Interlayer grafting of glycidol (2,3-epoxy-1-propanol) on kaolinite

S. Letaief and C. Detellier

Abstract: An organic–inorganic nanohybrid material was prepared by grafting glycidol (2,3-epoxy-1-propanol) on the interlayer aluminol groups of kaolinite (K) using DMSO–K precursor as a starting material. The results of the physicochemical characterization of the synthesized materials (XRD, FTIR, DTA–TG, ^{13}C and ^{29}Si CP/MAS NMR) confirm that the grafting reaction of glycidol involved the opening of the oxirane ring. The resulting nanohybrid material is similar to the one obtained by the interlayer grafting of glycerol (M. Janek, K. Emmerich, S. Heissler, and R. Nüesch. Chem. Mater. **19**, 684, (2007)). Approximately, one glycidol moiety is grafted on each structural unit of kaolinite to afford a material with the chemical composition $Al_2Si_2O_5(OH)_4[C_3H_6O_2]_{0.9}$.

Key words: clays, clay minerals, kaolinite, intercalation, grafting, nanohybrid materials, DMSO, glycidol, glycerol, oxirane.

Résumé : Un matériau nanohybride organo–inorganique a été obtenu par greffage du glycidol (2,3-époxy-1-propanol) sur les groupements aluminol interfoliaires de la kaolinite (K), à partir des précurseurs DMSO–K. Les résultats de la caractérisation physico-chimique des matériaux synthétisés (DRX, IRTF, ATD–TG, RMN PC/RAM du ^{13}C et du ^{29}Si) confirment que la réaction de greffage du glycidol met en jeu l'ouverture de l'anneau oxirane. Le matériau nanohybride résultant est semblable à celui obtenu par le greffage interfoliaire du glycerol (M. Janek, K. Emmerich, S. Heissler, and R. Nüesch. Chem. Mater. **19**, 684, (2007)). Approximativement une unité de glycidol est greffée sur chaque unité structurale de la kaolinite pour donner un matériau de composition chimique $Al_2Si_2O_5(OH)_4[C_3H_6O_2]_{0.9}$.

Mots-clés : argiles, minéraux argileux, kaolinite, intercalation, greffage, matériaux nanohybrides, DMSO, glycidol, glycérol, oxirane.

Introduction

Recently, the preparation and the characterization of new organo–inorgano nanohybrid materials have received a lot of attention because of the combined benefits of the structural and textural properties of the inorganic matrix, joined to specific functionalities of the guest organic entities (1). These nanocomposite materials can be applied in several fields, such as catalysis, separation, isolation, biomaterials, and so forth. Due to their low price, large availability, and their environmental benefit, clay minerals are good candidates to be used as the inorganic component of nanohybrid materials (2).

Kaolinite (K) is one of the most common minerals on Earth. It is a 1:1 phyllosilicate, characterized by a dioctahedral structure composed of silicate sheets (Si_2O_5) bonded to aluminum oxide/hydroxide layers $Al_2(OH)_4$ with the global chemical composition $Al_2Si_2O_5(OH)_4$ (3). Kaolinite does not swell when exposed to water. It is mainly used in the ceramics industry for the production of bricks and pottery and also in the paper industry. Kaolinite can be directly intercalated by selected dipolar molecules, such as dimethylsulfoxide (DMSO), *N*-methylformamide (NMF) or urea, or by salts like potassium acetate. These intercalates were successfully used as precursors for further intercalation reactions of other organic molecules or polymers (4).

To achieve successfully the interlayer modification of kaolinite and to obtain a well-ordered nanohybrid material in which the guest organic entity is located between two adjacent individual aluminosilicate layers, several factors must be taken into account. The size and the physical properties of the organic molecules (melting point, boiling point, charge, and solubility) can give a good indication on the success of the interlayer structural modification. The nature of the starting intercalates, usually DMSO–K, Urea–K, NMF–K or K^+OAc^-–K can also be crucial for the success of the interlayer modification of kaolinite.

A variety of organic molecules have been grafted so far on the interlayer surfaces of kaolinite by making a covalent link with the aluminol groups of the internal surfaces (5). In view of future design of more sophisticated nanohybrid materials based on kaolinite, it is highly desirable to graft molecular entities with pending functionalities. The grafting of triethanolamine, with an available amino group for potential subsequent functionalizations was recently reported (5*m*).

In this work, the first grafting of an oxirane on the interlayer surfaces of kaolinite is reported, leading to available hydroxyl functions in the confined interlayer spaces (Scheme 1).

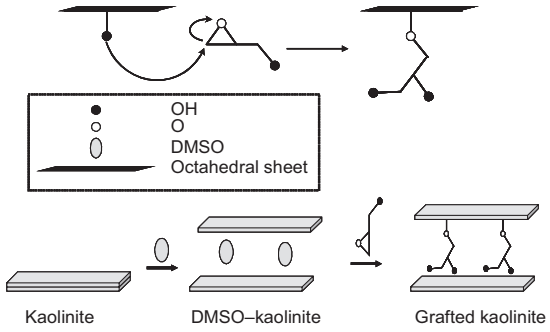
Scheme 1. Process of intercalation and grafting of kaolinite by consecutive treatments with DMSO first, then glycidol.



Experimental

Materials

Well-crystallized kaolinite (KGa-1b; Georgia) was obtained from the Source Clay Minerals Repository, University of Missouri. It was purified using standard sedimentation techniques and the <2 μm fraction was used in the experiments. DMSO and Glycidol (Aldrich; 96%) were used as received.

Sample preparation

DMSO–kaolinite intercalate (DMSO–K)

10 g of kaolinite were added to a mixture of 60 mL of DMSO and 5 mL of H_2O. The suspension was maintained under magnetic stirring for 10 d at 80 °C. The mixture was then allowed to stir for 5 d at room temperature. The resulting material was recuperated after two series of washing–centrifugation using dioxane (2 × 50 mL) first, then isopropanol (2 × 50 mL). The product was finally dried at 50 °C.

Glycidol–kaolinite grafting (Gly–K)

DMSO–K was used as starting material for the grafting of glycidol in the interlayer space of kaolinite. The reaction of Glycidol with DMSO–K was performed at 180 °C for 2 h under nitrogen. In a typical set of experiments, 0.5 g of DMSO–K was dispersed in 2 g of glycidol. The temperature of the mixture was then increased slowly from room temperature to 180 °C and maintained stable for 2 h. A few minutes after reaching 180 °C, a change in the color of solution (from white to sandy) is observed because of the removal and decomposition of DMSO. The resulting nanohybrid materials were recuperated after three series of centrifugation following washing with isopropanol (3 × 50 mL). They were dried at 60 °C overnight. Finally, to be sure that the compound was successfully grafted, the material was suspended in water and stirred for 72 h. It was washed, filtered, and ground for further characterization.

Characterization

XRD patterns were obtained using a Philips PW 3710 instrument equipped with Ni-filtered and Cu Kα radiation (λ = 0.15418 nm) operating at 45 kV and 40 mA, scanning from 2–70°.

Fourier transform infrared spectroscopy (FTIR) was carried out on the solid sample with a Mattson 3000 FTIR spectrometer by averaging 128 scans with a resolution of 4 cm^{-1}. The spectra were recorded using KBr pellets. Before recording the spectrum, a flow of hot air was circulated in the chamber containing the pellet during 30 min to remove water molecules adsorbed physically on the sample.

Differential thermal analysis (DTA) and thermogravimetric analysis (TGA) were recorded on a SDT 2960 Simultaneous DSC–TGA instrument under N_2 flow (100 mL min^{-1}) with a heating rate of 10 °C min^{-1}.

Solid-state ^{13}C CP/MAS NMR and ^{29}Si spectra were collected on a Bruker AVANCE 500 NMR spectrometer operating at 125.7 and at 99.35 MHz, respectively. The ^{13}C chemical shifts were referenced to TMS at 0 ppm using the high-frequency signal of adamantane at 38.4 ppm as a secondary standard. The ^{29}Si chemical shifts were referenced to TMS at 0 ppm using the high-frequency signal of tetrakis(trimethylsilyl) silane at 29.9 ppm as a secondary standard.

The ^{1}H and ^{13}C NMR spectra in solution were recorded on a Bruker 400 MHz spectrometer.

Elemental analysis (CHN) was performed at Guelph Chemical Laboratories Ltd.

Results and discussion

XRD patterns of kaolinite, DMSO–K intercalate, and Gly–K grafted nanohybrid are shown in Fig. 1. The basal spacings of kaolinite and DMSO–K are 0.71 nm and 1.10 nm, respectively. The intercalation ratio of DMSO–K is close to 98%. It is obtained as an approximation, by the ratio of the intensities of the 001 diffraction peaks of kaolinite and DMSO–K. After the treatment with glycidol, the XRD patterns present well-ordered reflections indicating that the structure of kaolinite was not affected or altered during the intercalation process. The intercalate resists hydrolysis, since it was recuperated without modification after treatment with water during 72 h. This confirms that glycidol is grafted to the interlayer aluminol groups (5*m*). The d_{001} spacing is 1.14 nm, very close to the one reported by Janek et al. (5*l*) (1.10 nm) when glycerol was grafted on the interlayer surfaces of kaolinite, using KOAc–kao as starting material (5*l*). The similarity of the d_{001} spacings results from the formation of very similar nanohybrid materials in the two cases. The ^{13}C CP/MAS NMR spectra show that glycidol reacts through opening the oxirane ring, resulting in the grafting of glycerol moieties (see later).

^{13}C CP/MAS NMR spectra of DMSO–K, Gly–K, glycidol, and glycerol are shown in Fig. 2. ^{13}C CP/MAS NMR constitutes a powerful technique to determine the structure of the organic host grafted into kaolinite. In the case of DMSO–K, the two signals at 43.9 and 42.8 ppm correspond to a dissymmetrical structuration of DMSO in the interlayer space of kaolinite. These two peaks disappear completely after treatment with glycidol, indicating a complete displacement of DMSO from the interlayer spaces of kaolinite. The NMR spectrum of Gly–K is characterized by two broad peaks at 72.0 and 65.1 ppm, which is quite different from the spectrum of glycidol. The NMR spectrum of glycidol is composed of three peaks at 62.3, 52.6, and 44.4 ppm. They correspond to the carbon bearing the hydroxyl group and to the carbons of the oxirane ring, re-

Fig. 1. XRD patterns of pure kaolinite, DMSO–K intercalate, and Gly–K grafted nanohybrid obtained from DMSO–K.

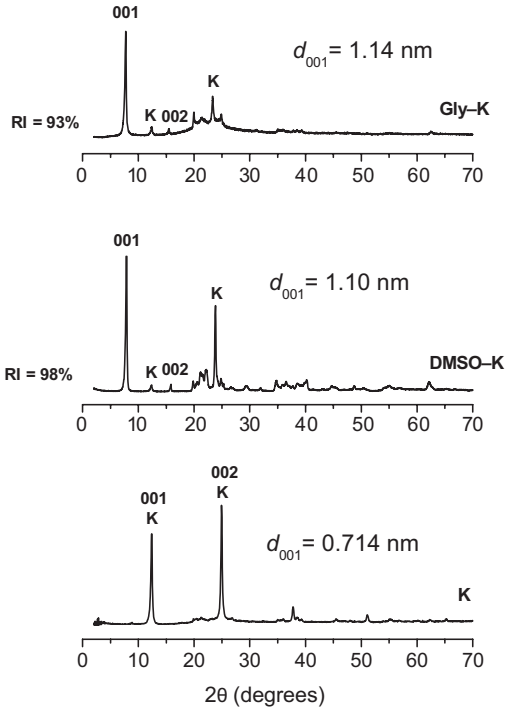

Fig. 2. ^{13}C NMR spectra DMSO–K intercalate (solid state), Glycidol (solution), Gly–K grafted nanohybrid obtained from DMSO–K (solid state), and Glycerol (solution).

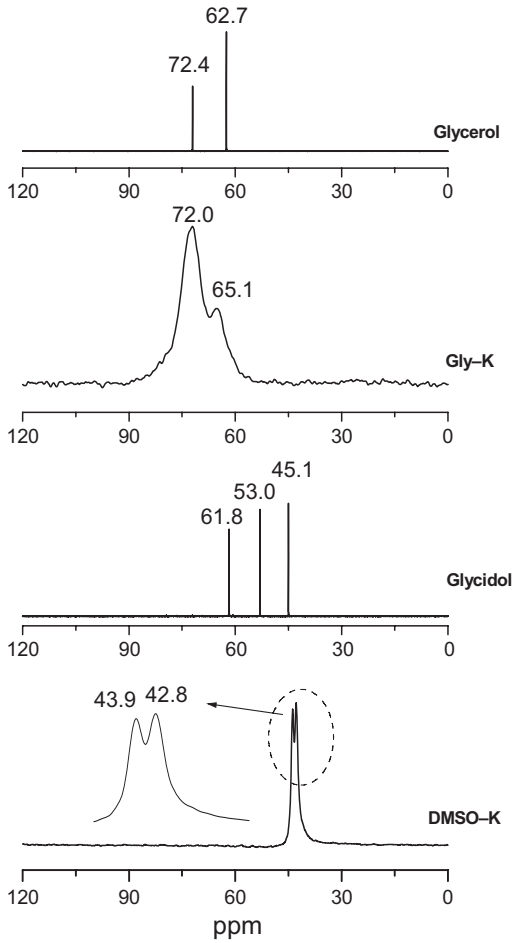

spectively. The ^{13}C CP/MAS NMR spectrum of Gly–K (two broad peaks at 65.1 and 72.0 ppm) is very similar to the one of glycerol, characterized by two peaks at 62.7 and 72.4 ppm (Fig. 2). Since the chemical shift of the Al–O–^{13}C group is close to the chemical shift of the H–O–^{13}C group (4*m*), and given the chemical shift dispersion expected in this kind of material, the observed ^{13}C CP/MAS NMR spectrum of Gly–K can be attributed to a grafted glycerol moiety. During the grafting process, glycidol undergoes a ring-opening reaction. Consequently, the grafting of glycidol or of glycerol (5*l*) leads to the same nanohybrid material.

Thermogravimetric traces (TG–DTG) of kaolinite, DMSO–K, and Gly–K are presented in Fig. 3. In the case of kaolinite, only one weight loss at 510 °C is observed, corresponding to the dehydroxylation. The experimental weight loss is 14%, very close to the theoretical value corresponding to the amount of removed water during the structural transformation of kaolinite $Al_2Si_2O_5(OH)_4$ to metakaolinite $Al_2Si_2O_7$. Upon intercalation of DMSO, three weight losses are observed. The first one, at a low temperature (59 °C), corresponds to the removal of water physically adsorbed on the external surfaces. The second one, around 180 °C, corresponds to the de-intercalation and decomposition of DMSO. Finally, the third one, which occurs at a temperature close to the case of kaolinite, corresponds to the dehydroxylation of the layers.

The dehydroxylation takes place in the same range of temperatures because the internal layer structure of the clay is not modified. After displacement of DMSO, the decomposition must be similar to the one observed for the pristine clay. In the case of the grafted nanohybrid, three weight losses are observed. The first one, at low temperature, corresponds also to the removal of water physically adsorbed. The second one, at 372 °C, corresponds to the decomposition of the organic entities, and the last one, which takes place at 480 °C, is due to the removal of the remaining organic molecules and to the dehydroxylation of the layer. The removal of the organic material, with a maximum at 372 °C, is also indicative of the grafting of the organic units (5*m*, 5*l*). Obviously, the TG behavior is quite different from the one observed in cases of intercalates, such as DMSO–K, since it happens at much higher temperatures. It is generally observed that, in the case of grafting on the interlayer surfaces, the dehydroxylation of kaolinite occurs at temperatures lower than what is observed in the case of intercalation (5*m*).

The TGA data give a direct measure of the amount of organic moieties into Gly–K; it is 31.5%. On the basis of this percentage, and of the weight loss of water to form metakaolinite $Al_2O_3{\cdot}2SiO_2$, the TGA data allow the calculation of the formula unit of Gly–K as $Al_2Si_2O_5(OH)_4[C_3H_6O_2]_{0.89}$. This stoichiometry is in fair agreement with the one obtained independently from elemental analysis (C: 9.29%; H: 2.76%), where a slightly lower stoichiometry was obtained: $Al_2Si_2O_5(OH)_4[C_3H_6O_2]_{0.82}$. The difference can be attributed mainly to the difficulty in combusting all the carbonaceous material during the elemental analysis, as was observed be-

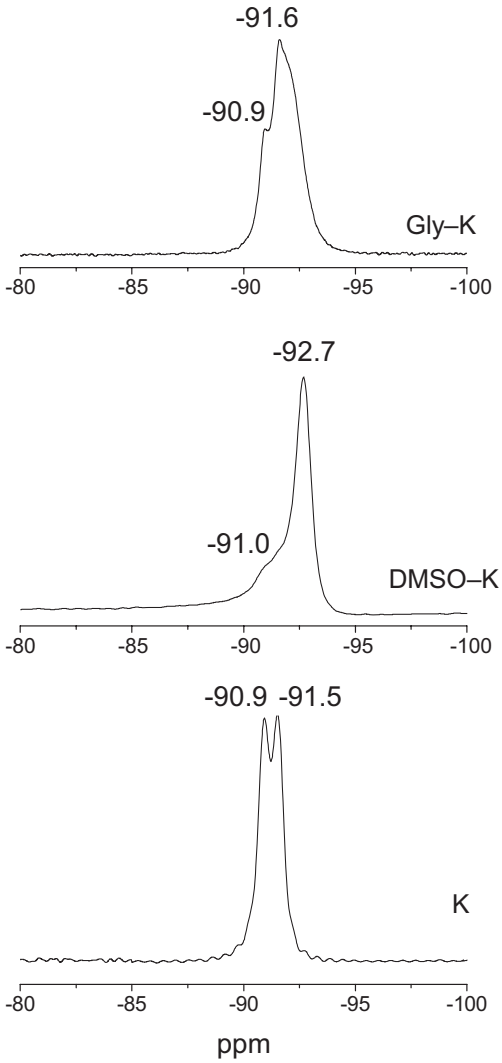
fore for other thermally robust organokaolinite derivatives (5*c*). Carbon–mineral nanocomposites are formed during the thermolysis process, by the trapping of carbonaceous materials in the interlayer spaces of kaolinite. This is indicated by a continuous slight decrease of weight up to 1100 °C, above the transition temperature from metakaolinite to mullite, normally observed near 1000°.

The ^{29}Si CP/MAS NMR spectra of kaolinite, DMSO–K, and Gly–K are shown in Fig. 4. In the case of kaolinite, two well-separated signals of equal intensities are observed, as expected, at –91.5 and –90.9 ppm (6). In the case of DMSO–K, the signal is shifted to lower frequencies, at –92.7 ppm, accounting for the keying of one of the DMSO methyl groups in the siloxane rings of the tetrahedral sheets (6). In contrast, the ^{29}Si CP/MAS NMR spectrum of the Gly–K material displays a relatively broad envelope around –91.6 ppm, with a dispersion of chemical shifts in the range of the kaolinite chemical shifts. This is an indication that the silicate layer is less affected by the presence of the glycerol moiety than it is by the strong interactions with DMSO. The local environments of the ^{29}Si nuclei are relatively similar in Gly–K and in kaolinite, since the structural stress imposed by the DMSO methyl group keyed into the siloxane ring, disappears when DMSO is replaced by the glycerol group grafted on the opposing aluminol surface.

FTIR spectra corresponding to the OH-stretching region of kaolinite, DMSO–K, and Gly–K are presented in Fig. 5. The band observed in the IR spectrum of kaolinite at 3621 cm^{-1} corresponds to the stretching vibrations of the internal hydroxyl group, while those at 3695, 3670, and 3653 cm^{-1} correspond to interlayer hydroxyl stretching modes (7). The intensity as well as the position of these

Fig. 4. ^{29}Si MAS NMR spectra of untreated kaolinite (K), kaolinite intercalated with DMSO (DMSO–K), and kaolinite grafted with glycidol (Gly–K).



bands is usually sensitive to intercalation of organic molecules. Upon treatment with DMSO, the 3670 and 3653 cm^{-1} peaks disappear completely, and new peaks appear at 3664, 3538, and 3503 cm^{-1}. The band at 3620 cm^{-1} remains unperturbed, which confirms its attribution to the stretching of the inner hydroxyls. The two bands at 3538 and 3503 cm^{-1} can be attributed to the perturbed inner-surface hydroxyl groups, hydrogen bonded to the DMSO (8). After displacement of DMSO, we note the disappearance of the bands at 3664, 3538, and 3503 cm^{-1} and the appearance of new broad bands between 3660 and 3630 cm^{-1}. The broadness of this band could be plausibly due to the different positions of the hydroxyl groups. The IR spectrum of Gly–K shows also the bands at 2928 cm^{-1} ($\nu_{as}CH_2$) and 2881 cm^{-1} (ν_sCH_2), confirming the presence of the organic entity in the grafted material.

In conclusion, a functionalized nanohybrid material was prepared by the ring-opening reaction of an oxirane, glycidol, with the aluminol groups covering the interlayer surfaces of kaolinite. The resulting nanohybrid material,

similar to the material obtained by direct grafting of glycerol, is well-structured, with two hydroxyl groups available for further reactions in the confined, dissymetric, interlayer space of kaolinite.

Effect of chain ends on the structure of aramid oligomers

Hakim Mehenni, Hélène Guillou, Christian Tessier, and Josée Brisson

Abstract: Synthesis, X-ray diffraction, and Fourier transform infrared spectroscopy of aliphatic–aromatic aramid oligomers are reported with the aim of shedding light on the effect of end-chain substituent on the morphology and structure of poly(*para*-phenylene terephthalamide) or PPTA. Three types of X-ray powder diffraction patterns were observed: one similar to that of PPTA form I, one similar to that of PPTA form II, and an additional form never reported. Some compounds, differing by their internal distribution of amide–aromatic rings, adopt two different crystal structures, whereas compounds having the same internal amide–aromatic arrangements, but differing by the nature of the end-groups, can adopt the same crystal structure. This clearly shows that both factors influence the packing adopted by the chains. Single-crystal structures of two polymorphs of a nitro-terminated model compound were resolved; both forms incorporate dimethyl formamide, and both show completely different packing. Infrared amide I and II band positions of most studied compounds match those observed for PPTA forms I or II, indicating that they exhibit planar hydrogen bonded sheets of molecules.

Key words: aramid, crystal structure, poly(*para*-phenylene terephtalamide).

Résumé : La synthèse et des études de diffraction des rayons X, et de spectroscopie infrarouge à transformée de Fourier ont été effectués sur des oligomères aramides, dans le but de fournir des informations sur l'effet de substituants en bout de chaîne sur la morphologie et la structure du poly(*para*-phénylene téréphthalamide), ou PPTA. Trois types de clichés de diffraction de poudre ont été observés: un similaire à celui de la forme I du PPTA, un similaire à celui de la forme II, et une forme additionnelle jamais rapportée auparavant. Certains composés modèles qui diffèrent de par leur distribution interne de cycles aromatiques et de groupements amides adoptent des structures cristallines différentes, alors que certains composes modèles ayant le même arrangement interne de cycles aromatiques, adoptent la même structure cristalline. Ceci démontre clairement que ces deux facteurs influencent l'arrangement moléculaire adopté par les chaînes. Les structures cristallines de monocristaux de deux polymorphes d'un composé modèle ayant un substituant nitro en bout de chaîne ont été résolues, les deux incluent des molécules de diméthylformamide, et les deux adoptent des types d'empilement moléculaire complètement différents. En spectroscopie infrarouge, les positions des bandes amide I et II de la plupart des composes étudiés correspondent à celles observées pour les formes I et II du PPTA, indiquant que ces composés possèdent probablement des feuillets de molécules assemblées par liaison hydrogène.

Mots-clés : aramide, structure cristalline, poly(*para*-phénylène téréphtalamide).

Introduction

The variety of ways in which molecules can organize in a crystal phase has long fascinated scientists. Crystal structures obey symmetry and packing requirements, which are still largely unpredictable. Polymer structures offer even greater challenges as, more often than not, they are polymorphic, and diffraction data are too few for statistical direct structure resolution methods to apply. Polymer crystal-structure determination therefore still relies heavily on modelling techniques and on insights gained by model-compound studies.

The crystal structure has profound implications on most polymer properties. The knowledge of crystal structure can therefore be used in various ways, for example, to better understand the structure–property relationship, to help fine-tune the processing conditions, or to design polymers for specific applications.

Our group has been studying a specific subclass of rigid–flexible copolymers, referred to as hinged copolymers, with rigid crystallizable blocks linked via short flexible spacers to control chain folding. We have recently shown that, although poly(*para*-phenylene terephthalamide) (abbreviated PPTA) does not crystallize via chain folds, monosingle crystals of PPTA-based hinged copolymers can (1). This polymer, under highly oriented form, is commercialized as Kevlar™, and thus has received considerable attention. Two crystal structures have been proposed for PPTA: form I, obtained by pre-

cipitation in methanol (2–4), and form II, obtained by precipitation in water (5–7). The crystal structure of both forms is the object of considerable debate (8–10). Various studies indicate that additional PPTA crystalline forms may exist, although experimental data are even further limited (11–12). New data is clearly needed to gain a better insight on the polymorphism of this polymer.

Inclusion of spacers in regular polymers has previously been shown to allow retention of crystallinity in polyethylene-based copolymers, although in the case of flexible–flexible copolymers, length and regularity in the size of the crystallizable block is critical (13). For PPTA-based hinged copolymers, length of the crystallizable block seems less of an issue, i.e., a block as small as one and a half repeat units (therefore containing three aromatic groups) crystallized in the same crystal structure as the parent PPTA polymer (1), whereas for polyethylene, 22 repeat unit blocks were necessary for crystallization to occur (13).

These observations prompted many questions. In particular, would such three aromatic-ring molecules crystallize alone in the same crystal structure when no flexible spacer was placed between them, or could flexible end-groups favor a different crystal phase? What is the influence of the substitution of the middle para-aromatic ring (NH-linked vs. C=O linked)?

Therefore, a series of aramids, comprising three aromatic rings, were synthesized in the aim of providing model compounds for PPTA polymporphism. These model compounds are also possible candidates for organic gelators (14), as their aspect ratio should favor the existence of fibrils, leading to sol–gel formation. Only one model structure of this type has been reported (15–16), the *N,N′-p*-phenylene dibenzamide, in which no substitution is present on the terminal aromatic rings. This compound has been shown to exist in two main forms, one crystal structure exhibiting hydrogen-bonded sheets of molecules placed in a parallel fashion, as in PPTA forms I and II, whereas the second exhibited a packing in which molecules overlap in a staggered arrangement. An infrared and Raman spectroscopy study has also been reported for this model compound, but in this study, the focus was put on normal vibrational analysis and estimation of tensile modulus using diagonal force constants derived from the spectroscopic data (17). No study has been reported on three-ring PPTA model compounds bearing para end-groups at each molecule extremity, and therefore, the effect of substituents of the crystal structure and chain packing of such rigid molecules remains to be investigated.

The present article will therefore report the synthesis of various three-ring aramid PPTA model compounds bearing para-substituents, and a preliminary investigation to determine to what extent these substituents and the internal arrangement of the amide–aromatic ring linkages affect crystal structures.

Experimental

All chemicals used were ACS reaction-grade and were purchased from Aldrich, unless otherwise specified. 1-Methyl-2-pyrrolidinone was purified by fractional distillation at 10 Torr (1 Torr = 101 325/760 Pa) to remove water as benzene azeotrope. Terephthaloyl chloride was crystallized from dry hexane. Tetrahydrofuran was distilled over sodium metal before use. *para*-Phenylenediamine was sublimed under vacuum to remove degradation products. Poly(methaphenylene isophtalamide) (mpI) was synthesized as described by Morgan (18).

Synthesis of *para*-diphenylene terephthalamide model compounds

A series of model compounds in which the central aromatic ring is C=O substituted have been synthesized according to the reaction scheme in Fig. 1. These are abbreviated 3ARA-X, where 3 stands for the number of aromatic rings, A corresponds to the CO substitution of the central aromatic ring, and X is the terminal substitution (or salient group thereof). In all cases, abbreviations are given in the figure.

Synthesis of undecanoyl chloride

Undecanoic acid (1 g) was inserted in a flask containing 10 mL oxalyl chloride under nitrogen atmosphere. The reactive medium was brought to reflux under nitrogen, and the reaction proceeded for 45 min. Residual oxalyl chloride was removed by evaporation under vacuum. Final product was liquid at room temperature. Yield: 100%. FTIR (cm^{-1}): 2922 (ν_a aliphatic (C–H)), 2851 (ν_s aliphatic (C–H)), 1775 (acid chloride ν(C=O)). ^{1}H NMR (δ, from TMS in DMSO-d_6): 2.23 (t, $2H_e$), 1.22 (q, $2H_f$), 1.15–1.25 (m, $18H_g$), 0.80 (t, $3H_h$).

Synthesis of 3ARA-NO_2 and 3ARA-NH_2

Synthesis of 3ARA-NO_2 was performed as described by Nakata and Brisson (19).

Synthesis of 3ARA-C10

To a solution of 0.42 (1.22 mmoles) 3ARA-NH_2 in 70 mL NMP were added 500 mg (2.44 mmol) undecanoyl chloride under nitrogen atmosphere. Reaction medium was mechanically stirred 3 h, during which time the desired product reprecipitated out. The resulting suspension was poured in water, the yellow precipitate filtered, washed with water, and dried under vacuum at 120 °C. Yield: 96%; decomposes above 350 °C before melting. FTIR (cm^{-1}): 2922 (δ_a aliphatic (C–H)), 2851 (δ_s aliphatic (C–H)), 1656 + 1640 (amide I), 1553 (amide II). ^{1}H NMR (δ, from TMS in DMSO-d_6): 10.10 (s, $2H_b$), 9.6 (s, $4H_e$), 8.03 (t, $4H_a$), 7.65 (d, $2H_c$), 7.51 (d, $2H_d$), 2.52 (t, $4H_f$), 1.57 (t, $4H_g$), 1.15–1.25 (m, $24H_h$), 0.80 (t, $6H_i$)

Synthesis of 3ARA-C12

Synthesis was performed as described for 3ARA-C10, using 1.8 mg (2.44 mmol) dodecanoyl chloride. Reaction medium was diluted by a factor of two (140 mL NMP instead of 70). Yield: 84%; decomposes above 350 °C before melting. FTIR (cm^{-1}): 2922 (ν_a aliphatic (C–H)), 2849 (ν_s aliphatic (C–H)), 1657 + 1641 (amide I), 1553 (amide I). ^{1}H NMR (δ, from TMS in DMSO-d_6): 10.30 (s, $2H_b$), 9.80 (s, $4H_e$), 8.05 (t, $4H_a$), 7.65 (d, $2H_c$), 7.52 (d, $2H_d$), 2.25 (t, $4H_f$), 1.50 (t, $4H_g$), 1.20–1.25 (m, $32H_h$), 0.81 (t, $6H_i$).

Synthesis of the *N,N′-para*-phenylene dibenzamide model compounds

A second series of model compounds has been synthesized, as depicted in Fig. 2. In this case, the central aromatic

ring is NH-substituted. These are abbreviated 3ARB-X, B corresponding to the central NH aromatic ring substitution.

Synthesis of *para*-methoxycarbonyl benzoyl chloride

Synthesis for this product was already reported by Boivin and Brisson (20).

Synthesis of 3ARB-COOMe

A solution of 0.92 g (8.5 mmoles) *para*-phenylene diamine and 0.68 g (17 mmoles) NaOH in 35 mL distilled water was introduced in a flask. A solution of 3.4 g (17 mmoles) *para*-methoxycarbonyl benzoyl chloride in 15 mL tetrahydrofuran (THF) was added under vigorous mechanical stirring. Stirring was maintained for 30 min, after which the solution was poured in water and the resulting white precipitate filtered, washed thoroughly with water, dried under vacuum for 12 h, and recrystallized with DMF. Yield: 70%; mp (T_f): 310 °C. FTIR (cm^{-1}): 1725 [ester ν (C=O)], 1650 (amide I), 1556 (amide II). ^{1}H NMR (δ, from TMS in DMSO-d_6): 3.86 (s, $6H_e$), 7.73 (s, $4H_a$), 8.05 (t, $4H_c + 4H_d$), 10.42 (s, $2H_b$).

Synthesis of 3ARB-COOH

A solution was prepared using 1 g (2.5 mmoles) 3ARB-COOMe, 0.3 g (5.4 mmoles) KOH, 18 mL 95% ethanol, and 8.5 mL water. The solution was brought to reflux for 10 h. Then, the solution was poured in water and hydrochloric acid added until neutral pH was reached. Water was removed by evaporation under a rotating evaporator, and the resulting white solid was recrystallized using dimethylformamide and

dried 12 h under vacuum. Yield: 94%; mp (T_f): 339 °C. FTIR (cm^{-1}): 1724 (ν carboxylic acid (C=O)), 1654 (amide I), 1556 (amide II). ^1H NMR (δ, from TMS in DMSO-d_6): 7.73 (s, $4H_d$), 7.90 (s, $4H_c$), 10.2 (s, $4H_b$), 10.40 (s, $2H_e$).

Synthesis of 3ARB-COCl

3ARB-COOH (1.15 g, 2.8 mmoles) was introduced in a flask containing 12 mL oxalyl chloride. The reactive medium was brought to reflux under nitrogen atmosphere for 45 min. Residual oxalyl chloride and solvent were removed by vacuum distillation. Yield: 100%; white solid. FTIR (cm^{-1}): 1782 and 1738 (ν acid chloride (C=O)), 1655 (amide I), 1527 (amide II). ^1H NMR (δ, from TMS in DMSO-d_6): 7.75 (s, $4H_a$), 1.86 (d, $4H_d$), 7.92 (d, $4H_c$), 10.20 (s, $4H_b$).

Synthesis of 3ARB-C10

To a solution of 0.6 g (1.4 mmole) 3ARB-COCl in 70 mL THF were added 0.56 mL (2.8 mmoles) undecaneamine under nitrogen atmosphere. Reaction and purification were performed as in the synthesis of 3ARA-C10. Yield: 42%; mp (T_f): 395 °C. FTIR (cm^{-1}): 2915 (ν_a aliphatic (C–H)), 2849 (ν_s aliphatic (C–H)), 1654 (amide I), 1554 and 1527 (amide

II). ^{1}H NMR (δ, from TMS in DMSO-d_6): 0.80 (t, $6H_i$), 1.15–1.30 (m, $24H_h$), 1.49 (q, $4H_g$), 2.71 (t, $4H_f$), 7.75 (s, $4H_a$), 7.86 (d, $4H_d$), 7.92 (d, $4H_c$), 10.20 (s, $4H_b$).

Synthesis of 3ARB-C12

The reaction was performed as for 3ARA-C10, using a solution of 0.6 g (1.4 mmol) 3ARB-COCl in 70 mL THF, to which was added a solution of 0.52 g dodecylamine in 20 mL THF containing 0.12 g NaOH. Yield: 74%; white solid; mp (T_f): 400 °C. FTIR (cm^{-1}): 2922 (ν_a aliphatic (C–H)), 2849 (ν_s aliphatic (C–H)), 1653 (amide I), 1554 (amide II). ^{1}H NMR (δ, from TMS in DMSO-d_6): 0.80 (t, $6H_i$), 1.15–1.30 (m, $32H_h$), 1.49 (q, $4H_g$), 2.45 (s, $4H_f$), 7.75 (s, $4H_a$), 7.85 (d, $4H_d$), 7.92 (d, $4H_c$), 10.20 (s, $4H_b$).

X-ray diffraction

X-ray powder diffraction was performed using a Bruker diffractometer, equipped with Kristalloflex 760 generator, a 3-circle goniometer, and a Hi-Star area detector. The generator produced a graphite monochromatized copper radiation (Cu Kα, λ = 1.5418 Å) at 40 kV and 40 mA.

Single crystals of 3ARA-NO_2 were obtained by slow cooling of a saturated dimethyl formamide solution. Two different crystal morphologies were observed, needles with square sections, which rapidly lost their birefringence upon being taken out of the solvent (form I), and needles with rectangular section, which kept longer their birefringence upon drying (form II). Details on the crystal structure data acquisition appear in Table 1. Crystals were mounted on a glass fiber using Paratone N hydrocarbon oil. Measurements were made on a Bruker APEX II area detector diffractometer with graphite monochromated Mo Kα radiation. Frames corresponding to an arbitrary hemisphere of data were collected using ω scans of 0.5° counted for a total of 30 s per frame. Orientation matrices corresponding to cell constants listed in Table 1 were obtained from a least-

© 2007 NRC Canada

squares refinement using the measured positions of 2546 centered reflections for form I 3ARA-NO_2 and 3455 centered reflections for form II. The program used for retrieving cell parameters and data collection was APEX version 2.0.2. from Bruker AXS Inc. Data were integrated using the program SAINT version 7.07a. from Bruker AXS Inc. The data were corrected for Lorentz and polarization effects. Multiscan absorption corrections were performed using the SADABS program for form I (21) and the TWINABS program for form II (22). The form II crystal was twinned. Data for this compound were integrated using two domains that are related by the transformation matrix 1 0 0, 0 –1 0, –0.75 0 –1 and a BASF factor of 0.248.

Structures were solved and full-matrix least-squares refinements performed on F^2 using SHELXS-97 and SHELXL-97 (23). All non-H atoms were refined anisotropically. Hydrogen atoms were placed at idealized positions, with the exception of the amide H atom for form II. For form II, NO_2 were found to be disordered, and the two positions were fixed during refinement at a 1:1 ratio. Neutral atom scattering factors were taken from the International Tables for X-Ray Crytallography (24). All calculations and drawings were performed using the SHELXTL version 6.12 supplied by Bruker AXS. The final model was checked either for missed symmetry or voids in the crystal structure using the approach proposed by Speck (25), as implemented in the PLATON software (26). None was found, these structures give a satisfactory chekcif report. Weighting schemes used were $w = 1/[s^2(F_o^2) + (0.0685P)^2]$, for 3ARA-$NO_2$ form I, and $w = 1/[s^2(F_o^2) + (0.0536P)^2]$for form II, where $P = (F_o^2 + 2F_c^2)/3$.[2]

Fourier transform infrared spectroscopy

Fourier transform infrared (FTIR) transmission spectra of the molecules blended and pressed into KBr disks were taken at a resolution of 4 cm^{-1} using a Nicolet Magna-IR 560 spectrometer equipped with a liquid nitrogen MCT detector, in the 4000–650 cm^{-1} spectral domain. FTIR attenuated total reflectance spectra (ATR) spectra of molecules and of mpI were also taken, using a resolution of 4 cm^{-1}, using the same spectrometer, using a Golden Gate sample holder and a DTGS detector in the 4000–530 cm^{-1} spectral domain.

^{1}H NMR spectra were recorded on a Bruker AC-300 apparatus functioning at 300 MHz, using tetramethylsilane (TMS) as an internal reference. The spectra consisted of 16 acquisitions and were analyzed using the SpinWorks version 1.3B software.

Results and discussion

Choice and synthesis of oligomer model compounds

To investigate the effect of end-groups on the crystallization of PPTA, it was essential to select oligomers for which the rigid block was of the same size, thus eliminating one variable from the system. It was further essential to select oligomers which could be obtained as pure and as monodisperse as possible. For this purpose, the three-ring oligomers were ideal: Short enough to be synthesized by usual organic-chemistry methods, which allowed perfect monodispersity to be obtained, relatively soluble as compared with their polymeric counterpart, allowing easier purification. Two series were selected, based on symmetry of the inner aromatic group: the 3ARA series, in which the inner aromatic group is –C=O substituted, and which corresponds to the previously studied copolymers (1), and the 3ARB series, in which the inner aromatic ring substitution is –NH based, as can be seen in Figs. 1 and 2, respectively. In both cases, these blocks correspond to AABB type polymers, as in poly(*para*-phenylene terephthalamide). A variety of end-groups to be added: –COOH, $–NH_2$, $–NO_2$, –COOMe, or longer aliphatic chains ($–COOC_{10}H_{21}$, $–COOC_{12}H_{25}$, $–NHCOC_{10}H_{21}$, and $–NHCO\text{-}C_{10}H_{25}$). In all cases, oligomers are abbreviated 3ARA-X or 3ARB-X, X corresponding to the chain-end substitution, as defined in Figs. 1 and 2.

Oligomer synthesis was performed using classical routes, and was fairly straightforward. In many cases, reaction conditions were taken from previous work in our group (19–20). The main problem encountered was the limited solubility of these oligomers, attributed to the formation of strong hydrogen bonds. Therefore, in many cases, dimethyl acetamide, dimethyl formamide, or 1-methyl-2-pyrrolidinone were used as solvents, based on PPTA synthesis conditions.

Effect of end-groups on X-ray powder diffraction

The two series of model compounds, 3ARA-X and 3ARB-X, differ by the presence of a carbonyl-bonded middle aromatic ring in the 3ARA-X series, whereas the middle aromatic group is amide NH bonded in the ARB-X series. Both molecules nevertheless exhibit the same two-dimensional symmetry. Symmetry in the crystalline form may differ because of the non-planarity of the aromatic ring and the amide group, a torsion angle of approximately 30° representing the equilibrium position between two opposing effects: electron delocalization, which favors planarity, and non-bonded interatomic repulsion between the aromatic ring hydrogens and the hydrogen atom of the amide group (27–28). Two main conformations can be adopted. In the first, torsion angles of +30° and –30° exist on each side of the aromatic ring, which is proposed to be the case for PPTA forms I and II (2–4), and leads to quasi-planar molecules, which form hydrogen bonded ribbons, the proposed forms I and II differing by the lateral packing of the hydrogen-bonded ribbons. In the second, +30° torsions occur on each side of the aromatic ring, a 60° dihedral angle is observed between the two amide groups, and hydrogen bonds are formed in two roughly perpendicular directions. This is the case of the crystal structure of poly(*meta*-phenylene isophtalamide), or mpI, an aramid from which the Nomex™ commercial fibers are made (29).

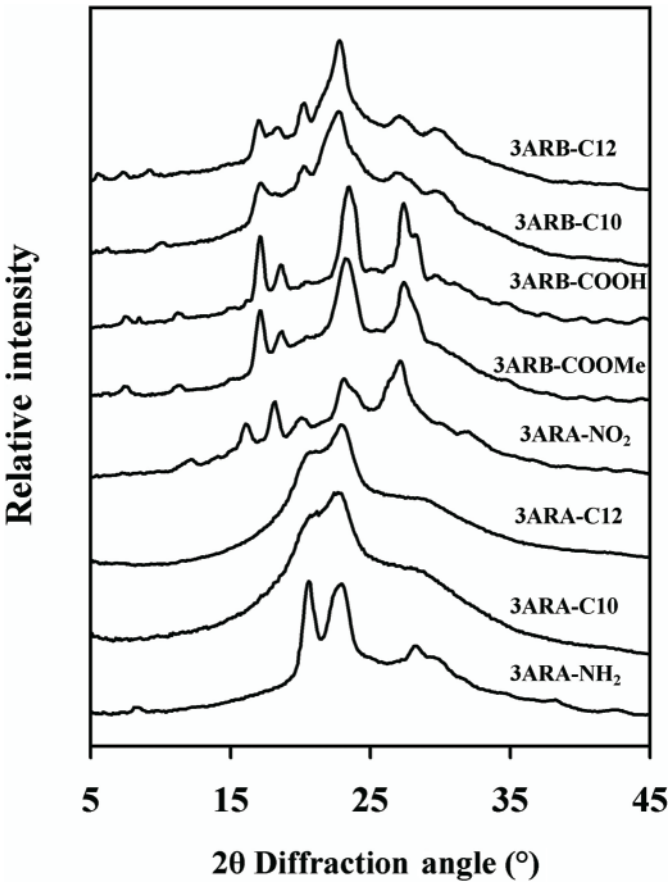
Fig. 3. Effect of end-group length on structure, as observed by X-ray powder diffraction.



X-ray powder diffraction spectra of the two model compound series appear in Fig. 3. Three of the four powder spectra in the 3ARA series, appearing at the bottom of the figure, are similar. 3ARA-NH_2, 3ARA-C10, and 3ARA-C12 spectra all present, with various diffraction peak widths and therefore crystalline order, three main intense peaks: one at 20.6° (4.31 Å), a second at 22.9° (3.88 Å), and a wide peak (which is composed of at least two distinct diffraction peaks) between 28° and 30° (3.0–3.2 Å). These powder spectra correspond well to the observed diffraction diagram of PPTA form I, where these three main diffraction peaks are also observed. 3ARA-C10 and 3ARA-C12 show wider diffraction peaks, suggesting a less ordered crystalline form.

On top of the figure appear 3ARB-C10 and 3ARB-C12 spectra, which exhibit one main intense diffraction peak at 22.9° (3.88 Å) and medium-intensity peaks at 17.3° (5.13 Å), 20.3° (4.37 Å), 26.9° (3.31 Å), and 29.8° (3.40 Å). Powder diagram is similar to that of form II, obtained normally by water precipitation, as reported by Shen and coworkers (37).

Finally, 3ARA-NO_2, 3ARB-COOMe, and 3ARB-COOH show similar powder diffraction spectra, which differ from the ones discussed earlier, with main peaks located at 17.2° (5.15 Å), 18.7° (4.74 Å), 23.3° (3.82 Å), and 27.5° (3.24 Å). Peak positions are similar to those of PPTA form II, although relative intensities of the 23.3° and 27.5° peaks differ significantly from those of PPTA form II.

Surprisingly, in the 3ARB series, no compound seems to adopt a structure similar to that of PPTA form I. This is unexpected, as the rigidity of both series is comparable. The fact that 3ARA-C10 and 3ARA-C12 compounds show a completely different diffraction spectrum from that of the 3ARB-C10 and 3ARB-C12 compounds demonstrates the importance of internal group arrangements. The 3ARA-NO_2 powder diffraction spectrum is similar to that of 3ARB-COOH and 3ARB-COOMe, on the other hand, demonstrating that these internal differences can be counterbalanced by end-group interactions. It is noteworthy that the internal amide groups and aromatic ring arrangement appears to be as important, structure-wise, as the nature of end-groups.

X-ray diffraction on single crystals[2]

Although all model compounds were subjected to crystallization experiments, only one, 3ARA-NO_2, gave crystals large enough for single-crystal structure determination to be performed as of yet. Two distinct forms were observed, both incorporating DMF solvent molecules, hydrogen-bonded to the amide groups. Atomic coordinates and isotropic temperature factors are given for 3ARA-NO_2 form I in Table 2, and 3ARA-NO_2 form II in Table 3. For form I, two crystallographically independent molecules were located, each presenting an inversion center at the middle of the central aromatic ring. Interatomic bond distances, angles, and torsion angles (not shown) are very similar, and therefore packing requirements are probably responsible for this specific arrangement. For form II, a single molecule was located, again with an inversion center at the middle of the central aromatic ring. In this specific case, however, oxygen atoms of the NO_2 groups were found to be disordered with a ratio of 1:1. Both structures incorporate dimethyl formamide solvent molecules hydrogen-bonded to the 3ARA-NO_2 molecules in a very similar fashion, as seen in Fig. 4, where the hydrogen-bonding scheme of each independent molecule is seen. Hydrogen-bond geometry is in agreement with previous structures, i.e., for 3ARA-NO_2 form I, the N···O distance is 2.944(2) and 2.946(2) Å, whereas for form II, it is 2.971(2) Å. These values are well within those obtained for structures containing a benzamide group, such as the *N*,*N*′-oligomethylene dibenzamide series, for which the N···O distances varied from 2.790(2) Å (30) to 3.027(2) Å (31), which indicates that the strength of hydrogen bonds is typical to that found for similar compounds.

In both structures, the amide groups and aromatic cycles are planar. However, and in spite of their appearance, they are not perfectly coplanar with one another, i.e., the middle aromatic group deviates from the rest of the molecular plane, the C–C–C–O torsion angle, linking the central aromatic ring to the amide groups, have values of 168.3(2)° and 8.5(3)° for form I, whereas as value of –33.0(2)° is found in form II. The latter value is in good agreement with previous studies (27–28), whereas the values for the first structure are atypically low, indicating a better planarity. On the other hand, in all cases, the values for the C–C–C–N torsion angle between the aromatic cycles at the molecular extremities and the amide groups, which varies from +3.6(4) to –3.6(4) for form I, and to 0.4(3) for form II, indicate almost perfect planarity, as expected for this torsion angle.

Packingwise, both structures are however completely different from one another. In form I, molecules are staggered, but in such a way that aromatic cycles form stacks perpendicular to the hydrogen bonding direction. Such a packing is reminiscent of the staggered packing previously observed for *N*,*N*′-*p*-phenylene dibenzamide (16), in that the axis of staggered molecules form approximately a 60° angle with one another. However, the packing differs in many respects. First, the molecules are hydrogen-bonded only to solvent molecules in the present case, contrary to the *N*,*N*′-*p*-phenylene dibenzamide structure in which aramid molecules were hydrogen-bonded to one another. Second, as can be seen on Fig. 5, the aromatic cycles on each end are stacked perpendicular to the hydrogen-bond plane in 3ARA-NO_2, and only the central aromatic ring is not found to π-stack. No such π-stacking was reported in the staggered *N*,*N*′-*p*-phenylene dibenzamide structure. Both staggered packings are unlikely to be present in crystal structures of PPTA derived from the liquid–crystalline form, as are forms I and II of PPTA, but variations thereof could exist in unknown polymorphs obtained by direct crystallization.

In form II, shown in Fig. 5*b*, sheets of molecules are observed, as in the case of PPTA forms I and II, and one of the observed polymorphs of *N*,*N*′-*p*-phenylene dibenzamide (15). As solvent molecules are intercalated between 3ARA-NO_2 molecules, this packing does not provide information on the way hydrogen-bonded sheets of PPTA can form. In this case, π-stacking results in a perfect alignment of the molecules perpendicular to the hydrogen-bonded sheets, which point to this feature as possible stabilizing effect for PPTA structures as well.

The amide I and II infrared spectral region

It is well-known that polyamide vibrations found in the infrared spectral region are sensitive to the strength of hydrogen bonds (32–35), to local conformations (36), and to the type of packing that the chains adopt (37). Comparison with infrared spectra reported in the literature should therefore give information on these specific aspects of model compounds. Figure 6 reports the amide I and II spectral region of the model compounds, whereas Table 4 reports assignments in this spectral region, based on the work by Shen, and co-workers (37). This region also features weak- or medium-intensity aromatic deformation vibrations. For 3ARB-COOMe, 3ARB-COOH, and 3ARA-NO_2, an additional intense vibration occurs, that of the carbonyl stretch-

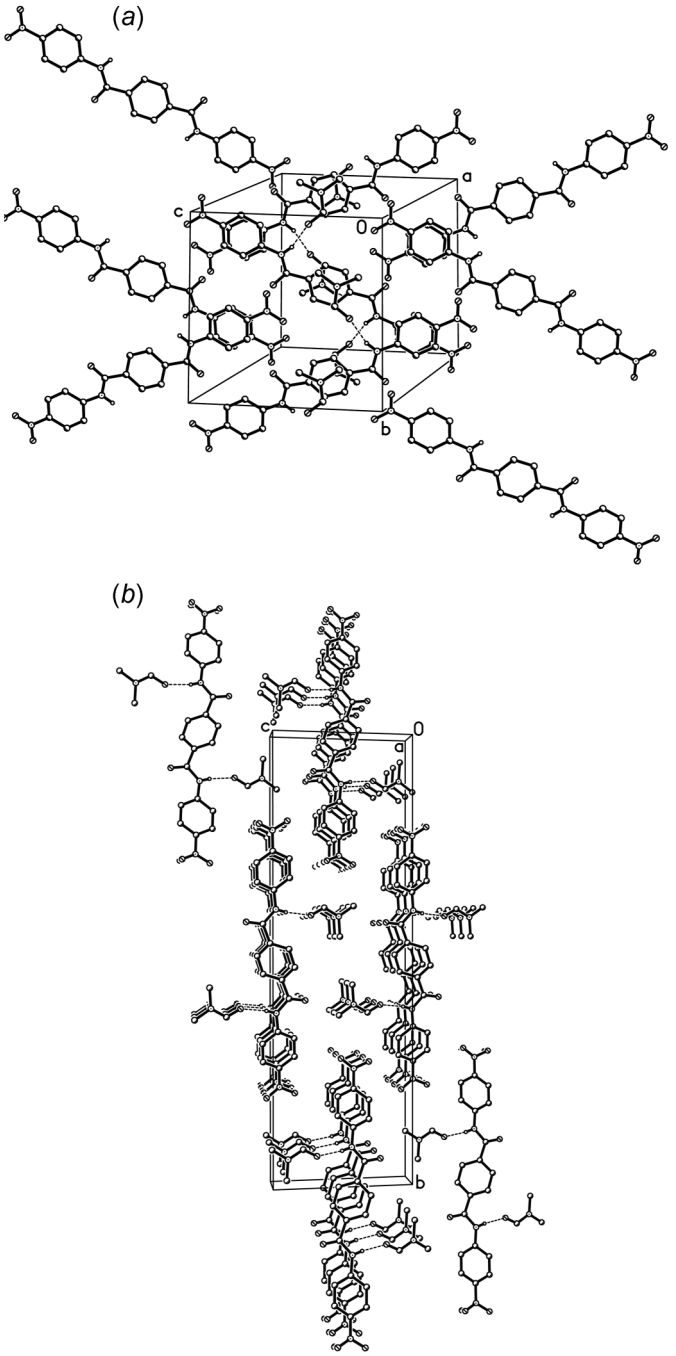

Fig. 6. The amide I and II spectral region (dotted lines indicate the peak positions of PPTA forms I and II at the same position for both forms).

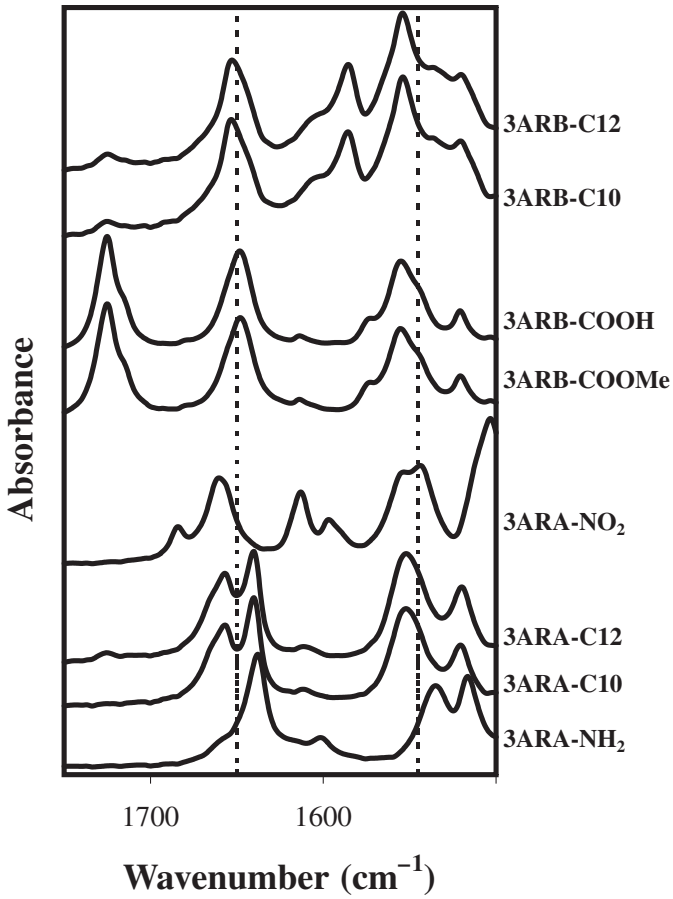

ing vibration around 1725 cm^{-1} for 3ARB-COOMe and 3ARB-COOH, and that of N=O asymmetrical stretching for 3ARA-NO_2 at 1504 cm^{-1}.

The position and intensity of ν(NH) and amide I bands are sensitive to the strength of hydrogen bonds and have been used to quantify the proportion of free and hydrogen-bonded amide groups in polyamides (32–35). The amide I band is attributed mostly to C=O stretching, but C–N stretching and C–C–N deformation also contributes to this band (38). For PPTA forms I and II, which only differ by the packing of the hydrogen-bonded sheets, this vibration does not show any shift in position (37).

Positions of the amide I and II bands of PPTA are indicated by dotted lines in Fig. 6. These positions are the same for forms I and II, hence a single dotted line is made for each band. For amide I, this position matches that observed for 3ARB model compounds. In the 3ARA series, however, variations occur. For 3ARA-C10 and 3ARA-C12, this vibration is split in two, with a difference in frequency of 20–25 cm^{-1}. This splitting may be due to transition dipole coupling, as the average position matches that observed for PPTA. In polypeptides and proteins, transition dipole coupling has been shown to cause splittings of the order of 5 cm^{-1} to 20 cm^{-1}, depending on the conformation of the polypeptides (39, 40). For 3ARA-NO_2, a shift is observed towards higher frequencies, which, in view of the known crystal structures, could be attributed to hydrogen bonds with solvent molecules, or alternatively to the formation of weaker hydrogen bonds after solvent removal from the structure. A small peak also occurs at a higher frequency of 1681 cm^{-1} for this compound, which is attributed to the presence of free amide carbonyl groups, and also indicates some disorder compatible with solvent removal. For 3ARA-NH_2, on the other hand, this band shifts to lower frequencies, indicative of stronger hydrogen bonding, possibly due to the presence of NH_2 groups.

3ARA-NO_2	748 m	720 m + 709m	685 m
3ARB-COOMe	787 m	700 m + 724 m	681 w + 645 m
3ARB-COOH	787 m	700 m + 724 m	681 w + 645 m
3ARB-C10	791 vw	730 m + 718 sh	647 m
3ARB-C12	791 vw	730 m + 718 sh	647 m

Note: vs = very strong, s = strong, m = medium, w = weak, vw = very weak, and sh = shoulder.

The amide II band is a mixed band comprising contributions from N–H in-plane bending, C–N stretching, and C–C stretching. Its position has been shown not to vary with relative strength of hydrogen bonds, and is correlated to pleated sheets or helicoidal structures in proteins (41). In poly(*n*-methylene terephthalamides) or nylons nT, the position of the amide II vibration has been correlated to two-dimensional versus three-dimensional hydrogen-bond network formation (36).

In the case of model compounds studies here, the amide II band is at a slightly higher frequency than in the case of PPTA for most model compounds. As this band position is sensitive to the hydrogen-bonded network, this shift may be attributed to the limited length of the molecules, and hence to the smaller size of hydrogen-bonded ribbons or sheets. Two compounds are at variance with this general behavior, and these are the same as in the case of the amide I band. First, for the 3ARA-NO_2, two peaks are observed in this region, in agreement with the observation of two different chemical structures. Second, for the 3ARA-NH_2 compound, a shift towards lower frequencies is observed, as in the case of three-dimensional networks found for nylon nT model compounds (28), in spite of the strong resemblance between the powder spectra of 3ARA-NH_2 and that of PPTA form I. It is therefore proposed that the network is different in this case, due to the presence of NH_2 end-groups, which can form additional hydrogen bonds. Hydrogen-bonded molecular ribbons or sheets may exist in arrangements similar to that of PPTA form I, whereas additional hydrogen bonds could link, in this particular case, various ribbons or sheets together, thus explaining the observed frequency shift.

The amide IV and V infrared spectral region

The second vibration region of interest, structurewise, for polyamides, is that of the amide IV and V bands. Both bands stem from highly mixed modes: the amide IV has been attributed mainly to O=C–N bending, whereas the amide V band is dominated by N–H out-of-plane deformation. For these medium-intensity bands, differences between PPTA forms I and II have been reported by Shen and co-workers (37) (as indicated in Table 5), showing that these are packing-sensitive. This may be linked in part to deformations in the hydrogen-bond geometry, as it has been proposed that frequency changes in this vibration are due to non-linearity of the proton donor (42). Further, in the case of aliphatic–aromatic nylons, the position of the amide V vibration was indicative of the torsion angle present between the terephthalamide moeity and the aliphatic chains (36). In poly(*meta*-phenylene isophtalamide), in which a three-dimensional network of hydrogen-bonded molecules exist,

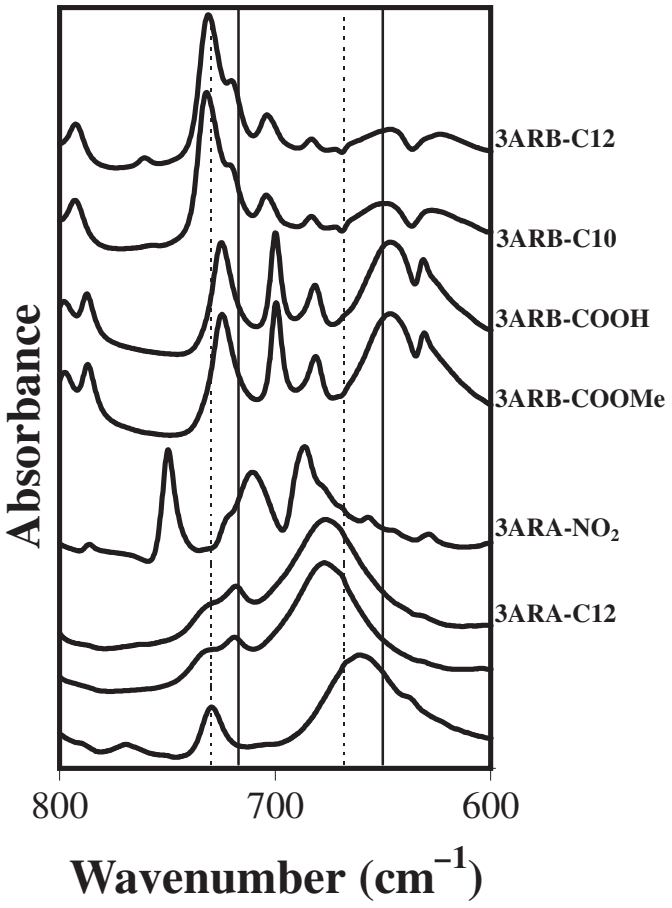
Fig. 7. The amide IV and V spectral region (dotted lines indicate peak positions of PPTA form I, and full lines of PPTA form II).



the position of these two vibrations is different from that of PPTA forms I and II, as seen in Table 5, thus showing that these vibrations are also hydrogen-bond-network-sensitive.

This spectral region for the ARA and ARB model compounds is reported in Fig. 7, and spectral assignments in Table 5. In this figure, positions of the amide IV and V bands for PPTA form I are depicted in dotted lines, and for form II in full lines.

In the case of the amide V vibration, which occurs in the 640–680 cm^{-1} range, model-compound peak positions correlate well to the form expected from X-ray diffraction diagrams, i.e., two main peak positions are found, one at 676 cm^{-1}, slightly above that for PPTA form I, which is at 668 cm^{-1}, and it can therefore be assigned to compounds exhibiting a structure similar to form I (3ARA-C10 and 3ARA-C12), and 645–647 cm^{-1}, at a position close to that of the PPTA form II at 660 cm^{-1}, observed for the 3ARB-C10, 3ARB-C12, 3ARB-COOH, and 3ARB-COOMe, indicative of a structure similar to PPTA form II for all these models compounds, in spite of the differences observed in the X-ray diffraction spectra. For 3ARB-C10 and 3ARB-C12, this was expected from X-ray diffraction data, whereas for 3ARB-COOH and 3ARB-COOMe, it indicates that the crystal form observed, although exhibiting different relative intensities in X-ray spectra, nevertheless presents packing similarities to PPTA form II. Again, two compounds differ from this basic behavior: for 3AR-NH_2, the peak is large and intermediate in position between that of forms I and II, which may be due to the disruptive effect of additional hydrogen bonds due to the NH_2 end-groups, as seen on the amide I and II vibration regions. Finally, for the 3ARA-NO_2, only weak peaks are observed in the amide V band region, which is attributed to the presence of the terminal nitro groups, which may affect specifically this vibration mode.

For the amide IV band, on the other hand, only 3ARA-NH_2 exhibits solely a medium-intensity band at the same position as form I of PPTA. In all other cases, variations occur. Two peaks of varying relative intensity are observed for 3ARA-C10, 3ARA-C12, 3ARB-C10, and 3ARB-C12, a peak at an intermediate position for 3ARB-COOH and 3ARB-COOMe, and a medium-intensity peak at a lower frequency for 3ARA-NO_2. It is concluded that the amide IV vibration, due to its complex nature, is sensitive to substituent effects as well as packing interactions, and cannot be used to compare packings of molecules having different end-groups.

Conclusion

X-ray and FTIR spectroscopy have been used to investigate the types of chain packing and hydrogen bonding occurring in rigid oligomers. These serve as model compounds to better understand structural changes in para-substituted aramids and are possible candidates as organogelators. The present work shows important structural variations occurring in these compounds. Molecules having a flexible aliphatic chain as an end-group present structures similar to PPTA form I (3ARA-C10 and 3ARA-C12) and II (3ARB-C10 and 3ARB-C12), indicating that the alternance of amide groups plays a role in the preferred chain packing. 3ARA-NH_2 also exhibits a structure similar to that of PPTA form I, but appears more complex in terms of hydrogen bonds, and it would be of particular interest to obtain its crystal structure. 3ARB-COOH and 3ARB-COOMe appear to present a chain packing close to PPTA form II, although the relative X-ray diffraction intensities are different, which is also of interest. Finally, 3ARA-NO_2, the model compound for which FTIR spectroscopy showed the largest differences as compared with PPTA, was the only compound for which single-crystal structure determination could be performed. It was found to adopt two different crystal structures, both incorporating solvent molecules hydrogen-bonded to the aramid oligomer, in one case a staggered structure and in the other, a pleated sheet structure (form II). Both forms showed, to a varying degree, π-stacking, which indicates that this feature should not be overlooked in proposed PPTA crystal structures.

Synthesis of the bulky *m*-terphenyl phenol Ar*OH (Ar* = C_6H_3-2,6-Mes_2, Mes = 2,4,6-trimethylphenyl) and the preparation and structural characterization of several of its metal complexes

Diane A. Dickie, Ian S. MacIntosh, Daisuke D. Ino, Qi He, Ojisamola A. Labeodan, Michael C. Jennings, Gabriele Schatte, Charles J. Walsby, and Jason A.C. Clyburne

Abstract: The bulky *m*-terphenyl phenol Ar*OH **1** (Ar* = C_6H_3-2,6-Mes_2, Mes = 2,4,6-trimethylphenyl) was synthesized via the treatment of Ar*Li with nitrobenzene. The phenol **1** is prepared in modest to good yield using this method. Attempts were also made to prepare **1** through oxidation of the bulky boronic acid Ar*$B(OH)_2$ with Oxone®, but this reaction was not suitable for preparative-scale reactions. Side products of the reaction between Ar*Li and nitrobenzene were identified as Ar*[N(O)Ph] and $[C_6H_5N(O)]_2$ and were characterized by X-ray crystallography and EPR spectroscopy. A variety of main-group and transition-metal complexes of Ar*OH were prepared, namely $Sn(OAr^*)_2$, $Ge(OAr^*)_2$, $[N(SiMe_3)_2]Ge(OAr^*)$, $[Me_2Al(OAr^*)]_2$, and $Ti(NMe_2)(OAr^*)_2$. All compounds were characterized spectroscopically and most were studied by single-crystal X-ray diffraction as well.

Key words: *m*-terphenyl, main-group compounds, X-ray crystallography, multinuclear NMR spectroscopy, EPR spectroscopy.

Résumé : On a réalisé la synthèse du *m*-terphénylphénol encombré, Ar*OH, **1**, (Ar* = C_6H_3-2,3-Mes_2; Mes = 2,4,6-triméthylphényle) en faisant réagir du Ar*Li avec du nitrobenzène. Avec cette méthode, on obtient le phénol **1** avec des rendements allant de modestes à bon. On a aussi tenté de préparer le phénol **1** en procédant à l'oxydation de l'acide boronique encombré Ar*$B(OH)_2$ avec de l'Oxone®, mais cette réaction n'est pas appropriée pour des réactions à l'échelle préparative. On a identifié des sous-produits de la réaction entre le Ar*Li et le nitrobenzène, dont le Ar*[N(O)Ph] et le $[C_6H_5N(O)]$ et on a procédé à leur identification par diffraction des rayons X et par spectroscopie RPE. On a préparé une variété de complexes du Ar*OH avec des métaux de transition et du groupe principal, dont $Sn(OAr^*)_2$, $Ge(OAr^*)_2$, $[N(SiMe_3)_2]Ge(OAr^*)$, $[Me_2Al(OAr^*)]_2$ et $Ti(NMe_2)(OAr^*)_2$. On a caractérisé tous les composés par spectroscopie et la plupart de ces composés ont été étudiés par diffraction des rayons X de cristaux uniques.

Mots-clés : *m*-terphényle, composés du groupe principal, diffraction des rayons X, spectroscopie RMN multinucléaire, spectroscopie RPE.

Introduction

The ability to control the coordination environment around a metal is perhaps the most important factor in controlling its reactivity. This is often achieved with the use of sterically demanding ligands. Perhaps the most common class of bulky substituents currently in use are *m*-terphenyls (1), molecules with two aryl substituents arranged *meta* to one another on a central phenyl ring. As shown in Fig. 1, the aryl groups twist out of the plane of the central ring to form a bowl-shaped pocket with a diameter of approximately 12 Å. This pocket acts as a steric shield for reactive species found within it. The steric protection provided by the *m*-terphenyl can be tuned by varying the nature of the aryl

substituents. Common groups include phenyl, 2,4,6-trimethylphenyl (mesityl, Mes), 2,6-diisopropylphenyl (Dipp), and 2,4,6-triisopropylphenyl (Trip).

During the past several years, we have been interested in the coordination chemistry of "substituted" *m*-terphenyl ligands. These studies have resulted in the isolation of unusual coordination geometries for amidinates (2) and carboxylates (3), and here we continue with an examination of phenoxide chemistry. Alkoxides and aryloxides are among the most versatile ligands known and have been placed on virtually every element of the periodic table (4). It is not surprising, therefore, that one of the very first substituted *m*-terphenyls to be used as a ligand was 2,6-diphenylphenol, in a tungsten complex that was subsequently used as an olefin metathesis catalyst (5). Rothwell (6) and others (7) have since explored the structure and reactivity, including catalytic behavior, of many other early transition-metal complexes of this ligand.

The search for new and improved catalysts has also motivated much of the research into main-group *m*-terphenyl phenol complexes (8), based largely on the pioneering work by Yamamoto and co-workers on aluminium tris(2,6-diphenylphenoxide) (9). This molecule and related complexes have served as useful catalysts for stereoselective Claisen rearrangements as well as conjugate addition to α,β-unsaturated carbonyl compounds, and *exo*-selective Diels–Alder additions (opposite to the typical *endo* preference) (10).

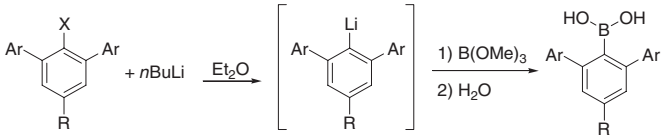
Key to the successful use of these bulky complexes is a simple preparation of the ligands. Whereas some bulky phenols, such as 2,6-diphenylphenol, are commercially available, most others are not. Since steric bulk often dominates or governs the chemistry observed for the complexes, a convenient route into these molecules is desirable. We note here that recent reports by the research group of Power and co-workers described the preparation of bulky phenols **2** and **3** (11) (Fig. 2). Our work aims to complement these studies.

Results and discussion

Ligand synthesis

The targeted *m*-terphenyl phenol for this study was 2,6-bis(2,4,6-trimethylphenyl)phenol, Ar*OH **1**, which had previously only been synthesized as a by-product in the reaction of the corresponding *m*-terphenyl copper complex with

Scheme 1. Synthesis of boronic acids **4** and **5**.



X = Br, Ar = Ph, R = Ph **4**
X = I, Ar = Mes, R = Ph **5**

oxygen (12), or through the palladium-catalyzed cross coupling of phenol with 2,4,6-trimethylbromobenzene (13). Neither of these routes involved the *m*-terphenyl precursors that were readily available, namely Ar*I or a convenient metallated derivative, so two alternative routes were developed.

One proposed route involved the oxidation of *m*-terphenyl boronic acids with Oxone® (14). Lithiation of either 2,4,6-triphenylbromobenzene or 2,6-bis(2,4,6-trimethylphenyl)iodobenzene (Ar*I) in diethyl ether, followed by addition of trimethylborate and aqueous work-up gave the *m*-terphenyl boronic acids **4** and **5**, respectively (Scheme 1). NMR spectroscopy was used to characterize the boronic acids **4** and **5**. The most definitive signal was the two-proton singlet at 4.11 or 4.06 ppm in the spectra of **4** and **5**, respectively, assigned to the $-B(OH)_2$ protons. The upfield shift of these protons relative to phenylboronic acid (4.61 ppm) (15) may be due to shielding by the aryl substituents. The ^{11}B NMR spectra of **4** and **5** each showed a single sharp peak, at 31.4 ppm for **4** and 29.3 ppm for **5**. These values are comparable to other phenylboronic acids (16).

Although these compounds were initially prepared as starting materials for the *m*-terphenyl phenol synthesis, somewhat surprising differences in the O–H absorption region in the IR spectra of **4** and **5** prompted us to more closely examine their intrinsic properties before proceeding further. In the triphenyl-substituted derivative **4**, there was a very strong O–H stretch at 3586 cm^{-1} and a broad absorption at 3280 cm^{-1}, while **5** showed instead four weak absorptions between 3668 and 3417 cm^{-1}. Since this region is primarily affected by hydrogen bonding interactions, attempts were made to grow crystals of both new *m*-terphenyl boronic acids to see if they exhibited different intermolecular interactions. Unfortunately, only **5** yielded crystals suitable for single crystal X-ray diffraction (Fig. 3).

The X-ray crystallographic analysis revealed that, as expected, there is intermolecular [O–H···O] hydrogen bonding in **5**, with O(2) as the donor and O(1) as the acceptor, forming a zigzag chain (Fig. 4). In the absence of other hydrogen bond donor/acceptor groups, all other structurally characterized (17) phenylboronic acid derivatives form homodimers with eight-membered $B_2O_4H_2$ rings rather than infinite chains like **5**. Similar head-to-head homo-dimerization was also observed in two related *m*-terphenyl substituted carboxylic acids (18). Since the carboxylic acids both feature smaller aryl substituents than **5** (phenyl vs. 2,4,6-trimethylphenyl), **4**, which also has the smaller phenyl substituents, may also form a homo-dimer, and that would explain the differences in the IR spectra of **4** and **5**.

Once the boronic acids **4** and **5** were in hand, reactions to oxidize them to the respective *m*-terphenyl phenols were performed using Oxone® in basic solution (14). This reac-

tion produces very low yield (trace) of the desired bulky phenols, and hence work in this area was stopped and a new route was sought.

Generation of bulky phenols from Ar*Li and nitrobenzene

During the course of our boronic acid experiments, Power and co-workers (11) developed a synthesis of bulkier *m*-terphenyl phenols, namely **2** and **3**, directly from the lithiated intermediate Ar*Li, so this more direct and higher yielding route was pursued. Lithiation of Ar*I with *n*-butyllithium in ethereal solution followed by addition of excess nitrobenzene at –78 °C results in the immediate formation of a dark red solution that is quenched with methanol to give **1** (Scheme 2).

In the ^{1}H NMR spectrum of the *m*-terphenyl phenol **1**, the O*H* appears as a singlet at 4.53 ppm. The methyl groups are found at 2.33 (*para*) and 2.06 (*ortho*) ppm. Additional evidence for the presence of the OH was provided by strong IR absorptions at 3486 and 3451 cm^{-1}. These stretches are comparable to those reported by Lüning and co-workers (19) for 2,6-bis(2,6-dimethylphenyl)phenol, at 3482 and 3431 cm^{-1}. Four other previously published *m*-terphenyl phenols, namely 2,6-diphenylphenol (20), 2,6-bis(3,5-dimethylphenyl)phenol (19), 2,6-bis(2,6-diisopropylphenyl)phenol **2** (11), and 2,6-bis(2,4,6-triisopropylphenyl)phenol **3** (11), each reported only a single OH stretch between 3520–3533 cm^{-1} in the IR spectrum. Since three of these five compounds had been crystallographically characterized, single-crystal X-ray diffraction studies were performed on **1** to see if there was a difference in hydrogen bonding that could explain the differences in the IR spectra.

Fig. 4. [O–H···O] hydrogen bonds in **5**, viewed along the crystallographic *a* axis.

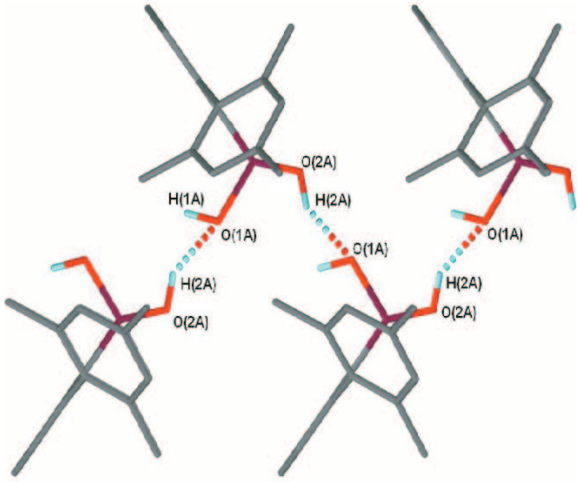

Fig. 5. Molecular structure of 2,6-bis(2,4,6-trimethylphenyl)phenol **1**. Thermal ellipsoids are shown at 50% probability, and all hydrogens, except phenolic protons, have been removed for clarity. Selected bond lengths (Å) and angles (°): O(1)—C(2) 1.356(3); O(31)—C(32) 1.375(3); O(1)–C(2)–C(7) 116.7(2); O(1)–C(2)–C(3) 121.7(2); O(31)–C(32)–C(37) 116.3(2); O(31)–C(32)–C(33) 121.0(2). Hydrogen-bond lengths (Å) and angles (°): O(1)···O(31) 2.823(3); O(1)–H(1A)···O(31) 152.9.

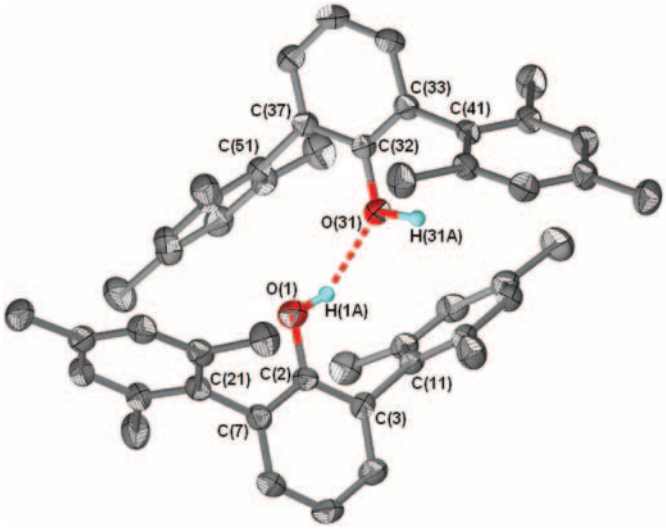

The crystallographic studies revealed that in the solid state, **1** exists as two crystallographically distinct molecules (Fig. 5). These molecules are connected by a weak [O–H···O] hydrogen bond to form a dimer. This is in contrast to the unsubstituted phenol (C_6H_5OH), which forms infinite hydrogen-bonded chains (21) with an average [O···O] distance of 2.67 Å, compared with 2.823(3) Å in **1**. It is also in contrast to all three previously structurally characterized *m*-terphenyl phenols, none of which exhibits [O–H···O] hydrogen bonds. Based on the IR evidence, it would appear that Lüning's 2,6-bis(2,6-dimethylphenyl)phenol follows the

Selected bond lengths (Å) and angles (°):N(1)—O(1) 1.290(2); N(1)—C(1) 1.443(3); N(1)—C(31) 1.406(3); N(2)—N(2)* 1.128(6); N(2)—O(2) 1.301(5); N(2)—C(41) 1.564(5); O(1)–N(1)–C(1) 116.86(18); O(1)–N(1)–C(31) 119.32(17); C(1)–N(1)–C(31) 123.82(18).

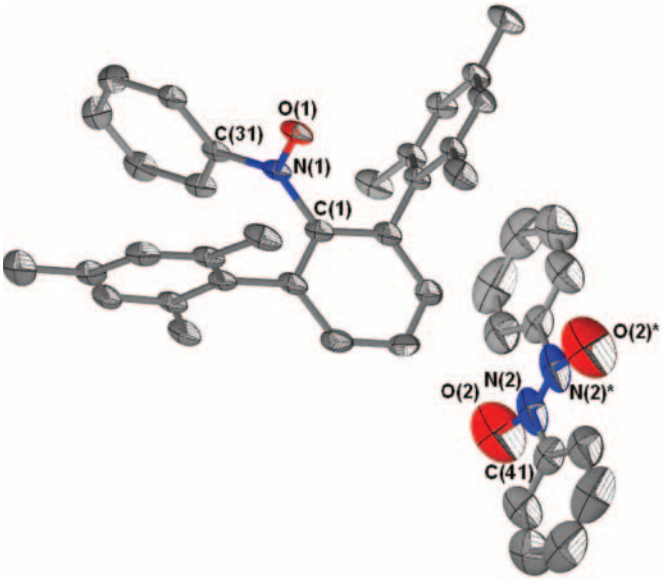

Fig. 7. Main panel: Experimental (top) and simulated (bottom) EPR spectra of nitrosobenzene complex **6** dissolved in CH_2Cl_2. Experimental parameters: ν = 9.86 GHz, microwave attenuation = 20 dB, scan time = 21 s, time constant = 10.24 ms, modulation amplitude = 0.0125 mT, receiver gain = 2.5×10^3, average of 17 scans. Simulation parameters: $a(^{14}N)$ = 1.024 mT; $a(^1H \times 3)$ = 0.247 mT; $a(^1H \times 2)$ = 0.088 mT, $a(^1H \times 3)$ = 0.054 mT, linewidth = 0.047 mT. Inset: EPR spectrum of single co-crystal of nitrosobenzene complex **6** with $[C_6H_5N(O)]_2$. Experimental parameters: ν = 9.86 GHz, microwave attenuation = 25 dB, scan time = 21 s, time constant = 10.24 ms, modulation amplitude = 0.01 mT, receiver gain = 6.3×10^3, 1 scan.

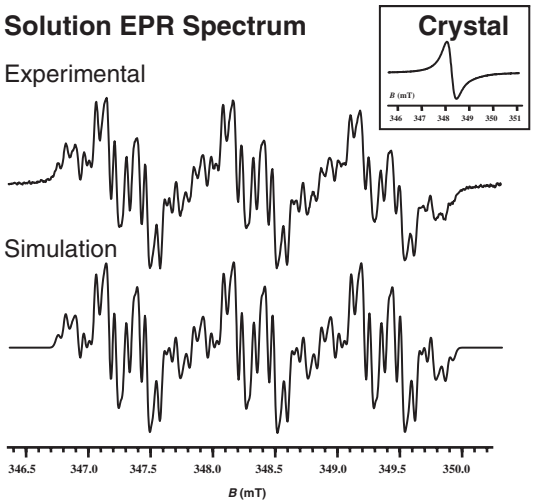


same pattern as **1**, while his 3,5-derivative is more similar to the others (11, 20).

Another feature that was found in each of the crystallographically characterized *m*-terphenyl phenols, including **1**, is an intramolecular [O–H···π] interaction. In the case of the extremely bulky 2,6-bis(2,4,6-triisopropylphenyl)phenol and 2,6-bis(2,6-diisopropylphenyl)phenol, steric hindrance hampers intermolecular [O–H···O] interactions, but does not prevent intramolecular [O–H···π] interactions with a flanking aryl. This interaction occurs primarily through the *ipso* carbon atoms (H···C_{ipso} = 2.64 and 2.39 Å, respectively) (11). In fact, the restricted rotation caused by the presence of such bulky groups may even enhance the interaction by locking the aryls into place.

Restricted rotation is clearly not necessary though, since the crystal structure of the least hindered *m*-terphenyl, 2,6-diphenylphenol, also showed an [O–H···π] interaction of 2.43 Å (20). The corresponding H···C_{ipso} distances in **1** are 2.41 and 2.47 Å [H(1A)···C(11) and H(31A)···C(41), respectively]. It is not immediately clear why 2,6-diphenylphenol does not also engage in [O–H···O] hydrogen bonds like **1**, but it may be that [C–H···π] interactions through the *para* hydrogen of the central phenyl provide more favorable packing interactions. Taken together, these examples illustrate how subtle changes in steric demands can have a large effect on intermolecular interactions.

During the work-up and recrystallization of **1**, a small amount of a highly colored red by-product was also isolated. We performed spectroscopic studies on the red material, and found that NMR studies were not informative because of extensive line broadening, and the IR studies indicated the presence of both aromatic C–H and alkyl C–H fragments, as well as peaks that were tentatively assigned to N–O bonds.

To unambiguously assign the structure, a crystallographic study was performed on the block-shaped crystals (Fig. 6). The results of these studies indicate that the *m*-terphenyl nitrosobenzene addition complex **6** was formed and co-crystallized with homodimerized nitrosobenzene, the other by-product of the phenol synthesis. The formation of the *m*-terphenyl by-product **6** was proposed by Power and co-workers during the preparation of the bulkier *m*-terphenyl phenols **2** and **3**, but was not observed because of the higher steric demands of his *m*-terphenyl backbone (11).

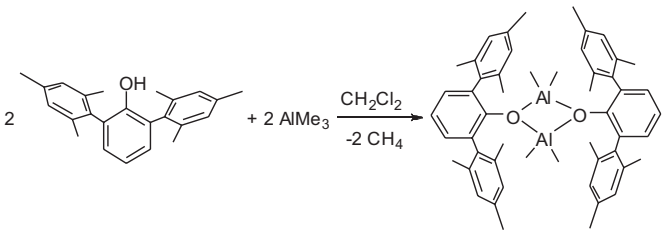
The structure of the nitrosobenzene compound **6** is interesting for two reasons. First of all, it confirms that the bulky Ar*Li can react with nitrobenzene either via oxygen atom abstraction or it can react via addition to nitrogen. Furthermore, the co-crystallized PhNO dimer was isolated in a rare *trans* configuration. Typically, PhNO does not dimerize, and when it does, it crystallizes in the *cis* form (22). Other structural parameters for both components of the red co-crystal are unremarkable, and no other unusual contacts were observed in the packing diagrams.

EPR of nitrobenzene complex 6

The EPR spectrum of a single co-crystal of complex **6** with homodimerized nitrosobenzene shows a single Lorentzian line with a relatively large peak-to-peak linewidth of 0.42 mT (Fig. 7, inset). This result is consistent with the presence of the paramagnetic nitroxide species,

© 2007 NRC Canada

Scheme 3. Synthesis of $[Me_2Al(\mu\text{-}OC_6H_3Mes_2)]_2$ **7**.



1 **7**

complex **6**; the broad, unresolved line is due to cross-relaxation between the spins of the radical species.

The crystal was dissolved in CH_2Cl_2 and a complex spectrum resulted, which was simulated accurately (Fig. 7, main panel). The magnitude and multiplicity of the hyperfine couplings are consistent with the structure of complex **6**. The large ^{14}N coupling (I = 1, $a(^{14}N)$ = 1.024 mT) indicates that the majority of the spin density lies on the nitroxide moiety; couplings from a total of eight ^1H nuclei (I = ½, $a(^1H \times 3)$ = 0.247 mT; $a(^1H \times 2)$ = 0.088 mT, $a(^1H \times 3)$ = 0.054 mT) demonstrate interactions with the eight protons of the phenyl groups directly attached to the nitroxide and indicate delocalization of spin density across both rings. The ^{14}N and ^1H hyperfine coupling constants measured for compound **6** are comparable to those observed for the symmetrical nitrosyl radical $C_6H_5N(O)C_6H_5$ (23).

Metal complexes derived from Ar*OH

The reaction of the *m*-terphenyl phenol **1** with an equimolar amount of $AlMe_3$ in dichloromethane gives the dialkylaluminium monophenoxide **7** (Scheme 3). Evidence for this product is found in the ^1H NMR spectrum, which showed peaks at –1.26, 2.15, and 2.19 ppm with relative intensities of 6:12:6, due to the aluminium methyls and *m*-terphenyl *ortho* and *para* methyl groups, respectively.

X-ray crystallographic studies (Fig. 8) confirmed the formula suggested by the ^1H NMR data, and showed that despite the bulk of the *m*-terphenyl ligand, **7** exists in the solid state as an oxygen-bridged dimer with a planar Al_2O_4 core. An identical motif was described by Rothwell for his less hindered 2,6-diphenylphenol aluminium complex (24). In contrast, Power's bulkier 2,6-bis(2,4,6-triisopropylphenyl)phenol aluminium complex was isolated as a base-stabilized monomeric ether solvate (25). As was the case in the free ligands, the effects of subtle steric differences around the *m*-terphenyl pocket have a remarkable effect on coordination within that pocket (Fig. 9).

To see if it was possible to establish a trend in the coordination behavior of the *m*-terphenyl phenols, group 14 derivatives were also prepared. Despite the fact that the first Sn(II) and Ge(II) compounds found to exist as dicoordinate monomers in the solid state were based upon bulky phenol ligands (26), structural data on divalent group 14 alkoxy or aryloxy compounds remains relatively rare. This makes the preparation of such compounds interesting simply from a fundamental perspective, but the fact that they are also being studied as catalysts (27) and as molecular precursors to superconductors and (or) ceramic materials for applications,

Fig. 8. Structure of $[Me_2Al(\mu\text{-}OC_6H_3Mes_2)]_2$ **7**. Thermal ellipsoids are shown at 50% probability, and hydrogen atoms and CH_2Cl_2 solvent have been removed for clarity. Fig. 10. Structure of $[Sn(OC_6H_3Mes_2)_2]$ **8**, showing Sn–π interactions. Thermal ellipsoids are shown at 50% probability, and hydrogen atoms have been removed for clarity. Selected bond lengths (Å) and angles (°): Sn(1)—O(1) 2.039(3); Sn(1)—O(2) 2.043(3); O(1)—C(101) 1.343(5); O(2)—C(201) 1.342(5); O(1)–Sn(1)–O(2) 87.32(11); Sn(1)–O(1)–C(101) 127.7(2); Sn(1)–O(2)–C(201) 125.7(2).

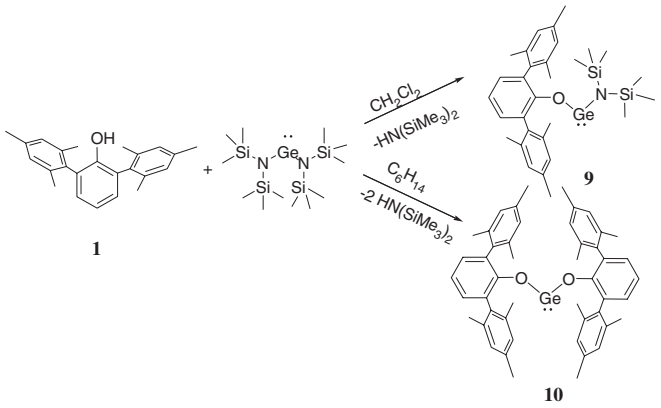
including flat panel displays, gas sensors, solar cells, and lithium battery anodes (28), makes structural data all the more important.

The protonolysis reaction (Scheme 4) of $Sn[N(SiMe_3)_2]_2$ with **1** in benzene gives the tin(II) complex **8** in good yield. No signal from the C*H*$_3$ groups of the trimethylsilylamide ligand was observed ^{1}H NMR spectrum of **8**, indicating that both amido groups had been lost to give the tin(II) bis(phenoxide) complex. The disappearance of the O*H* signal in both the ^{1}H NMR and IR spectra also indicated the formation of **8**, as did the peak at –344 ppm in the ^{119}Sn NMR spectrum. This value is upfield of the signal at –289 ppm for the most closely related $Sn(OAr)_2$ compound in the literature, namely Power's recently reported tin(II) bis(phenoxide) based on the *m*-terphenyl 2,6-bis(2,6-diisopropylphenyl)phenol **2** (25).

Final confirmation of the structure of **8** was provided by single-crystal X-ray diffraction. The crystallographic studies revealed that it does indeed exist as a monomer in the solid state (Fig. 10). The geometry at tin is v-shaped, due to the stereochemically active lone pair. As in the few other known monomeric Sn(II) bis(aryloxides) (25, 29), the O–Sn–O angle is quite acute, measuring only 87.32(11)°. The tin atom in **8** is not truly dicoordinate, however, as it has extensive Sn–π interactions resulting from being sandwiched between two flanking aryls of the *m*-terphenyl ligand. The Sn···centroid distances measure 2.942 and 2.980 Å for the C(111) and C(221) rings, respectively. Such interactions are also present in $Sn(OAr)_2$, where Ar = 2,6-bis(2,6-diisopropylphenyl) although they are somewhat longer [3.064 (C49 ring) and 3.262 (C7 ring)]. The observed upfield ^{119}Sn NMR shift for compound **8** may be due to the stronger Sn–arene interaction, but overall the interaction appears to be weak as shown by the appearance of only one set of signals for the *o*-Me protons in the ^{1}H NMR spectra of **8**.

Scheme 5. Synthesis of $[(Me_3Si)_2NGe(OC_6H_3Mes_2)]$ **9** and $Ge(OC_6H_3Mes_2)_2$ **10**.



The reaction in dichloromethane of $Ge[N(SiMe_3)_2]_2$ with the *m*-terphenyl phenol **1** gave a mixture of compounds, one of which was the mixed aryloxy-amido germanium complex **9** (Scheme 5). This complex could be identified in the ^{1}H NMR spectrum of the crude reaction mixture as a singlet of 18 hydrogens at 0.00 ppm [–Si(C*H*$_3$)$_3$], and singlets at 2.18 and 2.42 ppm for the *ortho* and *para* methyls of the *m*-terphenyl ligand. Since $Sn[N(SiMe_3)_2]_2$ is known to react with dichloromethane solvent (3c, 30), it seemed possible that this could also be happening during the synthesis of **9**, so an attempt was made to repeat the synthesis in hexanes. Unfortunately, only traces of the mixed complex **9** were observed in the ^{1}H NMR spectrum. The major product was the germanium bis(aryloxide) **10**. As with the tin bis(aryloxide) **8**, the ^{1}H NMR spectrum of **10** showed a pronounced upfield shift of the *ortho* methyl protons to 1.79 ppm (1.82 ppm in **8**). Similarities were also seen in the elevated melting point of **10** at 318 °C, compared with 321 °C in **8**. Elemental analysis was consistent with the proposed composition of **10**.

Several attempts were made to grow crystals of **9** and **10**, but only **9** yielded single crystals suitable for X-ray diffraction studies (Fig. 11). Compound **9** is, to the best of our knowledge, the first structurally characterized monomeric, dicoordinate mixed aryloxy-amido germanium(II) complex (31). The Ge—O bond length of 1.8414(16) Å is longer than those found in other dicoordinate non-calixarene Ge(II) compounds [1.814(2) to 1.8296(14) Å] (25, 32). The opposite is true of the Ge—N bond, which, at 1.851(2) Å is shorter than in comparable compounds [1.855(2) to 1.939(6) Å] (33). The germanium atom does not engage in any significant inter- or intra-molecular interactions.

Given the interesting coordination patterns observed in the main-group complexes of **1**, we also wanted to probe its transition-metal coordination. For the related ligand 2,6-diphenylphenol, titanium complexes are by far the most common. Virtually, all of these complexes feature two *m*-terphenyl phenol ligands on the titanium centre, and a few even accommodate three (34). Only one complex is known with a single 2,6-diphenylphenol ligand, and it uses cyclo-

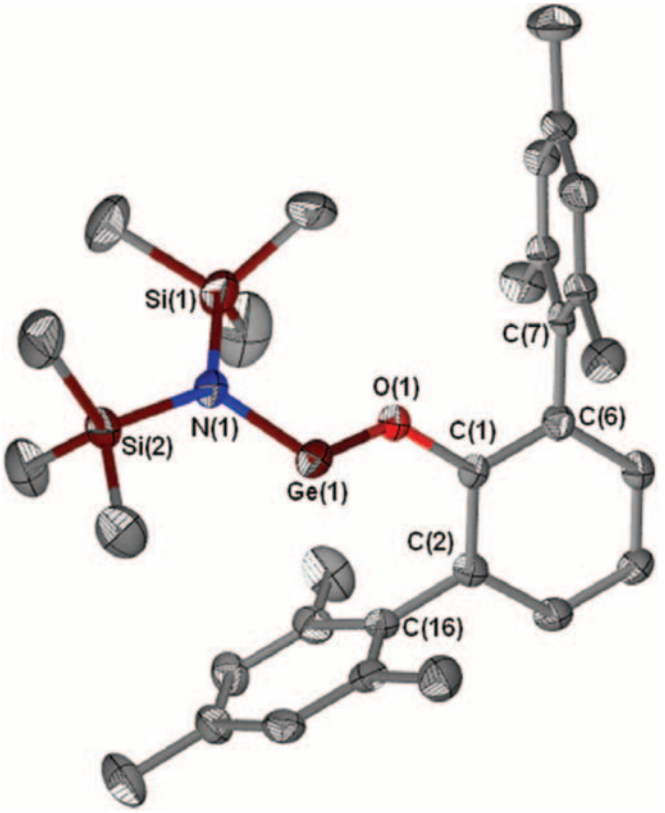
Fig. 11. Structure of $[(Me_3Si)_2NGe(OC_6H_3Mes_2)]$ **9**. Thermal ellipsoids are shown at 50% probability, and hydrogen atoms have been removed for clarity. Selected bond lengths (Å): Ge(1)—N(1) 1.851(2); Ge(1)—O(1) 1.8414(16); Si(1)—N(1) 1.753(2); Si(2)—N(1) 1.750(2); C(1)—O(1) 1.366(3). Selected bond angles (°): O(1)–Ge(1)–N(1) 97.59(8); Ge(1)–N(1)–Si(1) 122.83(11); Ge(1)–N(1)–Si(2) 114.71(11); Si(1)–N(1)–Si(2) 122.42(12).



pentadienyl as an ancillary ligand (35). Would the increased bulk of **1** make it possible to isolate a titanium monophenoxide complex?

Addition of tetrakis(dimethylamino)titanium to a solution of **1** in dichloromethane resulted in the formation of an orange solid **11** (Scheme 6). The ^{1}H NMR spectrum showed a 1:1 ratio between the N*Me*$_2$ ligand at 2.30 ppm and the *m*-terphenyl at 2.24 (*para*) and 2.11 (*ortho*) ppm. Given that titanium is tetravalent, these data suggested the formation of a bis(phenoxide) complex with a formula of $(Me_2N)_2Ti(OC_6H_3Mes_2)_2$. This product was formed even when substoichiometric amounts of the *m*-terphenyl phenol ligand were added.

X-ray crystallographic studies of **11** confirmed the proposed structure (Fig. 12). The geometry at titanium is tetrahedral, with the greatest deviation in the O(11)–Ti(1)–O(21) angle [119.25.(5)°] and N(31)–Ti(1)–N(41) angle [102.88(6)°]. The Ti—O bonds are the same within experimental error, and are within the range of similar titanium complexes [1.786(2)–1.862(5) Å] (36). The same is true for the two Ti—N bond lengths, for which literature values of similar compounds range from 1.854(7) to 1.897(5) Å (36). The nature of the oxygen ligand appears to be the most-important factor governing the coordination at titanium. All but one of the structurally characterized examples of tetra-

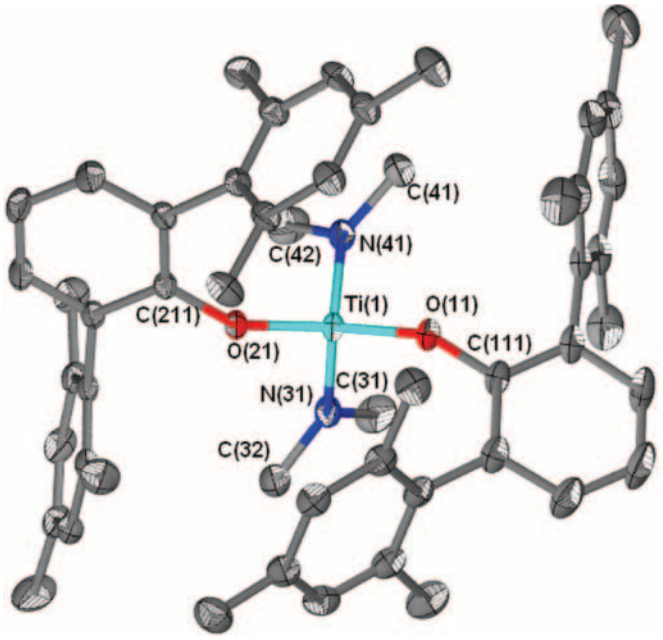
Selected bond angles (°): O(11)–Ti(1)–O(21) 119.25(5); O(11)–Ti(1)–N(41) 106.63(5); O(21)–Ti(1)–N(31) 107.72(5); O(21)–Ti(1)–N(41) 109.98(5); O(11)–Ti(1)–N(31) 109.17(5); N(31)–Ti(1)–N(41) 102.88(6).



coordinate titanium complexes with two oxygen donors and two nitrogen donors of any type, i.e., $[(R_2N)_2Ti(OR)_2]$, were based on 2,6-disubstituted phenol ligands. The one exception featured a 2,6-disubstituted aniline instead (37). It is not immediately clear if this is merely a coincidence or if the steric shielding of the *meta* substituents is chemically required.

Summary and conclusions

The X-ray crystal structures of a *m*-terphenyl phenol and a *m*-terphenyl boronic acid were described. The hydrogen bonding pattern observed in phenol **1**, intermolecular [O–H···O] dimerization, is very different from that observed in related *m*-terphenyl phenols. The steric demands of **1** are intermediate between those of previously characterized derivatives. This balance appears to be the key to the supramo-

© 2007 NRC Canada

lecular interactions, as the same 2,4,6-trimethylphenyl substituent was used in the boronic acid **5** that also exhibited unprecedented [O–H···O] hydrogen bonds.

Given the differences in the structures of the free ligands, it seemed possible that the main-group and transition-metal complexes of **1** would also have features not found in more and (or) less bulky analogues. This was not the case for the titanium complex **11** and aluminium complex **7**. Both molecules were essentially isostructural to known 2,6-diphenylphenol derivatives. The tin complex **8**, on the other hand, did exhibit a spectroscopic difference. The secondary metal–π interaction between the tin atom and flanking aryls of the *m*-terphenyl ligand in **8** result in an up-field shift of the ^{119}Sn NMR resonance relative to that observed for $Sn(OAr)_2$, where Ar = 2,6-bis(2,6-diisopropylphenyl).

Experimental

General experimental

A nitrogen-atmosphere MBraun UL-99-245 dry box and standard Schlenk techniques on a double manifold vacuum line were used in the manipulation of air and moisture sensitive compounds. Solution-state NMR spectra were recorded in five millimetre tubes at Simon Fraser University on a Bruker AMX 400 or 600 MHz spectrometers or Varian AS 400 or 500 MHz spectrometers. Chemical shifts are reported in parts per million (ppm) downfield from $SiMe_4$ (^{1}H and ^{13}C), $BF_3{\cdot}Et_2O$ (^{11}B), or $SnMe_4$ (^{119}Sn). ^{1}H and ^{13}C spectra are calibrated to the residual signal of the solvent. ^{11}B and ^{119}Sn spectra are calibrated to the external $BF_3{\cdot}Et_2O$ or $SnMe_4$ standard. Infrared spectra were obtained using a Bomem MB spectrometer with the % transmittance values reported in cm^{-1}. EPR spectra were collected on a Bruker ECS-106 EPR spectrometer. The CH_2Cl_2 solution was deoxygenated by bubbling with nitrogen gas, to increase spectral resolution. Spectral simulation used the Bruker WinEPR SimFonia software. Melting points were measured using a Mel-Temp apparatus and are uncorrected. Elemental analyses were obtained at Simon Fraser University by Mr. M.K. Yang on a Carlo Erba Model 1106 CHN analyzer.

Anhydrous solvents were obtained from an MBraun Solvent Purification system, or were purchased from Aldrich and used without further purification. All other reagents and solvents were purchased from commercial sources, including Aldrich, Strem, and Gelest, and used without further purification, except deuterated solvents for NMR experiments on air- and (or) moisture-sensitive compounds, which were dried over P_2O_5 and distilled prior to use. The halogenated *m*-terphenyl precursors 2,4,6-triphenylbromobenzene (38) and 2,6-dimesityliodobenzene (39) were prepared according to literature procedures.

Synthesis of ligands and precursors

2,6-bis(2,4,6-Trimethylphenyl)phenol (1)

Under an inert atmosphere, *n*-BuLi (2.8 mL, 4.5 mmol, 1.6 mol/L in hexanes) was added dropwise to a suspension of 2,6-bis(2,4,6-trimethylphenyl)iodobenzene (1.32 g, 3.0 mmol) in 20 mL anhyd. Et_2O. After 2 h, the solution was cooled to –78 °C, and freshly distilled nitrobenzene (1.5 mL, 15 mmol) was added dropwise. The bright red solution was allowed to stir for 5 min, and then 20 mL of methanol was added slowly. After warming to RT, 30 mL of H_2O was added, and the organic layer was separated. The aq. layer was acidified with 1 mL concd. HCl and then extracted with Et_2O. The combined organic fractions were washed with water and saturated $NaCl_{(aq)}$ and then dried over $MgSO_4$. The solution was concentrated to ~10 mL and then passed through a plug of silica. After addition of ~10 mL pentane, the solution was left to evaporate slowly at room temperature overnight. The resultant pale brown solid was recrystallized to give colorless to pale blue crystals. Yield = 0.39 g (40%); mp = 145 °C. ^{1}H NMR ($CDCl_3$, 499.767 MHz,) δ: 7.03 (m, 3H), 6.98 (s, 4H), 4.53 (s, 1H), 2.33 (s, 6H), 2.06 (s, 12H). ^{13}C{^{1}H} NMR ($CDCl_3$, 100.624 MHz) δ: 137.5, 137.2, 135.9, 133.4, 129.6, 128.5, 128.1, 120.7, 21.2, 20.4. IR (nujol mull) ν: 3486 (s), 3451 (s), 1611 (w), 1584 (w), 1573 (w), 1490 (m), 1320 (s), 1260 (m), 1221 (vs), 1170 (s), 1089 (m), 1071 (m), 1030 (w), 1008 (w), 848 (vs), 829 (s), 797 (s), 780 (w), 752 (vs), 740 (w), 715 (w). Anal. calcd. for $C_{24}H_{26}O$: C, 87.23; H, 7.93. Found: C, 87.50; H, 8.04. HR-MS (*m/z*): [M$^+$] calculated for $C_{24}H_{26}O$, 330.198. Found: 330.198. During recrystallization small red single crystals of **6** can be isolated, a material that was identified as a co-crystal of $[C_6H_5N(O)]_2$ with $C_6H_5N(O)C_6H_3Mes_2$. The crystals can be isolated reproducibly in low yield (mg) per reaction. Mp = 120–123 °C. HR-MS $C_{30}H_{30}NO$ calcd.: 420.2327; found, 420.2315. IR (KBr pellet) ν: 2914 (s), 2857 (m), 1607 (m), 1573 (m), 1446 (vs), 1360 (m), 1307 (m), 1265 (m), 1221 (m), 1074 (m), 1024 (m), 846 (s), 753 (vs), 683 (s), 563 (m).

2,4,6-Triphenylphenylboronic acid (4)

Under an inert atmosphere, *n*-BuLi (9.7 mL, 1.6 mol/L in hexanes) was added to a suspension of 2,4,6-triphenylbromobenzene (5.00 g, 12.98 mmol) in 50 mL anhyd. Et_2O. After 2 h, the solution was cooled to –30 °C in a methanol/ice bath, and $B(OMe)_3$ (1.62 g, 15.57 mmol) was added dropwise. The reaction was warmed to RT and stirred overnight. The reaction was quenched with H_2O and allowed to stir 4 h before being extracted with Et_2O. The combined organic fractions were dried over $MgSO_4$, and then the solvent was removed under vacuum to give a pale yellow solid. Yield = 1.29 g (27%); mp = 356–357 °C. ^{1}H NMR ($CDCl_3$, 400.137 MHz) δ: 7.67 (d, 2H, *J* = 7.1 Hz), 7.63 (s, 2H), 7.53 (d, *J* = 6.8 Hz, 4H), 7.45 (t, *J* = 6.8 Hz, 6H), 7.40 (t, *J* = 7.1 Hz, 3H), 4.11 (s, 2H, B(O*H*)$_2$). ^{13}C{^{1}H} ($CDCl_3$, 125.679 MHz) δ: 146.8, 143.2, 142.1, 129.1, 128.8, 127.8, 127.5, 127.1, 126.9. ^{11}B ($CDCl_3$, 128.370 MHz) δ: 31.37. IR (nujol mull) ν: 3586 (vs), 3280 (br), 3056 (w), 3057 (w), 1595 (s), 1575 (w), 1538 (w), 1492 (s), 1445 (s), 1396 (s), 1335 (vs), 1208 (w), 1193 (w), 1083 (m), 1041 (m), 1030 (m), 983 (w), 917 (w), 888 (s), 821 (m), 782 (m), 761 (s), 751 (s), 699 (vs). Synthesis of metal complexes

[$Me_2Al(\mu$-$OC_6H_3Mes_2)]_2$ (7)

Under an inert atmosphere, $AlMe_3$ (1.01 mL, 2.0 mol/L in hexanes) was added dropwise to a solution of 2,6-bis(2,4,6-trimethylphenyl)phenol **1** (0.56 g, 1.69 mmol) in 10 mL anhyd. CH_2Cl_2. After stirring for 5 min at RT, the solution was concentrated under vacuum and then cooled to –30 °C. The next day, the solution was decanted from colorless crystals. Yield = 0.25 g (38%); mp = 238–240 °C. ^{1}H NMR (C_6D_6, 499.767 MHz) δ: 6.85 (s, 4H), 6.69 (t, J = 7 Hz, 1H), 6.59 (d, J = 7 Hz, 2H), 2.19 (s, 6H), 2.15 (s, 12H), –1.26 (s, 6H). ^{13}C NMR (C_6D_6, 125.680 MHz) δ: 138.3, 137.9, 135.9, 133.1, 129.5, 129.3, 128.3, 21.9, 21.7. IR (nujol mull) ν: 1610 (w), 1405 (m), 1261 (w), 1190 (m), 1182 (m), 1091 (m), 1032 (w), 848 (m), 825 (m), 803 (w), 774 (w), 758 (w), 701 (s), 635 (m). Anal. calcd. for$C_{52}H_{62}Al_2O_2$, C, 80.80; H, 8.08. Found: C, 81.14; H, 8.18.

[$Sn(OC_6H_3Mes_2)_2$] (8)

Under an inert atmosphere, a solution of $Sn[N(SiMe_3)_2]_2$ (0.33 g, 0.76 mmol) in 2 mL anhyd. benzene was added dropwise to a solution of 2,6-bis(2,4,6-trimethylphenyl)phenol **1** (0.50 g, 1.51 mmol) in 10 mL anhyd. benzene. The mixture was allowed to stir for 3 h at RT and then filtered. Slow evaporation of the solvent gave a yellow solid that was recrystallized from warm hexanes to give colorless crystals: Yield = 0.48 g (81%); mp = 321–322 °C. ^{1}H NMR (CD_2Cl_2, 499.767 MHz) δ: 6.84 (d, J = 6.9 Hz, 2H), 6.79 (s, 4H), 6.73 (t, J = 6.9 Hz, 1H), 2.29 (s, 6H), 1.82 (s, 12H). ^{13}C NMR (100.624 MHz, C_6D_6) δ: 157.8, 138.5, 137.8, 137.4, 129.7, 129.5, 129.2, 117.9, 21.1, 20.5. ^{119}Sn{^{1}H} (CD_2Cl_2, 223.867 MHz) δ: -344.23. IR (nujol mull) ν: 1610 (m), 1584 (m), 1412 (s), 1262 (m), 1246 (s), 1088 (w), 1072 (m), 1031 (br), 844 (vs), 798 (w), 787 (w), 752 (m), 739 (w), 649 (m). [$(Me_3Si)_2NGe(OC_6H_3Mes_2)$] (9)

Under an inert atmosphere, a solution of $Ge[N(SiMe_3)_2]_2$ (0.57 g, 1.45 mmol) in 2 mL CH_2Cl_2 was added dropwise to a solution of 2,6-bis(2,4,6-trimethylphenyl)phenol **1** (0.48 g, 1.45 mmol) in 5 mL anhyd. CH_2Cl_2. After 5 min, the solvent was removed under vacuum, and the crude product was recrystallized from benzene. Mp = 84–86 °C. ^{1}H NMR (C_6D_6, 499.768 MHz) δ: 7.62 (t, J = 7.5 Hz, 1H), 7.22 (d, J = 7.5 Hz, 2H), 7.03 (s, 4H), 2.42 (s, 6H), 2.18 (s, 12H), 0.00 (s, 18H). (This molecule was not isolated as an analytically pure compound).

[$Ge(OC_6H_3Mes_2)_2$] (10)

Under an inert atmosphere, a solution of $Ge[N(SiMe_3)_2]_2$ (0.24 g, 0.61 mmol) in 2 mL hexanes was added dropwise to a suspension of 2,6-bis(2,4,6-trimethylphenyl)phenol **1** (0.20 g, 0.61 mmol) in 5 mL anhyd. hexanes. After 45 min, the solvent was decanted from a white precipitate. Yield = 0.16 g (72%); mp = 318–319 °C. ^{1}H NMR (CD_2Cl_2, 499.767 MHz) δ: 6.81–6.88 (m, 3H), 6.75 (s, 4H), 2.29 (s, 6H), 1.79 (s, 12H). ^{13}C NMR (CD_2Cl_2, 125.678 MHz) δ: 138.1, 136.2, 129.5, 129.2, 128.8, 128.5, 119.2, 21.0, 20.1. IR (nujol mull) ν: 1610 (w), 1585 (w), 1484 (m), 1414 (s), 1260 (s), 1230 (vs), 1091 (m), 1071 (s), 1016 (m), 948 (w), 845 (vs), 799 (m), 754 (s), 739 (w), 728 (w), 670 (m), 659 (s), 609 (m). [$(Me_2N)_2Ti(OC_6H_3Mes_2)_2$] (11)

Under an inert atmosphere, a solution of $Ti(NMe_2)_4$ (0.26 g, 1.15 mmol) in 5 mL anhyd. CH_2Cl_2 was added dropwise to a solution of 2,6-bis(2,4,6-trimethylphenyl)phenol **1** (0.76 g, 2.30 mmol) in 10 mL anhyd. CH_2Cl_2. The solution was allowed to stir for 10 min at RT and then cooled to –30 °C. After 3 h, the solution was decanted from orange crystals. Yield = 0.59 g (64%); mp 180 °C (dec.). ^{1}H NMR (C_6D_6, 400.137 MHz) δ: 6.82–6.87 (m, 7H), 2.30 (s, 6H), 2.24 (s, 6H), 2.11 (s, 12H). ^{13}C NMR (C_6D_6, 100.624 MHz) δ: 160.2, 137.3, 136.7, 135.6, 131.1, 130.5, 128.3, 120.2, 43.8, 21.0, 20.9. IR (nujol mull) ν: 3279 (m), 1611 (m), 1580 (m), 1484 (m), 1413 (vs), 1345 (m), 1251 (vs), 1229 (vs), 1146 (m), 1083 (s), 1054 (m), 1029 (m), 1008 (m), 950 (s), 904 (m), 876 (vs), 849 (vs), 799 (m), 778 (m), 757 (vs), 741 (w), 691 (vs), 679 (s), 597 (s). Anal. calcd. for $C_{52}H_{62}N_2O_2Ti$: C, 78.57; H, 7.86; N, 3.52. Found: C, 78.20; H, 7.83; N, 3.37.

Crystallographic studies[2]

The crystal was mounted on a glass fibre (**1**, **10**) or on the top of the nylon fibre of a CryoLoop™ (diameter of the nylon fibre: 10 microns (1 micron = 1 μm); loop diameter = 0.2–0.3 mm; Hampton Research, USA) (**5**–**8**, **11**). Data were collected at the temperature indicated in Table 1 on a Nonius Kappa-CCD diffractometer using monochromated Mo Kα radiation (λ = 0.71073 Å) with COLLECT (40). The unit-cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using DENZO (41). The data were scaled using SCALEPACK (41). The structures were solved by direct methods using SHELXTL-NT V6.1 suite of programs (42) (**1**, **6**, **8**, **10**) or SIR-97 (43) (**5**, **7**, **11**). All of the non-

hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen-atom positions were calculated geometrically and were included as riding on their respective heavy atoms. All figures were generated using X-SEED (44).

Due to the poor quality of the crystals for compound **5**, the quality of the data is rather low (parameter-to-reflection ratio is 1:6), and the bond distances and angles for the disordered BO_2 part and for the hydrogen bonding are not precise (rotational disorder of the oxygen atoms around the C–B bond). However, we believe that the molecular structure of **5** is correct. The Friedel pairs were averaged during the refinement, since this structure does not contain elements heavier than Si.

The crystal structure of compound **7** contains a severely disordered CH_2Cl_2 solvent molecule per asymmetric unit. Attempts to refine, applying a split-atom model, were unsuccessful. The data were corrected for the disordered electron density using the SQUEEZE (45) procedure as implemented in PLATON (46). A total solvent-accessible void volume of 539.5 $Å^3$ (11% of the unit-cell volume). Its contribution to the structure factors was ascertained using PLATON/SQUEEZE (35 e/unit cell). Derived values (formula weight, density, absorption coefficient) do not contain the contribution of the disordered solvent molecule

A convenient and efficient protocol for the synthesis of symmetrical *N,N′*-alkylidine bisamides by sulfamic acid under solvent-free conditions

Nagarajan Panneer Selvam, Sundar Saranya, and Paramasivan T. Perumal

Abstract: A simple and convenient approach to the synthesis of symmetrical *N,N′*-alkylidine bisamides is described. Aromatic and aliphatic nitriles react with aromatic aldehydes in the presence of sulfamic acid to give the corresponding bisamides in moderate yields.

Key words: alkylidine bisamides, nitrile, sulfamic acid.

Résumé : On a mis au point une méthode simple et pratique de réaliser la synthèse de *N,N′*-alkylidinebisamides symétriques. Les nitriles aliphatiques et aromatiques réagissent avec les aldéhydes aromatiques, en présence d'acide sulfamique, pour conduire à la formation des bisamides correspondants avec des rendements modérés.

Mots-clés : alkylidinebisamides, nitrile, acide sulfamique.

[Traduit par la Rédaction]

Introduction

The amidation of organic compounds using nitriles is a very useful tool in organic chemistry, as amide moieties are important constituents of many biologically significant compounds. In the last years, retro-amide links have successfully been incorporated in the synthesis of retro-inverso peptide analogues, such as enkephalinamide (1), substance P (2), somatosatin (3), or gastrin (4). Residues with retro-amide links are also the basic units of some aliphatic polyamides (nylons) (5), which are closely related to fibrous proteins. Specifically, bisamides are key fragments for the introduction of gem-iminoalkyl residues in retro-inverso pseudo peptide derivatives (6) by treating the corresponding amide with iodobenzene bistrifluoroacetate (7). In this regard, bisamides are of considerable interest in the synthesis of peptidomimetic compounds (5).

Result and discussion

Magat et al. (8) reported the synthesis of bisamides using sulfuric acid in good yields. However, this method suffers from few disadvantages, such as the use of 85% sulphuric acid (solvent) and the scope of the reaction was limited to few aldehydes only. Hence, the development of highly expedient protocol with wide applicability is necessary for their syntheses.

The increasing demands of environmental legislation have been prompting the chemical industry to minimize or preferably eliminate waste production in chemical manufacture (9). During the last few years, sulfamic acid has emerged as a substitute for conventional acidic catalysts. Sulfamic acid has been used as an efficient heterogeneous catalyst for acid-catalyzed reactions (10), Biginelli condensation (11), Beckmann rearrangement (12), inter- and intra-molecular imino Diels–Alder reactions (13), and Pechmann condensations (14). The distinctive catalytic features and intrinsic Zwitter ionic property of sulfamic acid are very different from conventional acidic catalysts. This has encouraged us to investigate further the application of sulfamic acid in carbon–carbon and carbon–hetero atom bond-forming reactions.

Recently, we reported the synthesis of acetamidophenols (15) from aldehydes, β-naphthols and acetonitrile via modified Ritter-type protocol catalyzed by anhyd. ceric sulphate. Encouraged by these results, we also extented the protocol by replacing β-naphthols with activated substituted benzenes, like anisole, toluene, and so forth. Interestingly, we observed that anisole or toluene was not involved in the reaction, while the aldehyde reacted with acetonitrile in the presence of anhyd. ceric sulfate, yielding symmetrical bisacetamides as the major product (Scheme 1).

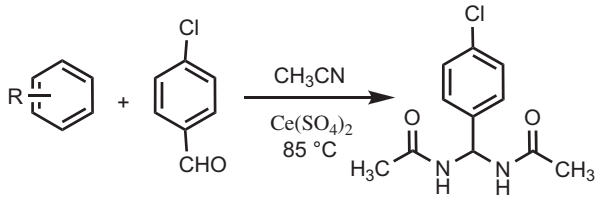
However, this methodology suffers from few limitations; the reaction was not complete even after refluxing for 24 h, and it requires stoichiometric amount of catalyst. Hence, to overcome these limitations, we focused on an efficient and eco-benign protocol for the synthesis of bisamides.

In the present study, we report a highly efficient method for the synthesis of biologically valuable bisamides from aromatic aldehydes with a series of nitriles using sulfamic acid in moderate yields (Scheme 2).

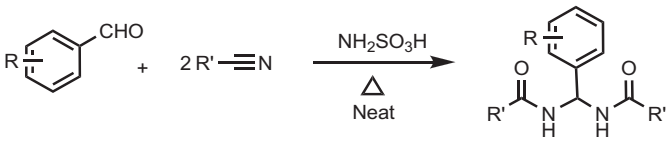
Initially, we carried out the reaction of 4-nitrobenzaldehyde in acetonitrile using various catalysts for the synthesis of bisacetamides (Scheme 3). After systematic screening

 doi:10.1139/V07-134 © 2007 NRC Canada

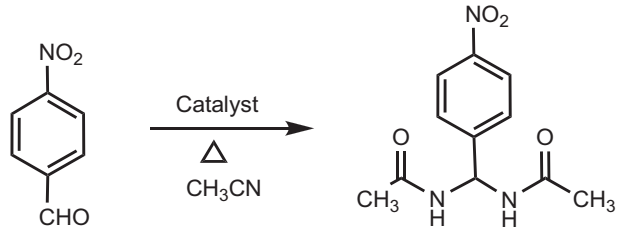
Scheme 1.



Scheme 2.



Scheme 3.



(Table 1), sulfamic acid was found to be the catalyst of choice. Similarly, the mole ratio of sulfamic acid was studied and found 50 mol% of sulfamic acid to be optimum.

We extended our protocol with various substituted aromatic nitriles. In the course of our study, we investigated the reaction of 3-nitrobenzaldehyde and 2-chlorobenzonitrile with sulfamic acid using various solvents for the synthesis of bisamides (Scheme 4), and found that solvent-free condition was the best for the conversion. The results are listed in Table 2.

The reaction was carried out with aldehyde (10 mmol) and nitrile (22 mmol) in the presence of sulfamic acid (50 mol%) and heated at 125 °C under solvent-free condition. This protocol is remarkably simple and requires non-hazardous reagents or inert atmosphere.

A mechanistic rationale portraying the probable sequence of events is given in Scheme 5. The substrate scope of the reaction under the optimized condition was investigated, and the results are summarized in Table 3. The reaction was amenable to wide variations in nitriles. The reaction went smoothly with aromatic aldehydes containing electron-withdrawing groups, while no product formation was seen with electron-rich aldehydes and aliphatic aldehydes. However, in the case of terephthalaldehyde, mono bis-amide was formed, wherein only one aldehydic group was involved in the reaction with nitrile (Table 3, entry 5).

Conclusion

Clearly, the results show that the sulfamic-acid-catalyzed protocol provides an efficient tool for the synthesis of *N*,*N*′-alkylidine symmetrical bisamides under relatively mild conditions. In conclusion, we have developed a green approach to the synthesis of symmetrical bisamides that requires neither harsh conditions nor hazardous acids. The present protocol offers several advantages, including clean and simple reaction procedure, isolation of products by crystallization without employing purification methods like column chromatography, use of an eco-friendly catalyst, and solvent-free conditions, which make it an attractive method for the synthesis of *N*,*N*′-alkylidine symmetrical bisamides.

Experimental

General

Glassware was dried in a hot-air oven prior to use. 2-(Trifluoromethyl)benzonitrile and benzonitrile were purchased from Lancaster Research Chemicals. All other reagents were purchased from S. D. Fine. Chem. Limited and used as received. Acetonitrile was distilled from CaH_2 under nitrogen and stored over 4 Å molecular sieves. DMSO-d_6 was purchased from Aldrich. IR measurements were done as KBr pellets for solids using PerkinElmer Spectrum RXI FTIR. The ^{1}H and ^{13}C NMR spectra were recorded in DMSO-d_6 with JEOL 500 MHz high-resolution NMR spectrometer. DMSO-d_6 was used as the solvent for the NMR spectral measurements, and the spectra were recorded in ppm with TMS as internal standards. Multiplicities are abbreviated as follows: singlet (s), doublet (d), triplet (t), multiplet (m), and broad (br). Mass spectra were recorded by using an Electrospray Ionization Method with Thermo Fennigan Mass spectrometer. Melting points were determined in capillary tubes and are uncorrected. Analytical TLC was performed on precoated plastic sheets of silica gel G/UV-254 of 0.2 mm thickness (Macherey–Nagel, Germany). Elemental analysis data were recorded using Thermo Finnigan FLASH EA 1112 CHN analyzer. Column Chromatography was carried out using 100–200 mesh silica gel.

Representative procedure for the synthesis of *N*,*N*′-alkylidine bisamides

A mixture of aldehyde (10 mmol), nitrile (22 mmol), and sulfamic acid (5 mmol) was stirred at 125 °C for the appropriate time as mentioned in Table 3. When acetonitrile (taken in excess, 10 mL) was used, the reaction was carried out at 85 °C. After the completion of the reaction (as monitored by TLC), ethanol:water (8:2 mL) was added, and the reaction mixture was refluxed for 20 min and allowed to stay overnight. The solid obtained was filtered and dried.

[a]Isolated yield.

N-[acetylamino-(4-nitrophenyl)methyl]-acetamide (Table 3, entry 1)

Pale brownish yellow solid. Yield: 65%, mp: 270–272 °C (Lit. 272 °C) (16). IR ν_{max}: 3270, 3107, 1672, 1518, 1352, 1194, 1094, 824 cm^{-1}. ^1H NMR (500 MHz, DMSO-d_6) δ: 1.85 (s, 6H), 6.53 (t, 1H, J = 7.65 Hz), 7.54 (d, 2H, J = 8.4 Hz), 8.17 (d, 2H, J = 9.15 Hz), 8.70 (d, 2H, J = 7.5 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 22.94, 57.45, 123.99, 128.28, 147.41, 148.36, 169.53. MS (ESI): 251 (M^+). Anal. calcd. for $C_{11}H_{13}N_3O_4$: C 52.59, H 5.22, N 16.73. Found: C 52.68, H 5.15, N 16.67%.

N-[acetylamino-(4-chlorophenyl)methyl]-acetamide (Table 3, entry 2)

White solid. Yield: 60%, mp: 258–260 °C (Lit. 260–261 °C) (17). IR ν_{max} KBr: 3271, 3123, 1670, 1093, 1529, 1370 cm^{-1}. ^1H NMR (500 MHz, DMSO-d_6) δ: 1.83 (s, 6H), 6.42 (t, 1H, J = 8.05 Hz), 7.28 (d, 2H, J = 8.6 Hz), 7.37 (d, 2H, J = 8.6 Hz), 8.52 (d, 2H, J = 8.05 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 22.96, 57.33, 128.73, 128.80, 132.66, 139.87, 169.35. LR-MS (EI^+): 240 (M^+). Anal. calcd. for $C_{11}H_{13}N_2O_2Cl$: C 54.89, H 5.44, N 11.64. Found: C 54.86; H 5.42; N,11.62%.

N-[acetylamino-(3-nitrophenyl)methyl]-acetamide (Table 3, entry 3)

White solid. Yield: 68%, mp: 256–257 °C (Lit 256–257 °C) (18). IR ν_{max}: 3275, 3118, 2369, 1665, 1561, 1529, 1350, 1272, 1095, 764 cm^{-1}. ^1H NMR (500 MHz, DMSO-d_6) δ: 1.86 (s, 6H), 6.53 (t, 1H, J = 7.45Hz), 7.62 (t, 1H, J = 8.05Hz), 7.74 (d, 1H, J = 7.45Hz), 8.14 (s, 2H, br), 8.71 (d, 2H, J = 7.45Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 98, 57.45, 121.47, 123.16, 130.50, 133.99, 143.22, 148.31, 169.49. MS (ESI): 251(M^+). Anal. calcd. for $C_{11}H_{13}N_3O_4$: C 52.59, H 5.22, N 16.73. Found: C 52.65, H 5.18, N 16.68%.

N-[acetylamino-(2-nitrophenyl)methyl]-acetamide (Table 3, entry 4)

Reddish brown solid. Yield: 60%, mp: 231–232 °C (Lit. 231–232 °C) (19). IR ν_{max}: 3273, 1668, 1526, 1359, 1097, 776 cm^{-1}. ^1H NMR (500 MHz, DMSO-d_6) δ: 1.79 (s, 6H), 6.82 (t, 1H, J = 7.65 Hz), 7.69 (t, 3H, J = 6.9 Hz), 7.88 (d, 1H, J = 8.4 Hz), 8.62 (d, 2H, J = 7.65 Hz, D_2O exchangeable).^{13}C NMR (125 MHz, DMSO-d_6) δ: 22.74, 54.83, 124.80, 128.92, 129.69, 133.60, 134.61, 148.81, 169.29. MS (ESI): 251 (M^+). Anal. calcd. for $C_{11}H_{13}N_3O_4$: C 52.59, H 5.22, N 16.73. Found: C 52.40, H 5.26, N 16.70%.

N-[(acetylamino)(4-formylphenyl)methyl]acetamide (Table 3, entry 5)

Off white solid. Yield: 40%, mp: 258–260 °C. IR ν_{max}: 3261, 3116, 1665, 1560, 1373, 1094, 802 cm^{-1}. ^1H NMR

Interactions among $^{18}O_2$, C_2H_4, and NO on the surface of stepped Pt(332)

Yuhai Hu and Keith Griffiths

Abstract: The influence of co-adsorbed $^{18}O_2$ (^{18}O) on NO/C_2H_4 reactions on the surface of stepped Pt(332) has been investigated using Fourier transform infrared reflection–absorption spectroscopy (FTIR-RAS) and thermal desorption spectroscopy (TDS). The presence of $^{18}O_2$ (^{18}O) results in changes in C_2H_4 dissociation behavior, with formation of ethylidyne taking place at surface temperature much higher than that in the absence of $^{18}O_2$ (^{18}O). Pre-annealing $^{18}O_2/C_2H_4$ co-adlayers to 250 and 300 K does not lead to significantly different IR spectra, but a variety of spectra are observed when the 250 K and 300 K $^{18}O/C_2H_4$ co-adlayers are further exposed to 0.8 L NO at 90 K, depending on the $^{18}O_2$ pre-exposure. NO adsorption in bridge sites, both on steps and on terraces is more significantly suppressed for the co-adlayers in which $^{18}O_2/C_2H_4$ is pre-annealed to 250 K. This site-blocking effect is enhanced with increasing $^{18}O_2$ exposure. However, no new surface species, which are intermediates for N_2 production, are detected. Thermal desorption spectra indicate that various species are produced, but only N_2 and H_2 desorption have intensities that can be reliably analyzed (that is to be able to quantitatively elucidate how the yields of these two species vary with change in the ratios of NO to C_2H_4 and $^{18}O_2$). Desorption of both N_2 and H_2 is more strongly dependent on $^{18}O_2$ exposure than on the temperature to which $^{18}O_2/C_2H_4$ adlayers are pre-annealed. The presence of $^{18}O_2$, irrespective of the dosing sequence, suppresses N_2 desorption, but this effect is much weaker when $^{18}O_2$ is post-dosed. For the case with $^{18}O_2$ pre-dosed, irrespective of the annealing temperature (250 K or 300 K), N_2 desorption is greatly suppressed at an $^{18}O_2$ exposure of 0.2 L, but thereafter remains almost unchanged with increasing $^{18}O_2$ exposure from 0.4 to 1.6 L. This feature of N_2 desorption is explained by the restoration of the adsorption of NO onto steps and the subsequent NO dissociation on these sites. In contrast, H_2 desorption decreases continuously and disappears at 0.8 L $^{18}O_2$ and higher. It is concluded that the presence of $^{18}O_2$ in the reaction of NO with C_2H_4 on the surface of Pt(332) does not play any role of activating the surface reactants.

Key words: NO, platinum, C_2H_4, deNO*x*, hydrocarbon, selective catalytic reduction.

Résumé : Faisant appel à la spectroscopie de réflexion–absorption infrarouge en transformée de Fourier et à la spectroscopie de désorption thermique, on a étudié l'influence des entités coadsorbées $^{18}O_2$ (^{18}O) sur les réactions du NO et du C_2H_4 sur la surface de Pt(332) en escalier. La présence de $^{18}O_2$ (^{18}O) provoque des changements dans le comportement dissociatif du C_2H_4 avec une formation d'éthylidyne qui se fait sur la surface à une température beaucoup plus élevée qu'en l'absence de $^{18}O_2$ (^{18}O). À des températures allant de 250 et 300 K, la préannellation de couches coadsorbées de $^{18}O/C_2H_4$ ne conduit pas à des spectres IR qui présenteraient des différences significatives, mais dépendant de la nature de la préexposition au $^{18}O_2$, on observe une variété de spectres lorsque les couches de $^{18}O/C_2H_4$ qui ont été coadsorbées à des températures allant de 250 et 300 K sont exposées à 0,8 L de NO à 90 K. L'adsorption du NO sur les sites pontés, tant sur les marches que sur les terrasses est beaucoup plus supprimé pour les couches coadsorbées dans lesquelles la préannellation du $^{18}O/C_2H_4$ a été faite à 250 K. Cet effet de blocage de site est rehaussé avec une augmentation de l'exposition au $^{18}O_2$. Toutefois, on n'a pas détecté de nouvelles espèces à la surface qui pourraient conduire à la production de N_2. Les spectres de désorption thermiques indiquent qu'il y a production de diverses espèces, mais que seules les désorptions du N_2 et du H_2 présentent des intensités qui peuvent être analysées avec une exactitude suffisante pour être capable d'élucider comment les rendements de ces deux espèces varie avec un changement dans les rapports de NO / C_2H_4 et $^{18}O_2$. Les désorptions du N_2 et du H_2 dépendent toutes les deux beaucoup plus sur l'exposition au $^{18}O_2$ que sur la température à laquelle la préannellation des couches coadsorbées du $^{18}O/C_2H_4$ a été faite. Quelle que soit la séquence de dosage, la présence de $^{18}O_2$ supprime la désorption du N_2, mais cet effet est beaucoup faible lorsque le ^{18}O est post-dosé. Dans le cas du $^{18}O_2$ prédosé, quelle que soit la température d'annellation (250 K ou 300 K), la désorption du N_2 est fortement supprimée à une exposition de 0,2 L de $^{18}O_2$, mais par la suite elle demeure pratiquement constante avec un changement d'exposition au $^{18}O_2$ allant de 0,4 à 1,6 L. Cette caractéristique de la désorption du N_2 s'explique par une restauration de l'adsorption du NO sur les marches et une subséquente dissociation du NO sur ces sites. Par opposition, la désorption du H_2 augmente continuellement et elle

Introduction

The contribution of oxygen to the selective catalytic reduction (SCR) of NO in the presence of organic compounds is widely acknowledged. Oxygen is indispensable for the reaction to proceed effectively (1–4). Several mechanisms have been proposed to explain the role of oxygen in this kind of reactions (1). So far, more and more data from studies under ambient conditions support a mechanism of activation of one of the reactants (NO or organic compound) followed by scavenging polymeric carbonaceous deposits on the surface of working catalysts (1, 5, 6). Nonetheless, a consensus has not yet been reached.

Investigation of NO reduction in the presence of CO, NH_3, and H_2 has been extensively performed under ultra high vacuum (UHV) conditions (7, 8), providing insightful information on these reactions. However, few studies have dealt with the reactions with organic compounds in the same way (9–12). Therefore, we have attempted to address this problem by studying NO reactions with a series of organic compounds including C_2H_4, CH_3OH, and C_6H_6 on the surface of stepped Pt(332) (13–15). Very recently, we have extended our study to exploring the role of oxygen in the SCR of NO in the presence of C_2H_4, with special attention paid to understanding whether NO is activated (e.g., oxidized to higher-valence NO*x*) (16). In this paper, our effort concentrates on defining whether C_2H_4 reacts with O_2 (O) to produce new surface species that promote NO reduction; in other words, whether C_2H_4 is activated.

For this purpose, we annealed Pt(332), exposed at 90 K to various amounts of $^{18}O_2$ (pre-dosed) and a fixed amount of C_2H_4, to 250 and 300 K, producing a variety of co-adlayers with different carbon-containing species depending on the annealing temperatures and $^{18}O_2$ exposure. The resultant co-adlayers were then exposed to a fixed amount of NO at 90 K, and were interrogated using IR and TDS. It is found that the presence of oxygen does not apparently activate C_2H_4 to new surface species that promotes NO reduction.

Experimental

All the experiments were carried out in a standard UHV system described elsewhere (17, 18). Briefly, a stainless steel UHV chamber is pumped by a turbo-molecular pump, which is in turn backed by an oil diffusion pump. A base pressure of 1×10^{-10} Torr (1 Torr = 133 Pa) is routinely attained. The chamber is fitted with potassium chloride windows for grazing incidence surface IR spectroscopy.

The Pt(332) crystal was cleaned by repeated cycles of Ar^+ ion bombardment and oxidation. The final cleanliness was judged by the CO infrared spectrum, which is sensitive to the cleanliness and the state of perfection of the surface (19, 20). IR spectra were obtained in a single-reflection geometry at 7° grazing incidence using a Digilab FTS 7000 spectrometer. 1000 scans, which takes less than 2 min, were co-added at a resolution of 8 cm^{-1}. A narrow band mercury cadmium telluride (MCT) detector was used throughout, with a cut-off around 1000 cm^{-1}. Although some IR data is shown extending down to 800 cm^{-1}, the steep spectral function (cut-off) in the frequency region 800–950 cm^{-1} makes the data unreliable below about 950 cm^{-1}.

C_2H_4, $^{18}O_2$, and NO were introduced into the chamber by backfilling. The highly efficient pumping system can restore the background to workable levels quickly. Thermal desorption spectra were recorded by resistively heating the crystal at a rate of 4 K/s.

Results

IR spectra

C_2H_4 dissociation

The Pt(332) surface, exposed to only 0.8 L C_2H_4 at 90 K, was annealed to various target temperatures. IR spectra were recorded after cooling the annealed adlayer down to 90 K and are shown in Fig. 1. No peaks are observed in the spectra at this coverage (exposure) for annealing temperatures ≤200 K because C_2H_4 is adsorbed molecularly with its axis parallel to the surface. When the annealing temperature is increased to 300 K and higher, two peaks appear at ~1124 and ~1341 cm^{-1}, assigned to C–C stretching and CH_3 bend of ethylidyne, respectively, resulting from C_2H_4 dissociation (21). Both peaks disappear at 450 K, indicating that ethylidyne is dissociated completely.

$^{18}O/C_2H_4$ interaction

On Pt surfaces exposed to oxygen only, upon heating these adlayers, desorption competes with dissociation. Desorption becomes the predominant process at higher (close to saturation) oxygen exposure (22, 23). As a result, oxygen (as atoms) might be limiting in the $^{18}O_2/C_2H_4$ co-adlayers even when the surface is saturated with $^{18}O_2$. This could lead to a misinterpretation of the interaction between $^{18}O_2/C_2H_4$ in the adlayer. Bearing this in mind, we recorded IR spectra of $^{18}O_2$(saturation)/C_2H_4 and 18O(saturation)/C_2H_4 co-adlayers following the same annealing-temperature program. The spectral changes do not differ significantly between the two protocols. Therefore, only the interactions in the ^{18}O(saturation)/C_2H_4 co-adlayers are discussed in this paper.

The saturated layer of ^{18}O is prepared through three cycles of exposing Pt(332) at 90 K to 3 L $^{18}O_2$ and subsequent annealing to 200 K. The final ^{18}O adlayer was exposed at 90 K to 0.8 L C_2H_4 and was annealed to various target temperatures. IR spectra were recorded after cooling the annealed co-adlayers down to 90 K and are shown in Fig. 2. No peaks are detected in the spectra when the annealing temperatures are ≤250 K. At 300 K and higher, four peaks at

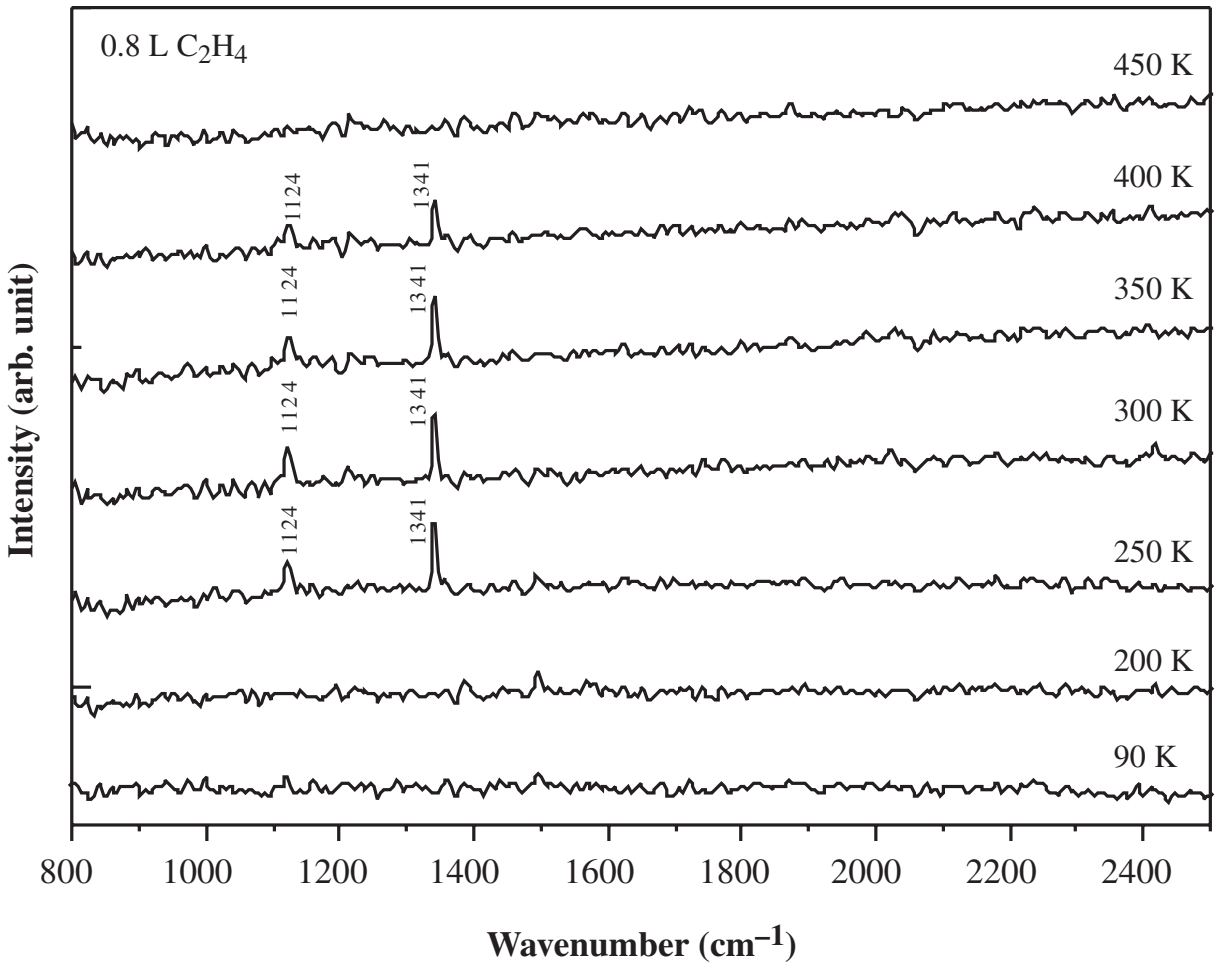
Fig. 1. IR spectra of 0.8 L of C_2H_4 adsorbed on Pt(332) following an anneal to various temperatures. C_2H_4 was exposed at 90 K. Spectra were recorded after cooling the annealed adlayer down to 90 K.



~1124, ~1342, 2000–2003, and ~2048 cm^{-1} are clearly observed. The first two peaks increased slightly with increasing the annealing temperature; the latter two gaining intensity steadily. Considering the fact that both ethylidyne from C_2H_4 dissociation and formate (formic acid) from C_2H_4 oxidation give rise to a vibrational peak at about 1340 cm^{-1}(21, 24), we repeated the experimental procedure by using $^{16}O_2$. The vibrational frequency of this peak (1340 cm^{-1}) does not vary from that in the presence of $^{18}O_2$, excluding the contribution of formate (formic acid). As such, this peak and the one at ~1124 cm^{-1} can both be attributed to the vibrations of ethylidyne, as assigned earlier. However, by comparing these results with those in Fig. 1, it is interesting that the temperature at which ethylidyne is formed in the presence of ^{18}O (300 K) is evidently higher than that in the absence of ^{18}O (250 K). This means that the process of C_2H_4 dissociation is changed in the presence of ^{18}O. Interaction of C_2H_4 with O on the surface of Pt(111) has been investigated in detail previously (25–28). It is generally agreed that C_2H_4 decomposes first via H_2 and H_2O desorption, followed by complete combustion of the remnants to CO_2 and more H_2O. However, so far, debate on the formation of ethylidyne and its contribution to the oxidation mechanism still exists. Our current results support suggestions of the formation of ethylidyne and will be discussed in more detail in another paper.

The peaks at 2000–2003 and ~2048 cm^{-1} most likely correspond to characteristic vibrations of $C^{18}O$ and $C^{16}O$ either from background exposure or from surface reaction. The experimental approach for distinguishing these two possibilities has been described in detail in another paper (29). In brief, when annealing ^{18}O(saturation)/C_2H_4 co-adlayer prepared at 90 K *directly* to 350 K (or 400 K), the peak at ~2048 cm^{-1} was not detected. This procedure vastly decreases the time that the crystal spends in ambient vacuum. The peak at 2000–2003 cm^{-1} is much less intense than that shown in Fig. 2. Consequently, we conclude that $C^{16}O$ and most of the $C^{18}O$ are from background exposure during long experiments, and only a very small amount of $C^{18}O$ is produced from the reaction. We estimate the total CO coverage to be 5% of saturation coverage of CO on the same surface (this amount of $C^{18}O$ can not be detected by TDS).

$^{18}O_2$/C_2H_4/NO interaction

The Pt(332), exposed at 90 K to various amounts of $^{18}O_2$ (pre-dosed) and 0.4 L C_2H_4, was annealed to, and held for 10 s at 250 K. The resultant co-adlayers were further exposed to 0.8 L NO at 90 K. IR spectra were recorded at

Fig. 2. IR spectra of $^{18}O/C_2H_4$ co-adlayer following an anneal to various temperatures. The Pt(332) surface was exposed at 90 K to a saturation of ^{18}O atoms and 0.8 L C_2H_4. Spectra were recorded after cooling the annealed co-adlayer down to 90 K.

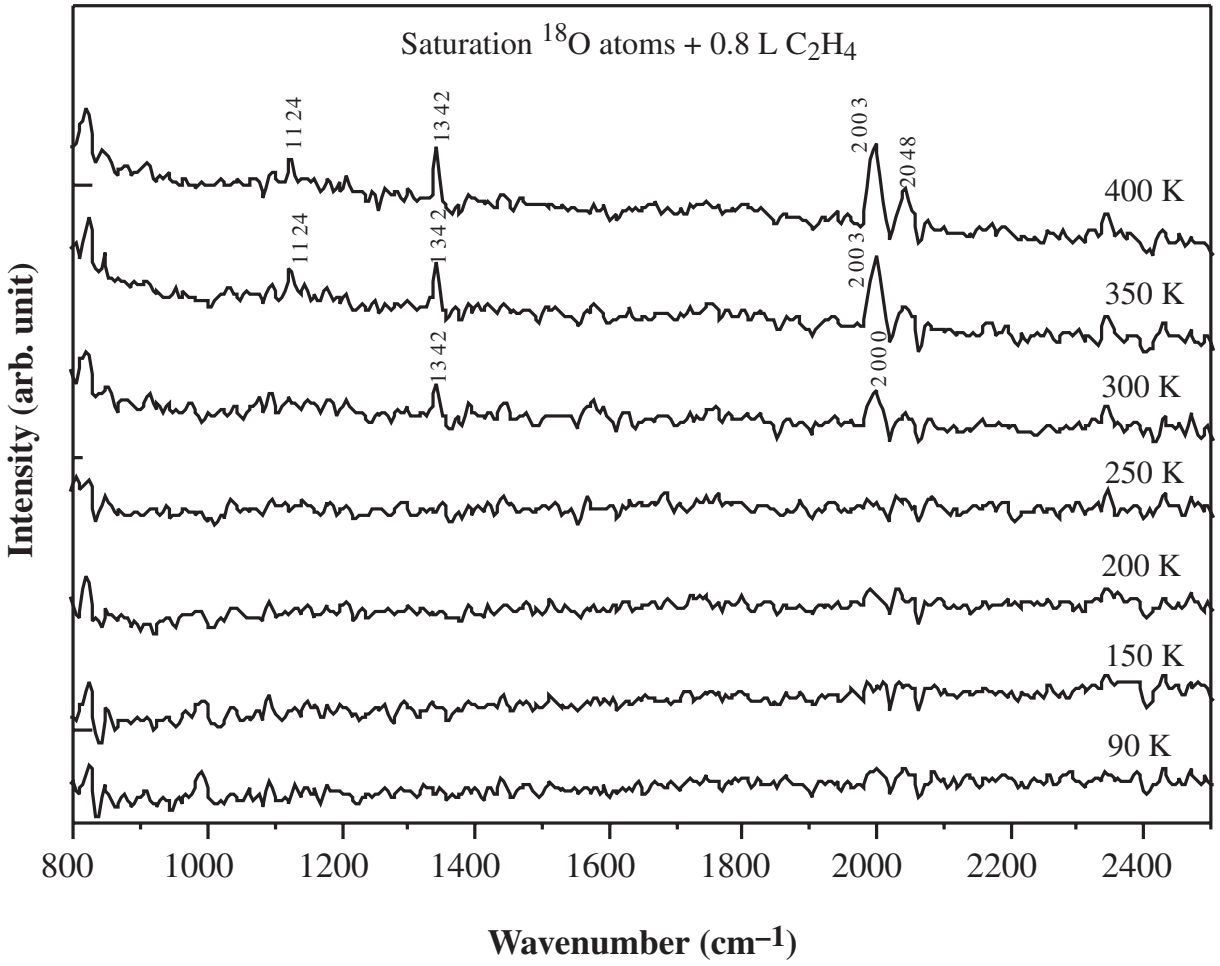

Table 1. Assignments for the infrared peaks observed in $^{18}O_2/C_2H_4/NO$ co-adlayers.

Vibrational frequency (cm^{-1})	Assignments
~1124	C–C stretching of ethylidine
~1340	CH_3 bend
1473–1487	Stretch of NO in bridge site on terrace
~1582	Stretch of NO in bridge site on steps that directly interacting with C_2H_4
1598–1600	Bent NO on steps
1620–1631	Stretch of NO in bridge sites on steps
1686–1723	Stretch of NO in atop sites
1819–1828	Stretch of NO in atop sites on step edge

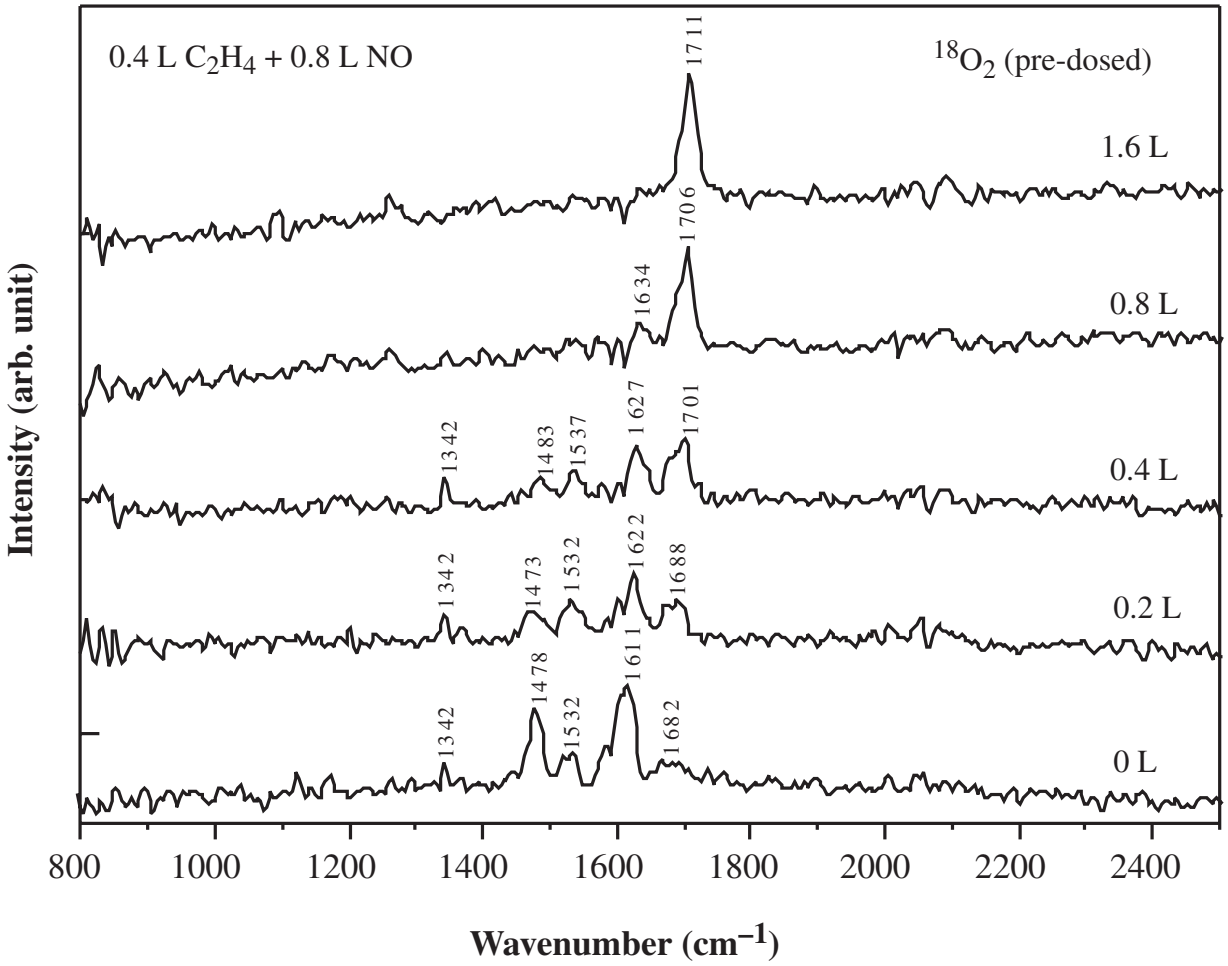
90 K and are shown in Fig. 3. For the C_2H_4/NO coadlayer, i.e., without $^{18}O_2$, several peaks associated with characteristic vibrations of NO molecules adsorbed in different sites are observed, including that in bridge sites on terraces (~1478 cm^{-1}), in bridge sites on steps (~1611 cm^{-1}), and in atop sites (1682 cm^{-1}) (13–15). These assignments are collected in Table 1. The peak at ~1532 cm^{-1} has been attributed to the vibration of NO molecules adsorbed in other defect sites in our previous study (13). The validity of this assignment is to be discussed later.

The presence of pre-dosed $^{18}O_2$ results in significant changes in the spectra. The peaks associated with NO molecules adsorbed in bridge sites both on steps and on terraces are steadily attenuated with increasing $^{18}O_2$ pre-exposure. The peak at 1473–1483 cm^{-1} and 1532–1537 cm^{-1} disappear completely at an $^{18}O_2$ exposure of 0.8 L, the one at 1611–1634 cm^{-1} disappearing completely at 1.6 L $^{18}O_2$. In contrast, the peak associated with NO molecules adsorbed in atop sites (1688–1711 cm^{-1}) increases rapidly with increasing $^{18}O_2$ exposure, dominating in the spectra following $^{18}O_2$ exposures of 0.8 and 1.6 L.

Moreover, increasing the $^{18}O_2$ pre-exposure also leads to noticeable changes in the peak at ~1342 cm^{-1}. This peak is retained for $^{18}O_2$ exposures below 0.8 L, but disappears

© 2007 NRC Canada

Fig. 3. IR spectra of $^{18}O/C_2H_4/NO$ co-adlayers prepared as follows: the Pt(332), exposed at 90 K to various amounts of $^{18}O_2$ (prior to C_2H_4) and 0.4 L C_2H_4, was annealed to 250 K. The resultant co-adlayers were further exposed to 0.8 L NO at 90 K. Spectra were taken at 90 K.



completely for $^{18}O_2$ exposures of 0.8 L and higher. The same change is observed in the IR spectra of co-adladyers with 0.4 L C_2H_4 following the same train of $^{18}O_2$ pre-exposure (spectra not shown here), confirming that the loss of this peak mainly results from interactions of C_2H_4 with $^{18}O_2$ rather than with NO and that the ratios of C_2H_4 to $^{18}O_2$ plays a key role.

Figure 4 shows IR spectra of co-adlayers prepared following the same procedure as that for the co-adlayers in Fig. 3, with the exception that $^{18}O_2/C_2H_4$ co-aldayers are pre-annealed to 300 K before being exposed to NO at 90 K. This temperature program results in spectra that are markedly different from those in Fig. 3. All the peaks associated with adsorbed NO molecules that appear in the $^{18}O_2$-free spectrum (the bottom one in Fig. 4, following exposures of only 0.4 L C_2H_4 and 0.8 L NO) are also observed in the spectra with $^{18}O_2$ exposures from 0.2 to 1.6 L, except that the peak intensities change slightly. This indicates that pre-annealing $^{18}O_2/C_2H_4$ co-adlayers to 300 K only slightly suppresses the adsorption of NO molecules in bridge sites both on steps and on terraces even when $^{18}O_2$ exposure is increased to 1.6 L. As a consequence, it can be deduced that the surface condition of $^{18}O_2/C_2H_4/NO$ co-adlayers in which $^{18}O_2/C_2H_4$ is pre-annealed to 300 K is very different from that following an anneal to 250 K (to be discussed later).

It is also evident that for these co-adlayers, the peak at 1527–1540 cm^{-1} persists throughout $^{18}O_2$ exposures, giving rise to intensities that are comparable to those at 1481–1486 cm^{-1}. This significant intensity has never been observed in the spectra of just NO adlayers (without co-adsorbents) or C_2H_4/NO co-adlayers when the C_2H_4 pre-exposures are less than about 0.16 L (13). Noticing that changes in this peak correspond to changes in the peak at 1473–1483 cm^{-1}, i.e., disappearing completely at 0.8 L O_2 (in Fig. 3), and that this peak is *not* detected in the absence of NO, we also tentatively assign this peak to vibrations of NO molecules adsorbed in bridge sites on terraces that are influenced in some way by C_2H_4-related surface species.

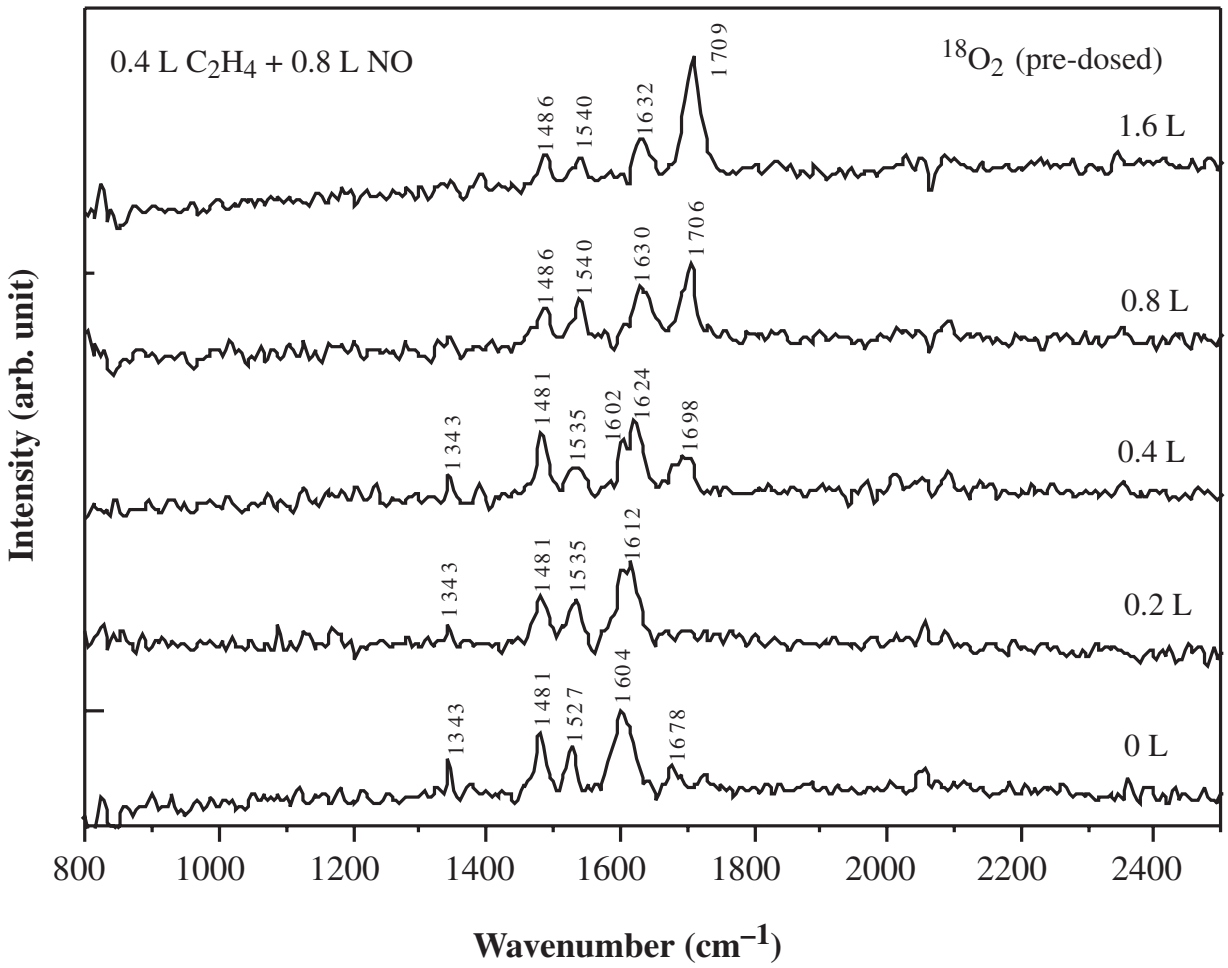
Thermal desorption spectra of N_2 and H_2

A general picture

Thermal desorption spectra indicate that a variety of desorbing species are detected from the surface reactions involving C_2H_4, NO, and $^{18}O_2$, but only desorption of N_2 and H_2 gives rise to intensities that can be reliably analyzed, en-

© 2007 NRC Canada

Fig. 4. IR spectra of $^{18}O/C_2H_4/NO$ co-adlayers prepared as follows: the Pt(332), exposed at 90 K to various amounts of $^{18}O_2$ (prior to C_2H_4) and 0.4 L C_2H_4, was annealed to 300 K. The resultant co-adlayers were further exposed to 0.8 L NO at 90 K. Spectra were taken at 90 K.



abling us to quantitatively elucidate how the yields of these two species vary with change in the ratios of NO to $^{18}O_2$ and C_2H_4. As such, this paper only addresses the desorption of these two species. Moreover, to provide a more detailed profile of the influence of oxygen on C_2H_4/NO interactions, such as coverage and the state (^{18}O and $^{18}O_2$) of oxygen, N_2 and H_2 desorption from co-adlayers in which $^{18}O_2$ is dosed after C_2H_4 and NO are also presented.

Co-adlayer in which $^{18}O_2$ is post-dosed

Thermal desorption spectra of N_2 and H_2 from co-adlayers in which $^{18}O_2$ is dosed "after" C_2H_4 and NO are shown in Fig. 5. The Pt(332) was exposed to 0.4 L C_2H_4 at 250 K. The higher adsorption temperature is used to prevent ethylene multi-layers from forming and so effectively reducing the contribution of C_2H_4 (also mass 28) to the N_2 desorption signal. The resultant C_2H_4 adlayer was further exposed to 0.8 L NO at 90 K (prior to $^{18}O_2$) and various amounts of $^{18}O_2$.

Compared to the N_2 desorption yield following *just* an exposure of 0.8 L NO, N_2 desorption is significantly enhanced in the presence of 0.4 L C_2H_4 (and no oxygen) which is predosed at 250 K. Two peaks appear at ~376 and ~455 K. This feature of N_2 desorption has been discussed previously (13) in detail, being attributed to facile NO dissociation arising from an electron-donation effect exerted by co-adsorbed C_2H_4 molecules. Both desorptions, i.e., at 376–380 K and at 455–460 K, are retained following $^{18}O_2$ exposures of up to at least 1.6 L, though the intensity of the desorption at ~380 K decreases somewhat at higher $^{18}O_2$ exposures.

H_2 desorption also undergoes some changes with varying post-exposures of $^{18}O_2$. For the co-adlayer without $^{18}O_2$, three peaks are observed at ~303, ~410, and ~530 K, corresponding to stepwise dehydrogenation of C_2H_4 (13). At an $^{18}O_2$ exposure of 0.4 L, the peak at ~303 K disappears completely. Simultaneously, the peak at 405–412 K is significantly enhanced, but the peak at 530–538 K remains almost unchanged. At higher $^{18}O_2$ exposures, i.e., 0.8 and 1.6 L, the peaks at 405–412 K and at 530–538 K do not appear to be changed. If we consider both N_2 and H_2 desorption, it is reasonable to suggest that increasing $^{18}O_2$ post-exposure *higher than* 0.4 L does not significantly affect the surface reaction, and the adsorbed $^{18}O_2$ molecules mostly desorb rather than decompose and react with C_2H_4. $^{18}O_2$ desorption from these co-adlayers was monitored. The higher-temperature recombinative desorption beyond 600 K was not

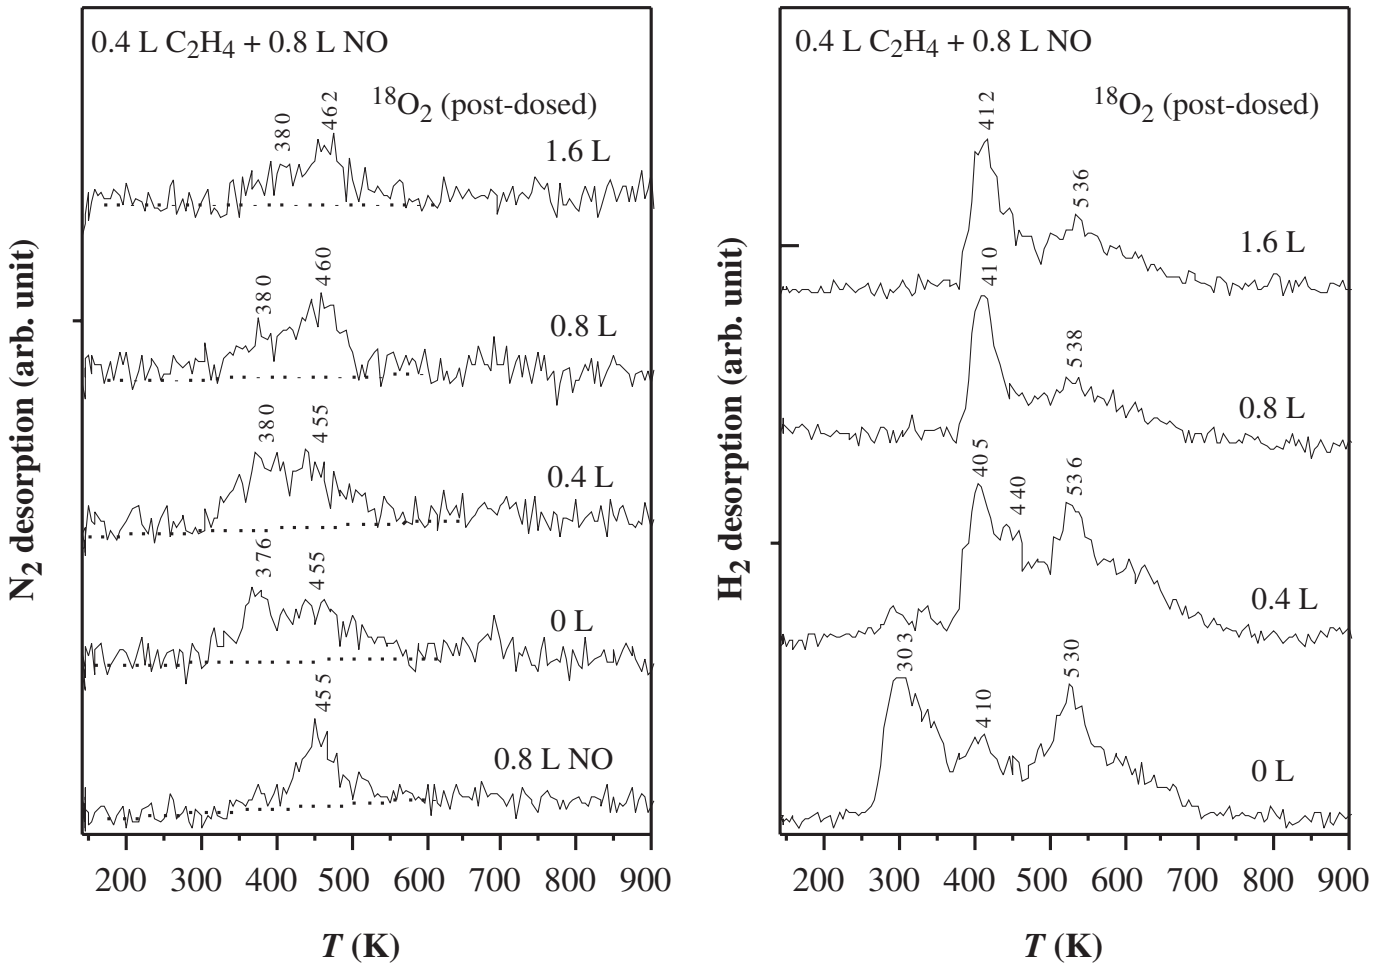
Fig. 5. Thermal desorption spectra of N_2 and H_2 from C_2H_4/NO/$^{18}O_2$ co-adlayers prepared as follows: the Pt(332) was exposed to 0.4 L C_2H_4 at 250 K. The resultant adlayer was further exposed to 0.8 L NO at 90 K (prior to $^{18}O_2$) and various amounts of $^{18}O_2$.



detected in these co-adlayers, but the lower-temperature molecular desoprtion, below 200 K, increases significantly with increasing the exposure from 0.4 to 1.6 L. (These spectra are not shown here for brevity).

Co-adlayers in which $^{18}O_2/C_2H_4$ is pre-annealed to 250 and 300 K

Figure 6 shows thermal desorption spectra of N_2 and H_2 from the surface in which $^{18}O_2/C_2H_4$ adlayers are pre-annealed to, and held for 10 s at 250 K before being exposed to NO at 90 K. In the absence of $^{18}O_2$, N_2 desorption gives rise to a primary peak at ~386 K, on the high-temperature side of which, a shoulder appears at ~455 K, as shown in the bottom spectrum in Fig. 6A. The lower-temperature desorption feature at ~386 K decreases rapidly following $^{18}O_2$ exposure and disappears completely at $^{18}O_2$ exposures of 0.4 L and higher. In contrast, the higher-temperature desorption at 455–462 K does not appear to change much.

Compared with N_2 desorption, H_2 desorption from the same co-adlayers is much more strongly related to $^{18}O_2$ exposure, undergoing dramatic changes both in peak shape and in peak intensity with increasing ^{18}O exposure, as shown in Fig. 6B. The peak at ~308 K, observed in the spectrum without $^{18}O_2$, disappears completely at an $^{18}O_2$ exposure of 0.2 L, at which the peak at ~412 K is significantly enhanced. H_2 desorption is further suppressed at an $^{18}O_2$ exposure of 0.4 L and disappears completely at 0.8 L and higher, suggesting that H_2 has been fully consumed by reaction with oxygen. However, it should be noted that almost no water was detected from these co-adlayers. This is a disappointing but explicable experimental artifact of our vacuum system (13). The vacuum system contains many surfaces, which are held at liquid-nitrogen temperature, providing an almost infinite pumping speed for water. Unfortunately, the geometry of the chamber cannot be reconfigured at this time for several reasons. It is worth noting that Friend et al. also reported difficulty in detecting water from methanol/NO_2 reaction (30).

Thermal desorption spectra of N_2 and H_2 from the co-adlayers in which $^{18}O_2/C_2H_4$ is pre-annealed to, and held for 10 s at 300 K are shown in Fig. 7. The development of N_2 desorption with varying $^{18}O_2$ pre-exposure is consistent with that for the co-adlayers in which $^{18}O_2/C_2H_4$ is pre-annealed to 250 K, as shown in Fig. 7A. To get further insight into the mechanism for N_2 production from the $^{18}O_2/C_2H_4$/NO co-adlayers, we quantified the relative N_2 desorption from the co-adlayers shown in Figs. 5, 6, and 7. The peak areas are collected in Table 2. It is evident that more N_2 is produced

from the co-adlayers with $^{18}O_2$ post-dosed. For the case with O_2 *pre-dosed*, the desorption is almost equal at both annealing temperatures for $^{18}O_2$ exposures greater than 0.2 L. The slight difference at lower $^{18}O_2$ exposures is mainly due to the change in the amount of active C_2H_4-related species resulting from the change in surface temperature, as discussed previously (13). Consequently, it seems reasonable to suggest that even though the surface condition changes with varying the annealing temperature for $^{18}O_2/C_2H_4$ co-adlayers, N_2 production does not appear to be greatly affected.

Unlike N_2 desorption, changes in H_2 desorption induced by increasing the annealing temperature from 250 to 300 K are more evident, as shown by a comparison of the bottom spectrum in each of Figs. 6B and 7B. For these spectra (without $^{18}O_2$), the peak at ~338 K is significantly suppressed, and the spectrum is dominated by two peaks at ~414 and ~526 K. Increasing $^{18}O_2$ exposure quickly reduces H_2 desorption, which completely disappears at $^{18}O_2$ exposure of 0.8 L. This result indicates that increasing the annealing temperature leads to more H reacting with ^{18}O.

Discussion

N_2 and H_2 desorption arising from the reaction of NO with $^{18}O_2/C_2H_4$ co-adlayers that are pre-annealed to 250 and 300 K, combined with IR data, provides very insightful information on the role of oxygen in SCR of NO with hydrocarbons. Figures 1–4 unambiguously confirm that the

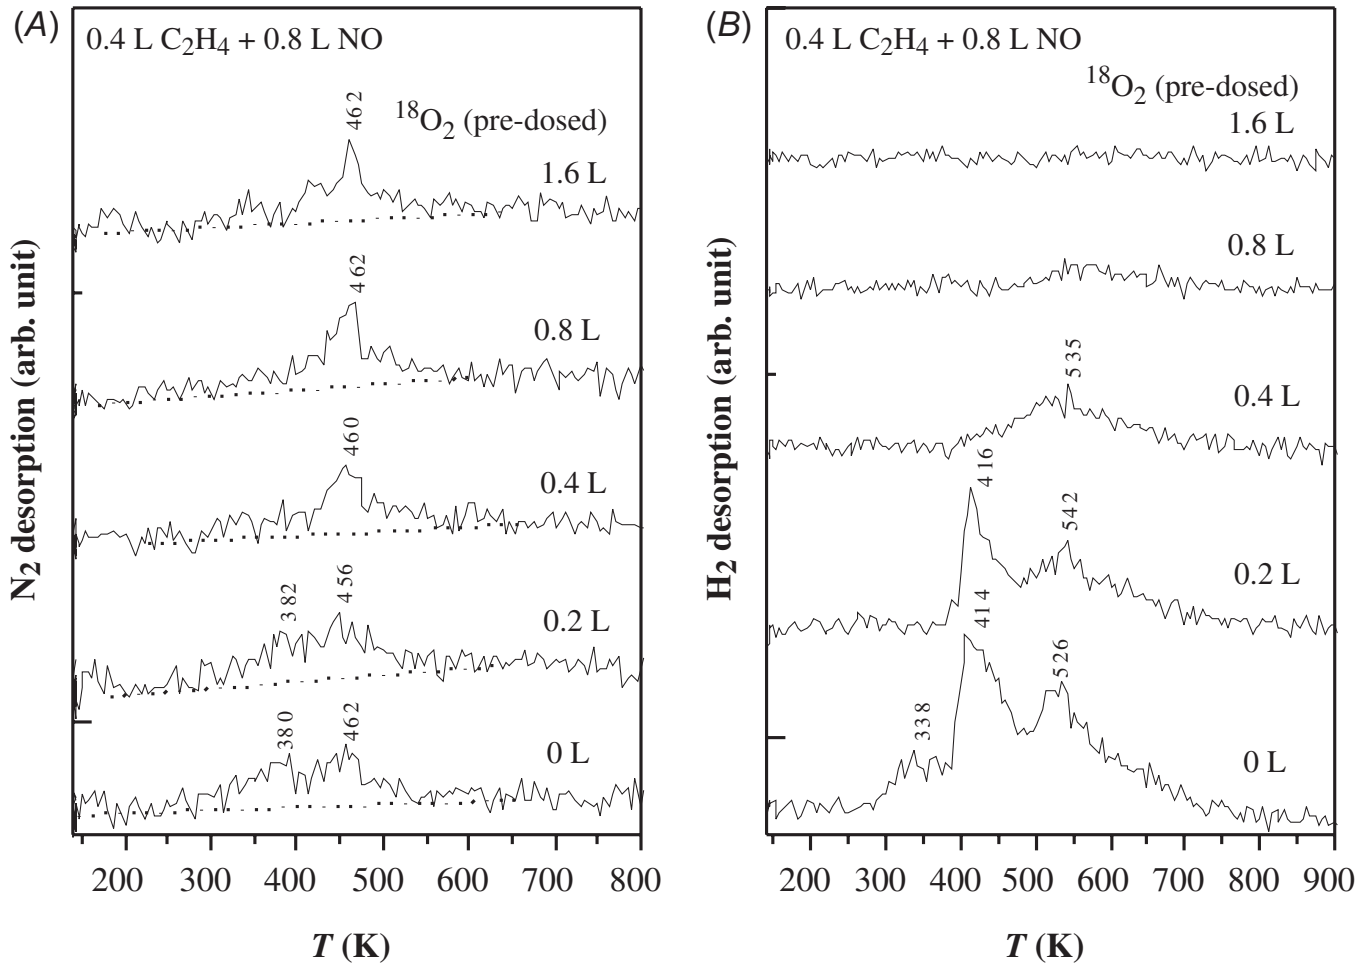
Fig. 7. Thermal desorption spectra of N_2 and H_2 from $^{18}O/C_2H_4$/NO co-adlayers prepared as follows: the Pt(332) was exposed to various amounts of $^{18}O_2$ (prior to C_2H_4) and 0.4 L C_2H_4 at 90 K. The surface was then annealed to 300 K. The resultant co-adlayers were further exposed to 0.8 L NO at 90 K.



presence of $^{18}O_2$ (^{18}O) leads to evident changes in C_2H_4 dissociation. Specifically, formation of ethylidyne takes place at surface temperature higher than that in the absence of $^{18}O_2$ (^{18}O). The oxygen-induced changes for C_2H_4 dissociation also intimately depend on pre-exposure of $^{18}O_2$ in the co-adlayers (i.e., the ratio of $^{18}O_2$ to C_2H_4). For 0.4 L C_2H_4, formation of ethylidyne cannot be detected at a pre-exposure of 1.6 L $^{18}O_2$ at the annealing temperatures of 250 K and 300 K adopted in this study. These figures also indicate that no oxygen-containing surface species other than ^{18}CO (also a very small amount) are detectable under present experiment conditions, such as acetaldehyde, formate, acetate, and C_2H_4 oxide.

The adsorption of NO molecules on the surface of Pt(332) pre-exposed to $^{18}O_2$ and C_2H_4, is also strongly dependent on $^{18}O_2$ exposure and the temperatures to which $^{18}O_2/C_2H_4$ adlayers are pre-annealed. The presence of pre-dosed $^{18}O_2$ obviously suppresses the adsorption of NO molecules in bridge sites both on steps and on terraces, leading the post-dosed NO molecules to be mainly adsorbed in atop sites in the co-adlayers following higher $^{18}O_2$ pre-exposures. Moreover, a comparison between the IR spectra in Figs. 3 and 4 indicates that, unlike that at 250 K, the site-blocking effect induced by pre-dosed $^{18}O_2$ molecules is somewhat diminished when the annealing temperature is increased to 300 K, at which the adsorption of NO in bridge sites and in atop sites on both steps and terraces is retained. Figures 3 and 4 also indicate that there are no new surface species detectable that are supposed to be intermediates for N_2 production.

The site-blocking effect on NO adsorption exerted by $^{18}O_2/C_2H_4$ adlayers and its dependence on the annealing temperature and $^{18}O_2$ pre-exposure can be explained by the surface chemistry of C_2H_4 and ^{18}O atoms ($^{18}O_2$ has decomposed into ^{18}O at 250 and 300 K). A previous study has shown that the adsorption of C_2H_4 at a surface temperature of ~200 K on stepped Pt surfaces proceeds with C=C π-bound to the step corner and with the molecular axis perpendicular to the step edge (31). This configuration will inevitably shield (or block) the step sites that are preferred by NO adsorption. When the surface temperature reaches 250 K and higher, C_2H_4 dissociation begins, giving rise to ethylidyne initially. Unlike adsorbed C_2H_4, ethylidyne is preferentially adsorbed in terrace sites with its molecular axis parallel to the terrace normal (31), and as such, the step sites that were shielded (or blocked) are released and become available for NO adsorption.

This surface process for C_2H_4 does not apply to the situa-

© 2007 NRC Canada

tion in the presence of ^{18}O because the reaction of C_2H_4 with ^{18}O dominates. Like NO molecules, the adsorption of ^{18}O atoms on stepped Pt surfaces also prefers step sites, being mainly located in three-hollow sites. The adsorbed ^{18}O atoms recombinatively desorb only when the surface temperature is increased beyond 600 K. As a consequence, the adsorption of NO on steps is blocked when ^{18}O atoms are present on the surface of Pt(332). Besides the site-blocking effect, the presence of adsorbed ^{18}O atoms also weakens the NO/Pt interaction due to the much higher electronic affinity of ^{18}O (more d-electron density of Pt overlaps with O atoms rather than with anti-bond orbital of NO), leading NO dissociation to be suppressed. This situation can be reversed when a reducing species, e.g., C_2H_4, is added to the ^{18}O layer. Due to the reaction between these two species, which gives rise to H_2O (which is not detectable in our system) and $C^{18}O_2$, the site-blocking effect exerted by ^{18}O atoms and C_2H_4 lessens when the $^{18}O_2/C_2H_4$ co-adlayers are pre-annealed, as indicated by a comparison of the spectra at 250 and 300 K.

In conjunction with the analysis mentioned, the mechanism for N_2 production can be elucidated in detail by analysis of the thermal desorption spectra in Figs. 5, 6, and 7. It is shown that N_2 desorption is promoted in the presence of C_2H_4, but is significantly suppressed when ^{18}O is added into C_2H_4 adlayers. This effect occurs to a much larger extent when $^{18}O_2$ is "pre-dosed" to the surface. The positive contribution of C_2H_4 to NO reduction has been addressed in detail previously (13). The oxygen-induced suppression in N_2 desorption in this study can be explained by the facile reaction of ^{18}O with C_2H_x species that are supposed to be the key component that facilitates NO dissociation and N_2 desorption at ~380 K (13).

Another feature worth noting is that in the case in which $^{18}O_2$ is "pre-dosed", the amount of N_2 desorption does not appear to change significantly once the $^{18}O_2$ exposure exceeds 0.4 L, at which only one peak at ~460 K is detected irrespective of the annealing temperature as shown in Table 2. Since our IR results do not support a mechanism in which intermediates are needed for N_2 production, N_2 production from $^{18}O_2/C_2H_4$/NO co-adlayers most likely proceeds through a mechanism of NO dissociation and subsequent ^{18}O removal. Generally, it is well-known that the dissociation of the adsorbed NO molecules on stepped Pt surfaces mainly proceeds on the steps as the surface temperature is increased beyond 300 K (32–34). In another paper (16), we will confirm that although the adsorption of NO on steps is blocked by ^{18}O and C_2H_4; the restoration of NO to step sites is very rapid, enabling adsorbed NO molecules to be dissociated. This process accounts for N_2 production in the co-adlayers with annealing temperature of 250 K, at which the adsorption of NO on step sites would otherwise be fully suppressed.

On the other hand, though not quantified in detail, we also confirmed that only a limited amount of NO molecules are decomposed on the surface of Pt(332). This is because the (111)-oriented steps of the FCC (332) surface are less reactive than (100)-type steps to NO dissociation (35–37). A maximum N_2 desorption follows NO exposures of ~0.3 L and higher (15). This maximum value has been shown in Table 2, in which an NO exposure of 0.8 L is adopted. Accordingly, it is reasonable to suggest that N_2 production is to some extent, less dependent on how many NO molecules are present on the surface of Pt(332) to begin with. This reasoning accounts for the present observation that at both annealing temperatures, N_2 desorption does not appear to change much with increasing $^{18}O_2$ pre-exposure higher than 0.4 L, holding an intensity close to the same maximum one as observed for the NO/Pt(332) system (e.g., no other adsorbate present). In other word, providing that the adsorption of NO molecules on steps is restored (through an appropriate anneal step), a N_2 desorption, with an intensity at least comparable to the maximum one following only NO exposure, can be expected.

