spirocyclic radical **9** (not isolated), followed by neophyl rearrangement (16) to radical intermediate **10**. Abstraction of a hydrogen from *n*-Bu_3SnH by radical intermediate **7** may give the [6,6]-fused cyclized products **6**.

Aryl radical cyclization normally gives a high 5-exo : 6-endo ratio indicating a stronger preference for exo cyclization than for alkyl radical cyclization. However, suitably substituted 5-hexenyl radicals are known to undergo 6-endo cyclization to give six-membered rings. It is interesting to note that six-membered rings are formed regioselectively in all cases we have studied at present. Earlier we had reported the synthesis of the [6,6]pyranopyrans by sequential Claisen rearrangement of the 4-aryloxy-2-ynyloxy derivatives of uracil and coumarin (7). This radical cyclization protocol is found to give the polycyclic heterocycles in better yields under mild conditions.

Conclusion

In conclusion, we have successfully extended the *n*-Bu_3SnH mediated radical cyclization reaction to the regioselective synthesis of coumarin- and pyrimidine-annulated [6,6]-fused heterocycles. The process is quite general and regioselective and afforded the desired products in good-to-excellent yields. The mildness of the reaction conditions and high level of regioelectivity allow this radical cyclization to serve as a powerful synthetic tool for the preparation of complex aromatic heterocycles.

Experimental

Melting points were determined in an open capillary and are uncorrected. IR spectra were recorded on a

PerkinElmer L 120-000A spectrometer (ν_{max} in cm^{-1}) on KBr disks. ^1H NMR (300 MHz, 400 MHz, and 500 MHz) and ^{13}C NMR (125.7 MHz) spectra were recorded on a Bruker DPX-300, Varian-400 FT–NMR, Bruker DPX-500 and spectrometer in $CDCl_3$ (chemical shift in δ) with TMS as internal standard. Silica gel [(60–120 mesh), Spectrochem, India] was used for chromatographic separation. Petroleum ether refers to the fraction boiling between 60 and 80 °C.

General procedure for the preparation of compounds 4a–4l

The compounds **4a–4l** were synthesized according to the earlier published procedure (7).

5-({4-[(2-Bromo-6-methylphenyl)oxy]but-2-ynyl}oxy)-1,3-dimethyl-1,2,3,4-tetrahydropyrimidine-2,4-dione (4a)

Yield 91%; colorless solid; mp 161–163 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 2923, 1707, 1648. ^1H NMR (400 MHz, $CDCl_3$) δ_H: 2.56 (s, 3H, $ArCH_3$), 3.61 (s, 6H, $-NCH_3$), 4.94 (s, 2H, $-OCH_2$), 4.99 (s, 2H, $-OCH_2$), 7.51 (m, 3H), 7.76 (s, 1H, C_6H). MS *m/z*: 392, 394 (M^+). Anal. calcd. for $C_{17}H_{17}N_2O_4Br$: C 51.92, H 4.36, N 12; found: C 52.06, H 4.31, N 7.14.

5-({4-[(2-Bromo-4,6-dimethylphenyl)oxy]but-2-ynyl}oxy)-1,3-dimethyl-1,2,3,4-tetrahydropyrimidine-2,4-dione (4b):

Yield 90%; colorless solid; mp 122–123 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 2982, 1706, 1642. ^1H NMR

General procedure for the radical cyclization of compounds 5

A suspension of the compounds **5** (0.30 mmol, 0.01mol/L), *n*-Bu_3SnH (0.08 mL, 0.30 mmol), and AIBN (25 mg) in dry degassed toluene (for **5a**–**f**) or benzene (for **5g**–**l**) were heated for 3–4 h under N_2. After the completion of the reaction the solvent was removed under reduced pressure. The residue was dissolved in CH_2Cl_2 (15 mL) and stirred with 10% aqueous KF solution (10 mL) for 1 h. The aqueous phase was extracted with CH_2Cl_2 (3 × 10 mL). The combined CH_2Cl_2 extract was washed with water (2 × 20 mL) and then brine solution (1 × 20 mL), and was dried (Na_2SO_4). The solvent was removed and the residual mass was subjected to column chromatography over silica gel using petroleum ether – ethyl acetate as eluant to give **6a**–**l**. Compounds **6a**–**f** were recrystallized from acetonitrile–methanol mixture and compounds **6g**–**l** were recrystalized from dichloromethane – petroleum ether (60–80 °C).

2,4,7-Trimethyl-1,2,3,4,4b,5,10b,11-octahydrochromeno[3′,4′:4,5]pyrano[3,2-d]pyrimidine-1,3-dione (6a)

Yield: 81%; colorless solid; mp 171–172 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 1655, 1633. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 2.20 (s, 3H, $ArCH_3$), 3.24 (dt, *J* = 3.8, 11.6 Hz, 1H), 3.36 (dt, *J* = 3.8, 11.7 Hz, 1H), 3.41 (s, 3H, -NCH_3), 3.52 (s, 3H, -NCH_3), 3.90 (t, *J* = 11.2 Hz, 1H), 4.00 (t, *J* = 11.3 Hz 1H), 4.46 (ddd, *J* = 1.8, 4.3, 11.6 Hz, 1H), 4.53 (ddd, *J* = 1.3, 4.3, 11.6 Hz, 1H), 6.87 (t, *J* = 7.5 Hz, 1H), 7.00 (d, *J* = 7.5 Hz, 1H), 7.07 (d, *J* = 7.2 Hz, 1H). MS *m*/*z*: 314 (M^+). Anal. calcd. for $C_{17}H_{18}N_2O_4$: C 64.96, H 5.77, N 8.91; found: C 65.18, H 5.85, N 8.99.

2,4,7,9-Tetramethyl-1,2,3,4,4b,5,10b,11-octahydrochromeno[3′,4′:4,5]pyrano[3,2-d]pyrimidine-1,3-dione (6b)

Yield: 86%; colorless solid; mp 190–192 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 1657, 1633. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 2.21 (s, 3H, $ArCH_3$), 2.32 (s, 3H, $ArCH_3$), 3.23 (dt, *J* = 4.4, 11.6 Hz, 2H), 3.41 (s, 3H, -NCH_3), 3.51 (s, 3H, -NCH_3), 3.90 (t, *J* = 11.2 Hz, 1H), 3.93 (t, *J* = 11.4 Hz, 1H), 4.47 (ddd, *J* = 1.3, 4.1, 11.3 Hz, 1H), 4.55 (ddd, *J* = 1.8, 4.1, 11.4 Hz, 1H), 6.79 (s, 1H), 6.89 (s, 1H). ^{13}C NMR (75.5MHz, $CDCl_3$): δ_C 16.2, 20.8, 28.9, 31.3, 31.8, 32.9, 65.7, 67.7, 117.7, 126.7, 127.4, 127.9, 130.7, 131.5, 132.2, 150.8, 151.1, 158.7. MS *m*/*z*: 328 (M^+). Anal. calcd. for $C_{18}H_{20}N_2O_4$: C 65.84. H 6.14, N 8.53; found: C 66.02, H 6.11, N 8.56.

2,4,9-Trimethyl-1,2,3,4,4b,5,10b,11-octahydrochromeno[3′,4′:4,5]pyrano[3,2-d]pyrimidine-1,3-dione (6c)

Yield: 85%; colorless solid; mp 130–132 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 1651, 1627. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 2.29 (s, 3H, $ArCH_3$), 3.30 (dt, *J* = 4.4, 11.7 Hz, 2H), 3.41(s, 3H, -NCH_3), 3.50 (s, 3H, -NCH_3), 3.91 (t, *J* = 11.2 Hz, 2H), 4.44 (ddd, *J* = 1.7, 4.5, 11.3 Hz, 2H), 6.78 (d, *J* = 8.2 Hz, 1H), 6.95 (s, 1H), 7.01 (t, *J* = 8.1 Hz, 1H). MS *m*/*z*: 314 (M^+). Anal. calcd. for $C_{17}H_{18}N_2O_4$: C 64.96, H 5.77, N 8.91; found: C 65.19, H 5.79, N 8.88.

2,4-Dimethyl-1,2,3,4,4b,5,12c,13-octahydrobenzo[5′,6′]chromeno[3′,4′:4,5] pyroano[3,2-d]pyrimidine-1,3-dione (6d)

Yield: 76%; colorless solid; mp 156–157 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 1654, 1631. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 3.35 (dt, *J* = 3.8, 11.0 Hz, 1H), 3.44 (s, 3H, -NCH_3), 3.54 (s, 3H, -NCH_3), 3.88 (dt, *J* = 3.9, 11.4 Hz, 1H), 4.00 (t, *J* = 11.4 Hz, 1H), 4.16 (t, *J* = 11.3 Hz, 1H), 4.57 (dd, *J* = 2.4, 11.6 Hz, 1H), 4.86 (dd, *J* = 3.2, 11.8 Hz, 1H), 7.06 (d, *J* = 8.9 Hz, 1H), 7.39 (t, *J* = 7.6 Hz, 1H), 7.54 (t, *J* = 8.2 Hz, 1H), 7.71 (t, *J* = 8.9 Hz, 1H), 7.80 (d, *J* = 8.1 Hz, 1H), 7.90 (d, *J* = 8.5 Hz, 1H). MS *m*/*z*: 350 (M^+). Anal. calcd. for $C_{20}H_{18}N_2O_4$: C 68.56, H 5.18, N 8.00; found: C 68.73, H 5.22, N 8.13.

2,4-Dimethyl-1,2,3,4,4b,5,10b,11-octahydrochromeno[3′,4′:4,5]pyrano[3,2-d]pyrimidine-1,3-dione (6e)

Yield: 89%; colorless solid; mp 200-202 °C (acetonitrile–methanol). IR (KBr, cm^{-1}): 1651, 1623. ^1H NMR (300 MHz, $CDCl_3$) δ_H: 3.17–3.36 (m, 2H), 3.41 (s, 3H, -NCH_3), 3.51 (s, 3H, -NCH_3), 4.00 (dt, *J* = 4.1, 11.1Hz, 2H), 4.47–4.50 (m, 2H), 6.89–7.36 (m, 4H). REVIEW / SYNTHÈSE

Mechanistic principles and applications of resonance energy transfer

David L. Andrews

Abstract: Resonance energy transfer is the primary mechanism for the migration of electronic excitation in the condensed phase. Well-known in the particular context of molecular photochemistry, it is a phenomenon whose much wider prevalence in both natural and synthetic materials has only slowly been appreciated, and for which the fundamental theory and understanding have witnessed major advances in recent years. With the growing to maturity of a robust theoretical foundation, the latest developments have led to a more complete and thorough identification of key principles. The present review first describes the context and general features of energy transfer, then focusing on its electrodynamic, optical, and photophysical characteristics. The particular role the mechanism plays in photosynthetic materials and synthetic analogue polymers is then discussed, followed by a summary of its primarily biological structure determination applications. Lastly, several possible methods are described, by the means of which all-optical switching might be effected through the control and application of resonance energy transfer in suitably fabricated nanostructures.

Key words: FRET, Förster energy transfer, photophysics, fluorescence, laser.

Résumé : Dans une phase condensée, le transfert de l'énergie de résonance est le mécanisme primaire pour la migration de l'excitation électronique. Bien connu dans le contexte particulier de la photochimie moléculaire, c'est un phénomène dont la prévalence beaucoup plus grande tant dans les matériaux naturels que ceux de synthèse n'a été appréciée que lentement et pour laquelle la théorie fondamentale et sa compréhension ont fait des progrès importants au cours des dernières années. Avec la maturité croissante de bases théoriques solides, les derniers développements ont conduit à une identification complète des principes fondamentaux. Le présente revue décrit d'abord le contexte et les caractéristiques générales du transfert d'énergie avant de passer à une mise au point de ses caractéristiques électrodynamiques et photophysiques. On discute ensuite du rôle particulier que joue le mécanisme dans les matériaux photosynthétiques et les polymères synthétiques analogues et puis on résume ses applications principalement dans la détermination des structures biologiques. Enfin, on décrit plusieurs méthodes potentielles à l'aide desquelles il serait possible d'effectuer des commutations complètement optiques par le biais du contrôle et de l'application du transfert de l'énergie de résonance dans des nanostructures fabriquées d'une façon appropriée.

Mots-clés : « FRET », transfert d'énergie Förster, photophysique, fluorescence, laser.

1. Introduction

In a variety of complex materials, the close juxtaposition of basic units with suitable spectral character leads to a remarkable phenomenon: the absorption of light by one molecular species produces fluorescence unambiguously attributable to another. The effect is most readily apparent in chemical systems comprising two or more light-absorbing components (chromophores) with well-characterized absorption and fluorescence bands at broadly similar, but experimentally differentiable wavelengths. Observations of such phenomena illustrate the operation of a fundamental mechanism (the transfer of energy between molecules or chromophores) known as resonance energy transfer (RET) (1–3).[1] It is a mechanism that is found to operate across a chemically diverse and extensive range of systems, encompassing protein complexes, doped crystals, and solutions, to name but a few. Moreover, it also operates in systems where the end re-

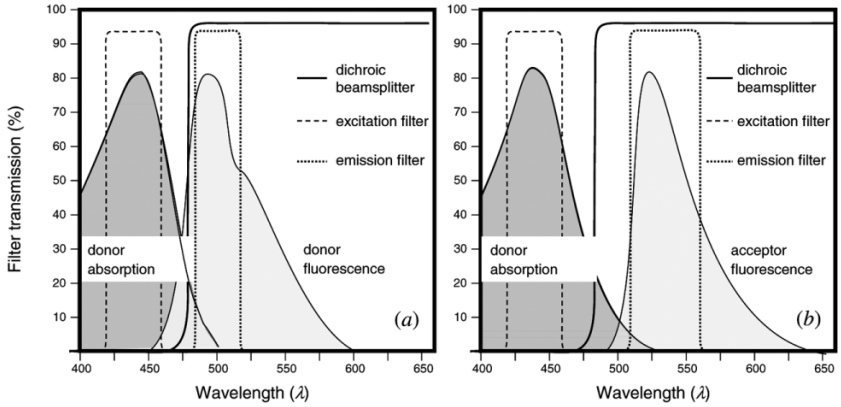
Fig. 1. Typical spectral discrimination between the fluorescence from donor and acceptor species (here, notionally based on a cyan fluorescent protein donor and a yellow fluorescent protein acceptor): (*a*) the transmission characteristics of a short-wavelength filter ensure initial excitation of only the donor; a dichroic beam-splitter and another narrow emission filter ensuring that only the (Stokes-shifted) fluorescence from the donor reaches a detector; (*b*) in the same system, a longer-wavelength emission filter ensures capture of only the acceptor fluorescence, following RET.



sult of optical absorption is not the release of energy in the form of fluorescence but optical frequency up-conversion or excitation capture in the form of chemical energy.

The singular properties of RET allow the flow of energy to exhibit a directed character (4–7). In complex multi-chromophore materials this effect contributes to a crucial, property-determining characteristic for the channeling of electronic excitation in photosynthetic systems (8), and the same principles are emulated in synthetic energy-harvesting systems such as the fractal polymers known as "dendrimers" (9). However, the observation and applications of RET extend well beyond the technology of light harvesting into numerous areas, several of which will be illustrated in later sections of this review. The phenomenon has an important function in the operation of organic light-emitting diodes (OLEDs) and luminescence detectors (10–14): in crystalline solids and glasses doped with transition metal ions, mechanisms based on RET are also engaged for laser frequency conversion (15–19). In the fields of optical communications and computation, a number of optical-switching and logic-gate devices are founded on the same principle (20–22). In the realm of molecular biology, the determination of protein structures and the characterization of dynamical processes is furthered by studies of the transfer of energy between intrinsic or "tag" chromophores (23–28); other ultra-sensitive molecular-imaging applications are again based on the same underlying principle (29–31). Further applications include the study of polymer interfaces (32), energy-transfer systems designed to act as sensitizers for photodynamic therapy (33), and as analyte-specific sensors (34–36).

The structure of the review is as follows: Section 2 describes the nature and general features of RET, focusing on its optical and photo-physical characteristics, and its uses in molecular structure determination: the underlying electromagnetic mechanism is addressed in more detail in Section 3. In Section 4, the particular role that energy transfer plays in photosynthetic materials and synthetic analogue polymers is discussed. Several possible methods are then described, in Section 5, for exerting optical control over RET, leading into a more general discussion of novel applications and nano-devices in the concluding Section 6.

2. Nature and characteristics of resonance energy transfer

To begin, it is appropriate to review the major features of RET. In this section, where the common attributes are first identified, "chromophore" is used as a generic term for the individual particles between which energy is exchanged. In crystalline, semi-crystalline, or glassy media, these centers of photon absorption (and subsequent energy release) may in fact take the form of ions, atoms, or colour centers; in other types of medium they may be small molecules, electronically distinct parts of large molecules, or nanoparticles, such as quantum dots. For their role in each transfer event, the participating chromophores in any such medium are designated "donor" and "acceptor", though it should be understood that any single chromophore acting in the capacity of acceptor for one transfer event may subsequently become the donor for a subsequent RET process.

A. Migration of electronic excitation in the condensed phase

When resonant ultraviolet or visible radiation impinges on any non-homogeneous dielectric material, the primary result of photon absorption is the population of electronic excited states in individual atomic, molecular, or other nanoscale centers. Typically, such absorption is followed immediately by a rapid but partial degradation of the acquired energy; the associated losses (largely due to vibrational dissipation) ultimately to be manifest in the form of heat. However, if any nearby chromophore has a suitably disposed electronic state, of a similar or slightly lower energy, that neighbour may acquire the major part of the electronic excitation through resonance energy transfer (a process that takes place well before thermal degradation of the excited state energy nears completion). The process is most commonly studied through spectrometric differentiation of fluorescence emerging from the initially excited energy donor and from the energy acceptor species, as illustrated in Fig. 1.

As will be shown in the following, the propensity for energy to be transferred between any two chromophores is severely restricted by distance, and if no suitable acceptor is

© 2008 NRC Canada

within reach, the donor will generally shed its energy by fluorescence or local dissipation. Conversely, any flow of energy that extends beyond conventional molecular dimensions will usually comprise a series of small-scale hops between near-neighbours. Pair interactions are therefore not only important in systems where the absorption of optical energy leads by direct transfer to the excitation of acceptor species; such interactions are also significant as representative components of the overall flow in complex, multichromophore systems. As such, it is appropriate to focus on the detailed character of these pair-transfer events.

B. Spectral overlap and the Förster equation

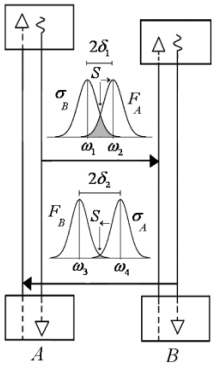
Though other possibilities exist, most transitions of donor decay and acceptor excitation are electric-dipole-allowed. Accordingly, the theory of pair transfer, beyond any region of wavefunction overlap, is traditionally based on electrodynamical coupling between transition dipoles. The first such formulation of the theory, which identified the inverse sixth power distance dependence (now often considered a hallmark of the transfer process) was made by Förster (37). Subsequently recast in quantum mechanical terms and experimentally verified by Latt et al. (38), this early theory of "radiationless" energy transfer remains widely applicable. Nonetheless, the Förster theory is subject to some conditions that were not originally appreciated, and it is not uncommon to find literature on the subject still perpetuating initial overstatements. Certain sources (see, for example, iupac.org) wrongly treat Förster "radiationless" energy transfer as exact, distinct, and separable from "radiative" energy transfer (the latter signifying successive but independent processes of fluorescence emission by a donor and capture of the ensuing photon by an acceptor). Although that certainly is the observed character of resonance energy transfer over relatively long distances, as for example between donor and acceptor components in a dilute solution, it is now known that both radiative and Förster transfer are simply the long- and short-range limits of one powerful, all-pervasive mechanism, as will be discussed in Section 3.

With this caution in mind, let us proceed to consider the pairwise transfer of excitation between two chromophores *A* and *B*. In the context of this elementary mechanism (potentially one RET component of a complex, multi-step migration process), *A* is designated the donor and *B* the acceptor. Specifically, let it be assumed that prior excitation of the donor generates an electronically excited species *A**. Forward progress of the energy is then accompanied by donor decay to the ground electronic state. Acquiring the energy, *B* undergoes a transition from its ground to its excited state. The complete RET process may be expressed by the following chemical equation:

$$[1] \qquad A^* + B \xrightarrow{\text{RET}} A + B^*$$

The excited acceptor, *B**, subsequently decays either in a further transfer event, or by another means, such as fluorescence. Because the *A** and *B** excited states are real, with measurable lifetimes, the core process of energy transfer itself is fundamentally separable from the initial electronic excitation of *A* and the eventual decay of *B*; the latter processes do not, therefore, enter into the theory of the pair transfer.

Fig. 2. Energetics and spectral overlap features (top) for energy transfer from *A* to *B* (and below, potentially backward transfer from *B* to *A*). For each chromophore, *F* denotes the fluorescence spectrum and σ the absorption. Wavy downward lines denote vibrational dissipation.



To delve more deeply into the nature of the process, it needs to be recognized that eq. [1] tells only part of the story, dealing as it does with only electronic excitations. In general, other dissipative processes are engaged (such features will be discussed in detail in later sections). In a solid, the linewidth of optical transitions manifests the influence of local electronic environments, which, in the case of strong coupling, may lead to the production of phonon sidebands. Similar effects in solutions or disordered solids represent inhomogeneous interactions with a solvent or host, while the broad bands exhibited by chromophores in complex molecular systems signify extensively overlapped vibrational levels, including those associated with skeletal modes of the superstructure. In each case, the level broadening allows pair transfer to occur at any energy level within the region of overlap between the donor emission and acceptor absorption bands, as illustrated in Fig. 2 (39).

For any donor–acceptor separation, *R*, substantially smaller than the wavelengths of visible radiation, the Förster theory gives the following expression for the rate of pairwise energy transfer w_F, for systems where the common host material for the donor and acceptor has refractive index *n*, at the optical frequency corresponding to the mean transferred energy (40):

$$[2] \qquad w_F = \frac{9\kappa^2 c^4}{8\pi\tau_{A^*} n^4 R^6} \int F_A(\omega)\sigma_B(\omega)\frac{d\omega}{\omega^4}$$

In this expression, $F_A(\omega)$ is the normalized fluorescence spectrum of the donor, τ_{A^*} is the associated radiative decay lifetime (related to the measured fluorescence lifetime τ_{fl} through the fluorescence quantum yield $\eta = \tau_{fl}/\tau_{A^*}$), $\sigma_B(\omega)$ is the linear absorption cross-section of the acceptor, ω is an optical frequency in radians per unit time, and *c* is the speed of light. The spectral functions F_A and σ_B are mathematically defined and discussed in detail in Section 3. As is evident from Fig. 2, the propensity for forward transfer is usually significantly greater than that for backward transfer owing to a sizeable difference in the spectral overlaps for the two processes. This feature, which is highly important in

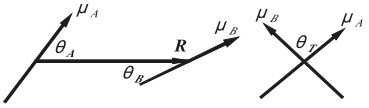
Fig. 3. Relative orientations and positions of the donor and acceptor and their transition moments: (*a*) angles θ_A and θ_B subtended by donor and acceptor transition moments (not necessarily in the plane of the drawing) against the inter-chromophore displacement vector; (*b*) in-plane angle θ_T between the transition moments.



determining the efficiency of energy harvesting materials, is to be discussed in detail in Section 4.

The κ factor in [2] depends on the orientations of the donor and acceptor, both with respect to each other, and with respect to their mutual displacement unit vector $\hat{\boldsymbol{R}}$, as follows:

$$[3] \qquad \kappa = (\hat{\boldsymbol{\mu}}_A \cdot \hat{\boldsymbol{\mu}}_B) - 3(\hat{\boldsymbol{R}} \cdot \hat{\boldsymbol{\mu}}_A)(\hat{\boldsymbol{R}} \cdot \hat{\boldsymbol{\mu}}_B)$$

For each chromophore, $\hat{\boldsymbol{\mu}}$ designates a unit vector in the direction of the appropriate transition dipole moment (see Section 3). The possible values of κ^2, as featured in eq. [2], lie in the range (0, 4). It is evident that in the case of fixed chromophore positions and orientations, the result delivered by eq. [3] is a function of three independent angles as shown and defined in Fig. 3,

$$[4] \qquad \kappa = \cos\theta_T - 3\cos\theta_A \cos\theta_B$$

Unfavourable orientations can thus reduce the rate of energy transfer to zero; other configurations, including many of those found in nature, optimize the transfer rate. The angular disposition of chromophores is therefore a very important facet of energy transfer, and one that invites careful consideration in the design of light-harvesting materials. Note that transfer is not "necessarily" precluded when the transition moments lie in perpendicular directions (provided that neither is orthogonal to $\boldsymbol{R}$ (= $R\hat{\boldsymbol{R}}$)).

In any, at least partially, fluid or disordered system the relative orientation of all donor–acceptor pairs may not be identical, and it is then the distributional average of κ^2 that determines the overall measured response. In the isotropic case (completely uncorrelated orientations), the κ^2 factor averages to 2/3; departures from this value signify a degree of orientational correlation. In molecules of sufficiently high symmetry, it can also happen that either the donor or the acceptor transition moment is not unambiguously identifiable with a particular direction in the corresponding chromophore reference frame. Specifically, the electronic transition may then relate to a transition involving a degenerate state (as can occur with square-planar complexes, for example) (41). Alternatively, the same observational features might indicate rapid but orientationally confined motions. The considerable complication, which each of these effects brings into the trigonometric analysis of RET, has been extensively researched and reported by van der Meer (42).

C. Functional group separation and conformation diagnostics

One obvious field of applications for RET, based on its strong distance dependence, is the identification of motions in molecules, or parts of molecules, that can bring one chromophore into the proximity of another. There are many examples in biology, such as the molecular traffic across a cell membrane and protein folding (43–45). These and other similar processes can be registered by selectively exciting one chromophore using laser light and monitoring either the decrease in fluorescence from that species or the rise in the generally longer-wavelength fluorescence from the other chromophore as it adopts the role of acceptor. The judicious use of optical dichroic filters can make this fluorescence RET or "FRET" technique perfectly straightforward (see Fig. 1). In cases where the two material components of interest do not have suitable overlapped display absorption and fluorescence features in an appropriate wavelength range, molecular tagging with site-specific "extrinsic" (i.e., artificially attached) chromophores can solve the problem. Lanthanide ions, with their characteristically prominent and line-like absorption features, prove particularly useful in this connection (46).

In some applications, the actual distance between the chromophore groups is of specific interest. When the same two chromophores feature, in spatially different configurations, in the chemical composition of two different systems (again, a common feature in biology), then the relative displacements of the chromophores can be quantitatively assessed on the basis of comparisons between the corresponding RET efficiencies (23–28, 47). Such a technique is popularly known as a "spectroscopic ruler". Such elucidations of molecular structure usually lack information on the relative orientations of the groups involved, and as such, the calculations usually ignore the kappa parameter (see eq. [3]). The apparent crudeness of this approach becomes more defensible on realizing that even if it were to introduce a factor of two inaccuracy, the deduced group spacing would still be in error by only 12% (since $2^{1/6} = 1.12$). Refinements to the theory to accommodate the effect of fluctuations in position or orientation of the participant groups introduces considerable complexity, though progress is being made in several areas (48–50).

In experimental studies of RET, it is usually significant that the electronically excited donor can in principle release its energy by spontaneous decay, the ensuing fluorescence being amenable to detection by any suitably placed photodetector. Since the alternative possibility (that of energy being transferred to another chromophore within the system) has such a sharp decline in efficiency as the distance to the acceptor increases, it is commonplace to introduce the concept of a critical distance R_0 (a separation at which the theoretical rates of RET and spontaneous emission by the donor are equal, now known as the Förster distance). The Förster rate eq. is often cast in an alternative form, exactly equivalent to eq. [2], explicitly exhibiting this critical distance (51).

$$[5] \qquad w_F = \frac{3\kappa^2}{2}\frac{1}{\tau_{A^*}}\left(\frac{\overline{R}_0}{R}\right)^6$$

Here, $\overline{R}_0$ is defined as the Förster distance for which the orientation factor κ^2 assumes its isotropic average value, 2/3 (52). For complex systems the angular dependence is quite commonly disregarded, and the following, simpler expression employed

© 2008 NRC Canada

$$[6] \qquad w_F = \frac{1}{\tau_{A^*}}\left(\frac{R_0}{R}\right)^6$$

leading to a transfer efficiency Φ_T expressible as

$$[7] \qquad \Phi_T = \frac{1}{1+(R/R_0)^6}$$

Typical values of the Förster radius range over a few nanometers. Thus, when a given electronically excited chromophore is within a distance R_0 of a suitable acceptor, RET will generally be the dominant decay mechanism; conversely, for distances beyond R_0, spontaneous decay will be the primary means of donor deactivation.

Before continuing, it is nonetheless worth observing that other forms of coupling are also possible, although less relevant to most systems of interest in the following account. For example, the transfer of energy between particles or units with significantly overlapped wavefunctions is usually described in terms of Dexter theory (53), where the coupling carries an exponential decay with distance, directly reflecting the radial form of overlapping wavefunctions and electron distributions. Compared to materials in which the donor and acceptor orbitals do not spatially overlap, such systems are of less use for either device or analytical applications largely because the coupled chromophores lose their electronic and optical integrity. This is the main reason why complex light-harvesting systems are commonly designed with "non-conjugated" linkages or spacer units between the chromophores, or else with the latter held on a host superstructure preventing direct chromophore contact. Parallels can be drawn with the way a dielectric layer operates in a simple electrical capacitor. In the alternative scenario, where spacer units act as a "conductive" bridge through delocalization and mixing of their orbitals with the donor or acceptor orbitals, energy transfer is specifically expedited by the operation of a special "superexchange" mechanism (54, 55), which, despite efficiency gains, compromises diagnostic applications.

D. Decay kinetics and polarization features

When linearly polarized laser light is used to excite any specific species within a complex disordered solid or liquid system, the probability for excitation of any particular molecule is proportional to $\cos^2\theta$, where θ is the angle between the appropriate excitation transition moment and the electric polarization vector of the input radiation. Consequently, the population of excited molecules has a markedly anisotropic distribution, a phenomenon associated with the term "photoselection". If radiative decay were to ensue instantaneously, i.e., from precisely the same excited level, then the fluorescence would carry the full imprint of that anisotropy and itself exhibit a degree of polarization (the highest value possible). Accounting for the necessary three-dimensional rotational average (56), it is readily shown that the fluorescence intensity components polarized parallel to and perpendicular to the polarization of the excitation beam, $I_\parallel$ and $I_\perp$ respectively, would then lie in the ratio 3:1. Commonly observed departures from this result thus signify the extent to which the orientation of the emission dipole differs from that of the prior, initial excitation, which may be due to intervening decay, molecular motion, or intermolecular energy transfer. The two most widely used quantitative expressions of this effect are the "fluorescence anisotropy", r, or the "degree of polarization", P, defined and related as follows

$$[8] \qquad r = \frac{I_\parallel - I_\perp}{I_\parallel + 2I_\perp}, \qquad P = \frac{I_\parallel - I_\perp}{I_\parallel + I_\perp} \quad \Rightarrow \quad r = \frac{2P}{3-P}$$

When the donor and acceptor have transition dipole moments oriented in parallel, then $r = 0.4$ and $P = 0.5$.

The key factor determining any loss in polarization is the angle θ between the directions of the absorption and emission transition dipole moments. In terms of this indicator, the case where internal decay intervenes between excitation and fluorescence decay, within a single molecule, is no different from that of a donor–acceptor pair where the absorption and emission processes are spatially separated (provided the donor and acceptor have a fixed mutual orientation, and the orientation of the pair is random). The following result, derived by Levshin (57) and Perrin (58), can be applied in both cases

$$[9] \qquad P = \frac{3\cos^2\theta - 1}{3 + \cos^2\theta}$$

In the case of a donor–acceptor pair, θ is to be interpreted as the angle θ_T shown in Fig. 3. Equation [9] thus allows direct calculation of this microscopic parameter through measurement of the macroscopic quantity P. Moreover, when P proves to exhibit a time-dependent decay, a study of the kinetics provides information on the extent of rotational motion intervening between the absorption and emission events.

Very different behaviour is observed for RET systems in which the donor and acceptor are orientationally uncorrelated, i.e., where they are both, independently, randomly oriented. In such cases, there is a very rapid loss of polarization "memory", and it transpires that the associated degree of anisotropy is precisely 1/25, i.e., $r = 0.04$ (1); two or more energy-transfer jumps will therefore usually, to all intents and purposes, totally destroy any polarization in any ensuing fluorescence. However, it should be noted that there is a surprising recovery in the anisotropy at distances approaching the transfer wavelength, as will be shown in Section 3C. The effect is sufficiently strong to warrant attention in dilute solution studies.

3. Electromagnetic mechanism

In each area of application, RET measurements exploit key features that originate in the detailed electromagnetic origins of RET coupling. To elicit these features, it is necessary to look more closely at the fundamental nature of the interactions involved.

A. Transition dipole coupling

The spectral functions featured in eq. [2] can be expressed in terms of the electronic transition properties of the chromophores, taking into account their vibrational structure. Although each transition spans a range of frequencies within the overall spectral bandwidth, it can be assumed under the conditions of the Born–Oppenheimer approximation that the vibrational factors in the transition dipole moments

© 2008 NRC Canada

factor out as Franck–Condon factors. The mathematical definitions of $F_A(\omega)$ and $\sigma_B(\omega)$ are then expressible as follows, using Dirac notation

$$[10] \quad F_A(\omega) = \frac{\omega^3 \tau_{A*} \mu_A^2}{3\varepsilon_0 \pi c^3} \sum_{n,r} \rho_{A*}^{(n)} \left| \left\langle \varphi_A^{(r)} \middle| \varphi_{A*}^{(n)} \right\rangle \right|^2 \delta(E_{A_n^*} - E_{A_r} - \hbar\omega)$$

$$[11] \quad \sigma_B(\omega) = \frac{\pi\omega \mu_B^2}{3\varepsilon_0 c} \sum_{m,p} \rho_B^{(m)} \left| \left\langle \varphi_{B*}^{(p)} \middle| \varphi_B^{(m)} \right\rangle \right|^2 \delta(E_{B_p^*} - E_{B_m} - \hbar\omega)$$

Here, μ_A and μ_B are the transition electric dipole moments for the donor decay and acceptor excitation, specifically given by

$$[12] \quad \boldsymbol{\mu}_A = \left\langle \psi_A \middle| \boldsymbol{\mu} \middle| \psi_{A*} \right\rangle, \quad \boldsymbol{\mu}_B = \left\langle \psi_{B*} \middle| \boldsymbol{\mu} \middle| \psi_B \right\rangle$$

where the μ is the dipole operator and each ψ is an electronic-state wavefunction. The indices *m*, *n*, *p*, and *r* in eq. [11] are generic labels denoting vibrational sub-levels, with each φ representing an associated wavefunction and *E* the corresponding energy; ρ denotes a population distribution function for the initial state of each species. Comparing the above results with eqs. [2] and [3] reveals the intrinsic quadratic dependence of the energy transfer rate on a coupling of the form

$$[13] \quad C = \frac{\left|\boldsymbol{\mu}_A\right| \left|\boldsymbol{\mu}_B\right|}{4\pi\varepsilon_0 R^3} [(\hat{\boldsymbol{\mu}}_A \cdot \hat{\boldsymbol{\mu}}_B) - 3(\hat{\boldsymbol{R}} \cdot \hat{\boldsymbol{\mu}}_A)(\hat{\boldsymbol{R}} \cdot \hat{\boldsymbol{\mu}}_B)$$

isomorphous with the usual formula for the interaction of two static dipoles. However, the result given by eq. [13] is an off-diagonal quantum amplitude connecting different initial and final states (only a diagonal quantum amplitude can directly signify energy). This is one of several important distinctions, the significance of which becomes more apparent when the quantum electrodynamical theory is developed.

Before continuing, it is worth emphasizing that the familiar inverse sixth power distance dependence of RET rate in the short range specifically owes its origin to the quadratic rate dependence on a coupling of transition electric *dipoles*. The result is, of course, applicable only when both the donor-decay and acceptor-excitation transitions are electric dipole (*E*1) allowed. In general, the coupling is effected by the lowest orders of multipole, electric or magnetic, that can support the necessary donor and acceptor transitions. In the Förster range, the distance dependence exhibits the form $R^{-(P+Q+1)}$ for the coupling of two transition electric multipoles *EP-EQ*, or two magnetic multipoles *MP-MQ*; whilst for the coupling of an electric with a magnetic multipole, *EP-MQ*, the distance dependence is $R^{-(P+Q)}$ (59, 60). For example, the coupling of an electric dipole decay with an electric quadrupole excitation, *E*1-*E*2, has an R^{-4} distance dependence within the Förster range. However, it should be borne in mind that each unit increase in multipolar order and each substitution of an electric transition by a magnetic counterpart lowers the strength of the coupling by a factor of two to three orders of magnitude. The decreasing efficiency of successive multipole orders increasingly disfavours the role of RET in the decay of the donor, compared with other decay mechanisms.

B. Near-field and long-range behaviour

As mentioned above, Förster theory is subject to several limitations. It is a theory specifically applicable under near-field conditions, i.e., over donor–acceptor distances significantly less than the optical wavelength for the energy being transferred, and this is a constraint that is effective for the coupling between any order of multipolar transitions. This condition is not always satisfied; however, there are numerous systems in which typical donor–acceptor distances approach or even exceed such wavelengths. Under those circumstances, new "retardation" features emerge, reflecting the finite time for the propagation of energy between molecular sites.

To ascertain rate expressions that correctly represent both short- and long-range transfer requires a fundamentally rigorous, quantum mechanical basis that delivers properly retarded solutions. The most suitable framework is afforded by quantum electrodynamics (QED) (61, 62) whose wider successes, such as its correct predictions of the magnetic moment of the electron, the Lamb shift, and the Casimir effect, are well-known (63). Less well-known is the fact that QED alone provides a satisfactory mechanistic explanation for the much more familiar process of spontaneous emission, or that even the use of electric and magnetic multipoles is ultimately defensible only in the context of a fully quantum electrodynamical theory (64). In connection with the theory of resonance energy transfer, the development of a theory based on QED began in pioneering work by Avery, Gomberoff, and Power (65, 66), culminating in a unified theory (67) whose ramifications continue to be explored today (68). A concise exposition is presented below.

A suitable starting point is the following Hamiltonian, for the simple RET system comprising chromophores A and B

$$[14] \quad H = H_A + H_B + H_{int}(A) + H_{int}(B) + H_{rad}$$

Here, the first two terms are the unperturbed Hamiltonian operators for the chromophores, and the two H_{int} operators represent interactions of the radiation field with A and B. The final term, H_{rad}, is the radiation Hamiltonian, which, as befits an operator, is always part of the sum even when there are no photons present. No term in eq. [14] directly links A with B, in other words, there is no static or "longitudinal" coupling; any form of coupling between the two chromophores can only be mediated by their individual interactions with the radiation field. This is an exact feature of any development in terms of multipole transitions (true not only for electric dipole interactions but for every other order of electric and magnetic multipole).

In the electric-dipole approximation, each $H_{int}(\xi)$ is given by the usual dipole coupling formula

$$[15] \quad H_{int}(\xi) = -\sum_{\xi} \boldsymbol{\mu}(\xi) \cdot \boldsymbol{e}^{\perp}(\boldsymbol{R}_{\xi})$$

where the electric-dipole moment operator, $\mu(\xi)$, operates on matter states, and the transverse electric field operator, $\boldsymbol{e}^{\perp}(\boldsymbol{R}_{\xi})$ on electromagnetic radiation states; $\boldsymbol{R}_{\xi}$ is the position vector of the chromophore labeled ξ. By standard methods, the electric field operator can be cast in the form of a summation over optical modes, each mode characterized by wavevector and polarization. Every operation of H_{int} is then asso-

© 2008 NRC Canada

ciated with the creation or annihilation of a photon from one of these modes. Throughout the usual pairwise process of RET, there is no applied radiation involved (the initial photoexcitation and any fluorescence being physically separable events); hence, the lowest order process that can couple the donor-decay and acceptor-excitation transitions is one involving the creation and annihilation of a "virtual" photon. Such photons are not physically observed; the quantum theory accordingly requires a sum to be taken over all radiation modes (i.e., all possible wave-vectors and polarizations). Since $H_{\rm int}$ must feature twice (once to create the virtual photon and the second time to annihilate it), the quantum amplitude $M_{\rm fi}$ for RET is determined by second-order perturbation theory

$$[16] \qquad M_{\rm fi} = \sum_r \frac{\langle f|H_{\rm int}|r\rangle\langle r|H_{\rm int}|i\rangle}{(E_i - E_r)}$$

where i, f, and r denote initial, final, and intermediate states of the system, respectively, and E signifies an energy. Two possible interaction sequences arise: (*a*) the virtual photon is created at A (effecting the decay of the donor excited state) and subsequently annihilated at B (effecting the acceptor excitation); (*b*) the virtual photon is created at B (along with the acceptor excitation) and annihilated at B (with the donor decay). These two possibilities are both represented within a state-sequence diagram as shown in Fig. 4. The counter-intuitive nature of case (*b*) does not preclude its inclusion in the calculation; it can be understood that exact energy conservation is not imposed during the interval between creation and annihilation of the virtual photon, i.e., the ultrashort photon flight-time. This, a key feature of virtual photon behaviour, is consistent with the time-energy Uncertainty Principle. When the whole system enters its final state, the balance of energy conservation is once again restored.

The explicit evaluation of eq. [16] by any of several standard techniques requires a considerable amount of algebra and calculus; details can be found in the original papers and subsequent reviews (69, 70). The result emerges in a form concisely expressible as follows

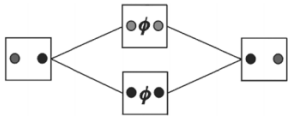
$$[17] \qquad M_{\rm fi} = \mu_{{\rm A}i} V_{ij}(k,\boldsymbol{R}) \mu_{{\rm B}j}$$

where the subscript indices i and j stand for Cartesian components, and the convention of summation over repeated indices is implicit. The value of k is $2\pi/\lambda$, where λ is the wavelength associated with the transfer energy. In eq. [17], the two transition dipole moments, for the donor-decay and acceptor-excitation transitions, are coupled by an $E1 - E1$ coupling tensor defined by

$$[18] \qquad V_{ij}(k,\boldsymbol{R}) = \frac{e^{ikR}}{4\pi\varepsilon_0 R^3}\{(\delta_{ij} - 3\hat{R}_i\hat{R}_j) - (ikR)(\delta_{ij} - 3\hat{R}_i\hat{R}_j) - (kR)^2(\delta_{ij} - \hat{R}_i\hat{R}_j)\}$$

Before considering the rate equation that ensues from the above QED treatment, some features of physical significance can be identified directly from the quantum amplitude. First,

Fig. 4. State-sequence diagram for RET, progressing from the initial system state of the left, through intermediate states, to the final state on the right. In each box, the two circles designate the states of *A* and *B*, black indicating the ground state; ϕ denotes a virtual photon. The lower route (*a*) and the upper route (*b*) signify the two quantum pathways.]



it is important to note that for short-range distances where $k\boldsymbol{R} << 1$ (signifying a length significantly smaller than the wavelength of the donor decay), eq. [18] couples with the transition dipoles in [17] to deliver a result that equates exactly with the classical expression for the coupling, eq. [13]. The additional terms in [18], identified by QED, come into play at larger distances (signifying the accommodation of retardation principles). These are features that reflect the finite interval over which the energy exchange between A and B can be accomplished which is restricted by the photon propagation time, in accordance with relativistic causality.[2]

To appreciate the range-dependent character of the RET rate on its own merits, let it be assumed for simplicity that the donor and acceptor have isotropically averaged orientations, and that the refractive index of the medium is unity. It then follows that the distance-dependence of the transfer rate factorizes out in the following form (67, 71) (one that also identifies it with the tensor inner product of the coupling tensor in eq. [18]).

$$[19] \qquad \langle A(k,R)\rangle = \frac{1}{8\pi^2\varepsilon_0^2 R^6}\{3 + (kR)^2 + (kR)^4\} = V_{ij}(k,\boldsymbol{R})\overline{V}_{ij}(k,\boldsymbol{R})$$

This orientationally averaged transfer function is a scalar characterizing the distance dependence of $E1$-$E1$ coupling in RET. A key property of the result is that as the distance R increases into the range where it substantially exceeds the wavelength for the transfer energy, i.e., where $k\boldsymbol{R} >> 1$, the third term in eq. [19] begins to dominate, and the overall dependence on R assumes an inverse-square form. Detailed calculations reveal that the limiting result tallies exactly with radiative emission by the donor, followed by acceptor absorption of the ensuing radiation. In other words, the photons involved in the energy transfer lose their virtual character and become real, as is consistent with their acquiring a finite (and in principle measurable) time of flight. This change in character of RET with distance is neatly illustrated by a plot of the isotropically averaged excitation transfer function, as shown in Fig. 5. This figure gives a readily comprehensible representation of the Förster radiationless and radiative transfer processes as short- and long-range asymptotes, respectively, shown by the change in gradient of the log–log plot between the short- and long-range regions.

The discovery that Förster radiationless and radiative coupling are components of a single mechanism that operates seamlessly over *all* distances beyond wavefunction overlap

[2] Equally when $k = 0$ (essentially the transfer of an infinitesimal energy with infinitely long wavelength) the result (see eq. [18]) reduces to a form in which the near-field term alone operates out to infinity, duly corresponding to a coupling of "static" dipoles.

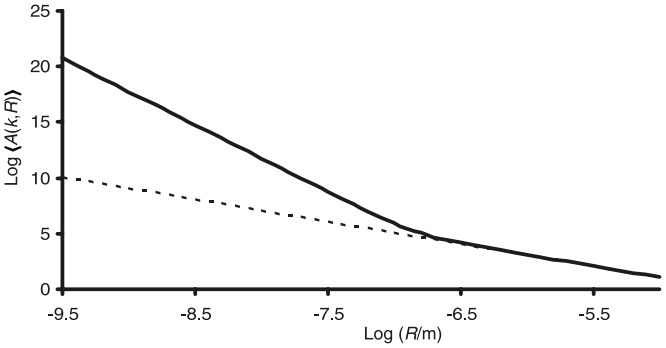
Fig. 5. Log–log plot of the RET excitation transfer function $\langle A(k,R)\rangle$, as defined by eq. [19], against log R (in meters), for $k = 9 \times 10^6$ m^{-1} (corresponding to a wavelength at the red end of the visible region). The dotted line shows the radiative asymptote (slope –2).



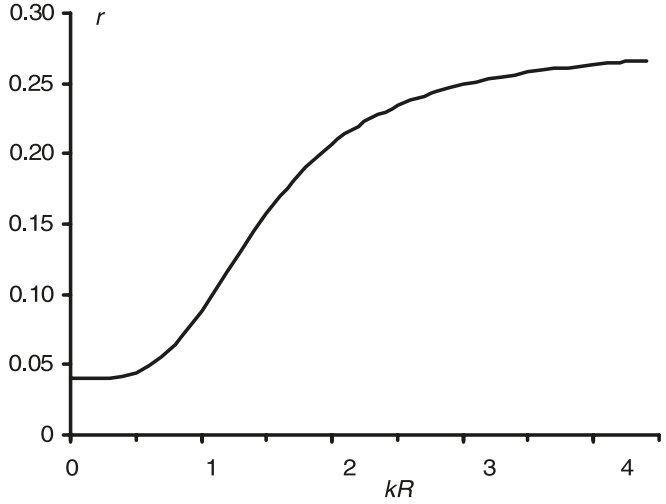
resulted in a paradigm shift in the understanding of RET, and it is the reason why the QED theory has been termed a "unified" theory (67). This theory is valid over a span ranging from the nanoscale up to indefinitely large distances; Förster energy transfer is the short-range asymptote and radiative transfer the long-range asymptote. One consequence of this discovery is that it has become meaningless to entertain any notion of competition between these processes. Recently, a revisitation of the QED theory has enabled the individual contributions associated with each of the two quantum pathways to be disentangled (72), proving that the long-range R^{-2} behaviour is completely identifiable with the physically more intuitive sense of propagation, the lower pathway in Fig. 4. In the same regime, the contribution from the upper pathway unexpectedly drops off as R^{-8}. Nonetheless in the near-zone, both run as R^{-6}. However, it should be emphasized that the unified theory establishes more than this; it also addresses donor–acceptor separations in an intermediate range where neither the radiative nor the Förster mechanism is truly valid. An experimental verification of the behaviour in this region remains a currently unfulfilled objective, a point we shall return to shortly.

The majority of applications of RET relate to the Förster regime, i.e., they involve systems in which stepwise energy transfer events occur between chromophores separated by less than the Förster distance, and as such they are also usually operating within the short-range, $k\boldsymbol{R} << 1$. Systems in which the mean transfer distance might fall in the long-range regime, $k\boldsymbol{R} >> 1$, would necessarily require the optically relevant species to be present in low concentrations; moreover, any diffusion processes that could produce transient short-range donor–acceptor juxtapositions should also have a timescale significantly longer than the donor decay time, or else diffusion-limited Förster transfer would result. The radiative transport that ensues in the latter case is exhibited in a variety of systems, such as dilute dye solutions, and it leads into a distinct branch of the theory where multiple scattering must also be taken into account. A detailed account is given by Berberan-Santos et al. (73).

C. Orientational and refractive effects

It is not only the effective power law governing distance that changes form as donors and acceptors move further apart, but also their functional dependence on orientation changes. To fully describe this feature, it is expedient to introduce the following generalization of the κ factor earlier defined by eq. [4]

Fig. 6. Variation with distance of the fluorescence anisotropy following RET between freely and independently rotating (or randomly oriented) donor and acceptor chromophores. Plot shows the acceptor fluorescence anisotropy r as a function of distance, represented on the abscissa scale as values of kR.



$$[20] \qquad \kappa_n = \cos\theta_T - n\cos\theta_A\cos\theta_B$$

Then, it can be shown that the excitation transfer function, whose isotropic average was given as eq. [19], more generally takes the form

$$[21] \qquad A(k,R) = \frac{9}{16\pi^2\varepsilon_0^2 R^6}\{\kappa_3^2 + (\kappa_3^2 - 2\kappa_1\kappa_3)(kR)^2 + \kappa_1^2(kR)^4\}$$

Equation [21] applies in the case of chromophores that are fixed, or have limited orientational freedom. Although most configurations will exhibit a variation in their orientational dependence with any significant change in donor–acceptor separation, it is the case that when $\mu_A \perp \mu_B$ and one of these transition dipoles is also orthogonal to $\boldsymbol{R}$, RET is entirely dipole forbidden "at all" distances. It is also notable that, although different kappa factors characterize the terms in R^{-6}, R^{-4}, and R^{-2}, both κ_3 and κ_1 feature in the expression for R^{-4}. This is the main reason why the intermediate term has eluded experimental identification, because it is technically difficult to envisage any circumstances in which its contribution could be isolated.

An interesting interplay of distance and orientational factors does however arise in connection with fluorescence polarization measurements, and this might afford the best means of identifying the onset of retardation effects. Calculations show that the fluorescence anisotropy in a system of freely and independently rotating donors and acceptors dramatically increases from its usual value $r = 0.04$, for transfer distances beyond the usual near-zone. The result, shown in Fig. 6, exhibits a long-range asymptote of precisely $r = 0.28$ (74). The reason for this behaviour is best understood as reflecting a "decreased" anisotropy in the short range (where

© 2008 NRC Canada

the transfer is effected by a photon whose virtual character means its propagation is not specifically aligned to the interchromophore direction) (69). Consequently its communication of polarization information is also less precise than is the case for the increasingly real-character photons that become involved in propagation over larger distances. Significant though the result is, its interpretation in any solution study would be significantly complicated by the need to accommodate an ensemble distribution of transfer distances.

To finally secure a completely general and rigorous result for RET requires that due consideration be given to the electronic influence of other material in the vicinity of the donor and acceptor. For optically dense systems, such matter could comprise other potential donor or acceptor species; in doped solids, it would be the host crystal that exerts the primary electronic influence; in the case of solutions, the surroundings would mostly comprise solvent, whereas in photobiological materials, it would usually be a protein superstructure and solvation, for example. Scholes et al. have recently performed extensive quantum chemical calculations quantifying such effects in a host of photosynthetic light-harvesting systems (75, 76).

A more comprehensive and general representation of media effects in each of these systems can be secured from the premise that the bulk material exerts an influence over resonance energy transfer by its effect on real or virtual photon propagation. The detailed form of this influence is duly accommodated in the theory by the introduction of an effective radiation field operator whose eigenstates signify modes in which photons are "dressed" by the electromagnetic influence of the host (77). Strictly, these dressed photons are "polaritons", though the distinction is not important if one is dealing with frequencies at which the host is relatively transparent. By a lengthy development, it transpires that the effect of making this correction is for the coupling tensor in eq. [18] to emerge in the following modified form, assuming Lorentz local field factors are assimilated into the expressions for the spectral functions $F_A(\omega)$ and $\sigma_B(\omega)$.

$$[22]\quad V_{ij}(k,\boldsymbol{R}) = \frac{1}{n^2(\omega)}\frac{e^{in(\omega)kR}}{4\pi\varepsilon_0 R^3}\{(\delta_{ij}-3\hat{R}_i\hat{R}_j) - (in(\omega)kR)(\delta_{ij}-3\hat{R}_i\hat{R}_j) - (n(\omega)kR)^2(\delta_{ij}-\hat{R}_i\hat{R}_j)\}$$

Here, $n(\omega)$ is the complex refractive index for optical frequency $\omega = ck$. The imaginary part of this index leads, through its inclusion in the phase factor in eq. [22], to dissipative losses, which properly increase with distance.

In its final and most general form, consistent with eqs. [21] and [22], it emerges that the RET rate can be written as follows (78)

$$[23]\quad w = w_F + w_I + w_{rad}$$

$$[24]\quad \left.\begin{aligned} w_F &= \frac{9\kappa_3^2 c^4}{8\pi\tau_{A^*}R^6}\int F_A(\omega)\sigma_B(\omega)\frac{d\omega}{\omega^4 n^4(\omega)} \\ w_I &= \frac{9c^2}{8\pi\tau_{A^*}R^4}(\kappa_3^2-2\kappa_i\kappa_3)\int F_A(\omega)\sigma_B(\omega)\frac{d\omega}{\omega^2 n^2(\omega)} \\ w_{rad} &= \frac{9\kappa_i^2}{8\pi\tau_{A^*}R^2}\int F_A(\omega)\sigma_B(\omega)\,d\omega \end{aligned}\right\}$$

The first term of eq. [24] is the usual Förster rate, identical to eq. [1] if the refractive index is taken as a constant. The second contribution, w_I, is a correction that comes into play at distances beyond the near-field, where the assumption $k\boldsymbol{R} << 1$ no longer holds. The third term, w_{rad}, which dominates over both other contributions when $k\boldsymbol{R} >> 1$, equates to radiative transfer. For donor–acceptor distances in the hundreds of nanometers range, where $k\boldsymbol{R} \approx 1$ to the nearest order of magnitude, all three terms of eq. [24] significantly contribute to resonance energy transfer.

4. Role in energy-harvesting materials

A. Optical energy collection and directed transfer

Many of the most widely studied and well-characterized theatres of operation for RET are to be found in connection with light-harvesting materials (both naturally occurring biological systems and synthetic structures). Following the capture of a photon by any such system, the transfer mechanism dictates that the migration of the acquired energy from the site of the initial photoabsorption through to the site of its utilization is at every stage subject to an inverse sixth-power dependence on distance. As a result, energy migration over distances beyond the Förster radius mostly operates through a series of short hops rather than one long one. Moreover, a "spectroscopic gradient" is commonly associated with these hops (79), the term signifying progressively longer wavelengths for absorption and fluorescence in successively visited chromophores (recall Section 2B). This property contributes significantly to the high efficiency of photosynthetic and allied energy-harvesting systems.

In considering the effectiveness of a preferred direction to the traffic between any two chromophores involved in such a sequence of energy transfer steps, it will be immediately apparent that there is a close similarity of form between the eqs. for "forward" and "backward" transfer between any given pair of electronic levels. The distance aspects for forward and backward transfer are obviously the same; moreover, since the unit displacement vector becomes $-\hat{\boldsymbol{R}}$ for back-transfer, its quadratic involvement in the orientation factor κ^2 means the latter is also identical. By reference to eqs. [10] and [11], and considering their counterparts for the inverse transfer process, it is in fact clear that the key to imposing directedness principally lies in exploiting differences in the relative spectral profiles. To quantify the relative rates or propensities for forward and backward transfer, it has been found convenient to introduce a dimensionless relative directional efficiency, ε, defined by

$$[25]\quad \varepsilon = \frac{\tau_B\int F_A(\omega)\sigma_B(\omega)\omega^{-4}d\omega}{\tau_A\int F_B(\omega)\sigma_A(\omega)\omega^{-4}d\omega}$$

The spectral curves illustrated in Fig. 2 exhibit typical implications for the spectral overlaps in the numerator and denominator of eq. [25]. For each chromophore, the fluorescence peak is Stokes-shifted to a lower frequency with respect to its absorption counterpart. Moreover, in the majority of cases of interest the peak of the acceptor absorption curve lies at a lower frequency than that of the donor emission. Thus, it becomes clear that forward transfer in any one step is generally favoured because (with reference to the

© 2008 NRC Canada

parameters shown in Fig. 2) $\omega_4 - \omega_3 > \omega_2 - \omega_1$, signifying that δ_2 will exceed δ_1.

In a recent study accommodating both symmetric and asymmetric lineshapes, detailed analytical results have been determined for the directional efficiency ε (39). In the case of Gaussian spectra, a particularly simple result applies if the two species possess similar fluorescence lifetimes, and if their absorption and fluorescence curves have similar heights and full-widths at half maximum, ω_{FWHM}. Under these conditions, the following result emerges

$$[26] \quad \varepsilon \cong e^{2k(\delta_2^2 - \delta_1^2)}$$

where $k = (4 \ln 2)\omega_{FWHM}^{-2}$. Equation [26] exhibits a transfer efficiency that strongly increases with δ_2 and decreases with δ_1, as might qualitatively be anticipated. Furthermore, if the Stokes shifts for A and B are equivalent and represented by $\omega_S = \omega_4 - \omega_2 = \omega_1 - \omega_3 = \delta_2 - \delta_1$, and the shift characterizing the spectroscopic gradient is defined as $\omega_G = \omega_4 - \omega_1 = \omega_2 - \omega_3 = \delta_1 + \delta_2$, then the directional efficiency is expressible in its simplest form

$$[27] \quad \varepsilon = e^{2k\omega_G\omega_S}$$

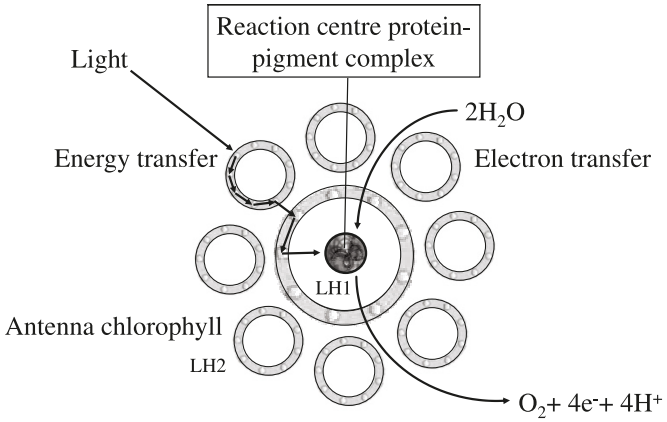
It is notable that this result shows the same functional dependence on the spectroscopic gradient and the Stokes shift; both are equally important in determining the directedness of the energy transfer. In an energy-harvesting system consisting of a number of chemically or environmentally different fluorophores, a progressive spectroscopic gradient operating at every energy transfer step thus ensures an overall directionality of flow, a characteristic summarized in the term "energy funnel".

B. Excitons and excitation pooling in photosynthetic systems

To achieve their primary purpose in green plants, leaf structures contain numerous copies of the complex molecular apparatus for synthesizing sugars from carbon dioxide and water. Further to these photosynthetic reaction centres, simpler and more numerous antenna pigments are additionally required to absorb incident light. However, many other structural elements have also to be present; crucially, there must be components that deliver H_2O, CO_2, and photoexcitation energy to the reaction centres, and still others to take the sugars off to where they are required as building materials for new plant tissue. To optimize the overall photosynthetic efficiency of the organism, a trade-off is therefore necessary between the density and arrangements of pigments and reaction centres. Such organizational criteria are further complicated by a consequence of simple chemical energetics; the fact that several visible photon energies are required to effect the synthesis of each carbohydrate unit. Photosynthesis thus also requires a gathering of the necessary energy into one location.

To most effectively utilize the sunlight that falls upon them, photosynthetic organisms typically have a system of antenna complexes surrounding the reaction centers where photosynthesis takes place (80–83). The antenna complexes absorb light, and the acquired energy is transferred onwards through a series of short-range, radiationless energy-transfer steps as illustrated in Fig. 7. Specific channelling to the reaction centres is cleverly accomplished by connectivity between spectroscopic and kinetic features, i.e., a correlation of the spatial locations of the chromophores with a progressive spectroscopic gradient. In the overall migration of energy from the site of its initial deposition to the site of its chemical action, this directionality obviates what would otherwise be random diffusion; on the contrary, it means that energy is quickly and efficiently directed to the site of its chemical utilization. Not only does this allow an organism to harvest light incident on a large surface area but also by pooling energy from a large number of antenna chromophores, energy of a higher equivalent frequency can be produced.

Fig. 7. Schematic energy flow in a bacterial photosystem for the oxidation of water.



Not only the spectroscopic properties of the chromophores determine the character and direction of energy flow, but the chromophore positioning and orientation are also important. Two-dimensional optical spectroscopy can unveil the intricate interplay between spectral and spatial overlap features in light-harvesting complexes, as beautifully exhibited in a recent study on bacteriochlorophyll (84). Interrogating the system with a sequence of ultrashort laser pulses, the optical response reveals linear absorption processes as well as couplings between the chromophores and dynamical aspects of the energy transfer. The results show that excitation relocation does not simply proceed by stepwise transfer from one energy state to another of nearest energy, but it depends on strong coupling between chromophores (as determined by the extent of their spatial overlap), further limiting any residual randomness in direction of the energy transfer. In other studies on photosynthetic systems, it has also emerged that energy transfer can propagate with a wave-like motion due to quantum coherence (85).

Fluorescence polarization measurements are a powerful means of eliciting other structural information. Because photosynthetic systems are relatively rigid systems with chromophores held at fixed positions and orientations relative to each other, then even when there are several successive energy jumps, any resulting emitted fluorescence is generally polarized. The extent of this polarization affords invaluable information about the internal orientational structure, as was outlined in Section 2D.

C. Energy-harvesting dendrimers

The proven efficiency of photosynthetic units and the elucidation of the responsible mechanisms have stimulated the

© 2008 NRC Canada

design of a variety of synthetic light-harvesting systems (86–88). The materials that have received most attention are dendrimers (89–92) (macromolecules consisting of molecular units repeatedly branching out from a central core designed to act as an excitation trap, exemplified by the structure in Fig. 8).

The outward branching leads to successive generations of structures, each with an increased number of peripheral antenna chromophores. In ideal cases, the requisite spectroscopic gradient is established through chemically similar chromophores in generationally different locations (93, 94). Most recent work on dendrimers has utilized branching motifs of vertex degree three and four, based on tri-substituted benzene (90) and porphyrin rings (95), respectively.

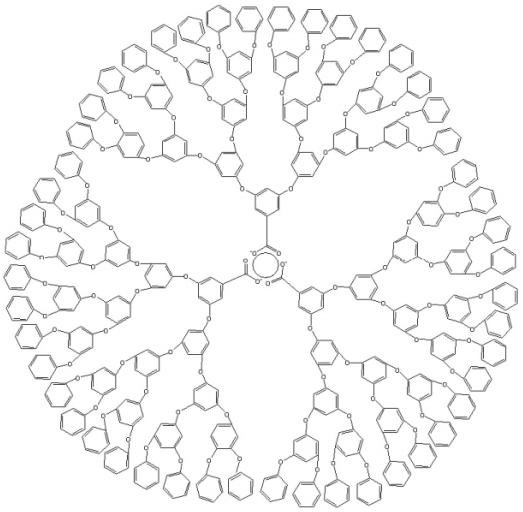
Modelling the multi-step flow of energy in dendrimers presents a considerable challenge (96, 97), and a variety of calculational methods have been brought to bear on the problem. Often, simplifying assumptions are required; for example, in work by Blumen et al. (98) an exact solution has been derived for fractal polymers in which all chromophores have the same absorption cross-section and all rates of transfer between nearest neighbours are considered equal. More radical approaches to the problem have also been attempted, such as modeling the diffusion of the excitation under a constant force as a continuum process (99), or using the Eyring (membrane permeation) model to treat the energy flux as diffusion in a potential energy landscape with thermal barriers (100).

One recently developed method that shows promise is an operator approach developed from an "adjacency matrix" representation, based on the chemical connectivity between individual chromophores (101–103). Here, a square matrix, whose order equals the number of chromophores, represents the propensities (probabilities associated with a specific time interval) for energy migration between the chromophores. This matrix operates upon a vector representation of the population conditions, each iteration representing an advance in time. Considerable simplification is effected, without compromising the fidelity of the model, by collapsing the representation into a reduced basis whose order is generational number of the dendrimer. For a three-generation dendrimer, for example, the RET propensity matrix in the shell basis may be written as follows

$$[28] \qquad \tilde{\mathbf{C}} = \begin{pmatrix} 1-a_3 & 2\varepsilon_3^{-1}a_3 & 0 & 0 \\ a_3 & 1-a_2-2\varepsilon_3^{-1}a_3 & 2\varepsilon_2^{-1}a_2 & 0 \\ 0 & a_2 & 1-a_1-2\varepsilon_2^{-1}a_2 & 3\varepsilon_1^{-1}a_1 \\ 0 & 0 & a_1 & 1-3\varepsilon_1^{-1}a_1-\xi \end{pmatrix}$$

where a_i is the propensity for transfer from a chromophore in the ith shell to another, to which it is chemically bonded, in the $(i-1)^{\text{th}}$ shell (or to the core, if $i = 1$); ε_i is the ratio of efficiencies for inward and outward energy transfer between the same pair of chromophores (the latter usually expressible through eq. [27] as a simple function of the chromophore lineshapes and spectroscopic gradients). Lastly, ξ signifies losses associated with emission or irreversible energy utilization at the core. One advantage of the above representation is that it obviates any assumption of symmetry that chemical connectivity would suggest; this is a facet of particular relevance when issues of folding are to be entertained.

Fig. 8. Fifth-generation polyphenylether dendrimer, centred on a lanthanide ion such as Er^{3+} or Tb^{3+}. The threefold branching is formally described by a vertex degree $r = 3$. Such planar depictions misrepresent the three-dimensional folding that increasingly takes place with successive generations.



Results based on this model have already indicated a promising potential for representing the time-dependent energy flow towards the core, as indicated in Fig. 9*a*, lending a new capacity to interpret experimentally determined kinetic data in terms of physically meaningful quantities with a clear molecular interpretation. The significance of inter-shell directional transfer efficiency is readily exhibited by results such as that shown in Fig. 9*b*, where the increasingly strong dependence with successive generations of dendrimer growth are dramatically illustrated. In the more extensive results reported elsewhere (103), the effects of spectroscopic gradient and Stokes shift are also detailed.

In other recent developments of the theory based on molecular QED (104, 105), attention has become focused on optically "nonlinear" mechanisms for RET in dendrimers. Such mechanisms naturally fall into two classes: those in which two-photon absorption by individual donors is followed by a direct transfer of their acquired energy to an acceptor, and other processes wherein the excitation of two electronically distinct but neighbouring donor groups is followed by a collective migration of their energy to a suitable acceptor. These two types of transfer process are subject to markedly different forms of dependence on energy level structures, laser coherence factors, chromophore selection rules and architecture, possibilities for the formation of delocalized excitons, spectral overlap features, and the overall distribution of donors and acceptors. With such an array of measures to choose between, experimental differentiation of the mechanisms should prove relatively straightforward, and the first experimental results are awaited with keen interest.

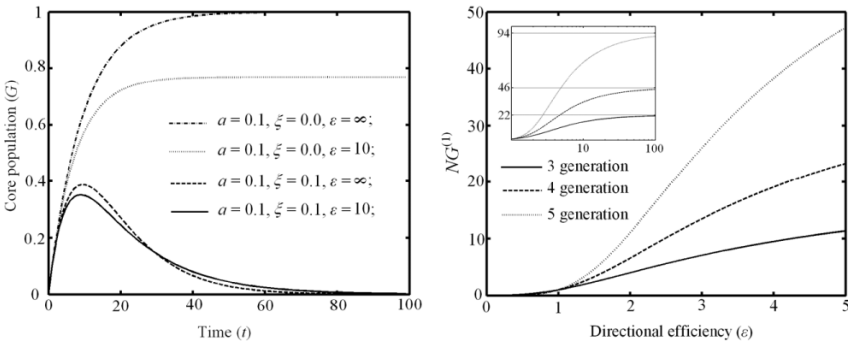
5. Optical control of resonance energy transfer

A. Laser-assisted resonance energy transfer

The pace of development in nanofabrication techniques has promoted an increasing interest in the specific effects of

© 2008 NRC Canada

Fig. 9. (*a*) Extent of core excitation in a single-generation dendrimer of vertex degree ρ = 3, plotted as a function of time, for different values of the parameters *a*, ξ, and ε. (*b*) Core excited-state population (scaled by the number of chromophores) in dendrimers of vertex degree = 3, as a function of the inter-shell transfer efficiency, for third-, fourth- and fifth-generation dendrimers. Adapted from (103).



donor and acceptor placement in nanoscale geometries and periodic structures. However, the possibility of influencing the operation of RET by an optical field only recently began to receive notice. Specifically, attention has become focused on possible means to enhance energy transfer, or even switch it on and off, through the controlled input of an off-resonant, auxiliary beam of laser radiation, as schematically illustrated in Fig. 10. The first work in this area considered amplification effects that might be induced by such an auxiliary beam in systems where energy transfer will occur spontaneously (following initial excitation of the donors). It was shown that, at the levels of intensity currently available from mode-locked solid-state lasers, significant enhancements of the transfer rate could be expected (106). The discovery led to a coining of the term "LARET" to denote laser-assisted RET.

The quantum electrodynamical mechanism for LARET involves fourth-order time-dependent perturbation theory. Each interaction is linear in the electric field operator, see eq. [15], and thus entails the absorption or emission of a photon. Specifically, in addition to the two virtual photon events (creation and annihilation) of normal RET, this process involves the absorption and the stimulated re-emission of a photon from the throughput, off-resonant, laser light; each of these real photon events may also occur at either the donor or the acceptor. In general, all four of the resulting possible combinations contribute to the overall quantum amplitude; moreover, each has 24 different time-orderings associated with it. State-sequence representations (107, 108), such as the one illustrated in Fig. 11 (compare Fig. 4), represent a tractable basis for QED calculations that lead to the following eq. for the transfer probability at time *t*

$$[29]\qquad P(t) = \frac{\rho_f}{32\hbar c^2 \pi \varepsilon_0^4 R^6} \left| e_i \alpha_{lk}^{A}(-k')(\delta_{jk} - 3\hat{R}_j\hat{R}_k)\,\alpha_{lk}^{B}(k')\bar{e}_l + \bar{e}_i \alpha_{ij}^{A}(k')(\delta_{jk} - 3\hat{R}_j\hat{R}_k)\,\alpha_{lk}^{B}(-k')e_l \right|^2 \int_0^t I^2(t)\,\mathrm{d}t$$

Here, the α tensors are generalized polarizabilities (61) and $I(t)$ signifies the time-dependent pulses of irradiance delivered by the off-resonant beam; notice the recurrence of the characteristic short-range R^{-6} dependence on distance. Model calculations based on eq. [29] suggest that prominent departures from the normal kinetic behaviour of RET can be expected, as indicated in Fig. 12.

Fig. 10. General schematic of laser-assisted or optically controlled resonance energy transfer.

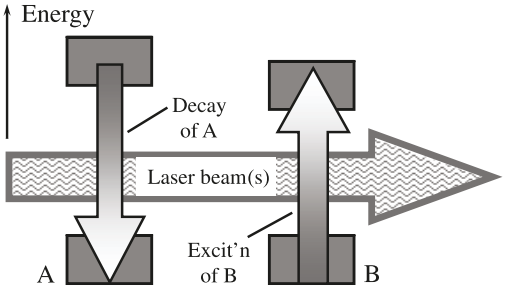


Fig. 11. One of four state-sequence diagrams for LARET. There are 24 pathways from the initial state on the left (excited *A*, ground state *B*) to the final state on the right left (ground state *A*, excited *B*), each progressing through three virtual intermediate states. In each case, ω denotes the off-resonant throughput radiation; in intermediate state boxes where the symbol is absent, a photon has been absorbed, while two ω symbols signify that stimulated emission has added an additional photon into the throughput. As with RET, ϕ denotes a virtual photon.

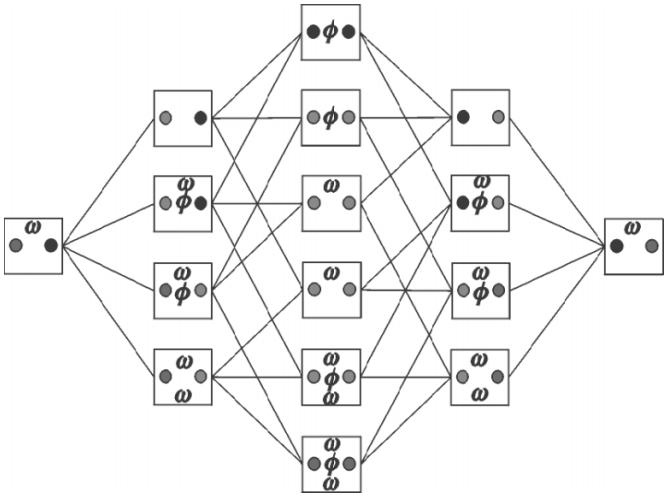

B. Optical switching in array devices

Recently, further interest has focused on structures that can be tailored to exploit the laser-assisted phenomenon. Specifically, consideration has been turned to systems in

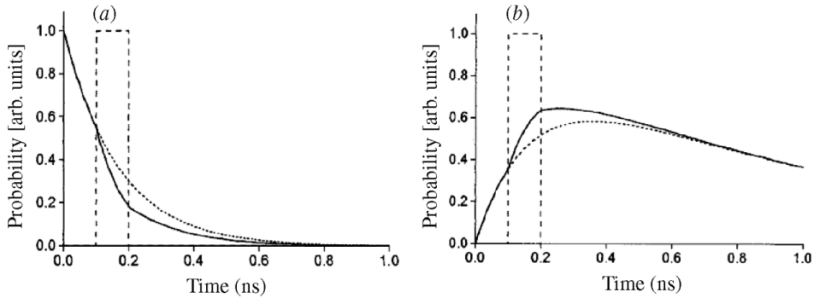
Fig. 12. Profiles illustrating the effects of LARET on the kinetics of fluorescence, (*a*) from a donor and (*b*) acceptor, produced by introducing a square pulse of off-resonance laser radiation (dashed line) 100 ps after the initial donor excitation. The solid line shows the LARET behaviour, departing from the usual RET trace shown by the dotted segment. The pulse duration is 100 ps, and its intensity is 5×10^{12} W cm^{-2}. Adapted from (106).



which each donor–acceptor pair has optical properties that satisfy the spectral overlap condition, but for which RET is designedly precluded by a customized geometric configuration (109). For example, as was observed in Section 3C, both short- and long-range RET is forbidden when the donor and acceptor undergo electric dipole transitions whose transition moments are perpendicular both to each other and also to the donor–acceptor displacement vector. For any such donor–acceptor pair, the LARET mechanism offers a means by which the throughput of non-resonant laser pulses can facilitate energy transfer when it would otherwise be rigorously forbidden. This optical switching of energy transfer, which has acquired the acronym OCRET (optically controlled resonance energy transfer), thus achieves the functionality of an optical transistor, with the electronic excitation representing a signal whose throughput is switched on by one or two auxiliary beams (110, 111).

The laser systems most capable of delivering the necessary levels of irradiance prove to be precisely those that will also offer directly controllable, ultrafast speeds of switching. Auspicious results have been obtained from detailed calculations on a prototype implementation of OCRET in planar nano-arrays (Fig. 13); results are illustrated by 3D plots in Fig. 14.

C. Implementation issues and applications

Results such as those shown in Fig. 14 encourage a view that the OCRET mechanism affords a realistic basis for a configuration of optical switches with parallel processing capability, operating without significant cross-talk. To address possible applications, a detailed analysis (112) has recently focused on the critical issue of transfer fidelity, defined as the efficiency of direct energy relocation, from an excited donor to its designated partner in the acceptor array, compared to the summed efficiencies for transfer to any other molecules within either array. The square-planar configuration proves to afford a significantly higher level of transfer fidelity than other likely contenders. It has also emerged that for optimal exploitation of the transition selection rules, the donor and acceptor molecules should belong to one of two common symmetry point groups, D_2 and C_{2v}. For such systems, through judicious choice of the relative values of the array spacing and lattice constant and the laser intensity, cross-talk can be driven down to arbitrarily low levels.

Generally, it may prove expedient to construct the donor and acceptor arrays as film layers, separated by a suitably

Fig. 13. Array implementation of OCRET: (*a*) overhead view of closely separated layers; the upper is a square-planar array of uniformly oriented donors, and the lower is a similarly constructed and registered array of acceptors. Black arrows represent donor transition dipoles in the upper layer, and grey arrows represent acceptor transition dipoles in the lower array; open arrows show an excited donor and its corresponding ground-state acceptor; (*b*) artist's impression of the view between the layers; the separation is exaggerated for clarity; (*c*) inter-layer depiction of the transition-moment orientations.

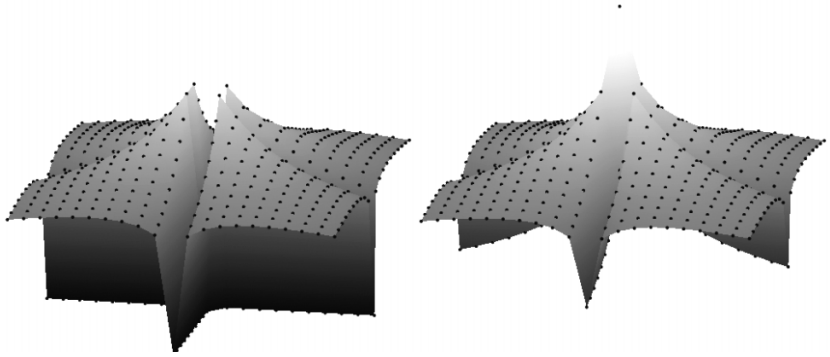
Fig. 14. Contour graphs depicting on a logarithmic scale the probability of energy transfer to the array of acceptors in the absence (left) and presence (right) of laser light. Efficiency of energy transfer is represented by the vertical scale, and dots indicate the locations of each acceptor.



transparent ultra-thin spacer material. Organic dyes represent an extensive range of possibilities for the donor and acceptor species; the use of quantum dots is also conceivable, though their relative isotropy could make it difficult to preclude conventional RET unless spin-imprinted excitation and excitation transfer were to be engaged (113, 114). Two techniques that could offer promise for the deposition and tailoring of the molecular components in each active layer are dip-pen nanolithography and thermochemical nanolithography, in each of which the potential to order and chemically modify molecular units is now established (115–118).

The achievement of RET-based optical switching in an extensive parallel-processing unit introduces a number of potential applications beyond simple switching. The array results signify that, for example, pixel-based images, written by donor excitation, could be transferred with high fidelity to the acceptor film. In the realm of optical communications, possibilities might be built on the obvious capacity of such a system to act as an ultrafast information buffer; the high level of interest in such devices has already prompted others to explore "slow-light" methods, where a host of more problematic limitations apply (119, 120). In the longer term, OCRET may prove a significant channel of progress towards reliable systems for use in optical computing and communications routing.

6. Conclusion

Resonance energy transfer is a fundamental mechanism widely operative in complex multi-component systems. In this review, it has been shown how an increasingly diverse range of applications and devices can exploit features of the process, such as its dependence on the degree of spectral overlap between donor and acceptors, the sharp distance dependence, and transfer selectivity determined by the orientation of transition moments. Attention has been drawn to a number of novel schemes for the control and application of energy transfer, offering particularly bright new prospects for energy-harvesting and all-optical switching.

Acknowledgements

It is a pleasure to acknowledge the involvement of past and present members of my group in the unified theory developments at the University of East Anglia, and I gladly acknowledge their contributions. In particular, I must thank Philip Allcock, David Bradshaw, Richard Crisp, Gareth Daniels, Luciana Dávila Romero, Robert Jenkins, Gediminas Juzeliūnas, Justo Rodríguez, and Brad Sherborne. I gratefully acknowledge funding from the Engineering and Physical Sciences Research Council, the Leverhulme Trust, and the Royal Society.

Convenient synthesis of ferrocene amines via Cu-catalyzed coupling reaction

Jinsheng Wu, Xiaolong Li, Mingyu Yang, Yujie Gao, Qianru Lv, and Baohua Chen

Abstract: An efficient copper-catalyzed Ullmann-type cross-coupling reaction without ligand of iodo-ferrocene with amines has been reported. In this process, a range of ferrocenyl amine compounds have been prepared in moderate to good yields.

Key words: amines, iodo-ferrocene, cross-coupling, copper, Ullmann coupling.

Résumé : On a mis au point une méthode efficace de l'iodoferrocène avec des amines qui est catalysée par le cuivre, mais ne donne pas lieu à une réaction de couplage croisé de type Ullmann avec le ligand. Dans ce procédé, on a préparé une grande variété de ferrocénylamines avec des rendements allant de modérés à bons.

Mots-clés : amines, iodoferrocène, couplage croisé, cuivre, couplage d'Ullmann.

[Traduit par la Rédaction]

Introduction

During the past few decades, a wide range of substituted ferrocene derivatives have been synthesized and studied. The ferrocenyl moiety has played a useful role, either as backbone or substituent in ancillary ligands (1). In addtion, it is a metal–organic nonlinear optical material used as a donor moiety (2) and in functional polymers with unusual properties (3).

Although ferrocenes are classical aromatic compounds, they can have rather unique properties due to their particular electronic and geometric features. As an example, the synthetic availability of heteroatom-substituted (oxygen, nitrogen) ferrocene is rather limited, since many methods for the functionalization of aromatics are unsuitable for modifying ferrocene derivatives. Typically, a few reports have been published concerning the synthesis of amino and diaminoferrocene derivatives (4).

Although it is well-known that the Ullmann reaction (copper-catalyzed N-arylation of amines) (5) predates the palladium-catalyzed amination methodology by many decades and that its applications in academic and industrial laboratories are well-documented (6), the methods have some deficiencies. For example, it is necessary to use temperatures as high as 210 °C, highly polar solvents, and often large amounts of copper reagents, to produce only modest yields (7). Without doubt, these factors have limited its usability in this field. Important alternatives have been reported recently, using the Ullmann-type methodology for the N-arylation of iodobenzene with a CuI/glycine/K_3PO_4/dioxane catalyst system (8) and that of iodobenzene using a CuI/K_3PO_4/PPAPM/DMF catalyst system (9). Özçubukçu et al. reported that ferrocenyl amides could be obtained from iodo-ferrocene and amides, pyrazole, imidazole, and triazole in the presence of copper (I) iodide and *t*–BuOK (10).

In the present work, we wish to report a rapid and convenient method for the synthesis of ferrocenyl amines via a Cu-catalyzed Ullmann-type coupling reaction of amines and iodo-ferrocene.

Result and discussion

In the first stage of the study, we focused on the coupling reaction between 2-nitrobenzenamine and iodo-ferrocene. We examined the effects of various copper salts, bases, solvents, and reaction time on the yields of the coupling reaction. The results are shown in Scheme 1 and Table 1.

It can be seen from Table 1 that the effect of the base on the coupling reaction was significant. In general, K_2CO_3 gives superior yields to those obtained by *t*–BuOK, K_3PO_4, and Et_3N (Table 1, entries 2–4). Further optimization of the reaction conditions reveals that the use of xylene is more effective than other solvents, such as toluene, DMSO, DMF, and benzene (Table 1, entries 4–7). In addition to Cu, we also used CuI, Cu(acac)$_2$, Cu_2O, CuCl, $CuCl_2$, CuBr, and $CuBr_2$ as the catalysts. However, the yields given by these other seven copper catalysts are much lower than those produced with Cu. Thus, it is obvious that the inexpensive Cu is the most desirable catalyst of this reaction.

On the basis of the above results, we consider that Cu powder (10 mol%) /K_2CO_3/xylene is a very suitable catalyst system for N-arylation (Scheme 2 and Table 2).

As expected, we have prepared a series of aminoferrocenes via this process. We have not found any side product formation, such as biferrocene, bisarylamines, etc. It seems that the electron-poor amines (e.g., Table 2, entries 1, 4–8, 10) react fairly well in the coupling. The substituted amines having an electron-rich (Table 2, entry 14) group at

the ortho position are often more difficult, compared with those having an electron-poor group, and those having electron-poor groups at the para positions (Table 2, entry 15) give no reaction. We also found that the substituent at the para and ortho positions cannot be tolerated either (Table 2, entries 12 and 13). The mechanism could not be completely elucidated from these results.

In summary, we have described a simple and efficient method for the preparation of a range of N-substituted valuable ferrocene derivatives via Ullmann-type coupling reaction mediated by Cu powder. Attractive features of this protocol are that the reactions are carried out easily in the given conditions, the operation is simple, the reagents used are inexpensive (metal salt and base), and the yields are satisfactory.

Table 2. Ullmann-type coupling of iodo-ferrocene with amines.

Experimental

NMR spectra were recorded in $CDCl_3$ using TMS as internal standard on a Varian Mercury 300 spectrometer (at 300 and 75 MHz for ^1H and ^{13}CNMR spectra, respectively). IR spectra were carried out on a Nicolet Nexus 670 FT/ IR spectrometer. FAB-MS were obtained on a ZAB-HS mass spectrometer. Elemental analysis was performed by an Elementar Vario EL analyzer.

The substituted amines (Table 2, entries 5, 6, and7), as well as iodo-ferrocene (11), were prepared according to the literature. All other starting materials were obtained from commercial suppliers and used without further purification.

Typical procedure for the preparation of of *N*-ferrocenyl-2-nitrobenzenamine (3a)

In a Erlenmeyer flask, xylene (1 mL), iodo-ferrocene (0.25 mmol), amines (0.3 mmol), Cu powder (10 mol%), and K_2CO_3 (0.5 mmol) were added successively under argon atmosphere with stirring. The mixture was reacted at 140 °C until complete consumption of iodo-ferrocene, as monitored by TLC. After cooling, the mixture was extracted with ethyl acetate (3 × 10 mL), the combined organic layer was washed with water and brine, then dried ($MgSO_4$), filtered, and concentrated in vacuo. The residue was purified by column chromatography, petroleum/ethyl acetate. Red solid (**3a**) was obtained; mp 104–105 °C. IR (neat, cm^{-1}) ν: 489, 1265, 1614, 3039, 3379. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.26 (s, 5H), 4.37 (s, 2H), 4.17 (s, 2H) 6.65–6.70 (t, *J* = 6.9 Hz, 1H), 7.09–7.12 (d, *J* = 7.5 Hz, 1H), 7.32–7.36 (t, *J* = 7.2 Hz, 1H), 8.14–8.17 (d, *J* = 7.8 Hz, 1H), 9.12 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 65.8, 66.1, 69.6 94.2, 115.9, 116.4, 126.3, 132.2, 135.6, 145.2. Anal. calcd. for $C_{16}H_{14}FeN_2O_2$: C 59.65, H 4.38, N 8.70; found: C 59.86, H 4.58, N 8.60. FAB-MS *m*/*z*: 322 [M^+].

Characterization data for products

N-*Ferrocenyl-2-bromobenzenamine (3b)*

Yellow solid, mp 110–112 °C. IR (neat, cm^{-1}) ν: 742, 1521, 1592, 3405. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.14 (s, 2 H), 4.24 (s, 5H), 4.35 (s, 2H), 5.43 (s, 1H), 6.60–6.62 (d, 1H), 7.03 (m, 1H), 7.1 (m, 1H), 7.42–7.45 (m, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 65.3, 69.4, 114.4, 119.1, 128.0, 132.2. A novel and efficient synthesis of *bis*(benzofuranyl)methanes and 2-benzofuran-1-nitroalkanes catalyzed by $Bi(OTf)_3$

Ren Er Chen, Yan Li Wang, Zhi Wei Chen, and Wei Ke Su

Abstract: Bismuth (III) triflate-catalyzed Friedel–Crafts reactions between benzofuran and aldehydes in different solvents were investigated. Bis(benzofuranyl)methanes were obtained with good yields when acetonitrile was used as solvent, while in the case of nitromethane the multi-component reaction products, 2-benzofuran-1-nitroalkanes, were formed under similar conditions. A plausible mechanism is given.

Key words: benzofuran, aldehyde, bis(benzofuranyl)methanes, $Bi(OTf)_3$, 2-benzofuran-1-nitroalkane.

Résumé : On a étudié les réactions de Friedel–Crafts catalysées par le triflate de bismuth(III) et effectuées entre le benzofurane et les aldéhydes dans divers solvants. Avec l'acétonitrile comme solvant, on obtient de bons rendements de bis(benzofuranyl)méthanes alors que dans le nitrométhane, dans des conditions semblables, il y a formation de 2-benzofurane-1-nitroalcanes, des produits qui résultent de réactions entre plusieurs réactifs. On propose un mécanisme plausible.

Mots-clés : benzofurane, aldéhyde, bis(benzofuranyl)méthanes, $Bi(OTf)_3$, 2-benzofurane-1-nitroalcanes.

[Traduit par la Rédaction]

Introduction

Most natural and synthetic compounds with benzofuran moieties exhibit broad bioactivities (1, 2) such as antitumor, antifungal, antivirus activities, 5-lipoxygensase and 5α-reductase inhibitory activity (3–5). Moreover, they are also key intermediates for constructing some natural bioactive quinines (6). Though there are some reports of bis(benzofuranyl)methanones (7) and macrocyclic trimer (8), which were prepared from activated benzofurans, bis(benzofuranyl)methanes were only reported in one article (9). In that article, an environmentally harmful mineral acid was chosen as catalyst.

Recently, metal triflates have been widely used as Lewis acids that have low toxicity, low cost, high stability, are easy to handle and recover from water (10–13). In our ongoing green chemistry research program, investigating the use of environmentally friendly reagents, catalysts, and processes for organic reactions, we wish to study the activities of metal triflates in catalyzing the Friedel–Crafts alkylation and multi-component reaction. Herein, we wish to introduce $Bi(OTf)_3$ as a mild, highly efficient, and environmentally benign catalyst for the preparation of benzofuran derivatives. An effective, convenient, and economic method for the synthesis of bis(benzofuranyl)methanes was developed. Additionally, the first three-component synthetic procedure of 2-benzofuran-1-nitroalkane derivatives are reported here. The catalyst could be recovered easily after the reactions and reused without evident loss of activity.

Results and discussion

The condensation between benzofuran (2 equiv.) and benzaldehyde **1a** (1 equiv.) in CH_3NO_2 at refluxing temperature was used as a model reaction (Scheme 1) for the screening of a suitable metal triflate catalyst, and the results are summarized in Table 1. It can be seen that all metal triflates, with the exception of $Mg(OTf)_2$ and $Sr(OTf)_2$, showed good catalytic effects. $Sc(OTf)_3$ and $Bi(OTf)_3$ were particularly effective for this Friedel–Crafts alkylation reaction in short reaction times (Table 1, entries 1–8). Considering its low cost, $Bi(OTf)_3$ was chosen as reaction catalyst. The amounts of metal triflate were also examined in CH_3NO_2. When $Bi(OTf)_3$ and $Sc(OTf)_3$ were used as catalysts, 1 mol% was enough to finish the reaction in 1 h. There is no obvious influence on the yield on increasing the amount of $Bi(OTf)_3$ and $Sc(OTf)_3$ (Table 1, entries 6 and 9).

Solvents such as DMF, CH_3CN, EtOH, and PhMe (Table 1, entries 10–13) were also tested. Acetonitrile was found to give maximum yield followed by nitromethane. Reaction temperature was also explored in CH_3CN. No product was found at room temperature after 3 h. When the reaction temperature was increased to reflux, the yield was obviously improved. In light of this, subsequent studies were carried out under the following optimized conditions: 1 mol% $Bi(OTf)_3$ at refluxing temperature in CH_3CN. In this reac-

tion, $Bi(OTf)_3$ could be reused three times without obvious loss of activity (Table 2, entry 1).

To extend the scope of the metal triflate-catalyzed method for the synthesis of bis(benzofuranyl)methanes, a series of aldehydes were investigated (Table 2). Both aromatic and aliphatic aldehydes were applicable to this reaction, except for **1q** and **1r**. The results indicated that a spacial steric effect had an obvious influence on the reaction (Table 2, entries 14–17). Furthermore, the substituted groups on the aromatic ring also had evident influence on the reaction. The aromatic ring-bearing electron-withdrawing groups only required short times with high yields, excluding the sterically hindered 2-nitrobenzaldehyde **1o**. The *m*-substituted benzaldehyde with electron-withdrawing groups were more beneficial to the reactions (Table 2, entries 6, 7, 9, and 11). To our surprise, good yield was also obtained when 3-hydroxybenzaldehyde was used as substrate (Table 2, entry 10). Considering the good reaction activity of aldehydes, benzophenone, acetone, and cyclohexanone were chosen as substrates. Trace reactions took place as indicated by TLC.

The formation of 2-benzofuran-1-nitroalkane derivatives was discovered serendipitiously. During the preparation of bis(benzofuranyl)methanes in nitromethane, another product was detected by TLC and identified as compound **3** (Scheme 2) by ^1H NMR, ^{13}C NMR, and MS. Thus, the catalytic activity of $Bi(OTf)_3$ was explored for the multicomponent condensation using 4-hydroxybenzaldehyde as model substrate. 4-Hydroxybenzaldehyde, benzofuran, and nitromethane were stirred at room temperature for 4 h at the molar ratio of 1:1:1 in CH_3CN. No product was found, as monitored by TLC. But when it was heated to refluxing temperature, contrary to our expectation, compound **2** were obtained instead of compound **3**. We also carried out the condensation of 4-hydroxybenzaldehyde, benzofuran, and nitromethane in CH_3NO_2. Interestingly, compound **3** was obtained as major product along with compound **2** as minor product (Table 3, entry 2). To extend the scope of the metal triflate-catalyzed method for the synthesis of 2-benzofuran-1-nitroalkane derivatives, we also tried other aldehydes. The results are summarized in Table 3. It can be seen that this condensation was only suitable for the aromatic aldehydes bearing strong electron-donating groups (Table 3, entries 2–5).

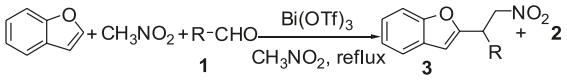
Scheme 2.



A possible mechanism for the formation of bis(benzofuranyl)methanes and 2-benzofuran-1-nitroalkane derivatives is proposed in Scheme 3 (paths A and B). When CH_3CN was used as reaction solvent, intermediate [**a**] was formed, which was easily attacked by another benzofuran in the presence of $Bi(OTf)_3$ (14). Furthermore, the aromatic ring-bearing electron-withdrawing group was more beneficial to the formation of compound **2,** except for 3-hydroxybenzaldehyde. To our surprise, when CH_3NO_2 is utilized as reaction media there may exist another reaction mechanism

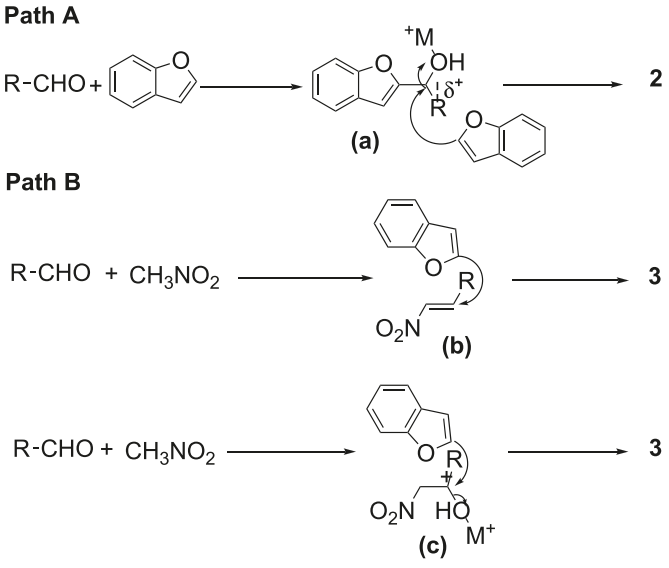
Scheme 3.



(path B). Compound **3** was synthesized via two possible processes. Intermediate [**b**] was attacked by benzofuran to obtain the Michael adduct **3**. Intermediate [**c**] suffered a nucleophilic attack by benzofuran to give compound **3**. We predicted the mechanism by performing the following reactions. The condensation of **1** and nitromethane in CH_3CN at the molar ratio of 1:1 at refluxing temperature, catalyzed by $Bi(OTf)_3$, gave no product. But when this reaction proceeded in CH_3NO_2 at refluxing temperature, a henry product was obtained with high yield. The aromatic ring-bearing electron-donating groups were apt for the synthesis of the henry product. This may be explained because the electron-donating groups are crucial to the stability of intermediate [**b**]. We also tried the condensation of benzofuran and the henry reaction. Only the aromatic ring-bearing strong electron-donating groups can react easily, which helped us explain the result in Table 3.

Conclusion

In summary, we have developed a simple, convenient, and efficient synthetic protocol for bis(benzofuranyl)methanes using a catalytic amount of $Bi(OTf)_3$ in CH_3CN. Additionally, $Bi(OTf)_3$ efficiently promotes three-component coupling reactions of aldehyde, benzofuran, and nitromethane. The simplicity, efficiency, easy work-up, and the need for only a small amount of $Bi(OTf)_3$ makes it the preferred procedure for the preparation of different kinds of 2-benzofuran-1-nitroalkane derivatives. This class of compounds may be used to construct some bioactive compounds.

Experimental section[2]

General method

All reagents are commercially available. Bismuth(III) triflate was prepared from triphenylbismuth and triflic acid (15). Melting points were measured on a digital melting point apparatus WR-1B and were uncorrected. ^1H NMR and ^{13}C NMR spectra were recorded on a Varian 400 MHz or Bruker Anance III (500 MHz) instrument using $CDCl_3$ as the solvent, and chemical shifts were expressed in parts per million (ppm) using TMS as an internal standard. Mass spectra were measured with a Trace Finnigan DSQ. High-resolution mass spectral (HRMS) analyses were measured on an Agilent 6210 TOF LC/MS using APCI and EI (electrospray ionization) techniques. IR measurements were carried out with a Nicolet Aviatar-370 instrument. Elemental analysis was performed on a VarioEL-III instrument. All spectral data of the products were identical to authentic samples.

General procedure for the preparation of bis(benzofuranyl)methanes

A mixture of benzofuran (2 mmol), benzaldehyde (1 mmol), and $Bi(OTf)_3$ (0.01 mmol) in CH_3CN (1 mL) was heated at refluxing temperature for 1 h. Then water was added, and the mixture was extracted with ethyl acetate (3 × 10 mL). The combined organic phases were dried over Na_2SO_4 and concentrated under reduced pressure. The crude product was purified by flash chromatography (silica gel, petroleum ether / methylene chloride *v*/*v* 16:1) to afford the adduct. The aqueous layer was washed by ethyl acetate and concentrated in vacuo to give white crystals [$Bi(OTf)_3$],

which was finally heated at 180 °C for 48 h in vacuo to afford $Bi(OTf)_3$ as a colorless crystal.

General procedure for the preparation of 2-benzofuran-1-nitroalkane derivatives

$Bi(OTf)_3$ (0.01 mmol) was added to a solution of benzofuran (1 mmol), 4-hydroxybenzaldehyde (1 mmol) in 2 mL of nitromethane. The reaction mixture was stirred at 101 °C for 2 h and then cooled to room temperature. Water (10 mL) was added and the mixture was extracted with ethyl acetate (3 × 10 mL). The combined organic phases were dried over Na_2SO_4, evaporated, and the crude product was purified by flash chromatography (silica gel, petroleum ether / ethyl acetate *v*/*v* 4:1) to afford the corresponding products. The aqueous layer was washed by ethyl acetate and concentrated in vacuo to give white crystals [$Bi(OTf)_3$], which was finally heated at 180 °C for 48 h in vacuo to afford $Bi(OTf)_3$ as a colorless crystal.

Probing DNA polymerase activity with stereoisomeric 2′-fluoro-β-D-arabinose (2′F-araNTPs) and 2′-fluoro-β-D-ribose (2′F-rNTPs) nucleoside 5′-triphosphates

Chang G. Peng and Masad J. Damha

Abstract: 2′-Deoxy-2′-fluoro-β-D-ribonucleosides (2′F-rN) and 2′-deoxy-2′-fluoro-β-D-arabinonucleosides (2′F-araN) differ solely in the stereochemistry at the 2′-carbon of the furanose sugar ring. 2′F-rN 5′-triphosphates (2′F-rNTPs) are among the most commonly used sugar-modified nucleoside 5′-triphosphates (NTPs) for in vitro selection; however, the epimeric 2′F-araN 5′-triphosphates (2′F-araNTPs) have only recently been applied to polymerase-directed biosynthesis [C.G. Peng and M.J. Damha. J. Am. Chem. Soc. **129**, 5310 (2007)]. The present study describes primer extension assays that compare, for the first time, the incorporation efficiency of the two isomeric NTPs, namely, 2′F-araNTPs or 2′F-rNTPs, by four DNA polymerases [Deep Vent (*exo*-), 9°N_m, HIV-1 RT, and MMLV-RT]. Under the conditions used, incorporation of 2′F-araTTP proceeded more efficiently relative to 2′F-rUTP, while the incorporation of 2′F-araCTP is comparable or slightly less efficient than that observed with 2′F-rCTP. Interestingly, these preferences were observed for all four of the DNA polymerases tested. Unexpected differences in NTP incorporation were observed for 2′F-rCTP vs. rCTP. Despite their seemingly similar conformation, they behaved striking differently in the in vitro polymerization assays. 2′F-rCTP is a much better substrate than the native counterpart (rCTP), an observation first made with human DNA polymerases [F.C. Richardson, R.D. Kuchta, A. Mazurkiewicz, K.A. Richardson. Biochem. Pharmacol. **59**, 1045 (2000)]. In contrast, 2′F-rUTP behaved like rUTP, providing poor yield of full-length products. Taken together, this indicates that 2′F-rCTP is very unusual with regard to enzyme/substrate recognition; an observation that can be exploited for the production of DNA oligomers enriched with both ribose and arabinose modifications. These findings are timely given the significant interest and growing need to develop chemically modified oligonucleotides for therapeutic and diagnostic research. By examining the structure–activity relationship (SAR) of the ribose and arabinose sugar, this study furthers our understanding of how the nature of the 2′ substituent (e.g., α vs. β; F vs. OH) and the heterocyclic base affect NTP selection (specificity) by DNA polymerases.

Key words: 2′F-rNTPs, 2′F-araNTPs, DNA polymerases, biosynthesis, modified nucleoside triphosphates.

Résumé : Les 2′-désoxy-′2-fluoro-β-D-ribonucléosides (2′F-rN) et les 2′-désoxy-2′-fluoro-β-D-arabinonucléosides (2′F-araN) ne diffèrent que par la stéréochimie au niveau du carbone 2′ du furanose du noyau du sucre. Les 5′-triphosphates de 2′F-rN (TP de 2′F-rN) les 5′-triphosphates de nucléosides (TPN) de sucres modifiés les plus fréquemment utilisés pour des sélections in vitro; toutefois, les 5′-triphosphates de 2′F-araB épimères (TP de 2′F-araN) n'ont que récemment été appliqués à la biosynthèse dirigée par une polymérase [C.G. Peng et M.J. Damha. J. Am. Chem. Soc. **129**, 5310 (2007)]. La présente étude décrit les premiers essais d'extension qui comparent pour la première fois l'efficacité d'incorporation de deux TPN isomères, à savoir le TP de 2′F-araN et le TP de 2′F-rN par quatre polymérases d'ADN [Deep Ven (exo-), 9°N_m, HIV-1 RT et MMLV-RT]. Dans les conditions utilisées, l'incorporation du TP de 2′F-araN se fait d'une façon plus efficace que celle du TP de 2′F-rU alors que celle du TP de 2′F-araN est comparable ou légèrement inférieure à celle observée avec le TP de 2′F-rC. Il est intéressant de noter que cette préférence a été observée avec chacune des quatre polymérases d'ADN qui ont été utilisées. On a observé des différences inattendues dans l'incorporation de TPN pour le TP de 2′F-rC par rapport au TP de rC. Malgré leurs conformations qui semblent semblables, ils se comportent de façons totalement différentes dans les essais de polymérisation in vitro. Le TP de 2′F-rC est un meilleur substrat que son pendant natif (TP de rC), une observation qui a été faite pour la première fois avec des polymérases d'ADN humain [F.C. Richardson, R.D. Kuchta, A. Mazurkiewicz, K.A. Richardson. Biochem. Pharmacol. **59**, 1045 (2000)]. Par ailleurs, le TP de 2′F-rU se comporte comme le TP de rU et il fournit de

faibles rendements de produits pleine grandeur. Si on prend l'ensemble de ces résultats en considération, on peut en déduire que le TP de 2′F-rC présente des caractéristiques inhabituelles par rapport à la reconnaissance enzyme/substrat et que cette observation peut être exploitée pour la production d'oligomères d'ADN enrichis de modifications tant de ribose que d'arabinose. Ces observations arrivent à point compte tenu de l'intérêt significatif qu'elles présentent et du besoin croissant de développer des oligonucléotides chimiquement modifiés pour la recherche thérapeutique et diagnostique. En examinant la relation structure activité (RSA) des sucres ribose et arabinose, cette étude permet de plus d'étendre notre compréhension de la façon dont la nature du substituant 2′ (par exemple, α versus β ou F versus OH) et la base hétérocyclique affectent la sélection du TPN (spécificité) par les polymérases d'ADN.

Mots-clés : 2′-désoxy-′2-fluoro-β-D-ribonucléosides (2′F-rN), 2′-désoxy-′2-fluoro-β-D-arabinonucléosides (2′F-araN), polymérases d'ADN, biosynthèse, triphophosphate de nucléoside modifié.

[Traduit par la Rédaction]

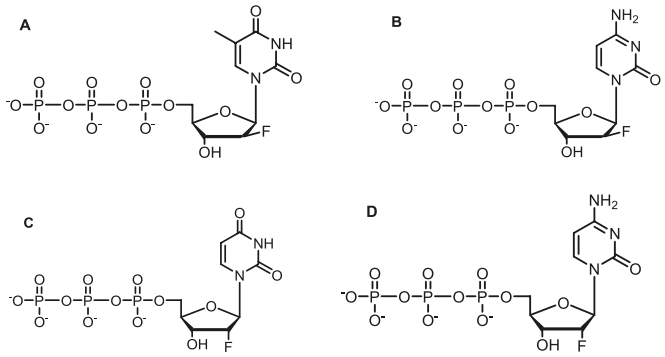
Introduction[3]

Nucleoside 5′-triphosphates (NTPs) (Fig. 1) are extensively used as probes to elucidate mechanistic details of DNA biosynthesis, and they represent the active form of several approved and pre-clinical antiviral and anticancer agents (1–3). Chemically-modified NTPs are also of great importance in the development of aptamers as research, therapeutic, and diagnostic agents (4, 5). Aptamers are generally obtained from the process of systematic evolution of ligands by exponential enrichment (SELEX) (6–8) and have gained recognition with the recent FDA approval of Macugen, a 2′F/2′-OMe ribose-modified oligonucleotide indicated for the treatment of neovascular age-related macular degeneration (9).

Modified NTPs can serve either as substrates or inhibitors of polymerases depending on the structural changes introduced through modifications to the base, phosphate, and (or) sugar moieties relative to the natural NTPs (i.e., deoxyribonucleoside 5′-triphosphates (dNTPs) and ribonucleoside 5′-triphosphates (rNTPs)) (2). Introducing a fluorine (F) atom into the sugar moiety of nucleosides, particularly at C2′, has a strong impact on the sugar ring conformational equilibrium (10). When the 2′-fluorine atom is "up" (or β) in 2′-deoxy-2′-fluoro-β-D-arabinonucleic acid (2′F-ANA), the arabinofuranose sugar ring predominantly puckers in the south/east (C2′/O4′-*endo*) conformation (11, 12), whereas a "down" (or α) fluorine in 2′-deoxy-2′-fluoro-β-D-ribonucleic acid (2′F-RNA) steers the ribofuranose ring into the north (C3′-*endo*) conformation (13–15). These C2′-modified sugars in turn dictate the conformation of the corresponding oligonucleotides (2′F-ANA and 2′F-RNA).

A fluorine atom at C2′ significantly impacts the thermodynamic stability and biological activity of duplexes. For example, oligonucleotides modified with 2′F-RNA units have enhanced binding affinity with mRNA (~+2 °C/nt) relative to the unmodified counterparts (16–19). The incorporation of 2′F-ANA units also raises the T_m of different systems, i.e., duplexes (~+1 °C/nt) (20), triplexes (~+0.8 °C/nt) (21), C-rich tetrads (~+1 °C/nt, pH < 4.0) (22), and G-rich tetrads (~+2 °C/nt) (23). Pyrimidine-based 2′F-RNAs were introduced into hammerhead ribozymes (24) or siRNAs (25) and exhibited increased or maintained activity. Antisense DNA or siRNA strands containing a significant 2′F-ANA content displayed gene-silencing efficacy in the low nanomolar range (26, 27).

Fig. 1. (A) 1-(2-Deoxy-2-fluoro-β-D-arabinofuranosyl)thymine 5′-triphosphate (2′F-araTTP); (B) 1-(2-deoxy-2-fluoro-β-Darabinofuranosyl) cytosine 5′-triphosphate (2′F-araCTP); (C) 1-(2-deoxy-2-fluoro-β-D-furanosyl)uracil 5′-triphosphate (2′F-rUTP); (D) 1-(2-deoxy-2-fluoro-β-D-ribofuranosyl)cytosine 5′-triphosphate (2′F-rCTP).



Given that 2′-deoxy-2′-fluoro-β-D-ribonucleoside 5′-triphosphates (2′F-rNTPs) are good substrates for T7 RNA polymerase (28), they are among the most commonly used in RNA-based SELEX (29–31) and, most recently, siRNAs generated by polymerase-catalyzed biosynthesis (32). A few studies have shown that 2′F-rNTPs are also substrates for DNA polymerases (33, 34). Richardson et al. reported that all four 2′F-rNTPs are substrates of human DNA pol γ, and DNA poly α can accept 2′F-rUTP, 2′F-rCTP, and 2′F-rGTP, but not 2′F-rATP (35). Furthermore, the incorporation efficiency of 2′F-rCTP by pol α is 17 fold higher compared to that of 2′F-rUTP (35). Thermostable DNA polymerases [Pfu (*exo*-), Vent (*exo*-), Deep Vent (*exo*-), and UlTma] are also able to incorporate 2′F-rUTP and 2′F-rCTP with reasonable efficiency (36).

2′-Deoxy-2′-fluoro-β-D-arabinonucleoside analogues have been studied for antiviral and anticancer applications. The recently approved anticancer drug clofarabine (37) is 2-

chloro-2′F-araA. Once triphosphorylated at their 5′ end, 2′F-araNTPs can be incorporated into eukaryotic as well as viral DNA (38–40). One of clofarabine's mechanisms of action, in fact, is the induction of strand breaks after incorporation into cellular DNA (41). 2′F-araNTPs incorporating a ^{18}F radionuclide ($t_{1/2}$ = 110 min) allows for the non-invasive imaging of tumors through positron emission tomography (PET) (42, 43). The successful application of these NTPs in PET relies on the ability of DNA polymerase to largely (and more selectively) incorporate these NTPs in tumor cells (44). 2′F-araNTPs have not been extensively investigated for in vitro selection/amplification processes (45).

Our group has recently shown that thermostable Family A DNA polymerases such as Deep Vent (*exo*-) (DV), 9°N$_m$ (9N), Therminator, and Phusion (46), accept both purine and pyrimidine 2′F-araNTPs as substrates and are able to synthesize long (30 nt) stretches of 2′F-ANAs with high efficiency and fidelity. In addition, these enzymes are capable of synthesizing DNA on a 2′F-ANA template, and can drive the formation of 2′F-ANA/2′F-ANA base pairs on chimeric 2′F-ANA-DNA templates (47).

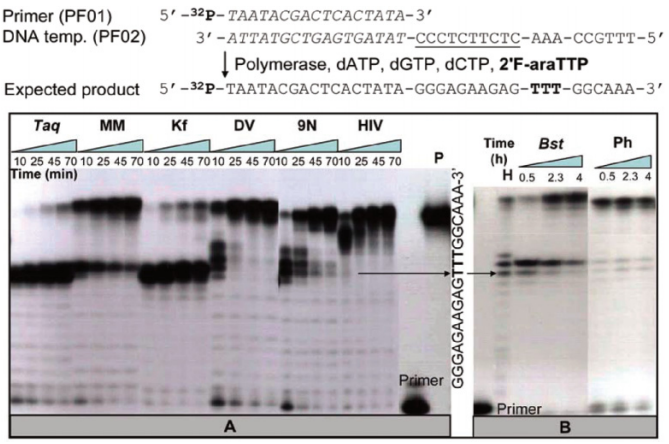
In this follow-up study, we first assessed the incorporation of contiguous pyrimidine 2′F-araNTPs (i.e., 2′F-araTTP or 2′F-araCTP) into a DNA strand. Then, we compared, for the first time, the incorporation efficiency of pyrimidine 2′F-araNTPs to that of the corresponding 2′F-rNTP stereoisomers by two retroviral DNA polymerases, namely, HIV-1 reverse transcriptase (RT) and Moloney Murine Leukemia (MMLV)-RT, and two thermostable DNA polymerases, namely, DV and 9N. Finally, we also compared the incorporation efficiency of various combinations of pyrimidine 2′F-araNTP, 2′F-rNTP, and native rNTP along with dATP and dGTP. These studies further our understanding of how the nature (and stereochemistry) of the 2′ substituent and the heterocyclic base affect NTP selection (specificity) by DNA polymerases.

Results

Incorporation of three contiguous 2′F-araTTPs and 2′F-araCTPs

Primer extension assays were used to assess the incorporation of three contiguous 2′F-araTTPs on the DNA template PF02 (Table 1). Under the conditions used, all of the polymerases studied generated full-length products, although to different extents (Fig. 2). Pausing was observed for *Taq*, MMLV-RT, DV, 9N, and *Bst*. Remarkably, the thermophilic

Fig. 2. DNA-template directed polymerization of three contiguous 2′F-aratTs by DNA polymerases. (A) All reactions at 37 °C, 20 μL reaction volume, 1 μL polymerase, dNTPs, and 2′F-araTTP concentrations: 0.2 mmol/L for Taq, DV, 9N, and H1V-1 RT; 0.5 mmol/L for MMLV; and 0.033 mmol/L for Kf; (B) reactions at 55 °C, 20 μL reaction volume, 2 μL Bst and 0.4 μL Ph, and 0.2 mmol/L triphosphates; **P**: full-length product control; **H**: products formed through a chain termination assay with 0.1mmol/L dATP, dGTP, dTTP, dTTP+ddTTP (1:1 molar ratio), 0.4 μL HIV-1 RT in 20 μL reaction volume, on the same template PF02.



enzymes DV, 9N, and *Taq* were able to incorporate three 2′F-araTTPs even at 37 °C (Fig. 2A). Ph could afford full-length products without any pausing at 55 °C.

The same primer extension assays were used to assess the incorporation of three 2′F-araC units on the DNA template PF03 (Fig. S1, Supplementary Data).[4] MMLV-RT, Kf, and HIV-1 RT all gave full-length products (Fig. S1A).[4] Thermophilic enzymes DV and *Taq* could incorporate three consecutive 2′F-araCTPs at 37 °C; however, the rate of polymerization was significantly slower and some premature products (pausing) were observed. 9N and *Bst* failed to generate full-length products at 37 °C (Fig. S1A, Supplementary Data) but were able to incorporate three 2′F-araCTPs and gave the expected full-length products at higher temperature (55 °C) (Fig. S1B and S1C, Supplementary Data).[4] The high-fidelity enzyme Ph also easily provided a full-length product at 55 °C. Overall, all the DNA polymerases tested were able to incorporate three 2′F-araTTPs and 2′F-araCTPs into a DNA strand and afforded full-length products. 9N and DV could incorporate 2′F-araTTP better than 2′F-araCTP (Table 2).

Table 2. Polymerase used and efficiency of three 2′F-araT(C)TP incorporations.

Polymerases[a]	Short name	Incorporation of three 2′F-araTTPs[b]	Incorporation of three 2′F-araCTPs
Thermophilic DNA polymerases (assays conducted at 55 °C except otherwise indicated)			
Deep Vent (3′→ 5′ exo-) DNA polymerase	DV	++++ (37 °C)	+++ (37 °C) ++++
9° N_m DNA polymerase	9N	++++ (37 °C)	+ (37 °C) ++++
Bst DNA polymerase large fragment	*Bst*	++ (37 °C) +++	+ (37 °C) ++++
Taq DNA polymerase	*Taq*	++ (37 °C)	++ (37 °C) ++++
Phusion High-Fidelity DNA polymerase	Ph	++++	++++
Mesophilic DNA polymerase (assays conducted at 37 °C)			
Klenow fragment DNA polymerase (3′→ 5′ exo-)	Kf	++	++
Reverse transcriptase DNA polymerases (assays conducted at 37 °C)			
HIV-1 RT (recombinant)	HIV-1	++++	++++
Moloney Murine Leukemia Virus RT	MMLV	+++	++++

[a]Enzyme sources: all from New England Biolabs (NEB) except for Ph from Finnzymes (distributed by NEB); HIV-1 RT from Worthington Biochemical Corp.; Polymerases can be classified into different enzyme families such as family A (*Bst*, *Taq*, Kf), family B (DV, 9N, Ph) and family RT (MMLV, HIV-1) (46).

[b]++++: excellent (full-length products and no pausing observed); +++: very good (full-length products with slight pausing); ++: good (full-length products with significant pausing); +: No full-length products obtained.

Incorporation efficiency of 2′F-araTTP vs. 2′F-rUTP

Once the conditions of the primer extension assays were established, the incorporation efficiencies of 2′F-araNTPs and 2′F-rNTPs by viral reverse transcriptases (HIV-1 RT and MMLV-RT) on a DNA template (PF02) were compared. As shown in Fig. 3A, 2′F-araTTP was an excellent substrate of HIV-1 RT and its incorporation proceeded more efficiently compared to 2′F-rUTP and rUTP. Interestingly, different pausing patterns were observed. In the absence of 2′F-modifed NTPs, the expected full-length DNA product was obtained from DNA-primed (PF01) reverse transcription on the DNA template PF02. Addition of an equivalent amount of the dideoxynucleoside 5′-triphosphate (ddTTP) led to the formation of three new bands resulting from chain termination directly opposite the d(AAA) residues present in the template strand (Fig. 3, lane **H**). These bands served as "markers" facilitating the identification of products formed in the 2′F-modifed NTP-based assays. The replacement of dTTP with either 2′F-rUTP or rUTP strongly inhibited RT-catalyzed synthesis of full-length product, as evidenced by the appearance of significant amounts of products resulting from chain termination after incorporation of one or two rNTPs. Even the incorporation of the first rUTP or 2′F-rUTP unit proceeded with difficulty as evidenced by the band patterns observed after 5 min. These truncated products represented more than 94% of the total polymerization products even after 1 h incubation with the enzyme. In sharp contrast, polymerization in the presence of 2′F-araTTP provided a significant amount of the full-length product after 30 min. However, the appearance of a significant amount of two shorter products, 5′-[DNA primer]-2′F-ara(TpTpT)-dGG-3′ and 5′-[DNA primer]-2′F-ara(TpTpT)-dGGC-3′, was observed during the first 5–20 min of reaction. This suggests that while the arabinose units do not cause significant chain termination as observed with both 2′F-rUTP and rUTP, the efficiency of subsequent steps, particularly the addition of subsequent dNTPs, is somewhat hindered following incorporation of 2′F-araTTPs. In other words, "delayed pausing" was observed in this case.

Similar results were obtained with MMLV-RT. This enzyme was able to incorporate 2′F-araTTP more efficiently than 2′F-rUTP and rUTP (Figs. S2 and S3, Supplementary Data).[4] Similarly, pausing was observed "after" the first incorporation of 2′F-araTTP, and "before" the first incorporation of 2′F-rUTP and rUTP. By analyzing the second incorporations of modified triphosphates in Fig. S3, it is clear that 2′F-araTTP is a better substrate than 2′F-rUTP.

We also wished to compare the efficiency of incorporation of 2′F-araTTP and 2′F-rUTP by thermostable polymerases DV and 9N, as these enzymes were previously found to be the most effective at polymerizing 2′F-araNTP units (47). With DV, incorporation of 2′F-araTTPs proceeded efficiently giving nearly quantitative yield of full-length product after 5 min. Accumulation of an intermediate band corresponding to 5′-[DNA primer]-2′F-ara(TpTpT)-dG-3′ was observed in the first 2 min (Fig. 4A). With 2′F-rUTP, however, abrupt pausing was observed after the first and second 2′F-rUTP incorporation, yielding only 20% of the desired full-length product after 9.5 h (Fig. 4A). The same trends were observed with 9N DNA polymerase (Fig. S4A, Supplementary Data).[4] Incorporation efficiencies of 2′F-araTTP and dTTP were comparable and ~100% full-length products were generated within 2 min and without pausing, whereas the reaction with 2′F-rUTP paused after one incorporation producing little of the expected full-length product (~20% after 1 h).

Incorporation efficiency of 2′F-araCTP vs. 2′F-rCTP

The same primer extension assays were used to evaluate the efficiency of DNA-template (PF03) directed incorporation of the cytosine NTPs by HIV-1 RT and MMLV-RT. Remarkably, 2′F-rCTP was found to be a significantly better

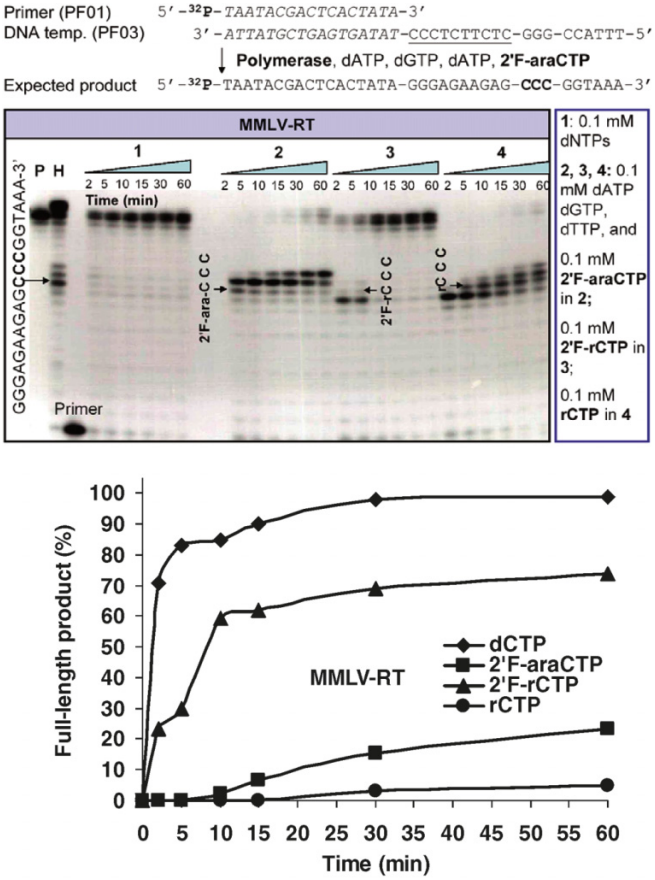
Fig. 5. Efficiency of incorporation of 2′F-araCTP vs. 2′F-rCTP through DNA template PF03 mediated by MMLV-RT DNA polymerization. Lower figure is a plot of time-course of full-length product (%). Reactions conducted at 37 °C, in a 40 μL reaction volume, with 0.6 μL (12 units) enzyme; triphosphate concentrations were shown; products shown on lane **H** were formed through a chain termination assay with 0.1 mmol/L dATP, dGTP, dTTP, dCTP+ddCTP (1:1 molar ratio) on the template PF03, 0.4 μL HIV-1 RT in 20 μL reaction volume at 37 °C. **P**: full-length product control.



substrate than rCTP. In fact, with rCTP significant pausing was observed before the first rCTP incorporation (Fig. 3B and Fig. 5).

Generally, the incorporation efficiency of 2′F-araCTP by HIV-1 RT and MMLV-RT is comparable to or slightly less efficient than that observed with 2′F-rCTP. Binding of 2′F-araCTP at the active site of MMLV-RT appears to occur more readily over its isomeric counterpart 2′F-rCTP, since pausing was observed "after" the first 2′F-araCTP incorporation but "before" the first 2′F-rCTP incorporation (Fig. 5). Further elongation beyond the first 2′F-araC unit, however, seemed very difficult and mainly premature products (~90%) were observed after 60 min; in contrast, once the first 2′F-rCTP was incorporated, synthesis proceeded readily giving rise to almost 100% of full-length product (Fig. 5).

DV and 9N were able to incorporate 2′F-araCTP as well as 2′F-rCTP under the conditions studied here (Fig. 4B; Fig. S4B in Supplementary Data).[4]

Table 3. The order of incorporation efficiency of 2′F-araT(C)TP vs. 2′F-rU(C)TP.

Polymerases	Order of incorporation efficiency[a]	Figures
HIV-1 RT	dTTP > 2′F-araTTP > 2′F-rUTP > rUTP	3A
	dCTP ≈ 2′F-rCTP ≥ 2′F-araCTP > rCTP	3B
MMLV-RT	dTTP > 2′F-araTTP > 2′F-rUTP > rUTP	S2; S3
	dCTP ≈ 2′F-rCTP ≥ 2′F-araCTP > rCTP	5
DV	dTTP ≈ 2′F-araTTP > 2′F-rUTP	4A
	dCTP ≈ 2′F-rCTP ≈ 2′F-araCTP	4B
9N	dTTP ≈ 2′F-araTTP > 2′F-rUTP	S4A
	dCTP ≈ 2′F-araCTP ≈ 2′F-rCTP	S4B

[a]Incorporation efficiency is evaluated by the percentage of full-length products from primer extension assays.

Fig. 6. DNA-template (PF04)-mediated DNA polymerization assay catalyzed by 9N DNA polymerase comparing the efficiency of incorporation of dATP, dGTP in the presence of various pyrimidine NTP combinations, namely: 2′F-araTTP/2′F-araTTP; 2′FaraTTP/2′F-rCTP; 2′F-rUTP/2′F-rCTP; and rUTP/rCTP. Reactions were carried out at 55 °C; 40 μL reaction volume, 9N enzyme (2 μL; 4 units); 0.2 mmol/L triphosphates; products shown on lane **H1** were formed through a chain termination assay with 0.1 mmol/L dATP, dGTP, dCTP, dTTP+ddTTP (1:1 molar ratio), 0.4 μL HIV-1 RT in 20 μL reaction volume on the same template PF04; bottom figure is a plot of time-course of full-length product (%).

In summary, incorporation of 2′F-araTTP proceeded more efficiently relative to 2′F-rUTP. Incorporation of 2′F-araCTP at the 3′-end of a DNA primer strand also proceeded more readily than incorporation of 2′F-rCTP. However, once the first 2′F cytosine unit was incorporated, synthesis proceeded more efficiently from the DNA primer containing the 3′ terminal 2′F-rCTP unit. While the substrate specificities towards the 2′F-rUTP and rUTP pair were similar, a different specificity towards the corresponding cytosine pair (i.e., 2′F-rCTP and rCTP) was observed. The order of incorporation efficiency of 2′F modified pyrimidine NTPs is summarized in Table 3.

Incorporation efficiency of pairs of modified triphosphates

Next, we conducted primer extension assays on the DNA template PF04 to synthesize for the first time chimeric (ribo/arabino/deoxy) oligonucleotides using 9N, DV, and HIV-1 RT DNA polymerases. The monomers consisted of dATP, dGTP, and one of five different pyrimidine pairs: 2′F-araTTP/2′F-araCTP (Group 3 in Fig. 6), 2′F-araTTP/2′F-rCTP (Group 4), 2′F-rUTP/2′F-araCTP (Group 5), 2′F-rUTP/2′F-rCTP (Group 6), and rUTP/rCTP (Group 7). Control reactions with the native dNTPs and rNTPs were carried out as well (Group 1 and 2 in Fig. 6). Incorporation efficiency was measured either as the percentage of full-length products, or the number of nucleotides incorporated if no full-length products were obtained. With 9N and DV, incorporation efficiencies followed the same trend (Table 3). Interestingly, HIV-1 RT produced opposite results for Groups 3, 4, and 6 (Table 4). Generally, dNTPs are the best and rNTPs are the worst substrates; the combination of 2′F-modified NTPs showed different incorporation efficiencies. The results are summarized in Table 4, and possible explanations for these results are discussed below.

Discussion

Nucleoside analogues have been studied extensively from the standpoint of the biochemical consequences of these analogues on DNA polymerase activity. Much is also known about the structural effects of nucleoside analogues when incorporated into DNA duplexes (10, 11), but relatively little information is available concerning the impact of 2′-isomeric modified NTPs on polymerase function. The biochemical experiments presented herein represent the first results obtained with the isomeric 2′F-rNTP and 2′F-araNTPs.

The data obtained show that DNA polymerases can incorporate contiguous pyrimidine 2′F-araNTPs into a growing DNA strand to afford full-length products (Table 2), consistent with data reported in our recent preliminary study. For example, incorporation of three contiguous 2′F-araTTP units proceeded more efficiently relative to three contiguous 2′F-rUTPs, but this was not the case for the 2′F-araCTP/2′F-rCTP pair where equal efficiencies were observed with DV and 9N polymerases (Table 3). With the RT enzymes, incorporation of the first 2′F-araCTP unit proceeded more efficiently relative to its 2′-isomeric counterpart. However, further elongations proceeded more efficiently with 2′F-rCTP. Furthermore, when comparing polymerization patterns, 2′F-rUTP behaved like rUTP, but surprisingly the same was not true for the cytosine pair, 2′F-rCTP and rCTP. Below, we attempt to rationalize these interesting results.

Co-crystallization of HIV-1 RT with a double-stranded DNA template–primer (binary complex: RT-dsDNA) (48), and with dsDNA and dNTP (ternary complex: RT-dsDNA-dNTP) (49) suggest that the dsDNA adopts an A-like (North) structure near the polymerase active site, which gradually converts to the B-form conformation (south) as this DNA region moves away from polymerase active site. Therefore, it is expected that incoming NTPs with an A-like

© 2008 NRC Canada

conformation should be favoured for binding at the active site. Other factors such as steric interactions between incoming NTPs and the polymerase amino acid residues also help dictate the specificity of NTP binding. For instance, models based on crystal structures suggest that Phe155 in MMLV-RT (or Tyr-115 in HIV-1 RT) acts as a "steric gate" that discriminates between the 2′H of a dNTP and the 2′OH group of an NTP (49–51). Studies reported by Marquez and coworkers on conformationally biased NTP analogues and HIV-1 RT fully support this hypothesis (52, 53). They explained the contrasting inhibitory behaviour of αFddATP and (the more potent) βddATP stereoisomer through molecular dynamics simulations that revealed unfavourable steric interaction between "north" puckered αFddATP and Tyr115 (HIV-1-RT) (analogous to the interaction of 2′-OH of rNTPs with Tyr115) (52). Our observation that 2′F-araTTP is incorporated more efficiently than 2′F-rUTP is consistent with these studies (52), suggesting that when the fluorine is on the same face of the ring as the 5 carbon (i.e., β-F) as in 2′F-araTTP, the steric interaction with Tyr115 in HIV-1 RT is avoided. 2′F-araTTP, however, must pay an energy penalty, since it must switch to the "north" conformation to bind at the active site of RT. Such conformation is possible and precedented for some arabinonucleosides (54). The more flexible dTTP thus shows the highest efficiency of incorporation.

Nucleoside analogues that do not block DNA synthesis at the point of incorporation, but only after additional incorporations of normal dNTPs have been termed "delayed chain terminators", which have been shown to be relatively resistant to excision by HIV-1 RT mutant, one of HIV-1 RT's drug-resistance mechanisms (55). The noticeable delayed pausing observed with 2′F-araTTPs may be due to the inclusion of three contiguous 2′F-araT in the dsDNA. The more rigid arabinose units likely affects the A/B form conformational change in the RT–primer–template complex, which should result in a diminished rate of dNTP incorporation or, in the dissociation of RT from the primer–template duplex resulting in abortive products. The pausing observed "before" the incorporation of 2′F-rUTP or rUTP (Fig. 3A) indicates that 2′F-rUTP or rUTP has difficulty in binding at the active site of RT, consistent with the proposal of steric gate control. Similar pausing "patterns" are observed for 2′F-rUTP and rUTP, consistent with the fact that 2′F-rUTP is a mimic of rNTPs and are both excellent substrates for T7 RNA polymerase (28).

Similar results are obtained for MMLV-RT, DV, and 9N (Table 3). One can speculate that these enzymes use the same discrimination mechanism (conformational preference and steric gate) to distinguish between dTTP, 2′F-araTTP, 2′F-rUTP, and rUTP during incorporation. Our finding that the incorporation efficiency of 2′F-araTTP is higher than that of 2′F-rUTP by HIV-1 RT, MMLV-RT, DV, and 9N is not surprising, since 2′F-araTTP is a dTTP mimic (and thus favoured by DNA polymerases) and does not have an α-substituent at C2′, while 2′F-rUTP is a rUTP mimic (with α-substituents at C2′) and should be more favoured by RNA polymerases. A similar pattern was observed among the cytosine series and the thermostable enzymes DV and 9N.

Surprisingly, a more complex pattern of incorporation efficiency was observed among dCTP, 2′F-araCTP, 2′F-rCTP, and rCTP in the primer extension reactions catalyzed by HIV-1 RT and MMLV RT. Based on the pausing patterns observed, binding of 2′F-araCTP at the active site of MMLV-RT seemed to be more advantageous over its ribose counterpart, 2′F-rCTP (Fig. 5). This is again consistent with steric gate control for NTP binding (52). The further elongation observed, however, indicates that other factors play important roles in single-base incorporation, aside from the steric gate factor and conformational bias of sugar pucker. Previous studies on the fidelity of base incorporation have shown that the rate-limiting step could be different among multiple molecular checkpoints involved in DNA-polymerase-directed polymerization (56, 57). Our experiments simply measure the overall result of all possible factors governing base incorporations. The factors governing the specificity and efficiency of base incorporation by DNA polymerases are complex and not completely understood (58). Preferential geometry (1), sugar pucker (53), topology, and size of the polymerase active site (1) are all important considerations. In our screening experiments, we found that the efficiency of incorporation of 2′F-araCTP < 2′F-araTTP in same primer extension conditions with some DNA polymerases (e.g., DV and 9N). For 2′F-rCTP, the literature has shown that the incorporation rate of 2′F-rCTP is much higher than that of 2′F-rUTP by human polymerases α and γ (35). We therefore propose that the observed incorporation efficiency of 2′F-rCTP ≥ 2′F-araCTP is the superposition of two factors: first, the overall incorporation efficiency of 2′F-rCTP may be higher than 2′F-rUTP by HIV-1 RT and MMLV-RT; second, the incorporation efficiency of 2′F-araCTP is lower than that of 2′F-araTTP. As to why 2′F-rCTP differs strikingly from rCTP remains an unsolved question in this work and requires further study. For example, it may be worthwhile in future studies to examine the structure of modified DNA primers differing only in the nature of their 3′-terminal unit (e.g., 2′F-rC vs. and rC). It is conceivable that the north–south population of the fluorinated nucleoside, once incorporated, remains highly biased towards the North, but that of the natural nucleoside resembles that of rU 5′-phosphate in solution, which in fact has an slight excess of the south conformer (N:S ratio < 1) (59, 60).

