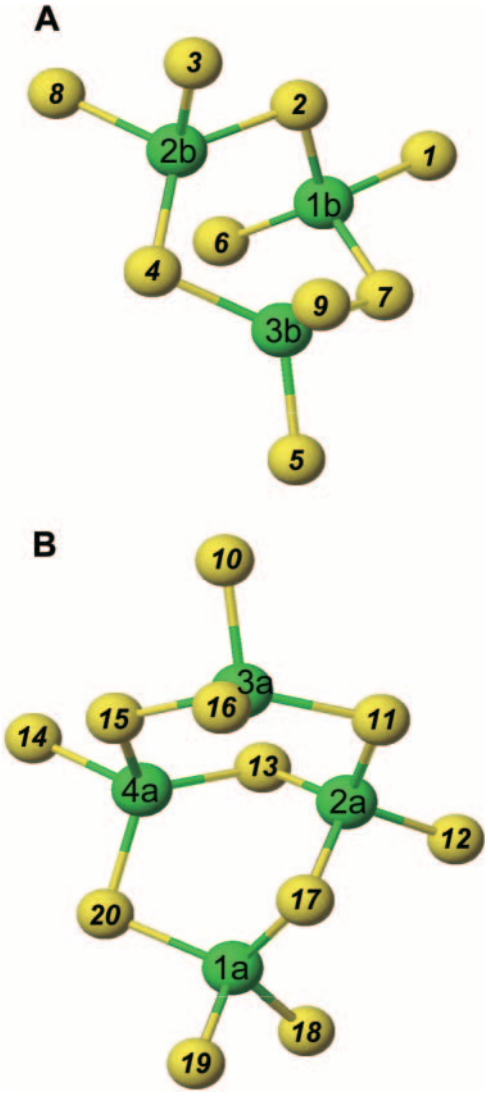
Introduction

Metal-dependent protein folding is an elaborate reaction that is still not well-understood, having the added complexity of metal coordination chemistry, but is important in our understanding of the relationship between overall structure and metalloprotein function. A major difficulty in probing metal-induced protein folding arises from the speed of the reactions. Spectroscopic measurements, for example, can provide protein structural details, but as a sample average, and data collection is slow to capture these short-lived folding events. In metalloproteins, metal-induced protein folding offers both the chromophores for spectroscopic analysis and speciation data. Metallothionein (1–8) is a metalloprotein for which metal-dependent folding is important. Metal-ion chelation by MT causes the protein to fold into metal-thiolate clusters that define their three-dimensional structure via the coordination of the cysteinyl sulfurs to the metal ions. Stoichiometric and spectroscopic studies of mammalian MTs have shown that the N-terminal β-domain forms M_3S_9 clusters and the C-terminal α-domain forms M_4S_{11} clusters via tetrahedral coordination with divalent metal ions, such as Zn^{2+} and Cd^{2+} (Fig. 1) (6). The structure and metal–cysteine connectivities for Cd_7-MT have been studied by ^{1}H–^{113}Cd NMR (9–11) and by X-ray crystallography (12, 13), and the interatomic distances within the clusters have been refined by X-ray absorption spectroscopy (XAS) (14–16) and molecular modeling (17–34). However, the structures of partially metallated and metal-free, or apo, metallothioneins are extremely difficult to determine.



Electrospray ionization mass spectrometry (ESI-MS) provides both speciation and structural information because different ligands change the measured mass, and structural effects are observed from the changes in the number of protonatable sites on the protein observed from the charge distribution (35, 36). The charge distributions change as the protein folds to envelop the incoming metal. In the mass spectrum, the relative abundance of charge states is measured, which leads directly to quantification of the degree of exposure of (in positive-ion measurements) basic sites (37). The number of protonatable sites is related to the three-dimensional structure, which in turn is related to the extent of protein folding. The capability of ESI-MS to analyze samples at various temperatures, pH values, and solvent conditions, which monitors the unique molecular species within a single-sample mixture (38), allowing observation of reaction intermediates that cannot be isolated in significant quantities. These "snapshots" can provide mechanistic information of the protein-folding events. Determination of the protein-surface locations of the acidic and basic sites may provide useful information on the availability of the protonation sites, which may control the unfolding of the protein via electrostatic interactions, and consequently affect the observable charge states seen in the ESI-MS spectra (39). Molecular modeling has made significant progress in elucidating molecular structures and molecular motions (40, 41). Molecular modeling can provide realistic models of the molecules, allowing one to visually interpret the molecular structure (bonding and chemistry) (42–44). Molecular modeling can provide chemical and spectroscopic information that is especially relevant to the interpretation of structures formed in the vacuum space of the mass spectrometer. In addition, molecular modeling has been utilized in simulating chemical reactions and molecular folding.

In this present study, we have probed the cadmium-binding properties of a series of related peptides, each of which are made recombinantly and based on the human MT-1a sequence (rhMT). This series of peptides includes the novel αβ-rhMT, altered from the native sequence by placing the α sequence at the N terminus and the β sequence at the C terminus. This altered peptide will in the future be used to test the question of the significance of the presence of two slightly different domains on metal binding. To explore the metal-dependent structural and functional features of this human metallothionein isoform, the properties of Cd-α-rhMT, Cd-β-rhMT, Cd-αβ-rhMT, and Cd-βα-rhMT recombinant human MT samples were examined by ESI-MS over a wide pH range. The molecular species of metallothionein that exist within the neutral to acidic pH range prove to play physiologically relevant roles in the cytosol, where the pH is neutral, and in lysosomal function, where the pH is strongly acidic (45, 46). Demetallation reactions of the holoproteins as a function of solution pH occur in a very narrow range with specific metallated structures present and allow an understanding of the extent of unfolding as the metals leave the binding site. Changes in charge state distributions and the molecular species present were monitored to gain information regarding solvent accessibility, conformational changes, and the extent of unfolding in response to changes in pH. Structures in the metal-free, apoproteins were also studied from the charge state distributions.

A calibrated MM3/MD force field (26) was applied to simulations of the metallated and demetallated conformations of α-rhMT, β-rhMT, αβ-rhMT, and βα-rhMT to mimic the initial and final conformations expected for the demetallation reaction of metallothionein by acidification. These simulations were carried out to pinpoint the locations of exposed acidic and basic residues on the folded and unfolded conformations for comparison with the charge states measured by ESI-MS. Molecular dynamics simulations of these proteins may also uncover regions of flexibility in the protein that might allow partial access to protonation sites.

Fig. 1. Metal-thiolate cluster models of mammalian metallothioneins determined by NMR spectroscopy (9–11) and X-ray crystallography (14, 16): (A) β domain with a stoichiometric ratio of $M^{II}{}_3S_{Cys9}$ and (B) α domain with a stoichiometric ratio of $M^{II}{}_4S_{Cys11}$ (the green spheres represent tetrahedrally coordinated divalent metal atoms, such as Zn^{2+} and Cd^{2+}, which are numbered based on their NMR chemical shifts and lettered based on the domain in which they are found. The numbering scheme for the S_{Cys} represents the cysteine residues in the order they appear in any general mammalian holoprotein sequences, and are similarly numbered in Fig. 2. The yellow spheres represent sulfur atoms, which are numbered based on the position of the cysteines in the protein sequence of the mammalian MTs.

Materials and Methods

Materials

Sephadex™ G-25 Fine Grade and HiTrap™ SP Sepharose™ HP cation-exchange cartridges were purchased from Amersham Pharmacia. All buffers and reagents used were analytical-grade products. Cadmium sulfate ($3CdSO_4{\cdot}8H_2O$), isopropyl-β-D-thiogalactoside (IPTG) (Biotech Grade), ammonium formate, and guanidine chloride were purchased from Caledon Laboratories Ltd. BL21(DE3) strain of *E. coli* was purchased from Novagen EMD. Kanamycin monosulfate, 5,5-dithio-bis(2-nitro)benzoic acid (DTNB), LB broth (Miller), LB agar (Miller), and tris(hydroxymethyl)aminomethane (Tris) were purchased from Sigma-Aldrich Chemical Company, Inc., and mercaptoethanol (EtSH) was purchased from EM Science. All buffer solutions were pH-adjusted by pH meter (Fisher Scientific) at 25 °C and prepared using water that was deionized to 18 MΩ cm using a Millipore Nanopure Infinity RO System (Barnstead).

Methods

Recombinant human MT plasmid vectors

The plasmid vectors used to express the human metallothionein proteins used here were constructed and transformed into *E. coli* (BL21(DE3)*pLys*S) at Cardiff University, Wales, UK. These vectors were constructed using the pET vector system purchased from Novagen. The recombinant proteins used here were the single-domain α-rhMT-1a and β-rhMT-1a, and the two-domain βα-rhMT-1a and αβ-rhMT-1a, based on the human metallothionein 1a sequence with sequences shown in Fig. 2 and reported by I. Watt (47). All expressed fusion proteins included an S-peptide tag (labeled "S-tag" in Fig. 2) on the N terminus of each protein (48). The S-tag was originally used as an affinity tag for isolation, but currently is retained purely for protein stability during isolation. We have no evidence that the S-tag interacts with the metal binding site, and so we find the data with and without the S-tag to be equivalent.

Protein expression, isolation, and purification

The plasmid vectors were transformed into the *E. coli* bacterial cells using the protocol as described by the supplier (Novagen, EMD Biosciences). The transformed cells were incubated on LB agar culture plates containing 50 μg/mL kanamycin and 50 μmol/L $CdSO_4$ at 37 °C. Large-scale preparations (4 L) of the recombinant proteins were produced by mid-log phase induction in LB media containing 50 μg/mL kanamycin (sterilized by filtration), 50 mmol/L $CdSO_4$, and swabs from the culture plates, incubated at 37 °C for about 3 h until the solution OD_{600} reached 0.6. Protein expression was induced by IPTG and incubation continued for 4 h at 37 °C, during which time the cadmium concentrations in the culture medium were elevated with two additions of $CdSO_4$, to reach a final solution concentration of 250 μmol/L to stabilize the MT via metallation.

The cells were harvested by centrifugation at 6000 rpm for 30 min at 4 °C, and the cellular pellets were resuspended in 40 mL of 50 μmol/L ammonium formate buffer solution at pH 7.4 containing 3 mmol/L mercaptoethanol per liter of induction volume, and the resuspension mixture was rapidly frozen at –70 °C. The cells were partially thawed and then lysed by FRENCH® Pressure Cell (Thermo IEC), using a 40 mL cell. The cellular debris was removed by centrifugation at 13 000 rpm for 1 h at 4 °C. A 5 μL aliquot of 1 mol/L $CdSO_4$ was added to the 40 mL supernatant to stabilize the MT (this is equivalent to adding a reducing agent in that the slight excess of Cd(II) ensures continuing metallation and no free thiolates during isolation). The supernatant was kept

Cysteine residues are represented by the dark ovals, basic residues are represented by blue ovals, and acidic residues are represented by red ovals. The metals are numbered 1a–4a in the α domain and 1b–3b in the β domain, and the cysteine residues are numbered in order of occurrence from the N terminus to the C terminus. (A) Recombinant human MT-1a 11cys α domain; (B) Recombinant human MT-1a 9cys β domain; (C) Recombinant human MT-1a 20cys βα domain; and (D) Recombinant human MT-1a 20cys αβ domain.

cold throughout the rest of the procedure to reduce the chance of oxidation. The protein solution was gravity-filtered followed by isolation by cation exchange using a HiTrap™ SP cartridge coupled to a Millipore Consep™ LC100 system by the following method: All eluents were prepared using cold deionized water, deoxygenated with argon. The effluent was passed through a quartz flow-cell and monitored by absorption spectroscopy (Cary 1E UV–vis Spectrophotometer, Varian Canada Inc.), recording scans continuously over the wavelength range of 200–300 nm. The protein was loaded onto the SP cartridge and then rinsed thoroughly with Tris buffer solution until the absorbance of the effluent went to baseline. The eluents used were 10 mmol/L Tris buffer (pH 7.4) (eluent A) and 1 mol/L NaCl in 10 mmol/L Tris buffer (pH 7.4) (eluent B). Recombinant human MTs were each eluted from the column during a salt gradient that increased from an eluentA:eluentB ratio of 100:0 to 90:10 within 15 min. A Buchler Fractomette Alpha 200™ automated fraction collector was used to collect the effluent in 3–5 mL fractions.

The metallation quality of the strongly absorbing protein fractions were measured by circular dichroism (CD) (Jasco J-500C spectropolarimeter controlled by an IBM 9000 computer using the program CDSCAN) (49). The high-quality fractions were combined and concentrated using an Amicon Stirred Cell filtration system, then desalted using a Sephadex™ G-25 size exclusion column with cold 25 mmol/L ammonium formate buffer as the eluent. The effluent was monitored over the wavelength range of 300 to 200 nm as described earlier. The protein fractions were again isolated, combined, and concentrated using the Amicon Stirred Cell filtration system. The homogeneity of the purified recombinant human MTs was confirmed by CD spectroscopy, absorption spectroscopy, and ESI-MS.

Concentration of recombinant human MTs

Protein concentrations were estimated from measurements of the –SH group by Ellman's method (50, 51), and cadmium concentrations were estimated by atomic absorption spectrometry (AAS). These estimations were based on the assumption that the number of –SH groups in each of the recombinant human MTs bind a specific number of metal ions. Metal content was determined by flame AAS using a Varian model 875 atomic absorption spectrometer with a Varian model 55 programmable sample changer.

ESI-MS measurements

The PerkinElmer SCIEX API 365 triple quadrupole electrospray ionization mass spectrometer (PE-SCIEX, Concord, ON, Canada) was calibrated using polypropylene glycols and myoglobin. The scan conditions for the spectrometer were positive ion mode, ion-spray needle potential = +4.9 and +5.6 kV, and orifice potential = 30 to 40 V. The *m*/*z* range was 500 to 2300, step size of 0.5 Da, and dwell time

of 1.0 ms. Solutions were delivered through a long fused-silica capillary (I.D. = 75 μm, Polymicro Technologies, Phoenix, AZ) by a syringe pump (Harvard Apparatus, South Natick, MA) with 2.0 and 5.0 μL/min flow rate. Orifice and the focusing ring potentials were also optimized to enhance detector sensitivity and signal stability. The measured spectra were analyzed using BiomultiView Version 1.5.1b. The pH values of the rhMT solutions were adjusted from pH 7.5 to pH 1.80 with formic acid or HCl (for extremely acidic pH). Following treatment with acid, the solutions were allowed to reach equilibrium prior to analysis by ESI-MS.

The AAS measurements were adapted from the Ph.D. thesis by Watt (47). These AAS measurements were carried out on α-rhMT, β-rhMT, and βα-rhMT samples of known cadmium concentration and were pH-adjusted to the desired level. The protein solutions were then separated by size-exclusion chromatography to remove the free metal ions. AAS measurements were carried out on the remaining protein solution and compared to the original cadmium concentration to give the percentage of cadmium recovery. This was carried out over the pH range of 7 to 1.

Molecular models

MM3/MD calculations parameterized using the modified force field described by Chan et al. (26) and the dielectric constant for water (78.4) were carried out to obtain minimum-energy structures of both the metallated (at neutral pH) and the demetallated (at acidic pH) structures of various metallothionein structures. All MM3/MD calculations and model-structure rendering were carried out using CAChe WorkSystem Pro 6.1.1 Software (Fujitsu America). Calculations were carried out using a simple PC (Intel P4 3.0 GHz) with 1.00 Gb RAM. The original metallated MT structure was taken from the RCSB protein databank (52) (1MHU, 2MHU (53)) and was modified using CAChe to produce molecular models for Cd_4-α-rhMT, Cd_3-β-rhMT, Cd_7-αβ-rhMT, and Cd_7-βα-rhMT. The structure was atom-typed and energy-minimized as follows: the structure was energy-minimized using the MM3 calculation followed by the MD simulation at 300 K for 500 ps. MM3 and MD calculations were cycled until no change in energy was observed. The apo-MT structure was energy minimized from the linear sequence as described for metallated MT, with the appropriate residues protonated based on their pKa values.

Results

Protein quality

Samples of Cd_4-α-rhMT, Cd_3-β-rhMT, Cd_7-αβ-rhMT, and Cd_7-βα-rhMT were first characterized by AAS and Ellman's method to determine the stoichiometry of metal

and Figs. 7 and 8 show the spectra for the two-domain rhMTs. Spectra were measured at six different pH levels during a pH titration over the range of neutral to acidic pH (~2), and Fig. 9 summarizes the observed metallation states for each rhMT species plotted with the metallation data from AAS measurements over the same pH range.

Species present during acid-induced demetallation

Cd_4-α-rhMT

AAS measurements show that demetallation of Cd_4-α-rhMT begins around pH 4; the point of inflection is at pH 3.1, and complete demetallation is reached by pH 2.4.

			7Cd	6	10657.6	10656.2±0.6
βα-rhMT	99	20	0	20	9884.8	9886.5±0.5
			7Cd	6	10657.6	10656.2±0.6

[a]Calculated molecular masses of the rhMTs with a 27 amino acid N terminal S-tag. Calculated masses were based on their polypeptide sequence and the loss of two protons per divalent metal bound.
[b]Measured molecular masses of the rhMTs with S-tag, measured experimentally by ESI-MS.

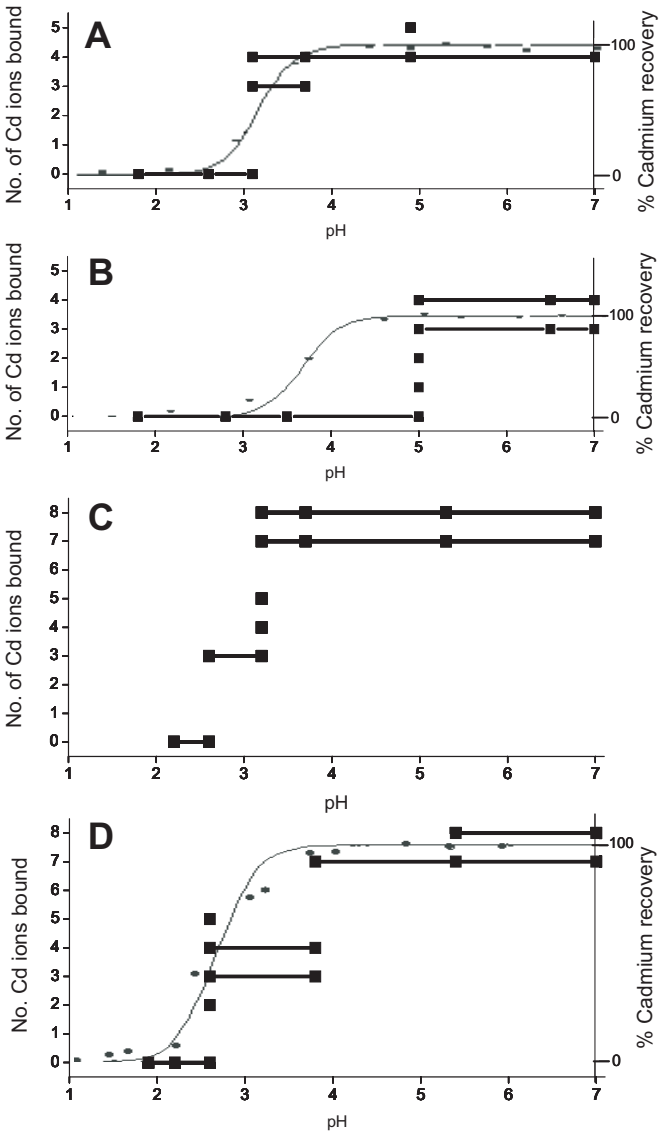

Fig. 9. Summary of the metallation states observed by ESI-MS during pH titration and the associated demetallation curves measured by AAS for (A) α-rhMT, (B) β-rhMT, (C) αβ-rhMT, and (D) βα-rhMT (demetallation curve for αβ-rhMT is not available).

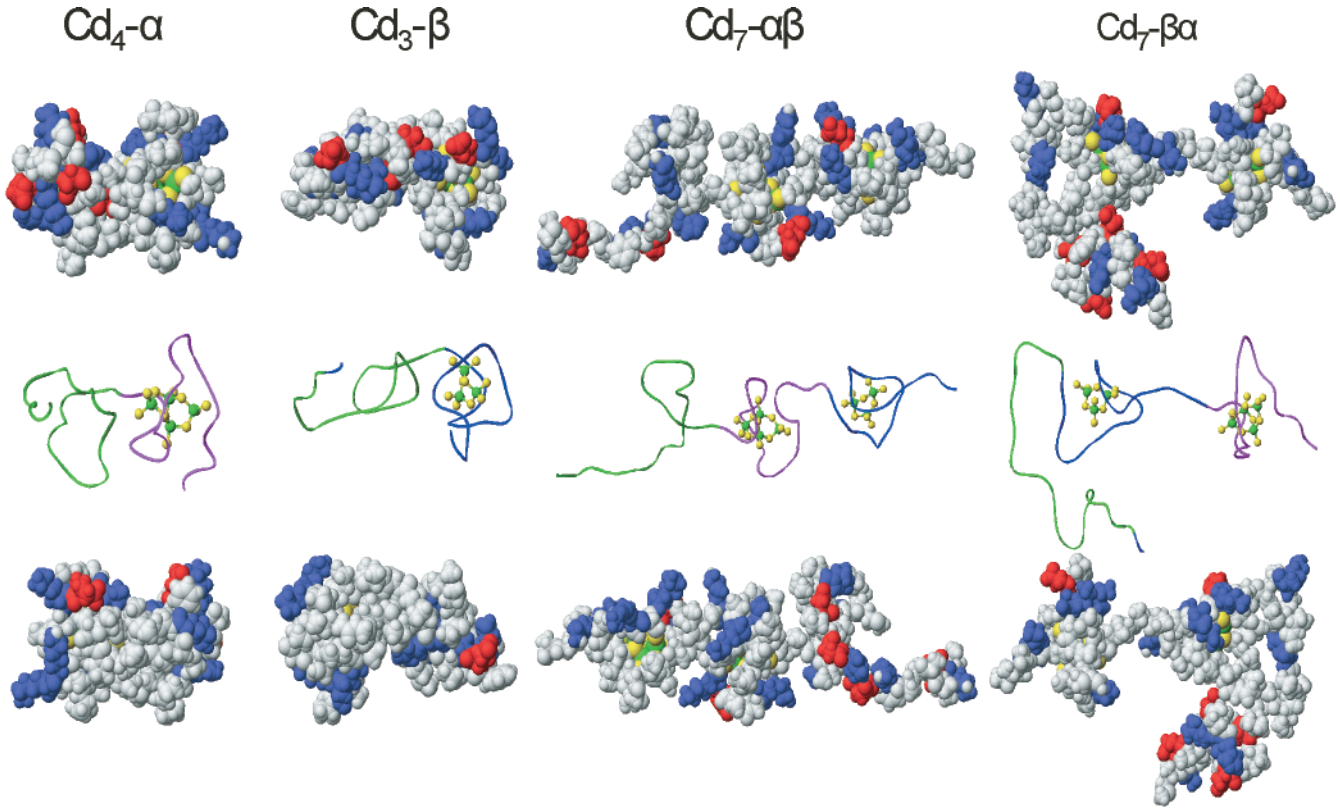
The ESI-MS data indicate that excess metallation of one Cd^{2+} ion is observed, but only as a minor component of the sample. Demetallation of Cd_4-α-rhMT begins at pH 3.7 with the loss of a single Cd^{2+} ion. At pH 3.1, Cd_4-α-rhMT and apo-α-rhMT coexist. The lack of intermediates suggest that protonation of the coordinated thiolates takes place over a very narrow range, and that species with less than a full complement are unstable under the ESI-MS conditions. Full demetallation is achieved by pH 2.6. These findings strongly correlate with the AAS data.

Cd_3-β-rhMT

For Cd_3-β-rhMT, the AAS measurements show that demetallation begins at pH 4.5, the point of inflection is at pH 3.6, and complete demetallation is reached at pH 2.9. The reconstructed ESI-MS spectra show a small fraction of protein with an additional Cd^{2+} ion. Partial demetallation at pH 5.0 is observed where all β-rhMT metallation states from zero to four cadmiums coexist, suggesting that intermediate metallation species exist, and becomes fully demetallated by about pH 3.5. There is a small discrepancy in the pH of demetallation between the ESI-MS results and the AAS results for the β domain, yet both results show that the β domain demetallates at a higher pH than the α domain.

Cd_7-βα-rhMT



AAS measurements show that demetallation begins at pH 3.9, the point of inflection is at pH 2.7, and complete demetallation is reached by pH 1.9. The reconstructed ESI-MS spectra show that βα-rhMT substantially binds an excess of one Cd^{2+} ion. Partial demetallation is observed at pH 3.8 where metallation states of 3, 4, and 7 coexist, a difference of three to four metal ions. The protein continues to demetallate through pH 2.6 where metallation states of 0 and 2–5 coexist, and is fully demetallated by pH 2.2. These demetallation transitions measured by AAS strongly agree with the results of ESI-MS.

Cd_7-αβ-rhMT

AAS measurements were not available for this protein. Much like Cd_7-βα-rhMT, a substantial amount of the sample shows excess metallation of one Cd^{2+} ion. The reconstructed spectra show that αβ-rhMT is partially demetallated at pH 3.2 where metallation states of 3–5, and 7–8 coexist, and is fully demetallated by pH 2.2; a difference of three to four

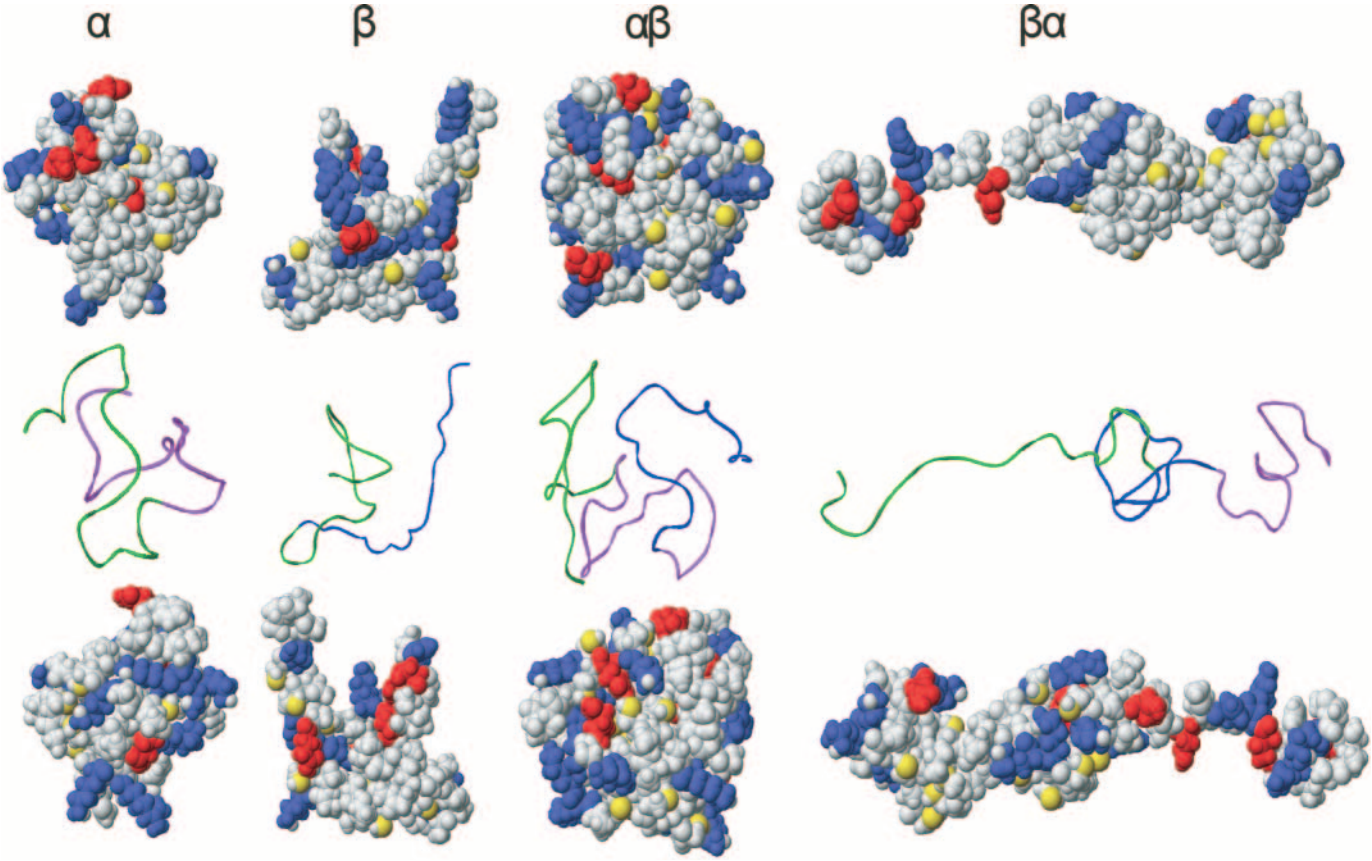
Fig. 10. Metallated metallothionein structures generated from MM3/MD calculations. The colored atoms correspond to the residues shown in Fig. 2 where the red atoms represent acidic residues, the blue atoms represent basic residues, the yellow atoms represent the cysteinyl sulfurs, and the green atoms represent the cadmium or zinc ions bound. The top row of structures shows one side of the molecules. The middle row of structures shows the protein backbone where the green represents the S-tag sequence, the purple represents the α-MT sequence, and the blue represents the β-MT sequence, also showing the location of the metal-thiolate cluster. The bottom row of structures represents the other side of the molecules.

metal ions. The metallation states appear as two groups, fully metallated (seven to eight Cd^{2+} ions) and partially demetallated (three to five Cd^{2+} ions), again a difference of three to four metal ions. There is an absence of the Cd_6-αβ-rhMT species. This suggests that αβ-rhMT has a demetallation mechanism that involves the demetallation of one domain at a time. At pH 2.6, there are again two sets of metallation states, 0 Cd^{2+} and 3 Cd^{2+} (1 Cd^{2+} and 2 Cd^{2+} are absent), further supporting initial demetallation of a single domain, and also suggesting that the β-domain is still metallated, but this may be an artifact, as the signal-to-noise level of the Cd_3-αβ-rhMT species is very low. By pH 2.2, αβ-rhMT is completely demetallated.

Molecular models

Molecular models of Cd_4-α-rhMT, Cd_3-β-rhMT, Cd_7-αβ-rhMT, and Cd_7-βα-rhMT were constructed and energy-minimized to mimic the conformations at neutral pH (fully metallated with Cd^{2+}), shown in Fig. 10. Similarly, models of apo-α-rhMT, apo-β-rhMT, apo-αβ-rhMT, and apo-βα-rhMT were prepared to mimic the conformations at low pH (fully demetallated) when the proton concentration in solution is high, shown in Fig. 11. Dynamics simulations of each of the metallated rhMTs show that the metal-thiolate clusters have some short-range freedom of motion, but are otherwise fairly rigid structures. The peptides that wrap around the clusters have more freedom of motion than the clusters, but do not move significantly. Upon removal of the metals, the apo-rhMTs demonstrate significantly higher freedom of movement in the peptide chain, but the overall conformation does not change significantly. In each of the metallated and demetallated molecular models, the majority of the charged residues are located at the protein surface, which would make them solvent-accessible and easily protonatable.



With respect to the S-tag, over many calculations we have found that it is quite fluxional and does not adopt a fixed or even sticky association with the MT peptide chain. Therefore, we believe these MT fusion proteins do adopt well-formed structure even at neutral pHs in the presence of the S-tag.

Correlation of calculated and measured charges

Table 2 summarizes the total charges, the expected charges based on the solvent accessible protonatable groups observed on the molecular models, and the charges measured by ESI-MS (collected from Figs. 5–8) for both the metallated and apo forms for each of the rhMTs. The protonatable residues include the following: N-terminus (pKa 10), C-terminus (pKa 2), Asp (pKa 4), Glu (pKa 4), His (pKa 6), Lys (pKa 10), Arg (pKa 12.5), and Cys (pKa

Fig. 11. Apo metallothionein structures generated from MM3/MD calculations. The colored atoms correspond to the residues shown in Fig. 2 where the red atoms represent acidic residues, the blue atoms represent basic residues, and the yellow atoms represent the cysteinyl sulfurs. The top row of structures shows one side of the molecules. The middle row of structures shows the protein backbone where the green represents the S-tag sequence, the purple represents the α-MT sequence, and the blue represents the β-MT sequence. The bottom row of structures represents the other side of the molecules.

8). However, the data show (Fig. 9) that the pKa of the cysteine groups within metallothionein are significantly lower due to metal-ion coordination, and histidine (only in the S-tag) has a borderline pKa at neutral pH and therefore is likely that the sample only partially contains protonated histidine groups. In addition, the clusters in the metallated structures have a net –3 charge, but it is suspected to be of little influence on the charge, since the cluster is largely shielded inside the core of the protein (54), and hence these clusters are not included in the calculated charge. Lower charge states indicate more compact structures (less solvent-exposed protonatable groups), while higher charge states are associated with more open or unwound structures (more solvent-exposed protonatable groups), of the same peptide chain.

Cd_4-α-rhMT

At neutral pH, the molecular model of Cd_4-α-rhMT has the protein strand tightly wrapped around the cluster, with the S-tag slightly folded but does not appear to interact strongly with the metallated domain. The sulfurs of the cluster are well-buried, though there is a tight crevice site observed that may allow solvent access. The histidine residue in the S-tag is exposed, so it will have an impact on the molecular charge. Of all the protonatable residues, only a single aspartic acid (residue 18) is buried within the protein, which may play a role in protein unfolding at intermediate pH.

Based on this analysis, the expected charge is +6 at neutral pH. The ESI-MS spectra show that one series of charge states is observed ranging from +4 to +7 with the maximum charge intensity centered at +5 and a hint of a maximum at +7. The distribution of charge suggests that there is one principal protein conformation, and one minor protein conformation. The observed charge is comparable to the expected charge of +6.

At pH 3.1, a complex pattern of overlapping charge distributions emerges. The *m*/*z* values belonging to Cd_4-α-rhMT are still present, but the *m*/*z* values of 863.0, 986.0, 1150.0, 1380.0, and 1725.0 amu, arise from apo-α-rhMT and corresponding to charges states ranging from +8 to +4 where there are two maxima centered on +7 (986.0 amu) and +5 (1380.0 amu). At pH 2.6, only the distribution of apo-α-rhMT, consisting of the two maxima, remains.

Further acidification to pH 1.8 results in the charge distribution collapsing to a single distribution ranging from +4 to +10 and centered at +8, corresponding to apo-α-rhMT. The model of the apo structure shows the S-tag folds up close with the α portion of the protein strand, which has a more open structure than the metallated form, and many of the sulfur groups are now found at the protein surface. The basic

βα-rhMT	Metallated	13 Lys, 2 Arg N-terminus 3 Cd^{2+} 1 His	4 Glu, 2 Asp C-terminus 9 S^-	+4	+10	+6→+9→+11
	Apo	8 Lys, 2 Arg N-terminus		+16/+17	+16/+17	+5→+7, +11→+13

sites and all the sulfur groups of α-rhMT are therefore accessible, giving a predicted charge of +11 at acidic pH. These results indicate that the measured apo structure is more compact than the calculated structure, suggesting that the demetallated structure is still partially folded.

Cd_3-β-rhMT

At neutral pH, the molecular model of Cd_3-β-rhMT has a structure similar to that of Cd_4-α-rhMT in that the protein wraps around the cluster with a non-interacting S-tag. The protein itself has the equivalent number of acidic and basic residues as the α-domain. An arginine (residue 11) and an aspartic acid (residue 15) are buried within the protein, but are inconsequential at pH 7. The sulfurs appear to be significantly more exposed for solvent access than the α domain, which may explain why the α-domain stability is greater than that of the β domain. The histidine residue of the S-tag is buried in the folded structure so is less likely to be protonated compared to that in the α domain. Therefore, the expected charge is +5 for the metallated β-rhMT. A single-charge distribution is observed for Cd_3-β-rhMT, ranging from +4 to +8 and centered on +5, matching the expected charge. At pH 5.0, masses of the intermediate metallation states emerge, which become more prevalent by pH 3.5, where these masses dominate the spectrum, and the original masses attributed to Cd_3-β-rhMT disappear. The new distribution attributed to apo-β-rhMT has a strong maximum at +5 and a weak maximum at +7.

Further acidification to pH 1.8 refines the double maxima at +5 (major) and +7 (minor). In the molecular model, the β portion of the protein strand becomes linear and significantly less compact than the metallated structure, with the sulfurs exposed at the protein surface. In addition, the S-tag folds up but does not strongly interact with the β portion of the protein. The predicted charge of +11 is significantly higher than observed, suggesting that the apo-protein still has significant structure, and the two distributions measured in the MS data indicate that there are at least two different conformations present.

Cd_7-αβ-rhMT

At neutral pH, the molecular model of Cd_7-αβ-rhMT demonstrates the characteristic dumbbell shape of mammalian MT, and the additional S-tag peptide portion of the protein is non-interacting with the metallated domains. An aspartic acid (residue 18) in the α domain of this metallated protein, the same as in α-rhMT, is also buried. In addition, the arginine (residue 11) and aspartic acid (residue 15) are buried in this metallated protein just as they are in the metallated β-rhMT. The structure exhibits crevice sites similar to those found in the separate α and β domains. The expected charge is +10 at neutral pH. The observed charge states range from +6 to +9 in which the principal maximum is centered at +8, and a secondary maximum is centered at +6, which is lower than the expected charge, suggesting a more-compact structure than expected. At pH 5.3, the charge distribution widens significantly, and several new masses with lower m/z values, associated with αβ-rhMT bound to seven to eight Cd^{2+}, emerge, indicating the inhomogeneity of the sample. At pH 3.2, when metal loss is observed, the

© 2007 NRC Canada

charge distribution becomes even more complicated, but the overall charge distribution shifts to higher charge values. At pH 2.6, the distribution is still rather complicated, but the charge ranges from +5 to +11 with a single maximum observed at +8, which can be correlated to apo-αβ-rhMT.

When the pH is further reduced to pH 2.2, the spectral resolution improves significantly as only apo-αβ-rhMT is observed. However, a splitting of the charge state distributions is observed such that two maxima are centered at +11 and +7 over the range of +5 to +13 charge states. The molecular model shows the protein strand collapsing into a ball, and the sulfur groups again invert to the protein surface. The predicted charge at acidic pH is +16 (or +17, since the acidic pH borderlines the pKa of the C terminus), so the observed charge states are again lower than this, indicating that more compact structures are present with buried charges.

Cd_7-βα-rhMT

Like αβ-rhMT, at neutral pH, the domains of the molecular model of Cd_7-βα-rhMT are distinct from each other, making the structure appear linear. The dumbbell shape of the βα portion is quite distinct, with the S-tag noninteracting. Again, like metallated α-rhMT, the aspartic acid (residue 18) is buried. However, unlike the metallated β-rhMT structure, the arginine (residue 11) and the aspartic acid (residue 15) are exposed. These differences may play a role in the unfolding of the protein and may be the key differences between this two-domain protein and the reverse-domain αβ-rhMT. Again, the crevice sites are quite prominent, as in the Cd_7-αβ-rhMT structure. The expected charge was +10. The observed charge states range from +6 to +11, where the maximum is centered at +9, which is comparable to the expected charge. The solvent exposure of Cd_7-βα-rhMT is similar to that of Cd_7-αβ-rhMT. No significant changes occur to the spectrum until about pH 3.8 where new charge states emerge, and the overall charge distribution shifts to higher charges centered at about +10. Multiple distributions overlap as expected, given the coexistence of multiple species with adducts. At pH 2.6, several new masses emerge and several disappear, but no major shift in the charge distribution is observed.

At pH 2.2, the spectrum resolves significantly as the masses resolve to a mass attributed to apo-βα-rhMT. A charge distribution ranging from +5 to +13 is observed with two maxima centered at +7 and +11, again indicating compact structures with buried charges and two different protein conformations. Further acidification to pH 1.9 results in no significant changes to the spectrum, and the two-maxima distribution remains. The molecular model shows that the strand maintains a similar conformation to that of the metallated structure with the domains remaining folded, which is a significant difference from αβ-rhMT. This implies that the apo structure may have some inherent structure that facilitates metal binding. Like apo-αβ-rhMT, the predicted charge is +16 (or +17), showing the observed conformation of the protein to be more compact than predicted.

Discussion

Protein folding is important because of the implication of the overall three-dimensional structure on biologically significant function and our understanding of factors that change the structure and hence modify function. The recent use of ESI-MS studies has provided details of intermediates not easily obtained by other methods leading to ESI-MS as one of the foremost contributors to this area (55–58). Our interest in this paper is in the structural role of metals in metalloproteins, especially those proteins with structures dominated by the metal coordination (rather than structures where the metal-free or apo-protein is similar to that of the metallated or holoprotein). We are also interested in the possible structure in the metal-free, apoMT, as these structures may play a role in metallation as well as in functions yet to be understood but involving the redox properties of the large numbers of cysteine thiols present.

The ESI-MS data described here identify first the presence of species with intermediate metal loading (partially demetallated) states. These data can be associated with metal-loading values determined by AAS to construct a titration curve that yields the modified pKa values for the coordinating cysteine thiols. The ESI-MS and AAS data correlate extremely well and show that the Cd-rhMTs demetallate at a significantly lower pH (~3) than the pKa of cysteine (pKa = 8), as expected. We should briefly comment on the appearance of one "extra" cadmium in most of the mass spectra. For many years, these additional cadmium atoms have been deduced from spectroscopic data (changes to the Cd spectrum when loading apo-MT with Cd^{2+}, blurring of NMR signals, and so forth) and in the mass spectral data. Generally, the cause has been attributed to adducts. Very recently, Rigby-Duncan and Stillman (unpublished) have determined that Cd_5-α-rhMT1a exists with 5 unique Cd atoms present at high cadmium loadings. We interpret the minor contribution of five Cd in the α, and eight Cd in the αβ mass spectra as arising from Cd_5-α domains.

The changes in the conformation of the protein, deduced from the ESI-MS charge states, in response to systematic pH changes provide information about the mechanism of acid-induced protein unfolding. The key information is contained in the number and intensity distribution of the ESI-MS charge states for each species that exists at each pH. The observed multiple-charge states result from the protonation of exposed basic amino acids. The presence of different numbers of the protonated groups is an indicator of exposure to solvent such that protein conformations with more positive charge indicate a more unfolded structure, though the charge does not provide an absolute number of exposed basic amino acids. The expectation is that there should be a distribution about a single-charge state, representing the equilibrium distribution of protons across all basic amino acids. As the pH is lowered, the less-basic sites will be protonated and the mean charge state will increase in charge. These changes in charge states are a very sensitive indicator of three-dimensional structure, as they are measured in solution and can help characterize intermediate species from the mass and the degree of compactness from the charge state maximum; data that are difficult to quantify from methods such as NMR and CD spectroscopy.

Since the coordination of the metal ions to MT is essential to maintain its structural integrity, demetallation by acidification results in the unfolding of the protein, becoming much less compact and more susceptible to solvent exposure, thus increasing the extent of protonation of additional

© 2007 NRC Canada

basic sites. This is indeed what is observed for each of the rhMTs in the ESI-MS data. In the proteins studied in this work, it is clear that the additional S-tag sequence will provide several exposed sites that will be available for protonation in addition to the peptide in the region of the metal binding site. The histidine residue in the S-tag does not affect the spectroscopy of the rhMTs, so it is not likely to be involved in the metallated metallothionein, since coordination of a metal ion by the histidine and any of the cysteines would be energetically unfavorable for the protein conformation. Table 2 lists the frequency of the basic residues in the MT sequence. Even at neutral pH, many of these residues are protonated as the maximum intensity charge state is +5 for the fragments and +8/+9 for the βα and αβ peptides (Fig. 3). Indeed, the low pH data (Fig. 4) indicate that only the protonation of the cysteines is new at low pH. The pKa of the cys thiolates is clearly reduced from the usual 8 to between 3.7 (β) and 2.8 (βα) (Fig. 9).

The structures calculated using the Molecular Mechanics/Molecular Dynamics (MM3/MD) methods showed the fully metallated and the metal-free protein, the starting and ending structures expected for the metal-release reaction of metallothionein by acidification. We can correlate these findings with the demetallation sequence determined by Rigby et al. (31, 32) The orientation of the cysteinyl sulfurs in the de novo apo protein can be compared to those in the metallated form to determine any potential preexisting three-dimensional structural features of the apo protein in the aqueous environment that may facilitate the metal binding. Following complete demetallation, the peptide may still have some conserved structure because of the non-covalent interactions, such that conformational changes in the apo-protein may also be observed upon further acidification.

Demetallation events

The Cd-rhMTs begin to demetallate around pH 4.5. They are about 50% demetallated (the point of inflection) at about pH 3 and are completely demetallated at around pH 2.9 or lower. Therefore, the Cd-rhMTs have a narrow range of pH for demetallation (1–1.9 pH values), indicating that the demetallation reaction in metallothionein occurs in a fairly concerted manner involving all coordinating cys thiolates. There are obvious differences between the demetallation reactions of the single domains, α-rhMT and the β-rhMT. First, demetallation of the α domain (~pH 4) occurs at a lower pH than the β domain (~pH 4.5), indicating that the α domain is more stable than the β domain as has been previously found by Jiang et al. (59). Second, the ESI-MS data suggest that because the α domain demetallates over such a narrow range of pH, this accounts for the lack of partially metallated species (Fig. 5), whereas the β domain demetallates over a wider range of pH allowing the one Cd and two Cd species to be observed. When the two domains are linked together in the naturally occurring βα-MT, the two-domain structure has comparable stability to that of the α domain, and these results suggest that it has a slightly higher binding constant than the α domain. Reversing the order of the two domains in the αβ-rhMT has surprisingly little effect, and the stability is comparable to that of α-rhMT and βα-rhMT. The data of the αβ and βα proteins suggest that the β domain demetallates completely first leaving the four-metal α domain intact as the pH is lowered. The data provide an excellent example of the metal-induced pKa lowering effect for coordinated amino acid side chains.

Conformational changes

The fully folded, metallated α-rhMT initially exhibits two conformations, the dominant conformation being more compact, both of which are stable until demetallation begins at pH 3.7. Throughout most of the demetallation reaction, α-rhMT maintains these two conformations, showing the apo-rhMT retains some structure. The calculation of the single parent molecular ions for the apo-α-rhMTs from the double maxima shows that the double maxima in the charge states arise from equilibrium between two protein conformations that exhibit different exposures to the protons. Further acidification causes the complete unfolding of α-rhMT to a single, open conformation, as indicated by the shift in the total charge distribution centered at a single, higher charge, showing that the two conformations were in equilibrium and that acidification shifted the equilibrium to the more-stable conformation under low pH conditions.

The initial conformation of β-rhMT, like α-rhMT, is stable until demetallation. When β-rhMT is fully demetallated, two conformations are observed where the dominant conformation is more compact, much like what is observed in demetallated α-rhMT, indicating some retained structure in apo-β-rhMT because of the hydrogen bonding. Further acidification does not cause any changes in conformation, indicating that the hydrogen-bonding network in β-rhMT is stronger than that of α-rhMT.

The charge states of αβ-rhMT are proportionally higher than that of α-rhMT and β-rhMT (αβ-rhMT is about 1/3 larger in size than both α-rhMT and β-rhMT). αβ-rhMT also has a wider charge distribution than α-rhMT and β-rhMT, demonstrating the heterogeneity of the sample. αβ-rhMT has two different metallated conformations of which the dominant conformation has a more-open structure. A decrease in intensity of the minor conformation as the pH is lowered shows that there is some instability in the protein conformation prior to demetallation. This may be the result of the flexibility of the linker region between the two domains. Complete demetallation of αβ-rhMT results in a single conformation with moderate charge. Further acidification results in complete unfolding, as indicated by the shift of the charge distribution to higher charge states, though a minor conformation does exist.

βα-rhMT has a more-open conformation and is more heterogeneous than αβ-rhMT, as indicated by the higher charge. Metallated βα-rhMT appears to have two conformations with the more-open structure being the dominant form, though the dominant conformation may be less stable prior to demetallation, as seen by the decrease in the intensity of the distribution. Complete demetallation results in the formation of two stable conformations of which the dominant conformation has a more-open structure, as is observed for αβ-rhMT.

The molecular models, which were calculated for each of the fully metallated and metal-free species, show the compact nature of the metal-containing proteins, but surprisingly, predict that demetallated structures should exhibit a

© 2007 NRC Canada

structure that is unrelated to the metals. The calculations of the models of the demetallated proteins are quite compact and in fact represent the structures of the metallated species. The models also identify the basic and acidic amino acids on the surface of the protein; the fraction of basic amino acids protonated will increase from pH 7 to low pH. The observation of multiple charge state distributions at low pH for the single parent molecule provide evidence that the metal-free, apoMT do exhibit a structure as predicted by the MM3/MD calculations.

Conclusions

The metallothionein proteins have been very well characterized by many spectroscopic and analytical techniques. ESI-MS provides a way of determining structural details of intermediate structures that cannot be measured by any other method currently. Structure in the apo-proteins is reported for each of the species lending support for the previous proposals that apo-MT may have a specific function. In the future, rapid measurement of ESI-MS data will allow a more detailed view of the folding and unfolding processes.

BIOGRAPHY / BIOGRAPHIE

Mike Bancroft was born in Saskatoon in 1942. He was educated in Winnipeg and obtained his B.Sc. (Honours) and M.Sc. in Inorganic Chemistry at the University of Manitoba, the latter supervised by H.D. Gesser. After obtaining a Shell Postgraduate Scholarship, he went to the University of Cambridge in 1964 for his Ph.D. studies. Under the supervision of A.G. Maddock, he set up one of the first automated Mössbauer spectrometers and used this early spectrometer to study structure and bonding in inorganic compounds and silicate minerals (in a remarkable collaboration with R.G. Burns). After his Ph.D. in early 1967, he did a postdoc with J.B. Westmore at the University of Manitoba before returning to the University of Cambridge as a Research Fellow at Christ's College and Demonstrator in the Chemistry Department. At that time, he obtained contracts to publish a book and a large review article (with R.H. Platt) on Mössbauer spectroscopy, both of which appeared in 1972 and 1973.

In 1970, he joined the University of Western Ontario Department of Chemistry as an Assistant Professor and rose through the ranks, becoming a Professor in 1974, and Chair in 1986–1991 and 1992–1995. As Director of the Centre for Chemical Physics from 1977 to 1981, he established Surface Science Western in 1979 and the Canadian Synchrotron Radiation Facility (CSRF) in Madison, Wisconsin, in 1980, directing the latter facility until 1999.

Bancroft is best known as a pioneer in the use of gamma ray (Mössbauer specroscopy) and X-ray spectroscopies (using laboratory UV and X-ray sources, as well as synchrotron radiation) to record high-resolution spectra of inorganic molecules, minerals, tribochemical films, and other surfaces. He has published over 400 papers, supervised 39 graduate students and 37 postdoctoral fellows, and worked with several large industries. Most of these excellent students and postdocs have had very productive careers in academia, industry, and (or) government.

He has been recognized for his scholarly work by numerous prizes including Western's Florence Bucke and the Hellmuth Research Awards, and others from the Royal Society of Canada (FRSC), the Canadian Society of Chemistry, the American Chemical Society, the British Chemical Society.

His multidecade long dream and effort to establish a national synchrotron facility (beginning with a UWO proposal headed by Bill McGowan in 1975) became a reality when the Canadian Light Source was built at the University of Saskatchewan, and he became its first Director from 1999 to 2001. For this achievement and his productive research and administrative career, he was appointed as Officer of the Order of Canada in 2003, and awarded two Honorary degrees in 2006.

He has had an active love of classical music as a boy and adult chorister, and as a piano and flute player. Global warming is a current passion, and he is currently serving on a committee at UWO to set up a pan-University Liberal Studies program to bring many disciplines together (including science, music, and religion) to discuss important topics such as global warming and evolution and creation.

Mike Bancroft est né à Saskatoon, en 1942. Il a commencé ses études à l'Université du Manitoba, à Winnipeg, où il a obtenu un baccalauréat ès sciences (avec mention), puis une maîtrise en chimie inorganique, sous la direction de H.D. Gesser. Après avoir obtenu une bourse d'études supérieures de la société Shell, il a entrepris ses études de doctorat à l'Université de Cambridge, en 1964. Sous la direction de A.G. Maddock, il a assemblé l'un des premiers spectromètres Mössbauer automatiques et utilisé ce dernier pour étudier la structure et les liaisons chimiques de composés inorganiques et de silicates minéraux (collaboration remarquable avec R.G. Burns). Après l'obtention de son doctorat, au début de l'année 1967, il a effectué un postdoctorat sous la direction de J.B. Westmore, à l'Université du Manitoba, avant de retourner à l'Université de Cambridge à titre de chercheur universitaire au Christ's College et de chargé de travaux pratiques au Département de chimie. A cette époque, il a obtenu des contrats pour publier un livre et un article de synthèse important (en collaboration avec R.H. Platt) sur la spectroscopie Mössbauer, parus respectivement en 1972 et en 1973.

En 1970, il s'est joint au Département de chimie de l'Université Western Ontario (UWO) à titre de professeur adjoint et a gravi les échelons, obtenant le poste de professeur en 1974 et occupant celui de titulaire de la chaire de 1986 à 1991, et de 1992 à 1995. A titre de directeur du Centre for Chemical Physics, de 1977 à 1981, il a mis sur pied Surface Science Western, en 1979, et le Canadian Synchrotron Radiation Facility (CSRF), à Madison (Wisconsin), en 1980. Il a dirigé le CSRF jusqu'en 1999.

M. Bancroft est surtout connu en tant que pionnier de l'utilisation de la spectroscopie des rayons gamma (spectroscopie Mössbauer) et des rayons X (utilisant aussi bien des sources UV et de rayons X en laboratoire que le rayonnement synchrotron) pour enregistrer des spectres à haute résolution de molécules inorganiques, de minéraux, de films tribochimiques ou d'autres surfaces. Il a publié plus de 400 articles, dirigé 39 étudiants diplômés et 37 boursiers postdoctoraux, et a collaboré avec plusieurs grandes entreprises. La plupart de ces excellents étudiants et boursiers postdoctoraux poursuivent des carrières très productives dans le milieu universitaire, industriel ou gouvernemental.

Il a été reconnu pour son travail scientifique en recevant de nombreux prix dont le Florence Bucke et l'Hellmuth Research de l'UWO, ainsi que d'autres distinctions de la Société royale du Canada (MSRC), de la Société canadienne de chimie, de l'American Chemical Society et de la British Chemical Society. Son rêve, caressé depuis plusieurs décennies, et ses efforts pour créer une installation nationale de rayonnement synchrotron (qui a débuté par une proposition de l'UWO dirigée par Bill McGowan, en 1975) se sont concrétisés lorsqu'on a construit le Centre canadien de rayonnement synchrotron, à l'Université de la Saskatchewan, et qu'il est devenu son premier directeur, de 1999 à 2001. En raison de cette réalisation et de sa carrière productive de chercheur et d'administrateur, il a été nommé officier de l'Ordre du Canada, en 2003, et a reçu deux doctorats honorifiques, en 2006.

Son amour indéfectible pour la musique classique se traduit par le chant choral auquel il s'adonne depuis l'enfance ainsi que par la pratique du piano et de la flfte. Le réchauffement climatique est sa passion actuelle et il fait partie d'un comité à l'UWO qui vise à instaurer un programme de formation générale continue panuniversitaire regroupant de nombreuses disciplines (dont les sciences, la musique et la religion) afin de discuter de sujets importants comme le réchauffement climatique ainsi que l'évolution et la création.

TRIBUTE / HOMMAGE

It is an honour and pleasure to present this tribute to Dr. G. Michael Bancroft, an outstanding scientist and colleague whom I have known for 35 years and for whom I have the greatest respect and admiration. Born in Saskatoon in 1942, Mike Bancroft became intrigued by spectroscopy and the practical application of spectroscopic measurements to determine the structure of matter as an undergraduate chemistry student at the University of Manitoba. (Little did he know at the time but his love affair with spectroscopy would eventually bring him back full circle to the city of his birth where the opening of the Canadian Light Source in 2004, a project he had pioneered for almost 30 years, was the crowning achievement of an outstanding scientific career.) A summer spent in Shier Berman's analytical laboratory in the Division of Chemistry at NRC, following his fourth year and a master's degree at Manitoba supervised by Dr. Hymie Gesser, further convinced him that his future lay in spectroscopy. The discovery by chance of a new book on Mössbauer Spectroscopy — the effect that had been only recently observed by German Nobel Laureate Rudolph Mössbauer in 1959 and named after him — was the final icing on the cake for Mike Bancroft. He wrote to Dr. Ian Smith, now of NRC and at that time a Ph.D. student at Cambridge, about the possibility of a Ph.D. studentship in Cambridge and learnt that Dr. A.G. Maddock, a radiochemist planned, to construct a Mössbauer spectrometer and would welcome a new student to build it. With a Shell Commonwealth Scholarship in hand, Bancroft began his research and within six months had a working spectrometer functioning, at that time one of relatively few automated systems in the world. The novelty of a new technique capable of identifying the form, oxidation state, and coordination number of metal atoms (e.g., 57Fe, ^{119}Sn) in complexes and minerals attracted considerable attention worldwide and produced some very fruitful scientific collaborations. It also brought home a lesson that Mike has practiced for the rest of his career — collaborative research in different scientific fields, with both basic and applied components. In his own words, "…with any new spectroscopy there are opportunities to develop the spectroscopic method, discovering new phenomena and devising simple theories to explain and predict new and previously known features. A good understanding of spectroscopy can then be applied to an enhanced understanding in both basic and applied areas".

Over a 20 year period (1964–1984), Bancroft became one of the world's leading experts in Mössbauer spectroscopy producing some 80 papers, a major 200-page review, and an authoritative 252-page textbook *Mössbauer Spectroscopy: An Introduction for Inorganic Chemists and Geochemists.* His distinctive contributions to this field were threefold: (*i*) the demonstration for the first time of the use of Mössbauer spectroscopy to quantitatively analyse the chemical states of metals (e.g., Fe^{2+}/Fe^{3+}) in mineral silicates; (*ii*) the application of Mössbauer chemical shifts and quadrupole splittings to provide structural and bonding information in coordination and organometallic compounds; (*iii*) the development of a simple point charge model for rationalising and predicting quadrupole splittings in Mössbauer spectra. That Bancroft's pioneering work in the 1960s–1970s on Mössbauer studies of ^{57}Fe in minerals, including Apollo lunar samples, has stood the test of time is shown by the presence of a Mössbauer spectrometer aboard the US Mars probe in December 2003.

Following his return to Canada at the University of Western Ontario in 1970 and with the publication of his major review and book on Mössbauer spectroscopy and its applications in 1972 and 1973, Bancroft began to turn his attention to another spectroscopy: UV and X-ray photoelectron spectroscopy to probe the valence and core levels in organic, organometallic, and non-metal compounds. This work, using a new PES spectrometer at UWO purchased via an NRC grant for a team from the universities of Western Ontario, Toronto, and Windsor, produced a wealth of data on the electronic structures and ordering of molecular orbitals in main group and transition metal organometallics. A major discovery here — the observation for the first time of a new parameter in PES, the ligand field splitting — encouraged Bancroft to look to synchrotron radiation as a much more intense and higher resolution source for his photoelectron work.

Between 1975 and 1979, Bancroft and his group carried out preliminary experiments at the Tantalus Synchrotron at the University of Wisconsin and began to realise the truly exciting opportunities for a new era of high-resolution photoelectron, Auger, and absorption spectroscopy. In 1978 the first small step towards a Canadian synchrotron was made with grants from the Natural Sciences and Engineering Research Council (NSERC) and NRC for a soft X-ray beamline at Madison; the Canadian Synchrotron Radiation Facility (CSRF) was created for the use of all Canadian researchers. This facility, now more than 25 years old, has played a pivotal role in the evolution of synchrotron science in Canada: more than 500 papers have been produced by researchers and 120 faculty, students, and postdoctoral fellows have been users of the suite of beamlines, which was expanded to three in 1995. There is no doubt that Mike Bancroft, as the Scientific Director of the CSRF, was not only instrumental in its success but also integral to the development and growth of a significant community of Canadian synchrotron scientists. Bancroft sparked the idea of a uniquely Canadian beamline at Tantalus and spearheaded successful applications for infrastructure funding from NSERC, NRC, Materials and Manufacturing Ontario (part of the Ontario Centres of Excellence), and his own university, UWO. His personal belief and commitment together with that of his many students, postdoctoral fellows, and colleagues who spent countless hours on the road to Madison and gathering data on the CSRF, ensured that not only did the facility produce a great scientific return on the Canadian investment but it also kept the fire burning ever brighter for a national synchrotron light source at home on Canadian soil.

From a personal scientific point of view, Bancroft's hope that the very intense focussed radiation in the far UV and soft X-ray region, from a synchrotron source, would open up new vistas in high resolution PES, Auger, and absorption spectroscopies was not disappointed. Following up on earlier observations in 1976–1978 of electric field gradient splittings in gas phase PES spectra, Bancroft established using synchrotron radiation that ligand field splitting is a fundamental principle in core level spectroscopy (Phys. Rev. Lett. **67**, 1531 (1991)). Another key discovery was the resonant Auger (Raman) effect in a molecule (Phys. Rev. Lett. **72**, 621 (1994)). The CSRF beams also enabled some very successful collaborations, most notably perhaps on variable energy PES studies elucidating the ordering of molecular orbitals for a wide range

© 2007 NRC Canada

of transition metal organometallics. A seminal review of these insights was published in Accounts of Chemical Research **30**, 213 (1997).

An analysis of Bancroft's publications over the period 1980–1999 reveals that he was incredibly prolific with 227 papers in peer-reviewed journals in a diverse range of projects and fields. Although many important contributions were made to advances in state of the art electron and X-ray spectroscopies, Bancroft also collaborated with geologists and mineralogists, surface scientists, tribologists, and industrial scientists on a spectacular array of innovative multi-disciplinary investigations. Typical of this were pioneering studies on X-ray absorption spectroscopy to investigate mechanisms of tribochemical film formation (Tribology Letters, **3**, 47 (1997)), on the details of surface reactivity and surface states in pyrite minerals as determined by synchrotron XPS (Surface Science Letters, **411**, 321 (1998)), and on the deposition of metallic gold on sulphide mineral surfaces (Geochim. Cosmochim. Acta. **49**, 979 (1985)).

With the success of CSRF and the founding of the Canadian Institute for Synchrotron Radiation in 1990, a new thrust towards a dedicated Canadian synchrotron facility began. Following a peer review decision to select the University of Saskatchewan as the preferred site over Bancroft's home institution UWO, the lobbying effort was led by a team consisting of Mike Bancroft, Dennis Skopik, Dennis Johnson, and George Ivany (then President of U of S). One amusing story from this "dog and pony show" was that on one visit, Mike Bancroft, unknowingly at first, turned up for the presentation wearing shoes of different colours, undoubtedly prompting the comment that he still had his feet in two separate camps! Finally in 1999, following a competition for infrastructure grants from the newly created Canada Foundation for Innovation, the announcement came that the University of Saskatchewan would receive $56.4CAN million (40% of total funding) from CFI to build a third generation 2.9 GeV Canadian Light Source (CLS), with other partners (federal agencies, governments, industry) providing the remainder of the funding. At long last the pioneering efforts and leadership of Mike Bancroft were to be fulfilled! That is not of course the end of the story. Bancroft continued to contribute to the CLS project, seconded from UWO to be the first Director of CLS (1999–2001) in its formative years, member of the Board (1999–2006), and Acting Director of Research from 2001–2004). He saw the opening of the new building in 2001 and the official opening of the facility in October 2004. The last of the instruments at the CSRF will be transferred from Madison to the CLS in 2007–2008, thus completing a 28 year gestation and birth for the synchrotron community in Canada.

Mike Bancroft is an inveterate spectroscopist who has spent his entire research career developing, exploring, and exploiting spectroscopies covering almost half of the electromagnetic spectrum from γ-rays (1.24 MeV) to the far IR (12.4 meV). His major contributions have been to Mössbauer, photoelectron, absorption, and Auger spectroscopies, using both laboratory and synchrotron sources. One of his strengths has been an ability to bring a deep fundamental understanding of spectroscopic principles, tools, and experiments to bear in resolving challenging problems across a wide variety of scientific domains and disciplines. His contributions have gone far beyond physical chemistry and some of his most notable work has been at interfaces with mineralogists, tribologists, and industry.

Recognition for Bancroft's talents and work has come from many national and international bodies going back to the award of an NSERC studentship in 1963–1964. In 1972 he won two important British awards for young researchers: the Harrison Memorial Prize from the British Chemical Society and the Meldola Medal from the Royal Institute of Chemistry. An E.W.R. Steacie Fellowship from NRC quickly followed on his return to Canada from Cambridge. He was elected a Fellow of the Royal Society of Canada in 1979 at the almost unprecedented age of 37, received the Rutherford Memorial Medal of the RSC in 1980, and a Guggenheim Fellowship from the US Guggenheim Foundation in 1982–1983. Other Canadian recognitions include: the Alcan Lecture Award in Inorganic Chemistry (1990), the CIC and Montreal Medals of the Chemical Institute of Canada (1996 and 2002), the Herzberg Award of the Spectroscopy Society of Canada (1991), and two awards from the University of Western Ontario (Florence Bucke Science Prize 1983 and Hellmuth Research Award 1999). He received the Morley Medal of the American Chemical Society in 1998. Finally he was honoured by the Saskatchewan Centennial Medal (2005) and recognized by Canada's highest civilian honour, the Order of Canada in 2003. Mike has also served as President and Vice President of the Canadian Society for Chemistry.

With more than 400 publications in refereed journals, 150 invited talks, and a stellar record of funding from granting agencies, industry, and government programs, Bancroft's work has been acclaimed by peers around the world. Finally, 36 doctoral students have completed Ph.D.s under his supervision, and he has overseen the training of some 33 postdoctoral fellows and research associates, most of whom have gone on to positions in academia and industry.

Although Mike Bancroft was born in Saskatoon in 1942, the son of an accountant, the family moved to Winnipeg soon afterwards and he received his school and early University education (B.Sc., M.Sc. Manitoba) in that city. Following his Ph.D. at Cambridge and three years as a teaching fellow at Christ's College, he returned to Canada in 1970 to take up an assistant professorship at the University of Western Ontario. He rose rapidly to full professor in 1974. In 1975–1976 he spent two 6 month periods as a visiting investigator–scientist in the Synchrotron Group at Madison, Wisconsin, and at the University of Uppsala, Sweden, which had a major impact on the development of his career. Dr. Bancroft played important roles at Western as Director of the Centre for Chemical Physics (1977–1981), then Founder and Director of Surface Science Western (1981–1984), and as Chairman of the Department of Chemistry (1986–1991 and 1992–1995). He was the Scientific Director for CSRF from 1981–1999 when he took on the challenging task of leading the construction phase of the Canadian Light Source to 2004. Mike retired from UWO in 2005 becoming Professor Emeritus. He still operates an active research laboratory at the university.

Despite the recognition he has received and his stature and credibility in the community, Mike has remained a modest, generous, and sincere individual, who continues to set an example to all of us for his spirit of collaboration and commitment.

Arthur Carty

TRIBUTE / HOMMAGE

C'est un honneur et un grand plaisir pour moi de présenter cet hommage à monsieur G. Michael Bancroft, Ph.D., chercheur et collègue exceptionnel que je connais depuis 35 ans, et pour qui j'ai le plus grand respect et une admiration sans bornes.

Né à Saskatoon en 1942, Mike Bancroft s'est intéressé à la spectroscopie et à l'application pratique des mesures spectroscopiques pour déterminer la structure de la matière lorsqu'il était étudiant de premier cycle en chimie à l'Université du Manitoba. (A cette époque, il ne se doutait guère que son histoire d'amour avec la spectroscopie le ramènerait finalement dans la ville qui l'a vu naître pour l'entrée en service, en 2004, du Centre canadien de rayonnement synchrotron, un projet dont il a joué le rôle de précurseur pendant près de 30 ans et qui est le point culminant d'une carrière scientifique exceptionnelle). Un été passé dans le laboratoire de chimie analytique de Shier Berman à la Division de la chimie du CNRC, après sa quatrième année d'études, et l'obtention d'une maîtrise à l'Université du Manitoba, sous la direction de monsieur Hymie Gesser, Ph.D., ont renforcé sa conviction selon laquelle son avenir résidait dans le domaine de la spectroscopie. Pour Michael Bancroft, le comble a été la découverte fortuite d'un nouveau livre portant sur la spectroscopie Mössbauer (l'effet nommé en l'honneur de Rudolph Mössbauer, lauréat allemand du prix Nobel en 1959, qui ne l'avait observé que récemment). Il a donc écrit à Ian Smith, maintenant au CNRC, mais qui était alors étudiant de troisième cycle à Cambridge, au sujet de la possibilité d'une bourse d'études de troisième cycle à Cambridge. Ainsi, il a appris qu'un radiochimiste, A.G. Maddock, Ph.D., planifiait de construire un spectromètre Mössbauer et qu'il accepterait d'accueillir un nouvel étudiant pour ce faire. Grâce à une bourse du Commonwealth de Shell, Bancroft a commencé ses recherches et, en moins de six mois, il a réussi à produire un spectromètre fonctionnel qui, à l'époque, figurait parmi les quelques rares systèmes automatisés au monde. La nouveauté d'une technique qui permet d'identifier la forme, l'état d'oxydation et le nombre de coordination d'atomes métalliques (p. ex. ^{57}Fe et ^{119}Sn) dans des complexes et des minéraux a attiré une attention internationale considérable et donné des collaborations scientifiques très fructueuses. Cette technique a permis également de tirer une conclusion que Mike a mise en pratique dès son retour au pays et tout au cours de sa carrière : faire de la recherche en collaboration dans différents domaines scientifiques et qui comprend des composantes autant fondamentales qu'appliquées. Pour reprendre dans ses propres mots : « Dans le cas de toute nouvelle spectroscopie, il est possible de développer la méthode spectroscopique par la découverte de nouveaux phénomènes et l'élaboration de théories simples pour expliquer et prévoir à la fois les nouvelles caractéristiques et celles déjà connues. Une bonne compréhension de la spectroscopie permet ensuite de mieux comprendre des domaines de recherche fondamentale et appliquée. »

Sur une période de 20 ans (1964-1984), Bancroft est devenu l'un des chercheurs les plus éminents du monde dans le domaine de la spectroscopie Mössbauer, ayant produit quelque 80 articles, une recension importante de 200 pages et un manuel rigoureux de 252 pages intitulé *Mössbauer Spectroscopy: An Introduction for Inorganic Chemists and Geochemists*. Ce domaine de recherche a bénéficié de trois contributions remarquables de sa part : *i*) la démonstration pour la première fois de l'utilisation de la spectroscopie Mössbauer pour analyser quantitativement les états chimiques de métaux (p. ex. Fe^{2+}/Fe^{3+}) dans des silicates minéraux; *ii*) l'application des déplacements chimiques et des dédoublements quadrupolaires Mössbauer pour fournir de l'information sur la structure et les liaisons des composés organométalliques et de coordination; *iii*) l'élaboration d'un modèle simple de charge ponctuelle pour trouver une explication logique aux dédoublements quadrupolaires et les prédire dans les spectres Mössbauer. Les travaux précurseurs de Bancroft effectués dans les années 1960-1970 portant sur des études de l'effet Mössbauer sur le ^{57}Fe dans les minéraux, y compris les minéraux d'échantillons lunaires de la mission Apollo, ont résisté à l'épreuve du temps puisqu'en 2003, la sonde spatiale américaine à destination de Mars était équipée d'un spectromètre Mössbauer.

Aprs son retour au Canada à l'Université Western Ontario, en 1970, et la publication de son importante recension ainsi que de son livre portant sur la spectroscopie Mössbauer et ses applications, en 1972 et 1973, Bancroft a commencé à porter son attention sur un autre type de spectroscopie : la spectroscopie photoélectronique (SPE) des rayons X et UV pour examiner de façon approfondie les couches d'électrons internes et de valence dans les composés organiques, organométalliques et non métalliques. Ces travaux, effectués au moyen d'un nouveau spectromètre photoélectronique situé à l'UWO et obtenu grâce à une subvention du CNRC accordée à une équipe de chercheurs des universités Western Ontario, de Toronto et de Windsor, ont produit une énorme quantité de données sur les structures électroniques et la mise en ordre des orbitales moléculaires dans des composés organométalliques du groupe principal et des métaux de transition. On assiste alors, pour la première fois, à l'observation d'un nouveau paramètre en SPE : le dédoublement du champ des ligands. Une découverte majeure qui a encouragé Bancroft à considérer le rayonnement synchrotron comme une source beaucoup plus intense et de meilleure résolution pour ses travaux en photoélectronique.

Entre 1975 et 1979, Bancroft et son équipe ont effectué des expériences préliminaires au synchrotron Tantalus de l'Université du Wisconsin, et se sont rendu compte rapidement des possibilités vraiment exceptionnelles pouvant mener vers une nouvelle ère de la spectroscopie photoélectronique, Auger et d'absorption à haute résolution. En 1978, la première étape, modeste, vers un synchrotron canadien a été franchie grâce à des subventions accordées par le Conseil de recherches en sciences naturelles et en génie du Canada (CRSNG) et le CNRC pour l'obtention d'une source de faisceau de rayons X mous à Madison; le Canadian Synchrotron Radiation Facility (CSRF) a été créé pour Ltre utilisé par tous les chercheurs canadiens. Cette installation, qui existe depuis maintenant plus de 25 ans, a joué un rôle essentiel dans l'évolution de la science du rayonnement synchrotron au Canada : des chercheurs ont écrit plus de 500 articles sur ce sujet et 120 professeurs, étudiants et boursiers postdoctoraux ont utilisé cette série de faisceaux, passée au nombre de trois en 1995. Il n'y a aucun doute que Mike Bancroft, à titre de directeur scientifique du CSRF, a non seulement joué un rôle important dans la réussite de cette installation, mais a été également un élément indispensable à la création et à la croissance d'une com-

© 2007 NRC Canada

munauté importante de chercheurs canadiens intéressés par le rayonnement synchrotron. Bancroft a fait surgir l'idée d'un faisceau exclusivement canadien à Tantalus et a ouvert la voie à des applications fructueuses qui ont apporté des fonds d'infrastructure provenant du CRSNG, du CNRC, de Materials and Manufacturing Ontario (un des centres d'excellence de l'Ontario) et de sa propre université, l'UWO. Sa croyance et son engagement personnels, jumelés à ceux de ses nombreux étudiants, boursiers postdoctoraux et collègues qui ont passé d'innombrables heures sur la route de Madison à recueillir des données au CSRF, ont fait en sorte que non seulement cette installation a produit un grand retour scientifique sur l'investissement canadien, mais a également entretenu davantage le feu qui mènerait plus tard à l'obtention d'une source de rayonnement synchrotron nationale au Canada.

D'un point de vue scientifique personnel, l'espoir de Bancroft a aussi été nourri en ce sens que le rayonnement focalisé très intense dans les régions des ultraviolets lointains et des rayons X mous, provenant d'une source synchrotron, a ouvert de nouvelles perspectives en spectroscopie photoélectronique, Auger et d'absorption à haute résolution. Pour faire suite aux observations antérieures effectuées en 1976-1978 sur les dédoublements des gradients de champ électrique dans les spectres photoélectroniques en phase gazeuse, Bancroft a démontré, en utilisant le rayonnement synchrotron, que le dédoublement du champ des ligands est un principe fondamental en spectroscopie des couches internes d'électrons (*Phys. Rev. Lett*. **67**, 1531 (1991)). L'effet Auger (Raman) de résonance dans une molécule a été une autre découverte importante (*Phys. Rev. Lett*. **72**, 621 (1994)). Les faisceaux du CSRF ont également permis des collaborations très fructueuses, notamment pour des études portant sur la SPE à énergie variable, qui ont permis d'élucider la mise en ordre des orbitales moléculaires de nombreux composés organométalliques des métaux de transition. Une synthèse fondamentale de ces observations a été publiée dans *Accounts of Chemical Research* **30**, 213 (1997).

Une analyse des publications de Bancroft couvrant la période de 1980 B 1999 révèle qu'il a été incroyablement prolifique, ayant produit 227 articles publiés dans des revues à comité de lecture, pour une variété de travaux et dans divers domaines. Bien que de nombreuses contributions importantes à l'avancement des domaines de pointe de la spectroscopie électronique et de la spectroscopie des rayons X aient été apportées, Bancroft a également collaboré à un éventail impressionnant de travaux de recherche multidisciplinaires novateurs avec des géologues et des minéralogistes, des chercheurs de la science des surfaces, des tribologistes ainsi que des chercheurs du secteur industriel. Des études originales portant sur la spectroscopie d'absorption des rayons X pour examiner les mécanismes de formation d'un film tribochimique (*Tribology Letters* , **3** , 47 (1997)), sur les détails de la réactivité de surface et des états de surface dans les pyrites tels que déterminés par la SPE des rayons X au moyen d'un rayonnement synchrotron (*Surface Science Letters*, **411**, 321 (1998)) et sur le dépôt d'or métallique sur des surfaces de minéraux de sulfure (*Geochim. Cosmochim. Acta.* **49**, 979 (1985)) sont des exemples typiques de ces collaborations.

Grâce au succès remporté par le CSRF et la fondation de l'Institut canadien du rayonnement synchrotron en 1990, un nouvel élan à l'égard d'une installation réservée à un synchrotron canadien a été donné. A la suite d'une décision issue d'une évaluation par les pairs désignant l'Université de la Saskatchewan comme site de choix de l'installation au lieu de l'établissement d'attache de Bancroft, l'UWO, une campagne de lobbying a été menée par une équipe composée de Mike Bancroft, Dennis Skopik, Dennis Johnson et George Ivany (alors président de l'Université de la Saskatchewan). Une anecdote amusante est ressortie de cette « tournée de présentation »… Lors d'une des visites, Mike Bancroft, sans le savoir au départ, est arrivé en portant deux chaussures de couleur différente, ce qui a immanquablement soulevé le commentaire qu'il avait encore les pieds dans deux camps distincts! Finalement en 1999, à la suite d'un concours pour l'obtention de subventions d'infrastructures de la Fondation canadienne pour l'innovation (FCI), créée peu avant, il en est ressorti que l'Université de la Saskatchewan recevrait 56,4 millions de dollars canadiens (40 % du financement total) de la part de la FCI pour la construction d'un centre canadien de rayonnement synchrotron comportant un synchrotron de troisième génération de 2,9 GeV, le reste du financement étant assuré par d'autres partenaires (organismes fédéraux, gouvernements, secteur industriel). Enfin, les efforts de pionnier et le rôle de chef de file de Mike Bancroft allaient porter des fruits! Bien sûr, l'histoire est loin d'Ltre terminée. Bancroft a continué d'apporter son concours à la réalisation du CCRS. Il a été détaché de l'UWO pour Ltre le premier directeur du CCRS pendant ses années de formation (1991-2001), membre du conseil d'administration (1999-2006) et directeur intérimaire de la recherche (2001-2004). Il a assisté à l'ouverture du nouvel immeuble, en 2001, et à l'inauguration officielle de l'installation, en octobre 2004. Le dernier des instruments encore présent au CSRF de Madison sera transféré au CCRS en 2007-2008, ce qui mettra fin à une gestation qui aura duré 28 ans pour la communauté canadienne du rayonnement synchrotron.

Mike Bancroft est un spécialiste invétéré de la spectroscopie qui a passé sa carrière scientifique entière à mettre au point, à explorer et à exploiter des types de spectroscopie couvrant près de la moitié du spectre électromagnétique, des rayons γ (1,24 MeV) aux infrarouges lointains (12,4 meV). Ses principales contributions ont été sur le plan des spectroscopies Mössbauer, photoélectronique, d'absorption et Auger, au moyen de sources en laboratoire et de rayonnement synchrotron. L'une de ses forces est sa capacité d'amener une compréhension fondamentale profonde des principes, des outils et des expériences spectroscopiques, et de les appliquer à la résolution de problèmes difficiles dans une grande variété de domaines et de disciplines scientifiques. Ses contributions ont largement dépassé la chimie physique, et certains de ses travaux les plus remarquables l'ont été grâce à des échanges avec des minéralogistes, des tribologistes et le secteur industriel.

La reconnaissance des talents et du travail de Bancroft provient de nombreux organismes nationaux et internationaux, et remonte à l'obtention d'une bourse d'études du CRSNG, en 1963-1964. En 1972, il a gagné deux prix britanniques importants pour jeunes chercheurs : le prix Harrison Memorial de la British Chemical Society et la médaille Meldola du Royal Institute of Chemistry. Une bourse E.W.R. Steacie du CNRC a suivi rapidement après son retour au Canada de Cambridge. Il a été élu membre de la Société royale du Canada, en 1979, à l'âge presque sans précédent de 37 ans; il a aussi reçu la médaille commémorative Rutherford de la SRC, en 1980, et une bourse de recherche Guggenheim de la Guggenheim Foundation des États-Unis, en 1982-1983. Il compte également d'autres distinctions canadiennes : le prix Alcan pour un exposé en chimie inorganique (1990), les médailles ICC et Montréal de l'Institut de chimie du Canada (1996 et 2002), le prix Herzberg de la Société de spectroscopie du Canada (1991) et deux prix de l'Université Western Ontario (le Florence Bucke,

© 2007 NRC Canada

en 1983, et le Hellmuth Research, en 1999). Il a reçu également la médaille Morley de l'American Chemical Society, en 1998. Finalement, on lui a rendu hommage en lui décernant la médaille du centenaire de la Saskatchewan, en 2005, et la plus haute distinction civile au pays, l'Ordre du Canada, en 2003. Mike a également exercé les fonctions de président et de vice-président de la Société canadienne de chimie.

Ayant à son actif plus de 400 publications dans des revues à comité de lecture, 150 présentations invitées et une fiche longue et édifiante de financement provenant d'organismes de subvention, du secteur privé et des programmes gouvernementaux, Bancroft et ses travaux ont été accueillis de façon élogieuse par ses pairs de partout dans le monde. Enfin, 36 étudiants de troisième cycle ont effectué leur doctorat sous sa direction, et il a veillé à la formation de quelque 33 boursiers postdoctoraux et assistants de recherche, la plupart d'entre eux occupant maintenant des postes dans le milieu universitaire ou le secteur privé.

Bien que Mike Bancroft, fils de comptable, soit né à Saskatoon en 1942, sa famille a déménagé à Winnipeg peu de temps après, où il a effectué ses études jusqu'à l'université (B.Sc. et M.Sc. à l'Université du Manitoba). Après avoir fait son doctorat à Cambridge et enseigné trois ans au Christ's College, il est revenu au Canada en 1970 et a accepté un poste de professeur adjoint à l'Université Western Ontario. Il est devenu rapidement professeur titulaire, en 1974. En 1975-1976, il a passé deux périodes de six mois à titre de chercheur invité : l'une au sein du groupe Synchrotron à Madison (Wisconsin), et l'autre à l'Université Uppsala, en Suède. Ces deux invitations ont eu des répercussions importantes sur l'avancement de sa carrière. M. Bancroft, a joué des rôles importants au sein de l'UWO à titre de directeur du Centre for Chemical Physics (1977-1981), ensuite comme fondateur et directeur de Surface Science Western (1981-1984) et directeur du Département de chimie (1986-1991 et 1992-1995). Il a occupé le poste de directeur scientifique du CSRF, de 1981 à 1999, et a accepté le grand défi de piloter la phase de construction du Centre canadien de rayonnement synchrotron jusqu'à son inauguration, en 2004. Mike a pris sa retraite de l'UWO en 2005, devenant ainsi professeur émérite. Par contre, il assure encore le fonctionnement d'un laboratoire de recherche à l'université.

Malgré la reconnaissance qu'il a reçue ainsi que sa stature et sa crédibilité dans la communauté, Mike demeure un homme modeste, généreux et sincère, qui continue à nous donner l'exemple en matière d'esprit de collaboration et d'engagement.

Nucleophilic substitution reactions of *N*-alkoxyimidoyl fluorides by carbon nucleophiles

Debra D. Dolliver, David B. Delatte, Derek B. Linder, James E. Johnson, Diana C. Canesco, and Jeffrey E. Rowe

Abstract: Nucleophilic substitutions of *N*-alkoxybenzoimidoyl fluorides [*p*-ClArC(F)=NOR; R = CH_3, *i*-Pr] by enolate-type ions have been performed to produce compounds that can exist in two tautomeric forms: the imine form{*p*-ClArC(Y)=NOR [Y = $CH(CN)_2$, $CH(CN)(CO_2Et)$, $CH(CO_2Et)_2$]}or the enamine form {*p*-ClArC(NHOR)=C(R_1)(R_2) [R_1, R_2 = CN, CO_2Et]}. These compounds display varying ratios of imine–enamine tautomerizm in chloroform: the diester compound exists almost solely in the imine form, the dicyano compound exists solely in the enamine form, and the cyano-ester compound exists in both tautomeric forms. Comparison of the imine–enamine equilibrium in chloroform of the cyano-ester compound to an analogue where the *p*-ClAr group has been replaced by a methyl group reveals that the aromatic ring has a significant effect on the imine–enamine distribution. The former exists in both the imine and enamine form, while the latter exists solely in the enamine form. Complete NMR characterization data for the enamine form of $CH_3C(NHOCH_3)=C(CN)(CO_2Et)$ is also reported. The acidity of *p*-ClArC(NHOR)=C$(CN)_2$ is demonstrated by a high degree of dissociation of the enamine proton in DMSO. Substitution reactions of *p*-ClArC(F)=NO*i*-Pr by Grignard reagents (PhMgBr, CH_3MgBr, and PhCCMgBr) have also been performed to produce single geometric isomers of *p*-ClArC(Ph)=NO*i*-Pr, *p*-ClArC(CCPh)=NO*i*-Pr, and *p*-ClArC(CH_3)=NO*i*-Pr. A modified synthesis of *N*-alkoxyimidoyl fluorides, which prevents a competing reaction of the product with the solvent, is reported.

Key words: *N*-alkoxyimidoyl fluoride, enolate ion substitution, Grignard substitution, imine–enamine tautomerizm, carbon acid.

Résumé : On a effectué des réactions de substitutions nucléophiles de fluorures de *N*-alkoxybenzoimidoyle [*p*-ClArC(F)=NOR; R = CH_3, *i*-Pr] par des ions de type énolate pour obtenir des composés qui existent sous deux formes tautomères: la forme imine {*p*-ClArC(Y)=NOR [Y = $CH(CN)_2$, $CH(CN)(CO_2Et)$, $CH(CO_2Et)_2$]} ou la forme énamine {*p*-ClArC(NHOR)=C(R_1)(R_2) [R_1 = R_2 = CN, CO_2Et]. Dans le chloroforme, ces composés présentent des rapports divers de tautomérie imine–énamine; le composé dicyano existe uniquement sous la forme énamine alors que le composé cyano-ester existe sous les deux formes tautomères. Une comparaison de l'équilibre imine–énamine dans le chloroforme du composé cyano-ester avec celui observé avec un analogue dans lequel le groupe *p*-ClAr a été remplacé par un groupe méthyle révèle que le noyau aromatique joue un rôle important sur la distribution imine–énamine. Le premier existe dans les deux formes imine et énamine alors que le deuxième n'existe que sous la forme énamine. On rapporte aussi les données RMN pour une caractérisation complète de la forme $CH_3C(NHOCH_3)=C(CN)(CO_2Et)$. L'acidité du composé *p*-ClArC(NHOR)=C$(CN)_2$ est démontrée par le degré élevé de dissociation du proton énamine dans le DMSO. On a aussi réalisé des réactions de substitutions en solution du *p*-ClArC(F)=NO*i*Pr par des réactifs de Grignard (PhMgBr, CH_3MgBr et PhCCMgBr) qui ont conduit aux isomères géométriques uniques *p*-ClArC(Ph)=NO*i*Pr, *p*-ClArC(CCPh)=NO*i*Pr et *p*-ClArC(CH_3)=NO*i*Pr. On a aussi mis au point une synthèse modifiée des fluorures de *N*-alkoxyimidoyles qui élimine une réaction compétitive avec le solvant.

Mots-clés : fluorure de *N*-alkoxyimidoyle, substitution par un ion énolate, substitution de Grignard, tautomérie imine–énamine, carbone acide.

Introduction

Nucleophilic addition–elimination reactions at the C=O bond of acid halides are commonplace in synthetic schemes. This type of reaction has also been studied in imidoyl halides (1), hydrazonyl halides (2), and *N*-alkoxyimidoyl halides (3). These latter reactions, however, have been limited because of the diminished electrophilicity of the azomethine carbon in these compounds and the lability of the N–O bond. In addition, there are synthetic challenges posed because of the existence of possible *E*–*Z* isomeric mixtures around the C=N bond (4). To enhance the electrophilicity of the C=N bond of *N*-alkoxyimine compounds, Lewis acids have sometimes been included in the reaction medium (5). *N*-Alkoxyimidoyl chloride (**2**) and bromide (**3**) compounds (Fig. 1) are known to undergo nucleophilic substitution reactions with nucleophiles, such as amines, amide ions, and alkoxide ions, but these types of substitution reactions are relatively sluggish and are viewed as having limited synthetic utility (3). It has been found, however, that *N*-alkoxyimidoyl fluorides (**1**) are much more electrophilic than their bromo- or chloro-analogues (**2** or **3**) and will undergo nucleophilic attack by methoxide ion at an accelerated rate (3*a*). The tetrahedral intermediate formed from the nucleophilic attack of methoxide then rapidly loses the fluoride ion to reform the C=N bond faster than it undergoes rotation to another conformer. Therefore, the stereochemistry of the product from this reaction is retained exclusively when starting from the *Z* isomer and is predominately retained when starting from the *E*-isomer. This is due to the fact that the tetrahedral intermediate first formed by methoxide attack in the case of the *Z* isomer (**A** in Scheme 1) already has a pair of electrons anti-periplanar to the fluoride leaving group. In the *E*-isomer case, the first-formed intermediate (**B**) must undergo rotation to align lone pair electrons in an anti-periplanar configuration. The rotational barrier 1 is lower than rotational barrier 2, and conformer **B** therefore predominately rotates over the lower rotational energy barrier to a conformation that leads to retained stereochemistry (3*a*). Owing to the enhanced electrophilicity of (*Z*)-*N*-alkoxyimidoyl fluoride compounds, their ability to undergo a methoxide substitution at a much faster rate, and the retention of stereochemistry demonstrated in the product, it was felt that they might be good candidates for synthetically useful routes to specific geometric isomers of oxime ethers.

This paper discusses the nucleophilic substitution of *N*-alkoxyimidoyl fluoride compounds (**1a** and **1b**) by enolate-type anions and Grignard reagents.

The *N*-alkoxyimine or oxime ether moiety has become important in pharmaceutical compounds and as a starting material for the synthesis of asymmetric amines, which are also widely incorporated in pharmaceuticals and agrochemicals (4–6). It has been found that the geometric stereochemistry around the C=N bond (*E* vs. *Z*) has a direct effect on the stereochemical purity of an asymmetric amine derived from an oxime ether (5, 7). Many methods for the synthesis of oximes and oxime ethers produce either a mixture of geometric isomers or allow only the preparation predominantly of the thermodynamically more stable isomer (5, 8). Oftentimes, subsequent separations must be performed to prepare a single geometric isomer (5, 6*b*). This paper discusses a technique by which a specific geometric stereoisomer of an oxime ether may be prepared even when there is little difference in the thermodynamic stability of the two geometric isomers. This can be accomplished by nucleophilic substitution of an *N*-alkoxyimidoyl fluoride by a Grignard reagent. In addition, the nucleophilic substitution reaction of *N*-alkoxyimidoyl fluorides by enolate-type anions will be discussed. The compounds produced by this technique are interesting in that they display varying degrees of imine–enamine tautomerizm.

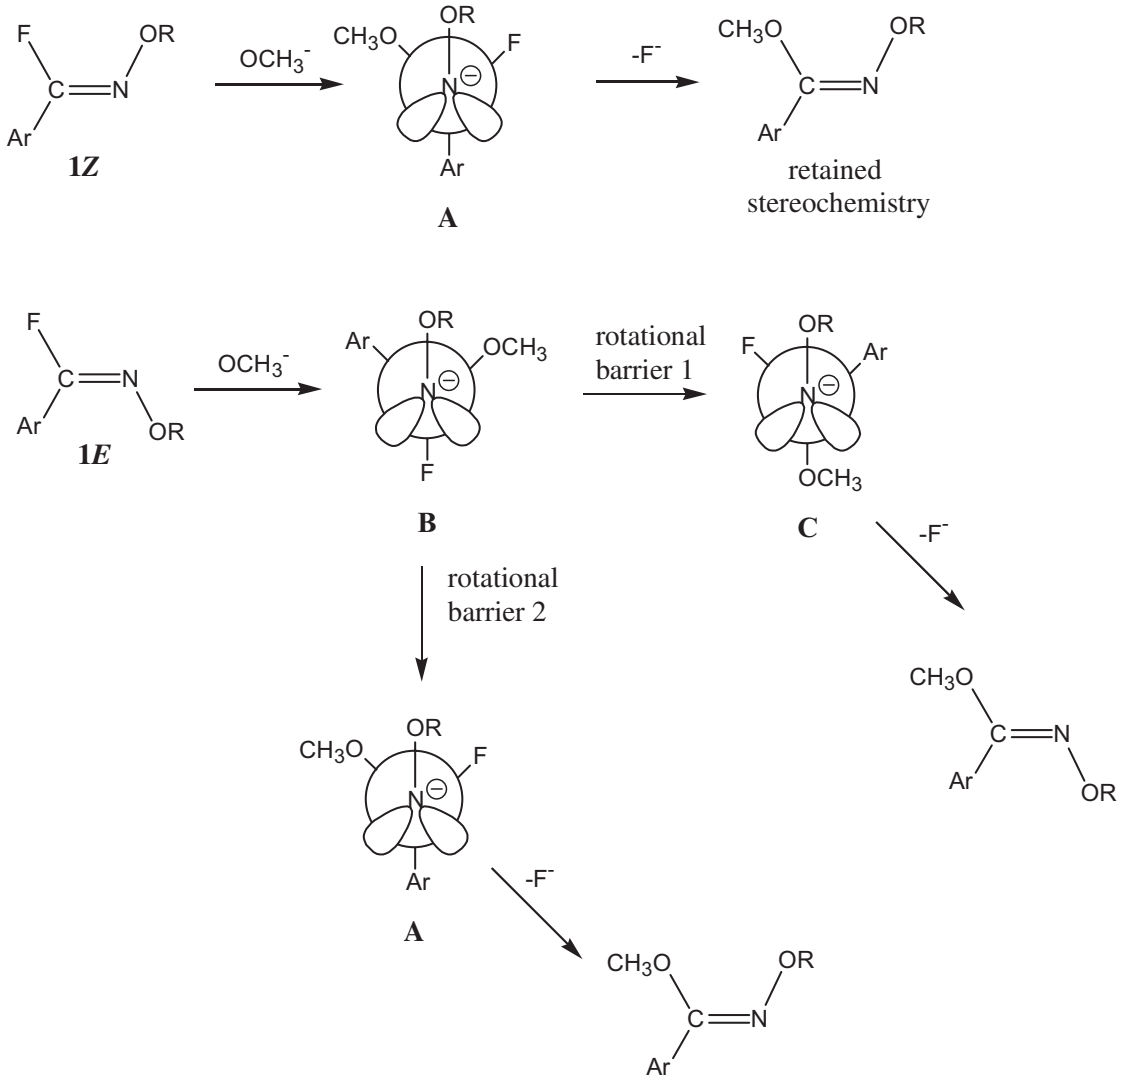
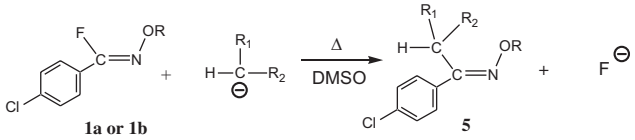
Results and discussion

Enolate-type ion substitution of *N*-alkoxyimidoyl fluorides



The substitution of the fluorine in (*Z*)-*N*-alkoxy-4-chlorobenzenecarboximidoyl fluoride (**1a** and **1b**) with different enolate-type ions to produce **5** was achieved in moderate yields (Scheme 2). The target molecules of this study are interesting in that they contain three electron-withdrawing groups attached to a single carbon (R_1, R_2, and the oxime ether moiety). Related molecules have been previously synthesized by methods similar to those discussed in this paper with comparable yields. Methanetricarboxylic esters have been made by acylating malonates with various acid chlorides with yields that vary from 30% to 90% (9). In addition, trifluoromethyl imidoyl chlorides have been acylated with lithium enolates (1*a*, 1*b*).