Conclusion

The role of oxygen in the SCR of NO with C_2H_4 was investigated by interrogating surface interactions in and measuring N_2 desorption from $^{18}O/C_2H_4$/NO co-adlayers, in which $^{18}O_2/C_2H_4$ is pre-annealed to 250 and 300 K before being exposed to 0.8 L NO at 90 K. The IR spectra of $^{18}O_2/C_2H_4$ co-adlayers are identical at annealing temperatures of 250 and 300 K, following the same amount of $^{18}O_2$ exposure. However, the adsorption of NO molecules on these co-adlayers and the resultant IR spectra are quite different with varying the annealing temperature and $^{18}O_2$ pre-exposure. The adsorption of NO molecules in bridge sites on steps is more significantly suppressed for the co-adlayers in which $^{18}O_2/C_2H_4$ is pre-annealed to 250 K. This site-blocking effect proceeds to a larger extent with increasing $^{18}O_2$ exposure. Nonetheless, no new surface species arising from the interaction among ^{18}O, C_2H_4, and NO, which are intermediates for N_2 production, are detected.

N_2 and H_2 are the primary desorbing species from the surface reaction, and their desorption is strongly dependent on $^{18}O_2$ exposure and the temperature to which $^{18}O_2/C_2H_4$ is pre-annealed. The presence of $^{18}O_2$, irrespective of the dosing sequence, suppresses N_2 desorption, but the suppression effect is much slighter when $^{18}O_2$ is "post-dosed". For the case with $^{18}O_2$ pre-dosed, despite the annealing temperature (250 or 300 K), N_2 desorption is greatly suppressed at an $^{18}O_2$ exposure of 0.2 L, but remains almost unchanged with increasing $^{18}O_2$ exposure from 0.4 to 1.6 L. In contrast, H_2 desorption is continuously decreased and disappears at 0.8 L $^{18}O_2$ and higher. This feature of N_2 desorption is explained by the restoration of the adsorption of NO molecules onto steps and the subsequent NO dissociation on these sites. It is concluded that the presence of $^{18}O_2$ in SCR of NO with C_2H_4 on the surface of Pt(332) does not play an role of activating reactants.

New diformyldihydroxyaromatic precursors for luminescent Schiff base macrocycles: Synthesis, characterization, and condensation studies

Britta N. Boden, Amir Abdolmaleki, Cecily T.-Z. Ma, and Mark J. MacLachlan

Abstract: With the goal of preparing luminescent, fully conjugated Schiff base macrocycles, a series of precursors based on benzene, phenanthrene, and triphenylene with formylhydroxy functionalization have been prepared and characterized. The condensation of these compounds with substituted phenylenediamines to afford conjugated [2+2] or [3+3] Schiff base macrocycle has been investigated. Although the [3+3] Schiff base macrocycles could not be isolated, two new soluble and luminescent [2+2] Schiff base macrocycles with N_2O_2 binding pockets have been prepared and characterized.

Key words: Schiff base, macrocycle, condensation, salicylaldehyde, conjugated.

Résumé : Afin de pouvoir obtenir des bases de Schiff macrocycliques complètement conjuguées et luminescentes, on a préparé et caractérisé une série de précurseurs à base de benzène, de phénanthrène et de triphénylène portant des groupes hydroxyle et formyle. On a ensuite étudié la condensation de ces composés avec des phénylènediamines substituées qui peuvent conduire à des bases de Schiff macrocycliques avec conjugaison [2+2] ou [3+3]. Même si on n'a pas pu isoler les bases de Schiff macrocycliques [3+3], on a pu préparer et caractériser deux nouvelles bases de Schiff macrocycliques [2+2], solubles et luminescentes, comportant des poches de fixation du N_2O_2.

Mots-clés : base de Schiff, macrocycle, condensation, salicylaldéhyde, conjugué.

[Traduit par la Rédaction]

Introduction

Schiff base macrocycles formed from the condensation of diamines and dialdehydes are attractive ligands for multimetallic complexes (1–20). 2,6-Diformylphenol **1** and its analogues condense with diamine compounds in a 2:2 ratio to form compartmental ligands (Robson macrocycles **2**) (21–25) (Chart 1). Bimetallic complexes formed in the interior of this macrocycle are of interest for studying magnetic and electronic interactions between metal centres, and may serve as models for the active sites of enzymes (26, 27).

The hydroxyl group adjacent to the formyl moiety in the precursor is important for producing an N_2O_2 chelate and for stabilizing the imine in the metal-free macrocycle. While a vast assortment of diamines is available for incorporation into Schiff base macrocycles, much less attention has been placed on the bis(formylhydroxy) precursor development. By varying the geometry and structure of this component, one may access novel macrocycles with different sizes, shapes, and number of metal-binding sites (28–30). For example, condensation of compounds **3** (31–33) and **4** (34) with *o*-phenylenediamines gives triangular [3+3] and hexagonal [6+6] Schiff base macrocycles, respectively, and **5** (35) is expected to form [2+2] Schiff base macrocycles. Only a few other bis(formylhydroxy) compounds have been explored as precursors for Schiff base macrocycles (36–40). Expanding the number of bis(formylhydroxy) compounds available will open up avenues to explore macrocycles with new electronic, optical, and coordinating properties.

In this paper, we significantly expand the library of dihydroxydiformyl compounds predisposed for [2+2] and [3+3] Schiff base macrocycles. In an effort to obtain fully conjugated, luminescent macrocycles, we have prepared the first phenanthrene and triphenylene precursors with bis(formylhydroxy) functionality. Phenanthrene and triphenylene have received very little attention for incorporation into macrocycles (41, 42), yet they may have a large effect on the ring size and electronic or optical properties of the products. In addition, we have prepared new conjugated *m*-diethynylbenzene precursors for the preparation of [2+2] Schiff base macrocycles. We report on the optical properties of the novel diamond-shaped macrocycles.

benzenes **28** (50), and BOC-protected phenylenediamine **32** (51) were prepared according to literature procedures. $Pd(PPh_3)_4$ was obtained from Strem Chemicals, Inc. Deuterated solvents were obtained from Cambridge Isotope Laboratories, Inc. All other chemicals were purchased from Aldrich, TCI, or Fisher and used as received. All reactions were carried out under nitrogen unless otherwise noted. ^{1}H NMR (300 or 400 MHz) and ^{13}C NMR (75.5 or 100.7 MHz) spectra were recorded on Bruker Avance 300 or Bruker Avance 400 spectrometers and were referenced internally to residual protonated solvent. Infrared spectra were obtained as KBr discs or on NaCl plates with a Bomem MB-100 spectrometer or a Nicolet 4700 FTIR spectrometer. UV–vis spectra were obtained on a Varian Cary 5000 UV–vis/near IR spectrometer using a 1 cm cuvette. Fluorescence spectra were obtained on a Photon Technology Intl. QuantaMaster fluorimeter. Matrix assisted laser desorption/ionization(MALDI) mass spectra were obtained on a Bruker Biflex IV time-of-flight (TOF) mass spectrometer equipped with a MALDI ion source. Electrospray ionization (ESI) mass spectra were obtained on a Micromass LCT time-of-flight (TOF) mass spectrometer equipped with an electrospray ion source. Samples were analyzed in methanol:dichloromethane at 1 μmol/L. EI spectra were obtained with a double focusing mass spectrometer (Kratos MS-50) coupled with a MASPEC data system with EI operating conditions of: source temperatures 120–220 °C and ionization energy 70 eV. Elemental analyses were obtained at the UBC Microanalytical facility. Melting points were recorded on a Fisher John's melting point apparatus.

Synthesis of 2,7-diformyl-3,6-dimethoxyphenanthrene (8)

3,6-Dimethoxyphenanthrene **7** (0.718 g, 3.01 mmol) was dissolved in 20 mL THF. BuLi (6.1 mL, 1.6 mol/L) was added, and the solution was stirred for 30 min, after which anhyd. DMF (0.77 mL, 9.98 mmol) was added. The reaction solution was poured into aq. HCl and extracted with dichloromethane (DCM). After drying over $MgSO_4$, the solvent was removed by rotary evaporation to reveal an orange solid. The product was chromatographed over silica with DCM and recrystallized from DCM to obtain 0.150 g of yellow solid (17% yield).

Synthesis of 2,7-diformyl-3,6-dihydroxyphenanthrene (9)

To an ice-cooled solution of compound **8** (0.413 g, 1.40 mmol) in DCM was added BBr_3 (1 mL, 10.6 mmol). After stirring overnight, the solution was poured into 200 mL of ice water to obtain an orange solid. The solid was filtered, and the remaining aq. solution was extracted with DCM. The organic layer was dried and combined with the solid. After flashing the product through silica with DCM, 0.268 g (1.01 mmol) of orange crystals were obtained (72% yield).

Data for 9

Synthesis of 2,7-diformyl-3,6-dihydroxyphenanthrene-9,10-quinone (14)

Compound **13** was dissolved in 10 mL dry DCM and cooled to 0 °C. To the solution was added BBr_3. After stirring overnight, the dark solution was poured into H_2O to precipitate a purple solid. After filtration, some of the solid was dissolved in THF to make an initially purple solution, which slowly became yellow upon standing. The solvent was removed to give a brown solid (**14**). We believe the initially obtained solid is a tautomer or partially reduced form of **14**, but it was not possible to obtain a pure sample of the purple intermediate.

Data for 14

Mp > 300 °C. UV–vis (DMSO): λ_{max} (ϵ) = 314 nm. Synthesis of 4-Iodosalicylaldehyde (23)

Under a nitrogen atmosphere, dry paraformaldehyde (4.05 g, 135 mmol) was added to a mixture of the 3-iodophenol **22** (4.40 g, 20 mmol), anhyd. $MgCl_2$ (2.86 g, 30 mmol), and anhyd. Et_3N (10.5 mL) in dry MeCN (100 mL). After heating the mixture to reflux for 2 h, the mixture was cooled to RT, and 100 mL of 2 mol/L aq. HCl was added. The product was extracted with 3 × 100 mL of Et_2O, dried over $MgSO_4$, filtered, and dried by rotary evaporation. The residue was dissolved in a mixture of 1:1 CH_2Cl_2/hexanes and was filtered through a short pad (~5 cm) of SiO_2 using the same solvent mixture as eluent. Rotary evaporation of the filtered solution gave an off-white solid. Recrystallization from hexanes gave white crystals of **23** (2.22 g, 9.0 mmol, 45%).

Data for 23

Anal. calcd. for $C_7H_5IO_2$: C, 33.90; H, 2.03. Found: C, 34.11; H, 2.10.

Synthesis of Compound 26

Under a nitrogen atmosphere, 1,3-diethynylbenzene **24** (0.254 g, 2.0 mmol), 4-iodosalicylaldehyde **23** (0.992 g, 4.0 mmol), Ph_3P (0.015 g, 0.06 mmol), and *trans*-$[PdCl_2(Ph_3P)_2]$ (0.06 g, 0.08 mmol) were dissolved in 25 mL of anhyd. THF. Dry Et_3N (2.3 mL) was added, turning the solution from yellow to orange. After stirring for 20 min, CuI (0.02 g, 0.10 mmol) was added, and the solution then turned to dark brown. The solution was stirred overnight at RT, then the yellow precipitate was isolated on a Büchner funnel and washed with CH_2Cl_2/hexane (1:2). Yield: 0.549 g (1.5 mmol, 75%) of yellow powder.

Data for 26

Mp > 250 °C dec. UV–vis (CH_2Cl_2): λ_{max} (ϵ) = 297 (3.24×10^4), 331 (3.29×10^4) nm (L $mol^{-1}cm^{-1}$). EI-MS: *m*/*z* = 367 (M^+, 100%), 339 (80%). Anal. calcd. for $C_{23}H_{13}O_4N \cdot 0.5H_2O$: C, 73.40; H, 3.75; N, 3.72. Found: C, 73.51; H, 3.75; N, 4.36.

Attempted synthesis of macrocycle 29

Equimolar amounts of compound **9** and 1,2-diamino-4,5-dialkoxybenzenes **28** were combined in a Schlenk flask. Degassed $CHCl_3$ was added, and the resulting solution was heated to reflux for 24 h. After cooling, any precipitate was filtered, or MeCN was added until precipitate formed. The products are unstable to chromatographic separation on silica or alumina.

Data for the insoluble product obtained when R = $^nC_6H_{13}$ (29b)

IR (KBr): ν = 3051, 2952, 2928, 2857, 1636, 1611, 1506, 1465, 1370, 1256, 1190, 1165, 1120, 1017, 959 cm^{-1}.

Data obtained for filtrate when R = $^nC_8H_{17}$ (29c)

^1H NMR (400 MHz, $CDCl_3$, 25 °C) δ: 12.97, 10.61, 10.07, 10.05, 8.66, 8.01, 7.99, 7.82, 7.49, 6.80, 6.34, 3.95, 1.82–0.86 (hexyloxy chain) ppm. ESI-MS: *m*/*z* = 614 (M^+, 1+1 fragment).

Data for solid obtained from reaction with R = $^nC_8H_{17}$ (29c)

^1H NMR (400 MHz, $CDCl_3$, 25 °C) δ: 13.00, 12.93, 10.63, 10.11, 10.09, 8.72, 8.52, 8.06, 8.03, 7.87, 7.51, 7.49, 6.83, 6.36, 3.95, 1.83–0.86 (hexyloxy chain) ppm. MALDI-TOF: *m*/*z* = 1785 ([**29c** + H]$^+$).

Attempted synthesis of macrocycle 30

Equimolar amounts of compound **21** and 1,2-diamino-4,5-dialkoxybenzenes were combined in a Schlenk flask. Solvent was added, and the resulting solution was heated to reflux. For specific conditions, see later. In each case, nearly the same inseparable mixture was obtained as indicated by ^1H NMR spectroscopy.

Data for 30

^1H NMR (300 MHz, $CDCl_3$, 25 °C) δ: 14.84, 13.66, 13.21, 13.02, 12.35, 12.28, 12.06, 11.65, 9.2–6.3, 4.2–3.8, 2.9–2.7, 2.0–0.8 ppm. MALDI-TOF-MS: *m*/*z* = 1935 ([M + H]$^+$).

Synthesis of compound 33

Compound **21** (0.058 g, 0.120 mmol) and *p*-anisidine **31** (0.46 g, 0.373 mmol) were combined in a flask and dissolved in dry THF to form a yellow solution. After refluxing for 4 h, the solution was cooled, and the volume of solvent was reduced. Upon addition of MeOH, an orange solid precipitated, was filtered, and was washed with MeOH and petroleum ether to yield 0.071 g (0.102 mmol, 86%) of product.

Data for 33

Mp 212–213 °C. UV–vis (CH_2Cl_2): λ_{max} (ϵ) = 287 (5.8×10^4), 340 (2.8×10^4), 359 (3.2×10^4), 401 (5.2×10^4) nm (L $mol^{-1}cm^{-1}$). X-ray crystallography[2]

A crystal of **14**·2DMSO was mounted on a glass fiber, and data were collected on a Bruker X8 APEX II diffractometer with graphite monochromated Mo Kα radiation. The data were collected to a maximum 2θ value of 55° in a series of ϕ and ω scans in 0.5° oscillations with 20 s exposures. The crystal-to-detector distance was 36 mm. Compound **14** crystallizes as a two-component twin with the two components related by a 180° rotation about the (010) reciprocal axis. Data were integrated for both twin components, including both overlapped and non-overlapped reflections. In total, 25882 reflections were integrated (10175 from component one only, 9903 from component two only, 5804 overlapped). Data were collected and integrated using the Bruker SAINT software packages (53). Data were corrected for absorption effects using the multi-scan technique (54), and were corrected for Lorentz and polarization effects.

The structure was solved by direct methods using non-overlapped data from the major twin component (55). Subsequent refinements were carried out using an HKLF 5 format data set containing complete data from both twin components. The material crystallizes with two molecules of DMSO in the asymmetric unit. All non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were included in calculated positions but were not refined. The batch scale refinement showed a roughly 3:1 ratio between the major and minor twin components. The final cycle of full-matrix least-squares refinement (56) on F^2 was based on 5845 reflections from component one (including overlaps with component two) and 278 variable parameters. The data converged (largest parameter shift was 0.0 times its esd) with unweighted and weighted agreement factors of R_1 = 0.111 and wR_2 = 0.191. The standard deviation of an observation of unit weight (57) was 0.96. The weighting scheme was based on counting statistics. Neutral atom scattering factors were taken from Cromer and Waber (58). Anomalous dispersion effects were included in F_{calcd} (59); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (60). The values for the mass attenuation coefficients are those of Creagh and Hubbell (61). All refinements were performed

Goodness-of-fit on F^2	0.96
Final *R* indices ($I > 2\sigma(I)$)	R_1 = 0.069, wR_2 = 0.171
R indices (all data)	R_1 = 0.111, wR_2 = 0.191
Largest diff. peak and hole (e Å^{-3})	0.80 and –0.60

using the SHELXTL crystallographic software package of Bruker-AXS (62). Additional details of the data collection and refinement are in Table 1.

Results and discussion

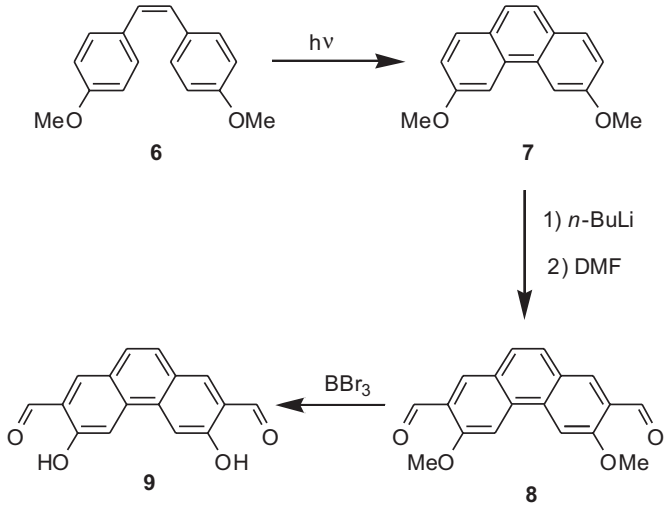
Diformyldihydroxy precursors

Phenanthrene derivatives

Scheme 1 shows the sequence of reactions used to obtain the parent diformyldihydroxyphenanthrene **9**. Photocyclization of 4,4′-dimethoxystilbene **6** gave 3,6-dimethoxyphenanthrene **7**. Dilithiation of **7** followed by quenching with DMF gave (after work-up) compound **8** with formyl groups in the 2,7 positions. Deprotection of the phenol groups with BBr_3 afforded target compound **9** in moderate yield. ^{1}H NMR spectroscopy of **9** confirms the structure of the diol, with a single hydroxyl resonance observed at 10.96 ppm (DMSO-d_6), shifted downfield due to hydrogen-bonding with the formyl groups.

The low solubility of compound **9** is a potential limitation to its further utility. To make soluble diformyldihydroxyphenanthrenes, we attempted to incorporate alkoxy groups

Scheme 1. Synthesis of diformyldihydroxyphenanthrene **9**.



on the ring as shown in Scheme 2. We have previously reported the preparation of 3,6-dimethoxyphenanthrene-9,10-quinone **10** (45). Bromination of this compound gave **11**, along with some other by-products, which can easily be separated by chromatography. Reduction and methylation of the quinone yielded **12**, which was subsequently lithiated and quenched with dimethylformamide to give compound **13**. Reaction of **13** with BBr_3 gave, after work-up, compound **14**. This compound showed the expected ^{1}H NMR resonances, but we undertook a single crystal X-ray diffraction study to verify the correct tautomer was present. The solid-state structure of crystals of **14** grown from DMSO is depicted in Fig. 1, with relevant crystallographic details summarized in Table 1. The compound exhibits a nearly planar structure, with the formyl groups directed slightly out of the plane. In structures of salicylates, the formyl groups are typically hydrogen-bonded to the hydroxyl groups. The structure for **14** shows the oxygen of the aldehydes pointing away from the alcohol and the hydroxyl moieties instead hydrogen-bonding with the oxygen in co-crystallized DMSO. The extended structure shows phenanthrene molecules stacked in a staggered arrangement, with intermolecular separations of 3.1–3.3 Å, characteristic of π–π interactions.

To incorporate alkoxy groups on phenanthrene **14**, it was necessary to protect the hydroxyl groups. Having confirmed that the 3,6-dihydroxy tautomer was in solution, we anticipated that these could be readily protected. Unfortunately, attempts to selectively protect the 3,6-dihydroxy groups of **14** failed. Upon adding base to **14**, the compound undergoes a dramatic color change to purple, and reaction with protecting groups (e.g., Me_2SO_4) gave mixtures of products. It seems that with deprotonation compound **14** tautomerizes changing the reactivity of the hydroxyl groups, though we cannot isolate this intermediate in pure form. This approach was abandoned.

Triphenylene derivatives

We prepared diformyldihydroxytriphenylene **21** with peripheral hexyl groups by the route shown in Scheme 3. The synthesis of triphenylene **18** was based on previous research into unsymmetrically hexasubstituted triphenylenes (63, 64).

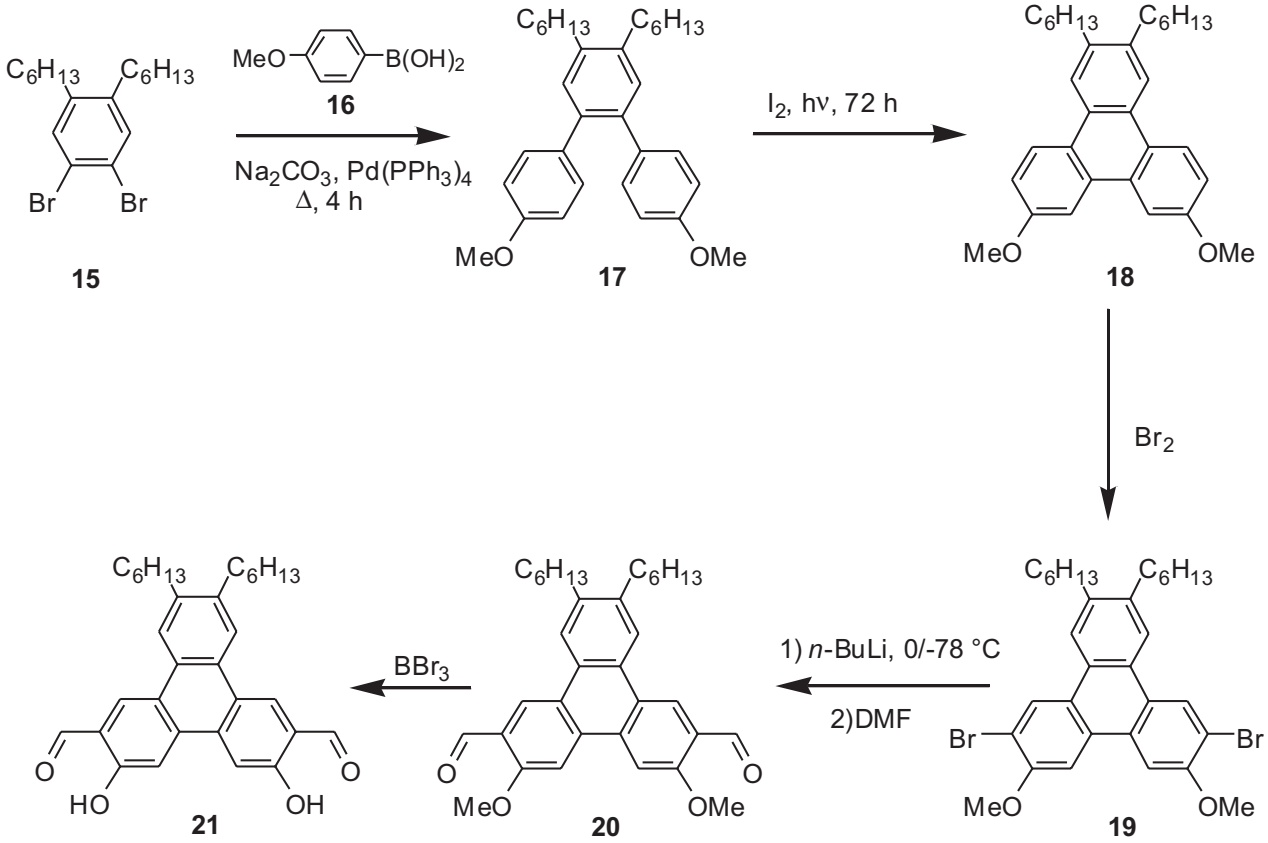
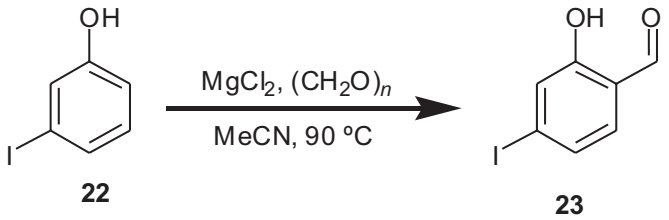
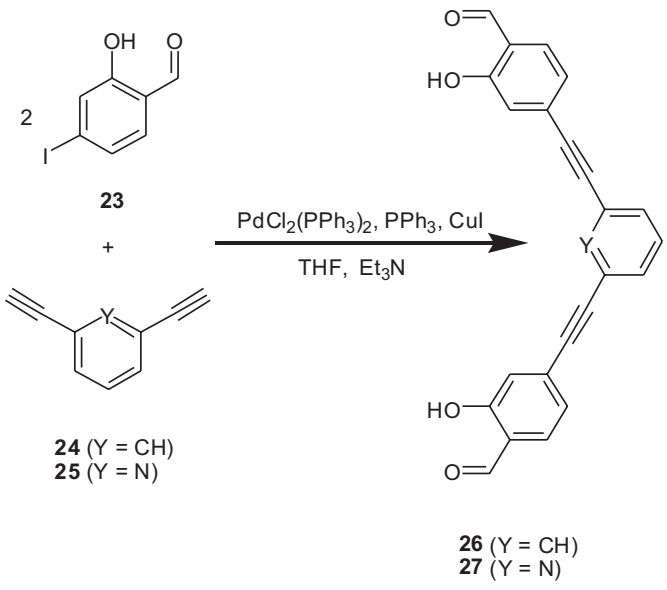
Scheme 3. Synthesis of diformyldihydroxytriphenylene **21**.



Scheme 4. Synthesis of 4-iodophenol **23**.



Scheme 5. Synthesis of bis(salicylaldehyde)s **26** and **27**.



In the first step, terphenyl **17** was formed by Suzuki coupling of 1,2-dibromo-4,5-dihexylbenzene **15** and 4-methoxyphenylboronic acid **16**. Photocyclization in the presence of iodine gave triphenylene **18**. Selective double bromination of triphenylene **18** occurred at the 6,11 positions, yielding compound **19**. Subsequent metal–halogen exchange with ^{n}BuLi, and reaction with DMF gave the diformyldimethoxytriphenylene **20** after work-up. In the last step, the phenol was deprotected with BBr_3 to afford the diformyldihydroxytriphenylene **21** in 20% overall yield. All of the steps, with the exception of the photocyclization, are fast and high-yielding. Compounds **18**–**21** are easily purified through recrystallization, making **21** a convenient precursor for macrocycle studies.

m-*Bis(4-ethynylsalicylaldehyde)benzene and* m-*Bis(4-ethynylsalicylaldehyde)pyridine*

To synthesize conjugated bent bis(4-ethynylsalicylaldehyde) compounds, we required 4-iodosalicylaldehyde **23**. This compound has been made previously by the Reimer–Tiemann reaction starting with 3-iodophenol **22**, but this reaction generally proceeds in low yield and gives a mixture of products; the major products are 3-iodosalicylaldehyde and 2-iodo-4-hydroxybenzaldehyde (65–67). We found that using $MgCl_2$ and paraformaldehyde (68,69) reliably gave compound **23** in better (45%) yield, Scheme 4. This compound will likely prove useful for synthesizing other functionalized precursors to large macrocycles, such as [3+3] macrocycles we have previously studied (37).

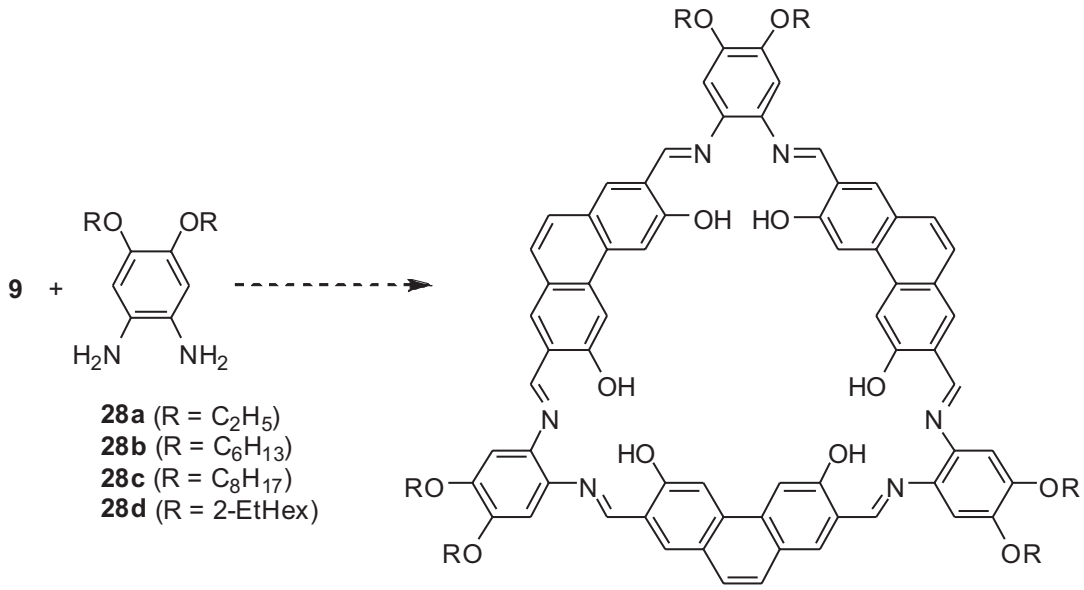
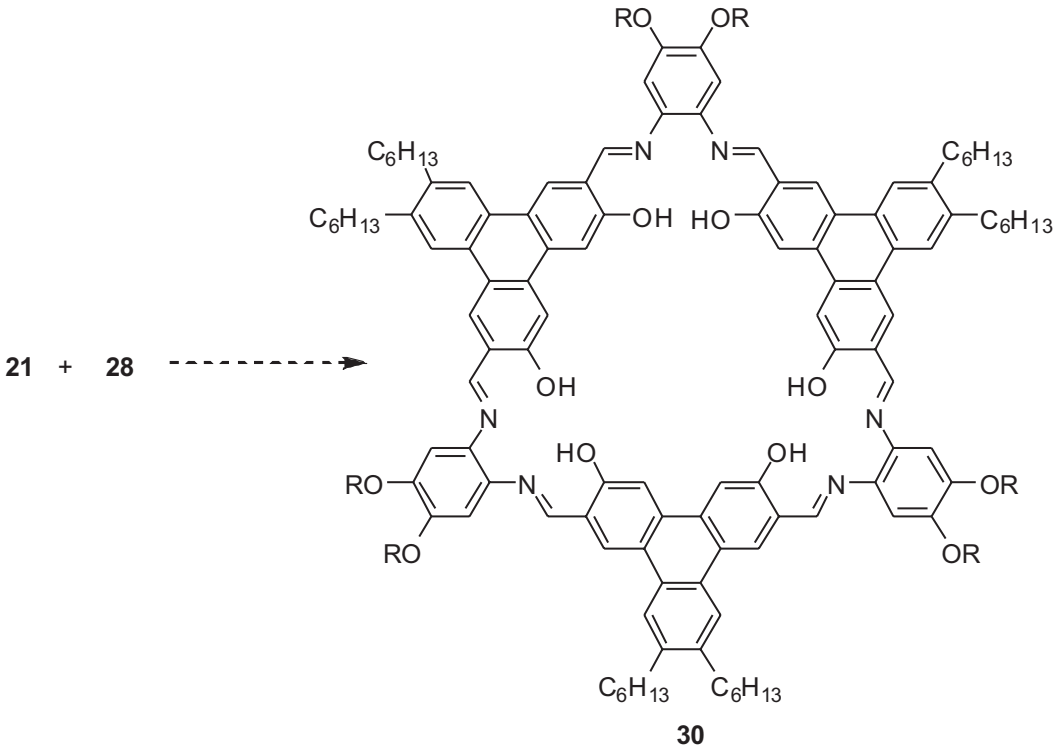
Scheme 6. Proposed syntheses of target macrocycles **29** and **30**.





Pd(0)-catalyzed Sonogashira–Hagihara coupling of **24** with two equiv. of **23** yielded the bis(salicylaldehyde) **26** in 75% yield, Scheme 5. Pyridine analogue **27** was prepared by a similar procedure in 70% yield from **25**. The elbow-shaped bis(ethynylsalicylaldehyde) compounds were characterized by NMR spectroscopy and mass spectrometry.

Condensation studies

We investigated the condensation of the new diformyl-dihydroxy precursors with 4,5-diamino-1,2-dialkoxybenzenes in an effort to obtain conjugated Schiff base macrocycles. Reactions to form macrocycles are typically performed in mixtures of organic solvents selected to precipitate the macrocycle as it forms.

Phenanthrene derivatives

We expected that the reaction of **9** with diaminobenzene derivatives would afford [3+3] Schiff base macrocycle **29**, Scheme 6. Reaction of **9** was undertaken with several different *o*-phenylenediamines to control solubility. With 1,2-

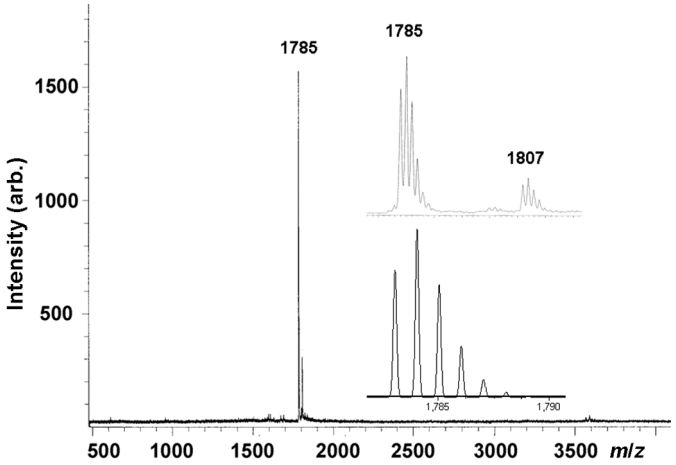
Fig. 2. MALDI-TOF mass spectral evidence for the formation of macrocycle **29** (R = n-C_8H_{17}). The insets show a simulation of the isotope distribution for the [**29** + H]$^+$ ion (bottom) and the expanded experimental data for this peak (top). The peak at m/z = 1807 is the [**29** + Na]$^+$ ion.



dioctyloxy-4,5-diaminobenzene **28c**, a solid was obtained. The ^{1}H NMR spectra of the product showed that multiple species were formed, and it appears that the major product is the 1:1 diol:diamine condensation species. Electrospray ionization mass spectrometry (ESI-MS) showed this fragment as the dominant species and also showed larger fragments of the expected macrocycle. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (Fig. 2) of the solid showed the presence of macrocycle **29** as the dominant high molecular mass component, along with traces of a larger [4+4] macrocycle. While there was evidence for the formation of the desired macrocycle in this reaction, we were unable to find conditions where the macrocycle selectively formed in the reaction mixture, an essential feature since the Schiff base macrocycles cannot be separated by column chromatography.

Triphenylene derivatives

Condensation of **21** with *o*-phenylenediamines was anticipated to form macrocycle **30**, Scheme 6. Unfortunately, the reaction of **21** with 4,5-dialkoxy-1,2-phenylenediamines **28** in an appropriate solvent, conditions that have worked well for other [3+3] Schiff base macrocycle reactions, afforded only inseparable mixtures of products. The ^{1}H NMR spectrum of the orange solid collected from the reaction showed several hydroxyl protons between 11.6 and 14.8 ppm. While the largest resonance at 13.2 ppm is characteristic of a hydroxyl group hydrogen-bonded to an imine, as in the intended Schiff base macrocycle, the positions of the other peaks are reminiscent of those observed for partially reduced Schiff base macrocycles, where imines are reduced in situ (this is a common problem in the formation of Schiff base macrocycles) (70–75). MALDI-TOF mass spectrometry of the orange product confirmed that the macrocycle was indeed present in the mixture. In fact, only the ring-closed [3+3] macrocycle **30** is observed in the MALDI-TOF mass spectrum. Further evidence for the formation of the [3+3] Schiff base macrocycle came from a metallation experiment, wherein the product was heated in THF in the presence of a metal salt. A color change indicated that reaction occurred, and, with vanadyl acetylacetonate, the MALDI-TOF mass spectrum clearly shows the incorporation of three metal centers into the macrocycle. The incorporation of three metals into the macrocycle supports the formation of macrocycle **30** in the reaction mixture.

Table 2. Conditions attempted for macrocycle **30** synthesis.

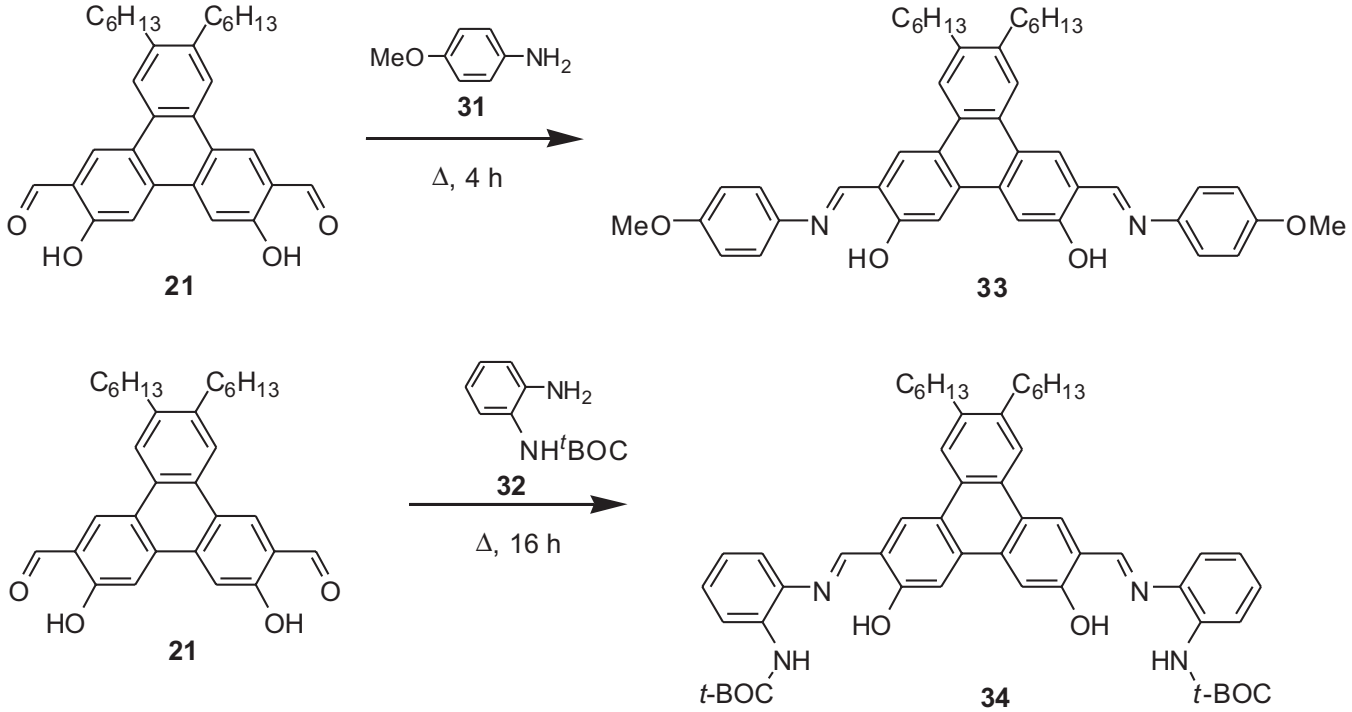
Solvent	R	Metal
$CHCl_3$/MeCN	C_6H_{13}	N/A
CH_2Cl_2/MeCN	C_2H_5	N/A
THF	C_2H_5	N/A
Toluene	C_2H_5	N/A
EtOH	C_2H_5	$Ni(OAc)_2$
EtOH	C_2H_5	$Zn(OAc)_2$

In an effort to selectively form macrocycle **30**, and to prevent possible side reactions (e.g., partial reduction of the macrocycle), a variety of conditions was used (Table 2). In all cases, the exact same series of resonances was reproduced in the ^{1}H NMR spectrum of the isolated solid, sometimes combined with fragments of the macrocycle. ESI-MS confirmed that fragments of the macrocycle were also present. Metal templation, which has proved to be critical in the synthesis of many Schiff base macrocycles, was also unsuccessful to obtain the fully conjugated macrocycle. Reaction of the diol and diamine in the presence of Ni^{2+} gave a black solid, which was revealed to be a 2:1 diol to diamine fragment coordinated to the metal through MALDI-TOF mass spectrometry. The same reaction in the presence of Zn^{2+} gave a mixture that included the starting material.

We were frustrated and surprised that compounds **9** and **21**, which appear ideal for forming [3+3] Schiff base macrocycles, were only yielding inseparable mixtures. In our experience, most diformyldihydroxyaromatics, such as **3**, yield the macrocycle in high yield. To understand whether or not the reactivity of the aldehydes on **9** and **21** were unusual, we made two model compounds by reaction of **21** with aniline derivatives **31** and **32**, Scheme 7. Compounds **33** and **34** were obtained as microcrystalline solids in high yield. The ^{1}H NMR spectra of these compounds show imine resonances

© 2007 NRC Canada

Scheme 7. Synthesis of model compounds **33** and **34**.



at 8.86 and 8.90 ppm, respectively. There is no indication of either reduction of the imine bond or isomerization to the keto–enamine tautomer, which was observed previously in a macrocycle prepared with a naphthalene diol (40). Isolation of these model compounds supports the use of **9** and **21** to build new multidentate Schiff base ligands.

m-*Bis(4-ethynylsalicylaldehyde)benzene and* m-*Bis(4-ethynylsalicylaldehyde)pyridine*

The geometry of compounds **26** and **27** are likely to favor [2+2] Schiff base macrocycles. Condensation of precursor **26** with 4,5-bis(2-ethylhexyloxy)-1,2-phenylenediamine **28d** gave the diamond-shaped macrocycle **35** in 88% yield, Scheme 8. Ethylhexyloxy substituents were required to render the macrocyclic product soluble. In this case, the branched substituents and the presence of a chiral center impart disorder to the macrocycles and ensure solubility. Macrocycles were initially prepared using phenylenediamines substituted with *n*-alkoxy chains (**28a**, **28b**), but these macrocycles were found to be insufficiently soluble in organic solvents to easily characterize or purify, though MALDI-TOF mass spectra indicated that the [2+2] macrocycles were the major, if not exclusive, products in each case.

The structure of red macrocycle **35** was verified by ^{1}H and ^{13}C NMR spectroscopies. Notably, the OH and imine groups are evident as singlets at 13.34 and 8.61 ppm, respectively, in $CDCl_3$, consistent with average D_{2h} symmetry for the macrocycle. The large downfield shift of the phenol resonance is characteristic of strong hydrogen-bonding to the imine group in the macrocycle. MALDI-TOF MS of **35** (Fig. 3) showed the molecular ion expected for the macrocycle ([**35** + H]$^+$) at *m*/*z* = 1390. The aldehyde C=O stretch observed at 1664 cm^{-1} in the IR spectrum of **26** was replaced by an intense C=N stretching mode at 1609 cm^{-1}.

With the goal of incorporating coordinating pyridine moieties into the macrocycles, we reacted **27** with diamine **28d** to yield macrocycle **36** in 80% yield, Scheme 8. The ^{1}H and ^{13}C NMR data were consistent with the proposed ring structure. MALDI-TOF MS showed the expected protonated molecular ion as the major peak for macrocycle **36**.

During the synthesis of macrocycles **35** and **36**, we found no evidence for formation of polymeric by-products. ^{1}H NMR analysis of the supernatant solution from the reaction showed mostly more macrocycle as well as putative oligomers that could not be separated. As with [3+3] Schiff base macrocycles we have previously investigated, these conjugated [2+2] macrocycles can be cleanly prepared in high yield. It was not necessary to use high dilution methods to favor macrocycle formation, or to remove water during the reaction to promote the condensation reaction. The macrocycles are stabilized from hydrolysis by the formation of strong hydrogen bonds between the imine and the phenol.

Optical properties

Our stated goal in expanding the conjugation of the dialdehyde precursors was to develop luminescent Schiff base macrocycles. These may be useful for chemical sensing applications or electronic devices. Figure 4 illustrates the absorption and emission spectra of macrocycle **35** in solution, which are similar to those of macrocycle **36**. An intense π–π* transition at 345 nm is accompanied by weaker transitions that extend the absorption edge to ~500 nm. Both macrocycles are weakly luminescent in solution, with maxima observed at 564 nm for both compounds, and quantum yields of 3%–5% in THF. This is almost identical to the fluorescence spectrum for **37**, a previously reported macrocycle (37) (Fig. 5), indicating that conjugation is essentially localized to the *N*,*N*′-bis(salicylidene)-1,2-phenylenediimine moi-

ety and is unaffected by the spacer. The meta linkage of the phenyl and pyridyl groups in **35** and **36**, respectively, should limit conjugation between the salicylaldehyde groups, and this is observed.

Conclusions

We have developed convenient routes to the first examples of diformyldihydroxy-functionalized phenanthrene (**9**, **14**) and triphenylene (**21**), as well as two new *m*-bis(4-ethynylsalicylaldehyde)aromatic compounds (**26**, **27**). Studies showed that **9** and **21** do not undergo clean cyclization reactions with *o*-phenylendiamines to selectively afford [3+3] Schiff base macrocycles, but these compounds are useful precursors for other Schiff base ligands, and perhaps even macrocycles with the appropriate choice of diamine. On the other hand, **26** and **27** underwent selective condensation to form fully conjugated [2+2] Schiff base macrocycles **35** and **36**. These luminescent macrocycles with two N_2O_2 binding pockets are anticipated to have interesting coordination chemistry and aggregation behavior, which we are studying.

Synthesis of β-amino alcohols using MgO as a new catalyst under solvent-free conditions

Mona Hosseini-Sarvari

Abstract: MgO catalyzed efficiently the ring opening of epoxides with a range of aromatic and aliphatic amines to produce β-substituted alcohols in high yields under solvent-free conditions. Exclusive trans stereoselectivity is observed for cyclic epoxide.

Key words: MgO, β-amino alcohols, solvent-free, epoxide, amine.

Résumé : Dans des conditions n'impliquant aucun solvant, l'oxyde de magnésium, MgO, catalyse d'une façon efficace l'ouverture du cycle des époxydes avec une grande variété d'amines aliphatiques et aromatiques pour conduire avec des rendements élevés aux alcools β-substitués correspondants. On observe exclusivement l'ouverture stéréosélective *trans* avec les époxydes cycliques.

Mots-clés : MgO, β-aminoalcools, sans solvant, époxyde, amine.

[Traduit par la Rédaction]

Introduction

The formation of β-amino alcohols from epoxides and amines is an important reaction in medicinal and organic chemistry, as they are useful synthetic intermediates for the preparation of β-amino acids, natural products, and chiral auxiliaries (1). Opening of epoxides with amines developed in the past few years, and many catalysts (reagents) were used, such as metal triflates (2), metal halides (3), polymer supported (4), montmorillonite K10 (5), and metal salt (6). Different reaction media, such as ionic liquids (7), ultrasound (8), microwave irradiation (9), solvent-free conditions (SFC), and water (10) were also employed. These processes are useful; however, they suffer from disadvantages, such as the use of expensive or air-sensitive reagents, extended reaction times, and the requirement for protracted work-up procedures, or are limited in the range of amines specially aliphatic amines.

MgO is an environmentally safe, non-volatile, non hygroscopic, odourless, and white powder with outstanding physical properties and stability. It is commercially available and is a very cheap chemical. Recently, it was shown that MgO has the prospect to be used as a substitute for conventional basic catalytic materials. It has been used as an efficient heterogeneous catalyst in many important organic reactions (11).

In this pursuit, and during the course of the studies aimed at developing solvent-free procedures (12), for the first time, MgO-catalyzed ring opening of epoxides by amines in solvent-free conditions is reported in this paper (Scheme 1).

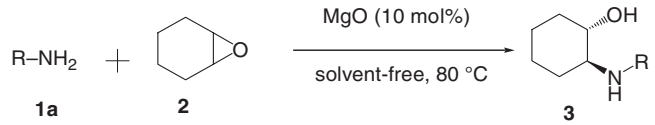
Scheme 1. Synthesis of β-amino alcohols catalyzed by MgO.



1a 2 3

R = alkyl and aryl

Results and discussion

The condensation between an amine and an epoxide leading to the formation of a β-amino alcohol should be a facile reaction due to the good electrophilic and nucleophilic properties of the epoxide and amine groups, respectively. This reaction may not require any catalytic assistance in the absence of electronic/steric factors that might decrease the electrophilicity/nucleophilicity of the epoxide/amine groups. Thus, the condensation of cyclohexene oxide with 4-methylaniline, 4-methoxyaniline, and 4-bromoaniline afforded 70%–90% yields, in 6–8 h, under neat conditions at 80 °C without the requirement of any additional reagent/catalyst. The treatment of cyclohexene oxide with aniline afforded the corresponding β–aminol alcohols in 60% yields in 12 h. However, no significant β-amino alcohol formation was observed (^{1}H NMR) when cyclohexene oxide was treated with 4-nitroaniline at 100 °C under neat conditions.

The presence of the strong electron-withdrawing property of the nitro group in 4-nitroaniline decreases the nucleophilicity of the amine group. Thus, the combination of this substrate with cyclohexene oxide constitutes a model reaction for evaluating the efficiency of a catalyst. Hence, cyclohexene oxide was treated with 4-nitroaniline under various conditions (Table 1). Clearly, the best results were reached with MgO under solvent-free conditions (Table 1, entry 1).

To evaluate the generality, reaction of various epoxides were carried out with various aromatic, aliphatic, primary,

[a]Yields are for the isolated compounds.

and secondary amines under the catalytic influence of MgO, and excellent results were obtained (Table 2). The reaction protocol is simple and does not require dry glassware and reagents. This is very important for scaling-up the process. The final amino alcohol was isolated in >99% purity in 50%–98% yield.

The results summarized in Table 2 reveal that excellent yields were obtained with aromatic and aliphatic amines. In the case of cyclohexene oxide, in each occasion, the resultant racemic 2-aryl/alkylaminocyclohexanol was obtained with exclusive trans diastereoselectivity as detected by ^{1}H NMR spectroscopic analysis (Table2, entries 5–26). The reactions are remarkably clean, and no chromatographic separation is necessary to get the spectra-pure compounds except in a few cases (Table 2, entries 16–20) where some starting materials remained; the conversion being less than 100%. Primary and secondary amines react very rapidly. Aniline and its derivatives with electron-donating substitutes also react quite fast. However, anilines with electron-accepting substitutes, as well as satirically hindered anilines, react very slowly, and aminolysis required prolonged reaction times. The reaction of diamines showed good results without any significant influence of their structures on the product yields; these products can be used for preparation of macrocyclic compounds. The conversion of aniline into 2-aryl/alkylaminocyclohexanol on a 100 mmol scale proceeded just as well as the 1 mmol reaction.

The ratio of the two regioisomeric products was determined by GC–MS and ^{1}H NMR (based on the methane and methylene proton signals). In the MS the regioisomer of α-product exhibited a daughter ion at *m*/*z* ($M^+ - 31$) due to the CH_2OH, and the diagnostic feature in the mass spectra of the β-product (**3a**) was the ion peak at *m*/*z* ($M^+ - 106$) arising from the loss of PhCHO. The GC–MS revealed the product to be a mixture of β-product (**3a**) and α-product in a ratio of 95:5 on the basis of the daughter ions at *m*/*z* 228–106 and 228–31, corresponding to β-product (**3a**) and α-product, respectively. Also, a 95:5 ratio could be determined for β-product (**3a**): α-product, taking into consideration the integral values of the corresponding benzyl protons.

Excellent chemo selectivity was achieved with epichlorohydrin (Table 2, entry 4) resulting in 93% yield of the amino alcohol corresponding to nucleophilic attack at the terminal carbon of the epoxide moiety. No product arising from nucleophilic displacement of the chlorine could be detected through MS analysis of the reaction mixture.

The reuse ability and catalytic activity of MgO was studied in this system. The catalyst was recovered by centrifugation after diluting the reaction mixture with Et_2O and dried in an oven at 100 °C for 3 h and was reused repeatedly without any significant loss of catalytic activities. As shown in Table 3, the yields of 2-(2-picolylamine)cyclohexanol (**3d**) only decreases a little after the reuse of MgO for three times.

In conclusion, the results demonstrated that MgO efficiently catalyze the formation of β-amino alcohols from amines and epoxides in high yields under mild and solvent-free reaction conditions. The facile synthesis of these materials, their benign nature, the ease of handling, and the simplified reaction and isolation procedures make them a highly attractive alternative to current methodologies.

Experimental

Chemicals were purchased from Fluka, Merck, B. D. H., and Aldrich Chemical Companies. Progress of the reactions was followed by TLC using silica-gel polygrams SIL G/UV 254 plates. NMR spectra were recorded on a Bruker DPX 250 MHz instrument. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus. Microanalyses were performed on a PerkinElmer 240-B microanalyzer.

General procedure

A mixture of MgO (10 mol%, 0.004 g), amine (1 mmol), and 1,2-epoxide (1 mmol) was heated in an oil bath at 80 °C and stirred with a magnetic stirrer. The progress of the reaction was monitored by TLC. After the reaction was complete, the obtained product was poured into water, stirred well to dissolve the MgO, and then extracted with ethyl acetate. The organic solvent was then evaporated, and the pure product was obtained. This was further purified by recrystallization with a suitable solvent (ether). The regioisomers were separated after silica-gel column chromatography (20% Hexane/EtOAc). The structures of the products were confirmed by GC–MS, ^{1}H NMR, ^{13}C NMR, and comparison with authentic samples obtained commercially or prepared by reported methods.

Lewis acid catalyzed Claisen rearrangement: Regioselective synthesis of oxygen, nitrogen, and sulfur heterocycles

K.C. Majumdar and A.K. Pal

Abstract: Regioselective synthesis of pentacyclic heterocycles containing oxygen, nitrogen, and sulfur has been achieved in good to excellent yields by the sequential Claisen rearrangement of but-2-ynyl ethers and sulfides containing quinolone moiety. The substrates ethers and sulfides were prepared from 1-aryloxy-4-chlorobut-2-ynes with *N*-alkyl-4-hydroxyquinoline-2(1*H*)-ones.

Key words: regioselectivity, [3,3] sigmatropic rearrangement, nucleophilicity of sulfur, aluminium chloride, heterocycles.

Résumé : On a réalisé la synthèse régiosélective d'hétérocycles pentacycliques contenant des atomes d'oxygène, d'azote et de soufre avec des rendements allant de bons à excellents en procédant à un réarrangement de Claisen séquentiel d'éthers et de sulfures de but-2-ynyle comportant une portion quinoléinone. Les éthers et les sulfures utilisés comme substrats ont pour leur part été préparés à partir de 1-aryloxy-4-chlorobut-2-ynes avec des *N*-alkyl-4-hydroxyquinoléin-2-(1*H*)-ones.

Mots-clés: régiosélectivité, réarrangement sigmatropique [3.3], caractère nucléophile du soufre, chlorure d'aluminium, hétérocycles.

[Traduit par la Rédaction]

Introduction

Quinolone alkaloids are interesting owing to their antimicrobial activity and cytotoxicity against animal and plant tumors (1). Recently, a novel class of 4-hydroxy quinolin-2(1*H*)-one derivatives as selective glycine site NMDA antagonist, possessing potent centrally mediated in vivo activity on oral administration, has been reported (2). Quinolone derivatives exhibit different activities depending on their structural type (3). Flindersine, 2,2-dimethylpyrano[3,2-*c*]quinolin-5(2*H*)-one, various substituted flindersine, furo[3,2-*c*]quinolin-4(5*H*)-one, and 2*H*-pyrano[3,2-c]quinolin-5(6*H*)-one derivatives are widely distributed in nature (4). A good deal of work has been done on the synthesis (5) of these types of compounds with various substitutions in the aromatic ring. The familiar bioactivity of various quinolone derivatives has drawn our attention to this area, and we became interested in synthesizing [6,5] fused pentacyclic heterocycles in which the bioactive quinolone moiety is fused with benzofuran moiety.

Strategies involving Claisen rearrangement have emerged as important tools in the synthesis of various heterocyclic compounds. Since 1912, several classes of organic compounds have been synthesized by Claisen rearrangement, and many of them are biologically active (6). Claisen rearrangement can be performed catalytically (6, 7). Earlier studies in the synthesis of different oxygen, sulfur, and nitrogen heterocycles by the application of [3,3] sigmatropic rearrangement of suitably tailored 1,4-disubstitued but-2-ynes have led to the synthesis of new heterocyclic compounds derived from 4-hydroxy coumarin (8), 4-hydroxy dithiocoumarin (9). Both the first and second Claisen rearrangements were achieved thermally. This result has encouraged us to undertake a study on the sequential [3,3] sigmatropic rearrangement of *N*-alkyl-4-(4′-aryloxybut-2′-ynyloxy)quinolin-2(*1H*)-one and *N*-alkyl-(4-aryloxybut-2-ynyloxy)quinolin-2(*1H*)-thione to achieve our goal. Herein, we report the results.

Results and discussion

The requisite starting materials for this study, 1-alkyl-4-[(4′-aryloxybut-2′-ynyl)]quinoline-2(1*H*)-ones (**3a**–**3h**), were prepared by either classical alkylation of *N*-alkyl-4-hydroxyquine-2(1*H*)-ones (**1**) with a number of different 1-aryloxy-4-chlorobut-2-ynes (**2a**–**2e**) in acetone/K_2CO_3 or PTC alkylation using TBAB as a catalyst in aq. NaOH/chlorobenzene at 100 °C. The PTC alkylation was faster and gave higher yields (71%–85%), whereas classical alkylation needed longer reaction time, and yields of **3a**–**3h** were relatively lower (30%–40%). The formation of **3a**–**3h** was indicated in the IR spectra by the absence of –OH stretching and also from their ^{1}H NMR spectra (Scheme 1). When compound **3e** was refluxed with phosphrous pentasulfide in dry benzene for 3 h, a yellow solid was isolated from the reaction mixture. This was characterized as **4e** from its elemental analysis and spectroscopic data. Formation of a

single product from the reaction encouraged us to synthesize other derivatives **4f**–**4h** from **3f**–**3h** in 63%–69% yields (Scheme 1).

Compounds **3a**–**3f** and **4e**–**4h** contain allyl-propargyl ether moiety and are prone to undergo [3,3] sigmatropic rearrangement. The substrate **3a** was refluxed in chlorobenzene (bp 132 °C) for 8 h to give angularly fused compound **5a** in 43% yield, whereas under the same reaction conditions, compound **4e** furnished linearly fused **6e** in 49% yield. When high boiling solvent like *o*-dichlorobenzene (bp 180 °C) was used, overall yields of the products were increased to 83% and 85%, respectively, and it also shortened the reaction time. On similar treatment, compounds **3b**–**3f** and **4f**–**4h** afforded **5b**–**5f** and **6f**–**6h** in 70%–81% and 81%–89% yields, respectively (Scheme 2).

The formation of products **5a**–**5f** and **6e**–**6h** from substrates **3a**–**3f** and **4e**–**4h** may easily be explained by the initial [3,3] sigmatropic rearrangement followed by rapid enolisation and [1,5] hydrogen shift to give intermediate **9** and 6π electrocyclic ring closure (ECR) to give final products **5a**–**5f** and **6e**–**6h**. The exclusive formation of **6e**–**6h** instead of **11** from **4e**–**4h** may be due to the presence of sulfur, which has larger nucleophilicity and greater polarisibility (10) (Scheme 3).

The products **5a**–**5f** and **6e**–**6h** contain allyl aryl ether moiety and therefore are suitable substrates for the occurrence of a second Claisen rearrangement. However, this would require higher temperature and longer time than the first [3,3] sigmatropic rearrangement of compounds **3a**–**3f** or **4e**–**4h**, as during this rearrangement, the aromaticity of the aryl moiety would be disturbed. The same transformation could also be carried out by using Lewis-acid-catalyzed Claisen rearrangement under mild conditions. The reaction of the substrates **5a** and **6e** were conducted with catalytic amount of anhyd. $AlCl_3$ in dry DCM and stirred at room temperature for 30–45 min. The rearranged products **12a** and **13e** were obtained in 79% and 75% yields, respectively (Scheme 4). Encouraged by the initial success, substrates **5b**–**5f** and **6f**–**6h** were similarly treated, and the corresponding products **12b**–**12f** and **13f**–**13h** were obtained in 72%–83% and 72%–79% yields, respectively. The stereochemistry of the furopyran ring junction, previously surmised from molecular model (Dreiding model) in similar situation to cis (10), was now established to be cis on the basis of molecular modeling and NOE correlation. In case of compound **12f**, NOE correlation was found between the ring junction methyl proton resonance at δ = 1.84 ppm and benzylic proton resonate at δ = 3.44 ppm, (Scheme 4).

The formation of products **12a**–**12f** may be mechanistically explained by the charge-accelerated [3,3] sigmatropic rearrangement of **5a**–**5f** to **15** via ether oxygen $AlCl_3$ complex **14** followed by rapid tautomerization and proton exchange to give intermediate **16**, which may then undergo 5-exo-cyclization leading to products **12a**–**12f**. Previously, [6,6] fused products were obtained (11). Intermediates, similar to **16**, were isolated (12) and converted to [6,6] fused products with pyridine hydrotribromide ($PyHBr_3$). However, we failed to isolate intermediate **16** or [6,6] fused products;

only [6,5] fused products **12a**–**12f** were obtained under catalytic condition. Formation of the products **13e**–**13h** from **6e**–**6h** can also be explained by the same mechanism as shown in Scheme 5.

In summary, we have successfully performed sequential Claisen rearrangement, a *oxy*-Claisen rearrangement of *N*-alkyl-4-(4′-aryloxybut-2′-ynyloxy)-quinoline-2(1*H*)-ones and *thio*-Claisen rearrangement of compound *N*-alkyl-4-(4′-aryloxybut-2′-ynyloxy)-quinoline-2(1*H*)-thione. This methodology is simple for the construction of furo pyran and furo thiopyran rings and displays appreciable regioselectivity.

Experimental

Melting points were determined in open capillaries and are uncorrected. IR spectra were recorded on a PerkinElmer L 120–000A spectrometer (ν_{max} in cm^{-1}) using samples as neat liquids, and solid samples were recorded in

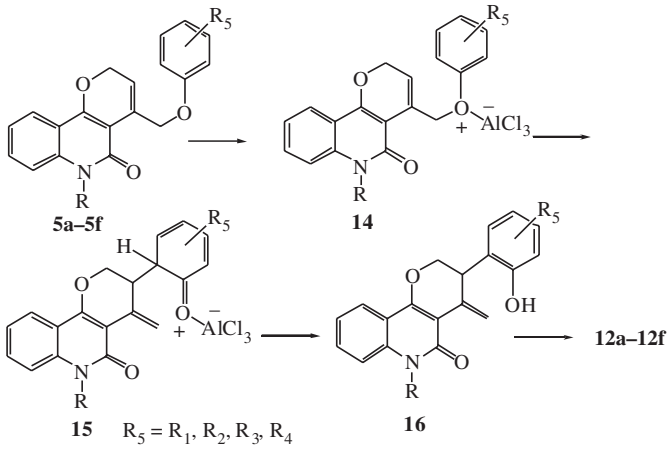
Scheme 5.



KBr disks. ^{1}H NMR (300 MHz, 400 MHz, 500 MHz) spectra were recorded on a Bruker DPX-300, Bruker DPX-400, and Bruker DRX-500 spectrometer in $CDCl_3$ (chemical shift in δ) with TMS as internal standard. Silica gel [(60–120 and 230–400 mesh), Spectrochem, India] was used for chromatographic separation. Silica gel G [E-Merck (India)] was used for TLC. Petroleum ether refers to the fraction boiling between 60 °C and 80 °C.

Preparation of *N*-alkyl-4-(4′-aryloxybut-2′-ynyloxy)quinoline-2(1H)-one derivatives 3a–3h

To a mixture of *N*-alkyl-4-hydroxy quinoline-2(1*H*)-one (**1**) (6 mmol) and 1-aryloxy-4-chloro-but-2-ynes (**2a**–**2e**) (7.2 mmol) in chlorobenzene (50 mL) was added a solution of TBAB (0.23 g, 0.72 mmol) in 1% aq. NaOH (50 mL), and the mixture was stirred for 3–4 h at 100 °C. The reaction mixture was diluted with water and extracted with CH_2Cl_2 (2 × 50 mL). The combined extract was washed successively with 2 N HCl (2 × 20 mL), water (3 × 30 mL), saturated brine solution (25 mL), and dried (Na_2SO_4). The solvent was removed in vacuo, and the crude products were purified by column chromatography over silica gel using petroleum ether/ethyl acetate (3:2) as eluant and recrystallized from dichloromethane/petroleum ether.

Compound 3a

Yield: 80%. Light yellow solid; mp 112–114 °C. IR (KBr) ν: 2978, 1641 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 2.18 (s, 3H), 3.67(s, 3H), 4.75 (s, 2H), 4.84 (s, 2H), 6.13 (s, 1H), 6.87–8.03 (m, 8H) ppm. MS *m*/*z*: 333 [M$^+$]. Anal. calcd. for $C_{21}H_{19}NO_3$: C, 75.66; H, 5.74; N, 4.20; found: C, 75.87; H, 5.86; N, 4.13.

Compound 3b

Yield: 76%. Light yellow solid; mp 101–103 °C. IR (KBr) ν: 2923, 1638 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 2.17 (s, 3H), 2.25 (s, 3H), 3.66 (s, 3H), 4.73 (s, 2H), 4.84 (s, 2H), 6.10 (s, 1H), 6.67–7.97 (m, 7H) ppm. MS *m*/*z*: 347 [M$^+$]. Anal. calcd. for $C_{22}H_{21}NO_3$: C, 76.06; H, 6.09; N, 4.03; found: C, 76.32; H, 6.23; N, 4.06.

Compound 3c

Yield: 71%. Light yellow solid; mp 120–122 °C. IR (KBr) ν: 2922, 1655 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 3.67 (s, 3H), 4.80 (s, 2H), 4.84 (s, 2H), 6.08 (s, 1H), 6.93–7.95 (m, 8H) ppm. MS *m*/*z*: 353, 355 [M$^+$]. Anal. calcd. for $C_{20}H_{16}ClNO_3$: C, 67.90; H, 4.56; N, 3.96; found: C, 67.87; H, 4.58; N, 3.89.

Compound 3d

Yield: 79%. Light yellow solid; mp 124–126 °C. IR (KBr) ν: 2937, 1642 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 1.34 (t,

J = 7.05 Hz, 3H), 2.23 (s, 3H), 4.29 (q, J = 7.02 Hz, 2H), 4.74 (s, 2H), 4.82 (s, 2H), 6.10 (s, 1H), 6.94–7.99 (m, 8H) ppm. MS *m/z*: 347 [M^+]. Anal. calcd. for $C_{22}H_{21}NO_3$: C, 76.06; H, 6.09; N, 4.03; found: C, 75.85; H, 6.08; N, 4.07.

Compound 3e

Yield: 85%. Light yellow solid; mp 119–121 °C. IR (KBr) ν: 2924, 1642 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 2.27 (s, 3H), 3.67 (s, 3H), 4.69 (s, 2H), 4.84 (s, 2H), 6.09 (s, 1H), 6.69–7.96 (m, 7H) ppm. MS *m/z*: 367, 369 [M^+]. Anal. calcd. for $C_{21}H_{18}ClNO_3$: C, 68.57; H, 4.93; N, 3.81; found: C, 68.40; H, 4.96; N, 3.84.

Compound 3f

Yield: 82%. Light yellow solid; mp 127–128 °C. IR (KBr) ν: 2912, 1644 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 2.28 (s, 6H), 3.66 (s, 3H), 4.68 (s, 2H), 4.84 (s, 2H), 6.09 (s, 1H), 6.65–7.96 (m, 6H) ppm. MS *m/z*: 381, 383 [M^+]. Anal. calcd. for $C_{22}H_{20}ClNO_3$: C, 69.20; H, 5.28; N, 3.67; found: C, 69.27; H, 5.24; N, 3.78.

Compound 3g

Yield: 74%. Light yellow solid; mp 145–147 °C. IR (KBr) ν: 2929, 1645cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 1.31 (t, J = 7.12 Hz, 3H), 2.28 (s, 3H), 4.29 (q, J = 7.12 Hz, 2H), 4.69 (s, 2H), 4.83 (s, 2H), 6.08 (s, 1H), 6.69–7.97 (m, 7H) ppm. MS *m/z*: 381, 383 [M^+]. Anal. calcd. for $C_{22}H_{20}ClNO_3$: C, 69.20; H, 5.28, N, 3.67; found: C, 69.27; H, 5.22; N, 3.55.

Compound 3h

Yield: 81%. Light yellow solid; mp 132–134 °C. IR (neat) ν_{max}: 2927, 1629 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 1.30 (t, J = 7.05 Hz, 3H), 2.29 (s, 6H), 4.27 (q, J = 7.04 Hz, 2H), 4.68 (s, 2H), 4.84 (s, 2H), 6.09 (s, 1H), 6.66–7.97 (m, 6H) ppm. MS: *m/z* 395, 397 [M^+]. Anal. calcd. for $C_{23}H_{22}ClNO_3$: C, 69.78; H, 5.60; N, 3.54; found C, 69.52; H, 5.55; N, 3.75.

Thionation of compounds 3e–3h

P_2S_5 (3.35 g, 15 mmol) was added to a solution of **3e**–**3h** (6 mmol) in dry benzene (50 mL) and refluxed for 3–4 h. The reaction mixture was cooled and extracted with benzene (3 × 30 mL), and the benzene layer was washed with water (4 × 30 mL), brine solution (25 mL), and dried (Na_2SO_4). Evaporation of the solvent gave a crude mass, which was chromatographed over silica gel (60–120 mesh). Solid products **4e**–**4h** were isolated in 63%–69% yields when the column was eluted with petroleum ether/ethyl acetae (8.5:1.5). The products were recrystallized from dichloromethane/petroleum ether.

Compound 4e

Yield: 65%. Yellow solid; mp 147–148 °C. IR (neat) ν_{max}: 2952, 1591 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.29 (s, 3H), 4.28 (s, 3H), 4.68 (s, 2H), 4.88 (s, 2H), 6.71–8.04 (m, 7H) ppm. MS *m/z*: 383, 385 [M^+]. Anal. calcd. for $C_{21}H_{18}ClNO_2S$: C, 65.70; H, 4.73; N, 3.65; found C, 65.51; H, 4.63; N, 3.52%.

Compound 4f

Yield: 63%. Yellow solid; mp 136–138 °C. IR (neat) ν_{max}: 2948, 1600 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.28 (s, 6H), 4.29 (s, 3H), 4.67 (s, 2H), 4.88 (s, 2H), 6.65–8.02 (m, 6H) ppm. MS *m/z*: 397, 399 [M^+]. Anal. calcd. for $C_{22}H_{20}ClNO_2S$: C, 66.40; H, 5.07; N, 3.52; found C, 66.45; H, 5.16; N, 3.38.

Compound 4g

Yield: 69%. Yellow solid; mp 119–121 °C. IR (neat) ν_{max}: 2953, 1592 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 1.42 (t, J = 7.08 Hz, 3H), 2.28 (s, 3H), 4.70 (s, 2H), 4.87 (s, 2H), 5.01 (br s, 2H), 6.69–8.03 (m, 7H) ppm. MS *m/z*: 397, 399 [M^+]. Anal. calcd. for $C_{22}H_{20}ClNO_2S$: C, 66.40; H, 5.07; N, 3.52; found C, 66.64; H, 5.14; N, 3.37.

Compound 4h

Yield: 67%. Yellow solid; mp 155–157 °C. IR (neat) ν_{max}: 2948, 1610 cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz) δ: 1.42(t, J = 7.01 Hz, 3H), 2.30 (s, 6H), 4.70 (s, 2H), 4.88 (s, 2H), 4.95(br s, 2H), 6.67–8.04 (m, 6H) ppm. MS *m/z*: 411, 413 [M^+]. Anal. calcd. for $C_{23}H_{22}ClNO_2S$: C, 67.06; H, 5.38; N, 3.40; found C, 66.87; H, 5.39; N, 3.51.

Rearrangement of compounds 3a–3f and 4e–4h

Compound **3a**–**3f** and **4e**–**4h** (1.2 mmol) was dissolved in *o*-dichlorobenzene (5 mL) and refluxed for 1–4 h. The reaction mixture was chromatographed over silica gel (60–120 mesh). *o*-Dichlorobenzene was removed by washing the column with petroleum ether (60–80 °C), and pure products **5a**–**5f** and **6e**–**6h** were isolated by eluting the column with petroleum ether/ethyl acetate. These were recrystallized from dichloromethane/petroleum ether.

Compound 5a

Yield: 83%. Light yellow solid; mp 124–126 °C. IR (neat) ν_{max}: 2921, 1631 cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.30 (s, 3H), 3.68 (s, 3H), 4.95 (d, J = 1.65 Hz, 2H), 5.27 (d, J = 1.53 Hz, 2H), 5.96 (t, J = 1.72 Hz, 1H), 6.82–7.97 (m, 8H) ppm. MS *m/z*: 333 [M^+]. Anal. calcd. for $C_{21}H_{19}NO_3$: C, 75.66; H, 5.74; N, 4.20; found C, 75.62; H, 5.97; N, 4.02.

Compound 5b

Yield: 77%. Light yellow solid; mp 139–142 °C. IR (neat) ν_{max}: 2923, 1654 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.25 (s, 3H), 2.30 (s, 3H), 3.68 (s, 3H), 4.96 (d, J = 1.88 Hz, 2H), 5.24 (d, J = 1.92 Hz, 2H), 5.99 (t, J = 1.88 Hz, 1H), 6.65–7.96 (m, 7H) ppm. MS *m/z*: 347 [M^+]. Anal. calcd. for $C_{22}H_{21}NO_3$: C, 76.06; H, 6.09; N, 4.03; found C, 76.32; H, 6.23; N, 4.05.

Compound 5c

Yield: 70%. Light yellow solid; mp 158–160 °C. IR (neat) ν_{max}: 2935, 1663 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 3.67 (s, 3H), 4.97 (d, J = 1.76 Hz, 2H), 5.33 (d, J = 1.84 Hz, 2H), 6.08 (t, J = 1.61 Hz, 1H), 6.86–7.96 (m, 8H) ppm. Rearrangement of compounds 5a–5f and 6e–6h

Anhydrous $AlCl_3$ (0.025 mmol) was added to a solution of **5a** (0.25 mmol) in dry dichloromethane (10 mL) under nitrogen atmosphere and stirred at room temperature for 30–45 min. Dichloromethane (20 mL) and crushed ice were added to the reaction mixture. Dichloromethane layer was washed with water (2 × 10 mL), brine (10 mL), and dried over anhyd. Na_2SO_4. The solvent was distilled off and the residue was subjected to column chromatography over silica gel. Elution of the column with petroleum ether/ethyl acetate afforded compound **12a**. Products **12b**–**12f** and **13e**–**13h** were also similarly obtained. These products were recrystallized from dichloromethane/petroleum ether.

Compound 12a

Yield: 79%. Light yellow solid; mp 160–161 °C. IR (neat) ν_{max}: 2947, 1627 cm^{-1}. ^1H NMR ($CDCl_3$, 500 MHz) δ: 1.96 (s, 3H), 2.25 (s, 3H), 3.46 (dd, *J* = 4.64 and 8.97 Hz, 1H), 3.70 (s, 3H), 4.06 (t, *J* = 9.09 Hz, 1H), 4.45 (dd, *J* = 4.64 and 11.24 Hz, 1H), 6.78–7.95 (m, 7H) ppm. MS *m/z*: 333 [M+]. Anal. calcd. for $C_{21}H_{19}NO_3$: C, 75.66; H, 5.74; N, 4.20; found C, 75.69; H, 5.57; N, 4.03.

Compound 12b

Yield: 75%. Light yellow solid; mp 177–178 °C. IR (neat) ν_{max}: 2952, 1613 cm^{-1}. ^1HNMR ($CDCl_3$, 400 MHz) δ: 1.82 (s, 3H), 2.23 (s, 3H), 2.33 (s, 3H), 3.43 (dd, *J* = 4.52 and 8.02 Hz, 1H), 3.59 (t, *J* = 9.04 Hz, 1H), 3.71 (s, 3H),), 4.54 (dd, *J* = 4.65 and 11.18 Hz, 1H), 6.61–7.98 (m, 6H) ppm. ^{13}CNMR ($CDCl_3$, 125 MHz) δ: 15.6, 18.6, 23.6, 29.5, 48.4, 66.7, 82.5, 109.9, 114.2, 115.9, 118.8, 121.9, 122.0, 123.7, 124.3, 130.8, 131.8, 132.5, 139.8, 157.0, 159.0, 162.2. MS *m/z*: 347 [M+]. Anal. calcd. for $C_{22}H_{21}NO_3$: C, 76.06; H, 6.09; N, 4.03; found C, 75.94; H, 6.13; N, 4.14.

Compound 12c

Yield: 72%. Light yellow solid; mp 203–205 °C. IR (neat) ν_{max}: 2956, 1615 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ: 2.03 (s, 3H), 3.55 (dd, *J* = 4.49 and 8.56 Hz, 1H), 3.69 (s, 3H), 4.11 (t, *J* = 8.70 Hz, 1H), 4.45 (dd, *J* = 4.64 and 11.35 Hz, 1H), 6.80–7.93 (m, 7H) ppm. Co-operative hydration of the carbonyl group — "Bifunctional catalysis" by 2-hydroxypyridine is achieved via a dihydrate of 2-pyridone

Yih-Huang Hsieh, Noham Weinberg, and Saul Wolfe

Abstract: Although 2-hydroxypyridine is one thousand times less acidic than its isomer 3-hydroxypyridine and ten million times less acidic than acetic acid, in the aqueous hydration of 1 mol/L acetone at 298 K the catalytic effect of added 2-hydroxypyridine is 600 000 times greater than that of 3-hydroxypyridine and 20 times greater than that of acetic acid. This experimental result is successfully reproduced by a theoretical treatment that assumes that solvent molecules participate in a cyclic cooperative mechanism that avoids the formation of charged intermediates. However, the theoretical treatment does not support the seemingly obvious conclusion that the origin of the enhanced catalytic activity of 2-hydroxypyridine lies in its bifunctional nature. Rather, this enhanced catalytic activity can be traced to the exceptional thermodynamic stability of the principal reactant complex, which contains a dihydrate of 2-pyridone.

Key words: hydration, isotope shift, bifunctional, cooperativity, cyclic mechanism, ab initio, SCRF

Résumé : Même si la 2-hydroxypyridine est mille fois moins acide que son isomère, la 3-hydroxypyridine, et dix millions de fois moins acide que l'acide acétique, l'effet catalytique provoqué par l'addition de 2-hydroxypyridine sur la réaction d'hydratation aqueuse d'une solution 1 mol/L d'acétone à 298 K est 600 000 fois plus grand que celui de la 3-hydroxypyridine et que 20 fois celui de l'acide acétique. On peut facilement reproduire ce résultat expérimental par un traitement théorique qui fait l'hypothèse que les molécules de solvant participent à un mécanisme coopératif cyclique qui évite la formation d'intermédiaires chargés. Toutefois, le traitement théorique n'apporte aucun support à la conclusion qui paraît évidente que l'origine de l'activité catalytique élevée de la 2-hydroxypyridine tient à sa nature bifonctionnelle. Cette activité catalytique élevée est plutôt attribuée à la stabilité thermodynamique exceptionnelle du complexe réactif principal qui contient un dihydrate de la 2-pyridone.

Mots-clés : hydratation, déplacement isotopique, bifonctionnel, coopération, mécanisme cyclique, ab initio, champ réactionnel autocohérent (CRAC).

[Traduit par la Rédaction]

Introduction

We have recently reported that the neutral hydration of a carbonyl group in water solvent *does not proceed via ionic intermediates* (1). Instead, as originally suggested by Eigen and by Long and co-workers (2), a cyclic *cooperative* process (e.g., eq. [1]) in which concurrent C–O bond formation and proton transfer to oxygen take place through a solvent bridge, comprises a neutral alternative that avoids the need to solvate and desolvate charged species continuously as these species appear and disappear.

The mechanism depicted in eq. [1] seems superficially to resemble eq. [2], "bifunctional" acid-base catalysis of the anomerization of tetramethylglucose (3), and other reactions (4) that are coupled to 2-hydroxypyridine/2-pyridone tautomerism within a cyclic neutral complex. However, unlike eq. [1], bifunctional catalysis by 2-hydroxypyridine requires a *nonaqueous* nonpolar environment that resembles the "water-repelling lipid-like" active site of an enzyme (5, cited in ref. 6), and this has led to the suggestion that "enzyme model studies in nonpolar solvents are … more relevant than similar studies in aqueous media" (5).

[2] 
In the present paper we provide experimental evidence of substantial catalysis of the aqueous hydration of acetone by added 2-hydroxypyridine together with continued theoretical support for the notion of cooperativity in this reaction. However, the theoretical analysis also leads to the unexpected conclusion that the catalysis does not originate in the bifunctional nature of 2-hydroxypyridine, so that the aqueous and gas-phase (7) catalytic mechanisms are not the same.

Materials and methods

2-Hydroxypyridine (Sigma-Aldrich) and 3-hydroxypyridine (Sigma-Aldrich) were recrystallized from ethyl acetate-hexane. $H_2{}^{16}O$ was obtained from an Easypure UV/UF ultra pure water system. $H_2{}^{18}O$ (95% enriched) was purchased from Sigma-Aldrich. $D_2{}^{16}O$ (99.99% enriched) was obtained from CDN isotopes, Pointe Claire, Quebec. $H_2{}^{18}O$ (49.1% enriched), prepared by mixing $H_2{}^{18}O$ (2.2995 g, 95% enriched) with $H_2{}^{16}O$ (2.1714 g), was stored at –20 °C in a five-dram vial fitted with a Teflon pad. Acetone-2-^{13}C (1.0 g, 98% enriched, Sigma-Aldrich) was transferred by syringe into 50 microcapillary tubes which were sealed and stored at room temperature (22 °C).

Kinetic measurements

NMR spectra were recorded on a Bruker 600 AMX spectrometer operating at a frequency of 150.03 MHz. The probe temperature was maintained at 298.0 ± 0.1 K using a Euroterm VT temperature regulator. All runs were performed in the same 2.0 mm diameter micro NMR tube. Before every run, the tube was rinsed with acetone and water, oven dried at 110 °C for at least 15 min, and then cooled in vacuo for an additional 30 min.

Proton decoupled ^{13}C NMR spectra were recorded as a single scan at different times to obtain the peaks of $(CH_3)_2{}^{13}C={}^{16}O$ [^{16}O] and $(CH_3)_2{}^{13}C={}^{18}O$ [^{18}O], whose chemical shifts differ by 0.05 ppm (1*b*, 1*c*). These spectra were integrated to obtain the [^{18}O]/[^{16}O] ratio (ρ) as a function of time.

The pseudo first-order rate constant k_{obs} for 2-hydroxypyridine was obtained from the kinetic data by nonlinear least-squares fit to eq. [3*a*] (1*c*) using Version 3.07 of the computer programme GRAFIT (Erithacus Software Ltd., P. O. Box 274, Horley Surrey, UK, RH6 9YJ).

$$[3a] \quad \frac{1}{1+\rho} = Ae^{-k_{obs}t} + C$$

In the case of 3-hydroxypyridine, where the reaction was significantly slower and did not approach equilibrium, the rate constant k_{obs} was obtained from a linear least-squares fit to eq. [3*b*] (1*b*), which is derived from eq. [3*a*] when the equilibrium value of ρ is 1.

$$[3b] \quad \ln\left(\frac{1-\rho}{1+\rho}\right) - k_{obs}t + \ln\left(\frac{1-\rho_0}{1+\rho_0}\right)$$

Experiments with 2-hydroxypyridine (2-HP)

2-Hydroxypyridine (104.6 mg, 1.10 mmol), in $H_2{}^{16}O$, was diluted to 25.00 mL to give a 44.04 mmol/L solution, 2.50 mL of this solution were diluted to 25.00 mL with $H_2{}^{16}O$ to give a 4.40 mmol/L solution, 2.50 mL of the 4.40 mmol/L solution were diluted to 25.00 mL with $H_2{}^{16}O$ to give a 0.44 mmol/L solution, and 0.1596 g (8.9 mmol) of this solution was added to $H_2{}^{18}O$ (0.1800 g, 9.0 mmol, 95.0% enriched) to give 50.4% ^{18}O-enriched water. To begin a run, 8.0 µL of acetone-2-^{13}C (6.4 µg, 0.11 µmol, 98% enriched) were injected into 100.0 µL of the above solution to give a solution of 1.0 mol/L in acetone and 0.22 mmol/L in 2-hydroxypyridine. This solution was transferred immediately to the micro NMR tube and the spectra were recorded.

Experiments with 3-hydroxypyridine (3-HP)

3-Hydroxypyridine (26.0 mg, 0.27 mmol) was dissolved in 10.00 mL of $H_2{}^{16}O$ to give a 2.7×10^{-2} mol/L solution, and 47.0 µL of this solution were injected into $H_2{}^{18}O$ (53.0 µL, 95.0% enriched) to give a 1.3×10^{-2} mol/L 3-hydroxypyridine solution in 50.4% enriched $H_2{}^{18}O$. To begin a run, 8.0 µL of acetone-2-^{13}C (6.4 µg, 0.11 µmol, 98% enriched) were injected into 100.0 µL of the 3-hydroxypyridine solution to give a solution 1.0 mol/L in acetone and 1.3×10^{-2} mol/L in 3-hydroxypyridine. This solution was transferred immediately to the micro NMR tube and the spectra were recorded.

Computational details

Calculations were performed using Gaussian 98 (8) at the Hartree–Fock level with the 3–21G basis set (9). The nature of the fully optimized stationary points was verified using

© 2007 NRC Canada

frequency analysis. All transition structures exhibited one imaginary frequency.[4]

As in our previous work (1) the SCRF (Onsager) model (10, 11) was used to describe water solvent with a dielectric constant of 78.5. Free energies of bimolecular processes were corrected for the loss of translational and rotational degrees of freedom and were calculated using eq. [4] as described in refs. 1*a* and 1*b*.

$$[4]\qquad \Delta G = \Delta H - T\Delta S_{\text{vib}} - \\ -6RT\left\{\frac{\hbar\omega/kT}{\exp(\hbar\omega/kT)-1} - \ln\left[1-\exp\left(\frac{\hbar\omega}{kT}\right)\right]\right\}$$

The first term on the right is the enthalpy change calculated by the Gaussian programme corrected for the basis set superposition error (BSSE) (1, 12) associated with the use of the 3–21G basis set. The second term on the right accounts for the intramolecular vibration entropy change and is also calculated by the Gaussian programme. The third term on the right describes the entropy change because of the loss of six low-frequency vibration modes representing rotational and translational motions in solution. These vibrations are described by a mass-dependent effective frequency ω, scaled as a root of molecular mass (1*b*),

$$\omega = \omega_0\sqrt{m/m_0}$$

and defined in terms of a single adjustable parameter ω_0, that is estimated numerically for water monomer (m_0 = 18 au) to be ca 20 cm^{-1} (1*a*).

As a first step, the treatment of the cooperative *neutral* hydration of a carbonyl compound included the calculation of the free energies of each of the stationary structures and the equilibrium and rate constants shown in Scheme 1 in water solvent, wherein W_nC is a cyclic complex of a carbonyl compound C (RR′C=O) with n water molecules (n = 1–4), and $(TS)_n$ is a cyclic transition structure derived from W_nC.

The assumption that the water clusters W_n are in rapid equilibrium with each other and with the W_nC complexes allow the effective pseudo first-order rate constant k to be expressed as,

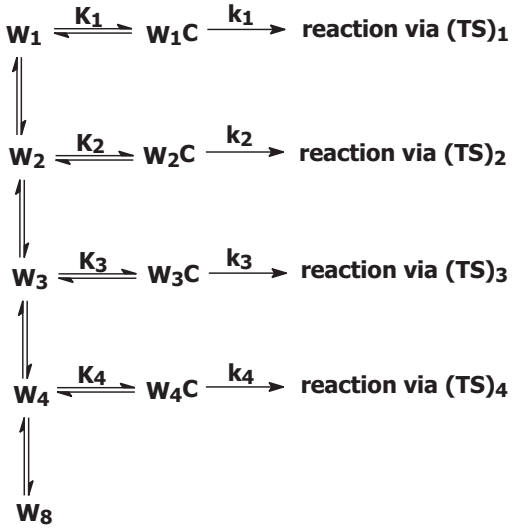
$$[5]\qquad k = \frac{\sum k_n[W_nC]}{[C]+[W_nC]} = \frac{\sum k_n K_n K_n^w [W_1]^n}{1+\sum K_n K_n^w [W_1]^n}$$

In eq. [5] the equilibrium constants K_n^w relate the concentrations of water clusters $[W_n]$ to the concentration of water monomer $[W_1]$, which can be expressed in terms of C_w, the overall concentration of water, by eq. [6],

$$[6]\qquad \sum K_n^w [W_1]^n = C_w$$

To extend this protocol to the hydration of acetone in the presence of 2-hydroxypyridine, Scheme 1 has to be expanded to Scheme 2, which includes monohydrates and dihydrates (13) of 2-hydroxypyridine (2-HP) and its 2-pyridone tautomer (2-PD) (14).

Scheme 1.



Here, as in Scheme 1, W_n, W_nC, and TS_n are water clusters, acetone–water complexes, and associated transition states, respectively. The unhydrated tautomers H (≡2-HP) and P (≡2-PD) are in equilibrium with each other and with their dimers H_nP_m ($n + m = 2$, structures **9a**–**9c**) (15), as well as with their monohydrates $W_1H\mu$ (μ = 1–4, structures **1a**–**1d**) and $W_1P\mu$ (μ = 1–3, structures **3a**–**3c**), and dihydrates $W_2H\mu$ (μ = 1–5, structures **2a**–**2e**), and $W_2P\mu$ (μ = 1, structure **4a**); $W_1HC\mu$ (μ = 1–2, structures **5a** and **5b**), $W_2HC\mu$ (μ = 1–4, structures **6a**–**6d**), $W_1PC\mu$ (μ = 1, structure **7**), and $W_2PC\mu$ (μ = 1–2, structures **8a** and **8b**) are acetone–water catalyst complexes, and TSH1μ, TSH2μ, TSP1μ, and TSP2μ are the transition structures of the catalyzed channels.

With K_n, K_τ, K_{nm}^{D}, K_n^{W}, $K_{n\mu}^{WH}$, $K_{n\mu}^{WP}$, $K_{n\mu}^{H}$, and $K_{n\mu}^{P}$ as the equilibrium constants, the following relationships exist among the equilibrium concentrations of the components of Scheme 2:

$$[P] = K_\tau[H]$$

$$[H_nP_m] = K_{nm}^{D}[H]^n[P]^m = (K_\tau)^m K_{nm}^{D}[H]^2$$

$$[W_nH\mu] = K_{n\mu}^{WH}[W_n][H] = K_{nm}^{WH}K_n^{W}[H][W_1]^n$$

$$[W_nP\mu] = K_{n\mu}^{WP}[W_n][P] = K_\tau K_{nm}^{WP}K_n^{W}[H][W_1]^n$$

$$[7]\qquad [W_nC] = K_n[W_n][C] = K_nK_n^{W}[C][W_1]^n$$

$$[8]\qquad [W_nHC\mu] = K_{n\mu}^{H}[W_nH\mu][C] \\ = K_{n\mu}^{H}K_{n\mu}^{WH}K_n^{W}[C][H][W_1]^n$$

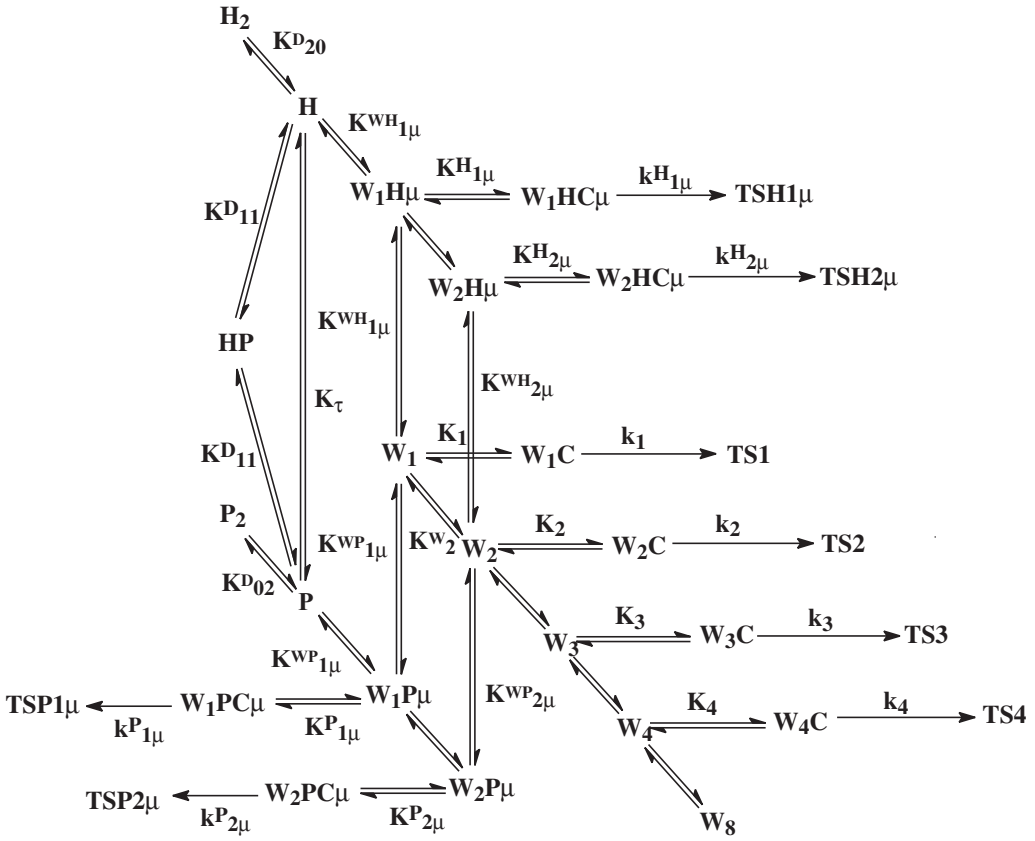
Scheme 2.



$$[9]\qquad [W_nPC\mu] = K^{P}_{n\mu}[W_nP\mu][C] = K_\tau K^{P}_{n\mu} K^{WP}_{n\mu} K^{W}_{n}[C][H][W_1]^n$$

Results

Hydration kinetics

Figures 1–4) show the kinetics of hydration of 1.0 mol/L aqueous solutions of acetone at 298 K in the presence of 2×10^{-4} mol/L 2-hydroxypyridine (Table 1) and 1.3×10^{-2} mol/L 3-hydroxypyridine (Table 2). The rate constants shown in these tables and figures contain contributions from k_o, the neutral reaction, and from $k_A C_A$, the catalyzed reaction (eq. [10]).[5] Table 3 collects the k_A determined in this work, together with those obtained in our previous work for HA = HOH and HOAc (1*b*, 1*c*).

$$[10]\qquad k_{obs} = k_o + k_A C_A$$

Although 2-HP is one thousand times less acidic than its isomer 3-HP and ten million times less acidic than acetic acid in the aqueous hydration of 1 mol/L acetone at 298 K, 2-HP is 600 000 times more reactive than 3-HP and 20 times more reactive than acetic acid. This would seem to constitute a priori evidence of bifunctional catalysis in water solvent.

The theoretical rate constant

The equilibrium and rate constants of Scheme 2 that are needed for the computation of the overall rate constant and the contributions to this rate constant from the different channels were obtained from the calculated thermodynamic data collected in Tables 4–8.

The overall reaction rate v is a sum of partial reaction rates arising from the reactant complexes $[W_nC]$, $[W_nHC\mu]$, and $[W_nPC\mu]$,

$$v = \sum_n k_n[W_nC] + \sum_{n,\mu} k^{H}_{n\mu}[W_nHC\mu] + \sum_{n,\mu} k^{P}_{n\mu}[W_nPC\mu]$$

Here k_n are partial rate constants for the neutral channels and $k^{H}_{n\mu}$ and $k^{P}_{n\mu}$ are partial rate constants for the catalyzed channels. Equations [7]–[9] allow the rate of the reaction to be expressed in terms of the concentrations of water monomer $[W_1]$, acetone [C], and 2-hydroxypyridine [H],

$$[11]\qquad v = \sum_n k_n K_n K^{W}_{n}[C][W_1]^n + \sum_{n,\mu} k^{H}_{n\mu} K^{H}_{n\mu} K^{WH}_{n\mu} K^{W}_{n}[C][H][W_1]^n + \sum_{n,\mu} k^{P}_{n\mu} k_\tau K^{P}_{n\mu} K^{WP}_{n\mu} K^{W}_{n}[C][H][W_1]^n$$

These concentrations were found as numerical solutions of a set of material balance equations for the overall concentrations of water (CW), acetone (CC), and 2-hydroxypyridine (CA),

$$C_C = [C] + \sum_n [W_nC] + \sum_{n,\mu} [W_nHC\mu] + \sum_{n,\mu} [W_nPC\mu]$$

The final results are collected in Tables 9 and 10.

Discussion

It is known (18, 19) that at 20 °C an aqueous solution of 2-hydroxypyridine consists predominantly of the 2-pyridone tautomer. The tautomeric equilibrium constant K_{t} = [2PD]/[2HP] is over 900, corresponding to a free energy difference of 3.97 kcal/mol (1 cal = 4.184 J). It is also known (13) that 2-pyridone forms specific complexes to two water molecules, and that 2-hydroxypyridine complexes one water

molecule. The extent to which these complexes contribute to the tautomeric equilibrium constant has not previously been a topic of interest but has become known as a result of the present work (20). It is remarkable that a 3–21G/SCRF computational strategy does so well in reproducing kinetic (1*b*, 1*c*) and thermodynamic (20) experimental results in water solvent. A thermodynamic preference for the 2-pyridone tautomer is already evident in Table 4, which considers only the uncomplexed monomeric tautomers. From Table 6, the most stable complexes are the 2-HP monohydrate **1a** and the 2-PD dihydrate **4a**. In the presence of acetone, **1a** is the precursor of **5a**, and **4a** is the precursor of **8a**. From Table 7, **8a** is significantly more stable than **5a**, but the most stable acetone complex is **7**, derived from the 2-PD monohydrate **3b**. When the barriers are examined (Table 8), it is seen that **5a** and **8a** are comparable, but **7** is significantly higher. It is interesting that **6c**, which resembles a 3-water molecule neutral complex, has the lowest barrier, but **6c** is not stable (Table 7).

When the concentrations of the complexes are combined with the barriers (Table 9), the experimental rate constant is reproduced (Table 10) and **8a** is seen to be by far the dominant reaction channel, with minor contributions from **7**, **6c**, and $\mathbf{W_4C}$, the four-water molecule neutral channel.

The notion of cooperativity can, therefore, be extended from neutral (1*a*, 1*b*) and acetic acid-catalyzed (1*c*) to "2-hydroxypyridine"-catalyzed hydration of acetone. In each case the theoretical treatment reproduces experiment quite well. However, as seen in Table 11, it would be misleading to attribute 2-HP catalysis to its bifunctional character. Ta-

© 2007 NRC Canada

ble 11 compares the calculated barriers, the calculated concentrations of the principal reactive species, and the calculated rate constants of the hydration of acetone under neutral conditions and in the presence of acetic acid and 2-hydroxypyridine. *For the principal reaction channels*, *the neutral barrier and the 2-HP barrier are almost the same!* The acetic acid barrier is significantly lower. The predominance of 2-HP catalysis is seen to reside in a much higher concentration of the principal reactant complex. The relevance of this finding to the subject of bifunctional catalysis and the relationship of bifunctional catalysis to what takes place at an enzyme active site will be examined elsewhere (7).

Methanolysis of organophosphorus esters promoted by an M^{2+} catalyst supported on polystyrene-based copolymers

Benoit Didier, Mark F. Mohamed, Elizabeth Csaszar, Kate G. Colizza, Alexei A. Neverov and R. Stan Brown

Abstract: The methanolysis of three neutral organophosphorus esters (a phosphonate, a phosphonothioate, and a phosphorothionate) promoted by several polymer-supported Zn(II) or Cu(II) containing catalysts was studied. The catalysts consist of a Zn(II) or Cu(II) complex with 1,5,9-triazacyclododecane or phenanthroline attached to a porous polystyrene resin. In each case, the polymer supported catalyst showed activity at near neutral $^{s}_{s}$pH in methanol (8.38) and ambient temperature and provided accelerations of up to a factor of 2.9×10^6 relative to the background reaction at $^{s}_{s}$pH 9.05. The solid materials could be reused several times and could be reactivated when the activity diminished. Various polymers of different porosity and extent of cross-linking were studied, with the net result being that larger porosities offer the best reactivity for catalyzed methanolysis of these OP species in methanol. This is explained by different parameters including the accessibility to reactive sites, the increase of concentration of catalytic sites on the surface of the polymer, and some cooperative effects between neighboring catalytic groups.

Key words: functionalized polymer, metal containing, methanolysis, organophosphorus pesticides and CW agents, catalyst.

Résumé : La méthanolyse de trois esters organophosphorés neutres (un phosphate, un phosphonothioate et un phosphorothionate) ont été étudié en présence de plusieurs catalyseurs contenant du Zn(II) et du Cu(II) compléxés avec du 1,5,9-triazacyclododécane ou de la phénantroline supportés par des matrices polymères poreuses. Dans chacun des cas, le catalyseur supporté par le polymère est actif à température ambiante et à $^{s}_{s}$pH proche de la neutralité dans le méthanol (8,38) en fournissant des accélérations allant jusqu'à 2,9 x 10^6 par rapport aux vitesses de réaction obtenues en l'absence de catalyseur métallique à un $^{s}_{s}$pH de 9,05. Les matériaux utilisés peuvent être réutilisés plusieurs fois ou réactivés lorsque leur activité diminue. Divers matrices polymères de porosité et de degrés de réticulation différents ont été étudiés et il a été observé que les catalyseurs fixés sur les matrices ayant la porosité la plus large ont la plus forte activité catalytique pour la méthanolyse de ces esters phosphoriques dans le méthanol. Ce résultat s'explique par divers paramètres, incluant l'accessibilité des sites réactifs, l'augmentation de la concentration des sites catalytiques à la surface du polymère et de quelques effets de synergie entre des espèces catalytiques voisines.

Mots-clés : polymère fonctionnalisé contenant un métal, méthanolyse, pesticides organophosphorés, gaz de combat, catalyse.

Introduction

Neutral organophosphorus (OP) compounds with leaving groups having pK_a values less than 8 comprise a very toxic family of compounds that inhibit acetylcholinesterase (1, 2) and thus have uses as chemical warfare (CW) agents, pesticides, and acaricides (3). Among the most nefarious of the CW agents are the phosphonothioate esters that are V-agents, such as VX (**1**) and Russian VX (**2**) and the phosphonoflouridate G-agents such as soman (**3**) and sarin (**4**). Other kinds of OP esters, such as the phosphate triesters and phosphorothionate esters (**5**, **6**), are used as pesticides.

Due to the noxious nature of these materials and the fact that some of them linger in the environment, methods for the decomposition and decontamination of these are continually sought (4). Only a few methods employ metal ions, but generally these are not very effective in water for hydrolysis because of substrate and metal ion solubility problems and also the inherent low activity of the metal ions in promoting solvolysis, which has yet to be overcome in aqueous media. In practice, a decomposition method should be inexpensive, have a high reaction rate, occur at neutral pH and ambient temperature, and convert the toxic starting material into far less toxic or nontoxic products.

Recent work in our laboratories indicates that neutral (uncharged) esters of phosphates and phosphorothioates (5*a*, 5*b*), phosphonates (5*c*), and phosphonothioates (5*d*) are rapidly solvolyzed in methanol solution in the presence of La^{3+} or a Zn(II)-complex of 1,5,9-triazacyclododecane (**7*a***), forming nontoxic methyl esters. In addition, we have found that the corresponding Cu(II)($^{-}OCH_3$) or Zn(II)($^{-}OCH_3$) complexes of **7a** (6, 7) and **8** (7) catalyze the methanolysis of phosphate triesters and phosphorothionate triesters with a particular propensity for the latter. Routinely we find that a 1 mmol/L solution of the metal species gives accelerations of the methanolysis of these materials by factors of 10^8–10^9 over the background reactions at neutral $^{s}_{s}$pH and ambient temperature (8). All these exhibit true catalytic turnover, and all seem to function according to the simple kinetic scheme given in eq. [1]. The disadvantage of complex with **8** is the formation of dimers that are inactive, so it seemed reasonable that fixing the ligands on a solid support could form exclusively monomeric catalysts and prevent the formation of inactive species.

In some cases, affixing the catalytic group to a solid support can be expected to confer particular advantages of efficiency and cost effectiveness that come from being able to recover and reuse the catalyst. There are several reported studies of the hydrolytic decomposition of organophosphorus compounds promoted by solid supported M(II)-containing catalysts (9–12). In several cases the reactivity of the polymer supported catalyst decreases considerably compared with the activity in solution because of surface and diffusion effects, but in other cases the activity was still acceptable, particularly when the polarity of polymeric matrix was changed (10*b*, 10*c*), the coordination sphere of catalytic complex was modified (10*c*), or a linker was introduced between matrix and catalytic system (9). Nevertheless, all the prior reported studies concentrated on hydrolytic systems where the expected OP products would be acids that may present problems, such as inhibiting the activity of the M(II) through binding of the ionized anionic phosphate or phosphonate. In some cases, such as with the hydrolysis of V-agents, some of the hydrolytic products arise through cleavage of the P-OEt linkage, giving a product that is just as toxic as the starting materials but far more resistant to hydrolysis (1, 2).

Herein we report on the synthesis and analysis of some divinylbenzene (DVB) cross-linked meso- and macro-porous polystyrene resins functionalized with **7a**, **7b**, or 5-amino-1,10-phenanthroline (5-NH_2-**8**). After loading the resins with an M^{2+} ion (Cu^{2+} or Zn^{2+}), the catalytic activity was determined for the methanolysis of three different OP compounds proposed as simulants for the G-agents (*O*-ethyl-*O*-4-nitrophenyl methylphosphonate (**9**)), the V-agents, (3,5-*O*-ethyl-*S*-3,5-dichlorophenyl methylphosphonothioate (**10**)), and for phosphorothionate pesticides (fenitrothion® (**11**)).

Experimental

Materials

Methanol (99.8% anhydr.), DMF (99.8%), sodium methoxide (0.5 mol/L solution in methanol), $Cu(CF_3SO_3)_2$, $Zn(CF_3SO_3)_2$, 1,5,9-triazacyclododecane, styrene, 4-(chloromethyl)styrene, divinylbenzene, benzoyl peroxide, boric acid, and sodium hydroxide were purchased from Sigma-Aldrich and used as supplied. THF (extra dry, with molecular sieves, water < 50 ppm) and $HClO_4$ (70% aq. solution) was purchased from Acros Organics and used without further purification. Cellosize, xantham gum, and 5% Pd/C catalyst were purchased from Fluka and *n*-pentanol was purchased from BDH Chemical; these were used as supplied. Merrifield's polymer resin mesoporous (Meso-Ald) (2% crosslinked with DVB, 0.6–0.8 mmol Cl/g, 200–400 mesh) and macroporous (Macro-Ald) (1.2 mmol Cl/g, 100–200 mesh) were purchased from Sigma-Aldrich. PL-CMS MP resin (Macro-PL) (>12% of cross-linking with DVB, 2.8 mmol Cl/g, porosity size 100 Å, particle size 150–300 μm) was purchased from Polymer Laboratories. Fenitrothion (**11**, *O*,*O*-dimethyl *O*-(3-methyl-4-nitrophenyl) phosphorothioate), was a gift from Professors Erwin Buncel and Gary van Loon of this department. *O*-Ethyl-*S*-3,5-dichlorophenylmethylphosphonothioate (**10**) and *O*-ethyl-*O*-4-nitrophenylmethylphosphonate (**9**) were synthesized as reported previously (5*e*, 5*d*).

Suspension polymerization syntheses of macroporous resins (DVB20, DVB50, and DVB50-hl).

The following procedure was based on the work of Durie et al. (13). An aqueous phase was prepared by dissolving 0.087 g of xantham gum, 0.012 g of Cellosize, and 1.73 g of boric acid in 100 mL of water. This mixture was vigorously stirred to obtain a cloudy solution. Using 20% divinylbenzene cross-linker as an example to make DVB20, the monomer mixture comprised DVB (~80% grade) (1.50 mL, ~20 wt% actual DVB as compared with the other monomers), styrene (4.33 mL), and 4-(chloromethyl)styrene (0.59 mL, ~10% molar ratio with styrene), to which was added benzoyl peroxide (0.080 g) and *n*-pentanol (4.22 mL, ~40 vol% of the entire organic phase). The combined organic phase was added dropwise into the aqueous phase with vigorous stirring. The suspension was then stirred at 80 °C for six hours, cooled, and the polymeric beads were collected by filtration and washed with water (50 mL). The material was washed with methanol (50 mL) and then acetone (50 mL). The yield of polymeric beads was 60% after drying in an oven at 60 °C for 24 h.

Characterization of porosity

To characterize the porosity of the beads, we followed a procedure reported by Chemin et al. (14) where the volume of porosity and the accessible porous volume for methanol were characterized by a measurement of the apparent density of the polymeric beads in different solvents. Around 2 g of dry polymeric beads were weighed in a tared 50 mL volumetric flask, after which 40 mL of solvent were introduced. For the measurement with hexane, the flask was placed in an ultrasonic bath for 10 min, after which the mixture was allowed to stand for 2 h at room temperature. The volume was adjusted with hexane and the flask was weighed again. This procedure gives an apparent volumetric weight of beads in the given solvent (e.g., hexane, water, and methanol) by using the following formula:

$$[2] \qquad \rho^{s}{}_{a} = \frac{W_p}{100 - (W_2 - W_1) \times 1/\rho_s}$$

where W_p is the weight of polymer in g, W_1 is weight of the flask with beads, W_2 is the weight of the flask with the beads filled with the solvent, ρ_s is the density of the solvent, and $\rho^{s}{}_{a}$ is the apparent density of the beads in the solvent (in g/mL). The pore volume ($P\%$) or the accessible porous volume in methanol was calculated with the following equation:

$$[3] \qquad P(\%) = \left(1 - \frac{\rho^{w}{}_{a}}{\rho^{s}{}_{a}}\right) \times 100$$

where $\rho^{w}{}_{a}$ is the apparent density of the beads in water in g/mL, and $\rho^{s}{}_{a}$ is the apparent density of the beads in hexane for total pore volume or in methanol for accessible porous volume in methanol.

5-Amino-1,10-phenanthroline

5-Amino-1,10-phenanthroline was prepared via a modification of a previously published route (15).

***N*-benzyl-1,5,9-triazacyclododecane**

The title compound was made as described in ref. 16.

Modification of polymeric resins with 7a or 7b

Commercial Macro-Ald resin (0.50 g, 0.6 mmol of Cl, 1 equiv.) was swelled in 10 mL of THF for 1 h. 1,5,9-Triazacyclododecane (**7a**) (0.12 g, 0.7 mmol, 1.15 equiv.) was added and the mixture was heated at reflux and stirred carefully overnight. The polymer was recovered by filtration and washed with THF (3 × 10 mL) and dried in oven at 60 °C for 24 h.

The modification with the immediate precursor of **7a**, triazatricyclo[7.3.1.0]tridecane (**7b**), was done by the same procedure using the same molar ratios, after which the recovered polymer was subjected to hydrolysis using a solution of 10 mL each of ethanol and water containing 1.07 g of sodium hydroxide heated at reflux overnight to liberate the 1,5,9-triazacyclododecane-functionalized resin. In all cases the final polymer functionalized with **7a** was subsequently treated with a solution of THF–methanol (50:50 *v*/*v*, 20 mL) containing 200 µL of sodium methoxide (0.5 mol/L) for 15 h to remove all traces of acid and residual exposed chloromethyl functionality.

Modification of polymeric resins with 5-amino-1,10-phenanthroline

Polymer-bound phenanthroline was prepared via a modification of a published route (15). Commercial PL-CMS MP resin (0.824 g, 2.31 mmol of Cl, 1 equiv.) and solid 5-amino-1,10-phenanthroline (0.724 g, 3.71 mmol, 1.6 equiv.) were added to a 100 mL round-bottomed flask equipped with a reflux condenser and a small magnetic stirbar. To the flask was added 50 mL of anhydrous DMF and the mixture was gently stirred, to avoid crushing of the polymer, and heated to reflux. After 1 h of heating, triethylamine (520 µL, 3.7 mmol) was added to the reaction mixture and the mixture was allowed to continue refluxing. An additional 230 µL (1.65 mmol) of triethylamine was added after 24 h of heating and the two phase mixture was left to reflux for another 48 h. After cooling, the polymer was filtered and washed with 20 mL of DMF and 100 mL of methanol. The resin was left to stir gently in boiling DMF for three hours followed by filtration and rinsing with methanol. To remove residual DMF, the polymer was boiled in acetone at 60 °C overnight, collected, filtered, and washed with acetone and then methanol. The functionalized polymer was treated with a 20 mL solution of sodium methoxide (5 mmol/L) in methanol for 15 h to remove any traces of acid and residual exposed chloromethyl functionality.

Metal complexation of polymer bound ligand

A 0.1 mol/L solution of $M(OTf)_2$ was prepared in methanol and the polymer was immersed in this solution for 4 h after which it was separated by filtration, washed with methanol, and dried in oven at 60 °C for 24 h. A final step placed the material into a basic methanol solution (20 mL of methanol with 200 µL of 0.5 mol/L sodium methoxide) to obtain the active catalytic species of complexed M(II):($^{-}OCH_3$).

Analysis of the M(II) loading

The metal-loaded polymer (around 0.01 g) was immersed

[d]NA = not available.

in 2 mL of nitric acid solution in methanol (5% *v*/*v*) for 30 min. The methanol solution was carefully decanted away from the polymer, reserved, and the acid wash was repeated with this material four times. The combined methanol washes were stripped of solvent to produce ~0.2 mL of a residue, which was diluted with water in a volumetric flask (25 or 50 mL). The concentration of M^{2+} in this solution was obtained by atomic absorption spectrometry using a Varian Spectra AA-20 Plus spectrometer. The spectrometer was calibrated with known [M^{2+}] solutions (0.5–5 ppm for copper, and 0.1–0.5 ppm for zinc).

Kinetics

All kinetics experiments with the polymers were conducted in 2.5 mL of a methanol solution buffered with *N*-*iso*-propylmorpholine (6.8×10^{-3} mol/L) at $^{s}_{s}$pH = 9.0 ± 0.4. The rates of methanolysis of **9** and **11** (0.03 mmol/L) catalyzed by heterogeneous M(II)-**7** complex (0.08 g to 0.75 g; 1×10^{-3} mol/L < [M(II)-**7**] < 30×10^{-3} mol/L suspended in the buffered methanol) were followed by monitoring the appearance of *p*-nitrophenol (or 3-methyl-4-nitrophenol) at 312 nm or the disappearance of starting material at 264 nm, using a Cary 100 UV–vis spectrophotometer with the cell compartment thermostatted at 25.0 ± 0.1 °C. The rates of methanolysis of **10** (0.3 mmol/L) were followed by monitoring its disappearance at 253 nm.

Kinetic experiments with the Zn(II) complex of *N*-benzyl-1,5,9-triazacyclododecane (**7c**/Zn(II)) were conducted in methanol under self-buffered conditions where the ligand, $Zn(OTf)_2$, and $NaOCH_3$ were formulated in stock solutions in a 1:1:0.5 molar ratio ($^{s}_{s}$pH = 10). The kinetics of the methanolysis of phenyl acetate (1.0×10^{-4} mol/L) and **9** (3.6×10^{-5} mol/L) were monitored at 280 and 320 nm, respectively, as a function of [**7c**/Zn(II)]$_{total}$. The k_2 value for the catalyzed methanolysis was determined as twice the gradient of the k_{obs} vs. [**7c**/Zn(II)]$_{total}$ plot, the factor of two being introduced because the active form is [**7c**/Zn(II):$^{-}$OCH$_3$], which is present at 1/2 the concentration of the total Zn(II) complex.

Results and discussion

Functionalized polymer preparation

The chloromethylated polystyrene support matrix was chosen for its desirable (17) physical and chemical properties, which include chemical inertness, structural stability that enables a controllable porosity that ensures accessibility of reagents to the internal catalytic domains, and the $ClCH_2$-functionalities that can be modified to attach various catalytic systems to the matrix. Three different commercial polymers were used in this study, one mesoporous (Meso-Ald) and two macroporous (Macro-Ald and Macro-PL). Macro-PL is defined by its manufacturer as macroporous but has an average size porosity of 10 nm and does not correspond to the IUPAC definition (18) that distinguishes three porous domains: microporosity (<2 nm), mesoporosity (2–50 nm), and macroporosity >50 nm).

Three other polystyrene resins were synthesized in this work by radical suspension polymerization wherein a mixture of monomer and a radical precursor (benzoyl peroxide) was dissolved in a solvent and was finely dispersed in an aqueous phase. Three different monomers in varying proportions were used, styrene and 4-(chloromethyl)styrene to ensure the reactive function of polymer and divinylbenzene to obtain cross-linking of the polymeric matrix. The solvent (pentanol) containing the monomeric phase was used as the porogen (17, 19) because it is known to permit a large porosity (19, 20). During the polymerization process, a phase separation occurs between the growing polymeric chain and the porogenic agent, and the matrix forms around the space where the solvent is occluded creating the porous structure. Two polymers were synthesized, one (DVB20) with 20 wt% of divinylbenzene and another (DVB50) with 50 wt%. In all cases the porogen was introduced to make up 40% of the volume of the organic phase. A third matrix was prepared with the same amount of DVB as for DVB50 but with only 4-(chloromethyl)styrene as the other monomer, to obtain a polymer with high loading (designated as DVB50-hl).

The porosities of the resins were characterized by measuring their apparent densities in different solvents (hexane, water, and methanol). From those values one calculates, from eqs. [2] and [3], the volume of total porosity and porous volume accessible to methanol (14). Data are reported in Table 1. The results show slightly higher pore volumes for the commercial polymers than for the synthesized polymers. However, the ratio of this volume to that accessible to methanol is 70%–80% for prepared polymers and somewhat less for the commercial polymers, ~60% for Macro-PL and ~40% for Macro-Ald. This result shows that a majority of pores are not accessible to methanol in Macro-Ald. For

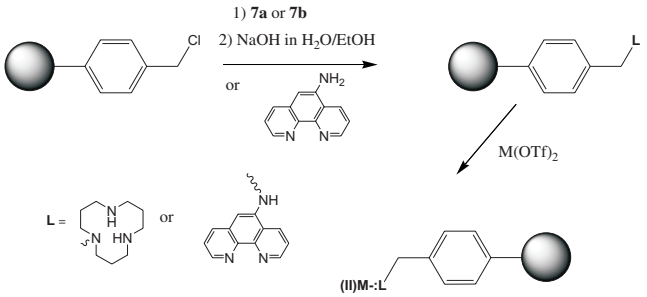
Macro-PL-(II) **8**/Zn^{2+}	0.098	11.75	0.61

Note: Error limits considered to be ±20%, based on the errors in the determination of metal loading and uncertainties in the duplicate rate measurements.

Fig. 1. Scheme of the modification of polystyrene resins.



Macro-PL, the advertised pore size is 10 nm but the porosity for Macro-Ald, although not specified, seems to be smaller according to the criteria here.

All the polymeric matrices were functionalized by nucleophilic substitution of the benzylic chloride by 1,5,9-triazacyclododecane (**7a**) or its immediate precursor triazatricyclo[7.3.1.0]tridecane (**7b**) as shown in Fig. 1.

Using **7b**, the polymer must then be subjected to base catalyzed hydrolysis with sodium hydroxide in water–ethanol, to obtain the 1,5,9-triazacyclododecane functionalized polymer. Once functionalized, all the polymers are treated with a sodium methoxide THF–methanol solution to deprotonate the highly basic triazacyclododecane and to react with any residual benzylic chloride that might affect the future characteristics of the material. The subsequent steps involve the M^{2+} loading (Cu^{2+} or Zn^{2+}), wherein the polymeric matrix was immersed in an 0.1 mol/L $M(OTf)_2$ solution in methanol. In the case of copper, the loading is visually characterized for the **7a** functionalized polymer by an immediate green-blue colouring of the solid, which remained so after a final washing with methanol.

The M^{2+} loading was quantified by immersing a known quantity of the resin in a known volume of a 5% solution of nitric acid in methanol, which protonates the ligand and releases metal ion into the solution, as judged by the loss of colour of the solid in the case of copper. The solution was then analyzed by atomic absorption spectroscopy and the results are presented in Table 1. The data show that, in all cases, there is an incomplete conversion of chloride into metal complex. The best result was obtained with Macro-Ald with a conversion of 13% of the available chloride. The low conversion likely stems from the fact that some of the Cl is buried inside the polymer in sites inaccessible to the triaza ligand although the functionalization was done in THF, which is known to swell polystyrene appreciably. Since the metallation step was done in the nonswelling solvent methanol, it is possible that some of the ligand sites could not be accessed, which could also contribute to the relatively low amount of Cu^{2+} on the polymer. In fact, we have chosen to do the metallation under nonswelling conditions as this is the medium where all the subsequent catalytic reactions are performed, and the metal ion loading was determined under non-swelling conditions in aqueous acid. Another possibility for some materials is a difference in reactivity of **7a** and its precursor **7b**, since it is generally observed that materials prepared with the latter always have a slightly lower Cu^{2+} loading. Indeed, the only difference between Macro-PL and Macro-PL-(II), where the polymeric matrix is the same for each, is the triazacyclododecane precursor, which is **7b** for Macro-PL and **7a** for Macro-PL-(II). It could be that there is a higher reactivity with the more flexible **7a** relative to **7b** or that the hydrolysis step required for the latter in ethanol–water is not very efficient because of the low affinity between polystyrene resin and this solvent mixture. As a final note, we observed that the polymers prepared for this study have much lower conversion of chloride into the Cu^{2+}-loaded resin (<3%) relative to the commercial resins. This is possibly due to the high level of cross-linking, since it is known (21) that a higher level decreases the reactivity of functional groups on a rigid polymeric backbone.

The modification of polymeric resins with 5-amino-1,10-phenanthroline was done following a published procedure (15). The loading of zinc after this modification was low (see Table 2) with 0.035 mmol/g compared with 0.14 mmol/g for zinc loading to Macro-PL-(II) functionalized with **7a**. Subsequently we changed the functionalizing solvent to DMF, in which the 5-amino-1,10-phenanthroline is more soluble than in dioxane. The solvent change increased the loading about three-fold, giving a loading of ~0.1 mmol/g, which is close to that found with **7a**.

Catalytic studies

Study of the catalytic activity of the materials was conducted by determining the rate of change in the UV–vis absorbance for loss of substrate and formation of product in methanol solutions containing known amounts of the solid resins. Polymer (0.05 g to 0.75 g) was put into 2.5 mL of methanol solution buffered by *N*-*iso*-propylmorpholine (6.8 × 10^{-3} mol/L) at $^{s}_{s}$pH ~ 9 (the range of $^{s}_{s}$pH values is between 8.6 and 9.8) (22), which is slightly above neutrality ($^{s}_{s}$pH = 8.4 (22)). For practical reasons owing to the high absorptivities of the turbid media, the heterogeneous mixtures were not stirred continuously; rather, the cell was shaken every 2 to 5 min and the particles were allowed to settle prior to measurement of

the absorbance. In an attempt to quantify the amount of M^{2+} in the solution, the known amount of the heterogeneous resin was converted to concentrations as if it were completely dissolved (this is termed [bound M^{2+}]). Under this assumption, the metal concentration varied between 1 and 30 mmol/L, while those of the substrates were 0.3 mmol/L for **10** and 0.03 mmol/L for **9** and **11**. Under these conditions, the change in absorbance followed good first-order behaviour, and the pseudo first-order rate constants, k_{obs}, were evaluated by fitting the Abs. vs. time curves to a standard exponential model. The apparent second-order rate constants were evaluated as k_{obs}/[bound M^{2+}] and are given in Table 3 for material with **7a**/M^{2+} and in Table 2 for **8**/Zn^{2+}. Control experiments showed that in all but one case the rate constant obtained did not depend upon the frequency of shaking the mixture. This suggests that for these cases the overall catalytic process is not limited by transport through solution, although it might be limited by transport through the polymer or across the phase boundaries. On the other hand, we do have one case where there is a dependence of the reaction rate on the frequency of shaking for methanolysis of **9** in the presence of a relatively large amount (0.32 g) of Macro-PL-(II) **8**/Zn^{2+}. The kinetic results for the rate of disappearance of **9** and appearance of *p*-nitrophenol at $^{s}_{s}$pH = 8.52 (6.5 mmol/L *N-iso*propyl morpholine) shown in Table 4 indicate that the rate constants for each process increase with the frequency of shaking, although in all cases the rate for liberation of product is slower by roughly a factor of two than the rate of disappearance of **9**. This is consistent with a process where the reaction rate is partially limited by the diffusion of the substrate into the polymer and more so by the chemical step of methanolysis to form *p*-nitrophenol and (or) its diffusion out of the polymer.

To demonstrate that the polymers are truly catalytically active, an experiment with an excess of substrate was done

Table 4. Dependence of the pseudo first-order rate constants for the disappearance of **9** (0.03 mmol/L) and appearance of *p*-nitrophenol mediated by 0.32 g of Macro-PL-(II) **8**/Zn^{2+} on the frequency of

Frequency of shaking	k_{obs} for the loss of **9** (s^{-1})	k_{obs} for the appearance of *p*-nitrophenol (s^{-1})
30 s	0.011	0.0045
60 s	0.009	0.0038
120 s	0.007	0.0032

with 5.2 mg of Macro-PL-(II) **7a**/Cu^{2+} in 2.5 mL of methanol solution buffered by *N-iso*-propylmorpholine (6.8 mmol/L) at $^{s}_{s}$pH = 8.8 in presence of **9** at 1 mmol/L. In that case, the pseudo concentration of copper was 0.48 mmol/L and the Abs vs. time curve showed a complete loss of starting material with a k_{obs} value of 0.0083 min^{-1}, which corresponds to a second order rate constant of 0.28 (mol/L)$^{-1}$s^{-1}.

In the cases of the commercial macroporous polymers, and most prominently with Macro-Ald functionalized with **7a**/Cu^{2+} and **7a**/Zn^{2+}, a less than expected amount of product phenol was observed during the reaction of **9** and **11**, along with a complete disappearance of starting material, although analysis of the Abs vs. time curves for each gave the same value of k_{obs}. This suggests that the starting material is at equilibrium with respect to partitioning into the polymer and the rate-limiting step is the chemical one of cleavage, but the product partitions between the solution and the polymer phase.

Where comparisons can be made, and using the pseudo M^{2+} concentrations for the catalysts as described earlier, none of the functionalized polymers have second-order rate constants approaching those of the free **7a**/M^{2+} catalysts in

© 2007 NRC Canada

solution. This is a commonly observed phenomenon with polymeric catalysts and probably stems from a diminution of mobility in the solid catalytic systems, which impedes diffusion of substrate to the reactive sites. It is also possible that since the polymer supports described here require N-benzylated 1,5,9-triazacyclododecanes, that these are far more sterically hindered than **7a**/M^{2+}. Indeed, a recent report (23) indicates that the methanolysis of the carboxylate ester phenyl acetate promoted by **7c**/Zn(II):$^{-}OCH_3$ proceeds with a second-order rate constant of 0.046 $(mol/L)^{-1}s^{-1}$, which is fully 300 times slower than what is reported for the methanolysis of phenyl acetate by **7a**/Zn(II):$^{-}OCH_3$ (13.9 $(mol/L)^{-1}s^{-1}$ (24)). Our own repetition of the catalysis of methanolysis of phenyl acetate promoted by **7c**/Zn(II):$^{-}OCH_3$ indicates that the second-order rate constant is 4.0 ± 0.2 $(mol/L)^{-1}s^{-1}$, which is only a factor of three less than that reported for **7a**/Zn(II):$^{-}OCH_3$, which suggests that there is some anomalous error in the recently reported value (23). A similarly small steric effect of 2.5 fold is also evident in the second-order rate constant for the methanolysis of **9** exhibited by **7c**/Zn(II):$^{-}OCH_3$ (18.2 ± 0.2 $(mol/L)^{-1}s^{-1}$) relative to that of **7a**/Zn(II):$^{-}OCH_3$ (46.8 ± 0.5 $(mol/L)^{-1}s^{-1}$ (5*c*).

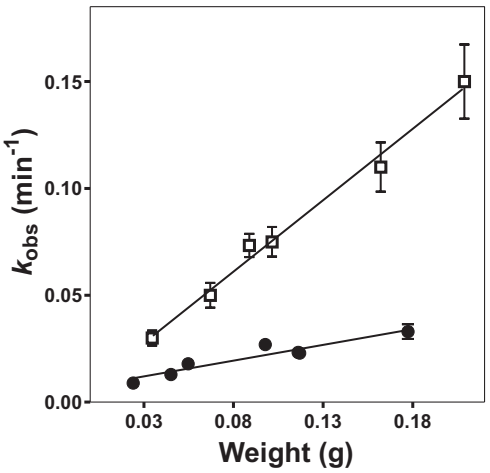
It therefore seems reasonable to ascribe the reduced activity of these functionalized polymers relative to the solution catalysts to surface effects with the polymers that impeded the mobility of the substrate in reaching the active sites. Nevertheless, the catalysts supported on these resins do accelerate appreciably the methanolysis of all the substrates compared with the background $^{-}OCH_3$-promoted reaction at the $^{s}_{s}$pH where the catalyzed reactions are conducted. For example, the acceleration of the methanolysis of fenitrothion (**11**), mediated by the catalyst at an apparent concentration of 1 mmol/L (0.028 g of DVB50-(II) **7a**/Cu^{2+} suspended in 2.5 mL of solution) is a factor of 2.9×10^6 greater at $^{s}_{s}$pH = 9.

In the case of the polymers containing **8**/Zn^{2+}, the k_2 values are higher than those obtained with **7a**/M^{2+} (see Tables 2 and 3). Previously we have found that the solution reactions of phenanthroline/M^{2+} complexes are slower than with the triazamacrocycle/M^{2+} complexes because of the fact that the former are inactivated by dimerization and must dissociate to the active monomeric forms (7, 25). However, the dimerization is minimized or precluded on the polymers so the phenanthroline grafted resins now become more active than their triazamacrocyle grafted comparisons (see Macro-PL-(II) **8**/Zn^{2+} and Macro-PL-(II) **7a**/Zn^{2+} entries in Tables 2 and 3).

As shown in Fig. 2, a plot of the pseudo first-order rate constant for the methanolysis of **9** at $^{s}_{s}$pH = 8.7 as a function of weight of added Macro-PL-(II)**7a**/Cu^{2+} or **7a**/Zn^{2+} polymer is linear, indicating there is no saturation phenomenon such as was observed with a previously reported (9) catalyst and the substrate diphenyl *p*-nitrophenyl phosphate in aqueous solution. The same linear dependence was observed with the **8**/Zn^{2+}-functionalized polymer except at high weight, where the reaction rate depends on the frequency of shaking.

There are other subtle differences observed between the phenanthroline and triazamacrocyle grafted complexes. In the case of **8**/Zn^{2+} grafts on the Macro-PL polymer, stronger absorption of the phenol products is initially observed relative to the **7a**/M^{2+} material. However, after several reactions

Fig. 2. Pseudo first-order rate constant, k_{obs}, for the methanolysis of **9** mediated by **7a**/Cu^{2+} (□) and **7a**/Zn^{2+} (●) functionalized Macro-PL-(II) vs. weight of the polymer at $^{s}_{s}$pH = 8.7, T = 25 °C.



with the same **8**/Zn^{2+}-grafted polymer, the appearance of phenol in the solution is more pronounced. Control experiments establish that the absorbance of a solution of *p*-nitrophenol decreases in the presence of fresh polymer functionalized with **8**/Zn^{2+}. These observations confirm that phenol does partition between the polymer and solution, but that after several reactions the polymer eventually becomes saturated with the product.

Reuse of polymer catalysts

Except in the case of the methanolysis of substrate **10**, the activity of most of the polymeric catalysts showed good stability over several catalytic cycles. With substrate **9**, the second-order rate constant of 0.1 g of Macro-PL-(II) **7a**-Cu^{2+} ($[Cu^{2+}]$ = 9.20 mmol/L) is stable 0.14 ± 0.02 $(mol/L)^{-1}s^{-1}$ over 10 consecutive experiments. Similar experiments conducted with Macro-PL(II) Zn^{2+}/**7a** polymers showed a large inconsistency in reactivity between cycles (a complete cycle comprises the reaction to completion, followed by filtration, washing of the recovered polymer with 50 mL of methanol, and drying in air overnight). However, it was observed that the Macro-PL(II) Zn^{2+}-loaded polymers do recover complete reactivity when they are allowed to stand in the *N-iso*-propylmorpholine buffer solution for more than 12 h after a cycle. This phenomenon is tentatively attributed to an interaction between CO_2 and Zn^{2+}/**7a** complex in the air, which reversibly inhibits the catalyst. This decrease of reactivity is not observed with material functionalized with **8**/Zn^{2+}.

As a further check to see that any loss in acitivty was not due to the loss of metal ion through subsequent reactions, we have reanalyzed the polymers for metal ion content following at least three cycles. For example, Macro-Ald **7**a/Cu^{2+} and Macro-Ald **7**a/Zn^{2+}, after at least three cycles reacting with **9**, showed an analytical Cu^{2+} loading of 0.17 and 0.15 mmol/g before and after use, while the Zn^{2+} loading was 0.023 and 0.020 mmol/g before and after use. While the absolute numbers seem to show some decrease after use, the fact that the catalytic activity is unchanged with **9** over prolonged reuse suggests that the analytical numbers are the same within experimental uncertainty.

Table 5. Apparent second-order rate constants for different polymer resins functionalized with **7a**/M^{2+} or **8**/Zn^{2+}, determined at $^{s}_{s}$pH = 8.9 in methanol buffered with *N-iso*-propylmorpholine, T = 25 °C, [**10**] = 3×10^{-4} mol/L.

Polymer	k_2 (**10**), 1st exp. $((mol/L)^{-1}s^{-1})$	k_2 (**10**), 2nd exp. $((mol/L)^{-1}s^{-1})$
DVB50 **7a**/Cu^{2+}	3.1	0.36
Macro-Ald **7a**/Cu^{2+}	0.22	No reaction
Meso-Ald **7a**/Cu^{2+}	0.17	0.011
Macro-Ald **7a**/Zn^{2+}	0.20	0.18
DVB50-hl **8**/Zn^{2+}	0.49	0.49

However, in the case of *O*-ethyl-*S*-3,5-dichlorophenyl methylphosphonothioate (**10**) the results given in Table 5 with DVB20 and DVB50 show that the reactivity of the supported Cu((II) catalysts decreases with each cycle. For example, with [**10**] = 0.3 mmol/L, DVB50 **7a**/Cu^{2+} exhibits a k_2 = 3.1 $(mol/L)^{-1}s^{-1}$ for its first cycle and 0.36 $(mol/L)^{-1}s^{-1}$ for the second cycle. This drop of reactivity is also accompanied by a change of the blue-green color of the solid to yellow, suggesting that the active Cu(II) form of the metal ion was reduced to Cu(I). Monitoring the reaction of 0.3 mmol/L **10** at 253 nm shows that the starting material disappears, but none of the thiolate product, which should absorb strongly at 270 nm, is observed to appear, Fig. 3). This observation, coupled with the loss of activity of the catalyst suggests that the thiolate product is absorbed by the catalyst and oxidized to the disulfide with concomitant reduction of the Cu(II) to Cu(I) and loss of activity. Although it seems counterintuitive that the small amount of S-containing substrate could inactivate all the Cu(II) through reduction, it is possible that there exists a variety of Cu-containing sites that have variable accessibility, with the most available and reactive ones being inactivated first.

For the Zn^{2+} catalysts, a redox reaction between metal and thiolate cannot happen, and as shown in Table 5 there is no loss of reactivity observed for complex with **7a** and **8**.

Influence of water

Experiments to determine the effect of 2% of added water on the reactivity of the polymers in methanol were conducted in the presence of *N-iso*-propylmorpholine buffer (6.8 mmol/L) at $^{s}_{s}$pH = 8.9. The results over 10 cycles (defined earlier) for the reaction of **9** mediated by 50 mg of Macro-PL-(II) **8**/Zn^{2+} ([Zn^{2+}] = 1.96 mmol/L) are reported graphically in Fig. 4.

The first reaction is a reference one for the reaction using substrate **9** without water, after which the 2% water was added to the UV cell for all the subsequent reactions. As can be judged from the appearance of Fig. 4, water continually degrades the activity until it reaches a stable value of 0.03 min^{-1} after the **9** runs, corresponding to a loss of 85% of the initial reactivity.

General comments on activities

Comparison of the kinetic reactivities given in Table 3 suggests a general order of reactivity of Meso-Ald < Macro-Ald < Macro-PL < Macr-PL-hl ≈ synthesized polymers. The difference in reactivity between mesoporous and macroporous commercial polymers shows the importance of

Fig. 3. UV spectra for the disappearance of **10** (at 0.3 mmol/L) catalyzed by DVB50-(II) **7a**/Cu^{2+} ([Cu^{2+}] = 6.8 mmol/L) at $^{s}_{s}$pH = 9.1.

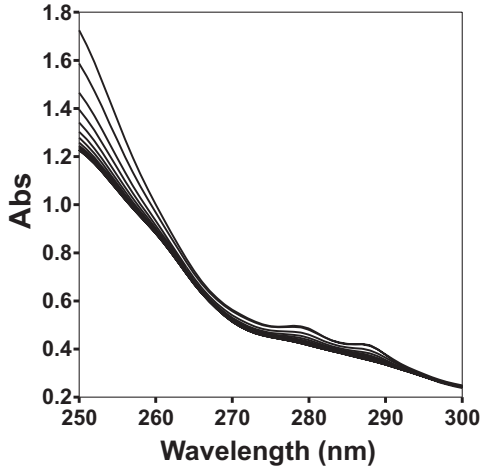

Fig. 4. Pseudo first-order rate constant, k_{obs}, for the methanolysis of **9** (10 cycles each with 0.03 mmol/L) with functionalized Macro-PL-(II) **8**/Zn^{2+} (50 mg) at $^{s}_{s}$pH = 8.9 in presence of 2% *v*:*v* of water.

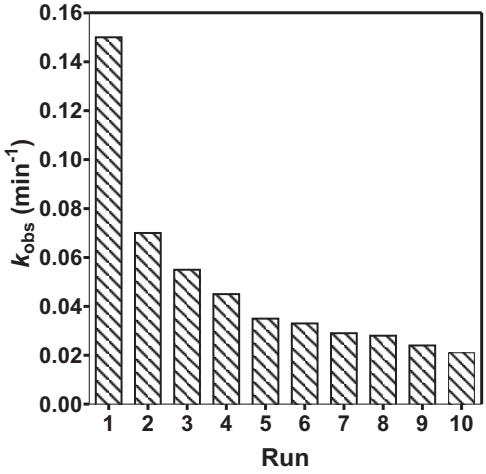

porosity in the activity of these supported catalysts. Since the polystyrene matrices used here as support materials do not swell in methanol solvent during the M^{2+}-complexation steps, the mesoporous polymers have the accessible catalytic sites present only on the surface of beads. It is known (21) that catalytically active polymers having an increased pore size allow an increased permeation of reagent and substrate into the beads, effectively increasing the local concentration of accessible catalyst. The activities of the synthetic resins made here are around 10 times better than the commercial polystyrenes, which is probably due, at least in part, to an increase in their pore size relative to the commercial macroporous polymers. However, the accessibility is not the only parameter that explains the difference of reactivity. The concentration of catalytic sites relative to the surface area is also important. The rather small bead size of the synthesized polymers and their higher loading gives a higher concentration of catalytic species on the surface. This is demonstrated by the difference in reactivity observed between Macro-PL

Fig. 5. Continuous flow system of total volume 1.5 mL, with polymer in the column represented as the shaded rectangle, a flow through UV cell, and a peristaltic pump to drive the solution at a flow rate of 1.17 mL/min.

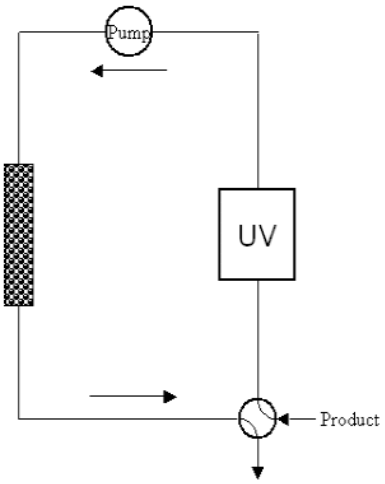

Fig. 6. Absorbance vs. time curves for the disappearance of **9** (0.03 mmol/L) (▲, absorbance at 275 nm) catalyzed by 0.113 g of functionalized Macro-PL **7a**/Cu^{2+} and for the appearance of *p*-nitrophenol (■, absorbance at 310 nm) at $^{s}_{s}$pH = 8.8.

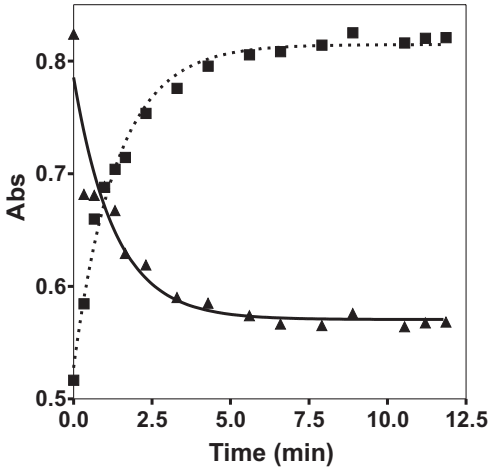


7/Cu^{2+} and Macro-PL-(II) **7**/Cu^{2+} for which the matrices are the same, but the loading of Macro-PL-(II) is higher by a factor 2 (see Table 1). The main difference between those materials is the surface concentration of Cu^{2+}, but the rate constant for the reaction with **9** and **11** vary by factors of 7 and 10 respectively. The increase of reactivity in the case of higher Cu^{2+} concentration on the surface is consistent with a cooperative effect between two neighboring metal ions.

Column system

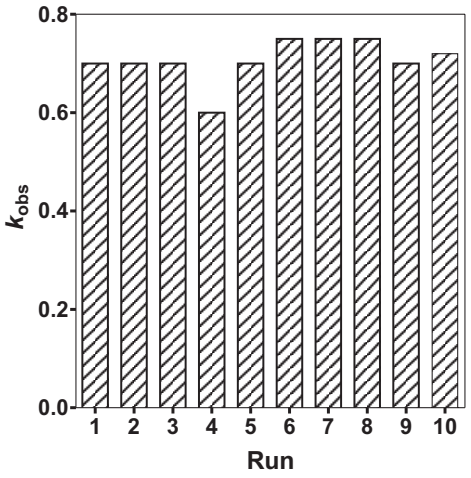
The most efficient materials made with polystyrene resin purchased from Polymer Laboratories (PL-CMS MP resin) were used in an improvised column system. This system, as illustrated in Fig. 5, consists of a variable-flow low-flow peristaltic pump connected to a column (i.d. 3.0 mm, length 50 mm, from Chrom Tech), which was filled with about ~0.1 g of the polymer support, and an injection valve (Chrom Tech, OM-1114) permitting the injection of a known volume of methanol containing the OP substrate.

Also included in the system is a UV–vis flow cell that allows monitoring of the absorbance vs. time profile of the circulating solution. The total volume of the circulating system is around 1.5 mL. A solution containing the OP substrate was introduced through the system and the valve was closed to permit continuous circulation. Shown in Fig. 6 is the kinetic curve of disappearance of **9** catalyzed by functionalized Macro-PL **7**/Cu^{2+} (0.1130 g) with a rate flow of 1.17 mL min^{-1}.

Both absorbance vs. time curves can be fitted by NLLSQ fitting to a first-order kinetics model giving a pseudo first-order rate constant of 0.72 ± 0.05 min^{-1}. In general for this circulating system, the data do not exactly follow a first-order profile because of the fact that they have stairlike profile, where each step corresponds to one cycle of the system. In the case of the data in Fig. 6, the reaction appears to be done after three cycles through the polymeric support.

As shown in Fig. 7, the reaction of phosphonate **9** with Macro-PL-(II) **7a**/Cu^{2+} has the same rate constant over 10 different injections of 0.03 mmol/L OP solution. The same

Fig. 7. Pseudo first-order rate constant, k_{obs}, for the methanolysis of **9** (at 0.03 mmol/L) with Macro-PL-(II) Cu^{2+}/**7a** (0.1130g) in a column at a flow rate of 1.17 mL/min at $^{s}_{s}$pH = 8.8.



stability was observed for **11** with Macro-PL-(II) **7a**/Cu^{2+}, and **9** and **10** with Macro-PL-(II) **7a**/Zn^{2+}.

To demonstrate turnover of the catalyst on the polymer, an experiment monitoring the decomposition of an excess of substrate was conducted wherein 25 mL of methanol solution containing 1.2×10^{-2} mmol of **9** was circulated through a column (i.d. 3.0 mm, length 25 mm) containing 46.6 mg of Macro-PL-(II) **8**-Zn^{2+} (total amount of Zn^{2+} was 4.6×10^{-3} mmol). The observed rate constant for the disappearance of the substrate was 0.002 ± 0.0007 min^{-1}, corresponding to a rather large half-time of 5.75 h. However, under these conditions the volume of the column containing the active polymer was only 0.175 mL, and since the flow rate was 0.29 mL/min, the great bulk of the substrate was not in contact with the polymer. These data indicate that the polymer is capable of destroying an excess of substrate, surviving prolonged contact with the reacting system and suggest that far greater efficacy would be possible with large columns in

© 2007 NRC Canada

circulating systems, where the ratio of the column volume to total circulating volume is maximized.

Conclusion

In this work we have shown that polymer-supported metal and (or) complex catalysts can be prepared by grafting a ligand (**7a** or **8**) onto a suitable chloromethylated polystyrene resin, which can then be loaded with M^{2+} (Cu^{2+} or Zn^{2+}). This catalytic matrix shows good activity for mediating the methanolysis of different kinds of OP esters like *O*-ethyl-*S*-3,5-dichlorophenyl methylphosphonothioate (**10**), *O*-ethyl-*O*-4-nitrophenyl methylphosphonate (**9**), and fenitrothion (**11**), which are simulants for V-agents, G-agents, and P=S pesticides. In the most favourable case, 28 mg of DVB50-(II) **7a**/Cu^{2+} suspended in 2.5 mL of solution provides a factor of 2.9×10^6 in acceleration of the methanolysis of fenitrothion over the background reaction at ${}^{s}_{s}$pH = 9. The methanolysis reactivity is shown to be enhanced by a large porosity of the solids, which allows access of the OP ester substrates to the catalytic centers. This material can be used in column systems with a continuous flow and may show some promise for larger scale applications to cleanups of OP esters, where the contaminants can be dissolved in methanol that is passed through a column for decontamination.

Ketonization of the unusually acidic elongated enol generated by flash photolytic decarboxylation of *p*-formylphenylacetic acid in aqueous solution

Yvonne Chiang, Kirill Kolmakov, and A. Jerry Kresge

Abstract: Rates of photolysis of *p*-formylphenylacetic acid were measured flash photoytically in perchloric acid and sodium hydroxide solutions, and also in acetic acid, biphosphate ion, and tris-(hydroxymethyl)methaneammonium ion buffers, using H_2O and D_2O as solvents. The results provide rate profiles and solvent isotope effects, which indicate that photolysis occurs through an elongated enol intermediate. This enol is unusually strongly acidic, by some two to three pQ_a units, when compared with simple non-elongated enols.

Key words: flash photolysis, elongated enols, rate profiles, solvent isotope effects.

Résumé : Faisant appel à la photolyse éclair, on a mesuré les vitesses de photolyse de l'acide *p*-formylphénylacétique dans des solutions aqueuses ou dans le l'eau lourde d'acide perchlorique et d'hydroxyde de sodium ainsi que dans l'acide acétique en présence d'ion biphosphate et de tris(hydroxyméthyl)méthaneammonium comme tampons. Les résultats permettent d'obtenir des profils de vitesse et des effets isotopiques de solvant qui indiquent que la photolyse se produit par le biais d'un intermédiaire énolique allongé. Cet énol est particulièrement acide, par des valeurs de pQ_a de deux à trois unités supérieures à celles d'énols simples non allongés.

Mots-clés : photolyse éclair, énols allongés, profils de vitesse, effets isotopiques de solvant.

[Traduit par la Rédaction]

Introduction

Photodecarboxylation of *p*-benzoylphenylacetic acid (**1**) when carried out in aqueous solution, gives *p*-methylbenzophenone (**2**) as its reaction product (eq. [1]) (1).

[1] 
1 **2**

This substance is formed through a carbanion intermediate, whose negative charge is delocalized from methylene carbon (**3**) onto carbonyl oxygen (**4**) (eq. [2]).

[2] 
3 **4**

[1]Corresponding author (e-mail: akresge@chem.utoronto.ca).

Product formation could therefore occur either by direct protonation of methylene carbon (eq. [3]) or by protonation of carbonyl oxygen to give an elongated enol intermediate, **5**, whose ketonization would afford the observed product (eq. [4]). In previously reported work (2), we carried out this decarboxylation flash photolytically and detected a short-lived transient species that we identified as elongated enol **5**. This enol has proved to be an unusually strong acid, several orders of magnitude more acidic than other simple enol analogs without the elongating cyclohexadienyl spacer.

[3] 
3 **2**

[4] 
4 **5** **2**

We have now added to that previous study a companion investigation of the photodecarboxylation of *p*-formylphenylacetic acid (**6**) (eq. [5]). We found that this reaction

[5] 
6 **7**

 doi:10.1139/V07-095 © 2007 NRC Canada

also occurs through an elongated enol intermediate, which is also unusually strongly acidic.

Experimental Section

Materials

p-Formylphenylacetic acid was prepared by a Sommelet reaction (3) on 4-chloromethylphenylacetic acid, itself synthesized by chloromethylation of phenylacetic acid (4).

4-Chloromethylphenylacetic acid

A 10 mL capacity vial, equipped with septa and stirring bar, was purged with argon, and 0.8 mL (1.78 g, 0.0068 mol) of $SnCl_4$ was introduced through a syringe. Dry phenylacetic acid (1.36 g, 0.010 mol) was dissolved in 2 mL (2.12 g, 0.026 mol) of monochloromethyl ether ($ClCH_2OCH_3$) at room temperature and the solution was slowly added into the vial within 20 min upon vigorous stirring at 0 °C. The reaction mixture was left at room temperature for 1 h under argon and then quenched with 30 mL of ice-cold water upon vigorous stirring. An amorphous white precipitate was separated. This was washed with water and dissolved in 20 mL of $CHCl_3$, and the solution was dried over $MgSO_4$. The solvent was evaporated to dryness, and the residue was recrystallized from a mixture of CH_2Cl_2 (10 mL) and hexane (20 mL) to afford 0.82 g (44%) of a product whose melting point (149–151 °C) was consistent with the literature (4). Its ^{1}H NMR ($CDCl_3$, 300 MHz) had the following signals: δ: 3.65 (s, 2H, CH_2), 4.57 (s, 2H, CH_2Cl), 7.26 (d, 2H, J = 9 Hz, *p*-C_6H_4), 7.35 (d, 2H, J = 9 Hz, *p*-C_6H_4).

4-Formylphenylacetic acid

Hexamethylenetetramine (840 mg, 0.0060 mol) and 4-chloromethylphenylacetic acid (740 mg, 0.0044 mol) were heated under reflux for 1 h in 20 mL of chloroform. The solvent was then evaporated to one half of its initial volume, and 990 mg (75%) of a colorless quaternary ammonium salt separated. This was dried and then heated under reflux in 10 mL of 50 vol% aqueous acetic acid for 1.5 h under an argon atmosphere. Upon cooling to ambient temperature, the mixture was quenched with a solution of 10 g of NH_4Cl in 40 mL of H_2O and was then extracted with CH_2Cl_2 (3 × 15 mL). The extract was washed with a solution of NH_4Cl (1.0 g) and 0.5 mL of concd. HCl in 10 mL of H_2O and was dried over $MgSO_4$. The solvent was removed under vacuum to afford 460 mg (70%) of crude product, which was chromatographed on a column containing 8 g of silica gel with mobile phase MeCN–CH_2Cl_2 (1:1 *v*/*v*). The main fraction furnished 330 mg (44%) of a relatively pure (>90%, NMR) compound. The course of the separation was monitored by TLC on SIL-G/UV 254 plates with acetone–acetonitrile (3:1) as the mobile phase. Further, an analytical sample (80 mg) with no detectable impurities (HPLC, TLC) and mp 128 to 129 °C was obtained, starting from 150 mg of the material, by recrystallization (2 times) from CH_2Cl_2–hexane (1:3 *v*/*v*) under an argon atmosphere. (Baker et al. (5), who originally obtained 4-formylphenylacetic acid with a very poor yield, reported mp 131 °C). The spectroscopic data (NMR, MS) listed here confirm the structure.

^{1}H NMR ($CDCl_3$, 300 MHz) δ: 3.75 (s, 2H, CH_2), 7.46 (d, 2H, J = 8 Hz, p-C_6H_4), 7.86 (d, 2H, J = 8 Hz, *p*-C_6H_4), 10.01 (s, 1H, CHO). ^{13}C NMR ($CDCl_3$, 75 MHz) δ: 41.05 (CH_2), 130.09, 130.19, 135.56 and 140.30 (C_{Ar}), 176.51 (CO_2H), 191.90 (C=O). MS (EI) *m*/*z*: 164 M^+ (85), 119 M^+ – CO_2-H (55), 91 M^+ –CO_2–OH (100). HRMS (EI) calcd. for (M^+) $C_9H_8O_3$: 164.0473; found 164.0476.

All other materials were best available commercial grades.

Kinetics

Rate measurements were made using either a conventional flash lamp (microsecond) flash photolysis system (6), or an eximer laser (nanosecond) system (7) operating at λ_{exc} = 248 nm, which have already been described (6, 7). This revealed a short-lived transient species, subsequently identified as an elongated enol intermediate (vide infra) with broad UV absorbance centered at λ = 330 nm. Decay of this absorbance, for the most part, followed the first-order rate law well, and rate constants were obtained by least-squares fitting of a single exponential function. In some cases, however, the data fit a double exponential function better than a single exponential function, and a double exponential was therefore used. In this situation, one of the two rate constants obtained changed its value when the reacting solution was degassed, and the other unchanging rate constant was then taken to be that for ketonization of the elongated enol intermediate.

Product identification

The reaction investigated was shown to be the decarboxylation of eq. 5 by HPLC analysis using an authentic sample of the expected product *p*-methylbenzaldehyde (**7**).

Results

Rates of decay of the broad UV absorption band centered at λ_{max} = 330 nm, generated by flashing 4-formylphenylacetic acid, were determined in aqueous perchloric acid and sodium hydroxide solutions, and also in acetic acid, biphosphate ion, and tris-(hydroxymethyl)methaneammonium ion buffer solutions, using H_2O as solvent; some rate measurements were made as well in perchloric acid and sodium hydroxide solutions and biphosphate ion buffers, using D_2O as solvent. The ionic strength of all reacting solutions was kept constant at 0.10 mol/L with sodium perchlorate as the inert electrolyte. The results are summarized in Tables S1–S3.[2,3]

[2] Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. [3] In perchloric acid solutions the absorbance from the transient species of interest here diminished as the acid concentration increased, consistent with decarboxylation occurring through the carboxylate form of the substrate, and HPLC analysis showed the formation of other (uninvestigated) products. These interferences could be diminished somewhat by using deoxygenated solutions and accumulating data from several replicate flash photolysis shots.

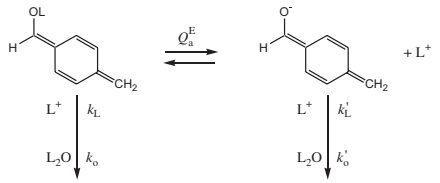
© 2007 NRC Canada

The measurements in buffers were made in a series of solutions of constant buffer ratio, and therefore constant hydronium ion concentration, but varying total buffer concentration. Buffer catalysis was strong, and observed rate constants within a given buffer solution series were accurately proportional to buffer concentration. The data were therefore analyzed by least-squares fitting of the linear buffer dilution expression shown in eq. [6]. The zero buffer concentration intercepts, k_{int}, obtained in this way, plus the rate constants determined in perchloric acid and sodium hydroxide solution, are displayed as the rate profiles shown in Fig. 1.

[6] $$k_{obs} = k_{int} + k_{buff}[buffer]$$

The shape of these rate profiles is characteristic of enol ketonization reactions, which are known to occur by rate-determining β-carbon hydronation of either the enol or its enolate ion by any available acid (8). Because these profiles refer to solvent-related species, the available acids will be either the hydronium ion, written here as L^+, or a solvent water molecule, L_2O, as shown in the reaction scheme of eq. [7].[4] The acid-catalyzed descending diagonal portions at the high acidity ends of these profiles then represent β-carbon hydronation of the enol by hydronium ion. These sections are followed by short "uncatalyzed" horizontal portions, which could be due either to β-carbon hydronation of enol by solvent water or to the ionization of enol to enolate and hydronium ions followed by β-carbon hydronation of the enolate ion by hydronium ion. This latter process generates hydronium ions in its rapid pre-equilibrium ionization step and then uses them up in its rate-determining step, to give an overall reaction independent of hydronium ion concentration.

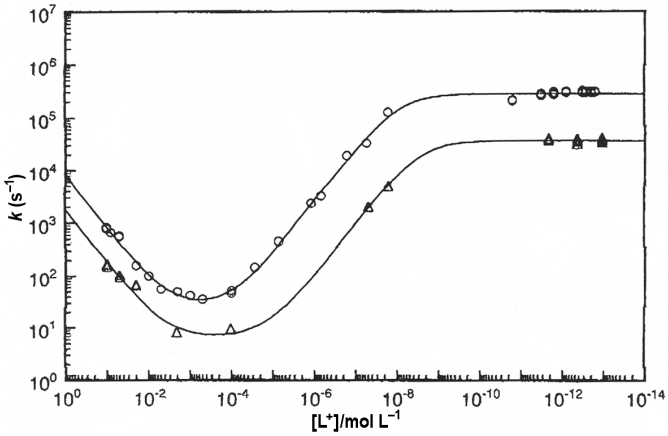
[7]



These short horizontal sections are followed by base-catalyzed ascending diagonal portions that can be assigned to the ionization of enol to enolate ion followed by hydronation of enolate by solvent water. This process produces hydronium ions in its rapid pre-equilibrium step but does not use then up in its rate-determining step, to give an overall reaction whose rate is inversely proportional to hydronium ion concentration and has the appearance of hydroxide ion catalysis. Finally at sufficiently low acidity, the position of the enol–enolate equilibrium shifts over to the side of the enolate ion, and the process reduces to simple hydronation of enolate β-carbon by solvent water. This gives the final horizontal rate profile plateau.

The rate law that applies to this reaction scheme is shown in eq. [8], where k_{uc} is used to designate the process of an uncertain mechanism represented by the central short horizontal sections of the rate profiles, and the other rate and equilibrium constants are defined by eq. [7].

Fig. 1. Rate profiles for the ketonization of elongated enol **8** in H_2O (○) and D (△) solutions.



[8] $$k_{obs} = k_L[L^+] + k_{uc} + k_o'Q_a^E/(Q_a^E + [L^+])$$

Least-squares fitting using this expression gave for H_2O solutions: $k_H = (8.11 \pm 0.48) \times 10^3$ $(mol/L)^{-1}s^{-1}$, $k_{uc} = (2.62 \pm 0.28) \times 10^1$ s^{-1}, $Q_a^E = (9.20 \pm 0.58) \times 10^{-9}$ mol/L, $pQ_a^E = 8.04$, and $k_o' = (2.82 \pm 0.05) \times 10^5$ s^{-1}, and results for D_2O solutions that, when combined with their H_2O counterparts, gave the isotope effects: $k_H/k_D = 4.49 \pm 0.09$, $(k_o')_H/(k_o')_D = 7.74 \pm 0.36$, and $(Q_a^E)_H/(Q_a^E)_D = 3.41 \pm 0.14$.[5] The lines through the data points shown in Fig. 1 were drawn using these results. It may be seen that the data fit the reaction scheme of eq. [7] well and thus provide strong evidence that the process under observation is an enol ketonization reaction.

Further support for the assignment of the rate profiles of Fig. 1 to enol ketonization comes from the isotope effects obtained by comparing results determined in H_2O solution with those obtained in D_2O. The rate constants k_L and k_o' refer to rate-determining substrate hydronation, and isotope effects on these quantities can therefore be expected to contain primary isotope effect components in the normal direction ($k_H/k_D > 1$) of appreciable magnitude. These isotope effects, however, will also contain secondary components, with that on k_L in the inverse direction ($k_H/k_D < 1$) and that on k_o' in the normal direction ($k_H/k_D > 1$) (9). This will make the isotope effect on k_o' considerably stronger than that on k_H', which is nicely consistent with our observation, i.e., $(k_o')_H/(k_o')_D = 7.7$ whereas $k_H/k_D = 4.5$. The isotope effect on Q_a^E is also consistent with this quantity being the acidity constant of an enol ionizing as an oxygen acid. Such equilibrium isotope effects lie in the normal direction and generally fall in the range 3–5 (8); that of course agrees well with the observed value $(Q_a^E)_H/(Q_a^E)_D = 3.4$.

Thus, both solvent isotope effects and rate profiles agree that decarboxylation of *p*-formylphenylacetic acid occurs through an elongated enol intermediate, **8**, as shown in eq. [9].

[4] The symbol "L" is used to denote either protium or deuterium, "H" is used specifically for protium, and "D" specifically for deuterium.
[5] This is a concentration equilibrium constant applicable at the ionic strength (0.10 mol/L) of the solutions in which it was determined.

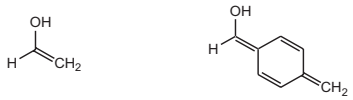
Discussion

The present results show the elongated enol **8** with pQ_a^E = 8.04, to have an unusually strongly acidic hydroxyl group; simple enols ionizing as oxygen acids ordinarily have acidity constants in the range pQ_a^E = 10–11 (8). An especially apt comparison of the present system can be made with the enol of acetaldehyde **9**, which lacks the elongating cyclo-



9 8

hexadienyl spacer
of enol **8**; acetaldehyde enol has pQ_a^E = 10.50 (6), some two and a half p*Q* units weaker than the acidity constant of elongated enol **8**. This striking difference is a result of the fact that ionization of enol **8** (eq. [10]) creates an anion whose negative charge can be delocalized from enolate oxygen **10** onto methylene carbon **11** (eq. [10]); this converts a cyclohexadienyl moiety into a benzene ring and thus benefits from a gain in benzene resonance energy. A similar shift of negative charge density is of course possible in the unionized enol, but that involves generation of charge and is consequently not as energetically advantageous. The anion is consequently stabilized more than the unionized enol, and that reduces the energy gap between the enol and enolate ion, making the enol a stronger acid than it would otherwise be.

Chemistry of photogenerated α-phenyl-substituted *o*-, *m*-, and *p*-quinone methides from phenol derivatives in aqueous solution

Li Diao and Peter Wan

Abstract: The enhanced photochemical reactivity of o-substituted phenols in its propensity to give *o*-quinone methide (*o*-QM) intermediates via excited state intramolecular proton transfer (ESIPT) was uncovered by Keith Yates as part of his now classic studies of photohydration of aromatic alkenes, alkynes, and related compounds. Photogeneration of QMs and the study of their chemistry along with potential biological applications are the focus of many groups. In this work, photochemical precursors to *o*-, *m*-, and *p*-QMs based on substituted phenols (hydroxybenzyl alcohols) and related compounds have been studied in aqueous solution as a function of pH and water content. The focus will be on QMs that are stabilized by an α-phenyl substituent, which enhances quantum yields for their formation, with the resulting QMs having longer lifetimes and easier to detect. Noteworthy is that all QM isomers can be photogenerated with the o and m isomers being the most efficient, consistent with the Zimmerman "ortho–meta" effect. *m*-QMs have formal non-Kekulé structures, and although they can be routinely photogenerated, are found to be most reactive. One *m*-QM was found to undergo a photocondensation reaction at high pH giving rise to m-substituted oligomers. The mechanism of QM formation in aqueous solution is believed to involve singlet excited phenols that undergo adiabatic deprotonation to give the corresponding photoexcited phenolate ion, which subsequently expels the hydroxide ion (photodehydroxylation). A pathway involving direct loss of water for the o-isomers is also possible in organic solvents.

Key words: quinone methides, phenols, excited state acidity, solvolysis, carbocations, meta effect, photopolymerization, non-Kekulé intermediates.

Résumé : La réactivité photochimique accrue des phénols *o*-substitués dans sa tendance à donner des intermédiaires *o*-quinométhides (*o*-QM) par le biais d'un transfert de proton intramoléculaire dans l'état excité (TPIEE) a été découverte par Keith Yates dans le cadre de ses études maintenant classiques sur la photohydratation des alcènes et des alcynes aromatiques et des composés apparentés. La photogénération de QM et l'étude de leur chimie en relation avec leurs applications biologiques potentielles sont les objets principaux de recherches de plusieurs groupes. Dans ce travail, opérant en solution aqueuse, on a examiné les précurseurs photochimiques de *o*-, *m*- et *p*-QM issus de phénols substitués (alcools hydroxybenzyliques) et de composés apparentés en fonction du pH et de la quantité d'eau présente. On s'est orienté vers les QM qui sont stabilisés par un substituant ἀ-phényle, ce qui augmente les rendements quantiques de leurs formations et qui conduit à des QM de temps de vie plus longs et une plus grande facilité de détection. Il est important de noter que tous les isomères de QM peuvent être photogénérés, mais que les isomères *o*- et *m*- sont les plus efficaces; ce qui est en accord avec l'effet "ortho-méta" de Zimmerman. Les *m*-QM comportent des structures formelles qui ne correspondent pas à celles de Kekulé et qui, même si elles peuvent facilement être photogénérées, sont les plus réactives. On a trouvé qu'un QM subit une réaction de photocondensation à un pH élevé conduisant à la formation d'oligomères *m*-substitués. On croit que le mécanisme de formation des QM en solution aqueuse implique l'état singulet de phénols excités qui subissent une déprotonation adiabatique conduisant à la formation de l'ion phénolate excité correspondant qui expulse subséquemment l'ion hydroxyde (photodéshydroxylation). Une voie réactionnelle impliquant une perte directe d'eau à partir des isomères ortho est aussi possible dans les solvants organiques.

Mots-clés: quinométhides, phénols, acidité de l'état excité, solvolyse, carbocations, effet méta, photopolymérisation, intermédiaires qui ne correspondent pas à ceux de Kekulé.

Introduction

The study of photochemical generation and structure-reactivity of polar intermediates derived from substituted aromatic compounds gained a new practitioner in Keith Yates, starting in the early 1980s. After a distinguished career studying classic organic reaction mechanisms (e.g., hydrolysis of esters and amides) and the behaviour of strong acids on organic compounds (acidity functions and their applications), Keith Yates decided to investigate how organic photochemistry could serve the study of organic reaction mechanisms, with initial work on the photohydration of aromatic alkenes and alkynes (1). The idea he had at the time was that the well-known phenomenon of enhanced acidity or basicity of many aromatic compounds (2) could manifest itself in enhanced reactivity such as hydrolysis or electrophilic attack, under the right conditions. Yates and coworkers successfully demonstrated the utility of their ideas in a series of papers that span over 15 years. In particular, in one their studies of photohydration Yates and Kalanderopoulos (3) proposed that the photohydration mechanism of *o*-hydroxystyrene (**1**) involved initial irreversible excited state intramolecular proton transfer (ESIPT) from phenol OH to the β-carbon of the alkene moiety, to give *o*-quinone methides (*o*-QM) **2a** and **2b**, which on trapping by water, would give the expected hydration product **3** (eq. [1]). This mechanism offers a reasonable explanation for the much lower photohydration efficiency observed for *o*-methoxystyrene. Yates and Kalanderopoulos (3) initially wrote only species **2a** as the proposed intermediate in the initial ESIPT step. However, one would expect that the dominant resonance contributor is **2b**, which has the well-known *o*-QM structure. Although Yates ultimately did not pursue a study of QMs, this initial paper (3) indicated that he was already at its doorstep. QM intermediates have a long history, but more recently it has become a topic of renewed interest in both thermal chemistry and photochemistry (4, 5). In particular, recent studies concerning biological applications of QMs as electrophiles for DNA cross-linking and general reactivity and (or) stability with deoxynucleosides as nucleophiles have appeared (5*j*–5*m*) that improve the current understanding along with demonstrated potential applications of these intermediates in biology. With respect to photochemical generation of QMs, initial systematic studies could be traced back to Seiler and Wirz (5*a*) who studied the photohydrolysis of a variety of trifluoromethylphenols and naphthols (e.g., eq. [2]) and demonstrated the viability of photogenerating a variety of difluoro-substituted QMs.

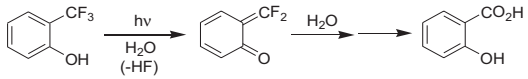
[2]



Continuing in the spirit of research direction laid out by Keith Yates, we reported a general method for photogenerating all of the parent QM isomers from hydroxyl-substituted benzyl alcohols (5*c*, 5*d*). This method offered an efficient and general method for making a variety of simple QMs in aqueous solution — including all three parent systems — from simple phenol derivatives and takes direct advantage of the enhanced acidity of phenols in the excited singlet state. Moreover, hydroxybenzyl alcohols are readily available and have a high tendency to give polar intermediates in aqueous solution even though the hydroxide ion is considered to be a very poor leaving group. Although the method and proposed mechanism(s) of reaction are now well known amongst practitioners, many of the original details have not been published. It is the purpose of this paper to address this deficiency and to provide additional new reactivity data for compounds that have been studied before and also for new substrates. The results that will be reported are for hydroxybenzyl alcohols and related derivatives that have at least one α-phenyl substituent (**4**–**11** and **15**–**17**), the latter having the desirable effect of making these systems much easier to handle and study.

Results and discussion

Materials

The compounds studied (**4**–**11** and **15**–**17**) were readily synthesized using standard procedures, most involving the use of Grignard reagents (see Experimental section).

Product studies

Photolysis of *o*-, *m*-, and *p*-hydroxybenzhydrols (**4**–**6**) in 1:1 (*v*/*v*) H_2O/CH_3OH (Rayonet photochemical reactor, 254 nm lamps, argon purged, 3 min) gave the corresponding methyl ethers **12** (17%), **13** (15%), and **14** (7%), respectively, as the only products in low conversion runs (<20%) (eq. [3]). The ^1H NMR spectrum of the reaction mixture showed the characteristic methoxy singlet for the methyl ether product at δ 3.3–3.4. Similar photolysis of their methoxy-substituted analogs (**15**, **16**, and **17**) gave no reaction except for **15**, which gave about 4% of the corresponding methyl ether. Control experiments performed in the absence of light indicated that only the o and p isomers were reactive (yield up to 5%) if a small amount of $NaHCO_3$ was not added to the solution prior to photolysis. Therefore, all runs (photochemical and thermal) using CH_3OH were carried out in the presence of a pinch of $NaHCO_3$. It is postulated that the residual thermal reaction (solvolysis) in the absence of added $NaHCO_3$ is due to traces of acid present in CH_3OH.

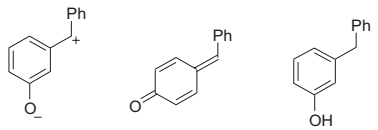
Prolonged photolysis (>20 min) of **4**–**6** gave increasing yields of the methyl ether and also formation of a secondary benzylphenol product (e.g., eq. [4]), which has a characteristic singlet at δ 4.0. As shown in Fig. 1 for **4**, the yield of methyl ether **12** rises rapidly within the first 20 min of irradiation after which its formation slows down and levels off at about 60% yield, while benzylphenol **18** builds up in the product mixture although never becoming a major product. It is reasonable to propose that **18** is the secondary product from photolysis of **12**. The mechanism probably involves initial homolytic cleavage of the C–OMe bond, followed by a disproportionation of the radical pair to form **18** and formaldehyde. We have shown (6) that related benzyl methyl ethers react this way on photolysis.

[4] 
4 **12** **18**

Irradiation of coumaranone **7**, a known photoprogenitor (7) of *o*-QM **19**, gave **12** as the only product (~3% yield) under identical conditions as used for **4**. Extended photolysis (254 nm, 8 min), however, resulted in both methyl ether **12** (~13%) and benzhydrol **4** (~9%) as products (eq. [5]). These results are consistent with a mechanism of reaction via *o*-QM **19** from the photolysis of **7** via a standard photodecarbonylation mechanism. Since the photolysis of **4** resulted in similar chemistry, it is reasonable to suggest that *o*-QM **19** is also the essential intermediate in the photolysis of **4**. Following this rationale, the photomethanolysis of **5** and **6** are proposed to proceed via *m*- and *p*-QMs **20** and **21**, respectively. These proposals are confirmed in UV–vis and laser flash photolysis (LFP) studies (vide infra).

[5] 
7 **19**

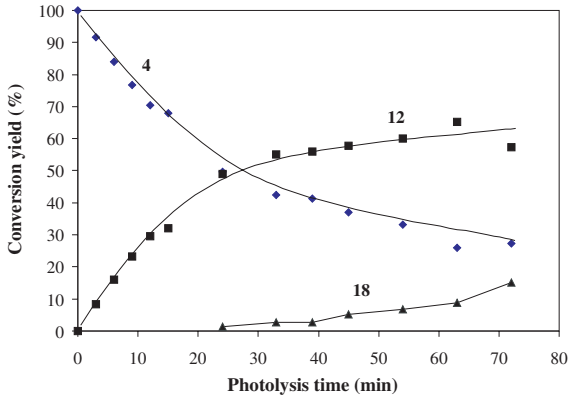


20 **21** **24**

Photolysis of α,α-diphenyl-substituted systems **8** and **9** in 1:1 H_2O/CH_3OH under identical conditions as for **4** and **5** resulted in significantly higher conversions to the corresponding methyl ethers (28% and 60%, respectively). Secondary photochemistry to give the reduced disproportionation products (vide supra) were not observed under the conditions employed. One possible reason for the lack of secondary photochemistry for these compounds is that the increased steric hindrance at the benzylic position (two phenyl groups) retards biradical disproportionation.

The effect of solution pH (aqueous portion) was examined. Acidic pH (pH < 4) could not be employed in product studies for the o and p isomers because of significant residual thermal reaction. Therefore, only the pH 7–14 range was examined for all substrates, although acidic pH levels were used for selected m isomers. In all cases, higher conversions to the methyl ethers were observed at higher pH values. For example, a plot of yield of **12** vs. pH (from 7–14) from photolysis of **4** in 1:1 H_2O/CH_3OH showed a sigmoid curve in the pH 11–13 range with an apparent inflection point at around 12. Since phenols have $pK_a(S_o)$ in the 9–12 range (in neat water), the increase in reaction efficiency at high pH is consistent with higher reactivity observed on directly exciting the phenolate ion. Indeed, the apparent pK_a of **4** in 1:1 H_2O/CH_3OH, as determined by UV–vis spectrometry, was estimated to be about 12.

Fig. 1. Plot of the photochemical conversion of **4** to **12** and **18** in 1:1 H_2O/MeOH as a function of photolysis time (λ_{ex} 254 nm).



Photolysis of m isomers **5** and **9** in basic solution resulted in the formation of a cloudy solution. It was more pronounced for the α,α-diphenyl derivative **9** and not observed for all o and p isomers. Initial MS analysis of the precipitate showed formation of dimers and trimers, suggesting that a photoinitiated self-condensation pathway may be operative for the m isomers. To enhance the yield of these condensation products, photolysis of **9** was carried out in neat water at pH 12 to avoid the presence of CH_3OH acting as a nuclephile. Photolysis (10 min) gave a cloudy solution that was subsequently neutralized and extracted with CH_2Cl_2. The ^1H NMR spectrum of the product mixture showed a group of new peaks including two exchangeable protons (hydroxy singlets at δ 5.1 and 8.2) and a triplet near the aromatic region (δ 6.4), in addition to those expected for **9**. Prolonged irradiation (30 min) caused the formation of pale yellow flakes that precipitated out of solution and aggregated upon the addition of salt. This yellow substance gave a much cleaner ^1H NMR spectrum in which there are twice as many aromatic protons as hydroxyl protons than in the starting material and a $M^+ - 1$ of 533 (negative FAB), indicative of a dimeric structure. There are two pathways in which a dimer can arise. A "head-to-tail" dimerization pathway to give dimer **22** or electrophilic aromatic substitution of the diphenylmethyl moiety (as the cation) onto the phenolate (more activated) ring, which would give a tetraphenylmethane-type structure. We believe a head-to-tail pathway has occurred to give **22** (Scheme 1), since treatment of this dimer (and longer oligomers, vide infra) in mild acid (pH 1) in 1:1 $H_2O/(CH_3)_2CO$ gave back starting material **9**. Such a reversible reaction in mild acid would be anticipated for a highly activated benzylic ether linkage but not for the alter-

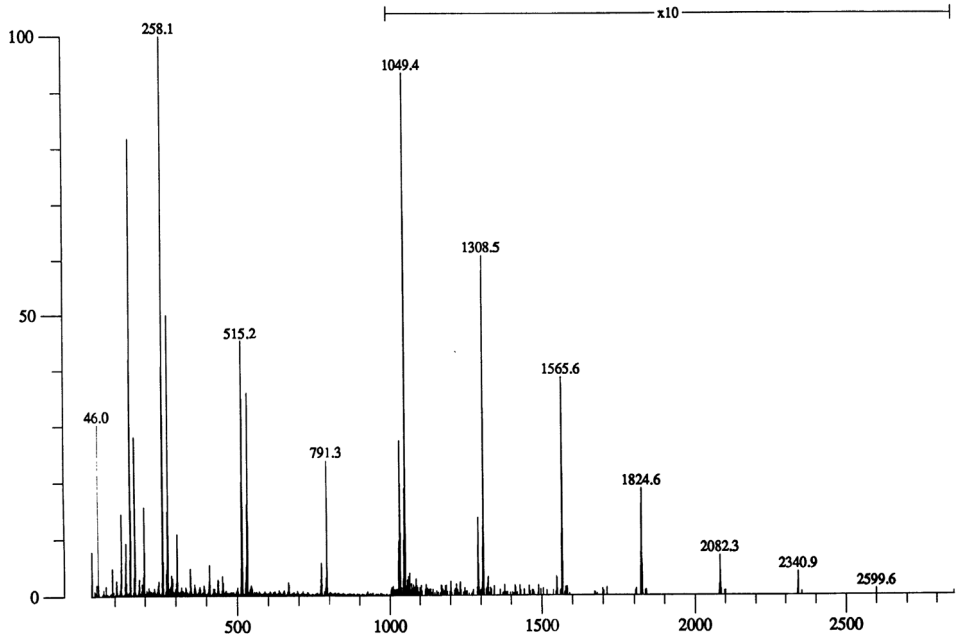
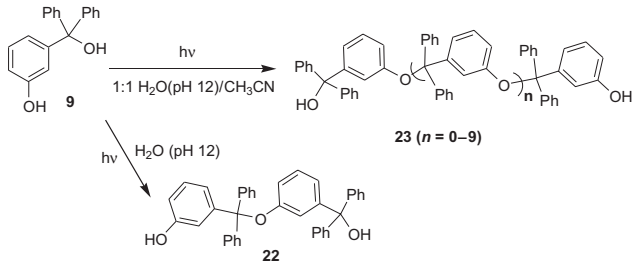
Fig. 2. Mass spectrum (negative ion FAB) of photoproduct **23** obtained on photolysis of **9** in 1:1 H_2O (pH 12)/CH_3CN. The highest mass observed at 2856 (n = 9; see Scheme 1) is not shown. All others from n = 8 to n = 0 match the expected masses reasonably well.



Scheme 1.



native tetraphenylmethane structure. Interestingly, similar photolysis of **9** in basic 1:1 H_2O/CH_3CN gave a yellow homogeneous solution after 30 min photolysis, which upon work-up was found to contain oligomers **23** of up to 11 units by negative ion FAB MS (Scheme 1, Fig. 2). The chemistry observed here for m isomer **9** is consistent with an *m*-QM intermediate that has a zwitterionic structure (**20** from **5** or **32** from **9**). In basic pH, the starting material **9** is in the (nucleophilic) phenolate form and shows great propensity to attack the positive charge of the *m*-QM structure, hence dimerization and oligomerization. Moreover, *m*-QM from **9** is longer lived than the corresponding QM from **5** (vide infra) and hence more prone to attack by the phenolate ion. The *o*- and *p*-QMs **19** and **21** are less reactive (they have a neutral quinoid structure) in this respect and dimerization and oligomerization is not as prominent, although it has also been reported for an o isomer under extended photolysis (8) and also in the photolysis of (2-hydroxybenzyl)trimethylammonium iodide precursor (5*j*), both in basic solution.

Quantum yields

Quantum yields for methyl ether formation for selected substrates were measured in 1:1 H_2O/CH_3OH using the photomethanolysis of **4** (Φ_p = 0.46) (5*c*) as a secondary actinometer (λ_{ex} 254 nm). Although in general, product quantum yields cannot be used as a direct measure of reactivity, comparisons of Φ_p values in Table 1 reveal that the hydroxyl-substituted alcohols have much higher quantum yields that their methoxy-substituted counterparts. The addition of an extra α-phenyl group also enhances quantum yield. Furthermore, o and m isomers have higher quantum yields than p isomers, which is consistent with Zimmerman's "ortho–meta" effect (9) for photoreactivity of substituted benzenes that undergo reaction via polar intermediates.

Table 1. Quantum yields (Φ_p) for methyl ether formation

Compound	Φ_p

Note: In 1:1 (*v*/*v*) H_2O/CH_3OH. Measured using **4** as the secondary actinometer. Photolyses were carried out in a Rayonet RPR reactor (λ_{ex} 254 nm). Estimated errors are 10%–15% of quoted value. Conversions were kept <30%.

UV–vis studies

Selected o and p substituted isomers were studied using UV–vis spectrophotometry in aqueous CH_3CN (to avoid complications from methyl ether formation if MeOH was used) to gain insight into whether the corresponding pro-

[b]Results from LFP studies.

posed QMs are observable without the need for LFP. None of the m isomers gave observable transients using standard UV–vis techniques and *m*-QM intermediates could only be observed using LFP (vide infra).

Photolysis of **4** in neat CH_3CN (~10^{-2} mol/L, 254 nm for ~1–5 min) in a quartz cuvette resulted in the formation of a initially yellow, then orange-red, and eventually a deep red-brown solution. UV–vis spectra were recorded before and after photolysis and are shown in Fig. 3 where the starting material absorbs only below 300 nm, with λ_{max} at 276 nm. On photolysis, the appearance of new absorption bands at 333 and 423 nm indicated the formation of a new species. This transient decayed slowly in neat CH_3CN; the yellow color remained even on sitting overnight. A similar transient was observed in THF and cyclohexane (at ca. –15 °C) (Table 2). The red shift of λ_{max} on going to more polar solvents indicate that these transitions of π,π^* in character, consistent with a highly conjugated *o*-QM **19**.

Photolysis of **4** in 1:9 H_2O/CH_3CN at ~5 °C produced an orange-red solution, which was formed more efficiently than in neat CH_3CN but with similar λ_{max} (Table 2). Upon removal from the UV source, the color gradually faded ($\tau \approx$ 40 s; shorter at 20 °C) with complete recovery of the UV spectrum prior to irradiation. When photolyzed in essentially neat H_2O (<5% CH_3CN as co-solvent), the same orange-red transient was generated but disappeared quickly (τ < 5 s), preventing the recording of a UV–vis spectrum.

Table 3. Absorption maxima (λ_{max}) and estimated lifetimes (τ) of photogenerated transient QMs from hydroxybenzhydrols.

Compound	Solvent[a]	λ_{max} (nm)[b]	τ[c]
4	100% H_2O	333, 438	<5 s

[a]At ~20 °C unless otherwise specified.
[b]Error is ca. 2 nm.
[c]Estimated lifetime from a fit to a single exponential decay.

Similar photolysis of *p*-hydroxybenzhydrols **6**, **10**, and **11** in aqueous CH_3CN also gave red colored transients, but none was capable of giving such a colored transient when photolyzed in neat CH_3CN. The transient from **6** absorbed strongly at 372 nm in H_2O (<5% CH_3CN) with a 10 s lifetime. It was 20 times longer-lived in 1:1 H_2O/CH_3CN (τ = 216 s.). Similar transient absorptions were observed for **10** (at 377 nm) and for **11** (at 356 nm) in either neat water or in 1:1 H_2O/CH_3CN. Table 3 summarizes the λ_{max} and τ for the transients observed. All of the observed transients return to starting materials eventually. The transient from **6** (*p*-QM **21**) has a longer lifetime than that from **4** (*o*-QM **19**). Electron-donating groups on the benzene ring (in **10** and **11**) produce transients that are even longer-lived and hence may be thought of as stabilizing substituents. This result is consistent with recent results of Rokita and co-workers (5*m*) in their study of *o*-QM adducts of deoxynucleotides. All of these observations are consistent with the transients being assignable to the corresponding *p*-QMs.

Fluorescence measurements

There is now considerable evidence supporting singlet state reactivity for substituted benzenes (without carbonyl substituents) undergoing photochemical reactions that gives rise to ionic (polar) intermediates (1–3, 5, 6). Earlier studies (5*c*, 5*d*, 6*c*) have shown that it is the singlet excited state of the precursor phenols that give rise to QMs. Nevertheless, fluorescence studies can give much additional ancillary data regarding mechanism and reactivity that cannot be easily obtained by other means.

o-Hydroxybenzyl alcohols **4** and **8** gave similar fluorescence emissions centered at ~300 nm in neat CH_3CN. The fluorescence quantum yields (Φ_f) measured using anisole (Φ_f = 0.29 in cyclohexane) as secondary standard (10) were drastically reduced by H_2O addition, accompanied by the red-shifted emission maxima (Table 4). Of the two alcohols, the fluorescence intensity of **4** was affected the most, where only a weak emission band was observed beside a clearly visible Raman band in 100% H_2O. The fluorescence lifetimes (τ) were essentially the same in 100% CH_3CN but were drastically decreased with increased water concentration. Similar fluorescence emissions were observed for two related derivatives of **4** (**15**, **18**) in the above mentioned sol-

[b]Measured using PTI LS-1 time-correlated single photon counting system.