Delayed pausing was often observed with the incorporation of 2′F-araTTP and 2′F-araCTP (Figs. 3, 4, 5, and Fig. S2 in Supplementary Data).[4] These results are somewhat consistent with studies previously reported by our group, in which a DNA primer strand containing a single 3′-arabinocytidine unit (araC; in this case the 2′-substituent is an OH group) was found to serve as a primer of DNA synthesis. However, significant pausing of HIV-1 RT was observed after extension with 4 × dNTP units (61).

The order of the incorporation efficiency of the NTP mixtures shown in Table 4 is an overall effect of the incorporation efficiencies of individual modified NTPs (Table 3). The first modified NTP incorporated is either 2′F-araTTP or 2′F-rUTP, so the rate-limiting step could be the incorporation of the first NTP. This seems to be the case for 9N and DV. For example, the order of incorporation efficiency Group 3 ≈ Group 4 > Group 6 > Group 5 (Table 4) can be explained by the general trend of incorporation efficiency 2′F-araTTP > 2′F-rUTP and 2′F-rCTP ≥ 2′F-araCTP. The other combinations of rNTPs (Group 2 and Group 7) were not favoured by

© 2008 NRC Canada

9N in this primer extension assay, consistent with the poor incorporation of rNTPs by DNA polymerases (Table 3).

Interestingly, the 2′F-rUTP/2′F-rCTP pair (Group 6) was incorporated by HIV-1 RT more efficiently than the 2′F-araTTP/2′F-rCTP pair (Group 4) (Table 4; Fig. S6 and Supplementary Data)[4], suggesting that 2′F-rUTP is favoured over 2′F-araTTP. However, when comparing 2′F-araTTP/2′F-araCTP (Group 3) with 2′F-rUTP/2′F-araCTP (Group 5), the order of efficiency of incorporation observed suggests that 2′F-araTTP is the better substrate, consistent with the findings shown on Fig. 3A. The greater incorporation efficiency of 2′F-araTTP/2′F-rCTP (Group 4) vs. 2′F-araTTP/2′F-araCTP (Group 3) is also fully consistent with the finding that elongation with 2′F-araCTP seems less efficient than with 2′F-rCTP (Fig. 3B). Taken together, these results indicate that that the rate-limiting step in HIV-1 RT may be different from DV and 9N, since incorporation of 2′F-modified CTPs seems more important in determining the yield of the full-length products.

Conclusion

2′F-araTTP and 2′F-araCTP are substrates of all the DNA polymerases tested in the present study. DV and 9N were the most efficient at incorporating 2′F-araTTP and 2′F-araCTP and afforded good yields of full-length chimeric oligonucleotide products. Our comparative studies of the efficiency of incorporation of 2′F-araNTPs vs. 2′F-rNTPs by four DNA polymerases demonstrate that, under the conditions used, incorporation of 2′F-araTTP proceeded much more efficiently relative to 2′F-rUTP, while the incorporation of 2′F-araCTP was comparable or slightly less efficient than that observed with 2′F-rCTP (Table 3). Generally, dNTPs were found to be better substrates than rNTPs; 2′F-rUTP behaves much like rUTP but 2′F-rCTP is strikingly different from rCTP. Furthermore, we demonstrate that mixtures of 2′F-araNTPs and 2′F-rNTPs can be used to generate 2′F-r/2′F-ara-oligonucleotides through template-directed DNA polymerization reactions. The 2′F-araTTP and 2′F-rCTP pair gave excellent results with the DNA polymerases tested. Considering the potential advantages of these modifications in oligonucleotide-based gene-silencing approaches (16–27), our studies suggest that it should be possible to generate chimeric 2′F-arabinose/ribose oligonucleotide aptamers through an in vitro selection (SELEX) process. By examining the structure–activity relationship (SAR) of the ribose and arabinose sugar, this study also contributes to the understanding of how C2′ stereochemistry, the nature of the 2′subsitutent (F vs. OH), and heterocyclic base affect NTP selection (specificity) by DNA polymerases.

Experimental

Nucleotides

dNTPs were purchased from Fermentas. 2′-Deoxy-2′-fluoro-β-D-arabinonucleosides were obtained from Topigen Pharmaceuticals, Inc. The introduction of the 5′-triphosphate moiety was conducted by Rasayan, Inc. 2′F-rUTP and 2′F-rCTP were purchased from Rasayan, Inc. The structures of the fluorinated nucleoside 5′-triphosphates are shown in Fig. 1.

Template and primer design

DNA and 2′F-ANA-DNA templates and primers used in this study are shown in Table 1. The primer (PF01) is a 17 nt DNA sequence 5′-*TAATACGACTCACTATA*-3′. Each template strand comprises three sequence segments: a 17 nt primer binding sequence 5′-*TATAGTGAGTCGTATTA*-3′, a 10 nt running start sequence 5′-CTCTTCTCCC-3′ (62, 63), and a variable DNA "test sequence". The oligomers were designed to test the incorporation of three 2′F-araT units on the DNA template PF02, three 2′F-araC units on the DNA template PF03, and six mixed 2′F-araT and 2′F-araC units on the DNA template PF04. DNA sequences were obtained from Integrated DNA Technologies (IDT).

Primer extension reactions

We adapted primer extension assays (62, 63) to first screen eight DNA polymerases (Table 2) for their ability to incorporate three consecutive 2′F-araT and 2′F-araC units. Enzyme activity and default reaction buffer conditions suggested by the manufacturers are shown in Table S1 (Supplementary Data).[4] All reaction buffers were provided by the manufacturers except the HIV-1 RT buffer, which was prepared in-house. The DNA primer (PF01) was first labeled by a radioactive phosphorus probe (^{32}P) at the 5′-hydroxyl terminus according to a published procedure (64). Unlabeled DNA primer was also used to adjust the primer concentration. The final concentrations were 85 nmol/L for the primer and 255 nmol/L for the template in the screening experiments, and 100 nmol/L for the primer and the template in the comparison studies. The primer and template were heated at 95 °C for 5 min and annealed at 4 °C at least 2 h before use. In a microtube, the mixture of buffer, triphosphates (different combinations of four dNTPs, 2′F-araNTPs, 2′F-rNTPs, and (or) rNTPs), water, primer, and template was prepared according to pre-calculated reaction volume and concentrations. Mineral oil (20 μL) was used to prevent evaporation for assays running at 55 °C. A polymerase was added to initiate the primer extension reaction. Time points were obtained by removing 4 μL or 8 μL aliquots from the reaction mixture and quenching with an equal volume of a stopping dye solution (98% deionized formamide, 10 mmol/L EDTA, 1 mg/mL bromophenol blue, and 1 mg/mL xylene cyanol). The product pattern was analyzed by 12% denaturing polyacryamide gel electrophoresis (PAGE) and subsequent autoradiography analysis.

Chemical-constituent diversity of *Tridax procumbens*

Wen-Hao Chen, Xing-Ming Ma, Quan-Xiang Wu, and Yan-Ping Shi

Abstract: Three new phytochemicals, a polyacetylene, 1,2-dihydrodendroarboreol B (**1**), an ionone derivative, (3*S*,5*R*,6*S*,7*E*)-3-tetradecanoate-5,6-epoxy-β-ionone (**4**), and a flavonol diglycoside, quercetagetin-3,6,4′-trimethoxy-7-*O*-neohesperidoside (**38**), along with 35 known compounds with diverse structures, were isolated from the EtOH extract of the aerial parts of *Tridax procumbens*. The structures of **1**, **4**, and **38** were determined on the basis of comprehensive methods including UV, IR, NMR, HR-ESI-MS, and CD, and by comparison of the spectroscopic data with those reported for structurally related compounds. Compounds **4**, (3*S*,5*R*,6*S*,7*E*)-5,6-epoxy-3-hydroxy-7-megastigmene-9-one (**5**), and icariside B_1 (**12**) were tested for their abilities to inhibit SGC-7901 and HL-60 cells. The antioxidant activities of quercetagetin-3,6,4′-trimethoxyl-7-*O*-β-D-glucopyranoside (**36**), quercetin-3-methoxyl-4′-*O*-β-D-glucoside (**37**), and **38** were evaluated by measuring their free-radical-scavenging effects, using the DPPH free-radical method.

Key words: Tridax procumbens, polyacetylene, ionone, flavonol, cytotoxicity, antioxidant activities.

Résumé : L'extraction des parties aériennes du *Tridax procumbens* à l'aide d'éthanol a permis d'isoler trois nouveaux produits phytochimiques, un polyacétylène, le 1,2-dihydroendroarboréol B (**1**), un dérivé de l'ionone, la (3*S*,5*R*,6*S*,7*E*)-3-tétradécanoate-5,6-époxy-β-ionone (**4**) et un diglycoside de flavonol, la quercétagénine-3,6,4′-triméthoxy-7-*O*-néohespéridoside (**38**) aux côtés de 35 produits connus de structures diverses. Les structures des composés **1**, **4** et **38** ont été déterminées sur la base de méthodes spectroscopiques, telle l'UV, l'IR, la RMN, la DC et la spectrométrie de masse à haute résolution avec ionisation par électronébulisation ainsi que par comparaison des données spectroscopiques avec celles rapportées pour des composés apparentés d'un point de vue structural. On a évalué les capacités du composé **4**, de la (3*S*,5*R*,6*S*,7*E*)-5,6-époxy-3-hydroxy-7-mégastigmène-9-one (**5**) et de l'icariside B_1 (**12**) à inhiber des cellules SGC-7901 et HL-60. On a évalué les activités antioxydantes du quercétagénine-3,6,4′-triméthoxy-7-*O*-β-D-glucopyranoside (**36**) et des quercétine-3-méthoxy-4′-*O*-β-D-glucosides (**37**) et (**38**) en mesurant leurs effets comme pièges à radicaux libres à l'aide de la méthode au radical libre DPPH.

Mots-clés : Tridax procumbens, polyacétylène, ionone, flavonol, cytotoxicité, activités antioxydantes.

[Traduit par la Rédaction]

Introduction

Tridax procumbens (Compositae) is the only species of *Tridax* L. genus distributed in China, but is a native plant in tropical America, Asia, and Australia (1). It is used in Indian traditional medicine as anti-coagulant, hair tonic, antifungal, insect repellent, also against bronchial catarrh, diarrhea, dysentery, and wound healing (2–4). To the best of our knowledge, not much attention has been detailed to the chemical constituents of *T. procumbens*, as only fumaric acid (5), β-sitosterol and tannin (6), flavone glycosides, and bergenin derivatives (7, 8) have been reported as constituents of the plant. The medicinal importance and the unusual distribution of this species promoted us to undertake phytochemical studies systematically, which resulted in the isolation and structure elucidation of a new polyacetylene (**1**), a new ionone derivative (**4**), and a novel flavonol diglycoside (**38**), together with 35 known secondary metabolites belonging to various classes of compounds, from the EtOH extract of the aerial parts of *T. procumbens* collected from Wenchang town, Hainan Island, China.

The known compounds were identified by comparing ^{1}H NMR, ^{1}H–^{1}H COSY, ^{13}C NMR (DEPT), MS, CD, and optical rotation data with published values (9–36). The present paper deals with the structure elucidation of **1**, **4**, and **38**. Compounds **4**, **5**, and **12** were tested for their abilities to inhibit human gastric carcinoma (SGC-7901) and human promyelocytic leukemia (HL-60) cells, while **36**–**38** were examined for their antioxidant activities in the free-radical 1,1-diphenyl-2-picrylhydrazyl (DPPH) test.

Results and discussion

Structure elucidation

Compound **1** (Fig. 1) was obtained as yellow optically active oil, which showed [α] = –10 (*c* 0.2, $CHCl_3$). The molecular formula of **1** was determined to be $C_{17}H_{24}O_2$ based on its HR-ESI-MS (*m/z* 278.2117 $[M + NH_4]^+$) and the ^{13}C NMR data (Table 1), implying six degrees of unsaturation. The UV spectrum showed typical absorption bands for a conjugated ene-3,5-diyne chromophore (λ_{max} at 215, 241, 253, 268, and 284 nm) (37). Its IR spectrum showed the presence of hydroxy (br 3374 cm^{-1}), alkyne (2232 and 2212 cm^{-1}), and double bond (1640 cm^{-1}) functional groups.

The ^{13}C NMR (Table 1) spectrum with DEPT experiment indicated four nonprotonated acetylene resonances as well as a terminal olefin (δ_C 138.9 (d), 114.4 (t)). Another olefin (δ_C 108.2 (d), 149.6 (d)) accounted for the last unsaturation as the conjugated ene-3,5-diyne, that inherent in the molecular formula. ^1H NMR (Table 1) analyses indicated that the other terminus consisted of a spin system that began with a methyl triplet (δ_H 1.02). The ^1H–^1H COSY experiment showed that H-1 was coupled to H-2 that was further coupled to H-3, making the end of the spin system. Partial structures were linked by the HMBC experiment (Fig. 2). Key correlations included those observed between H-3 and C-4 and C-5, H-2 and C-3 and C-4. On the opposite side of the ene-3,5-diyne, we observed a correlation between H-10 and C-8, C-9, C-11, and C-12. All data (Table 1 and Experimental section) and compared with the isolated compounds **2** and **3,** was consistent with assignment of compound **1** as the analogue of diynene. The paucity of **1** precluded the possibility of defining its absolute configuration. Thus, compound **1** was elucidated as 1,2-dihydrodendroarboreol B (Fig. 1).

Compound **4** was obtained as colourless optically active needles, with [α] = –40 (*c* 0.2, $CHCl_3$). The molecular formula of **4** was determined to be $C_{27}H_{46}O_4$ based on its HR-ESI-MS (*m/z* 457.3293 $[M + Na]^+$) and the ^{13}C NMR (Table 2) data, implying five degrees of unsaturation. The UV spectrum showed an absorption maximum at 229 nm, suggesting an α,β-unsaturated ketone, and the IR spectrum showed the presence of ester carbonyl (1732 cm^{-1}), α,β-unsaturated carbonyl (1672 cm^{-1}), and a long straight-chain aliphatic unit $[(CH_2)_n\ n \geq 4]$ (719 cm^{-1}).

The ^1H NMR (Table 2) spectrum revealed the presence of five methyl groups at δ_H 0.88 (3H, t, H-14′), 0.99 (3H, s, H-12), 1.19 (3H, s, H-13), 1.21 (3H, s, H-11), and 2.29 (3H, s,

H-10), the last one being due to a methyl ketone. The signals of δ_H 0.88 (3H, t, H-14′) and 1.27 (16H, m, H-(4′–11′)) suggested the presence of a long-chain hydrocarbon. The ^{13}C NMR spectrum of **4** showed signals characteristic of an long-chain ester (δ_C 173.1 and 14.1) moiety and the remaining 13 signals, including those of four methyl groups, indicating that the alcohol part of the ester was a derivative of megastigmane, a pair of trans-double-bond proton signals at δ_H 6.32 (1H, d, J = 15.6 Hz) and 7.04 (1H, d, J = 15.6 Hz) must be present at $\Delta^{7(8)}$ in the side chain, and the attachment point of the fatty-acid chain was assigned to the C-3 position by comparing the ^1H NMR chemical shift of H-3 (δ_H 4.94) with those of 3-acetoxy-5,6-epoxy-β-ionone (δ_H 4.87) (38) and compound **5** (δ_H 3.93, H-3), which must be in an axial orientation ($J_{H\text{-}2\alpha,\ H\text{-}3}$ = 13.2 Hz) on the basis of ^1H NMR and ^1H–^1H COSY experiment. The position of C-5 and C-6, were thus available for two quaternary carbons, each bearing an oxygen function, as demanded by the elemental composition. This premise was really satisfied by the presence of an epoxy ring between the C_5- and C_6-position, which was supported by the HMBC experiment (Fig. 2) and comparison with the data of the related compound 3β-acetoxy-5α, 6α-epoxy-β-ionone (38).

The NOE effect between H-13 and H-7 confirmed a cis stereochemistry for this epoxy. Furthermore, NOESY interactions between H-11 and H-7, H-12 and H-3 revealed the relative stereostructure of **4** as shown in Fig. 1. Finally, The CD spectrum (Fig. 3) showed a negative CE, $\epsilon_{232\ nm}$ –20, confirming the absolute configurations as *S*, *R*, and *S* for C-3, C-5, and C-6, respectively, as previously discussed (38). On the basis of the above data, compound **4** was deduced unambiguously as (3*S*,5*R*,6*S*,7*E*)-3-tetradecanoate-5,6-epoxy-β-ionone (see Fig. 1).

Compound **38** was obtained as yellow amorphous powder, which showed [α] = –56 (*c* 0.5, CH_3OH). The HR-ESI-MS

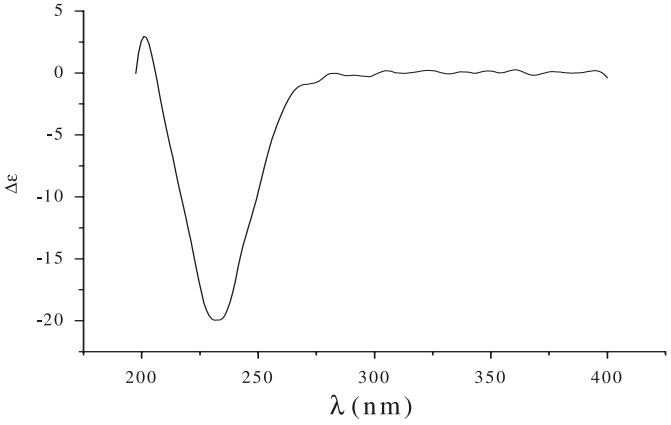
Fig. 3. The CD spectrum of **4**.



m/z $[M + Na]^+$ 691.1839 indicated its molecular formula to be $C_{30}H_{36}O_{17}$. The UV spectrum was characteristic for flavonoids showing UV maxima at 347 and 258 nm. The IR spectrum showed the presence of hydroxyl (3394 cm^{-1}), chelated hydroxyl (2931 cm^{-1}), conjugated carbonyl (1657 cm^{-1}), and aromatic (1598 cm^{-1}) functional groups. The ^1H NMR spectrum also showed **38** was a flavonoids derivative with the expected signals for the aromatic protons at δ_H 7.54 (1H, br s), 7.52 (1H, d, J = 8.0 Hz), and 7.07 (1H, d, J = 8.0 Hz) for H-2′, H-6′, and H-5′, respectively, the remaining downfield singlet at δ_H 6.96 (1H, s) was due to H-6 or H-8 of ring A. The proton signals for three methoxyl groups were observed at δ_H 3.82, 3.76, and 3.74 (3H, each, s), and the signal at δ_H 12.65 indicated the presence of chelated 5-hydroxyl group. The anomeric protons appeared at δ_H 5.34 (1H, d, J = 7.6 Hz) and 5.25 (1H, br s) with 1.08 (3H, d, J = 5.6 Hz) in ^1H NMR spectrum and ^{13}C NMR data (δ_C 98.5 and 100.6) showed the presence of a β-D-glucose and a α-L-rhamnose, and the α-L-rhamnose moiety was attached to the C-2″ of glucose, judging from the downfield shift of the C-2″ and the upfield shift of C-1″, respectively, from those of **36** (Table 3). The EI-MS showed base peak at *m/z* 360 (100%), a large peak at *m/z* 359 (50%) typical of C-3 methoxylate flavonoids (39), and a strong peak at *m/z* 345 (32%) consistent with the presence of a methoxyl group at C-6 or C-8 (40). The locations of the different groups were made possible through ^1H and ^{13} C NMR data compared with those of **36**.

The proposed structure of **38** was further confirmed by the HMBC experiment (Fig. 2). The correlations between H (δ_H 6.96) and C-6 (δ_C 133.2) as well as C-7 (δ_C 156.6), C-9 (δ_C 151.9), and C-10 (δ_C 107.0) indicated that the aromatic proton was at C-8 (δ_C 94.8). Furthermore, HMBC correlation between H-1″ (δ_H 5.34) and C-7 indicated that the Glc unit was located at C-7. The methoxyl protons δ_H 3.76, 3.74, and 3.82 showed ^3J interactions with C-3 (δ_C 138.6), C-6 (δ_C 133.2) and C-4′ (δ_C 147.1), respectively. Further support for the location of the methoxyl δ_H 3.82 at C-4′ but not C-3′ was derived from a significant NOE correlation between H-5′ and OMe-4′, and compared the physical data with its isomeric compound quercetagetin-3,6,3′-trimethoxy-7-*O*-neohesperidoside (41). Thus, from the above data, the structure of **38** was elucidated as quercetagetin-3,6,4′-trimethoxy-7-*O*- neohesperidoside (see Fig. 1).

(35) and quercetin-3-methoxyl-4-*O*-β-D-glucoside (**37**) (36), as well as their structures relative new compounds **1**, **4**, and **38** were showed in the Fig. 1.

Activity evaluation

Compounds **4**, **5**, and **12** were tested for their abilities to inhibit SGC-7901 and HL-60 cells using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) method (42,43). Compared with 5-fluorouracil (5-Fu), unfortunately, none of them exhibited significant inhibitory effects with IC_{50} values over 100 μmol/L against SGC-7901 and HL-60 cells.

Compounds **36**, **37**, and **38** were tested for their antioxidant activities using the DPPH test, with VE (vitamin E) as positive control (44, 45). In the DPPH system, the free-radical-scavenging activity of tested samples was expressed as IC_{20}. Compounds **38** and **36** (46) showed limited antioxidant capacity with $IC_{20} > 100$ μmol/L, which indicated that the additional presence of a α-L-rhamnose group in position C-2″ of **38** does not influence its radical-scavenging activity, as expected. On the other hand, **37** showed slight activity with $IC_{20} = 95.57$ μmol/L, when compared with the $IC_{20} = 7.60$ μmol/L of the reference, VE.

Experimental section

General experimental procedures

DPPH was obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Silica gel GF_{254} (10–40 μm; Qingdao Marine Chemical Factory) was used for TLC. Column chromatography (CC) experiments were carried out on silica gel (200–300 mesh; Qingdao Marine Chemical Factory). Melting points were determined on a X-4 Digital Display Micro-melting point apparatus, uncorrected. UV and IR spectra were recorded on a Shimadzu UV-260 and a Nicolet *NEXUS-670* FT-IR spectrophotometer, respectively. Optical rotations were recorded on a PerkinElmer 341 polarimeter; CD spectra were recorded on an Olis DSM 1000 spectrophotometer; ^1H and ^{13}C NMR spectra were recorded on a Varian INOVA-400 spectrometer at 400 MHz (for ^1H) and 100 MHz (for ^{13}C) or a Varian INOVA-300 spectrometer 300 MHz (for ^1H) and 75 MHz (for ^{13}C) with TMS as internal reference (δ 0); and EI-MS and HR-ESI-MS were measured on a VG ZABHS and a Bruker APEX-mass spectrometer, respectively.

Plant material

The air-dried aerial parts of *Tridax procumbens* were collected in Wenchang town (latitude 19° 61 N; longitude 110° 72 E), Hainan Province, P. R. China, in August 2004, and were identified by adjunct Professor Huan-Yang Qi. A voucher specimen (No. 2004002) has been deposited in the State Key Laboratory of Applied Organic Chemistry, Lanzhou University, P. R. China.

Extraction and isolation

The air-dried powder of the aerial parts of *T. procumbens* (3.9 kg) was extracted with 95% EtOH (3 × 7 d) at room temperature. After concentration under reduced pressure, the extract (400 g) was suspended in water and fractionated by successive partitioning with petroleum ether (60:90), EtOAc, and *n*-BuOH. After removal of the solvents in vacuo, the following residues were obtained: Rp (73.8 g), Re (8.5 g), Rb (19.3 g). Rp was fractionated on a silica-gel column eluting with a petroleum ether–EtOAc gradient system and then with acetone to give six main fractions (Fr. Rp1–Rp6). Fr. Rp1 mainly contained fatty materials, while the last fraction (Fr. Rp6, eluted with acetone) was a complex mixture. Fr. Rp2 was rechromatographed with petroleum ether – EtOAc (35:1) followed by petroleum ether–actone (25:1) to give **4** (10 mg), **15** (20 mg), **18** (20 mg), and **29** (180 mg), respectively. Fr. 3 was subjected to CC (SiO_2; $CHCl_3$:EtOAc, 30:1) to provide **1** (2 mg). The compounds were eluted in the following order: **20** (15 mg), **16** (20 mg), **19** (2 mg), **3** (30 mg), **21** (4 mg), **2** (7 mg), **22** (10 mg), **23** (6 mg), **27** (5 mg), **17** (11 mg), **24** (10 mg), **8** (10 mg), **5** (15 mg), **6** (2 mg), **7** (2 mg), **14** (5 mg), **26** (15 mg), **28** (3 mg), **25** (15 mg), and **30** (120 mg). From the Re residue, compounds **9** (2 mg), **31** (18 mg), **32** (4 mg), **13** (15 mg), **33** (3 mg), and **10** (5 mg) were isolated using silica-gel chromatography and preparative TLC. From the Rb residue, compounds **36** (30 mg), **11** (10 mg), **34** (5 mg), **37** (15 mg), **35** (15 mg), **12** (12 mg), and **38** (20 mg) were isolated after repeated column chromatography and recrystallization.

Bioassays

Tests of cytotoxicity against tumor SGC-7901 and HL-60 cells

A MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] colourimetric assay was performed in 96-well culture plates. The assay was based on reduction of MTT by the mitochondrial dehydrogenase of viable cells to yield a blue formazan product that could be measured spectrophotometrically. In the experiment, the negative controls were isochoric normal saline, 1% DMSO or 0.1% DMSO; positive control was 5-Fu at concentrations of 25, 50, 100, and 200 μmol/L. SGC-7901 and HL-60 cells at a log phase of their growth cycle (1×10^4 cell/mL) were added to each well (90 μL/well), then treated in four replicates at various concentrations of the drugs with six vacant reference wells set in one plate (100 μL cultured madia in each well) and incubated for 44 h at 37 °C in a humidified atmosphere of 5% CO_2. After 44 h, 10 μL of MTT solution (5 mg/mL) was added to each well, which was incubated for another 4 h, after which a solution of 10% sodium dodecyl sulfate (SDS) was added to each well (100 μL/well). Twelve hours later at room temperature, the optical density (O.D.) of each well was recorded on an ELISA reader (Bioteck EL-340) at one wavelength of 578 nm.

Scavenging activity of DPPH radicals

The antioxidant activities of the pure compounds were assessed on the basis of the radical-scavenging effect of the stable DPPH free radical. Aliquots of 30 μL of an ethanol solution containing each pure compound were added to 3 mL of 100 μmol/L ethanol solution of DPPH. Absorbance at 517 nm was determined after 30 min at room temperature, and the percent antioxidant activity (AA) was calculated using the following formula: $AA\% = 100\{[(Abs_{sample} - Abs_{blank}) \times 100]/Abs_{control}\}$.

© 2008 NRC Canada

Ethanol (3 mL) was used as a blank. 100 μmol/L of DPPH ethanol solution (3 mL) was used as a negative control. The IC_{20} value was the concentration of test sample required to scavenging 20% DPPH free radicals. VE was used as positive control.

Spectral data

1,2-Dihydrodendroarboreol B (1)

Yellow oil. [α] = –10 (*c* 0.2, $CHCl_3$). UV (MeOH, nm) λ_{max} (log ε): 215 (2.26), 241 (0.85), 253 (1.22), 268 (1.56), 284 (1.28). Ytterbium(III) triflate catalyzed synthesis of calix[4]pyrroles in ionic liquids

Anil Kumar, Israr Ahmad, and M. Sudershan Rao

Abstract: Ytterbium(III) triflate has been utilized as a mild Lewis-acid catalyst for the synthesis of various calix[4]pyrroles by the condensation of pyrrole with different ketones in ionic liquids. The calix[4]pyrroles were obtained in high yield under ecofriendly, economical, and noncorrosive conditions, and the catalyst was recovered and recycled.

Key words: calix[4]pyrrole, ionic liquid, ytterbium triflate.

Résumé : On a utilisé le triflate d'ytterbium(III) comme catalyseur acide de Lewis doux pour la synthèse de divers calix[4]pyrolles par condensation du pyrrole avec diverses cétones dans des liquides ioniques. Les calix[4]pyrolles ont été obtenus avec des rendements élevés dans des conditions économiques, non corrosives et respectueuses de l'environnement alors que le catalyseur peut être récupéré et recyclé.

Mots-clés : calix[4]pyrolle, liquide ionique, triflate d'ytterbium.

[Traduit par la Rédaction]

Introduction

Calix[4]pyrroles, a class of tetrapyrrolic macrocyclic molecules, have been known for a long time but recently have become the subject of intensive research because of their properties for binding with anions, transition metals, and neutral molecules (1). Their anion-binding properties has been extensively studied as a result of their potential biological applications (2). Calix[4]pyrroles were first synthesized over a century before by the condensation of acetone and pyrrole in the presence of hydrochloric acid (3). Since then various methods have been developed to increase the yield and selectivity of the products (4–6). The disadvantages of these methods are that the acid catalysts are corrosive in nature and the workup procedure is tedious and it involves neutralization. Moreover, the yields of calix[4]pyrrole are low and they are accompanied by a mixture of linear oligomers. There is a need to develop a method for the synthesis of calix[4]pyrroles that is ecofriendly, economic, and noncorrosive.

To meet the increasing demands of environmental legislation for the development of organic reactions in environmentally friendly media, synthetic manipulations have to be made to minimize the use of hazardous chemicals, such as replacing the traditional organic solvents in reactions and their subsequent workup with nontoxic solvents. In this regard, ionic liquids, especially those based on 1,3-dialkylimidazolium cations (Fig. 1), have gained considerable interest as a green alternative to volatile organic solvents (VOS) in recent years (7). Their nonvolatile nature and lack of any detectable vapour pressure gives them a significant advantage in minimizing solvent consumption and also addresses the problem of the emission of VOS into the atmosphere, thus making these solvents an environmentally attractive alternative to classical organic solvents (8). The recoverability and reusability of the catalysts immobilized in ionic liquids are key features required to develop economical, efficient, and green chemical processes (9).

[bmim][PF_6] [bmim][BF_4]

Lanthanide(III) trifluromethanesulfonates, $Ln(OTf)_3$, have enjoyed extensive applications in a variety of Lewis acid catalyzed organic reactions (10). The growing interest in the use of these salts is due to their ease of handling, noncorrosiveness, reusability, and unique reactivity and selectivity. Ytterbium(III) *tris*-trifluromethanesulfonate, $Yb(OTf)_3$ (commonly called ytterbium triflate), is known to be a useful mild Lewis acid and has gained importance in organic synthesis in recent years (11). It was first used by Forsberg et al. (12) and since then it has found a wide utility in organic synthesis (13). Lanthanide triflates immobilized in ionic liquids have been used as efficient and recyclable catalysts for different organic reactions. The chemistry of lanthanides and actinides in ionic liquids was recently reviewed by K. Binnemans (14).

As a part of our ongoing research, we became interested in ionic liquids as an alternative reaction media for various organic transformations (15). We also reported $Yb(OTf)_3$ catalyzed synthesis of 1,3-oxathiolanes in ionic liquids (16). Herein, we report for the first time the synthesis of calix[4]pyrroles catalyzed by $Yb(OTf)_3$ in ionic liquids

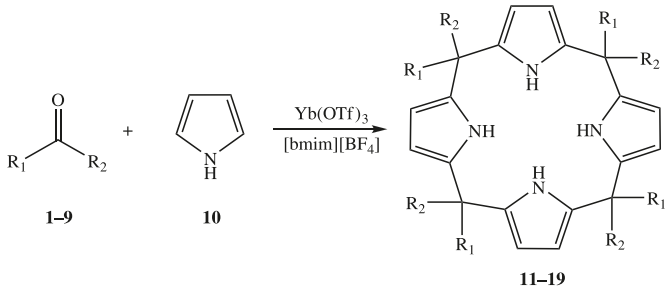
Scheme 1. Synthesis of calix[4]pyrroles in ionic liquid.



(Scheme 1), which is superior to previous Brønsted and Lewis acid catalyzed methods and overcomes the problems encountered with classical Lewis acids.

Results and discussion

The cyclocondensation of acetone (**1**) and pyrrole (**10**) at room temperature in ionic liquid [bmim][BF_4] containing 20 mol% $Yb(OTf)_3$ gave 100% conversion of acetone after 10 h as monitored by GC analysis. After completion of the reaction, the product was extracted with an ethyl acetate – hexane mixture and purified by column chromatography to give pure *meso*-octamethyl calix[4]pyrrole (**11**) in 92% yield (Table 1, entry 1). The ^{1}H NMR spectrum of **11** showed a broad singlet at δ 9.23 for NH protons and a singlet at δ 5.67 and δ 1.50 for 8 β-pyrrolic protons and 24 *meso*-methyl protons, respectively. It showed a $[M + H]^+$ ion peak at *m/z* 429.2360 in the positive ion mode HRMS (ESI-MS) spectrum. In the IR spectra of **11**, a peak appeared at 3438 cm^{-1} for N–H stretching.

The reaction was also carried out in a more hydrophobic ionic liquid, [bmim][PF_6], and an almost equal yield of calix[4]pyrrole (**11**) was obtained under these conditions. Therefore, we chose [bmim][BF_4] as the solvent of choice for further reactions. After the success of this reaction, the synthesis of *meso*-substituted calix[4]pyrroles (**12**–**19**) was also studied by the condensation of different cyclic and acyclic ketones with pyrrole catalyzed by $Yb(OTf)_3$ in ionic liquid and the results are shown in Table 1. The products were characterized by IR, HR-MS, and ^{1}H NMR spectroscopy. Higher cyclic ketones and substituted acyclic ketones produced slightly less yields as compared with acetone (Table 1). The reaction of unsymmetrical ketones produced a mixture of isomers, but αααα-isomer was in the majority. We did not observe the formation of N-confused calix[4]pyrroles under these conditions, which are reported to be accompanied in minor amounts, along with calix[4]pyrrole in a recently reported amberlyst 15 catalyzed synthesis of calix[4]pyrroles (6*d*).

To study the reusability, the recovered ionic liquid containing $Yb(OTf)_3$ was reused for the synthesis of **16**. After extraction of calix[4]pyrrole from the ionic liquid with an ethyl acetate – hexane mixture, the ionic liquid containing $Yb(OTf)_3$ was dried under vacuum for 30 min. To this dried ionic liquid containing $Yb(OTf)_3$, pyrrole and acetophenone (**6**) were added and stirred at room temperature for 12 h. The reaction mixture was extracted by the ethyl acetate – hexane mixture and the combined organic layer was evaporated to give **16**. This cycle was repeated five times. The catalysts showed good reactivity and yield even after five cycles with little deterioration in catalytic activity as shown in Table 2. The slight deterioration in catalytic activity may be due to a slight decomposition of the ionic liquids because of the release of water in the reaction. Generally, ionic liquids based on imidazolium cation with either tetrafluoroborate or hexafluorophosphate as anions are water insensitive; however, the exposure to moisture for a long time can cause some changes in their physical and chemical properties (17). The products obtained were of the same purity as in the first reaction.

Conclusion

In conclusion, we have developed an efficient, simple, economical, noncorrosive, and ecofriendly method for the synthesis of various calix[4]pyrroles catalyzed by ytterbium(III) triflate in ionic liquids. This method provides several advantages such as easy synthesis, simple workup, and satisfactory recovery and reuse of the ionic liquid immobilized ytterbium triflate with no diminution of product yields.

Experimental section

All the chemicals and reagents were of analytical grade. Ketones and pyrrole were purchased form S.D. Fine and Spectrochem, India. Sodium tetrafluoroborate and 1-methylimidazole were purchased from Sigma-Aldrich. Ionic liquid [bmim][BF_4] was prepared according to an earlier reported procedure (15*a*, 15*b*). The ^{1}H NMR spectra were recorded on a Bruker Avance II 400 (400 MHz) spectrophotometer using TMS as internal standard and $CDCl_3$ as solvent, and the chemical shifts were expressed in ppm. The IR spectra were recorded using KBr pellets on a Shimadzu Prestige-21 FTIR spectrophotometer and ν_{max} was expressed in cm^{-1}. Mass spectra were recorded on a KC455 Waters TOF MS spectrometer. TLC was run on silica gel coated aluminium sheets (silica gel 60 F_{254}, E. Merck, Germany) and visualized in UV light at 254 nm.

General procedure for the synthesis of calix[4]pyrrole in ionic liquid catalyzed by $Yb(OTf)_3$

To a 10 mL round bottom flask containing ionic liquid [bmim][BF_4] (3.0 mL) was added acetone (110 μL, 1.49 mmol), freshly distilled pyrrole (103 μL, 1.49 mmol), and $Yb(OTf)_3$ (20 mol%, 46.2 mg). The reaction mixture was stirred at room temperature for 10 h. Twenty microlitres of the reaction mixture were removed after every 1 h interval and analyzed by TLC and GC. After completion of the reaction, the reaction mixture was extracted with hexane – ethyl acetate (2 × 5 mL, 1:1 *v*/*v*). Ionic liquid containing ytterbium triflate was recovered and dried under vacuum. The combined organic layer was evaporated under reduced pressure. The residue was column chromatographed over silica gel 60–120 mesh using hexane – ethyl acetate as eluent to give pure **11** (146 mg, 92%). The calix[4]pyrrole obtained was characterized by IR, ^{1}H NMR, ^{13}C NMR, and HRMS spectroscopic data.

Strategic efficiency — The new thrust for synthetic organic chemists

Fayang Qiu

Abstract: A standard for gauging the efficiency of synthetic strategies has been proposed. Synthetic efficiency is correlated to the molecular-complexity index, which is the cumulative total number of chiral centers, independent functional groups, and rings contained in a molecule. The number of reaction steps for an efficient synthetic design must be smaller than that of molecular-complexity index. This standard will motivate organic chemists to work harder on the synthetic design prior to execution.

Key words: strategic efficiency, total synthesis, synthetic design, complexity index.

Résumé : On propose un standard pour évaluer l'efficacité des stratégies de synthèse. On établit une corrélation entre l'efficacité d'une synthèse et l'indice de complexité moléculaire qui est la somme totale du nombre de centre chiraux, de groupes fonctionnels indépendants et de cycles contenus dans une molécule. Le nombre d'étapes réactionnelles dans une synthèse efficace devrait être plus petit que l'indice de complexité moléculaire. Ce standard motiverait les organiciens à réfléchir plus longuement avant de se lancer dans une synthèse.

Mots-clés : efficacité stratégique, synthèse totale, planification d'une synthèse, indice de complexité.

[Traduit par la Rédaction]

Introduction

Since Wöhler's conversion of ammonium cyanate into urea, numerous synthetic reactions have been discovered, many synthetic methodologies have been invented, and a wealth of detailed reaction mechanisms has been understood. These discoveries and inventions, combined with the mechanistic understanding of reaction pathways, have enabled organic chemists to meet many challenges in the synthesis of complex molecules. When Corey proposed retrosynthetic analysis (1), he enabled the entire synthetic community to deduce synthetic strategies. Since then, the bar for organic synthesis has been raised to a new level and retrosynthetic analysis has become the most powerful tool for synthetic chemists to arrive at proper commercial or readily accessible starting materials.

Although there is plenty of information about the available synthetic methodologies, useful chemical reactions, and reaction mechanisms, not much can be found in the literature about how to define an efficient synthetic strategy. Therefore, many synthetic chemists would ask: Of the many possible synthetic strategies for a given structure, how does one know if the one in hand is efficient? To answer such a question, one needs to have a standard that defines what an efficient strategy is. Surprisingly, the synthetic community has been interested mostly in the structural challenges of the target molecules. For example, chemists have been trying to claim the first synthesis of a new structure, while efficient synthetic design has been overlooked or has not received as much attention as it deserves.

In a recent paper, Corey pointed out that there is little in the existing literature to define an effective strategy of synthesis (2). Thus, in this paper, a standard for strategic efficiency assessment by correlating the molecular-complexity index with the number of reaction steps in the longest reaction sequence of a synthetic design is proposed.

Results and discussion

Synthetic efficiency can be divided into two parts: tactical efficiency and strategic efficiency. While tactical efficiency refers to the efficiency of the individual steps in a reaction sequence, strategic efficiency deals with the entire synthetic design. Since tactical efficiency depends mostly on the optimization of the reaction conditions and has been addressed under the term of atom economy and ideal synthesis (3), in this paper we will only discuss the strategic efficiency of a synthesis because such efficiency can be enhanced through the improvement of the synthetic design prior to execution.

Thanks to Corey's retrosynthetic analysis, at present, even an undergraduate student knows how to do synthetic designs. However, according to the literature, only a small group of synthetic chemists can design highly efficient synthetic strategies through the creative application of the principle of retrosynthetic analysis and new powerful synthetic methodologies. Thus, it is the right time to raise the bar again for organic synthesis so that the entire synthetic community can do efficient synthesis by integrating the knowledge of reaction mechanisms and conformational analysis into the synthetic design in a way that is more creative than ever before.

To work on an efficient synthetic strategy, chemists need a tool to do efficiency assessment for the design prior to its execution. Unfortunately, strategic efficiency is not clearly defined. Offhand, one may think of using the overall yield of a reaction sequence as a measure of the efficiency of a synthetic strategy. This is not appropriate because reaction yields can only be obtained after the execution of a strategy. Therefore, we should only consider those reactions that are mechanistically sound as a standard element of strategic efficiency. Even so, the evaluation of strategic efficiency is totally dependent upon the personal interest and experience of the individual who is carrying out the evaluation. For example, consider the synthesis of Taxol. Some chemists may claim that a thirty-step synthesis is very efficient, while others may believe that only a strategy with less than twenty reaction steps can be considered efficient. Obviously, they have different standards. Hence, it is necessary to set a generally acceptable and reasonably high standard for the assessment of strategic efficiency.

In reality, this task is difficult because different molecules possess different types of structural features, which present different levels of challenge and require different synthetic strategies. Even for the same molecule, one may come up with several synthetic strategies at the same time. It is difficult to compare the efficiency of different strategies for the same molecule because each strategy may have its own advantages and drawbacks. It is more difficult to compare the synthetic strategies for different molecules. Nevertheless, since diverse structural features represent the degree of molecular complexity and the levels of synthetic challenge, if we can define molecular complexity and use it as a frame of reference for the analysis of strategic efficiency, we will be able to establish a standard to perform efficiency assessment for every synthetic strategy.

Although there are some reports about molecular complexity and analysis of synthetic strategies in the literature (4–12), all of them were trying to either describe or analyze how a change in molecular complexity had occurred along a sequence of chemical reactions. So far, no one has indicated how molecular complexity can be used as a standard to determine whether a synthetic design is strategically efficient or not without comparing with other people's synthetic designs. This is important for the large majority of synthetic chemists because even though they can compare their own different strategies and tell which is more efficient, they would very likely have no clue if their design is still efficient when compared to another one, possibly from a top chemist.

Given the fact that every reaction may be optimized in a sufficiently long period of time, we can treat every mechanistically sound reaction to be equivalent, i.e., assume that they are the standard reactions. Therefore, the total number of chemical transformations is the only variable in the determination of strategic efficiency. Obviously, the fewer the total number of reaction steps in a synthetic design, the higher the level of strategic efficiency.

For the sake of convenient calculation to synthetic chemists, molecular complexities are described with three elements: chiral centers, functional groups, and rings. These elements have different weights in different treatments. Among the many different weighting factors in molecular complexity, we believe that the one proposed by Fuchs (4) best fits our needs with a slight modification (see below).

At present, even though an undergraduate knows that different arrangement of functional groups, ring sizes, or chiral centers in a molecule represent different levels of synthetic challenge, it is reasonable for us to assume that the formation of each of these complexity elements will require at least one chemical transformation. The challenge is that we do not allow more than one chemical transformation for the introduction of any complexity element, regardless of the difficulty one may face when introducing it. As a result, the efficiency of a synthetic design can be directly correlated to the number of reaction steps in a synthetic strategy. Thus, we can consider the total number of reaction steps as a measure of strategic efficiency. Here, we propose that an efficient synthetic strategy for any given structure should satisfy this inequality

$$[1] \qquad Ns < I = C + (F - O) + R$$

where Ns is the number of reaction steps in the "longest" reaction sequence starting from "commercial materials"; I is the molecular-complexity index defined as the sum of the following elements: C, the number of chiral centers in a molecule; F, the number of functional groups, including heteroatoms and non-aromatic unsaturations; O, the number of overlaps between C and F; and R, the number of rings.

Note that molecular complexity only refers to the structural features associated with the major backbone of a molecule. Very often, a functional group may also be part of a chiral center. In any case, each atom, if counted, can only be counted once. One convenient way to calculate molecular complexity is to first count the number of chiral centers, followed by the number of hetero atoms that are "not" connected to a chiral center, and then count the number of other functional groups and rings. The sum will be the molecular-complexity index. The allowed number of reaction steps for an efficient synthetic design of a target molecule will be smaller than the index number.

Generally speaking, if a reaction needs a "separation" to isolate the desired product, then the reaction is counted as one step; if no separation is involved in a series of chemical operations, e.g., tandem reactions, then these reactions are "not" counted until a separation is involved. *A higher degree of challenge will be to count each reaction as one step whether or not a separation is involved, excepting tandem and cascade reactions.* Although the idea of starting from a known but not commercially available intermediate is acceptable, the number of reaction steps for the synthesis of that intermediate should be included if it is in the longest reaction sequence.

Although some syntheses have already met or even surpassed the proposed standard (13–21), the large majority of the published syntheses are far from being efficient. The purpose of this paper, however, is not to defeat or embarrass those people whose synthetic strategies did not meet the proposed standard but to provide a guideline for future syntheses. For example, when designing a synthetic strategy for a challenging molecular structure such as Taxol, a chemist would first calculate the complexity index for the molecule: the number of chiral centers contained in Taxol is nine; the

© 2008 NRC Canada

number of functional groups that are not a part of a chiral center includes four ester functional groups, one ketone, and one alkene functional groups. Here, the side chain as a whole is counted as one ester group, while the cyclic ether of the four-membered ring is counted as one functional group. Thus, the total number of functional groups is seven, and the number of rings is four. Thus, the molecular-complexity index for Taxol is

[2] $I = C + (F - O) + R = 9 + 7 + 4 = 20$

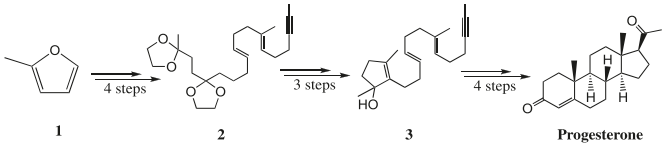
Therefore, an efficient synthetic strategy for Taxol will be 19 operational steps or less. If the number of reaction steps in his design is larger, then the chemist is motivated to design a more efficient route and count the number of reaction steps again. This process is repeated until he comes up with a strategy that meets or exceeds the standard. The reward for this effort is that when the strategy possesses the desired efficiency, it will be close to the limit of the state-of-the-art. If the current state-of-the-art cannot meet this standard, he will have to consider creating some new reactions or new methodologies for the synthetic strategy. Hence, the proposed standard also calls for creativity in the search of new chemical reactions and the development of new synthetic methodologies.

Some selected efficient synthetic strategies

Although the proposed standard for strategic efficiency assessment is simple to understand, it is difficult to practice. Nevertheless, there are many examples of synthetic designs in the literature (13–21) whose efficiency has already met or even surpassed the proposed standard, though only three examples are listed below for educational purposes.

A. Progesterone

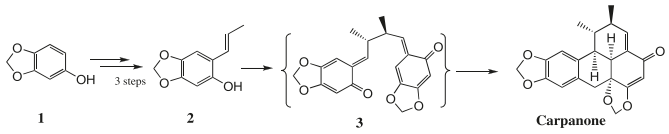
This molecule contains six chiral centers: $C = 6$; three functional groups that are not a part of a chiral center: two C=O and one C=C, $(F - O) = 3$; and four rings: $R = 4$. Thus, the molecular-complexity index for progesterone is $I = 13$. W.S. Johnson (1971) (14) synthesized the molecule in 11 steps from methacrolein, 5-bromo-2-pentyne, 1,4-dibromobutane, and 2-methylfuran. A brief scheme is outlined below.



The key features of this synthesis include a highly convergent approach to quickly put the four smaller molecules together and arrange those functional groups in a way such that the functional groups are well-positioned to undergo a biomimetic cascade reaction sequence. The stereochemical outcome of the cascade reaction is predicted on the basis of the chair-like transition-state structures.

B. Carpanone

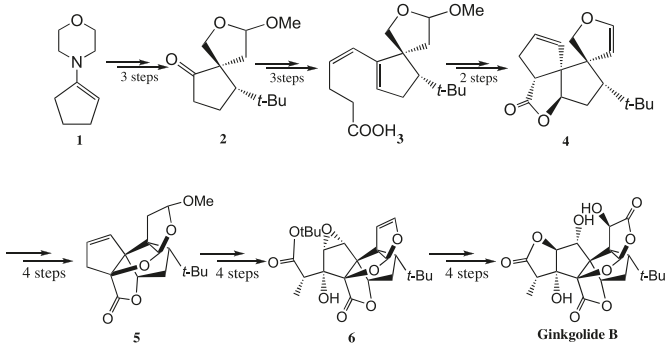
The number of chiral centers: $C = 5$; the number of functional groups that are not a part of a chiral center: two C=C, one C=O, and two OCH_2O. Since the two pairs of O atoms are each a part of a ring, they are not counted, $(F - O) = 5$; the number of rings: $R = 6$. Thus, the molecular-complexity index for carpanone is $I = 16$. O.L. Chapman (1971) (15) achieved the synthesis in four steps starting from the commercial 3,4-methylenedioxyphenol and allyl bromide as is shown below.



This synthesis is convergent as well as biomimetic. The oxidative coupling of intermediate **2** through the phenolic palladium salt and the subsequent intramolecular Diels–Alder reaction is a remarkable transformation, which establishes two rings, five chiral centers, and one double bond. This synthesis has demonstrated the power of organopalladium chemistry in organic synthesis.

C. Ginkgolide B

Ginkgolide B is a molecule that is composed of 11 chiral centers, $C = 11$; three carbonyl groups and one *t*-butyl group (a quaternary carbon is counted as one if it is not a part of a chiral center), $(F - O) = 4$; and six rings, $R = 6$. Thus, the molecular-complexity index is $I = 21$. Ginkgolide B is a molecule of ultimate challenge for synthesis because the functional groups are highly densely distributed in the molecule. There are four consecutive quaternary bridge-head carbon centers. E.J. Corey (1988) (16) not only successfully synthesized Ginkgolide B, but he also achieved a high level of strategic efficiency (20 steps).



In this synthesis, introduction of the *tert*-butyl group furnished the first chiral center, which was then used to control the configuration of all other chiral centers. There are several major challenges in this synthesis. The first one is the intramolecular [2+2] ketene-olefin cycloaddition, which involves facial selectivity; the most challenging problem, however, is perhaps the subsequent Baeyer–Villiger oxidation of the cyclobutanone in which the regiochemistry is difficult to control; the third challenge is the diastereoselective addition of an enolate generated from *tert*-butyl propionate to the sterically congested ketone carbonyl group. In this synthesis, Corey has extensively applied the knowledge of reaction mechanisms and conformational analysis to solve the selectivity problems.

All the above examples have demonstrated that the proposed standard for strategic efficiency assessment is practi-

© 2008 NRC Canada

cally achievable. However, these strategies are not selected because they have represented a first total synthesis or have dealt with a very complex synthetic target, but because they possess the key features that, in addition to solving the structural challenges, have enhanced the strategic efficiency to the desired level.

Conclusion

The proposed standard for efficient synthetic design invites competition for all chemists in the field on a more equal basis than any other means. Every chemist can thus fully exercise his intellectual power. Being the first in a total synthesis is important and desirable, but it is often associated with the amount of allocated resources; being the best in a total synthesis is more admirable because it creates more value and represents true intellectual progress. Overall, the synthetic community should present more creativity in the practice of organic synthesis and meet the challenge of the proposed standard.

Friedel–Crafts alkylation of indoles with nitroolefins in the presence of β-cyclodextrin in water under neutral conditions

Vydyula Pavan Kumar, Regati Sridhar, Boga Srinivas, Mendu Narender, and Kakulapati Rama Rao

Abstract: Various indolyl nitroalkanes were prepared by the reaction of indoles with nitroolefins in the presence of β-cyclodextrin in water under neutral conditions. β-Cyclodextrin can be recovered and re-used several times without loss of activity.

Key words: β-cyclodextrin, nitroolefins, indoles, neutral conditions, water.

Résumé : On a préparé divers nitroalcanes d'indolyle par réaction d'indoles avec des nitrooléfines, en présence de cyclodextrine, dans des conditions aqueuses neutres. On peut récupérer la β-cyclodextrine et la réutiliser un certain nombre de fois sans perte d'activité.

Mots-clés : β-cyclodextrine, nitrooléfines, indoles, conditions neutres, eau.

[Traduit par la Rédaction]

Introduction

Indoles are present in many biologically active and naturally occurring compounds (1) and are also important intermediates for the synthesis of drugs and pharmaceuticals (2). Many indole alkaloids were synthesized utilizing the increased nucleophilic reactivity of the 3-position of the indole ring (3). The addition of indoles to electron-deficient alkenes, which in many respects is considered as Friedel–Crafts reaction (4), is a reaction of considerable synthetic utility, and the adducts resulting from the reaction are key intermediates for the synthesis of many biologically active compounds (5). However, the synthesis of 3-substituted indoles in the classical methodologies utilized indolylgrignard reagent (6), whereas the later reports involved either acid or base catalysts (7). These methods suffer from various disadvantages, such as drastic reaction conditions, longer reaction times, lower yields, and undesirable side products due to polymerization (8). Thus, there is a need to develop mild and environmentally benign Friedel–Crafts synthesis of these high value 3-substitued indoles in water under neutral conditions with a recyclable catalyst. The use of aqueous medium as solvent under neutral conditions reduces the harmful effects of organic solvents and also precludes the use of either acid or base. This becomes further sophisticated if these reactions can be performed under supramolecular catalysis. Though there are reports in aqueous media with Lewis-acid catalysts (9), there are no reports under neutral conditions in water. The fundamental problem in performing these reactions in water is that many organic substrates are hydrophobic and are insoluble in water. Therefore, we made an attempt at the Friedel–Crafts synthesis of 3-substituted indoles in water through supramolecular catalysis using β-cyclodextrin (β-CD) under neutral conditions.

The choice towards cyclodextrins was dictated by the fact that many interactions are dominated by hydrogen bonding in organocatalysis. Recently, metal-free hydrogen-bonding based catalysts have been put on a rational basis (10). Hydrogen-bonding motif is becoming a powerful tool in organocatalysis for the activation of carbonyl groups and related compounds through weak hydrogen-bond interactions (11). It is well-known that substituents of aromatic rings capable of hydrogen bonding can bind the OH groups of the cyclodextrin edges (12). Cyclodextrins, which are cyclic oligosaccharides, exert micro-environmental effects leading to selective reactions (13). They catalyze reactions by supramolecular catalysis through noncovalent bonding as seen in enzymes. Complexation depends on the size, shape, and hydrophobicity of the guest molecules. These attractive features of cyclodextrins and our earlier expertise in the biomimetic modeling of chemical reactions (14) prompted us to examine their utility in Friedel–Crafts reaction of indoles with nitroolefins.

Results and discussion

In general, the reactions were carried out by the in situ formation of the β-CD complex of the indole in water followed by the addition of nitroolefin and stirring for 1–3 h at 50 °C to give the corresponding products (Scheme 1). Alkylated indoles were formed as single products with high

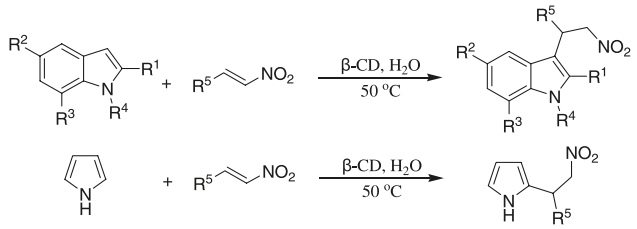
Scheme 1.



degree of conversion (Table 1). This methodology is also compatible with various substituted indoles and nitroolefines. Several examples illustrating this simple and practical methodology are summarized in Table 1. All the products were characterized by ^{1}H NMR, IR, mass spectroscopy, and elemental analysis. No asymmetric induction was observed in these reactions. The catalyst β-CD can be easily recovered and re-used. To see the further application of this reaction, it was also extended to pyrrole heterocycle (Table 1, entries 17 and 18).

The reaction also occurs at room temperature, but longer reaction times (48 h) are required and the isolated yields of products obtained are also low (1%–15%). All compounds listed in Table 1 failed to react with nitroolefins in water at 50 °C without the presence of β-cyclodextrin. Use of a catalytic amount of β-CD (0.1 mmol per mole of the substrate) at 50 °C had no impact on the reaction. These experiments indicate the substantial role of cyclodextrin. However, the reaction did not proceed when substituents such as bromo and nitro were present in the 5-position of indole ring, whereas the presence of other functionalities improved the reaction, which explains the important role of electron density on heterocycle. It is observed that the reaction did not proceed with alkyl substituted nitroolefins such as ((*E*)-2-nitrovinyl)cyclohexane and (*E*)-1-nitrobut-1-ene. The importance of this methodology can be seen in the case of 5-hydroxy indole (Table 1, entries 9 and 10), which reacts with nitroolefins in very good yields, whereas the reported methodologies utilize either acidic or basic catalysts leading to low yields even after prolonged reaction times because of the interaction of the indolyl hydroxyl group with the catalyst (4*d*, 7*f*).

Inclusion complexes of indole with β-cyclodextrin have been studied by Galian et al. (15). In this model, it was proposed that the indole is included in the β-cyclodextrin cavity in such a way that the pyrrole moiety of indole ring is directed towards primary face of β-cyclodextrin and a hydrogen bonding formed between indolic proton and oxygen of the primary hydroxyl (C_6–O) of β-cyclodextrin. This hydrogen bonding enhances the nucleophilicity of indole. Under the present reaction conditions of supramolecular catalysis, this type of positioning of indole in the cyclodextrin cavity facilitates the complexation of nitroolefin from the primary side, which can be activated by hydrogen bonding with C_6–OH of cyclodextrin for further reaction with indole. This is depicted in Fig. 1. However, in the case of *N*-substituted indoles (Table 1, substrates **1g** and **1h**), longer reaction times are required, since the hydrogen bonding is not possible in these cases. This clearly explains the importance of the presence of free indolic NH group.

The evidence for this mechanistic approach (Fig. 1) was deduced from ^{1}H NMR spectroscopy. The studies were carried out with indole (**1a**) and 2-((*E*)-2-nitrovinyl)furan (**2b**) as representative examples. NMR spectroscopy is one of the most important techniques used for the characterization of inclusion complexes. The formation of an inclusion complex results in the shift changes in the resonances of the host cyclodextrin and the guest protons (16). A comparison of the ^{1}H NMR spectra (D_2O) of β-CD, β-CD : indole complex, and freeze-dried reaction mixture of β-CD : indole complex with the nitroolefin **2b** at 1 h were studied. It is observed from Fig. 2 that there is an upfield shift of H_3 (0.03 ppm) and H_5 (0.05 ppm) protons of cyclodextrin in the β-CD : indole complex as compared with β-CD, indicating the formation of an inclusion complex of indole with β-CD from the secondary side of cyclodextrin. It is further observed from the spectra of the reaction mixture of β-CD : indole complex with the nitroolefin **2b** at 1 h that there is also an upfield shift of H_6 proton by 0.06 ppm. This indicates the complexation of the nitroolefin **2b** from the primary side of cyclodextrin for the reaction to proceed (Fig. 2). This clearly demonstrates that the nitroolefin is elegantly set for the addition reaction with the indole in the hydrophobic microenvironment of β-cyclodextrin cavity.

Thus, we have demonstrated for the first time an operationally simple and efficient aqueous phase Friedel–Crafts synthesis of indolyl nitroalkanes and pyrrolyl nitroalkanes by using β-cyclodextrin under neutral conditions. β-Cyclodextrin, apart from being nontoxic is also considered metabolically safe (17). In contrast with the existing methodologies using many acidic and basic catalysts, this method is very simple, high-yielding, and environment-friendly. Further potential applications of this reaction are under study.

Experimental

General

Melting points were recorded on a Buchi R-535 apparatus and are uncorrected. IR spectra were recorded on a PerkinElmer FTIR 240-c spectrometer using KBr optics. ^{1}H NMR spectra were recorded on Gemini-200 spectrometer in DMSO using TMS as internal standard. Mass spectra were recorded on an Agilent 1200 spectrometer. Starting materials were obtained commercially from Aldrich, Lancaster and were used without purification.

General procedure for the synthesis of indolyl nitroalkanes and pyrrolyl nitroalkanes

β-CD (1 mmol) was dissolved in water (20 mL) by warming to 50 °C until a clear solution was formed. Then, indole/pyrrole (1 mmol) dissolved in methanol (0.5 mL) was added dropwise, followed by nitroolefin (1 mmol), and the mixture was stirred at 50 °C until the reaction was complete (as monitored by TLC) (Table 1). The mixture was extracted with ethyl acetate, and the extract was filtered. The organic layer was dried over anhyd. Na_2SO_4, the solvent was removed under reduced pressure, and the resulting product was further purified by column chromatography. The aqueous layer was cooled to 5 °C to recover β-CD by filtration.

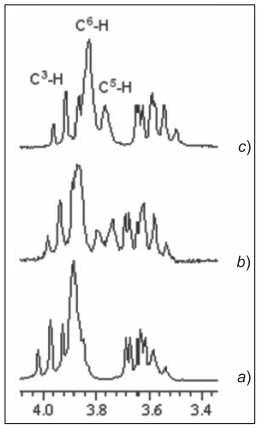
*3-(1-(Furan-2-yl)-2-nitroethyl)-2-phenyl-1*H*-indole (3f)*

Light yellow solid; mp 125–127 °C. IR: 3429, 3057, 2924, 1456 cm^{-1}. ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 8.13 (s, 1H), 7.59–7.04 (m, 10H), 6.35–6.27 (m, 1H), 6.14 (d, 1H, *J* = 3.21 Hz), 5.35 (t, 1H, *J* = 7.74 Hz), 5.22 (dd, 1H, *J* = 12.46, 7.55 Hz), 4.93 (dd, 1H, *J* = 12.46, 7.93 Hz). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 152.58, 142.16, 136.98, 135.97, 131.90, 129.08, 128.73, 126.72, 122.59, 120.25, 119.82, 111.32, 110.46, 107.37, 107.31, 77.12, 35.48. ESI-MS *m*/*z*: 333 (M + 1). Anal. calcd. for $C_{20}H_{16}N_2O_3$: C, 72.28; H, 4.85; N, 8.43. Found: C, 72.02; H, 4.98; N, 8.56.

*3-(2-Nitro-1-phenylethyl)-1*H*-indole-2-carboxylic acid (3g)*

White solid; mp 198–200 °C. IR: 3367, 2961, 1556 cm^{-1}. ^{1}H NMR ($CDCl_3$ + DMSO-d_6, 200 MHz) δ: 11.15 (s, 1H), 7.53–7.07 (m, 8H), 6.96 (t, 1H, *J* = 7.32 Hz), 6.08 (t, 1H, *J* = 8.05 Hz), 5.47–5.12 (m, 2H). ^{13}C NMR ($CDCl_3$ + DMSO-d_6, 75 MHz) δ: 168.43, 156.72, 146.14, 141.83, 132.52, 130.65, 128.31, 125.64, 122.84, 122.31, 121.74, 121.43, 120.58, 80.74, 41.27. EI-MS *m*/*z*: 310 (M^+). Anal. calcd. for $C_{17}H_{14}N_2O_4$: C, 65.80; H, 4.55; N, 9.03. Found: C, 66.04; H, 4.43; N, 9.12.

Fig. 2. ^{1}H NMR spectra of (*a*) β-CD, (*b*) β-CD : indole complex, and (*c*) reaction mixture after 1 h. The spectra were obtained in D_2O at 25 °C.



*3-(1-(Furan-2-yl)-2-nitroethyl)-1*H*-indole-2-carboxylic acid (3h)*

Brown solid; mp 201–203 °C. IR: 3506, 2972, 1574 cm^{-1}. ^{1}H NMR ($CDCl_3$ + DMSO-d_6, 200MHz) δ: 11.44 (b s, 1H), 7.65–6.84 (m, 5H), 6.39–6.06 (m, 3H), 5.27 (dd, 1H, *J* = 12.50, 8.59 Hz), 5.02 (dd, 1H, *J* = 13.28, 7.03 Hz). ^{13}C NMR ($CDCl_3$ + DMSO-d_6, 75 MHz) δ: 168.16, 157.41, 146.52, 141.19, 130.93, 129.84, 129.67, 125.66, 125.10, 121.53, 117.76, 115.38, 111.79, 81.81, 39.48. ESI-MS *m*/*z*: 301 (M + 1). Anal. calcd. for $C_{15}H_{12}N_2O_5$: C, 60.0; H, 4.03; N, 9.33. Found: C, 60.23; H, 4.11; N, 9.24.

Metal-induced facile synthesis of a tricyclic system — 10-Methyl-12-thia-2,9-diaza-tricyclo[8.3.1.0^{3,8}]tetradeca-3,5,7-triene-1-carbonitrile. Formation of an intramolecular carbon–carbon bond

Santokh S. Tandon and C. Robert Lucas

Abstract: The reaction between 4-thiaheptane-2,6-dione and 1,2-diaminobenzene in the presence of nickel(II) perchlorate results in the formation of a nickel(II) complex of a novel new heterotricyclic system: 1-methoxy-10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.0^{3,8}]tetradeca-3,5,7-triene, which on treatment with potassium cyanide gives 10-methy-12-thia-2,9-diaza-tricyclo[8.3.1.0^{3,8}]tetradeca-3,5,7-triene-1-carbonitrile, a case of metal-induced carbon–carbon bond formation.

Key words: nickel-induced carbon–carbon bond formation, intramolecular cyclization, tricyclic formation.

Résumé : La réaction de la 4-thiahpeptane-2,6-dione avec le 1,2-diaminobenzène, en présence de perchlorate de nickel(II), conduit à la formation d'un complexe de nickel(I) d'un nouveau système hétérotricyclique, le 1-méthoxy-10-méthyl-12-thia-2,9-diazatricyclo[8.3.1.0^{3,8}]tétradéca-3,5,7-triène, qui par traitement avec du cyanure de potassium fournit le 10-méthyl-12-thia-2,9-diazatricyclo[8.3.1.0^{3,8}]tétradéca-3,5,7-triène-1-carbonitrile, un cas de formation d'une liaison carbone-carbone induite par un métal.

Mots-clés : formation d'une liaison carbone–carbone induite par le nickel, cyclisation intramoléculaire, formation d'un tricycle.

[Traduit par la Rédaction]

Introduction

This paper reports the observation of the unexpected and useful synthetic reaction shown in eq. [1]. Reaction of 4-thiaheptane-2,6-dione (**1**) with 1,2-diaminobenzene (**2**) in presence of nickel(II) perchlorate results in formation of a nickel(II) complex of a novel new heterotricyclic system: 1-methoxy-10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.0^{3,8}]tetradeca-3,5,7-triene (**3**), which on treatment with potassium cyanide, gives 10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.0^{3,8}]tetradeca-3,5,7-triene-1-carbonitrile (**4**), a case of metal-induced intramolecular carbon–carbon bond formation.

The use of transition-metal ions as catalysts in the synthesis of organic compounds with anti-tumoral and anti-viral activities and in the formation of carbon–carbon or carbon–heteroatom (N, S, or O) bonds has attained prominence in recent years (1). Medium-sized heterocyclic benzodiazepines constitute an important class of therapeutic compounds because of their special affinity for serotonin (5-HT2) and acetylcholine receptors. The benzodiazine skeleton is commonly found in compounds exhibiting a wide range of biological properties (2), such as inhibition of tyrosine kinase (3), anti-malarial (4), anti-convulsive (5), anti-hypertensive (6), hypolipidemic (7), anti-tumoral (8), and anti-viral activity (9). More than a dozen benzodiazepines are available by prescription (10), while similar compounds, such as pyrido[2,3-*b*]benzodiazepinones, have been screened as cardioselective muscarinic receptor antagonists and as po-

tential HIV-1 reverse transcriptase inhibitors (11). Pyrrolo[2,1-*c*][1,4]benzodiazepines and other tricyclics are well-known antibiotics (12) and anti-tumor agents (13). It has been proposed that the cytotoxicity and anti-tumour activity of these compounds result from the formation of a covalent bond between the azomethine unit of the diazepine ring and the C(2)-amino group guanine nucleus in the minor groove of the DNA double spiral (14). Benzothiodiazepinones are used as anti-herpetic agents (15). Recently, the synthesis and in vitro anti-hepatitis B and C virus activities of ring-expanded compounds containing the imidazo[4,5-*e*][1,3]diazepine-4,8-dione ring system have been reported (16). Interest, associated with the pharmacological activities of medium-sized heterocyclics and tricyclics, justifies a continuation of work on novel synthetic methodologies for compounds of these types. However, the difficulties involved in synthesis of tricyclics have prevented in-depth studies on these systems. In this report, we describe a facile, one-step synthesis (see eq. [1]) of a novel heterotricyclic system involving the 1,4-benzodiazepine ring system that has very substantial pharmaceutical implications.

Experimental

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc. and were used without further purification. Spectroscopic data were obtained by using the following instruments: IR, Mattson Polaris FT; UV–vis Carey model 17; NMR, General Electric 300 NB. Analyses were performed by Canadian Microanalytical Service Ltd.[2]

Synthesis of $[Ni(TCS)_2](ClO_4)_2$ (3)

4-Thiaheptane-2,6-dione (2 mmol, 0.29 g), prepared by the reported method (18), was dissolved in dry methanol (10 mL). This solution was added dropwise to a hot methanolic solution (10 mL) of $Ni(ClO_4)_2{\cdot}6H_2O$ (1 mmol, 0.37 g) with stirring. A green solution thus formed was refluxed for ~10 min, and to it, while refluxing, was added dropwise over a period of 10 min a solution of 1,2-diaminobenzene (2 mmol, 0.22 g) in the same solvent (10 mL). The colour of the reaction mixture changed from green to brownish green. The resulting mixture was stirred under reflux, and after ~15 min, a purplish-brown solid separated. The reaction mixture was further refluxed for ~4 h and kept at ambient temperature overnight. The purplish-brown solid was filtered off, washed with dry methanol (3 × 5 mL), and dried under vacuum at room temperature for 12 h. Yield: 0.62 g (82%). Crystals suitable for X-ray studies were obtained by slow diffusion of diethyl ether into a solution of the complex in a mixture of methanol:dimethylformamide (1:1). UV–vis in *N*,*N*-dimethylformamide λ nm (ε $dm^3\ mol^{-1}\ cm^{-1}$): 341 (3620), 267 (6970). UV–vis (Nujol mull, λ nm): 970 mb, 880 mb, 520 sh, 341 vs. IR (Nujol mull, cm^{-1}) υ: 3246 s (N–H). Anal. calcd. for $C_{26}H_{36}N_4Cl_2NiO_{10}S_2$: C 41.18, H 4.79, N 7.39, Ni 7.74; found: C 41.08, H 5.12, N 6.97, Ni 7.68.

Isolation of 10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.$0^{3,8}$]tetradeca-3,5,7-triene-1-carbonitrile (4)

To a solution of $[Ni(TCS)_2](ClO_4)_2$ (3) (0.92 mmol, 0.70 g), dissolved in a mixture of dimethylformamide:methanol (10 + 20 mL), was added a solution of potassium cyanide (31 mmol, 2.0 g) in water (50 mL). The reaction mixture was stirred for ~10 min. After adding water (100 mL), the mixture was stirred for another 5 min. A yellowish-white solid separated and was extracted with chloroform (100 mL). The chloroform extract was washed with distilled water (4 × 150 mL) and dried over anhyd. sodium sulphate. The extract was filtered, and the solvent was removed at a rotary evaporator. A dirty white solid was obtained and was dissolved in chloroform and treated with activated charcoal. The mixture was filtered, and the filtrate was left at ambient temperature for slow evaporation of solvent. After 24 h, nearly colourless needles suitable for X-ray structure determination had formed. Diethyl ether (5 mL) was added, and the needles were separated by filtration. Yield: 0.37 g (80%). IR (Nujol mull, cm^{-1}) υ: 3301 s and 3317 s (N–H), 2273 m (CN). ^{1}H NMR ($CDCl_3$) δ: 1.28 (s, 3H, CH_3), 1.68 (d, J = 15 Hz, 1H, CH_3CCH_aH), 2.27 (d, J = 15.0 Hz, 1H, CH_3CCH_bH), 2.48 (d, J = 14.0 Hz, $NCCCH_aH$), 2.86 (d, J = 14.0 Hz, $NCCCH_bH$), 2.88 (d, J = 12.0 Hz, 1H, bridge CH_aH), 3.13 (s, 1H, NH_a), 3.18 (d, J = 12.0 Hz, bridge CH_bH), 3.82 (s, NH_b), 6.75 (d, J = 7.0 Hz, 1H, C_6H_4), 6.94 (d, J = 3.5 Hz, 1H, C_6H_4), 6.99 (m, 2H, C_6H_4). ^{13}C{^{1}H} NMR ($CDCl_3$) δ: 31.81 (CH_3), 38.04 (bridge CH_2), 40.11 (S–C_aH_2), 40.35 (S–C_bH_2), 49.51 (C_{Ar}), 50.87 (C_{Ar}), 121.79 ($C_{Ar}H$), 122.14 (*C*N), 123.28 ($C_{Ar}H$), 123.75 ($C_{Ar}H$), 125.58 ($C_{Ar}H$), 134.49 ($C_{Ar}H$), 138.52 ($C_{Ar}H$). Anal. calcd. for $C_{13}H_{15}N_3S$: C 63.64.18, H 6.16, N 17.13, S 13.07; found: C 63.40, H 6.10, N 17.38, S 12.53.

X-ray study

A summary of crystallographic data for 10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.$0^{3,8}$]tetradeca-3,5,7-triene-1-carbonitrile (**4**) is found in Table 1. X-ray diffraction data were collected by using a Rigaku AFC6S diffractometer. All measurements were made with graphite monochromated Cu Kα radiation (λ = 1.54178 Å) and the ω-2θ scan technique at a scan rate of 4°/min (in ω). Weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of five scans), and the counts were accumulated to ensure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The intensities of three representative reflections were measured after every 150 reflections and no significant crystal decay was detected. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range 55.22° <2θ <59.02°, corresponded to a primitive orthorhombic cell with dimensions as shown in Table 1. The space group was determined by systematic absences, a statistical analysis of intensity distribution, packing considerations, and the successful solution and refinement of the structure. Of the 1115 reflections collected, 1096 were unique. The data were corrected for Lo-

[2] Perchlorate salts are often treacherously explosive (see ref. 17), and although we have been unable to cause the compound described to detonate from shock or heat, we recommend suitable precautions be taken whenever perchlorates are handled.

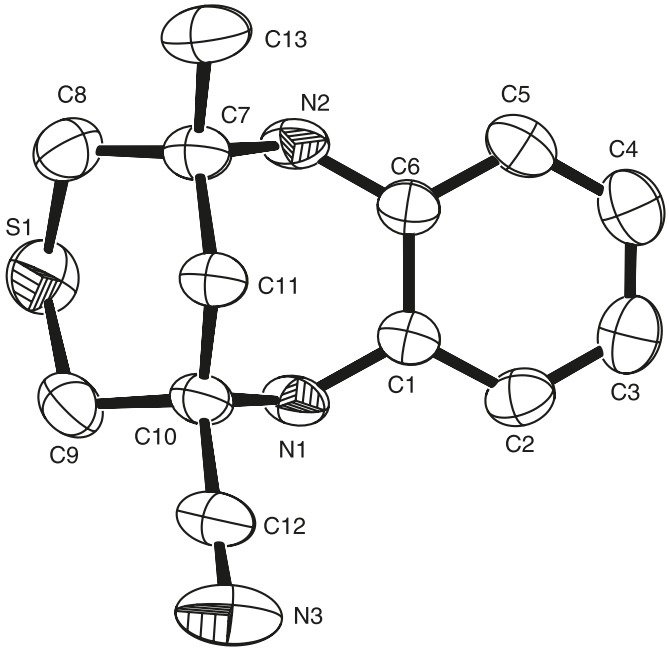
$wR2$ (all refl.)	0.0754[b]
Last D-map	
Deepest hole (e/Å^3)	–0.13
Highest peak (e/Å^3)	0.12

Note: Throughout this work, esd's are in parentheses and refer to the last digit printed.
[a] $R1 = \sum\|F_o| - |F_c\|/\sum|F_o|$.
[b] $wR2 = [\sum(w(F_o^2 - F_c^2)^2)/\sum w(F_o^2)^2]^{1/2}$

rentz and polarization effects, and a correction for secondary extinction was applied (coefficient = 0.001 040). The linear absorption coefficient, μ, for Cu Kα radiation is 21.276 cm^{-1}.

The structure was solved by direct methods (19) and expanded using Fourier techniques (20). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model. The final cycle of full matrix least-squares refinement on F^2 was based on 1096 observed reflections and 156 variable parameters and converged with unweighted and weighted agreement factors $R1 = \sum\|F_o| - |F_c\|/\sum|F_o|$ and $wR2 = [\sum(w(F_o^2 - F_c^2)^2)/\sum w(F_o^2)^2]^{1/2}$ equal to 0.0304 and 0.0754, respectively. Unit weights were used. Neutral atom scattering factors were taken from the usual source (21). Anomalous dispersion effects were included in $F_{calcd.}$ (22); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (23). The values for the mass attenuation coefficients are those of Creagh and Hubbell (24). All calculations were performed using the CrystalStructure (25, 26) crystallographic software package except for refinement, which was performed using SHELXL-97 (27). A description of the experimental procedure, anisotropic thermal parameters and a full listing of bond lengths and bond angles are available as Supplementary Data.[3] Figure 1 shows a view of the structure and its numbering scheme.

Fig. 1. ORTEP of compound **4**. Thermal ellipsoids are shown at the 50% probability level.



Results and discussion

Earlier, we reported (28) that condensations of diphenacyl sulfide (**1** but with R = Ph) with 1,2-diaminoethane, 1,2-diaminopropane, and 1,3-diaminopropane result in the formation of 5,8a-diphenyl-2,3,8,8a-tetrahydro-1*H*-imidazo[2,1-*c*][1,4]thiazine, 5,8a-diphenyl-2,3,8,8a-tetrahydro-2-methyl-1*H*-imidazo[2,1-*c*][1,4]thiazine (two isomeric products differing in the orientation of the methyl group at position 2 with respect to the plane of the molecule) and 6,9a-diphenyl-1,2,3,4,9,9a-hexahydropyrimido[2,1-*c*][1,4]thiazine, respectively (See eqs. [2—4]).

Likewise, treatment of 4-thiaheptane-2,6-dione (**1**) with triethylenetetramine results in formation of a novel heterocycle 1,1′-ethylenebis[5,8-dimethyl-2,3,8,8a-tetrahydro-1*H*-imidazo[2,1-*c*][1,4]thiazine] (18) as shown in eq. [5].

[4] 
[5] 
However, attempts to prepare 1,4,7-thiadiazonine by reacting 4-thiaheptane-2,6-dione (**1**) with 1,2-diaminobenzene (**2**) with or without catalytic amounts of acid or base result only in a multitude of products, none of which is present in isolable amount. On the other hand, in presence of nickel(II) perchlorate, this reaction unexpectedly provides a nickel(II) complex (**3**) of a novel tricyclic system, 1-methoxy-10-methyl-12-thia-2,9-diaza-tricyclo[8.3.1.$0^{3,8}$]tetradeca-3,5,7-triene, in which an intramolecular carbon–carbon bond has been formed.

Compound **3** has been characterized through spectroscopic and analytical data, and on treatment with potassium cyanide, it reacts to form **4**, which has been characterized using multinuclear NMR, mass spectroscopy, and single-crystal X-ray studies. Multinuclear 1D and 2D NMR (HETCOR and COSY) experiments, IR, analytical, and mass spectral data confirm that the structure of **4**, determined in the solid state by single-crystal X-ray crystallography, is maintained in solution. The structure of **4** and its numbering scheme in the context of the structural study are shown in Fig. 1.

The bond lengths and angles of **4** are unexceptional and lie in the range observed in similar medium-sized heterocycles and heterobicycles. For example, the angle C10–C11–C7 is 115.1(3)°, N1–C10–C9 is 110.6(3)°, C8–S1–C9 is 98.62(18)°, and C1–N1–C10 is 120.6(3)°. The distance S1—C9 is 1.788(4) Å, C10—C11 is 1.521(4) Å, C10—C12 is 1.494(5) Å, and C10—N1 is 1.455(4) Å.

Because compounds **3** and **4** might not be expected a priori to have the tricyclic organic structures as shown in Fig. 1, their characterization warrants some discussion. Compound **3** has been unequivocally characterized by conventional means not including X-ray structural methods. Notwithstanding that X-ray quality crystals of **3** are relatively easily grown and several samples from independent syntheses were submitted to several different crystallographic laboratories, the structural results obtained in every case were similar and were not completely satisfactory. In every case, despite apparently reasonable residuals, goodness-of-fit and other conventional evidence for satisfactory solution of the structure, an unexplained residual electron density in the vicinity of the methoxyl group in **3** and unacceptably large thermal ellipsoids in the same part of the structure occurred that could not be modelled in a chemically or structurally sensible way. However, because the structure of **3** is relevant to an appreciation of the overall process and notwithstanding the unsatisfactory nature of its X-ray structural study, its ORTEP is nonetheless presented but should be used for general guidance only (Fig. 2), as should details of its coordination sphere (Table 2).

Table 2. Selected bond angles and lengths of compound **3**.

Bond lengths (Å)	
Ni—N(1)	2.141(7)
Ni—S(1)	2.4055(11)
Ni—N(2)	2.170(7)
Bond angles (°)	
N(1)–Ni–N(1A)	105.3(4)
N(1A)–Ni–N(2)	179.4(3)
N(1)–Ni–S(1A)	93.8(2)
N(2)–Ni–S(1A)	94.55(18)
S(1A)–Ni–S(1)	179.69(16)
N(1)–Ni–N(2)	74.78(14)
N(2)–Ni–N(2A)	105.2(4)
N(1A)–Ni–S(1A)	86.0(2)
N(2A)–Ni–S(1a)	85.64(18)

In the light of this experience and in an attempt to separate the ligand from its metal for independent study, **3** was treated with potassium cyanide to sequester the nickel. Although this did successfully separate the nickel from the organic portion of the complex, it was readily apparent that at the same time the ligand had also reacted to become **4**. Compound **4** has also been unequivocally characterized by conventional means, including X-ray structural analysis. The formation of a tricyclic system only in the presence of nickel and the apparent ease with which the methoxyl group of **3** is replaced by a cyano group raises two questions. First, what is the probable mechanism for the formation of the tricyclic system? And second, is the mechanism by which cyano replaces methoxyl related to it? A plausible mechanism for the formation of the intramolecular carbon–carbon bond and the tricyclic system is suggested in Fig. 3. Based upon the structure of compound **3** (Fig. 2), it would be reasonable to as-

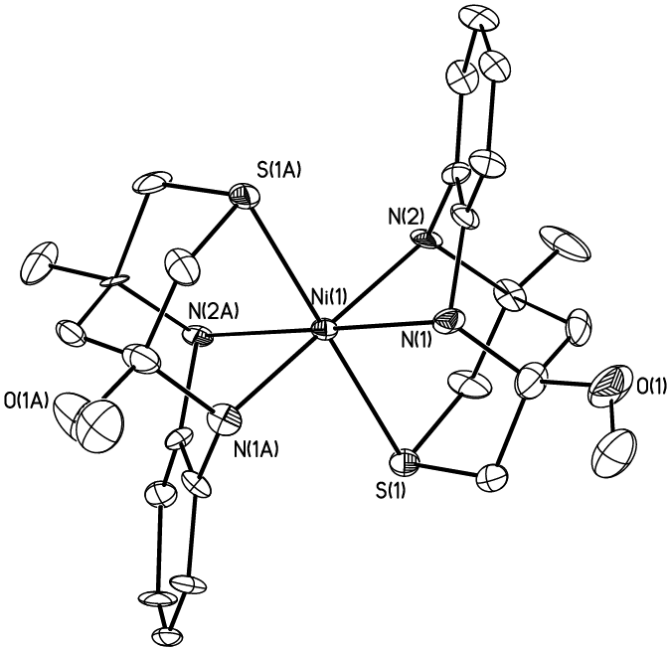
Fig. 2. ORTEP of **3**. Thermal ellipsoids are shown at the 50% probability level.



sume the role of the metal is, inter alia, to hold the bridge-forming methyl carbon in appropriate proximity to the other methyl-bearing carbon atom so that they may bond by the sequence shown in Fig. 3 to form the bridge.

One can also easily imagine a process involving CN^- instead of CH_3OH in the latter part of the mechanism in Fig. 3 that would account for conversion of the ligand of **3** into **4** in the presence of potassium cyanide.

Conclusions

Herein, we report a facile, one-step synthesis of a novel heterotricyclic system involving the 1,4-benzodiazepine ring system that has immense pharmaceutical implications. The importance of this work lies in the fact that by using easily available thiodiketone and benzodiamine reagents, a new tricyclic system can be obtained in high yield in a one-step reaction. We are currently collaborating with other research groups for testing the anti-tumor and anti-viral activity of this and similar compounds.

First-order parallel and consecutive reaction mechanisms — Isosbestic points criterium

A.E. Croce

Abstract: A criterium for the selection of reaction mechanism derived from a condition for isosbestic points occurrence is presented. Analytical relationships involving the molar absorption coefficients of the species, which participate in a mechanism of parallel first-order reactions and the corresponding rate coefficients, are also reported. A model system of four species that present overlapping absorption spectra may correspond to the reactant and products of a system of parallel or consecutive first-order reactions. In the first case, under experimental conditions in which the absorbances are additive, the presence of an isosbestic point in the spectrum of the reaction mixture at a given wavelength leads to a time-independent ratio of the degree of advancement of reaction variables. From this, relevant kinetic information may be extracted, namely, the ratio of the reaction rate coefficients. Moreover, the occurrence of isosbestic points allows discarding the second mechanism. This conclusion is independent of the number of absorbing species. Model calculated examples show the application of the equations here derived. The resolution for the general case of mechanisms of N first-order reactions is provided.

Key words: chemical kinetics, time-resolved absorption spectra, reaction mechanism.

Résumé : On propose un critère pour la sélection des mécanismes réactionnels qui est dérivé d'une condition pour la présence de points isosbestiques. Les relations analytiques impliquées dans les coefficients d'absorption molaire de l'espèce qui participe dans un mécanisme de réactions du premier ordre parallèles et on rapporte aussi les coefficients de vitesse correspondants. Un système modèle de quatre espèces qui présentent des chevauchements dans leurs spectres d'absorption peut correspondre aux réactifs et aux produits d'un système de réactions du premier ordre parallèles ou consécutives. Dans le premier cas, sous des conditions expérimentales dans lesquelles les absorbances sont additives, la présence d'un point isosbestique dans le spectre du mélange réactionnel, à une longueur d'onde donnée, conduit à un rapport indépendant du temps du degré d'avancement des variables réactionnelles. À partir de ceci, on peut relever les informations cinétiques qui présentent de l'intérêt, soit le rapport des coefficients de vitesse des réactions. De plus, la présence d'un point isosbestique permet d'éliminer le deuxième mécanisme. Cette conclusion est indépendante du nombre d'espèces absorbantes. Des exemples calculés à l'aide de ce modèle montrent les domaines d'application des équations dérivées dans ce travail.

Mots-clés : cinétique chimique, spectre d'absorption résolu en fonction du temps, mécanisme réactionnel.

Introduction

Many photochemical and thermal reaction systems in solution are investigated employing UV–vis spectrophotometry (1). Successive scans of the spectrum of the reaction mixture are performed: the initial spectrum usually corresponds to a light-absorbing reactant, and as the reaction proceeds the total absorbance of the mixture changes with time, following the changes in composition (2, 3). The application of such transient absorption methods requires that the Beer–Lambert law applies, and the resulting absorbance for a system of N species absorbing in a given spectral region be given by $A = \sum_i \varepsilon_i c_i l$ (i = 1, 2, …, N) where ε_i is the molar absorption coefficient of the i component, c_i is the corresponding molar concentration, and l is the path length. Therefore, in a reacting system at constant temperature and volume, A becomes a function of two relevant variables, namely, wavelength and time.

Frequently, isosbestic points constitute a feature of such transient absorption spectral families. When the spectra of two or more species participating in a reaction overlap, the total absorbance of the reaction mixture may remain invariant with respect to time during the course of the reaction at certain wavelengths, which define the isosbestic points (4). It is generally asserted that the occurrence of an isosbestic point in a reaction system requires that the changes in the concentrations of the various components are linearly related (1) at one or more crossing points of the spectra of the single contributors (5). Operative criteria have been developed: the existence of an isosbestic point is believed to prove the existence of only two absorbing species (6). It is easily proven that this is true in the case of a single absorbing species A

converting into a single absorbing B; at the λ at which both spectra cross, an isosbestic point will certainly appear (7).

Exhaustive theories for the interpretation of the occurrence of isosbestic points in chemical analytical systems (8) and useful correlations between isosbestic wavelength shift and composition (9) are based mainly on two-absorbing-species systems. An extensive treatment that employs the tools of linear algebra has been performed by Mauser and Gauglitz (10). More recently, the particular case of constant absorption by two absorbing species has been used for the determination of quantum efficiency (11). However, no reference to competing reaction mechanisms involving several absorbing species has been made to date in formal kinetic treatments.

The appearance of isosbestic points in time-resolved spectra can be easily recognized in absorbance difference representations in which the difference between the absorbance A at time t and A_0, the initial value at $t = 0$, $\Delta A = A - A_0$, is plotted against the wavelength. In this kind of plot, an isosbestic point satisfies the condition

$$[1] \qquad \Delta A_{ip} = 0$$

as it is defined by the wavelength, λ_{ip}, at which the absorbance of the mixture is independent of time. In the following, the subscript ip indicates the correspondence to an isosbestic point. The high sensitivity of difference spectra has been demonstrated even in radiation chemistry of DNA studies (12).

Moreover, the graphs of A or ΔA as a function of λ present an inflection point at the isosbestic point, at which the mathematical condition

$$[2] \qquad (\partial^2 A/\partial\lambda^2)_{ip} = 0$$

has to be fulfilled. Besides, eq. [1] implies that

$$[3] \qquad (\partial \Delta A/\partial t)_{ip} = 0$$

at each λ_{ip}.

For a given reaction mechanism, which governs the increase and decay of the concentrations of the components of a reaction system as a function of time, the application of the above given conditions leads to general criteria related to the presence and number of isosbestic points in families of time-resolved absorption spectra. A detailed kinetic analysis is presented here for mechanisms involving first-order reactions.

A recent study, the experimental investigation of the acid-catalyzed intramolecular attack of β-phenylthioureido group on amide function (13), provides a nice illustration of the present discussion.

Results and discussion

Case I: parallel reactions mechanism

The final criteria derived in the following are valid independent of the order of the reactions for a parallel reaction mechanism. However, for the sake of mathematical simplicity, the particular case of first-order reactions will be discussed.

A system of N parallel first-order reactions such as $Y_1 \rightarrow \nu_{Y_i} Y_i$ ($i = 1, 2, \ldots, N$) is considered. The type of product being irrelevant from the kinetics standpoint, only one for each reaction has been chosen. The molar concentrations at a given reaction time are given by

$$[4] \qquad c_{Y_i} = c_{Y_{i0}} - \sum_i \nu_{Y_i} x_i$$

which takes the form $c_{Y_i} = \nu_{Y_i} x_i$ for the products. ν_{Y_i} represents the stoichiometric coefficient of each product Y_i, and x_i the degree of advancement variable for reaction i (14). In this case, $\nu_{Y_1} = 1$ for the reactant Y_1 and $c_{Y_{10}}$ the initial concentration, such that $c_{Y_1} = \sum_i x_i$. The reaction rate eq. can be expressed as

$$[5] \qquad dc_{Y_i}/dt = d(\textstyle\sum_i x_i)/dt = \sum_i k_i c_{Y_1}$$

where k_i represent the reaction rate coefficient for reaction i. These eqs. lead to

$$[6] \qquad \textstyle\sum_i (dx_i/dt) = \sum_i (c_{Y_{10}} - \sum_i x_i)\, k_i = (c_{Y_{10}} - \sum_i x_i) \sum_i k_i$$

which can be expressed in terms of a single variable y

$$[7] \qquad dy/dt = (c_{Y_{10}} - y)\textstyle\sum_i k_i$$

taking $y = \sum_i x_i$. The solutions (15)

$$[8] \qquad x_j(t) = (k_j c_{Y_{10}} / \textstyle\sum_i k_i)[1 - \exp(-t \sum_i k_i)]$$

yield time independent $x_h(t)/x_j(t)$ ratios, and therefore ratios of the form $x_h/x_j = k_h/k_j$ are obtained.

The above treatment may be easily applied to the case of four species, which absorb light additively at a given wavelength, linked by a two first-order parallel reactions mechanisms: (I) $R \rightarrow \nu_B B + \nu_C C$ and (II) $R \rightarrow \nu_D D$.

The total absorbance A at a given reaction time t is given by

$$[9] \qquad A = \varepsilon_R c_R l + \varepsilon_B c_B l + \varepsilon_C c_C l + \varepsilon_D c_D l$$

where c_i denotes molar concentrations, l the optical path length, and ε_i the respective molar absorption coefficients at a given wavelength. Let's assume that the time-resolved spectra present an isosbestic point at λ_{ip}.

Assuming $c_{R_0} \neq 0$ and $c_{B_0} = c_{C_0} = c_{D_0} = 0$ for the initial concentrations of the reactant and products, and replacing the concentrations given by eq. [4] in the difference absorbance ΔA, the condition

$$[10] \qquad \Delta A_{ip} = x_I(\nu_B \varepsilon_B^{ip} + \nu_C \varepsilon_C^{ip} - \varepsilon_R^{ip}) + x_{II}(\nu_D \varepsilon_D^{ip} - \varepsilon_R^{ip}) = 0$$

is obtained at the isosbestic point, λ_{ip}, according to eq. [1].

As the extent of reaction variables are $x_i > 0$ for any reaction time, in the case of only two absorbing species, namely, R and D, and a single reaction leading to the transformation of R, then $\nu_D \varepsilon_D^{ip} = \varepsilon_R^{ip}$, in agreement with the particular though universally accepted (7) conclusion that the existence of an isosbestic point indicates that two and only two species are responsible for the absorption. The condition given by eq. [10] will be fulfilled in trivial cases, which do not lead to any kinetic information, such as $\nu_B \varepsilon_B^{ip} + \nu_C \varepsilon_C^{ip} - \varepsilon_R^{ip} = 0$, giving rise to isosbestic points at which $\nu_D \varepsilon_D^{ip} = \varepsilon_R^{ip}$.

However, if for example, $\nu_B \varepsilon_B^{ip} + \nu_C \varepsilon_C^{ip} - \varepsilon_R^{ip} \neq 0$, the condition $\Delta A_{ip} = 0$ leads to

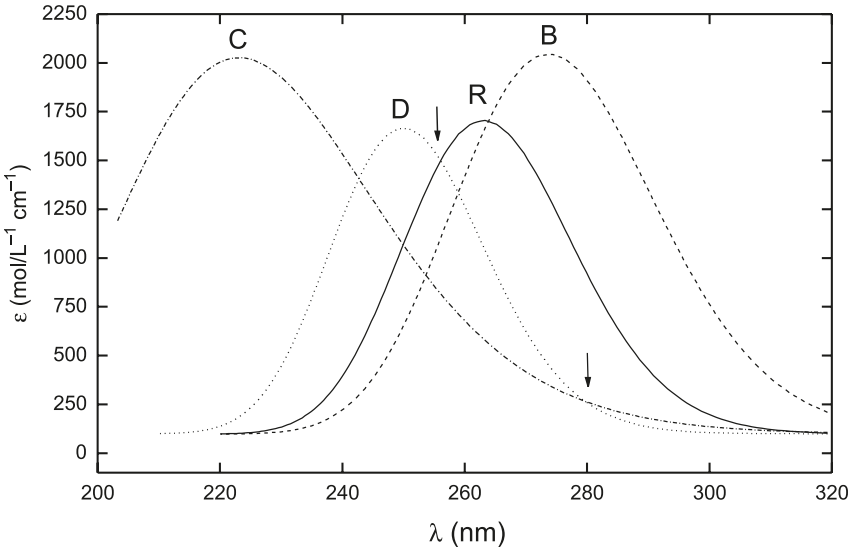
Fig. 1. Model spectra for the reactant R (solid line) and the products B (– – –), C (–·–·–), and D (·····). The arrows point to the wavelengths of the isosbestic points.



[11] $x_I/x_{II} = (\varepsilon_R^{ip} - \nu_D\,\varepsilon_D^{ip})/(\nu_B\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip})$

Even though the right hand term of eq. [11] will clearly vary according to the identity and the number of absorbing species, this term will remain constant at an isosbestic point. Therefore, the ratio x_I/x_{II} should be time-independent to observe an isobestic point at a given wavelength.

Equation [10] together with the condition imposed by eq. [3] $(\partial\Delta A/\partial t)_{ip} = (\nu_B\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip})\,(dx_I/dt) + (\nu_D\,\varepsilon_D^{ip} - \varepsilon_R^{ip})(dx_{II}/dt) = 0$ leads to the relationship

[12] $x_I(dx_{II}/dt) = x_{II}(dx_I/dt)$

which must hold if an isosbestic point is possible.

As a consequence, the eq.

[13] $(\varepsilon_R^{ip} - \nu_D\,\varepsilon_D^{ip})/(\nu_B\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip}) = k_I/k_{II}$

results. Even though x_I and x_{II} depend on time (eq. [8]) the ratio x_I/x_{II} remains time-independent. Consequently, the first member of eq. [13], which is constant at the isosbestic points, takes the same value k_I/k_{II} at every λ_{ip}. Therefore, if the spectra of the components of the reaction mixture and the stoichiometric coefficients of the products are known and one or more isosbestic points are observed, the first member of eq. [13] can be calculated at λ_{ip}, such that the ratio k_I/k_{II} can be obtained.

In the particular case of the photochemical decomposition of a single reactant R through two competing pathways, in the absence of secondary reactions involving R and the products of steps (I) and (II), eq. [13] leads to the ratio of the respective quantum yields, $x_I/x_{II} = (\varepsilon_R^{ip} - \nu_D\,\varepsilon_D^{ip})/(\nu_B\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip}) = \Phi_I/\Phi_{II}$, with the additional constraint $\Phi_I + \Phi_{II} = 1$, within the experimental error limits.

Another important example of parallel mechanisms is represented by a system of two or more emissive species formed from a single precursor. In fact, iso-emissive points are observed in the time-resolved area-normalized emission spectroscopy (TRANES) approach to time-resolved fluorescence studies (16).

Model example

The absorption cross-sections (σ base *e* in cm^2 molecule^{-1}), for each hypothetical absorbing species R, B, C, and D participating in reactions (I) and (II), are taken as Gaussian functions of the wavenumber in cm^{-1} (15). After the transformation of σ into molar absorption coefficients (ε base 10 in mol^{-1} L cm^{-1}), these have been represented as a function of wavelength as shown in Fig. 1. These values have been employed to calculate the total absorbance at three given reaction times. To this end, the concentration of each species has been calculated by numerical integration of the kinetic eq. [5] employing the Runge–Kutta method. For simplicity, $\nu_B = \nu_C = \nu_D = 1$ has been assumed. The results for $c_{R_0} = 10^{-4}$ mol/L, $k_I = 10^4$ mol^{-1} L s^{-1}, and $k_{II} = 2 \times 10^4$ mol^{-1} L s^{-1}, and $l = 1$ cm are shown in Fig. 2*a*. Thus, the difference spectra depicted in Fig. 3*a* show two isosbestic points. The isosbestic point condition (1) leads to eq. [11], which therefore should yield finite values for x_I/x_{II}, precisely at the isosbestic points. Figure 4 shows the dependence of $(\varepsilon_R^{ip} - \varepsilon_D^{ip})/(\varepsilon_B^{ip} + \varepsilon_C^{ip} - \varepsilon_R^{ip})$ on wavelength, according to the shape of the individual spectra. However, only positive values of this ratio have a physical interpretation as x_I/x_{II}. This fact precludes that isosbestic points appear at wavelengths at which eq. [11] is not fulfilled. In the present example, for the arbitrarily chosen ratio $k_I/k_{II} = 0.5$, two isosbestic points are predicted at the wavelengths at which they appear in Fig. 3*a*. More generally, the range of wavelengths at which isosbestic points may appear is restricted by the ratio k_I/k_{II}, and the number of possible isosbestic points may be already extracted from the known spectra of the reactants and products, as shown in Fig. 4.

Conversely, from the known spectra of the reactants and products and the "experimental" isosbestic points from Fig. 3*a*, the ratio k_I/k_{II} can be determined using Fig. 4.

Moreover, k_I and k_{II} may depend on temperature in a way that the ratio also depends on temperature. In contrast to the ample variation of absorption coefficients for numerous species observed between room temperature and shock wave conditions (17), no detectable dependence is expected in

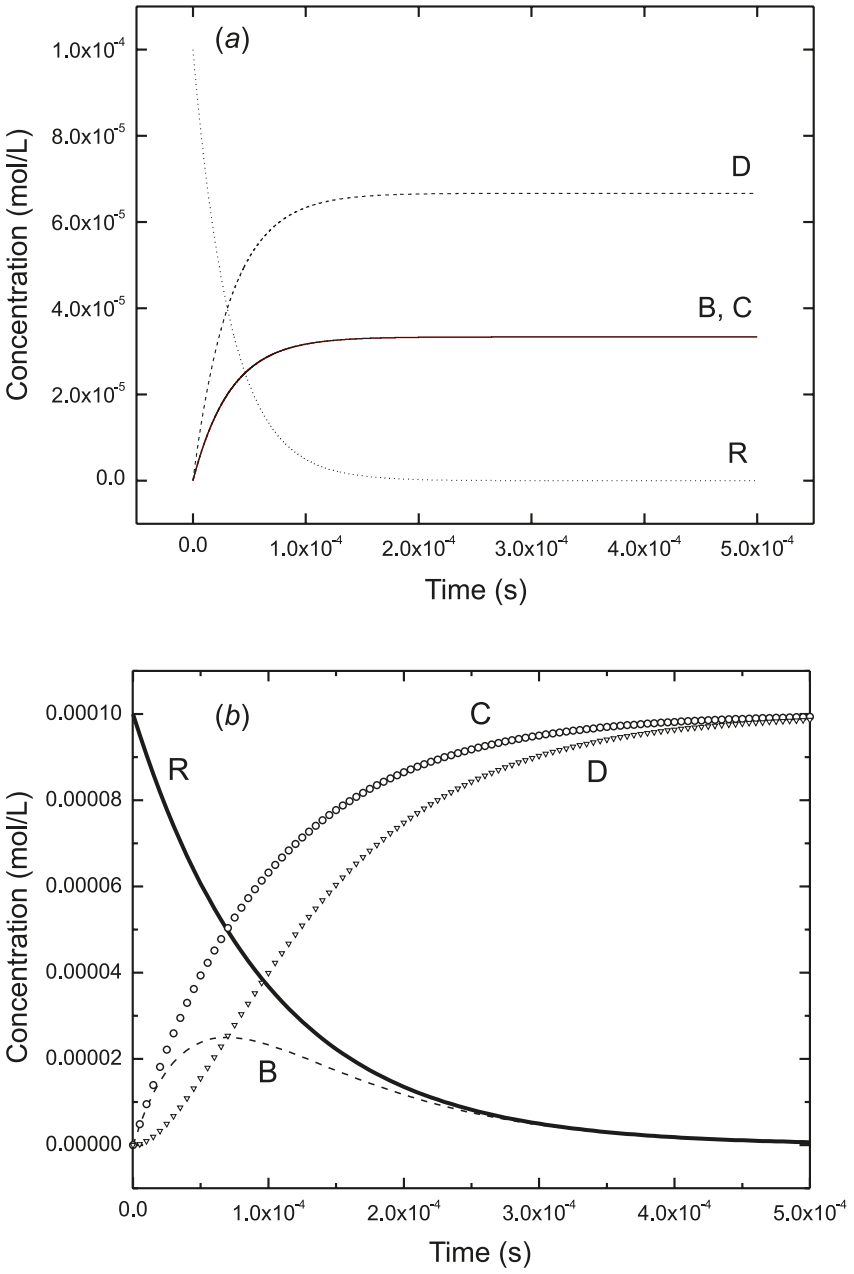
Fig. 2. (*a*) Calculated concentrations for R (·····), B or C (solid line), and D (– – –), with $k_I = k_{II}/2 = 10^4$ (mol/L)$^{-1}$ s^{-1}and $[R]_o = 10^{-4}$ mol/L for the parallel reactions mechanism. (*b*) Calculated concentrations for R (solid line), B (– – –), and C (◦◦◦), or D (▽▽▽), with $k_I = k_{II}/2 = 10^4$ (mol/L)$^{-1}$ s^{-1}and $[R]_o = 10^{-4}$ mol/L for the consecutive reactions mechanism.



conditions close to the room temperature or below the boiling point of the usual solvents. However, if k_I/k_{II} depends on temperature, the numerical value of the quotient $(\varepsilon_R^{ip} - \varepsilon_D^{ip})/(\nu_B \varepsilon_B^{ip} + \varepsilon_C^{ip} - \varepsilon_R^{ip})$ will change such that a shift of the isosbestic points is expected. In the present example, the behaviour shown in Fig. 4 will not persist; the number and position of the isosbestic points will vary accordingly, leading to the temperature coefficient of the ratio of the rate constants involved.

In a similar way to that presented above, a mechanism of three parallel first-order reactions with at least four absorbing species will lead to $x_I/x_{II} = k_I/k_{II}$, $x_I/x_{III} = k_I/k_{III}$, and $x_{II}/x_{III} = k_{II}/k_{III}$, and more generally, for N parallel reactions, there are N^2 possible $x_i(t)/x_j(t)$ ratios from which $\sum_i i = N(N + 1)/2$ (14) are either unity (for $i = j$) or the inverse of another, namely, $(x_j(t)/x_i(t))$, such that $N(N + 1)/2$ linearly independent relationships $x_i/x_j = k_i/k_j$ with $i, j = 1, 2, 3, \ldots, N$ are obtained. However, the kinetic information becomes less available from the resulting relationships as the number of elementary steps increases.

Case II: consecutive reactions mechanism

On the contrary, a mechanism involving two first-order consecutive steps: (I) $R \rightarrow \nu_{BI}B + \nu_C C$ and (II′) $B \rightarrow \nu_D D$ will not lead to an isosbestic point at λ_{ip}. Should this be the case, then the condition

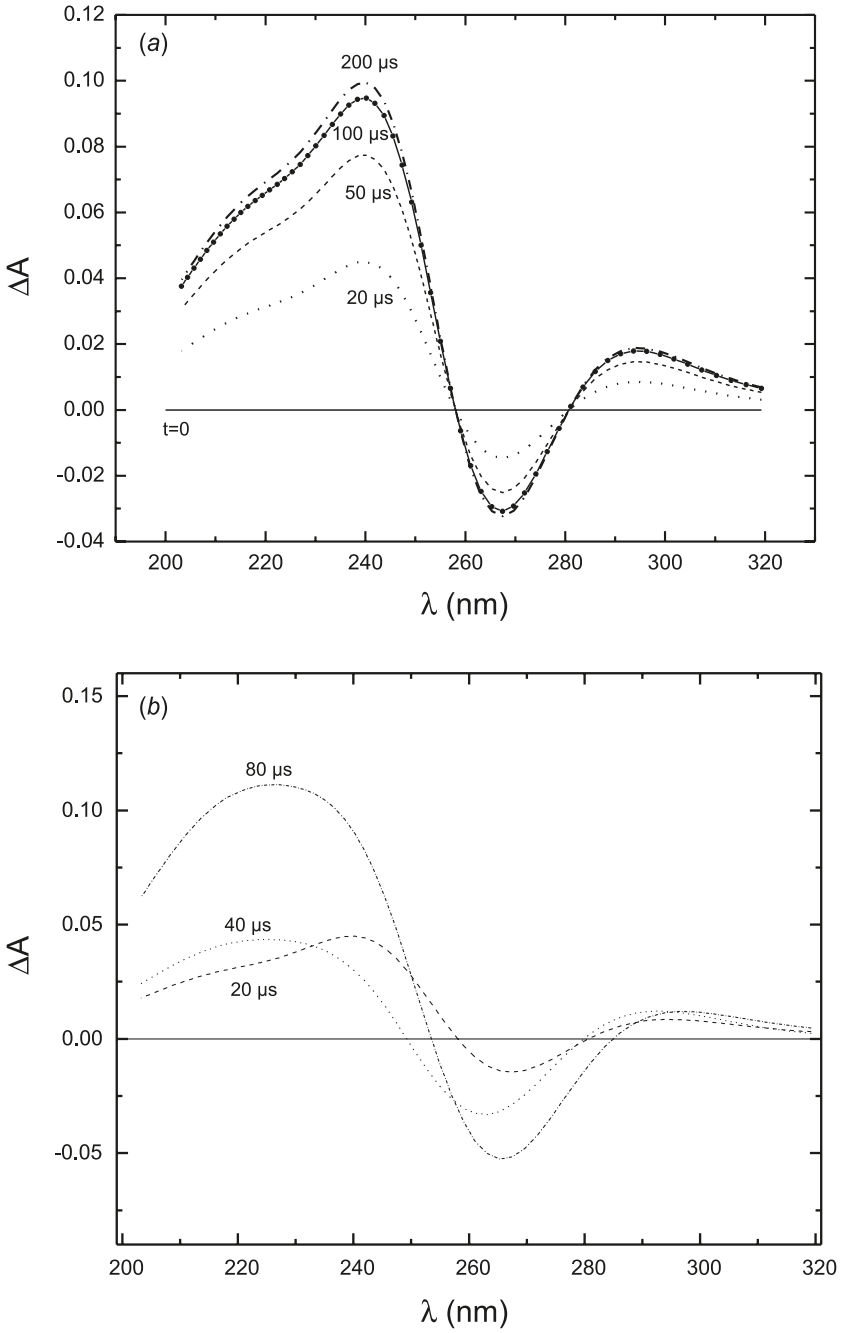
Fig. 3. Difference spectra as a function of the reaction time. (*a*) Parallel reactions from 0 (solid line) to 20 μs (···), 50 μs (– – –), 100 μs (–•–•–), and 200 μs (–·–·–). (*b*) Consecutive reactions from 0 (solid line) to 20 μs (– – –), 40 μs (·····) and 80 μs (–·–·–).



[14] $$\Delta A = x_I(\nu_{BI}\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip}) + x_{II}(\nu_D\,\varepsilon_D^{ip} - \varepsilon_B^{ip}) = 0$$

would imply

[15] $$x_I/x_{II} = (\varepsilon_B^{ip} - \nu_D\,\varepsilon_D^{ip})/(\nu_{BI}\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip})$$

namely, a time-independent $x_I/x_{II'}$ ratio.

Also in this case, the extent of reaction variables are $x_I > 0$ and $x_{II'} > 0$ for any reaction time, and the condition of eq. [14] will be fulfilled in the trivial case of $\varepsilon_B^{ip} = \nu_D\,\varepsilon_D^{ip}$ such that $\nu_{BI}\,\varepsilon_B^{ip} + \nu_C\,\varepsilon_C^{ip} - \varepsilon_R^{ip} = \nu_D\,\varepsilon_D^{ip} - \varepsilon_B^{ip}$, which does not lead to any kinetic information.

Equation [15] is analogous to eq. [11], which is yielded from the parallel reaction mechanism.

The mechanism (I) – (II′) is a particular case of (1): $Z \rightarrow \nu_{Y_i}\,Y_1$ for $(i + 1)$: $Y_i \rightarrow \nu_{Y_{i+1}}\,Y_{i+1}$, and for (N): $Y_{N-1} \rightarrow \nu_{YN}\,Y_N$.

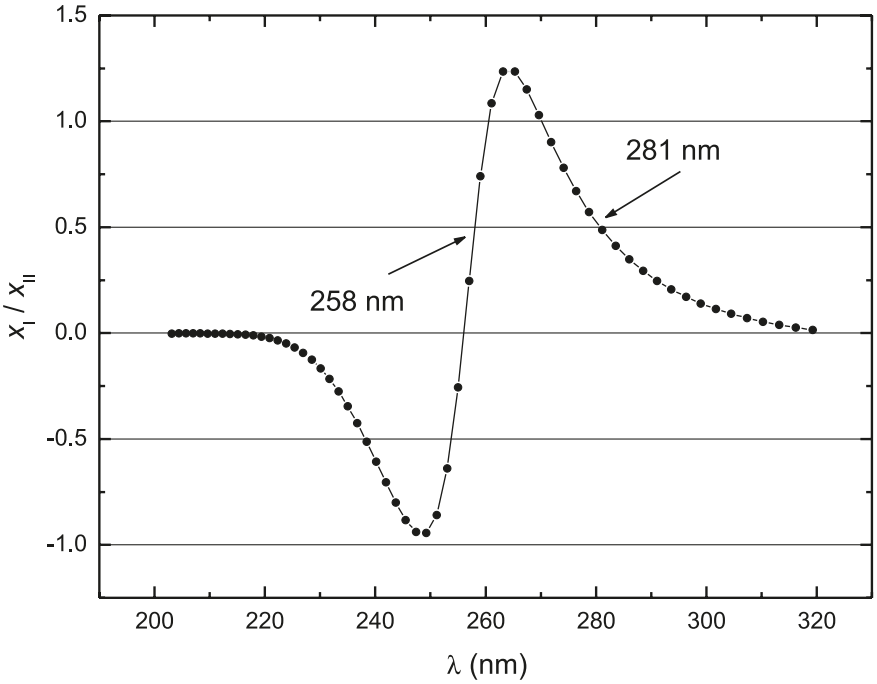
If, for the sake of simplicity, $\nu_{Yi} = 1$ is assumed the concentrations are given by

[16] $$c_{Yi} = x_i - x_{i+1} \qquad (i = 1, 2, \ldots, N - 1)$$

which takes the form $c_{YN} = x_N$ for the last product, and $c_Z = c_{Z_0} - x_1$ for the reactant Z. The reaction rate equations in terms of the degree of advancement variables can be expressed as

© 2008 NRC Canada

Fig. 4. Dependence of x_1/x_2 on wavelength for the spectra of Fig. 1. The arrows point to wavelengths for which the ratio $k_I/k_{II} = 0.5$.



[17] $dx_1/dt = -k_1(c_{Z_0} - x_1)$

[18] $dx_i/dt - dx_{i+1}/dt = k_i(x_{i-1} - x_i) - k_{i+1}(x_i - x_{i+1})$

[19] $dx_N/dt = k_N(x_{N-1} - x_N)$

where all the variables have the same meanings as above.

In the case of the mechanism (I) – (II′), with $\nu_{BI} = \nu_C = \nu_D = 1$, these eqs. lead to solutions of the form

[20] $x_I = c_{R_0}[1 - \exp(-k_I t)]$

and

[21] $x_{II'} = [c_{R_0}/(k_{II'} - k_I)][k_I \exp(-k_{II'} t) - k_{II'} \exp(-k_I t)]$

In contrast to the parallel first-order reactions mechanism, in this case, a time-dependent $x_I/x_{II'}$ is obtained

[22] $x_I/x_{II} = [1/(k_{II'} - k_I)][1 - \exp(-k_I t)]/[k_I \exp(-k_{II'} t) - k_{II'} \exp(-k_I t)]$

Therefore, the first member in eq. [15] would be a function of time clearly contradicting the isosbestic point condition and the relationship $x_I(dx_{II'}/dt) = x_{II'}(dx_I/dt)$ will not hold. This result expresses that the presence of isosbestic points allows the rejection of a consecutive reactions mechanism.

Figure 3*b* shows the difference spectrum at three different reaction times for the mechanism of two consecutive first-order reactions involving the four absorbing species of Fig. 1, for $\nu_{BI} = \nu_C = \nu_D = 1$.

For more complex mechanisms, the occurrence of isosbestic points may not lead to kinetic information; the integration of the corresponding differential equations may not be available. However, the isosbestic-point condition (1) will always allow relating the degree of advancement of reaction variables, the stoichiometric coefficients, and the molar absorption coefficients of the participating species, in a similar way as eqs. [11] and [15] were obtained for two elementary reaction steps.

Conclusions

The detailed discussion given so far leads to general criteria based on the isosbestic point occurrence in difference spectra, which may be formulated as follows. Let a set of two or more species absorbing in a given wavelength range in which the spectra overlap. Let one of them participate as the reactant of two first-order reaction steps.

(*i*) Then, the occurrence of one or more isosbestic points in the time-resolved difference spectra allows the rejection of a consecutive reaction mechanism.

(*ii*) The wavelength of isosbestic points in the time-resolved difference spectra is determined by the ratio of the reaction rate coefficients.

A practical procedure may be outlined as follows. If the spectra of the reactant and products are known, x_I/x_{II} may be calculated using eq. [11] and a figure similar to Fig. 4 may be constructed. In the case of a parallel mechanism, the positive values of the ordinates correspond to the ratios k_I/k_{II}, which lead to isosbestic points. Then, if isosbestic points appear in the experimental ΔA vs. λ graphs, we conclude that the reactions are parallel. Moreover, the experimental λ_{ip} leads to k_I/k_{II}, or Φ_I/Φ_{II}.

Unfortunately for the laboratory worker, not all the absorption coefficients are known or even what the products are, but the occurrence of isosbestic points shows that parallel reactions mechanisms independent of the number of species involved are operating.

The course of the spectral changes observed in a recent study on the acid-catalyzed intramolecular attack of β-phenylthioureido group on amide function provides an illustration of the first conclusion given above (13). The kinetics

© 2008 NRC Canada

follows two mechanistically different stages, each involving three species with overlapping spectra. A system of pseudo first-order reactions A $\leftrightarrow$ B, A $\rightarrow$ C, and B $\rightarrow$ C operates, where A stands for *cis*-2-(3-phenylthioureido)cyclopentanecarboxiamide, B for 4-imino-2-thiooxopyrimidine, and C for *cis*-4-oxo-2-thiooxopyrimidine. Starting the reaction either from A or B, an equilibrium is established, while concomitantly A and B convert into C. In a first stage, e.g., starting from A, the kinetic system behaves as two parallel reactions of A into B and A into C, and isosbestic points are observed. When B accumulates, the isosbestic points are lost because a consecutive reactions mechanism is settled.

Reactions of 6-aminouracils — A novel and highly efficient procedure for preparation of some new spiro pyridodipyrimidines under classical or microwave-assisted solvent-free conditions

Mohammad R. Mohammadizadeh, Javad Azizian, Fatemeh Teimouri, Ali A. Mohammadi, Ali R. Karimi, and Esmail Tamari

Abstract: A versatile and highly efficient procedure has been introduced for preparation of spiro pyridodipyrimidines during the investigation of the reaction of 1,3-dimethyl-6- aminouracil with isatin derivatives, ninhydrin, and acenaphthoquinone under classical or microwave-assisted solvent-free conditions.

Key words: isatin, ninhydrin, acenaphtoquinone, 1,3-dimethyl-6-aminouracil, solvent-free.

Résumé : Dans le cadre d'une étude de la réaction du 1,3-diméthyl-6-aminouracil avec des dérivés de l'isatine, la ninhydrine et l'acénaphtoquinone dans des conditions classiques ou des conditions sans solvant, assistées par des microondes, on a développé une méthode versatile et très efficace de préparation de spiropyridodipyrimidines.

Mots-clés : isatine, ninhydrine, acénaphtoquinone, 1,3-diméthyl-6-amino-uracile, sans solvant.

Introduction

Synthetic heterocycles have widespread interest as herbicides, insecticides, dyes, organic conductors, and drugs. Nitrogen-containing heterocycles are of broad synthetic and pharmaceutical interest. This fact justifies continuing efforts in the development of structure–activity relationships as well as new synthetic strategies in these series of compounds (1). There is an enormous interest in the synthesis of new heterocyclic rings, stimulated by recent reports showing anti-tumor activity in a wide range of polyheterocyclic compounds isolated from marine organisms (2). Compounds containing a fused pyrimidine ring have significant biological activities, particularly in cancer and virus research (3). Among these heterocycles, pyridopyrimidine derivatives are of particular importance in pharmaceutical discovery research. Several reports have been sited for the preparation of these fused heterocycles, claiming that these derivatives are useful as bronchodilators (4), vasodilators (5), anti-allergic (4, 6), anti-hypertensive (7), and anti-cancer (4) agents. Therefore, considerable efforts have been directed towards the synthetic manipulation of uracils for preparing these complex molecules. A number of reports have appeared in the literature that usually describe forcing conditions, long reaction times, and complex synthetic pathways (8). Considerable attention has been paid to the new simple and rapid routes for the synthesis of the heterocycles.

Recently, we have studied the reaction of 6-aminouracils with aromatic aldehydes (9). As a continuation of our previous report, in this work we investigate the reaction of 6-aminouracils with reactive cyclic ketones and introduce a novel and highly efficient method for preparation of some spiro pyridodipyrimidines.

Results and discussion

According to the hard–soft acid–base (HSAB) theory, first introduced by Pearson in 1963 (10, 11), and later developed by Mendez (12), softer nucleophiles react with softer centers, whereas harder nucleophiles preferably react with harder electrophiles (13). Some fundamental studies about this behaviour were performed by Klopman (14, 15).

From a literature survey, we found that 1,3-dimethyl-6-aminouracil **1** may show an ambident nucleophilic character (16, 17). It has two reactive centers (Fig. 1), which can interact with electrophiles: the NH_2 group (16) and C-5 position (17). Such centers can be classified according to the HSAB principle as the amino group, which is a harder nucleophile as a result of its smaller atomic size and its higher charge density and the C-5 carbon position, which is a softer

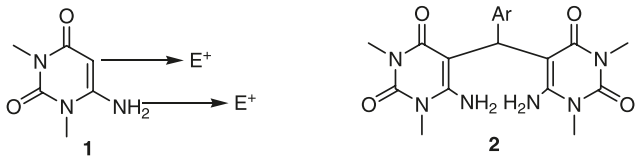
Fig. 1. Nucleophilic positions of 6-aminouracil **1** and its condensation product **2** with aromatic aldehydes.



nucleophile because of its lower electronegativity and its higher atomic size.

In our previous investigation (9), we studied condensation reaction of 6-aminouracils and aromatic aldehydes, and consequently we reported a microwave-accelerated procedure for the synthesis of bis(6-aminopyrimidonyl)methanes **2** under solvent-free conditions. We found that 6-aminouracil attacked aldehydes from the C-5 position as a result of more favourable soft–soft interaction between C-5 and the carbonyl groups of aldehydes (Fig. 1). It is worth considering that the carbonyl groups of aldehydes are usually thought of as hard centers in comparison with relatively softer electrophilic centers (13, 15).

In this study, we choose isatin derivatives **3**, which supply more positive and hence harder carbonyl groups for condensation with 6-aminouracil **1**. It is found that 6-aminouracil **1** reacts with isatins **3** to give spiro pyridodipyrimidine derivatives **4** (Scheme 1). The reaction goes to completion at 80 °C in ethanol over 4–5 h, and the pure products were obtained in good yields by simple filtration of the reaction mixture (Table 1).

The possible mechanism for the formation of product **4** is shown in Scheme 2. It is conceivable that the initial event is the formation of iminium **5** from 6-aminouracil **1** and isatin **3**. Intermediate **6** is then produced by nucleophilic attack of another 6-aminouracil **2** to iminium **5**. Finally, cyclization is accomplished by nucleophilic attack of one 6-aminourcil moiety of intermediate **6** to other one to produce compound **4**.

The isolated spiro pyridodipyrimidines **4a**–**4d** were unambiguously characterized on the basis of IR, ^{1}H and ^{13}C NMR spectroscopy, mass spectrometry, and elemental analysis. The mass spectrum of **4a** displayed the molecular ion (M^+) peak at *m*/*z* 422, which is 17 mass units lower than **6**, the initial 1:2 adduct of isatin **3** and 6-aminouracil **1**, confirming elimination of an ammonia molecule. The IR spectrum of **4a** shows absorptions at 3436 and 3284 cm^{-1}, indicating the presence of N–H, and 1699 and 1645 cm^{-1} due to carbonyl of amide functionalities. The ^{1}H NMR spectrum of **4a** exhibited four sharp distinct singlets at δ = 2.97, 3.04, 3.36, and 3.43 ppm due to four methyl groups along with characteristic signals with appropriate chemical shifts for the four aromatic protons. Two relatively broad signals at δ 9.31 and 11.51 ppm were observed for the two N–H protons. In the ^{13}C NMR spectrum of **4a**, four methyl groups distinctly resonated at δ = 27.8, 28.3, 30.9, and 32.3 ppm, and the signal for spiro carbon was evident at δ = 51.7 ppm. These signals together with the other 15 separated signals all are in agreement with the proposed structure.

Two major differences are found between reaction of 6-aminouracil with aromatic aldehydes (9) and isatin derivatives: firstly, one molecule of 6-aminouracil regioselectively

reacted from its NH_2 group, as a result of more favourable hard–hard interaction of the nitrogen and the highly positive carbonyl group; secondly, due to the lower torsional freedom of aminouracil moieties in intermediate **6** with respect to **2**, the C-5 positions get very close to each other and consequently the reaction goes ahead via the cyclization of intermediate **6** to produce the final product **4**.

Microwave-assisted organic synthesis is an increasingly popular field as indicated by numerous publications in the past few years owing to several advantages such as enhanced reaction rates and increase in yields under milder conditions (18). The combination of solvent-free reaction conditions and microwave irradiation leads to large reduction in reaction times, enhancement in conversion, and sometimes in selectivity with several advantages of the eco-friendly approach, termed green chemistry (19). In the context of our general interest in the use of microwave technology in synthetic organic reactions (20), we have also considered the microwave-assisted reaction of 6-aminouracils with cyclic dicarbonyls under solvent-free conditions (Scheme 1, method B). When a homogenous mixture of 6-amino-1,3-

© 2008 NRC Canada

dimethyluracil **1** and cyclic dicarbonyls **3**, **7**, or **9** was wetted with a few drops of dimethylsulfoxide (DMSO) and then irradiated in a microwave oven, the condensation reaction proceeds more efficiently, and it takes only 3 min to complete the reaction. We observed that yields were significantly increased, as can be easily seen from the results mentioned in Table 1.

To explore the synthetic utility of the process, we have investigated the reactivity pattern of 6-amino-1,3-dimethyluracil **1** with ninhydrin **7** in ethanol at reflux temperature as well as under microwave-assisted conditions in the solid state. This reaction was found to proceed in a smooth manner providing spiro pyridodipyrimidines **8** in good yield (Scheme 3). Ninhydrin is a relatively unstable, highly reactive compound, and adducts bearing ninhydrin moiety are prone to undergo rearrangement (21). Consequently, when the reaction was run under more vigorous microwave radiation, the yield of spiro pyridodipyrimidine **8** was lower than that of thermal condition. The structure of this product was confirmed from spectroscopic data and elemental analysis. The ^{1}H NMR spectrum showed the four characteristic signals at δ 3.00, 3.04, 3.20, and 3.28 for the methyl groups of pyrimidine rings.

In a similar way, treatment of 6-amino-1,3-dimethyluracil **1** with acenaphthoquinone **9** under classical or microwave-assisted solvent-free conditions afforded spiro pyridodipyrimidine **10** in good yields (Scheme 4).

However, under the same conditions, this reaction almost could not be observed when the phenanthrenedione **11** and naphthoquinone **12** were used as starting diketones (Scheme 5). This is probably due to the lesser reactivity of sp^2 carbons of six-membered rings with nucleophiles in comparison to five-membered rings (22).

Conclusion

A versatile and highly efficient procedure has been introduced for the preparation of some new spiro pyridodipyrimidines during the investigation of the reaction of 1,3-dimethyl-6-aminouracil with isatin derivatives, ninhydrin, and acenaphthoquinone under classical or microwave-assisted solvent-free conditions. Besides the extension of the chemistry of 6-aminouracils, this work is a further example of the utility of microwaves in organic synthesis.

Experimental section

Melting points were measured on an Electrothermal 9100 apparatus and are uncorrected. IR spectra were recorded as KBr pellets on on a Shimadzu FTIR-8300. ^{1}H NMR and ^{13}C NMR spectra were determined on a Bruker DRX-300 Avance instrument in $CDCl_3$ using TMS as internal standard. The reactions were carried out using CEM MARS 5™ microwave oven. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus. The purity of the obtained spiro compounds was tested by the CHN analysis using a Heraus CHN rapid analyzer.

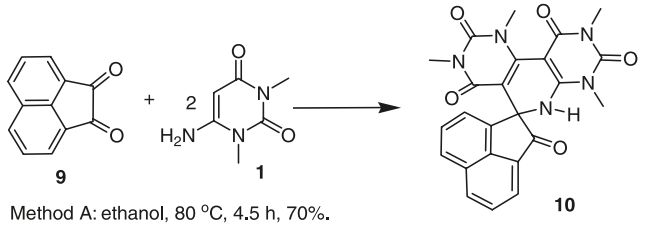
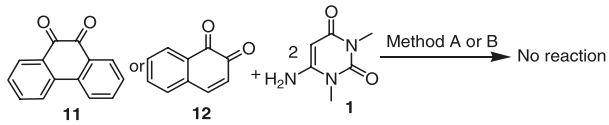
Method A: ethanol, 80°C, 3.5 h, 74%.
Method B: solvent-free, MW, 3 min, 60%.

Scheme 4. Synthesis of spiro pyridodipyrimidine **10**.



Method A: ethanol, 80 °C, 4.5 h, 70%.
Method B: solvent-free, MW, 3 min,78%.

Scheme 5. No condensation reaction was acquired between aminouracil **1** and cyclic diketones **11** and **12**.



Representative procedure for the synthesis of spiro pyridodipyrimidines

Method A

A solution of the cyclic ketone **3**, **7**, or **9** (1 mmol) and 6-amino-1,3-dimethyluracil **1** (2 mmol) in ethanol (10 mL) was refluxed for an appropriate time (Table 1 and (or) Schemes 3 and 4). Completion of the reaction was evidenced by TLC analysis. The reaction mixture was cooled to room temperature, filtered, and solids washed with 10 mL of hot water. Recrystallization of products from a 1:1 mixture of ethanol/DMSO gave the pure products.

Method B

Appropriate amounts of cyclic ketone **3**, **7**, or **9** (1 mmol) and 6-amino-1,3-dimethyluracil **1** (2 mmol) were wetted with 2–3 drops of DMSO, mixed thoroughly, put in an open vessel, and exposed to microwave irradiation (CEM MARS 5™, 300 W) for 3 min in a three step mode with interval (1 min – 30 s – 1 min). Then, the reaction mixture was allowed to cool down, 20 mL water was added, and the resulting solid was filtered off, washed with 10 mL of hot water, and recrystallized from 1:1 mixture of ethanol/DMSO.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Inside the black box — Perspectives on transformations in catalysis

Deryn E. Fogg

Abstract: Tandem catalysis and olefin metathesis are powerful tools in the development of sustainable synthetic practices. This Award Lecture describes our advances in designing new tandem metathesis-hydrogenation methodologies for the synthesis of "designer materials" and Ru-pseudohalide metathesis catalysts that amplify opportunities for tuning catalyst activity, selectivity, and lifetime. Also discussed is the operation of a previously unrecognized oligomerization-backbiting pathway in ring-closing metathesis of conformationally flexible α,ω-dienes, which has important implications for the sustainable synthesis of medium and large rings.

Key words: tandem catalysis, green chemistry, olefin metathesis, ring-closing metathesis, mechanism.

Résumé : La catalyse en tandem et la métathèse d'oléfines sont de puissants outils dans le développement de pratiques synthétiques renouvelables. Dans cette présentation on décrit les développements réalisés dans nos laboratoires dans la conception de nouvelles méthodologies de tandems catalyse/métathèse qui permettent d'obtenir des produits ciblés ainsi que des catalyseurs de métathèse à base de ruthénium et d'un pseudohalogène qui amplifient les opportunités d'ajustement de l'activité, de la sélectivité et du temps de vie du catalyseur. On discute aussi de l'opération d'une voie réactionnelle antérieurement inconnue d'oligomérisation "par transfert de chaîne interne" dans la métathèse de la fermeture de cycle de α,ω-diènes conformationnellement flexibles qui présente d'importantes implications pour la synthèse renouvelable de cycles de tailles moyennes ou grandes.

Mots-clés : catalyse en tandem, chimie verte, métathèse d'oléfine, métathèse de fermeture de cycle, mécanisme.

Introduction

Efficiency is a central challenge in chemical synthesis. It is also a central concept in "green chemistry" initiatives directed at development of environmentally more benign chemical practices, grounded in appropriate stewardship of chemical resources. Green chemistry advocates, in part, the efficient conversion of molecular precursors into products via convergent, atom–economic transformations that minimize energy consumption and production of waste (1). Despite committed industrial interest (2), these principles have made slow headway in fine chemicals and pharmaceutical synthesis, where lower production volumes and the value-added nature of the products have historically shielded manufacturing inefficiencies. Pharmaceutical synthesis, still heavily reliant on stoichiometric technologies and batch processes, is characterized by particularly high environmental "*E* factors" (25–100 vs. <1–5 for bulk chemicals synthesis), where *E* = kg of waste per kg of product (1). Increased pressure on profits, stemming from a decline in new drug approvals and exacerbated by the withdrawal of blockbuster drugs, is now bringing the economics of efficiency into sharper focus.

Selective catalysis offers important opportunities to reduce both waste and energy consumption. (While energy expenditures impose less stringent demands in fine chemicals and pharmaceutical synthesis than the commodity sector, the industry is nevertheless vulnerable to spiralling energy costs). Catalysis is especially valuable where coupled with convergent methods of assembly, which reduce total process stages and time, while improving yields and diversity. Olefin metathesis, as an exceptionally powerful method for the convergent assembly of C=C bonds, offers major opportunities in the "greening" of the chemical industry (1), as indeed noted by the Swedish Academy in awarding the 2005 Nobel Prize to Chauvin, Schrock, and Grubbs. Process rationalization is likewise under scrutiny. Coupled, one-pot synthetic procedures are increasingly important as a way of minimizing work-up demands: their efficiencies are further enhanced for coupled catalytic reactions, and this drives the tremendous interest in tandem catalysis.

Our research centers on the design of new catalysts and methodologies for the efficient construction of organic molecules and specialty polymer materials, with a particular fo-

cus on olefin metathesis and tandem catalysis. This article summarizes our progress in these areas. Realization of their full potential rests on a detailed understanding of the underlying inorganic chemistry. We recently described simple adaptations of MALDI-TOF mass spectrometry that create a powerful tool for insight into the identity, speciation, and reactions of transition metal complexes (3). Anaerobic charge-transfer MALDI-MS is highly complementary with electrospray mass spectrometry (4). Of particular value is its capacity to aid in the identification of charged, neutral and even insoluble complexes. A detailed discussion of this topic, however, is deferred for reasons of space.

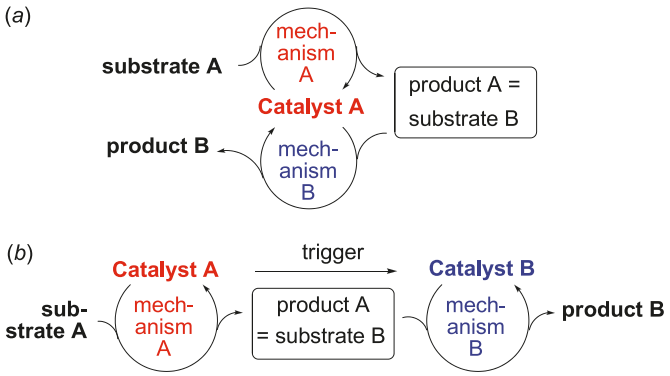
Discussion

Tandem catalysis

One-pot reactions are of compelling interest in development of sustainable synthetic practices, owing to the significant process efficiencies that result from eliminating unnecessary work-up stages, as noted above (1*c*, 5). Minimizing solvent wastes is a key aspect of this efficiency. Increasingly recognized as a critical issue in fine chemicals and pharmaceutical manufacturing, inefficient solvent use is a major contributor to high *E* factors and process costs (1*c*). The scale of the problem is highlighted by a recent GSK estimate that puts solvents at 85%–90% of the total mass of chemicals used in pharmaceutical manufacturing (6). Tandem catalysis, an important subclass of one-pot reactions, combines the advantages inherent in such processes with reduced catalyst and purification costs. In its most powerful form, tandem catalysis exploits the tremendous catalytic versatility of certain transition metals. The central idea is very simple: where two sequential catalytic steps are required to elaborate a substrate, catalyst consumption and product purification can be minimized if the catalyst used in the first reaction can also promote the second.