The methine carbon attached to the three electronegative groups in these molecules is felt to have a fairly acidic proton and would exhibit a pKa range similar to that of related compounds. By making comparisons to similar compounds, one may begin to predict pKa ranges for **5a**–**5d** (Table 1). The acidities of **5c** and **5d** were qualitatively demonstrated by low integration for this proton's signal when these compounds were dissolved in d_6-DMSO. This indicates that these compounds are partially ionized in the case of **5d** and extensively ionized in the case of **5c** and would suggest that **5c** and **5d** have pKa's around –1.5 (pKa of protonated DMSO) (12).



In similar compounds, which contain a carbon attached to three electron withdrawing groups, keto–enol and imine–enamine tautomerizm is seen (1*a*, 1*b*, 13). One would also expect the compounds described in this paper to display

some degree of tautomerizm. Figure 2 displays the theoretically possible tautomeric forms for **5a**, **5b** and **5c**, and **5d**. In addition, the imine tautomers of **5a**–**5d** could theoretically exist in either the *E* or *Z* isomeric form around the C=N bond.

To determine the tautomeric form(s) of each compound, NMR experiments were performed. ^{1}H NMR and ^{13}C NMR of compound **5a** in $CDCl_3$ showed primarily one species in solution. No appreciable signal in the region expected for an enamine (N–H) proton was seen. There was an indication of a methine proton at δ 5.17, which integrated for one proton. In addition, a DEPT experiment in $CDCl_3$ indicated the presence of a C–H bond for the signal at δ 51.73. From these experiments, it appears that compound **5a** exists in the imine tautomeric form in chloroform solution.

^{1}H NMR of compounds **5c** and **5d** also show these molecules to exist in predominantly one tautomeric form in chloroform solution; however, they appear to be in the enamine form rather than the imine form. There is no discernable resonance in the region expected for the methine proton of the imine tautomer. Compound **5c** was so sparingly soluble in $CDCl_3$ that ^{13}C NMR could not be effectively run. Additional ^{1}H NMR and ^{13}C NMR studies on these compounds were therefore run in d_6-DMSO. ^{1}H NMR of compound **5c** in d_6-DMSO revealed no appreciable signal for this acidic proton (either in the enamine or imine tautomeric form). ^{1}H NMR of compound **5d** in d_6-DMSO revealed a signal for the N–H proton of the enamine form (δ 12.09), but it only integrated for 0.7 protons. The absence of this proton signal for

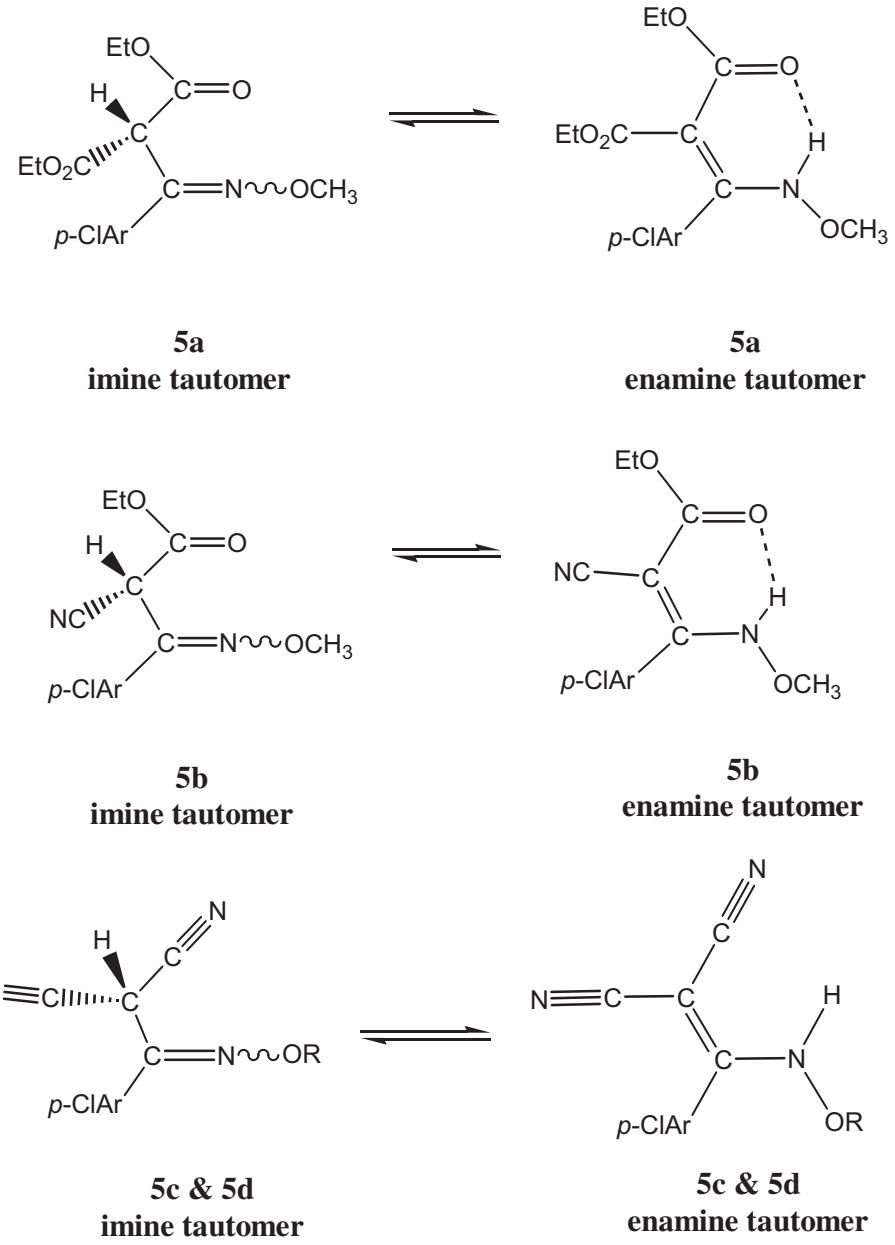
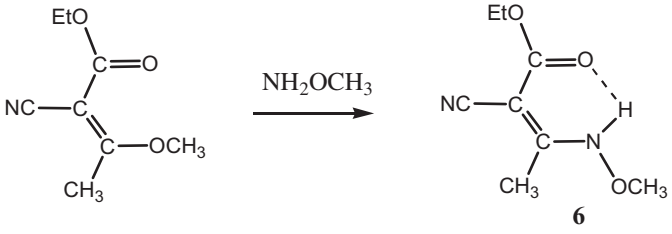
5c and the low integration value for this proton in **5d** could be due to ionization to some degree of this fairly acidic proton. Protonated DMSO has a pKa value of –1.5 (12). It is estimated by comparison with similar compounds that compound **5c** would have a pKa approaching that of methyl-2,2-dicyanoacetate (Table 1, entry 7), which is –2.8. If this is the case, this low or negligible integration value for the N–H proton may actually represent a partial loss of this proton to the solvent. Since **5d** was more soluble in chloroform, it was possible to run the ^{13}C NMR on this compound. The ^{13}C NMR of **5d** showed two signals for the cyano carbons. This observation is consistent with the compound being in the enamine tautomer rather than the imine form. If **5d** existed in the imine form, the two cyano carbons signals would have to be explained by the presence of *Z* and *E* isomers. This explanation is not plausible, since the ^{13}C NMR spectrum of **5d** shows only two signals for the isopropyl carbons.

^1H NMR of compound **5b** in $CDCl_3$ reveals a mixture of the two tautomeric forms. ^{13}C NMR of **5b** in $CDCl_3$ reveals 21 distinct signals, while there are only 11 unique carbons in the molecule. Every non-aromatic carbon appears as two signals, and all of the aromatic carbons are also doubled up except for one quaternary carbon that could not be located. This too suggests that two distinct tautomeric species are present in solution. All the NMR studies suggest that molecule **5b** exists in two predominant tautomeric forms in chloroform solution, and one is the imine form. While the enamine N–H proton resonance for **5c** in chloroform is at δ 8.15, and the proton of interest in compound **5b** has a resonance of δ 11.69, it is not reasonable to rule out the enamine tautomeric form for **5b** because of the rather large difference in the chemical shift. It should be recognized that there are enhanced intramolecular H-bonding capabilities through a six-membered ring system in the enamine tautomer of **5b** compared with that of the enamine tautomer of **5c**, which could account for large differences in the chemical shift of an N–H proton in these species.



To help solve this problem, X-ray crystallography was performed on a single crystal of **5b**. This showed that **5b** existed in the enamine form in the solid state. This crystal structure shows the intramolecular H-bonding seen in other similar enamine compounds capable of forming a six-membered cyclic N–H···O=C interaction (14).

Interestingly, a similar compound (**6**) has been previously made by reacting ethyl-α-cyano-β-methoxycrotonate with methoxylamine (15) (Scheme 3). Only the chemical shift of the N–H proton of **6** was reported (11.64 ppm in $CDCl_3$) in this work. As compound **6** was reported to only exist in the enamine tautomer in $CDCl_3$ solution, and as the initial report on the synthesis of this compound only supplied limited NMR data, **6** was synthesized in our lab, and its ^1H NMR and ^{13}C NMR data were recorded. Both the ^1H NMR and ^{13}C NMR spectra of **6** showed no evidence of the imine tautomer in solution. Therefore, it appears that the aromatic ring in **5b** has a significant effect on the imine–enamine equilibrium. While both tautomers of **5b** have resonance with the aromatic ring and are thereby stabilized by this resonance effect, the relative stabilizing effect must be more significant in the imine tautomer.



Comparisons with ^1H NMR resonances of other known enamine N–H protons were also made. It appears that the N–H chemical shift for compounds capable of a six-membered cyclic intramolecular H-bond can be found from δ 9.18–15.90 in $CDCl_3$ (13*a*, 13*f*) and δ 9.3–11.99 in d_6-DMSO (13*c*). All of the compounds used for comparison display intramolecular H-bonding through a six-membered cyclic structure. The N–H chemical shift for **5b**, which can form the six-member cyclic intramolecularly H-bonded

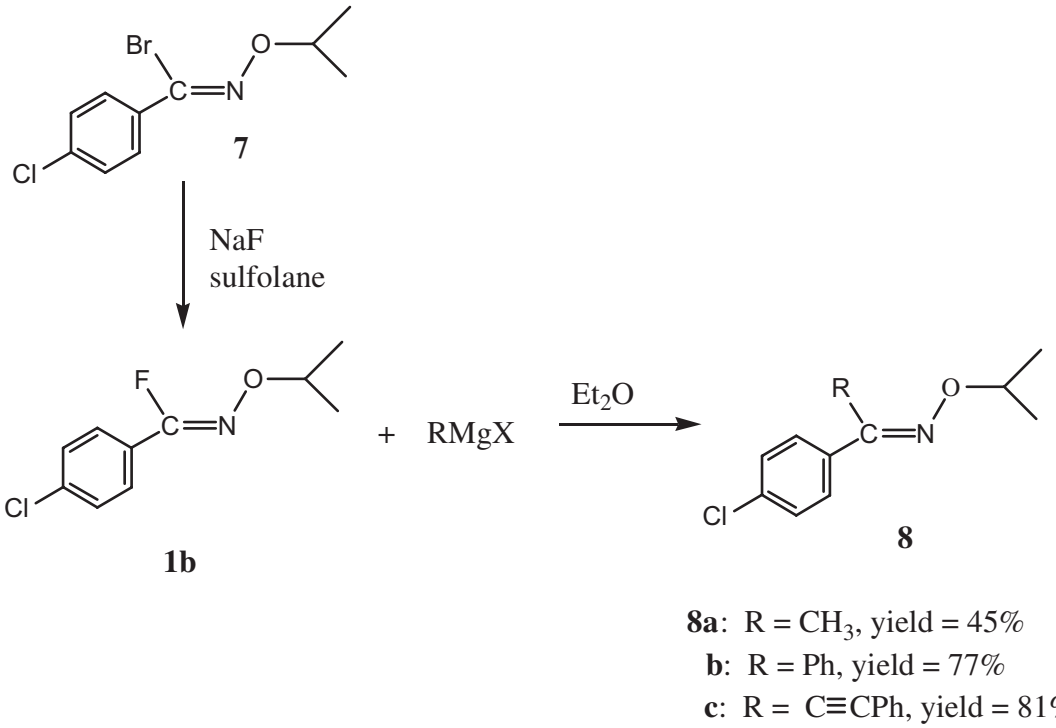
Scheme 3. Synthesis of a similar enamine compound (15).



structure is δ 11.69 in $CDCl_3$. This value falls in the middle of those found for the comparison structures. For **5c** and **5d**, the N–H chemical shifts were found to be δ 8.15 and 8.56, respectively, in $CDCl_3$ and δ 12.09 for **5d** in d_6-DMSO. These values fall outside the ranges seen for the structures capable of the intramolecular hydrogen bonding through a six-membered ring, but are still suggestive of a highly deshielded proton, which would be expected for a proton in the enamine form.

Grignard reagent substitution of (*Z*)-*N*-isopropoxy-4-chlorobenzenecarboximidoyl fluoride

Nucleophilic substitution of hydroximates [RC(OR')=NOR', **4**] by Grignard reagents have previously been reported (16). This same type of reaction was initially attempted with **1a**; however, it was found that a competing nucleophilic attack of the Grignard reagent on the *O*-methyl group appeared to account for about 50% of the reaction process. Therefore, the alkyl group attached to oxygen was changed to an isopropyl group to slow down the S_N2 attack at this site. In previous work (17), hydroximoyl fluorides were prepared by heating a hydroximoyl bromide with potassium fluoride in

© 2007 NRC Canada

Scheme 4. Route to nucleophilic substitution of **1b** by a Grignard reagent.

c: R = C≡CPh, yield = 81%

DMSO. Under these reaction conditions a methyl *O*-methylbenzothiohydroximate was also formed by reaction of the hydroximoyl fluoride with DMSO. In the present work, (*Z*)-*N*-isopropoxybenzenecarboximidoyl bromide (**7**) was reacted with sodium fluoride in sulfolane to make (*Z*)-*N*-isopropoxybenzenecarboximidoyl fluoride (**1b**). This new synthetic procedure prevents subsequent reaction of the hydroximoyl fluoride with the solvent. Grignard reagents were then reacted with **1b** to make **8a**–**8c** with the yields indicated in Scheme 4.

By NMR and GC–MS, these reactions yield only one geometric stereoisomer of the product (**8a**–**8c**). Substitution of (*Z*)-*N*-methoxybenzenecarboximidoyl fluoride (**1a** and **1c**) by methoxide is known to also yield only one isomer: the product isomer with retained stereochemistry around the C=N bond. This reaction is believed to go through an addition–elimination step in which the nucleophilic attack by methoxide is rate-limiting. The stereochemistry is maintained in this process, despite the formation of a single bond between carbon and nitrogen in the intermediate. This has been found to be due to high barriers to rotation around the C–N bond of the intermediate compared with the barrier for elimination of the fluoride ion from the intermediate (3*a*). With this in mind, it is likely that the isomer produced by nucleophilic substitution of the fluoride of **1b** by a Grignard reagent is also the one with retained stereochemistry.

To demonstrate the difficulty in preparing a single geometric isomer of an oxime ether where the substituents on carbon are similar, the *O*-methyloxime of 4-chlorobenzophenone and 4-nitrobenzophenone were prepared by a commonly used method (5*c*, 18). The reaction of 4-chlorobenzophenone with methoxylamine hydrochloride in pyridine yielded both the *E* and *Z* isomers, which were only discernable by ^{13}C NMR spectra with the two signals for the OCH_3 carbon of each isomer at 61.89 and 61.86 ppm. Because of the poor resolution of these two isomers by 300 MHz NMR, it was difficult to determine the absolute percentages of each isomer. Additionally, these isomers were inseparable by TLC on silica or by GC–MS and therefore would present a considerable challenge for isolation of a single geometric isomer. The reaction to produce the *O*-methyloxime of 4-nitrobenzophenone by the same method also yielded two geometric isomers. These isomers were almost resolvable by 300 MHz ^1H NMR with OCH_3 chemical shifts of 4.04 and 4.00 ppm in a 62%:38% ratio by integration. These isomers were also almost resolvable by GC–MS and yielded approximately the same ratio composition with the first eluted isomer comprising 61%–62% of the mixture. Again, these two isomers did not separate well on TLC and would prove difficult to isolate from each other, thereby demonstrating the potential utility of the substitution of an *N*-methoxyimidoyl fluoride by a Grignard reagent.

Conclusions

N-alkoxyimidoyl fluorides have undergone nucleophilic substitution reactions with enolate-type anions and with Grignard reagents. The products of the enolate-type anion substitutions are compounds that contain a single methine carbon that bears three electron withdrawing groups. The proton on this carbon is therefore believed to be fairly acidic, and these compounds display varying degrees of imine–enamine tautomerizm and ionization in chloroform and DMSO. The products derived from the nucleophilic substitution of *N*-alkoxyimidoyl fluorides by Grignard reagents result in a single geometric configuration about the C=N bond. Comparison studies using common methods to synthesize similar oxime ethers demonstrate that the other methods

© 2007 NRC Canada

would result in mixtures of both geometric isomers, which would prove difficult to separate.

Experimental section

General procedure

All chemicals used in this research were reagent-grade except as noted. The ^{1}H NMR and ^{13}C NMR spectra were performed on either a Varian Mercury 300 MHz spectrometer or a Bruker AC 300 MHz NMR spectrometer using either $CDCl_3$ or d_6-DMSO. Melting points were determined on a Thomas–Hoover capillary melting-point apparatus and are uncorrected. IR spectra were either determined from Nujol mulls between sodium chloride plates for solids or neat on sodium chloride plates for liquids on a Nicolet Magna IR 560 spectrometer or a PerkinElmer 16 PC FTIR over the frequency range of 4000–600 cm^{-1}. Elemental analyses of the new compounds were performed at Midwest Microlab, Indianapolis, Inc. Exact masses were obtained by the Central Science Laboratory at the University of Tasmania.

Preparation of diethyl 2-[2-aza-1-(4-chlorophenyl)-2-methoxyvinyl]propane-1,3-dioate (5a)

Lithium diisopropylamide (2.0 mol/L in heptane, ethylbenzene, and tetrahydrofuran) (6.3 mL, 0.013 mol) was added dropwise with stirring to diethylmalonate (2.67 g, 0.017 mol) under nitrogen purge. (*Z*)-*O*-Methyl-4-chlorobenzohydroximoyl fluoride (**1a**) (1.50 g, 0.0080 mol) in dimethyl sulfoxide (10 mL) was added dropwise to the flask. The reaction mixture was heated under nitrogen at 115 °C for 27 h. The reaction mixture was cooled to room temperature, acidified with concentrated HCl, and placed in a continuous liquid–liquid extractor with chloroform for 50 h. The chloroform was then removed by rotary evaporation to yield a dark brown liquid. Purification was performed on silica gel, 200–300 mesh, with an eluent progressively changing from 1:10 $CHCl_3$:hexane to 7:3 $CHCl_3$:hexane. This yielded a very light yellow viscous oil (1.07 g, 41%). IR (neat); 2986, 2933, 1754, 1739, 1600, 1489, 1370, 1152 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.55 (d, 2H, *J* = 9.0 Hz, ArH), 7.33 (d, 2H, *J* = 9.0 Hz, ArH), 5.17 (s, 1H, CH), 4.16 (q, 4H, *J* = 7.2 Hz, OCH_2), 4.01 (s, 3H, OCH_3), 1.15 (t, 6H, *J* = 7.2 Hz, OCH_2CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 165.96 (C=O), 149.32 (C=N), 135.16 (Ar C), 132.51 (Ar C), 129.53 (Ar CH), 128.32 (Ar CH), 62.49 (OCH_3), 61.96 (OCH_2), 51.73 (CH), 13.82 (CH_2CH3). Anal. calcd. For $C_{15}H_{18}NO_5Cl$: C, 54.97; H, 5.54; N, 4.27; Cl, 10.82. Found: C, 54.74; H, 5.59; N, 4.19; Cl, 10.73.

Preparation of ethyl 4-aza-3-(4-chlorophenyl)-2-cyano-4-methoxybut-3-enoate (5b)[2]

Lithium diisopropylamide (2.0 mol/L in heptane, ethylbenzene, and tetrahydrofuran) (17.5 mL, 0.035 mol) was added dropwise with stirring to ethylcyanoacetate (8.02 g, 0.071 mol) under nitrogen purge. (*Z*)-*O*-Methyl-4-chlorobenzohydroximoyl fluoride (**1a**) (1.68 g, 0.0090 mol) in dimethyl sulfoxide (5 mL) and hexane (3 mL) was added dropwise to the flask. The reaction mixture was heated under nitrogen at 80 °C for 3 h. The reaction mixture was cooled to room temperature, acidified with concentrated HCl, and placed in a continuous liquid–liquid extractor with chloroform for 24 h. The chloroform was then removed by rotary evaporation to yield a dark brown liquid. Purification was performed on silica gel, 200–300 mesh, with an eluent progressively changing from 3:7 $CHCl_3$:hexane to 1:1 $CHCl_3$:hexane. This yielded very light yellow crystals (1.82 g). These crystals were recrystallized in 2:1 hexane: chloroform to yield whitish crystals (1.41 g, 56%). IR (nujol): 3198, 2203, 1666, 1547, 1461, 1375 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 11.69 (s, 0.6 H, NH), 7.60–7.38 (m, 4 H, ArH), 5.32 (s, 0.2 H, CH), 4.26 (q, 2H, *J* = 6.9 Hz, OCH_2), 4.09 (s, 0.7 H, OCH_3), 3.56 (s, 2.3 H, OCH_3), 1.41–1.23 (m, 3H, CH_2CH_3). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 167.64 (C=O), 167.16 (C=O), 162.54 [C=C(CN)(CO_2Et)], 145.00 (C=N), 137.09 (Ar C), 136.18 (Ar C), 130.76 (Ar C), 129.74 (Ar CH), 128.85 (Ar CH), 128.70 (Ar CH), 127.59 (Ar CH), 117.16 (CN), 112.87 (CN), 71.50 [C=C(CN)(CO_2Et)], 64.84 (OCH_3), 63.44 (OCH_2), 63.03 (OCH_3), 61.18 (OCH_2), 35.68 (CH), 14.28 (CH_2CH_3), 13.81 (CH_2CH_3).[2] A DEPT experiment showed only C–H attachments belonging to the aromatic ring except for a single C–H bond belonging to the resonance at δ 35.69, indicative of the imine tautomer. Anal. calcd. For $C_{13}H_{13}N_2O_3Cl$: C, 55.62; H, 4.67; N, 9.98; Cl, 12.63. Found: C, 55.67; H, 4.70; N, 9.94; Cl, 12.66.

Preparation of [2-aza-1-(4-chlorophenyl)-2-methoxyvinyl]methane-1,1-dicarbonitrile (5c)

A sodium ethoxide solution was prepared by dissolving sodium metal (1.63 g, 0.071 mol) in absolute ethanol (30 mL). Malononitrile (5.02 g, 0.076 mol) was placed in the sodium ethoxide solution. The mixture was stirred for approximately five minutes, and a visible solid formed in the flask. The remaining ethanol was removed under a vacuum with heating for 1 h. (*Z*)-*O*-Methyl-4-chlorobenzohydroximoyl fluoride (**1a**) (3.25 g, 0.017 mol) and the freshly prepared sodium salt of malononitrile (4.55 g, 0.052 mol) were placed in a 25 mL round-bottomed flask. The flask was sealed and heated to 90 °C with periodic venting at the beginning of the reaction. At 3.5 h, another portion of the dry sodium salt of malononitrile (1.52 g, 0.017 mol) was added. The reaction mixture was then heated at 90 °C for an additional 50 h. The reaction mixture was then cooled to room temperature, placed in 100 mL of ice-cold water, and acidified with concentrated HCl. The reaction mixture was placed in a liquid–liquid continuous extractor with chloroform for 72 h. The chloroform was then removed by rotary evaporation. The crude yield was 3.54 g of light brownish-yellow solid. This solid was recrystallized in 2:1 hexane:chloroform to yield a slightly yellow powder (1.88 g, 46%). IR (nujol) 2217, 2200, 1458, 1377 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.15 (br s, 0.8 H, NH), 7.51–7.41 (m, 4H, ArH), 3.89 (s, 3H, OCH_3). ^{1}H NMR (300 MHz, *d*6-DMSO) δ: 7.63 (s, 4H, ArH), 3.84 (s, 3H, OCH_3). ^{13}C NMR (75.5 MHz, *d*6-DMSO) δ: 162.23 (C–N), 136.63 (Ar C), 130.59 (Ar CH), 128.67 (Ar CH), 127.60 (Ar C), 116.16 (CN), 64.17 (OCH_3), 46.69 [C($CN)_2$]. A DEPT experiment performed on **5c** revealed no C–H attachments other than those seen in the aromatic system. Anal. calcd. for $C_{11}H_8N_3OCl$: C, 56.55; H, 3.45; N,

[2] This ^{13}C NMR is corrected from a previous erroneous report in ref. 14 where an additional resonance frequency of δ 43.93 is reported.

Preparation of [2-aza-1-(4-chlorophenyl)-2-isopropoxyvinyl]methane-1,1-dicarbonitrile (5d)

Malononitrile (1.69 g) was added to a solution of sodium methoxide prepared from 0.545 g (0.0237 mol) of sodium in absolute ethanol (20 mL). After evaporation of the ethanol, a portion of the solid sodium salt of malononitrile (1.5 g, 0.023) was added to O-isopropyl-4-chlorobenzohydroximoyl fluoride (1.2 g, 0.0056 mol) in a sealed flask. The flask was heated to 90 °C in a sand bath with periodic venting. After three hours, the remaining portion of the sodium salt was added to the flask, and the reaction was heated for 50 h at 90 °C. The resulting dark solid was extracted with chloroform (3 × 100 mL). Evaporation of the chloroform gave 1.36 g of a yellowish solid. One recrystallization from 2:1 hexane–chloroform gave a light yellow solid (0.85 g, 62%). Several additional recrystallizations from hexane–chloroform gave a light yellow powder 138–139 °C (dec). IR (nujol): 3190, 2217, 2198,1581, 1541 cm^{-1}. ^1H NMR (300 MHz, $CHCl_3$) δ: 1.33 (6H, d, J = 6 Hz, $(CH_3)_2$), 4.27 (1H, m, CH), 7.40 (2H, d, J = 9 Hz, ArH), 7.48 (2H, d, J = 8.4 Hz, ArH), 8.56 (1H, s, NH). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 19.72 [$CH(\underline{C}H_3)_2$], 52.02 [$\underline{C}(CN)_2$], 80.35 [$\underline{C}H(CH_3)_2$], 114.36 (CN), 116.07 (CN), 117.58 (ArC) 127.27 (ArC), 129.65 (ArCH), 129.93 (ArCH), 139.06 (=CNH). ^1H NMR (300 MHz, d_6-DMSO) δ: 1.30 [6H, d, J = 6 Hz, $(CH_3)_2$)], 4.30 (1H, septet, J = 6 Hz, CH), 7.40 (4H, s, ArH), 12.09 (0.7H, broad s, NH). ^{13}C NMR (75.5 MHz, d_6-DMSO) δ: 19.57 [$CH(\underline{C}H_3)_2$], 47.11 [$\underline{C}(CN)_2$], 78.70 [$\underline{C}H(CH_3)_2$], 128.25 (Ar C), 128.93 (ArCH), 130.94 (ArCH) 136.72 (ArC), 163.20 [$\underline{C}$=C(CN)$_2$]. (Found: $M^{+\bullet}$, 261.06685. $C_{13}H_{12}ClN_3O$ requires $M^{+\bullet}$, 261.06688).

Preparation of ethyl α-cyano-β-methoxyaminocrotonate (6)

The procedure for the synthesis of this compound is as that described by Baba et al. (15). ^1H NMR (300 MHz) δ 1.28 (t, J_{HH} = 7.11 Hz, 3H, CH_3), 2.33 (s, 3H, C=CCH_3), 3.77 (s, 3H, OCH_3), 4.17 (q, J_{HH} = 7.11 Hz, 2H, OCH_2), 11.60 (s, 1H, N–H). ^{13}C NMR (75 MHz) δ: 14.14 (CH_3), 15.28 (CH_3), 60.50 (CH_2), 64.73 (OCH_3), 68.95 [C=$\underline{C}$(CN)(CO_2Et)], 117.72 (CN), 166.88 [$\underline{C}$=C(CN)(CO_2Et)], 167.75 (C=O).

Preparation of (*Z*)-*O*-isopropyl-4-chlorobenzohydroximoyl bromide (7)

The procedure for the synthesis of this compound is as that described by Johnson et al. (3*b*) in their synthesis of (*Z*)-*O*-methyl-4-nitrobenzohydroximoyl bromide. This yielded a yellow semi-solid material, which was recrystallized in methanol. The first recrystallization yielded light tan crystals (16.177 g, 73%). A second recrystallization in methanol yielded white crystals (12.210 g, 55%), mp 37.0–37.5 °C. R_f (hexane, alumina): 0.88. IR: 1592, 1583, 1465, 1092, 996 cm^{-1}. ^1H NMR (300 MHz) δ: 1.39 (d, J_{HH} = 6.4 Hz, 6H, CH_3), 4.61 (m, J_{HH} = 6.2, 1H, OCH), 7.36 (d, J_{HH} = 8.6 Hz, 2H, ArH), 7.79 (d, J_{HH} = 8.6 Hz, 2H, ArH). ^{13}C (75 MHz) δ: 21.64 (CH_3), 77.77 (CH), 127.92 (C=N), 128.45 (Ar CH), 129.30 (Ar CH), 132.82 (Ar C), 136.26 (Ar C). GC–MS: *m*/*z* 277 (18%), 275 (M, 13), 235 (11), 233 (9), 198 (4), 196 (14), 156 (32), 154 (100), 139 (11), 137 (35), 125 (11), 123 (20), 113 (9), 111 (29), 102 (23), 75 (18). Anal. calcd. Preparation of (*Z*)-*O*-isopropyl-4-chlorobenzohydroximoyl fluoride (1b)

(*Z*)-*O*-Isopropylbenzohydroximoyl bromide (7) (6.723 g, 0.0243 mol), potassium fluoride (Aldrich, spray-dried, 99%) (10.405 g, 0.179 mol) in 108 mL of sulfolane was placed in a 250 mL round-bottomed flask fitted with a thermometer, a $CaCl_2$ drying tube, and a nitrogren gas inlet. The resulting solution was heated to 146 °C with stirring for 10 days. The reaction mixture was cooled to room temperature. Water (100 mL) was poured into the cooled reaction mixture, and the mixture was continuously extracted with heptane for 4 days. Heptane extract was washed with water (2 × 50 mL), and the heptane extract was dried with anhyd. magnesium sulfate. Heptane was removed by rotary evaporation. This yielded a yellowish liquid (4.938 g). The compound was purified by vacuum distillation to yield a clear, colorless liquid (3.362 g, 64%). IR (neat): 2978, 2933, 1646, 1601, 1494, 1321, 993 cm^{-1}. ^1H NMR (300 MHz) δ: 1.34 (d, J_{HH} = 6.4 Hz, 6H, CH_3), 4.39 (m, J_{HH} = 6.3, 1H, OCH), 7.40 (d, J_{HH} = 8.6 Hz, 2H, ArH), 7.70 (d, J_{HH} = 8.6 Hz, 2H, ArH). ^{13}C (75 MHz) δ: 21.38 (CH_3), 77.32 (d, J_{CONCF} = 1.8, CH), 125.59 (d, J_{CCF} = 31.9 Hz, Ar C), 126.90 (d, J_{CCCF} = 5.0 Hz, Ar CH), 128.80 (d, J_{CCCCF} = 1.8 Hz, Ar CH), 136.76 (Ar C–Cl), 151.00 (d, J_{CF} = 320.0 Hz, C=N). GC–MS: *m*/*z* 217 (9%), 215 (M, 26), 175 (31), 173 (100), 158 (5), 156 (13), 111 (30), 107 (32), 75 (22). (Found: $M^{+\bullet}$, 215.05072. $C_{10}H_{11}ClFNO$ requires $M^{+\bullet}$, 215.05132).

Preparation of the (*E*)-isomer of *O*-isopropyloxime of 4-chloroacetophenone (7a)

Preparation of Grignard reagent

Magnesium metal (1.372 g, 0.0564 mol) was placed in a dry 25 mL round-bottomed flask fitted with a dry Claisen adaptor, a dry dropping funnel, a dry water-cooled condenser with a dry nitrogen inlet and a $CaCl_2$ drying tube-protected outlet. Methyl iodide (4 mL, 0.0640 mol) in 6 mL of anhyd. ether was added dropwise to form Grignard reagent. This resulted in approximately 6 mL of an approximately 10 mol/L methylmagnesium iodide solution.

Reaction of 4-chloro-*O*-methylbenzohydroximoyl fluoride with methylmagnesium iodide

4-Chloro-O-methylbenzohydroximoyl fluoride (0.635 g, 0.00294 mol) in 7 mL of anhyd. ether was added dropwise to approximately 6 mL of ~10 mol/L methylmagnesium iodide in diethyl ether solution. This mixture was refluxed for 4 h. The reaction was then poured onto approximately 40 g of dry ice. The resulting residue was washed with hexane (approximately 300 mL). The hexane was evaporated under reduced pressure. This yielded a light yellow oil (0.280 g, 45%). This was distilled under vacuum with short path distillation apparatus to yield microanalytically pure sample of a colorless oil (0.200 g, 32.1%). IR (neat): 2975, 2930,

Preparation of the (*E*)-isomer of *O*-isopropyloxime of 4-chlorobenzophenone (7b)

(*Z*)-*O*-Isopropyl-4-chlorobenzohydroximoyl fluoride (**1b**) (0.308g, 0.00143 mol) was placed in a dry 25 mL round-bottomed flask fitted for distillation under nitrogen purge. Phenylmagnesium bromide (4.7 mL of 1.0 mol/L in THF, 0.00470 mol) was added to the flask, and the mixture was heated to distill off 2.2 mL of THF. Reaction was then heated at reflux for 17 h. Mixture was then cooled to room temperature and quenched in 25 mL of ice-cold water. This was extracted with ether (5 × 50 mL). The ether layer was dried with magnesium sulfate and ether removed by rotary evaporation. This yielded 0.471 g of medium yellow colored oil. This material was purified by column chromatography (silica 63–200 and hexanes) to yield a colorless viscous oil (0.299g, 77%). IR (neat): 3082, 3058, 3029, 2975, 2932, 1577, 1488, 1444, 1369, 1324, 1121, 1092, 971. ^{1}H NMR (300 MHz) δ: 1.27 (d, J_{HH} = 6.2 Hz, 6H, $C(CH_3)_2$), 4.48 (m, J_{HH} = 6.2 Hz, 1H, CH), 7.25–7.43 (m, 9 H, ArH). ^{13}C (75 MHz) δ: 21.88 (CH_3), 76.56 (CH), 128.15 (Ar CH), 128.51 (Ar CH), 128.93 (Ar CH), 129.31 (Ar CH), 129.69 (Ar CH), 133.20 (Ar C), 135.08 (Ar C), 135.79 (Ar C), 154.68 (C=N). (Found: $M^{+\bullet}$, 273.09238. $C_{16}H_{16}ClNO$ requires $M^{+\bullet}$, 273.09204).

Preparation of the (*Z*)-isomer of the *O*-isopropyloxime of 1-(4-chlorophenyl)-3-phenyl-prop-2-yn-1-one (7c)

(*Z*)-*O*-Isopropyl-4-chlorobenzohydroximoyl fluoride (**1b**) (0.240g, 0.00111 mol) was placed in a dry 25 mL round-bottomed flask fitted for distillation under nitrogen purge. Phenylmagnesium bromide (3.7 mL of 1.0 mol/L in THF, 0.00370 mol) was added to the flask, and the mixture was heated to distill off 1.5 mL of THF. Reaction was then heated at reflux for 48 h. Mixture was then cooled to room temperature and quenched in 30 mL of ice-cold satd. ammonium chloride solution. This was extracted with ether (4 × 50 mL). The ether layer was dried with magnesium sulfate and ether removed by rotary evaporation. This yielded 0.778 g of reddish-amber colored liquid. This material was purified by column chromatography (silica 63–200 and hexanes) to yield a colorless viscous oil (0.268g, 81%). IR (neat): 3056, 2976, 2929, 2202, 1598, 1488, 1328, 1120, 1094, 1052, 983. ^{1}H NMR (300 MHz) δ: 1.37 (d, J_{HH} = 6.3 Hz, 6H, $C(CH_3)_2$), 4.55 (m, J_{HH} = 6.2 Hz, 1H, CH), 7.29–7.85 (m, 9 H, ArH). ^{13}C (75 MHz) δ: 21.66 (CH_3), 77.31 (CH), 79.50 (CC), 100.90 (CC), 121.83 (Ar C), 127.50 (Ar CH), 128.35 (Ar CH), 128.44 (Ar CH), 129.37 (Ar C), 132.01 (Ar CH), 132.50 (Ar C), 135.16 (Ar C), 137.90 (C=N). GC–MS: *m/z* 299 (16%), 297 (M, 45), 257 (3), 255 (9), 227 (17), 225 (48), 189 (57), 105 (100), 77 (11), 75 (23). (Found: $M^{+\bullet}$, 297.09206. $C_{18}H_{16}ClNO$ requires $M^{+\bullet}$, 297.09204).

Methanol electro-oxidation at $Pt_x Ru_{(1-x)}O_y$ electrodes — An in situ FTIR study

Luciene P.R. Profeti, Françoise Hahn, Kouakou B. Kokoh, and Paulo Olivi

Abstract: In this work we investigated the nature of the intermediates adsorbed during the electrooxidation of methanol on $Pt_xRu_{(1-x)}O_y$ electrodes, where $0.5 < x < 0.9$, prepared by the decomposition of polymeric precursors. Thin layer electrodes with different compositions were prepared directly on a gold substrate by thermal decomposition of ethylene glycol – citric acid solutions containing the precursor salts at 400 °C. In situ IR reflectance spectra were obtained using the SPAIRS (single potential alteration infrared reflectance spectroscopy) and SNIFTIRS (subtractively normalized interfacial Fourier transform IR reflectance spectroscopy) techniques. For all the investigated compositions, the SNIFTIRS and SPAIRS spectra displayed three main bands, which were attributed to CO species in the linear (CO_L) and bridged (CO_B) forms adsorbed over Pt and linearly adsorbed over Ru. Formation of CO_2 carbonyl species was also detected. The spectra features were analyzed in terms of the applied potential and they were compared with those reported for Pt–Ru electrodes prepared by other methods.

Key words: methanol, electrocatalytic oxidation, in situ infrared reflectance spectroscopy, $Pt_xRu_{(1-x)}O_y$, adsorption

Résumé : Dans ce travail, on a étudié la nature des intermédiaires adsorbées au cours de l'électrooxydation du méthanol sur des électrodes de $Pt_xRu_{(1-x)}O_y$ dans lesquels $0{,}5 < x < 0{,}9$ et qui ont été préparées par décomposition de précurseurs polymères. On a préparé des électrodes à couches minces de diverses compositions directement sur un substrat d'or en procédant à la décomposition thermique à 400 °C de solutions d'éthylèneglycol et d'acide citrique contenant les sels précurseurs. On a déterminé les spectres de réflectance infrarouge in situ en faisant appel aux techniques de spectroscopie infrarouge de réflexion in situ lors d'une variation linéaire de potentiel (« SPAIRS ») et de spectroscopie de réflectance infrarouge à transformée de Fourier interfaciale normalisée par soustraction (« SNIFTIRS »). Pour toutes les compositions étudiées, les spectres « SPAIRS » et « SNIFTIRS » présentent trois bandes principales qui ont été attribuées aux espèces CO dans les formes linéaire (CO_L) et pontée (CO_B) adsorbées sur le platine et adsorbée d'une façon linéaire sur le ruthénium. On a aussi détecté la présence d'espèces carbonyles CO_2. On a analysé les caractéristiques spectrales en fonction du potentiel appliqué et on les a comparées avec celles rapportées pour des électrodes Pt–Ru préparées par d'autres méthodes.

Mots-clés : méthanol, oxydation électrocatalytique, spectroscopie de réflectance infrarouge in situ; $Pt_xRu_{(1-x)}O_y$, adsorption.

[Traduit par la Rédaction]

Introduction

In the last decades there has been increasing interest in the development of energy conversion devices, including fuel cells (1). In this kind of device, chemical energy is converted into electric energy by fuel anodic oxidation and cathodic oxygen reduction. The electrodes are separated by a suitable electrolyte, and electrons flow in the external circuit to generate electric current. The electrode compositions and the fuel depend on the kind of cell used in the process.

The most promising system for autonomous fuel cell devices is the hydrogen–oxygen system, where hydrogen is oxidized in the anode and power densities as high as 0.7 W cm^{-2} (2) can be achieved. However, the use of hydrogen as fuel may pose some difficulties in terms of storage, not to mention the fact that it is potentially explosive. The possibility of substituting methanol for hydrogen has been largely exploited, since the former fuel can be directly reformatted in certain devices, like automobiles, generating hydrogen in situ. An alternative approach to use methanol as fuel is to oxidize it directly on the anode, so that it could be easily stored and there would be no need for a reformer. Direct methanol fuel cells (DMFC) power densities are lower than those of hydrogen, i.e., 0.15–0.3 W cm^{-2} (2), but the use of methanol as fuel is still interesting.

The best metal for the methanol electrooxidation is platinum (3), but the presence of strongly adsorbed intermediates on this metal restricts its practical use. These intermediates block the electrode surface and prevent adsorption of other

 doi:10.1139/V07-098 © 2007 NRC Canada

species. Different authors have identified these "poisoning" species as carbon monoxide adsorbed in distinct forms, namely the linear (CO_L), bridged (CO_B), and multibonded (CO_M) forms (4). These species cannot be oxidized at potentials lower than 0.7 V (vs. RHE) on Pt electrodes, which decreases cell performance.

To overcome this problem, different modifications to Pt electrodes have been suggested. The main adopted strategy is to add another element to Pt to inhibit the CO layer formation or to facilitate its oxidation. Among the elements used as the second metal are Ru, Sn, Mo, and W (5–8). These metals can be applied in their alloy form or as adatoms (9). Different investigations have shown that binary catalysts containing Pt and Ru lead to the best results (10–13). The Ru action mechanism in the catalyst is not exactly established, but the most accepted proposition supposes that the Ru atoms facilitate the oxidation of CO species because of the formation of adsorbed OH, which can combine with CO and lead to CO_2. Another interesting proposition is the possible modification of the electronic structure of Pt upon Ru addition, which can facilitate CO desorption by lowering the bond strength (14–18).

Metal oxides can also be used as catalysts for the electrooxidation of small organic molecules. The use of such oxides with Pt has proven to be a promising system since they can assume different oxidation states. They are also capable of adsorbing large quantities of oxygenated species, which may aid the electrooxidation of strongly adsorbed intermediates (19). The electroactivity of electrodes consisting of metal oxides has been intensively investigated for the Cl_2, O_2, and H_2 evolution reactions (20), but their use as catalyst for the oxidation of organic molecules has not been much exploited (19, 21–24).

Besides electrode composition, the preparation method plays an important role in electroactivity since it determines surface morphology, crystalline structure, and surface composition. We have recently proposed the use of the polymeric precursor method to prepare oxide electrodes containing tin and ruthenium oxides with platinum, to oxidize methanol (25, 26), formic acid and formaldehyde (27), and ethanol (28). Results showed that this method produces electrodes with activity comparable to that of electrodes prepared by other methods, with the advantage of being convenient for the preparation of small particles (26). Results from the characterization of $Pt_xRu_{(1-x)}O_y$ prepared by the polymeric precursor method in powder form and the performance of these materials on DMFC (26) have been recently published. The preparation method leads to a material with low crystallinity, which contains RuO_2 as well as Pt and Ru in their metallic form. Additionally, DMFC results showed that the thermal decomposition of polymeric precursors is a promising alternative route for the preparation of catalysts applicable to DMFC (26).

The development of efficient catalysts for methanol electrooxidation depends on the understanding of the reaction mechanism involving the adsorption of several intermediates. Different in situ IR spectroscopy techniques have been used to identify such species, and they have permitted the proposition of mechanisms for the electrodic process (29–31).

In this work we prepared electrodes containing Pt and Ru by decomposition of polymeric precursors on a gold surface and we investigated the intermediates adsorbed on the electrode surface during methanol oxidation by the SNIFTIRS and SPAIRS techniques. SPAIRS and SNIFTIRS techniques are complementary and allowed the detection of adsorbed species and reaction products at the vicinity of the electrode surface. With the first one, reflectivities were recorded each 50 mV during a slow voltammetric scan (1 mV s^{-1}), each spectrum resulting from the co-addition of 128 interferograms. The acquisition required 20 s, i.e., over 20 mV. Spectra were calculated as $(RE_i - RE_{ref})/RE_{ref}$, where the reference spectrum RE_{ref} was the one recorded at the most negative potential. In this way, SPAIRS technique is more suitable to obtain information about reaction intermediates and reaction products (CO_2 is a good example). With the second, reflectivities were obtained at two electrode potentials (frequency of potential modulation 0.025 Hz and amplitude 200 mV). These reflectivities resulted from the co-addition of 128 interferograms, co-added 30 times at each potential. Final spectra were normalized as $(RE_2 - RE_1) / RE_1$. SNIFTIRS is better adapted to the detection of adsorbed species.

Experimental

Catalyst preparation

In this work, we used the polymeric precursor method, also known as the Pechini method (32), in the preparation of Pt and Ru oxide electrodes. The Pt and Ru precursor solutions were prepared from the dissolution of H_2PtCl_6 or $RuCl_3$ (both in HCl 1:1 *v*/*v*) in a citric acid and ethylene glycol solution under constant stirring at 90–95 °C. The metal/citric acid/ethyleneglycol molar ratio employed in the preparation of these precursor solutions was 1:4:16. Atomic absorption spectrophotometry was used to determine the concentrations of Pt or Ru in the respective precursor solutions. The final solutions were obtained by mixing the precursor solutions in appropriate proportions, to achieve the desired electrode composition. Different Au/$Pt_xRu_{(1-x)}O_y$ molar compositions (x = 0.5, 0.6, 0.7, 0.8, and 0.9) were prepared. The value of y is not known because the formation of different amounts of oxides and metals can be formed. The solutions were carefully brushed on 8 mm diameter gold disc surfaces. The electrodes were finally calcinated at 400 °C. The gold discs had been previously polished with alumina until a 0.05 μm grain size was achieved.

Electrochemical and spectroscopic techniques

Voltammetric experiments were carried out in a conventional three-electrode Pyrex electrochemical cell. The apparatus consisted of a waveform generator (Wenking Model VSG72, Bank Electronik), a potentiostat (Wenking Model LB81), and an X–Y recorder (Linseis LY 17100). The counter electrode was a vitreous carbon plate and a reversible hydrogen electrode (RHE) was used as reference.

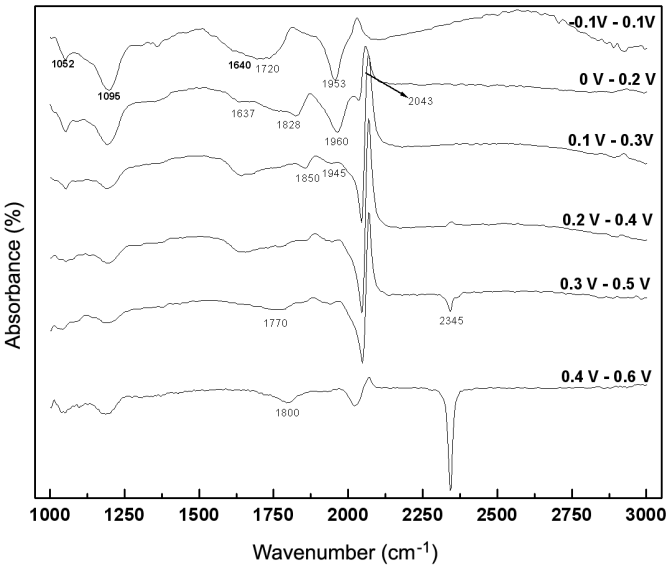
The Fourier transform IR spectrometer used in this work was a Bruker IFS 66v equipment containing a modified sample compartment that allowed the IR beam to be reflected on the electrode surface (8mm diameter) with an incidence angle of 65°, after passing through the IR window (CaF_2) of a conventional thin layer spectroelectrochemical cell. The

© 2007 NRC Canada

working electrode was connected to a glass rod fitted through the top of the cell, allowing it to be pressed down against the IR window. The beam path was placed under vacuum (to remove interferences from atmospheric water and CO_2) and a liquid nitrogen-cooled HgCdTe detector (Infrared Associates) was used. The spectral resolution was 4 cm^{-1}.

Using the single potential alteration IR reflectance spectroscopy (SPAIRS) technique, reflectivities were recorded at 100 mV intervals during the first voltammetric scan at a slow sweep rate (1 mV s^{-1}). Each spectrum resulted from the co-addition of 128 interferograms. Data acquisition required 20 s; i.e., over ca. 20 mV. Spectra were calculated as $\Delta R/R = (R_{E2} - R_{E1}) / R_{E1}$, where the "reference" reflectivity R_{E1} was the one recorded at the most negative potential.

Similarly, using the subtractively normalized interfacial Fourier transform IR reflectance spectroscopy (SNIFTIRS) method, reflectivities were obtained at two electrode potentials E1 and E2 (potential modulation frequency = 0.025 Hz) and co-added 30 times at each potential. Final spectra were normalized as $\Delta R/R = (R_{E2} - R_{E1}) / R_{E1}$. For the SNIFTIRS and SPAIRS techniques, $E_2 > E_1$, so that a positive absorption band indicates the species consumption and a negative absorption band corresponds to species production at the electrode surface.



Both techniques allowed the detection of the adsorbed species, reaction intermediates, and reaction products on and in the vicinity of the electrode.

The solutions were prepared from ultrapure water (Millipore Milli-Q System), and Merck Suprapur reagents. Before each experiment, the solutions had been purged with nitrogen (U Quality from Air Liquide) and a nitrogen stream was maintained over the solution during the measurements. All the voltammetric experiments were performed at room temperature.

Results and discussion

Using the SNIFTIRS technique, the surface reflectivity was recorded at two different potential values, E_1 and E_2, with $E_2 - E_1 = +200$ mV. E_1 values were set from –0.1 to 0.4 V, with a 100 mV interval. The spectra obtained for the $Pt_{0.6}Ru_{0.4}O_y$ electrodes are presented in Fig. 1 for the various potential modulation conditions. The bands observed at 1052 and 1195 cm^{-1} in almost all the spectra can be attributed to the symmetric and asymmetric stretching modes (33), respectively, because of the presence of bisulfate ions, HSO_4^-, with C_{3v} symmetry. These bands can be seen because of the subtractive characteristic of the technique. The sulfate species can be present in the small volume between the electrode surface and the CaF_2 window, and if a decrease in the amount of these ions occurs because of a perturbation in the double layer region during the application of one potential value (E_1 or E_2), a positive or negative band is expected. Two main bands at 1720 and 1953 cm^{-1} can be seen (Fig. 1, spectrum 1) in the potential modulation between –0.1 and 0.1 V. The first is a clearly asymmetrical broad band lying between 1500 and 1800 cm^{-1}, which indicates that it is formed by the overlap of at least two bands. Since the band maximum is at 1720 cm^{-1} and because a broad region can be detected at lower wavenumbers, it is very probable that this

Fig. 1. SNIFTIR spectra of 0.1 mol/L methanol in 0.5 mol/L H_2SO_4 on a $Pt_{0.6}Ru_{0.4}O_y$ electrode at various potential modulations and at a constant modulation amplitude of 200 mV.

broad band is a result of the presence of a band at 1720 cm^{-1} and another one around 1640 cm^{-1}. The latter band is due to the water absorption, which is related to the in-plane deformation vibration of adsorbed water. The band at 1720 cm^{-1} is related to the C=O stretching mode of a carbonyl group of either a carboxylic acid or an aldehyde. However, it is not possible to actually distinguish between these two latter species because of the low separation expected between their C=O stretching bands (34). The assignment of the band at 1953 cm^{-1} may be interpreted in different ways. Iwasita et al. (12) have found a similar band at 1965 cm^{-1} on $Pt(111)/Ru_{ads}$ electrodes, and the authors assigned it to CO adsorbed on Ru sites. Meanwhile, Kabbabi et al. (35) found a CO absorption band at 2023 cm^{-1} when CO was adsorbed on pure Ru. Lin et al. (36) have also attributed a band found in the 2000–2045 cm^{-1} region to the linear CO adsorbed on the Ru (0001) surface, which is coincident with that observed by Kabbabi et al. (35). On the other hand, Yajima et al. (37) investigated the methanol oxidation reaction on Pt–Ru sputtered Ru electrodes by using in situ FTIR spectroscopy and they found a band between 1950 and 2010 cm^{-1}, which were assigned to CO linearly adsorbed on Ru. Koper et al. (38) presented the results of a density functional theory study on the adsorption of carbon monoxide (CO) and hydroxyl (OH) on platinum, ruthenium, and a series of platinum–ruthenium alloys. These authors showed that the vibrational frequencies of linearly adsorbed CO on Ru sites may vary between 1950 and 2010 cm^{-1}, depending on the electrode composition. So, in the presence of Pt the stretching frequencies of CO_L adsorbed on Ru shift to lower values. Therefore, we conclude that the band at 1953 cm^{-1} is most probably due to CO adsorbed on Ru sites in its linear form (CO_L).

At potential modulations between 0 and 0.2 V (Fig. 1, spectrum 2), the band at 1720 cm^{-1} practically disappears and a band at 1637 cm^{-1} due to interfacial water can be seen. The band due to CO adsorbed on Ru sites is slightly shifted

© 2007 NRC Canada

to higher wavenumbers, i.e., 1960 cm^{-1}. Two other bands can be seen, one at 1828 cm^{-1} and a bipolar band at 2043 cm^{-1}. The former can be attributed to the presence of CO adsorbed in two Pt sites, normally called bridged CO, CO_B, (39). The bipolar band at 2043 cm^{-1} is related to CO linearly adsorbed on Pt surface, CO_L (39).

When potential modulation between 0.1 to 0.3 V is applied (Fig. 1, spectrum 3), the intensity of the band related to bridged CO decreases, whereas the intensity of the band at 2043 cm^{-1} increases. Apart from the bands attributed to adsorbed water and sulfate, no other bands can be distinguished in the spectrum. The intensities of the bands due to CO_B and CO adsorbed on Ru sites are very small, whereas the intensity of the CO_L band increases when a potential modulation between 0.2 and 0.4 V is applied (Fig. 1, spectrum 4). Another small band can be seen at 2345 cm^{-1}, which can be attributed to CO_2 absorption. The same behavior can be seen for the potential modulation ranging from 0.3 to 0.5 V (Fig. 1, spectrum 5), where an increase in the CO_2 band can be observed, while the intensity of the CO_L band remains practically constant. A small band at 1770 cm^{-1} can be seen, but it is very difficult to ascribe it because of the proximity to the values expected for formic acid or formaldehyde carbonyl bands. However, the three-fold hollow CO appears typically around 1780 cm^{-1} on Pt(111) and related stepped surfaces and may exist in this region (40). This band can also be seen when potential modulation between 0.4 to 0.6 V is applied, but it is slightly shifted to 1800 cm^{-1} (Fig. 1, spectrum 6), which indicates the presence of the three-fold hollow CO. The CO_L band decreases and the CO_2 band increases in this potential modulation condition, i.e., during the oxidation process.

The spectra obtained for $Pt_{0.5}Ru_{0.5}O_y$ (Fig. 2), $Pt_{0.7}Ru_{0.3}O_y$ (Fig. 3), and $Pt_{0.8}Ru_{0.2}O_y$ (Fig. 4) are very similar to those presented in Fig. 1 for the $Pt_{0.6}Ru_{0.4}O_y$ electrode. The main differences lie in the intensities of the bands under different potential modulation conditions and in the small shifts in band positions. The intensities of the CO_L bands are presented in Fig. 5 for the different electrodes in relation to the potential modulation. In this picture, the amplitude of the band was normalized by subtracting the maxima of the bipolar band peak to peak. It can be seen that the band maxima arise at ca. 250 mV for the $Pt_{0.8}Ru_{0.2}O_y$ electrode, at 275 mV for the $Pt_{0.5}Ru_{0.5}O_y$, and $Pt_{0.6}Ru_{0.4}O_y$ electrodes, and at 330 mV for the $Pt_{0.7}Ru_{0.3}O_y$ electrode. It is important and noteworthy that the CO_2 absorption band appears only at potentials higher than the potential corresponding to the maxima of the CO_L band. Another important fact is that the bands related to CO_B decrease in the potential range in which the CO_L band increases, and no CO_2 is detected in this range. This fact indicates that CO_B is transformed into CO_L at high CO surface coverage. However, the CO_B bands do not disappear completely at more positive potentials, but coexist with the CO_2 band.

The spectra obtained with the SPAIRS technique are shown in Fig. 6 for the $Pt_{0.6}Ru_{0.4}O_y$ electrode. In the spectrum for the 0.1 V potential (Fig. 6, spectrum 1) a band is found at 1954 cm^{-1}, which is related to the CO species adsorbed on Ru sites. This band is also seen in all the spectra but with a shift towards lower wavenumbers. Two weak bands can also be found at 1710 and 1744 cm^{-1} as in the case of the SNIFTIRS spectra, and they can be related to the C=O stretching mode of a carbonyl group, which may be due to the presence of either a carboxylic acid or an aldehyde. These bands decrease at higher potentials and disappear completely for potentials higher than 0.5 V. In spectrum 1 (Fig. 6), a band at 2022 cm^{-1} related to the CO adsorbed linearly on Pt sites can also be seen. This band is also observed for the spectra obtained for potentials up to 0.8 V, with an initial increase in intensity for potentials up to 0.4 V and a decrease for higher potentials. At 0.4 V (Fig. 6, spectrum 4), a CO_2 absorption band at 2344 cm^{-1} can be seen and this band is also present in all the spectra re-

Fig. 2. SNIFTIR spectra of 0.1 mol/L methanol in 0.5 mol/L H_2SO_4 on a $Pt_{0.5}Ru_{0.5}O_y$ electrode at various potential modulations and at a constant modulation amplitude of 200 mV.

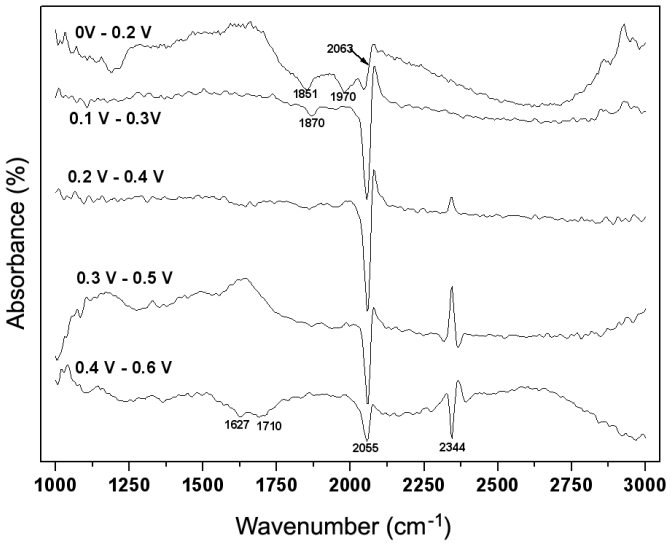
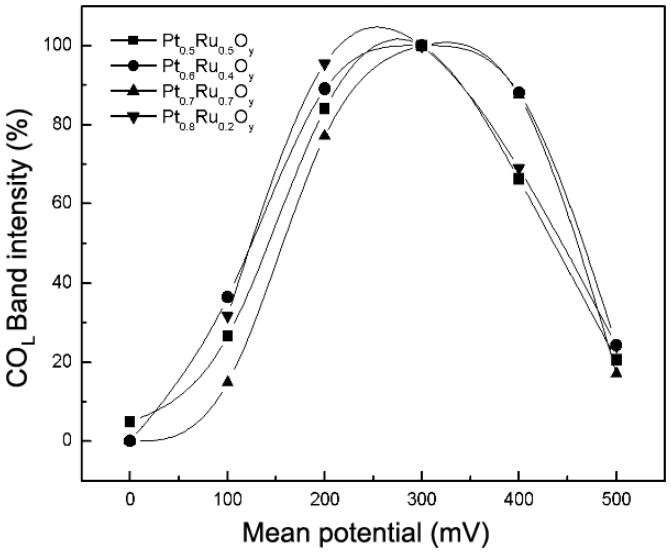
Fig. 4. SNIFTIR spectra of 0.1 mol/L methanol in 0.5 mol/L H_2SO_4 on a $Pt_{0.8}Ru_{0.2}O_y$ electrode at various potential modulations and at a constant modulation amplitude of 200 mV.





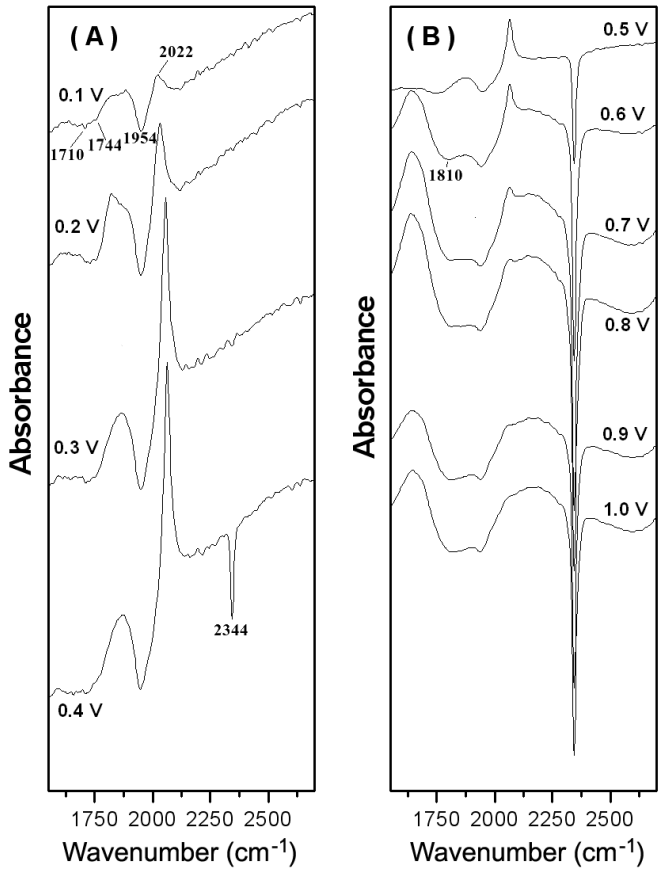


Fig. 5. CO_L band intensity (%) of 0.1 mol/L methanol in 0.5 mol/L H_2SO_4 on a $Pt_xRu_{(1-x)}O_y$ electrodes as a function of potential modulation and at a constant modulation amplitude of 200 mV. Mean potential = $E_2 - E_1$.

corded at potentials up to 1.0 V. The intensities of the CO_2 absorption bands vary with at the different potential values. These results are presented in Fig. 7. In that picture, the intensities of the CO_2 band rapidly increase with increasing potential values, but they reach a maximum around 0.65 to 0.75 V, depending on the electrode composition. A small decrease is observed after the maximum and the potential in which the CO_2 band intensity begins to decrease coincides with the potential values where the CO_L begins to decrease. This suggests that CO_L is being oxidized to CO_2. A band at ca. 1810 cm^{-1} can be seen in all the spectra for potentials higher than 0.6 V and may be assigned to the presence of CO adsorbed in the bridge form. The spectra obtained for

the other electrode compositions present almost the same behavior.

Figure 6 shows that the bands shift to higher values with increasing applied potential. The wavenumber shifts are presented in Fig. 8. Analysis of Fig. 8 reveals an interesting behavior regarding the band related to the CO_L species adsorbed on Pt. This absorption band apparently presents two linear coefficients, one at low potential values (ca. 165 cm^{-1} V^{-1}) and another one at high potentials (14 $cm^{-1}V^{-1}$). The latter value agrees with the values found in the literature but the coefficient found at low potential values can be considered "anomalous" and does not correspond to the values expected for the Stark effect. To understand this behavior it is necessary to take into account the characteristics of the catalysts. Previous X-ray diffraction results revealed that the electrodes employed in this work consist mainly of metallic platinum, metallic ruthenium, and ruthenium oxide in the RuO_2 form (26), which means that at least three different phases can be present in the electrode surface. Another important characteristic of the catalyst is that small crystals are formed and a homogeneous distribution is obtained (25). In a recent work, Baranova et al. (41) showed that the vibrational wavenumbers for CO linearly adsorbed on Pt depended on the particle size. Pt particles of around 1 nm presented a CO_L absorption band at 2017 cm^{-1}, corresponding to CO adsorbed preferentially on the Pt edges (41). The CO_L wavenumber increased for larger particles, being

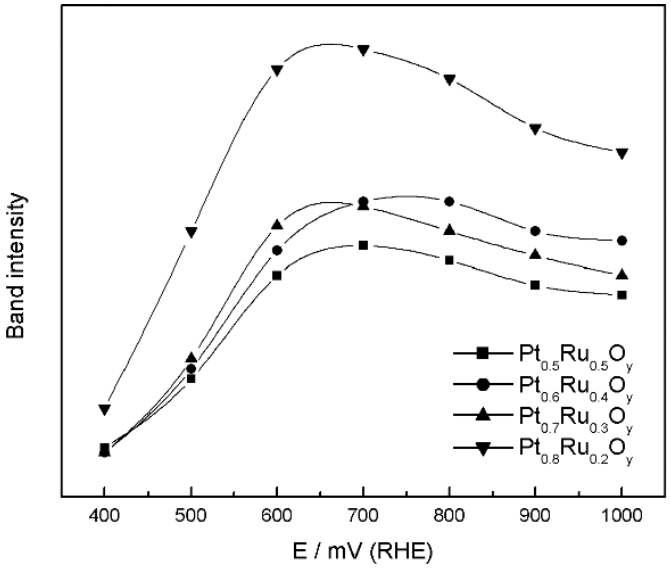

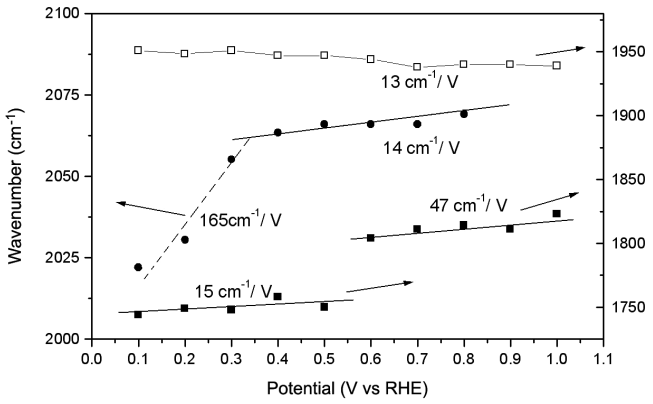

Fig. 8. Band wavenumber of Pt-adsorbed CO_L band as a function of applied potential.

2046 cm^{-1} for particles of around 5.5 nm, where CO must be adsorbed preferentially on Pt terrace sites (41). Arenz et al. (42) also showed that the wavenumber for CO adsorbed on Pt depends on the particle size, and a difference of 15 cm^{-1} was found for particles with sizes of 2 and 5 nm at the same applied potential. In other words, the CO_L band shift shown in Fig. 8 is related to the adsorption of CO in different Pt sites. At low potential values, CO_L is adsorbed mainly in small Pt particles occupying Pt edges. As for higher potential values, CO_L adsorption occurs preferentially at larger particles where the amount of Pt terrace sites is larger.

An analysis of the present results is complicated because the electrode surface is not a well-defined structure (26). Direct comparison of our results with results obtained for Pt–Ru bulk alloys cannot be made, and analysis of the role of RuO_2 is hindered because of the possible presence of a Pt–Ru solid solution. However, some comments may be made. An important point is the detection of the carbonyl band in the ca. 1720–1740 cm^{-1} region, which suggests the existence of an oxidation route involving the formation of either an aldehyde or a carboxylic acid species. Although the presence of these species was not detected in Pt–Ru alloys by some authors (3, 39), Kabbabi et al. (35) reported the presence of a band at 1695 cm^{-1} on Pt–Ru alloys in the presence of methanol. This apparent discrepancy is attributed to the different forms used in the alloy preparations. The presence of this band suggests the occurrence of a parallel path in the methanol oxidation that does not necessarily include the formation of adsorbed CO (39).

The CO_2 absorption band can be seen at 0.4 V potential values in all the electrodes employed in this work, which is the same potential expected for CO_2 detection in Pt–Ru alloys (39). This potential value is more negative than the potential where CO_2 is detected on pure Pt electrodes, a feature that is attributed to the ability of RuO_2, an oxygen donor, to oxidize CO (35). In the case of Pt–Ru alloys, the anodic formation of RuO_2 is seen as inhibitory of electrode activity, since it is believed that it is not capable of donating oxygen to oxidize CO (43). In the present case, RuO_2 was thermally prepared and the present results indicate that this oxide may act also as an oxygen donor. This observation agrees with the behavior observed by J.W. Long et al. (44) that suggests that Pt modified by the addition of hydrous ruthenium oxide presents a high catalytic activity for the methanol electrooxidation.

Conclusion

In this work we investigated the species formed on $Pt_xRu_{(1-x)}O_y$ electrodes in methanol solutions using in situ IR reflectance spectroscopy techniques (SNIFTIRS and SPAIRS). We observed the formation of adsorbed CO species in different geometries, i.e., in the linear and bridged forms. Carbonyl stretching bands in the 1720–1740 cm^{-1} region were also detected, and they were attributed to the possible formation of aldehyde or carboxylic acid intermediates. The detection of the CO_2 absorption band at potential values below the values expected for pure Pt indicates that the electrodes prepared by decomposition of polymeric precursors are promising candidates for use in DMFC. The wavenumber shift for the CO_L adsorbed on Pt sites suggests that this species are adsorbed preferentially on small Pt particles at low potentials and on larger particles at higher potentials.

DDQ-promoted thiocyanation of aromatic and heteroaromatic compounds

Hamid R. Memarian, Iraj Mohammadpoor-Baltork, and Kobra Nikoofar

Abstract: Thiocyanation of various aromatic and heteroaromatic compounds has been achieved using ammonium thiocyanate in the presence of 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) in methanol solution at room temperature and under reflux condition. The rate of reaction is influenced by the electron-donor ability of the aromatic nucleus.

Key words: amines, DDQ, indoles, thiocyanation.

Résumé : On a effectué la thiocyanatation de divers composés aromatiques et hétéroaromatiques en utilisant du thiocyanate d'ammonium en présence de 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), en solution dans le méthanol, à la température ambiante ainsi que sous des conditions de reflux du méthanol. La vitesse de la réaction est influencée par le caractère électrodonneur des substituants sur le noyau aromatique.

Mots-clés : amines, DDQ, indoles, thiocyanatation.

[Traduit par la Rédaction]

Introduction

The electrophilic thiocyanation of aromatic and heteroaromatic compounds is an important process of carbon–sulfur bond formation in organic synthesis, since the nucleophilic attack of the thiocyanate ion to the aromatic nucleus by displacement reactions is not the easy way to form thiocyanated compounds. Thiocyanates constitute an interesting group, which could be readily transformed into other sulfur-bearing functionalities (1–4), especially for producing drugs and pharmaceuticals (5). Therefore, it is important to find new methods for the thiocyanation of aromatic systems. Several methods have been developed for the thiocyanation of aromatic systems using bromine/potassium thiocyanate (6), *N*-thiocyanatosuccinimide (7), cerric ammonium nitrate (CAN) (8), montmorillonite K-10 (9), iodine/methanol (4), oxone (10), and ferric(III) chloride (11). However, some of these methods suffer from disadvantages, such as low yields, especially in the case of aromatic amines, the use of strongly acidic or oxidizing conditions, the use of special conditions (long reaction time and (or) high temperature), and also the use of expensive reagents. In this research, we have developed a new route for the thiocyanation of aromatic and heteroaromatic systems.

2,3-Dichloro-5,6-dicyanobenzoquinone (DDQ) is a versatile reagent for organic synthesis. Owing to its oxidizing ability and also its relative stability under various reaction conditions, this reagent has been used for various organic transformations, e.g., benzylic oxidation of Catechine (12), oxidation of benzhydrols (13), selective oxidation of allylic or benzylic hydroxyl groups (14), anodic oxidation of naphthalenes (15), and oxidation of thioglycosides (16).

DDQ has also been used alone for a wide range of transformations, such as dehydrogenation (17), carbon–carbon bond cleavage (18), and alcoholysis of epoxides (19); or in combination with triphenylphosphine for the conversion of epoxides to halohydrines (20), thiocyanation of α-hydroxy phosphonates (21), and thiocyanation and isothiocyanation of some alcohols and ethers (22). DDQ is also a well-known electron-acceptor species, and its interaction with a variety of electron donors has been the subject of several investigations concerning the formation of charge-transfer (CT) complexes (23–28). Herein, we wish to report an effective and benign method for the thiocyanation of aromatic and heteroaromatic compounds using ammonium thiocayanate, as a thiocyanating agent, in the presence of DDQ at room temperature (Method A) and under reflux conditions (Method B).

Results and discussion

Solvent effect and optimization of the reactants

Since the nature of solvent influences the rate of reaction, thiocyanation of 2-methylindole as a model substrate was performed in various solvents at room temperature. According to the data presented in Table 1, methanol has been chosen as the best solvent for this purpose. One reason for the observed different reaction times could be the solubility of the starting materials, especially DDQ, in solvents used in this study. Therefore, we carried out the reaction with the same concentration of the dissolved reactants in *n*-hexane (as non-polar solvent) and methanol (as polar solvent). We found that methanol is the suitable solvent for our reaction.

The next step is the optimization of NH_4SCN:DDQ molar ratio in thiocyanation reaction under two reaction conditions.

Table1. Solvent effect on the reaction of 2-methylindole with NH_4SCN in the presence of DDQ at room temperature (method A).

Entry	Solvent	Time (min)	Yield (%)
1	H_2O	180	0
2	H_2O–CH_3OH (1:1)	70	10
3	DMF	75	10
4	CH_3CN	25	99
5	CH_2Cl_2	90	85
6	$CHCl_3$	90	75
7	*n*-hexane	180	40
8	EtOAc	40	93
9	CH_3OH	15	99

Note: All reactions were performed in the presence of 2 mmol of NH_4SCN and 1.5 mmol of DDQ in 5 mL of solvent.

Table 2. Optimization of NH_4SCN:DDQ molar ratio in the thiocyanation of 2-methylindole under two different conditions.

Entry	Molar ratio of NH_4SCN:DDQ	Method A[a] Time (min) [yield (%)]	Method B[b] Time (min) [yield (%)]
1	3:1.5	15 [99]	15 [99]
2	3:0.5	—	90 [35]
3	3:1	40 [75]	70 [85]
4	3:1.25	60 [88]	15 [90]
5	2:1.25	25 [95]	15 [99]
6	1:1.5	—	35 [62]
7	2:1.5	15 [99]	15 [99]
8	2:1	—	40 [78]
9	2.5:1.5	15 [99]	—

Note: In all cases, methanol (5 mL) was used as solvent.
[a]Room temperature conditions.
[b]Under reflux conditions.

The results presented in Table 2 showed that the optimized molar ratio of NH_4SCN:DDQ is 2:1.5 for method A and 2:1.25 for method B. These data also show that an increase of the amount of NH_4SCN did not affect the yield or the rate of the reaction.

Thiocyanation of aromatic and heteroaromatic systems

Under optimized reaction conditions, the thiocyanation of different aromatic and heteroaromatic compounds was investigated under two conditions, at room temperature (method A) and under reflux conditions (method B). The results are summarized in Table 3. Clearly, various compounds were converted to their corresponding thiocyanation products in good to excellent yields. The products were identified by IR, ^1H NMR, and MS spectra. IR spectra showed the characteristic peaks of –SCN between 2120–2150 cm^{-1} and the C–S stretching between 650–750 cm^{-1}. The regiochemistry of substitution was achieved by the interpretation of ^1H NMR spectra and their comparison with the spectra and physical data of authentic samples (see Experimental Section).

According to the results obtained from the control experiment and the results presented in Table 3, we can summarize the following:

(*i*) The presence of DDQ is necessary for the reaction because the reaction of **1b** as a test compound with NH_4SCN in methanol in the absence of DDQ did not proceed at all.

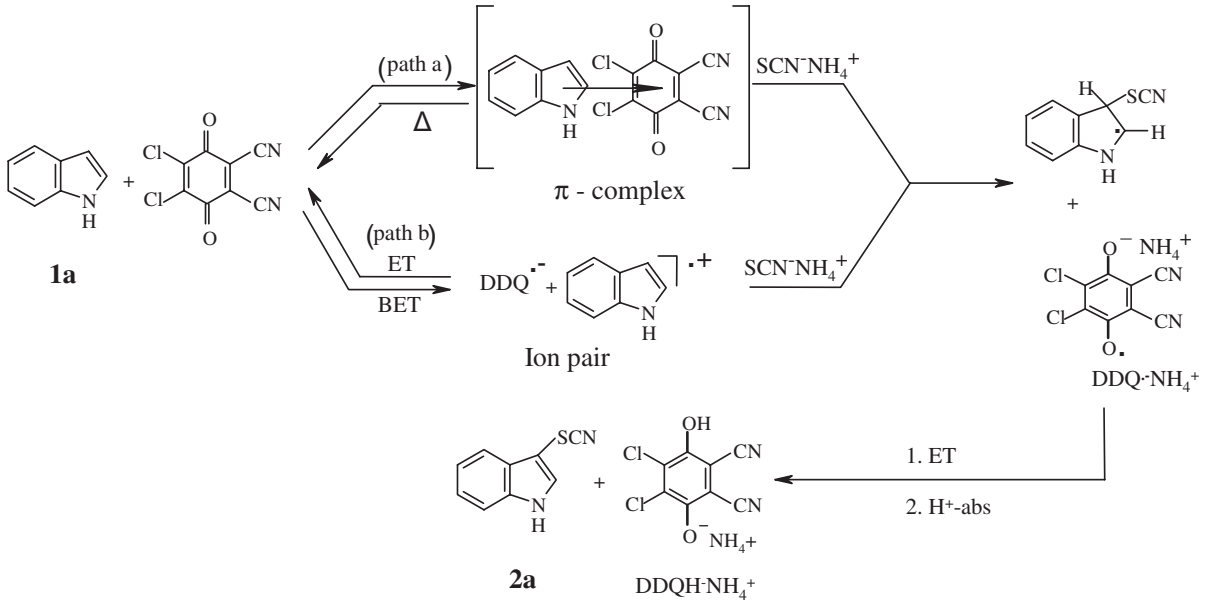
(*ii*) The use of DDQ in a molar ratio of 1.25 and 1.5 to 1 of the aromatic compound indicates that DDQ does not act as a catalyst, since it is consumed during the reaction.

(*iii*) The times and the yields of the reactions are dependent on the electron-donating ability of the aromatic and heteroaromatic compounds.

On the basis of the forgoing results, the following mechanism is proposed for the reaction, by taking (**1a**) as an example (Scheme 1).

According to the proposed mechanism, either the formation of a π complex between the aromatic system and DDQ can occur (path a) or an electron-transfer process leads to the formation of an ion pair, namely, the radical cation of aromatic system and $DDQ^{\bullet-}$ (path b). Nucleophilic attack of one of these intermediates by the thiocyanate ion leads to the formation of a thiocyanated radical system accompanied by $DDQ^{\bullet-}$. An electron transfer from the radical intermediate to $DDQ^{\bullet-}$, followed by the proton abstraction, accomplished the reaction under the formation of the thiocyanated product and $DDQH^-NH_4^+$. The following experiments support the involvement of a π complex (path a) in the reaction rather than the electron-transfer process (path b):

(*i*) The electronic absorption spectra of 0.001 mol/L solutions of the donor molecule **1b** or **1c** with the acceptor molecule DDQ (0.001 mol/L) and also the mixture of either **1b** + DDQ or **1c** + DDQ in methanol show the formation of the weak charge-transfer (CT) complexes between both donor and acceptor molecules (Figs. 1 and 2).



(*ii*) Addition of ammonium thiocyanate to the mixture of either **1b** + DDQ or **1c** + DDQ at room temperature causes a decrease of CT-complex absorption (Figs. 3 and 4).

(*iii*) To obtain more information about the formation of charge-transfer complexes between DDQ and the aromatic and heteroaromatic systems as a key step in the reaction, conductance measurements, as a much sensitive method, was used. Conductance measurements were carried out on the solutions of **1b**, **1c**, DDQ and their mixtures **1b** + DDQ and **1c** + DDQ at three molar ratios (0.5:1, 1:1, and 2:1) at 23 °C and 50 °C. The results are summarized in Table 4.

The results showed that the addition of DDQ to the solutions of **1b** and **1c** causes a sharp increase in the conductivity. The conductivities of the mixture of **1b** with DDQ or **1c** with DDQ are more than the sum of conductivities of the separated compounds. The results clearly indicate that the charge-transfer complexes are more mobile than the individual compounds (29). The differences between the conductivities of the mixture of **1b** with DDQ and (**1c**) with DDQ and the sum of the conductivities of the individual compounds at the same concentration could be related to the extent of CT formation, which is directly related to the electron-donor ability of **1b** compared with **1c**. This is supported by comparing the rate of thiocyanation of **1b** (15 min) with **1c** (30 min). These experiments show clearly that by increasing DDQ ratio from 0.5 to 1 and 2, the difference in conductivity is increased, but there is no difference between the conductivities of the 1:1 and 1:2 molar ratios. This result

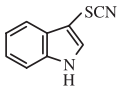
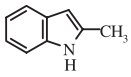
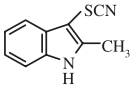
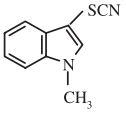
Scheme 1.

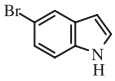
confirms that a 1:1 complex is formed between the donor and the acceptor molecules (Figs. 5 and 6).

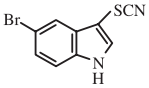


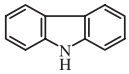


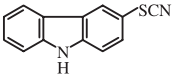


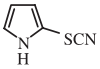


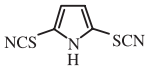


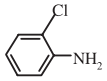


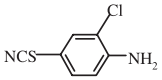


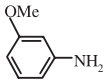


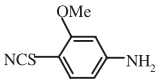












Interestigly, conductivity measurements showed that by increasing the temperature, the conductivities are decreased. This clearly indicates that the cleavage of a π complex occurs by increasing the temperature and supports the reaction path a. In path b and formation of the ionic intermediates, we expected that ion mobility should be increased by increasing temperature. All these observations support the involvement of a π complex in the thiocyanation in our study. These observations are also supported by the fact that the reaction of thiophene, furan, pyridine, and their benzocondenced derivatives, namely, benzothiophene, benzofuran, and quinoline, as less electron-donor compounds compared with the compounds considered in this study, under the same reaction conditions did not result in changing the color of solution (indicating the lack of any CT-complex formation) or in the formation of any product(s) even after stirring the reaction mixture at room temperature for 6 h.

The results presented in Table 3 showed that various aromatic and heteroaromatic compounds are converted to their corresponding thiocyanated derivatives in good to excellent yields. A comparison of the times for the maximum progression of reactions indicates that the electron-donor ability of compounds is an important factor for this reaction. These results indicate that the steric and electronic effects (e.g., the HOMO energy) are responsible for the CT-complex formation, which supports our suggestion of the involvement of the π complex in the rate-determining step. In comparison with the results obtained by the thiocyanation of indolic compounds (Table 3, entries 1–4), we found that the inductive effect of the methyl group at the 2 position (Table 3, entry 2) decreases the time required for the completion of the reaction, compared with compound **1a** (Table 3, entry 1) that does not have this substituent. Contrary to these observations, the presence of the methyl group at position 1 (compound **1c**) increases the time required for the completion of the reaction. It is expected that the presence of the methyl group in position 1, should increase the electron-donating character of the nitrogen; therefore, a reaction-time decrease should be observed for the thiocyanation of compound **1c** (Table 3, entry 3) compared with compound **1a** (Table 3, entry 1). The obtained reaction times do not confirm these suggestions. The reason is probably that because of the rehybridization of the nitrogen atom from sp^3 to sp^2 for better participation of the nitrogen lone pair in a conjugative system, the repulsive effect of the methyl group in position 1 (compound **1c**) with the hydrogen in position 7 is increased, which leads to the aversion of the nitrogen of pushing electron to the pyrrole ring to increase the HOMO energy. Due to cross conjugation of the nitrogen to both phenyl rings in carbazole **1e**, compared with indole **1a**, the energy of the HOMO should lay lower; therefore, a longer reaction time is expected. The most interesting results were obtained for the thiocyanation of aniline and its *N*- and ring substituted derivatives. While the presence of the methyl group(s) on the nitrogen decreases the reaction time, the presence of electron-withdrawing substituents, such as chlorine, methoxy, or phenyl groups, increases the reaction time. The data reported in Table 3 also showed that for pyrrole **1g** and diphenylamine **1l**, both mono- and dithiocyanated products were formed.

Concerning the regiochemistry of thiocyanate-ion addition, especially for indole and its derivatives, two possible radical intermediates **3** (a donor-substituted radical center) and **4** (a benzylic radical center) should be considered (Scheme 2). The stability of these radical intermediates explains the direction of thiocyanate addition to the heteroaromatic ring. The conjugation of a radical center in **4** with the aromatic ring should disturb the aromaticity of ring, whereas the interaction of the nitrogen lone pair with the adjacent radical center in **3** should increase the stabilization of a radical center, while the aromaticity of ring stays intact (30). For other starting materials (Table 3, entries 5–12), the

resonance effect of the nitrogen lone pair directs the position of thiocyanate addition after complexation with DDQ.

Experimental

Melting points were determined using a Stuart Scientific SMP2 capillary apparatus and are uncorrected. IR spectra were recorded from KBr discs (unless otherwise mentioned) on Shimadzu IR-435. ^{1}H NMR spectra were recorded with a Brucker drx 500 (500 MHz) machine. They are reported as follows: chemical shifts (multiplicity, number of protons, coupling constants *J* (Hz), and assignment). Mass spectra were obtained on Platform II spectrometer from Micromass; EI mode at 70 eV. Elemental analysis was run on CHN-O-RAPID analyzer from Heraeus. Conductance measurements were carried out with an ORION (**1c**) Model 180 coductivity meter. A dip-type cell with a cell constant of 0.723 cm^{-1} of platinum blank was used. Stock solutions of **1b** and DDQ were prepared in methanol. Varying concentrations of DDQ were added to a fixed concentration of **1b** and **1c** to prepare the desired DDQ to **1b** or **1c** molar ratios of 0.5:1, 1:1, and 2:1 for conductance measurements at 23 and 50 °C. Preparative layer chromatography (PLC) was carried out on 20 × 20 cm^2 plates, coated with a 1 mm layer of Merck silica gel PF_{254}, prepared by applying the silica gel as a slurry and dying in air.

General procedure for the thiocyanation of aromatic and heteroaromatic compounds at room temperature (method A)

To a solution of the aromatic or heteroaromatic compound (1 mmol) and NH_4SCN (2 mmol) in CH_3OH (5 mL), was added DDQ (1.5 mmol) at room temperature. The reaction mixture was stirred for the appropriate time according to Table 3. The progress of the reaction was monitored by TLC. The solvent was evaporated; the residue was diluted with water (10 mL) and extracted with chloroform (3 × 10 mL). The combined organic layers were dried over $MgSO_4$ and evaporated under reduced pressure. The resulting crude product was purified by plate chromatography on silica gel (PLC; eluent: *n*-hexane–EtOAc, 9:1). Further recrystallization from petroleum ether – EtOAc gives the pure product (Table 3).

General procedure for the thiocyanation of aromatic and heteroaromatic compounds under reflux conditions (method B)

To a solution of the aromatic or heteroaromatic compound (1 mmol) and NH_4SCN (2 mmol) in CH_3OH (5 mL), was

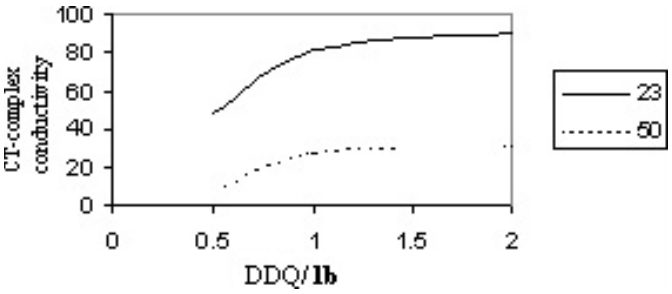
[c]Conductance of DDQ at 23 (50 °C) and 0.005 mol/L, 0.01 mol/L, and 0.02 mol/L was 11.18 (126.41), 23.81 (127.01), and 38.34 (131.41), respectively.

Fig. 5. The plot of conductances vs. DDQ–**1b** in different molar ratios at 23 and 50 °C.



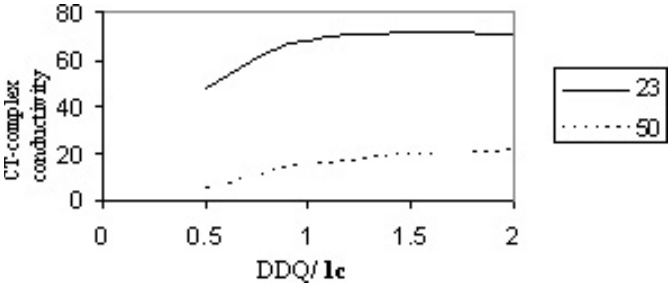


Fig. 6. The plot of conductances vs. DDQ–**1c** in different molar ratios at 23 and 50 °C.

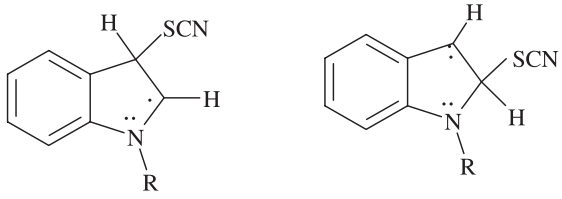

added DDQ (1.25 mmol). The reaction mixture was taken in pre-heated oil bath for the appropriate time according to Table 3. The progress of the reaction was monitored by TLC. The solvent was evaporated; the residue was diluted with water (10 mL) and extracted with chloroform (3 × 10 mL). The combined organic layers were dried over $MgSO_4$ and evaporated under reduced pressure. The resulting crude product was purified by plate chromatography on silica gel (PLC; eluent: *n*-hexane–EtOAc, 9:1). Further recrystallization from petroleum ether – EtOAc gives the pure product (Table 3).

3-Thiocyanatoindole (2a)

Mp 105–106 °C (Lit. (11) 125–127 °C). IR ν: 3334 (NH), 2150 (SCN), 1435, 1410, 1232, 1095, 735 (N–H), 658 (C–S) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.29–7.42 (m, 4H, 4-, 5-, 6-, 7-H), 7.81 (d, 1H, *J* = 8.72 Hz, 2-H), 8.90 (brd s, 1H, NH). EI-MS *m/z* (%): 174 [M$^+$] (100), 148 [M$^+$ – CN] (63), 116 [M$^+$ – SCN] (28).

Scheme 2.

2-Methyl-3-thiocyanatoindole (2b)

Mp 99–101 °C (Lit. (11) 102–103 °C). IR ν: 3324 (NH), 2140 (SCN), 1582, 1540, 1455, 1408, 1228, 738 (N–H), 658 (C–S) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 2.58 (s, 3H, CH_3), 7.23–7.28 (m, 2H, 5-, 6-H), 7.34 (d, 1H, *J* = 7.63 Hz, 4-H), 7.69 (d, 1H, *J* = 7.52 Hz, 7-H), 8.41 (brd s, 1H, NH). EI-MS *m/z* (%): 188 [M$^+$] (100), 173 [M$^+$ – CH_3] (5), 161 [M$^+$ – HCN] (22), 146 [M$^+$ – HCN, – CH_3] (6), 117[M$^+$ – SCN, – CH_3] (15).

1-Methyl-3-thiocyanatoindole (2c)

Mp 83–84 °C. IR ν: 2145 (SCN), 1514, 1240, 748 (C–S), 661 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 3.82 (s, 3H, CH_3), 7.31–7.41 (m, 4H, 4-, 5-, 6-, 7-H), 7.81 (d, 1H, *J* = 7.56 Hz, 2-H). EI-MS *m/z* (%): 188 [M$^+$] (100), 173 [M$^+$ – CH_3] (37), 162 [M$^+$ – CN] (27), 146 [M$^+$ – HCN, – CH_3] (40), 130 [M$^+$ – SCN] (12).

5-Bromo-3-thiocyanatoindole (2d)

Mp 127–129 °C. IR ν: 3321 (NH), 2122 (SCN), 1452, 1408, 1106, 794 (N–H), 654 (C–S), 601 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.31 (d, 1H, *J* = 8.68 Hz, 7-H), 7.41 (dd, 1H, *J* = 8.65 Hz, *J* = 1.71 Hz, 6-H), 7.53 (d, 1H, *J* = 2.79 Hz, 4-H), 7.93 (s, 1H, 2-H), 8.72 (brd s, 1H, NH). EI-MS *m/z* (%): 253 [M$^+$] (27), 227 [M$^+$ – CN] (7), 173 [M$^+$ – Br] (100), 146 [M$^+$ – HCN, – Br] (19), 114 [M$^+$ – HSCN, – Br] (8).

3-Thiocyanatocarbazole (2e)

Mp 80–81 °C (Lit. (6) 76.5–78 °C). IR ν: 3295 (NH), 2155 (SCN), 2925, 1721, 1620, 1472, 1208, 1121, 1062, 734 (N–H), 702 (C–S) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.41–7.47 (m, 4H, 6-,7-,8-, 9-H), 7.53 (d, 1H, *J* = 8.55 Hz, 2-H), 7.59 (d, 1H, *J* = 3.1 Hz, 5-H), 7.68 (dd, 1H, *J* = 8.53 and 1.86 Hz, 2-H), 8.31 (brd S, 1H, NH). EI-MS *m/z* (%): 224 [M$^+$] (2), 191 [M$^+$ – SH] (4), 165 [M$^+$ – SCN, – H] (100).

2-Thiocyanatopyrole (2fa)

Liquid (Lit. (4) liquid). IR (film) ν: 3395 (NH), 2902, 2126 (SCN), 1462, 1381, 1115, 735 (N–H), 662 (C–S) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 6.29 (dd, 1H, *J* = 5.91 and 2.91 Hz, 4-H), 6.66 (s, 1H, 3-H), 6.99 (s, 1H, 5-H), 8.87 (brd s, 1H, NH). EI-MS *m/z* (%): 124 [M^+] (100), 98 [M^+ – CN] (10).

2,5-Dithiocyanatopyrole (2fb)

Mp 97–99 °C (Lit. (10) 99–102 °C). IR ν: 3392 (NH), 2906, 2122 (SCN), 1623, 1381, 1105, 792 (N–H), 683 (C–S) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 6.71 (d, 2H, *J* = 1.18 Hz, 3-, 4-H), 9.38 (brd s, 1H, NH). EI-MS *m/z* (%): 181 [M^+] (92), 154 [M^+ – HCN] (77), 123 [M^+ – SCN] (99), 96 [M^+ – HCN, – SCN] (100), 64 [M^+ – HSCN, – SCN] (27).