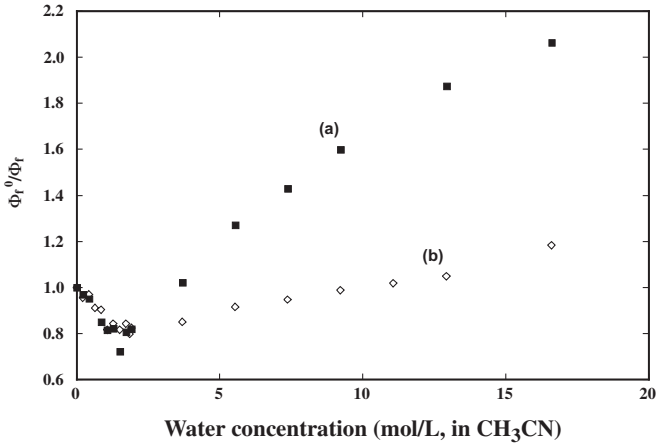
vent systems. Measurement of Φ_f revealed that the fluorescence of **18** was quenched by 90% in 100% H_2O, while the fluorescence of **15** was much less sensitive to the presence of water than that of **4** and **18**. The fluorescence lifetimes (τ) of **18** has an initial decrease to 3 ns in 1:1 H_2O/CH_3CN and then to <2 ns in 100% H_2O, while the τ of **15** was almost unchanged by the addition of 50% water and then dropped to 1.9 ns in 100% H_2O. Thus, the overall magnitude of water effect on these three compounds followed the order **4** > **18** > **15**. The lack of a fluorescence quenching effect for **15** can be attributed to its lack of a phenol moiety. Similar trends in fluorescence behaviour were observed for a series of m-substituted compounds (Table 5).

Fluorescence emissions of **4** and **8** were also observed in aqueous solutions of different pH values. However, their fluorescence emissions were in general so weak that it was not feasible to accurately measure the fluorescence quantum yield. Therefore, relative fluorescence intensity measurements (Φ_f^o/Φ_f; Φ_f^o = fluorescence quantum yield at pH 7) at ~290 nm were employed. No emission was observed in basic solution (0.1 N NaOH) for either ortho compound. Since their UV–vis spectra showed growth of the absorption of the corresponding phenolate ion (~290 nm) in basic media, excitation at 290 nm gave weak emissions at ~350 nm, which presumably are the fluorescence emissions of the corresponding phenolate. Similar experiments with phenol itself gave a weak emission at 335 nm, while *o*-cresol gave a weak emission at 346 nm. These weak signals indicate that excited phenolate ions are photochemically reactive, i.e., they decay through other routes competitive with fluorescence emission.

Stern–Volmer type plots of fluorescence quenching by added water (in CH_3CN solution) were carried out for a number of substrates. All the phenols displayed increasing fluorescence emission on the addition of small amounts of water (up to about 2 mol/L water) after which the fluorescence was quenched. The addition of initial water results in hydrogen bonding to the phenol OH (and to benzylic alcohol OH) resulting in a water–substrate complex that is more fluorescent than the substrate alone in CH_3CN. Addition of more water causes quenching of fluorescence due to water-mediated proton transfer from phenol OH to solvent. For those alcohols that can give rise to QMs, the addition of water also promotes the photodehydroxylation pathway. Indeed,

© 2007 NRC Canada

Fig. 4. Stern–Volmer plot of relative fluorescence intensity (Φ_f^o/Φ_f) vs. water concentration in CH_3CN for **4** (λ_{ex} 270 nm).



these substrates (e.g., **4**–**6**) are quenched more efficiently by water. A particularly informative Stern–Volmer type plot is shown in Fig. 4 in which H_2O and D_2O were employed as quenchers (in CH_3CN) for **4**. There was no observable solvent isotope effect in the enhanced fluorescence observed at low water content. However at higher water content, H_2O quenched significantly more efficiently (up to twofold) than D_2O at the same concentration. This is consistent with a mechanism of reaction in which **4** undergoes a concerted loss of H_2O (D_2O) assisted by solvent water to form *o*-QM **19**. A mechanism involving initial simple phenol ionization to solvent water such as that only available in **18** would not give rise to such a large solvent isotope effect.

Nanosecond laser flash photolysis (LFP)

The UV–vis studies described earlier have already shown that *o*- and *p*-QMs are observable under certain conditions. However, *m*-QMs are presumably too short-lived for this technique. Use of LFP should provide a better picture for whether transients can be assigned to all QM isomers and their relative efficiency for formation under various conditions and hence provide additional insights into reaction mechanism.

LFP of **4** in 1:1 H_2O/CH_3CN under either N_2 or O_2 gave the same strong signals as reported in the already mentioned UV–vis studies, with no observable decay within the millisecond range, the limit of the nanosecond LFP system. A significant amount of transient was also formed on photolysis in neat CH_3CN (under either N_2 or O_2), although the absorption bands were significantly blue-shifted (the 455 and 345 nm bands were shifted to 410 and 330 nm, respectively). Relative quantum yields for the formation of the transients as a function of water content in CH_3CN were measured by monitoring the ΔA at both 350 and 450 nm (Fig. 5). Interestingly, the yield of the transient decreased initially (at low water content), followed by a dramatic increase with the increase in water concentration. This observation corroborates the enhanced fluorescence emission observed at low water content and suggests that when the substrates is hydrogen-bonded to small amounts of water, it is *less* reactive than without water. When the water content reaches above 2 mol/L the compound becomes more reactive, consistent with a water-mediated mechanism. The maximum yield was reached in ca. 75% H_2O/CH_3CN, which was followed by a slight drop on approaching 100% H_2O.

Fig. 5. Relative quantum yields for the formation of *o*-QM **19** from **4** as a function of water content (in CH_3CN) as monitored at 350 and 450 nm using LFP (λ_{ex} 266 nm).

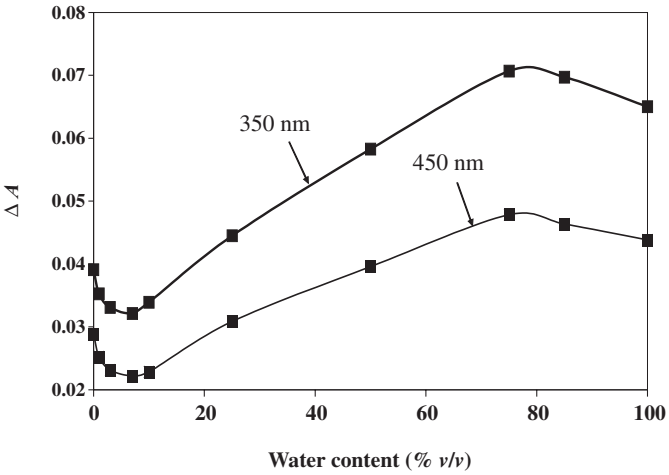


Fig. 6. Relative quantum yields (ΔA) for the formation of *o*-QM **19** from **4** vs. pH, monitored at 350 and 450 nm using LFP in neat H_2O (λ_{ex} 266 nm).

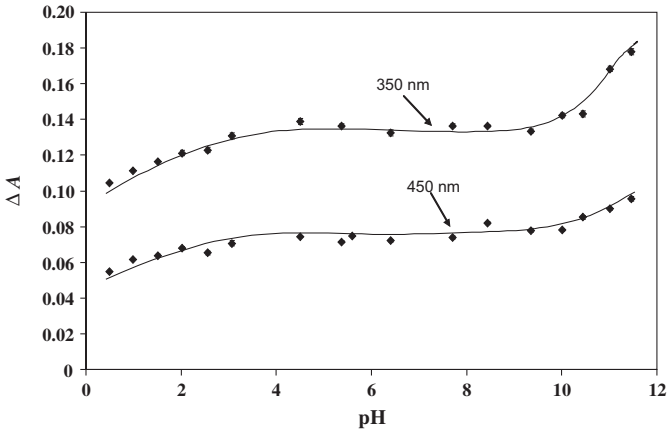


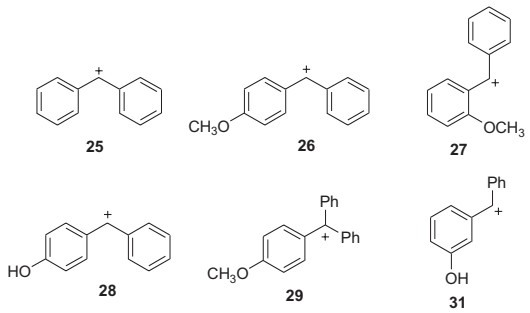
Transient spectra from **4** were also taken in neat H_2O at different pH values with the same transient being observed in the whole pH range. A plot of ΔA (relative quantum yield) vs. pH (Fig. 6) showed two "titration" regions, at pH ~1 to 2, and at pH 11 to 12. The first of these is shallow and not prominent but approximately corresponds to the $pK_a(S_1)$ of phenols, whereas the second corresponds to $pK_a(S_0)$. Although we were not able measure yields for methanolysis in acid for **4** because of competing thermal reactions, the LFP method is not encumbered by this problem since it monitors for transient QM formation on excitation. The "shallow" titration curve at low pH suggests that excited state proton dissociation prior to reaction is important but that there may also be an independent acid-catalyzed pathway operating at these values of pH that involves an acid-mediated loss of water followed by deprotonation of the phenol OH to give the QM. The lifetimes of this transient (pseudo first-order

© 2007 NRC Canada

decays) were measured between pH 0 and 5 (above pH 5 the lifetimes were too long for the detection system employed). A plot of log k_{obs} vs. pH gave a slope of –1 indicating that the transient has an acid-catalyzed pathway for reaction (with $k_{H+} = 1.0 \times 10^6$ (mol/L)$^{-1}$ s^{-1}), in general agreement with results of Kresge and co-workers (5*f*–5*h*) and McClelland et al. (5*i*).

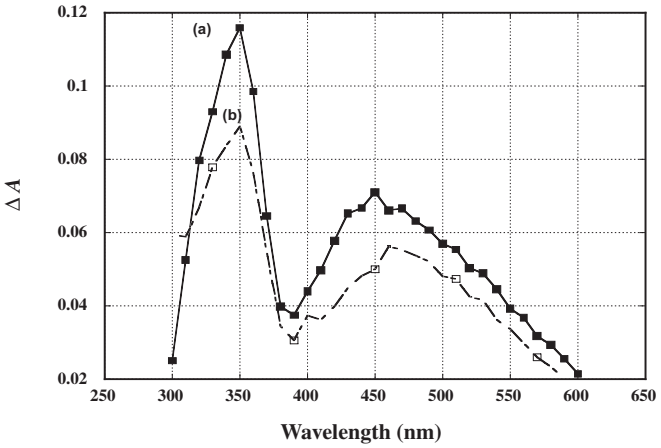
LFP of **7** in 1:1 H_2O/CH_3CN afforded a transient spectrum essentially identical to that observed for **4** but with much weaker signal intensity, consistent with the lower reactivity of photomethanolysis and photohydration observed for **7**. Since **7** is known to give *o*-QM **19** upon photolysis (7), it is reasonable to infer that the transient from **4** is indeed *o*-QM **19**.

LFP of the *o*-methoxy derivative **15** 1:1 H_2O/CH_3CN gave a weak absorption at 420 nm, with a short-lived (13 ns) and a longer-lived species (~0.5 μs) (fitted to the sum of two single exponential decays). These transients are very different from those observed for **4**. Chateauneuf (11) found that the diphenylmethyl cation (**25**) has λ_{max} at 435 nm with ~1 ns lifetime by using picosecond LFP, while McClelland and co-workers (12) reported that (*p*-methoxyphenyl)phenyl methyl cation (**26**) absorbs at 455 nm with a 0.5 μs lifetime in 2:1 H_2O/CH_3CN. Since the LFP system used by the McClelland group has a pulse of ~20 ns, they were unable to observe the short-lived species. Considering that substituents on the benzene ring have similar electron donating and withdrawing abilities at the ortho and para positions, it is reasonable to propose that the ortho-substituted diphenylmethyl cations also absorb in the 400–500 nm region and have microsecond lifetimes. Therefore, the long-lived (~0.5 μs) species observed from **15** is assigned to carbocation **27**. Since Peters and Li (13) showed that the contact ion pair from diphenyl chloride had a lifetime of 150 ps, the short-lived (13 ns) species that we observed may be a radical cation.



LFP of *p*-hydroxybenzhydrol (**6**) gave one strong absorption band at 360 nm with no observable decay within ms range in 1:1 H_2O/CH_3CN, under either N_2 or O_2. The signal was also observed in 5% H_2O/CH_3CN but not in neat CH_3CN. The yield of the transient (as measured by ΔA) increased with the increase in the water content to a maximum at 75% H_2O/CH_3CN. The transient absorption spectrum observed for the *p*-methoxy analog **17** had a weak band at 455 nm with small shoulders at 340 and 360 nm. Monitored at 455 nm, the decay consisted of two components, one with ~45 ns lifetime and another with a ~1 μs lifetime. The lifetime of the longer-lived species decreased significantly with increasing water content. In 0.5 mol/L NaOH, essentially no signal was observable in 400–500 nm region. These facts

Fig. 7. Transient absorption spectra observed from **8** by LFP under O_2 in (a) pH 7 and (b) pH 12 in 1:1 H_2O/CH_3CN (λ_{ex} 266 nm).



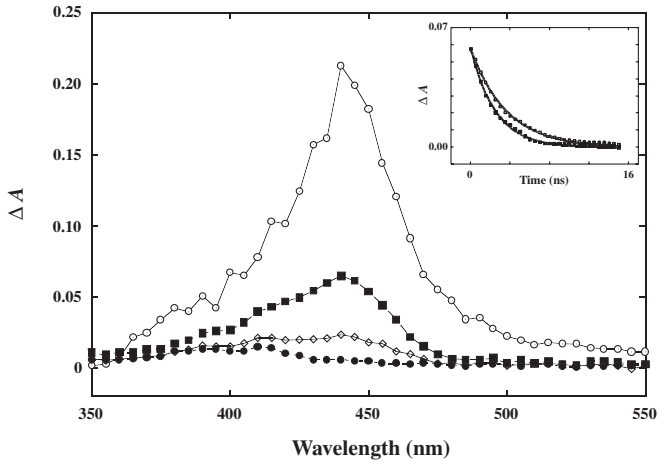
imply that the transient has cationic character. According to McClelland and co-workers (12) (*p*-methoxyphenyl)phenyl methyl cation (**26**) has λ_{max} = 455 nm in CH_3CN (diarylmethyl chloride as precursor), which is also accompanied by the (*p*-methoxyphenyl)phenylmethyl radical at 340 nm. The cation has a lifetime of 0.5 μs in 2:1 H_2O/CH_3CN. The long-lived species generated from **17** has absorption characteristics and lifetime that matches those of **26**. Although the transient generated from **6** (τ = 216 s in 1:1 H_2O/CH_3CN, vide supra) has similar absorption characteristics as cation **26**, it is too long-lived to be **28**. It seems reasonable that the transient is that of *p*-QM **21** consistent with it being much less reactive. Similarly, the transients observed for **10** and **11** (vide supra), which were quenchable by water and had even longer lifetimes than *p*-QM **21** are also the respective *p*-QMs.

[6] 
LFP of triphenyl alcohol **8** produced a strongly absorbing transient in either neat acetonitrile or in 1:1 H_2O/CH_3CN (Fig. 7), with no observable decay within 2 ms. The transient spectrum is almost identical to those obtained from **4** and **7**, indicating that a similar transient was being generated by all of these compounds and the additional phenyl substitution on benzylic carbon had little effect on absorption characteristics. McClelland et al. (12*b*) have reported that the (*p*-methoxyphenyl)diphenylmethyl cation **29** has a lifetime of 0.71 ms in 2:1 H_2O/CH_3CN, which is much shorter than the transient observed from **8**. Using the same rationale as for the benzhydrols, the transient observed for **8** is most likely *o*-QM **30**. Moreover, it is known that **8** and related compounds are thermo and photochromic and their coloured forms are believed to be due to their corresponding *o*-QM structures, with absorptions bands at 340 and 440 nm (14) (eq. [6]).

LFP of **5** in 1:1 H_2O/CH_3CN (O_2 purged) generated a strongly absorbing but short-lived transient with λ_{max} = 440 nm and a 30.1 ns lifetime (Fig. 8). This species was in-

© 2007 NRC Canada

Fig. 8. Transient absorption spectra observed for **5** (assigned to **20**) in 1:1 H_2O/CH_3CN (O_2) (λ_{ex} 266 nm). Top to bottom: recorded 10, 40, 80, and 200 ns after the laser pulse (Inset: top without ethanolamine and bottom with 0.24 mol/L ethanolamine, monitored at 450 nm).



sensitive to oxygen and quenchable by water, added $NaBH_4$, and ethanolamine. A weak residual signal (390 and 410 nm) was observable after the 440 nm transient had decayed (Fig. 8, bottom trace), which is more predominant with decreased water content. LFP of **5** in neat CH_3CN under N_2 gave two strong signals at 330 and 410 nm, respectively, both of which disappeared with O_2 purging. No 440 nm transient was observed. LFP of *m*-methoxybenzhydrol (**16**) generated a short-lived transient with a lifetime of 75.5 ns and a long-lived one of 6.3 μs (λ_{max} = 428 nm) in 1:1 H_2O/CH_3CN (O_2). A similar LFP study of *m*-benzylphenol (**24**) gave a weak but long-lived transient at around 400 nm and a short-lived one at 750 nm. Both long-lived species from **16** and **24** might be the radical cation formed from an electron ejection, which is not the same as either transient from **5**. The relative quantum yield of formation of the 440 nm (ΔA_{440}) transient increased with increasing pH (in 1:1 H_2O/CH_3CN, lifetimes and ΔA_{440} could not be accurately measured at all pH values in 100% water because of acid quenching). The resulting plot of ΔA_{440} vs. pH showed a titration curve in basic pH at an apparent $pK_a(S_0)$ value of 12 and a $pK_a(S_1)$ of 2. A plot log k_{obs} vs. pH in 1:1 H_2O/CH_3CN showed that the lifetimes were unchanged between pH 4 and 11 and were shortened in either acidic or basic media.

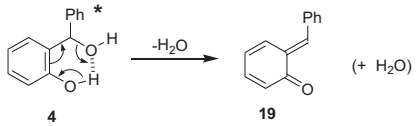
The λ_{max} and band shape of the 440 nm transient observed on LFP of **5** is essentially identical to that of the corresponding diarylmethyl cations reported by McClelland et al. (12*b*). Although they did not photogenerate the exact *m*-hydroxy-substituted cations, the lifetimes of those that were reported are informative. For example, diarylmethyl cations without strongly electron donating substituents have lifetimes of less than 10 ns in aqueous solution and are not detectable by standard nanosecond LFP; τ was estimated to be 1 and 5 ns for the **25** and the (*p*-methylphenyl)phenylmethyl cations, respectively. Clearly, the transient observed from **5** is similar to an arylmethyl carbocation, but its lifetime is too long to be simply the (*m*-hydroxyphenyl)phenylmethyl cation (**31**). Additional evidence available is that the methoxy derivative of **16** did not produce any cationic transient by LFP. Moreover, **5** gave a significantly higher yield of the methyl ether product on photolysis in 1:1 $MeOH/H_2O$ compared with **16**, with a quantum yield (Φ_p = 0.40) only fractionally lower than that measured for the corresponding ortho isomer **4**. More important is the fact that the transient is quenchable both electrophilically and nucleophilically since its lifetime decreased in both acidic and basic media. The deprotonated hydroxy group (σ^-) is electron-donating on the benzene ring at a meta position (σ_m = –0.47) unlike the hydroxy group itself, which is electron-withdrawing at the meta position (σ_m = + 0.12). If the transients from **5** were simply the cation **31**, its expected lifetime in aqueous solution, using data from McClelland et al. (12*b*), would be less than 1 ns and hence not observable using our LFP system. Its much longer observed lifetime (30 ns) is consistent with the hydroxyl group having been deprotonated. We thus assign this transient as *m*-QM **20**. Therefore, the present method offers a simple and efficient way for photogeneration of *m*-QMs in their zwitterionic form.

Mechanisms of reaction

There are four aspects of the reaction mechanism that can be addressed for the QMs studied in this work: (*i*) their photochemical mechanism(s) of formation, (*ii*) their thermal mechanism(s) for subsequent hydration, methanolysis, or nucleophilic attack, depending on the solvent system and nucleophiles used, (*iii*) [4+2] cycloaddition with added dienophiles such as ethyl vinyl ether, and (*iv*) self-condensation (polymerization). Thermal hydration and nucleophilic attack of photochemically generated QMs (*o* and *p*) have been studied by several other groups (5*e*–5*k*). Some initial studies of [4+2] cycloaddition have been reported (5*c*, 5*d*), but more studies are required in this area before a more complete picture is available. Therefore, only the first and last aspects will be addressed in this section.

Formation of *o*-QMs **19** and **30** from **4** and **8**, respectively, in neat CH_3CN probably involves a unimolecular dehydration pathway as shown in eq. [7]. This mechanism takes advantage of the enhanced acidity of phenols in S_1 and the presence of the nearby benzylic alcohol (hydrogen bonded as shown), which in this mechanism formally acts as hydroxide ion. When these moieties are too far from each other, the mechanism does not operate. Indeed, none of the m and p isomers give QMs on photolysis in neat CH_3CN (they all require the presence of water). The addition of small amounts of water to CH_3CN (up to 2 mol/L) resulted in reduction of yield of *o*-QM and an enhancement of fluorescence yield and lifetime. Water is expected to hydrogen bond to the phenol and alcohol OH groups and break up the internal hydrogen bond already in place. This retards the simple dehydration mechanism and hence results in a drop in yield. Addition of more water opens up a new pathway for *o*-QM formation, viz., the water-assisted mechanism shown in eq. [8]. In this mechanism, the details of the water–hydrogen bonding is not known and only one water

[7]



© 2007 NRC Canada

molecule is shown for hydrogen bonding to each of the substrate OH groups. Interestingly, Freccero and co-workers (5*k*) have carried out DFT calculations on the alkylation of the parent unsubstituted *o*-QM with water (in the gas phase) and found that the presence of two water molecules (one acting as a catalyst) accelerates the addition.

[8] 
The observation that direct photolysis of the phenoate form of **4** (that is, **4**$^-$) resulted in a higher quantum yield of **19** supports the notion that the reaction probably involves two steps: the ionization step (-H^+) and the dehydroxylation step (-HO^-), although a concerted mechanism cannot be ruled out. Another pathway in which loss of hydroxide ion takes place first (photodehydroxylation) to give a cation followed by deprotonation of the phenol to give the *o*-QM can be ruled out, since this would not explain the enhanced quantum yield for the formation of QMs derived from these hydroxybenzyl alcohols (**4**–**6**) compared with the corresponding methoxy-substituted analogs **15**–**17**. Indeed, for **15**–**17** and related compounds, a simple photodehydroxylation pathway is operative for the formation of the corresponding benzylic cations (15).

A similar mechanism for the formation of *m*-QM **20** that requires the presence of water is shown in eq. [9]. The difference here is that the excited state of **5**$^-$ is expected to have a substantial portion of the negative charge localized at the m position (Zimmerman ortho–meta effect (9)), hence allowing the subsequent dehydroxylation step. Deactivation back to the ground state gives rise to a zwitterionic *m*-QM **20**, which has a non-Kekulé structure. Although no polymeric material was isolated from photolysis of **5** in base, photolysis of **8** gave substantial amounts of oligomers (Scheme 1). This is because the corresponding zwitterionic *m*-QM **32** is about 1000-fold longer-lived (30 ns for **20** compared with 10 μs for **32**). Thus, bimolecular attack by **8**$^-$ (eq. [10]) competes with attack by water and hydroxide ion. It is interesting to comment that *m*-QM condensation is due to attack of oxygen on the benzylic carbon, giving rise to oligomers held together with benzylic ether bonds. For comparison, the photocondenation of *o*-hydroxybenzyl alcohol (eq. [11]) results in attack via the benzene ring carbon (enolate-like attack), giving rise to phenol-formaldehyde condenation polymers (8). The key difference may be the increased steric

[9] 
[10] 
bulk of the two benzylic phenyl groups of **32**, which would hinder attack via the o position on the benzene ring.

In summary, QMs are the key intermediates in the

[11]

photochemistry of hydroxyl-substituted benzyl alcohols. These compounds are suitably designed to take advantage of the enhanced acidity of the phenol in S_1 and the propensity of benzylic alcohol to depart as hydroxide ion or water and its reluctance to leave as hydroxyl radical. This is unlike the situation if other leaving groups such as halides and acetate are used. Thus, hydroxyl-substituted benzyl alcohols react almost exclusively via polar or ionic intermediates. An added bonus is that they are generally fluorescent making them ideal for fluorescence studies. Other added features and uses await further discovery.

Experimental section

General

^{1}H NMR spectra were recorded on either a PerkinElmer R32 (90 MHz), a Bruker AC 300 (300 MHz), or a Bruker AM 360 (360 MHz) instrument using $CHCl_3$-*d*, CH_3CN-d_3 or acetone-d_6 as solvents. Mass spectra were taken on either a Finnigan 3300 (CI) or a Kratos Concept H (EI and FAB) instruments. Melting points were determined on a Koefler hot stage microscope (uncorrected). UV–vis spectra were recorded either on a Phillips PU 8740, Varian Cary 5, or Pye Unicam SP8–400 spectrophotometer. Analytical thin layer chromatogaphy (TLC) was performed on precoated silica gel plates (Macherey-Nagel, Sil/UV–vis_{254}), using solvent systems as indicated in each experiment. Preparative TLC was carried out on 20 cm × 20 cm silica gel GF 1000 micrometer Uniplates (Analtech).

Common laboratory reagents

Methylene Chloride (A.C.S., reagent grade) was distilled before use. Anhydrous THF was obtained by distillation over potassium. Acetonitrile was either HPLC grade for photolysis, UV and LFP studies or freshly distilled over CaH_2 under N_2 for steady state fluorescence measurements. HPLC grade MeOH was stirred with $NaHCO_3$ for at least one hour to remove any trace of acid prior to photolysis. Cyclohexane (HPLC) were used as received. Deuterated solvents, including D_2O, $CDCl_3$, $(CD_3)_2CO$, and CD_3CN were purchased from Cambridge Isotopes (99.9% D). Standard buffers were purchased from Fisher. Aqueous solutions of the appropriate pH were used directly or diluted from standardized stock of NaOH or H_2SO_4 with known concentration. Prior to photolysis, pH values of the water portion were checked by a pH meter. *o*-Benzylphenol (**18**) was purchased from Sigma-Aldrich Reagents and used as received. ^{1}H NMR and GC analysis showed that it was >98% pure. Ethanolamine (Sigma-Aldrich) was distilled before use. *o*-Methoxybenzhydrol (**15**) was available in the laboratory. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.8 (s, 3H), 4.6 (d, 1H, D_2O

exchangeable), 6.1 (d, 1H), 6.8–7.6 (m, 9H). MS (CI) *m/z*: 197 (M^+ – 17, base peak), 215 (M^+ + 1). (EI) 214 (M^+).

Materials

All readily available organic and inorganic reagents required in the synthesis reported below were purchased from Sigma-Aldrich and used as received.

Grignard reaction

Magnesium was washed with dilute HCl to remove magnesium oxide and thoroughly dried. Pre-dried PhBr was dissolved in freshly distilled THF and added dropwise (under N_2) to magnesium/THF (a pinch of I_2 added) in an ice bath, which was then vigorously stirred. After the addition, the reaction mixture was refluxed for 1 h and cooled to room temperature (RT). The reacting PhMgBr was transferred to a dropping funnel and added dropwise to a THF solution of the appropriate carbonyl compound. After addition, the solution was refluxed and reaction progress monitored by NMR. Work-up consisted of the addition of saturated aq. NH_4OAc to a cooled solution to quench excess PhMgBr. Diluted HCl was also used to further acidify the solution, if required. The solution was then extracted with CH_2Cl_2.

$NaBH_4$ reduction

The ketone was dissolved in 50–100 mL of MeOH and cooled in an ice bath. To this stirred solution, a suspension of $NaBH_4$ in ice water was added dropwise. The solution was then heated to 40–50 °C for 1–2 h. After cooling by ice, the solution was neutralized with aq. NH_4Cl and extracted with 3 × 50 mL of CH_2Cl_2. The organic solvent was removed using a rotary evaporator and residue was dried on a vacuum pump.

o-Hydroxybenzhydrol (4)

Method A

To a stirred solution of salicyaldehyde (Sigma-Aldrich, 2.0 g, 17.9 mmole) in 50 mL of dry THF, 30 mL of 1.8 mol/L phenyllithium solution (54 mmole) was added under nitrogen in a dry ice–acetone bath. After reflux (4 h), the reaction mixture was cooled to RT and 50 mL of wet THF was added carefully followed by a further 10 min reflux to decompose the excess phenyllithium. The reaction mixture was then transferred to a 500 mL erlenmeyer flask, and 100 mL of ice water was added and the solution acidified with saturated NH_4Cl. The solution was extracted with diethyl ether (3 × 70 mL). Removal of the ether afforded an oil (3.2 g, 90%), which solidified overnight.

Method B

Following the general procedure described above for making PhMgBr, 10 g salicyaldehyde (0.08 mol) was reacted with PhMgBr (0.24 mol). The crude yellow solid was recrystallized from 1:1 toluene/hexane to afford pure **112** as white crystals, mp 86 to 87 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 4.3 (b, 1H, D_2O exchangeable), 6.1 (s, 1H), 6.7–7.3 (m, 9H), 8.6 (b, 1H, D_2O exchangeable). MS (CI) *m/z*: 183 (base peak, (M^+ – 17).

3-Phenylisocoumaranone (7)

The compound was made according to the procedure of Padwa et al. (7). To an ice-cooled mixture of finely pulverized phenol (26.5 g) and mandelic acid (30.45 g) was added 80 mL of a 70% sulfuric acid solution. The mixture was stirred at 0 °C until dissolution was nearly obtained and then heated at 115 °C for 45 min. The mixture was cooled to RT, poured into 400 mL of ice water slurry, and extracted with three 100 mL portions of methylene chloride. The combined organic layers were washed with 100 mL of a saturated aqueous sodium bicarbonate solution and dried over magnesium sulfate. The evaporation of the solvent under reduced pressure gave a red liquid as the crude product. When placed under vacuum, crystals slowly formed. White crystals were obtained after recrystallization from 95% ethanol, mp 111–114 °C (lit. value (7) 113 to 114 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 5.2 (s, 1H), 7.1–7.5 (m, 9H). MS (CI) *m/z*: 211 (M^+ + 1, base peak), 183 (M^+ – 28).

m-Hydroxybenzhydrol (5)

Method A

Crude **5** was obtained by reducing *m*-hydroxybenzophenone (2.6 g, 0.013 mol) with $NaBH_4$ (0.75 g, 0.019 mol) following the general procedure.

Method B

Following the general procedure using PhMgBr, 4.3 g Mg (0.18 mol), and 27.4 g PhBr (0.18 mol) were used to make the Grignard reagent, which was reacted with 7 g of *m*-hydroxybenzaldehyde (0.057 mol) to give a brownish solid. The crude product was recrystallized from 8:1 toluene/ligroin to afford white fine needlelike crystals, mp 115 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 4.7 (d, 1H, D_2O exchangeable), 5.7 (d, 1H), 6.4–7.5 (m, 9H), 8.2 (s, 1H, D_2O exchangeable). MS (CI) *m/z*: 183 (M^+ – 17, base peak), 201 (M^+ + 1).

m-Methoxybenzhydrol (16)

Using the general procedure for PhMgBr, 10 g of *m*-anisaldehyde (0.074 mol) was reacted with PhMgBr (0.24 mol). The crude product (yellow oil) was distilled under reduce pressure to afford pure **16** (clear oil). ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.7 (s, 3H), 4.8 (d, 1H, D_2O exchangeable), 5.8 (d, 1H), 6.7–7.5 (m, 9H). MS (CI) *m/z*: 197 (M^+ – 17, base peak), 215 (M^+ + 1).

p-Hydroxybenzhydrol (6)

Following the general procedure for $NaBH_4$ reduction, *p*-hydroxy-benzophenone (1.98 g, 0.01 mol) was reduced by $NaBH_4$ (0.75 g, 0.02 mol). The crude product was recrystallized from toluene to afford **6**, mp 159–162 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 4.6 (d, 1H, D_2O exchangeable), 5.7 (d, 1H), 6.4–7.5 (m, 9H), 8.2 (s, 1H, D_2O exchangeable). MS (CI) *m/z*: 183 (M^+ – 17, base peak), 201 (M^+ + 1).

3-Methoxy-4-hydroxybenzhydrol (10)

Following the general procedure for PhMgBr, 1 g of Mg (0.042 mol) and 6.54 g (0.042 mol) of PhBr were used to produce PhMgBr, which was subsequently reacted with

© 2007 NRC Canada

1.27 g (0.008 mol) of 3-methoxy-4-hydroxybenzaldehyde. On work-up, the resulting yellow oil was twice eluted through a silica gel column (CH_2Cl_2), which afforded **10** as a pure clear oil. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.4 (s, 3H), 4.6 (d, 1H, D_2O exchangeable), 5.7 (d, 1H), 5.9 (d, 1H, D_2O exchangeable), 7.0–7.5 (m, 8H). MS (CI) *m*/*z*: 213 (M^+ – 17), 231 (M^+).

3,5-Dibutyl-4-hydroxybenzhydrol (11)

Following the general procedure for PhMgBr, 1 g of Mg (0.042 mol) and 6.54 g (0.042 mol) of PhBr were used to produce PhMgBr, which was subsequently reacted with 3.36 g (0.014 mol) of 3,5-di-*t*-butyl-4-hydroxybenzaldehyde. The crude product was obtained as an orange solid which was recrystallized in ligroin to give white crystals, mp 123 to 124 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 1.4 (s, 18H), 4.6 (d, 1H, D_2O exchangeable), 5.7 (d, 1H), 5.9 (d, 1H, D_2O exchangeable), 7.0–7.5 (m, 7H). MS (CI) *m*/*z*: 295 (M^+ – 17, base peak), 313 (M^+ + 1).

***p*-Methoxybenzhydrol (17)**

p-Methoxybenzophenone (2 g, 0.01 mol) was reduced using $NaBH_4$ (4.29 g, 0.13 mol) according to the general procedure. The crude product was recrystallized from petroleum ether to give a white crystalline solid, mp 59–62 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.7 (s, 1H), 4.7 (d, 1H, D_2O exchangeable), 5.8(d, 1H), 6.7–7.5 (m, 9H), 8.2 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 197 (M^+ – 17, base peak), 215 (M^+ + 1). (EI) 214 (M^+).

α,α-Diphenyl-*o*-hydroxybenzyl alcohol (8)

Following the general procedure for PhMgBr, Mg (4.2 g, 0.17 mol) and PhBr (27 g, 0.17 mol) were used to make the PhMgBr, which then reacted with *o*-hydroxybenzoic acid methyl ester (4.5 g, 0.03 mol). The crude product was recrystallized from toluene to afford a white crystalline solid, mp 148–150 °C. ^{1}H NMR (360 MHz, acetone-d_6) δ: 6.4 (s/b, 1H, D_2O exchangeable), 6.4–7.5 (m, 14H), 9.1 (s/b, 1H, D_2O exchangeable); (300 MHz, $CDCl_3$) δ: 3.7 (s, 1H, D_2O exchangeable), 6.4–7.4 (m, 14H), 8.1 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 259 (M^+ – 17, base peak).

α,α-Diphenyl-*m*-hydroxybenzy alcohol (9)

The methyl ester of *m*-hydroxybenzoic acid was prepared by refluxing 20 g of *m*-hydroxybenzoic acid in 400 mL of MeOH with 1 mL of concd. H_2SO_4 for 10 h. After cooling to RT, 2–4 g of $NaHCO_3$ was added with stirring and most of the MeOH evaporated. To this was added 200 mL of CH_2Cl_2 and the solution backwashed with water and saturated aq. $NaHCO_3$. Crude *m*-hydroxybenzoic methyl ester was obtained after removal of the solvent and used without further purification.

Using the Grignard reaction procedure, 2 g of *m*-hydroxybenzoic methyl ester (0.013 mol) was reacted with PhMgBr produced from 2 g of Mg (0.083 mol) and 13 g of PhBr (0.084 mol) to generate a yellow gel as the crude product. The product was recrystallized from CH_3CN to give white crystals, mp 151 to 152 °C. ^{1}H NMR (300 MHz, acetone-d_6) δ: 5.2 (s, 1H, D_2O exchangeable), 6.6–7.4 (m, 14H), 8.2 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 199 (M^+ – 77, base peak), 277 (M^+ + 1).

***m*-Benzylphenol (24)**

A THF solution of 2.0 g of **5** was shaken under H_2 (2 atm, 1 atm = 101.325 kPa) for 30 h. The product mixture was eluted by CH_2Cl_2 in a silica column, which gave the initial crude product. Colorless **24** was obtained by distillation under reduced pressure. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.9 (d, 2H), 6.6–6.8 (m, 3H), 7.0–7.4 (m, 6H), 8.2 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 185 (M^+ + 1).

General photolysis procedure

All preparative photolysis were carried out in a Rayonet RPR 100 photochemical reactor equipped with 254 lamps, using quartz tubes (100–200 mL), which were cooled with an internal cold finger (tap water, <15 °C). Solutions were continuously purged with a stream of argon via a stainless steel syringe needle for 10 min before and during the irradiation to effect stirring and deoxygenation. The length of photolysis varied from 3–60 min depending on the conversion desired. After photolysis, work-up involved adding a saturated aqueous solution of NaCl and extracting with 5 × 75 mL portions of CH_2Cl_2. The organic extracts were then combined and dried over $MgSO_4$. Filtration of the $MgSO_4$ and evaporation of CH_2Cl_2 under reduced pressure provided crude photochemical products, which were then separated by preparative TLC, if necessary, and characterized by ^{1}H NMR and mass spectroscopy. Control experiments were repeated in the absence of light at RT (~22 °C). Possible thermal reactions in photomethanolysis were eliminated by the addition of a pinch of $NaHCO_3$.

Photolysis o-hydroxybenzhydrol (4)

A solution of 40 mg **4** in 100 mL 1:1 H_2O/MeOH ($NaHCO_3$ treated) was photolyzed at 254 nm. ^{1}H NMR analysis showed that ether **12** was the only product in low conversion runs and *o*-benzylphenol **18** was formed only in high conversion runs. Preparative TLC separation afforded pure **12**. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.3 (s, 3H), 5.7 (s, 1H), 6.7–7.4 (m, 9H), 8.5 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 183 (M^+ – 31, base peak). The identity of **18** was confirmed by comparison with an authentic sample.

Photolysis p-hydroxybenzhydrol (6)

A solution of 40 mg of **6** in 100 mL 1:1 H_2O/MeOH ($NaHCO_3$ treated) was photolyzed at 254 nm for 3 min. Methyl ether **14** was the only product purified by preparative TLC. ^{1}H NMR (300 MHz, acetone-d_6) δ: 2.9 (s, 3H), 5.2 (s, 1H), 6.6–7.4 (m, 9H), 8.3 (b, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 121 (M^+ – 93, base peak), 183 (M^+ – 31), 215 (M^+ + 1).

Photolysis of 3-phenylisocoumaranone (7)

A solution of 40 mg of **7** in 100 mL 1:1 H_2O/MeOH was photolyzed at 254 nm for 3 min. The ^{1}H NMR of the product mixture showed that ~3% of **12** was formed, as indicated by the characteristic methoxy singlet at δ 3.3 (s, 3H) and methine singlet at δ 5.7 (s, 1H).

Photolysis of α,α-diphenyl-o-hydroxybenzyl alcohol (8)

A solution of 55 mg of **8** in 100 mL 1:1 H_2O/MeOH ($NaHCO_3$ treated) was photolyzed at 254 nm for 3 min. The product was its corresponding methyl ether (28%), purified

© 2007 NRC Canada

by preparative TLC. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.2 (s, 3H), 5.6 (s, 1H), 6.4–7.8 (m, 14H), 8.7 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 259 (M^+ – 31, base peak).

Photolysis m-hydroxybenzhydrol (5)

A solution of 100 mg of **5** was dissolved in 100 mL 1:1 H_2O/MeOH and photolyzed at 254 nm for 5, 30, and 60 min, respectively. The product mixture contained **13** (methoxy singlet δ 3.3 (s, 3H)) and **24** (methylene δ 3.9 (d, 2H) both of which were purified by preparative TLC. Compound **13**: ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.2 (s, 3H), 5.2 (s, 1H), 6.3 (s, 1H), 6.8–7.8 (m, 18H), 8.3 (s, 1H, D_2O exchangeable); MS (FAB/LSIMS, *m*-NBA as Matrix) *m*/*z*: 395 (M^+ – 1, base peak). Product **24**: ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.9 (s, 2H), 6.6–6.8 (m, 3H), 7.0–7.4 (m, 6H), 8.3 (s, 1H, D_2O exchangeable).

Photolysis of α-phenyl-m-hydroxybenzhydrol (9)

A solution of 55 mg of **9** in 100 mL 1:1 H_2O/MeOH ($NaHCO_3$ treated) was photolyzed at 254 nm for 3 min. The product was the corresponding methyl ether (10%), which was purified by preparative TLC. ^{1}H NMR (300 MHz, acetone-d_6) δ: 3.0 (s, 3H), 6.6–7.4 (m, 14H), 8.2 (s, 1H, D_2O exchangeable). MS (CI) *m*/*z*: 259 (M^+ – 31, base peak), 291 (M^+ + 1).

A solution of 200 mg of **9** was dissolved in 200 mL of neat water (pH 12) and photolyzed at 254 for 30 min (vigorous Ar purge), which resulted in very cloudy (milky) solution. The product mixture was worked up by adding large amounts of aq. NH_4Cl to aggregate the fine pale yellowish precipitate, which was then filtered out of the solution and allow to dry on the filter paper. ^{1}H NMR (300 MHz, acetone-d_6) showed that a new product was formed (>80%) which was identified as condensation product **22**, δ: 5.1 (s, 1H, D_2O exchangeable), 6.4 (t, 1H), 6.6–7.4 (m, 27H), 8.2 (s, 1H, D_2O exchangeable). Negative FAB/LSIMS (*m*-NBA as matrix) *m*/*z*: 533 (M^+ – 1, base peak).

A solution of 100 mg of **9** in 100 mL 1:1:2 1 mol/L of NaOH solution/H_2O/CH_3CN was photolyzed at 254 nm for 30 min. A clear and pale yellow solution was obtained. To this solution, 300 mL of water was added to give milky solution, which aggregated upon the addition of aq. NH_4Cl. The yellow precipitate thus obtained was filtered out and allowed to dry on filter paper. Negative FAB/LSIMS (*m*-NBA as Matrix) 258 (M^+ – 18, base peak), $n \times 258 + 275$ (*n* from 1 to 10, see Fig. 2). Therefore, the product was identified as a mixture of oligomers **23**.

Steady-state fluorescence and lifetime measurements

Steady-state fluorescence spectra (uncorrected) were recorded on a PerkinElmer MPF-66 or Photon Technology International (PTI) A-1010 fluorimeter. Fluorescence lifetimes were obtained by a PTI LS-1 time-correlated single photon counting system using a hydrogen flash lamp as the excitation source (λ_{ex} = 270 nm), with data fit using the iterative deconvolution program. Each sample (~10^{-5} mol/L, OD < 0.02) was prepared in 3.0 mL four-sided suprasil quartz cuvettes with flat transparent bottoms and saturated with a stream of Ar (10 min) prior to the measurement. Absolute fluorescence quantum yields (Φ_f) were measured in CH_3CN, using anisole (Φ_f = 0.29 in cyclohexane) (10) as external standard. Excitation wavelength was 275 nm. OD_{275} was measured for individual sample and kept at ~0.1.

Laser Flash Photolysis (LFP)

Nanosecond laser flash photolysis (LFP) experiments were carried out at the University of Victoria LFP Facility at 20 ± 2 °C. A Spectra Physics YAG laser Model GCR-12 (266 nm, ≤70 mJ/pulse) was used as excitation source. The laser pulse energies were typically attenuated to less than 20mJ/pulse by adjusting the high voltage for the flash lamp to avoid multiple photon process. The analyzing beam employed consists of a pulsed 150 W xenon lamp (Oriel housing Model 66057, PTI power supply Model LPS-220). Generally, a solution of $OD_{266} \leq 0.3$ was prepared by dilution from a stock solution, followed by 10 min prepurge of oxygen or nitrogen. Experiments were carried out in a flow system (7 mm × 7 mm quartz cell) with continuous purge of oxygen or nitrogen.

Synthesis of possible *o*-thioquinone methide precursors

Kirill A. Kolmakov and A. Jerry Kresge

Abstract: Investigating the synthetic accessibility of *o*-thioquinone methide precursors containing electron donating groups, we prepared four methyl- and methoxy-substituted 2*H*-benzo[b]thiete derivatives by means of flash vacuum pyrolysis of the corresponding benzooxathiinone species. Methyl- and methoxy-substituted substrates proved to be compatible with the pyrolysis protocol. The pyrolysis can be performed at considerably lower temperatures and with higher yields than in previously reported syntheses of nonsubstituted 2*H*-benzo[b]thiete. Under proper conditions the reaction products can be isolated in excellent yields and with 100% purity, so the troublesome purification of temperature sensitive and volatile 2*H*-benzo[b]thiete derivatives becomes unnecessary. The sulfur-containing compounds so obtained are efficient *o*-thioquinone methide precursors and possible synthones for heterocyclic chemistry.

Key words: 2*H*-benzo[b]thietes, flash vacuum pyrolysis, methyl-substituted, methoxy-substituted, *o*-thioquinone methide precursors.

Résumé : Dans le cadre de nos travaux sur l'accessibilité synthétique de précurseurs de méthides de *o*-thioquinone contenant des groupes électrodonneurs, on a préparé quatre dérivés du 2*H*-benzo[b]thiète substitués par des groupes méthyles et méthoxy en faisant appel à la pyrolyse éclair sous vide des espèces benzooxathiinones correspondantes. Il est possible d'effectuer les pyrolyses à des températures beaucoup plus basses et avec de meilleurs rendements que ceux rapportés antérieurement pour les 2*H*-benzo[b]thiètes non substitués. Dans les bonnes conditions, les produits de la réaction peuvent être isolés avec d'excellents rendements et une pureté de 100, ce qui rend inutile la purification des dérivés 2*H*-benzo[b]thiètes volatils et sensibles à la température. Les composés contenant du soufrant ainsi obtenus sont des précurseurs efficaces de méthides de *o*-thioquinone et pourraient servir de synthons en chimie hétérocyclique.

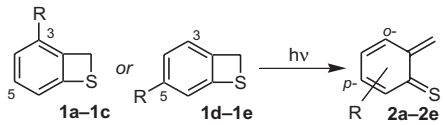
Mots-clés : 2*H*-benzo[b]thiètes, pyrolyse éclair sous vide, substitué par un méthyle, substitué par un méthoxy, précurseurs de méthides de *o*-thioquinone

[Traduit par la Rédaction]

Introduction

Quinone methides and their far less studied sulfur analogs are interesting molecules with wide application in organic synthesis (1). Extending our investigation of quinone methides generated by flash photolysis to sulfur-containing species, we synthesized some substituted 2*H*-benzo[b]thiete derivatives (Scheme 1, structure **1**) as possible precursors of *o*-thioquinone methides (Scheme 1, structure **2**). In our previous research (2), we had established that 2*H*-benzo[b]thiete (**1a**, R = H), containing a strained four-membered ring, is a good precursor for clean and high-yielding photo-generation of **2a** (R = H), needed for accurate kinetic measurements of its hydration in aqueous solution by means of flash photolytic methods. *o*-Thioquinone methide (**2a**, R = H) proved to be quite short-lived in aqueous solutions (2). Expecting to obtain transients **2** with considerably longer lifetimes, we were particularly interested in the preparation of compounds **1** containing electron donating groups at 3- or 5- positions, which would correspond to ortho and para positions, respectively, in the "thioquinone" ring of **2**, relative to the methylene group.

Scheme 1.



R = H, 3- *or* 5-Me, 3- *or* 5-MeO

Despite the merits of the 2*H*-benzo[b]thiete molecule, no compounds of type **1** *substituted in the benzene ring* have been described previously. The few known syntheses of **1a** made use of flash vacuum pyrolysis (FVP) at very high temperatures (700–1200 °C (3*a*–3*c*)), and no mention was made of substituted precursors (R = Me, MeO) that could be used in the synthetic procedures.

One could get the impression that because of the drastic reaction conditions of FVP, the synthesis of substituted 2*H*-benzo[b]thietes was unfeasible. Also, it is known that methyl- and methoxy-substituted aromatic hydrocarbons, including such simple derivatives as toluene and anisole,

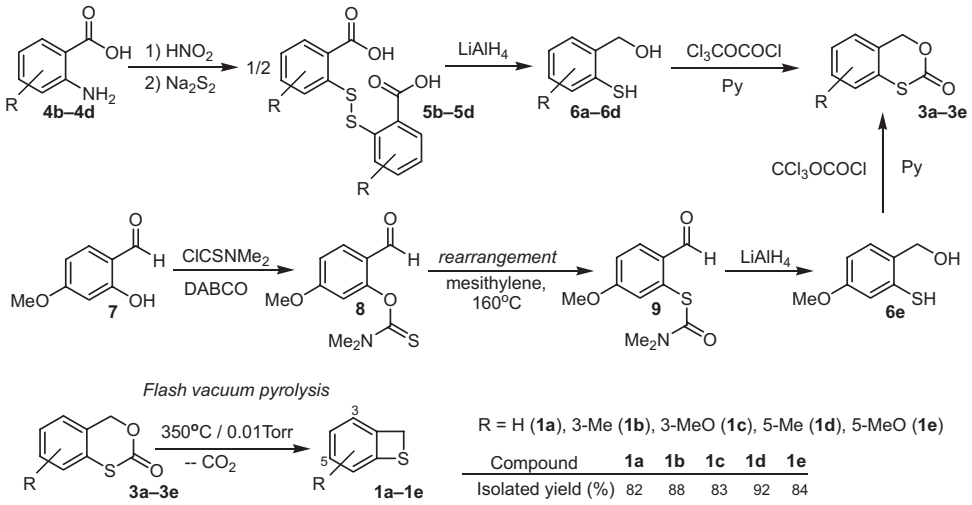
Scheme 2. (1 torr = 133.322 4 Pa)



undergo demethylation when exposed to high temperatures (typically above 700 °C); soot and many other products are formed depending on conditions of the gas-phase pyrolysis (4). Finally, the existing syntheses of **1a** leave much to be improved.

According to H. Meier and A. Mayer (3*d*), 4*H*-benzo[d][1,3]oxathiin-2-one (Scheme 2, compound **3a**, R = H) undergoes decarboxylation at 140 °C already and therefore can be used as a synthetic equivalent of 2*H*-benzo[b]thiete (**1a**, R = H) in some reactions. Nonetheless, in the course of the preparative synthesis of **1a** via pyrolysis of **3a**, the authors maintained a rather high (550 °C) temperature (3*d*). We decided to check if the pyrolysis temperature could be considerably decreased. The lower the temperature, the better the chances are to obtain the derivatives of **1** in greater diversity, and, also importantly, utilize a pyrex apparatus instead of the traditionally used quartz. We explored the synthetic accessibility of *o*-thioquinone methide precursors of structure **1** containing methyl and methoxy groups. Now that the synthetic part of our research is complete, we wish to report the properties of the novel 2*H*-benzo[b]thiete derivatives and details of the syntheses.

Results and discussion

In our syntheses of compounds **1b**–**1e**, we decided to follow the route described by H. Meier and A. Mayer (5) for **1a**, which involved the preparation of the 4*H*-benzo[d][1,3]oxathiin-2-one (Scheme 2, **3a**, R = H) followed by decarboxylation performed under FVP conditions. As seen in Scheme 2, compounds **3b**–**3e** were obtained from the corresponding 2-mercaptobenzyl alcohols (**6a**–**6e**) by the reaction with trichloromethyl chloroformate (diphosgene). The alcohols **6**, of which all except **6a** are new compounds, were prepared from the commercially available substituted 2-aminobenzoic acids (**4a**–**4d**). The first stage of the syntheses involved a simplified Leukart reaction, which is known to provide good yields for 2,2′-dithiosalicylic acid **5a** and its methyl and methoxy derivatives **5b**–**5d** (5). The diazotization of the amino groups in **4a**–**4d** was followed by decomposition in aqueous solutions of sodium disulfide, and the disulfides **5a**–**5d** were reduced with a large excess of $LiAlH_4$, as described (6) for **5a** (R = H). On the other hand, the synthesis of 4-methoxy derivative (**6e**, R = 4-MeO) involved a Newman–Kwart reaction (7) on the commercially available 2-hydroxy-4-methoxybenzaldehyde (Scheme 2, **7**) followed by reduction (see the Experimental section for details).

Flash vacuum pyrolysis (FVP) generally involves controlled vaporization of neat compounds in vacuo and vapor passage through tube type reactors maintained at high temperatures (3–6). The initial experiments on the compound **3a** as a substrate gave promising results. First, we established that the flash vacuum pyrolysis does occur at considerably lower temperatures (i.e., 250–300 °C) than H. Meier and A. Mayer suggest (550 °C). Further, we found that the decarboxylation in this temperature range is selective. Apart from **1a**, the unreacted starting material **3a** was detected as the only impurity in some experiments (at low pyrolysis temperatures and with high substrate sublimation rates). This means that, under the right conditions, the reaction product can be collected pure, which is a great advantage considering the instability and volatility of 2*H*-benzo[b]thiete. The latter usually poses difficulties when solvents are being evaporated from dilute compound solutions — for example, after chromatographic separation in the final purification stage.

Besides the reaction temperature, another important parameter of the process is the so-called "contact time", which indicates how long the compound vapor is exposed to high temperature in the reactor. This depends on the length of the reaction tube and (or) substrate sublimation rate. Despite 100% selectivity achieved for the gas phase pyrolysis itself, all the compounds **3**, including the nonsubstituted **3a**, proved temperature sensitive and underwent polymerization to a noticeable extent even at 30–40 °C. Therefore, there is a limit to the sublimation temperature and consequently the process output. When we switched to methyl and methoxy derivatives **3b**–**3e** as substrates, we found that their volatility was 3–5 times lower than that of **3a**. As expected, the introduction of substituents into the small molecule **3a** drastically decreased the volatility. With the apparatus we had at our disposal and under high vacuum (0.005–0.010 torr, 1 torr = 133.322 4 Pa), the process output was some 1–1.5 mg/h.

© 2008 NRC Canada

With lower substrate sublimation rates and consequently longer contact times, temperature variations in the 300–450 °C range did not affect either yield or purity of the products. All the compounds were isolated in the pure state (~99%, HPLC, NMR) and in excellent yields (82–92%, see Scheme 2). The general procedure for flash vacuum pyrolysis is described in the Experimental section. The four derivatives **1b**–**1e** were characterized by ^{1}H and ^{13}C NMR, high- and low-resolution mass spectrometry, and by melting points.

In the NMR spectra of **1b**–**1e** at 4.30–4.40 ppm (^{1}H) and at 35.10–36.55 ppm (^{13}C), signals were observed that could be unmistakeably attributed to methylene groups (CH_2) in the four-membered ring. As expected, those signals were markedly shifted upfield, compared with that of oxymethylene groups (OCH_2) in oxathiinone precursors **3b**–**3e** (5.10–4.50 ppm (^{1}H) and 66.60–72.60 ppm (^{13}C), respectively). The latter compounds also develop "carbonyl" signals resonating in the low-field area at 166–168 ppm (^{13}C). Also, in proton NMR spectra of compounds **1b** and **1c**, one could observe the typical picture of meta-substituted benzene rings with well-resolved singlets and doublets (see Experimental section for NMR spectroscopic data).

It should be noted that compounds **1b**–**1e** proved much more temperature sensitive, especially in solutions, than the nonsubstituted compound **1a**. Polymerization of **1a** has been described in the literature (4c), and polymerization of the derivatives **1b**–**1e** was evidenced in our research by the formation of insoluble precipitates upon storage (even at –10 °C). In addition, chromatographic analyses showed a decrease in compound concentration, while no other products were detected (polymers could not pass through the column we have used for the analysis of compounds **2** and **3**; see Experimental section for details).

Conclusions

Four methyl- and methoxy-substituted 2*H*-benzo[b]thietes **1b**–**1e** were synthesized in excellent yields from the corresponding 4*H*-benzo[d][1,3]oxathiin-2-ones **3b**–**3e** via flash vacuum pyrolysis. The process was a substantial improvement on the previously reported syntheses of **3a**. Particularly, we showed that the pyrolysis can be performed at considerably lower temperatures (300 °C), which allows the use of pyrex instead of quartz in the apparatus. Our experiments demonstrated that methyl- and methoxy-substituted substrates are compatible with the pyrolysis protocol. Under proper conditions, the reaction products can be isolated in excellent yields and with a very high purity. The final purification step is thus avoided, which is very important in dealing with the temperature sensitive and volatile 2*H*-benzo[b]thiete derivatives.

Experimental section

General

Substituted 2-aminobenzoic acids (**4b**–**4d**) were purchased from Peakdale Molecular (UK), and the rest of the chemicals from Aldrich. Progress of the reactions was monitored either by HPLC using a 5500 Varian Vista chromatograph equipped with Waters Symmetry C-18 reverse-phase column (4.6/150 mm, 5 μ particle size, methanol/water (50:50 vol.) as mobile phase) or by or TLC on silica gel SIL G/UV 254 plates developed in hexane. Mass spectra were recorded on a Micromass 70S-250 sector mass spectrometer and NMR spectra on a Varian spectrometer at 300 MHz (^{1}H) and 75 MHz (^{13}C). All the solvents, including THF and pyridine, were freshly distilled and dried by conventional methods.

Flash vacuum pyrolysis — General procedure for the preparation of 2*H*-benzo[b]thiete derivatives (1a–1e).

The apparatus for flash vacuum pyrolysis consisted of a test tube for sublimation connected to a pyrex reactor (2.5 cm × 35 cm) placed inside a tube furnace. The oxathiinone precursors (30–50 mg) were dissolved in ~2 mL of methylene chloride and the solutions were evaporated inside the test tube under an argon purge to achieve better coverage of its inner surface by the solids, which assisted sublimation. The test tube was mainained at 30–35 °C by means of external heating. The vacuum was maintained at 0.005–0.010 torr by means of a rotary pump. The products were condensed in a trap, cooled with liquid nitrogen, and handled uner inert atmosphere. In a typical experiment, about 20 mg of a compound **1a**–**1e** was isolated.

General procedure for the preparation of 4*H*-benzo[d][1,3]oxathiin-2-one derivatives (3a–3e)

To a stirred solution of the thiol substrates (2 mmol) and pyridine (470 mg, 6 mmol) in 40 mL of THF, trichloromethylchlorocarbonate (260 mg, 1.30 mmol) in 5 mL of THF was added at –5 °C in 20 min under an argon atmosphere. Further, 0.5 mL of concd. HCl in 50 mL of water, 50 mL of saturated brine, 25 mL of hexane, and 5 mL of methylene chloride was added successively upon stirring at RT. The organic layer was separated, and the aqueous layer was extracted with a mixture of hexane (25 mL) and methylene chloride (5 mL). Combined extracts were washed with 15 mL of water and then with a solution of 28 mg (0.5 mmol) KOH in 10 mL of water. The extracts were dried over $MgSO_4$, and the solvents were evaporated under reduced pressure. Crude products were purified by column chromatography over a short column containing ~8 g of silica gel with methylene chloride/hexane (1:2 vol.) as liquid phase.

2-Mercaptobenzyl alcohols (6b–6d)

The compounds **6b**–**6d**were obtained by reduction of the corresponding dithiosalicylic acids **5b**–**5d** (Scheme 2), themselves prepared via a simplified Leukart reaction on 2-aminobenzoic acids (**4b**–**4d**) in good yields, according to known procedures (5*b* and 5*c*). The identity of the products identity was confirmed by melting point determination and by ^{1}H NMR spectroscopy. The most recent report on the preparation of 2-mercaptobenzyl alcohol **6a** (R = H) belongs to A. Arnoldi and M. Carughi (6), who used it as an intermediate without purification. Our recipe for the preparation of **6b**–**6d** is very simple and, more importantly, provides very high purities (~99%, HPLC) for all the produts. In a typical experiment, the reduction was carried out as follows: To an ice-cooled solution of the dithiosalicylic acid substrate **5b**–**5d** (0.004 mol) in THF (60 mL), $LiAlH_4$ powder

© 2008 NRC Canada

(0.800 g, 0.021 mol) was added in a few portions upon stirring under an argon purge. The solution was slowly (~30 min) warmed up to RT, stirred for 1 h at 55–60 °C, cooled again, and carefully poured onto a mixture of ice (100 g) and 30 mL of 10 wt% H_2SO_4 upon vigorous stirring. Benzene (20 mL) was added immediately afterwards, and the organic layer separated. Water phase was extracted with benzene (20 mL × 2) and the combined organic extract was washed with water (15 mL) and a saturated $NaHCO_3$ solution (10 mL). From the benzene solution, the compounds **6b**–**6d** were extracted with NaOH (0.400 g, 0.010 mol) in 15 mL of water. The alkaline extract was acidified with concd. HCl (1.5 mL) and treated with CH_2Cl_2 (20 mL × 2). The organic phase was washed with brine (10 mL), dried and evaporated in vacuo. For the final purification, the alcohols were decolorized with silica gel (0.10 g) in methylene chloride/pentane (~1:10 vol.) solutions at RT, and crystallized upon cooling to (–20)–(+30) °C (because of their low melting points; properties and yields are reported later). All the compounds **6** are air-sensitive, and therefore all the manipulations were carried out under an argon atmosphere. The identity and purity of the alcohols **6b**–**6d** (all four are new compounds) was confirmed by ^1H and ^{13}C NMR spectroscopic data and mass spectrometry (see following).

2-Mercapto-6-methylbenzyl alcohol (6b)

Yield 67%. Colorless needles, mp 74–76 °C (methylene chloride/pentane). ^1H NMR ($CDCl_3$, ppm) δ: 1.84 (br s, 1H, OH) 2.41 (s, 3H, CH_3), 3.64 (s, 1H, SH), 4.88 (s, 2H, CH_2) 6.99–7.25 (m, $3H_{Ar}$). ^{13}C NMR ($CDCl_3$, ppm) δ: 19.72 (CH_3), 60.57 (CH_2OH), 128.52, 128.73, 129.39, 131.90, 136.72, 138.40. MS EI (70 eV) *m/z* (%): 154 (10, M^+), 136 (100, $M^+ - H_2O$), 121 (12, $M^+ - H_2O - CH_3$). HRMS (EI) calcd. for (M^+) $C_8H_{10}O_2S$: 154.0452; found: 154.0456.

2-Mercapto-6-methoxybenzyl alcohol (6c)

Yield 62%. Colorless needles, mp 68 to 69 °C (methylene chloride/pentane). ^1H NMR ($CDCl_3$, ppm) δ: 2.22 (br s, 1H, OH), 3.64 (s, 1H, SH), 3.83 (s, 3H, OCH_3), 4.66 (s, 2*H*, CH_2), 6.71–7.49 (m, $3H_{Ar}$). ^{13}C NMR ($CDCl_3$, ppm) δ: 55.70 (OCH_3), 58.26 (CH_2OH), 108.52, 123.62, 127.20, 129.16, 132.77, 158.40. MS EI (70 eV) *m/z* (%): 170 (15, M^+), 152 (100, $M^+ - H_2O$), 121 (20, $M^+ - H_2O - OCH_3$). HRMS (EI) calcd. for (M^+) $C_8H_{10}O_2S$: 170.0402; found: 170.0407.

2-Mercapto-4-methylbenzyl alcohol (6d)

Yield 73%. Colorless needles, mp 42 to 43 °C (methylene chloride/pentane). ^1H NMR ($CDCl_3$ ppm) δ: 1.85 (br s, 1H, OH) 2.30 (s, 3H, CH_3), 3.66 (s, 1H, SH), 4.69 (s, 2H, CH_2) 6.98 (d, *J* = 7Hz, $1H_{Ar}$), 7.19 (s, $1H_{Ar}$), 7.24 (d, *J* = 7Hz, $1H_{Ar}$). ^{13}C NMR ($CDCl_3$, ppm) δ: 20.91 (CH_3), 64.29 (CH_2OH), 127.19, 128.94, 130.13, 131.99, 135.89, 138.48. MS EI (70 eV) *m/z* (%): 154 (12, M^+), 136 (100, $M^+ - H_2O$), 121 (15, $M^+ - H_2O - CH_3$). HRMS (EI) calcd. for (M^+) $C_8H_{10}O_2S$: 154.0452; found: 154.0451.

2-Mercapto-4-methoxybenzyl

The alcohol (**6e**) was obtained via a Newman–Kwart reaction (see Scheme 2) on the commercially available 2-hydroxy-4-methoxybenzaldehyde (**7**) by the following steps.

Dimethylthiocarbamic acid *O*-(2-formyl-5-methoxyphenyl) ester (8)

A solution of *N*,*N*-dimethylthiocarbamoyl chloride (3.10 g, 0.025 mol), 2-hydrohy-4-methoxybenzaldehyde (3.04 g, 0.02 mol), and DABCO (3.02g, 0.027 mol) in 20 mL of anhyd. DMF was stirred overnight at RT for 2 h at 35–40 °C, and then poured into 200 mL of ice cold water. The yellow powder was collected, dried, and recrystallized from a benzene/hexane mixture (1:3 vol.) to afford 3.32 g (70%) of a colorless product whose melting point was 88 to 89 °C. ^1H NMR and mass spectra agreed with the structure **8**. ^1H NMR ($CDCl_3$, ppm) δ: 3.41, 3.47 (2s, 6H, NCH_3), 3.88 (s, 3H, OCH_3), 6.63 (s, $1H_{Ar}$), 6.90 (d, *J* = 6Hz, $1H_{Ar}$), 7.85 (d, *J* = 6Hz, $1H_{Ar}$), 9.92 (s, 1H, CHO). MS (ESI) *m/z* (%): 262 (100, M + Na^+), 239 (15, M + H^+), 212 (10, M^+ – CO). HRMS (ESI) calcd. for (M + Na^+) $C_{11}H_{13}O_3NaS$: 262.0508; found: 262.0501.

Dimethylcarbamic acid *S*-(2-formyl-5-methoxyphenyl) ester (9)

The rearrangement of the *O*-ester **8** to the corresponding *S*-ester **9** (see Scheme 2) was performed at 165 °C using mesithylene as solvent instead of the commonly used biphenyl ether (7b). Mesithylene proved much easier to remove and, more importantly, higher reaction temperatures (190–200 °C) are unsuitable for **8** because of its thermal sensitivity. Compound **8** (2.00 g, 0.008 mol) was refluxed in 20 mL of mesithylene for 25 h under an argon atmosphere. The rearrangement was monitored by TLC on silica plates using methylene chloride/acetone (10:1) as mobile phase. The solution was evaporated in a Petrie plate at atmospheric pressure, the residue dissolved in a methylene chloride/hexane (1:2 vol.) mixture (180 mL), decolorized with 0.40 g of silica gel, and crystallized to afford 1.65 g (80%) of pale yellow needles with mp 78 °C. ^1H NMR ($CDCl_3$, ppm) δ: 3.04, 3.16 (2s, 6H, NCH_3), 3.88 (s, 3H, OCH_3), 7.02 (s, $1H_{Ar}$), 7.05 (d, *J* = 6Hz, $1H_{Ar}$), 8.01 (d, *J* = 6Hz, $1H_{Ar}$), 10.27 (s, 1H, CHO). MS (ESI) *m/z* (%): 262 (100, M + Na^+), 239 (30, M + H^+), 212 (10, M^+ – CO), 167 (20, $M^+ - CON(CH_3)_2$). HRMS (ESI) calcd. for (M + Na^+) $C_{11}H_{13}O_3NaS$: 262.0508; found: 262.0504.

Compound **9** (0.956 g, 0.004 mol) in 5 mL of THF was added to a stirred suspension of LiAlH4 (0.800 g, 0.021 mol) in 30 mL of THF at 0 °C during 10 min under an argon purge, the reaction mixture was stirred for 4 h at 50°, and then treated exactly as described for the alcohols **6b**–**6d** (see earlier) to furnish **6e** (0.456 g, 67%) as colorless needles with mp 26–28 °C (methylene chloride/pentane). ^1H NMR ($CDCl_3$, ppm) δ: 1.84 (br s, 1H, OH) 3.78 (s, 3H, OCH_3), 3.90 (s, 1H, SH), 4.66 (s, 2H, CH_2) 6.64 (d, *J* = 7Hz, $1H_{Ar}$), 6.87 (s, $1H_{Ar}$), 7.22 (d, *J* = 7Hz, $1H_{Ar}$). ^{13}C NMR ($CDCl_3$, ppm) δ: 55.52 (OCH_3), 64.09 (CH_2OH), 111.81, 116.69, 130.45, 131.20, 132.14, 159.45. MS EI (70 eV) *m/z* (%): 170 (25, M^+), 152 (100, $M^+ - H_2O$), 121 (15, $M^+ - H_2O - OCH_3$). HRMS (EI) calcd. for (M^+) $C_8H_{10}O_2S$: 170.0402; found: 170.0401.

3-Methyl-2*H*-benzo[b]thiete (1b)

Yield 88%. Colorless liquid, fp (–10)–(+)9 °C. ^1H NMR (CD_3CN, ppm) δ: 2.27 (s, 3H, CH_3), 4,33 (s, 2H, CH_2), 6.91–6.98 (m, $2H_{Ar}$), 7,18–7.24 (m, $1H_{Ar}$). ^{13}C NMR

(CD_3CN, ppm) δ: 15.08 (CH_3), 35.88 (CH_2), 118.52, 125.42, 129.51, 133.12, 138.88, 142.46. MS EI (70 eV) *m/z* (%): 136 (100, M^+), 121 (20, $M^+ - CH_3$), 91 (45, $M^+ - S - CH_3$). HRMS (EI) calcd. for (M^+) C_8H_8S: 136.0347; found: 136.0348.

5-Methyl-4*H*-benzo[d][1,3]oxathiin-2-one (3b)

Yield 55%. Colorless needles, mp 64–66 °C. ^1H NMR (CD_3CN, ppm) δ: 2.44 (s, 3H, CH_3), 5.47 (s, 2H, CH_2), 7.23–7.27 (m, $2H_{Ar}$), 7.33–7.38 (m, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 18.31 (CH_3), 69.39 (CH_2), 124.44, 128.18, 129.73, 130.09, 131.18, 136.47, 167.20 (C=O). MS EI (70 eV) *m/z* (%): 180 (20, M^+), 136 (100, $M^+ - CO_2$), 121 (45, $M^+ - CO_2 - CH_3$). HRMS (EI) calcd. for (M^+) $C_9H_8O_2S$: 180.0245; found: 180.0248.

3-Methoxy-2*H*-benzo[b]thiete (1c)

Yield 83%. Colorless liquid, fp 11–13 °C. ^1H NMR (CD_3CN, ppm) δ: 3.95 (s, 3H, OCH_3), 4.41 (s, 2H, CH_2), 6.64–6.66 (m, $2H_{Ar}$), 7.21–7.26 (m, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 35.10 (CH_2), 56.05 (OCH_3), 109.76, 114.41, 124.12, 130.67, 143.96, 153.01 (C3). MS EI (70 eV) *m/z* (%): 152 (100, M^+), 137 (10, $M^+ - CH_3$), 121 (40, $M^+ - OCH_3$), 107 (15, $M^+ - CH_2 - OCH_3$). HRMS (EI) calcd. for (M^+) C_8H_8OS: 152.0296; found: 152.0299.

5-Methoxy-4*H*-benzo[d][1,3]oxathiin-2-one (3c)

Yield 63%. Colorless needles, mp 68 to 69 °C. ^1H NMR (CD_3CN, ppm) δ: 3.93 (s, 3H, CH_3), 5.49 (s, 2H, CH_2), 7.95–7.10 (m, $2H_{Ar}$), 7.41–7.49 (m, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 56.25 (OCH_3), 66.63 (CH_2), 110.82, 117.42, 118.56, 131.17, 132.34, 156.61 (C3), 166.88 (C=O). MS EI (70 eV) *m/z* (%): 196 (15, M^+), 152 (100, $M^+ - CO_2$), 121 (40, $M^+ - CO_2 - OCH_3$). HRMS (EI) calcd. for (M^+) $C_9H_8O_3S$: 196.0194; found: 196.0193.

5-Methyl-2*H*-benzo[b]thiete (1d)

Yield 92%. Colorless prisms, mp 54 to 55 °C. ^1H NMR (CD_3CN, ppm) δ: 2.35(s, 3H, CH_3), 4.32 (s, 2H, CH_2), 6.81 (d, J = 8Hz, $1H_{Ar}$), 6.95 (s, $1H_{Ar}$), 6.97 (d, J = 8Hz, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 21.65 (CH_3), 36.55 (CH_2), 121.96, 123.13, 125.30, 137.23, 139.24, 142.53. MS EI (70 eV) *m/z* (%): 136 (100, M^+), 121 (15, $M^+ - CH_3$), 91 (25, $M^+ - S - CH_3$). HRMS (EI) calcd. for (M^+) C_8H_8S: 136.0347; found: 136.0346.

7-Methyl-4*H*-benzo[d][1,3]oxathiin-2-one (3d)

Yield 60%. Colorless needles, mp 71 to 72 °C. ^1H NMR (CD_3CN, ppm) δ: 2.40 (s, 3H, CH_3), 5.37 (s, 2H, CH_2), 7.24 (d, J = 8Hz, $1H_{Ar}$), 7.25 (s, $1H_{Ar}$), 7.36 (d, J = 8Hz, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 20.69 (CH_3), 72.19 (CH_2), 126.59, 126.87, 127.20, 128.81, 130.95, 140.57, 166.89 (C=O). MS EI (70 eV) *m/z* (%): 180 (25, M^+), 136 (100, $M^+ - CO_2$), 121 (8, $M^+ - CO_2 - CH_3$). HRMS (EI) calcd. for (M^+) $C_9H_8O_2S$: 180.0245; found: 180.0246.

5-Methoxy-2*H*-benzo[b]thiete (1e)

Yield 84%. Colorless prisms, mp 27 to 28 °C. ^1H NMR (CD_3CN, ppm) δ: 3.79 (s, 3H, OCH_3), 4,41 (s, 2H, CH_2), 6.55 (d, J = 7Hz, $1H_{Ar}$), 6.61 (s, $1H_{Ar}$), 6.69 (d, J = 7Hz, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 37.07 (CH_2), 56.11 (OCH_3), 108.18, 111.68, 118.80, 132.35, 143.91, 161.70 (C5). MS EI (70 eV) *m/z* (%): 152 (100, M^+), 137 (5, $M^+ - CH_3$), 121 (10, $M^+ - OCH_3$), 107 (25, $M^+ - CH_2 - OCH_3$). HRMS (EI) calcd. for (M^+) C_8H_8OS: 152.0296; found: 152.0297.

7-Methoxy-4*H*-benzo[d][1,3]oxathiin-2-one (3e)

Yield 62%. Colorless needles, mp 76 to 77 °C. ^1H NMR (CD_3CN, ppm) δ: 3.74 (s, 3H, CH_3), 5.16 (s, 2H, CH_2), 6.73 (d, J = 7.5Hz, $1H_{Ar}$), 6.76 (s, $1H_{Ar}$), 7.18 (d, J = 7.5 Hz, $1H_{Ar}$). ^{13}C NMR (CD_3CN, ppm) δ: 56.43 (OCH_3), 72.57 (CH_2), 112.46, 114.26, 121.92, 128.99, 133.10, 161.44 (C5), 167.23 (C=O). MS EI (70 eV) *m/z* (%): 196 (25, M^+), 152 (100, $M^+ - CO_2$), 121 (10, $M^+ - CO_2 - OCH_3$). HRMS (EI) calcd. for (M^+) $C_9H_8O_3S$: 196.0194; found: 196.0197.

Bismuth(III)-catalyzed rapid and highly efficient synthesis of 2-aryl-1-arylmethyl-1*H*-benzimidazoles in water

J.S. Yadav, B.V. Subba Reddy, K. Premalatha, and K. Shiva Shankar

Abstract: 2-Aryl-1-arylmethyl-1*H*-benzimidazoles are prepared in high yields under extremely mild conditions via the condensation of aryl-1,2-diamines with aromatic aldehydes using 10 mol% of bismuth triflate in water. The use of water and readily available bismuth triflate makes this process quite simple, more convenient, and environment-friendly.

Key words: aryl-1,2-diamines, aromatic aldehydes, bismuth catalysis, benzimidazoles.

Résumé : On a préparé des 2-aryl-1-arylméthyl-1*H*-benzimidazoles avec des rendements élevés, sous des conditions extrêmement douces, en faisant appel à une condensation d'aryl-1,2-diamines avec des aldéhydes aromatiques en utilisant 10 moles pour cent de triflate de bismuth dans l'eau. L'utilisation de l'eau et la grande accessibilité du triflate de bismuth font que ce procédé est simple, très commode et environnementalement acceptable.

Mots-clés: aryl-1,2-diamines, aldéhydes aromatiques, catalyse par le bismuth, benzimidazoles.

[Traduit par la Rédaction]

Introduction

Benzimidazoles are important biologically active heterocycles possessing selective neuropeptide YY1 receptor antagonists (1) and as 5-lipoxygenase inhibitors for use as novel antiallergic agents (2), 5-HT3 antagonists in isolated guinea pig ileum (3), poly(ADP-ribose) polymerase (PARP) inhibitors (4), and factor Xa (Fxa) inhibitors (5). In addition, they exhibit significant activity against several viruses, such as HIV, herpes (HSV-1), RNA influenza, and human cytomegalovirus (HCMV) (6). Benzimidazole derivatives have found commercial applications in veterinarian medicine as anti-helmintic agents and in diverse human therapeutic areas, such as treatment of ulcers and as anti-histamines (7). Medicinal chemists would certainly classify benzimidazoles as privileged sub-structures for drug design, as they display affinity towards a variety of enzymes and protein receptors (8). Consequently, a variety of methods have been developed for the preparation of substituted benzimidazoles (9). Of these, one of the most traditional methods involves the condensation of an *o*-phenylenediamine with carboxylic acid or its derivatives (10). Subsequently, several improved protocols have been developed for the synthesis of benzimidazoles via the condensation of *o*-phenylenediamines with aldehydes in the presence of acid catalysts under various reaction conditions (11). However, many of these methods suffer from certain drawbacks, including longer reaction times, unsatisfactory yields, harsh reaction conditions, expensive reagents, tedious work-up procedures, co-occurrence of several side reactions, and poor selectivity. Since benzimidazole derivatives are useful and important in the field of drugs and pharmaceuticals, the development of simple, convenient, high yielding, and environmentally benign protocols is desirable. Therefore, the search continues for a better catalyst for the synthesis of benzimidazoles, in terms of operational simplicity, economic viability, and selectivity.

Recently, great attention has been focused on the use of water as green solvent for various organic transformations (12). In addition to its abundance and for economical and safety reasons, water has naturally become a substitute and an alternative environmentally benign solvent in organic synthesis. This becomes further sophisticated if these reactions can be performed using inexpensive and readily available reagents. Lanthanide triflates are unique Lewis acids that are currently of great interest (13). The high catalytic activity, low toxicity, moisture and air tolerance, and their recyclability make lanthanide triflates attractive alternatives to conventional Lewis acids (14). However, lanthanide triflates are rather expensive, and their use in large-scale synthesis is limited. Therefore, cheaper and more efficient catalysts are desirable. In this direction, bismuth triflate has evolved as remarkable Lewis acid catalyst for effecting various organic transformations (15). Compared with lanthanide triflates, bismuth triflate is cheap and is easy to prepare, even on a multi-gram scale, from commercially available bismuth oxide and triflic acid (16). The use of bismuth triflate for the synthesis of benzimidazoles has recently been reported under solvent-free conditions (17).

Results and discussion

Inspired by recent reports on the use of $Bi(OTf)_3$ in aqueous conditions (18) and our interest on the catalytic use of

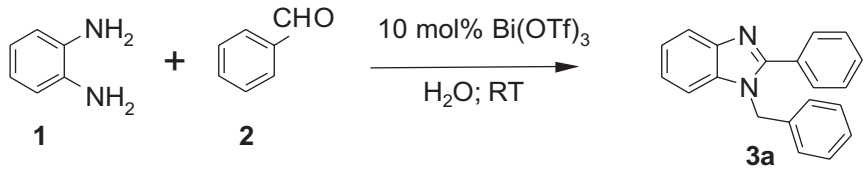
Scheme 1.



$Bi(OTf)_3$ (19), we herein report a mild and rapid synthesis of 2-aryl-1-arylmethyl-1*H*-benzimidazoles using a catalytic amount of $Bi(OTf)_3$ in water. Accordingly, treatment of *o*-phenylenediamine (**1**) with benzaldehyde (**2**) in the presence of 10 mol% of $Bi(OTf)_3$ in water resulted in the formation of benzimidazole (**3a**) in 97% yield (Scheme 1).

This result provided the incentive for further study of reactions with various substituted aryl 1,2-diamines and aryl aldehydes. Interestingly, several mono- and di-substituted aryl 1,2-diamines reacted efficiently with aldehydes to give the corresponding benzimidazoles (Table 1). The present protocol is effective for aromatic aldehydes bearing either electron-rich or electron-deficient substituents on the aromatic ring (Table 1, entries **b**–**h**). Similarly, α-naphthaldehyde (Table 1, entry **j**) and heteroaromatic aldehydes (Table 1, entries **k**–**m**) also reacted well with *o*-phenylenediamine to furnish the corresponding benzimidazoles in good yields. In all cases, the reactions proceeded rapidly at room temperature with high efficiency and were complete within a short time. The products were characterized by ^1H, ^{13}C NMR, IR, and mass spectroscopy and also by comparison with authentic samples (11). Unlike reported methods, the present protocol does not require harsh or drastic conditions to produce benzimidazoles. The effects of various metal triflates, such as $Cu(OTf)_2$, $In(OTf)_3$, and $Ce(OTf)_3$ were screened. Of these catalysts, bismuth(III) triflate was found to be the most effective in terms of conversion and reaction rates. Interestingly, 10 mol% of $Sc(OTf)_3$ was found to be an equally effective for this conversion. In the absence of catalyst, the reaction did not proceed in water even after long reaction times (12–24 h). Compared with conventional Lewis acids, $Bi(OTf)_3$ is particularly attractive because it can be used in water (18). Since a water solution of $Bi(OTf)_3$ is acidic (16), it may be possible that the true catalyst is TfOH produced from the hydrolysis of $Bi(OTf)_3$. However, TfOH is not as effective as $Bi(OTf)_3$ to catalyze the condensation of *o*-phenylenediamine with benzaldehyde (10% TfOH at 25 °C, 3 h, 65%), thus suggesting that a Lewis acid is likely involved in activating the aldehyde. Furthermore, the recovered aqueous solution of $Bi(OTf)_3$ could be reused in further reactions with gradual decrease in activity. For instance, treatment of *o*-phenylenediamine with benzaldehyde over 10 min gave 97%, 85%, and 71% yield, respectively, over three cycles. This observation clearly shows the reusability of the catalyst. The scope and generality of this process is illustrated with respect to various aryl 1,2-diamines and aldehydes, and the results are summarized in Table 1.

In conclusion, we have described a mild, convenient, and efficient protocol for the synthesis of highly substituted benzimidazoles using bismuth(III) triflate as the novel catalyst. This method not only offers substantial improvements in reaction rates and yields but also avoids the use of hazardous acids, environmentally unfavorable organic solvents, and harsh reaction conditions, which makes it useful and environment-friendly for the synthesis of biologically relevant benzimidazole scaffolds.

Experimental

Melting points were recorded on Buchi R-535 apparatus and are uncorrected. IR spectra were recorded on a PerkinElmer FTIR 240-c spectrophotometer using KBr optics. ^1H NMR spectra were recorded on Gemini 200 and Varian Bruker 300 spectrometers in $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on a Finnigan MAT 1020 mass spectrometer operating at 70 eV. TLC was monitored on 0.25 mm pre-coated silica-gel plates (60F-254).

General procedure

A mixture of the 1,2-diamine (1.0 mmol), aldehyde (2 mmol), and $Bi(OTf)_3$ (10 mol%) in water (2 mL) was stirred at room temperature for the specified time (see Table 1). After completion of the reaction as indicated by TLC, the reaction mixture was extracted with ethyl acetate (2 × 10 mL). Evaporation of the solvent, followed by purification on silica gel (Merck, 100–200 mesh, ethyl acetate/hexane (1:5)), afforded pure benzimidazole.

1-Benzyl-2- phenyl-1*H*-benzo[*d*]imidazole (3a)

Solid; mp 139–141 °C. IR (KBr) ν_{max}: 3031, 2947, 1452, 1348, 1162, 967, 697 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.45 (s, 2H), 7.08–7.12 (m, 3H), 7.21–7.30 (m, 5H), 7.35–7.44 (m, 3H), 7.62 (dd, J = 8.0 and 2.0 Hz, 2H), 7.84 (d, J = 8.0 Hz, 1H). EI-MS *m*/*z* (%): 284 (M^+, 45), 156 (10), 142 (30), 92 (100).

1-(4-Methylbenzyl)-2-(4-methylphenyl)-1*H*-benzo[*d*]imidazole (3b)

Solid; mp 128–130 °C. IR (KBr) ν_{max}: 3024, 2917, 2861, 1411, 1249 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 2.34 (s, 3H), 2.40 (s, 3H), 5.37 (s, 2H), 6.96 (d, J = 8.1 Hz, 2H), 7.11–7.26 (m, 6H), 7.55 (d, J = 8.3 Hz, 2H), 7.79 (d, J = 7.9 Hz, 2H), EI-MS *m*/*z* (%): 312 (M^+, 92), 208 (26), 105 (100), 77 (10).

1-(4-Methoxybenzyl)-2-(4-methoxyphenyl)-1*H*-benzo[*d*]imidazole (3c)

Solid; mp 121–123 °C. IR (KBr) ν_{max}: 3064, 3043, 2959, 2943, 1604, 1452, 1243, 750 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.65 (s, 3H), 3.85 (s, 3H), 5.38 (s, 2H), 6.78–6.85 (m, 3H), 6.95–7.05 (m, 3H), 7.08–7.35 (m, 4H), 7.62 (d, J = 8.0 Hz, 2H). EI-MS *m*/*z* (%): 344 (M^+, 64), 329 (6), 299 (30), 223 (100), 91 (64).

1-(4-Hydroxybenzyl)-2-(4-hydroxyphenyl)-1*H*-benzo[*d*]imidazole (3d)

Solid; mp 111–113 °C. IR (KBr) ν_{max}: 3420, 3089, 3045, 2955, 1605, 1455, 1245, 750 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.28 (s, 2H), 6.87–6.90 (m, 3H), 7.02–7.08 (m, 3H), 7.18–7.25 (m, 4H), 7.78 (d, *J* = 8.0 Hz, 2H). ESI-MS *m/z* (%): 317 (M + 1).

1-(4-Fluorobenzyl)-2-(4-fluorophenyl)-1*H*-benzo[*d*]imidazole (3e)

Solid; mp 110–112 °C. IR (KBr) ν_{max}: 3032, 2935, 2835, 1465, 1423, 1078, 750 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.45 (s, 2H), 6.92–7.18 (m, 4H), 7.21–7.32 (m, 5H), 7.62–7.78 (m, 3H). ESI-MS *m/z* (%): 321 (M + 1).

1-(4-Chlorobenzyl)-2-(4-chlorophenyl)-1*H*-benzo[*d*]imidazole (3f)

Solid; mp 137–139 °C. IR (KBr) ν_{max}: 3038, 2923, 2853, 1473, 1439, 1091 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.39 (s, 2H), 7.03 (d, *J* = 9.0 Hz, 2H), 7.11–7.34 (m, 4H), 7.42 (d, *J* = 8.3 Hz, 2H), 7.58 (d, *J* = 8.3 Hz, 2H), 7.82 (d, *J* = 7.5 Hz, 2H). EI-MS *m/z* (%): 352 (M^+, 52), 227 (4), 192 (30), 125 (100), 90 (13).

1-(4-Bromobenzyl)-2-(4-bromophenyl)-1*H*-benzo[*d*]imidazole (3g)

Solid; mp 160–162 °C. IR (KBr) ν_{max}: 3045, 2928, 1569, 1468, 1091 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.42 (s, 2H), 7.01 (d, *J* = 7.8 Hz, 2H), 7.15–7.35 (m, 3H), 7.42–7.59 (m, 6H), 7.78 (d, *J* = 7.8 Hz, 1H). ESI-MS *m/z* (%): 441 (M + 1).

1-(4-Nitrobenzyl)-2-(4-nitrophenyl)-1*H*-benzo[*d*]imidazole (3h)

Solid; mp 175–177 °C. IR (KBr) ν_{max}: 3043, 2978, 2240, 1470, 1352, 1188 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.45 (s, 2H), 7.26–7.32 (m, 4H), 7.70–7.74 (m, 4H), 8.07–8.25 (m, 4H). ESI-MS *m/z* (%): 375 (M + 1).

2-Cyclohexyl-1-(cyclohexyl methyl)-1*H*-benzo[*d*]imidazole (3i)

Solid; mp 82–84 °C. IR (KBr) ν_{max}: 3743, 3042, 2926, 1581, 1454, 1344, 742 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 0.995–2.0 (m, 22H), 3.88 (d, *J* = 7.8 Hz, 2H), 7.05–7.20 (m, 2H), 7.68–7.75 (m, 2H). EI-MS *m/z* (%): 296 (M^+, 15), 241 (10), 213 (20), 141 (40), 83 (15), 41 (100).

2-(Napthalene-3yl)-1-(napthlen-3-yl)methyl)-1*H*-benzo[*d*]imidazole(3j)

Solid; mp 122–124 °C. IR (KBr) ν_{max}: 3075, 2955, 1443, 1348, 1242, 1178, 968 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$): 5.65 (s, 2H), 7.21–7.35 (m, 4H), 7.42–7.52 (m, 5H), 7.69–7.75 (m, 2H), 7.81–7.98 (m, 6H), 8.18–8.22 (m, 1H). ESI-MS *m/z* (%): 385 (M + 1).

2-(Thiophen-2yl)-1-(thiophen-2yl)methyl)-1*H*-benzo[*d*]imidazole (3k)

Solid; mp 150–152 °C. IR (KBr) ν_{max}: 3095, 3072, 2929, 1449, 1421, 1219 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$): 5.71 (s, 2H), 6.86–6.70 (m, 2H), 7.12–7.16 (m, 1H), 7.23–7.40 (m, 4H), 7.46–7.53 (m, 2H), 7.82–7.85 (m, 1H). EI-MS *m/z* (%): 296 (M^+, 78), 172 (6), 109 (2), 97 (100), 77 (6).

2-(Furan-2-yl)-1-((furan-2-yl)methyl)-1*H*-benzo[*d*]imidazole (3l)

Solid; mp 88–89 °C. IR (KBr) ν_{max}: 3378, 3150, 1605, 1332, 1007, 735 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.65 (s, 2H), 6.18 (d, *J* = 7.7 Hz, 1H), 6.24–6.26 (m, 1H), 6.59–6.61 (m, 1H), 7.17–7.32 (m, 4H), 7.40–7.44 (m, 1H), 7.61–7.62 (m, 1H), 7.71–7.74 (m, 1H). EI-MS *m/z* (%): 264 (M^+, 80), 141 (20), 81 (100), 53 (30).

2-(Pyridine-2-yl)-1-(pyridine-2-yl)methyl)-1*H*-benzo[*d*]imidazole (3m)

Solid; mp 128–123 °C. IR (KBr) ν_{max}: 3055, 2993 1675, 1442, 1350, 1256, 1135 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.32 (s, 2H), 7.03–7.10 (m, 2H), 7.25–7.35 (m, 5H), 7.45–7.53 (m, 3H), 7.82–7.85 (m, 2H). ESI-MS *m/z* (%): 287 (M + 1).

1-Benzyl-2-phenyl-1*H*-benzo[*d*]imidazole-5-yl)(phenyl)methanone (3n)

Solid; mp 195–197 °C. IR (KBr) ν_{max}: 3053, 2995, 1673, 1453, 1350, 1236, 1145 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.50 (s, 2H), 7.05–7.12 (m, 2H), 7.21–7.39 (m, 5H), 7.41–7.52 (m, 5H), 7.62–7.75 (m, 3H), 7.81–7.90 (m, 2H), 8.25 (d, *J* = 7.8 Hz, 1H). ESI-MS *m/z* (%): 389 (M + 1).

1-Benzyl-5-methyl-2-phenyl-1*H*-benzo[*d*]imidazole (3o)

Solid; mp 170–172 °C. IR (KBr) ν_{max}: 3062, 2954, 1670, 1441, 1355, 1265, 1150, 750 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.0 (s, 3H), 5.45 (s, 2H), 7.05–7.12 (m, 3H), 7.28–7.33 (m, 4H), 7.43–7.51 (m, 4H), 7.59–7.61 (m, 2H). ESI-MS *m/z* (%): 299 (M + 1).

1-Benzyl-5,6-dimethyl-2-phenyl-1*H*-benzo[*d*]imidazole (3p)

Solid; mp 187–189 °C. IR (KBr) ν_{max}: 3422, 2919, 1448, 1314, 697 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 2.35 (s, 6H), 5.41 (s, 2H), 7.28–7.49 (m, 10H), 7.65 (d, *J* = 7.7 Hz, 1H), 8.12 (d, *J* = 7.7 Hz, 1H). EI-MS *m/z* (%): 312 (M^+, 90), 222 (15), 141 (30), 119 (35), 91 (100).

4-(2-(4-(Dimethylamino)phenyl)-1*H*-benzo[*d*]imidazole-1-yl)methyl-*N*,*N*-dimethylbenzamine (3q)

Solid; mp165–167 °C. IR (KBr) ν_{max}: 3062, 2954, 1670, 1441, 1355, 1265, 1150, 750 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 2.93 (s, 6H), 3.00 (s, 6H), 5.37 (s, 2H), 6.66–6.75 (m, 4H), 7.14–7.29 (m, 3H), 7.63–7.65 (m, 4H), 7.78 (d, *J* = 7.9 Hz, 1H). ESI-MS *m/z* (%): 371 (M + 1).

Theoretical study on NO_3-initiated oxidation of acenaphthene in the atmosphere

Xiaohui Qu, Qingzhu Zhang, and Wenxing Wang

Abstract: Acenaphthene is widespread and toxic, and thus of substantial environmental concern. The reaction with NO_3 radicals is an important atmospheric loss process of acenaphthene at night time. In this work, the mechanism for the NO_3-initiated atmospheric oxidation reaction of acenaphthene has been studied using high level molecular orbital theory. Geometries of all the related species have been optimized at the MPWB1K level with the 6–31G(d,p) basis set. The single-point energy calculations have been carried out at the MPWB1K/6–311+G(3df,2p) level. The possible secondary reactions were also studied. Several energetically favorable reaction pathways were revealed for the first time.

Key words: acenaphthene, NO_3 radicals, reaction mechanism, product information, oxidation degradation.

Résumé : L'acénaphtène est toxique et très répandu et, d'un point de vue environnemental, il soulève donc beaucoup d'inquiétudes. La réaction des radicaux NO_3 est un processus atmosphérique important de perte de l'acénaphtène durant la nuit. Dans ce travail, faisant appel à la théorie des orbitales molécules à un niveau élevé, on a étudié le mécanisme de la réaction d'oxydation atmosphérique de l'acénaphtène initiée par le NO_3. Les géométries de toutes les espèces reliées ont été optimisées au niveau MPWBIK avec un ensemble de base 6-31G(d,p). Les calculs d'énergie ponctuelle ont été réalisés au niveau MPWB1K/6-311+G(3df,2p). On a aussi étudié les réactions secondaires potentielles. On a mis en évidence pour la première fois plusieurs voies réactionnelles énergétiquement favorables.

Mots-clés : acénaphtène, radicaux NO_3, mécanisme réactionnel, information sur le produit, dégradation par oxydation.

[Traduit par la Rédaction]

Introduction

Polycyclic aromatic hydrocarbons (PAHs) have attracted substantial environmental attention because of the widespread occurrences of these compounds and their adverse impacts on ecosystems and human health (1–6). PAHs are released into the atmosphere during incomplete combustion of fossil fuels and biomass from natural and agricultural fires (7–9). Vehicle emission also represents an important source of PAHs in urban areas (10–12).

Acenaphthene belongs to the family of PAHs. It is found both in outdoor and indoor air and is observed in high concentration in certain areas (13–16). Under typical atmospheric conditions, acenaphthene is predominately found in the gas phase and thus can be removed from the troposphere by gas-phase reactions with hydroxyl (OH) radicals, nitrate (NO_3) radicals, ozone (O_3), and by photolysis (16–19). These reactions are important sinks of acenaphthene in the atmosphere. Because of the presence of a cyclopenta-fused ring, the reactivity of acenaphthene may be significantly different from those PAHs only containing six-membered aromatic rings. Another reason why the atmospheric reactions of acenaphthene have drawn considerable environmental concern is because the reactions of acenaphthene in the atmosphere often yield degradation products that may be more carcinogenic and more mutagenic than the parent PAH. Thus, it is important to understand the transformation and fate of acenaphthene in the atmosphere.

Since OH radicals are ubiquitous in the atmosphere, the most important removal reactions of PAHs are initiated by OH radicals. However for acenaphthene, which contains a cyclopenta-fused ring, the reaction with NO_3 radicals is also expected to be an important atmospheric loss process (18). Moreover, as the formation of OH radicals only takes place under illumination, OH concentration rapidly decreases after sunset. As a consequence, OH-initiated reactions only occur during the day and strongly depend on the photon flux. NO_3 radicals undergo rapid photolysis upon absorption of radiation. The daytime NO_3 chemistry is expected to be unimportant for PAHs. However, NO_3 radicals have been identified and measured by long-path spectroscopic techniques in the nighttime atmosphere. The reaction with NO_3 radicals will dominate the loss pathway of acenaphthene during nighttime. Environmental chamber studies show generally high nitro-PAH yields from the NO_3-initiated reactions compared with OH-initiated reactions (2, 17–18). However, the current knowledge of the NO_3-initiated atmospheric oxidation of acenaphthene is very limited. Only two studies on the experimental rate constants are on record (17, 18). The reaction rate constant was measured to be $(4.6 \pm 2.6)\ 10^{-13}$ cm^3

molecule^{-1} s^{-1} at room temperature. The mechanism has not been elucidated. In this work, we have initiated a theoretical study on the NO_3-initiated atmospheric oxidation reaction of acenaphthene. Fundamental knowledge of specific pathways, stable end products, and energy profile surface are vital in understanding the removal process of acenaphthene and the formation of secondary pollutants.

Computational methods

Using the Gaussian 03 program suite (19), high-level molecular orbital theory calculations have been carried out. The geometries have been optimized at the MPWB1K level (20) with the 6–31G(d,p) basis set. The vibrational frequencies have been calculated at the same level to determine the na-

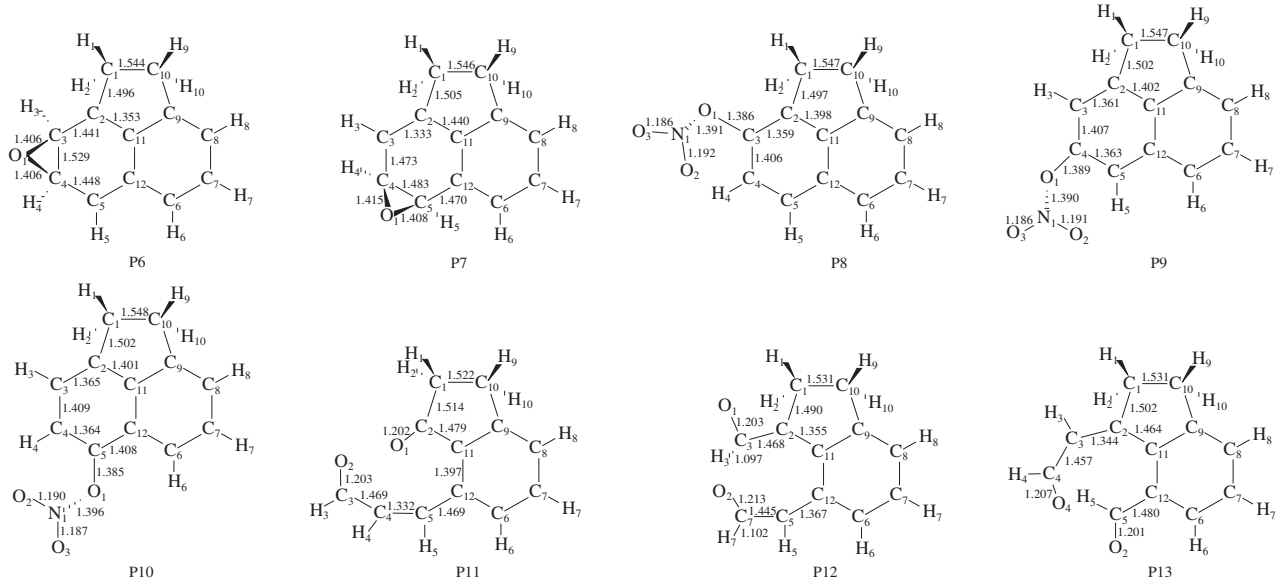
Fig. 1 (*concluded*).



ture of the stationary points. Each transition state was verified to connect the designated reactants and products by performing an intrinsic reaction coordinate (IRC) (21) analysis. In the paper of Truhlar (22), the MPWB1K level was tested to be a good method for weak interaction and barrier height calculations. In this work, the MPWB1K level with a more flexible basis set, 6–311+G(3df,2p), was employed to calculate the single-point energies of various species.

To clarify the general reliability of theoretical calculations, it is useful to compare the predicated chemical properties of the present particular systems of interest with experimental data (23). The theoretical and geometry experimental parameters are shown in Figs. 1 and 2. The maximum relative errors are less than 1.6%. These good agreements give us confidence that MPWB1K/6–31G(d,p) theory is adequate to optimize the geometries.

Results and discussion

The reaction of acenaphthene with NO_3 radicals

H-abstraction channels

Hydrogen atoms in acenaphthene can be divided into two kinds: hydrogen atoms in the cyclopenta-fused ring (H_1, H_2, H_9, H_{10}) and the ones in the aromatic ring (H_3, H_8, H_4, H_7, H_5, H_6). Four hydrogen atoms in the cyclopenta-fused ring are equivalent. Thus, a primary process has been identified for H-abstraction from the cyclopenta-fused ring. First, a hydrogen bonding intermediate, IM1, is formed. Then, a H atom is abstracted via the transition state TS1. The unpaired electron is delocalized in the whole transition state. The atomic spin densities obtained by Mulliken population analysis are O_1 (0.307), C_1 (0.108), H_1 (0.002), C_5 (0.270), C_3 (0.196), C_6 (0.134), C_4 (–0.115), C_8 (0.104). It is interesting to note that spin densities on the C atoms of the aromatic ring are higher than on the C_1 atom from which the H atom is abstracted by NO_3 radicals. The electron delocalization stabilizes this H-abstraction transition state. Figure 3 shows that H-abstraction from the cyclopenta-fused ring has a rather low barrier height, only 3.06 kcal/mol (1 cal = 4.184 J). This process is strongly exothermic. Thus, H-abstraction from the cyclopenta-fused ring can occur readily and is expected to play an important role for the degradation of acenaphthene in the atmosphere. Atkinson (17) postulated that the reaction of NO_3 radical with acenaphthene proceeds mainly by H atom abstraction from the -CH_2- group of the cyclopenta-fused ring. The quantum calculation result is consistent with the postulation of Atkinson. It is interesting to compare the H-abstraction reactions by OH radical to H-abstraction reactions by NO_3 radical. The energy for the transition state of H-abstraction from the -CH_2- group of cyclopenta-fused ring by NO_3 radicals is 4.56 kcal/mol lower than the total energy of reactants. The energy for the transition state of H-abstraction from the -CH_2- group of cyclopenta-fused ring by OH radicals is only 0.79 kcal/mol lower than the total energy of reactants.

Six hydrogen atoms in the aromatic ring are unequivalent. Three transition states, denoted as TS2, TS3, and TS4, were located for H-abstraction from the aromatic ring. In contrast to the H-abstraction process from the cyclopenta-fused ring, H-abstraction reactions from the aromatic ring have high potential barriers, 8.06, 8.04, and 8.94 kcal/mol. Furthermore, all of these H-abstraction channels are endothermic. Therefore, the most important H-abstraction channel is H-abstraction from the cyclopenta-fused ring.

Association–elimination pathways

There exist C–C double bonds in the structure of acenaphthene. Thus, association–elimination is a possible reaction pathway for the reaction of acenaphthene with NO_3 radicals. Four different reaction sites are revealed; C2, C3, C4, and C5 atoms in acenaphthene are attacked by an O atom in NO_3 to form NO_3-acenaphthene adducts, IM2, IM3, IM4, and IM5, respectively. The energies of IM2, IM3, IM4, and IM5 are lower than the total energy of the original reactants by 16.04, 14.14, 13.12, and 17.80 kcal/mol, respectively. The energy-rich adducts can further react via unimolecular decomposition. The decomposition pathways

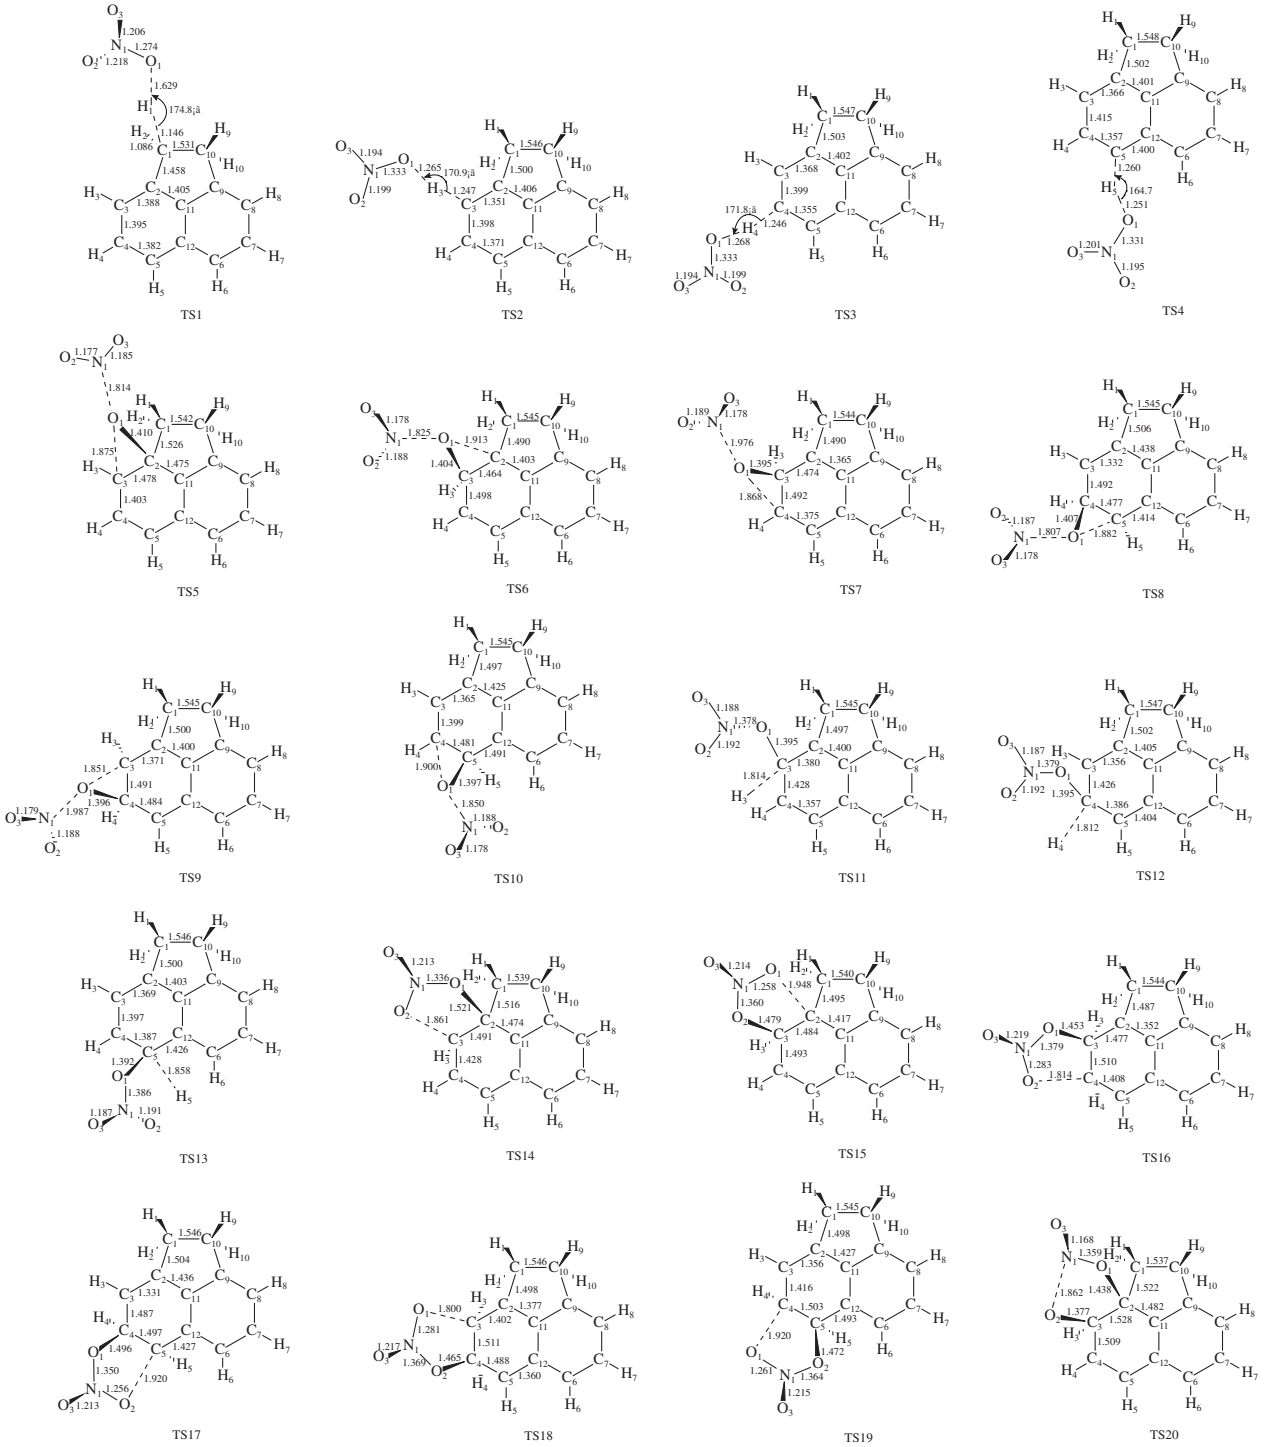
Fig. 2. MPWB1K/6–31G(d,p) optimized geometries for the transition states involved in the reaction of acenaphthene with NO_3 radicals. Distances are in ångströms and angles are in degrees.



are too complicated. To clarify, we show the potential energy profiles in two different figures. The direct decomposition channels are shown in Fig. 4. The multi-step isomerization–decomposition pathways are depicted in Fig. 5. In the following discussion, the decomposition channels of the NO3-acenaphthene adducts, IM2, IM3, IM4, and IM5, were divided into three kinds.

The first decomposition channel is the loss of NO_2 to form epoxyacenaphthene. There are three different epoxyacenaphthene products, denoted as P5, P6, and P7 in Fig. 1. Both the formations of 2,3-epoxyacenaphthene (denoted as P5) and 4,5-expoxyacenapthene (denoted as P7) are exothermic by 5~10 kcal/mol, and the corresponding barrier heights are about 25 kcal/mol; whereas the formation of 3,4-expoxyacenaphtene (denoted as P6) is endothermic by about 11 kcal/mol, and the corresponding barrier height is more than 35 kcal/mol. Thus, the formations of P5 and P7 are relatively energetically favorable. Therefore, the main

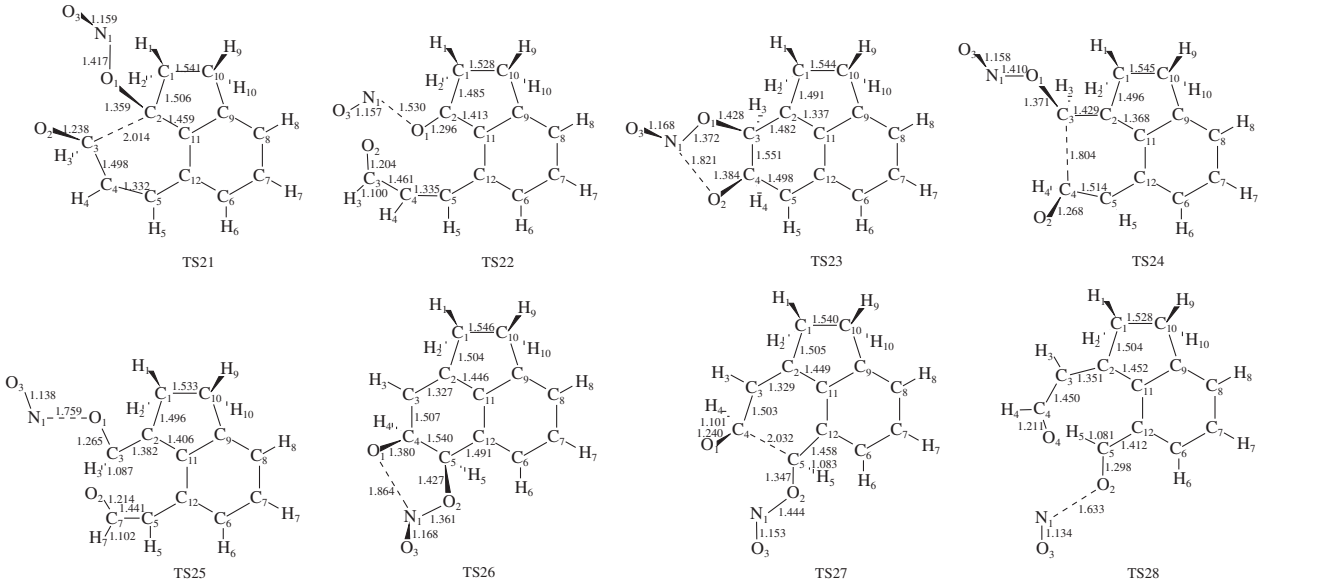

Fig. 3. Profile of the potential energy surface for H-abstraction channels at the MPWB1K /6–311+G(3df,2p) level (1 cal = 4.184 J).

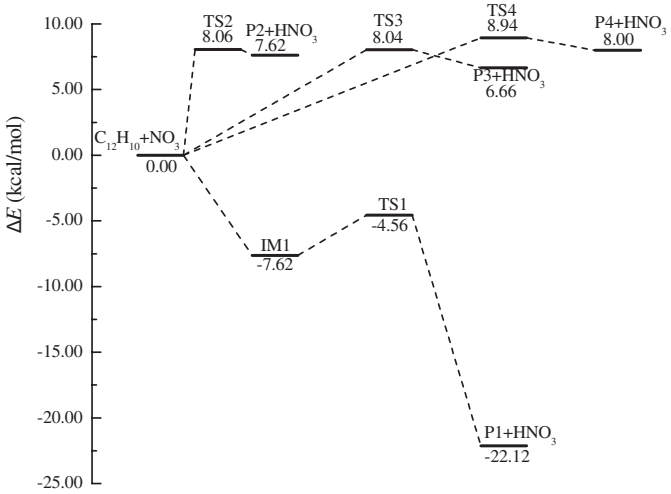

Fig. 4. Profile of the potential energy surface for the direct decomposition channels of NO_3-acenaphthene adducts at the MPWB1K /6–311+G(3df,2p) level.

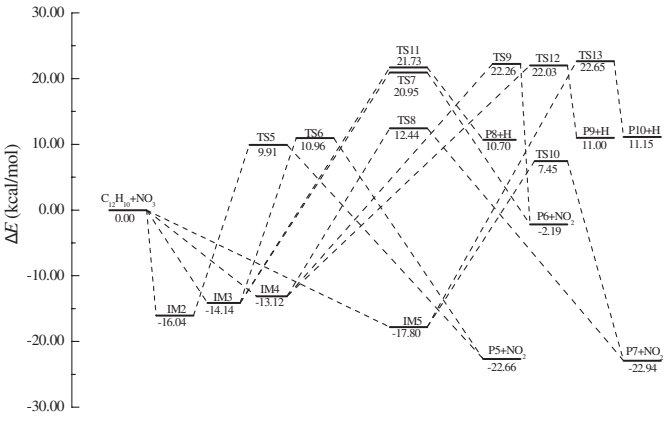


epoxyacenaphthene products will be 2,3-epoxyacenaphthene and 4,5-expoxyacenapthene. The detailed barrier heights and reaction enthalpies can be clarified as follows:

$$IM2 \rightarrow TS5 \rightarrow P5 + NO_2$$
$$\Delta E = 25.95 \text{ kcal/mol}, \Delta H = -6.62 \text{ kcal/mol}$$

$$IM3 \rightarrow TS6 \rightarrow P5 + NO_2$$
$$\Delta E = 25.10 \text{ kcal/mol}, \Delta H = -8.52 \text{ kcal/mol}$$

$$IM3 \rightarrow TS7 \rightarrow P6 + NO_2$$
$$\Delta E = 35.09 \text{ kcal/mol}, \Delta H = 11.95 \text{ kcal/mol}$$

$$IM4 \rightarrow TS8 \rightarrow P7 + NO_2$$
$$\Delta E = 25.56 \text{ kcal/mol}, \Delta H = -9.82 \text{ kcal/mol}$$

$$IM4 \rightarrow TS9 \rightarrow P6 + NO_2$$
$$\Delta E = 35.38 \text{ kcal/mol}, \Delta H = 10.93 \text{ kcal/mol}$$

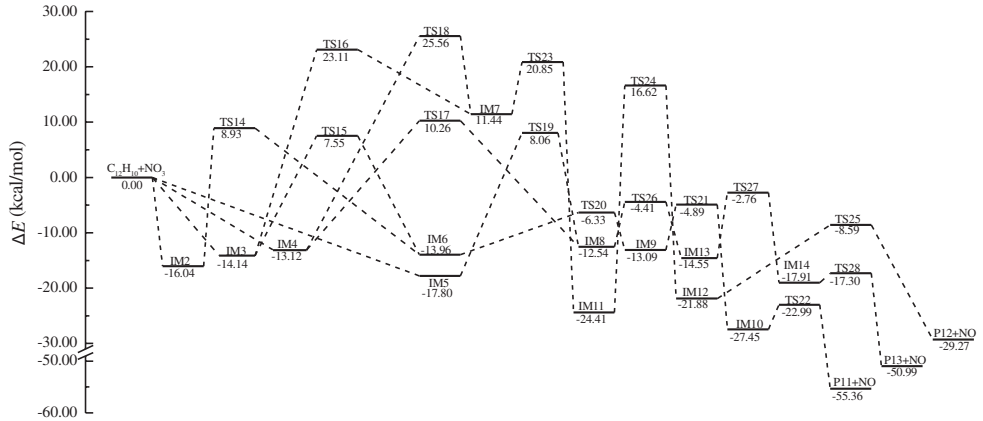
$$IM5 \rightarrow TS10 \rightarrow P7 + NO_2$$
$$\Delta E = 25.25 \text{ kcal/mol}, \Delta H = -5.14 \text{ kcal/mol}$$

Another possible decomposition channel of the NO_3-acenaphthene adducts (IM3, IM4, or IM5) is the loss of an H atom bonded with the carbon atom (C_3, C_4, or C_5) to form nitrate species P8, P9, or P10. Figure 4 shows that all of these decomposition processes have high barrier heights, 35.87, 35.15, 40.45 kcal/mol, respectively. Furthermore, these channels are highly endothermic by 24.84, 24.12, or 28.95 kcal/mol, respectively. Therefore, these processes are the energetically unfavorable channels for the decomposition of NO_3-acenaphene adducts.

The third possible pathway involves multi-step isomerization and decomposition. The potential energy profile is shown in Fig. 5. First, the pathways initiate from the isomerization of NO_3-acenaphthene adducts to three intermediates containing a five-membered heterocyclic ring, IM6, IM7, and IM8. The formation of IM6 and IM8 are weakly endothermic, whereas the formation of IM7 is strongly en-

© 2008 NRC Canada

Fig. 5. Profile of the potential energy surface for the multi-step isomerization–decomposition pathways of NO_3-acenaphthene adducts at the MPWB1K /6–311+G(3df,2p) level.



dothermic by about 25 kcal/mol, and the corresponding barrier height is about 38 kcal/mol. Thus, the formation of IM7 is energetically unfavorable. The most energetically favorable channel is the isomerization of IM3 to IM6. These pathways can be clarified as follows:

$$\text{IM2} \rightarrow \text{TS14} \rightarrow \text{IM6}$$
$$\Delta E = 24.97 \text{ kcal/mol}, \Delta H = 2.08 \text{ kcal/mol}$$

$$\text{IM3} \rightarrow \text{TS15} \rightarrow \text{IM6}$$
$$\Delta E = 21.69 \text{ kcal/mol}, \Delta H = 0.18 \text{ kcal/mol}$$

$$\text{IM3} \rightarrow \text{TS16} \rightarrow \text{IM7}$$
$$\Delta E = 37.25 \text{ kcal/mol}, \Delta H = 25.58 \text{ kcal/mol}$$

$$\text{IM4} \rightarrow \text{TS17} \rightarrow \text{IM8}$$
$$\Delta E = 23.38 \text{ kcal/mol}, \Delta H = 0.58 \text{ kcal/mol}$$

$$\text{IM4} \rightarrow \text{TS18} \rightarrow \text{IM7}$$
$$\Delta E = 38.68 \text{ kcal/mol}, \Delta H = 24.56 \text{ kcal/mol}$$

$$\text{IM5} \rightarrow \text{TS19} \rightarrow \text{IM8}$$
$$\Delta E = 29.20 \text{ kcal/mol}, \Delta H = 5.26 \text{ kcal/mol}$$

IM6 will isomerize to IM9. The potential barrier of this process is 7.63 kcal/mol. Then, IM9 will further isomerize to IM10. IM10 is more stable by 14.36 kcal/mol than IM9. The potential barrier of this process is 8.20 kcal/mol. The subsequent unimolecular decomposition of IM10 will produce a dicarbonyl product (denoted as P11) and NO. This process has a very low potential barrier, only 4.46 kcal/mol. The process is exothermic by 27.91 kcal/mol. The isomerization and decomposition of IM7 and IM8 is similar to that of IM6, except that the formation and isomerization of IM7 is not energetically favorable. Figure 5 shows that the dominant dicarbonyl products of the third possible pathway will be P11 and P13, which have been detected in Arey's environmental chamber experimental study for OH radical-initiated reactions of alkylnaphthalenes (24). The detailed mechanisms can be clarified as follows:

$$\text{IM6} \rightarrow \text{TS20} \rightarrow \text{IM9} \rightarrow \text{TS21} \rightarrow \text{IM10} \rightarrow \text{TS22} \rightarrow \text{P11} + \text{NO}$$

$$\text{IM7} \rightarrow \text{TS23} \rightarrow \text{IM11} \rightarrow \text{TS24} \rightarrow \text{IM12} \rightarrow \text{TS25} \rightarrow \text{P12} + \text{NO}$$

$$\text{IM8} \rightarrow \text{TS26} \rightarrow \text{IM13} \rightarrow \text{TS27} \rightarrow \text{IM14} \rightarrow \text{TS28} \rightarrow \text{P13} + \text{NO}$$

The study shows that H-abstraction from the cyclopenta-fused ring is the most energetically favorable reaction channel for the reaction of acenaphthene with NO_3 radicals. Because of the high potential barriers, other pathways cannot occur to any significant extent under atmospheric conditions. Thus, acenaphthenyl (P1) will be the dominant product. Figures 4 and 5 show that all of the decomposition channels of NO_3-acenaphthene adducts need high potential barriers, more than 20 kcal/mol. Therefore, their removal reactions with NO_x or O_2 may be competitive with their decompositions.

Secondary reactions

The NO_3-acenaphthene adducts (IM2, IM3, IM4, IM5) and acenaphthenyl (P1) are open-shell radicals and can react with NO_x or O_2 their removal from the troposphere (Fig. 6).

The reactions of acenaphthenyl (P1) with NO/O$_2$

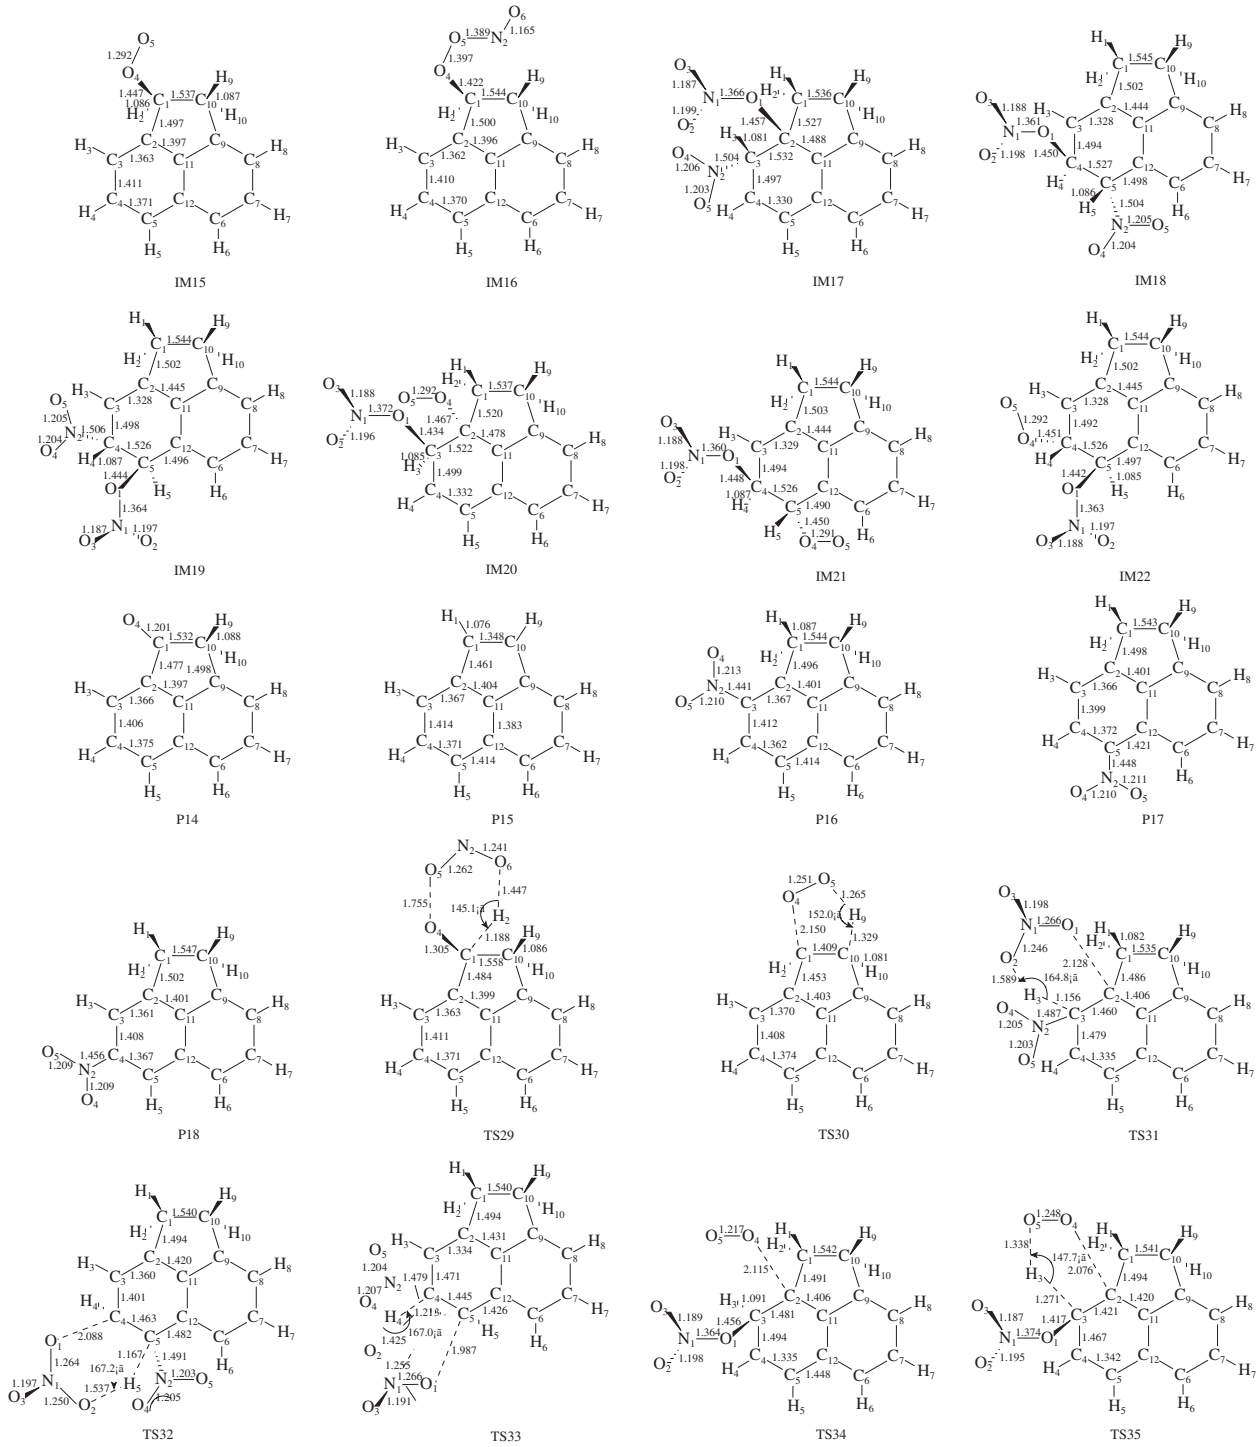
Acenaphthenyl (P1) radicals can react with O_2 via barrierless association to form an intermediate, IM15. The energy of IM15 is 15.35 kcal/mol lower than the total energy of P1 and O_2. The energy-rich adduct IM15 has two forward reaction pathways. The first is the association with NO to form IM16. This process is also barrierless. Then, IM16 will decompose via transition state TS29 to produce acenaphthylen-1(2*H*)-one (denoted as P14) and HNO_2. Another reaction pathway of IM15 is to decompose via transition state TS30. The barrier height is 28.80 kcal/mol. This process is endothermic by 15.63 kcal/mol. The decomposition products are acenaphthylene (denoted as P15) and HO_2 radical. The mechanism can be clarified as follows:

$$\text{P1} + \text{O}_2 \rightarrow \text{IM15}$$
$$\Delta H = -15.35 \text{ kcal/mol}$$

$$\text{IM15} + \text{NO} \rightarrow \text{IM16}$$
$$\Delta H = -15.72 \text{ kcal/mol}$$

© 2008 NRC Canada

Fig. 6. MPWB1K/6–31G(d,p) optimized geometries for the products, transition states, and intermediates involved in the NO_3 radical-initiated secondary reactions. Distances are in ångströms and angles are in degrees.



$$IM16 \rightarrow TS29 \rightarrow P14 + HNO_2$$

$$\Delta E = 42.44 \text{ kcal/mol}, \Delta H = -61.93 \text{ kcal/mol}$$

$$IM15 \rightarrow TS30 \rightarrow P15 + HO_2$$

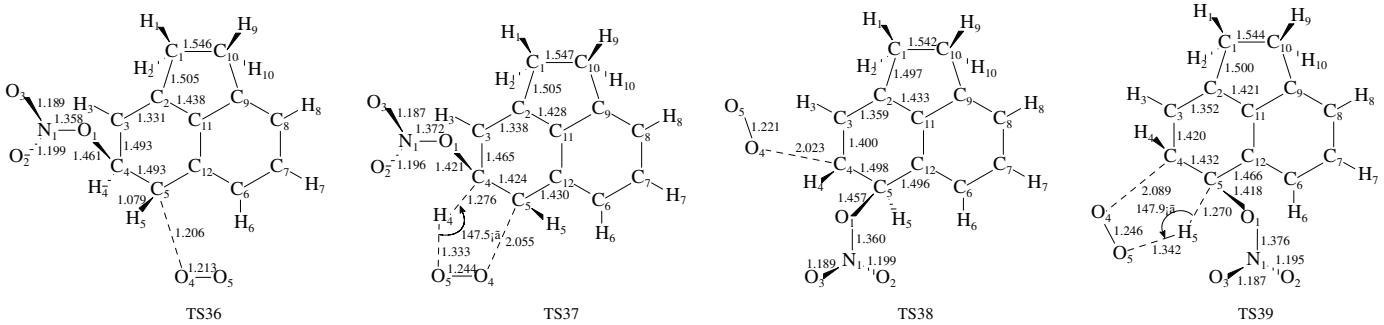
$$\Delta E = 28.80 \text{ kcal/mol}, \Delta H = 15.63 \text{ kcal/mol}$$

The reactions of NO_3-acenaphthene adducts with NO_2

IM2 can react with NO_2 radicals via a barrierless association to form an intermediate, IM17. The energy of IM17 is 33.60 kcal/mol lower than the total energy of IM2 and NO_2. Then, the energy-rich adduct IM17 will further decompose. A transition state, denoted as TS31, corresponding to the decomposition of IM17 was located. This decomposition involves H-migration and cleavage of the C_2–O_1 bond.

© 2008 NRC Canada

Fig. 6 (*concluded*).



H-migration leads to a six-membered cycle in the structure of TS31. The decomposition products are 3-nitroacenaphthene (denoted as P16) and HNO_3. The potential barrier of this decomposition is 22.02 kcal/mol. The process is exothermic by 18.27 kcal/mol.

The reactions of IM4 and IM5 with NO_2 radicals are similar to the reactions of IM2, both reactions produce nitroacenaphthene. Atkinson (17) found that the NO_3 radical-initiated acenaphthene oxidation reaction rate depend on the NO_2 concentration. This is consistent with our calculation. The mechanism can be clarified as follows:

$$IM2 + NO_2 \rightarrow IM17$$
$$\Delta H = -33.60 \text{ kcal/mol}$$

$$IM17 \rightarrow TS31 \rightarrow P16 + HNO_3$$
$$\Delta E = 22.02 \text{ kcal/mol}, \Delta H = -18.27 \text{ kcal/mol}$$

$$IM4 + NO_2 \rightarrow IM18$$
$$\Delta H = -39.23 \text{ kcal/mol}$$

$$IM18 \rightarrow TS32 \rightarrow P17 + HNO_3$$
$$\Delta E = 26.80 \text{ kcal/mol}, \Delta H = -12.42 \text{ kcal/mol}$$

$$IM5 + NO_2 \rightarrow IM19$$
$$\Delta H = -34.75 \text{ kcal/mol}$$

$$IM19 \rightarrow TS33 \rightarrow P18 + HNO_3$$
$$\Delta E = 29.59 \text{ kcal/mol}, \Delta H = -14.14 \text{ kcal/mol}$$

The reactions of NO_3-acenaphthene adducts with O_2

For the reaction with IM3, O_2 attacks the aromatic ring to form an intermediate, IM20, via the transition state TS34. The barrier height for this process is only 4.56 kcal/mol. The reaction enthalpy is –12.68 kcal/mol. A possible decomposition channel will open for IM20. This decomposition will proceed via the transition state TS26. The products of this decomposition are a nitrate species (denoted as P8) and HO_2. The potential barrier is 19.56 kcal/mol. The process is exothermic by 6.89 kcal/mol.

The reactions of IM4 and IM5 with O_2 will also produce nitrate species (denoted as P9 and P10, respectively) and HO_2. The mechanism can be clarified as follows:

$$IM13 + O_2 \rightarrow TS34 \rightarrow IM20$$
$$\Delta E = 4.56 \text{ kcal/mol}, \Delta H = -12.68 \text{ kcal/mol}$$

$$IM20 \rightarrow TS35 \rightarrow P8 + HO_2$$
$$\Delta E = 19.56 \text{ kcal/mol}, \Delta H = -6.89 \text{ kcal/mol}$$

$$IM4 + O_2 \rightarrow TS36 \rightarrow IM21$$
$$\Delta E = 5.38 \text{ kcal/mol}, \Delta H = -12.81 \text{ kcal/mol}$$

$$IM21 \rightarrow TS37 \rightarrow P9 + HO_2$$
$$\Delta E = 21.31 \text{ kcal/mol}, \Delta H = -7.48 \text{ kcal/mol}$$

$$IM5 + O_2 \rightarrow TS38 \rightarrow IM22$$
$$\Delta E = 6.69 \text{ kcal/mol}, \Delta H = -7.53 \text{ kcal/mol}$$

$$IM22 \rightarrow TS39 \rightarrow P10 + HO_2$$
$$\Delta E = 18.78 \text{ kcal/mol}, \Delta H = -7.93 \text{ kcal/mol}$$

Conclusion

In this work, we present an exhaustive and theoretical study on the NO_3-initiated atmospheric oxidation reaction of acenaphthene. The comprehensive mechanism study has led to the following specific conclusions. (*i*) The reaction of acenaphthene with NO_3 radicals occurs primarily by H-abstraction from the cyclopenta-fused ring and NO_3 addition to the aromatic ring. Acenaphthenyl, acenaphthylen-1(2*H*)-one, acenaphthylene, epoxyacenaphthene, and dicarbonyl species are the possible products. (*ii*) The removal reactions of open-shell NO_3-acenaphthene adducts with NO_x, or O_2 are strongly competitive with their decompositions.

Synthesis of isoxazole conjugates of sugars via 1,3-dipolar cycloaddition

Vipraja V. Vaidya, Karuna S. Wankhede, Manikrao M. Salunkhe, and Girish K. Trivedi

Abstract: Isoxazole conjugates of sugar have been synthesized by the aid of 1,3-dipolar cycloaddition in a click chemistry approach. The sugar-derived propargyl ethers underwent 1,3-dipolar cycloadditions smoothly with in situ generated nitrile oxides from aromatic oximes in good yields. The reaction exhibited a high degree of regioselectivity.

Key words: isoxazole conjugates, 1,3-dipolar cycloadditions, nitrile oxides.

Résumé : Faisant appel à une cycloaddition 1,3-dipolaire et une approche chimique qui marche très bien, on a réalisé la synthèse d'isoxazoles conjugués à un sucre. Les éthers propargyliques dérivés du sucre donnent lieu en douceur et avec de bons rendements à des réactions de cycloaddition 1,3-dipolaire avec les oxydes de nitrile générés in situ à partir d'oximes aromatiques. La réaction présente un degré élevé de régiosélectivité.

Mots–clés : produits conjugués de l'isoxazole, cycloadditions 1,3-dipolaires, oxydes de nitrile.

[Traduit par la Rédaction]

Introduction

Several compounds of natural and non-natural origin comprised of the isoxazole moiety possess a broad spectrum of biological properties viz., fungicidal, antibacterial, anti-inflammatory, anti-allergic, anti-tumor, herbicidal, etc. The isoxazole class of compounds are also synthetically important as 1,3-dicarbonyl equivalents (1). Among the plethora of protocols reported for the synthesis of the isoxazole skeleton, two major routes are the 1,3-dipolar cycloadditon of alkenes and alkynes with nitrile oxides and the reaction of hydroxylamine with a three-carbon atom component, such as 1,3-diketone or an α,β-unsaturated ketone. 1,3-Dipolar cycloaddition has proven particularly valuable for the construction of complex five-membered conformationally rigid heterocycles (2). Isoxazoles, also among the five-membered heterocycles, can be accessed by 1,3-dipolar cycloaddition reaction. In particular, nitrile oxides undergo cycloaddition with alkynes resulting in good yields of isoxazoles (3). A similar class of compounds, i.e., triazoles, have been synthesized via 1,3-dipolar cycloaddition of azides and alkynes. This reaction has been considered as the prototype of click chemistry (4). There are several excellent contributions from various groups in the domain of click chemistry, wherein 1,3–dipolar cycloadditions are employed as a tool to conjugate molecules of structural diversity (5). Such linkage may result in altogether new attributes and (or) an ensemble of attributes. The continuing interest in this field and the importance of the isoxazole moiety has encouraged us to report our results.

Results and discussion

We herein report regioselective syntheses of sugar conjugates of isoxazoles (**1**–**10**) via 1,3-dipolar cycloaddition of carbohydrate derived alkynes and in situ generated nitrile oxides from oximes (Scheme 1). D-Glucose was utilized as a precursor to prepare all dipolarophiles i.e., sugar alkynes. The dipolarophiles (**1a**–**5a**) were synthesized following standard procedures. The dipoles, i.e., nitrile oxides, were generated in situ from the biphasic oxidation of the oximes with NaOCl in dichloromethane-triethyl amine (6). These dipoles underwent cycloaddition with dipolarophiles to afford cycloadducts, i.e., new isoxazole conjugates of sugars in good yields.

D-Glucose was utilized to synthesize 1,2:5,6 diisopropylidene-α-D-glucofuranose, which was subsequently subjected to etherification using propargyl bromide to yield the dipolarophile **1a**. The dipolarophile **1a** upon treatment with benzonitrile oxide, 4-methoxy benzonitrile oxide, and 3,4-dimethoxy benzonitrile oxide afforded cycloadducts (**1**–**3**) in 75%–80% yields.

The dipolarophile **2a** was also treated with the three previously mentioned nitrile oxides separately to generate corresponding cycloadducts (**4**–**6**) in 69%–75% yields. The dipolarophile **3a** was treated with benzonitrile oxide to yield cycloadduct **7** in 74% yield. The dipolarophile **4a** was accessed by Ferrier *O*-glycosylation of 3,4,6-tri-*O*-acetyl-D-glucal with propargyl alcohol. It was further subjected to 1,3-dipolar cycloaddition with benzonitrile oxide to yield cycloadduct **8** in 67% yield.

Our next objective was to synthesize bis-isoxazole derivatives, and in that direction we carried out the propargylation of the cycloadduct **7** to have one more site for cycloaddition

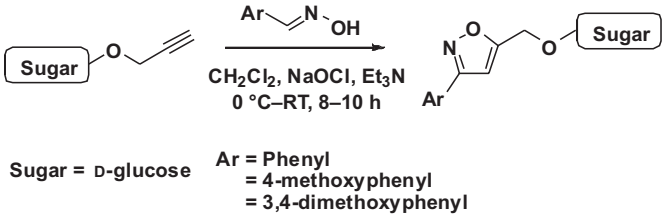
Scheme 1. Synthesis of isoxazole conjugates of sugars.



to yield the dipolarophile **5a**. The compound **5a** was subjected to cycloaddition with benzonitrile oxide and 4-methoxy benzonitrile oxide to afford bisisoxazole **9** and mixed bis-isoxazole **10**, in 65% and 67% yields, respectively. All gummy products (Table 1) were purified by silica gel column chromatography. The reaction exhibited a high degree of regioselectivity, which was confirmed from ^{1}H NMR spectra of the products. The signals in the range of δ 6.5–6.7, as singlet for vinylic proton, indicated only 5-substituted products were formed. Furthermore, all these isoxazole conjugates possess a protected furanoside ring that is accessible for elaboration after deprotection. The isoxazole moiety present can be cleaved to yield 1,3-functionalized compounds that can serve as handles for further manipulation.

In conclusion, we successfully employed a 1,3-dipolar cycloaddition strategy to conjugate sugar molecules with isoxazoles, which resulted in compounds bearing an appendage of aromatic moieties on sugar molecules. Thus, the biological profile of isoxazole coupled with sugar through C-O linkage was diversified. In the near future, we will continue our efforts to synthesize novel hybrid entities using the 1,3-dipolar cycloaddition reaction of nitrile oxides as a key step.

Experimental

General procedure for the preparation of isoxazole conjugates

A solution of the aldoxime (dipole precursor) (1 mmol), sugar alkyne (dipolarophile) (1 mmol), and triethylamine (2 to 3 drops) in dichloromethane (10 mL) was cooled to 0 °C. To this solution, sodium hypochlorite (4%, 10 mL) was added dropwise with stirring at 0 °C. The reaction mixture was warmed to RT and stirred for 8–10 h. On the disappearance of the starting material (TLC), the reaction phases were separated and the aqueous phase was extracted with dichloromethane. The combined layers were washed with brine, dried with sodium sulphate, and the solvent evaporated under reduced pressure to yield the crude cycloadduct. The crude product was chromatographed on a silica gel column. The purified products were characterized.

Ring opening of α,β-epoxy phenyl ketones with ceric ammonium nitrate (CAN) and potassium bromide

Zhou Lu, Wentao Wu, Lijun Peng, and Longmin Wu

Abstract: Ring-opening reaction of α,β-epoxy phenyl ketones was achieved cooperatively using cerium ammonium nitrate (CAN) and potassium bromide. The reaction occurred regioselectively at the β-C to afford *syn*-β-bromo-α-hydroxyl ketones as main outcomes.

Key words: ring-opening, epoxide, ceric ammonium nitrate, potassium bromide.

Résumé : Utilisant l'effet combiné du nitrate d'ammonium cérique (NAC) et du bromure de potassium comme catalyseurs, on a réalisé la réaction d'ouverture de cycle de α,β-époxy phénylcétones. La réaction se fait d'une façon stéréosélective au niveau du carbone β et elle conduit aux β-bromo-α-hydroxycétones *syn* comme produits principaux.

Mots-clés : ouverture de cycle, époxyde, nitrate d'ammonium cérique, bromure de potassium.

[Traduit par la Rédaction]

Introduction

Epoxides are important starting materials and intermediates in organic synthesis (1) because of their easy preparations and ready reactivities toward nucleophiles. Among the reports on epoxides, many were involved in ring-opening reactions (2). Most of the nucleophilic ring-opening reactions proceeded via an S_N2-like mechanism and afforded the corresponding *trans*-β-Nu alcohols (3). Our recent studies found that nitric oxide (NO) caused ring opening of 2,3-epoxides in either syn- or anti-selective fashion, which is strongly dependent on the α-C substituent (4). It was found that cerium ammonium nitrate (CAN, $(NH_4)_2Ce(NO_3)_6$), a single electron oxidant in organic oxidation reactions (5–11), efficiently catalyzed most ring-opening reactions of epoxides (12). These reactions occurred in distinct regioselectivity, β- or α-attack (12*e*–12*f*), and in anti and (or) syn manners, strongly depending upon the molecular structure, the stoichiometry of CAN used, and the solvent (12). CAN brought about the conversion of epoxides into β-nitrato alcohols in the presence of an excess of nitrate ion (12*a*–12*b*). Recently, it was reported that CAN mediated ring opening of cyclopropyl alcohols and specifically gave β-functionalized ketones in the presence of selected anions (13). The substitutent-dependent fashion in the NO-mediated ring-opening reaction of epoxides (4) stimulated us to explore whether a similar effect also exists in the ring-opening reaction of epoxides with CAN. In addition, the resulting vicinal alcohols from the ring-opening reaction of epoxides will be important intermediates in organic synthesis (14).

Result and discussion

In the present work, *trans* chalcone epoxides were employed as substrates. We started with α,β-epoxy phenyl ketones **1**, which were easily prepared by the reaction of chalcone with H_2O_2. Upon treatment of 1 equiv. of **1** with 2.2 equiv. of CAN and 5 equiv. of KBr in acetone at room temperature (RT), ring-opening reactions occurred regioselectively at the β-C and brominations specifically at the β-C, giving β-bromo-α-hydroxyl ketones **2** in moderate yields (Scheme 1 and Table 1). All products were characterized by IR, MS, HRMS, ^1H, and ^{13}C NMR. Weber first synthesized chalcone bromohydrins using $SnBr_4$ in 1992. He determined his products to be syn configurations mainly by NMR parameters (15). As such, the configuration of products **2** was confirmed to be dominantly syn (4*a*, 15, 16).

It was also found that CAN and KBr acted cooperatively to cause the ring-opening reactions. No ring-opening reaction occurred in the absence of either CAN or KBr. Furthermore, the reaction proceeded very slowly when a catalytic amount of CAN was applied. One reason for this may be partially attributed to polar substituted epoxides having less activity toward the ring-opening reaction (12*d*). Although the reaction mechanism is far from clear, a possible pathway for the present ring-opening reaction and bromination may be rationalized in terms of bromine radical, which is formed by the oxidation of bromide ion with an excess amount of CAN (13, 17) and the subsequent addition of bromine radical to three-membered epoxide ring (10a, 18), leading to the ring opening. On reviewing previous works on similar topics (4, 19), it is found that the carbonyl group plays a key role in ring-opening regioselectivity. The carbonyl group causes

[a]Yields refer to isolated products.
[b]The ratio of *syn*-**2** to *anti*-**2** was evaluated using the characteristic ^{1}H NMR peaks both of α- and β-H, such as in **2j**, 5.56 (*syn*-α-H) to 5.41 ppm (*anti*-α-H) as well as 5.33 (*syn*-β-H) to 5.10 (*anti*-β-H).
[c]Material decomposed in 5 min, giving 91% of 4-methoxybenzaldehyde.
[d]Along with 55% of 4-methylbenzaldehyde.

the ring opening uniquely at β-C, yet the stereochemistry strongly depends on reaction conditions. The assumption of a one-electron transfer reaction between epoxide and Ce(IV), with a catalytic amount leading to the formation of an expoxonium radical cation (12*b*–12*e*), will be ruled out in the present case.

The effect of solvents on this reaction was examined using **1a** as a substrate (Table 2). From Table 2 we can find that some aprotic solvents such as acetone and THF were the most favorable solvents, whereas CH_2Cl_2 disfavored the ring-opening reaction. In general, CAN is insoluble in organic solvents. If a small amount of water is contained in solvents, then the solvent polarity somewhat affects the solubility of CAN in reaction media. Otherwise, protic solvents would join the reaction (12*c*, 19*a*), as in the case of methanol (Table 2).

In summary, we have developed an efficient method for the regioselective and syn-selective conversion of *trans* chalcone epoxides to *syn* chalcone bromohydrins by CAN and potassium bromide.

Table 2. Effect of solvents on the yield of **2a**.

Solvent	Yield of **2a** (%)
CH_3COCH_3	77
CH_3CN	60
THF	66
Et_2O	64
CH_3COOEt	33
CH_2Cl_2	0
CH_3OH	19[a]

Note: The ratio of syn to anti in all solvents was ca. 99:1.
[a]Along with 75% of 2-hydroxy-3-methoxy-1,3-diphenylpropan-1-one (19*a*).

Experimental

General

Flash chromatography was carried out using silica gel 60 (200–300 mesh, particle size 0.040–0.062 mm) supplied by Qingdao Ocean Chemical Plant. Melting points were measured with a digital Koffer apparatus and were uncorrected. IR (KBr) analysis of solid compounds was performed on a Nicolet NEXUS 670 FT-IR spectrophotometer and reported in cm^{-1}. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury Plus 300 MHz NMR spectrometer. Chemical shifts (δ) for ^{1}H and ^{13}C NMR spectra are reported in parts per million (ppm) from solvent $CDCl_3$ (7.26 ppm) and (77.0 ppm), respectively, as internal standards relative to tetramethylsilane. MS data were obtained with EI (70 eV) on an HP-5988 spectrometer by direct inlet at 70 eV. HRMS data was obtained on a Bruker Daltonics APEX FT-ICR spectrometer. Chemicals were of highest grade commercially available and used as received, unless otherwise stated. All reagents were weighed and handled in air at RT.

Typical procedure for the preparation of 1a

To a solution of 1.040 g of chalcone (5 mmol) in 25 mL of methanol were added 1.035 g of K_2CO_3 (7 mmol) and

© 2008 NRC Canada

2 mL of H_2O_2 (30%). The mixture was stirred at ambient temperature until a white precipitate appeared, then isolated by filtration with the aid of Celite, and washed with water, affording **1a**. Other substrates were prepared by similar procedures.

Typical procedure for the ring-opening reaction of 1a with CAN and KBr

To a solution of 0.112 g (0.5 mmol) of **1a** in 15 mL of acetone were added 0.300 g of KBr (2.5 mmol) and 0.600 g of CAN (1.1 mmol). The mixture was stirred at ambient temperature until the reaction completed, water then added to dissolve the salts, and extracted with 3 × 10 mL Et_2O. The organic layer was dried over anhyd. Na_2SO_4, filtered, concentrated under vacuum, and purified by flash column chromatography on silica gel (petroleum ether/acetic ether 10:1), giving pure **2a**. All compounds were recrystalized from petroleum ether (60–80 °C)-acetic ether. Other ring-opening reactions were performed accordingly.

Characterization data for products

Syn-2a (15)

Yellow solid, yield 77%, mp 90–92. IR (KBr, cm^{-1}) ν: 3472, 1673, 1271, 977. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.85 (d, *J* = 7.2 Hz, 2H), 7.64 (t, *J* = 7.5 Hz, *J* = 7.8 Hz, 1H), 7.50 (m, *J* = 7.5 Hz, *J* = 7.8 Hz, 2H), 7.18–7.23 (m, 5H), 5.59 (dd, *J* = 3.9 Hz, *J* = 7.2 Hz, 1H), 5.34 (d, *J* = 3.9 Hz, 1H), 3.73 (d, *J* = 7.5 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 197.2, 135.8, 134.4, 134.2, 129.0, 128.9, 128.7, 128.6, 128.2, 76.9, 53.4. EI-MS *m/z*: 306 [M + 2], 304 [M^+], 224, 135. HRMS *m/z* calcd. for $C_{15}H_{13}O_2Br$ [M + Na]$^+$: 326.9991; found: 326.9995.

2b (15) (Obtained as a mixture 7:1 syn/anti isomers)

Yellow solid, yield 73%, mp 128–130. IR (KBr, cm^{-1}) ν: 3489, 1677, 1300, 860. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.87 (d, *J* = 9.0 Hz, 0.4H), 7.72 (d, *J* = 9.0 Hz, 2H), 7.63 (d, *J* = 9.0 Hz, 2H), 7.46 (d, *J* = 9.0 Hz, 0.4H), 7.38 (d, *J* = 9.0 Hz, 0.4H), 7.33 (m, 2H), 7.23 (m, 3H), 5.72 (d, *J* = 8.1 Hz, 0.16H), 5.53 (d, *J* = 3.6 Hz, 1.1H), 5.31 (d, *J* = 3.6 Hz, 0.98H), 5.15 (d, *J* = 8.1 Hz, 0.14H), 3.73 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 196.5, 135.8, 133.0, 132.2, 131.3, 130.1, 129.3, 128.4, 127.2, 77.6, 53.2. MS-EI *m/z*: 304 [M – HBr], 303 [M – Br], 305, 302, 215, 213.

2c (15) (Obtained as a mixture 6.7:1 syn/anti isomers)

Yellow solid, yield 70%, mp 98–101. IR (KBr, cm^{-1}) ν: 3510, 1680, 1270, 863. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.05 (t, *J* = 8.1 Hz, 0.17H), 7.89 (t, *J* = 8.1 Hz, 1.4H), 7.48 (t, *J* = 8.1 Hz, 0.6H), 7.46–7.15 (m, 7.7H), 6.87 (t, *J* = 8.1 Hz, 0.35H), 5.75 (d, *J* = 8.1 Hz, 0.15H), 5.53 (d, *J* = 4.2 Hz, 1H), 5.29 (d, *J* = 4.2 Hz, 1H), 5.20 (d, *J* = 8.1 Hz, 0.16H), 3.91 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 195.8, 167.9, 135.9, 131.4, 130.5, 128.7, 128.4, 127.2, 116.3, 76.3, 53.3. MS-EI *m/z*: 322 [M^+], 324 [M + 2], 306, 304, 169, 171, 153.

2e (15) (Obtained as a mixture 9.5:1 of syn/anti isomers)

Yellow solid, yield 76%, mp 88–91. IR (KBr, cm^{-1}) ν: 3480, 1658, 1266, 810. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.92 (d, *J* = 8.1 Hz, 0.2H), 7.87 (d, *J* = 8.1 Hz, 2H), 7.70 (d, *J* = 8.1 Hz, 0.12H), 7.61 (d, *J* = 8.1 Hz, 1H), 7.53 (d, *J* = 8.1 Hz, 0.2H), 7.50 (d, *J* = 8.1 Hz, 2H), 7.28 (d, *J* = 8.1 Hz, 2H), 7.20 (d, *J* = 8.1 Hz, 0.2), 7.13 (d, *J* = 8.1 Hz, 2H), 7.07 (d, *J* = 8.1 Hz, 0.2H), 6.08 (d, *J* = 4.2 Hz, 1H), 5.81 (d, *J* = 8.1 Hz, 0.11H), 5.54 (d, *J* = 8.1 Hz, 0.11H), 5.37 (d, *J* = 4.2 Hz, 1H), 4.11 (s, 1H), 2.35 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 197.5, 139.3, 133.7, 130.8, 129.2, 128.6, 128.3, 127.8, 127.0, 84.3, 74.2, 21.1. MS-EI *m/z*: 318 [M^+], 320 [M + 2], 239 [M – Br], 238 [M – HBr].

Syn-2f (15)

Yellow solid, yield 80%, mp 93–95. IR (KBr, cm^{-1}) ν: 3512, 1692, 1280, 836. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.84 (d, *J* = 7.5 Hz, 2H), 7.64 (t, *J* = 7.5 Hz, 1H), 7.45 (d, *J* = 7.5 Hz, 2H), 7.17 (m, 4H), 5.57 (d, *J* = 3.0 Hz, 1H), 5.30 (d, *J* = 3.0 Hz, 1H), 3.84 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 196.9, 134.7, 134.5, 134.4, 133.8, 129.9, 129.2, 128. 6, 128.4, 76.8, 52.1. MS-EI *m/z*: 338 [M^+], 340 [M + 2], 259 [M – Br], 258 [M – HBr], 261, 260.

2g (New compound obtained as a mixture 6.7:1 of syn/anti isomers)

Yellow solid, yield 76%, mp 140–142. IR (KBr, cm^{-1}) ν: 3510, 1688, 1276, 830. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.86 (d, *J* = 8.4 Hz, 0.6 H), 7.70 (dd, *J* = 8.4 Hz, *J* = 8.4 Hz, 4H), 7.37 (d, *J* = 8.4 Hz, 0.6H), 7.21 (dd, *J* = 8.4 Hz, *J* = 8.4 Hz, 4H), 5.49 (d, *J* = 3.9 Hz, 1H), 5.30 (d, *J* = 9.0 Hz, 0.16H), 5.22 (d, *J* = 3.9 Hz, 1H), 5.06 (d, *J* = 8.7 Hz, 0.15H), 3.70 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 196.3, 134.9, 134.4, 132.7, 132.5, 132.2, 130.4, 130.1, 128.5, 76.7, 51.9. MS-EI *m/z*: 337 [M – Br], 336 [M – HBr], 338, 339. HRMS *m/z* calcd. for $C_{15}H_{11}O_2ClBr_2$ [M + Na]$^+$: 440.8398; found: 440.8392.

2h (New compound obtained as a mixture 25:1 of syn/anti isomers)

Yellow solid, yield 85%, mp 88–90. IR (KBr, cm^{-1}) ν: 3515, 1684, 1286, 836. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 7.83 (d, *J* = 8.7 Hz, 2H), 7.17 (m, 3H), 6.98 (t, *J* = 8.7 Hz, 3H), 5.73 (d, *J* = 8.1 Hz, 0.06H), 5.50 (d, *J* = 3.6 Hz, 1H), 5.27 (d, *J* = 3.6 Hz, 1H), 5.11 (d, *J* = 8.1 Hz, 0.04H), 3.91 (s, 3H), 3.82 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 194.9, 164.6, 134.5, 131.0, 129.9, 128.8, 128.2, 126.5, 114.3, 76.2, 55.5, 52.5. MS-EI *m/z*: 289 [M – Br], 288 [M – HBr], 291, 290, 135. HRMS *m/z* calcd. for $C_{16}H_{15}O_3ClBr$ [M + Na]$^+$: 392.9868; found: 392.9862

2i (New compound obtained as a mixture 2.3:1 of syn/anti isomers)

Yellow solid, yield 51%, mp 112–115. IR (KBr, cm^{-1}) ν: 3530, 1705, 1355, 844. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.22 (d, *J* = 8.1 Hz, 1H), 8.04 (m, 2H), 7.86 (d, *J* = 7.8 Hz, 1H), 7.49 (m, 3H), 7.36 (d, *J* = 8.1 Hz, 1H), 5.61 (d, *J* = 4.2 Hz, 0.7H), 5.41 (d, *J* = 8.4 Hz, 0.3H), 5.26 (d, *J* = 4.2 Hz, 0.7H), 5.14 (d, *J* = 8.4 Hz, 0.3H), 3.89 (s, 1.38H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 197.2, 193.5, 148.2, 146.3, 144.7, 142.3, 134.5, 133.3, 133.1, 132.7, 128.4, 128.1, 127.5, 127.1, 119.4, 119.1, 76.3, 74.5, 55.2, 52.8. MS-EI *m/z*: 270 [M – Br], 269 [M – HBr], 165, 105. HRMS *m/z* calcd. for $C_{15}H_{12}O_4NBr$ [M + H]$^+$: 351.0111; found: 351.0115.

Evaluating and understanding the hydrothermal stability of alumina aerogel doped with yttrium oxide and used as a catalyst support for the thermo-catalytic cracking (TCC) process

Nabil Al-Yassir and Raymond Le Van Mao

Abstract: The current work presents results concerning the hydrothermal stability of yttria-doped alumina aerogel, which was prepared by the sol–gel method using a supercritical drying technique. The influence of atmospheric steam at 750 and 1000 °C on the rate of sintering of yttria-doped alumina aerogel with various yttria contents was investigated. BET N_2 adsorption measurements, X-ray diffraction, thermogravimetric analysis, FTIR of adsorbed pyridine, and ^{1}H and ^{27}Al MAS NMR were used for characterization of solid samples. It was found that the hydrothermal stability of yttria-doped alumina aerogel was greatly improved compared with alumina aerogel and conventional alumina. This was evident from the decrease in the loss of surface area and pore volume, and the minimization of structural transformations. These significant improvements were attributed to the combined effect of sol–gel method and the presence of yttrium ions. Yttria-doped alumina aerogel with various yttria loadings, when compared with undoped alumina aerogel, exhibited lower concentrations of surface –OH groups, higher amounts of bridged –OH groups, and lower degrees of crystallinity with smaller particle sizes. It was also observed that the thermal and hydrothermal stabilities of both yttria-impregnated alumina aerogel and conventional alumina were improved but to a much lower extent. These improvements were attributed to the presence of yttria, and subsequently the formation of surface yttrium aluminate. This structure was found to be more thermally stable than bare alumina owing to the presence of less surface defects and –OH groups. Therefore, it was concluded that to observe the most effective role of yttria, it is quite essential to incorporate it into the alumina structure via the sol–gel technique.

Key words: thermo-catalytic cracking (TCC), yttria-doped alumina aerogel, yttria-impregnated alumina, hydrothermal stability, surface –OH groups, Lewis sites.

Résumé : Dans ce travail, on présente les résultats qui ont été obtenus relativement à la stabilité hydrothermique d'un aérogel d'alumine dopé à l'yttria qui a été préparé par la méthode sol-gel combinée à la technique de séchage supercritique. On a étudié l'influence d'une atmosphère de vapeur à 750 et 1000 °C sur la vitesse d'effritement de l'aérogel d'alumine dopé avec des quantités variable d'yttria. On a fait appel à des mesures d'adsorption de l'azote, de diffraction des rayons X, d'analyse thermogravimétrique, d'infrarouge à transformée de Fourier de la pyridine adsorbée et des spectres RMN du ^{1}H et du ^{27}Al à l'angle magique de spin pour faire la caractérisation des échantillons solides. On a trouvé que la stabilité hydrothermique de l'aérogel d'alumine dopé à l'yttria est de beaucoup améliorée par rapport à un aérogel d'alumine ou à de l'alumine conventionnelle. Ce fait était évident sur la base de la diminution de la perte de l'aire de superficie et du volume des pores ainsi que sur la minimisation des transformations structurales. Ces améliorations significatives sont attribuées à l'effet combiné de la méthode sol-gel et de la présence d'ions yttrium. Lorsqu'on a comparé l'aérogel d'alumine non dopé avec l'aérogel d'alumine dopé avec des quantités variable d'yttria, on a constaté que ce dernier comporte des concentrations plus faibles de groupes hydroxyles en surface, des quantités plus élevées de groupements hydroxyles pontés et des degrés plus faibles de cristallinité avec des grosseurs de particules plus faibles. On a aussi observé que les stabilités thermiques et hydrothermiques de l'aérogel d'alumine imprégné d'yttrie et l'alumine conventionnelle sont aussi améliorées, mais à un degré beaucoup moindre. Ces améliorations sont attribuées à la présence d'yttrie et, par la suite, à la formation en surface d'aluminate d'yttrium. On a trouvé que cette structure est thermiquement plus stable que l'alumine nue en raison de la présence, en surface, de moins de défauts et de moins de groupes hydroxyles. On en conclut donc que si on veut observer le rôle le plus efficace de l'yttrie, il est essentiel de l'incorporer dans la structure de l'alumine par le biais de la technique sol-gel.

Introduction

Recently, there has been much interest in the production of light olefins (i.e., ethylene and propylene) from petroleum feedstocks. The market demand for ethylene and propylene in year 2000 was 89 and 51 million tons, respectively, and will increase (projection) by year 2010 to about 140 and 90 million tons, respectively (1). The increase is driven largely by the escalating demand for the production of polyethylene and polypropylene, which was estimated to be approximately 110 million tons of polyolefins in 2005 (70 million tons of polyethylene and 40 million tons of polypropylene) (2, 3). Several light olefin technologies have been developed and are currently used for the production of ethylene and propylene, including steam cracking (SC), conventional fluid catalytic cracking (FCC), ZSM-5 modified FCC, and deep catalytic cracking (DCC) (4–6). However, these current technologies cannot respond sufficiently to the rapidly growing demand for propylene, which is growing at much faster rate than ethylene, since propylene is only produced as a co-product of ethylene production (2, 3). In addition, the high-energy consumption and the increasingly stringent environmental regulations that require low green-house gas emissions are also putting a pressure on the main light olefin technology (SC) (3).

Thermo-catalytic cracking (TCC) of petroleum feedstocks for the production of light olefins has been developed in an attempt to overcome some of these challenges (7–15). This emerging technology is considered more advantageous than others, since it produces higher combined yields of ethylene and propylene, it requires lower energy consumption, and is a more environment-friendly process. In one of its several versions, the TCC process employs supported metal oxides catalysts (i.e., bi-oxide MoO_3/CeO_2), which operates at mild temperature (725–750 °C) and in the presence of steam. Therefore, it is important to evaluate the thermal and hydrothermal stability of the catalyst support, as well as its ability to promote a homogenous dispersion and distribution of active species and promoters at high temperature.

Conventional γ-alumina was found to have poor thermal and hydrothermal stability, and also to show a weak ability to homogenously disperse active species at high temperature (16–23). Thus, to overcome these setbacks, alumina doped with Y_2O_3 was prepared via solution sol–gel using supercritical drying technique (14, 15). The resulting yttria-doped alumina aerogel exhibited outstanding physico-chemical properties, when compared with conventional γ-alumina. It displayed high surface area and enhanced thermal stability (14). Furthermore, it was characterized by superior ability to homogenously disperse the active species and the promoters at quite high calcination temperature (15). The overall improvements were attributed to the sol–gel method and more significantly to the incorporation of Y_2O_3 into alumina aerogel structure (14, 15). In addition to these enhanced properties, the hydrothermal stability remains a significant property to examine. Steam is co-fed in the TCC process along with hydrocarbons to lower the partial pressure of hydrocarbons (i.e., minimize the condensation-side reaction rate), and partially removed carbonaceous (coke) deposits ($C + H_2O \rightarrow CO + H_2$) (4). However, steam could have a negative impact on the catalyst, particularly the alumina-based support. This is attributed to the fact that surface area loss and phase transition of alumina are greatly facilitated by the presence of steam (19–25). Johnson (19) has investigated the effect of steam on the rate of sintering of alumina and concluded, "The main role of steam is to maintain the surface concentration of hydroxyl groups leading to an increase in the rate of sintering." Therefore, in this present work, we attempt to analyze and evaluate in details the hydrothermal stability of yttria-doped alumina aerogel under the TCC and harsher conditions. In addition to that objective, we would like to examine another interesting feature. It was noted (14, 26, 27) that Y_2O_3 played a major role in improving the thermal stability of alumina aerogel. This was observed when yttria precursor was incorporated into the alumina aerogel structure via the sol–gel preparation (one-pot synthesis) (14, 26, 27). We would like to investigate whether yttria will exert a similar effect on the thermal and hydrothermal stability if it is added onto the alumina via the impregnation method. It is worth mentioning that the outcome of this work will be of great significance to other industrial applications that require the presence of steam at high temperature, such as methane steam reforming for hydrogen production (28).

To the best of our knowledge, no work has been reported yet on hydrothermal stability of yttria-doped alumina aerogel, and only scarce reports (29) are available on the role of yttria on the thermal stability of alumina, via impregnation. Therefore, to fulfill our objectives, conventional alumina (conv.alumina), undoped alumina aerogel, and a series of yttria-doped alumina aerogel and yttria-impregnated alumina (conventional alumina and alumina aerogel) with variable amounts of Y_2O_3 were prepared. They were thoroughly characterized by diverse techniques such as Brunauer–Emmett–Teller (BET) surface area, X-ray diffraction (XRD), thermo gravimetric analysis (TGA), Fourier transform infrared spectroscopy (FTIR) of adsorbed pyridine, and ^1H and ^{27}Al solid-state nuclear magnetic resonance (^1H and ^{27}Al MAS NMR).

Experimental

Materials

Yttria-doped alumina aerogel

The yttria-doped alumina aerogel was prepared by previously reported synthetic technique (14, 26, 27), using aluminum tri-*sec*-butoxide (Strem chemicals, 98%) and yttrium (III) nitrate hexahydrate (Strem chemicals, 99.9%) as precursors. Yttrium concentration was varied to have 5, 10, and 20 wt%. Y_2O_3/Al_2O_3 with different Y_2O_3 contents is noted as

© 2007 NRC Canada

xY_2O_3/Al_2O_3, where x is the Y_2O_3 content in wt%. The preparation procedures for undoped alumina aerogel noted in this text as alumina aerogel were similar to that of yttria-doped alumina aerogel, except no dopant was used.

Yttria-impregnated alumina (i.e., conventional alumina and undoped alumina aerogel)

The required amount of yttrium (III) nitrate hexahydrate was dissolved in distilled water and then impregnated onto alumina. After impregnation, samples were first left at 60 °C for 10 h for slow evaporation of water, dried overnight at 120 °C, and finally calcined in air at either 750, 1000, 1100, or 1200 °C for 6 h. Two different aluminas were used: conventional alumina and alumina aerogel. The conventional alumina (γ-form, fine powder) was available commercially from Strem Chemicals and noted as conv.alumina. Y_2O_3/alumina with different Y_2O_3 loadings are noted as xY_2O_3/alumina, where x is the Y_2O_3 content in wt%. Prior to impregnation, the supports were calcined at 750 °C for 6 h.

Extrudates

The extrudates of all prepared supports were obtained by extrusion with bentonite clay (Aldrich), (Spectrum products, 20 wt%). They were dried overnight at 120 °C and then activated in air at 750 or 1000 °C for 3 h, depending on the test conditions. These extrudates were prepared and used solely in the hydrothermal stability tests.

Characterization

The specific surface areas and pore volume of samples were determined by the BET method using nitrogen physisorption at 77 K. The measurements were carried out using Micromeretics ASAP 2000 apparatus. Samples were outgassed in a vacuum for 3 h at 220 °C before N_2 physisorption. Specific surface areas were calculated by a multipoint point according to the Brunauer–Emmett–Teller (BET) method. The S_{BET} surface area results were reproducible within ±3 m^2/g. Pore volume results were obtained according to the Barret–Joyner–Halenda (BJH) method from the adsorption data, and were reproducible within ±0.003 cm^3/g.

X-ray powder diffraction (XRD) was carried out on a Philips diffractometer equipped with a PW 1050/25 focusing goniometer, which has been automated with the VisX122D system from diffraction technologies. The Ni filtered Kα radiation of Cu was used ($\lambda_{K\alpha 1}$ = 1.54051 Å) and diffractometer was operated at 40 kV and 20 mA. The patterns were recorded in the step scanning mode from 5°–60° (2θ) at a detector angular speed of 0.3°/min with a step size of 0.05°. The XRD phases were identified with the help of JCPDS (Joint Committee on Powder Diffraction Standards) powder files (30).

Thermogravimetric and differential thermal analysis (TGA/DTA) was carried out using the Stanton Redcroft STA 1500 simultaneous thermal analyzer (PL Thermal Sciences). The samples were heated from ambient temperature to 750 °C under dry air flow (20 mL min^{-1}). The sample weights were ~10 mg, and the heating rate was 10 °C min^{-1}. The average uncertainty in the TGA results was determined to be ±0.9 wt% for the weight loss.

Fourier transform infrared spectra of adsorbed pyridine were recorded to elucidate the presence of Lewis acid sites. The transmission spectra were recorded in Nicolet FTIR spectrometer (Magna 500 model) in the region of 1400–1700 cm^{-1}, with resolution of 4 cm^{-1}. The samples in the form of a self-supporting thin wafer were obtained by compressing a uniform layer of powder (sample/KBr mixture ≈ 0.020 g). The thin wafer was then placed in a pyrex cell and outgassed under vacuum (10^{-2} mbar; 1 bar = 100 kPa) at 300 °C for 4 h. Then, pyridine adsorption was carried out at 100 °C for 2 h under vacuum. After the evacuation at 100 °C for 1 h, the spectra of adsorbed pyridine were recorded at ambient temperature. Pyridine (Aldrich) was stored on activated molecular sieves. The area under each Lewis IR band was calculated using the Omnic software after correcting the baseline.

^{27}Al magic-angle spinning nuclear magnetic resonance (MAS NMR) measurements were carried out in a Bruker NMR spectrometer model DSX-300 (magnetic field 7.04 T). ^{27}Al MAS NMR spectra were obtained at frequency of 78.23 MHz with a 20° pulse length of 2 μs and 1 s delay between pulses and a spectral range of 40–75 kHz. The samples were spun at 14 KHz in N_2 using 4 mm ZrO_2 rotors, and typically 540 FID were collected for each sample. The chemical shifts were measured relative to external Al $(OH_2)_6^{3+}$ standard with an accuracy of ±0.5 ppm.

^1H MAS NMR measurements were carried out in a Bruker NMR spectrometer model AV-600 (magnetic field 14.1 T). ^1H MAS NMR spectra were obtained at frequency of 600.14 MHz with a 90° pulse length of 1.7 μs and 5 s delay between pulses and a spectral range of 100 kHz. The samples were spun at 25 KHz in air using 2.5 mm ZrO_2 rotors, and typically 32 FIDs were collected for each sample. The chemical shifts were referenced TMS (0 ppm). Prior to analysis, samples were dehydrated by evacuation to a pressure below 5 μm Hg (1 mm Hg = 133.322 Pa) in a Micromeritics ASAP-2000 instrument (BET apparatus) at 300 °C overnight. The samples were then transferred in helium atmosphere to a moisture-free N_2 atmosphere glovebox and packed in sealed tubes. Then, they were transferred from sealed tubes and packed into ZrO_2 rotors.

Hydrothermal stability tests

Hydrothermal stability experiments were performed using a Lindbergh one-zone tubular furnace. About 1 g of sample extrudate was placed in a quartz tube (55 cm in length and 1.5 cm in diameter). They were heated at 750 and 1000 °C, respectively, for n h (n = 1–24 h) in the presence of steam (H_2O flow = 1.1 mL/h) at atmospheric pressure.

Results and discussion

Short review of pertaining information to the thermal and hydrothermal stability of alumina

A great number of studies have shown that the thermal and hydrothermal stability of transition alumina, currently used as catalyst supports for many reactions, is influenced by several factors (16–24). These factors include the presence of intrinsic cationic and anionic vacancies, and more significantly the surface –OH groups. Burtin et al. (17) stated that the mechanism by which alumina loses its surface

Note: No significant area loss was observed as a result of calcination in dry air.
[a]Number in parenthesis is the ratio of S_{BET} of sample exposed to wet air (in the presence of steam) to S_{BET} in dry air, at the same temperature.

area at high temperature is a direct result of an interaction between the intrinsic cationic vacancies and anionic vacancies. The latter is also formed by the dehydroxylation of surface –OH groups. The outcome of that reaction is the annihilation of these vacancies and subsequently the destruction of the spinel lattice and structural rearrangement of constituent ions. Johnson (19) suggested that the surface hydroxyl groups play a major role in alumina stability. In his proposed model, he stated that particle growth (sintering) occurs by successive elimination of water from two –OH groups residing on adjacent particles, close to an area of contact (19–22). These groups interact through lateral hydrogen bonding (19–22, 31). Subsequently, this will generate an Al–O–Al bond, which will bring more –OH groups into adjacency (condensation). A diffusive process is expected to follow condensations to form "necks" between particles. Finally, small particles will grow to larges ones accompanied by significant surface area loss (19). Whatever the case may be, it is quite evident that –OH groups play the foremost role in alumina sintering, and subsequently in the thermal and hydrothermal stability.

The presence of steam is expected to significantly participate in increasing the rate of sintering (19–25). This can be attributed to the main function of steam, which is to maintain the concentration of surface –OH groups that are mainly responsible for the nucleation and particle growth of transition alumina as described earlier. The ability of steam to rehydroxylate (rehydrate) the surface of alumina is enhanced by the presence of Lewis acid sites (coordinative unsaturated (cus) cations), which are formed as a result of the dehydroxylation (32–34). In the dehydroxylation process, oxygen ion is lost, and hence, oxygen vacancy should be created to maintain the electrical neutrality of the structure ($2{<}OH^-{>}^{+}_{2-} \rightarrow H_2O + {<}O^{2-}{>}^{0}_{2-} + {<}\ {>}^{2+}_{2-}$) (17). This will give rise to the coordinative unsaturated sites (Lewis sites). These sites will allow the interaction with water vapor via a two-step mechanism, which can be summarized as follow ($\square M^{n+1}O^{2-} + H_2O \rightarrow HO^-M^{n+-}OH$) ($\square$ indicates the vacancy or a coordinative unsaturation) (33–35). It involves a non-dissociative adsorption of water vapor on a Lewis acid sites that will essentially involve a transfer of electron density to a Lewis acid site (cus Al), followed by a dissociative chemisorption of water (33, 34). Therefore, to improve the hydrothermal stability, it is essential to have, to some extent, a low concentration of Lewis sites, which are mainly responsible for the rehydroxylation process. This can be achieved by reducing the degree of dehydroxylation process (removal of –OH groups) from the surface, which can be accomplished by reducing the number of hydroxyl groups that are responsible for the sintering process. It is worth mentioning that such reduction should not considerably diminish the acid–base properties or more significantly the ion-exchange properties of alumina. Moreover, the degree of dehydroxylation can be minimized by having higher number of bridged –OH groups (i.e., held by more than one bond) compared with the terminal ones (i.e., held by one bond) (31). The latter has been shown to be quite susceptible to sintering process (31). Furthermore, the contact between alumina particles should be minimized, since dehydroxylation is enhanced by close proximity of condensing particles (36). In addition, the utilization of strong and stable binder (i.e., bentonite) can also play a role in enhancing the hydrothermal stability. It is also vital to mention that the factors that influence the thermal stability should be also taken into consideration to improve the hydrothermal stability. This is due to the fact that hydrothermal stability is measured at high temperature. These factors include the presence of surface defects, degree of crystallinity (i.e., amorphous, crystalline, and so forth), and the crystallite sizes of crystalline materials (14). The presence of high number of surface defects and larger crystallites have shown to greatly enhance the sintering process (14).

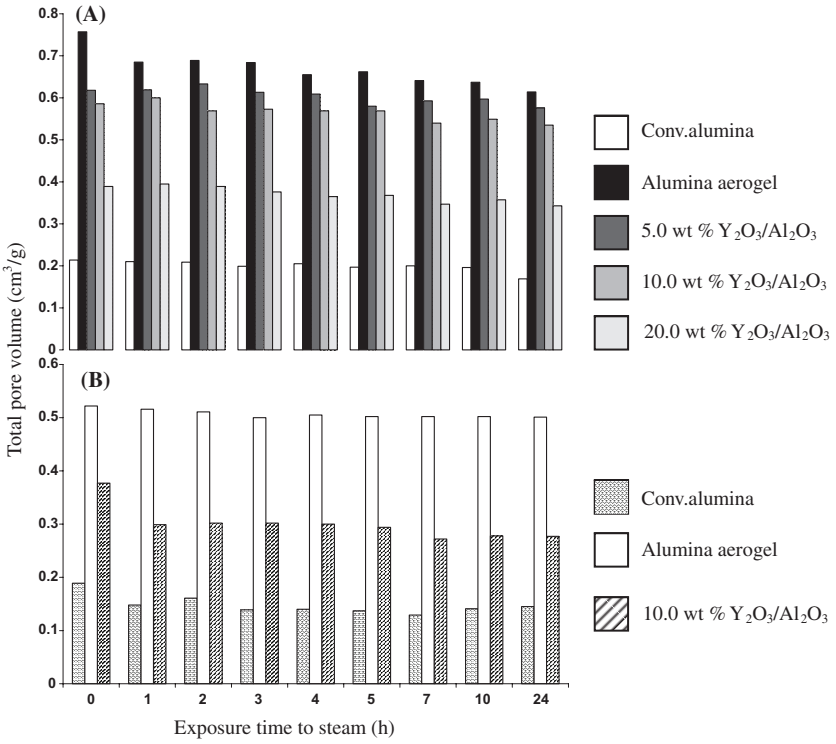
Hydrothermal stability of yttria-doped alumina aerogel

BET surface area, pore volume, and XRD patterns

The changes in BET specific surface area and pore volume of different catalyst supports, which were subjected to

© 2007 NRC Canada

Fig. 1. Loss of total pore volume of various samples as a function of different exposure times to steam at (A) 750 °C and (B) 1000 °C.



steam at 750 °C with different exposure time are shown in Table 1 and Fig. 1A, respectively. It can be seen that the rate of hydrothermal sintering of conv.alumina was greatly facilitated in the presence of steam at 750 °C, which has resulted in ~22% and 35% surface area loss when exposed for 1 h and 24 h, respectively (Table 1). Undoped alumina aerogel showed an improvement in the hydrothermal stability. The area loss of undoped alumina aerogel was ~18% and 26%, when exposed to steam for 1 h and 24 h, respectively (Table 1). On the contrary, the influence of steam becomes significantly less pronounced in yttria-doped alumina aerogel, and in fact it decreases as the amount of yttria increases from 5 to 10 wt%. For example, the area loss for 5 wt% yttria-doped alumina aerogel was ~5% and 15%, when exposed to steam for 1 h and 24 h, respectively (Table 1). Alumina aerogel doped with 10 wt% yttria showed more outstanding improvements in the hydrothermal stability. This was supported by the small loss in the surface area when compared with the other investigated supports (i.e., only ~1.6% and 10% area loss when subjected to steam for 1 h and 24 h, respectively (Table 1)). Although, alumina aerogel doped with 20 wt% yttria displayed a slightly higher surface area loss than 10 wt% yttria-doped alumina aerogel, it is still more hydrothermally stable than conv.alumina and alumina aerogel (Table 1). In addition, it was found that Bentonite (extrudate) is hydrothermally stable, as suggested by the low reduction of S_{BET} as function of exposure time to atmospheric steam (Table 1). It is worth mentioning that the changes in the total pore volume also followed the same pattern as the surface area loss (Fig. 1A). Furthermore, the XRD patterns of various investigated supports (extrudates) subjected to steam at 750 °C show that the diffraction peaks appeared to be quite the same when compared with the calcined extrudates (dry air only). The comparison between the XRD patterns of 10 wt% yttria-doped alumina aerogel extrudates that was subjected to dry air with those of the same treated with wet air leads to the same conclusion of unchanged structure. These results clearly suggest that the observed loss of surface area was due only to surface and textural transformations (i.e., condensation between hydroxyls on adjacent particles) and did not involve any structural transformation (i.e., formation of new phases such as δ, θ, or α).

It is worthwhile to note that the same pattern of improvements in the hydrothermal stability of yttria-doped alumina aerogel compared with alumina aerogel and conv.alumina was observed at 1000 °C (Table 2 and Fig. 1B). For example, the area loss of conv.alumina was ~28% and 37%, when exposed to steam for 1 h and 24 h, respectively (Table 2). Undoped alumina aerogel showed a significant improvement, as evidenced by the lower area loss, which was 22% and 32%, when exposed to steam for 1 h and 24 h, respectively (Table 2). As expected, alumina aerogel doped with 10 wt% yttria displayed much better hydrothermal stability compared with the other supports. The area loss, which was significantly lower than those observed with other studied supports, was ~9% and 14%, when exposed to steam for 1 h and 24 h, respectively (Table 2). Careful assessment of Fig. 1B, which displays the total pore volume loss of different supports as function of exposure time to steam at 1000 °C, displayed similar conclusion as surface area loss. It was also noted from the XRD patterns of different supports exposed to steam at 1000 °C (Figs. 2A–2C) that steam has provoked structural rearrangements to very small extent. On the other hand, it was quite clear that the structural rear-

rangements caused by steam were less prominent in yttria-doped alumina aerogel samples compared with other studied supports. For instance, the XRD patterns of conv.alumina extrudates that were subjected to steam at 1000 °C showed that the intensity of the reflections that are assigned to α–phase increases when subjected to steam. In addition, the XRD patterns of undoped alumina aerogel extrudates displayed that the intensity of the reflections that are assigned

to θ-phase increases when subjected to steam. Although, the reflections that are assigned to the θ-phase start to appear in the 10 wt% yttria-doped alumina aerogel extrudates, they were enormously weak and broad when compared with those observed with undoped alumina aerogel extrudates. The broadness of these reflections clearly indicates that the θ–phase is not well-crystalline.