Most users of homogenous catalysis have probably been struck by the similarity sometimes evident between catalysts that enable widely different transformations. In the extreme, a single versatile catalyst can promote sequential elaboration of a substrate through multiple, distinct reaction types (Fig. 1*a*). We have termed such processes "spontaneous" or "auto-tandem" catalysis (7). A classic example in industrial use was the formation of long-chain alcohols as a key sequence in the Shell oxo process: here the $HCo(CO)_3(P^nBu_3)$ catalyst promoted both hydroformylation of α-olefins and subsequent hydrogenation of the aldehyde products (8). More commonly, the active site must be modified using a trigger that toggles the catalyst from one chemical manifold to another (Fig. 1*b*, "assisted tandem" catalysis). Either of these processes enables multistep, one-pot elaboration of substrates via sequential, distinct catalytic operations, using a single catalyst precursor, without intermediate work-up. Advantages and limitations of each are inherent in the concurrent (autotandem) or consecutive (assisted tandem) nature of the macroscopic processes. Autotandem catalysis, for example, is attractive for its "walk-away" efficiency: reactions can be set up and left to evolve, because the product from one catalytic cycle automatically enters as substrate into a second. However, the demand for orthogonality between the two processes is often incompletely met. This means, in part, that the substrate for either process may be consumed in the other, undermining product selectivity. As well, because both reaction types proceed concurrently, it is not possible to independently optimize reaction conditions for each, and elimination of incompatible species can be challenging.

Fig. 1. Schematic illustrations of (*a*) spontaneous (autotandem) catalysis and (*b*) assisted tandem catalysis.



While incompatibility between species that are concurrently present must likewise be addressed in assisted tandem catalysis, greater control results from the temporal segregation of different catalytic processes. Because the second transformation cannot occur until the trigger is added, each process can be independently optimized. Such strategies form part of an emerging paradigm in homogeneous catalysis (7, 9). The startlingly high number of Ru-based processes is in part due to the exceptional catalytic scope (10) of this metal, as well as its relatively low cost, Ru historically trading at 1/20 to 1/30 of the price of Rh (11). Much attention has focused on metathesis-hydrogenation, particularly in the context of materials design (7, 12–14). Tandem processes of ring-opening metathesis polymerization (ROMP) and hydrogenation offer major opportunities, as noted below. However, the macromolecular nature of the hydrogenation substrates presents greater technical challenges than hydrogenation of small molecules. Advances in this area are therefore of added interest for their relevance to ring-closing metathesis (RCM)-hydrogenation and cross-metathesis (CM)-hydrogenation (15–18).

ROMP is one of the most powerful methods now in use for the molecular-level design of macromolecular materials (19). Despite its versatility, a limitation lies in the vulnerability of unsaturated sites in the polymer backbone to thermal or photochemical cross-linking and oxidative degradation (20, 21), which compromise the control over chain lengths that represents a core advantage of ROMP materials. Reduction of ROMP polymers has thus received much attention as a potentially straightforward route to functionalized polyolefins (7, 9), a long-standing goal in Ziegler–Natta catalysis, with enormous implications for materials design. Efficient access of the metal to these sterically encumbered olefinic sites necessitates use of homogeneous catalysis, ideally, in terms of process costs and efficiency, tandem catalysis. The opportunity crystallized with Grubbs' 1995 report of **1** (Chart 1), the first readily accessible, highly active ruthenium catalyst for olefin metathesis (22).

I was then a postdoc with Dick Schrock, designing quantum dot-ROMP polymer composites for device applications

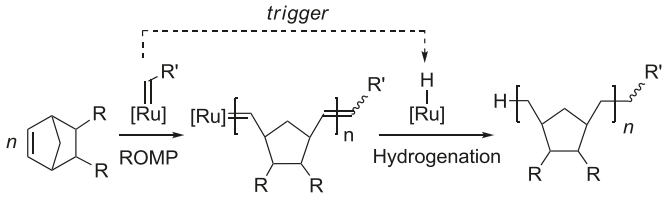
(using strictly group 6 catalysts in the ROMP chemistry!). Device fabrication is a demanding test for polymer materials, and this experience gave me a greater familiarity than I necessarily desired with cross-linking issues. The limitations of then-current, forcing, diimide and heterogeneous reduction methods were becoming evident (23, 24), while the potential opportunities of homogeneous hydrogenation methods (25) were familiar to me from my Ph.D. background with Brian James. The structural resemblance between the new Grubbs catalyst and known Ru hydrogenation catalysts (five-coordinate, square pyramidal complexes with an apical, high-trans-influence active site) led me to wonder about the possibility of transforming the metathesis-active ruthenium alkylidenes into hydrogenation-active ruthenium hydrides (Scheme 1). The concepts of tandem catalysis shown in Fig. 1 were then incompletely formulated (and the term "sustainable chemistry" was itself newly coined), but this struck me as a potentially elegant and economical solution to the problem of hydrogenating ROMP polymers, and it formed the basis for one of the research proposals with which I interviewed for faculty positions.

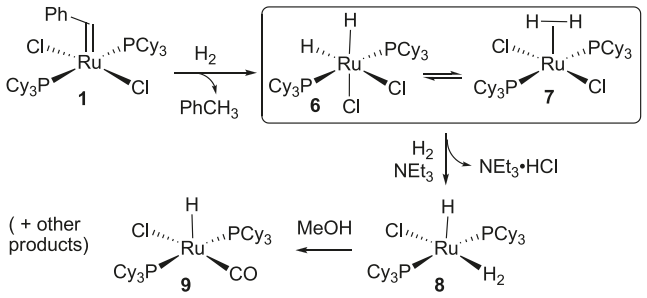
In the event, my first year at Ottawa saw the seminal report by McLain, Brookhart, and co-workers of precisely such a procedure, in which cyclooctene monomers were transformed into functionalized polyolefins via sequential processes of Ru-catalyzed ROMP, then hydrogenation (12*a*). However, the conditions were forcing (135 °C, 400 psi of H_2, 1 psi = 6.894 757 kPa), the high temperatures being of particular concern because of the risk that thermally induced cross-linking could compete with hydrogenation (20, 21). We took a different approach to the problem, focusing on clarifying the nature of the transformation in the belief that this could aid in designing a more efficient process. In a mechanistic study of the first-generation Grubbs catalyst **1** (26), we showed that the key step is H_2 hydrogenolysis of the [Ru]=CHR functionality to liberate alkane and the Ru(IV) dihydride **6**, which exists in equilibrium with its dihydrogen tautomer **7** (Scheme 2). The more reactive, and more robust, hydridochloro catalyst **8** was obtained by adding base to abstract a chloride ligand, this enabling reduction of cyclooctene-based ROMP polymers at 60 °C and 100 psi H_2 (13, 27). (Of great interest in this connection is subsequent work by the Schmidt group, in which post-metathesis addition of NaH enabled hydrogenation of cyclopentenols at ambient temperature and under 14.6 psi (1 atm, 1 atm = 101.325 kPa) H_2 (17, 18). While the difference in substrates precludes direct comparison, the strikingly mild conditions point toward greater efficiency in the **1**–**8** transformation; i.e. a high concentration of the hydrogenation-active species.)

Another advance, however, resulted in a yet more active catalyst. In the course of patenting this methodology, we en-

Scheme 1.



Scheme 2. One-pot procedure for transformation of Ru alkylidenes (e.g., **1**) into hydrogenation-active Ru hydride catalysts by use of appropriate triggers (H_2, base, MeOH).



countered at a late stage a "submarine" patent (i.e., one that emerged from examination days before we were to file), which described synthesis of saturated ROMP polymers, albeit without base and in an "inert solvent", at pressures as low as 2 atm of H_2 (28). This drove us to try a number of less obvious potential improvements to reduce the pressure limit, the most successful of which we subsequently described (13, 27) as the "unorthodox expedient" of adding methanol as a co-solvent in the hydrogenation step. We were inspired to do so by scattered literature precedents that suggested curious effects of alcohols on hydrogenation rates, sometimes detrimental but sometimes beneficial (29). The unorthodoxy lies in the fact that organic polymers are rarely methanol-soluble; indeed, methanol is typically added to precipitate such polymers from solution. As well, though this had not been established at the time, the Grubbs catalysts do not tolerate alcohols well (see later). Indeed, methanol is much more inimical to Ru ROMP than has been generally recognized, particularly in terms of control over chain lengths: decomposition of the metathesis-active metal endgroup competes with chain growth unless the monomer is very highly reactive (30). In view of these hazards, we took a cautious approach, adding methanol only once ROMP was complete and only at levels that maintained polymer solubility during and following reduction. Despite the relatively low proportion of MeOH (maximum 20% in CH_2Cl_2), a dramatic increase in hydrogenation activity resulted, which allowed us to reduce the pressure of H_2 to as little as 1 atm for polyoctene hydrogenation (13,27).

Under these modified conditions, we described partial conversion of the Ru species present into the known, potent (20, 31) hydrogenation catalyst **9**. While the activating effect of the CO ligand in **9** was well-established, many will find this difficult to reconcile with its *deactivating* effect in hydrogenation via arylphosphine complexes of Ru, Rh, and Ir (25), and with the much higher hydrogenation activity of electron-rich alkylphosphine catalysts, vs. their arylphos-

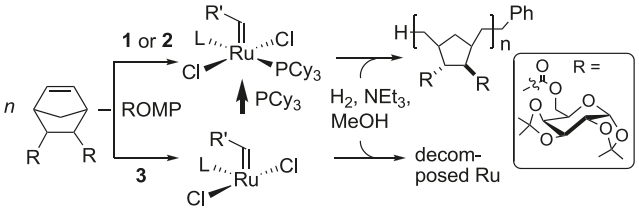
© 2008 NRC Canada

phine analogues (32), which suggests the importance of an electron-rich metal centre. While potential explanations come to mind, the uncertainty of the origin of the activating effect continued to trouble us, and we recently undertook a collaborative computational study of model $RuHCl(L)(P^iPr)_2$ systems (L = CO (33), PH_3) with Tom Woo's group at Ottawa. Consistent with our original chemical intuition, the energetic pathway for ethylene hydrogenation was systematically higher for the π-acid CO system, vs. the σ-donor PH_3 complex (34). We suspect that the outstanding performance of **9**, despite these higher barriers, indicates superior productivity rather than superior activity. Indeed, ongoing experimental studies of **8** and **9** (aided by an improved synthesis of **9** (35)) suggest that the basis for the enhanced activity of the latter may be its longer lifetime. The very strong binding of the carbonyl ligand may thus be important chiefly for its non-lability and its capacity to stabilize the catalyst, leading to higher total productivity.

Also important for the efficiency of hydrogenation, as noted above, is the efficiency with which **1** or its derivatives undergo conversion into **9**. The procedure in Scheme 2 effects ca. 60% conversion of **1** into **8** and **9** (ratio 2:1), among other unidentified products. Subsequent to this study, the Mol and Grubbs groups showed that transformation of first- and second-generation Grubbs catalysts into the corresponding hydridocarbonyl complexes (among other products) can be effected by reaction with alcohols alone, i.e., in the absence of added H_2 or base (36–38). Dinger and Mol showed that the proportion of **9** could be increased to 70% by use of *n*-propanol and NEt_3 base (36). Given that our experimental protocol involves, for simplicity, near-simultaneous addition of H_2, NEt_3, and methanol, followed by heating to 60 °C, it is highly probable that conversion to **9** involves both Ru-alkylidene and Ru-hydride precursors, i.e., methanolysis, as well as hydrogenolysis. Other reagents, including vinyloxytrimethylsilane and ethyl vinyl ether, also trigger the alkylidene-hydridocarbonyl transformation (39, 40). In related work, the Cossy group recently utilized silanes as triggers to turn on hydrogenation activity (41). We are presently assessing the relative efficiency of these methods and variants on the Schmidt protocol (17, 18), under controlled conditions, to determine whether we can improve performance further. Beyond metathesis-hydrogenation, this would advance our efforts in developing other tandem catalysis procedures, now under exploration, that exploit the remarkable catalytic versatility of **9** (35).

Our methodology, though a breakthrough in terms of materials design, has some important limitations. A major one is the fact that it can only be applied to monomers that are efficiently polymerized by the first-generation Grubbs initiator **1**. Our appreciation for this problem was driven home by a collaboration with researchers at the Ottawa Eye Institute, directed at the development of an innervated, cell-based artificial cornea (42). In this work, we sought to cross-link a jelly-like collagen matrix with carbohydrate-functionalized ROMP polymers, to develop strong, flexible, and biocompatible corneal transplants with the porosity required for cell in-growth (43). The galactose groups are designed to enable controlled cross-linking of the lysine residues in the collagen fibrils, while also ensuring biocompatibility (galactose groups being native to the collagenous stroma of the cornea (44)). The problem lies in the bulk of the monomers, which impedes ROMP. Two galactose groups are required on each norbornene repeat unit to confer water-solubility on the reduced polymers, and their bulk is further increased by the carbohydrate protecting groups. ROMP of the unprotected monomers, while nominally attractive, is ruled out on the basis of the very poor control over polymer chain lengths characteristic of ROMP of sterically encumbered norbornenes in aqueous (or, worse, methanolic) media (30).

Scheme 3.



Such bulky 5,6-disubstituted norbornene monomers are polymerized very slowly by **1** (days (14)). While ROMP is rapid using second- or third-generation Grubbs catalysts containing an activating NHC ligand (Chart 1, e.g., **2**, **3**; NHC = *N*-heterocyclic carbene), this levies an unacceptable price: for **2**, control over polymer chain lengths (19); for **3**, activity in the hydrogenation step. In short, none of the existing metathesis catalysts offers all three features — high ROMP activity, controlled polymerization, and high hydrogenation activity — essential to transform sterically demanding monomers into saturated polymers with well-defined chain lengths. However, the problem of instability that limits **3** seems much more readily addressed than the problems of low activity or poor initiation efficiency that plague **1** and **2**, and we therefore turned our attention to devising ways to stabilize the polymer-bound Ru center derived from **3**. The high stability of **2** vs. **3**, clearly a function of the PCy_3 ligand present in the former, afforded a powerful clue. Our ultimate solution is represented in Scheme 3. Here, use of **3** as ROMP initiator affords well-defined polymer chains with excellent control over the chain lengths. Addition of PCy_3 once ROMP is complete effectively transforms the Ru endgroup on the polymer into that generated from **2** itself. This stabilizes the Ru complex under conditions of hydrogenolysis and hydrogenation, restoring hydrogenation activity to the level found with **2a** as initiator. We were thus able to retain the ROMP activity and precision of the third-generation catalyst **3**, without sacrificing the hydrogenation efficiency of the more robust initiator **2** (14).

The approach summarized in Scheme 3 answers a pressing need in materials design, reconciling the requirement for high reactivity in demanding ROMP and hydrogenation reactions, with that for precise control over polymer chain lengths. It is thus likely to find widespread application in the burgeoning area of ROMP-based "designer materials" (19). It also represents an expansion of our perspective on tandem catalysis, beyond manipulation of the active site, to consideration of the ligand architecture and properties best suited to meeting the demands unique to each stage of catalysis, including those of robustness and lifetime. Beyond hydrogenation, this approach holds promise for improving catalyst

efficiency in tandem metathesis-functionalization reactions, emerging applications of which include RCM-oxidation (45, 46) and RCM-cyclopropanation (47, 48) methodologies.

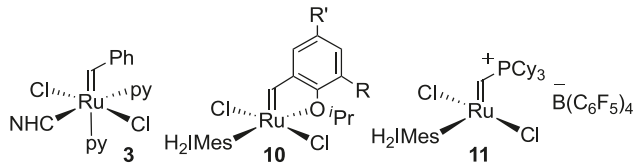
Catalyst design in Ru-promoted olefin metathesis

A second major theme in our research program centers on the design of robust, stereoselective, and tunable catalysts for olefin metathesis. When we began this work in 1997, the power of olefin metathesis in materials chemistry was well-established, but its applications in synthetic organic chemistry were just beginning to take off. This balance has now reversed (49). The tremendous expansion in uptake of metathesis methodologies in organic synthesis was due largely to the advent of robust, easily handled (and commercially available) ruthenium catalysts, of which the first- and second-generation Grubbs catalysts **1** and **2** remain most prominent. The Schrock Mo catalysts of type **4** and **5**, while superior in terms of their exquisite selectivity, ease of tuning, and very high reactivity (as well as a brilliantly conceived ligand architecture, which maximizes tunability while inhibiting bimolecular decomposition), have been less popular with organic chemists because of their thermal instability and their high sensitivity to traces of air or water, and protic or aldehydic functional groups.

Persuaded of the opportunities of the Ru catalysts (including the remarkable catalytic versatility of this metal noted above, with the attendant opportunities in tandem catalysis), but with a keen appreciation for the elegance and design strengths of the Schrock catalysts, we embarked on a program directed at integrating the best features of both. At the time, and indeed until very recently, the overwhelming focus in design of new Ru metathesis catalysts was on improving reactivity, largely by modification of the neutral, L-donor ligands on **1** and later in its second-generation derivative **2**. Following the unexpected finding that the lability of the phosphine ligand in **2** is *lower* than that in the less active complex **1** (50), an intensive, global effort focused on synthesis of derivatives of **2** containing a donor more labile than PCy_3. Examples include Grubbs' pyridine derivatives **3** (51), Grela's and Blechert's modified "Hoveyda"-type catalysts **10**, containing a sterically or electronically weakened ether chelate (52, 53), and, in the extreme, Piers' remarkable four-coordinate phosphonium alkylidene **11** (54) (Chart 2).

While this concerted effort resulted in impressive increases in metathesis activity, it also highlighted the fundamental limitations in catalyst lifetime already established for **1** and **2** (55). Within these catalysts, higher metathesis reactivity is offset by accelerated catalyst decomposition, because metathesis and deactivation proceed via the same 14-electron intermediate, $RuCl_2(NHC)(=CHR)$ **12**. This intermediate is identical to that formed from **2** itself; despite the structural diversity of the precatalysts, therefore, common decomposition routes (as well as selectivity) can be anticipated (56).[1] Concurrent work in our group was connecting the problems of lifetime and selectivity as common design issues. We were struck by the high catalyst loadings required in RCM and CM reactions, especially given that robustness

Chart 2.



was widely regarded as one of the major assets of the Ru systems. For many industrial applications, prohibitively high catalyst costs could be anticipated from the low catalyst productivity (at that time, routinely 5-20 turnovers). In pursuing a design solution, we began by seeking insight into the nature of the problem. In 2002, we described a chloride-mediated decomposition pathway implicated in the short lifetimes of Grubbs-type alkylidene catalysts (58, 59). Triply chloride bridged diruthenium species result from bimolecular coupling of the alkylidene complexes, consistent with the kinetics data earlier reported (55). Decomposition of the methylidene complexes, in contrast, appears to be unimolecular, though a later report proposed a bimolecular, chloride-mediated deactivation pathway for methylidene species as well (60). The contribution of each pathway to overall catalyst lifetime depends on the extent of initiation and thus on the catalyst, the substrate, and the reaction conditions.

The ability of the chloride ligands to participate in catalyst deactivation is compounded by the isotropic nature of these donor groups, which offers little aid in steric definition of the active site. The potential to modulate not only catalyst lifetime, but tunability and selectivity, we viewed as a powerful case for exploring "pseudohalide" catalysts. While the role of the neutral donor ligands in Ru-catalyzed olefin metathesis has received much attention, as noted above, the role and optimum properties of the anionic ligands have been examined in much less detail. We analyzed the design limitations that have resulted in low activity for the majority of Ru-pseudohalide complexes studied (19, 56). These can be summed up as: (*i*) excessive steric crowding, which hinders the approach of substrate, (*ii*) the absence of a labile neutral ("placeholder") ligand, which impedes substrate binding, or (*iii*) the absence of a strong, activating donor (such as an alkylphosphine or NHC group) among the ligands present in the active catalyst. It was clear that none of these limitations is inherent, and that highly active $RuX_2LL'(CHR)$ catalysts might be accessible if the appropriate anionic ligands could be identified. We sought pseudohalide ligands that could be readily tuned for selectivity, solubility, etc., and that confer minimal inessential three-dimensional bulk. Aryloxide ligands derived from phenols satisfy both criteria.

An initial challenge in installing aryloxide ligands within our target environments was the ease with which the aryloxide ligand undergoes $\sigma \rightarrow \pi$ isomerization in coordinatively unsaturated or labile Ru complexes. Despite the strength of the Ru–OAr bond (61), the reservoir of electron density in the aryloxide ring, in conjunction with the accessibility of three coordination sites on the metal, enables

[1] "Boomerang" strategies involving recapture of the active species may extend the lifetime of the *precatalyst*, replenishing the reservoir for regeneration of the active catalyst. The efficiency of this approach is determined by the relative rates of both recapture and release. Rates of recapture by bulky or electron-deficient styrene ethers may be low in Ru systems (57).

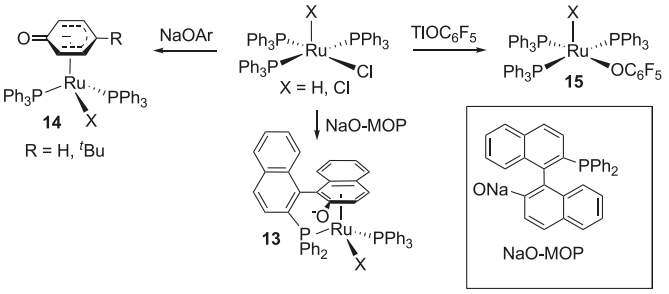
Scheme 4.



rapid isomerization to piano-stool complexes (62, 63). Model studies with $RuHCl(PPh_3)_3$ showed this behaviour for both monodentate aryloxides and for aryloxides that form seven-membered chelate rings (Scheme 4, see **13** and **14**).

In these model studies, use of an electron-deficient monodentate aryloxide enabled us to curb isomerization; see **15** (64, 65). Alternatively, smaller, more rigid chelates can be used (66). We have now developed a large family of pseudohalide catalysts, of which three important examples are shown in Scheme 5. These complexes are prepared from **3**, the essentially two-dimensional nature of the pyridine and NHC ligands removing the steric driving force for α-elimination (67), which otherwise culminates in Ru-alkylidyne products (64, 68). Use of thallium aryloxides was dictated by the instability of **3** over the timescale required for reaction with the alkali metal salts.

Perfluoroaryloxide catalyst **17**, the first highly active Ru-pseudohalide metathesis catalyst, effects RCM of the benchmark substrate diethyldiallyl malonate **S1** at loadings 10^4 times lower than those conventionally employed (64). Lower overall productivity (maximum TON 21 000), but dramatically increased activity, was found for perbromophenoxide derivative **18**, in which one chloride ligand is retained (a function of the increased aryloxide bulk). Catalyst **18** exhibits particularly high efficiency in RCM and enyne metathesis (Fig. 2).

The range of activity within the pseudohalide catalysts is important in enabling tuning of catalyst reactivity to match the demands of the reaction under study. In ROM–CM reactions of norbornenes such as **S8**, for example, excessive catalyst reactivity leads only to ROMP, and the lower reactivity of **17** is critical to achieving the desired selectivity. In other cases, high activity is essential; in recent work, not yet published, we have been able to achieve efficient RCM of enyne substrates (e.g., **S7**) to yield challenging tetrasubstituted olefins. Tuning of reactivity, of steric demands, and of electronic properties is particularly important for developing versatile methodologies for asymmetric catalysis. The amplified "tunability" of these pseudohalide catalysts is clearly an asset in this regard, complementing the many advances in development of chiral NHC ligands in recent years (70). Building on these advances, we have now incorporated chiral NHC ligands into the aryloxide catalysts and are presently exploring their utility in asymmetric metathesis.

Perhaps most significant in the currently established metathesis behaviour of the Ru-aryloxide catalysts, however, is their performance in RCM synthesis of medium and macrocyclic rings. Detailed examination of this behaviour, and comparison with the Grubbs systems, revealed unexpected insights into the mechanism by which such conformationally unbiased substrates undergo metathesis (71).

Scheme 5. Highly active Ru-pseudohalide metathesis catalysts. Initiation efficiency can be increased further by the use of 3-bromopyridine in place of pyridine (69).

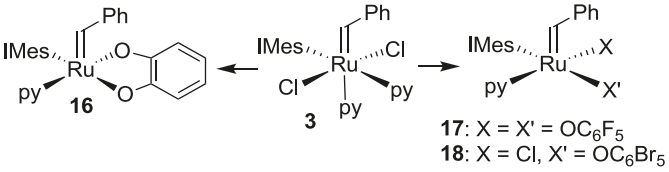


Fig. 2. Activity and (bottom) tunable selectivity in RCM of representative substrates by aryloxide catalysts; yields quantitative unless otherwise indicated.

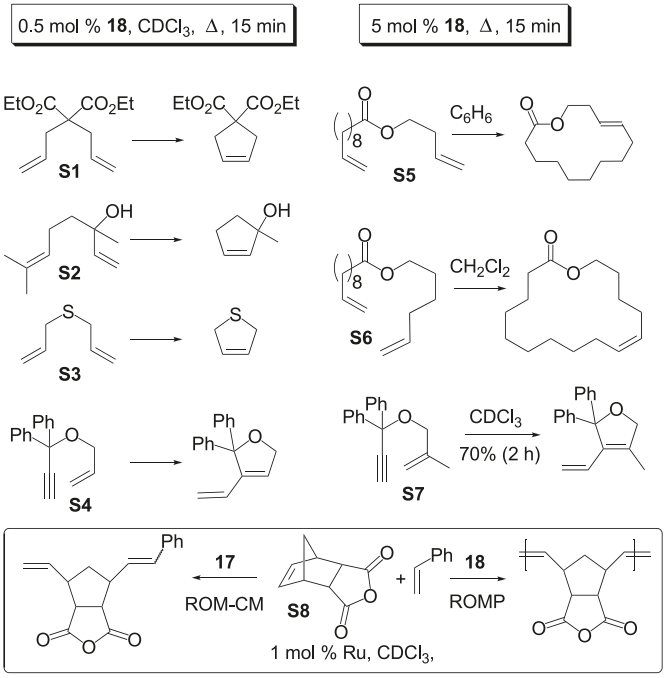
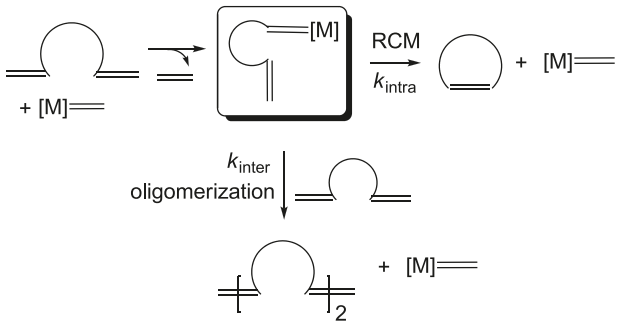


RCM assembly of five- and six-membered rings from unhindered α,ω-dienes is typically straightforward, presuming a conventionally competent catalyst and barring electronic deactivation or poisoning effects. The low ring strain, high probability of chain-end encounter, and high translational entropy of these small molecules combine to favour intramolecular RCM over intermolecular oligomerization, even in the absence of any additional conformational constraints. Construction of larger rings, while of compelling interest (72, 73), is more challenging. The challenge originates in competing oligomerization, as indeed noted in Villemin's original report of macrocycle RCM, which described successful cyclization at 6 mmol/L but polymerization at 15 mmol/L (74).

High dilutions have long been used to create a kinetic bias toward intramolecular cyclization of bifunctional molecules in irreversible, stoichiometric reactions (75). In context of metathesis, concentration effects remain important for the thermodynamic reasons discussed below, but the kinetic effects are less straightforward because the initial reaction be-

© 2008 NRC Canada

Scheme 6. Standard view of competing cyclization and oligomerization manifolds in metathesis.



tween substrate and catalyst is necessarily bimolecular (Scheme 6). Elevated temperatures or prolonged reaction times are generally required to compensate for the unfavourable effect of dilution on the rate of this initial reaction (76), but higher catalyst decomposition rates under such conditions can limit yields. Adding both substrate and catalyst dropwise can aid in minimizing oligomerization while inhibiting catalyst decomposition. Surprisingly, this protocol — common in "early" RCM reactions involving **1** — is now little used. In RCM reactions involving **2**, for example, solutions of substrate and catalyst are typically subjected to thermolysis at some arbitrarily high dilution, and further doses of catalyst are added when reaction appears to have stalled. The limitations of this approach will become clear shortly.

In applying the dropwise addition protocol to RCM assembly of conformationally unbiased large and medium-sized rings (initially in macrolactonization studies), we were struck by the high efficiency of RCM via **18**, relative to second- and third-generation Grubbs catalysts. Closer examination of this behaviour uncovered an unexpected pathway for cyclization (Scheme 7 (71)).

While **18** effects quantitative macrolactonization of dienes such as **S6** within 15 minutes (Figs. 2 and 3*a*), the major species produced by **2** or **3** at the same stage are the oligomers, despite net dilutions much lower than 5 mmol/L. Importantly, however, cyclization is near-quantitative if the reaction is allowed to evolve (9 h for **2**; 1 h for **3**). Ethenolysis of the oligomers cannot contribute to this convergence on the lactone products beyond the initial stages of reaction, given the low solubility of ethylene in organic solvents (77) and the effectiveness of its removal under normal conditions of metathesis, as applied here (open vessel, reflux, N_2 or Ar atmosphere). In the absence of ethylene, liberation of cyclic products can only occur by backbiting RCM (BRCM), in an intramolecular metathesis step directly analogous to that required for direct RCM.

These observations have several important implications. First, observation of oligomers under the high-dilution conditions designed to minimize their formation indicates that the chloride catalysts **2** and **3** have a strong kinetic bias toward intermolecular reaction (i.e, in the context presented in Scheme 6, $k_{inter} >> k_{intra}$). Secondly, the fact that the oligomers convert directly into the RCM product rather than through back-reaction with ethylene indicates that these species are not inimical to RCM, as has been generally as-

Scheme 7. Oligomerization-backbiting mechanism for RCM (71). Ethylene-evolving reactions shown as irreversible. Only dimeric oligomers shown; larger oligomers form similarly. Backbiting RCM (BRCM) at a remote olefinic site can liberate cyclodimers and (or) cyclooligomers.

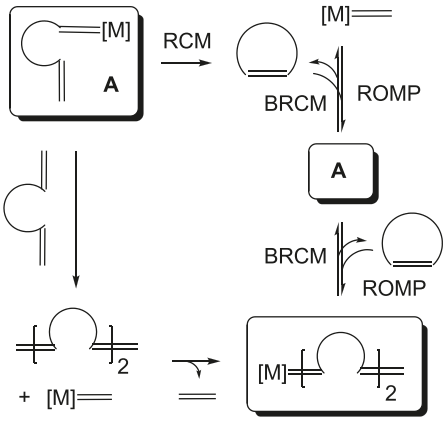


Fig. 3. RCM of **S6** via (*a*) **18** and (*b*) **2**. Dashed lines: disappearance of **S6**; solid lines: appearance of product; dotted lines: oligomers. Conditions: dropwise addition of both **S6** and Ru catalyst; [**S6**] « 5 mmol/L.

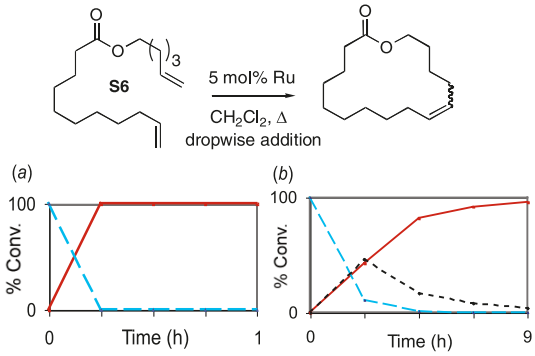

sumed. Rather than being the hallmark of a failed reaction, the oligomers are in fact precursors to the desired RCM target. This underscores the importance of understanding the factors that favour backbiting and hence liberation of the RCM products.

As it happens, these factors are already well understood. Formation and disappearance of oligomers occurs via a polymerization–cyclodepolymerization mechanism long recognized in ROMP chemistry (78), though little considered in context of RCM. Once diene consumption is complete and the methylidene endgroup is installed, we are dealing with a classic ring-chain equilibrium, shown in simplified form in eqn. [1].

Unless catalyst deactivation arrests the process, RCM yields are determined by the relevant equilibrium constant. The concentration-dependence of K_{eq} for such equilibria is also well-established: Jacobson–Stockmayer theory states that oligomeric–polymeric chains are favoured at high concentration and that cyclics are favoured at high dilution (79). By manipulating concentration, therefore, the ring-chain equilibrium can be biased in favour of either cyclic or polymeric products. Dilution is also the key to product selectiv-

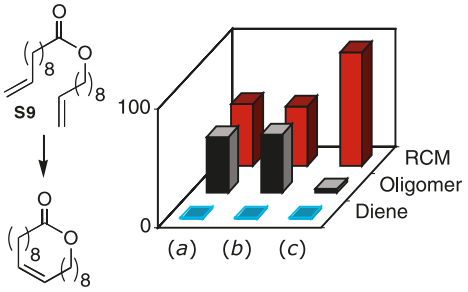
[1] 
ity, i.e., liberation of the smallest cyclic species (the RCM targets) in preference to cyclooligomers resulting from backbiting at a remote site. The formation of progressively smaller cyclic species is favoured with increasing dilution because the higher translational entropy of the smaller molecules is expressed more strongly as viscosity decreases.

Consistent with this analysis, we observe oligomers as the dominant species at high concentrations (100 mmol/L diene) and the target macrocycles at high dilutions (≤5 mmol/L). At intermediate concentrations, mixtures are obtained. Product distributions can thus be reliably manipulated by altering the concentration, providing that catalyst deactivation does not interfere. Figure 4 shows an example: metathesis of **S9** via **3** at 5 mmol/L results in a 50:50 distribution of oligomer and RCM product at equilibrium (3 h), all diene having been completely consumed. Dosing with fresh **3** at this point does not increase the RCM yield, indicating that the system is indeed at equilibrium. If instead we simply dilute, the yield of RCM product increases to 96%.

In synthesis of medium-sized rings, the thermodynamics of cyclization are adversely affected by the presence of higher ring strain (i.e., increased enthalpic costs) and the smaller difference in translational entropy between cyclomonomer and cyclodimer, cyclotrimer, etc. (i.e., reduced entropic discrimination). Higher dilutions are therefore necessary. Effective molarity (EM) values are useful in predicting the probability of cyclization and the relative dilutions required.[2] Mandolini and Illuminati and co-workers have tabulated values for a range of compounds, including saturated lactones of up to 30 members, as well as catechol and malonate derivatives (80, 81). EM values of 20-30 mmol/L for the saturated macrolactones (14–20 membered rings) compare with values of over 10^6 for the five-membered malonate, vs. ca. 0.6 mmol/L for eight-membered hexalactone (80). We examined RCM of diene substrates roughly corresponding to these saturated species, for which the EM values span six orders of magnitude. As expected, a very wide range of concentrations is required to favour RCM: malonate **S1** can be cyclized at 100 mmol/L, vs. 5 mmol/L for macrolactone **S6**, and 0.5 mmol/L for the unsaturated seven- and ten-membered lactones. The corresponding eight-membered lactone is not formed even at concentrations below 0.5 mmol/L. Formation of such strained products is inhibited not merely by the kinetic and thermodynamic bias toward lower-strain cyclodimers but also by the slow rate of metathesis at very high dilutions, which enables competing catalyst decomposition. Even for those ring sizes that can be attained in good yields, the solvent costs associated with dilution become increasingly untenable (particularly for industrial applications) as the effective molarity of the substrate declines.

Fig. 4. RCM of **S9** using catalyst **3**. (*a*) Equilibrium yield at 3 h, (*b*) RCM yield following addition of fresh **3** and re-equilibrating, and (*c*) RCM yield following dilution and re-equilibration. Initial conditions: CH_2Cl_2, reflux, 5 mmol/L substrate (batchwise addition), 5 mol% Ru.



These issues notwithstanding, the insights above are important in revising our understanding of the "problem" of competing oligomerization in challenging RCM reactions. Oligomers have overwhelmingly been regarded as inimical, rather than intrinsic to formation of ring-closed products. This is evidently a false premise. The experiments with **2** and related catalysts outlined above show that under dilutions compatible with efficient metathesis, the dominant route to conformationally flexible RCM products is a concentration-dependent oligomerization–backbiting pathway. An important implication is that some of the "failed" RCM reactions reported in the literature may be less difficult than they initially appeared. Frequently, researchers respond to the observation of oligomerization by abandoning the reaction, or in some cases, adding more catalyst. The former course of action amounts to discarding an essential, valuable intermediate, the latter, to discarding the catalyst itself. Adding further catalyst cannot improve RCM yields if the reaction is not at an appropriately high dilution.

The foregoing offers some practical guidelines for maximizing BRCM, and hence RCM yields, for reactions in which oligomerization is recognized. An important issue, which we defer to a later paper, is how oligomerization is detected. NMR analysis is often misleading, GC or LC quantification require compilation of calibration curves for sometimes precious starting materials and products, while GC does not reveal the oligomers, and LC can be time-consuming. Also of interest is the strong bias of the aryloxide catalysts toward RCM, as shown for **18** vs. **3** in Fig. 4*b*. It is as yet unclear whether this reflects faster backbiting, or an intrinsic bias toward intramolecular reaction. A thermodynamic influence of the catalyst can be anticipated from its participation in the ring-chain equilibrium (that is, the thermodynamic EM value in RCM is not due to the diene alone, but is a function of the substrate-catalyst pair). The RCM bias of **18** we initially rationalized in terms of the

[2] Most reported EM data are the kinetic (EM_k) values, rather than the thermodynamic (EM_K) values of most relevance in the present, equilibrium systems. As the two tend to track together, the EM_k trend is nonetheless often useful, though discrepancies emerge for 7- and 10-membered lactones (80). Definitions: EM_k = the concentration at which $k_{intra}/k_{inter} = 1$ (where k_{intra} and k_{inter} are the rate constants for the intramolecular and intermolecular reactions, respectively). Likewise, $EM_K = K_{intra}/K_{inter}$. It should be noted that reported values typically refer to saturated ring structures formed from bifunctional substrates and do not take into account the effect of the metal endgroup on ring strain.

steric influence of the aryloxide ligand vs. chloride, which we envisaged as inducing buckling of the pendant oligomer chain. We have now abandoned this hypothesis, as the sterically restrained catecholate catalysts likewise exhibit a kinetic preference for RCM. The effect is therefore clearly electronic, and we are now undertaking a computational exploration of the factors involved. More generally, the unexpected discovery of this "back-door" route to RCM products brings out a new element of selectivity. We had originally conceived of our catalyst design approach as a way of modulating stereoselectivity, in particular *E/Z* ratios, and ultimately asymmetric induction. While these studies continue with chiral catalysts now in hand, their scope has expanded to include the consequences for selectivity of driving the reaction manifold through direct RCM, vs. the oligomerization-backbiting pathway. Finally, the convergence of the Grubbs-class catalysts on the $RuCl_2(L)(=CHR)$ intermediate (e.g. **12**, L = NHC) underscores the importance of utilizing the anionic sites, as well as the neutral L-donor ligand, to expand the tunability and diversity of catalyst structures. This will undoubtedly lead to new advances in selectivity and EM modulation, and to further improvements in catalyst lifetime.

Summary

Development of sustainable chemical practices is a collective effort, requiring the talents and expertise of a diverse scientific, technical, and business community. Homogeneous catalytic methodologies have much to contribute to this enterprise. In the overview above, I hope to have shown how a largely inorganic perspective on tandem catalysis and olefin metathesis — two technologies of keen relevance to green chemistry initiatives — has helped to expand the scope of these methodologies and to open up new areas of opportunity.

Acknowledgements

I thank the Inorganic Division of the CSC for this award recognizing early career achievement, and Mike Strem and Strem Chemicals for their generosity in funding it. I am grateful to Natural Sciences and Engineering Research Council of Canada (NSERC) for Discovery, Strategic, and Accelerator grants, to the Canada Foundation for Innovation (CFI), and Ontario Innovation Trust (OIT) for enabling infrastructure, and the Ontario government for a Premier's Research Excellence Award. Ottawa provided me with a wonderfully stimulating environment to establish my research program. In particular, I thank Tito Scaiano, Howard Alper, David Bishop, and Christian Detellier for their friendship and the example they set in a multitude of contexts; Dr. Glenn Facey of our NMR Facility for his unfailing expertise and humour; and Dr. Sander Mommers, Dr. Henry Stronks (Bruker), and Mr. Tom Dobbins (MBraun) for their generous support for our anaerobic MALDI facility. I am grateful to my many inorganic friends and colleagues in Canada and abroad for friendship and inspiration: especially, I thank my collaborators Eduardo dos Santos and José Antonio Mayoral, for stimulating and educational discussions. Most importantly, I thank the past and present members of my research group for their enthusiasm, insight, and effort; the work above is that of Dino Amoroso, Fojan Zamanian, Samantha Drouin, Jennifer Snelgrove, Jay Conrad, Henrietta Parnas, Sebastien Monfette, Johanna Blacquiere, Ken Camm, Nicholas Beach, Heather Foucault, Maeve Moriarty, Matt Kotyk, Ureshini Dharmasena, Yuwen Liu, Nemesio Castro, Pawel Czechura, and Mel Eelman. I am profoundly grateful to them and to my other co-workers who contributed to other work not described. I am honoured to share this award with them.

Vibrational spectroscopic characterization of some environmentally important organoarsenicals — A guide for understanding the nature of their surface complexes

Scott Cowen, Megha Duggal, Tuan Hoang, and Hind A. Al-Abadleh

Abstract: Organoarsenicals are found in the environment from the biomethylation of inorganic arsenic compounds and from anthropogenic sources. It is clear that organoarsenicals pose a health and an environmental risk due to their potential cycling to the most toxic forms of arsenic as a result of redox activity in soils and natural waters. The environmental fate of arsenic compounds depends to a large extent on the surface interactions with geosorbents, mainly minerals and organic matter. Hence, elucidating the nature of surface complexes is important in understanding binding mechanisms and thermodynamics. In this paper, we report the vibrational spectra of a number of organoarsenicals in the aqueous and solid phases using attenuated total internal reflectance Fourier transform infrared (ATR-FTIR), transmission FTIR, and Raman spectroscopies. Analysis of the aqueous phase spectra revealed that for completely deprotonated anions, increasing the organic substituents on the AsO_x moiety results in increasing the frequency of $\nu(AsO_x)$, whereas the opposite trend is observed for completely protonated molecules. Analysis of solid phase spectra showed that incorporation of water molecules in the crystalline structure and extensive hydrogen bonding with neighboring molecules significantly affect As–O bond lengths and hence frequencies of $\nu(AsO_x)$. Results are discussed in the context of identifying geometry of organoarsenicals surface complexes in situ using the ATR-FTIR technique.

Key words: ATR-FTIR, organoarsenicals; oxyanion adsorption, arsenate, in situ spectroscopy.

Résumé : On retrouve des dérivés organiques de l'arsenic dans l'environnement qui résultent de la biométhylation des composés inorganiques de l'arsenic ainsi que de sources anthropogéniques. Il est clair que ces dérivés de l'arsenic posent un risque à la santé et à l'environnement en raison de la possibilité qu'ils soient recyclés en formes plus toxiques de l'arsenic à la suite d'activités redox dans les sols et les eaux naturelles. Le sort environnemental des composés de l'arsenic dépend en grande partie des interactions de surface avec les géosorbants, particulièrement les minéraux et les matières organiques. Il est donc important d'élucider la nature des complexes de surface pour comprendre les mécanismes de liaison et leur thermodynamique. Dans ce travail, faisant appel à la spectroscopie infrarouge à transformée de Fourier en transmission et à la spectroscopie infrarouge à transformée de Fourier et à réflexion totale atténuée (IRTF-RAT), on a déterminer les spectres vibrationnels d'un certain nombre de dérivés organiques de l'arsenic dans des solutions aqueuses et en phases solides. L'analyse des spectres en phase aqueuse révèle que, pour des anions complètement déprotonés, une augmentation de substituants organiques sur la portion AsO_x provoque une augmentation de la fréquence de $\nu(AsO_x)$ alors qu'on observe la tendance inverse pour les molécules complètement protonées. L'analyse des spectres en phase solide a montré que l'incorporation de molécules d'eau dans la structure cristalline et le réseau étendue de liaisons hydrogènes avec les molécules adjacentes affecte d'une façon importante les longueurs des liaisons As–O et, en conséquence, les $\nu(AsO_x)$. On discute des résultats dans le contexte de l'identification de la géométrie des composés organiques de l'arsenic des complexes de surface in situ à l'aide de la technique IRTF-RAT.

Mots-clés : IRTF-RAT, dérivés organiques de l'arsenic, adsorption d'oxyanions, arsenate, spectroscopie in situ.

Introduction

Arsenic (As) contamination of soils, surface, and groundwater is a serious problem in many parts of the world, including North America (1). Sources of this pollution can either be natural from the weathering of arsenic-containing minerals or anthropogenic from industrial effluents of the petrochemical and coal industries (2–4), tailings of abandoned and recent gold mining operations (1), wood preservative facilities (5), use of arsenical herbicides (5), and poultry industry (6). People near geological and industrial sources of arsenic pollution are exposed to high concentrations of As and hence prone to developing chronic diseases, including cancer (5, 7). This is why arsenic and its compounds are listed on the pollutant priority lists of the Canadian Environmental Protection Act (CEPA) and the US EPA. The current Canadian maximum acceptable limit of total arsenic in drinking water is 25 ppb (8), while that of the US EPA is 10 ppb (9).

Arsenic speciation in environmental samples have identified four major classes of compounds: inorganic As, aliphatic organic As, aromatic As, and arsenosugars (5). The most common organoarsenical species contain arsenic in the oxidation states of +III and +V. In general, trivalent organoarsenical compounds are more toxic and mobile than the pentavalent compounds (7, 10–12). Table 1 lists the chemical formula, structure, and pK_a of organoarsenicals identified in environmental samples. *Methylated arsenic* compounds such as the sodium salts of monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA) are used as herbicides (5) and are also produced in biomethylation processes of inorganic As (iAs) that occur under aerobic and anaerobic conditions (13, 14). On the other hand, *aromatic organoarsenical* compounds such as *p*-arsanilic acid (4-aminobenzenearsenic acid, *p*-AsA), and Roxarsone (4-hydroxy-3-nitrobenzenearsenic acid) are used as feed additives in the U.S. poultry industry (6) and are introduced into the environment through disposal and land application of contaminated poultry litter (see references in (15)). The biogeochemical transformation of these compounds in soils is a result of enhanced microbial activity and (or) exposure to UV radiation and leads to the formation of the more toxic trivalent forms of MMA, DMA, and eventually iAs species through a series of volatilization and mineralization reactions (16, 17). It is clear that As(V) associated with organoarsenicals pose a health and an environmental risk due to its potential cycling to As(III) as a result of redox activity in soils and natural waters.

Determining the mobility and chemical speciation of arsenic compounds is often used to assess their overall environmental impact (1, 14). These properties depend to a large extent on their surface interactions with geosorbents, mainly minerals and organic matter (1, 18, 19). Several bulk and surface-sensitive techniques are employed to quantify binding thermodynamics and elucidate the structure of surface complexes which include inductively coupled plasma mass spectrometry (ICP-MS) (20), and in situ near edge synchrotron X-ray based and total internal reflectance IR spectroscopic techniques, respectively, (19). In particular, ATR-FTIR spectroscopy has proven to be a very useful technique for studying surface interaction of arsenic compounds on a number of metal oxide surfaces using solution concentrations as low as 1 μmol/L (19, 21). Using ATR-FTIR for adsorption experiments of oxyanions in general, factors such as the degree of protonation, the presence of organic substituents, and binding to surfaces that affect the overall spectral features could be observed experimentally. To aid in the interpretation of spectra collected in the presence of the metal oxide coating on the ATR internal reflection element (IRE), spectra are often collected for standards of oxyanions including solids with known crystal structure and aqueous solutions of known pH. While there is a relatively large number of published articles on the interpretation of IR spectra of iAs(V) and iAs(III) in different bulk phases (19, 22–24), there are no systematic ATR-FTIR studies on standard organoarsenical

compounds that could be used as a guide for adsorption studies of these compounds.

In this work, we report the vibrational spectra of MMA(V), DMA(V), and *p*-AsA in the aqueous and solid phases using ATR-FTIR, transmission FTIR, and Raman spectroscopies. Spectra of standard aqueous solutions were collected at different pH values above and below the pK_a of these compounds such that the effect of protonation on spectral features could be investigated. These spectra were compared to those collected for iAs(V) to study the effect of organic substituents on the vibrational spectra of the arsenate ion. The results are discussed in the context of geometry identification of adsorbed organoarsenicals using ATR-FTIR.

Experimental

Chemicals

All chemicals were used as received without further purification: MMA-1 (monosodium acid methane arsonate sesquihydrate, $CH_3AsO_3HNa{\cdot}1.5H_2O$, 99%, Chem Service), MMA-2 (disodium methyl arsonate hexahydrate, $CH_3AsO_3Na_2{\cdot}6H_2O$, 98%, Chem Service), DMA-1 (dimethylarsinic acid, $C_2H_6AsO_2H$, 98%, Sigma-Aldrich), DMA-2 (cacodylic acid sodium salt trihydrate, $C_2H_6AsO_2Na{\cdot}3H_2O$, Alfa Aesar), *p*-AsA (*p*-arsanilic acid, $C_6H_8NO_3As$, 99%, Sigma-Aldrich), and iAs (sodium arsenate, $AsO_4HNa_2{\cdot}7H_2O$, ACS reagent, J.T. Baker). Stock solutions in millipore water (18.2 MΩ) were prepared by dissolving the crystalline material in concentrated NaOH (EMD, ACS grade) with continuous mechanical stirring, and then lowering the pH using HCl (Ricca Chemical, 6 N). *Caution: The aforementioned organoarsenicals are highly toxic via inhalation and skin contact and are carcinogens.* The ionic strength of these solutions was adjusted to 0.01 mol/L KCl. Exact concentrations are provided in the figure captions.

ATR-FTIR experiments

ATR-FTIR spectra were collected using a HATRPlus accessory (Pike Technologies) installed in a Nicolet 8700 FTIR spectrometer (Thermo Instruments) equipped with a purge gas generator and a liquid N_2-cooled MCT-A detector. The HATR flow cell houses a 45° Ge crystal as the IRE (trapezoid, 80 mm × 10 mm × 4 mm). All single beam spectra were collected at 4 cm^{-1} resolution by averaging 300 scans. Absorbance spectra were obtained by referencing single beam spectra of the sample to that collected for the 0.01 mol/L KCl solution held at the same pH of the sample. Subtraction factors were varied between 0.95 and 1 to avoid baseline correction of the resulting absorbance spectra. The ATR-FTIR measurement of each solution was repeated for at least three times to ensure reproducibility. Absorbance of most intense bands is within experimental error (±5%) and band locations are ±2 cm^{-1}.

Transmission FTIR experiments

IR absorption spectra of solid organoarsenicals were obtained from KBr pellets prepared using the Quick Press kit (International Crystal Laboratories). Sample concentrations ranged from 2% to 10% in potassium bromide (SpectroGrade™). Single beam spectra were collected in the transmission mode using the aforementioned FTIR spectrometer at 4 cm^{-1} resolution by averaging 250 scans. Single beam spectra of plain KBr pellets were used as the background to generate absorbance spectra. Similar to ATR-FTIR measurements, a number of spectra for each chemical was acquired to ensure reproducibility. Variation of band intensities for nearly the same sample concentrations is within 10% and band locations are ±2 cm^{-1}.

Raman spectroscopy experiments

The Raman spectra of solid organoarsenicals contained in a glass vial were recorded using an integrated fiber optic Raman spectrometer R-3000 QE (Ocean Optics) equipped with 785 nm diode laser and CCD array. Spectra were collected using a laser power in the range 150–200 mW at 6 cm^{-1} resolution and 60–100 s integration time. Multiple spectra collected for the same sample on different days were reproducible in peak position, band shape, and ratio of band intensities obtained from selected peaks in a given spectrum.

Results and discussion

Solution phase speciation of organoarsenicals using ATR-FTIR

Figure 1 shows the ATR-FTIR spectra of aqueous (*a*) iAs(V), (*b*) MMA, (*c*) *p*-AsA, and (*d*) DMA, respectively, in the spectral range of 650–1100 cm^{-1}. These spectra are shown in the order of increasing organic substituents on the arsenate group. For each compound, spectra were recorded at different pH values, which affect the degree of protonation and hence distribution of species in the solution phase governed by the pK_a of these molecules (see Table 1). While the ATR-FTIR spectra of iAs(V) have been measured by a number of researchers (22, 25, 26), the spectrum shown in Fig. 1 for iAs(V) at pH 1.5 and those for the organoarsenicals studied herein are the first ATR-FTIR spectra to be reported at known pH values. Changes in molecular symmetry of these compounds due to changes in protonation state and the presence of organic substituents dictate the number of observed resolved spectral components. Vibrational analysis and the derivation of symmetry point group and coordinates have been summarized by Myneni et al. (22) for iAs(V), and were reported for MMA and DMA by Herman and co-workers (27, 28). The symmetry point group of aqueous phase species dominant at each pH is shown in Table 2 except for *p*-AsA given that it is the least symmetric among the molecules studied.

The spectral range shown in Fig. 1 (650–1100 cm^{-1}) contains the stretching vibrations of the (-AsO_x) moiety in the molecules. Table 2 lists the assignment of the observed frequencies of AsO_x stretching vibrations in the bulk phases of arsenic(V)-containing compounds used in our studies, which are in agreement with previously published values. In general, fully deprotonated arsenate anion AsO_4^{3-} had T_d symmetry and exhibits symmetric (ν_s, singly degenerate) and asymmetric (ν_{as}, triply degenerate) stretching vibrations. The polarization characteristics of these bands led to assigning the lower frequency value to ν_{as}, which is a behavior also seen for completely deprotonated MMA (28, 29). As discussed by Myneni et al. (22), species with lower symmetry

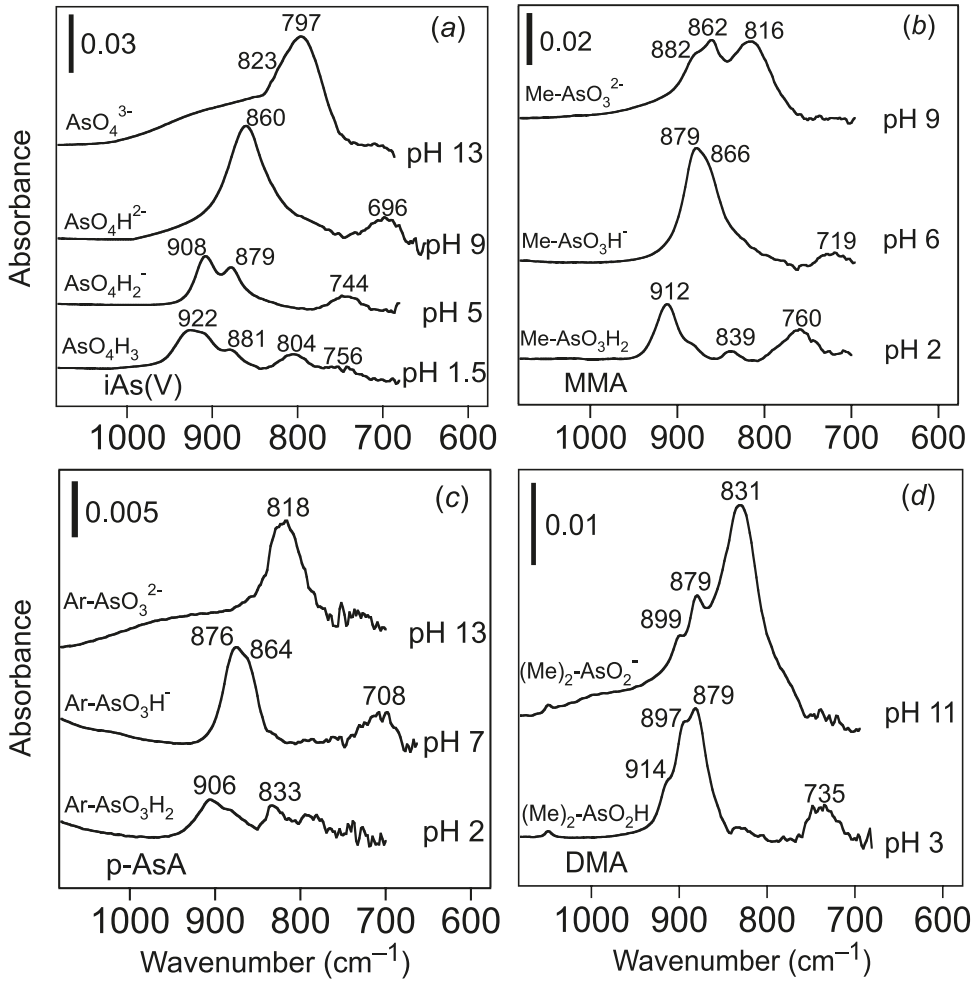
Fig. 1. ATR-FTIR spectra of aqueous arsenic(V)-containing compounds as a function of pH. (*a*) 0.2 mol/L iAs(V), (*b*) 0.2 mol/L MMA, (*c*) *p*-AsA (0.06 mol/L for pH 13 and 7 and 0.025 mol/L for pH 2), and (*d*) 0.2 mol/L DMA. The ionic strength of the solution is 0.01 mol/L (KCl). Based on the pK_a values of each compound shown in Table 1, the dominant species at each pH are shown next to the corresponding spectrum. Notes: Ar- = $H_2NC_6H_4$– and Me- = CH_3–.



than T_d exhibit energy shifts in ν_s and splitting of ν_{as}, which are influenced by a number of factors including extensive hydrogen bonding and complexation to cations, such as protons and metals. Myneni et al. (22) also emphasized that low symmetry species may not result in enough splitting to be identified in the spectra, and similarly the presence of all $\nu(AsO_x)$ peaks may not exclude high symmetry species.

The spectrum shown in Fig. 1*a* for iAs(V) at pH 1.5 for fully protonated arsenic acid (H_3AsO_4, C_{3v} symmetry) has not been measured before using an ATR accessory because of the instability of ZnSe ATR crystals used in previous studies. Our measurement herein was possible using a Ge ATR crystal, which is stable in solution with pH values between 1 and 14. There are four bands observed in the $\nu(AsO_x)$ spectral region at 922, 881, 804, and 756 cm^{-1}, which are in agreement with the Raman bands reported by Vansant et al. (29) for H_3AsO_4 aqueous solutions. Moreover, shown in Fig. 1*c* are the spectra of *p*-AsA(aq) at pH 3, 7, and 13, which were measured at higher concentrations than our previous work (15). Relatively weak intensity bands were easily observed given that the IRE used in this study results in a higher penetration depth and number of reflections, and hence higher effective pathlength compared to ZnSe. For example, the bands at 708 cm^{-1} (pH 7) and 833 cm^{-1} (pH 2) for *p*-AsA are well defined and they correlate very well with those observed for aqueous MMA at pH 6 and 2, respectively. Hence, given that both *p*-AsA and MMA are monosubstituted arsonic acids, we assigned the former band at 708 cm^{-1} to ν(AsOH) and the 833 cm^{-1} to $\nu_s(AsO_x)$. There were no bands observed for *p*-AsA below 800 cm^{-1} at pH 2, most likely due to the weak intensity of that component at the concentration used (0.025 mol/L). Higher concentrations of *p*-AsA at acidic pH were observed to form precipitates and could not be used for ATR-FTIR measurements.

Moreover, the spectra of methylated arsenical compounds exhibit features due to rocking vibrations of methyl groups, $\rho(CH_3)$, in the spectral range of 650–1100 cm^{-1}. For example, the spectral feature at 862 cm^{-1} in the ATR-FTIR spectrum of aqueous $CH_3AsO_3^{2-}$ (C_{3v} symmetry) at pH 9 is assigned to $\rho(CH_3)$, which is close to the frequency reported by Vasant et al. (28) at 854 cm^{-1}. This vibration occurs as a shoulder at 875 cm^{-1} for fully protonated aqueous $CH_3AsO(OH)_2$ (C_s symmetry) (28), which could explain the

component visible at pH 2 in Fig. 1*b* giving rise to an asymmetrical band centered at 912 cm^{-1}. However, $\rho(CH_3)$ vibration is overshadowed by the intense $\nu(AsO_x)$ at pH 6 and hence not observed in the spectrum. For comparison, $\rho(CH_3)$ for completely deprotonated methylphosphonic acid, $CH_3PO_3^{2-}$, occurs as a very weak feature at 880 cm^{-1} (30). The difference in frequency values could be explained in light of the effect that the different masses of arsenic and phosphorus have on their bonding to carbon, giving rise to lower ν(C-As) than ν(C-P) (683 cm^{-1} vs 750 cm^{-1}). As for aqueous DMA, features assigned to $\rho(CH_3)$ occur at higher frequencies compared to MMA. The features observed at 914 and 897 cm^{-1} in the spectrum of aqueous $(CH_3)_2AsO(OH)$ at pH 3 (C_s symmetry, Fig. 1*d*) have been assigned to $\rho(CH_3)$ (27, 31). Hence, by analogy, we assign the medium intensity features at 899 and 879 cm^{-1} to $\rho(CH_3)$ in aqueous $(CH_3)_2AsO_2^-$ at pH 11 (C_{2v} symmetry). This assignment is based on their medium intensity profile relative to $\nu(AsO_x)$ and the trend observed for the frequency of $\rho(CH_3)$ in MMA species that the frequency of the $\rho(CH_3)$ vibration occurs at a lower value for deprotonated versus acidic species.

Examination of Fig. 1 and Table 2 for all compounds investigated herein reveals two distinct trends that may aid in the interpretation of IR spectra recorded for the adsorbed phase of these compounds. It could be observed that for a given molecule, decreasing the pH (i.e., increasing protonation state of solution phase species) results in shifting the frequency of $\nu(AsO_x)$ bands to higher values, decreasing their intensity, and emerging of bands assigned to ν(AsOH) groups. This observation has been attributed to an increase in the force constant of As–O and As–OH bonds with increasing proton concentration on the AsO_x moiety, which is consistent with the structural analysis of Gründler et al. (32) who attributed the aforementioned trends to changes in the mesomeric (i.e., resonance) effect between AsO_x bonds upon protonation. Deprotonated oxygen atoms participate in multiple bonding, whereas As–OH and As–C bonds do not participate in that process (32). Similar findings were reported for other oxyanions such as phosphates, sulfates, and selenate (22).

It could also be observed from Fig. 1 and Table 2 that for the completely deprotonated anions, increasing the organic substituents on the AsO_x moiety results in increasing the frequency of $\nu(AsO_x)$. For instance, for completely deprotonated anions, $\nu(AsO_x)$ increases in this order, AsO_4^{3-} (T_d: 823, 797 cm^{-1}) < $CH_3AsO_3^{2-}$ (C_{3v}: 882, 816 cm^{-1}) ≈ $H_2NC_6H_4AsO_3^{2-}$ (818 cm^{-1}) < $(CH_3)_2AsO_2^-$ (C_{2v}: 831 cm^{-1}). The effect of methyl substituents on AsO force constant and bond order was calculated by Gründler et al. (32), who found that for the fully deprotonated anions, the force constant and bond order increases in this order, AsO_4^{3-} < $CH_3AsO_3^{2-}$ < $(CH_3)_2AsO_2^-$. They attributed the increase in force constant to increasing AsO bond polarity and decreasing degree of multiple bonding upon oxygen substitution with carbon. Moreover, it could be concluded from the above order in $\nu(AsO_x)$ that the splitting of degenerate bands in organoarsenicals due to lower symmetry (e.g., completely deprotonated *p*-AsA and DMA) is not observed experimentally. Although one could use a routine curve fitting procedure to resolve the spectral components contributing to the observed bands, questions remain regarding the physical significance of the chosen number of components in the fitting and their assignment, whether they are due to splitting of degenerate bands or due to the presence of aqueous phase species of different symmetry groups.

Moreover, for completely protonated molecules, the trend in $\nu(AsO_x)$ is opposite to that observed for the completely deprotonated anions. Values of $\nu(AsO_x)$ decrease in this order, H_3AsO_4 (C_{3v}: 922, 881 cm^{-1}) > $CH_3AsO(OH)_2$ (C_s: 912, 839 cm^{-1}) ≈ $H_2NC_6H_4AsO(OH)_2$ (906, 833 cm^{-1}) > $(CH_3)_2AsO(OH)$ (C_s: 879 cm^{-1}). This trend may be explained by the fact that increasing organic substitution occurs at the expense of the number of As-OH in the molecule. Since both increasing organic substitution and As-OH concentration on the AsO_x moiety of the molecule result in increasing the force constant of As–O bonds, the number of As-OH groups seems to have a more profound effect on the force constant of As–O bonds than organic substitution. Myneni et al. (22) calculated As–O bond length for solvated arsenic acid, $H_3AsO_4(H_2O)_4$, to be 1.60 Å. Similar calculations were not performed for solvated MMA and DMA, $CH_3AsO(OH)_2$ and $(CH_3)_2AsO(OH)$, but Gründler et al. (32) calculated the AsO bond order for these isolated compounds and found them to be 1.23 and 1.18, respectively. As detailed below, the same trend is observed in solid organoarsenicals since these compounds form hydrogen bonding with water molecules in their crystal structure and with neighboring molecules.

Solid phase speciation of organoarsenicals

Figure 2 (panels *a* and *b*) shows the transmission FTIR and Raman spectra of the organoarsenicals used in our studies, respectively. The IR spectrum of solid iAs(V) is also shown for comparison. The Raman spectra shown in Fig. 2*b* for solid *p*-AsA and MMA-1 were not published previously. The Raman spectrum of DMA-1 was included in Fig. 2*b* for comparison with previously published work (27, 33). Raman spectra of MMA-2, DMA-2, and iAs(V) were collected as well (not shown here) and agree with the spectra published recently by Mosley et al. (33). The assignment of peaks observed for solid organoarsenicals is listed in Table 2.

Following the analytical approach of Myneni et al. (22), it is instructive when discussing the vibrational spectra of solids to recall AsO_x bond lengths from the crystal structure and make comparisons with similar species in the solution phase. For solid iAs(V), bond lengths are 1.66, 1.67, and 1.68 Å for As–O and 1.74 Å for As–OH (22), with a C_1 site symmetry of the $HAsO_4^{2-}$ group. It is clear from the IR spectrum shown in Fig. 2*a* for solid iAs(V) that the band assigned to $\nu(AsO_x)$ has more components than that recorded for aqueous $HAsO_4^{2-}$ (C_{3v} symmetry) at pH 9 (Fig. 1*a*). This observation is in contrast with the interpretation made by Myneni et al. (22), who concluded that the spectrum of solid $Na_2(HAsO_4)\cdot 7H_2O$ exhibits features similar to those of respective ions in aqueous solutions. Their conclusion was made despite the fact that the diffuse reflectance FTIR spectrum shown for solid $Na_2(HAsO_4)\cdot 7H_2O$ in their paper has a FWHM of the $\nu(AsO_x)$ band that exceeds that recorded for $HAsO_4^{2-}$ species at pH 9.1, which indicates more spectral components for the solid case consistent with lower site symmetry.

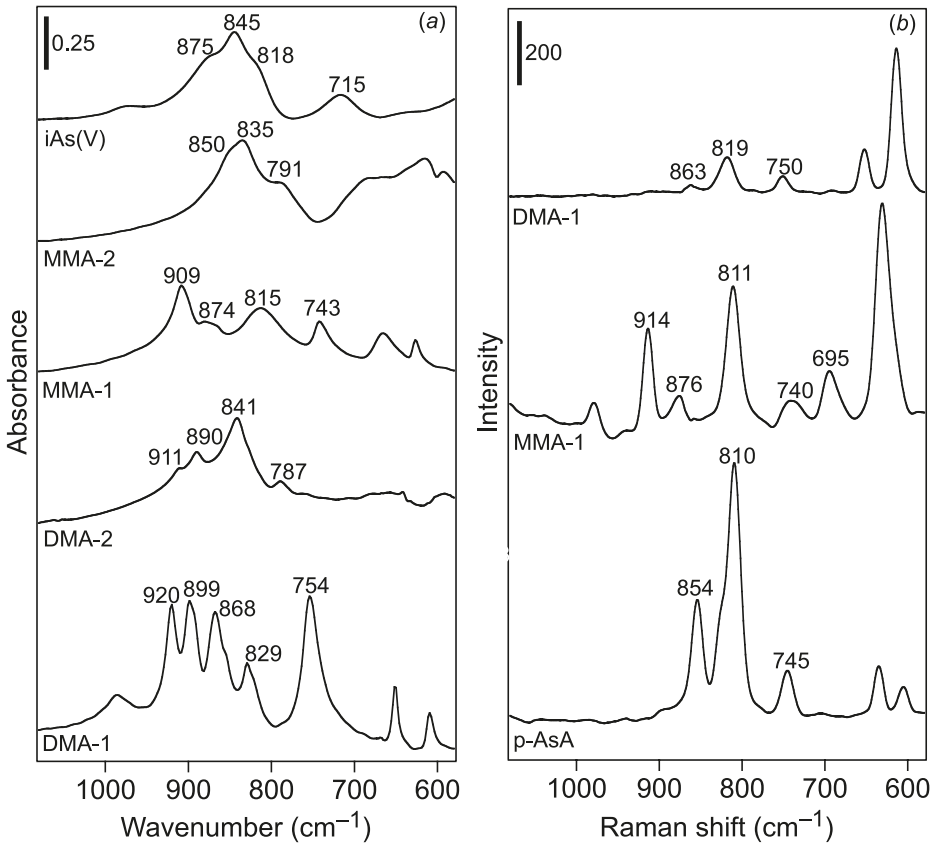
Fig. 2. (*a*) Transmission FTIR spectra of solid arsenic(V)-containing compounds in the form of KBr pellets. The concentrations in *w*/*w* are (from top): 9.5%, 5.3%, 2.0%, 4.6%, and 4.8% for iAs(V), MMA-2, MMA-1, DMA-2, and DMA-1, respectively. (*b*) Raman scattering spectra of solid DMA-1, MMA-1, and *p*-AsA (from top). Assignment of observed peaks is listed in Table 2.



Substitution of one oxygen with a methyl group, in the cases of MMA-1 and MMA-2s, did not significantly affect bond lengths in these molecules relative to iAs(V). Crystal structure of both compounds have not been determined previously, but As–O bond lengths were calculated by Vansant et al. (28) for $CH_3HAsO_3^-$ and $CH_3AsO_3^{2-}$ species to be 1.65 and 1.69 Å, respectively, and 1.71 Å for As–OH in the former species. The FTIR spectra of solid MMA-1 and MMA-2 differ from the aqueous phase spectra of $CH_3HAsO_3^-$ and $CH_3AsO_3^{2-}$ species in that bands assigned to $\nu(AsO_x)$ are lower in frequency for the solid materials than in solution. The same observation was found for solid $CH_3AsO(OH)_2$ compared with the same species in solution by Vasant et al. (27), who attributed it to the stronger hydrogen bonding network between neighboring acid molecules in the solid structure than hydrogen bonds with water molecules in solution. This explanation can be applied to spectral differences between solid and aqueous phase MMA-1 and MMA-2, since both salts contain water molecules in their crystal structure. Moreover, the presence of As-OH groups in solid MMA-1 gives rise to stretching vibration bands at 743 cm^{-1} in the FTIR spectrum, and at 740 and 695 cm^{-1} in the Raman spectrum, which are absent from the spectra of MMA-2. The apparent splitting in ν(As-OH) observed in the Raman spectrum is expected given that the As-OH and As-O^- groups in solid MMA-1 are perturbed by hydrogen bonding with water molecules in the crystalline structure. This analysis may also explain the asymmetrical shape of the band at 743 cm^{-1} in the FTIR spectrum of MMA-1, suggesting the presence of a low frequency component.

In addition, the intense bands at 909 and 914 cm^{-1} (Fig. 2) in the FTIR and Raman spectra of solid MMA-1, respectively, are found in the Raman spectrum of solid $NaH_2AsO_4 \cdot 2H_2O$ at 912 cm^{-1} and assigned for ν_{as}(As-O) (22). For comparison, similar bands at this frequency are observed for aqueous $H_2AsO_4^-$, and $CH_3AsO(OH)_2$, and fully protonated *p*-AsA at 908, 912, and 906 cm^{-1}, respectively. Hence, this spectral feature is associated with molecular species containing relatively high $As(OH)_n$ group concentration, particularly for $n \geq 2$. The fact that a similar feature is observed for solid MMA-1 suggests that -AsO^- moiety is involved in strong hydrogen bonding with neighboring water or MMA molecules. This analysis may explain the absence of this spectral feature from the FTIR spectra of aqueous $CH_3AsO_3H^-$ at pH 6 (Fig. 1*b*), $HAsO_3^{2-}$ at pH 9 (Fig. 1*a*), and solid MMA-2, where weak hydrogen bonding interactions exist with water molecules in solution and solid phases, respectively.

Figure 2*b* shows the measured Raman spectrum of solid *p*-AsA, which contains three well-defined bands at 854, 810, and 745 cm^{-1}. Spectral assignment of the observed bands is given in Table 2. The bands at 854 and 810 cm^{-1} are assigned to $\nu_{as}(AsO_x)$ and $\nu_s(AsO_x)$, respectively. There is also a component at ca. 826 cm^{-1} appearing as a shoulder of the intense band centered at 810 cm^{-1}. The FTIR spectrum of solid *p*-AsA was interpreted in our earlier publication in

© 2008 NRC Canada

light of its crystalline structure (15). Briefly, *p*-AsA molecules in the solid phase exist in a zwitterionic form (i.e., $NH_3^+C_6H_4AsO_2(OH)^-$) in which arsonic groups are involved in two H-bonds (34). Bond lengths in the arsonic group equal 1.66 and 1.67 Å for As–O and 1.74 Å for As–OH groups. Splitting in degenerate ν_{as} vibrations is clear in the Raman spectrum in Fig. 2*b*. It is interesting to note the absence of bands >900 cm^{-1} in the Raman spectrum of solid *p*-AsA as expected from that of MMA-1. However, weak intensity component is visible at ca. 914 cm^{-1} in the FTIR spectrum of *p*-AsA (15). This observation may be explained by the involvement of AsO bonds of *p*-AsA in multiple bonding giving rise to less than 900 cm^{-1} $\nu_{as}(AsO_x)$ vibrations. This observation also suggests that the molecular environment around the -AsO_3 moiety in both solid monosubstituted organoarsenicals, MMA-1 and *p*-AsA, is different most likely due to differences in the hydrogen bonding network in both crystalline structures.

Also shown in Fig. 2 are the FTIR spectra of DMA-1 and DMA-2, in addition to the Raman spectrum of DMA-1. The Raman spectrum of DMA-2 was collected (not shown) and is similar to the recently published one by Mosley et al. (33). Band assignment is provided in Table 2 and agrees very well with previously published values. The crystal structure of DMA-1 was described by Vasant et al. (27), where the unit cell contains two monomeric acid molecules held together by hydrogen bonding, R(OH···O) = 2.57 Å, with two As-O distances at 1.625 and 1.609 Å (35). The lower value of the IR frequency of $\nu(AsO_x)$ in solid DMA-1 (829 cm^{-1}, Fig. 2*a*) relative to aqueous $(CH_3)_2AsO(OH)$ (879 cm^{-1}, Fig. 1*d*) was attributed to stronger hydrogen bonding linking the molecules in the solid structure relative to that with water molecules in solution (27). The corresponding $\nu(AsO_x)$ band in the Raman spectrum of DMA-1 shown in Fig. 2*b* occurs at 819 cm^{-1}, which agrees with previous reports (27). Moreover, the presence of As-OH groups in solid DMA-1 gives rise to stretching vibration bands at 754 and 750 cm^{-1} in the FTIR and Raman spectra, respectively, which are close to the value observed for aqueous $(CH_3)_2AsO_2H$ at pH 3 (Fig. 1*d*). The bands at 868 and 863 cm^{-1} in the FTIR and Raman spectra of solid DMA-1, respectively, have been assigned to γ(OH) (27). The crystal structure of DMA-2 has not been reported, but by comparing the FTIR spectrum of solid DMA-2 (Fig. 2*a*) to that of $(CH_3)_2AsO_2^-$ at pH 11 (Fig. 1*d*), it could be concluded that the site symmetry of the -AsO_2^- group in solid DMA-2 is C_{2v}, similar to its symmetry in solution. Hence, the bands at 841 and 787 cm^{-1} in the FTIR spectrum of DMA-2 are assigned for $\nu_{as}(AsO_x)$ and $\nu_s(AsO_x)$, respectively.

Moreover, the spectral range shown in Fig. 2 contains features that arise from binding of As to organic substituents. Bands associated with As-C stretching vibrations in MMA-1 and MMA-2 occur below 650 cm^{-1} (28, 33), which are absent from the Raman spectra of different iAs(V) minerals (23, 24). Similar to MMA, the two spectral features observed in the Raman spectrum of *p*-AsA at 636 and 605 cm^{-1} are assigned to the As–C stretching vibrations. These features appear at 652 and 614 cm^{-1} for DMA-1, which agree with previous studies (27, 31, 33). Bands associated with ρ(CH_3) are only observed for DMA-1 at 899 and 920 cm^{-1} in Fig. 1*a*, which agree with previous work showing strong features at 891 and 913 cm^{-1} (27), and at ca. 900 and 922 cm^{-1} (31). For DMA-2, whose IR spectrum was not previously published, we assign the two bands at 911 and 890 cm^{-1} to ρ(CH_3), which are red shifted compared with the same features observed for DMA-1. This observation is consistent with the trend observed for these bands in solution for $(CH_3)_2AsO_2^-$ and $(CH_3)_2AsO_2H$ (vide supra). To summarize, while organic substituents did not result in significant change in As–O bond lengths in the solid phase of organoarsenicals compared to iAs(V), it is the incorporation of water molecules and extensive hydrogen bonding with neighboring molecules that significantly affect As–O bond lengths and hence frequencies of $\nu(AsO_x)$.

Implications for the surface complexation of organoarsenicals

Our studies reported herein summarize the factors (i.e., organic substitution on AsO_x moiety and hydrogen bonding) that influence the frequencies and splitting in degenerate bands assigned to $\nu(AsO_x)$ in organoarsenicals. Location of spectral components assigned to $\nu(AsO_x)$ are also sensitive to coordination to mineral surfaces, where arsenic(V)-containing molecules could form inner-sphere (i.e., direct bonding to surface metal cations) and (or) outer-sphere surface complexes (i.e., hydrogen bonding to hydroxyl groups on the surface or binding mediated by water molecules) (19). Myneni et al. (22) have summarized vibrational spectroscopic studies on the binding of iAs(V) to mineral surfaces, where the assignment of bands was aided by the analysis of the vibrational spectra of iAs(V) in aqueous and solid phases, and by X-ray absorption spectroscopy (XAS) results of arsenate adsorbed at the mineral-water interface. They concluded that the value of ν_s(As-OX), where X = metal, H^+, and H_2O, of all AsO_4 surface complexes shift to lower frequency values (≤820 cm^{-1}) relative to uncomplexed AsO_4, and for metal unprotonated-AsO_4 complexes (i.e., inner sphere), the shifts in As-OM (M = metal) vibrations are influenced only by the nature of complexing cation and the type of coordination, which will result in splitting the As-O degenerate vibrations and shifting As-OM modes.

Recently, we have reported the first ATR-FTIR investigation of *p*-AsA binding to Fe-(oxyhydr)oxides including α- and γ-Fe_2O_3 and α-FeOOH particles (15). Adsorption of *p*-AsA was carried out in situ and at equilibrium using solution concentrations in the range of 1 μmol/L–8 mmol/L at pH 7. We found that the spectra of adsorbed *p*-AsA were clearly distinguishable from that of aqueous *p*-AsA at pH 7 and that increasing solution concentration results in increasing the intensity of the resolved components indicating an increase in the surface coverage of *p*-AsA. Peaks <800 cm^{-1} were assigned to symmetric stretch (ν_s) of As-OFe and uncomplexed As-OH. Hydrogen bonded complexes were characterized by the peaks >837cm^{-1}, which could also arise from binding mediated by water molecules. Our data suggested the presence of either two types of *p*-AsA surface complexes including an inner-sphere monodentate and hydrogen bonded complexes *or* one type of surface complexes whose symmetry is much lower than aqueous *p*-AsA at pH 7.

While IR spectroscopy measurements of surface complexes are invaluable in providing structural information (19), results often need to be complemented with synchrotron-

© 2008 NRC Canada

based XAS measurements to aid in the interpretation of the IR spectra. Jing et al. (36) have studied surface complexation of MMA and DMA on nanocrystalline titanium dioxide using extended X-ray absorption fine structure spectroscopy. Their data shows the formation of inner-sphere mono- and bi-dentate complexes for DMA and MMA, respectively. It was also found, by measuring the thermodynamics of binding using batch techniques, that the degree of methylation and oxidation state of methylated arsenic compounds affect their binding affinities to iron minerals (20). Based on the above studies, it will be interesting to see how the IR spectra of adsorbed methylated arsenicals compare to the spectra shown herein for the bulk phases. This work in currently underway in our lab, which will also be complemented with XAS studies at the Canadian Light Source.

Synthesis of dipyrrins bearing chirality adjacent to the conjugated skeleton — Electron-poor pyrroles exhibit dramatically reduced nucleophilicity

Cory S. Beshara, Beth M. Pearce, and Alison Thompson

Abstract: With the aim of furthering our investigations into the asymmetric complexation of dipyrrinato ligands, a dipyrrin bearing a stereogenic centre directly adjacent to the conjugated skeleton was synthesized. The electron-withdrawing nature of the chiral 4-(2,2,2-trifluoro-1-hydroxyethyl)- substituent significantly reduced the nucleophilicity of corresponding pyrroles, such that 2,2′-symmetrically substituted bis(dipyrrin)s bearing this motif were inaccessible. Furthermore, solutions of mononuclear dipyrrinato complexes were found to be less stable to acid-catalyzed decomplexation than the corresponding dinuclear complexes.

Key words: dipyrrin, dipyrromethene, complexation, electron-poor pyrrole, chirality.

Résumé : Dans le cadre de nos travaux sur la complexation asymétrique des ligands dipyrrinato, on a effectué la synthèse d'une dipyrrine portant un centre stéréogène directement adjacent du squelette conjugué. La nature électro-affinitaire du substituant chiral 4-(2,2,2-trifluoro-1-hydroxyéthyle) réduit d'une façon significative le caractère nucléophile des pyrroles correspondants et, en conséquence, des bis(dipyrrines) substituées d'une façon symétrique dans les positions 2 et 2′ et portant ce motif ne sont pas accessibles. De plus, on a observé que les solutions de complexes dipyrrinato mononucléaires sont moins stables vis-à-vis les décomplexations catalysées par les acides que les complexes binucléaires correspondants.

Mots-clés : dipyrrine, complexation, pyrrole déficient en électron, chiralité.

[Traduit par la Rédaction]

Introduction

The asymmetric synthesis of dipyrrinato complexes is a field of current interest because dipyrrins (1) give mono-anionic, planar, bidentate ligands that complex to a wide variety of metal ions. For example, chiral fluorescent boron-dipyrrinato (BODIPY) (2) complexes have been synthesized through the use of chiral dipyrrins (3–5), and chiral metal-organic frameworks incorporating dipyrrinato ligands are also known (6). 2,2′-Bis(dipyrrin)s (Fig. 1) with methylene, ethylene, or propylene linkers joining the dipyrrinato units generate dinuclear (M_2L_2) double helicates with tetrahedrally coordinated metal ions, and mononuclear (ML) helicates are formed if the alkyl linker is four atoms or more in length (7). The incorporation of chiral auxiliaries within the ligand allows the diastereoselective synthesis of helicates. Indeed, excellent diastereoselectivity has been obtained in the synthesis of mononuclear bis(dipyrrinato) helicates bearing templating BINOL and tartrate moieties attached via ethanoate groups within the linker (8). However, the most successful asymmetric synthesis of dinuclear bis(dipyrrinato) helicates to date gives a diastereomeric ratio of only 69:31 (9–11). In all reported diastereoselective syntheses of dinuclear bis(dipyrrinato) helicates, the chiral auxiliary is attached through a pendent ester or amide linkage and thus the chiral centre itself is quite remote from the helical axis.

Cognizant that the degree of stereoselectivity depends upon the effectiveness of the chiral auxiliary in inducing asymmetric complexation and thus the distance between the site of the auxiliary and the helical axis, we explored the value of incorporating a chiral centre directly adjacent to the dipyrrin; such a motif is somewhat rare for pyrroles (12–17) and extremely rare for dipyrrins (16, 18, 19). β-Keto pyrroles are readily available through Knorr-type syntheses (20, 21) and asymmetric reduction would generate a chiral alcohol. Further derivitization would serve to incorporate the pyrrole into a dipyrrin and thus place a chiral centre directly adjacent to the dipyrrinato unit (Fig. 2). Previous studies involving haematoporphyrin have shown that such hydroxyl groups are labile under mildly acidic conditions thus introducing the possibility of racemization through reversible elimination and addition. The lability is caused by the electron-rich nature of the pyrrole ring facilitating racemization at the pseudobenzylic position. Kumadaki provided a viable solution to potential racemization of this nature through the use

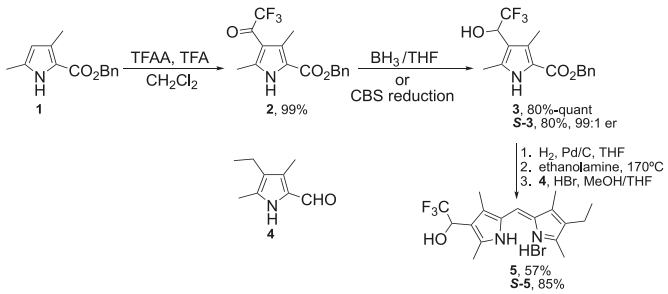
of 4-(2,2,2-trifluoro-1-hydroxyethyl)-substituted pyrroles (18, 19) in the construction of homochiral haematoporphyrins (16). We herein report our work with 4-(2,2,2-trifluoro-1-hydroxyethyl)-substituted dipyrrins. Our goals included the investigation of: the syntheses of dipyrrins and 2,2′-bis(dipyrrin)s incorporating 4-(2,2,2-trifluoro-1-hydroxyethyl)-substituents; the stereochemical stability of 4-(2,2,2-trifluoro-1-hydroxyethyl)-substituted dipyrrins; the ability of 4-(2,2,2-trifluoro-1-hydroxyethyl)-substituted dipyrrinato units to undergo complexation; and the potential of the 4-(2,2,2-trifluoro-1-hydroxyethyl) group to influence diastereoselective complexation, either as an alcohol or as bulkier ether or ester derivatives.

Results and discussion

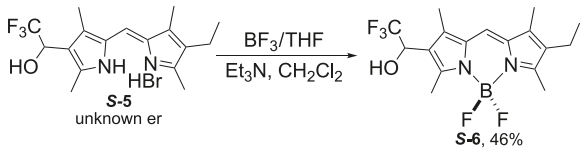
Synthesis of the first dipyrrin bearing a 4-(2,2,2-trifluoro-1-hydroxyethyl)-substitutent was achieved according to Scheme 1. Benzyl 3,5-dimethyl-pyrrole-2-carboxylate (**1**) (22) was converted to the corresponding trifluoroacetoxy-substituted pyrrole **2** using triflouroacetic acid (TFAA) under acidic conditions (23). Reduction of **2** with borane gave racemic alcohol **3**, and the use of the CBS protocol gave ***S*-3** with 99:1 enantiomeric ratio (er), akin to that reported by Kumadaki and co-workers (16). Hydrogenolysis of the benzyl ester, followed by thermolytic decarboxylation, gave the corresponding α-free pyrrole that was reacted directly with 4-ethyl-2-formyl-3,5-dimethylpyrrole (**4**) (24) under MacDonald-type coupling conditions (1) to afford the requisite racemic dipyrrin **5**, and the single enantiomer ***S*-5**.

The literature supports the stereochemical stability of the 2,2,2-trifluoro-1-hydroxyethyl moiety under acidic conditions (16, 18, 19), but we were concerned that the MacDonald-type coupling conditions (48% HBr, MeOH–THF) (1) might have afforded some racemization as exposure of enantiopure ***S*-3** to the same conditions resulted in loss of stereochemical integrity with the recovered material having only 76:24 er. To investigate its stereochemical purity a sample of the dipyrrin prepared from enantiopure ***S*-3** was converted into the corresponding BODIPY complex **6** (2) (Scheme 2). Because boron-dipyrrinato complexes are achiral at boron and amenable to chromatography, the enantiopurity of **6**, established by chiral HPLC, would reveal the enantiopurity of ***S*-5** by correlation.

Scheme 1. Synthesis of **5**.



Scheme 2. Synthesis of boron-dipyrrinato complex **6**.



HPLC-analysis (Fig. S1) was used to determine that ***S*-6**, synthesized using ***S*-3**, had retained its enantiopurity during the MacDonald-type coupling step.[2] Thus, with a source of enantiopure ***S*-5** in hand, and having secured both the synthesis and the stereochemical stability of dipyrrins bearing the 4-(2,2,2-trifluoro-1-hydroxyethyl)-group, we progressed to investigating the stability of the corresponding complexes and assessing the influence of the electron-withdrawing substituent, essential for the stability of the chiral centre upon complexation. Racemic **5** was treated with zinc acetate under standard conditions (10) to give the homoleptic zinc complex **7** in 64% yield. The efficiency of complexation was then improved through the use of zinc perchlorate instead of the acetate salt and lithium hydroxide as base; complexation using enantiopure ***S*-5** was conducted in the same manner (Scheme 3). Although the zinc complex (**7**) was noticeably less stable under mildly acidic conditions (silica gel, aqueous extractions, wet solvents) than dipyrrinato complexes not bearing electron-withdrawing groups, isolation of **7** in good yield was achieved by rapid precipitation from the methanolic reaction mixture upon the addition of water. Mass spectrometry confirmed the formation of a mononuclear ML_2 complex.

Efforts turned to the investigation of the stereochemical outcome of the complexation reactions to determine whether **5** had undergone complexation with simple diastereo-

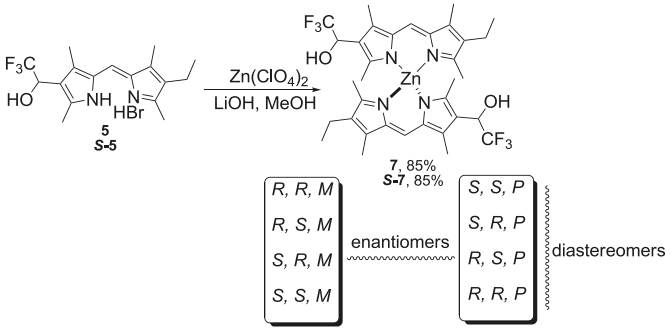
Scheme 3. Complexation of **5** and possible stereochemical outcomes.

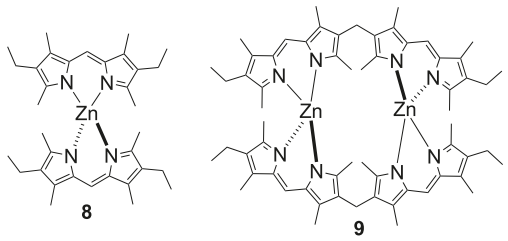


selectivity. Previously, NMR and circular dichroism (CD) spectroscopy, alongside chiral HPLC analysis, have been extremely useful for the evaluation of diastereoselective reactions involving dipyrrinato ligands. The neutral complexes are amenable to chromatography, and the helical nature of the chromophoric dipyrrinato units fixed in space through coordination to metal ions renders CD data very useful. As **5** constitutes an unsymmetrical A–B ligand architecture, the tetrahedrally coordinated metal ion in **7** gives rise to helicity. Thus, the complexation of racemic **5** allows for the possible production of eight ($2^3 = 8$) stereoisomers; *R* and *S* for the stereocentres on the ligands, and *M* and *P* for the metal centre (Scheme 3). Two species in each enantiomeric set (*R*,*S*,*P* – *S*,*R*,*P* and *R*,*S*,*M* – *S*,*R*,*M*) are identical, simplifying the possible outcomes to three (racemic) stereoisomers, with a 1:2:1 statistical ratio.

HPLC analysis of the crude product mixture obtained using racemic **5** showed one signal due to dipyrrinato complex(es) and two minor non-dipyrrinato impurities. The ChiralPak®-IA column used herein had previously proven to be superior for the resolution of dipyrrinato complexes and attempts to resolve the signals of **7** with other columns were unsuccessful. The ^{1}H NMR spectrum for the same product mixture was not useful for assigning stereoisomers but the ^{13}C nucleus allowed for improved resolution. The stereogenic carbon atom bearing the trifluoromethyl group normally appears as a quartet in the ^{13}C NMR spectrum with $J_{CF} \approx 33$ Hz. Indeed, **5** exhibits a quartet with $J_{CF} = 32$ Hz at a chemical shift of 65.8 ppm for this carbon atom. For the product mixture, the stereogenic carbon atom gave signals in the 64 ppm range that appeared as a pair of quartets of equal intensity ($J_{CF} = 33$ Hz), indicative either of a mixture of isomers or of two non-equivalent dipyrrinato units within a single ML_2 complex. Preparative HPLC served to separate the dipyrrinato complex(es) from the impurities, and ^{13}C NMR spectra of the isolated material retained the characteristic 1:1 pair of quartets. We identified that decomposition did not occur during HPLC, because NMR spectra of the initial product mixture and the material after preparative HPLC (and recombination of all fractions) were identical. Complex ***S*-7** was prepared from ***S*-5** (Scheme 3). With enantiopure ligand, the product mixture was found to exhibit identical HPLC and NMR characteristics to **7** (prepared from racemic dipyrrin **5**), thus suggesting that the chiral HPLC column was unable to resolve isomers of **7**.

Although the coordination abilities of dipyrrin ligands have been reported previously (25–27), a comparison of mononuclear and dinuclear analogues has not appeared. Using absorption spectroscopy, solutions of mononuclear **7**, bearing the 4-(2,2,2-trifluoro-1-hydroxyethyl)- substituent, were compared with solutions of the peralkyl mononuclear complex **8** (28) and the peralkyl dinuclear complex **9** (29) (Fig. 3). Studies at a variety of concentrations in technical-grade CH_2Cl_2 indicated that solutions of mononuclear complexes **7** and **8** are less stable to acid-catalyzed decomplexation than the dinuclear complex **9**; spectrophotometric-grade CH_2Cl_2 did not cause any decomplexation. These studies are important as dipyrrinato complexes are typically exposed to a range of solvents (including water) during work-up, purification, and analysis. As mentioned previously, the electron-deficient nature of **7** was a concern in terms of complex stability, and thus discovering that dinuclear dipyrrinato complexes are more stable than their mononuclear analogues suggested that the 4-(2,2,2-trifluoro-1-hydroxyethyl)- substituent might be more appropriate for use in bis(dipyrrinato) ligands. Furthermore, although ***S*-5** is unsymmetrical and thus gives an A–B dipyrrinato ligand that generates tetrahedrally coordinated Zn(II) helicates, formally the helicity is a consequence only of the two differently substituted pyrrolic units, that is, 4-ethyl versus 4-(2,2,2-trifluoro-1-hydroxyethyl).

Fig. 3. Mononuclear complex **8** and dinuclear complex **9**.



To increase the degree of asymmetry within the ligands, to thus improve both the stereoselectivity of complexation and the resolution by chiral HPLC, and to study the more stable dinuclear dipyrrinato complexes, we turned to the preparation of a bis(dipyrrin) bearing the chiral 4-(2,2,2-trifluoro-1-hydroxyethyl)- substituent directly adjacent to the conjugated skeleton. Retrosynthetic analysis (Fig. 4) of the symmetrical bis(dipyrrin) **10** reveals that the 2,2′-dipyrroles **11** and **12** are essential intermediates in the synthetic sequence, with successful condensation of **11** with **4** giving the required bis(dipyrrin). Three routes to **12** were envisaged, and each was investigated.

Trifluoroacylation of **13** (30), followed by reduction of the two trifluoromethyl ketones, was thought to be the most direct route to **12**. Unfortunately treatment of **13** with TFA and TFAA, under the conditions that had been successful for the synthesis of **2**, did not produce the required material and instead gave, tentatively, the pyrrolo-[3,2-*f*]-indole **18** where presumably mono-trifluoracylation had been followed by acid-catalyzed intramolecular condensation (Scheme 4) (31–33). Since indolic **18** does not feature the required prochiral signature, we sought an alternative route for the synthesis of **12**.

We thus investigated the synthesis of **12** through the homocoupling of **14** (34), itself prepared by mono-oxidation of **15** (16) using $Pb(OAc)_4$ (Scheme 5). Homocouplings of this type, using 2-methylene pyrroles, are commonplace for the synthesis of symmetrical dipyrromethanes and involve

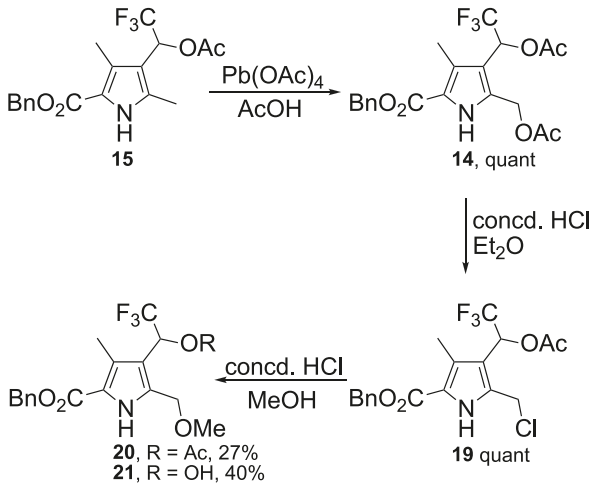
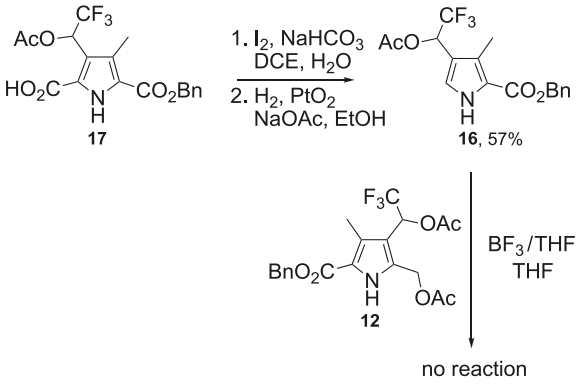


Scheme 6. Synthesis and attempted coupling of **16**.



initial ring-protonation followed by the loss of an equivalent of formaldehyde to give in situ 5-unsubstituted pyrroles that then produce dipyrromethanes through condensation with remaining starting material (21, 35). However, treatment of **14** with HCl served only to effect substitution to give **19** and milder conditions (Montmorillonite K-10 clay (36)) gave no reaction at all. Presumably electron-poor **14** is resilient to ring-protonation and thus substitution dominates (12) under forcing conditions, preventing the typical nucleophilic chemistry of pyrroles from occurring; the presence of the electron-withdrawing ester and 2,2,2-trifluoro-1-acetoxyethyl substituents serves to inhibit the traditional nucleophilicity of the pyrrolic unit such that dipyrrins cannot be accessed using these intermediates.

Our final attempts to synthesize **12** required the condensation of a 5-unsubstituted pyrrole with **14**, in effect pre-preparing the same intermediate that was not formed in situ within the previous strategy; this strategy is often implemented for the synthesis of unsymmetrical dipyrromethanes (1). Thus, **16** was prepared via iodinative decarboxylation of **17** (16) followed by dehalogenation of the resulting iodopyrrole (Scheme 6). Attempted reaction of **16** with **14** met with failure and only starting materials were recovered. Once again, the classic nucleophilicity of pyrroles was absent for these electron-deficient pyrroles bearing both ester and (2,2,2-trifluoro-1-acetoxyethyl) substituents. In an attempt to reduce the electron-withdrawing nature of the 4-substituent in pyrrole **20**, the *O*-acyl protecting group was omitted from the synthesis and the free alcohol was exposed to the decarboxylation conditions. Unfortunately, these conditions resulted only in decomposition and the decarboxylated product could not be isolated.

Challenges associated with the low or unusual reactivity of electron-deficient pyrroles are not new. Indeed, Handy and co-workers have described problems associated with the *N*-protection of poly-halogenated pyrroles (37) and Clezy has made observations concerning problems in constructing dipyrromethanes using electron-deficient pyrroles (30). The poor reactivity of pyrroles substituted with the 4-(2,2,2-trifluoro-1-hydroxyethyl)- substituent have prevented our synthesis of a bis(dipyrrin) bearing this chiral moiety adjacent to the conjugated skeleton. The conflicting requirements of (i) electron-withdrawing groups to stabilize the stereocentre adjacent to the pyrrolic core and (ii) adequate nucleophilicy of the pyrrolic heterocycle render the (2,2,2-trifluoro-1-hydroxyethyl)- substituent an inappropriate group with which to introduce chirality directly adjacent to the pyrrolic core.

© 2008 NRC Canada

In summary, a dipyrrin containing a chiral 4-(2,2,2-trifluoro-1-acetoxyethyl)- substituent directly adjacent to the pyrrolic core was prepared and complexed with Zn(II). Although the corresponding mononuclear helicate was isolated in good yield, complexation occurred with poor selectivity. Attempts to prepare an analogous bis(dipyrrin), a skeleton that was found to be generally more stable in solution than the monomeric homologue, were thwarted by the low reactivity of electron-deficient pyrroles. These results again demonstrate that the balance between the reactivity and stability of pyrroles is a fine balance indeed (38, 39): the search continues for moieties that facilitate the introduction of chirality directly adjacent to the pyrrolic core without concurrent inhibition of pyrrolic reactivity.

General experimental

All reagents were purchased from Sigma-Aldrich and used as received, except phosphoric acid that was purchased from Fischer Scientific and reagent grade acetonitrile that was purchased from Caledon. Dry THF and CH_2Cl_2 were obtained from a solvent purification system and stored under nitrogen unless otherwise indicated. Dry ether was obtained via distillation from benzophenone sodium ketal. Unless otherwise indicated all glassware was flame-dried under vacuum prior to use, followed by a nitrogen fill. Column flash chromatography was performed using Silicycle Ultra Pure Silica Gel 60, 230–400 mesh. TLC was performed using Silicycle Ultra Pure Silica Gel 60 aluminum-backed plates, visualized under UV light, and stained using an ethanolic vanillin dip. Absorption spectroscopy was performed with samples in quartz cuvettes with a standard path-length of 1 cm. HPLC separations were performed using a Chiralpak®-IA column composed of amylose tris(3,5-dimethylphenylcarbamate) with particle size of 5 μm; the analytical column had an ID of 0.46 cm and the preparatory column an ID of 2 cm with both columns having a length of 25 cm. The chiral analytical column used for the determination of er in compound ***S*-3** was the Chiralpak® AD-RH, also composed of amylose tris(3,5-dimethylphynylcarbamate) but with a silica support (ID 0.46 cm; length 15 cm). NMR spectroscopy utilized 500 MHz, 400 MHz, and 250 MHz spectrometers at 300 K, as indicated. All ^1H and ^{13}C chemical shifts (δ) are referenced to TMS at 0 ppm in the solvents indicated and are reported on the ppm scale. All coupling constants (*J*) are reported in Hz. ^{19}F NMR spectra were referenced to $CFCl_3$ as an external standard at 0 ppm. Mass spectra were obtained using double focusing magnetic sector (EI) and TOF (ESI) spectrometers. Compounds **1** (22), **2** (3), **3** (16), **4** (24), **8** (28), **9** (29), **13** (30), **15** (16), and **17** (16) were prepared according to known procedures. WARNING: Perchlorate salts are powerful oxidants and care should be taken to avoid exothermic or explosive conditions.

2,3-Dimethyl-4-(2,2-2-trifluoroethyl-1-hydroxy-)-5-(3,5-dimethyl-4-ethylpyrrol-2-ylmethylidene)pyrrole hydrobromide (5)

Pd–C catalyst (10% on C, 0.306 g, 10 mol%) was added to a solution of pyrrole **3** (1.00 g, 3.06 mmol) in THF (40 mL) through a stream of nitrogen and the reaction mixture was then stirred under a hydrogen (1.0 atm) atmosphere. After three days the mixture was filtered through celite and concentrated to facilitate the precipitation of the carboxylic acid (87%), which was then suspended in ethanolamine (25 mL), and the mixture was heated to 170 °C for 45 min, after which the mixture was poured into ice water and extracted with CH_2CH_2 (3 × 20 mL). The combined organic layers were washed with water (50 mL) and then brine (50 mL), followed by drying over sodium sulfate and concentratation. The residue was dissolved in $CHCl_3$ and reconcentrated to yield the α-free intermediate as a yellow crystalline solid (72%). This pyrrole (0.384 g, 1.99 mmol) and **4** (0.190 g, 2.00 mmol) were dissolved in 1:1 MeOH–THF (25 mL) and 48% aq hydrogen bromide (0.300 mL) was added to the solution. After stirring overnight at room temperature, the mixture was concentrated until very little solvent remained. Ether, pre-treated with sodium borohydride, was then added until a copious precipitate was present. Filtration and drying in air gave the title compound as a red solid (0.399 g, 57%); mp 190–230 °C. ^1H NMR (500 MHz, DMSO-d_6) δ_H: 1.04 (t, J_{HH} = 8 Hz, 3H), 2.34 (s, 3H), 2.42–2.45 (m, 5H), 2.58 (s, 3H), 2.60 (s, 3H), 5.27 (q, J_{HF} = 8 Hz, 1H), 6.83 (bs, 1H), 7.45 (s, 1H), 12.52 (bs, 1H), 12.69 (bs, 1H). ^{13}C NMR (125 MHz, DMSO-d_6) δ_C: 10.7, 11.1, 13.6, 14.2, 15.0, 17.4, 65.8 (q, J_{CF} = 32 Hz), 121.9, 122.3, 126.2, 126.4 (q, J_{CF} = 281 Hz), 128.5, 132.6, 143.9, 145.2, 151.7, 158.1. ^{19}F NMR (235 MHz, $CDCl_3$) δ_F: -78.2 (d, J_{HF} = 8 Hz). MS-ESI *m/z*: 327.1 $(M + 1 - Br)^-$.

N,N′-Difluoroboryl-[2,3-dimethyl-4-(1-hydroxy-2,2-2-trifluoroethyl)-5-(3,5-dimethyl-4-ethylpyrrol-2-ylmethylidene)pyrrolato-kN] (6)

To a suspension of **5** (1.00 g, 2.4 mmol) in CH_2Cl_2 (15 mL) under a nitrogen atmosphere was added, first, NEt_3 (6.37 mL, 45 mmol) and, second, $BF_3{\cdot}OEt_2$ (6.33 mL, 51.3 mmol) giving a colour change from brown-orange to dark orange-pink. After stirring the solution (the suspension becomes a solution after the addition of $BF_3{\cdot}OEt_2$) for one hour at room temperature the reaction mixture was concentrated. The residue was taken up in Et_2O and run through a plug of silica to remove baseline material and then further purified using chromatography and 1:50 to 1:10 ethyl acetate – hexanes as eluent to yield the title compound as a pink-red solid (0.395 g, 46%); mp 175–178 °C. R_f (1:5 ethyl acetate – hexanes): 0.19. UV (nm) λ_{max}: 514. ^1H NMR (500 MHz, $CDCl_3$) δ_H: 1.07 (t, J_{HH} = 7.5 Hz, 3H), 2.17 (s, 3H), 2.27 (s, 3H), 2.39 (q, J_{HH} = 7.5 Hz, 2H), 2.52 (s, 3H), 2.54 (s, 3H), 2.55 (d, J_{HH} = 3 Hz, 1H), 5.04 (qd, J_{HF} = 7 Hz, J_{HH} = 3 Hz, 1H), 7.03 (s, 1H). ^{13}C NMR (125 MHz, $CDC1_3$) δ_C: 9.7, 10.3, 13.2 (2C), 14.6, 17.6, 67.7 (q, J_{CF} = 33 Hz), 119.9, 120.2, 125.3 (q, J_{CF} = 280 Hz), 131.7, 134.1, 134.5, 138.0, 139.4, 152.6, 159.8. ^{19}F NMR (235 MHz, $CDCl_3$) δ_F: –78.77 (d, J_{FH} = 7 Hz), –146.16 to –146.85 (m). MS-ESI *m/z*: 354.3 (28%), 355.3 [$(M - F)^+$, 100%)], 356.3 (26%), 374.1 (20%).

Zinc bis[2,3-dimethyl-4-(2,2-2-trifluoroethyl-1-hydroxy-)-5-(3,5-dimethyl-4-ethylpyrrol-2-ylmethylidene)pyrrolato-kN] (7)

Dipyrromethene salt **5** (1.00 g, 2.5 mmol) was dissolved in methanol (80 mL) and lithium hydroxide monohydrate (0.932 g, 9 mmol) was added directly to the solution causing a dramatic shift in colour from orange-red to yellow.

© 2008 NRC Canada

Zinc(II) perchlorate (CAUTION, 1.30 g, 5.0 mmol) was then added and the yellow solution turned orange immediately. The mixture was stirred for one hour followed by dilution with water to precipitate the desired product, which was isolated by filtration as a very fine orange powder after drying overnight in a vacuum oven at room temperature (0.763 g, 85%); mp 197–198 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ_H:1.01 (t, J_{HH} = 7.5 Hz, 3H), 1.02 (t, J_{HH} = 7.5 Hz, 3H), 1.89–1.94 (m, 3H), 1.95–2.20 (m, 3H), 2.20 (bs, 1H), 2.22 (d, J_{HH} = 1.5 Hz, 3H), 2.35–2.40 (m, 5H), 5.00–5.05 (m, 1H), 7.04 (s, 1H). ^{13}C NMR (125 MHz, $CDC1_3$) δ_C: 10.6, 10.7, 15.1, 15.5, 15.6, 18.2, 68.1 (q, J_{CF} = 33 Hz), 68.1 (q, J_{CF} = 33 Hz), 117.9, 121.8, 125.6 (q, J = 280 Hz), 132.3, 134.8, 134.9, 137.8, 139.6, 153.3, 161.5. ^{19}F NMR (235 MHz, $CDCl_3$) δ_F: –78.9 (d, J = 7.5 Hz). MS-ESI *m/z*: 327.2 (ligand), 715.1 $(M + 1)^+$, 737.1 $(M + Na)^+$.

Benzyl 5-acetoxymethyl-4-(1-acetoxy-2,2,2-trifluoroethyl)-3-methylpyrrole-2-carboxylate (14)

According to a published procedure (18), to a solution of benzyl 4-(1-acetoxy-2,2,2-trifluoroethyl)-3,5-methylpyrrole-2-carboxylate (381.5 mg, 1.03 mmol) in acetic acid (9 mL) under N_2 at room temperature was added $Pb(OAc)_4$ (490.7 mg, 1.107 mmol) as a solid with stirring. The resulting mixture was stirred at 50 °C and monitored using TLC. After full conversion was apparent (4 h), the reaction mixture was cooled to room temperature and then diluted with ethylene glycol (1.0 mL). Distilled water (20 mL) was added to the solution, and the product was extracted using dichloromethane (3 × 50 mL). The organic layer was washed with 5% sodium bicarbonate (3 × 50 mL) and dried over sodium sulfate, and the solvent removed in vacuo to give the product (34) as a white solid (435.6 mg, 99%). ^{1}H NMR (500 MHz, $CDCl_3$) δ_H: 2.06 (3H, s), 2.17 (3H, s), 2.39 (3H, s), 5.16 (2H, q, J = 13.5 Hz), 5.31 (2H, d, J = 12.5 Hz), 5.33 (1H, d, J = 12.5 Hz), 6.23 (1H, q, J = 7.0 Hz), 7.33–7.42 (5H, m), 9.45 (1H, bs). ^{13}C NMR (125 MHz, $CDCl_3$) δ_C: 10.5, 20.6, 20.9, 57.2, 66.3, 66.3 (q, J = 139 Hz), 114.2, 119.7, 123.7 (q, J = 1114 Hz), 127.7, 128.3, 128.4, 128.7, 130.3, 136.1. ^{19}F NMR (235 MHz, $CDCl_3$) δ_F: –76.62. MS-ESI *m/z* for $C_{20}H_{20}F_3NNaO_6$ calcd.: 450.1140; found: 450.1130.

Benzyl 4-(1-acetoxy-2,2,2-trifluoroethyl)-3-methylpyrrole-2-carboxylate (16)

Water (2 mL) and dichloroethane (DCE, 4 mL) were added to a flask containing pyrrole **17** (0.16 g, 0.40 mmol) and sodium bicarbonate (0.11 g, 1.3 mmol). Sodium iodide (0.16 g, 1.1 mmol) and iodine (0.48 g, 1.9 mmol) were added to the biphasic reaction mixture, which was heated at reflux temperature for an hour. After the mixture cooled to room temperature, sodium bisulfite was added very slowly as a solid, to quench the excess iodine (quenching was complete with loss of colour and cessation of effervescence). The layers were then separated and the aqueous layer was extracted with CH_2Cl_2 (3 × 10 mL). The combined organic layers were dried with magnesium sulfate followed by concentration to give the iodopyrrole as an off-white solid. The crude product was suspended in ethanol (4 mL) followed by the addition of sodium acetate (0.045 g, 0.55 mmol) and platinum(IV) oxide (0.014 g, 0.06 mmol) through a stream of nitrogen. A hydrogen atmosphere was maintained utilizing a balloon and needle through a septum and the reaction was stirred for 0.5 h. The product was partially purified using flash column chromatography and 1:5 EtOAc–hexanes as eluent to yield the title compound as a white solid which was used without further purification (0.080 g, 57%). ^{1}H NMR (500 MHz, acetone-d_6) δ_H: 2.12 (s, 3H), 2.40 (s, 3H), 5.31 (s, 2H), 6.20 (q, J_{HF} = 7 Hz, 1H), 7.00 (d, J_{HH} = 3 Hz, 1H), 7.32–7.42 (m, 5H), 9.50 (bs, 1H).

Benzyl 4-(1-acetoxy-2,2,2-trifluoroethyl)-5-chloromethyl-3-methylpyrrole-2-carboxylate (19)

To a solution of benzyl 5-acetoxymethyl-4-(1-acetoxy-2,2,2-trifluoroethyl)-3-methylpyrrole-2-carboxylate (278.6 mg, 0.652 mmol) in dichloromethane (DCM, 20 mL) under nitrogen was added HCl (1 mol/L in ether, 3.129 mL) and the solution was stirred at room temperature overnight. The solution was washed with 5% aqueous sodium bicarbonate (3 × 10 mL) and the aqueous layer extracted using DCM (3 × 20 mL). The organic layers were combined, dried over sodium sulfate, filtered, and concentrated in vacuo to give the product as a light pink solid (111 mg, 40%). ^{1}H NMR (500 MHz, $CDCl_3$) δ_H: 2.20 (3H, s), 2.39 (3H, s), 4.63 (1H, d, J = 13.0 Hz), 4.79 (1H, d, J = 13.0 Hz), 5.33 (2H, d, J = 12.5 Hz), 5.36 (1H, d, J = 12.5 Hz), 6.24 (1H, q), 7.35–7.43 (5H, m), 9.52 (1H, bs). ^{13}C NMR (125 MHz, $CDCl_3$) δ_C: 10.5, 20.7, 36.5, 66.1 (q, J = 139 Hz), 66.5, 113.8, 120.1, 123.7 (q, J = 1114 Hz), 127.9, 128.4, 128.5, 128.8, 131.0, 135.9, 161.1, 168.6. ^{19}F NMR (235 MHz, $CDCl_3$) δ_F: –7.06. MS-ESI *m/z* for $C_{18}H_{17}ClF_3NO_4$ calcd.: 403.0798; found: 402.0717.

Benzyl 4-(1-acetoxy-2,2,2-trifluoroethyl)-5-methoxymethyl-3-methylpyrrole-2-carboxylate (20)

To a solution of benzyl 4-(1-acetoxy-2,2,2-trifluoroethyl)-5-chloromethyl-3-methylpyrrole-2-carboxylate (50 mg, 0.124 mmol) in methanol (2 mL) at room temperature was added concd. HCl (12 mol/L, 0.07 mL), and the mixture was then stirred at room temperature for 4 h. The solvent was removed in vacuo, and the crude mixture was purified using preparative TLC and 70:30 hexane–ethyl acetate as the eluent to give the product as a colourless oil (16.2 mg, 33%). ^{1}H NMR (500 MHz, $CDCl_3$) δ_H: 2.15 (3H, s), 2.41 (3H, s), 3.40 (3H, s), 4.52 (1H, d, J = 13.5 Hz), 4.55 (1H, d, J = 13.5 Hz), 5.31 (2H, s), 6.20 (1H, q, J = 7.5 Hz), 7.34–7.43 (5H, m), 9.20 (1H, bs). ^{13}C NMR (125 MHz, $CDCl_3$) δ_C: 10.7, 20.6, 58.8, 66.1, 66.2, 66.2 (q, J = 138.5 Hz), 111.7, 118.7, 123.9 (q, J = 1114 Hz), 128.4, 128.6, 133.5, 136.3, 161.0, 168.6. ^{19}F NMR (235 MHz, $CDCl_3$) δ_F: –76.93. MS-ESI *m/z* for $C_{19}H_{20}F_3NO_5Na$ calcd.: 422.1191; found: 422.1175.

Comparison of chelating ion exchange resins in sorption of copper(II) and zinc(II) complexes with ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA)

Dorota Kołodyńska and Zbigniew Hubicki

Abstract: This paper investigates the macroporous chelating ion exchangers with different functional groups for their sorption properties towards the copper(II) and zinc(II) ions. The investigations by the dynamic and static methods were carried out in the presence of traditional complexing agents. The differences in affinity of Cu(II) and Zn(II) complexes with these complexones result from the kind of functional groups of the chelating ion exchangers, such as thiourea, aminomethylphosphonate, iminodiacetate, and polyamine groups as well as from the pH value. The quantitative removal of studied heavy metal complexes using chelating ion exchangers is achieved in the case when resins compete successfully for the heavy metal ions against these chelators.

Key words: chelating resins, heavy metals, EDTA, NTA.

Résumé : Dans ce travail, on a étudié les propriétés de sorption d'échangeurs d'ions chélatants microporeux, portant divers groupes fonctionnels, vis-à-vis des ions cuivre(II) et zinc(II). On a effectué ces études par des méthodes dynamiques et statiques en présence d'agents complexant traditionnels. Les différences d'affinité des complexes de Cu(II) et de Zn(II) avec ces complexones résultent de la valeur du pH et de la nature des groupes fonctionnels présents dans les échangeurs d'ions chélatants, tels les groupes thiourée, aminométhylphosphonate, iminodiacétate et polyamine. L'élimination quantitative des complexes métalliques étudiés à l'aide des échangeurs d'ions chélatants a été réalisée dans le cas où les résines peuvent compétitionner avec succès pour les ions métalliques lourds contre ces agents de chélation.

Mots-clés : résines chélatantes, métaux lourds, EDTA, NTA.

[Traduit par la Rédaction]

Introduction

Environmental pollution by toxic metals occurs through industrial and agricultural processes and waste disposal. Fuel and power industries generate about 2.4 million tons of heavy metals (As, Cd, Cr, Cu, Hg, Ni, Pb, Se, V, and Zn) annually. Wastes generated by the electronic industry during printed circuit board production, metal finishing industries, storage battery, and semiconductor manufacturing as well as paper and pulp, pigment, and tanning industries contain relatively high levels of metals (copper, chromium, lead, cadmium, nickel, cobalt, iron, zinc) and inorganic (fluoride, sulphate, chloride) as well as organic ligands (ethylenediaminetetraacetate, nitrilotriacetate, citrate, tartrate, etc.) (1–10).

Removal of high concentrations of heavy metals is normally achieved by such technologies as precipitation, coagulation/flocculation, sedimentation, and filtration. However, in many situations these processes are inefficient or do not reduce metal concentrations below the accepted standards. Additionally, precipitation processes produce intractable sludge that must be treated and disposed at high cost. Because of the fact that heavy metal ions are often present in various industrial wastewaters along with complexing agents, the treatment of such heavy metal complex-bearing wastewaters requires, in the first step, separation of heavy metals from complexing agents. This is achieved by precipitation of the complexing agents EDTA (ethylenediaminetetraacetic acid) or NTA (nitrilotriacetic acid) by strong acids. In the second step, heavy metal ions are precipitated by means of sodium hydroxide or calcium oxide.

Therefore the most important technologies for the removal of toxic metals or reduction of their concentrations are adsorption and ion exchange. Solvent extraction, phytoextraction, and biosorption can also be used to this end (11–20). Different types of membrane filtrations (ultrafiltration, nanofiltration, reverse osmosis) and electrotreatments (electrodialysis, membrane electrolysis) are also used (21–23). Each of these methods has some limitations in practice, e.g., some of them are economically unfavourable (because

 © 2008 NRC Canada

of high operating cost caused by energy consumption) or technically complicated. Although liquid–liquid extraction can be selective and effective for the removal of heavy metals from wastewaters some loss of solvent and difficulties in phase separation and emulsion formation occur. Therefore, sorption operations including adsorption and ion exchange opposed to the conventional chemical methods are more promising in that they achieve higher removal levels over a wider range of solution conditions, less sludge volumes, and strict discharge specifications. However, in the case of removal of heavy metal ions in the presence of complexing agents using activated carbons, the adsorption of metal ions is related to the electrostatic interaction between the charges of solutes and the surface of activated carbon, which is a function of metal and ligand types, metal–ligand molar ratio, and pH. For solutions greater than pH 6, the negatively charged species of type $[M(edta)]^{2-}$ are repelled from the negatively charged surface groups of activated carbon (11). Additionally, these inexpensive adsorbents as well as biological materials (peanut hulls, coconut copra meal, red cedar wood, pinewood, corn cobs, etc.) do not possess the possibility of their multiple regeneration (23–26). In this regard, ion exchange resins have great potential for the removal of heavy metals from water and industrial wastewaters.

The sorption of heavy metal ions onto ion exchangers has been studied in recent years (27–38). Anionic heavy metal complexes have been eliminated by means of anion exchangers. In the M(II)-EDTA system, removal of $[M(edta)]^{2-}$ complexes is achieved using polystyrene and polyacrylate anion exchangers. Nelson et. al (39) studied the sorption of Cr(III) and V(IV) complexes with EDTA on Dowex 1 × 4 in the H_2edta^{2-} form. Also, elution separations of Ni(II) from V(IV) and K(I), Mn(II) from Co(II), and a mixture of Ba(II), Sc(III), Cr(III), and V(IV) in the 0.01 mol/L EDTA–0.01 mol/L NH_4Cl solution by 0.01 mol/L EDTA with different amounts of NH_4Cl were presented. Dudzinska et al. (40, 41) indicated that the sorption of complexes of Pb(II) and Cd(II) with EDTA on the polyacrylate anion exchangers Amberlite IRA 458, Amberlite IRA 68, as well as on the polystyrene anion exchanger Amberlite IRA 400 is also effective. The polyacrylate anion exchangers (Amberlite IRA 458, Amberlite IRA 68, and Amberlite IRA 958) were used for the removal of copper(II) complexes with IDA (iminodiacetic acid), NTA, and EDTA (42, 43). Also, the studies by Juang et al. (44) have demonstrated the possibility of using the anion exchanger Amberlite IRA 400 for copper(II) removal from such solutions.

Recent studies have also shown that chelating resins could be used for selective removal and recovery of metals containing strong organic and inorganic ligands. Contrary to the conventional ion exchangers, the chelating ion exchangers are characterized by high selectivity towards various metal ions. Their selective properties depend mainly on the kind of functional group. Sorption selectivity is particularly affected by mutual position of functional groups, their spatial configuration, and steric effects and to a smaller degree by matrix properties. Their exchange capacity depends also on the number of functional groups and pH of solution. Important features of macroporous chelating ion exchangers are their better kinetic properties compared with those of the conventional gel ion exchangers of that type.

Chelex 100 and Amberlite IRC 718 have been used to treat the waste effluents containing Cu(II), Ni(II), and Na(I) ions as well as EDTA and citrate discharged from printed circuit board manufacturing (45). Korngold et al. (46) removed Cu(II), Ni(II), Co(II), and Cd(II) from tap water containing small amounts of complexing agents such as humates and salts of carboxylic acids onto the chelating ion exchanger. A new class of polymers with oligo(ethyleneamine) (OEA) moieties such as ethylenediamine (EDA), diethylenetriamine (DETA), triethylenetetraamine (TETA), tetraethylenepentaamine (TEPA), and pentaethylenehexaamine (PEHA) attached to the acrylamide resins has recently been developed and compared to commercially available resins such as Sumichelate MC 10, Lewatit E-TEPA, Lewatit HLH-TETA, and Purolite D 2914 by Matejka et al. (47, 48). The sorption of heavy metal ions by oligo(ethyleneamine) resins is based on the coordination bond of a heavy metal cation to the N-atom of the functional group in the free base form and formation of a very strong amine complexe $[M(OEA)]^{2+}$ so that the electrostatic attractive forces do not contribute to metal sorption. Electrical neutrality inside the resin phase is maintained by the electrostatic uptake of anions of EDTA from solutions. It was found that only the resin having PEHA moiety can be applied for sorption of Cu(II). However, the obtained breakthrough capacity decreases with the increasing concentration of EDTA as well as metal concentration in the loading solution. It was also pointed out that the presence of an alkaline earth metal cation (Mg(II) or Ca(II)) improves the sorption capacities towards chelated heavy metals (Cu(II), Zn(II), and Ni(II)). Desorption of heavy metal cations can be carried out by H_2SO_4, but in this case the clogging of the resin bed by EDTA is a limitation that should be taken into account.

The chelating hydrogel resin containing the PEHA functional groups obtained by inversion copolymerisation of glycidyl methacrylate (GMA)-ethylene dimethacrylate (PEHA) with GMA-ED (ethylenediamine) has also been shown to remove the Cu(II)-EDTA complexes to some extent (49). The maximum sorption capacity of 1.08 mmol/g of copper(II) ions was achieved at pH 6.0, and the Cu(II)-EDTA molar ratio was equal to 1:0.5 (initial concentration of Cu(II) was 300 mg/L). It was also shown that as the amount of EDTA in the solution increases, more EDTA is available to compete for copper(II) ions against the chelating ion exchanger. When the Cu(II)-EDTA ratio exceeds 0.75, the efficiency of removal of copper(II) ions is limited. Then the sorption capacity of copper(II) ions is lower and almost equal to the sorption capacity of copper(II) ions without EDTA (about 0.52 mmol/g), but for the Cu(II)-EDTA = 1:1 system this value is about 0.18 mmol/g. Another ion exchanger containing the hydroxyl group and iminodiacetic acid was applied for sorption of copper(II), cadmium(II), and cobalt(II). The obtained sorption capacities for these ion metals were 1.46 mmol/L, 1.10 mmol/L, and 1.02 mmol/L, respectively (initial metal concentration was 7.87 mmol/L at pH 4.5). The sorption/desorption test showed that only 4% of the sorption capacity decreased after 15 cycles (50).

The aim of this paper is to examine the rate of removal of Cu(II) and Zn(II) ions from wastewaters containing

© 2008 NRC Canada

ethylenediaminetetraacetic (EDTA) or nitrilotriacetic (NTA) acids on the commercial chelating ion exchangers Lewatit TP 214, Lewatit TP 260, Purolite S-920, and Purolite S-930 as well as Diaion CR-20. There is a need for such comparison to be made to know the possibility of their application in treatment of wastewaters containing typical complexing agents. The parameters that influence the sorption process (the initial ions concentrations, pH, metal-ligand molar ratio) and isotherm studies were investigated.

Materials and methods

Chelating ion exchangers

The chelating resins selected for the study were Lewatit TP 214 (with thiourea groups), Lewatit TP 260 (with aminomethylphosphonate groups), Purolite S-920 (with thiourea groups), Purolite S-930 (with iminodiacetate groups), as well as Diaion CR-20 (with polyamine groups). Prior to their use they were washed with 1 mol/L NaOH and 1 mol/L HCl (to remove organic and inorganic impurities) and then several times with deionized water. The resin was finally converted to the H^+ or Na^+ forms. Important physical and chemical properties of these ion exchangers are presented in Table 1.

Preparation of solutions

The aqueous solutions of each heavy metal ion in the presence of EDTA or NTA were prepared by dissolving equimolar amounts of metal chloride, $CuCl_2 \cdot 2H_2O$ or $ZnCl_2 \cdot 2H_2O$, in the sodium salts of EDTA or NTA solution at pH 4.6 and 4.0, respectively. The initial pH values for individual complexes (without pH adjustments) were 3.05 $[Cu(edta)]^{2-}$, 3.00 $[Zn(edta)]^{2-}$, 3.00 $[Cu(nta)]^{-}$, and 3.00 $[Zn(nta)]^{-}$. In the case where NaOH was added, the pH of the $[Cu(edta)]^{2-}$ complexes was 5.50. All used chemicals were of analytical reagent grade (POCH S.A. Gliwice, Poland).

Dynamic method – column procedure

To measure affinity of the above mentioned Cu(II) and Zn(II) complexes, the breakthrough curves were determined using 20 mL of the swollen chelating ion exchanger in the appropriate form. The prepared solutions were passed continuously downward through the resin beds keeping the flow rate at 0.8 mL/cm^2 min. The effluent was collected in fractions in which the metal(II) content was determined. The mass (D_g) and volume (D_v) distribution coefficients as well as the working ion exchange capacities (C_w) were calculated according to the following equations (51)

$$[1] \qquad D_g = \frac{\overline{U} - U_0 - V}{m_j}$$

$$[2] \qquad D_v = \frac{\overline{U} - U_0 - V}{V_j}$$

$$[3] \qquad C_w = \frac{U \cdot c_0}{V_j}$$

where $\overline{U}$ is effluent volume at $c = c_0/2$ (determined graphically) (mL), U_0 is dead volume in the column (liquid volume in the column between the bottom edge of ion exchanger bed and the outlet) (mL), U is effluent volume to the break point (L), V is void (inter-particle) ion exchanger bed volume, which amounts to ca. 0.4 of the bed volume (mL), m_j is dry ion exchanger weight (g), V_j is bed volume (mL), and c_0 is initial concentration of M(II) in the aqueous phase (g/L).

The total ion exchange capacities (C_r) were calculated by integration along the curve.

Static method

In batch experiments, about 0.5 g of appropriate dry ion exchanger was placed in a 100 mL stoppered conical flask containing 50 mL of heavy metal ion solution of the initial concentration, c_0, complexed with EDTA or NTA. The flask was shaken using the laboratory shaker of ELPHINE type 357 produced in Poland. The measurements were made at the constant temperature 298 K in the three parallel series. The stirring speed was 180 rpm to maintain resin particles in the suspension. After the pH of the solution was stabilized and equilibrated, the ion exchanger was filtered to determine the content of metal(II) ions. Preliminary experiments showed that the sorption process is fast and the removal rate is constant after 90 min. Therefore, the contact time of 90 min was used for batch tests. Series of experiments were conducted to determine the effect of initial metal ion concentration and pH on sorption. The pH was measured with a Radiometer pH meter (Model PHM 82). The concentrations of Cl^- ions were not determined. The metal ion concentrations obtained for batch experiments were converted to the percentage of metal ions removed (%R) and the amount of metal sorbed per unit weight of ion exchanger at the specific time and at the equilibrium (q_t, q_e).

The recovery factor was calculated from the equation

$$[4] \qquad \%R = \frac{c_0 - c_t}{c_0} \times 100\%$$

The sorption capacity (q_t) at the specific time (t) was calculated from the equation

$$[5] \qquad q_t = \frac{(c_0 - c_t) \times V}{m}$$

The total sorption capacities (q_e) of ion exchangers for heavy meal ions were given by

$$[6] \qquad q_e = \frac{(c_0 - c_e) \times V}{m}$$

where c_0 is initial concentration of M(II) in the aqueous phase (mg/L), c_t is concentration of M(II) in the aqueous phase at time t (mg/L), c_e is concentration of M(II) in the aqueous phase at equilibrium (mg/L), V is volume of the solution (L), and m is mass of the ion exchanger (g).

AFM studies

To compare the surface morphologies of the studied ion exchangers before and after the sorption process, atomic force microscopy (AFM) scans were also made by means of AFM Digital Instrument NanoScope III (U.S.A.). The scans were taken at room temperature, in air, and in contact mode

conditions, i.e., at direct contact between the sample and the tip.

FT-IR/PAS and Raman studies

The FT-IR/PAS (the Fourier transform IR photoacoustic spectroscopy) spectra of the ion exchangers before and after the sorption processes were recorded by means of a Bio-Rad Excalibur 3000MX spectrometer equipped with the photoacoustic detector MTEC 300 (in the helium atmosphere in a detector) over the 4000–400 cm^{-1} range at the resolution of 4 cm^{-1} and the maximum source aperture. The spectra were normalized with reference to the MTEC carbon black standard.

The Raman spectra of the ion exchangers before and after the sorption processes were recorded by means of an inVia Reflex Raman spectrometer.

Analytical procedure

The concentrations of the solutions were analyzed using an atomic absorption spectrophotometer Varian Spectr AA-880.

Results and discussion

In the system containing heavy metals and EDTA or NTA, heavy metals tend to form thermodynamically stable complexes so the following equations can be assumed

$$M^{2+} + edta^{4-} \rightleftarrows [M(edta)]^{2-}$$

$$M^{2+} + nta^{3-} \rightleftarrows [M(nta)]^{-}$$

The concentration of present metal ions and ligands and the stability constants of formed complexes control the equilibrium in the system. The addition of another ligand or metal ion to the solution causes a new equilibrium to be attained. An analogous situation occurs when the chelating ion exchanger occurs in the system. As mentioned above, the quantitative removal of heavy metal ions in the presence of EDTA or NTA using the ion exchange method is achieved only in the case when chelating resins are strong enough to compete successfully for the heavy metal ions against chelators. Stability constants for heavy metal complexes with EDTA are very high, whereas the stability of its NTA complexes is several orders of magnitude lower, so the competition by chelating ion exchanger of these complexes should be easier. Additionally, as follows from the comparison of conditional stability constants of studied complexes these values increased with the increasing pH and at low pH the tendency for metal–EDTA complexes formation may be assumed to have the following sequence, Fe(III) > Cu(II) >Pb(II) >Zn(II). Therefore the research was done at low pH. For comparison, research was also done at a higher pH value for some systems.

The analysis of speciation distributions of copper(II) and zinc(II) in the presence of EDTA and NTA (calculated by using a SPE computer program) (Fig. 1) shows that in the strong acidic medium (pH < 2) there are predominant uncomplexed metal(II) ions whose concentration decreases with the increasing pH, which results in the formation of the complexes $[M(H_2edta)]$ and $[M(Hedta)]^-$. At a higher pH the complexes of $[M(edta)]^{2-}$ and $[M(nta)]^-$ types are predominant. The degree of M(II) complexation increases at pH >10 due to transformation of the complex $[M(edta)]^{2-}$ to the more stable $[M(edta)(OH)]^{3-}$, and in the case of NTA, the $[M(nta)]^-$ type to the $[M(nta)(OH)]^{2-}$. For pH >12 copper(II) and zinc(II) hydroxocomplexes appear in the system. As follows from the analysis of AFM scans, the surfaces of studied chelating ion exchangers before and after the sorption process are differentiated. Exemplary AFM scans for Diaion CR-20 are presented in Fig. 2. Topography scans in Fig. 2 show three-dimensional and two-dimensional AFM images of Diaion CR-20 (*a*) before and (*b*) after the sorption process, respectively. As follows from comparison of FT-IR/PAS (Fig. 3) as well as Raman spectra (Fig. 4) of the

Fig. 2. The two-dimensional and three-dimensional AFM scans of Diaion CR-20 (*a*) before and (*b*) after the sorption process of Cu(II) in the presence of EDTA (surface area 500 nm × 500 nm, z = 1 nm).