4-Thiocyanatoaniline (2g)

Mp 51–52 °C (Lit. (10) 51–52 °C). IR ν: 3375 (NH_2), 2144 (SCN), 2902, 1595, 1382, 1095, 795 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.95 (brd s, 2H, NH_2), 6.68 (d, 2H, *J* = 8.59 Hz, 2-, 6-H), 7.37 (d, 2H, *J* = 8.56 Hz, 3-, 5-H). EI-MS *m/z* (%): 150 [M^+] (33), 134 [M^+ – NH_2] (4), 123 [M^+ – HCN] (14), 91[M^+ – HSCN] (53).

4-Thiocyanato-*N*-methylaniline (2h)

Liquid. IR (film) ν: 3385 (NH), 2908, 2142 (SCN), 1596, 1508, 1305, 1181, 814 (N–H), 745 (C–S) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 2.84 (s, 3H, CH_3), 4.12 (brd s, 1H, NH), 6.58 (d, 2H, *J* = 8.67 Hz, 2-, 6-H), 7.38 (d, 2H,, *J* = 8.64 Hz, 3-, 5-H). EI-MS *m/z* (%): 164 [M^+] (100), 149 [M^+ – CH_3] (820), 138 [M^+ – CN] (69), 105 [(M^+ – SCN, – H] (60), 90 [M^+ – SCN, – H, – CH_3] (21), 77 [M^+ – CH_3, – NH, – SCN] (38).

4-Thiocyanato-*N*,*N*-dimethylaniline (2i)

Mp 71–72 °C (Lit. (4) 72–74 °C). IR ν: 2130 (SCN), 1585, 1504, 1368, 1079, 803 (C–S) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.00 (s, 6H, $2CH_3$), 6.68 (d, 2H, *J* = 8.97 Hz, 2-, 6-H), 7.43 (d, 2H, *J* = 8.99 Hz, 3-, 5-H). EI-MS *m/z* (%): 178 [M^+] (100), 163 [M^+ – CH_3] (15), 152 [M^+ – CN] (29), 134 [M^+ – $N(CH_3)_2$] (11), 108 [M^+ – CN, – $N(CH_3)_2$] (23).

2-Choloro-4-thiocyanatoaniline (2j)

Mp 60–61 °C. IR ν: 3457 (NH_2), 3385 (NH_2), 2142 (SCN), 1627, 1595, 1482, 1153, 809, 702 (N–H), 668 (C–S), 563 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 4.39(brd s, 2H, NH_2), 6.77 (d,1H, *J* = 8.47 Hz, 6-H), 7.28 (dd, 1H, *J* = 8.46 and 2.14 Hz, 5-H), 7.50 (d, 2H, *J* = 2.14 Hz, 3-H). EI-MS *m/z* (%): 184 [M^+] (98), 158 [M^+ – CN] (78), 149 [M^+ – Cl] (98), 133 [M^+ – Cl, – NH_2] (18), 125 [M^+ – HSCN] (20). $C_7H_5N_2ClS$ (184.58) calcd.: C 45.54, H 2.71, N 15.17; found: C 45.48, H 2.69, N 15.13.

3-Methoxy-4-thiocyanatoaniline (2k)

Mp 99–100 °C. IR ν: 3368 (NH_2), 3415 (NH_2), 2121 (S–CN), 1627, 1593, 1462, 1327, 1218, 1047, 821 (N–H), 796 (C–S). ^1H NMR ($CDCl_3$) δ: 3.88 (s, 3H, CH_3), 3.99 (s, 2H, NH_2), 6.25 (d, 1H, *J* = 2.12 Hz, 2-H), 6.29 (dd, 1H, *J* = 8.29 and 2.24 Hz, 6-H), 7.30 (d, 1H, *J* = 8.30 Hz, 5-H). EI-MS *m/z* (%):180 [M^+] (100), 164 [M^+ – NH_2] (17), 149 [M^+ – OCH_3] (12), 110[M^+ – HCN, – $COCH_3$] (9), 91 [M^+ – SCN, – OCH_3] (13). $C_8H_8N_2OS$ (180.13) calcd.: C 53.34, H 4.44, N 15.54; found: C 53.40, H 4.41, N 15.49.

4-Thiocyanatodiphenylamine (2la)

Mp 62–64 °C. IR ν: 3332 (NH), 2132 (SCN), 1602, 1578, 1525, 1488, 1330, 820, 745 (N–H), 692 (C–S) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 5.93 (brd s, 1H, NH), 7.03 (d, 2H, *J* = 8.65 Hz, 2-,6-H), 7.07 (t, 1H, *J* = 7.38 Hz, 4′-H), 7.14 (d, 2H, *J* = 7.82 Hz, 2′-, 6′-H), 7.34 (t, 2H, *J* = 7.84 Hz, 3′-, 5′-H), 7.43 (d, 2H, *J* = 8.67 Hz, 3-,5-H). EI-MS *m/z* (%): 226 [M^+] (100), 200[M^+ – CN] (30), 167 [M^+ – H, – SCN] (66), 77 [Ph^+] (36).

4,4′-Dithiocyanatodiphenylamine (2lb)

Mp 110–111 °C. IR ν: 3342 (NH), 2125 (SCN), 1582, 1516, 1482, 1335, 803 (N–H) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 6.09 (brd s, 1H, NH), 7.12 (d, 4H, *J* = 8.68 Hz, 3-, 5-, 3′-, 5′-H), 7.49 (d, 4H, *J* = 8.68 Hz, 2-, 6-, 2′-, 6′-H). EI-MS *m/z* (%): 283 [M^+] (19), 257 [M^+ – CN] (4), 225 [M^+ – SCN] (23), 149[M^+ – PhSCN] (11), 122 [M^+ – PhSCN, – HCN] (22), 90 [M^+ – PhSCN, – HSCN] (4).

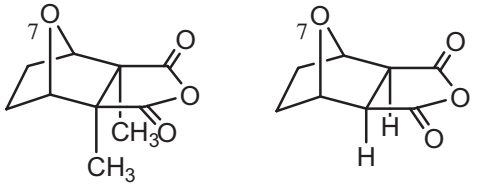
Norcantharidin analogues — Synthesis and evaluation of growth inhibition in a panel of selected tumor-cell lines

Liping Deng, Li Shen, Jing Zhang, Bo Yang, Qiaojun He, and Yongzhou Hu

Abstract: A series of norcantharidin (NCTD) analogues have been synthesized by [3+2]1,3-dipolar cycloaddition reaction of norcantharidin derivatives of substituted aromatic amines with four nitrile oximes. All analogues have been screened for their antiproliferative activity in vitro against a panel of tumor cell lines: KB, SGC-7901, HL60, Bel-7402, HO-8910, and ECA109, producing IC_{50} values from 0.36 μmol/L to >100 μmol/L. Compound **9d** showed potency for the treatment of hepatoma, with IC_{50} value to Bel-7402 cell line comparable to that of norcantharidin.

Key words: norcantharidin analogues, isoxazoline, growth inhibition.

Résumé : On a réalisé la synthèse d'une série d'analogues de la norcantharidine en procédant à une réaction de cycloaddition 1,3-dipolaire [3+2] de dérivés de la norcantharidine d'amines aromatiques substituées avec quatre oximes de nitriles. On a évalué l'activité comme inhibiteur de croissance in vitro de chacun des analogues contre un ensemble de souches de cellules tumorales: KB, SGC-7901, HL60, Bel-7402, HO-8910 et ECA109 pour lesquelles les valeurs de IC_{50} varient de 0,36 μmol/L à plus de 100 μmol/L. Le composé **9d** présente un grand potentiel pour le traitement de l'hépatome, avec une valeur de IC_{50} qui, par comparaison avec celle des cellules Bel-7402, est comparable à celle de la norcantharidine.



Mots-clés : analogues de la norcantharidine, isoxazoline, inhibition de la croissance.

[Traduit par la Rédaction]

Introduction

Traditional Chinese medicine is a rich source of potential anticancer agents. In particular, cantharidin (CAN; exo, exo-2,3-dimethyl-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylic acid anhydride; Fig. 1) is the active ingredient of Mylabris, which has been used in China as a medicinal agent for the treatment of cancer, particularly hepatoma (1). Although cantharidin is cytotoxic to cancer cells and stimulatory on the bone marrow, the renal toxicity of this drug has limited its application (2). A series of bioactive analogues have been synthesized in an attempt to increase the utility and to reduce the toxicity of cantharidin. Norcantharidin (NCTD; Fig. 1), the demethylated analogue of cantharidin, has been used to treat human cancers in China since 1984 (2). NCTD appeared to improve the awkward side of cantharidin, making the drug safer in application. It was recently found to be capable of inducing apoptosis in human cervical, tongue, ginival, mucoepidermoid carcinoma, adenocystic carcinoma, neuroblastoma, bone, leukaemia, ovarian, and colon cancer cell lines (3–5); however, the main application so far is treating hepatoma. We have referred to all the known cantharidin SAR data; briefly, no modification of the bicyclo[2.2.1] skeleton is permissible, the 7-oxa bridge is required to maintain activity, and the presence of a double bond (5,6-ene) has little effect on activity (6–10). Replacement of the O-atom (anhydride) with N (as N–H and N–R, where R = aryl or thiazolyl) allows the development of a new series of anhydride-modified cantharidin analogues; some are more potent than CAN or display potency similar to NCTD (11, 12). On the other hand, it is well-known that isoxazoline derivatives possess a wide range of pharmacological activities (13). These observations prompted us to design a new series of norcantharidin analogues by combining isoxazoline with norcantharidin derivatives in one single molecule to improve their antiproliferative activities and to carry out a structure–activity relationship study. In this paper, we describe the synthetic methodology towards the development of a series of norcantharidin analogues and their antiproliferative activities in vitro against various human tumor-cell lines.

Results and discussion

Synthesis

Norcantharidin analogues were prepared as shown in Scheme 1. Treatment of furan with maleic anhydride resulted in 5,6-dehydronorcantharidin **1**, then compound **1** reacted with substituted phenylamine **2a–2f** to give compounds **3a–3f** according to the published procedure (16). [3+2] Cycloaddition of **3a–3f** with four nitrile oximes **4–7** in the presence of chloramine T yielded target compounds **8a–8f**, **9a–9f**, **10a–10f**, and **11a–11f**. All compounds were tested as racemic mixtures.

To identify the configuration of the norcantharidin analogues (**8a–8f**, **9a–9f**, **10a–10f**, and **11a–11f**), we have studied selective ^{1}H–^{1}H COSY spectra and NOESY spectra of the compounds. ^{1}H–^{1}H COSY spectra showed cross peaks between H-2 and H-3 and H-5 and H-6. NOESY spectra showed cross peaks between H-2 and H-6 and H-3 and H-5. The Diels–Alder adduct 5,6-dehydronorcantharidin of furan with maleic anhydride have the exo configuration exclusively; the endo isomer has never been reported (14, 15), which, combined with ^{1}H–^{1}H COSY and NOESY spectra data, give us a reasonable exo-adduct configuration, as we have proved before similarly (16, 17).

Biological activity

The norcantharidin analogues **8a–8f**, **9a–9f**, **10a–10f**, and **11a–11f** were screened for their antiproliferative activity against a panel of six tumor-cell lines: KB, SGC7901, HL60, Bel7402, HO8910 and ECA109. CAN and NCTD were included as internal standards. IC_{50} values of different compounds are summarized in Table 1.

As shown in Table 1, the synthesized compounds displayed growth inhibition with IC_{50} values ranging from 0.36 μmol/L to >100 μmol/L. Most norcantharidin analogues were antiproliferative against HL60 cell line after 72 h treatment and were inactive to the KB and SGC7901 cell lines. Some norcantharidin analogues exhibited higher growth inhibition than NCTD, e.g., **9c** was more potent than NCTD against HL60 cell line, and **11c** was more potent than NCTD against HL60 and HO8910 cell lines. Also, compound **9d** displayed potency against Bel-7402 cell line comparable to that of NCTD, suggesting that the halogeno group in the aryl moiety (R_1) might be crucial for activity. It is also noteworthy that the presence of the methoxyl (such as **8f**, **9f**, **10f**, and **11f**) appeared to have an unfavorable effect.

The apoptosis-inducing activity of NCTD and its analogues was dose- and time-dependent; for instance, the antiproliferative activity of compound **9d** and cantharidin against Bel-7402 cell line are shown in Fig. 2.

Conclusion

From the data presented, subtle modifications of norcantharidin's skeleton permitted the development of a new series of analogues with alterations in their antiproliferative activity against a panel of tumor-cell lines. The lead compounds cantharidin and norcantharidin are somewhat more potent against tumor-cell lines, respectively. Of the synthesized analogues, the notable exception being **9c**, which showed both good potency and selectivity for the HL60 cell line, and compound **9d** displayed moderate potency for the treatment of hepatoma with IC_{50} values to Bel7402 cell line comparable to that of norcantharidin. We are currently working towards the development of more po-

[a]The IC_{50} values represent the concentration that results in a 50% decrease in cell growth after 72 h incubation.
[b]The IC_{50} values were the mean values of three repeated experiments.

tent and selective analogues of this nature and will report the outcome of these studies in due course.

Experimental section

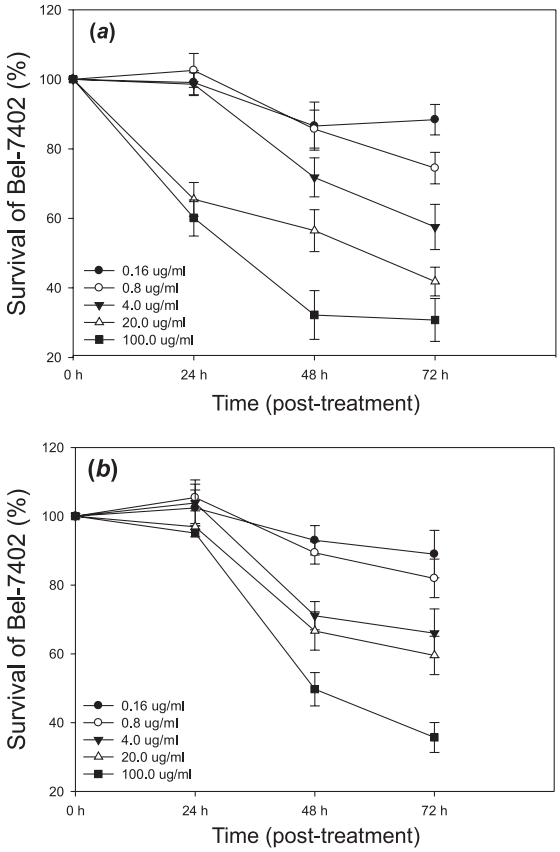
General

All reagents were of commercial quality and were used as received (Aldrich). Solvents were dried and purified using standard techniques. Reactions were monitored by TLC on aluminum plates coated with silica gel with fluorescent indicator (Merck 60 F254). Melting points were obtained on a B-540 Büchi melting-point apparatus and are uncorrected. ^{1}H NMR and NOESY spectra were recorded on a Brucker AM-400 MHz spectrometer with $SiMe_4$ as the internal standard in DMSO-d_6. Mass Spectra were recorded with a HP5989B analyzer. Elemental analyses were performed on an EA-1110 instrument.

General procedure for the preparation of the 5,6-dehydronorcantharidinisoxazoline adducts (8a–8f, 9a–9f, 10a–10f, 11a–11f)

To a solution of 3-acetyl-7-oxa-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid phenylamide **3a** (1 mmol) and **4** (1 mmol) in ethanol (20 mL) was added chloramine T (1.2 mmol), and the reaction mixture was refluxed in ethanol for 4–7 h. Then, it was cooled to room temperature, water (10 mL) was added to the reaction mixture, and it was extracted with dichloromethane (30 mL). The extract was dried over anhyd. sodium sulfate, concentrated in vacuum, and the residue was recrystallized from acetone to give the compound **8a**. The synthesis of compounds **8b–8f, 9a–9f, 10a–10f, 11a–11f** were performed using the same method.

exo,exo-4,8-Epoxy-3a,4,4a,7a,8,8a-hexahydro-6-phenyl-3-(3,4,5-trimethoxyphenyl)-pyrrolo[3,4-f]-1,2-benzisoxazole (8a)



Compound **8a** was obtained as a colorless solid: yield 94%; mp 284 °C. IR ν (KBr, cm^{-1}): 3062 and 3027 (ArH), 1778, 1721 (C=O), 1598 (C=N), 1240 (C–O–C). ^{1}H NMR (DMSO-d_6) δ: 7.83–7.19 (m, 7H, Ar–H), 5.24 (d, J = 7.9 Hz, 1H, H-5), 4.98 (s, 1H, H-4), 4.75 (s, 1H, H-1), 4.52 (d, J = 7.9 Hz, 1H, H-6), 3.77 (s, 9H, 3 × OCH_3), 3.59 (d, J = 7.9 Hz, 1H, H-3), 3.38 (d, J = 7.9 Hz, 1H, H-2). MS m/z: 450 (M^+). Anal. calcd. for $C_{24}H_{22}N_2O_7$: C 63.99, H4.92, N 6.22; found: C 63.80, H 4.99, N 6.18.

exo,exo-6-(4-fluorophenyl)-4,8-epoxy-3a,4,4a,7a,8,8a-hexahydro-3-(3,4,5-trimethoxyphenyl)-pyrrolo[3,4-f]-1,2-benzisoxazole (8b)

Compound **8b** was obtained as a colorless solid: yield 81%; mp 300 °C (Dec.). IR ν (KBr, cm^{-1}): 3121 and 3010

Cell culture and antiproliferative assays

Stock solutions of drugs were prepared as follows (and stored at –20 °C): Cantharidin (Biomol, USA) as a 12 mmol/L solution in dimethylsulphoxide (DMSO); norcantharidin and cantharidin analogues as 10 mmol/L solutions in phosphate buffered saline. All cell lines were cultured at 37 °C in 5% CO_2.

Antiproliferative activity of different compounds was determined by MTT method. Cells in logarithmic growth were plated in triplicate in 100 μL medium at a density of 3 000–5 000 cells/well in 96-well plates. When the cells were in logarithmic growth, 100 μL medium with or without the test compounds were added to each well. After 72 h, MTT solution (5.0 mg/mL) was added (10.0 μL/well), and plates were incubated for a further 4 h at 37 °C. The purple formazan crystals were dissolved in 100.0 μL DMSO. After 5 min, the plates were read on an automated microplate spectrophotometer at 570 nm. Concentration of drug that inhibited 50% of cells (IC_{50}) was calculated using the software of Dose–Effect analysis with Microcomputers.

An ab initio investigation of bismuth hydration

Cory C. Pye, C. Mahesh Gunasekara, and Wolfram W. Rudolph

Abstract: A series of geometry, frequency, and energy calculations of aquabismuth(III) complexes were carried out at up to the MP2/CEP-121G* level. A thorough examination of all species up to and including enneacoordinate species was carried out. The structures of the complexes are compared with experimental data where available. Deviations from the most highly symmetric structures are consistent with the inert-pair effect. In addition, protonated bismuth–oxo clusters of the stoichiometry $Bi_6O_{8-n}(OH)_n^{(2+n)+}$, n = 0–4 are examined. The Raman spectrum of bismuth perchlorate with added perchloric and hydrochloric acid is measured.

Key words: bismuth, aqua complexes, ab initio, Raman spectra.

Résumé : Opérant au niveau MP2/CEP-121G*, on a effectué une série de calculs de géométrie, de fréquence et d'énergie de complexes du aqua(bismuth(III)). On a effectué un examen critique de toutes les espèces, y compris celles qui comportent une enneacoordination et on a comparé les structures des complexes avec les données expérimentales disponibles. Les déviations par rapport aux structures les plus symétriques pourraient correspondre avec l'effet de la paire inerte. On a étudié de plus, les agrégats oxo du bismuth de stoechiométrie $Bi_6O_{8-n}(OH)_n^{(2+n)+}$ dans lesquels n = 0–4. On a mesuré le spectre Raman du perchlorate de bismuth additionné d'acide perchlorique et d'acide chlorhydrique.

Mots-clés : bismuth, aqua, complexes, ab initio, spectre Raman.

[Traduit par la Rédaction]

1. Introduction

Bismuth preparations have been used for medicinal purposes for some time and are currently used mostly in stomach remedies, such as Pepto-Bismol (1). The coordination chemistry of bismuth (III) has recently been reviewed (2). However, the poor solubility and difficult characterization of most of its compounds has hampered efforts to systematically characterize the structure and chemistry of this heavy element. In fact, non-aaquabismuth(III) was only characterized a decade ago as the trifluoromethanesulfonate (triflate) salt (3). In this compound at 133 K, the Bi–O distances are 2.448(2) and 2.577(2) Å for the tricapped trigonal prism of C_{3h} symmetry. A redetermination at 298 K gave 2.435(2) and 2.595(6) Å (4). The corresponding acidified bismuth perchlorate solutions gave a low-angle X-ray scattering (LAXS) result, consistent with an eight-coordinate square antiprism with a mean Bi-O distance of 2.41 Å, with one or two perchlorate ions in the inner coordination shell (4). A recent molecular dynamics study, however, suggested a nine-coordinate tricapped trigonal prism (5), as found in the solid state. Vibrational studies of bismuth(III) nitrate solutions indicate the presence of up to four bidentate nitrates binding to the cation (6). Similar studies of the chlorides and bromides suggest that up to six halides may be associated with the metal (7). In dilute strongly acidic bismuth perchlorate solutions, a weak polarized band at 390 cm^{-1} was assigned to the bismuth–oxygen symmetric stretching mode.

Some polynuclear bismuth compounds based on the common Bi_6O_8 core have also been prepared. The $Bi_6O_4(OH)_4^{6+}$ cation has been explored both as the nitrate monohydrate (8, 9) and tetrahydrate (10) salt and as the perchlorate aqueous solution (11). It was originally thought that this ion was $Bi_6(OH)_{12}^{6+}$ (12–14). A related structure containing a $Bi_6O_5(OH)_3^{5+}$ dimer has also been examined (15). Very recently, much larger bismuth–oxygen clusters have been prepared (16).

In this work, we examine both bismuth aqua complexes and protonated bismuth–oxo clusters using ab initio theory. In the bismuth aqua complexes, several levels of theory were employed and compared and represent the speciation of bismuth at extremely low pH. For the bismuth–oxo clusters, increasing levels of protonation of the "bismuth-oxide-like" clusters should eventually solubilize the oxide and represent the speciation at higher pH. Previous work in this group include studies of other metal–aqua complexes (17–19), hydrated oxoanions (20–22), and metal–anion complexes (23, 24).

2. Method

Calculations were performed using Gaussian 98 (25). As this program version allows, for the first time, analytical frequency calculation of molecules in which core electrons are described by effective core potentials (ECPs), many variants of these were tried. The MP2 calculations utilize the frozen core approximation. The geometries were optimized using a stepping stone approach, in which the geometries at the levels HF/CEP-4G, HF/CEP-31G*, HF/CEP-121G*, HF/LANL2MB, HF/LANL2DZ, and HF/SDD were sequentially optimized. For minimum energy structures, the MP2/CEP-31G* and

Fig. 1. Optimized structures of aquabismuth(III) complexes.

MP2/CEP-121G* calculations were also performed. Calculations were also carried out using the 6-31G* (26) and 6-31+G* (27) basis sets on the atoms of the water molecules with an effective core potential and basis set on bismuth. Default optimization specifications were normally used. After each level, where possible, a frequency calculation was performed at the same level and the resulting Hessian used in the following optimization. Z-matrix coordinates constrained to the appropriate symmetry were used as required to speed up the optimizations. Since frequency calculations are done at each level, any problems with the Z-matrix coordinates would manifest themselves by giving imaginary frequencies corresponding to modes orthogonal to the spanned Z-matrix space. The Hessian was evaluated at the first geometry (opt = CalcFC) for the first level in a series to aid geometry convergence.

A stock solution (1.48 mol/L $Bi(ClO_4)_3$ and 2.36 mol/L $HClO_4$) was prepared from bismuth oxide and 6.8 mol/L perchloric acid. This unstable solution precipitated a white solid (presumably BiOOH) so the mixture was diluted with an equal volume of 10.0 mol/L perchloric acid. Details of the spectral measurement are given in ref. 24.

3. Results and literature comparison

3.1. Aquabismuth complexes, $Bi(H_2O)_n^{3+}$

Figure 1 gives the structures of the aquabismuth clusters. Our experience with other trivalent ions suggested that the mono- through ennea-hydrate should have C_{2v}, D_{2d}, D_3, S_4, C_{2v} (trigonal bipyramid), T_h, C_2, S_8, and D_3 symmetries, respectively (17, 28–30), so our initial structures corresponded to these. The optimized structures for the di- through hexa-aquabismuth were actually of C_2, C_3, C_2, C_{2v} (square pyramid), and C_3 symmetries, respectively, as further discussed in the Supplementary material.[2] The distortions relative to other trivalent ions in di- to hexa-aquabismuth(III) are consistent with what has been termed the inert pair effect. The occupied $6s^2$ orbital behaves as if it is a lone pair, from the point of view of VSEPR theory. The ligands then undergo the usual repulsions. For coordination numbers greater than 6, the lone pair stereochemistry is often absent (31). More sophisticated theories on this phenomenon have been developed (32).

The variation of the average Bi–O distance as a function of coordination number is given in Fig. 2. Comparison between the different levels of theory is given in the Supplementary material.[2] Experimentally, the solid-phase bismuth triflate enneahydrate has bond lengths 2.438–2.448 Å (prism) and 2.577–2.595 Å (caps) (3, 4). Although the Bi–O distances (caps) are well described, the CEP-31G* Bi–O distances (prism) seem to be much longer than experimental values (see Table S2 of the Supplementary data).[2] The HF/LANL2DZ, HF/SDD, and the MP2/CEP levels seem to have too short Bi–O (cap) distances and too long Bi–O (prism) distances. The putative octaaquabismuth(III) ion is found to have a Bi–O distance of 2.41 Å by extended X-ray absorption fine structure (EXAFS) and LAXS (4), which is also quite a bit shorter than our calculations (2.48–2.50 Å). The temperature dependence of the structures may account for some of the difference, as the predictions are for

Fig. 2. Average Bi–O distance of aquabismuth(III) complexes as a function of coordination number (pure ECP).

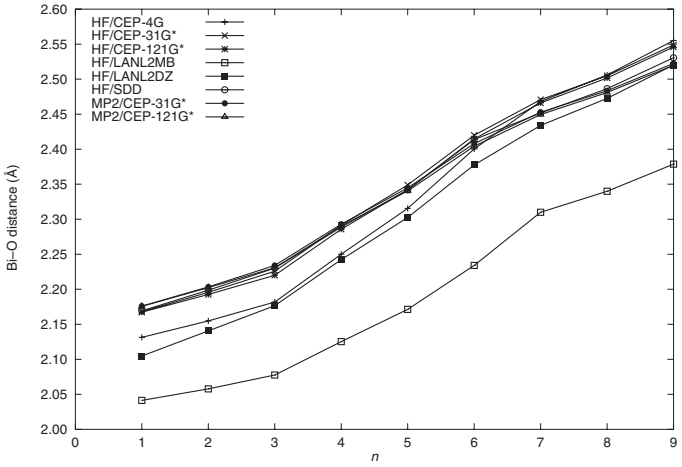

Fig. 3. Average Bi–O distance of aquabismuth(III) complexes as a function of coordination number (mixed).

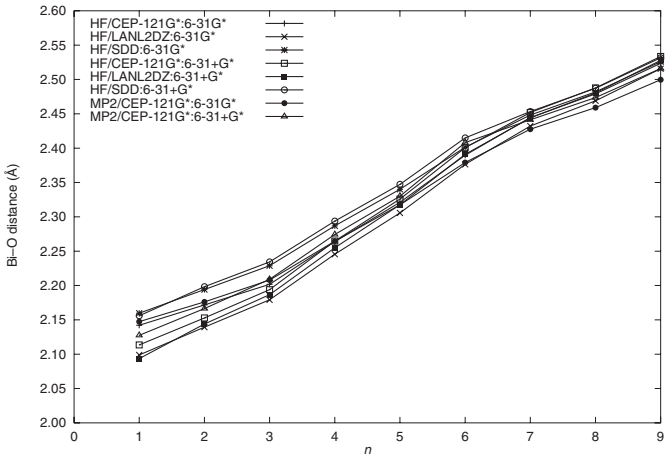

Fig. 4. Incremental hydration energy of bismuth(III), $Bi(H_2O)_{n-1}^{3+} + H_2O \rightarrow Bi(H_2O)_n^{3+}$ (kJ/mol) (pure ECP).

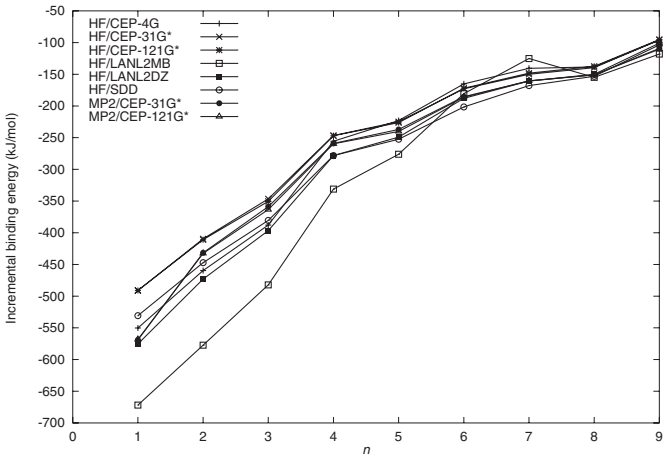

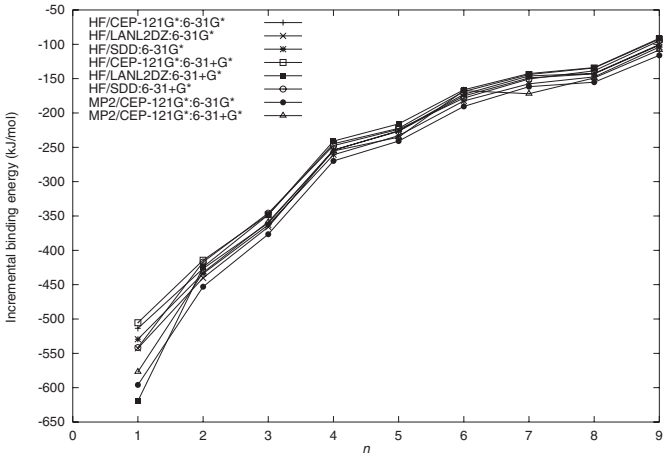

Fig. 5. Incremental hydration energy of bismuth(III), $Bi(H_2O)_{n-1}^{3+} + H_2O \rightarrow Bi(H_2O)_n^{3+}$ (kJ/mol) (mixed).

0 K. The influence of the environment (slight shortening of M–O bonds), omitted in these calculations, and deficiencies in the levels chosen probably account for the rest.

To clarify the role of choice of level, we also carried out mixed basis set calculations where the standard 6-31G* and 6-31+G* basis sets (5d) were used on the oxygen and hydrogen atoms, and the effective core potentials and valence basis sets were used on bismuth (see Fig. 3). When comparing the pure ECP basis sets and the mixed basis sets, we noticed that the Bi–O distances using the CEP type basis sets were shortened by between 0.015–0.030 Å, whereas not much difference was found for LANL2DZ and SDD. Adding a diffuse function tended to shorten the Bi–O distances in the complexes with only a few waters but lengthened it in those with more waters.

The incremental binding energy of bismuth hydration is given in Fig. 4. A pronounced kink at $n = 4$ can be seen, whereas similar plots for other metal ions such as aluminum, scandium, zinc, gallium, and indium show a kink at $n = 5$. This presumably is due to the onset of significant ligand–ligand repulsion for the other metal ions at $n = 5$ and can be interpreted as ligand–inert pair repulsion in bismuth, which would occur at $n = 4$.

We may compare the incremental binding energies (HF) using the ECP basis sets with those using the 6-31G* (5d) basis set on the atoms of the water molecules (see Fig. 5). No general trend was found, only specific trends that changed with each ECP choice, as discussed in the Supplementary material.[2] Within the mixed basis set results, adding a diffuse function typically lowers the magnitude of the binding energy by around 10 kJ/mol for CEP-121G* but slightly more for SDD and LANL2DZ, except for the first incremental binding energy, which is raised by 80 and 12 kJ/mol, respectively. The diffuse functions make a larger difference at the MP2 level. It is anticipated that binding energies will soon be able to be measured for trivalent ions by mass spectrometry, as there has been some recent progress (33).

The Raman spectrum of acidified bismuth perchlorate solution in R-format is given in Fig. 6. In addition to the perchlorate modes at ca. 455 and 625 cm^{-1}, a totally polarized mode is seen at 393 cm^{-1} and is assigned to the Bi–O totally symmetric stretch. If bismuth perchlorate is acidified with excess hydrochloric acid instead (to a 9:1 chloride/bismuth ratio), then the perchlorate modes remain, but the band at 393 cm^{-1} disappears, and a new polarized mode at 266.5 cm^{-1} appears in

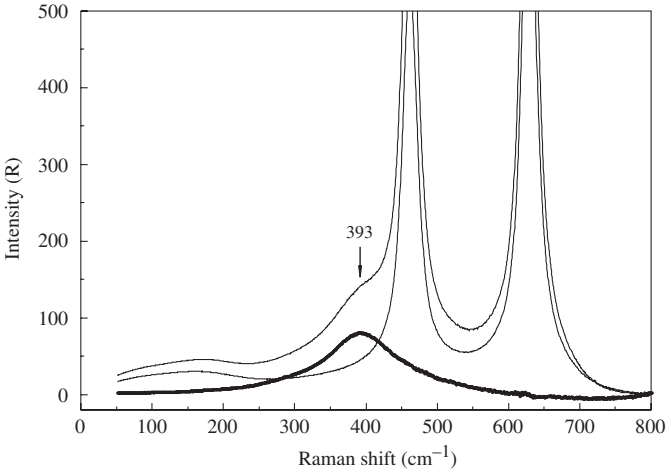
Fig. 6. Raman spectra of acidified bismuth perchlorate solution (0.74 mol/L $Bi(ClO_4)_3$ and 6.2 mol/L excess $HClO_4$).



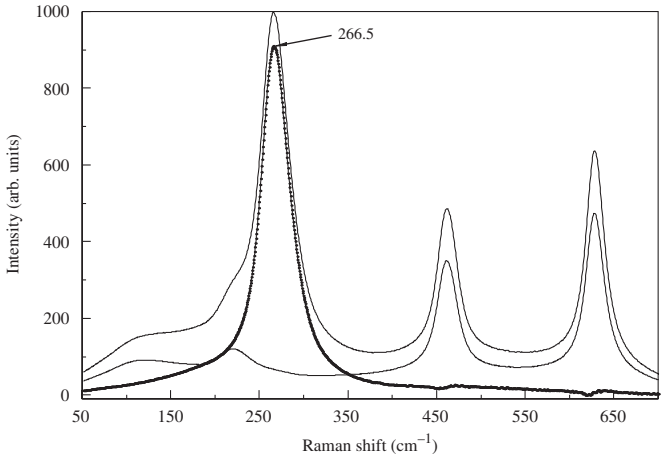


Fig. 7. Raman spectra of acidified bismuth perchlorate solution (0.6 mol/L $Bi(ClO_4)_3$ and 5.5 mol/L excess HCl).

addition to depolarized modes at 120 and 220 cm^{-1} (see Fig. 7). These most likely arise from the formation of a chlorobismuth complex, possibly hexachlorobismuthate(III).

The vibrational frequencies of the Bi–O stretching modes are given in Table 1. The totally symmetric stretching frequency of the octa- and ennea-hydrate complexes differs by only 15 cm^{-1} (Table 1). Based on comparison with other trivalent metal ion hexahydrates using similar quality basis sets, we expect these frequencies to be too low by between 50–70 cm^{-1} (28–30). For bismuth, the ν_1 frequency (HF/SDD) of the T_h hexahydrate is 59 cm^{-1} lower than the corresponding mode in the T octadecahydrate. If the effect of the second hydration sphere can be regarded to be of the same magnitude for both the octa- and ennea-hydrate, then we might be able to differentiate by empirically correcting the ν_1 frequency by 60 cm^{-1} and seeing which gives a closer match to experiment. This suggests (albeit weakly) that the complex in solution is more likely the octahydrate rather than the enneahydrate.

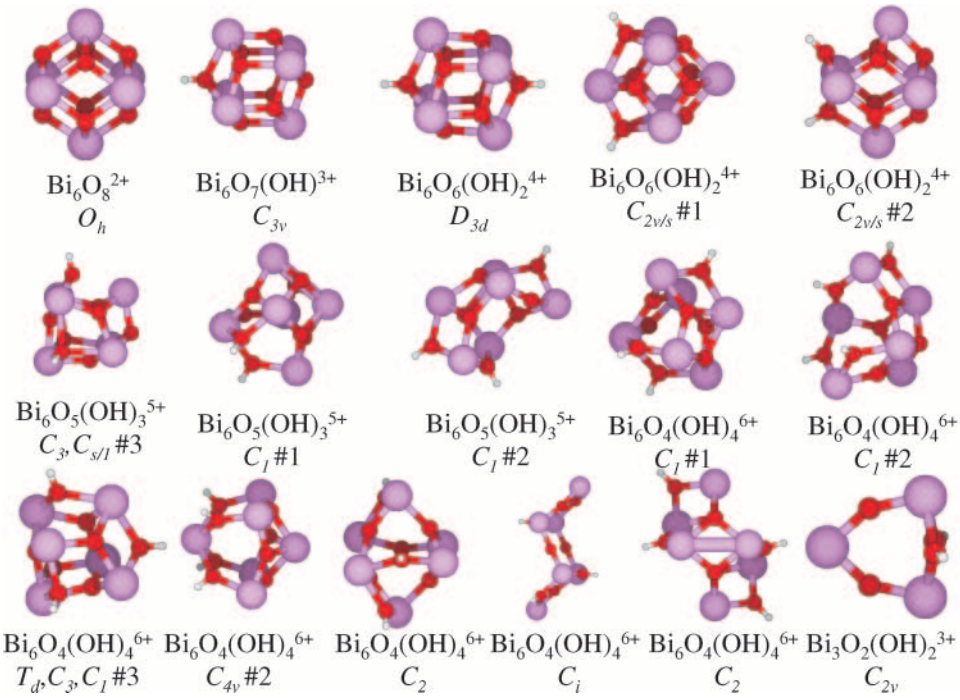
3.2. Polynuclear bismuth–oxo clusters

The $Bi_6O_8^{2+}$ can exist in aqueous solution and the solid state in varying degrees of protonation. The unprotonated form has O_h symmetry (see Fig. 8). A proton inside the cage does not give a stable O_h structure, whereas a proton located on an oxygen gives a stable $Bi_6O_7(OH)^{3+}$ C_{3v} structure. A second proton added to form $Bi_6O_6(OH)_2^{4+}$ can situate itself opposite to the first proton to form a D_{3d} structure, on a different face not opposite to form a C_{2v} # 1 structure, or on the same face to form C_{2v} # 2. The C_{2v} # 1 structure is the most stable, followed by the D_{3d}, with the C_{2v} # 2 structure being the least stable. At some levels the C_{2v} structures desymmetrize to C_s along with a conversion of one μ_3-OH into a μ_2-OH.

A third proton can be added to give either a C_{3v} or one of two different C_s structures. The first C_s structure has all three OH groups interacting with a common Bi atom. The C_{3v} structure is not stable, but it is always lower in energy than the other two forms. It desymmetrizes to either C_3, C_s # 3, or C_1 # 3 structure depending on level. The C_s # 1 and # 2 structures both have an imaginary frequency at all levels and desymmetrize to the corresponding C_1 # 1 and #2 structures. Some of these structures have significantly longer Bi–O distances and have partially opened up the Bi_6O_8 cage. The structure of Lazarini corresponds nominally to the C_{3v} structure, although distortions are evident (15).

A fourth proton can be potentially added to form one of five maximally symmetric structures: T_d, C_{4v}, C_{3v}, D_{2h}, or C_s # 1. For the T_d structure, most levels desymmetrize to either a C_3 or C_1 # 3. The C_{4v} structure descends (C_4) and re-ascends in symmetry to a new stable C_{4v} # 2 structure in which four Bi–O bonds were broken. The C_{3v} structure can convert into two $Bi_3O_2(OH)_2$ fragments or desymmetrize to the stable C_1 # 2 structure. The D_{2h} structure either fragments into Bi_2O_2 and two $Bi_2O(OH)_2$ or desymmetrizes into a stable C_2 or an open C_i structure. The C_s # 1 structure desymmetrizes to the stable C_1 # 1 form. The structure of Lazarini (9, 10) and of Sundvall (8, 11) correspond to the T_d form. In perchlorate solution, the Bi–O (Bi–OH) distance is 2.19 (2.37) Å, and our HF/SDD calculation that predicts this structure to be a minimum gives 2.180 (2.445) Å.

Table 1. Bi–O totally symmetric stretching mode of $Bi(H_2O)_n^{3+}$, $n = 8$, 9.



Level	$n = 8$	$n = 9$

MP2/CEP-121G*	324	310
Experiment	393	

4. Conclusions

The structures of bismuth aqua complexes up to the hexaaqua complex are distorted relative to other trivalent metal ions, consistent with the inert pair effect. The earlier kink appearance in the incremental hydration energies is also consistent with the inert pair effect. Fair agreement with experimental Bi–O distances was reached. In solution, our calculations are consistent with either the octa- or ennea-hydrate, with a slight preference for the former. For the bismuth–oxo clusters, good agreement

Fig. 8. Optimized structures of oxobismuth(III) clusters.

was found with the structures found experimentally in terms of symmetry and Bi–O distance, but somewhat poorer agreement for the Bi–OH distance was found.

Synthesis, crystal structure, and growth inhibition of human hepatoma cell (HepG2) of polyphenolic compounds based on gallates

Zhu-Ping Xiao, Rui-Qin Fang, Lei Shi, Hui Ding, Chen Xu, and Hai-Liang Zhu

Abstract: Seven compounds (**1**–**7**) based on gallate were synthesized and characterized by elemental analysis, ^{1}H NMR, and MS spectra. 2-(3,5-Dibenzyloxy-4-methoxy)phenyl-2-propanol (**6**) was a new compound. Methyl 3,5-dihydroxy-4-methoxybenzoate (**3**), methyl 3,5-dibenzyloxy-4-methoxybenzoate (**4**), 3,5-dibenzyloxy-4-methoxybenzyl alcohol (**5**), and compound **6** were structurally determined by single-crystal X-ray diffraction for the first time. Crystallographic data for **3**: space group $P2_12_12_1$; a = 4.0750(8) Å, b = 7.5880(15) Å, c = 29.802(6) Å; V = 921.5(3) Å^3; Z = 4. **4**: space group P-1; a = 10.068(2) Å, b = 10.499(2) Å, c = 11.388(2) Å; α = 76.84(3)°, β = 66.79(3)°, γ = 64.10(3)°; V = 993.0(3) Å^3, Z = 2. **5:** space group P-1; a = 8.1410(16) Å, b = 8.7590(18) Å, c = 12.879(3) Å; α = 91.66(3)°, β = 94.69(3)°, γ = 91.73(3)°; V = 914.4(3) Å^3; Z = 2. **6**: space group $P2_1/c$; a = 5.8100(12) Å, b = 15.778(3) Å, c = 23.237(5) Å; β = 96.09(3)°; V = 2118.1(7) Å^3; Z = 4. All of the seven compounds were evaluated for the inhibition of growth of human hepatoma (HepG2) cells. Comparison with the positive-control 5-fluorouracil (IC_{50} 51.6 μmol/L), **5** showed stronger cytotoxic activity with an IC_{50} around 15.3 μmol/L, while IC_{50} value of **3** was 90.3 μmol/L. The effect of slight structural variations in this series of compounds was found to cause a marked change in their activity against HepG2 cells.

Key words: gallates, benzyl alcohol, human hepatoma cells, crystal structure, anti-cancer activities.

Résumé : On a réalisé la synthèse de sept composés apparentés au gallate (**1**–**7**) dont le 2-(3,5-dibenzoyloxy-4-méthoxy)phénylpropan-2-ol (**6**) est un nouveau produit, et on a les a caractérisés par leur analyse élémentaire, leur spectre de RMN et leur spectre de masse. Faisant appel à la diffraction des rayons X par un cristal unique, on a déterminé pour la première fois les structures du 3,5-dihydroxy-4-méthoxybenzoate de méthyle (**3**), du 3,5-dibenzyloxy-4-méthoxybenzoate de méthyle (**4**), de l'alcool 3,5-dibenzyloxy-4-méthoxybenzylique (**5**) et du composé **6**. Les données cristallographiques sont les suivantes: pour le composé **3**, groupe d'espace $P2_12_12_1$ avec a = 4,0705(8) Å, b = 7,5880(15) Å et c = 29,802(6) Å, V = 921,5(3) Å^3 et Z = 4; pour le composé **4**, groupe d'espace P-1 avec a = 10,068(2) Å, b = 10,499(2) Å et c = 11,388(2) Å, α = 76,84(3)°, β = 66,79(3)° et γ = 64,10(3)°, V = 993,0(3) Å^3 et Z = 2; pour le composé **5**, groupe d'espace P-1 avec a = 8,1410(16) Å, b = 8,7590(18) Å et c = 12,879(3) Å, α = 91,66(3)°, β = 94,69(3)° et γ = 91,73(3)°, V = 914,4(3) Å^3 et Z = 2; pour le composé **6**, groupe d'espace $P2_1/c$ avec a = 5, 8100(12) Å, b = 15,778(3) Å et c = 23,237(5) Å, β = 96,09(3)°, V = 2118,1(7) Å^3 et Z = 4. On a évalué les capacités inhibitrices des sept composés vis-à-vis de la croissance de cellules d'hépatome humain (HepG2). Par comparaison avec le produit de contrôle positif, 5-fluorouracil (IC_{50} = 51,6 μmol/L), le composé **5** présente une activité cytotoxique plus importante (IC_{50} = 15,3 μmol/L), alors que pour le composé **3**, la valeur de IC_{50} = 90,3 μmol/L. On a observé que de faibles changements de structures dans cette série de composés provoque dans changements importants dans leur activité contre les cellules HepG2.

Mots-clés : gallates, alcool benzylique, cellules d'hépatome humain, structure cristalline, activités anticancérigènes.

[Traduit par la Rédaction]

Introduction

Gallic acid and its derivatives are widely present in the plant kingdom and represent a large family of secondary plant polyphenolic metabolites. Toxicological studies showed that the no-observed-adverse-effect-level (NOAEL) of gallic acid is at least 120 mg kg^{-1} day^{-1} for F334 rats, and the level of gallates was reported to be as high as 1000 mg kg^{-1} for mice (1, 2).

Gallic acid and its alkyl esters derivatives are added to foods to prevent oxygen-induced lipid peroxidation (3). The alkyl gallates can inhibit 7,12-dimethylbenz[*a*]anthracene-initiated mammary tumorigenesis (4, 5) and decrease benzo[*a*]pyrene metabolite formation (6) in vivo, and they

protect against hydroperoxide-induced cytotoxicity (7) and mutagenicity (8) in vitro. The ability of the alkyl gallates to induce apoptosis in several tumor-cell lines has recently attracted much interest (9, 10). At the cellular level, they have been shown to inhibit cell adhesion (11) and induce apoptosis of tumor cells (12). Toshihiko Osawa found that alkyl gallates suppress the 3-methylcholanthrene-mediated cytochrome $P_{45}0$ 1A induction in human hepatoma (HepG2) cells. The suppressions were dependent on the length of the alkyl chain of the gallates (13). The cytotoxic activity of phenolic derivatives depends on their rate of incorporation into cells, directly related to their lipophilicity as much as to their antioxidant activity.

The gallates investigated in the literature for their antitumor activity in a human cancer-cell line varied mainly in the number of phenolic substituents and (or) in the length of the alkyl side chain. In the present paper, some structurally distinct derivatives based on gallate were synthesized and evaluated for the inhibition of growth of liver (HepG2) cancer cells. Compounds **4**, **5**, and **6** showed potent anticancer activities with IC_{50} values of 23.1, 15.3, and 20.2, respectively, and crystal structures of **3**–**6** were described to determine the effect of the structural characteristics on their antiproliferative activity.

Experimental

Reagents

MTT cell-proliferation assay kits were purchased from ATCC. Cell-death detection ELISA kits were purchased from Roche. The HepG2 cell line was purchased from ATCC.

Cell cultures and cell viability assay

The HepG2 cells were cultured in ATCC minimum essential medium (Eagle) with 2 mmol/L L-glutamine and Earle BSS adjusted to contain 1.5 g/L sodium bicarbonate, 0.1 mmol/L non-essential amino acids, 1.0 mmol/L sodium pyruvate (90%), and 10% fetal bovine serum. Cells were incubated under 37 °C with 5% CO_2. The medium was changed 2–3 times per week.

After digestion with trypsin-EDTA, uniform amounts ($\sim 2 \times 10^4$) of HepG2 cells in growth media were inoculated into each well of a 96-well flat-bottomed plate. After 24 h of incubation at 37 °C in 5% CO_2, the growth medium was replaced with 100 media, containing different concentrations of compounds **1** to **7**, respectively. DMSO was added initially to the test compounds to help dissolve the sample. After 48 h of incubation, cell population growth was determined using the ATCC MTT cell proliferation assay at 570–655 nm with a Bio-Rad Model 680 Microplate Reader (Hercules, California). Briefly, a mitochondrial enzyme in living cells, succinate dehydrogenase, reduced the yellow tetrazolium salt (MTT) to insoluble purple formazan crystals. Therefore, the amount of formazan produced was proportional to the number of viable cells (14). To better explain the inhibitory results, the inhibition of cell population growth was calculated based on the following formula:

> Inhibition percentage = (cell no. in control – cell no. in treatment) / (cell no. in control – original cell no. before the compounds were added) × 100%.

IC_{50} is the extract concentration under which a 50% inhibition of cell population growth occurs.

Single-crystal analysis

The purified products were dissolved in ethyl acetate, then petroleum ether was added carefully. The crystals suited for X-ray analysis were obtained after 3 to 4 days by volatilization of the solvents.

The crystal data, data collection, and refinement parameters for compounds **3**–**6** are listed in Table 1.[3] The crystal data were collected with a Bruker SMART APEX CCD diffractometer, using graphite monochromatized Mo Kα radiation (λ = 0.71073 Å) (15). All calculations were performed by using the SHELXTL package and refined with full-matrix least-square procedures on desktop computers (16). All non-hydrogen atoms were located from a difference Fourier map and were placed at calculated positions, refined isotropically with riding model position parameters.

Chemistry

The compounds previously reported were synthesized according to the methods in the references with appropriate modifications. Separation of the compounds by column chromatography was carried out with silica gel 60 (200–300 mesh ASTM, E. Merck). The quantity of silica gel used was 50–100 times the weight charged on the column. The eluates were monitored using TLC. Melting points (uncorrected) were determined on a XT4 MP apparatus (Taike Corp., Beijing, China). ESI mass spectra were obtained on a Mariner System 5304 mass spectrometer, and ^{1}H NMR spectra were recorded at DPX500 on a Bruker spectrometer. Elemental analyses were performed on a CHN-O-Rapid instrument and were within ±0.4% of the theoretical values.

Compounds **1** to **5** were synthesized according to refs. 17 and 18.

Methyl 3,4,5-triacetoxybenzoate (1)

Melting point 130 to 131 °C. ^{1}H NMR ($CDCl_3$) δ: 2.29 (s, 9H, C(=O)CH_3), 3.89 (s, 3H, OCH_3), 7.79 (s, 2H, ArH). ESI-MS: $C_{14}H_{15}O_8$ $[M + H]^+$ 311. Anal. calcd. for $C_{14}H_{14}O_8$: C 54.18, H 4.56; found: C 54.20, H 4.55.

Methyl 3,5-diacetoxy-4-methoxybenzoate (2)

Melting point 83–83.5 °C. ^{1}H NMR ($CDCl_3$) δ: 2.32 (s, 6H, C(= O)CH_3), 3.87 (s, 6H, OCH_3). ESI-MS: $C_{13}H_{15}O_7$ $[M + H]^+$ 283. Anal. calcd. for $C_{13}H_{14}O_7$: C 55.35, H 4.98; found: C 55.32, H 5.00.

Methyl 3,5-dihydroxy-4-methoxybenzoate (3)

Melting point 148 to 149 °C. ^{1}H NMR ($CDCl_3$) δ: 3.73 (s, 3H, $ArOCH_3$), 3.77 (s, 3H, OCH_3), 6.94 (s, 2H, ArH), 9.51 (s, 2H, OH). ESI-MS: $C_9H_{11}O_5$ $[M + H]^+$ 199. Anal. calcd. for $C_9H_{10}O_5$: C 54.52, H 5.10; found: C 54.55, H 5.09.

Methyl 3,5-dibenzyloxy-4-methoxybenzoate (4)

Melting point 119 to 120 °C. ^{1}H NMR ($CDCl_3$) δ: 3.88 (s, 3H, $ArOCH_3$), 3.94 (s, 3H, OCH_3), 5.16 (s, 4H, $ArCH_2$), 7.33 (t, 2H, J = 7.0 Hz, benzyl H-4′), 7.31 (s, 2H, H-2, 6), 7.39 (t, 4H, J = 7.3 Hz, benzyl H-3′, 5′), 7.46 (d, 4H, benzyl H-2′, 6′). ESI-MS: $C_{23}H_{23}O_5$ $[M + H]^+$ 379. Anal. calcd. for $C_{23}H_{22}O_5$: C 73.04, H 5.84; found: C 73.00, H 5.86.

3,5-Dibenzyloxy-4-methoxybenzyl alcohol (5)

Melting point 105 to 106 °C. ^{1}H NMR ($CDCl_3$) δ: 1.76 (s, 1H, OH), 3.90 (s, 3H, OCH_3), 4.54 (s, 2H, $HOCH_2$), 5.13 (s, 4H, $ArCH_2$), 6.64 (s, 2H, H-2, 6), 7.32 (t, 2H, J = 7.3 Hz, benzyl H-4′), 7.38 (t, 4H, J = 7.3 Hz, benzyl H-3′, 5′), 7.45 (d, 4H, J = 7.5 Hz, benzyl H-2′, 6′). ESI-MS: $C_{22}H_{23}O_4$ $[M + H]^+$ 351. Anal. calcd. for $C_{22}H_{22}O_4$: C 75.45, H 6.30; found: C 75.41, H 6.33.

2-(3,5-Dibenzyloxy-4-methoxy)phenyl-2-propanol (6)

Methyl iodide (4.26 g, 29.6 mmol) was dissolved in 25 mL of dry ether and the resultant mixture added dropwise with stirring to magnesium turnings (0.68 g, 28.5 mmol) in 5 mL of dry ether. The mixture was heated to reflux for 0.5 h. A solution of 3,5-dibenzyloxy-4-methoxybenzoate (**5**; 3.96 g, 10.5 mmol) in 20 mL dry tetrahydrofuran was added dropwise with stirring. After heating to reflux for 1.5 h, the mixture was cooled and poured into an NH_4Cl solution. The ethereal layer was separated, and the aqueous layer was extracted with ether. The combined ethereal extracts were washed with solutions of $NaHSO_3$, $NaHCO_3$, and water and dried over anhyd. Na_2SO_4. The solvent was removed, and the residue was purified by flash chromatography with EtOAc – petroleum ether (1:4) to afford colorless crystals (3.45 g, 87%). Melting point 63 to 64 °C. ^{1}H NMR ($CDCl_3$) δ: 1.49 (s, 6H, CH_3), 2.05 (s, 1H, OH), 3.90 (s, 3H, OCH_3), 5.14 (s, 4H, $ArCH_2$), 6.77 (s, 2H, H-2, 6), 7.31 (t, 2H, J = 7.3 Hz, benzyl H-4′), 7.38 (t, 4H, J = 7.4 Hz, benzyl H-3′, 5′), 7.46 (d, 4H, J = 7.4 Hz, benzyl H-2′, 6′). ESI-MS: $C_{24}H_{25}O_3$ $[M - H_2O + H]^+$ 361. Anal. calcd. for $C_{24}H_{26}O_4$: C 76.09, H 6.94; found: C 76.17, H 6.92.

3,5-Dibenzyloxy-4-methoxyphenol (7)

Boron trifluoride etherate (83 mmol, 10 mL) was added to a suspension of sodium perborate (15.8 mmol, 2.7 g) in dry tetrahydrofuran (72 mL) contained in a nitrogen-flushed flask cooled to 0 °C. The mixture was stirred for 30 min at room temperature, and then the compound **7** (7.2 mmol, 2.71 g in 20 mL of dry tetrahydrofuran) was added. After stirring for 13 h, the reaction was quenched with sodium sulfite; the product was extracted into ethyl acetate and dried over $MgSO_4$. Removal of the solvent followed by column chromatography (EtOAc – petroleum ether, 1:4) produced compound **7** as colorless crystals (2.25 g, 93%). Melting point 86–88 °C. ^{1}H NMR (DMSO-d_6) δ: 3.64 (s, 3H, OCH_3), 5.04 (s, 4H, $ArCH_2$), 6.14 (s, 2H, H-2, 6), 7.33 (t, 2H, J = 6.9 Hz, benzyl H-4′), 7.40 (t, 4H, J = 7.4 Hz, benzyl H-3′, 5′), 7.44 (d, 4H, J = 7.1 Hz, benzyl H-2′, 6′), 9.22 (s, 1H,

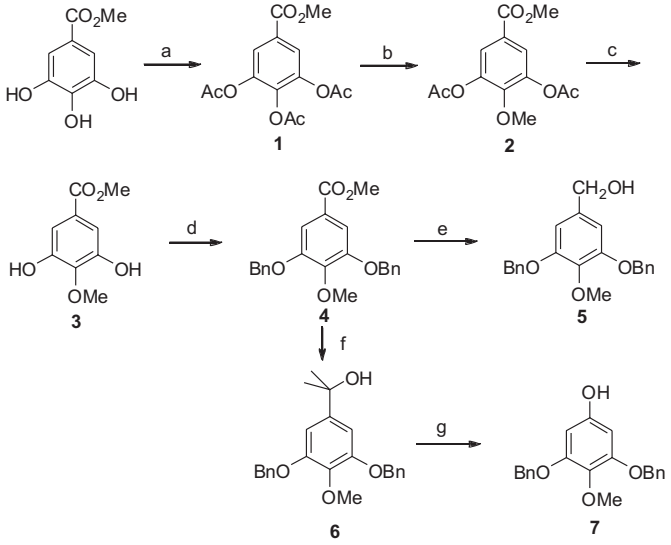
ArOH). ESI-MS: $C_{21}H_{21}O_4$ $[M + H]^+$ 337. Anal. calcd. for $C_{21}H_{20}O_4$: C 75.02, H 5.97; found: C 74.98, H 5.99.

Result and discussion

Chemistry

Gallates are known to display variety of biological functions, including anticancer activity. To investigate the effect of the ester moieties on their antiproliferative and (or) cytotoxic activity, we successfully synthesized compounds **5**–**7** (shown in Scheme 1). Guzmán et al. reported that oxidation of hydroxy and alkoxybenzaldehydes afforded phenols with H_2O_2 and SeO_2 in *t*-butyl alcohol at room temperature (19). Thus, we designed a rout to synthesize compound **7** (shown in Scheme 2). However, compound **8** was obtained in good yield instead of **7** when the route was carried out. Kabalka et al. reported another method to synthesize phenols. Namely, sodium perborate could convert benzylic alcohols to phenols with boron trifluoride etherate in tetrahydrofuran (20). Compound **6** was treated under similar conditions to afford **7** in 93% yields. In contrast, compound **7** was not formed by similarly treating **5**.



Structure analysis

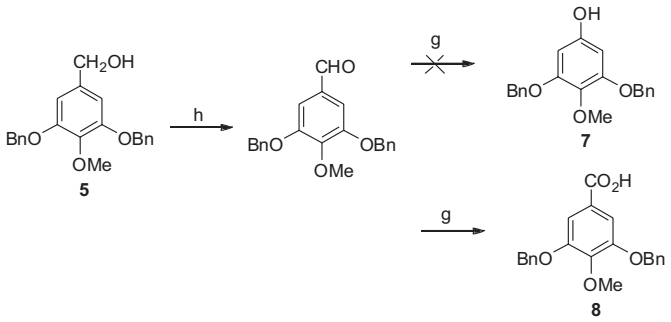
Figures 1–4 represent the crystal structures of compounds **3**–**6** with thermal ellipsoids at 30% probability, respectively. For compound **6**, the hydroxyl O(4) and the two methyl groups C(23) and C(24) were disordered and were refined in three different orientations. The cause is the rotation about C(1)–C(22) bond. The selected bond lengths and bond angles are listed in Table 2.

In the crystal structures of compounds **4**–**6**, there are three benzene rings for each molecule. Although they are structurally similar, the dihedral angels between the central benzene ring and the two peripheral ones in different compounds have significant differences. In compounds **4**–**6**, C(1), C(2), C(3), C(4), C(5), and C(6) form the first plane, defined as plane I; C(8), C(9), C(10), C(11), C(12), and C(13) form the second plane, defined as plane II; C(16), C(17), C(18), C(19), C(20), and C(21) form the third plane, defined as plane III. Plane II and plane III make dihedral angles of 83.064(84) and 62.153(112)°, respectively, with plane I, and the dihedral angle between plane II and plane III is 88.847(112)° in compound **4**. Whereas, plane II and plane III make dihedral angles of 84.899(61) and 50.761(66)°, respectively, with plane I in compound **5** vs. 36.582(81) and 31.189(98)°, respectively, in compound **6**, and the dihedral angle between plane II and plane III is 53.726(73)° in **5** and 37.767(87)° in **6** (Table 3).

In compound **3**, the bond length of C(8)—O(4) is 1.202(3) Å, which is comparable with the corresponding bond length (C(22)—O(4) = 1.197(3) Å) in compound **4**. This is in good agreement with the standard values of C=O bond. In both compounds **3** and **4**, the bond lengths of C(=O)–O are shorter than that of the other C—O single bond in the ester moieties, and the bond lengths of C(=O)–C(phenyl) are slightly shorter than that of normal C—C single bond (1.530 Å) (Table 2), but they are still within the normal scope. This indicated that p–π conjugation exists between O and C=O and the existence of a week π–π conjugation between C=O group and the benzene ring.

Scheme 1. (a) Ac_2O, Et_3N; (b) K_2CO_3, CH_3I; (c) CH_3OH/H_2O, K_2CO_3; (d) DMF, K_2CO_3, BnCl; (e) THF, $LiAlH_4$; (f) Et_2O, CH_3I, Mg; and (g) THF, $NaBO_3{\cdot}4H_2O$, $BF_3{\cdot}Et_2O$.

Scheme 2. (h) Pyridine/CrO_3, THF and (g) SeO_2, H_2O_2, *t*-butyl alcohol.



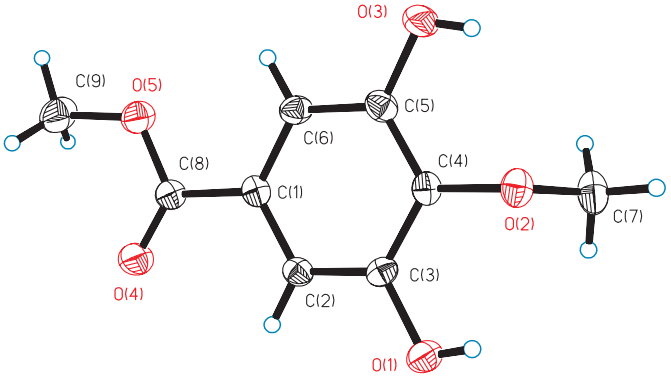


Fig. 1. The crystal structure of compound **3** (30% probability ellipsoids).

In compound **3**, the bond length of C(3)—O(1) (1.373(3) Å) is longer than that of C(5)—O(3) (1.354(3) Å), this difference may be caused by the different type of intermolecular hydrogen bonds. In fact, the intermolecular hydrogen bonds are as follows: O(3)–H(1)···O(4) has length of 2.819(4) Å and an angle of 147(4)°, with symmetry code

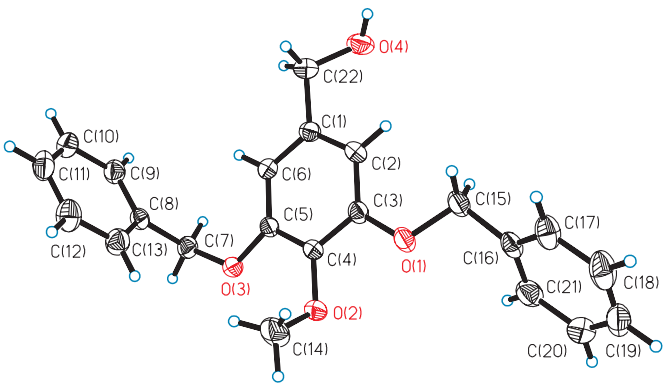

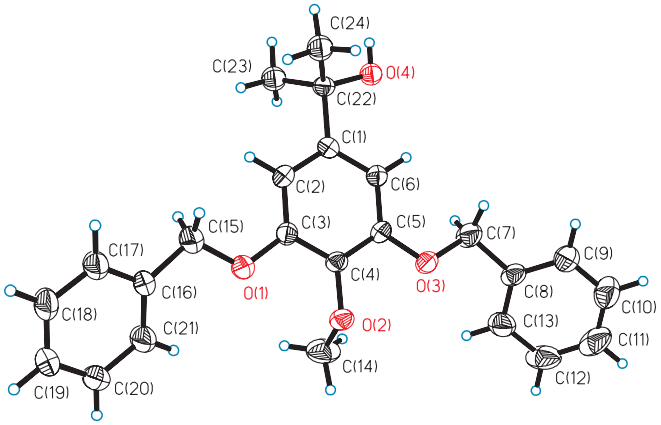

Fig. 4. The crystal structure of compound **6** (30% probability ellipsoids).

x–1, *y*–1, *z*, respectively. On the other hand, O(1)–H(3)···O(1) has length of 2.775(4) Å and an angle of 146(3)°, with symmetry code *x* – 1/2, –*y* + 3/2, –*z*, respectively, (Table 4). One hydrogen bond acceptor is the carbonyl O(4) atom and the other, however, is the phenolic hydroxyl O(1) atom. The corresponding bond lengths of C=O in compounds **4**–**5** verified that hypothesis. The two C=O bond lengths in each compound (**4** or **5**) are almost identical (Table 2). Obviously, the reason is that the hydrogen bonds mentioned do not exist any longer owing to the hydrogen atoms in hydroxyl groups being substituted.

The packing diagrams in Figs. 5 and 6 show the stacking patterns of compounds **3** and **5**, respectively. In the crystal cell of compound **3**, intermolecular hydrogen bonds lead to forming three-dimensional supramolecular network (Fig. 5); meanwhile, the intramolecular hydrogen bonds were also observed between the two hydroxyl groups and O(2) atom. On the other hand, the molecules of compound **5** are linked by the intermolecular hydrogen bonds to form a one-

dimensional hydrogen-bonded linear wire, and the linear wires interact by face-to-face aromatic interactions (Fig. 6). Table 4 shows the hydrogen bonds in compounds **3**–**5**. All the geometrical data fall into the normal range of the hydrogen bonding interactions.

Biological assays

A few studies have evaluated the inhibitory effects of phenolic compounds on HepG2 cancer-cell growth (21) and studied the effects of pure polyphenols (quercetin, chlorogenic acid, and epicatechin) on HepG2 cell population growth and apoptosis. They found that quercetin was the most active with an IC_{50} of 87 μmol/L. Table 5 represented the cytotoxic effect of compounds **1**–**6** against the HepG2 cell lines. Compounds **4**, **5**, and **6** showed more potent-cell-growth inhibitory activities than the positive control 5-FU (IC_{50} 51.6 μmol/L). Compound **5** showed the highest bioactivity with an IC_{50} around 15.3 μmol/L, and compound

Fig. 6. View of the packing diagram of compound **5** showing intermolecular hydrogen bonds. The chains run along the *a* axis.

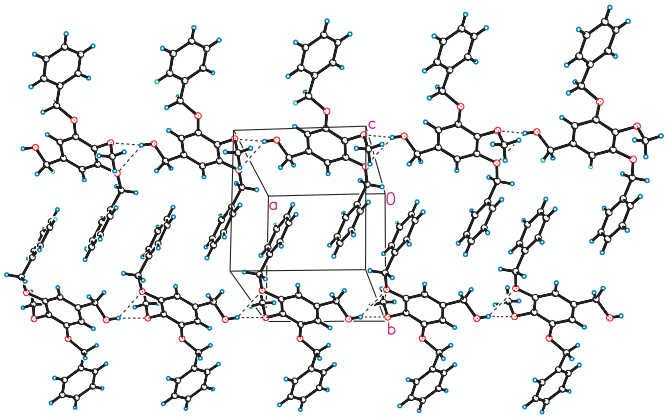

Table 5. Inhibition of HepG2 cells by compounds **1–7**.

Compounds	IC_{50} (μmol/L)
5-UF	51.6±0.2
1	77.8±0.7
2	69.6±0.4
3	90.3±0.6
4	23.1±0.1
5	15.3±0.2
6	20.2±0.5
7	67.8±0.3

4 (IC_{50} 23.1 μmol/L) was as potent as **6** (IC_{50} 20.2 μmol/L). In contrast, other compounds showed intermediate IC_{50} values. This suggested that the lipophilic group makes it easier for the molecule to permeate the cell membrane and interact with the enzymes in the cells. Roy et al. reported that lauryl gallate is able to inhibit protein tyrosine kinases (PTKs) in whole cells and in crude extracts (22). This allows us to make the following consideration: the compounds based on gallates in this paper may exert their proapoptotic activity

© 2007 NRC Canada

through the mechanism mentioned earlier. The study of the detailed mechanism is in progress.

Conclusion

A structural analysis of compounds **3**–**6** was carried out by single-crystal X-ray diffraction. The cytotoxic effects of seven derivatives of gallates tested against the HepG2 cell lines were evaluated. The effect of slight structural variations in this kind of systems was found to cause a marked change in their biological activity. Compound **5** showed the highest bioactivity with an IC_{50} around 15.3 μmol/L. The understanding of the structure–activity relationships ruling their biological function lies in more specific assays, the target particular binding sites, and the mechanisms of action. Further structure–activity relationship study is undergoing and will be reported in due course.

An exploratory ab initio study of the S_N2 reaction of 1,3,3-trimethyltriazene with halide ions

Katherine G. Doucet, Cory C. Pye, and Thomas G. Enright

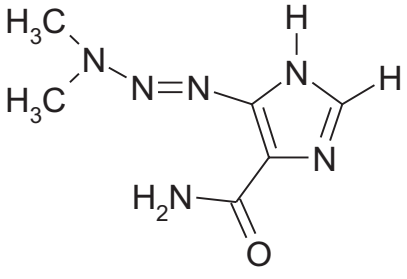
Abstract: Methyltriazene and the O6 oxygen of guanine are believed to undergo a bimolecular nucleophilic substitution (S_N2) reaction to form methylguanine, which is proposed to be responsible for the cytotoxic properties of triazene-containing anti-neoplastic agents, such as Dacarbazine. To better understand the proposed mechanism of triazene-containing anti-neoplastic agents, a series of ab initio studies investigating the S_N2 reaction between methyltriazenes and halide ions were undertaken. The results of our investigation of the S_N2 reaction between 1,3,3-trimethyltriazene and the halide ions are presented here.

Key words: triazene, trimethyltriazene, Dacarbazine, Temozolomide, bimolecular nucleophilic substitution reaction.

Résumé : On fait généralement l'hypothèse que le méthyltriazène et l'oxygène O6 de la guanidine donnent lieu à une réaction de substitution nucléophile bimoléculaire (S_N2) qui conduirait à la méthylguanidine et on attribue à cette réaction la responsabilité des propriétés cytotoxiques des agents anti-néoplasiques qui contiennent du triazène, tel le Dacarbazine. Dans le but de mieux comprendre le mécanisme proposé pour l'action des agents anti-néoplasiques contenant du triazène, on a entrepris des études ab initio sur la réaction S_N2 entre les méthyltriazènes et les ions halogénures. On rapporte ici les résultats de notre investigation de la réaction S_N2 entre le 1,3,3-triméthyltriazène et les ions halogénures.

Mots-clés : triazène, triméthyltriazène, Dacarbazine, Temozolomide, réaction de substitution nucléophile bimoléculaire.

[Traduit par la Rédaction]



Introduction

Dacarbazine, 5-(3,3-dimethyl-1-triazenyl)imidazole-4-carboxamide (Fig. 1) is the single most-reactive agent known for the treatment of malignant melanoma (1–3). The mechanism of action of these anti-neoplastic agents remains unknown (4). It has been proposed that triazene-containing anti-neoplastic agents, especially Dacarbazine, require demethylation, a process that is known to be carried out by hepatic cytochrome P450 enzymes (5) (Scheme 1). The active metabolite, a monomethyltriazene, is believed to methylate DNA, as other methyltriazenes have been shown to be DNA and RNA methylating agents (6, 7). It has been proposed that monomethyltriazenes methylate the O6 oxygen of guanine to form methylguanine through a carbon-centered bimolecular nucleophilic substitution (S_N2) reaction (8) (Scheme 2).

Previous studies have focused on triazene and its mono-, di-, and tri-methyl analogues (9). In addition to this, more recent studies focused on the S_N2 reaction pathways of monomethyltriazene (10) and dimethyltriazene with halide ions (11). The present study focuses on the S_N2 reaction between 1,3,3-trimethyltriazene (Fig. 2) and the halide ions. 1,3,3-Trimethyltriazene contains three potential sites for attack by a halide ion and can exist as one of two isomers, (*E*) or (*Z*) with respect to the N=N bond of the triazene moiety (9). The (*E*) form is 56–64 kJ mol^{-1} more stable than the (*Z*) form. The S_N2 reaction between the 1-methyl of 1,3,3-trimethyltriazene and halide ions results in halomethane, molecular nitrogen, and dimethylamide ion (Scheme 3). The S_N2 reaction with either 3-methyl of 1,3,3-trimethyltriazene results in halomethane and a dimethyltriazenide ion (Scheme 4).

This series of studies was intended to provide a framework for future studies involving the active metabolite of Dacarbazine and its simple structural analogues. It is believed that these studies will provide a better understanding of the chemistry behind the proposed mechanism of action of triazene-containing anti-neoplastic agents.

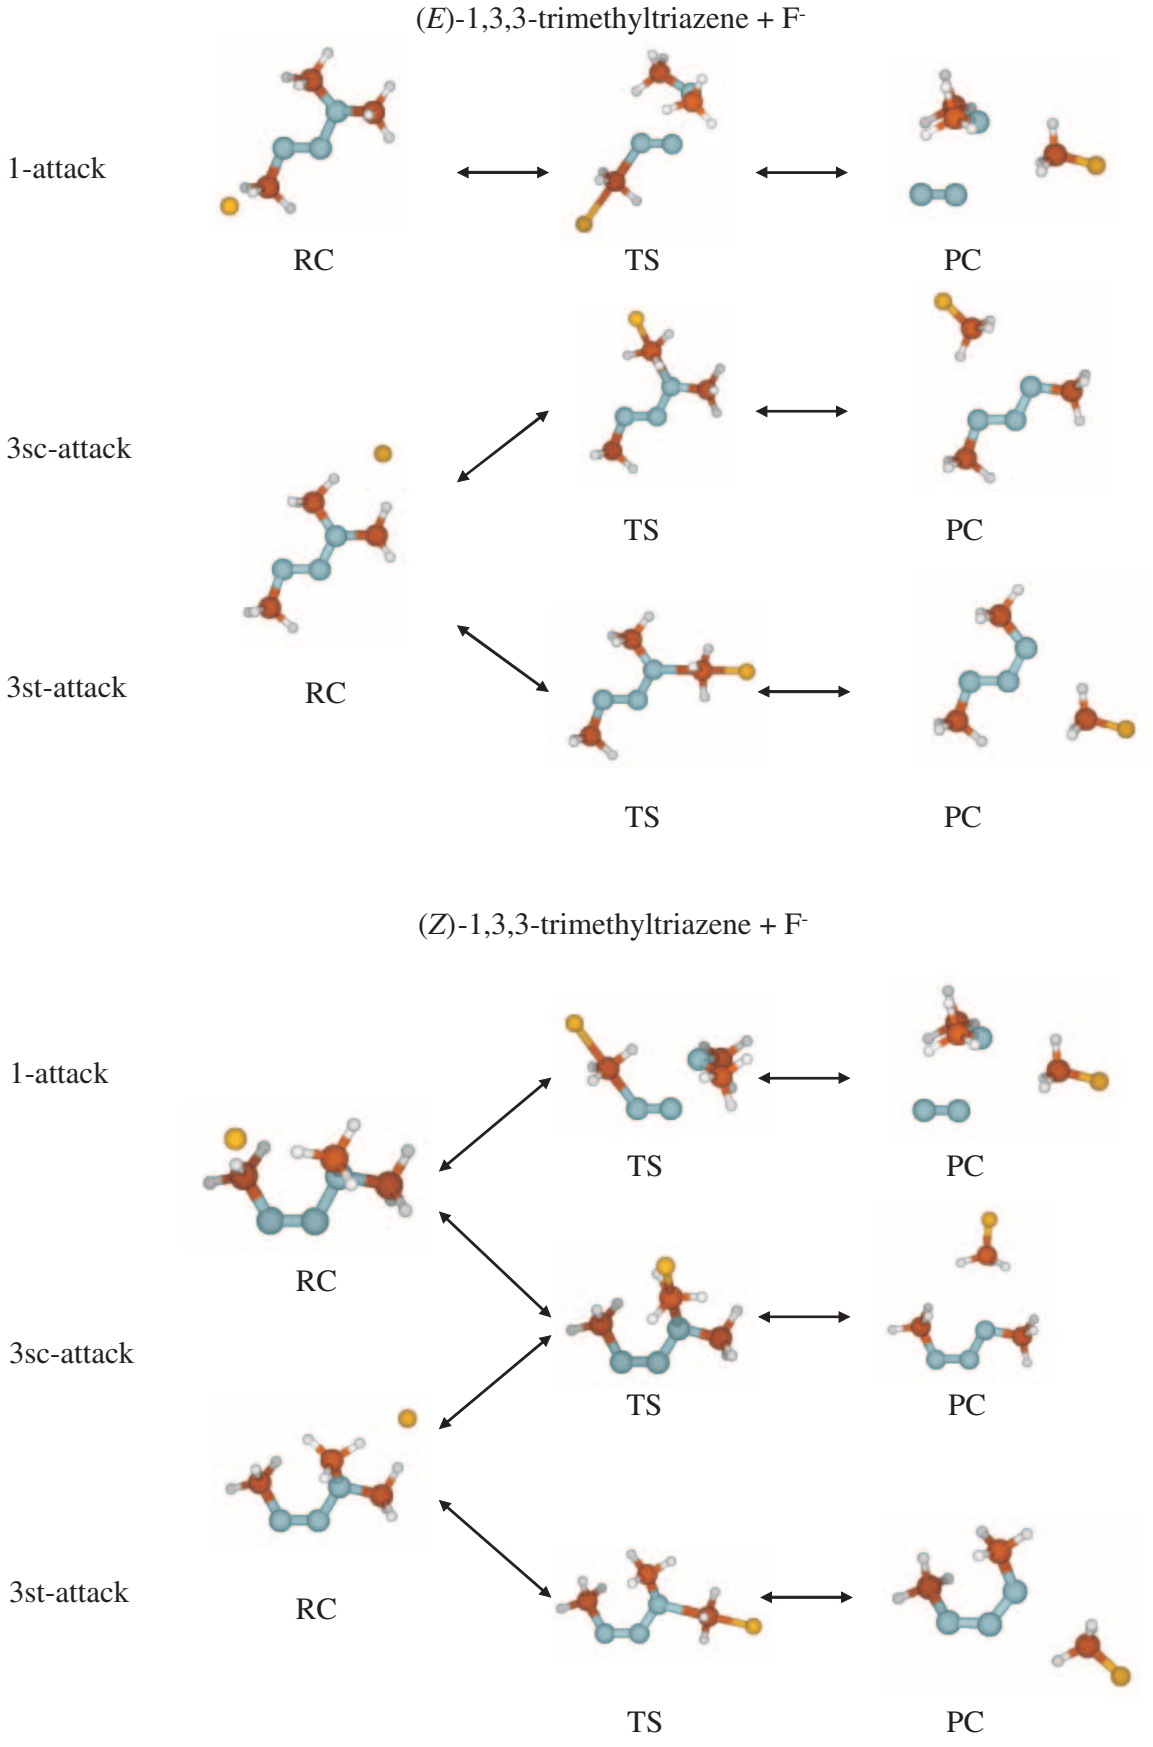
Method

Gaussian 98 (12) or Gaussian 03 (13) were used to perform all calculations for this computational study. Geometry optimizations were sequentially performed at the HF/STO-3G, HF/3–21G, HF/6–31G(d), HF/6–31+G(d), MP2/6–31G(d), and MP2/6–31+G(d) levels of theory. For MP2 calculations, the frozen-core approximation was utilized. Harmonic vibrational frequencies and zero-point vibrational energy (ZPVE) corrections were performed sequentially at the previously mentioned levels of theory. Harmonic vibrational frequency calculations characterized the geometry optimizations. A previously determined scaling factor was used to correct the ZPVE (14). Modified Huzinaga basis sets were used for iodine (15, 16). Only the results at MP2/6–31+G(d) will be presented; the rest are given in the Supplementary Data.[2] Because the halide ions were chosen as a very simple model for guanine in this initial survey, errors resulting from this choice would overshadow errors from neglecting temperature, free-energy, and solvation corrections. To allow direct comparison with our previous work (10, 11), we do not invoke these corrections.

Fig. 2. The chemical structure of 1,3,3-dimethyltriazene.



Results and discussion

Each reaction pathway passes through five stationary structures; the separated reactants (SR), a reactant complex (RC), a transition structure (TS) that corresponds to the characteristic Walden inversion of the methyl group, a product complex (PC), and the separated products (SP). The separated reactants and products are assumed to be at an infinite distance. For the (*E*) structures, the RC is the same for both syn-periplanar (sp, "s-cis") and anti-periplanar (ap, "s-trans") attack, whereas for the (*Z*) structures, each of the two RCs leads to one of two TSs, with the 3 sp TS being arrived at from either RC (see Fig. 3). We consider the net barriers, the energy difference between separated reactants and transition state, unless otherwise specified.

Fig. 4. The structures on the reaction pathways of dimethyltriazenide rearrangement and fragmentation.

For 3-methyl attack, the dimethyltriazenide ion formed in the product complex depends on the isomer of 1,3,3-trimethyltriazene and which one of the two 3-methyl groups is attacked. The sp methyl attack of (*Z*)-1,3,3-trimethyltriazene results in the formation of (*E*,*Z*)-1,3-dimethyltriazenide ion, whereas the ap methyl attack results in (*Z*,*Z*)-1,3-dimethyltriazenide ion. Attack of (*E*)-1,3,3-trimethyltriazene at the sp methyl results in (*E*,*E*)-1,3-dimethyltriazenide ion, whereas attack at the ap methyl results in (*E*,*Z*)-1,3-dimethyltriazenide ion formation. Of the three distinct dimethytriazenide ions (Fig. 4), the (*E*,*Z*)-dimethyltriazenide ion was found to be more stable than the (*E*,*E*) and (*Z*,*Z*) conformers (Table 1), with the (*Z*,*Z*) isomer being especially unstable because of the steric collision of the methyl groups forcing a non-planar C_2 arrangement. Comparison to methyltriazenide ion reveals that the barrier to fragmentation via a methyl shift is nearly identical. However, the (*E*,*Z*) to (*E*,*E*) rotational barrier is, for the most part, slightly lower, and the (*E*,*Z*) to (*Z*,*Z*) barrier is higher. This trend was also revealed for the comparison between triazenide and methyltriazenide.

The relevant geometrical parameters are given in Tables S7-S10 of the Supplementary Data.[2] At most levels of theory, reactions involving fluoride were exothermic, whereas those involving chloride, bromide, and iodide were progressively more endothermic (Tables 2 and S11–S14). We were able to note some general trends for all of the S_N2 reactions. The (*Z*) barriers are generally lower than the (*E*) barriers, except for the 3 ap attack. For the (*Z*) forms, the barrier increases from 1-attack to 3 sp to 3 ap. For 1-attack of fluoride, the barrier for 1,3,3-trimethyltriazene is lower than that of 1-methyltriazene and 1,3-dimethyltriazene. For 3 ap attack, the barriers are higher than that of the less-substituted 3-methyltriazene (ap), 1,3-dimethyltriazene (ap),

Table 2. Relative energy comparison (MP2/6–31+G*, kJ mol^{-1}), with respect to the separated reactants of each reaction, of the 1,3,3-trimethyltriazene S_N2 reaction pathways.

	Relative energy (kJ mol^{-1})							
	(*Z*)-				(*E*)-			
Level of theory	RC	TS	PC	SP	RC	TS	PC	SP
F^-, 1-attack	–92.0	22.1	–188.0	–119.3	–43.2	77.0	–128.3	–59.5
F^-, 3 sp attack	–92.0	32.4	–63.3	–20.0	–82.2	76.8	3.4	50.7
F^-, 3 ap attack	–84.7	72.0	10.3	55.8	–82.2	63.3	–4.6	39.8
Cl^-, 1-attack	–55.9	78.7	–80.9	–9.0	–20.1	137.7	–21.1	50.8
Cl^-, 3 sp attack	–55.9	105.8	51.8	90.3	–50.6	152.6	109.5	161.0
Cl^-, 3 ap attack	–52.7	154.1	116.4	166.0	–50.6	144.3	102.0	150.0
Br^-, 1-attack	–58.8	79.3	–49.7	30.4	–43.1	140.3	10.1	90.2
Br^-, 3 sp attack	–58.8	105.8	72.8	129.6	–53.8	154.3	130.2	200.4
Br^-, 3 ap attack	–56.1	157.9	139.4	205.4	–53.8	147.8	125.3	189.4
I^-, 1-attack	–44.9	100.5	–17.9	66.3	–44.9	100.5	–17.9	66.3
I^-, 3 sp attack	–44.9	138.7	121.4	176.5	–40.2	187.4	175.3	236.2
I^-, 3 ap attack	–42.8	193.9	185.6	241.3	–40.2	182.8	170.0	225.3

and 3,3-dimethyltriazene. The poor stability of the product (*Z*,*Z*)-dimethyltriazenide ion accounts for trends involving ap attack on the (Z) form. For the fluoride ion, with the (*E*) form of 1,3,3-dimethyltriazene, the barrier increases from 3 ap to 3 sp to 1-attack, whereas for the other halogens, the barrier increases from 1 attack to 3 ap to 3 sp. For the fluoride ion attacking the sp position, no trend is noted upon comparison with the less-substituted triazenes, whereas for the other halogens, the barriers are mostly lower than that of 3-methyl- (10), 1,3-dimethyl-, and 3,3-dimethyltriazene (11).

To summarize, the reaction pathways of (*E*)- and (*Z*)-1,3,3-dimethyltriazene with the halides are endothermic, with the exception of the fluoride reaction. The endothermicity increases with the size of the halide anion. The (*E*) barriers are usually higher than the (*Z*) barriers. The barriers of 1 attack decrease upon increasing methyl substitution. Because the S_N2 barriers are usually lower for 1 attack, and because of the high rearrangement and fragmentation barriers in the dimethyltriazenide ion resulting from 3 attack, the 1 attack is expected to be the dominant mode of action of triazene-based drugs.

Glycoluril-derived crown clips as new ditopic receptors

Mohammad Rahimizadeh, E. Rezaei Seresht, Mehdi Bakavoli, and Mehdi Pordel

Abstract: Several new ditopic receptors have been synthesized from 4,4′-bis(methoxyphenyl)glycoluril (**1**). The first receptor site is a cleft composed of two fused 2-imidazolone rings, which are flanked by two aromatic side walls, and the second site is a crown ether moiety.

Key words: receptors, crown compounds, glycoluril, molecular clips.

Résumé : On a effectué la synthèse de plusieurs nouveaux récepteurs ditopiques au départ de la 4,4′-bis(méthoxyphényl)glycoluril (**1**). Le premier site récepteur est une fente formée par deux noyaux 2-imidazole condensés flanqués de deux murs latéraux aromatiques alors que le second site récepteur est un éther couronne.

Mots-clés : récepteurs, composés couronnes, glycoluril, pinces moléculaires.

[Traduit par la Rédaction]

Introduction

Receptors in living organisms play fundamental roles in the growth, nutrition, and differentiation of animal cells (1). Artificial receptors are capable of mimicking this function, which can lead to a better understanding of the natural processes and additionally to the development of new artificial systems for use in drug delivery, catalysis, and so forth (2).

Diphenylglycoluril-based clip molecules have been prepared and extensively studied in the Nolte group over the past decade (3). These molecules possess a well-defined cavity that allows the binding of different phenolic guests via a combination of several non-covalent interactions (H-bonding, π–π stacking, and the cavity effect) (3). The introduction of crown ether chains and alkyl tails to these receptors can lead to a new generation of the so-called amphiphilic basket receptors, which are also able to bind alkaline metal ions and aggregate in water into well-defined nanostructures (4, 5). Here, we describe the synthesis of new diphenylglycoluril-based ditopic receptors, bearing crown ether units, with potential ability to bind both neutral aromatic guests and alkaline metal ions, simultaneously.

Results and discussion

We have utilized the commercially available 4,4-dimethoxybenzil (**7**) as a potentially interesting candidate for the synthesis of more engineered clips, since the ring-activating *p*-methoxy group on the phenyl nucleus could allow the possibility of electrophilic aromatic substitution ortho- to it. Alternatively, the methoxy group could be demethylated to give the more-reactive hydroxy group that can start up a variety of methods for further structural elaboration and derivatization. Therefore, 4,4-bis(methoxyphenyl)glycoluril (**1**) was prepared quantitatively from compound **7** and urea in trifluoroacetic acid and toluene by azeotropic distillation according to a published method (Scheme 1) (6). The molecular clips **3a**–**3c** were subsequently synthesized from **1** by means of an amido alkylation reaction in the presence of potassium hydroxide in DMSO (Scheme 1). Notably, the clip-like structures of these molecules can be easily deduced from the X-ray structure of **3a** (6). Therein, the *o*-xylene rings define a tapered cavity, and the two fused five-membered rings of the glycoluril form a shallow floor, which is electron-rich with two hydrogen-bond-acceptor sites. ^{1}H NMR studies were the first to reveal that the molecular clips, with their pre-organized clefts, are excellent receptors for neutral aromatic guests, particularly dihydroxybenzenes (7–11). For example, upon binding of resorcinol, the guest simultaneously forms two hydrogen bonds to the π orbitals of the carbonyl groups of the clip. The binding strength of this type of guests within the molecular clips can span a wide range of values ($K_{association}$ = 0–10^5 (mol/L)$^{-1}$), which vary with simple modification in either host or guest molecule. Compounds **2b** and **2c** are more susceptible to nucleophilic attack by **1** than **2a**. So, the reaction time was changed from 2 h for **2a** to 4 h for **2b** and **2c**. The side wall **2a** is commercially available, and the other side walls (**2b** and **2c**) were prepared via chloromethylation of *o*-xylene and 1,2,3,4-tetramethylbenzene, recpectively. For the demethylation of the methoxy groups of the clips **3a**–**3c**, pyridine hydrochloride was used as a demethylating agent and as a result, compounds **4a**–**4c** were produced in yields higher than 65%. Then, the hydroxy-functionalized clips **4a**–**4c** were reacted with ditosylates **6a**–**6c** in acetonitrile with K_2CO_3 as a base to yield **5a**–**5i** (Scheme 2). The structures of compounds **5a**–**5i** were confirmed from their spectral and analytical data. For example, in the ^{1}H NMR spectrum of

Scheme 2.

5g, an AB system (3.97 and 5.17 ppm) with geminal coupling (J = 16 Hz) indicates the non-equivalent methylene protons of the clip moiety. The methyl groups on aromatic side walls appeared as two sharp singlets at δ 2.16 and 2.46 ppm, the protons of para-disubstituted aromatic rings as two doublets at δ 6.61 and 6.93 ppm (J = 9 Hz), and the methylene protons in polyether moiety as two triplets at δ 3.67 and 4.28 ppm (J = 4 Hz).

Conclusion

In summary, several new glycoluril-based receptors with crown ether moieties have been synthesized and characterized. These ditopic receptors are good candidates to bind with dihydroxybenzene derivatives as well as alkaline metal ions, simultaneously. We expect that the binding strength of dihydroxybenzenes with the cleft will be influenced by steric hindrance on side-wall rings. So, the repulsive van der Waals interactions between methyl groups in **3b** and **3c** can alter the cleft shape and hence causes an appreciable change in the binding strengths. On the other hand, it seems viable that compounds **5a**–**5i** are able to show allosteric behavior, as the binding of alkaline metal ions with the crown ether moiety may have influence on the binding of dihydroxybenzenes in the cleft. These studies are currently in progress in our laboratory.

Experimental

Toluene was distilled from sodium benzophenone ketyl. MeCN was distilled from $CaCl_2$. CH_2Cl_2 and MeOH were distilled from CaH_2. Silica gel 60 (0.040–0.063 mm, Merck) was used for column chromatography. 4,4′-Dimethoxybenzil (**7**) and 1,2-bis(bromomethyl)benzene (**2a**) were purchased from Merck company. 1,2,3,4-Tetramethylbenzene was purchased from Aldrich company. 1,2-Bis(chloromethyl)-4,5-dimethylbenzene (**2b**) (12), pyridine hydrochloride (13), and oligoethylene glycol ditosylates (**6a**–**6c**) (14) were prepared according to the literature. Melting points were recorded on an Electrothermal type 9100 melting-point apparatus and are uncorrected. The IR spectra were obtained on a 4300 Shimadzu spectrometer and only noteworthy absorptions are listed. The ^{1}H NMR (100 MHz) spectra were recorded on a Bruker AC 100 spectrometer. Chemical shifts are reported in ppm downfield from TMS as internal standard; coupling constants *J* are given in Hertz. The mass spectra were scanned on a Varian Mat. CH-7 at 70 eV. Elemental analysis was performed on a Thermo Finnigan Flash EA microanalyzer.

1,2-Bis(chloromethyl)-3,4,5,6-tetramethylbenzene (2c)

The title compound was prepared similar to **2b** with slight modification as follows: a mixture of 1,2,3,4-tetramethylbenzene (26.8 g, 0.2 mol), paraformaldehyde (18 g, 0.6 mol) and concd. HCl (125 mL) was refluxed with stirring for 10 h. The reaction mixture was cooled, and the precipitated solid was filtered, washed with water (2 × 50 mL) and cold hexane (30 mL), and dried in vacuo.

Yield: 27.7 g (60%); white needles; mp 140–142 °C. IR (KBr): 2913, 1439, 1270, 685 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 2.25 (s, 6 H, 2 × CH_3), 2.36 (s, 6 H, 2 × CH_3), 4.80 (s, 4 H, 2×CH_2). EI-MS *m*/*z* (%): 231 (M^+). Anal. calcd. for $C_{12}H_{16}Cl_2$: C, 89.94; H, 10.06. Found: C, 89.76; H, 10.26.

*13b,13c-Di(4-methoxyphenyl)-5,7,12,13b,13c,14-hexahydro-5a,6a,12a,13a-tetraaza-benzo[5,6]azuleno[2,1,8-*ija*]benzo[*f*]azulene-6,13-dione (3a)*

This compound was synthesized according to a literature procedure (6). Mp > 300 °C. ^{1}H NMR ($CDCl_3$) δ: 3.70 (s, 6 H, 2 × OCH_3), 4.15 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 4.76 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.67 (d, *J* = 8 Hz, 4 H, Ar–H), 6.97–7.30 (m, 12 H, Ar–H).