Therefore, BET specific surface area, total pore volume, and XRD patterns results have shown that the hydrothermal stability of yttria-doped alumina aerogel was by far greatly improved compared with alumina aerogel and conv.alumina. The results of all investigated supports, which were exposed to steam at either 750 or 1000 °C, have unambiguously revealed that the loss of surface area and pore volume and structural transformation were greatly minimized according to the following order: yttria-doped alumina aerogel, followed by undoped alumina aerogel, followed by conv.alumina.

Sintering effects of high temperature and steam

It becomes evident that both the sol–gel preparation method and the incorporation of yttrium ions into the alumina aerogel structure play an important role in these improvements. Subsequently, these factors should have a direct effect on the number of Lewis acid sites (the main interaction sites of steam with the alumina surface at high temperature), which are influenced by the surface –OH groups (i.e., concentration and structure). Thus, evaluating the dehydroxylation pattern of surface hydroxyl groups and the Lewis acid sites are of paramount importance to elucidate the exact mechanism of hydrothermal stability.

Thermal gravimetric and differential analysis (TGA/DTA) and FTIR of adsorbed pyridine techniques were employed in this investigation to examine the dehydroxylation pattern and the Lewis sites of different supports, respectively. ^1H MAS NMR measurements were used to investigate the structure of surface –OH groups. It is worth mentioning that the TGA/DTA analysis was performed on samples calcined at 400 °C to be able to observe the dehydroxylation pattern, whereas the FTIR of adsorbed pyridine was carried out on samples that were calcined at 750 °C, which is the same temperature used to evaluate the hydrothermal stability. The TGA results obtained with conv.alumina, alumina aerogel, and yttria-doped alumina aerogel with different yttria loadings are shown in Table 3 (The TGA/DTA graphs are not shown here). The first weight loss in the range 25–250 °C, which was accompanied by an endothermic peak is primarily due to the removal of physisorbed water held on the surface by hydrogen bonding. This weight loss could be also due to the removal of water held in the small pores (Table 3). The second weight loss in the range of 300–750 °C (very broad endothermic peak) corresponded to the loss of water due to dehydroxylation of the surface. Thus, the approximate amounts of surface OH removed upon dehydroxylation by heating between 300–750 °C (N (OH) in mol/g of alumina) were determined by counting 2 mol of OH groups for 1 mol of water evolved. It is quite apparent from data of Table 3 that the dehydroxylation pattern was significantly influenced by the structure of the support. Conv.alumina displayed OH loss of about 0.28×10^{-2} mol/g, while the number for undoped alumina aerogel was much higher (0.98×10^{-2} mol/g). However, the OH loss for yttria-doped alumina aerogel was continuously decreasing as the amount of yttria-doped into alumina aerogel increased (Table 3). Therefore, it can be inferred from these results that undoped alumina aerogel had higher concentration of –OH groups, whereas the concentration of these removed groups decreased as the content of yttria-doped into alumina aerogel increased. It is worth mentioning that the noted weight loss in the region of 300–750 °C was a continuous mass loss. Thus, it could be suggested that the loss was not related to a multiple discrete –OH sites. In addition, the observed weight loss should be entirely due to the dehydroxylation, since the DTA curves did not show any exothermic peaks that can suggest a decomposition process for instance. The FTIR of pyridine adsorption technique was also employed to reveal the presence of Lewis acid sites. Figure 3 shows the presence of several IR bands, which are characteristics of different types of Lewis acid sites (35, 37, 38). The observed bands, which are more sensitive to aluminum coordination

and structural vacancies were 1595, 1610–1620, and 1625 cm^{-1} (37). The band observed at 1595 cm^{-1} is ascribed to Lewis coordinated to $_{VI}Al_{cus}$ ions ($[py–L]_o$) (37). The band observed at 1610–1620 cm^{-1} can be ascribed to pyridine Lewis coordinated by an $_{VI}Al–Al_{IV}$ cation pair ($[py–L]_{o,t}$) (37), or to vacancies hared by two Al^{3+} ions according to Busca's model [35]. The band observed at 1625 cm^{-1} is ascribed to pyridine Lewis coordinated to $_{IV}Al_{cus}$ ions ($[py–L]_t$) (37). The band observed at 1440–1450 cm^{-1} is also ascribed to Lewis sites (37). Figure 3 shows the FTIR spectra of pyridine adsorbed on conv.alumina, alumina aerogel, and yttria-doped alumina aerogel with different yttria loadings (all being calcined at 750 °C), and the approximate concentrations of different Lewis acid sites are reported in Table 3 (the extinction coefficients of these adsorbed pyridine peaks being assumed to be equal). It is clear from Fig. 3 and Table 3 that alumina aerogel has a higher number of Lewis sites when compared with conv.alumina, as suggested by the higher Lewis site band area. Furthermore, the number of these sites decreases as the amount of yttria-doped into alumina aerogel increases, when compared with undoped alumina aerogel. It is worth mentioning that the observed Lewis sites are not entirely due to the dehydroxylation of the surface. Some of these sites are believed to exist in the structure as intrinsic (17).

Although the alumina aerogel, when compared with the conv.alumina, showed a higher dehydroxylation rate, and consequently a higher number of Lewis sites, it did not (surprisingly at first) experience a higher rate of hydrothermal sintering. The main reason behind the slightly lower rate of sintering of the undoped alumina aerogel can be ascribed to the sol–gel method, which strongly influenced the degree of crystallinity of the resulting material, and the structure and concentration of surface –OH groups. In fact, this aerogel was characterized by a low degree of crystallinity with small particle sizes compared with conv.alumina, as suggested by XRD and TEM measurements carried out in our previous communication concerning the thermal stability of alumina (14). Therefore, it can be inferred from these results that the degree of crystallinity and particle size by minimizing the extent of hydrothermal sintering played a larger role than expected. The observed significant improvements in the hydrothermal stability of alumina aerogel upon the incorporation of yttria are ascribed to the combined effect of sol–gel method and the presence of yttrium ions. The utilization of such procedures has resulted in minimizing the effect of several factors that are believed to favor the hydrothermal sintering. First, the number of –OH groups, which are well-known to play the foremost role in the sintering, has been reduced upon the incorporation of yttrium ions into the lattice gel. The reduction can probably be ascribed to an exchange interaction mechanism (cross-condensation) between yttrium and hydroxyl groups of alumina aerogel (19). Data of Table 3 showed that the dehydroxylation rate, and subsequently the number of Lewis sites were reduced as the amount of yttria loadings increased. Second, yttria-doped alumina aerogel is expected to contain higher number of bridged –OH groups with respect to terminal ones. This can be attributed to the sol–gel method, which allows in general the formation of different types of –OH groups. These groups are the bridging groups between metal (M) centres (M–OH–M) and the terminal ones (M–OH). The structure of these groups depends to a large extent on the degree of hydrolysis reaction, which is in turn dependable on the ratio of water to alkoxide. In our current synthesis, the ratio of water to aluminium tri-*sec*-butoxide (aluminium precursor) was 2.5, which is very close to the required stoichiometric ratio of 3 (14). This has allowed an increase in the extent of hydrolysis reaction (close to completion), and consequently the formation of highly branched polymeric alumina aerogel instead of linear structure that would have been observed at lower ratio (i.e., 1:1 water/alkoxide) (39). The highly branched structure would certainly be characterized with higher number of bridged hydroxyl groups over terminal ones. The presence of bridged –OH groups plays a major role in minimizing the extent of sintering. For instance, hydroxyl groups that are held by more than one bond (i.e., bridged, such as $Al_o–OH–Al_o$, $Al_t–OH–Al_o$, $3Al_o–OH$, and $Al_t–OH–Y$ where Al_o and Al_t are octahedral and tetrahedral alumina, respectively) are thus in fixed positions, and therefore, their relative orientation of their O–H bonds and free orbitals is very unfavorable for H-bonding between two adjacent hydroxyl groups (31). On the other hand, hydroxyl groups that are held by only one bond (i.e., terminal, such as $Al_o–OH$ and $Al_t–OH$) can provide more favorable orientation for H-bonding, since they will have more degree of freedom (31). It is worth mentioning that ^1H MAS NMR measurements were in complete agreement with these expectations. FTIR spectroscopy can be also used for that purpose; however, poor resolution of the hydroxyl stretching bands in the region of 3200–4000 cm^{-1} often makes it quite difficult to determine whether any changes have actually occurred (i.e., appearance of new bands or modification of existing bands) (40, 41). The ^1H MAS NMR spectra of conv.alumina, undoped alumina aerogel, and yttria-doped alumina aerogel with different yttria loadings, all calcined at 750 °C are presented in Fig. 4. The ^{1} H MAS NMR spectra of all samples clearly suggest a wide distribution of surface hydroxyl groups of variable basic and acidic strength of different structures (i.e., terminal and bridged –OH groups). ^1H MAS NMR spectrum of conv.alumina (Fig. 4A) exhibits

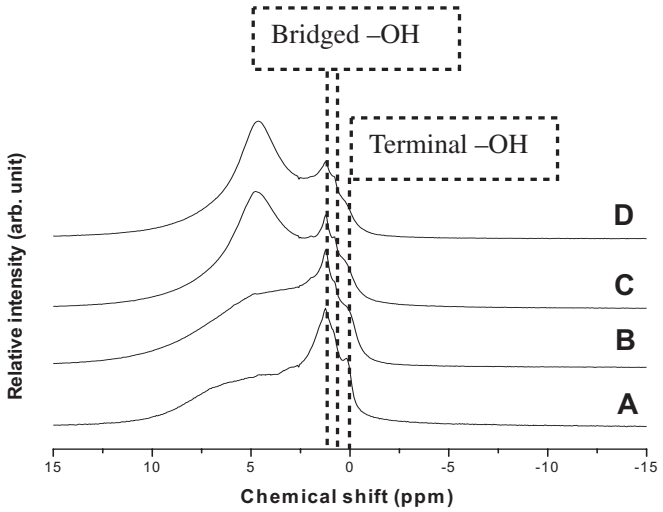
Fig. 4. ^{1}H MAS NMR of samples calcined at 750 °C for 3 h: (A) conv.alumina, (B) undoped alumina aerogel, (C) 10 Y_2O_3/Al_2O_3, and (D) 20 Y_2O_3/Al_2O_3.



several resonance lines at approximately –0.3 (shoulder), 0.2, 0.7, 1.3, and 1.9 (shoulder) ppm, which shows that there are five different OH groups present on the surface of alumina. This is in complete agreement with the Knözinger and Ratnasamy model that was developed for alumina surface (31). The peak at –0.3 ppm was previously attributed to the terminal basic OH groups attached to one aluminum atom in octahedral coordination (Al_o–OH) (31, 40–43). The peak at 0.2 ppm can be also attributed to (Al_o–OH) but with an intermediate basic character (31). The remaining peaks at 0.7, 1.3, and 1.9 ppm, with the peak at 1.3 ppm being the most intense line of these lines, are attributed to an overlap of more than one type of bridged –OH groups (i.e., Al_o–OH–Al_o, Al_t–OH–Al_o and $3Al_o$–OH, where Al_o and Al_t are octahedral and tetrahedral coordination, respectively) (31, 40–43). The low-field shift of these peaks indicates their acidic character. In addition, a very broad signal was found at 4.7 ppm and assigned to small amount of physisorbed and chemisorbed water on the alumina surface that probably occurred during transferring samples into the NMR holder (ZrO_2 rotor) (43). Figure 4B also indicates that undoped alumina aerogel has the same types of hydroxyl groups as conv.alumina. However, Fig. 4B showed that the peak that is normally assigned to terminal –OH groups (~–0.3 and 0.2 ppm) was less-resolved and broader when compared with the one observed with conv.alumina. This could suggest that undoped alumina aerogel contained lower number of terminal –OH groups than conv.alumina. Yttria-doped alumina aerogel with 10–20 wt% Y_2O_3 loadings (Figs. 4C–4D), when compared with undoped alumina aerogel, showed that the intensity of the peak that is attributed to bridged –OH groups decreased with increasing the amount of yttria-doped into the alumina aerogel. No significant changes were observed with respect to the terminal –OH peak. The reduction in the intensity, which may reflect that the population of alumina surface bridged –OH groups were decreased, can be attributed to an interaction mechanism between alumina aerogel hydroxyl groups and yttrium ions, as stated previously. It is very important to mention that the appearance of the very broad ~4.7 ppm peak (due to physisorbed water) could have serious implications on our ^{1}H MAS NMR results. For instance, it will be tricky to distinguish between the real –OH groups and those formed as a result of H-bonding. Therefore, our observed results should be analyzed with extra caution. Detailed and thorough investigation of the chemistry of surface –OH groups on alumina aerogel and yttria-doped alumina aerogel with various contents using ^{1}H MAS NMR, which should take into consideration the complete elimination of the ~5.5 ppm peak, will be carried out, and the results will be the subject of future publication. Third, yttria-doped alumina aerogel with various yttria loadings displayed a lower degree of crystallinity with smaller particle sizes, when compared with undoped alumina aerogel and conv.alumina, as suggested by XRD and TEM measurements (14). Fourth, it is worthwhile mentioning that the improvements in the hydrothermal stability of alumina aerogel upon the incorporation of yttria into the alumina structure can be also attributed in part to the fact that yttria forms fairly stable $Y(OH)_3$ on contact with water. This can be ascribed to the highly alkaline character of yttrium oxide. Fifth, the utilization of stable and strong binder (Bentonite (Table 1)) also played a small role in the improvements of the hydrothermal stability. This effect appeared to exist on all investigated supports.

Thermal and hydrothermal stability of yttria-impregnated alumina

The thermal stability of both conv.alumina and alumina aerogel was improved upon the addition of yttria via impregnation method, as suggested by XRD and BET specific-surface-area results. Clearly, there was a delay or retardation of sintering and phase transformation of γ-phase into θ-phase and α-phase upon the addition of yttria via impregnation method. Furthermore, it was observed that the extent of stabilization was higher for alumina aerogel than conv.alumina.

The X-ray diffraction patterns of yttria-impregnated conventional alumina, which was calcined for 6 h at 750, 1000, 1100, and 1200 °C, are shown in Fig. 5. Their XRD patterns results are summarized in Table 4. Conv.alumina being metastable is transformed into several phases with increasing temperature. The observed phase transformation of conv.alumina in the present investigation was $\gamma \rightarrow \theta \rightarrow \alpha$, which was in complete agreement with previous investigations (14). Conventional alumina that was calcined at 750 °C showed the presence of γ-phase, and at 1000 °C, this phase was transformed to both θ- and α-phase. Calcination at 1200 °C resulted solely in the formation of the α-phase (corundum). Y_2O_3/conv.alumina with different yttria loadings (5–20 wt%), which were calcined at 750 °C, showed the presence of γ-phase in samples containing 5–10 wt% Y_2O_3. However, yttria-impregnated alumina with 20 wt% Y_2O_3 showed clearly the presence of segregated bulk Y_2O_3 crystallites. Further calcination of yttria-impregnated alumina with yttria loadings of 5–10 wt% to 1000 °C did not result in any changes when compared with the same samples calcined at 750 °C. In particular, the XRD pattern of sample containing 20 wt% yttria showed the presence of bulk Y_2O_3 crystallites, along with traces of $YAlO_3$. The latter was probably formed as a result of solid-state reaction between yttria and alumina. It is quite clear that yttria-impregnated conv.alumina with yt-

Note: γ-Al_2O_3 (JCPDS No. 10-425), θ- Al_2O_3 (JCPDS No. 35-0121), α-Al_2O_3 (JCPDS No. 10-173), $YAlO_3$ (JCPDS No. 16-219 or 38–222), and Y_2O_3 (JCPDS No. 25-1200).

tria loadings up to 10 wt% did not show any diffraction peaks that could be attributed to either θ- or α-phase. This can be viewed as a clear indication of the improved thermal stability. However, further calcination of yttria-impregnated alumina (with yttria loadings up to 10 wt%) to 1100 °C showed, in addition to θ-phase, the presence of yttrium aluminate ($YAlO_3$) phase. The diffraction peaks of the latter were increased with increasing amount of yttria. It was also noted that yttria-impregnated alumina samples that were calcined at 1200 °C displayed clearly the presence of α-phase, along with $YAlO_3$, whose peaks were more pronounced with higher yttria loadings (10 wt%). The XRD pattern of 20 wt% yttria-impregnated alumina showed the presence of several reflections, which were attributed to bulk yttria and $YAlO_3$ crystallites, along with traces of α-phase. The X-ray diffraction patterns of Y_2O_3/alumina aerogel, which was calcined for 6 h at 750, 1000, 1100, and 1200 °C, are shown in Fig. 6 (also Table 4). Comparison between the XRD patterns of Y_2O_3/conv.alumina and Y_2O_3/alumina aerogel reveals that the thermal stability of alumina aerogel (which was already higher than that of conv.alumina (14)) was further improved upon incorporating yttria via impregnation. This was evident from the retardation of sintering and phase transformation of γ-alumina into θ-phase and α-phase. Furthermore, the formation of segregated yttria crystallites in yttria-impregnated alumina aerogel with 20 wt% yttria loading was significantly hindered when compared with conv.alumina. This can be attributed to the large surface area (14) and high number of –OH groups observed with undoped alumina aerogel. It is quite important to mention that the stabilization of conv.alumina and alumina aerogel upon incorporating yttria (5–10 wt%) via impregnation was noted to be no longer effective at temperatures higher than 1000 °C. This is due to nucleation of $YAlO_3$ structure at 1100 °C and due to the presence of $YAlO_3$ and α-phase at 1200 °C. Another important point to emphasize on is that the addition of 20 wt% yttria was not so effective in promoting thermal stabilization of alumina. This is due to the formation of segregated bulk yttria and yttrium aluminate crystallites. Table 5 also reports the changes in the BET specific surface area and total pore volume of yttria-impregnated alumina and alumina aerogel with various yttria loadings (5–20 wt% yttria) calcined at different temperatures for 6 h. It can be seen that yttria-impregnated alumina aerogel showed higher specific surface area when compared with its conv.alumina counterpart, irrespective of the calcination temperature (750 to 1100 °C) and the yttria loading (5–20 wt%). This can be mainly attributed to the higher specific surface area of alumina aerogel, which was ascribed to the supercritical (or hypercritical) drying of liquids contained in the gel (14). In addition, the N_2 adsorption results displayed in Table 5 are in complete agreement with the XRD measurements. First, the addition of yttria via impregnation onto either conv.alumina or alumina aerogel has resulted in significantly improved thermal stability, as suggested by the decrease in the sintering rate (smaller area loss). Second, the extent of the decrease was observed to be higher for yttria-doped alumina aerogel. It was also noted from Table 5 that 5 wt% yttria-impregnated conv.alumina or alumina aerogel that was calcined at 750–1100 °C displayed the higher S_{BET} area, when compared with the bare support or other yttria-loadings samples. The losses of specific surface area of yttria-impregnated conv.alumina and of alumina aerogel after 50 h of calcination at 750 and 1000 °C are presented in Fig. 7. Clearly, yttria-impregnated conv.alumina and alumina aerogel displayed higher thermal stability compared with the bare supports. This was observed irrespective of yttria loadings. In addition to that, it was demonstrated that the extent of thermal stability improvement upon the addition of yttria via impregnation was higher for alumina aerogel than for conv.alumina. For instance, yttria-impregnated conv.alumina with 5 wt% Y_2O_3 that was calcined at 1000 °C for 50 h suffered a loss of ~35% of its surface area, while alumina aerogel counterpart lost only ~18% of its surface area. The observed loss for undoped alumina aerogel was ~44%, whereas conv.alumina suffered ~69% loss upon calcination for 50 h at 1000 °C.

The change in BET specific surface area of 10 wt% yttria-impregnated conv.alumina or alumina aerogel, which were subjected to steaming at different temperatures with different exposure times are shown in Fig. 8 (the correlation factor (R^2) was obtained to evaluate the linearity of the noted changes, which in turns may reflect the extent of surface area loss). It was noted that the hydrothermal stability of conv.alumina and alumina aerogel were also improved as a result of adding yttria via impregnation. This was suggested

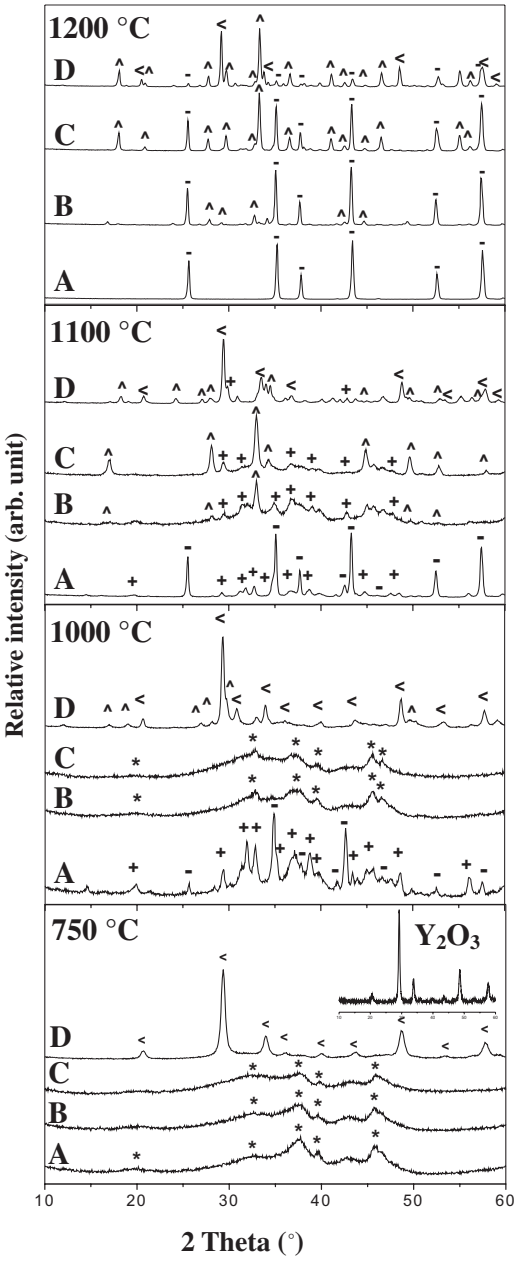

Fig. 6. XRD patterns of calcined samples at at different temperature: (A) alumina aerogel, (B) 5 wt% Y_2O_3/aerogel, (C) 10 wt% Y_2O_3/aerogel, and (D) 20 wt% Y_2O_3/aerogel. (Note: for symbols refer to Fig. 5).

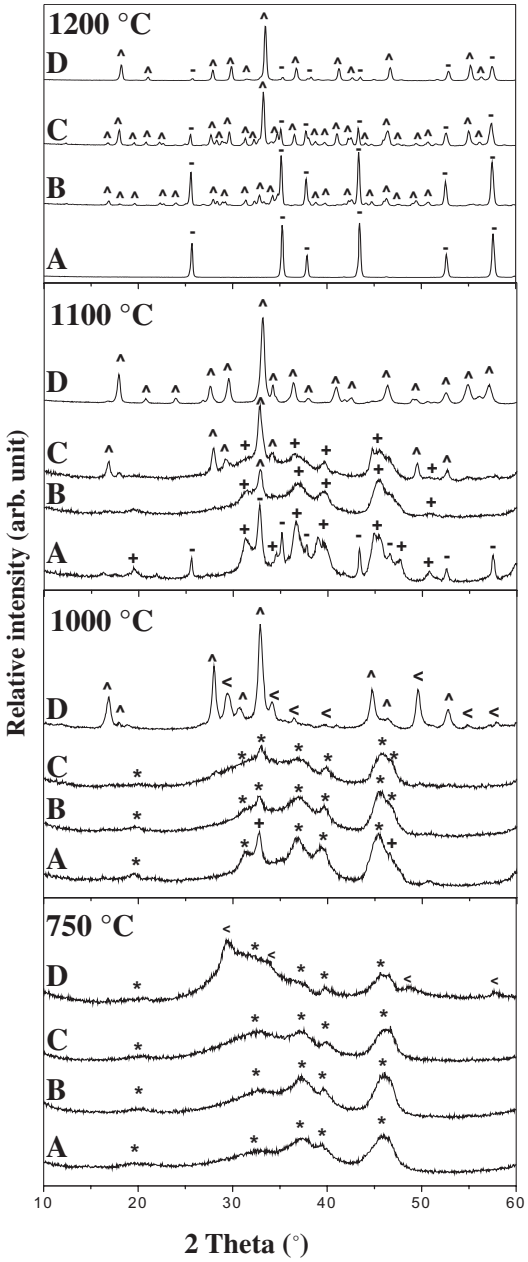

by the small loss in the surface area (Fig. 8A) and the minimization of structural transformations (XRD patterns not shown here), when compared with the bare support. For instance, the area loss for 10 wt% Y_2O_3/conv.alumina was ~6.5% and 14% when exposed to steam at 750 °C for 1 h and 24 h, respectively (Fig. 8A), while the corresponding area losses for conv.alumina were ~22% and 35%, respectively (Table1). On the other hand, the area loss for 10 wt% Y_2O_3/alumina aerogel was ~6.2% and 11% when exposed to steam at 750 °C for 1 h and 24 h, respectively (Fig. 8B), while these numbers for alumina aerogel were ~18% and 26%, respectively (Table 1). These results also suggested that the extent of hydrothermal stability was slightly higher for alumina aerogel than for conv.alumina upon yttria impregnation. It is worth mentioning that similar results were observed for 10 wt% yttria-impregnated conventional alumina or alumina aerogel, which were subjected to atmospheric steam at 1000 °C with different exposure times (Fig. 8B).

The improved thermal and hydrothermal stability of yttria-impregnated conventional alumina and alumina aerogel with yttria loadings of 5–10 wt% up to 1000 °C, when compared with the bare supports, can be attributed to the yttria. The loading of yttria via impregnation onto the

surface of alumina has resulted in decreasing or neutralizing the effect of cationic and anionic surface defects, and more importantly in reducing the number of –OH groups. The TGA and FTIR spectra of adsorbed pyridine clearly showed that the number of removed –OH groups (Table 3) and subsequently the number of Lewis sites (cus (surface defects)) (Fig. 3 and Table 3) were drastically reduced. The noted effect of yttria occurred most probably through the formation of dispersed yttrium aluminate structure, which is more thermally stable than alumina and whose presence has been confirmed indirectly by XRD patterns (i.e., bulk $YAlO_3$ crystallites were clearly detectable at $T > 1000$ °C). The higher extent of thermal and hydrothermal stability of alumina aerogel compared with conv.alumina, upon yttria impregnation, can be mainly attributed to alumina aerogel itself and in turn to the sol–gel method.

Comparison between yttria-doped alumina aerogel and yttria-impregnated alumina (conventional alumina and alumina aerogel)

Careful comparison between the properties of yttria-doped alumina aerogel and that of yttria-impregnated conv.alumina and alumina aerogel can lead to one explicit conclusion. The textural properties (i.e., surface area and dispersion) (14, 15) and thermal (14) and hydrothermal stability of alumina aerogel (current work) were significantly improved when yttria was incorporated via the sol–gel rather than the impregnation method. First, the surface area was noted to be much higher for alumina aerogel, even after incorporating the yttria. For instance, the S_{BET} of 10 wt% yttria-doped alumina aerogel was 319 m^2/g (14), which is 161 m^2/g higher than its impregnated alumina aerogel counterpart (158 m^2/g) (Table 5). Second, yttria-doped alumina aerogel was more ther-

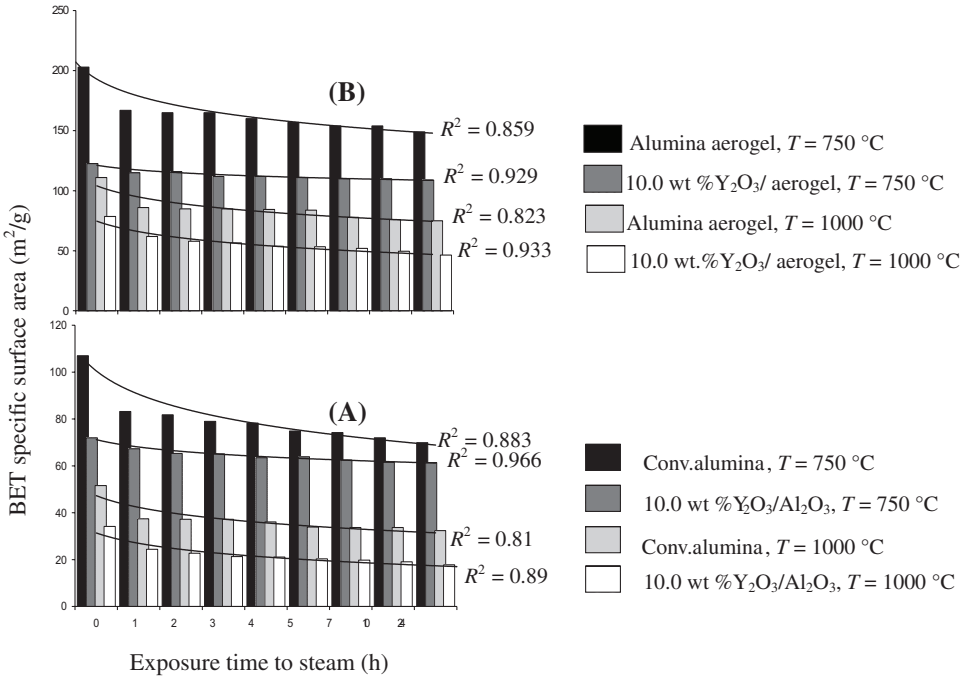
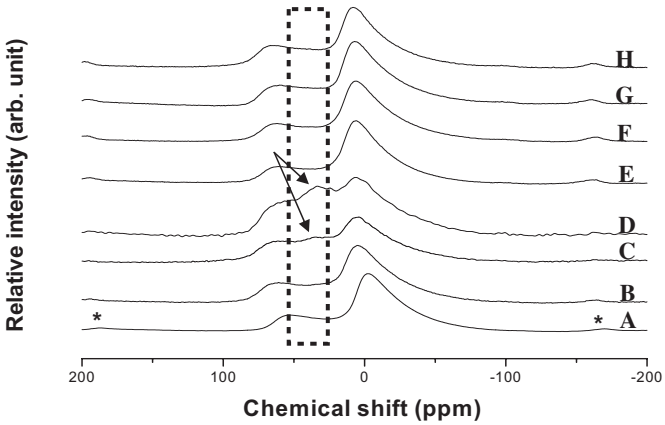
Fig. 8. Loss of BET specific surface area (S_{BET}) as a function of different exposure times to steam at different temperatures: (A) 10 wt% yttria-impregnated conventional alumina and (B) alumina aerogel, respectively.



mally stable (14) compared with yttria-impregnated alumina (conv.alumina and aerogel). This was suggested by the lower area loss and further delay in the phase transitions upon calcination at high temperature (Figs. 5 and 6; Tables 4 and 5) (14). In addition, it was concluded that yttria-doped alumina aerogel, impregnated aerogel, and impregnated conv.alumina are only thermally stable up to temperatures below 1100 °C. The instability at higher temperature is due to nucleation of bulk $YAlO_3$ crystallites. Third, the influence of steam at high temperature was less pronounced in yttria-doped alumina aerogel (Figs. 1 and 2; Tables 1 and 2), compared with yttria-impregnated alumina (Fig. 8). Fourth, it was possible to incorporate a high loading of yttria (20 wt%) into alumina aerogel without observing the oxide segregation phenomenon (14), which on the contrary occurred easily with the impregnated samples (Figs. 5 and 6). Fifth, although the incorporation of yttria into alumina aerogel via sol–gel or impregnation has led to a reduction in the number of –OH groups, it was apparent that the extent of such reduction was smaller for yttria-doped alumina aerogel (Table 3). All this has a practical consequence: the important properties of alumina such as the acid–base characteristics and the ability to disperse active species and promoters are significantly preserved. In fact, we have unambiguously found that the dispersion of mono-oxide MoO_3 and bi-oxide MoO_3/CeO_2 were significantly improved when impregnated onto alumina aerogel (15). We do anticipate that such dispersion will be enormously weakened if yttria-impregnated alumina was used as a catalyst support. The main reason behind these outstanding properties of yttria-doped alumina aerogel when compared with yttria-impregnated alumina can be attributed to the fact that yttria was allowed to be efficiently inserted into the alumina aerogel lattice (or network). On the contrary, the solubility of yttria in alumina lattice

Fig. 9. ^{27}Al MAS NMR of samples calcined at 750 °C for 6 h: (A) conv.alumina (15), (B) alumina aerogel (15), (C) and (D) 10 and 20 wt% yttria-doped alumina aerogel, respectively (15), (E) and (F) 10 and 20 wt% yttria-impregnated conv.alumina, respectively, and (G) and (H) 10 and 20 wt% yttria-impregnated alumina aerogel, respectively. *: Spinning side bands (SSB).



was quite limited in the case of impregnation method. This was clearly supported by the ^{27}Al MAS NMR study. The ^{27}Al MAS NMR of conv.alumina (14), alumina aerogel (14), 10 and 20 wt% yttria-doped alumina aerogel (14), and yttria-impregnated conv.alumina and alumina aerogel with various yttria loadings (current work) are shown in Figs. 9A–9H. The ^{27}Al MAS NMR spectra of yttria-impregnated conv.alumina or alumina aerogel with various yttria loadings (Fig. 9E–9H) reveal the presence of two peaks, at ~–3.0–7.0 ppm and another one at ~57–65 ppm. These peaks are assigned unambiguously to octahedral and tetrahedral coordinated aluminium, respectively (44, 45). No change can be

© 2007 NRC Canada

observed when comparing these spectra to those of the bare supports, which were performed during our previous study (Fig. 9A–9B) (14). On the contrary, these spectra are noticeably different from those of yttria-doped alumina aerogel, which were also carried out during our previous study (Fig. 9C–9D) (14). The peak at ~33.0 ppm, which was clearly observed in yttria-doped alumina aerogel and assigned to surface distorted Al_{tetra}–O–Y bond) (14), was absent in yttria-impregnated conv.alumina or alumina aerogel. Therefore, it can be inferred from these results that the incorporation of yttria via the sol–gel method provoked structural rearrangement of the aluminum coordination that played a major role in preventing the formation of segregated bulk Y_2O_3 crystallites, and hence decreasing the tendency of forming large $YAlO_3$ crystallites.

Conclusions

The results presented in this work reinforce our conclusion that yttria-doped alumina aerogel is an effective support for TCC process. It was found that the incorporation of Y_2O_3 into alumina aerogel structure via the sol–gel method has another significant beneficial role, besides improving the thermal stability (14) and the ability to homogenously disperse the active species and promoters at high calcination temperature (15). Yttria-doped alumina aerogel with various yttria loadings (5–20 wt%) was highly hydrothermally stable when compared with alumina aerogel and conv.alumina, as suggested by N_2 adsorption measurements, XRD, TGA, FTIR of adsorbed pyridine, and ^{1}H MAS NMR. We have also observed that the thermal and hydrothermal stability of both yttria-impregnated alumina aerogel and conv.alumina were improved but to a lower extent. These improved stabilities were attributed to the presence of yttria and subsequently the formation of surface yttrium aluminate. Therefore, it can be concluded that to observe the most efficient stabilizing effect of yttria, it is quite essential to incorporate it into the alumina structure via the sol–gel preparation technique.

Photochemistry of 1,1′-bi-2-naphthol (BINOL) — ESIPT is responsible for photoracemization and photocyclization

Mitchel Flegel, Matthew Lukeman, and Peter Wan

Abstract: The photochemistry of 1,1′-bi-2-naphthol (BINOL, **5**) has been studied in aqueous solution and found to undergo rapid deuterium incorporation at the 4 and 5 positions (in D_2O-CH_3CN). All data is consistent with exchange arising via a formal excited state intramolecular proton transfer (ESIPT) from the naphtholic OH to the 4 and 5 positions of the other ring to give quinine methides (QMs) **8** and **9**, respectively, both of which subsequently revert to starting material. Photolysis of enantiomerically pure (+)-**5** in D_2O-CH_3CN resulted in racemization concurrent with deuterium incorporation. This is strong evidence to indicate that photoracemization of BINOL is a direct result of ESIPT, in keeping with the invocation of planar QM intermediates. Prolonged irradiation also gave a ring-closed product that is assigned as dihydrobenzoxanthene **7**, based on NMR and UV–vis data, and in analogy to known reactions of similar biaryl systems initiated by ESIPT. The formation of **7** is believed to arise via initial ESIPT from the naphtholic OH to the 7 position of the other naphthol ring generating an *o*-quinone methide intermediate that subsequently undergoes exclusive electrocyclic ring closure to give **7**. The deuterium exchange and photocyclization reach maximum quantum efficiency at ~8 mol/L water (in CH_3CN). A "water relay" mechanism for ESIPT is proposed that is consistent with the need for water in the photochemical deuterium exchange, racemization, and formation of **7**. The photostability and photoracemization of other related BINOL asymmetric catalysts in water should be a concern based on the reported results herein.

Key words: BINOL, ESIPT, photoprotonation, photoracemization, photocyclization, quinone methide.

Résumé : On a étudié la photochimie du 1,1′-bi-2-naphtol (BINOL, **5**) en solution aqueuse et on a trouvé que, dans un mélange D_2O/CH_3CN, il se produit une incorporation rapide de deutérium dans les positions 4 et 5. Toutes les données sont en accord avec un mécanisme d'échange qui se produirait formellement par le biais d'un transfert de proton intramoléculaire dans l'état excité (TPIEE) des groupes OH du naphtol vers les positions 4 et 5 de l'autre noyau avec les formations respectivement des quinines de méthides (QM) **8** et **9** qui se retransforment subséquemment en produit de départ. La photolyse du (+)-**5** énantiomériquement pur dans un mélange de D_2O/CH_3CN conduit à une racémisation qui accompagne l'incorporation du deutérium. Il y a beaucoup d'indications qui suggèrent que la photoracémisation du BINOL résulte directement du TPIEE en raison du fait qu'on invoque la présence d'intermédiaires QM plans. Une irradiation prolongée conduit aussi à la formation d'un produit à cycle auquel on a attribué la structure dihydrobenzoxanthène **7** en se basant sur les données de RMN et de spectroscopie UV–vis et en faisant une analogie avec des réactions connues de systèmes biaryles semblables initiées par de TPIEE. On croit que la formation du produit **7** se fait par le biais d'un TPIEE initial du groupe OH du naphtol avec la position 7 de l'autre noyau de naphtol qui conduit à la formation d'un intermédiaire méthide de *o*-quinone qui subit ensuite une fermeture de cycle électrocyclique exclusive conduisant au produit **7**. L'échange de deutérium et la photocyclisation atteignent une efficacité quantique maximale à environ 8 M d'eau dans le CH_3CN. On propose l'intervention d'un relais aqueux pour le TPIEE qui est en accord avec la nécessité de la présence d'eau dans l'échange photochimique de deutérium, la racémisation et la formation du produit **7**. Sur la base des résultats rapportés ici, on devrait s'inquiéter de la photostabilité et de la photoracémisation d'autres catalyseurs asymétriques apparentés au BINOL dans l'eau.

Mots-clés : BINOL, transfert de proton intramoléculaire dans l'état excité (TPIEE), photoprotonation, photoracémisation, photocyclisation, méthide de quinone.

Introduction

Excited state intramolecular proton transfer (ESIPT) is a fundamentally important reaction that has been studied in considerable detail (1, 2). ESIPT arises when a molecule contains both acidic and basic functionalities, which upon electronic excitation experience simultaneous enhancement of both their acidity and basicity allowing for the transfer of a proton from the acidic group to the basic group. Almost all

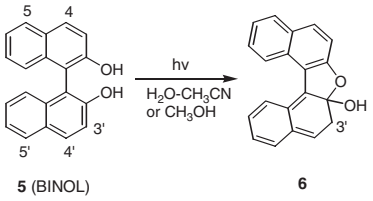
 doi:10.1139/V07-143 © 2008 NRC Canada

the known examples of ESIPT involve heteroatoms serving as the basic site with an OH or NH moiety serving as the acidic site, either as a substituent on or part of an aromatic ring system. ESIPT in these systems may be intrinsic or solvent-assisted, and are in general wholly reversible and in most cases are extremely fast, occurring on the subpicosecond time scale.

We recently reported the first examples of ESIPT from a phenol OH (or naphthol OH) to the carbons of an adjacent aromatic ring system, giving rise to *ortho* quinine methide (QM) intermediates (3). For example, photolysis of 1-(1′-naphthyl)-2-naphthol (**1**) in aqueous solution resulted in two modes of this new type of ESIPT (Scheme 1): (*i*) proton transfer from the phenol OH to the 2′ position, giving rise to the proposed *o*-QM **2**, which results in only deuterium incorporation at the 2′-position (observed when photolysis was carried out in D_2O-CH_3CN), and (*ii*) transfer to the more distal 7′ position, giving rise to the proposed *o*-QM **3**, which on (exclusive) electrocyclic ring closure gives the observed dihydropyran derivative **4**. Interestingly, these ESIPT reactions of **1** are observed only in the presence of water (maximal quantum efficiency in ~5 mol/L water), and no reaction was observed in dry CH_3CN. These observations suggest that these ESIPT processes for **1** are water-mediated.

Our current interest in the photochemistry of the title compound **5** (BINOL) stems naturally from our current investigations of the generality of the new type of ESIPT. BINOL and its derivatives have received considerable attention for their extensive use as ligands in stoichiometric and catalytic asymmetric reactions and in chiral recognition (4). Moreover, we note that an initial report by Cavazza et al. (5) on the photochemistry of **5** (in MeOH and aqueous CH_3CN) appeared some time ago in which compound **6** was reported to be isolated as the exclusive product using 334 nm argon ion laser excitation (Φ = 0.038) and as the most relevant product using traditional Hg lamp excitation (eq. [1]). In this same study, the authors also noted the photoracemization of **5**, although the mechanism for this process and its connection to formation of **6** was not made clear.

[1]



5 (BINOL) **6**

It was anticipated that a formal ESIPT process for **5**, from the naphthol OH to one or more aromatic carbon positions of the second naphthol moiety might lead to similar reactivity as observed for **1**, namely deuterium incorporation and (or) photocyclization. In this work, we show that the exclusive reaction pathways on photolysis of **5** in aqueous solution is water-mediated ESIPT from the 2-naphthol to the 4′, 5′, and 7′ positions of the other 2-naphthol ring. The QM arising from protonation at the 7 position undergoes exclusive cyclization to give a ring-closed product **7**. In addition, we show that the water-mediated ESIPT is directly correlated to the photoracemization of BINOL (**5**), an issue of some importance in the use of these types of materials in asymmetric catalysis and as fluorescent sensors in enantioselective recognition (6, 7), especially in aqueous systems. To our knowledge this is the first report of a photoracemization being the direct result of ESIPT.

Scheme 1.

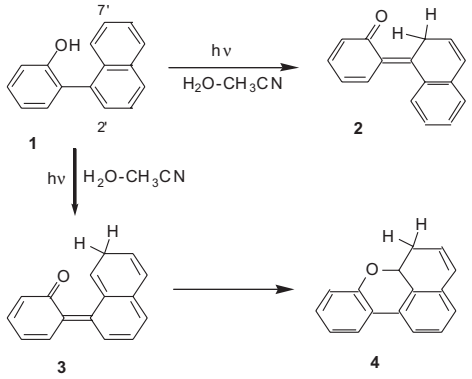


Fig. 1. UV–visible spectra showing the conversion of **5** to **7** with photolysis time. Traces were recorded every 10 s for a total of 140 s in a RPR 100 photoreactor fitted with 16 lamps (300 nm) (1:2 H_2O/CH_3CN, argon saturated). Spectral data for wavelengths longer than 250 nm are expanded in the inset. UV–vis changes are characterized by loss of absorbance at 225 nm and growth at 325 and 352 nm on photolysis.

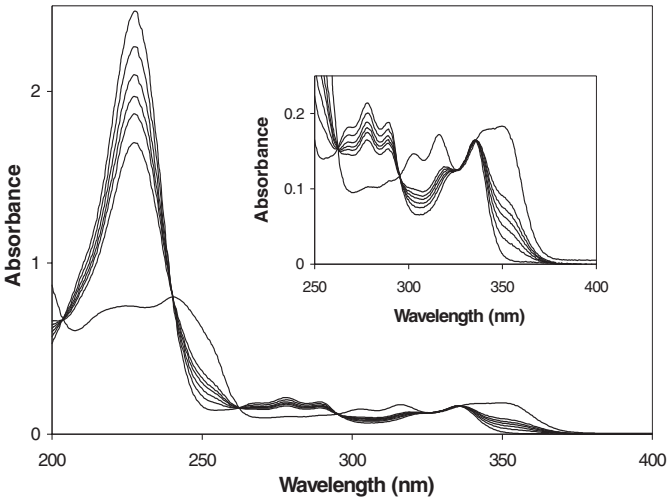

Results and discussion

Product studies and deuterium incorporation.

We first examined the photoreactivity of **5** by monitoring for changes in the UV–vis absorption spectra upon photolysis. Initial studies were carried out in 1:2 (*v*/*v*) H_2O/CH_3CN (~10^{-5} mol/L; argon saturated) in a Rayonet RPR 100 photochemical reactor (300 nm lamps). Traces were recorded at regular time intervals throughout the course of the irradiation and led to dramatic changes in the UV–vis spectrum (Fig. 1), indicating the photoreactivity of **5** under these conditions. The absorption maxima at 225, 276, and 334 nm, characteristic of **5**, were converted to new bands with maxima at 314 and 352 nm on photolysis. The spectra in Fig. 1 exhibit distinct isosbestic points, suggesting that

© 2008 NRC Canada

the photochemical reaction gives only one major photoproduct. The UV–vis spectra show a substantial decrease of the 225 nm naphthol absorption band intensity, suggesting loss of a naphthol ring system. The disappearance of the 225 nm band is accompanied by growth of a longer wavelength 352 nm band, indicating an increase of the conjugation in the molecule that would arise from rotation of the two naphthol rings towards planarity. Irradiation of **5** in anhyd. CH_3CN did not lead to any observable changes in the absorption spectrum, whereas photolysis in neat CH_3OH led to similar changes as observed for aq. CH_3CN, but much less efficiently, indicating that the reaction requires the mediation of a hydroxylic solvent. The photoproduct absorption bands reverted back to those of **5** when the temperature of the cuvette was raised to ~80 °C (<10 min). Photolysis of matched solutions of **5** in 1:2 H_2O/CH_3CN and 1:2 D_2O/CH_3CN (in UV cuvettes) gave a solvent deuterium isotope effect (Φ_H/Φ_D) of 1.3 ± 0.1 for formation of the 352 nm band assigned to the photoproduct. This is consistent with the requirement of a proton transfer step to form the more conjugated planar photoproduct. Although these initial observations are similar to those already reported (5), our results (vide infra) are entirely consistent with the operation of a new type (3) of water-mediated ESIPT reaction for **5**, a pathway that was not recognized by Cavazza et al. (5).

ESIPT pathways for **1** that did not give associated isolable products were implicated by irradiating in D_2O and analyzing the recovered starting material for deuterium exchange. To probe whether such processes can occur for **5**, irradiations were carried out as described above but with the H_2O portion replaced with D_2O. Irradiation of **5** in 1:3 D_2O/CH_3CN (~10^{-3} mol/L, λ_{ex} 300 nm, 1 h) yielded **5** (after H_2O wash) deuterated at the 4(4′) and 5(5′) positions (eq. [2], 96% and 56% exchange, respectively, by ^{1}H NMR). This method of analysis cannot differentiate between the extent of monodeuteration and dideuteration of the two positions. The reduction in the area of the NMR signal assigned to the 4(4′) and 5(5′) positions (δ 7.97 (d) and δ 7.88 (d), respectively) on photolysis is accompanied by formation of a singlet assigned to the neighbouring 3 position proton (δ 7.37 (d) and a broad doublet of the peak assigned to the 6 position proton (δ 7.36 (td)), as shown in Fig. 2. Analysis by ^{1}H NMR and ^{13}C NMR showed only deuterated **5** and no detectable side products upon photolysis. MS data confirmed the overall deuterium incorporation in **5** and significant amounts of M + 1 to M + 4 peaks were observed. No deuterium incorporation took place in the dark at ambient or at elevated temperatures up to 80 °C. This suggests that the deuterated photoproducts from the formal ESIPT in **5** most likely arise from the proposed *o*-QM intermediates **8** and **9** (eq. [2]). Therefore, formation of **5**–4(4′)D and **5**–5(5′)D most likely occur via tautomerization of **8** and **9**, respectively.

The dimethyl ether analogue **10** was studied in a similar manner as **5**. This derivative lacks an acidic proton and thus cannot undergo excited state proton transfer (ESPT) or ESIPT processes. Irradiation of **10** under the same conditions as **5** did not yield any photoproducts, and the recovered substrate did not show deuterium incorporation when D_2O was used as the co-solvent. Its lack of photoexchange is consistent with reaction in **5** resulting from a formal ESIPT pro-

Fig. 2. ^{1}H (500 MHz) NMR showing the spectrum (expanded aromatic region) of **5** before (top) and after (bottom) photolysis (300 nm, 1:3 D_2O/CH_3CN). NMR integration indicates 96% and 56% deuteration at the 4 and 5 positions, respectively.

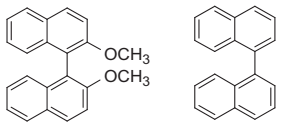
cess that requires an *o*-aryl-substituted naphthol (phenol) capable of undergoing ESIPT to the adjacent ring (3).



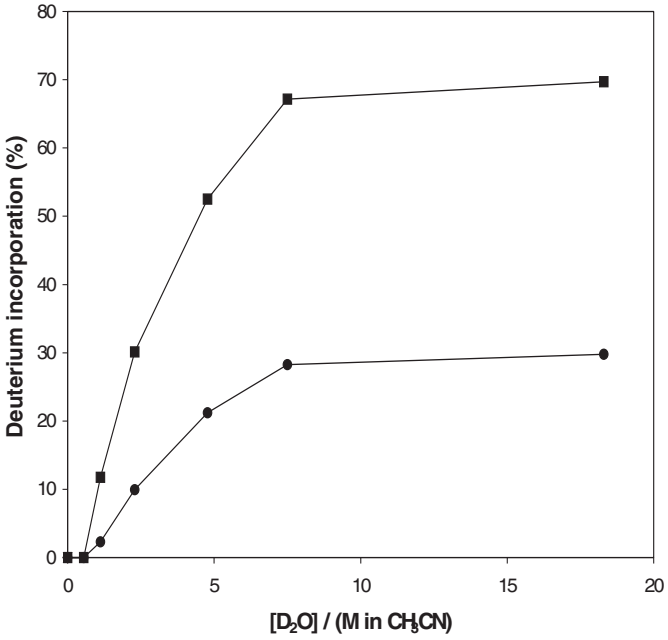
10 14

It is well known (8) that high water content is generally required for the efficient excited state proton transfer (ESPT) of phenols and other hydroxyarenes to water, while water-assisted ESIPT requires much less water for high quantum efficiency (2*g*, 3*b*). To explore the effect of water content on the proposed ESIPT of **5**, solutions containing varying amount of D_2O (in CH_3CN) were irradiated. The extent of exchange at the 4(4′) and 5(5′) positions was determined by ^1H NMR, and results are presented in Fig. 3. The efficiency of exchange (and hence formation of **8** and **9**) shows a strong dependence on water content with minimal reaction observed at low water concentrations. The yields of both 5–4(4′)D and 5–5(5′)D increased sharply as more D_2O was added to the solvent mixture, reaching a maximum at approximately 8 mol/L D_2O. Above 8 mol/L D_2O, the exchange efficiency becomes independent of water concentration as shown by the plateau in Fig. 3. No measurable deuterium incorporation occurred below 1 mol/L D_2O, and at all water concentrations the efficiency of exchange at the 5(5′)position was lower than that of the 4(4′) position.

Quantum yields of deuterium incorporation (Φ_{ex}) for **5** were measured using the deuterium exchange reaction of dibenzosuberene as a secondary reference standard. Dibenzosuberene is known to undergo deuterium exchange of the benzylic C-H hydrogens when irradiated in 1:4 D_2O/CH_3CN (Φ_{ex} = 0.021) (9). Φ_{ex} at the 4(4′) and 5(5′) positions of **5** (measured in 1:4 D_2O/CH_3CN) were 0.11 ± 0.01 and 0.040 ± 0.006, respectively. These values are similar to quantum efficiencies for deuterium exchange reported for **1** (3). The quantum yield for the actual protonation step should be higher than the measured quantum yield of exchange because the intermediate obtained from ESIPT can also lose deuterium to regenerate non-deuterated starting material.

Since the UV–vis traces (Fig. 1) give clear evidence of a reasonably stable photoproduct, attempts at its isolation were carried out. Prolonged irradiation of **5** in 1:3 H_2O/CH_3CN or MeOH (~10^{-3} mol/L, λ_{ex} = 300 nm, 15 h) resulted in the formation of a photoproduct that could be chromatographically isolated (30% ether in hexane, silica gel) in low quantum yield (Φ <0.01) as a mixture contaminated by about 20%–25% of starting material **5**. Indeed, heating this mixture or further treatment on silica gel gave higher proportions of **5**, indicating that this compound is thermally reverting back to **5**. Recent work from our group (3*b*) has shown that related naphthol biaryls such as **11** undergo an electrocyclic ring closure to yield the stable dihydroaromatic compound **12** in high quantum yield,

Fig. 3. Plot showing percent yield of **5**–4(4′)D (squares) and **5**–5(5′)D (circles) present in photolysate following irradiation of **5** in solvents of varying D_2O concentration (~10^{-3} mol/L, argon saturated, 300 nm lamps, 30 min) as measured by ^1H NMR.



initiated by an ESIPT process to the 7′ position of the naphthalene ring (eq. [3]). Thus, we anticipated an analogous ring-closed product on photolysis of **5** in water. In the present case, the extra OH group on the adjacent naphthalene ring might make an analogous photoproduct much less stable because of increasingly crowded steric interactions. Moreover, the initial report of the photochemistry **5** in aqueous solution by Cavazza et al. (5) claimed that the only significant (ring-closed) product that is formed is **6**, which has a hemi-acetal functionality and has lost the aromaticity of both rings in one naphthalene system. Compound **6** would also not be expected to be stable and should readily revert back to **5**. More importantly, formation of compound **6** (on photolysis in D_2O) would be expected to eventually lead to deuterium incorporation at position 3(3′) of **5** when **6** decomposes thermally. Under our experimental conditions, no deuterium incorporation at the 3 position of **5** could be detected, a finding which is at odds with the photoproduct claimed by Cavazza. Therefore, if compound **6** is formed at all under our conditions, it must be formed at an exceedingly low yield to not perturb the observed deuterium incorporations observed.

Since we were able to isolate a sample of the photoproduct generated in our studies (albeit not with 100% purity), we used NMR to determine its structure (see Supplementary Data).[2] Our NMR data (^1H, ^1H-^1H COSY, and NOESY) are wholly consistent with the assignment of the photoproduct to dihydrobenzoxanthene **7** (eq. [4]), which is completely analogous to the photoproducts observed for both **1** and **11**. This product, in analogy to **1** and **11**, is most

readily visualized as arising from a third QM **13**. The UV–vis spectrum of this compound is shown by the "final" trace in Fig. 1. The significant loss of naphthalene absorption at 225 nm and growth of the 352 nm absorption are consistent with structure **7**, since one naphthalene ring has lost aromaticity in one ring (loss of 225 nm absorption), and there is now better conjugation in the biaryl system (phenyl and naphthalene rings) because of the more planar structure (growth of the 352 nm absorption). We note that structure **6** would be expected to have an absorption band in the visible (which was not observed) since the structure has a naphthalene (base peak at about 315 nm) conjugated to four double bond units (each contributing about 30 nm in red-shift).

Photodeuteration and photoracemization

The photoracemization of a number of biaryl compounds, including BINOL derivatives, have been reported in the literature (5, 6, 10). The photoracemization of (–)-**5**, which has a rotational barrier of 158.3 kJ/mol in the ground state (11), was reported to occur upon irradiation at 334 nm in MeOH through a similar process that has been observed for other atropisomeric biaryl compounds (simple excited state planarization), although no direct evidence of this mechanism was reported (5, 10). In view of the extensive photodeuteration of **5** described earlier, we decided to examine the possible connection between ESIPT and photoracemization. A sample of (+)-**5** was irradiated in 2.8 mol/L D_2O/CH_3CN (~10^{-3} mol/L, λ_{ex} = 300 nm, 30–120 min), and aliquots were periodically removed. The optical rotation of each aliquot was measured, followed by evaporation of each sample and analysis by ^1H NMR. Since the racemization of **5** is expected to arise from the formation of the more planar *o*-QM intermediates **8**, **9**, and **13**, the total deuterium incorporation can be taken as a measure of the formation efficiency of these intermediates. Photolysis of (+)-**5** showed a significant decrease in the optical rotation and an increase in total deuterium incorporation with approximately the same time dependence (Fig. 4). Racemization was not observed in the dark (in aq. CH_3CN) or on photolysis in neat CH_3CN. The strong correlation between racemization and deuterium incorporation at the 4′ and 5′ positions strongly indicate that the racemization is a direct result of the ESIPT process.

Fluorescence measurements

In many of the systems (2*g*, 3) studied in our laboratory water is essential for reaction, acting as a bridge for the formal transfer of a phenol proton to a carbon site further away. The results obtained in the product studies for **5** indicate that

Fig. 4. Plot of optical rotation (circles) showing the racemization of **5** and total% deuterium incorporation at the 4 and 5 positions of **5** (squares) with photolysis time (~10^{-3} mol/L, argon saturated, 1:19 D_2O/ CH_3CN, 300 nm lamps). Points were recorded every 30 min.

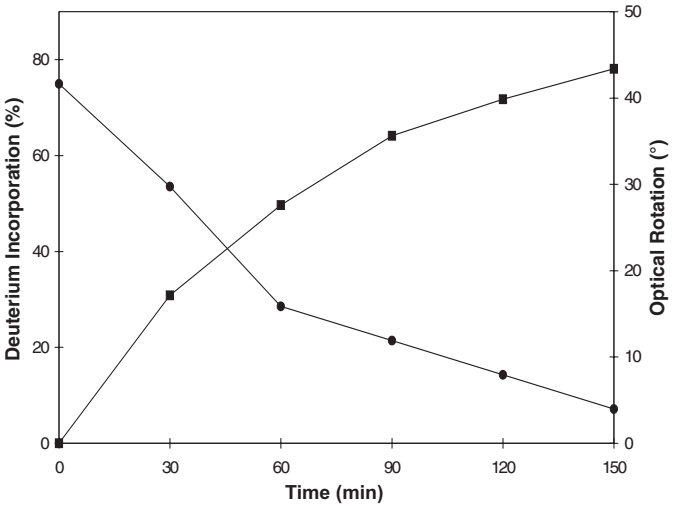

Fig. 5. Representative traces for **5** showing quenching of fluorescence emission (in CH_3CN) with added water (λ_{ex} = 300 nm). Concentrations are given in the figure.

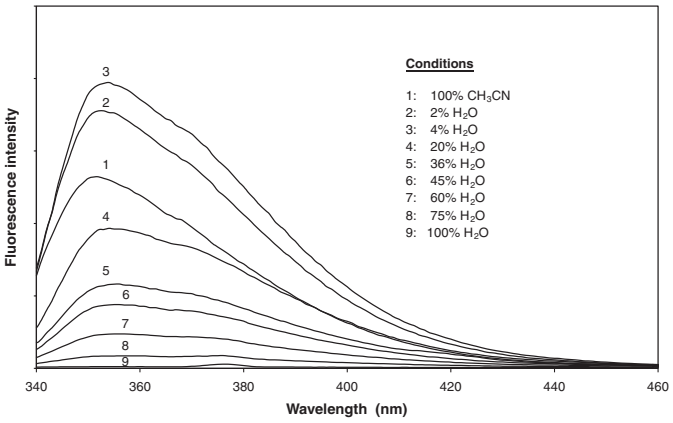
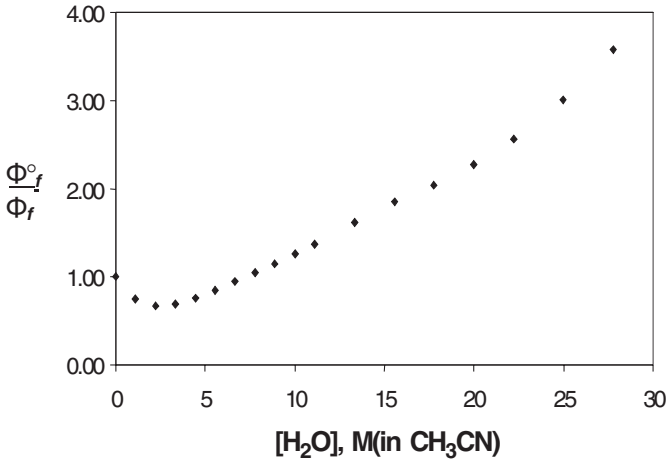


water is essential for formation of all QM intermediates. Fluorescence measurements should provide additional insights into the requirement of water on reactivity. Strong broad fluorescence emission was observed for **5** in neat CH_3CN (Fig. 5). The Stokes shift observed was much smaller than that observed for the parent 1,1′-binaphthyl (**14**). It has been shown for **14**, through Raman spectroscopy (12), that the equilibrium biaryl twist angle changes from 90° in the ground state to 69° in S_1. It is this twisting on excitation that is largely responsible for its sizable Stokes shift. The minimal Stokes shift observed for **5** suggests that little or no twisting takes place on excitation, presumably because of the additional steric crowding imparted by the two hydroxyl substituents (of the naphthols).

The addition of water (to CH_3CN) led to efficient quenching of the fluorescence emission above 2 mol/L H_2O (Fig. 5). A slight red shift in the λ_{max} is observed on addition of water

© 2008 NRC Canada

Fig. 6. Stern–Volmer plot of fluorescence emission quenching vs. water concentration (in CH_3CN) for **5**.



and is likely due to hydrogen bonding of the added water with the naphthol OH groups. The addition of up to ~2 mol/L water caused an increase in the emission, probably because of highly ordered solvent orientation. This is supported by the deuterium incorporation studies, where exchange was not observed below 1 mol/L H_2O content. Above 2 mol/L H_2O, the intensity of this band was progressively reduced because of the emergence of the ESIPT process. A Stern–Volmer plot of the quenching of the steady-state fluorescence by water is shown in Fig. 6. Addition of water led to the efficient quenching of the fluorescence emission above 2 mol/L H_2O content in a nonlinear fashion. Nonlinear fluorescence quenching by water has been previously shown for related phenols that can undergo water-mediated ESIPT processes and has been associated with the involvement of water clusters in the ESIPT process (2*g* and *h*). At water concentrations above 8 mol/L, there is significant deviation from linear behaviour. This deviation is indicative of a change in the mechanism of fluorescence quenching. It is important to note that the water concentration at which the deviation becomes pronounced (8 mol/L) coincides with the concentration of water at which the formation of **8** and **9** reached maximum efficiency, as described by product studies. On the basis of this correlation, we can assign the fluorescence quenching at concentrations between 1 mol/L and 8 mol/L H_2O as due to the increasing efficiency of the formal ESIPT reaction to give *o*-QMs **8**, **9**, and **13**, suggesting that the formation of QMs from **5** occurs from the S_1 state. The quenching of fluorescence at higher water concentrations is probably due to competitive formation of naphtholate $\mathbf{5}^-$ via ESPT to solvent (a known process for phenols at high water content). No new emission band was observed at high water content, indicating that $\mathbf{5}^-$, if formed, is not emissive.

Mechanism of deuterium incorporation, cyclization, and racemization

Our data and previous studies within our group (3, 13) are fully consistent with formation of *o*-QM intermediates **8**, **9**, and **13** on photolysis of **5** in aqueous CH_3CN or alcohol solutions. Singlet state reactivity is inferred from the fluorescence studies and is in accord with previous results of related systems (3, 13). It is informative to consider the changes in geometry that are required for these transformations. Chem 3D (MOPAC) minimized ground state structures are shown in Fig. 7 for **5**, **8**, and **9**. The two naphthol rings of the starting compound **5** are essentially orthogonal to each other, being able to rotate between 70° and 110° with an experimental ground state dihedral angle of 88° and an energy minimized dihedral angle of 95° (14). The distance between the naphtholic OH and carbon 4′ and 5′ positions on the other naphthol ring (positions of protonation) are 4.198 and 4.399 Å, respectively, which are too distant for simple direct proton transfer from the naphthol. Thus, similar to other previously reported systems, compound **5** does not react without the mediation of water (3*b*, 13). Moreover, reaction of **5** involves significant molecular distortions: (*i*) the original twisted biaryl rings must twist by about 90° such that it becomes coplanar and (*ii*) the naphthol ring puckers out of planarity as the 4′ and 5′ positions are protonated. The timing of these events is probably very fast (picosecond or faster time scale), and indeed our initial nanosecond laser flash photolysis (LFP) studies (~20 nanosecond time resolution) were only able to discern the "instantaneous" formations of three long-lived transients assignable to QMs **8** and **9** and the triplet state of **5**. QM **13** is not expected to be detectable owing to its low quantum yield of formation. These results agree with a number of other photoreactions of phenols in aqueous solutions reported by our group (2*h*, 2*g*, 3, 13, 15).

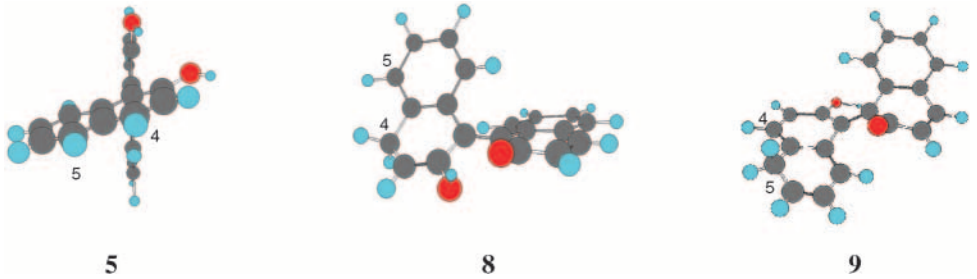
A provisional mechanism that is consistent with all experimental data for the observed photochemistry of **5** is presented in Scheme 2. On irradiation, a water-mediated ESIPT occurs from the S_1 state to give quinone methides **8**, **9**, and **13**. Both **8** and **9** return to **5** via enolization, while QM **13** is transformed to **7** via an electrocyclic ring closure. It is the formation of these more planar QM intermediates that is responsible for racemization.

For **5** to proceed to *o*-QMs **8** and **9**, the following must occur: (*i*) a formal proton transfer from the naphthol OH to the carbon atom at the 4′ and 5′ positions of the other naphthol ring, the latter resulting in the puckering of the naphthol ring and (*ii*) twisting about the biaryl bond to (or toward) planarity. These two events may be coupled (i.e., concerted) or stepwise. Fluorescence results indicate that in neat CH_3CN (a solvent that is unable to mediate the proton transfer and where there is no photochemistry), the excited state geometry remains highly twisted with essentially no Stokes shift. Charge transfer from one naphthol ring to the other in the excited state is thought to be the driving force for the ESIPT, but this cannot occur if the two rings remain in a perpendicular arrangement. The situation is altered when water (or alcohol) is present in the solvent mixture. Then, the formal ESIPT reaction proceeds readily, as determined by the product studies and fluorescence quenching results.

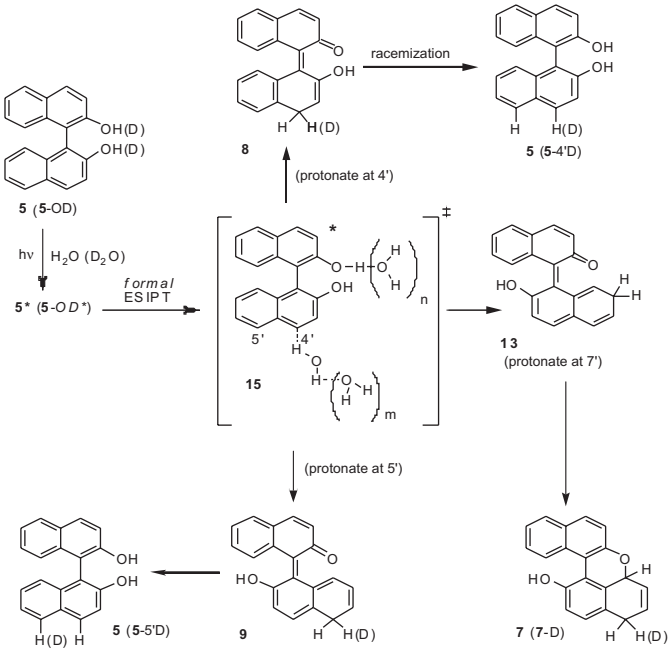
A simple pathway for the overall conversion is as follows. The added water mediates the ionization of the naphthol to give rise to the electronically excited naphtholate, which twists to a more planar form $\mathbf{5}^{-*}$. The planarization of these compounds has been shown to be possible in a stepwise fashion, where dissociation of the OH proton proceeds twisting (16). The more planar form can then protonate at either

© 2008 NRC Canada

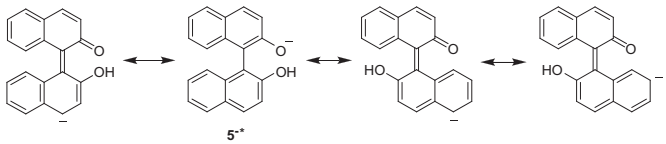
Fig. 7. Chem 3D (MOPAC) minimized ground state structures of substrate **5** and proposed QM intermediates **8** and **9**. The dihedral angle between the naphthol rings of **5** is about 95°. The distance between the naphthol OH and the naphthol 4 and 5 positions (sites of protonation) of **5** are 4.198 and 4.399 Å, respectively, which is too far for a simple direct proton transfer.



Scheme 2.



at either 4′, 5′, or 7′ position to give the *o*-QMs **8**, **9**, or **13**, respectively, depending on the direction that the biaryl system twists.



A more speculative mechanism for the efficient formation of **8** and **9** involves the concerted deprotonation of the naphthol with twisting motion of the naphthol ring coupled with proton transfer to either the carbon 4′ or 5′ position, mediated by water in a "water relay" mechanism as indicated in structure **15** (Scheme 2) (13). These intermediates can then undergo reverse proton transfer to generate **5**–4′D and **5**–5′D if the reaction is carried out in D_2O. No evidence of naphtholate formation was shown by fluorescence data (Fig. 5), which leads us to believe that the ESIPT mechanism is a concerted process. The racemization of (+)-**5** is also a direct result of proton exchange of the 4(4′) and 5(5′) positions. The high reactivity of biaryl naphthols is due to the tendency of the excited states of these species both to planarize and to become highly polarized.

The proposed mechanism for the formation of **7** is also outlined in Scheme 2. Much less efficient ESIPT to the 7′ position will generate QM **13**. This QM can then undergo electrocyclic ring closure to directly give **7** in a reaction that is entirely analogous to that already reported by us (3). We believe the electrocyclization to be strongly driven by the restoration of two aromatic rings. The photoproduct **7** is also thermally unstable to elevated temperatures due to the steric interaction between the alcohol and the naphthol ring and can decompose back to **5**. Similar instability was not seen in compound **12**, previously reported by our group (3*b*). No structures assignable to photoproduct **6** previously reported by Cavazza et al. (5) were observed under steady-state lamp photolysis.

The identification of a *formal* ESIPT process for **5** shows that the generality of ESIPT from phenol to aromatic ring carbons can be extended to 2-naphthols. The observation that only the derivative with the acidic naphthol OH group (**5** but not **10**) is reactive demonstrates the unique ability of naphthols to bring about the phototransformation of attached aromatic rings (via ESIPT). Of additional interest in this system is the apparently unique role of water in mediating the ESIPT reaction. While the ESIPT was also observed in CH_3OH, the highest efficiencies were observed when water was present in solution, presumably because of its superior ability to mediate the proton transfer. The use of chiral BINOL-type ligands is widespread in asymmetric chemistry, but the photoracemization reported herein should be a concern when these reactions are carried out in the presence of UV light (e.g., sunlight) in hydroxylic solvents.

Experimental section

General

^{1}H NMR spectra were recorded on Bruker AC300 (300 MHz) and Bruker 500 UltraShield (500 MHz) instruments. MS were recorded on a Kratos Concept H spectrometer using the LSIMS ionization method, using *m*-nitrobenzyl alcohol. UV–vis spectra were run on the Varian Cary 50 Bio instrument. Preparatory photolyses were carried out using a Rayonet RPR 100 photochemical reactor using 300 nm lamps.

© 2008 NRC Canada

Materials

Compounds (±)- and (+)-1,1′-bi-2-naphthol (**5**) (99%) were purchased from Sigma-Aldrich. 2,2′-Dimethoxy-1,1′-binaphthyl (**10**) (98%) was purchased from Acros. CH_3CN was dried over CaH_2 and distilled prior to use. Other solvents were spectral grade from Sigma-Aldrich and used as received.

UV–vis studies

Solutions (10^{-6}–10^{-5} mol/L) of **5** in the appropriate solvent system were prepared in 1.0 cm quartz cuvettes (3.0 mL) and deoxygenated by bubbling with a stream of argon gas (syringe needle) for 5 min and irradiated in a RPR 100 photochemical reactor containing 16 lamps (300 nm). A merry-go-round apparatus was employed if needed. Cooling was achieved with a fan. The irradiation was stopped at regular time intervals and UV–vis traces were recorded. Transfer time between the photoreactor and the spectrometer was approximately 5 s.

Product studies

Solutions (~10^{-3} mol/L) were prepared in a 100 mL quartz tube and purged with argon gas for 10 min prior to and continuously during irradiation in a RPR 100 photochemical reactor containing 16 lamps (300 nm). Cooling was achieved with an internal cold finger (~15 °C). To the photolysate was added 100 mL of H_2O, and the resulting mixture was extracted with CH_2Cl_2 and dried over $MgSO_4$; the solvent was removed under reduced pressure.

Photolysis of 5 in 1:3 D_2O/CH_3CN

A solution of 28 mg of **5** in 50 mL of 1:3 D_2O/CH_3CN was irradiated for 30 min (300 nm), and the photoproducts were analyzed by ^1H NMR, which showed deuterated starting material. The area of the peak corresponding to the 4 position of **5** (δ 7.97) was reduced by 70% and the area of the peak corresponding to the 5 position of **5** (δ 7.88) was reduced by 30%. This method of analysis cannot differentiate between the extent of mono- vs. di-deuteration of the above 4(4′) and 5(5′) positions. MS indicates extensive deuteration with noticeable M + 1 to M + 4 peaks. Runs at different D_2O concentrations were performed in the same way. Results from these runs appear in Fig. 3.

Prolonged irradiation of 5 in 1:9 H_2O/CH_3CN

A solution of 50 mg of **5** in 80 mL of 1:9 H_2O/CH_3CN was irradiated for 15 h (300 nm), and the photoproducts were analyzed by ^1H NMR, which showed a mixture of **5** and **7** in a 9:1 ratio. Attempts were made to isolated **7** in pure form but the best that could be achieved (silica, 3:7 ether/hexanes) was as a 4:1 ratio of **7/5** (see Supplementary Data).[2] The peaks assigned to **7** are listed as follows: ^1H NMR (500 MHz, $CDCl_3$) δ: 3.45–3.48 (m, 2H, H-3), 4.99 (broad s, exchangeable in D_2O, OH), 5.08–5.11 (m, 1H, H-6), 6.25–6.33 (m, 2H, H-4 and H-5), 7.04 (d, 1H, J = 8.5 Hz, H-1), 7.22 (d, 1H, J = 8.5 Hz, H-2), 7.36 (d, 1H, J = 8.5 Hz, H-7), 7.44 (ddd, 1H, J = 7.5 Hz, 7.0 Hz, 1.0 Hz, H-10), 7.60 (ddd, 1H, J = 7.7 Hz, 7.0 Hz, 1.5 Hz, H-11), 7.81 (d, 1H, J = 9.0 Hz, H-8), 7.84 (d, 1H, J = 8.5 Hz, H-12), 7.90 (d, 1H, J = 8.0 Hz, H-9). MS (m/z), 286 (M^+).

Racemization of (+)-5 in 1:19 D_2O/CH_3CN.

A solution of 200 mg of (+)-**5** in 1:19 D_2O/CH_3CN was irradiated in 30 min intervals (300 nm). In each interval, 10 mL of solution was removed from the photolysis and diluted with 10 mL of CH_3CN. The diluted solution was then placed in a 1 dm polarimetry cell, and the optical rotation was recorded. Following the measurement, the solution was evaporated to dryness and the ^1H NMR was recorded in $CDCl_3$ to follow the deuterium incorporation. A second experiment was done without the presence of D_2O. Racemization was not apparent in 100% CH_3CN.

Quantum yield of deuterium incorporation

A solution of 20 mg of suberene in 1:4 D_2O/CH_3CN was irradiated for 30 min (254 nm), and the photoproduct was analyzed by ^1H NMR, which showed 19% deuterium incorporation. A solution of 20 mg of **5** in 1:4 D_2O/CH_3CN was irradiated for 5 min (254 nm), and the photoproduct was analyzed by ^1H NMR, which showed 22% deuterium incorporation at the 4 position and 9% at the 5 position. This method was repeated twice to give a quantum yield (Φ_{ex}) of 0.11 ± 0.01 and 0.040 ± 0.006 at the 4 and 5 positions, respectively.

Steady-state and time-resolved fluorescence measurements

All solutions (OD ≈ 0.1 at excitation wavelength) were purged with argon for 5 min before analysis. Steady-state fluorescence spectra were obtained using a Photon Technology International A-1010 (PTI) Quanta-Master luminescence spectrometer.

Ground State geometry optimizations

The MOPAC module from the CambridgeSoft Chem 3D (pro version 5.0) was used for all geometry optimizations. Structures were drawn in ChemDraw 5.0 and imported into MOPAC before optimization. The AM1 method (closed shell, restricted) was used throughout.

Novel chiral fluorescent chemosensors for malate and acidic amino acids based on two-arm thiourea and amide

Xiao-Huan Huang, Yong-Bing He, Zhi-Hong Chen, Chen-Guang Hu, and Guang-Yan Qing

Abstract: The charge neutral anthracene based chiral fluorescent receptors **4a** and **4b** containing thiourea and amide groups were synthesized by simple steps in good yields, and their enantioselective recognition for chiral dicarboxylic anions (L/D-malate, L/D-aspartate, and L/D-glutamate) were examined by UV–vis, fluorescence, and ^{1}H NMR spectroscopy. The sensor **4a** exhibited an excellent enantioselective recognition ability towards malate (K_{ass} (L)/K_{ass} (D) = 9.65).

Key words: enantioselective recognition, chiral chemosensor, fluorescence, malate.

Résumé : Faisant appel à une méthode n'impliquant que des étapes simples, on a effectué avec de bons rendements la synthèse des récepteurs fluorescents chiraux liés à des anthracènes électriquement neutres, **4a** et **4b**, qui contiennent des groupes amide et thiourée; faisant appel à la spectroscopie UV-visible, à la spectroscopie de fluorescence et à la spectroscopie RMN du ^{1}H, on a aussi évalué leur habilité à reconnaître d'une façon énantiosélective les anions dicarboxyliques chiraux (L/D-malate; L/D-aspartate et L/D-glutamate). Le senseur **4a** possède une excellente habilité à reconnaître d'une façon énantiosélective le malate (K_{ass} (L)/K_{ass} (D) = 9,65).

Mots–clés : reconnaissance énantiosélective, senseur chimique chiral, fluorescence, malate.

[Traduit par la Rédaction]

Introduction

The development of molecule-based enantioselective fluorescence receptors is receiving growing research attention because such receptors can potentially provide a real time technique to determine the enantiomeric composition of chiral molecules and contribute to the understanding of biochemical systems, offering new perspectives for the development of pharmaceuticals, enantioselective sensors, and other molecular devices (1). The molecular recognition of biologically important anions by simple synthetic receptors is a hot topic in the field of supramolecular chemistry. Despite the fact that several elegant examples of chiral anion receptors have been reported over the years, these often involve the synthesis of complex and challenging organic hosts from scaffolds such as cholic acid (2*a*, 2*b*), calixarenes (2*c*), binaphthyls (2*d*), cyclodextrins (2*e*), but the use of anthracene based electroneutral chiral anion receptors has been less investigated (3).

The sensing and monitoring of dicarboxylates is of great interest in areas of bioanalytical and biomedical research (4). Thiourea and amide moieties have become the focus of the development of neutral anion receptors, because the hydrogen binding of these functional groups is directional in character, resulting in relatively strong complexes with various dicarboxylate anions (5). Gunnlaugsson et al. (6) have developed a series of anthracene based receptors for dicarboxylic acids and pyrophosphate, but the sensors for the enantioselective recognition of chiral dicarboxylates are still rare.

To our best knowledge, some receptors have been reported to bind and recognize the malate enantiomers. In our previous work, two sensors based on calix[4]arenes have been reported (7*a*), which showed good enantioselectivity for malate, but the structure is complex. Gonzalez-Alvarez et al. (7*b*) synthesized a water-soluble receptor for malate, but it does not exhibit a fluorescence response. Herein, we report two chiral fluorescent receptors **4a** and **4b** bearing anthracene, amino acid, and thiourea units, which were synthesized by simple steps and in good yields. Their enantioselective recognition of malate and acidic amino acids were studied by fluorescence emission, UV–vis, and ^{1}H NMR spectra.

Results and discussion

The synthesis of chiral fluorescent receptors **4a** and **4b** is outlined in Scheme 1. 9,10-Bis (aminomethyl)anthracene was prepared following the published procedure in ref. 6*a*. The intermediate **2** was obtained by the reaction of **1** and *N*-Boc-L-alanine in the presence of CDI, which was treated with trifluoroacetic acid to obtain compound **3**. Receptors **4a** and **4b** were synthesized by the reaction of *p*-nitrophenylisothiocyanate or *p*-tolylisothiocyanate and **3** in

high yields. All of these compounds were characterized by IR, ^{1}H NMR, ^{13}C NMR, MS, and elemental analysis.

Fluorescence and UV–vis spectra study

The chiral recognition properties of receptors **4a** and **4b** were investigated for the enantiomers of malate, aspartate, and glutamate (Scheme 2). The fluorescence and UV–vis spectra were recorded from a solution of receptors **4a** and **4b** (5.0×10^{-5} mol/L) in DMSO in the absence or presence of various anions, and in each case the counter cations were tetrabutylammonium.

Figures 1*a* and 1*b* show the fluorescence emission and UV–vis spectra of **4a** with different concentrations of L-malate in DMSO. When gradually increasing the concentration of the anions, the fluorescence emission intensities of **4a** (5.0×10^{-5} mol/L) at 429 nm (λ_{ex} = 372 nm) decreased, while it gradually enhanced at 538 nm. A discernible isoemissive point was observed at 510 nm (8). It was particularly noteworthy that adding a small amount of L-malate (0.5 equiv.) made the color of solution of receptor **4a** change from light yellow to orange-red, which could be easily observed by the naked eye. When the receptor bound anions, hydrogen bonds were constructed to form stable complexes, and the electron density in the supramolecular system was increased to enhance the charge-transfer interactions between the electron-rich donor nitrogen of the thiourea units and electron-deficient *p*-nitrophenyl moieties, which resulted in a visible color change (9). As shown in Fig. 1*a*, the introduction of L-malate to the solution of receptor **4a** resulted in

Scheme 2. Structures of the chiral dicarboxylates.

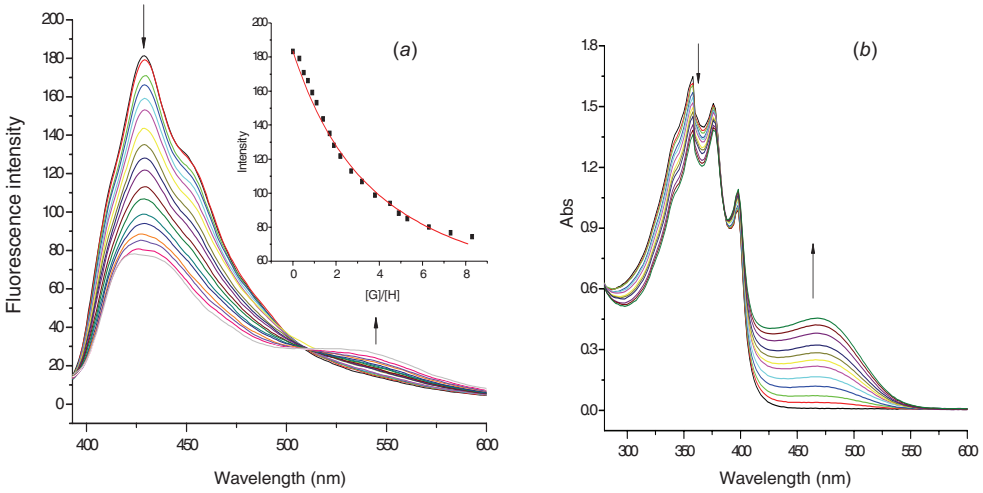
Fig. 2. (*a*) Fluorescence spectra of receptor **4a** (5×10^{-5} mol/L) with D-malate anion in DMSO. Anion equiv. 0→8.3. λ_{ex} = 372 nm. Inset: changes of fluorescence intensity of **4a** at 429 nm upon addition of L-malate anion. The line is a fitted curve. The correlation coefficient (*R*) of nonlinear curve fitting is 0.9941. (*b*) UV–vis absorption spectra of **4a** (5×10^{-5} mol/L) upon the addition of various amounts of D-malate in DMSO. Anion equiv. 0→9.5.



quenching of the locally excited emission at 429 nm, while enhancing the emission at 538 nm; the dual fluorescence peaks at 429 and 538 nm may be due to the locally excited (LE) state and charge transfer (CT) state in equilibrium, respectively (10). As shown in the inset of Fig. 1*a*, the satisfactory nonlinear fitting curve verified the formation of a 1:1 complex between **4a** and L-malate.

Figure 1*b* shows the UV–vis spectra of **4a** with different concentrations of L-malate in DMSO. On gradual increase of the concentration of L-malate, the intensity of the absorption band at 375 nm decreased gradually, and a new absorption band appeared with a maximum absorption at 470 nm. The obvious color change can be observed from light yellow to orange-red. The color change can be attributed to the appearance of a new long wavelength peak (9). When a protic solvent such as methanol was added to the orange-red solution of **4a** and L-malate in DMSO, the color of the solution returned to colorless, which illustrates that the interaction between **4a** and the anions was in essence a hydrogen-binding interaction.

Figures 2*a* and 2*b* show the fluorescence emission and UV–vis spectra of **4a** with different concentrations of D-malate in DMSO. When gradually increasing the concentration of the D-malate, the changes in fluorescence emission and UV–vis spectra were similar but smaller than when adding the equivalent L-malate into the solution of **4a**. The color change from light yellow to orange-red can also be observed. The quenching efficiency was about 50% with the addition of 2.0 equiv. of L-malate (Fig. 1*a*), while it was 30% with 2.0 equiv. of D-malate (Fig. 2*a*). The different quenching efficiencies ($\Delta I_L/\Delta I_D = 1.67$) indicated that receptor **4a** has a good enantioselective recognition ability for L- and D-malate. In addition, the association constants (K_{ass}) are different; the association constant of **4a** with L-malate is $(3.62 \pm 0.25) \times 10^4$ $(mol/L)^{-1}$, while that of **4a** with D-malate is $(3.75 \pm 0.33) \times 10^3$ $(mol/L)^{-1}$, and the enantioselectivity ($K_{ass}(L)/K_{ass}(D)$) is 9.65 for malate. These obvious changes in fluorescence and UV–vis spectra show that **4a** has an excellent chiral recognition ability towards the enantiomers of malate. Similar but smaller variations in the fluorescence and absorption spectra were obtained when adding L- or D-aspartate and L- or D-glutamate into the solution of **4a** in DMSO, respectively (see Supplementary Data, parts 1 and 3).[2] The corresponding association constants (K_{ass}) and correlation coefficients (*R*) of interaction between host and guest are listed in Table 1.

Figure 3 exhibits the fluorescence change of receptor **4a** with L- or D-malate. Different fluorescent responses indicate that **4a** has good enantioselective recognition ability for malate.

Figures 4*a* and 4*b* show the fluorescence emission spectra of **4b** with different concentrations of L- or D-malate in DMSO. When gradually increasing the concentration of the anions, the fluorescence emission intensities of **4b** (5.0×10^{-5} mol/L^{-1}) at 429 nm (λ_{ex} = 372 nm) decreased. The fluorescence quenching of receptor **4b** most likely arose from the change in free energy (ΔG_{PET}) of electron transfer between the excited fluorophore and the receptor (11*a*). When L- or D-malate interacted with receptor **4b**, the reductive potential of the amide group increased along with the ratio of the electron transfer from the HOMO orbit of the receptors to the excited anthracene group, which in turn leads to the intramolecular PET (photo-induced electron transfer) process being facilitated (11*b*), and therefore fluorescence quenching was observed. The changes in the absorption spectra of the anthracene moiety were only minor for **4b** in the presence of L- or D-malate (see Supplementary Data, part 4), which implies that a PET process occurred with anion binding.[2] Similar variations in the fluorescence and absorption spectra were observed when **4b** interacted with L- or D-aspartate and L- or D-glutamate (see Supplementary Data, part 2), respectively.[2] It was proposed that upon anion recog-

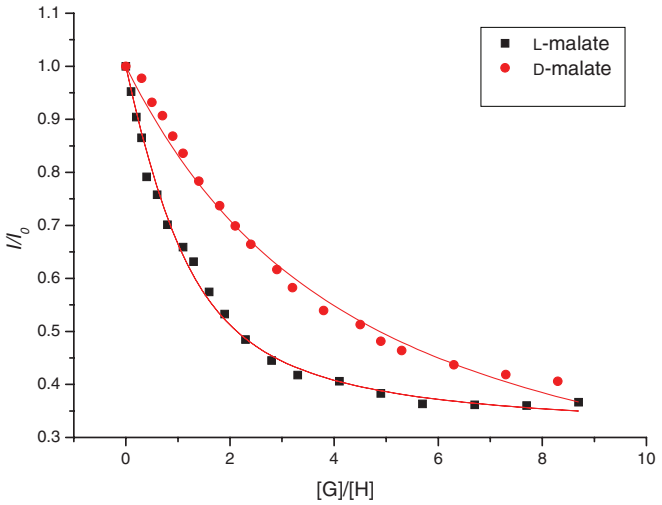
[a]The anions were used as their tetrabutylammonium salts.
[b]The data were calculated from results of fluorescence titrations in DMSO.
[c]All error values were obtained by the results of nonlinear curve fitting.

Fig. 3. Fluorescence intensity change of receptor **4a** (5×10^{-5} mol/L) with L- or D- malate in DMSO; the line is a fitted curve



nition, the rate of the electron transfer from the HOMO orbit of the anion-receptor complex to the anthracene excited state enhanced, which caused the fluorescence emission to be quenched, with a little change of UV–vis spectra in the complexation.

The association constant of **4b** with L-malate is (5.18 ± 0.26) × 10^3 (mol/L)$^{-1}$, while that of **4b** with D-malate is (2.38 ± 0.32) × 10^3 (mol/L)$^{-1}$, which corresponds to the L/D-selectivity (K_{ass}(L)/K_{ass}(D)) of 2.18 for malate. Figure 5 shows the fluorescence change of receptor **4b** with L- or D-malate. K_{ass} and R of interaction between **4b** and aspartate and glutamate are listed in Table 1.

Continuous variation methods were employed to determine the stoichiometric ratio of the receptor **4a** with L/D-malate and **4b** with L/D-aspartate. The total concentration of host and guest was constant (1.0×10^{-4} mol/L^{-1}) in DMSO, with a continuously variable molar fraction of host ([H] / ([H] + [G])). Figure 6 shows the Job plots of receptors **4a** and **4b** with chiral anions (at 429 nm). When the molar fraction of the host was 0.50 the fluorescence intensity reached a maximum, which demonstrated that receptors **4a** and **4b** formed a 1:1 complex with L/D-malate and L/D-aspartate, respectively (12).

Assuming that the complex stoichiometry was 1:1, the association constant (K_{ass}) can be calculated by the following equation in Origin 7.0 (13),

$$X = X_0 + (X_{lim} - X_0)/2c_0 \{c_H + c_G + 1/K_{ass} - [(c_H + c_G + 1/K_{ass})^2 - 4c_H c_G]^{1/2}\}$$

where X represents the fluorescence intensity, c_H and c_G represent the corresponding concentrations of host and guest. The nonlinear curve fitting results of the fluorescence intensity (at 429 nm) of the interaction between **4a** or **4b** with L/D-malate, L/D-aspartate, and L/D-glutamate are shown in Table 1. The satisfactory result (the correlation coefficient is over 0.99) of the nonlinear curve fitting confirmed that the 1:1 complex between **4a** or **4b** and the chiral dicarboxylate anions has been formed.

The data in Table 1 illustrates that the association constants of **4a** with the anions are much higher than for **4b**. The results demonstrated that the introduction of a *p*-nitrophenyl group into the thiourea moiety provided an effective intromolecular charge transfer, conjugated with anion binding and enhanced the hydrogen bond ability, resulting in a strong anion binding. Receptor **4a** revealed an excellent enantioselective recognition to the enantiomers of the malate anion (K_{ass} (L)/K_{ass} (*d*) = 9.65). Receptors **4a** and **4b** exhibited good enantioselective recognition towards the L-enantiomer of the chiral guests, which is probably due to the L-enantiomer having a more complementary structure with receptors **4a** and **4b**.

^{1}H NMR study

^{1}H NMR experiments were undertaken to assess the enantioselective recognition properties between host and guest, because they can provide direct structural and dynamic information (14). Studies on the enantioselective recognition were carried out on a 300 MHz NMR spectrometer, using the receptor **4a** as a chiral solvating agent in DMSO at room temperature (RT).

Figure 7 shows the spectra of receptor **4a** and its complex with equimolar amounts of L-, D-, or racemic malate in DMSO-d_6. When treated with L-malate, the characteristic peaks of thiourea (N*H* b and N*H* c) of **4a** disappeared, while the amide (N*H* a) had a downfield shift from 8.36 to 8.52 ppm; the singlet peak of the CH_2 protons at 5.35 ppm linking with anthracene cleaved into multiple peaks when L-malate was added to the solution; when treated with D-malate, the peak of the amide (N*H* a) shifted from 8.36 to 8.68 ppm, while thiourea (N*H* c) became broadened and shifted from 10.41 to 10.65. When adding equimolar amounts of the racemic malate, thiourea (N*H* b and N*H* c) also disappeared, and the peak of the amide (N*H* a) shifted

to 8.62 ppm. These results indicate that **4a** has a stronger interaction with L-malate than with D-malate. Notably, the signal change of the CH_2 protons of **4a** from singlet to multiple peaks when adding L-malate, means that there was strong interaction between **4a** and L-malate.

Conclusion

The anthracene based chiral fluorescent receptors **4a** and **4b** containing thiourea and amide groups were synthesized. The enantioselective recognition ability of **4a** and **4b** towards a series of chiral dicarboxylates were evaluated by fluorescence and ^{1}H NMR spectra. Receptor **4a** exhibits excellent chiral recognition ability towards the enantiomers of

Fig. 5. Fluorescence intensity change of receptor **4b** (5×10^{-5} mol/L) with L- or D-malate in DMSO; the line is a fitted curve.

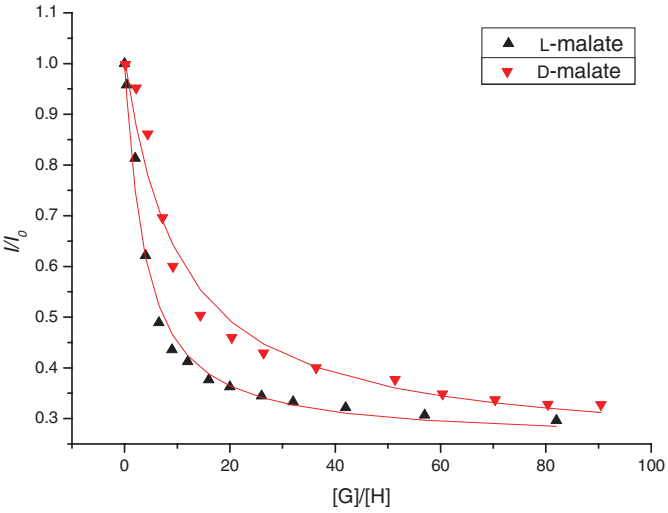

Fig. 6. Job plots of **4a** with L- or D-malate and **4b** with L- or D-aspartate (at 429 nm). The total concentration of the host and guest is 1.0×10^{-4} mol/L in DMSO. I_0 is the fluorescence intensity of **4a** or **4b**; *I* is the fluorescence intensity of **4a** or **4b** in the presence of the guest.

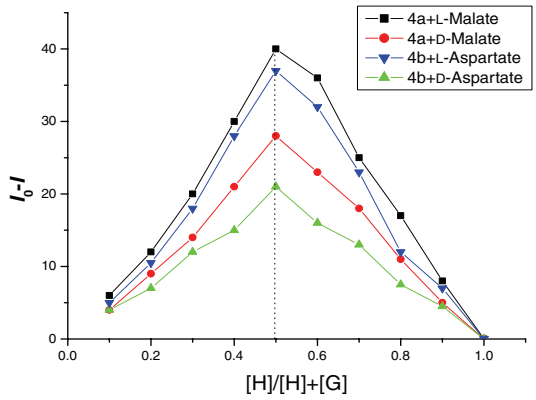

malate, while both **4a** and **4b** also shown good chiral recognition abilities towards L/D-aspartate. The steric effect of the receptors, structure-complementary with guest, and multiple hydrogen binding may be responsible for the enantioselective recognition. Sensitive fluorescent response and good enantioselective recognition ability reveal that **4a** can be used as fluorescent chemosensor for malate.

Experimental section

General methods

CH_2Cl_2 and Et_3N were dried and distilled from CaH_2. All other commercially available reagents were used without further purification. Melting points were determined with a Reichert 7905 melting-point apparatus and are uncorrected. Optical rotations were taken on a PerkinElmer Model 341 polarimeter. IR spectra were obtained on a Nicolet 670 FT-IR spectrophotometer. ^{1}H NMR spectra were performed on a Varian Mercury VX 300 MHz spectrometer in DMSO-d_6. ^{13}C NMR spectra were recorded on a Varian Inova Unity

Synthesis

Compounds 2

To a stirred and ice-cooled solution of *N*-Boc-L-alanine (0.38 g, 2.0 mmol) in dry CH_2Cl_2 (10 mL) was added 1,1′-carbonyldiimidazole (CDI) (0.39 g, 2.4 mmol), and the mixture was stirred for 2 h. Then a solution of 9,10-biaminomethylanthracene (0.24 g, 1.0 mmol) was added dropwise to the stirred mixture. The mixture was stirred under N_2 protection at RT for 18 h, and the yellow solid produced was filtered off, washed with $CHCl_3$ three times, and dried under vacuum. Pure compound **2** (0.55g) was obtained as a yellow solid in 95% yield, mp 175 to 177 °C. [α] = –7.5° (*c* 0.02, DMSO). IR (KBr, cm^{-1}) 3320, 2978, 2931, 1693, 1644, 1525, 1448, 1367, 1250, 1166, 1051, 754, 654. ^{1}H NMR (DMSO-d_6, ppm) δ: 8.38–8.41 (m, 4H, AnH), 8.21 (bs, 2H, CH_2NH), 7.56–7.59 (m, 4H, AnH), 6.84 (bs, 2H, NHBoc), 5.28 (bs, 4H, $AnCH_2$), 3.94–3.95 (m, 2H, *CH), 1.30 (s, 18H, CH_3), 1.08 (d, *J* = 7.5Hz, 6H, $^*CHCH_3$). ^{13}C NMR (DMSO-d_6, ppm) δ: 173.2, 155.6, 131.3, 130.4, 126.5, 125.8, 78.6, 50.3, 35.9, 19.1. ESI-MS *m/z* (%): 578 (M^+, 100). Anal. calcd. for $C_{32}H_{42}N_4O_6$: C 66.40, H 7.33, N 9.68; found: C 66.35, H 7.38, N 9.65.

Compounds 4a and 4b

TFA (0.5 mL) was added to the solution of compound **2** (0.29 g, 0.5 mmol) in dry CH_2Cl_2 (10 mL). The mixture was stirred at RT for 30 min to remove the Boc protecting groups. Then the solvent and excess acid was removed in vacuo, giving the TFA salt of **3** as a green solid, which was used directly without further purification. The green solid and triethylamine (0.5 mL) were dissolved in dry CH_2Cl_2 (10 mL), and a solution of *p*-nitrophenylisothiocyanate (0.18 g, 1.0 mmol) or *p*-tolylisothiocyanate (0.15 g, 1.0 mmol) was added slowly. The mixture was stirred vigorously overnight under N_2 protection at RT. The resulting precipitate was filtrated off and purified by crystallization from $CHCl_3$, obtaining pure products **4a** and **4b**, respectively.

Compound 4a

Yield 87%, mp 198 to 201 °C. [α] = +37.3° (*c* 0.02, DMSO). Tetrabutylammonium salts

All tetrabutylammonium salts were prepared by adding 2 equiv. of tetrabutylammonium hydroxide in methanol to a solution of the corresponding malic acid (1 equiv.) or N-protected (by Boc) aspartic acid and glutamic acid (1 equiv.) in methanol. The mixture was stirred at RT for 4 h and evaporated to dryness under reduced pressure. The resulting syrup was dried at high vacuum for 24 h, checked by NMR, and stored in a desiccator.

Binding studies

The studies on the binding properties of **4a** and **4b** were carried out in DMSO. The fluorescence titration was performed with a series of 5×10^{-5} mol/L solutions of receptors **4a** and **4b** containing different amounts of chiral anions. The excited wavelengths were both 372 nm, ^{1}H NMR studies were recorded after adding equivalent anions into receptors (4×10^{-2} mol/L). Association constants were calculated by means of a nonlinear least-square curve fitting method with Origin 7.0 (Origin-Lab Corporation).

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Gaseous ions and chemical mass spectrometry[1]

Diethard K. Böhme

Abstract: The intrinsic chemical reactivities of ions can be monitored in the gas phase using mass spectrometers that are coupled to appropriate ion sources and reaction cells. Here the author surveys his own experiences over the past 40 years as an ion chemist. He used flow-tube techniques for room temperature measurements of the intrinsic chemical reactivities of a large variety of positive and negative ions, including bare atomic ions, ions found in solution, biological ions, carbonaceous ions, and interstellar, cometary, and ionospheric ions. Progress in the measurement of chemical reactions of these ions with flow-tube mass spectrometry in the author's laboratory was been driven largely by developments in techniques of ion injection into the flow tube and of ion production (e.g., by electron impact, plasma ionization, and electrospray ionization). Chemical topics that are covered include: acid-base and nucleophilic displacement reactions that have bridged the gap between the gas phase and solution; interstellar ions and their role in molecular synthesis such as the synthesis of amino acids; the chemistry of fullerene cations as a function of charge state; fundamentals and applications of the chemistry of atomic cations with an emphasis on transition metal and lanthanide cations; atomic metal-ion catalysis; and chemical reactions of singly and multiply charged biological anions and cations in the gas phase.

Key words: ions, mass spectrometry, kinetics, ion chemistry.

Résumé : Faisant appel à des spectromètres de masse couplés à des sources ioniques et des cellules réactionnelles appropriées, on a déterminé les réactivités chimiques intrinsèques d'ions en phase gazeuse. Voici une revue de mes propres expériences sur la période des quarante dernières années, en tant que chimiste des ions, que j'ai utilisées à mesurer les réactivités chimiques intrinsèques à la température ambiante d'une grande variété d'ions positifs et négatifs, y compris des ions atomiques nus, des ions en solution, des ions biologiques, des ions à base de carbone et des ions interstellaires, des ions associés à des comètes et des ions de l'ionosphère. Les progrès réalisés dans le laboratoire de l'auteur dans la mesure des réactions chimiques de ces ions à l'aide de la spectrométrie de masse à tube d'écoulement ont été régis principalement par les développements dans les techniques de l'injection des ions dans le tube à écoulement et de la production de l'ion (par exemple, par impact électronique, ionisation au plasma ou ionisation par électronébulisation). Les sujets chimiques qui sont couverts comprennent les réactions de déplacement acide-base ou nucléophile qui forment un pont entre la phase gazeuse et la solution; les ions interstellaires et leur rôle dans la synthèse moléculaire, telle la synthèse des acides aminés; la chimie des cations fullurènes comme fonction de l'état de charge; les fondements et les applications de la chimie des cations atomiques avec une emphase sur les cations des métaux de transition et des lanthanides; la catalyse atomique ion-métal et les réactions chimiques en phase gazeuse d'anions ou de cations biologiques à charge unique ou multiple.

Mots-clés : ions, spectrométrie de masse, cinétique, chimie des ions.

[Traduit par la Rédaction]

Introduction

Ernest Rutherford once remarked that "ions are jolly little beggars, you can almost see them !" (1). I can very much relate to that remark as I've been pleasantly teased by ions during my entire research career, ever since my training as a physical chemist at McGill University in the early 1960s. Not only have I been fascinated by the structures and energies of ions and their many chemical reactions in a wide range of natural environments, but I also have searched for better ways of seeing these ions, of producing and detecting them, and of measuring their stabilities and reactivities using

evolving techniques of mass spectrometry. The happy result has been a journey of excitement and discovery and I will attempt here to share some of this with you.

Gaseous ions

Gaseous ions that have captured my attention over the years include small and large, positive and negative, singly and multiply charged, inorganic and organic, as well as biological ions.

Bubble 1 shows some smaller ions that are found or postulated to move freely in interstellar (2) and cometary (3) environments where they can be involved in collisions with molecules or particles and so promote molecular synthesis, including even the synthesis of biological molecules. In planetary ionospheres, the reactions of some of these ions play a role in determining the relative abundance of atomic and molecular ions (4) and, because there are huge differences in the rates of electron–ion recombination between atomic and molecular ions, in determining the densities of free electrons that are important in radio communication here on Earth.

Carbonaceous ions and metallated carbonaceous ions of the kind shown in Bubble 2 have intrigued physical chemists and astrochemists in their attempts to understand the molecular composition and chemistry of interstellar clouds and the atmospheres of carbon stars. These ions include carbon-chain and especially "bucky-ball" ions, which burst upon the chemical scene in 1990 when buckminsterfullerene powder first became available,

Here on earth, ions are often found in solution. The generation in the gas phase of ions that are found solvated in solution, such as those included in Bubble 3, allows studies of intrinsic reactivities in the absence of solvent and even as a function of added solvent molecules. So classic solution reactions, such as acid-base and nucleophilic displacement reactions and other reactions of organic and organometallic ions, can be investigated in the gas phase in the complete absence of solvent. Even biological ions, such as oligonucleotide anions (see Bubble 4), now can be transferred into the gas phase and exposed to chemistry that promises new insights into molecular biology.

Atomic ions, the smallest of all ions, become favoured in high-temperature environments where they carry information about the elemental composition of the environment. So atomic ions and their chemistry are important in elemental

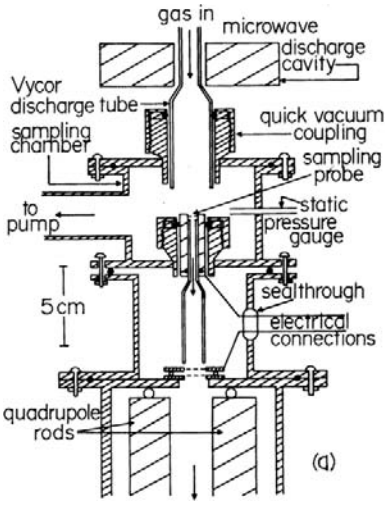
Fig. 1. Schematic view of sampling probe designed for sampling ions from a flowing nitrogen plasma excited with a microwave discharge (6).



analysis. But atomic cations of alkali, alkali-earth, transition, main-group, and lanthanide metals, both singly and multiply charged, also have a wider function in physics, chemistry, and biology generally. For example, the catalytic activity of atomic ions can be explored, both as free or ligated atomic ions, and such studies promise new fundamental insights into the efficiency and mechanism of catalysis.

Looking for ions in a flowing nitrogen discharge plasma

I first saw ions slightly more than 43 years ago in Montreal as a graduate student at McGill University. My project was to build a quadrupole mass spectrometer and to look for ions in flowing nitrogen gas activated by a microwave discharge. This was before quadrupole mass spectrometers were commercially available and less than 10 years after Paul and Steinwedel (1953) published their paper in *Zeitschrift für Naturforschung* on the theory and operation of quadrupoles (5) (for which Paul would later win a Nobel Prize).

So my first task as a new graduate student was to design and construct a quadrupole mass spectrometer. This included building a high-voltage radio-frequency power supply from scratch, with the help of a *Radio Amateur's Handbook,* under the close and necessary guidance of my doctoral supervisor, John Goodings. The construction was a success and we did see ions in a microwave discharge of flowing nitrogen, with the help of the discharge-sampling probe that we invented and that is shown in Fig. 1 (6, 7). The first quadrupole mass spectra that we recorded on March 2, 1964, and probably the first such spectra recorded in Canada, are shown in Fig. 2. The main ions found to be present in the activated nitrogen included atomic and molecular nitrogen ions and there was a hint of the occurrence of ionic or molecular reactions with these ions, if not within the discharge itself, then at least in the sampling region.

Fig. 2. First mass spectra recorded with the quadrupole mass spectrometer fitted to the plasma sampling probe shown in Fig. 1. The spectrum on the right shows some resolved m/z OH_n^+ (n = 0–3) ion peaks (mis-assigned in the original scan).

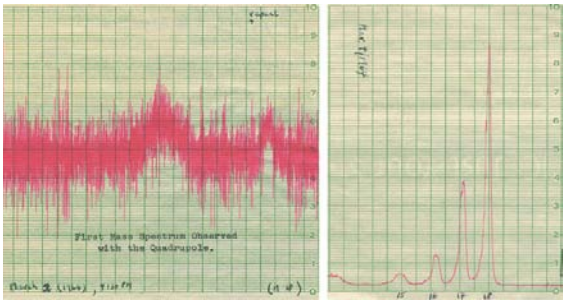


Fig. 3. Artistic view of the early flowing afterglow apparatus in Boulder, Colorado (8).

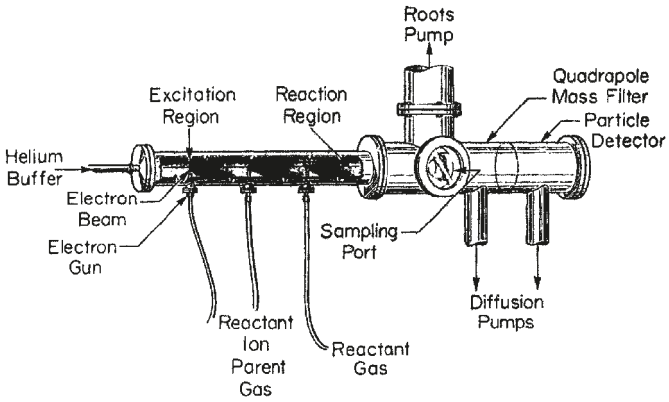


Ion chemistry in a flowing helium plasma

Meanwhile, quite independently, three physicists from Texas working at Environmental Science Services Administration (ESSA, now NOAA), a government research laboratory in Boulder, Colorado, showed that you could employ a flowing discharge plasma to study chemical reactions between ions and molecules, and to do so quantitatively! Eldon Ferguson, Fred Fehsenfeld, and Art Schmeltekopf set up the flowing He (instead of nitrogen) plasma that was activated with an electron gun (rather than microwaves) as shown in Fig. 3 (8). They demonstrated that, knowing the speed v of the flow (about 200 mph, 1 mile = 1.609 344 km), the length z of the reaction region, and the flow of the reagent, you could measure the rate coefficient k for a bimolecular reaction, say A^+ reacting with B, by monitoring the ions A^+ as a function of addition of neutral reagent B (at a fixed reaction time $t = z/v$) under pseudo first-order operating conditions, $[B] \gg [A^+]$! The rate eq. [1] can be cast in the form of eq. [2] and integrated. Equation [3] indicates that a semi-logarithmic plot of $[A^+]$ against the flow of B with a slope of $-k\ z/v$ can provide the rate coefficient k. The basic kinetic experiment then involves simply following the reactant (and product) ion signal as a function of added reagent and plotting the results appropriately.

$$[1] \qquad -d[A^+]/dt = k\ [A^+][B]$$

$$[2] \qquad -v\ d[A^+]/dz = k\ [A^+][B]$$

© 2008 NRC Canada

[3] $[A^+]_z = [A^+]_{z=0}\ e^{-k[B]z/v}$

In the example of experimental results shown in Fig. 4, electron ionization of oxygen upstream in the flow tube leads to formation of O^+ and O_2^+ ions that were exposed to hydrogen downstream in the flow tube. O_2^+ is seen to be unreactive, but O^+ reacts with a rate coefficient of 2.0×10^{-9} cm^3 molecule^{-1} s^{-1} that can be derived from the measured semi-logarithmic decay of O^+ as more and more hydrogen is added to the flow tube (9). Through a sequence of three H-atom transfer reactions, reactions 4a–4c, O^+ is rapidly converted to the hydronium ion, H_3O^+.

[4*a*] $O^+ + H_2 \rightarrow OH^+ + H$

[4*b*] $OH^+ + H_2 \rightarrow H_2O^+ + H$

[4*c*] $H_2O^+ + H_2 \rightarrow H_3O^+ + H$

Using this experimental approach in the 1960s and early 1970s, the three physicists from Texas were able to solve all of the important ion chemistry that occurs naturally in the earth's upper atmosphere (10, 11)!

Getting at the heart of chemistry: Bridging the gap between the gas phase and solution

By good fortune, I joined the Boulder group of physicists in 1967 along with Brewster Young, a graduate student at the University of Colorado at the time. With a freshman chemistry text book in our hands, we realized that chemical reactions predominant in solution could be investigated in a flowing He plasma in the gas phase, for the first time *in the complete absence of solvent*. We realized that appropriate neutral molecules, when ionized with an electron gun, could be deprotonated (reaction [5*a*]) or protonated (reactions [6*a*, 6*b*]) to produce negative or positive ions in the gas phase of the type found solvated in solution. These ions could then be exposed to chemical reaction downstream in the flow tube for measurements of reaction rates and products. Furthermore, they could even be solvated upstream first (reactions [5*b*] and [6*c*]), before reaction downstream so that the chemistry actually could be followed as a function of stepwise solvation.

[5*a*] $e + H_2O \rightarrow OH^- + H$

[5*b*] $OH^-(H_2O)_n + H_2O + He \rightarrow OH^-(H_2O)_{n+1} + He$

[6*a*] $e + H_2O \rightarrow H_2O^+ + 2e$

[6*b*] $H_2O^+ + H_2O \rightarrow H_3O^+ + OH$

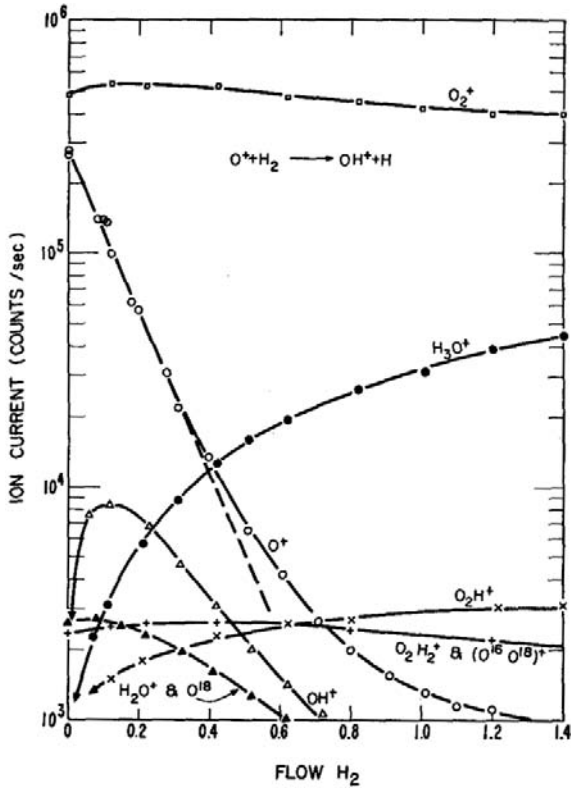
[6*c*] $H_3O^+(H_2O)_n + H_2O + He \rightarrow H_3O^+(H_2O)_{n+1} + He$

With such ions in hand, I spent several intense years in the laboratory exploring the kinetics of textbook ion–molecule reactions such as acid base (e.g., reactions [7] and [8]) and nucleophilic substitution reactions (e.g., reaction [9]), in the absence and presence of solvent molecules.

[7] $OH^-(H_2O)_n + CH_3OH \rightarrow CH_3O^-(H_2O)_n + H_2O$

[8] $H_3O^+(H_2O)_n + CH_3OH \rightarrow CH_3OH_2^+(H_2O)_n + H_2O$

Fig. 4. Raw data recorded for the addition of H into a flowing He plasma in which O^+ and O_2^+ have been established upstream as predominant ions (9).



[9] $OH^-(H_2O)_n + CH_3Cl \rightarrow Cl^-(H_2O)_n + CH_3OH$

I continued these studies later at York University as an Assistant Professor with my first graduate student, Gervase Mackay, in the laboratory of Harold Schiff, who also had set up a flowing afterglow mass spectrometer. Here are some of our major findings.

Intrinsic acidities and the influence of solvation

Figure 5 shows data that illustrate the kinetics of proton transfer from methanol to the hydroxide anion and the influence of sequential hydration of the hydroxide anion on its ability to abstract a proton from methanol. The bare hydroxide ion was found to react at essentially every collision with $k = 1.5 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} at 296 ± 2 K (12–14).

[10] $OH^- + CH_3OH \rightarrow CH_3O^- + H_2O$

Equilibrium-constant measurements provided the means to track the shifting equilibrium and the reversal of the relative acidity of water and methanol from what it is in solution. The bare reaction was found to have a measured equilibrium constant at 296 K of 2.2×10^7, $\Delta G^\circ = -9.9$ kcal mol^{-1} (14). Also, the equilibrium constant is seen in Fig. 5 to decrease in magnitude with increasing hydration, as water becomes increasingly more acidic than methanol, and approach a value of 1 and even less than 1, at which point the standard free energy of reaction [10] has changed in sign and the relative acidity of water and methanol has reversed to that in solution. This appears to require hydration with

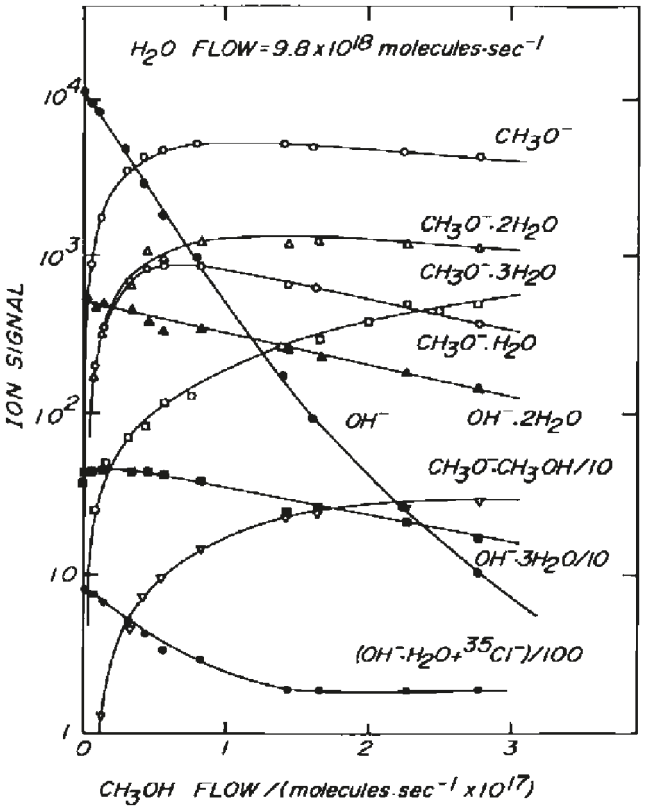
Fig. 5. (Top) Raw data for the room-temperature reaction between OH^- and methanol and for the step-wise hydration with up to three water molecules (14). (Bottom) Measured variation in the room-temperature equilibrium constant for proton transfer from methanol to OH^- with hydration and methanol solvation with up to three molecules of solvent (14).



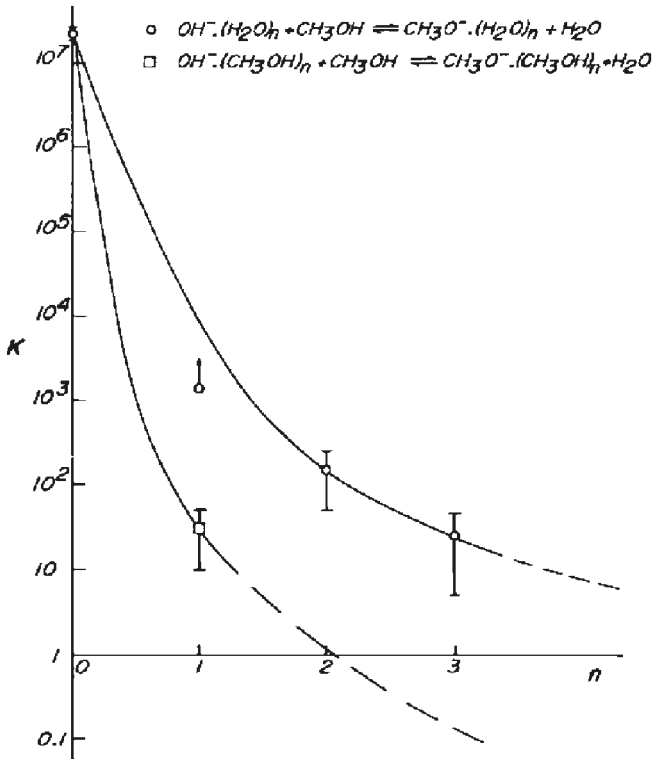


Fig. 6. Observed trends in the rate coefficient with extent of hydration for proton transfer reactions of hydrated hydroxide anions with several acids at 298 K. The values in parentheses indicate the relative intrinsic acidity of the acids AH and H_2O, $-\Delta G^o$ (in kcal mol^{-1}), for the unhydrated reactants (15).

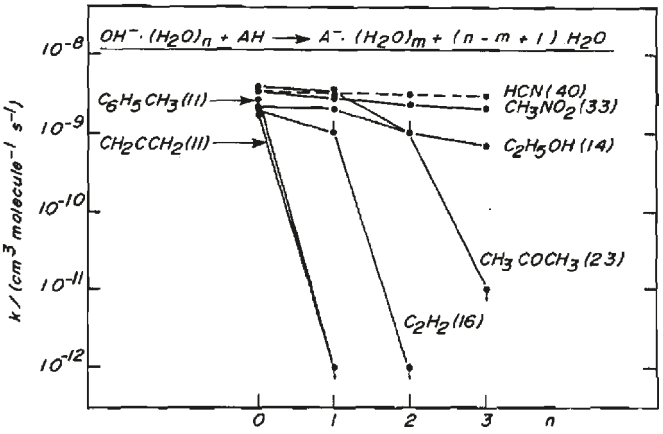

about 6 or 7 molecules of water and methanol solvation by only 2 molecules.

The influence of stepwise hydration on the kinetics of acid–base reactions with $OH^-(H_2O)_n$ also was explored (15).

[11] $OH^-(H_2O)_n + AH \rightarrow A^-(H_2O)_m + (n–m+1)\ H_2O$

The overview in Fig. 6 illustrates a reversal in acidity with hydration as signaled by a sharp drop in the rate of proton transfer with the addition of another water molecule. One water molecule appears sufficient with toluene and allene, two are required with acetylene, and three with acetone; no reversal is observed with hydrogen cyanide, nitromethane, or ethanol with up to four molecules of water.

Similar measurements became possible for reactions with protonated molecules. For example, reactions of H_3O^+ could be investigated in the gas phase as a function of molecular hydration, as shown in reaction [12]. Figure 7 shows results for the protonation of formaldehyde by "dry and wet" hydronium ions (16, 17) and the shifting equilibrium upon hydration.

[12] $H_3O^+(H_2O)_n + B \rightarrow BH^+(H_2O)_n + H_2O$

Reaction [12] was investigated with 11 different bases: 9 oxygen bases, NH_3, and H_2S. Figure 8 shows the measured variation in the rate coefficient for proton transfer with extent of hydration.

Transition between the gas phase and solution in the kinetics of nucleophilic displacement reactions

Another major finding, and this is perhaps an understatement, was that the hydroxide anion reacts with methyl chloride in the gas phase to yield Cl^- according to reaction [13] with a rate coefficient at room temperature of 1.9×10^{-9} cm^3 $molecule^{-1}$ s^{-1} (18), a stunning 17 orders of magnitude larger than in water where $k = 10^{-26}$ cm^3 $molecule^{-1}$ s^{-1}! The reaction occurs at essentially every collision in the gas phase without any kinetic barrier (19), an astounding illustration of the solvent effect.

[13] $OH^- + CH_3Cl \rightarrow Cl^- + CH_3OH$

© 2008 NRC Canada

Fig. 7. (Left) Raw data for the room-temperature reaction between H_3O^+ and formaldehyde and for the step-wise hydration with up to three water molecules. (Right) Measured variation in the room-temperature equilibrium constant for proton transfer from H_3O^+ to formaldehyde with hydration (16).

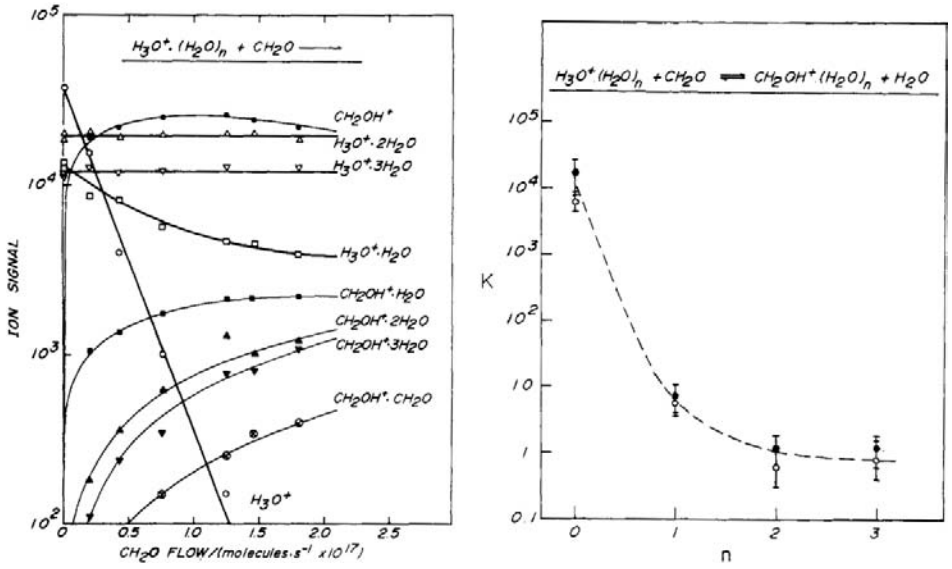

Fig. 8. Variation in the rate coefficient with extent of hydration for proton transfer reactions of the hydrated hydronium ion with several oxygen bases and ammonia at room temperature (16).

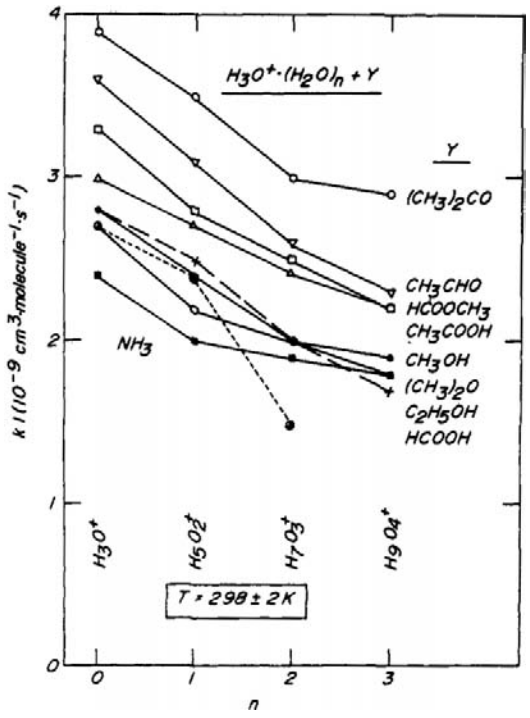

Molecular hydration in the gas phase was observed (20,21) to drop the rate by at least 4 orders of magnitude with the addition of only 3 solvent molecules (see Fig. 9). So there is no intrinsic activation energy at the heart of the reaction; rather, an activation energy emerges upon solvation (see Fig. 10).

These early measurements clearly demonstrate the usefulness and power of flow-tube mass spectrometry in determining intrinsic reactivities of chemical reactions that occur in solution and in tracking changes in reactivity with solvation at the molecular level.

Kinetics, collision theories, and thermodynamics

We have performed extensive kinetic measurements of numerous proton-transfer reactions involving small molecules and ions (unsolvated), to determine both the rate coefficients and the position of equilibrium.

[14] $XH^+ + Y \rightarrow YH^+ + X$

[15] $X^- + YH \rightarrow Y^- + XH$

The rate in the preferred directions of reactions [14] and [15] was observed to be controlled by the thermodynamics of reaction (22, 23): proton transfer was seen to be fast when it was seen to be thermodynamically favoured (exoergic) from equilibrium constant measurements (see Fig. 11).

Because the rate of proton transfer is expected to be collision-controlled, the measurements of the rate coefficients of proton transfer proved to be valuable for testing the various collision theories that evolved at about the same time as the measurements were being made. Collision theories are based on the electrostatic interaction between the colliding ion and the molecule, and this depends on the physical properties of the neutral molecule such as its polarizability, dipole moment, and quadrupole moment. A wide choice in these physical properties is available with the neutral reagents that can be added into the flow tube, and this has allowed extensive testing of the various collision theories. Some representative results are given in Figs. 12 and 13. Figure 12 provides a comparison between experiment and theory for proton-transfer reactions of type [14] and [15] with the dipolar HCN molecule (24) and also reactions of type [14] with quadrupolar acetylene (25). Figure 13 presents results for proton-transfer reactions of H_3O^+ with a variety of polar molecules according to reaction [14] (26). The best agreement for proton-transfer reactions with polar molecules is found with the average dipole orientation theory. The aver-

age quadrupole orientation theory provides a good prediction for the protonation of acetylene in which the collision is controlled by ion–quadrupole interaction.

Equilibrium constant measurements and bracketing measurements that establish the preferred direction for reactions of type [14] and [15] have provided the magnitude or sign of the standard free energy change for proton transfer (ΔG^o = –*RT* ln *K*). Equilibrium constants were determined either from measurements of equilibrium concentrations or from measurements of the forward and reverse rate coefficients (27, 28). These measurements provided important new absolute and relative values for gas-phase acidities, basicities and proton affinities of small molecules. For example, we reported very early (1971) measurements of the gas-phase acidities of alcohols (29) and later on of several aliphatic amines (30), and acidity orders for other Brönsted acids and several inorganic acids (31, 32). Some early (1980) definitive values determined for the proton affinities of small molecules and enthalpies of formation of protonated molecules are given in Table 1.

Table 1. Recommended proton affinities, PA, and enthalpies of formation, $\Delta H^o_f(XH^+)$, at 298 K (in kcal mol^{-1}) (22).

X	PA_{298} (X)[a]	$\Delta H^0_{f,298}$ (XH^+)

O_2	100.4±	266.8±0.4

[a]CO, O, and O_2were used as benchmarks.

Proton transfer to and from a suitable "transporter" molecule also can provide an alternative route for the isomerization of protonated molecules and this was recognized with the notion of proton-transport catalysis (33). Such catalysis is often efficient when the proton affinity of the transporter molecules has

a value in between the proton affinities of the different sites of protonation of the two isomers.

Selected-ion flow tube (SIFT) tandem mass spectrometry

A major advance in flow-tube mass spectrometry was achieved in the late 1970s by two British physicists, Nigel Adams and David Smith, then at the University of Birmingham. They showed in 1976 that ions could be produced and mass-selected *outside* the flow tube and then injected through a Venturi-type interface that is able to maintain the pressure difference across a hole large enough (ca. 5 mm in diameter) to transmit enough ions into the flowing He buffer gas at a pressure of ca. 0.35 Torr (1 Torr = 133.322 Pa) (34). With this innovation, the chemistry of one type of ion could be followed in the absence of other ions, as well as metastable atoms and electrons. The selected-ion flow tube

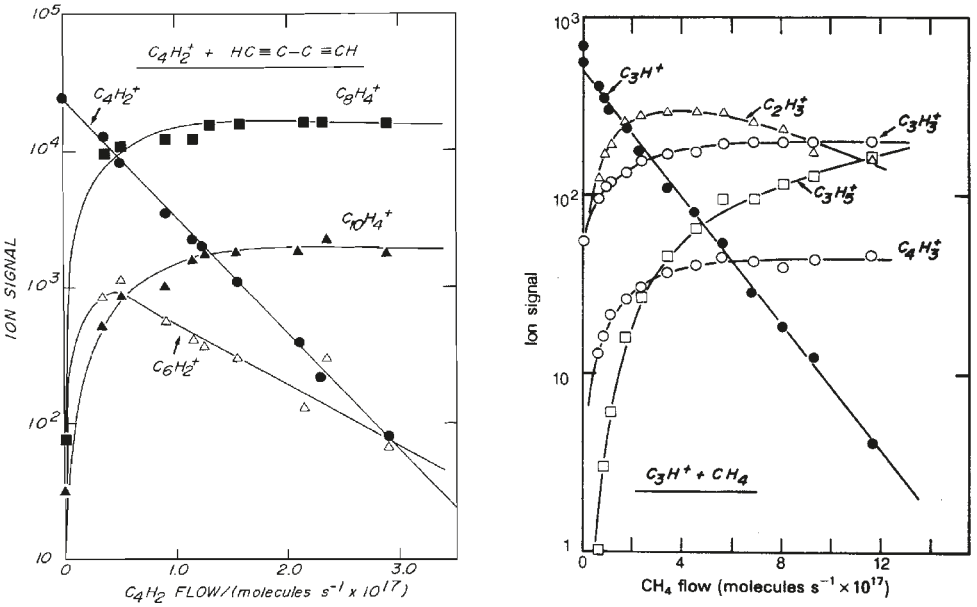
Fig. 16. Observed variations of ions recorded with the addition of diacetylene (left) and methane (right) into the reaction region of a SIFT apparatus in which $C_4H_2^+$ (ionized diacetylene) and C_3H^+, respectively, were established as the predominant upstream ions (56, 57).



(SIFT) tandem mass spectrometer constructed and operative shortly thereafter at York University is shown in Fig. 14 (35). The SIFT technique proved to be particularly useful for measurements with atomic ions and reactive ion intermediates that are elusive otherwise.

Chemical bond formation initiated by atomic ions

A variety of atomic ions could be produced by electron-impact ionization of appropriate parent molecules and injected into the flow tube. Examples include C^+ (36), S^+ (37), Si^+ (38–42) (see Fig. 15), and the atomic metal ions Mg^+ (43–46) and Fe^+ (47–49). Reactions with the non-metallic ions invariably lead to heavy-atom bond formation and the initiation of ionic growth; atomic metal cations also can mediate bond formation. Ionic growth by successive ion–molecule reactions is useful in neutral molecular synthesis if the grown ions can be neutralized, for example by proton transfer or recombination with electrons, without excessive dissociation.

Thus C^+ was observed to react with hydrocarbons such as methane, ethylene, and acetylene by C–C bond formation to form hydrocarbon ions that may neutralize to form larger hydrocarbons (36); see reaction [16], for example. S^+ was observed to react with diacetylene by C–S bond formation according to reaction [17] to form HC_4S^+, a possible precursor of C_4S in interstellar clouds (37). We also investigated in much detail the rich chemistry initiated by reactions with Si^+ leading to Si–H (41), Si–C (39), Si–O (40), Si–N (42), and Si–S (40) bond formation as in reactions [18] to [22]. A large variety of Si-containing neutrals, including some interesting silicon carbides (38, 39, 42), silicon oxides (40, 41), and silicon hydroxides (41), become accessible to these initiating reactions and these have been described in considerable detail (50, 51). Much of this chemistry is also of great interest in the silicon chemistry of interstellar clouds (52, 53).

[16] $C^+ + C_2H_2 \rightarrow C_3H^+ + H$

[17] $S^+ + C_4H_2 \rightarrow HC_4S^+ + H$

[18] $Si^+ + C_4H_2 \rightarrow C_4H^+ + SiH$

[19] $Si^+ + C_2H_2 \rightarrow SiC_2H^+ + H$

[20] $Si^+ + H_2O \rightarrow SiOH^+ + H$

[21] $Si^+ + NH_3 \rightarrow SiNH_2^+ + H$

[22] $Si^+ + OCS \rightarrow SiS^+ + CO$

Hydrocarbon-ion chemistry and ionic origins of carbenes in space

The value of the SIFT technique is further illustrated by the development in our laboratory of models for the ionic synthesis of hydrocarbon molecules (54) including cyanoacetylenes (55) and carbenes (56) known to be present in regions of ionizing radiation such as the tails of comets, the atmospheres of carbon stars, and cool molecular gas clouds. Figure 16 shows raw data for the reaction of diacetylene with the diacetylene radical cation $C_4H_2^{+\bullet}$ selected from an electron-impact source in which diacetylene was ionized (57) and for the reaction of the carbene cation $:C_3H^+$ derived from the electron impact of propylene (56). The following reaction sequence observed in diacetylene (57) can lead to the growth of carbon-chains.

[23] $C_4H_2^{+\bullet} + C_4H_2 \rightarrow C_4H_2^{+\bullet}(C_4H_2)$
$\rightarrow C_6H_2^{+\bullet} + C_2H_2$

[24] $C_6H_2^{+\bullet} + C_4H_2 \rightarrow C_{10}H_4^{+\bullet}$

One early focus in our laboratory of interstellar and circumstellar ion chemistry was the exploration of possible ionic origins of carbenes such as $:CH_2$, :C=C:, :C=S, :C=O, :C=NH, :C=C=C:, *l,c*-$:C_3H_2$, and $:C_3O$. Figure 17 shows a model scheme for the ionic synthesis of :C=C=C:, *c*-$:C_3H_2$ and $:C=C=C=CH_2$ (56) based, in part, on SIFT measurements of ion–molecule reactions.

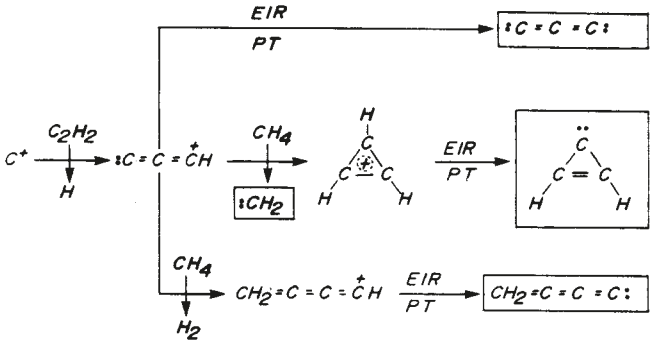

Fig. 18. (Left) Data recorded for the sequential addition of cyanoacetylene to Mg^+ to form $Mg(HC_3N)_n^+$ in a He buffer gas at 294 ± 3 K and 0.35 ± 0.01 Torr (46). (Right) Results of multi-CID experiments (46). The fractional abundance of ion signals for $Mg(HC_3N)_n^+$ are plotted against the nose-cone potential, U_{nc}. The flow of cyanoacetylene is 6.0×10^{17} molecules s^{-1}.

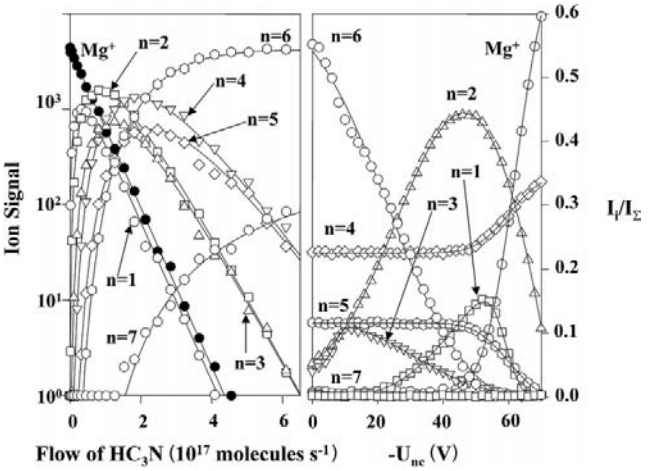

Fig. 19. Proposed routes for the synthesis of amino acids in interstellar environments (59). M and A represent any neutral atom or molecule with an ionization energy suitable for neutralization or ionization by electron transfer. RH^+ represents a proton carrier with PA(R) < PA(NH_2OH).

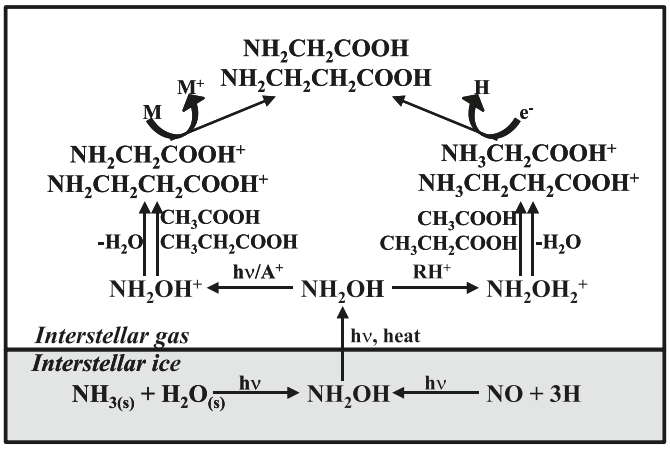


Furthermore, multi-collision induced dissociation experiments using the sampling nose cone in the flow tube as an "ion attractor" (58) pointed toward an extraordinary stability for the fourth adduct, also seen in Fig. 18. Why should this be so? Our molecular orbital calculations with density functional theory showed the existence of at least two very stable isomers of $(HC_3N)_4$, 1,2,5,6-tetracyano-1,3,5,7-cyclooctatetrene and 2,4,6,8-tetracyanosemibullvalene (46). The isomerization of $(HC_3N)_4$ into one of these isomers mediated by $Mg^{+\bullet}$ became an attractive proposition as a consequence. So we have suggested the formation of these exotic ring molecules in extraterrestrial environments by the sequence of radiative association and electron–ion recombination expressed in reactions [26] and [27]. $Mg^{+\bullet}$ ions, cyanoacetylene, and electrons are known to be present in circumstellar envelopes and the atmosphere of Titan.

[25] $Mg(HC_3N)_{n-1}^{+\bullet} + HC_3N \rightarrow Mg(HC_3N)_n^{+\bullet}$,

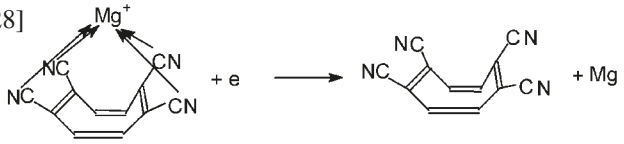
where n = 1 to 7

[26] $Mg(HC_3N)_{n-1}^{+\bullet} + HC_3N \rightarrow Mg(HC_3N)_n^{+\bullet} + h\nu$

[27] $Mg(HC_3N)_n^{+\bullet} + e \rightarrow (HC_3N)_n + Mg$

The formation of cyclooctatetrene is illustrated in eq. [28].

[28]



Ions and life

The "holy grail" for many ion chemists is a gas-phase ionic reaction mechanism that leads to the formation of neutral amino acids, the building blocks of life, in outer space. We tried for many years to identify and characterize ion–molecule reactions appropriate for such formation. The SIFT mass spectrometer provided the right tool to do so, but the right chemistry was elusive. Earlier searches for the direct formation of glycine from plausible ionized and molecular fragments of this molecule were hampered by the preference of N–O bond formation over the desired C–C or C–N bond formation. For example, the reactions of $CH_3NH_2^+$ with HCOOH, CO_2, or CO + H_2O, of NH_3^+ with CH_3COOH, and of CH_2COOH^+ with NH_3 all failed to produce glycine. Finally in 2003, we were able to report that ionized glycine and β-alanine are produced in the reactions of hydroxylamine ions, NH_2OH^+, with acetic and propanoic acid, respectively, and the corresponding production of the protonated amino acids from analogous reactions with

© 2008 NRC Canada

protonated hydroxylamine (59). We have since explored the potential energy surfaces of the latter reactions and explained the observed preference for the formation of β-AlaH$^+$ over the α-AlaH$^+$ isomer (60). Figure 19 summarizes our proposed routes for the synthesis of amino acids in interstellar environments (59).

The striking specificity of these syntheses for the β-isomer of alanine suggests that the amino acids of CI chondrites, a class of carbonaceous meteorites, are products of interstellar chemistry and supports the hypothesis that these meteorites are of cometary origin (59). Now we are targeting the formation of larger and more complex biomolecules by ionic synthesis.

Chemistry with buckyballs

Thanks to the generosity of Wolfgang Krätschmer who had produced buckminsterfullerene C_{60} powder for the first time in 1989 in Heidelberg at the Max-Planck Institute for Nuclear Physics (61), I was able to bring a small sample to Canada in 1990. We had just had resounding success at the Technical University of Berlin in the laboratories of Helmut Schwarz (where I was on sabbatical leave) in producing endohedral cluster compounds of He and $C_{60}^{+\bullet}$ at high collision energies (62). So my two postdoctoral fellows at the time, Simon Petrie and Reza Javahery, and I had an unprecedented opportunity to do chemistry here in Canada with this fascinating new molecule whose discovery would lead to a Nobel Prize in 1996. The next three years of research were packed with numerous discoveries and were among the most exciting and rewarding of my entire career (63).

Chemical ionization of fullerenes

We quickly found out that the buckminsterfullerene molecule could undergo completely novel chemical ionizations at room temperature. We first demonstrated the single ionization of C_{60} with metastable atoms (the well-known Penning ionization) (64), reaction [29], but then also observed the occurrence of double ionization by concomitant electron transfer and electron detachment (65), reaction [30], a thermal ionization process that was completely unknown at the time and which we attribute to the metallic character of C_{60}, a cage of 60 C nuclei surrounded by an ocean of electrons. Since then we also have discovered the occurrence of "double-electron transfer / electron detachment" with Ar^{2+} (66), reaction [31].

[29] $\quad He\ (^3S_1,\ ^1S_1) + C_{60} \rightarrow He(^1S_0) + C_{60}^{+\bullet} + e$

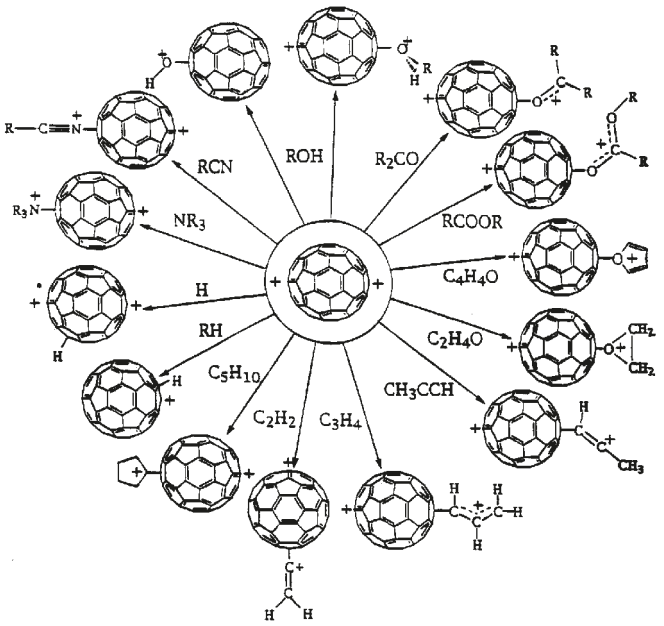
[30] $\quad He^{+\bullet} + C_{60} \rightarrow C_{60}^{2+} + He + e$

[31] $\quad Ar^{2+} + C_{60} \rightarrow C_{60}^{3+\bullet} + Ar + e$

Reactions of fullerene cations: Electron transfer and derivatization

Our studies of ion–molecule reactions of mono-, di-, and tri-cations of C_{60} have provided a wealth of new information about the physical and chemical properties of this fascinating molecule and other fullerene relatives. The observation of, or failure to observe, electron transfer to multiply charged fullerene cations from molecules of known ionization energy provided insights into the electron recombination

Fig. 20. Overview of the chemistry of C_{60}^{2+} recorded with our SIFT apparatus at RT and a He bath gas pressure of 0.35 Torr (63).



energies of the fullerene cations as well as the magnitude of the barrier to electron transfer that can arise from the Coulombic repulsion between the charged product ions (67). An unprecedented transfer of *two electrons* was observed between triply charged $C_{60}^{3+\bullet}$ cations and the PAHs anthracene, pyrene, corannulene and benzo[rst]pentaphene (68). These reagent molecules have sufficiently low first and second ionization energies to make double-electron transfer thermodynamically and kinetically favourable.

Reactions that lead to chemical bond formation also face an activation barrier (estimated to be 15 kcal mol^{-1}) because a transition is required from largely sp^2 to sp^3 hybridization at the C atom that becomes bonded. This intrinsic activation barrier is overcome with increasing charge on the fullerene cation because of the resulting increase in electrostatic interaction between reactants. Thus, higher charge states tend to exhibit higher chemical reactivity (69–71) and greater efficiency of ligation (72). Figure 20 captures an overview of the chemistry observed with the fullerene dication.

Chemistry as a function of charge state

The extraordinary stability of buckminsterfullerene in multiple charge states provides an extremely rare opportunity to investigate systematically the influence of charge state on chemical reactivity (73). An overview of the results of such investigations in our laboratory is provided in Fig. 21. Experimental results with a large variety of neutral molecules as reagents indicated that chemistry (chemical-bond formation) is increasingly pre-empted by physics (electron transfer) with increasing charge state (63). The competition between electron transfer and bond formation has been monitored quantitatively for reactions of C_{60}^{2+} with ammonia and several amines as displayed in Fig. 22. However, the onset for electron transfer as the dominant channel is delayed by the activation barrier that arises from the Coulomb repulsion between the charged products (73).

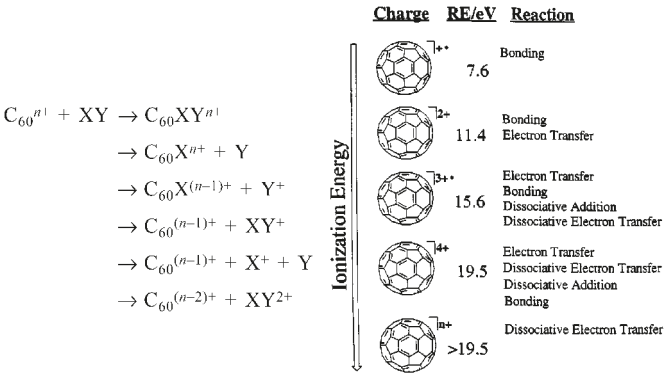

Fig. 22. The competition between electron transfer (dashed line) and ligation (solid line) observed for reactions of C_{60}^{2+} with ammonia and several amines in a SIFT apparatus at 294 K and a He bath gas pressure of 0.35 Torr (63).

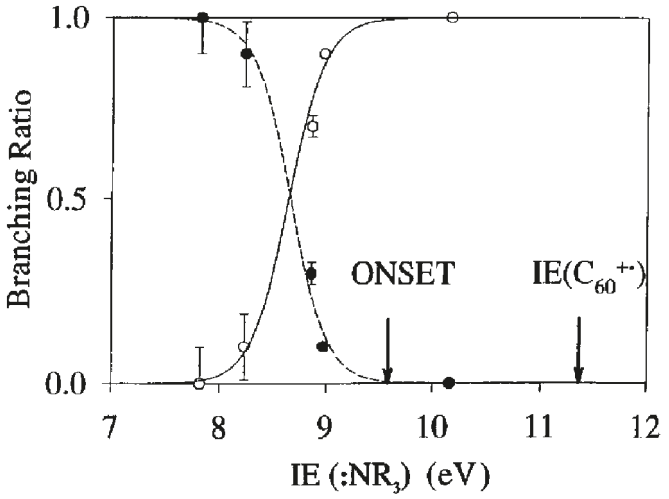

Higher-order fullerene ion chemistry

We have observed higher-order reactions of derivatized fullerene cations that exhibit proton (74) and cation (75) transfer as illustrated in reactions [32] and [33], double and multiple derivatization of the surface of C_{60} (71, 75 and example in Fig. 23) including sequential hydrogenation with hydrogen atoms (76), and cation-induced polymerization of several small unsaturated hydrocarbon monomers by "ball-and-chain" propagation (76). The latter can be assisted by intramolecular Coulomb repulsion.

[32] $C_{60}(XH)_n^{2+} + XH \rightarrow C_{60}(XH)_{n-1}^{+} + XH_2^{+}$

[33] $C_{60}(XCH_3)^{3+} + XCH_3 \rightarrow C_{60}(X)^{2+} + X(CH_3)_2^{+}$

Chemistry and physics in concert

We have found that chemistry and physics can operate in concert in reactions involving multiply charged derivatized fullerene ions, when Coulomb repulsion between the charges drives intramolecular charge transport that enhances charge

Fig. 23. Data recorded for the sequential addition of methyl isocyanide to $C_{60}^{3+\bullet}$ in He buffer gas at 0.35 Torr and 294 K.

localization on the substituent and so the chemical reactivity of the derivatized ion. This mechanism is illustrated in Fig. 24 and explains the products of the reaction between C_{60}^{2+} and cyanoacetylene that we have observed in our SIFT (77). The 2+2 cyclization that is envisaged leads to the remarkable formation of the derivatized cyclobutadiene isomer

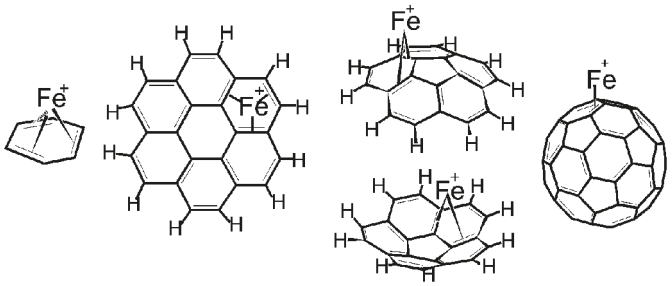
Scheme 1.



of $(HC_3N)_2^{+\bullet}$ that is not directly accessible to the reaction of ionized cyanoacetylene with cyanoacetylene, as we have shown by the collision-induced dissociation of the isomers formed in these two different ways. The same mechanism, which we have called the "molecular dock mechanism", might well apply to the formation of other derivatized cyclobutadienes from higher homologs of cyanoacetylene and should be applicable more generally to any carbonaceous molecule or particle that can carry multiple charges and provide an atomic site for covalent bonding. The generalized case is illustrated in reaction [34]. We have proposed such reactions as a source of neutral derivatized cyclobutadiene ring molecules in interstellar and circumstellar environments when the cyclic product ion is subsequently neutralized by electron transfer.

[34] $$X^{2+} + 2\ H(C_2)_nCN \rightarrow X^+ + c\text{-}C_4H_2((C_2)_{n-1}CN)_2^+$$

Gas-phase surface chemistry: The influence of curvature

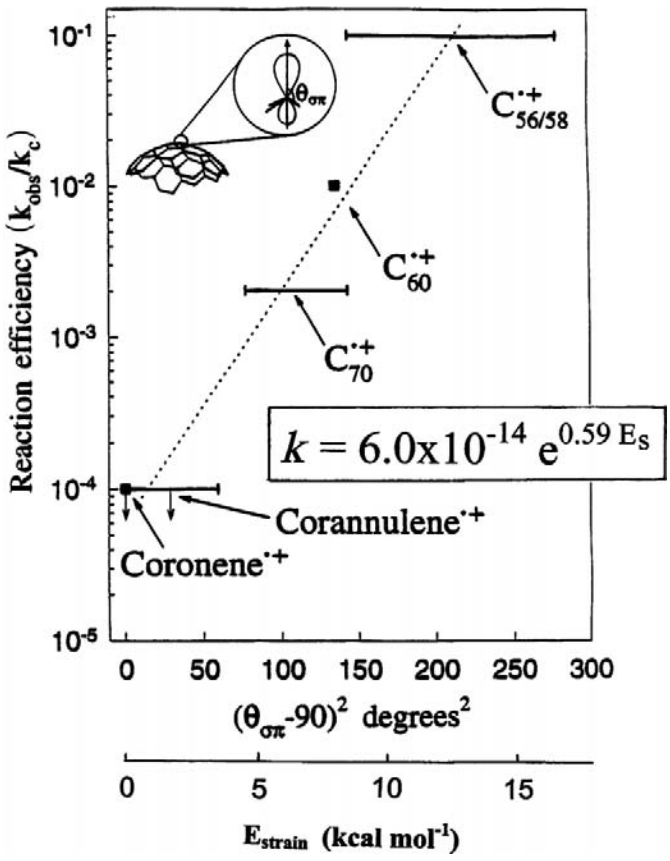
The availability of fullerenes provides an unprecedented opportunity to investigate carbonaceous surface chemistry in the gas phase at the molecular level in the absence of boundary effects and free of contamination and surface imperfections. For example, the influence on the chemistry of individual atomic ions attached (ligated) to various molecular carbonaceous surfaces (here defined as such by their much larger size) can be studied in splendid detail. Our emphasis so far has been on the modification of the reactivity of Fe^+ by the various carbonaceous molecules shown in Scheme 1 (78, 79).

Some progress has been made in investigating the influence of surface features on the chemical reactivity of fullerene cations themselves. Early SIFT investigations of addition reactions of fullerene cations C_{56}^+, C_{58}^+ and C_{60}^+ with NH_3, of addition reactions of C_{56}^{2+}, C_{58}^{2+} and C_{60}^{2+} with C_2H_4 and CH_3CN, and of hydride-transfer reactions of C_{56}^{2+}, C_{58}^{2+} and C_{60}^{2+} with n-C_4H_{10}, revealed an enhanced reactivity for the adjacent-pentagon fullerene ions(80). More recent systematic studies of addition reactions of C_{56}^+, C_{58}^+, C_{60}^+, C_{70}^+, corannulene$^+$, and coronene$^+$ with cyclopentadiene (see Fig. 25) and 1,3-cyclohexadiene indicate that the efficiency of bond formation with these two molecules also depends strongly on the curvature of the carbonaceous surface of the reacting cation (81, 82).

Extraterrestrial fullerene ion chemistry

There are very good reasons to expect the presence of fullerene and derivatized fullerene cations in the interstellar medium and in the circumstellar envelopes of carbon-rich

Fig 25. A correlation between reaction efficiency k_{obs}/k_c with the square of the pi orbital axis vector angle and the strain energy for addition reactions with cyclopentadiene at room temperature and a He pressure of 0.35 ± 0.01 Torr (81). k_{obs} is the measured rate coefficient and k_c is the collision rate coefficient which is estimated to be 10^{-9} cm^3 molecule^{-1} s^{-1}. The dotted line defines the dependence of k_{obs} on strain energy, E_s, which is indicated.



stars, as well as the formation of molecules in these regions that is assisted by fullerene cations (83, 84) including the formation of derivatized cyclobutadienes in the presence of cyanoacetylenes (77). For example, Fig. 26 provides an overview of chemical pathways that we have proposed that can be initiated by doubly charged fullerenes in interstellar or circumstellar environments (84).

The ICP/SIFT/QqQ instrument: Atomic ion chemistry

At the turn of the millennium, I became reconnected with a former graduate student, Scott Tanner, then working at MDS Sciex, a company that manufactures ICP/MS instruments for atomic ion analysis. He and his colleague, Vladimir Baranov, a former postdoctoral fellow of mine, had developed a "dynamic reaction cell" for the chemical resolution of isobaric interferences between atomic ions for use in ICP/MS (85) and they needed information on atomic ion reactivities. We formed a partnership with the Natural Sciences and Engineering Research Council of Canada (NSERC) and the National Research Council Canada and were able to fit a commercial ICP to the front end of the SIFT and so to inject mass selected atomic cations into the

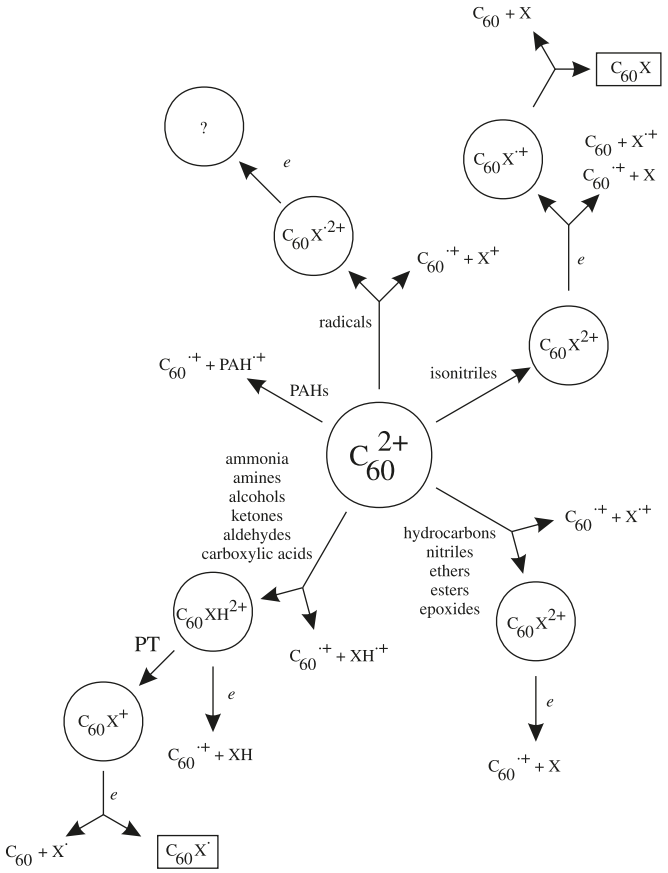
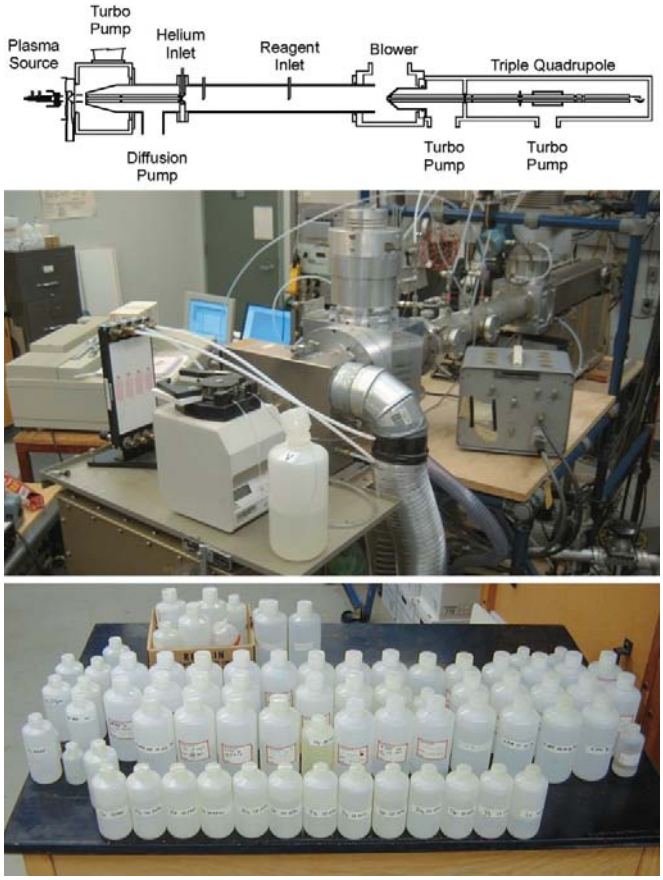
Fig. 26. Schematic view of possible chemical pathways initiated by doubly charged fullerene cations.



flow tube (86). Schematic and pictorial views of the instrument are shown in Fig. 27.

Fig. 27. Schematic and pictorial views of the ICP/SIFT/QqQ multipole mass spectrometer originally built at York University in 2000, initially with a single rather than a triple quadrupole mass spectrometer as the ion detector (86). Also shown is the "periodic table" of the bottled solutions of atomic cations that were sprayed into the ICP.



Reactions of atomic cations: Surfing the periodic table

The availability of the ICP as a source of atomic cations has made it possible to thoroughly investigate reactions of some 60 different atomic cations with a large variety of different molecules. Indeed, we now can routinely measure reactions with alkali, alkaline earth, transition metal, main group, and lanthanide atomic cations.

Figure 28 shows an example of some of the more extreme data obtained for the chemistry initiated by atomic niobium cations with nitrous oxide (87). N_2O was found, somewhat surprisingly, to transfer an N atom or an O atom to Nb^+, and both transfers were seen to trigger extensive secondary and higher-order chemistry, including further oxidation and substantial clustering with nitrous oxide.

We have surveyed the reactivity of nitrous oxide with 59 elemental cations and so characterized the periodic behaviour of this reactivity over most of the periodic table as illustrated in Fig. 29 (87). Systematic studies of this type now have been performed for reactions of up to 61 atomic cations with 15 different molecules including O_2, NO, D_2O, CO_2, NO_2, N_2O, OCS, CS_2, NH_3, CH_4, CH_3F, CH_3Cl, C_6H_6, C_6F_6 and SF_6. Except for Mg^+ and Si^+, which were produced only by conventional electron impact ionization of suitable parent gases, all atomic cations were generated using the ICP. A data base is now available on the web that provides measured reaction rate coefficients and product distributions as well as the observed higher order chemistry of almost 1000 reactions that we have investigated.[3]

Periodicities were observed in overall reaction efficiency and these were scrutinized in terms of kinetic constraints that determine chemical reactivity such as overall exothermicity, the presence of an activation barrier in the reaction co-ordinate, and the overall conservation of spin (87). The measured periodic behaviour is especially intriguing for the reactions with lanthanide cations (88).

Often, higher-order reactions have been observed and reported, as have reactions of singly and multiply ligated atomic cations, for example reactions of $M^+(C_6H_6)$ and $M^+(C_6H_6)_2$ (89).

The special case of lanthanide cation reactions: Arrhenius would be interested!

Measured rates for reactions of lanthanide cations with small molecules often were observed to vary from close to

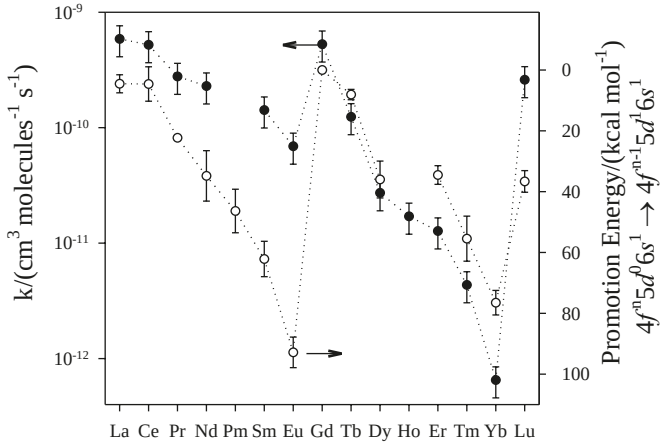
Fig. 30. Reaction-rate coefficient (solid circles and left ordinate axis) and electron-promotion energy of the Ln^+ cation (open circles and right ordinate axis) plotted versus element for lanthanide cations reacting with N_2O (88). There is an apparent correlation between reaction rate and electron-promotion energy.



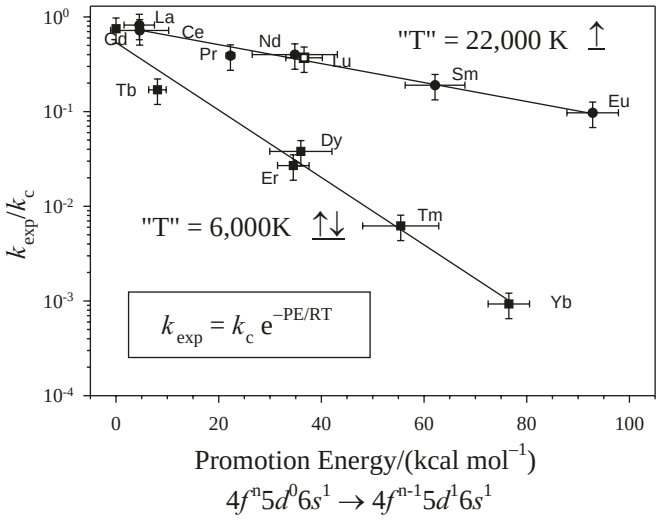
the predicted ion–molecule collision rate down to less than 0.1% efficiency. These observations were rationalized in terms of reaction thermodynamics and electronic structure effects. For example, the efficiency for exothermic reactions with N_2O (88) was found to decrease as the energy required to promote an electron in the lanthanide cation from the $4f^n5d^06s^1$ to the $4f^{n-1}5d^16s^1$ configuration increases (see Fig. 30). Furthermore, remarkably different Arrhenius-like correlations are found in the reactivity of the early and late lanthanide cations with this electro-promotion energy. The correlations for reactions with N_2O are shown in Fig. 31. Here we are using the Arrhenius equation in a novel way: we plot the efficiency for O-atom transfer against promotion energy, using the activation energy rather than T as the variable. The slope of such a plot provides an effective way to measure temperature or energy RT, and differs for the early and late lanthanides. The interpretation of this difference remains a puzzle.

Chemical resolution in elemental analysis

Atomic ion reactions have found application in elemental analysis using ICP/MS (90). Isobaric interferences are resolved chemically in a dynamic reaction cell placed between the ICP and the MS by adding an appropriate gas that reacts selectively with only one of the interfering ions and so moves its signature to another *m/z* that can be easily resolved. A good example is the interference of Rb^+ with Sr^+ at *m/z* = 87 that arises in the use of these two ions for age dating (91). ^{87}Sr arises, in part, from the natural β-decay of ^{87}Rb. This means that the $^{87}Rb/^{87}Sr$ ratio must be measured accurately. The data shown in Fig. 32 indicate that SF_6 can shift the mass of Sr^+ by 19 mass units while leaving the Rb^+ ion untouched. Rb^+ (s^0), which has a rare-gas configuration, is measured to be unreactive while Sr^+ (s^1) reacts rapidly, almost at the collision rate, primarily by F-atom abstraction as indicated in reactions [35] and [36].

[35] $Rb^+ (s^0) + SF_6 \rightarrow NR$
$(k \leq 1 \times 10^{-13}\ cm^3\ molecule^{-1}\ s^{-1})$

Fig. 31. A correlation of reaction efficiency with the electron promotion energy that is proposed to be required for Ln-O^+ bond formation in the reactions of early (solid circles) and late (solid squares) Ln^+ ions with N_2O (88). Lu^+ (open square) clearly is an exception to the trend observed for the late Ln^+ ions.



[36] $Sr^+ (s^1) + SF_6 \rightarrow SrF^+ + SF_5$ (97%;
$\rightarrow SrSF_5^+ + F$ (3%)\
$(k = 5.7 \times 10^{-10}\ cm^3\ molecule^{-1}\ s^{-1})$

We have surveyed the general utility of SF_6 for resolving isobaric interferences. The boxes on the periodic table in Fig. 33 encompass adjacent ions with large differences in reactivity that may be used to resolve them.

Atomic ions: The ultimate sites for catalysis

Another potential application of atomic ion chemistry is in the field of catalysis (92). Our measurements have demonstrated that atomic metal cations with appropriate O-atom affinities can serve to transport O-atoms from one neutral molecule to another and so to catalyse the neutral redox reaction. This is illustrated in Fig. 34 for the catalytic reduction of N_xO_y molecules by CO (93).

This computed energy landscape that nicely illustrates the catalytic activity of Fe^+ for the reduction of N_2O by CO is shown in Fig. 35 (94). The two legs of the catalytic cycle that involve ion–molecule reactions follow potential energy surfaces with double minima, with only a very small barrier in the first leg.

Packing atomic metal cations with fullerenes

The atomic cations of Sr and Mo have been observed (95) to add sequentially up to four molecules of C_{60} in He at 0.35 Torr and RT using the ICP/SIFT/QqQ configuration (see Fig. 36). The available center-of-mass energy in collision-induced dissociation experiments within the triple quadrupole provided a *lower* limit to the binding energy of the fourth C_{60} molecule of approximately 1.3 eV. A structure is proposed for $M^+(C_{60})_4$ cations in which the bonding involves η^6 interaction of the metal with the C_{60} ligands and η^2-to-η^2 interactions between the C_{60} ligands (see Fig. 36).

Fig. 32. Observed ion profiles recorded with the ICP/SIFT tandem mass spectrometer for the reactions of Rb^+ and Sr^+ with SF_6 in He buffer gas at 0.35 Torr and 295 K.

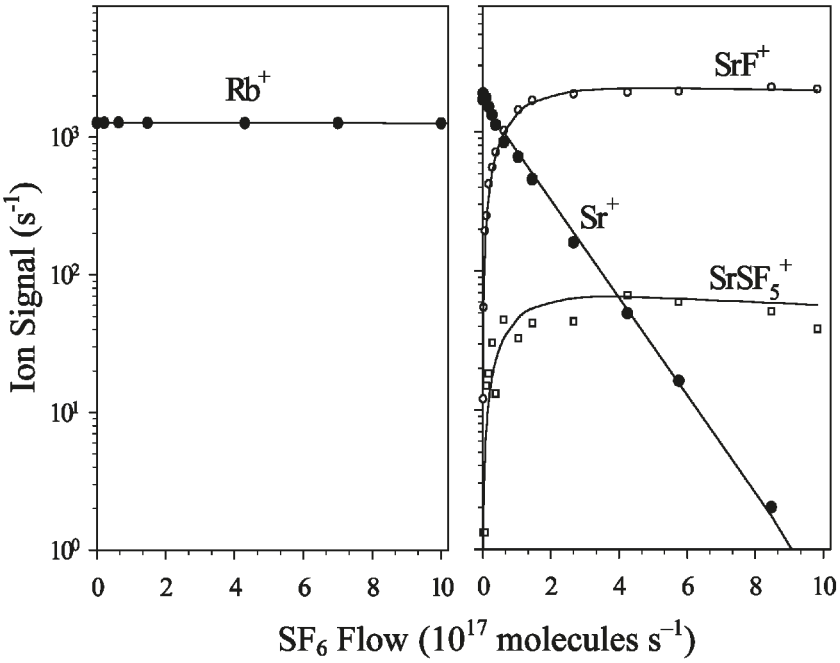

Fig. 33. Periodic variations observed in the efficiencies, k/k_c (represented as solid circles), for reactions of atomic cations with SF_6. k represents the measured room-temperature reaction rate coefficient and k_c is the calculated collision rate coefficient. Also indicated are the ground-state electronic configurations of the atomic cations. The different colours designate the different product channels that were observed.

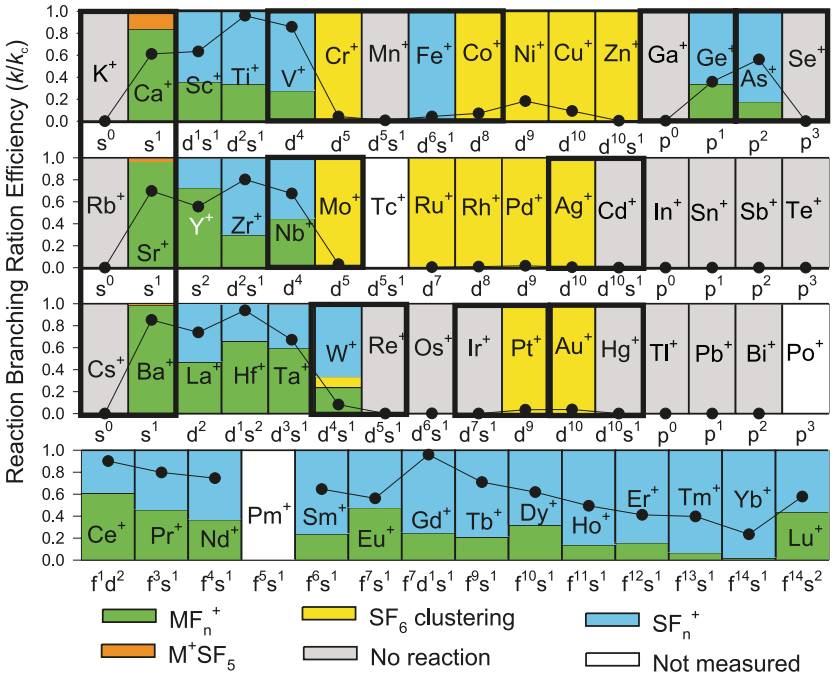

The ESI/qQ/SIFT/QqQ instrument: The ultimate chemical mass spectrometer

Our most recent breakthrough in flow-tube mass spectrometry involved interfacing an ESI source at the front end of the flow tube as shown schematically and pictorially in Fig. 37 (96). The Nobel Prize winning (John B. Fenn, 2002) ESI source is very powerful as it provides a near-universal source for ions: essentially any ion that forms spontaneously in solution, can be sprayed in a droplet into the gas phase and be liberated as a free or solvated ion. The ESI interface in our instrument permits complete desolvation of electrosprayed ions. Moreover, this desolvation region can be used to fragment weaker covalent bonds, further extending the di-

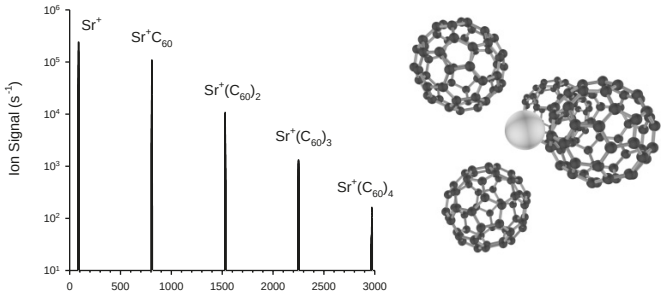
versity of reactant ions generated by the ESI source. Mass selection prior to entering the flow tube removes complications due to charge state distributions and can eliminate complications due to isotope distributions. The operation of the instrument has been demonstrated with a selection of reactivity and kinetic measurements and threshold collision-induced dissociation determinations. Reactions investigated include H–D exchange between protonated bradykinin and deuterated ammonia, the protonation of the oligo-nucleotide anion $[AGTCTG\text{-}5H^+]^{5-}$ with HBr, the ozonolysis of Ca^{2+}, the reaction of protonated phthalic anhydride with dimethyl disulfide, and the Ar collision-induced dissociation of $Ba(C_6H_6)^{2+}$.

The chemistry of atomic metal dications

The ESI source provides access to multiply charged atomic ions that are formed in solution. Recently we have extracted doubly charged atomic cations of the alkaline earth metals from solutions of their salts. An early result shown in Fig. 38 indicates that the oxidation of the calcium dication

Fig 36. ICP/SIFT/QqQ mass spectrum and proposed tetrahedral structure for $Sr(C_{60})_4^+$ (95).



with ozone proceeds first by charge separation and then by sequential O-atom abstraction. The Ba dication on the other hand was observed simply to add up to four ozone molecules to form fascinating ozone clusters such as $Ba(O_3)_4^{2+}$ (97). We are able now to extract singly charged atomic cations from solution and some of their oxides and hydroxides and to measure their reactions as well.

The intrinsic reactivity of multiply charged oligonucleotides

We are now also able to probe, for the first time, intrinsic chemical properties of multiply charged biological ions, including highly charged DNA-like anions, derived by ESI. We have shown that such anions can be produced by ESI, injected into our flow reactor, and exposed to chemical reactions in the gas phase (98). This allows the quantitative measurement for the very first time of *intrinsic* kinetic and thermodynamic properties of reactions of such biological ions at room temperature. We began with studies of the chemistry of the oligo-nucleotide $[AGTCTG\text{-}nH]^{n-}$ anions. Against our wishes, these anions were found generally to be quite unreactive in the gas phase (see Fig. 39), a result that is perhaps not surprising in retrospect because *Mother Nature* wished it so! The oligonucleotide $[AGTCTG\text{-}nH]^{n-}$ anions were found to be intrinsically stable; they could not be oxidized with strong oxidants, were not hydrated with D_2O, and were not easily protonated. No reactions, $k < 10^{-13}$ cm^3 molecule^{-1} s^{-1}, were observed with O_2, N_2O, O_3, D_2O, and benzene, for n = 2, 3, 4, and 5. However, proton transfer from HBr to the $[AGTCTG\text{-}5H]^{5-}$ anion (see Fig. 40) was observed to be rapid, $k = 3.2 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}, and also to proceed sequentially to produce ultimately the $[AGTCTG\text{-}2H]^{2-}$ anion according to charge-separation reactions of the type indicated in reaction (37).

$$[37] \quad [AGTCTG\text{-}nH]^{n-} + HBr \rightarrow [AGTCTG\text{-}(n-1)H]^{(n-1)-} + Br^-$$

The measured reaction profiles for sequential proton transfer and an overview of the complete chemistry that was identified are shown in Fig. 40. Extensive HBr addition to the oligonucleotide was observed to compete with proton transfer. From 5 to 7 molecules of HBr were observed to add to each of the four charge states of the oligonucleotide anions and this is interpreted as addition to the various basic sites of the nucleobase substituents. HBr is effective in "counting" the number of such available sites (99).

As shown in Fig. 40, the measured reaction rates with HBr increase with increasing charge state from 2– to 5–, but

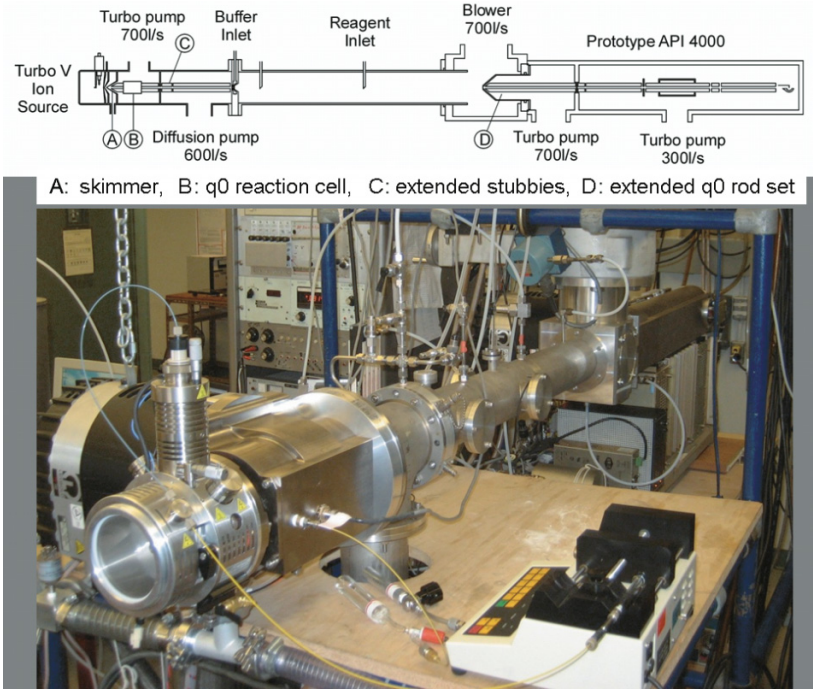

Fig. 38. (Left) Experimental results obtained for the gas-phase ozonolysis of calcium dications in He buffer gas at 0.35 Torr and 295K (97). (Right) The chemical reactions and their kinetics that explain the experimental observations (97). The Ca^{2+} ions were derived from a solution of 100 mM CaAcetate in H_2O/CH_3OH (1/1).

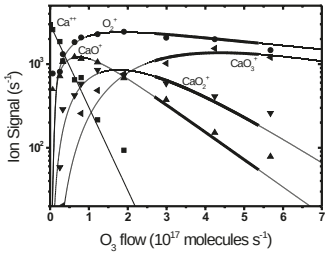

$Ca^{++} + O_3 \rightarrow CaO^+ + O_2^+$
($k = 1.5 \times 10^{-9}$ cm^3 mol^{-1} s^{-1})

$CaO^+ + O_3 \rightarrow CaO_2^+ + O_2$
($k = 5 \times 10^{-10}$ cm^3 mol^{-1} s^{-1})

$CaO_2^+ + O_3 \rightarrow CaO_3^+ + O_2$
($k = 6 \times 10^{-10}$ cm^3 mol^{-1} s^{-1})

the efficiency of reaction, k_{obs}/k_{cap} (where k_{cap} is the computed capture rate coefficient) remains unchanged and equal to 1 within experimental uncertainty. Proton transfer predominates (> 70%) with the two highest charge states, drops to 20% for the 3– charge state, and does not occur with the 2– anion.

Fig. 39. Summary of the intrinsic non-reactivity of [AGTCTG-*n*H]$^{n-}$ observed under SIFT conditions in He at 0.35 Torr and 295 K (98).

	k_{295} (cm^3 molecule^{-1} s^{-1})	
+ O_3	<10^{-13}	No oxidation
+ O_2	<10^{-13}	
+ N_2O	<10^{-13}	
+ D_2O	<10^{-13}	No hydration
+ C_6H_6	<10^{-13}	No intercalation
+ HBr	fast	Protonation Hydrobromination

New horizons

We are very encouraged with the performance of our new ESI/qQ/SIFT/QqQ instrument and are now extending our measurements in still other directions. For example, we are exploring the influence of metal dications on the reactivity of oligonucleotide anions. Recently we have investigated the influence of Zn^{2+} on the hydrolysis of beta-lactam antibiotics in the gas phase and have explored the oxidation of metal – tetraphenyl porphyrin, bleomycin, fatty acid, and lipid cations in the gas phase.

In a separate study of the kinetics of ion–molecule reactions of potential use in the suppression of chemical noise in mass spectrometry (100), we have used the ESI/qQ/SIFT/QqQ multipole mass spectrometer to explore the reactivity of dimethyl disulphide with a number of chemical background ions commonly observed in atmospheric pressure ionization mass spectrometry along with several model analyte ions such as protonated caffeine and doubly protonated bradykinin. Background ions that were studied include protonated acetonitrile, phosphoric acid, phthalic anhydride, and triphenyl phosphate.

Clearly our newest SIFT mass spectrometer will challenge our ingenuity in the study of new ion–molecule reactions for many years to come. There is much else left to be learned!

Acknowledgments

First I want to thank John Goodings, my Ph.D. supervisor, and Eldon Ferguson, my postdoctoral mentor, for my formative years as a research scientist. Much of the credit for the achievements in my own research laboratory belongs to the students and postdoctoral fellows that joined my research group over the years, especially Simon Petrie with whom I continue to collaborate, and my research associate, Greg Koyanagi, and I am grateful to all of them for their valued contributions and inspiration. The continuous financial support over the years from the Natural Sciences and Engineering Research Council of Canada (NSERC) is greatly appreciated. Also, I acknowledge support from the National Research Council Canada, the Natural Science and Engineering Research Council, and MDS SCIEXciex in the form of several Research Partnership grants. Timely Research Fellowships from the A.P. Sloan, A.V. Humboldt, and Killam Foundations need to be recognized with thanks. Finally, as holder of a Canada Research Chair in Physical Chemistry, I also acknowledge the contributions of the Canada Research Chair Program to my research over the past seven years.