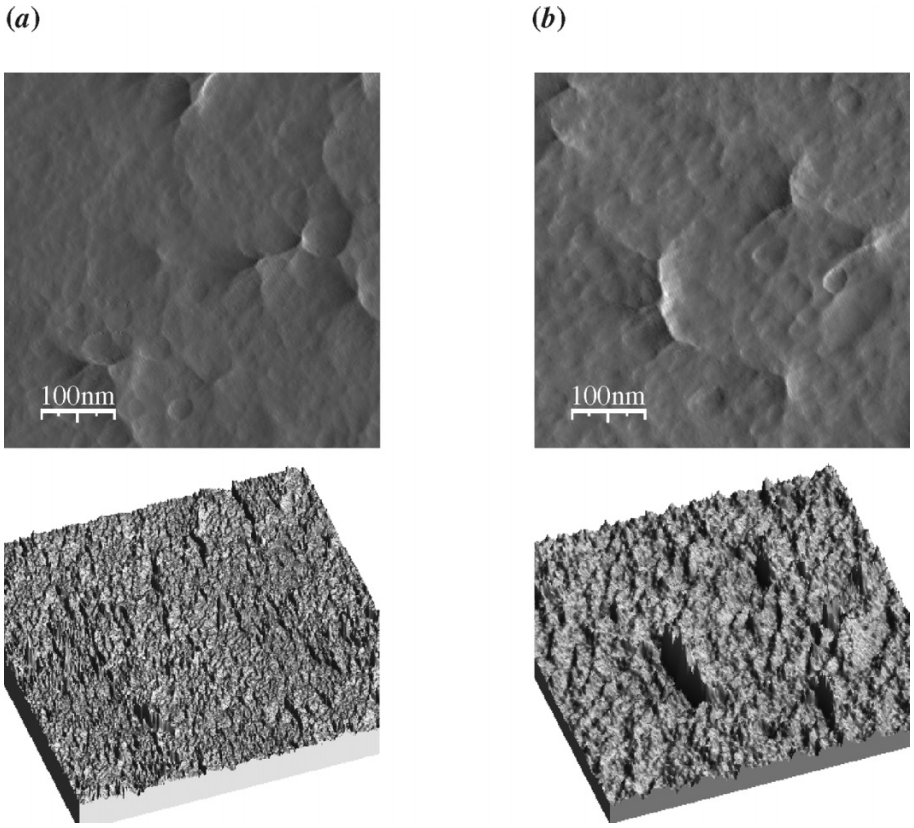

Fig. 3. FT-IR/PA spectra of chelating ion exchangers before and after the sorption of Cu(II) in the presence of EDTA.

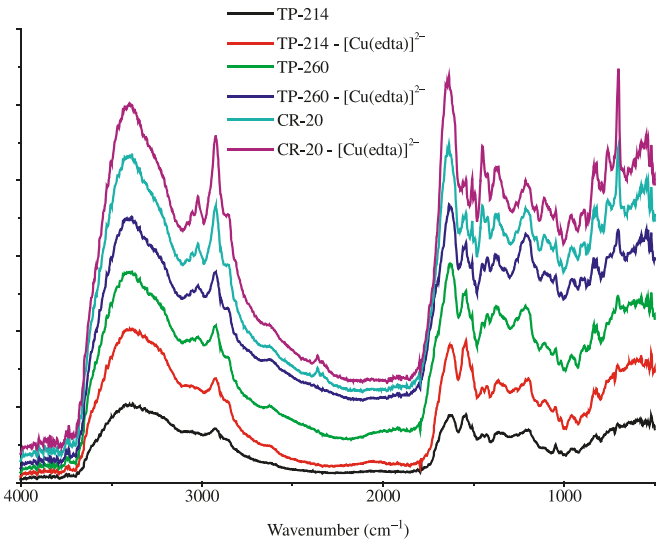

Fig. 4. The Raman spectra of the chelating ion exchanger Diaion CR-20 before and after the sorption of Cu(II) in the presence of EDTA.

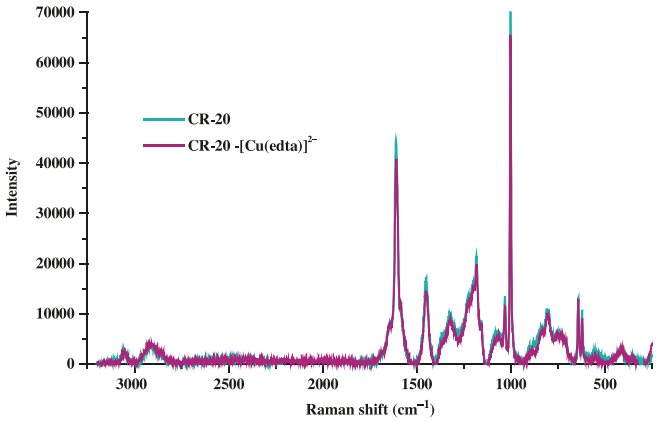
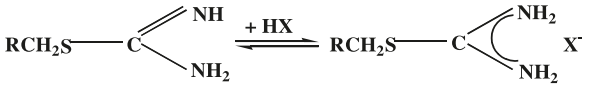


studied chelating ion exchangers Lewatit TP 214, Lewatit TP 260, and Diaion CR-20 possess bands related to the matrix of ion exchanger (cross-linked polystyrene by divinylbenzine). In the case of Lewatit TP 214 with the thiouronium functional groups, the board peak at 3200–3400 cm^{-1} should be associated with the asymmetric and symmetric stretching bonds of the $-NH_2$ groups of thiouronium. The other bands of this functional group are at 519 cm^{-1}, 1103 cm^{-1}, and 1394 cm^{-1}. After the sorption of Cu(II) ions in the presence of EDTA, the FT-IR/PAS spectrum of Lewatit TP 214 possesses two strong bands at 1629 cm^{-1} and 1542 cm^{-1} assigned to the asymmetrical and symmetrical stretching of the COO^- group, respectively. This can also be related to the deformation band of the $-NH_2$ group. Other peaks for the $-COO^-$ group are at 1424–1455 cm^{-1} and at 1365–1395 cm^{-1} as well as at 900–960 and 815–865 cm^{-1}. The position of the band assigned to the $[M(edta)]^{2-}$ complex can be employed as the indication of

© 2008 NRC Canada

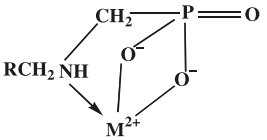
the nature of the M–O bond because its position is influenced by the charge (q) and the ionic radius of metal ions (r). For a q/r ratio larger than 3.6, the carbonyl absorption maxima occuring in the 1625–1650 cm^{-1} region indicate the covalent bonding but for a q/r less than 3.6 they are in the 1590–1615 cm^{-1} region and indicate that the bonding is primarily ionic. When the peaks occur between these regions, the bonding is probably partially ionic and partially covalent. However, in the obtained spectrum the band at 1607 cm^{-1} assigned to the $[Cu(edta)]^{2-}$ complex is difficult to identify because of ion exchanger band overlapping. In the case of formation of the coordination bond of copper(II) with the nitrogen or sulphur atom from the thiouronium group, the bands at about 460 cm^{-1} and 280 cm^{-1} (conform to the stretching frequency of Cu-N (ν(Cu-N)) or Cu–S (ν(Cu-S)) bonds) in the FT-Raman spectrum could confirm the presence of complexes of this type.

It is well-known that the selective ion exchangers containing thiouronium functional groups exhibit high selectivity for metal ions, especially for noble metal ions. Depending on the pH, these groups assume the following forms shown in the figure below.



They are able to form coordination bonds with metal cations (the first form), but in the second form the anion complexes are bonded according to the anion exchange mechanism. Also, other ion exchangers can behave as basic anion exchangers in the acidic medium but in the pH range of 4–10 they exhibit properties of chelating ion exchangers.

As follows from the recorded spectrum of Lewatit TP 260, after the sorption of Cu(II) ions in the presence of EDTA there appears to be a band connected with asymmetric vibrations stretching the C-O band at 1641 cm^{-1} and a slightly weaker band of symmetric stretching vibrations at 1453 cm^{-1}. However, the band connected with the vibrations of the -NH group disappears (Fig. 3), which can indicate decomposition of the Cu(II)-EDTA complex and formation of the coordination bond between a nitrogen atom and a phosphorous atom.



In the hydrochloric acid medium, Diaion CR-20 also behaves like a weakly basic anion exchanger. According to the anion exchange mechanism the sorption process has a two stage character. In the first stage, the functional groups are protonated. It results in the positively charged surface of resin pore walls, which in the second step, leads to the association of anions due to electrostatic interactions between positively charged groups and the anions in the solution. The obtained FT-IR/PAS spectra of Diaion CR-20 before and after sorption of Cu(II) ions in the presence of EDTA are very similar.

Effect of metal(II)-ligand molar ratio

To measure affinity of Cu(II) and Zn(II) in the presence of EDTA and NTA, the breakthrough curves were determined using the above mentioned chelating ion exchangers. The exemplary breakthrough curves of Cu(II) complexes with EDTA or NTA in the Cu(II)-EDTA = 1:1, Cu(II)-EDTA = 1:2, and Cu(II)-EDTA-NaOH = 1:1:2 as well as in the Cu(II)-NTA = 1:1 and Cu(II)-NTA = 1:2 systems on Lewatit TP 214, Lewatit TP 260, Purolite S-920, and Purolite S-930 as well as Diaion CR-20 are presented in Figs. 5 and 6. The mass (D_g) and volume (D_v) distribution coefficients as well as the working (C_w) and total (C_r) ion exchange capacities of M(II) were calculated from the determined breakthrough curves (Tables 2 and 3).

As follows from the obtained results, the factor influencing effectiveness of sorption on chelating ion exchangers is the kind of form in which the metal ion is presented in the system (related with the solution pH). In the case of sorption of heavy metal complexes with EDTA using chelating ion exchangers, the highest effectiveness of sorption is obtained at the complexation of M(II):EDTA = 1:1 and a lower pH. This is in agreement with a reverse tendency compared to the case of sorption of heavy metal complexes with EDTA on the strongly basic polystyrene anion exchangers with quaternary ammonium groups where anionic complexes take part in the sorption process (52). The obtained results were also confirmed by the sorption parameters, calculated values of distribution coefficients, as well as sorption capacities of ion exchangers towards Cu(II) and Zn(II) (Tables 2 and 4). As follows from the speciation distribution diagrams (Fig. 1) in this system (pH of about 3), the neutral complexes of $[M(H_2edta)]$ type (about 18% for Cu(II) and about 6% for Zn(II)) and anionic complexes of $[M(Hedta)]^-$ type (about 65% for Cu(II) and about 70% for Zn(II)) as well as of $[M(edta)]^{2-}$ type (about 18% for Cu(II) and about 10% for Zn(II)) should participate in the sorption process. With the higher pH, percentage contributions of neutral and one-negative anionic complexes decrease. At higher pH (more than 4) in the case of EDTA, two-negative complexes of $[M(edta)]^{2-}$ type are present (about 99%).

In the case of copper(II) and zinc(II) complexes with NTA, higher affinity for chelating ion exchangers is exhibited in the M(II)-NTA = 1:1 system. Larger differentiation in the affinity of Cu(II) and Zn(II) complexes with NTA is found for the chelating ion exchanger Lewatit TP 214 than for Diaion CR-20 (Table 3).

Effect of the type of ion exchanger functional group

The research results also showed the effect of the type of ion exchanger functional groups on sorption effectiveness of Cu(II) and Zn(II) in the presence of EDTA and NTA (Figs. 5 and 6). In the case of ion exchangers with thiourea groups (Lewatit TP 214 and Purolite S-920) in the sorption process, two stages can be distinguished: the initial stage of slow sorption (up to about 0.1 c/c_0) and the other is much faster until the total exhaustion of the bed (c/c_0 >0.1) takes place. This suggests the possibility of occurrence of various types of complexes or uncomplexed ions during formation of the exchange zone. In the case of the chelating ion exchanger Lewatit TP 260 of the aminomethylphosphonate functional group, fast sorption is observed in the first stage (to about

0.8 c/c_0), then it is much slower until complete bed exhaustion is observed. The exchange zone formation time is much shorter than for the previously discussed ion exchangers. For the ion exchangers Diaion CR-20 and Purolite S-930 containing polyamine and iminodiacetate groups, respectively, the respective curves are typical for the ion exchange process. In the case of the chelating ion exchanger Purolite S-930, $[Cu(edta)]^{2-}$ complexes pass through the column without displaying any reaction to the active group in the ion exchanger. This indicates that decomposition of sorbed complexes does not occur in the resin phase. As follows from the obtained results in this paper as well as literature data, the chelating ion exchangers with the iminodiacetate groups do not exhibit affinity for the heavy metal anionic complexes with EDTA. It should be added that the distribution coefficients calculated from the breakthrough curves for copper(II) complexes are much higher than that of analogous zinc(II) complexes (Tables 2 and 3). A reverse dependence was observed only for Purolite S-920. It is also evident that the sorption capacities for the M(II)-NTA system are slightly higher than that for the M(II)-EDTA system. It is worth mentioning that heavy metal ions were desorbed by 1 mol/L HCl almost quantitatively.

As follows from the research, the chelating ion exchangers, according to their applicability for sorption of Cu(II) and Zn(II) in the presence of EDTA in the

Zn(II)-NTA = 1:2	253.41	76.35	0.0013	0.0108

0.001 mol/L M(II)-0.001 mol/L EDTA system can be put in the order Purolite S-920 >Lewatit TP 214 >Diaion CR-20 >Lewatit TP 260 >Purolite S-930. The affinity series for the NTA was found to be as follows, Lewatit TP 214 >Diaion CR-20.

Effect of phase contact time

The investigations of sorption by the static method depending on the phase contact time were carried out in the 0.001 mol/L M(II)-0.001 mol/L EDTA and the 0.001 mol/L M(II)-0.002 mol/L EDTA systems using Purolite S-920, Lewatit TP 214, and Diaion CR-20. The analogous relationships were determined in the 0.001 mol/L M(II)-0.001 mol/L NTA and 0.001 mol/L M(II)-0.002 mol/L NTA systems. These values of recovery factors (*%R*) are presented in Fig. 7. When the phase contact time was increased from 1 to 90 min, the percentage of removal of Cu(II) complexes with EDTA (Cu(II)-EDTA = 1:1) using Purolite S-920 increases from 23% to 95%. For the Zn(II)-EDTA complexes these values are similar. For the M(II)-NTA complexes obtained, values are lower and the percentage of recovery reached the constant value about 58% at 90 min. This part of experimental work is the basis for the remaining batch of experiments.

Effect of initial metal ion concentration

As shown in Table 5, the highest amount of metal ions adsorbed per unit weight of ion exchanger are for Purolite S-920 for the M(II)-EDTA system and for Diaion CR-20 for the M(II)-NTA system. In the concentration range from 0.0005 mol/L to 0.001 mol/L, the ratio of functional groups of ion exchanger to the total metal ions in the solution is high and hence all metal ions may interact with the ion exchanger and be removed from the solution so the percentage of metal ions increases. The sorption behaviour of studied chelating ion exchangers was followed by the Langmuir isotherm equation represented by

$$[7] \qquad q_e = \frac{q_0 b c_e}{1 + b c_e}$$

where q_0 is Langmuir isotherm constant (mg/g of dry resin) and b is Langmuir constant (L/mg).

The constants q_0 and b are characteristic of this equation and for the studied chelating ion exchangers (determined from its

linearzed form) are presented in Table 5 The coefficients of determination (R^2) were also presented. As follows from the presented data, there is quitean agreement found between the determined and theoretical capacities of investigated chelating ion exchangers for Cu(II) and Zn(II) ions.

Effect of solution pH

Effect of initial solution pH on the sorption process was determined at various pH values ranging from 2 to 9. The values of solution pH were adjusted with 0.1 mol/L HCl or NaOH. The heavy metal ions recovery factors in the system with EDTA determined under noncompetitive conditions (sorption from single metal complex solution) on the chelating ion exchanger i.e., Lewatit TP 214, Purolite S-920, and Diaion CR-20, as a function of pH were shown in Fig. 8. Cu(II) shows maximum removal in the pH range 4–5 for Lewatit TP 214 and Purolite S-920, and 2–3 for Diaion CR 20. In these ranges the sorption is very fast and then gradu-

ally decreases (pH from 6 to 9). The analogous data were obtained for Zn(II) ions (not presented). It is well-known that the ion exchange mechanism of sorption by chelating ion exchangers with thiourea groups is predominant at high acidities than those chelating or coordinating at low acidities. In the in-between media, both mechanisms are assumed to compete with each other. The explanation for behaviour of such ion exchangers at different acidities is attributed to weak base properties of the functional thiourea groups. In the thiourea form this ion exchanger binds metal ions by coordination, but when converted to the thiouronium form it binds anions by an anion exchange mechanism. The behaviour of Diaion CR-20 is in agreement with the behaviour of weakly basic anion exchangers with primary, secondary, and tertiary amino groups, which exchange anions for alkaline and neutral solutions to a lesser degree than from acid solutions.

Conclusion

As follows from the research results, the selectivity and possible separations of heavy metal ions from aqueous solutions in the presence of chelating agents such as EDTA or NTA depend on both their speciation and on the properties of the chelating ion exchanger. The distribution coefficients as well as the ion exchange capacities of Cu(II) and Zn(II) ions for the above mentioned chelating ion exchangers are differentiated. The differences in affinity of Cu(II) and Zn(II) complexes with EDTA and NTA depend on the kind of functional groups of the chelating anion exchangers, thiourea groups (Lewatit TP 214 and Purolite S-920), aminomethylphosphonate groups (Lewatit TP 260), iminodiacetate groups (Purolite S-930), and polyamine groups (Diaion CR-20), as well as on the pH value. The sorption mechanism of metal ions(II) in the presence of chelating complexing agents such as EDTA or NTA on the chelating ion exchangers is difficult to specify. It is possible that the size of the metal ions could affect the metal sorption whereas the stability constants could be a minor factor.

Radical addition to ynol ethers — A convenient procedure for the stereoselective preparation of α-iodo enol ethers in neutral conditions

Fanny Longpré, Natalia Rusu, Maxime Larouche, Rana Hanna, and Benoit Daoust

Abstract: α-Iodo enol ethers, precursors of acyl anion equivalents, are not easily prepared. Herein we report that addition of activated iodoalkanes to ynol ethers under mild and neutral radical reaction conditions leads to α-iodo enol ethers in moderate to excellent yields with high stereoselectivity. The reaction can be carried out in various solvents at different temperatures. The methodology allows the preparation of β-alkylated and β,β-dialkylated α-iodo enol ethers. Reduction of the carbon-iodine bond of these species leads to the corresponding enol ethers with good yields.

Key words: ynol ethers, enol ethers, radical addition, stereoselective.

Résumé : Les α-iodoéthers d'énol, des précurseurs d'équivalents d'anions acyles, sont difficiles à préparer. Cet article présente nos résultats de notre étude sur l'addition d'iodoalcanes activés sur des éthers d'ynol. Cette réaction, qui conduit à des α-iodoéthers d'énol avec des rendements allant de bons à excellents, s'effectue en milieu neutre et dans des conditions réactionnelles très douces. De plus, cette réaction est très stéréosélective. La réaction peut être effectuée dans différents solvants, à différentes températures. Cette méthodologie permet de préparer des α-iodoéthers d'énol β-alkylés et β,β-dialkylés. La réduction du lien carbone-iode de ces composés permet d'isoler des éthers d'énol avec de bons rendements.

Mots-clés : éthers d'ynol, éthers d'énol, addition radicalaire, stéréosélectif.

Introduction

α-Halo enol ethers are interesting precursors of substituted enol ethers and are also umpolungs for acyl groups (1). Transmetallation of the α-halo enol ether halogen atom produces α-alkoxy vinyl anions that have shown versatile applications in organic synthesis (2, 3). These halogenated species were also used in cross-coupling reactions (4). However, very few methods exist for preparing these useful α-halo enol ethers (2, 5). Most of them require the use of strong bases or the intermediacy of α-alkoxy vinylstannane compounds. Recently, Yu and Jin developed a more convenient method using in situ produced hydrohalic acids (2). These then react with ynol ethers to produce α-halo enol ethers with good to excellent yields. Unfortunately, this method requires acidic reaction conditions that are known to be deleterious to a number of α-halo enol ethers (1). Also, only *mono* β-alkylated α-halo enol ethers can be prepared by this method. As a consequence, the development of a new methodology for the preparation of β-alkylated and β,β-dialkylated α-halo enol ethers under neutral and mild reaction conditions emerges as an important and challenging synthetic endeavor.

Results and discussion

Our strategy for the preparation of α-iodo enol ethers is outlined in Scheme 1. We hypothesized that intermediate electrophilic radical **2** formed by homolytic cleavage of iodinated active methylene **1** (Z = CO_2Et, CN, $CONH_2$) would add to the electron-rich β-carbon of **3** to give trans radical adduct **4**. The anti attack leading to trans radical **4** should be favored for stereoelectronic reasons (6). The use of iodides, which are efficient halogen-atom transfer agents, should ensure rapid trapping of vinyl radical **4** before its interconversion leading to *E*-isomer **5** with stereoselection (7).

We first examined the radical addition of ethyl iodoacetate (**1a**) to ethoxyacetylene (**3a** ; R = ethyl, R′ = H), the only commercially available ynol ether. In CH_2Cl_2 at room temperature (Table 1, entry 1), completion of the reaction was observed within 15 min using Et_3BO_2 as radical initiator. We were very happy to isolate 97% of the expected adduct **5a** with complete stereoselectivity. Indeed, only the *E*-isomer could be observed in NMR spectra and GCMS chromatographs (*E*/*Z* > 99:1). This result not only supports our hypothesis about the ability of ynol ethers to accept electrophilic radicals but also confirms the slow interconversion of vinyl radical **4** (see Scheme 1). We were very pleased to observe that low temperature (–78 °C) had no important effect on the reaction efficiency (entry 2, 90% yield). We then tested an ynol ether possessing a more sterically de-

[c]The *E*-isomer was easily detected by ^{1}H and ^{13}C NMR, TLC, and GCMS ; we could not detect the presence of any of the *Z*-isomers with these methods.
[d]The geometries of the double bond of **5a** and **5b** were determined by the characteristic coupling constants of their reduced counterparts **6a** and **6b** (see Table 4). The geometry of the double bond of **5d** was determined by NOESY spectra of the reduced counterpart **6d**.

manding group attached to the oxygen atom: menthoxyethyne **3b** (R = menthyl, R′ = H) (8). As one can see from entries 3 and 4, the reaction with **3b** proceeds with good yields (75% and 70%) and complete stereoselectivity at RT and at –78 °C. When we tried an ynol ether with even more sterically demanding adamantyl group (**3c** ; R = adamantyl, R′ = H) (9), no desired adduct was observed (entry 5); only the starting material was recovered.

These results suggest that the menthyl group might be the steric limit on the oxygen side of the ynol ether for our reaction to occur. We then decided to prepare a series of substituted menthoxyethyne (R = menthyl) possessing groups with increasing bulkiness at the β-position. First, 1-menthoxypropyne **3d** (R = menthyl, R″ = Me) was tested (8). The radical reaction between **3d** and ethyl iodoacetate occured with yields comparable to those obtained with **3b** (entries 6 and 7, 72% and 70% yield). Again, complete stereocontrol of the double bond was observed. We then decided to install groups possessing secondary carbon at the β-position. Isopropyl was our first choice. We examined the possibility of producing compound **3e** (R = menthyl, R″ = *i*-Pr) by reacting menthoxyethyne **3b** with triisopropylborane (10) using Greene's protocol (8). Unfortunately, we were not able to isolate the desired product. Though TLC revealed the presence of a new compound with an R_f characteristic of ynol ethers, compound **3e**, if ever produced, seemed to be very unstable and degradation was observed before any characterization could be performed. We also tried to prepare compound **3f** (R = menthyl, R′ = *s*-Bu) according to Greene's protocol (8). In that case, the desired compound **3f** could be obtained and isolated, though it showed a very high propensity to decomposition. We submitted this freshly produced ynol ether to our radical reaction conditions. Unfortunately, compound **3f** decomposed before any addition reaction could occur. Hoping that highly encumbered triple bonds would be easier to handle, we tried to prepare very crowded ynol ethers **3g** (R = Et, R′ = Si-*t*-BuMe$_3$) and **3h** (R = Et, R′ = Si-*t*-BuPh$_3$) (11). Fortunately, these compounds were chemically stable and could thus be isolated and purified. However, radical addition of these two ynol ethers with ethyl iodoacetate did not produce the desired adducts **5g**–**5h** (entries 8 and 9, 0% yield in both cases). Only the starting materials were recovered.

Other solvents were then assessed (Table 2) for the reaction involving ethyl iodoacetate (**1a**) and ynol ether **3b**. In benzene (entry 1), the reaction took place with a slightly better yield (80%) compared to CH_2Cl_2 (Table 1, entry 3). In hexanes, acetone, and DMSO (Table 2, entries 2, 3, and 4), the yields were slightly lower (51%–65%). Reaction did not occur in THF (entry 5, 0% yield).

It is of note that when volatile solvents were used (for example, CH_2Cl_2 or hexanes), no aqueous work-up was required, thus reducing the risk of hydrolysis of iodo vinyl ethers **5**. The adducts **5** must be isolated by carefully evaporating the solvent and Et_3B with a nitrogen gas flow. Indeed, we observed that rotary evaporation dramatically accelerated decomposition of these highly functionalized adducts.

Table 3 summarizes results of radical addition of two other iodinated active methylenes towards ynol ether **3d** in CH_2Cl_2. Entries 1, 2, and 3 reveal that iodoacetonitrile added to ynol ether **3d** at different temperatures (RT, 0 °C and –78 °C) with poorer yields (49%–57%) than ethyl iodoacetate (**1a**). Here again, only one isomer of the double bond was observed. Iodoacetamide (entries 4, 5, and 6) added to ynol ether **3d** with modest yields (18%–30%) but with high stereoselection. We also tried the addition of two other α-iodo carbonyl compounds, namely diethyl iodomalonate and 1-iodopropan-2-one. Unfortunately, both iodinated compounds failed to react with ynol ethers **3a** and **3b**. Brominated activated methylenes $BrCH_2CO_2Et$, $BrCH_2CN$, and $BrCH(CO_2Et)_2$ were also reacted with ynol

ethers **3a** and **3b**. In all cases, only the starting materials were recovered.

The radical nature of this new methodology was confirmed using a radical scavenger. Addition of *tert*-butylphenylnitrone to a mixture of **1a** and **3a** followed by Et_3B addition gave ~ 0% yield of the desired adduct.

To demonstrate the usefulness of α-iodo enol ethers, we performed C–I bond reductions of adducts **5a**, **5b**, and **5d** (Table 4). Di and trisubstituted cis enol ethers were obtained with modest to excellent yields (15%–96%) using tributyltin hydride, *n*-BuLi or *t*-BuLi as reducing agents. The desired compounds **6a**, **6b**, and **6d** were all isolated with complete stereoretention. A one-pot procedure involving radical addition of ethyl iodoacetate **1a** to ynol ether **3d** followed by Bu_3SnH reduction without isolation of the intermediate iodo enol ether **5d** did not lead to the desired reduced compound **6d** (0% yield).

Conclusion

In conclusion, we demonstrated, for the first time, that activated methylenes add to ynol ethers in neutral radical conditions. The yields obtained vary from moderate to excellent. The diastereoselectivity of the addition is very high in all cases. The possibility of avoiding the aqueous work-up represents a great advantage over existing methods for preparing hydrolysis-sensitive α-iodo enol ethers. The latter are interesting precursors of substituted enol ethers and are acyl anion equivalents. This method is one of the very few that allowed the stereo-controlled formation of α-iodo β,β-disubstituted enol ether (12). We are now working on the radical addition of activated iodoalkanes to silyl ynol ethers. This should allow us to prepare stereocontrolled β,β-disubstituted silyl enol ethers, enolate equivalents, known to be difficult to prepare (13).

Experimental[2]

All reactions requiring anhydrous conditions were conducted under positive nitrogen atmosphere in oven-dried glassware and the reaction flasks were fitted with rubber septa for the introduction of substrates and reagents via standard syringe techniques. All solvents were distilled prior to use, except for anhydrous tetrahydrofuran (THF) that was used as received from Sigma-Aldrich (SureSeal). *n*-Butyllithium (1.6 mol/L solution in hexanes) and *tert*-butyllithium (1.7 mol/L solution in pentane) were purchased from Sigma-Aldrich and titrated prior to use (diphenylacetic

acid end-point in dry THF). Tributyltin hydride, ethoxyacetylene (40% in hexanes), and triethylborane (1 mol/L in hexane) were also purchased from Sigma-Aldrich and used as received. Flash chromatography was performed on triethylamine pretreated Merck silica gel 60 (0.040–0.063 mm) using compressed air pressure. Analytical thin-layer chromatography (TLC) was carried out on precoated (0.25 mm) Merck silica gel F 54 plates previously treated with triethylamine. ^{1}H NMR spectra were recorded on a Varian 200 MHz NMR spectrometer using $CDCl_3$ (δ = 7.26 ppm) or CD_3COCD_3 (δ = 2.09 ppm) as the reference. ^{13}C NMR were recorded at 50.3 MHz using $CDCl_3$ (δ = 77.1 ppm), CD_3COCD_3 (δ = 30.6 ppm), or C_6D_6 (δ = 128.6 ppm) as the reference. NMR data are reported as follows: chemical shift in ppm, multiplicity (d = doublet, t = triplet, q = quartet, m = multiplet, br = broad, dd = doublet of doublets, dt = doublet of triplets, td = triplet of doublets), number of protons, and coupling constants in Hertz. IR spectra were recorded on a Nicolet Impact 420 spectrophotometer. Gas chromatography – mass spectra (GC–MS) were recorded on an Agilent model 6890N. High-resolution mass spectra (HRMS) were recorded on a ZAB-2F model VG apparatus.

Preparation of starting materials

The preparation and characterization of menthoxyethyne (**3b**), 1-menthoxypropyne (**3d**), and 1-menthoxy-3-methylpentyne (**3f**) have been reported previously (8). Compounds **3c** (9) and **3g** (11) have also been prepared and characterized previously (9). Ethoxyacetylene (**3a**) is commercially available.

Ethoxyethynyl(1,1-dimethylethyl)diphenylsilane (3h)

The preparation of the title compound was carried out according to the procedure described by Pericas and co-workers for the synthesis of similar compounds (10*b*). Under inert atmosphere, *n*-BuLi (3 mL, 1.50 mol/L in *n*-hexane, 4.60 mmol) was added dropwise to a solution of ethoxyacetylene (40% in hexanes, 1 mL, 4.18 mmol) in anhydrous THF (2.9 mL) at 0 °C over a period of 10 min. The mixture was stirred for 1.5 h and hexamethylphosphoric triamide (0.81 mL) was added. After 10 min, *tert*-butyldiphenylsilyl chloride (1.17 mL, 4.51 mmol) was added. The cooling bath was removed and the mixture was stirred overnight at room temperature. The reaction mixture was poured on a mixture of ice (3 g) and *n*-hexane (6 mL). The organic layer was separated, and the aqueous layer was extracted twice with *n*-hexane (4 mL). The combined organic layers were washed with brine (4 mL), dried over $MgSO_4$, and concentrated in vacuo. The crude product was chromatographed through silica gel (pretreated with 1% *v*/*v* of triethylamine) eluting with hexane to give 90% yield of **3h** as a colorless oil.

IR (cm^{-1}): 3065, 3048, 2959, 2929, 2891, 2857, 2174, 1427, 1103. ^{1}H NMR ($CDCl_3$) δ: 8.09 (m, 4H), 7.58 (m, 6H), 4.38 (q, 2H, *J* = 7.0 Hz), 1.60 (t, 3H, *J* = 7.0 Hz), 1.36 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 14.7, 19.0, 27.6, 33.0, 75.6, 113.0, 128.0, 129.6, 135.0, 136.0. General procedure for radical addition of iodoalkanes to ynol ethers

In a 10 mL round-bottomed flask, 0.28 mmol of ynol ether and 1.5 equiv. of the appropriate iodoalkane were dissolved in 2 mL of freshly distilled solvent at the desired temperature. Triethylborane (1.0 mol/L in hexane) was added (100 μL) to initiate the radical chain process. Triethylborane (100 μL) was then added every 15 min until no starting material was detectable by TLC. The solvent was removed by a gentle flow of dry nitrogen gas. The crude product was *rapidly* purified by flash chromatography using 100% hexanes to 10% acetone–hexanes (the contact time with the silica gel must be less than 15 min to avoid decomposition).

α-Iodo enol ethers **5a**, **5b**, **5d**, **5i**, and **5j** were not fully characterized because of their instability. HRMS could not be recorded. In most cases, recording ^{13}C NMR spectra was not possible. When using diluted solutions in the NMR tube, the long acquisition time led to decomposition before ^{13}C spectra could be recorded. Concentrating the solution (to reduce the time required to obtain the ^{13}C NMR) accelerated decomposition, thus precluding the recording of the spectra. However, the stable reduced parents of **5a**, **5b**, and **5d**, the enol ethers **6a**, **6b**, and **6d**, were fully characterized.

The geometry of double bonds was determined by NOESY spectra for compounds **5d**, **5i**, **5j**, and **6d**. For the reduced compounds **6a** and **6b**, the geometry of the double bonds was determined with the help of the characteristic cis-isomer coupling constants.

General procedure for tributyltin hydride reduction of α-iodoenol ethers

In a 10 mL round-bottomed flask, 0.250 mmol of freshly prepared α-iodoenol ether was dissolved in 1.5 mL of benzene along with 0.300 mmol (87 mg, 80 μL) of tributyltin hydride (1.2 eq.). Triethylborane (1.0 mol/L in hexane) was added (100 μL) to initiate the radical chain process. Triethylborane (100 μL) was then added every 15 min until no starting material was detectable by TLC (1–3 h). A saturated aqueous solution of $NaHCO_3$ was poured into the reaction mixture. After the aqueous layer was extracted with Et_2O (3×), the organic layers were combined, washed with brine, dried ($MgSO_4$), filtered through a pad of silica-KF, and concentrated. The crude product was purified by flash chromatography using 100% hexanes to 10% acetone–hexanes.

General procedure for *n*-butyllithium and *tert*-butyllithium reduction of α-iodoenol ethers

In a 10 mL round-bottomed flask, 0.250 mmol of freshly prepared α-iodoenol ether was dissolved in 5 mL of anhydrous THF. The reaction mixture was cooled to –78 °C and 0.300 mmol (1.2 eq.) of freshly titrated BuLi was added dropwise. After 30 min (when TLC confirms that the reaction was completed), 1 mL of distilled water was added dropwise. The cooling bath was removed and the reaction mixture was stirred for another 10 min. A saturated aqueous solution of $NaHCO_3$ was poured into the reaction mixture. After the aqueous layer was extracted with Et_2O (3×), the organic layers were combined, washed with brine, dried ($MgSO_4$), filtered, and concentrated. The crude product was purified by flash chromatography using 100% hexanes to 10% acetone–hexanes.

Synthesis and redox properties of a phosphine-subsituted *para*-dioxolene and its bimetallic palladium complex

Sharon L. Caldwell, Joe B. Gilroy, Rajsapan Jain, Evan Crawford, Brian O. Patrick, and Robin G. Hicks

Abstract: Oxidation of 2,5-bis(diphenylphosphino)-1,4-hydroquinone (**8**) with iodobenzene diacetate produces the corresponding bis(phosphine) substituted benzoquinone (**9**), the first phosphine-substitued quinone. Cyclic voltammetry studies reveal that the redox functionality of the quinone unit in **9** is retained, and the reduction potentials render this compound slightly more easily reduced than the parent *p*-benzoquinone. Reaction of the precursor hydroquinone **8** with $Pd(hfac)_2$ affords a binuclear complex **10** with the hydroquinon*ate* ligand bridging two Pd(hfac) substrates. The redox activity of the bridging dioxolene ligand is retained in complex **10**, although there are significant changes in the redox potentials relative to those of the free quinone **9**. Chemical oxidation of **10** with $AgPF_6$ yields a persistent cationic complex **11**, which, based on EPR and electronic spectroscopy, can be formulated as containing a bridging semiquinone ligand.

Key words: p-quinones, phosphines, bridging ligands, redox properties.

Résumé : L'oxydation de la 2,5-bis(diphénylphosphino)-1,4-hydroquinone, **8**, par le diacétate d'iodobenzène conduit à la formation de la benzoquinone substituée par une bis(phosphine), **9**, le premier dioxolène substitué par une phosphine. Des études de voltampérométrie cyclique révèlent que la fonctionnalité redox de l'unité quinone du produit **9** est maintenue et que les potentiels de réduction rendent ce composé légèrement plus susceptible d'être réduit que la *p*-benzoquinone parente. La réaction de l'hydroquinone **8** avec du $Pd(hfac)_2$ conduit à un complexe binucléaire (**10**), dans lequel un ligand hydroquinonate sert de pont à deux substrats Pd(hfac). L'activité redox du ligand dioxolène servant de pont est maintenue dans le complexe **10**, même s'il y a des changements significatifs dans les potentiels redox par rapport à ceux de la quinone **9**. L'oxydation chimique du composé **10** à l'aide de $ONBF_4$ fournit un complexe cationique persistant, **11**, qui sur la base de la RPE et de la spectroscopie électronique contiendrait un ligand semiquinone servant de pont.

Mots-clés : p-quinones, phosphines, ligands servant de pont, propriétés redox.

[Traduit par la Rédaction]

Introduction

Metal complexes of *ortho*-dioxolenes have a number of interesting physical properties that derive from (*i*) the ability of the dioxolene ligand to exist in three different oxidation states (quinone, semiquinone, catecholate) and (*ii*) the stability of the open-shell (semiquinone) form of the coordinated dioxolene (1). Features such as strong ligand–metal magnetic coupling and "valence tautomerism" — a form of bistability — have made metal-dioxolene complexes interesting building blocks for magnetic and multifunctional materials (2).

Less well-studied are metal complexes of corresponding *para*-dioxolenes. These ligands offer one significant difference compared with their *ortho* counterparts, namely, the ability to bridge two metals, thereby opening up the possibility of making binuclear or polymeric materials that may exhibit *cooperative* valence tautomeric effects. Bis(pyrazolyl)hydroquinone (**1**) has been used sporadically as a bridging ligand (3). Derivatives of 2,5-dihydroxy-1,4-benzoquinone (**2**) have been extensively studied as structural linkers (4), although the redox activity of some of these has only recently been developed (5). Nitrogen analogues of **2**, e.g., 2,5-diamino-1,4-benzoquinones (**3**) and corresponding tetranitrogen species (6) have also appeared. But overall, the

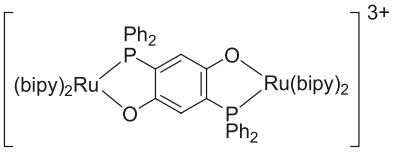
coordination chemistry of *p*-(hydro)quinones remains relatively underdeveloped.

Kaim and co-workers (7) reported the properties of a binuclear ruthenium complex (**4**) containing the bridging ligand 2,5-bis(diphenylphosphino)-1,4-hydroquinone. This complex presents an interesting conundrum in that the trication can be formulated *either* as a bis-Ru(II) complex bridged by a semiquinone radical anion $[Ru^{II}(SQ^{\bullet -})Ru^{II}]^{3+}$ *or* as a hydroquinonate-bridge mixed-valence species $[Ru^{II}(Q^{2-})Ru^{III}]^{3+}$. Spectroscopic data suggest that both forms contribute significantly to the overall electronic structure of **4**, a situation that arises from substantial mixing of metal- and ligand-based orbitals.



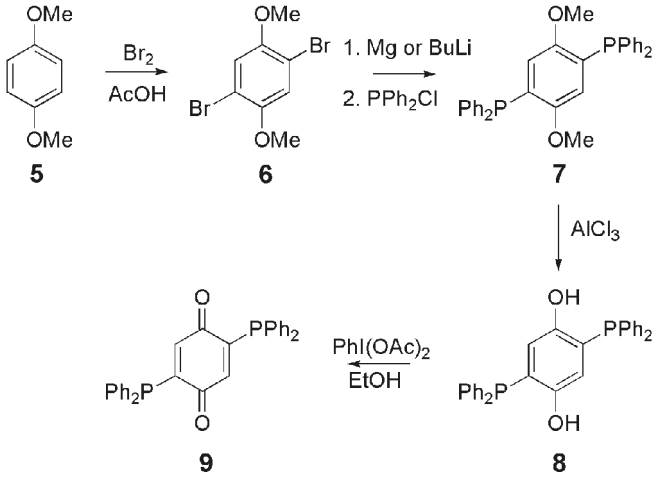
4

Aside from complex **4**, the only other phosphine-containing dioxolenes are Colbran's 1,4-hydroquinones containing a single phosphine substituent (8) (though there are a few examples of phosphonium-substituted $[R_3P^+]$ (9) or phosphonate-substituted $[X_2P(O)]$ (10) (hydro)quinones). These systems exhibit ligand-based redox-dependent hemilabile behaviour, further adding to the array of interesting metal-dioxolene chemistry. We are interested in developing the chemistry of bis(phosphine) dioxolenes because of the excellent donor qualities of phosphines and the electroactivity of the dioxolene unit. One of the fundamental aspects of redox-active ligand chemistry is how the redox properties of the ligand are perturbed upon coordination. Because of the complexities associated with the ruthenium system **4**, we decided to investigate other complexes with transition metals that are electronically "inactive". Herein we present the synthesis of a dipalladium complex of 2,5-bis(diphenylphosphino)-1,4-hydroquinone. We also present the synthesis and characterization of the corresponding free 2,5-bis(diphenylphosphino)-1,4-*benzo*quinone, the first phosphine-substituted quinone.

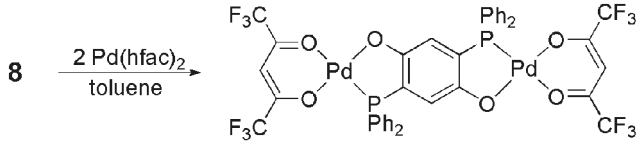
Results and discussion

The synthesis of 2,5-bis(diphenylphosphino)-1,4-benzoquinone (**9**) is shown in Scheme 1. The immediate precursor to **9**, namely the corresponding hydroquinone **8**, was prepared based on methodology described by Kaim (7). 1,4-Dimethoxy benzene **5** was brominated under acidic conditions to afford 2,5-dibromo-1,4-dimethoxybenzene (**6**). We found that the production of **7** through lithiation of **6** at –78 °C followed by chlorophosphine addition afforded more reproducible (albeit low) yields and cleaner samples of **7** compared with the Grignard route previously described. The methoxy groups in **7** were removed with excess aluminum chloride, affording hydroquinone **8**. Oxidation of hydroquinone **8** to quinone **9** proved challenging; a number of reagents known to convert hydroquinones to quinones (e.g., DDQ, $FeCl_3$, $NaIO_4$) were not successful. Iodobenzene diacetate proved to be a successful oxidant for the synthesis

Scheme 1. Synthesis of hydroquinone **8** and quinone **9**.



Scheme 2. Synthesis of palladium complexe **10**.



of **9**. The successful synthesis and isolation of **9** appears to counter the concerns raised by Colbran, who explicitly raised concerns about the stability of phosphine-containing quinones (8).

Hydroquinone **8** was reacted with two equivalents of palladium (II) hexafluoroacetylacetonate to afford bimetallic palladium complex **10** (Scheme 2). The complex was purified by extraction into a 50:50 mixture of diethyl ether and dichloromethane.

The crystal structure of the palladium complex **10** is shown in Fig. 1. The molecule resides on an inversion center. The palladium ion essentially lies within the plane of the hydroquinonate ligand, while the hfac ligand backbone plane lies at an angle of 8.63° relative to the plane of the hydroquinonate ligand. The structural metrics associated with the P,O chelate to the Pd ion are quite similar to those found in structures of the related ligand 2-(diphenylphosphino)phenol (11). The bond lengths within the central benzene ring and C–O bonds are typical for a hydroquinon(ate)-type electronic structure (Table 1).

The cyclic voltammograms (CVs) of **9** and **10** are shown in Fig. 2. The CV of quinone **9** has a reversible reduction wave at a potential of –0.83 V (vs. Fc/Fc^+) and a second quasi-reversible wave at –1.59 V. The reduction potentials of **9** render it slightly more easily reduced than *p*-benzoquinone, which under the same experimental conditions has reduction potentials of –0.94 and –1.60 V. The CV of **10**, which exists as the catecholate form of ligand **8** in its resting state, has two oxidation processes. The first of these is reversible and occurs at +0.44 V, while the second oxidation is irreversible with the anodic peak occurring at +1.04 V. Previous studies on a wide range of Pd (and Pt) complexes of *o*-dioxolenes have established that square pla-

nar Pd(II) is redox inert and that redox processes are invariably ligand-based, corresponding to interconversion between catecholate, semiquinone, and quinone forms of the (coordinated) dioxolene (12, 13). These studies, in conjunction with the spectroscopic data for the one-electron oxidized form of **10** (see below), suggest that the redox processes observed in **10** are ligand based, i.e., the two oxidation steps correspond

to formation of the semiquinone and quinone forms of the bridging ligand.

The electrochemical data for **9** and **10** are summarized in Table 2. The data are presented to permit direct comparisons of the two electron-transfer processes available to dioxolenes; thus, E_1° corresponds to the quinone/semiquinone redox couple, while E_2° is the semiquinone/hydroquinonate couple. The redox potentials for free ligand **9** and dipalladium complex **10** differ by approximately two volts, a difference that can be attributed to the presence of two positively charged metal ions in the latter. Another interesting contrast between **9** and **10** is the *difference* between E_1° and E_2° (ΔE) for each species. For free quinone **9**, this difference is +0.74 V, a fairly typical value for *p*-quinones (14). The irreversibility of the second oxidation process in **10** makes it difficult to accurately determine E_2° (and hence ΔE), but using the midpoint of anodic and cathodic peak potentials, an effective E_2° of +0.92 V can be estimated, which leads to a

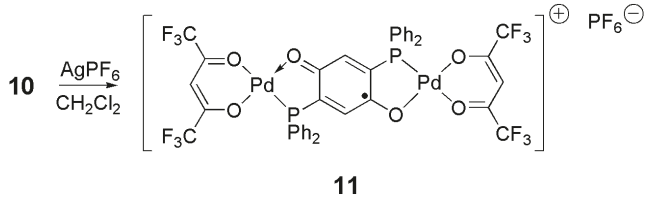
Scheme 3. Synthesis of palladium semiquinone complex **11**.



ΔE of 0.48 V, a substantially lower value compared with the uncoordinated dioxolene.

The reversibility of the first oxidation of **10** prompted attempts to prepare a cation of this species. Palladium hyroquinonate complex **10** was treated with one equivalent of silver hexafluorophosphate to afford semiquinone complex **11** (Scheme 3). This complex is air and moisture sensitive and also appears to slowly degrade in solution even under anaerobic conditions, but freshly prepared samples were sufficiently long-lived to permit solution characterization. Solutions of **11** could be re-reduced with Zn powder to regenerate **10** in ~ 70%–75% yield, demonstrating the persistence of **11** and ruling out the possibility that the spectroscopic data on **11** are from a decomposition product.

The electronic spectra of **11** and its precursor **10** are shown in Fig. 3. Complex **10** has absorption maxima at 358 and 442 nm, while the electronic spectrum of **11** has absorption maxima at 308 and 361 nm as well as low energy maxima at 464 and 582 nm. The broad maximum centered at 582 nm is characteristic of semiquinone radical anions (15).

The EPR spectrum of **11** recorded in degassed dichloromethane in a capillary tube at room temperature (RT) is shown in Fig. 4. The *g*-factor of 2.0084 is slightly higher than the free electron value (2.0023), indicating that the paramagnetic species has most of its spin density located on an organic moiety, as has been shown for Pd and Pt complexes of *o*-semiquinone-type radical anion ligands (12). The spectrum has a dominant five-line pattern with approximate 1:4:6:4:1 intensities; also evident are less intense satellite peaks on either side of this pentet. The overall pattern is suggestive of hyperfine coupling to four (approximately) equivalent S = 1/2 nuclei and additional coupling to two palladium ions (^{105}Pd, I = 5/2, 22.2% abundant). Unfortunately, the linewidths allow only for estimates of the hyperfine coupling to be made; the experimental spectrum could be simulated by coupling to two equivalent phosphorus nuclei and two equivalent protons with similar hyperfine coupling constants (a(P) ~ a(H) ~ 3 G) and additional coupling to the two palladium nuclei (a(Pd) = 2.1 G). The proton hyperfine coupling constants are consistent with other (free) semiquinone radical anions (16), supporting the notion that **11** is appropriately described as containing a bridging *p*-semiquinone ligand.

Summary

We have prepared the first example of a quinone with trivalent phosphorus as a substituent. The redox properties of phosphine-substituted quinone **9** are consistent with the *p*-dioxolene functionality. Coordination to a diamagnetic and redox-inactive metal allowed for the unambiguous elucidation of the redox properties of the *coordinated* dioxolene. In this case, coordination to two Pd ions produces dramatic changes in the ligand redox potentials as well as in the difference between the sequential redox events inherent in dioxolene compounds. These findings suggest that future efforts to design metal-*p*-dioxolene complexes with interesting redox characteristics (e.g., valence tautomerizm) will require careful consideration of how the redox properties of the bridging ligand are altered when bound to metals.

Experimental

General considerations

All reagents were purchased from either Lancaster or Sigma-Aldrich and were used as received. NMR spectra were obtained on a 300 MHz instrument. IR spectra were recorded as KBr pellets on a PerkinElmer Spectrum One FT-IR spectrometer. UV–vis spectra were taken on a Cary 50 instrument. Mass spectra were recorded on a Kratos Concept II instrument using electron impact (EI) or liquid secondary ion (LSIMS) source. Elemental analyses were performed by Canadian Microanalytical Services Ltd., Vancouver, BC, Canada. Cyclic voltammetry experiments were run on a Bioanalytical Systems CV50 voltammetric analyzer using an electrochemical cell containing the analyte (1 mmol/L), Bu_4NBF_4 (0.2 mol/L) as electrolyte, CH_2Cl_2 solvent, a silver wire as the reference electrode, and ferrocene/ferrocenium as an internal reference. The CV of *p*-benzoquinone (Table 2) was performed to enable direct comparisons with **9** run un-

[b] $wR_2 = [\Sigma w(|F_0| - |F_c|)^2/\Sigma w(|F_0|)^2]^{1/2}$.

der identical experimental conditions. EPR spectra were obtained using a Bruker EMX spectrometer with diluted samples (~10^{-5} mol/L) in capillary tubes. A capillary tube was employed to minimize the absorption of microwave radiation by the sample. Spectra were simulated using WinEPR SimFonia.

X-ray structure determination

X-ray diffraction data were collected on a Bruker X8 APEX II diffractometer with graphite-monochromatized Mo Kα radiation (λ = 0.710 73 Å). The structure was solved by direct methods (SHELXTL); see Table 3 for crystallographic data.[2]

Synthesis of 2,5-bis(diphenyl phosphino)-1,4-dimethoxybenzene (7)

n-BuLi (27.0 mL of a 1.6 mol/L hexanes solution, 43.2 mmol) was added dropwise to a –78 °C solution of 2,5-dibromo-1,4-dimethoxybenzene **6** (6.0 g, 20.3 mmol) in freshly distilled diethyl ether (100 mL) and tetrahydrofuran (50 mL) under argon. Upon addition, the solution was allowed to stir for 30 min at –78 °C before it was warmed to RT for an additional 4 h of stirring. The resulting slurry was once again cooled to –78 °C before diphenylchlorophosphine (8.5 mL, 47.0 mmol) was added dropwise. The reaction mixture was allowed to warm slowly to RT, stirring overnight to yield a pale yellow solution. The reaction mixture was then concentrated in vacuo, and the resulting residue was extracted into diethyl ether (3 × 100 mL). The ether fractions were combined and washed with distilled water (3 × 100 mL) before being dried with magnesium sulfate and taken to dryness in vacuo. Trituration of the residue with methanol afforded **7** as an off-white solid, yield 1.0 g (9.9%). NMR spectra were consistent with that the literature-reported compound (7).

Synthesis of 2,5-bis(diphenylphosphino)-1,4-benzoquinone (9)

Saturated solutions of 2,5-diphenylphosphino-1,4-hydroquinone **8** (100 mg, 0.21 mmol) and iodobenzene bisacetate (101 mg, 0.31 mmol) were obtained by heating the reagents in ethanol (20 mL and 5 mL respectively). The iodobenzene bisacetate solution was then added dropwise to the solution of **8**, causing an immediate colour change to dark red. The solution was stirred for 10 min with gentle heating before it was allowed to cool on ice for 30 min. The quinone was isolated by filtration and washed with methanol (2 × 5 mL) followed by diethyl ether (2 × 5 mL), affording **9** as a dark red microcrystalline solid; yield 46.8 mg, 47.0%. UV–vis (CH_2Cl_2) λ_{max}: 530 nm (ε = 752), 410 nm (ε = 2756), 230 nm (ε = 25660), 210 nm (ε = 7242). FT-IR (KBr, cm^{-1}): 3421 (w, br), 2972 (w), 1644 (vs), 1584 (m), 1556 (m), 1434 (m), 1322 (w), 1200 (m), 1067 (w), 1025 (w), 911 (w), 746 (m), 696 (m), 498 (w). ^{1}H NMR (CD_2Cl_2) δ: 7.39 (m, 20H), 6.18 ppm (dd, 2H, *J* = 1.5 Hz, 4 Hz). ^{13}C NMR (CD_2Cl_2, ppm) δ: (186.4, d, *J* = 16 Hz), (153.5, d, *J* = 27 Hz), (140.6, s (v.br)), (134.8, d, *J* = 22 Hz), (133.6, d, *J* = 9 Hz), (130.4, s), (129.6, d, *J* = 8 Hz). ^{31}P NMR (CD_2Cl_2, ppm) δ: –15.98. MS (EI) *m*/*z*: 475 (M^+, 100%). Anal. calcd. for $C_{30}H_{22}O_2P_2$: C 75.63, H 4.65, P 13.00; found: C 74.87, H 4.56, P 12.86.

Synthesis of μ-(2,5-diphenylphosphino-1,4-hydroquinone)-bis-palladiumhexafluoroacetylacetonate (10)

2,5-Diphenyl phosphine-1,4-hydroquinone **8** (250 mg, 0.52 mmol) and palladium (II) hexafluoroacetylacetonate (544 mg, 1.01 mmol) were dissolved in a minimum amount of toluene (15 mL and 5 mL respectively) with gentle heating. The hydroquinone solution was added dropwise to the solution containing bis(hexafluoroacetylacetonate)palladium. Immediately a dark brown precipitate formed. The reaction mixture was stirred for 5 min and filtered to isolate the precipitate. Purification of the isolated solid was achieved by dissolving the crude product in 50:50 CH_2Cl_2/Et_2O and filtering out insoluble matter. Palladium complex **10** was isolated as a golden brown solid; yield 204 mg, 35.4%. UV–vis (CH_2Cl_2) λ_{max}: 440 nm (ε = 5000), 360 nm (ε = 9900), 245 (ε = 79300), 215 nm (ε = 43600). FT-IR (KBr, cm^{-1}): 3446 (s, br), 2917 (w), 1629 (m), 1465 (w), 1439 (w), 1380 (w), 1259 (s), 1209 (m), 1152 (vs), 1098 (m), 566 (w), 532 (w). ^{1}H NMR (CD_2Cl_2) δ: 7.81 (m, 8H), 7.64 (m, 4H), 7.51 (m, 8H), 6.71 (dd, 2H, *J* = 6 Hz, 13 Hz), 6.17 ppm (s, 2H). ^{13}C NMR (CD_2Cl_2, ppm) δ: (176.8, q, *J* = 35 Hz), (175.0, q, *J* = 35 Hz), (168.8, t, *J* = 13 Hz), (133.4, d, *J* = 12 Hz),

Synthesis of μ-(2,5-diphenylphosphino-1,4-semiquinone)-bis-palladiumhexafluoroacetylacetonate (11)

Palladium complex **10** (130 mg, 0.12 mmol) was dissolved in freshly distilled dichloromethane (25 mL) under argon and allowed to stir for 10 min. In one portion, under a flow of argon, silver hexafluorophosphate (30 mg, 0.12 mmol) was added to the solution causing a colour change from orange to dark purple. The volume of the solution was reduced in vacuo (~10 mL), and dry hexane (~10 mL) was added causing the precipitation of a dark purple microcrystalline solid. The solution was cooled on ice for 10 min before it was filtered under inert atmosphere. The solid was washed with dry hexanes (2 × 10 mL) and dried in vacuo for 30 min before it was isolated in an inert atmosphere glove box. Semiquinone complex **11** was isolated as a microcrystalline dark purple solid; yield 125 mg, 85.0%. This complex is highly reactive in solution and in the solid state, precluding satisfactory elemental analysis. Characterization of **11** was completed using freshly prepared samples handled under an inert atmosphere. UV–vis (CH_2Cl_2) λ_{max}: 582 nm (ε = 6250), 464 (ε = 4000), 361 nm (ε = 8000), 308 nm (ε = 27500). FT-IR (KBr, cm^{-1}): 1630 (s), 1611 (m), 1449 (s), 1259 (s), 1225 (s), 1155 (s), 1103 (s), 833 (s), 691 (m), 557 (m), 530 (m). Satisfactory elemental analysis could not be obtained for this compound.

Synthesis and properties of end-capped bis(oligothienyl) sulfides

Daniel J. T. Myles, M'hamed Chahma, and Robin G. Hicks

Abstract: The synthesis, and the optical and electrochemical properties, of a series of mesitylthio (MesS-) end-capped bis(oligothienyl) sulfides are presented. The target compounds were synthesized principally by convergent protocols, whereby a series of short thiophene oligomers bearing one terminal mesitylthio (MesS-) substituent were first assembled by metal-catalyzed cross-coupling reactions and then coupled via divalent sulfur through reactions with bis(phenylsulfonyl) sulfide. The spectroscopic and electrochemical features of the bis(oligothienyl) sulfides are qualitatively similar to those of the related mesitylthio-capped fully conjugated oligothiophenes, suggesting that the degree of electronic communication between the two oligothiophene chromophores in the bis(oligothienyl) sulfides is low. Cyclic voltammetry studies on the bis(oligothienyl) sulfides reveal that these species can be reversibly oxidized to radical cations, but the reversibility of subsequent oxidations depends on oligothienyl chain length and the presence and position of more electron-rich ethylenedioxythiophene (EDOT) groups. In general, the bis(oligothienyl) sulfides possess fewer than the expected number of reversible oxidations based on comparisons with their corresponding mesitylthio-capped fully conjugated oligothiophenes; excessive charge accumulation at or near the central linking sulfur atom is believed to be responsible for the irreversible behavior. Analysis of the irreversible voltammetric response of one of the bis(oligothienyl) sulfides leads to the suggestion of a decomposition mechanism for the cationic species involving carbon–sulfur bond cleavage and subsequent coupling of thiophene fragments — a finding with potential implications for the poor environmental stability of doped poly(*p*-phenylene sulfide), one of the prototypical conducting polymers.

Key words: conjugated materials, conducting polymers, oligothiophenes, electronic communication.

Résumé : On a effectué la synthèse d'une série de bis(oligothiényl)sulfures fermés aux extrémités par des groupes mésitylthio (MesS–) et on en a déterminé les propriétés optiques et électrochimiques rapportées ici. Les produits recherchés ont été synthétisés par des protocoles convergents dans lesquels une série d'oligomères courts du thiophène portant un substituant terminal mésitylthio sont d'abord assemblés par des réactions de couplage croisées catalysées par un métal avant d'être couplés avec du soufre bivalent par le biais de réactions avec du sulfure de bis(phénylsulfonyle). Les caractéristiques spectroscopiques et électrochimiques des sulfures de bis(oligothiényle) sont qualitativement semblables à celles des oligothiophènes apparentés complètement conjugués et fermés aux extrémités par des groupes mésitylthio; ceci suggère que le degré de communication électronique est faible entre les deux chroromophores oligothiophènes des sulfures d'oligothiényle. Les études de voltampérométrie cyclique sur les sulfures de bis(oligothiényle) révèlent que ces espèces peuvent être oxydées d'une façon réversible en cations radicaux, mais que la réversibilité des oxydations subséquentes dépend de la longueur de la chaîne oligothiényle et de la présence et de la position de groupes éthylènedioxythiophène (EDOT) plus riches en électrons. En général, les sulfures de bis(oligothiényle) possèdent des nombres d'oxydation réversibles inférieurs à ceux qui pourraient être attendus sur la base de comparaison avec les oligothiophènes apparentés complètement conjugués et fermés aux extrémités par des groupes mésitylthio; l'accumulation excessive de charge au ou près de l'atome de soufre central pourrait être responsable de ce comportement irréversible. Une analyse de la réponse voltampérométrique irréversible d'un des sulfures de bis(oligothiényle) conduit à suggérer un mécanisme de décomposition pour l'espèce cationique impliquant une rupture de la liaison carbone-soufre et un couplage subséquent des fragments thiophènes, une observation qui présente des implications potentielles pour la mauvaise stabilité environnementale du poly(sulfure de *p*-phénylène) dopé, un des prototypes de polymères conducteurs.

Mots-clés : matériaux conjugués, polymères conducteurs, oligothiophènes, communication électronique.

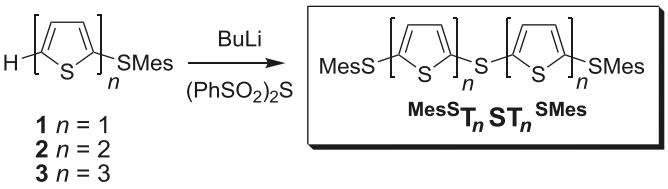
Introduction

The development of structure–property (electrochemical, spectroscopic, conducting, emissive) relationships for π-conjugated oligomers is a well-entrenched field of study (1). Many of these studies have produced important insights for the less well-defined — but technologically important — conjugated polymers. For example, the notion of π stacking as a mechanism for charge transport in conducting polymers was largely facilitated by electrochemical and spectroscopic studies on oligothiophenes (2). In addition, many conjugated oligomers are emerging as viable components of new electronic materials in their own right (3).

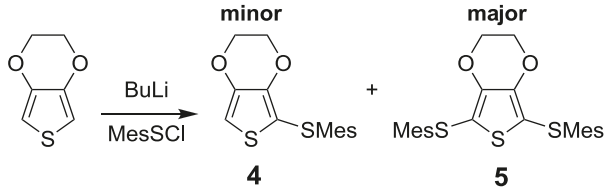
The diversity of functional polymers has increased greatly through the incorporation of inorganic segments into otherwise conventional organic systems. Many of these hybrid polymers are based on transition metals, (4), but there is a growing body of "organomain group" polymers containing p-block elements in the main chain (5). Polyaniline can be considered as a prototypical example (6), but polymers containing group 13 (7), 14 (8), or 15 (9) elements have been developed as well. Polymers containing group 16 elements in the main chain have a more sporadic history. Poly(thiazyl) $(SN)_x$ is noteworthy for its conducting and superconducting properties and as the forerunner to the field of organic conducting polymers (10). Poly(*p*-phenylene sulfide) (PPS) was one of the first conducting doped polymers and the first based on a commodity polymer (11). This material suffers from serious environmental stability problems in its oxidized (doped) forms. Related sulfur-bridged polymers are similarly unstable when doped (12). Nakayama and co-workers (13) have reported the synthesis of oligomeric analogues of PPS in which the *p*-phenylene is replaced by 2,5-thiophenediyl; no physical properties were presented. Finally, Manners and co-workers (14) have prepared poly(thiaferrocenes) via the ring-opening polymerization of [1]thiaferrocenophanes; the electronic properties of short, well-defined oligomers were also investigated as models for the polymer — a rare example of the application of the "oligomers approach" in conjugated main group polymer chemistry.

We have been investigating small molecule and polymeric conjugated oligothiophene–sulfur materials. We have demonstrated that mesitylthio- (MesS-) capped oligothiophenes $^{MesS}\mathbf{T}_n^{SMes}$ (n = 1–4) can be reversibly oxidized to radical cations and dications, some of which exhibit exceptional stability (15). The stability of the oxidized forms arises from both the blocking of the terminal (α and ω) carbon atoms of the oligothiophene segment as well as the strong π-donating nature of the thioether (-SR) group. We separately described several bis(oligothienyl) sulfides that could be electropolymerized to give poly(oligothienyl sulfide)s in which conjugated oligothiophene segments are linked together by divalent sulfur (16, 17); related poly(aryl sulfide)s and disulfides have been subsequently reported by other groups (18). The electrochemical properties of our poly(oligothienyl sulfide)s varied based on the structure of the monomer; generally, the polymers based on the electron-rich ethylenedioxythiophene (EDOT) building block showed reversible redox behavior, but those based on unsubstituted thiophenes showed significant irreversibility in their oxidative electrochemistry. The apparent differences between the oligomers

Scheme 1.



Scheme 2.



capped by SR groups and the polymers in which thiophene chromophores are *linked* by sulfur prompted us to prepare a series of model systems based on $^{MesS}\mathbf{T}_n\mathbf{ST}_n^{SMes}$ where $\mathbf{T}_n\mathbf{ST}_n$ is a bis(oligothienyl) sulfide segment — essentially a segment of the polymers — in which both terminal positions are also capped by SR groups to prevent electropolymerization (as opposed to the uncapped $\mathbf{T}_n\mathbf{ST}_n$ compounds, which upon electro-oxidation, polymerize to $(\mathbf{T}_n\mathbf{ST}_n)_m$.

Results and discussion

Synthesis

Scheme 1 outlines the general synthetic route to the mesitylthio end-capped bis(oligothienyl) sulfides. The target compounds were assembled by a convergent protocol, whereby two equivalents of an unsymmetrically substituted oligothiophene were metallated and then reacted with bis(phenylsulfonyl) sulfide; this sulfur transfer reagent has proven to be better than sulfur dichloride (SCl_2), for which these reactions typically proceed in low yield (14, 19, 20). (2-Mesitylthio)thiophene **1** was prepared by the reaction of 2-thienylmagnesium bromide with 2-mesitylenesulfenyl chloride (MesSCl). Subsequent lithiation of **1** with 1 equiv. of BuLi, followed by treatment with 0.5 equiv. of $(PhSO_2)_2S$ provided the desired sulfide $^{MesS}\mathbf{TST}^{SMes}$ in 80% yield. The bis(bithienyl) sulfide $^{MesS}\mathbf{T_2ST_2}^{SMes}$ was prepared by lithiation of bithiophene **2** (synthesized from 2,2′-bithiophene by deprotonation and reaction with MesSCl) and subsequent quenching with $(PhSO_2)_2S$. The bis(terthienyl) sulfide $^{MesS}\mathbf{T_3ST_3}^{SMes}$ required a slightly more elaborate route. Compound **2** was selectively brominated at the other terminal position with NBS in DMF (21) and then subsequently coupled with 2-tributylstannylthiophene using $Pd(PPh_3)_4$ as a catalyst to give **3** in 88% yield. Terthiophene **3** was converted to the targeted sulfide $^{MesS}\mathbf{T_3ST_3}^{SMes}$ by lithiation and quenching with $(PhSO_2)_2S$.

Variants of $^{MesS}\mathbf{TST}^{SMes}$ were also targetted in which the parent thiophene unit is replaced with the well-known (22) electron-rich 3,4-ethylenedioxythiophene moiety. However, the preparation of $^{MesS}\mathbf{ESE}^{SMes}$ by a convergent strategy was abandoned owing to difficulties in preparing the necessary precursor, namely, 2-mesitylthio-3,4-ethylenedioxythiophene **4**. The reaction of α-lithiated EDOT with 1 equiv. of

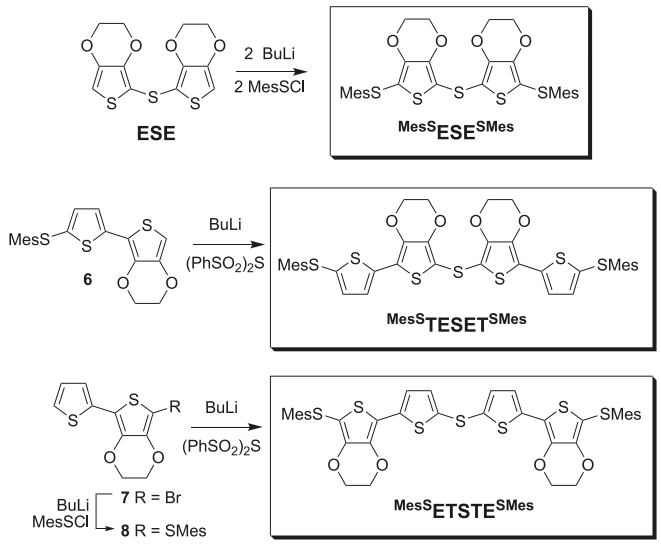
Scheme 3.



MesSCl preferentially gives the disubstituted compound **5** over the monosubstituted compound **4** (Scheme 2) (15).

The preparation of ^{MesS}**ESE**^{SMes} was accomplished by dilithiating bis(3,4-ethylenedioxythienyl) sulfide (6) **ESE** followed by treatment with 2 equiv. of MesSCl (Scheme 3). Two isomeric EDOT containing bis(bithienyl) sulfide derivatives were also prepared using convergent protocols as shown in Scheme 3. Lithiation of 6 (15) with *n*-BuLi followed by quenching with $(PhSO_2)_2S$ gave ^{MesS}**TESET**^{SMes}– with two EDOTs connected to the central sulfide, in 68% yield. The isomeric species required building block **8**, which was made by lithium–halogen exchange (BuLi) of **7** (25), followed by reaction with MesSCl to give the monosubstituted **8** in 66% yield. Finally, lithiation of **8**, followed by introduction of sulfur with $(PhSO_2)_2S$, afforded ^{MesS}**ETSTE**^{SMes}, in which the EDOT groups occupy the outer positions of the conjugated moieties, in 72% yield.

Electronic spectra

The solution spectra of the bis(oligothienyl) sulfides, together with the fully conjugated bis(mesitylthio) oligothiophenes previously reported (15), provide some insights into how the *terminal* and *internal* sulfur atoms perturb the π chromophores of oligothiophenes. The solution absorption spectral data are summarized in Table 1.

We have previously shown that mesitylthio (MesS-) substituents at the terminal (α, ω) positions cause moderate (~30 nm) red shifts in the lowest energy electronic transitions of oligothiophenes. This effect is apparent in the current series of bis(thienyl) sulfides. For example, the low energy transitions for the uncapped bis(thienyl) sulfides **TST** and **T$_2$ST$_2$** are at 268 and 335 nm, respectively; the maxima for the mesitylthio-capped analogues ^{MesS}**TST**^{SMes} and ^{MesS}**T$_2$ST$_2$**^{SMes} are 310 and 360 respectively. The incorporation of ethylenedioxy groups on the β-carbons also produces predictably moderate red shifts. On the other hand, the *internal* bridging sulfur units have little effect on extending the overall conjugation length. For example, λ_{max} for ^{MesS}**T$_2$ST$_2$**^{SMes}, with two single bithiophenes flanking a central sulfur, is only red-shifted by 2 nm relative to ^{MesS}**T$_2$**^{SMes}. which has a single bithiophene chromophore. In contrast, λ_{max} for ^{MesS}**T$_4$**^{SMes}, a fully conjugated tetrathiophene, is red-shifted by 50 nm relative to ^{MesS}**T$_2$ST$_2$**^{SMes}. Comparisons between other analogous pairs of oligomers (e.g., ^{MesS}**TST**^{SMes} vs. ^{MesS}**T**^{SMes}; ^{MesS}**ESE**^{SMes} vs. ^{MesS}**E**^{SMes}) reveal similar trends; overall the lowest energy absorption maxima is dominated by the nature of the individual thienyl segment: there is little additional delocalization between the two oligomeric units

© 2008 NRC Canada

through the central sulfur bridge. This is further corroborated by the fact that the extinction coefficients of the capped bis(thienyl) sulfides $^{MesS}\mathbf{T}_n\mathbf{ST}_n^{SMes}$ (see Experimental section) are *roughly* twice as large as the corresponding coefficients of the straight conjugated capped oligomers $^{MesS}\mathbf{T}_n^{SMes}$ (15). Thus, although the linking sulfur atom has two lone pairs of electrons, one of which in principle could engage in π overlap with the oligothienyl π system, the spectroscopic data suggests that the orientation of the thienyl units with respect to the S lone pair orbitals is not optimal for overlap and (or) π donation by S into what is already an electron-rich π system is ineffective.

Electronic spectra of the oxidized forms of several mesitylthio-capped oligothiophenes and bis (oligothienyl) sulfides were obtained either by electrochemical oxidation of the neutral species in solution or by chemical oxidation with $NOBF_4$. The cationic states of the "uncapped" oligomers are too reactive to observe, as they undergo the expected rapid coupling to yield polymers (16). Spectra of the cationic α,ω-bis-(mesitylthio) oligothiophenes $^{MesS}\mathbf{T}_n^{SMes}$ (n = 1–4) and $^{MesS}\mathbf{E}^{SMes}$ were obtained by chemical oxidation with $NOBF_4$ in CH_2Cl_2. Stable radical cations could be generated for all of these compounds, in accord with closely related bis(mesitylthio)oligothiophenes reported by us (15). Radical cation spectra could not be obtained for $^{MesS}\mathbf{ETSTE}^{SMes}$ or $^{MesS}\mathbf{T_3ST_3}^{SMes}$ owing to the small difference between first and second oxidation potentials for these compounds (see below); for the former, this problem is compounded by the instability of the dicationic state.

The electronic absorption spectrum for the radical cation of $^{MesS}\mathbf{T}^{SMes}$ has two absorption maxima at 412 and 638 nm. The corresponding EDOT-based compound $^{MesS}\mathbf{E}^{SMes}$ also has peaks at 405 and 551 nm. Within the thiophene series $^{MesS}\mathbf{T}_n^{SMes}$ (n = 1–4), as the thiophene chain length increases there is a shift to lower energies for the radical cation series and the (more limited) dication spectral series. The spectral features of these radical cations do not show any dependence on temperature (between –5 and +20 °C) or concentration (between 10^{-5} and 10^{-4} mol/L), suggesting that radical cation π dimerization does not occur. Dimer formation is most likely suppressed because of the steric hindrance of the capping mesityl groups.

Spectra of several of the capped bis(oligothienyl) sulfides in cationic states were also obtained. The radical cation of bis(thienyl) sulfide $^{MesS}\mathbf{TST}^{SMes}$ has two major bands at 555 and 896 nm. These are significantly red-shifted in comparison to the radical cation spectrum of $^{MesS}\mathbf{T}^{SMes}$ (412 and 638 nm). This sharply contrasts comparisons between the two neutral compounds, which are nearly identical to one another. This suggests that there may be a strong interaction between the two thiophene units *via* the sulfur bridge for $^{MesS}\mathbf{TST}^{SMes}$ in its radical cation state. This may arise from the fact that removal of an electron from the oligothiophene renders it a more electron-deficient π system, thereby facilitating stabilization (and hence delocalization) from a sulfur lone pair orbital. π-Dimer bands can be ruled out, based on the fact that the intensities of the 555 and 896 nm peaks show neither a concentration nor temperature dependence. Similar comparisons can be made for the EDOT analogues of these species: the radical cation of $^{MesS}\mathbf{E}^{SMes}$ has peaks at 405 and 551 nm, whereas bis(3,4-ethyelenedioxythienyl) sulfide $^{MesS}\mathbf{ESE}^{SMes}$ radical cation absorbs at 520 and 860 nm.

Table 2. Oxidation potentials of bis(oligothienyl) sulfides and related compounds as determined by cyclic voltammetry experiments (see Experimental section for details).

Compound	Oxidation potentials (V)	Reference
$^{MesS}\mathbf{TST}^{SMes}$	+1.14, +1.43*	This work

Note: All potentials are given as formal potentials ($E_{1/2}$) vs. SCE except for numbers denoted with an asterisk (*), which correspond to anodic peak potentials for irreversible oxidations.

Comparisons between the various compounds containing conjugated bithiophene chromophores are more complex. The radical cations of $^{MesS}\mathbf{T_2ST_2}^{SMes}$ (563 and 865 nm) and $^{MesS}\mathbf{T_2}^{SMes}$ (572 and 905 nm) have similar spectroscopic features, and in fact the absorption maxima of the former are actually slightly *blue*-shifted with respect to the latter. This indicates that little to no electronic coupling occurs between adjacent bithiophenes via the sulfur bridge, presumably because the radical cation in $^{MesS}\mathbf{T_2ST_2}^{SMes}$ is strongly localized in the bithiophene cores. However, this picture is complicated upon consideration of the spectrum of the radical cation of $^{MesS}\mathbf{TESET}^{SMes}$; the absorption maxima (725 and 1241 nm) are dramatically red-shifted compared with the all-thiophene analogue $^{MesS}\mathbf{T_2ST_2}^{SMes}$. This may suggest that the placement of the more electron-rich EDOT groups on the "internal" positions serves to concentrate spin and (or) charge closer to the central sulfur linker, thereby facilitating more effective delocalization.

The properties of the mesitylthio- capped model compounds can also be compared with the previously reported poly(oligothienyl sulfide)s. As a representative example, $^{MesS}\mathbf{E_2}^{SMes}$ has a S-EE-S unit that is also present in the polymer poly(ESE). Neutral poly(ESE) has its absorption maxima at 455 and 484 nm, whereas $^{MesS}\mathbf{E_2}^{SMes}$ absorbs at 362 nm. The fact that poly(ESE) has its absorptions red-shifted with respect to $^{MesS}\mathbf{E_2}^{SMes}$ provides evidence that the biEDOT units are electronically coupled in the neutral polymer; in this regard the "capped" molecules are analogous to the "uncapped" monomers (i.e., ESE) that were actually employed to synthesize the polymers. Furthermore, the doped polymer has absorptions at 605 and 1020 nm whereas the radical cation of $^{MesS}\mathbf{E_2}^{SMes}$ has two absorption bands at 509 and 900 nm. The red-shift is most likely due to strong intrachain electronic coupling of the biEDOT groups in the polymer, although interchain effects cannot be ruled out.

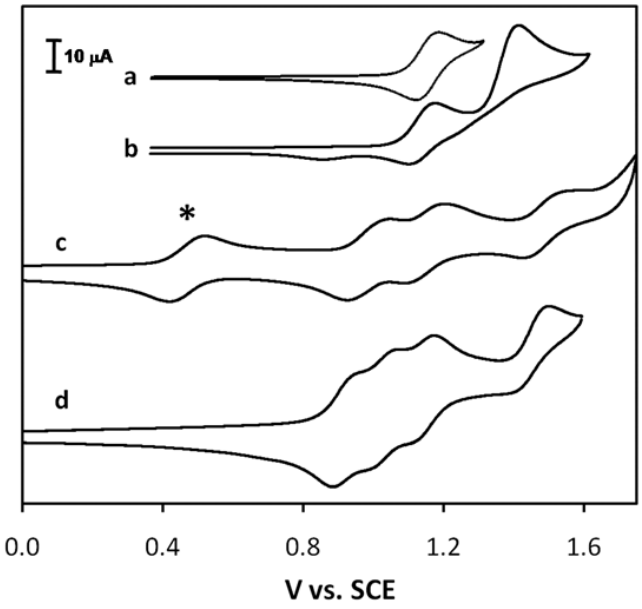
Electrochemical studies

The redox properties of the bis(thienyl) sulfides were studied using cyclic voltammetry. The results of these studies are summarized in Table 2, which also contains electrochemical data for the previously reported bis(mesitylthio)-capped oligothiophenes (15). Our previous work on the latter compounds established that the mesitylthio substituents provide stability to the oxidized forms of the oligothiophenes. This stability arises in part by "blocking" the α and ω positions, thereby preventing polymerization (via oxidative coupling) of the thiophene radical cation; the π-donating effect of the sulfur substituent also contributes to the stability of the cationic forms of the oligomers. These effects are also manifested in the bis(thienyl) sulfide compounds presented here. All of the new compounds exhibit at least one chemically reversible oxidation process (equivalence of anodic and cathodic peak currents, peak potentials that are scan-rate-independent); the anodic and cathodic peak separations for each compound lie in the range of 60–90 mV, which is comparable to that of the ferrocene/ferrocenium redox couple under the same experimental conditions and suggestive of quasi-reversible electrochemical behavior. Many of the bis(thienyl) sulfides can be reversibly oxidized to dications or even trications in a few cases.

In general, the oxidation potentials of oligothiophene are influenced by their chain length; longer oligomers are oxidized at lower potentials. Among the homologous series of bis(thienyl) sulfides $^{MesS}\mathbf{T}_n\mathbf{ST}_n^{SMes}$ (n = 1–3), this trend holds; however, the *change* in first oxidation potential as a function of chain length for this series is comparable to the corresponding changes in the fully conjugated thiophenes. The first oxidation potential of $^{MesS}\mathbf{T}^{SMes}$ is +1.05 V. Extending the conjugated segment from one to two thiophenes (i.e., $^{MesS}\mathbf{T}_2^{SMes}$, E_1° = +0.87 V) leads to a drop in first oxidation potential of 0.18 V. Analogous comparisons between $^{MesS}\mathbf{TST}^{SMes}$ (E_1° = +1.14 V) and $^{MesS}\mathbf{T}_2\mathbf{ST}_2^{SMes}$ (E_1° = +0.99 V) produce qualitatively similar results: the first oxidation potential for the longer oligomers is +0.15 V lower. Thus, although $^{MesS}\mathbf{T}_2\mathbf{ST}_2^{SMes}$ is *two* thiophene units longer than $^{MesS}\mathbf{TST}^{SMes}$, the comparative electrochemical properties (in conjunction with the electronic spectra, see above) suggest that the connection of two thiophene segments by a divalent sulfur linker does not lead to an extension of effective conjugation length.

Given that the bis(thienyl) sulfides contain two thiophene chromophores sharing a common linker, the electrochemical responses of these might naïvely be expected to consist of the sum of the individual processes associated with each thiophene segment, i.e., $^{MesS}\mathbf{T}_n\mathbf{ST}_n^{SMes}$ should possess twice as many oxidations as $^{MesS}\mathbf{T}_n^{SMes}$. This is not the case. Figure 1 shows the cyclic voltammograms of $^{MesS}\mathbf{T}_n\mathbf{ST}_n^{SMes}$ (n = 1–3). For example, $^{MesS}\mathbf{T}^{SMes}$ and $^{MesS}\mathbf{E}^{SMes}$ both possess one reversible oxidation process. Given that the bis(thienyl) sulfide analogues $^{MesS}\mathbf{TST}^{SMes}$ and $^{MesS}\mathbf{ESE}^{SMes}$ contain two "monothiophenes", these compounds might be expected to have two oxidation waves corresponding to one-electron removal from each of the two thiophene units. However, both of these can only be reversibly oxidized to radical cations; the second oxidation process in both compounds is irreversible. In a similar vein, all of the other "parent" oligomers $^{MesS}\mathbf{T}_n^{SMes}$ (n > 1) can be reversibly oxidized

Fig. 1. Cyclic voltammograms of (*a*) $^{MesS}\mathbf{TST}^{SMes}$ (first oxidation only), (*b*) $^{MesS}\mathbf{TST}^{SMes}$ (full scan), (*c*) $^{MesS}\mathbf{T}_2\mathbf{ST}_2^{SMes}$; and (*d*) $^{MesS}\mathbf{T}_3\mathbf{ST}_3^{SMes}$. The redox process labelled with an asterisk in (*c*) corresponds to the ferrocene/ferrocenium redox couple (added as a reference). See Experimental section for details.

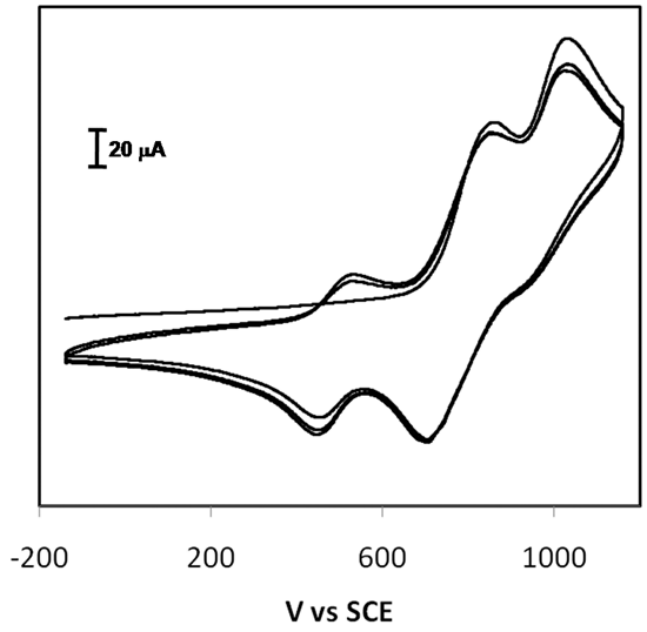


to radical cations and dications, but the corresponding bis(thienyl) sulfides $^{MesS}\mathbf{T}_n\mathbf{ST}_n^{SMes}$ (n = 2, 3) have fewer than the expected four reversible oxidation waves: the bis(bithienyl) sulfide $^{MesS}\mathbf{T}_2\mathbf{ST}_2^{SMes}$ has two reversible and one quasi-reversible wave, and the bis(terthienyl) sulfide $^{MesS}\mathbf{T}_3\mathbf{ST}_3^{SMes}$ has three very closely spaced reversible oxidations and a fourth irreversible one at higher potentials. Overall, the charge storage capacity of these compounds is relatively limited compared with the parent, fully conjugated counterparts.

The two mixed thiophene–EDOT compounds $^{MesS}\mathbf{TESET}^{SMes}$ and $^{MesS}\mathbf{ETSTE}^{SMes}$ contain the same fundamental chromophore — a bis(thioether) substituted unsymmetric bithiophene $^{RS}\mathbf{ET}^{SR}$. Given the analyses of the electrochemical properties of the other bis(thienyl) sulfides, it is not surprising that the first oxidation of $^{MesS}\mathbf{TESET}^{SMes}$ and $^{MesS}\mathbf{ETSTE}^{SMes}$ occur at the same potential. However, the electrochemical behavior of these two isomers beyond the first oxidations differs markedly. The former compound can only be reversibly oxidized to a radical cation, whereas the latter has two fully reversible oxidations and a third that is quasi-reversible (tending towards reversibility at high scan rates); it is not until the fourth oxidation that decomposition occurs. The differences in electrochemical responses between these compounds can be understood by consideration of the location of the more electron-rich EDOT moieties. $^{MesS}\mathbf{TESET}^{SMes}$ has the EDOTs directly flanking the central sulfur atom. The first two oxidations correspond to electron removal from each of the "**ET**" moieties, but with the spin and charge on both components more localized on the EDOT moieties. Thus the dication of this compound appears to have sufficient spin and charge concentration to render it unstable (a proposal of how this compound may degrade is provided below). In contrast, the isomeric $^{MesS}\mathbf{ETSTE}^{SMes}$

© 2008 NRC Canada

Fig. 2. Multiple cycle CV of ^{MesS}**TESET**^{SMes}. The redox process at +0.5 V vs SCE appears on the second anodic sweep.



has the EDOTs located near the ends of the molecule. The dication of this compound should therefore have its spin and (or) charge driven towards each end, meaning that the two cationic chromophores do not perturb one another to the same extent, and thereby providing stability to the dication. We have previously rationalized the differences between the electrochemical properties of fully conjugated mixed EDOT–thiophene compounds ^{MesS}**TEET**^{SMes} and ^{MesS}**ETTE**^{SMes} based on similar topological arguments (15).

Electrochemical cycling through the second (irreversible) oxidation of ^{MesS}**TESET**^{SMes} leads to the appearance of a growth of a new reversible redox couple on the second anodic scan at a potential of +0.5 V, substantially lower than the first oxidation potential of this compound (Fig. 2). The potential for this new process matches the first oxidation potential of ^{MesS}**TEET**^{SMes} (Table 2). We suggest that this species is in fact being formed during the course of the oxidative decomposition of ^{MesS}**TESET**^{SMes}. Although the precise mechanistic details are unclear, one possible process involves decomposition of the dication via carbon–sulfur bond scission involving the central sulfur atom. The resulting "**ET**^{SMes}" fragments could then couple via CC bond formation between two EDOTs to give ^{MesS}**TEET**^{SMes}.

Conclusions

Several bis(oligothienyl) sulfides have been prepared and their redox and spectroscopic properties investigated. The terminal mesitylthio substituents prevent oxidative polymerization of these species and facilitate the detailed examination of structure–property relationships. Overall, the "electronic communication", i.e., delocalization, between two oligothiophene segments via a sulfur atom connector is relatively weak. Nonetheless, there are clear sequential one-electron oxidation processes corresponding to electron loss from each of the two segments in the cyclic voltammograms of most of the oligomers. Electrostatic effects are the most likely reason behind this behavior, (i.e., the proximity of the first positive charge can make it harder to create a second positive charge) and can produce the same effect.

The capped bis(oligothienyl) sulfides can all be reversibly oxidized, but after that, deleterious effects of excessive charge begin to appear. We have previously established that MesS-capped oligothiophenes can be oxidized twice, in some cases affording very stable cationic species. The bis(oligothienyl) sulfides have two such moieties and also can be oxidized, though the charge storage capability does not scale with the doubling of thiophene chromophores. This may explain why the poly(oligothienyl sulfide)s were not as well-behaved electrochemically (17) — overoxidation leads to decomposition (a common fate of fully conjugated polymer redox processes). In fact PPS was one of the first polymers to be doped to conducting form, though the doped forms are highly reactive. Our electrochemical studies are consistent with the relatively poor charge storage capacity of these systems; the suggestion that carbon–sulfur bond cleavage as a major decomposition route, which is supported by the recent description of synthetically useful version of this reaction (23), may be a possible model for doped PPS (and relatives) itself.

Experimental[3]

General

Unless stated otherwise, all reactions and manipulations were carried out under an argon atmosphere using standard Schlenk line or glovebox techniques. Glassware was dried in an oven at 125 °C for 24 h prior to use. Solvents were dried and distilled under argon prior to use (acetonitrile, dichloromethane, and hexanes from CaH_2; diethyl ether, tetrahydrofuran, and toluene from sodium benzophenone ketyl). All reagents were purchased from commercial sources and used as received except as otherwise stated. The following compounds were prepared according to literature procedures: 2-mesitylenesulfenyl chloride (15), bis(phenylsulfonyl) sulfide (19), 2,2′-bithiophene (24), bis(3,4-ethylenedioxy-2-thienyl) sulfide (ESE) (16), 3,4-ethylenedioxy-5′-mesitylthio-2,2′-bithiophene (6, 15), and 3,4-ethylenedioxy-5-bromo-2,2′-bithiophene (7, 25).

^{1}H NMR spectra were recorded at 300 MHz and ^{13}C NMR spectra were recorded at 75 MHz, unless otherwise noted. Melting points are uncorrected. Electronic spectra were recorded on a Varian Cary 5 spectrometer using 10 mm quartz cuvettes. All UV–vis and NIR studies were performed in freshly distilled dichloromethane. Voltammetric measurements were performed at RT (22 ± 2 °C) (except for variable temperature studies) in dichloromethane containing 1 mmol/L substrate (except for the variable concentration studies) and 1 mol/L of *n*-Bu_4NBF_4 as electrolyte. Platinum

button (diameter 1.6 mm) was used as the working electrode. Platinum wire and silver wire were used as the counter and quasi-reference electrodes, respectively. The working electrode was polished on alumina before use. *iR* compensations were applied for all experiments for potential measurements. All redox potentials were calibrated by comparing to ferrocene, which was added as an internal reference and then reported vs. SCE (Fc/Fc_+ E_o = +0.46 V vs SCE in CH_2Cl_2). The number of electrons associated with the redox processes were determined by comparison of the peak current magnitudes with those of equimolar quantities of the internal reference. Solutions of cationic species were generated either electrochemically (by constant potential bulk electrolysis in a two-compartment cell using two 3 cm × 3 cm platinum plates as cathode and anode) or chemically (by additions of aliquots of substoichiometric quantities, typically 0.2 equiv. at a time, of $NOBF_4$ solutions as oxidant).

2-(Mesitylthio)thiophene (1)

2-Bromothiophene (4.00 g, 24.5 mmol) was added to a slurry of magnesium powder (0.90 g, 37.0 mmol) in diethyl ether (20 mL). The reaction was initiated with a small amount of the bromo reagent and a crystal of iodine. Once the exothermic reaction had started, the remaining bromo reagent was added dropwise to the ice-cooled magnesium slurry over the course of 20 min. The solution was allowed to warm to RT and then refluxed for 1 h, after which the brown Grignard solution was recooled to 0 °C, and a solution of 2-mesitylenesulfenyl chloride (4.57 g, 24.5 mmol) in hexanes (25 mL) was added dropwise via cannula. The resulting pale brown solution was stirred at 0 °C for an additional 30 min. The mixture was then warmed to RT and poured into brine (100 mL). The aqueous layer was extracted with ether (3 × 50 mL), and the combined organic extracts were further washed with water (3 × 50 mL) and dried over anhydrous sodium sulfate. After filtration, removal of the solvent gave a dark brown oil, which was purified by flash chromatography (silica gel, hexanes) to provide a pale yellow liquid of **1**, yield 4.41 g (77%). ^{1}H NMR (CD_2Cl_2) δ: 7.16 (dd, *J* = 5.1, 1.5 Hz, 1H), 6.95 (s, 2H), 6.92 (dd, *J* = 3.7, 1.5 Hz, 1H), 6.88 (dd, *J* = 5.1, 3.7 Hz, 1H), 2.49 (s, 6H), 2.25 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 142.82, 139.27, 137.42, 130.03, 129.36, 128.24, 127.09, 126.07, 21.82, 21.09. HRMS (EI) for $C_{13}H_{14}S_2$ [M^+]: calcd. 234.0537; found 234.0541.

Bis(5-mesitylthio-2-thienyl) sulfide (^{MesS}TST^{SMes})

This compound has been prepared previously by a different route (26). A solution of **1** (5.00 g, 21.3 mmol) in THF (100 mL) cooled to –70 °C was treated dropwise with *n*-butyllithium (13.3 mL, 21.3 mmol, 1.6 mol/L in hexanes). The resulting yellow solution was stirred at –70 °C for 1 h, after which a solution of bis(phenylsulfonyl) sulfide (3.34 g, 10.6 mmol) in THF (20 mL) was added dropwise via cannula, and the resulting golden yellow solution was stirred at –70 °C for an additional 1 h. The mixture was warmed to RT and poured into water (100 mL). The aqueous layer was extracted with ether (3 × 50 mL), and the combined organic extracts were further washed with water (3 × 50 mL), and dried over anhydrous sodium sulfate. After filtration, removal of the solvent gave a yellow oil, which was purified by column chromatography (silica gel, hexanes/ethyl acetate (9:1 *v*/*v*)) to provide a slightly yellow solid. Recrystallization from methanol/chloroform produced white crystalline flakes of ^{MesS}TST^{SMes}, yield 4.26 g (80%), mp 92 °C. UV–vis (CH_2Cl_2) λ_{max} (nm): 310 (ε 1.9 × 10^4). Remaining spectroscopic data are identical to those found in ref. 26.

5-Mesitylthio-2,2′-bithiophene (2)

To a solution of 2,2′-bithiophene (3.00 g, 18.0 mmol) in THF (60 mL) was added dropwise *n*-butyllithium (11.3 mL, 18.1 mmol, 1.6 mol/L in hexanes) at 0 °C. The mixture was warmed to RT and stirred for 1.5 h. The mixture was cooled to –70 °C, and a solution 2-mesitylenesulfenyl chloride (3.38 g, 18.1 mmol) in hexanes (25 mL) was then added dropwise via cannula. Stirring was continued at –70 °C for 0.5 h, then the mixture was allowed to warm to RT, and water (50 mL) was added. The aqueous layer was washed with ether (50 mL), and the organic extracts were washed with brine (3 × 50 mL), and dried over anhydrous magnesium sulfate. The solvent was removed by rotary evaporation, and the green oily residue was purified by column chromatography (silica gel, hexanes) to provide a slightly yellow solid. Subsequent recrystallization from methanol produced white crystalline flakes of 2, yield 3.60 g (63%), mp 46 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.13 (dd, *J* = 5.1, 1.1 Hz, 1H), 7.01 (dd, *J* = 3.6, 1.1 Hz, 1H), 6.96 (s, 2H), 6.94–6.92 (m, 2H), 6.81 (d, *J* = 3.7 Hz, 1H), 2.53 (s, 6H), 2.28 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 142.82, 139.46, 137.77, 137.17, 136.74, 129.55, 129.44, 128.82, 127.71, 124.15, 123.56, 123.44, 21.84, 21.11. MS (LSI) *m*/*z*: 316 (M^+, 100%). Anal. calcd. $C_{17}H_{16}S_3$: C 64.51, H 5.10, S 30.39; found: C 64.58, H 5.29, S 30.07.

Bis(5′-mesitylthio-5,2′-bithien-2-yl) sulfide (^{MesS}T$_2$ST$_2^{SMes}$)

A solution of 2 (6.00 g, 18.9 mmol) in THF (150 mL) cooled to –70 °C was treated dropwise with *n*-butyllithium (11.9 mL, 19.0 mmol, 1.6 mol/L in hexanes). The resulting bright yellow solution was stirred at –70 °C for 1 h. After which, a solution of bis(phenylsulfonyl) sulfide (2.98 g, 9.48 mmol) in THF (20 mL) was added dropwise via cannula, and the resulting orange solution was stirred at –70 °C for an additional 1 h. The mixture was warmed to RT and poured into water (100 mL). The fine yellow precipitate was filtered off and washed with cold methanol (3 × 50 mL). This solid was recrystallized from a mixture of chloroform and methanol (120 mL, 1:1 *v*/*v*) to afford ^{MesS}T$_2$ST$_2^{SMes}$ as pale yellow needles, yield 4.90 g (78%), mp 154 °C. UV–vis (CH_2Cl_2) λ_{max} (nm): 360 (ε 3.9 × 10^4). ^{1}H NMR ($CDCl_3$) δ: 7.00 (d, *J* = 3.7 Hz, 2H), 6.94 (s, 4H), 6.86 (d, *J* = 4.4 Hz, 2H), 6.80 (d, *J* = 3.7 Hz, 2H), 6.74 (d, *J* = 4.4 Hz, 2H), 2.48 (s, 12H), 2.27 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 142.82, 141.33, 139.57, 137.89, 136.72, 133.58, 133.48, 129.46, 129.27, 128.38, 124.02, 123.28, 21.78, 21.10. MS (EI) *m*/*z*: 662 (M^+, 100%). Anal. calcd. for $C_{34}H_{30}S_7$: C 61.59, H 4.56, S 33.85; found: C 61.40, H 4.49, S 33.85.

5-Bromo-5′-mesitylthio-2,2′-bithiophene

5-Mesitylthio-2,2′-bithiophene 2 (6.32 g, 20.0 mmol) was dissolved in DMF (100 mL). In the absence of light, NBS

© 2008 NRC Canada

(3.91 g, 22.0 mmol) was added portionwise to the solution at RT. After addition, the solution was stirred at RT overnight in the dark. The resulting pale yellow solution was diluted with dichloromethane (100 mL) and poured into brine (100 mL). The aqueous phase was collected and washed with a second portion of dichloromethane (100 mL). All organics were collected and extracted with water (5 × 100 mL) to remove any remaining DMF. The dichloromethane layer was dried over anhydrous sodium sulfate, filtered, and evaporated. The obtained pale orange liquid was purified by column chromatography (silica gel, hexanes/dichloromethane (4:1 *v*/*v*)) to provide 5-bromo-5′-mesityl-2,2′-bithiophene as a yellow liquid, yield 7.10 g (90%). This compound was used in the next step without further purification. ^{1}H NMR ($CDCl_3$) δ: 6.94 (s, 2H), 6.87 (d, *J* = 4.4 Hz, 1H), 6.84 (d, *J* = 3.7 Hz, 1H), 6.75 (d, *J* = 3.7 Hz, 1H), 6.72 (d, *J* = 3.7 Hz, 1H), 2.49 (s, 6H), 2.26 (s, 3H). MS (LSI) *m*/*z*: 394 (M^+, ^{79}Br, 90%), 395 (M + 1, ^{79}Br, 28%), 396 (M^+, ^{81}Br, 100%), 397 (M + 1, ^{81}Br, 27%).

5-Mesitylthio-2,2′:5′,2″-terthiophene (3)

A flask was charged with 2-(tributylstannyl)thiophene (3.05 mL, 9.59 mmol), 5-bromo-5′-mesitylthio-2,2′-bithiophene (3.79 g, 9.59 mmol), $Pd(PPh_3)_4$ (554 mg), and toluene (20 mL). The mixture was heated to reflux for 20 h. After cooling to RT, the black mixture was diluted with ether (100 mL) and poured into saturated potassium fluoride (100 mL). The resulting tributyltin fluoride was filtered off and washed with cold ether (3 × 15 mL). The organic phase was collected, washed with brine (3 × 100 mL), and dried over anhydrous sodium sulfate. The solvent was removed by rotary evaporation, and the dark yellow residue was purified by column chromatography (silica gel, hexane/EtOAc (9:1 *v*/*v*)) to provide a bright yellow solid. Recrystallization from ethanol produced yellow crystalline plates of **3**, yield 3.36 g (88%), mp 80 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.18 (dd, *J* = 5.1, 1.1 Hz, 1H), 7.11 (dd, *J* = 3.6, 1.1 Hz, 1H), 6.99 (d, *J* = 3.8 Hz, 1H), 6.98 (dd, *J* = 5.1, 3.6 Hz, 1H), 6.96 (s, 2H), 6.92 (d, *J* = 3.7 Hz, 1H), 6.90 (d, *J* = 3.8 Hz, 1H), 6.80 (d, *J* = 3.8 Hz, 1H), 2.52 (s, 6H), 2.28 (s, 3H). MS (LSI) *m*/*z* : 398 (M^+, 100%). Anal. calcd. $C_{21}H_{18}S_4$: C 63.27, H 4.55, S 32.18; found: C 63.47, H 4.51, S 31.92.

Bis(5″-mesitylthio-5,2′:5′,2″-terthien-2-yl) sulfide ($^{MesS}T_3ST_3^{SMes}$)

A solution of **3** (765 mg, 1.92 mmol) in THF (25 mL), cooled to –70 °C, was treated dropwise with *n*-butyllithium (1.20 mL, 1.92 mmol, 1.6 mol/L in hexanes). The resulting bright orange solution was stirred at –70 °C for 1 h. After which, a solution of bis(phenylsulfonyl) sulfide (302 mg, 0.96 mmol) in THF (10 mL) was added dropwise via cannula, and the resulting orange solution was stirred at –70 °C for an additional 1 h. The mixture was then warmed to RT and poured into a cold mixture of diethyl ether and water (120 mL, 1:5 *v*/*v*). The fine yellow precipitate was filtered off and washed with cold methanol (3 × 15 mL). This solid was recrystallized from a mixture of tetrahydrofuran and methanol (40 mL, 1:1 *v*/*v*) to afford $^{MesS}T_3ST_3^{SMes}$ as dark golden yellow crystals, yield 400 mg (50%), mp 156 °C. UV–vis (CH_2Cl_2) λ_{max} (nm) 395 (ε 6.5 × 10^4). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.08 d, *J* = 3.7 Hz, 2H), 6.93–6.95 (m, 8H), 6.90 (d, *J* = 3.7 Hz, 2H), 6.86 (d, *J* = 3.8 Hz, 2H), 6.78 (d, *J* = 3.7 Hz, 2H), 2.50 (s, 12H), 2.27 (s, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 143.06, 141.51, 139.78, 137.74, 137.22, 136.82, 135.30, 134.07, 133.89, 129.68, 129.54, 128.77, 124.91, 124.14, 123.94, 123.77, 22.01, 21.32. MS (LSI) *m*/*z:* 826 (M^+, 10%). Anal. calcd. $C_{42}H_{34}S_9$: C 60.97, H 4.14, S 34.88; found: C 60.67, H 4.17, S 34.27.

Bis(5-mesitylthio-3,4-ethylenedioxy-2-thienyl) sulfide (^{MesS}ESE^{SMes})

A solution of bis(3,4-ethylenedioxy-2-thienyl) sulfide ESE (2.06 g, 6.55 mmol) was cooled to –40 °C and treated slowly with *n*-butyllithium (8.19 mL, 13.1 mmol, 1.6 mol/L in hexanes). The bright red solution was stirred for 1.5 h at –40 °C. After which, the solution was cooled to –70 °C, and a freshly prepared solution of 2-mesitylenesulfenyl chloride (2.45 g, 13.1 mmol) in hexanes (15 mL) was added dropwise via cannula. The resulting pale brown solution was stirred at –70 °C for an additional 30 min. The mixture was then warmed to RT and poured into water (100 mL). The fine white precipitate of ^{MesS}ESE^{SMes} was filtered off, washed with cold methanol (3 × 20 mL), and dried in vacuo. Yield 2.10 g (52%), mp 206 °C. UV–vis (CH_2Cl_2) λ_{max} (nm) 309 (ε 2.3 × 10^4). ^{1}H NMR ($CDCl_3$) δ: 6.90 (s, 4H), 4.19 (m, 8H), 2.48 (s, 12H), 2.25 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 143.13, 142.92, 140.55, 139.40, 129.53, 128.99, 113.53, 107.17, 64.95, 64.77, 22.19, 21.27. MS (LSI) *m*/*z*: 614 (M^+, 18%), 463 ((M – $C_9H_{11}S)^+$, 100%). Anal. calcd. $C_{30}H_{30}O_4S_5$: C 58.60, H 4.92, S 26.07; found: C 58.21, H 4.72, S 26.07.

Bis(5′-mesitylthio-3,4-ethylenedioxy-5,2′-bithien-2-yl)sulfide (^{MesS}TESET^{SMes})

A solution of 3,4-ethylenedioxy-5′-mesitylthio-2,2′-bithiophene 6 (0.85 g, 2.27 mmol) in THF (15 mL) cooled to –40 °C was treated dropwise with *n*-butyllithium (1.42 mL, 2.27 mmol, 1.6 mol/L in hexanes). The bright orange solution was stirred at –40 °C for 1.5 h. After which, the solution was cooled to –70 °C, and a solution of bis(phenylsulfonyl) sulfide (0.36 g, 1.15 mmol) in THF (10 mL) was added dropwise via cannula. The resulting yellow solution was stirred at –70 °C for an additional 30 min. The mixture was then warmed to RT and poured into a cold mixture of diethyl ether and water (120 mL, 1:5 *v*/*v*). The fine yellow precipitate was filtered off and washed with cold water (3 × 15 mL). This solid was recrystallized from a mixture of chloroform and methanol (80 mL, 3:5 *v*/*v*) to afford ^{MesS}TESET^{SMes} as yellow flakes, yield 0.60 g (68%), mp 198 °C. UV–vis (CH_2Cl_2) λ_{max} (nm) 375 (ε 4.2 × 10^4). ^{1}H NMR ($CDCl_3$) δ: 6.93 d, *J* = 3.7 Hz, 2H), 6.92 (s, 4H), 6.76 (d, *J* = 3.7 Hz, 2H), 4.26 (m, 8H), 2.48 (s, 12H), 2.25 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 143.70, 142.94, 139.45, 136.82, 136.70, 134.90, 129.85, 129.60, 128.86, 123.55, 115.51, 104.47, 65.14, 64.85, 22.07, 21.29. HRMS (LSI) for $C_{38}H_{34}O_4S_7$ [M^+]: calcd. 778.0502; found 778.0502. Anal. calcd. for $C_{38}H_{34}O_4S_7$: C 58.58, H 4.40, S 28.81; found: C 58.47, H 4.39, S 28.38.

3,4-Ethylenedioxy-5-mesitylthio-2,2′-bithiophene (8)

A solution of 3,4-ethylenedioxy-5-bromo-2,2′-bithiophene 7 (3.90 g, 12.9 mmol) in THF (40 mL) cooled to –78 °C was

© 2008 NRC Canada

treated dropwise with *n*-butyllithium (8.04 mL, 12.9 mmol, 1.6 mol/L in hexanes). The resulting bright red solution was stirred for 1.5 h at –78 °C. A solution of 2-mesitylenesulfenyl chloride (2.41 g, 12.9 mmol) in hexanes (20 mL) was added dropwise via cannula, and the resulting rusty red solution was stirred at –78 °C for an additional 30 min. The mixture was warmed to RT and poured into water (100 mL). The aqueous layer was extracted with ether (3 × 50 mL), and the combined organic extracts were further washed with water (3 × 50 mL) and dried over anhydrous sodium sulfate. After filtration, removal of the solvent gave a dark yellow solid, which was purified by column chromatography (silica gel, hexanes/dichloromethane (1:1 *v*/*v*)) to provide a bright yellow solid. Recrystallization from methanol/chloroform produced bright yellow needles of **8**, yield 3.20 g (66%), mp 120 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.15 dd, *J* = 5.1, 1.1 Hz, 1H), 7.08 (dd, *J* = 3.7, 1.1 Hz, 1H), 6.94 (dd, *J* = 5.1, 3.7 Hz, 1H), 6.92 (s, 2H), 4.29 (m, 4H), 2.56 (s, 6H), 2.25 (s, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 142.68, 141.51, 138.91, 136.52, 134.25, 129.44, 129.23, 126.93, 123.74, 122.74, 113.00, 107.07, 64.76, 64.69, 21.97, 20.95. MS (EI) *m*/*z*: 374 (M^+, 100%). Anal. calcd. $C_{19}H_{18}O_2S_3$: C 60.93, H 4.84, S 25.68; found: C 60.75, H 4.92, S 25.67.

Bis(5′-mesitylthio-3′,4′-ethylenedioxy-5-2′-bithien-2-yl) sulfide (^{MesS}ETSTE^{SMes})

A solution of **8** (1.00 g, 2.67 mmol) in THF (30 mL), cooled to –40 °C, was treated dropwise with *n*-butyllithium (1.67 mL, 2.67 mmol, 1.6 mol/L in hexanes). The dark red solution was stirred at –40 °C for 1 h. After which, the solution was cooled to –70 °C, and a solution of bis(phenylsulfonyl) sulfide (0.42 g, 1.34 mmol) in THF (10 mL) was added dropwise via cannula. The resulting pale red solution was stirred at –70 °C for an additional 30 min. The mixture was then warmed to RT and poured into water (75 mL). The fine yellow precipitate was filtered off and washed with cold methanol (3 × 20 mL). This solid was recrystallized from a mixture of chloroform and methanol (80 mL, 3:5 *v*/*v*) to afford ^{MesS}ETSTE^{SMes} as yellow needles, yield 0.75 g, (72%), mp 213 °C. UV–vis (CH_2Cl_2) λ_{max} (nm) 375 (ε 4.4 × 10^4). ^{1}H NMR (500 MHz, THF-d_8) δ: 7.05 d, *J* = 3.9 Hz, 2H), 6.92 (s, 4H), 6.91 (d, *J* = 3.9 Hz, 2H), 4.27 (m, 8H), 2.51 (s, 12H), 2.22 (s, 6H). ^{13}C NMR (125 MHz, THF-d_8) δ: 143.48, 142.99, 139.84, 139.78, 138.69, 134.03, 133.77, 130.35, 130.10, 123.03, 112.90, 108.54, 65.96, 65.78, 22.26, 21.11. HRMS (LSI) for $C_{38}H_{34}O_4S_7$ [M^+]: calcd. 778.0502, found 778.0490. Anal. calcd. for $C_{38}H_{34}O_4S_7$: C 58.58, H 4.40, S 28.81; found: C 58.67, H 4.42, S 28.55.

FTIR spectroscopic investigation of pyruvate electroreduction on copper in alkaline medium — On the mechanistic aspects

Cédric Martin, Françoise Hahn, Karine Servat, Hervé Huser, Duarte Tito, Maher Kalaji, and K. Boniface Kokoh

Abstract: In this work some important aspects related to the electrocatalytic reduction of pyruvate on copper cathode were investigated in alkaline medium (0.5 mol/L NaOH). In situ IR reflectance spectroscopy (SPAIRS and SNIFTIRS techniques) was used to investigate the adsorbed intermediates and reaction products from the reduction of pyruvate. The results revealed that hydrogenation of the substrate to lactate occurred at the copper surface involving weakly adsorbed species. The identification of the different electroreactive species allowed to postulate a reaction mechanism for the transformation of pyruvate into lactate on copper.

Key words: copper, electroreduction, pyruvate, lactate, in situ infrared reflectance spectroscopy, reaction mechanism.

Résumé : D'importants aspects mécanistiques relatifs à la réduction électrocatalytique du pyruvate sur une cathode en cuivre ont fait l'objet dans ce travail d'une investigation en milieu alcalin (NaOH 0,5 mol/L). La spectroscopie infrarouge de réflexion, sous ses deux variantes SPAIRS et SNIFTIRS, a principalement été utilisée pour déterminer les intermédiaires adsorbés et les produits de réaction issus de la réduction de la fonction carbonyle du pyruvate. Les résultats ont révélé que l'hydrogénation du substrat en lactate a bien lieu à la surface du cuivre générant de très faibles adsorbats. L'identification des différentes espèces électroréactives ont permis de proposer un mécanisme réactionnel de la transformation du pyruvate en lactate sur le cuivre.

Mots-clés : cuivre, electroréduction, pyruvate, lactate, spectroscopie infrarouge de réflexion in situ, mécanisme réactionnel.

[Traduit par la Rédaction]

Introduction

The catalytic reduction of organic molecules containing a carbonyl group has been widely investigated in the preparation of intermediates for the fine chemicals and pharmaceutical industries. The control of selectivity is one of the important problems in organic electrosynthesis. Various reaction conditions, such as electrode materials, supporting electrolyte, electrode potential, reagent concentration, and pH, affect the product distribution. The electroreduction of carbonyl compounds can lead to varied products such as alcohols, hydrocarbons, or pinacols. Much research on the electroreduction of carbonyl compounds to monomeric and dimeric products has been done using acetophenone and furfural as model molecules (1–7). The selectivity of the electroreduction of acetophenone to the monomeric product, 1-phenylethanol, in aqueous media has been much studied with interesting results. The carbonyl function of pyruvate was reduced by redox reaction using sodium borohydride (8), perchlorate metallic cations (9), or by C2 symmetric diamines as chiral ligands (10). Lactate has also been synthesized from glucose by fermentative manufacture in the presence of externally added pyruvate (11, 12). Elsewhere, an electroenzymatic route for producing lactate from pyruvate has been used extensively (13–16). However, few results in the literature concern the electrochemical reduction of pyruvate. In this regard, the selectivity of lactate, which is an useful intermediate in the biological sector, food, and polymer industries (17, 18), on lead and copper cathodes in aqueous media was studied (19, 20). Recently, we have shown that the electrocatalytic reduction of pyruvic acid in different aqueous media led to either lactic acid or 2,3-dimethyltartaric acid with high selectivity, according to the operating experimental conditions (19–22).

The aim of the present work is to complete previous investigations by examining carefully the intermediates and products formed on the surface of a copper electrode during the course of the electroreduction of pyruvate in alkaline medium by means of in situ IR reflectance techniques (SPAIRS and SNIFTIRS). Interpretation of the results allowed us to detail some mechanistic aspects of the electrochemical process.

Experimental

All the experiments were carried out in aqueous solutions using "ultrapure" water (18.2 MΩ cm at 20 °C, Millipore

 doi:10.1139/V08-137 © 2008 NRC Canada

system). The analytical grade supporting electrolyte (NaOH) was purchased from Merck. Pyruvic and lactic acids were supplied by Sigma-Aldrich. The solutions were thoroughly deaerated by bubbling nitrogen (U Quality from Air Liquide).

The Fourier transform IR spectrometer used was a Bruker IFS 66v, with the sample compartment modified to allow the beam to be reflected on the electrode surface with an incidence angle of 65°, after passing through the IR window (CaF_2) of the conventional thin layer spectroelectrochemical cell. The beam path was under vacuum and a liquid nitrogen cooled HgCdTe detector (Infrared Associates) was used. The working cathode was a cooper disk with a geometric surface area of 0.8 cm^2. A platinum wire and a reversible hydrogen electrode (RHE) served as counter and reference electrodes, respectively. Before performing the spectroelectrochemical experiments, a voltammogram was recorded at 1 mV s^{-1} to observe the state of cathode.

In situ IR reflectance spectroscopy techniques are described elsewhere (23). To detect adsorbed species, intermediates, and reaction products near the electrode surface, SPAIRS and SNIFTIRS experiments are carried out. With the single potential alteration IR reflectance spectroscopy (SPAIRS) technique (24–26), reflectivities were recorded at 50 mV intervals during the first voltammetric scan at a low sweep rate (1 mV s^{-1}). Each spectrum resulted from the co-addition of 128 interferograms. The acquisition time required 20 s, i.e., corresponding to ca. 0.02 V. SPAIRS is convenient for the detection of intermediates in the vicinity of the electrode and reaction products. Spectra were normalized as $\Delta R/R = (R_{Ei} - R_{Eref})/R_{Eref}$, where the reference spectrum R_{Eref} was 0 V vs. RHE.

Similarly, using the subtractively normalized interfacial Fourier transform IR reflectance spectroscopy (SNIFTIRS) method (25–27), reflectivities were collected at two electrode potentials (frequency of potential modulation 0.025 Hz) and co-added 30 times at each potential. SNIFTIRS is better adapted to the detection of adsorbed species at the electrode. Final spectra were normalized as $\Delta R/R = (R_{E2} - R_{E1})/R_{E1}$ with a constant amplitude modulation of 200 mV.

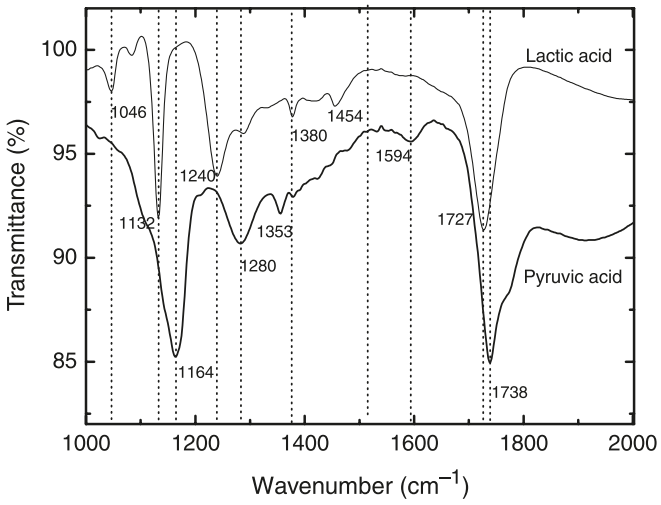
Results and discussion

In a recent paper (20), it was shown that the electroreduction of pyruvate in alkaline medium (i.e., 0.5 mol/L NaOH) on copper electrode selectively involves lactate. At low potentials, this reaction competed with hydrogen evolution reaction. Investigation of the overall kinetics of electrocatalytic reaction by electrochemical methods (cyclic voltammetry) revealed a diffusion controlled process. The present identification of the species adsorbed at the copper electrode, thanks to in situ spectroelectrochemistry techniques, can provide more evidence to assume a reaction mechanism of pyruvate reduction.

In situ spectroelectrochemical studies on a copper cathode in alkaline medium

SPAIR and SNIFTIR spectroscopy methods were performed to determine the adsorbed intermediates and the reduction products near the copper surface. To assign the main bands of pyruvate and its expected reduction product, lactate, transmission spectra of these compounds were recorded. The fundamental bands found in the spectra of Fig. 1 are summarized in Table 1.

Fig. 1. Transmission FTIR spectra of pyruvate and lactate recorded in water.



As can be seen, pyruvate and lactate spectra contain the same carboxylate group (1380 and 1727–1738 cm^{-1}) and methyl groups (1353 and 1454 cm^{-1}) bands. Their difference is due to the carbonyl (for pyruvate) at 1594 cm^{-1} and alcohol (for lactate) at 1240 and 1132 cm^{-1}.

SPAIRS technique consists of simultaneously recording spectroscopic measurements during cyclic voltammetry. A first cycle was thus recorded at a sweep rate of 1 mV s^{-1} to collect more information at the vicinity of the electrode surface in steady-state conditions. On the voltammogram of Cu represented in Fig. 2, one can notice during the negative potential scan a reduction peak of pyruvate followed by a reduction wave up to the cathodic potential limit. The positive going scan is characterized by another reduction peak at ca. –0.3 V vs. RHE.

SPAIR spectra were collected regularly between +650 and –650 mV vs. RHE, but the most significant spectra are shown in Fig. 3. At potentials lower than –400 mV vs. RHE, the spectra were disturbed by hydrogen production. Up to –100 mV vs. RHE, there is a large band (1570–1720 cm^{-1}) that includes the main vibration modes such as the carbonyl group (C=O stretching), the anti-symmetric OCO stretching (carboxylate), and the contribution of the HOH bending mode (δ_{HOH}) of interfacial water. As can also be seen on the voltammogram in Fig. 2, the reduction of pyruvate starts at ca. –150 mV vs. RHE. Up to this potential, the shape of the spectrum is similar to that of lactate, particularly with the presence of the band at 1132 and 1046 cm^{-1}, characteristic of the C–O stretching mode of the alcohol group and that of $\upsilon_{C\text{-}CH3}$ in lactate.

With the SNIFTIRS technique, the entire potential range from 0 to –700 mV vs. RHE was studied at a constant modulation potential (ΔE = 200 mV). The significant spectra are displayed in Fig. 4. At the beginning of pyruvate reduction, corresponding to the first potential modulation, all the bands assigned in Table 1 are present. As pointed out in previous SPAIR spectra, one can observe a small shift in the frequency of the bands due to the Stark effect. In the two other

spectra, a large absorption band including ν_{OCO}, $\nu_{C=O}$ stretching (represented by a derived band centered at 1594 cm^{-1}), and δ_{HOH} bending modes, become more and more intensive so that the other bands seem to disappear. Nevertheless, the characteristic band of the alcohol-containing species (ν_{CHOH}) remains visible at 1132 cm^{-1}. A band at 1046 cm^{-1} gives more evidence of the presence of lactate as expected reaction product.

Mechanistic implications

From the different results obtained, it is possible to infer the reduction mechanism of the formation of lactate from pyruvate on copper electrode in alkaline solution. Kinetic investigations showed that the solvent bore partly on hydrogenation of pyruvate on copper, whereas various physicochemical analyses focused on the selectivity of the reaction towards lactate (20). In addition, both IR reflectance techniques enabled us to detect the pyruvate and lactate weakly adsorbed at the copper cathode. Therefore, it can be suggested that pyruvate is reduced as follows.

Fig. 3. SPAIR spectra of 0.1 mol/L of pyruvate in 0.5 mol/L of NaOH on a copper electrode at various potentials.

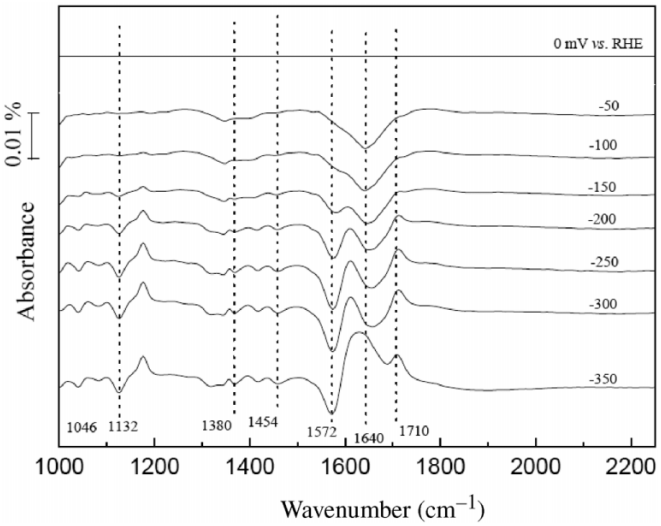

Fig. 4. SNIFTIR spectra of 0.1 mol/L pyruvate in 0.5 mol/L of NaOH on a copper electrode at various modulation amplitudes of potential.

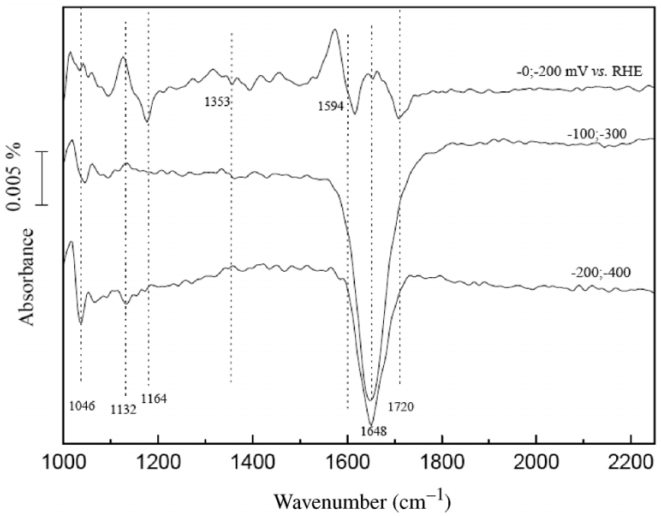

The first step is the reduction of solvent, as shown by Grez et al. (34),

[1] $$Cu + H_2O + e^- \rightarrow Cu - H_{ads} + HO^-$$

Then, the adsorption of the carbonyl group of pyruvate is favoured by the repulsive interaction between the charge of the cathode and that of the carboxylate. So the interaction of the carbonyl group of the reagent with the copper sites can be written,

[2] 
Hydrogenation then occurs by the interaction between two adsorbed species,

© 2008 NRC Canada

[3] 
As evidence of the presence of this organic species at the electrode surface, it can be seen in Fig. 4 that the entire spectra contain the main large band that continues to be centered at 1648 cm^{-1}, i.e., with the contribution of the strong feature of interfacial water, which includes the C=O stretching vibration of the carboxylate group (as shoulder at ca. 1720 cm^{-1}). Finally, lactate desorbs and diffuses into the bulk solution where hydrolysis takes place as follows,

These spectroscopic results are in good agreement with our previous chromatographic data (20) and also indicate that the reduction of pyruvate leads selectively to lactate on copper electrode in alkaline medium.

[4] 
Conclusion

This investigation was aimed at obtaining new insights on the spectroelectrochemical behavior of pyruvate reduction in an alkaline medium. Two complementary IR methods provided us a lot of information on its reaction mechanism on a copper electrode. The interaction between the electrode surface and the molecules led to weakly adsorbed species. The characteristic absorption band of alcohol-containing species (ν_{CHOH}) due to the presence of lactate at the vicinity of the electrode reinforced the results of the reduction of the carbonyl group. Moreover, equilibrium observed close to the cathode surface between consumed pyruvate and produced lactate, showed that lactate was produced by the reduction of pyruvate weakly adsorbed on the copper electrode and then diffused straight to the bulk solution after hydrogenation. No evidence of the cleavage of the C–C bond was observed in the different analytical measurements. However, Cu considered as an overvoltage material for hydrogen can be successfully used for reducing pyruvate to lactate in alkaline medium.

Sectroscopic study of stability and molecular species of 12-tungstophosphoric acid in aqueous solution

Ivanka Holclajtner-Antunović, Danica Bajuk-Bogdanović, Marija Todorović, Ubavka B. Mioč, Joanna Zakrzewska, and Snežana Uskoković-Marković

Abstract: The various molecular species of 12-tungstophosporic acid (WPA) in aqueous solutions of different pH values (from 1 to 11.5) were investigated by UV, IR, and NMR spectroscopy. The dependence of the attained equilibrium composition in solution on time, concentration of WPA, and type of buffer used was studied. Obtained results indicate that the buffer type and pH value greatly determine the equilibrium composition in the solution. The Keggin structure of the WPA is sustained only up to pH 1.5. With further increase in pH, the decomposition of Keggin anion does not lead directly to the monovacant lacunary anion. Between 1.5 and 2.0, the structures with 2 phosphorus atoms from the Dawson series are dominant as intermediate species. In the pH range 3.5–7.5, WPA is present in the form of the monovacant lacunary Keggin anion. These results are of special importance for the biomedical and catalytic applications of heteropoly compounds (HPCs) and for an improved understanding of the mechanism of their functioning.

Key words: heteropolyacids of the Keggin structure, hydrostability, UV, IR and NMR spectroscopy.

Résumé : Faisant appel aux méthodes de spectroscopie UV, IR et RMN, on a étudié diverses espèces moléculaires de l'acide 12-tungstophosphorique (ATP), dans des solutions aqueuses dont les pH s'étalent de 1 à 11,5. On a étudié la relation entre la composition de l'équilibre obtenu et le temps, la concentration en ATP et le type de tampon utilisé. Les résultats obtenus indiquent que le type de tampon et la valeur du pH jouent un rôle considérable sur la composition de l'équilibre en solution. La structure de Keggin pour l'ATP n'est maintenue que jusqu'à un pH de 1,5. Avec des augmentations supplémentaires de la valeur du pH, la décomposition de l'anion de Keggin ne conduit pas directement à l'anion lacunaire monovacant. Entre 1,5 et 2,0, les structures comportant deux atomes de phosphore des séries de Dawson sont les espèces intermédiaires dominantes. Dans la zone de pH allant de 3,5 à 7,5, l'ATP est présent sous la forme de l'anion lacunaire monovacant de Keggin. Ces résultats sont particulièrement important pour les applications biomédicales et catalytiques des composés hétéropolyacides (CHP) et pour une meilleure compréhension du mécanisme de leur fonctionnement.

Mots-clés : hétéropolyacides de la structure de Keggin, hydrostabilité, spectroscopies UV, IR et RMN.

Introduction

Polyoxometalates (POMs), made up of a great number of structures and compositions, constitute a large category of compounds that are interesting for theoretical investigations and practical applications. Their applications are based on their unique properties including size, mass, structure, electron and proton transfer/storage abilities, thermal stability, labile nature of lattice oxygen, and high Brönsted acidity of the corresponding acids. Therefore, POMs are used as good catalysts, superionic proton conductors, compounds with photoconductive and magnetic characteristics, reagents in analytical chemistry, and biochemically active species (1–6).

The properties of POMs in the solid state are rather well-established, but their behavior in solutions is not well explained in spite of numerous publications. The behavior of these compounds in solution is important from the aspect of their formation and degradation but particularly from the aspect of their analytical, biomedical, and catalytic applications.

In medicinal chemistry, POMs that are generally nontoxic to normal cells, exhibit highly selective inhibition of enzymes and antitumoral, antiviral, antibacterial, and anticoagulant activities (1–4, 6–7). However, a fundamental limitation in their application in physiological media in vitro and in vivo derives from their inorganic nature and in their con-

sequent instability in aqueous solutions. Namely, the problem of all biological and medical investigations of POMs relates to whether these compounds remain in their original molecular form during biomedical treatment. Generally, research articles consider the parent form of POMs anion as active, which is generally not the case. To consider and elucidate the proper mechanism of biomedical activity of POMs, it is indispensable to identify the real active molecular species present under physiological conditions, which is the main subject of this study.

Because of their properties, POMs have also been used as homogeneous and heterogeneous catalysts in oxidation reactions, in acid-catalyzed reactions, and as bifunctional catalysts (1–4, 8, 9). To improve the catalytic characteristics of these compounds and to follow the mechanism of catalytic processes, the formation of activation complexes, as well as the formation of complex catalysts on different supports by sol-gel processes or impregnation, it is essential to specify the nature of the active species present.

In spite of extensive study of stability and reaction pathways of heteropoly acids (HPAs) mostly of the Keggin type in solution, the obtained results and conclusions often are confusing and not in agreement, although obtained under similar experimental conditions (1, 4, 10–15).

Kepert and Kyle (16, 17) have studied the decomposition of the Keggin anions containing silicon, phosphorus, or boron as the central heteroatom and tungsten as an addenda metal atom. They have found that the equilibrium reaction in the solution proceeds in three distinct stages with $[SiW_{11}O_{39}]^{8-}$ and $[SiW_9O_{34}]^{10-}$ as intermediates. A few years later, stopped-flow kinetics studies of 12-molybdophosphate formation and decomposition were performed by Kircher and Crouch (18). Molybdophosphate complexes in aqueous solutions have been identified by ^{31}P NMR and Raman spectroscopy and differential pulse polarography (19), while ^{31}P NMR spectroscopy was applied to the stability study of HPAs by the rate of exchange of structural units between 12-tungstophosphoric acid (WPA) and 12-molybdophosphoric acid (MoPA) (15). Detusheva et al. (20) identified decomposition products of tungstophosphoric acid during its titration with NaOH up to pH 7.8 by NMR, IR, and Raman spectroscopy. McGarvey and Moffat (13) followed the major species present in tungstophosphate and molybdophosphate solutions as a function of pH by NMR and IR spectroscopy. They found that both acids decompose to the lacunary form of the Keggin anion that further decomposes to a phosphate species in alkaline solutions. The tungstophosphate system has been investigated over a wide range of pH (1–12) using preparation high performance liquid chromatography combined with IR, UV–vis, and ^{31}P NMR and ICP spectroscopy (21, 22). Smith and Patrick applied ^{31}P and ^{183}W NMR spectroscopy to the detailed study of tungstophosphoric and tungstosilicic acids in aqueous solutions (23–25). Identification and quantitative determination of the species present in these systems as a function of pH have been performed after a few months, which was considered an appropriate time for attaining equilibrium. Investigations of equilibria of α- and β-isomers of WPA as a function of pH have shown that β-type lacunary complexes are precursors for the formation of β-PW_{12}, and that β-type lacunary complexes always coexist with the corresponding α-type lacunary complexes (26).

On the basis of all these results, it can be concluded that the hydrolytic stability of HPAs depends on the anion structure, nature of the heteroatom, and peripheral metal atom that comprise the anion, as well as on the solution conditions. It is generally accepted that most POMs based on W or Mo are stable in acid solution, degrade in a complex way into a mixture of inorganic products with increasing pH and are totally decomposed in alkaline medium. However, the influence of buffer type on equilibrium composition has not been studied thus far. Also, the time data needed for establishing the equilibrium state and possible reversibility of the considered system when pH was increased and (or) decreased, were also not available.

The aim of this paper is to pay attention to the importance of molecular species of 12-tungstophosphoric acid ($H_3PW_{12}O_{40}$) in aqueous solutions of various pH, adjusted by addition of NaOH and HCl or by applying TRIS and acetate buffers. It is necessary to emphasize that TRIS and acetate buffers are frequently applied for pH adjustment when HPAs are used for biochemical and biomedical applications. For this purpose, three different spectroscopic methods were applied and their results were summarized and compared, to determine the dominant species present in solutions of various pH, with special attention to physiological conditions. The equilibrium composition of the solution was investigated for various buffers and for different time intervals. It was established that phosphate buffer is not appropriate for biochemical studies. The reversibility of the reaction pathway in the considered system, in which pH was increased to the values when the Keggin anion is decomposed and then decreased back to the pH values when it is formed, was also studied.

Experimental

Materials

WPA was prepared according to the literature method (27), recrystallized prior to use, and confirmed by IR spectroscopy. All chemicals were of analytical grade and were provided by Merck.

Methods

The pH of the solutions was adjusted with addition of NaOH, HCl and acetate, TRIS, and phosphate buffers and measured using a pH meter with a glass electrode. Solution pH was monitored until no apparent changes were observed.

UV spectra of aqueous solutions of 2×10^{-5} mol/dm^3 of WPA were obtained by the Cintra 10e (GBS) spectrophotometer.

Solid samples for IR measurements were obtained after evaporation of water from solutions of 5×10^{-2} mol/dm^3 WPA of different pH. The IR spectra were recorded on a PerkinElmer 983G spectrophotometer using the KBr pellet technique in the wavenumber range 1500–300 cm^{-1}.

The sample solutions for NMR measurements were prepared by adding the estimated quantities of NaOH or buffer solutions just after dissolving. The NMR experiments were carried out with a Bruker MSL 400 spectrometer at 161.978 MHz. The concentration of WPA was 5×10^{-2} mol/dm^3, with 2048 scans, 9.0 μs pulse, and 500 ms repetition time at 25 °C. Sample volume was about 2.5 mL

in a 10 mm tube. A metilenediphosphonate (MDP) solution of 17.05 ppm was used as the external reference relative to 85% H_3PO_4.

Results and discussion

UV spectra

The electronic spectra of HPAs of the Keggin structure exhibit two intense absorption bands in the UV range, with maxima at about 200 and 260 nm attributed to the transitions $O_d \rightarrow M$ and $O_b/O_c \rightarrow M$, respectively, (28).

The UV spectra of aqueous solutions of WPA of various pH are presented in Fig. 1. At pH 1, the absorption band maximum is at 263 nm, which corresponds to electron transition $O_b/O_c \rightarrow M$ of the parent Keggin's anion and is shifted to 252.5 nm at pH 3.5. If pH is increased to 7 by adding NaOH, the band maximum remains at the same position.