13b,13c-Di(4-methoxyphenyl)-2,3,9,10-tetramethyl-5,7,12,13b,13c,14-hexahydro-5a,6a,12a,13a-tetra-aza-benzo[5,6]azuleno[2,1,8-ija]benzo[f]azulene-6,13-dione (3b)

4,4-Bis(methoxyphenyl)glycoluril (**1**) (2.48 g, 7 mmol) and freshly ground potassium hydroxide (4.0 g, 70 mmol) in DMSO (50 mL) were heated to 120 °C with vigorous stirring for 30 min. Then, 1,2-bis(chloromethyl)-4,5-dimethylbenzene (**2b**) (3.04 g, 15.0 mmol) was added in one portion, and stirring was continued at this temperature for 4 h. On cooling, the reaction mixture was added to water (500 mL) and stirred for 30 min. The resulting light-brown precipitate was collected by filtration, washed with water (3 × 400 mL) and acetone (3 × 100 mL), and dried in vacuo.

Yield: 2.66 g (62%); mp > 300 °C. IR (KBr): 2963, 1709, 1611, 1512, 1458, 1253 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 2.12 (s, 12 H, 4 × CH_3), 3.70 (s, 6 H, 2 × OCH_3), 4.10 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 4.71 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.65 (d, *J* = 8 Hz, 4 H, Ar–H), 6.98 (d, *J* = 8 Hz, 4 H, Ar–H), 7.04 (s, 4 H, Ar–H). EI-MS *m*/*z* (%): 614 (M^+). Anal. calcd. for $C_{38}H_{38}N_4O_4$: C, 74.25; H, 6.23; N, 9.11. Found: C, 74.34; H, 6.48; N, 9.02.

*13b,13c-Di(4-methoxyphenyl)-1,2,3,4,8,9,10,11-octa-methyl-5,7,12,13b,13c,14-hexahydro-5a,6a,12a,13a-tetraazabenzo[5,6]azuleno[2,1,8-*ija*]benzo[*f*]azulene-6,13-dion (3c)*

The title compound was prepared as described for **3b** using 3.46 g (15 mmol) of compound **2c** and 2.48 g (7 mmol) of compound **1**. Yield: 2.67 g (57%); mp > 300 °C. IR (KBr): 2912, 1703, 1610, 1512, 1460, 1253 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 2.15 (s, 12 H, 4 × CH_3), 2.43 (s, 12 H, 4 × CH_3), 3.67 (s, 6 H, 2 × OCH_3), 3.85 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 5.12 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.62 (d, *J* = 8 Hz, 4 H, Ar–H), 7.02 (d, *J* = 8 Hz, 4 H, Ar–H). EI-MS *m*/*z* (%): 670 (M^+). Anal. calcd. for $C_{42}H_{46}N_4O_4$: C, 75.20; H, 6.91; N, 8.35. Found: C, 74.98; H, 6.86; N, 8.12.

Synthesis of hydroxy-funtionalized clips 4a–4c

General procedure

Compound **3** (2.5 mmol) was added to a flask containing pyridine hydrochloride (11.5 g, 0.1 mol), and the mixture was heated at 190–200 °C for 4 h. The hot brown syrup was poured into aq. HCl (5%, 50 mL), and the precipitated solid was filtered, washed with water (3 × 50 mL) and $CHCl_3$ (2 × 25 mL), and dried in vacuo at 80 °C to give compound **4**.

*13b,13c-Di(4-hydroxyphenyl)-5,7,12,13b,13c,14-hexahydro-5a,6a,12a,13a-tetraaza-benzo[5,6]azuleno[2,1,8-*ija*]benzo[*f*]azulene-6,13-dione (4a)*

Yield: 0.93 g (70%); mp > 300 °C. IR (KBr): 3356 (br), 1682, 1614, 1516, 1464, 1277 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ: 4.08 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 4.60 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.58 (d, *J* = 8 Hz, 4 H, Ar–H), 6.83 (d, *J* = 8 Hz, 4 H, Ar–H), 6.97–7.30 (m, 8 H, Ar–H), 9.49 (s, 2 H, 2 × OH). Synthesis of crown clips 5a–5i

General procedure

Ditosylate **6** (1.5 mmol) was added in small portions during a period of 12 h to the refluxing mixture of **4** (1.5 mmol) and K_2CO_3 (0.83 g, 6 mmol) in dry MeCN (60 mL). The reflux was continued for 3 days. Then, the solvent was evaporated in vacuo, and the light-brown solid was partitioned between aq. NaOH (5%, 75 mL) and CH_2Cl_2 (75 mL). The organic layer was washed with water (75 mL), dried (Na_2SO_4), and evaporated to dryness. After column chromatography (eluent: CH_2Cl_2 – MeOH, 100:3, *v/v*), compound **5** was obtained as white powder.

Crown clip 5a

The title compound was obtained according to the general procedure, starting with **4a** and **6a**.

Yield: 0.39 g (44%); mp > 300 °C. IR (KBr): 2917, 2849, 1703, 1509, 1455, 1233 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.68 (t, *J* = 6 Hz, 4 H, CH_2OCH_2), 4.19–4.34 (m, 8 H, 4 × *CH*H, 2 × $ArOCH_2$), 4.81 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.66 (d, *J* = 8 Hz, 4 H, Ar–H), 6.95–7.30 (m, 12 H, Ar–H). EI-MS *m/z* (%): 600 (M^+). Anal. calcd. for $C_{36}H_{32}N_4O_5$: C, 71.99; H, 5.37; N, 9.33. Found: C, 72.10; H, 5.42; N, 9.38.

Crown clip 5b

The title compound was obtained according to the general procedure, starting with **4a** and **6b**.

Yield: 0.40 g (42%); mp > 300 °C. IR (KBr): 2925, 2854, 1706, 1512, 1454, 1256 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.65–3.85 (m, 8 H, OCH_2CH_2O, 2 × OCH_2), 4.05–4.30 (m, 8 H, 4 × *CH*H, 2 × $ArOCH_2$), 4.78 6.91–7.30 (m, 12 H, Ar–H). EI-MS *m/z* (%): 644 (M^+). Anal. calcd. for $C_{38}H_{36}N_4O_6$: C, 70.79; H, 5.63; N, 8.69. Found: C, 70.51; H, 5.53; N, 8.83.

Crown clip 5c

The title compound was obtained according to the general procedure, starting with **4a** and **6c**.

Yield: 0.39 g (38%); mp > 300 °C. IR (KBr): 2917, 2852, 1709, 1610, 1457, 1254 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.68 (s, 8 H, 2 × OCH_2CH_2O), 3.80 (t, *J* = 5 Hz, 4 H, 2 × OCH_2), 4.02 (t, *J* = 5 Hz, 4 H, 2 × $ArOCH_2$), 4.18 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 4.77 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.66 (d, *J* = 8 Hz, 4 H, Ar–H), 6.93–7.30 (m, 12 H, Ar–H). EI-MS *m/z* (%): 688 (M^+). Anal. calcd. for $C_{40}H_{40}N_4O_7$: C, 69.75; H, 5.85; N, 8.13. Found: C, 69.98; H, 5.91; N, 8.18.

Crown clip 5d

The title compound was obtained according to the general procedure, starting with **4b** and **6a**.

Yield: 0.44 g (45%); mp > 300 °C. IR (KBr): 2922, 1706, 1608, 1508, 1455, 1236 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 2.10 (s, 12 H, 4 × CH_3), 3.63 (t, *J* = 4 Hz, 4 H, CH_2OCH_2), 4.08–4.25 (m, 8 H, 4 × *CH*H, 2 × $ArOCH_2$), 4.71 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.60 (d, *J* = 9 Hz, 4 H, Ar–H), 6.84 (d, *J* = 9 Hz, 4 H, Ar–H), 6.99 (s, 4 H, Ar–H). EI-MS *m/z* (%): 656 (M^+). Anal. calcd. for $C_{40}H_{40}N_4O_5$: C, 73.15; H, 6.14; N, 8.53. Found: C, 73.40; H, 6.22; N, 8.41.

Crown clip 5e

The title compound was obtained according to the general procedure, starting with **4b** and **6b**.

Yield: 0.44 g (42%); mp > 300 °C. IR (KBr): 2920, 1708, 1610, 1509, 1457, 1253 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 2.13 (s, 12 H, 4 × CH_3), 3.65–3.84 (m, 8 H, OCH_2CH_2O, 2 × OCH_2), 4.90–4.22 (m, 8 H, 4 × *CH*H, 2 × $ArOCH_2$), 4.72 (d, *J* = 16 Hz, 4 H, 4 × *CH*H), 6.63 (d, *J* = 8 Hz, 4 H, Ar–H), 6.92 (d, *J* = 8 Hz, 4 H, Ar–H), 7.02 (s, 4 H, Ar–H). Cross-conjugated *Z*- and *E*-3-ferrocenylmethylidene-4-methyl-2-phenylpenta-1,4-dienes — Synthesis and some chemical properties

Juan Manuel Martínez Mendoza, Lena Ruíz Ramírez, Ruben Alfredo Toscano, Simon Hernández Ortega, Cecilio Alvarez Toledano, Marcos Flores Alamo, and Elena I. Klimova

Abstract: Dehydration of (*Z*)- and (*E*)-4-ferrocenyl-3-isopropenyl-2-phenylbut-3-en-2-ols and *Z*-3-ferrocenylmethylidene-4-methyl-2-phenylpentane-2,4-diol affords (*Z*)- and (*E*)-3-ferrocenylethylidene-4-methyl-2-phenylpenta-1,4-dienes with a system of three cross-conjugated double bonds. One of the methylidene groups of the trienes obtained is smoothly protonated under the action of tetrafluoroboric acid etherate to yield (*Z*)- and (*E*)-3-ferrocenyl-2-isopropenyl-1-methyl-1-phenylallyl tetrafluoroborates. The cross-conjugated trienes undergo cationic cycloaddition to these allylic cations as well as proton-induced cyclodimerization resulting in 7-ferrocenyl-4-ferrocenylmethylidene-1,3-dimethyl-5-phenyl-8-(1-phenylethylidene)bicyclo[3.3.1]non-2-ene and isomeric 1,5-diferrocenyl-2,6-diisopropenyl-3,7-diphenylocta-1,3,6-trienes.

Key words: cross-conjugated trienes, ferrocenylallylic cations, cyclodimerization, cycloaddition, ferrocene.

Résumé : La déshydratation des (*Z*)- et (*E*)-4-ferrocényl-3-isopropényl-2-phénylbut-3-én-2-ols et du *Z*-3-ferrocényl-méthylidène-4-méthyl-2-phénylpentane-2,4-diol conduit aux (*Z*)- et (*E*)-3-ferrocényléthylidène-4-méthyl-2-phénylpenta-1,4-diènes qui comportent un système à trois doubles liaisons à conjugaison croisée. Sous l'action de l'éthérate de l'acide tétrafluoroborique, il se produit une protonation facile d'un des groupes méthylènes des triènes qui ont été obtenus avec production de tétrafluoroborates de (*Z*)- et (*E*)-4-3errocényl-2-isopropényl-1-méthyl-1-phénylallyle. Les triènes à conjugaison croisée conduisent à une cycloaddition cationique de ces cations allyliques ainsi qu'une cyclodimérisation induite par les protons qui conduit à la formation du 7-ferrocényl-4-ferrocénylméthylidène-1,3-diméthyl-5-phényl-8-(1-phényléthylidène)bicyclo[3.3.1]non-2-ène ainsi qu'aux 1,5-diferrocényl-2,6-diisopropényl-3,7-diphénylocta-1,3,6-triènes isomères.

Mots-clés : triènes à conjugaison croisée, cations ferrocénylallyliques, cyclodimérisation, cycloaddition, ferrocène.

[Traduit par la Rédaction]

Introduction

Recently, the interest in the chemistry of ferrocenes has increased because of their possible practical applications. Data on the industrial use of the ferrocene derivatives, available from the patent literature (1, 2), reflect mainly their employment in military-industrial establishment, rocket technologies, and medicine. Publications demonstrating the use of ferrocene derivatives in nonlinear optics devices, chemistry of polymeric materials, biology, and synthetic organic chemistry (asymmetric synthesis) has appeared since 1994 (3–7).

The ferrocene molecule itself is an energy-rich structure. Therefore, studies on compounds comprising other energy-rich fragments, such as ene, diene, and polyene chains, fused carbo- and hetero-cyclic systems, in addition to the ferrocene moiety, are of special interest.

Investigations into ferrocene-containing polyene compounds aim at the studies of strain energy, optical properties of ferrocenylpolyenes, mechanisms of highly selective reactions involved in the in vitro and in vivo syntheses of various aliphatic, carbocyclic, and heterocyclic compounds, and their potential use as molecular building blocks and in the realm of supramolecular chemistry as redox-switching receptors. The most-studied compounds of this type are represented by linear ferrocenylalkenes and alka-1,3-dienes (8–12).

The following approaches are employed for the synthesis of ferrocenylalka-1,3-dienes and exocyclic ferrocenylalka-1,2,3-trienes with a terminal methylidene group: dehydration

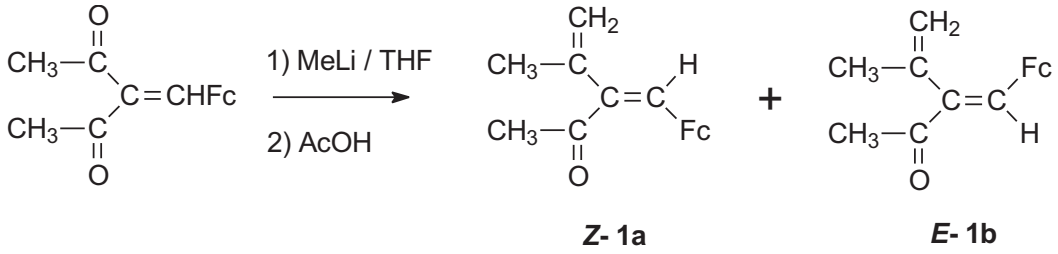
of ferrocenyl(methyl)allylic alcohols (13–15), deprotonation of ferrocenyl(methyl)allyl cations (13–18), and the Wittig reaction (19). Diferrocenyl-, aryl- and alkylferrocenyl-, aryl-, and alkyldiferrocenylbuta-1,3-dienes and 1,3-bis(ferrocenylmethylidene)-2-methylidenecycloalkanes have been synthesized (20, 21), and their highly diastereoselective thermally induced and acid-catalyzed cyclodimerization (13–22) and cationic cycloaddition (15, 19–22) have been studied. The reaction products comprised ferrocenyl-substituted six-membered carbocycles or carbocycles fused to other carbo- or hetero-cyclic systems. Some of them possessed high biological activities (17). Experimental evidence of the stepwise non-synchronous mechanism of acid-catalyzed cyclodimerization has been obtained (22), which is of theoretical significance.

With relation to synthetic and theoretical organic chemistry and the chemistry of high-molecular-mass compounds, it was of interest to inquire into the question of a feasibility of synthesizing the simplest representatives of linear cross-conjugated ferrocenyl-substituted trienes and to study their properties.

Previously, we have reported the synthesis of isomeric (*Z*)- and (*E*)-2-acetyl-1-ferrocenyl-3-methylbuta-1,3-dienes (**1a**, **1b**) (23) and 3-ferrocenylmethylidene-2,4-dimethylpenta-1,4-diene (**2**) (24), a new type of cationic cycloaddition of the triene **2** to a cation (**3**) and acid-catalyzed cyclodimerization of the triene **2** resulting in polycyclic structures

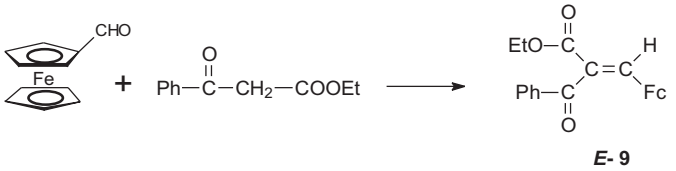
Scheme 4.

of the type (**4**–**7**) (Schemes 1–3). Naturally, it was suggested that the formation of the cyclodimers **4**–**7** is a characteristic feature of cross-conjugated heterotrienes of the type **1a**, **1b**, and triene **2**.



In continuation of our previous studies, we synthesized isomeric (*Z*)- and (*E*)-3-ferrocenylmethylidene-4-methyl-2-phenylpenta-1,4-dienes (**8a**, **8b**) (Scheme 4) as the new representatives of the cross-conjugated linear trienes and studied some of their chemical properties.

Results and discussion



(*Z*)- and (*E*)-2-Acetyl-1-ferrocenyl-3-methylbuta-1,3-dienes (**1a** and **1b**) and ethyl 2-benzoyl-ferrocenylacrylate (**9**) (Schemes 5 and 6) served as the starting compounds for the synthesis of the target trienes (**8a**) and (**8b**).

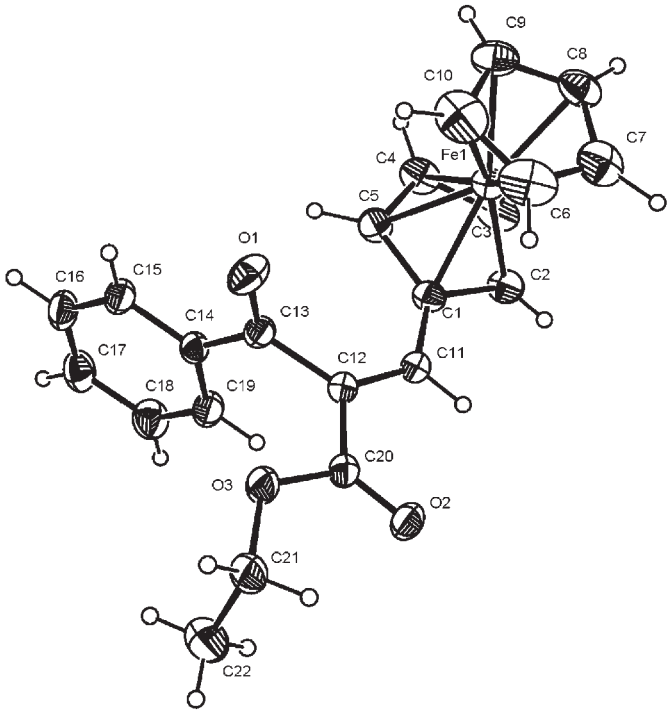
Scheme 5.

Scheme 6.



Compound **9** was obtained in high yield as a single isomer. The spatial structure of compound **9** was established on the basis of the X-ray diffraction analysis of a single crystal of compound **9** prepared by crystallization from dichloromethane (Table 1). The general view of the molecule **9** is shown in Fig. 1, and no special comments are needed. The X-ray results indicate that compound **9** has an (*E*)-configuration. (*Z*)-2-Acetyl-1-ferrocenyl-3-methylbuta-1,3-diene (**1a**) was found to react with PhLi to yield a mixture of 1,2- (**10a**) and 1,4-addition products (**11a** and **11b**) in a ~1:1 ratio, whereas the (*E*)-isomeric diene **1b** affords the (*E*)-isomeric alcohol (**10b**) (Scheme 7).

Compounds **10a** and **11** were separated by column chromatography on alumina. According to the data from ^{1}H and ^{13}C NMR spectra, the ferrocenyl ketone **11** is formed as a ~2:1 mixture of two diastereomers. They were separated by TLC on SiO_2; the structure of the major diastereomer **11a** was established by X-ray diffraction analysis on the single crystal grown by crystallization from chloroform. The general view of the molecule **11a** is shown in Fig 2, and its principal geometric parameters are presented in Table 1 without special comments. The results obtained suggest that **11a** is (*S,S*)-4-ferrocenyl-3-isopropenyl-4-phenylbutan-2-one (eclipsed conformation), and compound **11b** has apparently (*S,R*)-configuration.

The structures of compounds **10a** and **10b** were additionally confirmed by the data from ^{1}H and ^{13}C NMR and by formation of a Diels–Alder adduct (**12**) with *N*-phenylazodicarboximide (Scheme 8). According to the ^{1}H NMR spectra of compound **12**, it was formed as a single diastereomer, which suggests the stereospecificity of the process. Ethyl 2-benzoyl-3-ferrocenylacrylate (**9**) reacts with MeLi like acetylbutadiene (**1a**) to give a diol (**13**) and a hydroxy ketone (**14**) in a ~2:1 ratio (^{1}H NMR data) (Scheme 9); the latter being a ~5:1 mixture of two diastereomers, **14a** and **14b**.

These compounds were separated by column chromatography on Al_2O_3 and characterized by the data from mass spectrometry, elemental analysis, and ^{1}H and ^{13}C NMR spectroscopy. The structure of the diol **13**, including its (*Z*)-configuration, was established by X-ray diffraction analysis of a single crystal grown by crystallization from chloroform.

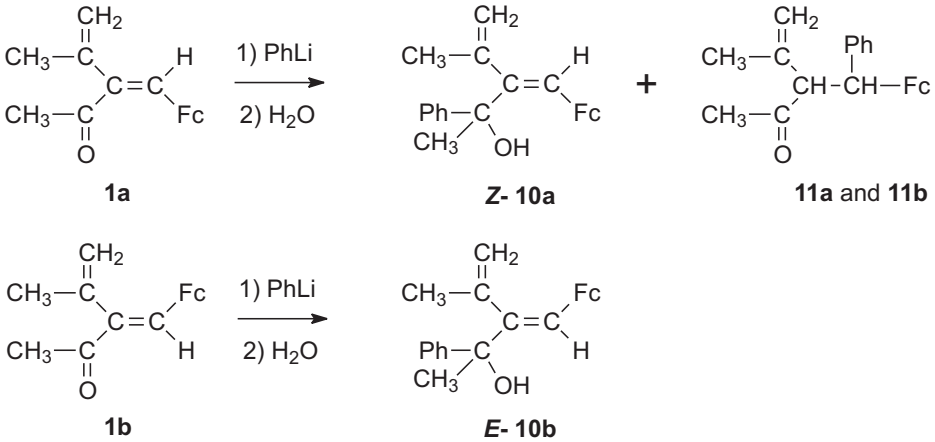
Fig. 1. Molecular structure of **9**.

The general view of compound **13** is shown in Fig. 3, and its geometric parameters (25) are given in Table 1.

Our attempts to establish configurations of the diastereomeric hydroxy ketones **14a** and **14b** failed.

We have found that all alcohols obtained (**10a**, **10b**, **13**, **14a**, and **14b**) underwent smooth dehydration when treated with $POCl_3$ in pyridine at 20 °C. The alcohols **10a**, **10b**, and **13** afforded mixtures of isomeric (*Z*)- and (*E*)-3-ferrocenylethylidene-4-methyl-2-phenylpenta-1,4-dienes (**8a** and **8b**) (Scheme 10).

Dehydration of the hydroxy ketones **14a** (or **14b**) did not affect the chiral centers to yield compounds **15a** (or **15b**), respectively, as single diastereomeric forms (Scheme 11).



The structures of these enones were confirmed by the data from mass spectrometry, elemental analysis, and ^{1}H and ^{13}C

NMR spectroscopy (see Experimental Section); however, we could not establish their configurations.

Dehydration of the alcohols **10a**, **10b**, and **13** under the action of boiling acetic acid afforded only one geometrical isomer, viz., (*E*)-3-ferrocenylethylidene-4-methyl-2-phenylpenta-1,4-diene **8b** (Scheme 12).

In our opinion, the change in the initial (*Z*)- or (*E*)-configuration of the tertiary alcohols (see Schemes 8 and 10) in the

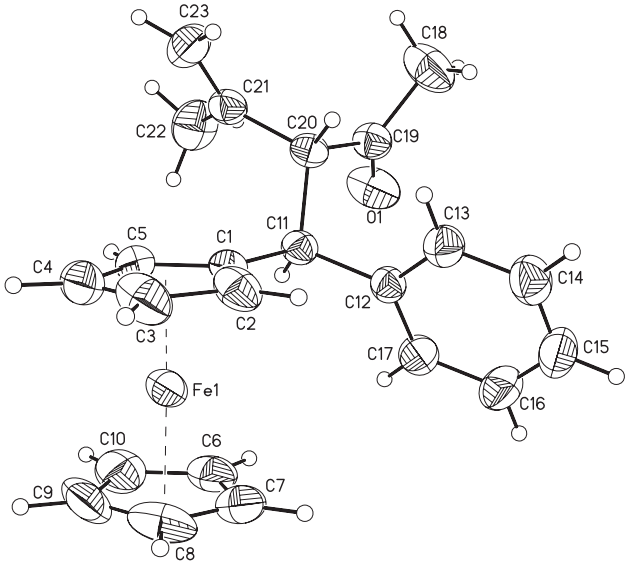

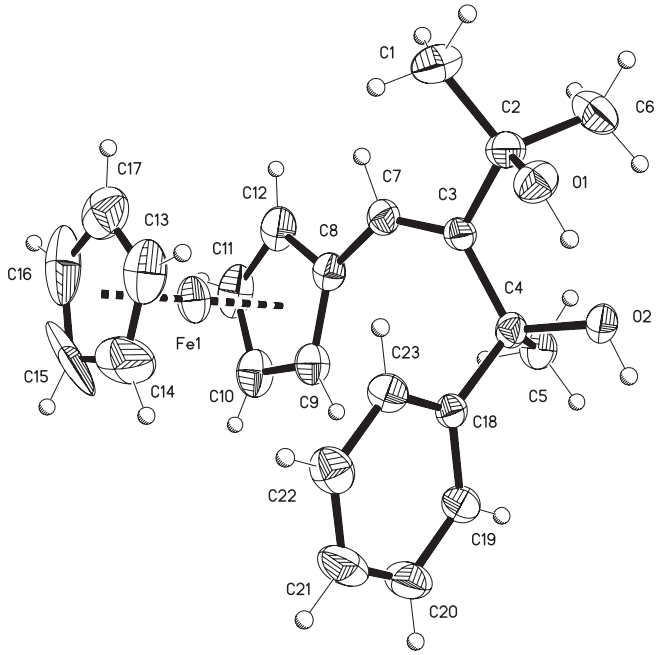

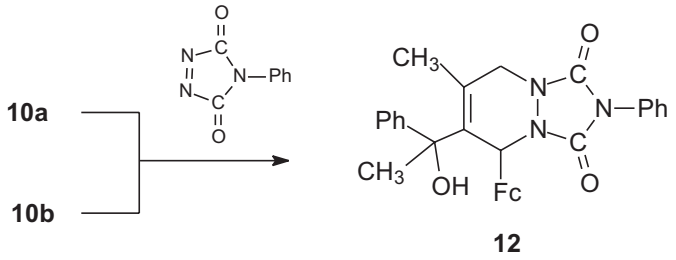

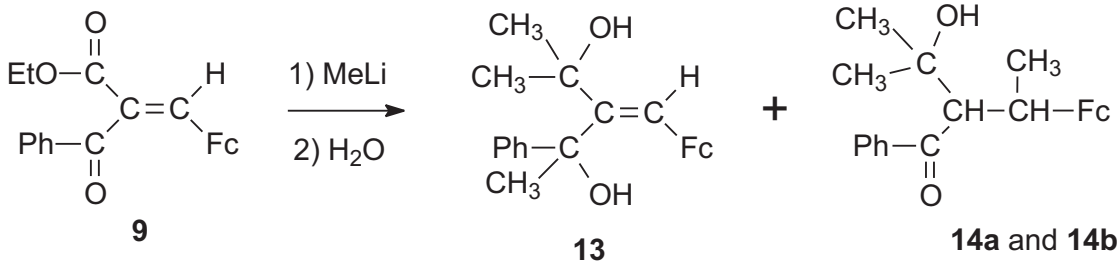

Fig. 3. Molecular structure of **13**.

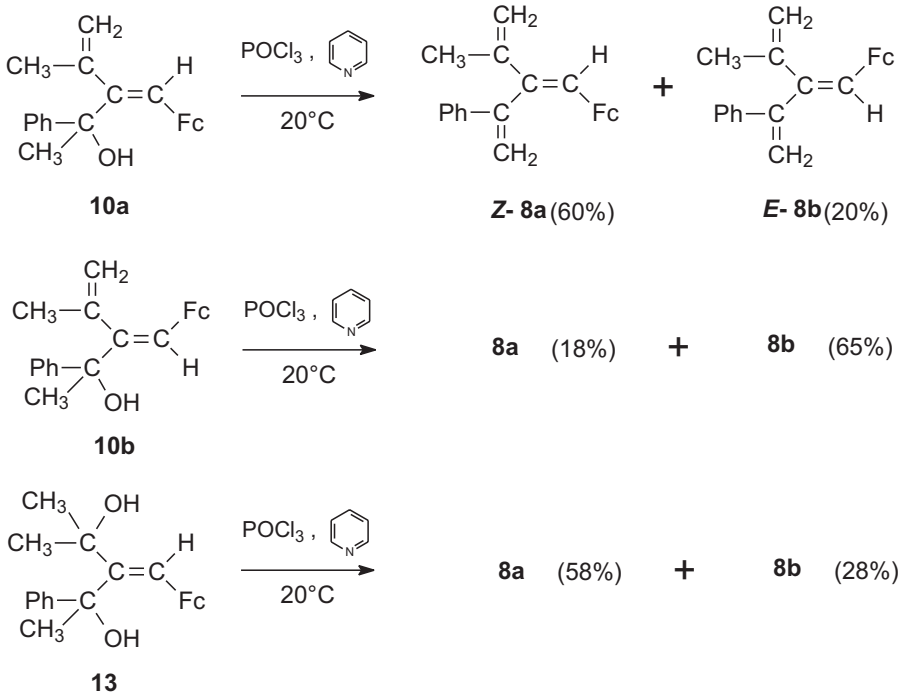
Scheme 8.

Scheme 9.

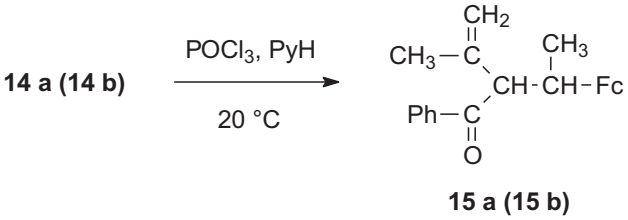
dehydration into (*E*)- and (*Z*)-trienes, respectively, results upon the rotation about the sesquialteral C(1)–C(2) bonds in the transient tetrafluoroborates of the ferrocenyl(methyl)phenylallylic cations (**16a**) and (**16b**) despite the fairly high energetic barrier (26–29) (Scheme 13).

This suggestion has been confirmed in the studies of the chemical behavior of tetrafluoroborates of the allylic cations **16a** and **16b** obtained upon action of tetrafluoroboric acid etherate on the trienes **8a** and **8b** (Scheme 14).



Treatment of the trienes **8a** and **8b** with HBF_4 – Et_2O results in crystalline salts **16a** and **16b** because of the protonation of only one CH_2=C group, namely, that bearing the phenyl substituent, and the formation of the most-stable phenylallylic cations. The ^{1}H NMR spectra of the cations **16a** and **16b** contain multiplets for the protons of the methyl groups of the CH_3–C=CH_2 fragments with a characteristic allylic coupling constant and the corresponding multiplets for the protons of the =CH_2 groups alongside low-field singlets for the protons of the methyl groups of the Ph–C–CH_3 fragments, which supports their structures.

In solutions (CD_2Cl_2), the salts **16a** and **16b** undergo gradual isomerization to form mixtures of two isomers (**16a** $\rightleftarrows$ **16b** and **16b** $\rightleftarrows$ **16a**) in variable proportions depending on the time of the experiment, judging from the ^{1}H NMR data.



Deprotonation of the solid tetrafluoroborates **16a** and **16b** under the action of *N,N*-dimethylaniline resulted in virtually pure original trienes **8a** and **8b**, respectively. Treatment of

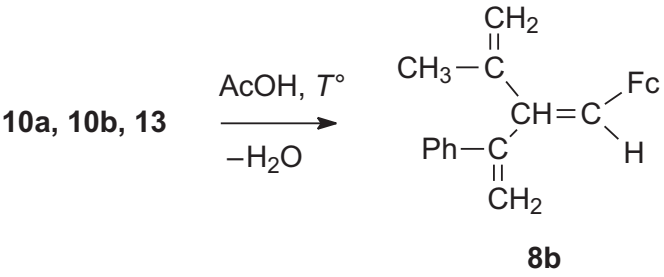


Scheme 10.

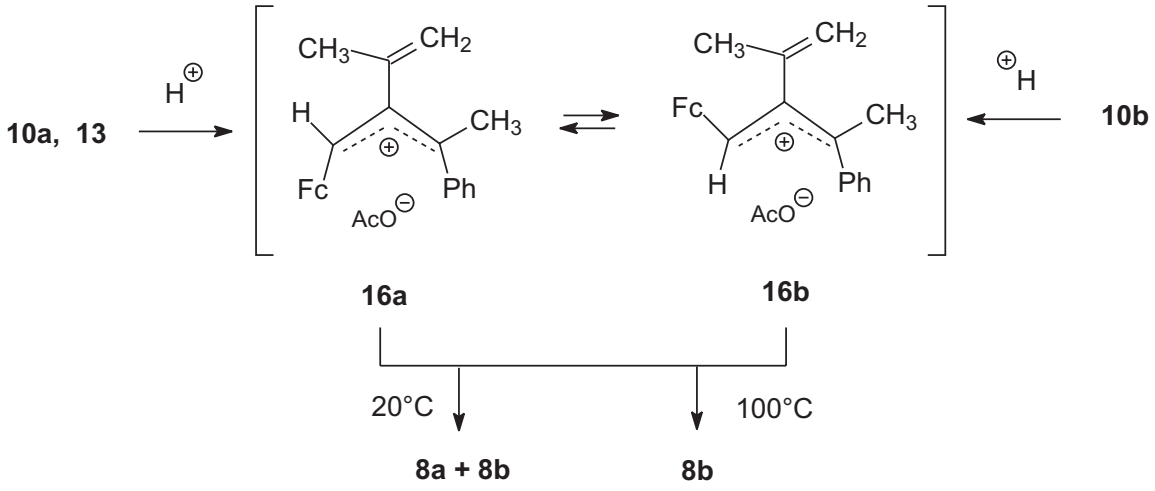
Scheme 11.

Scheme 12.

solutions of the salts **16a** and **16b** in CH_2Cl_2 with *N,N*-dimethylaniline at 20 °C for prolonged periods (1–2 h) afforded mixtures of the isomeric trienes **8a** and **8b** with (*E*)-isomer **8b** predominating.

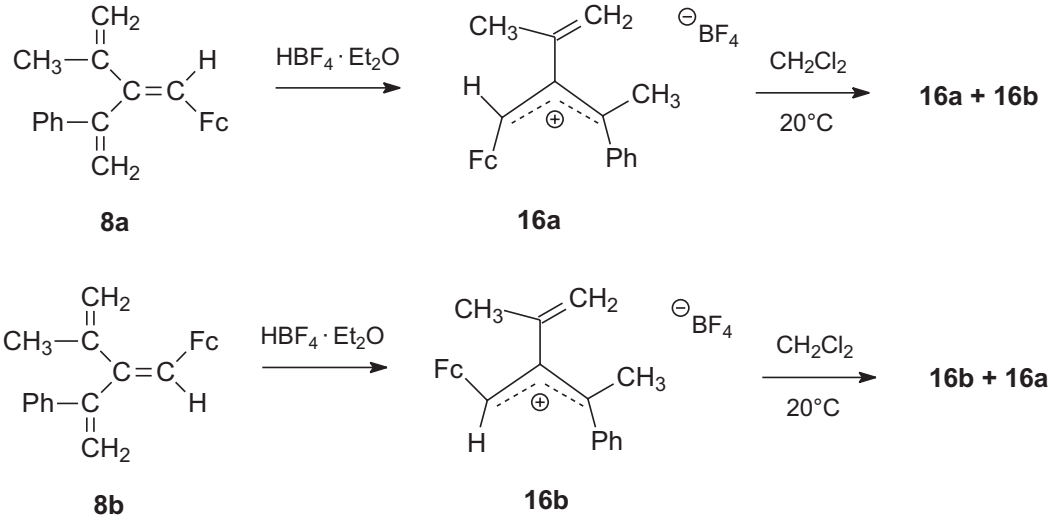
The trienes **8a** and **8b** are orange powders; they undergo oxidation and polymerization upon storage under ordinary conditions. In boiling benzene, they form [4+2]-cycloadducts with *N*-phenylmaleimide (Scheme 15).

The adduct (**17**) was isolated as a ~3:1 mixture of *exo*-**17a** and *endo*-**17b** isomers (^{1}H NMR data), which were separated by TLC on silica gel. Their structures were confirmed by the data from ^{1}H and ^{13}C NMR spectra, and assignment to the *exo*- and *endo*-isomers was made based on the previously established criteria (13, 14, 23). Assigining the adduct **17a** to the *exo*-series resulted from the fact that the signals for all the protons of the C_5H_4 moiety of the ferrocene unit appeared in a lower field of the ^{1}H NMR spectrum than those of the unsubstituted cyclopentadienyl ring. For the isomer **17b**, the multiplet for two protons of the C_5H_4 moiety (δ = 4.10) occurred in a higher field than the singlet for the protons of the C_5H_5 group (δ 4.18), which is typical of *endo*-adducts of ferrocenyl-substituted 1,3-dienes. The spectra of the adducts **17a** and **17b** contained signals for the isopropenyl groups with characteristic multiplicities of the $-CH_3$ and $=CH_2$ groups.



Boiling of the trienes **8a** and **8b** in a 10:1 mixture of acetic and trifluoroacetic acids afforded dimerization products with linear (**18a**–**18c**) and cyclic (**19**) structures (Scheme 16).

The linear dimer **18** was obtained as a ~3:2:1 mixture of three isomers (^{1}H NMR data), which were separated by TLC on SiO_2 and characterized by mass and ^{1}H and ^{13}C NMR spectra and data from elemental analysis, but their spatial structures have yet to be elucidated.



The cyclodimer **19** was isolated as a single diastereomer (yield: ~20%). The ^{1}H NMR spectrum of this compound contained three singlets for the methyl groups, two singlets for the olefinic protons, signals for the protons of two ferrocenyl and two phenyl fragments, a doublet of doublets and a singlet for the protons of two mtethylene groups, and a doublet of doublets of a methine proton. The ^{13}C NMR spectrum contained signals for the carbon atoms of two ferrocene units, three methyl, two methylene, and one methine groups, eight carbon atoms bearing no protons, and two olefinic carbon atoms. The spectroscopic data confirm unequivocally

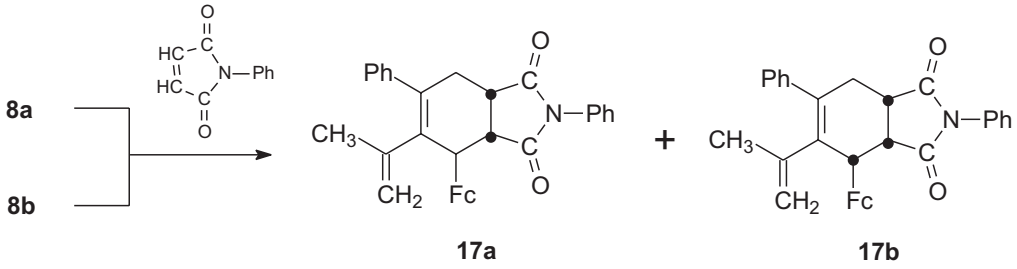


Scheme 13.

Scheme 14.

Scheme 15.

the cyclic structure of compound **19** analogous to that of compound **6**.

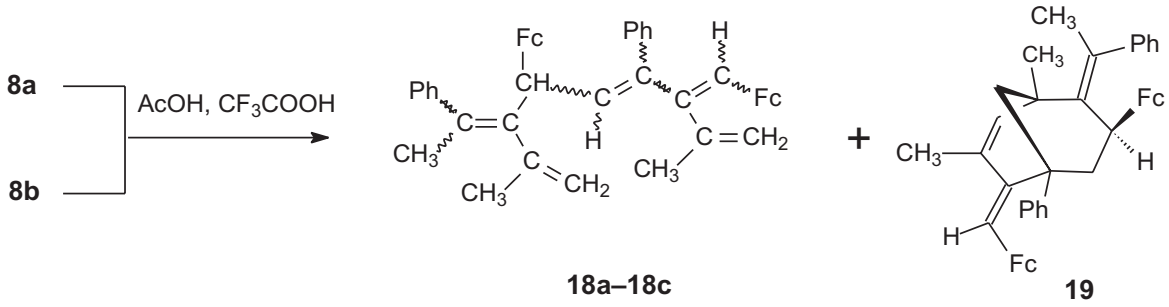
The structure of the cyclodimer **6** has been elucidated recently. According to the data from X-ray analysis of a single crystal prepared by crystallization from ethanol, the cyclodimer **6** is 7-ferrocenyl-4-ferrocenylmethylidene-8-isopropylidene-1,3,5-trimethylbicyclo[3.3.1]non-2-ene with a system of two fused six-membered rings (Fig. 4).

The main geometric parameters of this compound are listed in Table 1. The values of the C–C and C=C bond lengths in the carbocyclic fragments as well as of the Fe–C and C–C bond lengths and the geometric parameters of the ferrocene sandwiches are similar to the standard ones.

The compounds **18a**–**18c** and **19** were obtained from the reactions of the trienes **8a** and **8b** with the tetrafluoroborates **16a** and **16b** (Scheme 17).

© 2007 NRC Canada

Scheme 16.



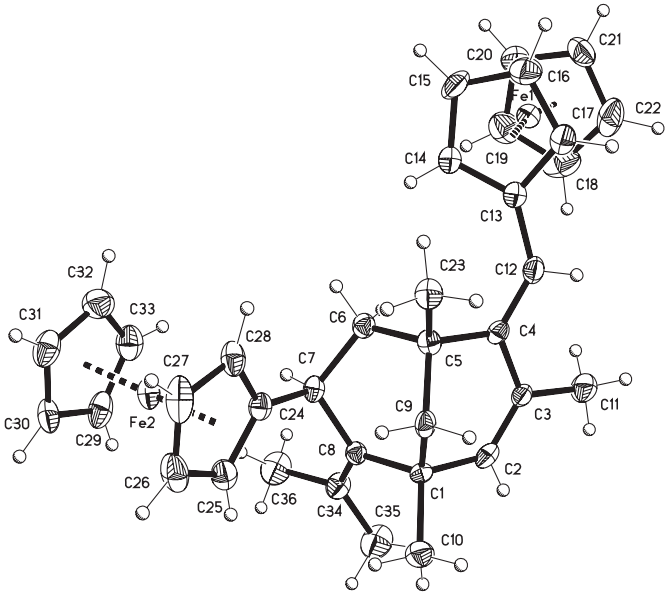


Fig. 4. Molecular structure of **6**.

Scheme 17.

The formation of compounds **18** and **19** seems to result from intramolecular transformation of an intermediate dimeric linear allylic cations (**20**) and (**21**) according to Scheme 18.

Deprotonation of the linear cation **20** under the action of *N,N*-dimethylaniline results in linear dimers **18a**–**18c**, while deprotonation of a bicyclic carbocation existing in equilibrium with the former cation yields the product **19**.

The stereospecific character of the formation of the cyclodimer **19** can apparently be rationalized by configurational features of the intermediate dimeric allylic cation **20** where the carbenium center and the carbon atom of the $=CH_2$ group, on one hand, and the terminal methylidene fragment and the carbon atom of the isopropenyl group, on the other hand, are spatially proximal to enable intramolecular double alkylation. In our opinion, studies of the effects of diverse factors on the features of dimerization of linear cross-conjugated trienes deserve undoubtedly detailed investigations aimed at revealing hitherto unknown processes of intermolecular interactions.

Experimental

The ^1H and ^{13}C NMR spectra were recorded on a Unity Inova Varian spectrometer (300 and 75 MHz, respectively) for solutions in $CDCl_3$ with Me_4Si as the internal standard. The mass spectra were obtained on a Varian MAT CH-6 instrument (EI MS, 70 eV). The ^1H NMR spectra of the tetrafluoroborates **16a** and **16b** were recorded for solution in CD_2Cl_2. An Elemental Analysis system (GmbH) was used for elemental analyses. IR spectra were obtained for KBr pellets on a PerkinElmer FTIR Spectrophotometer model 1605. Chromatographic separations were carried out on columns with alumina (Brockmann activity III).

The following reagents were purchased from Aldrich: ferrocenecarbaldehyde, 99%; pentane-2,4-dione, 99%; ethyl benzoylacetate, tech., 90%; methyllithium, 1.6 mol/L solution in diethyl ether; phenyllithium, 1.9 mol/L solution in cyclohexane–ether; acetic acid, glacial, 99.99%; *N,N*-dimethylaniline, 99%; *N*-phenylmaleimide, 97%; 4-phenyl-1,2,4-triazoline-3,5-dione, 98%; and pyridine, 99%. Tetrafluoroboric acid etherate, 50%–52%, was purchased from Alfa Aesar.

(*Z*)- and (*E*)-2-Acetyl-1-ferrocenyl-3-methyl-1,3-butadienes (1a) and (1b)

These compounds were prepared by reaction of 3-(ferrocenylmethylidene)pentane-2,4-dione (23) with methyllithium in tetrahydrofuran.

(*Z*)-2-Acetyl-1-ferrocenyl-3-methyl-1,3-butadiene (1a)

teristics of compound **6** were in accord with the literature data (24).

7-Ferrocenyl-4-ferrocenylmethylidene-8-isopropylidene-1,3,5-trimethylbicyclo[3.3.1]non-2-ene (6)

Yield: 10%; orange crystals, mp 204–205 °C (mp 204–205 °C (24)). MS *m/z*: 584 $[M]^+$.

(*E*)-Ethyl 2-(ferrocenylmethylidene)benzoylacetate (9)

A mixture of FcCHO (4.3 g, 0.02 mol), ethyl benzoylacetate (3 mL), piperidine (1 mL), and pyridine (1 mL) in dry benzene (100 mL) was refluxed for 10 h. The reaction mixture was washed with 5% HCl to remove the amines, and the organic layer was concentrated to dryness. Diethyl ether (100 mL) was added to the residue, and the precipitate was filtered off and dried on a filter to give (*E*)-ethyl 2-(ferrocenylmethylidene)benzoylacetate **9**: yield 6.01 g (81%), dark red crystals, mp 157–158 °C. IR (KBr, cm^{-1}): 818, 845, 1102, 1478, 1663, 1690, 1850, 1716, 3030. ^{1}H NMR (30 MHz, $CDCl_3$) δ: 1.14 (3H, t, *J* = 7.2 Hz, CH_3), 4.14 (5H, s, C_5H_5), 4.18 (2H, q, *J* = 7.2 Hz, CH_2), 4.27 (2H, m, C_5H_4), 4.31 (2H, m, C_5H_4), 7.45–7.62 (3H, m, C_6H_5), 7.78 (1H, s, CH=), 7.96 (2H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 14.02 (CH_3), 61.01 (CH_2), 70.92, 71.75 (C_5H_4), 69.75 (C_5H_5), 76.69 (C_{ipso}Fc), 128.69, 129.10, 133.66 (C_6H_5), 143.94 (CH=), 126.42, 136.55 (2C), 165.16, 195.90 (2 C=O). MS *m/z*: 388 $[M]^+$. Anal. calcd. for $C_{22}H_{20}FeO_3$: C 68.08, H 5.18, Fe 14.39; found: C 68.18, H 5.21, Fe 14.27.

The reactions of the dienes (1a) and (1b) with phenyllithium

A solution of PhLi (1.9 mol/L solution in cyclohexane – diethyl ether, 15 mL) was added to a stirred solution of compound **1a** (1.47 g, 5 mmol) in dry benzene (100 mL); the mixture was stirred for additional 30 min at 20 °C, and the excess of phenyllithium was quenched by addition of water (50 mL). The organic layer was separated, washed with water (2 × 20 mL), and dried (Na_2SO_4). The solvent was removed in vacuo, and the residue was chromatographed on Al_2O_3 (hexane–ether, 2:1) to give 0.74 g (40%) of the alcohol **10a** ((*Z*)-isomer) and 0.72 g (39%) of the ketone **11a** and **11b** (~2:1). The compounds **11a** and **11b** were separated by preparative TLC on silica gel (hexane).

(Z)-4-Ferrocenyl-3-isopropenyl-2-phenyl-3-buten-2-ol (10a)

Yield: 40%; yellow crystals, mp 142–143 °C. IR (KBr, cm^{-1}): 820, 851, 1002, 1100, 1467, 1643, 1667, 1845, 3030, 3340. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.67 (3H, dd, *J* = 1.2 and 1.5 Hz, CH_3), 1.84 (3H, s, CH_3), 2.50 (1H, bs, OH), 4.06 (5H, s, C_5H_5), 4.10 (2H, m, C_5H_4), 4.21 (2H, m, C_5H_4), 4.54 (1H, dd, *J* = 1.2 and 2.4 Hz, CH_2=), 4.92 (1H, dd, *J* = 1.5, 2.4 Hz, CH_2=), 6.28 (1H, s, CH=), 7.28–7.45 (5H, m, C_6H_5). MS *m/z*: 372 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 74.20, H 6.50, Fe 15.00; found: C 74.38, H 6.66, Fe 14.79.

4-Ferrocenyl-3-isopropenyl-4-phenyl-2-butanon (11a)

Yield: 20%; orange crystals, mp 178–179 °C. IR (KBr, cm^{-1}): 821, 834, 1025, 1103, 1473, 1640, 1658, 1708, 1912, 3030. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.60 (3H, dd, *J* = 0.9 and 1.5 Hz, CH_3), 1.88 (3H, s, CH_3), 3.72 (1H, d, *J* = 11.7 Hz, CH), 3.76 (5H, s, C_5H_5), 3.97 (1H, m, C_5H_4), 4.02 (1H, d, *J* = 11.7 Hz, CH), 4.04 (1H, m, C_5H_4), 4.07 (2H, m, C_5H_4), 4.88 (1H, bs, CH_2=), 4.90 (1H, dd, *J* = 0.9 and 1.8 Hz, CH_2=), 7.20 (1H, m, C_6H_5), 7.32–7.40 (4H, m, C_6H_5). MS *m/z*: 372 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 74.20, H 6.50, Fe 15.00; found: C 74.09, H 6.59, Fe 15.11.

4-Ferrocenyl-3-isopropenyl-4-phenyl-2-butanon (11b)

Yield: 12%; orange crystals, mp 184–186 °C. IR (KBr, cm^{-1}): 820, 832, 1009, 1102, 1469, 1648, 1662, 1716, 1926, 3024. ^{1}H NMR (300 MHZ, $CDCl_3$) δ: 1.67 (3H, dd, *J* = 1.2 and 1.5 Hz, CH_3), 1.96 (3H, s, CH_3), 3.83 (1H, d, *J* = 11.1 Hz, CH), 3.98 (5H, s, C_5H_5), 4.03 (2H, m, C_5H_4), 4.09 (1H, d, *J* = 11.1 Hz, CH), 4.13 (2H, m, C_5H_4), 4.67 (1H, bs,

CH_2=), 4.75 (1H, dd, J = 1.2 and 2.1 Hz, CH_2=), 7.28–7.54 (5H, m, C_6H_5). MS m/z: 372 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 74.20, H 6.50, Fe 15.00; found: C 74.31, H 6.35, Fe 15.18.

(E)-4-Ferrocenyl-3-isopropenyl-2-phenyl-3-buten-2-ol (10b)

Analogously, the reaction of the diene **1b** (1.47 g, 5 mmol) with PhLi gave 1.34 g of the alcohol ***(E)*-10b**. Yield: 72%; orange powder, mp 174–175 °C. IR (KBr, cm^{-1}): 818, 850, 1012, 1109, 1446, 1648, 1671, 1845, 3032, 3345. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.60 (3H, dd, J = 0.9 and 1.2 Hz, CH_3), 1.75 (3H, s, CH_3), 2.44 (1H, bs, OH), 4.10 (5H, s, C_5H_5), 4.18 (2H, m, C_5H_4), 4.45 (2H, m, C_5H_4), 4.65 (1H, dd, J = 0.9, 2.1 Hz, CH_2=), 5.09 (1H, dd, J = 1.2 and 2.1 Hz, CH_2=), 6.31 (1H, s, CH=), 7.32–7.61 (5H, m, C_6H_5). MS m/z: 372 $[M]^+$. Anal. calcd for $C_{23}H_{24}FeO$: C 74.20, H 6.50, Fe 15.00; found: C 74.17, H 6.37, Fe 15.19.

Condensation of the hydroxydienes (10a) and (10b) with 4-phenyl-1,2,4-triazoline-3,5-dione

4-Phenyl-1,2,4-triazoline-3,5-dione (0.2 g, 1.22 mmol) was added portionwise to a stirred solution of the diene **10a** (or **10b**) (0.37 g, 1 mmol) in benzene (30 mL) at 0–5 °C as the solution discolored. Stirring was continued for an additional 1 h, and the solvent was evaporated. Column chromatography of the residue on Al_2O_3 (hexane–dichloromethane, 2:1) gave the adduct **12**.

N-Phenyl-3-ferrocenyl-5-methyl-4-(1-phenyl-1-hydroxyethyl)-1,2,3,6-tetrahydropyridazine-1,2-dicarboximide (12)

Yield: 0.40 g (from **10a**) (73%), 0.44 g (from **10b**); yellow crystals, mp 223–225 °C. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.26 (3H, bs, CH_3), 1.67 (3H, s, CH_3), 2.19 (1H, s, OH), 4.01 (1H, d, J = 16.5 Hz, CH_2), 4.16 (1H, d, J = 16.5 Hz, CH_2), 4.25 (5H, s, C_5H_5), 4.21 (2H, m, C_5H_4), 4.27 (1H, m, C_5H_4), 4.44 (1H, m, C_5H_4), 6.28 (1H, s, CH), 7.28–7.63 (10H, m, 2 C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.09, 27.21 (2 CH_3), 48.41 (CH_2), 50.56 (CH), 65.88, 67.09, 68.15, 69.96 (C_5H_4), 69.12 (C_5H_5), 90.72 (C_{ipso}Fc), 125.50, 125.78, 127.79, 128.07, 128.67, 129.23 (2 C_6H_5), 75.20, 122.58, 131.60, 139.90, 146.91 (5 C), 148.78, 152.91 (2 C=O). MS m/z: 548 $[M]^+$. Anal. calcd. for $C_{31}H_{29}FeN_3O_3$: C 68.02, H 5.34, Fe 10.20, N 7.67; found: C 67.87, H 5.38, Fe 10.32, N 7.71.

The reactions of the *E*-ethyl 2-(ferrocenylmethylidene)benzoylacetate (9) with methyllithium

A solution of MeLi (1.6 mol/L solution in diethyl ether, 20 mL) was added to a stirred solution of compound **9** (1.94 g, 5 mmol) in dry benzene (100 mL); the mixture was stirred for additional 30 min at 20 °C, and the excess of methyllithium was quenched by addition of water (50 mL). The organic layer was separated, washed with water (2 × 20 mL), and dried (Na_2SO_4). The solvent was removed in vacuo, and the residue was chromatographed on Al_2O_3 (hexane–ether, 2:1) to give 0.95 g (50%) of the alcohol **13** ((*Z*)-isomer) and 0.48 g (25%) of the ketone **14a** and **14b** (~5:1), mp 113–114 °C. The compounds **14a** and **14b** were separated by preparative TLC on silica gel (hexane).

(Z)-4-Ferrocenylmethylidene-4-methyl-2-phenylpentan-2,4-diol (13)

Yield: 50%; yellow crystals, mp 142–143 °C. IR (KBr, cm^{-1}): 764, 858, 1006, 1101, 1460, 1642, 1670, 1859, 3030, 3343–3408. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.65 (3H, s, CH_3), 1.67 (3H, s, CH_3), 1.73 (3H, s, CH_3), 3.42 (1H, bs, OH), 4.04 (5H, s, C_5H_5), 3.45 (1H, m, C_5H_4), 3.88 (1H, m, C_5H_4), 4.06 (1H, m, C_5H_4), 4.10 (1H, m, C_5H_4), 4.13 (1H, bs, OH), 6.45 (1H, s, CH=), 7.27–7.55 (5H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 29.67, 31.85, 32.63 (3 CH_3), 67.90, 67.99, 69.25, 70.94 (C_5H_4), 68.97 (C_5H_5), 76.78, 79.21 (2 C–OH), 82.86 (C_{ipso}Fc), 123.02 (CH=), 126.13, 127.28, 128.37 (C_6H_5), 148.40, 148.67 (2 C). MS m/z: 390 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 70.77, H 6.72, Fe 14.32; found: C 70.59, H 6.86, Fe 14.47.

3-Benzoyl-4-ferrocenyl-2-methyl-2-pentanol (14a)

Yield: 17%; orange crystals, mp 121–122 °C. IR (KBr, cm^{-1}): 764, 849, 1005, 1103, 1468, 1649, 1668, 1710, 1929, 3034, 3358. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.20 (3H, s, CH_3), 1.36 (3H, s, CH_3), 1.42 (3H, d, J = 7.2 Hz, CH_3), 3.30 (1H, m, J = 3.9 and 7.2 Hz, CH), 3.52 (1H, d, J = 3.9 Hz, CH), 3.91 (1H, br s, OH), 4.09 (5H, s, C_5H_5), 3.66 (1H, m, C_5H_4), 3.82 (1H, m, C_5H_4), 4.05 (1H, m, C_5H_4), 4.17 (1H, m, C_5H_4), 7.23–7.60 (5H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.97, 28.07, 30.19 (3 CH_3), 33.29, 60.80 (2 CH), 66.97, 67.21, 67.65, 67.81 (C_5H_4), 68.84 (C_5H_5), 72.95 (C–OH), 95.31 (C_{ipso}Fc), 128.09, 128.60, 132.99 (C_6H_5), 138.56 (C_{ipso}), 206.43 (C=O). MS m/z: 390 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 70.77, H 6.72, Fe 14.32; found: C 70.63, H 6.81, Fe 14.41.

3-Benzoyl-4-ferrocenyl-2-methyl-2-pentanol (14b)

Yield: 6%; orange crystals, mp 136–137 °C. IR (KBr, cm^{-1}): 763, 853, 1004, 1107, 1478, 1656, 1668, 1715, 1932, 3033, 3367. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.23 (3H, s, CH_3), 1.30 (3H, s, CH_3), 1.40 (3H, d, J = 6.9 Hz, CH_3), 3.28 (1H, m, CH), 3.46 (1H, d, J = 5.4 Hz, CH), 3.90 (1H, br s, OH), 4.04 (5H, s, C_5H_5), 3.70 (1H, m, C_5H_4), 3.79 (1H, m, C_5H_4), 3.87 (1H, m, C_5H_4), 3.96 (1H, m, C_5H_4), 7.30–7.64 (5H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.02, 29.01, 30.05 (3 CH_3), 34.52, 60.05 (2 CH), 67.40, 67.51, 67.90, 68.65 (C_5H_4), 68.75 (C_5H_5), 72.30 (C–OH), 95.30 (C_{ipso}Fc), 128.25, 128.47, 128.55 (C_6H_5), 133.25 (C_{ipso}), 204.05 (C=O). MS m/z: 390 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 70.77, H 6.72, Fe 14.32; found: C 70.85, H 6.61, Fe 14.52.

Dehydration of the alcohols (10a), (10b), (13), (14a), and (14b) with $POCl_3$–PyH

The alcohols **10a**, **10b**, **13**, **14a**, or **14b** (0.01 mol) was added to a mixture of dry pyridine (100 mL) and $POCl_3$ (1.0 mL) and stirred at 30–40 °C for 3 h (TLC control). The reaction mixture was treated with water (100 mL) and benzene (100 mL); the organic layer was separated, washed with water (3 × 50 mL), and concentrated in vacuo. The residue was chromatographed on a column with Al_2O_3 in hexane to yield trienes **8a** and **8b** and dienes **15a** and **15b**.

(Z)- and (E)-3-Ferrocenylmethylidene-4-methyl-2-phenyl-1,4-pentadienes (8a) and (8b) from the alcohol (10a)

Yield: 80% (~3:1); orange powder, mp 61–64 °C.

© 2007 NRC Canada

(Z)-3-Ferrocenylmethylidene-4-methyl-2-phenyl-1,4-pentadiene (8a)

Yield: 54%; orange powder, mp 68–69 °C. IR (KBr, cm^{-1}): 817, 820, 841, 1005, 1100, 1475, 1642, 1661, 1698, 1927, 3032. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.09 (3H, dd, J = 0.6 and 1.2 Hz, CH_3), 4.00 (5H, s, C_5H_5), 4.13 (2H, m, C_5H_4), 4.35 (2H, m, C_5H_4), 4.94 (1H, m, J = 0.6 and 1.5 Hz, CH_2=), 4.97 (1H, m, J = 1.2 and 1.5 Hz, CH_2=), 5.13 (1H, d, J = 1.8 Hz, CH_2=), 5.86 (1H, d, J = 1.8 Hz, CH_2=), 6.46 (1H, s, CH=), 7.24–7.56 (5H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 20.87 (CH_3), 68.99, 69.70 (C_5H_4), 69.04 (C_5H_5), 81.32 (C_{ipso}Fc), 114.85, 114.90 (2 CH_2=), 125.11 (CH=), 126.11, 127.67,128.42 (C_6H_5), 139.06, 139.14, 143.21, 146.48(4C). 3-Benzoyl-4-ferrocenyl-2-methyl-1-pentene (15b)

Yield: 71%; orange powder, mp 126–127 °C. IR (KBr, cm^{-1}): 819, 840, 1004, 1103, 1468, 1652, 1660, 1728, 1921, 3028. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.26 (3H, d, J = 6.9 Hz, CH_3), 2.04 (3H, dd, J = 0.9 and 1.2 Hz, CH_3), 2.96 (1H, m, CH), 3.73 (1H, d, J = 9.9 Hz, CH), 4.04 (5H, s, C_5H_5), 3.96 (1H, m, C_5H_4), 4.06 (1H, m, C_5H_4), 4.10 (1H, m, C_5H_4), 4.14 (1H, m, C_5H_4), 5.02 (2H, m, CH_2=), 7.39–7.93 (5H, m, C_6H_5). MS m/z: 372 $[M]^+$. Anal. calcd. for $C_{23}H_{24}FeO$: C 74.20, H 6.50, Fe 15.00; found: C 74.11, H 6.63, Fe 14.89.

Dehydration of the alcohols (10a), (10b), and (13) with AcOH

A solution of the alcohols **10a**, **10b**, or **13** (5 mmol) in benzene (50 mL) and AcOH (20 mL) was stirred at 20 °C for 5 h. Then, water (50 mL) was added; the organic layer was separated, washed with 5% $NaHCO_3$, and concentrated. The residue was chromatographed on Al_2O_3 (hexane) to give the triene **8b**.

(E)-3-Ferrocenylmethylidene-4-methyl-2-phenyl-1,4-pentadienes (8b)

Yield: 74%–82%; orange powder, mp 74–75 °C.

(Z)- and (E)-3-Ferrocenyl-2-isopropenyl-1-methyl-1-phenylallylium tetrafluoroborates (16a and 16b)

These compounds were prepared by the addition of tetrafluoroboric acid etherate to a solution of the triene **8a** or **8b** in dry diethyl ether. The crystalline residues that precipitated were filtered off, washed with dry diethyl ether, and dried in vacuo. The yields of the salts were quantitative. All operations with solid salts were carried out in an atmosphere of dry nitrogen.

Compound (16a)

Yield: 91%; black crystals, mp 219–221 °C. ^1H NMR (300 MHz, CD_2CI_2) δ: 2.23 (3H, s, CH_3), 2.26 (3H, s, CH_3), 4.65 (5H, s, C_5H_5), 4.75 (2H, m, C_5H_4), 5.09 (2H, m, C_5H_4), 5.94 (1H, br s, CH_2=), 6.07 (1H, br s, CH_2=), 7.15–7.56 (5H, m, C_6H_5), 8.34 (1H, s, CHFc). MS m/z: 442 $[M]^+$. Anal. calcd. for $C_{23}H_{23}BF_4Fe$: C 62.49, H 5.24, F 17.19, Fe 12.63; found: C 62.34, H 5.31, F 17.27, Fe 12.56.

Compound (16b)

Yield: 94%; black crystals, mp 226–228 °C. ^1H NMR (300 MHz, CD_2CI_2) δ: 1.93 (3H, s, CH_3), 1.96 (3H, s, CH_3), 4.39 (5H, s, C_5H_5), 4.60 (2H, m, C_5H_4), 4.88 (1H, m, C_5H_4), 5.33 (1H, m, C_5H_4), 5.52 (1H, br s, CH_2=), 5.70 (1H, br s, CH_2=), 7.17–7.48 (5H, m, C_6H_5), 8.20 (1H, s, CHFc). MS m/z: 442 $[M]^+$. Anal. calcd. for $C_{23}H_{23}BF_4Fe$: C 62.49, H 5.24, F 17.19, Fe 12.63; found: C 62.63, H 5.13, F 17.02, Fe 12.88.

Isomerization of the tetrafluoroborates (16a) and (16b)

A solution of the salt **16a** or **16b** (0.44 g, 1 mmol) in dry CD_2CI_2 (10 mL) was kept at room temperature for 4. The ^1H NMR spectrum of the solutions contains signals for two products: **16a** and **16b** (~1:2).

The reaction of the tetrafluoroborates (16a) and (16b) with N,N-dimethylaniline

N,N-Dimethylaniline (1.5 mL) was added with stirring to a tetrafluoroborate **16a** or **16b** (0.88 g, 2 mmol). The nearly black solution gradually turns orange in ~20 min. The reaction products were extracted with benzene (3 × 30 mL); the combined extract was washed with water (20 mL), 5% HCl (2 × 20 mL), and water (20 mL); the organic layer was dried with $CaCl_2$; and the solvent was distilled off. The residue

© 2007 NRC Canada

was chromatographed on a column with Al_2O_3 (hexane). A fraction of pure triene **8a** or **8b** were isolated.

Triene (8a) (from the salt 16a)
Yield: 84%; mp 68–69 °C.

Triene (8b) (from the salt 16b)
Yield: 88%; mp 74–75 °C.

Condensation of the trienes (8a) and (8b) with *N*-phenylmaleimide

A solution of the triene **8a** (or **8b**) (0.35 g, 1 mmol) and *N*-phenylmaleimide (0.2 g, 1.24 mmol) in toluene (50 mL) was refluxed for 3 h and concentrated. The residue was chromatographed on Al_2O_3 (hexane – dichloromethane, 3:1) to give 0.37 g (70%) (from **8a**) or 0.40 g (75%) (from **8b**) of the adducts **17** as a mixture of two isomers **17a** and **17b** (~3:1, NMR data), yellow crystals, mp 188–200 °C. The isomers were separated by preparative TLC on Al_2O_3 (hexane–benzene, 1:1).

Endo-adduct (17a)
Yield: 50%; yellow powder, mp 208–209 °C. IR (KBr, cm^{-1}): 770, 826, 1002, 1035, 1102, 1157, 1186, 1385, 1436, 1498, 1629, 1685, 1711, 1776, 2872, 2937, 3081. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.64 (3H, m, J = 0.9 Hz, CH_3), 2.86 (1H, dd, J = 6.0 and 12.0 Hz, CH_2), 3.18 (1H, dd, J = 7.8 and 12.0 Hz, CH_2), 3.41 (1H, m, CH), 3.74 (1H, dd, J = 1.5 and 9.0 Hz, CH), 4.18 (5H, s, C_5H_5), 4.10 (2H, m, C_5H_4), 4.27 (2H, m, C_5H_4), 4.25 (1H, d, J = 1.5 Hz, CHFc), 4.93 (1H, m, J = 0.9 Hz, CH_2=), 5.00 (1H, m, CH_2=), 7.02–7.05 (2H, m, C_6H_5), 7.12–7.49 (8H, m, C_6H_5). MS *m*/*z*: 527 $[M]^+$. Anal. calcd. for $C_{33}H_{29}FeNO_2$: C 75.15, H 5.54, Fe 10.59, N 2.65; found: C 74.91, H 5.63, Fe 10.69, N 2.59.

Exo-adduct (17b)
Yield: 15%; yellow powder, mp 201–202 °C. IR (KBr, cm^{-1}): 767, 821, 1001, 1027, 1102, 1148, 1186, 1387, 1435, 1501, 1630, 1685, 1714, 1766, 2875, 2939, 3080. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.88 (3H, m, J = 1.2 Hz, CH_3), 2.75 (1H, dd, J = 9.6 and 15.3 Hz, CH_2), 3.07 (1H, dd, J = 8.1 and 15.3 Hz, CH_2), 3.24 (1H, m, CH), 3.37 (1H, dd, J = 5.4 and 9.6 Hz, CH), 4.04 (5H, s, C_5H_5), 4.11 (2H, m, C_5H_4), 4.14 (1H, m, C_5H_4), 4.27 (1H, m, C_5H_4), 4.47 (1H, d, J = 5.4 Hz, CHFc), 5.01 (1H, m, J = 1.2 Hz, CH_2=), 5.10 (1H, m, CH_2=), 7.09–7.13 (2H, m, C_6H_5), 7.23–7.46 (8H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.86 (CH_3), 28.57 (CH_2), 39.79, 42.21, 48.06 (3 CH), 67.07, 68.58 (C_5H_4), 69.21 (C_5H_5), 83.55 (C_{ipso}Fc), 117.29 (CH_2=), 126.70, 126.87, 127.66, 128.11, 128.49, 128.94 (2 C_6H_5), 131.71, 134.86, 140.39, 142.95, 144.54(5 C), 177.42, 178.53 (2 C=O). MS *m*/*z*: 527 $[M]^+$. Anal. calcd. for $C_{33}H_{29}FeNO_2$: C 75.15, H 5.54, Fe 10.59, N 2.65; found: C 75.29, H 5.43, Fe 10.42, N 2.71.

Dimerization of (*Z*)- and (*E*)-3-Ferrocenylmethylidene-4-methyl-2-phenyl-1,4-pentadienes (8a) and (8b)

A solution of the triene **8a** (or **8b**) (0.70 g, 2 mmol) in glacial acetic acid (50 mL) and CF_3COOH (5 mL) was refluxed for 4 h, cooled to ambient temperature, and diluted with water (100 mL). The reaction products were extracted with benzene (3 × 50 mL), 5% aq. $NaHCO_3$, and water and dried with Na_2OS_4. The solvent was distilled off, and the residue was subjected to preparative TLC on silica gel (hexane) to yield 6-ferrocenyl-3-ferrocenylmethylidene-7-isopropylidene-2-methyl-4,8-diphenyl-nona-1,4,7-trienes **18a**–**18c** and 7-ferrocenyl-4-ferrocenylmethylidene-8-(1-phenylethylidene)-1,3-dimethyl-5-phenyl-bicyclo[3.3.1]non-2-ene **19**.

6-Ferrocenyl-3-ferrocenylmethylidene-7-isopropylidene-2-methyl-4,8-diphenyl-nona-1,4,7-triene (18a)
Yield: 34%; R_f = 0.63, orange powder, mp 164–165 °C. IR (KBr, cm^{-1}): 820, 998, 1007, 1105, 1134, 1179, 1379, 1451, 1518, 1641, 1676, 1684, 2879, 2923, 3078. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.74 (3H, br s, CH_3), 1.90 (3H, s, CH_3), 2.07 (3H, m, J = 0.6 and 0.9 Hz, CH_3), 3.69 (5H, s, C_5H_5), 4.02 (5H, s, C_5H_5), 4.01 (1H, m, C_5H_4), 4.15 (2H, m, C_5H_4), 4.37 (2H, m, C_5H_4), 4.48 (1H, d, J = 10.8 Hz, CHFc), 4.57 (2H, m, C_5H_4), 4.70 (1H, m, C_5H_4), 4.83 (1H, m, CH_2=), 4.93 (1H, m, CH_2=), 4.98 (1H, m, CH_2=), 5.28 (1H, m, CH_2=), 5.49 (1H, s, CH=), 5.86 (1H, d, J = 10.8 Hz, CH=), 6.88 (2H, m, C_6H_5), 7.14–7.51 (8H, m, C_6H_5). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 21.95, 23. 34, 32,52 (3 CH_3), 41.74 (CH), 66.63, 66.81, 67.01, 67.23, 67.49, 67.89, 68.48, 69.34 (2 C_5H_4), 68.62, 69.17 (2 C_5H_5), 83.25, 90.34 (2 C_{ipso}Fc), 117.43, 118.21 (2 CH_2=), 124.31, 130.10 (2 CH=), 126.79, 126.99, 127.45, 128.32, 128.47, 128.98 (2 C_6H_5), 125.83, 131.87, 132.29, 134,09, 134.73, 139.91, 140.95, 143.54 (8C). ane). The following compounds were obtained: compounds **18a**–**18c** (42%, ~3:2:1), compound **19** (28%), and polymeric products.

Compound (18a)
Yield: 21%; R_f = 0.63, orange powder, mp 163–165 °C.

Compound (18b)
Yield: 14%; R_f = 0.57, orange powder, mp 171–172 °C.

Compound (18c)
Yield: 9%; R_f = 0.49, orange powder, mp 158–159 °C.

Compound (19)
Yield: 28%; R_f = 0.71, yellow powder, mp 182–183 °C.

X-ray crystallographic studies

The unit-cell parameters and the X-ray diffraction intensities were recorded on a Bruker Smart Apex CCD area detector/ω diffractometer (compounds **6**, **11a**, and **13**) and on a Siemens P4 diffractometer (compound **9**). The principal geometrical parameters of the molecules **6, 9, 11a**, and **13** are listed in Table 1. The crystallographic data, the parameters of the X-ray diffraction experiment, and refinements are listed in Table 2. The structure of compounds **6, 9, 11a**, and **13** were solved by the direct method [SHELXS-97, (30)] and refined using full-matrix least-squares on F^2.[2]

Coriolis coupling effects on energy transfer: classical-trajectories analysis for CO_2 + Ar collisions

E. Borges and J.P. Braga

Abstract: Energy transfer on CO_2 + Ar collisions is studied by performing classical-trajectories simulations in a non-rigid potential-energy surface. Partition of molecular kinetic energy into vibration, rotation, and Coriolis coupling is made in a Cartesian coordinates system, coupled to vibrational normal modes. Initial atomic translational energies are selected from a range of 0.004–0.4 au, and initial molecular rotational states are fixed at rotational quantum numbers *j*, equal to 1, 20, 40, and 60. Effects of these different initial conditions are investigated, and the Coriolis influence on the energy transferred is analyzed.

Key words: Coriolis coupling, energy, classical trajectories.

Résumé : On a étudié le transfert d'énergie lors de collisions de CO_2 + Ar en faisant appel à des simulations de trajectoires classiques dans une surface d'énergie potentielle non rigide. On a effectué la partition de l'énergie cinétique moléculaire en vibration, en rotation et en couplage de Coriolis dans un système de coordonnées cartésiennes couplé aux modes vibrationnels normaux. On a choisi les énergies de translation atomique initiales dans les valeurs allant de 0,004 à 0,4 au et on a fixé les états rotationnels moléculaires initiaux aux nombres quantiques rotationnels, j, 1, 20, 40 et 60. On a étudié les effets de ces conditions initiales diverses et on a analysé l'influence de Coriolis sur l'énergie qui est transférée.

Mots-clés : couplage de Coriolis, énergie, trajectoires classiques.

[Traduit par la Rédaction]

Introduction

Experimental and theoretical investigations about the rovibrational interaction in excited polyatomic molecules indicate that Coriolis coupling can account, in some cases, for more than 20% of the overall anharmonic correction for several medium-size molecules (1). In a dynamical process, the Coriolis coupling affects the intramolecular energy transfer, which cannot be characterized as vibrational or rotational energy.

For example, as discussed in ref. 2, close degenerate rovibrational levels of vibrationally excited polyatomic molecules were separated by Coriolis interactions during state-to-state energy transfer processes. A discrepancy between rotational energy transferred and collisional relaxation rates was attributed to the increase of vibrational energy transfer, caused by the Coriolis coupling. This effect is also responsible for the combination bands involving stretching and out-of-plane bending as discussed in ref. 3, in which a theoretical model was proposed to describe the interactions between (1,0,0) and (0,0,1) states of H_2O molecules. Therefore, the Coriolis coupling plays an important role in the energy transfer involving polyatomic molecules (4–6), and its quantification is essential for a complete energetic description of collisional processes. At the same time, particular attention has been devoted to interactions of CO_2 with rare-gas atoms. Several experimental and theoretical studies describing energetic effects and formation of CO_2–Ar clusters have been investigated in detail (7–10). However, there is no information about the Coriolis coupling effect in CO_2–Ar energetics. In a recent work, the Coriolis coupling influence on the rotational and vibrational energy transfer in H_2O + Ar collisions (11) was described by using a classical trajectory approach. The method proposed in ref. 11 is used in the present work to analyze effects of different rotational states and atomic translational energies on the energy transfer because of CO_2 + Ar collisions. The molecular kinetic energy is partitioned into vibrational, rotational, and Coriolis components. The relative importance of the Coriolis coupling is analyzed in the present study.

Computational method

Potential-energy surface

A fourth-order anharmonic potential surface, based on spectroscopic data, is used to describe the CO_2 molecule,

 doi:10.1139/V07-113 © 2007 NRC Canada

Fig. 1. Internuclear coordinates in the CO_2–Ar collision system.

$$[1]\quad V_{(\Delta r_1,\Delta r_2,\Delta r_3)} = f_{11}(\Delta r_1^2 + \Delta r_2^2) + f_{12}\Delta r_1\Delta r_2 + f_{\alpha\alpha}\Delta r_3^2 + f_{111}(\Delta r_1^3 + \Delta r_2^3) + f_{112}(\Delta r_1^2\Delta r_2 + \Delta r_1\Delta r_2^2) + f_{1\alpha\alpha}(\Delta r_1 + \Delta r_2)\Delta r_3^2 + f_{1111}(\Delta r_1^4 + \Delta r_2^4) + f_{1112}(\Delta r_1^3\Delta r_2 + \Delta r_1\Delta r_2^3) + f_{1122}\Delta r_1^2\Delta r_2^2 + f_{11\alpha\alpha}(\Delta r_1^2 + \Delta r_2^2)\Delta r_3^2 + f_{12\alpha\alpha}\Delta r_1\Delta r_2\Delta r_3^2 + f_{\alpha\alpha\alpha\alpha}\Delta r_3^4$$

The force constants are f_{11} = 0.5148, f_{12} = 0.0814, $f_{\alpha\alpha}$ = 0.0901, f_{111} = −0.6498, f_{112} = −0.0515, $f_{1\alpha\alpha}$ = −0.0747, f_{1111} = −0.4652, f_{1112} = −0.0429, f_{1122} = −0.1066, $f_{1\alpha\alpha 2}$ = 0.5139, $f_{11\alpha\alpha}$ = 0.2281, and $f_{\alpha\alpha\alpha\alpha}$ = −0.014; unit is au (12). Also, the internal coordinates Δr_1, Δr_2, and Δr_3 are generated in atomic units (au). Interactions between CO_2 and Ar are described by a Buckingham-form pair potential (13), which is written as

$$[2]\quad V_{\text{pair}} = \frac{6\varepsilon e^{\lambda(1-r/r_m)}}{\lambda - 6} - \frac{\lambda\varepsilon}{\lambda - 6}\left(\frac{r_m}{r}\right)^6$$

The pairwise potential parameters are $\varepsilon = 0.34 \times 10^{-3}$ au, r_m = 7.20 au, and λ = 1.70 for Ar–C; and $\varepsilon = 0.29 \times 10^{-3}$ au, r_m = 6.80 au, and λ = 1.50 for Ar–O in which ε and r_m are the potential's well depth and equilibrium distances, respectively. Figure 1 shows the internuclear coordinates used in the potential-energy surface for the CO_2–Ar system.

Initial conditions

Cartesian coordinates, coupled to vibrational normal modes, are used. The transformation between vibrational normal modes and Cartesian coordinates can be obtained by the matrix equation proposed by Crawford and Fletcher (14, 15)

$$[3]\quad \Delta u = M^{\frac{1}{2}}\tilde{B}G^{-1}LQ$$

in which Δu represents the displacements Cartesian coordinates, Q represents the normal coordinates, and M is a diagonal matrix that contains the mass factor of each particle. The vibrational matrices L, B, and G are related to molecular masses and geometries (16). Defining $m_T = m_C$ (carbon mass) + m_O (oxygen mass), fixing the molecule on the z axis, and using eq. [3], the molecule-fixed Cartesian coordinates for the CO_2 molecule are obtained as

$$[4]\quad z_1 = -\frac{1}{\sqrt{2m_O}}Q_1 - \sqrt{\frac{m_C}{2m_O m_T}}Q_3 + z_{1e}$$

$$z_2 = \sqrt{\frac{2m_O}{m_C m_T}}Q_3$$

$$z_3 = \frac{1}{\sqrt{2m_O}}Q_1 - \sqrt{\frac{m_C}{2m_O m_T}}Q_3 - z_{3e}$$

$$y_1 = -\sqrt{\frac{m_C}{2m_O m_T}}Q_{2a}$$

$$y_2 = \sqrt{\frac{2m_O}{m_C m_T}}Q_{2a}$$

$$y_3 = -\sqrt{\frac{m_C}{2m_O m_T}}Q_{2a}$$

$$x_1 = -\sqrt{\frac{m_C}{2m_O m_T}}Q_{2b}$$

$$x_2 = \sqrt{\frac{2m_O}{m_C m_T}}Q_{2b}$$

$$x_3 = -\sqrt{\frac{m_C}{2m_O m_T}}Q_{2b}$$

in which $z_{1e} = z_{3e}$ = 4.14 au are the equilibrium coordinates and Q_1, Q_{2a}, Q_{2b}, and Q_3 are the symmetrical, bending, and unsymmetrical normal modes (the bending mode, Q_2, is degenerate in two components Q_{2a} and Q_{2b}), respectively. If Ev_i is the spectroscopic vibrational energy, the normal coordinates are generated as

$$[5]\quad Q_i(t) = (2Ev_i/\lambda_i)^{1/2}\cos(\lambda^{1/2}{}_i + \sigma_i) \qquad i = 1,\ 2a,\ 2b,\ 3$$

in which $\lambda_i = 4\pi^2\upsilon_i^2$; υ_i are the vibrational frequencies, σ_i are arbitrary phase factors, $0 \le \sigma_i \le 2\pi$, which are randomly selected from $\sigma_i = 2\pi\xi_i$. The random numbers ξ_i are uniformly distributed between 0 and 1. If r_{kl} is the distance between the nuclei k and l, the potential energy surface can be described in relation to internuclear distances, $R_{kl} = [(x_k - x_1)^2 + (y_k - y_1)^2 + (z_k - z_1)^2]^{1/2}$. Defining b as the impact parameter selected from $b = b_{max}\,\xi_b{}^{1/2}$ and choosing r_{max} large enough to make the atom–molecule interaction negligible, the atomic position can be generated as

$$[6]\quad x_{Ar} = 0$$

$$y_{Ar} = b$$

$$z_{Ar} = -(r^2{}_{max} - b^2)^{1/2}$$

In this study, b_{max} = 9.45 au and r_{max} = 18.90 au. The molecular kinetic energy is $E_{kin} = E_{vib} + E_{rot} + E_{Cor}$ in which E_{vib},

© 2007 NRC Canada

E_{rot}, and E_{Cor} are the vibrational, rotational, and Coriolis terms, respectively. These components are defined in Cartesian coordinates as

$$[7] \qquad E_{\text{vib}} = \frac{1}{2}\sum_{1}^{3}(p_{ix}^2 + p_{iy}^2 + p_{iz}^2)$$

$$[8] \qquad E_{\text{rot}} = \frac{1}{2}\sum_{1}^{3}\begin{bmatrix} m_i\omega_x^2(z_i + y_i)^2 + m_i\omega_y^2(z_i + x_i)^2 + m_i\omega_z^2(x_i + y_i)^2 \\ -2m_i(\omega_x\omega_z x_i z_i + \omega_x\omega_x x_i y_i + \omega_x\omega_x y_i z_i) \end{bmatrix}$$

$$[9] \qquad E_{\text{Cor}} = \omega_x\sum_{1}^{3}[m_i(\Delta y_i\dot{z}_i - \dot{y}_i\Delta z_i)] + \omega_y\sum_{1}^{3}[m_i(\Delta z_i\dot{x}_i - \dot{z}_i\Delta x_i)] + \omega_z\sum_{1}^{3}\sum_{1}^{3}[m_i(\Delta x_i\dot{y}_i - \dot{x}_i\Delta y_i)]$$

in which p_{ix}, p_{iy}, and p_{iz} are the linear moments and ω_x, ω_y, and ω_z are the angular velocities. The symbol delta represents the possible displacements from the equilibrium position for each coordinate. The linear moments can be calculated by the temporal derivative of the kinetic energy in Cartesian coordinates, i.e,

$$[10] \qquad p_{z_i} = \sum_{i=1}^{3} m_i\dot{z}_i + \omega_x\sum_{i=1}^{3} m_i\Delta z_i - \omega_y\sum_{i=1}^{3} m_i\Delta x_i$$

$$p_{y_i} = \sum_{i=1}^{3} m_i\dot{y}_i - \omega_x\sum_{i=1}^{3} m_i\Delta z_i + \omega_z\sum_{i=1}^{3} m_i\Delta x_i$$

$$p_{x_i} = \sum_{i=1}^{3} m_i\dot{x}_i + \omega_x\sum_{i=1}^{3} m_i\Delta z_i - \omega_z\sum_{i=1}^{3} m_i\Delta y_i$$

By using the relations in eq. [4], the linear momenta can be rewritten as

$$[11] \qquad p_{z_1} = -\frac{m_{\text{O}}}{(2m_{\text{O}})^{1/2}}\dot{Q}_1 - \left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}\dot{Q}_3 - \omega_y\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_{2\text{a}} - \omega_x\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_{2\text{b}}$$

$$p_{z_2} = \left(\frac{2m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}\dot{Q}_3 - \omega_y\left(\frac{2m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_{2\text{a}} - \omega_x\left(\frac{2m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}Q_{2\text{b}}$$

$$p_{z_3} = \frac{m_{\text{O}}}{(2m_{\text{O}})^{1/2}}\dot{Q}_1 - \left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}\dot{Q}_3 - \omega_y\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_{2\text{a}} + \omega_x\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_{2\text{b}}$$

$$p_{y_1} = -\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}\dot{Q}_{2\text{b}} - \omega_x\frac{m_{\text{O}}}{(2m_{\text{O}})^{1/2}}\dot{Q}_1 - \omega_x\left(\frac{m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}Q_3$$

$$p_{y_2} = \left(\frac{2m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}\dot{Q}_{2\text{b}} + \omega_x\left(\frac{2m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}Q_3$$

$$p_{y_3} = -\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}\dot{Q}_{2\text{b}} + \omega_x\frac{m_{\text{O}}}{(2m_{\text{O}})^{1/2}}Q_1 - \omega_x\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_3$$

$$p_{x_1} = -\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}\dot{Q}_{2\text{a}} + \omega_y\frac{m_{\text{O}}}{(2m_{\text{O}})^{1/2}}Q_1 + \omega_y\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_3$$

$$p_{x_2} = \left(\frac{2m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}\dot{Q}_{2\text{a}} - \omega_y\left(\frac{2m_{\text{O}}m_{\text{C}}}{m_{\text{T}}}\right)^{1/2}Q_3$$

$$p_{x_3} = -\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}\dot{Q}_{2\text{a}} - \omega_y\frac{m_{\text{O}}}{(2m_{\text{O}})^{1/2}}Q_1 + \omega_y\left(\frac{m_{\text{O}}m_{\text{C}}}{2m_{\text{T}}}\right)^{1/2}Q_3$$

© 2007 NRC Canada

in which

$$[12]\quad \dot{Q}_1 = P_1 = (2Ev_i - \lambda_1 Q_1^2)^{1/2}$$

$$\dot{Q}_{2a} = P_{2a} - \omega_y Q_3 + \omega_z Q_{2b} = (2Ev_{2a} - \lambda_2 Q_{2a}^2)^{1/2} - \omega_y Q_3$$

$$\dot{Q}_{2b} = P_{2b} - \omega_x Q_3 - \omega_z Q_{2a} = (2Ev_{2b} - \lambda_2 Q_{2b}^2)^{1/2} - \omega_x Q_3$$

$$\dot{Q}_3 = P_3 - \omega_x Q_{2b} + \omega_y Q_{2a} = (2Ev_3 - \lambda_2 Q_3^2)^{1/2} - \omega_x Q_{2b} + \omega_x Q_{2a}$$

are the momenta conjugate to the normal modes.

The molecular kinetic energy can also be written as

$$[13]\quad 2E_{kin} = I_{xx}\omega_x^2 + I_{yy}\omega_y^2 - 2I_{xy}\omega_x\omega_y + \dot{Q}_1^2 + \dot{Q}_{2a}^2 + \dot{Q}_{2b}^2 + \dot{Q}_3^2 + 2\omega_x(Q_{2a}\dot{Q}_3 - Q_3\dot{Q}_{2a}) + 2\omega_y(Q_3\dot{Q}_{2b} - Q_{2b}\dot{Q}_3)$$

in which I_{xx}, I_{yy}, and I_{xy} are the moments of inertia. The center of mass of the system atom–molecule does not move with the time in the space-fixed system, and the molecular translational energy is zero. The atom moves toward the molecule with velocity equal to

$$[14]\quad V_{Ar} = \left(\frac{m_T}{m_T + m_{Ar}}\right) V_R$$

in which V_R is the relative velocity between the atom and the molecule, obtained from the initial collisional energy.

Final conditions

The molecule-fixed coordinates are randomly transformed to space-fixed coordinates, i.e., laboratory referential, through Euler's angles and for a given potential surface configuration, initial coordinates, and linear moments, the Hamilton's equations are integrated. A Runge–Kutta algorithm of fifth and sixth order was used as numerical integrator of the classical coupled equations of motion. All the trajectories were checked to produce relative errors of 10^{-4}% in the energy conservation during the integration. Final conditions are established by the final coordinates and linear moments after removing the center of mass motion (17), and final energies are calculated as in eqs. [7–9] in the molecule-fixed coordinates. For each set of 2000 trajectories, the average energy transferred was computed. This number of trajectories is sufficient to produce converged results to the energy transfer, i.e., the average energy transferred after 2000 trajectories or 2500 trajectories gives identical results within six significant figures.

Results and discussion

The transformation between Cartesian and normal coordinates described in eq. [3] is valid in the harmonic limit and can provide reliable results if the total molecular energy is not too large (18). By taking the higher molecular energetic states used in this work, together with eqs. [4] and [5], one obtains the correspondent Cartesian-coordinates values. The harmonic contribution can be obtained from these values and represents about 95.0% of the total intramolecular potential along the trajectories performed. Therefore, the partition of the internal energy into vibrational, rotational, and Coriolis, as in eq. [12], gives reliable results. Also, the present results can provide insights into the rovibrational coupling and rotational contribution to the molecular activation of CO_2 molecules by Ar. Atomic translational energies used in this work were taken from a range of 0.004–0.4 au. Values of molecular initial rotational states were fixed at rotational quantum numbers j, equal to 1, 20, 40, and 60. Initial vibrational levels were fixed in the ground vibrational state, i.e., vibrational quantum numbers n_1, n_{2a}, n_{2b}, and n_3 were equal to zero.

Time evolution of vibrational, rotational, and Coriolis molecular components, as a function of different rotational states, is simulated for the isolated molecule, without collision with the Ar atom, as shown in Fig. 2. Coriolis and rotational components are strongly mixed in low rotational states, $j = 1$. For rotational states corresponding to $j = 20$ and $j = 40$, Coriolis and rotational components are decoupled, and the increase in rotational activation energy is greater than Coriolis activation. Rotational and vibrational components are coupled for $j = 60$.

Atomic translational energy transferred into vibrational, rotational, and Coriolis molecular components are presented in Fig. 3. For all initial conditions used, the process was characterized by molecular activation. In some cases, vibrational and rotational deactivations are observed, although the overall effect was a molecular activation. This effect was attributed to high Coriolis activation, which is greater than total rovibrational deactivation in these cases. Results for the energy transfer, by fixing the initial vibrational energies in the ground state and initial rotational energies corresponding to $j = 1$ and $j = 20$, are presented in Figs. 3*a* and 3*b*. There are two regimes, which characterize the effect of atomic collisional energies on the vibrational, rotational, and Coriolis components during the CO_2 + Ar process:

(*i*) Collisional energy equal to 0.004–0.04 au, $j = 1$, and $j = 20$. Molecular activation is effective, since both rotational and Coriolis activation exceed the vibrational deactivation. Coriolis activation is greater than rotational activation, and T–C (translation to Coriolis), T–R (translation to rotation), V–R (vibration to rotation), and V–C (vibration to Coriolis) are the observed channels of energy transfer.

(*ii*) Collisional energy in the range of 0.08–0.4 au, $j = 1$, and $j = 20$. Coriolis, rotational, and vibrational activa-

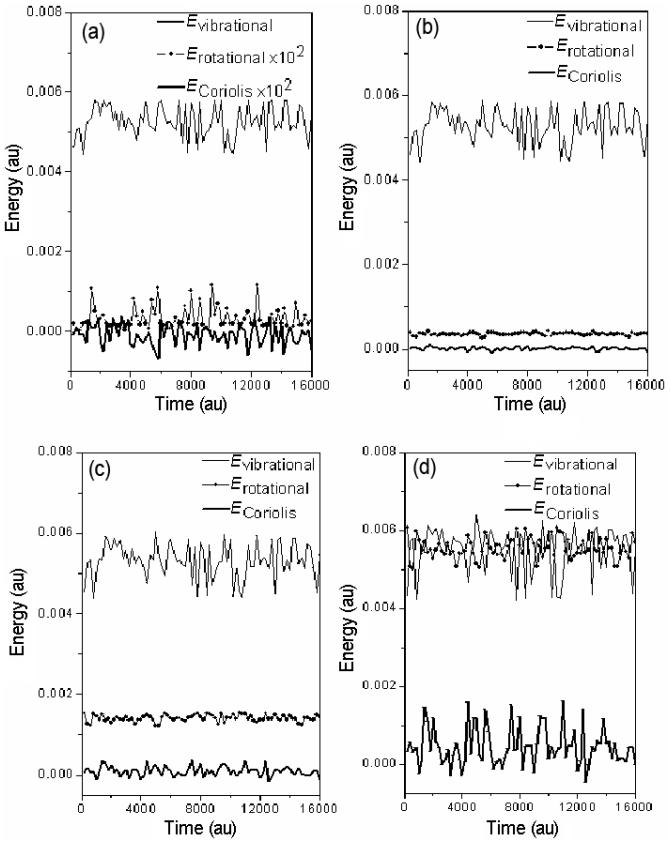
Fig. 2. Time evolution of the intramolecular energies for the molecule isolated. Vibrational states, n_1, n_{2a}, n_{2b}, and n_3 are equal to zero; and rotational states, j, are in the range of 1–60. (a) j = 1, (b) j = 20, (c) j = 40, and (d) j = 60.



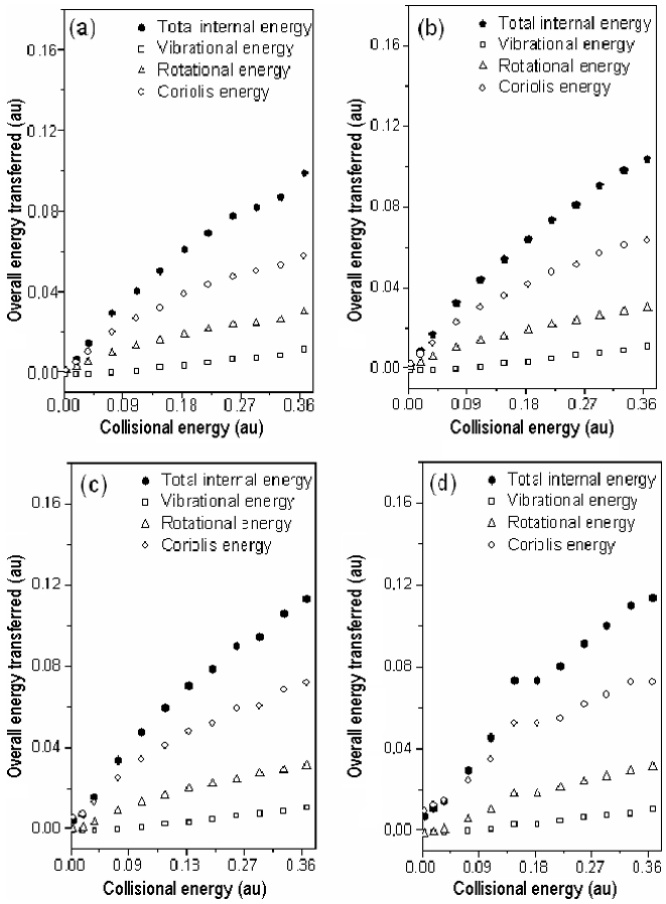


Fig. 3. Overall energy transferred for the CO_2 + Ar collisions. Vibrational states, n_1, n_{2a}, n_{2b}, and n_3 are equal to zero; and rotational states, j, are in the range of 1–60. (a) j = 1, (b) j = 20, (c) j = 40, and (d) j = 60.

tion is observed in this case. The main processes are T–C, T–R, and T–V (translation to vibration). The Coriolis activation is greater than rotational and vibrational activation. The sudden limit, in which the collision time decreases with the increasing of collisional energy, is reached.