Highly selective oxidation of toluene using air over [Fe(III)TPP]Cl supported on chitosan

Guan Huang, Chun-Cai Cai, Jin Luo, Hong Zhou, Yong-An Guo, and Shang-Yue Liu

Abstract: The highly selective catalytic oxidation of toluene with air to benzaldehyde and benzyl alcohol in the liquid phase has been studied with the use of iron tetraphenylporphyrin (Fe TPP) supported on chitosan (CTS), (Fe TPP/CTS). The rates of toluene conversion and selectivity (aldehyde + alcohol) were subject to the reaction temperature, air pressure, and amount of iron tetraphenylporphyrin. By the use of the Fe TPP/CTS, containing 2 mg of iron tetraphenylporphyrin as catalyst, toluene oxidation with air under the optimum conditions of 190 °C and 0.6 MPa produced benzaldehyde and benzyl alcohol at 90% selectivity and 5.4% conversion of toluene, the mole turnover of the catalyst was about 6×10^6, and it could be reused efficiently for one more time. It is suggested that the amine groups ($-NH_2$) on the chitosan chain act as a key assistor to the catalysis of Fe TPP for toluene oxidation. Compared with the conventional method of synthesizing benzaldehyde and benzyl alcohol, the new method has the advantages of reduced environmental pollution, higher selectivity for the two main products, and easy recovery of the catalyst.

Key words: chitosan-supported iron porphyrin, catalysis, toluene oxidation, benzaldehyde, benzyl alcohol.

Résumé : Utilisant un catalyseur formé de tétraphénylporphyrine-fer (TPP Fe) déposé sur du chitosane (CTS), (TPP Fe/CTS), on a étudié l'oxydation catalytique hautement sélective en phase liquide du toluène par l'air qui conduit à la formation de benzaldéhyde et d'alcool benzylique. Les vitesses de conversion du toluène et la sélectivité (aldéhyde + alcool) varient avec la température de la réaction, la pression de l'air et la quantité de tétraphénylporphyrine-fer. Lorsqu'on utilise du TPP Fe/CTS contenant 2 mg de tétraphénylporphyrine-fer comme catalyseur, dans les conditions optimales pour l'oxydation du toluène par l'air de 190 °C et de 0,6 MPa, il y formation de benzaldéhyde et l'alcool benzylique avec une sélectivité de 90%, une conversion de 5,4% du toluène et une réutilisation molaire interne du catalyseur d'environ 6×10^6 qui pouvait être réutilisé efficacement au moins une fois. On croit que les groupes amino ($-NH_2$) de la chaîne du chitosane sont des assistants clés pour la catalyse de l'oxydation du toluène par la TPP Fe. Par comparaison avec la méthode conventionnelle de synthèse du benzaldéhyde et de l'alcool benzylique, la nouvelle méthode présente des avantages en raison d'une réduction de la pollution environnementale, d'une grande sélectivité pour les deux produits principaux et de la facilité de récupération du catalyseur.

Mots-clés : porphyrine-fer déposée sur du chitosane, catalyseur, oxydation du toluène, benzaldéhyde, alcool benzylique.

Introduction

Benzaldehyde and benzyl alcohol are versatile intermediates in the chemical industry; therefore, much work has been devoted to the selective oxidation of toluene with air to synthesize these industrial products (1–3). Environmentally friendly and clean production processes are urgently required in the chemical industry. Although homogeneous catalysis for the oxidation of hydrocarbons has long been practiced in large-scale oxidation reactions (4), there are problems with corrosion, pollution, and recovery of the catalyst from the reaction mixture. Most of the problems related to the homogeneous catalyst can be solved by supporting the catalyst on an insoluble support (5). For example, impregnation of expensive metalloporphyrin catalysts on insoluble organic and inorganic supports can improve their stability and selectivity because of the support environment, and there are other advantages with respect to recovery and reuse. Supported metallo-porphyrins also provide physical separation of active sites, thus minimizing catalyst self-destruction (6). In the past decade, oxidation of hydrocarbons, catalyzed with molecular oxygen, by supported metalloporphyrins under mild conditions has attracted much interest because of its potential application and the environmentally friendly conditions (7, 8). However, there are few reports concerning the direct oxidation of toluene with air catalyzed by supported metalloporphyrin. When a simple metalloporphyrin (M TPP/CTS) was supported on polysaccharides as a catalyst for oxidation of cyclohexane using air, the best results (higher catalytic activity, better selectivity, and more efficient reuse) were obtained with chitosan as the support (9, 10).

The present work describes a new approach to the heterogeneous liquid-phase oxidation of toluene by air to benzaldehyde and benzyl alcohol; it uses iron tetraphenyl-

porphyrin supported on chitosan as catalyst. The system was tested under different temperatures and air pressure values and with different amounts of the catalyst. The data obtained are compared with those obtained with the unsupported catalyst.

Experimental

Instruments and reagents

The instruments used were a PE L-17 spectrometer (UV–vis), a PE-783 spectrometer (IR), a Class-5000 GC–MS spectrometer and an Agilent 1100LC-MS, a Shimadzu GC-16A equipped with a 0.5 mm i.d. × 25 m PEG20000 capillary column and flame ionization detector, and a WDF High Pressure Reactor with a high-speed magnetic agitator.

All reagents and solvents were analytical-grade and were obtained commercially. No impurities were found in the toluene by GC analysis before use. Fe TPP was synthesized according to the documented procedures (11).

Preparation of chitosan-supported Fe TPP

A mixture of 100 mL diluted hydrochloric acid and 4 g chitosan in a three-necked flask with an electro-magnetic stirrer was stirred at room temperature for 10 min. Then, 400 mL of distilled water was added to form the colloidal solution to which 5% NaOH solution was added until it became neutral. Then, 0.1 g of chloro[tetraphenylporphyrinato]iron(III) (Fe TPP) dissolved in 240 mL chloroform was slowly added. The mixture was vigorously stirred for 4 h, the reaction was stopped, and the mixture was filtered by pumping and then washed with distilled water; 3.90 g of brown solid was obtained by means of drying the filter cake at low temperature. This filtrate was used to analyze the amount of Fe TPP in the solid product. The amount of Fe TPP supported per 1 g chitosan was 0.0280 mmol as determined by UV–vis spectrophotometer technique (12).

Characterization of the supported catalyst

The supported catalyst was characterized by UV–vis spectroscopy by the same method (7). The electronic spectrum of the supported Fe TPP was obtained in a glycerol mull in a quartz vessel, and the UV–vis spectrum of Fe TPP/CTS was compared with that of Fe TPP in the region of 300–750 nm (Fig. 1). The chloroform extraction from the powder of the solid catalyst was measured by UV–vis spectrophotometry (Fig. 1*a*).

FTIR spectra were recorded on a PerkinElmer model 783 IR spectrophotometer in the range of 4000–450 cm^{-1} at a resolution of 2 cm^{-1}. Dry chitosan and chitosan-supported iron tetraphenylporphyrin samples were ground into fine powder, mixed with KBr, and then were pressed into their thin pellets, which were placed in the sample holder of the spectrometer to assay their spectra. IR spectra for them were shown in Fig. 2.

Procedure for the catalytic oxidation of toluene

Catalytic oxidation of toluene using air was performed according to the following standard reaction procedures: toluene (350 mL) and Fe TPP/CTS catalyst (containing 2 mg Fe TPP) were placed in a 500 mL autoclave reactor charged with nitrogen at 0.6 MPa. The reaction mixture was heated to 190 °C under stirring, and air was continuously injected at 0.020 m^3/h to maintain the pressure at 0.6 MPa. Subsamples of the reaction mixture were taken at regular intervals and analyzed by GC–MS. The oxygenated products were quantified by GC using chlorobenzene as the internal standard (13). The supported catalyst was recovered by simple separation from the reaction mixture followed by washing with ethanol and drying in air, and it was used in subsequent toluene oxidation.

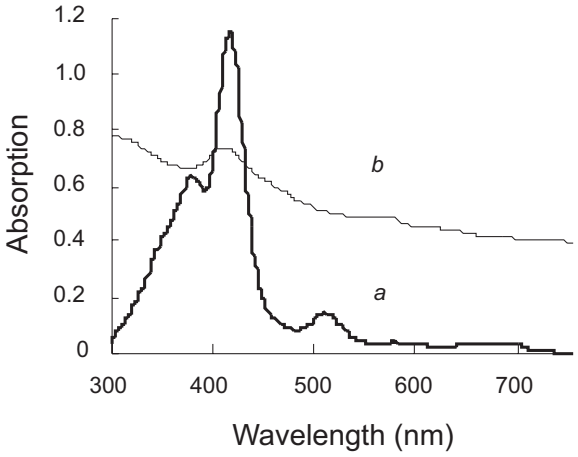

Fig. 2. FTIR spectra of pure chitosan (1) and chitosan-supported iron tetraphenylporpnyrin complex (2) with an effective frequency range of 4000–450 cm^{-1}.

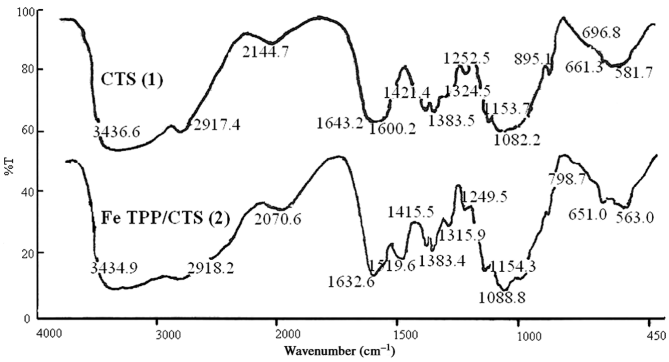

Results and discussion

Characterization of chitosan-supported Fe TPP

Fe TPP was successfully supported on CTS as shown by the UV–vis spectrum of a suspension of the material in a glycerol mull. The spectrum presented the characteristic Soret peak of the metalloporphyrin at 411 nm and the two Q peaks at 572 nm and 622 nm (Fig. 1*b*). The presence of the red-shifted Soret peak and the two Q peaks between 500 and 700 nm was similar to the UV–vis spectra of diamino metalloporphyrins reported by Yoshimura and Kobayashi (14). It indicates that the Fe TPP had been immobilized on the structure of the chitosan. The chloroform extraction from the powder of the solid catalyst presented the same peaks as

© 2008 NRC Canada

those shown in Fig. 1*a*, again showing that the metalloporphyrin had been adsorbed on the support.

The IR spectra of the two samples studied are characterized by the absorption bands of chitosan and its iron tetraphenylporphyrin complex (see Fig. 2): (A) a broad unstructured absorption around 3430 cm^{-1} related to the superposition of stretching vibrations for OH and NH groups; (B) narrow bands of stretching vibrations for CH group at ~2920 cm^{-1} and little shoulder bands near by them, assigned to CH (at ~2920 cm^{-1}) and CH_2 (at 2860–2930 cm^{-1}) fragments, which are similar to the reports (15); and (C) the carbonyl O=C–NHR band, observed at ~1643 cm^{-1}, and the amine $–NH_2$ band, observed at ~1600 cm^{-1}, for their deforming vibrations (see Fig. 2 (**1**)) (16). When iron tetraphenylporphyrins were added to chitosan to form a solid complex, the key bands assigned to chitosan in the complex shifted to lower wavenumbers. The carbonyl band is observed to shift to as low as 1632 cm^{-1} and the amine band to as low as 1519 cm^{-1} (see Fig. 2 (**2**)). These indicate that there is a strong interaction between the nitrogen atom in chitosan and iron tetraphenylporphyrin. It is known that the amine groups ($–NH_2$) on the chitosan chain act as electron donors. The nitrogen electrons present in the amine groups can establish dative bonds with transition-metal ions (17).

Catalysis of Fe TPP and Fe TPP/CTS for toluene oxidation

The role of the main catalysts, containing transition metals, in the partial oxidation of toluene has received much attention (2, 18). High activity and good selectivity for the oxidation of toluene are generally achieved by the Mo-based and V-based oxides (19). However, the chemical oxidation of toluene is not a suitable method for large-scale production of benzaldehyde and benzyl alcohol. Fe_2O_3 has been found to be a catalyst for complete oxidation of toluene under certain reaction conditions (19), and its catalytic activity can be regulated by changing the nature of the chemical bond and the microenvironment of the iron ion. Since Fe TPP and the corresponding chitosan-supported catalyst appeared to be suitable, they were tested as catalysts for toluene oxidation. We found that both could selectively catalyze aerobic oxidation of toluene to benzaldehyde and benzyl alcohol under our reaction conditions. The reaction catalyzed by the supported catalyst, or by the unsupported catalyst, with air is described in Scheme 1.

GC–MS and LC–MS analyses indicated that the by-products of toluene oxidation were chiefly benzoic acid, and to a lesser extent, benzyl benzoate, which can be disregarded. In the absence of the catalysts, toluene can not be oxidized by air under the same conditions.

Figure 3 shows the changes of benzaldehyde, benzyl alcohol, benzoic acid, and selectivity (aldehyde + alcohol) with reaction time for the aerobic oxidation of toluene catalyzed by Fe TPP/CTS and Fe TPP, respectively. The two catalysts had similar effects, i.e., the amounts of benzaldehyde and benzyl alcohol increased with reaction time to a maximum and then fell. First, it was because the desired products were partially oxidized into by-products, as a result, those of benzoic acid increased throughout and more and more. Second, iron tetraporphyrin catalyst suffered from oxidation degradation and lost its catalytic activity. With both catalysts, toluene oxidation is attributable to the iron ion coordinated by the four nitrogen atoms in porphyrin, but there were quantitative differences. Fe^{3+} in the supported catalyst gained more assistance of the nitrogen electrons present in the amine groups in chitosan than those in the unsupported catalyst; this has been explained by the IR spectra of Fe TPP/CTS. It is probable that chitosan had a great effect on Fe TPP or that it changed the original potential of Fe TPP by the action of amino groups, which conferred better activity and selectivity on Fe TPP/CTS. Therefore, after 3 h reaction time, the concentrations of the main products, benzaldehyde and benzyl alcohol, and of the by-product, benzoic acid, and even selectivity for main products were all higher with the supported catalyst than with the unsupported catalyst (Fig. 3). Based on the previous researches (9, 10), we suggest that it is probable that the amino of chitosan took part in the catalytic process, elevating the catalytic activity of the supported catalyst and more increasing the amount of main products, and the results were the increment of the toluene conversion, catalyst turnover, and selectivity for main products shown in Fig. 3 and Table 1 in which the data were obtained when the amount of main products reached the maximum in the oxidation process. At 4.5 h reaction time, the conversion of toluene was up to 5.5%, the selectivity of benzaldehyde and benzyl alcohol was about 91%, which is higher than the corresponding value for Fe TPP (Fig. 3), and the mole turnover of the catalyst reached 6 130 000 for the supported catalyst. Under the same reaction condition, the recovered supported

Table 1. The results of toluene oxidation catalyzed by Fe TPP/CTS and Fe TPP.

	Reaction products (mol%)					
Catalysts	Aldehyde	Alcohol	Acid	Selectivity (%)	Conversion (%)	Turnover number ($\times 10^6$)
Fe TPP/CTS	2.21	2.75	0.51	90.7	5.47	6.13
Fe TPP	0.87	0.29	0.12	90.6	1.26	1.44

Note: For reaction conditions, see Fig. 3. Reaction times are 4.5 h and 3 h for Fe TPP/CTS and Fe TPP, respectively.

catalyst catalyzed aerobic oxidation of toluene into main products with 5.2% toluene conversion and 89% selectivity to aldehyde and alcohol for once. The results are better than those for the unsupported catalyst in terms of toluene conversion and turnover number. This is in good agreement with the results of cyclohexane oxidation catalyzed by Fe TPP/CTS (10). Toluene oxidation has potential for the industrial production of benzaldehyde because it requires no more equipment than the conventional method of synthesizing benzaldehyde and benzyl alcohol, needs less extreme reaction conditions, and results in less environmental pollution. It was necessary to assess the effect of reaction temperature, air pressure, and quantity of Fe TPP/CTS catalyst on the toluene conversion and the selectivity for main products.

Influence of reaction temperature on toluene oxidation

Toluene conversion increased with each increment of reaction temperature from 170 to 190 °C, but at 200 °C, toluene conversion decreased (Fig. 4). The reason is that the supported catalyst was partially and gradually burned out in the oxidation process, thereby weakening its power, because when the recovered catalyst was employed to catalyze aerobic oxidation of toluene, no products were detected by GC. At <130 °C, very little benzaldehyde and benzyl alcohol was produced. Not only the toluene conversion but also the changes in selectivity to the main products (aldehyde + alcohol) were influenced by reaction temperature (Fig. 5). In general, the ratio of selectivity to reaction time differed in size in the order 200 °C > 190 °C > 180 °C > 170 °C, especially after a reaction time of 3 h. This indicates that overheating can be detrimental to the selective formation of aldehyde and alcohol, with the excessive temperature and longer reaction time favoring the production of benzoic acid. On the basis of these results for toluene conversion and selectivity, 190 °C was chosen as an optimum reaction temperature for further investigations of the effect of air pressure on the catalysis of Fe TPP/CTS for toluene oxidation.

Influence of air pressure on toluene oxidation

Generally, toluene conversion increased at a different pitch with reaction time (see Fig. 6). Under 0.8 MPa and 0.4 MPa air pressures, the toluene conversion increased with oxidation proceeding, reaching 2.88% and 2.05% at 2.5 h reaction time, respectively, and then the increment of toluene conversion slowed down. Under 0.6 MPa, however, toluene conversion increased at first, and then the increment also slowed down until 5.47% toluene conversion was obtained at 4.5 h reaction time. This indicates that at the highest air pressure tested (0.8 MPa), the dioxygen solubility in the liquid-phase toluene is higher, and the supported catalyst tends partially to break up and lose activity, thereby reducing its catalytic power to a level similar to that seen under 0.4 MPa. In addition, air pressure of 0.8 MPa caused a reduction in selectivity, with many main products being oxidized into benzoic acid (Fig. 7). At the lowest air pressure (0.4 MPa), the activated oxygen atoms in the catalytic reaction system were too few to oxidize toluene into more products, and this directly resulted in low toluene conversion and, since no more activated oxygen was available further to oxidize the main products into by-products, selectivity was high (Fig. 7). The most appropriate air pressure proved to be 0.6 MPa, which allowed not only the highest toluene conver-

sion (~5.5%; Fig. 5) but also considerable selectivity (90%; Fig. 7).

Influence of the amount of catalyst on toluene oxidation

With a reaction time of 4.5 h at 190 °C and 0.6 MPa, the amount of supported catalyst (1, 2, or 4 mg) had little effect on the product selectivity (Table 2). Toluene conversion increased significantly with an increase in catalyst from 1 to 2 mg but decreased with a further increase in catalyst to 4 mg. A similar phenomenon was observed in our previous work (10). This behavior can be identified with the so-called "catalyst inhibitor conversion" phenomenon already known for some auto-oxidations catalyzed by transition-metal salts in low polar media (20). Obviously, the optimum amount of catalyst is 2 mg.

Conclusions

Chitosan-supported iron(III) tetraphenylporphyrin is a catalyst for aerobic oxidation of toluene with high selectivity to main products and moderate toluene conversion under the optimum reaction conditions. It offers the opportunity to avoid some of the problems experienced with the traditional catalyst with regard to corrosion, pollution, and recovery of catalyst from the reaction mixture. Further studies in our laboratory will consider its high-efficiency reuse for catalytic oxidation of toluene with air under high temperature.

A novel limonoid from the seeds of *Chisocheton siamensis*

Surat Laphookhieo, Wisanu Maneerat, Sorwaporn Koysomboon, Rattana Kiattansakul, Kan Chantrapromma, and John Keith Syers

Abstract: Analysis of an acetone/hexane (1:1) extract of the seeds of *Chisocheton siamensis* led to the isolation of a novel limonoid, chisosiamensin (**1**), along with five known limonoids, dysobinin (**2**), azadiradione (**3**), mohinin (**4**), epoxyazadiradione (**5**), and 6α-acetoxyepoxyazadiradione (**6**). Their structures were characterized by spectroscopic methods, including UV, IR, NMR, and MS. All isolated limonoids were reported for the first time as secondary metabolites of *C. siamensis*.

Key words: Chisocheton siamensis, Meliaceae, chisosiamensin, limonoids.

Résumé : L'analyse d'un extrait par un mélange acétone-hexane (1:1) de graines de *Chisocheton siamensis* a permis d'extraire un nouveau limonoïde, la chisosiamensine (**1**), aux côtés de cinq limonoïdes connus, la dysobinine (**2**), l'azadiradione (**3**), la mohinine (**4**), l'époxyazadiradione (**5**) et la 6α-acétoxyépoxyazadiradione (**6**). On a caractérisé leurs structures par des méthodes spectroscopiques, incluant l'UV, l'IR, la RMN et la SM. Tous les limonoïdes isolés ont été identifiés pour la première fois comme métabolites secondaires du *C. siamensis*.

Mots-clés : Chisocheton siamensis, Meliaceae, chisosiamensine, limonoïdes.

[Traduit par la Rédaction]

Introduction

Meliaceae plants are known to be rich sources of limonoids. A number of limonoids have been isolated from several genera of Meliaceae and some of these exhibit antimalarial (1, 2), cytotoxic (3, 4), antiprotozoal (5), and antifeedant (6, 7) activities. *Chisocheton siamensis* is one of the Meliaceae plants, which is found in the northern part of Thailand. This plant has been used by local Thai people as anti plant pathogen and antimalarial. In the continuation of our research on secondary metabolites from Thai medicinal plants (8, 9), we have studied an acetone/hexane (1:1) extract of the seeds of *C. siamensis* identified a new limonoid, chisosiamensin (**1**), along with five known compounds (**2**–**6**). In this paper, we describe the isolation and identification of a new and known limonoids isolated from the seeds of *C. siamensis*. The plausible biogenetic pathway of the new compound **1** and limonoids **4**–**6** is also reported.

[a]The chisosiamensin data were analyzed by DEPT 90° and 135°.

cluding quick column chromatography (QCC) and column chromatography (CC) and crystallization to afford a new limonoid, chisosiamesin (**1**), along with five known limonoids (**2**–**6**).

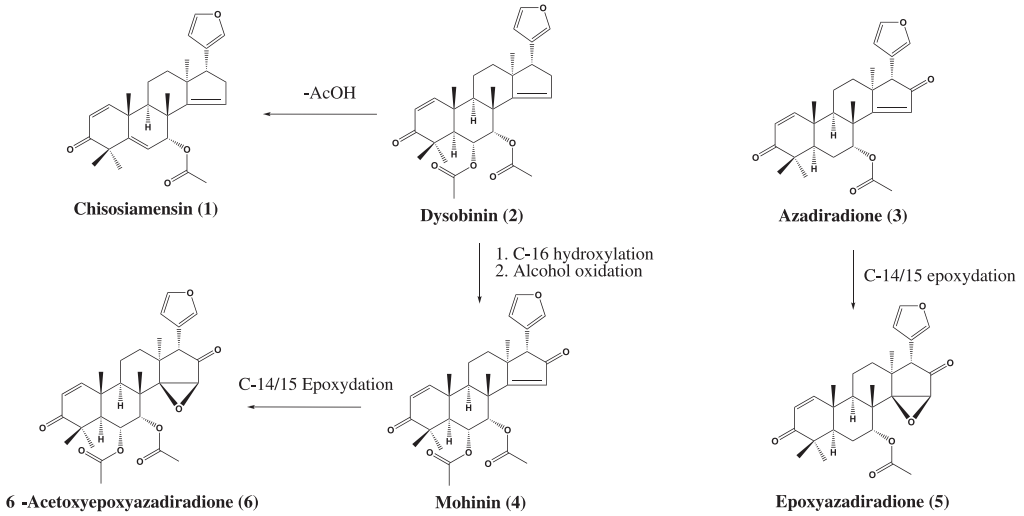
The ^{1}H NMR spectra of limonoids isolated from the seeds of *C. siamensis* that were tetranortriterpenoids indicated that all compounds contained an α,β-unsaturated ketone at ring A and a β-furan moiety at C-17 of ring D. Three of these were connected with two acetoxyl groups at C-6 and C-7 in ring B, which existed in compounds **2**, **4**, and **6**, whereas limonoids **1**, **3**, and **5** consisted of an acetoxyl group at C-7. In addition, compounds **3** and **4** also contained an additional α,β-unsaturated ketone at ring D, while compounds **5** and **6** had an epoxy ketone instead of an α,β-unsaturated ketone.

Chisosiamensin (**1**) was isolated as a colorless viscous oil with a molecular ion peak at m/z 435.4526 $[M + H]^+$ in HREI–MS, corresponding to the molecular formula $C_{28}H_{34}O_4$. The UV spectrum indicated the presence of α,β-unsaturated ketone at 218 nm, while the IR spectrum of this compound showed two carbonyl functionalities at 1750 and 1680 cm^{-1}. Compound **1** was classified as tetranortriterpenoidal limonoid by the presence of five methyl singlets at δ: 0.78 (Me-18), 1.07 (2 × Me, Me-19, and Me-30), 1.19 (Me-28), and 1.22 (Me-29) and a β-furan moiety at δ: 6.27 (s, H-22), 7.23 (s, H-21), and 7.37 (s, H-23) in the ^{1}H NMR spectrum (10, 11). The ^{1}H NMR and ^{13}C NMR spectral data of **1** (Table 1) were similar to nimonol (**7**), isolated from *Azadirachta indica* (10), except that **1** showed an olefinic proton at δ: 5.33 (m), which was connected to sp^2 carbon at δ: 129.7 (C-6) in the HMQC experiment, instead of the two methine protons (H-5 and H-6) of nimonol (Table 1). These results indicated that compound **1** consisted of a double at C-5/6. Therefore, chisosiamensin was identified as **1**, a dehydrated derivative of nimonol.

The remaining limonoids (**2**–**6**) were characterized as dysobinin (**2**) (12), azadiradione (**3**) (2), mohinin (**4**) (13), epoxyazadiradione (**5**) (14), and 6α-acetoxyepoxyazadiradione (**6**) (15) by the analysis of 1D and 2D NMR data and by comparison with their reported physical and spectroscopic data. It should be noted that the plausible biogenetic pathway of three limonoids (**1**, **4**, and **6**) could be derived from dysobinin (**2**) (Scheme 1). The elimination of AcOH of dysobinin produced chisosiamensin, whereas the hydroxylation at C-16 of dysobinin followed by alcohol oxidation yielded mohinin (**4**). Epoxidation at C-14/15 of mohinin (**4**) gave 6α-acetoxyepoxyazadiradione (**6**). In the case of epoxyazadiradione (**5**), this compound could be de-

© 2008 NRC Canada

Scheme 1. Plausible biogenetic pathway of compounds **1** and **4–6**.



rived from the epoxidation at C-14/15 of azadiradione (**3**) (Scheme 1). Finally, the control experiment of compound **2** (dysobinin) was done. Unfortunately, no compound **1** (chisosiamensin) was observed from this experiment. Therefore, compound **1** was a natural product produced from the seeds of this plant.

It is worth noting that a number of limonoids have been isolated from the Meliaceae species. However, less than 30 compounds have been isolated from the genus *Chisocheton*. In this study, we isolated an additional novel limonoid from the seeds of *C. siamensis* and all isolated limonoids were reported for the first time as secondary metabolites of *C. siamensis*.

Experimental section

General

Melting points were determined using a Fisher–John melting point apparatus. The optical rotation $[\alpha]_D$ values were determined with a JASCO P-1020 digital polarimeter. UV spectra were measured with a UV-160A spectrophotometer (Shimadzu). The IR spectra were measured with a PerkinElmer FTS FT-IR spectrophotometer. The ^{1}H NMR and ^{13}C NMR spectra were recorded using a 300 MHz Bruker FTNMR Ultra Shield spectrometer. Chemical shifts were recorded in parts per million (δ) in $CDCl_3$ with tetramethylsilane (TMS) as the internal reference. The EIMS was obtained from a MAT 95 XL mass spectrometer. Quick column chromatography (QCC) and column chromatography (CC) were carried out on silica gel 60 H (Merck, 5–40 μm) and silica gel 100 (Merck, 63–200 μm), respectively. Precoated plates of silica gel 60 F_{254} were used for the analytical procedure.

Plant material

Seeds of *C. siamensis* were collected from Queen Sirikit Garden, Mae Rim District, Chiang Mai Province, northern Thailand, in February, 2006. The botanical identification was made by Dr. Prachaya Srisanga, botanist at Queen Sirikit Garden. Voucher specimens are deposited in the Herbarium of Queen Sirikit Garden, Mae Rim District, Chiang Mai, Thailand.

Extraction and isolation

Seeds of *C. siamensis* (600 g) were extracted with acetone/hexane (1:1) over the period of 3 days at room temperature. The mixture was filtered and concentrated under reduced pressure to provide the crude extract (62.21 g). This crude extract was subjected to quick column chromatography (QCC, column size: 12 cm × 16 cm) over silica gel and eluted with a gradient of EtOAc/hexane to afford 13 factions (A1–A13). Fraction A2 (435.9 mg) was subjected to column chromatography (CC) using 15% EtOAc/hexane to give compound **1** (51.2 mg). Fraction A4 (4.0 g) upon standing at room temperature yielded compound **2** (3.30 g). Compound **5** (227.0 mg) was obtained from fraction A6 (576.9 mg) after repeated CC with 25% EtOAc/hexane. Purification of fraction A8 (1.01 g) by CC with 25% EtOAc/hexane gave compounds **6** (17.2 mg) and **3** (31.2 mg). Compound **4** (18.2 mg) was obtained from fraction A10 (65.5 mg) by repeated CC using 5% EtOAc/CH_2Cl_2 as eluent.

Control experiment of dysobinin (2)

A solution of dysobinin (10 mg) and 1:1 acetone/hexane (2 mL) was stirred at room temperature for three days. The solution mixture was monitored by TLC (15% EtOAc/hexane) and only dysobinin was observed on the TLC.

Chisosiamensin

Colorless viscous oil. $[\alpha]^{27}_D$ +49.0° (*c* 0.04, MeOH). UV λ_{max} (log ε) (MeOH): 218 (4.37). IR (neat): 1750, 1680. For ^{1}H NMR and ^{13}C NMR see Table 1. EI-MS *m/z*: 435 (87) $[M + H]^+$. HR-EI-MS *m/z*: 435.4526 $[M + H]^+$.

Diastereoselective bismuth triflate catalyzed Claisen rearrangement of 2-alkoxycarbonyl-substituted allyl vinyl ethers

Thierry Ollevier and Topwe M. Mwene-Mbeja

Abstract: In the presence of a catalytic amount of bismuth triflate, 2-alkoxycarbonyl-substituted allyl vinyl ethers as a mixture of enol ether double bond isomers were smoothly converted into the β,γ-alkyl-substituted α-keto esters. The isomerization reaction proceeded rapidly to afford smoothly the α-keto esters in good to excellent yields using catalytic amounts of $Bi(OTf)_3 \cdot 4H_2O$ (1 mol%). (*Z,Z*)-2-*iso*-Propyloxycarbonyl-substituted allyl vinyl ethers $\mathbf{3_{Z,Z}}$ afforded the corresponding β,γ-alkyl-substituted α-keto esters **4** with very good *syn* diastereoselectivity.

Key words: bismuth; bismuth(III) triflate; Claisen rearrangement; allyl vinyl ethers.

Résumé : En présence d'une quantité catalytique de triflate de bismuth, les allyl vinyl éthers substitués par un groupement 2-alcoxycarbonyl, et sous la forme d'un mélange d'isomères au niveau de la double liaison de l'éther d'énol, sont facilement convertis en α-céto esters β,γ-alkyl-substitués. La réaction d'isomérisation a lieu rapidement et conduit aux α-céto esters dans des rendements bons à excellents à l'aide de quantités catalytiques de $Bi(OTf)_3 \cdot 4H_2O$ (1 mol %). Les allyl vinyl éthers $\mathbf{3_{Z,Z}}$ substitués par un groupement (*Z,Z*)-2-*iso*-propyloxycarbonyle conduisent aux α-céto esters **4** β,γ-alkyl-substitués correspondants avec une très bonne diastéreosélectivité *syn*.

Mots-clés : bismuth; triflate de bismuth(III), réarrangement de Claisen, allyl vinyl éthers.

[Traduit par la Rédaction]

Introduction

The thermal aliphatic Claisen rearrangement of allyl vinyl ethers has been studied in numerous applications since the first example was reported by Claisen in 1912 (1). A limited number of metal catalysts that accelerate the Claisen rearrangement have been disclosed (2), i.e., lanthanides complexes (3), $TiCl_4$ (4), or Pd^{II} complexes (5). Recently, some precedents have been disclosed regarding metal salts (Cu^{II}, lanthanides(III), Sc^{III}) as catalysts for the Claisen rearrangement of 2-alkoxycarbonyl-substituted allyl vinyl ethers (6). High catalytic activity, low toxicity, moisture, and air tolerance make lanthanide triflates valuable catalysts (7). However, the high cost of some of these catalysts often restrain their use. Bismuth compounds provide a good alternative as they have recently attracted attention because of their low toxicity, low cost, and good stability (8). Bi^{III} salts have been reported as catalysts for the Sakurai reaction (9), opening of epoxides (10), Mukaiyama-aldol reaction (11), Mannich-type reactions (12), formation or deprotection of acetals (13), Friedel–Crafts reactions (14), and Fries rearrangements (15). $Bi(OTf)_3$ is particularly attractive because it is commercially available or can be easily prepared from commercially available compounds (16).

As a part of our ongoing interest in bismuth(III)-catalyzed Claisen rearrangements (17), we report herein our results in bismuth(III)-catalyzed rearrangement of 2-alkoxycarbonyl-substituted allyl vinyl ethers as a mixture of enol ether double bond isomers. They were prepared from **1** according to Hiersemann's method (18). Esters **1** were treated with LDA at –78 °C in THF, followed by the addition of an aldehyde to provide the desired β-hydroxyesters **2** in good yields but low diastereoselectivity. Mesylation of **2**, followed by treatment of the crude mesylate with DBU, afforded the α,β-unsaturated esters **3** in high yields as a mixture of double bond isomers (Scheme 1). *Z/E* Isomer ratio in **3** rose from 87:13 to 95:5, with the exception of a 68:32 ratio in $\mathbf{3b_{E,Z}}$. The use of this type of allyl vinyl ethers offers advantages in terms of synthesis, stability, and reactivity according to previous studies (2*b*, 18). We disclose herein the preparation of various substrates possessing a *n*-Pr group either in a *Z* or *E* stereochemistry at the allylic ether double bond ($\mathbf{3_{Z,Z}}$ and $\mathbf{3_{E,Z}}$ series).

Received 18 November 2007. Accepted 9 December 2007. Published on the NRC Research Press Web site at canjchem.nrc.ca on 5 February 2008.

Results and discussion

Initially, we screened the Claisen rearrangement on differently R^1-substituted (*Z,Z*)-2-*iso*-propyloxycarbonyl-substituted allyl vinyl ethers $\mathbf{3_{Z,Z}}$ (Table 1). The rearrangement occured with 1 mol% of $Bi(OTf)_3 \cdot 4H_2O$ in toluene. While using MeCN as the solvent did not lead to the formation of any product (Table 1, entry 2), toluene and CH_2Cl_2 were both

[c]Using 5 mol% of $Bi(OTf)_3 \cdot 4H_2O$.

solvents of choice (Table 1, entries 3 and 4). The β,γ-alkyl-substituted α-keto ester was systematically obtained as the major *syn* diastereoisomer $\mathbf{4_{syn}}$. The diastereoselectivity of the catalyzed rearrangement was high with the various substrates tested, except for the benzaldehyde-derived substrate **3c** leading to **4c** with a moderate *syn*/*anti* ratio (Table 1, entry 5). It should also be pointed out that the diastereoselectivity of the rearrangement was also dependent on the stereoisomeric purity of the substrate **3**.

When substrates in the $\mathbf{3_{E,Z}}$ series ((*E*)-configured allylic ether double bonds) were subjected to the same reaction conditions, the rearrangement produced the β,γ-alkyl-substituted α-keto ester **4** in good to excellent yields (Table 2). The *iso*-propyl-substituted derivative was isolated as the *syn* isomer $\mathbf{4_{syn}}$ in very low diastereoselectivity (Table 2, entries 1 and 2). Increasing the catalyst loading up to 5 mol% led to a slight decrease of yield and diastereoselectivity (Table 2, entry 2). The ethyl-substituted allyl vinyl ether showed a low diastereoselectivity in favor of the *anti* diastereoisomer (Table 2, entry 3). Various aryl-substituted substrates afforded the rearranged product with higher but still moderate diastereoselectivity (Table 2, entries 4–6). *o*-Tolyl- and *p*-tolyl-derived (*E,Z*)-2-*iso*-propyloxycarbonyl-substituted allyl vinyl ethers $\mathbf{3(d, e)_{E,Z}}$ led to excellent yields in rearranged products but with low diastereoselectivity (Table 2, entries 5 and entry 6).

At this point, it clearly appears that the ratio and sense of diastereoselectivity depend on the stereochemistry of the allyl ether double bond (compare Table 1, entry 5 with Table 2, entry 4). More detailed investigations on the mechanism of this transformation are in progress.

Conclusion

As an improvement over other catalytic systems, $Bi(OTf)_3 \cdot 4H_2O$ is a versatile catalyst for the rearrangement of 2-alkoxycarbonyl-substituted allyl vinyl ethers. The reaction affords good to excellent yields in the corresponding β,γ-alkyl-substituted α-keto esters **4** with a very good syn diastereoselectivity starting from the (*Z,Z*)-2-*iso*-propyloxycarbonyl-substituted allyl vinyl ethers $\mathbf{3_{Z,Z}}$. This method offers several advantages including mild reaction conditions, highly catalytic process (1 mol%), and no formation of by-products. The conditions are suitable for a variety of starting materials. Also, the practical use of $Bi(OTf)_3 \cdot 4H_2O$ is highly valuable as an environmentally benign Lewis acid. Because of its numerous benefits, this method for the diastereoselective synthesis of β,γ-alkyl-substituted α-keto esters using $Bi(OTf)_3 \cdot 4H_2O$ catalysis should find utility in the synthesis of biologically active compounds. Research is on its way to demonstrate other significant applications of this $Bi(OTf)_3 \cdot 4H_2O$-catalyzed rearrangement.

Experimental

General procedure for the bismuth triflate catalyzed rearrangement of the (*Z,Z*)- and (*E,Z*)-2-*iso*-propyloxycarbonyl-substituted allyl vinyl ethers 3

The substrate **3** (0.405 mmol) and $Bi(OTf)_3 \cdot 4H_2O$ (0.004 mmol) were mixed together in dry PhMe or CH_2Cl_2 (2 mL) under nitrogen atmosphere. The solution was stirred at 22 °C for 2–25 h. The resulting mixture was quenched with water, extracted with ethyl acetate (3 times), washed

© 2008 NRC Canada

with water (2 times), dried over Na_2SO_4, and concentrated under reduced pressure to afford the crude product. The crude was then purified by column chromatography (eluent hexane/EtOAc 95:5). Spectral data agree with those previously reported in the literature (6*a*, 18).

(3*RS*,4*SR*)-Isopropyl 3,4-diisopropyl-2-oxo-4-vinylheptanoate 4a

Table 1, entry 1. Reagents: (*Z*)-isopropyl 2-((*Z*)-hex-2-enyloxy)-4-methylpent-2-enoate (103 mg, 0.405 mmol) and $Bi(OTf)_3 \cdot 4H_2O$ (14.2 mg, 0.0202 mmol) in toluene (2.0 mL). Work-up followed by purification afforded 80 mg (78%) of the title compound as a mixture of unseparable diastereoisomers (colorless oil). R_f 0.33 (hexane/ethyl acetate 95:5). IR (cm^{-1}) ν: 3076, 2961, 2935, 2874, 2735, 1742, 1724, 1639. ^1H NMR ($CDCl_3$) δ: 5.60–5.67 (m, 1H), 5.08–5.14 (m, 1H), 5.03 (d, *J* = 12.2 Hz, 1H), 4.98 (d, *J* = 18.9 Hz, 1H), 3.31 (dd, *J* = 6.8 Hz, 6.8 Hz, 1H), 2.39–2.47 (m, 1H), 2.00–2.08 (m, 1H), 1.35–1.48 (m, 2H), 1.43 (d, *J* = 6.4 Hz, 6H–maj), 1.33 (d, *J* = 6.4 Hz, 6H–min), 1.10–1.27 (m, 2H), 0,95 (d, *J* = 6.6 Hz, 6H), 0.88 (t, *J* = 6.6 Hz, 3H–maj), 0.84 (t, *J* = 6.6 Hz, 3H–min). ^{13}C NMR ($CDCl_3$) δ: 199.7, 162.2, 138.7, 117.0, 70.6, 56.2, 44.5, 34.8, 28.8, 21.7, 21.5, 20.7, 20.5, 19.7, 14.1.

(3*RS*,4*SR*)-Isopropyl 3-ethyl-2-oxo-4-vinylheptanoate 4b

Table 1, entry 4. Reagents: (*Z*)-isopropyl 2-((*Z*)-hex-2-enyloxy)pent-2-enoate (90 mg, 0.457 mmol) and $Bi(OTf)_3 \cdot 4H_2O$ (3.2 mg, 0.00457 mmol) in dichloromethane (2.3 mL). Work-up followed by purification afforded 85 mg (94%) of the title compound as a mixture of unseparable diastereoisomers (yellowish oil). R_f 0.44 (hexane/ethyl acetate 95:5). IR (cm^{-1}) ν: 3077, 2963, 2935, 2875, 2737, 1723, 1640. ^1H NMR ($CDCl_3$) δ: 5.54–5.63 (m, 1H), 5.09–5.16 (m, 1H), 4.95–5.08 (m, 2H), 3.20–3.24 (m, 1H), 2.27–3.19 (m, 1H), 1.68–1.77 (m, 2H), 1.53–1.62 (m, 2H), 1.35 (d, *J* = 6.2 Hz, 6H–maj), 1.32 (d, *J* = 5.8 Hz, 6H–min.), 1.01–1.29 (m, 2H), 0.88 (t, *J* = 6.3 Hz, 3H), 0.84 (t, *J* = 7.2 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 198.5, 161.9, 139.4, 116.9, 70.5, 53.3, 45.7, 33.8, 21.7, 21.6, 21.5, 20.3, 14.0, 13.9, 12.1.

(3*RS*,4*RS*)-Isopropyl 2-oxo-3-phenyl-4-vinylheptanoate 4c

Table 1, entry 5. Reagents: (*Z*)-isopropyl 2-(hex-2-enyloxy)-3-phenylacrylate (0,161 g, 0,656 mmole) and $Bi(OTf)_3 \cdot 4H_2O$ (4.6 mg, 0.00656 mmole) in toluene (3.3 mL). Work-up followed by purification afforded 129 mg (80%) of the titled compound as a mixture of unseparable diastereoisomers (colorless oil). R_f 0.41 (hexane/ethyl acetate 95:5). IR (cm^{-1}) ν: 3079, 3064, 3029, 2981, 2959, 2934, 2873, 1746, 1725. ^1H NMR ($CDCl_3$) δ: 7.18–7.38 (m, 6H), 5.57–5.66 (m, 1H), 5.00–5.13 (m, 3H), 4.45 (d, *J* = 10.3 Hz, 1H–maj), 4.37 (d, *J* = 9.7 Hz, 1H–min), 2.87 (m, 1H), 1.29–1.42 (m, 2H), 1.23 (d, *J* = 6.2 Hz, 6H–maj), 1.20 (d, *J* = 6.2 Hz, 6H–min.), 1.02–1.18 (m, 2H), 0.75 (t, *J* = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 193.5, 160.8, 139.8, 138.8, 134.9, 130.2, 129.9, 129.0, 127.9, 117.6, 70.7, 59.0, 58.4, 45.6, 35.7, 33.9, 21.7, 20.5, 19.9, 14.0. Prodigiosin synthesis with electron rich 2,2′-bipyrroles

Benoit Jolicoeur and William D. Lubell

Abstract: The prodigiosins possess a linear tripyrrolic scaffold with the A and B pyrrolic rings connected directly in a bipyrrole unit, and the B and C rings joined in a dipyrrin. These red streptomycete metabolites exhibit among other activities, antitumor, antimicrobial, and immunomodulating properties. A new prodigiosin synthesis has been developed that employs electron rich 2,2′-bipyrroles. In particular, undecylprodigiosin and PNU-156804 were synthesized by condensations of 4-methoxy and 4-benzyloxy 2,2′-bipyrroles, **20a** and **20b**, respectively, with 5-undecylpyrrole-2-carboxaldehyde in 75% and 83% yields. The 4-alkoxy-2,2′-bipyrroles were synthesized from 4-alkoxypyrrolyl butenyl ketones (**15a** and **15b**), which were made by a novel one-pot process from 2-acyl-*N*-(PhF)pyrrolidin-4-one (**13**) [PhF = 9-(9-phenylfluorenyl)] using PhFNa in the presence of alkyl halide. A sequence of alkoxy pyrrole **15a** and **15b** protection, olefin oxidation, Paal–Knorr condensation, and deprotection gave the requisite 4-alkoxy-2,2′-bipyrroles (**20**). This route offers utility for making 4-alkoxybipyrroles as well as prodigiosins with diversity at the 6-position of the linear tripyrrolic skeleton.

Key words: prodigiosin, pyrrole, bipyrrole, PNU-156804, undecylprodigiosin.

Résumé : Les prodigiosines possèdent un squelette linéaire comportant trois pyrroles dont les pyrroles A et B sont connectés directement en une unité bipyrrole, et les pyrroles B et C sont joint en une unité dipyrrine. Ces métabolites rouges de streptomycète ont montré entre autre comme activité des propriétés antitumorales, antimicrobiennes et immunomodulatrices. Une nouvelle synthèse de prodigiosine, utilisant des 2,2′-bipyrroles riches en électron, a été développée. Undécylprodigiosine et PNU-156804 ont été synthétisés respectivement par la condensation de 4-méthoxy et 4-benzyloxy 2,2′-bipyrroles **20a** et **20b** avec 5-undécylpyrrole-2-carboxaldéhyde avec des rendements de 75 % et 83 %. Les 4-alkoxy-2,2′-bipyrroles ont été synthétisés à partir de 4-alkoxypyrrolyl butènyl cétones (**15a** et **15b**), lesquels ont été préparés par un nouveau procédé en un pot à partir de 2-acyl-*N*-(PhF)pyrrolidin-4-one (**13**) [PhF = 9-(9-phénylfluorènyl)] en utilisant PhFNa en présence d'un halogénure d'alkyle. Une séquence de protection d'alkoxypyrrole **15a** et **15b**, suivi d'une oxydation de l'oléfine, une condensation de Paal-Knorr et une déprotection a donné les 4-alkoxy-2,2′-bipyrroles (**20**) désirés. Cette route offre la possibilité de synthétiser des 4-alkoxybipyrroles ainsi que les prodigiosines possédant différents substituents en position 6 du squelette linéaire tripyrrolique.

Mots-clés : prodigiosine, pyrrole, bipyrrole, PNU-156804, undecylprodigiosine.

[Traduit par la Rédaction]

Introduction

Prodigiosins (1–4) and structurally related alkaloids (5–8) represent a family of naturally occurring red pigments produced by bacteria, such as *Streptomyces* and *Serratia*. These natural alkaloids, which include prodigiosin (**1**) and undecylprodigiosin (**2**), typically possess a methoxy bipyrrole moiety joined to a third pyrrole by a methene bridge (Fig. 1) (9). They have demonstrated antibacterial, antifungal, immunosuppressive, antimalarial, and cytotoxic properties (10–13). Methoxy bipyrrole alkaloids, such as undecylprodigiosin (**2**, so called prodigiosin 25-C or UP), have, however, exhibited side effects that have restricted their development as drugs such as immunosuppressants (14). To counter side effects, replacement of the 6-methoxy group on the B pyrrole ring of undecylprodigiosin by a 6-benzyloxy group has been used to improve the pharmacological profile in PNU-156804 (15), which has demonstrated potential for treating autoimmune diseases, such as multiple sclerosis and rheumatoid arthritis (16, 17) as well as for preventing solid organ transplant rejection (18). Methodology for modifying the 6-position substituent pattern of prodigiosin analogs has thus been pursued to harness their beneficial properties (19).

Since the pioneering synthesis of Rapoport and Holden (21), 2,2′-bipyrrole-5-carboxaldehyde (**4**) has served as a key precursor for the production of prodigiosins with different substituents on the C-ring pyrrole (Scheme 1) (22). The coupling between a bipyrrole methene triflate (**7**) and pyrrol-2-ylboronic acid (**8**) has offered an alternative method for assembling prodigiosins with other substitution patterns (15, 23). Recently, we prepared the first example of a 6-amino-prodigiosin (**3**) by a third route to the prodigiosin skeleton featuring condensation of an electron rich 4-morphilino-

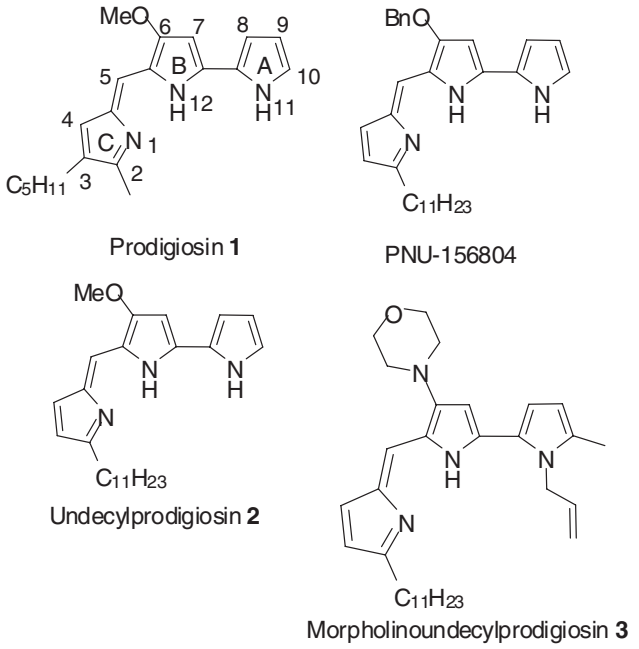
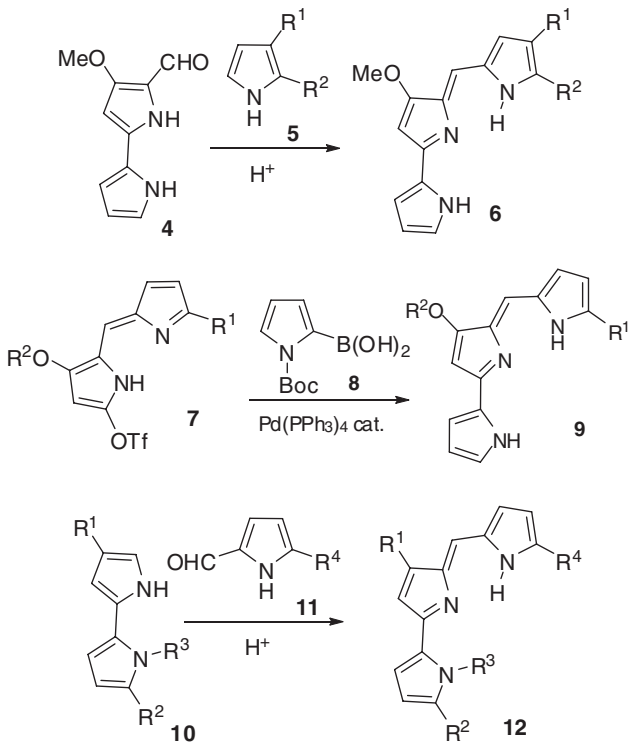


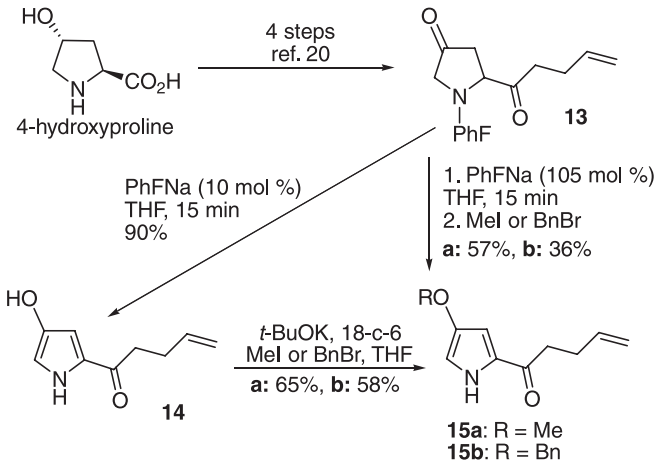
Scheme 1. Synthetic routes to prodigiosins.



2,2′-bipyrrole (**10**) with a pyrrole-2-carboxaldehyde (**11**) (19, 24). In developing this latter route to synthesize 4-alkoxy-2,2′-bipyrroles (**20**), we have now achieved the syntheses of prodigiosin analogs bearing 6-alkoxy substituents.

In parallel to their use in natural product synthesis, interest in the synthesis of bipyrrole derivatives has been driven by their potential for application in conducting organic materials in microelectronic devices, such as batteries, sensors, and fuel cells (25–27). In contrast to alkylbipyrroles (25), their alkoxy counterparts polymerize usually more readily to produce materials with enhanced conductivity contingent on the substitution pattern (28). Few methods exist, however, for making alkoxy bipyrroles, and many, such as oxidative Ullman-type homocouplings (29), typically provide symmetric materials. Transition metal cross couplings, employing pyrrole boronates and stannanes (23, 30) as well as reactions of donor-acceptor cyclopropanes with 2-cyanopyrroles have provided unsymmetrical bipyrroles, albeit with a limited structural variety (31). Diversity-oriented strategies for creating bipyrroles are thus desired for making innovations in the fields of medicinal chemistry and materials science.

Scheme 2. Synthesis of 4-alkoxypyrroles.



Results and discussion

4-Alkoxy-2,2′-bipyrrole synthesis began with pyrrolidinone **13**, which was prepared from 4-hydroxyproline in 4 steps commencing with protections of the carboxylic acid as a methyl ester and amine with the 9-(9-phenylfluorenyl) (PhF) group (Scheme 2) (19). Dione **13** was prepared by conversion of the carboxylate ester to a γ,δ-unstaturated ketone by a cascade addition of vinyl magnesium bromide (32–34) and oxidation of the 4-position alcohol using DMSO and oxalyl chloride (35).

Exposure of 2-acylpyrrolidin-4-one (**13**) to 10 mol% NaHMDS in THF for 15 min followed by chromatographic purification gave 4-hydroxypyrrole **14** in 89% yield (Scheme 2) (19). 2-Acyl-4-alkoxypyrroles (**15a** and **15b**) were then obtained from alkylation of 4-hydroxypyrrole (**14**) (19). Considering that liberated PhF anion acted as a base to continue the elimination reaction in the synthesis of **14**, pyrrolidinone **13** was treated with 10 mol% of PhFNa to provide **14** in similar yield. 4-Alkoxypyrroles (**15a** and **15b**) were found to also result from a one-pot process featuring treatment of pyrrolidinone **13** with 105 mol% of PhFNa in the presence of iodomethane and benzylbromide, respectively, albeit in 57% and 36% yields.

Attempts to oxidize γ,δ-unstaturated ketone **15** had previously failed due to competitive pyrrole degradation (19). Protection of 4-alkoxypyrrole (**15**) as phenyl sulfonamide (**16**) was necessary and achieved by reacting the pyrrolyl

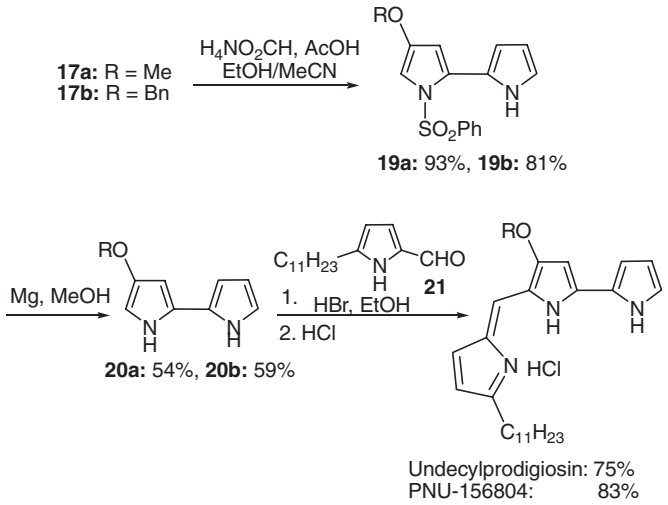
anion, formed with potassium *tert*-butoxide, with phenylsulfonyl chloride in THF (Scheme 3) (36). Oxidations of 1-phenylsulfonyl-4-alkoxy and 4-aminopyrroles were previously achieved using the Tsuji–Wacker process to provide the corresponding diones for Paal–Knorr condensation with an alkyl amine (19). Although attempts to prepare the corresponding δ-keto aldehyde have not been successful in the presence of a 4-amino substituent, oxidation of the olefin of 1-phenylsulfonyl-4-alkoxypyrroles (**16**) has now been achieved using osmium tetraoxide and sodium periodate (37) in dioxane–water to give δ-keto aldehydes (**17**) in 65%–75% yields after purification by chromatography.

With δ-keto aldehyde (**17**) in hand, Paal–Knorr condensations (38, 39) with dimethoxybenzylamine were performed using 100 mol% $TiCl_4$ in toluene (19). 2,2′-Bipyrroles (**18a** and **18b**) were isolated after chromatography in 65% and 67% yields, respectively.

Aiming at minimizing protection in the prodigiosin synthesis, attempts were focussed on employing ammonia in the Paal–Knorr condensation with δ-keto aldehyde (**17**) (Scheme 4). Various Paal–Knorr conditions were screened leading to either no reaction or decomposition (34, 39–41). Success was only obtained using ammonium formate and a catalytic amount of acetic acid in a 10:1 ethanol–acetonitrile solvent mixture. A homogeneous solution of ammonium formate and δ-keto aldehyde (**17**) was obtained using this solvent system, which delivered bipyrroles **19** in 81%–93% yields after purification by filtration through a short silica gel column.

Scheme 4. Synthesis of undecylprodigiosin and PNU-156804.



Removal of the sulfonamide group was next achieved by exposure of bipyrrole **19** to magnesium powder in methanol (36). 4-Methoxy and 4-benzyloxy-2,2′-bipyrroles (**20a** and **20b**) were respectively isolated in 54% and 59% yields after chromatography over neutral aluminium oxide.

In the final condensation step, undecylpyrrole-2-carboxaldehyde (**21**) (23) was respectively reacted with bipyrrole **20a** and **20b** in warm EtOH in the presence of aqueous hydrobromic acid to give undecylprodigiosin and PNU-156804 as their free bases after chromatography over neutral aluminium oxide. Treatment of the free bases with 1 mol/L HCl and freeze drying afforded the respective hydrochloride salts in 75% and 83% yields. These yields are notably higher than those reported earlier for condensations of the corresponding 2,2′-bipyrrole-5-carboxaldehyde with alkyl pyrroles (Scheme 1) (10, 21, 42, 43).

In conclusion, we have developed a route for adding diversity at the 6-position of the prodigiosin skeleton. 2-Acyl-4-alkoxypyrroles (**15a** and **15b**) were first obtained from dione **13** by a one-pot alkylative elimination. Access to unsymmetrical 4-alkoxy-2,2′-bipyrroles (**20**) was then achieved by sulfonylation of the nitrogen of 4-alkoxypyrrole (**15**), selective olefin oxidation to δ-oxo aldehyde (**17**), Paal–Knorr condensation with ammonium formate and deprotection. Condensations of bipyrroles **20** with a pyrrole aldehyde C-ring precursor then provided the respective prodigiosin analogs.

Experimental section[2]

General procedure for the one-pot synthesis of 4-alkoxypyrroles (15)

A solution of 9-phenylfluorene (65 mg, 0.27 mmol) and sodium hydride (6 mg, 0.26 mmol) in THF (5 mL) was stirred for 15 min, treated with pyrrolidinone **13** (100 mg, 0.245 mmol), stirred for 30 min, treated with methyliodide (26 μL, 0.42 mmol), stirred for 24 h, and treated with water (7 mL) and EtOAc (7 mL). The layers were separated. The aqueous layer was extracted with EtOAc (2 × 7 mL). The organic layers were combined, washed with brine, dried

($MgSO_4$), and concentrated to a residue that was purified by column chromatography on silica gel (15%–40% EtOAc–hexane). Evaporation of the collected fractions yielded 4-methoxypyrrole **15a** (25 mg, 57%) (19). 4-Benzyloxypyrrole (**15b**) was prepared in 36% yield from pyrrolidinone **13** (0.98 mmol) using the same procedure and benzylbromide (1.7 mmol) as electrophile.

4-Benzyloxy-2-(pent-4-enoyl)-1-(phenylsulfonyl)pyrrole (16b)

A solution of 4-benzyloxy-2-(pent-4-enoyl)pyrrole (**15b**) (700 mg, 2.74 mmol) in THF (40 mL) was added to a solution of potassium *t*-butoxide (493 mg, 4.39 mmol) and 18-crown-6 (72 mg, 0.27 mmol) in THF (40 mL) at 0 °C. The mixture was stirred for 30 min, and treated with a solution of benzenesulfonyl chloride (0.49 mL, 3.84 mmol). The ice bath was removed and the solution was allowed to warm to room temperature, stirred for 15 h, and treated with water followed by EtOAc. The layers were separated and the aqueous layer was extracted with EtOAc. The organic layers were combined, washed with brine, dried ($MgSO_4$), and concentrated to a residue that was purified by column chromatography on silica gel (40% EtOAc–hexane). Evaporation of the collected fractions yielded **16b** as a clear oil (858 mg, 79%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.96 (d, J = 7.9 Hz, 2H), 7.59 (t, J = 7.5 Hz, 1H), 7.50 (t, J = 8.0 Hz, 2H), 7.42–7.36 (m, 6H), 6.75 (d, J = 2.1 Hz, 1H), 5.74 (m, 1H), 4.94 (m, 4H), 2.71 (t, J = 7.3 Hz, 2H), 2.32 (q, J = 6.6 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 188.0, 146.7, 139.1, 136.7, 135.9, 133.5, 131.0, 128.7 (2C), 128.4, 127.9, 127.7, 115.4, 114.0, 111.9, 72.8, 38.5, 28.4. HR-MS calcd. for $C_{22}H_{22}NO_4S$ ([M + H^+]): 396.1264; found: 396.1274. 4-Benzyloxy-2-(pent-4-enoyl)pyrrole (**15b**) was also recovered in 20% yield (137 mg).

General procedure for the synthesis of aldehydes 17 (method A)

*4-(4-Methoxy-1-(phenylsulfonyl)-1*H*-pyrrol-2-yl)-4-oxobutanal (17a)*

To a solution of 4-methoxy-2-(pent-4-enoyl)-1-(phenylsulfonyl)pyrrole (**16a**, 595 mg, 1.86 mmol, prepared according to ref. 19) in dioxane (51 mL) and water (17 mL), 2,6-lutidine (0.43 mL, 3.7 mmol), OsO_4 (0.49 mL, 0.037 mmol), and $NaIO_4$ (1.59 g, 7.44 mmol) were added. The mixture was stirred for 15 h and treated with water followed by DCM. The layers were separated and the aqueous layer was extracted with DCM. The organic layers were combined, washed with brine, dried ($MgSO_4$), and concentrated to a residue that was purified by column chromatography on silica gel (25%–40% EtOAc–hexane). Evaporation of the collected fractions yielded aldehyde **17a** as a white solid (447 mg, 75%); mp 131 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 9.74 (s, 1H), 7.94 (d, J = 7.5 Hz, 2H), 7.59 (t, J = 7.4 Hz, 1H), 7.50 (t, J = 8.0 Hz, 2H), 7.31 (d, J = 2.1 Hz, 1H), 6.79 (d, J = 2.1 Hz, 1H), 3.79 (s, 3H), 2.98 (t, J = 6.5 Hz, 2H), 2.77 (t, J = 6.5 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 199.9, 185.8, 147.8, 138.6, 133.3, 130.1, 128.4, 127.5, 113.5, 110.7, 57.7, 37.1, 30.9. HR-MS calcd. for $C_{15}H_{16}NO_5S$ ([M + H^+]): 322.0743; found: 322.0737.

*4-(4-Benzyloxy-1-(phenylsulfonyl)-1*H*-pyrrol-2-yl)-4-oxobutanal (17b)*

The title compound was prepared according to method A from pyrrole **16b** (2.17 mmol). Purification by column chromatography on silica gel (30%–50% EtOAc–hexane) afforded aldehyde **17b** as a beige solid (580 mg, 67%); mp 123 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 9.72 (s, 1H), 7.92 (m, 2H), 7.57 (tt, J = 1.2, 7.5 Hz, 1H), 7.49 (m, 2H), 7.41–7.34 (m, 6H), 6.84 (d, J = 2.1 Hz, 1H), 4.98 (s, 2H), 2.97 (t, J = 6.5 Hz, 2H), 2.75 (t, J = 6.5 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 200.2, 186.1, 146.7, 138.8, 135.9, 133.5, 130.3, 128.64, 128.59, 128.3, 127.7, 127.6, 114.3, 112.1, 72.7, 37.3, 31.2. HR-MS calcd. for $C_{21}H_{20}NO_5S$ ([M + H^+]): 398.1057; found: 398.1057.

General procedure for the synthesis of 1′-(2,4-dimethoxybenzyl)-2,2′-bipyrroles (18) (method B)

4-(Methoxy)-1-benzenesulfonyl-1′-(2,4-dimethoxybenzyl)-2,2′-bipyrrole (18a)

A solution of $TiCl_4$ (1 mol/L in toluene, 75 μL, 75 μmol) was added dropwise to a solution of aldehyde **17a** (16 mg, 0.50 mmol) and 2,4-dimethoxybenzylamine (52 μL, 0.35 mmol) in toluene (5 mL). After stirring for 18 h, the reaction was treated with a solution of saturated aqueous NH_4Cl followed by 5 mL of EtOAc. The layers were separated and the aqueous layer was extracted with EtOAc (5 mL × 2). The organic layers were combined, washed with brine, dried ($MgSO_4$), and concentrated to a residue that was purified by column chromatography on silica gel using DCM as eluant. Evaporation of the collected fractions yielded bipyrrole **18a** as a colorless oil (15 mg, 65%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.54 (m, 3H), 7.40 (t, J = 7.6 Hz, 2H), 6.90 (d, J = 2.1 Hz, 1H), 6.69 (t, J = 2.0 Hz, 1H), 6.60 (d, J = 8.3 Hz, 1H), 6.37 (d, J = 2.3 Hz, 1H), 6.33 (dd, J = 2.3, 8.3 Hz, 1H), 6.08 (t, J = 3.0 Hz, 1H), 5.88 (d, J = 2.1 Hz, 1H), 5.85 (dd, J = 1.8, 3.5 Hz, 1H), 4.73 (s, 2H), 3.76 (s, 3H), 3.74 (s, 3H) 3.72 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 160.3, 157.7, 150.3, 138.3, 133.5, 129.5, 128.6, 127.4, 125.9, 122.9, 121.7, 119.1, 112.8, 111.0, 107.0, 103.9, 103.0, 98.2, 57.5, 55.3, 55.2, 45.7. HR-MS calcd. for $C_{24}H_{25}N_2O_5S$ ([M + H^+]): 453.1479; found: 453.1472.

4-(Benzyloxy)-1-benzenesulfonyl-1′-(2,4-dimethoxybenzyl)-2,2′-bipyrrole (18b)

The title compound was prepared according to method B from aldehyde **17b** (0.25 mmol). Purification by column chromatography on silica gel using DCM as eluant afforded bipyrrole **18b** as a green foam (88 mg, 67%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.57 (t, J = 7.4 Hz, 1H), 7.50 (d, J = 8.1 Hz, 2H), 7.39 (m, 7H), 6.99 (d, J = 2.1 Hz, 1H), 6.74 (t, J = 2.5 Hz, 1H), 6.64 (d, J = 8.3 Hz, 1H), 6.41 (d, J = 2.3 Hz, 1H), 6.36 (dd, J = 2.3, 8.4 Hz, 1H), 6.13 (t, J = 3.4 Hz, 1H), 5.97 (d, J = 2.1 Hz, 1H), 5.90 (dd, J = 1.7, 3.5 Hz, 1H), 4.94 (s, 2H), 4.79 (s, 2H), 3.77 (s, 3H), 3.75 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 160.3, 157.7, 149.0, 138.1, 136.3, 133.4, 129.4, 128.6, 128.5, 128.1, 127.6, 127.3, 125.9, 122.9, 121.7, 119.0, 112.8, 111.4, 107.0, 104.1, 103.9, 98.1, 72.2, 55.23, 55.16, 45.6. HR-MS calcd. for $C_{30}H_{29}N_2O_5S$ [M + H^+]: 529.1791; found: 529.1778.

General procedure for the synthesis of 2,2′-bipyrroles (19) (method C)

4-(Methoxy)-1-benzenesulfonyl-2,2′-bipyrrole (19a)

Ammonium formate (711 mg, 11.3 mmol) was added to a solution of 4-(4-methoxy-1-(phenylsulfonyl)-1*H*-pyrrol-2-yl)-4-oxobutanal (**17a**) (362 mg, 1.13 mmol) in EtOH–MeCN–AcOH (50 mL–5 mL–50 μL). After stirring for 18 h, the reaction was treated with water followed by EtOAc. The layers were separated and the aqueous layer was extracted with EtOAc. The organic layers were combined, washed with brine, dried ($MgSO_4$), and concentrated to a residue that was purified by filtration on silica gel (30% EtOAc–hexane). Evaporation of the collected fractions yielded bipyrrole **19a** as a dark oil (318 mg) in 93% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 9.10 (br s, 1H), 7.50 (t, *J* = 7.3 Hz, 1H), 7.36 (m, 4H), 6.90 (m, 1H), 6.82 (d, *J* = 2.1 Hz, 1H), 6.16 (m, 1H), 6.07 (m, 1H), 6.02 (d, *J* = 2.1 Hz, 1H), 3.73 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 150.8, 137.4, 133.7, 128.8, 127.8, 126.8, 121.1, 119.3, 110.9, 108.7, 107.9, 102.6, 57.6. HR-MS calcd. for $C_{15}H_{15}N_2O_3S$ ([M + H^+]): 303.0798; found: 303.0796.

4-(Benzyloxy)-1-benzenesulfonyl-2,2′-bipyrrole (19b)

The title compound was prepared according to method C from pyrrole **17b** (1.16 mmol). Purification by filtration on silica gel (25% EtOAc–hexane) afforded bipyrrole **19b** as a grey solid (355 mg) in 81% yield; mp 107 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 9.10 (br s, 1H), 7.40 (m, 10H), 6.90 (m, 1H), 6.87 (d, *J* = 2.0 Hz, 1H), 6.17 (m, 1H), 6.09 (m, 2H), 4.95 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 149.5, 137.2, 136.3, 133.6, 128.8, 128.5, 128.1, 127.7, 127.6, 126.8, 121.1, 119.3, 110.9, 108.7, 108.3, 103.8, 72.2. HR-MS calcd. for $C_{21}H_{19}N_2O_3S$ ([M + H^+]): 379.1111; found: 379.1121.

General procedure for the synthesis of 2,2′-bipyrroles (20) (method D)

4-(Methoxy)-2,2′-bipyrrole (20a)

Magnesium powder (255 mg, 10.5 mmol) was added to a solution of 4-(methoxy)-1-benzenesulfonyl-2,2′-bipyrrole (**19a**) (318 mg, 1.05 mmol) in methanol (20 mL). After stirring for 18 h, the reaction was treated with a solution of saturated aqueous NH_4Cl followed by EtOAc. The layers were separated and the aqueous layer was extracted with EtOAc. The organic layers were combined, washed with brine, dried ($MgSO_4$), and concentrated to a residue that was purified by chromatography over neutral aluminium oxide (10%–30% EtOAc–hexane). Evaporation of the collected fractions yielded bipyrrole **20a** as a grey solid (92 mg) in 54% yield; mp 143 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.24 (br s, 1H), 7.66 (br s, 1H), 6.76 (s, 1H), 6.30 (s, 1H), 6.23 (s, 1H), 6.22 (s, 1H), 5.94 (s, 1H), 3.75 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 149.8, 125.8, 124.2, 117.7, 109.4, 103.7, 98.8, 93.4, 57.9. HR-MS calcd. for $C_9H_{11}N_2O$ ([M + H^+]): 163.0869; found: 163.0866.

4-(Benzyloxy)-2,2′-bipyrrole (20b)

The title compound was prepared according to method D from bipyrrole **19b** (0.905 mmol). Purification by column chromatography on neutral aluminium oxide (10%–25% EtOAc–hexane) afforded bipyrrole **20b** as a grey solid (127 mg) in 59% yield; mp 155 °C. ^{1}H NMR (400 MHz, $(CD_3)_2CO$) δ: 10.14 (br s, 1H), 9.59 (br s, 1H), 7.46 (d, *J* = 7.2 Hz, 2H), 7.38 (t, *J* = 7.1 Hz, 2H), 7.31 (t, *J* = 7.2 Hz, 1H), 6.73 (s, 1H), 6.38 (s, 1H), 6.28 (s, 1H), 6.09 (m, 2H), 4.94 (s, 2H). ^{13}C NMR (100 MHz, $(CD_3)_2CO$) δ: 149.1, 138.9, 128.7, 128.0, 127.9, 126.9, 124.9, 117.5, 109.0, 103.4, 100.0, 93.5, 72.5. HR-MS calcd. for $C_{15}H_{15}N_2O$ ([M + H^+]): 239.1179; found: 239.1189.

General procedure for the synthesis of undecylprodigiosins (method E)

*4-Methoxy-5-[(5-undecyl-2**H**-pyrrol-2-ylidene)methyl]-2,2′-bi-1**H**-pyrrole hydrochloride (undecylprodigiosin hydrochloride)*

A solution of 4-(methoxy)-2,2′-bipyrrole **20a** (26.4 mg, 0.163 mmol) and 5-undecylpyrrole-2-carboxaldehyde **21** (44.6 mg, 0.179 mmol) in EtOH (4 mL) was warmed to 50 °C, and treated with concentrated hydrobromic acid (10 μL). The heating bath was removed and the reaction mixture was allowed to cool to room temperature while stirring for 15 h. The reaction mixture was concentrated in vacuo. Chromatography on neutral aluminium oxide (0%–10% EtOAc–hexane) and evaporation of the collected fractions afforded the free base, which was treated with HCl in ether (1 mol/L, 3 mL) and freeze dried to afford undecylprodigiosin hydrochloride as a red film (52 mg) in 75% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 12.5–11.7 (br s, 1H), 10.9–10.0 (br s, 1H), 6.91 (s, 1H), 6.71 (d, *J* = 3.5 Hz, 1H), 6.64 (s, 1H), 6.51 (d, *J* = 3.5 Hz, 1H), 6.14 (m, 2H), 5.86 (d, *J* = 3.5 Hz, 1H), 4.00 (s, 3H), 2.08 (t, *J* = 6.2 Hz, 2H), 1.4–1.1 (m, 18H), 0.95 (t, *J* = 6.6 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 169.0, 160.2, 144.8, 128.2, 128.1, 123.0, 121.2, 116.0, 112.9, 109.9, 109.2, 108.5, 95.7, 58.3, 31.9, 29.63, 29.59, 29.47, 29.33, 29.23, 29.15, 29.0, 27.2, 22.7, 14.1. HR-MS calcd. for $C_{25}H_{36}N_3O$ ([M + H^+]): 394.2857; found: 394.2853.

Ref. 15: ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.9 (m, 3H), 1.1–1.5 (m, 16H), 1.8 (m, 2H), 2.95 (t, *J* = 7.5 Hz, 2H), 4.05 (s, 3H), 6.0 (d, *J* = 1.8 Hz, 1H), 6.2 (dd, *J* = 1.8, 3.9 Hz, 1H), 6.5 (m, 1H), 6.85 (dd, *J* = 3.9, 2.6 Hz, 1H), 7.0 (m, 1H), 7.05 (s, 1H), 7.25 (m, 1H), 12.5–12.7 (2 bs, 2H), 12.9 (bs, 1H).

Ref. 44: ^{1}H NMR ($CDCl_3$) τ: 2.83 (br, 3H), 2.78 (m, 1H), 3.06 (s, 1H), 3.10 (m, 2H), 3.67 (m, 1H), 3.80 (m, 1H), 3.96 (d, 1H), 6.05 (s, 3H), 7.06 (t, 2H), 8.76 (m, 18H), 9.13 (t, 3H).

*4-Benzyloxy-5-[(5-undecyl-2**H**-pyrrol-2-ylidene)methyl]-2,2′-bi-1**H**-pyrrole hydrochloride (PNU-156804)*

The title compound was prepared according to method E from bipyrrole **20b** (0.090 mmol) to afford PNU-156804 hydrochloride as a red film (37 mg) in 83% yield. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 13.0–11.6 (br s, 1H), 11.0–9.7 (br s, 1H), 7.56 (d, *J* = 7.2 Hz, 2H), 7.49 (t, *J* = 7.0 Hz, 2H), 7.44 (t, *J* = 7.2 Hz, 1H), 6.99 (s, 1H), 6.72 (d, *J* = 3.4 Hz, 1H), 6.66 (s, 1H), 6.51 (d, *J* = 3.6 Hz, 1H), 6.23 (s, 1H), 6.15 (t, *J* = 3.2 Hz, 1H), 5.87 (d, *J* = 3.6 Hz, 1H), 5.21 (s, 2H), 2.09 (t, *J* = 7.3 Hz, 2H), 1.40–1.15 (m, 18H), 0.93 (t, *J* = 6.6 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 167.8, 160.0, 145.0,

Resolution of non-proteinogenic amino acids via microbial lipase-catalyzed enantioselective transesterification

Toshifumi Miyazawa, Motoe Mio, Yuko Watanabe, and Takashi Yamada

Abstract: A number of non-proteinogenic amino acids bearing aliphatic side chains were resolved with moderate to good enantioselectivities (E = 15–42) through the *Burkholderia cepacia* lipase-catalyzed enantioselective transesterification of the 2,2,2-trifluoroethyl esters of their *N*-benzyloxycarbonyl derivatives with methanol as a nucleophile in diisopropyl ether.

Key words: non-proteinogenic amino acids, microbial lipases, *Burkholderia cepacia* lipase, 2,2,2-trifluoroethyl ester, enantioselective transesterification, enantioselectivity.

Résumé : On a résolu un certain nombre d'acides aminés non-protéinogéniques portant des chaînes latérales aliphatiques, avec des énantiosélectivités allant de modérées à bonnes (E = 15–42), en faisant appel à une transestérification énantiosélective catalysée par la lipase *Burkholderia cepacia* des esters 2,2,2-trifluoroéthyles de leurs dérivés *N*-benzyloxycarbonyles et en utilisant le méthanol comme nucléophile dans l'éther diisopropylique comme solvant.

Mots-clés : acides aminés non-protéinogéniques, lipases microbiennes, lipase *Burkholderia cepacia*, ester 2,2,2-trifluoroéthylique, transestérification énantiosélective, énantiosélectivité.

[Traduit par la Rédaction]

Introduction

Lipases (triacylglycerol hydrolases, EC 3.1.1.3) have been employed as a very attractive group of enzymes for synthetic purposes (1) because they are stable and easy to handle and they have a rather broad substrate specificity. Moreover, as they are easily available from a variety of sources (especially bacteria and fungi), there must be a fair chance of finding a suitable enzyme for each transformation of interest in terms of catalytic activity and (or) selectivity. Since the first discovery of enzymatic activity in anhydrous organic media (2), 1ipase-catalyzed reactions, such as esterification and transesterification, have attracted an increasing attention in the field of organic synthesis. Thus, a large number of reports have dealt with the optical resolution of alcohols through lipase-catalyzed reactions in organic solvents. On the other hand, fewer examples have been accumulated for the resolution of carboxylic acids by means of the lipase-catalyzed esterification or transesterification procedure in organic milieu. We have previously reported on the resolution of 2-substituted carboxylic acids via the microbial lipase-catalyzed irreversible transesterification of their vinyl esters (3). We also have recently reported on the resolution of non-proteinogenic aliphatic amino acids through the *Carica papaya* lipase-catalyzed enantioselective transesterification of their *N*-benzyloxycarbonyl (*Z*) esters (4). In the present paper, we describe the details of our study on the resolution of non-proteinogenic amino acids via the similar enantioselective transesterification procedure mediated by microbial lipases (5). Homochiral non-proteinogenic amino acids are useful as building blocks for the synthesis of analogs of biologically active peptides (6) and as chiral auxiliaries for other synthetic purposes (7). We have already reported on the resolution of non-proteinogenic amino acids via the enantioselective hydrolysis of their *N*-*Z*-protected esters mediated by microbial and mammalian lipases (8) and via the enantioselective hydrolysis of their *N*-unprotected esters catalyzed by microbial lipases (9).

Results and discussion

Initially, the transesterification between *N*-*Z*-DL-norvaline (2-aminopentanoic acid) 2,2,2-trifluoroethyl ester (DL-**1c**) and methanol in diisopropyl ether was chosen as a model reaction (Scheme 1; R = n-C_3H_7; R′ = CH_3), and a dozen lipases of microbial and mammalian origins were screened: *Burkholderia* (*Pseudomonas*) *cepacia* (Amano P), *Rhizopus javanicus* (Amano F), *Mucor javanicus* (Amano M), *Rhizopus japonicus* (Rhilipase A5), *Chromobacterium viscosum* (Asahikasei LP), *Aspergillus niger* (Amano A), *Candida rugosa* (Sigma Type VII, Meito MY, Amano AY), and porcine pancreas (Sigma Type II). Part of the results are summarized in Table 1. We already reported that in the *Carica papaya* lipase-catalyzed enantioselective transesterification the 2,2,2-trifluoroethyl ester was an ester of choice (4). Also in the present case, the transesterification reactions

of other esters, such as the 2-chloroethyl and 2,2,2-trichloroethyl esters, were extremely slow, and moreover, such an active ester as *N*-hydroxysuccinimide ester proceeded with almost no enantioselectivity. As can be seen form Table 1, the rate and enantioselectivity observed varied largely with the enzyme employed, while the stereochemical preference remained unchanged, the preferred absolute configuration of the newly formed methyl ester (**2c**) being L. Among the enzymes tested, 1ipases from *B. cepacia* and *R. javanicus* showed a rather high reaction rate together with a good enantioselectivity, as judged from the value of enantiomeric ratio, *E* (10). With *M. javanicus* lipase, the fastest reaction was accompanied by a poor enantioselectivity. With other lipases, the reactions were slow, and enantioselectivities were practically unacceptable. This includes *C. rugosa* lipase, which is known to show a high enantioselectivity toward carboxylic acids (11).

Next, the effect of alcohols as a nucleophile was examined on the *B. cepacia* lipase-catalyzed transesterification of DL-**1c** in diisopropyl ether. The results are shown in Table 2. The preferred configuration of the newly formed esters was L, irrespective of the alcohol employed. There was almost no difference between methanol and ethanol as the nucleophile in terms of the reaction rate and enantioselectivity. There was a tendency for the enantioselectivity, together with the reaction rate, to decrease with the chain length of the alcohol. This is similar to that observed in the *A. niger* lipase-catalyzed transesterification of vinyl 2-phenoxypropanoate (3), though the differences among the alcohols were rather small in the present case. A reverse tendency, i.e., an increase in enantioselectivity with increasing chain length of the alcohol, has been reported in the *C. rugosa* lipase-catalyzed esterification of 2-(4-chlorophenoxy)propanoic acid (12). The discrepancy may be attributable to the nature of the lipases used and (or) a difference in the type of reactions (transesterification vs. esterification).

Among the external factors influencing the catalytic activity and enantioselectivity of enzymatic reactions, much attention has recently been focused on the solvent effect (2). However, it is still difficult to predict the solvent effect, especially on the enantioselectivity of a certain reaction, and the best way is still to select an appropriate solvent after the screening experiment. Among many solvent parameters proposed so far is the hydrophobicity parameter, log *P* (13), and a correlation has sometimes been observed between the *E* values of an enzymatic resolution carried out in organic solvents and their log *P* values. We also have reported such a correlation, though rough, in the *A. niger* lipase-catalyzed transesterification of vinyl 2-phenoxypropanoate with methanol: the larger the log *P* value, the higher the *E* value (3). A number of solvents having different log *P* values were screened next in the *B. cepacia* lipase-catalyzed transesterification between DL-**1c** and methanol (Table 3). In the table, the solvents are arranged in decreasing order of log *P*. The stereochemical preference remained to be L with all the solvents examined. Good-to-excellent *E* values were obtained in most of the solvents except methanol and *N*,*N*-dimethylformamide. Thus, it is difficult to find a correlation between the *E* value and the log *P* value. The solvent effect on enantioselectivity observed here resembles that reported previously in the transesterification of 1-nitro-2-propanol with vinyl acetate cata1yzed by a lipase from *Pseudomonas* sp. (14) in that tetrahydrofuran, 1,4-dioxane, and benzene give excellent enantioselectivities. In the *A. niger* lipase-catalyzed transesterification of vinyl 2-phenoxypropanoate

[b]Enantiomeric excess of the newly formed methyl ester (**2c**).

with methanol (3) and the *C. papaya* lipase-catalyzed transesterification of *N*-*Z*-amino acid esters (4), aliphatic hydrocarbons, especially cyclohexane, gave high enantioselectivities. Thus, the solvent effect on the enantioselectivity of lipase-catalyzed transesterifications of carboxylic acid esters is likely to be dependent largely on the lipase source. On the other hand, the solvent had a larger effect on the reaction rate of the present lipase-catalyzed transesterification. The reaction was fast in an aliphatic hydrocarbon, cyclohexane, while it was much slower in the aromatic hydrocarbons. It was extremely retarded in a halogenated methane, chloroform. In the acyclic ethers, the reaction proceeded rather smoothly. Although cyclohexane seemed to be the solvent of choice in terms of the reaction rate as well as enantioselectivity, it had a poor solubilizing power towards some of the substrates examined here. Thus, diisopropyl ether was chosen as the most practical solvent, taking into account not only the reaction rate and enantioselectivity but also the solubility of the substrates.

Based on these results, the transesterification between the 2,2,2-trifluoroethyl esters (DL-**1**) of the *N*-*Z*-derivatives of a number of non-proteinogenic amino acids and methanol in diisopropyl ether was examined using the two microbial lipases, *B. cepacia* lipase and *R. javanicus* lipase. The results are summarized in Tables 4 and 5, respectively, which include also those with proteinogenic amino acids for the purpose of comparison. The *B. cepacia* lipase-catalyzed transesterifications proceeded rather smoothly. The esters (DL-**1**) of amino acids carrying aliphatic side chains reacted generally with high enantioselectivities. One exception is the result with the alanine derivative (DL-**1a**). The enantioselectivity did not depend directly on the length of the side chain of amino acids. As the *E* values were larger than 15 in all these cases except **1a**, the recovered, unreacted substrate can be obtained with a practically high enantiomeric excess (ee) value when the reaction is allowed to proceed near or over ~60% conversion (10). In practice, this was confirmed experimentally in a gram-scale resolution of *N*-*Z*-norvaline mediated by *B. cepacia* lipase as described later. The enantiodiscrimination by *R. javanicus* lipase was poorer than that by *B. cepacia* lipase for each substrate. In comparison with the results with aliphatic amino acids, however, the enantioselectivities observed with aromatic amino acid derivatives were lower in the presence of both the microbial lipases. It is interesting to note that *R. javanicus* lipase showed better enantiodiscrimination than *B. cepacia* lipase for each aromatic substrate. In all the cases mentioned earlier, the preferential reaction of the L-enantiomers was confirmed by comparison with authentic samples prepared from the optically active amino acids, if available, on HPLC or suggested from the regularity of elution order of the enantiomers on HPLC (15). This stereochemical preference is the same as that observed in the lipase-catalyzed hydrolysis of the 2-chloroethyl or 2,2,2-trifluoroethyl esters of the *N*-*Z*-derivatives of amino acids (8) and that observed in the *C. papaya* lipase-catalyzed transesterification of the *N*-*Z*-amino acid 2,2,2-trifluoroethyl esters (4).

Furthermore, a gram-scale resolution of *N*-*Z*-DL-norvaline was carried out via the *B. cepacia* lipase-catalyzed transesterification of DL-**1c** with methanol in diisopropyl ether. After incubation of 9 h (33% conversion), the product methyl ester was isolated by column chromatography on silica gel, which after saponification yielded *N*-*Z*-L-norvaline with 92% ee. In another run, *N*-*Z*-D-norvaline with 97% ee was obtained from the remaining trifluoroethyl ester substrate separated after incubation of 35 h (55% conversion).

In the *C. papaya* lipase-catalyzed transesterification of *N*-*Z*-amino acid 2,2,2-trifluoroethyl esters, excellent enantioselectivities were obtained in cyclohexane. However, the enantioselectivity deteriorated by switching the solvent from cyclohexane to diisopropyl ether in which the starting esters were more soluble (4). On the other hand, although the enantioselectivities observed in the *B. cepacia* lipase-catalyzed transesterification of the same substrates were moderate to good, the fact that diisopropyl ether can be used as a solvent without lowering the enantioselectivity as compared with that in cyclohexane should make the present methodology applicable to more non-proteinogenic amino acids.

[a]Enantiomeric excess of the newly formed methyl ester (**2**).

Conclusion

In this paper, we have demonstrated that a number of non-proteinogenic amino acids carrying aliphatic side chains can be resolved with moderate-to-good enantioselectivities through the microbial lipase-catalyzed enantioselective transesterification of the 2,2,2-trifluoroethyl esters of their *N*-*Z* derivatives. Although *C. rugosa* lipase is known to show high enantioselectivity toward carboxylic acids, *B. cepacia* lipase is a preferable enzyme in the present case, with methanol being the nucleophile in diisopropyl ether. This, together with the results reported earlier on the resolution of 2-substituted carboxylic acids via the lipase-catalyzed irreversible transesterification where lipases from *A. niger* and *B. cepacia* were utilized, demonstrates that the microbial lipase-catalyzed transesterification procedure in organic milieu must be useful for the resolution of various racemic carboxylic acids, taking into account that these lipase preparations are available easily and inexpensively.

Experimental

General

Thin-layer chromatography was run on precoated silica gel plates (Merck). Melting points were determined on a Yamato MP-21 apparatus and are uncorrected. Optical rotations were measured with a JASCO DIP-4 digital polarimeter. ^{1}H NMR spectra were obtained at 300 MHz on a Varian Unity 300 spectrometer using chloroform-*d* as a solvent with TMS as an internal standard. The liquid chromatograph employed was a Shimadzu LC-5A instrument, equipped with a Rheodyne 7125 sample injector and a Shimadzu SPD-2A variable wavelength UV monitor. A Shimadzu C-R1A data processor was used for data acquisition and processing.

Chemicals

The racemic amino acids were benzyloxycarbonylated using benzyloxycarbonyl chloride (*Z*-Cl) under the usual Schotten–Baumann conditions (16) to give *N*-*Z*-DL-amino acids, which were purified by recrystallization from appropriate solvents (e.g., ethyl acetate–petroleum ether) (8). They were converted to the 2,2,2-trifluoroethyl, 2-chloroethyl or 2,2,2-trichloroethyl esters by the EDC [l-ethy1-3-(3-dimethylaminopropyl)carbodiimide]-DMAP (4-dimethylaminopyridine) method (17) using the corresponding alcohols. All alcohols and organic solvents employed in this study were obtained commercially, and they were distilled following standard protocols and dried over molecular sieves prior to use.

Enzymes

Lipases from porcine pancreas (Type II) and *Candida rugosa* (Type VII) were purchased from Sigma-Aldrich Chemical Co. (USA). Lipases from *Candida rugosa* (MY), *Chromobacterium viscosum* (LP) and *Rhizopus japonicus* (Rhilipase A5) were supplied by Meito Sangyo Co. (Japan), Asahi Chemical Industry (Japan), and Nagase ChemteX Corporation (Japan), respectively. All other enzymes used were supplied by Amano Pharmaceutical Co. (Japan).

Reactions

General procedure for the lipase-catalyzed transesterification

In a typical experiment, a solution of the 2,2,2-trifluoroethyl ester of a racemic *N*-*Z*-DL-amino acid (DL-**1**; 0.4 mmol) and an alcohol (1.2 mmol) in an anhydrous organic solvent (0.8 mL) was stirred with a lipase preparation (120 mg) at 25 °C. The progress of the reaction was monitored by reversed-phase HPLC on a Cosmosil 5C_{18} column (4.6 mm i.d. × 150 mm; Nacalai Tesque, Japan) using aq. methanol as an eluent. When the desired degree of conversion (~40 % based on the racemic starting ester) had been achieved, the enzyme was filtered off and washed with diethyl ether. The error of conversion determined by the HPLC method was estimated as ~±1%. The filtrate and washing were combined and concentrated to a small volume, and the newly formed ester (**2**) was separated from the unchanged starting ester (**1**) by preparative TLC using hexane–diethyl ether (mainly 2:1, *v*/*v*) as a developing solvent. After the absence of the contaminant starting ester (**1**) had been confirmed by reversed-phase HPLC, the ester formed (**2**) was saponified by 0.1 mol/L NaOH in methanol as usual. The ee value of the resolved *N*-*Z*-amino acids (*Z*-AA) was determined by the following HPLC procedure (18): the obtained *Z*-AA was coupled with Gly-L-Phe-OMe to afford the diastereomeric tripeptide *Z*-AA-Gly-L-Phe-OMe, which was separated by reversed-phase HPLC. The peak area of each diastereomer separated was measured to calculate the ee value of the resolved amino acid. When the amino acid AA bears an aromatic ring, *Z*-AA was converted to *Z*-AA-Sar-L-Phe-OMe (Sar = sarcosine or *N*-methylglycine) for a better diastereomeric separation. The kinetic resolution during the couplings was found to be negligible, probably because achiral Gly or Sar occupies the coupling site in the amino component. When the product of the transesterification was the methyl ester, another procedure was also employed. The enantiomers of the methyl ester product were separated directly by normal-phase HPLC on a chiral column, Chiralcel OD (4.6 mm i.d. × 250 mm; Daicel Chemical Industry, Japan), using hexane–2-propanol as an eluent (15). The ee values obtained by these different procedures were consistent with each other within the experimental error (±2%). The ee value for each compound compiled in Table 4 is that obtained by the HPLC procedure utilizing the diastereomeric separation.

The TLC and HPLC separations of the 2,2,2-trifluoroethyl esters (1) and methyl esters (**2**, R′ = CH_3) of *N*-*Z*-amino acids carrying aliphatic side chains are shown in Table 6.

Gram-scale resolution of N-Z-*norvaline*

The 2,2,2-trifluoroethyl ester of racemic *N*-*Z*-DL-norvaline (DL-**1c**; 1.40 g, 4.2 mmol) was dissolved in diisopropyl ether (8 mL), followed by the addition of methanol (520 µL, 12.8 mmol) and then *B. cepacia* lipase (1.2 g). The reaction mixture was stirred at 25 °C. The reaction was stopped after 9 h (33% conversion) by removing the enzyme powder by filtration. The enzyme was washed with diethyl ether. Evaporation of the solvent in vacuo from the combined filtrate and the washing afforded a pale yellow oil, from which the product (**2c**) was isolated by column chromatography on silica gel (Wakogel C-300) using hexane–diethyl ether (10:1, *v*/*v*) as an eluent. Thus, the unreacted trifluoroethyl ester (**1c**) eluted first, and further elution afforded the methyl ester (**2c**) as a colorless oil. The latter was saponified by 0.1 mol/L NaOH, and the raw material was recrystallized from EtOAc–petroleum ether to give *N*-*Z*-L-norvaline as colorless crystals: 290 mg (27% yield); mp 87–88.5 °C; $[\alpha]_D^{25}$ –4.2° (*c* 1.0, acetone). *N*-*Z*-L-norvaline thus obtained was re-esterified with diazomethane, and the resulting methyl ester was analyzed by HPLC on a Chiralcel OD column: 92% ee. In another run, the reaction was stopped after 35 h (55% conversion), and the unreacted trifluoroethyl ester (**1c**) was separated from the newly formed methyl ester (**2c**) by column chromatography in the same manner as mentioned earlier. The trifluoroethyl ester (**1c**) thus obtained was saponified by 0.1 mol/L NaOH, and the raw material was recrystallized from EtOAc–petroleum ether to give *N*-*Z*-D-norvaline as colorless crystals: 410 mg (39% yield); mp 89.5–90 °C; $[\alpha]_D^{25}$ +4.6° (*c* 1.0, acetone); 97% ee by HPLC. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.94 (3H, t. *J* = 7.4 Hz, CH_3), 1.30–1.50 (2H, m, C$H_2$$CH_3$), 1.61–1.95 (2H, m, CHC$H_2$), 4.41 (1H, q-like, CH), 5.12 (2H, apparent s, PhCH_2), 5.27 (1H, d, *J* = 8.1 Hz, NH), 7.26–7.41 (5H, m, Ph), 10.48 (1H, br, OH). Anal. calcd. for $C_{13}H_{17}NO_4$: C, 62.14; H, 6.82; N, 5.57%. Found: C, 62.30; H, 6.89; N, 5.58%.

Carbanion reactivity — σ-adduct formation and elimination in the reactions of the carbanion from bis(phenylsulfonyl)methane with 4-nitrobenzofurazan derivatives

Basim H.M. Asghar, Michael R. Crampton, and Chukwuemeka Isanbor

Abstract: ^{1}H NMR studies in [$^2H_6$]-DMSO show that the carbanion **4** from bis(phenylsulfonyl)methane reacts with 4,6-dinitrobenzofuroxan to yield a σ-adduct that undergoes base-catalysed elimination to yield an alkene derivative. Rate constants, measured spectrophotometrically, are reported for the corresponding reactions in methanol of **4** with 4-nitrobenzofurazan and some derivatives that give adducts at the 5-position. The intrinsic rate constant, k_o, for this process has a value of 1.5 ± 0.5. The 5-adducts undergo methoxide-catalysed elimination of phenylsulfinic acid to yield alkene derivatives and rate constants for this process are reported.

Key words: carbanions, 4-nitrobenzofurazan, σ-adducts, elimination reactions.

Résumé : Des études de RMN du ^{1}H dans du [$^2H_6$]-DMSO montrent que le carbanion **4** obtenu à partir du bis(phénylsulfonyl)méthane réagit avec le 4,6-dinitrobenzofuroxane pour donner un adduit σ qui subit une élimination catalysée par les bases pour conduire à la formation d'un alcène. On rapporte les constantes de vitesses, mesurées d'une façon spectroscopique, pour les réactions correspondantes du composé **4** avec le 4-nitrobenzofurazane et quelques dérivés qui conduisent à la formation d'adduits en position 5. La valeur de la constante intrinsèque de vitesse pour ce processus, k_0 = 1,5 ± 0,5. Les adduits en position 5 subissent une élimination d'acide phénylsulfinique catalysée par l'ion méthylate pour conduire à des alcènes et on rapporte les constantes de vitesse de ce processus.

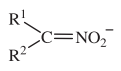
Mots-clés : carbanions, 4-nitrobenzofurazane, adduits σ, réactions d'élimination.

[Traduit par la Rédaction]

Introduction

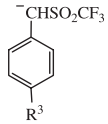
There is much current interest in quantitatively assessing both nucleophilic and electrophilic reactivities. The nucleophilicities of many carbanions have been measured (1–4) using their reactions with benzhydrylium cations and quinone methides, while the electrophilicities of compounds ranging in reactivity from 1,3,5-trinitrobenzene to 4,6-dinitrotetrazolopyridine have been compared by measuring rate constants for their σ-adduct forming reactions with some standard nucleophiles, such as *N*-methylpyrrole and indole derivatives (5–7).

We have recently used the reactions with 4-nitrobenzofurazan and some derivatives to compare the nucleophilicities in methanol of some nitroalkane anions (8) (**1**) and benzyltriflone anions (9) (**2**). These reactions result initially in the formation of anionic adducts at the 5-position of the nitrobenzofurazans, as shown in the general scheme 1. These results indicate that factors that affect the reactivities include the extent of charge delocalization, high in the case of **1** and low in the case of **2**, in the nucleophiles and steric hindrance to bond formation, which is significant for the reaction of **2**.



1

R^1,R^2 = H, Me



2

R^3 = H, CF_3, CN

It is also of interest that the initially formed adducts may undergo a base-catalysed elimination reaction to produce alkene derivatives.

Following many earlier studies (10–12), there has recently been renewed interest (13) in measuring nucleofugalities of leaving groups. The elimination process shown in Scheme 1 is likely (8, 9) to involve the bimolecular E2 mechanism so that values of the rate constants do not give nucleofugalities directly. Nevertheless, it is useful to examine how the structure of the leaving group Z^- affects the rate of the elimination process.

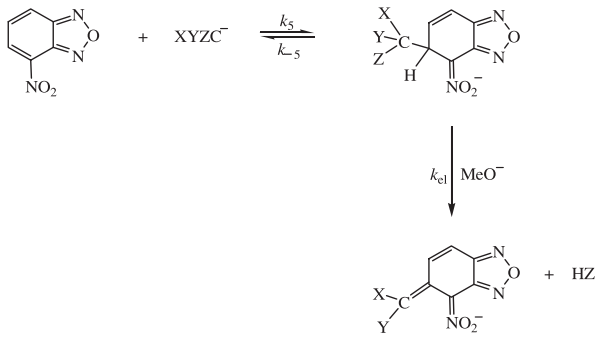
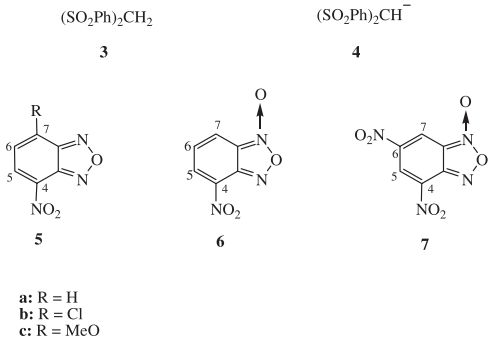
Scheme 1.



In the present work, we extend our studies to include reactions of the carbanion (**4**) from bis(phenylsulfonyl)methane (**3**). Rate constants in methanol as solvent are reported for the formation of the initial σ-adducts with some 4-nitrobenzofurazan derivatives (**5**), with 4-nitrobenzofuroxan (**6**), and also for the methoxide catalysed elimination of phenylsulfinic acid.



a: R = H
b: R = Cl
c: R = MeO

^{1}H NMR measurements in [$^2H_6$]-DMSO show that reaction of **4** with 4,6-dinitrobenzofuroxan (**7**) results in the initial formation of a σ-adduct at the 7-position followed by elimination of phenylsulfinic acid.

Results and discussion

pK_a Value of bis(phenylsulfonyl)methane 3 in methanol

Since kinetic measurements were made in methanol it was necessary to determine the pK_a value of **3** in this solvent. Reaction of **3** with sodium methoxide in methanol resulted in a strong absorbance band at 280 nm (ε 1.6 × 10^4 dm^3 mol^{-1} cm^{-1}) attributed to formation of the carbanion **4** as indicated in eq. [1]. Absorbance measurements gave a value for K of 40 ± 5 dm^3 mol^{-1}, and the use of eq. [2] leads to a value for pK_a of 15.3 for **3**.

[1] $\mathbf{3} + MeO^- \xleftrightarrow{K} \mathbf{4} + MeOH$

[2] $pK_a = pK_{MeOH} - \log K$

^{1}H NMR spectra

4,6-Dinitrobenzofuroxan **7** is classed as a super-electrophile (14) and will form σ-adducts at the 7-position by reaction with many weakly acidic carbon acids (15–16). ^{1}H NMR spectra in [$^2H_6$]-DMSO of a mixture of **7** (0.1 mol dm^{-3}), **3** (0.1 mol dm^{-3}), and triethylamine (0.1 mol dm^{-3}) provide evidence for the formation of the σ-adduct **8**. Chemical shifts are given in Table 1. Interestingly, the spectrum of **8** shows that the two phenyl rings are not exactly equivalent so that two sets of bands, with equal intensities, are observed for their ring hydrogens. In the presence of excess triethylamine, new bands are observed that are consistent with the formation of the product **9** of the elimination of phenylsulfinic acid. Notably, two singlets due to **9** are observed at δ 8.62 (H5) and δ 7.17 (CH). These results are summarized in Scheme 2. It is known (17) that **7** will react with methanol to give a very stable 7-methoxy adduct, and this precluded kinetic studies of reactions of **7** with **3** in this solvent.

Spectra of 1,3,5-trinitrobenzene in [$^2H_6$]-DMSO containing **3** and triethylamine gave no evidence of strong interaction. After several hours only bands due to the parent molecules were present.

Kinetic measurements

Reactions of the carbanion **4**, generated from **3** and sodium methoxide, with **5a**–**5c** and **6** were investigated spectrophotometrically in methanol. It is known that methoxide ions themselves will react with **5a**–**5c** and **6** to give σ-adducts (18, 19), and in the case of **5b** a substitution product (19). To minimize these reactions, the equilibrium methoxide concentrations were reduced to low levels by working with [**3**] >> [NaOMe] and (or) by using phenolic buffers. Under these conditions the UV–vis spectra of **5a** revealed two processes well separated in time. The first process resulted in a shift in the absorption maximum from 325 nm (ε 8 × 10^3 dm^3 mol^{-1} cm^{-1}) in the parent to 335 nm (ε 1.2 × 10^4 dm^3 mol^{-1} cm^{-1}) and is attributed to σ-adduct formation. The second slower process gave rise to a strong band at 430 nm (ε 2.0 × 10^4 dm^3 mol^{-1} cm^{-1}) and is attributed to the formation of the alkene derivative **11a** by elimination of phenylsulfinic acid from the σ-adduct. The UV–vis spectra of **5b**, **5c**, and **6** similarly showed a fast process, giving a band in the region 330–340 nm. In the case of **5b** and **6**, this was followed by a slower reaction giving an absorption band in the region 430–450 nm. However, with **5c** this process was too slow for measurement. These reactions are shown in Scheme 3.

Our justification for assigning structure **10**, resulting from attack at the 5-position, to the product of the fast reaction is that previous studies with carbanions derived from benzylcyanides (20), nitroalkanes (8), and benzyltriflones (9), have shown that formation of 5-adducts is kinetically favoured relative to the formation of the isomeric 7-adducts. Also in the case of **5b** and of **5c**, reaction at the 7-position is unlikely because of the presence of the 7-substituent (8, 21). That the slower process involves elimination follows by analogy with the behaviour of the nitroalkane adducts (8), which eliminate nitrous acid, and the benzyltriflone adducts (9), which eliminate trifluoromethylsulfinic acid. In these cases, as in the present case, the elimination process involves a shift to longer wavelength in the absorption maximum, consistent with the increased electron delocalization possible in the elimination products. A further analogy is with the behaviour of **8**, which will eliminate phenylsulfinic acid.

Kinetic measurements of the fast reaction were made either with [**3**] and [NaOMe] >> [**5**] or [**6**], or with methoxide

concentration (hence the concentration of **4**) buffered at constant values. Under these conditions, the fast reaction k_{fast} was observed as a first-order process, and eq. [3] will apply. Values of rate constants are given in Table 2. Linear plots of k_{fast} versus the carbanion concentration allowed the evaluation of k_5 and k_{-5}. Since the intercepts of the plots had low values, there are relatively high errors associated with the values of k_{-5} determined in this way. Therefore, measurements were also made, shown in the final three rows of Table 2, using buffered solutions where the concentrations of carbanion were reduced to low levels. Here the k_{-5} term made a large contribution to the overall value of k_{fast}. Using the known values of k_5, values of the term k_5[carbanion] were subtracted from k_{fast} to allow the evaluation of k_{-5}. The good correspondence between experimental and calculated values of k_{fast} (Table 2) gives confidence in the results obtained. Values for k_5, k_{-5}, and K_5, calculated as k_5/k_{-5}, are collected in Table 4.

[3] $$k_{fast} = k_5[(SO_2Ph)_2CH^-] + k_{-5}$$

Kinetic measurements for the slower reaction were made with concentrations of the carbanion **3** that were high enough to ensure that the initial conversion of parent nitrocompounds to adducts **10** was largely complete. In the cases of **5a**, **5b**, and **6**, a first-order process k_{slow} measured at 430–450 nm was observed and is attributed to the elimination of phenylsulfinic acid to give the alkene derivatives **11**. The results in Table 3 show that values of k_{slow} increase linearly with the equilibrium concentrations of methoxide ions, so that eq. [4] is applicable, and there is no dependence on the carbanion concentration. Values obtained for k_{el} were 2.6, 12, and 8 dm^3 mol^{-1} s^{-1} for **5a**, **5b**, and **6**, respectively. In the case of **5c**, this reaction was too slow for convenient measurement.

[4] $$k_{slow} = k_{el}[MeO^-]$$

Comparisons

Results are collected in Table 4. Variations in values among the compounds **5a**–**5c** and **6** are largely in line with data obtained with other nucleophiles (8, 19, 22, 23). Thus the higher value of k_5 found for **5b** compared with **5a** reflects the inductive effect of the chlorine meta to the position of attack. The reduced electrophilicity of **5c** is attributed to resonance stabilization in the parent between the NO_2 and OMe ring-substituents. The N→O functionality (18) in **6** results in increases in values of k_5 and K_5 compared with **5a**.

Although the data is limited, we thought it worthwhile to estimate a value for the intrinsic rate constant k_o, in the Marcus (24–26) sense, for reactions of the carbanion **3** with the nitrobenzofurazan derivatives. A plot, not shown, of the values of log k_5 and log k_{-5} vs. log K_5 gave a value for k_o of 1.5 ± 0.5. The values of intrinsic rate coefficients are thought (26–29) to reflect the amount of electronic–structural reorganisation and solvent reorganisation accompanying a reaction; the more reorganisation required, the lower the reactivity. The value obtained here is significantly higher than that (k_o = 0.05) found (8) for the reaction of nitroalkane anions **1** with nitrobenzofurazans. This suggests that in the carbanions **4**, as with the benzyltriflone anions (4,

Table 4. Summary of kinetic and equilibrium data for the reactions in Scheme 3.

Compound	k_5 (dm^3 mol^{-1} s^{-1})	k_{-5} (s^{-1})	K_5 (dm^3 mol^{-1})	k_{el} (dm^3 mol^{-1} s^{-1})
5a	500±100	0.04±0.01	$(1.25\pm0.4) \times 10^4$	2.6
5b	$(1.4\pm0.2) \times 10^4$	—	—	12
5c	350±50	0.08±0.02	$(4.4\pm1) \times 10^3$	—
6	$(1.6\pm0.2) \times 10^3$	0.05±0.02	$(3.2\pm1) \times 10^4$	8

9) **2**, the negative charge is more localized on the carbon atom than in the nitroalkane anions. In agreement with this, it should be noted that Hibbert (30, 31) found that little structural reorganisation was involved in ionization of disulfonyl carbon acids in water.

The previous study (9) with carbanions **2** derived from benzyltriflones found evidence for some steric hindrance to the reaction with 4-nitrobenzofurazan derivatives, and the reaction with the more sterically demanding 1,3,5-trinitrobenzene was not observed. The present results suggest that the nucleophilicity of the carbanion **4** from bis(phenylsulfonyl)methane may similarly be reduced by its high steric requirements. Thus again, no reaction is observed with 1,3,5-trinitrobenzene and the values of k_5 for the reaction with 4-nitrobenzofurazan are similar for carbanions **4** and **2** (R3=CN) derived from carbon acids with similar pK_a values. Thus for **4**, k_5 = 500 dm^3 mol^{-1} s^{-1} and pK_a for **3** is 15.3, and for **2** (R3 = CN) k_5 = 1500 dm^3 mol^{-1} s^{-1} and pK_a for 4-cyanobenzyltriflone (9) is 16.0.

Elimination reactions have now been observed from 5-adducts produced from 4-nitrobenzofurazan derivatives and three types of carbanion, i.e., nitroalkane anions (8), benzyltriflone anions (9), and the bis(phenylsulfonyl)methane anion, and it is useful to compare kinetic data in methanol. Values of the rate constant k_{el} for the methoxide-catalysed elimination of nitrous acid from the nitromethane and nitroethane adducts of 4-nitrobenzofurazan **5a** are 3.0 and 1.4 dm^3 mol^{-1} s^{-1}, respectively (8), and are similar to the value of 2.6 dm^3 mol^{-1} s^{-1} found here for the elimination of phenylsulfinic acid from **10**, R = H. In both types of reaction, the presence of the electron-withdrawing 7-chloro substituent in **5c** increases values of k_{el}. Interestingly, in the reactions with the benzyltriflone anion the elimination of trifluoromethylsulfinic acid from the initially formed 5-adducts is faster than their reversal to parent, $k_{el}[MeO^-] > k_{-5}$, so that values of k_{el} are not measurable (9). It might be inferred that the value of k_{el} for the elimination of trifluoromethylsulfinic acid is higher than the corresponding values for the elimination of nitrous acid and phenylsulfinic acid. Indeed, the high nucleofugal character of the SO_2CF_3 group and the possible use of SO_2CF_3 activated carbon acids in vicarious nucleophilic substitutions has been noted previ-

© 2008 NRC Canada

ously (32, 33). Nevertheless, our results (9) do not yield a value for k_{el} for trifluoromethyl sulfinic acid so that a direct comparison is not possible.

In fact, the elimination process is likely (34) to involve the E2 mechanism so that factors other than the nucleofugality of the leaving group are involved. These include steric factors involving the accessibility to the catalysing base of the acidic hydrogen to be removed from the reaction centre in the adducts, such as **10**, and possible steric interaction with the ring nitro-group in the alkene products, such as **11**. For example, the adduct **10**, carrying two phenylsulfonyl groups, is likely to be more sterically demanding than the corresponding adduct produced from the nitromethane carbanion. It should also be noted that in the elimination process in methanol, catalysis has been observed only by the methoxide ion and not by unreacted carbanions, present in excess, which will be more sterically inhibited.

Experimental

Nitro-compounds **5a**–**5c**, **6**, and **7** were available from previous work [9]. Bis(phenylsulfonyl)methane was a commercial sample. Solutions of sodium methoxide were prepared by dissolving clean sodium in AnalaR methanol under nitrogen. Solutions containing very low equilibrium concentrations of methoxide ions were prepared using buffers prepared from 4-bromophenol, whose p*K*a value (35) in methanol is 13.61. All other materials and solvents were the purest available commercial samples.

^{1}H NMR spectra in [$^2H_6$]-DMSO were recorded with a Bruker Avance 400 MHz instrument, UV-vis spectra and kinetic measurements were made at 25 °C with a Shimadzu UV-2101 PC spectrophotometer or an Applied Photophysics SX-17 MV stopped-flow instrument. First-order rate constants, precise to ± 5%, were evaluated using standard methods.

Bright blue luminescent pyrenyl-containing organosilicon compounds with contrasting charge transport functionality — $SiPh_2$(*p*-C_6H_4-pyrenyl)(*p*-C_6H_4-*N*-benzimidazolyl) and $SiPh_2$(*p*-C_6H_4-pyrenyl)[*p*-C_6H_4-NPh(1-naph)]

Dongren Bai, Shijin Han, Zheng-Hong Lu, and Suning Wang

Abstract: The authors investigated the impact of electron-transport and hole-transport functional groups on the properties and the performance of blue luminescent organosilicon compounds as bifunctional materials in organic light-emitting devices. Two new pyrenyl-containing organosilicon compounds, $SiPh_2$(*p*-C_6H_4-pyrenyl)(*p*-C_6H_4-*N*-benzimidazolyl) (**1**) and $SiPh_2$(*p*-C_6H_4-pyrenyl)[*p*-C_6H_4-NPh(1-naph)] (**2**) were synthesized. Both compounds display bright blue luminescence in solution and in the solid state with a high quantum efficiency, but they have contrasting electroluminescent properties. The presence of the benzimidazolyl group in **1** enables it to function as a bifunctional material (blue emitter and electron transporter) in OLEDs. An efficient triple-layer (CuPc/NPB/**1**) blue OLED (C.I.E. 0.15, 0.14) was fabricated successfully. The presence of the NPh(1-naph) group in **2** enables its use as an effective transparent hole injection material, but not a blue emitter in OLEDs.

Key words: organosilicon compounds, synthesis, luminescence, electroluminescence, devices.

Résumé : On a étudié l'impact des groupes fonctionnels transporteurs d'électron ou de trou sur les propriétés et la performance de composés organosiliciés luminescents dans le bleu comme matériaux bifonctionnels dans les systèmes organiques qui émettent de la lumière (SOEL). On a synthétisé deux nouveaux composés organosiliciés contenant du noyau pyrényle, $SiPh_2$(*p*-C_6H_4-pyrényl)(*p*-C_6H_4-*N*-benzimidazolyle) (**1**) et $SiPh_2$(*p*-C_6H_4-pyrényl)[*p*-C_6H_4-*N*-Ph(1-naphtyle) (**2**). En solution ainsi qu'à l'état solide, chacun de ces composés fournit une intense luminescence bleue, avec une efficacité quantique élevée, mais présentent des propriétés électroluminescentes différentes. La présence, dans le composé **1**, d'un groupe benzimidazolyle lui permet de fonctionner comme matériel bifonctionnel (émettant dans le bleu et transporteur d'électron) dans les SOEL. On a réussi à fabriquer un SOEL bleu à triple couche (CuPc/NPB/**1**) efficace (C.I.E. 0,15, 014). La présence du groupe Nph(1-naphtyle) dans le composé **2** permet de l'utiliser comme un matériel efficace comme trou d'injection transparent, mais il ne peut pas être utilisé comme émetteur dans le bleu dans les SOEL.

Mots-clés : composés organosiliciés, synthèse, luminescence, électroluminescence, systèmes.

[Traduit par la Rédaction]

Introduction

Organic light emitting diodes (OLEDs) have been widely recognized as a promising technology for second-generation flat-panel display because of advantages such as a wide viewing angle, operation over a wide temperature range, and low power consumption (1). Despite the tremendous progress achieved (2–6) since the seminal report (1*a*) by Tang and co-workers, device stability (2) and the lack of blue emitters (3) remain challenging tasks in OLEDs research. Bifunctional molecules, which can act as both emitter and charge-transport material, have recently attracted much attention because of their potential in simplifying OLED device structure and reducing manufacturing cost (4–6). Because most organic molecules can transport holes more effectively than electrons (7), hole-transport emitters constitute the majority of bifunctional emitters reported so far. Therefore emitters, especially blue emitters, with electron-transport capability are still very much in demand.

Saturated organosilicon compounds are attractive because of their high chemical and thermal stability and the possibility of attaching up to four different functional groups to the silicon center (5, 8). Chen and co-workers have demonstrated extensively the effectiveness of a tetraphenylsilane core in enhancing the glass-forming ability of the molecules and the successful use of derivatives with a tetraphenylsilane

core in OLEDs (5). We have also reported previously that homo-functionalizing the silicon center with dipyridylaminoaryl groups can produce blue emitters with good morphological and thermal stability (8). We have also demonstrated that hetero-functionalization of the silicon center by both donor and acceptor groups can result in not only efficient blue emitters but also molecules with dual emission, which has found important applications in fluorescent sensing for fluoride (9). In search of new and highly efficient bifunctional blue emitters, we have investigated several pyrene-functionalized silicon compounds, two of which, $SiPh_2$(*p*-C_6H_4-pyrenyl)(*p*-C_6H_4-*N*-benzimidazolyl) (**1**) and $SiPh_2$(*p*-C_6H_4-pyrenyl)[*p*-C_6H_4-NPh(1-naph)] (**2**), have been found to display bright blue emission in the solid state with contrasting charge transport properties in OLEDs. The details are presented herein.

Experimental

All starting materials were purchased from Sigma-Aldrich Chemical Company and were used without further purification. Solvents were freshly distilled over appropriate drying reagents. All experiments were carried out under a dry nitrogen atmosphere using standard Schlenk techniques unless otherwise stated. TLC was carried out on silica gel. Flash chromatography was carried out on silica (silica gel 60, 70–230 mesh). ^{1}H and ^{13}C NMR spectra were recorded on Bruker Avance 300, 400, or 500 MHz spectrometers. Excitation and emission spectra were recorded on a Photon Technologies International QuantaMaster Model 2 spectrometer. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Delta, British Columbia, Canada. Melting points were determined on a Fisher-Johns melting point apparatus. All DSC measurements were performed on a PerkinElmer Pyris DSC 6 with a heating rate of 10 °C/min and a cooling rate of 20 °C/min. Cyclic voltammetry was performed on a BAS CV-50W analyzer with a scan rate of 100 mV s^{-1}. The electrolytic cell used was a conventional three-compartment cell, with a Pt working electrode, Pt auxiliary electrode, and Ag–AgCl reference electrode. All experiments were performed at room temperature with 0.10 mol/L tetrabutylammonium hexafluorophosphate in CH_2Cl_2 as the supporting electrolyte. The ferrocenium–ferrocene couple was used as the internal standard. High-resolution mass spectra were obtained using electrospray mode with internal calibrants on an Applied Biosystems/MDS-Sciex QSTAR XL spectrometer. The synthesis of $SiPh_2${*p*-[(*N*-(1-naph)ph]Ph}(*p*-Br-Ph) was reported previously by our group (9).

Synthesis of $SiPh_2$(*p*-Br-Ph)(*p*-C_6H_4-*N*-benzimidazolyl) (1a)

Si(*p*-Br-Ph)$_2$$Ph_2$ (2.4 mmol, 1.19 g), benzimidazole (2.0 mmol, 0.241 g), cupric sulfate hydrate (0.025 g), and potassium phosphate (0.300g) were heated at 230 °C for 10 h under nitrogen. After cooling to ambient temperature, the reaction mixture was dissolved in 40 mL of CH_2Cl_2 and washed by water. The water layer was separated and extracted with CH_2Cl_2 (3 × 30 mL). The combined organic layers were dried over $MgSO_4$ and the solvents were evaporated under reduced pressure. The residue was subjected to column chromatography on silica gel (ethyl acetate / hexane as eluent) to afford a colorless solid of **1a** in 31% yield. ^{1}H NMR in $CDCl_3$ (25 °C, ppm) δ: 8.19 (s, 1H), 7.92 (d, *J* = 5.2, 1H), 7.78 (d, *J* = 7.6, 2H), 7.63 – 7.57 (m, 8H), 7.54–7.44 (m, 9H), 7.37 (t, *J* = 4.0, 2H). ^{13}C NMR in $CDCl_3$ (25 °C, ppm) δ: 140.85, 137.07, 136.84, 136.34, 135.25, 134.06, 133.52, 131.83, 131.48, 130.32, 129.14, 127.20, 127.08, 124.10, 123.13, 122.36, 122.22, 119.33, 109.74. HRMS *m/z*: found 531.0866 ([M + H]$^+$, calcd. 531.0892).

Synthesis of $SiPh_2$(*p*-C_6H_4-pyrenyl)(*p*-C_6H_4-*N*-benzimidazolyl) (1)

To a mixture of pyrenyl-1-boronic acid (0.375 mmol, 0.093 g), **1a** (0.25 mmol, 0.135 g), $Pd(PPh_3)_4$ (0.013 mmol, 0.015 g), and Na_2CO_3 (0.500 g) was added degassed EtOH (3 mL), H_2O (3 mL), and toluene (5 mL). The mixture was stirred and heated at reflux for 2 days. The reaction mixture was dissolved in 40 mL of CH_2Cl_2 and washed by water. The water layer was separated and extracted with CH_2Cl_2 (3 × 30 mL). The combined organic layers were dried over $MgSO_4$, and the solvents were evaporated under reduced pressure. The residue was subjected to column chromatography on silica gel (with ethyl acetate / hexane as eluent) to afford a colorless solid **1** in 65% yield. ^{1}H NMR in $CDCl_3$ (25 °C, ppm) δ: 8.31–8. 20 (m, 5H), 8.12 (s, 2H), 8.10–8.03 (m, 3H), 7.98 (d, *J* = 6.4, 1H), 7.94 (d, *J* = 6.8, 2H), 7.88 (d, *J* = 6.4, 2H), 7.80 (d, *J* = 6.0, 4H), 7.75 (d, *J* = 6.8, 2H), 7.68 (d, *J* = 6.8, 1H), 7.62 – 7.54 (m, 8H), 7.41 (t, *J* = 4.8, 2H). ^{13}C NMR in $CDCl_3$ (25 °C, ppm) δ: 143.50, 142.84, 142.30, 138.27, 137.44, 137.30, 136.52, 136.46, 135.03, 133.59, 133.42, 132.30, 131.52, 131.17, 131.00, 130.80, 130.13, 129.88, 128.47, 128.28, 127.67, 127.64, 127.45, 126.13, 125.91, 125.29, 125.21, 125.04, 124.98, 124.94, 124.79, 124.06, 123.26, 120.50, 110.82. HRMS *m/z*: found 653.24130 ([M + H]$^+$, calcd. 653.2412).

Synthesis of $SiPh_2$(*p*-C_6H_4-pyrenyl)[*p*-C_6H_4-NPh(1-naph)] (2)

To a mixture of pyrenyl-1-boronic acid (0.185 g, 0.74 mmol), $SiPh_2$ {*p*-[(*N*-(1-naph)Ph]Ph}(*p*-Br-Ph) (0.310 g, 0.49 mol), $Pd(PPh_3)_4$ (0.025 g, 0.022 mmol), and Na_2CO_3 (1.00 g) was added degassed EtOH (5 mL), H_2O (5 mL), and toluene (10 mL). The mixture was stirred and heated at reflux for 2 days. The reaction mixture was dissolved in 40 mL of CH_2Cl_2 and washed by water. The water layer was separated and extracted with CH_2Cl_2 (3 × 30 mL). The combined organic layers were dried over $MgSO_4$ and the solvents were evaporated under reduced pressure. The residue was subjected to column chromatography on silica gel (with methylene chloride / hexane as eluent) to afford a colorless solid **2** in 55% yield. ^{1}H NMR in $CDCl_3$ (25 °C, ppm) δ: 8.20 (m, 4H), 8.12 (s, 2H), 8.01 (m, 4H), 7.91 (d, 1H), 7.80 (m, 3H), 7.68 (m, 6H), 7.46 (m, 12H), 7.23 (t, 2H), 7.18 (d, 2H), 7.04 (d, 2H), 7.00 (t, 1H). ^{13}C NMR in $CDCl_3$ (25 °C, ppm) δ: 149.80, 147.70, 143.12, 142.31, 137.63, 137.46, 136.55, 136.48, 135.39, 134.82, 133.57, 131.62, 131.55, 131.50, 131.06, 130.72, 130.13, 129.67, 129.28, 128.53, 128.00, 127.71, 127.69, 127.57, 127.55, 127.49, 126.94, 126.63, 126.47, 126.30, 126.08, 125.41, 125.20, 125.05, 124.99, 124.93, 124.88, 124.77, 124.30,

122.95, 122.60, 119.88. HR-MS data *m/z*: found 792.2485 ($[M + K]^+$, calcd. 792.2489).

Solution photoluminescent quantum yield measurements

Emission quantum yields were determined relative to anthracene in CH_2Cl_2 at 298 K ($\Phi_r = 0.36$). The absorbance of all samples and the standard at the excitation wavelength was approximately 0.094–0.114. The quantum yields were calculated by previously reported procedures (10).

Thin-film photoluminescent quantum yield measurements

UV–vis absorption spectra were measured with a Cary 50 Bio (Varian) spectrophotometer. Photoluminescence spectra were recorded using a Horiba Jobin Yvon SPEX FluoroLog equipped with an integrating sphere. The solid-state absolute quantum yields of luminescence efficiencies were obtained using the integrating sphere. Excitation wavelengths of 320 and 330 nm were used for **1** and **2**, respectively.

OLED device fabrication

Electroluminescent (EL) devices were fabricated using a K.J. Lesker OLED cluster tool with six high-vacuum process chambers. For the current experiments, 2 in × 2 in (1 in = 25.4 mm) ITO coated-glass substrates were used. The patterned ITO surface was sequentially cleaned in acetone, methanol, and de-ionized water, and then with UV–ozone treatment. All the testing devices had an active area of 2 mm^2. The base pressures of the organic and metallization chambers were 4×10^{-8} and 1.9×10^{-6} Torr (1 Torr = 133.322 4 Pa), respectively. The pressures during the deposition process in the two chambers were lower than 1.9×10^{-6} Torr. The growth rates were ~1.5 Å s^{-1} for organic materials, 0.2 Å s^{-1} for LiF, and ~1.5 Å s^{-1} for metals (Al and Ag). Luminance – current density – voltage (L–J–V) characteristics were determined in ambient atmosphere using a HP 4140B pA meter and a Minolta LS-110 meter. The dwell time for each testing point was 2 s. EL spectra were recorded using a USB2000-UV-VIS Miniature Fiber Optic Spectrometer.

Results and discussion

Syntheses

The synthetic procedures for intermediate **1a** and final products **1** and **2** are depicted in Scheme 1. Intermediate **1a** was obtained by copper-catalyzed Ullmann condensation between benzimidazole and $SiPh_2(p\text{-Br-Ph})_2$ in 31% isolation yield (11). Due to the low reactivity of the bromide starting material, a high reaction temperature of 220 °C was employed. Excess $SiPh_2(p\text{-Br-Ph})_2$ was used to reduce the formation of di-substituted by-product. Palladium-catalyzed Suzuki–Miyaura cross-coupling between 1-pyrenylboronic acid and **1a** afforded product **1** in 65% yield (12). Similarly, product **2** was obtained from 1-pyrenyl boronic acid and $SiPh_2\{p\text{-}[(N\text{-}(1\text{-naph})Ph]Ph\}(p\text{-Br-Ph})$ via Suzuki–Miyaura cross-coupling in 55% yield.

Physical and electronic properties

Compounds **1** and **2** are stable in solution and the solid state upon extended exposure to air. DSC measurements were carried out to assess the thermal properties of both compounds. As shown in Fig. 1, compound **2** has a glass transition temperature at 110 °C, indicating that it is capable of forming an amorphous phase. The fact that the glass transition is observable after many repeated heating and cooling cycles confirms its excellent morphological and thermal stability, which can be attributed to the presence of the NPh(1-naph) moiety as well as the tetrahedral silicon core. A decomposition temperature of 500 °C from TGA measurement further confirms the outstanding thermal stability of **2**. **1** displays a decomposition temperature ~290 °C, but no glass transition temperature was observed.

Both **1** and **2** exhibit intense absorption bands at $\lambda >$ 380 nm with distinct pyrene features (see Supplementary Data).[2] In addition, the spectra of **1** and **2** have a distinct low-energy absorption band at $\lambda_{max} \approx 350$ nm, which can

be attributed to the benzimidazolyl group in **1** and the N(1-naph)Ph group in **2**. The redox potentials for **1** and **2** were obtained from cyclic voltammetry measurements. As shown in Fig. 2, there are two reversible oxidation peaks for **2** in CH_2Cl_2. Compared to the CV diagram of (1-naph)PhN-biphenyl-NPh(1-naph), NPB, the first oxidation peak at $E^{1/2}$ = ~1.04 V is assigned to the oxidation of the nitrogen center of the NPh(1-naph) group and the second oxidation peak at $E^{1/2}$ = ~1.36 V to the pyrene ring. No reduction peak was observed for **2** within the range of the solvent limit. In contrast, compound **1** displays an irreversible oxidation peak at E^{p} = ~1.50 V, corresponding to the oxidation of the pyrene ring and a quasi-reversible reduction peak at $E^{1/2}$ ~–1.2 V, which can be assigned to the reduction of the benzimidazolyl moiety. Using the oxidation potentials and the optical energy gaps obtained from the UV–vis absorption edge, the HOMO and LUMO energies were estimated and are provided in Table 1.

The luminescent data for **1** and **2** are summarized in Table 2. Both compounds are blue luminescent as shown in

Table 1. HOMO and LUMO energies of **1** and **2**.

Compound	HOMO[a] (eV)	LUMO[b] (eV)	Optical energy gap (eV)
1	–5.86	–2.76 (–3.10)[c]	3.10
2	–5.36	–2.24	3.12

[b]From the optical energy gap and the HOMO energy.
[c]From the reduction potential in THF ($E^{1/2}$ for $FeCp_2^{0/+}$ = 0.50 V).

Figs. 3 and 4. In solution, the emission spectrum of **1** does not change significantly with solvent polarity, wheras compound **2** shows solvent-dependant emission, and the Stokes shift of **2** was found to have a linear relationship with the polarity of the solvent (see Supplementary Data), an indication that the emission of **2** originates from intramolecular charge transfer (9, 13).[2] The emission spectra for both compounds in the solid state are considerably red-shifted to the blue region compared with the solution spectra, with λ_{max} = 440 nm for **1** and 455 nm for **2**. Quantum efficiency in CH_2Cl_2 was found to be 0.95 for **1** and 0.83 for **2**, confirming that both are highly emissive in solution. Many blue emitters such as 9,10-diphenylanthracene are known to have a high quantum efficiency in solution. Most of them, however, have much diminished emission quantum efficiencies in the solid state because of strong intermolecular interactions (14). In contrast, the new pyrenyl-containing silicon compounds **1** and **2** maintain a high quantum efficiency in the solid state with Φ = 0.58 for **1** and 0.72 for **2**, respectively. The tetrahedral silicon backbone in **1** and **2** is believed to play a key role in reducing intermolecular interactions in the solid state, thus effectively blocking intermolecular energy-transfer pathways, reducing luminescent quenching, and leading to high emission efficiency in the solid state.

Molecular orbital calculations

Molecular orbital calculations were performed to further understand the electronic and luminescent properties of compounds **1** and **2**. Geometric parameters were obtained from molecular modeling and geometric optimization. The Gaussian suite of programs (Gaussian 98) (15) was employed for the calculations, which were performed with the B3LYT 6–311G** basis set for both compounds. As shown in Fig. 5, both HOMO and LUMO levels for **1** involve orbital contributions from the pyrenyl-phenyl group only. Hence, the lowest electronic transition for **1** should be a π–π * transition centered on the pyrenyl-phenyl group. In contrast, the HOMO level of **2** has contributions nearly exclusively from the π orbitals of the *p*-[*N*(1-naph)ph]phenyl group and its LUMO consists of contributions exclusively from the π* orbitals of pyrenyl-phenyl group. As a result, the lowest electronic transition in **2** is likely charge-transfer from the phenyl-N(naph)Ph group to the pyrenyl-phenyl group, consistent with the observed solvent-dependent emission. The difference between **1** and **2** can be explained by the electron-withdrawing nature of the benzimidazolyl group, which reduces its energy level below that of the pyrene group (HOMO) in **1**. In both compounds, the silicon center is not involved in either HOMO or LUMO; therefore

the charge transfer emission in **2** most likely occurs in a through-space manner.

Electroluminescence

Although **1** and **2** are both highly efficient blue emitters, they are expected to display different charge transfer properties. Compound **1** is expected to perform as an electron transport layer (ETL) because of its deep LUMO and HOMO levels and the electronegative nature of the benzimidazolyl ring. In fact, the benzimidazolyl group is responsible for the electron transport property of the well-known electron transport molecule TPBI (16). In contrast, compound **2** is expected to function as either a hole-transport (HTL) or hole-injection material because of its relatively high HOMO level and the presence of the well-known hole-transport group Nph(1-naph) (17). Based on these considerations, a series of devices was fabricated to evaluate the EL performance of **1** as an electron-transport blue emitter and **2** as a hole-transport blue emitter in OLEDs. The device structures and data are presented in Table 3.

Devices A–D were fabricated to evaluate the performance of **1**. Other materials used for these devices include CuPc as the hole-injection layer (HIL), NPB as HTL, and BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) and Alq_3 as ETL. Devices A, B, and C employ **1** as the emitter with either Alq_3 or BCP as the ETL. These three devices all produced bright blue emission with the EL maximum (440 nm) matching the PL maximum of **1** (440 nm) very well (Fig. 6), with good color purity (C.I.E. 0.15, 0.14) and maximum brightness up to 3102 cd/m^2, confirming that **1** can indeed function as an efficient blue emitter in OLEDs. Interestingly, the inclusion of CuPc as HIL resulted in a lower maximum brightness and a higher turn-on voltage, as revealed by the performance of devices A and B. Similar phenomena have been noted by Chen et al. (18). Alq_3 appears to be a better ETL than BCP in these devices, based on the performance of devices B and C. Device D has the simplest structure where no conventional ETL material is used and compound **1** is used as both a blue emitter and an ETL layer. Most interestingly, however, as shown in Figs. 7 and 8, device D delivered the best EL performance with the highest maximum brightness of 3562 Cd/m^2 at 8 V and the lowest turn-on voltage at 3.2 V, which unambiguously established the bifunctionality of **1** as both a blue emitter and an effective electron-transport material. The outstanding performance of **1** as an electron-transporting blue emitter can be attributed to its high emission quantum efficiency and to the low LUMO level (–2.76 eV from absorption edge and the oxidation potential or –3.10 eV from the reduction potential). This level is close or comparable to that of TPBI (16), thus facilitating electron injection from the cathode (device D) or the ETL layer to the molecule (device A, B, C). Although the brightness and the device efficiency of D is not yet as good as some of the blue OLEDs known in literature (5), the simplicity of the device structure and the lack of exciplex emission still make compound **1** a very promising new bifunctional material for OLEDs. With further structural optimization, it is very likely that the performance of the device can be further enhanced.

	Structure (thickness, nm)	Turn-on voltage (V)	Max. L (Cd/m^2)	Max. efficiency (Cd/A)/(lm/W)
A	CuPc(25)/NPB(45)/**1** (20)/Alq_3 (20)	3.8	2665	0.6/0.5
B	NPB(60)/**1**(20)/Alq_3(20)	3.4	3102	0.7/0.5
C	NPB(60)/**1**(20)/BCP(20)	3.6	2190	0.8/0.4
D	CuPc(25)/NPB(45)/**1** (40)	3.2	3562	0.9/0.7
E	CuPc(50)/**2** (50)/Alq_3(40)	10	4.8	0.1/0.1
F	NPB(50)/**2**(50)/Alq_3(40)	7.5	388	0.9/0.6
G	**2** (50)/NPB(50)/Alq_3(40)	4.8	16 650	4.6/2.3
H	CuPc(50)/NPB(50)/Alq_3(40)	3.0	19 720	4.1/3.3

Devices E–H were constructed to evaluate the performance of compound **2**. Devices E and F are similar in structure to devices A and B where the silicon compound was intended to function as a blue emitter (F) or a hole-transport blue emitter (E). However, in contrast to the blue-emitting devices A and B, devices E and F produced green emission that is typical of Alq_3, an indication that compound **2** is not an effective blue emitter in these devices, perhaps because of the poor electron transport ability of **2**. Nonetheless, as shown by the performance of devices G and H (Figs. 9 and 10), compound **2** can perform as a very efficient HIL with similar maximum brightness to the most commonly used HIL, CuPc. Although the operating voltage of device G, where **2** is used as the HIL, is much higher than that of the CuPc device H, at low brightness device G has an excellent current efficiency. Furthermore, compared with CuPc which has considerable absorption in the red region (19), **2** is transparent over the entire visible region, making it attractive as a colorless HIL material for full-color OLED devices.

In summary, two bifunctional organosilicon compounds,

with a tetraphenylsilane core, a pyrene functional group, and either a hole-transport group NPh(1-naph) or an electron-transport benzimidazolyl group, were synthesized. Although both compounds display bright blue photoluminescence, only the molecule that bears the benzimidazolyl group was found to function as an efficient blue emitter as well as a bifunctional electron-transporting blue emitter in OLEDs. The molecule that contains the hole-transporting group NPh(1-naph) was demonstrated to be effective as a hole-injection material, in conjunction with the hole-transport material NPB.

An unexpected elimination product leads to 4-alkyl-4-deoxy-4-*epi*-sialic acid derivatives

Ivan Hemeon and Andrew J. Bennet

Abstract: A useful, unexpected β,γ-unsaturated-α-keto ester (ethyl (*E*)-5-acetamido-3,4,5-trideoxy-6,7:8,9-di-*O*-isopropylidene-D-*manno*-non-3-en-2-ulosonate **5**) was isolated in 91% yield following ozonolysis and chromatographic purification of its enoate ester precursor ethyl 5-acetamido-2,3,4,5-tetradeoxy-6,7:8,9-di-*O*-isopropylidene-2-methylene-4-nitro-D-*glycero*-D-*galacto*-nononate (**6**). When the 4*R* enoate ester (ethyl 5-acetamido-2,3,4,5-tetradeoxy-6,7:8,9-di-*O*-isopropylidene-2-methylene-4-nitro-D-*glycero*-D-*talo*-nononate, **7**) was subjected to the same conditions, enone **5** was a minor product (18%) while the major product did not eliminate HNO_2 but instead cyclized to form a five-membered ring containing a hemiaminal linkage between C-2 and the amide nitrogen on C-5 (**9**, 70%). Conjugate addition to enone **5** opens up the potential to generate 4-substituted sialic acid derivatives, a general route to such compounds that has not been previously reported. In a preliminary investigation of such a route, diethylzinc and dimethylzinc were added to enone **5** resulting in generation of 4-alkyl-substituted cyclic hemiaminal structures **11** and **13**, which could be deprotected to form 2,7-anhydrosialic acid analogues **14** and **15**. These products could then be converted to peracetylated glycals **16** and **17**, the 4-methyl-substituted compound **17** being finally deprotected to give a 4-methyl-substituted analogue of the glycal of sialic acid (5-acetamido-2,6-anhydro-3,4,5-trideoxy-4-methyl-D-*glycero*-D-*talo*-non-2-enonic acid **18**).

Key words: conjugate addition, dialkylzinc reagent, sialic acid, ozonolysis, inhibitors.

Résumé : À la suite de l'ozonolyse et la purification de son précurseur, l'ester énoate 5-acétamido-2,3,4,5-tétradésoxy-6,7:89-di-*O*-isopropylidène-2-méthylène-4-nitro-D-*glycéro*-D-*galacto*nononate d'éthyle (**6**), on a isolé avec un rendement de 91% le (*E*)-5-acétamino-3,4,5-tridésoxy-6,7:8,9-di-*O*-isopropylidène-D-*manno*-non-3-én-2-ulosonate d'éthyle (**5**), un α-cétoester β,γ-insaturé utile et inattendu. Lorsqu'on soumet l'ester énoate 4*R* [5-acétamino-2,3,4,5-tétradésoxy-6,7:8,9-di-*O*-isopropylidène-2-méthylène-4-nitro-D-*glycéro*-D-*tallo*-nononate d'éthyle (**7**)], aux même conditions, l'énone **5** n'est qu'un produit mineur (18%) alors que le produit majeur n'élimine pas de HNO_2, mais conduit plutôt à un produit de cyclisation comportant un cycle à cinq chaînons et une liaison hémiaminale entre le C-2 et l'azote de l'amide en C-5 (**9**, 70%). Une addition conjuguée sur l'énone **5** donne la possibilité de généré des dérivés de l'acide sialique substitués en position 4 pour lesquels aucune voie de synthèse générale n'avait été proposée antérieurement. Dans une étude préliminaire de cette route, l'addition de diéthylzinc et de diméthylzinc à l'énone **5** conduit à la formation des structures hémiaminales cycliques **11** et **13** portant des substituants alkyles en position 4 qui peuvent être déprotégées pour conduire aux analogues **14** et **15** de l'acide 2,7-anhydrosialique. Ces produits peuvent ensuite être convertis en glycals peracétylés **16** et **17**, le composé 17 portant un groupe méthyle en position 4 étant finalement déprotégé pour fournir un analogue substitué en position 4 de l'acide sialique, l'acide 5-acétamido-2,6-anhydro-3,4,5-didésoxy-4-méthyl-D-*glycéro*-D-*talo*-non-2-énonique, **18**.

Mots-clés : addition conjuguée, réactif dialkylzinc, acide sialique, ozonolyse, inhibiteurs.

Introduction

Sialic acid (*N*-acetylneuraminic acid, **1**) is a nine-carbon sugar that is often found α-ketosidically linked to the termini of oligosaccharides on glycoconjugates (1). These linkages can be hydrolyzed by sialidases (neuraminidases, EC 3.2.1.18). Because of their terminal locations on glycoconjugates, sialic acid and the proteins that recognize it are important in many biological events, including cell recognition and pathogen infectivity (1, 2). For instance, influenza virus sialidase activity is critical for viral proliferation (3). The virus first recognizes and binds to sialic acid residues on the surfaces of host-cell glycoconjugates in the upper respiratory tract, an event that initiates the infection cycle. After replication, the newly formed virus particles emerge from the infected cell and become coated in cellular sialic acids that cause the virus particles to clump together. The influenza sialidase then cleaves bound sialic acid residues and thus allows the virus particles to move freely to infect further cells. As a consequence, inhibitors of this enzyme, which include the glycal of sialic acid, 2-deoxy-2,3-didehydro-*N*-acetylneuraminic acid (DANA, **2**) and its 4-guanidinyl derivative

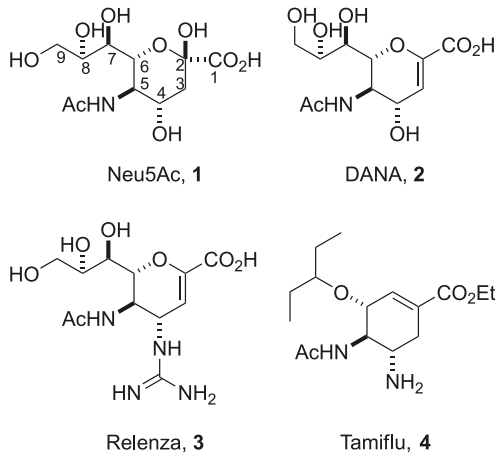
Fig. 1. Sialic acid (Neu5Ac, **1**) and structurally similar sialidase inhibitors (**2**–**4**).



that is marketed as Relenza™ (**3**), are useful biological tools (Fig. 1) (3).

It is important to be able to synthesize analogues of sialic acid to generate selective inhibitors of sialic acid-metabolizing enzymes, which can also be used as probes of the biological pathways. It is therefore advantageous to have access to general synthetic routes that can lead to a number of derivatives for the generation of compound libraries. While there are several positions that can be varied on sialic acid and many derivatives have been made (3, 4), carbon 4 remains a target for derivatization. This is partly due to the fact that variation at this position is tolerated by influenza sialidase as shown by the successful development of 4-substituted sialic acid analogues as influenza sialidase inhibitors, such as Relenza™ (**3**) and Tamiflu™ (**4**) bearing 4-guanidinyl and 4-amino substituents, respectively (Fig. 1) (5, 6).

Design of a general route to 4-modified sialic acid analogues is synthetically challenging. Sialic acid analogues can be made chemoenzymatically using sialic acid aldolase (*N*-acylneuraminate pyruvate lyase, EC 4.1.3.3), which catalyzes the nucleophilic attack of pyruvate on the aldehyde carbon of *N*-acetylmannosamine to form sialic acid. This enzyme is fairly promiscuous with respect to its specificity toward various aldose units, and it can thus be used to make many sialic acid analogues; however, a hydroxyl group is mandatorily installed at the 4-position in the resulting addition product (7). As well, many chemical synthetic routes involve nucleophilic attack of a three-carbon moiety on an aldose carbonyl group, also installing a 4-hydroxyl group (8–10).

While several 4-substituted sialic acid analogues have been synthesized (4), many of these substituents had to be incorporated early in the synthetic route giving intermediate compounds with limited synthetic versatility. Several 4-substituted sialic acid analogues had been synthesized from a common 4-oxo intermediate by Zbiral and co-workers in which the 4-hydroxyl group had been oxidized to a ketone. This could be reduced to give 4-*epi*-sialic acid (11), undergo addition of a nucleophilic methyl group to generate both diastereomers of the 4-methyl addition product (12) and be transformed into the 4-*C*-methylene derivative (12). The 4-*C*-methylene derivative could be reduced to give two 4-epimers of 4-deoxy-4-methylsialic acid (12) and was converted into an epoxide by von Itzstein and co-workers that could be opened with various nucleophiles to generate 4-disubstituted sialic acids (13). As well, several modifications at the 4-position of DANA (**2**) have been made from a common oxazoline intermediate resulting from the $BF_3{\cdot}OEt_2$-promoted displacement of a 4-acetyl group by the carbonyl oxygen of the neighbouring 5-acetamido group. This oxazoline intermediate has been hydrogenated to give 4-deoxy-DANA, hydrolyzed to give 4-*epi*-DANA, and opened with azide to give 4-azido-4-deoxy-DANA that was reduced to 4-amino-4-deoxy-DANA and then transformed into 4-formamido- and 4-acetamido-substituted 4-deoxy-DANA analogues (14). The oxazoline intermediate has also been opened with halogens to generate allylic halides (15), which have been used in palladium(0)-mediated couplings with organotin reagents to install unsaturated functional groups at the 4-position (16). Although these intermediates are useful for synthesizing 4-modified sialic acid analogues, the number of such analogues that can be generated is limited.

Recently, the synthesis of 4-deoxy-4-nitrosialic acid was reported (17), and during the course of that study, an unexpected β,γ-unsaturated-α-keto ester (**5**) was isolated following the ozonolysis of enoate ester **6**. The results described herein report the investigation into this elimination reaction and the use of this enone in conjugate addition reactions for the installation of different substituents at the 4-position in sialic acid analogues.

Results and discussion

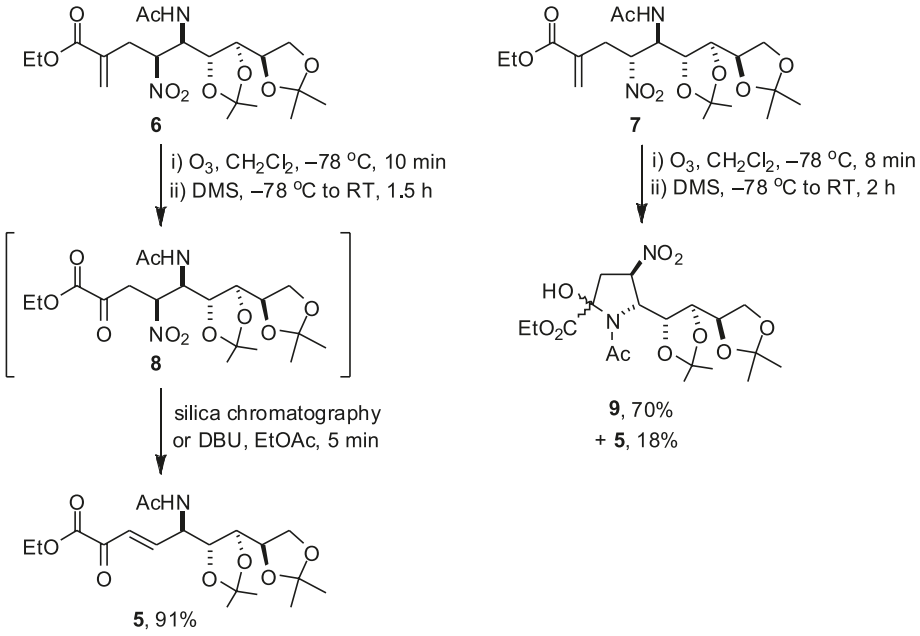
Isolation of β,γ-unsaturated α-keto ester 5

A diastereomeric mixture of isopropylidene-protected enoate esters **6** and **7** was synthesized in six steps from D-arabinose as previously reported (17). The intention was to cleave the methylene group of **6** through ozonolysis to install the α-keto ester moiety (**8**), which would allow the molecule to cyclize to the pyranose structure of sialic acid upon removal of the isopropylidene protecting groups. The initial ozonolysis was performed solely on the 4*S* enoate ester **6** rather than on the diastereomeric mixture of **6** and **7** to reduce the complexity of product identification. However, the only product isolated from the reaction, following chromatographic purification, was the β,γ-unsaturated-α-keto ester **5** in 91% yield resulting from oxidative cleavage of the methylene group and elimination of HNO_2 across carbons 3 and 4 (Scheme 1). IR, ^{1}H NMR, and ^{13}C NMR spectra supported the structure of enone **5** because of the presence of signals in the vinylic regions of the NMR spectra, a ketone in the ^{13}C NMR spectrum, and the absence of nitro stretching bands in the IR spectrum. The *trans*-geometry of the double bond was assigned based on the large H3/H4 coupling constant ($J_{3,4}$ = 15.9 Hz).

Isolation of enone **5** was an unexpected result, as no base is present during the ozonolysis of **6** that could effect such an elimination. It was reasoned that the elimination must be occurring post-ozonolysis because if the elimination occurred during ozonolysis, the newly-formed double bond would also be cleaved. The ozonolysis was repeated in the presence of acetic acid to neutralize any possible base generated during the reaction, but enone **5** was again the sole product isolated. Carrying out the ozonolysis in a 1:1

© 2008 NRC Canada

Scheme 1. Ozonolysis of 4*S* enoate ester **6** leads exclusively to unstable α-keto ester **8** that eliminates to enone **5** upon silica chromatography or treatment with DBU, while ozonolysis of 4*R* enoate ester **7** leads predominantly to hemiaminal **9**.



dichloromethane/methanol solvent mixture or using triphenylphosphine as a reducing agent in place of methyl sulfide also had no effect on the reaction outcome.

It was noticed that very little enone was present in the crude ozonolysis product mixture as judged by ^{1}H NMR spectroscopy. In fact, the major compound present in the crude product mixture appeared to be the α-keto ester **8** that had been originally desired (Scheme 1). No elimination had occurred owing to the absence of vinylic signals in the ^{1}H and ^{13}C NMR spectra, and the IR spectrum showed the nitro group was intact. Upon chromatographic purification on silica gel, however, complete elimination to enone **5** was observed, indicating that the elimination of HNO_2 was silica-induced (Scheme 1). Indeed, this silica-induced elimination was not efficient enough to convert α-keto ester **8** into enone **5** completely on larger scales (**5** and **8** are co-polar); thus, the elimination could be induced by treating the crude α-keto ester **8** with DBU (Scheme 1). It was crucial not to allow this elimination to proceed for extended periods, since complete product decomposition was observed after 15 min. Of note, Yao and co-workers noticed a similar silica-induced elimination when synthesizing an α-keto ester similar to **8** that contained a 4-azido group en route to 4-azido-4-deoxysialic acid; this ester eliminated HN_3 upon chromatographic purification (18). These researchers circumvented the problem by using the 4-azido α-keto ester without purification.

It was later noticed that ozonolysis of diastereomeric mixtures of the enoate esters **6** and **7** resulted in isolation of varying yields of enone **5** that reflected the **6/7** ratio, indicating that only one diastereomer may have eliminated HNO_2. When the 4*R* enoate ester **7** was subjected to ozonolysis by itself, enone **5** was isolated in 18% yield, but the major product, isolated in 70% yield, was a saturated product in which the 5-acetamido nitrogen cyclized onto the newly generated 2-keto group to form two five-membered ring hemiaminal anomers (**9**, Scheme 1). These anomers were observed to interconvert in solution by ^{1}H NMR spectroscopy, but only the major anomer could be isolated in sufficient quantities for adequate characterization. The hemiaminal structure was supported by the disappearance of the amide-proton signal around 6.0 ppm from the ^{1}H NMR spectrum and by the appearance of a singlet at 4.8 ppm that disappeared when a drop of D_2O was added to the $CDCl_3$ solution, corresponding to the new 2-hydroxyl group. In addition, an HMBC spectrum showed a correlation between H-5 and C-2, which would not be possible unless the amide nitrogen was bonded to C-2. As well, the IR spectrum indicated the nitro group was intact.

It therefore appears as though the ozonolysis product of the 4*S* enoate ester **6** prefers to eliminate HNO_2 to give enone **5**, while ozonolysis of the 4*R* enoate ester **7** gives rise to a product that cyclizes to a five-membered ring hemiaminal **9** (Scheme 1). Fortunately, the 4*R* enoate ester **7** could be epimerized to a 3:2 mixture of **6**/**7** that was separable by chromatography by treatment with DBU in THF for 40 min, allowing the conversion of **7** to the synthetically useful 4*S* enoate ester **6**. Interestingly, when enoate ester **6** does not have isopropylidene protecting groups, no elimination occurs after ozonolysis; the product spontaneously cyclizes to the sialic acid pyranose (17). This, in addition to the fact that the ozonolysis product of the 4*R* enoate ester **7** prefers to cyclize to a hemiaminal, suggests the possibility that cyclization is faster than elimination for these compounds and elimination is prohibited following cyclization. While the reasons for these differences in reactivity are not apparent, it appears as though something prevents or dramatically slows down cyclization of **8** to a hemiaminal structure, allowing it to undergo facile HNO_2 elimination.

Conjugate addition reactions with enone 5

Although isolation of enone **5** was initially disappointing,

© 2008 NRC Canada

it was quickly realized that this enone could be a useful synthetic intermediate, since a conjugate addition would afford a sialic acid analogue bearing a new substituent in the 4-position. Indeed, these types of enones have been deliberately synthesized for various purposes. Vasella and co-workers synthesized a similar enone from a protected enoate ester similar to **6**/**7** bearing a 4-*O*-acetyl group, eliminating HOAc with sodium bicarbonate during ozonolysis. They then hydrogenated the resulting double bond, leading to 4-deoxysialic acid (19). Shing also synthesized a related 4-deoxysugar by hydrogenation of such an enone resulting from a Wittig reaction between an aldose and a phosphorus ylide containing an α-keto ester moiety (20). As well, this enone was used in alkoxymercuration reactions resulting in installation of alkoxy groups in the 4-position after reduction of the organomercury intermediate (21). However, literature precedent could not be found for conjugate additions being attempted on such enones.

Introduction of a methyl group was attempted via well-known addition reactions using alkylcopper reagents (22). Several conditions were tried for the conjugate addition of a methyl group to enone **5**, including the following: (*i*) Me_2CuLi from 5 equiv. CuI and 10 equiv. MeLi, warming from –78 °C to room temperature while stirring overnight; (*ii*) Me_2CuLi with TMSCl and $BF_3{\cdot}OEt_2$ as promoters; (*iii*) $Me_2CuMgBr$ from MeMgBr instead of MeLi; and (*iv*) $MeCuBF_3$ prepared from 1 equiv. each of CuI, MeLi, and $BF_3{\cdot}OEt_2$. None of these conditions afforded appreciable quantities of conjugate addition products. Also, 1 equiv. of MeLi was added to enone **5** on one occasion, but no 1,2- or 1,4-addition products were observed, and most of the starting material was recovered, indicating the low reactivity of **5** toward these nucleophiles.

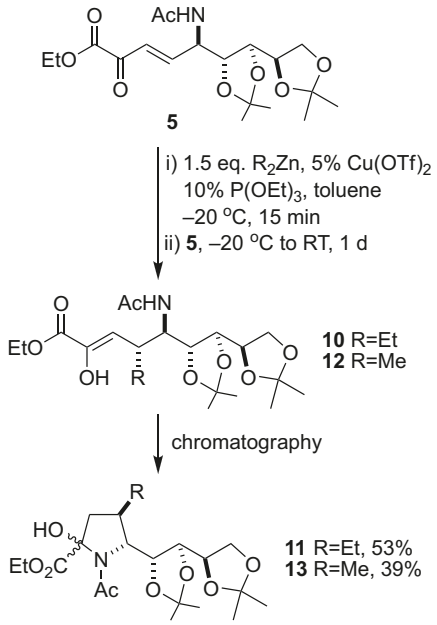
Since the conditions for conjugate addition of alkylcopper reagents to enone **5** seemed to be too harsh, conjugate additions of alkyl halides under radical conditions were attempted. These reactions are normally performed with Bu_3SnH/AIBN in refluxing benzene to generate radicals thermally that are added to α,β-unsaturated carbonyl compounds containing electron-withdrawing groups (23, 24). Initially, benzyl bromide was used as an alkylating agent with Bu_3SnH and AIBN in refluxing toluene. This yielded a complex mixture of products, none of which seemed to have incorporated a benzyl group. The same reagents were tried using a 100 W incandescent light source to generate radicals at room temperature but also gave no addition products. These conditions using a 100 W lamp at room temperature were tried with isopropyl iodide and allyl iodide as alkylating agents to try to generate a stable alkyl radical but resulted in decomposition of the enone. Slow addition of a solution containing Bu_3SnH and AIBN over 1 h via syringe pump to a solution of allyl iodide and enone **5** in toluene at 60 °C was attempted to generate radicals more slowly in hopes that they would react with the enone, but this reaction also failed.

Milder conjugate additions were attempted using a dialkylzinc reagent with a copper catalyst, as alkylzinc reagents are less reactive than their alkylcopper counterparts (25). Alexakis and co-workers have screened a number of copper catalysts for use in conjugate addition reactions with dialkylzinc reagents and found that $Cu(OTf)_2$ was one of the most active, and these reactions were greatly accelerated by the addition of a phosphorus ligand, usually PBu_3 or $P(OEt)_3$ (26, 27). Thus, $Cu(OTf)_2$ and $P(OEt)_3$ were mixed with diethylzinc and enone **5** to give a 53% yield of conjugate addition products (Scheme 2). The initial product in the crude reaction mixture appeared to be a single diastereomer of the enol tautomer **10** as observed by ^1H NMR spectroscopy. It was clear that the ethyl group had added due to the presence of two new signals in the ^1H and ^{13}C NMR spectra, and although H-4 had shifted upfield to 2.8 ppm in the ^1H NMR spectrum, H-3 appeared as a doublet integrating to one proton at 5.5 ppm, indicating that it was a vinylic proton. As well, a singlet was observed at 6.5 ppm that disappeared upon addition of a drop of D_2O to the $CDCl_3$ solution, indicating that this was the enol hydroxyl proton. However, the enol could not be purified for proper characterization, since upon silica chromatography, the product tautomerized to form an anomeric mixture of five-membered ring hemiaminal structures, giving **11** in 53% yield (Scheme 2). As with the 4-nitro hemiaminal **9**, the structure of 4-ethyl hemiaminal **11** was assigned based on the disappearance of the amide proton signal in the ^1H NMR and the appearance of a signal for the new hydroxyl group proton around 4.9 ppm that disappeared when a drop of D_2O was added to the $CDCl_3$ solution. An HMBC spectrum showed a correlation between H-5 and C-2, which further supported the five-membered ring structure. As well, the IR spectrum showed absence of an NH stretching band but did show an OH stretch. As with the 4-nitro hemiaminal **9**, only the major anomer of **11** could be purified for adequate characterization, but the two anomers were observed to interconvert when left for extended periods in $CDCl_3$ solution, indicating that they were indeed anomers and not C4-epimers. Since **11** was a five-membered ring, the stereochemistry of the ethyl addition could be probed through a series of 1D NOE difference ^1H NMR spectra. Upon irradiation of the methylene protons of the newly-installed ethyl group, enhancement of the signals for H-5 and H-3a (on the same face) was observed, while irradiation of H-3b (on the opposite face) only enhanced the signal for H-4. These spectra indicate that H-5 and the new ethyl group are on the same face of the ring, which possesses the 4*R*-configuration. The exclusive formation of the 4*R*-diastereomer is unfortunate, since natural sialosides possess the 4*S*-configuration; however, 4-*epi*-sialic acid derivatives can still be useful inhibitors/probes for various sialic acid processing enzymes (28). While there are several possible explanations for this diastereoselectivity, it is likely that the alkylzinc/alkylcopper complex is coordinating to the acetamido group, thus directing nucleophilic attack from the same face to give *cis*-addition.

Several variables were manipulated to try to increase the yield of the 4-ethyl hemiaminal **11**. Specifically, no reaction was observed when THF was used as a coordinating solvent, and when $BF_3{\cdot}OEt_2$ was used to replace $P(OEt)_3$, no reaction products were afforded in either THF or toluene. Moreover, longer reaction times resulted in the formation of increased amounts of other unidentified products, and the use of larger amounts of diethylzinc did not result in increased product yields. Alexakis and co-workers have observed that α,β-unsaturated esters are less reactive toward copper-catalyzed dialkylzinc conjugate additions (26); thus, the 53% yield of 4-ethyl hemiaminal **11** was considered to be satisfactory.

© 2008 NRC Canada

Scheme 2. Conjugate addition of diethylzinc and dimethylzinc to enone **5**, initially affording enol products **10** and **12** that rearrange to five-membered ring hemiaminals **11** and **13** upon chromatography.



The scope of the copper-catalyzed conjugate addition to enone **5** was examined by testing other dialkylzinc reagents. Commercially available dimethylzinc was added, which also afforded a single diastereomer of the conjugate addition product as its enol tautomer **12** that rearranged to the five-membered ring hemiaminal structure during silica chromatography to give **13** in 39% yield (Scheme 2). Lower product yields were expected, since dimethylzinc is known to be less reactive than diethylzinc (29). The 4-methyl hemiaminal **13** exhibited similar spectral characteristics to its ethyl homologue **11**; notably, a series of 1D NOE difference ^{1}H NMR spectra showed that **13** also had the 4*R*-configuration. Also similarly, the 4-methyl hemiaminal product was obtained as an interconverting mixture of anomers of which only the major anomer could be purified for adequate characterization although NMR spectra were obtained on the minor anomer.

Attempts to perform conjugate addition reactions were made using other alkylzinc reagents that had been synthesized. Benzyl zinc bromide was generated by stirring benzyl bromide with zinc dust in toluene at room temperature for 6 h (30, 31), but it afforded no conjugate addition products when reacted with enone **5** under the standard conditions despite giving a 26% yield of 3-benzylcyclohexanone when reacted with a model enone (2-cyclohexen-1-one). Dibenzylzinc was synthesized by zinc-halogen exchange from the reaction of 1 equiv. dimethylzinc with 2 equiv. benzyl bromide in toluene at –30 °C for 45 min (25, 32). When this was added to 2-cyclohexen-1-one, a 22% yield of 3-benzyl-2-methylcyclohexanone was isolated, as the enolate resulting from the dibenzylzinc conjugate addition was trapped by the in situ generated methyl bromide (33). Despite the generation of electrophilic methyl bromide during the synthesis of dibenzylzinc, these conditions were used with enone **5** but only afforded a very small amount of 4-methyl hemiaminal **13**, likely resulting from addition of unreacted dimethylzinc. The synthesis of diphenylzinc through transmetallation was accomplished by reacting 2 equiv. phenyl magnesium bromide with 1 equiv. $ZnCl_2$ in toluene at –30 °C for 2 h and gave a 68% yield of 3-phenylcyclohexanone when reacted with 2-cyclohexen-1-one. However, no conjugate addition products were obtained when diphenylzinc was added to enone **5**. The failure of benzyl and phenyl groups to add to enone **5** in a conjugate manner suggests that such groups may be too bulky to add to the sterically congested 4-position of this enone. It may also be that impurities generated during the synthesis of the alkylzinc reagents impeded the conjugate addition to enone **5**; thus, it may be useful to purify these alkylzinc reagents prior to performing the addition reactions.

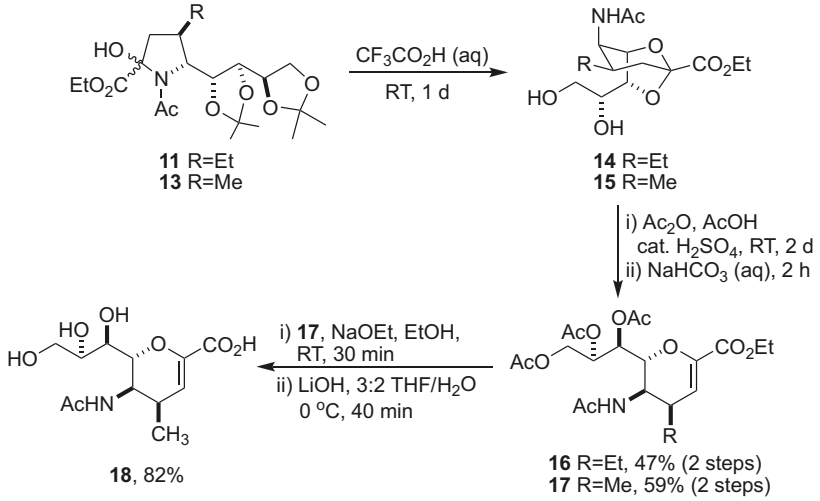
Conversion of 4-alkylhemiaminals to sialic acid analogues

To convert the conjugate addition products **11** and **13** into sialic acid analogues, removal of the isopropylidene protecting groups was necessary to allow rearrangement to the six-membered ring pyranose form of sialic acid. This was achieved by stirring the 4-alkyl hemiaminals **11** and **13** in 90% aq. trifluoroacetic acid. These conditions resulted in removal of the isopropylidene groups, allowing the compounds to cyclize to the pyranose form, but also induced the formation of a 2,7-anhydro linkage to give the 2,7-anhydro-4-ethylsialoside **14** and the 2,7-anhydro-4-methylsialoside **15** (Scheme 3). These 2,7-anhydrosugars were moderately unstable to silica gel chromatography and were normally used in subsequent reactions without purification. The 2,7-anhydro linkage in **15** was assigned based on NMR spectroscopic evidence, as H-5 and H-6 showed very little coupling to any other protons, indicating they were not trans-diaxial, and the frequencies of H-6 and C-2 were shifted downfield from 4.2 to 4.6 ppm and from 94 to 105 ppm, respectively. Zbiral and co-workers noticed similar spectral differences when they made a 4-deoxy-4-*epi*-4-methylsialic acid by deprotecting its precursor under acidic conditions, giving a product that contained a 2,7-anhydro linkage (12). HMBC spectra of **14** and **15** showed correlations between H-7 and C-2, which would only be possible if a 2,7-anhydro linkage existed. Incidentally, these spectra also showed correlations between H-6 and C-2, indicating that the compounds were indeed in their pyranose forms. It therefore seems as though 4-alkyl-4-deoxy-4-*epi*-sialic acid analogues preferentially form such 2,7-anhydro linkages under acidic conditions. Since 2,7-anhydrosialic acids are of interest themselves as conformationally restrained derivatives (34), this synthetic route has the potential to lead to a number of such derivatives.

It was decided to convert the 2,7-anhydro-4-alkylsialosides **14** and **15** into glycals so as to develop a route to give compounds that could be tested as sialidase inhibitors against benchmark compounds such as DANA (**2**). This was accomplished by stirring the crude 2,7-anhydrosugars in acetic anhydride/acetic acid with a catalytic amount of H_2SO_4 followed by stirring in saturated aq. $NaHCO_3$, a reaction sequence that opened the 2,7-anhydro linkage, peracetylated all hydroxyl groups, and eliminated HOAc in one pot (35).

© 2008 NRC Canada

Scheme 3. Conversion of 4-alkyl hemiaminals **11** and **13** into glycals **16** and **17** via their 2,7-anhydrosugars **14** and **15**.



This afforded the peracetylated glycals **16** and **17**, the 4-ethyl-DANA analogue **16** being obtained in 47% yield over two steps from 4-ethyl hemiaminal **11**, and the 4-methyl-DANA analogue being obtained in 59% yield over two steps from 4-methyl hemiaminal **13** (Scheme 3). As with the 2,7-anhydrosialoside precursors, these glycals could be purified by silica chromatography, but their yields decreased significantly despite the crude product mixtures being composed mainly of the glycal products. It was attempted to convert the 4-methyl hemiaminal **13** directly to glycal **17** by performing the deprotection, acetylation, and elimination reactions in one pot, but this did not result in the isolation of any useful products.

The deprotection of 4-deoxy-4-*epi*-4-methyl-DANA **17** was achieved first by removal of the acetyl groups using NaOEt in ethanol, followed by hydrolysis of the ethyl ester using LiOH in 3:2 THF/water to afford the deprotected 4-deoxy-4-*epi*-4-methyl glycal of sialic acid **18** in 82% yield over the two deprotection steps (Scheme 3). A series of 1D NOE difference ^{1}H NMR spectra again confirmed the 4*R*-stereochemical assignment, as irradiation of the 4-methyl group showed a strong contact to H-6 and a weak contact to H-5, indicating that the 4-methyl group and H-6 were on the same face of the six-membered ring. As well, H-4 showed a strong contact to H-5 and virtually no contact to H-6, indicating that H-4 and H-5 are on the same face.

Conclusions

Isolation of an unexpected β,γ-unsaturated α-keto ester **5** led to the development of a synthetic route leading to 4-substituted sialic acid analogues. Ozonolysis of the 4*S* enoate ester **6** led to enone **5** following elimination of HNO_2 during silica chromatography or upon treatment of the crude ozonolysis product with DBU, while ozonolysis of the 4*R* enoate ester **7** led mainly to a five-membered ring hemiaminal structure **9**. Conditions were developed to add alkyl groups to enone **5** through copper-catalyzed conjugate additions of diethylzinc and dimethylzinc. The resulting 4-alkyl-substituted conjugate addition products could be deprotected to generate 2,7-anhydro-4-alkylsialosides **14** and **15** that could then be converted into 4-modified DANA analogues **16** and **17**. Given the functional-group-tolerant nature of dialkylzinc additions, this synthetic route should allow the synthesis of a number of 4-modified sialic acid analogues, including 2,7-anhydrosugars and DANA analogues. Unfortunately, these conjugate addition reactions exclusively afforded the less desirable 4*R*-diastereomer. As well, addition of small nucleophiles from commercially available diethylzinc and dimethylzinc proceeded relatively smoothly, while the addition of bulkier dibenzylzinc and diphenylzinc did not proceed at all. Current work is focusing on attempts to change the diastereoselectivity of the conjugate addition to afford the more desirable 4*S*-diastereomer and on the search for nucleophiles that will participate in conjugate addition reactions with enone **5** to afford more interesting 4-modified sialic acid analogues.

Experimental

Thin-layer chromatography (TLC) was performed on aluminum-backed TLC plates pre-coated with Merck silica gel 60 F_{254}. Compounds were visualized with UV light and (or) staining with phosphomolybdic acid (5% solution in EtOH). Flash chromatography was performed using Avanco silica gel 60 (230–400 mesh). Melting points were recorded on a Gallenkamp melting point apparatus and are uncorrected. Solvents used for anhydrous reactions were dried and distilled immediately prior to use. Ethanol was dried and distilled over magnesium ethoxide. Dichloromethane and toluene were dried and distilled over calcium hydride. Toluene was degassed by repeated freezing, then thawing while under vacuum. Glassware for anhydrous reactions was flame-dried and cooled under a nitrogen atmosphere immediately prior to use. The majority of the NMR spectra were recorded on a Varian Unity 500 MHz spectrometer, while some were recorded on Bruker AMX-400 MHz or Bruker TCI-600 MHz spectrometers. Chemical shifts (δ) are listed in ppm downfield from TMS using the residual solvent peak as an internal reference. ^{1}H and ^{13}C NMR peak assignments are made based on ^{1}H–^{1}H COSY and ^{1}H–^{13}C HMQC experiments. IR spectra were recorded on a Bomem IR spectrometer, and samples were prepared as cast evaporative films on NaCl plates from CH_2Cl_2. Optical rotations were measured

using a PerkinElmer 341 polarimeter and are reported in units of deg cm^2 g^{-1} (concentrations reported in units of g/100 cm^3). Shown in the supporting information are the ^1H NMR and ^{13}C NMR spectra for compounds **14**–**18**.[2]

Ethyl 5-acetamido-3,4,5-trideoxy-6,7:8,9-di-*O*-isopropylidene-4-nitro-D-*glycero*-D-*galacto*-non-2-ulosonate (8)

The 4*S* enoate ester **6** (494 mg, 1.11 mmol) was dissolved in dry CH_2Cl_2 (50 mL) and cooled in a dry ice/acetone bath to –78 °C. The flask was fitted with a $CaCl_2$ drying tube and ozone was bubbled through the solution until a blue color persisted (10 min). The solution was purged with oxygen, and methyl sulfide (1 mL) was added. The colorless solution was allowed to warm to room temperature while stirring for 1.5 h, after which time it was concentrated under reduced pressure to yield a colorless syrup (588 mg) that consisted mainly of DMSO and α-keto ester **8**. The crude material was unstable and could not be fully characterized. IR (cm^{-1}): 1373 (NO_2), 1557 (NO_2), 1673 (amide C=O), 1733 (α-keto ester C=O, one band), 3267 (NH). ^1H NMR ($CDCl_3$, 500 MHz) δ: 1.35 (s, 3H, CMe_2), 1.377 (t, 3H, J = 7.1 Hz, C*H*$_3$CH$_2$O), 1.382 (s, 6H, CMe_2), 1.43 (s, 3H, CMe_2), 2.01 (s, 3H, NHCOC*H*$_3$), 3.46 (dd, 1H, $J_{3a,3b}$ = 19.2 Hz, $J_{3a,4}$ = 6.8 Hz, H-3a), 3.63 (dd, 1H, $J_{3a,3b}$ = 19.2 Hz, $J_{3b,4}$ = 7.3 Hz, H-3b), 3.76 (dd, 1H, $J_{6,7}$ = 5.2 Hz, $J_{7,8}$ = 8.8 Hz, H-7), 3.81 (dd, 1H, $J_{8,9a}$ = 6.7 Hz, $J_{9a,9b}$ = 8.7 Hz, H-9a), 3.98 (dt, 1H, $J_{7,8}$ = 8.8 Hz, $J_{8,9a}$ + $J_{8,9b}$ = 12.9 Hz, H-8), 4.13 (dd, 1H, $J_{5,6}$ = 9.8 Hz, $J_{6,7}$ = 5.2 Hz, H-6), 4.15 (dd, 1H, $J_{8,9b}$ = 6.2 Hz, $J_{9a,9b}$ = 8.7 Hz, H-9b), 4.35 (q, 2H, J = 7.1 Hz, CH$_3$C*H*$_2$O), 4.43 (dt, 1H, $J_{4,5}$ = 2.3 Hz, $J_{5,6}$ + $J_{NH,5}$ = 18.5 Hz, H-5), 5.49 (dt, 1H, $J_{3a,4}$ + $J_{3b,4}$ = 14.1 Hz, $J_{4,5}$ = 2.3 Hz, H-4), 5.96 (d, 1H, $J_{NH,5}$ = 8.7 Hz, N*H*COCH$_3$). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 13.2 (*C*H$_3$CH$_2$O), 22.2 (NHCO*C*H$_3$), 24.7, 25.8, 26.4, 26.9 (CMe_2 × 2), 38.4 (C-3), 52.3 (C-5), 62.1 (CH$_3$*C*H$_2$O), 66.4 (C-9), 75.9 (C-8), 77.5 (C-6), 80.5 (C-7), 80.7 (C-4), 109.0, 110.2 (*C*Me$_2$ × 2), 158.9 (C-1), 170.3 (NH*C*OCH$_3$), 188.7 (C-2).

Ethyl (*E*)-5-acetamido-3,4,5-trideoxy-6,7:8,9-di-*O*-isopropylidene-D-*manno*-non-3-en-2-ulosonate (5)

The crude α-keto ester **8** from ozonolysis of enoate ester **6** was subjected to flash chromatography (hexanes–EtOAc gradient solvent system from 1:1 *v*/*v* to 100% EtOAc), inducing the elimination reaction to afford enone **5** as a colorless syrup (403 mg, 1.01 mmol, 91%). The elimination could also be effected by stirring **8** with 1 equiv. DBU in EtOAc for 2 min, followed by quenching with saturated aq. ammonium chloride and extraction with Et_2O to afford crude enone **5** that could be purified as described earlier. $[\alpha]^{20}_D$ +18.8 (*c* 1.10, $CHCl_3$). Ethyl 5-acetamido-3,4,5-trideoxy-4-ethyl-6,7:8,9-di-*O*-isopropylidene-D-*glycero*-D-*talo*-non-3-enonate (10)

Copper(II) trifluoromethanesulfonate (10 mg, 0.028 mmol) was suspended in dry, degassed toluene (7 mL), and triethylphosphite (10 μL, 0.058 mmol) was added slowly. The resulting colorless solution was stirred under N_2 at room temperature for 15 min, after which it was cooled to –20 °C, and a solution of diethylzinc in hexanes (1.0 mol/L, 0.90 mL, 0.90 mmol) was added dropwise. After stirring under N_2 for 10 min, a solution of enone **5** (236 mg, 0.59 mmol) in toluene (3 mL) was injected dropwise. The solution was stirred under N_2 overnight as it warmed to room temperature. After 18 h, the reaction was quenched by the addition of saturated aq. NH_4Cl (5 mL). The mixture was diluted with water (15 mL) and extracted with Et_2O (2 × 50 mL). The combined organic layers were dried ($MgSO_4$), filtered, and concentrated under reduced pressure to give a mixture of compounds that contained mainly the enol tautomer of the ethyl addition product **10** as colorless syrup (217 mg). The enol addition product could not be purified for characterization as it rearranged to the five-membered

Ethyl 5-acetamido-7,8,9-tri-*O*-acetyl-2,6-anhydro-3,4,5-trideoxy-4-ethyl-D-*glycero*-D-*talo*-non-2-enonate (16)

The crude preparation of 2,7-anhydro-4-ethylsialoside **14** from the previous reaction (249 mg) was dissolved in acetic anhydride (2.0 mL) and glacial acetic acid (2.0 mL). Concentrated H_2SO_4 (15 drops) was added, and the resulting solution was stirred at room temperature. After 3 d, the reaction was poured into saturated aq. $NaHCO_3$ (100 mL), which bubbled vigorously, and the resulting basic mixture was stirred for 2 h. The mixture was then extracted with EtOAc (2 × 100 mL), and the combined organic layers were dried ($MgSO_4$), filtered, and concentrated under reduced pressure to give the 4-ethyl-substituted glycal **16** as a light brown syrup (119 mg, 0.261 mmol, 47%). The glycal could be further purified via flash chromatography (hexanes–EtOAc gradient solvent system from 1:2 *v*/*v* to 100% EtOAc) to afford a sample for characterization. $[\alpha]^{20}_D$ +3 (*c* 0.24, $CHCl_3$). IR (cm^{-1}): 1656 (amide C=O), 1747 (ester C=O). ^{1}H NMR ($CDCl_3$, 600 MHz) δ: 1.04 (t, 3H, J = 7.4 Hz, CH$_2$CH_3), 1.31 (t, 3H, J = 7.1 Hz, OCH$_2$CH_3), 1.34–1.39 (m, 1H, CH_aH$_b$CH$_3$), 1.48–1.56 (m, 1H, CH$_a$$H_bCH_3$), 1.97 (s, 3H, COC$H_3$), 2.06 (s, 3H, COC$H_3$), 2.07 (s, 3H, COC$H_3$), 2.11 (s, 3H, COC$H_3$), 2.56–2.60 (m, 1H, H-4), 4.20–4.31 (m, 4H, H-6, H-9a, OCH_2CH$_3$), 4.40 (dd, 1H, $J_{8,9b}$ = 4.4 Hz, $J_{9a,9b}$ = 12.0 Hz, H-9b), 4.55–4.58 (m, 1H, H-5), 5.19 (ddd, 1H, $J_{7,8}$ + $J_{8,9b}$ = 11.4 Hz, $J_{8,9a}$ = 3.2 Hz, H-8), 5.40 (dd, 1H, $J_{6,7}$ = 8.5 Hz, $J_{7,8}$ = 3.1 Hz, H-7), 5.54 (d, 1H, $J_{5,NH}$ = 9.4 Hz, NH), 6.03 (br d, 1H, $J_{3,4}$ = 2.6 Hz, H-3). ^{13}C NMR ($CDCl_3$, 150 MHz) δ: 11.4 (CH$_2$CH_3), 14.1 (OCH$_2$CH_3), 20.66 (COCH_3), 20.72 (COCH_3), 20.9 (COCH_3), 23.2 (CH_2CH$_3$), 23.3 (COCH_3), 33.9 (C-4), 43.7 (C-5), 61.1 (C-9), 61.5 (OCH_2CH$_3$), 68.7 (C-7), 69.3 (C-8), 76.7 (C-6), 112.8 (C-3), 141.1 (C-2), 161.8, 169.7, 170.0, 170.3, 170.6 (C=O × 5). 5-Acetamido-2,6-anhydro-3,4,5-trideoxy-4-methyl-D-*glycero*-D-*talo*-non-2-enonic acid (18)

A 1.2 mol/L solution of sodium ethoxide in ethanol (0.080 mL, 0.096 mmol) was added to a solution of peracetylated 4-methyl-substituted glycal **17** (29 mg, 0.065 mmol) in dry ethanol (3.0 mL). This solution was stirred at room temperature for 30 min, after which time TLC analysis indicated the absence of starting material. The reaction was neutralized with Amberlite™ H^+ resin and filtered. The resin was washed with methanol (30 mL), and the filtrate was concentrated under reduced pressure to give a light yellow syrup (21.1 mg, 0.065 mmol). The de-acetylated product was then dissolved in THF/water (3:2 *v*/*v*, 5 mL) and cooled in an ice bath. Lithium hydroxide monohydrate was added (23.7 mg, 0.565 mmol), and the solution stirred in ice for 30 min, after which time TLC analysis indicated complete de-esterification. The reaction was removed from the cooling bath, diluted with water (5 mL), and neutralized with Amberlite™ H^+ resin to pH 5, which was then filtered and washed with water (30 mL). The combined filtrates were concentrated under reduced pressure to afford the lithium salt of the deprotected glycal **18** as a colorless syrup (16.0 mg, 0.0542 mmol, 82%). $[\alpha]^{20}_D$ –100 (*c* 0.48, H_2O). IR (cm^{-1}): 1645 (amide C=O), 1712 (acid C=O), 3287 (NH), 3340 (OH). ^{1}H NMR (D_2O) δ: 1.04 (d, 3H, $J_{Me,4}$ = 7.2 Hz, 4-CH_3), 2.02 (s, 3H, NHCOCH_3), 2.70–2.76 (m, 1H, H-4), 3.64 (dd, 1H, $J_{8,9a}$ = 6.3 Hz, $J_{9a,9b}$ = 11.9 Hz, H-9a), 3.67 (dd, 1H, $J_{6,7}$ = 2.2 Hz, $J_{7,8}$ = 8.8 Hz, H-7), 3.86 (dd, 1H, $J_{8,9b}$ = 2.8 Hz, $J_{9a,9b}$ = 11.9 Hz, H-9b), 3.90 (ddd, 1H, $J_{7,8}$ = 8.9 Hz, $J_{8,9a}$ = 6.3 Hz, $J_{8,9b}$ = 2.8 Hz, H-8), 4.20 (dd, 1H, $J_{5,6}$ = 8.8 Hz, $J_{6,7}$ = 2.2 Hz, H-6), 4.30 (dd, 1H, $J_{4,5}$ = 5.8 Hz, $J_{5,6}$ = 8.8 Hz, H-5), 6.14 (d, 1H, $J_{3,4}$ = 5.0 Hz, H-3). ^{13}C NMR (D_2O) δ: 15.1 (4-CH_3), 21.9 (NHCOCH_3), 28.9 (C-4), 46.4 (C-5), 63.0 (C-9), 69.0 (C-7), 70.5 (C-8), 72.6 (C-6), 116.7 (C-3), 141.8 (C-2), 166.6 (C=O), 174.1 (C=O). Synthesis and tautomerization study of pseudonitrosites to 1,2-nitroximes

Ahmad Shaabani, Hamid Reza Bijanzadeh, Ali Reza Karimi, Mohammad Bagher Teimouri, and Kamal Soleimani

Abstract: 4-R-Substituted 2-nitro-1-nitrosoethylbenzenes (R = H, CH_3, OCH_3, Cl, F) have been synthesized under solvent-free conditions and the mechanism of their tautomerization to 2-isonitroso-1-nitro-2-phenylethanes have been investigated by ^{1}H NMR spectroscopy.