The further increase in pH to 11.5 causes the disappearance of this band, confirming the destruction of the parent Keggin structure. These results indicate the existence of various structural forms in pH regions: up to 2, from 3.5 to 7, and above 8.5, but it is hard to identify the individual formed products.

Our results are only partly in accordance with the findings of Z. Zhu et al. (21) who applied UV spectra for the identification of components eluted from an HPLC instrument. Namely, they identified the maximum absorption at 244 nm of the main component at pH 3.5 and 5.4 as $[PW_{11}O_{39}]^{7-}$. Our results show that the component with maximum absorption at 252.5 nm is stable in the pH region from 3.5 to 7.0. The differences can be explained by different experimental conditions, because the mentioned authors applied HPLC for the separation of decomposition products of WPA, where besides pH changes there is a continual change in eluent composition.

It is evident that pH influences the stability of WPA. All changes in the UV spectra of WPA solutions of different pH can be attributed to changes in the structure of an individual HPA at various pH values, but it is difficult to derive conclusions about the nature of the observed changes and identify the new formed products.

IR spectra

IR spectra of evaporated and dried sample solutions were recorded over the pH range 1 to 11.5, as in the case of UV spectra. IR spectra of dry residua of WPA solutions of different pH are presented in Fig. 2, while Table 1 summarizes the positions and intensities of some IR absorption bands. The bands of Na_2WO_4 are given for comparison.

The spectrum of WPA at pH 1 (5×10^{-2} mol/dm^3 of WPA, with no addition of HCl) is equivalent to the spectrum of solid WPA. This spectrum possesses vibration bands characteristic of the Keggin anion: 1080, 990, 890, and 810 cm^{-1}, corresponding to vibrations ν_{as}(P-O_a), ν_{as}(W-O_d), ν_{as} (W-O_b-W), and ν_{as} (W-O_c-W), respectively (29). It can be noticed that already at pH 2, bands associated with the Keggin anion are modified; some bands have disappeared, while new bands have appeared and remained to pH 7. Based on the obtained spectra, it can be observed that the stretching P-O vibration at 1080 cm^{-1} is split into two bands at 1100 and 1050 cm^{-1}. This indicates the existence of an anion structure with lower symmetry than T_d symmetry of the Keggin anion. Such a structure can be the lacunary $[PW_{11}O_{39}]^{7-}$ that belongs to the C_s symmetry group, or a structure with two P atoms such as $[P_2W_{18}O_{62}]^{6-}$ with C_{3v} symmetry. Typical bands that characterize the former monolacunary structure (arising by remov-

ing one WO unit from the Keggin anion) are 1085, 1040, 950, 900, 860, 810, and 725 cm^{-1} (30). The latter is the Dawson structure characterized by bands at 1108, 1050, 957, 920, 885, 818, and 735 cm^{-1} (13). There are also some slight changes in the spectrum related to the spectra of the Keggin anion's structure: bands at about 1050 and 990 cm^{-1} are split, while the band at about 900 cm^{-1} has a shoulder at 920 cm^{-1}.

IR spectra present further improvements in identification of dominant chemical species present in HPA solutions of various pHs, compared with UV spectra. However, bearing in mind that characteristic bands of the components of the Dawson series are close to the characteristic bands of the lacunary Keggin structure, it is difficult to recognize and identify properly all the structures present. The IR spectra at higher pH values indicate the total degradation of the parent anion to tungstate and phosphate anions.

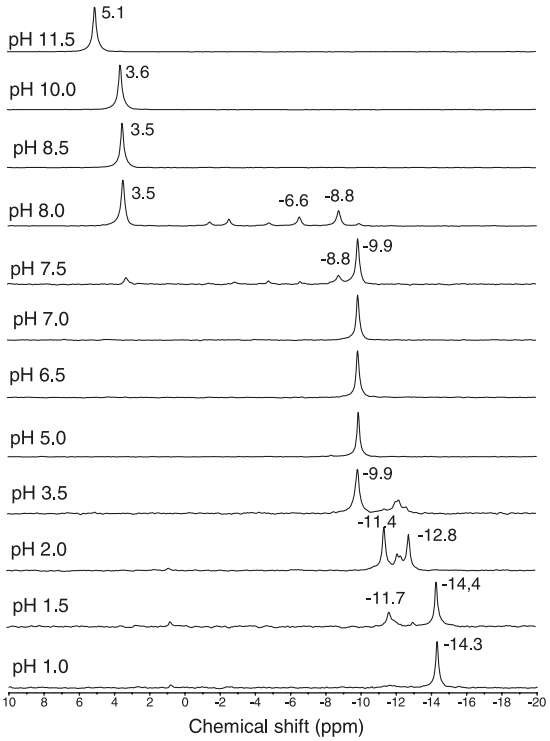
NMR spectra

To overcome the drawbacks of UV and IR spectroscopy in the identification of tungstophosphate species in solutions of various pH values, a complementary sensitive method of ^{31}P NMR was applied.

The ^{31}P NMR spectra of WPA samples over the pH range 1 to 11.5 are presented in Fig. 3. Literature values of chemical shifts were used for the identification of ions formed in solutions. As can be seen, the parent Keggin anion $[PW_{12}O_{40}]^{3-}$ can be easily recognized through its intense single signal at –14.3 ppm (13, 20–22, 25, 31–33). This signal was observed as dominant under our experimental conditions at pH 1 and 1.5, while at pH 2 this peak disappeared.

A few peaks near –12 ppm appear at pH 1.5 and 2. These peaks can be assigned to the structures with 2 phosphorus atoms from the Dawson series, such as $[P_2W_{21}O_{71}]^{6-}$, $[P_2W_{18}O_{62}]^{6-}$, and $[P_2W_{20}O_{70}]^{10-}$ (25, 33, 34). With further

Fig. 3. ^{31}P NMR spectra of WPA solutions at varying pH.



increases in pH, the peaks at ca. –12 ppm remain at pH 3.5, but their intensities decrease, while a dominant peak appears at ca. –9.9 ppm, which corresponds to the lacunary Keggin anion $[PW_{11}O_{39}]^{7-}$ (25, 34, 35). This peak remains the only one in the spectra of solutions of pH up to 7. Analysis of NMR spectra indicates the complex decomposition scheme of the Keggin anion in acidic region that does not lead directly to the lacunary monovacant anion, which was stated

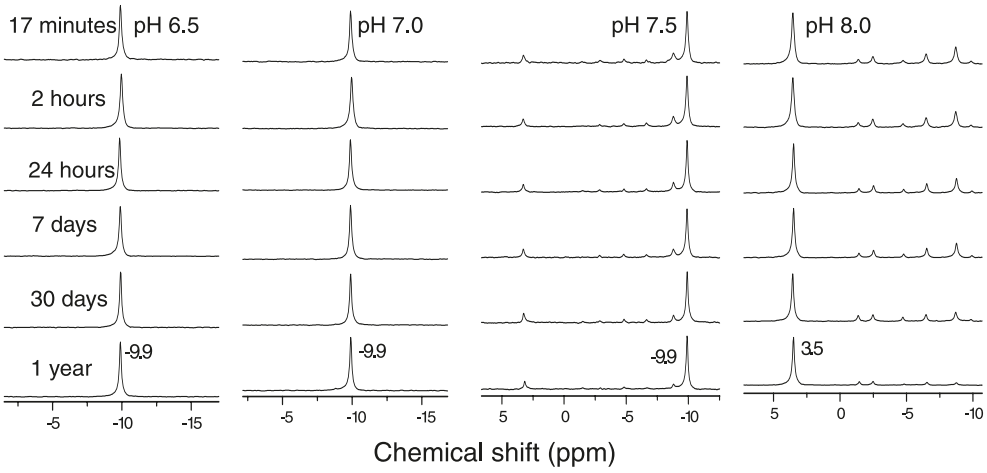
Fig. 4. ^{31}P NMR spectra of WPA solutions of pH 6.5, pH 7.0, pH 7.5, and pH 8.0, recorded 17 min, 2 h, 24 h, 7 days, 30 days, and one year after preparation of solutions.



previously (13). Our results confirm the findings of Smith and Patrick (25) that under these conditions, structures with 2 phosphorus atoms of the Dawson series are formed before their degradation to lacunary monovacant anions in the pH range from 3.5 to 5.

Because of the importance of the pH region found in physiological systems for biomedical investigations and in order to determine exactly the region of existence of the $[PW_{11}O_{39}]^{7-}$ anion, the NMR spectra are recorded for the pH values between 6.5 and 8.5, at each 0.5 pH. It is evident from these spectra that up to pH 7, the lacunary anion is the only structure present in the solution. At pH 7.5, which almost corresponds to physiological conditions, some other products also appeared in addition to the dominant lacunary anion. The change in pH from 7.5 to 8.0 causes complete destruction of the $[PW_{11}O_{39}]^{7-}$ anion and an increase in the intensity of the other peaks. The most intensive peak corresponds to the phosphate anion. One of the peaks, –8.8 ppm, corresponds to $[P_2W_{19}O_{69}(H_2O)]^{14-}$ and another at –6.6 ppm corresponds to $[PW_9O_{34}]^{9-}$. It can be supposed that the former consists of two $PW_9O_{34}^{9-}$ units bridged by one WO_2 group (25, 35). That is, in the pH range 7.5–8, in the course of decomposition of the major anion $[PW_{11}O_{39}]^{7-}$ to $[PW_9O_{34}]^{9-}$ and other unidentified species (corresponding to peaks with higher chemical shifts), some of the $[PW_9O_{34}]^{9-}$ anions dimerize, producing $[P_2W_{19}O_{69}(H_2O)]^{14-}$. It is obvious that in this narrow pH region (7.5–8) the dramatic decomposition of tungstophosphates occurs. In spectra of alkaline solutions of pH > 7.5, a total degradation to phosphate and tungstate is observed. A peak appeared at different chemical shifts, corresponding to the protonated phosphate anions, $[H_2PO_4]^{-1}$, $[HPO_4]^{2-}$, and $[PO_4]^{3-}$.

As mentioned in the introduction, literature data are not always in accordance. Thus, Nomiya et al. (36) have studied the insulin mimetic effect of POMs with Dawson structure and their stability, varying their concentration in the range 1.0–30.0 mmol/L. They found only one peak at –12.7 ppm in the ^{31}P NMR spectra due to the $[P_2W_{18}O_{62}]^{6-}$ anion in pH range 5.37–5.77, while a minor peak at –9.7 ppm assigned as the Preyssler $[NaP_5W_{30}O_{110}]$ structure appeared in addition to the main peak at ca. –12.6 ppm in the pH range 4.7–5.09. Our results and those of Smith and Patrick (25) show that the mentioned species are not stable at pH > 4.7. The findings in (36) related to the acidic region, for pH below 2.0, are in complete accordance with ours. It should be underlined again that the right explanation of any biochemical effects is impossible without proper and detailed knowledge of the considered system.

Time stability

In numerous studies of POMs, various time intervals for synthesis of the compounds were used. Thus, it could be very useful to consider the influence of time interval on WPA solutions stability in the range of pH between 6.5 and 8.0, which is very important for biomedical investigations. In Fig. 4 are shown ^{31}P NMR spectra of WPA solutions of several pH values (6.5, 7.0, 7.5, and 8.0), recorded immediately after preparation, after 2 h, 24 h, 7 days, 30 days, and one year, while kept at room temperature. All spectra confirmed pH stability of WPA solutions in the time ranges, except for minor changes in the spectra for pH 8.0 after one year, when total degradation of WPA was almost complete. It can be seen that the peaks at –8.8 and –6.6 ppm, corresponding to $[P_2W_{19}O_{69}(H_2O)]^{14-}$ and $[PW_9O_{34}]^{9-}$, respectively, slowly disappear with time.

Reversibility

Identification of species existing in solution by UV, IR, and ^{31}P NMR spectra was used to investigate the reversibility of the reaction pathway of WPA degradation and formation during pH changes. By adding NaOH to the WPA solution, pH is raised from pH 1 to 7 and to 8.5; then by HCl addition, pH was decreased back to pH 1. Figure 5 shows UV spectra obtained for solutions of 2×10^{-5} mol/dm^3 of WPA, where pH is changed from 1 to 7 (left side of figure) and from 1 to 8.5 (right side), and then changed back to 1. These data show that the absorption band maximum at 263 nm, characteristic for the Keggin anion at pH 1, disappears at pH 7 but appears again when pH 1 was attained. IR spectra of dried solutions of 2×10^{-2} mol/dm^3 concentration, where pH values were changed as in the case of UV spectra, confirmed that the Keggin anion is formed almost completely when pH was changed from 7 to 1, while in the case of pH 8.5 the reversibility is not complete (Fig. 6). ^{31}P NMR

spectra of the solution, with concentration and pH values as in IR measurements (Fig. 7), also show that reversibility is not complete. A peak at –14.3 ppm, characteristic for the Keggin anion, is dominant but there are also peaks at ca. –13 ppm, indicating the presence of species of the Dawson series. Therefore, it could be concluded that there is not complete but partial reversibility during the changes in pH, in the case of higher concentrations of WPA. Also, it is evident that concentration is also a parameter that determines the equilibrium of different forms in solutions of HPCs.

Buffered solutions

In in vitro experiments where heteropoly compounds are used as biochemical agents, pH values are usually adjusted by different buffers. For this kind of investigation, TRIS and phosphate buffers are most commonly used. However in the case of WPA, the use of phosphate buffer is not possible because of its interaction with WPA, i.e., destruction and precipitate formation. For pH values lower than physiological levels, acetate buffer could be used. Therefore, ^{31}P NMR and UV spectra are recorded for aqueous solutions of WPA buffered with acetate and TRIS buffers, and results are presented in Figs. 8 and 9. It is evident that the application of acetate buffer causes no change in UV and ^{31}P NMR spectra (spectra are identical to those obtained for solutions whose pH was adjusted with addition of NaOH). But it is evident that TRIS buffer at pH 7 causes the formation of lacunary WPA anion as dominant along with some other phosphorus-containing polytungstophosphates. Therefore, the application of this buffer is not recommended in such experiments. The results indicate that in biochemical applications of POMs, the buffer type must be chosen with care because of its significant importance for the obtained biochemical effects and their elucidation.

Conclusions

It can be concluded that all spectroscopic methods used in this work indicate the instability of WPA in aqueous solutions and considerable dependence on pH with regard to the dominant species present in the solution. Considering this, literature data are not always consistent because of the complexity of the system; many factors influence the equilibrium, primarily pH and HPA concentration, while the performance of different analytical techniques used for speciation should be taken in account as well. The concentration of the HPA in unbuffered solution can affect the pH (23). We have observed that plant juices can affect the pH and the observed structures, as seen by UV and NMR measurements (37).

Based on the results presented in this study, the following can be concluded. UV spectroscopy only indicates that some changes occur in the system but they cannot be specified. IR spectroscopy gives more information that is the basis for the identification of the dominant species as a function of the pH of the solution. However in some cases of similar spectral data, it is not possible to perform exact identification of major components. NMR spectroscopy provides unique data, which can be used for more accurate interpretation of changes in the solutions of various pH values, but is applica-

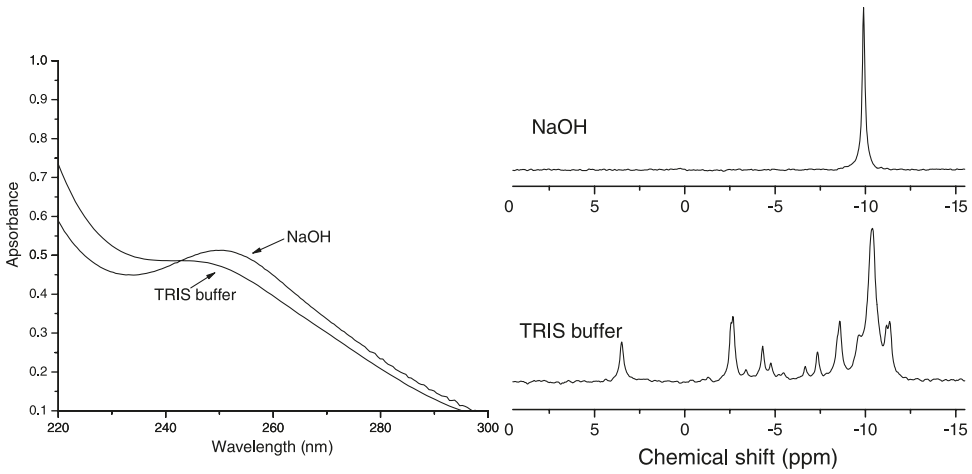
ble to higher concentrations as used in this work. Given that the behavior and nature of heteropoly and isopoly compounds is very complex, one must bear in mind whether the conclusions obtained for very low concentrations (e.g., 0.01–0.0001 mol L^{-1}) when using UV spectrometry, can be applied to higher concentrations (ca. 0.1 mol L^{-1}) of HPAs when IR and NMR spectrometry were employed to follow various species present in the equilibrium system.

The results presented indicate that in the case of aqueous solutions of WPA, the parent anion is present only in a very

© 2008 NRC Canada

Fig. 9. (left) UV spectra and (right) ^{31}P NMR spectra of WPA solution at pH 7 adjusted by NaOH and TRIS buffer.



acidic solution of ca. pH 1. It should be pointed out that in aqueous solution, WPA decomposes first to components of the Dawson series, $[P_2W_{21}O_{71}]^{6-}$, $[P_2W_{20}O_{70}]^{10-}$, and $[P_2W_{18}O_{62}]^{6-}$ in the pH range 1–3.5. With further increases in pH greater than 3.5, these species convert to the lacunary monovacant anion, $[PW_{11}O_{39}]^{7-}$, which is a major constituent in pH range up to 7.5. In the narrow pH range 7.5–8.0, remarkable changes occur; $[PW_{11}O_{39}]^{7-}$ decomposes to $[PW_9O_{34}]^{9-}$, but other tungstophosphate ions are also observed. The total decomposition of the Keggin anion to phosphate and tungstate occurs at pH > 7.5.

Some differences in interpretation of the molecular species present under various experimental conditions can be ascribed to some extent to the diversity of chemical shifts data of NMR found in the literature.

In the pH region 6.5–7.5, the equilibrium composition is established quickly after solution preparation, and the monovacant lacunary form of WPA is stable for a period of one year.

UV spectrometry has shown that when changing pH from 1 to higher values and back to pH 1 in a 2×10^{-5} mol/dm^3 aqueous solution of WPA, the reversibility of changes in molecular structures is completely attained. But for solutions of higher concentration, 0.05 mol/dm^3, the changes are not reversible. That is, when the pH of the solution is adjusted again to pH 1, the Keggin anion is formed only partially, and other molecular forms of the Dawson series are present as well.

The molecular forms present in the equilibrium system under specific conditions depend significantly on the buffer type. Therefore, the choice of buffer used for maintaining the physiological conditions must be made with care to attain the appropriate biochemical effect of POMs.

Under physiological conditions attained with the addition of NaOH, WPA is dominantly present in the form of the lacunary monovacant anion. This is of special importance for biomedical application of heteropoly acids and other compounds of this type.

The results presented have shown that before any use of HPCs as biochemical or biomedically active compounds and as catalysts, it is necessary to control their behavior under defined conditions. Without that, it is not possible to discuss the equilibrium between different forms of heteropoly anions and any mechanism of reactions.

Chemoenzymatic synthesis of ring ^{18}O-labeled sialic acid

Deepani Indurugalla and Andrew J. Bennet

Abstract: Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside was converted into methyl 2-azido-2-deoxy-4,6-*O*-benzylidene-α-D-altropyranoside via a synthetic route that incorporated two inversions of configuration. Activation of the C-3 hydroxyl group as a triflate ester followed by an S_N2 reaction with O-18 labeled benzoate gave, after standard functional group manipulations, 2-acetamido-2-deoxy-D-(3-^{18}*O*)mannose. Coupling of the labeled *N*-acetyl-mannosamine with pyruvate was catalyzed by sialic acid aldolase to give ring-oxygen-labeled sialic acid in an overall yield of 11.4% over 10 steps.

Key words: *N*-acetylneuraminic acid, sialic acid oxygen-18, chemoenzymatic.

Résumé : Le 4,6-*O*-benzylidène-α-D-glucopyranoside de méthyle a été transformé en 2-azido-2-désoxy-4,6-*O*-benzylidène-α-D-altropyranoside par le biais d'une voie de synthèse qui incorpore deux inversions de configuration. L'activation du groupement hydroxyle en C-3 sous la forme de triflate suivie par une réaction S_N2 avec du benzoate marqué au O-18 conduit, après des manipulations standards de groupes fonctionnels au 2-acétamido-2-désoxy-D-(3-^{18}O)mannose. Le couplage de la *N*-acétylmannosamine avec le pyruvate a été catalysé par l'aldolase de l'acide sialique et a conduit avec un rendement global de 11,4% pour les dix étapes, à un acide sialique dont le cycle comporte un atome d'oxygène marqué.

Mots-clés : acide *N*-acétylneuraminique, acide sialique, oxygène-18, chimioenzymatique.

[Traduit par la Rédaction]

Introduction

The sialic acids are a family of carbohydrates, containing a nine-carbon backbone, that are often found on the ends of oligosaccharide chains in biological systems. This prominent display of these sugars results in their importance in numerous biological recognition and communication events, which are mediated by sialic acid recognizing proteins. Therefore, many research groups have developed synthetic routes to the parent sugar, sialic acid (*N*-acetyl-neuraminic acid, **1a**), and its derivatives (1). In addition, the transfer of carbohydrate residues between various acceptors and donors is a critically important biological process (2–5). Accordingly, the mechanisms by which various anabolic and catabolic enzymes modify these important carbohydrate residues have received considerable attention (6).

As part of a program, which incorporates the measurement of kinetic isotope effects aimed at delineating the finer mechanistic details involved in enzymatic and non-enzymatic sialic acid transfer reactions, an efficient synthesis of ring-oxygen-labeled sialic acid was required. Specifically, kinetic isotope effects (KIEs) measured using compounds derived from (6-^{18}*O*)-sialic acid (**1b**), in conjunction those from anomeric ^{13}C- and leaving group ^{18}O-labeled materials, will allow evaluation of critical variables at the transition state(s) for the transfer of sialic acid residues, namely: (*i*) site of cleavage at the glycosidic centre, endo- or exo-cyclic; (*ii*) degree of C–O cleavage; (*iii*) amount of double-bond character at the oxacarbenium ion-like TS; (*iv*) degree of nucleophilic participation at the anomeric centre; (*v*) degree of proton-transfer, which occurs from an active-site aspartic acid residue for the enzyme-catalyzed reactions (7, 8).

To date, few reports of heavy-atom KIEs on sialyl transfer reactions have been published. Those include leaving-group ^{18}O-KIEs on the acid-catalyzed and spontaneous hydrolysis reactions of 4-nitrophenyl α-D-sialoside (9) and on the corresponding *Vibrio cholerae* sialidase-catalyzed reactions (10); anomeric ^{14}C-KIEs on the sialyl transferase catalyzed transfer of sialic acid from CMP- and UMP-β-sialoside (**2** and **3**, respectively; Fig. 1) to carbohydrate acceptors (11, 12); anomeric ^{14}C-KIEs on the hydrolysis of sialosides catalyzed by the trans-sialidase *Trypanosoma cruzi* (13).

With regard to the synthesis of heavy-atom-labeled sialic acids, the first reported synthesis involved a series of single-carbon chain extensions of *N*-acetyl-mannosamine to give *N*-acetyl-(1-^{13}*C*)-neuraminic acid (14). Specifically, the authors performed two Henry reactions that were followed by addition of ^{13}C-labeled cyanide to an eight-carbon aldehyde. However, now that the enzyme sialic acid aldolase is readily available, most syntheses involve the enzymatic coupling of *N*-acetyl-mannosamine and pyruvate (15, 16) to give ^{13}C-labels in carbon atoms 1–3 (17). Sato et al. have also reported the chemical synthesis of *N*-acetyl-(6-^{13}C)-

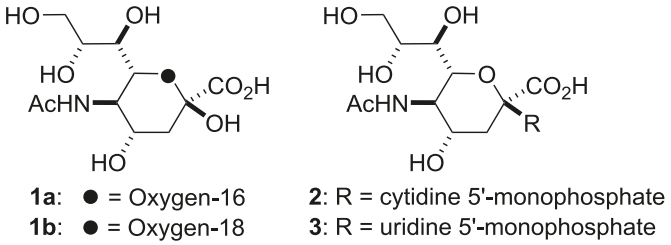
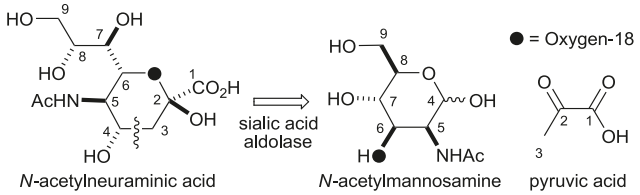
Fig. 1. Sialic acid (neu5Ac, **1a**), its ring-oxygen-labeled isotopomer **1b**, and activated sialosyl donors (**2** and **3**).



Scheme 1. Sialic acid aldolase catalyzed synthesis of target compound (**1b**) and the required building blocks for its synthesis; the numbering shown refers to the carbon atoms in the product.



mannosamine, which when coupled to 3-^{13}C and unlabeled pyruvate gave (3,9-$^{13}C_2$)- and (9-^{13}C)-labeled sialic acids (18).

A single publication reports the ^{18}O-labeling of sialic acid itself, which in this case involves the anomeric oxygen atom (19). That is, Ambrose et al. made a 50:50 mixture of singly and doubly labeled sialic acids, *N*-acetyl-(2-^{13}C)-[2-$^{18}O_{0,1}$]-neuraminic acid, to probe the mechanism of the CMP-sialic acid synthetase enzyme from *E. coli* (19). Also, Burke and Horenstein have reported the synthesis of [$P^{18}O_2$]-CMP β-[1-^{14}C]-*N*-acetyl-neuraminic acid (20).

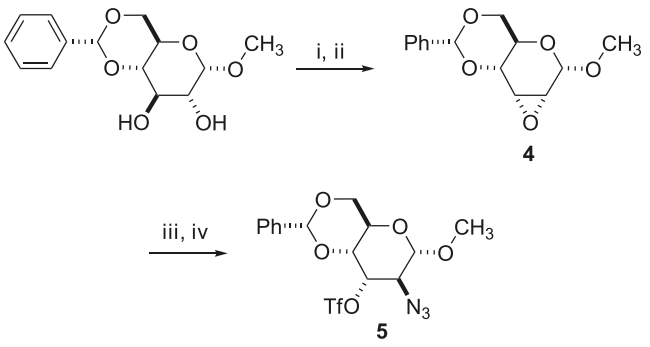
Results and discussion

The synthetic route to (6-^{18}O)-sialic acid (**1b**) requires *N*-acetyl-D-(3-^{18}O)mannosamine and pyruvate to be coupled enzymatically using sialic acid aldolase (Scheme 1).

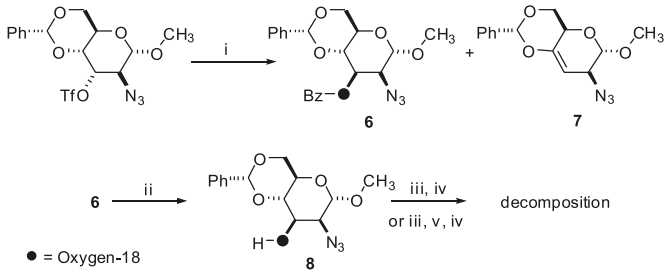
Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (21) was transformed into the 2,3-epoxysugar **4** by the procedure of Wiggins (22). Nucleophilic ring-opening with azide (23), followed by formation of a triflate ester (24), gave the required starting material **5** for the incorporation of the ^{18}O-label (Scheme 2).

Triflate displacement with ^{18}O-labeled benzoate in CH_2Cl_2 yielded 52% of methyl 2-azido-2-deoxy-3-benzoyl-4,6-*O*-benzylidene-α-D-(3-^{18}O)mannopyranoside (**6**) and 39% of the unsaturated product **7**, which results from a competitive E2 elimination reaction. It was observed that the percentage of the elimination product increases as the reaction temperature rises. Therefore, the reaction was carried out at room temperature until most of the starting material had reacted, and then the reaction temperature was raised to ensure complete conversion of **5** had occurred to give a mixture of **6** and **7**. The atom% of ^{18}O incorporated into **6** is evaluated to be 88.5%, a number, which is calculated from the percentage of doubly labeled benzoate (78.4%) + one-half of the fraction of singly labeled carboxylate nucleophile (20.2%).

Scheme 2. Conversion of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside into the activated azido triflate **5**. Reagents: (i) TsCl/pyridine (75%), (ii) NaOMe/MeOH (97%), (iii) NaN_3/DMF (84%), and (iv) Tf_2O/pyridine (88%).



Scheme 3. Incorporation of ^{18}O label into the C-3 position of protected azido mannose derivative **6** and its subsequent manipulations. Reagents: (i) PhC$^{18}O_2$H/K_2CO_3/18-crown-6 CH_2Cl_2 (52% **6** and 39% **7**), (ii) NaOMe/MeOH (92%), (iii) H_2/Pd (100%), (iv) Ac_2O/H_2SO_4, and (v) Ac_2O/pyridine.



At this point, removal of the benzoyl group on C-3 gave azido alcohol **8**, which upon reduction of the azido group using H_2 on Pd/C, gave a quantitative yield of the corresponding amine (**9**). However, an acetolysis reaction on this amine, using 5% H_2SO_4 in acetic anhydride at 0 °C, resulted in decomposition of the starting material. To circumvent this problem, the free hydroxyl and amino groups of **9** were acetylated, and this material was subjected to an acetolysis reaction (5% H_2SO_4 in Ac_2O at 0 °C) as reported by Krist et al. (24). Once again in our hands, this procedure gave extensive decomposition (Scheme 3).

It was therefore decided to perform the acetolysis reaction prior to the reduction of the azide functionality. Thus, following removal of the benzoyl group in a 92% yield, acetolysis was performed directly on azide **8**, a procedure that resulted in simultaneous removal of the benzylidene acetal and the methyl aglycone and complete hydroxyl group acetylation to give 1,3,4,6-tetra-*O*-acetyl-2-azido-2-deoxy-α-D-(3-^{18}O)mannopyranose (**10**) in good yield (85%). Following this, the C-2 azido group of **10** was reduced, using H_2 on 10% Pd/C, and the resulting amine was acetylated to obtain 2-acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-α-D-(3-^{18}O)mannopyranose (**11**). Subsequent O-deacetylation of **11** afforded 2-acetamido-2-deoxy-D-(3-^{18}O)mannose (**12**) in 90% yield (Scheme 4). Sialic acid aldolase catalyzed condensation of **12** was conducted at 37 °C with 10 equiv. of sodium

Scheme 4. Conversion of azido alcohol **8** into ring-oxygen-labeled sialic acid **1b**. Reagents: (i) Ac_2O/H_2SO_4 (85%), (ii) H_2/Pd (100%), (iii) Ac_2O/NaOAc (80%, two steps), (iv) NaOMe/MeOH (90%), and (v) CH_3COCO_2Na/NeuAc aldolase (58%).

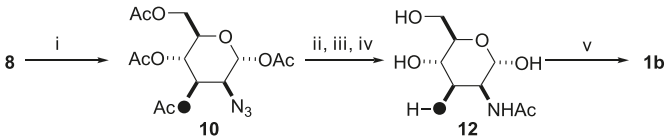

Fig. 2. HR-MS (negative-ion mode) of labeled sialic acid dimer (**1b**:**1b**–H^+; $C_{22}H_{37}N_2O_{16}{}^{18}O_2$ *m/z* calcd.: 621.2126) and the singly labeled material (**1a**:**1b**–H^+ *m/z* calcd.: 619.2083).

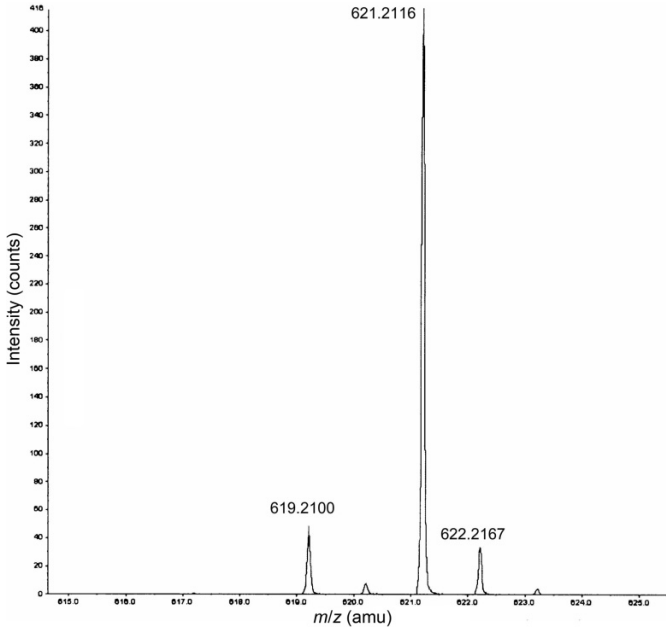

pyruvate in a 5 mmol/L tris buffer (pH = 7.5) containing 0.1% sodium azide (15). Following removal of the aldolase, the excess pyruvate and its reversibly formed *gem*-diol (25) were removed by the use of pyruvate decarboxylase (26). Final purification of the labeled sialic acid (**1b**) involved a flash chromatographic separation on normal-phase silica.

Shown in Fig. 2 is the negative-ion mode HR-MS for the labeled sialic acid dimer (**1b:1b-H$^+$**)$^-$. Also evident in the spectrum is the singly labeled dimer (**1a:1b-H$^+$**)$^-$ and their associated ^{13}C-satalite peaks.

Conclusions

Ring-oxygen-labeled sialic acid has been made by a concise and scaleable chemoenzymatic route in reasonable overall yield (11.4%) over 10 steps.

Experimental

NMR spectra were acquired on a Varian Inova-500 MHz or Bruker Avance 600 MHz spectrometer. Chemical shifts (δ_H and δ_C) are listed in ppm downfield from the signal for TMS using the residual solvent peak as an internal reference. Coupling constants (*J*) are given in Hz. NMR spectral peak assignments are based on COSY, HMQC, and HMBC experiments. Melting points were recorded on a Gallenkamp melting point apparatus and are uncorrected. Optical rotations were measured on a PerkinElmer 341 polarimeter and are reported in units of deg cm^2 g^{-1} (concentrations reported in units of g per 100 mL). Thin layer chromatography (TLC) was performed on aluminum plates pre-coated with Merck silica gel-60 F_{254}. Compounds were visualized with UV light and (or) staining with phosphomolyibdic acid (5% in ethanol) followed by heating. Flash chromatography was performed using Avanco silica gel-60 (230–400 mesh). Neu5ac aldolase (EC 4.1.3.3) was purchased from Julich Chiral Solutions (now Codexis; lot no. H70240.01) and pyruvate decarboxylase (EC 4.1.1.1) was purchased from Sigma. Shown in the supporting information is the ^{13}C NMR spectrum for compound **1b**, which exists as a 93:7 mixture of the two anomeric hemiketals.[2]

[$^{18}O_2$]Benzoic acid

Benzoic acid ($^{18}O_2$) was made by following the procedure of Wnuk et al. (27) using benzonitrile (1.8 g, 17.5 mmol) and ^{18}O-H_2O (1.04 g, 52.5 mmol; Marshall isotopes, 95.1 atom% O-18, batch no. 020414nw). Based on the observed intensities of the isotopic peak distribution for the M + H^+ peaks in a CI-MS, the composition of the isotopically labeled benzoic acid, [$^{18}O_2$], [$^{16}O^{18}O$], and [$^{16}O_2$], were calculated using the method of Brauman (28) to be 78.4%, 20.2%, and 1.4%, respectively.

Methyl 2-azido-2-deoxy-3-benzoyl-4,6-*O*-benzylidene-α-D-(3-^{18}O)mannopyranoside (6)

To a solution of **5** (4.7 g, 10 mmol) and $C_6H_5C^{18}O_2H$ (1.8 g, 14 mmol) in CH_2Cl_2 (150 mL), K_2CO_3 (2.2 g, 16 mmol) and 18-crown-6 (4.2 g, 16 mmol) were added. The resulting mixture was stirred at room temperature for 5 d, and then it was heated to reflux for further 16 h. After removal of the volatiles under reduced pressure, the crude product was purified by flash chromatography using ethyl acetate:hexanes (1:5) as the eluent to afford **6** as a white solid (2.3 g, 52%). The unsaturated compound **7** was isolated as a minor product (1.2 g, 39%).

Methyl 2-azido-2-deoxy-4,6-*O*-benzylidene-α-D-(3-^{18}*O*)mannopyranoside (8)

To a solution of **6** (2.2 g, 5 mmol) in dry methanol (25 mL) was added a methanolic sodium methoxide solution (25 mL), and the mixture was stirred for 30 min at RT. The solution was then neutralized by adding Amberlite IR-120 (H^+ form). The resulting solution was filtered, and the resin was washed several times with methanol. The methanolic solutions were combined and evaporated to give a solid residue, which was purified by flash chromatography using ethyl acetate:hexanes (1:4) as the eluent to afford **8** as syrup (1.5 g, 92%).

Synthesis and characterization of novel conducting homopolymers based on amino β-styryl terthiophene

Hakim Mehenni and Lê H. Dao

Abstract: Novel ECPs (electronic conducting polymers) based on amino β-styryl-substituted terthiophene (AST) were synthetized by direct electropolymerization. The ECPs were characterized by cyclic voltammetry, square-wave voltammetry, Fourier transform infrared (FTIR) spectroscopy, and X-ray photoelectron spectroscopy (XPS). The poly(amino β-styryl terthiophene) displayed cyclic and square-wave voltammograms with redox peaks that can be assigned to the aminophenyl moiety and the polyterthiophene backbone. The presence of free primary amine groups on the ECP film permitted further biological functionalization (i.e., covalent bonding of various bioreceptors on its surface). The electrochemical performance of Biotin grafted at the AST modified glassy carbon electrode was investigated to detect the Avidin protein in solution by cyclic voltammetry and square-wave voltammetry.

Key words: electronic conducting polymer, electrode surface modification, biosensor, β-styryl-substitued terthiophene, functionalization, cyclic, square-wave voltammetry.

Résumé : Faisant appel à une électropolymérisation directe, on a réalisé la synthèse de nouveaux polymères conducteurs électroniques (PCE) à base de terthiophènes portant des substituants β-styryles aminés (TSA). On a caractérisé les PCE par voltampérométrie cyclique, par voltampérométrie à onde carrée, par spectroscopie infrarouge à transformée de Fourier (IR-TF) et par spectroscopie photoélectronique de rayons X (SPX). Les poly(amino β-styryl terthiophènes) présentent des voltampérogrammes cyclique et à onde carrée comportant des pics redox qui peuvent être attribués à la portion aminophényle ainsi qu'au squelette polyterthiophène. La présence de groupes amines primaires libres sur le film de PCE a permis de réaliser une autre fonctionnalisation biologique, c'est-à-dire la formation de liaisons covalentes de divers biorécepteurs sur sa surface. On a évalué la performance électrochimique de la biotine fixée sur une électrode de carbone vitreuse modifiée par des TSA à détecter la protéine avidine en solution par les techniques de voltampérométrie cyclique et à onde carrée.

Mots-clés : polymère conducteur électronique, modification de la surface d'une électrode, biosenseur, terthiophène portant une β-styryle substitué, fonctionnalisation, voltampérométrie cyclique et à onde carrée.

[Traduit par la Rédaction]

Introduction

In recent years, conducting polymers have been the subject of considerable academic and industrial research because of their potential uses in areas such as storage and energy conversion, electrocatalysis, corrosion-resistant materials, and sensors (1–3). Moreover, the use of electronic conducting polymers (ECP) as an immobilization matrix of biomolecules on the electrode surface and as an electronic transducer has taken a considerably important place in the development of biosensors (4, 5). Generally, a biosensor, consisting of a transduction system coupled to a receptor, is prepared by immobilizing the molecular recognition bioreceptor onto the substrate materials (e.g., ECP), and this bioreceptor (e.g., antigen, biotin) recognizes a biomolecule compound (e.g., antibody, avidin) according to its specificity. Therefore, bioreceptors have to be properly immobilized on the sensor surface, and a transducer signal has to be generated, which is related to the concentration of the biomolecule in the sample (6). This kind of device is called reagentless "third-generation biosensor" in which a redox probe is not required (7).

Oligo and polythiophenes have also been functionalized as advanced materials for electrode surface modifications allowing the development of chemosensor (8–10) and biosensor devices (11–13). Effectively, the advantage of making polythiophene films from functionalized terthiophene is to avoid reaching a highly positive potential, which may cause the degradation of delicate functional groups because terthiophene has a lower oxidation potential than thiophene or bithiophene; thus, electrochemical polymerization is easier (14). Moreover, conducting polymers from terthiophene

are known for their simple functionalization and relatively good stability in air for the neutral and oxidized states (15).

Reeman et al. (16) developed an avidin biosensor based on a direct functionalization of terthiophene by biotin. Biotin was directly bonded to the central thiophene ring in the 3′ position by chemistry synthesis. A redox-inactive polythiophene film was obtained from an electrochemical polymerization of the biotin-functionalized terthiophene alone, because the bonded biotin has an insulating effect on the polythiophene backbone. Consequently, a polythiophene copolymer was realized from the biotin-functionalized terthiophene and 2,2′:5′,2″-terthiophene (1:5 molar ratio, respectively) to obtain a redox-active copolymer film. Another inconvenience was that the polythiohene redox signal was situated at a high potential, approximately 1 V vs. Ag/AgCl, leading usually to the degradation of the bioreceptor, i.e., of biotin. Also, no redox signal was clearly visible to allow the measurement of avidin by using a simple electrochemical method as cyclic voltammetry or square-wave voltammetry; for this reason, impedance was used without forgetting the inconvenience of using chemical synthesis to make biological functionalization of polythiophene film, because this type of biosensor system will be limited only for a single target biomolecule.

A new approach to the functionalization of the surface of polythiophene films appeared with the work of Shim et al. The terthiophene was functionalized by a carboxylic acid group (–COOH) in the 3′ position of the central thiophene ring to prepare the terthiophene 3′-carboxylic acid (TCA). Biosensors of vitellogenin (17), glutamatate (18), and H_2O_2 (19) have been developed after the biological surface functionalization of the poly(TCA) film electrodeposited on an electrode surface. The advantage of biosensor systems based on the poly(TCA) films is to be not restricted to a single target biomolecule. Indeed, various bioreceptors can be immobilized through a covalent bond by interaction with free carboxylic acid groups present on the poly(TCA) film surface. The inconvenience of this biosensor system is that, here also, the polythiophene backbone redox signal is situated at a high potential, which may cause the degradation of the immobilized bioreceptor on its surface.

So, another new approach is to functionalize the terthiophene by a redox group to use another redox signal rather than the polythiophene backbone redox signal to detect the target biomolecule. In this last approach, the terthiophene was used only to bind the redox group on the electrode surface by electropolymerization of the terthiophene moiety. This is the case of the terthiophene functionalization by a ferrocene (20) used to develop a cytochrome C biosensor. Wallace et al. have covalently bonded a ferrocene ring to the central thiophene ring in the 3′ position by a π-conjugated linker, allowing to make a redox-active polythiophene film from the ferrocene-functionalized terthiophene alone. Indeed, the π-conjuguated linker allows an electronic communication between the polythiophene backbone and the ferrocene group, so that the insulation of the polythiophene backone is avoided. The advantage of this last approach is the use of a redox signal from another redox group as electronic transductor (i.e., ferrocene ring) rather than from the polythiophene moiety of the poly(terthiophene 3′-ferrocene) film. Effectively, the ferrocene redox potentials were clearly visible to low potential (towards 0.4 V vs. Ag/AgCl), and were able to be exploited by a simple electrochemical technique such as cyclic voltametry to detect and to measure cytochrome C. On the other hand, the disadvantage of this biosensor system based on the poly(terthiophene 3′-ferrocene) film is that its use is restricted to a single biological target, here Cytochrome C. Also, the ferrocene ring is known for its toxicity in situ to the point that some of these by-products are the object of interest as anticancerous agents (21–23). This constitutes a major disadvantage in the development of biosensors for an in situ application in a medical field.

To bring a solution to the problematic context above, we chose to combine the strategies of Shim and Wallace. Herein, we report the synthesis and the characterization of novel conducting homopolymers based on amino β-styryl terthiophene, which have never been reported. The amino β-styryl terthiophene monomer corresponds to the functionalization of the terthiophene by an amino β-styryl group, covalently bonded to the central thiophene ring in the 3′ position. We have synthetized the 3′-(3-methyl-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4a**), the 3′-(3-chloro-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4b**), the 3′-(3-methoxy-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4c**), and the 3′-(2-methoxy-5-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4d**). This new strategy to functionalize the terthiophene by an amino β-styryl group gives a new ECP having the following properties:

(*i*) the ECP from amino β-styryl terthiophene monomers can be electrodeposited on an electrode surface by electropolymerization of the terthiophene moiety in which the redox signal of the aminophenyl moiety is used as an electronic transducer signal to detect and to measure target biomolecules. Also, we have introduced Y substitutes having different inductive, steric, and mesomeric effects on the aminophenyl ring to study their influences on its redox-activity to lower the aminophenyl anodic potential as low as possible towards 0 V vs. Ag/AgCl.

(*ii*) the π-conjuguated linker allows an electronic communication between the aminophenyl moiety and the polythiophene backbone to avoid an insulating effect on the polythiophene backbone. Consequently, copolymerization to obtain a redox-active polymer film is avoided.

(*iii*) the presence of free primary amine groups on the ECP film surface permits further biological functionalization of its surface by covalently bonding various bioreceptors. This biosensor system can be used for various targets biomolecules.

Experimental

Materials and instrumentation

All reagents were purchased from the Sigma-Aldrich Chemical Company (Canada) and used as received: 3-methyl-4-nitrobenzyl bromide, triphenylphosphine (PPh_3), 3-chlorobenzyl chloride, benzene, 1,8-diazabicyclo(5.4.0)undec-7-ene (DBU), iron powder (Fe), ammonium chloride (NH_4Cl), acetic acid glacial (AcOH), sulfuric acid fuming (H_2SO_4), nitric acid (HNO_3), 2-methoxy-5-nitrobenzyl bromide, tin(II) chloride-dihydrate ($SnCl_2{\cdot}2H_2O$), 5-methyl-2-nitrophenol,

dimethyl sulfate ($(CH_3)_2SO_4$), dibenzoyl peroxide, *N*-hydroxysuccinimide (NHS), *N*-bromosuccinimide (NBS), magnesium sulfate ($MgSO_4$), sodium sulfate anhydrate (Na_2SO_4), ethyl-3-(3-dimethylamino-propyl) carbodiimide (EDC), Biotin, and tetrabutylammonium perchlorate (TBAP, electrochemical grade). Dichloromethane (DCM, HPLC grade), avidin from egg white, and the phosphate buffer saline (PBS 0.1 mol/L) of pH 7.4 at 25 °C were purchased from Fischer Scientific (Canada). All experimental solutions were prepared using double-distilled water obtained from a Milli-Q water system.

Nuclear magnetic resonance (NMR) spectra were measured at 400.13 MHz (^{1}H) and 100.6 MHz (^{13}C) on a Bruker ARX 400. All NMR spectra were recorded in deuteroacetone solutions with tetramethylsilane as reference. Signals are described in terms of chemical shifts, multiplicity, and assignment. The following abbreviations were used: s (singlet), d (doublet), dd (doublet of doublet), m (multiplet), and b (broad). In the NMR spectrum interpretation, the phenyl protons will have a letter p accompagnying the position number to avoid the confusion with the protons of the first thiophene ring (e.g., H_{5p} corresponds to the proton of the phenyl in 5 position). Mass measurements were performed on a LC–MSD–TOF instrument from Agilent Technologies in positive electrospray mode. Either protonated molecular ions $(M + H)^+$ or sodium adducts $(M + Na)^+$ were used for peak assignment. The IR spectra were recorded on a NEXUS 670 FTIR apparatus over the 600–4000 cm^{-1} range. The melting points were measured using a Fisher–Johns melting point apparatus. The measuring set-up for the all electrochemical experiments consisted of a three-electrode system in which a glassy carbon electrode or a platinum electrode, Ag/AgCl (saturated KCl) electrode, and a platinum wire (0.5 mm of diameter) or platinum foil (dimension 1 cm × 1 cm, 0.025 mm^2 of thickness) were used as the working, the reference, and the auxiliary electrode, respectively. The cyclic voltammograms (CVs) and the square-wave voltammogram (SWVs) were recorded using a Solartron-SI 1287 potentiostat/galvanostat and a EG & G Princeton Applied Research 273 A one, respectively. The measurements were carried out in a 0.1 mol/L TBAP–DCM solution at room temperature.

General procedure for the synthesis of nitro β-styryl terthiophene (3a, 3b, 3c, and 3d)

A mixture of a terthiophene aldehyde (**1**) prepared according to the literature method (24) (1 mmol), the triphenylphosphonium bromide compounds (**2a**, **2c**, and **2d**) or triphenylphosphonium chloride compound (**2b**) (1.2 mmol), and DBU (1.2 mmol) in dichloromethane (15 ml) was heated under reflux. After 8 h, the reaction mixture was diluted with dichloromethane (100 ml) and washed with a 1 mol/L solution of HCl (2 × 40 ml), 10 % sodium bicarbonate solution (40 ml), and water (60 ml). The organic layer was dried and concentrated to give a crude organic solid. The pure product was obtained by chromatography on a silica-gel column using a dichloromethane/hexane solution (1:1) as eluent.

General procedure for the synthesis of amino β-styryl terthiophene monomers (4a, 4b, 4c, and 4d)

Amino-β-styryl terthiophene compounds **4a** and **4b** were obtained by the reduction of the nitro group of the corresponding compounds **3a** and **3b** using iron powder (Fe) in presence of NH_4Cl.

To nitrophenyl compounds (1 mmol) in THF/EtOH/H_2O with the ratio of 3:3:2 were added iron powder (3 mmol) and NH_4Cl (0.6 mmol). The reaction was stirred at 85 °C for 1 h, cooled to room temperature, and filtered through a Celite column. The filter cake was washed with $CHCl_3$, and the filtrate was concentrated to a low volume, diluted with CH_3Cl, and washed with H_2O. The organic extracts were dried over $MgSO_4$ and filtered. After removing the solvent, the compounds were separated by a silica column with EA:CH_2Cl_2 ratio of 2:1, then pure EA. After purification, the compounds were obtained with good yields. In this reduction process, to improve the solubility of the materials, the THF was used as co-solvent

3′-(3-Methyl-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (4a)

Colour: brown. Liquid, yield: 100%. IR (NaCl): 3473 and 3373 (NH_2), 3104, 3073, 2965, 2926, 2873, 1604, 1260, 1082, 1039, 960, 821, 760, 695 cm^{-1}. ^1H NMR (acetone-d^6, 400 MHz) δ: 7.66 (dd, 1H, $H_{5''}$), 7.5 (dd, 1H, H_5), 7.43–7.36 (m, 2H, $H_{3''}$, H_3), 7.34 (d, 1H, H_a), 7.31 (d, 1H, H_b), 7.25–7.18 (m, 2H, $H_{4''}$, H_4), 7.16 (s, 1H, $H_{4'}$), 7.14 (m, 2H, H_{5p}, H_{6p}), 6.7 (d, 1H, H_{2p}), 3.8 (sl, 2H, $–NH_2$), 2.8 (s, 3H, $–CH_3$). MS *m*/*z*: 380 (MH^+, 100%).

3′-(3-Chloro-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (4b)

Colour: brown. Liquid, yield: 100%. IR (NaCl): 3465 and 3373 (NH_2), 3104, 3069, 2960, 2921, 2852, 1613, 1265, 1095, 1043, 956, 817, 760, 700 cm^{-1}. ^1H NMR (acetone-d^6, 400 MHz) δ: 7.62 (dd, 1H, $H_{5''}$), 7.5 (dd, 1H, H_5), 7.45 (d,1H, H_b), 7.37 (dd, 1H, $H_{3''}$), 7.33 (dd, 1H, H_3), 7.31 (d, 1H, H_a), 7.22 (m, 2H, $H_{4''}$, H_4), 7.19 (s, 1H, $H_{4'}$), 7.14 (m, 2H, H_{2p}, H_{6p}), 6.9 (d, 1H, H_{5p}), 3.85 (sl, 2H, $–NH_2$). MS *m*/*z*: 400 (MH^+, 100%).

For the amino-β-styryl terthiophene compounds 4c and 4d, the nitro groups of **3c** and **3d** compounds were reduced by $SnCl_2{\cdot}2H_2O$. To nitrophenyl compounds (1 mmol) in $EtOH/CH_2Cl_2$ with the ratio of 5:2 were added $SnCl_2{\cdot}2H_2O$ (12 mmol). The reaction was stirred at 90 °C for 17 h, cooled to room temperature, and then 1 g sodium bicarbonate was added. The reaction mixture was stirred during 30 min and then diluted with dichloromethane (100 ml) and filtered through Celite. The filtrate was washed with 5% sodium bicarbonate solution (2 × 100 mL), washed with H_2O (1 × 100 mL), and then dried over anhyd. Na_2SO_4. After removing the solvent, the product was obtained by column chromatography (silica gel) with ethyl acetate as eluent.

3′-(3-Methoxy-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (4c)

Colour: brown. Liquid, yield: 74%. General procedure for the synthesis of ylides compounds 2a, 2b, 2c, and 2d

A mixture of the 3-methyl-4-nitrobenzyl bromide (1 mmol) or 2-methoxy-5-nitrobenzyl bromide (1 mmol) and PPh_3 (1.2 mmol) in benzene was heated under reflux. After 3 h, the pure product **2a** or **2d** was recuperated as a white solid by removal of the solvent. The ylide **2b** was synthesized from the commercially available 3-chlorobenzyl chloride according to the literature method (25) to prepare the 3-chloro-4-nitrobenzyl chloride and then according the synthesis of **2a** and **2d**. In this reaction, the **2b** and **2b′** were given. Because of the difficulty of the separation, the mixture was not separated before used for the Wittig reaction. After the Wittig reaction, the pure desired isomer **3b** was isolated by TLC plates of silica gel (20 × 20 cm, thickness of 2000 μm), with cyclohexane/acetone (10:1) as eluent, from the reaction mixture following removal of the major isomer (**3b′**) by recrystallization from dichloromethane/ether. The ylide **2c** was synthesized according to the literature method (26) to prepare the 3-methoxy-4-nitrobenzyl bromide and then according the synthesis of **2a** and **2d**.

Electrochemistry

Electrochemical polymerization of monomers 4a, 4b, 4c, and 4d

The monomers **4a**, **4b**, **4c**, and **4d** were electrodeposited on a polished glassy carbon electrode by electropolymerization of 5 mmol/L of the monomer in a 0.1 mol/L TBAP–DCM solution by potential cycling between 0.0 and 1.1 V (vs. Ag/AgCl) at 10 mV s^{-1}. After the polymerization, the electrode surface was rinsed with DCM to remove the excess monomer. Post-polymerization cyclic voltammograms and square-wave voltammograms of homopolymers **4a**, **4b**, **4c**, and **4d** were investigated in 0.1 mol/L TBAP–DCM solution.

The neutral polymers were characterized by reflectance FTIR experiments and X-ray photoelectron spectroscopy (XPS). FTIR spectra of polymers films on gold-coated glass electrodes were recorded on NEXUS 670 FTIR over the range 600–4000 cm^{-1}. XPS examination were carried out on the polymers films grown on ITO-coated glass electrodes using a Escalab 220i XL spectrometer.

Surface biofunctionalization

Poly(**4b**)- and poly(**4d**)-coated electrodes were immersed in a 0.1 mol/L phosphate buffer saline (PBS) solution (pH 8) containing 0.05 mol/L EDC and 0.05 mol/L biotin for 24 h at 40 °C. The biotin was immobilized through the formation of covalent bond with free primary amine groups on the polymer surface. These electrodes were then rinsed thoroughly with the same buffer to remove the non immobilized biotin, and their cyclic voltammograms (CVs) and square-wave voltammograms (SWVs) were recorded. Finally, this poly(**4c**)/ and poly(**4d**)/biotin-modified electrode were incubated in a 0.1 mol/L phosphate buffer saline (PBS) solution of 3.10^{-4} mol/L avidin for 15 min at room temperature to block active sites of avidin by a specific interaction with biotin. These electrodes were removed, rinsed with the same buffer to remove the non reacted avidin with biotin, and allowed to dry. Then, their CVs and SWVs were recorded.

Results and discussion

Synthesis of amino β-styryl terthiophene monomers (4a, 4b, 4c, and 4d)

Scheme 1 shows the synthetic routes for amino β-styryl terthiophene monomers (**4a**–**4d**). The terthiophene aldehyde precursor (**1**) was prepared according to ref. 24. Starting from compound **1**, two steps are necessary to prepare the monomers **4a**, **4b**, **4c**, and **4d**. The first step is a Wittig reac-

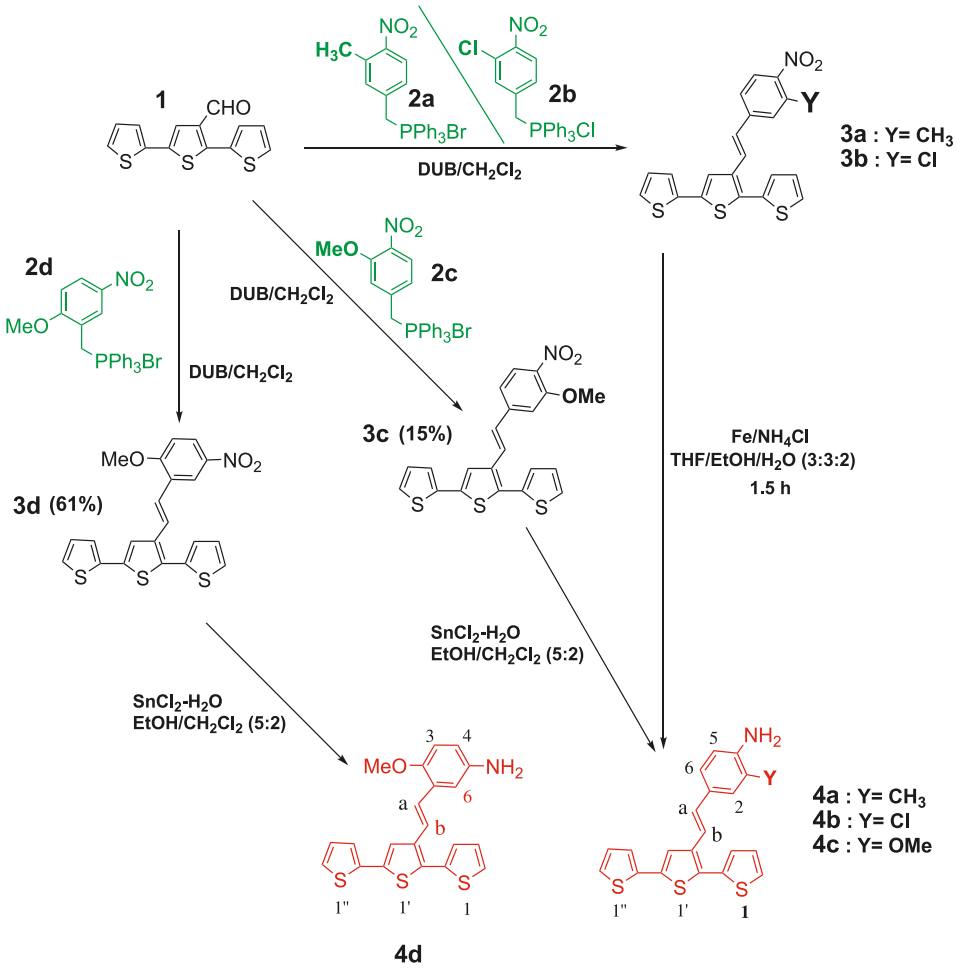
Scheme 1. The synthesis of the monomers.



tion to make the conjugated link between the aminophenyl moiety and the terthiophene. Compound **1** was treated with various ylide compounds (**2a**–**2d**) in DCM in presence of DBU to obtain the nitro β-styryl terthiophene compounds (**3a**–**3d**). The second step is a reduction of the nitro group of the compounds **3a**, **3b**, **3c**, and **3d** to provide the final amino β-styryl terthiophene monomers (**4a**–**4d**). Iron powder (Fe) was used as reducing agent for **3a** and **3b** and tin(II) chloride dihydrate ($SnCl_2 \cdot 2H_2O$) for **3c** and **3d**. The ylide compounds (**2a**–**2d**) were synthesized according to Scheme 2. The ylide compounds **2a** and **2b** were prepared from commercially available materials, the 3-methyl-4-nitrobenzyl bromide (**a**) and the 2-methoxy-5-nitrobenzyl bromide (**d**), which were treated by PPh_3 in benzene. The ylide **2b** was prepared according to ref. 27 to synthesize the 3-chloro-4-nitrobenzyl chloride, which was treated by PPh_3 in benzene. The ylide **2c** was synthesized according to ref. 28 to prepare the 3-methoxy-4-nitrobenzyl bromide (**c**), which was treated by PPh_3 in benzene.

Synthesis of poly(amino β-styryl terthiophene) (poly(4a), poly(4b), poly(4c), and poly(4d))

Monomers **4a**, **4b**, **4c**, and **4d** were electrodeposited on glassy carbon electrodes by cyclic voltammetry between 0 and 1.1 V (vs. Ag/AgCl). Figure 1 shows the CVs for the formation of poly(**4d**) film on a glassy carbon electrode. The cyclic voltammograms show the expected increase in current with increasing number of potential cycles, indicating the growth of electronic conducting polymers (ECP). The electrochemical polymerization of monomers **4a**, **4b**, **4c**, and **4d** results in the formation of a black uniform polymer film on the electrode surface.

Electrochemical characterization of poly(amino β-styryl terthiophene) films

Figure 2 shows cyclic voltammograms (CVs) of poly(**4a**), poly(**4b**), poly(**4c**), and poly(**4d**) films at scan rate 5 mV s^{-1} by potential cyclic between 0 and 1.0 V (vs. Ag/AgCl). The scanning from 0 to 1.0 V shows clearly two anodic peaks for poly(**4c**) and poly(**4d**) films, which we named a and c, and which we attributed to the oxidation of the aminophenyl moiety and to the polaronic oxidation of the polythiophene backbone, respectively. Indeed, it is reported that the aminophenyl moiety can be oxidized to give a radical cation (27). The oxidation removes an electron from the free electrons doublet of the nitrogen in its neutral state (NH_2), to give a radical cation nitrogen ($NH_2^{\bullet+}$). We were able to attribute the origin of the peaks a and c compared with the cyclic voltammogram of a polyterthiophene film prepared in the same conditions, and also by using literature results for polyterthiophene for which it is reported (28) that the polaronic oxidation peak is situated towards 1.05 V vs. SCE

Scheme 2. Synthesis of the ylide compounds.

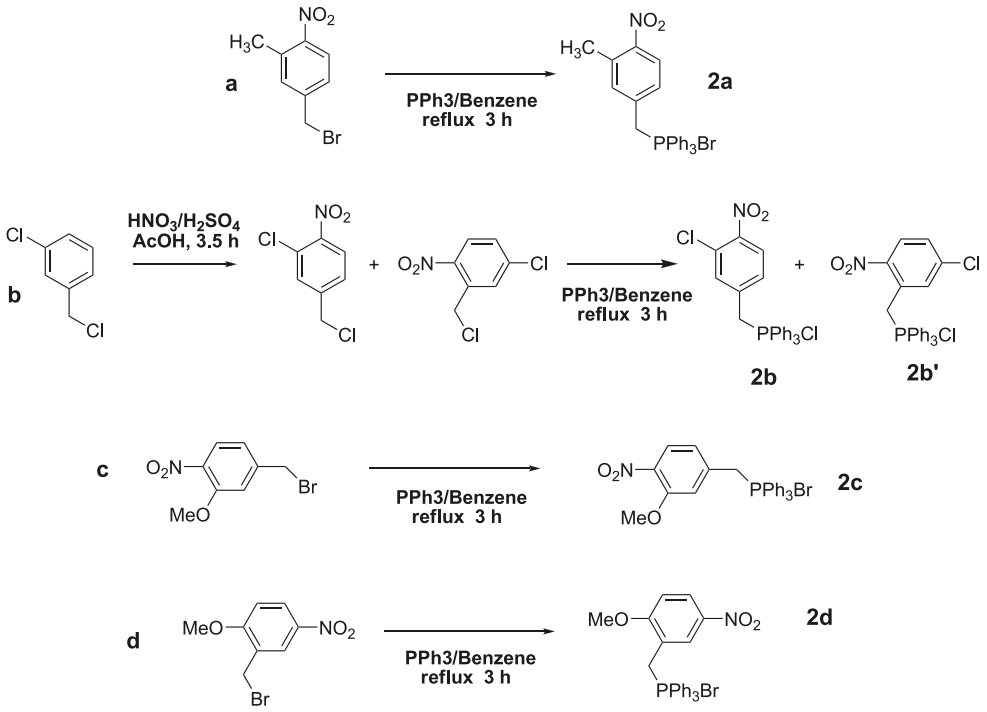

Fig. 1. Growth of poly(**4d**) by repetitive-scan cyclic voltammetry on a 7.068 mm^2 glassy carbon electrode between 0.0 and 1.1 V, auxiliary electrode: Pt foil, reference electrode: Ag/AgCl, scan rate: 10 mV s^{-1}m, 5 mmol/L monomer **4d**, 0.1 mol/L TBAP–DCM.

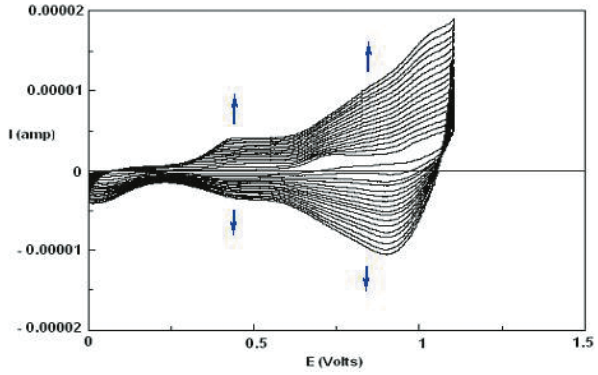

Fig. 2. Cyclic voltammogram of poly(**4a**), poly(**4b**), poly(**4c**), and poly(**4d**) films between 0.0 and 1.0 V, scan rate: 5 mV s^{-1} on a 7.068 mm^2 glassy carbon working electrode, auxiliary electrode: Pt wire, reference electrode: Ag/AgCl, 0.1 mol/L TBAP–DCM.

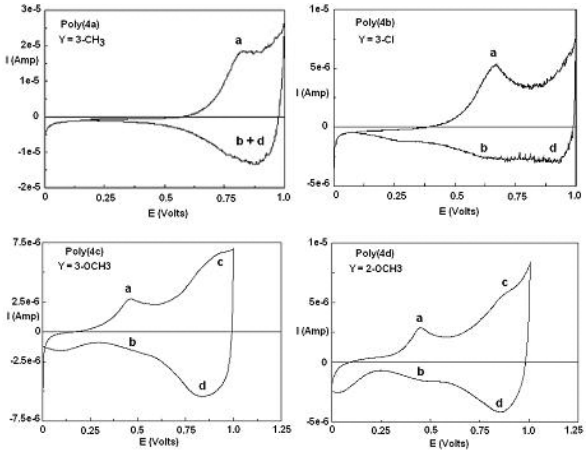

(corresponding to 1.09 V vs. Ag/AgCl). For poly(**4a**) and poly(**4b**) films, we can only see the peak a and an oxidation slope attributed to the polythiophene backbone oxidation. When the scanning direction is inverted from 1.0 to 0.0 V vs. Ag/AgCl, we see two cathodic peaks, d and b, for poly(**4c**) and poly(**4d**) films, which we attributed to the reduction of the polythiophene backbone and to the aminophenyl moiety reduction, respectively. The top of the peak b will be more clearly visible by SWV for the poly(**4b**) film. For the poly(**4a**) film, the last peaks are not distinctly visible because they are overlapping. So, the introduction of Y substitutes in the aminophenyl ring has for consequence to make the aminophenyl redox couple (a/b) visible and different from the polythiophene backbone redox couple (c/d). It lowers its anodic potential, in the first place situated at 0.98 V vs. Ag/AgCl (corresponding to the aminophenyl anodic potential (29)) towards a lower potential, especially when Y = OCH_3, which is a strong electronic donor and for which the aminophenyl anodic potential is slightly below 0.5 V vs. Ag/AgCl.

The square-wave voltammetry allows to eliminate the current overload (capacitive current *Ic*) visible in cyclic voltammetry (30–32). In other words, we can subtract *Ic* from the total current measured. Consequently, we used it to see clearly the redox couple (a/b) attributed to the aminophenyl moiety of poly(**4a**), poly(**4b**), poly(**4c**), and poly(**4d**) films. The square-wave voltammograms of polymer films are reported in Fig. 3. During the oxidation scanning from 0.0 to 1.0 V vs. Ag/AgCl, we can observe two

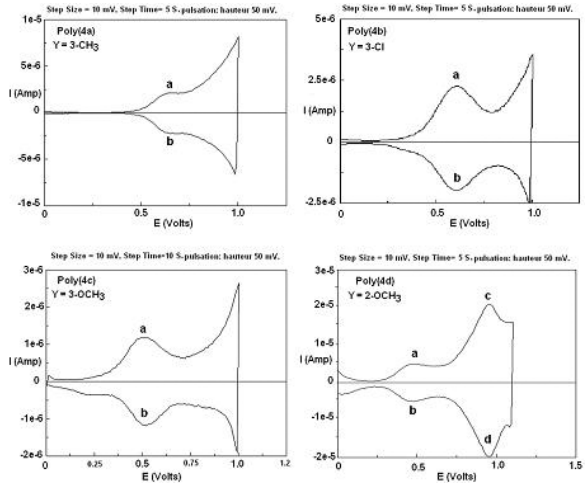
Fig. 3. Square-wave voltammograms of poly(**4a**), poly(**4b**), poly(**4c**), and poly(**4d**) films between 0.0 and 1.0 V on a 7.068 mm^2 glassy carbon working electrode, auxiliary electrode: Pt foil, reference electrode: Ag/AgCl, 0.1 mol/L TBAP–DCM.



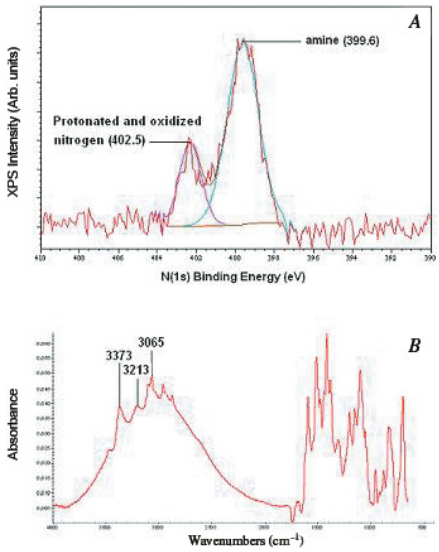
oxidation peaks, a and c, for the poly(**4d**) film. The anodic peak a situated towards 0.5 V vs. Ag/AgCl corresponds to the oxidation of the aminophenyl moiety, and the anodic peak c situated towards 0.9 V vs. Ag/AgCl corresponds to the polaronic oxidation of the polythiophene backbone. But for poly(**4a**), poly(**4b**), and poly(**4c**) films, we observe only the anodic peak a, situated towards 0.6 V vs. Ag/AgCl for poly(**4a**) and poly(**4b**), and towards 0.5 V vs. Ag/AgCl for poly(**4c**). In higher potentials, we observe an oxidation slope attributed to the oxidation of the polythiophene backbone. During the reduction scanning from 1.0 to 0.0 V vs. Ag/AgCl, we can observe two reduction peaks, d and b, for the poly(**4d**) film, corresponding to the reduction of the polythiophene backbone and to the aminophenyl moiety reduction, respectively. But for the poly(**4a**), poly(**4b**) and poly(**4c**), we observe a reduction slope corresponding to the reduction of the polythiophene backbone and the cathodic peak b.

Spectroscopic FTIR and XPS characterization

The studies of the poly(**4a**), poly(**4b**), poly(**4c**), and poly(**4d**) films by FTIR and XPS techniques, clearly show that there are free primary amine groups on the polymer film surface after electrochemical polymerization. This point proves that the amino β-styryl moiety is not destroyed during electropolymerization, and it does not bind anything by the amine groups. As an example, the XPS spectrum of the poly(**4d**) film and the FTIR spectrum of the poly(**4b**) film are shown in Fig. 4. FTIR spectrum of poly(**4b**) film grown on gold-coated glass shows two strong sharp peaks at 3373 and 3213 cm^{-1} (amine I band, N–H stretching vibration (33)) corresponding to the primary amine groups on the aminophenyl moiety, and a C–H stretching vibration of the aromatic ring (34) is also observed at 3065 cm^{-1}.

XPS spectrum shows the deconvoluted N1s spectrum of the poly(**4d**) film surface grown on ITO-coated glass electrode. The two features at 402.5 and 399.6 eV must be ascribed to a cationic nitrogen species (NH_3^+ and $NH_2^{\bullet+}$) and an amine I species (NH_2), respectively (35, 36).

Fig. 4. (*A*) XPS spectrum of the poly(**4d**) film and (*B*) FTIR spectrum of the poly(**4b**) film, grown on ITO-coated glass and gold-coated glass, respectively, at room temperature.



Biotin-modified electrodes

We have begun to investigate the possibility of using the poly(**4b**) and poly(**4d**) films in biosensor devices in which the redox signal of the aminophenyl moiety is used as an electronic transducer signal to detect a target biomolecule. We chose to begin with biotin–avidin interaction. Avidin is a highly stable glycoprotein and is able to be specifically bound by biotin to form an exceedingly strong complex (37). The steps used to link the biotin to the poly(amino β-styryl terthiophene)-coated electrode surface are summarized in Fig. 5. This procedure has the advantage of using simple conditions and of forming a covalent bond. The cyclic and the square-wave voltammograms of the poly(**4b**)- and poly(**4d**)-coated working electrode, before and after immobilization of biotin on their surfaces, are reported in Fig. 6*a* and Fig. 7*a*, respectively. We can observe for both polymer films that the biotin immobilization causes a shift towards a higher potential of the anodic peak initially attributed to the oxidation of the aminophenyl moiety. After biotin immobilization, the anodic peak corresponds to the oxidation of the amidophenyl resulting on the polymer film surface. Indeed, it is reported (29) that the amidophenyl anodic peak (Acetoamidophenyl *E*pA = + 1.24 V vs. Ag/AgCl) is higher than that of the aminophenyl (*E*pA = + 0.98 V vs. Ag/AgCl).

The cyclic and the square-wave voltammograms of the poly(**4b**)/ and poly(**4d**)/biotin-modified-coated working electrode, before and after exposure to a solution of 3.10^{-4} mol/L avidin in PBS 0.1 mol/L for 15 min are shown in Fig. 6*b* and Fig. 7*b*, respectively. We can observe in both cases, i.e., by CV or SWV, that the exposure of the poly(**4b**)/ or poly(**4d**)/biotin-modified-coated working electrode has a drastic effect upon its electrochemical response causing a significant diminution of the oxidation current measured on the anodic peak. This unusual voltammetry response after avidin exposure is explained by the presence of avidin covering the polymer film surface and thus causing the reduc-

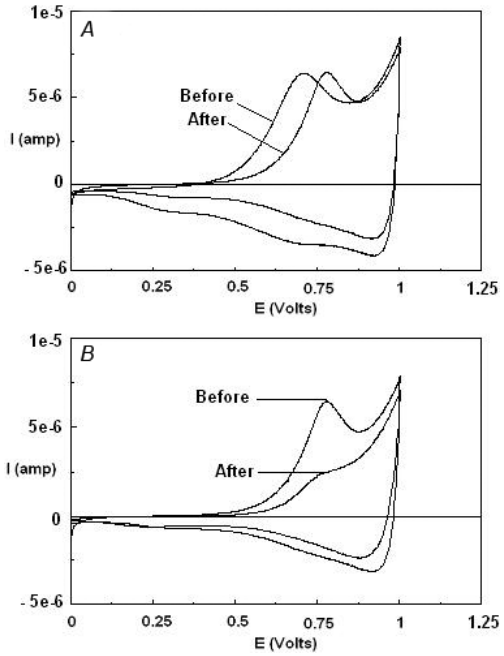
(*b*) Cyclic voltammograms of poly(**4b**)/biotin-modified-coated platinum working electrode before and after exposure in a solution of avidin 3.10^{-4} mol/L in PBS 0.1 mol/L during 15 min, auxiliary electrode: Pt foil, reference electrode: Ag/AgCl, scan rate: 25 mV s^{-1}, 0.1 mol/L TBAP–CH_2Cl_2.



tion in the number of amidophenyl moieties able to be oxidized at the polymer-film surface.

Conclusions

The terthiophene was successfully functionalized by an amino β-styryl moiety. We synthesized four new monomers according to the Y substituent, the 3′-(3-methyl-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4a**), the 3′-(3-chloro-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4b**), the 3′-(3-methoxy-4-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4c**), and the 3′-(2-methoxy-5-amino-β-styryl)-(2,2′:5′,2″-terthiophene) (monomer **4d**). The homopolymers from monomers **4a**, **4b**, **4c**, and **4d** have been successfully electrosynthesized. The electrochemical studies of these polymer films display both the aminophenyl moiety redox couple as well as the polythiophene backbone. The cyclic and square-wave voltammogram responses of the poly(**4b**)/ and poly(**4d**)/biotin-modified film on working electrode, after exposure to an avidin solution, suggest that these polymer films have potential application as biosensors.

We project to develop an avidin biosensor by using this last system to measure an unknown avidin concentration. Some of our results will be submitted soon. To investigate the possibility of using the poly(amino β-styryl terthiophene) films for various target biomolecules, we project also to make futher functionalization on the last ECPs surfaces by other bioreceptors.

Solvent-free syntheses of some quinazolin-4(3*H*)-ones derivatives

S. Mohana Roopan, T. Maiyalagan, and F. Nawaz Khan

Abstract: Solvent-free syntheses of quinazolin-4(3*H*)-ones were performed by reaction of anthranillic acid with different amides, such as nicotinamide, benzamide, formamide, etc., on montmorillonite K-10. Products were confirmed by FTIR, ^{1}HNMR, and ^{13}CNMR spectroscopic techniques. All synthesized compounds exhibited antioxidant properties and have been compared with standard antioxidant BHT.

Key words: quinazolinone, montmorillonite K-10, solvent-free conditions, antioxidant properties.

Résumé : On a réalisé des synthèses sans solvant de quinazolin-4(3*H*)-ones par réaction de l'acide anthranillique avec divers amides, tel le nicotinamide, le benzamide et le formamide sur de la montmorillonite K-10. Les produits ont été caractérisés par la spectroscopie infrarouge avec transformée de Fourier (IR-TF), et par les méthodes spectroscopiques de RMN du ^{1}H et du ^{13}C. Tous les produits synthétisés présentent une propriété antioxydante et ils ont été comparés avec l'antioxydant standard, BHT.

Mots-clés : quinazolinone, montmorrillonite K-10, conditions sans solvant, propriétés antioxydante

[Traduit par la Rédaction]

Introduction

The quinazoline ring skeleton is widely found in alkaloids and many biologically active compounds. In general, quinazolones were considered important compounds in the fields of pharmacology and biology (1) because of their wide range of strong biological activities (2–6). Some of these compounds are identified as drugs (7) and as diuretics. Among this class of molecules, quinazolin-4-ones and their derivatives are well-known to possess an array of physiological activities, e.g., antitubercular (8), antifungal (9), antibacterial (10), anti-inflammatory, anticancer (11), and anti-proliferative (5) activities.

Quinazolin-4(3*H*)-one was prepared by many methods (5, 8, 10–13). However, quinazoline derivatives were synthesized mainly by a common approach involving amidation, starting from anthranilic acid, 2-aminobenzonitrile, and 2-aminobenzamide. Other methods included the condensation of anthranilic acid, ammonium acetate, and the orthoesters (14), reaction of imidates and anthranilic acid (15), reaction of polymer-bound isothioureas with isatoic anhydride derivatives (16), and were associated with drawbacks such as multistep procedures (17), costly reagents, harse reaction conditions, complex experimental procedures, and low yields (18). Previous methods have been excluded from practical applications because of environmental and economic considerations. Finding an efficient method for the synthesis of quinazolin-4(3*H*)-one is still a challenge. Nowadays, solvent-free organic reactions have led to experimentally and industrially important organic syntheses that are more effective and eco-friendly than conventional reactions (19, 20).

In continuation of our interest in C–C bond-forming reactions (21–25), we have explored a one-pot synthesis of quinazolin-4(3*H*)-ones (Schemes 1 and 2, Tables 1 and 2) from anthranillic acid and amides, such as formamide, acetamide, benzamide, nicotinamide, etc., in the presence of montmorillonite K-10 catalyst and other inorganic catalysts such as acidic alumina, bentonite, etc., (Table 3), under solvent-free conditions. The above reactions, carried out over montmorillonite K-10 clay, give good yields because of the ditopic nature (26, 27) of montmorillonite K-10 clay. However, the reaction takes less time to complete. The optimization of catalyst amount was also done (Table 4). Thus, we have developed a simple, economical, and environmentally benign synthesis of classical procedures, by avoiding volatile and toxic organic solvents. The reusability of the catalyst in synthesis has also been explored (Table 5). Scope of the reaction (Tables 1 and 2) and antioxidant properties of the reaction products have also been discussed.

Experimental

Anthranillic acid and amides used for the reaction were from Sigma-Aldrich Co., and montmorillonite K-10 was obtained from Fluka. The substances were used as provided with no other purification. Melting points were taken in open capillary tubes and are corrected with reference to ben-

of the reaction, ethyl acetate was added to the reaction mixture, and the catalyst was recovered by filtration. Filtrate was washed with a 10% $NaHCO_3$ solution to remove any unreacted acid and further washed with water to remove any inorganic materials. The organic layer was dried, solvent evaporated to obtain the products. FT-IR and NMR spectral techniques were used for product analysis.

Synthesis of 2-pyridin-3-yl-3*H*-quinazolin-4-one (3a)

Anthranillic acid **1** (10 mmol), nicotinamide **2a** (10 mmol), and montmorillonite K-10 (0.1 g) were placed in a mortar and mixed well, transferred to a 50 mL round-bottomed flask, and refluxed at 150 °C for 30 min. The reaction was monitored by TLC, and after completion of the reaction, work-up was performed as above to give crude

product. Pure 2-pyridin-3-yl-3*H*-quinazolin-4-one **3a** was obtained by performing column chromatography using silica gel and petroleum ether/ethyl acetate as eluent. Yield was determined (Table 1, compound **3a**). The quinazolinone **3a** was recrystallized from petroleum ether and ethyl acetate. The melting point was found to be 114 °C.

A similar procedure was followed to obtain other quinazolinone derivatives **3** from different amides **2** (Scheme 1 and Table 1). Products were characterized by FTIR, ^{1}HNMR, ^{13}CNMR, and GCMS spectral techniques, and known compounds were compared with literature reports. The recrystallization of products was effected using petroleum ether and ethyl acetate.

Synthesis of 1*H*,3*H*-quinazolin-2,4-dione (5a)

A mixture of anthranillic acid **1** (10 mmol), urea **4a** (10 mmol), and 0.1 g of montmorillonite K-10 was heated under reflux conditions (150 °C) for 2 h. After completion of the reaction, the catalyst was removed by filtration; the mixture was poured into ice-cooled water and extracted with ethyl acetate. The product **5a**, obtained after solvent removal, was purified by performing column chromatography using silica gel and petroleum ether/ethyl acetate as eluent (Scheme 2, Table 2). The quinazolindione **5a** was recrystallized from petroleum ether and ethyl acetate. The melting point was found to be >300 °C.

Synthesis of 2-thioxo-2,3-dihydro-1*H*-quinazolin-4-one (5b)

A mixture of anthranillic acid **1** (10 mmol), thiourea **4b** (10 mmol), and 0.1 g of montmorillonite K-10 was heated under reflux conditions (150 °C) for 2 h. After completion of the reaction, the catalyst was removed; the mixture was poured into ice-cooled water and extracted with ethyl acetate. The product **5b**, obtained after solvent removal, was purified by column chromatography (Scheme 2, Table 2). The dihydroquinazolinone **5b** was recrystallized from ethyl acetate. The melting point was found to be >300 °C.

Life cycle of the catalyst

The reusability of catalyst was explored by checking the successive runs of the reactions on recycled catalyst; i.e., after first run of the reaction, the catalyst was recovered by a simple filtration from reaction mixture, washed with ethyl acetate, and dried. Then it was utilized in the second run of the reaction. It was noticed that use of recycled catalyst in subsequent experiments gave similar yields (Table 5). Thus, the catalyst is not leached.

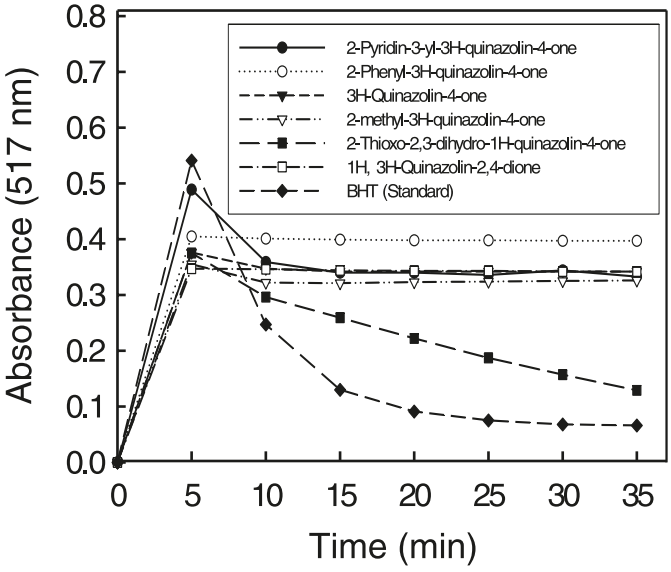
Free-radical scavenging activity of quinazolinone derivatives

Radical scavenging activities are very important due to the deleterious role of free radicals in foods and biological systems. In this study, the free-radical scavenging activity of quinazolin-4(3*H*)-ones derivative was measured by a 1,1-diphenyl-2-picryl-hydrazyl (DPPH) method. This activity was measured by the following Blos methodology as assessed by Ansari et al. (28). The absorbance of DPPH is monitored at a characteristic wavelength in the presence of a synthesized sample. In its radical form, DPPH absorbs at 517 nm, but upon reduction by an antioxidant or a radical species its absorption decreases. Briefly, a 1.5×10^{-4} mmol/L solution of DPPH in ethanol was prepared and 1 mL of this solution was added to 3 mL of 1.5×10^{-4} mmol/L of quinazolinone in ethanol. At each 5 min interval, absorbance was measured at 517 nm until 30 min. The standard used was butylated hydroxyl toluene (BHT), (1.5×10^{-4} mmol/L) in ethanol solution. Lower absorbance of reaction mixture indicates higher free-radical scavenging activity. Absorbance of the DPPH (control) is 1.544. The capability to scavenge DPPH radical (28, 29) was calculated using the following equation,

$$\text{DPPH Scavenging effect (\%)} = [(A_{\text{control}} - A_{\text{sample}} / A_{\text{control}}) * 100]$$

where A_{control} is the absorbance of the DPPH solution and A_{sample} is the absorbance in the presence of quinazolinone. Two different graphs (Figs. 1 and 2) are plotted with time vs. absorbance and time vs. % inhibition.

Fig. 1. Time vs. absorbance graph for antioxidant property of quinazolinone derivatives.



Results and discussion

Solvent-free syntheses of quinazolinone **3a** from anthranillic acid **1** and nicotinamide **2a** have been explored by using inorganic catalysts such as montmorillonite K-10, silica gel, acidic alumina, etc. (Table 3). Preliminary results indicated the formation of quinazolinone in high yield only in the case of montmorillonite K-10. The optimization of catalyst amount was done to improve the yield (Table 4). Montmorillonite K-10 has had a great impact in organic synthesis and has offered major breakthroughs for the manufacture of fine chemicals. This reagent has advantages over the

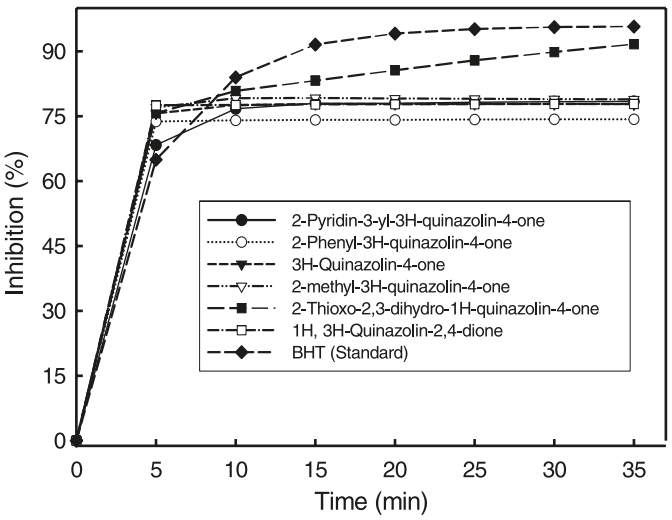
Fig. 2. Time vs. % inhibition graph for antioxidant property of quinazolinone derivatives.



conventional homogeneous solution techniques: easy set-up and work-up, mild experimental conditions, and high yield. As part of our research, quinazolin-4(3*H*)-ones were synthesized using K-10 as catalyst (Schemes 1 and 2). The results of the quinazolinones synthesis are summarized (Tables 1–5). The essence of the catalyst can be understood from the following facts: when anthranillic acid **1** was treated with montmorillonite K-10 under conventional heating in the presence of nicotinamide **2a**, the product **3a** was obtained in quantitative yield (Table 3, entry 5). When the same reaction was performed without montmorillonite catalyst, **3a** was obtained in much lower yield in 2 h (Table 4, entry 1). The reaction optimization with different amounts of montmorillonite K-10 was carried out, and at 0.1 g, the yield was good (Table 4).

In the IR spectra of all 4-quinazolinones **3**, absorption bands are observed in the region of 1690–1730 (Ar C=O), 1600–1635, 1510–1570, 1460–1500 cm $^{-1}$ (the quinazolone ring). Assignments of ^{1}H NMR signals of quinazolinones **3** were derived from splitting patterns and characteristic chemical shift values. The data consistently show that the homocyclic proton signal with the lowest field shift in series of compounds is a doublet with additional fine structure due to further *meta* and *para* couplings. This signal is assigned to H-5 on the basis of the proximity to the carbonyl group. The assignment of H-5 led to the assignment of H-8 by default. In the same spectral region, the signal for H-2 is found as a singlet. The signals for protons H-6 and H-7 show two *ortho* couplings. We have assigned the H-7 signal to the lower field.

In the present study, quinazolinone derivatives were evaluated for their free-radical scavenging activity using the DPPH radical assay. Reduction of DPPH radicals can be observed by a decrease in absorbance at 517 nm. Different derivatives of quinazolinones reduced DPPH radicals significantly. The activity of quinazolinone derivatives was compared with commercial antioxidant butylated hydroxyl toluene (BHT). 2-Thioxo-2,3-dihydro-1*H*-quinazolin-4-one had relatively high DPPH radical-scavenging activity. As shown in Figs. 1 and 2, all quinazolinone derivatives were found to have the ability to scavenge hydroxyl radical at a concentration of 1.5×10^{-4} mmol/L.

Analytical data

Data of the new compound **3a** and that of a few known compounds, **3b**–**3d**, **5a**–**5b**, which have not been reported earlier are given below. The data of a few compounds that have been found to be identical to those reported (30–32) are given as Supplementary Data available with this paper.[2]

Conclusion

In conclusion, we have reported a facile synthesis of quinazolin-4(3*H*)-ones under solvent-free conditions and conventional heating, demonstrating the use of montmorillonite K-10 as an efficient, rapid, mild, and inexpensive catalyst. The procedure has the advantages of simplicity and easy product isolation, coupled with high purity and yields.

A Fmoc/Boc pseudoisocytosine monomer for peptide nucleic acid synthesis

Filip Wojciechowski and Robert H.E. Hudson

Abstract: The synthesis of *N*-[2-(fluorenylmethoxycarbonyl)aminoethyl]-*N*-[(2-*N*-(*tert*-butoxycarbonyl)isocytosin-5-yl)acetyl]glycine peptide nucleic acid monomer is described. The *N*-*tert*-butoxycarbonyl protected monomer is compatible with commercially available monomers designed for the Fmoc-oligomerization strategy and is deprotected under mild acidolysis conditions.

Key words: PNA, polyamide, pseudoisocytosine, J-base, triplex.

Résumé : On décrit la synthèse du peptide monomère de l'acide nucléique *N*-[2-(fluorénylméthoxycarbonyl)aminoéthyl]-*N*-[2-*N*-(*tert*-butoxycarbonyl)isocytosin-5-yl)acétyl]glycine. Le monomère protégé par le groupe *N*-*tert*-butoxycarbononyle est compatible avec les monomères disponibles commercialement, développés pour la stratégie d'oligomérisation Fmoc, et il peut être déprotégé dans des conditions d'acidolyse douce.

Mots-clés : PNA, polyamide, pseudoisocytosine, base J, triplex.

[Traduit par la Rédaction]

Introduction

Peptide nucleic acid (PNA) is a nucleic acid analogue composed of a polyamide backbone to which the nucleobases are attached by a methylene carbonyl group (1). PNA oligomers hybridize to complementary DNA or RNA obeying Watson–Crick base-pairing rules and do so with remarkable sequence specificity and high affinity. Interest in PNAs as therapeutic agents (2) or as probes in clinical diagnostics (3) continues to motivate scientists to expand the frontiers of PNA chemistry and its applications. It is evident that such uses will only flourish if the building blocks for the synthesis of modified PNA are commercially available or readily prepared by straightforward synthetic procedures. Thus it becomes important to develop and detail the route to such reagents to benefit the community interested in PNA.

Although there have been a number of nucleobase modifications incorporated into PNAs (4), the majority of these nucleobases utilize Boc/Cbz-protected monomers. Removal of the Cbz exocyclic amino protecting group from the nucleobases requires harsh reagents, usually neat HF or TFMSA, and is generally disfavoured by the nonspecialist. Therefore, other protecting group strategies for mild deprotection have been investigated.

Currently, the most commonly used PNA building blocks for mild deprotection are the commercially available Fmoc/Bhoc monomers. While Bhoc-protected adenine, thymine, guanine, and cytosine are commercially available, other nucleobases that have shown beneficial properties are not, and synthetic procedures for N-protection with mild acid labile protecting groups have not been thoroughly investigated.

Nucleic acids (NAs) with purine-consecutive sequences may be targeted by homopyrimidine PNA forming a $(PNA)_2$:NA triplex that has a very high thermal stability (5). One PNA strand engages in Watson–Crick base-pairing, while the other PNA strand is involved in Hoogsteen binding. While thymine forms a stable Hoogsteen pair with adenine, cytosine requires protonation below physiological conditions to form a stable Hoogsteen pair with guanine. Such pH dependence may be alleviated by using nucleobase analogues of protonated cytosine such as N^7-guanine (6) or pseudoisocytosine (J) (7) (Fig. 1). To date, neither a synthetic procedure nor a commercial source for pseudoisocytosine protected by a mild acid labile protecting group has been reported.

We have recently developed a convenient route to benzyl, allyl, and 4-nitrobenzyl esters of *N*-[2-(Fmoc)aminoethyl]glycine to facilitate the syntheses of PNA monomers in which the nucleobases are protected with groups that could be liberated under mild acidic conditions. We have also successfully synthesized PNA oligomers using a bis-*N*-Boc nucleobase protecting group strategy to reduce aggregation during oligomer synthesis (8). Herein we report the first synthesis and oligomerization of a pseudoisocytosine monomer protected at the exocyclic amino group with a mild acid labile protecting group (Boc), which is fully compatible with standard Fmoc/Bhoc oligomerization–deprotection peptide synthesis.

Results and discussion

The synthesis of isocytosin-5-ylacetic acid (9) (**1**) was carried out as described by the modified procedure of Niel-

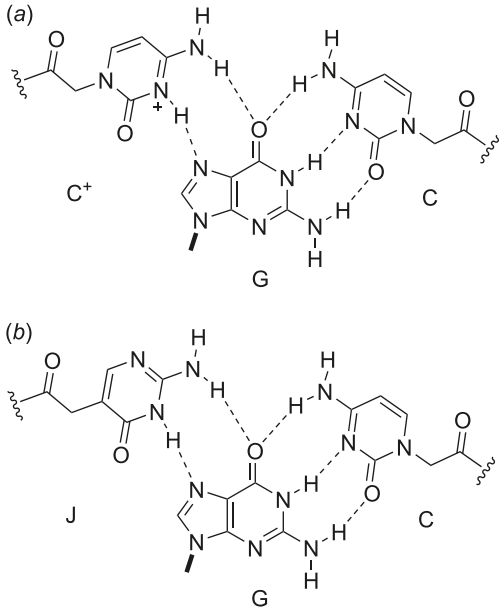
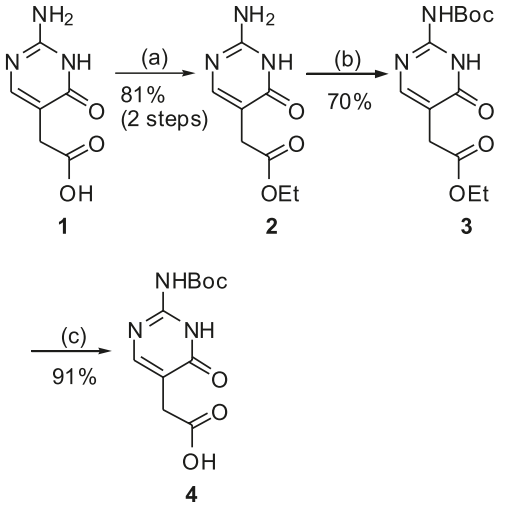
Fig. 1. Nucleobase interactions for a $(PNA)_2$:NA triple helix. (*a*) Protonated cytosine (C^+) and the G:C base pair (C^+:G:C) and (*b*) pseudoisocytosine (J) and the G:C base pair (J:G:C).



sen and co-workers (10). Condensation of dimethyl succinate with methyl formate gave methyl α-formylsuccinate as a colourless oil that was partially contaminated with dimethyl succinate. The product may be isolated free of dimethyl succinate by continuous extraction with diethyl ether but this greatly reduces the yield. Nielsen and co-workers proposed that this contaminated oil may be directly used in the next step. Therefore, the crude mixture was reacted with guanidine hydrochloride to give isocytosin-5-ylacetic acid **1** in good yield, confirming that it is suitable to use the crude mixture. Subsequent esterification with $EtOH/HCl_{(g)}$ gave ethyl isocytosin-5-ylacetate hydrochloride, which was dissolved in aqueous sodium bicarbonate and acidified to pH 6.0 to give ethyl isocytosin-5-ylacetate (**2**) in 81% yield.

We have previously reported the bis-*N*-Boc protection of ethyl cytosin-1-ylacetate, ethyl adenin-9-ylacetate, and ethyl (O^6-benzylguanin-9-yl)acetate. The exocyclic amino group of cytosine was most reactive towards $(Boc)_2O$ and gave the bis-*N*-Boc protected nucleobase in excellent yield. Likewise we reasoned that pseudoisocytosine, which is a cytosine analogue, should be prone to bis-*N*-Boc protection. Thus, ethyl isocytosin-5-ylacetate **2** was reacted with a catalytic amount of DMAP, 4.0 equiv. of $(Boc)_2O$, triethylamine in CH_3CN under reflux, but the major product was the mono-Boc protected derivative N^2-(*tert*-butoxycarbonyl)isocytosin-5-ylacetate (**3**) in 51% yield. Changing to *N*-methylimidazole as the catalyst, reducing the amount of $(Boc)_2O$ to 1.3 equiv., and changing to DMF as the solvent gave **3** in slightly better yield (57%). Final optimization gave **3** in 70% yield free of column chromatography, by simply using a catalytic amount of DMAP and 1.3 equiv. of $(Boc)_2O$ in DMF. Subsequent hydrolysis of **3** gave the carboxylate, which was acidified with citric acid to give a precipitate of N^2-(*tert*-butoxycarbonyl)isocytosin-5-ylacetic acid (**4**) in 91% yield

Scheme 1. Synthesis of N^2-(*tert*-butoxycarbonyl)isocytosin-5-ylacetic acid **4**. Reagents and conditions: (*a*) $HCl_{(g)}$, EtOH, reflux 2 h; (*b*) $(Boc)_2O$, DMAP, DMF, 36 h; (*c*) NaOH, THF/H_2O, 15 min.



(Scheme 1). Alternatively, acidification of the carboxylate of **4** with 4 mol/L of HCl followed by extraction into ethyl acetate resulted in a lower yield (73%) and required the use of copious amounts of ethyl acetate (400 mL) because of the poor solubility of **4** in ethyl acetate.

Carbodiimide-mediated coupling of **4** with *N*-[2-(Fmoc)aminoethyl]glycine benzyl ester (8) was accomplished using EDC/HOBt, to give the orthogonally protected monomer ester **5** in 74% yield. Removal of the benzyl ester using Pd/C and H_2 gave the desired monomer **6** in 86% yield (Scheme 2).

The performance of the Boc-protected pseudoisocytosine monomer (**6,** J) was judged by incorporation into a 10-mer PNA sequence (N-term: GTA GAT CJC T-Lys C-term, **7**) by standard Fmoc-mediated peptide synthesis along with commercially available Bhoc-protected monomers. The coupling of monomer **6** was qualitatively judged to be trouble-free by conductivity monitoring during the automated synthesis of the oligomer. Furthermore, RP-HPLC analysis of the crude oligomer (Fig. 2) indicated the coupling to be equivalent to the standard G, T, C, and A monomers with an average stepwise coupling yield of >98.5%.

Post oligomerization, removal of the Boc protecting group along with the Bhoc protecting groups was achieved using TFA/Et_3SiH (975:25 μL). The crude oligomer was purified by RP-HPLC; the major peak in the chromatogram corresponded to the full length oligomer (retention time: 28.375 min.). The identity of **7** was confirmed by mass spectrometry (Fig. 3). There was excellent agreement between the expected and found masses: TOF-MS (ESI) *m*/*z* calcd. for $C_{113}H_{148}N_{58}O_{32}$: 2830.75; found: 2830.80.

In summary, we report the synthesis of a pseudoisocytosine PNA monomer that possesses a Boc protecting group on the nucleobase and its subsequent incorporation into a PNA oligomer by Fmoc-based chemistry. Previous attempts at protection of pseudoisocytosine with acid labile protecting groups have resulted in poor yields (11) without reporting the experimental procedures. Thus, this is the first

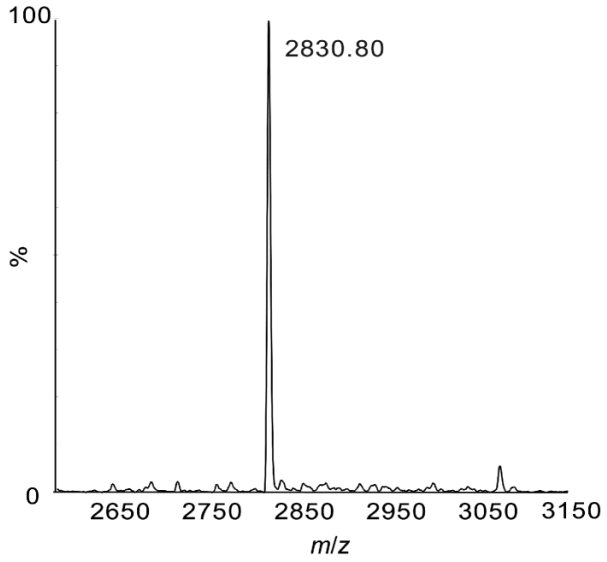
report for such a protection and will facilitate its future use in triplex forming PNA, assembled by Fmoc-based peptide synthesis.

Experimental

General

All reagents and solvents were obtained from commercial sources, were of ACS reagent grade or higher, and were used without further purification. Anhydrous solvents were prepared by passing the reagent-grade solvent through columns of activated alumina (Innovative Technologies). Flash column chromatography (FCC) was performed on Merck Kieselgel 60 (230–400 mesh). Thin layer chromatography (TLC) was performed on Merck Kieselgel 60 TLC plates. Chemical shifts are reported in parts per million (δ), were measured from tetramethylsilane (0 ppm), and are referenced to the residual proton in the otherwise perdeuterated solvents: $CDCl_3$ (7.26 ppm), DMSO-d_6 (2.49 ppm) for ^{1}H NMR and $CDCl_3$; (77.0 ppm), DMSO-d_6 (39.5 ppm) for ^{13}C NMR. Multiplicities are described as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), and broad singlet (br s). Resonances attributed to conformers due to restricted rotation around amide bonds (rotamers) are reported as major

Fig. 3. Transformed data for the ESI-TOF mass spectral analysis of the 10-mer PNA.



(ma.) and minor (mi.). Coupling constants (*J*) are reported in Hertz (Hz). High-resolution mass spectra (HRMS) were obtained using electron impact (EI) or electrospray (ESI).

Ethyl isocytosin-5-ylacetate (2)

To ethanol (150 mL) was added isocytosin-5-ylacetic acid **1** (4.5 g, 26.6 mmol) and $HCl_{(g)}$ in ethanol (50 mL, 1.5 mol/L). The mixture was heated to reflux, and within 15 min the mixture became homogeneous and the solution was refluxed for a further 2 h. The solution was cooled to room temperature, concentrated in vacuo to approximately 100 mL, and placed at –20 °C for 2 h. The precipitate was collected by filtration and washed with diethyl ether to give a white solid. The hydrochloride salt of ethyl isocytosin-5-ylacetate was dissolved in saturated aqueous sodium bicarbonate (50 mL), and then acidified to pH 6.0 by dropwise addition of 4 mol/L of HCl while being stirred. The precipitate was cooled at 4 °C for 1 h, collected by filtration, and washed with diethyl ether to give a white solid (4.2 g, 81%). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 10.98 (br s, 1H), 7.46 (s, 1H), 6.47 (br s, 1H), 4.03 (q, J = 7.1 Hz, 2H), 3.19 (s, 2H), 1.16 (t, J = 7.2 Hz, 3H). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 171.2, 164.7, 156.0, 151.5, 108.7, 60.0, 32.1, 14.1. HRMS (EI) calcd. for $C_8H_{11}N_3O_3$: 197.0800 [M^+]; found: 197.0809.

N^2-(*tert*-butoxycarbonyl)isocytosin-5-ylacetate (3)

A suspension of **2** (1.0 g, 5.0 mmol), DMAP (61 mg, 0.5 mmol), and Boc_2O (1.4 g, 6.4 mmol) in DMF (5 mL) was stirred for 48 h under N_2. To the solution was added ethanol (5 mL), followed by saturated aqueous sodium bicarbonate (25 mL), and the solution was stirred for 10 min. The mixture was extracted with EtOAc (4 × 50 mL), and the combined organic extracts were subsequently washed with brine (50 mL) and dried over Na_2SO_4. After removal of the solvent, the residue was triturated with equal volumes of diethyl ether/hexanes (50 mL) and collected by filtration to give **3** as a white solid (1.05 g, 70%). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 11.28 (br s, 2H), 7.67 (s, 1H), 4.03 (q, J = 7.0

Hz, 2H), 3.31 (s, 2H), 1.48 (s, 9H), 1.17 (t, J = 7.0 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 170.1, 160.2, 153.1, 151.4, 151.1, 115.1, 84.0, 60.6, 32.0, 27.7, 13.8. HRMS (EI) calcd. for $C_{13}H_{19}N_3O_5$: 297.1325 [M^+]; found: 297.1330.

N^2-(*tert*-butoxycarbonyl)isocytosin-5-ylacetic acid (4)

A suspension of compound **3** (1.0 g, 3.4 mmol) in water/THF (15 mL:5 mL) was placed in an ice bath, followed by the dropwise addition of NaOH (2.5 mol/L, 10 mL) over 1 min. The suspension was removed from the ice bath and stirred until TLC analysis indicated complete consumption of the starting material (15 min). The precipitate was cooled with the aid of an ice bath, and citric acid monohydrate (5.3 g, 25.0 mmol) dissolved in water (4 mL) was added in one portion. The mixture was stirred on ice for 1 h, and the solid precipitate was collected by filtration and washed with diethyl ether to give a white solid (830 mg, 91%). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 11.60 (br s, 3H), 7.65 (s, 1H), 3.23 (s, 2H), 1.48 (s, 9H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 172.1, 160.8, 154.2, 150.6, 115.4, 82.5, 32.4, 27.9. HRMS (EI) calcd. for $C_{11}H_{15}N_3O_5$: 269.1012 [M^+]; found: 269.1015.

Benzyl *N*-[2-(fluorenylmethoxycarbonyl)aminoethyl]-*N*-[(2-*N*-(*tert*-butoxycarbonyl)isocytosin-5-yl)acetyl]glycinate (5)

To an ice-cooled suspension of **4** (400 mg, 1.5 mmol) and benzyl *N*-[2-(Fmoc)aminoethyl]glycinate (430 mg, 1.0 mmol) in DMF (10 mL) was added EDC (575 mg, 3.0 mmol), and the reaction was stirred on ice for 0.5 h and at room temperature for 36 h. The reaction was poured into $NaHCO_3$ (50 mL) and extracted into CH_2Cl_2 (3 × 100 mL). The organic phase was washed sequentially with aqueous $NaHCO_3$ (2 × 50 mL) and brine (50 mL). After drying the organic phase and removal of the solvent, the residue was subjected to FCC using CH_2Cl_2/MeOH as the eluent. The combined fractions were reduced in vacuo to give **5** (523 mg, 74%). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 11.44 (br s, 1H), 11.01 (br s, 1H), 7.88 (d, J = 7.2 Hz, 2H), 7.67 (d, J = 7.2 Hz, 2H), 7.43–7.29 (m, 10H), 5.17 (s, 0.6 H, mi.), 5.12 (s, 1.4 H, ma.), 4.41–4.19 (m, 4H), 4.08 (s, 1H), 3.51–3.07 (m, 6H), 1.47 (s, 9 H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 171.3, 170.5, 169.5, 160.4, 156.4, 153.1, 152.0, 150.9, 143.6, 140.9, 135.0, 128.4, 128.3, 128.1, 127.9, 127.3, 126.8, 124.9, 119.7, 115.8, 84.2, 67.2, 66.8, 66.5, 51.2, 49.3, 48.6, 47.0, 39.3, 30.2, 27.8. HRMS (ESI-TOF) calcd. for $C_{37}H_{39}N_5O_8$: 704.2696 [MNa^+]; found: 704.2687.

N-[2-(fluorenylmethoxycarbonyl)aminoethyl]-*N*-[(2-*N*-(*tert*-butoxycarbonyl)isocytosin-5-yl)acetyl]glycine (6)

Compound **5** (423 mg, 0.62 mmol) was dissolved in MeOH (25 mL), purged with N_2, and then Pd/C (75 mg) was added and the solution was saturated with H_2 by slow bubbling over 3 h. The reaction was filtered through a short pad of Celite, and the solvent was removed in vacuo to give **6** as a white solid (316 mg, 86%). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 7.82 (d, J = 7.4 Hz, 2H), 7.61 (d, J = 7.4 Hz, 2H), 7.54–7.49 (m, 1H), 7.35 (t, J = 7.4 Hz, 2H), 7.26 (t, J = 7.4 Hz, 2H), 4.26–3.89 (m, 3H), 3.89 (s, 1H), 3.39–3.01 (m, 7H), 1.41 (s, 9 H). HRMS (ESI-TOF) calcd. for $C_{30}H_{33}N_5O_8$: 614.2227 [MNa^+]; found: 614.2236.

Synthesis of PNA

The 10-mer PNA oligomer was synthesized on a 5 umol scale using the standard FastMoc module on an Applied Biosystems 433A synthesizer. A NovaSyn TGR (Rink amide) resin preloaded with lysine (approximate loading of 0.065 mmol/g) was used. The resin bound oligomer (approx. 20 mg) was placed in a 2 mL screw top vial to which was added an ice-cold solution of the deprotection "cocktail" (TFA/Et_3SiH 975 uL:25 uL). The resin was agitated for 1.5 h. Filtration through a Pasteur pipette packed with glass wool (0.5 cm) into a clean 2 mL vial followed by removal of the TFA with a gentle stream of nitrogen and precipitation by the addition of cold diethyl ether (1 mL) gave an off-white solid. The crude oligomer was dissolved in aq. TFA (0.05%), filtered (0.45 μm), and purified by RP-HPLC using a 250 mm × 4.6 mm, C18-bonded phase, 300 Å pore, and 5 μm particle size column. Mass spectral analysis of the oligomer was performed at the UWO Biological Mass Spectrometry Laboratory using ESI-TOF MS.

Acknowledgements

We thank the Natural Science and Engineering Research Council of Canada (NSERC) for funding this work through their Discovery Grants program. FW acknowledges an NSERC PGS-D scholarship. Mr. Doug Hairsine, Department of Chemistry, is thanked for performing HRMS of small molecules. Ms. Paula Pittock of the Biological Mass Spectrometry Laboratories (UWO) is thanked for characterization of the polyamide.

Synthesis of novel 2-alkyl substituted oleobenzimidazole derivatives using ethylene glycol as solvent

K.M. Hosamani, V.B. Hiremath, R.S. Keri, R.S. Harisha, and S.B. Halligudi

Abstract: The objective of this research was to conduct constructive organic chemistry by using ethylene glycol as an efficient solvent and to achieve yields that were comparable to or better than those in other media. The reaction parameters, such as temperature (150–200 °C), density, and reaction time (6 h), have been systematically studied to understand whether ethylene glycol is as an efficient solvent and can have a positive effect on the chemistry with good yields. By tuning the parameters, the yields have been optimized to around 70%–80%. Thus, a new class of 2-alkyl substituted oleo-benzimidazole derivatives have been synthesized and characterized by FTIR, ^{1}H NMR, ^{13}C NMR, MS, and elemental analysis.

Key words: oleochemistry, ethylene glycol, oleo-benzimidazole derivatives, unusual fatty acids.

Résumé : L'objectif de ce travail était d'effectuer des synthèses organiques, en utilisant l'éthylèneglycol comme solvant efficace, et d'obtenir des rendements au moins aussi bon que ceux dans d'autres milieux. On a étudié d'une façon systématique les paramètres des réactions, tels la température (150 à 200 °C), la densité et le temps de réaction (6 h) déterminer si l'éthylèneglycol est un solvant efficace, s'il a un effet positif sur la chimie et aussi sur les rendements. En ajustant les paramètres, les rendements ont pu être optimisés entre 70% et 80%. Ainsi, on a pu synthétiser une nouvelle classe d'oléobenzimidazoles substitués par un groupement alkyle en position 2 qui a été caractérisée par infrarouge à transformée de Fourier, par RMN du ^{1}H et du ^{13}C, par spectrométrie de masse et par analyse élémentaire.

Mots-clés : oléochimie, éthylèneglycol, dérivés oléobenzimidazole, acides gras inhabituels.

Introduction

Because of environmental concerns, the use of benign catalysts as an alternative to hazardous solvents are of much interest to organic chemists. Thus, the use of such polar solvents as reaction media can offer an alternative to hazardous solvents (1, 2). Recently, polar solvents have been successfully employed for their catalytic activity in a variety of reactions (3). To reduce waste problems, we are reporting ethylene glycol as an efficient solvent. Moreover, their high boiling point affinity for water makes cyclocondensation easier.

Interest in the biological and industrial potentialities of oleochemicals has resulted in the development of various synthetic protocols for the introduction of potent heterocyclic moiety into the fatty acid chain. Thus, we explored the possibility of synthesizing 2-alkyl substituted oleo-benzimidazole derivatives libraries from o-phenylenediamine, 4-bromo-*o*-phenylenediamine, and 4-nitro-*o*-phenylenediamine with fatty acids using ethylene glycol as an efficient solvent. Such synthetic methods can facilitate the discovery of new class of oleochemicals.

The benzimidazole moiety is an important pharmacophore and potential heterocyclic nucleus in medicine. Thus, it has been used extensively in medicinal chemistry (4) because of its diverse range of biological activities including anti-arrhythmic, antifungal, antiulcer, antihistamine, and cytotoxicity (5). Benzimidazoles are a component of vitamin B12 and are related to the DNA base purine and the stimulant caffeine. Bisbenzimidazoles are being developed as DNA minor-groove binding agents with antitumor activity (6, 7) and can act as ligands to transition metals for modelling biological systems (8).

A literature survey reveals that *o*-phenylenediamine undergoes cyclo-condensation with aliphatic acids in aq. HCl method (9) and also with aromatic acids in PPA method (10), or PPE method (11) at 180–200 °C, or aromatic acids in ethylene glycol method (12), and it appears that there are no other methods for the cyclo-condensation of aliphatic acids with *o*-phenylenediamine. Hence, it was considered important to develop an efficient method for the cyclo-condensation of *o*-phenylenediamine with unusual fatty acids using ethylene glycol as a solvent. Considering the extensive applications of such oleochemicals as industrial and biological products, an attempt has been made to synthesize a single-step reaction with good yields of a new class of 2-

alkyl substituted oleo-benzimidazole derivatives using ethylene glycol as a solvent.

Results and discussion

Initial efforts focused on optimizing solvent conditions for the synthesis of 2-alkyl substituted oleo-benzimdazoles employing ethylene glycol. The cyclo-condensation reaction is carried out between *o*-phenylenediamine and 4-substituted *o*-phenylenediamines with unusual fatty acids under ethylene glycol as a solvent and successfully generated desired 2-alkyl substituted oleo-benzimidazole derivatives. Our preliminary success prompted an evaluation of the reaction scope aimed at achieving the ultimate goal of applying this solvent system for the synthesis of novel 2-alkyl substituted oleo-benzimidazole derivatives.

The structures of newly synthesized novel 2-alkyl substituted oleo-benzimidazole derivatives (I-aa′ to I-cd′) were determined by IR, ^{1}H NMR, ^{13}C NMR, MS and elemental analyses.

IR spectra of all the compounds were taken on Fourier transform infrared (FTIR) Nicolet 5700 instrument using KBr pallets and also as liquid films.

The compounds (I-aa′, I-ab′, I-ba′, I-bb′, I-ca′, and I-cb′) showed strong IR absorption bands at 3456–3440 cm^{-1} for the -OH functional group in the alkyl chain. All the compounds (I-aa′ to I-cd′) had -NH stretching bands at 3326–3210 cm^{-1} in all imidazole rings of oleo-benzimdazole derivatives. The characteristic -C=N stretching bands at 1630–1612 cm^{-1} were observed in all the compounds (I-aa′ to I-cd′).

The ^{1}H NMR spectra of the 5-substituted oleo-benzimidazoles (I-aa′ to I-cd′) were recorded on Bruker Avanace 300 (300 MHz) model instrument using $CDCl_3$ and DMSO as solvents and TMS as internal standard.

The ^{1}H NMR spectra of all the compounds (I-aa′ to I-cd′) exhibited structure-revealing proton signals at δ 7.0–7.6 (multiplet, aromatic protons), δ 7.1–7.3 (s, 1H, -N*H*, which merged with aromatic protons and disappeared on D_2O addition), δ 3.5–3.9 (multiplet, 2H, -CH_2OH), δ 3.3–3.6 (singlet, 1H, -O*H*, disappeared on D_2O addition), δ 4.2–4.8 (multiplet, 2H, -C*H*=C*H*-), δ 2.3–2.5 (singlet, 2H, 2 × [-C*H*-]), δ 1.1–1.6 (broad multiplet, shielded methylene protons) and δ 0.8–0.2 (singlet, 3H, terminal -CH_3).

The ^{13}C NMR spectra of all the compounds (I-aa′ to I-cd′) showed sharp singlet signals at δ 168–184 for imidazole carbon, at δ 128–146 for aromatic carbon atoms, δ 119–129 for sp^2 hybridized carbons, and at δ 10–94 saturated carbon atoms and tertiary carbon atoms with DMSO solvent signals.

The mass spectra of the 2-alkyl substituted oleo-benzimidazole derivatives (I-aa′ to I-cd′) were recorded on Shimazu mass spectrometer (GCMS) with ionization energy maintained at 70 eV. Thus, all the compounds (I-aa′ to I-cd′) showed the corresponding molecular ion peaks (M +1).

Conclusions

To summarize, a novel methodology provides a facile route for the synthesis of new class of 2-alkyl substituted oleobenzimidazole derivatives using easily available precursors with considerably good yield. The broad chemistry scope and the efficiency have been demonstrated through successful novel synthetic methodologies of a diverse set of 2-alkyl substituted oleo-benzimidazole derivatives. Further investigation to explore the synthetic strategy for designing various novel oleo-benzimidazoles and their biological evaluation is under way.

Experimental

The synthesis of 2-alkyl substituted oleo-benzimidazole derivatives (Scheme 1) is a typical method. A mixture of equimolar quantities of *o*-phenylenediamine dihydrochloride (10 mmol) and aleuritic acid (10 mmol) with ethylene glycol (10 mL) in a two-necked round-bottomed flask was stirred vigorously for about 30 min. Then it was refluxed for about 6 h maintaining the temperature at 150–200 °C. The reaction mixture was cooled to room temperature and poured into ice-cold water (100 mL). The soft, syrupy insoluble mass was stirred until the product had hardened to a solid. The product was treated with sodium bicarbonate solution and washed with distilled water, until free from alkali, and dried. The yield of 2-alkyl substituted oleo-benzimidazole was recorded.

Similarly, aleuritic acid, ambrettoliec acid, oleic acid, and undecelynic acid were treated with *o*-phenylenediamine dihydrochloride, 4-bromo-*o*-phenylenediamine dihydrochloride, and 4-nitro-*o*-phenylenediamine dihydrochloride to obtain 2-alkyl oleo-benzimidazole derivatives under the same reaction conditions, respectively. For analytical purposes, the crude products were recrystallized from alcohol with the treatment of animal charcoal. The melting points were determined by the open capillary method and are uncorrected.

Association of ruthenium complexes $[Ru(bpy)_3]^{2+}$ or $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ with Dawson polyanions $\alpha\text{-}[P_2W_{18}O_{62}]^{6-}$ or $\alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$

L. Ruhlmann, C. Costa-Coquelard, J. Hao, S. Jiang, C. He, L. Sun, and I. Lampre

Abstract: The formation of electrostatically linked complexes between $[Ru(bpy)_3]Cl_2$ or $[Ru(bpy)_2(Mebpy\text{-}py)](PF_6)_2$ and $(TBA)_6\alpha\text{-}[P_2W_{18}O_{62}]$ or $(TBA)_5K_2\alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]$ in solution were studied by steady-state absorption and luminescence spectroscopy. The stoichiometry and global association constants of the formed complexes were obtained by the Job method. The formed complexes were characterized by ^1H and ^{31}P NMR spectroscopy and their electrochemical properties compared to the precursor compounds were investigated by using the cyclic voltammetry method.

Key words: electrochemistry, polyoxometalate, ruthenium complex, electrostatic complex.

Résumé : Nous avons étudié la formation en solution de complexes, liés d'une façon électrostatique, entre le $[Ru(bpy)_3]Cl_2$ ou $[Ru(bpy)_2(Mebpy\text{-}py)](PF_3)_2$ et le $(TBA)_6\alpha\text{-}[P_2W_{14}O_{62}]$ ou $(TBA)_5K_2\alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]$ en faisant appel à la spectroscopie de luminescence et à la spectroscopie d'absorption à l'état stationnaire. On a déterminé la stoechiométrie et les constantes d'association globales des complexes formés en faisant appel à la méthode de Job. On a caractérisé les complexes formés à l'aide de la spectroscopie RMN du ^1H et du ^{31}P et on a étudié leurs propriétés électrochimiques à l'aide de la méthode de voltampérométrie cyclique par comparaison avec leurs précurseurs.

Mots-clés : électrochimie, polyoxométalate, complexe de ruthénium, complexe électrostatique.

Introduction

The Dawson-derived type polyoxometalates (POMs) are a versatile and robust group of compounds with many applications in fields such as molecular magnetism (1–2), catalysis (3–7), and photocatalysis (8). Indeed, the ability to modify the redox and chemical properties of heteropolyanions by replacing one or many elements renders them particularly attractive for catalytic and electrocatalytic applications (9–15). For instance, a cluster such as $[P_2W_{18}O_{62}]^{6-}$ could be modified under hydrolysis or hydrolytic conditions into lacunary complexes containing one, three, or more vacant sites (16–18). Ru–POM complexes appear to be quite promising in photocatalytic reactions since the ruthenium complex may play the role of photosensitizer or antenna for the redox-active heteropolyanion, provided that the latter has useful catalytic properties. The association of ruthenium complexes with polyanions has been of interest in recent years because of their application in catalysis. In the area of electrocatalysis, extensive work has been undertaken to probe the nature of polyoxometalate films formed on the electrode surfaces in the presence of cations including $[Os(bpy)_3]^{2+}$ or $[Ru(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine). For instance, the capacity of the multicharged cation $[Os(bpy)_3]^{2+}$ to bind electrostatically to polyoxomolybdate anions has been demonstrated by Anson and co-workers (19). Their observations are consistent with the fact that monolayers of $[P_2Mo_{18}O_{62}]^{6-}$ bind electrostatically to $[Os(bpy)_3]^{2+}$ cations on electrode surfaces, creating alternating multilayers of molybdate and osmium ions. Han et al. reported the synthesis and X-ray crystallographic study of the first $[Ru(bpy)_3]^{2+}$ complex with a decatungstate cluster anion (20). Hultgren et al. reported the formation of neutral ionic complexes $[Ru(bpy)_3]_2[S_2Mo_{18}O_{62}]$ at electrode–solvent interfaces by electrochemistry (21). Keyes et al. studied the photophysical properties of ion clusters formed between $[Ru(bpy)_3]^{2+}$ and the polyoxotungstate anions $[S_2M_{18}O_{62}]^{4-}$ or $[S_2W_{18}O_{62}]^{4-}$ in solution (22–23). Recently, McCormac and co-workers (24) published the preparation of $[Ru(bpy)_3]_3[P_2W_{18}O_{62}]$ complexes. The complexes were formed from $Ru(bpy)_3Cl_2$ and the mixture of isomers α- and β-$K_6[P_2W_{18}O_{62}]$, and these complexes were characterized by microanalysis (31), P NMR spectroscopy, and electrochemistry.

This work focuses on the cluster formation of $[Ru(bpy)_3]^{2+}$ (**Ru-1**) or $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (**Ru-2**) with polyoxometalates $\alpha\text{-}[P_2W_{18}O_{62}]^{6-}$ or $\alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$ (Scheme 1). Because the two reactants have opposite charges, the association should proceed mainly via electrostatic interactions. **Ru-2**, which has one pyridine carried by

one of the three 2,2′-bipyridine ligands, was synthesized for the purpose of forming a possible coordination bond between the pyridine ligand and the iron(III) of α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$ via the substitution of the labile (H_2O) ligand.

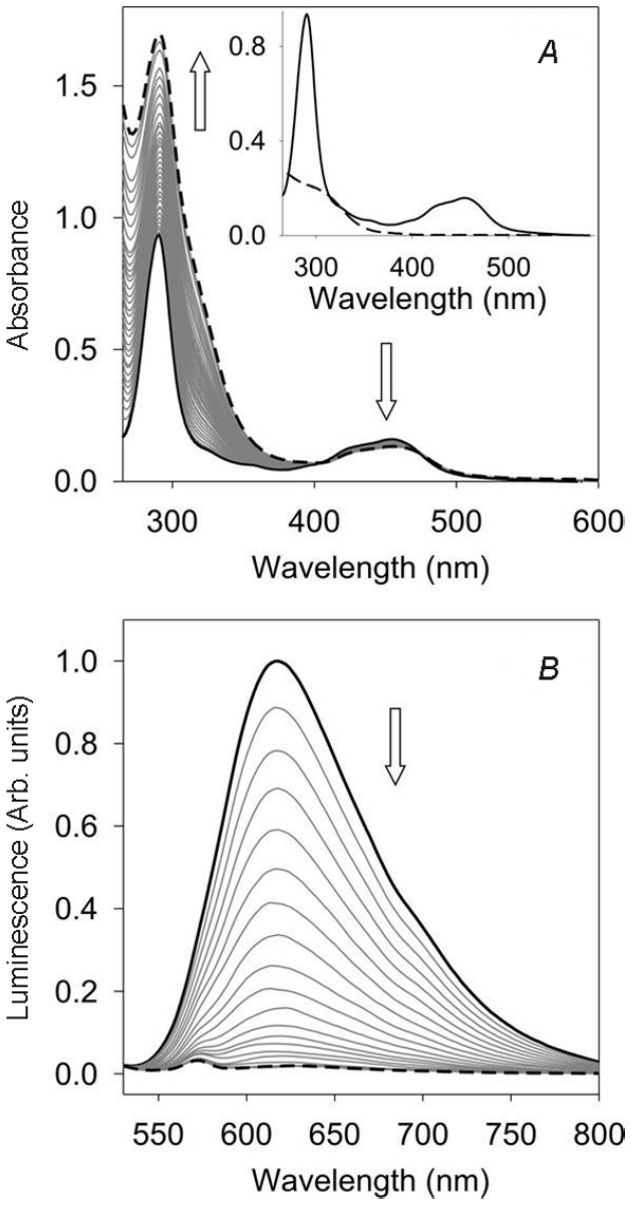
Results and discussion

UV–vis absorption and luminescence spectroscopies

The absorption and luminescence spectroscopic results were obtained with DMF as solvent. Similar results were obtained with DMSO solvent. The optical absorption spectrum of $[Ru(bpy)_3]Cl_2$ in DMF was characterized by a broad band in the visible domain around 450 nm ($\varepsilon_{454\ nm}$ = 12 850 $dm^3\ mol^{-1}\ cm^{-1}$) and an intense band peaking at 290 nm ($\varepsilon_{290\ nm}$ = 71 950 $dm^3\ mol^{-1}\ cm^{-1}$) (inset of Fig.1*A*). The visible absorption band is attributed to a metal-to-ligand charge transfer (MLCT) transition in which an electron located in a metal-based d orbital is promoted into a ligand-centered π^* orbital; the UV absorption band corresponds to a ligand-centered π–π^* transition (25). The observed emission of $[Ru(bpy)_3]^{2+}$ comes from the lowest energy ^{3}MLCT state, which is rapidly formed with a quantum yield near unity. The polyoxometalate $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$ in DMF absorbs in the UV spectral domain below 350 nm (inset of Fig. 1*A*) and is non-luminescent.

Fig. 1 presents the evolution of the absorption and emission spectra of a diluted DMF solution of $[Ru(bpy)_3]Cl_2$ (1.29×10^{-5} mol/L) titrated by a concentrated solution of $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$ (2.4×10^{-4} mol/L). During the titration, the absorbance around 290 nm increased strongly and the band broadened whereas the absorbance around 450 nm decreased slightly. Moreover, two isosbestic points appeared at 405 and 474 nm indicating equilibria between species in solution (Fig. 1*A*). The steady-state luminescence study showed that the $[Ru(bpy)_3]^{2+}$ emission spectrum decreased in intensity during the titration but its shape and the maximum position did not change. A total quenching of the $[Ru(bpy)_3]^{2+}$ emission was obtained when the added $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$ concentration was above 4.3×10^{-6} mol/L, which corresponded to one third of the initial concentration of $[Ru(bpy)_3]Cl_2$.

Fig. 1. Steady-state UV–vis (*A*) absorption and (*B*) luminescence spectra recorded during the titration of a 1.29×10^{-5} mol/L DMF solution of $[Ru(bpy)_3]Cl_2$ by a 2.40×10^{-4} mol/L solution of $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$ (optical length = 1 cm, λ_{ex} = 490 nm). Inset: absorption spectra of a DMF solution containing 1.29×10^{-5} mol/L of $[Ru(bpy)_3]Cl_2$ (solid line) or 3.02×10^{-6} mol/L of $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$ (dashed line).

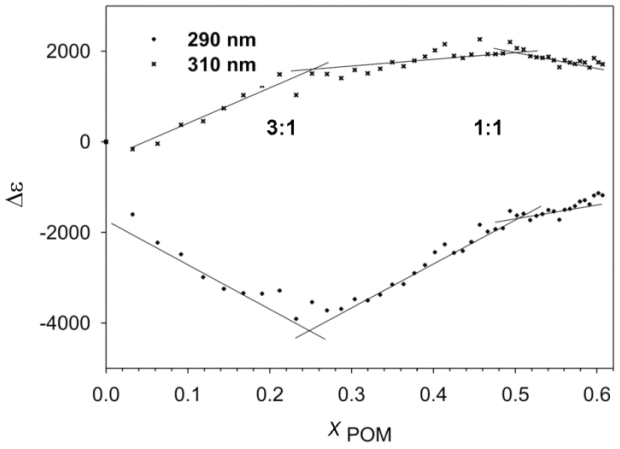


The absorption and luminescence results reveal strong interactions between the Ru compound and the polyoxometalate and indicate the formation of mixed complexes.

To determine the stoichiometry of the complexes formed during the titration and to estimate the global association constants, the well-known Job's method was used. For a given wavelength λ, the absorption difference $\Delta\varepsilon$ between

© 2008 NRC Canada

Fig. 2. Job Plot of the absorption change Δε at 290 nm and 310 nm versus the mole fraction of the added POM for the titration of Fig. 1.



the measured value and the expected value from two compounds is calculated according to the equation

$$\Delta\varepsilon = A/l\ C_t - (1 - X_{POM})\varepsilon_{Ru} - X_{POM}\varepsilon_{POM}$$

where A is the measured absorbance, l is the optical length, C_t is the total concentration of compounds in solution (C_t = [[Ru(bpy)$_3$]Cl$_2$] + [(TBA)$_6$α-[P$_2$W$_{18}$O$_{62}$]]), ε_{Ru} and ε_{POM} are the molar extinction coefficients at the chosen wavelength of [Ru(bpy)$_3$]$^{2+}$ and α-[P$_2$W$_{18}$O$_{62}$]$^{6-}$ respectively, and X_{POM} is the mole fraction of polyoxometalate.

In Fig. 2, Δε at two different wavelengths is plotted as a function of X_{POM} for the titration of [Ru(bpy)$_3$]Cl$_2$ by (TBA)$_6$α-[P$_2$W$_{18}$O$_{62}$]. The curves of Δε clearly show three parts that can be fitted by straight lines. The lines intersect at X_{POM} equal to 0.25 and 0.5. These results reveal the existence of two successive equilibria in solution with the formation of two complexes whose stoichiometries are determined by the intersection points. So the first complex, corresponding to a mole fraction of α-[P$_2$W$_{18}$O$_{62}$]$^{6-}$ equal to 0.25, is a 3:1 complex formed by three [Ru(bpy)$_3$]$^{2+}$ and one α-[P$_2$W$_{18}$O$_{62}$]$^{6-}$, whereas the second complex with X_{POM} equal to 0.5 is a 1:1 complex composed by one [Ru(bpy)$_3$]$^{2+}$ and one α-[P$_2$W$_{18}$O$_{62}$]$^{6-}$. Unfortunately, because of the scale of uncertainties for calculated Δε, it is not possible to estimate the global association constants $\beta_{3:1}$ and $\beta_{1:1}$ of the complexes from the Job's plot.