Results obtained for vibrational energies in the ground state, for different collisional energies and rotational energies corresponding to j = 40 and j = 60 are presented in Figs. 3c and 3d. The following regimes characterize the influence of collisional energies on intramolecular energy transfer:

(*i*) Collisional energy equal to 0.004 au, and j = 40. Vibrational and rotational deactivations are observed. The vibrational deactivation is greater than rotational deactivation. However, the Coriolis activation exceeds the deactivations, and a molecular activation is reached. Therefore, one can observe the following processes as the dominant ones: T–V, V–C, and R–C (rotation to Coriolis). These results indicate that the molecular rotational energy decreases after the collision, even for j = 40, and this fact can be partially attributed to rotational energy flux to the Coriolis coupling.

(*ii*) Collisional energy equal to 0.02–0.08 au, and j = 40. Vibrational deactivation is present, but rotational and Coriolis activations are present. As a global process, molecular activation is observed. The dominant channels are T–V, V–C, and V–R.

(*iii*) Collisional energy in the range of 0.16–0.40 au, and j = 40. Vibrational, rotational, and Coriolis activation are obtained together with the processes T–V, V–C, and V–R.

(*iv*) Collisional energy equal to 0.004 and 0.02 au, and j = 60. Vibrational and rotational deactivations are obtained. For the collision energy equal to 0.004 au, the rotational deactivation is greater than vibrational deactivation. Again, molecular activation is observed because of Coriolis activation. These regimes are characterized by the channels T–V, V–C, and R–C.

(*v*) Collisional energy of 0.04 au, and j = 60. Vibrational deactivation, rotational and Coriolis activation take place together with global molecular activation. The main processes are T–V, V–C, and V–R.

(*vi*) Collisional energy in the range of 0.08–0.4 au, and j = 60. Vibrational, rotational, and Coriolis activation are observed, and the main energy channels are T–V, V–C, and V–R. The sudden limit is reached.

The results presented here for the energy transferred are in agreement with previous works concerning this system (17). On the other hand, our results show the fundamental role played by the Coriolis coupling in the energetics of the

© 2007 NRC Canada

CO_2 + Ar system. The characterization of energy-transfer channels can be totally different if this coupling is not considered. For example, in ref. 17, it was proposed that most of translational energy absorbed by the molecule during the CO_2 + Ar collision was stored in the vibrational modes. After the collision, this stored energy will flow back to the atomic translational energy. However, our results suggest that the Coriolis coupling is the main drain of vibrational energy for low energetic states.

Another different point between this work and ref. 17 is the independence of the mechanism T–V with respect to the initial rotational states of the molecule, as discussed in ref. 17. However, if the Coriolis coupling is considered, the mechanism T–V is influenced by the initial rotational states, as presented in Fig. 3 and discussed before. The Coriolis component acts as an intermediate channel to the energy flux among the intramolecular components of the kinetic energy. A similar result has been also observed for the H_2O + Ar system (11), and the Coriolis coupling seems to be general and important for different noble gas atom – triatomic systems. Therefore, essential subtleties of energy-transfer processes can be missed if a rigid approximation is used. The active degrees of freedom in this analysis are the vibrational and rotational components, since translational motions are removed when the process is finished. In the initial conditions, the molecule was fixed on the z axis, but in the final conditions, the three components of the angular momentum are present. Therefore, the expression for the rovibrational coupling is

$$[15] \quad E_{\mathrm{Cor}} = 2\omega_x(Q_{2a}\dot{Q}_3 - \dot{Q}_3\dot{Q}_{2a}) + 2\omega_y(Q_3\dot{Q}_{2b} - Q_{2b}\dot{Q}_3) + 2\omega_z(Q_{2a}\dot{Q}_{2b} - Q_{2b}\dot{Q}_{2a})$$

Analysis of Coriolis coupling can be inferred from eq. [15]. Since $\dot{Q}_1$ does not contain terms in angular velocities, as written in eq. [12], one may conclude that $\dot{Q}_1$ is not important for the Coriolis coupling. This is in fact the case, as eq. [15] implies. Although one might expect that Coriolis coupling will be more effective for higher vibrational or rotational states, this assumption is clearly invalid if the Q_1 mode is excited for the CO_2 molecule. Coupling between vibrational and rotational degrees of freedom is caused by the asymmetric and bending normal modes.

Conclusion

The classical-trajectory approach has been used to analyze the Coriolis coupling on the rotational and vibrational energy transfer for CO_2 + Ar collisions. The molecular kinetic energy was partitioned in vibrational, rotational, and Coriolis components by using a Cartesian coordinates system coupled to vibrational normal modes. Collisional energies selected from a range of 0.004–0.4 au and initial rotational states corresponding to quantum numbers j in the range 1–60 were used as initial conditions. Molecular activation takes place for all energetic states analyzed. However, different intramolecular energies channels are observed. In some cases, molecular activation was observed even with vibrational and rotational deactivation, and this was attributed to Coriolis activation.

The Coriolis and rotational components are superimposed at low rotational states. For low collisional energies, the Coriolis coupling is the main drain of vibrational energy, and molecular activation becomes more important for higher collisional energies. The Coriolis activation is greater than rotational activation for all energies studied. As a general conclusion, the Coriolis coupling plays a fundamental role on the vibrational and rotational energy transfer mechanisms and should be quantified in a complete classical dynamics simulation for the CO_2–Ar system.

Ceric-sulfate-catalyzed synthesis of 14-aryl- or 14-alkyl-14*H*-dibenzo[*aj*]xanthene under conventional heating and microwave irradiation

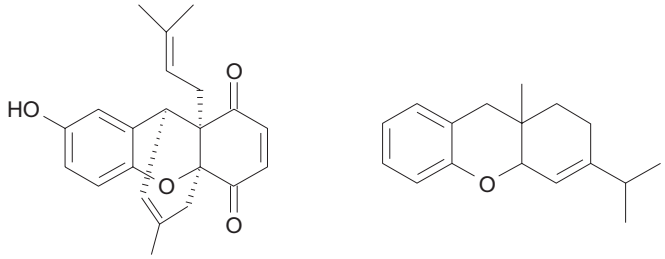
Nagarajan Panneer Selvam, Gnanamani Shanthi, and Paramasivan T. Perumal

Abstract: A simple and facile procedure for the synthesis of 14-aryl- or 14-alkyl-14*H*-dibenzo[*aj*]xanthenes is described. The procedure takes place by the one-pot condensation of 2-naphthol with aldehydes in the presence of anhydrous ceric sulfate as the catalyst under solvent-free conventional heating and microwave irradiation.

Key words: xanthene, one-pot condensation, aldehyde, 2-naphthol, ceric sulfate, solvent-free, microwave irradiation.

Résumé : On a mis au point une méthode simple et efficace d'effectuer la synthèse de 14-aryl- ou 14-alkyl-14*H*-dibenzo[*aj*]xanthènes qui implique une réaction de condensation monotope du 2-naphtol avec des aldéhydes en présence de sulfate cérique anhydre agissant comme catalyseur, en l'absence de solvant et faisant appel à des chauffages conventionnels ou des irradiations de microondes.

Mots-clés : xanthène, condensation monotope, aldéhyde, 2-naphtol, sulfate cérique, sans solvant, irradiation de microondes.



[Traduit par la Rédaction]

Introduction

Recently, much attention has been focused on the synthesis of aryl-14*H*-dibenzo[*aj*]xanthenes because of their significant biological activities as antibacterials (1), antivirals (2), anti-inflammatory agents (3), in photodynamic therapy (4), and for their role as antagonists of the paralyzing action of zoxazolamine (5). Xanthene-based compounds have also been investigated for agricultural bactericide activity, and some other benzoxanthenes find applications in industries, such as dyes in laser technology (6) and fluorescent materials for visualization of biomolecules (7). A number of xanthene-based skeletons are also available from natural sources; for example, tetrahydroxanthene **1**, ehretianone **2** (Fig. 1), and santalin pigments have been isolated from a number of plant species (8).

Various procedures have been reported for the synthesis of xanthene derivatives, including the reaction of aryloxy magnesium halides with triethyl orthoformate (9), cyclodehydration (10), trapping of benzynes by phenols (11), intramolecular phenyl carbonyl coupling reaction of benzaldehyde and acetophenones (12), cyclization of polycyclic aryl triflate esters (13), and cyclocondensation between 2-hydroxy aromatic aldehydes and 2-tetralones (14). Additionally, 14*H*-dibenzoxanthenes and its analogues are prepared by the reaction of 2-naphthol with 2-naphthol-1-methanol (15), formamide (16), carbon monoxide (17), and aldehyde acetals (18). Khosropour et al. (19) reported the synthesis of alkyl-14*H*-dibenzo[*aj*]xanthenes from aldehydes, β-naphthol, and *p*-toluenesulfonic acid in 1,2-dichloroethane as solvent and under solvent-free condition. The reaction required extended time as long as 2.5–24 h, and yields of some of the products were not satisfactory. Hence, practical methods of obtaining benzoxanthenes are of great interest in the lead optimization process of drug discovery.

Fig. 1. Examples of xanthene derivatives.

1 **2**

To avoid these limitations, we have started the search for a new catalyst with high catalytic activity and non-hazardous method with shorter reaction time involving simple work-up procedure. Recent literature has shown considerable interest in the use of Ce(IV) reagents, especially cerium(IV) ammonium nitrate (CAN) (20), in the construction of carbon–carbon and carbon–heteroatom bonds. The use of Ce(IV) sulfate (21) as Lewis acid catalyst is very scarce.

As part of our research program directed towards the development of highly expedient methods and the syntheses of diverse heterocyclic compounds of biological significance (22), we herein disclose a new, convenient, and one-pot synthesis of aryl-14*H*-dibenzo[*aj*]xanthene and alkyl-14*H*-

dibenzo[*aj*]xanthene from aldehydes and β-naphthol catalyzed by $Ce(SO_4)_2$ under solvent-free conventional and microwave conditions in excellent yields (Scheme 1).

Results and discussion

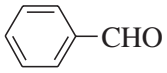
This work is an extension of our previous results describing the synthesis of acetamidophenols (23) by Ritter-type reaction from 2-naphthol and araldehydes in acetonitrile in the presence of anhyd. $Ce(SO_4)_2$, where acetonitrile is involved in the reaction sequence as a nucleophile (Scheme 2).

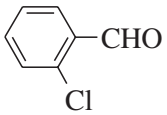
In an initial endeavor, we carried out the reaction of 2-naphthol with 4-chlorobenzaldehyde in the presence of one equiv. of the catalyst under different reaction conditions using various solvents (Table 1). Excellent results were obtained when the reaction was carried out neat. Similarly, the mole ratio of $Ce(SO_4)_2$ was studied, and the results are listed in Table 2. It was found that the amount of $Ce(SO_4)_2$ affects the yield of the product, with 20 mol% of $Ce(SO_4)_2$ being optimum (Scheme 3).

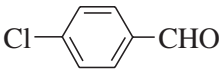
The substrate scope of the reaction under the optimized conditions was investigated, and the results were summarized in Table 3. The reaction was amenable to a wide variety of substituents on araldehydes. The nature of functional groups on the aromatic ring of the aldehyde exerted a strong influence on the reaction time. An increase in the reaction rate was observed with aryl aldehydes bearing electron-withdrawing group.

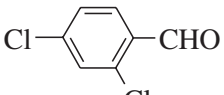
The reaction with pyrazolyl aldehyde afforded new pyrazolyl xanthene in good yield (Scheme 4). The structure of the product **3** was confirmed by single crystal X-ray analysis (Fig. 2) and spectral data.[2]

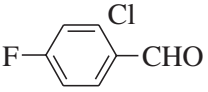
Encouraged by these results, we extended our protocol by using substituted phenols (e.g., 4-methoxyphenol, 4-chlorophenol, 3-nitrophenol, and 1-naphthol) instead of 2-naphthol. The reactions were very sluggish, and no product formation was observed.

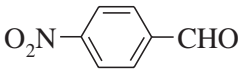


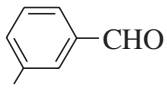


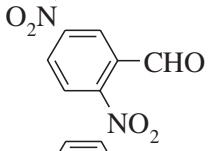


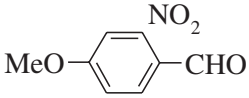


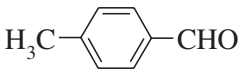


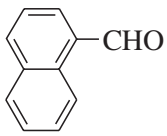


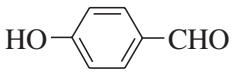


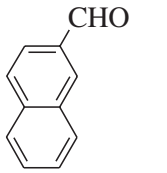












Conclusion

In summary, we have developed a convenient and efficient method for the synthesis of aryl- or alkyl-14*H*-dibenzo[*aj*]xanthenes, via three-component reaction offering various advantages, such as shorter reaction time, milder condition, high yield, general applicability, and the use of inexpensive and commercially available cerium(IV)sulfate.

Fig. 2. ORTEP diagram of compound **3**.

Experimental

Materials and general

Glassware were hot-air oven-dried prior to use. Cerium(IV) sulfate and 4-methoxy phenol were purchased from Lancaster Research Chemicals. All other reagents were purchased from S.D. Fine-Chem. Limited and used as received. Acetonitrile was distilled from CaH_2 under nitrogen and stored over 4 Å molecular sieves. DMSO-d_6 was purchased from Aldrich. Melting points were determined in open capillary tubes and are uncorrected. IR measurements were carried out using KBr pellets in PerkinElmer Spectrometer RXI–FTIR. ^{1}H NMR and ^{13}C NMR spectra were recorded in JEOL 500 MHz high-resolution NMR spectrometer with TMS as an internal standard. Mass spectra were obtained using JEOL DX–303 in EI ionization mode at 70 eV. TLC was performed on precoated Polygram SIL G/UV$_{254}$ sheets.

Typical experimental procedure for the synthesis of aryl-14*H*-dibenzo[*aj*]xanthenes

Method A

A mixture of the aldehyde (2 mmol), 2-naphthol (4 mmol), and anhyd. ceric sulfate (0.4 mmol) was stirred at 100 °C for the appropriate time as mentioned in Table 3. Completion of the reaction was confirmed by TLC. The reaction mixture was extracted with dichloromethane (3 × 15 mL), ceric sulfate was filtered off, and the filtrate was concentrated under reduced pressure. The solid obtained was recrystallized from ethyl alcohol.

Method B

A mixture of the aldehyde (2 mmol), 2-naphthol (4 mmol), and anhyd. ceric sulfate (0.4 mmol) was inserted in a microwave oven (BPL BMG 800 TS model) on a silica gel solid support and irradiated at 300 W for the appropriate time as mentioned in Table 3. Completion of the reaction was confirmed by TLC. The reaction mixture was extracted with dichloromethane (3 × 15 mL), ceric sulfate was filtered

14-(2-Chlorophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 2)

White solid, mp 212–214 °C (lit. value 215 °C) (19). IR (KBr) ν_{max} cm^{-1}: 3026, 1601, 1583, 1422, 1249, 820. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.79 (s, 1H), 6.88 (p, 2H, *J* = 8.4 Hz), 7.25 (d, 1H, *J* = 7.6 Hz), 7.38 (d, 1H, *J* = 7.6 Hz), 7.42 (t, 2H, *J* = 7.6 Hz), 7.48 (d, 2H, *J* = 8.4 Hz), 7.61 (t, 2H, *J* = 8.4 Hz), 7.78 (d, 2H, *J* = 8.4 Hz), 7.81 (d, 2H, *J* = 8.4 Hz), 8.73 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 34.7, 118.1, 118.2, 123.6, 124.5, 127.0, 127.9, 128.0, 128.8, 129.2, 129.7, 130.2, 130.9, 131.9, 131.9, 143.7. MS *m*/*z*: 393 (M + 1).

14-(4-Chlorophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 3)

White solid, mp 286–289 °C (lit. value 289 °C) (19). IR (KBr) ν_{max} cm^{-1}: 2925, 1590, 1484, 1242, 1083, 807. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.71 (s, 1H), 7.16 (d, 2H, *J* = 7.6 Hz), 7.4 (t, 4H, *J* = 7.6 Hz), 7.51 (d, 2H, *J* = 8.4 Hz), 7.60 (m, 4H), 7.89 (d, 4H, *J* = 7.6 Hz), 8.62 (d, 2H, *J* = 7.6 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 39.9, 117.5, 118.2, 123.8, 125.1, 127.6, 128.9, 129.2, 129.8, 130.2, 131.2, 131.3, 131.4, 145.0, 148.5. MS *m*/*z*: 393 (M + 1).

14-(2,4-Dichlorophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 4)

White solid, mp 252–254 °C (lit. value 253–255 °C) (24*a*). FTIR (KBr) ν_{max} cm^{-1}: 3059, 1620, 1590, 1465, 1247, 806. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.74 (s, 1H), 6.87 (d, 1H, *J* = 8.45 Hz), 7.26 (m, 2H), 7.42 (m, 4H), 7.60 (t, 2H, *J* = 6.9 Hz), 7.78 (d, 2H, *J* = 9.2 Hz), 7.81 (d, 2H, *J* = 8.4 Hz), 8.63 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 34.3, 117.5, 118.2, 123.2, 124.6, 127.1, 128.5, 128.8, 129.2, 129.4, 130.7, 130.9, 131.7, 132.8, 132.9, 142.3, 148.9. MS *m*/*z*: 428 (M + 2).

14-(4-Fluorophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 5)

Brown solid, mp 237–239 °C (lit. value 239 °C) (19). IR (KBr) ν_{max} cm^{-1}: 3068, 1623, 1592, 1242, 959, 744. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.47 (s, 1H), 6.80 (t, 2H, *J* = 9.15 Hz), 7.40 (t, 2H, *J* = 7.65 Hz), 7.45 (m, 4H), 7.57 (t, 2H, *J* = 7.65 Hz), 7.78 (d, 2H, *J* = 9.15 Hz), 7.82 (d, 2H, *J* = 7.6 Hz), 8.32 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 37.3, 115.3, 115.5, 117.2, 118.1, 122.6, 124.4, 126.9, 128.9, 129.1, 129.7, 129.7, 131.1, 131.4, 140.9, 148., 160.2, 162.08. MS *m*/*z*: 377.1 (M + 1).

14-(4-Nitrophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 6)

Pink-brown solid, mp 306–308 °C (lit. value 310 °C) (19). IR (KBr) ν_{max} cm^{-1}: 2930, 1594, 1517, 1343, 1241, 828. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.93 (s, 1H), 7.50 (m, 2H), 7.67 (m, 4H), 8.03 (m, 8H), 8.71 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 36.4, 116.2, 117.7, 123.1, 123.6, 124.7, 127.2, 128.7, 129.6, 130.7, 130.8, 145.9, 148.1, 152.6. MS *m*/*z*: 403 (M^+).

14-(3-Nitrophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 7)

Yellow solid, mp 210–211 °C (lit. value 211 °C) (19). IR (KBr) ν_{max} cm^{-1}: 3077, 1592, 1527, 1347, 1250, 810. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.55 (s, 1H), 7.23 (t, 1H, *J* = 7.65 Hz), 7.41 (t, 2H, *J* = 6.9 Hz), 7.49 (d, 2H, *J* = 8.4 Hz), 7.59 (t, 2H, *J* = 7.6 Hz), 7.79 (m, 6H), 8.27 (d, 2H, *J* = 8.4 Hz), 8.41 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 37.8, 115.9, 118.2, 121.8, 122.1, 122.8, 124.7, 127.3, 129.2, 129.6, 129.7, 131.1, 134.4, 147.0, 148.3, 148.8. MS *m*/*z*: 403 (M^+).

14-(2-Nitrophenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 8)

Yellow solid, mp 290–291 °C (lit. value 293 °C) (24*b*). IR (KBr) ν_{max} cm^{-1}: 2921, 1581, 1350, 1241, 809. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.02 (t, 1H, *J* = 7.6 Hz), 7.18 (t, 1H, *J* = 7.65 Hz) 7.41 (t, 2H, *J* = 6.85 Hz), 7.47 (t, 3H, *J* = 8.4 Hz), 7.54 (s, 1H), 7.58 (t, 2H, *J* = 7.6 Hz), 7.78 (t, 5H, *J* = 7.65 Hz), 8.51 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 32.6, 117.6, 118.1, 122.7, 124.8, 125.0, 127.4, 127.7, 128.8, 129.5, 131.0, 131.8, 132.3, 134.2, 140.9, 147.1, 149.5. MS *m*/*z*: 404.69 (M + 1).

14-(4-Methoxyphenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 9)

Yellow solid, mp 202–204 °C (lit. value 204 °C) (19). IR (KBr) ν_{max} cm^{-1}: 2922, 1592, 1510, 1030, 810. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.60 (s, 3H), 6.44 (s, 1H), 6.66 (d, 2H, *J* = 8.4 Hz), 7.39 (m, 4H), 7.47 (d, 2H, *J* = 8.4 Hz), 7.56 (t, 2H, *J* = 8.4 Hz), 7.77(d, 2H, *J* = 9.15 Hz), 7.81 (d, 2H, *J* = 8.4 Hz), 8.37 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 37.18, 55.1, 113.9, 117.6, 118.1, 122.8, 124.3, 126.9, 128.8, 128.9, 129.2, 131.1, 131.5, 137.5, 148.7, 157.9. MS *m*/*z*: 389.8 (M + 1).

14-(4-Methylphenyl)-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 10)

Light-brown solid, mp 224–227 °C (lit. value 229 °C) (19). IR (KBr) ν_{max} cm^{-1}: 2925, 1590, 1520, 1250, 810. ^1H NMR (500 MHz, $CDCl_3$) δ: 2.13 (s, 3H), 6.46 (s, 1H), 6.96 (d, 2H, *J* = 7.65 Hz), 7.42 (t, 4H, *J* = 7.6 Hz), 7.49 (d, 2H, *J* = 9.2 Hz), 7.57 (t, 2H, *J* = 8.4 Hz), 7.78 (d, 2H, *J* = 9.2 Hz), 7.82 (d, 2H, *J* = 7.6 Hz), 8.40 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 21.0, 37.7, 109.6, 117.5, 118.1, 122.8, 124.3, 126.8, 128.2, 128.9, 129.2, 131.1, 131.5, 136.0, 142.2, 148.8. MS *m*/*z*: 373 (M + 1).

14-Ethyl-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 11)

White solid, mp 148–151 °C (lit. value 152 °C) (19). IR (KBr) ν_{max} cm^{-1}: 3062, 2926, 1623, 1588, 1049, 1395. ^1H NMR (500 MHz, $CDCl_3$) δ: 0.55 (t, 3H, *J* = 7.65 Hz), 2.10 (p, 2H, *J* = 4.6 Hz), 5.58 (t, 1H, *J* = 3.8 Hz), 7.37 (d, 2H, *J* = 8.4 Hz), 7.44 (t, 2H, *J* = 6.9 Hz), 7.60 (t, 2H, *J* = 7.65 Hz), 7.77 (d, 2H, *J* = 8.4 Hz), 7.87 (d, 2H, *J* = 8.4 Hz), 8.25 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 9.1, 28.4, 31.7, 116.0, 117.6, 122.6, 124.2, 126.7, 128.3, 128.9, 131.1, 131.6, 150.2. MS *m*/*z*: 311 (M + 1).

14-Naphthalen-1-yl-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 12)

White solid, mp 202–204 °C. IR (KBr) ν_{max} cm^{-1}: 3049, 1590, 1397, 1245, 806. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.11 (s, 1H), 7.20 (t, 1H, *J* = 7.7 Hz), 7.29 (t, 2H, *J* = 6.7 Hz), 7.36 (t, 2H, *J* = 8.4 Hz), 7.48 (m, 4H), 7.69 (d, 1H, *J* = 6.9 Hz), 7.75 (m, 6H), 8.46 (d, 2H, *J* = 8.4 Hz), 9.14 (d, 1H, *J* = 9.2 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 34.53, 118.28, 118.47, 122.77, 123.51, 123.53, 125.28, 125.95, 126.56, 126.73, 127.61, 128.78, 128.94, 129.40, 129.66, 130.14, 131.12, 132.08, 133.91, 142.61, 148.68. EI-MS *m*/*z*: 410 (M + 2); Anal. calcd. for $C_{31}H_{20}O$: C, 91.15; H, 4.93. Found: C, 91.08; H, 4.94.

4-(14*H*-Dibenzo[*aj*]xanthen-14-yl)-phenol (Table 3, entry 13)

White solid, mp 200–204 °C. IR (KBr) ν_{max} cm^{-1}: 3373, 1593, 1511, 1243, 815, 744. ^1H NMR (500 MHz, $CDCl_3$) δ: 4.78 (s (br), 1H), 6.42 (s, 1H), 6.56 (d, 2H, *J* = 8.4 Hz), 7.35 (d, 2H, *J* = 8.4 Hz), 7.39 (t, 2H, *J* = 6.9 Hz), 7.46 (d, 2H, *J* = 9.2 Hz), 7.56 (t, 2H, *J* = 7.6 Hz), 7.77 (d, 2H, *J* = 8.4 Hz), 7.81 (d, 2H, *J* = 7.7 Hz), 8.35 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 37.17, 115.37, 117.55, 118.08, 122.74, 124.32, 126.85, 128.83, 128.89, 129.45, 131.12, 131.44, 137.56, 148.72, 153.90. EI-MS *m*/*z*: 375 (M + 1). Anal. calcd. for $C_{27}H_{18}O_2$: C, 86.61; H, 4.85. Found: C, 86.45; H, 4.86.

14-Naphthalen-2-yl-14*H*-dibenzo[*aj*]xanthene (Table 3, entry 14)

Pale-yellow solid, mp 198–200 °C. IR (KBr) ν_{max} cm^{-1}: 3052, 1594, 1430, 1250, 813, 742. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.67 (s, 1H), 7.31 (t, 1H, *J* = 7.7 Hz), 7.37 (m, 3H), 7.54 (d, 2H, *J* = 9.2 Hz), 7.58 (m, 5H), 7.81 (m, 5H), 8.09 (s, 1H), 8.51 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 38.42, 117.12, 118.14, 122.82, 124.38, 125.70, 126.09, 126.67, 126.95, 127.55, 127.98, 128.64, 128.94, 129.13, 131.20, 131.61, 132.18, 133.23, 133.91, 142.44, 148.85. EI-MS *m*/*z*: 410 (M + 2). Anal. calcd. for $C_{31}H_{20}O$: C, 91.15; H, 4.93. Found: C, 90.98; H, 4.94.

3-(14*H*-Dibenzo[*aj*]xanthen-14-yl)-1,4-diphenyl-1H-pyrazole (3)

White solid, mp 234–236 °C. IR (KBr) ν_{max} cm^{-1}: 3057, 1594, 1502, 1401, 1243, 742, 688. ^1H NMR (500 MHz, $CDCl_3$) δ: 6.53 (s, 1H), 7.14 (t, 1H, *J* = 7.7 Hz), 7.29 (t, 2H, *J* = 8.4 Hz), 7.35 (d, 2H, *J* = 8.4 Hz), 7.40 (m, 6H), 7.51 (m, 5H), 7.75 (d, 2H, *J* = 9.2 Hz), 7.83 (m, 3H), 8.13 (d, 2H, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 27.87, 117.67, 118.08, 119.02, 122.83, 124.37, 126.23, 126.34, 126.64, 126.98, 128.41, 128.46, 128.75, 128.80, 129.25, 129.98, 131.02, 134.15, 139.73, 149.17, 151.47. EI-MS *m*/*z*: 501 (M + 1). Anal. calcd. for $C_{36}H_{24}N_2O$: C, 86.38; H, 4.83; N, 5.60. Found: C, 86.50; H, 4.84; N, 5.58.

Acknowledgments

One of the authors, N.P., thanks the Council of Scientific and Industrial Research, New Delhi, India, for the research fellowship.

On the origin of some cubebene derivatives — Diels–Alder adducts and the diene structures of solidago compounds

Christopher K. Jankowski, André Pelletier, Eduardo Diaz T., Jacqueline M.R. Belanger, Jocelyn J.R. Paré, Andre Aumelas, Thierry Besson, Maria de Fatima Pereira, and Laurent Mauclaire

Abstract: Two reactions, HCl addition and the thermal and (or) microwave assisted Diels–Alder condensation, were performed on α-cubebene (**1**), a vinylcyclopropane-containing tricyclic sesquiterpene. The diene structures originating from these reactions and from subsequent rearrangements of **1** were identified. The stereochemistry of the resulting adducts was established using mostly 2D high-resolution NMR.

Key words: cubebene, tricyclic terpenes from Solidago Canadensis L, Diels–Alder microwave condensation on vinylcyclopropane system.

Résumé : Le α-cubébène (**1**), un sesquiterpène qui contient une unité vinylcyclopropane, a été soumis à une réaction d'addition de HCl et une de condensation de Diels–Alder thermique à l'aide de microondes. On a identifié les structures diéniques qui trouvent leur origine dans ces réactions et dans les réarrangements subséquents du composé **1**. On a déterminé la stéréochimie des adduits qui en résultent en se basant principalement sur la RMN bidimensionnelle à haute résolution.

Mots-clés : cubébène, terpènes tricycliques provenant de *Solidago Canadensis* L., condensation de Diels–Alder à l'aide de microondes sur un système vinylcyclopropane.

[Traduit par la Rédaction]

Introduction

Cyclopropane-containing terpenes are present in many botanical extracts (1). The complex relation between the biological origin of this strained cyclopropane system and its facile rearrangement in vitro complicates the exact structural identification. The cyclopropane system is even more susceptible to rearrangement when in proximity to a double bond, as this often induces diene character (2). If the interactive method of extraction, such as microwave-assisted extraction, is used, the likelihood of such reactions increases yet again (3).

We were interested in elaborating our hypotheses on the possible origin of α-cubebene (**1**), a popular vinylcyclopropane-containing tricyclic sesquiterpene present in several plant extracts (in particular, Solidago Canadensis L) (4). In previous papers, we have already reported on its microwave-induced rearrangement (3).

Our current hypothesis should take into account the predominantly photochemical (hν) mode of these transformations on the plant level, the symmetry-allowed processes relating various diene structures, and their stereochemistry.

For such a system one can consider various possibilities, including a Cope rearrangement (5), a relatively easy vinylcyclopropane-cyclopentene rearrangement (5), and exo–endo double bond isomerization. Finally, the entire system manifests several possible sigmatropic shifts with and without respect to Woodward–Hoffmann formalism because of uncertainty as to the concerted character of these transformations (7). The following hypothesis towards a possible retro-synthesis of **1** can then be elaborated as per Scheme 1.

Scheme 1 suggests that germacrene D (**4**) can be a precursor of tricyclic unsaturated sesquiterpenes such as cubebenes **2**, **5,** etc. It is worth noting that **4** is a naturally abundant

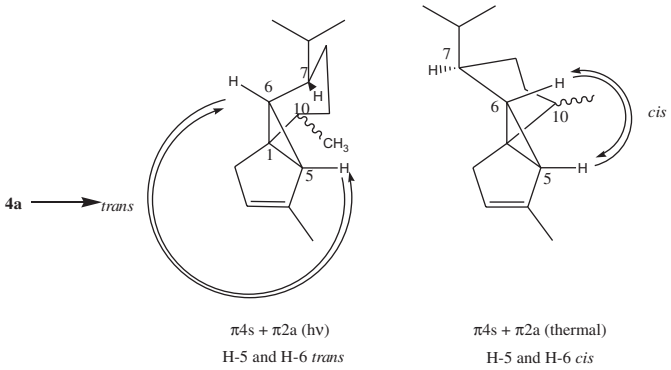
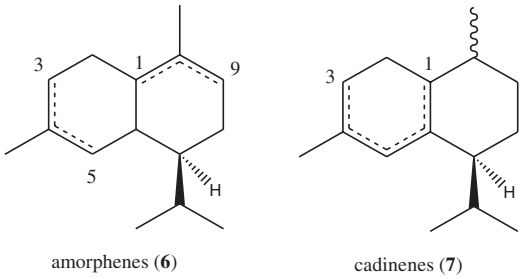
Scheme 1. Possible retro synthetic pathway for the biogenesis of α-cubebene **1**.

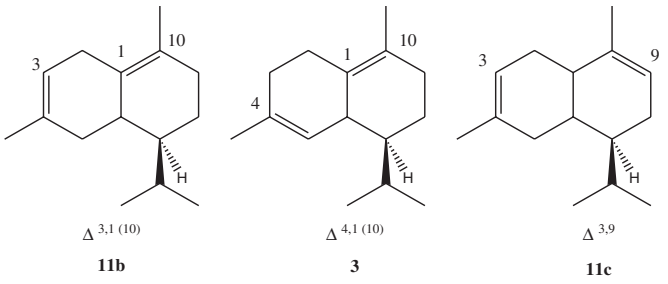


monocyclic sesquiterpene triene, and that like **1**, it has four unsaturations (cycle and three double bonds). It is often present together with natural α-cubebene (**1**) and *epi*-α-cubebene (**5**) as a potential precursor to both. As a part of this transformation it is assumed that **4** enters the isomerization of the double bond from exo to endo position, followed by the shift of the remaining double bond to a more stable conjugated position. One can assume that the rearrangement will then be reduced to a hexatriene-bicyclo[3.1.0]hexene transformation. The bio-originated product will have a geometry conforming to the photochemical pathways of π4s + π2a (Scheme 2) (7, 8) (or of its optical isomer, or both).



According to Scheme 2, the stereochemistry at the C-10 center is lost because of the non-regioselective H-shift at this carbon. The only remaining stereocenter, C-7 involved, has its isopropyl group β-oriented and is thus a valuable reference point to follow the stereochemistry of these compounds. The value of this hypothesis is reinforced by König transformation (9, 10) of the germacrene D (**4**) into the series of amorphanes (**6**) and closely related cadinenes (**7**) (Scheme 3).

To have the cubebene geometry conform to Scheme 3, H-5 and H-6 should be trans (this is true for both cubebenes and *epi*-cubebenes); as well, H-7 must be trans to H-6 to maintain the voluminous isopropyl group in the equatorial position (Scheme 4). The concerted character of such a photocyclisation, which was suggested by Padwa et al. (11), was subsequently challenged by Seeley (12). If this second hypothesis is retained, steric hindrance should be a driving force of the stereochemistry final product. The isopropyl group should remain in the equatorial position, and the C_1–C_5 bond should be formed through a less hindered pathway.



Scheme 2. Differences between thermal or photochemical ring closure leading to **1**.

Scheme 3. Skeleton structures of the amorphenes **6** and cadinenes **7** families.

Scheme 4. The dienes possibly coming from the cyclopropane ring opening of α-cubebene **1** and capable of forming the dichlorinated product **13**.

In such a manner, the hypothesis of formation of cubebene from germacrene D (**4**) via the photochemical pathway in plant could be advanced. Many uncertain points remain open. For example, the second vinylcyclopropane *iso*-cubebene **2** structure could undergo rearrangements leading to more strained structures prior to allowing the formation of either of the two cubebenes by thermal (13) or microwave-assisted conditions (14). Many of the compounds presented in Schemes 1–3 displayed the diene structures. It seems necessary then to show that the dienes are effectively present in these pathways. The best way to confirm this point is to perform two reactions: (*i*) in particular the Diels–Alder addition, enabling the trapping of the diene isomeric structure and the addition of HCl to the double bond and (*ii*) following the opening of the cyclopropane toward olefin, the second addition of HCl (with or without its previous rearrangement because of the carbocation formation).

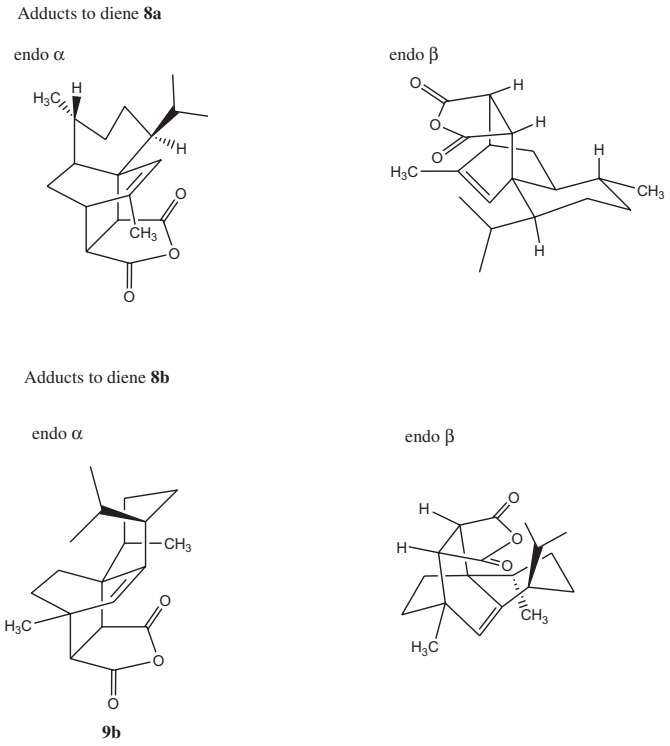
Results and discussion

Diels–Alder reaction on α-cubebene (1)

As a first step of this study, we performed molecular modelling of many of the dienes discussed here (Scheme 5). The dienes were limited here to those able to produce the homoannular *s-cis*-1,3-diene conformation from the cubebene structure. It is also observed that the cubebenes with the cyclopropane in the C1-C3 position are less stable than those having the cyclopropane in the C1-C5 position. A similar conclusion could be drawn for the monocyclic trienes presented in Scheme 1: the starting triene structure can undergo either the 1,5 sigmatropic shift or the less favoured 1,3 shift; however, germacrene D (**4**) remains among the most stable triene substrates. The most interesting six diene structures **8a**–**8f** were those that originated from the cyclopropane-bearing ring of **1** but were also 1,3-homoannular dienes with their natural s-cis conformation. Incidentally, the molecular modelling of these six diene structures shows that the diene, cadinene-3,5-diene (**8b**), is the most stable of this group of six homoannular dienes.

We chose maleic anhydride as a dienophile because of its proven dienophile character, its solubility, and its easy focalisation under microwave heating. Two different modes of Diels–Alder reaction were performed: thermal and microwave-assisted (MAP and in vessel) (14), and the reactions were monitored using GC-MS, GC, and TLC.



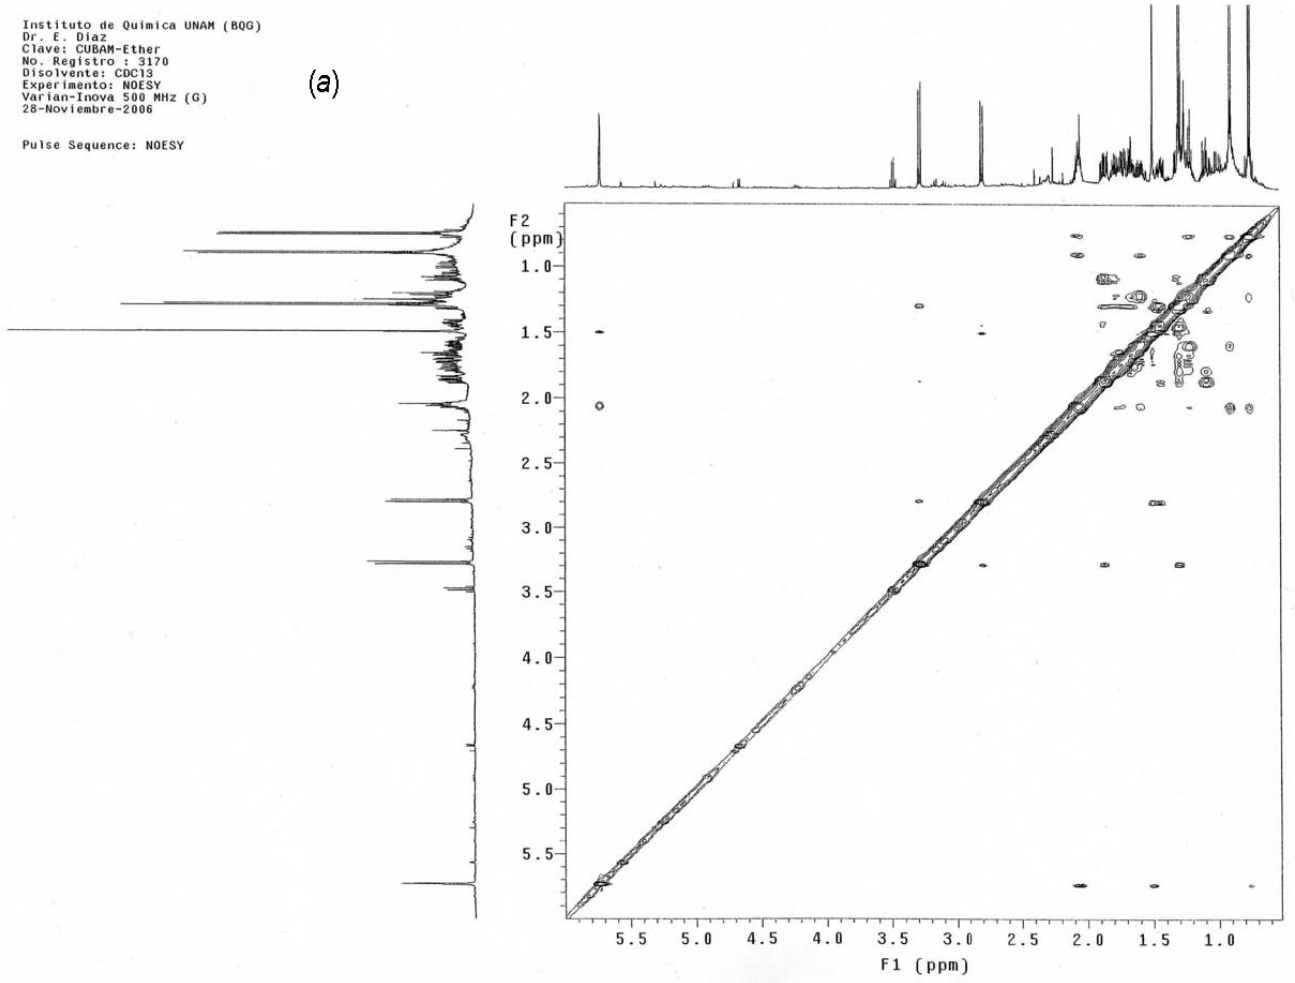
GC-MS revealed the presence of the Diels–Alder adduct at *m/z* 302, which was obtained by heating substrates at a 1:1 molar ratio in toluene, for variable amounts of time, or by microwave. The yield was optimized at 12% in the thermal reaction; it was up to 23% with microwave heating but only 15% using MAP method (15).

The careful chromatographic isolation of this adduct enabled us to further identify its structure as being **9**, essentially from the 2D NMR evidence. The final adduct structure relative configuration at asymmetric carbons, discussed as being a result of two diastereo differentiating approaches (endo, exo) from two possible sides of the molecule of cubebene **1**, was established from the NOESY experiments performed (Fig. 1). The problem of the structure of the starting diene was again examined at this point.

All six isomeric diene structures **8a**–**8f** (Scheme 5) are *s-cis* homoannular dienes. The most distinctive spectral characteristic of the adducts obtained from these dienes was predicted to be the number of vinylic proton signals and the methyl-15 being attached to sp^2 or to sp^3 carbon C-4. The presence of the signal at 5.73 ppm (doublet 2Hz) for one proton in its 500 MHz spectrum eliminates two of these structures from consideration; the methyl-15 singlet signal was then observed and identified as being attached to the sp^3 quaternary carbon at 1.286 ppm. The isopropyl signal displayed the large non-equivalence of its two methyls (0.90 and 0.75 ppm doublets), indicating the steric hindrance in this crowded structure (16).

These results lead to the conclusion that the adduct structure fitted best the structure of diene **8b** (Scheme 6). Further analyses were then performed, taking into consideration four structures — two possibilities of approaches (resulting in Diels–Alder adducts endo or exo) of the dienophile to diene **8b** — from the alpha or beta side of **1**, with the isopropyl

Scheme 5. Structures of the four most likely adducts, as supported by preliminary results.



beta orientation in this natural product serving as a reference to the identification of these sides of the molecule.

Molecular modelling indicates that the endo adducts obtained from α (opposite to the isopropyl side of **1**) are more stable than their corresponding exo adducts. The approach from the same side of the isopropyl (β) but according to the endo preference also gives a relatively stable adduct isomer (Scheme 4). The calculated energies of four isomeric structures resulting from the diene **8b** (endo or exo complexes) indicated that for diene **8b**, the adduct endo alpha displayed 55.77 kcal/mol (1 cal = 4.184 J), compared with the second endo beta of 56.53 kcal/mol and to two exo resulting complexes at α 61.29 kcal/mol and β at 58.28 kcal/mol. This difference is also an indication that the presence of a bulky isopropyl group played a direct role in this addition. The reciprocal trans orientation of methyl C-14 and the isopropyl groups should be maintained in this adduct structure and the *endo*-α adduct will, however, have both substituents in equatorial positions. The same analysis was performed for the diene **8a**, which does not lead to the obtained adduct **9**.

To complete the analysis, high-resolution 2D proton NMR experiments were performed. The NOE experiments enabled us to distinguish between these adducts, in particular between endo-α and endo-β, by evaluating the distance between the maleic methine protons and CH_3-4, for example, as well as the vinyl proton and three methyls (C-14 and two from the isopropyl group). The complete analysis of H-1 and C-13 is summarized in Table 1. The key element to support the proposed structure was the clean AB pattern for both methines belonging to the maleic anhydride moiety of adduct. The signals at 3.25 and 2.77 ppm (d, J = 9 Hz) show the lack of any additional couplings, which eliminated struc-

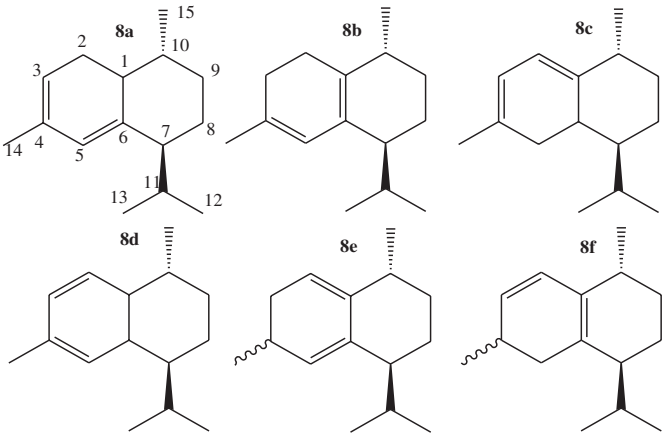
Fig. 1. NMR of adduct **9b** NOESY. (*a*) Upper run: 500 MHz ^{1}H spectrum. Lower run: NOESY within 0–6 ppm range. (*b*) Scheme of NOE interactions.



tures of adducts originating from dienes **a**, **d**, **e**, and **f**. The one vinylic proton at 5.73 ppm (d, J = 2 Hz) finally eliminates the structure of adduct arising from diene **8c**. (Fig. 1)

It is worth noting that the cubebene **1** vinylcyclopropane system should undergo a 1,3-sigmatropic shift to form diene **8a** instead of the usually more favoured 1,5-sigmatropic shift that would form diene **8b**. Conversely, assuming that the α-cubebene **1** is first isomerized via the vinylcyclopropane–cyclopentene rearrangement pathway (Scheme 5) to the isomeric cubebene **2** also with the vinylcyclopropane to form the 1,4-diene **8b**, it should undergo 1,3-sigmatropic migration but also a more complex two-step H-migration to

finally achieve the 3,5-diene. Incidentally, the cubebenes **1** and **5** have been found to be more stable than the *iso*-cubebene (**2**) by up to 5 kcal mol^{-1}.

The syntheses of the identical adduct by both thermal and microwave-assisted methods were observed. The difference between endo-β and endo-α approaches to the 1,4-diene (**8b**) is the presence of the bulky isopropyl group, which cannot share space with the relatively large maleic anhydride bridge. The β equatorial orientation of this isopropyl is also an important internal reference point to the identification of the stereochemistry of the entire adduct (absolute configuration **7*S***, **10*R***). The isopropyl-bearing ring of the diene remains, then, the stereo template to follow the regio and stereo specificity of the addition. The final stereochemistry of the adduct **9** can then be proposed as in Scheme 5 and Fig. 1, leading to the structure obtained in agreement to the diene behaviour, following the predictions of both Hirsch (7) and Padwa et al. (11), as far as absolute configuration is concerned. The appealing attempt of the separation of diene **8b** as a result of cubebene **1** rearrangement through heating or MAP modes, as in König's case (9, 10), was unsuccessful, and led instead to a mixture of olefinic compounds. It seems, then, that the maleic anhydride dienophile can be considered as an efficient and specific quencher of this diene among some other dienes.

HCl addition to cubebene (1)

The second attempted reaction was the addition of HCl in methanol solution of α-cubebene (**1**) at 0–5 °C. This was expected to produce the additional evidence for the diene structure discussed in the previous sections through, first, the Markovnikov addition to the 3,4-double bond of the α-cubebene (**1**) followed by an acid-catalyzed rearrangement of its cyclopropane moiety, rearranged through the carbocation pathway (these two reactions could take place in the opposite order). If the elucidation of the addition outcome in the first step is easy, the cyclopropane rearrangement is difficult to predict, especially for the terpenes. The bicyclo[3,1,0]hexene frame could undergo many types of rearrangement under acidic conditions, leading also to the opening of cyclopropane and the formation of dienes. The

© 2007 NRC Canada

presence of several potential tertiary carbocations bears witness to this difficulty.

When cubebene (**1**) was treated with a dry HCl saturated methanol solution at 0–5 °C, the major product (25% of yield) displayed the addition of two HCl molecules, as indicated by mass spectrometry. Unambiguous identification of the adduct stereochemistry is, therefore, the best proof of diene structure for **3**.

In the abundant literature on the subject of diene sesquiterpenes, some structures are of particular interest: those of dienes **11**, **9**, **10**, and **12**, the last one characterized by König et al. (9, 10). These dienes, however, were isolated from two completely different Solidago species; although in terpene chemistry the isomerization and rearrangement of the skeleton is relatively frequent, this does not lead to well-defined diene adducts. Diels–Alder reactions on these dienes were not attempted by König, but in 1998 he attempted to isomerize the diene with pTsOH and obtained another stable isomer. Incidentally, four structures with the best fit for the HCl addition product are described in the next section of this paper.

König's heating of this diene revealed an easy shift of the double bond of the structure, with three other dienes being obtained through this isomerization. The production of the Diels–Alder adduct in the case of α-cubebene (**1**) used in this study is thus a chemically formal proof of trapping of the double bond in the 1,3-conjugated *s-cis* homoannular position; however, this diene is isomeric to the one described by König (9, 10).

The NMR spectra (1D and 2D) of the dihydrochloro-cubebene adduct product showed that the adduct should have two *trans*-fused rings and that both methyls (C-14 and C-15) are equatorial (meaning that both chlorine atoms were axial, thus confirming the Markovnikov rules). It is generally accepted that in methyl derivatives of cyclohexane, as well as in a terpene field, the equatorial methyl-13 signal displays a chemical shift at 35–37 ppm, at ca. 10 ppm lower field than the axial one (20–23 ppm). The chemical shift in the 1D C^{13} NMR spectrum of compound **13c** shows two methyl signals, identified with help of DEPT experiments as being methyl-5 at 37.8 ppm and methyl-10 at 34.9 ppm. Because of the chemical shift, we can conclude that both methyls are in equatorial positions (17, 18). The 600 MHz spectra (Table 2) and Fig. 2) enabled us to establish the structure of the dichloro derivative as being **13c**, with two chlorine atoms placed on carbons 10 and 4, respectively. Further study of the dihydrochloro adducts **13** was performed with help of molecular modelling of eight possible structures for these dichloro adducts: four in *trans*-fused and four in *cis*-fused decalins. The most stable structures in the two series were those with the quaternary carbons bearing Cl and CH_3 groups (C-4 and C-10) and where both methyls were equatorial **13c**. It is necessary to point out that the presence of the CH_3 and Cl on the same carbon will always lead to one axial substituent contributing to the creation of two gauche interactions (19). When we consider the addition of the first HCl to the molecule under the two-step addition scheme, the original α-cubebene (**1**) double bond position responds well to the dichloro derivative structure. Under the same hypothesis, the second double bond can originate in either of two essentially similar structures: with the double bond in the 1,10/1,14 position or in position 9,10/1,14 where it is unrelated to the cyclopropane moiety.

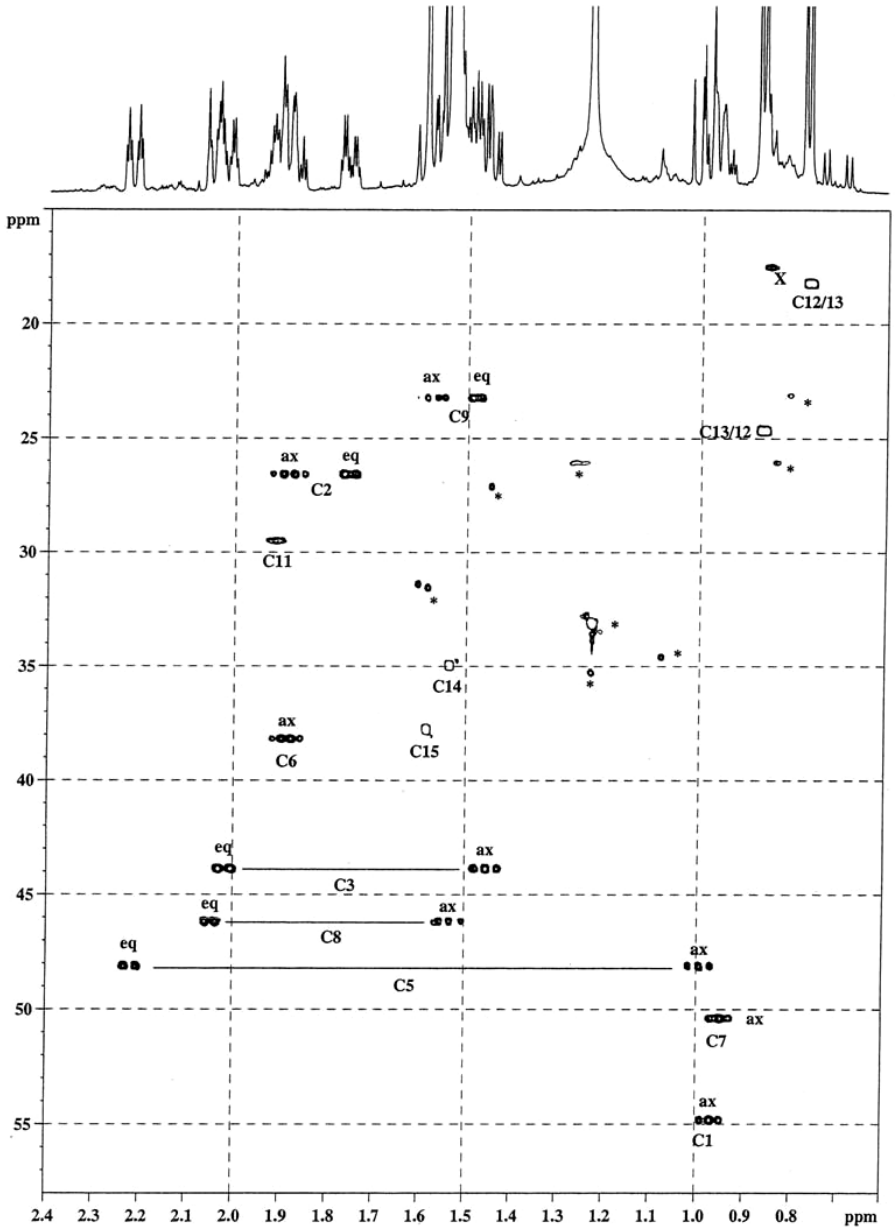
A second hypothesis of formation of the dichloro derivative could also be advanced. The acid catalysis of the cubebene **1** leads to diene **3**, already observed by König et al. (9, 10), which undergo double Markovnikov addition of HCl. Note that this second one-step route leads to the addition of protons from HCl to the carbons C-5 and C-1, instead of to C-3 and C-1 as in the first route. To clarify this point, deuteration with dry DCl in deuterated methanol was attempted. The reaction enabled us to establish the position of deuteration at C-1, C-9, C-3, and C-5. There are then four endocyclic unconjugated dienes with double bonds at -4,9 (**9**), -10,4 (**3**), -3,1, and -3,9, which can produce the Markovnikov's dihydrochloro adduct corresponding to the one identified in this work. The presence of exocyclic double bond dienes was turned down because of the absence of exocyclic methylene signals in the NMR proton spectra of this series. The fact that many amorphenes were identified in some extracts can be asserted by the deuteration (9, 20).



Because of the identification of reduced intensity of proton chemical shifts corresponding to the H-3, H-5, and H-9 in HSQC experiments on the DCl adduct, we concluded that the diene structures were one or many of the followings **3**, **11a**–**11c**.

Conclusion

The Diels–Alder adduct stereochemistry identification is an interesting attempt to show the corresponding isomeric diene presence within the very complex scheme for cubebene isomerization. The diene structure is then deduced from the adduct structural features. The stereochemistry of this adduct was established in a satisfactory manner con-

© 2007 NRC Canada

Fig. 2. NMR of dichloro derivative **13c** HSQC (600 MHz).

forming to the cycloaddition rules: the dienophile comes from the less hindered side of the diene to form the adduct. These results are reinforced by the molecular modelling calculations.

It is then assumed that the hydrochlorination of **1** proceeded via the formation of the protonated species, which is rearranged to the more stable of two possible carbocations leading to the Markovnikov addition as a final result.

Unfortunately, there are at least four possible diene structures that fit the HCl addition to the double bond: both vinylic carbons have the same substitution level but not the same access to the double bond for the bulky Cl^- ion.

More interestingly, to give such a dichloro adduct, the diene should have its double bond placed in, for example, -3,4 and -1,10 positions. This means that no single one of these dienes is able to produce the Diels–Alder addition described in this study. König's heating experiments revealed an easy shift of the double bond of the diene structure. The production of the Diels–Alder adduct in the case of α-cubebene (**1**) used in this study is thus a chemically formal proof of the quenching of the double bond in the 1,3-conjugated *s-cis* homo annular position; however, this diene is isomeric to the one described by König (9, 10).

The isomerization of the vinylcyclopropane to cyclopentene and the shift of the original double bond of cubebene both took place. In such a manner, the easy epimerisation of cubebene under microwave conditions is justified.

Once the dienes have been obtained, they can be further rearranged into those that are Diels–Alder precursors. In this respect, this diene is more stable since it is homonuclear and 1,3-conjugated and has natural *s-cis* conformation. For this purpose, the formal identification of the Diels–Alder adduct with maleic anhydride is very symptomatic. Both reactions,

[a]Assignment can be inversed.

Diels–Alder and the addition of HCl, proceeded by several stepwise mechanisms. In such a manner, the respecting or not of the Woodward–Hoffmann formalism for the Diels–Alder adduct stereochemistry should then be considered as accidental.

Incidentally, the structure of the dihydrochloro adduct **13c** (Tables 3 and 4) is different than those described by, for example Burk (21) and Piers (22); as well, it has a different isopropyl orientation. X-ray analysis of the equivalent dihydrohalo structures also displays such a differently oriented isopropyl (23).

It is thus concluded that the cubebenes **1** and **3** with their original cyclopropyl–vinyl system can isomerize to many dienes: to 1,3- conjugated or to several deconjugated ones. The first is able to produce the Diels–Alder adduct and the second system produces the addition of two HCl.

When considering the -1,2 and -1,10 double bond containing intermediates, it is also possible to assume that their spontaneous reaction should go in the direction of the cubenol, leaving the hydroxyl group on the angular C-1 position (3) as observed in our previous paper when reacting **1** with methanol/HCl (3, 24).

The results of this deuterium labelling should be interpreted cautiously because of the sigmatropic shifts possible in this system and because of, as usual, the partial and relatively low yield of this reaction.

Experimental

General

All chemicals, solvents, chromatographic materials, and deuterated solvents were purchased from Sigma-Aldrich Chemicals (USA). The cubebene sample was obtained from Solidago Canadensis L as described in ref. 3 and the pure samples of compound **1** were also purchased from Sigma-Aldrich Chemicals.

NMR spectroscopy

NMR 1D experiments were performed using a Varian Inova spectrometer at 500 MHz for proton and 125 MHz for carbon-13 and a Bruker AMX at 600 MHz for proton and 125 MHz for carbon-13, respectively. In all cases the samples recorded at 295 K were prepared in $CDCl_3$ (dimethylsulfoxide-d_6) ca. 10% solution at 25 °C; chemical shifts were referred to the TMS or referenced to a residual signal of chloroform at 7.24 ppm. Selected 2D experiments were run using a standard Varian package of Inova programs for COSY and NOESY. For HSQC experiments, the Inova program for short range coupling (less than 140 Hz for 1*J* Hz) was used. The long range proton–carbon experiments (HMBC) were recorded with a Varian Inova pulse program, optimized for long range couplings (3*J* C, H 9.0 Hz). A DQF-COSY spectrum (25) was collected on a 800 × 1024 data matrix and the TOCSY spectrum was collected with a mixing time of 80 ms (26). In all experiments the carrier frequency was set at the centre of the spectrum. The (^{1}H,^{13}C) HSQC (27) experiments were recorded with a delay of 3.5 ms (1*J* CH = 143 Hz) and the (^{1}H,^{13}C) HSQC-TOCSY experiment with a mixing time for proton–proton transfer of 80 ms to identify the network of one-bond and several proton–carbon connectivities, respectively. All data were processed with the XWINNMR software and one zero filling and π/3 phase shifted sine bell window function were applied in both dimensions before Fourier transform.

All NMR high resolution 1D and 2D detailed experiments data could also be transmitted to the interested persons from the corresponding author (CKJ, U de Moncton, Canada).

Mass spectroscopy

Mass spectra of all products were recorded on Agilent 6890 with mass selective detector (model 5973) (U de Moncton, Moncton, New Brunswick), the column used was a HP5-MS (30 m, 0.25 μm), the GC-MS EI and CI (NH_3) experiments on Riber 1030 GC-MS (U de Paris, Paris, France), and ESI-PI on a Micromass Quatro II (U de Paris, Paris, France), as well on an Agilent 19091S-436 with packed column HP5-MS (0.25 mm, 60 m, 0.25 μm) (Environment Canada, Ottawa, Canada). The GC-MS was used as the control of the progress of purification of chromatographic fractions for adduct **9b** and for the dichloro derivative **13c**. The mass spectroscopy was also used to determine the deuteration level of this last compound in a series of experiments as described in the following.

Molecular modelling

All molecular modelling results performed on HyperChem 6.02 on dienes and adducts are available on request from the corresponding author (CKJ, U de Moncton, Canada).

Microwaves

Microwave experiments were carried out at atmospheric pressure using a focused microwave reactor (CEM Discover™) (28) or MAP technology (14, 15). The instrument consists of a continuous focused microwave power output from 0 to 300W. Reactions were performed in a glass vessel equipped with a condenser; it is also possible to work under dry atmosphere, in vacuo, or under pressure (0–20 torr, tubes of 10 mL, sealed with a septum) (1 torr = 133.322 4 Pa). The temperature content of a vessel is monitored using a calibrated IR sensor mounted under the vessel. All experiments were performed using stirring option whereby the contents of a vessel are stirred by means of a rotating plate located below the floor of the microwave cavity and a Teflon-coated magnetic stir bar in the vessel. In all experiments a power of 300 W was selected and the reflux temperature was reached with a ramp of about 1 min. The time of the reaction does not include the ramp period.

Synthesis

*(4,10a-dimethyl-7b-*iso*-propyl-decaline-5ene)1a,4a-maleic acid anhydride (9b)*

Diels–Alder condensation of **1** with maleic anhydride (thermal reaction). Cubebene (**1**) (100 mg, ca. 0.5 mmol) and maleic anhydride (40 mg, 0.45 mmol, less than equimolar ratio) were dissolved in anhydrous toluene and heated in the stainless vessel for 24 h at 130 °C. Two consecutive flash column chromatography separations on silica gel column of adduct **9b** were then performed on the oily residue under TLC (hexane/ether 9:1, R_f = 0.7) and GC-MS controls (using mass chromatogram at *m/z* 302). The yield of pure adduct **9b** was 12% (16–18 mg) with an optical rotation of α_{25} = +38° (ethanol). MS eight main ions in **9b**, EI-spectrum *m/z* (I%): 302 (12, M^+), 274 (72), 259 (16), 231 (56), 203 (100), 185 (17), 164 (82), 145 (39).

Diels–Alder condensation of **1** with maleic anhydride (microwave reaction). Yield of **9b** 15%–23%. Conditions: CEM Discover™ 300 W at the reflux temperature of toluene for 5–30 min.

*4β,10β-dichloro-4α,10α-dimethyl-7β-*iso*-propyl-*trans*-decalin (13c)*

Addition of HCl to **1** at 0–5 °C. To a solution of α-cubebene (**1**) (90 mg, 0.5 mmol) in methanol (20 mL) (the equal volume of dry methanol saturated with hydrochloric acid (g) was added). The reaction mixture was left at 0–5 °C for 24 h then cautiously evaporated in vacuo. The resulting product **13c** (14 mg), mp 104–107 °C, TLC: petroleum ether, R_f = 0.4, isolated by column then by preparative TLC chromatographies on silica gel, yield 25%. In this separation, 31 mg of starting compound **1** and three unidentified compounds were separated. MS: For the compound **13c** CI-MS (NH_3) mass spectra revealed the presence of *m/z* 294 (100, NH_4^+), 277 (3, MH^+) 276 (2). The ESI spectrum confirmed double chlorination at *m/z* 277 (55, MH^+) and 279 (35, MH^+).

Addition of DCl to **1** was performed in a similar mode (also see ref. 3).

Synthesis by microwave-assisted addition of HCl

A solution of α-cubebene (100 mg, 0.5 mmol) in methanol (12.5 mL) (saturated with hydrochloric acid) was irradiated at 25 W with a ramp period of 1 min until reflux was reached. Heating of the solution was then maintained for 30 min, and after cooling the solvent was removed in vacuo. The various products observed by TLC analysis were then separated by column chromatography (petroleum ether) and analyzed as in previous procedure. Yield of **13c** 15%.

Acknowledgments

We would like to thank A. Savoie (U de Moncton) for helpful discussion and his involvement in the primary stage of this study, S. Arseneau (U de Moncton) for some molecular modelling and energy computing calculations and C. Fajolles (CEA) for precious graphical assistance. One of the authors (TB) thanks CEM Corp. for multiform support and technical assistance. The generous financial support of Environment Canada through Youth Horizons Fellowship was greatly appreciated.

Homoallylic ketones and pyrroles by way of copper-catalyzed cascade additions of alkyl-substituted vinyl Grignard reagents to esters

Aurélie A. Dörr and William D. Lubell

Abstract: Exploring the scope of the copper-catalyzed cascade addition of vinyl Grignard reagents to carboxylic esters, a set of substituted homoallylic ketones (γ,δ-unsaturated ketones) have been synthesized in 11%–94% yields from treatment of methyl 4-methoxybenzoate and methyl *N*-Boc-β-alaninate with different methyl-, dimethyl-, and phenyl-substituted vinyl Grignard reagents in the presence of catalytic amounts of CuCN in THF. The respective 2,4-di-, 2,3,5-tri-, and 2,3,4,5-tetrasubstituted pyrroles were obtained in 47%–93% yields from the homoallylic ketones by a sequence featuring ozonolysis followed by Paal–Knorr condensation with ammonium formate.

Key words: copper-catalyzed cascade addition, homoallylic ketone, alkyl-substituted vinyl Grignard reagents, ozonolysis, pyrrole, γ,δ-unsaturated ketone.

Résumé : En étudiant l'étendue de la réaction d'addition en cascade de réactifs de Grignard vinyliques sur des esters carboxyliques catalysée par des sels de cuivre, une série de cétones homoallyliques (cétones γ,δ-insaturées) substituées a été synthétisée avec des rendements de 11%–94% à partir du 4-méthoxybenzoate de méthyle et du *N*-Boc-β-alaninate de méthyle avec différents réactifs de Grignard vinyliques substitués par des groupements méthyle, diméthyle et phényle, dans le THF. Des pyrroles 2,4-di, 2,3,5-tri et 2,3,4,5-tétrasubstitués ont été obtenus avec des rendements de 47%–93% à partir des cétones homoallyliques suite à une séquence réactionnelle incluant une ozonolyse suivie d'une condensation de Paal–Knorr avec de l'ammonium formate.

Mots-clés : addition en cascade catalysée au cuivre, cétone homoallylique, réactif de Grignard vinylique substitués, ozonolyse, pyrrole, cétone γ,δ-insaturée.

[Traduit par la Rédaction]

Introduction

The γ,δ-unsaturated carbonyl unit is a structural component of natural products (1) and an important intermediate in the synthesis of terpenoids (2) and heterocycles such as pyrroles (3), dihydropyrroles (3*a*, 4), pyridines (5), and isoquinolines (5*a*). Moreover, homoallylic ketones (γ,δ-unsaturated ketones) are particularly useful as precursors to 1,4-diketone intermediates for the preparation of cyclopentanones (6), pyrroles (7), furans (7*h*–7*k*, 8), thiophenes (7*j*–7*k*), and pyridazines (7*k*, 9).

In light of their broad utility for making compounds of biological and technological importance, the synthesis of γ,δ-unsaturated carbonyl compounds has attracted considerable interest. Among the methods for synthesizing γ,δ-unsaturated systems (10–14), a notable one of choice has been the 1,4-addition of suitably substituted alkenyl metallic reagents to an α,β-unsaturated carbonyl compound. For example, conjugate additions to α,β-unsaturated ketones of alkenyl Grignard reagents in the presence (15*a*–15*h*) and absence (15*i*–15*k*) of catalytic copper salts, as well as the 1,4-additions of alkenyl copper (16–19) and boron (20) reagents, have all been used to make homoallylic ketones. Alternative methods for making γ,δ-unsaturated carbonyl units include the direct insertion of aroyl cyanides (21*a*) and aldehydes (21*b*, 21*c*) to zirconacyclopentenes, the allylation of silyl enol ethers (22), and various allylations of unsaturated compounds under ruthenium (23), palladium (24), copper (25) and nickel (26) catalysis. The Claisen–Cope (1*m*, 27) and Carrol (28) rearrangements (29) and the Wittig (30) methodology have also found utility in the construction of γ,δ-unsaturated carbonyl compounds.

Homoallylic ketones have been obtained by the reaction of excess vinylmagnesium halide onto various carboxylic acid derivatives, including carboxylic acids (31*a*–31*c*), esters (31*b*, 32), acid anhydrides (31*b*), and acid halides (33). Low yields and the competitive formation of side products, such as tertiary alcohols and alkenyl ketones, have limited the utility of this methodology (31*b*–31*c*, 33). Copper salts have been utilized to enhance product formation in these cascade addition processes. For example, CuCl was added to the cascade reaction of excess vinylmagnesium chloride to fatty carboxylic acids and esters to produce mixtures of 1,6-diones and homoallylic ketones in 6%–47% yields (32). Significantly improved yields of homoallylic ketone were

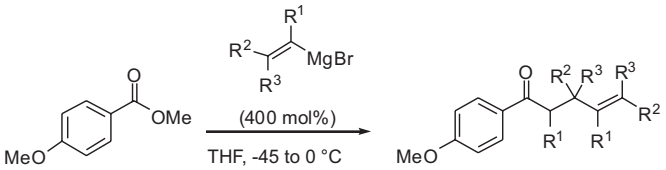
 doi:10.1139/V07-114 © 2007 NRC Canada

achieved in the cascade reaction of excess vinylmagnesium bromide to methyl esters by employing catalytic amounts of $Cu(OAc)_2$ or CuCN (34). This version of the copper-catalyzed cascade addition proved effective for the synthesis of the parent but-4-en-1-ones using a variety of methyl carboxylates, including aromatic and aliphatic esters as well as N-protected α-, β-, and γ-amino esters.



Mixtures of homoallylic ketone and tertiary alcohol were also isolated from cascade reactions using α-methyl-, β-methyl-, and β,β-dimethyl substituted vinylmagnesium halides in additions to carboxylic acids, esters, and acid anhydrides (35, 36) in the absence of copper. For example, the treatment of methyl *p*-toluate with isopropenyl- and prop-1-enyl-magnesium bromides gave, respectively, 2,4-dimethyl-1-(*p*-tolyl)pent-4-en-1-one and 3-methyl-1-(*p*-tolyl)hex-4-en-1-one in 65% and 54% yields, along with 7%–11% of the corresponding tertiary alcohol resulting from two sequential 1,2-addition reactions of the alkenyl Grignard reagent onto the ester carbonyl (35). On the other hand, treatment of ethyl benzoate with 2-methylprop-1-enyl-magnesium bromide was reported to produce exclusively the tertiary alcohol 2,6-dimethyl-4-phenyl-heptadi-2,5-en-4-ol in 70% yield (36).

In considering these issues (35–36), and the success of the copper-catalyzed cascade addition of vinyl Grignard reagent to esters for preparing the parent but-4-en-1-ones (34), the reactions of esters with various alkenyl Grignard reagents and CuCN have now been investigated to provide substituted homoallylic ketones. The scope of this reaction has been examined by employing a diverse set of methyl-, dimethyl-, and phenyl-substituted vinyl Grignard reagents on two substrates: methyl 4-methoxybenzoate and methyl *N*-Boc-β-alaninate. Furthermore, the corresponding homoallylic ketones **2**–**8**, which were obtained in 11%–94% yields, were subsequently used to provide a diverse set of substituted pyrroles **9**–**13** in 47%–93% yields by a route featuring ozonolysis of the olefin to provide 1,4-dione and 4-oxo aldehyde intermediates for Paal–Knorr condensations with ammonium formate.

Results and discussion

Methyl 4-methoxybenzoate and *N*-Boc-β-alanine methyl ester were treated with a set of commercially available α- and β-methyl and di-methyl substituted Grignard reagents, as well as α- and β-phenylvinyl Grignard reagents that were freshly prepared in-house. We first examined the cascade addition of 400 mol% of α- and β-methyl and dimethyl-substituted Grignard reagents to methyl 4-methoxybenzoate in the absence of copper salts (Scheme 1). Homoallylic ketones **3a** and **4a** were obtained in 80% and 36% yields from employing as Grignard reagent, respectively, 1-propenylmagnesium bromide and 2-methyl-1-propenylmagnesium bromide. Only starting methyl ester was, however, recovered from the reactions using isopropenylmagnesium bromide and 1-methyl-1-propenyl-magnesium bromide as Grignard reagent. The Cu-catalyzed cascade additions of substituted vinyl Grignard reagents were then performed using three types of conditions (Scheme 2). Condition A (Table 1) featured premixing Grignard reagent (400 mol%) and a catalytic amount of CuCN (30%–40 mol%) in THF at −45 °C for 10 min before treatment with a solution of the ester. Condition B (Table 1) employed more CuCN (60 mol%) and a longer premixing time (2 h) with the Grignard reagent (400 mol%) in THF at –45 °C before treatment with a solution of the ester. Condition C was identical to condition B except for the use of more Grignard reagent (500 mol%).

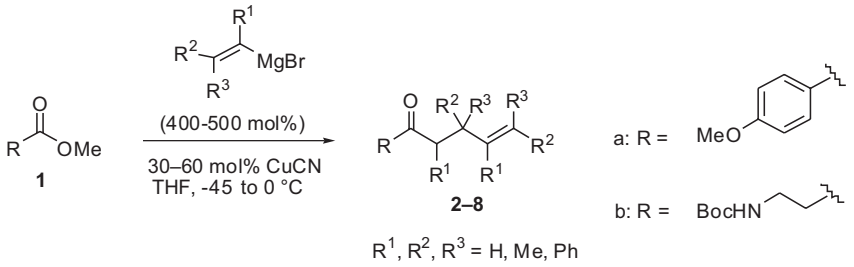
[a] Isolated yield



Substituted homoallylic ketones **3**–**8** were usually obtained in relatively higher yields (Table 1, 11%–94%) using Condition B vs. Condition A (Table 1, 9%–88% yields). This improvement was more evident in the synthesis of homoallylic ketones from methyl 4-methoxybenzoate rather than from *N*-Boc-β-alaninate, which seemed less sensitive to the change. For example, the yields of homoallylic ketone **4a** possessing a quaternary gem-dimethyl carbon were improved from 66% to 75% yield using Condition B (Table 1, entry 3); however, in the case of the *N*-Boc-β-alaninate-derived counterpart **4b**, they dropped from 25% to 20% (Table 1, entry 10).

Some changes were observed using Condition C vs. Condition B in the synthesis of homoallylic ketones from *N*-Boc-β-alaninate. This amelioration was particularly evident for the synthesis of homoallylic ketones **5b** and **7b**, respectively, from using isopropenylmagnesium bromide and 2-phenylvinylmagnesium bromide; the yields were improved from 38% to 63%, respectively, and from 11% to 78% (Table 1, entries 11 and 13). On the other hand, a minor 3%–5% improvement in yield was observed in the synthesis of homoallylic ketones **3b** and **6b** using 500 mol% of 1-propenylmagnesium bromide or 1-methyl-1-propenyl-magnesiumbromide, respectively, (Table 1, entries 9 and 12), and no amelioration was observed in the case of the synthesis of homoallylic ketones **4b** and **8b** from 2-methyl-1-propenylmagnesium bromide and 1-phenylvinylmagnesium bromide, respectively (Table 1, entries 10 and 14).

Olefins **3a**, **3b**, and **7b** were isolated as mixtures of double bond isomers from reactions employing the β-methyl- and β-phenyl-substituted vinyl Grignard reagents, 1-propenylmagnesium bromide and 2-phenylvinylmagnesium bromide. On the other hand, (4*Z*)-1-(4-methoxyphenyl)-3,5-diphenylpent-4-en-1-one (**7a**) was isolated in 61% yield as a single isomer. The ratios of *E*/*Z* isomers **3a**, **3b**, and **7b** were measured by integration of the olefinic protons in their respective ^{1}H NMR spectra as well as by LC-MS analysis in the case of **3a**. The *E* and *Z* geometry was assigned on the basis of the characteristic coupling constants of the vinylic protons (Table 1). Homoallylic ketones **3a** and **3b** were observed to contain predominantly the *Z*-isomer (*E*/*Z* 35:65

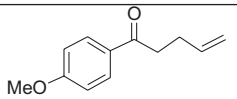
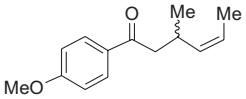
Scheme 2. Synthesis of homoallylic ketones **2–8** by copper-catalyzed cascade addition.

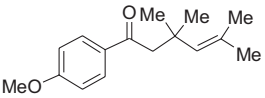
and 29:71), and low selectivity was observed for olefin **7b** (*E*/*Z* 60:40). The influence of the reaction conditions on the stereoselectivity of the olefin has yet to be investigated, however the geometry of the double bond in the final product does not reflect the geometry of the starting Grignard reagent. For example, when employing an isomeric mixture of *E*- and *Z*-2-phenylvinylmagnesium bromide, only *E*-isomer **7a** (Table 1, entry 6) was isolated from 4-methoxybenzoate and a nearly equal ratio of two isomers **7b** (Table 1, entry 13) was obtained from *N*-Boc-β-alanine methyl ester.

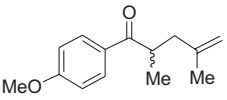
Mixtures of isomers were also isolated from the reactions using 1-methyl-1-propenylmagnesium bromide. Homoallylic ketone **6a** was isolated as a mixture of three isomers, which were observed to exist in a 7.1:1.6:1.3 ratio, by LC-MS analysis of three peaks possessing the same molecular weight, and in an 8.4:0.9:0.7 ratio, as esteemed by integration of the sets of aromatic doublets in the ^{1}H NMR spectrum. Homoallylic ketone **6b** was isolated as a mixture of two isomers that were inseparable by analytical LC-MS and measured as an 8.5:1.5 ratio by integration of the vinyl protons in the ^{1}H NMR spectrum. Homoallylic ketones **6a** and **6b** may exist as mixtures of syn and anti diastereomers as well as cis and trans olefins, however their assignment could not be made because of difficulties in separating pure isomers; instead, the mixtures were used directly for pyrrole synthesis as described below.

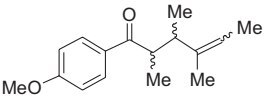
The ability to use mixtures of substituted vinyl organometallic reagents in multi-component reactions would provide novel access to a greater diversity of γ,δ-unsaturated ketones. The cascade addition of two different Grignard reagents was thus explored by adding vinylmagnesium bromide and isopropenylmagnesium bromide to 4-methoxybenzoate (Scheme 3, Table 2). In certain cases, the desired 4-methyl homoallylic ketone **14a**, resulting from the 1,2-addition of vinylmagnesium bromide to the ester followed by the 1,4-addition of isopropenylmagnesium bromide to the enone intermediate, was obtained as the major product, albeit in low yield. Homoallylic ketone **14a** was contaminated with 2,4-dimethyl homoallylic ketone **5a** and the parent homoallylic ketone **2a** resulting from 1,2- and 1,4-additions of only isopropenylmagnesium bromide or vinylmagnesium bromide, respectively. Four conditions were explored to optimize the production of 4-methyl product **14a**. The resultant crude product was then purified by column chromatography to give an inseparable mixture of homoallylic ketones **14a**, **5a**, and **2a**. The product ratio was determined by LC-MS analysis of the purified mixture of homoallylic ketones. Initially, relatively equal amounts of the Grignard reagents were premixed for 10 min at −45 °C with CuCN (30 mol%) before the addition of the ester to produce a 4.6:2.8:2.6 ratio of **14a/5a/2a** (Table 2, entry 1). Then varying amounts of the isopropenylmagnesium bromide and CuCN were premixed in THF for 2 h at −45 °C, prior to the addition of the vinylmagnesium bromide (100 mol%) and methyl ester (Table 2, entries 2–3). When 300 and 100 mol% of the methyl-substituted vinyl Grignard reagent were, respectively, premixed with 60 and 100 mol% of copper salt, homoallylic ketones **14a/5a/2a** were obtained in ratios of 4.1:4.4:1.6 (Table 2, entry 2) and 4.1:3.7:2.2 (Table 2, entry 3). To date, our best results were obtained by premixing isopropenylmagnesium bromide (110 mol%) with 60 mol% of CuCN prior to the addition of ester and vinylmagnesium bromide (100 mol%), which provided ketones **14a/5a/2a** in a 5.6:0.6:3.8 ratio (Table 2, entry 4). A sample of 4-methyl ketone **14a** was finally isolated by HPLC purification for characterization purposes.

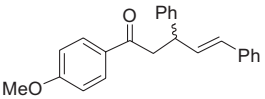


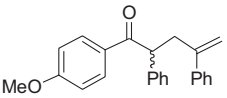


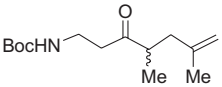


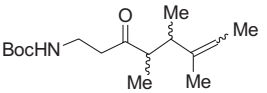


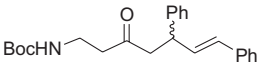


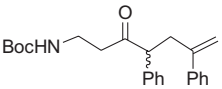












Pyrrole synthesis was next performed using the γ,δ-unsaturated ketones (Scheme 4). Previously, a library of 1,2,5-trisubstituted pyrroles was synthesized from homoallylic ketones that were obtained from the cascade reaction of vinyl Grignard reagent by an approach featuring olefin oxidation using the Tsuji–Wacker reaction and subsequent Paal–Knorr condensation on the resulting 1,4-diones with different amines (7*a*). With substituted homoallylic ketones **3** and **5–8** now in hand, we explored a similar olefin oxidation/Paal–Knorr strategy to prepare 2,4-di-, 2,3,5-tri-, and 2,3,4,5-tetra-substituted pyrroles **9–13** (Fig. 1). For the oxidation of homoallylic ketones **3** and **5–8**, ozonolysis in MeOH/CH_2Cl_2 at –78 °C, followed by treatment with Me_2S and freeze-drying gave crude 1,4-dicarbonyl compounds that were typically of sufficient purity for the subsequent condensation step. The Paal–Knorr reaction was accomplished by treatment of the crude 1,4-dicarbonyl compounds with ammonium formate. In the synthesis of pyrroles **10**, **11b**, **12**, and **13**, the ozonolysis product was condensed with ammonium formate in the presence of NaOAc/HOAc (100 mol% *w*/*w*) in acetonitrile at 65 °C to give the desired targets in 47%–93% yields from the corresponding homoallylic ketone (7*a*). Alternatively, substituted pyrroles **9** and **11a** were best obtained in 59%–70% yields by treating the ozonolysis product with ammonium formate and KOAc in a AcOH/CH_3CN/H_2O mixture (1:1:1) at 80 °C.

Conclusion

The scope of the copper-catalyzed cascade addition of vinylmagnesium bromide to carboxylic esters for the synthesis of homoallylic ketones has been expanded by the em-

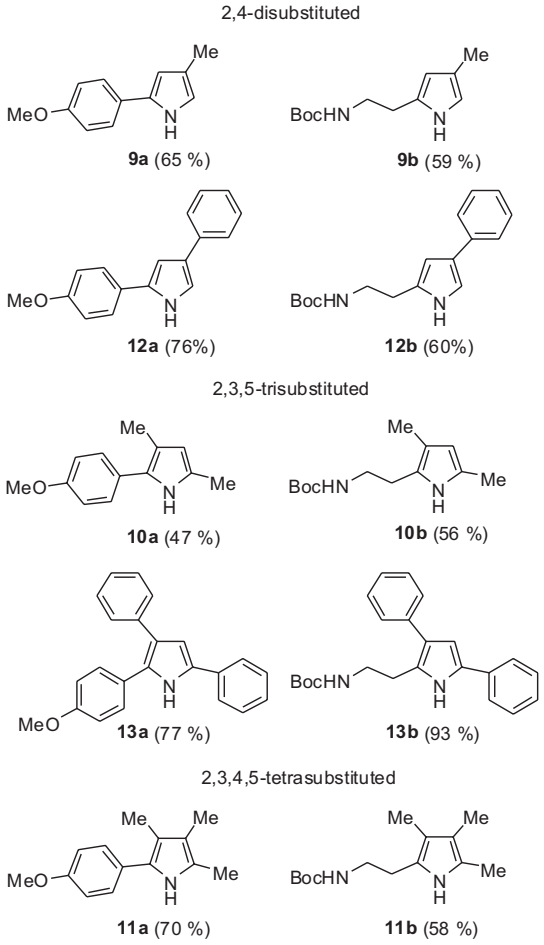
Scheme 3. Addition of two different Grignard reagents to methyl *p*-methoxybenzoate.

Scheme 4. Synthesis of 2,4-di-, 2,3,5-tri-, and 2,3,4,5-tetra-substituted pyrroles **9–13**.



ployment of substituted vinyl Grignard reagents. Substituted γ,δ-unsaturated ketones were synthesized in 11%–94% yields on respective treatments of methyl 4-methoxybenzoate and methyl *N*-Boc-β-alaninate with methyl-, dimethyl-, and phenyl-substituted vinyl Grignard reagents in the presence of catalytic CuCN in THF. A series of diverse substituted pyrroles were then prepared in two steps from the substituted γ,δ-unsaturated ketones, by employing an olefin ozonolysis/Paal–Knorr condensation procedure. 2,4-Di-, 2,3,5-tri-, and 2,3,4,5-tetra-substituted pyrroles **9–13** were synthesized in 47%–93% overall yields from their respective homoallylic ketones. Moreover, a cursory investigation of the addition of a combination of isopropenyl- and vinylmagnesium bromides onto methyl 4-methoxybenzoate demonstrated that two different vinyl Grignard reagents may be used in this cascade reaction to broaden the diversity of homoallylic ketone products.

Experimental

General

For reactions performed under anhydrous conditions, glassware was flame-dried, and the reaction was performed

Fig. 1. Yields of polysubstituted pyrroles **9–13** (see ref. 38 for **12a**).

under a positive pressure of argon using anhydrous solvents that were transferred by syringe. Anhydrous solvents (THF, CH_3CN, MeOH) were dried by passage through solvent filtration systems (GlassContour, Irvine, California). Final reaction mixture solutions were dried over $MgSO_4$. Chromatography was on a 230–400 mesh silica gel, and TLC was on aluminium-backed silica plates. Mass spectrometry data were obtained at the Université de Montréal Mass Spectrometry facility. The ratios of isomers of homoallylic ketones **3–8** were determined by analytical LC-MS (Prevail column from Alltech, Inc, 4.6 × 250 mm, 5 μm, C_{18}) with a flow rate of 0.5 mL/min using CH_3CN (0.1% TFA)/H_2O (0.1% TFA) from 20:80 to 80:20 in 45 min. The retention times (t_R) are reported in minutes. The product ratios of homoallylic ketones **14a/5a/2a** were deter-

mined by analytical LC-MS (Gemini from Phenomenex Inc., 4.6 × 50 mm, 5 μm, C_{18}) with a flow rate of 0.5 mL/min using CH_3CN (0.1% TFA)/H_2O (0.1% TFA) from 20:80 to 80:20 in 14 min. ^1H NMR spectra were measured in $CDCl_3$ or acetone-d_6 at 400 and 300 MHz and referenced to $CDCl_3$ (7.26 ppm) or acetone-d_6 (2.05). ^{13}C NMR were measured in $CDCl_3$ at 100 and 75 MHz and referenced to $CDCl_3$ (77.0 ppm) or acetone-d_6 (29.92). Methyl 4-methoxybenzoate **1a** was purchased from Sigma-Aldrich and *N*-Boc-β-alanine methyl ester **1b** was prepared from β-alanine by Boc-protection (di-*tert*butyl dicarbonate/Na_2CO_3 in dioxane/H_2O) followed by esterification using acetyl chloride in MeOH (7*a*). Except for α- and β-phenylvinyl Grignard reagents, which were freshly prepared in-house before use, Grignard reagents and copper (I) cyanide (99%) were all purchased from Sigma-Aldrich and used as received. The chemical shifts for the carbons and the protons of the minor isomers are respectively reported in parentheses and in brackets.

N-(Boc)-β-alanine methyl ester (1b)

A stirred suspension of β-alanine (26.7 g, 300 mmol) in dry MeOH (100 mL) was added dropwise to a premixed solution of acetyl chloride (27.7 mL, 400 mmol) in dry MeOH (100 mL, and the components were premixed at 5 °C and stirred in an ice bath for 30 min) at 8–10 °C. After 3 h the ice bath was removed and stirring was continued overnight. The solution was poured into Et_2O (600 mL) and cooled for 2 h. The precipitate was collected and the mother liquor was evaporated to a residue that yielded more product after addition of MeOH (50 mL) and Et_2O (70 mL). β-Alaninate methyl ester hydrochloride (33.5 g, 240 mmol) was dissolved in dioxane/H_2O (2:1, 260 mL) and treated with solid Na_2CO_3 (27.6 g, 260 mmol), cooled to 0 °C, treated with $(Boc)_2O$ (57.6 g, 260 mmol), stirred at room temperature (RT) overnight and evaporated to a residue, which was taken up in Et_2O. Water was added to the residue and the aqueous phase was extracted with Et_2O. The organic phases were combined and washed with water, dried ($MgSO_4$), filtered and evaporated to give a pale yellow gum (47.9 g, 98%). ^1H NMR (300 MHz, $CDCl_3$) δ: 1.41 (s, 9H), 2.50 (t, J = 6.1 Hz, 2H), 3.31–3.42 (m, 2H), 3.67 (s, 3H), 5.05 (br s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 173.0, 155.9, 79.4, 51.8, 36.1, 34.5, 28.4. HRMS *m*/*z* 226.1052 [M + Na, calcd. for $[C_9H_{17}NO_4Na]$: 226.1050].

Condition A for the synthesis of homoallylic ketone

A flask containing CuCN (30–40 mol%) was flame-dried and filled with dry THF (2.0 mL per 1.0 mmol of CuCN). The suspension was cooled to −45 °C under argon atmosphere and treated via syringe with the vinyl Grignard reagent (400 mol%). The slurry was stirred for 10 min and then treated dropwise with a solution of ester (100 mol%) in dry THF (2.0 mL per 1.0 mmol of ester). The resultant mixture was stirred for 1 h at −45 °C. The cold bath was removed and replaced with an ice bath and the reaction mixture was allowed to stir and warm slowly to RT overnight. The reaction mixture was quenched by treatment with NaH_2PO_4 solution (200% *v*/*v* based on total reaction volume; 1 mol/L aqueous) at 0 °C. After vigorous shaking, the layers were separated, and the aqueous phase was extracted with Et_2O (2 ×). The combined organic extracts were washed with saturated $NaHCO_3$ solution and brine, dried ($MgSO_4$), filtered, and evaporated to give the homoallylic ketone. The crude product was then purified as specified.

Condition B for the synthesis of homoallylic ketone

A solution of Grignard reagent (400 mol%) in THF was added to a flame-dried flask containing CuCN (60 mol%) at −45 °C under argon atmosphere. The slurry was stirred for 2 h and then treated dropwise with a solution of ester (100 mol%) in dry THF (2.0 mL per 1.0 mmol of ester). The resultant mixture was stirred for 1 h at −45 °C and treated as described in Condition A. The crude product was then purified as specified.

Condition C for the synthesis of homoallylic ketone

A solution of Grignard reagent (500 mol%) in THF was employed as described for Condition B.

1-(4-Methoxy-phenyl)-pent-4-en-1-one (2a)

According to procedure A, the treatment of methyl 4-methoxybenzoate (2.0 g, 12 mmol) with vinylmagnesium bromide (1.3 mol/L in THF, 37.0 mL, 3.41 mmol) in the presence of CuCN (321 mg, 3.61 mmol) gave a crude oil that was purified using column chromatography (10% ethyl acetate in hexane) to give homoallylic ketone **2a** (1.6 g, 70%) as a pale yellow oil. TLC R_f 0.36 (10:90 EtOAc/Hexane). ^1H NMR (300 MHz, $CDCl_3$) δ: 2.49 (q, J = 6.74 Hz, 2H), 3.04 (t, J = 7.44 Hz, 2H), 3.88 (s, 3H), 4.97–5.14 (m, 2H), 5.84–6.00 (m, 1H), 6.90–7.00 (m, 2H), 7.91–8.00 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 198.2, 163.5, 137.6, 130.4, 130.1, 115.3, 113.8, 55.6, 37.5, 28.5. HRMS *m*/*z* 191.1073 [M + H^+, calcd. for $[C_{12}H_{15}O_2]^+$: 191.1066].

1-(4-Methoxy-phenyl)-3-methyl-hex-4-en-1-one (3a)

According to procedure B, the treatment of methyl 4-methoxybenzoate (332 mg, 2.00 mmol) with 1-propenylmagnesium bromide (0.5 mol/L in THF, 16 mL, 8.0 mmol) in the presence of CuCN (107 mg, 1.20 mmol) gave a crude oil that was purified using column chromatography (10% ethyl ether in hexane) to give homoallylic ketone **3a** (411 mg, 94%) as a pale yellow oil. TLC R_f 0.27 (10:90 Et_2O/Hexane). LC-MS and ^1H NMR analysis showed a 6.5:3.5 mixture of 2 isomers. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.00–1.03 (2d partially overlapped, J = 6.39, 6.67 Hz, 3H), 1.56–1.67 (dd partially overlapped with m, J = 1.61, 6.70, 3H), 2.75–3.00 (m, 2.2 H), 3.11–3.28 (m, 0.8H), 5.19–5.30 (m, 0.8H), 5.32–5.47 (m, 1.2H), 6.91–7.00 (m, 2H), 7.91–8.00 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: (198.4) 198.4, 163.4, (136.1) 135.6, 130.6, 130.5, (123.6) 123.3, 113.8, 55.6, 45.7 (45.6), (33.2) 28.5, 21.2 (20.6), (18.1) 13.1. HRMS *m*/*z* 219.1378 [M + H^+, calcd. for $[C_{14}H_{19}O_2]^+$: 219.1380].