Key words: tautomerization, pseudonitrosite, mechanism, 2-nitro-1-nitrosoethylbenzene, ^{1}H NMR spectroscopy.

Résumé : Opérant dans des conditions n'impliquant aucun solvant, on a réalisé la synthèse de 2-nitro-1-nitrosoéthylbenzènes substitués en position 4 par des groupes R = H, CH_3, OCH_3, Cl et F et, faisant appel à la spectroscopie RMN du ^{1}H, on a étudié leur tautomérisation en 2-isonitroso-1-nitro-2-phényléthanes.

Mots-clés : tautomérisation, pseudonitrosite, mécanisme, 2-nitro-1-nitrosoéthylbenzène, spectroscopie RMN du ^{1}H.

[Traduit par la Rédaction]

Introduction

The discovery of important roles of *C*-nitroso compounds in various biological metabolic processes has generated a renewed interest in the general chemical properties of nitrosoarenes (1). For example, identification of the nitrosbenzene adduct of hemoglobin as a product of nitrobenzene poisoning (2, 3) and the realization that some amine containing drugs may metabolize to nitroso derivatives (4–7) led to an increased desire to study the biochemical properties of *C*-nitroso compounds. To this end, many studies have been reported on the fundamental chemistry of *C*-nitroso compounds under conditions that either stabilize the *C*-nitroso functionality or enhance their reactivity toward isomerization or reactivity with substrate.

There is a considerable variety of synthetic routes available for the preparation of *C*-nitroso compounds (1, 8–11). However, a major difficulty in *C*-nitroso chemistry is that the necessary high reactivity of these compounds imposes constraints upon the methods employed for their preparation, particularly with regard to the yield of the desired product. For example, the ease of oxidation of the desired nitroso product to its nitro derivative or its isomerization to corresponding oximes can restrict the choice of solvent for the preparation of these compounds.

Solvent-free reactions are of increasing importance because of their potential use in combinatorial chemistry and because they may result in less environmental impact during industrial applications (12, 13). Since tautomerization of *C*-nitroso compounds to the more stable oximes occurs readily in solutions, we have attempted to find solvent-free reactions that result in selective transformation of the styrene and para-substituted styrenes (**1**) to 2-nitro-1-nitrosoethylbenzenes (**2**) without further tautomerization to 2-isonitroso-1-nitro-2-phenylethanes (**3**). (Scheme 1)

C-Nitroso compounds are characterized as white solid dimers that result from a N-N connection to give diazene dioxides (14). Since 2-nitro-1-nitrosoethylbenzene derivatives are a monomer and has an asymmetric center, the dimer exists in two diastereomeric isomers namely meso (R,S) and racemate (R,R and S,S) (15). When the dimers are dissolved and (or) heated in an inert low polarity solvent, such as CH_2Cl_2 or ether, dissociation into blue (aliphatic) or green (aromatic) monomers usually occurs (1, 16–18).

Experimental

Melting points were measured on an Electrothermal 9100 apparatus and are uncorrected. Elemental analyses were performed using a Heraeus CHN-O-Rapid analyzer. NMR spectra were recorded on BRUKER DRX-500 AVANCE spectrometer. Temperatures ranged from 298 to 313 K. Infrared spectra were taken on a Shimadzu IR-470 spectrophotometer. Mass spectra were recorded on a FINNIGAN-MAT 8430 mass spectrometer operating at an ionization potential of 70 eV.

General procedure

Cation exchange resine (Rexyn 101 H obtained from Fisher Scientific, 0.350 g) and sodium nitrite (0.345 g, 5 mmol) were ground separately in a mortar and added to styrene or substituted styrene (2 mmol) in a round-bottomed flask. The reaction mixture was stirred magnetically at room temperature until TLC analysis indicated that all of the sty-

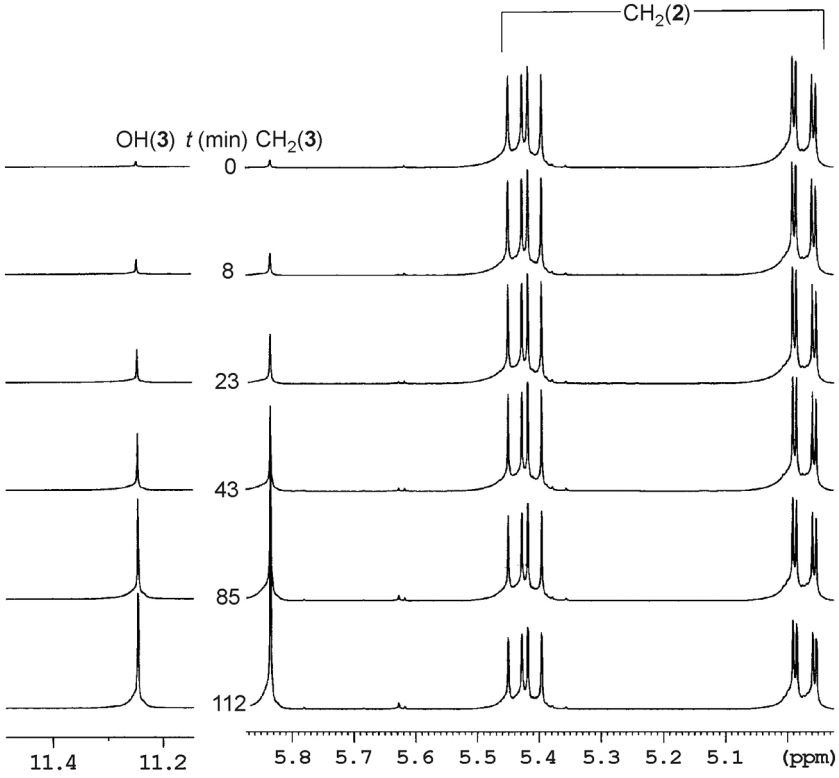
Fig. 1. ^{1}H NMR spectra of the appearance and disappearance of methylene signals of compound **3c** and **2c** at 298 K.



rene or substituted styrene had reacted. The product was separated by washing with acetone (3 × 10 mL) and the filtrate was evaporated to give the product. Compound **2** was obtained as a white solid, which without further purification was used for studying tautomerization.

Results and discussion

Products from the reaction of styrene and para-substituted styrenes

All of the products (except **2a** and **3a** (19)) are new compounds, which were identified from their IR, ^{1}H, and ^{13}C NMR spectra. The mass spectra of these compounds displayed molecular ion peaks at appropriate *m*/*z* values (Table 1).

The ^{1}H NMR spectrum of **2b** exhibited a single sharp line arising from methyl protons (δ 2.33) along with a three-spin AMX system for methylene and methine protons. This leads to a doublet of doublets for each of the protons of H^A, H^M, and H^X at 4.98 (1H, dd, $^2J_{HH}$ = 16.0 Hz, $^3J_{HH}$ = 3.0 Hz, CH_AH), 5.39 (1H, dd, $^2J_{HH}$ = 16.0 Hz, $^3J_{HH}$ = 11.1 Hz, CHH_M), and 6.90 ppm (1H, dd, $^3J_{HH}$ = 11.1 Hz, $^3J_{HH}$ = 3.0 Hz, CH_X), respectively. The aromatic protons appear at 7.24 and 7.38 ppm (4H, 2d, $^3J_{HH}$ = 7.9 Hz). The ^{1}H decoupled ^{13}C NMR spectrum of **2b** showed the distinct resonances in agreement with the proposed structure.

The ^{1}H NMR spectrum of **3b** exhibited two single sharp lines readily recognized as arising from methyl (2.34 ppm) and methylene (5.84 ppm) protons. The 4-substituted phenyl moiety gave rise to characteristic signals in the aromatic region of the spectrum (7.24 and 7.65 ppm, $^3J_{HH}$ = 8.7 Hz). A fairly broad singlet (11.40 ppm) is observed for the OH group, which upon addition of one drop of D_2O to the solution disappeared. The ^{1}H decoupled ^{13}C NMR spectrum of **3b** showed the distinct resonances in agreement with the proposed structure. Partial assignment of these resonances is given in the experimental section.

The ^{1}H and ^{13} C NMR spectra of **2a**, **2c**–**2e** and **3a**, **3c**–**3e** are similar to those of **2b** and **3b**, except for the phenyl groups, which exhibit characteristic signals with appropriate chemical shifts, respectively. The results are summarized in the experimental section.

Kinetics of the reaction of tautomerization

The discovery of new prototropic tautomerization and the study of its mechanism is one of the most important subjects in physical organic chemistry, and investigations on tautomeric processes were surveyed by several reviews (20–28). Tautomerization of 2-nitro-1-nitrosoethylbenzenes to the more stable oximes occurs readily in solution. Oximes are, of course, important synthons in many organic reactions of which Beckman rearrangement is illustrated (29, 30).

For the tautomerization study, a fresh sample of 4-X-substituted of 2-nitro-1-nitrosoethylbenzene (**2**) was dissolved in $(CD_3)_2CO$ (0.01 g in 0.4 mL $(CD_3)_2CO$ in 5 mm NMR tube) and equilibrated at the required temperature. The progress of the tautomerization was monitored by recording the appearance and disappearance of the methylene signal of **3** and **2**, respectively, (Fig. 1). Integration of the area under the methylene signal of **3** with respect to that of the methylene signals of **2** gave the relative concentrations of the species present, [C]. The rate of the reaction is given by rate = $+k[C]^x$, where x is the reaction order. The integrated rate equation for a first order reaction is $\ln[C]_t = kt + \ln[C]_0$. A

2d	Cl	3.4±0.4	0.25
2e	F	4.1±0.3	0.15

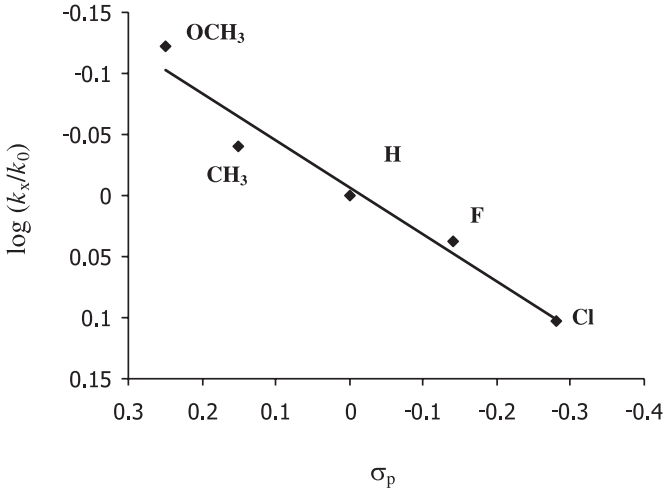
[a]Ref. 31.

plot of ln[C]$_t$ vs. time should yield a straight line if the reaction is first order. The slope of this line is equal to k. The rate constants were obtained at several temperatures: 298, 303, 308, and 313 K.

By taking the natural logarithm of the Arrhenius equation, the activating energy, E_{act}, was obtained from a plot of ln$k$ vs. 1/T. Enthalpies of activation, $\Delta H^{\#}$, were also obtained from a plot of ln(k/T) vs. 1/T. Furthermore, the intercept in such a correlation gives enthropies of activation, $\Delta S^{\#}$. These data (E_{act}, $\Delta H^{\#}$ and $\Delta S^{\#}$) are given in Table 2.

According to the Hammett equation of $\log(k_x/k_0) = \rho\sigma_p$, where k_x is the rate constant of the tautomerization being studied with a substituted X present and k_0 is the corresponding rate constant of the unsubstituted compound (X = H) (Table 3), a plot of $\log(k_x/k_0)$ vs. σ_p gives the slope of the

Fig. 2. Plot of $\log(k_x/k_0)$ vs. σ_p constant for para-subsituted styrene.



line or reaction constant, ρ. A Hammett plot of these data vs. σ_p (Fig. 2) gives a good straight line through the points for the para-H, CH_3, OCH_3, Cl, and F compounds and a value for $\rho = -0.38 \pm 0.02$ ($R^2 = 0.96$) at 298 K. The very small magnitude of ρ indicates relative insensitivity of the reaction to electronic effects.

The magnitude of the activation parameters, $\Delta H^{\#}$ and $\Delta S^{\#}$, reflects the transition state structure. It can be seen from Table 2 that the relatively low entropy of activation for this tautomerization suggests a mechanism that is compatible with a cyclic activated complex, in which bond-making accompanies bond-breaking. In addition, the fact that the entropies of activation are negative and their magnitudes are relatively large refers to the loss of rotational, translational, and vibrational degrees of freedom associated with highly ordered transition states supporting this complex formation.

In summary, all of the preceding data are fully consistent with and indicative of an intramolecular concerted 1,3-

© 2008 NRC Canada

hydrogen migration involving a four-center transition state (pathway A) or an intermolecular dimeric mechanism (pathway B) where O–H bond formation cannot significantly precede C–H bond-breaking to be consistent with observed $\Delta H^{\#}$ and ρ (Scheme 2).

The results of modern studies have shown that the mechanism of proton transfer through an intramolecular mechanism are sometimes both energetically and geometrically unfavorable (20). From this viewpoint and the negative large magnitude of $\Delta S^{\#}$, the intermolecular dimeric mechanism seems to be more reasonable for the tautomerization of compound **2** to **3**.

Synthesis, characterization, and X-ray structures of three iridium(III)-hydrido-cyclometallated-imine complexes, including the first reported hydrido-(η^1-imine)-Ir complex

Fabio Lorenzini, Paolo Marcazzan, Brian O. Patrick, and Brian R. James

Abstract: Reactions of *cis*,*trans*,*cis*-[Ir(H)$_2$(PPh$_3$)$_2$(solv)$_2$]PF$_6$ (solv = MeOH or Me$_2$CO) with the imines HN=CPh$_2$, (*o*-HOC$_6$H$_4$)C(Me)=NCH$_2$Ph, and PhC(H)=N(*p*-F-C$_6$H$_4$) in MeOH or acetone under Ar give the complexes [IrH{NH=C(Ph)(*o*-C$_6$H$_4$)}(NH=CPh$_2$)(PPh$_3$)$_2$]PF$_6$ (**3**), [IrH{PhCH$_2$N=C(Me)(*o*-C$_6$H$_3$OH)}(solv)(PPh$_3$)$_2$]PF$_6$, where solv = MeOH (**4**) or Me$_2$CO (**4a**), and [IrH{N(*p*-F-C$_6$H$_4$)=CH(*o*-C$_6$H$_4$)}(Me$_2$CO)(PPh$_3$)$_2$]PF$_6$ (**5a**), which have been isolated and characterized. The imine (C$_6$F$_5$)C(H)=NPh is unreactive toward the Ir precursors. The X-ray structures of **3**, **4**·2MeOH, and **5a**·1/2Me$_2$CO show an η^2-*N*,*C*-imine moiety coordinated via the N atom and an orthometallated-C atom. Complex **3**, which contains both an orthometallated imine and an η^1-imine, is the first structurally characterized hydrido-(η^1-imine)-Ir complex. Comparisons are made with data for the corresponding Rh systems.

Key words: iridium, hydride complexes, imines, fluoroimines, phosphine complexes, orthometallation, crystallography, NMR spectroscopy.

Résumé : Les réactions du *cis*,*trans*,*cis*-[Ir(H)$_2$(PPh$_3$)(solv)$_2$]PF$_6$ (solv = MeOH ou Me$_2$CO) avec les imines HN=CPh$_2$, (*o*-HOC$_6$H$_4$)C(Me)=NCH$_2$Ph et PhC(H)=N(*p*-F-C$_6$H$_4$), en solution dans le MeOH ou l'acétone, sous une atmosphère d'argon, conduit à la formation des complexes [IrH{NH=C(Ph)(*o*-C$_6$H$_4$)}(NH=CPh$_2$)(PPh$_3$)$_2$]PF$_6$ (**3**), [IrH{PhCH$_2$N=C(Me)(*o*-C$_6$H$_3$OH)}(solv)(PPh$_3$)$_2$]PF$_6$ dans lequel solv = MeOH (**4**) ou Me$_2$CO (**4a**) et [IrH{N(*p*-F-C$_6$H$_4$)=CH(*o*-C$_6$H$_4$)}(Me$_2$CO)(PPh$_3$)$_2$]PF$_6$ (**5a**) qui ont été isolés et caractérisés. L'imine (C$_6$F$_5$)CH=NPh n'est pas réactive vis-à-vis les précurseurs Ir. Les structures des composés **3**, **4**·2MeOH et **5a**·1/2Me$_2$CO telles que déterminées par diffraction des rayons X ont permis de montrer la présence d'une portion η^2-*N*,*C*-imine coordinée par le biais de l'atome d'azote et d'un atome de carbone orthométallé. Le complexe **3** qui comporte une imine orthométallée ainsi qu'une η^1-imine est le premier complexe hydrido-(η^1-imine)-Ir à être caractérisée d'un point de vue structural. On a effectué des comparaisons avec des données pour les systèmes correspondants du rhodium.

[Traduit par la Rédaction]

Introduction

Since 2003, we have published 10 papers (1), including one review (2), on the hydrogenation of imines catalyzed by the Rh- and Ir-bis(triphenylphosphine) precursor complexes [M(cod)(PPh$_3$)$_2$]PF$_6$ (M = Rh, Ir; cod = 1,5-cyclooctadiene). Much diverse imine-coordination chemistry has been unveiled, important parameters being the structure and physical nature (solid or liquid) of the imine, the imine:metal stoichiometry, the presence of trace water, the nature of the solvent, use of an inert or an H_2 atmosphere, and catalyst poisoning by the amine product. The studies on the Ir systems, because of their lack of catalytic activity, have been more limited than those on the Rh systems. With imines containing an aryl moiety at the imine-C atom, the Ir precursor has generally formed (at 1:1 imine/Ir stoichiometries) monohydrido-Ir^{III} species via orthometallation at an ortho-C atom of an assumed [*trans*-Ir(PPh$_3$)$_2$(η^1-imine)(solv)]$^+$ intermediate, where solv = MeOH or Me$_2$CO (3); this 'standard' chemistry is illustrated in Scheme 1. With use of excess of the imine PhCH$_2$N=CHPh, the presence of trace water results in Ir-promoted hydrolysis of the imine and the generated benzylamine simply replaces the coordinated solvent of the orthometallated species (3). This new paper reports on the reactions of the Ir precursor with three imines, HN=CPh$_2$ (**Im^1**), (*o*-HOC$_6$H$_4$)C(Me)=NCH$_2$Ph (**Im^2**), and PhC(H)=N(*p*-F-C$_6$H$_4$) (**Im^3**) (see Scheme 2), and notes the non-reactivity of (C$_6$F$_5$)C(H)=NPh (**Im^4**). The imines **Im^1** and **Im^2** were chosen for comparison with their known reactivity toward the corresponding Rh precursor species (1), while the fluoro-substituted imines were used in the hope

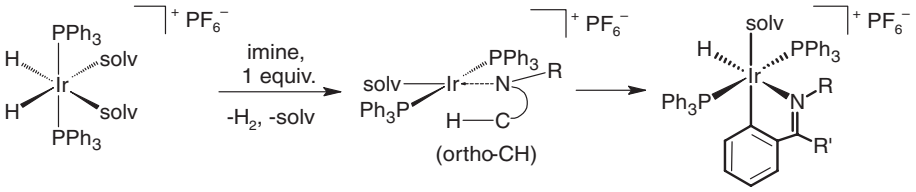
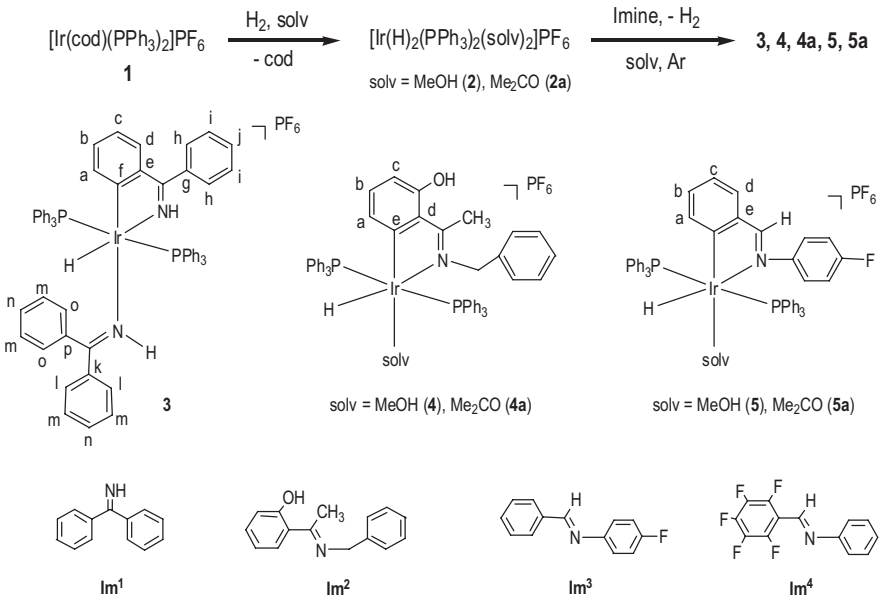
Scheme 1. Formation of Ir^{III}-cyclometallated-imine complexes (R, R′ = aryl or alkyl). $[Ir(cod)(PPh_3)_2]^+$ under H_2 is known to generate *cis*,*trans*,*cis*-$[Ir(H)_2(PPh_3)_2(solv)_2]^+$ (solv = Me_2CO or MeOH (refs. 3, 4)).



Scheme 2. Reactions of *cis*,*trans*,*cis*-$[Ir(H)_2(PPh_3)_2(solv)_2]PF_6$ (solv = MeOH (**2**) or Me_2CO (**2a**)) with the imines **Im[1]**, **Im[2]**, and **Im[3]** to form the complexes $[IrH\{NH{=}C(Ph)(o\text{-}C_6H_4)\}(\eta^1\text{-}NH{=}CPh_2)(PPh_3)_2]PF_6$ (**3**), $[IrH\{PhCH_2N{=}C(Me)(o\text{-}C_6H_3OH)\}(solv)(PPh_3)_2]PF_6$ (solv = MeOH (**4**) or Me_2CO (**4a**)), and $[IrH\{N(p\text{-}C_6H_4\text{-}F){=}CH(o\text{-}C_6H_4)\}(solv)(PPh_3)_2]PF_6$ (solv = MeOH (**5**) or Me_2CO (**5a**)). **Im[4]** showed no reactivity.



that the product might be a monometallic η^2-C=N (π-bonded) species because electron-withdrawing substituents appear to favour side-on bonding of imines (5). Such species have not been detected in metal complex-catalyzed hydrogenation of imines and whether they play a mechanistic role (as do π-bonded olefins in catalyzed olefin hydrogenations) is an important, unanswered question (6). We find, in fact, that **Im[1]**, **Im[2]**, and **Im[3]** all form hydrido-orthometallated species akin to those shown in Scheme 1, although in the **Im[1]** product the solvent has been replaced by a second η^1-bonded **Im[1]**. The product from the **Im[1]** reaction corresponds to that found earlier for the Rh system (1*b*); however, the structure presented is the first reported for a hydrido-η^1-imine complex of Ir. The product from the **Im[2]** reaction is different from that of the corresponding Rh system, which does not give an orthometallated product (1*a*). Comparisons between the Ir and Rh reactions with **Im[3]** and **Im[4]** systems are also mentioned.

Experimental

All manipulations and synthetic procedures were performed at room temperature (rt, ~20 °C) under an atmosphere of dry Ar or extra-dry H_2 (from Praxair, Edmonton, Alta.) as stated, using standard Schlenk techniques. The liquid imine $HN{=}CPh_2$ was a Sigma-Aldrich product, while the solid imines $(o\text{-}HOC_6H_4)C(Me){=}NCH_2Ph$, $PhC(H){=}N(p\text{-}F\text{-}C_6H_4)$, and $(C_6F_5)C(H){=}NPh$ were synthesized previously in this laboratory (7*a*); recent papers by other groups have also described the syntheses of the solid imines, which involve condensation of the ketones or aldehydes with the appropriate amine (7*b*, 7*c*).

The $[Ir(cod)(PPh_3)_2]PF_6$ complex (**1**) was prepared according to a literature procedure (8) using $IrCl_3{\cdot}3H_2O$ purchased from Colonial Metals Inc. Acetone and MeOH (Fisher Scientific) were dried over K_2CO_3 and Mg/I_2, respectively, and distilled under N_2. Acetone-d_6, CD_2Cl_2, and CD_3OD (Cambridge Isotope Laboratory) were used as received for measuring $^{31}P\{^1H\}$, $^{13}C\{^1H\}$, and ^1H NMR spectra at rt on a Bruker AV400 spectrometer. When necessary, atom assignments were made by means of $^1H\text{-}^{13}C\{^1H\}$ (HSQC and HMBC) and $^1H\text{-}^{31}P\{^1H\}$ (HSQC and HMBC) NMR correlation spectroscopies. Residual protonated species in the deuterated solvents were used as internal references (δ: 2.05 q for acetone-d_6; δ: 5.32 t for CD_2Cl_2; and δ: 3.31 q and 4.87 s for CD_3OD). All shifts are reported in ppm (s = singlet, d = doublet, t = triplet, q = quintet, spt = septet, m = multiplet, br = broad), relative to external $SiMe_4$ or 85% aq. H_3PO_4, with *J* values in Hz. Solid samples of the synthesized complexes were stored at rt under Ar; elemental

analyses were performed on a Carlo Erba 1108 analyzer. ESI-MS were acquired in the positive ion mode on a Bruker Esquire LC ion-trap mass spectrometer equipped with an electrospray ion source; solvents used were acetone/MeOH or CH_2Cl_2/MeOH, and the sample solution of concentration ~25–50 μmol/L was infused into the ion source by a syringe pump at a flow-rate of 700 μL/h. MALDI-MS were obtained on a Bruker Biflex IV MALDI-TOF spectrometer equipped with a nitrogen laser. The samples were dissolved in acetone/MeOH or CH_2Cl_2/MeOH and dithranol was used as matrix. The sample solutions (~1 mg/mL) and the matrix (20 mg/mL) were mixed in a ratio of 1:1 to 1:10, and 1 μL of the mixture was deposited onto the sample target; these spectra were acquired in the positive reflection mode with delay extraction by averaging 100 laser shots, and were calibrated externally using peptides. MS data are reported as *m*/*z* values. IR spectra were measured with a Thermo Nicolet FT-IR Nexus spectrometer using either a KBr pellet or a solution, as stated.

[IrH{NH=C(Ph)(*o*-C_6H_4)}(HN=CPh_2)(PPh_3)$_2$]PF_6 (3)

A red suspension of [Ir(cod)(PPh_3)$_2$]PF_6 (**1**) (61 mg, 0.063 mmol) in MeOH (1.8 mL) was reacted with 1 atm H_2 at rt to generate immediately a brown solution containing *cis*,*trans*,*cis*-[Ir(H)$_2$(PPh_3)$_2$(MeOH)$_2$]PF_6 (**2**) (3, 4). HN=CPh_2 (**Im^1**) (22.0 μL, 0.127 mmol) in MeOH (0.5 mL) was then added under H_2. Stirring the mixture at rt for 90 min resulted in precipitation of a yellow solid that was collected, washed with Et_2O (3 × 5 mL), and dried in vacuo (63 mg, 82% yield). IR (KBr, cm^{-1}): 3429 (ν_{N-H}), 2132 (ν_{Ir-H}), 1589, 1560 ($\nu_{C=N}$). IR (CH_2Cl_2, cm^{-1}): 3340 (ν_{N-H}), 2195 (ν_{Ir-H}), 1583, 1568 ($\nu_{C=N}$). ^{1}H NMR (CD_2Cl_2) (see Scheme 2 for atom-labeling) δ: –15.80 (t, 1H, $^2J_{HP}$ = 14.1, Ir*H*), 10.21 (s, *H*N=C(*o*-C_6H_4)), 9.98 (s, *H*N=CPh_2), 7.58 (t, 1H, $^3J_{HHi}$ ~ 7.6, H_j), 7.43 (d, 1H, $^3J_{HH}$ = 7.3, H_d), 7.39–7.06 (m, 38H, PC_6H_5, H_i, H_m, H_n), 6.86 (d, 2H, $^3J_{HH}$ = 7.7, H_l or H_o), 6.75 (t, 1H, $^3J_{HHa}$ ~ $^3J_{HHc}$ ≅ 7.3, H_b), 6.65 (t, 1H, $^3J_{HHb}$ ~ $^3J_{HHd}$ ~ 7.2, H_c), 6.56 (d, 1H, $^3J_{HH}$ = 7.5, H_a), 6.37 (d, 2H, $^3J_{HH}$ = 7.6, H_h), 6.28 (d, 2H, $^3J_{HH}$ = 7.5, H_l or H_o). ^{13}C{^{1}H} NMR (CD_2Cl_2) δ: 189.40 (s, NH=*C*(*o*-C_6H_4)), 179.32 (s, HN=*C*Ph_2), 151.59 (s, C_f), 147.32 (s, C_e), 142.04 (s, C_d), 137.97 (s, C_k or C_p), 137.01 (s, C_k or C_p), 134.69 and 131.88-127.93 (m, PC_6H_5, C_i, C_m, C_n), 133.82 (s, C_a), 131.18 (s, C_c), 129.86 (s, C_j), 129.43 (s, C_l or C_o), 128.65 (s, C_h), 128.64 (s, C_l or C_o), 121.23 (s, C_b); the C_g signal could not be assigned. ^{31}P{^{1}H} NMR (CD_2Cl_2) δ: 16.93 (s, *P*Ph), –143.70 (spt, $^1J_{PF}$ = 712.0, *P*F_6). ESI-MS: 1080 [M$^+$], 899 [M$^+$-NH=C(Ph)(*o*-C_6H_4)]. Anal. calcd. for $C_{62}H_{52}N_2F_6P_3Ir$: C 60.83, H 4.28, N 2.29; found: C 60.87, H 4.30, N 2.18.

Yellow, X-ray quality tablet crystals of **3** were grown at rt by diffusion of Et_2O into a CH_2Cl_2 solution (1.5 mL) of the complex (25 mg, 20.4 mmol).

[IrH{$PhCH_2$N=C(Me)(*o*-C_6H_3OH)}(solv)(PPh_3)$_2$]PF_6; solv = MeOH (4), Me_2CO (4a)

A red suspension of **1** (60 mg, 0.062 mmol) in acetone (1.0 mL) was reacted with 1 atm H_2 at rt to form a brown solution of *cis*,*trans*,*cis*-[Ir(H)$_2$(PPh_3)$_2$(Me_2CO)$_2$]PF_6 (**2a**).[2] Addition under Ar of (*o*-HOC_6H_4)C(Me)=NCH_2Ph (**Im^2**) (16 mg, 0.069 mmol) in acetone (1.0 mL) and subsequent stirring of the mixture at rt for 1 h generated a yellow solution. Addition of Et_2O (20.0 mL) precipitated a yellow powder that was collected, washed with Et_2O (2 × 10 mL), and dried in vacuo; the product is **4a** (51 mg, 72% yield). IR (KBr, cm^{-1}): 3057 (ν_{O-H}), 2195 (ν_{Ir-H}), 1587, 1579 ($\nu_{C=N}$). IR (acetone, cm^{-1}): 2034 (ν_{Ir-H}), 1581 ($\nu_{C=N}$). ^{1}H NMR (acetone-d_6) (see Scheme 2 for atom-labeling) δ: –15.48 (t, 1H, $^2J_{HP}$ = 17.6, Ir*H*), 8.94 (br s, 1H, O*H*), 7.51 (m, 5H, $CH_2C_6H_5$), 7.39 (m, 15H, PC_6H_5), 7.27 (t, 1H, $^3J_{HHa}$ ~ $^3J_{HHc}$ ~ 7.3, H_b), 7.04 (m, 15H, PC_6H_5), 6.49 (d, 1H, $^3J_{HHb}$ ~ 7.2, H_c), 6.28 (d, 1H, $^3J_{HHb}$ ~ 7.4, H_a), 5.50 (br s, 2H, NCH_2), 2.09 (br s, 3H, CH_3), 2.09 (br m, 6H, (CH_3)$_2$CO). ^{13}C{^{1}H} NMR (acetone-d_6) δ: 183.26 (s, *C*(H)=N), 159.20 (s, C_d), 136.52 (s, *C*-OH), 134.25 (m, PC_6H_5), 133.31 (s, C_a), 132.71 (m, $CH_2C_6H_5$), 128.59 (m, PC_6H_5), 127.94 (s, C_b), 110.83 (s, C_c), 56.99 (s, *C*H_2Ph) 20.66 (s, *C*H_3); the C_e signal could not be assigned. ^{31}P{^{1}H} NMR (acetone-d_6) δ: 17.91 (s, *P*Ph), –142.64 (spt, $^1J_{PF}$ = 707.3, *P*F_6). MALDI-MS: 942 [M-PF_6-Me_2CO]$^+$, 679 [M – H-PF_6-Me_2CO-PPh_3]$^+$.

X-ray quality, yellow prism crystals of **4**·2MeOH, as well as a yellow precipitate of **4**, were obtained at ~273 K from a saturated MeOH (2.0 mL) solution of **4a**; **4** was washed with Et_2O and dried in vacuo. Anal. calcd. for $C_{52}H_{49}N_4O_2F_6P_3Ir$ (**4**): C 55.81, H 4.41, N, 1.25; found: C 55.89, H 4.94, N 1.22.

[IrH{N(*p*-F-C_6H_4)=CH(*o*-C_6H_4)}(Me_2CO)(PPh_3)$_2$]PF_6 (5a)

A red solution of **1** (25 mg, 0.026 mmol) in acetone-d_6 (or acetone) (1.0 mL) was treated as above with H_2 to form a solution of **2a**. Addition under Ar of PhC(H)=N(*p*-F-C_6H_4) (**Im^3**) (6 mg, 0.030 mmol) in acetone-d_6 (or acetone) (0.5 mL) at rt resulted in a yellow solution into which slow diffusion of Et_2O generated overnight a yellow, crystalline powder (**5a**) and X-ray quality, yellow plate crystals of **5a**·1/2Me_2CO. The powder (**5a**) was collected, washed with Et_2O (3 × 5 mL), and dried in vacuo (24 mg, 83% yield). IR (KBr, cm^{-1}): 2206 (ν_{Ir-H}), 1599 ($\nu_{C=N}$). IR (CH_2Cl_2, cm^{-1}): 2217 (ν_{Ir-H}), 1599, 1587 ($\nu_{C=N}$). ^{1}H NMR (acetone-d_6) (see Scheme 2 for atom-labeling) δ: –16.98 (t, 1H, $^2J_{HP}$ = 15.8, Ir*H*), 8.15 (br s, 1H, C(*H*)=N), 7.49 (m, 6H, C_6H_4F, H_a, H_d), 7.40–7.30, 7.19–7.09 (m, 30H, PC_6H_5), 6.87 (br t, 1H, H_b or H_c), 6.55 (dt, 1H, $^3J_{HH}$ ~ 7.6, $^4J_{HH}$ ~ 1.2, H_b or H_c). ^{13}C{^{1}H} NMR (acetone-d_6) δ: 175.07 (s, *C*(H)=N), 146.88 (s, C_e), 131.43 (m, PC_6H_5), 129.42 (s, C_b or C_c), 128.84 (m, C_6H_4F, C_a, C_d), 126.69 (m, PC_6H_5), 119.39 (s, C_b or C_c). ^{31}P{^{1}H} NMR (acetone-d_6) δ: 17.69 (s, *P*Ph), –142.64 (spt, $^1J_{PF}$ = 707.3, *P*F_6). MALDI-MS: 917 [M-H-PF_6-Me_2CO]$^+$. Anal. calcd. for $C_{52}H_{48}NOF_7P_3Ir$: C 55.71, H 4.32, N 1.25; found: C 55.37, H 4.18, N, 1.25.

Attempted reactions with (C_6F_5)C(H)=NPh (Im^4)

Solutions of **2** and **2a** (and the corresponding species with solv = CD_3OD and acetone-d_6, see Scheme 2) were made in the appropriate solvents as described above, but using a smaller quantity of **1** (15 mg, 0.016 mmol) in 0.5 mL of the respective solvents. No rt reactions over several hours were seen on addition of **Im^4** (5 mg, 0.017 mmol), the NMR spec-

tra revealing the presence of only **2** or **2a**. ^{1}H NMR (CD_3OD) δ: –29.46 (t, 1H, $^2J_{HP}$ = 17.1, Ir*H*). $^{31}P\{^1H\}$ NMR (CD_3OD) δ: 27.16 (s, *P*Ph), –143.32 (spt, $^1J_{PF}$ = 707.5, *P*F_6). ^{1}H NMR (acetone-d_6) δ: –27.68 (t, 1H, $^2J_{HP}$ = 15.9, Ir*H*). $^{31}P\{^1H\}$ NMR (acetone-d_6) δ: 28.89 (s, *P*Ph), –142.62 (spt, $^1J_{PF}$ = 707.4, *P*F_6). These NMR data are in accord with literature values (3, 4).

X-ray crystallographic analyses of 3, 4·2MeOH, and 5a·1/2Me_2CO

Measurements were made at 173(1) K on a Bruker X8 APEX diffractometer using graphite-monochromated Mo-K α radiation (λ = 0.71073 Å); data were collected and integrated using the Bruker SAINT software package (9) and were corrected for absorption effects using the multi-scan technique (SADABS) (10) with minimum and maximum transmission coefficients of 0.551 and 0.798, respectively, for **3**, 0.434 and 0.715 for **4**·2MeOH, and 0.549 and 0.866 for **5a**·1/2Me_2CO. The data were corrected for Lorentz and polarization effects, and the structures were solved by direct methods (11). For **3**, one phenyl ring appears to be disordered over 2 sites; the 2 rings were thus refined using mild restraints with the major fragment refined anisotropically and the minor fragment isotropically. Located in difference maps and refined isotropically were the imine-H of the orthometallated imine of **3**, and the hydride and the H-atoms of the OH groups of the coordinated MeOH and the C_6H_3 ring of **4**. The hydrides of **3** and **5a** were not located and were thus not included in the models. All other H-atoms of the complexes were placed in calculated positions and were not refined. Some of the crystallographic data are given in Table 1, while selected bond lengths and angles are given in Table 2.

Results and discussion

The new complexes [IrH{NH=C(Ph)(*o*-C_6H_4)}(HN=CPh_2)-(PPh_3)$_2$]PF_6 (**3**), [IrH{$PhCH_2N$=C(Me)(*o*-C_6H_3OH)}(solv)-(PPh_3)$_2$]PF_6, where solv = MeOH (**4**) or Me_2CO (**4a**), and [IrH{N(*p*-F-C_6H_4)=CH(*o*-C_6H_4)}(Me_2CO)(PPh_3)$_2$]PF_6 (**5a**), were obtained by reaction of *cis*,*trans*,*cis*-[$Ir(H)_2(PPh_3)_2$(solv)$_2$]PF_6 (solv = MeOH (**2**) or Me_2CO (**2a**)) with the imine, with co-production of H_2 (Scheme 2); the complexes are of the well-documented hydrido-orthometallated-imine type (Scheme 1). Such complexes have been characterized for many metals (certainly for all the platinum metals; see following and ref. 12), and continue to attract attention because of their wide range of applicability in areas that include asymmetric synthesis, functionalization of C–H bonds, C-C coupling reactions, and biological systems (13).

Complex **3** was readily obtained in 82% yield from reaction in MeOH of **2** with 2 equiv. of benzophenone imine (HN=CPh_2, **Im^1**), and was fully characterized by X-ray analysis, elemental analysis, and NMR, IR, and MS data. Our group recently isolated the analogous Rh complex with essentially the same structure (see later), but the Rh species was formed more slowly via *cis*-[$Rh(PPh_3)_2$(η^1-NH=CPh_2)$_2$]PF_6 in which one imine ligand subsequently undergoes orthometallation (1*b*). No intermediates were detected in the Ir system, the stronger Ir-H bond (vs. Rh-H) presumably promoting the metallation step (14).

The reaction of **2** with (*o*-HOC_6H_4)C(Me)=NCH_2Ph (**Im^2**) in MeOH resulted in a mixture of products that could not be separated. However, a successful isolation of complex **4** was achieved by carrying out a 1:1 reaction of **2a** with **Im^2** in acetone and then recrystallizing the resulting isolated acetone analogue (**4a**) from MeOH. Complex **4a**, obtained in

[a]Data for one of the two molecules in the asymmetric unit.

72% yield, was well characterized by NMR, MS, and IR data, but a satisfactory elemental analysis could not be obtained, possibly because of the variable acetone solvate content; complex **4** as a yellow powder gave a good elemental analysis for a non-solvated species, while the crystal contained two MeOH solvates per molecule as determined by X-ray analysis (see later).

Of note, the rate of formation of **4a** appears to be dependent on the water content of the solvent (acetone or methanol); in the synthetic work carried out in dried solvents, reaction was complete in ~1 h, but the reaction of **2a** with **Im²**, as monitored by $^{31}P\{^1H\}$ NMR spectroscopy in non-dried acetone-d_6, took ~13 d for completion (Fig. S1, δ_P: 28.89 for **2a** and 17.91 for **4a**).[2] Presumably, water competes with the solvent for a coordination site in **2a** and (or) **4a** and somehow impedes the reaction, although there was no direct evidence for the presence of any aquo species.

Reaction of **2a** with PhC(H)=N(*p*-F-C_6H_4) (**Im³**) at ~1:1 stoichiometry in acetone led to the isolation of **5a** in 83% yield as a mixture of a yellow powder and crystals after slow diffusion of Et_2O into the solution of **5a**; higher yields were obtained when a 2:1 ratio of **Im³**/Ir was used. Elemental analysis of the powder corresponded to unsolvated **5a**, while X-ray analysis of the crystal revealed one-half an acetone solvate per molecule (see below). NMR, MS, and IR data were in accord with the solid state structure. The formation of **5a** is apparently a reversible process as evidenced by monitoring under H_2 an acetone-d_6 solution of isolated **5a** by $^{31}P\{^1H\}$ NMR spectroscopy (Fig. S2)[3]: the δ_P 17.69 resonance of **5a** decays over a week and is partially replaced by the δ_P 28.89 signal of the Ir-dihydride (**2a**, where solv = acetone-d_6). Of note, no formation of **5** (the MeOH/CD_3OD analogue of **5a**) was evident when **2** (solv = CD_3OD) was reacted with ~1 mol equiv. of **Im³** in CD_3OD at rt; in situ $^{31}P\{^1H\}$ NMR spectra over several hours revealed only the δ_P 27.16 resonance of **2**, although over the period of a week this was replaced completely by broad singlets at δ_P 21.00 and 19.68 due to unidentified species (at an **Im³**:Ir ratio of 2, ~15% of **5** was formed over a week as evidenced by a resonance at δ_P 17.66). The complications detected by the NMR experiments may again be symptomatic of water impurity in the deuterated solvents and stresses the need for dry solvents in the synthetic procedures.

As monitored by $^{31}P\{^1H\}$ NMR spectroscopy, there was no reaction at rt of **2** or **2a** with (C_6F_5)C(H)=NPh (**Im⁴**) in the respective solvents at imine:Ir ratios up to 2.

The X-ray structures of the cations of **3**, **4**·2MeOH, and **5a**·1/2Me_2CO are shown in Figs. 1–3, and some geometrical

Fig. 1. Structure of the $[IrH\{NH=C(Ph)(o\text{-}C_6H_4)\}(HN=CPh_2)(PPh_3)_2]^+$ cation of **3**, with 50% probability ellipsoids.

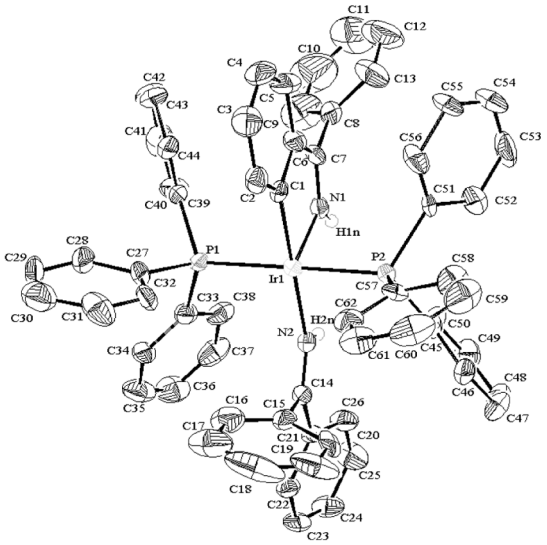

Fig. 2. Structure of the $[IrH\{PhCH_2N=C(Me)(o\text{-}C_6H_3OH)\}(MeOH)(PPh_3)_2]^+$ cation of **4**, with 50% probability ellipsoids.

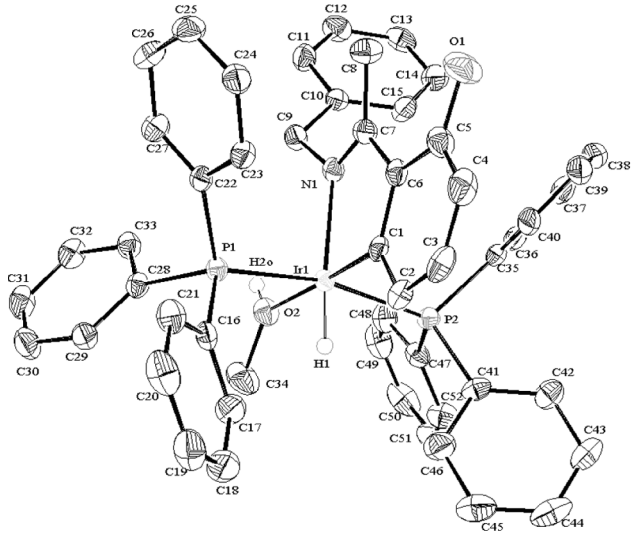
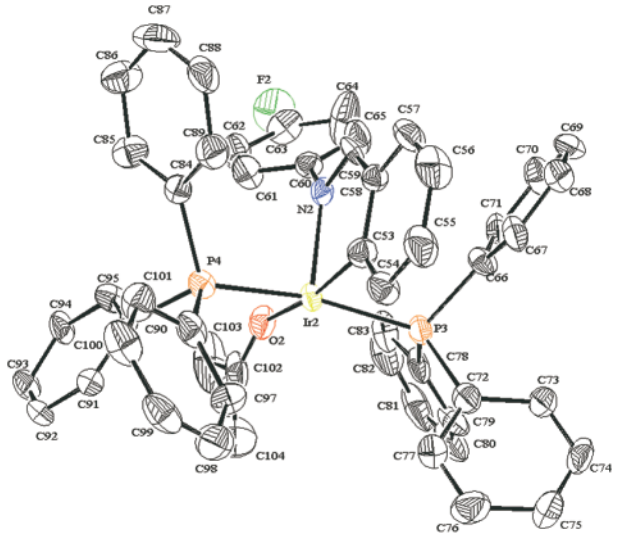


parameters are listed in Table 2. Complexes **3** and **4**·2MeOH crystallize with one molecule in the asymmetric unit, while **5a**·1/2Me_2CO crystallizes as two almost identical, crystallographically independent molecules with one molecule of free acetone in the asymmetric unit. The structures of the three distorted octahedral Ir^{III} cations exhibit similar features, all having five coordination sites occupied by the same arrangement of ligands: an η^2-imine moiety coordinated via the imine-N atom and the orthometallated-C atom (C_{ortho}), a hydride trans to the N-atom, and *trans*-PPh_3 ligands cis to the hydride (cf. Scheme 1), and, while **4** and **5a** respectively have MeOH or Me_2CO coordinated trans to C_{ortho}, **3** has a second imine, η^1-coordinated. The hydride attached to the heavy metal centre was successfully located by X-ray analysis only for **4**, but ^1H NMR data (a high-field triplet at δ_H –17 to –15 with $^2J_{HP}$ ~ 14–18 Hz, and IR data

Fig. 3. Structure of one of the two almost identical molecules of the $[IrH\{N(p\text{-}C_6H_4\text{-}F)=CH(o\text{-}C_6H_4)\}(Me_2CO)(PPh_3)_2]^+$ cation of **5a**, with 50% probability ellipsoids.



showing $\nu_{Ir\text{-}H}$ 2034–2217 cm^{-1}) unequivocally establish its presence in all three complexes. (Solid state and solution IR data for $\nu_{C=N}$ for **3**–**5**, $\nu_{N\text{-}H}$ for **3**, and $\nu_{O\text{-}H}$ for **4** are also noted). The hydride resonances are very similar to those we found earlier for an analogue of **5a** synthesized in the same manner but using $PhC(H)=NCH_2Ph$ (**3**). The imine-N*H* proton singlets for **3**, at δ 9.98 (for the η^1-imine) and 10.21 (for the η^2-imine), are close to the values reported for the same imine (**Im^1**) similarly coordinated at Ru^{II} and Os^{II} (15) but are ~3 ppm to lower field than those of the Rh analogue $[RhH\{NH=C(Ph)(o\text{-}C_6H_4)\}(HN=CPh_2)(PPh_3)_2]PF_6$ (1*b*). Measurements of 2D HSQC, HMBC $^{31}P\{^1H\}/^1H$, and 2D HSQC, HMBC $^{13}C\{^1H\}/^1H$ NMR spectra have allowed for assignment of all the ^1H NMR resonances of **3**, **4**, and **5a**. The $^{31}P\{^1H\}$ NMR spectra of **3**, **4a**, and **5a** each show a sharp singlet in the δ 18–17 region for the *trans*-phosphines, and a septet at δ ~–143 for the PF_6^- anion. Mass spectral data for complex **3** show the mass fragment of the intact cation, while the highest fragments seen for **4a** and **5a** correspond to $[IrH\{N(CH_2Ph)=C(Me)(o\text{-}C_6H_3OH)\}(PPh_3)_2]^+$ and $[Ir\{N(p\text{-}F\text{-}C_6H_4)=CH(o\text{-}C_6H_4)\}(PPh_3)_2]^+$, respectively.

The five-membered planar metallocycle ring within the complexes is essentially coplanar with the η^1-N atom of the second imine in **3**, the O-C of the MeOH in **4**·2MeOH, and the O-C-C_2 unit of the Me_2CO in **5a**. The N-Ir-C angle of the metallocycle of all three structures (79.3°–78.3°) is very similar to those found in other cyclometallated imine complexes of Ir^{III} (3) and also, for example, of Rh^{III} (16) and Os^{II} (17). The *trans*-PPh_3 ligands are bent slightly towards the hydride as indicated by P-Ir-P angles of 164.7° to 173.9° and other angles at the Ir centre (Table 2); all such hydridobis(phosphine)-orthometallated-imine complexes of Ir (3) and Rh (1*b*, 16) systems display such bending. The Ir-O-C angles of the coordinated MeOH in **4** and coordinated acetone in **5a** are 122.7° and 137.6°, respectively.

The Ir—P, Ir—N, and Ir—C_{ortho} bond lengths (and the C=N bond lengths for the η^2-*C*,*N*-imine) for the three complexes are in the range found previously for the closely re-

© 2008 NRC Canada

lated orthometallated-imine species [IrH{$PhCH_2N{=}CH(o\text{-}C_6H_4)$}$(PPh_3)_2L]PF_6$, where L = Me_2CO or $PhCH_2NH_2$ (3). The geometry of the orthometallated benzophenone ligand of **3** is also very similar to that of the same ligand within the Rh analogue of **3** (1*b*) and within complexes of Ru^{II} (15*d*) and Os^{II} (17). The C=N bond length of the η^1-NH=CPh_2 of **3** is about 0.2 Å shorter than that of the corresponding Rh complex (1*b*) and those found in other Rh^{I}- and Rh^{III}-(η^1-imine) complexes (18).

As far as we are aware, complex **3** is the first structurally characterized Ir(η^1-imine) complex, where the imine is a 'standard one', i.e., containing only alkyl, aryl, or hydrogen substituents at the imine-C and -N atoms; however, other such Ir(η^1-imine) complexes have been isolated, including benzophenone systems (19). Complex **3** is also a relatively rare example of a hydrido-η^1-imine species; except for the Rh analogue of **3** mentioned above (1*b*), all the other examples are η^1-benzophenone derivatives of Ru or Os (15). There is, of course, a vast literature on Ir complexes with 'non-standard' η^1-N=C < moieties within a range of ligands such as imine-ethers, iminols, and amidines (20), diimines (21), pyrazoles (22), imidazoles (22), oxazolines (23), oxazolones (24), anthranil (25), and creatinine (26).

The ketimine **Im^2**, containing an *o*-OH substituent in the imine-C phenyl group, forms complex **4**, a typical hydrido-orthometallated species akin to those we report here and elsewhere (3); however, this is the first type of such a complex derived from this ketimine. In complexes of Cu^{II} (27), Ru^{II} (28), and V^{IV} (29), the ketimine is chelated via the N-atom and the alkoxy-O atom from the hydroxy group. In recent work, on an analogous study of this imine with *cis*,*trans*,*cis*-$[Rh(H)_2(PPh_3)_2(MeOH)_2]PF_6$ (or *cis*-$[Rh(PPh_3)_2(MeOH)_2]PF_6$), we isolated an unique type of zwitterionic complex, namely $[Rh\{\eta^4\text{-}(C_6H_4O)^{(-)}C(Me){=}N^{(+)}(H)CH_2Ph\}(PPh_3)_2]PF_6$, in which the ketimine is coordinated via the C_4 part of the *o*-hydroxy-arene moiety in a quinoid form; this tautomer is generated via proton transfer from the O-atom to the N-atom within the molecular, benzenoid form. Presumably, the strength of the Ir–H bond again promotes the orthometallation.

Complex **5a** formed from **Im^3** is again a typical hydrido-orthometallated species, but we are unaware of any other such structures with this fluorinated imine. Of note, however, a recent structure with this imine, $Ni[^iPr_2P(CH_2)_2P^iPr_2]$-[PhC(H)=N(*p*-F-$C_6H_4$)], reveals the π-bonded **Im^3** (5), and indeed this report prompted us to investigate the reactivity of this particular imine toward Ir. The strength of the Ir–H bond again likely favours formation of **5a**. Of major interest, in a cursory study we have found that the reaction of **Im^3** with the Rh analogue of **2a** forms only a trace of a hydrido-orthometallated species, and the major product has yet to be identified.[3] The fluoro-aldimine $(C_6F_5)C(H){=}NPh$ (**Im^4**) was unreactive toward **2**, **2a**, or the corresponding Rh species; the reactivity of **Im^4** toward the Ni precursor used for the **Im^3** reaction, $[Ni\{^iPr_2P(CH_2)_2P^iPr_2\}]_2(\mu\text{-}H)_2$, was not reported (5). We continue studies with variation of the fluoroimine and the phosphine ligand in the hope of achieving an appropriate electronic and steric environment for formation of a π-bonded imine-Ir or -Rh complex.

Our previous studies have shown that isolated Ir-cyclometallated-imine complexes are stable toward H_2 in acetone or MeOH solution at ambient conditions and are not effective for catalytic hydrogenation of the imine (3, 30), and this has been confirmed recently by the Zaragosa group (31). The new complexes **3**–**5** are similarly inactive. In general, cyclometallated-imine Rh complexes can become active catalysts in MeOH, when they undergo partial reductive elimination of the cyclometallated imine (the reverse of orthometallation — cf. the intermediate shown in Scheme 1) to generate a solvated η^1-imine species that does react with H_2 (2, 16*a*). The Rh analogues of **3** (1*b*) and **5a**[4] are inactive toward H_2, while the Rh analogue of **4** (or **4a**) is unknown (see earlier), and the Ir and Rh complexes derived from **Im^3** in MeOH are not characterized.

Conclusions

Following our earlier work on the reactions between imines and *cis*,*trans*,*cis*-$[Rh(H)_2(PPh_3)_2(solv)_2]^+$ (solv = MeOH or Me_2CO), this article describes reactions of the imines with the corresponding Ir precursor species. The selected imines are $HN{=}CPh_2$, (o-HOC_6H_4)C(Me)=NCH_2Ph, and PhC(H)=N(p-F-C_6H_4), the last one being chosen with the aim of possibly favouring formation of an η^2-C=N (π-bonded) species. However, in each case, the product is a hydrido species containing an η^2-*N*,*C*-imine moiety coordinated via the N atom and an orthometallated-C atom. With benzophenone imine, the product contains also a second imine that is η^1-N coordinated, the product proving to be the first reported, structurally characterized hydrido-(η^1-imine)-Ir complex. The Ir complexes are inactive as precursor hydrogenation catalysts for the imines. Comparisons are made with the products formed in the corresponding Rh systems and significant differences are noted.

Asymmetric nitroaldol reaction with a chiral copper complex derived from D-tartaric acid

Changsheng Gan

Abstract: A novel catalytic enantioselective Henry reaction has been developed using a tetradentate copper complex derived from D-tartaric acid to give β-nitroalkanols in moderate to high enantioselectivities.

Key words: Henry reaction, D-tartaric acid, enantioselective, β-nitroalkanols.

Résumé : On a développé le champ d'application de la nouvelle réaction catalytique énantiosélective d'Henry en utilisant le complexe tétradentate de cuivre de l'acide D-tartrique pour préparer des β-nitroalcanols avec des énantiosélectivités allant de modérées à élevées.

Mots-clés : réaction d'Henry, acide D-tartrique, énantiosélective, β-nitroalcanols.

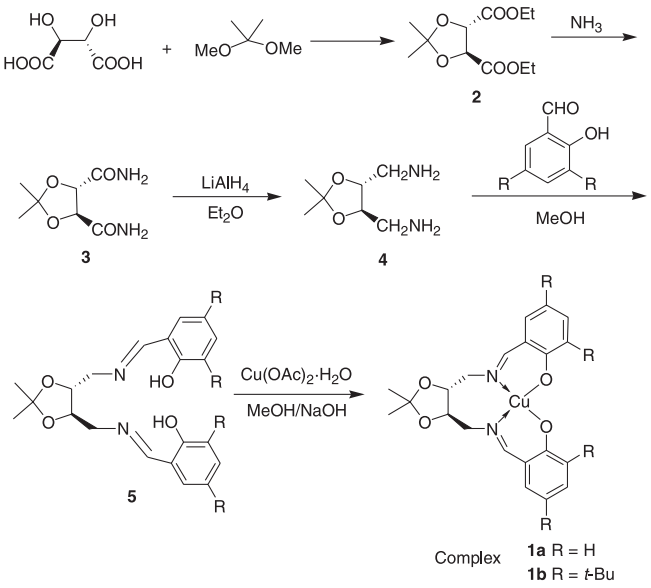
[Traduit par la Rédaction]

Introduction

The nitroaldol reaction (or Henry reaction) constitutes an important class of C–C bond-forming reactions that provide straightforward access to important synthetic intermediates from readily accessible nitroalkanes and carbonyl compounds (1). Because of its significance in organic synthesis, considerable efforts have been devoted to the development of catalytic asymmetric nitroaldol reactions (2). Several efficient catalysts have been developed, such as BINOL by Shibasaki (3), bis(oxazoline) by Evans and Jørgensen (4), cinchona alkaloid by Deng (5), dinuclear zinc complex by Trost (6), amino alcohol (7), thiourea (8), and Schiff base catalysts (9). Because D-tartaric acid is available very cheaply from natural chiral sources, it has been widely studied in asymmetric catalysis, and different catalysts have been developed for a series of asymmetric reactions (10). We have been studying it for some time. In this article, we report a novel enantioselective Henry reaction catalyzed by a C_2-symmetric tetradentate catalyst **1** derived from D-tartaric acid, which is similar in structure to the salen derivative (11).

Scheme 1 summarizes the synthesis of complex **1** from D-tartaric acid. (4*S*, 5*S*)-(–)-Diethyl 2, 3-*O*-isopropylidene-D-tartarate (**2**) was prepared from D-(–)-tartaric acid using a reported procedure (12, 13). Dropping 25% ammonia into **2** in the presence of ammonium chloride in an ice-salt bath, then stirring overnight, gave diamide **3** in 85% yield. Reduction of the diamide moiety of **3** to diamine **4** with $LiAlH_4$ in refluxing ether for 18 h, followed by condensation with corresponding salicylaldehyde, provided chiral ligand **5**. Finally, mixing **5** and $Cu(OAc)_2 \cdot H_2O$ in methanol followed by the addition of excess sodium hydroxide produced the tetradentate copper complex **1**.

Scheme 1. The synthetic route of complex **1**.



Results and discussions[2]

The complex **1** was added to a mixture of 4-nitrobenzaldehyde and nitromethane (Scheme 2). The results are shown in Table 1. Entries 1 and 2 show that the tetradentate complex **1b**, with a bulky *tert*-butyl substituent,

catalyzed the reaction much better than **1a**. Then different solvents were screened. Toluene proved the best, followed by THF, whereas EtOH, CH_2Cl_2, and CH_3CN gave only poor enantioselectivities (entries 2–5, 8). Increasing the amount of CH_3NO_2 to 0.5 mL promoted both the yield and the enantioselectivity (entry 6), but when 1 mL of CH_3NO_2 was used, the enantioselectivity was significantly decreased (entry 7). Neither increasing the amount of catalyst nor adding a molecular sieve to the reaction mixture was effective in improving the enantioselectivity (entries 9 and 10). But diluting the catalyst concentration by doubling the amount of solvent and nitromethane did further improve the enantioselectivity without significant loss of yield (entry 11). Conducting the reaction under lower temperature was then examined. However, very low enantioselectivity was obtained (entry 13). The absolute configuration of the product in Table 1 was determined as *S* by comparing the HPLC elution order of the enantiomers and the optical rotations reported in the literature (4*a*).

With the optimized reaction conditions, the complex **1b** was used to catalyze the addition of nitromethane to a variety of aldehydes (Scheme 3). The results are summarized in Table 2. Moderate enantioselectivities were obtained for the *para*-substituted aromatic aldehydes, such as 4-chlorobenzaldehyde (entry 2), 4-methoxybenzaldehyde (entry 5), and 4-methylbenzaldehyde (entry 8). 2-Chlorobenzaldehyde (entry 6) was shown to produce the highest enantioselectivity among all the substrates examined. When it came to the sterically less-encumbered benzaldehyde (entry 4), the ee value diminished to 48%. As far as aliphatic aldehydes were concerned, the enantioselectivities were only moderate (entries 9–11). The absolute configurations of the products in Table 2 were assigned as *S* based on the data reported in the literature (4, 9, 14), except for **6i**, whose configuration was not determined.

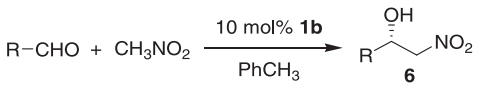
Scheme 3. Asymmetric nitroaldol reactions of nitromethane with various aldehydes.



Conclusions

In summary, we have developed a novel and facile enantioselective nitroaldol reaction. It is the first reported use of tartaric acid derivatives in the catalytic enantioselective Henry reaction. Moderate to high enantioselectivities were obtained for the *ortho*-substituted aromatic aldehydes. This reaction works quite well at room temperature, avoiding the use of low temperature. Since the catalyst is very stable in the air, airproof conditions in N_2 or Ar are also unnecessary. Considering that the chiral catalyst can be readily prepared from naturally abundant tartaric acid, this method provides a practical and convenient way to prepare optically active nitroalkanols. Further study is currently in progress to improve the yield and enantiomeric excess and to elucidate the reaction mechanism.

Synthesis of 2,4,5-trisubstituted imidazoles catalyzed by [Hmim]HSO_4 as a powerful Brönsted acidic ionic liquid

Ahmad R. Khosropour

Abstract: An efficient and green procedure for the synthesis of 2,4,5-trisubstituted imidazoles with various aldehydes using a catalytic amount of 1-methylimidazolium hydrogenesulfate as an active and low cost Brönsted acidic room temperature ionic liquid has been developed. The ionic liquid was easily separated from the reaction mixture and was recycled five times without any loss in activity.

Key words: ionic liquid, 2,4,5-trisubstituted imidazoles, [Hmim]HSO_4, aldehyde, benzil.

Résumé : On a mis au point une méthode efficace et environnementalement correcte pour la synthèse d'imidazoles 2,4,5-trisubstitués utilisant divers aldéhydes et une quantité catalytique d'hydrogénosulfate de 1-méthylimidazolium actif comme acide de Brönsted à la température ambiante et comme liquide ionique de faible coût. On peut facilement séparer le liquide ionique du mélange réactionnel et le recycler au moins cinq fois sans la moindre perte d'activité.

Mots-clés : liquide ionique, imidazoles 2,4,5-trisubstitués, [Hmim]HSO_4, aldéhyde, benzile.

[Traduit par la Rédaction]

Introduction

The imidazole nucleus constitutes the core unit of many natural products (1–3). Also, this moiety is a popular building block for the construction of pharmaceutically interesting compounds and has attracted the attention of synthetic chemists for over a century (4–7). Multi-aryl substituted imidazoles, especially trisubstituted ones, could potentially have novel therapeutic activities (8, 9). In addition, many of the 2,4,5-triarylimidazoles are known as herbicides, fungicides (10), or as inhibitors of IL-1 or P38 MAP kinase (11–13). This class of compounds can be prepared by the condensation of benzil, ammonium acetate, and aldehydes in the presence of either protic or Lewis acids (14–20). However, many of these methods still suffer from some disadvantages, such as the use of toxic or expensive catalysts or reaction media, drastic reaction conditions, unsatisfactory yields, and limited scopes. This is especially true with alkyl aldehydes and some aryl aldehydes, such as nitrobenzaldehydes, that limit these methods. Therefore, the introduction of a new and efficient method for this transformation is still in demand.

Results and discussion

Since there is a growing demand for the development of organic reactions in environmentally friendly media, synthetic manipulations are required to minimize the use of hazardous chemicals, such as replacing toxic catalysts or organic solvents in reactions and their subsequent workup with other nontoxic solvents like water (21) or super critical CO_2 (22). In recent years, ionic liquids have attracted increasing interest in the context of green synthesis (23). Although ionic liquids were initially introduced as alternative green reaction media because of their unique chemical and physical properties of nonvolatility, nonflammability, thermal stability, and controlled miscibility (24–26), today they have evolved beyond this, showing their significant role in controlling reactions as catalysts (27, 28). However, sensitivity to moisture and decomposition of some ionic liquids under normal atmospheric conditions are two major drawbacks to their practical use (29). On the other hand, the high cost of most conventional room temperature (RT) ionic liquids and apprehension about their toxicity (30, 31) have led us to explore the use of more benign salts as practical alternatives. Recently, Binnemans and co-workers (32) reported that 1-methylimidazolium hydrogenesulfate ([Hmim]HSO_4), a powerful Brönsted acidic RT ionic liquid (BARTIL) is relatively nontoxic, readily available at low cost, and fairly stable in water, unlike some ionic liquids (e.g., [bpy]$AlCl_4$) that decompose readily in aqueous media.

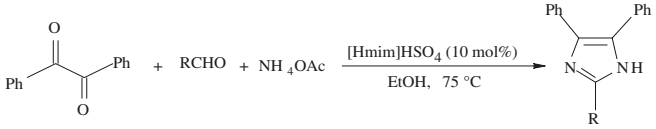
Scheme 1.



These results, in combination with our recent examination to design new synthetic methodologies (33–41) especially in RT ionic liquid (42–45), led us to develop a simple and efficient procedure for the direct synthesis of 2,4,5-trisubstituted imidazoles with various aldehydes using a catalytic amount of [Hmim]HSO_4 (Scheme 1).

The experimental procedure for this reaction is remarkably simple and does not require the use of toxic or expensive organic solvents or reagents. The reactions were carried out at 75 °C by taking a 1:1:10 mole ratio mixture of aldehydes, benzil, and ammonium acetate, respectively, in the presence of only 10 mol% of [Hmim]HSO_4 in ethanol to give the desired products in high to excellent yields.

It is important to note that the use of 10 mol% of [Hbim]BF_4 instead of [Hmim]HSO_4 resulted in no reaction.

To investigate the influence of the media, temperature, and amount of catalyst in this synthesis, for example, the condensation reaction of benzaldehyde with benzil and ammonium acetate was carried out (Table 1). Among all the systems tested, using 10 mol% of [Hmim]HSO_4 in EtOH (3 mL) at 75 °C proved to be the optimum condition (Table 1, entry 11). Using these optimized conditions, a wide range of substituted and structurally diverse aldehydes were subjected to this procedure to afford the corresponding products in good to excellent yields (Table 2).

The scope and generality of this process are illustrated by a series of 30 trisubstituted imidazoles, as can be seen in Table 2. The high-yield transformations were carried out without any significant amounts of undesirable side products. Unlike previously reported methods, the present method does not require toxic or anhydrous organic solvents to produce the 2,4,5-trisubstituted imidazoles derivatives. All the products were characterized by NMR, IR, and mass spectroscopy and also by comparison with authentic samples. A wide range of aromatic aldehydes were employed and all imidazoles were obtained in high to excellent yields (Table 2, entries 1–22), yielding a general method that tolerates both electron-withdrawing and electron-donating constituents. Another important aspect is that various functionalities such as ether, halide, nitro, nitrile, and hydroxyl, survived under the present reaction conditions.

Also, depending on the reaction times, terephthaldialdehydes can be selectively converted to their corresponding mono- or bis-(4,5-diphenyl)-1*H*-imidazole (Table 2, entries 9 and 10). Interestingly, we achieved that in the case of 4-(diethoxymethyl)benzenaldehyde (Table 2, entry 11); a one-pot deprotection–cyclization reaction was carried out in the reaction conditions. On the other hand, aliphatic aldehydes and unsaturated ones (Table 2, entries 23–30), which normally show extremely poor yields using previous methods, gave the corresponding imidazoles in high yields. The reaction conditions are mild enough not to induce any isomerization for conjugated aldehydes or damage to moieties, such as methoxy that often undergoes cleavage in strongly acidic reaction media (Table 2, entries 16–18, 20, and 23–25).

Table 1. Synthesis of 2-(phenyl)-4,5-diphenylimidazole in the presence of [Hmim]HSO_4 under different conditions.

Entry	[Hmim]HSO_4 (mol%)	Solvent (3 mL)	Temprature (°C)	Yield (%)[a]

11	10	CH_3CH_2OH	75	95
12	5	CH_3CH_2OH	75	89

Note: After 3 h.
[a]Isolated yields.

In addition, the synthesis of imidazoles on a large scale (50 mmol) was tested. The reaction was demonstrated to be very efficient on this scale, and the products were obtained in excellent yields using the same reaction conditions. Another advantage of this promoter system is the recycleability of the catalyst; [Hmim]HSO_4 can be reused in five runs without any loss of activity.

In summary, we have developed an efficient, economical, and environmentally friendly procedure for the synthesis of 2,4,5-trisubstituted imidazoles. This involves the use of [Hmim]HSO_4 as an inexpensive, stable, and easily available Brönsted acidic RT ionic liquid. The use of a powerful, easy accessible, and recyclable ionic liquid makes this procedure quite simple, more convenient, and environmentally benign.

Experimental

General experimental procedure

A mixture of aldehyde (1 mmol), benzil (1 mmol), ammonium acetate (10 equiv.), and [Hmim]HSO_4 (0.1 mmol) in ethanol (3 mL) was stirred at 75 °C for the appropriate time, according to Table 1. After completion of the reaction, as indicated by TLC, the mixture was concentrated in vacuo to remove the solvent. The resulting solution was extracted by Et_2O (3 × 10 mL). The organic layer was dried (Na_2SO_4), concentrated under vacuum, and recrystallized by 25% ethyl acetate/petroleum ether to give the corresponding imidazoles in 80%–97% yields.

Recycling of ionic liquid [Hmim]HSO_4

Residual ionic liquid was washed with Et_2O (3 × 10 mL) to remove any organic impurity and dried at 80 °C. Under this procedure, [Hmim]HSO_4 can be reused in five runs without any loss of its activity.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

The bioorganic chemistry of transglutaminase — from mechanism to inhibition and engineering

Jeffrey W. Keillor, Roberto A. Chica, Nicolas Chabot, Valerio Vinci, Christophe Pardin, Emanuelle Fortin, Steve M.F.G. Gillet, Yukiko Nakano, Mari T. Kaartinen, Joelle N. Pelletier, and William D. Lubell

Abstract: Through a multidisciplinary approach comprising organic synthesis, molecular biology, and physical organic kinetic studies, we have studied the mechanism of transglutaminase-mediated transamidation. More recently, we have applied our understanding of the mechanism to the design of reversible inhibitors and affinity labels for biological application. We have also undertaken the engineering of transglutaminase for its application as a "peptide synthase". Herein, we present a brief overview of previously published work as well as recent results presented at the 2007 Merck–Frosst Centre for Therapeutic Research Award Lecture.

Key words: transglutaminase, enzyme mechanism, enzyme inhibition, protein engineering

Résumé : Nous avons étudié le mécanisme de la transamidation catalysée par la transglutaminase, via une approche multidisciplinaire comprenant la synthèse organique, la biologie moléculaire et les études cinétiques physico-organiques. Plus récemment, nous avons appliqué notre compréhension du mécanisme à la conception d'inhibiteurs réversibles et de marqueurs par affinité pour des applications biologiques. Nous avons également entamé l'ingénierie de la transglutaminase pour son application en tant que « synthase de peptides ». Ici, nous présentons un bref survol des travaux déjà publiés ainsi que des résultats récents présentés à la conférence du Prix 2007 du Centre de recherche thérapeutique de Merck–Frosst.

Mot-clés : transglutaminase, mécanisme enzymatique, inhibition enzymatique, ingénierie des protéines.

[Traduit par la rédaction]

Introduction

While Keillor and co-workers have studied several subjects in bioorganic chemistry ranging from the development of protein labelling methods (1, 2) to the elucidation of transpeptidase mechanisms (3, 4), one of the most long-standing themes represented in their research interests has been their focus on transglutaminase (TGase). Information gleaned from their study of the mechanism of action of this class of enzymes underpins ongoing efforts regarding its inhibition, chemical biology, and engineering. An overview of this research was presented in the context of the 2007 Merck–Frosst Centre for Therapeutic Research Award Lecture and is summarized herein.

TGases (EC 2.3.2.13) are calcium-dependent aminoacyltransferases that catalyze acyl-transfer reactions between peptide-bound glutamine residues as acyl donors and peptide-bound lysine residues as acyl acceptors, leading to the formation of intermolecular ε-(γ-glutamyl)lysine crosslinks (5). While TGases are found in the plasma, tissues, and extracellular media of all vertebrates, our research interests have focused on the ubiquitous tissue TGase (TG2). TG2 is involved in critical physiological processes, such as the stabilization of extracellular matrices, formation of cross-linked cell envelopes, cell-matrix assembly, wound healing, and cellular adhesive processes (5). Its unregulated activity has also been linked to auto-immune gluten intolerance (Celiac disease) (6, 7) and neurodegenerative diseases, such as Hun-

tington's disease (8) and Parkinson's disease (9). Guinea pig liver TG2 (gTG2) is frequently studied as a model of the human enzyme because it is 88% homologous (10) to human TG2 (hTG2) and is readily purified in its recombinant His-tagged form (11). The catalytic acyl-transfer reaction has been known to proceed through a modified ping–pong mechanism (Scheme 1) for almost 40 years (12). According to this mechanism, in the first step of the catalytic cycle, the acyl-donor substrate undergoes nucleophilic attack by the active site thiolate, followed by the release of an equivalent of ammonia. The thiolester acyl-enzyme intermediate thus obtained then undergoes a second nucleophilic attack by the acyl-acceptor substrate, leading to the formation of isopeptide product and the regeneration of free enzyme.

Mechanistic studies of TG2

We have added structural and mechanistic details to our understanding of TG2 function through an approach that comprises the synthesis of substrate analogues, structure–function kinetic studies, and molecular modelling.

The synthesis of simple peptidic acyl-donor substrates **1**–**3** (Fig. 1) permitted the study of the acylation step of the catalytic cycle through pre-steady state (stopped-flow) kinetics (13). Even with substrate analogues of attenuated electrophilicity, acylation is still rapid, confirming that the active-site thiolate is a strong nucleophile.

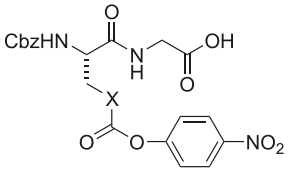
Peptide ester **1** was also used to study the deacylation step of the TG2 catalytic cycle (14). Using a series of primary amines of varying basicity (nucleophilicity) as acceptor substrates, isotope effects and linear free-energy relationships of the rate-limiting deacylation step were explored. These data implicated the involvement of a general base in the nucleophilic attack of the amine substrate on the acyl-enzyme thiolester.

The compilation of kinetic results obtained in the study of the acylation and deacylation steps are represented in the unified mechanism for TG2-mediated transamidation proposed in Scheme 2.

Reversible TG2 inhibitors

Over the course of the kinetic studies described previously, we remarked upon the ability of the benzoxycarbonyl

Fig. 1. Substrate analogues used to study TG2 acylation.



(Cbz) protecting group to confer affinity to small peptidic substrates. Molecular modelling studies suggested the Cbz group may form specific interactions in the donor substrate-binding site that favour binding (15). Subsequently, we explored the structural elements of the Cbz group important for this affinity by preparing and testing series of Cbz analogue derivatives. In doing so, we discovered *trans*-cinnamoyl compounds that serve as rapid, reversible inhibitors (16).

Shown in Fig. 2 are representative examples of these inhibitors, along with their relative IC_{50} values. Briefly, cinammoyl derivative **4** was prepared from *p*-nitrobenzaldehyde via Wittig chemistry to give *p*-nitrocinnamic acid, followed by coupling with hydroxybenzotriazole (16). Azachalcone **5** was obtained by aldol condensation of 3-acetylpyridine with *p*-nitrobenzaldehyde (16). Triazole **6** was made through Huisgen-type [3+2]-cycloaddition reaction of *p*-nitrobenzyl azide and the corresponding ynone (17).

Kinetic studies showed that these cinnamoyl inhibitors are competitive with respect to the acyl-donor substrate (16). More recently, we prepared a derivative of **5** that enabled the photolabelling of TG2 at residues in the donor substrate-binding site (18). Subsequent docking simulations, with a homology model generated for guinea pig liver TG2, support the favourable binding of these derivatives in modes that block access to the active-site tunnel (Fig. 3). Finally, when tested against Factor XIIIa, another TGase, and caspase 3, a similar cysteine protease, *no* inhibition was observed, up to the limits of their solubility. This selectivity bodes well for future in vivo testing.

TG2 affinity labels

Several classes of *irreversible* inhibitors of TG2 have also been developed in our group. In general, these inhibitors have been based on a peptidic scaffold thought to be bound in a peptide backbone-binding groove on the surface of TG2 (15, 19). Our inhibitors present an electrophilic group at the end of a flexible alkyl chain long enough to insert into the active site of TG2. Such inhibitors have been prepared so that they bear various electrophilic groups, such as thiadiazoles (20), epoxides (21), maleimides (22), or α,β-unsaturated amides (23). These amides proved to be the most potent irreversible TG2 inhibitors we have made, and a representative example (**7**) is shown in Fig. 4.

Based on the structure of **7**, we recently designed and prepared a series of TG2 affinity labels, bearing biotin groups or fluorophores via alkyl, PEG, or (cleavable) disulfide linkers (24). The fluorescent affinity labels shown in Fig. 4 were prepared from Cbz-Lys through Boc protection of its ε-

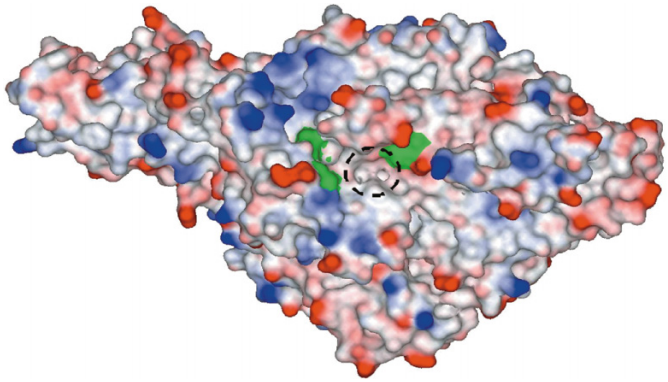

Fig. 4. Irreversible TG2 inhibitor **7** and analogous affinity labels.

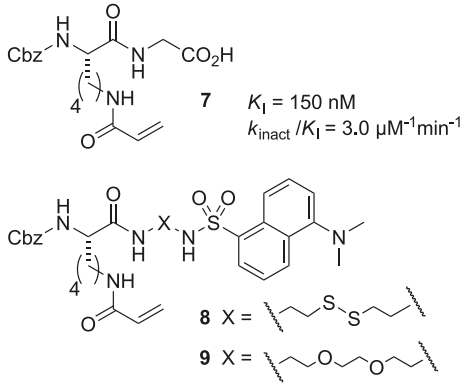

amino group, coupling with the diamine spacer and dansyl chloride, and finally deprotection and acrylation of the pendant amine (see Supplementary Data).[2]

Kinetic characterization of our affinity labels confirmed their efficiency, despite a decrease of roughly two orders of magnitude compared to the parent compound **7**. This decrease was due almost entirely to an increase in K_I, presumably due to the bulk added to the C-terminus of the peptide backbone. For example, for disulfide **8**, K_I = 11 μmol/L and k_{inact}/K_I = 0.030 (μmol/L)$^{-1}$min^{-1} and for the PEG derivative **9**, K_I = 29 μmol/L and k_{inact}/K_I = 0.014 (μmol/L)$^{-1}$min^{-1}.

Inhibitor **9** was then used in a cell culture system to test the role of TG2/TGases in the production of collagenous extracellular matrix. MC3T3-E1 osteoblasts grown for 12 days in the presence of ascorbic acid produce a thick col-

lagen layer, which mineralizes when a phosphate source is provided (in our experiments, β-glycerophosphate, see Supplementary Data).[2] As evident from Fig. 5, inhibitor **9** reduced collagen deposition and blocks mineralization of the cultures in a concentration-dependent manner. Complete inhibition of collagen deposition and mineralization was observed at 50 μmol/L concentration. Furthermore, inhibitor **9** is not toxic to the cells at the concentrations used. Fluorescence microscopy studies are ongoing to determine the localization of inhibitor **9** in the cells and the cellular mechanism of its inhibition.

TG2 engineering

Finally, we have also undertaken the engineering of TG2, with the goal of obtaining variants (TG2*) capable of catalyzing the specific, efficient, and economical formation of amide bonds between various synthetic peptide substrates. Typically, proteases are used for this purpose, but their application can be hindered by their propensity to catalyze the *hydrolysis* of the newly formed amide bond. This limitation can be overcome in part by reducing the activity of water in frozen (25, 26) or organic media (27), or by altering the specificity of the enzyme through engineering (28, 29). However, TGase is already designed to catalyze the desired transamidation reaction. It is thus capable of binding a primary amide, forming a high-energy thiolester intermediate, sequestering it from attack by water and selectively transferring the acyl group to a primary-amine substrate. We have therefore chosen it as a starting point for directed evolution modification, intended to alter its substrate specificity such that branched acyl-donor and acyl-acceptor substrates can be recognized and catalytically coupled (Scheme 3).

Native TG2 is already capable of recognizing a fairly broad range of primary amines as acceptor substrates (14), so our initial goal was to expand the specificity of TG2 with respect to its donor substrate. In this respect, previous modelling studies (15) served to identify residues in the proximity of the active site that may contribute to TG2 specificity.

Libraries of mutant gTG2 were then generated wherein 1–3 amino acids were randomly mutated (Table 1). Briefly, the gene encoding for gTG2 (11) was randomly mutated at each of these positions by cloning with oligonucleotide primers containing degenerate (NNS) codons. Bacterial colonies were transformed with the resulting mutant plasmids, grown on agar plates, then re-picked and grown in 1.5 mL of culture in 96-well plates (see Supplementary Data).[2]

A fluorogenic assay previously developed in the group (30) was then adapted to allow these libraries to be screened for mutant transpeptidase activity. The umbelliferyl ester of

[a]All substrates are of L configuration unless noted otherwise.

[b]Reaction not detected.

Cbz-Gly (Cbz-GlyOUmb, ZGU) was thus synthesized and used as a fluorogenic donor substrate (see Supplementary Data).[2] Initially, this assay was used to characterize the substrate specificity of wild-type gTG2, confirming its remarkable breadth and its capacity to function as a peptide synthase (Table 2).

Libraries 1–5 (Table 1) were then screened for transpeptidation activity, using Ac-Lys-OMe as an acceptor substrate. Two of those libraries gave interesting results. In library 5, many different mutants were found to be active (Table 2S, Supplementary Data), whereas in library 3, only the conservative mutants W332Y and W332F showed transamidation activity.[2] Subsequent expression, purification, and further kinetic characterization of the latter showed that its acceptor substrate specificity differed slightly from that of the wild-type enzyme. For example, as can be seen in Table 2, the W332F mutant is able to recognize ThrOMe as an acceptor substrate. These preliminary results validate efforts to engineer TG2 to create more efficient catalysts for the synthesis and modification of peptides. Currently, more sensitive screening methods, based specifically on *ligation* reaction assays, are currently under development for application to screening different, larger libraries of mutant TG2.

Summary

Our understanding of the mechanism of TG2-mediated transamidation has seen recent application in the design of TG2 inhibitors and affinity labels for the study of the chemical biology of TG2. We have also undertaken the engineering of TG2 as a catalyst for peptide synthesis and modification, and preliminary results validate its potential as a peptide synthase.

Role of solvent nucleophilicity in excess-acidity plots for equilibria in sulfuric acid – water mixtures

T. William Bentley

Abstract: For protonation of a base B to give BH^+ and for reaction of carbocations R^+ with water to give ROH in a range of sulfuric acid – water mixtures, slopes of excess-acidity plots of equilibrium data are discussed. Formal connections between the excess-acidity approach and the Grunwald–Winstein (GW) and extended GW equations, noted previously by Bagno et al., are evaluated. It is proposed that a major factor is variations in the solvent dependence of the rates of reactions of the cations (BH^+ or R^+) with water in the sulfuric acid – water mixtures. Rates of reactions of more stable cations (e.g., Ph_3C^+) with water are more sensitive to changes in solvent nucleophilicity, and the lower nucleophilicity of the water in sulfuric acid – water mixtures leads to an increase in $[BH^+]/[B]$ or $[R^+]/[ROH]$ concentration ratios (and hence to greater slopes m^* in excess-acidity plots).

Key words: excess acidity, sulfuric acid, kinetics, solvent nucleophilicity, solvolysis.

Résumé : On discute des pentes des courbes d'acidité en excès pour les données d'équilibre relatives à la protonation d'une base conduisant à la formation de BH^+ et pour la réaction des carbocations R^+ avec l'eau pour donner du ROH sur une large plage de concentrations pour des mélanges acide sulfurique – eau. On a évalué les corrélations formelles notées antérieurement par Bagno et al. entre l'approche de l'excès d'acidité et les équations de Grunwald–Winstein (GW) normales ou étendues. On suggère que, dans les mélanges d'acide sulfurique – eau, les variations dans la dépendance des vitesses de réaction des cations (BH^+ ou R^+) sur le solvant sont des facteurs importants. Les vitesses de réaction de l'eau avec les cations les plus stables, tel Ph_3C^+, sont beaucoup plus sensibles aux changements dans le caractère nucléophile du solvant et que le caractère nucléophile plus faible de l'eau dans des mélanges acide sulfurique – eau conduit à une augmentation des rapports des concentrations $[BH^+]/[B]$ ou $[R^+]/[ROH]$ et, comme conséquence, à des pentes m^* plus grandes dans les courbes d'acidité en excès.

Mots-clés : acidité en excès, acide sulfurique, cinétique, caractère nucléophile d'un solvant, solvolyse.

[Traduit par la Rédaction]

Introduction

The extent of protonation of a relatively strong base B to give BH^+ (eq. [1]) in dilute aqueous solution allows the calculation of the equilibrium constant pK_{BH^+} from the logarithm of the ratio of molar concentrations (I, eq. [2]) and the pH. However, if B is a weak base, relatively concentrated acid solutions are needed to obtain suitable values of log I. An extrapolation based on the excess-acidity (X) of the acid solution leads to the pK_{BH^+} for aqueous solution ($X = 0$, eq. [3]; the slope m^* depends on the substrate).

$$[1] \quad B + H^+ = BH^+$$

$$[2] \quad \log \{[BH^+]/[B]\} = \log I$$

Received 29 October 2007. Accepted 21 December 2007. Published on the NRC Research Press Web site at canjchem.nrc.ca on 1 February 2008.

This paper is dedicated to the memory of Keith Yates in recognition of his outstanding contributions to physical organic chemistry.

$$[3] \quad \log I - \log [H^+] = m^*X + pK_{BH^+}$$

Important contributions to the mathematical treatment of data for equilibria in acidic solutions were made using the H_o acidity function by Yates and McClelland (1) and using excess acidity by Cox and Yates (2) after earlier work by Marziano et al. (3). The topic has been reviewed recently by Cox (4).

Excess-acidity can also be used in the determination of K_{R^+} for the formation of a carbocation R^+ with water to form an alcohol ROH as in eq. [4]. In this case, the equilibrium constant K_{R^+} is given by eq. [5].

$$[4] \quad R^+ + H_2O = ROH + H^+$$

$$[5] \quad K_{R^+} = [ROH][H^+]/[R^+][H_2O]$$

In eq. [3], I and $[H^+]$ refer to molar concentrations (4), and m^* is usually discussed in terms of activities and activity coefficients (4). Two alternative explanations have also been published (5, 6). Bagno et al. (6) discussed in detail the slope parameter m^* of eq. [3] in terms of the solvation energies of the protonated bases, especially by hydrogen bonding; they also recognized the possible connection between eq. [3] and linear free energy relationships such as the Grunwald–Winstein (GW) eq. [6] (7) and the extended GW

 doi:10.1139/V08-003 © 2008 NRC Canada

eq. [7] (8) for medium effects on kinetic data for solvolysis reactions. In eq. [6], k is the rate constant in any solvent relative to k_o, the rate constant in 80% ethanol–water; Y is the solvent ionizing power (or polarity), defined by the slope parameter m = 1.00 for solvolyses of *t*-butyl chloride at 25 °C (7), and c is the intercept. In eq. [7], l is the substrate sensitivity to N (the solvent nucleophilicity, or cation solvating power).

$$[6] \qquad \log (k/k_o) = mY + c$$

$$[7] \qquad \log (k/k_o) = mY + lN + c$$

Subsequently, many modifications of eqs. [6] and [7] have been devised using different Y and N scales. From solvolyses of tosylates, we have previously obtained Y_{OTs} and N_{OTs} values for mixtures of water and sulfuric acid (up to 60 *w*/*w* in the absence of protonation of substrate) (5), and comparisons will be made with eq. [3] (see later). A good linear correlation leading to a slope and intercept, as in eq. [3], is expected (9) to be more reliable in practice than an equation with extra parameters, as in eq. [7]. Therefore, discussion based on eq. [7] is aimed towards new insights rather than practical applications.

A recent principal-component analysis of solvent effects on a range of equilibrium and kinetic data (10) indicated three recognizable groups of solvent properties, so the success of eq. [3] having only one solvent property (X) is noteworthy (6). Because many factors can contribute to observed solvent effects, identification of only the main factor(s) is the initial objective of the work reported here.

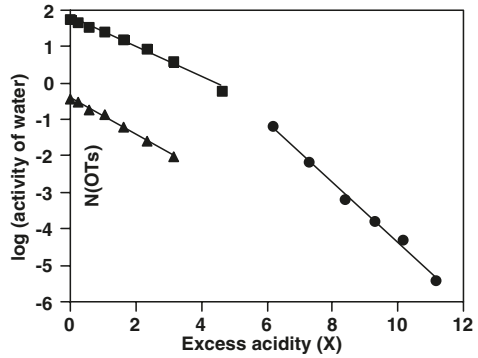
The validity of a "kinetic" approach is supported by the value of K_{R^+} for the triphenylmethyl cation (trityl, **1**) in the aqueous standard state, obtained (11) from the ratio of rate constants for the forward and reverse reactions in eq. [4], which is in satisfactory agreement with the other values of K_{R^+} (4). The possibility of relating other equilibria in acidic media to the rates of the forward and reverse reactions will be explored. Important supporting data will be provided by two types of research on aqueous and alcoholic solvents over a wide range of N: (*i*) the rates of reactions of carbocations investigated by laser flash photolysis (12, 13) and (*ii*) the rates of solvolyses of cationic substrates having neutral leaving groups (14).

The main aim is to try to obtain further insights into the solvation effects revealed in the m^* term of eq. [3] and to strengthen the existing connections (5, 6) between solvolysis research in aqueous and alcoholic media and studies of strongly acidic media. Changes in activities and activity coefficients of B and BH^+ and the effects of changes in ionic strength will not be considered explicitly.

Discussion

In the following sections, it will be assumed that (*i*) the Eigen cation H_3O^+ (not H^+) is reacting as a proton, as in eq. [8], showing nucleophilic substitution reactions of substrates H_3O^+ and BH^+ with B and H_2O representing either nucleophiles or neutral leaving groups (in eq. [8], H_3O^+ replaces H^+ in eq. [1]), and so eq. [9] (in which a_{H_2O} is the water activity) replaces eq. [3]; using eq. [9], m^* = 0.00 for B = H_2O (6);

Fig. 1. Logarithms of water activity (slopes: –0.41 ± 0.02 (r = 0.993) and –0.82 ± 0.04 (r = 0.997)), and (inset) N_{OTs} (slope: –0.51 ± 0.01, r = 0.999) vs. excess acidity (X); data from refs. 4 and 5.



(*ii*) experimental values of log I (eq. [2]) are reliable, although the spectroscopic methods for determining values of I are susceptible to different solvent effects (4) from those to be discussed here using eq. [7].

$$[8] \qquad B + H_3O^+ = BH^+ + H_2O$$

$$[9] \qquad \log I - \log [H^+] = m^* X - \log a_{H_2O} + pK_{BH^+}$$

Why is only one adjustable parameter (m^*) required?

It is well established (4, 6) that only one adjustable parameter (m^*) in eq. [3] is required to correlate the experimental data for log I – log $[H^+]$ in a binary mixture of water and a strong acid. The success of one parameter is remarkable (6) because the m^*X term of eq. [3] could include a large number of possible solvent effects and also a term for log a_{H_2O} (see eq. [9]). A plot of log a_{H_2O} vs. X (Fig. 1) shows two linear regions (slopes of –0.41 and –0.82); although there may be many ranges of log I data spanning only one of the two linear regions, linearity is only approximate over the whole range of X.

The success of eq. [3] is consistent with eq. [7] because, as shown later, the more significant factor is the nucleophilicity (lN) term. Also, a feature of binary mixtures is the tendency for changes in Y to correlate with changes in N for alcohol–water mixtures (15). Data for solvolyses of tosylates show that N_{OTs} values correlate linearly with Y_{OTs} values from water up to 60% *w*/*w* sulfuric acid (5). A plot of N_{OTs} vs. X (Fig. 1) is linear for the limited range of available data, with a similar slope (–0.51) to the log a_{H_2O} plot.

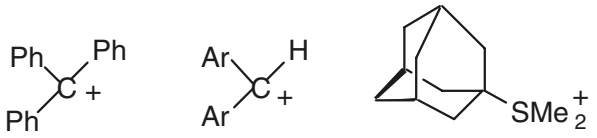
For trityl (**1**) and a variety of benzhydryl cations (**2**) and in acetonitrile–water mixtures (solvents with varying Y, but similar N), rates of nucleophilic attack (eq. [10]) are almost independent of solvent composition (11, 13). Literature data for Y values in acetonitrile–water are based on solvolyses of 1-adamantyl mesylate (16); N values, based on solvolyses of *S*-methylthiophenium ions (17), are almost constant (–0.94–1.06) for 40%–90% acetonitrile–water, and values for 20%–95% range from –0.94 to –1.27 (17). In solvolysis research, the solvent effect of changes in Y can be studied independently of N by examining bridgehead substrates such as

© 2008 NRC Canada

1-adamantyl (**3**) for which rearside nucleophilic attack is prevented by the hydrocarbon framework. Rates of such S_N1 solvolyses of substrates with neutral leaving groups (e.g., **3**) vary less than 20% from 95% to 20% acetone–water (14). These results indicate that the rates of the forward and reverse reactions of the types shown in eqs. [10] and [11] are (to a good approximation) independent of *Y*.

[10] $R^+ + H_2O \rightarrow (ROH_2^+) \rightarrow ROH + H^+$

[11] $RSMe_2^+ \rightarrow R^+ + Me_2S$



(1) **(2)** **(3)**

Generally, *m* values (eq. [7]) are reduced when nucleophilic attack also occurs (18), and it is assumed that the rates of solvolyses of most substrates (both S_N1 and S_N2) having neutral leaving groups will be independent of the solvent *Y* (19). *By analogy, the solvent effect on the rate of nucleophilic attack on BH^+ by water (the reverse step of eq. [8] in aqueous sulfuric acid) will be independent of Y; therefore, in terms of eq [7], rates will depend mainly on changes in N.*

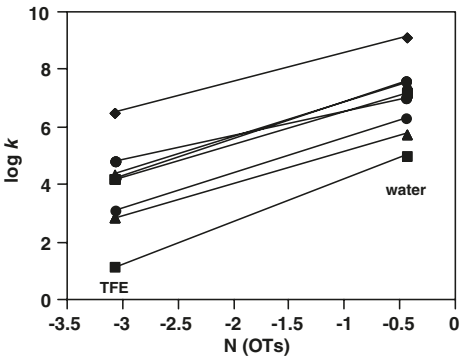
Factors controlling the magnitude of the slope (*m)**

Values of *m** vary from 0 to about 2.0 (4). As *X* varies from 0.00 in water to about 10 in highly concentrated acid (4), the maximum dependence of K_{BH^+} (eq. [3]) on composition is very large (10^{20}). For all equilibria of the type shown in eq. [8] (except B = water), the value of K_{BH^+} will depend on the water concentration. If this is excluded (as in eq. [1]), then variations in water concentration are included in the *m*X* term, and there will be a substantial contribution to the slope of 0.4–0.8 (Fig. 1).

The next step is to assess how *l* (the sensitivity to *N*, eq. [7]) depends on BH^+. If B = water in eq. [8], the rate of proton transfer in both forward and reverse steps is diffusion-controlled (20). For stronger bases (B), such as ammonia, aniline, and pyridine, the rate of protonation by H_3O^+ is also diffusion-controlled at 25 °C (~10^{10} $M^{-1}s^{-1}$). *Consequently, both the pK_a and the solvent dependence of pK_a are then determined by the rate constant for the dissociation or "hydrolysis" of BH^+ (the reverse reaction of eq. [8]);* as this step refers to a solvolysis with a neutral leaving group (B), the solvent dependence of relative rates will be almost independent of *Y*, but will depend mainly on the response (*l*) of the cation to the lowering of solvent nucleophicity (*N*) when sulfuric acid is added to water (i.e., variations in *m** are then due to changes in *l*, eq. [7] for hydrolysis of BH^+).

Bagno et al. (6) noted a connection between the gas-phase basicity of B and *m** — the least favorable cation H_3O^+ has an *m** of 0, and *m** increases in the order alcohols, ethers, amines — gas-phase proton affinities (the enthalpy change expressed as a positive value when B reacts with H^+) show the same trends (21). Kresge (20*b*) emphasized that large thermodynamic contributions to reaction barriers could lead to relatively slow proton transfers. The tendency for more stable cations (BH^+ or R^+), having smaller values of log *k*, to show a higher sensitivity to *N* is shown (Fig. 2) by the kinetic data for various benzhydryl and other cations (R^+) reacting with water and with 2,2,2-trifluoroethanol (TFE).

Fig. 2. Plots of logarithms of rate constants for reactions of benzhydryl (**2**) cumyl and other cations with acetonitrile–water and with 2,2,2-trifluoroethanol (TFE) at 20 °C vs. N_{OTs} (kinetic data from Table 6 of ref. 12 and N_{OTs} data from ref. 22); the cations can be identified as follows from the order of decreasing rate constants in TFE: $(C_6H_5)_2CH^+$; $4\text{-}MeOC_6H_4C^+(CF_3)_2$; group of three cations: $(4\text{-}MeC_6H_4)_2CH^+$, $4\text{-}MeOC_6H_4C^+(CH_3)_2$, 9-phenyl-9-fluorenyl; $(4\text{-}MeOC_6H_4)(C_6H_5)CH^+$; 2,4,6-trimethoxybenzenonium; $(4\text{-}MeOC_6H_4)_2CH^+$; additional rate constants for reactions of cations in TFE–water mixtures (Table S3 in ref. 13) show a gradual increase in rate constant as water is added to TFE; figure 2 shows k_{water}/k_{TFE} ratios graphically as two-point lines, but the plots would curve if the reactions reach a diffusion-controlled limit (12).



The slopes (*l*) of Fig. 2 can be linked semi-quantitatively to *m** for eq. [4] as follows. On the N_{OTs} scale of solvent nucleophilicity (see Table 5 in ref. 22), the value for 60% sulfuric acid – water of –2.02 is in between the values for water (–0.44) and TFE (–3.07). From a typical slope of Fig. 2 of 1.3 and a difference of 1.58 in N_{OTs}, a rate retardation of 10^2 is calculated for reaction of cations (R^+) with water in 60% sulfuric acid compared with reaction in water alone. Taking *X* = 3.3 for 60% sulfuric acid (4) gives an estimated contribution from the forward reaction in eq. [4] to the slope of 0.6 for *m**.

The slope *m** may also depend on the accessibility of the H in BH^+ to nucleophilic attack (eq. [8]) for the following reason. Extensive data for S_N2 solvolyses, including Et_3O^+ (23) and *S*-methyldibenzo-thiophenium ions (24) as well as many neutral substrates (8), show that *l* (eq. [7]) may also depend on steric effects (*l* increases in the order $Bu^t < Pr^i <$ Et < Me). The carbon atom acting as the site of nucleophilic attack in solvolyses of methyl substrates is the most accessible, and *l* values are highest. Alternatively, stabilization of a developing positive charge is least favorable for methyl substrates, and so there is a greater requirement for nucleophilic assistance. The alkyl effect and the effect of proton affinity of B combine in comparisons of solvolyses Et_3O^+ and *S*-methyldibenzo-thiophenium ions (23, 24) and the ratio of rate constants EtOH:TFE are almost 10-fold greater for the much less reactive *S*-methyldibenzothiophenium ions.

© 2008 NRC Canada

Further contributions to m^* arise from the reverse reaction to eq. [4] when redrawn as eq. [12].

[12] $ROH + H_3O^+ \rightarrow R^+ + 2H_2O \rightarrow$ oxygen exchange

Rate constants for formation of R^+ can be obtained from acid-catalysed oxygen exchange in alcohols (11), thought to occur via a carbocation – water molecule ion pair (25, 26), which is simplified to R^+ in eq. [12]. For 0.005 mol/L HCl, second-order rate constants for oxygen exchange in Ph_3COH increase 10-fold from 90% *v*/*v* acetonitrile–water to water, showing a small but significant dependence of the rate of eq. [12] on *Y*. A further increase in *Y* from water to sulfuric acid – water (5) will also contribute to m^*. The effect of changes in *Y* is consistent with formation of a cationic transition state with a more localized positive charge. In other words, H_3O^+ appears to be acting as a highly delocalized cation, because there is charge delocalization onto at least three hydrogen atoms (27) and extensive hydrogen bonding (6).

The slope of an excess-acidity plot will also include a log a_{H_2O} term because eq. [12] has an additional water molecule (cf. eq. [4]). Further complications arise from the previously mentioned assumption (*i*) that the reacting species is the Eigen cation (H_3O^+) rather than for example a mixture of solvated clusters of $(H_3O^+)(H_2O)_n$, the Zundel cation ($H_5O_2^+$) and solvated clusters $(H_5O_2^+)(H_2O)_n$ (27).

Conclusions

The solvent nucleophilicity term (*lN*) in eq. [7] provides the main connection between the slopes (m^*) of excess-acidity plots for equilibria (eq. [3]) and the Grunwald–Winstein eqs. [6 and 7] for medium effects on solvolyses. It is proposed that the pseudo first-order rate constants for solvolyses of the protonated bases (BH^+, eq. [1]) are more sensitive to changes in *l*, when the base B is more stable (e.g., when the proton affinity of B is lower or for less reactive carbocations (Fig. 2)). Alternatively, if the reaction of BH^+ is considered to be second-order (eq. [8]), rate constants (and hence m^*, eq. [9]) may depend on water activity. Both N_{OTs} and log a_{H_2O} are proportional to the excess-acidity (*X*) from water up to 60% *w*/*w* sulfuric acid (Fig. 1).

Triterpenoids from *Saussurea ussuriensis*

Xue-Hu Li, Jia-Tao Feng, and Yan-Ping Shi

Abstract: From an extract of the whole plant of *Saussurea ussuriensis*, three new triterpenoids, 1β-hydroxy-ursa-9(11), 12-dien-3β-yl palmitate (ussuriensin A) (**1**), 1β-hydroxy-oleana-9(11), 12-dien-3β-yl palmitate (ussuriensin B) (**2**), and 28-hydroxy-taraxast-20(30)-ene-3β-yl palmitate (ussuriensin C) (**3**), as well as five known triterpenoids, 11β-hydroxy-urs-12-en-3-one (**4**), 11β-hydroxy-urs-12-en-3β-yl palmitate (**5**), ursa-9(11), 12-dien-3-one (marsformosanone) (**6**), 3β-hydroxy-30-norlupan-20-one (**7**), and taraxast-20(30)-en-3β, 21α-diol (**8**) were isolated. Their structures were characterized by various spectroscopic methods, including 1D NMR, 2D NMR, and HR-ESI-MS.

Key words: Compositae, *Saussurea ussuriensis*, triterpenoids, ursane, oleanane, taraxastane.

Résumé : À partir d'un extrait de la plante complète de *Saussurea ussuriensis*, on a isolé trois nouveaux triterpénoïdes, le palmitate de 1β-hydroxyursa-9(11),12-dién-3β-yle (= ussuriensine A, **1**), le palmitate de 1β-hydroxyoléana-9(11),12-dién-3β-yle (= ussuriensine B, **2**) et le palmitate de 28-hydroxytaraxast-20(30)-én-3β-yle (= ussuriensine C, **3**) ainsi que cinq triterpénoïdes connus, la 11α-hydroxyurs-12-én-3-one (**4**), le palmitate de 11α-hydroxyuras-12-én-3β-yle (**5**), l'ursa-9(11),12-dién-3-one (= marsformosanone, **6**), la 3β-hydroxy-30-norlupan-20-one (**7**) et le taraxast-20(30)-én-3β,21-diol (**8**). Les structures ont été caractérisées par diverses méthodes spectroscopiques, dont la RMN en 1D et en 2D ainsi que par la spectrométrie de masse à haute résolution et ionisation par électronébulisation.

Mots-clés : composition, *Saussurea ussuriensis*, triterpénoïdes, ursane, oléanane, taraxastane.

[Traduit par la Rédaction]

Introduction

The genus *Saussurea* consists of about 400 species distributed throughout Asia and Europe. About 40 species have been investigated on their chemical constituents, and sesquiterpenes and triterpenoids have been reported as the most widespread constituents (1). In the course of our search of bioactive sesquiterpenes and triterpenoids, we selected the plant species, *S. ussuriensis*, which is a perennial herb mainly distributed in northwestern of China and has been used as a traditional folk remedy for the treatment of colds, headache, arthritis, and strain (2). Its chemical constituents have not been previously investigated. In our investigation on phytochemistry, eight steroids have been reported by us (3), and eight triterpenoids (**1**–**8**, Fig. 1) were further isolated from an alcoholic extract of the whole plant of this species. The compounds (**1**–**3**) were previously unreported natural products, and **4**–**8** were known. We report herein the isolation and structural elucidation of these triterpenoids.

Results and discussion

The 95% ethanol extract of the *S. ussuriensis* was subjected to column chromatography to give three new triterpenoids (**1**–**3**) together with five other know triterpenoids (**4**–**8**). Their structures were elucidated using 1D and 2D NMR spectroscopic data and compared with those reported in the literature.

Ussuriensin A (**1**) was obtained as colorless gum. The molecular formula was assigned as $C_{46}H_{78}O_3$ on the basis of HR-ESI-MS (*m/z* 679.6039 $[M + H]^+$). Its IR spectrum showed absorption bands for hydroxyl (3499 cm^{-1}) and ester carbonyl (1732 and 1257 cm^{-1}) groups. The ester group in **1** could be further deduced as a palmitoyl moiety because of the characteristic signal δ_C 173.50 (C-1′) in the downfield region of the ^{13}C NMR spectrum, as well as a saturated long-chain features: a methyl signal δ_H 0.89 (t, J = 6.8 Hz, H-16′), several methlene signals δ_H 1.28 (br s, H-15′ to H-4′, 24H), δ_H 1.75 (m, H-3′), and δ_H 2.31 (t, J = 7.2 Hz, H-2′) in the ^1H NMR spectrum (Table 1) (4–7). In addition to the long-chain ester group, it implied a pentacyclic triterpenes that the left 30 carbon signals (8 × CH_3, 7 × CH_2, 8 × CH, 7 × C) in the ^{13}C NMR combined with DEPT experiment (Table 1) and eight degrees of unsaturation. The deductive results could be demonstrated by the presence of eight methyl groups, in which six singlets (δ_H 0.87, 0.88, 0.90, 0.80, 0.92, 0.93), two doublets (δ_H 0.85, d, J = 6.4 Hz and 0.82, d, J = 6.4 Hz). These results and typical resonances at δ_C 152.08 (C-9), 117.72 (C-11), 123.50 (C-12) and 141.67 (C-13) further indicated a pentacyclic triterpene with an

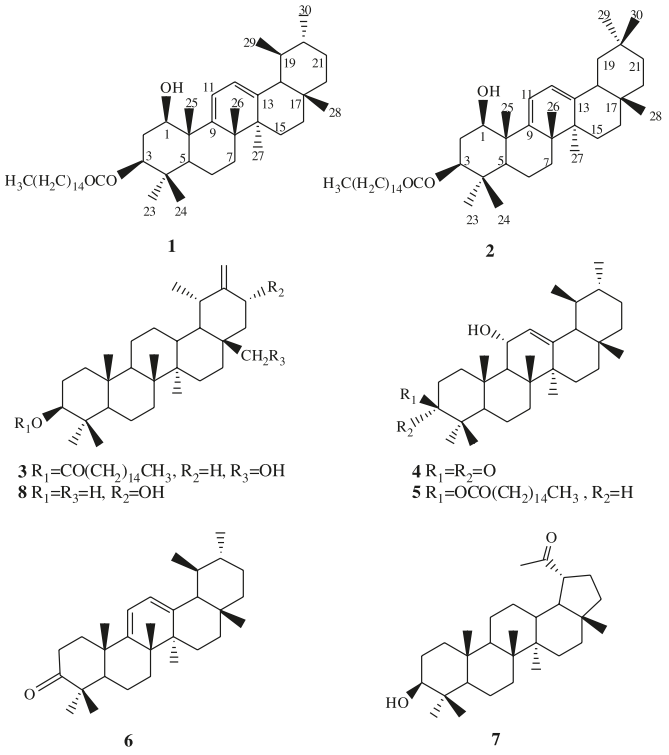
Fig. 1. Molecular structures of the triterpenoids isolated.



ursa-9(11), 12-diene skeleton (8, 9). This was confirmed by using a COSY experiment: H-11 (δ_H 6.20, d, J = 7.0 Hz) showing correlation with H-12 (δ_H 5.47, d, J = 7.0 Hz), and using a HMBC experiment (Fig. 2): H-11 showing correlation with C-9, C-10, C-12, C-13, and H-12 showing correlation with C-9, C-11, C-13, C-18. The correlation between H-3 (δ_H 4.55, dd, J = 4.4, 12.0 Hz) and C-1′ (δ_C 173.50), C-2 (δ_C 34.74), C-4 (δ_C 38.04) in the HMBC, together with comparison of the chemical shift, peak pattern, and coupling constant of H-3 with those of known triterpenoids in literature (4–7) suggested that the only ester group (palmitoyl) linked at C-3β position. The location of only hydroxyl group was assigned as C-1β using COSY experiment: H-1 (δ_H 3.94, dd, J = 4.4, 11.6 Hz) showing correlation with H-2αβ (δ_H 1.81, 1.94), and HMBC experiment: H-1 (δ_H 3.94) showing correlation with C-9, C-10, and C-25. Hence, compound **1** could be identified as 1β-hydroxy-ursa-9(11), 12-dien-3β-yl palmitate.

Ussuriensin B (**2**) was obtained as colorless gum. Its molecular formula of $C_{46}H_{78}O_3$ was deduced from HR-ESI-MS (*m*/*z* 679.6029 $[M + H]^+$) and indicated that it is an isomer of **1**. The IR spectrum showed strong absorptions for hydroxyl (3413 cm^{-1}) and ester carbonyl (1714, 1222 cm^{-1}) functions, similar to that of **1**. The palmitoyl ester group in **2** was also elucidated by the typical signal δ_C 173.49 (C-1′) and δ_H 2.31 (2H, t, J = 7.2 Hz, H-2′), δ_H 1.75 (2H, m, H-3′), δ_H 1.28 (br s, H-4′ to H-15′, 24H), and δ_H 0.89 (3H, t, J = 7.2 Hz, H-16′) due to saturated long-chain ester group (4–7). The ^1H and ^{13}C NMR spectra (Table 1) of **2** were close to those of **1**. The characteristic resonances at δ_C 151.88 (C-9), 118.28 (C-11), 121.16 (C-12), and 147.42 (C-13) of **2**, different from those of **1**, indicated that ussuriensin **2** was an pentacyclic triterpene with oleana-9(11), 12-diene carbon skeleton (8–10). The locations of the palmitoyl and hydroxyl groups were assigned at C-3β and C-1β, respectively, identical to that of **1**. Therefore, compound **2** was identified as 1β-hydroxy-oleana-9(11), 12-dien-3β-yl palmitate.

Ussuriensin C (**3**) was obtained as colorless oil. Its molecular formula was assigned as $C_{46}H_{80}O_3$ on the basis of EI-MS (*m*/*z* 662 $[M - H_2O]^+$) and ^{13}C NMR spectrum combined with DEPT experiment. Absorption bands for hydroxyl (3352 cm^{-1}), ester carbonyl (1732, 1246 cm^{-1}), and double bond (1653 cm^{-1}) functions were observed in IR spectrum. Detailed inspection of the ^1H (Table 1) and ^{13}C NMR (Table 1) of **3**, and comparison of its spectral data with those of compounds **1**, **2**, and **5** showed that there was a palmitoyl group attaching at C-3β position similar to **1**. Except for the NMR data of palmitoyl ester group, there were 30 carbon signals including six methyls, twelve methlenes, six methines, and six quaternary carbons, and indicating a pentacyclic triterpene. In the ^1H NMR spectrum, there were six methyl groups, in which five singlets (δ_H 0.78, 0.94, 0.85, 0.88, 0.86), one doublet (δ_H 1.03, d, J = 6.4 Hz), and two olefinic protons (δ_H 4.94, br s, 4.91, br s), three oxymethylene protons (δ_H 4.47, dd, J = 5.6, 10.8 Hz, 1H; 4.12, br s, 2H). These spectral data together with the characteristic resonances at δ_C 154.75 (C-20), 106.90 (C-30), and δ_C 48.90 (C-18) suggested that **3** was a taraxast-20(30)-ene type triterpenoid with one hydroxyl group, one palmitoyl ester group, and exocyclic double bond (9–13). By comparison of the ^{13}C NMR data of **3** with those of the known taraxasterol (9, 12) and taraxast-20(30)-ene-3β, 21β-diol (12), taraxast-20(30)-ene-3β, 21α-diol (10, 11), the absence of a methyl peak at δ_C 18.2 (C-28), and the presence of an oxymethylene carbon at δ_C 65.06 noted it was possible to place this hydroxyl group at C-28 position. This was confirmed by the downfield shift from δ_C 34.5 in taraxasterol to δ_C 43.01 in **3** due to the C-28 hydroxyl group. Consequently, compound **3** was elucidated as 28-hydroxy-taraxast-20(30)-ene-3β-yl palmitate. Unfortunately, the molecular composition has not been obtained by HR-ESI-MS like compounds **1** and **2** after trying to do that for several times. Up to now, we do not know the reason for its restricted ionization. However, we believe the structure of **3** must be corrected from NMR and EI-MS spectral data.

The remaining compounds were characterized as 11α-hydroxy-ursa-12-en-3-one (**4**) (14), 11α-hydroxy-urs-12-en-3β-yl palmitate (**5**) (15), ursa-9(11), 12-dien-3-one (marsformosanone) (**6**) (8), 3β-hydroxy-30-norlupan-20-one (**7**) (16), and taraxast-20(30)-en-3β, 21α-diol (**8**) (11) (Fig. 1) by comparison with their reported physical and spectroscopic data.

Experimental

General experimental procedures

Melting points were determined with an X-4 Digital Display Micro-Melting point apparatus and are uncorrected. Optical rotations recorded in $CHCl_3$ using a PerkinElmer 241 polarimeter. UV spectra were measured on a Spect 50-UV–vis instrument (Analytic Jena AG). IR spectra were measured on an FTS 165-IR spectrometer (Bio-Rad, USA). ^1H NMR (400.13 MHz), ^{13}C NMR (100.62 MHz), and 2D NMR were recorded on a Varian INOVA-400 FT NMR spec-

trometer (USA) in $CDCl_3$ with TMS as internal standard. HR-ESI-MS (High resolution electro-spray ionization mass spectrometry) was determined on a Bruker APEX II. EI-MS was determined on a HP 5988A MS (70 eV). Separation and purification were performed by chromatographic column (CC) over silica gel. Silica gel (200–300 mesh) used for CC and silica gel (GF_{254}) for TLC were supplied by the Qingdao Marine Chemical Factory, Qindao, P. R. China. Spots were detected on the TLC under UV light or by heating over 110 °C after spraying with 98% H_2SO_4–EtOH (*v*/*v* 5:95).

Plant material

S. ussuriensis belongs to genus *Saussurea* (Compositae) (17). The whole plant was collected in Zhang county, Gansu province, P. R. China in August 2001 and was identified by adjunct Professor Ji Ma, Faculty of Pharmacy, first Military Medical University of PLA, Guangzhou, P.R. China. A voucher specimen (No. 2001–02) has been deposited at key Laboratory for Natural Medicine of Gansu Province.

© 2008 NRC Canada

Extraction and isolation

The air-dried whole plant of *S. ussuriensis* (5.2 kg) was powdered and extracted with 95% EtOH at room temperature (20 L × 4, each extraction lasted 7 days). The combined extracts were evaporated to dryness under reduced pressure. The residue (240 g) was then suspended in H_2O (1.5 L), extracted with petroleum ether (60–90 °C)(1.0 L × 4), EtOAc (1.0 L × 4) and *n*-BuOH (1.0 L × 4), respectively. The petroleum ether (60–90 °C) extract (94 g) was subjected to column chromatography on silica gel (1000 g) using petroleum ether (60–90 °C) with increasing volume of acetone (*v*/*v* = 40:1, 20:1, 15:1, 10:1, 7:1, 4:1, 2:1, 1:1, each about 4.0 L) as eluent. The fractions A1–A10 were collected according to TLC analysis. Fraction A2 (3.5 g) was further fractionated on a silica gel column (80 g) using petrolemn ether – EtOAc (8:1, 1500 mL) to give impure compound **3** (40 mg) that was purified firstly on a silica gel column (60 g) using $CHCl_3$–Et_2O (30:1, 1000 mL) then on another silica gel column (30 g) with $CHCl_3$–EtOAc (30:1200 mL) to yield pure **3** (5 mg). Fraction A3 (2.4 g) was further fractionated on a silica gel column (70 g), eluting with petroleum ether – EtOAc (10:1, 2000 mL), to give four fractions (fr. A3a, 700 mL; fr. A3b, 200 mL; fr. A3c, 500 mL; and fr. A3d, 600 mL). Fraction A3a (0.8 g) was further subjected to column chromatography on silica gel column (50 g), eluting with $CHCl_3$–acetone (50:1, 2600 mL), to give mixture **1** and **2** (60 mg), and impure **6** (20 mg), that by CC over silica gel (30 g) with petroleum ether – EtOAc (7:1, 300 mL) gave pure **6** (9 mg). The mixture (**1** and **2**) was purified by another silica gel column (25 g), eluting with petroleum ether – EtOAc (4:1, 400 mL), to give pure **1** (8 mg) and **2** (20 mg). Fraction A3b (0.3 g) was purified by CC on silica gel (40 g) using $CHCl_3$ – acetone (50:1, 800 mL) to obtain compound **4** (7 mg), which was further purified by CC (15 g) with petroleum ether – EtOAc (8:1, 200 mL). Fraction A3c (0.5 g) was purified by CC on silica gel (40 g) using petroleum ether – EtOAc (5:1, 1000 mL) to obtain compound **7** (10 mg), which was further purified by CC (20 g) with petroleum ether – EtOAc (8:1, 300 mL). Fraction A3d (0.6 g) was purified using CC on silica gel (50 g) with petroleum ether – EtOAc (8:1, 2000 mL) to yield impure **5** (7 mg) and impure **8** (6 mg), which were further purified by CC on silica gel (20 g) with $CHCl_3$–acetone (40:1, 150 mL) and on silica gel (20 g) with $CHCl_3$–EtOAc (60:1, 200ml), respectively.

The Strecker reaction — an examination in terms of no-barrier theory

J. Peter Guthrie and Goonisetty Bhaskar

Abstract: For those examples of the Strecker reaction where information about both rate and equilibrium is available, we have been able to calculate rate constants for the addition of cyanide ion to the iminium ion by the no-barrier theory (NBT) approach. Both experimental and calculated values are for reaction in aqueous solution. Only for the reactions of benzaldehyde with benzyl or allyl amines and HCN are the equilibrium constants and rate constants for the final, rate-determining, step directly available from the literature. For the reactions of acetone with ammonia, methylamine, or dimethylamine and HCN rate constants for the retro-Strecker cleavage and the equilibrium constants for the overall Strecker reaction have been reported. These equilibrium constants, combined with equilibrium constants for iminium ion formation, which can be extracted from information in the literature, allow calculation of the equilibrium constants for the final step of these Strecker reactions. No-barrier theory has already been applied to carbonyl additions, including cyanohydrin formation; this report provides further evidence for the generality of this approach for calculating rate constants without using any kinetic information.

Key words: Strecker reaction, rate constant, equilibrium constant, no-barrier theory, computation.

Résumé : Pour les exemples de la réaction de Strecker pour lesquels on dispose à la fois des vitesses et des équilibres réactionnels, faisant appel à la théorie sans barrière, il nous a été possible de calculer les constantes de vitesse de réaction pour l'addition de l'ion cyanure sur l'ion iminium. Les valeurs expérimentales et les valeurs calculées se rapportent toutes à des réactions en milieu aqueux. Ce n'est que dans le cas des réactions du benzaldéhyde avec les amines benzyliques ou allyliques et le HCN qu'on retrouve dans la littérature les constantes d'équilibre et les constantes de vitesse pour l'étape finale cinétiquement déterminante. Pour les réactions de l'acétone avec l'ammoniac, la méthylamine ou la diméthylamine et le HCN, les constantes de vitesse pour le clivage rétro-Strecker et les constantes d'équilibre pour la réaction globale de Strecker sont aussi connues. Ces constantes d'équilibre combinées avec les constantes d'équilibre pour la formation de l'ion iminium qui peuvent être extraites de données disponibles dans la littérature permettent de calculer les constantes d'équilibre pour l'étape finale de ces réactions de Strecker. La théorie sans barrière a déjà été appliquée à des additions sur des groupes carbonyles, y compris la formation de cyanohydrines; les résultats obtenus dans ce travail permettent de démontrer la généralité de cette approche aux calculs de constantes de vitesse sans faire appel à des informations cinétiques.

Mots-clés : réaction de Strecker, constante de vitesse, constante d'équilibre, théorie sans barrière, calculs.

Introduction

The Strecker reaction (1, 2) has been used for amino acid synthesis (3, 4) and provides a route to weakly basic amines (5). The reaction is sufficiently complicated that it has been relatively little studied (6–14). In this work, a study is reported of this reaction in terms of no-barrier theory (NBT) (15–22), which permits calculation of rate constants, given only equilibrium constants and distortion energies.

Both rate and equilibrium constants for the rate-determining step are known for only two Strecker reactions (14). For three additional reactions, the rate constant and the overall equilibrium constant for cyanoamine formation are known (8). All of these studies were carried out in aqueous solution. For these reactions, we now report that the observed rates of reaction can be matched by values calculated by NBT.

Theory

NBT (15–22) asserts that reactions can be analyzed in terms of "simple reaction dimensions" such that for progress along only one such dimension the energy is a quadratic function of the corresponding progress variable. The somewhat paradoxical name "no-barrier theory" was chosen to stress the key idea "if only one thing happens, there is no barrier"; most real reactions involve several simple processes, which must happen simultaneously, and therefore there is a barrier, but the underlying simplicity provides a

basis for calculation of the rate constant. Simple reaction dimensions include such things as bond making or breaking involving heavy atoms, geometry change at a reaction center, bond-length change, and proton transfer between electronegative atoms. Each parabolic energy function has a minimum at the low-energy end of the coordinate, which runs from the starting material to the product value. The energies of each of the hypothetical corner species for a Strecker reaction are calculated from distortion energies (based on differences in MO energy between species differing only in geometry), the free energy of encounter complex formation calculated following Hine (23), desolvation of cyanide ion, and ion pairing between cyanide anion and iminium cation calculated by a simple electrostatic model (24). We estimate the desolvation cost of bringing a cyanide ion into contact with a carbon atom as the difference in p*K*a of HCN between water (25) and DMSO (26), assuming that the cyanide ion is predominantly hydrogen-bonded at carbon (15). There is however a problem because interaction of a small exposed $C^{\delta+}$ of the iminium ion should partially replace the interaction with the $H^{\delta+}$ of water, lessening the desolvation cost. It is hard to see how experimental evidence for such a phenomenon could be gathered because it will only be seen for inherently reactive complexes prone to form a covalent bond between $C^{\delta+}$ and $C^{\delta-}$.

Results

The available rate and equilibrium constants from the literature are found in Table 1. In only two cases were rate and equilibrium constants for formation of the Strecker product directly available. In three other cases there were rate constants for breakdown of the Strecker product (8) derived from acetone, and overall equilibrium constants for formation of this product from acetone, HCN, and the appropriate amine (ammonia, methylamine, or dimethylamine) (10).

To determine the equilibrium constant for the final rate-determining step of the Strecker reaction, we require the equilibrium constant for the reaction:

$$(CH_3)_2C{=}O + RR'NH + H^+ \rightleftharpoons (CH_3)_2C{=}NRR'^+$$

For methylamine, the equilibrium constant is known (27), and there is a plausible estimate for pK_{BH}^+ for the imine (27). This allows calculation of the desired equilibrium constant for the final step of Strecker product formation. For dimethylamine, the rate constant for iminium ion formation under conditions where the reaction is uncatalyzed has been reported by Hine et al. (28), and rate constants for the hydrolysis of this iminium ion have been reported by Taillades and Commeyras (8).

Unfortunately, the rate constants reported by Taillades and Commeyras are mostly for the uncatalyzed hydrolysis of the iminium ion, which is the microscopic reverse of the acid-catalyzed dehydration. One point at higher pH is significantly faster than the others, and they report that the reaction was too fast to measure at pH 13.5. Making the assumption that the kinetics should fit the rate law, $k_{obs} = k_{water} + k_{OH}[OH^-]$, and fitting to this rate law, we obtain a value for k_{OH}, which is the microscopic reverse of the process studied by Hine et al., and thus can calculate the equilibrium constant:

$$(CH_3)_2C{=}O + RR'NH \rightleftharpoons (CH_3)_2C{=}NRR'^+ + OH^-$$

Finally, Zuman reported an equilibrium constant for the formation of the imine from acetone and ammonia (29); if we make the same assumption as Bender and Williams, namely that the imininium ion will be three powers of ten more acidic than the corresponding ammonium ion, we can estimate an equilibrium constant for the formation of the iminium ion. All of these equilibrium constants are contained in Table 1.

An additional complication is that the various authors did not all use the same temperature. Hine et al. (28) used 35 °C, and Commeyras and Taillades (8) used 34 °C. The others used 25 °C, and we will report calculations for this temperature. We have approximated the desired rates and equilibria at 25 °C by working with free energies. The free energy, $\Delta G°$ or $\Delta G^‡$, is, for small changes in temperature, insensitive to temperature, because $\Delta G = \Delta H - T\Delta S$, and hence $\Delta\Delta G = \Delta G_{T2} - \Delta G_{T1} = (T_1 - T_2)\,\Delta S = -\Delta T\Delta S$. Now

[d]Free-energy cost of partial desolvation of the cyanide nucleophile; half the full desolvation cost was used.
[e]Total corner energy: Sum of the preceding terms.

ΔS is typically 0.03 kcal/K/mol or less so that for ΔT = 10 °C, $\Delta\Delta G$ = 0.3 kcal/mol or less, which is not important for our purposes (1 cal = 4.184 J).

The rates of these reactions were calculated by NBT, using a model for the addition of cyanide ion to the iminium ion involving three dimensions, the formation of the C–C bond, the geometry change at the carbonyl carbon, and the change in length of the C–N bond from that for a double bond to that for a single bond. This model is illustrated in the three dimensional reaction diagram for the Strecker reaction of acetone, dimethyl amine, and cyanide, shown in Fig. 1. The importance of the various terms contributing to the corner energies is shown for one reaction in Table 2; similar tables for all reactions are available as Supplementary Data as are structure files for the initial and final encounter complexes for all reactions.[2] Because of the uncertainty over whether the full potential desolvation cost would be expressed, we carried out calculations with 0.0, 0.5, and 1.0 times the expected full desolvation cost of 5.2 kcal/mol for cyanide in contact with the carbon of an iminium ion. These results are all found in Table 3. The RMS error was larger for zero or full desolvation, though in both cases less than 2 kcal/mol, and lower for 0.5 times the full desolvation cost. Least-squares fitting gave the best value as 0.49, which is not meaningfully different from 0.5. We therefore use the calculations with 0.5 × 5.2 = 2.6 kcal/mol as the best current values. With this model, we calculated the free energies of activation reported in Table 3. The RMS error for all values was 0.65 kcal/mol.

Discussion

It is gratifying that for cyanide addition to iminium ions, as for cyanide addition to carbonyl compounds (15), NBT has been able to predict the rate constants for addition for the range of compounds for which equilibrium data are available. This range is deplorably small, only three powers of ten in equilibrium constant for the rate determining step, in large part because these reactions are potentially complex to study, with three components and three steps, which could be rate-determining (carbinolamine formation, iminium ion formation, and cyanide addition). On top of this, there can be concurrent and competitive cyanohydrin formation. Indeed, some synthetic routes to Strecker adducts begin with

the cyanohydrin as source of both carbonyl compound and cyanide (5). We intend to examine a wider range of Strecker reactions to offer predictions of the rate constants for reactions as yet unstudied kinetically, but this requires development of computational methods for calculating the necessary equilibrium constants, which have not been measured.

It is of interest to look at the positions of the transition states found by the NBT approach, even though we have argued that transition-state positions are less well-specified than transition-state energies in these calculations (22).

The key observation is that all the transition states have values for all three coordinates in the range 0.2 to 0.5, i.e., somewhat central but a bit on the early side as is reasonable for exergonic reactions. None of the coordinates is close to either 0 or 1; thus, no lower dimensional transition state is likely to be competitive, and three dimensions are required to describe the reaction.

NBT gives the rate constant/free energy of activation corresponding to a particular detailed mechanism/model for the reaction. This approach requires more detailed models than have usually been proposed and explicit values for interactions often used only qualitatively. We are seeking consistent models over a range of related reactions. Our approach runs into problems where an interaction has not been studied experimentally, as for the question of desolvation of cyanide in contact with an iminium ion. Although we resorted to fitting to see what gave the best results (empirically determining one parameter used for five reactions), we wish to stress that with any plausible value (between 0.0 and 5.2 kcal/mol) for the desolvation energy of cyanide, NBT gave a good fit to the available experimental data. With the optimized fraction of this desolvation energy, the fit is distinctly better; that there should be partial compensation for loss of desolvation in the encounter complex for the Strecker reaction, more so than in cyanohydrin formation, seems reasonable.

Calculations

Methods

All molecular-orbital calculations were carried out using Gaussian 03 (30). Analysis of the reaction to pick out corner energies, creation of structure files for each corner structure, calculation of the distortion energies as differences in MO energies for structures differing only in geometry, calculation of corner energies, and searching for the lowest saddle point were all carried out using computer programs being developed in this laboratory.

Benzamide hydrolysis in strong acids — The last word[1]

Robin A. Cox

Abstract: Recently it has become apparent that the mechanism of amide hydrolysis in relatively dilute strong acid media is the same as the one observed for ester and benzimidate hydrolysis, two water molecules reacting with the O-protonated amide in the rate-determining step. This is not the whole story, however, at least for benzamide, *N*-methylbenzamide, and *N*,*N*-dimethylbenzamide, since the observed rate constants for these substrates deviate upwards from the observed excess acidity correlation lines at acidities higher than about 60% H_2SO_4, meaning that another, faster, reaction with a different mechanism is taking over at higher acidities. It has never been clear what this latter mechanism was until the work reported in this paper. An exhaustive excess acidity analysis of all the available measured reaction rate constants for the three substrates in three different acidic media, aqueous H_2SO_4, aqueous $HClO_4$, and aqueous HCl, shows that this second mechanism involves a second rate-determining proton transfer to the O-protonated benzamide, followed by (or possibly concerted with) irreversible loss of $^+NH_4$ to give an acylium ion. Subsequent reaction of this with water (or bisulfate, etc.) eventually gives the observed carboxylic acid product. This latter reaction mechanism has never been previously considered for amide hydrolysis, but it may not be uncommon; at least one other reaction with a similar mechanism is known, and another possible case is suggested.

Key words: amides, benzamides, hydrolysis, excess acidity, mechanism, acid media.

Résumé : Il est récemment devenu apparent que le mécanisme d'hydrolyse des amides dans des milieux dilués d'acides forts est le même que celui observé pour l'hydrolyse des esters et des benzamidates et que, dans l'étape cinétiquement déterminante, deux molécules d'eau réagissent avec l'amide protoné sur l'oxygène. Cette conclusion ne correspond toutefois pas à toute l'histoire, au moins pour le benzamide, la *N*-méthylbenzamide et le *N,N*-diméthylbenzamide, puisque les constantes des vitesses observées pour ces substrats, à des acidités supérieures à environ 60% de H_2SO_4, dévient d'une façon positive par rapport aux droites de corrélation des acidités en excès observées; cette observation signifie que, à des acidités plus élevées, une autre réaction plus rapide et avec un mécanisme différent devient prépondérante. La nature de ce dernier mécanisme n'avait jamais été établie avant le présent travail. Un examen exhaustif de l'acidité en excès pour toutes les constantes de vitesses réactionnelles mesurées avec ces trois substrats, dans trois milieux acides différents, H_2SO_4 aqueux, $HClO_4$ aqueux et HCl aqueux montre que ce second mécanisme implique un transfert de proton cinétiquement déterminant vers le benzamide O-protoné qui est suivi par (ou qui se produit possiblement d'une façon conertée) avec une perte irréversible de NH_4^+ qui conduit à la formation d'un ion acylium. Une réaction subséquente de cet ion avec de l'eau ou du bisulfate conduit éventuellement à l'acide carboxylique qui est obtenu comme produit. Ce dernier mécanisme réactionnel n'a jamais été considéré antérieurement pour l'hydrolyse des amides, mais il n'est pas inhabituel; au moins une autre réaction avec un mécanisme semblable est connue et on suggère un autre cas possible.

Mots-clés : amides, benzamides, hydrolyse, excès d'acidité, mécanisme, milieu acide.

[Traduit par la Rédaction]

Introduction

Recently the mechanisms of hydrolysis of benzimidates, esters, and amides in aqueous sulfuric acid were reviewed (1). It was shown that the hydrolysis mechanisms in relatively dilute H_2SO_4 for all of these substrates were the same, rate-determining reaction of the O-protonated substrate with two water molecules, but for benzamides another faster reaction of unknown mechanism became important at the higher acidities. It is the purpose of this paper to delineate this mechanism, which was not possible at the time.

It is highly appropriate that this paper is dedicated to the memory of Keith Yates; his name appears often in the references. He was very interested in amides throughout his ca-

reer in chemistry, and much of the experimental work used in this paper was carried out by one of his students (2, 3). For many years we thought that the problem of the mechanism of benzamide hydrolysis was solved; rate-determining reaction of the O-protonated amide with three water molecules in the most dilute acid media, followed by reaction with only one as the water activity diminished at the higher acid concentrations, and then with a bisulfate ion at the highest acidities used (4). However, as often happens in science we were overtaken by events; solvent isotope effects in amide hydrolysis are clearly only compatible with two water molecules reacting with the protonated amide in the transition state, not one or three (5), and Guthrie's multidimensional analysis (6) is not consistent with the involvement of three water molecules either. Also, it turns out that we had been using the wrong values for the water activities in the analysis of kinetic data in acid media (7). The values we had been using were based on a standard state of pure water (mole-fraction-based values), whereas all of the other concentrations in these media are based on the hypothetical ideal one molar acid concentration standard state (7). For some reactions, use of the correct water activities makes little difference (for instance ester hydrolysis (7)), but for others it does, and amide hydrolysis is one of these. (This means that Bunnett *w* values (8) and Yates and Stevens *r* values (9) listed in the literature are unlikely to be correct).

It is shown here that the reaction of amides in the stronger acid media is not a hydrolysis as such at all, and so all three of the mechanisms we believed were correct in 1981 (4) are in fact wrong. Every single rate constant in the literature (and there are a lot) for the hydrolysis of benzamide (**1**), its *N*-methylated derivative (**2**), and its *N*,*N*-dimethylated derivative (**3**) were used in the analysis, obtained in aqueous H_2SO_4, in aqueous $HClO_4$, and in aqueous HCl media, and the two proposed mechanisms correlate every one of them. The mechanism at the higher acidities, which is proposed in this paper, has not been previously considered.

Results

Hydrolysis rate constants as a function of sulfuric acid concentration and temperature for benzamide (**1**) are given by Smith and Yates (2, 3), by Rysman de Lockerente et al. (10), and by Bunton et al. (11); as a function of perchloric acid concentration and temperature by Bunton et al. (11), by Leisten (12), by Shingare et al. (13), and by Yamana et al. (14); and as a function of hydrochloric acid concentration and temperature, with some data in DCl/D_2O, by Bunton et al. (11). For *N*-methylbenzamide (**2**), the experimental data used in aqueous H_2SO_4 were obtained from Smith and Yates (2, 3) and from Bunton et al. (11); data at the single temperature of 95.0 °C in aqueous $HClO_4$ are given by Yamana et al. (14), and at the single temperature of 100.4 °C in aqueous HCl by Bunton et al. (11). For *N*,*N*-dimethylbenzamide (**3**) the data in H_2SO_4 come from Smith and Yates (2, 3) and from Bunton et al. (11), in $HClO_4$ from Yamana et al. (14) and Bunton et al. (11), and at the single temperature of 100.4 °C in HCl from Bunton et al. (11).

$$[1]\quad \log k_\psi - \log(C_{SH^+}/(C_{S^+}\,C_{SH^+})) - 2\,\log a_{H_2O} = \log k_0 + (m^\ddagger - 1)m^*X$$

$$[2]\quad \log k_0 = 10.31883 + \log T - (\Delta G^\ddagger/(RT\ln 10)) + (\Delta H^\ddagger/(RT\ln 10))((T-\Theta)/T)$$

These rate constants, k_ψ, were analyzed according to the excess acidity technique (1, 7). The rate equation which is relevant here is eq. [1] (1, 7), where the term $\log(C_{SH^+}/(C_{S^+}C_{SH^+}))$, hereinafter for simplicity called PCT for protonation correction term, is present to correct for the fact that these amides are not fully protonated at the lower acid concentrations. It is obtained from ionization ratios, $I = C_{SH^+}/C_S$, calculated using the excess acidity equation for basicities, $\log I - \log C_{(H^+)_{aq}} = m^*X + pK_{SH^+}$, writing $C_{(H^+)_{aq}}$ for the C_{H^+} used before (7) as this is a better representation of the true state of the proton in aqueous acid media (1). To use this, values for pK_{SH^+} and m^* for the amide substrates are needed; fortunately highly accurate ones are available (15), albeit that I had to develop an entirely new method of separating medium effects on the spectra used to obtain them from the effects due to protonation (16). The values used were: **1**, $pK_{SH^+} = -1.540 \pm 0.020$, $m^* = 0.539 \pm 0.021$; **2**, $pK_{SH^+} = -1.461 \pm 0.009$, $m^* = 0.529 \pm 0.012$; and **3**, $pK_{SH^+} = -0.998 \pm 0.019$, $m^* = 0.581 \pm 0.033$ (15), all measured at 25 °C. The terms m^* and $m^\ddagger$ in eq. [1] are activity coefficient ratios, m^* referring to the protonated substrate and $m^\ddagger$ to the transition state (7). The m^* values are independent of temperature (7), but the pK_{SH^+} values are not; to correct them to the reaction temperature they were converted to free energies via $\Delta G° = (RT\ln 10)pK_{SH^+}$, T being 298.15 K, and then to the reaction temperature T. This correction may not be very accurate, since $\Delta H°$ and $\Delta S°$ values seem to vary randomly for different types of substrate (17), but it is surely better than the often-used assumption that the pK_{SH^+} values are temperature-independent. In practice this method has always appeared to work well (7), and it did so here also. The values of the excess acidity X and $\log C_{(H^+)_{aq}}$ (or $\log C_{H^+}$) were those used previously (18); these and the molarity-based water activity values a_{H_2O} are temperature-corrected as before (7).

In eq. [1], k_0 is the rate constant for the reaction in the standard state at the reaction temperature. With results at different temperatures available, it can be replaced in eq. [1] by eq. [2], where $\Delta G^\ddagger$ is the free energy of activation and $\Delta H^\ddagger$ the enthalpy; the entropy of activation $\Delta S^\ddagger$ can easily be obtained from these via $\Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger$. This formulation is due to Clarke and Glew (19); I find it more useful than the usual Eyring formulation (20) as it is more natural to use, giving better numbers with errors that are independent of one another (19). The numerical term in eq. [2] contains the Planck and Boltzmann constants (20), R is the gas constant (1.98589 cal K^{-1} mol^{-1} here; 1 cal = 4.184 J), and Θ the reference temperature for the activation parameters, 298.15 K.

The low acidity mechanism for benzamide hydrolysis is given in Scheme 1; eq. [1] is the rate equation for this mech-

anism. All of the data for benzamide in sulfuric acid are plotted according to eq. [1] in Fig. 1. As can be seen, the data follow the fitted lines precisely up until an X value of about three (about 60% H_2SO_4), where they begin to deviate upwards. There is still plenty of water in the reaction medium at this point, the 2:1 mole ratio H_2O:H_2SO_4 is indicated on Fig. 1.

The only way of dealing with the data after $X = 3$ seemed to be to calculate what the rate constants according to eq. [1] would be at the higher X values, subtract these from the observed rate constants, and plot the resultant in various ways until linearity was achieved. When this was attempted it was soon apparent that a subsequent A1 reaction (21) did not fit the data, and other mechanisms were investigated. When this was done, the only rate equation that correlated all the data was one that included the proton concentration $\log C_{(H^+)_{aq}}$, eq. [3]. This means that the rate-determining step has to include a second proton transfer to the protonated substrate — not really surprising as the rate constants after $X = 3$ are still increasing with the solvent acidity. The proposed mechanism, for which eq. [3] is the rate equation, is given as Scheme 2; this has been proposed before (1) but had not been tested until now.

$$[3]\qquad \log k_\psi - \log(C_{SH^+}/(C_{S^+}C_{SH^+})) - \log C_{(H^+)_{aq}} = \log(k_0)_2 + (m^{\ddagger}_2 - 1)m^*X$$

To illustrate this second mechanism, the data for the hydrolysis of *N*-methylbenzamide in aqueous H_2SO_4 are plotted according to eq. [3] in Fig. 2 (the equivalent plot for benzamide itself does not form such a good illustration). Again, since data at several temperatures are used, the term $\log(k_0)_2$ is replaced according to eq. [2], as before. As can be seen the data approach the correlation lines quite well. For all of the substrates, figures at the higher acidities for the aqueous H_2SO_4, $HClO_4$, and HCl media resemble Fig. 2, and those at the lower acidities for all of these media resemble Fig. 1; for the sake of brevity only one other plot is included here. The correlation lines in these figures result from curve-fitting all of the data simultaneously to eqs. [1] and [3] (including eq. [2]), as before (7, 22). Any data points that do not form part of the data set, to 95% confidence, are rejected from the fit and are in parentheses in the Tables and Figures. Four of the data points for the reaction in the aqueous HCl medium were obtained in D_2O (11), and despite the paucity of data points it proved possible to obtain solvent isotope effects for both mechanisms, by allowing a different intercept for the D_2O data. All of the results for benzamide (**1**) are given in Table 1.

For *N*-methylbenzamide (**2**) and *N*,*N*-dimethylbenzamide (**3**) the results are essentially similar, except that there are fewer data — in some media the reaction was only followed

at a single temperature, and there are no results in deuterated media — and for these substrates the second mechanism is relatively more important than is the first. One other plot is given here, Fig. 3 for **3** in HCl at a single temperature, showing both mechanisms. Tables 2 and 3 give the summarized results for **2** and **3**.

Discussion

In the past it had been assumed that the O-protonated amide would somehow switch to an N-protonated one at high acidity, which would then lose ammonia and produce an acylium ion in the rate-determining step (21), which is an A1 reaction. However, this seems unlikely on the face of it. (Why would a perfectly stable O-protonated amide suddenly switch to an unstable N-protonated one in media in which the O-protonated amide would increase in stability?). The analysis of the rate constant results given in this paper is not consistent with an A1 mechanism of any sort, which rules out this "proton reorganization" process. The data are only consistent with Scheme 2 or with its kinetic equivalent.

For benzamide in sulfuric acid, the two data points at the highest acidities were rejected as being off the correlation line; they are above it (faster). It is suggested that here the catalyzing acid switches from $(H^+)_{aq}$ to undissociated H_2SO_4 molecules; for the two points in question, one is at an acidity close to the 1:1 mole ratio H_2O:H_2SO_4 point and the other is above it. We have seen undissociated H_2SO_4 molecules acting as acid catalysts in these media before (23, 24), after all, H_2SO_4 is a stronger acid than is $(H^+)_{aq}$. It is telling that the same thing does not happen in perchloric acid; there the highest acidities used were well short of the 1:1 mole ratio point. However, two points were not enough to quantify this, and so numbers are not given. There is one other systematic trend in the rejected points, involving the data for **2** in sulfuric acid obtained by Smith at 85.2 °C (2) (see Fig. 2). I am inclined to attribute this to some kind of experimental artifact, as these points were rejected whatever correlation scheme was used; perhaps there was some kind of systematic error in the measured sulfuric acid concentrations.

An examination of Table 1 reveals that the intercept rate constants and activation parameters for the low acidity mechanism for **1** are the same for all three acid media, which is gratifying as this is what would be expected if the same mechanism is operating in each case. The equivalent data are too sparse or the errors are too high for **2** and **3** to enable any real conclusion to be drawn. The $m^{\ddagger}$ values are not all the same, but since these are activity coefficient ratios it is at present difficult to know what to expect (7, 25); I will

comment that they do not appear to have the utility for mechanistic diagnosis for which I had once hoped (7).

The situation is different for the Scheme 2 results (high acidity mechanism); they are not the same in the three acid media used. This is not surprising insofar as general acid catalysis is involved, with the second proton transfer taking place in the rate-determining step (Scheme 2), and long ago Kresge et al. (26) discussed a similar effect they had observed in aromatic hydrogen exchange and later in alkene hydration (27). The results in Tables 1–3 seem to have no real trends. It is worth commenting that aqueous sulfuric acid is a quite highly structured medium (28), more so than aq. HCl and aq. HClO4, and one might expect a large effect on entropies of activation as the second protonation breaks up the structure of the medium. In Table 1 the entropy of activation for **1** is slightly positive, but the same is certainly not the case for **2** and **3** (Tables 2 and 3).

There were enough data (just) to enable the evaluation of solvent isotope effects for the two mechanisms for benzamide in aqueous HCl. These are in Table 1. For the Scheme 1 mechanism the effect is inverse, which is what would be expected for a pre-equilibrium proton transfer (29), but for the Scheme 2 mechanism it is normal (probably; the error in it is larger than the quantity itself). This is what would be expected for a reaction with a proton transfer involved in the rate-determining step (29).

For benzamide the low acidity reaction is fast by comparison to the high acidity one (compare the log k_0 values), but the opposite is true for **2**, where the high acidity mechanism has a greater relative importance (compare Figs. 1 and 2). This is probably because the electron-donating alkyl groups in **2** and **3** will help to stabilize the partial positive charge on the departing nitrogen in Scheme 2, lowering the overall activation energy for the reaction, as seems to be the case from the $\Delta H^{‡}$ values in Tables 1, 2, and 3. However, by and large there seems to be not very much in the way of trends, which can be rationalized, in many of the results obtained in this work.

The details of the reaction mechanism given in Scheme 2 are a little difficult to draw. I have commented there that all of the steps shown within the braces might be concerted, the proton transfer to nitrogen and the departure of ammonia with a proton so that a diprotonated acylium species does not actually form, but in fact the proton, which the nitrogen takes with it as it leaves, cannot be the same one as was on the carbonyl oxygen because the orbitals are not aligned in such a way as to make this possible. Consequently, proton transfers within the solvent medium must be involved too, one being water (or bisulfate) removing the proton from the carbonyl oxygen and another being the removal of one from the surrounding medium (which is very acidic) by the departing nitrogen. These would all be so fast, however, as to make the whole process *essentially* concerted. I have at-

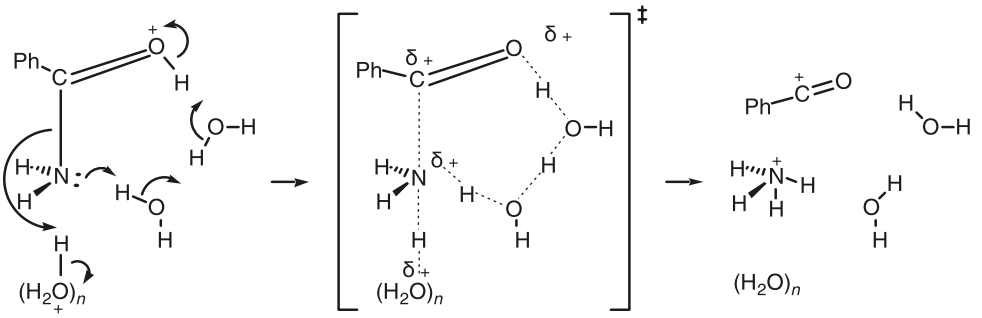
Scheme 3.

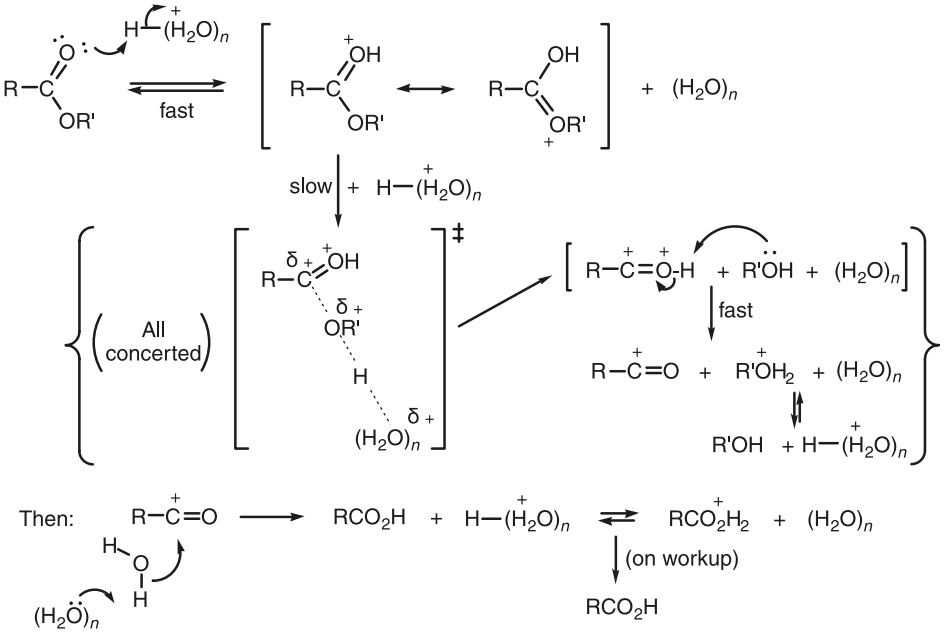


tempted to draw such a process involving surrounding water in Scheme 3, which although rather involved may be a better representation of the high acidity mechanism, if in fact the process really is wholly concerted.

Rate-determining proton transfers are well known to be involved in the Wallach rearrangement of aromatic azoxyarenes (30, 31), shown in Scheme 1 of ref. (31) for comparison with Scheme 2. In fact, diprotonated species in

© 2008 NRC Canada

Scheme 4.



strong acid media are becoming more numerous all the time. For instance, Shudo and co-workers (32) found dications to be important in a Friedel–Crafts type cyclodehydration in CF_3SO_3H; Klumpp and co-workers (33) cited dicationic intermediates as superelectrophiles in similar media; and Olah and his group (34) proposed species like HNO_2^{2+} in superacids.

Another class of reactions that would appear to have mechanisms very similar to Scheme 2 is the hydrolysis of esters in strong acid media. Typically, esters which cannot form stable acylium ions or alkyl cations still hydrolyze quickly in strong acids, with reaction rate constants which increase steeply with acidity (35), and it seems perfectly reasonable that these hydrolyses would have a mechanism like Scheme 4, rather than the proposed A1 process involving a "proton switch" from a stable position on the carbonyl oxygen to an unstable one on the ester oxygen, which subsequently decomposes in an A1 process (35). Again, the process will likely be concerted, but this is difficult to draw.

I have called this paper "the last word" because I have no intention of writing another word on the hydrolyses of **1**, **2**, or **3**. Of course, this does not exclude other amides, ring-substituted benzamides, and so on; there are plenty of available experimental data on some of these, but the results are not as readily accessible as are the data on **1**, **2**, and **3**. The mechanisms of Scheme 1 and Scheme 2 are now expected to apply to all amides, but the Scheme 2 process is only likely to be available to those substrates where the positive charge on the protonated amide can be supported in some way in the acylium ion which is formed. For instance in **1**, **2**, and **3**, it can be delocalized into the aromatic ring. Scheme 4 for esters also remains to be tested.

Acknowledgments

It is a pleasure to acknowledge the many discussions with my colleagues in physical organic chemistry, which have helped to stimulate my thinking in this area, particularly Stan Brown, Peter Guthrie, and Erwin Buncel. And, of course, I owe an immense debt of gratitude to Keith Yates, who got me started on all this over thirty years ago, and acted as friend and mentor for so many of them.

Wallach rearrangement of azoxypyridines and azoxypyridine *N*-oxides — Charge distributions and dramatic reactivity differences[1]

Erwin Buncel, Sam-Rok Keum, Srinivasan Rajagopal, Eric Kiepek, and Robin A. Cox

Abstract: Extension of our studies of the generic Wallach rearrangement (of azoxybenzene to 4-hydroxyazobenzene) to the heteroaromatic series (azoxypyridines and axoxypyridine *N*-oxides) has revealed some dramatic reactivity differences, particularly for the α and β compounds. We have studied the 3-isomers and the 4-isomers in each series, each with α and β forms, eight compounds in all, in the 100 wt% sulfuric acid region of acidity. In those cases in which a product could be observed, the α and β isomers both give the same one, the corresponding 4′-hydroxyazo compounds. All the compounds react much more slowly than does azoxybenzene itself, presumably because of the extra positive charge present in the substrates, but the β isomers have half-lives of seconds and the α isomers half-lives of hundreds of hours in the 100 wt% H_2SO_4 acidity region. The α compounds have measurable pK_{BH^+} values, but the β compounds do not, exhibiting only a medium effect in the acidity region in which the α compounds protonate. This means that for the β compounds, the protonated intermediates must be much less stable and the postulated reaction intermediates must be much more stable than for the α compounds. To clarify this, we have obtained Mulliken charge distributions for the various species concerned, calculating the charge carried by each half of the molecule, larger charge separations being taken to indicate lesser stability. As far as we can establish, this is the first time that this technique has been used to indicate the stabilities of carbocationic species.

Key words: azoxypyridines, azoxypyridine *N*-oxides, Wallach rearrangement, excess acidity, basicities, theoretical calculations, charge distributions, reactivities.

Résumé : Une extension de nos travaux sur le réarrangement générique de Wallach (de l'azoxybenzène en 4-hydroxyazobenzène) vers les séries hétéroaromatiques - azoypyridines et *N*-oxydes d'azoxypyridines - a mis en évidence des différences de réactivité dramatiques, en particulier avec les composés α et β. Opérant dans la région d'acidité à 100% en poids d'acide sulfurique, on a étudié les isomères 3 et 4 de chacune de ces séries, utilisant dans chaque cas les isomères α et β, soit huit produits en tout. Dans la cas où il était possible d'observer un produit, les isomères α et β conduisent tous les deux au mêmes produits, soit les composés 4'-hydroxyazo correspondants. Tous les composés réagissent beaucoup plus lentement que l'azoxybenzène lui-même, probablement en raison de la charge positive supplémentaire qui est présente dans les substrats, mais les demi-vies des isomères β sont de l'ordre de la seconde alors que celles des isomères α sont de l'ordre de centaines d'heures dans la région d'acidité de 100% en poids de l'acide sulfurique. On peut mesurer les valeurs de pK_{BH^+} des composés α, ce qui n'est pas le cas avec les composés β qui ne présente qu'un faible effet de milieu dans la région d'acidité dans laquelle les composés α se protonent. Ces résultats indiquent que dans le cas des composés β, les intermédiaires protonés doivent être beaucoup moins stables et que les intermédiaires réactionnels postulés doivent être beaucoup plus stables que pour les composés α. Dans le but de clarifier cette conclusion, on a obtenu les distributions de charge de Mulliken pour les diverses espèces concernées en calculant la charge portée par la moitié de la molécule et en faisant l'hypothèse que des séparations de charges plus grandes reflètent une stabilité plus faible. En autant qu'on puisse le savoir, c'est la première fois que cette technique est utilisée pour évaluer les stabilités d'espèces carbocationiques.

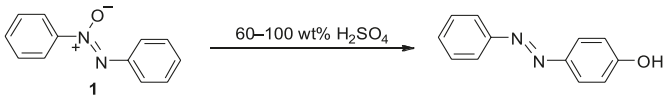
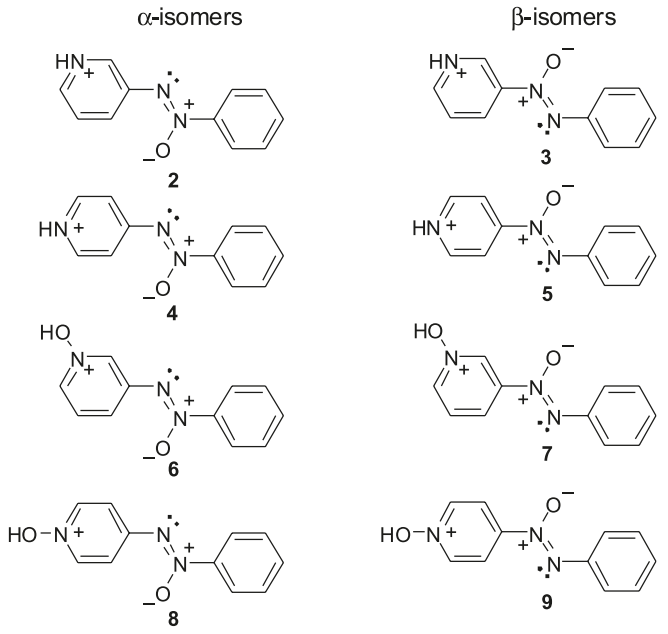
Introduction

The Wallach rearrangement, dating from 1880 (1), is the rearrangement of aromatic azoxyarenes, typically azoxybenzene **1**, to hydroxyazo compounds. We have studied the reaction of azoxybenzene itself extensively (2–6) and have recently established the mechanism to be that shown in Scheme 1 (7), in which the calculated geometries of the various species involved are also shown (7).



1

We have also studied a number of azoxynaphthalenes (8) and 2,2′,4,4′,6,6′-hexamethylazoxybenzene (9), and in this paper, we extend the study to include a number of azoxypyridines and azoxypyridine *N*-oxides, **2**–**9**. (The trivial and β nomenclature is used here, as it is more easily comprehensible than is the systematic NNO and ONN.)



Here, we report the basicities of these compounds as pK_{BH^+} values for the second protonation of the substrates, where measurable (they are all monoprotonated in the pH range, and thus we regard the monoprotonated species **2**–**9** as the true reactants), and their approximate half-lives in about 100 wt% H_2SO_4 if these could be determined. (A preliminary report on the reactivities of **4** and **5** has been published (10)). To explain the observed dramatic differences between the α isomers **2**, **4**, **6**, and **8** (on the left), and the β isomers **3**, **5**, **7**, and **9** (on the right), we found it necessary to perform theoretical calculations on **2**–**9** and various related structures. Most recently, we have reported the results of some detailed theoretical calculations for possible intermediates resulting from **1** and some other substrates (7), following much earlier theoretical studies (11).

Experimental

We have reported the syntheses of **2**–**9** previously (12). In brief, 4- and 3-phenylazopyridines were prepared by condensation of nitrosobenzene with 4- and 3-aminopyridine, according to Brown and Grammeman (13), and purified by column chromatography and recrystallization from hexane. Oxidation of these with *m*-chloroperbenzoic acid according to Badger and Lewis (14) gave the corresponding phenylazopyridine *N*-oxides. Further oxidation of these with H_2O_2/glacial acetic acid following Colonna, Risaliti, and Pentimalli (15, 16) gave mixtures of the α and β phenylazopyridine *N*-oxides, which could be separated by HPLC; these are **6**–**9**. The azopyridines **2**–**5** were obtained from these by selectively deoxygenating them at the *N*-oxide function with PCl_3 according to Pentimalli (16). The identities of the compounds were confirmed by X-ray structure analysis (12).

The basicities were determined in the same way as before (2). UV–vis spectra were obtained at the same substrate concentration, ~5×10^{-5} mol/L, but at differing acidities, using aqueous H_2SO_4, at 25 °C. Examples are given in Fig. 1 for **4** and Fig. 2 for **5**; the relevant experimental data are given as supplementary material, Tables S1–S4 for **2**, **4**, **6**, and **8**, the only compounds for which pK_{BH^+} values could be determined.[4] A PerkinElmer Lambda-5 UV–vis spectrophotometer was used for both the basicity determinations and for kinetic measurements (In Figs. 1 and 2, the unlabelled *y*-axis is the optical density *D*).

The acid solutions used for the kinetic measurements, in the 100 wt% H_2SO_4 range, were carefully prepared from Fisher Reagent Grade 96% sulfuric acid and fuming 30% sulfuric acid, and the concentrations determined accurately by conductivity measurements according to Gillespie and Wasif (17). Reaction rates were determined by the "direct method" (3), either by repeatedly scanning over 350–500 nm, or at a suitable constant wavelength for the faster reactions. Excellent isosbestic points were observed; byproduct formation was minimal. Infinity values after ten half-lives were stable, and were used directly to evaluate the

pseudo-first-order rate constants. Reaction products were initially identified by direct isolation as previously (9), and subsequently from a comparison of the final UV–vis spectra with those of the authentic products.

The Mulliken charges at the individual atoms for the various structures were obtained using GAUSSIAN 98, as before (7), at the High Performance Computing Virtual Laboratory of Queen's University.

Results

Basicities

[1] $$pK_{BH^+} = \log I - \log C_{(H^+)_{aq}} - m^*X$$

The basicities that could be obtained for some of the substrates in this work are given in Table 1, together with the observed m^* values, along with the value for azoxybenzene **1** obtained from preexisting data (3) in exactly the same way for comparison. These were obtained using the excess acidity method (18); eq. [1] was curve-fitted directly, with ionization ratio *I* values being obtained from the observed optical density *D* (or extinction ε) differences, $D = (D_B + ID_{BH^+})/(1 + I)$). Differences, usually the *D* (or ε) values at the unprotonated species peak wavelength subtracted from those at the peak wavelength of the protonated species (or vice versa), are used to minimize any errors caused by small differences in substrate concentration in the different acid media. These are given as supplementary information in Tables S1–S4, together with the values of *X* and log $C_{(H^+)_{aq}}$ used (19).[4] ($C_{(H^+)_{aq}}$ is written rather than C_{H^+} as used before (19) because it is a better representation of the actual state of the proton in acid media (20).) This excess acidity treatment

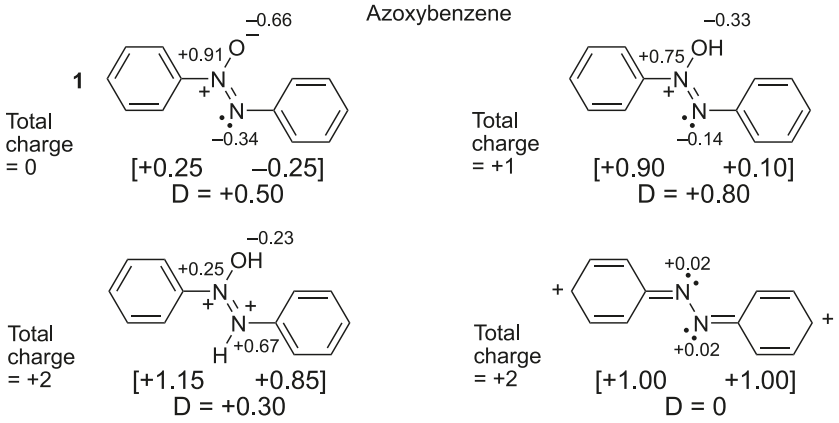
Scheme 2.



also gives estimated values of D_B and D_{BH^+}, with their errors, so log I values can be easily calculated as well if necessary (the method used actually includes and improves on all existing methods of pK_{BH^+} determination). As is apparent from Table 1, there were not enough data points available to enable calculation of m^* values for **2** and **4**, the numbers obtained having errors larger than the values themselves, so these substrates were assigned the fixed value $m^* = 1.122$, this being the average of that observed for the other three data sets, and the quite reasonable pK_{BH^+} values reported in Table 1 were the result.

Only values of pK_{BH^+} and m^* for the α-isomers could be obtained; examination of Figs. 1 and 2 reveals that only Fig. 1 (**4**) is a protonation equilibrium, with one peak decreasing in intensity while another one increases, clearly indicating a measurable pK_{BH^+}. Figure 2 (**5**) represents only a medium effect on the monoprotonated species — one peak red-shifting as the acidity increases (all of the UV–vis spectra obtained for **2**, **6**, and **8** resemble Fig. 1, and those for **3**, **7**, and **9** resemble Fig. 2; Figs. 1 and 2 are representative). A comparison of Figs. 1 and 2 with Figs. 5 and 6 of ref. 21 shows a remarkable similarity; in ref. 21, an excess acidity method for the reliable separation of medium effects from spectral changes due to protonation was developed, and Fig. 5 of ref. 21 shows the reconstructed spectra due to protonation, and Fig. 6 of ref. 21, the medium effect on the protonated species as the acidity continues to increase (the substrate in that case was *N-tert*-butylbenzamide).

Reactivities

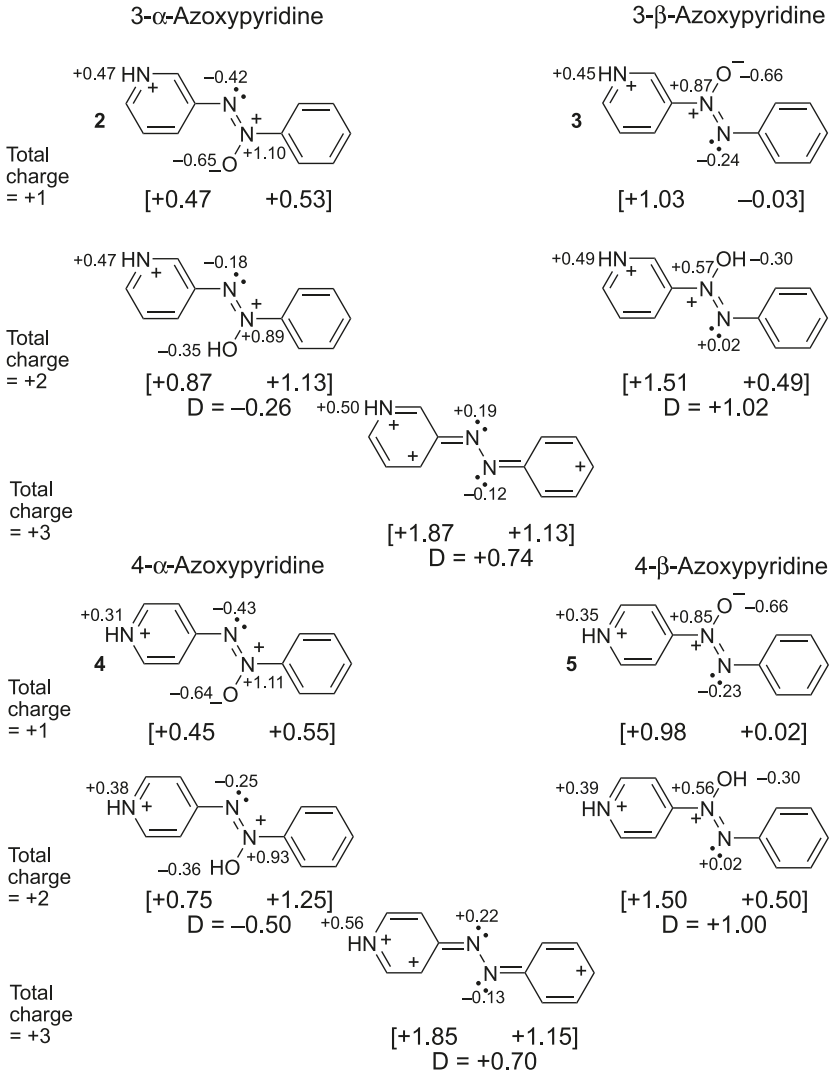
In contrast to the pK_{BH^+} situation, our preliminary results for the rates of the rearrangement reactions of **2**–**9** are essentially the opposite. No reaction at all was observed for the α-compound **2** at 50 °C (and thus, of course, the reaction product could not be determined either); whereas the β-compound **3** has a half-life of about 30 s at this temperature in 99.74 wt% H_2SO_4. Similarly, the α-species **4** gave no reaction, whereas **5** has a half-life of about 96 s in 99.74% H_2SO_4 at 50 °C (10). The *N*-oxides behave similarly; a higher reaction temperature of 65 °C was used for these, and under these conditions the α-isomers **6** and **8** have the very long half-lives of 98 h and 402 h in 99.76 wt% H_2SO_4, respectively. The β compounds **7** and **9** react very much more quickly under these conditions, with half-lives of 42 and 56 s, respectively. For comparison, azoxybenzene **1** itself has a half-life of 5.1 min at 25 °C in 99.59 wt% H_2SO_4 (5).

Charge distributions

To explain these considerable differences in reactivity and pK_{BH^+} value between the α and β isomers, it seemed necessary to examine the charge distributions in **1**–**9** and in the various possible intermediates formed from them on the way to product. We have previously carried out detailed theoretical calculations on the possible intermediates involved in the reaction of **1** and some other compounds (7), and have found that the proposed dicationic reaction intermediate was flat (both phenyl rings in the same plane) and had 120° bond angles at both of the nitrogens (which presumably retain their lone pairs) (7). For the purposes of keeping the calculations simple, it seemed reasonable to constrain the many structures we examined in this work to be flat and bent in the same way also. Mulliken charges at each atom were obtained as before (7), and for simplicity these are summed for the left-hand side and the right-hand side in the structures

© 2008 NRC Canada

Scheme 3.



which follow, dividing the molecule into two between the two nitrogen atoms in the middle. Some charges at individual atoms are also given. Azoxybenzene was also calculated for comparison; the resulting numbers were in exact agreement with those obtained before (7). These are given in Scheme 2; the azoxypyridinium cations **2**–**5** are in Scheme 3, and the protonated azoxypyridine *N*-oxides **6**–**9** in Scheme 4.

Discussion

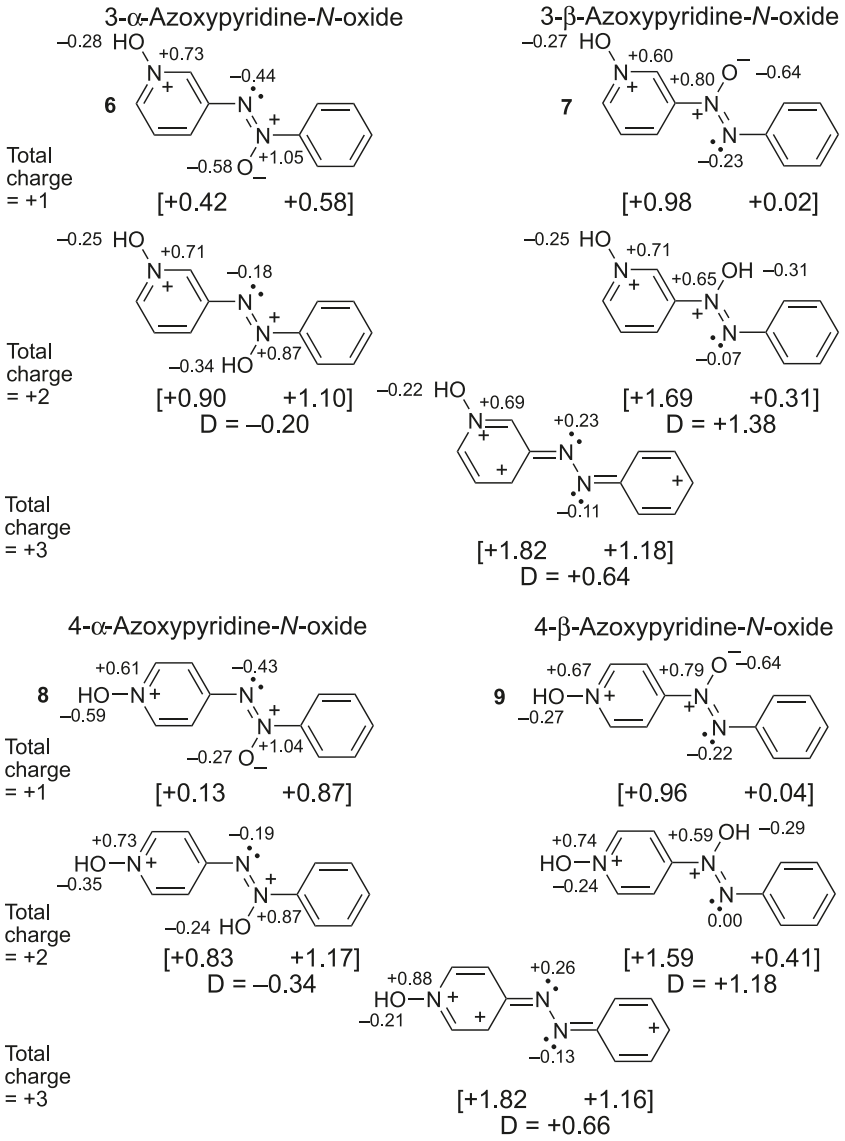
As far as we have been able to establish, this is the first time that charge distributions calculated in this way, by dividing the structures into two halves to calculate charge separations, have been used to estimate the stabilities of cationic species; charge separation is known to be important in carbanionic species (22). A comparison of Scheme 1 with Scheme 2, which gives these calculations for azoxybenzene **1** itself, is instructive. In Scheme 2, the total amount of charge borne by each side of the molecule is given below the structure, and the difference between them is given as Δ, charge on left side minus charge on right side. It would be reasonable to conclude that the smaller this difference, the more stable is the structure, the assumption being that large amounts of charge separation in a structure are destabilizing (this is an assumption that seems to be implicit in physical organic chemistry but does not seem to have been explicitly stated before).

Thus in Scheme 2, protonated azoxybenzene is not particularly stable, with a charge separation of 0.80, but the diprotonated species below it to the left (not actually formed during the course of the reaction, but the transition state does resemble it (7), see Scheme 1), has a charge separation of only 0.30, and in the dicationic intermediate it is zero. Thus, formation of the monoprotonated species is not easy (pK_{BH^+} = –5.18, which is quite a difficult protonation), but once formed, the reaction of it is fairly facile (easily observable reaction at 25 °C) (3, 5). None of the calculated charge separations in Scheme 2 are in accord with what might be expected from drawing simple resonance structures (3, 5).

In Schemes 3 and 4, we present some pertinent charge-distribution data for the azoxypyridine species investigated in this work. Charge densities are given for ring-nitrogen-protonated pyridine species, ring-nitrogen- (or $^{+}$N–OH) and

© 2008 NRC Canada

Scheme 4.



azoxy-oxygen diprotonated species, and for the presumed tripositive intermediates (10). Total charges vary from zero for the parent azoxybenzene **1** (Scheme 2) to +3 for the intermediates derived from the 3- and 4-α- and β-azoxypyridines (Scheme 3) and the 3- and 4-α and β-azoxypyridine *N*-oxides (Scheme 4).

Of particular interest are the fully deoxygenated structures (except for the *N*-oxide OH when present) formed following the loss of the azoxy oxygen in strong H_2SO_4 media. The parent dicationic structure in Scheme 1 was proposed as the key intermediate in the Wallach rearrangement of azoxybenzene (2–6, 23); its geometry was recently subjected to modern theoretical examination (7), resulting in the flat, bent structure for it as given in Schemes 1 and 2. The present study of charge distributions shows that these have a direct bearing on the basicities and reactivities of all of the azoxyarene reactant families.

The results presented in Schemes 2, 3, and 4 reveal some interesting general features. Nitrogens bearing formal positive charges remain, in the main, positively charged, but as the amount of positive charge in the molecule increases, more and more of it is borne by the aromatic rings. For instance, in the dicationic intermediate derived from **1** in Scheme 1, each ring bears 0.98 of a positive charge, leaving only 0.02 for the nitrogen. This undoubtedly explains why the structure can be bent (120° bond angles at nitrogen), and the nitrogens can retain their lone pairs. (In the rings, this positive charge resides mainly on the ring hydrogen atoms, with the carbons remaining essentially neutral). Formally neutral nitrogens remain neutral or can bear negative charge, sometimes a considerable amount. Almost never do they become positive. Oxygen atoms in the structures always retain a considerable amount of negative charge, even when protonated.

For the other azoxyarenes in Schemes 3 and 4, all of the αs (on the left) have a small charge separation, with the right-hand ring more positive than the left-hand one. In contrast, all of the tripositive intermediates formed from them,

© 2008 NRC Canada

presumably in the rate-determining step of the reaction (7), have a LARGER charge separation, with the left-hand ring more positive, as well as having an entire extra positive charge. Thus, the diprotonated species are stable (observable pK_{BH^+}), and are unreactive, because of the large activation energy caused by having to go to a species with greater charge separation. Thus for the αs, reaction is very slow or not observed at all.

For all of the βs (on the right in Schemes 3 and 4), the situation is exactly the opposite. All of the dipositive protonated species have a large charge separation (left-hand side more positive), and thus cannot be very stable (unobservable pK_{BH^+}). On the other hand, once they do form, they will react very quickly (small activation energy) because they are going to a species with a SMALLER charge separation, even though it has one more positive charge. Thus, the considerable reactivity differences in **2–9** can be easily explained on the basis of differing charge separations in the intermediate species.

Other points

The 4-α species have (presumably) better resonance interactions than the 3-αs do (slightly larger negative Δs), and thus have slightly less negative pK_{BH^+} values. As a whole, the azoxypyridine and azoxypyridine *N*-oxide families have pK_{BH^+} values, which are five powers of ten more negative than that of azoxybenzene, simply due to the presence of one more positive charge in these species. The 3-βs react slightly faster than the 4-βs because they gain slightly more charge dispersal in going from the dipositive protonated species to the tripositive intermediate than do the 4-βs. All of them react much more slowly than does azoxybenzene (i.e., the reactions have to be studied at a higher temperature), again because of the extra positive charge. There seems to be little difference between the azoxypyridinium ions and the azoxypyridine *N*-oxides.

Thus, it is apparent that charge distributions have a direct bearing on the basicities and reactivities of **1–9**, and undoubtedly of the entire azoxyarene family. These fascinating molecules continue to provide interesting and useful information about the mechanisms of many other reactions that take place in more dilute acid media (24) and the reactions of superelectrophiles in media such as pure CF_3SO_3H (25), as well as about the Wallach rearrangement itself. Detailed discussion of the reaction rates and mechanisms of **1–9** will follow in a forthcoming publication.

Adsorption of vapor-phase VOCs (benzene and toluene) on modified clays and its relation with surface properties

C. López-Cortés, G. Osorio-Revilla, T. Gallardo-Velázquez, and S. Arellano-Cárdenas

Abstract: A mexican bentonite was used to prepare three modified clays: an organoclay (OC–CPC) by intercalating cetylpyridinium chloride (CPC), an aluminum-pillared clay (Al-PILC), and an inorganic–organic clay (IOC–CPC) prepared from Al-PILC intercalating CPC. The infrared and thermogravimetric analyses enabled us to differentiate between the structures obtained. Interlayer distance was assessed through X-ray diffraction; the OC–CPC was the clay that showed the highest value (12.4 Å). The natural clay's specific area was 43.5 m^2/g, increasing to 157.2 m^2/g for Al-PILC. The OC–CPC and IOC–CPC specific areas were 13.27 m^2/g and 14.5 m^2/g, respectively. Al-PILC was a microporous material; whereas natural clays, OC–CPC and IOC–CPC were non-porous materials. Toluene and benzene adsorption on OC–CPC was higher than in IOC–CPC and Al-PILC. Natural clay showed no adsorption capacity for these compounds. Comparison of the GC retention times for non polar and low-polarity compounds (octyne and benzene) in columns packed with OC–CPC and a commercial non polar column (squalene) showed that the OC–CPC possessed a higher organophilic (non polar) nature than squalene. This explains the higher benzene and toluene adsorption capacity of the OC–CPC compared with the other modified clays. The toluene and benzene adsorption isotherm for OC–CPC was well-described by the GAB (Guggenheim–Anderson–De Boer) model for the whole range of relative pressure used in this work (0–0.9) describing multilayer adsorption and capillary condensation.

Key words: organoclay, inorgano–organo clay, vapor phase VOC's adsorption, clay surface properties.

Résumé : On a utilisé une bentonite mexicaine pour préparer trois argiles modifiées: une argile organique (AO-CCP) obtenue par intercalation de chlorure de cétylpyridinium (CCP), une argile pillée avec de l'aluminium (APIL-Al) et une argile inorganique organique (AIO-CCCP) préparée en intercalant du CCP dans de l'APIL-Al. Les analyses infrarouges et thermogravimétriques permettent de différencier les structures obtenues. On a évalué les distances intercouches par diffraction des rayons X; la valeur la plus élevée, 12,4 Å, est observée avec l'argile AO-CCP. La surface spécifique de l'argile naturelle est de 43,5 m^2/g et elle atteint 157,2 m^2/g avec l'argile APIL-Al. Les surfaces spécifiques pour les argiles AO-CCP et AIO-CCP sont respectivement 13,27 m^2/g et 14,5 m^2/g. L'argile APIL-Al est un matériau microporeux alors qu'on a démontrer que le l'argile naturelle et les argiles AO-CCP et AIO-CCP sont des matériaux non poreux. En chromatographie gazeuse, une comparaison des temps de rétention de composés non polaires et de faible polarité (octyne et benzène), dans des colonnes contenant de l'argile AO-CCP et une colonne non polaire commerciale (squalène) ont permis de montrer que le caractère organophile (non polaire) de l'argile AO-CCP est plus élevé que celui du squalène. Cette caractéristique explique la capacité d'adsorption du benzène et du toluène plus élevée de l'argile AO-CCP par comparaison avec les autres argiles modifiées. L'isotherme d'absorption du benzène et du toluène pour l'argile AO-CCP est très bien décrite par le modèle GAB (Guggenheim–Anderson–De Boer) pour toute la plage de pressions relatives utilisées dans ce travail (0 à 0,9) décrivant l'adsorption multicouche et la condensation capillaire.

Mots-clés : argile organique, argile inorganique organique, adsorption de composés organiques volatils en phase vapeur, propriétés superficielles d'argiles.

Introduction

Main air pollutants include gases, such as carbon monoxide, nitrogen oxides, sulfur oxides, partially burned hydrocarbons, and volatile organic compounds (VOCs), the latter constituting the second most abundant and diverse class of emissions after suspended particles. Most VOCs' emissions come from small sources, such as cars, nail enamel bottles, paint containers, solvents, and so forth. These represent a human health risk at high concentrations, mostly in indoor environments, either at home or in work environments, where pollution levels are higher and more hazardous than outdoors. Therefore, there is a need to clean the work environment. The reduction of the concentration of these gases and vapors to acceptable levels can be carried out by a number of methods, including adsorption processes, which use adsorbents like activated carbon and zeolites (1).