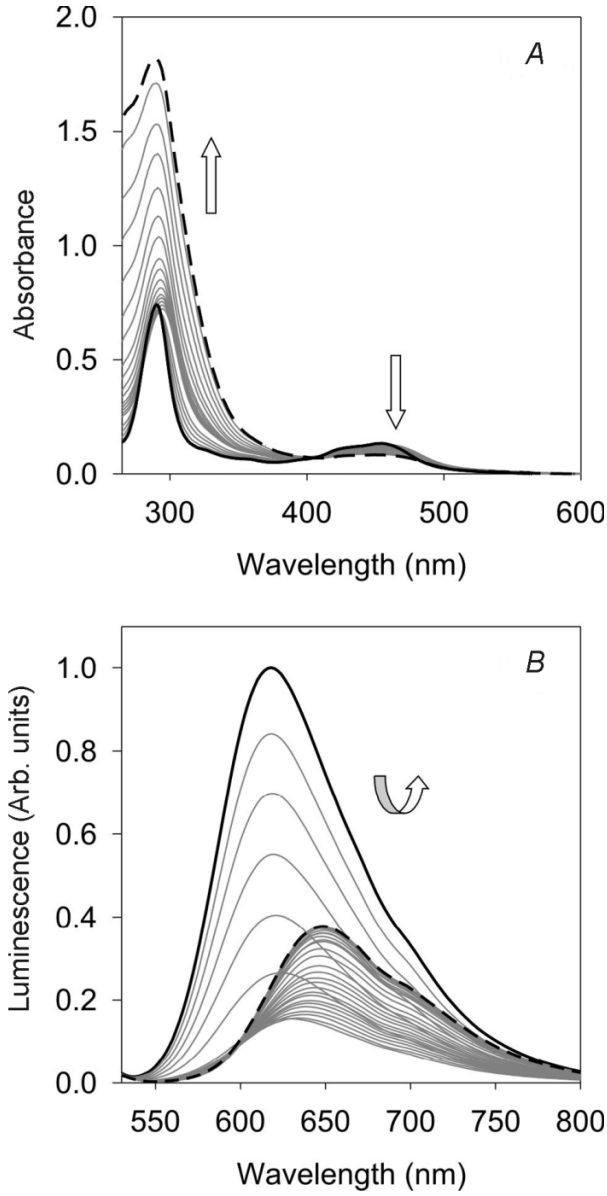
The successive formation steps of the mixed complexes during the titration of [Ru(bpy)$_3$]$^{2+}$ by α-[P$_2$W$_{18}$O$_{62}$]$^{6-}$ can be summarized as

$$3\ [Ru(bpy)_3]^{2+} + \alpha\text{-}[P_2W_{18}O_{62}]^{6-} \rightleftarrows [Ru(bpy)_3]_3[P_2W_{18}O_{62}]$$

$$[Ru(bpy)_3]_3[P_2W_{18}O_{62}] + 2\ \alpha\text{-}[P_2W_{18}O_{62}]^{6-} \rightleftarrows 3\ [Ru(bpy)_3][P_2W_{18}O_{62}]^{4-}$$

It is noticed that the first complex is a neutral one, suggesting that the association should be governed by electrostatic interactions. It is also worth mentioning that the formation of this 3:1 complex induces a total quenching of

Fig. 3. Steady-state UV–vis (*A*) absorption and (*B*) luminescence spectra recorded during the titration of a 1.03 × 10^{-5} mol/L DMF solution of [Ru(bpy)$_3$]Cl$_2$ by a 0.95 × 10^{-4} mol/L solution of (TBA)$_5$K$_2$α$_2$-[Fe(H$_2$O)P$_2$W$_{17}$O$_{61}$] (optical length = 1 cm, λ_{ex} = 490 nm).



the [Ru(bpy)$_3$]$^{2+}$ emission. No luminescence is observed as X_{POM} is above 0.25 where no free [Ru(bpy)$_3$]$^{2+}$ chromophore remains in solution. Consequently, the formed 3:1 and 1:1 mixed complexes are not luminescent. When the substituted ruthenium compound [Ru(bpy)$_2$(Mebpy-py)]$^{2+}$ was used instead of [Ru(bpy)$_3$]$^{2+}$, the titration by (TBA)$_6$α-[P$_2$W$_{18}$O$_{62}$] gave very similar results. Indeed, the spectroscopic study clearly indicates the successive formation of two complexes with the soichiometries of 3:1 and 1:1.

In contrast, when the iron polyoxometalate α$_2$-[Fe^{III}(H$_2$O)P$_2$W$_{17}$O$_{61}$]$^{7-}$ replaced α-[P$_2$W$_{18}$O$_{62}$]$^{6-}$ in the titration, a different behaviour was observed. Fig. 3 shows the impact on the absorption and luminescence spectra of small

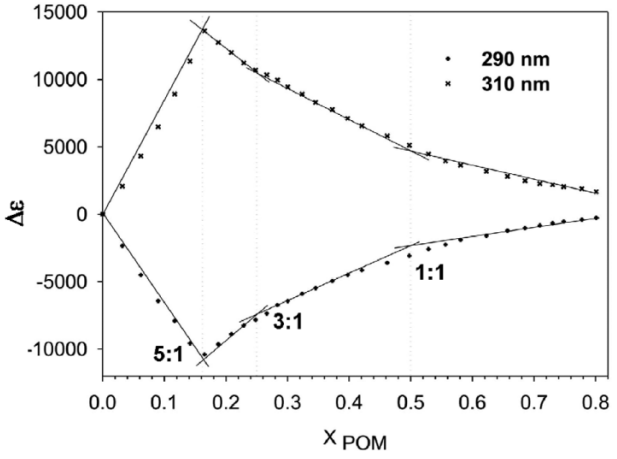
Fig. 4. Job plot of the absorption change Δε at 290 nm and 310 nm versus the mole fraction of the added POM for the titration of Fig. 3.



volumes of concentrated α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$ (9.5×10^{-5} mol/L) solution added to a diluted DMF solution of $[Ru(bpy)_3]^{2+}$. During the titration, the initial absorbance peak at 290 nm began to shift slightly to higher wavelengths and the absorption band broadened; then the absorption intensity increased strongly, while the absorption band around 450 nm broadened on the red side and its intensity decreased. An isosbestic point appeared at 278 nm at the beginning of the titration. A quasi-isosbestic point was observed at 405 nm for the overall titration process (Fig. 3*A*).

The steady-state luminescence study showed significant changes in the $[Ru(bpy)_3]^{2+}$ emission spectrum during the titration (Fig. 3*B*).

First, the luminescence intensity decreased progressively and the maximum shifted slightly from 618 nm to 631 nm with addition of α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$ up to X_{POM} close to 0.17. Then, the luminescence intensity rose and the luminescence maximum shifted further to the red zone to 648 nm for added α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$, corresponding to X_{POM} about 0.5. When an additional small volume of α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$ was added, the emission spectrum did not change any more. Only a small decrease in intensity was observed which may be attributed to the dilution factor.

This evolution in luminescence suggests the existence of at least two successive complexes with stoichiometry at 5:1 and 1:1, defined by X_{POM} equal to 0.17 and 0.5, respectively.

The formed complexes have radiative properties because the $[Ru(bpy)_3]^{2+}$ emission is not totally quenched but undergoes a bathochromic shift up to 30 nm. This red shift is larger than those previously observed for ion clusters formed between $[Ru(bpy)_3]^{2+}$ and $[S_2Mo_{18}O_{62}]^{4-}$ (12 nm)[22] or $[S_2W_{18}O_{62}]^{4-}$ (19 nm) (23), and considerably greater than that reported for interactions between $[Ru(bpy)_3]^{2+}$ and the Keggin anion $[(HO\text{-}Mn)PW_{11}O_{39}]^{6-}$ (4 nm) (26). The Job analysis of the absorption measurements along with the luminescence results indicate the existence of the 5:1 and 1:1 complexes and also reveal the existence of another intermediate complex at X_{POM} equal to 0.25, the 3:1 complex (Fig. 4).

Therefore, during the titration of $[Ru(bpy)_3]^{2+}$ by α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$, three complexes composed of one polyanion and 5, 3, or 1 ruthenium cation(s) were formed successively.

For these titrations, the calculated Δε are quite important and the point-to-point fluctuations are low. The difference between the calculated Δε and the ordinate of the intersection point at X_{POM} equal to 0.17 is very small, indicating that the global association constant $\beta_{5:1}$ is very high.

The high constant values make it difficult to estimate them precisely. As for the values of the other constants $\beta_{3:1}$ and $\beta_{1:1}$, they depend greatly on the value of $\beta_{5:1}$. The first two global association constants in terms of orders of magnitude can be determined. The third constant value is difficult to determine because of its high uncertainty. For these calculations, it is assumed that the salts are fully dissociated in solution before they react with each other. Hence

$$5\ [Ru(bpy)_3]^{2+} + \alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-} \rightleftarrows [Ru(bpy)_3]_5[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{3+} \qquad \beta_{5:1} \geq 3 \times 10^{41}\ M^{-5}$$

$$3\ [Ru(bpy)_3]^{2+} + \alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-} \rightleftarrows [Ru(bpy)_3]_3[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{-} \qquad 10^{32}\ M^{-3} \leq \beta_{3:1} \leq 2 \times 10^{33}\ M^{-3}$$

$$[Ru(bpy)_3]^{2+} + \alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-} \rightleftarrows [Ru(bpy)_3][Fe^{III}(H_2O)P_2W_{17}O_{61}]^{5-} \qquad 1.5 \times 10^{10}\ M^{-1} \leq \beta_{1:1} \leq 1.5 \times 10^{12}\ M^{-1}$$

As expected, the values obtained for the global association constants are very high and increase with the stoichiometry of the complex. The estimated values are much higher than those found in the literature for ionic complexes formed by $[Ru(bpy)_3]^{2+}$ and other polyoxometalates (23, 26). However, the stoichiometry of the complexes differ as well as the solvent.

It is also noticed that the charge increase for polyanion from α-$[P_2W_{18}O_{62}]^{6-}$ to α_2-$Fe^{III}(H_2O)[P_2W_{17}O_{61}]^{7-}$ leads to the formation of one supplementary complex with higher stoichiometry (5:1). The reverse titration induces the same phenomena with the formation of the 1:1 complex followed by the 3:1 and then the 5:1 complexes, which confirms our results and proves that the three equilibria are reversible.

The titration of $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (**Ru-2**) by α_2-$[Fe(H_2O)P_2W_{17}O_{61}]^{7-}$ exhibited a similar optical behaviour to that of **Ru-1**. During the titration, the absorption band around 290 nm shifted slightly to higher wavelengths with band broadening and absorbance increasing, while the absorption band around 450 nm broadened on the red side and its intensity diminished. When the concentration of α_2-$[Fe(H_2O)P_2W_{17}O_{61}]^{7-}$ gradually increased to a mole fraction X_{POM} close to 0.2, the luminescence intensity decreased progressively and the maximum shifted slightly from 624 nm to 639 nm. Then, the luminescence intensity rose and the luminescence maximum shifted to the red to reach 654 nm at X_{POM} about 0.5. When X_{POM} was above 0.5, the emission spectrum remained constant. Job's analysis shows the suc-

© 2008 NRC Canada

cessive formation of the 4:1, 2:1, and 1:1 complexes and makes it possible to estimate the global association constants

$$4\ [Ru(bpy)_2(Mebpy\text{-}py)]^{2+} + \alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-} \rightleftarrows [Ru(bpy)_2(Mebpy\text{-}py)]_4[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{+} \qquad \beta_{4:1} \geq 3 \times 10^{31}\ M^{-4}$$

$$2\ [Ru(bpy)_2(Mebpy\text{-}py)]^{2+} + \alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-} \rightleftarrows [Ru(bpy)_2(Mebpy\text{-}py)]_2[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{3-} \qquad \beta_{2:1} = (1.7 \pm 1.5) \times 10^{19}\ M^{-2}$$

$$[Ru(bpy)_2(Mebpy\text{-}py)]^{2+} + \alpha_2\text{-}[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-} \rightleftarrows [Ru(bpy)_2(Mebpy\text{-}py)][Fe^{III}(H_2O)P_2W_{17}O_{61}]^{5-} \qquad \beta_{1:1} = (3.8 \pm 3.0) \times 10^{10}\ M^{-1}$$

It is noticed that the substitution of the ruthenium compound does not modify the number of complexes formed but leads to a change in the stoichiometry of the complexes, which are 4:1, 2:1, and 1:1 instead of 5:1, 3:1, and 1:1. In addition, the values of the global association constants appear to be of the same order of magnitude or slightly lower, which probably indicates a low steric effect of the substituting pyridine. The pyridyl groups increase the distance between the two subunits and thus diminish the electrostatic interactions.

The purpose of preparing the $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ compound with a pyridyl group was to study the possible formation of a 1:1 coordination complex via the substitution of the labile (H_2O) ligand of the polyoxometalate α_2-$[Fe(H_2O)P_2W_{17}O_{61}]^{7-}$ (Scheme 2*a*).

Unfortunately, a 1:1 complex was also observed in the case of $[Ru(bpy)_3]^{2+}$ (without a pyridine group). Consequently, there is a competition between coordination and electrostatic interactions. This seems to favor the formation of an ion pair (Scheme 2*b*) rather than a coordination complex. The nature of the interaction in the studied systems was probed by addition of $TBAClO_4$ or $LiClO_4$ to solutions containing different mixed Ru–POM complexes (Fig. 5). Experiments performed with solutions in the absence of POM showed that the addition of either salt up to a concentration of 0.1 mol/L had no impact on the emission spectrum and the luminescent quantum yield for the ruthenium compounds. For solutions containing Ru–POM complexes, addition of $TBAClO_4$ or $LiClO_4$ led to an increase in the luminescence intensity. But the final intensity of the emission spectrum was about 10 or 20% lower than that expected for the free Ru compounds (Fig. 5).

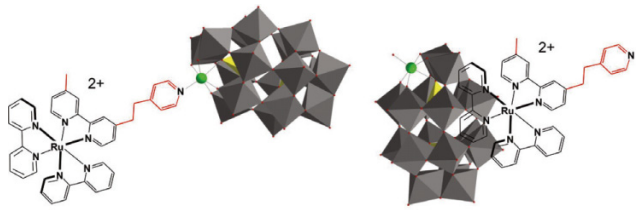
These observations are attributed to the dissociation of mixed Ru–POM complexes owing to competitive interactions of perchlorate with Ru cations and Li^+ or TBA^+ with POM. That indicates that the mixed complexes were mainly bound electrostatically. Similar results were previously observed by Hultgren and co-workers (21–23).

^{1}H and ^{31}P NMR spectroscopy

Fig. 6 compares the ^{1}H NMR spectra of the 3:1 and 1:1 complexes of, respectively, $[Ru(bpy)_3]_3[P_2W_{18}O_{62}]$ and $[Ru(bpy)_3][P_2W_{18}O_{62}]^{4-}$ with the precursor $[Ru(bpy)_3]^{2+}$. As is well-known, the 2,2′-bipyridine protons of $[Ru(bpy)_3]^{2+}$ (**Ru-1**) appear as two doublets and two triplets.

The doublet and the triplet at lower field correspond to protons H_c and H_d (see Scheme 1). The ^{1}H NMR spectra for the 3:1 and 1:1 electrostatic complexes are identical but

Scheme 2. Possible 1:1 complex formed with $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ and α_2-$[Fe(H_2O)P_2W_{17}O_{61}]^{7-}$ by (*A*) coordination bound or (*B*) electrostatic interactions.



(*A*) (*B*)

there is a significant shift compared to that of $[Ru(bpy)_3]^{2+}$ alone. These observations show that the three 2,2′-bipyridine ligands are equivalent for the electrostatic complexes. This might be due to (1) a rapid dynamic process of association and dissociation and (or) (2) the ability of the ruthenium complex to turn freely on the negatively charged polyoxometalate surface leading to three equivalent 2,2′-bipyridines.

For 3:1 or 1:1 complexes, the doublet and the triplet for $[Ru(bpy)_3]^{2+}$ at 7.73 ppm (H_a) and 7.54 ppm (H_b) shift 0.04 ppm toward the lower field, while the second triplet (H_c) does not move, and the second doublet (H_d) shifts to higher field from 8.89 ppm to 8.83 ppm. It is noted that ^{1}H NMR spectra for $[Ru(bpy)_3]^{2+}$ in the presence of one or three equivalent TBACl do not show any shift in the signals.

The chemical shift of H_d to higher field might be induced by the proximity of the six negative charges in the POM moieties leading to a decrease in the electron-withdrawing impact of Ru^{2+} on protons H_d.

In contrast, protons H_a and H_b are shifted to lower field, probably because of the proximity with the polyanion. ^{31}P NMR spectra do not show any change for $[Ru(bpy)_3]_3[P_2W_{18}O_{62}]$ and $[Ru(bpy)_3][P_2W_{18}O_{62}]^{4-}$ ionic complexes with one singlet observed at –12.40 ppm corresponding to the two P atoms in the Dawson moieties. $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (Ru-2) gives well-resolved ^{1}H NMR spectra, but they are more complicated than those of $[Ru(bpy)_3]^{2+}$ because of the loss of symmetry of the ruthenium complex (Fig. 7). The pyridine subunit of $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ appears as two doublets at 7.27 ppm ($2H_{e''}$) and 7.36 ppm ($2H_{e''}$), respectively.

Two singlets are also observed at 8.72 ppm and 8.76 ppm corresponding to $H_{a'}$ and $H_{a''}$ for the substituted 2,2′-bipyridine. The singlet at 8.76 ppm might correspond to

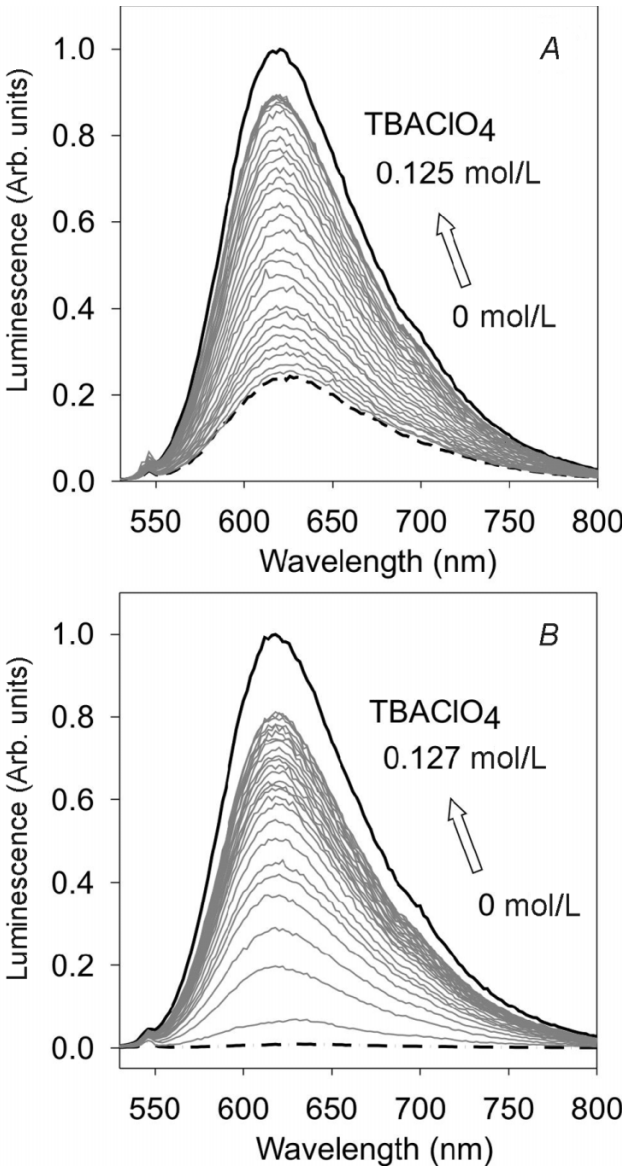
Fig. 5. Influence of the addition of $TBAClO_4$ on the luminescence spectra of DMF solutions containing (*A*) a 5:1 ratio of $[Ru(bpy)_3]Cl_2$ (1.29×10^{-5} mol/L) and $(TBA)_5K_2\alpha_2$-$[Fe(H_2O)P_2W_{17}O_{61}]$ (0.26×10^{-5} mol/L) and (*B*) a 1:1 ratio of $[Ru(bpy)_3]Cl_2$ (1.29×10^{-5} mol/L) and $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$ (1.29×10^{-5} mol/L) (optical length = 1 cm, λ_{ex} = 490 nm). Full line: free $[Ru(bpy)_3]Cl_2$ (1.29×10^{-5} mol/L).



$H_{a'}$ adjacent to the $-(CH_2)_2$-py group, while the second singlet at 8.72 ppm ($H_{a''}$) should be adjacent to the methyl group considering donor and acceptor effects of methyl and pyridyl groups. In the substituted 2,2′-bipyridine, protons $H_{d'}$ and $H_{d''}$ resonate as one doublet at 8.48 ppm while protons H_d appears as a doublet at 8.82 ppm.

Protons H_a, $H_{c'}$, $H_{c''}$, and H_b appear in the multiplet massif between 7.46 and 7.60 ppm. As expected, methyl group protons resonate as one singlet at 2.08 ppm and ethyl ones appear as a multiplet massif between 3.01 and 3.11 ppm. ^1H NMR spectra of the 3:1 and 1:1 complexes, namely $[Ru(bpy)_2(Mebpy\text{-}py)]_3[P_2W_{18}O_{62}]$ and $[Ru(bpy)_2(Me\text{-}bpy\text{-}py)][P_2W_{18}O_{62}]^{4-}$, show significant changes compared to the

Fig. 6. ^1H NMR of the $[Ru(bpy)_3]Cl_2$, $[Ru(bpy)_3Cl_2]_3[P_2W_{18}O_{62}]$ and $[Ru(bpy)_3][P_2W_{18}O_{62}]^{4-}$ complexes (300 MHz, DMSO-d_6, aromatic region of the spectrum).

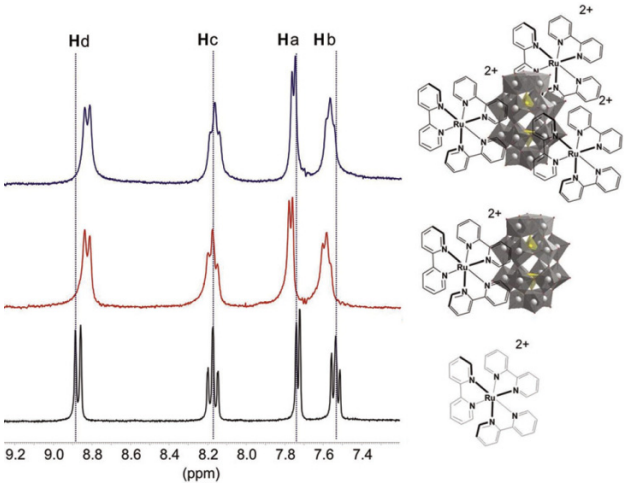


Fig. 7. ^1H NMR of the $[Ru(bpy)_2(Mebpy\text{-}py)](PF_6)_2$, $[Ru(bpy)_2(Mebpy\text{-}py)]$ $[P_2W_{18}O_{62}]$ and $[Ru(bpy)_2(Mebpy\text{-}py)][P_2W_{18}O_{62}]^{4-}$ complexes (300 MHz, DMSO-d_6, aromatic region of the spectrum).

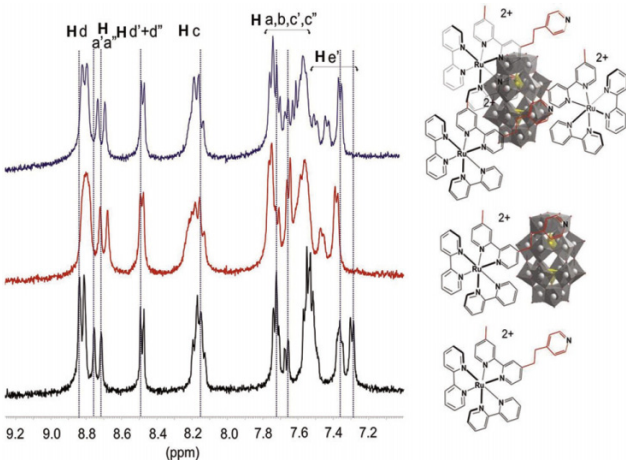

spectra from the precursor $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (Fig. 7). Shifts to higher field for protons H_d, as already shown for $Ru(bpy)_3^{2+}$, are observed. The shift for proton H_c is not noticeable. However, a drastic change in the signals belonging to the substituted 2,2′-bipyridine is observed. In the case of the 3:1 complex, the protons $H_{e'}$ in the pyridyl group become non-equivalent and are split into two doublets with integration of one proton.

In the case of the 1:1 complex, only one of the two doublets for proton $H_{e'}$ is observed with the integration of one proton.

The chemical shift of the methyl protons remains identical for the 3:1 and 1:1 complexes whereas the ethyl protons become unobservable because of the resonance of TBA^+ in the same field. As described with $[Ru(bpy)_3]^{2+}$, no change in the ^{31}P NMR spectra is observed for 3:1 or 1:1 complexes with $[Ru(bpy)_2(Me\text{-}bpy\text{-}py)]^{2+}$. The signal at –12.40 ppm was identical to that of the precursor α-$[P_2W_{18}O_{62}]^{6-}$.

© 2008 NRC Canada

These results suggest surprisingly that Mebpy-py should be closer to the POM than the other bpy as the interactions appear to be stronger. Consequently, the distance between the Ru and POM compounds should be larger for the **Ru-2** than the **Ru-1**. This is in agreement with lower global association constants for complexes with $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (**Ru-2**) than with $[Ru(bpy)_3]^{2+}$ (**Ru-1**).

^{1}H NMR spectra of the 1:1 mixed complex might have unravelled these types of interactions between **Ru-1** or **Ru-2** and α_2-$[Fe(H_2O)P_2W_{17}O_{61}]^{7-}$: coordination or electrostatic interactions. But, because of the low solubility of the Ru–POM complexes in DMF-d_7 or DMSO-d_6, only the free TBA^+ cation in solution was observed in the ^{1}H NMR spectra with a large signal because of the paramagnetism of the iron polyanion.

Electrochemical behaviors

To understand the electrochemical behavior of the Ru–POM complex, it is important to compare the redox processes among the $[Ru(bpy)_3]^{2+}$ or $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (**Ru-1** or **Ru-2**), α-$[P_2W_{18}O_{62}]^{6-}$ or α_2-$[(H_2O)FeP_2W_{17}O_{61}]^{7-}$ moieties and the Ru–POM complex. DMSO was preferred to DMF as solvent because of the higher solubility of Ru–POM complexes in DMSO.

The characteristic electrochemical behavior for the TBA salt of the Dawson-type polyoxometalate α-$[P_2W_{18}O_{62}]^{6-}$ in DMSO is illustrated in Fig. 8 (dotted line). The cyclic voltammogram of α-$[P_2W_{18}O_{62}]^{6-}$ exhibits five successive, but not well-defined, one-electron redox waves which all correspond to the couples of oxo W-based reduction in a negative potential range. In general, the reduction of heteropolyanions is easier in aqueous solution and is accompanied by protonation at low pH. In our case, addition of a small amount of water in DMSO improved the electrochemical behavior of α-$[P_2W_{18}O_{62}]^{6-}$ with better defined redox waves for at least the first three processes. A cyclic voltammogram of $[Ru(bpy)_3]Cl_2$ demonstrates the expected $Ru^{III/II}$ metal-based oxidation process and the three one-electron bipyridine ligand-based reduction processes. The one-electron $Ru^{III/II}$ oxidation process in cyclic voltammetry is masked by irreversible oxidation of Cl^- to Cl_2 whereas in the differential pulse voltammetry (DPV) mode, the redox oxidation process for $Ru^{III/II}$ (Figs. 8*A* and 8*B*) can be easily distinguished.

Fig. 9*A* illustrates the cyclic voltammetry of a DMSO solution containing three equivalents of **Ru-1** (0.50 mmol/L) and one or three equivalent(s) of α-$[P_2W_{18}O_{62}]^{6-}$ (0.17 or 0.50 mmol/L) in the presence of 0.1 mol/L $TBAClO_4$. The last three well-defined redox processes correspond to the reduction of both the 2,2′-bipyridine ligands and the tungsten–oxo framework, while the first two reduction processes are ascribed to oxo W-based reduction. The cathodic peak currents are almost proportional to the square root of the scan rate up to a value of 500 mV s^{-1}, which indicates that the electrode reaction is diffusion controlled.

The $E_{1/2}$ values obtained from the individual cationic and anionic species in a 0.1 mol/L solution of $TBAClO_4$ in DMSO are not apparently different from those measured from the mixture of 3:1 or 1:1 ($[Ru(bpy)_3]^{2+}$] = 0.50 mmol/L and α-$[P_2W_{18}O_{62}{}^{6-}]$ = 0.17 or 0.50 mmol/L). Moreover, the analysis of the voltammogram obtained from DPV mode shows only a small negative shift for the last two reduction processes. This corresponds to both the tungsten–oxo framework and the bipyridine ligand reduction processes comparable to that of the **Ru-1** species under the same conditions. These results are in agreement with the fact that increasing the ionic strength in solution induces a disruption of the electrostatic bond. Thus, the registered electrochemical behavior does not correspond to the **Ru-1**–POM complexes but to the individual or non-complexed ruthenium and POM moieties. Luminescence spectra of the electrochemical solution confirm this result. Indeed, the luminescence spectra of the free ruthenium compound in solution were recorded. Similar behaviors were observed with **Ru-2**. Since the presence of the supporting salt $TBAClO_4$ induces the disruption of the electrostatic complexes, the electrochemical behavior of **Ru-1**–POM complexes are studied without the conducting salt $TBAClO_4$. Fig. 9*B* illustrates the cyclic voltammetry of a DMSO solution containing **Ru-1** (0.50 mmol/L) alone or

Fig. 8. (*A*) Cyclic voltammograms obtained in DMSO containing 0.1 mol/L of $TBAClO_4$ (solid line) and 0.5 mmol/L of $[Ru(bpy)_3]Cl_2$ or 0.5 mmol/L of (dotted line) $(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$, at a scan rate of 20 mV s^{-1}; (*B*) differential pulse voltammetry $[Ru(bpy)_3]Cl_2$ at a scan rate of 20 mV s^{-1}.

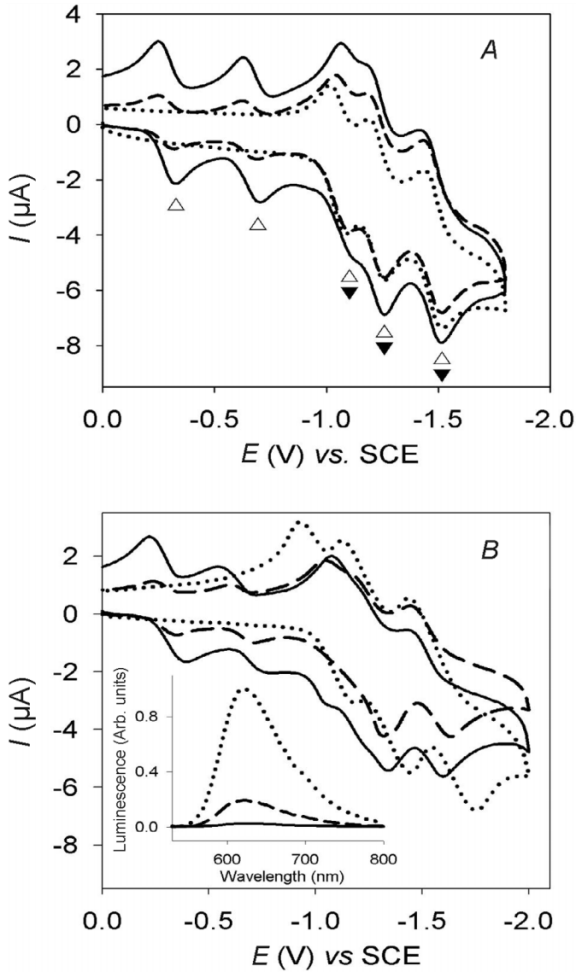

Fig 10. Cyclic voltammograms of DMSO solutions containing 0.5 mmol/L $[Ru(bpy)_3]Cl_2$ (1 equiv.) alone (dotted line) and with 1/5 (dashed line) or 1 (solid line) equiv. of $(TBA)_5K_2\alpha_2$–$[Fe(H_2O)P_2W_{17}O_{61}]$; glassy carbon electrode, scan rate 20 mV s^{-1}; (*A*) in the presence of 0.1 M $TBAClO_4$; (*B*) in the absence of $TBAClO_4$. Inset: Luminescence spectra (λ_{ex} = 490 nm) of the corresponding electrochemical solution; (△) Fe(III) and oxo W-based reduction; (▼) reduction of 2,2′-bipyridine ligand.

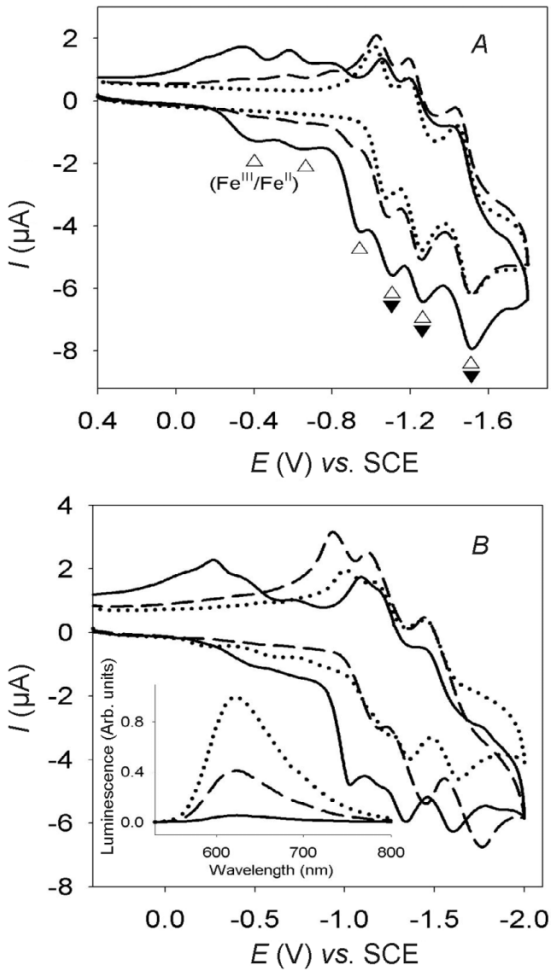


with one or three equivalent(s) of α-$[P_2W_{18}O_{62}]^{6-}$ in the absence of $TBAClO_4$.

It was noticed that the formation of the electrostatic complexes induced the release of TBACl in solution.

Quenching of the luminescence confirmed the presence of the 3:1 or 1:1 **Ru-1**–POM complexes that were not dissociated (inset of Fig. 9*B*). Three well-defined redox processes were also observed, corresponding to the reduction of both the 2,2′-bipyridine ligands and the tungsten–oxo framework. The first two reduction processes corresponded to the oxo W-based reduction. In the case of α_2-$[(H_2O)FeP_2W_{17}O_{61}]^{7-}$, the results were similar. Nevertheless, one additional process corresponding to the reduction of the Fe(III) to Fe(II) was observed. When using a conducting salt, we still recorded the electrochemical behavior of the individual uncomplexed **Ru-1** and iron POM moieties (Fig. 10*A*).

This was also confirmed by the absence of quenching of the luminescence for the ruthenium compound by the POM subunit. The last three well-defined redox processes correspond to the reduction of both the 2,2′-bipyridine ligands and the tungsten–oxo framework while the first three reduction processes correspond to the Fe(III) reduction first followed by oxo-W based reduction. But the electrochemical behavior of the 5:1, 3:1, and 1:1 Ru–POM complexes can be obtained in the absence of the conducting salt (Fig. 10*B*). In this case, the luminescence spectra of the electrochemical solution show the quenching of the ruthenium luminescence by the POM subunit(s). Discussion of the shift of the potential is difficult because of the increase in the solution ionic strength owing to the release of TBACl during the association processes.

Concluding remarks

UV–vis absorption and luminescence quenching measurements were performed during the titration of diluted solutions of Ru compounds by concentrated POM solutions.

© 2008 NRC Canada

The results clearly demonstrate the formation of mixed complexes between α-$[P_2W_{18}O_{62}]^{6-}$ or α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$ and ruthenium compounds $[Ru(bpy)_3]^{2+}$ (**Ru-1**) or $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}$ (**Ru-2**).

In the case of the formed complexes between **Ru-1** or **Ru-2** and α-$[P_2W_{18}O_{62}]^{6-}$, the quantitative quenching of the luminescence of the ruthenium subunits is observed with the formation of 3:1 complex ($[Ru(bpy)_3]_3[P_2W_{18}O_{62}]$ or $[Ru(bpy)_2(Mebpy)]_3[P_2W_{18}O_{62}]$). Nevetheless, the UV–vis titration indicates the formation of another electrostatic 1:1 complex. When using the iron polyanion α_2-$[Fe^{III}(H_2O)P_2W_{17}O_{61}]^{7-}$, three equilibria were observed at the mole ratios of 5:1, 3:1, or 1:1 for **Ru-1** and at the mole ratios of 4:1, 2:1, and 1:1 for **Ru-2**. The association constant values estimated from the Job's method suggest a small steric effect from the substituting pyridine group in **Ru-2**. The nature of the interactions involved in the complexes are mainly electrostatic since the addition of $TBAClO_4$ or $LiClO_4$ to the solution induces the dissociation of the complex. Consequently, electrochemical behavior of the Ru– POM complexes can be obtained only in the absence of conduction salts.

These ionic complexes with high global association constant, along with quantitative quenching behavior of the luminescence for the ruthenium complexes by the POM subunits, seem good candidates for photocatalytic applications.

Study of the possible electron transfers between the reactants in the mixed complexes as well as the photocatalytic reduction of NO_X or Ag(I) is currently under investigation.

Experimental section

Most common laboratory chemicals were reagent grade, purchased from commercial sources, and used without further purification.

The potassium salts $K_6\alpha$-$[P_2W_{18}O_{62}]$ and $K_7\alpha_2$-$[Fe(H_2O)P_2W_{17}O_{61}]$ were prepared by published methods (17, 27). The TBA salts of α-$[P_2W_{18}O_{62}]^{6-}$and α_2-$[Fe(H_2O)P_2W_{17}O_{61}]^{7-}$ were obtained from the metathesis reaction with excess of TBACl at a POM-to-TBACl ratio of 1:10 (equiv.).

^{1}H NMR spectra were recorded in 5 mm o.d. tubes on a Bruker AC 300 apparatus operating at 300 MHz in a Fourier transform mode. ^{31}P NMR spectra were recorded in 5 mm o.d. tubes on a Bruker AC 300 apparatus operating at 121.5 MHz in a Fourier transform mode (equipped with a QNP probe for ^{31}P NMR). The ^{31}P chemical shifts were measured at 300 K on 0.02 mol/L solutions of the polyanions in aqueous D_2O–H_2O (1:1) and were referenced to external 85% H_3PO_4 (IUPAC convention) by the substitution method.

IR spectra were recorded on a Bio-Rad FTS 165 FTIR spectrophotometer on KBr pellets.

Steady-state optical absorption spectra were recorded with a PerkinElmer Lambda 19 spectrophotometer. Steady-state luminescence emission spectra were obtained using a Spex Fluorolog 111 spectrofluorimeter equipped with a Hamamatsu R3896 photomultiplier which was cooled to the temperature of –20 °C. The luminescence spectra were not corrected for the response of the detection system. All the measurements were carried out at room temperature.

For the electrochemical experiments, the solutions were degassed thoroughly for at least 30 min with argon (Ar-U from Air Liquide) and then kept under argon atmosphere during the whole experimental period. The glassy carbon samples had a diameter of 3 mm. Measurements were made on an EG&G 273A potentiostat driven by a PC with 270 software. Potentials are quoted against a saturated calomel electrode (SCE). The counter electrode was platinum-gauzed with large surface area. All voltammetric experiments were conducted at room temperature.

Elemental analyses were performed by classical gravimetric and spectroscopic methods. The anions were first decomposed in boiling concentrated hydrochloric acid solution. Then W and P were precipitated together by adding cinchonium hydrochloride. Tungsten and phosphorus were determined simultaneously as WO_3 and P_2O_5 by gravimetry after calcination of the cinchonium salt. Iron was determined by atomic absorption spectroscopy. Phosphorus was determined independently by the spectroscopy of molybdovanadophosphate (29).

$(TBA)_6\alpha$-$[P_2W_{18}O_{62}]$

1 g of $K_6\alpha$-$[P_2W_{18}O_{62}]\cdot 33H_2O$ (0.193 mmol) was added to 20 mL deionized water with stirring. 1.5 g of TBACl was added to the solution. After stirring for 3 h, the solid was filtered and washed with hot water and then dried in the air (yield 1.02 g, 0.176 mmol, 91%). IR (KBr pellet, cm^{-1}): 2962 (s, TBA^+), 2935 (s, TBA^+), 2974 (s, TBA^+), 2361 (m, TBA^+), 2343 (shoulder, TBA^+), 1484 (s, TBA^+), 1380 (m, TBA^+), 1152 (m, TBA^+), 1091 (s), 1019 (m), 991 (m, TBA^+), 956 (s), 913 (s), 790 (s). ^{31}P NMR in DMSO-d_6 shows 1 peak at –12.4 ppm. Anal. calcd. for $C_{96}H_{216}N_6O_{62}P_2W_{18}$: C 19.82, H 3.74, N 1.44, P 1.06, W 56.88; found: C 19.80, H 3.71, N 1.44, P 1.02, W 56.31.

$(TBA)_5K_2\alpha 2$–$[Fe(H_2O)P_2W_{17}O_{61}]$

3 g of $K_7[Fe(OH_2)P_2W_{17}O_{61}]\cdot 7H_2O$ (0.647 mmol) was added to 20 mL of deionized water with stirring. 4.5 g TBACl was added to the solution with vigorous stirring. After three hours, the pH of the solution was adjusted to 4.3 with the addition of a drop of acetic acid, leading to instantaneous precipitation. After 2 h, the solid was filtered and washed with 150 mL hot water. Then, the powder was washed again with 20 mL ethanol followed by 20 mL ether and dried in the air (yield 3.37 g, 0.61 mmol, 94%). IR (KBr pellet, cm^{-1}): 2962 (s, TBA^+), 2935 (s, TBA^+), 2973 (s, TBA^+), 1485 (s, TBA^+), 1380 (m, TBA^+), 1152 (m, TBA^+), 1089 (s), 1019 (m), 953 (s), 911 (s), 790 (s). ^{31}P NMR in DMSO-d_6 shows 1 peak at –12.6 ppm ($\Delta\nu_{1/2}$ = 360 Hz). Anal. calcd. for $C_{80}FeH_{182}K_2N_5O_{62}P_2W_{17}$: C 17.38, H 3.32, N 1.27, P 1.12, W 56.54; found: C 16.89, H 3.45, N 1.49, P 1.10, W 56.12.

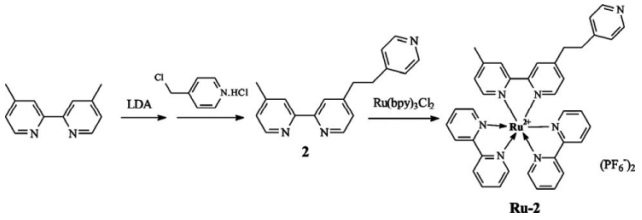
4-(4″-Pyridinyl ethyl)-4′-methyl-2,2′-bipyridine (2)

This compound was prepared by a modified literature procedure (Scheme 3) (28). Lithium diisopropyl amide (LDA) was prepared by a dropwise addition of *n*-butyllithium solution (3.5 mL, 1.6 mol/L solution in *n*-hexane, 5.6 mmol) to a solution of freshly distilled diisopropylamine (0.7 mL, 5.4 mmol) in THF (25 mL) with a syringe at a temperature of –20 °C under stirring and N_2 atmosphere.

After the solution was cooled to –78 °C in a liq. N_2–acetone bath, a 4,4′-dimethylbipyridine (1.0 g, 5.4 mmol)

© 2008 NRC Canada

Scheme 3. Synthetic route for the preparation of $[Ru(bpy)_2(Mebpy\text{-}py)]^{2+}\ 2PF_6^-$ (**Ru-2**).



solution in freshly distilled THF (35 mL) was added dropwise and the solution became grey immediately. After another 1.5 hour of stirring, 4-chloromethylpyridine hydrochloric salt (190 mg, 1.2 mmol) was added rapidly to the solution. The temperature was allowed to rise to room temperature and then water (3 mL) was added to quench the reaction. The resulting yellow cloudy solution was extracted with ether (3 × 25 mL), and the organic phases were combined and dried over anhydrous sodium sulfate. The crude product was obtained by evaporating the solvent in vacuum. Purification was conducted by column chromatography on silica gel with CH_2Cl_2 and CH_2Cl_2–MeOH (97:3) as eluents. The desired fractions were collected and further purified by recrystallization from ethyl acetate to give **2** (520 mg, 35%) as a white crystal. ^{1}H NMR ($CDCl_3$) δ: 2.44 (s, 3H, -C*H*$_3$), 3.10 (s, 4H, -C*H*$_2$C*H*$_2$-), 7.05–7.15 (m, 4H, 5,5′-bpy-*H*, 3″,5″-py-*H*), 8.24 (s, 1H, 3′-bpy -*H*), 8.28 (s, 2H, 3-bpy-*H*), 8.49–8.51 (m, 2H, 2″,6″-py-*H*), 8.53–8.57 (m, 2H, 6,6′-bpy-*H*). ESI–MS: 276.1 $(M+H)^+$.

$Ru(bpy)_2(Mebpy\text{-}py)(PF_6)_2$ (Ru-2)

To a solution of **2** (100 mg, 0.36 mmol) in methanol (40 mL), $Ru(bpy)_2Cl_2{\cdot}2H_2O$ (141 mg, 0.27 mmol) and few drops of water were added under stirring. The resulting brown solution was heated and the colour of the solution turned to a clear orange after two hour refluxing. The solvent was evaporated under vacuum, and a red solid residue was obtained. The residue was purified by column chromatography on silica gel (eluents CH_3CN/H_2O/sat. KNO_3 solution 8:1:1). The first violet band was the starting material $Ru(bpy)_2(NO_3)_2$. $Ru(bpy)_2(Mebpy\text{-}py)(NO_3)_2$ (184 mg, 83%) was obtained from the second orange band as a red solid after evaporation of the solvent. The complex $Ru(bpy)_2(Mebpy\text{-}py)(NO_3)_2$ was redissolved in a minimum amount of water followed by addition of a concentrated NH_4PF_6 solution to give a red precipitate, which was extracted by CH_2Cl_2 and evaporated to give the complex $Ru(bpy)_2(Mebpy\text{-}py)(PF_6)_2$ (**Ru-2**). ^{1}H NMR (DMSO) δ: 2.08 (s, 3H, -C*H*$_3$), 3.01–3.18 (m, 4H, -C*H*$_2$-(near pyridine) and -C*H*$_2$- (near Ru)), 7.27 (d, 2He′, Mebpy-py-*H*), 7.36 (d, 2He′, Mebpy-py-*H*), 7.46–7.60 (m, 5H, 4Hb + 2Ha, Mebpy-py-*H* + bpy-*H*), 7.66 (d, 1H, Hc′, or Hc″, Mebpy-py-H), 7.71 (d, 1H, 1Hc′, or 1Hc″, bpy-H), 7.73 (d, 2Ha, bpy-H), 8.14 (t, 2Hc, bpy-H), 8.16 (t, 2Hc, bpy-*H*), 8.46 (d, 2H, Hd′ + Hd″, Mebpy-py-*H*), 8.72 (s, 1Ha′, Mebpy-py-*H*), 8.76 (s, 1Ha″, Mebpy-py-*H*), 8.82 (d, 4Hd, bpy-*H*). ESI–MS: 344.5 $(M\text{-}2PF_6/2)^+$.

Copper-catalyzed one-pot synthesis of benzimidazole derivatives

Hashem Sharghi, Mona Hosseini-Sarvari, and Fatemeh Moeini

Abstract: A simple, efficient, and environmentally benign method has been developed for the synthesis of 2-substituted benzimidazoles through a one-pot reaction of phenylenediamines with aryl aldehydes in excellent isolated yields under mild conditions using Cu(II) complex as the selective, recyclable, and heterogeneous catalyst at ambient temperature. The Cu(II) complex as a heterogeneous catalyst can be reused in further catalytic reactions, and it was found that its activity remained largely unchanged for eight successive runs. No metal-complex leaching was observed after the consecutive catalytic reactions. The salient features of this method include mild conditions, high yields, simple procedure, and good recovery and reusability of the heterogeneous catalyst.

Key words: benzimidazole, *o*-phenylenediamine, arylaldehydes, heterogeneous catalyst, *N*,*N*-bis (2-hydroxyphenyl)pyridine-2,6-dicarboxamide.

Résumé : On a développé une méthode simple, efficace et respectueuse de l'environnement pour la synthèse de benzimidazoles substitués en position 2; elle est réalisée avec d'excellents rendements en produits isolés et elle implique une réaction monotope de phénylènediamines avec des aldéhydes aromatiques, à la température ambiante et elle utilise un complexe de Cu(II) comme catalyseur sélectif, recyclable et hétérogène. Le catalyseur de Cu(II) utilisé comme catalyseur hétérogène peut être réutilisé pour d'autres réactions catalytiques et on a trouvé que son activité demeure pratiquement inchangée après huit réutilisations. On n'a observé aucun lixiviation du complexe métallique après des réactions catalytiques consécutives. Les principales caractéristiques de cette méthode incluent des conditions douces, des rendements élevés, une procédure simple et une bonne récupération et possibilité de réutilisation du catalyseur hétérogène.

Mots-clés : benzimidazole, *o*-phénylènediamine, aldéhydes aromatiques, catalyseur hétérogène, *N,N*-bis(2-hydroxyphényl)pyridine-2,6-dicarboxamide.

[Traduit par la Rédaction]

Introduction

Benzimidazoles are very useful intermediates for the development of molecules of pharmaceutical or biological interest. The benzimidazole ring is an important pharmacophore in modern drug discovery (1). Benzimidazole derivatives exhibit significant activity against several viruses such as HIV (2), herpes (HSV-1) (3), RNA (4), influenza (5), and human cytomegalovirus (HCMV) (2*a*). Substituted benzimidazole derivatives have found commercial applications in veterinarian medicine as anthelmintic agents and in diverse human therapeutic areas such as treatment of ulcers and as antihistaminics (6). Because of their importance, the synthesis of substituted benzimidazoles has become a focus of synthetic organic chemistry. The most commonly used synthetic approaches typically entail the condensation of an arylenediamine with a carbonyl equivalent (7, 8). Likewise, esters, lactones, and anhydrides could produce benzimidazoles through the cyclization of amide. However, this might have a limited scope, since the necessary reaction conditions are harsh and result in a meager assortment of final products. For example, the reaction of arylenediamines with aliphatic esters and lactones, which uses strong mineral acids at high temperatures, necessitates conditions that would not allow for a wide range of functional groups and attractive substrates. The other synthetic approach involves a two-step procedure including the oxidative cyclodehydrogenation of aniline Schiff bases, which are often generated in situ from the condensation of phenylenediamines and aldehydes. Various oxidative and catalytic reagents, such as $TiCl_4$ (9*a*), H_2O_2/CAN (9*b*), $ZrOCl_2$ (10), $In(OTf)_3$ (11), $Sc(OTf)_3$ (12), $Yb(OTf)_3$ (13), I_2 in aqueous THF (14), BF_3–OEt_2 (15), H_2NSO_3H (16*a*), TsOH or *N,N*-dimethylaniline/graphite (16*b*), polyaniline – sulfate salt (17), and NH_4OAc (18), have been employed. The direct condensation of *o*-aryldiamines and aldehydes at room temperature is less developed, because it leads to the formation of a complex mixture of products containing 1,2-disubstituted benzimidazoles, the corresponding bis-anils, and dihydrobenzimidazoles as main byproducts (19). Unfortunately, some of these methods suffer from one or more limitations, such as high reaction temperature, prolonged reaction time, and toxic solvents. In addition, some of the catalysts are expensive, air sensitive, and homogeneous. The homogeneous catalysts cannot be separated from the reaction media and, subsequently, cannot be reused in further catalytic reactions.

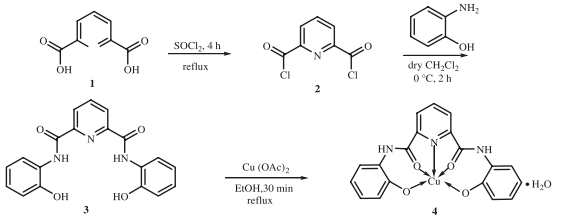
Scheme 1.



Recently, the development of heterogeneous catalysts (20) for fine chemicals synthesis has become a major area of research, since the potential advantages of these materials (i.e., simple recovery, reusability, and potential for incorporation in continuous reactors and microreactors) over homogeneous systems can have a major impact on the environmental performance of a synthesis (21). Considering the above issues, there is still a need to search for new catalysts superior to the existing ones with regards to toxicity, handling, operational simplicity, and heterogenicity. In continuation of our work (22) on the development of useful synthetic methodologies, herein, we wish to report a new Cu(II) complex as an excellent recoverable and heterogeneous catalyst for the synthesis of benzimidazole derivatives.

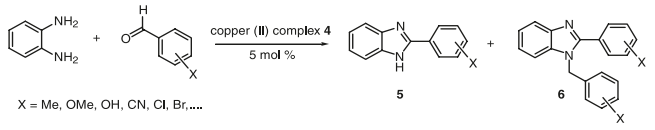
Results and discussion

The reaction pathway for the preparation of the catalyst is shown in Scheme 1. 2,6-Pyridinedicarboxylic acid (**1**) was boiled under reflux in $SOCl_2$ for 4 h. Excess of $SOCl_2$ was removed under reduced pressure to leave 2,6-pyridinedicarbonyldichloride (**2**). Then, a mixture of 2-aminophenol and triethylamine were dissolved in dry methylene chloride, temperature was adjusted to 0 °C, 2,6-pyridinedicarbonyldichloride was added dropwise, and the reaction mixture was stirred for 2 h. The resulting precipitate was filtered, washed with a saturated solution of $NaHCO_3$. Recrystallization of crude residue from an aqueous ethanol (50%) afforded 95% yield of yellowish solid of *N*,*N*-bis (2-hydroxyphenyl) pyridine-2,6-dicarboxamide (BHPPDAH) (**3**). In the next step, a mixture of BHPPDAH and cupric acetate was boiled under reflux in ethanol for 30 min. Finally, the reaction mixture was filtered, washed with H_2O, and air dried, which afforded 98% of brown solid of [Cu(BHPPDAH)H_2O] (**4**). This copper complex has already been synthesized by Gudasi and co-workers with different procedures and fully characterized (23).

In the presence of a catalytic amount of **4**, the reaction of *o*-phenylenediamine (*o*-PD) (1 mmol) was first examined with benzaldehyde (1 mmol) at room temperature in ethanol using atmospheric air as a green oxidant. Under optimized reaction conditions, we obtained exclusively the 2-substituted product, **5a** (x = H), and no N-alkylated product **6** was obtained (Scheme 2).

Control experiments without complex **4** under the same reaction conditions showed that no reaction occurred, thus confirming the effectiveness of Cu(II) complex as an effective heterogeneous catalyst (Table 1, entry 1). A catalytic amount of Cu(II) complex (5 mol%) is sufficient to obtain the desired product in high yield. A decrease in the amount of catalyst resulted in a significant reduction of the yield

Scheme 2.



while an increased amount of catalyst revealed negligible effect on the efficiency of the reaction (Table 1, entries 14 and 15). During the optimization studies, various solvents were examined, and it was found that solvent effect has an important role in terms of reaction rate, isolated yields, and selectivity (Table 1). *o*-Phenylenediamine and benzaldehyde were chosen as representative substrates. Among various solvents tested, acetonitrile, ethylene glycol, and 1,2-dichloroethane gave moderate yields of the expected product (Table 1, entries 8, 9, and 11). Methanol afforded the product in good yield (Table 1, entry 7). Obviously, ethanol was the solvent of choice owing to its fast reaction rate, high yield, good selectivity, cost effectiveness, and environmental acceptability (Table 1, entry 2). A trace benzimidazole was obtained when the reaction was operated in nitrogen atmosphere (Table 1, entry 5), supporting the fact that O_2 plays an important role in this reaction. Further bubbling of O_2 through the reaction mixture resulted in negligible change in the rate of reaction showing that the dissolved O_2 in solvent that is adsorbed by surface adsorption is sufficient for the efficient reaction completion.

To access the feasibility of applying this method in a preparative scale, we carried out the coupling of *o*-PD with benzaldehyde in 30 mmol scale in the presence of Cu(II) complex **4**. As expected, the reaction proceeded similar to the case in a smaller scale (Table 1, entry 2), and the desired 2-phenylbenzimidazole was obtained in 95% isolated yield in 2 h. The continuous bubbling of O_2 through the reaction mixture, instead of static atmosphere of air, did not accelerate the reaction rate, same as that mentioned in smaller scale reaction. $Cu(OAc)_2$ and Cu(II) salen were also examined as catalysts for this reaction; however, they were less effective compared with **4** and afforded banzimidazole **5** in 35% and 40% yields, respectively, (Table 1, entries 3 and 4).

From an environmental point of view, it is desirable to minimize the amount of waste for each organic transformation. In this context, the catalyst was recycled for subsequent runs. The recyclability of the catalyst was investigated using a model reaction between benzaldehyde and *o*-phenylendiamine in the presence of 5 mol% of the catalyst in ethanol as solvent. After the completion of the reaction, the mixture was filtered to separate the catalyst. The recycled catalyst was used for further runs, and it was found that its activity does not show any significant decrease even after 8 runs (Table 2).

Leaching experiment showed that the catalytic activity of Cu(II) complex **4** remained largely unchanged for 8 successive runs. To test the generality and versatility of this procedure in the synthesis of substituted benzimidazoles, we examined a number of differently substituted arylaldehydes and phenylendiamine using the optimized experimental conditions. As shown in Table 3, the aromatic aldehydes, having different substituents, such as methoxy, methyl, halogen, hydroxyl, nitrile, and nitro, were converted to the

corresponding benzimidazoles in high yields (Table 3, entries 2–11). Heteroaryl aldehydes, such as 2-thiophene and pyridinyl, also gave acceptable yields (Table 3, entries 13 and 14). The reactions of 3,4-diaminobenzoic acid, 3,4-diaminotoluene, and 3,4-diaminobenzophenon with benzaldehyde were also studied. As mentioned above, all the substrates consistently afforded the reaction selectively to the corresponding benzimidazoles in high yields (Table 3, entries 17, 18, and 19). The presented method is suitable for the preparation of benzimidazoles from an acid-sensitive aldehyde such as furfuraldehyde (Table 3, entry 12) and sterically hindered aldehyde such as 2-naphthaldehyde (Table 3, entry 15). The structures of the products were determined from their spectral (^{1}H NMR, ^{13}C NMR, IR, and MS) analysis.

The proposed mechanism for the Cu(II) complex-catalyzed synthesis of benzimidazole derivatives may tentatively be visualized to occur via a tandem sequence of reactions as depicted in Scheme 3.

Mechanistically, a plausible pathway for this reaction involves the formation of intermediate Schiff base **A** very rapidly, as monitored by GC analysis. So, the rate-determining step (RDS) was found to be the oxidative-cyclization step. The compound **B** was formed as a result of an intermolecular reaction between the aniline amine and the intermediate imine moiety in **A**. We propose that reaction of **B** with Cu(II) complex **4** is accompanied by the reduction of Cu(II) to Cu(I), the utilization of O_2, and the concomitant generation of H_2O_2, as depicted in Scheme 3 (24–26).

H_2O_2 as efficient oxidant has been shown to catalyze the oxidation of some organic reactions (27, 28). We thought that, in the presence of H_2O_2, the rate of this reaction might increase. As we expected, in the presence of H_2O_2 (1 mmol), (*o*-PD) (1 mmol), benzaldehyde (1 mmol), and 5 mol% of **4** in 5 mL ethanol, the reaction time decreases. The mechanism for the increase in the rate of this reaction in the presence of H_2O_2 can be described as follows (25, 26): In the presence of H_2O_2, oxidation of **B** by Cu(II) is enhanced because of the regeneration of Cu(II) by H_2O_2 oxidizing Cu(I). The redox cycling between Cu(I)/Cu(II) H_2O_2 also produces a highly reactive OH radical, which can then attack to **C**, as shown in Scheme 3.

Conclusion

In summary, we have presented the first example of copper(II) complex-catalyzed synthesis of benzimidazoles in benign condition. This new and efficient catalytic method is amenable to a parallel-synthesis approach, as demonstrated by the synthesis of a library of benzimidazoles substituted at various positions on the ring. The advantage of this method is the use of atmospheric air as oxidant. No toxic reagents or byproducts were involved, and no laborious purifications were necessary. These conditions are also environment-friendly, cost-effective, and possess high generality to make our methodology industrialized as a valid contribution to the existing methodologies in the field of benzimidazole synthesis.

Experimental

Starting materials were obtained from Fluka, Sigma-Aldrich, and Merk companies. Progress of the reactions was followed by TLC using silica-gel polygrams SIL G/UV 254 plates or by GC using a Shimadzu gas chromatograph GC-14A, equipped with a flame-ionization detector and a 3 m long glass column packed with DC-200 stationary phase using nitrogen as the carrier gas. The NMR spectra were recorded on a Bruker Avance DPX-250 (^{1}H NMR 250 and ^{13}C NMR 62.9 MHz) in pure duterated solvents with tetramethylsilane (TMS) as internal standard. Melting points were determined in open capillary tubes in a Buchi-545 circulating-oil melting-point apparatus.

Preparation of BHPPDAH

2,6-Pyridinedicarboxylic acid (3.34 g, 20 mmol) was boiled under reflux in $SOCl_2$ (40 mL) for 4 h. Excess of $SOCl_2$ was removed under reduced pressure to leave 2,6-pyridinedicarbonyldichloride. Then 2-aminophenol (4.36 g, 40 mmol) was dissolved in dry methylene chloride (100 mL) followed by triethylamine (5.5 mL, 40 mmol). After that, 2,6-pyridinedicarbonyldichloride (4.08 g, 20 mmol) was added dropwise to the above-mentioned solution at 0 °C,

and the reaction mixture was stirred for 2 h. Then, the precipitate was washed with a saturated solution of $NaHCO_3$. Recrystallization from aqueous ethanol (50%) afforded a yellowish solid of BHPPDAH in 95% yield. Mp 223 °C (Lit. 220–222 °C (23)). ^{1}H NMR (DMSO-d_6) δ_H: 6.82–7.06 (6H, m), 7.99 (2H, d, J = 7.9 Hz), 8.26–8.39 (3H, m), 10.02 (2H, s), 10.41(2H, s). ^{13}C NMR (DMSO-d_6) δ_C: 115.3, 119.1, 122.2, 124.9, 125.3, 125.4, 140.2, 148.5, 148.8, 160.9.

Prepration of [Cu (BHPPDA) H_2O] complex

A mixture of BHPPDAH (1.74 g, 5 mmol) and cupric acetate (2 g, 10 mmol) was boiled under reflux with ethanol (100 mL) for 30 min. Then, the reaction mixture was filtered, washed with H_2O, and dried in air to give a 98% yield of brown solid of [Cu(BHPPDAH)H_2O]. The copper(II) complex decomposes in two stages. The first step is 150–220 °C, and the second step is 220–470 °C ranges (23).

General method for the preparation of benzimidazole derivatives

A mixture of *o*-phenylendiamine (1 mmol), aldehyde (1 mmol), and catalyst (5 mol%) in 5 mL ethanol was stirred at room temperature for appropriate time. When the reaction was finished (monitored by TLC), the catalyst was filtered out, the filtrate was evaporated, and the residue was purified by short column chromatography over silica gel using *n*-hexane/ethyl acetate (7:1) or recrystallized from EtOH/H_2O (2:1) to afford the corresponding benzimidazole.

All produced benzimidazoles were characterized in detailed structural data by ^{1}H NMR and ^{13}C NMR, as given below.

*2-Phenyl-1*H*-benzimidazole (5a)*

Purification by flash column chromatography, eluted with *n*-hexane/ethyl acetate (7:1), gave compound **5a** as a colourless powder in 95% yield. Mp 290–292 °C (Lit. 292 °C (29)). ^{1}H NMR (DMSO-d_6) δ_H: 7.14–7.25 (2H, m), 7.44–7.61 (5H, m), 8.20 (2H, d, J = 7.2 Hz), 12.94 (1H, s). ^{13}C NMR (DMSO-d_6) δ_C: 122.1, 126.4, 128.4, 128.9, 129.2, 129.8, 130.1, 151.2.

*2-(4-Methoxyphenyl)-1*H*-benzimidazole (5b)*

Purification by flash column chromatography, eluted with *n*-hexane/ethyl acetate (7:1), gave compound **5b** as a colourless powder in 90% yield. Mp 226 °C (Lit. 226–227 °C (31)). ^{1}H NMR (DMSO-d_6) δ_H: 3.78 (3H, s), 7.10 (2 H, d, J = 8.8 Hz), 7.16 (2H, q, J = 3.0 Hz), 7.50 (2H, m), 8.12 (2H, d, J = 8.8 Hz), 12.76 (1H, s). ^{13}C NMR (DMSO-d_6) δ_C:

Facile reductive dehalogenation of organic halides with nickel boride at ambient temperature

Jitender M. Khurana, Sanjay Kumar, and Bhaskara Nand

Abstract: The hydrodehalogenation of a series of aryl, alkyl, allyl, and benzyl chlorides, bromides, and iodides has been carried out efficiently using nickel boride in methanol at ambient temperature, leading to the corresponding products resulting from hydrogen/halogen exchange.

Key words: hydrodehalogenation, reduction, organic halides, sodium borohydride, nickel boride.

Résumé : Faisant appel à l'action du borure de nickel à la température ambiante et dans le méthanol, on a effectué d'une façon efficace la hydrodéshalogénation d'une série d'iodures, de bromures et de chlorures d'aryle, d'alkyle, d'allyle et de benzyle conduisant à la formation des produits correspondants résultant d'un échange hydrogène/halogène.

Mots-clés : hydrodéshalogénation, réduction, halogénures organiques, borohydrure de sodium, borure de nickel.

[Traduit par la Rédaction]

Introduction

The development of effective procedures for the dehalogenation of organic halides is an important task, as it helps in the reduction of pollution by halogen-containing industrial wastes as well as for the synthesis of fine chemicals. Unlike oxidation methods, reductive dehalogenation processes are advantageous, as no toxic side products are formed. A wide variety of hydrodehalogenating systems have been used over the years and have been reviewed in detail (1–3). Thus, catalytic hydrogenation (4), dehalogenation by metals or low-valent metal compounds (5), metal hydrides, or complex metal hydrides (6–10) are some general reagents and methods able to accomplish the above-mentioned transformation. Nickel boride (11), first reported by Schlesinger and Brown, has been used as heterogeneous hydrogenation catalyst over the years (12). However, it is now known as a reducing agent by itself because of the adsorbed hydrogen (13). In recent years, we have used nickel boride as a novel reducing agent in multifarious transformations (14*a*–14*m*) (e.g., reductions, deoxygenations, desulfurisations, and so forth). In continuation to our studies on dehalogenation of various types of organic halides (15), we now wish to report the dehalogenation of benzylic, allylic, aryl, and alkyl halides with nickel boride in methanol at ambient temperature.

Results and discussion

In this paper, we report hydrodehalogenation of aryl, alkyl, and allyl halides to the corresponding hydrocarbons using nickel boride generated in situ from nickel(II) chloride and sodium borohydride. Benzylic halides were almost instantaneously reduced. Allylic halides underwent hydrodehalogenation and reduction of double bond concomitantly. Aryl halides, which are generally resistant to hydrodehalogenation, could also be easily dehalogenated to the corresponding arenes.

9-Bromofluorene was chosen as the model substrate to investigate and optimize the conditions for hydrodebromination of benzylic halides. The reactions of 9-bromofluorene were carried out with nickel boride in different solvents and in different molar ratios of substrate to nickel boride to achieve the desired transformation. Reactions carried out in THF, ethanol, and DMF were sluggish and gave a mixture of products, while no reaction was observed in acetonitrile and dichloromethane. Reaction of 9-bromofluorene in methanol yielded 96% fluorene in 15 min at ambient temperature. Further, it has been shown that the hydrodehalogenation is proceeding due to in situ formation of nickel boride, as no reaction of 9-bromofluorene was observed with nickel(II) chloride or sodium borohydride independently.

The hydrodehalogenation of a variety of benzylic halides was subsequently investigated under similar experimental conditions. Benzylic chlorides, bromides, and iodides underwent rapid hydrodehalogenation in different molar ratios of substrate:$NiCl_2{\cdot}6H_2O$:$NaBH_4$ (Scheme 1) (Table 1). The ease of dehalogenation BnI > BnBr > BnCl follows the order of bond energies C–Cl > C–Br > C–I, which is evident from molar ratios and the time required for the dehalogenation (Table 1, entries 1–21). Further, it can also be inferred from Table 1 that primary halides (Table 1, entries 1–4, 11, 12,

Scheme 1.

$$R{-}X \xrightarrow[\text{methanol, RT, 5–120 min}]{NiCl_2 \cdot 6H_2O\ ,\ NaBH_4} R{-}H$$

R = alkyl, aryl, benzyl; X = I, Br, Cl

and 19) undergo faster reduction than secondary halides (Table 1, entries 5–9, 13–17, 20, and 21), and tertiary halides (Table 1, entries 10 and 18) exhibit even slower reactivity.

Hydrodehalogenation of allylic halides (Table 1, entries 22–24), on the other hand, proceeds with the concomitant reduction of double bond to give the completely reduced product. No selective dehalogenation could be achieved even at lower temperatures.

Aryl halides and alkyl halides, which are generally resistant to dehalogenation, could also be dehalogenated successfully with nickel boride (Scheme 1). Thus, 1-iodonaphthalene, 1-bromonaphthalene, and 1-chloronaphthalene underwent rapid dehalogenation (Table 1, entries 25–27) giving naphthalene in excellent yields. The order of reactivity was the same as observed earlier, i.e., I > Br > Cl. Reaction of 9-bromoanthracene and 9-chloroanthracene with nickel boride (Table 1, entries 28 and 29) resulted in a mixture of anthracene and 9,10-dihydroanthracene. This is because anthracene itself was observed to undergo reduction with nickel boride to give 9,10-dihydroanthracene in an independent reaction.

Similarly, other aryl halides 9-bromophenanthrene, 4-bromophenol, 4-chlorophenol, methyl 4-bromobenzoate,

© 2008 NRC Canada

methyl 4-chlorobenzoate, and 4-bromobiphenyl were easily dehalogenated in quantitative yields. Dehalogenation of halobenzenes, however, required much higher molar ratios compared with halonaphthalenes and benzylic halides. This fact has been utilized to achieve regioselective dehalogenation of benzylic C–X over Ph–X bond. Thus, 4-bromobenzyl bromide and 4-chlorobenzyl bromide could be selectively dehalogenated to give 4-bromotoluene and 4-chlorotoluene, respectively (Table 1, entries 3 and 4).

Aliphatic alkyl halides, 1-bromohexadecane, 1-bromododecane, 1-bromoadamantane, 1-bromo-3-phenylpropane, and methyl 4-bromobutanoate also underwent successful dehalogenation but required higher molar ratio of 1:5:15 (Table 1, entries 36–40). Selective debromination of benzylic bromide over alkyl bromide could also be achieved when an equimolar mixture of 1-(bromomethyl)naphthalene and 1-bromo-3-phenyl propane was treated with nickel boride in 1:2:6 molar ratio. ^{1}H NMR spectra after 15 min showed complete disappearance of 1-(bromomethyl)naphthalene while 1-bromo-3-phenyl propane was found unreacted in the reaction mixture.

In conclusion, we have developed a highly efficient protocol for hydrodehalogenation of organic halides with nickel boride at ambient temperature. Compared with other hydrodehalogenating systems, several features make the procedure particularly attractive. Hydrogenolysis was very rapid. Yields of products were found good to excellent. Further, no coupled product or any other side product was either detected or isolated. Reaction was carried out at ambient temperature, and the products could be isolated by a simple workup procedure. However, the carbonyl and nitro groups are sensitive to nickel boride and get reduced (14*c*, 17).

Experimental

All products are known compounds. Melting points were recorded on a Tropical Labequip apparatus and are uncorrected. The PMR spectra were recorded on Hitachi FTNMR (60 MHz) using TMS as internal standard. The products were identified by mp and superimposable IR and NMR spectra with authentic samples. Methanol (S.D. Fine), nickel chloride hexahydrate (S.D. Fine), and sodium borohydride (E. Merck) were used in all reactions.

General procedure

In a typical reaction, a 50 mL round-bottomed flask fitted with a reflux condenser was mounted over a magnetic stirrer, and 9-bromofluorene (0.2 g, 0.81 mmol) dissolved in 10 mL of methanol was placed in it. $NiCl_2{\cdot}6H_2O$ (0.38 g, 1.63 mmol) was added followed by $NaBH_4$ (0.18 g, 4.89 mmol) cautiously. The reaction mixture was stirred vigorously at room temperature. The progress of reaction was monitored by TLC using petroleum ether as eluent. TLC of the reaction mixture showed the complete disappearance of starting material after 15 min. The reaction was quenched by adding 10 mL of methanol. The reaction mixture was filtered through a Celite pad (~2.5 cm) and washed with methanol (20 mL). Water (20 mL) was added to the filtrate, which was extracted with ethyl acetate (3 × 10 mL). The combined extract was dried over anhyd. $MgSO_4$, decanted through a cotton pad, and concentrated on a rotary evaporator. The product was recrystallized from ethanol to give 0.13 g of fluorene as characterized by mp and ^{1}H NMR spectra.

A capillary and microchip-based nanoelectrospray emitter using a mesoporous membrane

Shuqin Su and Richard D. Oleschuk

Abstract: A method is described for the fabrication of multipath electrospray emitters using hydrophobic porous polymer membranes. Polysulphone (PSF) and polycarbonate (PC) membranes, which possess pores with well-defined sizes, are glued onto the exit aperture of fused-silica capillaries or microfluidic chips to create multipaths to assist electrospray at moderate nano flow rates (e.g., 50–500 nL/min). A capillary-based multipath emitter fabricated with either PSF or PC membranes was prepared with a fused-silica capillary with 75 μm inner diameter and 360 μm outer diameter. Relative effects on electrospray performance at different flow rates, electrospray voltages, and solvent compositions are probed. The sensitivity and stability of electrospray signals were enhanced through spraying from multiple pores on the membrane. An embossed polycarbonate microchip was also interfaced to the mass spectrometer using the meso porous membrane approach.

Key words: nanoelectrospray, membrane, emitter, multipaths, microchip.

Résumé : On décrit une méthode de préparation d'émetteurs à électronébulusation par étape faisant appel à des membranes polymères poreuses et hydrophobes. Des membranes de polysulfone (PSF) et de polycarbonate (PC) qui possèdes des pores de tailles bien définies sont collées sur l'ouverture de sortie de capillaires de silice fondue ou de puces microfluides dans le but de créer des passages multiples pour aider l'électronébulisation à des vitesses d'écoulement nano modérées (c'est-à-dire de 50 nL/min à 500 nL/min). Utilisant des membranes PSF ou PC, on a préparé des émetteurs à passages multiples à base de capillaire, comportant un capillaire à silice fondue de diamètre interne de 75 μm et un diamètre externe de 360 μm. On a étudié les effets relatifs sur la performance de l'électronébulisation des variations dans les vitesses d'écoulement, les voltages d'électronébulisation et les compositions du solvant. La sensibilité et la stabilité des signaux d'électronébulisation sont augmentées par la nébulisation à partir des multiples pores de la membrane. On a aussi créé une interface entre une micropuce de polycarbonate et un spectromètre de masse en utilisant l'approche de la membrane méso poreuse.

Mots-clés : électronébulisation, membrane, émetteur, passages multiples, micropuce.

Introduction

Electrospray ionization (ESI), which transforms analytes from the liquid-phase to the gas-phase by forming fine droplets under an electric field, has revolutionized the study of large biomolecules, especially proteins and peptides (1–3). As an interface, electrospray emitters play an important role in coupling powerful separation technologies, such as liquid chromatography (LC) columns (4) or microfluidic chips (microchip) (5, 6), with a versatile detector of mass spectrometer (MS) for online sample preparation, separation, and analysis by ESI-MS. In addition, an electrospray emitter can also be used offline for the deposition of analytes onto a target plate for further analysis by matrix-assisted laser deposition ionization mass spectrometry (MALDI/MS) (7). Different approaches or designs have been explored to fabricate electrospray emitters for various purposes (8–26). Emitters with single micrometer-sized tapered-tips were developed to enable electrospray at nano-level flow rates for achieving highly sensitive detection (27). Furthermore, nano-ESI emitters are suitable for coupling nano-HPLC or microfluidic devices with mass spectrometry allowing the manipulation of small sample volumes (28, 29). Tapered emitters are traditionally used for nano-ESI. However, when using tapered emitters with a tip size of less than 20 μm, it is problematic due to the continuous clogging (30). Tapered emitters with a single-tip also have concerns of low liquid throughput for nano-electrospray (31).

Strategies for solving problems associated with tapered emitters have included using emitters with larger apertures or multiple spraying tips and channels. Emitters with larger apertures (> 50 μm i.d.) prepared by directly cutting fused-silica capillaries without further treatment are generally not able to produce stable sprays at nano flow rates (<1000 nL/min). Recently, Knapp and co-workers (31) have proposed a simulation model to facilitate nano-electrospray from a relatively large open tube. The model suggested growing an array of carbon nanofibers (CNFs) around the orifice of a capillary as multiple electrospray emitters, while

a higher fluidic throughput could be delivered through the open tube. Alternatively, emitters with multiple electrospray paths are becoming a more attractive option for generating nanoelectrospray because of their reduced susceptibility to clogging, higher sample throughput, and the improved sensitivity (31–33). Multiple electrospray paths can be generated from an array of tips fabricated by either simply manipulating capillary tubes parallel to each other or using microfabrication techniques such as photolithographic patterning, plasma etching, or laser ablation (34, 35). Tang et al. (33) reported a multiple electrospray emitter by fabricating an array of emitters on a polycarbonate substrate. The multiple paths for electrospray were also generated by drilling holes on a hydrophobic plate (32). However, these multiple electrospray emitters were designed to allow for increased sensitivity at a relatively large flow rate (>1 μL/min) (33). For generating electrospray at nanoliter per minute flow rates, we have developed emitters with multiple paths by forming porous polymer monolith (PPM) (25) or entrapping microspheres at the exit aperture of a fused-silica capillary channel (26). It was noticed that when using an emitter bearing multiple paths, electrospray can be generated from either a single emission jet or multiple emission jets depending on the emitter geometry and electrospray conditions (25, 33). To create multiple electrospray cone-jets with a good resolution from an emitter with multiple paths, the geometry of each individual emitter tip, the distance between the surface features, and the hydrophobicity of the surface on an emitter tip play an important role (31). If the distance between two emitter tips and the ratio of the height to the width of each emitter is too small, the liquid sprayed from individual tips is more likely to coalesce into a single Taylor cone.

Emitters with multiple paths can be fabricated for either a capillary-based or a microchip-based system. A capillary-based emitter such as PPM-filled or -entrapped microspheres can also be used in an integrated configuration for sample desalting, pre-concentration, and separation (26, 36). Furthermore, microchip-based emitters were also developed to allow the integration of more complicated functionalities as well as increased throughput (37, 38). Plastic materials are preferred for making disposable chips because they are less expensive. However, electrospray from the flat exit of a plastic chip channel is a challenge due to droplet spreading. A capillary-based emitter can be inserted into the channel of a microchip to assist with the electrospray (39). Although this technique has demonstrated good electrospray performance, it can leave a large dead volume that results in band broadening during separation. Micro-fabrication techniques have been used to form sharp tips to eliminate droplet spreading (40), but these techniques are usually complicated and expensive. Moreover, coating or bonding hydrophobic materials on the exit surface of a microchip-based emitter has also been demonstrated as an alternative solution (18). CF_4 coating by plasma deposition was used to increase the hydrophobicity of an emitter exit, but it exhibited limited robustness. A porous membrane was reported to enhance the hydrophobicity of an emitter exit surface by thermally bonding poly-tetrafluoroethylene (PTFE) onto the exit surface of a PC microchip (41). A piece of PTFE membrane with 50 μm thickness and an average pore size of 0.22 μm was bonded onto a microchip exit. However, it was difficult to precisely control the temperature and the force used during thermal bonding to bond membrane without pore deformation.

A novel technique is described in this paper to fabricate an emitter with multiple electrospray paths by simply gluing a piece of porous polymer membrane onto either the exit of a fused-silica capillary or the exit aperture of a polymer microchip under an optical microscope. Porous polymer membranes (polysulphone (PSF) and polycarbonate (PC)), which have precisely defined pore sizes, are used for the emitter fabrication. The overall electrospray performance was improved, compared with that of an open tubular emitter. The signal to noise ratio for the 482.4 *m*/*z* peak of jeffamine was increased from 6 to 34 for a membrane-assisted emitter compared with that of an open tubular emitter. Furthermore, hydrophobic membranes bonded onto the exit of a PC polymer microchip channel also prevented the liquid from spreading along the flat edge of the microchip, enabling a stable electrospray signal.

Experimental

Reagents and materials

Zinc nitrate hexahydrate, $Zn(NO_3)_2{\cdot}6H_2O$ (98%), hexamethylenetetramine, $C_6H_{12}N_4$ (99%), and glass plates coated with polycrystalline F-SnO_2 were purchased from Hartford Glass Inc. (USA). Polysulfone (Udel® P3500) was a gift from Solvay Advanced Polymers and was purified by precipitation fractionation using THF as a solvent and methanol as a precipitant. The weight-average molar mass *Mw* of the fractional sample was determined by light scattering, using the specific refractive index increment of 0.201 mL/g measured in THF and was 9.0×10^4 g/mol. The polydispersity index *Mw*/*Mn* of the sample was 1.42, as determined by size exclusion chromatography based on poly (methyl methacrylate) standards.

The PSF membrane was prepared in-house according to the procedures described below. Whatman PC membrane was purchased from Fisher Scientific (Ottawa, Ontario, Canada). Fused-silica capillaries (360 μm o.d., 75 μm i.d.) were purchased from Polymicro Technologies (Phoenix, Arizona, USA). Markrolon PC sheets were purchased from Sheffield Plastic Inc (Scarborough, Ontario, Canada). Epoxy resin (Torr Seal) was purchased from Varian, Canada. Syringe glue Speed Set epoxy was purchased from LePage (Missisauga, Ontario, Canada).

Glacial acetic acid, methanol (HPLC grade), and acetonitrile were all purchased from Fisher Scientific (Ottawa, Ontario, Canada) and used without purification. *O*-(2-aminopropyl)-*O*-(2-methoxyethyl) polypropylene glycol 500 (jeffamine) were purchased from Sigma-Aldrich (Oakville, Ontario, Canada) and also used without purification. Milli-Q water was obtained from Millipore (Bedford, Massachusettes, USA).

Preparation of PSF membrane

The PSF porous membrane was prepared by a patterning method that uses ZnO pillar arrays as a template (42). Briefly, ZnO pillars were prepared by immersing a SnO_2 coated glass plate into a solution containing $Zn(NO_3)_2{\cdot}6H_2O$ and $C_6H_{12}N_4$ (1:1 molar ratio) at 90 °C for 18 h. A 2–3 mm

dam was then built with epoxy resin along the periphery of a glass plate bearing ZnO pillars. We added 1.5 mL of 3.3 mg/mL PSF in THF solution onto a plate within the dam. After the THF evaporated, the PSF spherical end capping was etched off the pillar by soaking the plate bearing the PSF membrane in THF/methanol (*v*/*v* = 1:1). The plate was then immersed into 0.5 mol/L HCl to dissolve the pillars after the THF/methanol evaporated. Finally, the porous membrane was detached from the glass plate as ZnO was dissolved. Figure 1 shows the SEM image of (*a*) ZnO pillars with about (*b*) 1 μm width and (*c*) 6–7 μm length. By casting polysulfone solution onto these pillars, a 1 μm pore sized membrane can be obtained as shown in Fig. 1*d*.

Fabrication of a capillary-based nanoelectrospray emitter

UV-transparent fused-silica capillaries (360 μm o.d. and 75 μm i.d.) were used for emitter fabrication. Emitters were cut from 4 to 6 cm in length. The exit aperture was inspected under a microscope before testing. PSF membranes with 1.0 μm sized pores and PC membranes with 0.22 μm, 1.0 μm, and 5.0 μm sized pores were used for the emitter fabrication, respectively. A thin layer of the freshly mixed epoxy glue was applied onto a capillary exit using a sharp needle under an optical microscope. The glued exit aperture of the capillary was then stamped onto a piece of membrane. The extra membrane along the capillary edge was trimmed using tweezers after the epoxy had hardened. The exit image of a membrane assisted emitter is shown in Fig. 2.

Fabrication of a chip-based multipath electrospray emitter

Hot embossing, as described elsewhere (23), was used to fabricate a PC chip-based emitter. Briefly, as illustrated in Fig. 3, a fused-silica capillary (20 μm i.d and 150 μm o.d.) was used as a master to create a channel by embossing the capillary onto a PC sheet at 150 °C and 2000 N for 830 s. After peeling off the capillary, a channel is left on the sur-

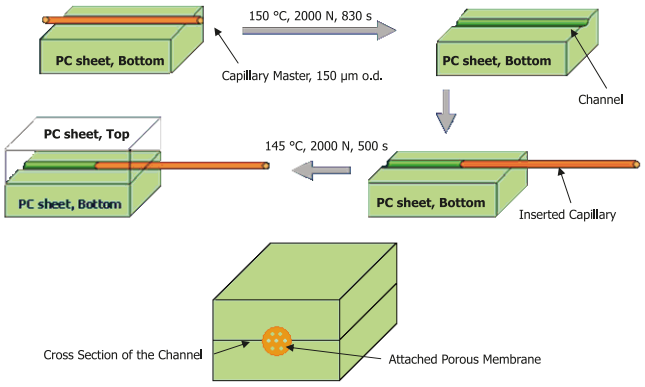
Fig. 3. Diagram of fabrication of microchip-based emitter with membrane bonded on channel exit.



face of the PC sheet. The channel was inspected under an optical microscope to ensure it was free of debris. Next, a capillary with 20 µm i.d and 150 µm o.d. was inserted 1 cm into the channel through one exit to deliver the fluid into the chip. A second sheet of unpatterned PC was then placed on top of the substrate bearing the positioned delivery capillary. The two PC sheets were then bonded at 145 °C and 2000 N for 500 s. The chip exit was shaped to a narrower end (0.5 cm in width) to facilitate easier access to the MS orifice. A piece of porous membrane (3 mm × 3 mm) was then glued onto the chip exit using the method described above for the fabrication of a capillary-based emitter.

Online electrospray mass spectrometry

Mass spectra acquisitions were conducted on an API 3000 triple-quadrupole mass spectrometer (MDS Sciex, Ontario, Canada). An online nanoelectrospray interface (Proxeon, Odense, Denmark) was installed with two CCD cameras, a micro-tee, and an x-y-z stage. The output of the CCD cameras was connected to a PC. A capillary-based emitter was first inserted into a MicroTight green sleeve (395 i.d. and 635 o.d.) and then affixed to a micro-tee, which was then mounted onto the x-y-z stage. An electrode was connected through the junction of the micro-tee. One end of the micro-tee was connected to a nano-LC pump by a capillary with a 360 µm o.d. and 20 µm i.d. as a transfer line.

For the chip-based emitter, the microchip was first affixed to a flat plastic holder, which was then mounted onto an x-y-z stage. A metal union was used to both connect a delivery capillary to the chip channel and a capillary from a nano-LC pump. It also facilitated the application of an ESI voltage. The relative distance between an emitter and the mass spectrometer orifice was about 0.5–2 cm. Positive ion mode was used for the detection of both jeffamine and leucine enkephalin. The curtain gas flow rate was set at 0.3 L/min, and the declustering potential and focusing potential were kept at 60 and 250 V, respectively. Quadrupole peak width (set to yield a unit mass resolution of 0.7 amu at FWHM) and the scan time (1 Hz) were kept constant for all the experiments.

Offline electrospray set-up

A membrane-assisted capillary emitter was set in a MicroTee (Upchurch, S.P.E., Toronto, Ontario, Canada), which was in turn mounted onto an x-y-z stage (Proxeon, Odense, Denmark). A CCD camera was used to record images through an ATI multimedia program. A high voltage supply (Micralyne, Edmonton, Alberta, Canada) was controlled by PC via µTK software and supplied the necessary electrospray potential. A small metal plate (3 cm × 3 cm), used as a counter electrode, was positioned 1 cm in front of the emitter. The positive high voltage was connected via a liquid–electrode junction within the MicroTee. A syringe pump (Harvard, Pennsylvania, USA) infused 1 µmol/L leucine enkephalin solution in 70% methanol to the membrane-assisted emitter, and electrospray images were recorded at different flow rates.

Investigation of electrospray performance

The influence of flow rates, spray voltages, and solvent compositions on the electrospray stability, sensitivity, and reproducibility was evaluated. A nano-pump was used to control flow rates from 50 to 500 nL/min. Spray voltages from 2.4 to 3.5 kV were applied through a metal wire inserted into the liquid junction within the micro tee. Standard solutions of 1 µmol/L polypropylene (jeffamine) were prepared in methanol/acetonitrile with 10%–90% water and 0.1% acetic acid. Leucine enkephalin (1 µmol/L) was prepared in 70% methanol and 0.1% acetic acid. Data acquisition was set to scan between 400–1000 *m/z*. The intensity of the total ion current (TIC) was used to represent the detection sensitivity. The electrospray stability was evaluated by the relative standard deviation (RSD%) of the TIC intensities, calculated by dividing the standard deviation (SD) of the TIC data points against the average of the TIC intensities. The signal to noise ratio (S/N) was calculated by dividing the background subtracted analyte peak heights against the standard deviation of the background signals.

Results and discussion

Fabrication of multipath electrospray emitters using porous polymer membranes

A novel method to fabricate a multipath electrospray emitter is reported by simply gluing a porous polymer membrane over the exit aperture of either a fused-silica capillary or a PC microfluidic chip. Various fabrication methods have been developed to fabricate emitters with an array of tips, channels, or simple holes to form multiple electrospray paths (12–14, 43). A thermal-bonded porous polytetrafluoroethylene (PTFE) membrane was used to enhance the hydrophobicity of the exit surface of a PC microfluidic chip (41). The liquid spreading at the exit aperture was reduced. Multiple fluidic paths were also formed as a result of the tortuous pores of the PTFE membrane. However, as a result of thermal bonding, the authors found that the pore size (average 0.22 µm) and the pore distribution of a membrane were modified during bounding because of the bonding force and high temperature. It was not easy to precisely control the temperature and force to allow a permanent bonding of membrane without deforming the channel exit or sealing the pores on the membrane.

In this method, PSF and PC membranes with precisely defined pore sizes (0.2–5.0 µm) are used with both fused-silica and plastic materials to fabricate capillary-based or chip-

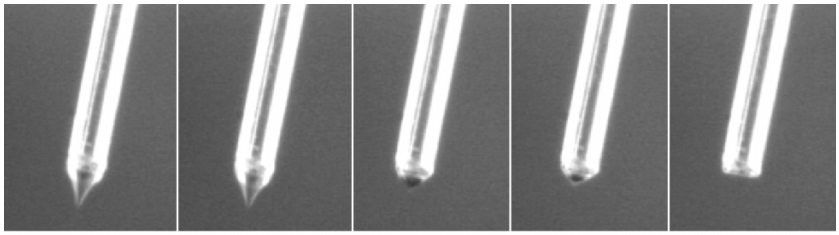
Fig. 4. Offline electrospray images from membrane-assisted emitters (PSF membrane bearing 1 μm sized pores) at different flow rates while continuously infusing 1 μmol/L leucine enkephalin in 70% methanol and 0.1% acetic acid at a spray voltage of 2.8 kV.



based emitters with multiple electrospray paths. A piece of membrane was glued onto the fused-silica capillary exit by first applying epoxy glue on the capillary exit, and then simply pressing the glued exit onto a piece of membrane. Optical microscopy and flow experiments show that following careful application of a very thin layer of epoxy glue onto the capillary exit under an optical microscope, enough membrane pores remain to permit liquid flow and facilitate nanoelectrospray. Electrospray performance is enhanced for both PSF and PC membrane-assisted emitters. Furthermore, the hydrophobic nature of the membranes prevented the liquid from spreading across the entire emitter exit aperture. PMMA, COC, and PC substrates were used to fabricate a chip-based emitter using hot embossing method, respectively, however the PC sheet was found to be the most compatible material with the gluing procedure. Membranes bonded to PMMA and COC devices frequently peeled from the substrate after several hours of spraying.

Electrospray from a membrane-assisted capillary-based emitter

Stable electrospray are generally not able to be produced at nano flow rates (e.g., <1000 nL/min) from emitters with larger apertures (>50 μm i.d.) prepared by directly cutting fused-silica capillaries without further treatment. By attaching a piece of porous polymer membrane at a capillary exit (75 μm i.d. and 360 μm o.d.), stable electrospray Taylor cones were observed from both offline and online electrospray at flow rates from 20 to 500 nL/min. Figure 4 shows offline electrospray images taken from an emitter bonded with a piece of PSF membrane bearing 1 μm sized pores. Pointed cone jets were visible at both 500 and 300 nL/min flow rates, but gradually became less visible as the flow rate was reduced below 100 nL/min. No visible Taylor cone was observed at a flow rate of 20 nL/min. Taylor cone observations produced by membrane-assisted emitters are consistent with the fundamental aspects of nanoelectrospray, which suggested a reduced emission diameter and thus a reduced size of droplets when lowering the flow rate (27).

A comparison of electrospray performance between an open tubular emitter with a 75 μm i.d and a PSF membrane-assisted emitter was conducted using a 1 μmol/L jeffamine solution. The results show that both the stability and sensitivity of electrospray signals were enhanced for the membrane-assisted emitter compared with that of the open tubular emitter, as shown in Fig. 5.

When utilizing an open tubular emitter at 500 nL/min, a stable signal was not obtained at any position or applied voltage. Instead, a "spitting" mode was predominate that manifested itself by the formation of large clusters rather than a cone jet mode, which resulted in signal spikes during electrospray (Fig. 5*a*) and caused MS signal suppression (Fig. 5*b*). Conversely, the stability and sensitivity were improved (Figs. 5*c* and 5*d*) using a porous membrane-assisted emitter. The signal to noise ratio increased for all *m*/*z* values for the jeffamine standard within the mass window from 400 to 900 *m*/*z*. As an example, the S/N ratio for 482.4 *m*/*z* increases from 7 to 34, as indicated in Figs. 5*b* and 5*d*.

For a given emitter geometry, the spray voltage, solvent composition, flow rate, and the relative distance between an emitter tip and a MS orifice have a strong influence on electrospray behavior (44). The effects of these electrospray parameters on performance were evaluated by maintaining the emitter position relative to an MS orifice and systematically adjusting the ESI parameters. The study showed that 2.4 kV voltage was necessary to initiate the electrospray process, and that increasing the electrospray voltage resulted in increased ion current until 3.5 kV (Fig. 6*a*).

The influence of solvent composition on electrospray performance was also investigated. Methanol, acetonitrile, and water are the most common solvents used during reverse phase separations for protein and peptide analysis. Typically, proteins are separated by eluting them from columns by gradually changing the composition of the mobile phase. As the organic concentration increases, the surface tension of the mobile phase decreases, which results in improved ionization efficiency and increased TIC intensities (Fig. 6*b*). Signals RSD of the total ion current increase markedly at higher methanol concentrations. Moreover, when organic component was less than 20%, it was difficult to generate an efficient or stable electrospray. The RSD of TIC intensity increased from 5% at a 3:7 (*v*/*v*) MeOH/water solution to 16% at a 1:9 (*v*/*v*) MeOH/water solution. Different compositions of acetonitrile in water showed a similar trend to that of methanol (data not shown). This was due to the larger surface tension of water, and a substantially larger Taylor cone base formed on the exit aperture of a membrane-assisted emitter compared with that of from a tapered tip. Although electrospray from higher aqueous solution became feasible with the aid of a hydrophobic porous membrane, ion suppression resulted in reduced sensitivity when the organic component was lower than 10%.

Utilizing a PSF membrane-assisted emitter at 2.8 kV spray voltage with 50% methanol solution, stable electrospray was easily obtained at flow rates ranging from 50 to 500 nL/min (Fig. 6*c*), which was impossible for an open tubular emitter (such as 75 μm o.d.) at less than 500 nL/min flow rates.

Fig. 5. Comparison of electrospray stability and sensitivity from an open tubular emitter and a membrane-assisted emitter by infusing 1 μmol/L jeffamine in 70% MeOH at 500 nL/min flow rate and 2.8 kV spray voltage. (5*a* and 5*c*) TIC trace and (5*b* and 5*d*) the mass spectrum of 1s elution as assigned from TIC signals respectively.

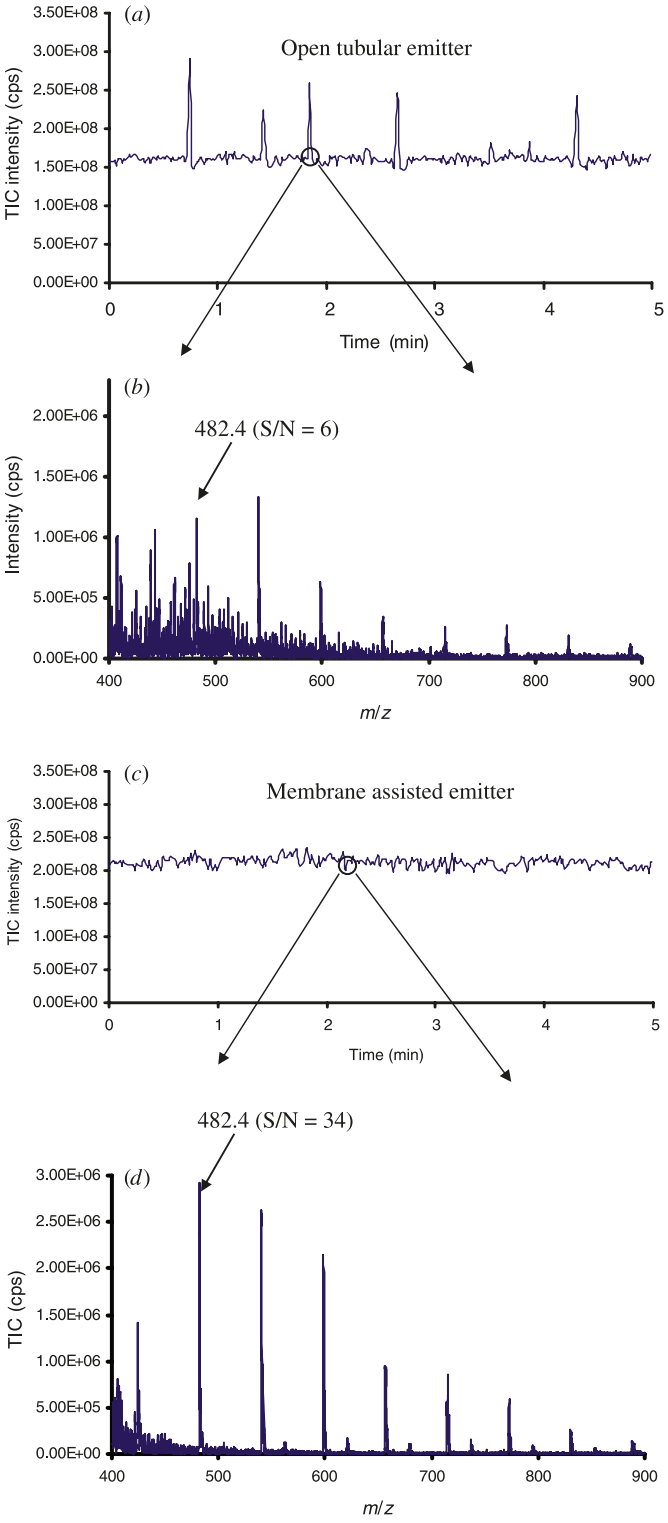

Fig. 6. Impact of spray voltage, solvent composition, and flow rate on electrospray performance using a PSF membrane-assisted emitter with a 1 μmol/L jeffamine solution. (*a*) TIC intensities at different spray voltages with 1:1 (*v*/*v* MeOH/water) and 500 nL/min flow rate. (*b*) TIC intensities with different methanol compositions at a 500 nL/min flow rate and 2.8 kV spray voltage. (*c*) TIC intensities at different flow rates with 1:1 (*v*/*v*) MeOH/water solution and 2.8 kV spray voltage.

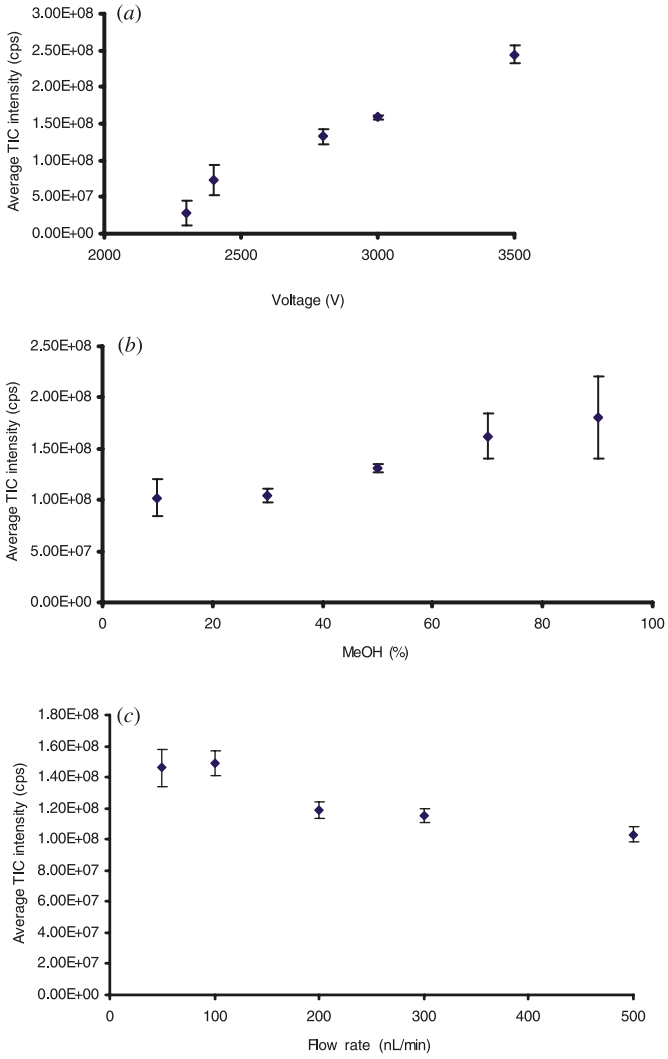

Further studies to examine the correlation between membrane pore sizes and sensitivity were conducted over the same flow rate range using emitters fabricated with commercial PC membranes. The TIC intensity can be used for the direct comparison based on the assumption that electrospray is generated with the same ion transfer and ionization efficiency. A comparison of electrospray performance from three emitters bonded with commercial polycarbonate membranes was conducted using a solution of 1 μmol/L jeffamine in 70% methanol at 500 nL/min flow rate and 2.8 kV spray voltage. These membranes contain well-defined and distributed pores with the sizes of 0.2, 1.0, and 5.0 μm, respectively. For each emitter, five replicates were tested for the comparison (Table 1).

As shown in table 1, the emitter with the smallest pore-sized membrane gave a slightly higher TIC intensity, while

Mean TIC (cps)	1.27 × 10^8
SD (cps)	3.47 × 10^6
RSD (%)	2.8

Fig. 7. Reproducibility for five different membrane-assisted (1.0 μm sized pores) emitters, TIC intensity was acquired with 1 μmol/L jeffamine in 70% MeOH at 500 nL/min and a 2.8 kV spray voltage.

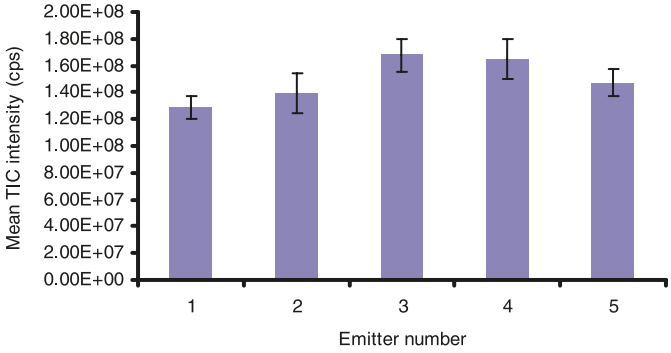

Fig. 8. Comparison of electrospray sensitivity and stability when using a membrane-assisted microchip and an open chip channel by infusing 1 μmol/L jeffamine in 70% methanol at 300 nL/min flow rate and 4.8 kV spray voltage.

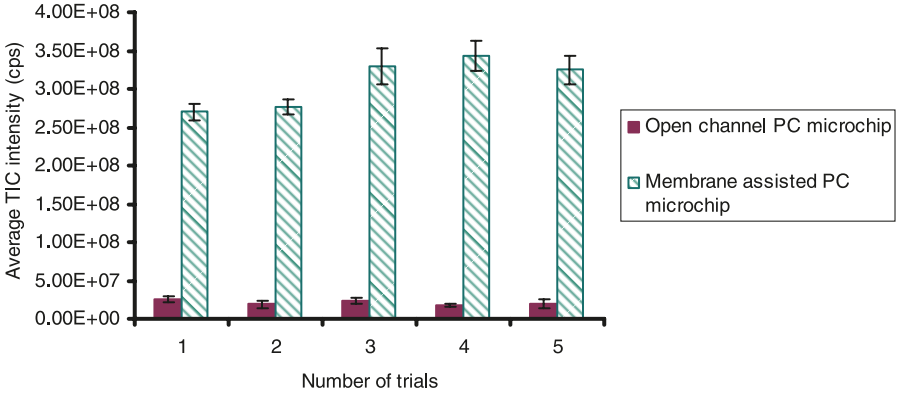

the TIC intensities for emitters with 1.00 and 5.00 μm pore-sized membranes were not statistically different, and all electrospray signals were below 6% RSD. However, no obvious correlation was found between the size of the pores and sensitivity improvements.

The reproducibility of the fabrication of porous polymer membrane-assisted emitters was demonstrated by making five emitters bonded with polycarbonate membranes bearing 1.0 μm sized pores. Significant dexterity is required when applying glue onto capillary exits under a microscope to facilitate membrane attachment. The RSD of the average TIC intensities between the five membrane-assisted emitters is about 11% as shown in Fig. 7.

Membrane-assisted electrospray from a microchip

Preliminary experiments were conducted to investigate the electrospray performance of a chip-based membrane bonded emitter. Electrospray performance from emitters with an open chip channel and a membrane-bonded chip channel were compared by infusing a solution of 1 μmol/L jeffamine in 70% methanol at a 300 nL/min flow rate. An electrical voltage of 4.8 kV was applied through a metal union connected to the transfer line on the microchip. TIC intensities increased about 5- to 7-fold when using a membrane-assisted chip-based emitter, compared with that of from an open chip channel as shown in Fig. 8. The variation of electrospray signals reduced from 25% to about 5% of RSD. This experiment demonstrated that by simply gluing a piece of porous membrane onto the exit aperture of a PC microchip, a porous membrane-assisted microchip can be coupled to a mass spectrometer as a facile interface for nanoelectrospray.

Conclusion

A novel method was introduced to fabricate a multiple path electrospray emitter by adhering a piece of porous polymer membrane onto either a fused-silica capillary or a plastic microfluidic chip. Both PSF and PC membranes contained well-defined pores to generate multiple paths for electrospray. Emitters with membranes containing pores of different sizes from 0.2 to 5.0 μm demonstrated improved electrospray performance. The S/N ratio for the 482.4 *m*/*z* peak of jeffamine was increased from 6 to 34 for a membrane-assisted capillary emitter compared with that of an open tubular emitter. No direct correlation between the pore size and the sensitivity of detection was found. Reproducible electrospray signals were obtained from five capillary emitters bonded with PC membranes. TIC intensity was increased by 5- to 7-fold, and variation of electrospray signals was reduced from 25% to 5% RSD when using a porous polymer membrane with a polycarbonate microchip. The po-

Carborane-carbohydrate derivatives — Versatile platforms for developing targeted radiopharmaceuticals

Andrew E.C. Green, Laura E. Harrington, and John F. Valliant

Abstract: A series of carborane-carbohydrate derivatives were prepared as model platforms for developing targeted radiopharmaceuticals in which a single ligand can be tagged with two different classes of radionuclides. A *nido*-carborane linked to glucose was synthesized and the cage labelled with a radiometal (^{99m}Tc) and a radiohalogen (^{125}I) in good radiochemical yield. The ^{99m}Tc-metallocarborane derivative was prepared via microwave-assisted reactions, while the iodinated derivative was prepared using oxidative labelling methods in mere minutes. Fully characterized reference standards were prepared using nonradioactive rhenium and iodine and used to demonstrate that the isolated radioactive compounds were in fact the desired targets. The work reported, which is one of the rare examples of a single ligand system that can be labelled with both radiohalogens and radiometals, forms the basis of a new paradigm for developing targeted radiopharmaceuticals.

Key words: carboranes, medical isotopes, technetium-99m, iodine-125, glucose.

Résumé : On a préparé une série de dérivés carborane-carbohydrates comme plate-formes modèles pour le développement de produits radiopharmaceutiques ciblés dans lesquels un seul ligand peut être marqué avec deux classes différentes de radionucléides. On a synthétisé avec un bon rendement un *nido*-carborane lié à un glucose et on a marqué la cage avec un métal radioactif (^{99m}Tc) et un halogène radioactif (^{125}I). On a préparé le dérivé ^{99m}Tc-métallocarborane par le biais de réactions assistées par les microondes alors que le dérivé iodé a été préparé par des méthodes oxydantes en quelques minutes. On a préparé des produits de référence complètement caractérisés à l'aide de rhénium non radioactif et d'iode et on les a utilizés pour démontrer que les composés radioactifs isolés sont bel et bien les cibles désirées. Le travail rapporté, qui est un des rares exemples d'un système de ligand unique qui peut être marqué avec des métaux et des halogènes radioactifs, forme la base d'un nouveau paradigme pour le développement de produits radiopharmaceutiques ciblés.

Mots-clés : carboranes, isotopes médicaux, technitium-99m, iode-125, glucose.

[Traduit par la Rédaction]

Introduction

Interest in developing targeted molecular radioimaging probes has been increasing because of the exquisite sensitivity offered by nuclear imaging methods (1, 2). This feature of single photon emission computed tomography (SPECT) and positron emission tomography (PET) creates the opportunity to use probes to monitor the very earliest stages of disease development and to study associated biochemical events noninvasively.

To meet the demand for new probes, more efficient and versatile radiolabelling and bioconjugation strategies are needed. For instance, the majority of ligands used to prepare molecular radioimaging and therapy agents are only able to carry a single class of radionuclides (halogens, radiometals, etc.). There would be tremendous advantages if a single prosthetic group could be tagged with different classes of radionuclides so that the physical properties of the isotope (half-life, emission energy, and decay mode) could be matched with the desired application and availability of instrumentation without having to synthesize an entirely new agent. Given the recent issues around supply shortages of specific medical isotopes, the ability to have flexible platforms that can be used with different radionuclides would be of significant utility.

Our group has been exploring the use of carboranes, more specifically 1,2-dicarba-*closo*-dodecaborane (ortho-carborane), as ligands from which to produce targeted radiopharmaceuticals. Carboranes are synthetically versatile, resistant to thermal and photochemical degradation, and they form stable η^5-complexes with a variety of metals (3–8), which include rhenium (9) and technetium (10, 11). Re(I) and ^{99m}Tc(I) metallocarborane complexes (10–14) can be prepared in water from $[M(CO)_3(H_2O)_3]^+$ (M = Re, ^{99m}Tc) (15, 16), a starting material that can be produced in a manner suitable for clinical use. In parallel, other groups have shown that carboranes can also be labelled with radiohalogens (17–

24) using standard electrophilic methods, providing the opportunity to prepare metallated and halogenated agents from a single core.

Although a few examples of molecular imaging agents labelled with both radiometals and radiohalogens have been reported (25–33), the labels are typically bound to the targeting vector at different positions (e.g., a chelate at the *N*-terminus for binding radiometals and a tyrosine residue for labelling with radiohalogens). It would be attractive to have the means to incorporate a single prosthetic group at a site on the targeting vector that has the least impact on target binding and to then be able to label the ligand with different radionuclides. Given their versatility (18), carboranes offer a means of developing such a system. Here we report the first steps in this regard by preparing a hydrophilic carborane ligand and then investigating the conditions needed to label the cluster with both ^{99m}Tc and ^{125}I.

Results and discussion

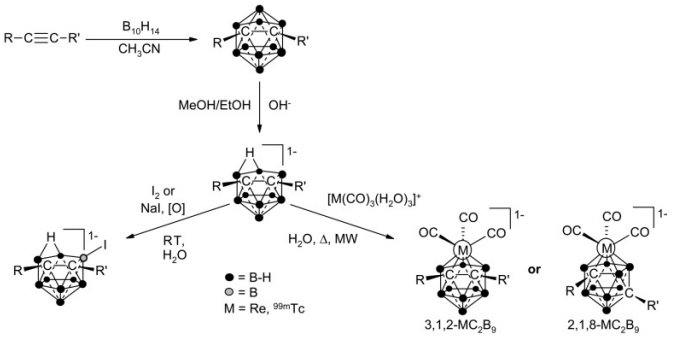
One of the major limitations ascribed to carboranes as it pertains to developing molecular imaging agents is that they are hydrophobic in nature. Prosthetic groups that are too lipophilic can increase the amount of nonspecific binding including unwanted uptake in the hepatobiliary system. To address this issue in concert with demonstrating for the first time that a single prosthetic group can be labelled with both a radiometal and a halogen, we present here the synthesis and characterization of ^{99m}Tc and ^{125}I tagged carborane-carbohydrate derivatives (Scheme 1).

The initial target ligand was a simple *nido*-carboranyl glycoside of glucose (**3**), which was designed as a model system from which to develop general purpose labelling strategies for both metal complexation and halogenation. If suitable labelling methods can be developed and if the products are sufficiently robust, the target compounds can ultimately be linked to vectors through functionalization of the remaining carborane CH group. This would result in a new general labelling technology whereby the nature of the radionuclide could be selected to suit the intended application while the polar carbohydrate would mask the lipophilic nature of the carborane core.

Compound **3** (Scheme 2) was synthesized from the known propargyl glycoside, **1**, (34) and *closo*-carborane, **2**, (35), by treating the latter with alcoholic NaOH (36). These conditions concomitantly removed the acetate protecting groups giving **3** in 63% yield following chromatographic purification. Since degrading carboranes can occur at either of two boron atoms, the product is isolated as a mixture of diastereomers (37, 38), which was apparent in the ^{1}H and ^{13}C NMR spectra. The ligand **3**, unlike most carborane derivatives, is freely soluble in water making it convenient to work with in terms of radiolabelling where the majority of reactions are performed in aqueous media.

Prior to labelling compounds with ^{99m}Tc, it is prudent to prepare and fully characterize the nonradioactive rhenium analogue as a reference standard for the products produced at the tracer level. The general method used by our group to produce Re-metallocarboranes is microwave heating, which greatly reduces the overall reaction time and improves the isolated yield of the product (13, 39, 40). In contrast to previous results, initial experiments using microwave heating yielded little of the desired product. ES-MS analysis of the reaction mixture indicated that the product was forming but was being degraded via hydrolysis of the glycoside bond connecting the metallocarborane to the carbohydrate. One suspected cause of this degradation was the high temperatures used, however this was dismissed when the ligand alone was shown to be stable to microwave heating in the absence of the metal. The actual source of bond cleavage was the acidic rhenium starting material (pK_a = 7.5) (41, 42), a problem that was addressed by adding a buffer to the reaction mixture (0.003 mol/L NaH_2PO_4, 0.01 mol/L Na_2HPO_4, and 0.5 mol/L NaF: "PBF", pH 7.2). Optimal conversion to **4a** was accomplished with two 10-minute irradiations at 200 °C using an excess of $[Re(CO)_3(H_2O)_3]Br$ (16) (Scheme 3). Isolation of the desired product via silica gel chromatography was accomplished successfully after complete consumption of the precursor **3**. Unfortunately, due to the highly hydrophilic nature of the ligands, a significant proportion of the material adsorbed onto the silica gel reducing the overall yield to 31%. Nonetheless, sufficient material was isolated for characterization and all data was consistent with the desired product.

Scheme 1. The preparation and labelling of carborane derivatives with iodine and the $[M(CO)_3]^+$ core (M = Tc, Re).



Scheme 2. Synthesis and NMR numbering scheme for compound **3**. Reagents and conditions: (a) propargyl alcohol (2.0 equiv.), $BF_3{\cdot}Et_2O$ (1.5 equiv.), CH_2Cl_2, RT, 12 h; (b) $B_{10}H_{14}$ (2.0 equiv.), CH_3CN, reflux, 48 h; (c) (*i*) NaOH (20 equiv.), EtOH, reflux, 12 h, (*ii*) 1 mol/L HCl, pH 4.

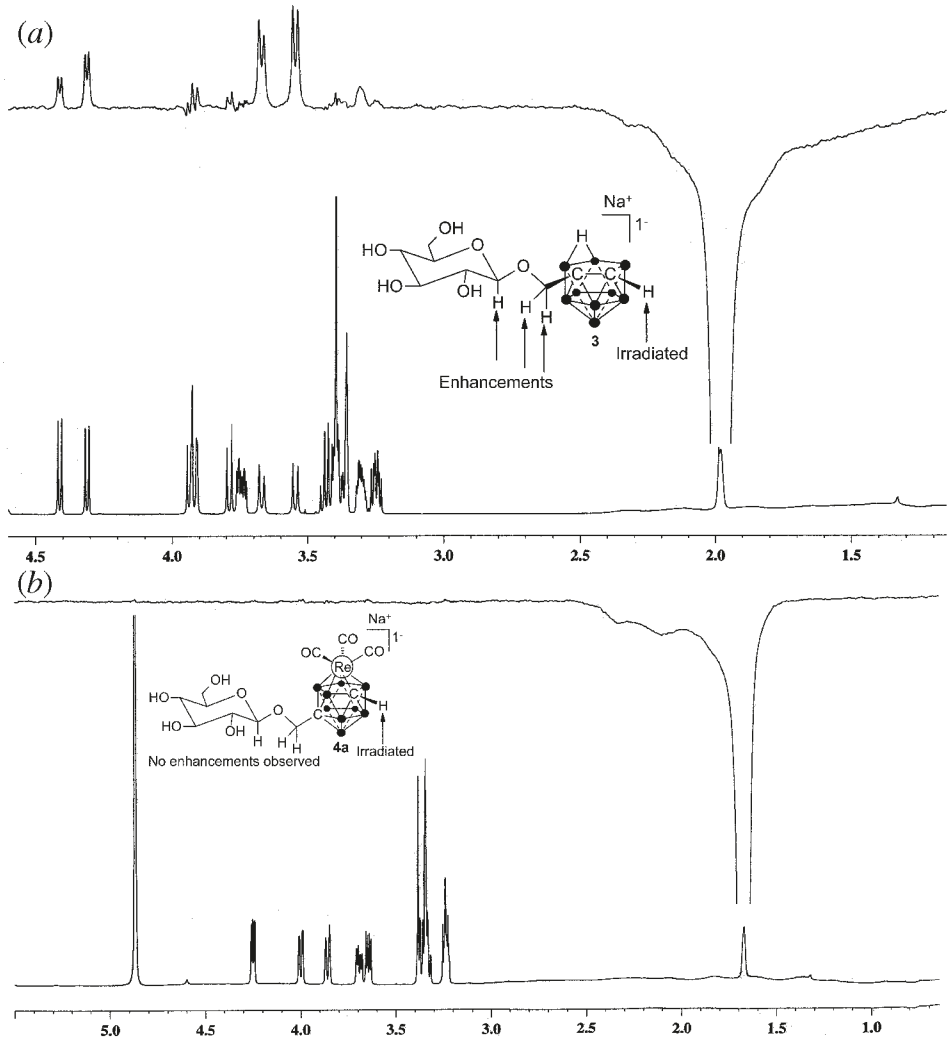
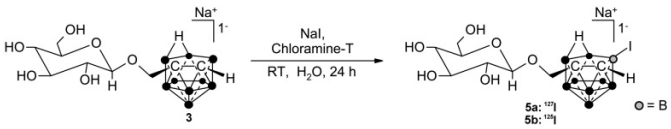
Fig. 1. ^{1}H NMR and ^{1}H nOe spectra for (top) **3** and (bottom) **4a** (600 MHz, CD_3OD).



During our investigations of the microwave-assisted synthesis of Re and Tc metallocarboranes, it was discovered that rearrangement of the cluster occurs when sterically demanding and (or) electron withdrawing ligands are present on the carbon atoms of the carborane cage (13, 14). In the absence of an X-ray structure, ^{1}H nOe experiments can be used to determine whether or not isomerization occurred. The nOe spectra for **4a** when compared to compound **3** suggested that the metallocarboranyl glycoside had in fact isomerized to the 2,1,8-ReC_2B_9-cage configuration (Fig. 1) in which the larger group migrates away from the bonding face. The migration of the C-atoms apart increases the thermodynamic stability of the cluster and it reduces steric interactions between the "large" carbohydrate substituent and the metal tricarbonyl core.

The nonradioactive iodinated carboranyl glycosides **5a** and **5b** were prepared using methods similar to those reported by Wilbur and co-workers (20, 21) (Scheme 4). Compound **3** was treated with NaI and chloramine-T and the reaction was allowed to stir for 24 h prior to quenching with $Na_2S_2O_5$. The target compound was isolated in 21% overall yield following semipreparative HPLC, which was necessary to separate a small amount of unreacted starting material

Scheme 4. Synthesis of **5**.



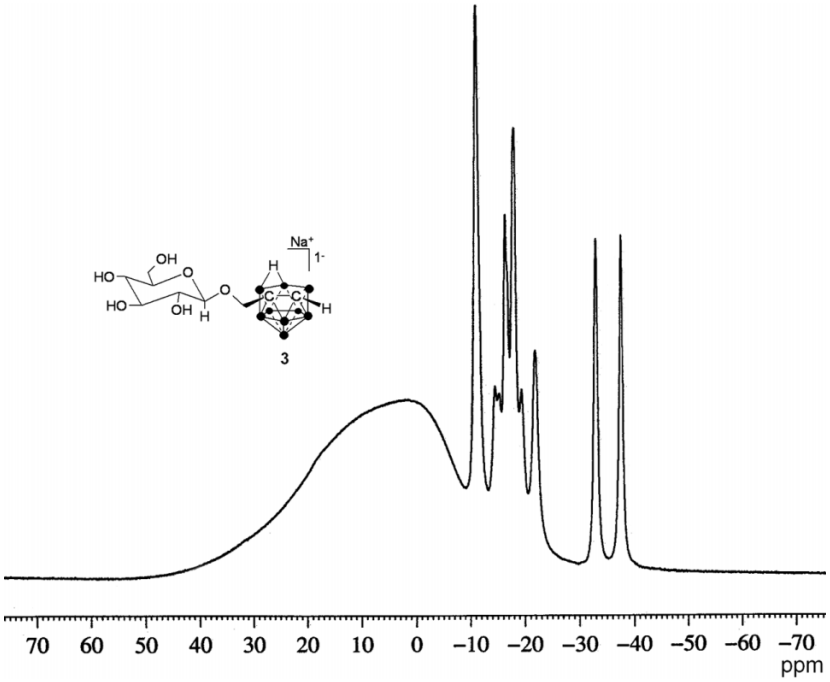
from the product (**3** and **5a** were not separable by normal-phase chromatography). Electrospray mass spectrometry gave the target anion mass at m/z = 452, with the expected isotope distribution for the B_9 cluster (43). The iodination of the *nido*-carborane in the product was readily observed in the $^{11}B\{^1H\}$ NMR spectrum in which one resonance shifted from –32.92 ppm in the spectrum of **3** to –29.56 ppm in the spectrum of **5a**, which is consistent with literature reports (44, 45).

Radiochemistry

Compound **3** was labelled with $[^{99m}Tc(CO)_3(H_2O)_3]^+$, which was generated from $^{99m}TcO_4^-$ in good yield following literature protocols (46, 47). Aliquots of the Tc(I) starting material (185–370 MBq, 5–10 mCi) were added to sealed microwave vials containing the ligand (5 μmol) in 0.5 mol/L

© 2008 NRC Canada

Fig. 2. $^{11}B\{^1H\}$ NMR spectrum of compound **3**.



NaF. The vials were then heated at 200 °C for 10 min. HPLC analysis indicated greater than 80% conversion to the desired product by comparison to the nonradioactive standards. The major radioactive byproduct was pertechnetate, which was easily separated from the desired product. It was also possible to isolate **4b** in high effective specific activity by solid-phase extraction (C_{18} SepPak®) in 58% radiochemical yield (Fig. 2).

The radiohalogenation of **3** was performed using Na[^{125}I] and chloramine-T or Iodogen® as oxidants. A series of radiolabelling experiments revealed that the use of Iodogen® resulted in greater yields in a shorter time. An additional benefit of the use of Iodogen® is that it is insoluble in water and can be introduced as a film on the inside surfaces of the reaction vessels, which simplified purification of the desired product. The synthesis of compound **5b** was successfully accomplished by adding 100 μg of the *nido*-carborane precursor (**3**) (100 μL of a 1 mg/mL solution in 5% HOAc/H_2O) to a vial coated with Iodogen®. The reaction was allowed to proceed at room temperature for 5 min, followed by quenching with a solution of sodium metabisulfite. HPLC analysis of the crude reaction mixture indicated one major product whose retention time corresponded to that of the reference standard. This product accounted for >90% of the total radioactivity. Semipreparative HPLC permitted the isolation of **5b** from precursor **3** in 29% radiochemical yield. Radiochemical purity of **5b** was greater than 99%.

Compound **4b** showed good stability to ligand challenges with 75% and 79% of the complex remaining intact following incubation at 37 °C for 18 h with l-cysteine and l-histidine, respectively. The stability of compound **5b** was excellent, with only 9% degradation being observed after 24 h in solution. The robust nature of the product, which is attributed to the strength of the B–I bond, is a particularly attractive feature of the reported system as premature loss of iodine from aryl-iodides is a significant problem with traditional iodinated radiopharmaceuticals.

Experimental[2]

General

All reagents used were purchased from Sigma-Aldrich, except for decaborane (14), which was purchased from Katchem (Czech Republic). [$Re(CO)_3(H_2O)_3$]Br was prepared by the method of Lazarova et al. (16). Solvents were purchased from Caledon. ^{99m}Tc was obtained from a ^{99}Mo/^{99m}Tc generator (Bristol-Myers-Squibb) as Na[$^{99m}TcO_4$]. No-carrier-added ^{125}I was obtained from the McMaster Nuclear Reactor as Na[^{125}I] in 0.1 N NaOH (17 Ci/mg). Microwave-assisted syntheses were performed in a Biotage Initiator 60 microwave reactor. NMR spectroscopy was performed on either a Bruker Avance DRX-500 or Avance AV-600 spectrometer. Residual ^{1}H signals from the NMR solvent and tetramethylsilane were taken as the internal reference for ^{1}H and ^{13}C spectra, respectively. ^{11}B spectra were referenced using a $BF_3{\cdot}Et_2O$ external standard. For reporting purposes, the label "*" was used to distinguish between the NMR signals arising from the two diastereomers (e.g., 7a versus 7a*). Assignments were made with the assistance of two-dimensional NMR techniques (COSY, HSQC, HMBC). A numbering scheme for the NMR assignments is provided in Scheme 2.

Infrared spectra were recorded on a BioRad FTS-40 FT-IR instrument. Mass spectra were obtained using a

Micromass Quattro-LC Triple Quadrupole mass spectrometer. Radioactivity measurements were made using a Capintec CRC-15W dose calibrator. High-performance liquid chromatography was performed with a Varian ProStar HPLC system. Radioactivity from ^{99m}Tc- and ^{125}I-labelled compounds was detected with a IN/US γ-RAM Model 3 detector. For analysis of compounds, either a Varian Nucleosil 4.6 mm × 250 mm C_{18} or Phenomenex Gemini 4.6 mm × 100 mm C_{18} column was used. For semipreparative HPLC, a Varian Dynamax 10 mm × 250 mm C_{18} column was used. Elution conditions: Method A: 80:20 A/B to 54:46 A/B, 0–20 min; 54:46 A/B to 100% B, 20–25 min; 100% B, 25–30 min (A = H_2O, B = CH_3CN); Nucleosil column; Method B: 80:20 A/B to 20:80 A/B, 0–20 min; 20:80 A/B to 100% B, 20–25 min; 100% B, 25–30 min (A = H_2O containing 0.05% TFA, B = CH_3CN containing 0.05% TFA); Nucleosil column; Method C: 80:20 A/B to 20:80 A/B, 0–20 min; 20:80 A/B to 100% B, 20–25 min; 100% B, 25–30 min (A = H_2O containing 0.05% TFA, B = CH_3CN containing 0.05% TFA); Gemini column. Analytical flow rate was 1.0 mL/min; semipreparative flow rate was 4.7 mL/min. Thin layer chromatograms (Merck F_{254} silica gel on aluminum plates) were visualized using 0.1% $PdCl_2$ in 3 mol/L HCl.

Sodium [7-methyl-(β-D-glucopyranosyloxy)-7,8-dicarba-nido-undecaborate] (3)

1,2-Dicarba-*closo*-dodecaboran-1-yl-methyl-2,3,4,6-tetra-O-acetyl-β-D-glucopyranoside (2.02 g, 4.02 mmol) and NaOH (3.20g, 80 mmol) were dissolved in absolute ethanol (20 mL) and the resulting solution was stirred at reflux overnight (~12 h). The reaction was cooled to room temperature and the excess NaOH was precipitated as Na_2CO_3 by passing a stream of CO_2 gas through the solution. The solid was removed by filtration and the residue washed with cold ethanol (20 mL). The solution was then concentrated under reduced pressure, yielding a white solid. The solid was dissolved in distilled water, and the solution adjusted to pH 4 by dropwise addition of 1 mol/L HCl. Isolation of the product was achieved using silica gel column chromatography (1:3 MeOH/CH_2Cl_2). The product fractions were concentrated by rotary evaporation giving white foam. Yield: 0.88 g (63%). TLC (1:3 CH_3OH/CH_2Cl_2): R_f = 0.34. HPLC: t_R = 9.7 min (Method B); 9.0 min (Method C). IR (KBr, cm^{-1}) ν: 3409, 2526. ^{1}H NMR (CD_3OD) δ: 4.46, 4.36 (d, 2H, J = 7.8 Hz, H-1,1*), 3.97 (m, 3H, H-7a, H-6a, 6a*), 3.82 (m, 3H, H-7a*, H-6b, 6b*), 3.72 (d, 1H, J = –10.7 Hz, H-7b*), 3.60 (d, 1H, J = –11.0 Hz, H-7b), 3.46 (m, 4H, H-3,3*, H-4,4*), 3.36 (m, 2H, H-5,5*), 3.01 (m, 2H, H-2,2*), 2.02 (br s, 2H, H-9,9*), 2.50 to –0.30 (br, B-H), –2.63 (B-H-B). ^{13}C NMR (CD_3OD) δ: 103.3, 102.9, 78.4, 78.0, 77.9, 77.7, 77.6, 75.1, 71.5, 62.5, 59.0, 47.80 45.9, 43.8. ^{11}B{^{1}H} NMR (CD_3OD) δ: –10.9, –14.5, –15.2, –16.3, –17.9, –19.3, –21.8, –32.9, –37.5. Sodium [8-Methyl(β-D-glucopyranosyloxy)-2,2,2-tricarbonyl-2-rhenium-1,8-dicarba-closo-dodecaborate] (4a)

Compound **3** (0.066 g, 0.19 mmol) and $[Re(CO)_3(H_2O)_3]Br$ (0.17 g, 0.42 mmol) were placed in a microwave reaction vial (2–5 mL) and dissolved in a phosphate buffer (pH 7.2) containing 0.5 mol/L NaF (2.2 mL). An aluminum cap containing a Teflon septum was attached to the vial and sealed by crimping. The reaction vessel was heated in the Biotage Initiator Sixty reactor for 10 min at 200 °C, after which the vial was uncapped and a further 0.12 g (mmol) of the rhenium reagent was added. The vial was sealed again and irradiated for a further 10 min at 200 °C, resulting in the formation of a clear yellow solution. The aqueous solution was diluted with acetonitrile and concentrated to dryness by rotary evaporation. The residue was extracted into methanol, and the target compound isolated by silica gel column chromatography (10%–15% MeOH/CH_2Cl_2). Further purification was accomplished using a C_{18} SepPak® cartridge (Waters), giving the target compound in 31% yield (0.037 g). TLC (1:4 MeOH/CH_2Cl_2): R_f = 0.45. HPLC: t_R = 19.8 min (Method A). ^{1}H NMR (CD_3OD) δ: 4.25 (d, 2H, J = 7.8 Hz, H-1,1*), 4.00 (d, 2H, J = –10.7 Hz, H-7a,7a*), 3.86 (m, 2H, H-6a, 6a*), 3.69 (m, 2H, H-6b,6b*), 3.64 (m, 2H, H-7b,7b*), 3.35 (m, 4H, H-3,3*,4,4*), 3.24 (m, 4H, H-2,2*,5,5*), 1.67 (br s, 2H, H-9,9*), 3.10–0.90 (br m, B-H). ^{13}C NMR (CD_3OD) δ: 200.4, 104.3, 77.9, 76.7, 75.2, 71.4, 62.5, 53.8, 29.6. ^{11}B{^{1}H} NMR (CD_3OD) δ: –6.4, –8.2, –9.4, –12.2, –18.9, –20.1. IR (KBr, cm^{-1}) ν: 3414, 2544, 2002, 1907. HR-MS (ESI): calcd. for $C_{12}H_{23}B_9O_9Re$: 595.1794; found: 595.1776.

Sodium [7-(methyl-β-D-glucopyranosyl)-iodo-7,8-dicarba-nido-undecaborate(-1)] (5a)

Compound **3** (0.093 g, 0.27 mmol) and NaI (0.048 g, 0.32 mmol) were dissolved in 5 mL of distilled H_2O to which was added chloramine-T (0.13 g, 0.57 mmol). The resulting mixture was stirred for 24 h at room temperature. The solution was filtered to remove the white precipitate that had formed, then concentrated to dryness by rotary evaporation. The residue was dissolved in a mixture of water and acetonitrile (80:20 H_2O/CH_3CN), and the target compound isolated by semipreparative HPLC (Dynamax C_{18} 10 × 250 mm column, elution method A). Yield: 0.027 g (21%). TLC (1:4 CH_3OH/CH_2Cl_2 + 0.1% HOAc): R_f = 0.35. HPLC: t_R = 12.2 min (Method C). ^{1}H NMR (600 MHz, CD_3OD) δ : 4.42 (m, 1H, H-1), 4.38 (m, 1H, H-1*), 3.98 (m, 3H, H-6a,6a*,7a), 3.83 (d, 1H, J = –10.9 Hz, H-7a*), 3.80 (m, 3H, H-6b,6b*,7b*), 3.70 (m, 1H, H-7b), 3.48 (m, 5H, H-3,3*,4,4*, 5 or 5*), 3.36 (m, 1H, H-5 or 5*), 3.29 (m, 2H, H-2,2*), 2.56 (br s, 2H, H-9,9*), 2.60–0.10 (br m, B-H), –2.74 (br s, B-H-B). ^{13}C NMR (151 MHz, CD_3OD) δ: 103.8, 102.0, 78.3, 77.8, 77.5, 77.4, 76.9, 75.0, 74.9, 71.3, 62.4, 62.2, 56.2, 53.3, 49.8. ^{11}B{^{1}H} NMR (192 MHz, CD_3OD) δ: –6.2, –15.8, –18.1, –21.4, –24.7, –29.6, –37.3. IR (KBr) ν: 3417, 2540 cm^{-1}. HR-MS (ESI^-): calcd. for $C_9H_{23}B_9O_6I$: 452.1421; found: 452.1438.

Radiochemistry

Caution: ^{99m}Tc and ^{125}I are radioactive and should only be handled in an appropriately equipped and licensed facility.

Synthesis of 4b

A solution of the *nido*-carborane ligand **3** in 0.5 mol/L NaF (0.5 mL) was transferred to an Emry microwave vial (0.5–2 mL) and sealed. A solution (0.5 mL) of $[^{99m}Tc(CO)_3(H_2O)_3]^+$ (typically 185–370 MBq, 5–10 mCi) prepared following literature methods was added through the

© 2008 NRC Canada

septum via syringe, and the vial heated for 5–10 min at 200 °C in an Initiator microwave reactor. After cooling, the product solution was taken up in a syringe and loaded onto a C_{18} Environmental SepPak Plus™ cartridge (Waters). Conditioning: (*i*) EtOH, 10 mL; (*ii*) CH_3CN, 10 mL; (*iii*) 1:1 CH_3CN/0.1 mol/L HCl, 10 mL; (*iv*) 0.1 mol/L HCl, 10 mL. Elution: (*i*) 0.1 mol/L HCl, 7 mL; (*ii*) 4:1 0.1 mol/L HCl/CH_3CN, 4 mL; (*iii*) 1:1 0.1 mol/L HCl/CH_3CN, 4 mL; (*iv*) 1:4 0.1 mol/L HCl/CH_3CN, 4mL; (*v*) CH_3CN, 5 mL. Yield: 58% (decay corrected). HPLC: t_R = 19.9 min (Method A).