1-(4-Methoxy-phenyl)-3,3,5-trimethyl-hex-4-en-1-one (4a)

According to procedure B, the treatment of methyl 4-methoxybenzoate (332 mg, 2.00 mmol) with 2-methyl-1-propenylmagnesium bromide (0.5 mol/L in THF, 16 mL, 8.0 mmol) in the presence of CuCN (107 mg, 1.20 mmol) gave a crude oil that was purified using column chromatog-

raphy (10% ethyl ether in hexane) to give homoallylic ketone **4a** (369 mg, 75%) as a yellow oil. TLC R_f 0.33 (10:90 Et_2O/Hexane). ^1H NMR (300 MHz, $CDCl_3$) δ: 1.25 (s, 6H), 1.63 (d, J = 1.24 Hz, 3H), 1.69 (d, J = 1.15 Hz, 3H), 3.00 (s, 2H), 3.85 (s, 3H), 5.21–5.28 (m, 1H), 6.87–6.96 (m, 2H), 7.87–8.00 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 198.5, 163.2, 133.4, 131.6, 130.8, 130.6, 113.5, 55.5, 49.8, 35.4, 29.6 (2C), 28.2, 19.1. HRMS *m/z* 247.1692 [M + H^+, calcd. for $[C_{16}H_{23}O_2]^+$: 247.1693].

1-(4-Methoxy-phenyl)-2,4-dimethyl-pent-4-en-1-one (5a)

According to procedure B, the treatment of methyl 4-methoxybenzoate (332 mg, 2.00 mmol) with isopropenylmagnesium bromide (0.5 mol/L in THF, 16 mL, 8.0 mmol) in the presence of CuCN (107 mg, 1.20 mmol) gave a crude oil that was purified using column chromatography (10% ethyl ether in hexane) to give homoallylic ketone **5a** (354 mg, 81%) as a colorless oil. TLC R_f 0.32 (10:90 Et_2O/Hexane). ^1H NMR (300 MHz, $CDCl_3$) δ: 1.18 (d, J = 6.87 Hz, 3H), 1.75 (s, 3H), 2.11 (dd, J = 7.69, 14.46 Hz, 1H), 2.54 (dd, J = 6.33, 14.43 Hz, 1H), 3.57–3.71 (m, 1H), 3.88 (s, 3H), 4.69 (s, 1H), 4.76 (s, 1H), 6.89–7.03 (m, 2H), 7.89–8.05 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 202.5, 163.5, 143.4, 130.7, 129.5, 113.9, 112.1, 55.6, 41.6, 38.3, 22.8, 17.5. HRMS *m/z* 219.1383 [M + H^+, calcd. for $[C_{14}H_{19}O_2]^+$: 219.1380].

1-(4-Methoxy-phenyl)-2,3,4-trimethyl-hex-4-en-1-one (6a)

According to procedure B, the treatment of methyl 4-methoxybenzoate (332 mg, 2.00 mmol) with 1-methyl-1-propenylmagnesium bromide (0.5 mol/L in THF, 16 mL, 8.0 mmol) in the presence of CuCN (107 mg, 1.20 mmol) gave a crude oil that was purified using column chromatography (5% ethyl ether in hexane) to give homoallylic ketone **6a** [116 mg, 24% (33% based on recovered starting material)] as a pale orange oil. TLC R_f 0.32 (10:90 Et_2O/Hexane). ^1H NMR (300 MHz, $CDCl_3$) measurement of aromatic signals showed a 8.4:0.9:0.7 mixture of 3 isomers, δ: 0.89–0.92 (m, 2.5H), 0.99–1.08 (m, 3H) [1.18–1.23 (m, 0.5H)], 1.55–1.70 (m, 6H), 3.02–3.55 (m, 1.8H) [2.45–2.72 (m, 0.1H), 4.25–4.44 (m, 0.1H)], 3.89 (s, 2.5H) [3.87 (s, 0.5H)], 5.30–5.43 (m, 0.8H) [5.00–5.30 (m, 0.1H) 5.50–5.65 (m, 0.1H)], 6.90–7.00 (m, 2H), [7.82–7.89 (m, 0.15H), 7.92–7.99 (m, 0.15H)] 8.00–8.08 (m, 1.7H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 203.9, 163.6, 137.3, 130.9 (130.8), (132.2) 130.6 (130.4), 121.4 (120.7), 113.9 (113.8) (113.6), 55.6, 43.2 (43.4), 36.9 (35.6), 18.5 (18.6), 17.7 (17.5), 17.1 (16.1), 13.3. HRMS *m/z* 247.1698 [M + H^+, calcd. for $[C_{16}H_{23}O_2]^+$: 247.1693].

1-(4-Methoxy-phenyl)-3,5-diphenyl-pent-4-en-1-one (7a)

According to procedure A, the treatment of methyl 4-methoxybenzoate (166 mg, 1.00 mmol) with β-phenylvinylmagnesium bromide (0.5 mol/L in THF, 8 mL, 4 mmol) in the presence of CuCN (36 mg, 0.40 mmol) gave a crude mixture that was triturated in Et_2O/Hexane (1:1) to give homoallylic ketone **7a** (209 mg, 61%) as a white crystaline solid, mp 107–110 °C. TLC R_f 0.21 (20:80 Et_2O/Hexanes). ^1H NMR (400 MHz, $CDCl_3$) δ: 3.40–3.53 (dd, J = 6.70, 16.35 Hz, 1H) partially overlapped with (dd, J = 7.39, 16.35 Hz, 1H), 3.88 (s, 3H), 4.30–4.40 (m, 1H), 6.39 (d, J = 15.90 Hz, 1H), 6.45 (dd, J = 5.63, 15.99 Hz, 1H), 6.93–7.01 (m, 2H), 7.16–7.38 (m, 10H), 7.93–8.02 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 196.8, 163.6, 143.6, 137.4, 132.9, 130.5, 130.4, 130.1, 128.8, 128.6, 127.9, 127.3, 126.7, 126.4, 113.9, 55.6, 44.3, 44,2. HRMS *m/z* 365.1510 [M + Na, calcd. for $[C_{24}H_{22}O_2Na]$: 365.1512].

1-(4-Methoxy-phenyl)-2,4-diphenyl-pent-4-en-1-one (8a)

According to procedure B, the treatment of methyl 4-methoxybenzoate (332 mg, 2.00 mmol) with α-phenylvinylmagnesium bromide (0.5 mol/L in THF, 16 mL, 8.0 mmol) in the presence of CuCN (107 mg, 1.20 mmol) gave a crude oil that was purified using column chromatography (10% ethyl acetate in hexane) to give homoallylic ketone **8a** (343 mg, 50%) as an orange oil. TLC R_f 0.47 (20:80 EtOAc/Hexane). ^1H NMR (400 MHz, $CDCl_3$) δ: 2.97 (ddd, J = 0.82, 6.97, 14.65 Hz, 1H), 3.52 (ddd, J = 0.87, 7.32, 14.62 Hz, 1H), 3.81 (s, 3H), 4.67 (t, J = 7.16 Hz, 1H), 4.93 (d, J = 1.21 Hz, 1H), 5.19 (d, J = 1.25 Hz, 1H), 6.80–6.86 (m, 2H), 7.17–7.41 (m, 10H), 7.82–7.88 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 197.5, 162.9, 145.4, 140.5, 139.2, 130.6, 129.3, 128.4, 128.0, 127.8, 127.1, 126.6, 126.0, 114.4, 113.2, 55.0, 51.0, 39.2. Condition D for the synthesis of homoallylic ketone with two different Grignard reagents

A solution of vinylmagnesium bromide (0.8 mol/L in THF, 1.25 mL, 1.00 mmol) and isopropenylmagnesium bromide (0.5 mol/L in THF, 2.40 mL, 1.20 mmol) was added to a flame-dried flask containing CuCN (27 mg, 0.30 mmol) at –45 °C under argon atmosphere. The slurry was stirred for 10 min and then treated dropwise with a solution of ester (166 mg, 1.00 mmol) in dry THF (2 mL). The resultant mixture was stirred for 1 h at –45 °C and treated as described in Condition A. The crude product was then purified using column chromatography (10% ethyl acetate in hexane) to give 98 mg of a mixture of **14a/5a/2a** in a ratio of 4.6:2.8:2.6 as determined by LC-MS analysis.

Condition E for the synthesis of homoallylic ketone with two different Grignard reagents

A solution of isopropenylmagnesium bromide (0.5 mol/L in THF, 6.00 mL, 3.00 mmol) was added to a flame-dried flask containing a suspension of CuCN (54 mg, 0.60 mmol) at –45 °C under argon atmosphere. The slurry was stirred for 2 h and then treated dropwise with a solution of vinylmagnesium bromide (1 mol/L in THF, 1.00 mL, 1.00 mmol) and ester (166 mg, 1.00 mmol) in dry THF (2 mL). The resultant mixture was stirred for 1 h at –45 °C and treated as described in Condition A. The crude product was then purified using column chromatography (10% ethyl acetate in hexane) to give 170 mg of a mixture of **14a/5a/2a** in a ratio of 4.1:4.4:1.6 as determined by LC-MS analysis.

Condition F for the synthesis of homoallylic ketone with two different Grignard reagents

The reaction was performed as described for condition E with isopropenylmagnesium bromide (0.5 mol/L in THF, 2.00 mL, 1.00 mmol), CuCN (90 mg, 1.0 mmol), vinylmagnesium bromide (1 mol/L in THF, 1.00 mL, 1.00 mmol), and ester (166 mg, 1.00 mmol) in dry THF (2 mL) to give

98 mg of a mixture of **14a/5a/2a** in a ratio of 4.1:3.7:2.2 as determined by LC-MS analysis.

Condition G for the synthesis of homoallylic ketone with two different Grignard reagents

A solution of isopropenylmagnesium bromide (0.5 mol/L in THF, 2.20 mL, 1.10 mmol) was added to a flame-dried flask containing CuCN (54 mg, 0.60 mmol) at −45 °C under argon atmosphere. The slurry was stirred for 1 h and then treated dropwise with a solution of ester (166 mg, 1.00 mmol) in dry THF (2 mL) and vinylmagnesium bromide (1 mol/L in THF, 1.00 mL, 1.00 mmol). The resultant mixture was stirred for 10 min at −45 °C and treated as described in Condition A. The crude product was then purified using column chromatography (10% ethyl acetate in hexane) to give 123 mg of a mixture of **14a/5a/2a** in a ratio of 5.6:0.6:3.8 as determined by LC-MS analysis.

1-(4-Methoxy-phenyl)-3-methyl-hex-4-en-1-one (14a)

A sample of **14a** was obtained by HPLC purification performed on a reverse-phase Prevail column from Alltech Inc. (22 × 250 mm, 5 μm, C_{18}) with a flow rate of 10 mL/min using CH_3CN (0.1% TFA)/H_2O (0.1% TFA) from 40:60 to 80:20 in 50 min. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.80 (s, 3H), 2.45 (t, J = 7.68 Hz, 2H), 3.08 (t, J = 7.70 Hz, 2H), 3.88 (s, 3H), 4.73 (s, 1H), 4.77 (s, 1H), 6.90–7.00 (m, 2H), 7.90–8.00 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 198.5, 163.5, 145.0, 130.7, 130.5, 113.9, 110.2, 55.6, 36.6, 32.2, 22.9. HRMS m/z 205.1223 [M + H^+, calcd. for $[C_{13}H_{17}O_2]^+$: 205.1221].

General procedure H: pyrrole synthesis

A solution of homoallylic ketone (100 mol%) in CH_2Cl_2/MeOH (1:5, 13.5 mL per 1.00 mmol of homoallylic ketone) was treated with ozone bubbles at –78 °C until a blue color persisted, purged with a stream of argon bubbles, treated with dimethyl sulphide (500 mol%), and stirred overnight, after which time the bath temperature had warmed to RT. Removal of the volatiles by rotary evaporation gave crude 1,4-dicarbonyl product, which was taken up into a solution of AcOH/H_2O/MeCN (1:1:1, 10 mL per 1.0 mmol of homoallylic ketone) and treated with ammonium formate (500 mol%) and KOAc (6 000 mol%). The mixture was heated at 80 °C until complete consumption of starting material was observed by TLC. After cooling to RT, the reaction mixture was partitioned between an organic phase of Et_2O/CH_2Cl_2 (2:1) and Na_2CO_3 solution (5% aq.). The layers were separated, and the aqueous phase was extracted twice with Et_2O/CH_2Cl_2 (2:1). The combined organic phases were washed with pH 6.8 phosphate buffer and dried ($MgSO_4$). Volatiles were removed by successive rotary evaporation and lyophilization to give the crude pyrrole product, which was purified as specified.

General procedure I — pyrrole synthesis

As described in general procedure H, crude 1,4-dicarbonyl product was produced by ozonolysis of the homoallylic ketone (100 mol%). It was then taken up into a solution of acetonitrile (12.5 mL per 1.00 mmol of homoallylic ketone) containing ammonium formate (500 mol%) and NaOAc/AcOH (100 mol% *w*/*w*, prepared by mixing equimolar quantities of NaOAc and HOAc). The mixture was heated at 65 °C until complete consumption of the starting material was observed by TLC. After cooling to RT, the reaction mixture was partitioned between Et_2O/CH_2Cl_2 (2:1) and pH 6.8 sodium phosphate buffer. The layers were separated, and the organic phase was washed with pH 6.8 sodium phosphate buffer. The aqueous phase was extracted twice with Et_2O/CH_2Cl_2 (2:1), and the combined organic phases were dried ($MgSO_4$). Volatiles were removed by successive rotary evaporation and lyophilization to give crude pyrrole product, which was purified as specified.

2-(4-Methoxy-phenyl)-4-methyl-1*H*-pyrrole (9a)

Prepared from homoallylic ketone **3a** (30 mg, 0.14 mmol) according to procedure H to yield crude product (19.4 mg), which was purified using column chromatography (20% ethyl acetate in hexane) to give pyrrole **9a** (17 mg, 65%) as a mauve gum. TLC R_f 0.40 (20:80 EtOAc/Hexane). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.16 (s, 3H), 3.83 (s, 3H), 6.26 (s, 1H), 6.59 (s, 1H), 6.85–6.95 (m, 2H), 7.33–7.42 (m, 2H), 8.08 (br s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.2, 132.2, 126.2, 125.2, 120.6, 116.1, 114.4, 106.6, 55.4, 12.1. ***tert*-Butyl-[2-(4-methyl-1*H*-pyrrol-2-yl)]ethylcarbamate (9b)**

Prepared from homoallylic ketone **3b** (32.5 mg, 0.120 mmol) according to procedure H to yield crude product (24.3 mg) that was purified using column chromatography (20% ethyl acetate in hexane) to give pyrrole **9b** (16 mg, 59%) as a brown gum. TLC R_f 0.20 (20:80 EtOAc/Hexane). ^{1}H NMR (300 MHz, acetone-d_6) δ: 1.38 (s, 9H), 1.98 (s, 3H), 2.68 (t, J = 7.43 Hz, 2H), 3.15–3.31 (m, 2H), 5.66 (s, 1H), 5.87 (br s, 1H), 6.36 (s, 1H), 9.42 (br s, 1H). ^{13}C NMR (75 MHz, acetone-d_6) δ: 156.8, 130.0, 118.3, 115.0, 107.8, 78.4, 41.5, 28.6, 12.1. HRMS *m/z* 247.1417 [M + Na^+, calcd. for $[C_{12}H_{20}N_2O_2Na]$: 247.1414].

***tert*-Butyl-[2-(3,5-dimethyl-1*H*-pyrrol-2-yl)]ethylcarbamate (10b)**

Prepared from homoallylic ketone **5b** (70 mg, 0.27 mmol) according to procedure I to yield crude product (63.8 mg) that was purified using column chromatography (20% ethyl acetate in hexane) to give pyrrole **10b** (36.3 mg, 56%) as a brown gum. TLC R_f 0.22 (20:80 EtOAc/Hexane). ^{1}H NMR (300 MHz, acetone-d_6) δ: 1.39 (s, 9H), 1.90 (s, 3H), 2.10 (s, 3H), 2.62 (t, J = 7.43 Hz, 2H), 3.11–3.21 (m, 2H), 5.46 (s, 1H), 5.96 (br s, 1H), 9.17 (br s, 1H). ^{13}C NMR (75 MHz, acetone-d_6) δ: 156.6, 125.5, 124.1, 114.6, 108.2, 78.4, 41.6, 28.6, 27.2, 12.9, 11.1. HRMS *m/z* 239.1766 [M + H^+, calcd. for $[C_{13}H_{23}N_2O_2]^+$: 239.1754].

***tert*-Butyl-[2-(3,4,5-trimethyl-1*H*-pyrrol-2-yl)]ethylcarbamate (11b)**

Prepared from homoallylic ketone **6b** (42.7 mg, 0.150 mmol) according to procedure I to yield crude product (29.1 mg) that was purified using column chromatography (20% ethyl acetate in hexane) to give pyrrole **11b** (22 mg, 58%) as a brown gum. TLC R_f 0.24 (20:80 EtOAc/Hexane). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.45 (s, 9H), 1.92 (s, 3H), 1.93 (s, 3H), 2.14 (s, 3H), 2.71 (t, J = 6.61 Hz, 2H), 3.23–3.36 (m, 2H), 4.66 (br s, 1H), 7.66 (br s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 156.3, 122.1, 121.8, 114.9, 113.9, 79.5, 40.6, 28.5, 26.9, 11.1, 9.3, 9.2. HRMS *m/z* 253.1910 [M + H^+, calcd. for $[C_{14}H_{25}N_2O_2]^+$: 253.1909].

***tert*-Butyl-[2-(4-phenyl-1*H*-pyrrol-2-yl)]ethylcarbamate (12b)**

Prepared from homoallylic ketone **7b** (140 mg, 0.370 mmol) according to procedure I to yield crude product that was purified using column chromatography (20%–30% ethyl acetate in hexane) to give pyrrole **12b** (63.4 mg, 60%) as a pink foam. TLC R_f 0.08 (20:80 EtOAc/Hexane). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.35 (s, 9H), 2.70–2.83 (m, 2H), 3.31–3.46 (m, 2H), 4.84 (br s, 1H), 5. 88 (s. 0.5H), 6.11 (d, J = 2.52 Hz, 1H), 7.05–7.27 (m, 8H), 8.48 (br s, 1H). HRMS *m/z* 287.1754 [M + H^+, calcd. for $[C_{17}H_{23}N_2O_2]^+$: 287.1759].

***tert*-Butyl-[2-(3,5-diphenyl-1*H*-pyrrol-2-yl)]ethylcarbamate (13b)**

Prepared from homoallylic ketone **8b** (91.8 mg, 0.242 mmol) according to procedure I to yield crude product (86.2 mg) that was purified using column chromatography (15% ethyl acetate in hexane) to give pyrrole **13b** (81.1 mg, 93%) as a beige powder. TLC R_f 0.26 (20:80 EtOAc/Hexane). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.44 (s, 9H), 3.07 (t, J = 6.22 Hz, 2H), 3.43–3.60 (m, 2H), 4.84 (br s, 1H), 6.65 (d, J = 2.65 Hz, 1H), 7.15–7.65 (m, 10H), 9.51 (br s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 156.9, 136.9, 132.7, 131.0, 128.9, 128.8, 128.6, 127.9, 126.6, 125.9, 125.6, 123.6, 106.3, 80.1, 39.6, 28.5, 28.3. HRMS *m/z* 385.1886 [M + Na^+, calcd. for $[C_{23}H_{26}N_2O_2Na]$: 385.1880].

Acknowledgement

This research was supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada as well as the Fond Québecois de Recherche sur la Nature et les Technologies (FQRNT) of Québec. We thank the Université de Montréal Mass Spectroscopy facility for mass spectral analyses.

Cytotoxic rotenoloids from the stems of *Derris trifoliata*

Sarot Cheenpracha, Chatchanok Karalai, Chanita Ponglimanont, and Kan Chantrapromma

Abstract: A new rotenoloid, designated 7a-*O*-methylelliptonol, was isolated from hexane and CH_2Cl_2 extracts from the stems of *Derris trifoliata* together with ten known compounds. Their structures were determined by spectroscopic methods, mainly 1D and 2D NMR. The cytotoxicity of all compounds was also evaluated against human cancer cell lines.

Key words: Derris trifoliata, Leguminosae, 7a-*O*-methylelliptonol, cytotoxicity, rotenoloids.

Résumé : À partir des produits extraits des tiges de *Derris trifoliata* à l'aide d'hexane et de dichlorométhane, on a isolé un nouvel roténoloïde dénommé 7a-méthylelliptonol aux côtés de dix autres composés connus. Leurs structures ont été déterminées par des méthodes spectroscopiques, particulièrement de RMN mono- et bidimensionnelles. On a aussi évalué la cytotoxicité de chacun des produits vis-à-vis de familles de cellules cancéreuses humaines.

Mots-clés : Derris trifoliata, légumineuse, 7a-méthylelliptonol, cytotoxicité, roténoloïdes.

[Traduit par la Rédaction]

Introduction

Derris trifoliata Lour. is a mangrove plant in the Leguminosae family (1, 2), distributed throughout the tropical regions of Asia and East Africa, and is widely used in cattle and sheep dips for the control of ticks and other ectoparasites. It is currently used in horticulture against aphids, caterpillars, sawflies, wasps, raspberry beetles, and red spiders (3). Previous chemical investigations of the leaves and stems have resulted in flavonoid glycosides (4) and rotenoids (5), whereas unusual rotenoloids (6, 7) were isolated from the roots and seeds of *D. trifoliata*. The inhibitory effect of several rotenoids, such as deguelin and α-toxicarol, on mouse skin tumor promotion in an in vivo test and on an invasion of human fibrosarcoma HT1080 cells through Matrigel-coat filters has been reported (5, 8). In this present study, we report the structural elucidation of a new rotenoloid, 7a-*O*-methylelliptonol (**1**), together with ten known compounds (**2**–**11**) from the stems of *D. trifoliata* as well as their cytotoxicity against KB, BC, and NCI-H187 cell lines.

Results and discussion

The hexane and CH_2Cl_2 extracts of the stems of *D. trifoliata* were subjected to column chromatography to give a new compound **1** together with ten known compounds (**2**–**11**) shown in Fig. 1. Their structures were elucidated using 1D and 2D NMR spectroscopic data and compared with those reported in the literature.

Compound **1** was obtained as a pale yellow viscous oil with a molecular formula $C_{21}H_{20}O_6$ determined by ESI-TOFMS ($[M + H]^+$ *m/z* 369.1345, calcd. 369.1338). The IR spectrum (1673 cm^{-1}) suggested the presence of a conjugated carbonyl system. UV absorptions at λ_{max} 205, 236, 257, 281, and 293 nm were characteristic of a benzofuran chromophore (9, 10). The ^{13}C NMR spectral data (Table 1) showed a total of 21 carbons with one carbonyl carbon at δ 204.4. The assignments of all carbons were achieved by ^{13}C NMR, DEPT, HMQC, and HMBC experiments. The carbon chemical shift values suggested an oxymethylene carbon (δ 63.5) and two aromatic rings with 12 aromatic carbons identified as four methines (δ 100.9, 112.8, 106.7, 126.5), eight quarternary carbons of which 5 were oxygenated (δ 143.0, 149.1, 149.2, 152.7, 158.8), and 3 non-oxygenated (δ 110.5, 117.9, 125.6). Moreover, the ^1H NMR spectral data of **1** (Table 1) displayed signals corresponding to three singlet signals of methoxyl groups at δ 3.60, 3.81, and 4.18, methylene protons at δ 2.15–2.23 (2H, m, H-6a), oxymethylene protons at δ 4.18–4.21 (2H, m, H-6), a methine proton at δ 4.69 (1H, dd, *J* = 5.7, 4.5 Hz, H-12a), two singlet signals of aromatic protons at δ 6.39 (1H, s, H-1) and 6.42 (1H, s, H-4) and two ortho-coupled doublets centered at δ 7.23 (1H, dd, *J* = 8.7, 0.6 Hz, H-10) and 7.46 (1H, d, *J* = 8.7 Hz, H-11). These ^1H and ^{13}C NMR data were similar to those of 7a-*O*-methyldeguelol (**2**) (6), except for the presence of a 1,2-disubstituted furan moiety at δ 7.01 (1H, dd, *J* = 2.4, 0.6 Hz,

H-3′) and 7.63 (1H, d, J = 2.4 Hz, H-2′) instead of a 2,2-dimethylchromene moiety [δ 5.71 (1H, J = 9.9 Hz, H-3′), 6.62 (1H, J = 9.9 Hz, H-4′), 1.45 and 1.46 (each 3H, s, 2′-Me_2)] of **2**. In the HMBC spectrum, correlations of H-2′ with carbons at δ 158.8 (C-9) and 117.9 (C-8) and of H-3′ with δ 158.8 (C-9), 152.7 (C-7a) and 117.9 (C-8) indicated the location of the furan ring at C-8 and C-9. A methine proton H-11 showed correlations with carbons at δ 204.4 (C-12), 158.8 (C-9), and 152.7 (C-7a); a methine H-12a with δ 204.4 (C-12), 149.2 (C-4a), 149.1 (C-2), 112.8 (C-1), 110.5 (C-1a), and 25.3 (C-6a); two methylenes 2H-6a with δ 204.4 (C-12), 110.5 (C-1a), 63.5 (C-6), and 45.8 (C-12a); and methoxyl protons at δ 4.18 with δ 152.7 (C-7a). Thus, the attachment of a carbonyl group at C-12 and a methoxyl group at C-7a could be assigned. The absolute configuration at C-12a of 7a-*O*-methyldeguelol (**2**) ($[\alpha]^{28}_D$ –18.2°) has been suggested by Yenesew et al. (6, 7). Compound **1** is levorotatory ($[\alpha]^{28}_D$ –17.4°), thus most likely has the same configuration at C-12a as **2**. However, the absolute configuration at C-12a in **1** remains to be determined. Therefore, the structure of the new compound **1** was elucidated as 7a-*O*-methylelliptonol.

The remaining compounds were characterized as 7a-*O*-methyldeguelol (**2**) (6), deguelin (**3**) (11), α-toxicarol (**4**) (11), tephrosin (**5**) (11), 6a,12a-dehydro-α-toxicarol (**6**) (11), 6a,12a-dehydrodeguelin (**7**) (11), rotenone (**8**) (12), 12a-hydroxyrotenone (**9**) (13), 6a,12a-dehydrorotenone (**10**) (12), and 12a-hydroxyelliptone (**11**) (10) by the analysis of 1D and 2D NMR, mass information, and comparison with their reported physical and spectroscopic data. In addition, compounds **6**, **9**, and **10** were reported for the first time as metabolites of *D. trifoliata*.

As summarized in Table 2, compounds **1**, **3**, **4**, **8**, and **9** exhibited significant cytotoxic effects against KB, BC, and NCI-H187 cell lines with ED_{50} values in the general range of 0.05 nM to 4.1 μM, whereas compounds **2**, **7**, and **10** were found to be selectively active against NCI-H187 cell lines. It should be noted that the rotenoids (**3**, **4**, **8**, **9**, and **11**) with sp^3 hybridization at C-6a and C-12a exhibited strong activity against KB and BC cell lines, whereas the rotenoids (**6**, **7**, and **10**) with olefinic carbons at C-6a and C-12a showed no activity at all. The most interesting finding is the extraordinarily potent anticancer activity against NCI-H187 cell lines (IC_{50} = 0.05 nM) of compound **8**, which showed a much higher effect than ellipticine (IC_{50} = 2.44 μM). The result of the present study indicates that rotenone (**8**) could be a potent candidate as a phytotherapeutic lung cancer inhibitor.

Table 2. Cytotoxic activities of compounds **1**–**11**.

	Cell lines (μM)		
Compounds	KB	BC	NCI-H187
1	4.1	3.8	3.0
2	30.5	13.9	4.1
3	1.8	1.5	0.1

Note: Key to cell lines used: KB = oral human epidermoid carcinoma; BC = human breast cancer cells; NCI-H187 = human small cells lung cancer. Compound 5 was not determined because of decomposition.
[a]Results are expressed as ED_{50} values in nM.

Experimental section

General experimental procedures

Melting points were determined on an Electrothermal melting point apparatus. The optical rotation $[\alpha]_D$ values were determined with a JASCO P-1020 polarimeter. UV spectra were measured with a Specord S 100 (Analytikjena). The IR spectra were measured with a PerkinElmer FTS FT-IR spectrophotometer. The ^1H and ^{13}C NMR spectra were recorded using a 500 MHz Varian Unity Inova and a 300 MHz Bruker FT-NMR Ultra Shield™ spectrometers. Chemical shifts are recorded in part per million (δ) in $CDCl_3$, acetone-d_6 or CD_3OD with tetramethylsilane (TMS) as an internal reference. The ESI-TOFMS were obtained from a Micromass LCT mass spectrometer. Quick column chromatography (QCC) and column chromatography (CC) were carried out on silica gel 60 F_{254} (Merck) and silica gel 100 (Merck), respectively. Precoated plates of silica gel 60 F_{254} and reversed-phase (RP-18 F_{254S}) were used for analytical purposes.

Plant material

The stems of *D. trifoliata* were collected in April 2002 at the Mangrove Research Station in Nakhon Si Thammarat Province, Thailand. The plant material was identified by Prof. Puangpen Sirirugsa and a voucher specimen (No. SC02) has been deposited in the Herbarium of the Department of Biology, Faculty of Science, Prince of Songkla University, Songkhla, Thailand.

Extraction and Isolation

Ground-dried stems of *D. trifoliata* (16.2 kg) were successively immersed at room temperature in hexane, CH_2Cl_2, and MeOH (each 2 × 10 L, 5 days). After evaporation, the viscous crude hexane (73.4 g), CH_2Cl_2 (118.1 g), and MeOH (350.5 g) extracts were obtained. A portion of crude hexane extract (21.7 g) was subjected to QCC and eluted with gradient elution of hexane, EtOAc, and MeOH which afforded ten fractions (A1–A10). Fraction A7 (0.94 g) was purified by CC and prep. TLC with EtOAc/hexane (1:3 *v*/*v*) to give **2** (16.6 mg), **3** (12.7 mg), **4** (5.0 mg), and **8** (8.2 mg). Fraction A8 (0.47 g) was further separated by CC (EtOAc/hexane, 1:3 *v*/*v*) followed by reversed-phase prep. TLC (MeOH/H_2O, 1:3 *v*/*v*) to afford **1** (55.5 mg), **5** (2.5 mg), **9** (9.7 mg), and **11** (16.7 mg). The crude CH_2Cl_2 extract (118.1 g) was fractionated by QCC over silica gel using gradient elution of hexane/EtOAc and EtOAc/MeOH. The eluate was combined on the basis of TLC analysis to give five fractions (B1–B5). Fraction B2 (6.82 g) was separated by CC with EtOAc/hexane (1:4 *v*/*v*), followed by prep. TLC with EtOAc/hexane (1:4 *v*/*v*) to afford **6** (17.2 mg). Fraction B4 (31.35 g) was purified by QCC with hexane and increasing polarity with EtOAc and MeOH to give five subfractions (B4a–B4e). Sub-

fraction B4c (4.96 g) was further separated by CC with CH_2Cl_2, followed by reversed-phase prep. TLC ($MeOH/H_2O$, 7:3 *v*/*v*) to yield **7** (2.2 mg) and **10** (101.1 mg).

7a-*O*-Methylelliptonol ((2,3-dimethoxy-chroman-12a-yl)-(7a-methoxy-benzofuran-11a-yl)-methanone)

Yellow viscous oil. $[\alpha]^{28}_D$ –17.4° (c 0.16, MeOH). UV (MeOH) nm (log ε): 205 (4.47), 236 (4.50), 257 (3.90), 281 (3.76), and 293 (3.78). IR (neat, cm^{-1}) δ: 2956, 1673, 1515. ^1H and ^{13}C NMR: Table 1. ESI-TOFMS $[M + H]^+$ *m*/*z* 369.1345; calcd. for $C_{21}H_{21}O_6$: 369.1338.

Cytotoxicity Assay

The cytotoxic assay employed the colorimetric method (14). Ellipticine, the reference substance, exhibited activity toward KB, BC, and NCI-H187 cell lines with ED_{50} ranges of 1.22–2.44 μM.

Acknowledgments

We thank the Center for Innovation in Chemistry: Postgraduate Education and Research Program in Chemistry, funded by the Royal Thai Government; Graduate School and Natural Products from Mangrove Plants and Synthetic Materials Research Unit (NSU), Prince of Songkla University; and the Biodiversity Research and Training Program (BRT) for financial support. The bioassays research facility of BIOTEC is also gratefully acknowledged for bioactivity tests.

A pentacene intermediate via formal intramolecular photoredox of a 6,13-pentacenequinone in aqueous solution

Yunyan Hou and Peter Wan

Abstract: The formal intramolecular photoredox reaction (or tandem phototautomerizations) of aromatic ketones in aqueous solution discovered in our laboratory has been extended to a number of acenequinones. In particular, we were interested in whether the photoredox reaction could be applied to 2-(hydroxymethyl)-6,13-pentacenequinone (**4**), which would result in 2-formyl-6,13-dihydroxypentacene (**10**) and hence offer a photochemical method for synthesizing a pentacene derivative. Whereas a number of acenequinones displayed a range of photoredox reactivity, photolysis of **4** in acidic aqueous solution (pH < 3) resulted in a clean intramolecular photoredox reaction, via an enol intermediate, to give **10** (green compound; $\Phi \sim 0.2$ at pH 1), which was too reactive for isolation or trapping by standard ArOH trapping agents such as acetic anhydride. These reactions may be viewed as a one-way photochemical intramolecular "redox switch" from quinone to hydroquinone with concurrent oxidation of an attached hydroxymethyl (alcohol) moiety. Without the attached alcohol moiety, these acenequinones are photostable in aqueous solution. The trend in observed relative reactivity may be partially rationalized by examining changes in molecular orbital coefficients observed in the calculated HOMOs and LUMOs (at the AM1 level).

Key words: pentacene, acenequinones, photoredox, enol, acid catalysis.

Résumé : La réaction photoredox intramoléculaire formelle (ou phototautomérisations en tandem) de cétones aromatiques en solution qui a été découverte dans notre laboratoire a été étendue à un certain nombre d'acènequinones. En particulier, nous étions intéressés à déterminer si la réaction photoredox pouvait être appliquée à la 2-(hydroxyméthyl)6,13-pentacènequinone (**4**) qui conduirait à la formation du 2-formyl-6,13-dihydroxypentacène (**10**) et qui offrirait une méthode de synthèse de dérivés pentacènes. Alors qu'un bon nombre d'acènequinones présentent des activités photoredox diverses, la photolyse du composé **4** dans une solution aqueuse acide (pH inférieur à 3) donne lieu à une réaction photoredox intramoléculaire propre, par le biais d'un intermédiaire énolique, et elle conduit à la formation du produit **10** (un composé vert; Φ approximatif de 0,2, à un pH de 1) qui est trop réactif pour être isolé ou piégé par les agents habituels de piégeage des ArOH, tel l'anhydride acétique. On peut donc considérer que ces réactions sont des "interrupteurs redox" à sens unique pour les réactions photochimiques intramoléculaires et qu'elles permettent le passage d'une quinone à une hydroquinone avec l'oxydation concurrente de la portion alcoolique, hydroxyméthyle, qui y est attachée. En l'absence de la portion alcoolique qui y est attachée, ces acènequinones sont photostables en solution aqueuse. La tendance qui a été observée pour la réactivité relative peut être partiellement rationalisée par un examen des changements dans les coefficients des orbitales moléculaires qui ont été observées dans les hautes élevées et basses vacantes, au niveau AM1.

Mots-clés : pentacène, acènequinones, photoredox, énol, catalyse acide.

[Traduit par la Rédaction]

Introduction

Pentacene is a promising candidate for application as a novel organic semiconductor (1). However, it is sensitive to both oxygen and light and has low solubility. To overcome these disadvantages, considerable efforts have been directed at synthesizing new pentacene derivatives (2). Among them, pentacenequinone derivatives have been employed as synthetic precusors because of their stability and ready accessibility. Recently, photochemical methods based on extrusion of molecular fragments for the synthesis of pentacenes have also been reported (3, 4).

Our group reported some time ago that 2-(hydroxymethyl)-9,10-anthraquinone (**1**) undergoes a very efficient new type of intramolecular photoredox reaction (or equivalently viewed as proceeding via tandem phototautomerizations) in neutral aqueous solution to give 2-formyl-9,10-dihydroxyanthracene (**2**) ($\Phi \sim 0.8$) (5). This reaction was ob-

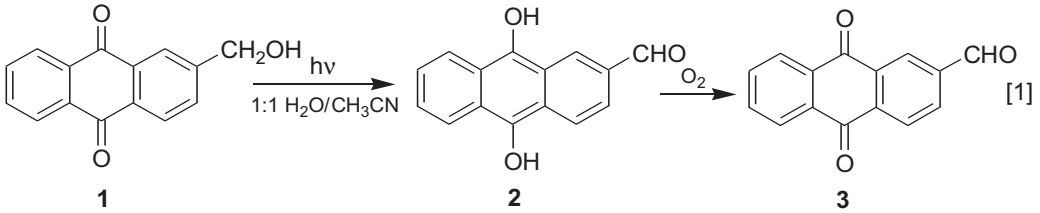
Scheme 1.

served only in protic solvents, with highest quantum yields in water. The mechanism is unimolecular in substrate but is catalyzed (mediated) by water. In the presence of oxygen, dihydroxyanthracene **2** is quantitatively converted to 2-formylanthraquinone (**3**) (eq. [1]) (5). We have also discovered that simple benzophenones can react via this pathway; thus, 3-(hydroxymethyl)benzophenone undergoes the same photoredox reaction (via T_1) but requires pH < 3 (6). These reactions are termed photoredox because of the fact that a formal transfer of electrons through the meta positions of the benzene ring is required. Based on these findings, we anticipated that 2-(hydroxymethyl)-6,13-pentacenequinone (**4**) might undergo the photoredox reaction as well, which would give rise to a corresponding dihydroxypentacene derivative. Herein, we report a new photochemical method involving an intramolecular redox process to prepare a pentacene intermediate from **4** and associated photochemistry for related acenequinones.

Results and discussion



Materials

The potential photoredox chemistry of pentacenequinone **4** and associated acenequinones **5**–**7** (chosen based on their relative ease of synthesis) was explored in this work. Acenequinones **4** and **7** were readily prepared via the condensation (in situ Diels–Alder) of the corresponding acenequinones **5** and **6**, respectively, with α,α,α′,α′-tetrabromo-*o*-xylene (Scheme 1). Acenequinones **5** and **6** are known compounds and were prepared by following or adapting the corresponding literature methods (7, 8). 2-Methyl-6,13-pentacenequinone (**8**) was also studied to test the requirement of a hydroxymethyl (alcohol) moiety in the anticipated photoredox chemistry. It was made using the same reaction shown in Scheme 1, starting with 6-methyl-1,4-anthraquinone (**9**).

UV–vis studies

As shown for the reaction of **1** (5), UV–vis studies were particularly informative of reaction because the photochemical transformation (eq. [1]) involves a substantial change in chromophore, going from an aromatic ketone/quinone to a dihydroxy-substituted polycyclic aromatic compound (anthracene). In the case of **1**, the initial photochemical product **2** is coloured (orange). We anticipated similar UV–vis changes on the photoredox reaction of **4**–**7**. UV–vis studies of **4** (10^{-6} to $10^{-}5$ mol/L, solvent: 1:3 H_2O/CH_3CN, pH 1 and 7 (water portion), argon purged, 350 nm lamps, 3.0 mL quartz cuvette) were carried out initially. No changes were observed in neat CH_3CN or in H_2O/CH_3CN (water at pH 7),

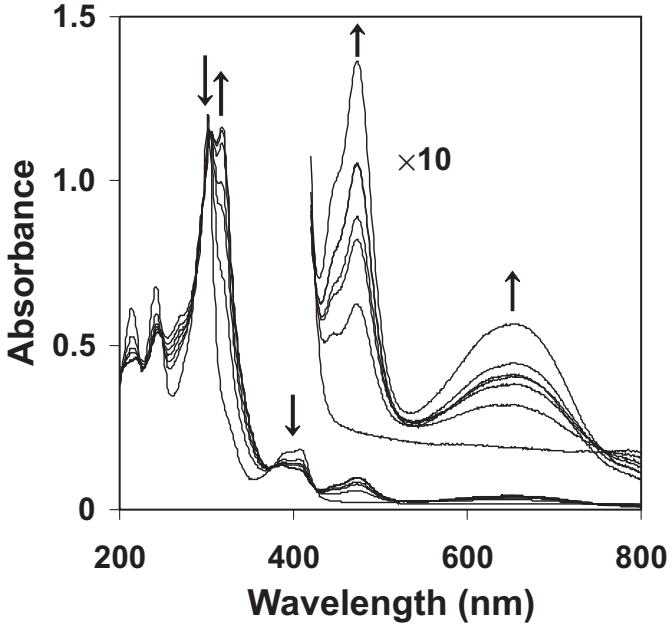
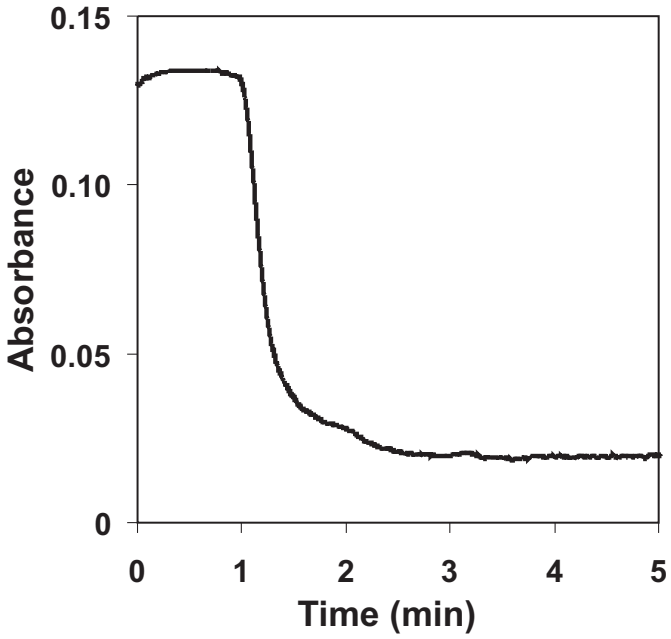
Fig. 1. UV–vis traces observed on photolysis of pentacenequinone **4** (1:3 H_2O/CH_3CN, pH 1, λ_{ex} 350 nm, argon purged). Photolysis times were 10–20 s except for the final trace (2 min). New absorption bands at 318, 473, and 657 nm are consistent with the formation of dihydroxypentacene **10** (Inset: expansion of the long wavelength region).





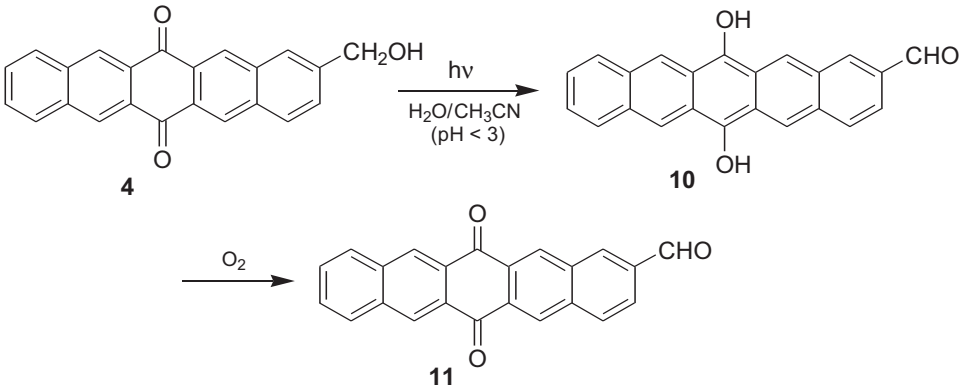


Fig. 2. Decay of photogenerated dihydroxypentacene **10** (from pentacenequinone **4** in 1:3 H_2O/CH_3CN, pH 1) on exposure to air upon opening cuvette (absorbance monitored at 473 nm).

but dramatic changes were observed in H_2O/CH_3CN at pH 1 (Fig. 1). Photolysis at this pH resulted in the formation of an intense new absorption band at 318 nm and two additional (less intense) visible bands at 473 and 657 nm, the latter being a very broad band covering 550–780 nm. Based on what is known for **1** shown in eq. [1], the same reaction for **4** would give rise to 6,13-dihydroxypentacene **10** (eq. [2]). Pentacenes are known to absorb strongly in the visible region, with the longest wavelength band in the 500–700 nm, depending on substituents (2*a*, 4). The broad absorption at 657 nm is consistent with the formation of a pentacene. These new absorption bands disappeared within 1 min of opening the cuvette to air or oxygen (Fig. 2) and within 1 h when the cuvette was unopened and sealed. The resulting UV–vis spectrum was identical to an authentic sample of pentacenequinone aldehyde **11**, which has a UV–vis spectrum similar to that of **4**. This is consistent with a highly reactive dihydroxypentacene derivative that is readily air-oxidized to give **11**. Notably, **8**, although structurally very similar to **4**, did not show reaction under the stated conditions.

The effect of pH on the relative quantum efficiency of the photoredox reaction of **4** was examined next. As noted for pH 7, no reaction was observed. Using the UV–vis method, the relative quantum efficiency for the formation of **10** was followed at different pH values (1:3 H_2O/CH_3CN, the pH of the water portion varied). The results show that the photoredox efficiency strongly depends on the pH of the solution (Fig. 3). The photoredox reaction was not observable above pH 3 and reaches maximum efficiency at about pH ≅ 0, although higher acidities were not employed in this study.

Whereas UV–vis studies of **5** (pH 1 and 7) gave only small incremental changes even on prolonged photolysis, indicative of a much less reactive chromophore, the same studies of **6** (pH 7) gave rise to two new strongly absorbing bands at 268 and 392 nm, which were assignable to dihydroxynaphthalene **12** (Fig. 4 and Scheme 2). For this compound, acid was not required for the efficient photoredox reaction, akin to what was observed for **4**. In-

[2]

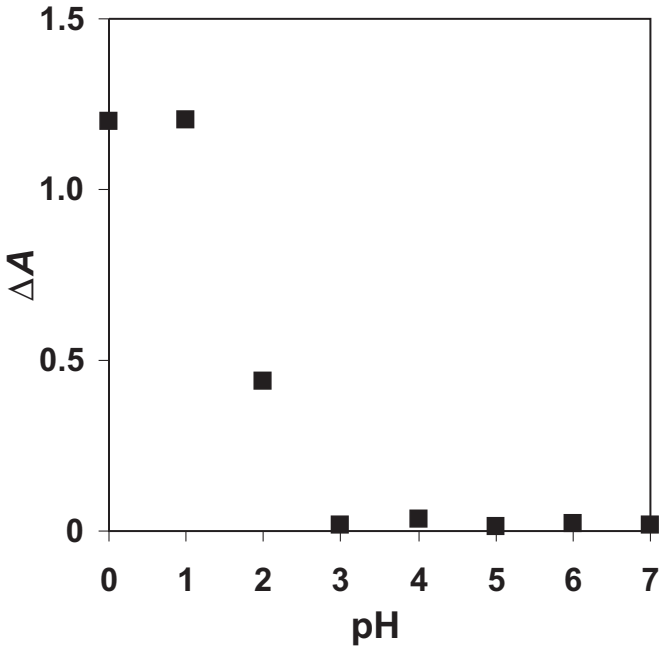
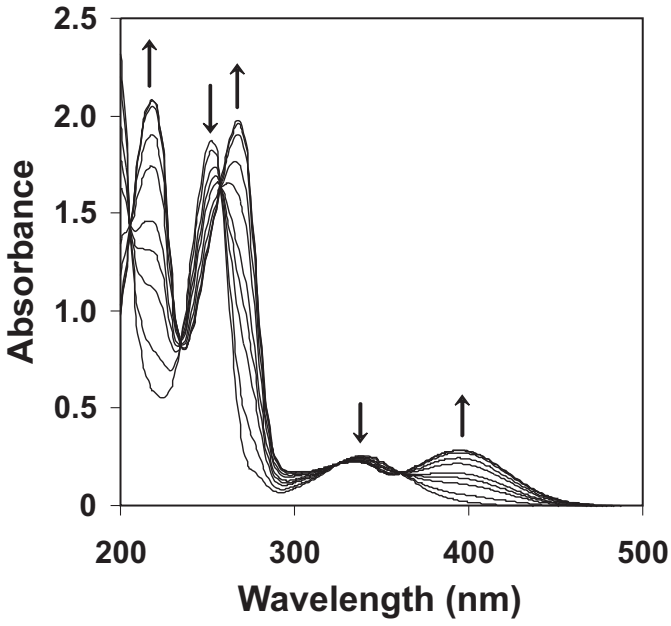
Fig. 3. Effect of pH on the efficiency of photoredox reaction of pentacenequinone **4** monitored at 318 nm (formation of dihydroxypentacene **10**; λ_{ex} 350 nm; 1:3 H_2O/CH_3CN (pH 1), argon purged). ΔA is the difference in the absorbance before and after irradiation.





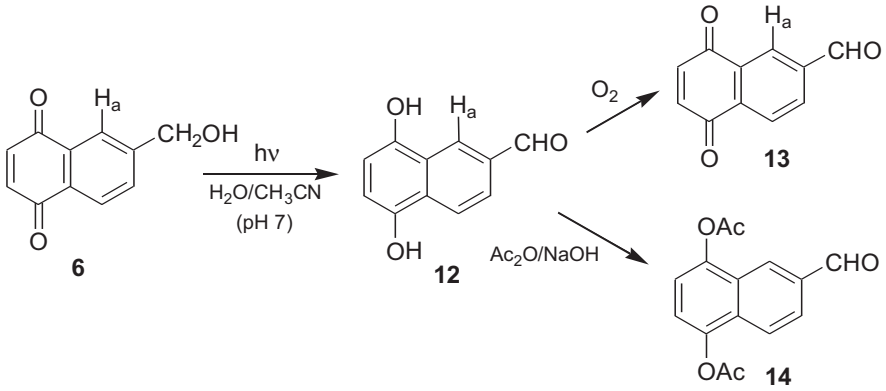


Fig. 4. UV–vis traces observed on photolysis of naphthoquinone **6** (1:1 H_2O/CH_3CN, pH 7, λ_{ex} 350 nm, argon purged). Photolysis times were 2–20 s. Growth of absorption bands at 268 and 392 nm is consistent with the formation of dihydroxynaphthalene **12**.

Scheme 2.

deed, the use of acid did not result in any enhancement of the photoredox reaction. Photolysis in neat CH_3CN gave no observable changes. The photoredox product in this case (dihydroxynaphthalene **12**) was more stable in air or oxygen, as the coloured intermediate remained unchanged for at least 1 day in the sealed cuvette. Shown in Fig. 5 are solutions of photolyzed acenequinones **1**, **4**, and **6** illustrating the varied colours observable in this family of photoredox reactions in aqueous solution. Finally, UV–vis studies of **7** gave no observable changes in the UV–vis spectrum (pH 1 or 7) with prolonged times, indicative of an essentially unreactive acenequinone.

Product studies

Semi-preparative photolyses were carried out to confirm the reactivity of the compounds (based on the previously mentioned UV–vis studies) and to isolate, characterize, and in some cases trap initial photoproducts. Acenequinones **4**–**8** were photolyzed (10^{-5} to 10^{-3} mol/L, λ_{ex} 350 nm, argon purged) in H_2O/CH_3CN (various pH values) as well as in neat CH_3CN. Semi-preparative photolysis of **4** (pale yellow) in 1:3 H_2O/CH_3CN (pH 1) gave a green to dark green solution depending on irradiation time, indicative of photoredox chemistry. When left standing in the photolysis tube after irradiation with no precautions to prevent entry of air, the colour changed to a pale yellow within 1 h, indicative of a reactive initial photoproduct. When the photolyzed solution was exposed to air after photolysis (pouring the solution into a flask exposed to air), the green colour disappeared immediately. In view of the reactive nature of the initially formed photoproduct, no attempts were made to isolate it in these runs. Instead, the solutions were exposed to air after photolysis and extracted with CH_2Cl_2. Work-up using this method gave exclusively 2-formyl-6,13-pentacenequinone

© 2007 NRC Canada

Fig. 5. Dramatic differences in observed colours in the photolysis of **6** (pH 7), **1** (pH 7), and **4** (pH 1) (L to R) in 1:1 H_2O/CH_3CN (λ_{ex} 350 nm, 15 min, argon purged). In sealed vessels, the colour remained unchanged for at least a day for **6** and **1** and a few hours for **4**.

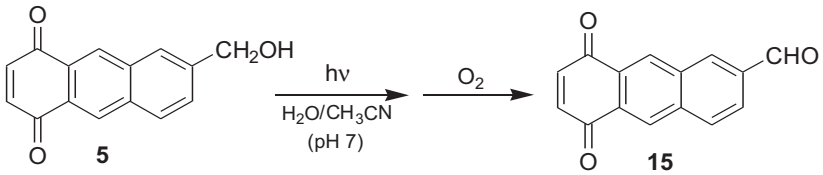
(**11**) (yields 20%–70% by NMR, depending on photolysis time). No reaction was observed when photoyzed in pH 7 or in neat CH_3CN, consistent with the UV–vis studies reported earlier. In addition, no reactions were observed without photolysis (in the presence or absence of oxygen).

Attempts were made to characterize the initially formed (green) dihydroxypentacene intermediate **10**. Initial experiments were carried out by photolyzing samples of **4** in an NMR tube so the formation of **10** could be observed directly by NMR without work-up or exposure to air. However, because of the very low solubility of **4** in aq. CH_3CN, these photolyses proved to be impractical. Attempts were also made to trap **10** using acetic anhydride (as the ester) and methyl iodide (as the methyl ether) in situ, but in all experiments attempted, only **11** was isolated, consistent with the highly reactive nature of the initially formed product **10**.

Photolysis of the closely related methylpentacenequinone **8** under similar conditions as for **4** or even on extended photolysis did not give any reaction. The photolyzed solution did not develop any colour and upon work-up, the starting material was recovered unchanged. Thus, the photoredox reaction requires an α-hydroxy moiety at the carbon directly attached to the aromatic ring for the reaction to proceed. As the chromophores (and structures) of **4** and **8** are otherwise identical, it would appear that the mechanism allows any formed intermediates — up to a critical product forming step — to return (deactivate) efficiently to starting material.

Photolysis of **6** (1:1 H_2O/CH_3CN, pH 7) resulted in a yellow solution that slowly (several days) faded when left in the vessel and turned to pale yellow within a few hours when exposed to air. On work-up in air, naphthoquinone aldehyde **13** was formed exclusively (30%–60%, depending on photolysis time). To provide further evidence for the reaction scheme shown in Scheme 2, trapping of **12** was attempted. Thus, after photolysis under an argon purge, sufficient solid NaOH was added to the photolysate to basicify the solution. This resulted in the solution turning from yellow to red, consistent with formation of a naphtholate chromophore (via deprotonation of **12**). Excess Ac_2O was then added under argon, which quenched the red colour. Upon work-up, the only product isolable was diacetoxyanthracene aldehyde **14** thus confirming the reaction sequence shown in Scheme 2.

As further evidence for the formation of **12** as the primary photochemical product from **6**, photolyses were also carried out in NMR tubes (10^{-3} mol/L, 1:9 D_2O/CD_3CN, pD 7, λ_{ex} 350 nm, argon purged, 10 min). Photolysis gave a dark yellow solution with a reduction of the signals at δ 4.80 (s) and 8.07 (s) assigned to the methylene and aromatic H_a protons of **6**, respectively, (Scheme 2), with concomitant growth of the aldehyde (CHO; δ 10.07) and H_a (δ 8.70) protons assignable to the initial photoredox product **12**. Based on NMR integration, the yield of **12** was estimated to be about 14%. Upon introduction of oxygen via a syringe needle, the dark yellow colour was bleached. In the NMR, the peaks assignable to **12** disappeared. In particular, a new aldehyde peak at δ 10.13 and an aromatic singlet (H_a) at δ 8.55 are assignable to oxidized product **13**.



Using the photoredox reaction reported for **1** as a secondary actinometer (Φ = 0.8, pH 2), we estimated a quantum yield of photoredox for **4** (1:3 H_2O/CH_3CN, pH 1) and **6** (1:1 H_2O/CH_3CN, pH 7) to be about 0.2 and 0.4, respectively. Although these compounds are not as reactive as the parent anthraquinone system **1**, they nevertheless have substantial quantum yields of reaction at a suitable pH.

Although acenequinone **5** also underwent the photoredox reaction, it exhibited low reactivity in neutral or acidic solution. This compound required photolysis times that were about an order of magnitude longer for similar conversion. Because of its much lower reactivity, no attempts were made to characterize the initially formed photoredox product and only the final air-oxidized product **15** was isolated (eq. [3]). No reaction was observed without irradiation (in the presence or absence of oxygen). Of all the acenequinones studied in this work, compound **7** proved to be the only one that was photochemically inert. Thus, photolysis of this compound (pH 1, 7) gave no reaction and the compound could be recovered unchanged. Initially we were puzzled by this result although one could imagine a number of photophysical reasons to explain the lack of reaction. However, the lack of reactivity of this compound as well as the reactivity of the other systems can be partly rationalized by resorting to an examination of HOMO and LUMO characteristics (vide infra).

Reaction mechanisms

We believe that the observed formal intramolecular photoredox reactions of the present acenequinones, includ-

[3]

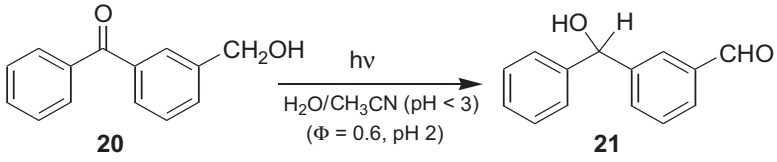
ing the "parent" anthraquinone (5) and "simple" benzophenone (6) systems, are closely related to the acid-catalyzed photohydration of benzophenone (**16**) reported by Wirz and co-workers (9) (eq. [4]). They discovered that the protonation (at the carbonyl) of triplet benzophenone **16** results in an overall *photohydration* reaction, to give water-adducts **18** and **19** with a preference for **18**, i.e., hydration at the meta position (eq. [4]). This reaction was unexpected and has missed detection in the past because of the instability of the hydration products (**18** and **19**), which readily revert back to **16**. Wirz and co-workers (9) assigned a pK_a of –0.4 for the protonated triplet excited state. The mechanism (9) of photohydration presumably involves initiation protonation of the carbonyl oxygen of triplet excited benzophenone **16**, to generate an excited triplet state conjugate acid **17** that has its positive charge significantly delocalized to the ortho and meta positions of the benzene ring (e.g., as shown in eq. [5]), as would be anticipated based on the Zimmerman "ortho–meta" effect for benzene ring site activation in photochemical reactions (10, 11). Attack by water at these sites of positive charge would lead to the observed hydration products, which upon deactivation to their ground states would not be expected to be long-lived and readily return to benzophenone (**16**) by dehydration (with re-aromatization). Although the above acid-catalyzed photohydration of benzophenone reported by Wirz and co-workers (9) gave no isolable *stable* product, it seemed reasonable to assume that the protonation of triplet excited benzophenone (**16**) and aromatic ketones and related compounds, such as acenequinones, might lead to other types of acid-catalyzed chemistry, a prime example of which was the photoredox reaction of benzophenone **20** to give **21** in acidic aqueous solution reported by us (6) (eq. [6]).]

In view of this background and the fact that acenequinones also tend to react via T_1 with photochemical behaviour (12) that is closely allied to what is known for benzophenones, we propose that the mechanism of photoredox reaction of the acenequinones reported in this work also start with a T_1 reactive state that is sufficiently basic to be protonated at pH 7 or at pH < 3, depending on the substrate. Intramolecular photoredox reaction requires protonation of the ketone (by acid or by water) and deprotonation of the C-H proton at the CH_2OH moiety. This is a unique mechanism in photochemistry in that two very different types of excited state proton transfers are required (simultaneously or sequentially). A working mechanism is shown for pentacenequinone **4** (Scheme 3). Although not shown explicitly, all excited states shown in this mechanism are triplets. Compound **4** requires acid for the photoredox pathway to be observed. Thus, excited state protonation gives rise to an excited triplet state conjugate acid **22a,b** that is sufficiently reactive for the subsequent deprotonation of the C-H proton in the CH_2OH moiety, this being the product forming step. That is, both the triplet excited state and the protonated triplet **22a,b** can return to starting material without going on to product. Deprotonation of the C-H proton in CH_2OH seems reasonable if the positive charge is strongly delocalized to the ring position with the CH_2OH group, acidifying the C-H proton. Such a step would give the double enol **23**, which is assumed to be initially generated in its



[4]

[5]

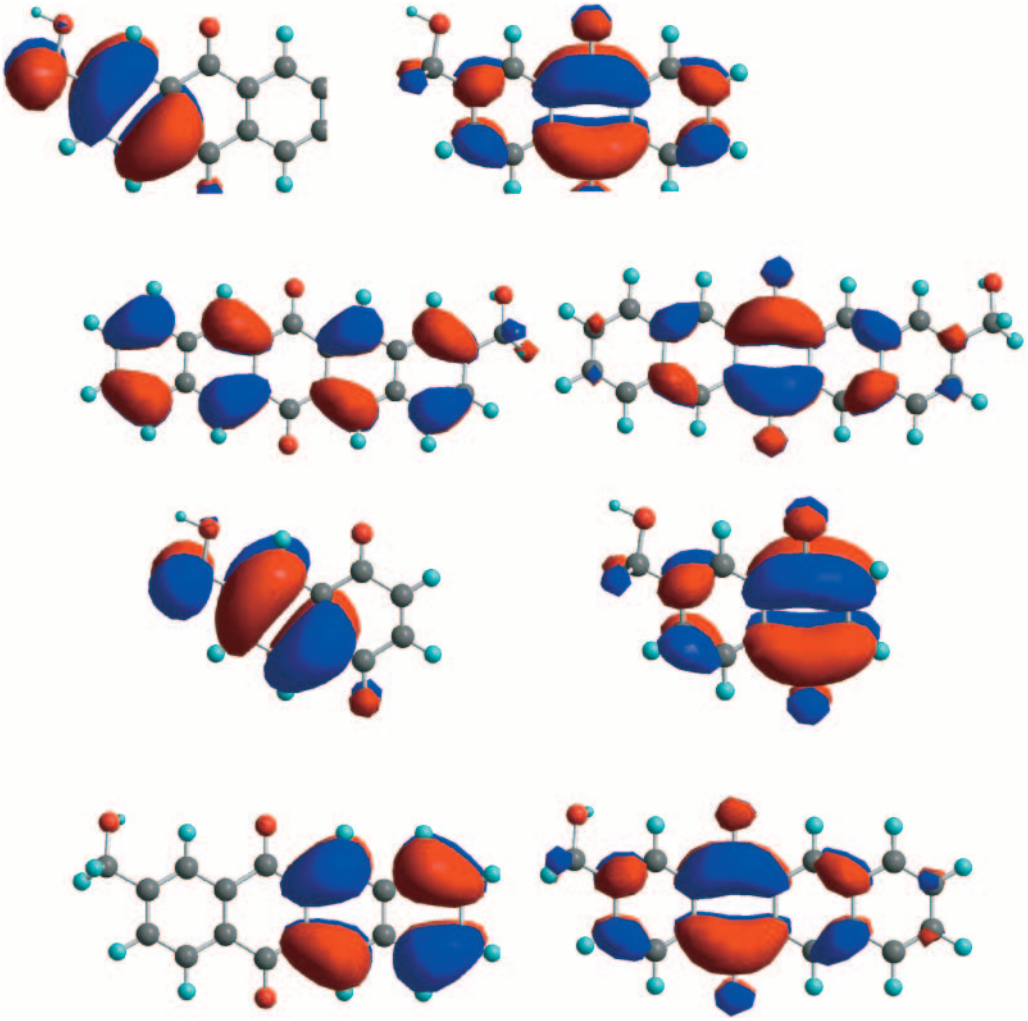
Scheme 3.



triplet excited state but subsequently deactivates to its ground state singlet. This is followed by ketonization–enolization (tandem tautomerization), which would give the formal redox product **10**. It is also possible that water could attack the positive charge on the ring (of **22b**) resulting in a photohydration reaction like that reported for benzophenone in acid (9). The extent of this pathway is unknown for these compounds.

The overall reaction requires the formal movement of π electrons from one end (CH_2OH) of the molecule to the other (C=O) (Scheme 3). That this can occur for such a large π system as a naphthalene ring in pentacenequinone **4** was unexpected. Since **4** absorbs into the visible (up to 450 nm), the photochemical transformation is a way of storing solar energy in the form of the high energy species dihydroxypentacene **10**, which is a compound capable of reducing other molecules such as molecular oxygen. Conceivably, other uses may be possible.

Although Wirz and co-workers (9) did not explicitly offer an explanation as to why the carbonyl oxygen of benzophenone (**16**) in T_1 becomes much more basic, one can envisage that in aqueous solution the T_1 state may have substantial charge transfer character (as opposed to its known diradical character in typical organic solvents). Such a highly polarized excited state enables the photohydration (9) and the intramolecular photoredox reactions to proceed. Moreover, water is also an essential medium to mediate proton transfer reactions that are required in the reaction mechanism. We have carried out calculations of HOMOs and LUMOs (Chem 3D, AM1) for all of the compounds studied in this work in an attempt to predict the migration of charge on excitation. We assume that a simple picture of the excited state can be obtained by the promotion of an electron from the HOMO to the LUMO without regard to spin multiplicity. For all the reactive acenequinones (**1**, **4**, **5**, and **6**), examination of HOMO and LUMO coefficients (some of which are shown in Fig. 6) show that there is significant to substantial migration of charge from at least the ring with CH_2OH substituent to the carbonyl and to the other ring(s) in the compound. This charge transfer (migration) would make the carbonyl oxygen more basic. On trapping of this charge transfer state with a proton (protonation of the carbonyl oxygen), one can assume that some of the residual positive charge (sites of electron deficiency) will be localized on the ring with the CH_2OH substituent, making the CH proton on the CH_2OH more acidic. At this level of calculation, there is also evidence to suggest that the C–H bond (of the CH_2OH) moiety also donates electron density for compounds **1**, **4**, and **6**, but less so for **4**. This would have the added effect of making this proton even more acidic. Indeed, **1** and **6** were the most reactive compounds (at pH 7). For pentacenequinone **4**, the HOMO and LUMO characteristics are not as optimal; for this compound, reaction was only observable below pH 3. The presence of the OH group is also particularly crucial, because it provides a further inductive acidifying effect and also makes the whole group readily oxidizable (to the aldehyde). For the unreactive compound **7** (Fig. 6), the same calculations show that the charge transfer is in the *opposite direction*, that is, from the rings without the CH_2OH group (the "naphthalene" ring) to the carbonyl and to the ring containing the CH_2OH group. Although this charge transfer will still make the carbonyl oxygen more basic in the excited state and hence undergo protonation, one would not anticipate the same reactivity of the CH_2OH group, since the ring in which it is attached is now more electron-rich than in the ground state. Indeed, this compound

proved to be photochemically inert! Thus, simple semi-empirical MO calculations at the AM1 level are useful for the prediction of qualitative reactivity patterns for these compounds.

Experimental section

Instrumentation

NMR spectra were recorded on a Bruker 300 or 500 MHz for ^{1}H and 75 or 125 MHz for ^{13}C. IR spectra were recorded on a PerkinElmer 283 instrument. UV–vis spectra were measured on a Cary 1 instrument. Mass spectra were obtained on a Kratos Concept H instrument.

Materials

All solvents were best reagent grade, except CH_3CN that was HPLC grade. Deuterated solvents $CDCl_3$, $(CD_3)_2CO$, DMSO-d_6 were purchased from the Cambridge Isotope Laboratory (99.9% D). All synthetic precursors used below were purchased from Sigma-Aldrich and used as received.

6-(Hydroxymethyl)-1,4-anthraquinone (5)

This compound was made according to the published procedure (7) with 45% overall yield (mp 180–182 °C, lit. value (7) 178 to 179 °C). IR (KBr, cm^{-1}) 3498, 1670, 1650. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.59 (s, 2H), 8.05 (d, 1H, J = 8.8 Hz), 8.03 (s, 1H), 7.68 (d, 1H, J = 8.8 Hz), 7.05 (s, 2H), 4.92 (s, 2H). ^{13}C NMR (DMSO- d_6, 75 MHz) δ: 184.4, 184.3, 144.6, 134.0, 139.9, 134.3, 133.4, 130.0, 128.8, 128.2, 127.9, 127.7 (2C), 126.3, 62.7. EIMS *m*/*z* 238 (M^+, 100), 221 (10).

2-(Hydroxymethyl)-6,13-pentacenequinone (4)

A mixture of **5** (0.43 g, 1.8 mmol), α,α,α′,α′-tetrabromo-o-xylene (1.14 g, 2.7 mmol), and NaI (2.70 g, 18 mmol) were heated in 5 mL DMF for 3 h at 80 °C to give a dark brown mixture. After cooling, 50 mL of cold water was added followed by the addition of 10 mL of 10% $NaHSO_3$ dropwise until the dark brown colour was bleached. The mixture was extracted with 3 × 25 mL CH_2Cl_2 and dried over anhydr. $MgSO_4$. Removal of the solvent gave a brown solid, which upon separation by column chromatography (silica gel; CH_2Cl_2 and ethyl acetate as eluents) gave 0.13 g of **4** (21%, yellow powder), mp (decomp) 286 °C. IR (KBr, cm^{-1}) 3403,

© 2007 NRC Canada

1691, 1676. ^{1}H NMR (DMSO-d_6, 500 MHz) δ: 8.95 (s, 1H), 8.94 (s, 1H), 8.93 (s, 1H), 8.89 (s, 1H), 8.38–8.33 (m, 2H), 8.31 (d, 1H, J = 8.5 Hz), 8.23 (s, 1H), 7.84–7.79 (m, 2H), 7.75 (d, 1H, J = 8.5 Hz), 5.54 (t, OH, J = 5.6 Hz), 4.75 (d, 2H, J = 5.6 Hz). ^{13}C NMR (DMSO-d_6, 125 MHz) δ: 182.2, 182.1, 144.7, 134.8 (2C), 134.74, 134.72, 133.9, 130.4, 130.3, 130.1 (2C), 129.9 (2C), 129.8 (2C), 129.1 (2C), 129.0, 128.9, 128.8, 126.2, 62.7. EI MS m/z 338 (M^+, 100), 321 (5). HRMS calcd. for $C_{23}H_{14}O3$ 338.0943; found 338.0928.

2-Methyl-6,13-pentacenequinone (8)

Following the method described for the synthesis of **4**, use of 6-methyl-1,4-anthraquinone (**9**, from ref. 7) (0.12 g, 0.54 mmol), α,α,α′,α′-tetrabromo-o-xylene (0.32 g, 0.81 mmol), NaI (0.81 g, 5.4 mmol) gave 60 mg (35%, yellow powder), mp (decomp) 307 °C. IR (KBr, cm^{-1}) 1676, 1615. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 8.92 (s, 2H), 8.89 (s, 1H), 8.83 (s, 1H), 8.13–8.09 (m, 2H), 8.01 (d, 1H, J = 8.4 Hz), 7.87 (s, 1H), 7.71–7.67 (m, 2H), 7.53 (d, 1H, J = 8.4 Hz), 2.58 (s, 3H). ^{13}C ($CDCl_3$, 125 MHz) δ: 183.4, 183.3, 140.2, 135.8 (2C), 135.52, 135.49, 133.8, 132.1, 130.98, 130.94, 130.3 (2C), 130.2, 130.1, 129.96, 129.94, 129.8, 129.6 (2C), 129.3 (2C), 22.2. EIMS m/z 322 (M^+, 100). HRMS calcd. for $C_{23}H_{14}O2$ 322.0994; found 322.0993.

6-(Hydroxymethyl)-1,4-naphthoquinone (6)

This compound was synthesized according to the published procedure (8), except for the last hydrolysis step involving 6-(bromomethyl)-1,4-naphthoquinone, in which 1.5 equiv. of silver trifluoacetate was used instead of 5 equiv. of $CaCO_3$. Upon column chromatography (silica gel; CH_2Cl_2), 0.2 g (70%, yellow powder) was obtained, mp 80–82 °C, lit. value (8) 81 to 82 °C. IR (KBr, cm^{-1}) 3447, 1662, 1598. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.07 (d, 1H, J = 8.1 Hz), 8.05 (s, 1H), 7.76 (d, 1H, J = 8.1 Hz), 6.96 (s, 2H), 4.85 (s, 2H). ^{13}C (75 MHz, $CDCl_3$) δ: 185.3, 185.1, 147.7, 139.0, 138.8, 132.2, 131.9, 131.3, 127.1, 124.4, 64.5. EIMS m/z 188 (M^+, 100), 160 (90).

2-(Hydroxymethyl)-5,12-naphthacenequinone (7)

A mixture **6** (0.22 g, 1.2 mmol), NaI (1.76 g, 11.7 mmol), and α,α,α′,α′-tetrabromo-*o*-xylene (0.74 g, 1.76 mmol) in 4 mL DMF was heated to 80 °C overnight. After work-up and purification (as described for **4**), 0.29 g (85%) of a yellow powder was obtained, mp (decomp) 190 °C. IR (KBr, cm^{-1}) 3327, 1675, 1603. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.84 (s, 2H), 8.40 (d, 1H, J = 8.1 Hz), 8.38 (s, 1H), 8.13–8.05 (m, 2H), 7.83 (d, 1H, J = 8.1 Hz), 7.73–7.64 (m, 2H), 4.91 (s, 2H). ^{13}C NMR (DMSO-d_6, 75 MHz) δ: 182.2, 181.9, 149.8, 134.5 (2C), 133.7, 132.5, 131.9, 130.0 (2C), 129.6 (2C), 129.3, 128.9, 128.8 (2C), 127.0, 124.1, 62.2. EIMS m/z 288 (M^+, 100), 259 (50). HRMS calcd. for $C_{19}H_{12}O3$ 288.0786; found 288.0792.

General photolysis procedure

Preparative photolyses were carried out using a Rayonet RPR 100 photochemical reactor using 350 nm lamps, a water-cooled cold finger, and 100 mL quartz tubes. Solutions (10^{-4} mol/L in substrate) were purged with argon for 15 min prior to photolysis and kept under a stream of argon during irradiation. Unless otherwise noted, all the photolyses were worked up in the presence of air. Photolyzed solutions were extracted with CH_2Cl_2. Upon solvent evaporation, the material was analyzed initially by NMR for product identification and determination of conversions and yields. Subsequently, separation and purification of products were achieved using prep. TLC (silica gel, CH_2Cl_2).

Photolysis of 2-(hydroxymethyl)-6,13-pentacenequinone (4)

Compound **4** (3 mg in 75 mL of CH_3CN and 25 mL of H_2O, pH 1) was irradiated (16 lamps) for 1 min to give 18% yield of **11** (2-formyl-6,13-pentacenequinone), which was subsequently isolated in pure form. IR (KBr, cm^{-1}) 1698, 1675. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 10.2 (s, 1H), 9.10 (s, 1H), 8.97 (s, 1H), 8.95 (s, 2H), 8.93 (d, 1H, J = 8.6 Hz), 8.58 (s, 1H), 8.23 (d, 1H, J = 8.6 Hz), 8.19–8.05 (m, 2H), 7.78–7.64 (m, 2H). EIMS m/z 336 (M^+, 100), 307 (10). HRMS calcd. for $C_{23}H_{12}O3$ 336.0786; found 336.0787.

Photolysis of 2-methylpentacenequinone (8)

Photolysis of **8** as for **4** gave no reaction. The NMR of the isolated material was identical to that of the starting material.

Photolysis of 6-(hydroxymethyl)-1,4-naphthoquinone (6)

Photolysis of **6** (5 mg in 50 mL of CH_3CN and 50 mL of H_2O, pH 7; 4 lamps, 1 min) gave **13** (6-formyl-1,4-naphthoquinone, 44% yield by NMR), which was subsequently isolated. IR (KBr, cm^{-1}) 1697, 1664, 1597. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 10.17 (s, 1H), 8.57 (s, 1H), 8.25 (s, 2H), 7.07 (s, 2H). ^{13}C NMR (CD_3Cl, 75 MHz) δ: 190.8, 184.4, 184.1, 139.9, 139.2, 139.1, 135.4, 133.4, 132.8, 128.7, 127.6. EIMS m/z 186 (M^+, 100), 157 (40). HRMS calcd. for $C_{11}H_6O3$ 186.0317; found 186.0322.

Photolysis of **6** was also carried out in which the initially formed photoredox product **12** was trapped with Ac_2O to give **14** as follows (all carried out under argon): A solution of **6** (10 mg in 50 mL of CH_3CN and 50 mL of H_2O, pH 7) irradiated for 5 min. Upon photolysis, sufficient solid NaOH was added to turn the yellow brown solution to red. This was followed by the addition of 1 mL of Ac_2O, which turned the solution to a brown colour. After work-up in air, the crude material was characterized with ^{1}H NMR, which was consistent with 50% conversion to **14** (6-formyl-1,4-diacetoxynaphthalene). Further separation and purification was achieved by prep. TLC (silica gel, CH_2Cl_2). IR (KBr, cm^{-1}) 1754, 1699. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 10.15 (s, 1H), 8.38 (s, 1H), 7.99 (s, 2H), 7.39 (dd, 2H, J = 8.1 Hz, J = 8.1 Hz,), 2.50 (s, 3H), 2.47 (s, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 191.9, 169.4 (2C), 145.5, 144.4, 134.8, 130.5, 127.9, 127.4, 124.3, 123.2, 121.4, 119.3, 21.4, 21.2. EIMS m/z 272 (M^+, 5), 230 (15), 188 (100), 43 (40). HRMS calcd. for $C_{15}H_{12}O5$ 272.0685; found 272.0687.

Photolysis of 6-(hydroxymethyl)-1,4-anthraquinone (5)

A solution of **5** (3 mg in 50 mL of CH_3CN and 50 mL of H_2O, pH 7, 16 lamps) was irradiated for 1 min, which gave an aldehyde product in less than 2% conversion. Upon photolysis for 30 min, 30% conversion to 6-formyl-1,4-

anthraquinone (**15**) could be achieved. IR (KBr, cm^{-1}) 1706, 1668, 1589. ^1H NMR ($CDCl_3$, 300 MHz) δ: 10.22 (s, 1H), 8.78 (s, 1H), 8.67 (s, 1H), 8.54 (s, 1H), 8.16 (dd, 2H, J = 8.1 Hz), 7.11 (s, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 191.5, 184.5, 184.3, 140.3 (2C), 137.9, 136.7, 135.7, 134.5, 131.5, 130.6, 130.3, 129.5, 128.8, 126.5. EIMS m/z 236 (M^+, 100), 207 (20). HRMS calcd. for $C_{15}H_8O3$ 236.0473; found 236.0466.

Comparison of colours observed in the photolysis of 1, 4, and 6

Solutions of **1** (5 mg, 1:1 H_2O/CH_3CN, pH 7), **4** (5 mg, 1:3 H_2O/CH_3CN, pH 1), and **6** (5 mg, 1:1 H_2O/CH_3CN, pH 7) were prepared in 100 mL Pyrex volumetric flasks. After purging with a stream of argon, the flasks were irradiated at 350 nm (16 lamps) for 15 min to develop the colours observed in Fig. 5.

(*R*)-1-Phenylethylamine as chiral auxiliary in the diastereoselective synthesis of tetrahydro-β-carboline derivatives

Aleksandra Siwicka, Krystyna Wojtasiewicz, Andrzej Leniewski, Jan K. Maurin, Anna Zawadzka, and Zbigniew Czarnocki

Abstract: Modified sodium borohydrides were used in the reduction of the imine moiety in compounds containing the (*R*)-1-arylethylamine motif as a chiral auxiliary. Diastereomeric products were formed with moderate to good stereoselectivity and were effectively separated by column chromatography.

Key words: asymmetric synthesis, indole alkaloids, hydrogen bond.

Résumé : On a utilisé des borohydrures de sodium modifiés pour effectuer la réduction de la portion imine de composés contenant un motif (*R*)-aryléthylamine comme auxiliaire chiral. Il y a formation de produits diastéréomères avec des stéréosélectivités allant de modérées à bonnes et il est possible de les séparer d'une façon efficace par chromatographie sur colonne.

Mots-clés : synthèse asymétrique, alcaloïdes de l'indole, liaison hydrogène.

[Traduit par la Rédaction]

Introduction

Both enantiomers of 1-phenylethylamine (α-methylbenzylamine, α-PEA **3**) remain as attractive chirality sources in various asymmetric transformations. Their use as resolving agents, chiral ligands in catalytic processes, and synthetic chiral auxiliaries in stereodifferentiating reactions of prochiral substrates have been the subject of in-depth reviews (1, 2).

More recently, an interesting example of the use of α-PEA **3** in an asymmetric Strecker reaction leading to enantiomerically enriched 1-amino-*cis*-3-azabicyclo[4.4.0]decan-2,4-diones has been reported (3). In this process, which is called a second-generation asymmetric synthesis, trimethylsilyl cyanide was the reagent allowing a stereoselective cyanide-ion addition to the prochiral precursor derived from α-PEA and cyclohexanone derivative. In another application, **3** was used as the chiral auxiliary in the preparation of enantiopure conformationally constrained Gly-(*s-cis*)-Pro Turn Mimetic (4). The reaction of the prochiral imine moiety in α-PEA derivatives gave an access to a variety of chiral, nonracemic aliphatic amines (5). Conveniently, these processes can be performed as one-pot procedures. The use of α-PEA, even in the industrial scale, was proven possible, as illustrated by the development and the scale-up of the endothelin antagonists synthesis (6). The process involves the preparation of a racemic intermediate followed by an efficient dynamic resolution with a chiral amine.

In the field of the stereoselective synthesis of pharmacologically relevant compounds, we presented recently the application of α-PEA in the preparation of enantiomerically pure lortalamine analogues (7) and (*R*)-(–)-mianserin (8) compounds that are well-known antidepressants. The Bischler–Napieralski cyclization followed by diastereoselective reduction of the imine bond were the key steps in the enantiodivergent synthesis of both enantiomers of *N*-acetylcalycotomine (9) that was carried out in our laboratory (10). Encouraged by the positive results of using α-PEA in the stereoselective formation of isoquinoline alkaloids, we decided to extend this procedure to tetrahydro-β-carboline analogues.

Results and discussion

The synthetic sequence started with the reaction of tryptamine **1** with diethyl oxalate followed by the treatment with (*R*)-1-phenylethylamine to afford the diamide **5** almost quantitatively (Scheme 1).

After careful optimization, we found that the subsequent Bischler–Napieralski cyclization gave best results when performed in refluxing dichloromethane with $POCl_3$.

Since all attempts to isolate and characterize the resulting imine **7** were unsuccessful because of its instability as a free base, we decided to subject its hydrochloride salt to a metal hydride reduction. Thus, upon treatment with sodium borohydride in EtOH, a pair of diastereomeric amines **9a** and **9b** was formed in 62:38 ratio, respectively, based upon

Scheme 1. Reaction sequence leading to diastereoselective synthesis of tetrahydro-β-carboline derivatives (**9a**, **9b**, **10a**, and **10b**).

^{1}H NMR spectrum of the crude reaction mixture. The ratio of **9a** and **9b** was not affected neither by a prolonged contact with strongly basic solution of the reducing agent nor by solvent variations; these observations ruled out the possibility of an asymmetric transformation caused by a base-catalyzed epimerization at C-1 atom.

Therefore, it seemed reasonable to assume that both diastereomers **9a** and **9b** were formed in unequal amounts because of the chiral induction during a kinetically governed hydride approach to the substrate **7**. The prochiral imine moiety can be regarded as a planar structure resembling a carbonyl group, and the reduction process can be rationalized using the Cram or Felkin stereochemical models (11). Accordingly, the increase of steric demands in the nucleophile and (or) the imine molecules might have a positive effect on the chirality transfer.

Since it is well-known that sodium borohydride, modified with controlled amounts of simple carboxylic acids, forms reducing agents of enhanced selectivity (12), we applied such combined reagents to C=N bond reduction in **7**. Disappointingly, the diastereoselectivity was not improved significantly when hydrides such as $NaBH(AcO)_3$, $NaBH(i\text{-}PrCOO)_3$, and $NaBH(t\text{-}BuCOO)_3$ were applied.

Fortunately, the mixture of isomers could be effectively separated by column chromatography, affording pure and stable compounds **9a** and **9b**. The configuration at C-1 stereogenic centre in compound **9a** was assigned as (*R*) by the chemical transformation of **9a** into (*1R*)-1-(hydroxymethyl)-2-acetyl-1,2,3,4-tetrahydro-β-carboline of known absolute configuration by the method developed earlier in our laboratory (13). Full details for this procedure will be published in due course.

Seeking further improvement in the stereoselectivity, we decided to apply the same synthetic sequence using (*R*)-(+)-1-(1-naphthyl)ethylamine (**4**), another well-known and effective chiral inductor (7), as a chiral auxiliary. Thus, compound **8** was prepared in a good yield from tryptamine **1** and was consecutively subjected to a series of reactions affording easily separable diastereomers **10a** and **10b**. The results were summarized in Tables 1 and 2.

In contrast to previous results, the increase of steric parameters neither in the reducing agent molecule nor in the imine-containing target derivative **8** did not give a significant improvement of the stereochemical outcome. In a search for a feasible explanation of the previous observations, we investigated the problem using quantum chemical methods. Despite considerable efforts, it was impossible to obtain good quality monocrystals of imine **7**, and therefore we performed a molecular modelling to find its optimal geometry. The procedure consisted of consecutive molecular- mechanic search through a conformational space and ab initio calculations used for conformers to optimize their geometries and to find the corresponding energies (14).[2] The two low-energy conformers **7a** and **7b** are shown in Fig. 1, where **7a** has the lowest total electron energy. Noticeably, in both conformers **7a** and **7b**, a strong hydrogen bond between the amide carbonyl group and the indole NH define the shape of the reacting part of the molecule. As a consequence, the chiral fragment derived from the 1-phenylethylamine was di-

[2]We used a Spartan'04 for Windows software for both tasks; a conformational search using MMFF94 force field and a Monte Carlo algorithm was performed. Two different low-energy conformers were selected for further ab initio optimization. A restricted Hartree–Fock method with the standard 6-31G** basis set was then applied. These calculations showed that the conformational energy ΔE between **7a** and **7b** was 2.383 kcal/mol.

rected apart from the imine area (consult also Fig. 2), thus lowering its ability to the chirality induction. Apparently, such a disfavored interaction was not present in the isoquinoline analogue of imine **7**, thus allowing us to observe much better diastereoselectivity (10).

When a Felkin–Evans trajectory (15) for an early transition state was applied to conformer **7a** (Fig. 2), two major conclusions can be drawn from this consideration. First, the model correctly predicts diastereomer **9a** as the major product of the reduction process. Second, the bulkiest substituent of the chiral auxiliary (phenyl or naphthyl ring) is located in the most-remote part of the molecule and is guided in the opposite direction to the incoming nucleophile. This model accounts convincingly for both the relatively low level of diastereodifferentiation during the addition step and for only a small improvement after the replacement of the phenyl in compound **7** by the naphthyl moiety in compound **8**.

Conclusion

In the presented approach, we demonstrated the possibility to extend our earlier findings concerning the diastereoselective preparation of tetrahydroisoquinoline derivatives using enantiopure (*R*)-1-arylethylamines onto β-carboline analogues.

Despite moderate selectivity, the described method might be an attractive alternative to the existing procedures (16, 17, 18) because of the relatively high chemical yields and facile chromatographic separation of diastereomers, which then may be subjected to further transformations leading to the pure enantiomers of 1-substitued-tetrahydro-β-carboline derivatives. The work in this area is in progress.

Experimental

(1*R*)-*N*-[(1*R*)-1-phenylethyl]-2,3,4,9-tetrahydro-1*H*-β-carboline-1-carboxamide 9a and (1*S*)-*N*-[(1*R*)-1-phenylethyl]-2,3,4,9-tetrahydro-1*H*-β-carboline-1-carboxamide 9b

In a typical experiment (see Table 1, entry 4), a sample of compound **5** (335 mg, 1 mmol) was refluxed in methylene chloride (15 mL) with $POCl_3$ (0.5 mL, 5.5 mmol) for 2 h. After that time, the volatiles were evaporated, and dry MeOH (10 mL) was slowly introduced. The mixture was evaporated into dryness, and the procedure was repeated twice followed by the evaporation with a fresh portion of xylene (20 mL) to remove traces of methanol. The residue was then dissolved in dioxane (20 mL), and a freshly prepared modified borohydride solution was introduced at 10 °C. The borohydride was prepared by stirring $NaBH_4$ (180 mg, 4 mmol) with pivaloyl acid (1.11 g, 12 mmol) in dry THF (10 mL) for 3 h. The resultant solution was stirred for 1 h at 10 °C and was poured onto 5% aq. NaOH (50 mL). The mixture was then extracted with methylene chloride (3 × 20 mL). After drying and evaporation, the residue was subjected to column chromatography on silica gel

A mild and efficient synthesis of chloroesters by the cleavage of cyclic and acyclic ethers using $Bi(NO_3)_3 \cdot 5H_2O$ as a catalyst under solvent-free conditions

V. Suresh, N. Suryakiran, and Y. Venkateswarlu

Abstract: A facile, efficient synthesis of chloroesters is described. The reaction of cyclic and acyclic ethers with acid chlorides in the presence of catalytic amounts of $Bi(NO_3)_3 \cdot 5H_2O$ under solvent-free conditions yielded the corresponding chloroesters. Also, the catalyst can be recovered conveniently and reused efficiently for at least six times.

Key words: Bismuth(III) nitrate pentahydrate, cyclic and acyclic ethers, chloroesters.

Résumé : On décrit une méthode simple et efficace de synthèse des chloroesters. La réaction d'éthers cycliques et acycliques avec des chlorures d'acides, en présence de quantités catalytiques de $Bi(NO_3)_2 \cdot 5H_2O$ et dans des conditions sans solvant, fournit les chloroesters correspondants. De plus, il est possible de récupérer facilement le catalyseur et de le réutiliser d'une façon efficace au moins six fois.

[Traduit par la Rédaction]

Introduction

The cleavage of cyclic and acyclic ethers with acid chlorides, leading to the synthesis of the corresponding chloroesters, is a versatile organic transformation, as they are important and key constituents in organic synthesis, particularly in the synthesis of natural products (1). Transformation of cyclic ethers into haloesters is a direct and straightforward method for producing bifunctional synthetic intermediates and also an important method for the removal of ethereal protecting groups (2). In organic synthesis, hydroxyl groups are protected as aliphatic, benzylic, and allylic ethers (3), which can subsequently be cleaved for further transformations (4–7). The cleavage of ethers with acyl chlorides has been reported using Lewis acids, such as SmI_2 (8), $ZnCl_2$ (9), $FeCl_3$ (10), I_2 (11), $MoCl_5$ (12), $PdCl_2(PPh_3)_2$ (13), $CoCl_2$ (3), and very recently $InBr_3$ (14). However, using strongly acidic conditions frequently leads to the formation of undesirable side products, which in turn decrease the purity and yields of the desired products. Most of the reported methods have one or other limitations, such as long reaction time, unavailability of the catalyst, difficulties in handling, and tedious workup procedures with unsatisfactory yields. Thus, a mild, efficient catalyst for the cleavage of cyclic and acyclic ethers with acid chlorides is highly desirable. In view of the merits in catalytic processes, we are interested in the development of inexpensive, mild, and non-polluting reagent for the acid-chloride-directed cleavage of cyclic and acyclic ethers.

Scheme 1.

Organic reactions using mild and water-tolerant catalysts received much attention in recent years, as they can be handled conveniently, and the products can be easily recovered from the reaction mixture, thus making the experimental procedure simple and eco-friendly. Among Lewis acid catalysts, the bismuth(III) nitrate pentahydrate is relatively non-toxic, inexpensive, stable in atmospheric conditions, and used in various organic transformations (15). Also, to the best of our knowledge, there is no report on the use of $Bi(NO_3)_3 \cdot 5H_2O$ for the cleavage of cyclic and acyclic ethers with acid chlorides. Recently, we reported $Bi(NO_3)_3 \cdot 5H_2O$ as a mild and efficient Lewis acid catalyst for *N-tert*-butoxycarbonylation of amines (16). In continuation of our work on catalytic application of metal nitrate salts in the multi-step synthesis of natural products in our laboratory, we have observed that $Bi(NO_3)_3 \cdot 5H_2O$ can be utilized efficiently for the cleavage of cyclic and acyclic ethers with different acid chlorides into the corresponding chloroesters under solvent-free conditions.

Results and discussion

In this report (Scheme 1), we describe an efficient and facile method for the synthesis of chloroesters. This method

does not need expensive reagents or special care to exclude the moisture from the reaction medium. All the reactions proceeded efficiently and smoothly at room temperature, and the products were obtained in excellent yields (Table 1). Furthermore, the reaction conditions are very mild. Bismuth(III) nitrate pentahydrate is highly oxophilic and forms labile bond with carbonyl oxygen to initiate the formation of C–O bond with cyclic and acyclic ethers (Scheme 2). We first examined the reaction of tetrahydrofuran **1** with acetyl chloride **2** under solvent-free conditions to give the corresponding chloroesters **3** in 95% yield (Table 2, entry 2). To compare the catalytic activity of the bismuth(III) nitrate pentahydrate, we carried out the reaction in different Lewis acid catalysts, such as $Bi(OTf)_3$, $BiCl_3$, $La(NO_3)_3{\cdot}6H_2O$, CAN, $ZrO(NO_3)_2{\cdot}xH_2O$, and other reported catalysts. However, bismuth(III) nitrate pentahydrate was found to be the most effective in terms of reaction time as well as yields of the product (Table 1). This success of the reaction encouraged us to carry out the reaction on various cyclic and acyclic ethers with different acid chlorides in the presence of 5mol% of $Bi(NO_3)_3{\cdot}5H_2O$. The ring cleavage of tetrahydropyran is considerably slower than that of tetrahydrofuran at room temperature with low yields (55%). Using slightly elevated temperature (50 °C), the reaction is completed in 1 h with 90% yield (Table 2, entries 7–9). In the case of asymmetrical ethers, the cleavage took place selectively at the unsubstituted side of ether (Table 2, entries 10 and 13). However, in the presence of cyclic and acyclic ethers in the same substrate, formation of products (chloroesters) was observed only with acyclic part of the substrate (Table 2, entries 17 and 18).

Further, we have studied the reusability of the catalyst without any modification of the reaction conditions. After completion of the reaction, ethyl acetate (10 mL) was added; the catalyst was recovered by filtration and reused without loss of its activity for six runs (Table 3). The organic layer was concentrated under reduced pressure to get the crude product. From the foregoing results, it is evident that $Bi(NO_3)_3{\cdot}5H_2O$ is an efficient and reusable catalyst for the synthesis of chloroesters under solvent-free conditions.

Conclusion

In conclusion, we described an efficient and facile synthesis of chloroesters in the presence of catalytic amount of $Bi(NO_3)_3{\cdot}5H_2O$ under solvent-free conditions. The advantages of the method are reduced reaction time, inexpensive catalyst, and simple experimental and work up procedure with high yields of products. This makes it a useful addition to the existing methodologies.

Experimental

Typical experimental procedure for preparation of chloroesters

To a mixture of cyclic/acyclic ether (10 mmol) and acid chloride (10 mmol), was added $Bi(NO_3)_3{\cdot}5H_2O$ (5 mol%) at 0–5 °C followed by stirring at room temperature for an appropriate time (Table 2). After completion of the reaction as monitored by TLC, ethyl acetate (10 mL) was added, and the catalyst was recovered by filtration. The solvent ethyl acetate was washed with water, brine, dried over anhyd. sodium sulphate, and removed under reduced pressure to give a crude product, which was purified on a silica-gel column to yield the pure products. The products were characterized by spectral and analytical data or by comparison with authentic samples.