A number of studies (2–4) have demonstrated that clay materials having a laminar structure like bentonite, can be chemically modified, changing their physicochemical characteristics, such as interlaminar distance, surface area, pore size, and polarity or chemical affinity. Some studies have focused mainly on obtaining modified clays to be used for the adsorption of organic and inorganic contaminants, which depends on both the nature of the mineral surface and the compound intercalated in the clay's interlayer space (5). Given their hydrophobic nature, organic clays (OC), as well as inorganic–organic clays (IOC), having an intermediate hydrophobicity have been used for the adsorption of toxic organic compounds in liquid phase, e.g., OC–TMAC (OC with tetramethyl ammonium chloride) for phenols and chlorophenols (6); IOC–CPC (IOC with cetylpyridinium chloride) for benzopyrene and chlorophenols (7); OC–TMA (OC with tetramethyl ammonium) for benzene, toluene, and xylene (8); OC–DDA (OC with dimethyl distearyl ammonium) for phenol and trichlorophenol (9); OC–TBA (OC with tetrabutyl ammonium bromide) for chlorobenzene (10); OC–TMPA (OC with trimethyl phenyl ammonium) in aqueous solution for the absorption of benzene, toluene, and ethyl benzene (11); and the removal of aqueous phenolic pollutants using pillared clays (PILC), organic clays (OC), and inorganic–organic clays (IOC) (12), among others. However, only few reports have been published on the use of modified clays for VOCs' adsorption in vapor phase, including trichloroethane, trichloroethylene, methanol, and propane in zeolites and PILCs (13); adsorption of VOCs on mineral clays (14); adsorption of gasoline hydrocarbons (BTEXs) on mineral clays (15); benzene vapor on organobentonites–cetyl trimethyl ammonium (4); and adsorption of benzene and toluene in vapor phase on modified clays (16).

In the present work, the potential use of modified clays in the adsorption of vapor-phase toluene and benzene (VOCs) present in air is investigated. The intercalated compound was cetylpyridinium chloride (CPC), based on the work reported by Keeran et al. (5), but conducting the adsorption of VOCs in the vapor phase. The modified clays OC–CPC, IOC, and Al-PILC were prepared for comparative purposes and were characterized using infrared spectroscopy, themogravimetric analysis, and X-ray diffraction. The surface properties were determined through nitrogen-adsorption isotherms, and the polarity of the organic clay was determined experimentally by gas chromatography. The benzene and toluene adsorption isotherms in modified clays were obtained in a static chamber using the gravimetric method (17).

Experimental

The natural clay used in this study was a Perfobent bentonite (cation exchange capacity CEC = 74 meq/100 g) supplied by Perfobent, Mexico City (a company that extracts minerals from northern Mexico). The natural clay was not refined for pillaring; the only treatment to which it was subjected was grinding to homogenize particle size and sieving through a 65 mesh sieve to obtain a maximum particle diameter of 0.210 mm.

Modified-clays preparation

The aluminum PILC (Al-PILC) was prepared following the method reported by Torkáz and Shabtai (18), preparing the pillaring agent (aluminum polyhydroxycation) with OH:Al molar ratio of 1.85, which is obtained at a pH of 4.35. The pillaring agent was mixed with the natural clay to obtain a ratio of 6 mmol Al/g clay. The inorganic–organic clay (IOC) was prepared mixing the Al-PILC previously prepared with cetylpiridinium chloride (CPC) as carbon source in an amount equivalent to 100% of its cation exchange capacity (5). The organic clay (OC–CPC) was prepared by mixing the natural clay with the organic surfactant CPC (5) in an amount equivalent to 100% of its cation exchange capacity.

IR analysis

Infrared analysis was used to differentiate between the structures obtained by the intercalation of organic and inorganic compounds. This analysis was carried out in a FTIR PerkinElmer 1600 spectrophotometer using the KBr pellet method.

Thermogravimetric analysis

Thermogravimetric analysis was used to evidence the change in chemical structure resulting from the intercalation of the aluminum polymer in Al-PILC and cetylpyridinium in the other modified clays (OC–CPC and IOC), using a Model 1090 AT thermoanalyzer, at 10 °C/min from 25 to 900 °C. The parameters determined were % weight loss as a function of temperature and the differential of this parameter as a function of temperature.

X-ray diffraction

X-ray diffraction was used to obtain the interlaminar distance in each sample, using a Siemens D-500 diffractometer. Nickel filter, Cu radiation Kα = 1.5406 Å operating at 30 kv and 20 mA with a 2θ angle scanning angle ranging from 2 to 64°. The basal distance d_{001} for each sample was calculated and identified using the diffractometer's software.

Nitrogen-adsorption isotherms

Nitrogen adsorption isotherms were obtained at –196 °C with a C.I. Electronics LTD Mark 2 automatic analyzer, from which the specific area was calculated using the Brunauer–Emmett–Teller (BET) model. The mean pore diameter and the micro or mesoporous nature of the

© 2008 NRC Canada

adsorbents were determined using the Lippens and De Boer's *t*-method (19). Determinations were made by replicate and the results averaged.

Experimental adsorption isotherms

The static-chamber method (17) was used to obtain the experimental adsorption isotherms. Each determination was replicated six times, and the result was averaged; the confidence limits were calculated using the *t*-distribution at 95% confidence. This method consisted in preparing a series of solutions having different benzene or toluene concentrations (0–1.0 mol fraction) in a non-volatile and non-reactive mineral oil. The different solutions were placed in 20 mL GC vials, and small aluminum trays containing a known amount of the adsorbent (100–200 mg) were suspended from the vial stopper to expose it to the vapor pressure generated from the oil–toluene or oil–benzene solution. Vials were tightly capped with silicone–Teflon™ stoppers and left at a controlled temperature of 23 °C in a stove until equilibrium, which was reached after 10 days. The amount of the adsorbed solvent per gram of dry solid was then calculated by gravimetry, and the solvent vapor content in the chamber in equilibrium with the solid was determined by GC, using a standard curve for the vapor-phase solvent. A PerkinElmer Sigma 3B gas chromatographer with a FID detector, carbowax 20M (Supelco) packed column, and a constant nitrogen flow rate of 20 mL/min was used. The column temperature was 120 °C with a detector and injector temperature of 140 and 130 °C, respectively. For this determination, 100 μL samples were collected from each vial's vapor atmosphere using a Hamilton syringe for gases, which were injected afterwards in the gas chromatographer. By relating the sample's peak areas with those of the standard curve, the amount of solvent present in the atmosphere of each vial was calculated.

The standard curve was obtained by preparing five solutions (liquid phase) with different toluene–hexane concentrations. The area (arbitrary units) for toluene and benzene present in each sample was determined by GC. The area vs. amount of toluene or benzene (in mg) was plotted and compared with the areas obtained from each vial's atmosphere.

Adsorption mathematical models

Benzene and toluene adsorption isotherms obtained for all modified clays were compared to those predicted by BET and GAB (Guggenheim–Anderson–De Boer) adsorption mathematical models to derive a possible explanation to the behavior observed.

Polarity (chemical affinity)

The polarity (chemical affinity) of the OC–CPC modified clay was determined through GC, obtaining the retention times of different compounds varying in polarity (pentanone, intermediate polarity; octyne, low polarity; and benzene, non-polar) in columns packed with OC–CPC and commercial columns of different polarity (Supelco): carbowax 20M; OV-25 (intermediate polarity), SE 30 (low polarity), and squalene (non-polar). The equipment used was a SIGMA 3B gas chromatographer (GC) with packed column, FID detector, and using nitrogen as carrier (20 mL/min) and a column temperature of 100 °C.

Table 1. % Weight loss of the modified clays and natural clay in the three regions in which the thermogram was divided.

Sample	Region I (30–230 °C)	Region II (230–530 °C)	Region III (530–900 °C)
Natural clay	8.24	0.9	3.12
Al-PILC	8.73	4.29	1.8
IOC	8.73	11.89	1.95
OC–CPC	1.99	21.36	2.13

Results and discussion

Figure 1*a* shows the infrared spectra of natural clay and Al-PILC. Natural clay shows vibration absorption bands of the stretching type of OH groups bound to Al^{3+} and (or) Mg^{2+} near 3600 cm^{-1}. The broad band in the 3000–3500 cm^{-1} region corresponds to the strong OH stretching of water in the interlayer space. This last band appears in Al-PILC, but with a broader and higher intensity peak, due to the presence of additional OH groups from the intercalated aluminum polyhydroxycation. This indicates that the pillaring process was successful. The infrared spectra of OC–CPC and IOC (Fig. 1*b*) also display the OH stretching band of water in the 3000–3500 cm^{-1} region, but the intercalation of the CPC in the OC–CPC caused a considerable decrease of the OH stretching frequency of water from that of the natural clay. The IOC, which was originated from the Al-PILC, shows a similar intensity band to the natural clay due to the OH

groups from the pillars. The OC–CPC and IOC showed additional bands at 2930, 2848, and 1484 cm^{-1} corresponding to asymmetrical, symmetrical stretching and asymmetric bending vibrations, respectively, of the CH_2 groups (20) of the CPC hydrocarbon chain intercalated into the interlaminar space of the original clay.

The results of the % weight loss as a function of temperature obtained in the thermogravimetric (TG) and diferential thermogravimetric (DTG) analyses for the three selected regions (Fig. 2) are displayed in Table 1. The TG curve (Fig. 2*a*) for natural clay showed the smectites' typical profile (21). An initial weight loss is observed in the 30–230 °C range, corresponding to the evaporation of water adsorbed between silicate layers. Afterwards, a pseudo-plateau occurred between 230–530 °C in which the slight weight loss is related to the removal of OH groups bound to the edges of the clay laminates. Finally, another weight loss was observed between 530 and 900 °C, which corresponds to the total dehydroxylation of the clay structure. This is clearly evident in Fig. 2*b* (DTG). Regarding the weight loss of the Al-PILC in TG, and the peak in the Al-PILC DTG profile in the first region, it corresponds to the loss of water adsorbed on the material, which, as shown in Fig. 2*b*, is lower than that for natural clay due to the lower presence of hydrated exchangeable cations in the interlayer space. In the second and third regions, there is a constant weight loss derived from the dehydroxylation of the polyhydroxycation OH groups and the total dehydroxylation of the structure. The profile of the

Table 2. First-order reflexion d_{001} and interlaminar distance (Δd) of the modified clays and natural clay.

Sample	2θ angle	d_{001} (Å)	Δd (Å)
Natural clay	7.032	12.5	3.0
Al-PILC	5.060	17.4	7.9
IOC	4.841	18.2	8.7
OC–CPC	4.033	21.9	12.4

TG and DTG curves obtained for OC–CPC and IOC shows a considerable difference compared with those of the natural clay for the second region (230–530 °C). The only difference between the natural clay and OC–CPC and IOC lies in the presence of the CPC intercalated in the clay interlaminar space, so it is reasonable to expect that the large weight loss in this region depends on the amount of intercalated CPC in OC–CPC and IOC.

From data on Table 1 and Fig. 2*b*, it can be seen that the thermal stability of the OC–CPC and IOC extends up to 230 °C, which implies that the possible regeneration of the adsorption capacity of these modified clays should be carried out at a temperature lower than 230 °C to ensure the structural integrity of both modified clays.

From the X-ray diffractograms obtained for the different samples (Fig. 3), the interlaminar distance was calculated using Bragg's equation (22) based on the position of the first-order reflection d_{001}, obtaining the basal distance (*d*) from which the montmorillonite layer thickness was subtracted (mean value 0.95 nm) (23). In Bragg's equation,

Sample	S_{total} (m^2/g)	S_{ext} (m^2/g)	S_{mp} (m^2/g)	V_{mp} (cm^3/g)	r_p (Å)
Natural clay	43.5	43.5	0	0	0
Al-PILC	157.2	44.6	112.6	6.29×10^{-2}	11.17
OC–CPC	13.27	13.27	0	0	0
IOC	14.5	14.5	0	0	0

Note: S_{total}: Specific area (evaluated by N_2 isotherms with BET equation); S_{ext}: external specific surface = $S_{total} - S_{mp}$; S_{mp}: microporous specific area; V_{mp}: microporous volume evaluated by ***t*** isotherm; r_p: mean pore radius.

higher values of the 2θ angle correspond to lower basal distance values (*d*). The results obtained are shown in Table 2. Figure 3 shows that the 2θ angle for natural clay is the highest, whereas OC–CPC has the lowest angle. The Al-PILC and IOC show practically the same value of 2θ angle and are located between that for the natural clay and the OC–CPC. This is due to the fact that pillaring caused an increase in the interlayer distance (Δ*d*) lower than that caused by the intercalation of CPC. Table 2 shows that OC–CPC displayed the highest interlaminar distance (12.4 Å). No differences were observed between IOC and Al-PILC in terms of interlaminar distances because the pillaring process fixed the structure in both samples, and therefore the interlayer distance did not change when the organic compound was introduced in the Al-PILC to obtain the IOC.

The surface properties of the modified clays are shown in Table 3. As it can be seen in this table, as a result of the pillaring process, the specific area (S_{total}) of natural clay increased from 43.5 m^2/g to 157.2 m^2/g in Al-PILC. On the contrary, for the OC–CPC clay, a value of 13.27 m^2/g was obtained, which was probably due to the fact that the CPC organic compound occupied available adsorption sites, thereby reducing the adsorption area. The same occurred with IOC, for which a specific area of 14.5 m^2/g was obtained. As regards of porosity, Table 3 shows that Al-PILC had a mean pore radius of 11.17 Å, so that it could be classified as a microporous material (19, 24). The natural clay sample was not porous, as well as the OC–CPC and IOC, because of the previous discussion.

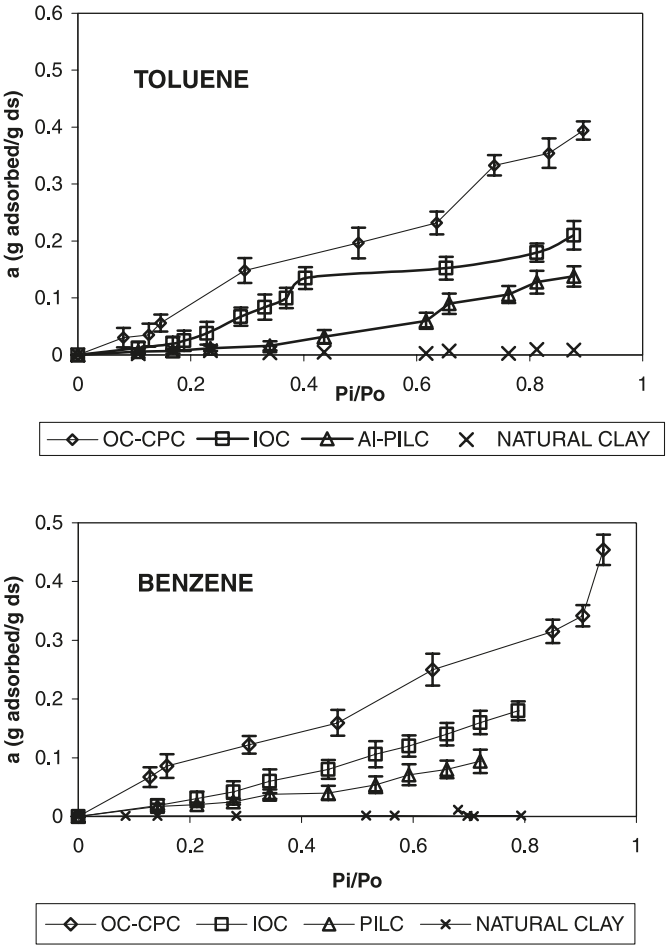
Determination of adsorption isotherms

Figure 4 shows the benzene and toluene adsorption isotherms for the modified clays at 23 °C. This figure illustrates that the organoclay OC–CPC is the one that shows the highest adsorption capacity for both benzene and toluene. This was derived from the strongly organophylic (non-polar) nature that resulted from the introduction of CPC. The natural clay did not adsorb either toluene or benzene because of its hydrophylic nature. The Al-PILC sample showed a very low adsorption capacity for both benzene and toluene, given the low organophylic character developed, while IOC showed a slightly higher adsorption than Al-PILC, since it acquired a more organophylic character (lower polarity) than Al-PILC because of the additional intercalation of CPC.

Since OC–CPC was the sample that showed the highest benzene and toluene adsorption, the BET and GAB adsorption mathematical models were applied to try to understand the OC–CPC adsorption behavior.

The values obtained for the constants of BET and GAB equations are shown in Table 4. Figure 5 shows the experimental adsorption isotherms for benzene and toluene compared with the predictions of both models.

Fig. 4. Adsorption isotherms of modified clays at 23 °C for toluene and benzene. P_i/P_o: relative pressure; a: adsorption in g adsorbed material/dry solid.



Compliance with the BET model is achieved when the energy of the adsorbate–adsorbent interaction is higher than that of the adsorbate–adsorbate interaction (high *C* values). However, the validity of the BET equation is restricted to low relative pressures, below 0.35 (Fig. 5). At high relative pressures, the BET equation overestimates the amount of adsorbed gas (as observed in Fig. 4), since it considers an infinite number of adsorbed layers (25).

The GAB model was valid in the whole relative pressure range used 0–0.9 (Fig. 5). The determination coefficient (R^2)

for the model was 0.905 for toluene and 0.911 for benzene. This model can be considered as an extension of the multimolecular BET model, taking into account the modified adsorbate properties in the multilayer region (adsorbate–adsorbent interaction) (26). The constants obtained for this model are also shown in Table 4, evidencing that both benzene and toluene adsorption in OC–CPC produced high C values, which represent a good adsorption capacity with the formation of polylayers. This polylayer formation may cause capillary condensation, mostly at high relative-pressure values. Constant K adopts low values (as in this case, Table 4) when molecules form polylayers accumulate at high relative pressures and may cause volumetric condensation. These results show that the adsorption of both benzene and toluene involves the formation of polylayers, resulting in capillary condensation, which can be explained by the high C values (Table 4).

The adsorption models were applied in an attempt to explain the way in which it takes place. However, considering that adsorption takes place on developed surfaces, and that OC–CPC displayed a low surface area, it is evident that another phenomenon might be occurring as well, which might correspond to partition, as reported by Lizhong and Yuhong (16). These investigators studied benzene adsorption in organobentonites, and reported that a partition phenomenon occurs preferentially in organic clays, which competes with adsorption. This supports the fact that, although the OC–CPC surface area decreases from 43.5 to 13.3 m^2/g through the surfactant intercalation process, it developed a strongly organophylic nature, which caused a strong affinity for toluene and benzene, favoring its absorption in CPC rather than its adsorption.

Polarity determination (chemical affinity) for the modified OC–CPC clay

Given that OC–CPC was the sample with the highest adsorption capacity for benzene and toluene, the polarity determination was conducted only with this modified clay. Retention times of compounds varying in polarity were determined in columns of different polarities. Retention values are a measure of polarity of a given column relative to a non-polar column (squalene).

The retention times obtained, columns used, and solvents studied are shown in Table 5. In physicochemical terms, a chemical compound is polar if it has a dipolar moment (charge separation). In GC, polar compounds are retained for longer times in a polar column compared with a non-polar one (27). Table 5 shows that OC–CPC displayed the highest retention times for non-polar or low-polarity compounds (octyne and benzene), and even higher values compared with the squalene non-polar column. Therefore, this chromatographic method revealed that the organoclay OC–CPC, with which the column was packed, possesses a strong organophylic (non-polar) nature.

Conclusions

Infrared and thermogravimetric analyses (TG and DTG) confirmed the intercalation of the aluminum pillar in Al-

Table 5. Retention times of compounds of various polarity in packed columns with OC and commercial columns of different polarities (Supelco).

	Retention times (min)				
Compounds	Carbowax 20M (P)	OV 25 (PI)	SE 30 (BP)	squalene (NP)	OC
Pentanone (PI)	0.98	0.88	0.88	7.9	18.26
Octyne (BP)	0.52	1.05	1.15	13.7	18.3
Benzene (NP)	0.84	0.82	0.82	15.97	20.5

Note: P = polar; PI = intermediate polarity; BP = low polarity; NP = nonpolar.

PILC and IOC, as well as the introduction of cetylpyridinium in the OC–CPC and IOC. The OC–CPC displayed the highest interlaminar distance (12.4 Å). Al-PILC and IOC showed almost identical interlaminar distances, due to the pillar fixing process prior to the CPC introduction in IOC. The Al-PILC showed the highest surface area, 157 m^2/g, belonging to the group of microporous materials. OC–CPC and IOC are non-porous materials. The reduction of surface area in the organoclays OC–CPC and IOC derived from the blockage of available spaces in clay laminates by the organic compound introduced.

The adsorption studies showed a great affinity of benzene and toluene in gas phase for OC–CPC due to the hydrophobic character that resulted and also to the increase in the interlaminar distance. IOC showed a lower affinity for benzene and toluene, followed by Al-PILC. Natural clay had no affinity for benzene and toluene due to its hydrophylic nature.

The model that best predicted toluene and benzene adsorption in organoclay (OC–CPC) was the GAB model through the whole range of relative pressures used. This indicates monolayer and multilayer adsorption, as well as condensation, depending on the environmental benzene and toluene relative pressure. However, given the low surface area in OC–CPC and the high retention of benzene and toluene content, it is very likely that the phenomenon of partition is also present.

Organoclays, like OC–CPC prepared in this investigation, represent a potential alternative for the adsorption of volatile organic compounds like benzene and toluene present in indoor environments. Given the hydrophobic nature of the OC–CPC, the relative humidity of water vapor in the environment would not affect its adsorption capacity as it is in the case of activated carbon, which is the most commonly used material for the adsorption of VOCs.

Determination of manganese and nickel in slurry sampling by graphite furnace atomic absorption spectrometry

Luciano Almeida Pereira, Simone Soares de O. Borges, Maurício Costa Castro, Waldomiro Borges Neto, Cláudia Carvalhinho Windmöller, and José Bento Borba da Silva

Abstract: Methods for the determination of manganese and nickel in lake and marine sediment slurries by graphite furnace atomic absorption spectrometry using permanent modifiers are proposed. The slurries were maintained homogeneous with air bubbling with an aquarium pump. For manganese, the best modifier was ruthenium permanent with m_o of 0.9 pg and of 1.0, 1.2, 1.5, and 1.8 pg, for Rh, without modifier, Ir, and Zr, respectively. For nickel, the best modifier was rhodium permanent with m_o of 33 pg, followed by 85, 120, 132, and 240 pg, without modifier, Zr, Ir, and Ru, respectively. After determining manganese and nickel in two certified marine sediment samples (n = 10) from NRCC, PACS-2, and MESS-2, and in the San Joaquin 2079 soil, the results agreed at the confidence level of 95% with the certified value for all analytes studied using aqueous calibration. Calibration curves of all analytes had correlation coefficients R^2 higher than 0.99. Recovery studies made in four levels for each analyte in sediments from Lake Pampulha showed acceptable values. The limits of detection (LODs) were 4.0 and 0.9 μg L^{-1} for manganese and nickel, respectively.

Key words: manganse, nickel, sediments, GF AAS.

Résumé : On a développé de nouvelles méthodes pour déterminer les quantités de manganèse et de nickel présentes dans les boues de sédiments marins et lacustres qui utilisent des modificateurs permanents et qui font appel à la spectroscopie d'absorption atomique avec fournaise de graphite. Les boues sont maintenues à l'état homogène en lui faisant barboter de l'air avec une pompe d'aquarium. Pour le manganèse, le meilleur modificateur est le ruthénium permanent avec m_o de 0,9 pg et respectivement de 1,0, 1,2, 1,5 et 1,8 pg pour le Rh, pour le cas sans modificateur, pour le Ir et le Zr. Pour le nickel, le meilleur modificateur est le rhodium permanent avec m_o de 33 pg, suivi respectivement de 85, 120, 132 et 240, pour le cas sans modificateur, pour le Zr, le Ir et le Ru. Après avoir déterminer les taux de manganèse et de nickel dans deux échantillons certifiés de sédiments marins (n = 10) provenant du NRCC, de PACS-2 et de MESS-2, et dans le sol de San Joaquim, les résultats obtenus en utilisant une calibration aqueuse sont en accord au niveau de confiance de 95% avec les valeurs certifiées pour les analytes étudiés. Les courbes de calibration des tous les analytes ont présenté des coefficients de corrélation R^2 supérieurs à 0,99. Des études de récupération faites à quatre niveaux, pour chacun des analytes dans des sédiments du Lac Pampulha ont présenté des valeurs acceptables. Les limites de détection (LDD) sont respectivement de 4,0 et 0,9 μg L^{-1} pour le manganèse et le nickel.

Mots-clés : manganèse, nickel, sédiments, spectrométrie d'absorption atomique avec fournaise de graphite.

[Traduit par la Rédaction]

Introduction

Manganese is largely distributed as particles in the earth's crust, in water, and in the atmosphere. It is an essential element for humans and animals (1). According to Flores et al. (2), the control of heavy metals in several types of samples (biological tissues, water, soil, foods, etc.) has made the degree of exposure and possible consequences for human health a relevant subject for evaluation.

Nickel is one of the five most abundant elements after iron, oxygen, magnesium, and silicon. The carcinogenicity of nickel is extensively discussed in the literature, being verified in exposed workers and in experimentation animals (3).

Water from rivers, lakes, and the sea contains metals of several origins, such as decomposition of rocks and minerals contained in soils and dry or wet deposition of particulate material. There are several possibilities for the natural origins for metals present in river, lake, and sea water. Some

examples are weathering of rocks and minerals present in the soil, humid or dry deposition of particulate material from the atmosphere, and anthropogenic action, such as industrial waste water and domestic sewage. These metals can associate to bottom sediments through two mechanisms, with the particulate material that contains the metal deposits with over time or the metal present in the water associates directly to the sediment already deposited through more complex mechanisms. Such mechanisms depend on several factors, such as redox conditions and water pH (4).

The use of slurries to determine metals in sediments has become an attractive technique for its simplicity of sample preparation and the diversity of the means to maintain slurry homogeneity with advantages over other techniques. In addition, the relative standard deviations are compatible with graphite furnace atomic absorption spectrometry (GF AAS), electrothermal vaporization inductively coupled plasma mass spectrometry (ETV ICP MS), and flame atomic absorption spectrometry (FAAS). In spite of this, the literature reports a series of procedures for the determination of metals in sediments. Chemical modifiers were used to avoid interferences caused by the matrix in the reading stage. They can be coinjected along with the sample or applied inside the graphite tube to form a permanent layer (permanent modifiers) (5). Permanent modification is better for allowing shorter furnace programs and for minimizing contamination related problems (6, 7). The elements (or mixtures) most commonly used as permanent modifiers in GF AAS are the carbide-forming ones (W, Zr, Nb, Ta, etc.) and platinum group metals (PGMs) (Pt, Rh, Ir, Ru, etc) (5). The influences of slurry concentration, modifier amount, and the pyrolysis step on the integrated absorbance signals for Pb and Sn in sediment slurry were studied, and it was proposed to coat the integrated platform of a transversely heated graphite atomizer with tungsten carbide–rhodium as a permanent modifier (8, 9).

Ultrasound-assisted extraction was compared with slurry sampling and microwave-assisted acid digestion for the determination of Cd, Pb, and Cu in biological and sediment samples by GF AAS (10). According to the authors, the main advantage of using ultrasound-assisted extraction in comparison with slurry sampling is the doubling of tube lifetime for all analytes.

Barbosa Jr. et al. (11) described a method for the determination of arsenic in sediment and soil slurries by GF AAS, using a W–Rh permanent modifier. In an experiment designed to optimize total tin determination in aqua regia-HF extracts from sediments by GF AAS, palladium was used as chemical modifier (12).

In another work, the use of ultrasonic agitation of the slurry followed by a fast electrothermal program using an Ir–Mg modifier provides the most consistent performance in terms of precision and accuracy for arsenic determination by GF AAS (13). A zirconium–iridium coating is proposed as a permanent modifier for the determination of tin in stream sediment, oyster tissue, and total diet slurries by GF AAS (14). Campillo et al. (15) proposed procedures by slurry preparation from a solution containing 2.5%, 25%, and 50% *v*/*v* of concentrated hydrofluoric acid for chromium, vanadium, and molybdenum determinations, respectively, by GF AAS.

Table 1. Temperature program for Mn and Ni determination in slurry sediment samples by GF AAS using permanent modifiers.

Fractionation of Cd and Pb was determined by GF AAS in the BCR (Communities Bureau of Reference of the European Commission, now the Standards, Measuring and Testing Programme) sediment reference material according to the BCR protocol. The use of palladium and magnesium nitrates modifiers in solution and use of Ru and Ir–Rh as permanent modifier were compared and showed similar results (16). Giacomelli et al. (16) studied different permanent modifiers (W, Rh, Ir, Ru, W–Rh, W–Ru, W–Ir) in the determination of arsenic, cadmium, and lead in microwave-digested environmental samples by GF AAS.

In a previous work (7), we developed methods for cadmium, chromium, and lead in marine sediments slurry samples by GF AAS using permanent modifiers.

In this work, some conditions were investigated (no modifier use, iridium, rhodium, ruthenium, and zirconium as permanent modifiers) to determine manganese and nickel in lake and marine sediments from a slurry sampling by GF AAS. The slurry was maintained homogeneous with air introduced by an aquarium pump.

Experimental

Instrumentation

All measurements were carried out with a GBC (Victoria, Australia) 906-AA atomic absorption spectrometer equipped with a graphite furnace and an autosampler PAL 3000 (GBC) with a deuterium arc lamp background correction, operated as recommended by the manufacturer. Integrated absorbance (peak area) was used exclusively for signal evaluation. Hollow cathode lamps from GBC were operated at 5.0 mA, with slit of 0.2 nm in at a wavelength of 279.5 nm for manganese (PN 41–0132–60) and at 4 mA, with a slit of 0.2 nm at 232.0 nm for nickel (PN 41–0136–00). The volume pipetted into the graphite tube was 20 μL for samples and calibration solutions. Argon (99.996%, White Martins, Belo Horizonte, MG, Brazil) was used as sheath gas. Pyrolytic graphite coated tubes without platform (GBC) were used in all studies. The treatment of the graphite tubes with the permanent modifiers was described previously, i.e., by applying 50 μL of a 1000 mg L^{-1} Ru, Ir, Zr, or Rh solution, independently for each modifier and submitting the tube to a specific temperature program (6, 7). This procedure was repeated 10 times to obtain a deposit of 500 μg of the permanent modifier. The graphite furnace temperature pro-

gram for the determination of all metals was optimized and is shown in the Table 1.

Reagents and solutions

All chemicals used were of analytical-reagent grade unless otherwise specified. Water was de-ionized in a Milli-Q system (Millipore, Bedford, Mass., USA). The nitric acid was from Vetec (Rio de Janeiro, Brazil, 022844).

The following 1000 μg mL^{-1} stock solutions were used: ruthenium (Fluka, Buchs, Switzerland, No. 84033), rhodium (Fluka, No. 83722), iridium (Fluka, No. 58195), and zirconium (Sigma-Aldrich, Milwaukee, Wis., USA, No. 27.497–6) all in 1 mol L^{-1} of hydrochloric acid. For the analytes the following 1000 mg L^{-1} solutions were used: all stock solutions for the two analytes were from titrisol Merck (Darmstad, Germany), in nitric acid (~0.5 mol L^{-1}).

Before use, all glasses were washed abundantly with solution of detergent, rinsed with water, maintained in bath with nitric acid (50% *v/v*) for a period of not less than 1 h, and then rinsed several times with deionized water. The autosampler cups were submitted to the same treatment. In all studies, the calibration was accomplished with aqueous solutions in nitric acid (0.5% *v/v*).

The limit of detection (LOD, μg L^{-1}) was calculated using the equation LOD = 3 × S_{BL}/b, where S_{BL} was the standard deviation of ten measurements of the blank (nitric acid, 0.5% v/v) and *b* is the slope of the calibration curve.

The following certified samples were analysed: PACS-S and MESS-2 from National Research of Council of Canada (NRCC) and San Joaquin Soil 2709 from National Institute of Standard and Tech nology (NIST, USA).

Procedure

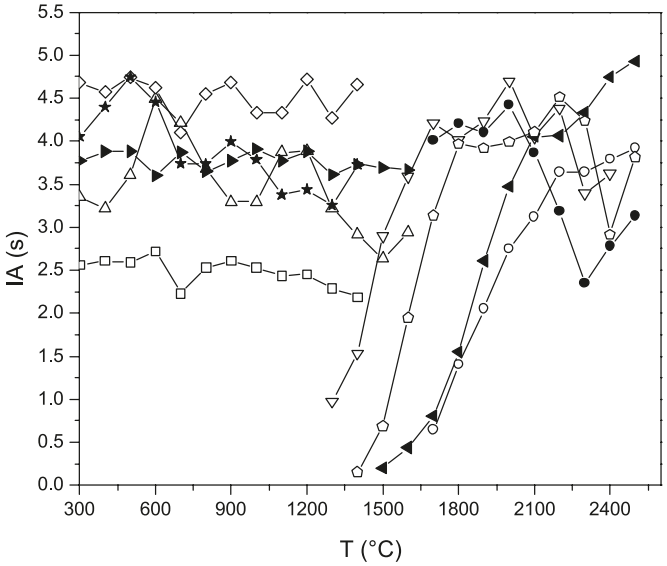
Samples of lake water (Lake Pampulha, MG, Brazil) were collected with a spatula of polyethylene and transferred to a polyethylene bottle, both decontaminated with nitric acid. Once taken to the laboratory, they were dried at 60 °C overnight, grinded in agate grail, passed consecutively in two screens until particles with grain size smaller than 50 μm were obtained. About 10 to 50 mg of the samples were weighted directly in the autosampler cups and added to a solution of nitric acid (3% *v/v*) and H_2O_2 (10%) until 1.0 g of solution was obtained. The suspension was maintained homogeneous with aid of air introduced by a capillary, produced by an aquarium pump (Big Air Super Pump A 230) (7). The capillary tube was placed into the bottom of the autosampler cups so that the bubbles were collected along with the sample. No problems caused by the introduction of air through the capillary tip of the autosampler were observed. This fact could be proved by the accuracy and precision of the results. For the certified materials, the preparation was made by using an appropriate mass of material and adding to the same solution already described to obtain a sample of 1.0 g.

Results and discussion

Thermal behavior of Mn and Ni in slurry sediments

By comparing the thermal behavior of each element submitted to the furnace temperature program, pyrolysis and atomization temperature curves were obtained for each analyte in sediment slurries using no modifier, iridium, rhodium, ruthenium, and zirconium (independently, 500 μg of each).

Fig. 1. Pyrolysis and atomization temperatures curve for 1 ng of Mn in slurry sediment with different modifiers: Zr (□), Zr′ (●) Rh (△), Rh′ (▽), Ru (◇), Ru′ (◀), Ir (▶), Ir′ (○), no mod (★), no mod′ (☆).



Pyrolysis and atomization temperature curves for manganese in slurry sediment samples are shown in Fig. 1. According to this figure, the best modifier for Mn is ruthenium permanent, with the best pyrolysis and atomization temperatures, respectively, of 1200 and 2500 °C, a characteristic mass of 0.9 pg and of 1.0, 1.2, 1.5, and 1.8 pg, respectively, for Rh, without modifier, Ir, and Zr. For the optimum conditions, the absorption pulses were symmetric, returning to the baseline in 2 s with a corrected background (about 0.1) and were similar to the peaks obtained for the calibration solutions. In the work of Tsalev and Slaveykova (17) on the behavior of ruthenium, rhodium, and palladium, the maximum pyrolysis temperatures for manganese were 1000, 600, and 600 °C for modifiers Ir, Rh, and Zr.

For nickel (Fig. 2), the best modifier was rhodium permanent with m_o of 33 pg, followed by 85, 120, 132, and 240 pg without modifier, Zr, Ir, and Ru, respectively. For this condition, the best pyrolysis and atomization temperatures were 600 and 2400 °C, respectively. For this condition the peak is also very symmetric and with corrected background, about 0.1 integrated absorbance s^{-1}.

Qi et al. (18) also have worked with Rh as a modifier and observed that chlorides of Pt, Rh, and Pd increased sensitivity for nickel only 1.02-fold to 1.09-fold. For ammonium vanadate, this increase was 1.52-fold and is the reason as why this modifier was used for the determination of nickel in plant materials.

Analytical figures of merit

Calibration curves with aqueous solutions were constructed following the procedure described in the Experimental section, applying the temperature programs given in Table 1. Before those curves for aqueous calibration and standard addition were built, similarities were observed for

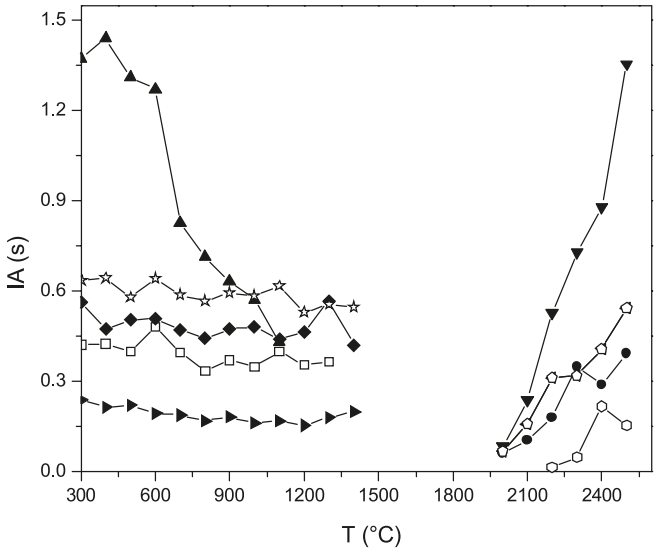
Table 2. Analytical characteristics for the determination of Mn and Ni in sediment samples by GF AAS using permanent modifiers.

Analyte	Modifier (500 µg)	mo* (pg)	mo (pg) (recommended)	LOD (µg L^{-1})	RSD (%) (n = 10)	R^2	Calibration range (µg L^{-1})
Mn	Ru	0.9	1.0	4.0	< 7.0	0.99978	0.0–100.0
Ni	Rh	33	20	0.9	< 8.8	0.99928	0.0–50.0

Table 3. Comparison between certified and determined values (µg L^{-1}) by GF AAS with the proposed methodologies.

	PACS-2		MESS-2		SAN JOAQUIN SOIL 2709	
Analyte	Certified	Determined	Certified	Determined	Certified	Determined
Mn	49.3±1.8	50.5±0.9	39.5±2.3	41.5±1.2	560±26	538±17
Ni	365±21	357±11	440±19	444±16	79±7	88±5

Fig. 2. Pyrolysis and atomization temperatures curve for 10 ng of Ni in slurry sediment with different modifiers: Ir (▫), Ir′ (●), Rh (▲), Rh′ (▼), Zr (◆), Zr′ (◀), Ru (▶), Ru′ (◇), no mod (★), no mod′ (☆).



the two analytes, and this way the calibration was accomplished with aqueous solutions. The analytical characteristics for the determination of all analytes are shown in the Table 2.

The calibration curves of all analytes had R^2 greater than 0.99 and were made employing the temperature programs optimized and presented in Table 1. The limits of detection (LODs) were satisfactory for GF AAS. The obtained RSD for all analytes were compatible for slurry GF AAS analysis, showing that the aquarium pump is appropriated for maintaining the stability of the slurry.

Table 3 shows the results obtained with the proposed methodologies for the two analytes (P > 0.05). All values determined were in agreement with the certified values, using aqueous calibration. Table 4 shows the recoveries of the two analytes in real lake sediments (Lake Pampulha, Belo Horizonte, MG, Brazil) in four levels of spike. As can be observed in Table 4, the recoveries showed acceptable values between 100.2% and 110.2% for manganese and 90.62% to 108.14% for nickel (19).

Table 4. Recovery studies of spiked Lake Pampulha sediments.

Expected concentration (µg L^{-1})	Recovery (%)	RSD (n = 5)
Mn		
5	100.2	1.41
7	104.8	1.68
8.5	109.6	1.39
10	110.2	1.88
Ni		
25	108.14	1.32
50	101.68	4.14
75	97.63	5.08
100	90.62	3.36

The lifetime of the graphite tubes was around 600 cycles of atomization. No significant changes in sensitivity were observed throughout the lifetime of the graphite tube.

Conclusions

The determination of manganese and nickel in certified sediment samples can be performed by GF AAS as slurries, using permanent modifiers. For manganese the best modifier was ruthenium and for nickel the best modifier was rhodium. The methodologies applied to the analysis of certified marine sediment samples (PACS-2 and MESS-2) and soil samples (San Joaquin 2079) showed results in agreement with the certified values (with a level of confidence higher than 95%) for all analytes, using aqueous calibration. Recovery studies in the spiked Lake Pampulha sediments showed acceptable values. The limits of detection were 4.0 and 0.9 µg L^{-1} for manganese and nickel, respectively.

Zinc oxide-tetrabutylammonium bromide tandem as a highly efficient, green, and reusable catalyst for the Michael addition of pyrimidine and purine nucleobases to α,β-unsaturated esters under solvent-free conditions

Abdolkarim Zare, Alireza Hasaninejad, Mohammad Hassan Beyzavi, Abolfath Parhami, Ahmad Reza Moosavi Zare, Ali Khalafi-Nezhad, and Hashem Sharghi

Abstract: An efficient procedure for the synthesis of carboacyclic nucleosides via microwave-assisted Michael addition of pyrimidine and purine nucleobases to α,β-unsaturated esters in the presence of catalytic amounts of zinc oxide (ZnO) and tetrabutylammonium bromide (TBAB) is described. The reactions proceed rapidly in good to excellent yields.

Key words: ZnO–TBAB, green chemistry, Michael addition, nucleobase, solvent-free, microwave.

Résumé : On a mis au point ne méthode efficace de réaliser la synthèse de nucléosides carboacycliques en faisant appel des additions de Michael assistées par les microondes de nucléobases purines et pyrimidines sur des esters α,β-insaturés en présence d'une quantité catalytique d'oxyde de zinc (ZnO) et de bromure de tétrabutylammonium (BTBA). Les réactions se produisent rapidement avec des rendements allant de bons à excellents.

Mots-clés : oxyde de zinc–bromure de tétrabutylammonium, chimie verte, addition de Michael, nucléobase, sans solvant, microonde.

[Traduit par la Rédaction]

Introduction

N-substituted pyrimidine and purine nucleobases have attracted much interest because of their potential use as antineoplastic (1), antiviral (1), and anticancer agents (2). Over the years, extensive efforts have been directed toward the synthesis of new classes of *N*-substituted nucleobases that brought about nucleoside subgroups with potent biological activities, including acyclic (3), carboacyclic (4), carbocyclic (5), aza (6), and thionucleosides (7). These compounds are usually prepared by *N*-alkylation of nucleobases with alkylating agents (8). Carboacyclic nucleosides can also be synthesized via Michael addition of nucleobases to electrophilic alkenes (9). This reaction normally requires a strong base to activate nucleobases. For this purpose, bases such as [bmim]OH (9*a*), 1,4-diazabicyclo[2,2,2]octane (DABCO) (9*b*), NaOEt (9*c*), K_2CO_3 (9*d*, 9*e*), and *t*-BuOK (9*f*) have been used. Moreover, an enzyme can also facilitate this transformation (9*g*).

The methods established for Michael addition of nucleobases to electrophilic alkenes are associated with one or more of the following drawbacks: (*i*) the use of solvents such as DMF or DMSO in which the workup of the reaction is not only cumbersome but also the green aspect of the reaction is annihilated by using DMF, (*ii*) long reaction times, (*iii*) low reaction yields and selectivity, (*iv*) the use of only unsubstituted electrophilic alkenes, and (*v*) the use of stoichiometric amounts of base or reagent.

Recently, mineral oxides have proved to be useful to chemists in the laboratory and industry because of the good activation of adsorbed compounds and reaction rate enhancement, selectivity, easier workup, recyclability of the supports, and the eco-friendly reaction conditions (10, 11). Zinc oxide (ZnO) is certainly one of the most interesting of these oxides that has been applied in different organic transformations (11). The coupling of microwave irradiation with the use of catalysts or mineral-supported reagents provides chemical processes with special attributes, such as enhanced reaction rates, higher yields, better selectivity, and improved ease of manipulation (12).

Having the above facts in mind and also in extension of our previous studies on aza-Michael reactions (9*b*, 10*a*, 11*a*,

11*b*, 13), solvent-free organic synthesis (8*a*, 9*b*, 13, 14), and nucleoside derivatives synthesis (8*a*, 8*b*, 9*b*, 14*c*, 14*d*, 14*h*, 15), we report herein a clean, facile, and rapid solventless method for Michael addition of pyrimidine and purine nucleobases to α,β-unsaturated esters in the presence of catalytic amount of ZnO–TBAB under microwave conditions (Schemes 1–3).

Results and discussion

To optimize reaction conditions, the reaction of uracil with *n*-butyl acrylate was studied as a model reaction to provide compound **1b**. At first, the catalytic effect of various catalysts in the presence of TBAB was examined under microwave conditions. The results are summarized in Table 1. As shown in Table 1, the best results were obtained when zinc oxide (20 mol%) was used. To understand the role of TBAB in the reaction, Michael addition of uracil to *n*-butyl acrylate was examined in the absence of TBAB under 200 W of microwave power (max. 100 °C). These conditions afforded the product in 39% yield after 40 min (Table 1, entry 8). Increasing the reaction time, the temperature, and the microwave power did not improve the reaction yield. Thus, the presence of TBAB in the reaction media is critically significant. In general, TBAB melts at 100 °C and creates a homogeneous reaction media whose resemblance is not far from that of ionic liquids (8*a*, 9*b*, 11*a*, 13). Moreover, this quaternary ammonium salt absorbs the microwave irradiation as well as generates in situ heat and increases the temperature

Table 1. The influence of different catalysts on Michael addition of uracil to *n*-butyl acrylate promoted by microwave irradiation (200 W, max. 100 °C) under solvent-free conditions.

higher than its melting point (100–103 °C) (8*a*, 9*b*, 11*a*, 13). TBAB may also act as a phase-transfer catalyst in our reaction (12*a*, 16). The model reaction was also tested in the presence of only TBAB. This reaction afforded the product in 64% within 25 min (Table 1, entry 9). Thus, ZnO and TBAB did not efficiently catalyze the Michael reaction separately; however, these catalysts together (ZnO–TBAB) act as an efficient catalytic system.

In another study, the model reaction was tested in several solvents to compare the efficiency and capacity of the solvent-free conditions with respect to solution conditions.

Table 2. Comparative synthesis of compound **1b** using solution versus the solvent-free conditions in microwave conditions (200 W, max. 100 °C).

Entry	Solvent	Time (min)	Yield (%)[a]
1	DMSO	35	82
2	DMF	35	77
3	HMPTA	35	42
4	*o*-Xylene	35	23
5	Solvent-free	25	93

[a]Isolated yield.

Thus, a mixture of uracil (2 mmol), ZnO (0.4 mmol), TBAB (0.4 mmol), and *n*-butyl acrylate (2.2 mmol) was irradiated in a microwave oven (200 W, max. 100 °C) in different solvents (10 mL) (Table 2). As is clear from Table 2, lower yields and longer reaction times were obtained in solution conditions. Therefore, the solvent-free method is more efficient.

The capability and efficiency of the microwave heating compared to conventional heating on the Michael reaction was also investigated. For this purpose, compound **1b** was prepared via Michael reaction between uracil and *n*-butyl acrylate in the presence of ZnO (20 mol%) and TBAB (20 mol%) under thermal conditions (100 °C). Using these conditions, the Michael adduct (**1b**) was isolated in 71% yield after 150 min. The reaction yield did not improve by increasing the reaction time and the temperature. Therefore, microwave irradiation is an essential factor to promote this reaction.

To establish the generality and applicability of this method, some pyrimidine and purine nucleobases were reacted with structurally diverse α,β-unsaturated esters to furnish the corresponding Michael adducts in good to high yields and short reaction times. The results are displayed in Table 3.

The presence of substituents (Me, F, and Br) on the 5-position of pyrimidine nucleobases had no significant effect on results of the reaction (Table 3, entries 3–5). The structural influence of α,β-unsaturated esters on the reaction was also investigated. Lower yields of products were obtained when both pyrimidine or purine nucleobases were introduced to sterically hindered α,β-unsaturated esters (Table 3, entries 8–10, 17, and 18). In these cases, prolonging the reaction times or increasing the microwave power or the temperature had no effect on the efficiency of the reaction. The bulkiness of alkoxy group (OR) affected the results of the Michael reaction. The yields decreased and the reaction times increased when nucleobase was added to esters possessing bulky alkoxy groups (Table 3, entries 6 and 7). Michael reaction of *N*-(2-oxo-1,2-dihydropyrimidin-4-yl)acetamide was also efficiently achieved (Scheme 2 and Table 3, entry 11).

Interestingly, in our method, pyrimidine nucleobases were regioselectively alkylated at the N1 positions. In these cases, N1,N3-dialkylated pyrimidines were obtained in trace yields. Moreover, pyrimidine nucleobases were not alkylated at the O-positions. Among the purine nucleobases, adenine and *N*-benzyl-9*H*-purin-6-amine were alkylated exclusively at the N9 positions; however, Michael reaction of hypoxanthine and 6-chloropurine afforded N7-adducts together with the N9 products in low yields (Table 3, entries 15 and 16). The sites of N-addition were indicated by ^{1}H and ^{13}C NMR spectral analysis. Several reports from the literature also confirmed these sites of N-addition (8*a*, 9*b*, 17).

Ease of recycling is a useful feature of zinc oxide; for the reaction of uracil with *n*-butyl acrylate no significant loss of product yields was observed when ZnO was used after recycling five times.

In summary, we have introduced an efficient new method for the preparation of carboacyclic nucleosides as biologically interesting compounds via microwave-assisted Michael addition of nucleobases to α,β-unsaturated esters. The advantages of this method are generality, high yields, short reaction times, simplicity, low cost, and matches with green chemistry protocols.

Experimental

All chemicals were purchased from Merck or Fluka chemical companies. ZnO powder (GR for analysis, 99%) from Merck company was used as a catalyst for all reactions. All known compounds were identified by comparison of their melting points and ^{1}H NMR data with the authentic samples. All reactions were carried out using laboratory microwave oven (MW 3000, Landgraf Company, Germany). IR spectra were run on a Shimadzu FTIR-8300 spectrophotometer, ν_{max} in cm^{-1}. The ^{1}H NMR (250 MHz) and ^{13}C NMR (62.5 MHz) were run on a Bruker Avanced DPX-250, FT-NMR spectrometer. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus. Microanalyses were performed on a PerkinElmer 240-B microanalyzer. Melting points were recorded on a Büchi B-545 apparatus in open capillary tubes.

General procedure for the synthesis of compound 1b

To a well ground mixture of uracil (0.224 g, 2 mmol), ZnO (0.033 g, 0.4 mmol), and TBAB (0.129 g, 0.4 mmol) in a microwave vessel was added *n*-butyl acrylate (0.282 g, 2.2 mmol) and mixed carefully with a small rod. The mixture was irradiated in a microwave oven for the powers, the temperatures, and the times reported in Table 3. Afterward, the reaction mixture was cooled to room temperature and suspended in EtOAc (50 mL), filtered, and the filtrate was washed with water (2 × 50 mL) and dried with $MgSO_4$. The solvent was evaporated and the crude product was purified by column chromatography on silica gel eluted with EtOAc–*n*-hexane (2:1). After isolation of the product, the remainder ZnO was reused.

Ethyl 3-(2,4-dioxo-3,4-dihydropyrimidin-1(2*H*)-yl)propanoate (1a)

Column chromathography on silica gel and eluting with EtOAc–*n*-hexane (2:1) gave a colorless solid. Isolated yield: 0.388 g (91%); mp 77–79 °C (lit. (9*b*) value mp 78–80 °C). ^{1}H NMR ($CDCl_3$, ppm) δ: 1.25 (t, 3H, *J* = 7.0 Hz, CH_3), 2.74 (t, 2H, *J* = 6.0 Hz, O = CCH_2), 3.85 (t, 2H *J* = 6.0 Hz, NCH_2), 4.11 (q, 2H, *J* = 7.0 Hz, OCH_2), 5.64 (d, 1H, *J* = 7.9 Hz, H_5 of uracil), 7.26 (d, 1H, J = 7.9 Hz, H_6 of uracil), 10.19 (s, 1H, *NH*).

152.9, 153.2, 158.0, 171.9. MS *m/z*: 264 [M^+]. Anal. calcd. for $C_{12}H_{16}N_4O_3$: C 54.54, H 6.10, N 21.20; found: C 54.33, H 6.36, N 21.35.

Butyl 3-(6-chloro-9*H*-purin-9-yl)propanoate (2e)

Column chromathography on silica gel and eluting with EtOAc–*n*-hexane (1:1) gave a colorless oil. Isolated yield: 0.381 g (67%). IR (KBr, cm^{-1}): 3090, 2965, 1730. ^1H NMR ($CDCl_3$, ppm) δ: 0.90 (t, 3H, *J* = 6.7 Hz, CH_3), 1.33 (m, 2H, CH_3CH_2), 1.56 (m, 2H, $CH_3CH_2CH_2$), 2.95 (t, 2H, *J* = 5.8 Hz, O=CCH_2), 4.09 (t, 2H, *J* = 6.9 Hz, OCH_2), 4.61 (t, 2H, *J* = 5.8 Hz, NCH_2), 8.52 (s, 1H, H_8 of 6-chloropurine), 8.99 (s, 1H, H_2 of 6-chloropurine). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 14.3, 19.8, 30.7, 38.8, 49.7, 65.6, 133.9, 148.3, 150.1, 151.3, 152.7, 172.3. MS *m/z*: 282 [M^+]. Anal. calcd. for $C_{12}H_{15}ClN_4O_2$: C 50.98, H 5.35, N 19.82; found: C 50.82, H 5.56, N 20.04.

Butyl 3-(6-chloro-9*H*-purin-7-yl)propanoate (3e)

Column chromathography on silica gel and eluting with EtOAc–*n*-hexane (1:1) gave a pale yellow solid. Isolated yield: 0.128 g (23%); mp 60–62 °C. IR (KBr, cm^{-1}): 3078, 2973, 1732. ^1H NMR ($CDCl_3$, ppm) δ: 0.93 (t, 3H, *J* = 6.8 Hz, CH_3), 1.35 (m, 2H, CH_3CH_2), 1.60 (m, 2H, $CH_3CH_2CH_2$), 2.99 (t, 2H, *J* = 5.8 Hz, O=CCH_2), 4.11 (t, 2H, *J* = 6.7 Hz, OCH_2), 4.87 (t, 2H, *J* = 5.8 Hz, NCH_2), 8.61 (s, 1H, H_8 of 6-chloropurine), 9.09 (s, 1H, H_2 of 6-chloropurine). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 14.1, 19.5, 30.4, 39.7, 52.3, 65.3, 122.0, 142.4, 150.3, 152.2, 161.9, 171.5. MS *m/z*: 282 [M^+]. Anal. calcd. for $C_{12}H_{15}ClN_4O_2$: C 51.07, H 5.35, N 19.82; found: C 50.74, H 5.16, N 20.01.

Ethyl 3-(6-amino-9*H*-purin-9-yl)-2-methylpropanoate (2f)

Column chromathography on silica gel and eluting with EtOAc–*n*-hexane (3:1) gave a colorless solid. Isolated yield: 0.186 g (37%); mp 134–136 °C (lit. (9*b*) value mp 134–137 °C). ^1H NMR ($CDCl_3$, ppm) δ: 1.12–1.21 (complex, 6H, CH_2CH_3 and $CHCH_3$), 3.13 (m, 1H, O=CCH), 4.09 (q, 2H, *J* = 6.9 Hz, OCH_2), 4.22 (m, 1H, one H of NCH_2), 4.43 (m, 1H, one H of NCH_2), 6.24 (s, 2H, NH_2), 7.83 (s, 1H, H_2 of adenine), 8.35 (s, 1H, H_8 of adenine).

Ethyl 3-(6-amino-9*H*-purin-9-yl)butanoate (2g)

Column chromathography on silica gel and eluting with EtOAc–*n*-hexane (3:1) gave a colorless solid. Isolated yield: 0.145 g (29%); mp 102–104 °C (lit. (9*b*) value mp 100–101 °C).^1H NMR ($CDCl_3$, ppm) δ: 1.14 (t, 3H, *J* = 6.8 Hz, CH_2CH_3), 1.66 (d, 3H, *J* = 4.7 Hz, $CHCH_3$), 2.89 (m, 1H, one H of O=CCH_2), 3.15 (m, 1H, one H of O=CCH_2), 4.06 (q, 2H, *J* = 6.8 Hz, OCH_2), 4.97 (m, 1H, NCH), 6.31 (s, 2H, NH_2), 7.80 (s, 1H, H_2 of adenine), 8.27 (s, 1H, H_8 of adenine).

Intramolecular cyclization reaction — Palladium(0)-catalyzed cyclization is more effective than tin hydride mediated reaction

Krishna C. Majumdar, Pradip Debnath, Abu Taher, and Amarta K. Pal

Abstract: Intramolecular CH arylation of pyrone, pyridone, uracil, imidazole, and benzimidazole derivatives are carried out in the presence of a Pd catalyst to form potentially bioactive fused heterocyclic compounds, whereas the *n*-Bu_3SnH-mediated aryl radical cyclization of the precursors **3** afforded mainly halogen-reduced uncyclized products.

Key words: Pd(0) catalyst, CH arylation, intramolecular cyclization, regioselectivity.

Résumé : Opérant en présence d'un catalyseur de palladium, on a réalisé l'arylation intramoléculaire du CH de dérivés de la pyrone, de la pyridone, de l'uracile, de l'imidazole et du benzimidazole pour former des composés hétérocycliques condensés potentiellement bioactifs alors que la cyclisation des précurseurs **3** à l'aide de radicaux aryles, catalysée par le *n*-Bu_3SnH, fournit principalement des produits non cyclisés desquels les halogènes ont été réduits.

Mots-clés : catalyseur de Pd(0), arylation du CH, cyclisation intramoléculaire, régiosélectivité.

Introduction

The synthesis of heteroaromatic compounds by intramolecular cyclizations has received increasing attention in organic chemistry, since a wide variety of such molecules show potential biological activities as pharmaceutical and agrochemical compounds (1). Several intramolecular reactions have been discovered, and their applications in organic chemistry have also been well documented in the literature. The most important ones include the Claisen rearrangement (2), free radical reactions (3), Pd(0)-catalyzed insertion reactions (4), etc. Free radical reactions are one of the most straightforward ways for carbon–carbon bond formation in organic synthesis. Several methods have been devised to effect such radical cyclizations, with *n*-Bu_3SnH- or *n*-Bu_3SnCl-mediated reactions being the most explored. The highly toxic nature of the tin reagent, the difficulties associated with the removal of toxic tin from the reaction products, and reduction of the intermediate carbon centered radical by *n*-Bu_3SnH are frequently highlighted as reasons to avoid these reagents (5). The disadvantages associated with these reagents have led synthetic organic chemists to find alternative methods and (or) reagents to accomplish such reactions. Reagents such as less toxic silanes and germanes have been used as substitutes for *n*-Bu_3SnH and *n*-Bu_3SnCl (6). In recent years, palladium-catalyzed (7) cyclization reactions have been shown to be a highly effective and practical method in organic synthesis. Having established this chemistry, it has been rapidly applied in an intramolecular sense to the synthesis of carbocyclic (8) and heterocyclic (9) compounds. The main advantage is that the reagent is non-toxic and involves an easy workup procedure, and hence can successfully be applied for the synthesis of bioactive molecules.

Recently, there is much interest in the synthesis of 2-pyrone derivatives due to their diverse pharmacological properties (10). Several natural (11) and synthetic (12) 2-pyrones exhibit remarkable biological activity. 3-Deazauridine, a pyridone-based compound, is currently undergoing clinical trials as an anticancer agent (13), and it is also effective against tumor growth (14). Some [1,2-*a*] fused imidazoles are also known to have anti-ulcer, antidepressant, and antimicrobial activity (15). Several [1,2-*a*]fused benzimidazoles have antitumor activity (16). Although Pd-catalyzed intramolecular cyclization is a well-known process, its application on pyrone, pyridone, uracil, imidazole, and benzimidazole systems is much less documented. Recently, the palladium-mediated three component synthesis of 2,3-fused furo-pyridones has been reported (17). An unsuccessful attempt to synthesize the 5-membered fused heterocycles by intramolecular aromatic substitution by an imidazol-2-yl radical has been reported (18). However, Dubois and co-workers (19) reported the synthesis of bioactive 5*H*-imidazol[2,1-*a*]isoindoles by the Pd-catalyzed intramolecular arylation of *N*-benzyl-2-iodoimidazole. Recently, we have successfully demonstrated the radical reaction (20) and a Pd-catalyzed Heck reaction (21) on

benzannulated analogues of pyrone and pyridone. Here, we describe a comparative study of radical and Pd(0)-catalyzed cyclizations as a synthetic method to access pyron-, pyridon-, imidazol-, benzimidazol-, and uracil-annulated heterocycles of biological interest.

Results and discussion

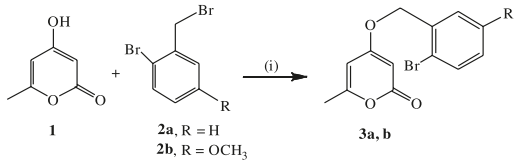
For our initial investigation, we have selected compounds **3a**–**3l** as starting materials. These ethers were prepared by the alkylation of 4-hydroxypyrone, 4-hydroxypyridones, 5-hydroxyuracil, imidazole, and benzimidazole with 2-bromobenzyl bromide and 2-bromo-5-methoxybenzyl bromide. Compounds **3a**–**3b** were prepared in 80% and 84% yields, respectively, by using a classical alkylation procedure from 4-hydroxypyrone (**1**) and 2-bromobenzyl bromide (**2a**) or 2-bromo-5-methoxybenzyl bromide (**2b**) in refluxing acetone in the presence of K_2CO_3 (Scheme 1). The compounds **3a**–**3b** were characterized by their elemental analyses and spectroscopic data. Similarly, other substrates **3c**–**3l** were also prepared.

As our goal was to synthesize new heterocycles by C–C bond formation, we first considered *n*-Bu_3SnCl-mediated radical cyclization conditions. The substrate **3a** was subjected to optimal reaction conditions (20), i.e., *n*-Bu_3SnCl, $Na(CN)BH_3$, AIBN in dry toluene under nitrogen atmosphere at 80 °C for 4 h. A single product, solid, mp 92–94 °C, was isolated by column chromatography. The ^1H NMR spectrum of the product revealed that cyclization did not occur. Only the halogen-reduced product **4a** was obtained. We then tried to carry out the cyclization reaction in the presence of *n*-Bu_3SnH, instead of *n*-Bu_3SnCl, in refluxing toluene. But we again failed to achieve the radical cyclization. However, radical cyclization between the precursors **3c**–**3f** and *n*-Bu_3SnH gave the cyclized products **5c**–**5f** in poor yields (4%–7%) with uncyclized reduced products **4c**–**4f** (64%–83%). The use of a stoichiometric amount (22) of radical initiator gave improved yields **5a** (20%), **5b** (17%), **5c** (29%), **5d** (25%), **5e** (27%), and **5f** (31%) respectively, with halogen-reduced products **4a**–**4f** (44%–56%) (Scheme 2).

Aryl radical cyclization onto the benzannulated analogues of these compounds (20), namely coumarins, quinolones, and uracil derivatives (precursors **3g**–**3h**) gave better yields of cyclized product with no reduced product. This may be due to the better stabilization of radical intermediates in the benzannulated series. Aryl radicals are nucleophilic, and electron-withdrawing and (or) radical-stabilizing groups improve the cyclization. The formation of six-membered ring heterocycles at C-3 (not at C-5) may easily be explained by the generation of aryl radical **6**, followed by a 6-*endo trig* cyclization to give allyl radical intermediate **7** (Scheme 2). The oxidative elimination of hydrogen from intermediate **7** may afford **5**. The regioselective formation of compounds **5** from substrates **3** may be attributed to the stability of the intermediate allylic radical **7**. Otherwise, a 6-*endo* attack at C-5 position would give a α-*oxo* radical (**8**), which is unstable.

Attempted five-membered ring aryl radical cyclizations with the azole, imidazole, and benzimidazole radical precursors **3i** and **3k** using *n*-Bu_3SnH gave only reduced uncyclized products **4i** and **4j**, respectively, even with slow addition of the tin reagent (Scheme 3). It is also important to note that attempts to effect the five-membered ring cyclization with a stoichiometric amount of the initiator did not divert the reaction away from dehalogenation. Since radical precursors **3i** and **3k** gave only the reduced products, we did not proceed further with the precursors **3j** and **3l**.

Scheme 1. Reagents and conditions: (*i*) dry acetone, K_2CO_3, reflux, 6 h.



1 **2a**, R = H; **2b**, R = OCH_3 **3a, b**

Cyclizations onto five-membered ring azoles is less favored due to the strain of formation of products with two five-membered rings, one of which is a heteroarene (23). Bowmen and co-workers (24) showed that alkyl radical cyclization onto imidazoles and benzimidazoles, 6-membered ring cyclization, gave better yields than five-membered ring cyclization, whereas aryl radical cyclization gave only reduced products in the case of five-membered ring cyclizations.

To increase the yield of cyclized products, we then utilized Pd(0)-catalyzed cyclization reactions. We have examined the influence of factors such as the nature of the base, the ligand, the solvent, and the reaction temperature, which might influence the efficiency of the reaction. The Heck reaction was carried out at 100 °C in DMF with 10 mol% of $Pd(OAc)_2$, tri-2-tolylphosphine as ligand, and K_2CO_3 as the base with substrate **3a**. Only one product was obtained after 6 h, in 25% yield, along with a large amount of starting material (62%). Increasing the reaction temperature (up to 150 °C) and also the reaction time did not improve the yield of the reaction due to extensive decomposition of the starting material. We have also examined the influence of bases like Cs_2CO_3, KOAc, organic bases like triethylamine, and the ligands triphenylphosphine and tri-4-tolylphosphine. Potassium acetate proved to be the best base with the tri-2-tolylphosphine ligand for this cyclization, improving the yield to 42%. Changing the solvent (DMSO, CH_3CN) did not provide any improvement in the yield. However, the best results were achieved under Jeffery's two phase conditions (25). The reaction conditions for this transformation involved dissolving compound **3a** (0.34 mmol) in dry DMF, followed by the addition of $Pd(OAc)_2$ (10 mmol%), TBAB (0.34 mmol), KOAc (0.85 mmol), and stirring the reaction mixture for 4 h at 95 °C under an inert atmosphere. The reaction was monitored by TLC and an appreciable change was observed. Isolation of the product by flash column chromatography furnished a solid in 87% yield. The product was characterized by elemental analysis and spectral data. Compounds **3b**–**3l**, on similar treatment, furnished compounds **5b**–**5l** in 61%–96% yields (Table 1).

The palladium(0)-catalyzed reaction affords better yields than the tin hydride protocol, except in the case of uracil derivatives, where the yields are comparable with the tin hydride-mediated reaction.

The coupling of the precursors **3a**–**3f** occurs regioselectively at C-3 as in the case of the radical cyclization re-

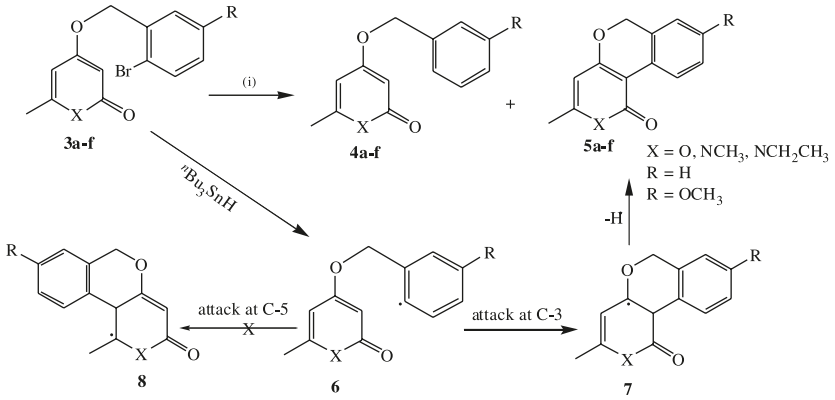
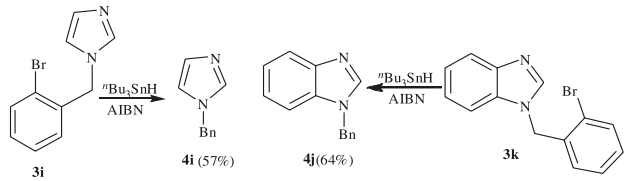


Scheme 3. Radical reactions of imidazole and benzimidazole.



actions. Mori and co-workers (26) also regioselectively synthesized compound **5i** by utilizing $PdCl_2$-$2PPh_3$ in DMSO at 140 °C, but we have achieved better results using Jeffery's protocol in a short reaction time and at a lower temperature.

The proposed mechanism for this annulation process is shown in Scheme 4. Initially, the oxidative addition of compound **3** to palladium may form the arylpalladium intermediate **9**. Complex **9** may then add to the double bond to give a σ–alkylpalladium intermediate **10**, and finally β–hydrogen elimination from intermediate **10** may provide products **5**. Similar mechanisms for the Pd-catalyzed CH-arylation of π-excessive heteroarenes have been reported in the literature (27). Recently, the mechanism of the Pd-catalyzed Heck reaction has been reviewed (28).

Conclusion

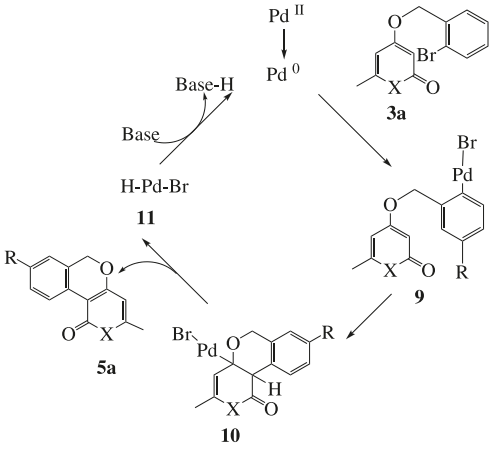
In conclusion, we have successfully extended the Pd(0)-catalyzed intramolecular Heck reaction to the regioselective synthesis of potentially bioactive heterocyclic compounds. The process is quite simple, practical, and affords good to excellent yields of the desired products and is far superior to the toxic tin hydride methodology. The mildness of the reaction conditions and the high level of chemoselectivity allow this annulation process to serve as a powerful synthetic tool for the preparation of complex aromatic heterocycles.

Experimental

General

Melting points were determined in open capillaries and are uncorrected. IR spectra were recorded on a PerkinElmer L 120-000A spectrometer (γ_{max} in cm^{-1}) using samples as neat liquids, and solid samples were recorded in KBr disks. ^1H NMR (300 MHz, 400 MHz, 500 MHz) spectra were recorded on a Bruker-300, Bruker DPX-400, and Bruker DRX-500 spectrometers in $CDCl_3$ (chemical shift in δ) with TMS as internal standard. Silica gel [(60–120, 230-400 mesh), Spectrochem, India] was used for chromatographic separation. Silica gel G [E-Merck (India)] was used for TLC. Petroleum ether refers to the fraction boiling between 60 and 80 °C.

Scheme 4.



General procedure for the preparation of compounds 3a–3l

A mixture of 4-hydroxy-6-methyl pyrone (**1a**, 0.20 g, 1.59 mmol) 2-bromobenzyl bromide (**2a**, 0.475 g, 1.90 mmol) or 2-bromo-5-methoxybenzyl bromide (**2b**, 0.530 g, 1.90 mmol) and anhydrous potassium carbonate (3 g) were refluxed in dry acetone (75 mL) on a water bath for 5–6 h. The reaction mixture was cooled, filtered, and the solvent was removed. The residual mass was extracted with CH_2Cl_2 (3 × 30 mL). The CH_2Cl_2 extract was washed with water (3 × 30 mL) and dried (Na_2SO_4). The residual mass, after removal of CH_2Cl_2, was subjected to column chromatography over silica gel (60–120 mesh) using petroleum ether – ethyl acetate as the eluant to give compounds **3a–3b.** Similarly, the substrates **3c–3l** were prepared from pyridone, uracil, imidazole, and benzimidazole, respectively. All solid compounds were recrystalized from an acetonitrile–methanol mixture.

General procedure for the radical reaction of compounds 3a–3i and 3k

A deoxygenated solution of *n*-Bu_3SnH in toluene (0.12 ml, 0.40 mmol) was added dropwise to a magnetically stirred solution of the precursors **3** (0.34 mmol) and azobis(isobutyro)nitrile (0.056 gm) in dry toluene (10 mL) under a nitrogen atmosphere. The mixture was refluxed for 4–7 h. After completion of the reaction, the solvent was removed under reduced pressure. The residue was dissolved in CH_2Cl_2 (10 mL) and stirred with 10% aq. KF solution (10 mL) for 1 h. The aqueous phase was extracted with CH_2Cl_2 (3 × 25 mL). The combined CH_2Cl_2 extracts were washed with water (2 × 20 mL), brine solution (1 × 20 mL), and dried (Na_2SO_4). The solvent was evaporated under reduced pressure. The crude products were purified by column chromatography over silica gel using petroleum ether – ethyl acetate mixture as eluant. All solid compounds were crystallized from an acetonitrile–methanol mixture.

4-Benzyloxy-6-methyl-2*H*-pyran-2-one (4a)

Eluted from the column with 20% ethyl acetate – petroleum ether mixture as colorless solid (53%), mp 92–94 °C (acetonitrile-methanol). IR (KBr, cm^{-1}) υ: 2923, 1728, 1244, 1035. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 2.20 (s, 3H), 4.99 (s, 2H), 5.48 (d, *J* = 2.1 Hz, 1H), 5.82 (t, *J* = 0.8 Hz, 1H), 7.34-7.42 (m, 5H). 4-Benzyloxy-1-ethyl-6-methyl-1,2-dihydropyridin-2-one (4e)

Eluted from the column with 55% ethyl acetate – petroleum ether mixture as a colorless solid (47%), mp 156 to 157 °C (acetonitrile–methanol). IR (KBr, cm^{-1}) υ: 2970, 1723, 1228. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 1.24 (t, *J* = 7.0 Hz, 3H), 2.32 (s, 3H), 3.98 (q, *J* = 7.1 Hz, 2H), 4.94 (s, 2H), 5.80 (d, *J* = 2.5 Hz, 1H), 5.88 (d, *J* = 2.6 Hz, 1H), 7.32-7.37 (m, 5H). MS *m/z*: 243 (M^+). Anal. calcd. for $C_{15}H_{17}NO_2$: C 74.05, H 7.04, N 5.76; found: C 74.24, H 7.14, N 5.94.

1-Ethyl-4-[(3-methoxybenzyl)oxy]-6-methyl-1,2-dihydropyridin-2-one (4f)

Eluted from the column with 55% ethyl acetate – petroleum ether mixture as a colorless solid (56%), mp 173 to 174 °C (acetonitrile–methanol). IR (KBr, cm^{-1}) υ: 2945, 1727, 1222. ^1H NMR ($CDCl_3$, 300 MHz, ppm) δ_H: 1.25 (t, *J* = 7.0 Hz, 3H), 2.33 (s, 3H), 3.81 (s, 3H), 3.99 (q, *J* = 7.1 Hz, 2H), 4.94 (s, 2H), 5.83 (d, *J* = 1.9 Hz, 1H), 5.89 (d, *J* = 2.4 Hz, 1H), 6.86-6.96 (m, 3H), 7.26 (dd, *J* = 1.3, 7.7 Hz, 1H). MS *m/z*: 273 (M^+). Anal. calcd. for $C_{16}H_{19}NO_3$: C 70.31, H 7.01, N 5.12; found: C 70.19, H 6.83, N 5.30.

The precursors **3g** and **3h** did not give any reduced uncyclized products (20*a*).

1-Benzyl-1*H*-imidazole (4i)

Eluted from the column with 40% ethyl acetate – petroleum ether mixture as a gummy mass (57%). IR (KBr, cm^{-1}) υ: 2919, 1233. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 5.08 (s, 2H), 6.87 (s, 1H), 7.06 (s, 1H), 7.11 (d, *J* = 6.5 Hz, 2H), 7.27-7.35 (m, 3H), 7.51 (s, 1H). MS *m/z*: 158 (M^+). Anal. calcd. for $C_{10}H_{10}N_2$: C 75.92, H 6.37, N 17.71; found: C 75.99, H 6.33, N 17.82.

1-Benzyl-1*H*-benzo[*d*]imidazole (4j)

Eluted from the column with 40% ethyl acetate – petroleum ether mixture as a colorless solid (64%), mp 110–112 °C (acetonitrile–methanol). IR (KBr, cm^{-1}) υ: 2919, 1265. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 5.31 (s, 2H), 7.13 (d, *J* = 7.5 Hz, 2H), 7.19-7.32 (m, 6H), 7.79 (d, *J* = 7.5 Hz, 1H), 7.90 (s, 1H). MS *m/z*: 208(M^+). Anal. calcd. for $C_{14}H_{12}N_2$: C 80.74, H 5.81, N 13.45; found: C 80.88, H 5.92, N 13.50.

General procedure for the Heck type of reaction for compounds 3a–3l

To a mixture of **3a–3l** (0.34 mmol), Bu_4NBr (0.113 g,

© 2008 NRC Canada

0.34 mmol), and KOAc (0.083 g, 0.85 mmol) in dry and degassed DMF (25 mL) in a screw-cap sealed tube was added $Pd(OAc)_2$ (0.008 g, 10 mol%) under an inert atmosphere, and the sealed tube was placed in a preheated oil bath at 80–120 °C (Table 1) with stirring for 1.5–12 h (Table 1, for each reaction). The reaction mixture was cooled and diluted with water (50 mL). This was extracted with ethyl acetate (3 × 20 mL). The organic extract was washed with hydrochloric acid (1N, 20 mL), water (3 × 30 mL), and saturated brine solution (25 mL), and dried (Na_2SO_4). The solvent was distilled off. The crude products were purified by column chromatography over silica gel (60–120 mesh) using petroleum ether – ethyl acetate mixture as the eluant to give compounds **5a**–**5l.** All solid compounds were recrystalized from dichloromethane–petroleum ether (60–80 °C).

3-Methyl-1*H*,6*H*-pyran[4,3-*c*]isochromen-1-one (5a)

Eluted from the column with 20% ethyl acetate – petroleum ether mixture as a colorless solid (87%), mp 110–113 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}) υ: 2924, 1705, 1240, 1042. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 2.26 (s, 3H), 5.22 (s, 2H), 5.90 (d, *J* = 0.6 Hz, 1H), 7.03 (d, *J* = 7.6 Hz, 1H), 7.22-7.26 (m, 1H), 7.33 (t, *J* = 8.0 Hz, 1H), 8.44 (d, *J* = 8.0 Hz, 1H). MS *m*/*z*: 214 (M^+). Anal. calcd. for $C_{13}H_{10}O_3$: C 72.89, H 4.71; found: C 72.82, H 4.75.

8-Methoxy-3-methyl-1*H*,6*H*-pyran[4,3-*c*]isochromen-1-one (5b)

Eluted from the column with 20% ethyl acetate – petroleum ether mixture as a colorless solid (94%), mp 122 to 123 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}) υ: 2920, 1704, 1246, 1045. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 2.24 (s, 3H), 3.80 (s, 3H), 5.19 (s, 2H), 5.89 (s, 1H), 6.58 (d, *J* = 2.5 Hz, 1H), 6.86 (dd, *J* = 2.6, 8.72 Hz, 1H), 8.39 (d, *J* = 8.7 Hz, 1H). ^{13}C NMR ($CDCl_3$, 125 MHz, ppm) δ_C: 20.4, 55.7, 69.5, 100.2, 100.6, 110.4, 113.7, 119.4, 126.0, 129.0, 159.5, 161.8, 162.2, 165.0. HRMS calcd. for $C_{14}H_{13}O_4^+$(MH): 245.0814, found 245.0807. Anal. calcd. for $C_{14}H_{12}O_4$: C 68.85, H 4.95; found: C 69.08, H 4.89.

2,3-Dimethyl-2,6-dihydro-1*H*-isochromeno[4,3-*c*]pyridin-1-one (5c)

Eluted from the column with 45% ethyl acetate – petroleum ether mixture as a colorless solid (88%), mp 100–102 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}) υ: 2916, 1643, 1239. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 2.35 (s, 3H), 3.55 (s, 3H), 5.09 (s, 2H), 5.89 (s, 1H), 7.04 (d, *J* = 7.4 Hz, 1H), 7.19-7.37 (m, 2H), 8.77 (d, *J* = 7.5 Hz, 1H). ^{13}C NMR (125 MHz, ppm) δ_C: 16.2, 25.9, 63.9, 95.2, 100.5, 118.6, 119.4, 121.7, 123.1, 123.5, 123.7, 141.2, 157.2, 157.6. MS *m*/*z*: 227 (M^+). Anal. calcd. for $C_{14}H_{13}NO_2$: C 73.99, H 5.77, N 6.16; found: C 74.20, H 5.69, N 6.29.

8-Methoxy-2,3-dimethyl-2,6-dihydro-1*H*-isochromen[4,3-*c*]pyridin-1-one (5d)

Eluted from the column with 45% ethyl acetate – petroleum ether mixture as a colorless solid (83%), mp 98 to 99 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}) υ: 2916, 1644, 1251. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 2.33 (s, 3H), 3.54 (s, 3H), 3.81 (s, 3H), 5.07 (s, 2H), 5.87 (s, 1H), 6.60 (d, *J* = 2.5 Hz, 1H), 6.86 (dd, *J* = 2.6, 8.7 Hz, 1H), 8.73 (d, *J* = 8.8 Hz, 1H). MS *m*/*z*: 257 (M^+). Anal. calcd. for $C_{15}H_{15}NO_3$: C 70.02, H 5.88, N 5.44; found: C 70.19, H 5.95, N 5.38.

2-Ethyl-3-methyl-2,6-dihydro-1*H*-isochromen[4,3-*c*]pyridin-1-one (5e)

Eluted from the column with 45% ethyl acetate – petroleum ether mixture as a colorless solid (78%), mp 113 to 114 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}) υ: 2982, 1644, 1246. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 1.32 (t, *J* = 6.9 Hz, 3H), 2.39 (s, 3H), 4.09 (q, *J* = 7.1 Hz, 2H), 5.09 (s, 2H), 5.85 (s, 1H), 7.03 (d, *J* = 7.6 Hz, 1H), 7.18-7.36 (m, 2H), 8.77 (d, *J* = 8.0 Hz, 1H). ^{13}C NMR (125 MHz, ppm) δ_C: 14.2, 20.8, 39.7, 69.3, 100.8, 106.1, 124.0, 124.7, 127.0, 128.5, 128.8, 129.1, 146.0, 162.0, 162.9. HRMS calcd, for $C_{15}H_{16}O_2^+$(MH): 242.1172; found 242.1184. Anal. calcd. for $C_{15}H_{15}NO_2$: C 74.67, H 6.27, N 5.81; found: C 74.62, H 6.04, N 5.99.

2-Ethyl-8-methoxy-3-dimethyl-2,6-dihydro-1*H*-isochromen[4,3-*c*]pyridin-1-one (5f)

Eluted from the column with 45% ethyl acetate–petroleum ether mixture as a colorless solid (81%), mp 105–107 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}) υ: 2917, 1643, 1215. ^1H NMR ($CDCl_3$, 400 MHz, ppm) δ_H: 1.30 (t, *J* = 7.0 Hz, 3H), 2.37 (s, 3H), 3.80 (s, 3H) 4.09 (q, *J* = 7.0 Hz, 2H), 5.06 (s, 2H), 5.84 (s, 1H), 6.59 (d, *J* = 2.5 Hz, 1H), 6.86 (dd, *J* = 2.6, 8.7 Hz, 1H), 8.73 (d, *J* = 8.7 Hz, 1H). MS *m*/*z*: 271 (M^+). Anal. calcd. for $C_{16}H_{17}NO_3$: C 70.83, H 6.32, N 5.16; found: C 71.05, H 6.33, N 5.20.

Generation, observation, and reactivity of furyl- and thienylketenes and bisketenes

Nanyan Fu, Annette D. Allen, Winnie Chan, Shinjiro Kobayashi, Thomas T. Tidwell, Daryoush Tahmassebi, Angelica Aguilar, Eduardo Peña Cabrera, and Jazmin Godoy

Abstract: 2- and 3-Furylketenes (**18** and **20**), 2- and 3-thienylketenes (**19** and **21**), and bis(2,5-ketenyl)thiophene (**24**) have been generated as observable reactive intermediates by photochemical Wolff rearrangements. Stabilization energies of the monoketenes **18**–**21** have been determined by DFT computations of isodesmic energy changes, and these ketenes are predicted to be modestly destabilized relative to phenylketene. Rate constants for reaction of **18**–**21** with H_2O and with *n*-$BuNH_2$ have been measured and are similar to those of the 2-, 3-, and 4-pyridylketenes (**1**). The product of reaction of 2-furylketene (**18**) with H_2O is calculated to be stable as an acid enol, and reaction of **18** with the stable free radical TEMPO forms a stable ester enol, consistent with stabilization by intramolecular H-bonding to the furyl oxygen. Bis(thienyl)-1,2-bisketenes **26** and **28** have been generated by photochemical cyclobutenedione ring opening and are highly reactive in ring closure. This is attributed to destabilization of the ketenes and stabilization of the cyclobutenediones by the electron donating aryl groups.

Key words: ketenes, furans, thiophenes, reactive intermediates, photolysis, mechanisms.

Résumé : Faisant appel à des réarrangements de Wolff photochimiques, on a pu générer des 2- et 3-furylcétènes (**18** et **20**), des 2- et 3-thiénylcétènes (**19** et **21**) ainsi que le bis(2,5-cétényl)thiophène (**24**) sous la forme d'intermédiaires réactifs observables. On a calculé les énergies de stabilisation des monocétènes (**18**–**21**) sur la base de la théorie de la fonctionnelle de densité de changements isodesmiques d'énergie et ces calculs permettent de prédire que ces cétènes sont légèrement déstabilisés par rapport au phénylcétène. On a mesuré les constantes de la vitesse de réaction des produits **18**–**21** avec l'eau et avec la butylamine et elles sont similaires à celles observées avec les 2-, 3- et 4-pyridylcétènes (**1**). On a calculé que le produit de la réaction du 2-furylcétène (**18**) devrait être stable sous la forme d'énol acide et la réaction du produit **18** avec le radical libre stable TEMPO forme un ester énolique stable qui est en accord avec la stabilisation par une liaison hydrogène intramoléculaire avec l'oxygène du furyle. On a généré les bis(thiényl)1,2-biscétènes (**26** et **28**) par ouverture photochimique de la cyclobutènedione et ils sont très réactifs vis-à-vis de la réaction de fermeture de cycle. Cette réactivité est attribuée à la déstabilisation des cétènes et à la stabilisation des cyclobutènediones par les groupes aryles électrodonneurs.

Mots-clés : cétènes, furanes, thiophènes, intermédiaires réactifs, photolyse, mécanismes.

[Traduit par la Rédaction]

Introduction

The chemistry of heteroarylketenes provides opportunities for the elucidation of the interaction of the highly electrophilic ketenyl group with heteroaryl groups. 2-Pyridylketene (**3**) was formed by photolysis of the diazo ketone **1** and observed in an Ar matrix at 10 K or in solution as a highly reactive species at 25 °C, along with the pyridyl ylide **2** (eq. [1]) (1). Photolysis of **2** in the matrix forms **3** (1*a*), and substituted analogues **4**–**6** of **2** have been generated and directly observed in solution at 25 °C, and interpreted as possessing antiaromatic character on the basis of the ^{1}H NMR chemical shifts of **4** (R = *i*-Pr_3Si), calculated nucleus independent chemical shifts (NICS), and calculated bond alternations (1*b*).

[1] 
1 2 3

2-Pyridylketene (**3**) forms a dimer **7** by a [4+2] cycloaddition (1*a*), and upon reaction with water (2*a*) and with *n*-$BuNH_2$ (2*b*) forms the dihydropyridine derivatives **8**

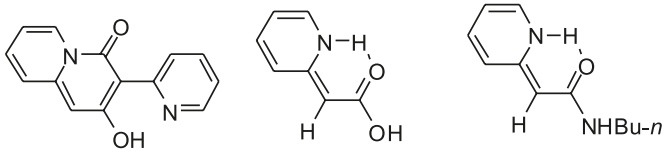
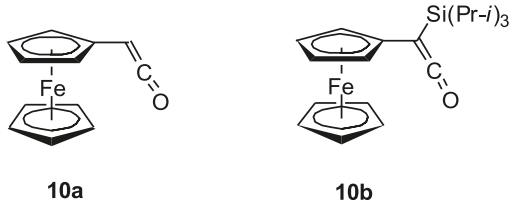
4 (R = *i*-Pr_3Si, Me, 2-Pyr) **5** **6**

and **9**, respectively, as observable reactive intermediates that lead to the corresponding pyridylacetic acid and amide (2*a*, 2*b*). The reactivities of the 3- and 4-pyridylketenes with water and with *n*-$BuNH_2$ have also been examined (2).



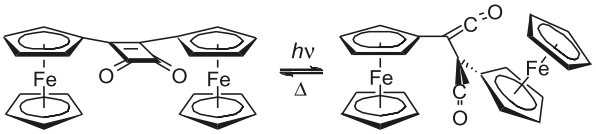
7 **8** **9**

Pyridyl groups are electron poor, and we have also recently reported on the reactivity of electron-rich ferrocenylketenes, including the highly reactive parent **10a** (3*a*) and the triisopropylsilyl derivative **10b**, which is very unreactive because of steric protection and electronic stabilization by the triisopropylsilyl group, and has been isolated as a crystalline solid and characterized by X-ray (3*b*). In studies of bisketene/cyclobutenedione interconversions (3*c*, 3*d*), diferrocenyl-1,2-bisketene **12** was generated by photolysis of the cyclobutenedione **11** (eq. [2]), and the thermal reformation of **11** from **12** was found to be quite rapid, a result attributed to destabilization of the bisketene by the electron-donating ferrocenyl groups, which however stabilize the cyclobutendione **11** (3*a*).



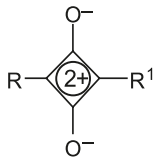
10a **10b**

[2]



11 **12**

The goal of the present investigation is to extend the examination of electron-rich arylketenes to furylketenes, thienylketenes, and the analogous bisketenes. The chemistry of furyl- and thienylketenes has been recently reviewed (3*e*, 4*a*), and these monoketenes have found significant applications in synthesis (4) and mechanistic studies of their formation (4*m*, 4*n*), but none of these have been characterized by direct observation in solution nor by quantitative reactivity studies. Furylcyclobutenediones have not been previously examined, but reactions of 1,2-bis(2-thienyl)cyclobutenedione with alkynes and carbene precursors have recently been studied (4*o*, 4*p*). Cyclobutenediones have many applications, including use as linkers in DNA analogues (5*a*), chemosensors (5*b*), bioactive compounds with medical applications (5*c*), and receptors for molecular recognition (5*d*). These may also be converted to 1,3-squaraines (**13**), which



13

have found many uses (6), especially as dyes (6*b*, 6*d*–6*g*), in photodynamic therapy (6*e*), as redox switches (6*f*), and as photoconducting and photoimaging agents (6*f*).

Furyl- and thienyl-ketenes contain electron-rich aryl groups, which are subject to oxidation, and in this respect, resemble ferrocenylketenes but differ from pyridylketenes. Thus, these promise to reveal new types of reactivity not observed with the pyridylketenes. The properties of furyl and thienyl groups may be expressed by their substituent constants, particularly the σ^+_p values, which are significantly more negative than for phenyl, showing their strong electron-donor properties (Table S-1).[2]

2-Furylketene **18** has been reported to form by Wolff rearrangement in a matrix at 10 K, and its structure confirmed by the IR absorption at 2135 cm^{-1} (4*e*), but has not been observed in solution. There is apparently no previous study of 3-furylketene, while 2- and 3-thienylketenes have been generated by dehydrochlorination of the corresponding thienylacetyl chlorides as unobserved intermediates, which reacted by in situ [2+2] cycloaddition with 1,3-cyclohexadiene (4*b*), but have not been directly observed.

Results

For preparation of the 2- and 3-furyl- and thienylketenes **18**–**21**, the known 2- and 3-diazoacetylfurans **14** (4*b*, 4*j*) and **16** (7*a*) and diazoacetylthiophenes **15** (7*b*) and **17** (4*j*) were prepared by the reaction of diazomethane with the corresponding furoyl and thiophenecarbonyl chlorides. Upon photolysis in CH_3CN or hexane of the diazoacetyl furans and thiophenes (eqs. [3] and [4]), formation of the corresponding ketenes was confirmed, as identified by their IR absorptions at 2132 (**18**), 2124 (**19**), 2127 (**20**), and 2122 (**21**) cm^{-1}.

Previously, we have reported the generation and direct observation of bis(ketenyl)benzenes prepared by dehydrochlorinations or by photochemical Wolff rearrangements (8). To extend this work to the heteroaryl field, 2,5-bis(diazoacetyl)thiophene (**23**) (4*k*, 4*l*) was prepared from the reaction of the bis(acyl choride) **22** with diazomethane, and upon photolysis in CH_3CN presumably gave the bisketene **24**, (eqs. [5] and [6]), as indicated by the ketenyl IR absorption at 2124 cm^{-1} (Fig. 1) and depletion of the diazo and keto absorption at 2112 and 1612 cm^{-1}, respectively. Reaction of both of the diazo ketone groups is not proven, but this was previously found for 1,3-bis(diazoacetyl)benzene (8).

3,4-Di-(2-thienyl)cyclobutenedione **25** (4*o*, 4*p*) and 3,4-di-

[5] 
22 **23**

[6] 
23 **24** (IR 2124 cm^{-1})

(3-thienyl)cyclobutenediones **27** (9) upon photolysis in CH_3CN gave bis(2-thienyl)- and bis(3-thienyl)-1,2-bisketenes **26** and **28**, respectively, as identified by their infrared absorption at 2111 and 2104 cm^{-1}, respectively (eqs. [7] and [8]). Rate constants for thermal ring closure of the bisketenes back to the cyclobutenediones were measured at 25 °C by UV as we have done previously (3*a*, 3*c*, 3*d*) by observing the disappearance of the ketene absorptions and the reformation of cyclobutenedione absorptions. Measured rate constants were obtained in $CDCl_3$ of 5.24 ± 1.20 and 1.51 ± 0.23 s^{-1}, **26** and **28** respectively. These are similar to the rate constant of 2.59 s^{-1} found for the corresponding bis(ferrocenyl) compound **12** (in CH_3CN), and are consistent with the strong electron-donating ability of all these groups (3*a*).

27 **28**

Upon laser flash photolysis (LFP) in CH_3CN in the presence of excess *n*-$BuNH_2$, the diazo ketones **14**–**17** each showed the immediate formation of a transient detected by UV spectroscopy, which decayed with evolution of a second transient, which decayed at a slower rate. As found in previous studies of ketene amination (2*b*,10), the first transients are assigned as the ketenes **18**–**21**, respectively, and the initial observed process rate is formation of the amide enols **29a**–**32a**, while the second step is their conversion to the amides **33a**–**36a** (Scheme 1).

Confirmation of these assignments was obtained by LFP of the 2-furyl- and 2-thienyl diazo ketones **14** and **15**, with

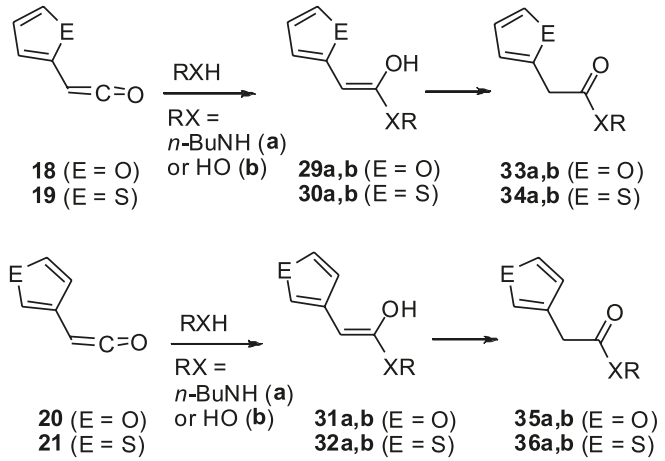
Scheme 1. Animation and hydration of furylketenes and thienylketenes.



detection of the corresponding ketenes **18** and **19** by observation of the characteristic ketenyl IR absorptions, which formed the respective amide enols **29a** and **30a**, also identified by IR, and finally conversion to the amides **33a** and **34a**, respectively. The IR absorption of the amide enol **30a** from ketene **19** is shown in Fig 2. A representative UV trace for the growth and decay of the UV spectrum of the amide enol **30a** from **19** is shown in the Supplementary data.[2] Rate constants determined by IR for the decay of the ketene absorption and for the formation of the amide enol by IR are in agreement, and also agree with the respective rate constants obtained by UV. Plots of the first-order rate constants obtained by UV vs. [*n*-BuNH$_2$] gave second-order rate constants as reported in Table 1, and the measured rate constants and the plots vs. [*n*-BuNH$_2$] as well as the IR rate data are given in the Supplementary data.[2]

Similarly laser flash photolysis of diazo ketones **14**–**17** in H_2O were monitored by time-resolved UV spectroscopy, and showed the growth of transients absorbing between 240 and 320 nm, followed by a slower decay, and these processes gave first-order rate constants as reported in Table 1. In studies of phenylketene hydration (2*a*, 11), there is some ambiguity in the assignment of these processes, as the identity of the reacting species cannot be confirmed by IR spectroscopic determination. For phenylketene, the growth in the absorption has been assigned to conversion of the acid enol to the acid and the decrease in the absorption to formation of the acid enol from the ketene (11*b*). For the conversion of ketenes **18**–**21** to enols **29b**–**32b** and acids **33b**–**36b** (Scheme 1), the assignments cannot be made with certainty.

For 2-thienylketene (**19**), rate constants for hydration in 80:20 (*v*/*v*) H_2O/CH_3CN were obtained by UV measurement of the decay of the ketenyl absorption at 250 nm and by UV measurement of growth of the acid enol at 300 nm, with good agreement between the two wavelengths.

Photolysis of 2-diazoacetylfuran (**14**) in the presence of 2,2,5,5-tetramethylpiperidinyl-1-oxyl (TEMPO) gave an initial diadduct assigned on the basis of its spectroscopic properties to the structure **37** from 1,2-diaddition of TEMPO to the ketene **18** (eq. [9]). However, upon standing, **37** underwent isomerization to a structure identified as the ester enol **38** (eq. [9]). The analogous reaction of 2-diazoacetylthiophene (**15**) gave the 1,2-addition product **39** (eq. [10]), which was stable over time. Reactions of arylketenes with TEMPO have been previously investigated and found to form 1,2-addition products analogous to **37** (12), but have not previously led to observable enols. The formation of **38** is attributed to the stabilization provided by an intramolecular hydrogen bond to the furyl oxygen shown (see Discussion).

Table 2. B3LYP/6–311++G(d,p) calculated relative minimum and maximum energies (kcal/mol) for conformations of furyl- and thienyl-ketenes.

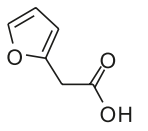
Ketene	Angle (°)	ΔE (kcal/mol)	Angle (°)	ΔE (kcal/mol)	Angle (°)	ΔE (kcal/mol)
2-Furyl	0.0	0.0	80.0	2.89	180.0	1.00
3-Furyl	20.0	0.86	100.0	2.40	180.0	0.0
2-Thienyl	0.0	0.0	80.0	1.48	160.0	0.13
3-Thienyl	0.0	0.64	100.0	2.86	180.0	0.0

Computational studies

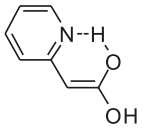
The favored conformations of 2- and 3-furyl-ketenes **18** and **20** and the 2- and 3-thienylketenes **19** and **21** were calculated at the HF/6–31G* and B3LYP/6–311G++(d,p) levels. For each ketene, two minimum energy conformations were found, with coplanar ketenyl and heteraryl groups, and the ring hetero atom *syn* or *anti* to the ketenyl group, as reported in Table 2. For the 2-furyl- and 2-thienylketenes, the *syn* conformations were favored by 1.00 and 0.13 kcal/mol, respectively, while for the 3-furyl- and 3-thienylketenes, the *anti*-conformations were favored by 0.86 and 0.64 kcal/mol, respectively (1 cal = 4.184 J).

Computations at the B3LYP/6–311++G(d,p) level of the structure of the enol **29b** from hydration of 2-furylketene (**18**) found the most stable geometry was a planar structure with the enediol moiety *syn* to the ring oxygen and with an intramolecular hydrogen bond between the oxygen atom in the furan ring and one of the OH groups on the enol (Fig. 3). This was 2.9 kcal/mol more stable than the other minimum energy structure, in which the enediol moiety is *anti* to the ring oxygen, and twisted 30° out of the furan plane. The most stable geometry calculated for the enol **30b** from hydration of 2-thienylketene (**19**) was a non-planar structure with the enediol moiety *anti* to the ring oxygen and twisted 40° out of the thiophene plane (Fig. 3). This was 0.6 kcal/mol more stable than the other minimum energy structure, which had the enediol moiety *syn* to the ring sulfur, and twisted 20° out of the thiophene plane. Details of the computations are given in Table S-2.[2]

2-Furylacetic acid (**40**) is calculated at the B3LYP/6–311++G(d,p) level to be 15.2 kcal/mol more stable than the enol **29b**. For comparison, 2-pyridylactic acid was found to be more stable than the hydrogen bonded enol **41** by 7.0 kcal/mol and more stable than the hydrogen bonded dihydropyridine **8** by 2.1 kcal/mol (2*c*). The comparatively greater stability of **8** and **41** relative to 2-pyridylacetic acid is consistent with the greater basicity of the pyridyl nitrogen.



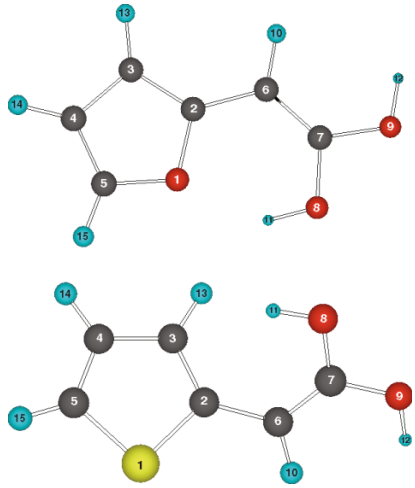
40



41

Stabilization energies for the furyl- and thienylketenes **18**–**21** were obtained at the B3LYP/6–31G(*d*) level from isodesmic energy comparisons using eq. [11] as done previously (3*a*, 13) and gave values (kcal/mol) of –1.41 (2-furyl-, **18**), –0.61 (3-furyl-, **20**), –1.53 (2-thienyl, **19**), and 0.00 (3-thienyl, **21**). These compare to *SE* values of –0.7 for ferrocenyl and 1.3 for phenyl. The phenyl value was obtained in this work at the B3LYP/6–31G(*d*) level and is close to the value of 0.9 previously (13) obtained at the HF/6–31G* level. The lower stabilization by the furyl, thienyl, and ferrocenyl groups relative to phenyl is modest but is consistent with the previously proposed destabilization of ketenes by strong π-donors.

Fig. 3. B3LYP/6–311++G(d,p) calculated energy minimum structures for 2-furyl enol **29b** (upper) and 2-thienyl enol **30b** (lower).



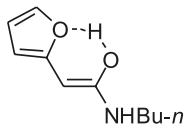
[11] 
Discussion

2-Furyl- and 2-thienylketene are somewhat more reactive than their 3-isomers in both amination and hydration, with relative rates ranging from 2.1 to 8.4 (Table 1). The Hammett σ_m and σ_p constants (Table S-1)[2] (14) are available for the thienyl derivatives and indicate the 2-isomer is somewhat more electron-withdrawing, and this may cause the difference, as the more electron-withdrawing group would preferentially stabilize a transition state for nucleophilic attack. A direct interaction between the heteroatom and the ketenyl oxygen in the transition state would be expected to be destabilizing, unless there is assistance by hydrogen bonding with the solvent.

There are significant reactivity differences between the initial first step of nucleophilic addition to the ketene, and the second step of conversion of the enol, with k_1/k_2 ratios of 58, 7.4, 40, and 17 for amination of ketenes **18**–**21**, respectively, while for hydration, the corresponding ratios are 2.7,

© 2008 NRC Canada

5.7, 2.2, and 2.5, respectively. For hydration and amination of 2-pyridylketene, corresponding rate ratios for formation and decay of the intermediates **8** (2*a*) and **9** (2*b*) were 110 and 1.8×10^7, respectively. The large rate differences for the 2-pyridyl system were attributed to the formation of dihydropyridine structures with strong intramolecular hydrogen bonds. 2-Furylketene gives a distinctly larger k_1/k_2 ratio in amination compared with 2–thienylketene, and this may also be attributed to formation of an intermediate hydrogen-bonded amide enol **42**. This effect is not observed in hydration, where hydrogen bonding to the solvent may preempt an intramolecular interaction. The B3LYP/6–311++G(d,p) computations suggest that the enol from hydration of 2-furylketene is stabilized by formation of an intramolecular hydrogen bond (Fig. 3), but this computation is for the gas phase, and in H_2O solvent, the formation of intermolecular hydrogen bonds would preclude formation of a long-lived enol. For addition of *n*-$BuNH_2$ in CH_3CN, hydrogen bonding to the solvent is much weaker, and so the enols are relatively longer lived, especially for the amide enol **42** from 2-furylketene.



42

As noted for the reaction of 2-furylketene with TEMPO, the final product was an ester enol **38** (eq. [9]), and the stability of this product may be attributed to the formation of an intramolecular hydrogen bond from the enol hydrogen to the furan oxygen, with a possible contribution from steric factors.

The ketene stabilization parameters *SE* (kcal/mol) of –1.41 (2-furyl-, **18**), –0.61 (3-furyl-, **20**), –1.53 (2-thienyl, **19**), and 0.00 (3-thienyl (**21**) do not differ greatly in magnitude, but indicate the 2-furyl- and 2-thienylketenes are less stable than their 3-isomers. However, the rather small variations in the reactivity of these ketenes in amination and in hydration suggest these are not major factors. This may arise because of opposing effects of these aryl groups on the reactant and transition state energies. Overall, the observed differences in reactivity of the heteroarylketenes are consistent with the small differences in the various measures of substituent effects.

The measured rate constants for ring closure of the 2- and 3-thienyl bisketenes **26** and **28** in $CDCl_3$ exceed that of the diphenyl bisketene of 3.89×10^{-2} s^{-1} in isooctane (3*d*) by factors of 130 and 39, respectively. The rate constants for ring closure of other bisketenes to cyclobutenediones have been found to be greater in CH_3CN compared with isooctane by factors of 9 to 16, but **26** and **28** still appear to be more reactive than the diphenyl bisketene, consistent with the ketene destabilizing and cyclobutenedione stabilizing effects of the thienyl substituents.

In summary, the various ketenes and bisketenes reported have been characterized as transient observable intermediates in solution, and quantitative measurements of their reactivities have been made. Contrasting behavior between the furyl- and thienylketenes compared with those of pyridylketenes may be interpreted in terms of the greater electron-acceptor character of the latter. Kinetic studies of ring closure of thienyl substituted bisketenes give quantitative measures of the substituent effects of the thienyl groups. Evidence for intramolecular hydrogen bonding in enols of furylacetic acid derivatives is observed, but not for the corresponding 2-thienyl products. These studies should facilitate the utilization of these intermediates in practical applications.

Experimental

Materials and instruments

Reagents and solvents were the best available commercial grade and were used as received. Time-resolved IR experiments at the University of Toronto were carried out with a Digilab instrument using a 1 mm CaF_2 IR flow cell and laser flash photolysis with a 308 nm excimer laser. The time resolution was 5 μs, and the spectral resolution was 4 cm^{-1}. UV measurements were carried out as described previously (2, 3*a*–3*c*).

2-Diazoacetylfuran (14) (4*j*, 7*b*)

2-Furoyl chloride (493 μL, 653 mg, 5 mmol) in ether (10 mL) was added dropwise to a stirred cooled solution of diazomethane (25 mmol) in ether (40 mL), and the solution was stirred overnight. Excess diazomethane was removed by evacuating with a water aspirator pump, and the remaining solution was concentrated. Chromatography (silica gel, CH_2Cl_2 1% Et_3N) gave the known compound as a yellow oil (457 mg, 67%), which gave yellow crystals on cooling with a mp near room temperature (lit. mp 25 °C) (15*a*). IR (CH_3CN): 2112, 1619 cm^{-1}; IR (hexanes): 2108, 1639 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.50 (dd, J = 0.8, 1.6 Hz, 1H), 7.13 (dd, J = 0.8, 3.6 Hz, 1H), 6.54 (dd, J = 1.6, 3.6 Hz, 1H), 5.92 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 175.5, 151.6, 145.4, 114.5, 112.6, 54.1.

2-Furylketene (18)

Using TRIR detection with LFP of 1.08×10^{-4} mol/L 2-diazoacetylfuran (**14**) in CH_3CN 2-furylketene was detected at 2132 cm^{-1}. Rayonet irradiation of **14** in hexane formed 2-furylketene as identified by the IR absorption at 2134 cm^{-1}.

N-*n*-Butyl 2-furylacetamide (33a)

A solution of **14** (20 mg, 0.15 mmol) and *n*-$BuNH_2$ (1.45 mL, 1.08 g, 14.7 mmol) in hexanes (50 mL) was photolyzed for 10 min with 300 nm light at room temperature. Excess *n*-$BuNH_2$ and solvent was removed at reduced pressure to give a yellow–brown oil. Chromatography (silica gel, EtOAc/hexanes 1:2 *v*/*v*) gave **33a** as a colorless oil (10 mg, 40%), which in the refrigerator gave white crystals, mp 35–36 °C. IR (CH_3CN) 3390 (br), 1678 cm^{-1}. UV–vis (CH_3CN) λ_{max} (ε): 213 nm (1.6×10^4); UV–vis (water) λ_{max} (ε): 220 nm (9.9×10^3). ^1H NMR (400 MHz, $CDCl_3$) δ: 7.39 (dd, J = 0.8, 1.8 Hz, 1H), 6.36 (dd, J = 1.8, 3.2 Hz, 1H), 6.23 (dd, J = 0.8, 3.2 Hz, 1H), 5.65 (s, br, 1H), 3.60 (s, 2H), 3.26–3.21 (m, 2H), 1.47–1.41 (m, 2H), 1.32–1.27 (m, 2H), 0.90 (t, J = 7.2 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 168.6, 149.2, 142.8, 111.0, 108.7, 39.7, 36.6, 31.7, 20.2,

13.9. ESI-MS *m/z*: 182 ([M + 1]$^+$). HR-ESI-MS *m/z* calcd. for $C_{10}H_{16}NO_2$: 182.1175, found: 182.1180.

3-Diazoacetylfuran (16) (7*a*)

3-Furoyl chloride (653 mg, 5 mmol) in ether (10 mL) was added dropwise to a stirred cooled solution of diazomethane (25 mmol) in ether (40 mL), and the solution was stirred overnight. Excess diazomethane and solvent were removed under reduced pressure. Chromatography (silica gel, CH_2Cl_2/hexanes 3:1 *v/v* 1% Et_3N) gave **15** as yellow crystals (454 mg, 67%), mp 43.0–43.5 °C. UV–vis (CH_3CN) λ_{max} (ε): 210 nm (1.34×10^4), 287 nm (1.36×10^4); UV–vis (water) λ_{max} (ε): 215 nm (1.10×10^4), 295 nm (1.68×10^4). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.93 (dd, *J* = 0.8, 1.5 Hz, 1H), 7.45 (dd, *J* = 1.5, 1.8 Hz, 1H), 6.68 (dd, *J* = 0.8, 1.8 Hz, 1H), 5.64 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 180.5, 144.9, 144.4, 126.4, 108.4, 54.8. EI-MS *m/z*: 136 (M$^+$, 100), 95 (60), 80 (93). HR-EI-MS *m/z* calcd. for $C_6H_4N_2O_2$: 136.0273, found: 136.0270.

Detection of 3-furylketene (20)

Laser flash photolysis of 5.5×10^{-3} mol/L 3-diazoacetylfuran (**16**) in isooctane gave IR absorption at 2110 cm^{-1} and 1646 cm^{-1}. Irradiation of **16** in a Rayonet reactor with 300 nm light for 2 min gave 80% conversion to ketene. Additional irradiation for 1 min gave only 3-furylketene at 2127 cm^{-1}.

***N*-*n*-Butyl 3-furylacetamide (35a)**

A solution of **16** (20 mg, 0.147 mmol) and *n*-$BuNH_2$ (1.45 mL, 1.075 g, 14.7 mmol) in hexanes (50 mL) was photolyzed for 20 min with 300 nm light at room temperature. Excess *n*-$BuNH_2$ and solvent were removed under reduced pressure to give a yellow oil, and chromatography (silica gel, ethyl acetate/hexanes 1:2 *v/v*) gave **35a** (13 mg, 48%) as white crystals, mp 40–41 °C. IR (CH_3CN): 3389 (br), 1674 cm^{-1}. UV–vis (CH_3CN) λ (ε): 220 nm (4.4×10^3); UV–vis (water) λ (ε): 220 nm (6.1×10^3). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.43 (dd, *J* = 0.4, 1.6 Hz, 1H), 7.38 (dd, *J* = 0.8, 1.6 Hz, 1H), 6.34 (dd, *J* = 0.4, 0.8 Hz, 1H), 5.55 (s, br, 1H), 3.39 (s, 2H), 3.25–3.20 (m, 2H), 1.46–1.42 (m, 2H), 1.32–1.26 (m, 2H), 0.90 (t, *J* = 7.2 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 170.4, 144.0, 141.0, 118.6, 111.5, 39.6, 33.2, 31.8, 20.2, 13.9. ESI-MS *m/z*: 182 ([M + 1]$^+$). HR-ESI-MS *m/z* calcd. for $C_{10}H_{16}NO_2$: 182.1175, found: 182.1180.

2-Diazoacetylthiophene (15) (7*b*, 15*a*–15*c*)

2-Thienylcarbonyl chloride (144 mg, 1 mmol) in ether (10 mL) was added dropwise to a stirred cooled solution of diazomethane (10 mmol) in ether (20 mL), and the solution was stirred overnight. Excess diazomethane and solvent were removed under reduced pressure, and chromatography (silica gel, CH_2Cl_2/hexanes 1:1 v/v 1% Et_3N) gave **15** as yellow crystals (130 mg, 85%), mp 58–59 °C. IR (CH_3CN): 2108, 1606 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.59 (dd, *J* = 1.1, 5.0 Hz, 1H), 7.51 (dd, *J* = 1.1, 3.7 Hz, 1H), 7.11 (dd, *J* = 3.7, 5.0 Hz, 1H), 5.82 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 179.1, 142.7, 132.4, 129.2, 128.2, 54.4. EI-MS *m/z*: 152 (100, M$^+$), 111 (71), 96 (98), 84 (16), 70 (62). HR-EI-MS *m/z* calcd. for $C_6H_4N_2OS$: 152.0044, found: 152.0049. Mp 67–68° (lit. (7b) 67 °C). UV: 216 nm, 309 nm (in methanol).

2-Thienylketene (19)

2-Diazoacetylthiophene (**15**, 1.34×10^{-4} mol/L in CH_3CN) upon LFP gave 2-thienylketene as detected at 2124 cm^{-1}.

***N*-*n*-Butyl 2-thienylacetamide (34a) (15*d*)**

A solution of **15** (20 mg, 0.13 mmol) and *n*-$BuNH_2$ (1.3 mL, 961 mg, 13.2 mmol) in hexanes (50 mL) was photolyzed for 10 min with 300 nm light at room temperature. Excess *n*-$BuNH_2$ and solvent were removed under reduced pressure to give **34a** (24 mg, 92%) as a brown oil. IR (CH_3CN): 1674 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.25–7.24 (m, 1H), 7.00–6.98 (m, 1H), 6.94–6.93 (m, 1H), 5.65 (s, br, 1H), 3.77 (s, 2H), 3.25–3.20 (m, 2H), 1.45–1.39 (m, 2H), 1.33–1.25 (m, 2H), 0.88 (t, *J* = 7.4 Hz, 3H).

Reaction of 2-furylketene (18) with TEMPO

A solution of 2-diazoacetylfuran (24 mg, 0.18 mmol) in hexane (10 mL) was irradiated with 300 nm light at room temperature with stirring for 9 min, followed by addition of TEMPO (47 mg, 0.30 mmol) dissolved in hexane (0.3 mL). After 2 h stirring, the mixture was filtered and concentrated. Chromatography (silica gel, EtOAc/hexane 1:9 *v/v*, 1% Et_3N) at 4 °C gave material identified as predominantly the unstable TEMPO ester **37** (61 mg, 47%). IR ($CDCl_3$): 1780 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.38 (d, 1H), 6.43–6.42 (d, 1H), 6.35 (s, 1H), 5.34 (s, 1H), 1.3–1.75 (m, 12H), 1.24 (s, 3H), 1.22 (s, 3H), 1.14 (s, 3H), 1.08 (s, 3H), 1.04 (s, 3H), 0.92 (s, 3H), 0.80 (s, 3H), 0.67 (s, 3H). On standing 14 h in the NMR tube, the product changed to **38**: IR ($CDCl_3$): 3689, 3607 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.55–7.54 (d, 1H), 6.61–6.60 (d, 1H), 6.35 (s, 1H), 5.42 (s, 1H), 1.3–1.75 (m, 12H), 1.35 (s, 3H), 1.29 (s, 3H), 1.23 (s, 3H), 1.20 (s, 3H), 1.19 (s, 3H), 1.14 (s, 3H), 1.11 (s, 6H), 1.10 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 136.4, 127.7, 114.6, 90.3, 88.9, 60.7, 60.7, 60.0, 59.9, 40.4, 39.9, 39.2, 33.7, 33.3, 32.0, 20.7, 20.6, 20.2, 17.2, 17.1. HR-ESI-MS *m/z* calcd. for $C_{24}H_{41}N_2O_4$: 421.3060, found: 421.3078.

3-Diazoacetylthiophene (17) (4*k*)

3-Thienylcarbonyl chloride (733 mg, 5 mmol) in ether (10 mL) was added dropwise to a stirred cooled solution of diazomethane (25 mmol) in ether (40 mL), and the solution was stirred overnight. Excess diazomethane and solvent were evaporated under reduced pressure, and chromatography (silica gel, CH_2Cl_2/hexanes 2:1 *v/v* 1% Et_3N) gave **17** as yellow crystals (468 mg, 62%), mp 59–60 °C. UV–vis (CH_3CN) λ_{max} (ε): 222 nm (1.43×10^4), 257 nm (1.35×10^4), 293 nm (1.50×10^4); UV–vis (water) λ_{max} (ε): 223 nm (1.09×10^4), 257 nm (9.01×10^3), 301 nm (1.88×10^4). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.90 (m, 1H), 7.41 (m, 1H), 7.33 (m, 1H), 5.80 (s, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 180.8, 140.9, 129.3, 126.8, 126.0, 54.7.

3-Thienylketene (21)

3-Diazoacetylthiophene (**17**, 7.7 mmol/L) in iso-octane (IR: 2106 cm^{-1} and 1639 cm^{-1}) upon 1 min irradiation in a Rayonet reactor with 300 nm light gave 50% conversion to

© 2008 NRC Canada

ketene. Additional irradiation for 2 min showed only **21**, IR: 2122 cm^{-1}.

***N*-*n*-Butyl 3-thienylacetamide (36a)**

A solution of **17** (20 mg, 0.13 mmol) and *n*-$BuNH_2$ (1.30 mL, 961 mg, 13.1 mmol) in hexanes (50 mL) was photolyzed for 15 min with 300 nm light at room temperature. Excess *n*-$BuNH_2$ and solvent were evaporated under reduced pressure, and the solid product was purified by chromatography (silica gel, EtOAc/hexanes 1:2 *v*/*v*) to give **36a** (21 mg, 81%) as white crystals, mp 51–53 °C. IR (CH_3CN): 3392, 1673 cm^{-1}. UV–vis (CH_3CN) λ_{max} (ε): 233 nm (6.3×10^3); UV–vis (water) λ_{max} (ε): 235 nm (6.8×10^3). ^1H NMR (400 MHz, $CDCl_3$) δ: 7.34 (dd, *J* = 2.8, 4.8 Hz, 1H), 7.14–7.13 (m, 1H), 7.00 (dd, *J* = 1.2, 4.8 Hz, 1H), 5.55 (s, br, 1H), 3.59 (s, 2H), 3.24–3.19 (m, 2H), 1.44–1.38 (m, 2H), 1.30–1.24 (m, 2H), 0.88 (t, *J* = 7.4 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 170.6, 135.2, 128.7, 126.9, 123.6, 39.6, 38.4, 31.7, 20.2, 13.9. EIMS *m*/*z*: 197 (29, M^+), 182 (1), 155 (3), 98 (100), 57 (52). HR-EI-MS *m*/*z* calcd. for $C_{10}H_{15}NOS$: 197.0874, found: 197.0874.

2,5-Bis(diazoacetyl)thiophene (23) (4*k*, 4*l*)

Thiophene-2,5-dicarbonyl chloride (418 mg, 2 mmol) in ether (10 mL) was added dropwise to a stirred cooled solution of diazomethane (20 mmol) in ether (40 mL), and the solution was stirred overnight. Excess diazomethane and residual solvent were evaporated under reduced pressure, and chromatography (silica gel; CH_2Cl_2 1% Et_3N) gave **23** as a pale yellow solid (187 mg, 42%), mp 150 °C (dec.). ^1H NMR (400 MHz, DMSO-d_6 and $CDCl_3$) δ: 7.69 (s, 2H), 6.71 (s, 2H). ^{13}C NMR (100 MHz, DMSO-d_6 and $CDCl_3$) δ: 178.4, 147.0, 129.5, 54.5. EI-MS *m*/*z*: 220 (100, M^+), 108 (100), 95 (57), 82 (28), 69 (47). HR-EI-MS *m*/*z* calcd. for $C_8H_4N_4O_2S$: 220.0055, found: 220.0061.

2,5-Bis(ketenyl)thiophene (24)

Upon LFP of 2,5-bis-diazoacety-thiophene (**23**, 1.82×10^{-5} mol/L in CH_3CN), an absorption at 2124 cm^{-1} with no change in OD for 5 ms was detected.

Photolysis of 3,4-di-(2-thienyl)cyclobut-3-ene-1,2-dione (25) forming 2,3-di-(2-thienyl)-2,3-bisketene (26)

Upon LFP of **25** (1.06×10^{-4} mol/L in CH_3CN), an absorption at 2111 cm^{-1} was detected with no change in OD for 1 ms.

Photolysis of 3,4-di-(3-thienyl)cyclobut-3-ene-1,2-dione (27) forming 2,3-di-(3-thienyl)-2,3-bisketene (28)

Upon LFP of **27** in CH_3CN, absorption at 2104 cm^{-1} was detected with no change in OD for 1 ms.

Reaction of 2-thienylketene (19) with TEMPO

A solution of 2-diazoacetylthiophene (**15**, 15 mg, 0.10 mmol) in pentane (50 mL) was purged with argon for 30 min and then irradiated with 300 nm light at room temperature for 5 min, followed by addition of TEMPO (31 mg, 0.20 mmol) dissolved in pentane (1 mL). After 2 h under Ar, the orange turbid solution was concentrated. Chromatography (silica gel, EtOAc/hexanes 1:10 *v*/*v* 1% Et_3N) gave the bis(TEMPO) adduct as colorless crystals (32 mg, 72 %), mp 37–40 °C, color change at 90–91 °C. IR ($CDCl_3$): 1774 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.25 (d, *J* = 0.8 Hz, 1H), 7.11 (d, *J* = 2.9 Hz, 1H), 6.95 (dd, *J* = 5.1, 3.5 Hz, 1H), 5.49 (s, 1H), 1.30–1.75 (m, 12H), 1.24 (s, 3H), 1.23 (s, 3H), 1.14 (s, 3H), 1.08 (s, 3H), 1.05 (s, 3H), 0.92 (s, 3H), 0.75 (s, 3H), 0.61 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 170.1, 141.6, 126.5, 126.4, 125.7, 83.4, 60.8, 60.7, 60.2, 59.8, 40.5, 40.4, 36.6, 39.4, 33.8, 33.5, 32.1, 31.1, 20.7, 20.3, 20.2, 17.2, 17.0. ESI-MS *m*/*z*: 437 ($[M + 1]^+$). HR-ESI-MS *m*/*z* calcd. for $C_{24}H_{41}N_2O_3S$: 437.2832, found: 437.2844.

Kinetic plasticity and the determination of product ratios for kinetic schemes leading to multiple products without rate laws — New methods based on directed graphs

John Andraos

Abstract: This paper presents two new and fast methods of determining product ratios for kinetic schemes leading to more than one product on which the Acree–Curtin–Hammett (ACH) principle is based. The methods involve rewriting a given kinetic scheme as a directed graph with nodes and arrows connecting the nodes and takes advantage of the directionality of the kinetic arrows and the enumeration of paths to the various target product nodes. The first, based on path divergent trees, is computationally simpler but works under a specific set of conditions, whereas the second, based on an adapted version of Chou's graphical method, works for all cases. By means of illustrated examples, both methods are shown to be completely verifiable with conventional more tedious treatments based on rate law determinations. The directed graph concept also works for kinetic schemes that involve entirely equilibrated species. In addition, the paper extends these ideas to variants of the basic ACH scheme, thereby testing the validity of the ACH principle and bringing about a deeper understanding of it. Generalization of the results yields a new parameter, called degree of kinetic plasticity, which completely describes the dynamics of kinetic resolution between the boundary limits of ACH behaviour (100% kinetic plasticity) and anti-ACH behaviour (100% kinetic rigidity). It is shown that this parameter is a good descriptor of all possible scenarios between and including these limits and can be determined experimentally by conducting a new kind of product study that tracks the behaviour of final product excesses as a function of initial substrate excesses. The resulting plot is always linear with a positive slope. The degree of kinetic plasticity is found by simply subtracting the slope from unity. These ideas are tested on complex kinetic schemes exhibiting dynamic kinetic resolution (DKR) by means of organocatalysis.

Key words: physical organic chemistry, kinetics, mechanism, directed graph, Chou digraph, Chou graphical rule, Acree-Curtin-Hammett principle, product ratio, dynamic kinetic resolution, organocatalysis.

Résumé : Dans ce travail on a développé deux nouvelles méthodes rapides pour déterminer les rapports des schémas conduisant à plus d'un produit sur lequel se base le principe d'Acree–Curtin–Hammett (ACH). Les méthodes impliquent une réécriture d'un schéma cinétique donné sous la forme d'un graphique dirigé comportant des nodes et des flèches reliant les nodes et elles tirent avantage du caractère directionnel des flèches cinétiques et de l'énumération des voies vers les divers nodes des produits prévus. La première, qui est basée sur des ramifications divergentes, est la plus simple d'un point de vue des calculs théoriques, mais elle ne s'applique que dans un ensemble spécifique de conditions alors que la deuxième qui est basée sur une version adaptée de la méthode graphique de Chou s'applique à tous les cas. En faisant appel à des illustrations appropriées, on peut démontrer que les deux méthodes peuvent être entièrement vérifier à l'aide de traitements conventionnels plus fastidieux basés sur des déterminations de lois de vitesses. Le concept du graphique dirigé fonctionne aussi pour les schémas cinétiques qui impliquent des espèces entièrement équilibrées. De plus, ce travail permet d'élargir ces idées à des variantes du schéma de base de Acree-Curtin-Hammett qui permet ainsi de vérifier la validité du principe d'ACH et de mieux la comprendre. La généralisation des résultats conduit à un nouveau paramètre, le degré de plasticité cinétique, qui décrit complètement la dynamique de la résolution cinétique entre les limites de la frontière entre le comportement Acree-Curtin-Hammett (100% de plasticité cinétique) et le comportement anti-Acree–Curtin–Hammett (100% de rigidité cinétique). On a montré que ce paramètre permet de bien décrire tous les scénarios entre, et incluant, ces limites et qu'il peut être déterminé expérimentalement en effectuant un nouveau type d'étude de produit qui permet de suivre le comportement des excès de produit final en fonction d'excès de substrats initiaux. La courbe qui en résulte est toujours linéaire avec une pente positive. On détermine le degré de plasticité cinétique en soustrayant la pente de l'unité. On a fait appel à l'organocatalyse pour tester ces idées sur les schémas cinétiques complexes qui présentent de la résolution cinétique dynamique (RCD).

Introduction

The Acree–Curtin–Hammett (ACH) principle is a fundamental concept in mechanistic chemistry that has been used to approximate under simplifying conditions the magnitude of the final product ratio for a pair of products originating from a pair of equilibrating starting materials as shown in Scheme 1. The starting materials may be equilibrating conformers, tautomers, or stereoisomers. Curtin and Hammett demonstrated this principle in the 1950s for products arising from equilibrating conformers (1, 2); however, it had already been described much earlier by Acree in 1907 for products arising from equilibrating tautomers (3). Moreover, Acree's work also derived what would be later known as the Winstein–Holness equation (4). A recent report has described the connections between these works and brought Acree's forgotten work to light (5). Throughout this paper, the principle is therefore referred to as the ACH principle or kinetic theorem to recognize the contributions of the three scientists. It is a concept that is well discussed in several textbooks of mechanistic organic chemistry (6–8), a review (9), and a pedagogical article (10).

Simply stated, the final product ratio $[P_X]$:$[P_Y]$ is equal to the ratio of product forming rate constants k_3:k_4 if the magnitudes of the rate constants k_1 and k_2 involved in the equilibration between X and Y are similar and are very large compared with those of the product forming steps. This independence of the final product ratio on the dynamics of the preceding equilibrium and the amounts of starting materials defines the ACH condition and is a direct result of applying *both* kinetic conditions. When these conditions are not met, an exact analytical solution to the above kinetic scheme becomes necessary to determine the complete form of the final product ratio. Equation [1] yields the complete dependence of the final product ratio on all four rate constants and the starting amounts of X and Y (11).

$$[1] \qquad \frac{[P_X]_\infty}{[P_Y]_\infty} = \left(\frac{k_3}{k_4}\right)\left[\frac{(a+b)\,k_2 + ak_4}{(a+b)\,k_1 + bk_3}\right]$$

where a and b represent the initial amounts of X and Y at time zero. It is easy to verify that the right-hand side of eq. [1] reduces to k_3/k_4 when (*i*) k_1 and $k_2 \gg k_3$ and k_4 and (*ii*) $k_1 = k_2$. Note that if only condition (*i*) holds, then the final product ratio will have a dependence on both the ratio k_3/k_4 and the equilibrium constant $K = k_1/k_2$, according to eq. [2].

$$[2] \qquad \frac{[P_X]_\infty}{[P_Y]_\infty} = \left(\frac{k_3}{k_4}\right)\left(\frac{1}{K}\right)$$

In addition to applying to equilibrating conformers or tautomers, the kinetic scheme shown in Scheme 1 is applicable to the technique of dynamic kinetic resolution (DKR) (12–38) used in synthetic organic chemistry to optimize the synthesis of stereoisomeric products from corresponding enantiomeric or diastereomeric starting materials that are in equilibrium. This is arguably the most important practical application of the ACH principle. In fact, it is this special phenomenon that blends the interests of both mechanistic and synthetic organic chemists. Mechanistic chemists are attracted to reactions that yield multiple products via multiple intermediates but that have the potential to be perturbed to produce one target product under the "right" set of conditions once their corresponding mechanism landscapes are completely elucidated. Synthetic chemists are of course interested in reactions that yield only one target product in high yield and high regio-, stereo-, and chemo-selectivity. Scheme 2 shows an analogous kinetic system to that in Scheme 1 with appropriate stereochemical descriptors R and S for substrates and products.

If a chemical reaction produces enantiomeric or diastereomeric products, and it is desired to carry out a subsequent transformation on one of them, then one is faced with the prospect of first separating or resolving the product mixture from the first reaction, usually racemic, before carrying out the second. Resolution of racemic mixtures by standard methods results in an automatic loss of half the starting material, assuming that the resolution procedure goes to completion. This means that if the individual stereoisomers in the starting racemic mixture are not interconvertible then the maximum amount of desired product formed in the subsequent step is exactly half that of the starting material, and so the maximum yield for this second step is 50%. This situation is designated as anti-ACH behaviour and corresponds to kinetic resolution. If, on the other hand, there is a possibility to have a rapid interchange between starting materials via a racemization process to an extent that the ACH condition applies, then in principle it is possible to shunt all of the starting material toward the product of interest in the subsequent reaction. The more dynamic the equilibration is between S_R and S_S, the more likely this outcome will occur. This situation is designated as ACH behaviour and corresponds to dynamic kinetic resolution.

In a recent report published in 2003, the complete dynamics of Scheme 2 was explored including a full kinetic analysis of the dependence of the initial and final product ratios on all four rate constants and starting amounts of S_R and S_S (11). The method used to derive expressions for these ratios shown in eqs. [3] and [4],

$$[3] \qquad \frac{[P_R]_0}{[P_S]_0} = \left(\frac{a}{b}\right)\left(\frac{k_3}{k_4}\right)$$

$$[4] \qquad \frac{[P_R]_\infty}{[P_S]_\infty} = \left(\frac{k_3}{k_4}\right)\left[\frac{(a+b)\,k_2 + ak_4}{(a+b)\,k_1 + bk_3}\right]$$

where a and b are the initial amounts of S_R and S_S respectively, was the method of Laplace transforms (39). It is important to point out that though there are no products formed initially their ratio extrapolated to zero time is in fact a finite

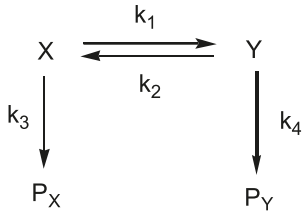
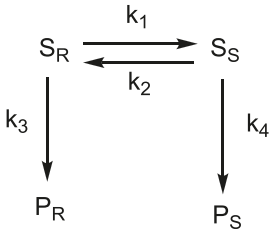
Scheme 1.



Scheme 2.



quantity. This observation is entirely consistent with the work of Noyori and co-workers (40, 41) who showed plots of % final enantiomeric excess of product versus % conversion that had well-defined nonzero intercepts. The two expressions given in eqs. [3] and [4] suggested a new kind of experiment that could be carried out that would quantitatively determine the intrinsic efficiency or plasticity of dynamic kinetic resolution that depended only on key rate constant ratios. This parameter was shown to be able to account for all experimentally observed cases between and including the limits of complete dynamic kinetic resolution (ACH conditions) and complete kinetic resolution (anti-ACH conditions) for simple kinetic schemes such as that shown in Scheme 2.

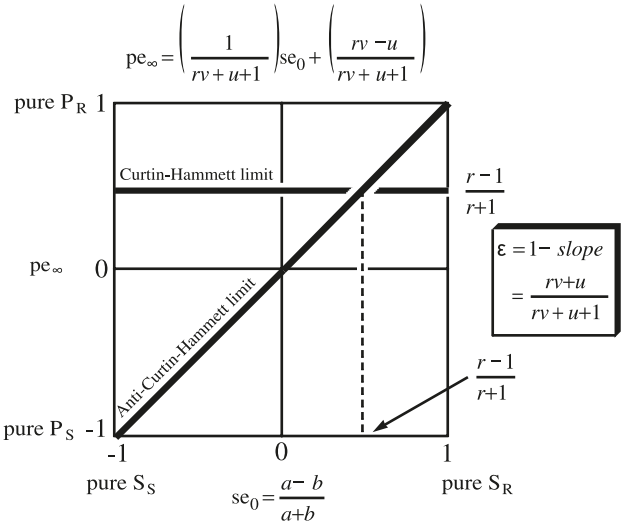
The crux of the new experiment is to determine initial and final product ratios for a *set* of initial substrate ratios covering the full range of possible optical purities of starting materials beyond the simple racemic condition, which is the universal initial composition of starting materials. Hence for a given starting substrate ratio *a*/*b*, one records time-dependent product progress curves, and from these the initial and final product ratios are determined by extrapolation to zero and infinite times. A plot of $[P_R]_0/[P_S]_0$ vs. *a*/*b* yields a slope equal to $r = k_3/k_4$. A plot of final product excess with respect to P_R and pe_∞ vs. initial substrate excess with respect to S_R and $(a–b)/(a+b)$, according to eq. [5],

$$[5] \qquad pe_\infty = \frac{[P_R]_\infty - [P_S]_\infty}{[P_R]_\infty + [P_S]_\infty} = \frac{\dfrac{[P_R]_\infty}{[P_S]_\infty} - 1}{\dfrac{[P_R]_\infty}{[P_S]_\infty} + 1}$$

$$= \frac{1}{rv + u + 1}\left(\frac{a-b}{a+b}\right) + \frac{rv - u}{rv + u + 1}$$

yields a slope equal to $1/(rv + u + 1)$ and an intercept equal to $(rv - u)/(rv + u + 1)$ where $r = k_3/k_4$, $u = k_1/k_3$, and $v = k_2/k_3$. The rate constant ratios *u* and *v* may be determined directly from the slope and intercept of such a plot using eqs. [6] and [7],

Fig. 1. Relationship between final product excess and initial substrate excess according to eq. [8], showing the two limiting slopes corresponding to the Curtin–Hammett condition (zero slope, *u* and $v \to 0$, 100% kinetic plasticity) and anti-Curtin–Hammett condition (unit slope, *u* and $v \to \infty$, 0% kinetic plasticity or 100% kinetic rigidity).



$$[6] \qquad u = \frac{1}{2}\left[\frac{1 - \text{intercept}}{\text{slope}} - 1\right]$$

and

$$[7] \qquad v = \frac{1}{2r}\left[\frac{1 + \text{intercept}}{\text{slope}} - 1\right]$$

An expression for the intrinsic efficiency or degree of kinetic plasticity of dynamic kinetic resolution, ε_{DKR}, may be obtained by examining the full range of possible values for the slope of this plot. In the ACH limit where $u = v \to \infty$ so that $k_1 = k_2$ and k_1, $k_2 \gg k_3$, k_4, the slope reaches a minimum value of zero. This result indicates that the final product ratio is independent of the starting amounts of S_R and S_S. In the anti-ACH limit where $u = v = 0$ so that $k_1 = k_2$ and k_1, $k_2 \ll k_3$, k_4, the slope reaches a maximum value of one. This case indicates that the final product ratio mirrors the initial starting material ratio. From these two boundary conditions, we set $\varepsilon_{DKR} = 1$ to represent the ACH case of 100% efficiency or complete kinetic plasticity and $\varepsilon_{DKR} = 0$ to represent the anti-ACH case of 0% efficiency or complete kinetic rigidity. Hence, we may define the intrinsic efficiency or performance of dynamic kinetic resolution as in eq. [8] to describe the pliability of the equilibrium toward being pulled in either direction by either of the product forming steps.

$$[8] \qquad \varepsilon_{DKR} = 1 - \text{slope} = 1 - \frac{1}{rv + u + 1} = \frac{rv + u}{rv + u + 1}$$

Figure 1 illustrates graphically the two limiting cases described earlier. Equation [5] predicts that experimental data should obey a linear relationship with a positive slope falling between these two limits. The intersection of the two limiting lines suggests that there exists a unique combination of initial substrate amounts that will result in the same final

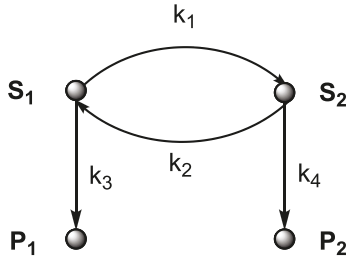
© 2008 NRC Canada

product ratio, and hence the same final product excess, under both limiting conditions. It should be noted that eq. [5] also predicts that we can never have a plot with a slope of zero and an intercept of zero, i.e., a line falling along the *x*-axis. Such a condition would correspond to the nonsense situation of a completely plastic kinetic system that begins with any combination of substrates and always ends up with a racemic mixture of products. Setting the slope and intercept to be simultaneously zero in eq. [5] leads to a contradiction in the allowable domains of the parameters *u* and *v*, namely, $u, v \to \infty$ for the slope and $u, v \to 0$ for the intercept. A racemic mixture of products can only arise from a racemic mixture of starting materials, which immediately suggests that the kinetic system is 100% rigid and hence the anti-ACH limiting line of unit slope and zero intercept is operative. However, ACH limiting lines with zero slopes and intercepts of +1 or –1 are allowed, i.e., lines falling along the top and bottom edges of the square in Fig. 1. These correspond to the fully dynamic situations where the equilibrium step is fast compared with the product forming steps ($u, v \to \infty$) and $r \to \infty$ (or $k_3 \ggg k_4$) for the case of an intercept of +1, and $r \to 0$ (or $k_3 \lll k_4$) for the case of an intercept of –1. From Scheme 2, the former case essentially corresponds to the case when the step from S_S to P_S is shut down so that the only product formed is P_R, and the latter case corresponds to the opposite situation when the step from S_R to P_R is shut down so that the only product formed is P_S. The plot shown in Fig. 1 may be used as a diagnostic test to verify if a given chemical system obeys ACH kinetic-type schemes.

Equation [8] is applicable to any kinetic scheme that looks like Scheme 1 or 2 regardless of the isomeric relationship of the starting materials so long as their starting ratio is controllable. In the case of isomeric substrates that cannot be easily separated and their initial ratio manipulated as described above, separate kinetic experiments are required to determine individual rate constants so that the kinetic plasticity parameter given in eq. [8] may be determined. To date there has not yet been any experimental verification of this new idea reported in the literature. However, the 2003 report did survey a number of published chemical systems where enough experimental detail was given so that minimum estimates of ε_{DKR} could be made, and thus the validity of eq. [8] was confirmed in principle. In that work, several variant kinetic schemes were examined and their properties and corresponding exact initial and final product ratio expressions were derived. The important point gleaned from that investigation was that all prior work on such kinetic systems *assumed* from the outset that the ACH condition was valid and that Winstein–Holness kinetic behaviour (4) was applicable. These claims were then verified by carrying out *independent* theoretical calculations to determine energy barriers pertaining to the relevant transition states (42). The above analysis clearly shows that the ACH condition may be verified directly from wholly experimentally acquired data without need for further computation. Moreover, even if it turns out that this special condition may not be met for a given chemical system it is still possible to quantify the actual extent of meeting this condition according to the parameter defined in eq. [8].

Having introduced the current understanding of the ACH principle on simple kinetic systems, we now report on further extensions that test the validity of this principle on complex kinetic systems. Extended linear and cyclic kinetic schemes are examined in detail. The concept of kinetic plasticity described above is generalized and the statement of the ACH principle is revised accordingly. In doing so, we also introduce two new time-saving methods of determining the required product ratio expressions for initial and final reaction times that serves as a check for conventional treatments, namely the Laplace transform method. As a bonus, it will be demonstrated that they also circumvent much of the tedious computation that is a consequence of handling complex kinetic systems. Limitations of the methods are also discussed.

Scheme 3.



Directed graph method

In this section we introduce easy-to-use algorithms for determining expressions as shown in eqs. [1] and [4], without the use of rate laws. The methods are based on directed graphs, or digraphs (43), and are applicable to competitive-type kinetic schemes leading to multiple products from one or more substrates. The schematic method of King and Altman described in 1956 is a forerunner report describing the use of graphs to derive rate laws for enzyme-catalyzed reactions (44). Chou has previously described powerful algorithms for analyzing non-steady-state and steady-state enzyme kinetics and protein folding kinetics (45–61).

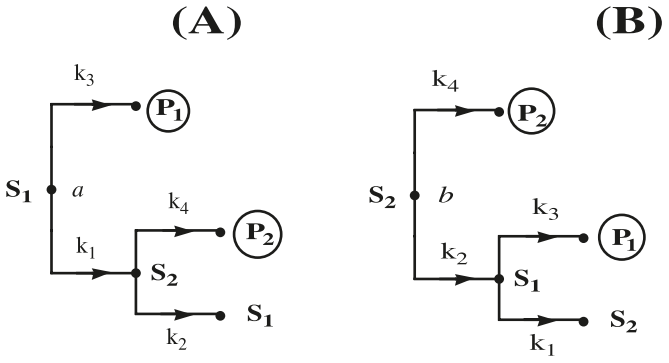
Digraphs are objects that consist of a finite set of vertices and a set of ordered pairs of distinct vertices called arcs. If the ordered pair $\{x, y\}$ is an arc, then the arc is said is to be directed from *x* to *y*. The kinetic schemes shown in Schemes 1 and 2 may be immediately drawn as digraphs, since the chemical entities and reaction arrows are translated as vertices and arcs, respectively, according to the above definitions (see Scheme 3).

The substrate vertices are designated as source nodes and the product vertices as sink nodes. The arrows and rate constant descriptors are retained as before in the usual sense. For the first method based on path divergent trees, beginning with each source node we draw a corresponding divergent tree that enumerates all paths from that node to all product nodes. In doing so, we apply the following rules. For irreversible steps one stops when a product node is reached and for reversible steps one stops when a previously traversed node along that branch is reached. Hence, we have for Scheme 3 the two divergent trees shown in Fig. 2 in which we assign the initial condition that we begin with amounts *a* and *b* for substrates S_1 and S_2.

Next, we write expressions for the expected contribution of each product based on the attenuation of the initial amounts of each source node that lead to each product. This

© 2008 NRC Canada

Fig. 2. Path divergent trees for paths emanating from S1 (A) and S2 (B). See Scheme 3.



is done following the connectivities between nodes in the path divergent trees. Thus, for paths leading to product P_1 we have eq. [9],

$$[9]\qquad a\left(\frac{k_3}{k_1+k_3}\right)+b\left(\frac{k_3}{k_1+k_3}\right)\left(\frac{k_2}{k_2+k_4}\right)=\left(\frac{k_3}{k_1+k_3}\right)\left[a+b\left(\frac{k_2}{k_2+k_4}\right)\right]$$

The first term in eq. [9] pertains to P_1 originating directly from S_1 along the k_3 branch (see Fig. 2*A*). Note that since there are two branches emanating from S_1, the fraction of starting material a leading to P_1 is $k_3/(k_3 + k_1)$. The second term pertains to P_1 originating from S_1, which in turn originated from S_2 (see Fig. 2*B*). The starting amount of S_2, b, is first split along the k_2 branch and then is split again along the k_3 branch. Hence, we have the corresponding multiplication of fractions.

Similarly, we have for paths leading to product P_2

$$[10]\qquad b\left(\frac{k_4}{k_2+k_4}\right)+a\left(\frac{k_1}{k_1+k_3}\right)\left(\frac{k_4}{k_2+k_4}\right)=\left(\frac{k_4}{k_2+k_4}\right)\left[b+a\left(\frac{k_1}{k_1+k_3}\right)\right]$$

Note that since we have a symmetrical digraph, the pairs of subscripts a and b, 1 and 3, and 2 and 4, are interchangeable in both expressions. This implies that the expression in eq. [10] could have been written at once from eq. [9] using these variable interchanges.

The final product ratio is then given directly by dividing eq. [9] by eq. [10] thus yielding eq. [11],

$$[11]\qquad \frac{[P_1]_\infty}{[P_2]_\infty}=\frac{\left(\frac{k_3}{k_1+k_3}\right)\left[a+b\left(\frac{k_2}{k_2+k_4}\right)\right]}{\left(\frac{k_4}{k_2+k_4}\right)\left[b+a\left(\frac{k_1}{k_1+k_3}\right)\right]}=\left(\frac{k_3}{k_4}\right)\left[\frac{(a+b)k_2+ak_4}{(a+b)k_1+bk_3}\right]$$

which is identical to eqs. [1] and [4]. The initial product ratio is also given directly by eq. [12],

$$[12]\qquad \frac{[P_1]_o}{[P_2]_o}=\frac{ak_3}{bk_4}$$

which is identical to eq. [3]. Note that in eq. [12] the numerator refers to the shortest path from S_1 to P_1 and the denominator refers to the shortest path from S_2 to P_2. This observation turns out to be always true in the determination of expressions for initial product ratios by the digraph method.

It is obvious how facile this method is compared with the standard method of Laplace transforms (39) that becomes more tedious as the number of substrate and product nodes increase and the number of rate constant connections between them increases. It may be recalled that the Laplace transform method involves taking determinants of square matrices whose dimension is equal to the sum of the number of substrates, intermediates, and products involved in the kinetic scheme. In addition, the method relies on tables of inverse transforms that need to be worked out separately, but such tables are readily available (62–64). A key limitation of the method is that it is applicable only to unimolecular or pseudo-unimolecular kinetic systems and not biomolecular ones, since the Laplace transform of a product of functions is not equal to the product of their Laplace transform functions as shown in eq. [13],

$$[13]\qquad L\{f(t)\cdot g(t)\}\neq L\{f(t)\}\cdot L\{g(t)\}$$

Figure 3 summarizes key definitions and the sequence of steps involved in this method. For illustration and comparison with the directed graph method, the Supplementary Data contains a full solution of the kinetic scheme shown in Scheme 3 by the Laplace transform method.[2]

For verification purposes, all of the expressions for initial and final product ratios derived previously (11) were confirmed by the new digraph method. These are also given in the Supplementary Data.[2] Reassuringly, this consistency demonstrates that the present new method also serves as an excellent checking device. However, this method does have its limitations. First, it does not give analytical expressions for the time-dependent substrate and product concentration profiles. For the purposes of determining analytical expressions for product ratios at the beginning and at the end of reactions, paradoxically these are not necessary. Second, like

[2] Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada DUD 3724. For more information on obtaining material, refer to cisti-icist-cnrc.gc.ca/irm/unpub_e.shtml. The Supplementary Data contains a full solution of the kinetic scheme shown in Scheme 3 by the Laplace transform method, solutions of kinetic schemes described in ref. 11 by both directed graph methods, a modified Chou digraph method applied to Schemes 6 to 10 in sections 6, 7, and 8.

Fig. 4. Example special bimolecular kinetic systems whose initial and final product ratios are determinable exactly by the directed graph method based on path divergent trees.

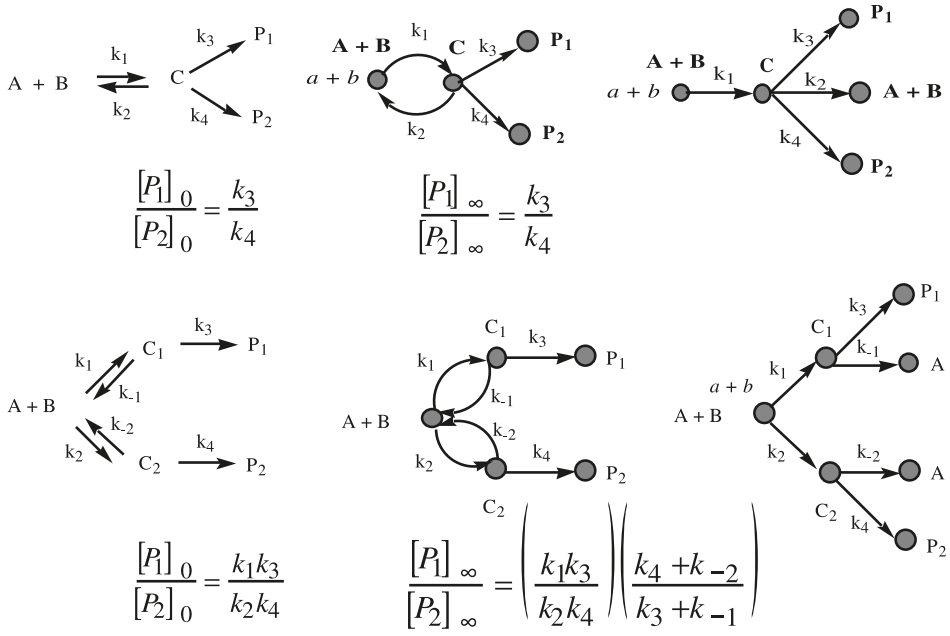

Fig. 3. Key definitions and sequence of steps involved in the Laplace transform method.

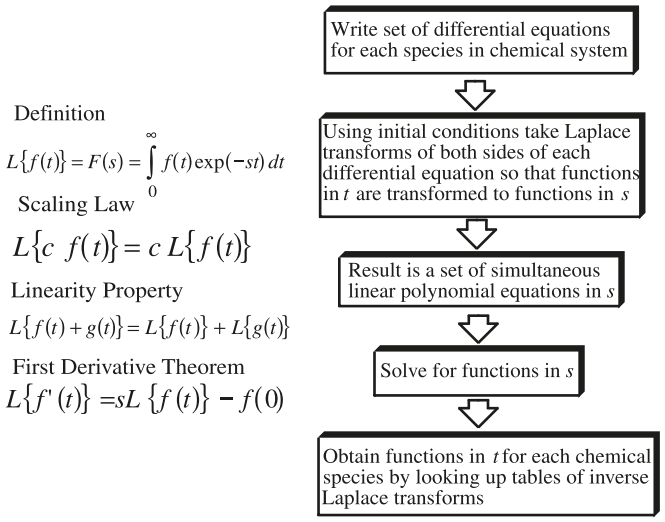
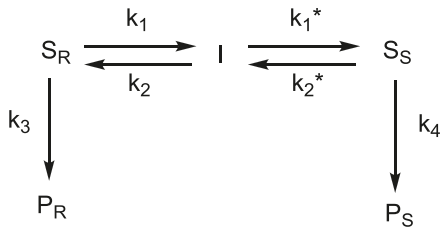


the Laplace transform method, it is applicable to unimolecular and pseudo-unimolecular kinetic systems. However, it can still be applied to special bimolecular systems, such as those shown in Fig. 4 where multiple products arise from a common intermediate via unimolecular steps though that intermediate itself arose from a prior bimolecular step. For these few examples, though time-dependent concentration profiles for products cannot be determined analytically, their product ratios are determinable exactly by the directed graph method.

A key observation from the path divergent trees shown in Fig. 2 is that each tree is composed of two stages or tiers with only one repeat node. For Fig. 2*A* the repeat node is S1 and for Fig. 2*B* it is S2. It turns out that if the construction of path divergent trees from a digraph pertaining to a kinetic

Scheme 4.



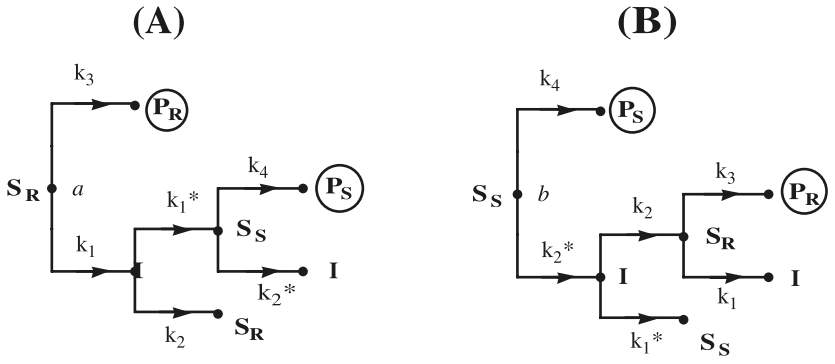
scheme according to the above algorithm leads to trees having more than one repeat node appearing in *different* stages, then the above digraph method does not yield expressions for the product ratio that are consistent with those obtained from the check Laplace transform method. Extra terms appear in the numerator and the denominator for the final product ratio expression, which ultimately yield an apparent dependency on the amounts of equilibrating starting materials when the ACH condition is applied. This would lead to the erroneous conclusion that the ACH principle is violated for such cases. Hence, the third and most important limitation of the above digraph algorithm is that it works only for kinetic schemes having corresponding path divergent trees with only one repeat node or ones with more than one repeat node appearing in the *same* stage or tier.

An example of a kinetic scheme yielding path divergent trees with multiple repeat nodes appearing in different stages or tiers is shown in Scheme 4, which is a more complete representation of the racemization process suggested by Scheme 2. Clearly, racemization between S_R and S_S necessarily takes place via a lower symmetry intermediate that is in equilibrium with both S_R and S_S since loss of chirality takes place via a bond-breaking process.

The corresponding path divergent trees are shown in Figs. 5*A* and 5*B*. Note that in Fig. 5*A* there is a repeat node

© 2008 NRC Canada

Fig. 5. Path divergent trees for paths emanating from SR (A) and SS (B). See Scheme 4.



S_R that appears in the second tier and another repeat node I that appears in the third tier. Similarly, repeat nodes in different tiers are observed in Fig. 5*B*. Application of the above digraph algorithm leads to the incorrect expression for the final product ratio shown in eq. [14],

$$[14] \quad \frac{[P_R]_\infty}{[P_S]_\infty} = \left(\frac{k_3}{k_4}\right)\left[\frac{(a+b)\,k_2k_2^* + ak_4(k_2+k_1^*) + ak_1k_1^*}{(a+b)\,k_1k_1^* + bk_3(k_1+k_2^*) + bk_2k_2^*}\right]$$

The correct expression found by the Laplace transform method is shown in eq. [15],

$$[15] \quad \frac{[P_R]_\infty}{[P_S]_\infty} = \left(\frac{k_3}{k_4}\right)\left[\frac{(a+b)\,k_2k_2^* + ak_4(k_2+k_1^*)}{(a+b)\,k_1k_1^* + bk_3(k_1+k_2^*)}\right]$$

Note the extra terms appearing in the numerator and denominator in eq. [14]. The ACH limit applied to eq. [14] leads to eq. [16],

$$[16] \quad \left(\frac{[P_R]_\infty}{[P_S]_\infty}\right)_{ACH} = \left(\frac{k_3}{k_4}\right)\left[\frac{2a+b}{a+2b}\right]$$

which shows a dependency on the starting amounts of S_R and S_S, *a* and *b*. When this limit is applied to eq. [15], however, the result is the expected no dependence on *a* and *b* as shown by eq. [17],

$$[17] \quad \left(\frac{[P_R]_\infty}{[P_S]_\infty}\right)_{ACH} = \frac{k_3}{k_4}$$

A second digraph method based on a variation of the Chou algorithm is found to work for all cases and thus circumvents the third limitation of the above path divergent tree method, as will be shown next. Again using the same kinetic schemes shown in Schemes 1 and 2, the Chou digraph is constructed as shown Scheme 5.

The digraph is similar to that shown in Scheme 3 except that the rate constants connecting the nodes are assigned a negative sign and loops are added to those nodes that have kinetic arrows emanating from them. The rate-constant weights assigned to the loop nodes correspond to the positive sum of the rate constants emanating from them. From this digraph, all subgraphs are enumerated according to the following steps. For a given target product node, draw all paths that lead to it from all starting substrate nodes. All other points not traversed by this path are connected by cycles that neither intersect each other nor intersect the path. Repeat the process for all other target product nodes. The contributing expression to each target product node is given by eq. [18],

Scheme 5.

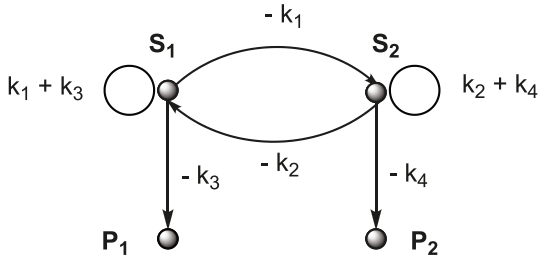


Fig. 6. Subgraphs from digraph shown in Scheme 5: (A) target product P_1; (B) target product P_2.

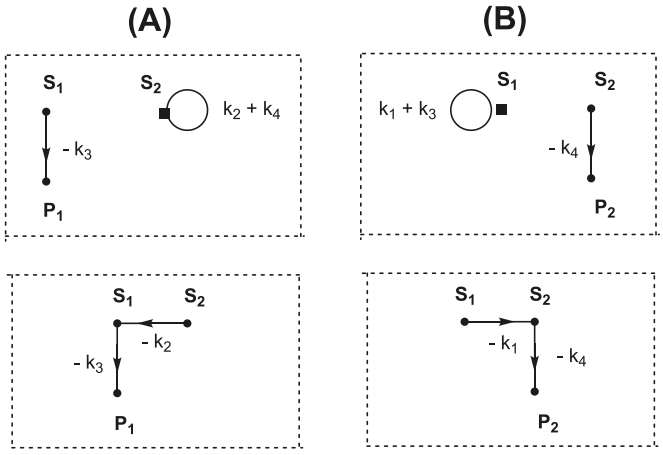
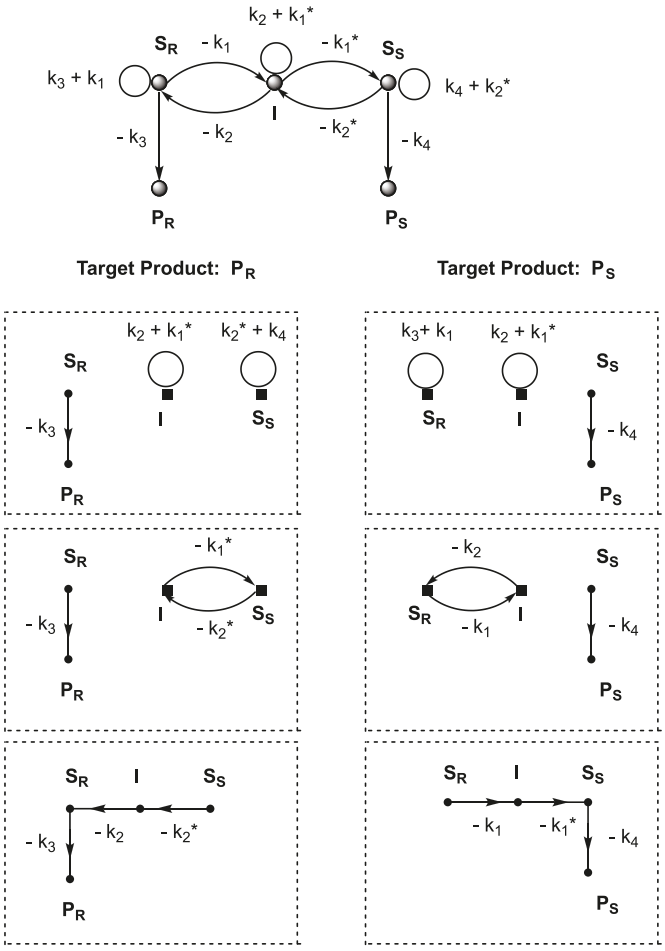


$$[18] \quad P_x \rightarrow \sum_{\text{subgraph}}\left[s_y(-1)^{n+c+1}\left(\prod_j k_j\right)\right]$$

where for a given subgraph, s_y is the starting amount of a starting node, *n* is the total number of nodes in the subgraph, *c* is the number of cycles, the product of rate-constant factors corresponds to all arrow and loop contributions, and the sum is taken over the number of subgraphs leading to common product node P_x. Hence, the subgraphs pertaining to the digraph in Scheme 5 are shown in Fig. 6.

© 2008 NRC Canada

Fig. 7. Digraph and subgraphs pertaining to Scheme 4.



The contributing expression for the P_1 node is,

$$[19]\quad [P_1]_\infty \rightarrow a(-1)^{3+1+1}(-k_3)(k_2 + k_4) + b(-1)^{3+0+1}(-k_2)(-k_3) = k_3[(a + b)k_2 + k_4]$$

and that for the P_2 node is,

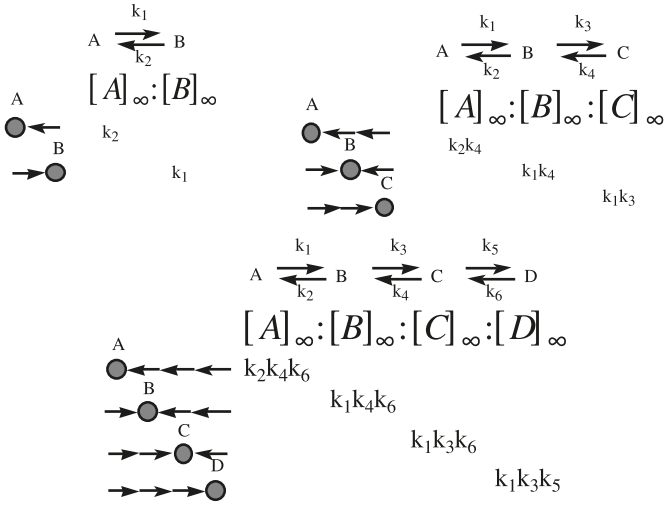
$$[20]\quad [P_2]_\infty \rightarrow b(-1)^{3+1+1}(-k_4)(k_1 + k_3) + a(-1)^{3+0+1}(-k_1)(-k_4) = k_4[(a + b)k_1 + k_3]$$

Note the following transposition of variables: $a \leftrightarrow b$, $k_1 \leftrightarrow k_2$, $k_3 \leftrightarrow k_4$. Hence, the final product ratio is found by dividing eq. [19] by eq. [20], which leads immediately to the previous expression given in eq. [11] found by the first digraph method based on path divergent trees. The application of the adapted Chou method to the kinetic scheme shown in Scheme 4 yields the digraph and subgraphs shown in Fig. 7.

The resulting contributing expressions for P_R and P_S are given by eqs. [21] and [22],

$$[21]\quad [P_R]_\infty \rightarrow a[(-1)^{4+2+1}(-k_3)(k_2 + k_1^*)(k_2^* + k_4) + (-1)^{4+1+1}(-k_3k_1^*k_2^*)] + b(-1)^{4+0+1}(-k_2^*k_2k_3) = ak_3(k_2k_2^* + k_2k_4 + k_1^*k_4) + bk_2k_2^*k_3$$

Fig. 8. Example acyclic equilibrium systems.



$$[22]\quad [P_S]_\infty \rightarrow b[(-1)^{4+2+1}(-k_4)(k_1 + k_2^*)(k_1^* + k_3) + (-1)^{4+1+1}(-k_4k_2^*k_1^*)] + a(-1)^{4+0+1}(-k_1^*k_1k_4) = bk_4(k_1k_1^* + k_1k_3 + k_2^*k_3) + ak_1k_1^*k_4$$

The ratio of these expressions is in agreement with the expected result given by eq. [15].

It is clear that the present new digraph methods confer key advantages that can be used to tackle rather complex schemes leading to multiple products that would otherwise be daunting to analyze by conventional means as will be shown, vide infra.

Equilibrium systems

The basic idea of keeping track of the arrow directionality in kinetic schemes may be used to full advantage to determine final equilibrium ratios of chemical species connected only by reversible steps by inspection, with almost no work involved. Figure 8 shows the results for acyclic equilibrium systems involving two, three, and four species in a linear arrangement. One can observe key patterns among these examples. If there are N species in an acyclic equilibrium, each term of the product ratio consists of N – 1 rate constants. The final equilibrium concentration expression for each species is determined by a single term equal to a product of rate constants corresponding to the combination of reaction arrows that points towards that species. For example, for the case of four species in an acyclic arrangement, the term for the final concentration of species A consists of a single product of three rate constants with descriptors 2, 4, and 6, which correspond to those that point toward A.

For cyclic equilibrium systems, the situation is more complicated but still can be deduced by the simple technique of following the reaction arrow directionality. Figure 9 shows the results for cyclic equilibrium systems involving three and four species. If there are N species in a cyclic equilibrium, each equilibrium product concentration expression consists of a sum of N terms, each of which consists of a product of N – 1 rate constants. The arrow directionality falls between the limiting clockwise and counter-clockwise

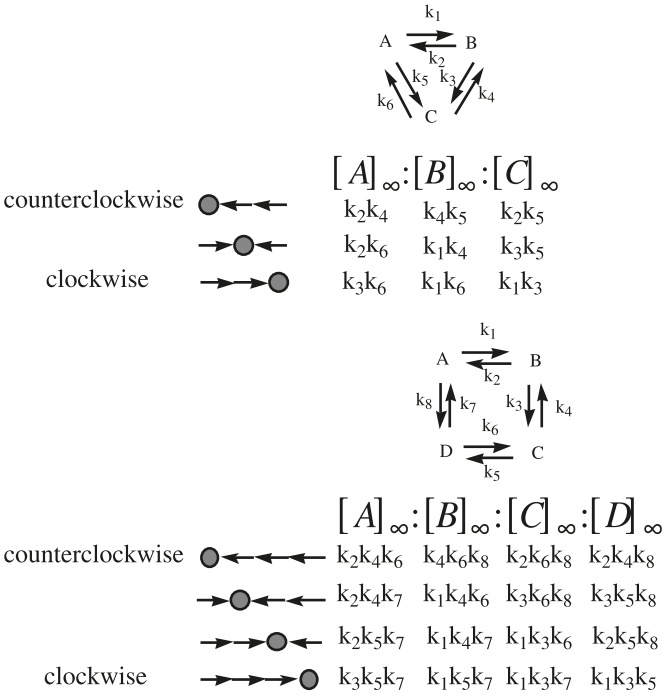
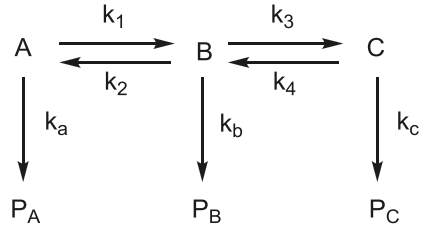
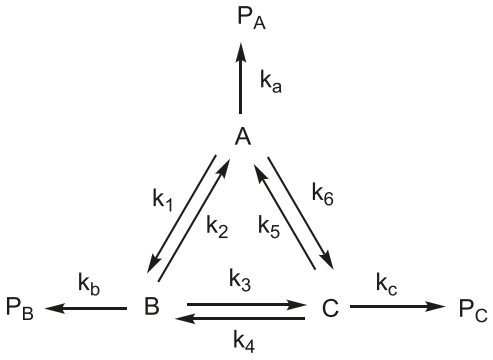
Fig. 9. Example cyclic equilibrium systems.



Scheme 6.



Scheme 7.



senses. For example, for the case of three species in a cyclic arrangement, the term for the final concentration of species A consists of a sum of three terms, each of which is composed of a product of two rate constants with pairwise descriptors (2,4), (2,6), and (3,6).

Extended variants of ACH kinetic schemes

In this section we examine extended variants of Scheme 1 in acyclic and cyclic arrangements and determine their associated initial and final product ratio expressions by the adapted Chou directed graph method. Consider the linear and cyclic triads shown in Schemes 6 and 7 with initial conditions $[A]_0 = a$, $[B]_0 = b$, and $[C]_0 = c$.

The determination of the final product ratios as given in the Supplementary Data results in the following relationships for the linear and cyclic triads, respectively,[2]

[23] $[P_A]_\infty:[P_B]_\infty:[P_C]_\infty$

$$= k_A\{a[(k_A + k_2)(k_4 + k_C) + k_3k_C] + bk_2(k_4 + k_C) + ck_2k_4\}$$
$$:k_B\{ak_1(k_4 + k_C) + b(k_A + k_1)(k_4 + k_C) + ck_4(k_A + k_1)\}$$
$$:k_C\{ak_1k_3 + bk_3(k_A + k_1) + c[(k_A + k_1)(k_3 + k_C) + k_2k_A]\}$$

[24] $[P_A]_\infty:[P_B]_\infty:[P_C]_\infty$

$$= k_A\{a[(k_B + k_2)(k_4 + k_5 + k_C) + k_3(k_C + k_5)] + b[k_2(k_4 + k_5 + k_C) + k_3k_5] + c[k_5(k_2 + k_3 + k_B)k_2k_4]\}$$
$$:k_B\{a[k_1(k_4 + k_5 + k_C) + k_4k_6] + b[(k_A + k_1)(k_4 + k_5 + k_C) + k_6(k_C + k_4)] + c[k_4(k_A + k_1 + k_6)k_1k_5]\}$$
$$:k_C\{a[k_6(k_2 + k_3 + k_B) + k_1k_3] + b[k_3(k_A + k_1 + k_6) + k_2k_6] + c[(k_A + k_6)(k_2 + k_3 + k_B) + k_1(k_B + k_3)]\}$$

In both cases the initial product ratio based on the shortest paths from A, B, and C to the respective target products is $[P_A]_0:[P_B]_0:[P_C]_0 = ak_A:bk_B:ck_C$. Also, in both cases the ACH limit and the anti-ACH limit lead to final product ratios of $([P_A]_\infty:[P_B]_\infty:[P_C]_\infty)_{ACH} = k_A:k_B:k_C$ and $([P_A]_\infty:[P_B]_\infty:[P_C]_\infty)_{anti\text{-}ACH} = a:b:c$, respectively. These results may be extended to tetrad, pentad, etc. arrangements of chemical species in equilibrium, each producing a unique product in an irreversible product-forming step. We may conclude that the forms of final product ratio expressions for both ACH anti-ACH limiting conditions are universal.

Generalization of kinetic plasticity in DKR systems

As demonstrated for Scheme 3, the key plot needed to determine the degree of kinetic plasticity is that given in Fig. 1, in which the final product excess is plotted against the initial substrate excess. The implication is that kinetic plasticity is defined in a pairwise sense since pairwise comparisons are made between pairs of products and pairs of substrates. For the trivial case of Scheme 3, there is only one pair of products and one pair of substrates. By analogy with the previous analysis based on limiting slopes, we may generalize the expression for kinetic plasticity starting from inequality [25],

[25] $$\text{slope}_{\text{ACH}} < \text{slope}_{\text{exp}} < \text{slope}_{\text{anti-ACH}}$$

Subtracting $\text{slope}_{\text{ACH}}$ from all terms results in

[26] $$0 < \text{slope}_{\text{exp}} - \text{slope}_{\text{ACH}} < \text{slope}_{\text{anti-ACH}} - \text{slope}_{\text{ACH}}$$

Dividing all terms by $(\text{slope}_{\text{anti-ACH}} - \text{slope}_{\text{ACH}})$ results in

[27] $$0 < \frac{\text{slope}_{\text{exp}} - \text{slope}_{\text{ACH}}}{\text{slope}_{\text{anti-ACH}} - \text{slope}_{\text{ACH}}} < 1$$

Using this definition, we may revise the ACH principle simply by stating that a kinetic model in which products are formed from equilibrating substrates satisfies the ACH condition when its degree of plasticity is 100%. For the kinetic model in Scheme 3, $\text{slope}_{\text{ACH}} = 0$ and $\text{slope}_{\text{anti-ACH}} = 1$, which implies by inequality [27] that $0 < \text{slope}_{\text{exp}} < 1$ is satisfied. The kinetic plasticity in this case was defined as $\varepsilon_{\text{DKR}} = 1 - \text{slope}_{\text{exp}}$ to make the zero value and the unit value in inequality [27] correspond to 100% plasticity and 0% plasticity, respectively. Hence for Scheme 3, eq. [8] resulted. Maintaining this sense, the general expression for kinetic plasticity becomes,

[28] $$\varepsilon_{\text{DKR}} = 1 - \frac{\text{slope}_{\text{exp}} - \text{slope}_{\text{ACH}}}{\text{slope}_{\text{anti-ACH}} - \text{slope}_{\text{ACH}}} = 1 - \text{slope}_{\text{exp}}$$

The determination of kinetic plasticity parameters for any kinetic scheme, such as those shown in Schemes 6 and 7, must be done on a pairwise basis such that adjacent pairs of products arising from their corresponding equilibrating substrates are considered. For example, for Scheme 6 there are three substrates leading to three unique products, and there are two pairs of adjacent products to consider in the pairwise analysis. This will result in two kinetic plasticity indices corresponding to the P_AP_B and P_BP_C pairs of products. The global kinetic plasticity for the scheme would be described by this set of two indices. The form of the expression for the kinetic plasticity index would be identical to eq. [8] with $r = k_a/k_b$, $u = k_1/k_a$, and $v = k_2/k_a$ for the P_AP_B pair, and $r = k_b/k_c$, $u = k_3/k_b$, and $v = k_4/k_b$ for the P_BP_C pair. For Scheme 7 there are three adjacent pairs of products to consider, leading to three kinetic plasticity parameters: P_AP_B, P_BP_C, and P_AP_C. Again, eq. [8] applies with $r = k_a/k_b$, $u = k_1/k_a$, and $v = k_2/k_a$ for the P_AP_B pair; $r = k_b/k_c$, $u = k_3/k_b$, and $v = k_4/k_b$ for the P_BP_C pair; and $r = k_a/k_c$, $u = k_6/k_a$, and $v = k_5/k_a$ for the P_AP_C pair. Unfortunately for both Schemes 6 and 7, it is not possible to obtain the kinetic plasticity indices directly by conducting product study experiments by varying in a pairwise fashion the initial substrate ratio as a function of the corresponding final product ratio, since neat expressions of the form of eq. [5] are not obtainable. Instead, the magnitudes of all rate constants need to be determined directly by independent kinetic experiments to make estimates of the above pairs of kinetic plasticity parameters using eq. [8].

Dynamic kinetic resolution by organocatalysis

The emerging field of organocatalysis (65–86) has undergone a rapid growth in recent years and provides several opportunities to test ideas presented in this work. Three examples are presented in which the versatility of the directed graph methods is applied to determine initial and final product ratio expressions. Corresponding expressions for the kinetic plasticity index are also determined in each case. These examples showcase the prowess of the new methods in tackling complex schemes with apparent ease. In addition, the new suggested product study experiment and corresponding linear relationship according to eq. [5] serves as a diagnostic test to verify the proposed kinetic schemes for these chemical systems and offers an opportunity to properly quantify their kinetic plasticities directly from experiment.

The first example (87) shown in Scheme 8 involves a double feed-in reaction that first produces racemizable chiral imine intermediates from chiral aldehydes and aromatic amines, followed by catalytic production of chiral iminium salts that are then finally reduced to their amine analogues via oxidation of Hantzsch dihydropyridine esters to pyridines. Figure 10 shows the corresponding directed graph and Section 6 of the Supplementary Data shows the list of subgraphs to consider with respect to P_1 as the target product by the adapted Chou method.[2] The subgraphs with respect to P_2 as the target product are found using the following transposition of variables: $[A]_0 \leftrightarrow [B]_0$, $k_1 \leftrightarrow k_8$, $k_2 \leftrightarrow k_7$, $k_3 \leftrightarrow k_6$, $k_4 \leftrightarrow k_5$, $k_9 \leftrightarrow k_{10}$, and $k_{11} \leftrightarrow k_{12}$. For the analysis it was assumed that the concentrations of aromatic amine, chiral acids HX*, and Hanzsch dihydropyridine esters were in excess compared with the chiral aldehydes A and B. The expressions for the initial and final product ratios and the final product excess are given by eqs. [29], [30], and [31],

[29] $$\frac{[P_1]_0}{[P_2]_0} = \frac{[A]_0}{[B]_0}\left(\frac{k_1}{k_8}\right)\left(\frac{k_9k_{11}}{k_{10}k_{12}}\right)$$

[30] $$\frac{[P_1]_\infty}{[P_2]_\infty} = \left(\frac{k_9}{k_{10}}\right)\left[\frac{[A]_0\alpha + [B]_0k_4k_6}{[A]_0k_3k_5 + [B]_0\beta}\right]$$

where

$$\alpha = k_4k_6 + k_{10}[HX^*](k_4 + k_5)$$

$$\beta = k_3k_5 + k_9[HX^*](k_4 + k_5)$$

© 2008 NRC Canada

Scheme 8.

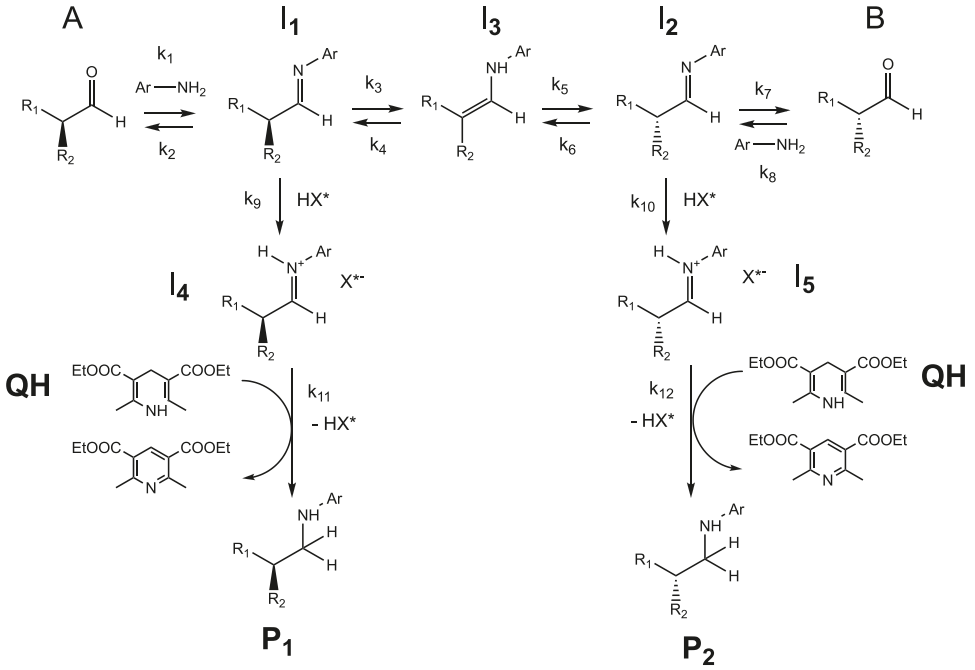

Fig. 10. Chou digraph pertaining to Scheme 8.

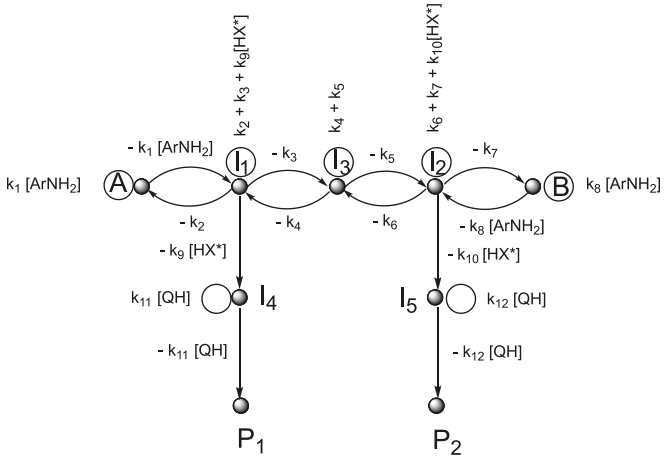


$$[31]\quad pe_\infty = \frac{\left(\frac{k_9}{k_{10}}\right)\left(\frac{[A]_0\alpha + [B]_0 k_4 k_6}{[A]_0 k_3 k_5 + [B]_0\beta}\right) - 1}{\left(\frac{k_9}{k_{10}}\right)\left(\frac{[A]_0\alpha + [B]_0 k_4 k_6}{[A]_0 k_3 k_5 + [B]_0\beta}\right) + 1}$$

$$= \frac{ru_2\nu_1 - u_1\nu_2}{ru_2\nu_1 + u_1\nu_2 + [HX^*](\nu_1 + \nu_2)} + \left(\frac{[A]_0 - [B]_0}{[A]_0 + [B]_0}\right)\left(\frac{[HX^*](\nu_1 + \nu_2)}{ru_2\nu_1 + u_1\nu_2 + [HX^*](\nu_1 + \nu_2)}\right)$$

where $r = k_9/k_{10}$, $u_1 = k_3/k_{10}$, $u_2 = k_6/k_{10}$, $v_1 = k_4/k_{10}$, and $v_2 = k_5/k_{10}$. Note that eq. [31] shows a linear dependence between pe_∞ and se_0. In the ACH limit when $k_i = k$ (for i = 1 to 8) and are very large compared with k_j (for j = 9 to 12), we have,

$$[32]\quad \alpha = k^2 + k_{10}[HX^*]2k$$

$$\beta = k^2 + k_9[HX^*]2k$$

so that the final product ratio becomes,

$$[33]\quad \left(\frac{[P_1]_\infty}{[P_2]_\infty}\right)_{ACH} = \lim_{k\to\infty}\left(\frac{k_9}{k_{10}}\right)\left[\frac{[A]_0(k^2 + k_{10}[HX^*]2k) + [B]_0 k^2}{[A]_0 k^2 + [B]_0(k^2 + k_9[HX^*]2k)}\right]$$

$$= \left(\frac{k_9}{k_{10}}\right)\lim_{k\to\infty}\left[\frac{([A]_0 + [B]_0)k^2 + [A]_0(k_{10}[HX^*]2k)}{([A]_0 + [B]_0)k^2 + [B]_0(k_9[HX^*]2k)}\right]$$

$$= \left(\frac{k_9}{k_{10}}\right)\left(\frac{[A]_0 + [B]_0}{[A]_0 + [B]_0}\right)$$

$$= \frac{k_9}{k_{10}}$$

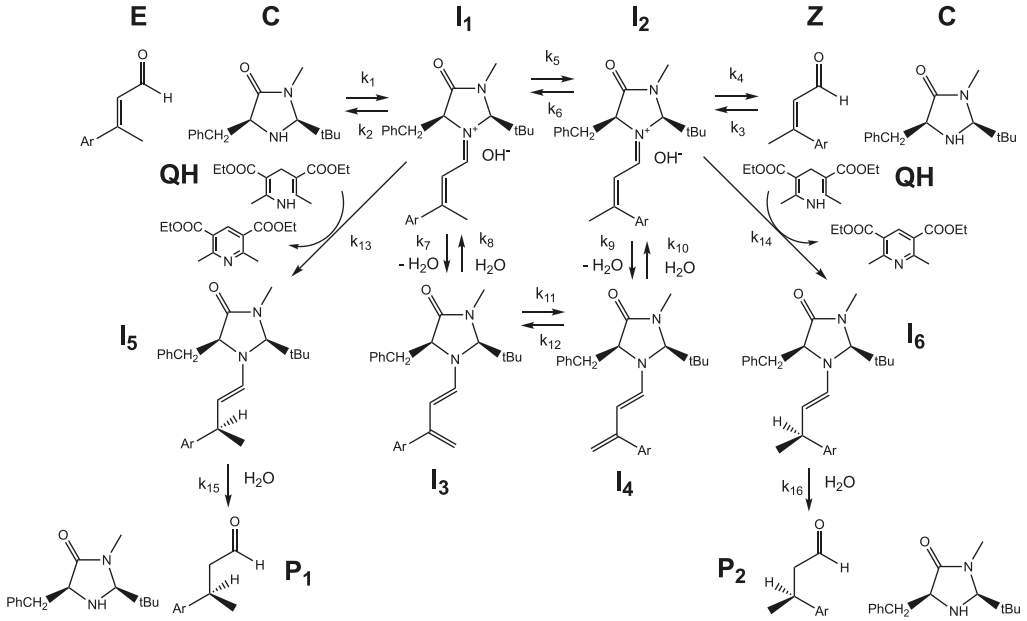
which shows a dependence only on the product forming rate constants emanating from intermediates I1 and I2.

In the anti-ACH limit when $k_i = k$ (for i = 1 to 8) and are very small compared with k_j (for j = 9 to 12), we have the same relations as in eq. [32] so that the final product ratio becomes,

$$[34]\quad \left(\frac{[P_1]_\infty}{[P_2]_\infty}\right)_{anti\text{-}ACH} = \lim_{k\to 0}\left(\frac{k_9}{k_{10}}\right)\left[\frac{[A]_0(k^2 + k_{10}[HX^*]2k) + [B]_0 k^2}{[A]_0 k^2 + [B]_0(k^2 + k_9[HX^*]2k)}\right]$$

© 2008 NRC Canada

Scheme 9.



$$= \left(\frac{k_9}{k_{10}}\right) \lim_{k\to 0} \left[\frac{([A]_0 + [B]_0)k^2 + [A]_0(k_{10}[HX^*]2k)}{([A]_0 + [B]_0)k^2 + [B]_0(k_9[HX^*]2k)}\right]$$

$$= \left(\frac{k_9}{k_{10}}\right)\left(\frac{[A]_0}{[B]_0}\right)\left(\frac{k_{10}}{k_9}\right)\left(\frac{2[HX^*]}{2[HX^*]}\right)$$

$$= \frac{[A]_0}{[B]_0}$$

which shows a dependence only on the starting amounts of aldehydes A and B.