Synthesis of 5b

To a 2 mL reaction vial filmed with 20 μg of Iodogen® was added 100 μL of a solution containing **3** (1.0 mg/mL in 5% aqueous acetic acid). To this was added Na[^{125}I] (0.74–5.6 MBq, 20–150 μCi) in 0.1 N NaOH. The vials were stirred for 5 min before the addition of 10 μL 0.1 mol/L $Na_2S_2O_5$. The product was isolated via semipreparative HPLC (Method B, Dynamax 10 × 250 mm C_{18} column at 4.7 mL/min). Yield: 29%. HPLC: t_R 12.7 (Method C).

Conclusion

The work reported here demonstrates that a single carborane-based synthon can be labelled with two different classes of radionuclides providing a new type of versatility when designing molecular imaging probes and therapeutics. A method to label a hydrophilic *nido*-carboranyl glycoside derivative with both ^{99m}Tc and ^{125}I radiolabelled analogues in good radiochemical yield was developed and the products are sufficiently robust to be used in vivo. Future investigations will include the preparation of bifunctional analogues of **3** so that the reported platform can be linked to targeting vectors as a means of preparing targeted radiopharmaceuticals that can carry more than one class of radionuclides.

Effect of substituents on absorption and fluorescence properties of pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines

Bhausaheb K. Ghotekar, Muddassar A. Kazi, Madhukar N. Jachak, and Raghunath B. Toche

Abstract: A convenient route was successfully developed for the synthesis of novel heterocycles such as pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines (PPP) from pyrazolo[3,4-*b*]pyridines in good yield. The PPP derivatives synthesized were further studied for their photophysical properties, and it was observed that absorption and emission λ_{max} changed, owing to the substituent effect at 4 positions. These compounds were obtained from highly reactive starting materials, 5-aminopyrazoles and α-acetyl γ-butyrolactone.

Key words: α-acetyl γ-butyrolactone, pyrazolo[3,4-*b*]pyrrolo[2,3-*d*] pyridine, absorption, emission, fluorescence.

Résumé : On a mis au point une voie réactionnelle qui permet de réaliser la synthèse de nouveaux hétérocycles, telles les pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines (PPP) à partir de pyrazolo[3,4-*b*]pyridines, avec de bons rendements. On a soumis les dérivés PPP synthétisés à des études de leurs propriétés photophysiques et on a observé que les valeurs des λmax de leurs absorptions et de leurs émissions varient sous l'effet d'un changement dans la nature des substituants en position 4. On a obtenu ces composés à partir de produits de départ très réactifs, soit les 5-aminopyrazoles et l'α-acétyl-γ-butyrolactone.

Mots-clés : l'α-acétyl-γ-butyrolactone, pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridine, absorption, émission, fluorescence.

[Traduit par la Rédaction]

Introduction

Photoinduced intramolecular electron transfer plays a key role in the photophysics of electron-donor (D)-electron-acceptor (A) pi/π conjugated systems connected formally by a single bond. The molecular structure of their charge-transfer excited states has been the object of numerous discussions for more than twenty years. One of the best known and also widely accepted proposals for such a system is the so-called TICT (twisted intramolecular charge transfer) state model (1–3). The perpendicular geometry was questioned recently as an inherent precondition to obtain intramolecular charge transfer in such D–A systems (4, 5). For bulky π donor and acceptor systems (e.g., 9-(4-dimethylaminophenyl)-anthracene or 9,9′-bianthryl), the D–A conformation in the fluorescing charge-transfer excited state was postulated to become more coplanar than in the ground state (6). Recently, several donor and (or) acceptor substituted compounds related to carbazoles, acridines, and so forth were synthesized, and their photoinduced charge separation has been intensively studied (7–9). The 4-*N*,*N*-dimethylaminophenyl derivatives of bis-pyrazolo[3,4-*b*;4′,3′-*e*]pyridine (DMA-DMPP) and pyrazolo[3,4-*b*]quinoline (DMA-DPPQ) (Fig. 1) are further representatives of bulky π-electron donor–acceptor compounds and were recently investigated in some detail both experimentally and semi-empirically (10–16). It has been shown that pyrazoloquinoline derivatives are efficient blue emitters with absorption in the near-ultraviolet region and with a fluorescence quantum yield near to unity. Substitution with a dimethylanilino donor group results in strongly solvent-polarity-dependent fluorescence properties (11, 12). Derivatives of 3,5-dimethyl-1,7-diphenyl-bis-pyrazolo-[3,4-*b*;4′,3′-*e*]-pyridine (DMA-DMPP) with different substituents in position 4 are compounds showing intense fluorescence in the blue–green region and are considered for application as fluorescence standards and luminophores in organic light-emitting diodes (17–20). The derivatives with phenyl and 4-methoxyphenyl substituent (H-DMPP and CH_3O-DMPP, respectively) are characterized by a very intense, solvent-independent fluorescence. The nitro derivatives (NO_2-DMPP) show an unexpected photophysical behaviour. Similarly, The pyrazolopyrrolopyridines with different substituents in position 4 are compounds that show intense fluorescence in the blue–green region with a fluorescence quantum yield near to unity (Fig. 2).

Apart from this, the pyrazolo[3,4-*b*]pyridines and pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridine are examples of condensed heterocyclic compounds with notable pharmacological and biological activities, such as hypotensive (21), cytotoxic (22), and antibacterial activity (23), and found to

be potential purine antagonists (24). Analogous to bis-pyrazolo-[3,4-b;4′,3′-*e*]-pyridines and pyrazolo-[3,4-*b*]-quinolines, the substituent effect of 4 position on the fluorescence of pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridine has attracted us to synthesize this particular family of compounds. As a part of our ongoing interest in this area (25–28), we have reported the synthesis of pyrazolo[3,4-*b*]pyridines, pyrazolo-[3,4-*b*]quinolines, pyrazolonaphthyridines, and pyrazolo-pyridopyrimidines by Friedlander condensation of reactive methylene compounds with 5-aminopyrazole and synthesis of fused pyrimidines. In our recent communications (29, 30), we reported the synthesis and study of fluorescence properties of benzo[*h*]quinolines and dipyrazolo[3,4-*b*:3,4-*d*]pyridines.

In the present article, we report the study of the photophysical properties of newly synthesized pyrazolo[3,4-*b*]pyridines with 4-chloro-5-chloroethyl side chain (31, 32) and pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines. All these compounds, having large non-coplanar π-electron donor and acceptor subsystems because of sterical hindrance, are suitable objects to check the validity of the photophysical properties of these compounds.

Results and discussion

The syntheses of pyrazolo[3,4-*b*]pyridines **3** were achieved from highly reactive starting materials, 5-aminopyrazoles **1** and α-acetyl-γ-butyrolactone **2**. Compounds **3** were used as precursors for the syntheses of compounds **4**. Thus, the syntheses of pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines **4** were achieved by the reaction of compounds **3** with primary aliphatic or aromatic amines containing catalytic amount of triethylamine at 120–150 °C to furnish the desired compound **4**. All crude products that were dissolved in methanol and collected by suction filtration, washed with ethanol, and purified by using suitable solvents, afforded the title compounds **4** in about 70%–80% yield. These compounds showed the absorption and fluorescence near ultraviolet region.

The structure of compounds **3** was confirmed by IR, ^{1}H NMR, ^{13}C NMR, mass spectroscopy, and formulae confirm by elemental analysis. For example, the ^{1}H NMR spectrum of **3a** showed a singlet at δ 2.81 for methyl protons, two triplets at δ 3.39 and 3.75 corresponding to $-CH_2$ and $-CH_2Cl$ protons, respectively, and aromatic protons showed expected chemical shifts and splitting patterns. The mass spectrum of **3a** revealed a molecular ion peak *m*/*z* at 416. The ^{13}C NMR spectrum of this compound is in agreement with the structure proposed. Further, this structure was confirmed by NOE experiment; thus, on irradiation of methyl signal at δ 2.81, the compounds showed no NOE enhancement of any aromatic protons. This indicated that the methyl group present at 6 positions and not at 4, which supported the proposed structure **3**. Similarly, the structure of **4** was confirmed by spectroscopic and analytical methods, which is given in the Experimental section. The absorption and fluorescence data listed in Tables 1 and 2 showed that the incorporation of constituent on to the pyrazolo[3,4-*b*]pyridine and pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridine nucleus at 4 position has profound influence on the absorption and emission properties. It was observed that substitution at 4 position showed considerable increase in the emission wavelength, as the π-electron-donating effect of amino group increases (Scheme 1).

It was interesting to note that the pyrazolo[3,4-*b*]pyridines showed the lower absorption and emission maxima than pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines. In the pyrazolo[3,4-*b*]pyridines **3**, this might be due to a chloro group at 4 position with a weak and small electron-donor unit in para position, and in pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines **4**, the substituted amino group at 4 position with a strong and bulky electron-donor unit at para position showed higher absorption and emission maxima.

It is clearly indicated that the fluorescence property of organic compounds is the substituent-dependent property, and it is changed with changing the nature of different substituent (e.g., in compounds **3** and **4**, the nature of substituent changed the photophysical properties of these compounds). It is enhanced by substituting the strong π-electron donor group at 4 position. Compounds **3a** and **4a** showed good absorption and emission spectra as shown in Fig. 3.

Photophysical properties

From the results obtained (Tables 1 and 2), it has been found that both pyrazolo[3,4-*b*]pyridines **3** and pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines **4** show florescence properties. The compounds **4f**, **4g**, **4k**, and **4l** exhibit remarkable fluorescence characters with high relative quantum yields. It is concluded that the attachment of an electron-donating group to phenyl function oriented at the 4 position of pyrazolo[3,4-

b]pyrrolo[2,3-*d*]pyridine enhances the fluorescence properties and in turn gives high relative quantum yield.

Conclusion

The reactions reported here represent the synthesis of a new class of fluorescent compounds in which the 4 position of pyrazolopyridine ring is substituted by the chlorine or nitrogen atom with different phenyl rings. These compounds showed considerable absorption and emission λ_{max}. Pyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridines showed higher fluorescent properties than the pyrazolo[3,4-*b*]pyridines; it might be due to the steric hindrance of bulky phenyl rings and large π-electron donor group at 4 position.

Experimental

General

Melting points were determined on a Gallenkamp melting-point apparatus, Model MFB595, in open capillary tubes

and are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded on a Varian XL-300 spectrometer (300 and 75 MHz). Chemical shifts are reported in ppm from internal tetramethylsilane standard and are given in δ units. The solvents for NMR spectra was duterio-chloroform unless otherwise stated. Infrared spectra were taken on a Shimadzu IR-408 (a Shimadzu FTIR instrument) in potassium bromide pellets unless otherwise stated. UV spectra were recorded on a Shimadzu UV-1601 UV–vis Spectrophotometer. Compounds for UV scan were dissolved in methanol. Fluorescence spectra were recorded using RF-5301 PC spectrofluorophotometer. Compounds for fluorescence measurements were dissolved in chloroform. UV and fluorescence scans were recorded from 200 to 600 nm. Elemental analyses were performed on a Hosli CH-Analyzer and the results are within ± 0.4 of the theoretical percentage. HR-MS were obtained with a Mat 112 Varian Mat Bremen (70 eV) mass spectrometer. Solutions were concentrated in a rotary evaporator under reduced pressure. All reactions were monitored by TLC, carried out on 0.2 mm silica gel 60 F 254 (Merck) plates, using UV light (254 and 366 nm) for detection. Common reagent-grade chemicals are either commercially available and were used without further purification or prepared by standard literature procedures.

General procedure for the 4-chloro-5-(2-chloroethyl)-3-(4-aryl)-6-methyl-1-phenyl-1*H*-pyrazolo[3,4-*b*]pyridine (3a–3c)

A mixture of 5-aminopyrazole **1** (0.01 mol) and α-acetyl-γ-butyrolactone **2** (1.282 g, 1.078 mL 0.01 mol) was refluxed in phosphorous oxychloride (20 mL) until the end of the exothermic reaction, which usually starts about 80–90 °C. The mixture was then refluxed for further 4 h. Excess $POCl_3$ was removed under vacuum, and the oily residue solidified upon treatment with ice-water, neutralization with sodium carbonate, and stirring overnight. The separated product was then filtered, dried, and recrystallized to afford compound **3** in good yield.

*4-Chloro-5-(2-chloroethyl)-3-(4-chlorophenyl)-6-methyl-1-phenyl-1*H*-pyrazolo[3,4-b]pyridine (3a)*

Yield: 3.25 g (78%), recrystallized from acetonitrile/ethanol (8:2) to afford colourless prisms; mp 163–164 °C. IR (KBr): 2918m, 1595m, 1500s, 1257m, 1147m, 1093w, 1018w, 906w, 756m, 686w cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.81 (s, 3H, CH_3), 3.39 (t, J = 7.2 Hz, 2H, CH_2), 3.75 (t, J = 7.2 Hz, 2H, CH_2), 7.44–7.54 (m, 5H, Ar–H), 7.69 (d, J = 8.2, Hz, 2H, Ar–H), 8.26 (d, J = 8.2, Hz, 2H, Ar–H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.3, 27.5, 55.4, 115.4, 121.2, 124.6, 126.5, 128.2, 129.6, 130.5, 131.1, 134.3, 139.5, 144.8, 154.2, 156.1, 159.2. General procedure for the synthesis of 1-phenyl-8-(4-aryl)-4-methyl-6-phenyl-1,2,3,6-tetrahydropyrazolo[3,4-*b*]pyrrolo[2,3-*d*]pyridine (4a–4n)

A mixture of **3** (0.01 mol) and primary aliphatic and aromatic amines (0.04 mol) was heated at 110–120 °C for about 2 h until TLC showed no more starting material. Then, the mixture was cooled at 20 °C. After cooling, methanol (20 ml) was added, and the resulting solid was filtered by suction, washed with methanol, dried, and recrystallized from the proper solvent to afford **4** in good yield.

1-Benzyl-8-(4-chlorophenyl)-4-methyl-6-phenyl-1,2,3,6-tetrahydropyrazolo[3,4-b]pyrrolo [2,3-d]pyridine (4a)

Yield: 4.01 g (89%), recrystallized from ethanol to afford colourless prisms; mp 150–151 °C. IR (KBr): 2909m, 1744m, 1598s, 1500s, 1257m, 1147m, 1093m, 1018m, 906m, 756w, 686m cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ:

8-(4-Chlorophenyl)-1-(2-methylphenyl)-4-methyl-6-phenyl-1,2,3,6-tetrahydropyrazolo-[3,4-b]pyrrolo[2,3-d]pyridine (4f)

Yield: 3.96 g (88%), recrystallized from ethanol/DMF (8:2) to afford light green prisms; mp 220–222 °C. IR (KBr): 2918m, 1743m, 1595s, 1500s, 1257m, 1147, 1093m, 1018m, 906m, 756w, 686m cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.30 (s, 3H, Ar–CH_3), 2.61 (s, 3H, CH_3), 3.25 (t, J = 7.2 Hz, 2H, CH_2), 4.22 (t, J = 7.2 Hz, 2H, CH_2), 7.24–7.45 (m, 9H, Ar–H), 7.45 (d, J = 8.2 Hz, 2H, Ar–H), 8.35 (d, J = 8.2 Hz, 2H, Ar–H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 15.8, 18.6, 21.3, 51.8, 105.6, 113.3, 117.1, 120.2, 124.7, 126.2, 126.3, 126.6, 128.9, 129.4, 129.9, 131.2, 134.3, 139.7, 145.9, 149.1, 154.9, 157.4. Anal. calcd. for $C_{28}H_{23}ClN_4$ (450.96): C, 74.57; H, 5.14; N, 12.42. Found: C, 74.78; H, 4.96; N, 12.18.

8-(4-Chlorophenyl)-1-(4-methylphenyl)-4-methyl-6-phenyl-1,2,3,6-tetrahydropyrazolo[3,4-b]pyrrolo[2,3-d]pyridine (4g)

Yield: 3.74 g (83%), recrystallized from ethanol/DMF (8:2) to afford light green prisms; mp 229–230 °C. IR (KBr): 2918m, 1743m, 1595s, 1500s, 1257m, 1147, 1093m, 1018m, 906m, 756w, 686m cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.30 (s, 3H, Ar–CH_3), 2.60 (s, 3H, CH_3), 3.25 (t, J = 7.2 Hz, 2H, CH_2), 4.22 (t, J = 7.2 Hz, 2H, CH_2), 7.24–7.45 (m, 9H, Ar–H), 7.45 (d, J = 8.2 Hz, 2H, Ar–H), 8.35 (d, J = 8.2 Hz, 2H, Ar–H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.6, 21.5, 24.3, 51.5, 103.6, 113.4, 120.2, 124.7, 126.3, 126.8, 128.9, 129.4, 129.9, 131.2, 134.9, 139.2, 145.9, 146.4, 149.9, 154.9, 157.4. Anal. calcd. for $C_{28}H_{23}ClN_4$ (450.96): C, 74.57; H, 5.14; N, 12.42. Found: C, 74.69; H, 5.32; N 12.61.

8-(4-Bromophenyl)-1-(3-chlorophenyl)-4-methyl-6-phenyl-1,2,3,6-tetrahydropyrazolo[3,4-b]pyrrolo[2,3-d]pyridine (4h)

Yield: 3.92 g (76%), recrystallized from ethanol/DMF (6:4) to afford light brown prisms; mp 226–227 °C. IR (KBr): 2918m, 1743m, 1595s, 1500s, 1257m, 1147, 1093m, 1018m, 906m, 756w, 686m cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.59 (s, 3H CH_3), 3.28 (t, J = 7.2 Hz, 2H, CH_2), 4.87 (t, J = 7.2 Hz, 2H, CH_2), 6.22–7.55 (m, 9H, Ar–H), 8.20 (d, J = 8.2 Hz, 2H, ArH), 8.33 (d, J = 8.2 Hz, 2H, ArH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.7, 21.3, 51.5, 104.6, 111.2, 113.8, 117.3, 120.8, 123.1, 124.9, 126.2, 129.1, 129.5, 131.6, 132.2, 132.1, 135.4, 139.7, 145.9, 149.3, 150.2, 154.6, 157.6. Anal. calcd. for $C_{27}H_{20}BrClN_4$

X-ray and high-resolution ^{1}H and ^{13}C NMR of smooth muscle relaxant sesquiterpene lactones

Marie-Rose Van Calsteren, Christopher K. Jankowski, Ricardo Reyes-Chilpa, Manuel Jiménez-Estrada, Maria G. Campos, Abraham Zarazua-Lozada, Martha Oropeza, and Denis Lesage

Abstract: The structure and stereochemistry of four sesquiterpene lactones, budlein A (**1**), zaluzanin A (**2**), and glaucolides D (**3a**) and E (**3b**), isolated from Mexican *Asteraceae* species, for which only partial NMR data could be found in the literature, were determined. A combination of 1D and 2D high-resolution NMR experiments, such as DEPT, COSY, NOESY, ROESY, HMQC, HSQC, and HMBC, were used to completely assign the ^{1}H and ^{13}C spectra. The crystal structures of zaluzanin A (**2**) and glaucolide E (**3b**) were also determined. Glaucolides D and E have been previously reported to relax KCl-induced contraction in rat uterine smooth muscle; therefore, the effects of zaluzanin A and budlein A were examined in the same model. It was found that both compounds can relax contraction induced by KCl, but only zaluzanin A induced relaxation when contraction was induced with oxytocin. The preliminary biological test results according to these profiles are reported in this paper.

Key words: NMR data, X-ray data, sesquiterpene lactones, Mexican *Asteraceae*, smooth muscle relaxant.

Résumé : On a déterminé la structure et la stéréochimie de quatre lactones sesquiterpéniques, la budléine A (**1**), la zaluzanine A (**2**), et les glaucolides D (**3a**) et E (**3b**), isolées d'espèces mexicaines d'*Asteraceae*, pour lesquelles seulement des données de RMN partielles ont pu être trouvées dans la littérature. On a utilisé une combinaison d'expériences de RMN à haute résolution 1D et 2D, telles que DEPT, COSY, NOESY, ROESY, HMQC, HSQC et HMBC, pour assigner complètement les spectres de ^{1}H et ^{13}C. On a aussi déterminé la structure cristalline de la zaluzanine A (**2**) et du glaucolide E (**3b**). Précédemment, on avait rapporté que les glaucolides D et E relaxent la contraction induite par le KCl dans le muscle utérin lisse de rate; en conséquence, on a examiné les effets de la zaluzanine A et de la budléine A dans le même modèle. On a trouvé que les deux composés peuvent relaxer la contraction induite par le KCl, mais que seule la zaluzanine A induit la relaxation quand la contraction est induite avec l'ocytocine. On présente les résultats préliminaires des tests biologiques appropriés dans cet article.

Mots-clés : données de RMN, données de rayons-X, lactones sesquiterpéniques, *Asteraceae* du Mexique, relaxant du muscle lisse.

Introduction

Asteraceae species contain sesquiterpene lactones with interesting biological properties (1); however, complete structural studies and stereochemistry are needed to understand how they act. In this study, we isolated four sesquiterpenes, budlein A (**1**), zaluzanin A (**2**), as well as the glaucolides D (**3a**) and E (**3b**), for which only partial NMR data could be found in the literature (Chart 1). The studied compounds were isolated from *Asteraceae* species from Mexico. Concerning the biological properties of these compounds, it has been described that budlein A is cytotoxic against human tumor cells L-929 and Hep-2, and it also shows antimicrobial (2) and mild fungistatic properties (3). Budlein A and zaluzanin A reduced in vitro human sperm motility by 60% and 16%, respectively, 15 min after incubation, but did not affect sperm viability. These two compounds also inactivated the thiol groups on the outer membrane of sperm cells

and have been proposed as potential male contraceptives (4). Glaucolides D and E are able to relax rat smooth muscle; the latter compound proved to be more potent than the former relaxing KCl- or noradrenaline-induced contraction in aorta and KCl-induced contraction in uterus (5).

The furanoheliangolide budlein A (**1**) was obtained from *Viguiera buddleiiformis* (DC.) Hemsl. This species is a shrub 1–3 m in height with yellow flowers, purplish stems, and whitened leaves beneath. It grows on rocky canyon slopes, grassy openings among shrubs and small trees in tropical deciduous, and oak forests or xerophytic vegetation at an altitude of 1800–2500 m in the Sierra Volcánica Transversal. It is known as "cerote" in the State of Hidalgo (6–8).

The guainolide zaluzanin A (**2**) was isolated from *Zaluzania augusta* (Lag.) Sch. Bip., a perennial shrub up to 2–5 m in height with yellow flowers. It grows in the southern part of the Central Plateau of Mexico. It is locally known as "Limpia tunas" and "Caxtidán" in the State of Querétaro and "Cenicilla" in the State of México (6–8). The leaves and roots water infusion is used as an abortive by peasants of the State of Querétaro, Mexico (9). There is some ambiguity in the stereochemistry of **2** as determined by NMR (10); for this reason, a detailed analysis of ^{1}H–^{1}H was performed, and other evidence was provided by the HMBC experiment. The structure of **2** was corroborated by means of its X-ray diffraction pattern.

The glaucolides D (**3a**) and E (**3b**) were isolated from *Vernonia liatroides* DC., a perennial shrub up to 3 m in height with purple or white flowers. It grows with abundance in openings in oak and pine forest at altitudes of 1000–2300 m in the northern and central parts of Mexico. It is locally known as "Tlamalacatlacotli" and "Vara de San Miguel". In the State of Michoacan, it is a medicinal plant. A water infusion of leaves and branches is prepared as a remedy against dysentery. The mashed leaves are applied to regenerate hair. It produces abundant pollen and nectar;

therefore, it is important for local apiculture. The leaves can be consumed by cattle (11). The structure of **3b** was corroborated by means of its X-ray diffraction pattern.

We have previously reported that glaucolides D and E, sesquiterpene γ-lactones lacking an exocyclic methylene double bond, can relax rat uterine smooth muscle contraction induced by KCl; this property was attributed to the existence of alternative alkylating sites such as C_{10} provided by the germacra-1(10),4-diene-4-epoxide skeleton (5). In this work, the effects of sesquiterpene lactones bearing an exocyclic methylene double bond in the γ-lactone (budlein A) and δ-lactone (zaluzanin A) moieties were examined using the same model.

Results and discussion

Budlein A

The ^1H NMR spectrum (Table 1) of **1** showed, among others, the following signals: a pair of low-field doublets at δ 6.37 and 5.71, characteristic of a γ-lactone conjugated with an exocyclic methylene group; a doublet of triplets centered at δ 6.22 for the vinyl hydrogen H_5; a quartet of quartets at δ 6.12, a chemical shift typical of the vinyl proton of angelic acid; two complex signals centered at δ 5.38 and 5.27 (H_6 and H_8); a triplet at δ 4.41 (2H) assigned to the $–CH_2–O–$ protons of an allylic primary alcohol; a signal corresponding to H_7 (δ 3.76); signals for the vinyl methyl groups (δ 1.94 and 1.80) of the angelate ester moiety; a singlet at δ 1.49 for the C_{14} methyl group. The stereochemistry of **1** at C_6 and C_8 was established from the dihedral angles (Table 1) calculated from the coupling constants. The calculated dihedral angle of –122° at the C_6–C_7 bond indicated a β-configuration for H_6 or a *trans*-lactone closure. The configuration of the oxygen function at C_8 was found to be β-oriented, since the coupling constants between the pairs H_7–H_8, H_8–$H_{9\alpha}$, and H_8–$H_{9\beta}$ have small values. This is in agreement with the required dihedral angles (Table 1). The ROESY spectrum displayed through-space correlations be-

[a]Multiplicity: s, singlet; d, doublet; t, triplet; m, multiplet; br, broad.
[b]H_6–C_6–C_7–C_8 and H_8–C_8–C_7–C_6.
[c]H_7–C_7–C_{11}–C_{12}.

tween the following noncoupled nuclei: H_6–$H_{9\beta}$, H_7–$H_{9\alpha}$, H_8–H_{13b}, $H_{9\alpha}$–H_{14}, and $H_{9\beta}$–H_{14}. The ^{13}C NMR spectrum (Table 2) was essentially identical to that reported previously (12, 13), with some re-assignments based on direct and long-range ^{1}H–^{13}C correlations. The NMR data are in agreement with the stereochemistry deduced for goyazensolide from X-ray studies (14), this compound is the C_8 α-methacrylate epimer of budlein A.

Zaluzanin A

The ^{1}H NMR spectrum of **2** exhibited the following signals (Table 3): two low-field signals at δ 6.15 and 5.54, corresponding to geminal olefinic protons; two broad signals, a multiplet centered at δ 4.20 and a triplet at δ 3.94, attributed to protons attached to carbons bearing hydroxyl groups; a broad doublet at δ 3.15 assigned to an allylic proton; a singlet at δ 1.06 and a doublet centered at δ 0.99 ascribed to a tertiary and a secondary methyl group, respectively; three protons, which exhibit signals to lower frequency, two doublets of doublets at δ 0.86 and 0.63 and a doublet of doublets of triplets at δ 0.57, indicative of a cyclopropane ring. Important differences can be noted between the ^{1}H (Table 3) and ^{13}C (Table 2) NMR data compared with reported values (10), such as reversed assignments for H_8 and $H_{9\beta}$ as well as C_4 and C_7. Biogenetic considerations suggest that the C_7 side chain possesses a β-configuration. Therefore, O_5 involved in the six-membered lactone is also β-oriented, because it accepts a hydrogen bond from 3-OH, as indicated by the large coupling constant between H_3 and 3-OH, compared with $J_{6,6\text{-OH}}$, which shows an averaged value. The long-range couplings exhibited by H_6 to both $H_{2\alpha}$ and H_8 indicate that it possesses the β-configuration, the hydroxyl group in position 6 being α-oriented. In the HMBC spectrum, H_6 shows a long-range coupling to C_8 but not to C_{11}, a further indication of its β-orientation. The NMR data are in agreement with the stereochemistry deduced from X-ray studies of this compound (Fig. 1). Previous correlations have been done using X-ray stereodiagrams of zaluzanin B and a diacetylated dibromated derivative of zaluzanin A (10).

[a]Multiplicity: s, singlet; d, doublet; t, triplet; br, broad.

Glaucolide D

The ^{1}H NMR spectrum (Table 4) of **3a** displayed the following features: a triplet of doublets at δ 5.57 (H_2); a broad doublet at δ 5.17 re-assigned from H_8 (15) to H_1 based on a cross-peak to H_{14}; a doublet of doublets at δ 5.04 re-assigned from H_2 (15) to H_8 based on its couplings to both protons on C_9 and on a cross-peak to H_6; two doublets of doublets at δ 5.03 and 4.87 corresponding to the vinyl methylene group at C_{13} substituted with an acetoxyl function; a doublet at δ 4.76 (H_6); the 13-acetate methyl singlet at δ 2.12; two signals overlapped at δ 2.03 (H_{14} and 2-Ac CH_3); two sharp three-proton singlets at δ 1.55 and 1.37 for two tertiary methyl groups, $H_{2'\text{-Me}}$ and H_{15}, respectively. Protons belonging to the epoxymethacrylate substituent were distinguished based on chemical shifts and two- and four-bond coupling constants (16). The following correlations were observed on the NOESY and ROESY spectra: H_1–H_5, H_1–$H_{9\alpha}$, H_2–H_{15}, $H_{3\alpha}$–H_5, H_6–H_{15}, H_8–H_{14}, H_8–H_{15}. Table 2 reports the ^{13}C NMR data of this compound, which could not be found in the literature. Peaks corresponding to C_9 and C_{14} were broadened, likely due to a conformational exchange on the ^{13}C chemical-shift timescale. The stereochemistry of **3a** is not ambiguous, since it has been determined by X-ray crystallography (17).

Glaucolide E

The ^{1}H NMR spectrum (Table 5) of compound **3b** showed a number of striking similarities to that obtained for **3a**; indeed, the differences could be accounted for on the basis of a methacrylate ester instead of an epoxydized methacrylate ester at C_8: the methacrylate vinyl protons as quintets at δ 6.12 and 5.68; a triplet of doublets at δ 5.59 (H_2); a broad doublet at δ 5.18 re-assigned from H8 (15) to H_1 as for **3a**; doublets of doublets at δ 5.00 and 4.85 for the methylene protons at C_{13}, indicating the same lactone function as in **3a**; a broad doublet at δ 4.84 (H_6); methyl group signals at δ 2.08 for the 13-acetyl methyl group, at δ 2.04 for the C_{14} vinyl methyl and at δ 2.03 for the 2-acetyl methyl; a second vinyl methyl signal at δ 1.93 ($H_{2'\text{-Me}}$); a tertiary methyl singlet (δ 1.39) corresponding to the C_{15} methyl group. Essentially, the same NOEs as those found for **3a** were found on the ROESY spectrum, except that H_2–H_{14} was present and H_2–H_{15} was absent. ^{13}C NMR data for **3b** are reported here for the first time (Table 2). A broadening of the same carbon peaks as in **3a** was observed. This compound must be the precursor of **3a** and would thus have the same stereochemistry. The NMR data are in agreement with the stereochemistry deduced from X-ray studies for this compound (Fig. 2).

Effect of budlein A and zaluzanin A on smooth muscle contraction

Both budlein A (**1**) and zaluzanin A (**2**) relaxed the oxytocin-induced (20 nmol/L) contractile response in rat uterine smooth muscle; however, KCl-induced contraction was relaxed only by zaluzanin A. These data indicate that zaluzanin A, but not budlein A, might exert its relaxant effect through a mechanism related with calcium influx through voltage-operated calcium channels (18), and that both sesquiterpene lactones might have a positive effect on the phosphatidylinositol signaling pathway of the smooth muscle cell (19–21).

Experimental section

Budlein A **1** (MW = 374, $C_{20}H_{22}O_7$) was isolated from *Viguiera buddleiaeformis* as previously described (22). The leaves and stems (10 kg) were extracted twice with ethanol. After evaporating the solvent, an oily residue was obtained,

which was dissolved in hot benzene and subjected to column chromatography (alumina). Fractions eluted with $CHCl_3$–acetone (9:1) were concentrated, obtaining an amorphous residue. Recrystallization from acetone – isopropylic ether yielded **1** (3.65 g, mp 106–108 °C).

Zaluzanin A **2** (MW = 264, $C_{15}H_{20}O_4$) was isolated from *Zaluzania augusta* as previously described (23). The aerial parts (1 kg) were extracted twice with ethanol (6 L, 20 h) under reflux. The volume was reduced to 2 L and treated with lead acetate aqueous solution (20 g/2 L) for 2 h at room temperature. The extract was filtrated through Celite and then partitioned with chloroform. The organic layer was concentrated, dissolved in benzene, and subjected to column chromatography (alumina). Fractions eluted with chloroform and ethyl acetate yielded a solid, which was recrystallized with acetone – diethyl ether and then with methanol, obtaining **2** as white crystals (1.2 g, mp 265 °C). X-ray: orthorhombic, space group $P2_12_12_1$, a = 6.7277(5) Å, b = 10.0202(7) Å, c = 19.5724(13) Å, V = 1319.45(16) Å^3, T = 291(2) K, Z = 4, $D_{calcd.}$ = 1.331 g/cm^3, $F(000)$ = 568, λ = 0.71073 Å, μ = 0.095 mm^{-1}, crystal size 0.34 mm × 0.23 mm × 0.16 mm. A total of 10770 reflections were collected for 2.08° < θ < 25.00° and $-8 \le h \le 7$, $-11 \le k \le 11$, $-23 \le l \le 23$. 2312 reflections with $I > 2\sigma(I)$ were used in the refinement. The final R indices were R_1 = 0.0357 and wR_2 = 0.0886 and R indices (all data): R_1 = 0.0401, wR_2 = 0.0906.

Glaucolide D **3a** (MW = 464, $C_{23}H_{28}O_{10}$) and glaucolide E **3b** (MW = 448, $C_{23}H_{28}O_9$) were obtained as previously described from the aerial parts of *Vernonia liatroides* (24). The dried plant material (3 kg) was extracted with hot methanol; while concentrating the extract, **3a** precipitated as a white amorphous solid (mp 186–188 °C). The methanol extract was then partitioned with hexane and $CHCl_3$. This last fraction was subjected to column chromatography (silica gel). Fractions eluted with hexane–EtOAc (6:4) afforded **3b** as white crystals (mp 149–150 °C) from acetone–hexane. X-ray: monoclinic, space group $P2_1$, a = 10.6585(8) Å, b = 8.2373(7) Å, c = 13.2507(11) Å, β = 90.334(2)°, V = 1163.36(16) Å^3, T = 291(2) K, Z = 2, $D_{calcd.}$ = 1.280 g/cm^3, $F(000)$ = 476, λ = 0.710 73 Å, μ = 0.099 mm^{-1}, crystal size 0.46 mm × 0.18 mm × 0.15 mm. A total of 9537 reflections were collected for 1.91° < θ < 25.00° and $-12 \le h \le 12$, $-9 \le k \le 9$, $-15 \le l \le 15$. 4070 reflections with $I > 2\sigma(I)$ were used in the refinement. The final R indices were R_1 = 0.0430 and

wR_2 = 0.0859 and R indices (all data): R_1 = 0.0563, wR_2 = 0.0901.

X-ray crystallography[2]

Data were collected on a Bruker Smart APEX AXS CCD area-detector diffractometer. No absorption correction was applied. The structures were solved by direct methods using SHELXS-97 and refined by full-matrix least squares. All non–hydrogen atoms were refined with anisotropic displacement parameters, the hydrogen atoms coordinates were estimated in riding mode.

NMR spectroscopy

The compounds were dissolved in $CDCl_3$, and TMS was used as an internal standard. High-resolution ^1H (300.3 MHz) and ^{13}C (75.5 MHz) NMR spectra were acquired at 25 °C on a Chemagnetics Infinity 300 spectrometer using a Nalorac *z*-gradient 5 mm inverse broadband $^1H\{^{15}N–^{31}P\}$ probe. A combination of 1D and 2D high-resolution NMR experiments were used to assign the ^1H and ^{13}C spectra. Connectivities between protons were obtained using 2D gradient-selected COSY (25). The 2D phase-sensitive NOESY (26) and ROESY (27) experiments were performed with a mixing time of 600 ms. The 1D ^{13}C NMR spectra were recorded with WALTZ proton decoupling (28). The multiplicity of the carbon signals was established using the 1D DEPT experiment (29) with a reading pulse of 135° and an evolution time of 3.5 ms. The 2D gradient-selected magnitude HMQC (30) and phase-sensitive HSQC (31) spectra were acquired with 3.5 and 1.7 ms evolution times, respectively, and MPF9 (32) carbon decoupling during acquisition. The 2D gradient-selected magnitude HMBC (33) was run without carbon decoupling with one-bond and long-range evolution times of 3.5 and 80 ms, respectively. Accurate ^1H chemical shifts and coupling constants were obtained by spectral simulation using the program gNMR from IvorySoft. Conformations were estimated from three-bond vicinal $^1H–^1H$ coupling constants and substituent electronegativities (34), from four-bond long-range $^1H–^1H$ coupling constants (35), and from three- and four-bond vinyl–allylic $^1H–^1H$ coupling constants (36), taking signs into account.

Molecular modeling

Geometry optimization was performed with the program HyperChem 7.03 Professional from Hypercube using the force field Hyper MM+, starting from the modified crystal structure of goyazenzolide A (14) for **1** and from a built structure for **2**.

Uterine smooth muscle assays

Relaxant activity of budlein A and zaluzanin A was evaluated on the contractile response to 60 mmol/L KCl and oxytocin (20 nmol/L) as previously described (5).

Control of DNA incorporation into nanoparticles with poly(L-lysine) multilayers

Annie C. Dorris, Kimberly L. Douglas, Maryam Tabrizian, and Christopher J. Barrett

Abstract: Nanoparticles coated with DNA and poly(L-lysine) (PLL) were prepared using a layer-by-layer assembly technique under various solution conditions. Both the level of DNA loading into the materials, the rate and the extent of DNA released from films upon degradation were controlled by varying the pH of polyelectrolyte assembly solutions. To determine optimal conditions for DNA loading, analogous films assembled on flat surfaces were prepared under various pH conditions. Using UV–vis spectroscopy and thin-film ellipsometry, it was found that the extent of DNA incorporation could be varied by more than a factor of two, and that the highest loading was obtained for films built using a combination of DNA and poly(L-lysine) solutions of pH = 4 and pH = 7, respectively. The layers coated onto the silica nanoparticles permitted the surface charge to be characterized by zeta potential electrophoresis. Furthermore, the acid–base dissociation constant measured for PLL on the outermost layer of the DNA/PLL film showed that the pK_a of PLL can be shifted by more than three units. Film degradability was investigated via the exposure of films assembled under different pH conditions to α-chymotrypsin. The fraction of DNA released from degraded films can also be increased by a factor of three when films are built under conditions of pH = 4 for the DNA solution. The resultant effect on the transfection ability of pEGFP-N1/PLL coated particles was then measured, and results suggest that the control achieved over the bulk film properties also extends to a strong influence on cell uptake and transfection.

Key words: polyelectrolyte multilayer, DNA incorporation, enzymatic degradation, nanoparticles, gene therapy.

Résumé : Des nanoparticules enrobées d'ADN et de poly(L-lysine) ont été preparées sous différentes conditions par la technique d'assemblage de multicouches. Le degré d'incorporation d'ADN dans le matériau ainsi que la vitesse et la quantité d'ADN libérée du film, préalablement soumis à une degradation enzymatique, peuvent être contrôlés par la variation du pH des solutions de polyélectrolytes utilisés lors de l'assemblage. Des films analogues assemblés sur des surfaces planes ont aussi été préparés sous des combinaisons de pH différentes afin de caractériser par ellipsométrie et spectroscopie UV–vis les conditions d'incorporation d'ADN optimales. Il a été démontré que l'incorporation d'ADN peut être multilplié par un facteur supérieur à deux et que son incorporation est maximale lorsque l'assemblage d'ADN et de poly(L-lysine) s'effectue à des pH respectifs de 4 et 7. Afin de permettre la caractérisation des charges de surface par electrophorèse du potentiel zeta, des multicouches ont été deposées sur des nanoparticules de silica. La mesure de la constante de dissociation acide-base du poly(L-lysine), formant la couche terminale des films d'ADN/poly(L-lysine), a démontrée que la valeur de pKa du polymère peut varier de trois unités. L'étude de dégradation des films par l'enzyme α-chymotrypsin a aussi demontrée que la fraction d'ADN libérée des films peut être augmentée d'un facteur de trois lorsque les films sont construits à partir de la solution d'ADN à pH 4. Finalement, les résultats de l'étude sur la capacité de transfection des particules enrobées de pEGFP/poly(L-lysine) suggèrent que le contrôle obtenu sur les propriétés du film d'origine influence fortement l'ingestion cellulaire et la transfection.

Mots-clés : multicouches de polyélectrolytes, incorporation d'ADN, dégradation enzymatique, nanoparticles, thérapie génique.

Introduction

Gene delivery systems based on polymer nanoparticles have received much recent attention due to improved therapeutic gene transfection and the potential to tune properties chemically. Inter-polyelectrolyte complexes (IPECs) formed between DNA and polycations, such as PEI (1), poly(L-lysine) (PLL) (2), and chitosan (3), are now widely used as

simple and effective vectors for the delivery of DNA into cells. In recent years, the use of polyelectrolyte multilayers (PEMs) in many biomedical applications has generated great interest, in particular as drug delivery systems, as they offer more precise control over structure and release properties (4). Layer-by-layer (l-b-l) deposition method is especially convenient for incorporating natural polymers into thin films and nanostructures. This self-assembly technique relies on the sequential adsorption of oppositely charged polymers onto a charged substrate or particle (5); film thickness, layer interpenetration, and water content can be tailored quite precisely by varying several parameters, such as the number of adsorption cycles, the pH, and the ionic strength of the assembly baths. The method allows for gentle ionic adhesion permitting subsequent facile release and good retention of the desired biological activity.

Most recently, the incorporation of DNA into multilayered films has been achieved (4, 6–18), and has been successfully applied to both targeted release (9, 10, 12) and as sensor devices (6, 7). Trubetskoy et al. in particular have reported coating poly(L-lysine) (PLL) and succinylated PLL on a condensed DNA core using the l-b-l method (13). Following their demonstration that these layered structures could be used as non-viral gene delivery vectors, several groups performed further studies on these potential vectors (10, 14, 19–22). Since DNA transport across the cell membrane is a fundamental requirement for successful gene delivery, localized delivery and controlled released of DNA incorporated into PLL multilayered films have been one of the most investigated systems (9, 10). Viral vehicles have also been used previously to carry DNA, but these approaches suffer limitations, such as high cost, toxicity, potential infection, and limited DNA carrying capacity, leading to interest in the development of non-viral gene vectors. Cationic polymers including PEI and PLL appear most promising because they can transport DNA efficiently across the cell membrane (2, 23–26). PLL especially has the significant advantage of offering the possibility of covalently attaching target ligands to the polymer backbone so that receptor-mediated uptake can be localized. In addition to the complex formation between DNA and the polycation, the layer-by-layer fabrication procedure offers a good way to incorporate the material in a controlled fashion by varying assembly parameters, such as the pH, the ionic strength, and the number of polymer layers. Lynn and co-workers were the first to study the sustained release of functional DNA from multilayered polyelectrolytes assemblies (15), and to enhance the localized transfection of cells in contact with the DNA multilayered film (4).

A key feature of these films is their variable composition, which influences the final transfection efficiency, the most crucial requirement for a system to be competitive. The ability of a gene to be transfected depends both on the shape and the size of the gene carrier, as well as its capacity to carry a significant amount of DNA to target cells. In addition to the degree of loading, two other factors can also be important to overall transfection efficiency: the conformation and density of the polyelectrolyte in the assembly (related to the water content) and its acid–base equilibria (surface charge). Both of these effects have been studied previously and extensively by our group with synthetic polyelectrolytes (27–31). By varying the l-b-l assembly pH (and to a lesser extent the ionic strength), good control over both morphology and charge could be achieved. Fluctuations by more than two units in the pK_a of weak-acid and weak-base functional groups can also result from pH variations. It is of great interest then to investigate whether it is possible to extend this pH control of parameters to DNA to optimize DNA loading conditions. Salt effects have been investigated previously by Nguyen (32), who studied the adsorption of supercoiled DNA to a natural organic matter-coated silica surface, and by Zhou and co-workers, who studied the extent of DNA incorporation in PLL/DNA films under the influence of different ionic strength assembly solutions (10). They have identified ionic strength conditions that favoured DNA incorporation but they did not investigate the effect of pH of the assembly, which has been shown to play a key role in DNA/dye film formation, and represents a more powerful parameter tool for tuning properties (33). Binding interactions between a cationic polymer and DNA are influenced by the degree of ionization of polyelectrolytes, molecular weight, and type of cationic polymer used; thus, it should be possible to control the degree of ionization of weak polyelectrolytes by varying the pH of the solution. Several groups have reported a pH influence on the formation of polycation/DNA complexes (34, 35), where they observed that under certain pH conditions polyelectrolyte affinities were greater and more favourable to complex stability.

Poly(L-lysine) is a weak polycation with an amino group on each lysine residue. In the pH range where amino groups are protonated (pK_a = 10.5–10.7), these functional groups can undergo strong ionic interaction with DNA. In dilute aqueous solution, PLL can adopt one of three significantly different conformations, depending on pH and temperature (36). Even though below its pK_a, PLL behaves as a random coil at room temperature; it has been found that when PLL is adsorbed on a surface the polymer can adopt a β-sheet structure (37). In this paper, we study the degree of DNA incorporation into PLL/DNA multilayered films submitted to different pH assembly solutions. As necessary for film characterization, such as the extent of polymer adsorption upon exposure to different ionic strength and pH conditions, analogous films were first coated on flat surfaces of silicon with an oxide layer. Multilayered films were then coated on nanoparticles (NPs) of silica from which surface charge analysis could be performed directly over an extended pH range. Degradation of films with different polyelectrolyte composition was then studied, and finally, the resultant transfection properties of films coated on silica nanoparticles were measured, demonstrating how the pH control of physico-chemical properties can be extended to control transfection efficiency by more than a factor of two.

Materials and methods

Materials

Poly(L-lysine) hydrobromide (MW 70 000–90 000) and salmon testes DNA (MW 1 300 000) were purchased from Sigma. MES and TRIS used to prepare buffer solutions, and α-chymotrypsin (from bovine pancreas 60 U/mg) were also obtained from Sigma. Plasmid DNA (pEGPF-N1) was provided by Clontech. Milli-Q water of 18.2 MΩ resistivity was

© 2008 NRC Canada

prepared with a Millipore MiliQ purification system. Silica nanoparticles (Snowtex-zl, 40 wt) with a diameter ranging between 70 and 100 nm were provided by Nissan chemical as a suspension in water.

Preparation of DNA/PLL multilayer films assembled on flat surfaces

Alternate layers of PLL and DNA were assembled onto silicon wafers (Wafernet Inc.) and quartz slides (Canadawide Scientific). Prior to their use, both substrates were first immersed for 30 min in a boiling piranha solution (sulfuric acid – hydrogen peroxide mixture, 1:3 ratio) and then rinsed with large amounts of Milli-Q water. The first layer of PLL was adsorbed onto the two substrates by dipping them for 20 min in a 1 mg/mL PLL solution at fixed pH and ionic strength. Then, the substrates were rinsed for 2 min in two consecutive water baths, whose pH and ionic strength were adjusted to those of the PLL solution. Dipping the substrate in a 1 mg/mL DNA solution allowed the formation of the DNA layer onto the pre-adsorbed PLL layer. Substrates were rinsed two times in water, and the whole deposition process was repeated until the desired number of layers was reached. Films were then rinsed with Milli-Q water and dried under a stream of argon gas. Citric acid (25 mmol/L, pH 4), MES (25 mmol/L, pH 5.5), MES/TRIS (25 mmol/L, 25 mmol/L, pH 7), and TRIS (25 mmol/L, pH 9) buffers were used to adjust pH of solutions. Ionic strength of all solutions was adjusted with NaCl. Ionic contribution of buffers to ionic strength was considered in the calculations.

Film characterization

Film thickness was measured using a Gaertner ellipsometer at 633 nm, and the absorbance of DNA incorporated into films was monitored by means of a UV–vis spectrophotometer (Varian) at the DNA characteristic absorbance wavelength of 260 nm. Both techniques were used to investigate the influence of pH conditions on DNA loading into films. Each reported value was the average of 20 measurements taken at various points on over the film.

Preparation of coated silica nanoparticles

Positively charged silica nanoparticles (0.25 g of suspension) were exposed to 20 ml of 1mg/mL PLL (pH 7, containing 0.1 mol/L NaCl) solution for 1 h. Sonication was performed on particles during the adsorption process. Suspensions were then centrifuged, rinsed twice with water, and re-dispersed in a minimal amount of water. Afterwards, a 20 mL aliquot of 1 mg/mL DNA solution (pH 7, 0.1 mol/L NaCl) was added to the suspension. The mixture was sonicated for 1 h, centrifuged, and washed. The PLL and DNA adsorption steps were repeated until the desired numbers of layers were coated on the particles.

Nanoparticle characterization

Layer adsorption was monitored using zeta potential electrophoresis (Zeta Plus, Brookhaven Instrument Corporation). A small sample of suspension (1 ml) was used for characterization. Samples were redispersed in aqueous solution of different pHs and ionic strengths. Dissociation constants of this particular system were determined by plotting the zeta potential of particles over a wide pH interval.

Film degradation

Enzymatic degradation of PLL/DNA multilayered films was monitored during the hydrolysis of poly(L-lysine) with the endopeptidase α-chymotrypsin. Selected multilayers were exposed to 5 U/mL enzyme solution under physiological pH (50 mmol/L TRIS, pH 7.4) at 37 °C. As controls, films of PLL and DNA were incubated in TRIS buffer alone. At pre-determined times, films were removed from these solutions, rinsed, and dried for analysis. Absorbance of the films on quartz surfaces was recorded with UV spectrophotometry, and the thickness of films deposited on silicon was measured by ellipsometry.

In vitro transfection

Three types of DNA carrier were assembled for transfection studies. Four layers of PEGFP-1 (plasmid DNA) and PLL were coated on silica nanoparticles (snowtex-zl) using the same layer-by-layer technique described previously, but with smaller aliquots of 200 μL, so that vortex mixing and microcentrifugation replaced the sonication and centrifugation steps, respectively. Particle suspensions (50 μg/mL) were prepared from DNA solutions (0.125 mg/mL) at pH values of 4, 7, and 9, while the pH of PLL (0.1 mg/mL) solution was fixed to pH = 7. The ionic strength of the assembly solutions was kept low, and autoclaved water was used for solution preparation. The ρEGFP-N1 plasmid (Clontech, Inc.) encoding for green fluorescent protein (GFP) was used to monitor gene transfer and transgene expression after transfection. The plasmid was amplified and isolated using the Plasmid Maxi Kit (QIAGEN). The concentration of the plasmid was measured by UV absorption at 260 nm and the purity was determined using agarose gel eletrophoresis following linearization using an appropriate enzyme. COS7 cells, African green-monkey kidney cells, were cultured in DMEM (Gibco) supplemented with 10% (*v*/*v*) FBS (ATCC) and 1% penicillin/streptomycin (Gibco) at 37 °C in a humidified 5% CO_2 atmosphere. Cells were sub-cultured prior to confluence using trypsin–EDTA. Cells were seeded in 12-well plates at a density of 6×10^4 cells/well 18 h prior to transfection in DMEM/10% FBS. For transfection, the culture medium was replaced with 600 μL serum-free medium containing either 4, 8, or 16 μL of PLL–pDNA coated nanoparticles. Lipofectamine™ (Invitrogen) was used as a positive control, with each well receiving 4 μL Lipofectamine™ and 1 μg pEGFP–N1. The medium was increased to 1000 μL with DMEM/10%FBS after 4 h, and completely replaced with fresh complete medium after 24 h. Transfection was assessed 72 h post-transfection using flow cytometry. Briefly, cells were removed from the wells using cold EDTA (0.6 mmol/L in PBS), transferred to FACS tubes and analyzed directly using a FACSCalibur. Appropriate controls and gates were used for analysis of the results. All experiments and protocols described here were carried out under ethics guidelines and approval of McGill University.

Results and discussion

Multilayers on flat surfaces

Before the study of DNA loading onto the NPs, analogous films were prepared on flat substrates of Si or quartz where

© 2008 NRC Canada

precise thickness and DNA density measurements could be taken. A thin native oxide layer of 1–2 nm on top of the cleaved Silicon provided a comparable surface chemistry of amorphous SiO_2 to that of the quartz and the silica NPs. Properties of DNA/PLL multilayers were studied in the pH range of 4 to 9; under these conditions, the negatively charged double helix of DNA is stable. At both pH extremes, the secondary structure of DNA can be somewhat perturbed due to base protonation; however, this process is reversible. Since DNA and PLL are oppositely charged within this pH range, it was possible to assemble multilayers of alternate polyelectrolyte layers. The ionic strength was fixed to either 1 mmol/L, 100 mmol/L, 150 mmol/L, and 500 mmol/L NaCl during the multilayer buildup to find the ionic strength conditions under which the pH will have the most pronounced effect on DNA loading.

As depicted in Figs. 1*a* and 1*b*, both the DNA incorporation (*a*) and film thickness (*b*) increase with increasing salt concentration. This phenomenon is attributed to the screening of the electrostatic repulsive forces between DNA segments by ions (16). Consequently, DNA can adopt a less rigid conformation, which in turn produced thicker layers, and further reduced repulsion at the polymer interface facilitating greater polyelectrolyte adsorption.

Similar results for DNA incorporation in multilayers have been reported by Shi and co-workers (10), and Zhou and Li (33). Salts will have the same effect on PLL, and within this salt concentration range, there is a non-uniform bonding between oppositely charged polymers, which is due to a non-cooperative and irreversible binding between poly(L-lysine) and DNA (38). At 0.5 mol/L NaCl, polyelectrolyte adsorption decreased as a result of reduced electrostatic attraction. To estimate a film's capacity to incorporate DNA (the DNA loading level), the relative ratio of DNA to PLL in the multilayers was determined. This simple ratio is an indicator of film density and is defined as the DNA absorbance per thickness. Qualitatively, this ratio provides a comparison between films built under different ionic strength and pH conditions.

Figure 2 shows that at very low salt concentrations, the variation of pH of the assembly solution has a higher impact in DNA incorporation. At higher salt concentrations, the double layer does not contribute significantly to the total potential of interaction due to charge screening by ions. Thus, the charges on polyelectrolytes will have a less significant effect in polymer interactions.

Using low ionic strength conditions, which were found to be favourable to DNA loading, the effect of pH was studied in greater detail. To determine optimal DNA incorporation, the pH of both PLL and DNA were varied. Figure 3 depicts that the best DNA loading is obtained at low pH of the DNA solution. This is because the cytosine (pK_a of 4.3) (39) and adenosine (pK_a of 3.8) (40) bases are partially protonated near pH 4 where they neutralize almost 40% of the negative charge on the DNA phosphate backbone. This can have a significant effect on DNA conformation in solution in reducing repulsion between segments, thus allowing DNA to adopt a more coiled conformation. This screening effect will increase the excluded volume of the molecule and produce thicker layers. This thickening phenomenon may also be attributed to the increase of DNA loading on PLL layers ow-

Fig. 1. PLL/DNA films (10 layers) built at different salt concentration whilst varying the pH of the DNA solution. The pH of the PLL solution was fixed to 7. (*a*) Absorbance measurements at 260 nm on a quartz substrate. (*b*) Film Thickness measurements on silica substrates via ellipsometry.

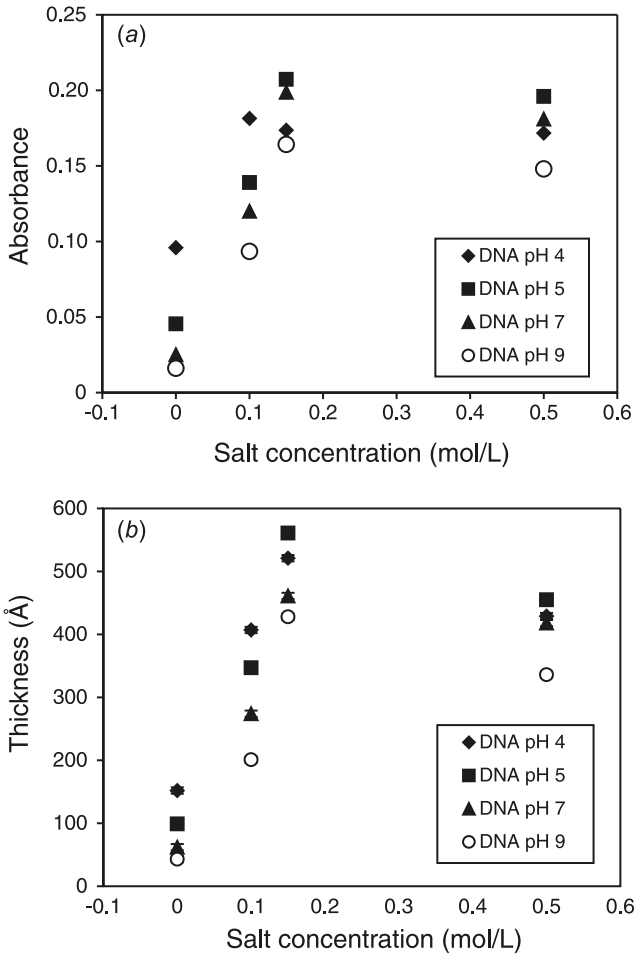

Fig. 2. Effect of DNA solution pH on the relative ratio calculated for DNA/PLL films built under different ionic strength conditions and a fixed pH of 7.

ing to charge equilibrium. Moreover, since DNA partial denaturation occurs at low pH, the absorbance increase can also arise from a hypochromic effect. At pH 9, the DNA solution DNA loading is not favoured because the guanine bases are partially deprotonated. It is likely that the creation of negative charges increases the repulsion with negatively charged phosphate groups on the backbone and reduces stability of the DNA helices.

The results presented in Fig. 3 also show that the pH of the PLL solution has a considerable effect on film composition. When the pH of the PLL solution reaches nine, twice as much DNA is incorporated into the films and film thickness is more than doubled. As the degree of protonation of PLL decreases when the pH of the solution approaches its pK_a, greater PLL adsorption is promoted by a charge equilibrium effect. The reason why DNA adsorption may also increase at pH 9 lies in the fact that when PLL is less protonated, the adsorbed weak polyelectrolyte on film surface will adopt a daisy-looped shape (41, 42), producing a rougher surface that creates more sites for DNA to adsorb and hence a greater incorporation of DNA into the films.

Fig. 4. Comparative pattern of DNA composition in films built at different pH values of assembly solution.

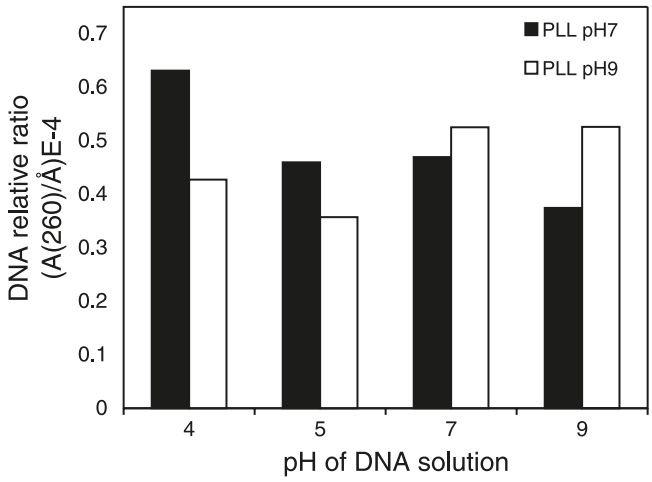

Figure 4 reveals that DNA loading is optimal when both assembly pH of PLL and DNA is low (near pH 4). Under these pH conditions, PLL is fully charged and DNA adopts a coil conformation.

Multilayers coated on silica nanoparticles

On the analogous flat surfaces, pH and salt effects were clearly shown to affect film architecture via a change in polymer conformation. Surface charge measurements could be made directly via zeta potential electrophoresis following polyelectrolyte adsorption on the surface of nanoparticles. Surface charge density on film surfaces can be affected by changes in secondary structure, intra-molecular repulsions, as well as the concentration of counterions in the film. The charge on the surface of the previous layer has also a known effect on the adsorption behaviour of the next polyelectrolyte layer (27, 28). Microelectrophoresis is a commonly used technique to determine the effect of various parameters (salt, pH) on surface charge properties of colloidal particles, and to study these surface properties, multilayers of PLL and DNA were coated onto the surface of silica NPs of 100 nm diameter. In some respects, these DNA-loaded NPs are still model systems, and in that end, pharmaceutical applications would more comprise DNA-filled or hollow capsules (obtained by dissolving the core). However, the Si particles used here as templates are ideal for the precise surface charge studies required, and also for solid state NMR studies that are being carried out in parallel by our group. Furthermore, the Si NPs possess acceptable non-toxicity so that exactly the same particles characterized here electrophoretically could be used for the in vitro transfection studies described presently.

Alternation of the zeta potential measured after every adsorption step is reported in Fig. 5. A potential of +30 mV is obtained when PLL is the outer layer, while the potential switches to –30 mV when DNA is the outermost layer. Plots of zeta potential vs. the pH of the solution for particle containing acid–base functional groups display similarities to titration curves used to determine acid–base dissociation constants. It is therefore possible to estimate the effective pK_a of polyelectrolytes coated on particle surfaces because

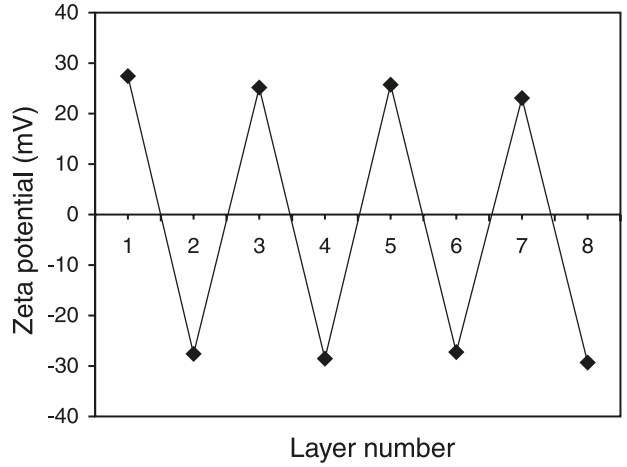
Fig. 5. Zeta potential of the surface of silica nanoparticles coated with PLL/DNA after each deposition step.

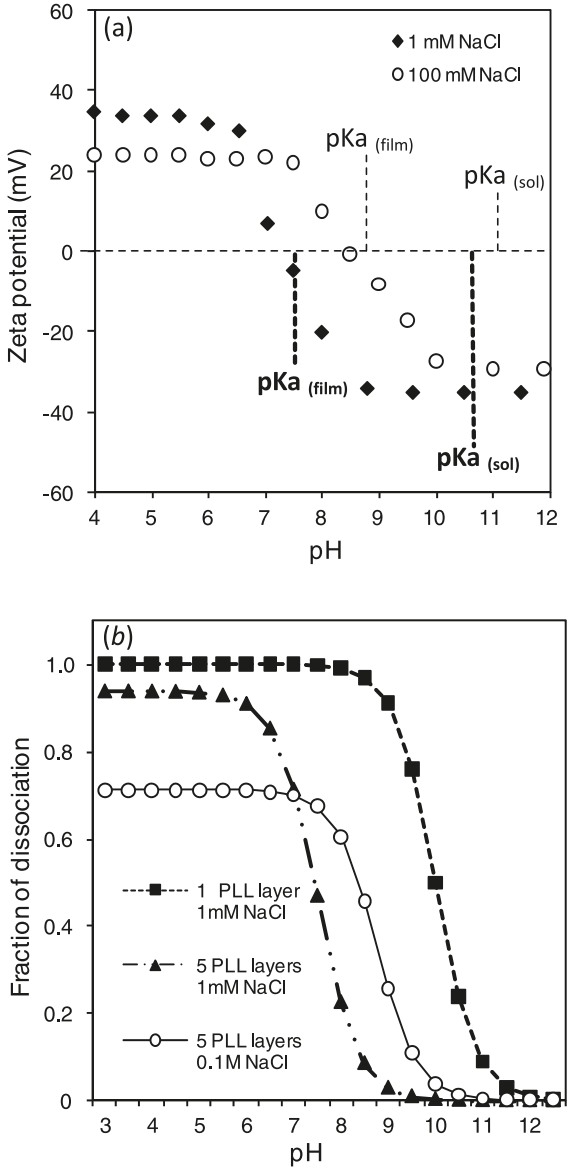


the inflection point of zeta curves corresponds to an apparent pK_a (27).

Figure 6 shows the surface charge of PLL on the surface of the ninth outer layer obtained by alternate deposition of DNA/PLL layers exposed to a range of pH between 4 and 12 at two salt concentrations of 1 mmol/L and 100 mmol/L, respectively. Corresponding apparent pK_a values are shown on the graph, and these are compared to pK_a of PLL measured free in solution, as measured by potentiometric titrations. These bulk solution pK_a values are in good agreement with those reported in the literature (43). At both salt concentrations, a shift of approximately three pK_a units is observed when PLL is adsorbed on top of multilayers. Several groups have reported that in self-assembled polymer systems, the acid–base equilibria deviates substantially from ideal behaviour (44–47). Our group has previously reported a pK_a shift of up to a few units in PLL and HA multilayer system as a result of layer accumulation (27), which perturbs the local environment of the outer layer of PLL. The ionic network created between PLL and DNA upon polymer adsorption leaves participating functional groups unavailable for proton exchange, which in turn decreases the degree of ionization of polymer on film surface, which results in a decrease of pK_a. Increasing the ionic strength has the opposite effect on apparent pK_a because ions in solution can stabilize the charged amino groups on PLL.

The fraction of dissociation was calculated for PLL at the terminal layer of a nine-layer film (Fig. 6*b*), assuming a degree of dissociation of one for one layer of PLL coated on a silica nanoparticles. At low salt concentration, the degree of ionization of PLL on top of the DNA multilayer is very high below pH 6.5. Above this pH, PLL dissociates, which reduces PLL net charge, hence lowering the attraction to the previous PLL layer, which can explain why higher DNA incorporation is observed under low pH conditions (Fig. 3). At pH 9, only 1% of PLL molecules are charged, which leads to a relatively poor DNA adsorption. When salt concentration is increased, the pK_a of PLL is higher. Within the pH range of 4 to 9, the charge density is constant except at pH 9 where the degree of dissociation decreases. This could explain why the pH has less of an effect on polymer adsorption at higher salt concentrations.

Fig. 6. Surface charge of PLL forming the terminal layer of a nine-layer film of PLL/DNA deposited on silica nanoparticles (snowtex-zl, 100 nm diameter). (*a*) A pK_a value on the PLL film surface corresponds to the inflexion point, which is then compared to the pK_a of PLL in solution obtained by a potentiometric titration. (*b*) Degree of dissociation of PLL adsorbed on PLL/DNA film surface coated on silica nanoparticles.



Degradation studies

In gene therapy, it is important to exert precise control over DNA release, and polymers and small molecules can be released from films by changing pH (29, 48), or salt concentration (12), or by using an enzyme (4, 9, 15), if the material is biodegradable. In a therapeutic context, physiological conditions restrict the layer degradation to a constant ionic strength and pH. This leaves biodegradation as the method of choice and indeed several proteolytic enzymes have been

Fig. 7. Level of DNA release from PLL/DNA films built under different pH conditions and at low ionic strength calculated from absorbance measurements on quartz slide. (*a*) PLL is fully charged. (*b*) PLL is partially charged.

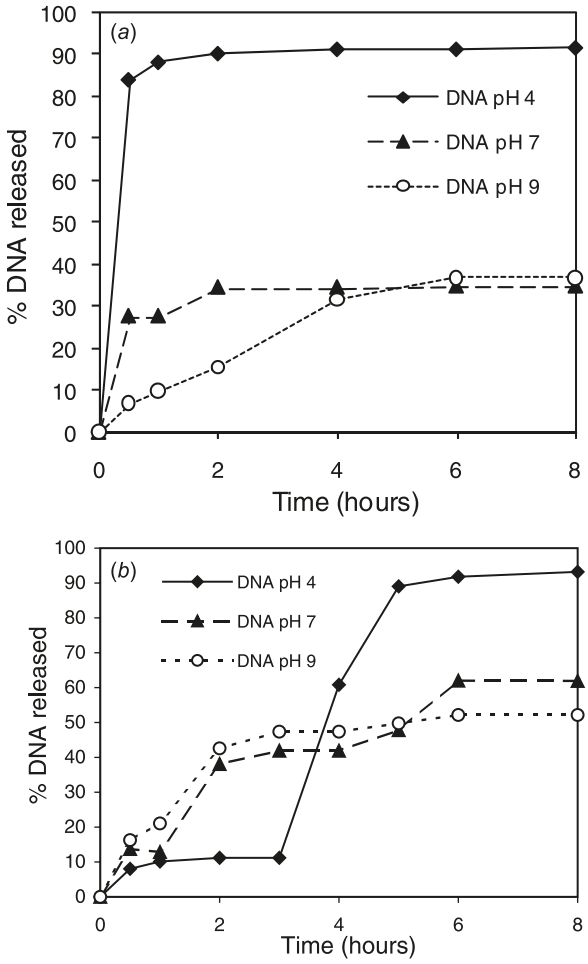

Fig. 8. The effect of film composition on the degradation of films of same thickness. Film 1: PLL pH 9 / DNA pH 4, 1 mmol/L NaCl. Film 2: PLL pH 7 / DNA pH 7, 0.15 mol/L NaCl. Film 3: PLL pH 7 / DNA pH 7, 0.5 mol/L NaCl. (*a*) Thickness variation of film exposed to α-chymotrypsin. (*b*) Percent of DNA released from films.

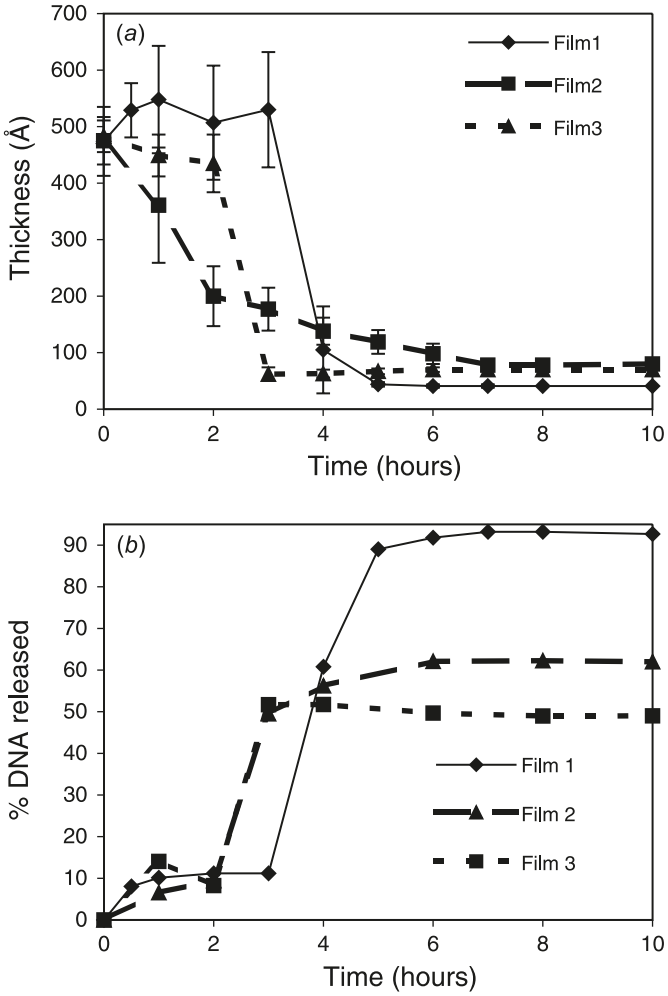


used for material degradation. It has been reported that films, which contain polyamino acid groups can be degraded by chymotrypsin, an endopeptidase widely used in in vitro polypeptide degradation (49). Although trypsin is the specific enzyme for lysine residue degradation, it has been observed that chymotrypsin shows similar degradation activity for PLL membranes (50). Moreover, DNA/PLL multilayered films have recently been successfully degraded with this enzyme (14). Since the architecture of the film affects the affinity of the polymer chain for the binding site of the enzyme molecule, and thus controls the rate at which the polymer is degraded, several PLL/DNA films built under different pH and salt conditions were exposed to the enzyme to track film deconstruction and hence study how film architecture influences degradation behaviour. Film thickness and accessibility of the bonds to be cleaved both influence the mechanism and rate of enzyme action. Indeed, it was noticed that film degradation varies strongly with the pH and salt conditions at which the films were built.

Figure 7*a* shows that less than 40% of the DNA is liberated after 2 h of enzyme treatment when the pH of DNA solution is 7 or higher. With films built with pH 4 DNA solution, DNA release is 1.5 to 3 times greater, with over 90% of DNA released. We note that control tests have shown that no DNA is lost when the same films were exposed to a buffered solution for the same period of time.

It was noticed that degradation of PLL/DNA films depends greatly on the film thickness. Ji and co-workers observed a progressive deconstruction of their PLL/DNA films of 170 nm thickness (14). After 35 h of enzyme exposition, 90% of DNA was released from their films, whereas the same release was obtained after only 2 h with a film of less than 10 nm thickness. Prolonged enzymatic treatments did not further degrade the film because as fragments depolymerize the effect of polymer end groups becomes more pronounced, and eventually, the polymer molecule is too short to form a sufficiently stable complex with the enzyme active site (51, 52). In our films built with a pH 4 DNA solution, DNA is more globular and less charged, and thus the interaction with PLL is weakened, and the reduced steric hindrance allows the enzyme to bind more easily to

© 2008 NRC Canada

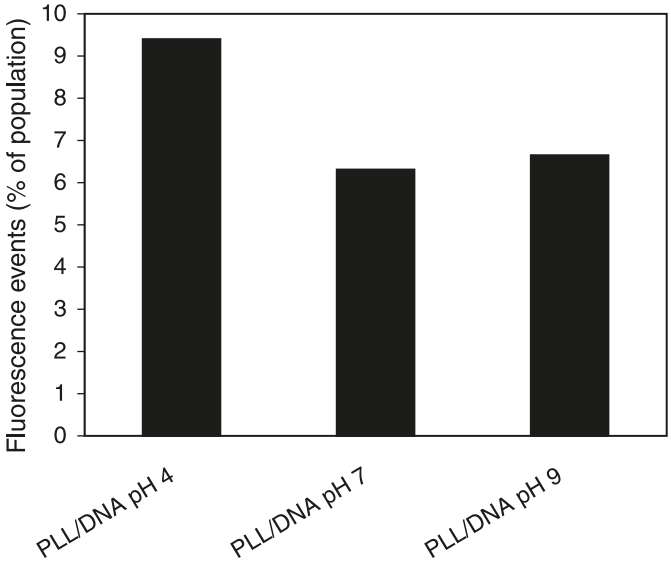
the PLL substrate. The same phenomenon is observed with films built with a pH 9 PLL solution (Fig. 7*b*). However, in this case, the percent of DNA release is more important for each film. At higher pH values, PLL is weakly bound to DNA, which leaves more amino groups available for degradation. Moreover, the loopy PLL conformation is more favourable for film degradation and DNA release. Since the thickness of these films was not constant however, it is difficult to make a critical comparison. As shown in Fig. 8, degradation follows a similar scheme for each film. Although films have been coated on two different substrates, it is worth mentioning that an early study had demonstrated that an equal extent DNA was released from a film deposited onto silicon or quartz (15). Early in the enzymatic treatment, Fig. 8*a* shows that film thickness and hence roughness increase early in the enzymatic treatment, as peptide bond cleavage loosens polymer linkages non-uniformly over the film surface.

When enough bonds are broken, clusters of polymer fragments are released, which lead to an abrupt thickness decrease. Further degradation occurred more slowly until polymer fragments are short enough to hinder the hydrolysis process. DNA release differs between films, and it appears that films built with pH 4 DNA and pH 9 PLL solutions have the best ability to release DNA from films exposed to the enzyme. Early studies demonstrated that even though compact complexation between DNA and the polycation is required to protect DNA from degradation, the DNA and the polymer must eventually decomplex to allow efficient transfection (53). Concurrent reduction of the positive PLL charge and the DNA negative phosphate net charge decrease the level of electrostatic interaction between polymers, which may favour dissociation of the complexes inside the cell. This is clearly revealed later in the degradation studies. Thus, we demonstrate that it is possible to tailor decomposition behaviour simply by changing film architecture and composition. Optimal DNA release is obtained when the DNA and PLL polyelectrolyte incorporated into the film are less charged, which in consequence weakens mutual attraction and allows DNA to be liberated more easily.

Transfection studies

To measure the transfection ability, PLL/DNA nanoparticles coated with pEGFP–N1 and PLL were prepared under different pH conditions and at low ionic strength. The salmon DNA used previously for film assembly was replaced by plasmid DNA (pEGPF–N1) that encodes for enhanced green fluorescent protein. However, it was not certain that the pH will have the same effect on the level of DNA incorporation into multilayered films, since DNA morphology has an impact on the structure of the formed complex. The multilayer support in this case is a silica spherical particle having a diameter between 70 and 100 nm. The main motivation for using silica NPs as a support was facility of zeta potential characterization, but silica is also an acceptable support for a DNA delivery system based on previously reported results, which demonstrated that silica nanoparticles with surface-modified aminosilane were an effective carrier for gene delivery (54). Five layers of alternated pEGFP–N1 and PLL were coated onto these silica nanoparticles, and the terminal layer was PLL layer to provide a positive outer charge to bind to the negatively charged cell membrane. Immediately after their preparation, particles were tested for transfection.

Fig. 9. Transfection of COS-7 cells by PLL/pDNA coated silica nanoparticles assembled with DNA solutions adjusted to three different pH values. The pH of the PLL solution during the assembly was maintained at neutral pH.



Fluorescence microscopy demonstrated that the COS-7 cell line remained healthy when treated with nanoparticles (Fig. 9). No dead or dying cells, which experienced changes in their cytoplasm size, were detected by microscopy. Compared with the positive Lipofectamine™ control (40% fluorescence events), coated nanoparticles were found to transfect cell lines relatively poorly, with the transfection efficiency of these un-optimized particles less than 30% relative to Lipofectamine™. However, it is important to note that tested nanoparticles had only two layers of DNA, and it would probably be possible to enhance cell transfection significantly by increasing the number of DNA layers. These results suggest that particles assembled with a pH 4 DNA solution transfect 30% more cells than other nanoparticles. This may be attributed to a combination of the high DNA density, and efficient DNA release specific to these particles as characterized independently (Figs. 4. and 7). To verify the reproducibility of the transfection results, these same particles were tested 2 month after their storage. Very little transfection was obtained this time (less than 4% relative to the control), and this could be due to particle aggregation that occurs with time. However, a difference in transfection is still observable between samples, showing that the transfection is still increased with particles assembled at pH 4 DNA solution. Our results thus suggest that these particles have a potential for good and facile control over transfection, and that the pH of assembly has a significant impact on the degree of transfection.

Conclusion

Multilayers constructed from PLL and DNA have been successfully optimized by the variation of the pH of the

© 2008 NRC Canada

polyelectrolyte assembly solutions. The optimization of DNA incorporation into multilayered films was achieved when the pH of both the PLL solution and the DNA solution was lowered to pH = 7 and pH = 4, respectively. Under these conditions, the reduced negative charge on DNA phosphate backbone allows DNA to adopt a more globular form that favours its incorporation into the multilayer. Degradation studies revealed that the film composition resulting from these pH conditions was more easily degraded by chymotrypsin and that more DNA was released during the film degradation. It appears that film architecture and composition play a crucial role in film degradability behaviour and that the pH of multilayer assembly alters the way polymers are degraded and released from these films. Transfection tests performed on the COS-7 line showed that NPs coated with DNA and PLL were non-toxic to living cells, and that particles assembled under optimal DNA-loading pH conditions were transfected more effectively than the ones that were built under other pH conditions. Although the efficiency of transfection was still poor compared with that of other DNA delivery vectors, these results demonstrate the possibility of creating a vector for DNA made of PLL multilayers that could eventually lead to better gene-therapy delivery systems. In summary, we demonstrated that DNA loading and release from polyelectrolytes films can be controlled well simply by varying the pH of assembly solutions used in film formation, and we determined how these variations in polymer conformation and surface charge affect film composition of this system.

Electronic structure characterization of Fe^{III}-protoporphyrin IX (Fe^{III}-PPIX) and β-hematin using calculated nuclear quadrupole resonance (NQR) and Mössbauer parameters

Marjan A. Rafiee and Nasser L. Hadipour

Abstract: In this work, we performed the ab initio calculation of quadrupolar parameters of ^{17}O and ^{14}N atoms in Fe^{III}-protoporphyrin IX (Fe^{III}-PPIX) and β-hematin molecules. Furthermore, the quadrupole splitting of iron atoms in these molecules were calculated. The calculations were carried out to explore the differences between the electronic structures of Fe^{III}-PPIX and β-hematin. The results show that the value of quadrupole splitting of iron atom, $\Delta(^{57}Fe)$, in Fe^{III}-PPIX is exactly three-fold of its value in β-hematin. The electric field gradient (EFG) at the site of quadrupolar nuclei were calculated to obtain quadupolar parameters (χ, η, and Δ), using B3LYP method and an all-electron representation for iron (62111111/3311111/3111), as well as the 6-31G* basis for all other atoms.

Key words: nuclear quadrupole resonance (NQR), hematin, β-hematin, malaria.

Résumé : Dans ce travail, on a effectué des calculs ab initio de paramètres quadripolaires des atomes de ^{17}O et de ^{14}N dans les molécules de la Fe(III)-protoporphyrine IX et de la β-hématine. On a calculé de plus le dédoublement quadripolaire des atomes de fer dans ces molécules. On a effectué les calculs afin d'explorer les différences entre les structures électroniques de la Fe(III)-protoporphyrine IX et de la β-hématine. Les résultats montrent que la valeur du couplage quadripolaire de l'atome de fer, $\Delta(^{57}Fe)$, dans la Fe(III)-protoporphyrine IX est exactement trois fois plus élevée que dans la β-hématine. En faisant appel à la méthode B3LYP et à la représentation de tous les électrons de Wachter pour le fer (62111111/3311111/4111) ainsi qu'à une base 6-31G* pour tous les autres atomes, on a aussi calculé le gradient du champ électrique (GCE) au niveau du noyau quadripolaire dans le but d'obtenir les paramètres quadripolai χ, η, reset Δ.

Mots-clés : résonance quadripolaire nucléaire (RQN), β-hématine, malaria.

Introduction

A detailed knowledge of charge distribution of any drug and its target is very important in drug development. This knowledge can be applied to investigate a possible relationship between their electronic structure and biological activity. Theoretical calculations, in particular calculation of quadrupolar parameters of nuclei, seem to be a proper tool for gaining a better understanding of these interactions.

Malaria is one of the world's biggest killers, affecting about half a billion people a year and causing one million deaths (1).

Like most living organisms, malaria parasites require amino acids and the presence of iron, which can both be obtained from hemoglobin. The parasite can digest up to 75% of the red blood cell (RBC) content, in a process whereby the globin is enzymatically cleaved in to small peptides, producing free heme (Fe^{II}- protoporphyrin IX: Fe^{II}-PPIX) as a byproduct. The toxic heme is rendered less harmful in the parasite by one electron oxidation, which produces hematin (Fe^{III}-protoporphyrin IX: Fe^{III}-PPIX). Eventual precipitation transforms nonreactive submicron to micron-sized crystals known as hemozoin in the acidic food vacuole (2, 3).

The quinoline containing antimalarial drugs have been mainstays in the treatment of the disease. The interaction of quinolines with hematin has been well-established and studied over the years and was initially proposed in 1967 by Macomber et al. (4) for chloroquine.

Two main routes have been invoked to account for the primary mode of action of the quinolines: complexation with hematin in solution (5) and inhibition of malaria-pigment growth by quinoline attachment to the growing hemozoin crystal (6–8).

The underlying electronic and steric factors controlling the ability of quinolines to form such complexes are still poorly understood.

To advance our understanding of the structural specificity of the binding of quinoline drugs to hemozoin or hematin and to test this hypothesis that Fe^{III}-PPIX can serve as a potential target for the design of new antimalarial agents, the electronic structures of Fe^{III}-PPIX and hemozoin may be

compared. The detailed analysis of charge density on quadrupolar nuclei in Fe^{III}-PPIX and hemozoin is a useful tool to investigate these electronic structural differences.

Nuclear quadrupole resonance (NQR) spectroscopy (9) is a very sensitive technique for measurement of the electric charge distribution around quadrupolar nuclei ($I > 1/2$).

The quantum mechanical approach has been shown to be an effective method in determination of the charge distribution in molecules or complexes (10). In this method, the electric field gradient (EFG), resulting from whole molecular charges, can be estimated at any point in the molecular space (11). Verification of the EFG has become possible by the quadrupolar nuclei, which possess a nuclear quadrupole moment and interact with the molecular EFG tensor (12). This interaction is measured by the nuclear quadrupole coupling constant (NQCC).

β-Hematin is chemically, spectroscopically, and crystallographically identical to the malaria pigment (13–16). In this work, attention has been focused on the details of the charge distribution on Fe^{III}-PPIX and β-hematin. For this purpose, we performed a theoretical investigation on the calculated NQR and Mössbauer parameters of these compounds. These results may give a better understanding of their biological activity based on their electronic structures.

Computational details

Electric field gradients of quadrupolar nuclei in Fe^{III}-PPIX and β-hematin were calculated using the Gaussian 98 program (17).

The three-dimensional structures of the above mentioned compounds were obtained from the Cambridge Crystallographic Database (18), where the hydrogen atoms were not given; they were added to the crystal structure using HyperChem (19). Both hemozoin and Fe^{III}-PPIX showed a spin state of 5/2, as determined by Mössbauer spectroscopy (20). This value was considered in the calculations performed in this study.

The EFGs were calculated using the B3LYP method and a Wachters' (21) all electron representation for iron (62111111/3311111/3111) and the 6-31G* basis for all other atoms. It has been previously demonstrated that there is excellent accord between theory and experiment using the hybrid exchange correlation functional (B3LYP) and the Wachters basis set for iron metalloporphyrins (22, 23). Moreover, based on the results reported in Table 1, the selected level and basis sets give the rather acceptable qualitative NQCCs of nitrogen and oxygen atoms.

The excited state of ^{57}Fe has a spin $I = 3/2$. The EFG has no effect on the $I = 1/2$ ground state but could remove degeneracy in the excited state, splitting it into two substates: $m_I = \pm 1/2$ and $m_I = \pm 3/2$, where $m_I = \pm 3/2$ states are higher in energy for positive q_{ZZ}. The two nondegenerate excited states give rise to a doublet in the Mössbauer spectrum. The separation between the lines, Δ, is known as quadrupolar splitting (QS)

$$[1] \qquad \Delta = 1/2e^2Qq_{ZZ}(1 + \eta^2 / 3)^{1/2}$$

where e is the charge of an electron, q_{ZZ} is the component of EFG in Z direction, and Q is the electric quadruple moment of the nucleus. η is the asymmetry parameter, which is defined using EFG components in principal axes as $\eta = (V_{YY} - V_{XX})/V_{ZZ}$, where $|V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}|$.

The expression $\chi = e^2Qq_{ZZ} / h$ is termed as the nuclear quadrupole coupling constant (NQCC) and has the unit of frequency (Hz). h is the Planck constant.

The most recent values of electric quadrupole moments for the nucleus, $Q(^{57}Fe) = 160$ mb, $Q(^{14}N) = 20.44$ mb, and $Q(^{17}O) = 25.58$ mb, already reported by Pyykko (24), were used in this study.

Results and discussion

In vitro experiments already revealed that the quinoline-containing antimalarial drugs are associated with the crystallization of hematin (8). This suggests that their therapeutic effect occurs by interference with hemozoin formation. It has been established that hemozoin is not a coordination polymer so that the growth of a chain cannot be stopped at a single site (18). Regarding the investigation of the nature of π-π interaction (25), properties of the atoms at the points of intermolecular contact are important rather than the overall molecular properties. Based on our previous study (26), the nitrogen ring of the drug and iron cation of hematin are essential in the π-π interaction between antimalarial quinolines and hematin. Therefore, investigation of the electronic structures of Fe^{III}-PPIX and hemozoin and particularly the charge density of the Fe atom in these compounds may provide important insights to better understand the drug-receptor mechanism. Since NQR parameters are very sensitive to the electronic structure, calculated NQR parameters reveal the details of the charge distribution of nuclei that may not be observed by other methods, such as atomic charge determination. Accordingly, the quadrupolar parameters of atoms in Fe^{III}-PPIX and hemozoin were calculated. Investigation of calculated nuclear quadrupolar parameters can be used as a useful probe to compare the charge density of those atoms.

Fe^{III}-PPIX and hemozoin (in which the hematin molecules are paired into dimmers by two reciprocal iron–oxygen bonds) are shown in Figs. 1 and 2.

The resultant NQCCs and quadrupole splitting from calculated EFG tensors for these compounds are given in Tables 2–5.

The NQCCs of nitrogen and oxygen atoms in both Fe^{III}-PPIX and β-hematin have rather comparable values (Tables 3 and 5).

© 2008 NRC Canada

Fig. 1. Atom numbering of the Fe^{III}–PPIX molecule in the structure solution.

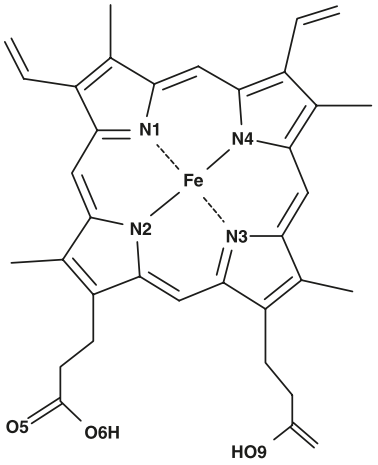

Fig. 2. Atom numbering in a unit cell of the crystal structure of β-hematin.

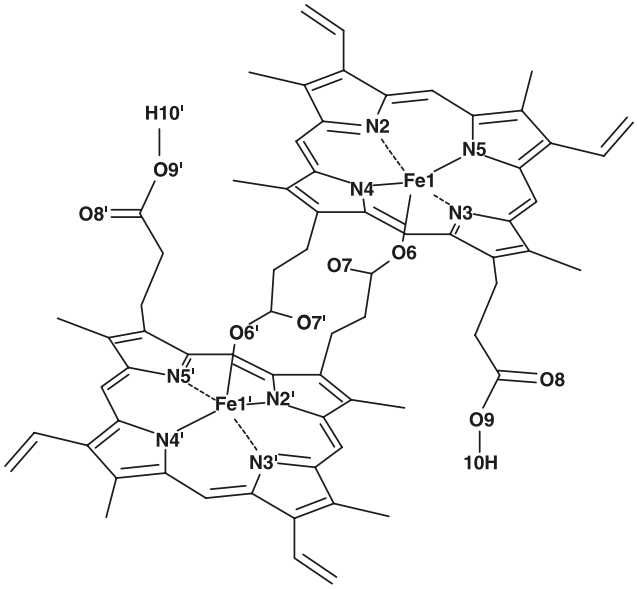

As it has been shown in related studies (27) the NQCC parameters at the coordinated N atom are sensitive indicators of binding to the metal center, so that rather detailed inferences regarding the extent of electron transfer can be obtained from the NQR data of this nucleus.

Since there is no experimental result for ^{14}N- and ^{17}O-NQCC of hemozoin and hematin, the calculated values in Tables 3 and 5 constitute theoretical predictions.

Calculated quadrupole splitting, $\Delta(^{57}Fe)$, in Fe^{III}-PPIX is three-fold larger than that of β-hematin (Tables 2 and 4). This ratio is in agreement with experimental data from Mössbauer spectroscopy (28).

Like NQCCs, the Mössbauer parameters, quadrupole splitting (Δ) and asymmetry parameter (η), depend on the EFG and reflect the spatial distribution of electrons around the iron atom.

The relation of Δ to q_{ZZ} shows quadrupole splitting is directly proportional to q_{ZZ}. There are two factors controlling the value of q_{ZZ} in a nucleus: charge density on the nucleus and symmetry of EFG around the quadrupolar nucleus. It is evident that an increase of the charge density causes the q_{ZZ}, and consequently the Δ, to increase. If charge distribution were such that the symmetry of EFG increased, then q_{ZZ}, and consequently Δ, will decrease. Based on these points, the larger value of $\Delta(^{57}Fe)$ in Fe^{III}-PPIX compared to its value in β-hematin is attributed to a greater charge density of the iron atom in Fe^{III}-PPIX. Furthermore, our results show that the value of the asymmetry parameter (η) in Fe^{III}-PPIX is less than that of β-hematin. Therefore, charge distribution around the iron atom in Fe^{III}-PPIX is more symmetric.

Tables 3 and 5 show that only the oxygen atoms coordinated to iron atom in β-hematin (O6 and O6′) have significantly different values of NQCC compared to other oxygen

atoms. In a simple word, an oxygen atom (as a coordinate) being adjacent to ^{57}Fe in β-hematin causes the iron charge density to be much less than its value in Fe^{III}-PPIX. These results suggest that the contribution of the bonded oxygen atom in decreasing charge density on the iron atom of β-hematin is greater than that of any other atom.

As mentioned before, it is recognized that malaria parasites avoid accumulation of the toxic Fe^{III}-PPIX produced by the digestion of host hemoglobin within the parasites food vacuole by conversion into the insoluble inert heme polymer, hemozoin. Furthermore, quinoline containing drugs are capable of hematin binding and inhibiting of hemozoin formation (the nitrogen atom in quinoline ring is the active site in these drugs (26)). Based on these points, it is expected that any status that increases the charge density on the nitrogen-ring may cause the interaction of quinolines with Fe^{III}-PPIX to be more rapid (before malaria pigment formation). As a result, the toxic Fe^{III}-PPIX accumulates in the parasite food vacuole and subsequently, the inert malaria pigment will not be formed. Further studies will be required to more fully interpret these points.

Conclusions

According to the calculated quadrupolar parameters in this work, it is concluded that (*i*) quadrupolar parameters of nuclei can be used as a useful tool to understand the electronic structure of the compounds; (*ii*) the value of $\Delta(^{57}Fe)$in Fe^{III}-PPIX is exactly three-fold its value in β-hematin; this might be attributed to the greater charge density of the iron atom in Fe^{III}-PPIX; (*iii*) the value of the asymmetry parameter (η) in Fe^{III}-PPIX is less than its value in β-hematin and therefore the charge distribution around the iron atom in Fe^{III}-PPIX is more symmetric than the other; (*iv*) the vicinity of oxygen atom (as a coordinate) to iron atom in β-hematin may play a dominant role in decreasing the quadrupole splitting and consequently the charge density of the iron atom in β-hematin.

$Al(OTf)_3$ — A highly efficient catalyst for the tetrahydropyranylation of alcohols under solvent-free conditions

Ahmed Kamal, M. Naseer A. Khan, Y.V.V. Srikanth, and K. Srinivasa Reddy

Abstract: A simple and highly efficient method has been developed for the tetrahydropyranylation of alcohols by their reaction with 3,4-dihydro-2*H*-pyran (DHP) using a catalytic amount (0.01–1 mol%) of aluminium triflate under solvent-free conditions. The effect of various factors like temperature, amount of the catalyst, and molar ratio of substrates on the reaction conditions has also been studied. The comparative study of tetrahydropyranylation of benzyl alcohol using various catalysts including some reported ones shows the efficiency of this catalyst.

Key words: tetrahydropyranylation, aluminium triflate, alcohols, catalysis.

Résumé : On a mis au point une méthode simple et efficace de préparer des dérivés tétrahydropyranyles d'alcools en les faisant réagir avec du 3,4-dihydro-2*H*-pyrane (DHP), dans des conditions sans solvant et en faisant intervenir une quantité catalytique (0,01 à 1 mol %) de triflate d'aluminium. On a aussi étudié les effets de divers facteurs, telle la température, la quantité de catalyseur et le rapport molaire des substrats sur les conditions de la réaction. Une étude comparative de la réaction de tétrahydropyranylation de l'alcool benzylique en faisant intervenir divers catalyseurs, y compris celui mentionné dans ce travail, met en évidence l'efficacité de ce catalyseur.

Mots-clés : tétrahydropyranylation, triflate d'aluminium, alcools, catalyse.

[Traduit par la Rédaction]

Introduction

Protection of hydroxy groups by their conversion to the corresponding tetrahydropyranyl (THP) ethers is one of the most frequently employed transformations in organic syntyhesis (1, 2). The wide use is due to their ease of preparation and stability under a variety of reaction conditions such as with hydrides, alkylating reagents, Grignard reagents, and organometallic reagents (2, 3). THP groups are also the protective groups of choice in peptide, nucleotide, carbohydrate, and steroid chemistry (4). A variety of catalysts that have been reported for this conversion includes the use of protic acids (5–7), acidic clay (4), triflates (8–11), ion exchange resins (12, 13), alumina impregnated with $ZnCl_2$ (14), sulfuric acid on silica gel (15), heteropoly acids (16), polystyrene supported aluminum chloride (17), ionic liquids (18), and many others (19–25). However, despite their potential utility in the protection of simple hydroxyl compounds, many of these methods have limitations such as elevated reaction temperatures, longer reaction times, non-reusability of catalysts, the use of volatile organic solvents, being incompatible with other acid-sensitive functional groups, and involving expensive and toxic catalysts apart from the occurrence of side-products and poor yield of desired products.

In view of the modern demands of organic synthesis, there is a need for a solvent-free and catalytically efficient alternative for the protection of hydroxy functionality as a THP ether, which works under mild and economically benign conditions in a cost-effective manner. In recent years, aluminium triflate has been found to be an efficient catalyst for various transformations like epoxide ring openings (26, 27), thiol protections (28), and silylation of alcohols as well as phenols (29). Recently, we have reported (30) the acylation of alcohols, phenols, and thiophenols in an efficient manner by employing this catalyst. In view of the high catalytic activity and in continuation to our earlier studies on this reagent, we wish to report a highly efficient method for the tetrahydropyranylation of alcohols in the presence of a catalytic amount of $Al(OTf)_3$ (0.01–1 mol%) under solvent-free conditions in excellent yields.

Results and discussion

The treatment of benzyl alcohol with 3,4-dihydro-2*H*-pyran in the presence of 0.01 mol% $Al(OTf)_3$ afforded the tetrahydropyranyl derivative in 92% yield in 2 h at room temperature (RT) (Table 1, entry 1b). Further, the rate of reaction enhanced by using 1 mol% of the catalyst at RT, along with the formation of side-products (10%–25%). To overcome this limitation, the reaction conditions were optimized by employing 1 mol% of the catalyst at 20 °C. A wide range of hydroxy compounds were converted to their

corresponding THP ethers in excellent yields by using this procedure (Scheme 1 and Table 1). The reactions are mild enough for functionalities like allylic ones (Table 1, entry 6) or other acid sensitive groups like epoxide (Table 1, entry 7) and triphenylsilyl groups (Table 1, entry 17), compared with the conventional conditions. All the assigned structures were established from their spectral properties (NMR, mass, and IR) and by comparison with available authentic data.

The reaction of benzyl alcohol and DHP was chosen as a model reaction to evaluate the effect of the amount of the catalyst employed for the conversion (%) of DHP ethers at 20 °C. As illustrated in Table 2, an increase in the amount of catalyst substantially increases the conversion. The reaction proceeds by using 0.01 mol% of the catalyst to yield 90% of the product in 2 h at RT. The reaction is greatly enhanced by increasing the quantity of catalyst. The enhanced rates are due to the increase in the number of catalytically active sites. However, this process reaches its optimum at 1 mol%, and further increases in the amount of catalyst fastens the process along with the formation of side-products (10%–25%). In addition, the effect of temperature on the

conversion of DHP ethers was also investigated for the temperatures ranging between 0 °C to 30 °C, with benzyl alcohol and DHP as a representative reaction using 1 mol% of catalyst (Table 3). The rate of conversion increases with increase in temperature, and the conversion is maximum at 20 °C. When the reaction was carried out at 30 °C, the formation of the side-products was observed. Moreover, no side-products were observed at this temperature when 0.01 mol% catalyst was employed, however the reaction time was much longer (Table 1, entry 1b). Therefore, the reactions carried out at 20 °C gave the desired results using an optimal amount of catalyst.

To investigate the efficiency of $Al(OTf)_3$, the results of the tetrahydropyranylation of benzyl alcohol were compared with those of the reported methods as well as various new catalysts (Table 4). This catalyst has been found to be more efficient with respect to reaction times, mol% of the catalyst

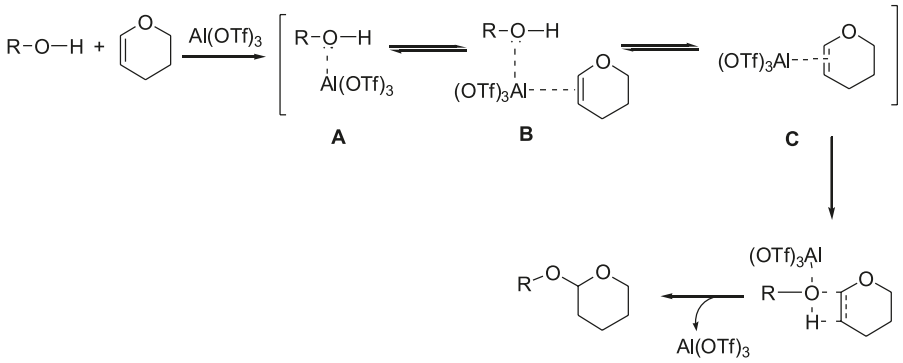
Scheme 2. Proposed mechanism for tetrahydropyranylation of alcohols.



used, and the yields of the desired products when compared with other catalysts.

The mechanism for tetrahydropyranylation can be rationalized based on the experimental and theoretical approaches reported in the literature (31). The mechanism pathway involves the coordination of $Al(OTf)_3$ to the oxygen atom of alcohol giving intermediate complex **A**. This intermediate may be in equilibrium with chelate **B** (in which the catalyst is coordinated with both the C–C double bond of DHP as well as the oxygen atom of the alcohol) and complex **C** (in which only the C–C double bond is coordinated with the catalyst) (Scheme 2). Finally, these transition states result in the formation of DHP ethers.

Conclusion

In conclusion, we have developed a simple and highly efficient method for the conversion of alcohols to tetrahydropyranyl ethers using catalytic amount of $Al(OTf)_3$ under solvent-free conditions, thereby leaving the acid and base sensitive groups intact. The added features of this method over earlier reported processes include its simplicity, clean reactions, high yields, shorter reaction times, absence of organic solvents, and large scale practical synthesis. Moreover, the effect of temperature and amount of the catalyst on the reaction feasibility has been investigated. We believe that this protocol makes an attractive strategy, offering advantages over other methods.

Experimental

General

^1H NMR spectra were recorded on Gemini Varian-VXR-Unity (200 MHz) or Bruker UXNMR/XWIN-NMR (300 MHz) instrument. Chemical shifts (δ) are reported in ppm downfield from internal standard TMS. LC-MS was recorded on an LC-MSD-Trap-SL instrument, and ESI mass spectra were recorded on a VG-7070H Micromass mass spectrometer at 200 °C, 70 eV, with a trap current of 200 μA and 4 kV of acceleration voltage. Reactions were monitored by TLC, performed on silica gel glass plates containing 60 F-254. Visualization on TLC was achieved by UV light or iodine indicator. Column chromatography was performed with Merck 60–120 mesh silica gel. Yields reported are based on isolated compounds. All the reagents used were ei-

ther commercially available or purchased from Lancaster and Sigma-Aldrich.

General procedure for the synthesis of tetrahydropyranyl ethers

To a mixture of alcohol (2 mmol) and 3,4-2*H*-dihydropyran (3 mmol), $Al(OTf)_3$ (1 mol%) was added. The reaction mixture was stirred at the given temperature for the appropriate amount of time (Table 1). After completion of the reaction as monitored by TLC, water was added to the reaction mixture and the product was extracted in ethyl acetate (3 × 25 mL). The organic layer was washed with a saturated solution of $NaHCO_3$, dried over anhyd Na_2SO_4, and concentrated in vacuo. Purification by column chromatography using hexane/ethyl acetate (9:1) furnished the corresponding DHP ethers.

Large-scale tetrahydropyranylation

A mixture of benzyl alcohol (10.80 g, 0.1 mol) and 3,4-2*H*-dihydropyran (13.70 mL, 0.15 mol) (Table 1, entry 1b) was stirred at RT (30 ± 1 °C), while $Al(OTf)_3$ (4.75 mg, 0.01 mol%) was also added to the mixture in an 100 mL round-bottomed flask. After 2 h, water was added to the reaction mixture and the THP ether was isolated by employing the above-described procedure.

Spectral data for new compounds

2-(2-Oxiranylmethoxy)tetrahydro-2H-pyran (Table 1, entry 7)

IR (KBr, cm^{-1}) ν: 2940, 2871, 1642, 1449, 1350, 1123, 1030, 812. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.67–4.50 (m, 1H), 4.00–3.26 (m, 4H), 3.19–3.02 (m, 1H), 2.78–2.50 (m, 2H), 1.90–1.32 (m, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 98.2, 68.3, 62.0, 51.0, 50.6, 44.5, 25.4, 19.5. HRMS (ESI) *m/z* $(M+Na)^+$: calcd. 181.0840; found 181.0826.

2-(2-Phenoxyethoxy)tetrahydro-2H-pyran (Table 1, entry 14)

IR (KBr, cm^{-1}) ν: 2941, 2867, 1453, 1124, 1034, 873, 741, 698. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.40–7.22 (m, 5H), 4.68–4.52 (m, 1H), 4.02–3.75 (m, 2H), 3.67–3.38 (m, 4H), 1.98–1.39 (m, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 156.2, 127.5, 120.1, 116.6, 97.2, 69.4, 67.2, 64.4, 28.2, 25.2, 19.3. HRMS (ESI) *m/z*: calcd. 245.1152; found 245.1143.

2-[4-(Benzyloxy)butoxy]tetrahydro-2H-pyran (Table 1, entry 15)

IR (KBr, cm^{-1}) ν: 2874, 1556, 1496, 1352, 1159, 1056, 814, 755. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.32–7.23 (m, 5H), 4.54 (t, *J* = 3.6 Hz, 1H), 4.47 (s, 2H), 3.88–3.28 (m, 6H), 1.77–1.42 (m, 10H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 132.7, 128.2, 127.5, 127.4, 98.7, 72.9, 70.2, 67.5, 62.1, 30.6, 29.7, 26.6, 25.1, 22.6, 19.8. HRMS (ESI) *m/z* $(M+Na)^+$: calcd. 287.1623; found 287.1610.

2-4-[(4-Methoxybenzyl)oxy]butoxytetrahydro-2H-pyran (Table 1, entry 16)

IR (KBr, cm^{-1}) ν: 2965, 2910, 2845, 1510, 1450, 1370, 1240, 1112, 1078, 815. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.18 (d, *J* = 8.5 Hz, 2H), 6.80 (d, *J* = 8.5 Hz, 2H), 4.54–4.47 (m, 1H), 4.37 (s, 2H), 3.77 (s, 3H), 3.75–3.60 (m, 2H), 3.50–3.26 (m, 4H), 1.75–1.40 (m, 10H). ^{13}C NMR (50 MHz, $CDCl_3$+DMSO) δ: 158.6, 130.4, 128.9, 112.7, 98.2, 72.1, 69.2, 66.9, 61.3, 54.7, 30.0, 25.9, 25.8, 24.8, 18.9. HRMS (ESI) *m/z*: calcd. 317.1728 $(M + Na)^+$: found 317.1720.

Triphenyl silytetrahydropyranyl ether (Table 1, entry 17)

IR (KBr, cm^{-1}) ν: 2935, 2840, 1605, 1512, 1336, 1255, 1115, 1080, 1008, 805. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.66–7.58 (m, 6H), 7.40–7.32 (m, 9H), 4.51 (t, *J* = 3.1 Hz, 1H), 3.90–3.60 (m, 4H), 3.48–3.28 (m, 4H), 1.70–1.38 (m, 6H), 1.12–0.95 (m, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 135.5, 134.0, 129.4, 127.5, 98.5, 67.6, 64.1, 62.2, 32.4, 30.7, 29.4, 26.8, 22.8, 19.1. HRMS (ESI) *m/z* $(M + Na)^+$: calcd. 455.2056; found 455.2038.

Substituent effects on silene reactivity — Reactive silenes from photolysis of phenylated tri- and tetrasilanes

William J. Leigh, Andrey G. Moiseev, Eugenie Coulais, Farahnaz Lollmahomed, and Mohammad S. Askari

Abstract: Laser flash photolysis of 2-phenylheptamethyltrisilane (**5d**), 2,2-diphenylhexamethyltrisilane (**5e**), and phenyltris(trimethylsilyl)silane (**5f**) in hexane and acetonitrile solution affords strong, long-lived transient absorptions centered in the 440–470 nm range, which are assigned to the transient silenes formed via [1,3]-trimethylsilyl migration into the ortho-position of a phenyl ring on the basis of their UV–vis spectra and kinetic data for their reactions with methanol (MeOH), acetic acid (AcOH), acetone, 2,3-dimethyl-1,3-butadiene (DMB), carbon tetrachloride (CCl_4), and oxygen. The silene derivatives are formed along with the corresponding silylenes (SiMePh, $SiPh_2$, and $Si(SiMe_3)Ph$, respectively) upon photolysis of these compounds in solution, and indeed, weak, short-lived transient absorptions assignable to the silylenes can also be detected in laser photolysis experiments with the three compounds in hexane, superimposed on the much more prominent absorptions due to the silenes. The silylene absorptions are quenched by MeOH and triethylsilane (Et_3SiH) with absolute rate constants varying over the narrow ranges of (1.1–1.8) × 10^{10} $(mol/L)^{-1}$ s^{-1} and (2.5–3.6) × 10^9 $(mol/L)^{-1}$ s^{-1}, respectively, in excellent agreement with previously reported values for $SiPh_2$ and $SiMe_2$ under the same conditions. The kinetic data obtained for the silenes are compared to previously reported data for the reactions of the same substrates with the related silenes (**6a**–**6c**) formed by photolysis of pentamethylphenyl-, 1,1,1,2-tetramethyl-2,2-diphenyl-, and 1,1,1-trimethyl-2,2,2-triphenyldisilane (**5a**–**5c**, respectively) under similar conditions. The comparison provides the first systematic, quantitative assessment of the stabilizing effects of trialkylsilyl substitution at the silenic silicon atom in silene derivatives.

Key words: silene, silylene, trisilane, tetrasilane, kinetics.

Résumé : La photolyse éclair au laser du 2-phénylheptaméthyltrisilane (**5d**), du 2,2-diphénylhexaméthyltrisilane (**5e**) et du phényltris(triméthylsilyl)silane (**5f**), en solution dans l'hexane et l'acétonitrile, permet d'observer de fortes absorptions transitoires de longue durée, centrées autour de 440 à 470 nm et qui, sur la base de leurs spectres UV/vis et des données cinétiques de leurs réactions avec le méthanol (MeOH), l'acide acétique (AcOH), l'acétone, le 2,3-diméthyl-1,3-butadiène (DMB), le tétrachlorure de carbone (CC_4) et l'oxygène, ont été attribuées aux silènes transitoires formés par le biais d'une migration [1,3]-triméthylsilyle vers la postion ortho d'un noyau phényle. Lors de la photolyse des ces composés en solutions, les dérivés silènes se forment aux côtés des silylènes correspondants [respectivement (SiMePh, $SiPh_2$ et $Si(SiMe_3)Ph$] et, dans les expériences de photolyse laser des trois composés en solution dans l'hexane, on peut de fait détecter des absorptions transitoires de courtes durées attribuables aux silylènes qui sont superposées sur les absorptions beaucoup plus prééminentes dues aux silènes. Les absorptions des silylènes peuvent être piégées par le méthanol et le triéthylsilane (Et_3SiH), avec des constantes de vitesse absolues qui s'étalent respectivement sur une plage étroite allant de (1,1–1,8) x 10^{10} $(mol/L)^{-1}$ s^{-1} à (2,5–3,6) x 10^{10} $(mol/L)^{-1}$ s^{-1}, en excellent accord avec les valeurs rapportées antérieurement pour le $SiPh_2$ et le $SiMe_2$, dans les mêmes conditions. On compare les données cinétiques obtenues pour les silènes avec celles obtenues antérieurement pour les réactions des mêmes substrats avec les silènes apparentés, **6a–6c**, formés par photolyse des pentaméthylphényl-, 1,1,1,2-tétraméthyl-2,2-diphényl- et 1,1,1-triméthyl-2,2,2-triphényldisilanes (**5a–5c**, respectivement), dans des conditions similaires. La comparaison fournit la première évaluation systématique et quantitative des effets stabilisants de la substitution par un groupement trialkylsilyle au niveau de l'atome de silicium silénique dans les dérivés silènes.

Mots-clés : silène, silylène, trisilane, tétrasilane, cinétique.

Introduction

The Si=C double bond is an intrinsically reactive bonding arrangement that has received a great deal of theoretical and experimental attention over the past few decades (1–4). Most silenes are transients in solution or the gas phase, reacting rapidly with nucleophiles or oxygen, or by dimerization when reactive substrates are absent. Successful attempts to synthesize isolable silene derivatives have invariably relied on the presence of sterically bulky substituents to suppress dimerization, which in most cases proceeds via formal head-to-tail [2+2] cycloaddition. This purely kinetic stabilizing effect has also been supplemented with thermodynamic stabilization, most notably with the introduction of trialkylsilyl substituents at the silenic silicon atom and alkyl- and (or) alkoxy-substituents at carbon, such as in the well-known silenes of Brook (**1** (5)) and Apeloig (**2** (6)) and their co-workers. It is well established that such substitution patterns lead to marked reductions in the natural ($^{\delta+}$Si=C$^{\delta-}$) polarity associated with the Si=C double bond, slowing the normally diffusion-controlled dimerization reaction (7, 8) and reversing its normal (head-to-tail) regiochemistry (6, 9) (Chart 1).

While an abundance of evidence suggests that, by and large, weakly polar silenes such as **1** and **2** display similar reactivity as do more polar derivatives toward most substrates in terms of reaction products, relatively few studies have been carried out with the aim of quantifying the effects of reduced Si=C bond polarity on reaction kinetics or mechanisms. Our group has studied the kinetics of the reaction of **2** and a sterically stabilized derivative with methanol (MeOH) in hexane solution, and found that not only does this silene derivative react several orders of magnitude more slowly with the alcohol than do other transient silenes that have been studied, it reacts via a different mechanism (8). The results (both experimental and computational) are consistent with a concerted mechanism involving reaction of the hydrogen-bonded dimer of the alcohol in hexane solution, in contrast to the two-step mechanism, initiated by nucleophilic attack at silicon followed by proton transfer to carbon, which is typical of more electrophilic, naturally polarized transient silenes such as 1,1-diphenylsilene (**3**) (3, 10, 11). Milnes and Baines (12) have recently reported a mechanistic probe study of the effects of Si=C bond polarity on the mechanism of the reaction of two kinetically stabilized silenes with aldehydes, and have shown it to change from one involving a zwitterionic intermediate in the case of the naturally polarized silene **4** to a biradical pathway in the case of the very weakly polar Brook silene **1** (R = *t*-butyl or adamantyl) (Chart 2).

Some time ago, we reported two experimental studies directed at quantifying the effects of substituents at silicon and carbon on the kinetics of nucleophilic additions to transient silenes (13, 14). Though systematic, these studies were limited to alcohol additions, and furthermore, covered only silenes of the general structure Me(R)Si=CH_2 and Me_2Si=CHR. We have continued to search for opportunities to extend the scope of these studies to include both mono- and bis-$SiMe_3$ substitution at the silenic silicon atom and to examine the effects of these substituents on other aspects of silene reactivity, in addition to nucleophilic addition reactions, in as systematic a manner as possible.

It occurred to us that just such an opportunity presents itself with the series of 1-silahexatriene derivatives, **6a**–**6f**, which are derived from the corresponding oligosilanes, **5a**–**5f**, by photochemical [1,3]-trimethylsilyl migration (Scheme 1). The first three members of the series (**6a**–**6c**) have been studied by us previously by laser photolysis methods (15–17), and so a considerable body of kinetic data already exists for these compounds. The last three members of the series (**6d**–**6f**) are known to be formed as coproducts in the photolysis of the tri- and tetrasilanes, **5d**–**5f**, which are better known as photochemical precursors of the transient *silylene* derivatives $SiPh_2$, SiMePh, and Si(Ph)$SiMe_3$, respectively (18–22). Photolysis of these compounds in solution is known to afford the corresponding silylenes in chemical yields of 40%–60%, from the results of trapping studies in which the silylenes of primary interest were scavenged with substrates such as alkenes, dienes, ketones, trialkylsilanes, and alcohols. *Some* of these studies also reported significant yields of products derived from trapping of the transient 1-silahexatriene derivatives, **6d**–**6f**, in chemical yields as high as ca. 40% (18, 23–30). Gaspar and co-workers employed **5d** and **5e** as precursors to SiMePh (31, 32) and $SiPh_2$ (33), respectively, in some of the earliest reported attempts to study reactive silylenes in solution by laser flash photolysis methods. They described strongly absorbing, long-lived transient species that they assigned (with some reservation) to the corresponding silylenes (31–33); however, as we have recently shown in the case of **5e** (34), it is more likely that the species they characterized in their experiments are in fact the corresponding 1-silahexatriene derivatives and not the silylenes of interest.

The course of the reactions of silenes of this type with typical "silenophiles" is often different than that found with most other silenes, owing to the fact that the silenic carbon is part of a carbocyclic ring system containing both an allylic hydrogen and a dienyl moiety in conjugation with the Si=C bond. For example, aliphatic dienes and alkenes react with these silenes via ene-addition rather than by the usual

© 2008 NRC Canada

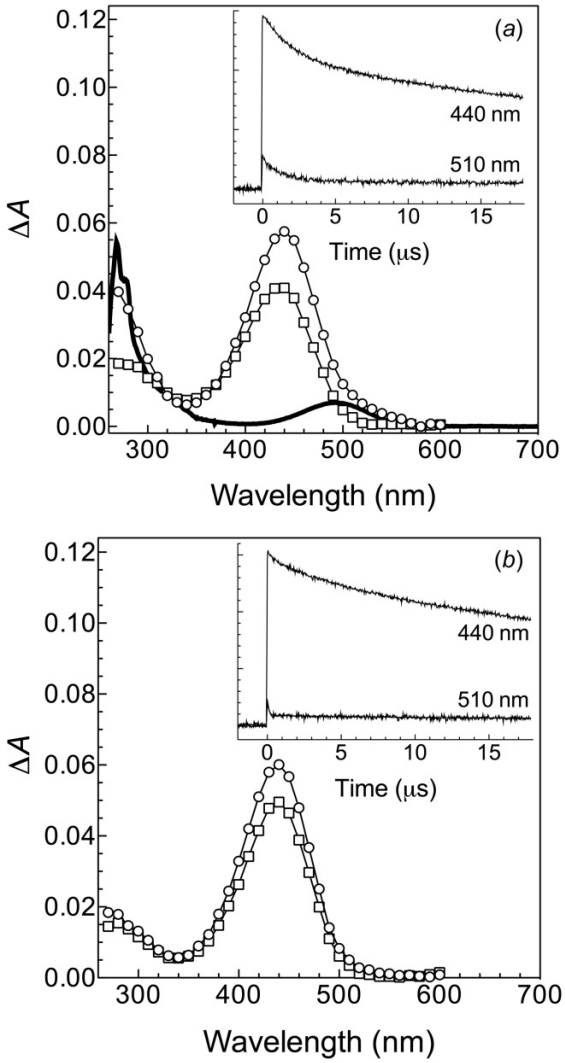
[4+2] or [2+2] cycloaddition pathways that are typical of most other silene derivatives (1, 2, 18, 35); these reactions are diverted from their normal course by the labile allylic hydrogen, whose transfer to a carbon in the substrate results in aromatization of the carbocyclic ring. Reaction with acetone proceeds via competing [2+2] and ene-addition (30, 36–38), the latter again involving transfer of the allylic hydrogen in the silene to the substrate rather than via the usual pathway (as exemplified by **3** (39)) to produce a silyl enol ether. Finally, the presence of the cyclohexadienyl-substituent in silenes of this type results in unusually high reactivity toward molecular oxygen and CCl_4, which are thought to react via mechanisms involving radical or biradical intermediates (16).

In the present paper, we report the results of a laser flash photolysis study of **5d**–**5f** in various solvents. As suggested above, the main goal of the work was to establish that the 1-silahexatriene derivatives are the dominant transient products detectable in experiments of this type with these compounds, to characterize their reactivities with a variety of substrates that show characteristically high reactivity toward silenes of this type, and to compare the results to previously published data for the related silenes **6a**–**6c** in the interest of elaborating on our understanding of substituent effects on various aspects of silene reactivity. A secondary goal was to attempt to detect the reactive silylenes SiMePh and $Si(Ph)SiMe_3$ in solution by laser photolysis of **5d** and **5f**, to provide a benchmark for future studies with potentially more appropriate photochemical precursors to these silylene derivatives; to our knowledge, **5f** has not been studied previously by laser photolysis methods.

Results

Laser flash photolysis of rapidly flowed solutions of 2-phenylheptamethyltrisilane (**5d**; ~10^{-4} mol/L) in dry, deoxygenated hexane, with the pulses from a KrF excimer laser (248 nm; ~20 ns; ~100 mJ) afforded strong transient absorptions centered at λ_{max} = 440 nm, which decay over several hundred microseconds with multiexponential kinetics, in good agreement with the results of earlier flash photolysis studies of this compound (31, 32). We assign this absorption to silene **6d** based on the similarity of its spectrum to those of **6e** (λ_{max} = 460 nm (34)) and **6a**–**6c** (λ_{max}= 425–490 nm (16, 17)), and the kinetic evidence described later in the paper. However, we also detected a second, much shorter-lived transient absorption that was superimposed on those due to the long-lived species and exhibited a lifetime τ ~ 3 μs. The species exhibited a distinct absorption band centered at λ_{max} ~ 270 nm and weaker absorptions throughout the 400–600 nm range. Figure 1 shows representative transient spectra, recorded 128–256 ns and 4.86–5.09 μs after the laser pulse, along with decay traces recorded at 440 nm and 510 nm. As in our previous study of **5e** (34), addition of 3 mmol/L Et_3SiH reduced the lifetime of the short-lived species to ca. 100 ns without affecting the lifetime of the strong 440 nm absorption, thus cleaning up the 128–256 ns spectrum considerably (see Fig. 1*b*). We also recorded a UV–vis spectrum of a photolysed solution of **5d** in 3-methylpentane (MP) at 78 K, which is shown as the solid

Fig. 1. Transient absorption spectra recorded 128–256 ns (-○-) and 4.86–5.09 μs (-□-) after the laser pulse, from the laser flash photolysis of 0.11 mmol/L solutions of 2-phenylheptamethyltrisilane (**5d**) in (*a*) hexane and (*b*) hexane containing 3.0 mmol/L Et_3SiH. The insets show transient decays recorded at 440 and 510 nm. The spectrum obtained from a photolysed solution of **5d** in 3-methylpentane at 78 K (—; scaled to match the absorption intensities below 310 nm) is also shown in (*a*).



line in Fig. 1. The low temperature matrix spectrum (λ_{max} = 268, 493 nm) agrees well with that reported by West and coworkers (40), who assigned it to methylphenylsilylene (SiMePh).

The low temperature spectrum is reproduced again in Fig. 2, along with solution phase difference spectra calculated from the spectra of Fig. 1 in two ways. The first spectrum (-□-) was calculated as the difference between the end-of-pulse (128–256 ns) spectra in pure hexane (Fig. 1*a*) and in hexane containing 3 mmol/L Et_3SiH (Fig. 1*b*), and thus isolates that portion of the end-of-pulse spectrum that is quenched by a primary reaction with the silane. Clearly, the difference spectrum (λ_{max} = 270, 510 nm) agrees with the matrix spectrum of SiMePh quite closely; it is also quite similar to the reported solution phase and low temperature

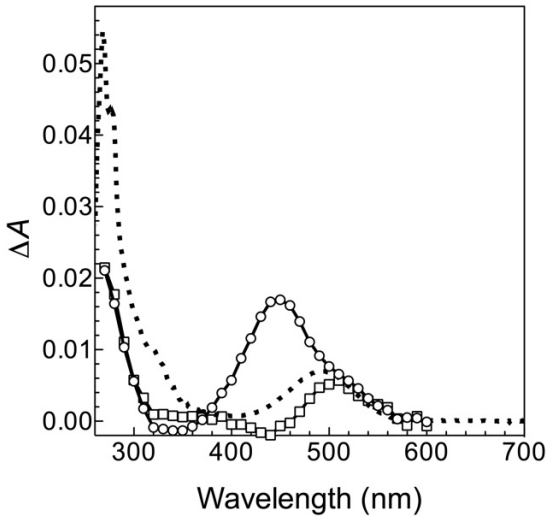
Fig. 2. Transient difference spectra, calculated as the difference between the 128–256 ns spectrum of Fig. 1*a* minus the 128–256 ns spectrum of Fig. 1*b* (-□-), and as the difference between the 128–256 ns and 4.86–5.09 μs spectra of Fig. 1*a* (-○-). The dashed line is the spectrum recorded of a photolysed solution of **5d** in 3-methylpentane at 78 K, reproduced from Fig. 1*a*.

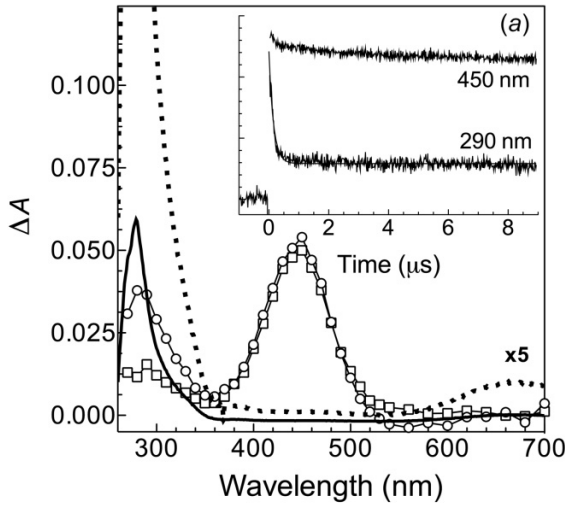


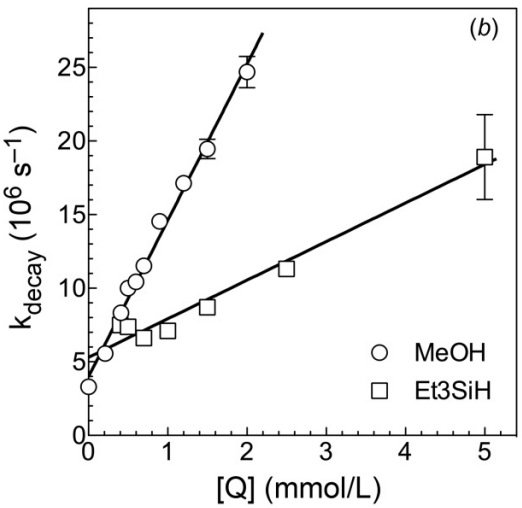
matrix spectra of $SiPh_2$ (34, 40). We thus assign the short-lived absorptions centered at 270 and 510 nm to the silylene, SiMePh. Further support for the assignment is provided by the second order rate constants for quenching of the species by MeOH (k_{MeOH} = (1.8 ± 0.3) × 10^{10} $(mol/L)^{-1}$ s^{-1}), Et_3SiH (k_{Et_3SiH} = (3.4 ± 0.3) × 10^9 $(mol/L)^{-1}$ s^{-1}), and molecular oxygen (k_{O_2} = (1.8 ± 0.2) × 10^8 $(mol/L)^{-1}$ s^{-1}), which were determined from (linear) plots of the pseudo first-order rate constant for decay of the transient signal at 520 nm versus substrate (Q) concentration according to eq. [1]. The rate constants are quite similar to those for the reaction of $SiMe_2$ and $SiPh_2$ with these three substrates in hexane under similar conditions (41); furthermore, the ratio of the absolute rate constants for quenching of the species by MeOH and Et_3SiH (k_{MeOH}/k_{Et_3SiH} = 5.3 ± 1.5) are quite close to the rate ratio determined by Hawari et al. (42) from the competitive trapping of SiMePh by ethanol and Et_3SiH in cyclohexane (k_{EtOH}/k_{Et_3SiH} = 4.8). The lifetime of the 440 nm absorption in the presence of millimolar concentrations of MeOH and Et_3SiH was roughly the same as in pure hexane solution, consistent with its assignment to silene **6d**.

$$[1] \qquad k_{decay} = k_0 + k_Q[Q]$$

The second spectrum of Fig. 2 (-○-) was calculated as the difference between the end-of-pulse and 4.9–5.1 μs spectra of Fig. 1*a*, and thus isolates that portion of the 128–256 ns spectrum of Fig. 1*a* that decays in the first 5 μs after excitation in pure hexane solution (i.e., in the absence of a silylene scavenger). This difference spectrum clearly contains contributions from both SiMePh and silene **6d**, consistent with the presence of a fast initial decay process for the silene that exists only in the absence of a silylene scavenger. We tentatively identify this process as a bimolecular reaction of the silene and silylene; comparison of the maximum absorbance values of the early and late spectra of Figs. 1*a* and 1*b* indicate that roughly 20% of the initially produced amount of **6d** undergoes this rapid initial decay process. No evidence for the formation of the silylene dimerization product, 1,2-dimethyl-1,2-diphenyldisilene ($Si_2Me_2Ph_2$; λ_{max} = 420 nm (43)), could be obtained in any of these experiments, consistent with its formation being quenched as a result of the competing reaction of SiMePh with silene **6d**.

Fig. 3. (*a*) Transient absorption spectra recorded 16–80 ns (-○-) and 432–544 ns (-□-) after the laser pulse, from the laser photolysis of a 0.07 mmol/L solution of phenyltris(trimethylsilyl)silane (**5f**) in deoxygenated hexane, and the scaled spectrum of a photolysed solution of **5f** in 3-methylpentane at 78 K (—); the dotted line shows the latter spectrum magnified by a factor of 5. The inset shows transient decays recorded at 290 and 450 nm. (*b*) Plots of k_{decay} vs [Q] for quenching of the short-lived transient (λ_{max} ~ 285 nm) from **5f** by MeOH (○) and Et_3SiH (□) in deoxygenated hexane at 25 °C; the solid lines are the linear least-squares fits of the data to eq. [1].





Similarly, laser flash photolysis of a rapidly flowed 7 × 10^{-5} mol/L solution of phenyltris(trimethylsilyl)silane (**5f**) in hexane afforded a transient spectrum consisting of two main components, one very long-lived one centered at λ_{max} = 450 nm, which decayed over several milliseconds with mixed order kinetics, and one very short-lived one centered at λ_{max} ~ 285 nm that decayed with first order kinetics and

lifetime τ ~ 300 ns. Figure 3*a* shows transient spectra recorded 16–80 and 432–544 ns after the laser pulse, along with the UV–vis spectrum of a photolysed sample of **5f** in a 3-MP matrix at 78 K. The matrix spectrum (λ_{max} = 280, 680 nm) agrees well with the one reported by Conlin and co-workers, who assigned it to phenyltrimethylsilylsilylene ($Si(Ph)SiMe_3$) (44). The lifetime of the transient signal at 290 nm was shortened upon addition of MeOH or Et_3SiH to the solution. Plots of k_{decay} versus [Q] were linear, analysis of which, according to eq. [1], afforded the second order rate constants $k_{MeOH} = (1.1 \pm 0.1) \times 10^{10}$ $(mol/L)^{-1}$ s^{-1} and $k_{Et_3SiH} = (2.6 \pm 0.4) \times 10^9$ $(mol/L)^{-1}$ s^{-1} for reaction of the species with MeOH and Et_3SiH, respectively. These results are consistent with the assignment of the short-lived 285 nm absorption band to $Si(Ph)SiMe_3$. Unfortunately, the presence of the weak long wavelength band, which is observable in the matrix spectrum, could not be detected in solution, due undoubtedly to the much lower extinction coefficient of this absorption relative to that at 285 nm, which is itself relatively weak. The lifetime of the 450 nm transient was unaffected in the presence of the millimolar quantities of MeOH and Et_3SiH that were required to effect a change in the lifetime of the 285 nm absorption, allowing preliminary assignment of the 450 nm absorption to silene **6f**.

Laser photolysis of solutions of **5e** (~10^{-4} mol/L) in deoxygenated hexane afforded similar results to those reported in our preliminary study of this compound (45): two distinct transient species are formed, one that exhibits λ_{max} = 460 nm and decays over several milliseconds, and one that exhibits a discrete absorption band at λ_{max} = 290 nm, weaker absorptions in the 490–530 nm range and decays over 1–2 μs. The latter is quenched efficiently by added MeOH ($k_{MeOH} = (1.32 \pm 0.04) \times 10^{10}$ $(mol/L)^{-1}$ s^{-1}) and Et_3SiH ($k_{Et_3SiH} = (3.5 \pm 0.2) \times 10^9$ $(mol/L)^{-1}$ s^{-1}), consistent with a silylene ($SiPh_2$) assignment (34). Again, the lifetime of the long-lived species is unaffected by these reagents in millimolar concentrations (34).

Addition of acetone or carbon tetrachloride (CCl_4) to the hexane solutions of **5d–5f** caused the decay of the silene absorptions to accelerate in proportion to substrate concentration and follow clean pseudo first kinetics. Plots of k_{decay} versus [Q] were linear, and were analyzed according to eq. [1] to obtain the second order rate constants listed in Table 1. Figure 4 shows representative plots of k_{decay} versus [Q] for quenching of silenes **6d–6f** by acetone and CCl_4. The lifetimes of the silenes were also observed to decrease upon addition of oxygen to the solutions; second-order quenching rate constants were estimated from three-point plots of k_{decay} values recorded in argon-, air-, and O_2-saturated solutions of **5d–5f** in hexane versus [O_2], which exhibited good linearity in all three cases. Addition of up to 10 mmol/L 2,3-dimethyl-1,3-butadiene (DMB) to hexane solutions of **5f** had little effect on the intensity or lifetime of the 450 nm signal due to silene **6f**, as expected considering the reported rate constants for reaction of the long-lived transients from **5d** and **5e** (i.e., silenes **6d** and **6e**) with this diene, which are in the range of ca. 10^5 $(mol/L)^{-1}$ s^{-1} in cyclohexane (31, 33). Addition of larger quantities of the diene (30–40 mmol/L) led to corresponding reductions in the intensity of the silene absorption due to screening of the excitation light by the added substrate, and very modest increases in the pseudo first order decay rate constant. A plot of k_{decay} versus [DMB] was linear over the 30–40 mmol/L range in added diene, and afforded an estimate of $k_{DMB} = (1.1 \pm 0.1) \times 10^4$ $(mol/L)^{-1}$ s^{-1} for the second order rate constant for reaction of DMB with **6f**.