Microwave-assisted one-pot synthesis of some new furo[2,3-*b*]quinolines using potassium carbonate under solvent-free conditions

M. Raghavendra, Halehatty S. Bhojya Naik, and Bailure S. Sherigara

Abstract: A rapid, solvent-free microwave-assisted method has been developed for the synthesis of novel furoquinolines. The title compounds were achieved by the reaction between corresponding 2-hydroxy-3-formyl-quinolines (**1a**–**1c**) with chloroacetamide, ethylchloroacetate, and phenacylbromide in specially designed microwave (MW) oven for organic synthesis in unsealed borosil vessel in presence of potassium carbonate. In this method, isolation is accomplished by just treating the reaction mixture with water, and products were obtained in high yield. Hence, this method was found to be very effective and ecofriendly. The structure of the newly synthesized compounds has been evaluated on the basis of analytical, IR, ^{1}H NMR, and mass spectral data.

Key words: furoquinoline, microwave irradiation, potassium carbonate, solvent-free conditions.

Résumé : On a mis au point une méthode rapide, sans solvant et assistée par les microondes pour la synthèse de nouvelles furoquinoléines. Les synthèses des composés mentionnés dans le titre ont été réalisées en faisant réagir les 2-hydroxy-3-formylquinoléines correspondantes (**1a**–**1c**) avec du chloroacétamide, du chloroacétate d'éthyle et du bromure de phénacylel, en présence de carbonate de potassium, dans un four à microondes spécialement conçu pour les synthèses organiques dans un contenant en borosil non scellé. Dans cette méthode, on isole les produits par un simple traitement du mélange réactionnel avec de l'eau et les rendements en produits obtenus sont élevés. On a donc trouvé que cette méthode est très efficace et écologiquement acceptable. Les structures des nouveaux composés synthétisés ont été déterminées sur la base d'analyses et de données de spectrométrie IR, RMN du ^{1}H et de masse.

Mots-clés : furoquinoléine, irradiation par microondes, carbonate de potassium, conditions sans solvant.

[Traduit par la Rédaction]

Introduction

Synthetic organic reactions performed under non-traditional conditions are gaining popularity, primarily to circumvent growing environmental concerns (1). Microwave-assisted heating is an invaluable synthesis technology, since it often dramatically reduces reaction times, typically from days or hours, minutes, or even seconds. It can also provide pure products in quantitative yields. Solvent-free reaction techniques are successfully coupled with microwave (MW) to avoid the use of low boiling point solvents, which may sometimes lead to explosions. Additionally, the use of poisonous and expensive solvents can also be avoided to make manipulations of the reactions much easier. The use of microwave for the synthesis of organic compounds under solvent-free conditions proved to be an efficient and safe technique, as it requires shorter reaction times, gives higher yield, and the reactions are easily carried out compared with conventional heating methods (2–3). In addition, the limitations of the microwave-assisted reactions in solvents, namely, the development of high pressure and the need for specialized sealed vessels, are circumvented via the solid-catalyst strategy, which enables organic reactions to occur rapidly at atmospheric pressures and scale up the reactions on a preparative scale (4).

Furo[2,3-*b*]quinoline derivatives constitute an important group of bioactive natural products, such as dictamnine, acrophylline, confusameline, skimmianine, kokusaginine, and aplopine (5–10). They were found to possess a wide-range of biological properties, such as anti-allergic (5), anti-inflammatory (6), cytotoxic (7), antiplatelet aggregation (8–9), and the voltage-gated potassium channel blocking activities (10). Due to their biological importance, several methods have been reported for the synthesis of furoquinoline derivatives (11–15). However, those methods involve multisteps, are time-consuming, produce low yield, and more importantly, the use of more solvents makes those methods less economic. So, there is still need for developing simple, efficient and eco-friendly methods.

Hence, in continuation of our studies on microwave-assisted organic synthesis of linearly condensed quinolines (16–19), by adopting green chemistry, we wish to report microwave-assisted novel synthesis of furo[2,3-*b*]quinoline derivatives using solid base catalyst under solvent-free microwave-irradiation conditions.

Scheme 1.

Results and discussion

2-Hydoxy-3-formyl quinolines (**1a**–**1c**), were found to be the excellent starting materials for the synthesis of novel furoquinoline derivatives. The starting compounds were prepared according to the literature method (20). In the present study, the cyclization of (**1a**–**1c**) with phenacylbromide, chloroacetamide, and ethylchloroacetate under microwave irradiation in one pot furnished the title compounds (**2a**–**2c**), (**3a**–**3c**), and (**4a**–**4c**) in good yields (Scheme 1).

The reaction proceeds through the nucleophilic substitution of a halogen. Then, the carbanion intermediate results after treatment by a base, which adds on the aldehydic carbon atom with simultaneous elimination of water, resulting in the formation of the cyclized products (21) (Scheme 1). The temperature was measured by introducing the thermometer inside the reaction mixture just at the end of the reaction, and the temperature was found to be 130–135 °C. To see whether these conditions work under non-microwave experiment, reactions were carried out in a pre-heated oil bath. It has been found that although the reaction did take place, the yield was quite low. The acceleration of reactions by microwave exposure results from material–wave interactions leading to thermal effects (which may be easily estimated by temperature measurements) and specific (non-purely thermal) effects. Clearly, a combination of these two contributions can be responsible for the observed effects.

Thermal effects (dielectric heating) can result from dipolar polarization as a consequence of dipole–dipole interactions between polar molecules and the electromagnetic field. They originate in the dissipation of energy into heat as an outcome of agitation and intermolecular friction of molecules when dipoles change their mutual orientation at each alternation of the electric field at a very high frequency.

This energy dissipation in the core of materials allows a much more regular repartition in temperature when compared with classical heating. Classical thermal phenomena (conduction, convention, radiation, and so forth) only play a secondary role in the a posteriori equilibration of temperature, and as a result of this, the rate of the reaction increases in MW method.

The IR absorption bands observed in the region 3000–3200 cm^{-1}, due to tautomeric form of –NH and –OH stretching frequency, and in ^1H NMR spectrum, a broad singlet due to –NH at δ 11.0 and a singlet at δ 10.5 due to –CHO group found in the starting compound (**1a**–**1c**) were absent in the final compounds.

The IR spectra of **3a** exhibited the typical ester carbonyl group absorption at 1680 cm^{-1}. The ^1H NMR (DMSO-d_6) spectrum of the compound (**3a**) displayed a triplet at δ 1.39 (3H), a quartet at 4.38 (CH_2) characteristic of an ethyl group, singlet at 8.56 (C_3–H), and singlet at δ 8.22 (C_4–H). The aromatic proton signals appeared between 7.35–8.10 ppm, indicating that the reactive partner was attached to

© 2007 NRC Canada

the quinoline moiety. The structure of **3a** was further confirmed by the appearance of the molecular-ion peak at *m*/*z* 241 (M^+).

Material and methods

Melting points were determined in open capillaries and are uncorrected. The FTIR spectra were recorded on NICOLETAVATAR 360-FTIR instrument by using KBr pellets. The ^{1}H NMR were recorded on a BRUKER AMX-400 spectrometer operating at 400 MHz and mass spectra on AGILENT LC-MSD-TRAP-XCT mass spectrometer. Elemental analyses were done on Vario EL CHNOS elemental analyzer. Focused microwave irradiations were performed with specially designed microwave oven (Biotage, Emrys Optimizer operating at 300 W) for organic synthesis.

Experimental

General microwave procedure for the synthesis of furo[2,3-*b*]quinolines

A mixture of **1a** (1.730 g, 10 mmol), phenacylbromide (1.990 g, 10 mmol), and anhyd. potassium carbonate (1.380 g, 20 mmol) was ground for uniform mixing. The mixture was then subjected to microwave irradiation in a microwave oven for 12 min at an interval of 1 min at 160 W to complete the reaction (TLC). The reaction mixture was then poured into water, stirred, and the solid obtained was filtered and dried. The crude product was recrystallized from aq. DMF to give 2.322 g (85%) of **4a**. All other compounds were prepared in a similar way with 85%–90% yield.

Physical and spectral data of the products

Furo[2,3-b]quinoline-2-carboxamide (2a)

Recrystallized from aq. DMF. Yield: 85% (MW). Mp: 226–228 °C. IR (KBr) cm^{-1}: 3330, 3145 ($CONH_2$). ^{1}H NMR (400 MHz, DMSO-d_6): 7.50 (2H, bs, –$CONH_2$), 8.55 (s, C_3–H), 8.20 (s, C_4–H), 7.33–8.12 (m, 4H, Ar–H). MS *m*/*z*: 212 (M^+). Conclusion

In conclusion, a simple microwave-assisted method has been developed for the synthesis of furo[2,3-*b*]quinolines under solvent-free conditions in presence of K_2CO_3. This microwave-irradiation method is superior from the view of the yield, reaction time, and facial workup compared with the conventional (thermal) method.

Molecular studies of the initiation and termination steps of the anionic polymerization of P=C bonds

Bronwyn H. Gillon, Kevin J.T. Noonan, Bastian Feldscher, Jennifer M. Wissenz, Zhi Ming Kam, Tom Hsieh, Justin J. Kingsley, Joshua I. Bates, and Derek P. Gates

Abstract: The initiation and termination steps of the anionic polymerization of P=C bonds have been modeled. The initiation step was investigated through the stoichiometric reaction of MesP=CPh_2 (**1**) with RLi (R = Me or *n*-Bu). In each case, the addition was highly regioselective with the formal attack of R^- at phosphorus to give the carbanion Li[Mes(R)P–CPh_2] (**3a**, R = Me; **3b**, R = *n*-Bu). To simulate the termination step in the anionic polymerization of **1**, carbanions **3a** and **3b** were quenched in situ with various electrophiles. Through these reactions, several new tertiary phosphines have been prepared, namely, Mes(Me)P–CPh_2H (**4a**), Mes(*n*-Bu)P-CPh_2H (**4b**), Mes(Me)P–CPh_2Me (**6a**), Mes(Me)P–CPh_2–$P(NEt_2)_2$ (**7a**), Mes(Me)P–CPh_2–$SiMe_2H$ (**8a**), and Mes(Me)P–CPh_2–$SiMe_3$ (**9a**). In addition, compounds **4a**, **7a**, **8a**, and **9a** were characterized by X-ray crystallography. Most of the metrical parameters are typical of tertiary phosphines; however, the P–CPh_2H bonds were elongated in all cases reflecting the considerable steric bulk surrounding this bond. Unexpectedly, an unusually large ^{31}P–^{31}P coupling constant ($^2J_{PP}$ > 200 Hz) was observed for **7a** both in solution and the solid state. This observation may be rationalized by a through space P···P interaction. This rationale is further supported by the short P···P distance [P(1)—P(2) = 2.966(1) Å; cf. $\Sigma\, r_{vdw}$ = 3.7 Å] and a small P–C–P bond angle for **7a** [P(1)–C(11)–P(1) = 99.17(9)°].

Key words: phosphaalkenes, phosphorus polymers, phosphines, anionic polymerization.

Résumé : On a développé un modèle pour les étapes d'initiation et de terminaison de la polymérisation anionique des liaisons P=C. On a étudié l'étape d'initiation par le biais de la réaction stoechiométrique du MesP=CPh_2 (**1**) avec du RLi (R = Me ou Bu). Dans chacun des cas, l'addition est très régiosélective avec une attaque formelle du R^- sur le phosphore pour conduire à la formation du carbanion Li[Mes(R)P–CPh_2] (**3a**, R = Me; **3b**, R = Bu). Dans le but de simuler l'étape de terminaison de la polymérisation du composé **1**, les carbanions **3a** et **3b** ont été piégés in situ avec divers électrophiles. Par le biais de ces réactions, on a obtenu plusieurs nouvelles phosphines tertiaires, soit: Mes(Me)P–CPh_2H (**4a**); Mes(Bu)P–CPh_2H (**4b**); Mes(Me)P–CPh_2Me (**6a**); Mes(Me)P–CPh_2–$P(NEt_2)$ (**7a**); Mes(Me)P–CPh_2–$SiMe_2H$ (**8a**) et Mes(Me)P–CPh_2–$SiMe_3$ (**9a**). De plus, on a caractérisé les composés **4a**, **7a**, **8a** et **9a** par diffraction des rayons X. La plupart des paramètres métriques sont typiques des phosphines tertiaires; toutefois, dans tous les cas, les liaisons P–CPh_2H sont allongées et cette caractéristique reflète l'encombrement stérique important aux abords de cette liaison. D'une façon inattendue, on a observé une constante de couplage ^{31}P–^{31}P exceptionnellement élevée ($^2J_{PP}$ > 200 Hz) avec le composé **7a**, tant à l'état solide qu'en solution. On peut rationaliser cette observation à l'aide d'une interaction P···P à travers l'espace. Ce raisonnement est supporté par la courte distance P···P [P(1)—P(2) = 2,966(1) Å; cf. $\Sigma\, r_{vdw}$ = 3,7 Å] et un faible angle P–C–P pour le composé **7a** [P(1)–C(11)–P(1) = 99,17(9)°].

Mots-clés : phosphaalcènes, polymères du phosphore, phosphines, polymérisation anionique.

[Traduit par la Rédaction]

Introduction

Phosphaalkenes, compounds with genuine (2p–3p) π bonds, are an intriguing class of low-coordinate phosphorus species. Although the first stable derivatives were reported in the late 1970s, interest in phosphaalkenes continues to grow because of their parallelism to the chemistry of C=C bonds and their potential applications (1–3). For example, compounds with P=C bonds are being explored as ligands in transition-metal-catalyzed reactions (4–7) and in polymer science (8–13).

Recently, we reported the polymerization of phosphaalkene **1** to afford poly(methylenephosphine) **2**, a new functional phosphine polymer with alternating phosphorus and carbon atoms in the main chain (see Scheme 1) (12). Our initial studies suggested that the polymerization of **1** required high temperatures (>150 °C), long reaction times, and high concentrations, even in the presence of radical or anionic initiators. We subsequently showed that short-chain oligomers could be obtained when **1** is treated with anionic

Scheme 1.

initiators (i.e., MeLi) in THF solution at ambient temperature (14). This solution oligomerization has now been extended to the living anionic polymerization of monomer **1** to afford homopolymer **2** and block copolymers with controllable architectures (11). To further develop the living anionic polymerization of P=C bonds and to prepare end-functionalized polymers, it is necessary to fully understand the mechanism of anionic chain growth for **1**.

To our knowledge, there is little previous work on the reaction of P=C bonds with typical anionic initiators. Of particular relevance to our studies is the synthesis of phosphine oxide **5a** from phosphaalkene **1** (15) (see Scheme 2). Specifically, treating **1** with MeLi followed by MeOH and air oxidation afforded **5a**. Both the carbanion (**3a**) and the phosphine (**4a**) were the proposed intermediates in this reaction. In a separate study, the addition of MeLi to $RP{=}C(SiMe_3)_2$ (R = Mes, *t*-Bu) afforded $Li[MeRPC(SiMe_3)_2]$, which was characterized spectroscopically (16–18). In several other studies, the addition of alkyllithium reagents across the P=C bond in phosphinines and triphosphafulvenes similarly afforded only the P-alkyl products (19). These regioselective additions are consistent with the predicted polarity of the P=C bond, based on the electronegativities of phosphorus (δ+) and carbon (δ–). Interestingly, alkyllithium reagents can also react with phosphaalkenes with preservation of the P=C bond (20).

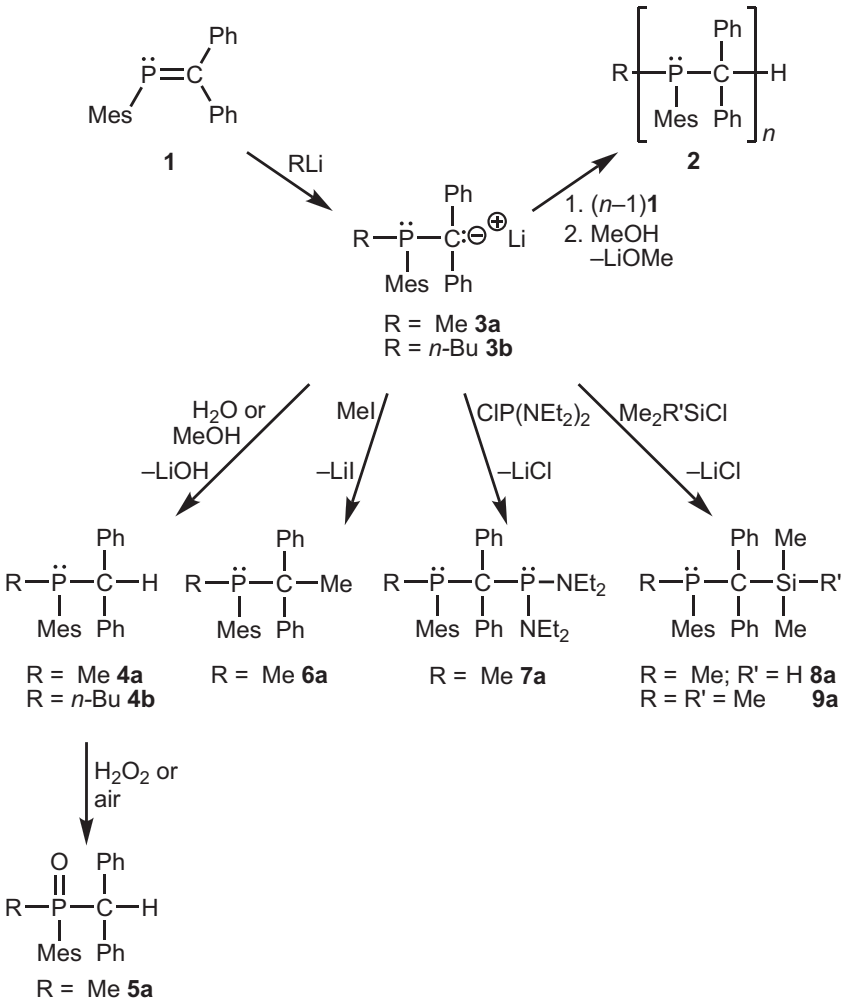
In this paper, we disclose our molecular-model studies of the initiation and termination steps of the anionic polymerization of **1**. Two initiators were chosen for the present studies: MeLi and *n*-BuLi. Although *n*-BuLi is a better initiator for the anionic polymerization of **1** (11, 12), MeLi is optimal in molecular-model studies, since the small Me substituent is more likely to afford crystalline products. The new compounds obtained may be utilized as molecular models for the development of the coordination chemistry of polymer **2**. Moreover, the development of methods to end-functionalize poly(methylenephosphine)s will afford telechelic polymers, which may function as precursors to novel block copolymers.

Results and discussion

The phosphaalkene **1** was prepared according to literature methods (21, 22). A pale-yellow solution of **1** in THF was treated with a slight excess of alkyllithium at low temperatures, resulting in an immediate color change to deep red. Analysis of the reaction mixture using $^{31}P\{^1H\}$ NMR spectroscopy confirmed the complete conversion of **1** to the carbanion **3a** (δ = −44.3) or to **3b** (δ = –31.1). These intermediates are believed to be related to the active species in the anionic polymerization of **1**.

Carbanion **3a** was quenched by addition of water or methanol to afford model compound **4a** ($\delta_{^{31}P}$ = –24.0). Additionally, $^{13}C\{^1H\}$, ^1H NMR spectroscopy, and low resolution EI-MS (M^+, m/z = 332) were consistent with the proposed structure. The ^1H NMR spectrum of **4a** shows a notably downfield doublet resonance at δ = 4.87 ($^2J_{HP}$ = 5 Hz), which is assigned to the benzylic proton. Importantly, a doublet resonance is observed in the alkyl region (δ = 1.31, $^2J_{HP}$ = 6 Hz), which is attributed to the $P\text{-}CH_3$ protons. Clearly, addition of the methyl anion occurs regioselectively at the phosphorus atom of the P=C bond. Also found in the alkyl region are sharp singlets at 2.52 and 2.21 ppm that are assigned to the ortho- and para-methyl protons of the mesityl group, respectively.

Clear, colorless crystals suitable for X-ray diffraction were obtained from the slow evaporation of a concentrated solution of **4a** in hexanes. The molecular structure and the crystallographic data appear in Fig. 1, Table 1, and the Supplementary data.[2] The molecular structure provides insight into the steric nature of the substituents around the P atom. Importantly, the cone angle of the model compound **4a** was estimated to be roughly 140°, which is comparable to that of triphenylphosphine (145°) (23).[3] The P—C bond lengths (Å) fall into the typical range for P—C single bonds [P(1)—C(1) = 1.852(1), P(1)—C(10) = 1.840(2), P(1)—C(11) = 1.882(1)] (24). Presumably, steric repulsion is responsible for the slight elongation of P(1)—C(11). For comparison, related P—C bonds where the carbon atom has two aryl substituents (i.e., $RArP\text{–}CHPh_2$) are ~1.90 Å in length (25, 26).



Using *n*-BuLi as the initiator for **1**, the related compound **4b**, was prepared by terminating carbanion **3b** with water. Again, the reaction was quantitative as suggested by $^{31}P\{^1H\}$ NMR spectroscopy (δ = –12.4). Upon workup, analytically pure **4b** was isolated in good yield (85%) as a yellow oil. Akin to the Me-initiated **4a**, the ^1H NMR spectrum of *n*-Bu-initiated **4b** showed a characteristic doublet resonance at 4.91 ppm ($^2J_{HP}$ = 5 Hz), which is assigned to the benzylic proton. A sharp singlet at 2.20 ppm is assigned to the para-methyl mesityl protons. In contrast to the sharp signals observed for **4a**, the ortho-methyl mesityl protons in **4b** exhibit a broad signal centred at 2.56 ppm. The broadening may be a consequence of restricted rotation about the P—C (ipso-mesityl) bond. Additionally, there is considerable broadening of the resonance assigned to the ortho-methyl mesityl carbon (δ = 23.8) in the $^{13}C\{^1H\}$ NMR spectrum. Another interesting feature in the ^1H NMR spectrum of **4b** is

[3] The ligand cone angle θ was estimated according to Tolman's method for an unsymmetrical phosphine ($PR_1R_2R_3$) ligand. The cone angle is the apex angle of a cylindrical cone centrally positioned 2.28 Å away from the P. The edges of the cylindrical cone encompassed the van der Waals radii of the outermost atoms on each substituent on P. Using X-ray crystallographic data for **4a**, θ was estimated to be ~140°.

Scheme 2. Initiation of **1** with alkyllithium reagents and subsequent termination with electrophiles.

the diastereotopic protons adjacent to the stereogenic phosphorus atom. In particular, they give rise to two sets of multiplets (δ = 2.02 and 1.55). Assignments were made with the help of ^{1}H–^{1}H COSY, HMQC, and HMBC experiments.

To model the end-functionalization of polymer **2**, we investigated the termination of the methyl-initiated species **3a** with different electrophiles. These end-functionalized products are envisaged as model systems for the heretofore-unknown telechelic polymers.

To obtain Me-terminated **6a**, carbanion **3a** was quenched with neat methyl iodide, affording an orange solution ($\delta_{^{31}P}$ = –13.5). Model compound **6a** was characterized by ^{1}H, ^{13}C{^{1}H}, and ^{31}P NMR spectroscopy and low resolution EI-MS (M^+, *m/z* = 346). Although analytically pure material could not be isolated, analysis by NMR spectroscopy suggests 95% or higher purity. As with butyl-initiated **4b**, the signal assigned to the ortho-methyl mesityl protons in the ^{1}H NMR spectrum (δ = 1.87) is broad. Two doublets are observed in the alkyl region (1.70 ppm, $^2J_{PH}$ = 13 Hz; 1.39 ppm, $^3J_{PH}$ = 7 Hz). The resonance with the larger P–H coupling constant is assigned to the P-CH_3 group whilst the other signal is attributed to the quenching methyl group.

Phosphine end-functionalized **7a** was prepared by quenching **3a** with a solution of $ClP(NEt_2)_2$ (1.1 equiv.) in THF. The crude diphosphine was purified by washing the solid with cold hexanes (–78 °C). As expected, the ^{31}P{^{1}H} NMR spectrum of the product showed that the phosphorus atoms are inequivalent and are observed as two doublets (P2: δ = 105.3, P1: δ = –9.4; $^2J_{pp}$ = 205 Hz). The observed coupling constant is considerably larger than in a related asymmetric diphosphine [$Ph_2PCH_2P(NC_4H_4)_2$, $^2J_{PP}$ = 147 Hz] (27) and suggests some direct P–P interaction. In contrast to the broadened signals observed in **4b** and **6a**, the ortho-methyl mesityl groups in **7a** are inequivalent in both the ^{1}H and ^{13}C{^{1}H} NMR spectra. Presumably, this results from restricted rotation due to the increased steric bulk in **7a**.

X-ray-quality crystals of **7a** were grown from toluene. Crystallographic data are shown in Fig. 2, Table 1, and the Supplementary data.[2] Interestingly, the P(1)–C(11)–P(2) bond angle (99.17(9)°) is more acute than a typical sp^3-hybridized C atom. This small bond angle, combined with the short P···P distance [P(1)—P(2) = 2.966(1) Å, cf. Σ r_{vdw} = 3.7 Å], may account for the large coupling constant ($^2J_{PP}$) observed in solution. To confirm that the structure observed in solution is the same as that in the solid state, a solid-state ^{31}P NMR spectrum was recorded, which revealed a similarly large coupling constant ($^2J_{PP}$ = 255 Hz). Surprisingly, both nitrogen atoms are planar with the sum of the bond angles at nitrogen totaling 360°. Likely, the planarity is due to donation of nitrogen electron density into P(2), and this notion is

Addition of Me_2HSiCl or Me_3SiCl to carbanion **3a** produced silane end-functionalized **8a** and **9a**, respectively. These compounds formed quantitatively from **3a** according to the ^{31}P NMR spectra of the reaction mixtures (**8a**: δ = –23.9, **9a**: δ = –25.4); however, their high solubility resulted in low isolated yields of pure product after recrystallization (**8a**: 50%, **9a**: 14%). Analogous to that mentioned previously for **7a**, the ^1H NMR signals for the ortho-methyl protons of the mesityl group were inequivalent, and two broad signals were observed (**8a**: δ = 3.1 and 1.1, **9a**: δ = 2.8 and 0.9). Importantly, for **8a**, a singlet resonance is observed at 4.58 ppm, which is assigned to the Si–H proton. Although the methyl protons of the $SiMe_3$ moiety are equivalent in **9a**, the methyl protons of the $SiMe_2H$ moiety are inequivalent in **8a**. In particular, the $SiHMe_2$ group in **8a** shows two sets of doublets at 0.10 ppm ($^3J_{HH}$ = 3 Hz) and 0.05 ppm ($^3J_{HH}$ = 3 Hz). Both **8a** and **9a** were also characterized by low resolution EI-MS (M^+: m/z = 390 for **8a** and 404 for **9a**), elemental analysis (**8a** only), and X-ray crystallography.

Crystals of **8a** and **9a** were obtained from hexanes. The molecular structures and important lengths and angles are given in Figs. 3 and 4, and additional data is provided in Table 1 and the Supplementary data.[2] As with the other model compounds, **4a** and **7a**, the P—CPh_2H bond lengths [**8a**: P(1)—C(11) = 1.902(1), **9a**: P(1)—C(1) = 1.920(1) Å] are significantly longer than the two other P—C bonds [avg. for **8a** and **9a** = 1.835(5) Å]. Similar to that discussed previously, this elongation may be attributed to steric congestion. The small size of the $SiMe_2H$ moiety compared with the $SiMe_3$ moiety is reflected by the smaller P–C–Si bond angles in **8a** [**8a**: P(1)–C(11)–Si(1) = 106.57(6)°, **9a**: P(1)–C(1)–Si(1) = 111.52(6)°]. Remarkably, these angles are much larger than the the analogous angle in diphosphine **7a** [P(1)–C(11)–P(2) = 99.17(9)°] in which we speculate there is a weak P···P interaction.

Summary

In closing, the initiation and termination steps in the anionic polymerization of P=C bonds have been modeled. The initiation step was investigated through the stoichiometric reaction of MesP=CPh_2 (**1**) with RLi (R = Me or *n*-Bu). In all cases, the addition was highly regioselective with the formal attack of R^- at phosphorus to give the carbanion Li[Mes(R)P–CPh_2] (**3a/3b**). To simulate the termination step in the anionic polymerization of **1**, carbanions **3a** and **3b** were quenched in situ with electrophiles such as a proton (from H_2O or MeOH), a methyl cation (from MeI), a phosphenium moiety (from $ClP(NEt_2)_2$), or a silylium moiety (from Me_2HSiCl or Me_3SiCl). In this way, five new tertiary phosphines and one diphosphine were accessed and will function as models for poly(methylenephosphine)s. Four of these molecules were characterized crystallographically.

In future, we will extend this chemistry to the polymer **2** with the goal of preparing end-functional telechelic polymers that can be employed in the synthesis of novel block copolymers. In addition, these new compounds will be used to prepare molecular complexes that will serve as models for macromolecular coordination complexes of poly(methylenephosphine)s.

Experimental

Materials and general procedure

All manipulations of oxygen- and (or) moisture-sensitive compounds were performed under a nitrogen atmosphere using standard Schlenk and (or) glovebox techniques. Hexanes, diethyl ether, and dichloromethane were deoxygenated with nitrogen and dried by passing through a column containing activated alumina. THF was freshly distilled from sodium/benzophenone ketyl. Distilled water and methanol were degassed prior to use. $CDCl_3$ was distilled from P_2O_5 and degassed. CD_2Cl_2 and C_6D_6 were purchased from Cambridge Isotope Laboratories and were dried over molecular

© 2007 NRC Canada

sieves (3 Å). PCl_3, $HNEt_2$, MeI, MeLi (1.6 mol/L in Et_2O), and *n*-BuLi (1.6 mol/L in hexanes) were purchased from Aldrich and used as received. Alkyllithium reagents were titrated prior to use. Me_2SiHCl and Me_3SiCl were distilled over CaH_2 and degassed prior to use. $MesP{=}CPh_2$, **1**, was prepared following literature procedures (21, 22). $ClP(NEt_2)_2$ was prepared from an adaptation of a literature method (33). A solution of $HNEt_2$ (190 mL, 1.84 mol) and CH_2Cl_2 (300 mL) was added slowly to a cooled (–78 °C) solution of PCl_3 (40 mL, 0.46 mol) in CH_2Cl_2 (250 mL). The reaction mixture was slowly warmed to room temperature and stirred for 1 h, and the solvent was removed in vacuo. The resulting solid was extracted with hexanes (3 × 150 mL) and filtered. Hexanes was removed in vacuo. The resulting oil was distilled under vacuum, yielding a colorless liquid (89 g, 92%). $^{31}P\{^1H\}$ NMR (C_6D_6, 121.5 MHz): δ = 154.8. ^1H NMR (C_6D_6, 300 MHz): δ = 2.9–3.1 (m, 8H, CH_2); 0.94 (t, 12H, $^3J_{HH}$ = 7 Hz, CH_3).

^{31}P, ^1H, and $^{13}C\{^1H\}$ NMR spectra were recorded on Bruker AV300 or AV400 spectrometers at room temperature. Solid-state NMR experiments were performed on a Bruker Avance DSX400 spectrometer operating at frequencies of 400.13 MHz and 161.98 MHz for ^1H and ^{31}P respectively, using a Bruker triple resonance 4mm MAS probe. Chemical shifts for ^{31}P NMR spectra are reported relative to H_3PO_4 as an external standard (85% in H_2O, δ = 0). Chemical shifts for $^{13}C\{^1H\}$ NMR spectra are reported relative to CD_2Cl_2 (δ = 54.0) or $CDCl_3$ (δ = 77.2). Chemical shifts for ^1H NMR spectra are reported relative to residual $CHDCl_2$ (δ = 5.32) or $CHCl_3$ (δ = 7.27) or C_6HD_5 (δ = 7.16). Mass spectra were recorded on a Kratos MS 50 instrument. Elemental analyses were performed by Mr. Minaz Lakha in the Departmental Microanalysis Facility.

Preparation of Mes(Me)P–CPh_2Li (3a)

Typical procedure

To a cooled (–78 °C) solution of phosphaalkene **1** (2.06 g, 6.5 mmol) in THF or Et_2O (~150 mL) was slowly added MeLi in Et_2O (5.2 mL, 1.5 mol/L, 7.8 mmol). Upon addition, there was an immediate color change from yellow to dark red. The cooled solution was stirred for 1 h and then warmed to room temperature where it was stirred for an additional 1 h. The concentration for use in subsequent steps was 0.043 mol/L (see preparation of **4a**). $^{31}P\{^1H\}$ NMR spectroscopy of an aliquot removed from the reaction mixture showed a single signal (δ = −42.0 in THF, −44.3 in Et_2O).

Preparation of Mes(*n*-Bu)P–CPh_2Li (3b)

To a stirred yellow solution of **1** (0.64 g, 2.0 mmol) in Et_2O (~30 mL) at –78 °C, a solution of *n*-BuLi in hexanes (3.0 mL, 1.4 mol/L, 4.2 mmol) was added rapidly. The mixture turned bright orange upon addition and was stirred at –78 °C for 30 min. Subsequently, the solution was warmed to room temperature where it was stirred for an additional 1 h. Over this time, the solution turned from bright orange to red. The reaction was monitored by $^{31}P\{^1H\}$ NMR spectroscopy, affording a single signal for **3b** (δ = –31.1). This solution was used in the preparation of **4b**.

Preparation of Mes(Me)P–CPh_2H (4a)

To a stirred red solution of **3a** in THF (150 mL, 0.043 mol/L, 6.4 mmol) was added degassed MeOH (0.4 mL). From the resultant colorless solution, THF was removed in vacuo, affording a white solid residue. The soluble fraction was extracted into hexanes (3 × 50 mL), and the resultant solution was evaporated to dryness, affording a yellow oil. The oil was dissolved in minimal hexanes at reflux (~5 mL). The solution was slowly cooled to room temperature to afford colorless crystals suitable for X-ray diffraction.

Yield: 0.50 g (24%). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 121.5 MHz): δ = –24.0 (s). ^1H NMR (CD_2Cl_2, 300 MHz): δ = 7.58 – 7.10 (m, 10H, Ph–*H*), 6.77 (s, 2H, *m*-Mes–*H*), 4.87 (d, $^2J_{HP}$ = 5 Hz, 1H, CPh_2H), 2.52 (s, 6H, *o*-Mes–CH_3), 2.21 (s, 3H, *p*-Mes–CH_3), 1.31 (d, $^2J_{HP}$ = 6 Hz, 3H, P–CH_3). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 75.5 MHz) (unassigned): δ = 146.0 (d, J_{CP} = 15 Hz), 144.3, 144.1, 144.0, 143.8 (4 × s or 2 × d), 140.4 (s), 131.4–127.4 (m), 52.8 (d, $^1J_{CP}$ = 16 Hz), 24.6, 24.4 (2 × s or 1 × d), 10.8 (d, $^1J_{CP}$ = 18 Hz, P–CH_3). MS (EI, 70 eV) *m*/*z* (%): 332 (28) [M^+], 167 (100) [$CHPh_2^+$], 165 (44) [M^+ – $CHPh_2$], 119 (12) [Mes^+].

Preparation of Mes(*n*-Bu)P–CPh_2H (4b)

To a stirred solution of carbanion **3b** in Et_2O (2.0 mmol) was added dropwise degassed H_2O until the reaction mixture turned pale yellow (several drops). The mixture was then dried with $MgSO_4$, filtered, and the soluble fraction was extracted with Et_2O (2 × 10 mL). The solvent was removed in vacuo at 60 °C to afford pure **4b** as a pale yellow oil.

Yield: 0.65 g (85 %). ^{31}P NMR (CD_2Cl_2, 121.5 MHz): δ = –12.4 (s). ^1H NMR (CD_2Cl_2, 400 MHz) (assignments made with the aid of a COSY experiment): δ = 7.57 (d, $^3J_{HH}$ = 8 Hz, 2H, Ph–*H*), 7.36 (m, 4H, Ph–*H*), 7.24 (m, 1H, Ph–*H*), 7.15 (m, 2H, Ph–*H*), 7.06 (m, 1H, Ph–*H*), 6.77 (br s, 2H, *m*-Mes–*H*), 4.91 (d, $^2J_{PH}$ = 5 Hz, 1H, CPh_2H), 2.56 (br s, 6H, *o*-Mes–CH_3), 2.20 (s, 3H, *p*-Mes–CH_3), 2.02 (m, 1H, P–C*H*H), 1.55 (m, 1H, P–C*H*H), 1.22 (m, 2H, $CH_2CH_2CH_3$), 1.08 (m, 2H, PCH_2CH_2), 0.74 (t, $^3J_{HH}$ = 7 Hz, 3H, CH_2CH_3). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 100.6 MHz) (assignments made with the aid of HMQC/HMBC experiments): δ = 143.6 (d, $^2J_{CP}$ = 12 Hz, *i*-Ph–*C*), 143.4 (d, $^2J_{CP}$ = 13 Hz, *i*-Ph–*C*), 139.5 (s, *p*-Mes–*C*), 130.2 (br, *m*-Mes–*C*), 129.7 (d, $^1J_{CP}$ = 26 Hz, *i*-Mes–*C*), 129.5 (d, $^3J_{CP}$ = 9 Hz, *o*-Ph–*C*), 129.1 (s, *o*-Mes–*C*), 128.9 (d, $^3J_{CP}$ = 9 Hz, *o*-Ph–*C*), 128.6 (s, *p*-Ph–*C*), 127.1 (d, $^4J_{CP}$ = 2 Hz, *m*-Ph–*C*), 126.5 (d, $^4J_{CP}$ = 2 Hz, *m*-Ph–*C*), 51.6 (d, $^1J_{CP}$ = 16 Hz, *C*HPh_2), 30.2 (d, $^2J_{CP}$ = 20 Hz, P–CH_2CH_2), 25.5 (d, $^1J_{CP}$ = 16 Hz, P–*C*H_2), 24.7 (d, $^3J_{CP}$ = 13 Hz, $CH_2CH_2CH_3$), 23.8 (v br, *o*-Mes–*C*H_3), 21.2 (s, *p*-Mes–*C*H_3), 14.1 (s, CH_2CH_3). MS (EI, 70 eV) *m*/*z* (%): 374 (29) [M^+], 167 (100) [CPh_2H^+], 151 (24) [$PMes^+$]. Found (calcd.) (%): C, 83.81 (83.39); H, 8.55 (8.34).

Synthesis of Mes(Me)P–CPh_2Me (6a)

MeI (1.6 mL, 26 mmol) was added dropwise to a solution of **3a** in Et_2O (160 mL, 0.16 mol/L, 26 mmol). The solution was stirred for 30 min over which time its color changed from red to orange. The solvent was removed in vacuo, the soluble fraction was extracted with hexanes, and evaporated

© 2007 NRC Canada

to dryness. The product was purified by sublimation (140 °C, 0.1 mmHg).

Yield = 5.7 g (64 %). ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ = –13.5 (s). ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 7.47 (m, 2H, Ph–*H*), 7.21 (m, 6H, Ph–*H*), 7.01 (m, 2H, Ph–*H*), 6.74 (s, 2H, Mes–*H*), 2.23 (s, 3H, *p*-Mes–CH_3), 1.87 (br, 6H, *o*-Mes–CH_3), 1.70 (d, $^2J_{PH}$ = 13 Hz, 3H, P–CH_3), 1.39 (d, $^3J_{PH}$ = 7 Hz, 3H, CPh_2CH_3). ^{13}C{^{1}H} NMR ($CDCl_3$, 75.5 MHz,) (unassigned): δ = 148.3 (d, J_{CP} = 14 Hz), 146.3 (d, J_{CP} = 16 Hz), 144.7 (s), 138.8 (s), 129.9 (s), 128.7–127.4 (m), 125.8 (s), 125.4 (s), 49.1 (d, J_{CP} = 24 Hz), 28.8 (d, J_{CP} = 15 Hz), 23.5 (d, J_{CP} = 18 Hz), 20.8 (s), 9.0 (d, $^1J_{CP}$ = 21 Hz, P–CH_3). MS (EI, 70 eV) *m*/*z* (%): 346 (7) [M^+], 181 (100) [M^+ – P(Mes)(CH_3)], 165 (16) [M^+ – $CPh_2(CH_3)$], 119 (5) [Mes^+].

Preparation of Mes(Me)P–CPh_2–$P(NEt_2)_2$ (7a)

To a cooled (0 °C) solution of **3a** in THF (20 mL, 0.32 mol/L, 6.4 mmol) was slowly added a solution of $ClP(NEt_2)_2$ (1.50 g, 7.1 mmol) in THF (20 mL). An aliquot was removed from the yellow reaction mixture for ^{31}P NMR spectroscopic analysis. After evaporation of the volatiles in vacuo, the soluble fraction was extracted into toluene (30 mL). Removal of the toluene in vacuo afforded the crude product, which was washed with hexanes at –78 °C two times. Crystals suitable for X-ray diffraction were obtained from slow evaporation of a saturated toluene solution.

Yield: 1.73 g (54%). ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ = 105.3 (d, $^2J_{PP}$ = 205 Hz, *P*N_2), –9.4 (d, $^2J_{PP}$ = 205 Hz, *P*Mes). ^{31}P MAS NMR (8.5 kHz, recycle delay of 20 s, 162.0 MHz): δ = 108.3 (d, $^2J_{PP}$ = 255 Hz, *P*N_2), –7.9 (d, $^2J_{PP}$ = 255 Hz, *P*Mes). ^{1}H NMR ($CDCl_3$, 400 MHz) δ = 7.79 (br, 2H, Ph–*H*), 7.43 (br, 2H, Ph–*H*), 7.28–7.14 (m, 6H, Ph–*H*), 6.90 (br, 1H, *m*-Mes–*H*), 6.55 (br, 1H, *m*-Mes–*H*), 3.01–2.52 (m, 11H, NCH_2 and *o*-Mes–CH_3), 2.25 (s, 3H, *p*-Mes–CH_3), 1.38 (d, $^2J_{PH}$ = 9 Hz, 3H, P–CH_3), 0.97 (m, 9H, NCH_2CH_3 and *o*-Mes–CH_3), 0.84 (t, 6H, $^3J_{HH}$ = 7 Hz, NCH_2CH_3). ^{13}C{^{1}H} NMR ($CDCl_3$, 100.6 MHz) (assignments made with the aid of HMQC/HMBC experiments): δ = 147.7 (s, *o*-Mes–*C*), 141.3 (br, Ar–*C*), 141.0 (t, J_{PC} = 5 Hz, Ar–*C*), 138.6 (s, *p*-Mes–*C*), 131.9–127.6 (m, Ar–*C*), 126.9 (s, Ar–*C*), 126.4 (s, Ar–*C*), 124.8 (d, J_{PC} = 4 Hz, Ar–*C*), 63.9 (dd, $^1J_{PC}$ = 46 and 34 Hz, P–*C*Ph_2–P), 44.5 (d, $^2J_{PC}$ = 21 Hz, N–*C*H_2), 44.0 (d, $^2J_{PC}$ = 20 Hz, N–*C*H_2), 26.2 (br s, *o*-Mes–*C*H_3), 21.6 (br s, *o*-Mes–*C*H_3), 21.0 (s, *p*-Mes–*C*H_3), 14.5 (d, $^3J_{PC}$ = 3 Hz, NCH_2CH_3), 14.0 (d, $^3J_{PC}$ = 5 Hz, NCH_2CH_3), 9.7 (t, $^1J_{PC}$ = 22 Hz, P–*C*H_3).

Preparation of Mes(Me)P–CPh_2–$SiMe_2H$ (8a)

To the red solution of **3a** (40 mL, 0.079 mol/L, 3.2 mmol) in THF (40 mL), neat Me_2HSiCl (0.5 mL, 4.6 mmol) was added. An immediate color change to yellow was observed. The solvent was removed in vacuo, and the residue was dissolved in hexanes (3 × 5 mL). Following solvent evaporation, the crude product was recrystallized from a minimal amount of hot hexanes in an inert atmosphere to afford large colorless crystals.

Yield: 0.62 g (50%). ^{31}P NMR (C_6D_6, 121.5 MHz): δ = –23.9 (s). ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.70 (br s, 2H, Ph), 7.3–6.5 (m, 10H, Ph and *m*-Mes–*H*), 4.58 (br s, 1H, Si–*H*), 3.1 (br s, 3H, *o*-Mes–CH_3), 2.18 (s, 3H, *p*-Mes–CH_3), 1.45 (d, $^2J_{PH}$ = 8 Hz, 3H, P–CH_3), 1.1 (br s, 3H, *o*-Mes–CH_3), 0.10 (d, $^3J_{HH}$ = 3 Hz, 3H, Si–CH_3), 0.05 (d, $^3J_{HH}$ = 3 Hz, 3H, Si–CH_3). ^{13}C{^{1}H} NMR (CD_2Cl_2, 75.5 MHz) (assignments made with the aid of HMQC/HMBC experiments): δ = 147.6 (s, Mes–*C*), 147.3 (s, Mes–*C*), 142.5 (s, Mes–*C*), 142.1 (d, $^1J_{PC}$ = 7 Hz, *i*-Mes–*C*), 139.5 (s, Mes–*C*), 131–128 (m, Ph–*C*), 125.7 (s, Ph–*C*), 45.7 (d, $^1J_{PC}$ = 45 Hz, P*C*Ph_2), 21.2 (s, *p*-Mes–*C*H_3), 7.81 (d, $^1J_{PC}$ = 23 Hz, P*C*H_3), –3.96 (d, $^3J_{PC}$ = 5 Hz, Si*C*H_3), –5.66 (d, $^3J_{PC}$ = 6 Hz, Si*C*H_3). MS (EI, 70 eV) *m*/*z* (%): 390 (38) [M^+], 375 (17) [M^+ – CH_3], 332 (45) [M^+ – $SiMe_2$], 223 (69) [M^+ – PMesMe], 167 (100) [CPh_2^+]. Found (calcd.) (%): C, 77.20 (76.88); H, 7.64 (8.00).

Preparation of Mes(Me)P–CPh_2–$SiMe_3$ (9a)

To the red solution of **3a** in Et_2O (22 mL, 0.14 mol/L, 3.2 mmol), neat Me_3SiCl (0.4 mL, 3.2 mmol) was added. An immediate color change to yellow was observed accompanied by the formation of a white precipitate. The solution was filtered, the solvent was removed in vacuo, and the soluble fraction was extracted into Et_2O (3 × 15 mL). The Et_2O was removed in vacuo. The crude product was dissolved in a minimal amount of hexanes, and slow evaporation afforded colorless crystals suitable for X-ray crystallography.

Yield = 0.18 g (14%). ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ = –25.4 (s). ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 7.6 (br s, 2H, Ph), 7.3–7.1 (m, 8H, Ph), 6.8 (br s, 2H, *m*-Mes–*H*), 2.8 (br s, *o*-Mes–CH_3), 2.22 (s, 3H, *p*-Mes–CH_3), 1.33 (d, $^2J_{PH}$ = 8 Hz, 3H, P–CH_3), 0.9 (br s, 3H, *o*-Mes–CH_3), –0.02 (s, 9H, $Si(CH_3)_3$). MS (EI, 70 eV) *m*/*z* (%): 404 (100) [M^+], 389 (26) [M^+ – CH_3], 331 (44) [M^+ – $SiMe_3$], 167 (39) [M^+ – CPh_2SiMe_3], 73 (34) [M^+ – MesMePCPh_2].

X-ray crystallography

Crystal data and refinement parameters are listed in Table 1. Additional data are available in the Supplementary data.[2] All single crystals were immersed in oil and mounted on a glass fiber. Data for **4a** were collected on a Bruker X8 APEX diffractometer with graphite-monochromated Mo Kα radiation. Data for **7a**, **8a**, and **9a** were collected on a Bruker X8 APEX II diffractometer. Data were collected and integrated using the Bruker SAINT software package (34). All structures were solved by direct methods and subsequent Fourier difference techniques and were refined anisotropically for all non-hydrogen atoms. Hydrogen atoms were included in idealized positions and refined isotropically except in **4a** where they were not refined. All data sets were corrected for Lorentz and polarization effects. All calculations were performed using the SHELXTL crystallographic software package from Bruker-AXS (35).

Compounds **4a**, **8a**, and **9a** did not show any crystallographic complexity. Compound **7a** was a split crystal, and cell_now (within SAINT) was used to determine that the second domain was rotated from the first domain by 4.4°. Only the first domain was integrated because there was little or no overlap between the two lattices. One of the ethyl groups was disordered at C(28) and C(29). The disorder at carbon was modeled by including two additional carbon at-

Structural finding of *R/S*-3,4-dihydro-2,2-dimethyl-6-halo-4-(substituted phenylaminocarbonylamino)-2*H*-1-benzopyrans as selective pancreatic β-cells $K_{ATP\text{-}p\beta}$ channel openers

Sk. Mahasin Alam, Soma Samanta, Amit Kumar Halder, Soumya Basu, and Tarun Jha

Abstract: *R*/*S*-3,4-Dihydro-2,2-dimethyl-6-halo-4-(substituted phenylaminocarbonyl-amino)-2*H*-1-benzopyrans are pancreatic β-cells potassium ($K_{ATP\text{-}p\beta}$) channel openers with inhibitory effect on insulin secretion. To find the more active and effective benzopyrans as selective potassium ($K_{ATP\text{-}p\beta}$) channel openers towards the pancreatic tissues, quantitative structure–activity relationships (QSAR) study was performed using E-state and R-state indices along with Wang–Ford charges, *n*-octanol/water partition coefficient, molar refractivity, and indicator parameters. QSAR models were developed by statistical techniques, e.g., multiple linear regression (MLR), principle component regression analysis (PCRA), and partial least squares (PLS) analysis. The generated equations were validated by the leave-one-out cross-validation method. The models show the importance of ETSA indices of atom numbers 16, 17, 18, 19, 21 as well as 22. The positive coefficient of S_{16}, S_{17}, S_{18}, S_{19}, S_{21}, and S_{22} indicate that with the increase of the value of E-state indices, desired activity decreases. RTSA index is also important for the biological activity, and the atom numbers 16, 17, 18, 19, 20 and 22 are involved in van der Waals interactions. RTSA index also possesses negative impact on the inhibition of residual insulin secretion. Wang–Ford charges of some particular atoms are also important for the inhibition. Increase of *n*-octanol/water partition coefficients of compounds inhibit insulin secretion, and the presence of chlorine atom at *m*- and *p*- positions of the phenyl ring B is necessary for the inhibition of residual insulin secretion.

Key words: benzopyran derivatives, potassium channel openers, PCRA, PLS, QSAR.

Résumé : Les *R*/*S*-3,4-dihydro-2,2-diméthyl-6-halogéno-4-(phénylaminocarbonylamino substitué)-2*H*-1-benzopyranes provoquent l'ouverture des canaux du potassium des cellules β du pancréas ($K_{ATP\text{-}p\beta}$) et de ce fait conduisent à une inhibition de la sécrétion de l'insuline. Dans le but de trouver des benzopyranes plus actifs et plus efficaces pour l'ouverture des canaux du potassium des cellules β du pancréas ($K_{ATP\text{-}p\beta}$) vis-à-vis des tissus du pancréas, on a réalisé une étude « QSAR » en utilisant des indices des états E et R ainsi que les charges de Wang-Ford, le coefficient de partage *n*-octanol/eau, la réfractivité molaire et les paramètres indicateurs. On a développé les modèles « QSAR » à l'aide de techniques statistiques, soit la régression linéaire multiple (RLM), l'analyse de la régression du composant principal (ARCP) et l'analyse des moindres carrés partiels (MCP). On a validé les équations générées par la méthode de validation croisée où on ne tient pas compte d'une valeur. Les modèles mettent en évidence l'importance des indices « ETSA » des numéros atomiques 16, 17, 18, 19, 21 ainsi que 22. Le coefficient positif de S_{16}, S_{17}, S_{18}, S_{19}, S_{21}, et S_{22} indique que l'augmentation de la valeur des indices de l'état E est accompagnée d'une diminution de l'activité recherchée. L'indice « RTSA » est aussi important pour l'activité biologique et les numéros 16, 17, 18, 19, 20 et 22 sont impliqués dans les interactions de van der Waals. L'indice « RSTA » possède aussi un impact négatif sur l'inhibition de la sécrétion résiduelle de l'insuline. Les charges de Wang-Ford de certains atomes sont aussi importants pour l'inhibition. L'augmentation des coefficients de partage *n*-octanol/eau des composés inhibe la sécrétion de l'insuline et la présence d'atomes de chlore dans les positions *m*- et *p*- du noyau aromatique B est nécessaire pour l'inhibition de la sécrétion résiduelle de l'insuline.

Mots-clés : dérivés benzopyrane, ouverture des canaux du potassium, ARCP, MCP, « QSAR ».

Introduction

Potassium channels are ion channels. The specificity of ion channels depends on the selectivity towards a specific inorganic ion and these are gated by the specific stimulus. Depending on the stimulus, these may be of voltage gated, mechanically gated or ligand gated. The ligand is either a neurotransmitter or a nucleotide (1). Potassium (K^+) channels have an entrance pore of about 0.4 nm (which is the size of dehydrated potassium ion) (2). When K^+ channels are opened, the cell hyperpolarizes i.e., inhibited. K^+ channel blocking, on the other hand, leads to the depolarization. K^+ channels are mainly of four types i.e., voltage gated (delayed rectifier K_V, rapid delayed rectifier or K_{VR}, slow delayed rectifier or K_{VS}, transient outward current or K_A, inward rectifier or K_{IR}), calcium activated (high conductance BK_{Ca}, intermediate conductance IK_{Ca}, small conductance SK_{Ca}), receptor coupled (muscarinic activated K_m) and ATP sensitive K^+ channels (K_{ATP}) (3). From the clinical point of view, K_{ATP} are of particular interest. These were first found in heart (3), now known to be present in wide varieties of tissues including the secretary cells, e.g., insulin secreting pancreas β cells ($K_{ATP\text{-}p\beta}$), neurons, skeletal and smooth muscles. With an increase in the cellular ATP levels, these channels are blocked and the membrane potential decreases. When the [ATP]:[ADP] ratio falls, potassium efflux is increased and the hyperpolarization of the cell occurs which prevents the voltage operated Ca^{2+} channel from opening (4). The structure of the K_{ATP} channel is a subunit organization consisting of an inward rectifier channel K_{ir} (either K_{ir} 6.1 or K_{ir} 6.2) with sulfonylurea receptors (SUR) subunit. The combination of K_{ir} and SUR constitute a pore-forming octameric complex. SUR is a member of ABC transporter protein and is a transmembrane protein containing 15 transmembrane sequences and two large cytosolic loops. SUR receptors have two isoforms, SUR1 (high affinity) and SUR2 (SUR2A and SUR2B – both low affinity). SUR1/K_{ir} 6.2 constitute the neuronal and the pancreatic β cells, SUR2A/K_{ir} 6.2 are present in the cardiac K_{ATP} channels and SUR2B/K_{ir} 6.1 or 6.2 constitute the vascular smooth muscle K_{ATP} channels (5).

Because K_{ATP} channel activation leads to the hyperpolarization of cells, it results in different physiological responses like smooth muscle relaxation, vasodilatation, insulin release inhibition, shortening of cardiac action potential. Thus, potassium (K_{ATP}) channel openers (PCOs), which antagonize the action of ATP, can be used in several disorders like hyperglycemia, hypertension, angina pectoris, asthma etc. Nicorandil (the drug which combines the action of K_{ATP} channel opening and nitrovasodilatory effects) is used in angina pectoris and hypertension. Cromokalim and its active isomer lemakalim are also used in hypertension (6). Minoxidil and diazoxide are used in the treatment of severe hypertension and in alopecia (7). Some benzopyran derivatives are now being used in the treatment of asthma. *R*/*S*-3,4-dihydro-2,2-dimethyl-6-halo-4-(substituted phenylaminocarbonylamino)-2*H*-1-benzopyrans are a new series of potassium ($K_{ATP\text{-}p\beta}$) channel openers selective towards pancreatic β cells (8).

To find the structural requirements for the more active and selective pancreatic β-cells potassium ($K_{ATP\text{-}p\beta}$) channel openers, quantitative structure-activity relationships (QSAR) study was performed on *R*/*S*-3,4-dihydro-2,2-dimethyl-6-halo-4-(substituted phenylamino-carbonylamino)-2*H*-1-benzopyrans as a part of our composite program of rational drug design (9–18). The general structure of these compounds is shown in Fig. 1.

Fig. 1. General structure of *R*/*S*-3,4-dihydro-2,2-dimethyl-6-halo-4-(substituted phenylaminocarbonylamino)-2*H*-1-benzopyrans with arbitrary numbering.

Three statistical analyses, e.g., multiple linear regression analysis (MLR), principle component regression analysis (PCRA) and partial least square (PLS) were used in the QSAR study to find out the structural requirement of this series of compounds.

Materials and methods

Dataset and parameters

The percentage of residual insulin secretion (PRIS) data of *R*/*S*-3,4-dihydro-2,2-dimethyl-6-halo-4-(substituted phenylaminocarbonylamino)-2*H*-1-benzopyrans was collected from the published work of Sebille et al. (8). PRIS is the measure of the percentage of insulin release from pancreatic islets isolated from adult fed Wistar rats. PRIS was converted to the logarithmic scale. The logarithm of the percentage of residual insulin secretion (Log PRIS) was used as the response variable in the present study and shown in Table 1. For the measurement of insulin secretion, isolated pancreatic islets from rats were used (8). Insulin release was measured radio-immunologically and expressed in terms of the percentage of residual insulin secretion (PRIS).

Topological indices like ETSA and RTSA indices (19–22) as well as Wang–Ford charges (q_x), n-octanol/water partition coefficient (log *P*), molar refractivity (MR) and indicator parameters are used as the predictor variables. ETSA and RTSA indices were calculated using the computer program "Mouse" (23). In the program, molecular connection table in a specified format is given along with the intrinsic state values of different atoms as inputs. Common atoms of molecule were numbered consecutively keeping the serial number same in all molecules. Wang–Ford charges, n-octanol/water partition coefficient (Log *P*) and molar refractivity (MR) were calculated using *Chem* 3D *Pro* package (24). Wang–Ford charges (q_x) were calculated from the energy minimized geometry. The energy minimization was done by using RHF (restricted Hartree-Fock: closed shell) wave function. Log *P* and MR were calculated based on Ghose and Crippen's fragmentation method. Indicator parameters were also used to find the role of the specific substituent(s)

[a]PRIS indicates percentage of residual insulin secretion (mean ± SEM).

at the specific position(s) towards the biological activity. I_ClR_2 and I_ClR_3 indicate the presence or the absence of chlorine atom at R_2 and R_3 positions respectively in the general structure.

Statistical analysis

Three statistical methods i.e., MLR, PCRA, and PLS were employed to develop QSAR models and briefly described in the following sections.

Multiple linear regressions (MLR)

The correlation analysis was carried out on the data set containing the response variable and all descriptors. Intercorrelated parameters were removed. All possible combinations of parameters were considered for the multiple regression analysis (25). Statistical qualities of MLR equations were judged by parameters like correlation coefficient (R), adjusted R^2 (R^2_a), variance ratio (F), probability factor related to F-ratio (p), and standard error of estimate (s).

Principle component regression analysis (PCRA)

In PCRA, the factor scores are used as the independent variables. Factor scores were obtained from factor analysis after *VARIMAX* rotation (26–29). The factor analysis was carried out on the data matrix containing all the independent variables. Regression analysis was performed using factor scores as the predictor variables. The factor loadings of all the variables are shown in Table 2.

Partial least square (PLS)

In PLS, the latent variables or components were determined which are linear combinations of the original variables (30). To avoid over fitting, the number of components were selected by the cross-validation method. The predicted variables were selected on the basis of the standardized regression coefficients. Variables with smaller standardized coefficients were removed from PLS regression. The PLS regression model was developed using variables with the larger standardized coefficients.

Validation of QSAR models

The predictive powers of MLR, PCRA and PLS models were validated by Leave-One-Out (LOO) cross-validation method. The predicted residual sum of square (*PRESS*), total sum of squares (*SSY*), cross-validated R^2 (R^2_{cv}), standard deviation error of prediction (*SDEP*) and Standard error of

PRESS (S_{PRESS}) were considered for the validation of QSAR models.

Results and discussion

The results of three statistical methods used to develop the QSAR models were discussed below under three different sections. For all statistical methods, the logarithm of the percentage of residual insulin secretion (log PRIS) was used as the response variable and shown in Table 1. The ETSA indices, RTSA indices and Wang–Ford charges of the selected atoms, n-octanol/water partition coefficients (log *P*) and indicator variables were used as the predictor variables to develop the QSAR models.

Multiple Linear Regressions (MLR)

Multiple Linear Regression analysis was performed to develop the QSAR models. Intercorrelated parameters were removed based on the correlation analysis. All the possible combinations of parameters were considered for the development of QSAR equations. Among all generated models four models are considered as better models based on the statistical qualities. Parameters selected for MLR models are listed in Table 3. Correlation matrix among the response variable and the selected parameters are shown in Table 4.

Combination of ETSA indices and log *P* yields the following equation:

$$\text{Log PRIS} = -4.676\ (\pm 0.575) + 2.134\ (\pm 0.233)\ S_{16} + 0.921\ (\pm 0.156)\ S_{19} + 0.067\ (\pm 0.020)\ S21 - 0.378\ (\pm 0.026)\log P \quad [1]$$

$n = 30$, $R = 0.968$, $R^2 = 0.937$,

$R^2_a = 0.927$, $F(4,25) = 92.851$, $p < 0.00001$,

s = 0.052, $SSY = 1.088$, $PRESS = 0.101$,

$R^2_{cv} = 0.907$, $SDEP = 0.058$, $S_{PRESS} = 0.064$.

where n is the number of data point. S_{16}, S_{19}, and S_{21} are the E-state indices of atoms 16, 19, and 21. Log *P* is the n-octanol/water partition coefficient of compounds in logarithmic scale. R, R^2_a, F, p, s, $PRESS$, SSY, R^2_{cv}, $SDEP$, S_{PRESS} are correlation coefficient, adjusted R^2, variance ratio, probability factor related to F-ratio and standard error of estimate, predicted residual sum of square, total sum of squares, cross-validated R^2, standard deviation error of prediction, and standard error of PRESS. The values mentioned in parentheses are the 95% confidence intervals of the regression coefficients. All regression coefficients are significant at 95% level as supported by their *t*- and *p*-values (shown in Table 5). The calculated values according to eq. [1] are listed in Table 6. Equation [1] explains 92.7% and predicts 90.7% of variances of the activity. The positive coefficient of S_{16}, S_{19} and S_{21} indicate the negative contribution of these indices towards the inhibition of insulin secretion. The negative coefficient of log *P* indicates that with the increase in

[a] S_{16}, S_{17}, S_{18}, S_{19}, and S_{21} indicate ETSA indices of atom numbers 16, 17, 18, 19, and 21, respectively.
[b] R_{20} indicates RSTA index of atom number 20.
[c] q_{18}, q_{19}, and q_{20} indicate Wang–Ford charges of atom numbers 18, 19, and 20, respectively.
[d] log P indicates the partition coefficient.
[e] I_ClR_2 and I_ClR_3 indicate presence or absence of chlorine atom at meta- and para- position of phenyl ring B.

the value of log P the inhibition of residual insulin secretion increases.

An attempt was also made to develop another model using combination of RTSA index of the atom 20 (R_{20}) containing the substitution R_3 with eq. [1] which yields the following equation:

[2] Log PRIS = – 4.540 (±0.536) + 2.092 (±0.217) S_{16} + 0.811 (±0.153) S_{19} + 0.090 (±0.021) S_{21} + 0.022 (±0.010) R_{20} – 0.361 (±0.025) log P

n = 30, R = 0.974, R^2 = 0.948, R^2_a = 0.937, $F(5,24)$ = 87.602 $p < 0.00001$, s = 0.049, SSY = 1.088, $PRESS$ = 0.090, R^2_{cv} = 0.917, $SDEP$ = 0.055, S_{PRESS} = 0.061.

The values mentioned in parentheses are the 95% confidence intervals of the regression coefficients. All regression coefficients are significant at 95% level as supported by their t- and p-values (shown in Table 5). Equation [2] explains 93.7% and predicts 91.7% of variances of the activity. The calculated values according to eq. [2] are presented in Table 6. R_{20} is the RTSA index of the atom 20. The positive coefficient of R_{20} indicates the negative contribution of R_{20} towards the inhibition of the residual insulin secretion.

Another model was developed using ESTA index, Wang–Ford charges, partition coefficient and the indicator parameter and is given below:

[3] Log PRIS = – 1.039 (±0.343) + 1.895 (±0.214) S_{18} – 1.101 (±0.200) q_{19} – 0.367 (±0.108) q_{20} – 0.192 (±0.031) log P – 0.273 (±0.037) I_ClR_2

n = 30, R = 0.969, R^2 = 0.939, R^2_a = 0.927, $F(5,24)$ = 74.399, $p < 0.00001$, s = 0.052, SSY = 1.088, $PRESS$ = 0.118, R^2_{cv} = 0.892, $SDEP$ = 0.063, S_{PRESS} = 0.070.

The values mentioned in parentheses are the 95% confidence intervals of the regression coefficients. All regression

coefficients are significant at 95% level as supported by their t- and p-values (shown in Table 5). Equation [3] explains 92.7% and predicts 89.2% of variances of the activity. The calculated values according to the eq. [3] are given in Table 7. S_{18} is ETSA index of the atom number 18; q_{19} and q_{20} are the Wang-ford charges of atom numbers 19 and 20 respectively. The positive coefficient of S_{18} suggests that with the increase in the value of S_{18} the inhibition of residual insulin secretion decreases. The negative coefficients of q_{19} and q_{20} indicate that the higher negative charges on atoms 19 and 20 are more detrimental for the inhibition of residual insulin secretion. The presence of chlorine atom at R_2 position of the general structure is favorable for the inhibition of residual insulin secretion as suggested by the negative coefficient of I_ClR_2.

Two indicator parameters were used with ETSA index of atom number 17 (S_{17}) as well as Wang–Ford charge of the atom number 18 (q_{18}) and log P to generate a fruitful QSAR model. These yield the eq. [4] as follows:

[4] Log PRIS = 1.864 (±0.088) + 0.783 (±0.120) S_{17} + 0.523 (±0.118) q_{18} – 0.123 (±0.026) log P – 0.343 (±0.031) I_ClR_2 – 0.306 (±0.030) I_ClR_3

n = 30, R = 0.978, R^2 = 0.957, R^2_a = 0.948,

$F(5,24)$ = 107.42, p < 0.00001, s = 0.044,

SSY = 1.088, $PRESS$ = 0.086, R^2_{cv} = 0.921,

$SDEP$ = 0.054, S_{PRESS} = 0.060.

Equation [4] explains 94.8% and predicts 92.1% of variances of the activity. The calculated values according to eq. [4] are presented in Table 7. The values mentioned in parentheses are the 95% confidence intervals of the regression coefficients. All regression coefficients are significant at 95% level as supported by their t- and p-values (shown in Table 5). The positive coefficient of S_{17} suggests that the higher value of S_{17} is unfavorable for the inhibition of the residual insulin secretion. The positive coefficient of q_{18} indicates that the higher negative charge on the atom 18 is

conducive for the inhibition. The negative coefficient of I_ClR_3 indicates that chlorine atom at para position of phenyl ring B is required for the inhibition of the residual insulin secretion. Equation [4] is the best MLR models amongst all developed MLR models.

Principle Component Regression Analysis (PCRA)

When factor scores were used as the independent parameters in multiple linear regressions, the following equation was obtained:

[5] Log PRIS = 1.774 (±0.010) + 0.083 (±0.010) f2 + 0.076 (±0.010) f3 – 0.060 (±0.010) f4 + 0.024 (±0.010) f6 + 0.130 (±0.010) f7 + 0.036 (±0.010) f9

$n = 30$, $R = 0.966$, $R^2 = 0.933$, $R^2_a = 0.915$, $F(6,23) = 53.000$, $p < 0.00001$ $s = 0.057$, SSY = 1.088, $PRESS = 0.119$, $R^2_{cv} = 0.891$, $SDEP = 0.063$, $S_{PRESS} = 0.072$.

Equation [5] explains 91.5% and predicts 89.1% of the variances of the activity. The calculated values of log PRIS according to eq. [5] are listed in Table 8. The values mentioned in parentheses are the 95% confidence intervals of the regression coefficients. All regression coefficients are significant at 95% level as supported by their *t*- and *p*-values (shown in Table 5). Any one factor contains the information for different descriptors. In eq. [5], the factor scores are used instead of the original variables. As the factor score contains information for the different descriptors, the loss of information is thus avoided. From the factor scores used, the significance of the original variable for the activity can be obtained. The factor score 2 indicates the importance of the RTSA indices of the atom numbers 16, 17, Wang–Ford charge of the atom numbers 14, 15, 16, 17, 18, and 22. The factor score 3 indicates the importance of Wang–Ford charge of the atom numbers 6, 7, 8 and 12. The factor score 4 indicates the importance of the ETSA index of the atom number 22, the RTSA index of the atom number 22 and Wang–Ford charge of the atom number 11. The factor score 6 indicates the importance of Wang–Ford charge of the atom numbers 19, 20, and 21. The factor score 7 indicates the importance of the ETSA index of the atom numbers 18 and 19. The factor score 9 indicates the importance of the RTSA index of

the atom number 18. The factor loadings of variables are shown in Table 2. All coefficients of parameters and intercepts in these equations are significant at more than 95% level as supported by their *t*- and *p*- values. *t*- and *p*- values of eqs. [1]–[5] are shown in Table 5.

Partial Least Squares (PLS)

The number of the optimum components (latent variables) was found to be 2 to obtain the final equation and optimization was done by cross-validation method. Based on standard regression coefficients, the following variables were selected for the final equation.

$$\text{[6]}\quad \text{Log PRIS} = -5.292 + 0.495\,S_{16} + 0.256\,S_{17} + 0.578\,S_{18} + 0.464\,S_{19} + 0.060\,S_{21} + 0.355\,R_{16} + 0.322\,R_{17} + 0.170\,R_{19} - 1.876\,q_6 - 0.101\log P - 0.133\,I_\mathrm{ClR}_2 - 0.14672\,I_\mathrm{ClR}_3$$

$n = 30$, $R = 0.972$, $R^2 = 0.944$, $R^2_a = 0.904$, $R^2_{cv} = 0.910$, $F = 229.19$, $p < 0.0001$, $s = 0.060$, SSY = 1.088, PRESS = 0.098, SDEP = 0.057, $S_{PRESS} = 0.076$.

Equation [6] explains 90.4% and predicts 91.0% of variances of the activity. The positive coefficient of S_{16}, S_{17}, S_{18}, S_{19}, S_{21}, R_{16}, R_{17}, and R_{19} indicate that the higher values of these parameters are detrimental for the inhibition of the residual insulin secretion. The negative coefficient of q_6 suggests that the higher negative charge on the atom number 6 is detrimental for the inhibition. The negative coefficient of log *P* indicates that with the increase in the value of log *P* the inhibition of the residual insulin secretion increases.

All models are validated by the leave one out (LOO) cross-validation method. The observed (Obs), calculated (Calc), residual (Res), predicted residual (Pres) and LOO-predicted (Pred) activities of eqs. [1]–[6] are shown in Tables 6, 7, and 8.

Conclusion

The results of QSAR analysis show the importance of ETSA indices of the atom numbers 16, 17, 18, 19, and 21. ETSA index of atom 22 is also important as observed in eq. [5]. As ETSA indices contain the electronic information,

these atoms may involve in the electronic interaction of compounds with receptors for inhibition of residual insulin secretion. The results also show the importance of RTSA indices of the atom numbers 16, 17, 18, and 20. R-state indices of atoms 19 and 22 are also important from the point of eq. [5]. Since the R-state index of an atom encodes the dispersive/van der Waals interactions with the active sites, the atom numbers 16, 17, 18, 19, 20, and 22 may be involved in the dispersive/van der Waals interactions with the receptor for the inhibition. Wang–Ford charge of the atom numbers 19 and 20 are important for the inhibition of residual insulin secretion. Similarly Wang–Ford charges of atoms 6, 7, 8, 11, 12, 14, 15, 16, 17, 18, 21, and 22 are important from eq. [5]. The results showed that the hydrophobicity of compounds (log *P*) is also important for the inhibition of residual insulin secretion. The results also show the importance of two indicator variables. The presence of chlorine atoms at m- and p- position of phenyl ring B is required for the inhibition of the residual insulin secretion. Among all generated MLR equations, eq. [4] is the best model with higher statistical qualities. The statistical qualities of the best MLR equation, PCRA and PLS equations are comparable with each other except the *F*-ratio PLS equation (*F*=229.19). All the models (MLR, PCRA, and PLS) show the importance of atom numbers 16, 17, 18, 19, and 20 for the inhibition of residual insulin secretion. Both the MLR and PLS models show the importance of two indicator parameters (*I*_ClR_2 and *I*_ClR_3) and log *P* for the inhibition. Both the PCRA and PLS models show the importance of atom number 6 and 21 for the inhibition of residual insulin secretion. Atoms and substituents important for the inhibition are shown in Fig. 2.

Fig. 2. Important atoms and substituents for the inhibition of insulin secretion. Atoms bounded by circles are important for van dispersive/dar Waals interactions.

Rotating ring-disk voltammetric investigations on the degradation rate of the nickel(III)-glycylglycyl-L-histidine complex

María V. Alipázaga, Denise Lowinsohn, Mauro Bertotti, and Nina Coichev

Abstract: The voltammetric behavior of the Ni(II)/glycylglycyl-L-histidine complex and the degradation of the electrogenerated Ni(III) species were investigated by cyclic voltammetry. Results of electrochemical and spectrophotometric experiments indicated some differences in the nature and reactivity of Ni(III) complexes formed by two independent routes, i.e., anodic oxidation of Ni(II) and homogeneous oxidation by an autocatalytic reaction in a medium containing oxygen and S(IV) (H_2SO_3, HSO_3^-, and SO_3^{2-}). The Ni(III) species formed electrochemically reacts in a fast chemical process (EC mechanism) and the observed rate constant of the degradation (k = 0.17 s^{-1}) was determined by a rotating ring-disk electrode technique measuring kinetic collection efficiency values as a function of the rotation rate.

Key words: nickel, glycylglycyl-L-histidine, sulfite, degradation reaction, rotating ring-disk voltammetry.

Résumé : Faisant appel à des méthodes de voltampérométrie cyclique, on a étudié le comportement voltampérométrique du complexe Ni(II)/glycylgly-L-cylhistidine et la dégradation des espèces Ni(III) électrogénérées. Les résultats des expériences électrochimiques et spectrophotométriques indiquent qu'il existe de légères différences dans la nature et la réactivité des complexes de Ni(III) qui se forment par deux voies réactionnelles indépendantes, soit l'oxydation anodique du Ni(II) et l'oxydation homogène par une réaction autocatalytique dans un milieu contenant de l'oxygène et des espèces à base de S(IV), telles H_2SO_3, HSO_3^- et SO_3^{2-}. Les espèces de Ni(III) qui se forment d'une façon électrochimique réagissent par un processus chimique rapide (mécanisme EC) et on a déterminé la constante de vitesse observée pour la dégradation (k = 0,17 s^{-1}) par la technique de l'électrode à disque tournant en mesurant les valeurs de l'efficacité de la collection cinétique en fonction de la vitesse de rotation.

Mots-clés: nickel, glycylglycyl-L-histidine, sulfite, réaction de dégradation, voltampérométrie à disque tournant.

[Traduit par la Rédaction]

Introduction

Nickel compounds are well established as human carcinogens (1). As nickel(II) aqua cation is physiologically redox inactive, its toxicity in vivo is inferred to involve activation by coordination with peptides and proteins in which the N-terminus, N-deprotonated amides, histidine imidazoles, and cysteine thiolates provide the principal ligand groups (2). Metallopeptides, of the general form Ni^{II}(Xaa-Xaa-His) (where Xaa is any amino acid), simple or when appended to proteins or other agents, have previously been shown to mediate oxidative protein cross-linking (3) and cleavage of DNA (4–7) and proteins (8) in the presence of $KHSO_5$, magnesium monoperoxyphthalate, or S(IV) (H_2SO_3, HSO_3^-, and SO_3^{2-}).

In suitable experimental conditions, the oxidation of some divalent transition metal ions is accelerated in the presence of S(IV) and dissolved oxygen (9–15). In the case of Ni(II), several works have been reported in the literature (11, 13, 16–19). Currently, increasing interest in the formation of Ni(III) peptide complexes has been noticed because of the probable participation of these species in DNA damage processes (7).

In our previous work (7), DNA strand breaks and oxidation of 2′-deoxyguanosine were observed in air saturated solutions containing micromolar concentrations of Ni^{II}GGH complex (GGH = glycylglycyl-L-histidine) and S(IV). This study showed that the extent of DNA damage depends on the ratio of both Ni^{II}GGH and S(IV) concentration and the ionic strength. It was also demonstrated that Ni^{II}GGH reacts rapidly with S(IV) in air saturated solution to produce Ni^{III}GGH. A mechanism was proposed where, in a first step, Ni^{III} oxidizes SO_3^{2-} to $SO_3^{\bullet-}$, which then reacts with dissolved oxygen to produce $SO_5^{\bullet-}$, initiating radical chain reactions.

As transition metal ions in the trivalent state can be conveniently generated by both chemical and electrochemical procedures, investigations on the nature and reactivity of Ni(III) peptide compounds constitute a topic of relevance. In the present work, a complementary study was carried out to better understand the stability of Ni^{III}GGH in aqueous solution.

Cyclic voltammetric measurements provide a simple diagnostic method for the preliminary study of homogeneous re-

actions coupled to redox processes. Quantitative information can be gained by performing the experiments in conditions where the mass transfer coefficient of the reactant or intermediate is experimentally varied relative to the inherent rate of the chemical reaction. A typical approach employed in studying coupled chemical reactions is based on the use of rotating ring-disk electrode voltammetry (RRDE). RRDE experiments allow the rate of mass transfer to be adjusted to a value comparable to the rate of the chemical reaction, and the limiting current is analyzed using appropriate kinetic equations to determine the rate constant of the homogeneous reaction. Hence in the present work, efforts to fully characterize the electrochemical behavior of the $Ni^{II}GGH$ species and to determine the rate constant of the degradation process, probably involving the reaction between anodically generated Ni(III) complex and the ligand, are shown. In addition, the formation of the Ni(III) complex was also verified by spectrophotometric techniques.

Experimental

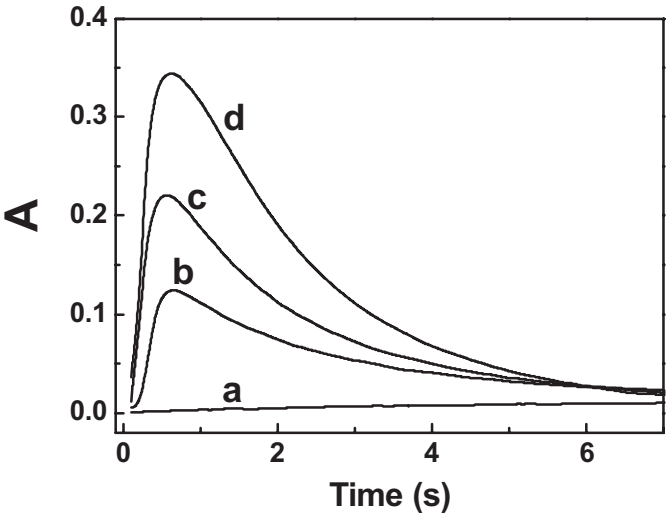
Reagents

All reagents were of analytical grade (Merck or Sigma-Aldrich) and were used as received. Solutions were prepared by using deionized water purified with a Milli-Q Plus Water system (Millipore). A S(IV) solution was prepared daily with the $Na_2S_2O_5$ reagent.

In the experiments fresh $Ni^{II}GGH$ solutions were used, which were prepared by dissolving GGH peptide in water (pH = 7.0) followed by the addition of a Ni(II) solution (solutions were prepared to have a 10% excess of peptide to restrain any $Ni(OH)_2$ precipitation). The final pH was adjusted with 0.1 mol/L NaOH or 0.1 mol/L $HClO_4$ solutions. No buffer was used since some anions (such as carbonate and phosphate) may displace de peptide ligand.

In some experiments, the ionic strength *I* was adjusted in 0.05 mol/L with $NaClO_4$.

In all experiments, air saturated solutions were employed for which the oxygen concentration can be considered to be 0.25 mmol/L (20). A pHmeter Metrohm model 713 with a glass electrode (filled with satd. NaCl) was used in the pH measurements. Measurements were performed at 25.0 °C.



Spectrophotometric measurements

In these experiments, an equal volume of S(IV) solution was mixed with the metal ion complex solution. UV–vis spectra of the $Ni^{II}GGH$ complex were obtained using a HP8453A diode array spectrophotometer, which was coupled to a Pro-K 2000 stopped-flow mixing accessory (Applied Photophysics) to collect kinetic information on the decomposition of the Ni(III) species upon addition of S(IV). Measurements were performed at 25.0 °C. In general, all kinetics traces were recorded at least 3–5 times. The final concentrations after the mixture are indicated in Fig. 1.

Electrochemical measurements

Rotating ring-disk electrochemical experiments were carried out using an analytical rotator (AFMSRX) connected to an AFCBP1 bipotentiostat (Pine Instrument Company) with data acquisition software made available by the manufacturer (ASWCV2, PineChem). Current potential curves were typically recorded at a 20 mV s^{-1} potential scan rate. The glassy carbon – glassy carbon ring-disk electrodes (AFMT29) had the following dimensions: disk radius 0.5613 cm, inner radius of the ring 0.6248 cm, and outer radius of the ring 0.7925 cm. The electrodes were polished using 0.3 μm alumina before use. A platinum wire and a Ag/AgCl (satd. NaCl) were used as counter and reference electrodes, respectively. During rotating ring-disk electrode (RRDE) experiments, the disk electrode potential was scanned between the limits 0.2 and 1.0 V, the ring being maintained at 0.1 V to collect the material generated at the disk. A 0.05 mol/L $NaClO_4$ solution (pH = 7.0) was used as supporting electrolyte. After the electrochemical generation of $Ni^{III}GGH$, the pH was about the same.

Fig. 1. Absorbance due to $Ni^{III}GGH$ formation after addition of S(IV) to a $Ni^{II}GGH$ solution. [$Ni^{II}GGH$] = 200 μmol L^{-1}, pH = 7.0, I = 0.05 mol L^{-1} ($NaClO_4$), T = 25.0 °C. [S(IV)]: (a) 0, (b) 25, (c) 50, and (d) 100 μmol L^{-1}.

Results and discussion

Spectrophotometric studies

Ni(II) can form square planar complexes with GGH by coordination of the terminal amine group, two deprotonated amide nitrogens, and the imidazole-N3 of the histidine residue (21). In addition, potentiometric studies (22) have shown that $Ni^{II}(H_{-2}GGH)^-$, containing two deprotonated amide nitrogens, is the major species present in solution at pH higher than 6.4. In the present work, $Ni^{II}GGH$ represents all species present in solution and $Ni^{II}(H_{-2}GGH)^-$ refers to the complex with the peptide ligand with two deprotonated nitrogens coordinated to the nickel ion.

Our detailed previous work showed that $Ni^{II}GGH$ is rapidly oxidized to $Ni^{III}GGH$ in the presence of S(IV) in air saturated solution (7). Figure 1 shows the absorbance changes at 340 nm (maximum absorption peak for the Ni(III) complex) obtained after the addition of S(IV) to a $Ni^{II}GGH$ solution. A short induction period can be observed especially at lower S(IV) concentrations, its extension depending on the S(IV) concentration and traces of $Ni^{III}GGH$ initially present. After the induction period, the absorbance reaches a maximum value within 0.6 s as a result of a very efficient and

fast formation of $Ni^{III}GGH$. The amount of generated $Ni^{III}GGH$ is a function of added S(IV) when both the metal complex and oxygen are in large excess.

Reactions 1 to 9 represent the main steps involving the oxidation of $Ni^{II}GGH$ in the presence of S(IV) and oxygen (7).

Initiation

[1] $Ni^{II}GGH + O_2 \rightarrow Ni^{III}GGH + O_2^{-}$

Autocatalytic process

[2] $HSO^{-}_3 \rightleftharpoons SO^{2-}_3 + H^+ \quad pK_a = 7.2$

[3] $Ni^{III}GGH + SO^{2-}_3 \rightarrow Ni^{II}GGH + SO^{\bullet -}_3$

[4] $SO^{\bullet -}_3 + O_2 \rightarrow SO^{\bullet -}_5$

[5] $Ni^{II}GGH + SO^{\bullet -}_5 \rightarrow Ni^{III}GGH + SO^{2-}_5$

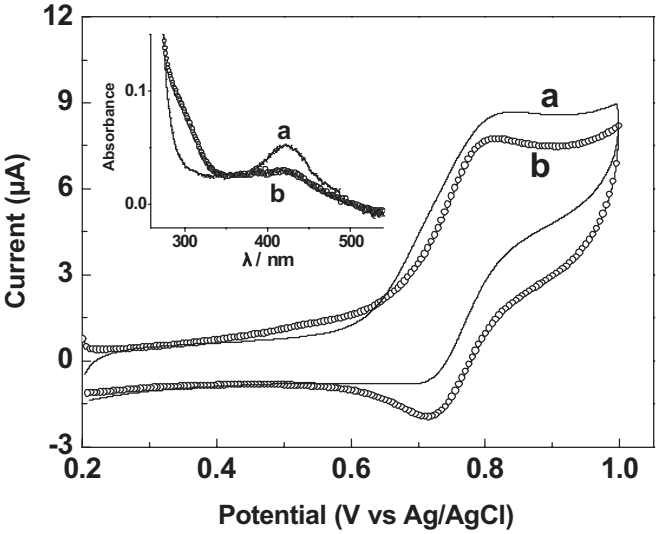
[6] $SO^{2-}_3 + O_2 \rightarrow SO^{2-}_5$

[7] $HSO^{-}_5 \rightleftharpoons SO^{2-}_5 + H^+ \quad pK_a = 9.4$

[8] $Ni^{II}GGH + HSO^{-}_5 \rightarrow Ni^{III}GGH + SO^{\bullet -}_4 + OH^-$

[9] $Ni^{II}GGH + SO^{\bullet -}_4 \rightarrow Ni^{III}GGH + SO^{2-}_4$

In this autocatalytic process, some Ni(III) is necessary to initiate the reactions. This species might be produced at trace levels by the spontaneous oxidation of $Ni^{II}GGH$ by dissolved oxygen (eq. [1]). $Ni^{III}GGH$ then reacts with SO^{2-}_3 to form the $SO^{\bullet -}_3$ radical (eq. [3]), and the further reaction with O_2 gives $SO^{\bullet -}_5$ (eq. [4]). In an autocatalytic process, $Ni^{II}GGH$ (in large excess, 2.0×10^{-4} mol/L) is oxidized to $Ni^{III}GGH$ by $SO^{\bullet -}_5$ (eq. [5]). HSO^{-}_5 and $SO^{\bullet -}_4$ can also oxidize $Ni^{II}GGH$ in subsequent steps (eqs. [6–9]). The $Ni^{III}GGH$ generated species can be also reduced by SO^{2-}_3 (eq. [3]), continuing the chain reaction. This redox cycling will depend on the critical balance between oxygen and sulfite concentrations, which will controll the overall reaction (S(IV) oxidation to S(VI) and concurrent oxygen consumption).



The $SO^{\bullet -}_3$ radical formation in this reaction has also been confirmed by previous EPR spin trapping studies (7) using DMPO (5,5-dimethyl-1-pyrroline-*N*-oxide). The possible involvement of $HO^{\bullet}$ in the mechanism was ruled out since the characteristic spectrum of the DMPO/$HO^{\bullet}$ adduct was not observed.

On the other hand, another interesting issue that can be observed in Fig. 1 is based on the decrease of the absorbance after less than 1 s. This process is associated with the decomposition of the Ni(III) species, which may involve a back-reaction to the Ni(II) complex (eq. [3], if S(IV) is in excess and in conditions of lack of oxygen) and oxidation of the ligand as it will be further discussed.

Voltammetric studies

To evaluate the relative stability of the Ni(III) complex produced on the surface of a glassy carbon electrode, some preliminary experiments were carried out using cyclic voltammetry at quiescent conditions. The voltammetric profile shown in Fig. 2, curve a, indicates the irreversibility of the electrodic process that presents an anodic peak, E_{pa}, at around 0.8 V vs. Ag/AgCl probably related to the oxidation of $[Ni^{II}(H_{-2}GGH)]^-$ (eq. [10]), the predominant species at pH 7. A $E_{1/2}$ of 0.96 V vs. NHE was found, similar to that previously reported in the literature (23). The absence of the corresponding cathodic peak can be a consequence of the degradation of the electrochemically generated $Ni^{III}GGH$ species at the timescale of the experiment.

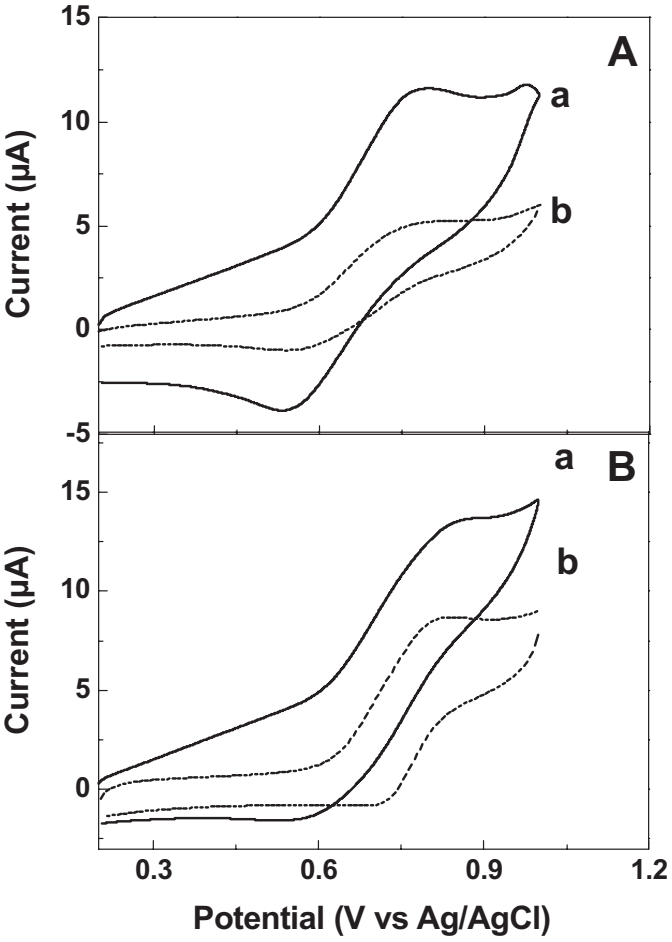


Fig. 2. Voltammograms recorded at the disk electrode in an air saturated solution containing 0.2 mmol L^{-1} $Ni^{II}GGH$ and 0.05 mol L^{-1} $NaClO_4$ (pH = 7.0) (a) before and (b) after addition of 0.2 mmol L^{-1} S(IV) (final concentration in solution). v = 20 mV s^{-1}, T = 25.0 °C. Inset shows the respective UV–vis spectra.

With the addition of S(IV) to an air saturated solution containing $Ni^{II}GGH$, a fast reaction occurs with the formation of $Ni^{III}GGH$, followed by its decomposition as discussed earlier (Fig. 1). Hence, curve b in Fig. 2 corresponds to the voltammogram of a solution containing the degradation product (some Ni(II) complex with the oxidized ligand) of the chemically generated $Ni^{III}GGH$ species and the remaining $Ni^{II}GGH$, which was present in large excess. Some differences are promptly noticed, the most relevant one being the appearance of a small cathodic wave at 0.72 V. This result may indicate that the anodic oxidation of these different Ni(II) complexes follows different pathways, one of the Ni(III) species being further reduced in the reverse potential sweep. The existence of a different Ni(II) species in solution, upon addition of S(IV), can be verified by analyzing the spectra shown in the inset of Fig. 2, obtained in the same conditions. After $Ni^{III}GGH$ decomposition, only the band at 420 nm (due to $Ni^{II}GGH$) and a new band and shoulder around 305 nm were observed in the final spectrum. The band at 305 nm may be evidence of the formation of a new species resulting from the process involving oxidative decarboxylation of ligand, according to the literature (eqs. [14–16]) (24). Thus, the chemical formation and further degradation of the $Ni^{III}GGH$ species yield a solution with different composition, probably containing the oxidized

Fig. 3. Voltammograms recorded at the disk electrode in an air saturated solution containing 0.2 mmol L^{-1} $Ni^{II}GGH$ and 0.05 mol L^{-1} $NaClO_4$ (pH = 7.0) at different scan rates (a) 100 mV s^{-1} and (b) 20 mV s^{-1} and at different temperatures (A) 7 °C and (B) 24 °C.

ligand, if a comparison is made with the initial solution containing Ni(II) and the ligand.

To clearly demonstrate the existence of a chemical step following the anodic process, voltammetry was also performed at different scan rates and temperature conditions. Accordingly, Fig. 3 shows in a convincing way that by performing the electrochemical experiment at low temperature (7 °C) and in a relatively short time window (100 mV s^{-1}), a cathodic response is noticed in the reverse potential sweep, whereas a similar process is absent at the other experimental conditions. These results support the conclusion on the existence of a coupled chemical reaction following the anodic oxidation of the Ni(III) complex (eq. [11]).

Figure 4 shows voltammograms obtained with the RRDE at different rotation rate values in a solution containing $Ni^{II}GGH$. The anodic wave and the concurrent cathodic step are one-electron processes represented by eqs. [10] and [12].

[10] $[Ni^{II}(H_{-2}GGH)]^- \rightarrow [Ni^{III}(H_{-2}GGH)] + e^-$

(at the disk)

Fig. 4. Current responses in RRDE experiments from a solution containing 0.2 mmol L^{-1} $Ni^{II}GGH$ and 0.05 mol L^{-1} $NaClO_4$ (pH = 7.0) at various rotation rates: (a) 100, (b) 900, and (c) 1600 rpm. Scan rate = 20 mV s^{-1}, E_{ring} = 0.1 V, T = 25 °C.

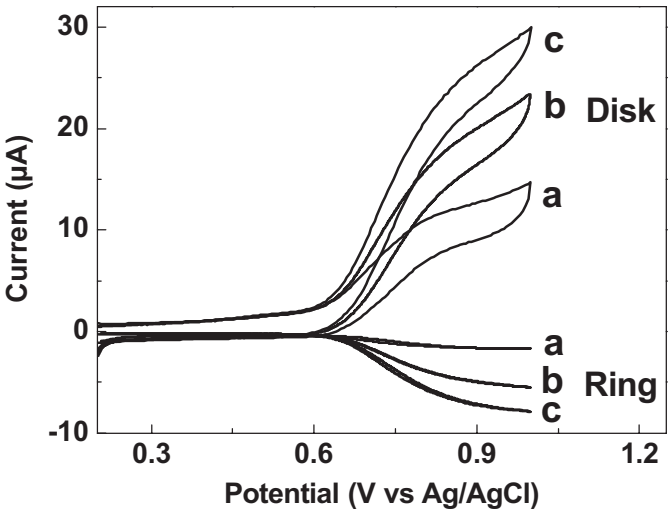

Table 1. N_k as a function of ω N_k was calculated as the ratio between limiting currents measured at the ring and the disk

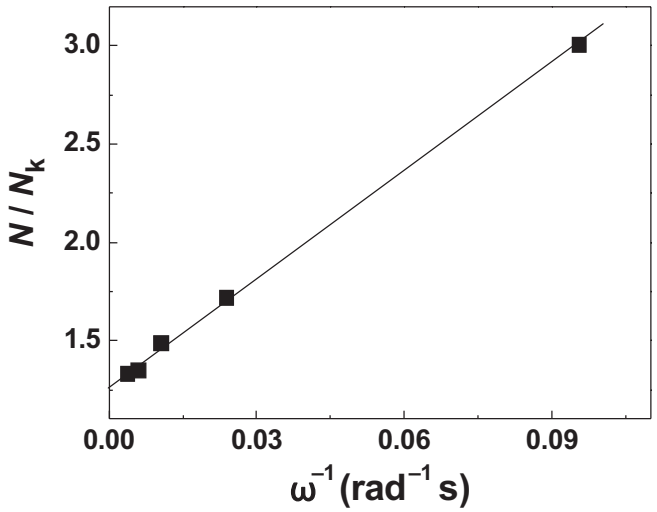
ω/rpm	100	400	900	1600	2500
N_k	0.12	0.22	0.25	0.27	0.28

[11] $[Ni^{III}(H_{-2}GGH)] \rightarrow$ products

[12] $[Ni^{III}(H_{-2}GGH)] + e^- \rightarrow [Ni^{II}(H_{-2}GGH)]^-$

(at the ring)

The collection efficiency (N), defined as the ratio of the limiting current values measured at the ring and the disk electrodes, indicates the amount of material electrogenerated at the disk that reaches the ring. Typical N values for $Fe(CN)_6^{3-}$ (an electroactive species whose cathodic reduction leads to the stable $Fe(CN)_6^{4-}$ anion) are close to 0.37; it is necessary to point out that in the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ system, no subsequent chemical reaction occurs after the generation of $Fe(CN)_6^{4-}$.