Quenching of the three silenes by methanol (MeOH) and acetic acid (AcOH) was studied in acetonitrile (MeCN) solution, as preliminary experiments indicated that the effects of these substrates on the silene lifetimes were too small for meaningful rate constants to be determined in hexane, given the solubility limits of the two substrates in the hydrocarbon solvent. Laser photolysis of **5d–5f** in deoxygenated MeCN led in each case to the formation of two long-lived transient

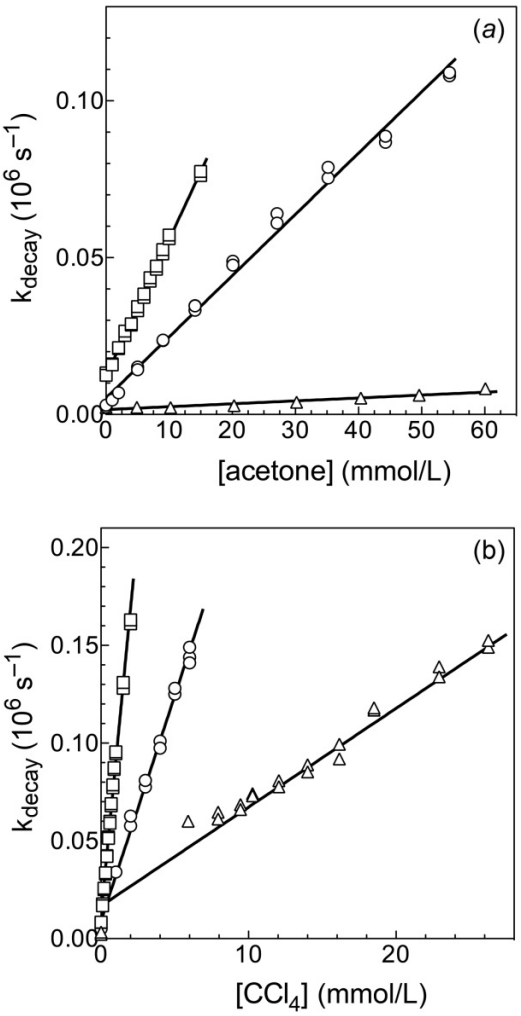
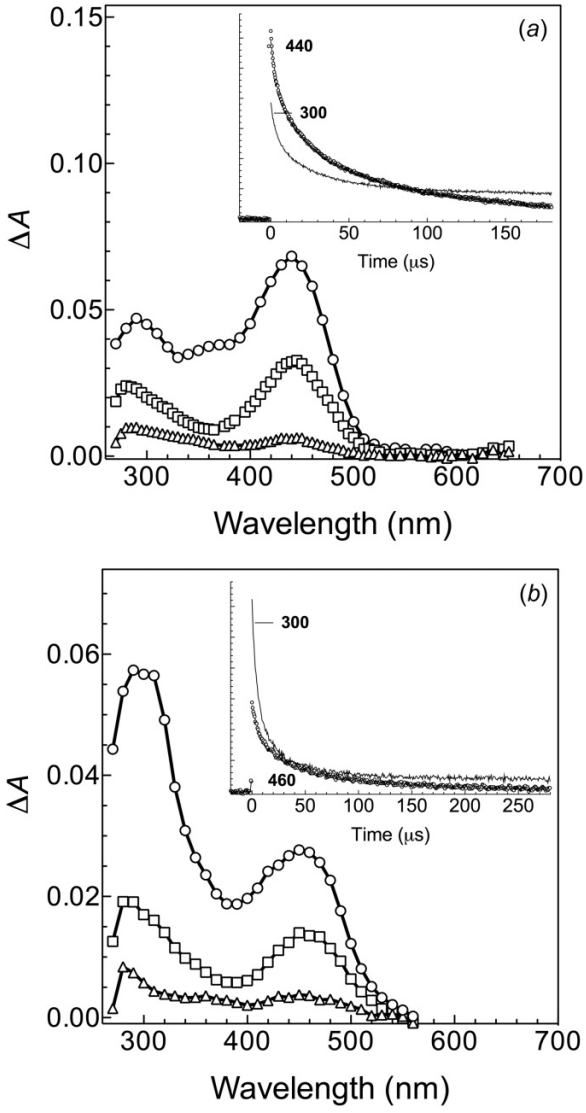
Fig. 4. Plots of k_{decay} vs [Q] for the quenching of silenes **6d** (□), **6e** (○), and **6f** (Δ) by (*a*) acetone and (*b*) CCl_4 in deoxygenated hexane at 25 °C. The solid lines are the linear least-squares fits of the data to eq. [1].



species, one exhibiting an absorption maximum in the 440–460 nm range and a lifetime similar to that of the corresponding transient in hexane and hence assignable to the corresponding silenes, and the second exhibiting λ_{max} ~ 310 nm. The latter absorptions decayed on a distinctly faster time scale with both **5d** and **5e**, but on a similar time scale to the 450 nm absorption in the case of **5f**. Transient absorption spectra recorded at various times after the laser pulse for **5d** and **5e** in MeCN are shown in Fig. 5, while the analogous spectra obtained with **5f** are shown in Fig. 6*a*. Addition of MeOH to the MeCN solutions of **5d** and **5e** caused the lifetimes at 450 nm to shorten and the decays to follow clean pseudo first order kinetics. As we anticipated based on our earlier studies of silenes **6a**–**6c** (16, 17), plots of k_{decay} versus [MeOH] exhibited positive curvature; polynomial least-squares fitting of the data to eq. [2] revealed a good correlation with the square of the MeOH concentration, as is illustrated in Fig. 7*a*. In contrast, the lifetime of silene **6f** in MeCN was barely affected upon addition of up to ca. 2 mol/L MeOH, so no attempt was made to determine a rate

Fig. 5. (*a*) Transient absorption spectra recorded 32–96 ns (-○-), 13.1–13.8 μs (-□-), and 139.5–140.6 μs (Δ) after the laser pulse, from the laser photolysis of a 0.07 mmol/L solution of **5d** in deoxygenated MeCN; the inset shows transient decays recorded at 300 and 440 nm. (*b*) Transient absorption spectra recorded 0–1.2 μs (-○-), 15.4–16.6 μs (-□-), and 99.8–101.1 μs (Δ) after the laser pulse, from the laser photolysis of a 0.07 mmol/L solution of **5e** in deoxygenated MeCN; the inset shows transient decays recorded at 300 and 460 nm.



constant in this case. Silene **6f** could actually be detected quite easily in neat MeOH solution, where it exhibited a lifetime of τ ~ 38 μs and the same absorption maximum as in hexane and MeCN; the spectrum is shown in Fig. 6*b*. The effect of added MeOH on the short wavelength signals observed in experiments in MeCN solution was not investigated.

$$[2] \qquad k_{decay} = k_0 + k_1[\text{MeOH}] + k_2[\text{MeOH}]^2$$

In contrast to the behavior observed with MeOH, addition of AcOH to MeCN solutions of **5d**–**5f** resulted in increases in k_{decay} that varied linearly with concentration in all three

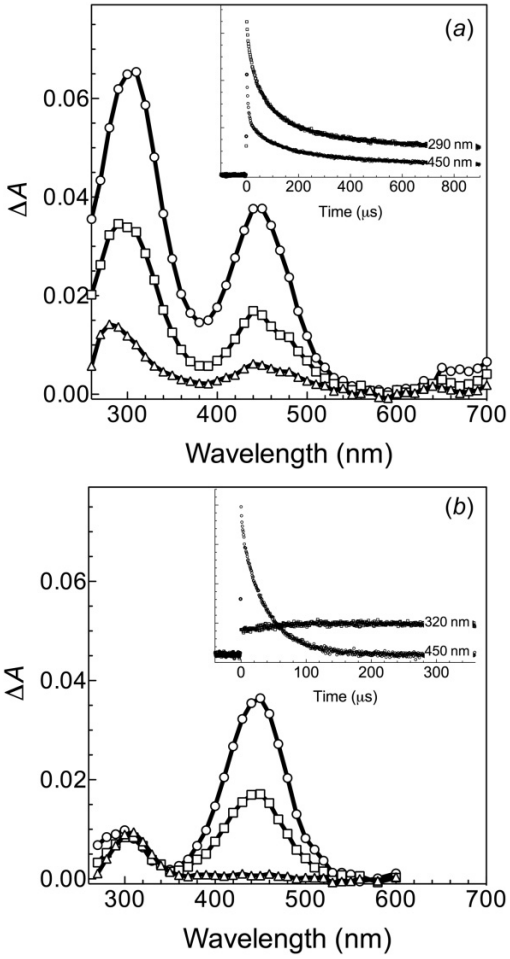
Fig. 6. (*a*) Transient absorption spectra recorded 0–3.2 μs (-○-), 57.6–60.8 μs (-□-), and 540–542 μs (Δ) after the laser pulse, from the laser photolysis of a 0.07 mmol/L solution of **5f** in deoxygenated MeCN; the inset shows transient decays recorded at 290 and 450 nm. (*b*) Transient absorption spectra recorded 0–0.6 μs (-○-), 23.0–24.3 μs (-□-), and 135–136 μs (Δ) after the laser pulse, from the laser photolysis of a 0.07 mmol/L solution of **5f** in deoxygenated MeOH; the inset shows transient decays recorded at 320 and 450 nm.



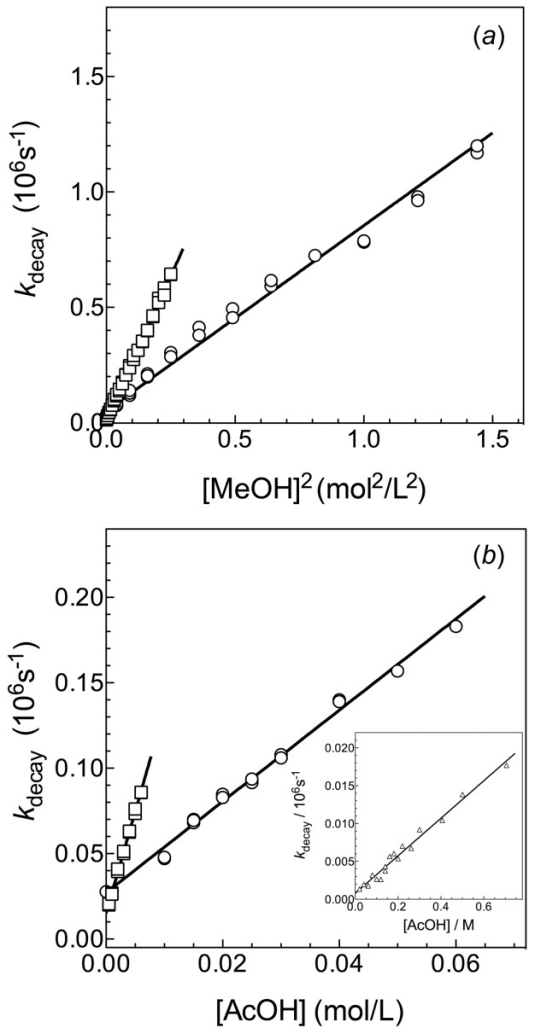
cases. The corresponding quenching plots are shown in Fig. 7*b*.

The kinetic data obtained in these experiments are summarized in Table 1, along with the corresponding, previously reported data for **6a**–**6c**.

Discussion

While early product studies of the photochemistry of **5d**–**5f** focused largely on the reactions of the corresponding silylenes (SiMePh, $SiPh_2$, and $Si(Ph)SiMe_3$, respectively) with various substrates (18, 19, 21, 22), several of them also reported the isolation of products derived from trapping of silenes **6d**–**6f**; specifically, those studies that employed aliphatic dienes (23, 26, 37), terminal alkenes (29, 30), acetone (37), or alcohols (24, 25, 27) as trapping agents. It is clear from these studies that the photolysis of **5d**–**5f** in fluid

Fig. 7. Plots of (*a*) k_{decay} vs $[MeOH]^2$ and (*b*) k_{decay} vs [AcOH] for the quenching of silenes **6d** (□) and **6e** (○) by MeOH and AcOH in deoxygenated MeCN at 25 °C; the inset in (*b*) shows the quenching plot for silene **6f** by AcOH.



solution produces the corresponding silene derivatives in yields comparable to those of the corresponding silylenes and their co-product, Si_2Me_6, in all three cases. Thus, both reactive intermediates should in principle be detectable by laser flash photolysis methods, given an adequate appreciation of what to expect in the way of relative absorption intensities and reactivity patterns for the two species. The lowest energy (π,π*) absorption band in the UV–vis spectra of silenes of this general structure is relatively intense ($\varepsilon_{max} \geq 2 \times 10^4$ $(mol/L)^{-1}$ cm^{-1}) (15), in contrast to the relatively weak ($\varepsilon_{max} \sim 10^3$ $(mol/L)^{-1}$ cm^{-1} (46)) lowest energy (n,p) absorption band in the UV–vis spectra of arylsilylenes. Given that the two types of products are formed in similar yields in all three cases, detection of the silene will clearly be a much easier task than detection of the silylene.

Our flash photolysis results for **5d**–**5f** are indeed consistent with the formation of two distinct transient products in all three cases. The dominant transient absorptions, which we assign to the silenes **6d**–**6f** based on comparisons of their absorption spectra and reactivities to those of the related an-

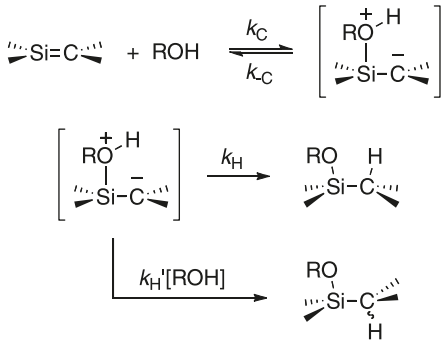
7 **8** **9**

alogues **6a**–**6c** (vide supra), are centered in the 440–460 nm spectral range and exhibit lifetimes of several hundred microseconds or greater; these are the species that were characterized in the earlier laser photolysis studies of **5d** (31, 32) and **5e** (33) in cyclohexane solution. Superimposed on these absorptions in hexane are those assignable to the corresponding silylenes, which are considerably shorter-lived and are quenched several orders of magnitude more rapidly than the 440–460 nm species by MeOH and Et_3SiH; in all three cases, the rate constants are close to the diffusion-controlled limit and are in good agreement with the values reported by us earlier for the reactions of $SiMe_2$ and $SiPh_2$ with the same substrates under similar conditions (34, 45). The presence of $SiPh_2$ in the end-of-pulse spectrum from **5e** is revealed by a relatively strong absorption band centered at λ_{max} = 290 nm, which is due to the $S_0 \rightarrow S_2$ transition of the silylene, and much weaker absorptions in the 480–530 nm range due to the $S_0 \rightarrow S_1$ transition, which we have shown is centered at λ_{max} = 515 nm in hexane at 25 °C (34). Similar short-lived absorptions (λ_{max} ~ 270, 510 nm) are observed in the end-of-pulse spectrum from laser photolysis of **5d**, superimposed on the much stronger absorptions of the long-lived transient coproduct (i.e., silene **6d**). The spectrum of this short-lived species is again quite similar to the low temperature matrix spectrum from **5d** (40), consistent with it being due to the corresponding silylene, SiMePh. With **5f**, on the other hand, the only short-lived absorptions detectable in the end-of-pulse spectrum are centered at λ_{max} ~ 290 nm, and the long wavelength absorption band expected for $Si(Ph)SiMe_3$ on the basis of its low temperature spectrum (44) could not be detected. This is very likely due simply to the lower sensitivity of our instrument at wavelengths above 600 nm coupled with the much lower extinction coefficient of the absorption compared to that at 290 nm (see Fig. 3*a*). Assignment of the latter to $Si(Ph)SiMe_3$ is supported by the observation that it is quenched by MeOH and Et_3SiH with rate constants similar to those measured for the other two silylenes.

The assignment of the dominant, long-lived absorptions to the corresponding silenes **6d**–**6f** is based on comparisons of their spectra and reactivities to those of the related analogues **6a**–**6c** (16, 17), coupled with a knowledge of the effects of methyl-, phenyl- and trimethylsilyl-substitution on the UV–vis spectra and reactivity of the "simple" silene derivatives **7**–**9** (Chart 3) and **3** (3, 13, 47–49). The difference in the absorption maxima of silenes **6d** (λ_{max} = 440 nm) and **6e** (λ_{max} = 460 nm) is consistent with the trend expected from consideration of the spectra of **6a**–**6c**, which exhibit a regular red-shift in λ_{max} as the methyl groups in **6a** (λ_{max} = 425 nm) are replaced with first one phenyl substituent (i.e., **6b**; λ_{max} = 460 nm) and then a second (i.e., **6c**; λ_{max} = 490 nm) (16). As has also been observed for **6a**–**6c** (16), there is no change in the positions of the absorption maxima of **6d**–**6f** upon changing the solvent from hexane to MeCN.

Scheme 2.



Similarly, the relative reactivities of **6d** and **6e** toward MeOH, AcOH, acetone, CCl_4, and O_2, with **6d** exhibiting modestly higher reactivity than **6e** in every case, are quite similar to the differences between the rate constants for reaction of **6a** and **6b** with the same six substrates, as well as to the corresponding differences between **6b** and **6c** (16, 17) (see Table 1). Substitution of a methyl substituent with trimethylsilyl at the silenic Si-atom is known to cause a somewhat smaller red-shift in the UV–vis spectra of silenes compared to phenyl-for-methyl substitution (cf. **7** (λ_{max} = 255 nm) (48), **8** (λ_{max} = 285 nm) (13), and **9** (λ_{max} = 315 nm) (49)), but results in substantially larger reductions in reactivity toward MeOH addition (cf. **7** ($k_1 = 4.9 \times 10^9$ $(mol/L)^{-1}$ s^{-1}) (48), **8** ($k_1 = 1.8 \times 10^8$ $(mol/L)^{-1}$ s^{-1}) (13), and **9** ($k_1 = 3.2 \times 10^9$ $(mol/L)^{-1}$ s^{-1}) (49)). These trends lead to the prediction that compared to the series **6a**–**6c**, there should be a smaller red-shift in λ_{max} as one proceeds through the series **6a**, **6d**, and **6f**, accompanied by a much larger reduction in reactivity towards MeOH. Clearly, the results are in excellent agreement with this prediction. It can be concluded that the UV–vis spectra and reactivity exhibited by **6d**–**6f** follow trends that are not only internally consistent, but are consistent as well with those exhibited by **6a**–**6c** given the known effects of methyl-, phenyl-, and trimethylsilyl-substitution at silicon on the spectra and reactivity of other transient silene derivatives.

Comparison of the kinetic data for the two groups of compounds **6a/6d/6f** and **6c/6e/6f** allows a more detailed assessment of the effects of sequential trimethylsilyl substitution on the kinetics of the six silene-substrate reactions that have been studied in this work. In general, increasing TMS substitution in both series of compounds leads to a reduction in the rate constant for all six of these reactions, which is consistent with previously established trends for other silene derivatives (8, 50). However, the effect varies tremendously with the specific reaction type. For example, the sequential decrease in the rate constants for quenching by CCl_4 and O_2 with increasing TMS substitution in the two series of compounds is relatively small and more or less additive, while for quenching by acetone and DMB the introduction of the first TMS group results in a substantially larger reduction in reactivity than the introduction of the second TMS group. Interestingly, the opposite is true for quenching by MeOH and AcOH.

Of the six reactions studied, that with MeOH exhibits the largest substituent effect on the reaction kinetics. The mech-

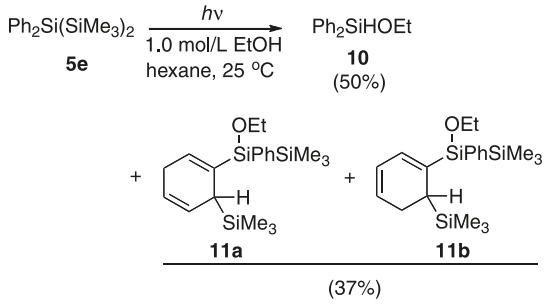
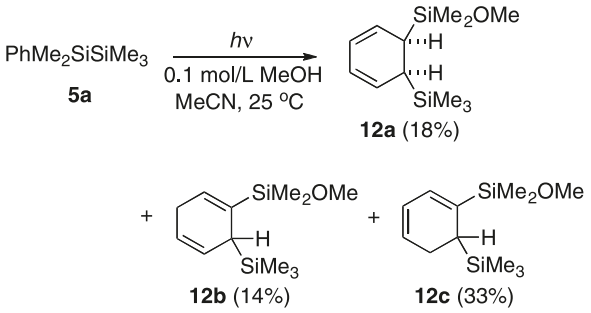


Scheme 4.



anism has been shown to involve initial, reversible nucleophilic attack at silicon to form a zwitterionic complex that proceeds to product via rate-controlling proton transfer from oxygen to the silenic carbon, the latter by competing unimolecular and catalytic pathways (Scheme 2) (10, 15, 17, 47). While this results in overall 1,2-addition in simple (nonconjugated) silenes, three regioisomers corresponding to 1,2-, 1,4-, and 1,6-addition are possible in the reaction of silenes of the type considered here, where the Si=C bond forms the terminus of a 1-silahexatrienyl system. The 1,4- and 1,6-addition products normally dominate the product mixtures from silenes of this type (51); this is exemplified by the results of Kira and co-workers (24, 25) for the photolysis of **5e** in hexane containing 1.0 mol/L ethanol, which yields ethoxydiphenylsilane (**10**; 50%; from trapping of $SiPh_2$) and the 1-silahexatriene-derived products **11a** and **11b** in a combined yield of 37% at 25 °C (Scheme 3). The corresponding 1,2-addition product has been reported in only one instance that we are aware of, from reaction of silene **6a** (generated by photolysis of **5a**) with MeOH (17). The product distribution obtained from reaction of silene **6a** with MeOH (Scheme 4) depends on the alcohol concentration, with reasonable yields of the 1,2-addition product (**12a**) being obtained only at very low alcohol concentrations (17). The 1,4- and 1,6-addition products (**12b** and **12c**, respectively) dominate the reaction mixture at higher alcohol concentrations, conditions that are typical of most of the published studies of the chemistry of silenes of this type. It can thus be concluded that these two regioisomers arise from the catalytic H-transfer pathway for decomposition of the initially formed silene-alcohol complex, while the 1,2-addition product results from the unimolecular H-transfer pathway (17).

The competition between unimolecular and catalytic intracomplex proton transfer is revealed in kinetic experiments by a quadratic dependence of the silene decay rate constant on alcohol concentration, since the catalyst for the latter pathway is a second molecule of the alcohol (see Scheme 2) (10, 15, 17). A variety of mechanisms are possible for the catalysis. With silenes such as **6a**–**6c** in polar solvents, the evidence suggests that it proceeds via a deprotonation-protonation sequence (17), favoring the formation of 1,4- and 1,6-adducts, as mentioned above. In principle, the process could alternatively proceed via a protonation-deprotonation sequence leading to predominant trans-addition (10) or via a concerted "proton-shuttling" mechanism in which the second molecule of alcohol acts simultaneously as acid and base. The transition state for this latter process is envisioned as being similar to that involved in the concerted reaction of the Si=C bond with the hydrogen-bonded dimer of the alcohol, as was proposed recently for the addition of MeOH to silene **2** in hexane solution (8) and should result in overall syn-addition. In any event, whether or not the predicted quadratic dependence of the silene decay rate constant (k_{decay}) on alcohol concentration can actually be observed with a given silene depends on the magnitude of the overall *second*-order rate constant and the maximum time resolution of the kinetic method. Strongly electrophilic silenes such as **3** and **9** (for which $k_1 \sim 10^9$ $(mol/L)^{-1}$ s^{-1} in MeCN) show only the first-order (in alcohol) kinetic component, because it is so fast that the lifetime of the silene becomes too short to be detected on the nanosecond time scale at the higher alcohol concentrations necessary for the second-order component (k_2) to become kinetically significant (47, 49). Moderately reactive silenes (such as **6a**–**6c**, for which $k_1 \leq 3 \times 10^8$ $(mol/L)^{-1}$ s^{-1} in MeCN) typically show both the first- and second-order components (3). Only the second-order component is observed with **6d** and **6e** (see Fig. 7*a*), indicating that the overall second-order reaction pathway is slowed so dramatically relative to that with **6a**–**6c** that it cannot be detected at all; the *only* kinetically significant mechanism for reaction of MeOH with these silenes involves two molecules of the alcohol in the transition state for the rate controlling step, and overall third order reaction kinetics. The rate constant for this process is more than 500 times slower than in **6a**–**6c**, reflecting a substantial reduction in electrophilicity due to the introduction of the TMS substituent at the silenic silicon atom. Silene **6f**, which bears *two* TMS-substituents at silicon, is so weakly electrophilic that its lifetime in MeCN is unaffected by addition of up to 2 mol/L MeOH, and it remains remarkably long-lived even in neat MeOH solution. There is not even a shift in the absorption maximum in the alcohol solvent relative to that in hexane or MeCN, which provides a further indication of the extremely low degree of electrophilicity of this silene derivative. The absorption spectra of all three derivatives are identical in THF and MeCN solution, as is also true of silenes **6b** and **6c**; of this series of silenes only **6a** exhibits a blue-shift of its absorption maximum in THF relative to its value in MeCN, due to complexation with the ether solvent (16). Silene **6f** is estimated to be roughly two orders of magnitude more reactive toward MeOH addition than the Apeloig silene **2**, from comparison of the lifetimes of the two species in MeOH (τ_{6f} =

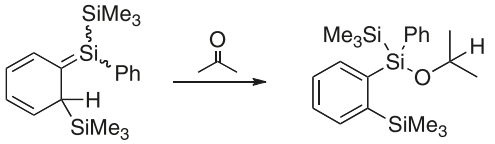
Scheme 5.

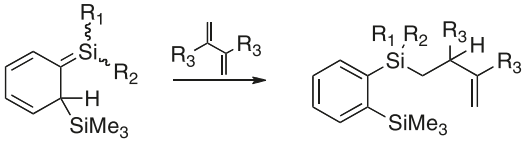


38 μs) or 9:1 *v*/*v* MeOH:THF (τ_2 ~ 14 ms (8)) at 25 °C. This could be the simple result of the pronounced differences in steric bulk of the adamantylidene and cyclohexadienylidene substituents at the silenic carbon in the two silenes.

More moderate variations in rate constants are observed for quenching of the six silenes by acetone, AcOH, and DMB, which proceeds with clean overall second order kinetics in all cases. The major product of the reaction of silene **6e** with acetone is the silyl enol ether derived from formal ene-addition of the ketone C=O bond across the 1-silaallyl moiety of the silene (**13**; Scheme 5) (37); the analogous compounds are also the major products of the reactions of **6a**–**6c** with this ketone, accompanied by minor amounts of the siloxetanes derived from formal [2+2] cycloaddition (16). The formation of the latter products from silenes of this type is most likely general, but as they are rather sensitive to thermal and (or) hydrolytic decomposition, they have been detected in only a few instances (16, 38). The reaction is thought to proceed via a two-step mechanism initiated by formation of a biradical or zwitterionic intermediate that collapses to products via competing ring-closure and intramolecular H-migration (16, 38). The course of the reactions of silenes of this type with AcOH has not been fully established; the product mixture resulting from reaction of AcOH with silene **6a** proved to be intractable in earlier studies, leading to a complex mixture of at least eight products in MeCN solution (17). However, with simpler silenes such as **3** the reaction is known to proceed via formal 1,2-addition of AcOH across the Si=C bond (47). The mechanism is presumably analogous to an ene-addition, involving bonding of the carbonyl oxygen to silicon and transfer of the hydroxyl proton to carbon. The reactions of 1,3-butadiene with **6d** and DMB with **6e** and **6f** afford the corresponding ene-addition products (**14**–**16**; Scheme 6) (23, 26, 37), in identical fashion to the reaction of aliphatic dienes with other (phenyldisilane-derived) 1-silahexatrienes, such as **6a**–**6c** (16, 52). It is interesting to note that the rate constants for reaction of **6a/6d/6f** and **6c/6e/6f** with DMB follow similar trends as those for reaction with acetone (see Table 1), suggesting that for these silenes, Si=C bond polarity provides a similar driving force in both reactions.

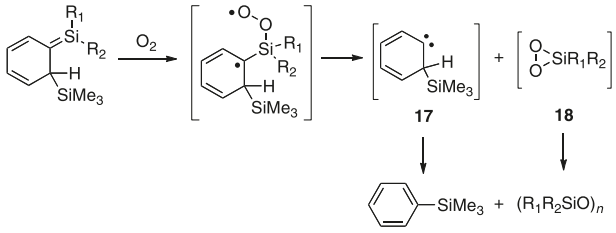
The reactions of silenes of this type with O_2 and CCl_4 are unique in that they proceed much faster than is the case with simpler silene derivatives (3). This suggests that the substitution pattern at the silenic carbon is the main factor controlling the rates of these reactions, with substitution at the silenic Si atom playing only a secondary role. Accordingly, the span in reactivity throughout the present series of compounds toward these two substrates is relatively small, varying by a factor of less than 100 throughout the series (see Table 1); with **6d**–**6f**, these are the fastest reactions that these silenes undergo.

Scheme 6.



6d (R_1 = Me, R_2 = $SiMe_3$, R_3 = H) **14**
6e (R_1 = Ph, R_2 = $SiMe_3$, R_3 = Me) **15**
6f (R_1 = R_2 = $SiMe_3$, R_3 = Me) **16**

Scheme 7.

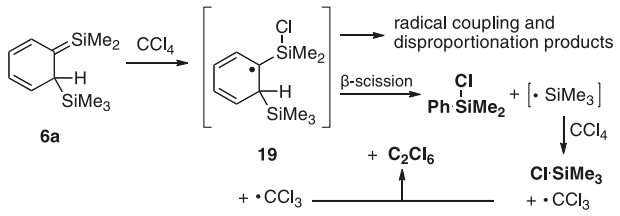


The reaction with O_2 is thought to proceed via rate-determining attack of the substrate at the silenic Si atom to yield the corresponding triplet 1,4-biradical, which in the present series of compounds enjoys significant resonance stabilization owing to the fact that the C-terminus is part of a cyclohexadienyl system (16). In the cases of **6a** and **6c**, the final products of the reaction are phenyltrimethylsilane and the corresponding silanone oligomers, $(Me_2SiO)_n$ from **6a** and $(Ph_2SiO)_n$ from **6c**, which have been proposed to be formed from carbene **17** and dioxasilirane **18**, respectively, produced by cleavage of the 1,4-biradical (Scheme 7) (16).

The product mixtures resulting from the reaction of silenes of this type with CCl_4 have not been fully characterized; we reported previously that photolysis of **5a** and **5c** in cyclohexane-d_{12} containing 0.03 mol/L CCl_4 leads to complex mixtures of products that include the chlorosilanes derived formally from Si–Si bond homolysis, and hexachloroethane (16). A reinvestigation of the photolysis of **5a** in the presence of CCl_4 under similar conditions to those used in our earlier study (0.03 mol/L **5a**; 0.03 mol/L CCl_4), and monitoring the course of the photolysis at low (ca. 3%–12%) conversions by (600 MHz) ^{1}H NMR spectroscopy, allowed quantification of the chemical yields of $PhMe_2SiCl$ (50%) and Me_3SiCl (26%) relative to consumed **5a**; chloroform (as $CHCl_3$; 14%) was also identified in the mixture. The spectra also showed evidence for the formation of at least one additional aromatic product, and a series of resonances in the δ 2.7–4 and δ 5.7–6.4 regions that are characteristic of 1,3- and 1,4-cyclohexadiene derivatives (16, 17), in significant yields. On the basis of these results, we suggest that the reaction of **6a** with CCl_4 most likely proceeds via Cl atom abstraction to yield cyclohexadienyl radical **19** and the trichloromethyl radical (Scheme 8). The formation of $PhMe_2SiCl$ is then accounted for by β-scission of radical **19**, while $CHCl_3$ and the unidentified aromatic and cyclohexadiene products are the products expected from coupling and disproportionation processes involving **19** and

© 2008 NRC Canada

Scheme 8.



trichloromethyl and trimethylsilyl radicals, the latter being produced as the coproduct of the β-scission process in **19**.

It has been suggested that the reaction is likely initiated by electron transfer, based on the facts that quenching of **6a**–**6c** by CCl_4 is significantly faster in MeCN than in hydrocarbon solvents and more than 100 times faster than quenching by chloroform (16). The very modest variation in rate constant throughout the present series of compounds is probably also consistent with this notion, to the extent that varying combinations of methyl-, phenyl-, and trimethylsilyl-substitution at the silenic silicon would be expected to have relatively small effects on the oxidation potential of the 1-silahexatrienyl moiety that is common to all six of these silenes.

Finally, it is interesting to note that the UV–vis spectra recorded after photolysis of **5d**–**5f** in 3-MP matrixes at 78 K differ significantly from the time-resolved spectra obtained by flash photolysis in fluid solution at room temperature (see Figs. 1–3 and ref. (33)). This is consistent with a marked difference in the temperature and (or) medium dependences of the quantum yields for formation of the corresponding silylenes and silenes from photolysis of these compounds, with silene formation being suppressed almost entirely when the three compounds are photolysed in solid matrixes at low temperature.

Summary and conclusions

Laser flash photolysis of the well-known silylene precursors **5d**–**5f** in hexane solution leads to strong, long-lived transient absorptions due to the corresponding silene derivatives **6d**–**6f**, superimposed on the very weak, much shorter-lived absorptions due to the silylenes SiMePh (from **5d**), $SiPh_2$ (from **5e**), and $Si(Ph)SiMe_3$ (from **5f**). The UV–vis spectra of the silylenes in hexane solution can be extracted from the raw transient spectra by selective quenching with Et_3SiH, which reacts several orders of magnitude more rapidly with the silylenes than with the corresponding silenes. The resulting spectra are quite similar to those recorded in a 3-methylpentane matrix at 78 K, where photolysis of **5d**–**5f** affords the silylenes with high selectivity. In solution at room temperature, photolysis of the three compounds affords the corresponding silenes and silylenes in nearly equal yields.

Along with the related, phenyldisilane-derived silene derivatives **6a**–**6c**, the three silenes studied in the present work form a contiguous series of silenes bearing the six possible combinations of methyl-, phenyl-, and trimethylsilyl-substituents at the silenic silicon atom. The UV–vis spectra of the six silenes vary in a rational way with substitution, as do the absolute rate constants for their reactions with methanol (MeOH), acetic acid (AcOH), acetone, 2,3-dimethyl-1,3-butadiene (DMB), molecular oxygen, and carbon tetrachloride in hexane or MeCN solution. The results allow the first systematic, quantitative study of the well-known stabilizing effects of trimethylsilyl substitution at the silicon atom in silenes, applied to a selection of different reaction types. These include the nucleophilic addition of alcohols, the formal ene-addition reactions of carboxylic acids, ketones, and dienes, and the radical-like reactions with oxygen and CCl_4. All are slowed significantly by trimethylsilyl substitition at the silenic silicon atom, underlining the importance of Si=C bond polarity as a common, general driving force in the reactions of silenes.

Experimental

Compounds **5a** and **5d**–**5f** were prepared by the published methods (26, 53–55) and purified by vacuum distillation followed by column chromatography on silica gel using hexanes as eluant. Acetone (Caledon Reagent) was used as received from the supplier. Methanol (Baker Photrex) and 2,3-dimethyl-1,3-butadiene (Sigma-Aldrich) were distilled. Carbon tetrachloride (Sigma-Aldrich) was purified by distillation over P_2O_5 and passed through a short silica gel column. Glacial acetic acid (Sigma-Aldrich), acetonitrile (Caledon HPLC), and 3-methylpentane (Sigma-Aldrich spectrophotometric grade) were used as received from the suppliers. Triethylsilane (Sigma-Aldrich) was distilled from lithium aluminum hydride. Hexanes (EMD OmniSolv) and tetrahydrofuran (Caledon Reagent) were dried by passage through activated alumina under nitrogen using a Solv-Tek solvent purification system (Solv-Tek, Inc). Deuterated solvents were used as received from Cambridge Isotope Laboratories.

Laser flash photolysis experiments employed the pulses from a Lambda Physik Compex 120 excimer laser filled with F_2/Kr/Ne mixtures (248 nm; 25 ns; 90–120 mJ/pulse), and a Luzchem Research mLFP-111 laser flash photolysis system, modified as described previously (56). Solutions were prepared at concentrations (ca. 10^{-4} mol/L) such that the absorbance at the excitation wavelength (248 nm) was ca. 0.7, and were flowed through a 7 × 7 mm Suprasil flow cell from calibrated 100 or 250 mL reservoirs, fitted with a glass frit to allow bubbling of argon gas through the solution for at least 30 min prior to and then throughout the duration of each experiment, using a Masterflex™ 77390 peristaltic pump fitted with Teflon tubing (Cole-Parmer Instrument Co.). The sample cell and transfer lines were dried before use in a vacuum oven at 65–85 °C, while the reservoir was flame-dried and allowed to cool under an argon atmosphere. Reagents were added directly to the reservoir by microliter syringe as aliquots of standard solutions. Rate constants were calculated by linear least-squares analysis of decay rate-concentration data consisting of at least 10 points for all substrates except oxygen. For the latter, they were calculated from k_{decay} values in Ar-, air- and O_2-saturated solution, with use of neutral density filters to achieve reasonably clean pseudo first order kinetics in Ar-saturated solution. The errors in the absolute rate constants are quoted as twice the standard error obtained from the least-squares analyses.

Low temperature UV–vis spectroscopic experiments employed 2 cm × 1 cm × 1 cm cuvettes constructed from Suprasil quartz tubing (Vitro Dynamics, Inc.) and an Oxford Optistat™ liquid nitrogen cryostat equipped with an Oxford ITC601 temperature controller. Samples were irradiated in a Rayonet Photochemical Reactor (Southern New England Ultraviolet Company) fitted with 12 RPR-2537 lamps.

Steady state photolysis of a 0.031 mol/L solution of **5a** in C_6D_{12} containing CCl_4 (0.03 mol/L) and CH_2Cl_2 (0.005 mol/L; internal standard) was carried out in a quartz NMR tube, after deoxygenating the solution with a fine stream of argon and sealing the tube with a rubber septum. The photolysis was monitored at periodic time intervals by 600 MHz ^{1}H NMR spectroscopy (Bruker AV600), and chemical yields were determined from the slopes of concentration versus time plots, constructed by integration of the peaks due to **5a** and those products that could be specifically identified in the photolysate ($PhMe_2SiCl$, Me_3SiCl, and $CHCl_3$) by spiking the mixture with authentic samples. Representative NMR spectra and concentration versus time plots are given in the Supplementary Data.[2]

Nonthermalized excited states in Ru(II) polypyridyl complexes probed by ultrafast transient absorption spectroscopy with high photon energy excitation

Sherri A. McFarland, Karen A.W.Y. Cheng, Felix S. Lee, Frances L. Cozens, and Norman P. Schepp

Abstract: The picosecond excited state dynamics of a series of homoleptic Ru(II) polypyridyl complexes (where LL = bpy, dmb, dmeob, dfmb, or dttb) have been investigated in aqueous solution at room temperature using femtosecond transient absorption spectroscopy with high photon energy excitation. All of the complexes studied produced similar spectroscopic signatures: a near-instantaneous bleach centered at 470–500 nm corresponding to the static absorption spectrum, as well as an intense absorption (475–650 nm) that decayed within the instrument response function (IRF) to form a broad, low-level absorption extending from 500–650 nm. Detailed analyses of both kinetic and spectral parameters by singular value decomposition (SVD) indicate that the excited state difference spectra contain contributions from at least three distinguishable species that have been assigned as ligand-based $\pi^* \leftarrow \pi^*$ and ligand-to-metal-charge-transfer (LMCT) transitions concomitant with the loss of the ground state metal-to-ligand-charge-transfer (MLCT) transition. Kinetic information extracted at 530 nm (an optical marker for the fully intraligand-delocalized ^{3}MLCT state) or 660 nm (LMCT transitions) appear to be biphasic in some cases with the amplitude of the IRF-limited component becoming larger with shorter wavelength excitation. Further, rise dynamics were observed at redder probe wavelengths for $Ru(bpy)_3^{2+}$ and $Ru(dttb)_3^{2+}$. These observations are different from those obtained using lower photon energy excitation and show that excitation wavelength strongly influences the early photophysical events in these Ru(II) complexes.

Key words: ruthenium, photophysics, lasers, transient absorption spectroscopy, excited states, singular value decomposition (SVD).

Résumé : Opérant à la température ambiante, en solution aqueuse, et faisant appel à la spectroscopie d'absorption des états transitoires au niveau de la femtoseconde et une excitation à l'aide de protons de haute énergie, on a étudié la dynamique d'états excités à la picoseconde d'une série de complexes polypyridyles du ruthénium(II) homoleptiques [dans lesquels LL = bpy, dmb, dmeob, dfmb ou dttb). Tous les complexes étudiés produisent des signatures spectroscopiques semblables: une décoloration pratiquement instantanée centrée aux environs de 470 à 500 nm correspondant au spectre d'absorption statique ainsi qu'une absorption intense (475–650 nm) qui décroît en dedans de la fonction de réponse de l'instrument (FRI) pour former une large absorption de faible intensité s'étendant de 500 à 650 nm. Des analyses détaillées des paramètres tant cinétiques que spectraux par la méthode de décomposition de valeur singulière (DVS) indique que le spectre différentiel de l'état excité contient des contributions provenant d'au moins trois espèces distinctes qui ont été attribuées à des transitions $\pi^* \leftarrow \pi^*$ à base de ligand et d'autres de transfert de charge ligand à métal (TCLM) concomitantes avec la perte de la transition de transfert de charge métal à ligand de l'état fondamental (TCML). L'information cinétique extraite des bandes à 530 nm (un marqueur optique pour l'état TCML) ou 660 nm (transitions TCLM) semble être biphasique dans certains cas, alors que l'amplitude de la composante limitée par la fonction de réponse de l'instrument devient plus importante lorsque la longueur d'onde de l'excitation devient plus courte. De plus, avec les complexes $Ru(bpy)_3^{2+}$ et $Ru(dttb)_3^{2+}$, on a observé une augmentation de la dynamique aux longueurs d'onde plus rouges de la sonde. Ces observations sont différentes de celles obtenues à l'aide d'une excitation avec des photons de plus faible énergie et elles démontrent que la longueur d'onde de l'excitation influence fortement les premiers événements photophysiques dans ces complexes du Ru(II).

Mots-clés : ruthénium, photophysique, lasers, spectroscopie d'absorption des espèces transitoires, états excités, DVS.

Introduction

A growing area of research involves the systematic investigation of photochemical and photophysical properties that define the behaviour of both organic and inorganic systems on short timescales. These endeavours not only provide invaluable information regarding the electronic structure of molecules, they also further our ability to use rational design in the construction of light-dependent molecular devices (1–4). Such an approach to functional chromophores requires a fundamental understanding of how molecules absorb and dissipate radiant energy. Often, absorption of photonic energy does not directly populate the lowest-lying electronic state of a molecule, the state that is usually involved in photon emission or photochemical reactions on conventional timescales. In fact, a host of states may be sampled between initial population of the Franck–Condon state and relaxation over all electronic and vibrational modes in the excited manifold, invoking a variety of radiationless decay mechanisms. Internal conversion (IC), intersystem crossing (ISC), and vibrational relaxation (VR) are important decay channels that ultimately dictate the path of excited state evolution and influence emission quantum yields as well as spectra.

The unifying feature of nonradiative decay among excited states is the short time that it takes for these transitions to occur. With the advent of femtosecond lasers, elucidation of ultrafast dynamics in both organic and inorganic systems is now possible, and reports from a number of groups studying diverse chemical systems continue to outline the importance of the earliest stages of excited state evolution (5–10). For example, nonthermalized excited states have been implicated in a variety of processes from electron and energy transfer (11, 12) to photochemical reactions including isomerization and ligand dissociation (13, 14). Perhaps more notable is the role that higher excited states play in applications involving solar energy conversion (15). Specifically, work from numerous laboratories has shown that the use of transition metal complexes as sensitizers for wide-band gap semiconductors is dependent on the efficiency of electron injection from the dye to the TiO_2 conduction band (16). This efficiency is determined by two competing processes: interfacial electron transfer and intramolecular relaxation dynamics (17, 18). Evidence suggests that electron transfer rates are maximal when operating in the nonergodic regime (19, 20)[2]; therefore, detailed investigation of the processes that immediately follow photon absorption is critical for developing more efficient devices based on this technology.

Nonradiative transitions among excited states are determined by the relative rates of electronic surface crossings and vibrational relaxation. Established models of intramolecular excited state relaxation are based largely on simple cascade population dynamics observed for organic molecules, wherein vibrational relaxation is much faster than formal changes in electron spin multiplicity ($k_{vib} \gg k_{IC} \gg k_{ISC}$) (21). Systems characterized by a large number of electronic and vibrational states that can participate in excited state decay do not adhere to this simplified kinetic scheme; consequently, excited state decay in transition metal complexes ultimately depends on the state(s) initially populated, resulting in a strong excitation-wavelength dependence of the observed kinetics, as well as ISC rates that are much faster than VR (9, 14, 22).

For example, both transient absorption and fluorescence upconversion experiments indicate that ISC in $Ru(bpy)_3^{2+}$ occurs with a time constant of $\tau = 40 \pm 15$ fs, whereas vibrational cooling in the ^{3}MLCT manifold spans several picoseconds when pumped at 400 nm (5, 23). Longer wavelength excitation ($\lambda_{ex} = 480$ nm) produces no significant changes in the excited state absorption spectra beyond 300 fs; these subpicosecond dynamics are reported to encompass a host of

[2] The term *nonergodic* in this context is used to describe a state that has not thermally equilibrated on the excited state surface. These states are intermediate in energy between the Franck–Condon state(s) and the Boltzmann-distributed ^{3}MLCT state(s).

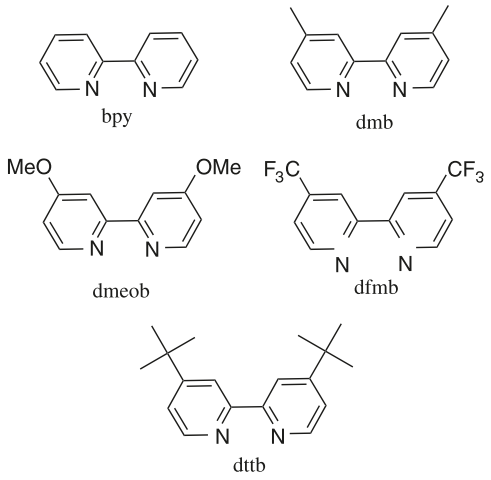
processes including ISC, IC, charge localization, VR, and intramolecular vibrational energy redistribution (IVR). Figure 1 summarizes these recent modifications to the well-established photophysical model for ruthenium(II) polypyridyl complexes.

To elucidate further the early events following photon absorption by transition metal complexes, our group has documented the picosecond dynamics produced in response to population of nonthermalized excited states in $Ru(bpy)_3^{2+}$ and a series of its derivatives by high photon energy excitation (24). Pump wavelengths of 388 and 258 nm produce emission at 500 nm that is more complex than previously reported using longer wavelength excitation (5, 6). Specifically, we determined additional time constants of τ = 1–3 ns for a series of 4,4′-substituted ruthenium(II) bipyridyl complexes (Fig. 2); while this additional relaxation pathway was not observed for $Ru(bpy)_3^{2+}$ with 388 nm excitation, 258 nm excitation of $Ru(bpy)_3^{2+}$ gave rise to a small contribution from the longer-lived component. These findings demonstrate the need for a comprehensive reassessment of our current understanding of inorganic photophysics, with an appreciation for the information that can be gleaned from close examination of the excitation-wavelength dependence of the observed kinetics.

Recently, our research efforts have concentrated on the use of picosecond luminescence and femtosecond absorption spectroscopy to address the excitation-wavelength dependence of excited state evolution in $Ru(bpy)_3^{2+}$ and related derivatives. In particular, we used femtosecond absorption spectroscopy to investigate the nature of a longer-lived state (τ = 1–3 ns) that was first detected in our earlier work involving picosecond luminescence experiments with short-wavelength excitation. We note a significant contribution to excited state decay from a broad band in the visible region that decays within the instrument response function (IRF) when pumped with 388 nm excitation. While the resolution of our instrument precluded the accurate determination of rate constants for the various processes, we were able to use

Chart 1. Bipyridyl ligands studied using transient absorption spectroscopy with 388 nm excitation.



singular value decomposition (SVD) to discern rise dynamics that have not been previously reported for several of the complexes. Through this work we show that both excitation wavelength and subtle changes in ligand identity influence the nature of excited state dynamics, a finding of significant importance in the field of optoelectronic device construction. Moreover, these findings further support the observation that simple cascade population dynamics are not sufficient to describe the photophysics of transition metal complexes, and a growing number of exceptions for organic molecules have been documented as well (25–27).

Experimental section

Materials

Ruthenium(II) complexes (Cl_2 and $(PF_6)_2$ salts) and their corresponding ligands (Chart 1) were synthesized according to modified literature protocols (24) and chromatographed on silica gel ($MeCON:H_2O:KNO_3$ gradient) or on Sephadex. Following recrystallization from an acetonitrile/toluene mixture, the complexes were characterized by TLC, ^1H NMR, ^{13}C NMR, HPLC, and mass spectrometry. HPLC traces were run on samples before and after laser irradiation to ensure sample degradation was not a factor in the transient absorption experiments.

Static and nanosecond time-resolved spectroscopies

Static absorption, emission, and nanosecond time-resolved emission measurements were carried out as previously described (24), and where possible, the parameters obtained from static and nanosecond spectroscopies were compared with those in the literature.

Picosecond time-resolved emission spectroscopy

Time-resolved luminescence measurements were performed using a Clark-MXR CPA-2001 femtosecond laser for sample excitation and a streak camera (Axis-Photonique) coupled to a CCD camera (SenSys) for detection. Experimental details are reported elsewhere (24).

Sample preparation for femtosecond absorption spectroscopy

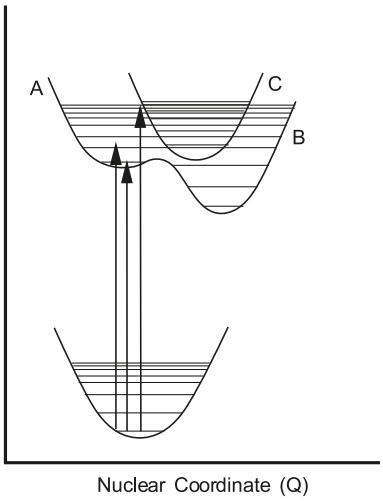
Ruthenium(II) complex (50 mL, 1 mmol/L) was diluted with solvent until the absorbance of the solution was 0.4–0.6 at 388 nm. This solution was recycled at a flow rate of 116.5 mL/min by a varistaltic pump through a Helma quartz flow cell (1 mm). The collection process was randomized to eliminate effects due to systematic sample degradation. Each raw spectrum consisted of 2500 accumulated shots and was corrected for luminescence and dark counts. Three of these raw spectra were averaged to produce the experimental spectrum recorded; each raw spectrum was manually inspected to discount faulty shots due to laser instability.

Femtosecond transient absorption spectroscopy

Femtosecond electronic absorption data were acquired using a Clark-MXR CPA-2001 femtosecond laser for generating pump and probe beams and a SpectroPro-300i Imaging spectrograph (Acton Research Corporation) equipped with an ST-116 photodiode array (PDA, Princeton Instruments, Inc.) for detection. Briefly, the CPA-2001 employs an all solid-state diode-pumped Erbium-fiber laser, which generates <150 fs, 775 nm pulses at 1 KHz with an output energy of ~800 μJ per pulse. The output is split by a STORC-2001 unit (Clark-MXR); one of the pulses is frequency-doubled to 388 nm (or tripled to 258 nm) to produce the pump beam, and the unchanged fundamental is used to generate a white-light continuum in sapphire (1 mm) or water contained in a 30 mm quartz cell. The frequency-doubled 388 nm pump beam (216 fs, 7 mm in diameter) is directed to the sample using a series of thin film mirrors and is softly focused (~1.5 mm) on the sample cell 15° from normal through a plano-convex lens with a 50 mm focal length. The excitation power at the sample is ~3.5 μJ, and for the series of complexes studied, the signal response varies linearly as the power is attenuated.

The 775 nm light used to generate the white light continuum is directed by a series of thin-film mirrors through two variable delay rails: the Parker Rail Table (Parker) allows time delays up to 7 ns with 188.3 fs resolution, while the NanoStepper (Baldor Motion Products) allows the probing of the first 500 fs of the experiment with 33.36 fs resolution. Once the fundamental beam passes through the second delay rail, it is directed through a Berek's compensator (New Focus), with the alignment and retardance set to emulate a 1/2 wavelength waveplate for 775 nm radiation, and a Glan-laser polarizer (Thorlabs). The Berek's compensator and Glan-laser polarizer together form a variable attenuator with output polarized at 54.7° with respect to the pump beam to avoid anisotropy effects. The polarized pump beam is focused by a 100 mm focal length BK7 broadband antireflective (BBAR)-coated planoconvex lens into a white light generator, and the broadband radiation is collimated by an achromatic MgF_2 lens with a focal length of 50.8 mm. If a water cell is used as the white light source, a Schott colour glass filter (S8612) is inserted to attenuate selectively the red wavelengths, and an iris is present to isolate the stable center of the broadband beam. Finally, the probe beam is focused (0.2 mm diameter) using an achromatic lens (150 mm focal length) through the sample onto a fibre optic cable.

Fig. 3. Potential energy surface diagram depicting the influence of excitation energy on population dynamics.



To collect full-spectrum data, the fibre optic cable directs transmitted light from the sample into a SpectroPro-300i Imaging spectrograph (Acton Research Corporation) coupled to a thermoelectrically cooled ST-116 PDA detector (Princeton Instruments, Inc.). A standard general purpose information bus (GPIB) computer interface allows data to be accumulated on a chip to maximize the number of laser experiments that can be measured while minimizing data transfer time. Absorbance values were calculated at each wavelength according to the following equation

$$A = \log\left(\frac{C_{\text{probe}} - D}{R_{\text{pump probe}} - F_{\text{pump}}}\right)$$

where A is the calculated absorbance value, C_{probe} is the probe data in the absence of the pump beam, D represents the dark counts, $R_{\text{pump,probe}}$ is the probe data collected while the pump beam is incident on the sample cell, and F_{pump} is the fluorescence data collected with the pump beam only. Since the chirp in our probe beam is significant over the spectral window (450–750 nm), distortion of the spectra at early times must be corrected. Unchirped spectra were produced from the original data using software written in-house. The temporal-spectral profile of the chirped pulse, a parameter required by the program, was calculated from two-photon absorption spectra of 2-methylnathphalene. Once $t = f(\lambda)$ has been determined, it remains invariant as long as the experimental setup is not altered.

Singular value decomposition

SVD analysis was carried out on the unchirped absorption spectra using MATLAB®. New matrices were constructed from the best three-component representations of the original, unchirped transient matrix spectra. Kinetics were then compared for the original data matrices and the results of the SVD at every 100th wavelength. Wavelength indices were selected to interrogate regions of the spectra corresponding to MLCT and LMCT transitions (480, 532, and 650 nm) and to determine the utility of SVD as a noise filter for address-

ing limitations imposed by the resolution of our current laser setup.

Results and discussion

Figure 3 provides a model illustrating the effect of excitation wavelength on the state(s) initially populated for some ruthenium(II) polypyridyl complexes. This qualitative picture is based on our recent discovery that 388 nm excitation produces picosecond luminescence at 500 nm that is not observed in experiments carried out with longer wavelength excitation (24). Femtosecond transient absorption spectra collected after 480 nm excitation as well as 400 nm excitation further corroborate this model (5, 6). The general trend is toward simpler kinetics when longer wavelength excitation is used, suggesting that less energetic wavelengths preclude access to some states. Our modification of the original kinetic model outlined by Bhasikuttan et al. (23) for $Ru(bpy)_3^{2+}$ (Fig. 2) proposes that state A represents the ^{1}MLCT manifold and state B represents the corresponding triplet manifold; the nature of state C, emissive only when high photon energy excitation is used, is the subject of this investigation.

We previously outlined three plausible scenarios concerning the nature of state C: (*i*) a higher vibrational level of state B, (*ii*) a local minimum on the surface of state B, or (*iii*) a distinct state altogether (24). If state C were indeed a "hot" vibrational state of B, then its lifetime would be expected to be much shorter than the observed lifetime (τ = 1–3 ns) since vibrational cooling is generally on the order of 0.5–5 ps. Therefore, only the latter possibilities need to be considered. To distinguish among these possibilities, we used femtosecond transient absorption spectroscopy to probe picosecond and subpicosecond dynamics.

Full-spectrum transient absorption data for all five ruthenium(II) homoleptic complexes (based on the ligands shown in Chart 1)[3] contained several unifying spectral features that were evident regardless of the timescale of the experiment (Figs. S1–S6).[4] Excitation at 388 nm produced the characteristic ^{1}MLCT ground state bleach centered in the range of 450–500 nm with maxima determined by the identity of the ligand substituents, which was superimposed on a broad absorption band spanning 475–650 nm. This extended absorption region consisted of two overlapping absorption bands as determined by spectroelectrochemical measurements: absorption transitions due to the reduced ligand at 500–530 nm and LMCT transitions involving the oxidized ruthenium center at 575–665 nm. These data agree well with spectra reported in the literature utilizing longer pump wavelengths (5, 6). However, the kinetics and relative amplitudes associated with these transitions exhibit an excitation-wavelength dependence not reported previously. Further, to our knowledge, the ultrafast dynamics of homoleptic 4,4′-methoxy, -trifluoromethyl, and -*tert*-butyl Ru(II) polypyridyl complexes have not been reported.

Upon excitation at 388 nm, all of the ruthenium(II) homoleptic complexes investigated produced spectroscopic signatures that remained unchanged when probed in 100 ps intervals from –0.5 ps to 5 ns. Considering the pronounced decay (τ = 1–3 ns) observed at 500 nm for the homoleptic 4,4′-substituted bipyridyl complexes in the luminescence experiments (τ_{ex} = 388 nm) and the absence of discernible decay kinetics in the region interrogating reduced bipyridine ligands in the corresponding transient absorption experiments, we conclude that the absorptive properties we observe are indicative of triplet surface dynamics.[5] The characteristic spectroscopic signatures, as well as established timescales for the formation of the ^{3}MLCT state (5, 6, 23) are consistent with such a conclusion. Based on the assumption that distinct states will produce distinct spectral characteristics, we assign state C as a metastable entity of ^{3}MLCT origin (scenario (*ii*), vide supra) that is accessed only with relatively short-wavelength excitation. Both steric and electronic perturbation of the complexes, by variation in ligand identity, produced similar results, indicating that this state is a general feature of homoleptic ruthenium(II) 4,4′-substituted bipyridyl complexes when probed with short-wavelength excitation. At even shorter wavelength excitation (τ_{ex} = 258 nm), similar states in the parent $Ru(bpy)_3^{2+}$ are populated (24). It should be noted that there is no reason a priori to expect that a decay in emission measurements should have a corresponding transient in the absorption measurements: the transitions being probed are not the same. Moreover, uncertainty exists with regard to whether the transients are actually absent in the absorption data as the absorption spectra are complicated by a superposition of MLCT and LMCT transitions that may mask any pertinent kinetics associated with the transition of interest.

Transient absorption spectra were also collected for all five homoleptic complexes on shorter timescales (t = 0–15 ps). Excitation with 388 nm radiation in aqueous solutions produced bleach signals corresponding to the ground

[3] The ultrafast dynamics of $Ru(bpy)_3^{2+}$ have been studied previously by fluorescence upconversion as well as transient absorption spectroscopy using longer pump wavelengths. $Ru(dmb)_3^{2+}$ has been studied previously by transient absorption spectroscopy with longer pump wavelengths. To the authors' knowledge, the nonthermalized excited states for homoleptic complexes derived from dmeob, dfmb, and dttb have not been reported previously.

[5] It should be noted that the luminescence we observed in the picosecond experiments at 500 nm occurred with a quantum yield having an upper limit of ~10^{-4}, estimated by the absence of 500 nm emission when using a conventional steady-state fluorimeter. If one assumes that this low quantum yield represents a rather small portion of the initially excited molecules, then corresponding changes in the transient absorption spectrum may not be detectable unless there is an allowed transition with appreciable oscillator strength from this weakly luminescent state. In the absence of significant changes in the spectroscopic profile of the complexes when probed with shorter wavelength excitation, we assume dynamics reflect relaxation in the triplet manifold. Similarly, we assume that the absence of dynamics in the transient absorption spectra indicates no signicant change in electronic configuration of the weakly luminescent state relative to the triplet state formed by ISC with a time constant of 40 fs. This assumption should be constantly re-examined for each particular case.

state ^{1}MLCT absorption, with precise maxima determined by the identity of the ligand (Fig. 4). Interestingly, the loss of ground state population did not appear instantaneous due to an overlapping broad absorption band that extended into the bleach region. This intense signal decayed within the instrument response function (~305 fs) to form a broad, low-level absorption extending from 500 to 650 nm that was identical to the absorption signature observed at 5 ns. After 1 ps, each absorption spectrum was relatively constant out to 15 ps in regions representative of the ground state bleach and bipyridine radical anions, a finding that contrasts with what others have measured for $[Ru(dmb)_3](PF_6)_2$ in acetonitrile resulting from 400 nm (~120 fs) excitation (6).

Previous femtosecond electronic absorption spectroscopy on $[Ru(dmb)_3](PF_6)_2$ reveals biexponential kinetics, which are not complete until ~15 ps at 532 nm. This portion of the spectrum is characteristic of the dmb^- chromophore (6). Deconvolution reveals a fast component ($\tau = 120 \pm 40$ fs) reported to reflect contributions from the ^{1}MLCT $\rightarrow$ ^{3}MLCT surface crossing on the timescale of the excitation pulse as well as a slower decay ($\tau = 5 \pm 0.5$ ps) due to vibrational cooling dynamics in the ^{3}MLCT excited state. With 388 nm (~150 fs) excitation, the slower dynamics previously associated with vibrational cooling in the triplet manifold are virtually absent and the signal is dominated by a transient that decays within the excitation pulse. In the absence of major changes in the overall spectroscopic signature for $[Ru(dmb)_3](PF_6)_2$ when excited with higher photon energy, we tentatively conclude that vibrational cooling is further facilitated when the Frank–Condon state possesses excess energy. The guiding principle in this assumption is that a constant spectral profile as a function of time indicates that the observed kinetics are not associated with a significant change in the electronic structure of the molecule (9). However, the excitation wavelength determines the nature of the initially populated vibronic hot state (16), and it is possible that the state initially populated could be fundamentally different, e.g., an intraconfigurational transition that does not significantly perturb the excited state absorption spectrum. Femtosecond infrared measurements will prove useful in future investigations regarding the dynamics associated with IVR and VC in these complexes.

Another interesting point of difference, with respect to the dynamics of $[Ru(dmb)_3](PF_6)_2$ when the pump wavelength is shortened, occurs in regions representative of predominantly LMCT transitions. With 388 nm excitation, we observed a sharp decay within the IRF superimposed on a low-level absorption that was constant out to 15 ps. According to Damrauer and McCusker (6), excitation (~120 fs) at 400 nm produces no discernible dynamics at 650 nm. Since spectroelectrochemical measurements indicate that there are contributions from both LMCT and dmb^- absorptions of the excited state, it is possible that this time-independent data at 650 nm reflect a superposition of decay and rise kinetics associated with two distinct signals that occur in a similar wavelength regime. In a case where a single process dictates evolution dynamics, time-independent data at 650 nm indicate that the dynamics must be highly localized, representing only the ligand housing the π^* electron of the ^{3}MLCT state. Our observation of a very fast decay in this region corroborates the assertion that the lack of dynamic features at 650 nm ($\lambda_{ex} = 400$ nm) in previous studies (6) is due to a superposition of LMCT and dmb^- absorptions, i.e., both the oxidized ruthenium center as well as a neutral ligand also contribute to the early events following photon absorption. Further, changing the excitation wavelength by only 12 nm changes the relative contributions of LMCT and dmb^- decay channels. Not only is this observation interesting from a photophysical standpoint, such control over excited state processes in transition metal complexes underscores the idea that judicious selection of excitation wavelength can profoundly influence the nature of excited state decay and may prove useful in tuning sensitizer properties for light-mediated applications.

To quantify time constants associated with the dynamics observed with 388 nm excitation of the complexes, we attempted to apply the method of singular value decomposition (SVD). SVD has been used successfully by others to analyze μs–fs transient absorption spectra when two or more transient species are involved (28–32). Briefly, a set of time-resolved spectra can be treated as a matrix **A**, where the *i*th row vector corresponds to the spectrum at the *i*th time delay point. According to the SVD theorem, the $m \times n$ $\Delta\mathbf{A}$ matrix can be written as the product of three matrices

$$\Delta\mathbf{A} = \mathbf{U}\cdot\mathbf{S}\cdot\mathbf{V}^T$$

where $\Delta\mathbf{A}$ is a $m \times n$ matrix consisting of absorbance changes at m wavelengths and n different time delays, **U** is a $m \times n$ matrix consisting of n orthonormal basis spectra, **S** is a $n \times n$ diagonal matrix containing the positive square roots of the eigenvectors (singular values) of **A**, and **V** is a $n \times n$ matrix where the columns (rows of $\mathbf{V}^T$) contain the time course amplitude for the corresponding basis spectra in matrix **U**. Basis spectra are scaled by their singular values to display their relative contributions to the observed data. The most useful information is contained in the first few components; increasing noise in the successive components results from the decreased amplitude of each basis spectrum in the observed spectra.

The SVD of the set of time-resolved spectra yielded four principal singular values (for all of the complexes) with $n =$

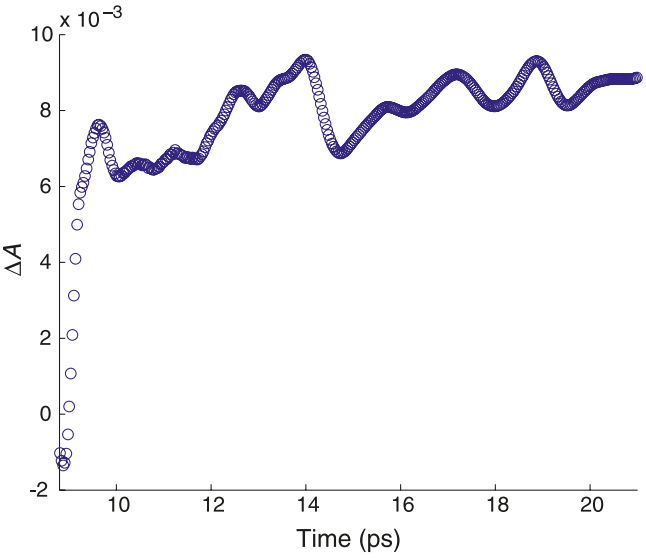
© 2008 NRC Canada

5 and higher singular values being almost zero and regarded as noise. Figure 4 was derived from the best four-component representation of the data matrix, illustrating the use of SVD as a noise filter (see Fig. S1 for original matrix).[4] Our attempts to use SVD as well as global analysis to extract kinetics did not yield readily interpretable results. This was not surprising given the lack of significant changes in the overall spectral profiles associated with relaxation processes such as vibrational cooling. A major problem with ultrafast dynamics is that nonthermalized excited states give rise to spectra that evolve continuously over time, precluding access to well-defined spectra.

Although the use of SVD and global analysis to extract time constants met with little success, the techniques did prove useful in analyzing the behaviour of the homoleptic complexes at long probe wavelengths, in the region dominated by LMCT transitions superimposed on the low energy shoulder of the reduced ligand $\pi^* \leftarrow \pi^*$ absorption. For both $Ru(dfmb)_3^{2+}$ and $Ru(dmb)_3^{2+}$, an IRF-limited decay to a constant background was observed. In the case of $Ru(dmb)_3^{2+}$, the absorption profile as a function of time with 388 nm excitation was very similar to that observed with longer excitation wavelengths (6), with the exception that the relative amplitude of the fast component to constant background was much larger with shorter wavelength excitation. This increased amplitude for the IRF-limited component with 388 nm excitation was a general feature that we observed for all of the complexes in regions probing both $\pi^* \leftarrow \pi^*$ and LMCT transitions. As indicated earlier, we are uncertain whether an increase in the rate of vibrational relaxation or a fundamental difference in the nature of the excited state(s) being probed is responsible; variable wavelength excitation should help clarify. These fast decay dynamics are difficult to interpret but are expected to reflect contributions from the ^{1}MLCT $\rightarrow$ ^{3}MLCT surface crossing. The absence of slower dynamics at 660 nm was not surprising given that λ_{probe} = 532 nm produced only an IRF-limited decay.

$Ru(bpy)_3^{2+}$ and $Ru(dttb)_3^{2+}$ showed interesting behaviour, as indicated in Fig. 5, for $Ru(dttb)_3^{2+}$. An IRF-limited decay followed by a slower rise that did not maximize over the observation window were noted in the transient absorption experiments collected over 15 ps. The slow rise must reach an asymptote shortly after 20 ps, however, since no changes were detected in this region in spectra collected over –0.5–5 ns. To our knowledge, this behaviour has not been documented for $Ru(bpy)_3^{2+}$ when excited at longer wavelengths, and this is the first report on the early dynamics of $Ru(dttb)_3^{2+}$. Curiously, λ_{probe} = 532 nm did not reveal similar rise kinetics, although others have observed analogous discrepancies for $Ru(dmb)_3^{2+}$ (6). In the case of $Ru(dmb)_3^{2+}$ excited at longer wavelengths, a slow decay is observed at λ_{probe} = 532 nm with no corresponding transient at λ_{probe} = 650 nm. The rationale behind this inconsistency, as well as others, has been attributed to an increase in the rate of vibrational cooling as the excited state(s) are probed farther to the red (6, 33, 34). Clearly, this particular explanation does not account for our observations for $Ru(dttb)_3^{2+}$ with shorter wavelength excitation and, therefore, should not be considered a general rule. Perhaps, in this case, there is a difference in the nature of the excited-state transitions being probed. Because the ligand participating in the LMCT transition is not the same ligand involved in the initial photon absorption, differences in the corresponding dynamics should not be surprising. Still, it is possible that that solution inhomogeneity becomes a factor on short timescales, producing distinct transients in the SVD analysis that arise from MLCT states involving ligands that have been rendered essentially nonequivalent. This phenomenon is well-known in solid-state spectroscopy, with MLCT energies shifted up to 1000 cm^{-1} between idential ligands on the same metal, owing to variations in their local environments (35, 36).

Fig. 5. Kinetic profile (λ_{probe} = 660 nm) for $Ru(dttb)_3^{2+}$ in aqueous solution following <150 fs excitation at 388 nm.



Concluding remarks

Our investigation of a series of related complexes underscores the effect that subtle changes in substituents on the bipyridine ligand have on the early relaxation processes that follow photon absorption. While our investigation produced qualitatively similar transient absorption spectra, the use of SVD revealed subtle differences between the complexes depending on the nature of the ligand. For the complexes where data are available, using longer wavelength excitation, namely $Ru(bpy)_3^{2+}$ and $Ru(dmb)_3^{2+}$, we compared our spectra for 388 nm excitation and noted several kinetic discrepancies, which further underscores the excitation and probe wavelength-dependence in transition metal photophysics. We acknowledge that information is lost within the IRF of our instrument in many cases. However, the pump wavelengths housed in our system allows for the probing of Franck–Condon states at the blue edge of the ^{1}MLCT absorption band as well as ligand-centered transitions, states that have not been probed by the conventional wavelengths used by others. While it is ideal to have data collected at various pump wavelengths, probe windows, and timescales on a single instrument, in reality this is feasible for only a very small portion of the overall timescale for electronic and vibrational relaxation, which can span from microseconds to femtoseconds in solution.

© 2008 NRC Canada

The impetus for using femtosecond absorption spectroscopy to characterize further the early events following photoexcitation of ruthenium(II) polypyridyl complexes was two-fold: (1) the τ = 1–3 ns time constant for luminescence at 500 nm that we measured for various 4,4′-substituted homoleptic complexes warranted further investigation, and (2) our ability to excite samples at both 258 and 388 nm, in conjunction with published transient absorption data collected at additional pump wavelengths for similar species, would begin a systematic investigation of the excitation-dependence of early photophysical events in transition metal complexes. Together with the findings of several other researchers, we anticipate that a detailed investigation of the excitation-wavelength dependence of transition metal complex photophysical parameters will outline a more realistic picture of inorganic photophysics where simple cascade population dynamics are not obeyed.

Modification of the NRTL and Wilson models for the representation of phase equilibrium behavior of aqueous amino acid – electrolyte solutions

Rahmat Sadeghi

Abstract: The extended NRTL and Wilson local composition models for amino acid solutions have been modified for the representation of the phase equilibrium behavior of aqueous amino acid – electrolyte solutions by considering cells with random composition for the reference Gibbs energies or enthalpies of local composition cells with a central amino acid molecule and also with a central ion. These new local composition models, which have a molecular thermodynamic framework, have been used to model the vapor–liquid and solid–liquid equilibrium behavior of amino acids and small peptides in aqueous solutions as functions of temperature, ionic strength, and amino acid compositions. The utility of the models is demonstrated with a successful representation of the activity coefficients and the solubility of several amino acids in different aqueous solutions.

Key words: amino acid, NRTL, Wilson, activity coefficient, solubility, aqueous solution.

Résumé : On a modifié les modèles de composition locale étendus de Wilson et NRTL pour représenter le comportement de la phase en équilibre de solutions aqueuses d'acides aminés en présence d'un électrolyte et, pour ce faire, on a considéré des cellules de composition aléatoire pour les énergies ou enthalpies de Gibbs de référence avec une molécule d'acide aminé central et aussi avec un ion central. On a utilisé ces nouveaux modèles de composition locale qui possèdent un squelette thermodynamique moléculaire pour le comportement de l'équilibre vapeur–liquide et solide–liquide d'acides aminés et de petits peptides dans des solutions aqueuses, en fonction de la température, de la force ionique et des compositions en acides aminés. On a démontré l'utilité des modèles à l'aide d'une représentation correcte des coefficients d'activité et de la solubilité de plusieurs acides aminés dans différentes solutions aqueuses.

Mots-clés : acide aminé, NRTL, Wilson, coefficient d'activité, solubilité, solution aqueuse.

[Traduit par la Rédaction]

Introduction

The thermodynamic properties of amino acids, such as solubility and activity coefficients in aqueous solutions, have been extensively studied to better understand their behavior in aqueous solution, the role of solute–solvent interactions on the conformational stability of proteins, and also the design and scale-up of chemical processes for the separation, concentration, and purification of valuable biochemicals (1). Therefore, the development of a model for the activity coefficients of amino acids in aqueous solutions has recently received a great deal of attention. In the last decade, several studies have been performed on the correlation of activity coefficients and solubilities of amino acids in water. In most of these studies, the conventional local composition thermodynamics models (2–7), group contribution methods (8–11), and models based on perturbation theory (12–19) were used to correlate the activity coefficients and solubility of amino acids in aqueous solutions.

One of the most successful models for the representation of phase equilibrium behavior of amino acids in aqueous solutions is the model developed by Chen et al. (4). They used their own version of the electrolyte NRTL model (20) to model the activity coefficients of amino acids and peptides. In this model, long-range interactions are represented by the Pitzer–Debye–Huckel form (21), and short-range interactions are given by a modified form of the NRTL equation [22]. Similar to the NRTL model (4) in our recent previous work (23), the Wilson model was extended to calculate activity coefficients and the solubility of amino acids in aqueous solutions. In these models (4, 23), the pure liquid solvent, the pure liquid amino acid, and the pure completely dissociated electrolyte, respectively, were used for the reference Gibbs energies or enthalpies of local composition cells with a central solvent molecule, central amino acid molecule, and central ion. It has been shown that (24–26) in the local composition models, when the random case is considered for the reference state of the components, the model becomes more flexible than the case in which a pure component is considered for the reference state of components. The promising features of the random case for the reference state of the components led us to improve the NRTL and Wilson models for mixture containing both amino acid and electrolyte, which is an important system in respect to its use in biotechnology. In this study, in continuation of our previous

 doi:10.1139/V08-166 © 2008 NRC Canada

work on the extension of local composition models for amino acid solutions (23), the extended NRTL (4) and Wilson (23) models for amino acid solutions have been modified for the representation of the phase equilibrium behavior of aqueous amino acid – electrolyte solutions. Although in the models proposed in this work, similar to the extended NRTL (4) and Wilson (23) models, the pure liquid solvent was used for the reference Gibbs energies or enthalpies of local composition cells with a central solvent molecule; however, cells with random composition are used for the reference Gibbs energies or enthalpies of local composition cells with a central amino acid molecule and also with a central ion. These extended models are applied to calculate the solubility of amino acids in pure water and in aqueous electrolyte solutions, and the solubility of a mixture of two amino acids in water are also investigated.

Theory

To generalize the modified NRTL and Wilson models for a multicomponent aqueous solution containing several electrolytes and zwitterions, the molar excess Gibbs energy g^{ex*} is expressed as the sum of two contributions,

$$[1] \qquad \frac{g^{ex*}}{RT} = \frac{g^{ex*,LR}}{RT} + \frac{g^{ex*,SR}}{RT}$$

where $g^{ex*,LR}$ is the long-range interaction contribution, $g^{ex*,SR}$ is the short-range interaction contribution, and the superscript * stands for unsymmetric convention. The long-range interaction term accounts for the electrostatic interactions between ions, and the short-range interaction term considers the non-electrostatic interactions between all species (ion, solvent, and zwitterion). In this work, the Pitzer extension of Debye–Huckel function (PDH) (21) and the modified NRTL or Wilson models are used to calculate $g^{ex*,LR}$ and $g^{ex*,SR}$, respectively.

Long-range interaction contributions to the excess Gibbs energy

The PDH equation for excess Gibbs energy normalized in Henry's convention can be written as,

$$[2] \qquad \frac{g^{ex*,\,PDH}}{RT} = -\left(\sum_i x_i\right)\frac{4A_x I_x}{\rho}\ln(1+\rho I_x^{0.5})$$

where

$$[3] \qquad A_x = \frac{1}{3}\left(\frac{2\pi N_A}{V_w}\right)^{\frac{1}{2}}\left(\frac{e^2}{4\pi\varepsilon D_w KT}\right)^{\frac{3}{2}}$$

where the ρ, N_A, K, ε and e are the closest distance parameter, Avogadro's number, Boltzmann constant, permitivity of vacuum and electronic charge, respectively. x_i is the mole fraction of component i. I_x is the ionic strength in mole fraction basis. The parameter ρ is related to the hard-core collision diameter, or distance of closest approach, of ions in solution. Therefore, the value of ρ depends on the electrolyte as well as the expression used to represent the short-range forces. To maintain simplicity in equations for more complex electrolyte systems, it is desirable that ρ should have the same value for a wide variety of salts. The value of $\rho = 14.9$ has been frequently used for aqueous electrolyte solutions (27). Therefore, this value was also used in this work. The V_w and D_w are the molar volume and dielectric constant of the solvent (or mixed solvent).

Short-range interaction contributions to the excess Gibbs energy

In a solution containing electrolytes and amino acids, the short-range forces originate from the zwitterion–zwitterion, solvent–solvent, solvent–zwitterion, solvent–ion, zwitterion–ion, and non-electrostatic ion–ion interactions. To consider these interactions in a similar manner to the approach of Chen and Evans (20), we assume the existence of four types of local cells, namely, cells with a central zwitterion, cells with a central cation, cells with a central anion, and cells with a central solvent molecule. According to the specific interaction theory, it is assumed that the like-ion repulsion is so strong that cells with a central cation do not contain any cations, and that cells with a central anion do not contain any anions. Since based on these assumptions the cells with a central ion contain only zwitterions, counterions, and solvent molecules, they are not necessarily electrically neutral. However, cells with a central zwitterion or solvent molecule contain zwitterions, cations, anions, and solvent molecules in the immediate neighborhood of the central zwitterion or solvent molecule. Therefore, cells with a central zwitterion or solvent molecule are electrically neutral.

NRTL model

For a multicomponent aqueous solution containing several solvents, electrolytes, and zwitterions, by summing the contributions of the different local composition cells to the excess Gibbs energy of the whole solution we have,

$$[4] \qquad g^{ex,NRTL} = \sum_w X_w(g^w - g^w_{ref}) + \sum_m X_m(g^m - g^m_{ref}) + \sum_n X_{c_n}(g^{c_n} - g^{c_n}_{ref}) + \sum_n X_{a_n}(g^{a_n} - g^{a_n}_{ref})$$

The Gibbs energy of cells with a central solvent w, amino acid m, cation of electrolyte n, and anion of electrolyte n denoted by g^w, g^m, g^{c_n}, and g^{a_n}, respectively, can be related to the effective local mole fractions by,

$$[5] \qquad g^w = \sum_{w'} X_{w'w}g_{w'w} + \sum_m X_{mw}g_{mw} + \sum_n X_{c_nw}g_{c_nw} + \sum_n X_{a_nw}g_{a_nw}$$

$$[6] \qquad g^m = \sum_w X_{wm}g_{wm} + \sum_{m'} X_{m'm}g_{m'm} + \sum_n X_{c_nm}g_{c_nm} + \sum_n X_{a_nm}g_{a_nm}$$

$$[7] \qquad g^{c_n} = Z_{c_n}\left(\sum_w X_{wc_n}g_{wc_n} + \sum_m X_{mc_n}g_{mc_n} + \sum_n X_{a_nc_n}g_{a_nc_n}\right)$$

$$[8] \qquad g^{a_n} = Z_{a_n}\left(\sum_w X_{wa_n}g_{wa_n} + \sum_m X_{ma_n}g_{ma_n} + \sum_n X_{c_na_n}g_{c_na_n}\right)$$

The main difference between the model developed in this work and the original NRTL (4) model is in their reference Gibbs energies of local composition cells with a central sol-

© 2008 NRC Canada

ute (zwitterions, cation, and anion). Following Jaretun and Aly (28), the reference Gibbs energies of local composition cells with a central solute (zwitterions, cation, and anion) are taken as a cell with random composition, as opposed to the original NRTL (4) model. The pure component is taken as the reference state for the Gibbs energies of local composition cells with a central solvent molecule. Thus we have,

[9] $$g_{\text{ref}}^{w} = g_{ww}$$

[10] $$g_{\text{ref}}^{m} = \frac{\sum_{w} X_w g_{wm} + \sum_{m'} X_{m'} g_{m'm} + \sum_{n} X_{c_n} g_{c_n m} + \sum_{n} X_{a_n} g_{a_n m}}{\sum_{w} X_w + \sum_{m'} X_{m'} + \sum_{n} X_{c_n} + \sum_{n} X_{a_n}}$$

[11] $$g_{\text{ref}}^{c_n} = Z_{c_n} \left(\frac{\sum_{w} X_w g_{wc_n} + \sum_{m} X_m g_{m c_n} + \sum_{n} X_{a_n} g_{a_n c_n}}{\sum_{w} X_w + \sum_{m} X_m + \sum_{n} X_{a_n}} \right)$$

[12] $$g_{\text{ref}}^{a_n} = Z_{a_n} \left(\frac{\sum_{w} X_w g_{wa_n} + \sum_{m} X_m g_{m a_n} + \sum_{n} X_{c_n} g_{c_n a_n}}{\sum_{w} X_w + \sum_{m} X_m + \sum_{n} X_{c_n}} \right)$$

The local mole fractions of component j and k in a local composition cell with a central species i are defined by the expression,

[13] $$\frac{X_{ji}}{X_{ki}} = \frac{X_j}{X_k} = G_{ji,ki}$$

By defining the following normalizing equations for the four kinds of local compositions cells that appear in the solution,

[14] $$\sum_{w'} X_{w'w} + \sum_{m} X_{mw} + \sum_{n} X_{c_n w} + \sum_{n} X_{a_n w} = 1$$

[15] $$\sum_{w} X_{wm} + \sum_{m'} X_{m'm} + \sum_{n} X_{c_n m} + \sum_{n} X_{a_n m} = 1$$

[16] $$\sum_{w} X_{wc_n} + \sum_{m} X_{mc_n} + \sum_{n} X_{a_n c_n} = 1$$

[17] $$\sum_{w} X_{wa_n} + \sum_{m} X_{ma_n} + \sum_{n} X_{c_n a_n} = 1$$

The modified NRTL model for the molar excess Gibbs energy is obtained as,

[18]
$$\begin{aligned}
\frac{g^{\text{ex,NRTL}}}{RT} = {} & \sum_{w} X_w \left(\frac{\sum_{w'} X_{w'} G_{w'w} \tau_{w'w} + \sum_{m} X_m G_{mw} \tau_{mw} + \sum_{n} (X_{c_n} + X_{a_n}) G_{e_n w} \tau_{e_n w}}{\sum_{w'} X_{w'} G_{w'w} + \sum_{m} X_m G_{mw} + \sum_{n} (X_{c_n} + X_{a_n}) G_{e_n w}} \right) \\
& + \sum_{m} X_m \left[\left(\frac{\sum_{w} X_w G_{wm} \tau_{wm} + \sum_{m'} X_{m'} G_{m'm} \tau_{m'm} + \sum_{n} (X_{c_n} + X_{a_n}) G_{e_n m} \tau_{e_n m}}{\sum_{w} X_w G_{wm} + \sum_{m'} X_{m'} G_{m'm} + \sum_{n} (X_{c_n} + X_{a_n}) G_{e_n m}} \right) \right. \\
& \left. - \frac{\sum_{W} X_w \tau_{wm} + \sum_{m'} X_{m'} \tau_{m'm} + \sum_{n} (X_{c_n} + X_{a_n}) \tau_{e_n m}}{\sum_{w} X_w + \sum_{m} X_m + \sum_{n} (X_{c_n} + X_{a_n})} \right] \\
& + \sum_{n} X_{c_n} \left[\left(\frac{\sum_{w} X_w G_{we_n} \tau_{we_n} + \sum_{m} X_m G_{me_n} \tau_{me_n} + \sum_{n'} X_{a_{n'}} G_{e_{n'} e_n} \tau_{e_{n'} e_n}}{\sum_{w} X_w G_{we_n} + \sum_{m} X_m G_{me_n} + \sum_{n'} X_{a_{n'}} G_{e_{n'} e_n}} \right) \right. \\
& \left. - \frac{\sum_{w} X_w \tau_{we_n} + \sum_{m} X_m \tau_{me_n} + \sum_{n'} X_{a_{n'}} \tau_{e_{n'} e_n}}{\sum_{w} X_w + \sum_{m} X_m + \sum_{n'} X_{a_{n'}}} \right] \\
& + \sum_{n} X_{a_n} \left[\left(\frac{\sum_{w} X_w G_{we_n} \tau_{we_n} + \sum_{m} X_m G_{me_n} \tau_{me_n} + \sum_{n'} X_{c_{n'}} G_{e_{n'} e_n} \tau_{e_{n'} e_n}}{\sum_{w} X_w G_{we_n} + \sum_{m} X_m G_{me_n} + \sum_{n'} X_{c_{n'}} G_{e_{n'} e_n}} \right) \right. \\
& \left. - \frac{\sum_{w} X_w \tau_{we_n} + \sum_{m} X_m \tau_{me_n} + \sum_{n'} X_{c_{n'}} \tau_{e_{n'} e_n}}{\sum_{w} X_w + \sum_{m} X_m + \sum_{n'} X_{c_{n'}}} \right]
\end{aligned}$$

In the above relations X_i is the effective mole fraction and is given by

[19] $$X_i = x_i K_i,$$

($K_i = Z_i$ for ions and K_i = unity for molecules)

where Z is the charge number, and G and τ are energy parameters given by,

[20] $$G_{ij} = \exp\left(-\alpha_{ij}\frac{(g_{ij}-g_{jj})}{RT}\right) = \exp(-\alpha_{ij}\tau_{ij}) = \exp\left(-a_{ij}\frac{a_{ij}}{RT}\right)$$

[21] $$G_{ij,kj} = \exp\left(-\alpha_{ij,kj}\frac{(g_{ij}-g_{kj})}{RT}\right) = \exp(-\alpha_{ij,kj}\tau_{ij,kj}) = \exp\left(-\alpha_{ij,kj}\frac{a_{ij,kj}}{RT}\right)$$

[22] $$a_{c_n m} = a_{a_n m} = a_{e_n m}, \quad a_{c_n w} = a_{a_n w} = a_{e_n w}$$

[23] $$a_{mc_n,a_n c_n} = a_{ma_n,c_n a_n} = a_{m,e_n}, \quad a_{wc_n,a_n c_n} = a_{wa_n,c_n a_n} = a_{w,e_n}$$

[24] $$a_{a_n c_{n'}} = a_{c_n a_{n'}} = a_{e_n e_{n'}}$$

where α is the nonrandomness factor, which is symmetric. The nonrandomness factor was fixed at 0.2 for binary electrolyte–molecule pairs and binary electrolyte–electrolyte pairs. It was set at 0.3 for binary molecule–molecule pairs (4). The interaction energy g_{ij} is also symmetric.

Wilson model

The main difference between the Wilson model and the extension of the NRTL model is the assumption that the short-range energy parameter between species in a local cell has an enthalpic rather than Gibbs energy nature. Therefore, similar to the NRTL model, for a multicomponent aqueous solution containing several solvents, electrolytes, and zwitterions, by summing the contributions of the different local composition cells to the excess enthalpy of the whole solution we have,

[25] $$h^{ex,Wilson} = \sum_w X_w(h^w - h^w_{ref}) + \sum_m X_m(h^m - h^m_{ref}) + \sum_n X_{c_n}(h^{c_n} - h^{c_n}_{ref}) + \sum_n X_{a_n}(h^{a_n} - h^{a_n}_{ref})$$

The enthalpy of cells with a central solvent w, amino acid m, cation of electrolyte n, and anion of electrolyte n denoted by h^w, h^m, h^{c_n}, and h^{a_n}, respectively, can be related to the effective local mole fractions by,

[26] $$h^w = \sum_{w'} X_{w'w}h_{w'w} + \sum_m X_{mw}h_{mw} + \sum_n X_{c_n w}h_{c_n w} + \sum_n X_{a_n w}h_{a_n w}$$

[27] $$h^m = \sum_w X_{wm}h_{wm} + \sum_{m'} X_{m'm}h_{m'm} + \sum_n X_{c_n m}h_{c_n m} + \sum_n X_{a_n m}h_{a_n m}$$

[a]The models binary interaction parameters were set to zero.

$$[28]\quad h^{c_n} = Z_{c_n}\left(\sum_w X_{wc_n} h_{wc_n} + \sum_m X_{mc_n} h_{mc_n} + \sum_n X_{a_n c_n} h_{a_n c_n}\right)$$

$$[29]\quad h^{a_n} = Z_{a_n}\left(\sum_w X_{wa_n} h_{wa_n} + \sum_m X_{ma_n} h_{ma_n} + \sum_n X_{c_n a_n} h_{c_n a_n}\right)$$

Similar to the NRTL model for the reference enthalpy of local composition cells we have,

$$[30]\quad h^{w}_{\text{ref}} = h_{ww}$$

$$[31]\quad h^{m}_{\text{ref}} = \frac{\sum_w X_w h_{wm} + \sum_{m'} X_{m'} h_{m'm} + \sum_n X_{c_n} h_{c_n m} + \sum_n X_{a_n} h_{a_n m}}{\sum_w X_w + \sum_{m'} X_{m'} + \sum_m X_{c_n} + \sum_n X_{a_n}}$$

$$[32]\quad h^{c_n}_{\text{ref}} = Z_{c_n}\left(\frac{\sum_w X_w h_{wc_n} + \sum_m X_m h_{mc_n} + \sum_n X_{a_n} h_{a_n c_n}}{\sum_w X_w + \sum_m X_m + \sum_n X_{a_n}}\right)$$

$$[33]\quad h^{a_n}_{\text{ref}} = Z_{a_n}\left(\frac{\sum_w X_w h_{wa_n} + \sum_m X_m h_{ma_n} + \sum_n X_{c_n} h_{c_n a_n}}{\sum_w X_w + \sum_m X_m + \sum_n X_{c_n}}\right)$$

The local mole fractions of component *j* and *k* in a local composition cell with a central species *i* are defined by the expression,

$$[34]\quad \frac{X_{ji}}{X_{ki}} = \frac{X_j}{X_k} H_{ji,ki}$$

By considering the normalizing eqs. [14–17], the modified Wilson model for the molar excess enthalpy is obtained as,

lytes, and the species *i*, *j*, and *k* can be cation, anion, amino acids, or solvent molecules. The reference state for a solvent molecule is the pure liquid at system temperature and pressure. The reference state for ionic species and neutral dipolar species, or zwitterions, is the infinite dilution state in aqueous phase. The NRTL relation for the activity coefficient of a species *i* in the system can be obtained from appropriate differentiation of eqs. [1], [2], and [18]. Similarly, the Wilson relation for the activity coefficient of a species *i* in the system can be obtained from appropriate differentiation of eqs. [1], [2], and [37]. In fact, the dissociation extends of amino acids in unbuffered, pure water are relatively insignificant. In other words, in the unbuffered solutions of amino acids, the neutral dipolar species are predominant amino acid species, while the concentration of ionic amino acid species is negligible (5).

Results and discussion

Activity coefficients of amino acids

The models were employed to correlate the activity coefficient data of several amino acids and peptides in binary aqueous solutions. As the activity coefficient calculated from the models is normalized on the mole fraction base, the activity coefficients of amino acids reported in the literature were converted from the molality base to the mole fraction base using the following relation (29),

$$[43] \quad \gamma^{(x)} = \gamma^{(m)}(1 + 0.001 M_w m)$$

where M_w is the molecular weight of the solvent, γ is the activity coefficient, m is the molality of the amino acid, and the superscripts m and x represent the molality and mole fraction base, respectively. The adjustable water-amino acid energy parameters a_{wm} and a_{mw} for the NRTL model and E_{wm} and E_{mw} for the Wilson model were estimated by minimizing the following objective function,

$$[44] \quad \text{OF} = \sum_{l=1}^{N} (\gamma_{m,l}^{*,\text{cal}} - \gamma_{m,l}^{*,\text{exp}})^2$$

The fitting parameters of the models along with the corresponding root-mean-square deviations (RMSD) are given in Table 1. On the basis of the obtained deviations given in Table 1, we conclude that the both models presented in this work can accurately describe the activity coefficients of amino acids and small peptides with good results. Figure 1 shows the correlation results by the modified NRTL model for the activity coefficients for several amino acids as a function of molality at T = 298.15 K.

Solubilities of amino acids in water

Amino acids, peptides, and proteins are ampholytes that exist in solutions partly as cations and anions. The neutral dipolar species are the predominant species in isoelectric solutions of amino acids and proteins. In fact, in the absence of a proton donor or acceptor, up to 99% of the amino acid molecules are in their zwitterionic form. In other words, in the absence of a proton donor or acceptor, the physicochemical properties of different ionized forms of the amino acids in aqueous solutions are represented by those of the zwitterionic form, and the formations of amino acid cations and anions have little impact on the amino acid solubilities and they can be ignored. Therefore, the solubility data can be represented by regressing the thermodynamic solubility constant of following equation,

$$[45] \quad A(\text{s}) \leftrightarrow A^{+-}(\text{aq})$$

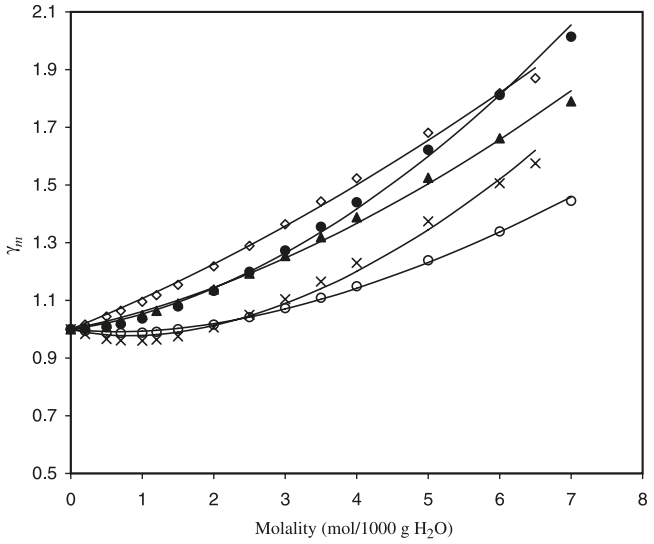
Fig. 1. Comparison between experimental and calculated amino acid activity coefficient by the modified NRTL model for several amino acid + H_2O systems at 298.15 K: β-alanine (○), DL-β-aminobutyric acid (▲), DL-β-aminvaleric acid (◇), γ-aminobutyric acid (×), DL-γ-aminovaleric acid (●), calculated (—).



The chemical equilibrium relationship for the reaction above can be written as follows,

$$[46] \quad K_s = a_{A^{+-}} = x_{A^{+-}}\gamma_{A^{+-}}$$

where A(s) and A^{+-} (aq) are the solid form of amino acid and dissolved amino acid (as neutral zwitterions), respectively. K_s and a are the equilibrium constant and activity, respectively. For each model, the amino acid activity coefficients in water were computed with the corresponding models parameters presented in Table 1. It should be mentioned that since the activity coefficient data, and therefore binary interaction parameters, for the amino acids that are not tabulated in Table 1, are not available, as an assumption their solutions with water were considered ideal and the corresponding binary interaction parameters were set to zero. In fact, the model parameters reported in Table 1 are independent of temperature. In this work, following Chen et al. (4), the following equation is used to calculate the temperature dependency of the thermodynamic solubility constant,

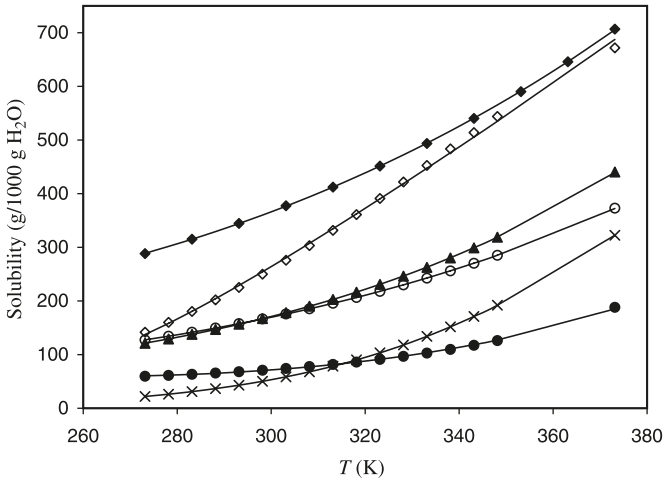
$$[47] \quad \ln K_s = a + b/T + c\ln T$$

The adjustable parameters a, b, and c were estimated by minimizing the following objective function,

$$[48] \quad \mathrm{OF} = \sum_{l=1}^{N}(S_l^{\mathrm{cal}} - S_l^{\mathrm{exp}})^2$$

where S is the solubility in grams of amino acid per kilogram of water. In the most cases, the used experimental data cover the temperature range 273.15–373.15 K. The fitting parameters a, b, and c, along with the corresponding RMSD for S are given in Table 2. On the basis of the obtained deviations given in Table 2, we conclude that the frameworks proposed here seems to be very satisfactory. Figure 2 shows the correlation results by the Wilson model for the solubility for several amino acids as a function of temperature.

Fig. 2. Comparison between experimental and calculated solubility by the modified Wilson model for several amino acid + H_2O systems: D-alanine (○), DL-alanine (▲), glycine (◇), DL-serine (×), DL-valine (●), hydroxyproline (◆), calculated (—).



Solubilities of amino acids in the presence of dipolar amino acid species

The effect of an amino acid on the solubility of another amino acid depends on the chemical structure of both amino acids present in the solution (5). The presence of an amino acid in the liquid phase may either increase or decrease the solubility of the other amino acid. It is the molecule–molecule physical interactions between the two dipolar amino acids that result in the change in the solubility. From appropriate differentiation of eqs. [18] and [37], respectively, the NRTL and Wilson relation for the activity coefficient of amino acid 1 (m_1) in ternary solution water (w) + amino acid 1 (m_1) + amino acid 2 (m_2) can be obtained.

The binary energy parameters for the amino acid–water pairs listed in Table 1 and the solubility constant of the amino acids listed in Table 2 are directly used to calculate the solubility of a mixture of two amino acids in water. For both models presented in this work, one of the amino acid – amino acid energy parameters was set to zero and another amino acid – amino acid energy parameter is treated as an adjustable parameter. Therefore, for an amino acid 1 (m_1) + amino acid 2 (m_2) + water (w) system, only one adjustable parameter is required to correlate the solubility data. Table 3 summarizes the values of the binary interaction parameters between two amino acids along with the corresponding RMSD values. It can be seen that the models developed in this work can successfully represent the solubility of a mixture of two amino acids in aqueous solutions. Figure 3 shows the correlation results by the NRTL model for the solubility data in water (w) + L-aspartic acid (m_1) + L-glutamic acid (m_2) at different temperatures. In Fig. 4, the correlation results by the Wilson model for the solubility data in water (w) + glycine (m_1) + L-glutamic acid (m_2) system are shown at different temperatures. That is to say, the obtained binary interaction parameters are independent of temperature and, in fact, for the each model one set of parameters has been successfully used to correlate all solubility data at different temperatures.

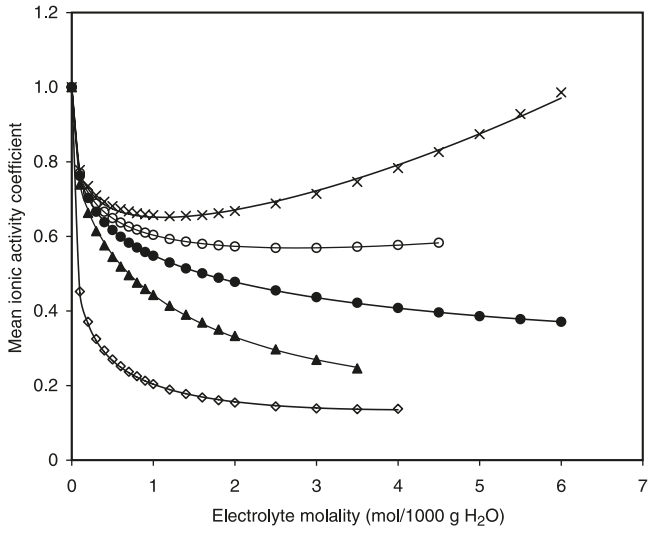
Solubilities of amino acids in the presence of salts

The presence of an electrolyte changes the solubility of an amino acid and usually increases it. This phenomenon is known as the salting-in effect. The reverse of this phenomenon, in which the solubility of the amino acid decreases with an increase in the electrolyte concentration may also happen, and it is called the salting-out effect. It is the ion–molecule physical interactions that result in the salting effects. The NRTL relation for the activity coefficient of amino acid (m) in ternary solution water (w) + amino acid (m) + salt (e) can

Fig. 5. Comparison between experimental and calculated mean ionic activity coefficient by the modified NRTL model for the investigated salt + H_2O systems at 298.15 K: KCl (○), KNO_3 (▲), Na_2SO_4 (◇), NaCl (×), $NaNO_3$ (●), calculated (—).



be obtained from appropriate differentiation of eqs. [1], [2], and [18]. Similarly, the Wilson relation for the activity coefficient of amino acid (m) in ternary solution water (w) + amino acid (m) + salt (e) can be obtained from appropriate differentiation of eqs. [1], [2], and [37]. The binary energy parameters for the amino acid–water pairs (listed in Table 1) and for the electrolyte–water pairs and the solubility constant of the amino acids listed in Table 2 are directly used to calculate the solubility of amino acids in aqueous electrolyte solutions. The NRTL parameters, a_{ew} and a_{we}, and the Wilson parameters, E_{ew} and E_{we}, between salt and water have been determined from the simultaneous correlation of the experimental osmotic coefficient and mean ionic activity coefficient data of corresponding binary aqueous electrolyte solutions at T = 298.15 K (29). The evaluated electrolyte–water energy parameters along with the corresponding RMSD values for osmotic coefficient and mean ionic activity coefficient data of binary aqueous electrolyte solutions are listed in Table 4. Figs. 5 and 6, respectively, show the correlation results for the modified NRTL model for the mean ionic activity coefficients and osmotic coefficients of investigated aqueous electrolyte solutions at T = 298.15 K. As can be seen in Table 4, the energy parameters a_{ew} and E_{ew} have negative values and energy parameters a_{we} and E_{we} have positive values. This is not surprising since the interaction between the cation and the anion is stronger than the interaction between the water molecules and the ionic species, which, in turn, is stronger than the interaction between two solvent molecules. The electrolyte–amino acid energy parameters a_{me} and E_{me} were set to zero and the energy parameters a_{em} and E_{em} are treated as adjustable parameters. Table 5 summarizes the values of the electrolyte–amino acid binary interaction parameters along with the corresponding RMSD values. It can be seen that the models developed in this work can successfully represent the solubility of amino acids in aqueous electrolyte solutions. Figure 7 shows the comparison of the literature data and the correlation results

Fig. 6. Comparison between experimental and calculated osmotic coefficient by the modified NRTL model for the investigated salt + H_2O systems at 298.15 K: KCl (○), KNO_3 (▲), Na_2SO_4 (◇), NaCl (×), $NaNO_3$ (●), calculated (—).

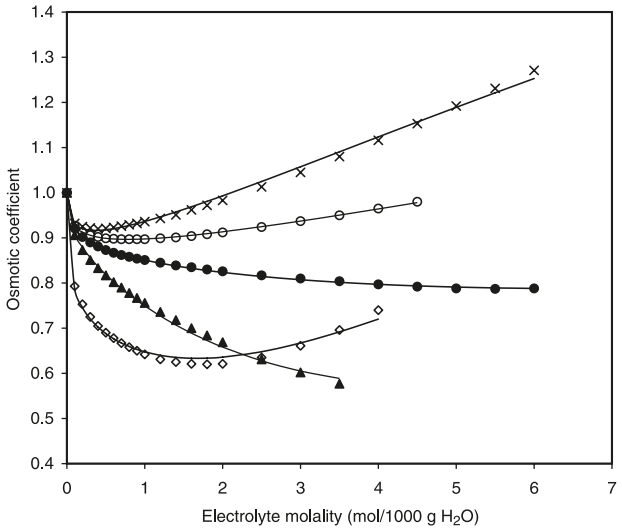

Fig. 7. Solubilities of DL-alanine in several aqueous electrolyte solutions at T = 298.15 K: NaCl (○), Kcl (▲), KNO_3 (◇), $NaNO_3$ (×), calculated by the modified Wilson model (—).

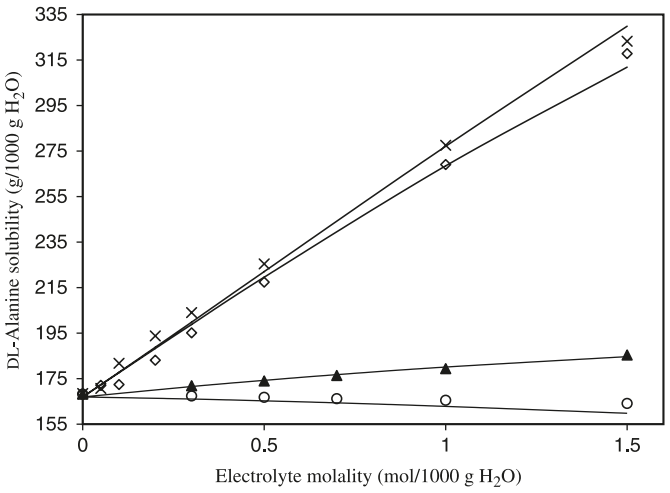

with the Wilson model for the solubility of dl-alanine in aqueous solutions of NaCl, KCl, KNO_3, and $NaNO_3$ at T = 298.15 K. As can be seen in Fig. 7, DL-alanine shows a strong salting-in effect in the presence of $NaNO_3$ and KNO_3, a weak salting-in effect in the presence of KCl, and a weak salting-out effect in the presence of NaCl. As can be seen in Table 5, for the salting-in effects the energy parameters a_{em} and E_{em} have negative values and increases in magnitude as the salting-in effect increases. The negative values of a_{em} and E_{em} indicate that the interaction between the amino acid molecules and the ionic species is stronger than the interaction between two amino acid molecules. Also, Table 5 shows that for salting-out effects, the energy parameters a_{em} and E_{em} have positive values, which indicates that the interaction between two amino acid molecules is stronger than the interaction between the amino acid molecules and the ionic species.

Conclusions

Two molecular thermodynamic frameworks, modified NRTL and Wilson models, were established to investigate the phase equilibrium behavior of amino acids and small peptides in aqueous solutions. The models were used successfully to represent the activity coefficients and solubility of amino acids in water. The models were also used to represent the solubility of an amino acid both in aqueous solutions of another amino acid and in aqueous solutions of an electrolyte. The calculated solubility data are in good agreement with the available literature experimental data. On the basis of the obtained deviations, we conclude that the two models have similar behavior in the representation of the phase equilibrium behavior for the investigated aqueous amino acid solutions. Also, the models developed here correlate with the experimental data with comparable and in some cases with better accuracy than the extended NRTL (4) and Wilson (23) models.

The quantitative removal of metal catalyst from multi-walled carbon nanotubes with minimal tube damage

Trisha A. Huber, Michael C. Kopac, and Catherine Chow

Abstract: A purification method for multi-walled carbon nanotubes (MWCNTs) has been developed to remove almost all (>98%) residual metal catalyst without introducing a significant amount of surface functionality. The process involves alternating mild acid oxidation and thermal oxidation in an iterative fashion with progressively higher temperatures for thermal treatment, in accordance with the increasing thermal stability. Thermogravimetric analysis and inductively coupled plasma mass spectrometry were employed to assess thermal stability and residual catalyst content, respectively, throughout the process. Transmission electron microscopy confirms the integrity of the nanotubes, and the degree of acid functionalization introduced by the acid oxidation is minimal, as determined by titration analysis.

Key words: multi-walled carbon nanotube, purification, ICP-MS, TGA, FTIR.

Résumé : On a développé une méthode de purification de nanotubes de carbone à parois multiples qui permet d'éliminer pratiquement tous les résidus de catalyseur (>98 %) sans introduire de quantités significatives de fonctionnalité à la surface. Le processus implique une alternance d'oxydation acide douce et une oxydation thermique de façon itérative, en augmentant progressivement les températures des traitements thermiques, en fonction de l'augmentation de la stabilité thermique. Tout au long du processus, on a fait appel à l'analyse thermogravimétrique et à la spectrométrie de masse avec couplage plasma pour évaluer respectivement la stabilité thermique et la quantité résiduelle de catalyseur. La microscopie électronique de transmission confirme l'intégrité des nanotubes et, d'après une analyse par titrage, le degré de fonctionnalisation acide introduit par l'oxydation acide est minimal.

Mots-clés : nanotube de carbone à parois multiples, purification, spectrométrie de masse avec couplage plasma, analyse thermogravimétrique, infrarouge à transformée de Fourier.

[Traduit par la Rédaction]

Introduction

Although many advances in the field of carbon nanotube synthesis have been made, a synthetic process yielding pure nanotubes has yet to be developed. Raw carbon nanotubes (CNTs) typically contain non-nanotube carbon (primarily amorphous carbon, but also graphitic carbon and (or) fullerenes) and residual metal catalyst. The presence of impurities alters the bulk properties of the carbon nanotubes and can be detrimental to the applications of interest, rendering purification necessary in most instances. Furthermore, the inhomogeneity of impurity distribution hinders the assessment of the effect of impurities on the properties of the bulk nanotubes. The purification of nanotubes is not straightforward (see below), and in many cases nanotubes are used in the raw (as-prepared) state to avoid purification difficulties.

The process most commonly employed in the purification of nanotubes is oxidation; however, the selective oxidation of amorphous carbon requires different conditions from that for metallic species; hence, more than one step is required for purification. As amorphous carbon is generally less stable than CNTs, reduction of amorphous carbon content is commonly achieved by thermal oxidation. Unfortunately, some CNTs, particularly narrow diameter tubes (which are more reactive owing to a high degree of curvature), are also oxidized in the process, especially if metallic species are present. Furthermore, it is difficult to assess the relative quantity of amorphous carbon in CNT samples; thus, it is challenging to determine whether quantitative removal has been achieved.

The simplest and most common method for residual catalyst removal is acid oxidation, in which the residual catalyst is oxidized, and therefore solubilized, in the acid solution. Hot, concentrated acids and acid mixtures are commonly employed, and such harsh conditions result in substantial damage to the tubes. Oxidation of carbon atoms at existing defect sites (1) (imperfections in the hexagonal lattice of the nanotubes) occurs as well as the introduction of new defect sites at which oxidation of carbon atoms also occurs. Oxidation results in the introduction of acid functionality, such as lactone, phenolic hydroxyl, or carboxylic acid groups (2). Although much of the nanotube structure remains intact un-

 doi:10.1139/V08-160 © 2008 NRC Canada

der relatively mild conditions, the effect of functionalization can be dramatic due to the disruption of the extended π system from which the nanotubes gain their extraordinary electrical, mechanical, and thermal properties (3–5). Moreover, the acid oxidation process is only effective when the metal is accessible; when the metal catalyst particle is encapsulated in carbon, which commonly occurs during CNT synthesis, the metal is not accessible for oxidation.[2] Thermal treatment may be applied to effect de-encapsulation; however, care must be taken to ensure that CNT oxidation is minimized during this carbon cracking step.

The requirement for a multi-step process has been recognized, and there are several reports in the literature, mostly pertaining to single-walled carbon nanotubes (SWCNTs) (6–10) in which both acid and thermal oxidation processes are utilized. However, relatively harsh acid oxidative conditions are employed, and the metal content is accurately assessed in only a few reports (7, 10). Chiang et al. (8) have demonstrated the effectiveness of a multi-step iterative approach with SWCNTs, and although the study was quite thorough, the effect of the use of concentrated HCl was not investigated. Furthermore, no comment was made on the scale of the purification. Other effective purification methods have been developed to avoid harsh oxidative conditions, although these methods require the use of specialized equipment and (or) expensive instrumentation (11–16).

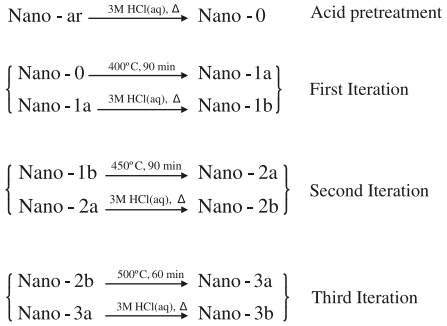
We demonstrate the efficacy of an iterative purification protocol that alternates thermal oxidation with mild acid oxidation and can be applied to relatively large quantities of multi-walled carbon nanotubes (MWCNTs). This method effects the quantitative removal of catalyst particles without the significant damage typically associated with acid oxidation. The iterative nature of the approach addresses the shortcomings that exist with each individual step (ineffective metal oxidation due to carbon encapsulation and catalytic thermal oxidation of MWCNTs). In addition, this method significantly reduces the amorphous carbon content. Throughout the purification, the stability of the nanotubes is assessed by thermogravimetric analysis (TGA), and the efficacy of each iterative step is determined by inductively coupled plasma mass spectrometry (ICP-MS). Nanotube integrity was assessed by titration analysis, which quantifies acid functionality, and transmission electron microscopy (TEM). The relative degree of acid functionality is corroborated by Fourier transform infrared (FTIR) spectroscopy.

Experimental

Materials

Industrial grade thin multi-walled carbon nanotubes (MWCNTs, Nanocyl-7000, ~90% C purity, Lot 257–1) were purchased from Nanocyl Inc. Aqueous sodium hydroxide solution (NaOH (aq.), 0.100 mol/L, Fisher), sodium bicarbonate ($NaHCO_3$, 99%, Caledon Laboratories), and concentrated acids (hydrochloric and nitric) were used without purification.

Scheme 1. Overview of purification method.



Purification

A 10.14 g sample of as-received MWCNTs, denoted herein as Nano-ar (see Scheme 1 for purification overview), was ground with a mortar and pestle and refluxed overnight (~17 h) in ~600 mL of 3 mol/L HCl (aq.). The acid-treated material, denoted as Nano-0, was isolated by filtration (medium frit) and washed with distilled water until the washings were neutral. Nano-0 was dried thoroughly (50 °C in vacuo), then heated (uncovered) in air for 90 min at 400 °C. The thermally treated material, Nano-1a, was refluxed in 3 mol/L HCl (aq.) overnight. The resulting material, Nano-1b, was isolated and dried as described above. The process of thermal treatment followed by acid oxidation was repeated twice more (samples denoted by Nano-2a/b and Nano-3a/b), except the thermal treatment was performed at 450 °C (for 90 min) for Nano-2b, and 500 °C (60 min) for Nano-3b.

Characterization

Thermal stability was assessed by TGA using a TA Instruments TGA 51 thermogravimetric analyzer. Small samples (~1–2 mg) were heated from ambient to 800 °C at a rate of 10 °C/min in air (~120 mL/min).

ICP-MS analyses were performed with a Varian Ultramass 700 for the quantitative determination of residual metal catalyst. Sample preparation involved the complete oxidation of carbon (ashing) to ensure that all catalyst particles were accessible (not encapsulated in carbon). This was accomplished by heating an accurately weighed sample at 700 °C for 30 min in air. The ash was digested in an acid mixture (2:1, HCl/HNO_3) at 90 °C for 2 h, and the resulting solution was analyzed.

To assess the extent of acid functionality, titration analyses were performed on Nano-ar, Nano-2b, and Nano-3b. Typically, a 20.00 mL aliquot of 0.100 mol/L NaOH (aq.), diluted to 40 mL, was added to an accurately known mass of nanotubes (80–100 mg), sonicated for 2 h, and then stirred for 3 days under a blanket of argon. The suspension was filtered (0.2 μm polycarbonate membrane), and the collected solid was washed thoroughly with distilled water; the filtrate and washings were combined and titrated against standardized 0.025 mol/L HCl (aq.) to a phenolphthalein endpoint. The degree of acid functionality, expressed in milliequivalents per gram of material, was determined from the mequiv of base required to neutralize surface acid functionality (mequiv base added – mequiv acid required to reach

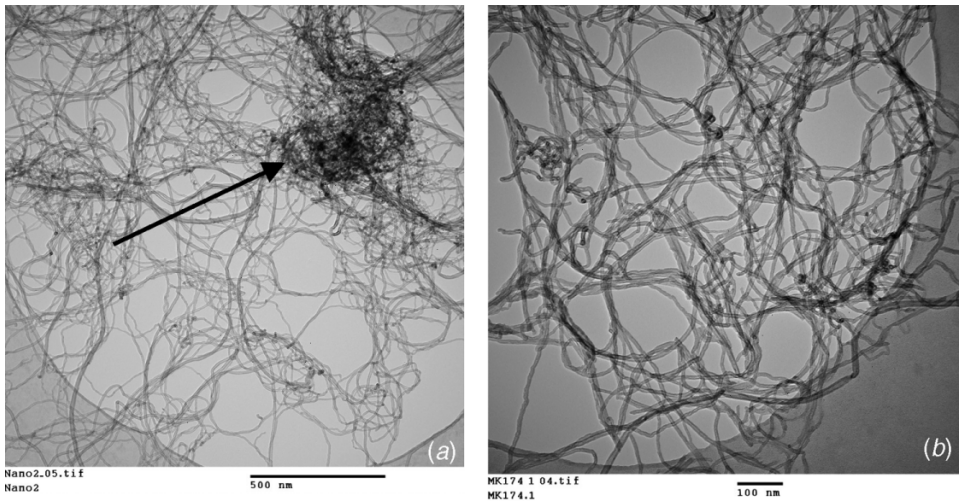
Fig. 1. Transmission electron micrographs of (*a*) Nano-ar and (*b*) Nano-2b. The arrow in (*a*) indicates impurities.



equivalence point) divided by the mass of the sample. The analyses were performed in triplicates, and the average values are reported. Purified MWCNTs were also subjected to titration analysis with $NaHCO_3$ as the base (to assess the degree of carboxylic acid functionality) and bromcresol green as the indicator.

Infrared spectral analysis was performed to further investigate the degree of acid functionality. FTIR data were acquired using a Nicolet Nexus 670 Fourier transform infrared spectrometer. Samples were prepared by grinding the material with dry potassium bromide and pressing into a pellet. Spectra were acquired in transmission mode; 256 scans were collected at a resolution of 4 cm^{-1}. The absorbance spectra are uncorrected.

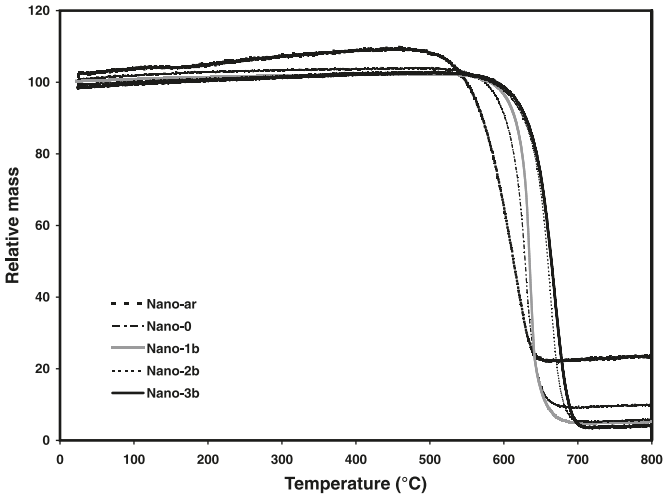
Transmission electron microscopy (TEM) was employed to qualitatively assess the nature of the impurities in the MWCNTs, as well as to assess the integrity of the nanotubes after purification. TEM samples were prepared by depositing a drop of dispersion (prepared by sonicating a small amount of material in ethanol) on a holey carbon-coated copper TEM grid and images were acquired on a Hitachi H-7000 transmission electron microscope.

Results and discussion

The purification protocol was developed for purifying thin MWCNTs prepared by a catalytic chemical vapour deposition (CVD) method. The first step in the purification is acid oxidation to remove any accessible metallic species (see Scheme 1). The subsequent steps are comprised of iterations of thermal treatment followed by acid oxidation. At various stages of the purification, the material was characterized by TGA, ICP-MS, titration analysis, and TEM.

TEM of the as-received MWCNTs (Nano-ar) confirms the presence of impurities (non-nanotube carbon and (or) metallic particles), visible as dark spots indicated in Fig. 1*a*. TGA was performed to determine the thermal stability of the as-received MWCNTs (Nano-ar) (see Fig. 2); the presence of metal catalyst results in the catalytic oxidation of carbon (nanotubes and other forms); thus, the oxidation occurs at a lower temperature than pure nanotubes. Peak mass loss was determined from the derivative (d*m*/d*T*) of the TGA trace,

Fig. 2. TGA traces for Nano-ar, Nano-0, Nano-1b, Nano-2b, and Nano-3b.



and the data are presented in Table 1. ICP-MS analysis of Nano-ar indicates that the catalyst is comprised largely of iron (Fe) and cobalt (Co). Although the supplier indicates ~10% non-carbon content, the majority of this is alumina, which is used as a catalyst support, and ~0.4% is metallic catalyst (see Table 2).

Nanotube defect sites are relatively reactive, and it is known that the presence of adsorbed oxygen can result in the formation of oxygen-containing surface functionality (17); hence, even raw CNTs may contain acid functionality (or at least adsorbed oxygen that will result in surface functionality upon thermal treatment). Upon oxidation, acid functionality (lactone, phenolic hydroxyl, carbonyl, and carboxylic acid moieties) are formed at defect sites (2), including opened end caps. A semi-quantitative assessment of these functional groups may be obtained through titration analysis. This analysis involves the reaction of excess base with the material, followed by back titration of unreacted base with a standardized acid solution (2, 18, 19). Although these functional groups are of varying acidity, the use of a strong base, such as hydroxide, ensures that complete reac-

Table 1. Synopsis of mass loss, total catalyst content, peak mass loss, and titration analysis data.

Sample	Mass loss (%)	Catalyst content (%)	Peak mass loss (°C)	Acid functionality (mequiv/g)[a]
Nano-ar	—	0.36	618	1.5 (0.6)
Nano-0	11	0.39	634	
Nano-1a	1.8			
Nano-1b	0.6	0.11	638	
Nano-2a	51			
Nano-2b	0	0.019	668	1.5 (0.2)
Nano-3a	9.2			
Nano-3b	3.2	0.014	669	1.1 (0.4)

[a]These values are uncorrected for the slight acidity of the distilled water used in the analysis.

Table 2. ICP-MS data for as-received MWCNTs (Nano-ar) and MWCNTs after each acid oxidation (Nano-0, Nano-1b, Nano-2b, and Nano-3b).

	ICP-MS data[a] (ppm)			
Sample	Fe	Co	Al	Total catalyst content (%)[b]
Nano-ar	2400 (300)	1200 (90)	N.A.[c]	0.36 (0.04)
Nano-0	2850 (400)	1010 (10)	31 (8)	0.39 (0.04)
Nano-1b	710 (50)	375 (2)	13 (11)	0.108 (0.005)
Nano-2b	110 (10)	84 (5)	6 (3)	0.019 (0.002)
Nano-3b	100 (60)	43 (10)	7 (10)	0.014 (0.007)

[a]Average of three samples; uncertainty in parentheses.
[b]These values exclude the catalyst support (alumina).
[c]The limited solubility of alumina in the digestion solution precluded accurate determination, although the concentration of aluminum in solution was in the order of 15 000 ppm.

tion of all acid functionality will occur. Hydroxide titration analysis of Nano-ar indicates that the degree of acid functionalization is 1.5 ± 0.6 milliequivalents of acid per gram of material (mequiv/g). This value represents functionalization at approximately one out of every 50 carbon atoms (using the molar mass of carbon to approximate the molar mass of the material), i.e., ~2% of the potential sites are functionalized. The magnitude of the uncertainty is not surprising given that this method is fraught with issues, including incomplete titration (due to the potential intercalation of base), the pH contribution of distilled water, and the potential for reaction with impurities. In addition, the inhomogeneous distribution of impurities will also affect the data spread. Furthermore, it is expected that the more reactive end caps will possess higher functionality than the sidewalls of the nanotubes; thus, shorter tubes will exhibit a higher degree of acid functionality on a mass basis, compared with longer tubes. Hence, a distribution of values is anticipated even if consistence in sidewall functionalization exists.

To minimize any catalytic oxidation of nanotubes during the first thermal treatment, an acid pretreatment (3 mol/L HCl (aq.) reflux overnight) was performed on Nano-ar to oxidize any accessible metal catalyst. Although the pretreatment resulted in a mass loss of ~11%, ICP-MS analysis of the resulting material (Nano-0) indicated that the majority of the catalyst remained (see Table 1). This implies that the majority of catalyst particles are inaccessible for oxidation. It is anticipated that any catalyst particles that exist within the tips of the nanotubes will become accessible during the acid pretreatment because of the high reactivity of the endcaps resulting from curvature strain. Hence, it may be concluded that the inaccessible catalyst particles are encapsulated by a carbon shell, formed during synthesis, which must be cracked to access the metal. Interestingly, the aluminum (Al) content in Nano-0 was determined to be very low (<40 ppm), and the digestion solution did not contain undissolved alumina, as was observed with Nano-ar. Hence, it is reasonable to conclude that the pretreatment had removed most of the catalyst support. Furthermore, the observed mass loss in this step (~11%) is consistent with quantitative removal of the alumina, although some loss of carbon is expected.

TGA was used to determine the optimal temperature for the first thermal treatment, the purpose of which is to de-encapsulate catalyst particles; the TGA trace of Nano-0 (see Fig. 2) indicates that the onset of oxidation occurs at ~500 °C; thus, a conservative temperature of 400 °C was chosen. The material was heated in air for 90 min, yielding Nano-1a. The mass loss was very small (<2%), indicating that little carbon was oxidized. The next step involved the acid oxidation of Nano-1a, yielding Nano-1b. The effectiveness of the de-encapsulation is evident in the ICP-MS data for Nano-1b (see Table 2). Nano-1b contains substantially less catalyst than Nano-ar (710 ppm Fe and 375 ppm Co, and 2400 ppm Fe and 1200 ppm Co, respectively); considering that the mass of the material had been reduced by only ~13% up to this point, these data indicate that acid oxidation had removed ~75% of the catalyst. Furthermore, an increase in the thermal stability is evident in the TGA data, which exhibit a peak mass loss of 634 °C.

With the majority of the catalyst removed and an increase in thermal stability, the thermal treatment of the second iteration (yielding Nano-2a) was performed at a slightly higher temperature for 90 min in air, to effect thermal oxidation of amorphous carbon and to de-encapsulate any remaining carbon-coated catalyst. The choice of 450 °C is fairly conservative based on the TGA data of Nano-1b, which exhibits the onset of oxidation at ~540 °C. The mass loss associated with this step was substantial (~51%); presumably any amorphous carbon present would have been oxidized at this point, although it is anticipated that some nanotubes were also oxidized. The subsequent acid oxidation (Nano-2b) resulted in a further metal content reduction, bringing the total amount removed approaching 98%, and an overall mass loss of 57%. After the second iteration, the metal content was determined

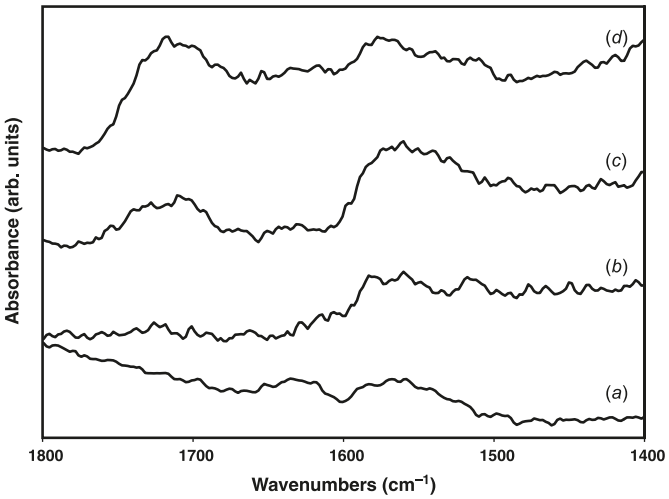
© 2008 NRC Canada

to be 110 ppm Fe and 84 ppm Co, which is 0.019% *of the purified material*, which has suffered significant mass loss. The acidic surface functionality was determined to be 1.5 ± 0.2 mequiv/g; this value is the same, within experimental error, as that determined for the as-received MWCNTs. In addition, titration analysis with $NaHCO_3$ was also performed on the second iteration product. The data indicate that ~40% (0.58 ± 0.08 mequiv/g) of the total acidic sites are carboxylic acid groups.

For comparison, the purification was also performed with 3 mol/L HNO_3 (aq.) in place of the HCl (aq.); titration analysis of the material purified with the nitric acid indicated an acid functionality of 3.7 ± 0.4 mequiv/g, which is significantly (and statistically) higher than that of the hydrochloric acid purification (1.5 ± 0.2 mequiv/g). Furthermore, titration analysis of MWCNTs that have been intentionally acid functionalized indicates that the surface functionality is ~9 ± 1 mequiv/g. Titration analysis supports the contention that this relatively mild purification method introduces minimal surface functionality.

To further investigate the extent of acid functionalization, IR spectra for four different samples were acquired: as-received MWCNTs, MWCNTs purified using 3 mol/L HCl, MWCNTs purified using 3 mol/L HNO_3, and intentionally acid-functionalized MWCNTs (see Fig. 3). For pristine carbon nanotubes, two absorbances (~1575 and ~868 cm^{-1}) are expected in the infrared spectrum arising from C–C stretching; however, the exact location is diameter-dependent (20). The utility of IR spectroscopy is fairly limited for pristine nanotubes but does provide some qualitative information regarding the nature of surface functionality. Absorbances due to acidic functional groups (lactone, phenolic hydroxy, carbonyl, and carboxylic acid groups) may be observed in the IR spectrum, although subtle differences in the bond order (as a resulting of differing environments) can give rise to fairly broad absorbances relative to those of discrete molecules. In preparing the IR samples, only small amounts of material could be used, as all absorb very strongly. Thus, any moisture is readily observed. All spectra exhibit a broad absorbance at ~1580 cm^{-1} attributed to the carbon skeleton, as well as a peak at ~1630 cm^{-1} (of varying intensity) that is assigned to water contamination. In terms of acid functionality, the region of greatest interest is the carbonyl region (1700–1750 cm^{-1}), as C=O stretching gives rise to a very intense peak; thus, small quantities of carbonyl-containing species are readily evident. There is no obvious peak in the carbonyl region of the as-received MWCNT spectrum, although a small peak at ~1720 cm^{-1} does appear in the spectrum after purification, attributed to a small quantity of carbonyl-containing species (carboxylic acid, lactone, ketone). The intensity of this absorbance is quite small relative that of the carbon skeleton (~1580 cm^{-1}). In contrast, the spectrum for the MWCNTs that were purified with 3 mol/L HNO_3 exhibits a stronger C=O absorbance, indicating a higher acid functionality. This is consistent with the titration analysis data, which indicate a degree of acid functionality of 3.7 ± 0.4 mequiv/g for the HNO_3-purified MWCNTs (compare with 1.5 ± 0.2 mequiv/g for the HCl-purified MWCNTs). Furthermore, the sample of intentionally acid-functionalized MWCNTs yield a very strong carbonyl peak in the IR spectrum, which is consistent with the high degree of acid functionality, 9 ± 1 mequiv/g, determined by titration analysis.[2] IR data support the titration analysis findings of minimal acid-group introduction. Moreover, the corroboration suggests that although the titration analysis method can result in large relative uncertainties, it can differentiate between varying degrees of acid functionality.

Fig. 3. FTIR spectra of as-received (*a*) MWCNTs, (*b*) HCl-purified MWCNTs, (*c*) HNO_3-purified MWCNTs, and (*d*) acid-functionalized MWCNTs.



The surface functionality may be removed by annealing under vacuum (7); however, this process requires a high-temperature vacuum oven. Attempts to graphitize the MWCNT surface by heating in argon (500 °C for 1 h) were unsuccessful, presumably due to the presence of oxygen, resulting from incomplete purging or the presence of adsorbed oxygen on the nanotube surface (21, 22). Titration analysis indicated that heating under an inert atmosphere had no effect on the surface functionality (1.3 ± 0.4 mequiv/g).

Although ~98% of the catalyst originally present had been removed after two iterations, a third was performed to assess its effectiveness. In this iteration, the thermal step was performed at 500 °C, but only for 60 min (Nano-3a). Given the high temperature, the mass lost in this step was relatively small (9.2%), indicating that the material is fairly stable; thus, it was concluded that the amorphous carbon content was low. After the acid oxidation, yielding Nano-3b, TGA data indicate that, based on thermal stability, the third iteration did not significantly enhance the purity; the peak mass loss for Nano-3b is the same as for Nano-2b, and the residual mass is only marginally smaller (the observed residual mass is likely due to trace quantities of metal oxide and instrument uncertainty). Furthermore, ICP-MS data indicate that the metal content is approximately the same as after the second iteration (~0.014%). Thus, the ICP-MS data validate the TGA results, indicating that the high level of purity was obtained after the second iteration. Moreover, this conclusion could have been reached by monitoring thermal stability (by TGA) alone. Titration analysis of Nano-3b indicates that the degree of surface functionality is approximately the same (within experimental error) (1.1 ± 0.4 mequiv/g). Although the difference is statistically insignificant, this

© 2008 NRC Canada

could be an indication of some loss of functionality as a result of the higher temperature of thermal treatment (500 °C). TEM indicates that the nanotubes are still intact after purification (see Fig. 1*b*).

Including the third iteration data, the overall mass loss was 62%; thus, the yield of purified MWCNTs is ~38%. In all likelihood, the original MWCNT content was higher, but suffered loss because of catalytic oxidation and the presence of defects due to the synthetic method (CVD).

Although this protocol was assessed with thin MWCNTs, its versatility has been successfully demonstrated with wider diameter MWCNTs (~30–50 nm). TGA data for each iteration show a progression in thermal stability, and ICP-MS data indicate that quantitative (~98%) removal of catalyst has occurred after two iterations.[2] Furthermore, as this method removes both free and carbon-encapsulated catalyst particles, it should be applicable to MWCNTs that have a substantial amount of catalyst. It is expected that the pretreatment would oxidize almost all unencapsulated metal, and the remainder would be liberated in the subsequent thermal treatments. The number of iterations may be dependent on the thickness of the encapsulating carbon, but should be independent of the quantity of catalyst.

Conclusions

We have demonstrated a simple but effective large-scale method for the quantitative removal (>98%) of catalyst from MWCNTs utilizing mild acid oxidation in conjunction with thermal treatment. The successful application of the iterative process has been validated by TGA, ICP-MS, and TEM. Titration analysis and infrared spectroscopy demonstrate that mild acid oxidation conditions cause minimal introduction of acid functionality. Furthermore, TGA alone may be sufficient for determining the optimal number of iterations.

NOTE OF APPRECIATION / NOTE DE RECONNAISSANCE

The quality of the papers in this journal depends a great deal on the efforts of those who agree to act as critical readers of manuscripts. The editors gratefully acknowledge the following who helped us between 1 November 2007 and 31 October 2008:

La qualité des articles publiés dans notre revue dépend beaucoup de ceux qui acceptent de faire une lecture critique des manuscrits. Les directeurs scientifiques expriment leur reconnaissance aux personnes suivantes qui nous ont aidés, du 1er novembre 2007 au 31 octobre 2008 :

Abou-Zaid, M.