Since the transit time between the disk and the ring is dependent on the rotation rate, a more noticeable signal at the ring is observed at the higher rotation rate (1600 rpm) because at this experimental condition the decomposition reaction (eq. [11]) takes place to a less significant extent. Kinetic collection efficiency values (N_k) at various rotation rates are shown in Table 1 and corroborate these conclusions because the likelihood of detecting a short-lived intermediate is increased at short time windows. The determination of the rate constant associated with the coupled chemical reaction (eq. [11]) was based on the N/N_k vs. $1/\omega$ plot that would give a straight line according to the following equation

[13] $N/N_k = 1 + 1.28(\nu/D)^{1/3}(k/\omega)$

where N was calculated as 0.37, N_k is the kinetic collection efficiency, D is the diffusion coefficient of the electroactive

Fig. 5. Dependence of N/N_k (where N is collection efficiency measured for ferrocyanide and N_k is the collection efficiency measured for $Ni^{II}GGH$) on the reciprocal of the rotation rate for data in the 0.2 mmol L^{-1} $Ni^{II}GGH$ and 0.05 mol L^{-1} $NaClO_4$ (pH = 7.0), T = 25 °C.

species (calculated as 1.80×10^{-6} cm^2 s^{-1} by using data from the limiting current values in steady-state hydrodynamic voltammetric experiments), ν is the solution viscosity, and k is the rate constant. By using the slope of the straight line shown in Fig. 5, k was found to be 0.17 s^{-1}.

The decomposition process of $Ni^{III}GGH$ may involve highly reactive species (eqs. [14–16]) (24) as proposed in studies on the oxidation of $Ni^{II}GGH$ by oxygen (in the absence of S(IV)). In this mechanism, after $Ni^{III}GGH$ formation the carboxylate group of the peptide might donate an electron to that transiently formed Ni^{III} species, resulting a carboxyl radical, which could undergo rapid decarboxylation. The loss of CO_2 to form a His Cα-centered free radical (eq. [14]), which would be highly reactive with oxygen, is followed by superoxide formation (eq. [15]) and subsequent $N^{II}GGH'$ generation (eq. [16]) (where $Ni^{II}GGH'$ is Ni^{II}Gly-Gly-α-hydroxy-D,L-histamine).

[14] $Ni^{III}GGH \rightarrow Ni^{II}GGH^{\cdot} + CO_2$

[15] $Ni^{II}GGH^{\cdot} + O_2 \rightarrow Ni^{II}GGH\text{-}O_2^{\cdot}$

[16] $Ni^{II}GGH\text{-}O_2^{\cdot} \xrightarrow{H_2O} Ni^{II}GGH'$

Further evidence of the formation of a highly reactive nickel superoxide complex during the $Ni^{III}GGH$ decomposition comes from our previous EPR spin trapping studies (7). A solution containing only $Ni^{II}GGH$ and DMPO (in absence of S(IV)) generated the characteristic spectrum of DMPOX (5,5-dimethyl-pyrrolidone-(2)-oxy-(1)) (25). The formation of DMPOX is indirect evidence for peroxy radical ($ROO^{\cdot}$) generation, which is trapped by DMPO. Therefore, an intermediate radical, such as $Ni^{II}GGH\text{-}O_2^{\cdot}$ (eq. [15]), is likely to be the species capable of oxidizing DMPO (1.87 V vs. NHE) (26) to DMPOX.

Conclusions

Cyclic voltammetry and rotating ring-disk electrode voltammetry provided qualitative and quantitative information on the reaction involving the electrogenerated transient Ni(III) and the ligand GGH. However, the combination of spectrophotometry (7), EPR spin trapping (7), electrochemical techniques, and the available literature (eq. [14–16]) (24) still does not allow a definitive assignment of the many species involved in the autocatalytic process of $Ni^{II}GGH$ oxidation in the presence of S(IV) and dissolved oxygen and the further decomposition step. The system is complex and the results can only explain in part the observed spectra and voltammetric changes.

Reactions of aniline in acetic acid solutions containing cyanuric chloride and hydrogen chloride acceptors

Kirill A. Kolmakov

Abstract: Two reaction pathways in acetic acid solution containing cyanuric chloride, aniline, and some hydrogen chloride acceptors (triethylamine, sodium acetate, pyridine) were studied. Both aryl amination and acylation can be performed with high yields under proper reaction conditions. Contrary to the only known literature report on the reactions between carbonic acids and cyanuric chloride in the presence of a hydrogen chloride acceptor (triethylamine), it was established that acid chlorides are not formed. A scheme involving the replacement of chlorine atoms by acetate ion in the initial stage was proposed for the acylation of aniline promoted by cyanuric chloride.

Key words: acetic acid, acylation, aniline, cyanuric chloride, aryl amination.

Résumé : On a étudié deux voies réactionnelles pour les réactions de l'aniline dans des solutions d'acide acétique contenant du chlorure cyanurique et des accepteurs du chlorure d'hydrogène, tels la triéthylamine, l'acétate de sodium et la pyridine. En choisissant les conditions expérimentales appropriées, on peut réaliser aussi bien les réactions d'amination aromatique que celles d'acylation, avec de bons rendements. Contrairement à ce qui a été rapporté dans la seule publication connue sur les réactions entre les acides carboniques et le chlorure cyanurique en présence d'un accepteur de chlorure d'hydrogène (triéthylamine), on a démontré qu'il n'y a pas de formation de chlorures d'acide. On propose un schéma impliquant le remplacement des atomes de chlore par l'ion acétate dans l'étape initiale de la réaction d'acylation de l'aniline catalysée par le chlorure cyanurique.

Mots-clés : acide acétique, acylation, aniline, chlorure cyanurique, amination aromatique.

[Traduit par la Rédaction]

Introduction

Acetic acid as solvent has a unique combination of valuable qualities, the most important of which are environmental compatibility, low toxicity, low flammability, and the possibility to recycle. All these are complemented by miscibility with water and most organic solvents, high polarity, and high boiling point. At the same time, its application in preparative organic chemistry is narrow. The reactions of cyanuric chloride (2,4,6-trichloro-1,3,5-triazine (**1**, Scheme 1)) with aniline and with acetic acid, respectively, have been known for more than 60 years (1), while the interactions between *all three* still have not been studied. In our most recent research, we devised an efficient and "green" synthetic approach to aryl amination of cyanuric chloride with various aromatic amines using acetic acid as solvent (2). No attempts to perform amination (or other type of nucleophilic substitution) in acetic acid medium had been reported previously. We found that mono- and di-arylamino derivatives (**2a**, **2b**) are formed smoothly at ambient temperature in the absence of hydrogen chloride acceptors, while conventional procedures utilize bases (1). The final third stage of substitution in **1**, a typically difficult transformation to achieve with aromatic amines, is complete after 30 min heating at 118 °C in acetic acid (2). One needs to know why acetic acid is superior to conventional polar organic solvents in the aryl amination of **1** and why acylation, as an expected side reaction, is eliminated. Apart from acid–base interaction between aniline and acetic acid, it is well known that carbonic acids can act as acylating agents, especially at elevated temperatures (3). One could expect that **1**, with the reactive C-Cl function, may interact with acetic acid and thus promote acylation of aniline. The formation of acetyl chloride and cyanuric acid (Scheme 1, **3a**), as a result of cyanuric chloride dechlorination (solvilysis) in boiling acetic acid, was mentioned in the literature (1*a*, 1*d*). Further, in 1981 Lahoti and Wagle (4) suggested cyanuric chloride as a reagent for preparation of acid chlorides, amides, and esters. The authors claimed that when **1** was treated with a carbonic acid and triethylamine (1 equiv. each) in acetone, the corresponding acid chloride was readily formed. We decided to check whether the recipe (4) worked for acetic acid as substrate. If it did, acetyl chloride could form in the process of aryl amination. This extremely reactive acylating agent definitely would compete with **1** in reaction with aniline. In the context of further utilization of acetic acid for nucleophilic substitution reactions in preparative organic chemistry, we decided to explore the two alternative reaction pathways

Scheme 1.

Scheme 2.

(aryl amination of **1** and acylation of aniline) in an acetic acid – cyanuric chloride – triethylamine – aniline system with acetic acid as solvent. Even though the two reaction pathways in the system seem to be obvious and involve simple and readily available reagents, no comparative studies have been published. The influence of hydrogen chloride acceptors, especially homogeneous (e.g., triethylamine, pyridine, sodium acetate) acceptors, must be deciding and should also be studied.

Results and discussion

In our initial experiments on acylation assisted by cyanuric chloride, we attempted to follow the recipe suggested by Lahoti and Wagle (4) with acetic acid as a substrate and acetone as solvent. According to the authors, insoluble 4,6-dichloro-[1,3,5]triazin-2-ol (Schemes 1 and 2, **3b**) was formed as a by-product, while acid chlorides were isolated in good and moderate yields by simple evaporation of filtrates that also contained Et_3N.

Regarding the isolation protocol, we considered it unlikely that acid chlorides and a tertiary amine could exist unreacted in the same solution (quarternary ammonium salt has to be formed (3*d*). Note that by-product **3b** is rather acidic (pK = 3.2 (2*d*)) and also would have reacted. When we added Et_3N to an acetone solution containing acetic acid and cyanuric chloride in molar ratio 1:1:1, a precipitate did form, as described, but turned out to be triethylamine hydrochloride ($Et_3N \times HCl$) rather than **3b**. The salt was identified by means of ^1H NMR, mass-spectrometry, and by melting point.

We took two other substrates, i.e., 4-nitrobenzoic and trichloroacetic acids (mentioned in (4) among illustrative examples) and obtained exactly the same salt ($Et_3N \times HCl$) as a by-product. Importantly, acid chlorides were not detected in the reaction mixtures (see Experimental section).

Regarding the reaction scheme in general, we would like to emphasize that 1 equiv. of chlorine (one chlorine atom) goes to form triethylamine hydrochloride, as we established. Logically, acid chlorides cannot be the major reaction products. All of this makes the formation of acid chlorides, as described in the above mentioned paper (4), very doubtful. Further tests showed that amides, namely acetanilide (Scheme 2, **4**), were formed (together with other products including aryl amination products **2a** and **2b**) when aniline (1 equiv.) was added to the reaction mixtures. However, amides proved to be problematic to isolate from reaction mixtures without using preparative chromatography, and we focused on experiments in acetic acid medium. The interaction between carbonic acids and **1** can be illustrated by Scheme 2. It explains the formation of triethylamine hydrochloride. The key point is that in acetic acid – cyanuric chloride – triethylamine system, the only possible nucleophile is acetate ion. Acetate replaces the chlorine atom in the course of aromatic nucleophilic substitution. Chlorine is a leaving group, while 4,6-dichloro-[1,3,5]triazin-2-ol acetate (acetate of compound **3b**) or 1,3,5-triazine-2,4,6-triol acetate (**5**) (when 1 or 3 equiv. of Et_3N is added, respectively) are the products. The presence of **5** in the reaction mixtures was detected by mass spectrometry. Importantly, we established that the reaction does not proceed in the absence of Et_3N. Cyanuric chloride is stable in acetic acid at room temperature; the ^1H NMR or ^{13}C NMR spectra of **1** in CD_3COOD solution are invariant over 2 days. Equilibrium is only shifted when an acetic acid solution of cyanuric chloride is heated to boil so that acetyl chloride distills off. Another way to shift the equilibrium is the introduction of Et_3N (or other HCl acceptors). In this case triethylamine hydrochloride is formed, which binds HCl. In the final stage of the re-

© 2007 NRC Canada

action sequence, 4,6-dichloro-[1,3,5]triazin-2-yl group has to be the leaving group, because the acidity of 4,6-dichloro-[1,3,5]triazin-2-ol **3b** is higher (pK = 3.2 (1*d*)) than that of aliphatic carbonic acids or benzoic acid. As a result, target amides are formed, and compound **3b** is washed off by basic solutions. Cyanuric acid (**3a**), with pK value about 4.7, is acidic enough to be the leaving group. We would prefer to consider the formation of amides promoted by cyanuric chloride as a case of activated ester method (see Scheme 2), which has a wide application in organic (mostly peptide) synthesis (5). The method involves the conversion of acids to esters with hydroxy compounds whose anions are good leaving groups (4-nitrophenol, 1-hydroxybenzitriazole, and many others). The esters then react with amines or amino acids to furnish amides.

To embark on experiments with acetic acid as solvent, we first combined aniline, cyanuric chloride, and Et_3N in the molar ratio 1:1:1 (1 equiv. each). Triethylamine, a strong base, was neutralized with acetic acid, and the mixture was cooled to ambient temperature before being added to the solution of cyanuric chloride. Aniline was also neutralized with acetic acid beforehand (see experimental details later). We tried different sequences of the reagent addition. When aniline (1 equiv.) was added immediately or even 3 h after Et_3N (1 equiv.), aryl amination proved to be the predominant reaction. Only trace amounts of acetanilide **4** were detected. Further experiments showed that the course of the reaction could be changed when no less than 3 eqiuv. of Et_3N was added to the reaction mixture. To completely eliminate the aryl amination, the acetic acid solution of cyanuric chloride and Et_3N must be left for a long time (10–12 h) before the addition of aniline. Aniline was taken in excess (~4 equiv.) to provide maximum yield. Extraction of the reaction mixture with benzene and subsequent treatment with dilute hydrochloric acid and alkali gave a chromatographically pure sample of **4** (the purity and identity was checked by means of ^{1}H NMR and HPLC). The isolated yield was 77%, assuming all three chlorine atoms of **1** reacted. The yield of **4** is slightly higher (81%) when Et_3N is replaced by sodium acetate and is considerably lower (56%) when pyridine is used instead.

The analysis of an acetic acid solution containing cyanuric chloride and Et_3N (in the form of its acetate) revealed some interesting facts. First, a precipitate of cyanuric acid **3a** was formed. It was identified by mass spectroscopy and elemental analysis; the isolated yield was about 72%. Further, triethylamine hydrochloride was isolated with 92% yield from the liquid phase upon diluting with hexane. The formation of this salt confirms the proposed reaction scenario (Scheme 2). Regarding the reactivity of cyanuric chloride in general, our results are consistent with some of the previously reported data, showing that selective substitution of one chlorine atom in cyanuric chloride is often problematic (1*d*). To explain the formation of cyanuric acid (**3a**), one should keep in mind that acetic acid is a protonic solvent. Such solvents must cause solvolysis of the "active ester" **5**. We observed a rapid formation of **3a** when water was added to the solutions of **1** and Et_3N in acetone or acetic acid. In dry acetic acid medium, the only possible solvolysis product was acetic anhydride (Scheme 2, **6**), whose presence in the reaction mixture was confirmed by means of mass spectrometry and ^{1}H NMR. No trace of acetyl chloride was detected. We may assume that the formation of insoluble cyanuric acid **3a** could be an additional driving force of the solvolysis, which leads to the formation of acetic anhydride. Finally, we found it possible to perform acylation of aniline with acetic acid as a "green reaction" simply by heating aniline in a large volume (~ 80 mol excess) of acetic acid under reflux (~1 h) in the absence of catalysts or dehydrating agents, as recommended in (3*a*).

Meanwhile, no trace of **4** was detected when 3 equiv. of all three reagents were mixed simultaneously. Thus, when aniline (3 equiv.) was added to the reaction mixture immediately after Et_3N (3 equiv.), aryl amination prevailed and a precipitate was formed (see Experimental section). The major product (92%, according to HPLC) was 6-chloro-*N*,*N*′-diphenyl-[1,3,5]triazine-2,4-diamine (Scheme 1, di-substituted product **2a**). Up to 66% of this compound was isolated by simple filtration of the reaction mixture after 6 h exposure at ambient temperature. Et_3N can be replaced by sodium acetate or pyridine with the same result. An excellent yield (96%, isolated) of di-substituted product was achieved when water was added to the reaction mixture (together with the reagents), which precipitated the reaction product. To obtain pure mono-substituted product **2b** in the reaction with 1 equiv. of aniline, the temperature should be maintained at about 15 °C and water should also be added. Otherwise, substantial amounts of di-substituted product **2a** are formed.

All these experiments demonstrate that acetate ion, as a weaker nucleophile, fails to compete with aniline in the reaction with cyanuric chloride in acetic acid solutions. It was established in the late 1940s that salts and acids are dissociated to a very little extent (6) in acetic acid medium, in contrast to water solutions. Thus, acetates are barely dissociated in anhydrous acetic acid, and consequently the effective concentration (activity) of the nucleophile is very low. Note that neat acetic acid exists in the form of dimers with strong intramolecular hydrogen bonds and, as acid, dissociates weakly (6).

Conclusions

Two reactions of aniline in acetic acid solutions containing cyanuric chloride and hydrogen chloride acceptors have been established, not considering the acid–base interaction between aniline and acetic acid. Either transformation, aryl amination or acylation, can be performed smoothly and with high yields under proper reaction conditions. The results show that acetic acid can be used as solvent for aryl amination of cyaniric chloride **1** and most probably other heterocyclic halides with no risk of acylation. This is due to the lower nucleophilicity of the acetate ion and a weak dissociation of acetates in anhydrous acetic acid medium. The presence of HCl acceptors (triethylamine, pyridine, sodium acetate) does not influence the aryl amination, which predominates in acetic acid solution. Mono- or di-phenylamino-1,3,5-triazine derivatives (**2a** and **2b**) were obtained in good and excellent yields when acetic acid solutions of cyanuric chloride, aromatic amines (1 or 2 equiv.), and an acetate (1 or 2 equiv., respectively) were combined simultaneously at ambient temperature. On the other hand, a clean procedure

for the preparation of acetanilide **4** promoted by cyanuric chloride has been developed. It is very likely to be applicable to other acids and amines. To achieve acylation, it is first necessary to complete the reaction between cyanuric chloride and 3 equiv. of triethylammonium acetate, which causes the replacement of all three chlorine atoms; sodium or pyridinium acetates can also be used. For acylation, acetic acid has to be dry, while aryl amination is not impeded by the addition of water. Acetyl chloride is never formed in the course of the reaction between cyanuric chloride and acetic acid in the presence of triethylammonium acetate in acetone or acetic acid solutions. In acetic acid solution containing cyanuric chloride and triethylammonium (or sodium) acetate, cyanuric acid **3a** and acetic anhydride **6** are formed as solvolysis products. Acetic anhydride is the actual acylating agent in the subsequent reaction with aniline.

Experimental section

General

All chemicals were purchased from Sigma-Aldrich Chemical Company and used as received. Progress of the reactions was monitored by HPLC or TLC on silica gel SIL G/UV 254 plates and chloroform/acetone (10:1) as mobile phase. HPLC was performed using a 5500 Varian Vista chromatograph equipped with Waters Symmetry C-18 reverse-phase column (4.6/150 mm, 5 μ particle size, methanol/water (80:20 vol.) as mobile phase). Mass spectra were recorded on Micromass 70S-250 sector mass spectrometer; NMR spectra on a Varian spectrometer at 300 MHz (^{1}H) and 75 MHz (^{13}C). Acetic acid (Sigma-Aldrich, 99.7%, ACS reagent grade) was freshly distilled and subjected to fractional crystallization under inert atmosphere. Triethylamine and pyridine were distilled over KOH and dried over CaH_2. Sodium acetate (anhydrous) was dried at 150 °C under vacuum. All the experiments on acylation and aryl amination were carried out under inert atmosphere, unless otherwise noted.

Aryl amination of cyanuric chloride

*Preparation of 6-chloro-*N,N′*-diphenyl-[1,3,5]triazine-2,4-diamine (di-substituted derivative 2b)*

Method A (in glacial acetic acid medium)

Triethylamine (3.6 mL, 0.025 mol) and aniline (1.95 g, 0.021 mol) were added dropwise upon cooling (t < 35 °C) to 30 mL of acetic acid and the solution was combined with **1** (1.84 g, 0.01 mol) dissolved in 30 mL of AcOH. After 6 h a precipitate was filtered, washed with boiling water (20 mL × 2) to neutral pH, and dried to furnish 1.96 g (66%) of **2b**.

Method B (in the presence of water and with sodium acetate as HCl acceptor)

A solution of **1** (1.84 g, 0.01 mol) in 30 mL of AcOH was combined with a solution of aniline (1.95 g, 0.021 mol) and CH_3COONa (2.0 g, 0.025 mol) in the mixture of AcOH (10 mL) and H_2O (10 mL) at RT without protection from air and then left for 4 h. The precipitate was treated as described above to furnish 2.85 g (96%) of compound **2b**. Melting point (192–194 °C) and spectroscopic data agreed with previoulsy reported data (1*e*).

Preparation of 4,6-dichloro-[1,3,5]triazin-2-yl-phenylamine (mono-substituted derivative 2a)

To a stirred solution of **1** (9.2 g, 0.05 mol) in 150 mL of acetic acid 4.65 g (0.05 mol, 1 equiv.) of aniline and 7.2 mL (0.05 mol, 1 equiv.) of Et_3N in a mixture of 20 mL of AcOH and 80 mL of H_2O was added dropwise within 15 min at 15–17 °C upon cooling with ice water (not letting AcOH to freeze). In the open air, the reaction mixture was left for 1 h at this temperature and then diluted with 1 L of brine. The solid was collected, dried, and recrystallized from 330 mL of heptane (insoluble impurities were filtered off the hot solution) to afford 7.47 g (62%) of pure (HPLC, NMR) compound **2a**, whose melting point (136 to 137 °C) and spectroscopic data was in accordance with that previously reported (1*d*).

Acylation of aniline

Acylation promoted by cyanuric chloride

Et_3N (0.60 mL, 4 mmol) was added dropwise to 5 mL of AcOH, the mixture cooled to RT, combined with a solution of **1** (0.184 g, 1 mmol) in 5 mL of AcOH and left overnight. Aniline (0.370 g, 4 mmol) in 3 mL of AcOH was added and left for 6 h upon stirring. The mixture was diluted with 30 mL of water containing 10 g of NH_4Cl and extracted with benzene (3 × 10 mL). The extract was consequently washed with 10 mL of 0.5 mol/L HCl and 10 mL of 0.5 mol/L NaOH, dried over $MgSO_4$, and evaporated under reduced pressure to furnish 312 mg (77%) of chromatographically pure (~99%, according to HPLC) acetanilide **4**, whose melting point (113 to 114 °C) and ^{1}H NMR agreed well with the literature data (7).

Acylation of aniline with acetic acid as solvent

Aniline (0.93 g, 0.01 mol) was refluxed in 50 mL of glacial acetic acid for 2 h, the solvent evaporated under vacuum, the residue washed with 0.1 N HCl (20 mL), then H_2O (3 × 10 mL) to neutral pH and dried to furnish 1.11g (82%) of pure acetanilide.

Identification of by-products

Triethylamine hydrochloride

Colorless needles, mp 251–253 °C (lit. value 254–260 °C, Merk Index Vol. 13, p. 9740). ^{1}H NMR (300 MHz, D_2O) δ: 1.10 (t, 3H, Et), 3.02 (m, 2H, Et), 4.67 (br. s, H_2O + H^+). HRMS (EI, 70 eV) calcd. for $C_6H_{15}N$ (M^+ – HCl): 101.1204; found: 101.1204.

Cyanuric acid (3a)

Colorless solid, does not have a clear melting point (1*a*). MS (EI, 70 eV) *m*/*z*: 129 (M^+, 100), 86 (M^+ – NHCO, 25), 70 (M^+ – NHCO – O, 20), 58 (NHCONH, 10). HRMS (EI, 70 eV) calcd. for $C_3H_3N_3O_3$: 129.0174; found: 129.0176.

Acetic anhydride (6)

Isolated by fractional distillation of the reaction mixtures under reduced pressure (dry argon atmosphere was maintained), bp 80–83 °C/100mm. ^{1}H NMR (300MHz, $CDCl_3$) showed the characteristic signal of acetyl group protons in Ac_2O at 2.22 ppm (acetyl group protons in AcOH and AcCl

© 2007 NRC Canada

resonated at 2.09 and 2.62 ppm respectively). MS (EI, 70 eV) *m*/*z*: 101 (M^+, 100), 43 (CH_3CO^+, 40).

Acid chlorides

Careful fractional distillation of the reaction mixtures in inert atmosphere did not lead to isolation of the chlorides, as claimed in (4). Because of the extremely high reactivity, no "direct" methods for chromatographic detection of acid chlorides are known. Derivatization, which is normally used in the preparation step of chromatographic analysis (8), fails to distinguish chlorides from anhydrides or other acylating agents. While working with acetic, 4-nitrobenzoic, and trichloroacetic acids as substrates, ^{13}C NMR spectroscopic study of the reaction mixtures showed that they contain several components, including unreacted cyanuric chloride **1**. We compared ^{13}C NMR spectra of authentic samples of 4-nitrobenzoyl chloride, acetyl chloride, and trichloroacetyl chloride with that of reaction mixtures but did not observe the characteristic signals of "acid chloride" carbonyl groups. Mass spectrometric analysis did not reveal any peaks that could be attributed to the acid chlorides either.

Primary ion fluence dependence in time-of-flight SIMS of a self-assembled monolayer of octadecylphosphonic acid molecules on mica discussion of static limit[1]

M. Nieradko, N.W. Ghonaim, L. Xi, H.Y. Nie, J. Francis, O. Grizzi, K. Yeung, and W.M. Lau

Abstract: By using a self-assembled monolayer of octadecylphosphonic acid molecules, $CH_3(CH_2)_{17}PO(OH)_2$, on mica as a model of the "soft" materials, such as self-assembled monolayers (SAMs) and multilayers in many biological systems as well as artificially engineered molecular electronic systems, we have examined the effects of primary ion fluence on time-of-flight secondary ion mass spectrometry (TOF-SIMS) of the technologically important model. Our measurements clearly show that although the intensity per unit primary ion fluence of most atomic ions and many small fragment ions do not vary by more than 10% for the fluence range of 10^{10}–10^{13} cm^{-2}, the intensity of the parent molecular ion can drop by two orders of magnitude in this fluence range. While the changes are different for the primary ion beams of Bi_3^+ (25 keV, 45°), Bi^+ (25 keV, 45°), and Ar^+ (8 keV, 45°), they are all substantial, with the damage cross section induced by the Bi_3^+ beam being the largest (6 000 $Å^2$). Since different secondary ions have quite different intensity changes, the analytical results derived from TOF-SIMS can vary significantly by the time and duration of the measurements in the TOF-SIMS experiment. Therefore, our results suggest that for TOF-SIMS of molecular layers such as SAMs, the primary ion fluence condition should be recorded and reported. In general, the validity of the static condition becomes questionable when the cumulative primary ion fluence exceeds 1×10^{11} cm^{-2}.

Key words: SIMS, static SIMS, TOF-SIMS, soft materials, self-assembled monolayer, bilayer, surface of biological materials.

Résumé : En prenant une monocouche autoassemblée de molécules d'acide octadécylphosphonique, $CH_3(CH_2)_{17}PO(OH)_2$, sur du mica comme modèle des matériaux souples, tels les monocouches autoassemblées (MAA) et les multicouches qu'on retrouve dans plusieurs systèmes biologiques ainsi que les systèmes électroniques moléculaires mis en place artificiellement, on a examiné les effets de la fluence ionique primaire sur la spectrométrie de masse de l'ion secondaire en temps de vol (SMIS-TDV) du modèle technologiquement important. Nos mesures montrent clairement que, même si l'intensité par unité de fluence de l'ion primaire de la plupart des ions atomiques et que plusieurs petits ions fragments ne varient pas plus de 10% pour la plage de fluence allant de 10^{10} à 10^{13} cm^{-2}, l'intensité de l'ion moléculaire parent peut diminuer par deux ordres de grandeur dans cette plage de fluence. Même si les changements diffèrent avec les divers faisceaux des ions primaires du Bi_3^+ (25 keV, 45°), Bi^+ (25 keV, 45°) et Ar^+ (8 keV, 45°), ils sont toutefois toujours importants et la section droite du dommage induit par le faisceau de Bi_3^+ est le plus important (6 000 $Å^2$). En se basant sur le fait que les changements dans les intensités varient d'une façon importante avec la nature des ions secondaires, les résultats analytiques obtenus à l'aide de la spectrométrie de masse de l'ion secondaire en temps de vol peuvent donc varier d'une façon significative avec le temps et la durée des mesures faites de cette façon. Les résultats obtenus suggèrent donc que pour les SMIS-TDV de couches moléculaires telles que les monocouches autoassemblées, la condition primaire de fluence ionique devrait être enregistrée et rapportée. En général, la validation de la condition statique peut être remise en question quand la fluence cumulative de l'ion primaire dépasse 1×10^{11} cm^{-2}.

Introduction

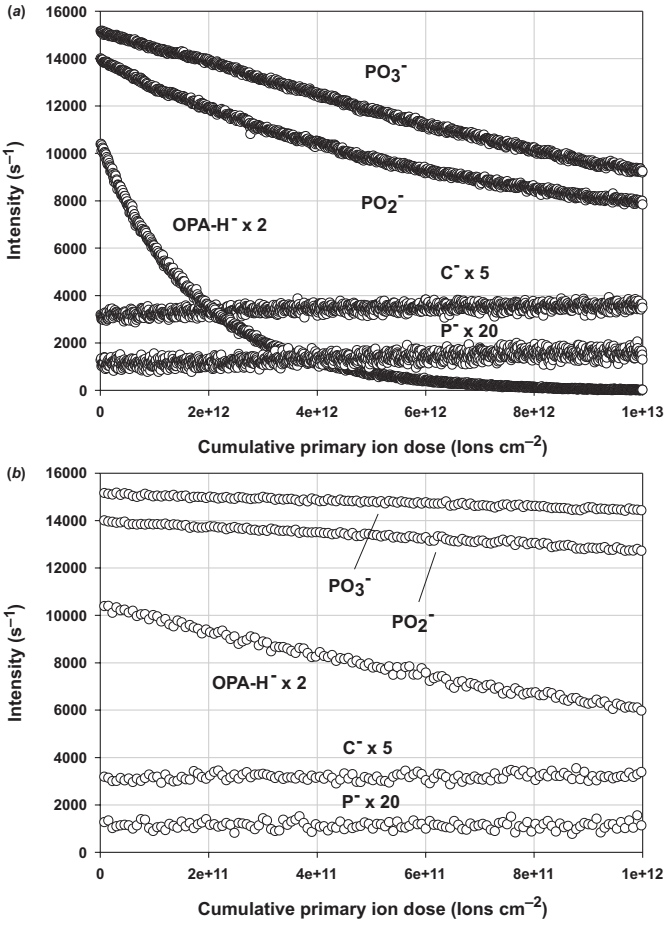
The surface analytical technique of static secondary ion mass spectrometry (static SIMS), as a means of nondestructive characterization, is now widely used for many surface science applications (1). One emerging field of applications bearing particular importance is the analysis of "soft" molecular layers in both molecular electronics and biological systems, soft materials that include submonolayers of adsorbed organic molecules, self-assembled monolayers (SAM), bi-layer and multi-layer lipid molecules, cell membranes, and surfaces of other biological systems (2–9). They are soft because the intermolecular bonding is commonly van der Waals in nature. In these studies the characterization often requires the detection and imaging of the parent and fragment ions of a constituent with a concentration much less than a monolayer. SIMS, in conjunction with the time-of-flight (TOF) technique, is indispensable because of its rather unique capability in detecting such a trace surface concentration. This detection sensitivity allows the completion of an analysis with a very low primary ion irradiation fluence so that in the course of the analysis only very few of the surface atoms and (or) molecules are struck by a primary ion. As such, when they are probed, all the atoms and (or) molecules are likely in their original condition because all prior probing events are too far away to affect them. Under this "static" condition the SIMS signals can be used to deduce the very original nature of the surface. The accomplishment of this measurement outcome is attractive to most studies, including studies of molecular layers in molecular electronics and biological systems. However, the soft nature of these molecular layers makes them susceptible to changes induced by ion bombardment; hence, further clarification of the static condition in this context is required.

By definition, the maximum primary ion fluence below which the static condition is valid really depends on the radial range of the surface interactions induced by the arrival impact of a specific primary ion on a specific surface. Hence, the static condition itself is by no means "static", and it is more difficult to satisfy when the surface is soft and more susceptible to ion-induced changes. In fact, in the early development of static SIMS most specimens of interest were stable inorganic materials with surfaces relatively immune to ion-induced changes. The radial range is often correlated to the collision cross-section, which is typically about 10^{-14} cm^2 for most ion bombardment at the keV range for many metals, semiconductors, and dielectrics (10–12). For an analysis of this type, the static condition can be quite forgiving and is often specified with a primary ion fluence lower than 1×10^{13} cm^{-2}. In 1991 and 1992, Legett and Vickerman measured (13–14) the primary ion fluence dependence of secondary ion signals from polymers poly(ethylene terephthalate), poly(tetrafluoroethylene), poly(vinyl chloride), and poly(methyl methacrylate) and showed the damage of the original nature of the polymer caused by both ion bombardment and ion neutralization. In 1995, Delcorte et al. (15) cautioned any casual claim of nondestructive measurements and insightfully proclaimed that there is no real "static" condition, and one should always be careful about bombardment-induced effects during any ion beam analysis. In 1996, Gilmore and Seah (16) carefully examined the static SIMS condition for polymers such as poly(ethyleneterephthalate) and poly(tetrafluoroethylene) with 4 keV argon and xenon primary ions and made the practical recommendation that for the analysis of polymers, the primary ion fluence limit for maintaining the static condition should not be higher than 1×10^{12} cm^{-2}. Since then, most studies of soft materials have indeed adopted this recommendation.

Because primary ion bombardment effects on soft molecular layers have not yet been studied thoroughly, we have begun to study the effects of primary ion fluence in TOF-SIMS and TOF ion scattering spectroscopy (ISS) for the soft molecular layers in the molecular electronics and biological systems in our own on-going research. In this article, we report on some of our results collected from the special specimens of octadecylphosphonic acid, $CH_3(CH_2)_{17}PO(OH)_2$, on mica in the form of a self-assembled monolayer (referred to as OPA/mica, with the molecule referred to as OPA-H). These specimens were used to model the silane-based and phosphyl-based molecular layers in molecular electronics and cell membranes. They were also chosen because our research group had already acquired some prior knowledge on their formation mechanism and technical skills on the use of TOF-SIMS and atomic force microscopy (17, 18).

The article will focus on the exemplification of the sensitive TOF-SIMS changes in the fluence regimes of 10^{11} to 10^{13} cm^{-2}, with some data points collected below 10^{11} cm^{-2} whenever the data collection is practical. Since the Bi_3^+ ion beam is one of the primary ion beams of choice in the recent research of soft molecular layers, most of the results shown in this article were collected with it. To illustrate some of our ideas on the possible ion–surface interactions causing the observed sensitivity of primary ion fluence, we will also show some TOF-SIMS results of Bi^+ and Ar^+ on OPA/mica and of Bi_3^+ on alkyl-thiols/Au(111).[4] In addition, we will briefly correlate these results with those from our scanning probe microscopic studies of the ion–surface interactions on these molecular layers (19).

Results and discussion



Primary ion fluence dependence of negative secondary ions from OPA/mica with Bi_3^+

As expected, the secondary parent ion intensity critically depends on the primary ion fluence for the model molecular layer sample of OPA/mica in the entire primary ion fluence

[4] N. Ghonaim. Manuscript in preparation.

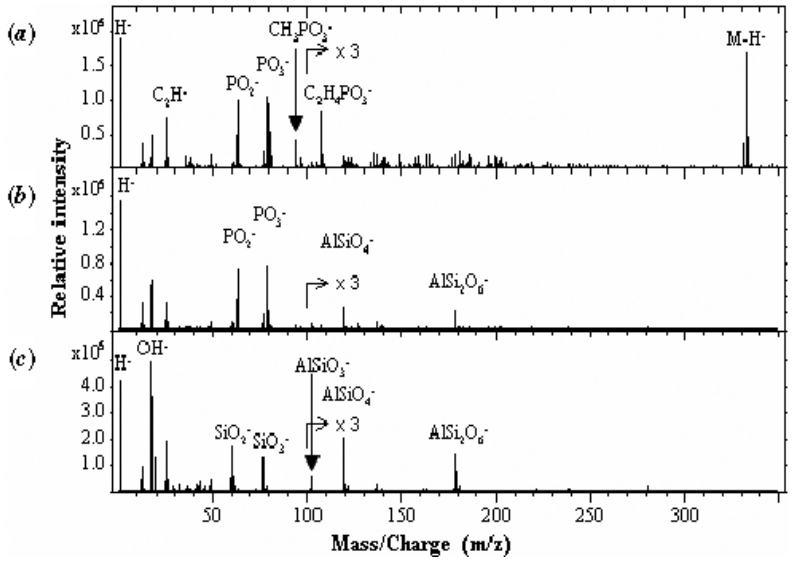
Fig. 1. Relative TOF-SIMS negative secondary ion intensities as a function of primary ion fluence for OPA on mica using a Bi_3^+ ion beam within a cumulative primary ion fluence of (*a*) 10^{13} cm^{-2} and (*b*) 10^{12} cm^{-2}.

range from about 1×10^{10} to 1×10^{13} cm^{-2}. Negative secondary ion intensities are shown in this example because the negative secondary ion yield is much higher than the positive ion counterpart. The comparison between negative and positive secondary ions can be found later in the paper. From Figs. 1*a* and 1*b*, one sees that the parent molecular ion (OPA-H$^-$) drops exponentially, with a decrease in intensity of two orders of magnitude when the cumulative primary ion fluence increases from 1×10^{10} to 1×10^{13} cm^{-2}. Similarly, the characteristic phosphate fragments PO_3^- and PO_2^- decrease in intensity immediately as well, but these changes are much less marked within 1×10^{12} cm^{-2}. The measured changes are definitely not caused by any system error because the negative fragment ion intensity of elemental carbon (C$^-$) and phosphorus (P$^-$) change very little in the same cumulative primary ion fluence range. Conceivably the bombardment leads to bond breakage in the adsorbed molecules causing a drop in the concentration of the virgin molecules. The bond breakage, on the other hand, increases the number of carbon atoms having dangling bonds, which may lead to the observed increase in the C$^-$ intensity. As revealed in the following sections, the C$^-$ intensity for TOF-SIMS with Bi^+ and Ar^+ and that of C^+ for Bi_3^+ also increase with increasing cumulative primary ion fluence. All these observations, together with the observations that the parent ion intensities in all these bombardment conditions consistently decrease exponentially with the cumulative primary ion fluence, converge to the inference that the primary ion bombardments in all these cases are causing a very significant damage to the adsorbed molecules. To further support the results shown by the plots of the primary ion fluence dependence of the selective ions in Fig. 1, we show the negative ion mass spectra of OPA/mica at a cumulative primary ion fluence of 1×10^{11} cm^{-2} (Fig. 2*a*) and 1×10^{13} cm^{-2} (Fig. 2*b*) and those of a bare mica at a cumulative primary ion fluence of 1×10^{13} cm^{-2} (Fig. 2*c*). Once again, the parent molecular ion intensity in Fig. 2*a* drops rapidly in Fig. 2*b* and is obviously absent in Fig. 2*c*. In Fig. 2*b*, some fragments derived from the bombardment damage of OPA, such as PO_2^- and PO_3^-, are seen; once again, they are absent in Fig. 2*c*. A comparison of Figs. 2*a* and 2*b* also shows that the intensity drop for the OPA parent molecular ion is much more significant than those of the PO_2^- and PO_3^- fragment ions. While no signals from the mica substrate are seen in Fig. 2*a*, they appear in Fig. 2*b*. However, this does not necessarily mean that a large fraction of the OPA coverage has been completely removed, because the PO_2^- and PO_3^- signals are still strong in Fig. 2*b* and a careful examination of the intensity of P$^-$ (see also Fig. 1*b*) shows little change up to a primary ion fluence of 1×10^{13} cm^{-2}.

In principle, the observed exponential decrease of the parent molecular secondary ion intensity is a convoluted effect of damage and removal of the OPA molecule, together with the possible change in ion yield. However, OPA removal due to sputtering or desorption should not be an important attribute in the low primary ion fluence range of the present work. For example, if a removal yield of 10 molecules per primary ion is assumed, the decrease in OPA surface density should still be less than 10% for a primary ion fluence of 1×10^{13} cm^{-2}. There are further experimental observations supporting the insignificance of OPA removal. First, the P$^-$ intensity does not change significantly at the primary ion fluence of 1×10^{13} cm^{-2}, as shown in Fig. 1. If removal of OPA is important, one would expect a significant drop in the P$^-$ intensity. Second, an atomic force microscopic analysis of the sample after receiving a primary ion fluence of 1×10^{13} cm^{-2} shows no void in the self-assembled monolayer. Regarding the ion yield factor, subsequent sections of this article show that similar exponential decreases of the parent molecular ion intensity are evident for positive ion measurements with Bi_3^+ and negative ion measurements with Ar^+ and Bi^+. This indicates that the observed exponential decreases of the parent molecular ion intensity in all these cases are mainly due to the damage of the parent molecules induced by the primary ion bombardment.



To further analyze the observed secondary parent ion intensity changes as a function of primary ion fluence, we assume that the observed exponential drop of the parent molecular ions is due to the damage of the parent molecule, OPA-H, by the primary ion bombardment. Taking this assumption, we adopt the following common description with the concept of damage cross-section (1),

$$[1] \qquad I_t(\phi) = I_o \exp(-\sigma\phi)$$

where I_o and I_t are the respective secondary parent ion intensities at the beginning of the measurements and at time t, ϕ is

Fig. 2. TOF-SIMS negative secondary ion mass spectra for OPA on mica using a Bi_3^+ ion beam within a cumulative primary ion fluence of (*a*) 1×10^{11} cm^{-2} and (*b*) 1×10^{13} cm^{-2}. The spectrum from bare mica with a cumulative primary ion fluence of 1×10^{13} cm^{-2} is included in (*c*).

the cumulative primary ion fluence after time *t*, and σ is the damage cross-section for the parent molecule. It turns out that the damage cross-section of the parent OPA-H$^-$ molecule by Bi_3^+ at 25 keV and at an incident angle of 45° is about 6×10^{-13} cm^2 (or 6 000 Å^2). This is consistent with the work by Galera et al. (20) on the Langmuir–Blodgett monolayer of arachidic acid on gold with 2 keV Cs^+ and an ion incident angle of 20°. The damage cross-section in this previous case is ~1×10^{-13} cm^2. In comparison, Benninghoven and Sichtermann (11) reported significantly smaller damage cross-sections (from 1 to 7×10^{-14} cm^2) for various parentlike ions from a sample of leucine (with 2.25 keV Ar^+ as the primary ion). We speculate that the relative large damage cross-sections for molecular layers such as self-assembled monolayers and Langmuir–Blodgett films may arise from the agility of the damaged molecules and their diffusion inevitably extends the radial range of molecular damage.

With the estimated damage cross-section value of 6×10^{-13} cm^2 and eq. [1], we can further calculate the primary ion fluence limit for the static condition by adopting the Gilmore and Seah recommendation of setting the fluence limit by allowing not more than a 10% change in the secondary ion intensity. The result in this case is 2×10^{11} cm^{-2}, which is significantly lower than the prevalent assumption of a fluence limit of 1×10^{12} cm^{-2} for the static condition. If this prevalent fluence limit assumption were adopted in the study of OPA/mica under the same analysis condition in this work, the maximum secondary ion intensity change in the fluence range of 1×10^{12} cm^{-2} is 39%. Obviously, the claim of the static condition is invalid.

What are the practical scientific implications of erroneously going beyond the primary ion fluence limit of the static condition? The immediate implication is that any measurements of the surface density of a molecule with a large damage cross-section will become rather arbitrary when the measurements only claim the validity of the static condition without specifying the actual cumulative primary ion fluence for the measurements. In addition, rectifying this error by resorting to calculations of relative intensities with one molecular species as an internal reference may not work because the damage cross-sections are likely molecule and (or) fragment dependent, even for the same primary ion bombardment conditions. For example, the data in Fig. 1 clearly show that the damage cross-section for OPA-H$^-$ is higher than PO_3^- and PO_2^-. Hence, we advocate that in TOF-SIMS studies of soft molecular layers, one should mind the effects of primary ion fluence. With our estimated primary ion fluence limit of 2×10^{11} cm^{-2} for OPA/mica with 25 keV Bi_3^+, we recommend that the static condition should be set to 1×10^{11} cm^{-2} for TOF-SIMS studies of soft molecular layers. However, we prefer to recommend that a thorough check of the primary ion fluence dependence is the best remedy for reducing any measurement errors induced by the dependence of primary ion fluence.

Primary ion fluence dependence of positive secondary ions from OPA/mica with Bi_3^+

Under Bi_3^+ bombardment, the detection of negative secondary ions commonly gives more intense signals than that of positive secondary ions from an oxide matrix. For the sake of completeness of illustrating the primary ion fluence dependence in this work, we show the secondary ion intensities of OPA+H$^+$ and C$^+$ as a function of primary ion fluence in Figs. 3*a* and 3*b*. Although the signal-to-noise statistics displayed in Fig. 3 are far from ideal, the data do show clearly that while the intensity of C$^+$ increases slowly, the parent molecular ion intensity drops rapidly. When we fit the data for OPA+H$^+$ using eq. [1], we obtain a damage cross-section of ~ 5×10^{-13} cm^{-2}. Because the signal-to-noise level of this set of data is poor, we do not speculate on any difference in damage cross-section or damage mechanism between the negative secondary ion detection and the positive ion detection.

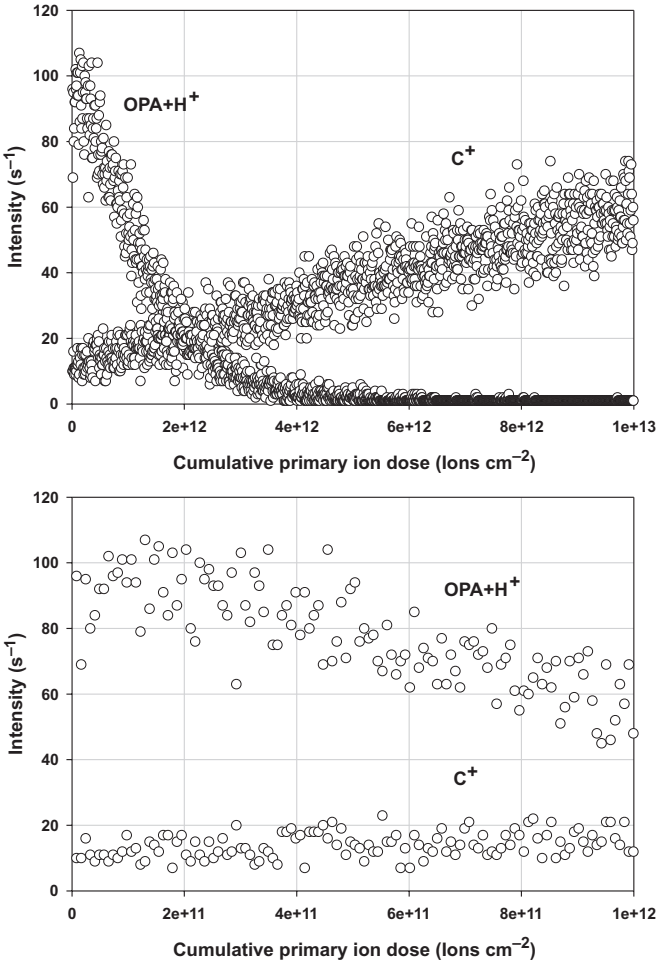
Fig. 3. Relative TOF-SIMS positive secondary ion intensities as a function of primary ion fluence for OPA on mica using a Bi_3^+ ion beam within a cumulative primary ion fluence of (*a*) 10^{13} cm^{-2} and (*b*) 10^{12} cm^{-2}.



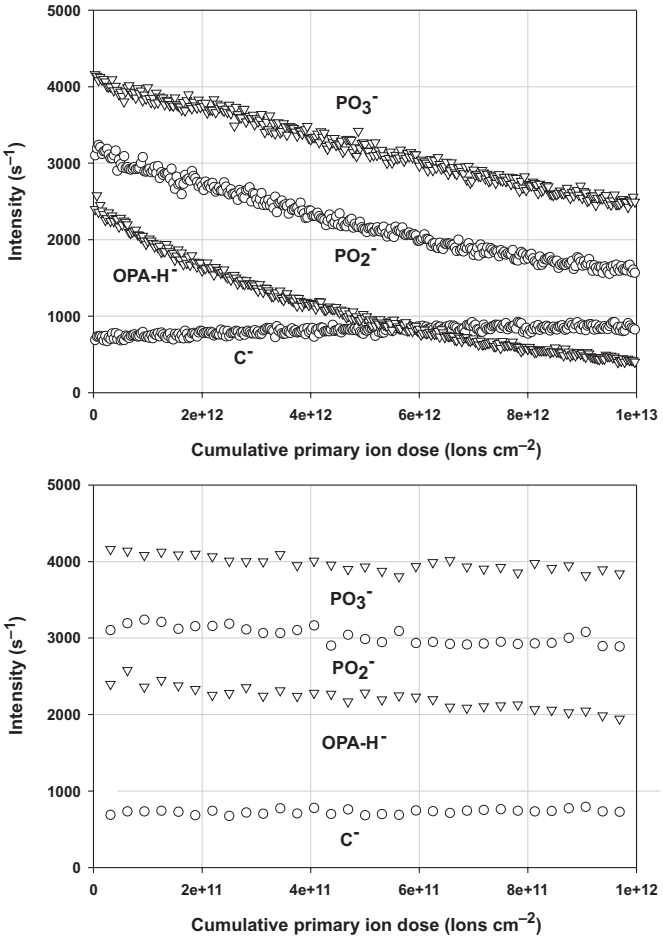


Fig. 4. Relative TOF-SIMS negative secondary ion intensities as a function of primary ion fluence for OPA on mica using a Bi^+ ion beam within a cumulative primary ion fluence of (*a*) 10^{13} cm^{-2} and (*b*) 10^{12} cm^{-2}.

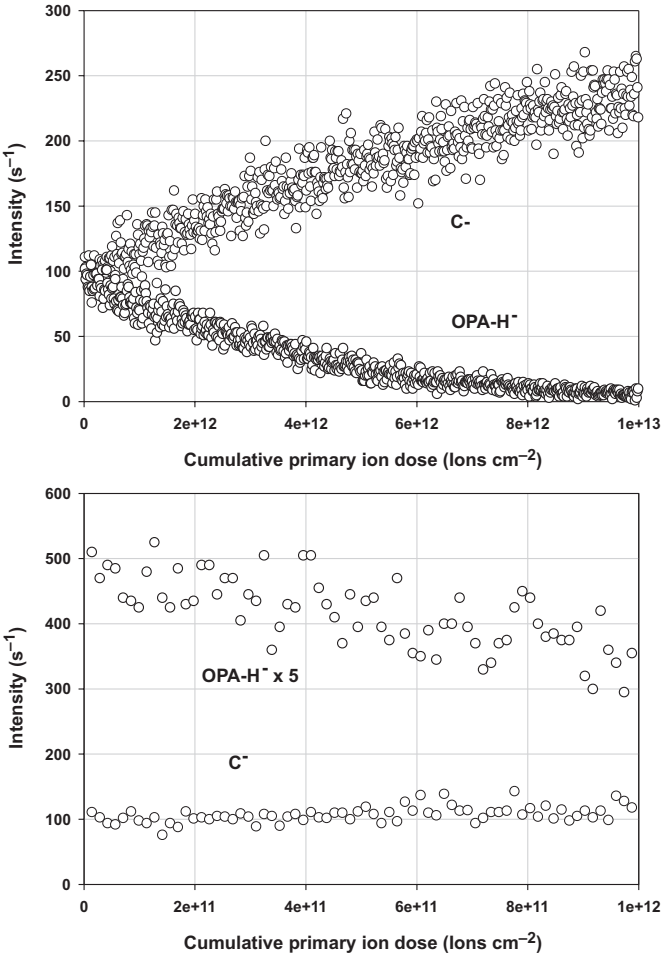

Comparison of the results from OPA/mica with Bi_3^+ with those with Bi^+ and Ar^+

Our preliminary results from bombardment of the OPA/mica by a 25 keV Bi^+ source shows similar dependencies on primary ion fluence for OPA-H$^-$ and C$^-$ as well as the characteristic phosphate headgroups PO_3^- and PO_2^-, as shown in Figs. 4*a* and 4*b*. The intensity of the carbon fragment ion slowly increases throughout the experiment while the intensity of the parent molecular ion drops exponentially. As expected, the Bi_3^+ ion beam outperforms the Bi^+ ion beam in producing characteristic secondary ion intensities in the same fluence range because of the nature of cluster ion bombardment (2). Fitting of the Bi^+ OPA-H$^-$ profile with eq. [1] gives a damage cross-section of 2×10^{-13} cm^2. For comparison purposes, bombardment of the OPA/mica by an 8 keV Ar^+ source is shown in Figs. 5*a* and 5*b*. The molecular ion is only weakly detected compared with using either of the bismuth ion sources. As a result, each point of the profile is summed over five scans to give a less noisy appearance. Fitting of the Ar^+ OPA-H$^-$ profile with eq. [1] gives a damage cross-section of 3×10^{-13} cm^2. The smaller damage cross-section of OPA-H$^-$ using the Bi^+ source compared with the Bi_3^+ source is expected, as discussed in the literature with various studies of thin organic layers under cluster ion bombardment (3, 5). The kinetic energy of the Bi^+ source is 25 keV while that of the Bi_3^+ source is ~8 keV per atom. Therefore the Bi^+ source will penetrate deeper into the specimen while producing less damage in the near-surface plane compared with each atom of the Bi_3^+ source.

With the readily available TRIM/SRIM codes for studying molecular dynamics in the collision cascades, we use a hypothetical sample of 2 nm polyethylene on alumina to cross-check the effects of primary ion bombardment for Bi^+ (25 keV, 45°), Bi^+(8 keV, 45°), and Ar^+ (8 keV, 45°). The calculations give the 3-dimensional ion, recoil, and vacancy distribution statistics, and have been prevalently used in the interpretation of SIMS results (2, 5). In the present work, we find that Ar^+ at 8 keV produces 3 to 4 carbon vacancies and 10 hydrogen vacancies per Ar^+ in the polymer layer, which is about two times less than Bi^+ at 25 keV. However, the lateral range of the vacancy distribution in the polymer layer in both cases is about the same. This may be the reason the damage cross-section of Ar^+ at 8 keV is close to that of Bi^+ at 25 keV. Although the TRIM calculations do not take into

Fig. 5. Relative TOF-SIMS negative secondary ion intensities as a function of primary ion fluence for OPA on mica using an Ar^+ ion beam within a cumulative primary ion fluence of (*a*) 10^{13} cm^{-2} and (*b*) 10^{12} cm^{-2}.

account many-body interactions and likely over-simplify the collision cascade activities induced by cluster ion bombardment, we find that three Bi^+ ions at 8 keV produce at least two times more hydrogen and carbon vacancies in the top polymer layer than 1 Bi^+ at 25 keV. Our experimental results show that the damage cross-section of Bi_3^+ at 25 keV is indeed larger than that of Bi^+ at 25 keV.

Comparison of the SIMS results from OPA/mica with those from alkyl-thiols/Au(111)

In our on-going research on TOF-SIMS and TOF-ISS of soft molecular layers, we have used the OPA/mica model to represent the silane and phosphyl self-assembled monolayer families and the alkyl-thiol/Au(111) model to represent the thiol self-assembled monolayer family. Briefly, the TOF-SIMS of the alkyl-thiol/Au(111) model is also sensitively dependent on the primary ion fluence, and the primary ion fluence limit for the static condition is also much lower than 1×10^{12} cm^{-2}. Hence, the extent of molecular damage is not fundamentally different from the OPA/mica model. In fact, our TOF-ISS studies of the alkyl-thiol/Au(111) model, which detect neutral recoil emission as well as ion emission from the surface, have also independently confirmed that primary ion fluence causing damage to 10% of surface molecules is below 1×10^{12} cm^{-2}, even for 4 keV Ar^+ (20° incidence).[5] Although the TOF-SIMS of the OPA/mica and the alkyl-thiol/Au(111) model are both influenced by molecular damage, the overall primary ion fluence dependence of the alkyl-thiol/Au(111) model is different from that of the OPA/mica model. For example, while the SIMS signals of the large molecular ions from OPA/mica generally drop exponentially, those from thiols/Au do not change monotonically. In other words, those from thiols/Au are quite complicated. The difference arises from the fact that during TOF-SIMS with a reactive primary ion such as bismuth, cesium, or oxygen, the primary ion bombardment does not only cause molecular damage but also affects the relative ion yields of some ions. By examining the intensity changes of all secondary ions (or the lack of changes) in the OPA/mica model with Bi_3^+ (both negative secondary ions and positive secondary ions), Bi^+ (negative secondary ions), and Ar^+ (negative secondary ions), we have not observed any obvious ion yield changes induced by the accumulation of primary ion fluence. In comparison, the ion yield changes are very obvious in the alkyl-thiols/Au model. The detailed description of the results collected from the alkyl-thiol/Au(111) model will be given elsewhere.[4]

Complementary results from scanning probe microscopy of relevant model specimens

In the present study of the OPA/mica model, we have used atomic force microscopy to verify the presence of a "complete" monolayer of OPA molecules on a freshly cleaved flat mica surface. In this context, complete means no observation of any detectable voids in the layer. After the TOF-SIMS experiments, we used AFM to track the molecular damage inferred from the TOF-SIMS data. Interestingly, no clear evidence of void formation has been detected. The fact that the molecular damage inferred from TOF-SIMS is not accompanied by sputter removal or desorption of the molecules is further confirmed by the observation of a constant P^- intensity for a primary ion fluence up to 1×10^{13} cm^{-2} in the Bi_3^+ experiment, which has the highest damage cross-section. As mentioned earlier in this article, we speculate that the "molecular damage" inferred from the changes of parent molecular ion intensity may be the combined effect of the fragmentation of some parent molecules being influenced by a primary ion arrival and the diffusion of the altered molecules. Drastic removal of the parent or altered molecules from the surface are not necessary conditions for the observed primary ion fluence dependence of secondary ion intensity. If so, AFM cannot detect the surface chemistry changes induced by the primary ion fluence.

We want to note in this discussion that in our recent examination of short-chain alkyl-thiols on Au(111), we have observed from scanning tunneling microscopy that while the original surface lattice of short-chain alkyl-thiols (C_2H_5S or C_3H_7S) on Au(111) is ordered, a seemingly armless ion bombardment with a low fluence of 10 eV H^+ can cause some drastic changes on the ordering of the surface lattice

[5] O. Grizzi. Manuscript in preparation.

and clear evidence of bombardment-induced diffusion of molecules can be recorded (19). This set of new results supports our speculation of a "fragmentation + diffusion" mechanism causing our observed sensitive primary ion fluence on TOF-SIMS analysis of a soft molecular layer.

Conclusion

The primary ion fluence effects on the TOF-SIMS data from an octadecylphosphonic acid (OPA) self-assembled monolayer (SAM) on freshly cleaved mica (muscovite) have been studied with Bi_3^+, Bi^+, and Ar^+ primary ion beams. The parent molecular secondary ions in all change rather drastically as a function of primary fluence below 1×10^{11} to 1×10^{13} cm^{-2}. Fitting of the OPA-H^- data (Bi_3^+ ion beam, 25 keV, 45° incident angle) to a single exponential function gives a damage cross-section of 6×10^{-13} cm^2 (6 000 $Å^2$) for the parent molecular ion. A similar damage cross-section of the parent molecular ion is observed during the collection of positive secondary ions. The static limit for TOF-SIMS of OPA/mica with Bi_3^+ is estimated to be 2×10^{11} cm^{-2}, which is significantly lower than the prevalent static limit of 1×10^{12} cm^{-2} in TOF-SIMS. In comparison to Bi_3^+ (25 keV, 45°), Bi^+ (25 keV, 45°), and Ar^+ (8 keV, 45°) have OPA-H^- damage cross sections of 2×10^{-13} cm^2 and 3×10^{-13} cm^2, respectively. With these data, we recommend that it is safer to set the static condition to 1×10^{11} cm^{-2} for TOF-SIMS of soft molecular layers. Ideally, the primary ion fluence condition and the secondary ion changes as a function of primary ion fluence should be measured and reported.

Experimental

Sample preparation

Crystalline octadecylphosphonic acid (OPA), $CH_3(CH_2)_{17}PO(OH)_2$, was obtained from Alfa Aesar (Ward Hill, Massachusetts). The sample preparation was performed according to the procedure of Nie et al. (16). An OPA SAM of approximately 100% coverage was prepared by spin-coating a 2 mmol/L solution of OPA in trichloroethylene onto freshly cleaved muscovite mica at 5 000 rpm. This coating was then dried with nitrogen to remove any weakly adsorbed molecules or other loose contaminants. The mica was 1 cm x 1 cm in size. Four regions were etched onto this coated mica, one for each TOF-SIMS time profile performed. A second bare piece of muscovite mica was also cleaved for comparison purposes in the TOF-SIMS studies.

AFM measurements

Topography measurements were performed using a PSIA XE-100 microscope. The sample surface was scanned in noncontact, low-voltage mode with a scan area of 1 μm × 1 μm. The low voltage mode was used to observe fine surface features that were present in SAMs

TOF-SIMS measurements

An ION-TOF (Gmbh) TOF-SIMS IV single-stage reflectron instrument with 10 kV post acceleration was used to study the OPA SAMs prepared on the mica substrate. A pulsed, low-energy electron flood gun was used to neutralize sample charging. All measurements were performed at room temperature. The raw data was analyzed using the IonSpec program. All intensities were normalized against the total intensity of each particular spectrum. The lack of detectable damage arising from the low energy electron irradiation during the measurements was confirmed by the fact that no change was observed after the TOF-SIMS measurement was paused, by blanking the primary ion beam without stopping the low energy electron irradiation.

Negative secondary ion OPA on mica time profile with Bi_3^+ source

Negative secondary ion measurements were performed using a (10 kHz) pulsed 25 keV Bi_3^+ primary ion beam at an incidence angle of 45°. The primary ion beam with a pulsed current of 0.12 pA was focused and rastered onto a 128 × 128 μm^2 area, delivering a cumulative ion dose of 1 x 10^{13} ions cm^{-2}.

Negative secondary ion OPA on mica time profile with Bi^+ source

Negative secondary ion measurements were performed using a (10 kHz) pulsed 25 keV Bi^+ primary ion beam at an incidence angle of 45°. The primary ion beam with a pulsed current of 0.5 pA was focused and rastered onto a 128 × 128 μm^2 area, delivering a cumulative ion dose of 1×10^{13} ions cm^{-2}.

Positive secondary ion OPA on mica time profile with Bi_3^+ source

Positive secondary ion measurements were performed under these same conditions and an identical cumulative ion dose. The primary ion beam pulsed current was 0.13 pA.

Positive secondary ion mica time profile with Bi_3^+ source

Positive secondary ion measurements were performed under these same conditions and an identical cumulative ion dose. The primary ion beam pulsed current was 0.13 pA

Negative secondary ion OPA on mica time profile with Ar^+ source

Negative secondary ion measurements were performed using a (10 kHz) pulsed 8 keV Ar^+ primary ion beam at an incidence angle of 45°. The primary ion beam with a pulsed current of 0.182 pA was focused and rastered onto a 256 × 256 μm^2 area, delivering a cumulative ion dose of 1×10^{13} ions cm^{-2}.

Accurate UV–visible spectral analysis of thiomolybdates

R. Stephen Reid, Rhett J. Clark, and Emmanuel K. Quagraine

Abstract: The UV–visible spectra of various thiomolybdates have been studied. Cross-contamination during synthesis and extensive overlap in the spectra have hindered the UV–vis characterization to date. We report the use of multivariate curve fitting for the accurate quantification of the composition of thiomolybdate mixtures as well as the molar absorptivities at key wavelengths of the spectrum of each pure thiomolybdate. The synthesis and isolation of all four thiomolybdates by a common synthetic route using $(NH_4)_2S$ is also reported. This is the first time that monothiomolybdate has been isolated from aqueous solution.

Key words: Thiomolybdates, UV–visible spectroscopy, speciation, curve fitting.

Résumé : On a déterminé les spectres UV–visible de divers thiomolybdates. Des contaminations croisées au cours des synthèses et des recouvrements dans les spectres avaient toujours empêché leur caractérisation jusqu'à maintenant. On a fait appel à une méthode d'ajustement de courbe à plusieurs variables pour faire une quantification précise de la composition de mélanges de thiomolybdates et pour déterminer les absorptivités molaires à des longueurs d'onde clés des spectres de chacun des thiomolybdates purs. On rapporte aussi la synthèse et l'isolement de chacun des quatre thiomolybdates par une voie de synthèse commune à l'aide de $(NH_4)_2S$. C'est la première fois que le monothiomolybdate a pu être isolé à partir d'une solution aqueuse.

Mots-clés : thiomolybdates, spectroscopie UV–visible, spéciation, ajustement de courbe.

[Traduit par la Rédaction]

Introduction

Thiomolybdates (MoS_xO_{4-x}), herein called TM*x* where *x* represents the number of S ligands, are known to cause copper deficiency in ruminants (1). For an overview of TM chemistry, see the review by Laurie (2). TM interconversions are relatively slow processes (minutes to hours), and the determination of these rate constants is paramount to modeling the actions of copper in the rumen. The work reported here forms part of an ongoing study toward this goal (3, 4).

TM4 and, likely, TM3 are the primary copper antagonists, while TM2 and TM1 are probably not responsible (5). However, because of the sequential nature of TM formation, the synthesis of pure (>99.5%) TM compounds is difficult. A reliable means for determining the composition (±0.1%) of all TMs in a mixture is crucial for quantitative study.

TMs are formed by successive substitution of O with S ligands (Scheme 1). The synthesis is well-known in general terms and has been performed for some time (6), with the exception of TM1, which is said to be difficult to isolate (6–8). Previously, the synthesis required H_2S gas, which is toxic and harmful to the environment. However, since H_2S has a pKa1 of 7 and a pKa2 of about 17 (9), and TM synthesis is performed at pH values ranging from 10 to 13, HS^- is certainly the dominant sulfide species and probably the nucleophilic species involved in the reaction. This was first proposed by Harmer and Sykes (6).

Scheme 1.

$$TM_{x-1} \underset{OH^-}{\overset{HS^-}{\rightleftharpoons}} TM_x \underset{OH^-}{\overset{HS^-}{\rightleftharpoons}} TM_{x+1}$$

To synthesize a pure TM, the reaction conditions must be such that reaction is stopped when the desired TM is at a maximum. To favor further substitution of S, one can increase the S:Mo ratio, decrease the pH, increase the temperature, and increase the reaction time. To synthesize TM1, TM2, and TM3, careful adjustment of the parameters is necessary, and even then, it is extremely difficult to avoid cross-contamination with other TMs. An effective means of characterizing the TM purity and composition is therefore required.

Pure TM4 synthesis, on the other hand, is very easy because the reaction is simply forced to proceed completely, avoiding cross-contamination. Manipulation of the synthesis by increasing reaction times and using greater S:Mo ratios did not effect the UV–vis spectrum. This indicated that TM4 was already being obtained at 100% purity.

TM purity has been obtained by a variety of techniques and reported in the literature. One common method used is elemental analysis (6, 10, 11). However, a positive result with elemental analysis must be backed up by another method because an equimolar mixture of the two surrounding TMs gives the same theoretical values as the pure de-

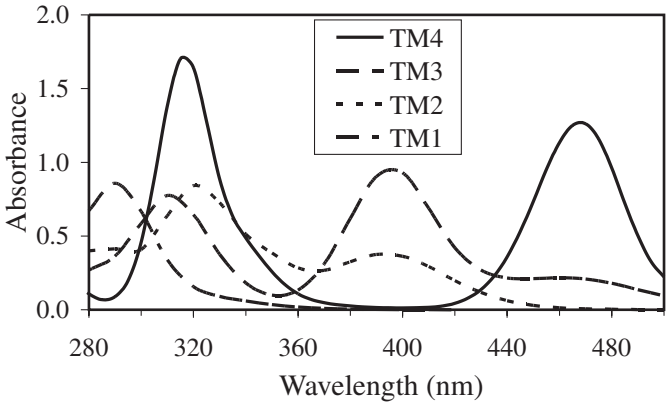
 doi:10.1139/V07-122 © 2007 NRC Canada

sired TM. Also, the differences typically determined between theoretical and experimental percentages of Mo and S are insufficient for accurately determining purity.

^{95}Mo NMR has shown some promise for determining TM purity. Each TM gives a single, sharp peak, well-resolved from the others (12). Despite the nucleus's significant quadrupole moment, the electronic environment around Mo in all four thiomolybdates is apparently sufficiently symmetric to result in minimal quadrupolar broadening. ^{95}Mo, however, has a natural abundance of 15.72% and is a low-sensitivity nucleus resulting in a poor signal-to-noise ratio. To get a reasonable spectrum for quantitative analysis, high concentrations (~0.1 mol/L) and long acquisition times (>10 min) are needed. Contributions of other TMs, up to about 5%, may go undetected. TMs are also rather unstable in water with decreased stability with decreased number of S atoms. These long acquisition times mean that hydrolysis will occur before the spectrum is obtained.



Ogra et al. used fast atom bombardment mass spectrometry (FAB-MS) to identify the presence and molecular mass of the TM of interest (13). However, attempts in our group to quantify purity using FAB and electrospray (ES)-MS were ineffective because of a large degree of fragmentation (12). This is partly due to degradation and hydrolysis of the samples at the high temperatures that were incurred. ES-MS also caused a loss of S during the analysis and may have even reacted with the less-stable TMs (TM1 and TM2) to form increased amounts of TM3 or TM4.

All TMs give characteristic UV–vis spectra (Fig. 1), making this technique useful for speciation. It has been used extensively for this purpose (6, 10, 14, 15). The strongly overlapping absorbances, however, make it difficult to identify molar-absorptivity constants because purity cannot be readily determined by inspection. Originally, elemental analysis was used to confirm a pure compound, and then the UV–vis spectrum was taken and used to directly measure absorptivity constants, which were subsequently used as a reference for purity. The uncertainty of the purity of the original compound makes the resultant absorptivities suspicious.

Some workers have used single-wavelength measurements, selecting a wavelength where there are only two absorbing species, particularly when performing kinetic studies (6, 16). The assumption made in such an approach is that contributions of all other TMs in the sample to the spectrum are negligible. The quantities of the absorbing species are determined by a simple fit. This method relies on the quality of the absorptivity constants available as the composition is directly related to it. It also requires that the assumed species make up 100% of all absorbing TM species present. This is rarely the case. Thus, it can be concluded that the monitoring of a single wavelength is insufficient for quantitative determinations.

TM1 has proven to be difficult to synthesize in pure form. The only reported isolation of TM1 was the potassium salt using methanol at –15 °C for 24 h with a yield of 10% (17). Otherwise, its presence has been inferred using UV–vis spectroscopy during TM formation (18). Supposed characteristic λ_{max} and ε (molar absorptivities) have also been inferred during reaction in solution (15) but again do not account for contamination.

Fig. 1. Simulated UV–vis spectra of 10^{-4} mol/L solutions of TM1, TM2, and TM3. The TM4 spectrum is of an actual synthesized sample.

The entire TM2 spectrum is overlapped by TM3, a common contaminant when synthesizing TM2. This makes ε determination via standard Beer's Law curve highly suspected. The corresponding elemental analysis seen in the literature for TM2 also leaves doubt that the original sample was pure (10).

Because mutual TM contamination is so common, an effective method for determining accurate concentrations of individual TMs in mixed-TM samples is necessary. Preliminary results obtained by analyzing data at six wavelengths using Microsoft Excel® readily displayed discrepancies with literature results obtained from univariate analysis. This demonstrates the need for a more-robust mode of analysis.

Multivariate curve fitting provides simultaneous determination of large numbers of parameters; in this case, these parameters are molar absorptivities of all TMs present at each wavelength selected as well as the fractional composition of all species present in a given sample. This method has a number of advantages over univariate analyses. First, it eliminates the need for selecting an appropriate single wavelength. Second, absorbance errors will be averaged out over data at all wavelengths and will not directly affect any single result. It also removes the linear dependence amongst the parameters. Overall, multi-wavelength analysis is more-robust, and the determination of purity simultaneously with absorptivities improves the accuracy of both values. For an overview of mathematical modeling, see the text by Gershenfeld (19).

This paper describes the synthesis of TMs using $(NH_4)_2S$ solution as a reagent. Curve-fitting techniques are then used to determine both the absorptivities for each TM and the composition of TM mixtures in aqueous solutions. This work differs from others in the literature in that there are no assumptions made as to the initial purity of the synthesized samples. TM1 is also isolated for the first time.

Experimental

All chemicals used were reagent-grade and used without purification. Sodium molybdate ($Na_2MoO_4 \cdot H_2O$, 99.5%–103%), cesium chloride (CsCl), aq. ammonia solution (28%–30%), and anhyd. diethylether were obtained from BDH (Toronto, Canada). Ammonium sulfide (minimum

© 2007 NRC Canada

20% $(NH_4)_2S$) and Sephadex® G-25 were obtained from Sigma (St. Louis, USA.). Anhyd. ethanol was purchased from Commercial Alcohols Inc. (Brampton, Canada). The thiomolybdates; mono-, $Cs_2MoO_3S{\cdot}1/2H_2O$; di-, $(NH_4)_2MoO_2S_2{\cdot}2H_2O$; tri-, Cs_2MoOS_3; and tetra-, $(NH_4)_2MoS_4$; were synthesized as described in this paper. H_2O was millipore-grade and was deoxygenated with argon before use.

TM absorptivities

UV–vis spectra were taken on a Beckman 640 diode array spectrometer with single beam using a 1 cm quartz cuvette. Spectra were typically taken over a range of 275 to 500 nm. When measuring TM0-contaminated TM1 samples for the purpose of determining molar absorptivities, a range of 200 to 500 nm was used.

The pure salts of TM0 and TM4 were dissolved in water, and the UV–vis absorbances were measured. Absorptivities were determined from the slope of the Beer's Law plots at the desired wavelengths. TM1 and TM3 were synthesized to contain contamination from only TM0 and TM4, respectively. All TMs were added to clean, dry volumetric flasks. Measurements were taken immediately after dilution to avoid hydrolysis.

Preliminary studies showed that TM1, the least stable TM in solution, underwent minimal hydrolysis in the first three minutes, TM2 was stable for about 10 min with TM3 and TM4 showing increasing stability. Errors due to hydrolysis are expected to be minimal for TM1 and negligible for all other TMs.

The absorptivities of these TMs were then determined by curve fitting using Origin7 and the principle that absorbances are additive (see eq. [1]). TM2 was synthesized and characterized in the same fashion.

$$[1] \qquad A = \sum_{i=0}^{4} \alpha_i \varepsilon_i c_i$$

The subscript i represents the TMs (0–4), α is the fraction of a given TM, and ε is the molar absorptivity at a given wavelenth. A and c are the absorbance and concentration, respectively.

Test solutions containing all TMs were made by dissolving TMs of known composition in water with varying concentrations and measuring their UV–vis absorbance. For hydrolysis experiments, a single TM of known purity was dissolved in water and made to volume. In this case, the solution was left in the cuvette to hydrolyze and the UV–vis spectra were taken at regular time intervals. Typically, 5 min intervals were used, but in the case of TM3, hydrolysis was sufficiently slow that 10 min intervals were used. For TM4, 30 min intervals were used.

Synthesis

For TM1, TM3, and TM4, the presence of air was not found to have an effect during synthesis, and so no precautions were taken. TM2, however, was synthesized under inert atmosphere, as discoloration due to oxidation occurred quickly in air. All TMs were stored under Argon.

TM1 $(Cs)_2MoO_3S{\cdot}1/2H_2O$

$Na_2MoO_4{\cdot}H_2O$ (1.0 g, 4.13 mmol) was dissolved in a solution of water (1.2 mL) and 8 mL of aq. ammonia (28%–30%) and placed in an ice bath to reduce the temperature to ~5 °C. 2 mL of $(NH_4)_2S$ solution (20%) was also cooled in an ice bath and was added to the molybdate solution. The reaction mixture (~pH 13) was mixed and allowed to stand for 10 min before a CsCl solution (2.8 g, 16.63 mmol in 2 mL of water) was added. The reaction mixture was added to a previously cooled mixture of 15 mL diethyl ether and 5 mL ethanol, shaken, and left to stand to precipitate for about 15 min. A fine yellow precipitate (1.39 g, 75% yield) formed. This precipitate was filtered and washed three times with 10 mL of ethanol then twice with 10 mL of diethyl ether. The pale yellow, crystalline $Cs_2MoO_3S{\cdot}1/2H_2O$ was dried and stored under an inert atmosphere. The level of hydration was determined by X-ray crystallography (20).

TM2 $(NH_4)_2MoO_2S_2{\cdot}2H_2O$

$Na_2MoO_4{\cdot}H_2O$ (1.0 g, 4.13 mmol) was dissolved in 1.2 mL of water and 5 mL of aq. ammonia (28%–30%) and cooled in an ice bath. 4.8 mL of cold $(NH_4)_2S$ solution (20%) was added, mixed, and allowed to react in an ice bath for 10 min. Precipitation occurred by adding 20 mL of a cold 1:1 ethanol/ether mixture, followed by 20 mL of ether, and then 12 mL of ethanol. The mixture was allowed to stand for another 15 min before the fluffy yellow-orange precipitate was filtered out. This precipitate easily browned in air, so precipitation was performed in a filter flask attached to a Schlenk line with thorough washing with ethanol then ether. The dried TM2 was quickly transferred to a storage vial and stored under inert atmosphere. The product was amorphous, making X-ray crystallography ineffective. A ^1H NMR standard-additions experiment was used to determine the stoichiometry of hydration.

TM3 Cs_2MoOS_3

$Na_2MoO_4{\cdot}H_2O$ (0.5 g, 2.07 mmol) was dissolved in 1 mL of water and 1 ml of aq. ammonia (28%–30%). To this was added 5 mL of $(NH_4)_2S$ solution (20%). To avoid precipitation of $(NH_4)_2MoO_2S_2{\cdot}2H_2O$ before the addition of CsCl, neither solution was precooled, and the mixture was mixed with gentle swirling. The mixture was then allowed to stand at room temperature for 8 min before a CsCl solution (1.4 g in 2 mL of water) was added. Deep-orange precipitate formed immediately, and 10 mL of 1:1 ethanol/ether was added to improve the yield (71%). The product was washed with 10 mL of cold water, twice with 10 mL of ethanol and twice with 10 mL of diethyl ether, dried, and stored under inert atmosphere. The addition of non-polar solvents to the filtrate caused the product that was dissolved by water to precipitate. This product is of higher purity as determined by techniques described elsewhere in this paper. The product was then filtered, washed with ethanol and ether, and stored under inert atmosphere.

TM4 $(NH_4)_2MoS_4$

$Na_2MoO_4{\cdot}H_2O$ (1.0 g, 4.13 mmol) was dissolved in 2 mL of water, and to it was added 15 mL of $(NH_4)_2S$ solution (20%). The contents (~pH 10) were stoppered, shaken, and allowed to stand in a 35 °C water bath. After about 3 h, dark

Note: λ_{max} is in nm, and ε is in $Lmol^{-1}cm^{-1}$; ± in this work is the standard deviation from the experimental values, ± in reference 14 is the standard deviation of the slope of absorbance vs. concentration curves.

green rod-like crystals began to form, but the mixture was allowed to stand for at least 4 h to ensure completeness of reaction. 10 mL of a cold mixture of 1:1 ethanol/ether was added, shaken vigorously, and left in an ice bath for 30 min to improve the yield (79%). The precipitate consisted of fine dark-red crystals with a green shimmer as well as the rod-like crystals that had formed previously. The product was filtered and washed with 10 mL of cold water, 10 mL of 1:1 ethanol/ether, and 10 mL of ether before storing under inert atmosphere. As with TM3, a second precipitate formed in the filtrate. This was filtered and washed with 10 mL of 1:1 ethanol/ether and twice with 10 mL of ether to obtain a red scaly precipitate (22% yield). This product was also dried and stored under inert atmosphere.

Results and discussion

UV–vis characterization

The inevitability of mutual contamination of TM samples makes it necessary to have an effective means of analyzing the composition of the sample. UV–vis spectroscopy is a useful technique for analyzing TMs, but it is limited by the great deal of overlap in the TM spectra. It also typifies the limitations of assuming that a synthesized TM is pure when measuring its spectrum.

To use UV–vis effectively for speciation, the molar absorptivities of each pure species must be determined despite the inevitable contamination of all real samples. The Origin7 software contains a curve-fitting routine that was used to find these constants. The molar absorptivities at λ_{max} of the pure TMs as determined by fitting are shown in Table 1, along with selected literature values for comparison. Errors for TM1, TM2, and TM3 are in terms of standard deviation of the measured and fitted absorbances. For TM0 and TM4 where ε values were determined by Beer's Law plots, errors are standard deviation of the slope. Solution concentrations are assumed to be exact.

The use of curve-fitting techniques allows for the simultaneous fitting of multiple variables. The software iterates all parameters beginning at preset values. Iterations stop when the overall error, the difference between actual and fitted values, is minimized. Also, to reduce the error, a minimum of ten solutions of the same composition but differing concentrations were fit.

Curve fitting was done by fitting the absorbances at a subset of selected wavelengths. The wavelengths included all λ_{max} as well as a few other chosen wavelengths that would help to characterize all of the peaks such that all peaks were represented by at least three wavelengths. If too many points are selected, there is no further improvement of the results. If there are too few points selected, there may be more combinations of absorptivities possible to fit the data, especially when there are multiple TMs overlapping. In all, 13 wavelengths were selected.

When fitting UV–vis data of the TM solutions, there are two sets of unknowns, the absorptivities of each pure TM at the selected wavelengths and the composition of the real (impure) TM sample. These unknowns cannot be fit simultaneously, and so each set was fit separately.

The absorptivities were fit using eq. [2].

$$[2] \qquad A_\lambda = \left(\sum_{i=0}^{4} \alpha_{i\text{“}x\text{”}} \varepsilon_{i\lambda} \right) c_{\text{“}x\text{”}} / \mathrm{Fm}_{\text{“}x\text{”}}$$

A_λ is the absorbance at wavelength λ, $\alpha_{i\text{“}x\text{”}}$ is the fraction of a given TM in the impure "TM*x*" sample, *c* is the g/L concentration of the impure TM sample, Fm is the average formula mass of the sample, and $\varepsilon_{x\lambda}$ is the molar absorptivity of TM*x* at wavelength λ.

Absorbance values are the dependent variables, and each array consists of absorbances at an individual wavelength in-

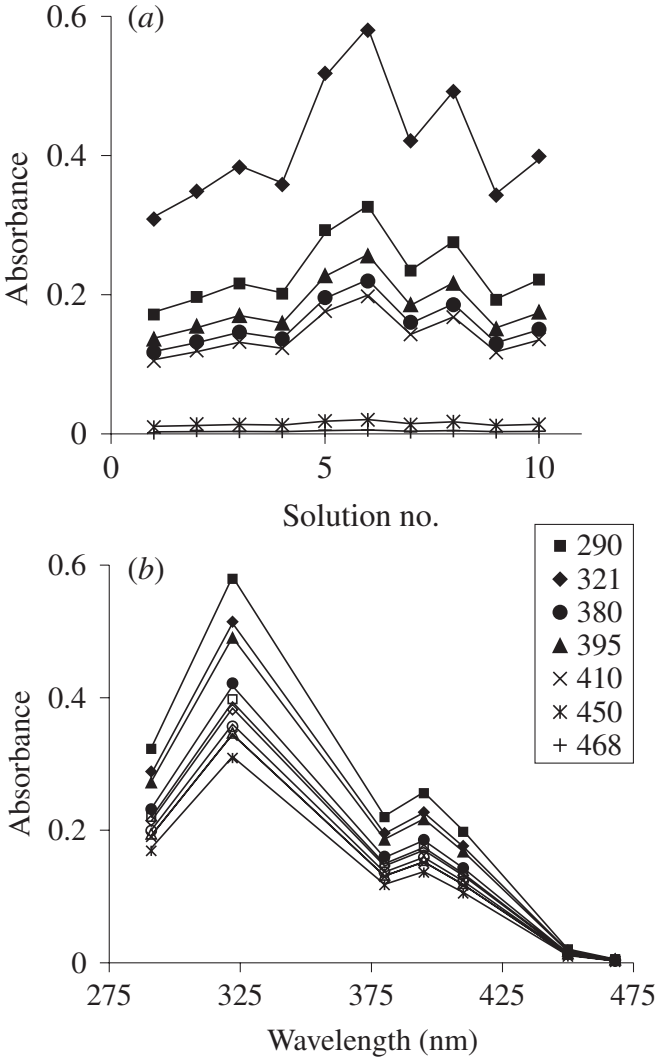
curred by all solutions. The concentrations of the solutions are the independent variables, and the absorptivities are the parameters to be fitted. The absorptivities of any known TMs and the fractional TM composition are input as constants.

The fractional TM composition is set at an estimated value based on inspection of the UV–vis spectrum of the sample. The formula mass is then calculated from the formula mass of each TM component and the fraction present in the sample. However, it must be noted that the counter ion of each TM is dependent on which TM was the target of the synthesis. For example, when synthesizing TM3, the target would be $Cs_2MoO_3S \cdot 1/2H_2O$, and so any TM4 that forms would be Cs_2MoS_4 as opposed to the ammonium salt that would be produced by TM4 synthesis. If the contaminating TM was accompanied by a different counter ion, the FM would not be determinable prior to the fit. Figure 2*a* illustrates the quality of fit for absorptivity determination. Some wavelengths have been removed for clarity.

Attempts to determine all TM absorptivities simultaneously failed because of the large number of variables and the great dependency of the variables on each other. Each TM was therefore characterized individually. TM0 and TM4, which were available in pure form, were measured directly, and their absorptivities were determined via Beer's Law curves.

TM4 is the final product in the series to be formed. The ability to synthesize it in pure form facilitated the characterization of the other TMs. We are certain of the purity of TM4 because the reaction could be driven to completion by increasing the S:Mo ratio, a more acidic pH, and a longer reaction time. It was found that attempts to force the reaction further, i.e., even greater S:Mo ratios, resulted in no changes to the product, indicating that only TM4 was present.



Further evidence of TM4 purity can be seen in the UV–vis spectrum. It contains no evidence of a peak around 395 nm. This would be indicative of TM3, the primary contaminant. Also, when mixtures of synthesized TMs were measured, there were no irregularities observed between theoretical and actual values. Misidentified TM4 purity would have become evident at this point.

Each subsequent TM was carefully synthesized to contain contamination only by already characterized TMs. For example, synthesized "TM3" contained TM4 but no TM2, while "TM1" contained only TM0 as a contaminant. Initially, the identities of the contaminants were determined by qualitative inspection of the UV–vis spectra.

The TM3 or TM1 absorptivities were thus the only unknowns. This reduced the number of variables and improved the quality of fit. It should be noted that, initially, all TMs were included to establish those that weren't present. Once all absorptivities were known, fitting was again repeated with all TMs included to ensure the results.

The second fitting stage involved finding the composition of a given impure sample. The absorbance is still the dependent variable, but the array consists of the absorbance values of all selected wavelengths for one solution. The independent variables are now the TM absorptivities from the fit in step 1. The solution concentrations and average formula mass are input as constants, and the α values are the parameters to be determined. Figure 2*b* shows the quality of fit when determining the TM composition. Again, some wavelengths were removed for clarity.

Fig 2. (*a*) Origin7 fit to find molar absorptivities. (*b*) Origin7 fit to find TM composition in impure sample. The data points are the selected wavelengths used in this study; the solid lines represent the fit. Each curve was obtained by measuring solutions of varying concentration but constant composition. The legend values are in nm.

With the TM fractions determined, the average formula mass was recalculated based on the new results, and the composition was reacquired. This process was repeated until the parameters no longer changed. The compositional data were then input into the first-fitting program to recalculate the absorptivities, which were subsequently used to redetermine the composition. This process was repeated until convergence was achieved.

There are some significant discrepancies between absorptivities achieved in this work compared with other works. This is due to the characterization methods in conjunction with potentially impure samples that are assumed to be pure. By determining the composition concomitantly with the absorptivities, all values are more reliable and not dependent on the purity of the synthesized sample.

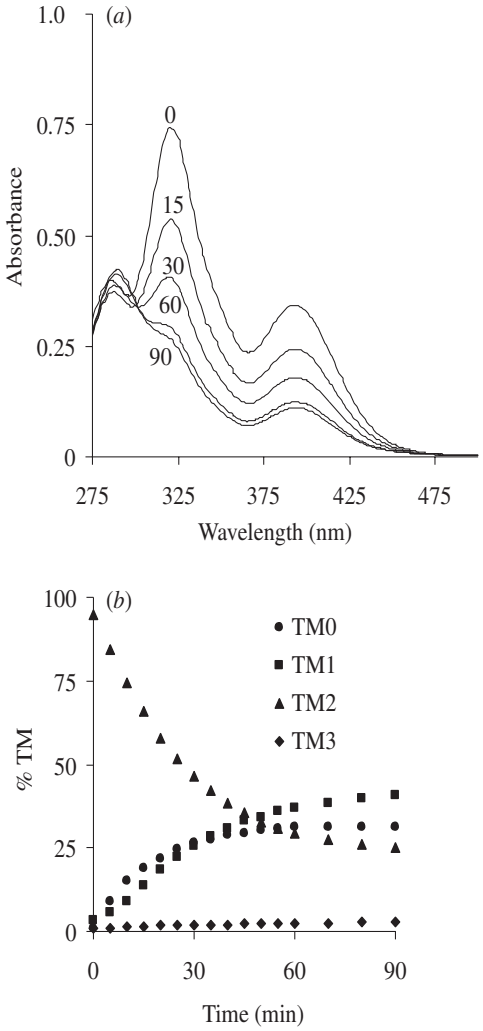
In the case of TM1, the absorptivity obtained in this work at 290 nm is greater than the absorptivities obtained from other works. Because TM1 was difficult to synthesize, this value was previously obtained by monitoring its formation in solution. During formation, there is no point at which only TM1 is present because of the rapid formation of TM1 and TM2. It is likely that TM2 will begin to form before conversion to TM1 is complete. The presence of TM2 accounts for the second small peak that was often recorded as belonging to TM1 (6, 15, 18). Being able to synthesize and isolate the TM1 salt was paramount to being able to characterize TM1 and subsequently TM2. This will also improve our ability to study TM kinetics in the future.

TM2 was difficult to synthesize in pure form. It was also very difficult to identify contamination by inspecting the UV–vis spectrum. The presence of TM1 is completely overlapped by the TM2 peak at 286 nm. Contamination by TM3 would produce an increase in the peak at 321 nm. Even though TM3 absorbs around 461 nm, the absorbance is weak, and so small amount of TM3 may go unnoticed in the TM2 spectrum. It also may be possible to have some contribution of TM0 in the sample, which does not absorb in the studied region, and would reduce the overall absorbance.

The TM3 spectrum gives away the fewest clues about contamination. One method of attempting to quantify purity was to find a characteristic peak ratio between the peaks at 396 and 461 nm (11). There has been very little agreement on this value in the literature (7, 8, 11). However, the presence of TM2 will decrease both absorbances by a similar amount, since the difference in absorptivities between the TMs at both wavelengths is similar. This method still carries the assumption of purity.



Qualitatively, one can identify the primary contaminant in synthesized "TM3". Around 461 nm, TM3 has a plateau. The formation of a discernable peak is due to TM4. If TM2 is the primary contaminant, a shoulder should appear at 286 nm. This may be difficult to observe if there is only a small amount of TM2 present. Curve fitting is a reliable way of quantifying TM impurities in TM3.

The primary difference between this method of characterization and others is that purity and absorptivities are determined simultaneously. Direct measurement of absorptivities may result in very good precision, but the accuracy is intimately dependant on the initial purity of the sample. By fitting both absorptivity and composition together, the error in one is not compounded in the determination of the other. This method also utilizes the mass of the sample and accounts for the actual formula mass and not that of the target species. This minimizes errors incurred by assuming molar concentrations.

The ultimate goal of this work is to be able to find TM concentrations in a mixture. Equation [2] was used to determine the percentage of each TM in the solution at that time. All TMs were included in the equation. Because only one solution is being fit at a time, the error in the fit is expected to be greater than is achieved from fitting multiple data sets at once. This error is much more sensitive to the quality of the original solution. However, the results over time are expected to be consistent.

Figure 3*a* shows UV–vis spectra of a "TM2" sample in water as hydrolysis occurs. For clarity, some spectra in the series have been removed. Figure 3*b* shows the percentage of each TM present during each measurement. This task was performed with all different TMs as the starting material with the same success (data not shown). These percentages can be easily converted to TM concentrations for kinetic analysis.

Fig 3. (*a*) UV–vis spectra of a TM2 solution sample hydrolyzing with time. The numbers represent the incubation time in minutes. (*b*) Composition data obtained from Origin7 fit of UV–vis spectra in Fig. 3*a*.

The increase in absorbance at 461 nm indicates the formation of TM3 as is confirmed during fitting. This is significant because it shows that hydrolysis is not a unidirectional process. This phenomenon has implications with the kinetic treatment of the data. This will be discussed in future publications.

The rise in the peak at 286 nm is accompanied by a slight bathochromic shift, indicating an increase in TM1. TM1 absorbs more strongly than TM2 at this wavelength, resulting in an overall increase in absorbance. The strong decrease in absorbance at 321 and 396 nm indicates the loss of TM2. TM1 absorbs very weakly in these regions, and TM3 is being formed in very small quantities.

After about 90 min, there is very little change in the UV–vis spectrum. Because the reaction is occurring in a sealed

cuvette, sulfide cannot be released to the atmosphere and thus remains in the space above the solution. Equilibrium is attained between the sulfide in gas phase and liquid phase, and so the TM composition stabilizes. No TM4 is formed in this experiment, as expected.

These observations are mirrored in the fitting results shown in Fig. 3*b*. A good quality of fit was maintained throughout the analysis. The percentage TM curves also appear to have very little scatter, indicating that the fitting is sensitive to small changes in concentration.

The ability to determine TM concentrations accurately provides the basis for being able to accurately calculate TM formation and hydrolysis rate constants toward the ultimate goal of modeling rumen copper. These results are currently being pursued and will be reported at a later date.

Conclusion

Multi-wavelength curve fitting has been used to accurately characterize the UV–vis spectra of the TMs as well as to quantify TM mixtures. Effective characterization is a crucial step toward measuring the kinetics of TM interconversions and their relevance to Cu antagonism, which in turn is necessary for our final goal of modeling Cu–ligand speciation in the bovine rumen. Synthesis and isolation of all TMs are also reported using a common synthetic route using $(NH_4)_2S$ as a sulfide source. TM1 was isolated in solid form for the first time from aqueous solution.