The final product excess as a function of initial substrate excess for these two limits is given by eqs. [35] and [36],

$$[35] \quad (\mathrm{pe}_\infty)_{\mathrm{ACH}} = \lim_{\substack{u_i\to\infty \\ \nu_i\to\infty}} \mathrm{pe}_\infty = \frac{r-1}{r+1} = \frac{\dfrac{k_9}{k_{10}} - 1}{\dfrac{k_9}{k_{10}} + 1}$$

$$[36] \quad (\mathrm{pe}_\infty)_{\text{anti-ACH}} = \lim_{\substack{u_i\to\infty \\ \nu_i\to\infty}} \mathrm{pe}_\infty = \mathrm{se}_0$$

where

$$\mathrm{se}_0 = \frac{[A]_0 - [B]_0}{[A]_0 + [B]_0}$$

Using the definition given in eq. [28], the expression for the kinetic plasticity for this kinetic model is given by eq. [37],

$$[37] \quad \varepsilon_{\mathrm{DKR}} = 1 - \frac{\left(\dfrac{\mathrm{d}(\mathrm{pe}_\infty)}{\mathrm{d}(\mathrm{se}_0)}\right)_{\mathrm{exp}} - \left(\dfrac{\mathrm{d}(\mathrm{pe}_\infty)}{\mathrm{d}(\mathrm{se}_0)}\right)_{\mathrm{ACH}}}{\left(\dfrac{\mathrm{d}(\mathrm{pe}_\infty)}{\mathrm{d}(\mathrm{se}_0)}\right)_{\text{anti-ACH}} - \left(\dfrac{\mathrm{d}(\mathrm{pe}_\infty)}{\mathrm{d}(\mathrm{se}_0)}\right)_{\mathrm{ACH}}}$$

$$= 1 - \frac{\left(\dfrac{\mathrm{d}(\mathrm{pe}_\infty)}{\mathrm{d}(\mathrm{se}_0)}\right)_{\mathrm{exp}} - 0}{1 - 0}$$

$$= 1 - \left(\frac{\mathrm{d}(\mathrm{pe}_\infty)}{\mathrm{d}(\mathrm{se}_0)}\right)_{\mathrm{exp}}$$

$$= 1 - \frac{[HX^*](\nu_1 + \nu_2)}{ru_2\nu_1 + u_1\nu_2 + [HX^*](\nu_1 + \nu_2)}$$

$$= \frac{ru_2\nu_1 + u_1\nu_2}{ru_2\nu_1 + u_1\nu_2 + [HX^*](\nu_1 + \nu_2)}$$

The second example (88) shown in Scheme 9 is a more complex variant of Scheme 8. The aim is to stereoselectively reduce a mixture of (*E*/*Z*) α,β-unsaturated aldehydes to their dihydroaldehyde analogs via Hanzsch dihydropyridines and a chiral organocatalyst that produces (*E*/*Z*) iminium intermediates that are interconvertible. Figure 11 shows the corresponding directed graph and Section 7 of the Supplemenatry Data shows the subgraphs with respect to P1 as the target product.[2] As in the previous case, the subgraphs with respect to P_2 are found using the following transposition of variables: $[E]_0 \leftrightarrow [Z]_0$, $k'_1 \leftrightarrow k'_3$, $k_2 \leftrightarrow k_4$, $k_5 \leftrightarrow k_6$, $k_7 \leftrightarrow k_9$, $k'_8 \leftrightarrow k'_{10}$, $k_{11} \leftrightarrow k_{12}$, $k'_{13} \leftrightarrow k'_{14}$, and $k'_{15} \leftrightarrow k'_{16}$.

The expressions for the initial and final product ratios and the final product excess are given by eqs. [38], [39], and [40],

$$[38] \quad \frac{[P_1]_0}{[P_2]_0} = \frac{[E]_0}{[Z]_0}\left(\frac{k_1}{k_3}\right)\left(\frac{k_{13}k_{15}}{k_{14}k_{16}}\right)$$

$$[39] \quad \frac{[P_1]_\infty}{[P_2]_\infty} = \left(\frac{k'_{13}}{k'_{14}}\right)\left(\frac{([E]_0 + [Z]_0)\alpha + [E]_0 k'_{14}\beta}{([E]_0 + [Z]_0)\alpha^* + [E]_0 k'_{13}\beta}\right)$$

where

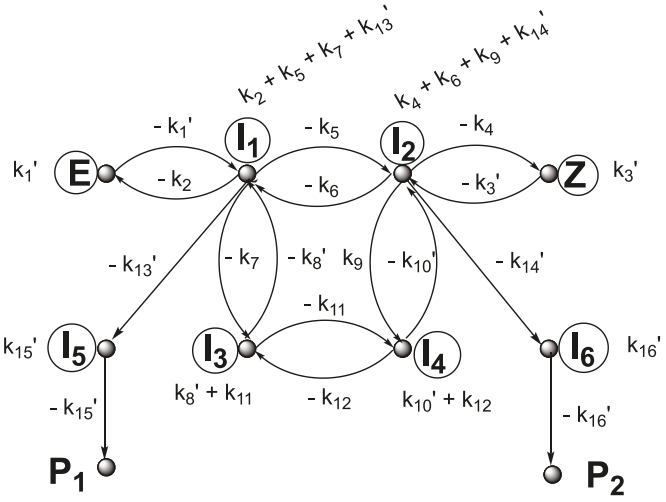
Fig. 11. Chou digraph pertaining to Scheme 9.



$$\alpha = k_6\beta + k_9k'_8k_{12}$$

$$\alpha^* = k_5\beta + k_7k'_{10}k_{11}$$

$$\beta = k'_8k'_{10} + k'_8k'_{12} + k'_{10}k'_{11}$$

$$k'_1 = k_1[\mathrm{C}],\ k'_3 = k_3[\mathrm{C}],\ k'_8 = k_8[\mathrm{H_2O}],$$

$$k'_{10} = k_{10}[\mathrm{H_2O}]$$

$$k'_{15} = k_{15}[\mathrm{H_2O}],\ k'_{16} = k_{16}[\mathrm{H_2O}],$$

$$k'_{13} = k_{13}[\mathrm{QH}],\ k'_{14} = k_{14}[\mathrm{QH}]$$

[40] $$\mathrm{pe}_\infty = \frac{\left(\frac{k'_{13}}{k'_{14}}\right)\left[\frac{([\mathrm{E}]_0 + [\mathrm{Z}]_0)\alpha + [\mathrm{E}]_0k'_{14}\beta}{([\mathrm{E}]_0 + [\mathrm{Z}]_0)\alpha^* + [\mathrm{E}]_0k'_{13}\beta}\right] - 1}{\left(\frac{k'_{13}}{k'_{14}}\right)\left[\frac{([\mathrm{E}]_0 + [\mathrm{Z}]_0)\alpha + [\mathrm{E}]_0k'_{14}\beta}{([\mathrm{E}]_0 + [\mathrm{Z}]_0)\alpha^* + [\mathrm{E}]_0k'_{13}\beta}\right] + 1}$$

$$= \frac{r\alpha - \alpha^*}{r\alpha + \alpha^* + k'_{13}\beta} + \left(\frac{[\mathrm{E}]_0 - [\mathrm{Z}]_0}{[\mathrm{E}]_0 + [\mathrm{Z}]_0}\right)\left(\frac{k'_{13}\beta}{r\alpha + \alpha^* + k'_{13}\beta}\right)$$

where $r = k'_{13}/k'_{14}$. Note that eq. [40] shows a linear dependence between pe_∞ and se_0. In the ACH limit when $k_i = k$ (for i = 1 to 12) and very large compared with k_j (for j = 13 to 16), we have

[41] $$\alpha \to 4k^3$$
$$\alpha^* \to 4k^3$$
$$\beta \to 3k^2$$

so that the final product ratio becomes,

[42] $$\left(\frac{[\mathrm{P_1}]_\infty}{[\mathrm{P_2}]_\infty}\right)_{\mathrm{ACH}} = \lim_{k\to\infty}\left(\frac{k'_{13}}{k'_{14}}\right)\left[\frac{([\mathrm{E}]_0 + [\mathrm{Z}]_0)4k^3 + [\mathrm{E}]_0k'_{14}3k^2}{([\mathrm{E}]_0 + [\mathrm{Z}]_0)4k^3 + [\mathrm{Z}]_0k'_{13}3k^2}\right]\left(\frac{k'_{13}}{k'_{14}}\right)$$

which shows, as in the previous example, a dependence only on the ratio of product forming rate constants emanating from intermediates $\mathrm{I_1}$ and $\mathrm{I_2}$.

In the anti-ACH limit when k_i — > 0 (for i = 1 to 12), we have the same relations as in eq. [41], so that the final product ratio becomes,

[43] $$\left(\frac{[\mathrm{P_1}]_\infty}{[\mathrm{P_2}]_\infty}\right)_{\text{anti-ACH}} = \lim_{k\to 0}\left(\frac{k'_{13}}{k'_{14}}\right)\left[\frac{([\mathrm{E}]_0 + [\mathrm{Z}]_0)4k^3 + [\mathrm{E}]_0k'_{14}3k^2}{([\mathrm{E}]_0 + [\mathrm{Z}]_0)4k^3 + [\mathrm{Z}]_0k'_{13}3k^2}\right]\left(\frac{[\mathrm{E}]_0}{[\mathrm{Z}]_0}\right)$$

The final product excess as a function of initial substrate excess for these two limits are given by eqs. [44] and [45],

[44] $$(\mathrm{pe}_\infty)_{\mathrm{ACH}} = \frac{r-1}{r+1} = \frac{\frac{k'_{13}}{k'_{14}} - 1}{\frac{k'_{13}}{k'_{14}} + 1}$$

[45] $$(\mathrm{pe}_\infty)_{\text{anti-ACH}} = \mathrm{se}_0$$

where

$$\mathrm{se}_0 = \frac{[A]_0 - [B]_0}{[A]_0 + [B]_0}$$

Using the definition given in eq. [28], the expression for the kinetic plasticity for this kinetic model is given by eq. [46],

[46] $$\varepsilon_{\mathrm{DKR}} = \frac{r\alpha + \alpha^*}{r\alpha + \alpha^* + k'_{13}\beta}$$

The final example (89) shown in Scheme 10 involves stereoselective α-fluorination via an electrophilic "F^+" species of an achiral aldehyde using a chiral proline analogue as an organocatalyst. The two products of interest are $\mathrm{P_1}$ and $\mathrm{P_2}$. The third difluorinated product arises from intermediate $\mathrm{I_4}$ which is in equilibrium with $\mathrm{I_2}$ and $\mathrm{I_3}$. All three products arise from the same source, namely intermediate $\mathrm{I_1}$. Since the products do not arise from different equilibrating starting substrates, kinetic control to produce one of the products over the others will depend on the relative magnitudes of the rate constants and not on the initial amount of starting material. Figure 12 shows the corresponding directed graph and Section 8 of the Supplementary Data shows the subgraphs with respect to $\mathrm{P_1}$, $\mathrm{P_2}$, and $\mathrm{P_3}$ as the target products.[2] The following transposition of variables applies: $k'_3 \leftrightarrow k'_8$, $k_7 \leftrightarrow k_9$, $k'_5 \leftrightarrow k'_8$, and $k'_8 \leftrightarrow k'_{10}$. The initial and final product ratios are given by eqs. [47] and [48], respectively.

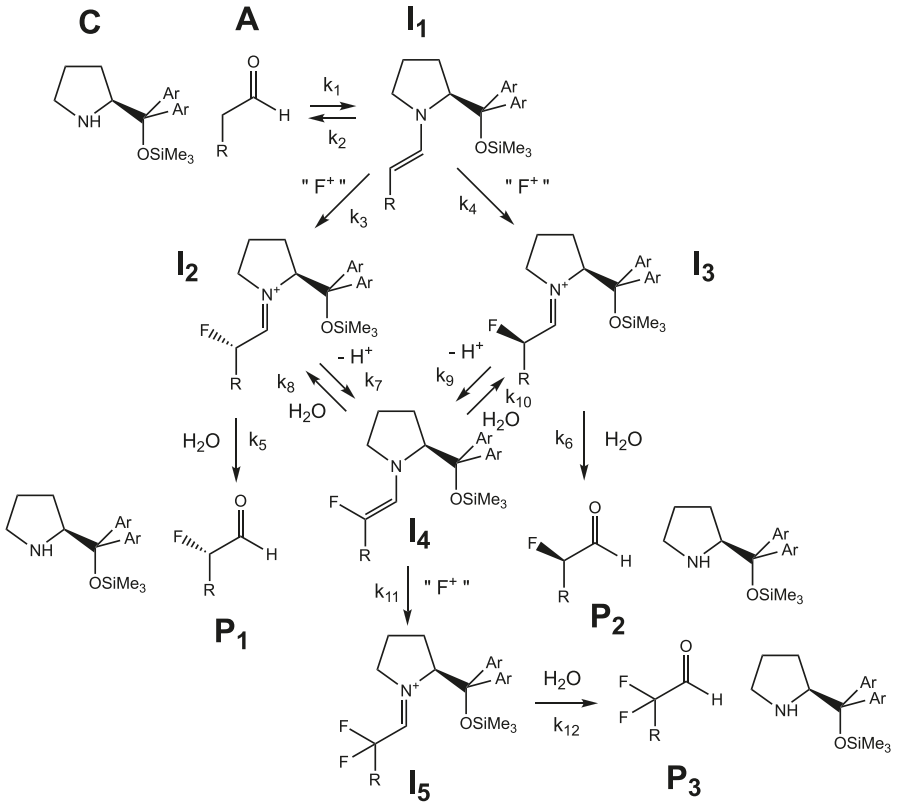
[47] $$[\mathrm{P_1}]_0:[\mathrm{P_2}]_0:[\mathrm{P_3}]_0 = k'_3k'_5 : k'_4k'_6 : k'_{11}k'_{12}(k'_3k_7 + k'_4k_9)$$

[48] $$[\mathrm{P_1}]_\infty:[\mathrm{P_2}]_\infty:[\mathrm{P_3}]_\infty$$
$$= k'_5\{k'_3k'_6\,\alpha + k_9(k'_3k'_8 + k'_4k'_8 + k'_3k'_{11})\}$$
$$: k'_6\{k'_4k'_5\,\alpha + k_7(k'_4k'_{10} + k'_4k'_{11} + k'_3k'_{10})\}$$
$$: k'_{11}\{k'_3k_7(k'_6 + k_9) + k'_4k_9(k'_5 + k_7)\}$$

where

© 2008 NRC Canada

Scheme 10.



$$\alpha = k'_8 + k'_{10} + k'_{11}$$

$$k_3' = k_3[F^+],\ k'_4 = k_4[F^+],\ k'_{11} = k_{11}[F^+]$$

$$k'_5 = k_5[H_2O],\ k'_6 = k_6[H_2O],\ k'_8 = k_8[H_2O]$$

$$k'_{10} = k_{10}[H_2O],\ k'_{12} = k_{12}[H_2O]$$

In the ACH limit when there is rapid equilibration between intermediates I_2, I_3, and I_4 so that $k_i = k$ (for i = 7 to 10) is very large compared with the product forming rate constants, then the final product ratio becomes,

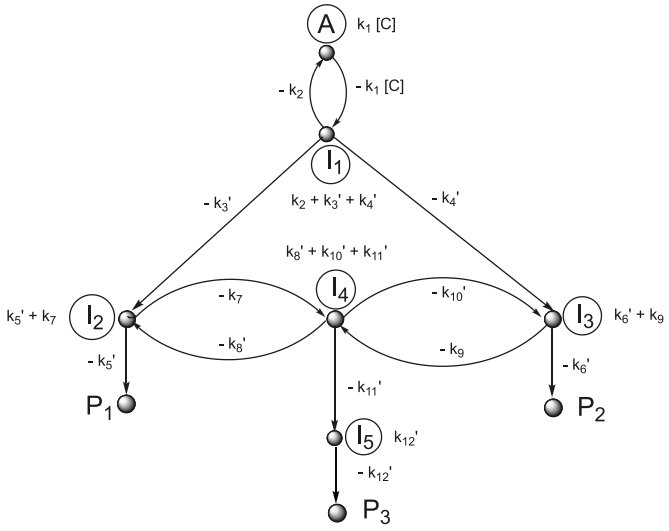
$$[49]\quad ([P_1]_\infty:[P_2]_\infty:[P_3]_\infty)_{ACH} = k'_5:k'_6:k'_{11} = k_5[H_2O]:k_6[H_2O]:k_{11}[F^+]$$

Again, these are the product-forming rate constants emanating from intermediates I_2, I_3, and I_4. On the other hand, the anti-ACH limit results in a final product ratio given by eq. [50], which predicts the absence of the difluorinated product P_3,

$$[50]\quad ([P_1]_\infty:[P_2]_\infty:[P_3]_\infty)_{anti\text{-}ACH} = k'_3:k'_4:0$$

Since all three products arise from the same source substrate, it is not possible to obtain estimates of kinetic plasticity parameters for this scheme by varying substrate amounts. Direct estimates of the appropriate rate constants need to be made. The two pairs of products to consider are P_1P_3 and P_3P_2 that will lead to two kinetic plasticity indices. They will be of the form of eq. [8] with $r = k'_5/k'_{11}$, $u = k_7/k'_5$, and $v = k'_8/k'_5$ for the P_1P_3 pair and $r = k'_{11}/k'_6$, $u = k'_{10}/k'_{11}$, and $v = k_9/k'_{11}$ for the P_3P_2 pair.

Fig. 12. Chou digraph pertaining to Scheme 10.



Conclusions

The present work introduces new algorithms based on directed graphs to determine initial and final product ratios for simple and complex kinetic models leading to multiple products for unimolecular transformations and under pseudo-order conditions. These are found to circumvent the tedious and error prone computations that are characteristic of conventional treatments based on rate laws. A degree of kinetic plasticity parameter is introduced and shown to be general in

© 2008 NRC Canada

describing the ACH condition (100% dynamic kinetic resolution), the opposite anti-ACH condition (0% dynamic kinetic resolution), and all other scenarios in between these limits. To empirically probe the full scope of the dynamics of a kinetic system one needs to begin from more than one set of starting substrate conditions. Thus, it is impossible to obtain a full picture by carrying out product studies from one set of starting substrate conditions such as a racemic mixture. For a practicing organic chemist who wishes to understand their kinetic schemes more deeply without having to invoke external assumptions, this means that they must move beyond the confines of racemic mixtures as the only starting point to obtain direct experimental measures of the dynamics of their systems. The determination of the degree of kinetic plasticity is thus based on a key experimental plot that relates final product excess and initial substrate excess in a pairwise fashion. Such a plot is always linear with a positive slope, and the degree of kinetic plasticity is found directly by subtracting the slope from unity. Furthermore, it may be used as a diagnostic test for checking the validity of proposed ACH-type kinetic schemes for a given chemical system. A key bonus of the new methods of obtaining product ratio expressions is that the precise rate constant dependence of the degree of kinetic plasticity is obtained explicitly. Such dependencies may be further checked by direct determination of absolute rate constants from independent kinetic measurements. Examination of extended variants of ACH-type schemes indicates that the ACH principle holds universally and may be elevated to the status of a kinetic theorem. The next challenge for organic chemists is to provide experimental verification of the predictions made in this work.

Correlation of the rates of solvolysis of acetyl chloride and α-substituted derivatives

Malcolm J. D'Souza, Zoon Ha Ryu, Byoung-Chun Park, and Dennis N. Kevill

Abstract: Additional specific rates of solvolysis have been determined for acetyl chloride and diphenylacetyl chloride. These are combined with literature values to carry out correlation analyses, using the extended Grunwald–Winstein equation with incorporation of literature values for solvent nucleophilicity (N_T) and solvent ionizing power (Y_{Cl}). Parallel analysis are carried out using literature values for the specific rates of solvolysis of trimethylacetyl chloride, chloroacetyl chloride, phenylacetyl chloride, and α-methoxy-α-trifluoromethylphenylacetyl chloride (MTPAC). Chloroacetyl chloride and MTPAC react by an addition-elimination pathway, with the addition step rate-determining, over the full range of solvents. Acetyl chloride reacts over the full range of solvents by an ionization pathway, with considerable nucleophilic solvation. The other three substrates can solvolyze with the domination of either mechanism, depending on the properties of the solvent. Reports concerning the use of product selectivity values, kinetic solvent isotope effects, and computational studies as additional probes of the mechanism of solvolysis are discussed.

Key words: Grunwald–Winstein equation, acyl chlorides, mechanism of solvolysis, solvent nucleophilicity.

Résumé : On a déterminé de nouvelles vitesses spécifiques de solvolyse pour le chlorure d'acétyle et le chlorure de diphénylacétyle. Les valeurs ainsi déterminées ont été combinées à celles qu'on peut retrouver dans la littérature pour effectuer une analyse de corrélation, à l'aide de l'équation étendue de Grunwald–Winstein et avec l'incorporation des valeurs obtenues dans la littérature pour le caractère nucléophile du solvant (N_T) et le pouvoir ionisant du solvant (Y_{Cl}). On a effectuer des analyses parallèles à l'aide des valeurs de la littérature pour les vitesses spécifiques de solvolyse du chlorure de triméthylacétyle, du chlorure de chloroacétyle, du chlorure de phénacétyle et du chlorure du α-méthoxy-α-trifluorométhylphénylacétyle (CMTPA). Le chlorure d'acétyle et le CMTPA réagissent par une voie d'addition/élimination dans laquelle l'addition est l'étape cinétiquement déterminante pour l'ensemble des solvants. Pour l'ensemble des solvants, le chlorure d'acétyle réagit par une voie d'ionisation impliquant une forte solvatation nucléophile. Pour les trois autres substrats, les deux mécanismes peuvent être prépondérants suivant les propriétés du solvant. On discute des rapports faisant état de l'utilisation des valeurs de sélectivité du produit, des effets isotopiques cinétiques du solvant et des études théoriques comme sondes additionnelles dans l'étude du mécanisme de solvolyse.

Mots-clés : équation de Grunwald–Winstein, chlorures d'acyles, mécanisme de solvolyse, caractère nucléophile du solvant.

[Traduit par la Rédaction]

Introduction

The extended (two-term) Grunwald–Winstein eq. [1] has been shown to be a useful probe of solvolytic reaction mechanism. In eq. [1], k and k_o are the specific rates (first-order rate coefficients) of solvolysis in a given solvent and in the standard solvent (80% aq. ethanol), respectively, l represents the sensitivity to changes in solvent nucleophilicity (N_T), m represents the sensitivity to changes in the solvent ionizing power (Y_X for a leaving group X), and c is a constant (residual) quantity.

$$[1] \qquad \log k/k_o = lN_T + mY_{Cl} + c$$

The l and m values are closely related to the extent of nucleophilic and electrophilic assistance within the rate-determining step, with solvent polarity and other additional effects being incorporated into the mY_X term. Scales of ionizing power vary somewhat depending on the leaving group, hence the designation Y_X. The scales are available for about a dozen leaving groups, based on the specific rates of solvolysis of 1- and (or) 2- adamantyl derivatives (2). The solvent nucleophilicity (N_T) is based on the specific rates of solvolysis of the *S*-methyldibenzothiophenium ion (3). In addition to its predictive value, the equation can also be useful in establishing the presence of a change in dominant mechanism as the solvent is varied. If the change is towards the middle of the range of solvents and the l and (or) m values differ sufficiently, the two regions can be treated independently in terms of eq. [1].

The mechanisms of nucleophilic substitution at an acyl carbon have been extensively studied. The earlier studies of both haloformate esters (4) and acyl halides (5, 6) have been reviewed. Many of the earlier studies were of chloroformate esters, which solvolyze at a convenient rate at ambient temperatures. Depending on the R group of ROCOCl, the solvolysis can follow bimolecular and (or) unimolecular pathways.

The solvolysis of phenyl chloroformate (PhOCOCl) has been extensively studied (7–10), and there is convincing evidence, independent of the Grunwald–Winstein correlations, that the reaction involves an addition–elimination mechanism, with the addition step being rate-determining. The strongest evidence is that, for the solvolyses of several chloroformates and the corresponding fluoroformates, the two haloformates (including aryl haloformates) react at similar rates, with the fluoroformate frequently faster (11–13). Because of the considerably stronger carbon–fluorine bond, this would be very difficult to reconcile with any mechanism requiring appreciable C–X bond fission within the rate-determining step. The solvolysis of PhOCOCl in 49 solvents, covering a wide range of N_T and Y_{Cl} values, when analyzed (10) in terms of eq. [1], involve an l value of 1.66 ± 0.05 and an m value of 0.56 ± 0.03 (multiple correlation coefficient R of 0.980). The data are very robust and various subsets of values give essentially the same sensitivity values. These values can be taken as typical values for attack at the acyl carbon proceeding by the addition–elimination mechanism, with the addition step rate-determining.

At the other extreme, 1-adamantyl chloroformate containing the tertiary 1-adamantyl cage structure, shows essentially no dependence on solvent nucleophilicity and an unusually low m value (0.47 ± 0.03) for a reaction proceeding with rate-determining ionization. The low value is probably associated with the solvolysis–decomposition nature of the reaction (14), with the ionization accompanied by loss of CO_2 and the formation of the chloride accompanied by ether and (or) alcohol, depending on the solvent. The change from an associative to an ionization rate-determining step can also be brought about, without decomposition, by the substitution of sulfur for one or both oxygens for phenyl chloroformate. For example, for 31 solvents the solvolyses of PhSCSCl show specific rates that can be correlated (15) using eq. [1] with values of 0.69 ± 0.05 for l and 0.95 ± 0.03 for m (R = 0.987). The rather large l value is believed to be due to an appreciable nucleophilic solvation of the developing acylium ion.

Solvolyses of aromatic acyl halides (ArCOCl) also proceed at convenient rates and several specific rate determinations have been made. Recent correlations of the available data using eq. [1] have used data from previous publications in conjunction with a few new values (16). Evidence was again obtained for both addition–elimination and ionization pathways, with the ionization pathway being assisted by nucleophilic solvation of the developing acylium ion. For *p*-nitrobenzoyl chloride solvolyses, with the electron–withdrawing substituent hindering the ionization pathway, the addition–elimination pathway (l = 1.78 ± 0.08, m = 0.54 ± 0.04) was observed over almost the full range of solvents. For solvolyses of *p*-methoxybenzoyl chloride with a powerful electron-supplying substituent, the ionization pathway was dominant over the full range of solvents (l = 0.31 ± 0.05, m = 0.81 ± 0.02). The parent benzoyl chloride and the *p*-chloro derivative both showed a switch-over in the dominant mechanism as one moved across the range of solvents. Other earlier approaches indicating such a change in mechanism, largely from the laboratories of Bentley, are extensively reviewed in this article. In contrast, benzoyl fluoride (17) with the stronger C–F bond retarding the heterolysis required in the ionization pathway followed the addition–elimination pathway over the full range of solvents (l = 1.58 ± 0.09, m = 0.82 ± 0.05).

The solvolyses of aliphatic acyl halides are considerably faster than those for aromatic acyl halides. For example, acetyl chloride solvolyzes about 150 times faster than *p*-methoxybenzoyl chloride over a range of relatively polar hydroxylic solvents (18). For this reason, the early studies were usually done with small concentrations of water or alcohol in the presence of an excess of inert solvent, such as ether, acetone, acetonitrile, or nitrobenzene (5). Studies of the specific rates of methanolysis and phenolysis of acetyl chloride and derivatives, in acetonitrile, led for the methanolyses to the operation of concurrent second-order and third-order pathways. A powerful catalysis by chloride ion was observed, with first-order kinetics in each of the substrate, methanol, and chloride ion. A loose S_N2 transition state was proposed (19, 20) with general base catalysis by solvent, methanol, or chloride ion. Consistent with this picture, modest rate decreases were observed on the introduction of one or two methyl groups, with a larger (about one order of magnitude) reduction on the introduction of a third.

The phenolysis of acetyl chloride (20) and its methyl-substituted derivatives (19) proceeds kinetically by a first-order pathway in each reactant. An alternative pathway was proposed in which the phenol rendered electrophilic assistance to chloride ion removal followed by return of the anionic species at the oxygen when proceeding to product (eq. [2]).

$$[2] \qquad \mathrm{RCOCl + HOPh \rightleftarrows (RCO)^+(ClHOPh)^- \rightarrow RCOOPh + HCl}$$

Consistent with the overall picture, the introduction of one or two chlorine atoms into the methyl group of acetyl chloride accelerated the methanolysis, presumably by superimposing a dominant addition–elimination pathway, but very large rate reductions were observed for the phenolysis, consistent with a large unfavorable electronic effect on the electrophilically assisted ionization reaction.

The kinetics of the solvolyses can be conveniently studied by rapid-response conductivity measurements. The ease with which a homogenous solution of the substrate can be obtained is usually the limiting factor as regards the range of binary aqueous solvents for which meaningful specific rates of solvolysis can be obtained (18).

A study of the ethanolysis of acetyl chloride (21) and a series of derivatives (22) by a rapid-response technique (23, 24) showed, consistent with the studies under nonsolvolytic conditions (19, 20), a faster reaction in presence of a chloro-substitutent, modest rate reductions in the presence of one or two methyl groups or a phenyl group, and a sharp fall-off in rate on the introduction of the third methyl group (22). An

attempted correlation of the effects of the structural changes using the two-term Taft equation (eq. [3]) was only moderately successful ($R = 0.933$).

$$[3] \qquad \log (k/k_o) = \rho^*\sigma^* + \delta E_s$$

In eq. [3], k is the appropriate rate coefficient for the reaction of a member of the series of subtrates, k_o is the corresponding rate coefficient for the standard substrate, ρ^* is the sensitivity to changes in the polar substituent constant σ^*, and δ is the sensitivity to changes in the steric substituent constant E_s. The tabulated substituent constants would only be expected to be valid for a pathway resembling that for the standard system, ester hydrolysis. Since the ethanolysis of the series of acetyl chlorides correlate rather poorly, the addition–elimination pathway, believed to hold for ester hydrolysis, is not supported for all of these formally similar reactions. A change in mechanism at or near the ethanolysis of the parent acetyl chloride was put forward as a possible rationalization.

The effect of the variation of solvent in the solvolyses of aliphatic acyl chlorides has been studied more recently by Bentley and co-workers (18, 25, 26), by Koo and co-workers (27), and by Ryu and co-workers (28–30). The relevant data from these reports will be combined with new data for the solvolyses of acetyl chloride and diphenylacetyl chloride, allowing correlations, in terms of eq. [1], with from 24 to 38 total solvents for each of the subtrates: acetyl chloride, trimethylacetyl chloride, chloroacetyl chloride, phenylacetyl chloride, diphenylacetyl chloride, and α-methoxy-α-(trifluoromethyl)phenylacetyl chloride (MTPAC).

Molecular orbital calculations to predict the pathway for the methanolysis of protonated acetyl chloride, with up to six methanol molecules available, favor an ionization mechanism (31). In contrast, it has been claimed (32) that the methanolyses of a paclitaxel (Taxol) analog bearing a chloroacetyl group at the C2′ position proceeds by a concerted (one-step) substitution process at the acyl carbon with regeneration of the hydroxyl group. Esters of this type are very important in terms of drug design and development because of increases in both stability and water solubility.

Results

The specific rates of solvolysis of acetyl chloride were determined in methanol, ethanol, and 2,2,2-trifluoroethanol (TFE) at 0.0 °C, and the values were found to be in good agreement with literature values. Previously unreported values were obtained at 0.0 °C for solvolyses in three water-1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) solvents. These values are reported in Table 1.

Similarly, the specific rates of solvolysis, at 10.0 °C, of diphenylacetyl chloride were found to be in good agreement with literature values for 100% ethanol, 80% aq. ethanol, and 100% TFE, and new unreported values were obtained for two additional aqueous ethanol compositions, for four aqueous methanol compositions, and for three aqueous acetone compositions. These values are reported in Table 2.

Discussion

Solvolyses of acetyl chloride

The literature values (18, 30) for the specific rates of solvolysis, in combination with the HFIP-H_2O values from this study, are used to carry out correlations using eq. [1]. The results are shown in Table 3, together with values for trimethylacetyl chloride and chloroacetyl chloride. The analyses with one or two phenyl substituents present are presented in Table 4.

It has previously been demonstrated that when undergoing solvolysis the parent acetyl chloride shows appreciable sensitivities towards changes in both solvent nucleophilicity and solvent ionizing power over the full range of solvents involved in the studies. The original values, reported as a footnote (18) for only six solvents, were of 0.86 for l and 0.68 for m and these have held up very well. A correlation of data from 20 solvents, with a good representation of TFE-containing solvents, led (30) to values of 0.79 for l and 0.67 for m ($R = 0.988$). The five data points in TFE-EtOH mixtures were excluded from the correlation because, as is often the case (33), they fell below the correlation line. No evi-

dence was obtained for a solvent-induced change in mechanism and a loose S_N2 transition state was proposed (18, 30).

We extended the range of solvents to more ionizing and less nucleophilic types by adding specific rate values in 97%, 90%, and 70% HFIP (*w*/*w*). These values are reported in Table 1. In total there have now been determinations in 30 solvents, which have both N_T and Y_{Cl} values available. Use of all 30 data points leads to *l* and *m* values (Table 3 and Fig. 1) that are essentially unchanged from the two earlier correlations. Sensitivity values are obtained of 0.83 for *l* and 0.72 for *m* (R = 0.953). Omitting the five TFE-EtOH data points does not appreciably change the *l* and *m* values, but it markedly improves the goodness-of-fit parameters (l = 0.83, m = 0.70, R = 0.989).

Two other subsets of correlation values for acetyl chloride solvolysis are reported in Table 3. Of particular interest is the one involving eight TFE-H_2O and HFIP-H_2O solvents. The *l* and *m* values are essentially identical to those for the larger data sets, confirming the absence of any change to a mechanism involving increased importance for ionization

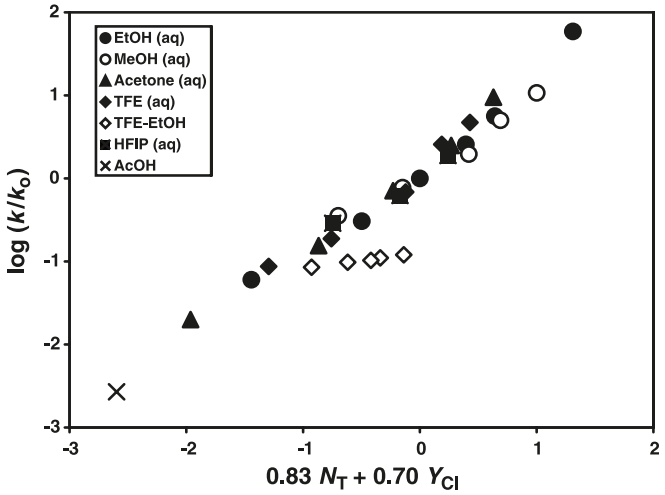
Fig. 1. Plot of log (k/k_o) for solvolyses of acetyl chloride at 0.0 °C against (0.83 N_T + 0.70 Y_{Cl}). The five log (k/k_o) values for the TFE-EtOH mixtures are not included in the correlation; they are added to show the extent of their deviation from the correlation line.



and (or) reduced importance for nucleophilicity in the highly ionizing and low nucleophilicity solvents. However, a correlation of the eight data points using the one-term Grunwald–Winstein equation (eq. [1] without the lN_T term) gives what is essentially a scatter plot with an m value of –0.06 ± 0.27 and a correlation coefficient of 0.086, showing the importance of using the two-term equation when nucleophilic participation is an important component of the mechanism.

The Grunwald–Winstein equation represents only one way in which solvent variation can lead to evidence concerning the mechanism. For example, the kinetic solvent isotope effect (KSIE) can be useful, frequently involving solvolyses in MeOH and MeOD. For acetyl chloride, the KSIE (k_{MeOH}/k_{MeOD}) of 1.29 (18) or 1.32 (29) at 0.0 °C is comparable with that of *p*-methoxybenzoyl chloride (34), which is believed to involve an ionization reaction with moderate nucleophilic solvation (16, 34). The value is significantly lower than the 1.55 for benzoyl chloride (35) or the 2.17 for *n*-propyl chloroformate (36), which are believed to undergo methanolysis by the addition–elimination pathway with a general base catalysis to the nucleophilic attack by a second methanol molecule (26).

A second approach to obtaining evidence that is potentially useful in studying reaction mechanisms for solvolytic reactions is to study the trend in product selectivity values (S) as the composition of a mixture of two hydroxylic solvents, usually water and an alcohol, is varied. Discontinuities indicate the possibility of a change in mechanism at that composition (25, 26). For acetyl chloride, the product selectivities in mixtures of water with ethanol or methanol show slightly increasing S values as the water content increases, with no discontinuity, consistent with the presence of only one mechanism over the full range of 10% to 90% water content (18).

We favor, over the full range of solvents, an ionization reaction with extensive nucleophilic solvation for the solvolysis of acetyl chloride. The l value is quite large, but evidence exists for increased sensitivity for attack at an sp^2 carbon relative to attack at an sp^3 carbon. This evidence has been summarized by Mayr and co-workers (37). The l value is 0.69 for PhSCSCl (15), and solvolyses of carbamoyl chlorides have l values in the 0.4 to 0.7 range (10, 38, 39), systems that are believed to follow an ionization pathway. We cannot, however, argue strongly against the possibility that they should be considered as S_N2 reactions with a very loose transition state (18, 26, 28).

Solvolyses of trimethylacetyl chloride

Based primarily on an early maximum in S values, at 90%–95% alcohol content (as water is progressively added to methanol or ethanol), a duality of mechanism was proposed, with the addition–elimination mechanism dominant only in the solvents of very high alcohol content (25). A curvature in the plots against Y values was considered to give support for the mechanistic change. However when both ionizing power and solvent nucleophilicity terms are important, care must be exercised in interpreting plots against only a solvent ionizing power scale. The detailed behavior will be very dependent upon the relative magnitudes of the l and the m values.

The claim for an ionization pathway being observed for acetyl chloride but not under identical conditions for trimethylacetyl chloride is worthy of further consideration, since electronic factors would suggest a more favorable ionization reaction for the trimethylacetyl chloride. However as mentioned earlier, it undergoes a slower ethanolysis, about one order of magnitude slower than acetyl chloride (22). This suggests that there must be a substantial steric effect towards the nucleophilic solvation, and for the claimed (25) change of mechanism to operate this must be sufficiently strong that the addition–elimination pathway becomes favored for solvolyses of trimethylacetyl chloride in methanol, ethanol, and binary mixtures with water that are rich in alcohol.

This is a situation that can be very nicely investigated using eq. [1] and correlations of available data are reported in Table 3. With the data for the five TFE-EtOH solvents removed, values for 33 solvents of 0.66 for l and 0.68 for m (R = 0.965) are obtained. This correlation is fair, but it can be considerably improved by removing those solvents that appeared to deviate in the consideration of S values: 100% and 90% ethanol and methanol, and also 90% acetone. For the 28 remaining solvents, values are obtained of 0.73 for l and 0.84 for m (R = 0.989). In addition to the improvement in the R value, the F-test value increased from 203 to 540. As with the solvolyses of acetyl chloride, the l and m values obtained using only the eight fluoroalcohol–water solvents are essentially identical to those obtained with a much wider range of solvents.

The observation of a discontinuity at essentially the same solvent compositions, when studied either by product selectivity (S) values or in terms of eq. [1], provides strong support for the view that it is of mechanistic significance.

The KSIE for the solvolyses in methanol or methanol-d has been determined as 1.46. This is intermediate between the values of 1.3 for acetyl chloride (18, 29) and the value of 1.55 for benzoyl chloride (35). It may well be for the solvolyses of trimethylacetyl chloride that the change from the ionization pathway to the addition–elimination pathway

© 2008 NRC Canada

as the water content becomes small is not complete at 100% methanol, and both reaction channels are operating simultaneously (25).

Solvolyses of chloroacetyl chloride

Chloroacetyl chloride reacts faster than acetyl chloride both with small amounts of methanol in acetonitrile (19) and in ethanolysis in 100% ethanol (22). Recently, specific rates of solvolysis were made available at –10.0 °C for 34 solvents, including values in TFE-H_2O and TFE-EtOH (26). Application of eq.[1] led to the values reported in Table 3. With all 34 solvents, values are obtained of 1.40 for l and 0.40 for m (R = 0.978). In this instance, exclusion of the five TFE-EtOH points leads to only minor changes in the values (l = 1.41, m = 0.40, R = 0.977). The magnitudes of the l and the m values suggest an addition–elimination pathway with addition rate-determining, and they are in reasonable agreement with values of 1.54 for l and 0.45 for m given in a footnote to the manuscript (26) presenting the determinations of specific rate. The KSIE (MeOH/MeOD) was determined as 2.18, consistent with the proposed mechanism and the operation of general base catalysis (26).

Solvolyses of phenylacetyl chloride

Values for the specific rates of solvolysis of phenylacetyl chloride are available (26, 30) in 33 solvents at 0.0 °C. The results from the correlations using eq. [1] are shown in Table 4. Both with and without the five TFE-EtOH solvents, poor correlations (R < 0.9) are obtained. The data can, however, be treated in terms of two competing reaction pathways. In TFE and all TFE-H_2O and HFIP-H_2O solvents, plus 80TFE-20EtOH (10 solvents) values are determined of 0.81 for l and 0.88 for m (R = 0.986). In the remaining 23 solvents, values are obtained of 1.59 for l and 0.58 for m (R = 0.923).

The S values (26) are a little ambiguous as regards a change in mechanism in aqueous ethanol or aqueous methanol. In aqueous ethanol, a maximum is observed at around 60% ethanol, but in aqueous methanol the values fall over the full 80%–40% methanol range studied. The Grunwald–Winstein treatment suggests that the addition–elimination pathway is dominant over the full range of aqueous methanol, ethanol, and acetone studied, and only in solvents rich in fluoroalcohol is there a changeover to a dominant ionization pathway. The reported KSIE at 10.0 °C (26, 29) for MeOH/MeOD of 1.40 is unusually low for a reaction following the addition–elimination pathway and it is only slightly greater than the value of 1.3 observed for acetyl chloride at 0.0 °C (18, 29). This suggests that only a weak general base catalysis operates in these solvolyses.

Solvolyses of diphenylacetyl chloride

Earlier studies (29, 30), mainly in TFE-H_2O, TFE-EtOH, and HFIP-H_2O, have been supplemented by measurements in aqueous ethanol, aqueous methanol, and aqueous acetone (Table 2) to give in total 24 data points at 10.0 °C. These have been correlated using eq. [1] and the results are presented in Table 4 and in Figs. 2–4.

As with phenylacetyl chloride, use of all of the data points in the correlations leads to a poor correlation (Fig. 2) and the correlation coefficient is even lower (R = 0.827). Dividing

into two subgroups in the identical manner to that used for phenylacetyl chloride, led to values in nine fluoroalcohol-rich solvents of 0.61 for *l* and 0.72 for *m* ($R = 0.972$), as shown in Fig. 3. The remaining 15 solvents give a linear plot (Fig. 4) requiring an *l* value of 1.56 and an *m* value of 0.46 ($R = 0.933$).

The KSIE (MeOH/MeOD) at 10.0 °C is 1.61 (29), compatible with the addition–elimination mechanism, with general base catalysis from a second solvent molecule proposed for the subgroup of solvents that includes methanol.

Solvolyses of α-methoxy-α-trifluoromethylphenylacetyl chloride (MTPAC)

Specific rates of solvolysis are available at 25.0 °C in 37 solvents, including four TFE-H_2O and four TFE-EtOH solvents (27). The TFE-H_2O solvents were prepared on a *v*/*v* basis, and the required N_T and Y_{Cl} values are obtained by interpolation within values for solvents prepared on a *w*/*w* basis. The values obtained are: 97% TFE, $N_T = -3.41$, $Y_{Cl} = 2.82$; 90% TFE, $N_T = -2.73$, $Y_{Cl} = 2.81$; 70% TFE, $N_T = -2.13$, $Y_{Cl} = 2.94$; 50% TFE, $N_T = -1.62$, Y_{Cl} 3.07. The correlations are reported in Table 4. With the use of all data points, values of 1.75 for *l* and 0.71 for *m* ($R = 0.967$) are obtained. These are little changed on removing the four TFE-EtOH solvents, with values of 1.66 for *l* and 0.66 for *m* ($R = 0.973$).

Whereas the "parent" phenylacetyl chloride showed a change in mechanism from addition–elimination to ionization on moving from solvents such as aqueous ethanol or methanol to solvents rich in fluoroalcohol, the insertion on the α-carbon of the powerfully electron-withdrawing methoxy and trifluoromethyl groups severely inhibits the ionization pathway, and as with chloroacetyl chloride, the addition–elimination pathway is observed across the full range of solvents. The KSIE (MeOH/MeOD) at 25.0 °C is of value 2.4 (27), larger than with simple alkyl and arylalkyl groups attached to the carbonyl carbon and comparable to the 2.2 value obtained for chloroacetyl chloride. It has been shown that the KSIE values trend upward as the value for the inductive parameter for R in RCOCl rises (29). This can be interpreted as a more favorable general base catalysis to the solvolysis as the electron-withdrawing power of the R group increases.

Relevance of computational studies to the solvolysis

The extension from computationally favored pathways in the absence of bulk solvents to the reactions as carried out in solution has many potential pitfalls. The observation that the mechanism in solution can, for the hydrolysis component of the solvolysis of several acyl chlorides, be switched between alternative mechanisms by a change of a binary solvent containing water from one of high nucleophilicity and modest ionizing power to one of low nucleophilicity and high ionizing power emphasizes the difficulty involved in making this extension.

A paper by Fox, Bach, and co-workers (31) includes a treatment of the methanolysis of an acetyl chloride molecule with up to six methanol molecules present. Unfortunately, the relevance to the presence study is limited by a prior protonation of the acetyl chloride before the involvement of the methanol molecules. Indeed, for phenolysis where we have proposed (19, 20) electrophilic interaction at the chlorine to generate an acylium ion (eq. [2]), a prior protonation would be very unfavorable to such a pathway. For methanolysis, the perturbation would be expected to be less severe but significant.

When the influence of solvent upon the addition–elimination pathway is considered, it includes both nucleophilic attack at the carbonyl carbon and stabilization of the negative charge developing at the acyl oxygen. The latter effect will be negated by prior protonation, and one can concentrate on nucleophilicity effects. However, the detailed interactions at the transition state will be quite different to those for the neutral substrate.

Nonetheless, the computational analysis leads to essentially the same conclusion as the Grunwald–Winstein treatment of the solvolyses of the neutral (unprotonated) substrate. It is concluded that with either four or six methanol molecules available for possible interaction with the protonated acetyl chloride, the formation of the methyl ester follows a pathway with considerable ionic (S_N1) character in the rate-determining step, consistent with present and previous (18, 26) proposals based on experimental evidence from solvolysis reactions.

Conclusions

It was previously demonstrated (16) that benzoyl chloride and *para*-substituted derivatives react by ionization with modest nucleophilic solvation when a *p*-methoxy substituent is present, and the addition–elimination mechanism, with the addition step rate-determining, becomes of increasing importance as one moves to the parent and on to derivatives with electron-withdrawing substituents. When one arrives at the *p*-nitro derivative, the dominant mechanism is addition–elimination across the full range of solvents, except for the highly ionizing and low nucleophilicity 97% HFIP.

This type of behavior is repeated in the solvolyses of aliphatic acyl chlorides. The parent acetyl chloride is found to follow the ionization pathway with appreciable nucleophilic solvation over the full range of solvents. Various subsets of data points give essentially unchanged *l* and *m* values, showing the correlation to be very robust.

The trimethylacetyl chloride shows similar behavior, except that in methanol, ethanol, 90% MeOH, 90% EtOH, and 90% acetone there is evidence for a superimposed addition–elimination contribution. The incursion of the additional pathway at high organic solvent content is nicely consistent with the evidence, from a reversal in trend of product selectivity (*S*) values, for a change in mechanism at about 90% alcohol content (25).

The consequences of the introduction of powerful electron-withdrawing substituents mirrors the influences of a *para*-nitro substituent introduction into benzoyl chloride. Both chloroacetyl chloride and MTPAC give good correlations over the full range of solvents with *l* and *m* sensitivity values consistent with the addition–elimination pathway.

When all available specific rates of solvolysis are used in the correlations, both phenylacetyl chloride and diphenylacetyl chloride give poor correlations. Acceptable correlations can be obtained when the specific rate data are divided into two subsets. One subset includes the data in TFE, TFE-

© 2008 NRC Canada

H_2O, HFIP-H_2O, and 80%TFE-20%EtOH. The other solvents are assigned to the other subset. The *l* and *m* values for the two subsets are consistent with ionization, with appreciable nucleophilic solvation, and addition–elimination, respectively. Two pathways were also indicated from a maximum in the *S* values for the solvolyses of phenylacetyl chloride in aqueous ethanol (26), but the use of eq. [1] indicates a much more extensive addition–elimination region than that deduced from a consideration of the trend in *S* values.

Literature KSIE values also support the division into two types of reaction channels. Relatively low values of about 1.3 for the methanolysis of acetyl chloride (MeOH/MeOD) increase in value as the addition–elimination pathway takes over and as general base catalysis becomes an increasingly important rate-determining factor. The KSIE value rises to 2.2 for chloroacetyl chloride and 2.4 for MTPAC.

It is probable that the only moderate, at best, success in using the Taft equation (eq. [3]) to correlate the effects of structural change upon the rates of ethanolysis of a series of aliphatic acyl chlorides (22) is due, at least in part, to changes occurring in the dominant mechanism as the structure is changed. For example, the series includes both acetyl chloride (ionization) and chloroacetyl chloride (addition–elimination).

Calculations on reaction of a protonated acetyl chloride molecule with up to six methanol molecules present (31) found that with either four or six methanol molecules an ionization (S_N1-like) mechanism was favored, consistent with the experimental evidence, and no evidence was found for a competitive addition–elimination pathway. The confidence with which this can be considered as support for the experimental findings is, however, tempered by the protonation that is introduced prior to the computations.

The *l*/*m* ratio can be a useful mechanistic indicator. For the correlations believed to be for ionization reactions with nucleophilic solvation, the values from Tables 3 and 4 range from 0.82 to 1.21, and the values for the correlations believed to be for the addition–elimination pathway range from 2.46 to 3.53.

Experimental

Acetyl chloride (Sigma-Aldrich ≥ 99%) and diphenylacetyl chloride (Lancaster >98%) were used as received. Solvents were purified as previously described (40). The determinations of the specific rates reported in Table 1 were carried out by injecting 4.0 μL of a 0.30 mol/L solution of acetyl chloride in acetonitrile into 2.0 mL of the solvent under investigation. Specific rates and the associated standard deviations were determined from a computer analysis (Guggenheim method, ref. 41) of the plots of conductivity against time. The apparatus has been previously described (42).

The determinations of the specific rates reported in Table 2 involved addition of 12 μL of substrate to 25 mL of solvent followed by conductance measurements at appropriate time intervals. The measurements were used in conjunction with the infinity value to obtain the integrated rate coefficients and all values from duplicate runs were averaged to obtain the reported values. The conductivity apparatus consisted of an efficiently stirred cell connected to a TENMA multimeter (72-602 model with a 72-6251 connector), linked to a PC through a RS232C port and with a Simpson 420 function generator.

The multiple regression analyses were performed using commercially available statistical packages.

Chemical functionalization and modification of surface-bound cystamine–glycine monolayers on gold nanoparticles

Mita Dasog, Amir Kavianpour, Matthew F. Paige, Heinz-Bernhard Kraatz, and Robert W.J. Scott

Abstract: Herein, we report the synthesis, characterization, and post-functionalization of Au nanoparticles that have been surface-modified with glycine–cystamine (Gly-CSA) stabilizing groups. We show that Au monolayer protected clusters (MPCs) can be synthesized via the Brust–Schiffrin method using a Boc-Gly–CSA stabilizer, followed by efficient removal of the Boc protecting group with trifluoroacetic acid. The resulting Gly–CSA Au MPCs are characterized via UV–vis, TEM, and ^{1}H NMR, and are stable in solution over long periods of time. Finally, we show that the Gly–CSA Au MPCs can be further functionalized with nearly stoichiometric yields using activated esters of stearic acid and a Bodipy dye derivative. Thus, this work provides an alternative, general approach for the modification of the surface chemistry of MPCs.

Key words: gold nanoparticles, peptide stabilizers, dyes.

Résumé : Dans ce travail, on rapporte la synthèse, la caractérisation et la post-fonctionalisation de nanoparticules d'or dont on a modifié la surface par des groupes stabilisants de glycine–cystamine (Gly–CSA). On démontre que les agrégats protégés de monocouches (APM) d'or peuvent être synthétisés par la méthode de Brust–Schiffrin en utilisant un Boc-Gly–CSA comme stabilisant, suivie par une élimination efficace du groupe protecteur Boc à l'aide d'acide trifluoroacétique. On a caractérisé les agrégats de monocouches d'or protégés par le groupe glycine–cystamine « Gly–CSA Au MPC » par la spectroscopie UV–vis, la microscopie électronique à transmission (MET) et la RMN du ^{1}H et ils sont stables en solution pour de longues périodes de temps. On démontre enfin que les « Gly–CSA Au MPC » peuvent aussi être fonctionnalisés avec des rendements pratiquement stoechiométriques en utilisant des esters activés de l'acide stéarique et un dérivé colorant Bodipy. Ce travail fournit donc une approche alternative générale à la modification de la chimie de surface des APM.

Mots-clés : nanoparticules d'or, stabilisants peptidiques, colorants.

Introduction

Modifying the chemical properties of nanoparticle surfaces has been a challenging and active area of research over the past decade (1–6). As the use of metal nanoparticles in biological fields becomes more common for various applications, such as bioimaging, biosensors, drug delivery, and tagging of nucleic acids and proteins, it has become extremely important to control the surface functional groups of these nanoparticles precisely both in vivo and in vitro (7–10). Water soluble, monolayer protected gold clusters (Au MPCs) have attracted a great deal of interest in the field as they are, for the most part, chemically inert (11), and offer a range of chemical functionalities for subsequent modification (12–15). While there have been many examples of propagation reactions on halide and carboxylic acid terminated Au MPCs (12, 16–18), it is highly desirable to directly synthesize stable Au MPCs that have free amine surfaces, as these functional groups are amongst the most useful for further chemical modification. It is our goal to design a synthetic pathway towards stable, monodisperse peptide-stabilized MPCs in which the surface chemistry of the nanoparticle can be further tuned via simple amide coupling reactions with primary amine groups on the surface of the MPC. Such a strategy is complementary to earlier studies by Murray and co-workers who showed further functionalization of tiopronin and mercaptoundanoic acid coated MPCs, which have surface carboxylic acid groups (12, 17). Thus, this work expands the chemical toolbox of peptide-stabilized MPCs whose surface chemistry can be further modified via simple amide coupling reactions.

There are a number of effective strategies, which have been used to functionalize Au nanoparticle surfaces with peptide stabilizers. One popular approach for synthesizing multifunctional, water-soluble Au MPCs is to pre-design a

thiol-containing biomolecule, followed by ligand exchange reactions with preexisting Au MPCs. These reactions often involve ligand exchange of thiols onto citrate-stabilized Au nanoparticle surfaces in acidic conditions (13, 19–23), or place-exchange of thiol ligands (1, 24). Another promising route pioneered by the groups of Jacobson (25) and Huo (26–28) is to use solid-phase syntheses to make MPCs with the appropriate arrangement of functional groups. Direct synthetic routes have also been pursued for peptides, such as cysteine (29–32), homocysteine (33), and glutathione (34, 35), and other ligands, such as aminothiophenol (36, 37), which contain both amine and thiol functional groups. However, such bi-functionalized particles often aggregate in solution over time, either because of hydrogen-bonding interactions between particles (13, 29, 30, 33, 37), or the high affinities of both thiols and amines for Au surfaces, leading to cross-linking between particles (36, 38). While these are all effective strategies to design complex peptide-stabilized particles, it can often be difficult to prepare clean, stable amine-terminated particles in solution by these routes. We chose to pursue a direct synthesis route in which amine groups on the peptide were protected during Au nanoparticle synthesis, followed by purification and deprotection of the terminal amine groups.

Herein, we report an effective strategy to synthesize glycine–cystamine-derivatized Au MPCs with protected glycine groups on the exterior surface of the particles, followed by deprotection of the glycine groups to free amine groups. Furthermore, we show that the resulting amine-terminated particles can be effectively coupled with a range of activated ester compounds to give nearly stoichiometric functionalization of the MPCs. More specifically, MPCs were effectively functionalized with activated esters of stearic acid and a Bodipy dye derivative through the formation of amide bonds. In addition, we show that the short distance between the Au surface and terminal amine groups in these particles allows for studies of quenching interactions between particles and covalently attached dyes.

Experimental

Materials

Hydrogen tetrachloroaurate (III) salt ($HAuCl_4 \cdot 3H_2O$) and stearic acid were bought from Alfa Aesar. Triethylamine, trifluoroacetic acid (TFA), cystamine dihydrochloride (CSA), and sodium borohydride ($NaBH_4$) were purchased from Sigma-Aldrich. *N*-Hydroxybenzotriazole (HOBt) and *O*-*b*enzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium hexafluorophosphate (HBTU) were from Synpep and Boc-glycine (Boc-Gly–OH) and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) were bought from Advanced Chemtech. Sodium bicarbonate ($NaHCO_3$), citric acid, and organic solvents (HPLC grade chloroform, dichloromethane (DCM), and acetonitrile) were from EMD Chemicals Inc. 4,4-Difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid (Bodipy Fl) was purchased from Invitrogen. Deuterated solvents were purchased from Cambridge Isotope Laboratories. All the chemicals were used without further purification. 18 MΩ·cm Milli-Q deionized water (Millipore, Bedford, MA) was used throughout.

Synthesis of Boc-glycine–cystamine (Boc-Gly–CSA)

The amide coupling synthesis was carried out using an established literature synthesis (see Supplementary Data for details) (39).[2]

Synthesis of Boc-glycine–cystamine (Boc-Gly–CSA) Au MPCs

All syntheses and purifications were done under N_2 to avoid oxidation of thiols and Au MPCs (11). $HAuCl_4$ (20 mmol) salt was dissolved in 5 mL chloroform, followed by the addition of Boc-Gly–CSA (40 mmol) in 50 mL of chloroform. After stirring for 30 min, 10 mL of a 0.5 mol/L aqueous $NaBH_4$ solution at 0 °C was then added as a reducing agent. This solution mixture was stirred vigorously for 2 h. The chloroform layer was separated and washed twice with 20 mL of Millipore water. The solvent was removed, and the particles were redissolved in 10 mL of chloroform and dried over anhydrous $CaSO_4$ for 24 h.

Deprotection of the Boc group

To deprotect the Boc group on the Boc-Gly–CSA Au MPCs, the MPCs were dissolved in 5 mL dichloromethane (DCM), followed by the addition of 20 mL of 50% TFA solution in DCM. This solution was stirred for 1 h. Unreacted TFA was completely removed by rotary evaporation. The resulting Gly–CSA Au particles were dissolved in deionized water, and dialyzed for 120 h in deionized water to remove excess peptide not coordinated to the Au MPCs. A similar deprotection procedure was used to synthesize free Gly–CSA ligands. In addition, for IR studies, Gly–CSA was reduced in Zn/HCl to give the corresponding free thiol.

Synthesis of activated esters of stearic acid and Bodipy dye derivative

To activate stearic acid, HBTU (30 mmol), HOBt (30 mmol), and stearic acid (25 mmol) were stirred together for 1 h in 50 mL acetonitrile (40). The activated stearic acid was purified by column chromatography. A similar procedure was used to form the activated ester of the Bodipy dye derivative, except the activated ester of 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid was purified by removal of impurities via crystallization at –10 °C.

Amide coupling of Gly-CSA Au MPCs with activated esters

Amide coupling reactions with activated stearic acid were done with 5 mmol of Au MPCs (moles with respect to Au) dissolved in 5 mL of deionized water. Known amounts of the activated stearic acid (the absolute concentration of Gly–CSA was extrapolated via ^{1}H NMR using an internal standard of absolute ethanol), dissolved in 10 mL acetonitrile,

[2] Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. were added to the nanoparticle solution in the presence of 3 mL of triethylamine. After stirring the reaction mixture for 3 h, the solvent was removed, followed by washing with 5 mL of a saturated $NaHCO_3$ solution and then 5 mL of a 10% citric acid solution. This alternate washing with saturated $NaHCO_3$ and 10% citric acid was done three times, followed by a final wash with 25 mL of deionized water. The Au MPCs were dried over anhydrous $CaSO_4$ over 24 h and dissolved in acetonitrile.

For the activated ester of the dye, the amide coupling reaction was carried out in a similar manner as outlined above. The number of Au MPCs was extrapolated from TEM measurements (see Discussion) given a known concentration of Au (1 μmol); then the required volume of activated Bodipy dye (0.685 mmol/L solution) was added to give 160, 80, 40, 20, 15, 10, 5, and 1 dye molecule(s) per nanoparticle. The Au MPCs were dissolved in acetonitrile to carry out the amide coupling reaction. After 3 h of stirring, the acetonitrile was pumped off and the MPCs were redissolved in chloroform, followed by removal of impurities via crystallization at –10 °C and drying over anhydrous $CaSO_4$ for 24 h. Control samples in which there was no covalent bonding between MPC and dye were synthesized by combining dodecanethiol-derivatized Au MPCs (11) with the activated Bodipy dye.

Characterization

Absorption spectra were recorded on a Varian Cary 50 Bio UV–vis spectrometer with an optical path length of 1.0 cm. Transmission electron micrographs (TEM) were obtained with a Philips 410 microscope operating at 100 keV. Samples were prepared by placing a drop of solution on a holey-carbon-coated Cu TEM grid and allowing the solvent to evaporate in air. In all cases, many TEM images were collected at multiple locations for each sample, and the images shown are representative of the samples. Size distributions from TEM were obtained by measuring the diameters of several hundred particles. ^{1}H NMR were recorded on a Bruker 500 MHz Avance spectrometer; chemical shifts were referenced to the residual protons of the deuterated solvent. FTIR measurements were made on a Bruker Tensor 27 spectrometer. Infrared spectroscopy (FTIR) was done in chloroform and acetonitrile, using KBr windows, and a background spectrum of pure solvent was subtracted from the sample signal. The sample chamber was purged with nitrogen gas for 15 min before analysis and 128 scans per sample were obtained for each spectrum. Fluorescence measurements were performed on a SPEX 212 spectrofluorometer. The emission spectra were collected in the range of 515–600 nm with an excitation wavelength of 508 nm.

Results and discussion

Boc-Gly–CSA Au MPCs were synthesized in a single step using a modified Brust–Schiffrin method (41). The Au MPCs were made in quantitative yield, and no precipitation of particles due to aggregation was seen. As it was difficult to purify the MPCs at this stage by selective precipitation or column chromatography, deprotection of the Boc group was done immediately after synthesis. The Boc deprotection was carried out using 50% TFA to give Gly–CSA derivatized

Scheme 1. Schematic representation of Au MPCs stabilized with Boc-Gly–CSA before and after removal of the Boc group.

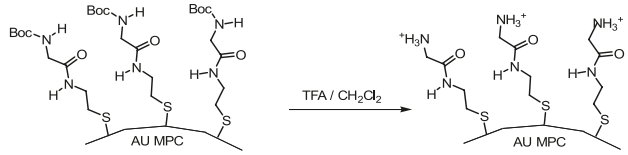

Fig. 1. UV–vis spectra of Boc-Gly–CSA and Gly–CSA Au MPCs.

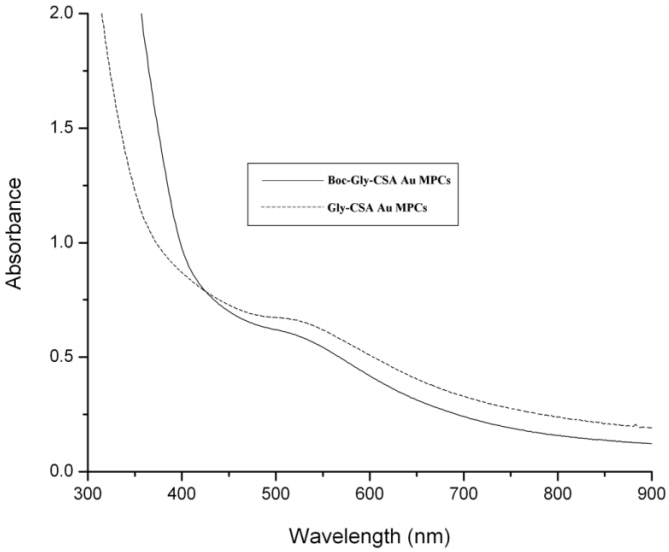

particles, which were soluble in water at pHs between 4 and 5, as shown in Scheme 1. Figure 1 shows the UV–vis spectra of the Boc-Gly–CSA Au MPCs before and after deprotection of the amine group with TFA. The initial Boc-Gly–CSA Au MPCs show a weak plasmon shoulder around 530 nm, suggesting the Au MPCs are above 2 nm in size (42, 43). This plasmon shoulder shifts to 540 nm and increases slightly in intensity for the deprotected Gly–CSA MPCs, suggesting a slight increase in particle size accompanying deprotection. While this shift in the plasmon band could also be the result of particle aggregation, no particle aggregation in solution was seen at acidic pHs between 4 and 5, while reversible aggregation due to H-bonding was seen at pHs near 7. In addition, no aggregates were seen in TEM images of the deprotected samples. Figure 2 shows representative TEM images and particle-size histograms of the Boc-Gly–CSA Au MPCs before and after deprotection; the average particle size increases from 3.2 ± 0.6 nm to 4.4 ± 0.8 nm. We believe that this increase in size may be due to instability of the Gly–CSA Au MPCs in the highly acidic TFA environment. Several other groups have attempted similar Boc deprotections on Au MPCs, though there was no specific mention in either case as to whether any Au nanoparticle growth was seen (12, 24).

The number of Au atoms in the final 4.4 ± 0.8 nm Gly–CSA Au MPCs is estimated to be approximately 2600 atoms using eq. [1] below (44), where n is the number of atoms per particle, R is the particle diameter and V_g is the molar volume of Au, 10.2 cm^3/mole. Hostetler et al. have shown that the percentage thiolate coverage on Au MPCs approaches

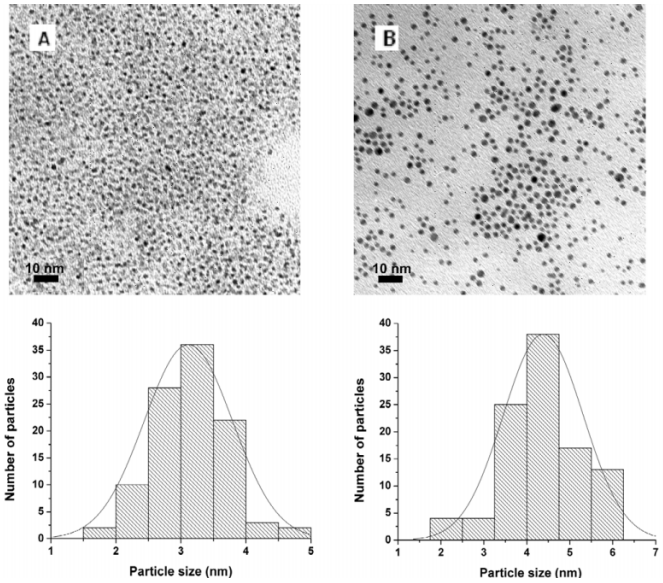
Fig. 2. TEM images and size-distribution histograms of (A) Boc-Gly–CSA Au MPCs and (B) Gly–CSA Au MPCs.



the single-crystal Au(111) limit of 33% as nanoparticles increase in size, with similarly sized particles estimated to have ~42% thiolate coverage on the surface (45). Using this estimate, there are, on average, approximately 350 Gly–CSA groups on each Au nanoparticle surface. Attempts were made to extrapolate more exact ligand–metal ratios from TGA measurements; however, it was extremely difficult to remove chemisorbed water and anions associated with the protonated Gly–CSA ligands. Thus, broad TGA decomposition peaks were seen from 240–340 °C and TGA mass losses were quite high.

$$[1] \qquad n = 4\pi R^3/3V_g$$

The final Gly–CSA Au MPCs are fairly monodisperse and are stable in water at pH between 4 and 5. It should be noted that similar syntheses of Au MPCs using deprotected Gly–CSA stabilizers gave rise to larger particles that had a mixed monolayer; that is, attachment of both amine and thiol groups of the bifunctional Gly–CSA ligand to the Au nanoparticle surfaces was seen by ^{1}H NMR (see Supplementary Data).[2] These particles were unstable in solution and typically precipitated from solution over a period of 6 to 7 days.

The Gly–CSA particles were dialyzed for 120 h to remove excess free peptide and other impurities. Figure 3 shows ^{1}H NMR of the Gly–CSA Au MPCs and free Gly–CSA in D_2O. Note that the α-H signal for the surface-bound Gly–CSA groups is not observed, and the β-H signal at 3.5 ppm is significantly broadened in the pure Au MPCs as a result of their proximity to the Au surface (1). A less-broadened singlet at 3.7 ppm is seen in the Gly–CSA Au MPCs, which corresponds to protons on carbon d in the free Gly–CSA. The lack of significant broadening seen for these protons as compared with the β-H signal indicates it resides further from the Au surface. This is in agreement with the proposed structure for the Gly–CSA Au MPCs in which the thiol group is associated with the Au surface. Further evidence of this bonding arrangement is a broad peak at 10.5 ppm for the Gly–CSA Au MPCs, which corresponds to the protonated amine group; this peak is significantly shifted from the free Gly–CSA peak at 8.3 ppm. This shift is likely due to spatial confinement of protonated amines on the nanoparticle surface (46). We also note the ^{1}H peak for the amide proton (proton c) is not seen for the Gly–CSA Au MPCs, which may be due to extensive H-bonding. FTIR data provide further support for the thiol–Au bonding arrangement, as shown in Fig. 4. The FTIR spectra of the free Gly–CSA thiol and Gly–CSA Au MPCs showed similar N–H stretching vibrations at 3512 cm^{-1} and 3405 cm^{-1} as well as a N–H bending vibration at 1603 cm^{-1}; this indicates that the amine groups are in similar chemical environments for both samples. Also, a weak S–H stretching band can be seen at 2563 cm^{-1} for the free Gly–CSA thiol, and is completely absent in the spectra of Gly–CSA Au MPCs, indicating that all thiols are functionalized on the Au surface.

Coupling reactions with an activated ester of stearic acid were carried out to determine the extent to which the free amine groups could be functionalized on the Gly–CSA Au MPCs. Both the Gly–CSA Au MPCs and the activated stearic acid were completely purified, followed by the addition of stoichiometric amounts of the activated ester to the MPCs. The ^{1}H NMR spectrum of Gly–CSA Au MPCs coupled with stearic acid in a 1:1 ratio shows nearly complete functionalization of all the terminal amine groups (see Supplementary Data).[2] Table 1 shows the quantitative yields of the coupling reactions as determined by ^{1}H NMR for reactions run at different Gly–CSA: stearic acid ratios; nearly stoichiometric yields were typically seen for all coupling reactions. Verification of amide-coupling was seen upon inspection of the FTIR spectrum of the conjugated MPCs (Fig. 4C); a carbonyl stretch at 1678 cm^{-1} corresponding to the new amide group was seen, along with the disappearance of the N–H stretching bands above 3300 cm^{-1}. It should be noted that while the amide conjugation onto the Gly–CSA MPCs was nearly quantitative, TEM images of the final particles after stearic acid conjugation often showed increases in particle size. For example, MPCs synthesized with a 1:1 ratio of Gly–CSA MPCs: stearic acid showed an increase in average nanoparticle size from 4.4 ± 0.8 nm to 6.2 ± 1.4 nm after conjugation, with bimodal distributions of particle sizes emerging (see Supplementary Data).[2] We still do not fully understand the reasons for these size increases, though we believe that it may be due to reagents present in the conjugation and (or) cleaning steps.

Having successfully demonstrated that nearly-quantitative conjugation could be obtained between the terminal surface amine groups of the Gly–CSA MPCs and an activated ester, an activated ester of a Bodipy dye derivative, 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid, was synthesized and reacted with the Gly–CSA MPCs. A series of Gly–CSA: dye conjugates was then synthesized; for all solutions the final concentration of dye was kept constant, while the concentration of the Gly–CSA Au MPCs was varied to give loadings of approximately 160, 80, 40, 20, 15, 10, 5, and 1 dye molecules per nanoparticle (note these loadings are all significantly below the earlier estimate of 350 Gly–CSA groups per nanoparticle). Because of the low concentrations of these conjugated systems, ^{1}H NMR and FTIR studies could not be carried out; rather, the conju-

gation reaction was followed by fluorescence emission studies. Figure 5 shows the UV–vis and emission spectra for a series of Bodipy propionic ester samples conjugated with Gly–CSA Au MPCs (Figs. 5A and 5B), and the corresponding UV–vis and emission spectra of non-conjugated Bodipy propionic ester mixed with dodecanethiol Au MPCs (Figs. 5C and 5D). For these experiments, the total amount of Bodipy dye in the mixture was kept constant. As the ratio of dye to Au nanoparticle increased, the absorbance peak height decreased, reflecting the change in concentration of Au MPCs. For the emission studies, it was observed that the fluorescence emission of the dye-conjugated particles was significantly quenched over that of the non-conjugated system.

The quenching of fluorescence emission from fluorophores near metal surfaces has been observed in a number of

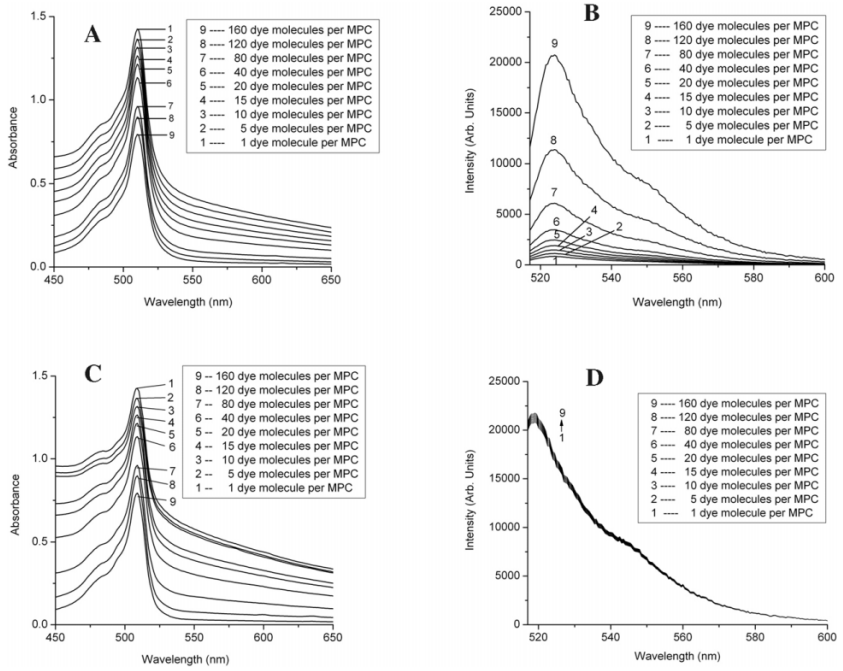
Fig. 5. UV–vis and emission spectra of (A, B) Gly–CSA Au MPCs conjugated with Bodipy dye, and (C, D) dodecanethiol Au MPCs, which are not conjugated with the dye. Note that the dye concentration is kept constant for all samples.



systems, including both planar surfaces and colloidal particles, and has been attributed to a number of different mechanisms, including energy transfer, electron transfer, and others (47). However, for this system, it was observed that the extent of quenching depends strongly on the amount of fluorophore loading. A significant amount of quenching of the fluorescence of the fluorophore that is bound to the Au MPCs is seen at low fluorophore loadings for the Gly–CSA MPCs with conjugated fluorophores as compared with high loadings of 160 dyes per nanoparticle (for an average fluorophore loading of 1 molecule per Au nanoparticle, the emission signal was 4% of that of the 160:1 fluorophore–nanoparticle sample, as determined by the relative areas under the emission curves). Similar effects have been described by Kamat and others for various fluorophore–nanoparticle conjugated systems (48–52). While not direct evidence of amide bond formation, we believe the strong quenching seen in the emission spectra, in conjunction with the stearic acid studies, are indicative of amide bond formation; only weak "collisional" quenching is seen for the non-conjugated system (53). In addition, preliminary single-molecule fluorescence studies of nanoparticles with high dye loadings have shown exponential decay of the fluorescence intensity, which is consistent with multiple fluorophores per Au nanoparticle, and little to no on–off fluorophore blinking of free fluorophores in solution is seen.

The above studies show that amine-terminated Au MPCs can indeed be used as effective precursors for further functionalization of nanoparticles, with nearly stoichiometric reactivity. However, it should be noted that it cannot be assumed that the Au–thiol chemistry is inert under all chemical conditions; particle growth was seen both during the deprotection of Boc groups using TFA and during the amide functionalization/purification of activated esters to the terminal amine groups of the MPCs. This is most likely due to either incomplete steric stabilization of the particles or ligand oxidation of the relatively short Gly–CSA stabilizer used in this work. There are other examples of decomposition of MPCs with short-peptide stabilizers; Tsukuda and coworkers have previously noted that many small glutathione MPCs can spontaneously decompose (54), while Gies et al. have detected the presence of Au–thiolate tetramer species

© 2008 NRC Canada

in samples of tiopronin stabilized MPCs (55). While such problems may often be overcome by carefully adjusting experimental procedures or post-synthesis fractionation of MPCs, it is important to note that there is still much unknown about the chemistry of Au MPCs under different chemical conditions, particularly when the stabilizing ligands do not form a dense, close-packed monolayer.

Conclusion

We have shown that peptide-stabilized Au MPCs can be synthesized via Brust–Schriffin syntheses using protected Boc-Gly–CSA stabilizers, followed by deprotection of the glycine amine groups with trifluoroacetic acid. In addition, we have shown that the surface-modified Au MPCs can be further functionalized by a variety of activated esters with nearly stoichiometric reactivity. In principle, this system allows for facile access to nanoparticle surfaces with multiple functional groups via one-pot syntheses involving activated esters and Gly–CSA MPCs. Further studies are underway to investigate the synthesis of other simple peptide Au and CdSe nanoparticle systems.

One-pot preparation of β-amido ketones/esters in a three-component condensation reaction using magnesium hydrogensulfate as an effective and reusable catalyst

Hamid Reza Shaterian, Asghar Hosseinian, and Majid Ghashang

Abstract: A one-pot, three-component condensation of an aryl aldehyde, an enolizable ketone or β-keto ester, acetyl chloride, and acetonitrile or benzonitrile in the presence of magnesium hydrogensulfate as an active, recoverable, and reusable green catalyst is described for the synthesis of β-amido ketones/esters at room temperature. The key features of this methodology are simplicity, mild reaction conditions, and high to excellent yields.

Key words: multi-component reaction, magnesium hydrogensulfate, heterogeneous catalyst, β-amido ketone/ester, mild conditions.

Résumé : On décrit une condensation monotope à trois composants dont un aldéhyde aromatique, une cétone ou un β-cétoester énolisable et du chlorure d'acétyle, de l'acétonitrile ou du benzonitrile, en présence de sulfate acide de magnésium comme catalyseur vert actif, récupérable et réutilizable, pour réaliser la synthèse à la température ambiante la synthèse de β-amidocétones et de β-amidoesters. Les caractéristiques principales de cette méthodologie sont sa simplicité, des conditions réactionnelles douces et des rendements allant d'élevés à excellents.

Mots-clés : réaction à plusieurs composants, sulfate acide de magnésium, catalyseur hétérogène, β-amidocétones, β-amidoesters, conditions douces.

[Traduit par la Rédaction]

Introduction

Today, with the emergence of high-speed parallel synthesis, the multi-component reaction (MCR) is widely employed for the rapid assembly of arrays with high molecular diversity (1). Due to their inherent simple experimental procedures and their one-pot character, they are perfectly suited for automated synthesis. Thus, MCRs have attracted considerable interest owing to their exceptional synthetic efficiency (2–7).

β-Amido ketones are important building blocks and intermediates in synthesis For example, they are important precursors of heterocyclic compounds (8), as well as of β-amino alcohols, which are common units in both natural and synthetic biologically or pharmacologically important compounds (9). The reported one-pot syntheses of the title compounds from aldehydes, enolizable ketones, acetyl chloride, and acetonitrile or benzonitrile are based on some Lewis or Brønsted acid catalysts such as $CoCl_2$ (10, 11), Montmorillonite K-10 clay (12), silica sulfuric acid (13), $BiCl_3$ generated from BiOCl (14), $ZrOCl_2{\cdot}8H_2O$ (15), heteropoly acid (16), sulfuric acid absorbed on silica gel (17), $Sc(OTf)_3$ (18), silica supported $H_3PW_{12}O_{40}$ (19), $K_5CoW_{12}O_{40}{\cdot}3H_2O$ (20), $CeCl_3{\cdot}7H_2O$ (21), ZnO (22), iodine (23), sulfated zirconia (24), iron(III) chloride (25), and *p*-TSA (26). Herein we wish to report an efficient method for the synthesis of β-amido carbonyl compounds in high to excellent yields by employing $Mg(HSO_4)_2$ as an active environmentally friendly heterogeneous catalyst (Scheme 1). We believe that our method is simple, mild, and rapid for the synthesis of the mentioned compounds at room temperature (RT).

Scheme 1. Synthesis of β-amido carbonyl compounds using $Mg(HSO_4)_2$ as an active heterogeneous catalyst.

This catalyst is safe, easy to handle, environmentally benign, presents fewer disposal problems, and is stable in reaction media. Magnesium hydrogensulfate has been used in some organic reactions, such as acetylation and formylation of alcohols (27), cleavage of C=N (28), and oxidation of thiols (29).

Results and discussion

First, we optimized the amount of magnesium hydrogensulfate as catalyst in the reaction among benzaldehyde, acetophenone, acetyl chloride, and acetonitrile (Table 1). The amount of magnesium hydrogensulfate was chosen to be 20 mol%.

Thus, we continued preparation of β-amido ketones in an optimum model experiment: aldehydes (1 equiv.), enolizable ketone or β-keto ester (1 equiv.), acetyl chloride (0.5 mL), and acetonitrile or benzonitrile (reactant, as well as solvent, 2 mL) in the presence of magnesium hydrogensulfate (20 mol%, Table 2).

As shown in Table 2, aromatic aldehydes and acetophenone derivatives with both electron-withdrawing and electron-donating substituents afforded to the corresponding β-amido ketones without the formation of any side products and in high to excellent yields at RT (Table 2, entries 1–22). Phenolic-OH groups under present reaction conditions were converted to acetate (-OAc) groups (Table 2, entries 19, 20).

Under the optimized reaction conditions, by using benzonitrile in place of acetonitrile, aldehydes were transformed to their corresponding β-benzamido ketones in high yields (Table 2, entries 2, 15).

We also studied the multi-component reaction of aromatic aldehydes with other enolizable ketones (methyl acetoacetate, ethyl acetoacetate, and propiophenone) and acetonitrile in the presence of acetyl chloride and $Mg(HSO_4)_2$ as catalyst. In all cases, mixtures of syn and anti diastereomers were obtained. The amount of syn and anti products was determined by ^{1}H NMR spectra, the coupling constant between H-2 and H-3 is 6–9 Hz for an anti isomer and 2–5 Hz for a syn isomer (10-12, 26). As shown in Table 3, anti diastereomers were found to be major products. The conformational preference of these anti diastereomers depend on the intramolecular H-bonding between the acidic proton and the carbonyl oxygen This phenomenon was confirmed by Ghosh et al. (15) with the X-ray crystallographic analysis data. Methyl and ethyl acetoacetate afforded the corresponding β-acetamido esters and the anti/syn diastereoselectivity further increased from 61:39 to 81:19 (Table 3).

In a typical experiment, after a period of time in which the reaction was completed, the mixture was filtered and the heterogeneous catalyst was recovered. Then, the residue solution was poured into the cooled water until a solid crude product was formed. In every experiment all of the magnesium hydrogensulfate was easily recovered from the reaction mixture. The reusability of the catalysts is one of their most important benefits and makes them useful for commercial applications. Thus, the recovery and reusability of magnesium hydrogensulfate was investigated. The separated catalyst can be reused after washing with $CHCl_3$ and drying. The reusability of the catalyst was checked by the reaction of benzaldehyde and acetophenone in the presence of acetyl chloride and acetonitrile using 20 mol% of $Mg(HSO_4)_2$ at RT. The results indicate that the catalyst can be used five times without any loss of its activity (Table 4).

[a]Isolated yields.

To show the merit of the present work in comparison with reported results in the literature, we compared results of magnesium hydrogensulfate with BiOCl (14), $ZrOCl_2 \cdot 8H_2O$ (15), $CeCl_3 \cdot 7H_2O$ (21), ZnO (22), and I_2 (23) in the synthesis of β-acetamido ketone derivatives. As shown in Table 5, magnesium hydrogensulfate can act as an effective catalyst with respect to reaction times, yields, and the obtained products.

Conclusion

In summary, we have demonstrated a new and important catalytic activity of magnesium hydrogensulfate as an inexpensive, commercially available, and reusable catalyst for the synthesis of β-amido ketones/esters in high to excellent yields under mild conditions at RT. The simple experimental procedure combined with the easy work-up and high to excellent yields of products are strong features of the presented method.

Experimental

All reagents were purchased from Merck and Sigma-Aldrich and used without further purification. All yields refer to isolated products after purification. Products were characterized by comparison with authentic samples and by spectroscopy data (IR, ^{1}H NMR, ^{13}C NMR spectra). The NMR spectra were recorded on a Bruker Avance DEX 500 and 300 MHz instrument. The spectra were measured in $CDCl_3$ (and DMSO-d_6) relative to TMS (0.00 ppm). Elemental analyses for C, H, and N were performed using a Heraeus CHN-O-Rapid analyzer. IR spectra were recorded on a JASCO FT-IR 460plus spectrophotometer. Mass spectra were recorded on a Agilent technologies 5973 network mass selective detector (MSD) operating at an ionization potential of 70 eV. Melting points were determined in open capillaries with a BUCHI 510. TLC was performed on silica-gel Poly-Gram SIL G/UV 254 plates.

Preparation of magnesium hydrogensulfate

A 500 mL suction flask was equipped with a constant-pressure dropping funnel. A gas outlet was connected to a vacuum system through an adsorbing solution (water) and an

1				2.5	89	102–104, 103–105, 16
2				2.5	90	153–155 153–154, 25
3				2.5	95	129–131, 130, 14
4				2.5	93	112–115, 121–123, 17
5				4	79	74–76, 74–76, 16
6				3	87	108–110, 108–110, 17

alkali trap. Anhydrous magnesium chloride (47.6 g, 0.5 mol) was charged into the flask and concentrated sulfuric acid (98.07 g, 1 mol) was added dropwise over a period of 30 min at RT. HCl gas was evolved immediately. After completing the addition of the H_2SO_4, the mixture was shaken for 30 min; meanwhile, the residual HCl was exhausted by suction. A white solid material was thus obtained (108.5 g) (28).

Typical experimental procedure for the one-pot preparation of *N*-(3-oxo-1,3-diphenylpropyl) acetamide (Table 2, entry 1)

A solution of the benzaldehyde (1 mmol), acetophenone (1 mmol), acetyl chloride (0.5 mL), and acetonitrile in the presence of magnesium hydrogensulfate (20 mol%) was stirred at RT for the appropriate time (Table 2). The progress of the reaction was followed by TLC. After completion of the reaction, the reaction mixture was filtered and the heterogeneous catalyst was recovered. Then, the residue solution was poured into 50 mL of ice water, the solid was separated and recrystallized twice using ethyl acetate/petroleum ether, which gave the desired pure *N*-(1,3-diphenyl-3-oxo-propyl) acetamide in 89% yield (Table 2, entry 1). IR (KBr, cm^{-1}): 3286, 3091, 1693, 1650, 1556, 1273, 1066, 753, 691. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 2.03 (s, 3H), 3.45 (dd, J = 6.0 and 16.9 Hz, 1H), 3.77 (dd, J = 5.2 and 16.9 Hz, 1H), 5.58 (dd, J = 5.6 and 13.1 Hz, 1H), 6.90 (d, J = 6.3 Hz,1H), 7.24-7.60 (m, 8H), 7.91 (d, J = 7.5 Hz, 2H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 23.5, 43.3, 50.0, 126.6, 127.5, 128.2, 128.7, 128.8, 133.6, 136.7, 141.6, 169.6, 199.3.

The desired pure product(s) was characterized by comparison of their physical data with those of known β-amido carbonyl compounds (10–26). The spectral data of some representative β-amido ketones/esters are given as follows.

N-(1,3-Diphenyl-3-oxo-propyl) benzamide

Table 2, entry 2. IR (KBr, cm^{-1}): 3306, 3062, 1681, 1634, 1599, 1488, 1357, 981, 754. ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 3.52 (dd, J = 6.0 and 16.4 Hz, 1H), 3.87 (dd, J = 4.8 and 16.8 Hz, 1H), 5.73–5.78 (m, 1H), 7.22 (t, J = 7.2 Hz, 1H), 7.30 (t, J = 7.6 Hz, 2H) 7.37–7.45 (m, 5H), 7.49 (t, J = 7.2 Hz, 2H), 7.55 (t, J = 7.2 Hz, 1H), 7.60 (d, J = 8.0 Hz, 1H), 7.82 (d, J = 8.0 Hz, 2H), 7.90 (d, J = 8.0 Hz, 2H). ^{13}C NMR (75 MHz, $CDCl_3$, ppm) δ: 43.1, 50.4, 126.6, 127.2, 127.6, 128.3, 128.7, 128.8, 128.9, 131.8, 133.8, 134.4, 136.7, 141.1, 166.9, 199.3.

Frontier orbital interactions in the hetero Diels–Alder cycloaddition of diazadienes

Pratibha Sharma, Ashok Kumar, Vinita Sahu, and Jitendra Singh

Abstract: This work deals with the molecular orbital calculation studies performed on different diazadienes to assess their reactivity pattern. The interaction of these diazadienes with various electron-poor and electron-rich dienophiles leads to the formation of diazines and tetrazines as the cycloadducts. The results from frontier orbital interactions were used to rationalize the reactivity and predictability of NDAC and IEDDAC reaction pathways. Correlation studies were also performed to predict reactivity sequence using a number of electronic descriptors, such as electrophilicity index (ω), chemical potential (μ), electronic charge ΔN_{max}, and chemical hardness η. Moreover, these studies exhibit good compatibility with experimental observations.

Key words: AM1, MNDO, PM3, diazadienes, tetrazines, electrophilicity index, chemical potential.

Résumé : Dans ce travail, on rapporte les résultats obtenus lors de calculs d'orbitales moléculaires effectués sur divers diazadiènes dans le but d'évaluer leur mode de réactivité. L'interaction de ces diazadiènes avec divers diénophiles riches et pauvres en électrons conduit, suivant le cas, à la formation de diazines et de tétrazines comme cycloadduits. On a utilisé les résultats d'interactions d'orbitales frontières pour rationaliser la réactivité et pour vérifier si les voies réactionnelles de cycloaddition de Diels–Alder normale et de cycloaddition de Diels–Alder à demande inversée d'électrons peuvent être utilisées pour les prédire. Utilisant un certain nombre de descripteurs électroniques, tel l'indice du caractère électrophile (ω), le potentiel chimique (μ), la charge électronique (ΔN_{max}) et la dureté chimique (η), on a aussi effectué des études de corrélation pour prédire la séquence de réactivité. De plus, ces études présentent une bonne compatibilité avec les observations expérimentales.

Mots-clés : modèle Austin-1 ("AM1"), négligence modifiée du recouvrement différentiel ("MNDO"), modèle paramétrisé numéro 3 ("PM3"), diazadiènes, tétrazines, indice du caractère électrophile, potentiel chimique.

[Traduit par la Rédaction]

Introduction

The Diels–Alder (1) (DA) reaction is one of the most prominent synthetic strategies in organic chemistry to craft annular compounds from small fragments. The DA reactions of 2-azadienes (2) is a very useful method for providing rapid access to a range of highly substituted biologically active heterocyclic system like pyridines, dihydropyridines, and tetrazine (3). The development of synthetic methodologies based on aza-DA reactions to obtain six-membered tetrazines has attracted much interest because of their utility in the field of medicinal chemistry as antitumor drugs and in energetic chemistry as powerful explosives. Hence, the DA reaction is found to be most a promising method for tetrazine synthesis. With the advancement of computational chemistry to predict the fate of a reaction, herein we have tried to incorporate the quantum mechanical results to interpret DA cycloaddition. In this context, the Fukui's FMO method (4) is found to be the most suitable synthetic tool to predict selectivity and reactivity of compounds. A systematic perusal of the literature (5) reveals that the prediction and reactivity of DA reaction are normally based on the strength of HOMO–LUMO interactions between diene and dienophlie. In view of these precedents and as part of our research program devoted to the study of heterocycles (6), we have made an effort to interpret experimental outcomes through normal Diels–Alder cycloaddition (NDAC) and inverse electron-demand Diels–Alder cycloaddition (IEDDAC) pathways. Moreover, we have also incorporated electronic descriptors, such as the electrophilicity index ω, the chemical potential μ, and ΔN_{max}, to interpret cycloaddition reactivity.

A number of diazadienes bearing one or more electron-withdrawing and electron-donating groups have been chosen to initialize these studies using semi-empirical probes (7). These dienes undergo DA reactions with a variety of dienophiles to achieve tetrazines as the final product in appreciable yield under optimum reaction conditions. A judicious selection of the best method to predict the FMO energies of dienes and various dienophiles has been done. A comparative evaluation of different Hamiltonians for various dienes is shown in Table 1, and the AM1 method was found to show good correlation with Fukui's approximations. Hence, we have chosen the AM1 method for further discussion. Moreover, it is to be emphasized here that the MO semi-empirical method allows the study of more complex diazadienes in a very much more facile manner in compari-

son to ab initio methods. To make a comparative study, we have used some reference dienes and have revealed that 1,3-butadiene (**1**), being an electron-rich diene is prone to undergo NDAC reaction with electron-deficient dienophlie. However, the similar prediction is not easy for heterodienes, because upon substituting one CH moiety of 1,3-butadiene with N, the energy of **2** HOMO–LUMO decreases, while substitution with another N does not show a major decrease in HOMO energy of diene **3** (Figs. 1 and 2).

Furthermore, upon comparing the relative reactivity of diazadienes **4**–**10**, it has been inferred that diazadiene **5**, bearing an electron-donating substituent (i.e., $–NMe_2$) at the phenyl ring, was expected to be more electron-rich compared with **4**, and therefore it is more likely to react with electron-deficient dienophile through the NDAC pathway. On the other hand, **6** takes part in the IEDDAC reaction only with electron-rich dienophile. Similarly, diazadienes **7** and **8**, bearing electron-donating substituents, also show the precedence of the NDAC pathway over IEDDAC with electron-deficient dienophile.

The CH→N substitution in the dienes enhances their reactivity towards electron-rich dienophiles in IEDDAC reactions. However, further decreases in electrophilicity by electron-withdrawing substituent, as in **9** and **6**, makes them more favored species for IEDDAC reactions.

Also, in an attempt to synthesize tetrazines, reference diene **4** was allowed to react with a number of dienophiles **11**–**20** (Figs. 3 and 4) and the experimental results were correlated with theoretical outcomes. The AM1 optimized geometry of cycloadduct **25** is depicted in Fig. 5.

Reactivity of diazadienes 4–10

Table 1 shows the frontier orbital energies of diazadienes **4–10** calculated at the AM1 level. The AM1 calculations described above were performed considering the *S-cis* conformations of dienes.

It is deduced from the aforementioned discussion that HOMO–LUMO energies lowers upon CH→N substitution, making them more reactive species towards electron-rich dienophiles. Substitution of an electron-donating group (–NMe_2) at the phenyl ring raises the HOMO energy by 0.995 eV and lowers the LUMO energy, thereby explaining their preferred participation in NDAC reactions. The calculated HOMO energies of **4**, **6, 9**, and **10** are lower than those of **5**, **7**, and **8**. This explains the lack of reactivity of these diazadienes towards electron-deficient dienophiles (NDAC). On the other hand, the predicted LUMO energies of **4**, **6–10** are lower than that of **5**, pointing to an increased reactivity toward electron-rich dienophiles (IEDDAC). Diazadienes **6**, bearing a nitrophenyl group, has the lowest energy followed by **9**, **10**, and **4**. This indicates that the addition of one nitro group at the 4-position of phenyl ring of diazadienes has a more substantial effect than the introduction of N at the same position.

It can be concluded that on the basis of HOMO energy from AM1 calculations, the reactivity of different diazadienes to participate in inverse electron-demand DA reactions would be in the following order: **6** > **9** > **10** > **4** > **8** > **7** > **5**.

NDAC and IEDDAC

In a view to unravelling the understanding of the mechanistic details of DA cycloaddition, we have taken the Fukui's assumption into consideration and tried to associate the experimental results with computational semi-empirical outcomes. Hence to gain deeper insight into the DA cycloaddition strategy, we proceeded with the treatment of diazadiene **4** with different dienophiles **11–20** and the pertinent results are presented in Tables 2 and 3.

Here we offer an interesting and novel interpretation of eigenfunctions to predict the outcomes of DA reactions. In this context, diazadiene **4**, which is an electron-rich diene, shows similar reactivity with maleic anhydride **16**, bis-4-nitrophenyl diazene **19**, and 4-[4-nitrophenyl]-diazenyl phenol **20**, which are electron-deficient dienophiles. The reaction time required for **4** and dienophiles **16**, **19**, and **20** was found to be approximately similar, favoring NDAC pathway. Moving toward more electron-rich dienophiles, other than **16**, **19**, and **20**, the reaction time increases and sometimes no reaction occurs. 1,2-Ethoxyethene **11** and allyl chloride **18** should take the longest time for reaction with **4**. In actuality, the reactions of **4** with allyl halide **18** requires 13 h, which may be due to the high HOMO–LUMO energy gap for this NDAC reaction, which includes a significant molecular orbital energy gap. A close inspection of eigenfunctions suggests that the dienophile 1,2-ethoxyethene **11**, *N*,*N*-dimethy-4-phenyldiazenyl aniline **12**, and 4-phenyldiazenyl aniline **13**, are likely to undergo IEDDAC reaction, and the experimental results show that dienophiles **11** and **12**, being highly electron-rich dienophiles, remain unreactive with diene **4** after a long time. According to the energy level gap between participating molecular orbitals for dienophiles **12** and 1**3**, both are prone to undergo the IEDDAC pathway, but experimentally no reaction occurs with diazadiene **4** under similar reaction conditions. With dienophile 4-phenyldiazenyl phenol **14**, 1-(dinitrophenyl)-2-phenyldiazene **15**, and diethyl fumarate **17**, reactions proceed according to our expectations, and the experimental results are in agreement with computational outcomes with nearly similar reactivity. It has been experimentally found that the normal DA cycloaddition of diazadiene **4** with allyl chloride **18** provides better yield of the adduct, although the HOMO–LUMO energy gap is larger for these reactions, in contrast with other cycloadditions.

Discussion

A perusal of the calculated energies (Table 2) of the frontier orbitals for the diazadiene **4** and the dienophile points out the significance of the HOMO–LUMO energy gap (Fig. 6). Here Lde-Hdo represents the calculated energy gap (eV) between each dienophile with respect to the LUMO of diene **4**. Ldo-Hde represents the calculated energy gap (eV) between the dienophile's LUMO with respect to the HOMO of diene **4**. The Ldo-Hde energy gap is least (7.695 eV) for diazadiene **4** and maleic anhydride **16**. As **16** is an electron-deficient dienophile, this energy gap favors the NDAC reaction, while the highest energy gap for 1,2-ethoxyethene **11** makes this reaction IEDDAC. Furthermore, it is interesting to note that the energy gap (Lde-Hdo) between diazadiene **4** and *N*,*N*-dimethy-4-phenyldiazenyl aniline **12**, and 4-phenyldiazenyl aniline **13** and 4-phenyldiazenyl phenol **14** dienophiles, are nearly similar, but their reactivities differ markedly, which further emphasizes that the Lde-Hdo en-

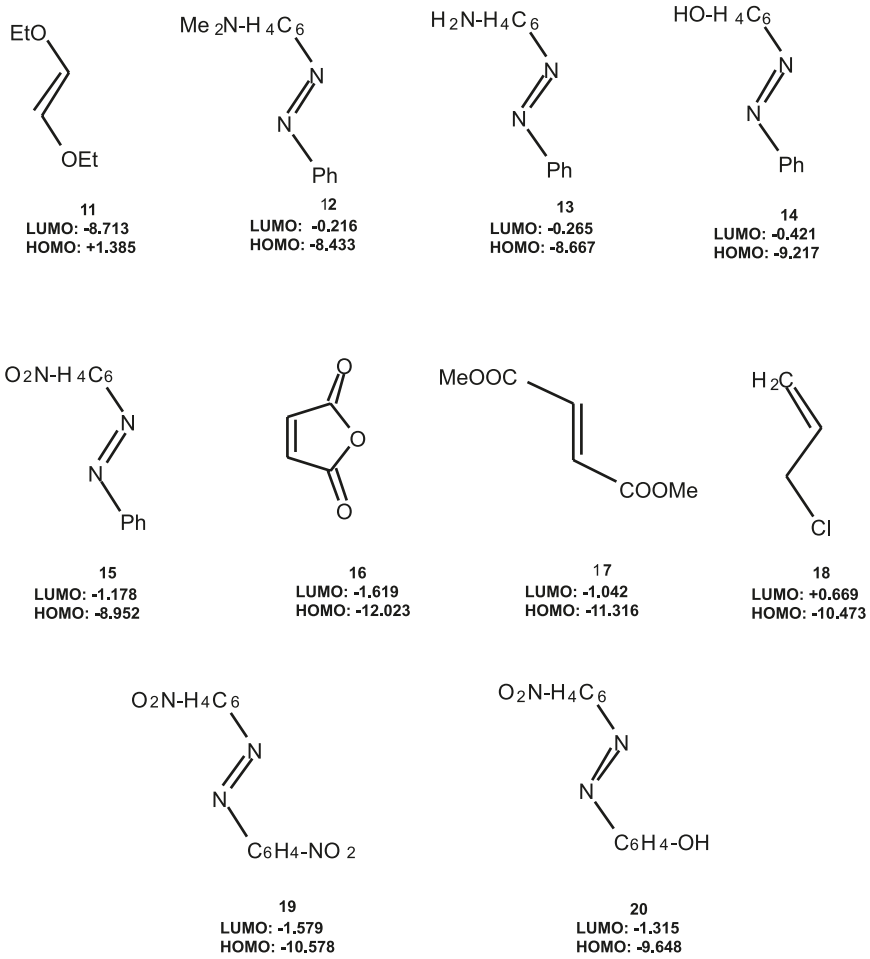
Fig. 3. Orbital energies (eV) and geometries of dienophile **11**–**20**.



ergy gap is not a reliable tool to predict the reactivity of dienes and dienophiles toward IEDDAC reactions. However, the Ldo-Hde energy gap reasonably predicts the reactivity of dienes and dienophiles. Hence, the NDAC is a more favored pathway for DA reactions than is IEDDAC.

Global electrophilicity index

For a long time Domingo's group has been interested in the study of the molecular mechanism of the polar DA reactions (8–9). Recently, the use of the global electrophilicity index ω proposed by Parr et al. (10), has been reported to classify the global electrophilicity of a series of dienes and dienophiles currently present in DA reactions (11). We found a good correlation between the difference in electrophilicity for the diene and dienophile pair, Δω, and the feasibility of the cycloaddition. Therefore, Δω for a diene–dienophile pair is a valuable tool to predict the polar character of a DA reaction. The global electrophilicity index ω, which measures the stabilization in energy when the system acquires an additional electronic charge N_{max} from the environment, has been given the following simple expression,

$$\omega = \mu^2/2\ \eta$$

where $\mu \approx (I + A)/2$ and $\eta = (A - I)$ are the electronic chemical potential and chemical hardness of the ground state of atoms and molecules, respectively, approximated in terms of the vertical ionization potential (I) and electron affinity (A) using Koopman's theorem. Here, in our calculations $I = E_{HOMO}$ and $A = E_{LUMO}$ were used.

The electrophilicity index encompasses both the propensity of the electrophile to acquire an additional electronic charge driven by μ^2 (the square of the electronegativity) and the resistance of the system to exchange electronic charge with the environment described by η simultaneously. The maximum electronic charge N_{max} is another useful quantity; it is the maximal electronic charge which electron accept from environment, giving a better understanding of Fukui's model.

Table 4 presents an overview of electronic parameters such as electronic chemical potential μ, chemical hardness η, and global electrophilicity index ω. The electronic chemical potential for dienophile **11**–**20** lies in the range –6.821 to –3.664, whereas for diene **4** this value is an intermediate one, –4.779. Dienophiles**11**, **12**, and **13** have higher chemical potentials than **4**, which further suggests that a net charge transfer will take place from electron-rich dienophiles to electron-poor diene **4** in an IEDDAC reaction pathway. In addition, a good correlation can be observed between the substitution pattern on dienophile and the chemical potential μ for the remaining dienophiles **14**–**20**, where charge transfer take place from an electron-rich diene to an electron-deficient dienophile through the NDAC pathway.

© 2008 NRC Canada

Fig. 4. Various cycloadducts **21**–**30**.

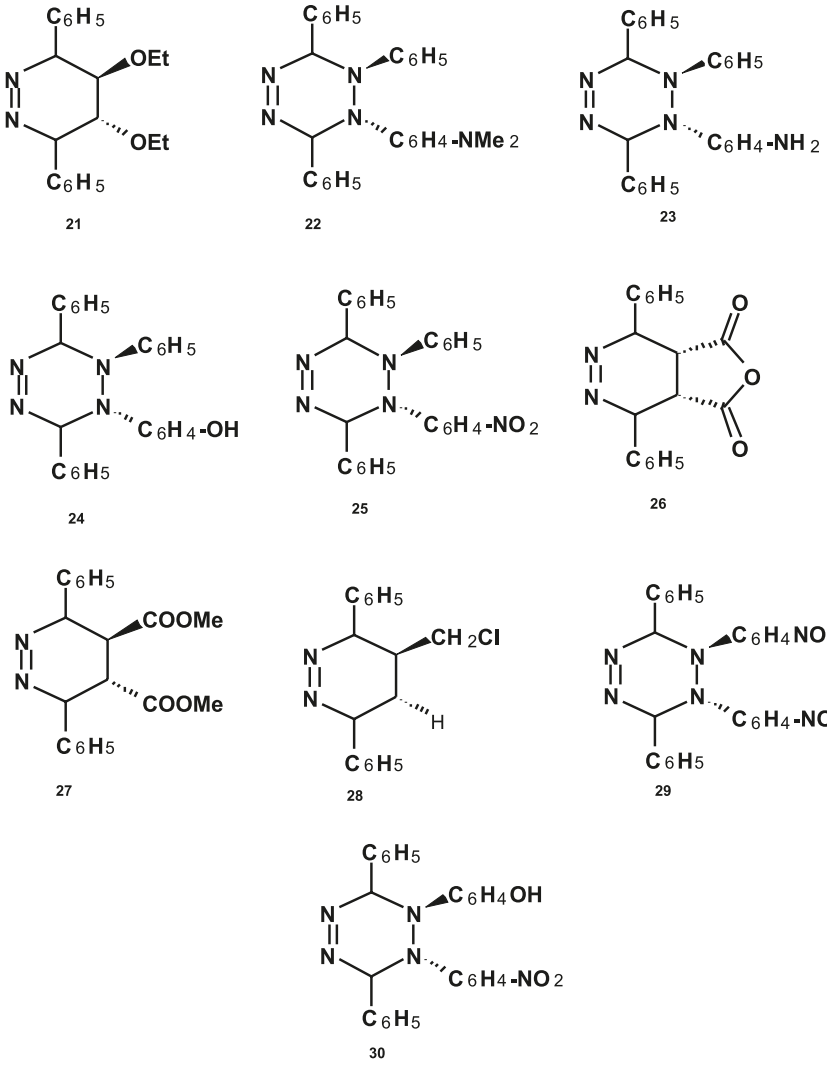


Fig. 5. Optimized geometry of tetrazine cycloadduct **25**.

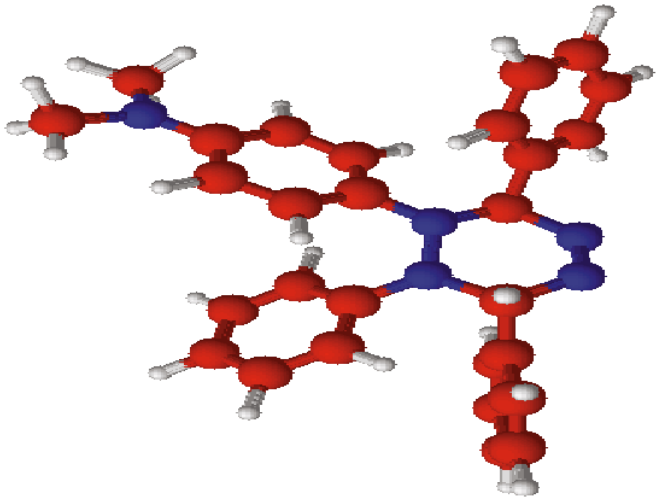

The μ value is found to be lowest for **16** amongst dienohiles **11**–**20**, indicating ease of reaction with the least Ldo-Hde energy gap (7.695) in DA cycloaddition. Experimentally this reaction took the least reaction time to completion (~2 h) in the presence of xylene.

The highest μ value of –3.664 for **11** opens up the possibility of an inverse electron-demand DA reaction in which charge transfer direction is from an electron-rich dienophile to an electron-deficient diene, making this reaction experimentally not feasible under similar reaction conditions. The electrophilicity index ω values for the diene and dienophile falls within the range 18.08–60.84 eV; the highest ω value obtain for **16** illustrates the highly electrophilic nature of this dienophile and is supported by experimental observations. Moreover, the difference in electrophilicity between the diazadiene **4** and dienophiles (Δω) gives a measure of the reactivity of diene and dienophiles in a cycloaddition reaction, where the smallest value of Δω for dienophile **16** suggests the nonpolar synchronous nature of transition states in normal DA cycloaddition.

On the other hand, the highest Δω difference value for the **4a+1** reaction provides an asynchronous polar transition state and IEDDAC pathway, which is experimentally not observable and no reaction occurs at all.

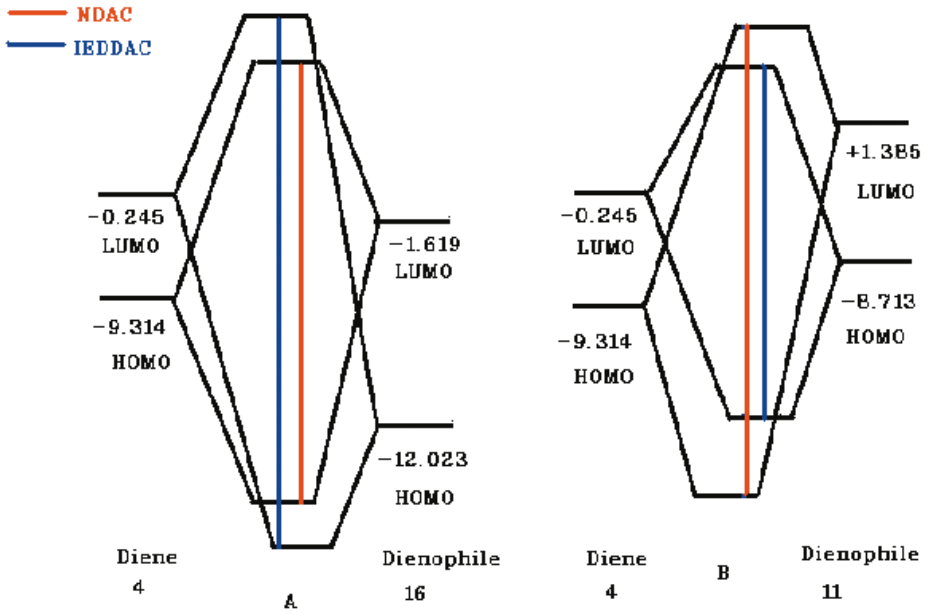
9	19	29	4	79
10	20	30	6	78

Fig. 6. Molecular orbital energy gap between diene **4** and dienophile **11** and **16**.



Multiple analysis regression (MAR) data between the electrophilicity index ω and electron affinity EA for 11 compounds (Table 4) shows that the statistical parameters (standard deviation) SD ≈ 0.31 and (correlation co-efficient) $R \approx 0.95$ significantly support excellent correlation (Fig. 7) between the electrophilicity index ω and electron affinity EA.

The stereo- and regio-selectivity of DA cycloadditions are easily rationalized by examining the orbital coefficient values on the molecular orbitals. The preferred regioisomeric transition states in DA cycloadditions depends upon the terminal coefficient of the interacting orbitals. Table 5 shows the orbital coefficient at different carbon atoms of dienes **1**–

4 and **10**. The results demonstrate that in 1,3-butadiene **1**, the terminal coefficient at C-1 and C-4 of HOMO wave functions are of equal magnitude, but upon CH→N substitution the coefficient magnitude suddenly decreases and so 1-azadienes becomes regiospecific for the unsymmetrical substituted dienophile. Introduction of N in 1,3-butadiene enhances the electrophilicity of the diene, making it a preferred species for IEDDAC reaction. In azadienes, the C-1 position is more polarized than the C-4 position. A similar decrease in orbital coefficient is found upon introducing another N in the diene moiety. A close examination of the orbital coefficients on azadienes **2** and **3** reveals that the magnitude of the orbital coefficients is larger on the C-3/N-3 position than on the C-2/N-2 position, which could play an immense role in the preferred formation of regioisomers through secondary orbital interactions.

An exhaustive exploration of orbital coefficients on different dienophiles (Table 6) provides regioselective understanding toward the DA cycloadduct. The orbital coefficients of the symmetrical molecule (dienophile) are identical in magnitude at terminal atomic centers. These studies show that **D-1** (here **D-1** is taken as reference dienophile to interpret the comparative results of dienophiles **11**–**20** in terms of orbital coefficients, C_6H_5-N=N-C_6H_5) has a similar orbital coefficient at N-1 and N-2 in LUMO, while these values are considerably lower due to the electron-withdrawing phenyl substituent, which makes this species more electron-withdrawing and favorable for NDAC reactions. 1-(Dinitrophenyl)-2-phenyldiazene **15** and 4-[4-nitrophenyl]-diazenyl phenol **20**, having at least one electron-withdrawing moiety attached to the phenyl ring, show the low orbital coefficient at N-2, which is in accordance with literature data. Similarly, 4-phenyldiazenyl aniline **13** and 4-phenyldiazenyl phenol **14**, having electron-releasing substiutents at the phenyl ring, possess larger orbital coefficients at N-1 than at N-2, making these species regiospecific towards unsymmetrical dienes. However, similar predictions cannot be made for *N*,*N*-dimethy-4-phenyldiazenyl aniline **12**, which remains unreactive in DA cycloaddition with diazadiene **4**.

Regioselective studies

When an unsymmetrical diene **10** is allowed to react with a certain range of the aforementioned unsymmetrical dienophiles, the regioselectivity of the cycloadduct was also taken into consideration. We have calculated atomic orbital coefficients at interacting orbitals to check their participation in DA cycloaddition. The orbital coefficient values on diazadienes are very much lower than for their carbon congeners. A close inspection of the coefficients of diene **10** and dienophlie **15** suggest the preferred formation of regioselective **R-31b** over **R-31a**. The experimental results were in accordance with these findings. For a better understanding of regioselectivty in hetero DA reactionsm, diene **10** was also treated with dienophile **20** and preferred formation of **R-32a** rather than **R-32b** was in support of Houk's assumption. Both of these reactions follow the NDAC pathway under similar reaction conditions (Fig. 8).

Furthermore, the role of secondary orbital interactions in deciding the regioselectivity of the product was also envisaged in the case of unsymmetrical diene **10**. It has been revealed that when diazadiene **10** was allowed to react with dienophile **15**, **R-31b** was solely obtained as the regioselective cycloadduct because of primary orbital interactions between terminal orbital coefficients of the HOMO diene and the LUMO dienophile. It has been noticed that preferred regioisomers can still be predicted by considering secondary orbital interactions between the N-2 and N-3 positions of diene **10** and the C_6H_4-NO_2 moiety of dienophlie **15**. A close inspection of the orbital coefficients at N-2 and N-3 in diene **10** show that N-2 has higher orbital coefficient than N-3. Thus, the stabilization of an endo transition state is greater when the C_6H_4-NO_2 group of dienophile **15** is near

the secondary position of the diene, yielding the **R-31b** isomer as the favourable product.

Upon similar analysis, the regioselective formation of **R-32a** can be explained by considering the secondary orbital interactions between orbital coefficients at N-2 of diene **10** and the C_6H_4-NO_2 moiety of dienophile **20**. Thus, secondary orbital interactions exerted a significant effect on the regioselectivity of the Diels Alder reaction between unsymmetrically substituted diene and dienophile.

Conclusion

Concluding, we have performed and interpreted FMO interactions with a critical evaluation of the reaction pathways. Highlights of all the studies can be summarized as follows. (*i*) The relative reactivity of different diazadienes in DA reactions was studied in a selective and predictive way. (*ii*) The Ldo-Hde energy gap was found to a be a favored tool to predict DA cycloaddition. These predictions are in good agreement with experimental findings where diene **4** exhibited high reactivity towards **15**, which is a electron-deficient species in NDAC pathway. (*iii*) Synthesis of different substituted tetrazines were achieved via NDAC and IEDDAC DA pathways. (*iv*) All the results were interpreted in terms of electrophilicity index ω and a good correlation was observed between global electronic parameters and experimental findings. Hence, the FMO interactions are the key players to decide the fate of DA reactions. Similar studies on hetero DA reactions are in progress.

Acknowledgements

We are grateful to the Central Drug Research Institute, Lucknow, India for providing spectroanalytical facilities. One of the authors (VS) is also thankful to the Council of Scientific and Industrial Research (CSIR), India, for providing a junior research fellowship.

Experimental

Computational method

The AMl, MNDO, and PM3 approximations to molecular orbital theory have been employed using the MOPAC 2007 computer program (12). The geometries were fully optimized at minimum gradient level (0.01). The minimum energy conformations were used to compute molecular orbital and charge distributions. To explain the results in terms of global electronic parameters viz., electrophlicity index ω, chemical potential μ, etc., the calculations were done at MOPAC 2007 program.

General

All the chemicals used were of AR grade purity. IR spectra were recorded on PerkinElmer model 377 spectrophotometer in KBr pellets. ^{1}H NMR spectra were recorded on a Bruker DRX300 instrument. The FAB mass spectra were recorded on a JEOLSX102/DA–6000 Mass Spectrometer using argon–xenon (6 kv, 10 mA) as the FAB gas. Analytical thin layer chromatography was performed using E. Merck silica gel G (0.50 mm plates, Merck No. 5700). The melting points were determined on an electric melting point apparatus in open capillaries and are uncorrected.

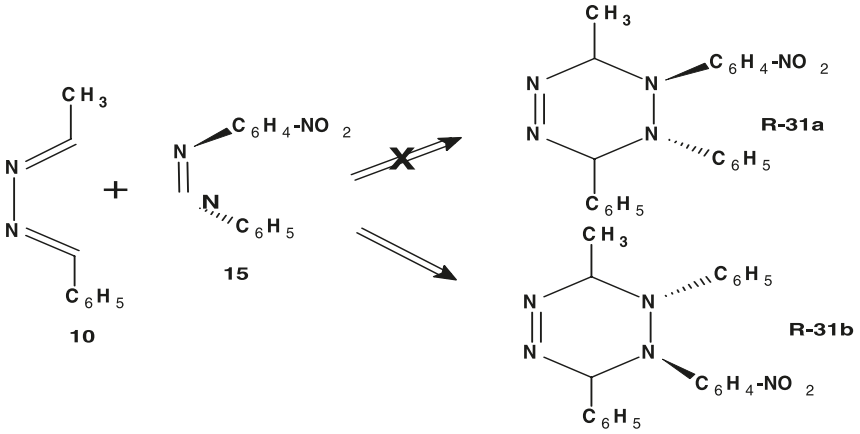
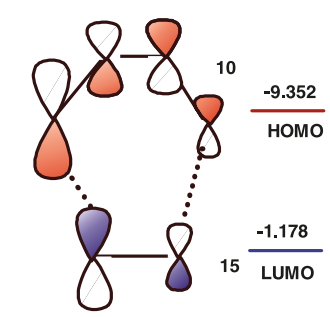
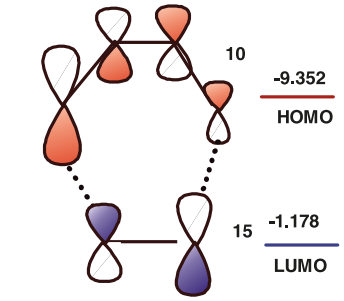
Fig. 8. Predictions of regioselectivity for diazadiene **10** and dienophiles **15** and **20**.

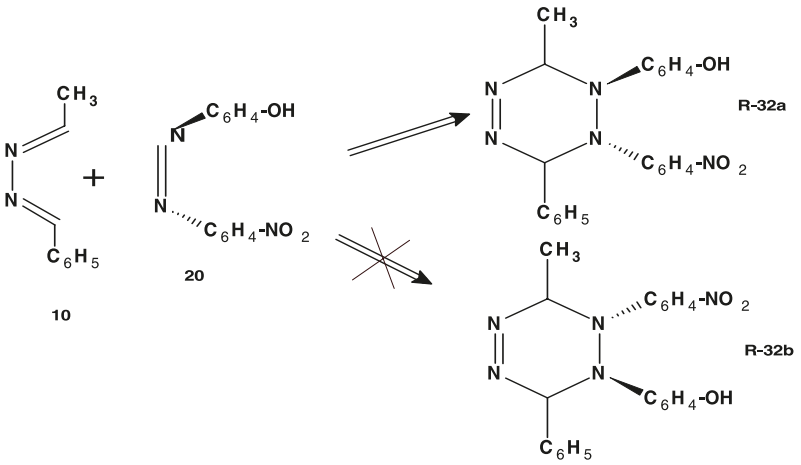




Orbital interactions in diene 10 and dienophile 15 to form R 31b



Orbital interactions in diene 10 and dienophile 15 to form R 31a



Synthesis of diazadiene 4

The diazadiene **4** was prepared by condensing together dissolving hydrazine hydrate (0.05 mol) into 50% glacial acetic acid (10 mL), and to this solution bezaldehyde (0.10 mol) was added to obtained diazadiene **4** in good yield (80%) as a yellow-green crystalline product. It was washed with cold water and recrystallized from ethanol.

Typical procedure for Diels–Alder reactions

To a solution of diazadiene **4** (0.01 mol) in dry xylene was added dienophile **11**–**20** (0.01 mol) in equimolar quantity. The solution was then refluxed for the required time (Table 3) with constant stirring. At the end of the reaction, solvent were distilled off at reduced pressure from the reaction mixture and the crude cycloadduct was recrystallised and purified by TLC resolution studies on silica gel (E Merck) using ethyl acetate–xylene (4:6, *v*/*v*).

Efficient syntheses of four chiral phenylcyclopropanes

John E. Baldwin and Stephanie R. Singer

Abstract: An efficient four-step synthetic route from each of four crystalline isotopically labeled (1*R*)-menthyl (1*S*,2*S*)-(+)-2-phenylcyclopropanecarboxyates of better than 99% enantiomeric excess has provided multi-gram quantities of the corresponding chiral phenylcyclopropanes. The key transformation involved a bis[1,3-bis(diphenylphosphino)propane]rhodium chloride that catalyzed a highly stereoselective decarbonylation of a *trans*-2-phenylcyclopropanecarboxaldehyde.

Key words: cyclopropanes chiral thanks to isotopic substituents, catalytic decarbonylations of cyclopropanecarboxaldehydes.

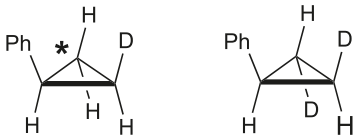
Résumé : Une méthode de synthèse efficace et en quatre étapes pour chacun des quatre (1*S*,2*S*)-(+)-2-phénylcyclopropanecarboxylates de (1*R*)-menthyle isotopiquement marqués avec un excès énantiomérique de plus de 99 % a permis de préparer des quantités supérieures au gramme des phénylcyclopropanes chiraux correspondants. La transformation clé implique une réaction très stéréosélective de décarbonylation d'un *trans*-2-phénylcyclopropanecarboxaldéhyde catalysée par un chlorure de bis[1,3-bis(diphénylphosphino)propane]rhodium.

Mots-clés : cyclopropanes chiraux en raison de substituants isotopiques, décarbonylation de cyclopropanecarboxaldéhydes.

[Traduit par la Rédaction]

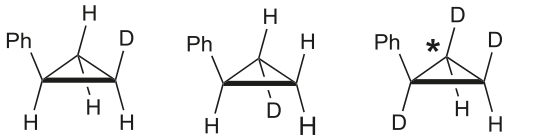
Introduction

This article reports the preparation of four chiral isotopically labeled phenylcyclopropanes (**1**-d_i). In the representations of structures **1**-d_i, and elsewhere, the asterisk symbol (*) denotes a carbon-13 atom.



1-d_1 **1**-d_2 **1**-d_3 **1**-d_3'

A long-standing interest in mechanistic questions posed by the thermal chemistry exhibited by relatively simple hydrocarbons, including cyclopropanes (1), led years ago to the preparation and utilization in mechanistic studies of **1**-d_3' and three other isotopically labeled chiral phenylcyclopropanes, (1*S*,2*R*)-**1**-d_1, (1*R*,2*R*)-**1**-d_1 and (1*R*,2*S*,3*R*)-**1**-d_3 (2). The present work extends, and greatly improves upon these earlier synthetic endeavors.



(1*S*,2*R*)-**1**-d_1 (1*R*,2*R*)-**1**-d_1 (1*R*,2*S*,3*R*)-**1**-d_3

To make multi-gram quantities of each of the **1**-d_i compounds (**1**-d_1, **1**-d_2, **1**-d_3, and **1**-d_3') with reasonable efficiency would require thrifty preparations of chiral intermediates of high enantiomeric purity, high stereochemical integrity, and high incorporations of the requisite labels. Once these demands were satisfied, a functional group temporarily used for securing a specific enantiomer of a given diastereomer of high stereochemical purity would need to be replaced by a hydrogen, or possibly a deuterium atom.

The first of these two desiderata has been achieved: each of the four crystalline (1*R*)-menthyl (1*S*,2*S*)-(+)-2-phenylcyclopropanecarboxyates (**2**-d_i) has been prepared efficiently on a 20 g scale (3). No trace of a (1*R*)-menthyl (1*R*,2*R*)-(+)-2-phenylcyclopropanecarboxyate was detected by capillary GC analyses in once recrystallized **2**-d_i compounds.

Received 14 November 2007. Accepted 12 February 2008. Published on the NRC Research Press Web site at canjchem.nrc.ca on 1 April 2008.

To satisfy the second requirement, a conventional reaction sequence was projected: hydroylysis of a menthyl ester to the corresponding carboxylic acid (4), reduction of the acid to a *trans*-2-phenylcyclopropanemethanol (5), oxidation of the alcohol to an aldehyde with PCC (pyridinium chlorochromate), and finally a Rh-catalyst-promoted decarbonylation. Not surprisingly, the first three steps were easily accomplished, while the decarbonylation proved challenging.

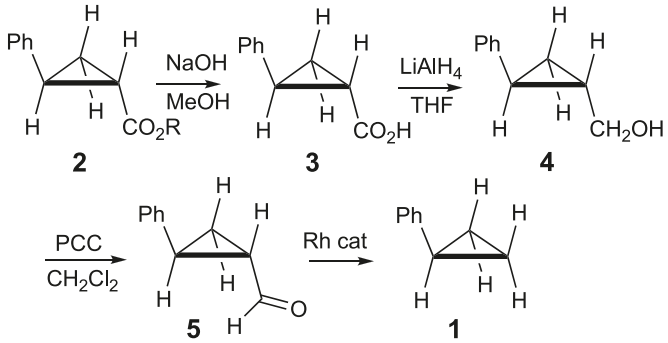
Results and discussion

The reaction sequence used to prepare chiral phenylcyclopropanes (**1**-d_1, **1**-d_2, **1**-d_3, and **1**-d_3') is summarized without full detail in Scheme 1 for unlabeled structures. Earlier preparations of chiral isotopically labeled phenylcyclopropanes, such as **1**-d_3' and stereoisomers (1*S*,2*R*)-**1**-d_1, (1*R*,2*R*)-**1**-d_1, and (1*R*,2*S*,3*R*)-**1**-d_3, depended on this scheme, though two limitations led to far from optimal overall yields (2, 5).

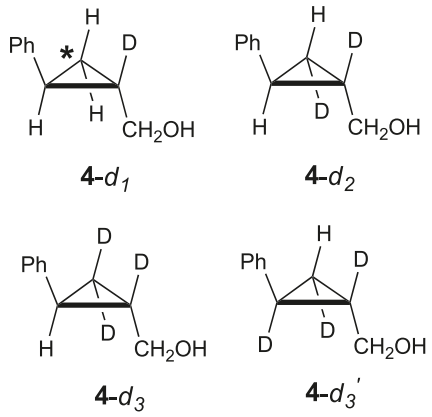
The first limitation was inherent in the presupposition of Scheme 1 that the starting material **2** or at least intermediates **3**, **4**, and **5** would be enantiomerically pure. One enantiomer of acid **3** may be secured through a chiral copper catalyst promoted diastereoselective and enantioselective condensation of racemic menthyl α-deuteriodiazoacetate and styrene or an isotopically labeled styrene, followed by a separation of cis and trans diastereomers, and then fractional crystallization of quinine salts of the trans acids (2, 5). This sequence of steps works, but it is both tedious and inefficient. This first limitation has been overcome by adopting and developing an efficient route to crystalline, enantiomerically pure esters (**2**-d_1, **2**-d_2, **2**-d_3, and **2**-d_3') (3).

The second limitation in earlier work was associated with the decarbonylation step: decarbonylations of *trans*-2-phenylcyclopropanecarboxaldehydes using stoichiometric amounts of chlorotris(triphenylphosphine)rhodium(I) (Wilkinson's catalyst) (6–8) were realized (in 8 reactions) with yields ranging from 42% to 72% (55% ± 12% on average) on scales affording from 124 to 630 mg of a labeled phenylcyclopropane product (330 ± 164 mg on average). Given the investments required to secure 20 g amounts of intermediates **2**-d_1, **2**-d_2, **2**-d_3, and **2**-d_3', and the cost of commercial $RhCl(PPh_3)_3$, a catalytic and more efficacious decarbonylation reaction option seemed essential.

Scheme 1. Reaction sequence to convert (1*R*)-menthyl (1*S*,2*S*)-(+)-2-phenylcyclopropanecarboxyate to phenylcyclopropane (R = (1*R*)-menthyl).



The first three steps outlined in Scheme 1, starting with enantiomerically pure **2**-d_i esters, were implemented without difficulty and in high yields. The two-step hydrolysis-then-reduction sequence converting a **2**-d_i ester to the corresponding colorless distilled **4**-d_i alcohol was completed with an average overall yield of 92% ± 3%.



The oxidation of a **4**-d_i alcohol with PCC in CH_2Cl_2 afforded the related aldehyde, essentially quantitatively; it was typically stored briefly under argon and decarbonylated as promptly as possible. The all-important decarbonylation step was not so easily dispatched.

Decarbonylations of aldehydes using $RhCl(Ph_3P)_3$ in stoichiometric proportions are generally successful for aryl, alkenyl, and primary alkyl aldehydes at modest temperatures (8). They involve a reversible dissociation of the reagent to $RhCl(PPh_3)_2$ and PPh_3 as a key step, and usually take place with excellent stereochemical selectivity, with the retention of configuration (9). Other reactions may sometimes intervene, but are not of significant concern in the present context. The co-product of the decarbonylation reaction, $RhCl(CO)(PPh_3)_2$, is relatively stable thermally at normal reaction temperatures; the thermal dissociation of $RhCl(CO)(PPh_3)_2$ to give CO and $RhCl(PPh_3)_2$ is typically too slow to facilitate a catalytic decarbonylation process.

Primary alkyl aldehydes may be decarbonylated catalytically in high yields when combined with only 5% of Wilkinson's catalyst and a stoichiometric portion of diphenylphosphoryl azide, but more sterically crowded aldehydes are relatively inert (10).

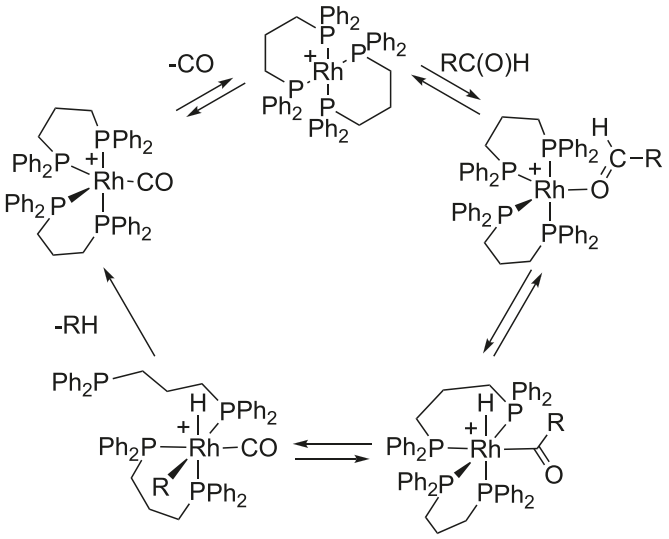
Scheme 2. Catalytic decarbonylation of an aldehyde (R-C(O)H) by $[Rh(dppp)_2]^+$.



Bisdiphosphine complexes of Rh(I), such as [bis(1,3-bisdiphenylphosphino)propane]rhodium chloride or tetrafluoroborate, $[Rh(dppp)_2]Cl$ or $[Rh(dppp)_2]BF_4$ (11, 12), will decarbonylate an aldehyde following a mechanistic path much like one postulated for Wilkinson's catalyst mediated decarbonylations. The reductive elimination step gives a $[Rh(dppp)_2]^+CO$ complex that dissociates relatively easily to $[Rh(dppp)_2]^+$, and the process can continue, as schematized in the putative mechanistic model outlined in Scheme 2.

The $[Rh(dppp)_2]^+$ structure is probably not square planar but distorted so as to position the two P-Rh-P planes at a dihedral angle approximately midway between 0° and 90°, as has been found for $Rh(PMe_3)_4^+$ and [bis(1,4-bisdiphenylphosphino)butane]rhodium$^+$ (13, 14). The pentacoordinate complexes with CO or an aldehyde are approximately trigonal bipyramidal, though they exhibit considerable conformational flexibility. At room temperature (RT) all four phosphorous atoms are equivalent: $^{31}P\{^1H\}$ NMR spectra exhibit a simple doublet due to P-Rh spin–spin coupling, while at –80 °C an A_2B_2X pattern of multiplets is observed (15).

Kinetic evidence points toward the oxidative addition step being rate-limiting (12). The catalytic cycle is completed through a reverse migration followed by an irreversible reductive elimination to give the decarbonylation product and a carbon monoxide complex, one that can dissociate readily at modest temperatures.

Reported decarbonylations of aryl, alkenyl, and primary alkyl aldehydes with reagents providing a source of $[Rh(dppp)_2]^+$ are impressively efficient, but similar reactions of secondary alkyl aldehydes using these catalysts have not been entirely encouraging: 2-ethylbutanal and a catalytic amount of $[Rh(dppp)_2]BF_4$ at 110 °C for 36 h gave pentane in only 15% yield (12).

The $[Rh(dppp)_2]Cl$ or $[Rh(dppp)_2]BF_4$ catalysts may be prepared in crystalline form. A convenient alternative is to make the former in situ by combining $RhCl(CO)(PPh_3)_2$ with 1,3-bis(diphenylphosphino)propane in a 1:2 ratio, respectively (16). The present work opted for this option. When a labeled aldehyde, **5**-d_i, was combined with a catalyst prepared from 3.6 mol% of $Cl(CO)Rh(PPh_3)_2$ and 7.2 mol% of dppp in anhydrous, degassed toluene, and heated at reflux for about a day, analysis by capillary GC revealed that the decarbonylation reaction was progressing slowly. An additional increment of catalyst was prepared and added, and the reaction mixture was heated at reflux for another day. A third increment of catalyst was prepared and added. After another day at reflux, all of the aldehyde had reacted, according to GC analyses. Following workup, the labeled phenylcyclopropane was secured in good yields, with very little contamination by the side-product α-methylstyrene. In three of the eight decarboxylation reactions, two from each of the labeled phenylcyclopropanecarboxaldehydes, four or five increments of catalyst and additional days of heating the reaction mixture at reflux were invested, prompted by indications of incomplete reactions gained from GC analyses. The annoyingly inconsistent rates of decarbonylation may be associated with various intrusions of adventitious oxygen, which binds reversibly but tightly to $[Rh(dppp)_2]^+$, and stalls but does not shut down the catalytic cycle (17).

Proton NMR spectra of **1**-d_1, **1**-d_2, **1**-d_3, and **1**-d_3' were completely consistent with expectations. For **1**-d_2, for example, the three equal-intensity cyclopropyl H multiplet absorptions were observed at δ 1.97, 1.02, and 0.78 (Fig. 1). In **1**-d_3, the upfield absorption of the H cis to phenyl at δ 0.78 is nearly absent, and the two cyclopropyl H doublets for cis related hydrogens at C1 and C3 are separated by 0.95 ppm. In **1**-d_3', the spectrum has the expected pair of doublets for trans disposed hydrogens at C2 and C3 and no significant absorption intensity at δ 1.97. For **1**-d_1, the spectrum is complicated just as one might anticipate from ^{13}C-H spin–spin couplings.

The eight decarbonylation reactions (Scheme 3), two from each **5**-d_i isotopomer, gave phenylcyclopropanes **1**-d_i in 79% yields, on average, from the precursor alcohols **4**-d_i. The catalytic decarbonylation reactions were slow but effective. The four **1**-d_i chiral phenylcyclopropanes prepared, secured in quantities ranging from 5.4 to 5.9 g, should prove sufficient for projected stereochemical and mechanistic studies.

The synthetic project reported in this work realized its objective, but surely did not validate an optimal experimental protocol for the catalyzed decarbonylation reactions. The goal was to make useful amounts of the required chiral isotopically labeled phenylcyclopropanes efficiently, not to perfect the decarbonylation step. Work in that direction might well find that employing $[Rh(dppp)_2]Cl$ or $[Rh(dppp)_2]BF_4$ directly, rather than making a catalyst in situ, would bring better yields or shorter reaction times; perhaps another solvent at another reaction temperature rather than toluene at reflux would be preferred; perhaps different and more rigorous measures to keep oxygen from the catalyst at every stage would prove beneficial. A systematic optimization effort could be most useful, but even now an efficient (though slow) catalytic decarbonylation procedure for cyclopropanecarboxaldehydes, one that should work for other secondary aldehydes, has been exemplified. Especially for reactions on a multi-gram scale; it should prove a practical and valuable synthetic method, and in certain situations make possible mechanistic studies that otherwise would remain imagined but not undertaken.

Experimental section

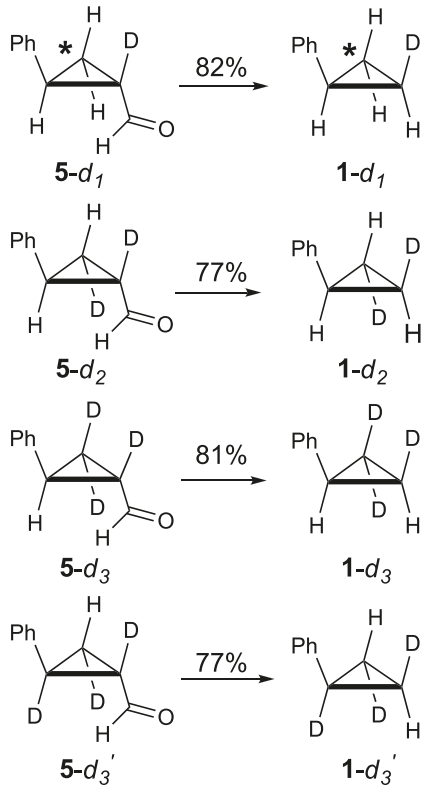
trans-2-Phenylcyclopropanemethanol

The following general procedures for the hydrolysis of (1*R*)-menthyl (1*S*,2*S*)-(+)-2-phenylcyclopropanecarboxylate was used to prepare acids **3**-d_1, **3**-d_2, **3**-d_3, and **3**-d_3' from esters **2**-d_1, **2**-d_2, **2**-d_3, and **2**-d_3', and to reduce these acids to **4**-d_1, **4**-d_2, **4**-d_3, and **4**-d_3'.

(1*R*)-Menthyl (1*S*,2*S*)-(+)-2-phenylcyclopropanecarboxylate (9.65 g, 31.9 mmol) suspended in 300 mL of CH_3OH was stirred for 30 min. Aqueous 25% NaOH (56 g) was added, and the reaction mixture was heated at reflux for 21 h. It was cooled to RT and concentrated by rotary evaporation. The white residue was dissolved in 225 mL of H_2O and the basic solution was extracted with ether (3 × 100 mL). The aqueous layer was separated, acidified with concd HCl (~30 mL), and extracted with ether (4 × 100 mL). The ether extracts were combined, dried ($MgSO_4$), and filtered. The colorless filtrate was concentrated by distillation to remove all but about 30 mL of the ether.

This concentrate was added dropwise by addition funnel along with anhydrous THF (~30 mL, used to rinse out the flask) to a suspension of $LiAlH_4$ (3.03 g, 79.8 mmol) in anhydrous THF (250 mL) under argon. The resulting gray suspension was heated at reflux for 42 h, cooled in an ice bath, and quenched with H_2O (3.0 g), 15% aqueous NaOH (3.03 g), and H_2O (9.09 g), with 5 min of stirring the quenched reaction mixture after each addition. The resulting mixture was stirred for an additional 30 min, dried over K_2CO_3, and filtered through Celite. The solid collected over Celite was washed with THF (~75 mL) and the filtrates were combined and concentrated by distillation. The colorless liquid remaining was purified by Kugelrohr distillation at 75–95 °C under reduced pressure. The colorless oil collected (4.45 g, 93% yield) had a ^{1}H NMR spectrum matching the reference data for *trans*-2-phenylcyclopropanemethanol (5). In **4**-d_2 and **4**-d_3' the C3-H cis to phenyl was seen at δ 0.95 (1H); in **4**-d_1, **4**-d_2, and **4**-d_3 the benzylic H was recorded at δ 1.81–1.85 (1H).

Scheme 3. Stereoselective Rh-catalyzed decarbonylation reactions.



trans-2-Phenylcyclopropanecarboxaldehydes

trans-2-Phenylcyclopropanecarboxaldehydes (**5**-d_i) were prepared as described in this specific example, starting from **4**-d_2. Alcohol **4**-d_2 (4.87 g, 32.4 mmol) in anhydrous CH_2Cl_2 (25 mL) was added dropwise by addition funnel to an orange suspension of PCC (11.18 g, 51.9 mmol) in 100 mL of anhydrous CH_2Cl_2. The flask containing **4**-d_2 and the addition funnel were rinsed with dry CH_2Cl_2 (3 × 5 mL). A dark brown suspension formed immediately, and the reaction mixture was stirred for 4 h at RT under argon. Ether (150 mL) was added and a light brown precipitate was formed. The mixture was stirred for 5 min and then filtered through a short column of Florisil. The reaction flask residue and the Florisil column were rinsed with additional ether (3 × 50 mL). All ethereal material was combined and concentrated by distillation under an aspirator vacuum, and then using a vacuum pump. The residue, a green oil of crude aldehyde **5**-d_2 (4.80 g, ≈100% yield), was stored briefly under argon and subjected to catalytic decarbonation without delay.

Labeled chiral 2-phenylcyclopropanes by catalytic decarbonylation of labeled chiral *trans*-2-phenylcyclopropanecarboxaldehydes

Labeled chiral 2-phenylcyclopropanes (**1**-d_i) by catalytic decarbonylation of labeled chiral *trans*-2-phenylcyclopropanecarboxaldehydes (**5**-d_i) were synthesized as described in this specific example, starting from the sample of crude **5**-d_2 prepared immediately above.

An argon atmosphere was established for an oven-dried 500 mL three-necked round-bottomed flask equipped with an addition funnel, condenser, and a specialized adapter to connect a septum to the flask through a stopcock to protect the septum from toluene at reflux. Then $RhCl(CO)(PPh_3)_2$ (0.78 g, 1.5 mmol) and 1,3-bis(diphenylphosphino)propane (dddp; 1.3 g, 2.5 mmol) were added quickly, and 160 mL of anhydrous, degassed toluene was added by syringe. The resulting mixture was heated to 70–90 °C for 1 h. To the orange solution in the reaction flask was added a yellow solution of **5**-d_2 (4.80 g, 32.4 mmol) in anhydrous, degassed toluene (20 mL) through an addition funnel. The small flask that had contained the aldehyde solution was rinsed with toluene (3 × 5 mL) and the washings were added to the reaction mixture, which was then heated to reflux for 21 h.

A mixture of $RhCl(CO)(PPh_3)_2$ (0.78 g, 1.5 mmol), dddp (1.03 g, 2.5 mmol), and toluene (40 mL) in a separate flask was heated for 1 h at 65–80 °C and then added to the reaction mixture. The small flask was rinsed with toluene (2 × 5 mL) and the washings were added to the reaction mixture, which was then heated to reflux for an additional 24 h. Analysis by GC showed that the aldehyde (**5**-d_2)/phenylcyclopropane (**1**-d_2) ratio was about 1:1. An additional 1.5 mmol of catalyst was prepared and added to the reaction mixture, which was heated to reflux for another 24 h. The (**5**-d_2)/(**1**-d_2) ratio was 0.46:1. Additional toluene (50 mL) was added, and the mixture was heated to reflux for 26 h. Another increment of catalyst (0.49 mmol) was prepared and added, and the reaction mixture was heated to reflux for an additional 44 h, by which time the reaction had gone to completion. Pentane (200 mL) was added to the cooled reaction mixture; the mixture was passed through a silica gel column, followed by 275 mL of pentane. The colorless, clear liquid collected was concentrated by distillation using an efficient teflon spinning band column (a B/R Instrument Corporation 36T 100 system rated at up to 200 theoretical plates with microprocessor controller). The dark yellow pot residue (9.69 g) was characterized by capillary GC: it contained the phenylcyclopropane **1**-d_2 (31.6 weight%, 3.06 g, 79% yield for the two steps from alcohol **4**-d_2), toluene (56.1%, 5.44 g) and α-methylstyrene (1.4%, 0.14 g). Further concentration using a micro spinning band distillation system (B/R 800), followed by a Kugelrohr distillation at 130 °C, afforded a colorless liquid. ^{1}H NMR δ: 0.78 (m, 1H), 1.02 (m, 1H), 1.97 (m, 1H), 7.15–7.37 (m, 5H). ^{13}C NMR δ: 9.25 (1:1:1 triplet), 15.63, 125.78, 126.09, 128.71.

This decarbonylation reaction utilized four additions of catalyst, 12 mol% in all, and 139 h of heating the reaction mixture at reflux. A second preparation of **1**-d_2 starting with 4.70 g of **4**-d_2 used three 3.5 mol% additions of catalyst and keeping the reaction mixture at reflux for 73 h gave 2.83 g (75% yield) of the d_2-phenylcyclopropane.

Other labeled **1**-d_i phenylcyclopropanes were prepared from **4**-d_i alcohols in like fashion. For the eight preparations, times at reflux ranged from 66 to 146 h. Five reactions took three portions of catalyst (10.5% in all); three took four portions (12.5 mol% in total); the 146 h reaction required five portions of catalyst (4 × 3.5% + 2%).

Pure **1**-d_i samples could be secured easily by preparative GC using an Apiezon L column at 125 °C. Under the conditions employed, the retention times for toluene, α-methylstyrene, and a phenylcyclopropane were 2.66, 9.16, and 11.83 min, respectively.

Feasibility of sigmatropic rearrangement on electron-deficient coumarinyl ketones

Lakshmi Narayan Dutta, Banani De, Godhuli Pal, and Amarendra Patra

Abstract: Different alkyl/aryl 7-hydroxy-8-coumarinyl ketones were converted to 7-*O*-allyl and 7-*O*-cyclohexenyl ethers and the study of hitherto unreported sigmatropic rearrangement on 7-*O*-allyl and 7-*O*-cyclohex-2′-ene-1′-ylcoumarinyl ketones prepared is accounted herein. The rearrangement yielded alkyl/aryl 6-allyl-7-hydroxy-8-coumarinyl ketones **3** and alkyl/aryl 6-cyclohex-2′-en-1′-yl-7-hydroxy-8-coumarinyl ketones **7** as the major products. Interestingly, unusual selectivity was observed in the case of alkyl 7-*O*-allylcoumarinyl ketones. Thus alkyl 3-allyl-7-hydroxy-8-coumarinyl ketones **4** and alkyl 8-allyl-7-hydroxy-6-coumarinyl ketones **5** were the outcome from alkyl 7-*O*-allyl-8-coumarinyl ketones and alkyl 4-methyl-7-*O*-allyl-8-coumarinyl ketones, respectively, albeit in minor yields.

Key words: allyloxycoumarinyl ketones, 7-*O*-cyclohex-2′-en-1′-ylcoumarinyl ketones, sigmatropic rearrangement, 3-allylcoumarinyl ketones, 8-allylcoumarinyl ketones.

Résumé : On a transformé diverses alkyl/aryl 7-hydroxy-8-coumarinylcétones en leurs éthers, les oxydes de 7-*O*-allyle et 7-*O*-cyclohexényle correspondants, et on rapporte les résultats obtenus lors des réarrangements sigmatropiques qui n'avaient jamais été rapportés antérieurement et qui ont été effectués sur les 7-*O*-allyl- et 7-*O*-cyclohex-2′-én-1′-ulcoumarinylcétones ainsi préparées. Les produits principaux de ces réactions sont les alkyl/aryl 6-allyl-7-hydroxy-8-coumarinylcétones, **3**, et les alkyl/aryl 6-cyclohex-2′-én-1′-yl-7-hydroxy-8-coumarinylcétones, **7**. On a observé une sélectivité inhabituelle intéressante dans le cal des alkyl 7-*O*-allylcoumarinylcétones. Même s'ils n'ont été obtenus qu'avec de faibles rendements, les alkyl 3-allyl-7-hydroxy-8-coumarinylcétones, **4**, et alkyl 8-allyl-7-hydroxy-6-coumarinylcétones, **5**, sont les produits obtenus à partir respectivement des 7-*O*-allyl-8-coumarinylcétones et alkyl 4-méthyl-7-*O*-allyl-8-coumarinylcétones.

Mots-clés : allyloxycomarinylcétones, 7-*O*-cyclohex-2′-én-1′-ylcoumarinylcétones, réarrangement sigmatropique, 3-allylcoumarinylcétones, 8-allylcoumarinylcétones.

Introduction

Coumarins (1, 2) have attracted the attention of synthetic organic chemists (3–5) throughout the globe for building up new exotic molecules owing to their well-established range of biological activities (6–10). In quest of newer synthetic methodologies we have successfully carried out a series of systematic studies on the selectivities of different organometallics (11, 12) and ylids (13) involving typical non-concerted processes on coumarinyl ketones and coumarincarboxaldehydes. Under the scope of concerted process we have extensively applied a sigmatropic reaction in the form of thermal Claisen rearrangement for the synthesis of various natural and unnatural coumarins. In spite of a flurry of activity in the synthesis of coumarin employing Claisen rearrangement (14–20), there is virtually no report on the efficacy of the rearrangement on the coumarin moiety bearing further electron-rich and electron-deficient functionalities. Herein we report the findings of an intense investigation on Claisen rearrangement restricting the functionalisation to the electron-deficient coumarinyl ketones.

Discussion

The starting materials selected for this study, viz. 7-allyloxy-8-coumarinyl alkyl/aryl ketones **2a**–**2h** and 7-cyclohex-2′-en-1′-yloxy-8-coumarinyl alkyl/aryl ketones **6a**–**6h** were prepared from 7-hydroxy-8-coumarinyl alkyl/aryl ketones **1a**–**1h**. The hydroxycoumarinyl ketones could be procured from 7-hydroxycoumarin and 4-methyl-7-hydroxycoumarin, as appropriate, exploiting Fries rearrangement (21). The aforesaid allyl coumarinyl ethers have thus been successfully prepared in good yield by following the usual protocol of refluxing the compounds for 8 h in dry acetone with allyl bromide in the presence of anhydrous K_2CO_3. An initial sigmatropic rearrangement study revealed that the allyl ethers failed to record any positive result in solvents like chlorobenzene and polyethylene glycol 400. Consequent to that, the rearrangement was tried and ultimately became successful in *N,N*-diethylaniline. The C–C bond formations showed typical selectivities by yielding 6-allyl substituted coumarinyl ketones **3** and 3-allyl substituted coumarinyl ketones **4** with 7-allyloxy-8-coumarinyl ketones

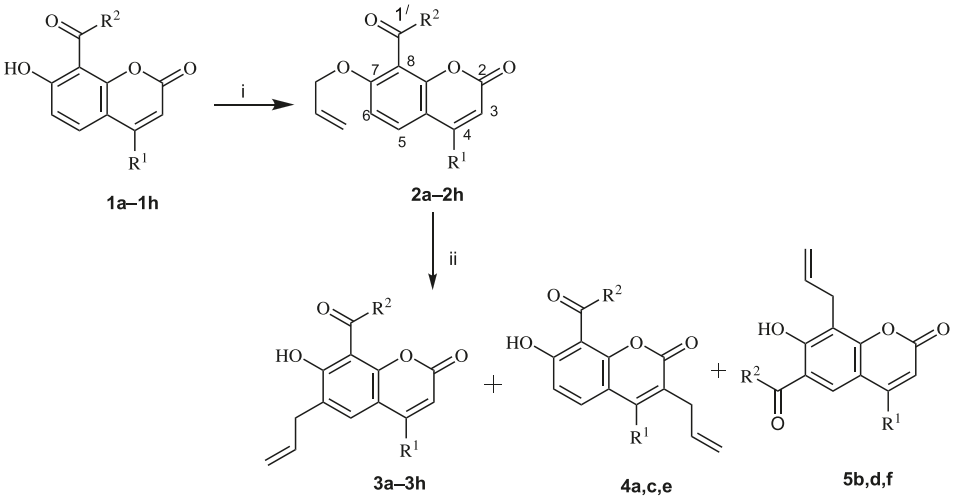
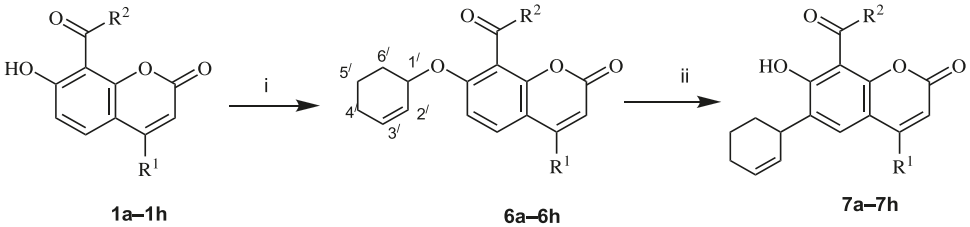
Scheme 1. Reagents and conditions: (*i*) , anhyd. K_2CO_3, dry Me_2CO, 14 h, and reflux; (*ii*) $PhNEt_2$, 195 °C, and 8 h.



Scheme 2. Reagents and conditions: (*i*) , NEt_3, dry Me_2CO, 4 h, and reflux. (*ii*) Ph_2O, reflux for 10 min.



2a, **2c**, and **2e**, whereas the 4-methyl-7-allyloxy-8-coumarinyl ketones **2b**, **2d**, and **2f** resulted in 6-allyl substituted coumarinyl ketones **3** along with 8-allyl substituted 6-coumarinyl ketones **5** as a consequence of unusual acyl migration. The allyl ethers having benzoyl coumarinyl functionality, **2g** and **2h**, did produce only the usual 6-allyl substituted coumarinyl ketones without any trace of other rearranged products (Scheme 1).

It should be noted that attempted cyclohexenylation of hydroxycoumarinyl ketones following the usual protocol of refluxing in dry acetone with 3-bromocyclohexene in the presence of anhydrous K_2CO_3 (22) turned out to be entirely unsuccessful. Finally the problem was overcome through the judicious selection of a base, viz. triethylamine instead of anhydrous K_2CO_3 (Scheme 2). It should be emphasized that the study of Claisen rearrangement turned out to be remarkably successful in diphenyl ether as solvent, while the yield was extremely poor when carried out in chlorobenzene (<5%) and *N,N*-diethylaniline (~10%). The cyclohexenyl ethers on Claisen rearrangement underwent regioselective formation of 6-cyclohex-2′-ene-1′-yl-8-coumarinyl alkyl/aryl ketones **7a**–**7h** in good yields (Table 1). No unusual acyl migration or Claisen rearrangement on other positions of coumarin moiety was observed with cyclohexenyl ethers.

The formation of 6-allyl and 6-cyclohexenyl substituted coumarinyl ketones turned out to be quite obvious via an intermediate **A** (Scheme 3). In the formation of 3-allylcoumarinyl ketones, the intermediate **C** may be visualized as a consequence of a [3,3] Cope rearrangement of the intermediate **B** produced via a [3,3] sigmatropic shift. Alternatively, the genesis of 3-allylcoumarinyl ketones from alkyl 7-allyloxy-8-coumarinyl ketones may be rationalized from the intermediate **C** formed via a [3,3] sigmatropic shift, which further underwent Cope rearrangement with the transfer of allyl functionality at the 4a position, leading to the intermediate **C**. The intermediate **C** follows an itinerary of further [3,3] Cope rearrangement followed by [1,7] tautomeric shift to afford the 3-allyl substituted coumarinyl ketones. The 4-methyl-7-allyloxycoumarinyl ketones prefer to follow from the intermediate **B** as an alternative pathway leading to the anionic intermediate **D**, along with the ejected acylium ion R-C≡O^+ that may exist, most plausibly enjoying the character of an intimate ion pair though the feasibility of a concerted mechanism cannot be ruled out. On further chemical mutation to intermediate **F**, the 6-acyl-8-allylcoumarinyl ketones are being derived via the [1,3] tautomeric shift.

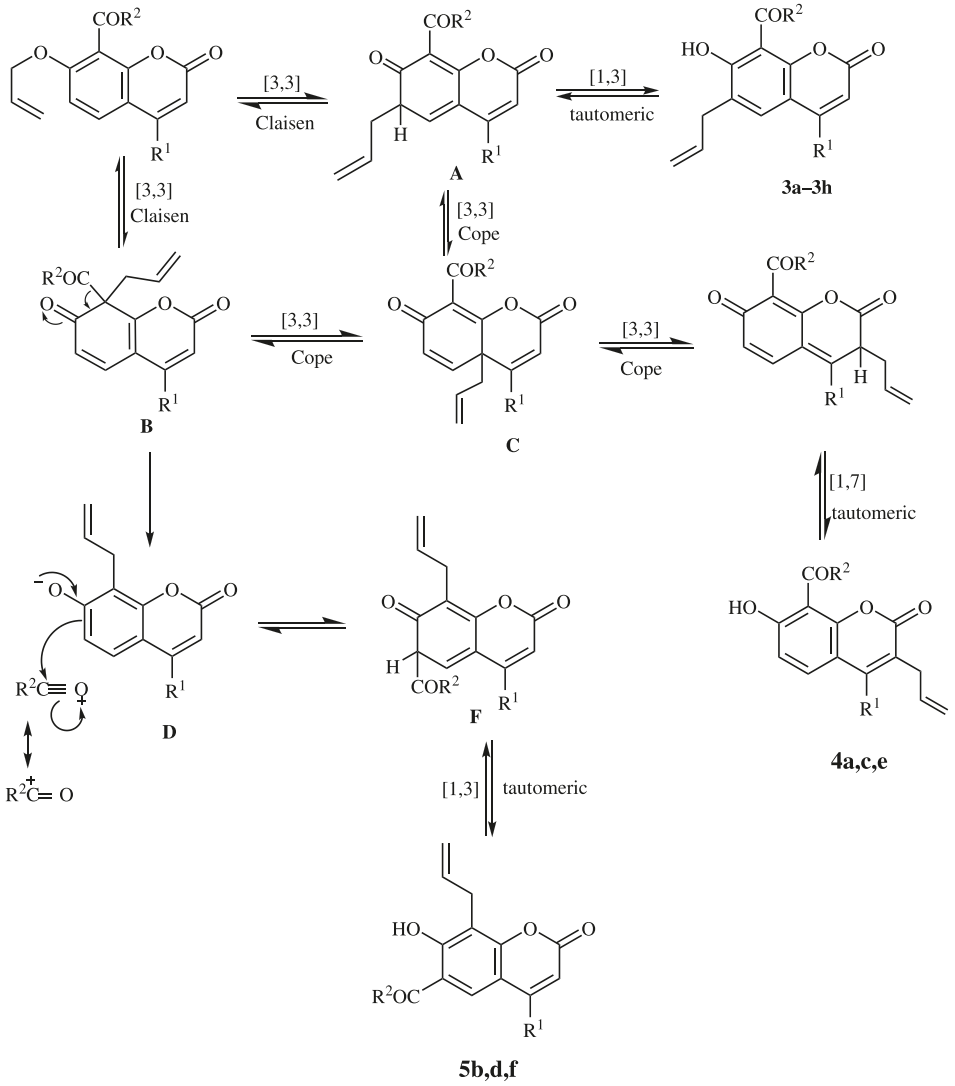
Scheme 3.



The structures of the compounds were unequivocally settled from elemental analyses and extensive spectroscopic investigations. Assignment of the structures of 6-allyl and 8-allylsubstituted coumarinyl ketones posed an interesting problem and could be unequivocally solved by critical analysis of the ^{1}H NMR and ^{13}C NMR spectra, with particular emphasis on the proton signals of C-5 and carbon signals of C-6 and C-8. The proton signals at the 5-position enjoy more deshielding because of the anisotropic effect offered by the newly arrived adjacent ketocarbonyl functionality. On the contrary, the C-6 carbon signal of 8-allyl substituted compounds are more shielded than those of the 6-allyl substituted compounds (23) (Table 2), and the C-8 signals varied oppositely.

Table 2. Chemical shift (δ) values of C-5 protons and C-6, C-8 carbon signals.

Compound	Location of ketoalkyl functionality	δ Value		
		C-5 proton signal	C-6 carbon signal	C-8 carbon signal
3b	C-8	7.48	126.1	108.6
5b	C-6	7.88	112.4	116.3
3d	C-8	7.43	126.2	108.7
5d	C-6	7.95	112.5	116.0
3f	C-8	7.49	126.1	108.7
5f	C-6	7.95	112.5	116.2

Conclusion

In conclusion, it is worth mentioning that an unusual selectivity was observed in the product formation with the introduction of a methyl group at the 4-position of the 7-allyloxy-8-coumarinyl ketone moiety. The changeover in the character of the minor products with the introduction of methyl group at the 4-position of the 8-coumarinyl ketone moiety may be rationalized either from steric or electronic considerations. The plausible explanation of such selectivity in favor of the electronic and (or) steric effect of methyl group can only be confirmed on further study of Claisen rearrangement on 7-allyloxy-8-coumarinyl ketones with varying substituents (Et, *n*-Pr, *i*-Pr, *t*-Bu, CHO, CN, CO_2Me, CH_2OH) at the 4-position.

Experimental

All melting points were determined in open capillaries and are uncorrected. IR spectra (ν_{max} in cm^{-1}) were recorded in KBr with a PerkinElmer 883-IR and RXI FT IR spectrophotometers. The UV spectra were measured in 95% ethanol using an Hitachi U 2000 and Lamda 20 ELMER spectrophotometers. The elemental analyses were carried out in a PerkinElmer 240C elemental analyzer. The ^1H NMR and ^{13}C NMR spectra were recorded in a Bruker AV300 supercon NMR spectrometer operating at 300.13 MHz for proton and 75.47 MHz for carbon, using $CDCl_3$ as solvent and TMS as an internal standard. Mass spectra were recorded on a Finnigan Mat 1020 C, Shimadzu Model GEMS QP1000A, and LC-MS MS Q-TOF-micro spectrometers and a Q TRAP LC/MS/MS system operative at 70 eV. The column chromatographic separation and filtration were performed with silica gel (mesh size 60–120) prepared by Glaxo (India) Ltd and Merck (India) Ltd. Petroleum ether used had a boiling point 60–80 °C.

Preparation of 7-allyloxycoumarinyl ketones 2a–2h

General procedure

7-Hydroxycoumarinyl ketones (4.3 mmol) dissolved in dry acetone (50 mL) were treated with allyl bromide (4.9 mmol) and anhydrous K_2CO_3 (4.3 mmol) and refluxed under anhydrous conditions on water bath for ~14 h. Excess acetone was distilled off and the residual solid cakelike mass was treated with water (150 mL). The mixture was acidified in cold conditions with cold dil HCl (4 N). The solid separated was filtered out and washed with cold water until it was neutral. The resultant solid was dried and crystallized from EtOAc/petroleum ether to obtain crystals of 7-allyloxycoumarinyl ketones **2a**–**2h**.

Preparation of 6-allyl-8-coumarinyl alkyl/aryl ketones 3a–3h

General Procedure

The allyloxycoumarinyl ketones **2a**–**2h** (2.0 mmol) dissolved in distilled $PhNEt_2$ (30 mL) were heated at 195 °C for 8 h under anhydrous conditions. $PhNEt_2$ was then distilled off and the residual mass left was dissolved in $CHCl_3$ (30 mL). The $CHCl_3$ solution of the mass was washed successively with cold dil. HCl (3 × 15 mL), a saturated brine solution (1x15 mL), followed by a saturated aqueous solution of $NaHCO_3$ (2 × 15 mL), and again with a saturated brine solution (2 × 15 mL). Removal of solvent after drying over anhydrous Na_2SO_4 afforded a semi-solid mass, which was found to be a mixture of three components. Column chromatographic resolution over silica gel yielded the 6-allyl-8-coumarinyl ketones **3a**–**3h** from petroleum ether and EtOAc (99:1) eluate fractions. The products were crystallized from EtOAc/petroleum ether.

Compound 3a

Mp 121 °C. UV–vis (EtOH) λ_{max} (log ϵ): 321.7 (4.78), 270.5 (4.76), 254.5 (4.75). IR (cm^{-1}): 3080, 2920, 1730, 1710, 1610, 1560, 1400, 1365. ^{1}H NMR δ: 2.89 (sharp s, 3H, 1′-CH_3), 3.35 (br d, J = 6.5 Hz, 2H, 6-CH_2CH=CH_2), 5.071 (d, J = 10.0 Hz, 1H, CH_2CH=CH_AH_B), 5.072 (d, J = 18.0 Hz, 1H, CH_2CH=CH_AH_B), 6.01 (m, 1H, CH_2CH=CH_2), 6.20 (d, J = 9.5 Hz, 1H, 3-H), 7.33 (s, 1H, 5-H), 7.57 (d, J = 9.5 Hz, 1H, 4-H), 14.02 (s, 1H, 7-OH). ^{13}C NMR δ: 33.0 (2°, CH$_2$CH=CH_2), 33.7 (1°, 1′-CH_3), 108.7 (4°, C-8), 110.3 (4°, C-4a), 112.0 (3°, C-3), 116.9 (2°, CH_2CH=CH_2), 126.7 (4°, C-6), 133.9 (3°, CH_2CH=CH_2), 135.1 (3°, C-5), 144.2 (3°, C-4), 154.4 (4°, C-8a), 159.6 (4°, C-2), 165.1 (4°, C-7), 204.3 (4°, C-1′). 7-*O*(Cyclohex-2′-ene-1′-yl)-8-coumarinyl ketones 6a–6h

General procedure

Pure and dried 7-hydroxy-8-coumarinyl ketone **1a**–**1h** (2.5 mmol) taken in dry acetone (50 mL) were refluxed with 3-bromocyclohexene (0.4 mL, 0.003 mole) and NEt_3 (1 mL, 0.726 g, 0.007 mole) for 4 h. After distilling off acetone, water (10 mL) was added, and the content was acidified with cold dil HCl (4 N, 15 mL). The organic part of the mixture was then extracted with $CHCl_3$ (50 mL), which was washed successively with a saturated brine solution (15 mL), a saturated $NaHCO_3$ solution (2 × 15 mL), and again with a saturated brine solution (3 × 15 mL). The $CHCl_3$ layer was dried over anhydrous Na_2SO_4 for 30 min, filtered, and excess $CHCl_3$ was distilled off to obtain an oily mass. TLC experiment showed that the oily mass was more polar than the starting material on using 5% EtOAc/benzene as developer solvent. The oily mass was then column chromatographically filtered. Crystals of **6a**–**6h** were obtained on eluting with 10% EtOAc/petroleum ether and subsequent crystallization of the products.

6-(Cyclohex-2′-ene-1′-yl)-7-hydroxy-8-coumarinyl ketones 7a–7h

General procedure

Pure and dry 7-(cyclohex-2′-ene-1′-yloxy)-8-coumarinyl ketones **6a**–**6h** (1.8 mmol) were taken in Ph_2O (10 mL) and refluxed for 10 min. The brown viscous liquid formed was less polar than the starting material (as shown by TLC experiment on using 5% EtOAc/benzene as developer). The brown liquid was then charged on a column of silica gel and eluted with petroleum ether and then with EtOAc/petroleum ether (1:9 *v*/*v*). The crystals of pure Claisen products **7a**–**7h** were obtained from the later eluate fraction.

Linear free-energy correlation analysis of the electronic effects of the substituents in the Sonogashira coupling reaction

Christine Gottardo, Thomas M. Kraft, M. Selim Hossain, Peter V. Zawada, and Heidi M. Muchall

Abstract: Relative rate constants (k_{rel}) for the Sonogashira coupling were determined in competitive reactions between iodobenzene and a series of *para*- and *meta*-substituted iodobenzenes and compared to the charge on iodine and the *z*-component of the quadrupole moment of the iodine-bearing carbon. We use an Hammett correlation analysis and the computational data to provide further evidence that the rate limiting step of the Sonogashira reaction is the initial oxidative addition of Pd to the carbon–iodine bond.

Key words: Sonogashira, competitive reactions, Hammett correlation.

Résumé : On a déterminé les constantes de vitesses relatives (k_{rel}) pour le couplage de Sonogashira dans des réactions compétitives entre l'iodobenzène et une série d'iodobenzènes substitués en positions *méta* et *para* et on a les a comparées à la charge sur l'iode et au composant *z* du moment quadripolaire du carbone portant l'iode. On a utilisé une analyse par corrélation de Hammett et des données de calculs théoriques pour obtenir d'autres bases pour établir que l'étape cinétiquement limitante de la réaction de Sonogashira est l'addition initiale oxydante du palladium sur la liaison carbone–iode.

Mots-clés : Sonogashira, réactions compétitives, corrélation de Hammett.

[Traduit par la Rédaction]

Introduction

Preparations of aryl alkynes have been described in the literature using the Sonogashira reaction since 1975 (1). As this coupling reaction has become the most important method for the synthesis of terminal aryl alkynes that have found use as building blocks in materials chemistry and natural product synthesis, amongst others, numerous variations in reaction conditions have been reported (2), and the efforts have culminated in a recent review (3). The original reaction involved the presence of a palladium catalyst, a base, and cuprous iodide. Studies investigating the nature of the aryl halide, the base, the solvent, and the palladium catalyst have all been reported with changes to the reaction that result in improved yields and reduced reaction times (4). In fact, the Sonogashira reaction was developed from earlier reports by Stephens and Castro who used cuprous acetylides to couple with phenyl halides (5). In their report, they indicate that electron-withdrawing groups in the *para*-position increase the ease of substitution with respect to electron-donating groups in the following manner: *p*-nitro > H > *p*-methoxy. Subsequent reports of Sonogashira coupling reactions have described improved yields when electron-withdrawing substituents, such as carboxaldehydes, nitro groups, and esters, are used (6).

The Sonogashira reaction is one of a family of coupling reactions; these reactions are proposed to proceed via an oxidative addition–reductive elimination via the use of d^{10} or d^8 catalysts such as Pd^0 or Pd^{2+} (1, 7, 8) or Ni^0 or Ni^{2+} (9, 10). The mechanisms of other reactions in this family, such as the Heck reaction (11, 12), Stille coupling (13), and Suzuki reaction (8, 9, 14) have been investigated previously, with a focus on the oxidative addition. Those studies focussed primarily on changes in reactivity resulting from changes in *para*-substitution. All but one (11) obtained a positive Hammett ρ value, indicating that the reaction involves an oxidative addition as the rate-determining step. Even in the case where a negative value (ρ = –1.6) was obtained, the researchers suggest that the oxidative addition is rate-limiting (11) and proceeds through a three-center reaction model, based on work presented for a d^9 iridium catalyst (15, 16).

In light of these studies, and having previously reported competitive Sonogashira reactions between iodobenzenes with electron-donating and electron-withdrawing groups in the *para*-position, which support the observations by Stephens and Castro (17), we would like to report on an extension of this research. A kinetic competition experiment between iodobenzene and a large number of *para*- and *meta*-

substituted iodobenzenes is presented. The majority of studies presented in the literature have focused on *para*-substitution, and we present a number of new *meta*-substituted compounds to extend the scope of the study. Furthermore, a computational study was undertaken to analyze the relationship of the kinetic data with the electron density within the quantum theory of atoms in molecules (18).

Results and discussion

The substituted iodobenzenes were chosen for their availability and to ensure a range of electron-donating and electron-withdrawing substituents. The intermolecular competition was carried out using 1 equiv. each of iodobenzene and the substituted iodobenzene and 0.05 equiv. of the trimethylsilylacetylene. The Pd catalyst and CuI catalyst were present in 0.02 and 0.06 mol equiv., respectively. The choice of reaction conditions (catalyst, solvent, and base) was based on established reaction conditions that allow the Sonogashira coupling to occur for a wide variety of substituents (4). The alkyne was present at a level of 0.05 equiv. to establish pseudo first-order reaction conditions with respect to the aryl iodides. Biphenyl was used as an internal standard in the GC analysis and was added after the desired reaction time. The yields of the aryl alkynes were determined using this internal standard with the relative areas of the GC peaks (aryl alkyne : biphenyl) being compared to the response factors that had been previously obtained using pure samples of the products of known concentrations with known amounts of biphenyl added. To obtain pure samples of the aryl alkynes, samples of each of the aryl alkynes, **3** and **4a**–**4r**, were synthesized using an excess of the alkyne to ensure sufficient yields (Scheme 1). The relative rate constants for the substituted iodobenzenes were determined from the yield of products and are reported in Table 1. No products other than **3** and **4** could be detected by GC. A reaction containing iodobenzene in the presence of the catalysts (no alkyne present) was run to ensure that homocoupling of the aryl iodides did not occur. The products of oxidative homocoupling of the alkyne [bis(trimethylsilyl)butadiyne], Buchwald–Hartwig type amination of **3g** and **3r**, or Ulmann ether coupling could not be detected by GC.

The relative rate constants follow a predictable trend with the exception of the *m*-OH and *m*-NH_2 substituents. In both of these cases, the resonance effects of the substituents greatly overwhelm the inductive effects. Even more strikingly, *m*-OH appears to have a greater electron-donating effect than *p*-OH as evidenced by the relative rate constants, k_{rel} values of 0.0948 and 0.199, respectively. It is interesting to note that the effect of substituting a proton with a methyl group (**4p** to **4o** vs. **4r** to **4q**) has a more pronounced effect for the oxygen-containing substituent than for the nitrogen-containing substituent, with the *p*-OCH_3 group leading to a rate enhancement over the *p*-OH group of 2.6 times, while the rate increase of *p*-$N(CH_3)_2$ is only 1.5 times that of the *p*-NH_2 group. If the anomalous rates for the hydroxyl and primary amino groups are a result of coordination with the metal catalyst, removing two potential bonding sites from **4r** to **4q** vs. one site from **4p** to **4o** should have shown the greater effect. However, the overall effectiveness of the coordination in **4p** must have a greater relative influence on reactivity.

We next correlated the relative rate constants with the Hammett substituent constants (19) and found the best correlation with σ_p (Table 2; Fig. 1). The Hammett reaction constant ρ shows a higher sensitivity to substituent change than with the standard Hammett reaction (dissociation of benzoic acid), which is reasonable for a reaction site directly

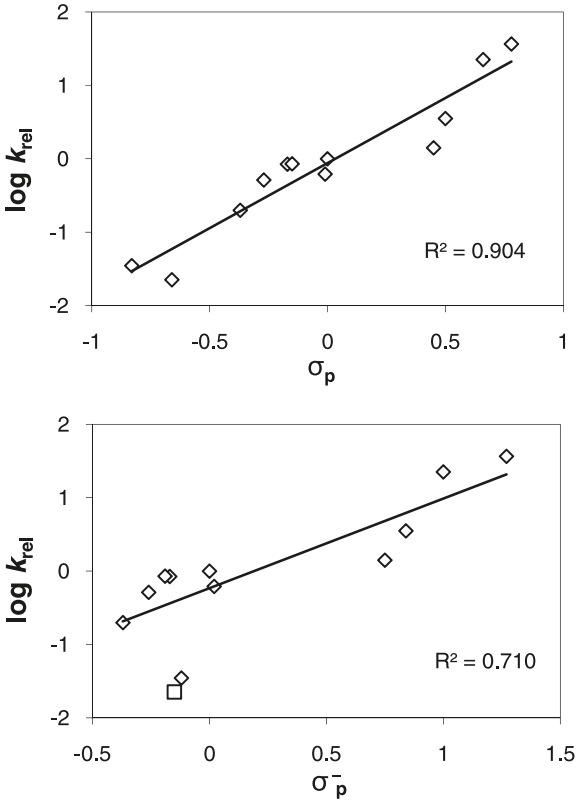
Table 2. Hammett correlation data of relative rate (Log k_{rel}).

Substituent constant[11]	ρ^a	$R^{2\ b}$
σ^+_p	1.229	0.854
σ_p	1.803	0.904
σ^-_p	1.089	0.710

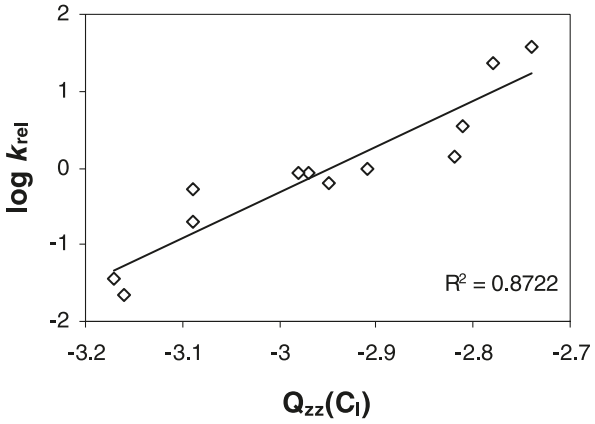
Fig. 1. Plot of (*a*) log k_{rel} against σ and (*b*) log k_{rel} against σ^- relationships for *para*-substitution (excluding the point for *p*-NH_2, □).



on a ring carbon atom, i.e., closer to the perturbing substituent. The positive value (1.8) indicates an increase in electron density at the rate-limiting step, suggesting a nucleophilic attack. In comparison, this ρ value is closest to that presented by Fauvarque et al. (7). Their conditions are significantly different, having completed an electrochemical kinetic study in which the results were obtained in the absence of copper. In their study, they attribute the rate-limiting step to the oxidative addition of the Pd to the aryl halide (7). In the study by Weissman and Milstein, an investigation of Suzuki coupling with aryl bromides, the best fit was with σ_p^- (R^2 = 0.97) with a ρ value of close to 1, which they attribute to conjugation with electron donors (14). They present data for only four *para*-substituted compounds, one of which is a strong resonance donator (14). Our data stem from a greater range of compounds, including strong resonance withdrawers; we do not see an effect that would indicate a strong direct resonance in either direction, i.e., anomalously high or low values of k_{rel} for withdrawers or donators.

The ease with which a nucleophilic attack on a ring carbon of the iodobenzenes occurs should be reflected in the

Fig. 2. Plot of the log of the rate against the *z*-component of the quadrupole moment of the iodine-bearing carbon for *para*-substitution.



atomic properties of that carbon. Analyzing the electron density within the quantum theory of atoms in molecules (18), we obtained the charge on the ipso-C atom that bears the iodine atom, $q(C_I)$, and the *z*-component of the quadrupole moment of C_I, given as $Q_{zz}(C_I)$, as it has been correlated with the π-density on carbon atoms in aromatic systems (18). For comparison and because the first step in the suggested mechanism (see below) involves the C–I bond of the iodobenzenes, the charge on iodine, *q*(I), and its quadrupole moment component Q_{zz}(I) were obtained as well.

It is known that substituent effects in electrophilic aromatic substitutions cannot be explained through total atomic charges of the carbon atoms, because the σ and π contributions to the density are not affected uniformly by different substituents; while CH_3 is both σ and π electron-donating and CN is both σ and π withdrawing, OH is σ withdrawing and π donating (20). On the other hand, the negative values of Q_{zz}, indicative of a charge accumulation at the atom above and below the molecular plane, i.e., where one would expect π-density, are known to parallel the observed reactivity (20). These findings should also hold for the nucleophilic aromatic substitution. As expected in the iodobenzenes, therefore, while $q(C_I)$ for *meta*- or *para*-substitution does not correlate with a Hammett substituent constant, $Q_{zz}(C_I)$ shows a strong correlation with σ_p (R^2 = 0.9604). In contrast, *q*(I) correlates equally well with both σ_m (R^2 = 0.9060) and σ_p (R^2 = 0.9043). For relationships involving k_{rel} and log k_{rel}, we find that, for *para*-substitution, log k_{rel} correlates only with $Q_{zz}(C_I)$ (Fig. 2), while, for *meta*-substitution, the best correlation is found for k_{rel} with *q*(I) (Fig. 3).

The palladium cycle in the proposed mechanism of the Sonogashira reaction involves an oxidative addition (to give intermediate **5**) followed by a reductive elimination (to give product) (Fig. 4) (1). Electron density on the reactive site is most likely to be impacted in one of these two steps, since addition of the alkyne/ligand exchange on Pd would rely on the electronic effects being transmitted through the metal. Both the correlation of log k_{rel} with σ_p and with $Q_{zz}(C_I)$ indicate that the first insertion step is rate-limiting for the *para*-substituted iodobenzenes. The positive reaction constant of 1.8 indicates an increased electron density in the rate-

Fig. 3. Plot of the rate against the charge of the iodine atom for *meta*-substitution.

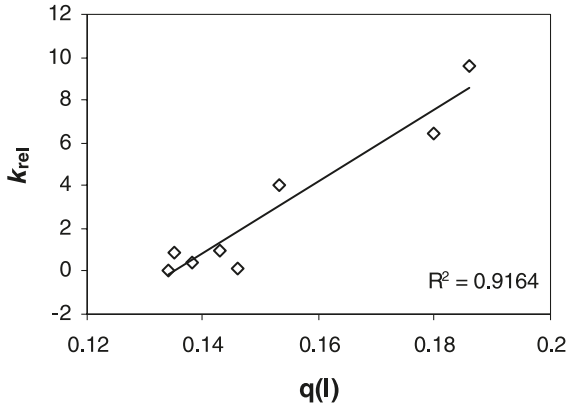

Fig. 4. Proposed mechanism of the Sonogashira reaction (1).

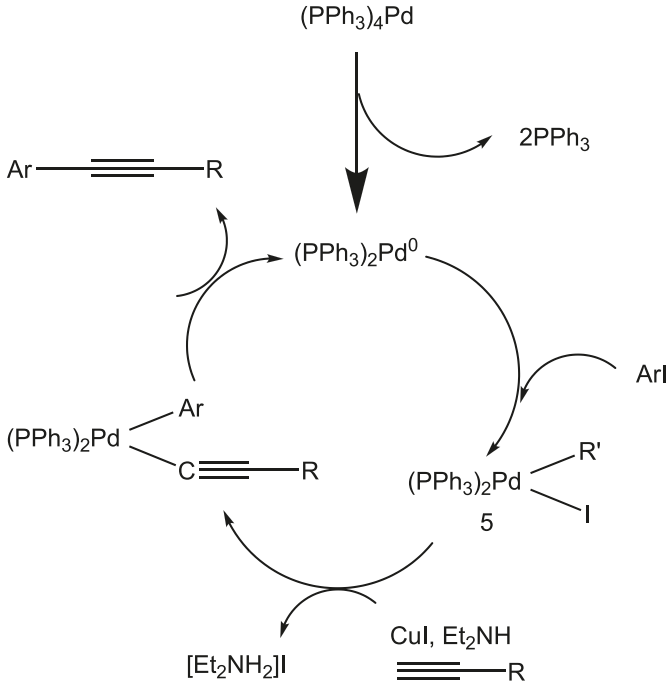

limiting step; the largest increase in electron density at the reaction site, according to Sonogashira's proposed mechanism, would occur to give **5** (Fig. 4). Furthermore, this proposed rate-limiting step is supported by the correlation of the rate with $Q_{zz}(C_I)$, i.e., a strong correlation existing with the undisturbed iodobenzenes. When we turned our attention to the *meta*-substituents, a correlation could be found between k_{rel} and σ_m (R^2 = 0.8849); when log k_{rel} was used, a correlation was not obtained (R^2 = 0.6768). Even though k_{rel} for the *meta*-substituted iodides correlates with q(I), a correlation supporting the first step of the reaction as being rate-determining is not as obvious. Since the final step of the reaction would result in a decreased electron density at the carbon, it should, therefore, result in a reaction constant with a negative value, which was not observed.

Conclusion

Both the experimental and computational results provide evidence that the rate-limiting step of the Sonogashira reaction is the oxidative addition of the metal catalyst. The evidence to support this rate-limiting step is not as compelling with the *meta*-substituted iodobenzenes as with the *para*-substituted iodobenzenes.

Experimental

Solvents and reagents were used as purchased unless otherwise noted. THF was dried over sodium. $Pd(PPh_3)_4$ was synthesized according to literature procedure (21) and stored under nitrogen at –4 °C.

General procedure for the Sonogashira coupling reactions– Preparation of aryl alkynes 3 and 4a–4r for use as standards

Iodobenzene, **1**, or the substituted iodobenzene, **2a**–**2r** (1.0 mmol), $Pd(PPh_3)_4$ (0.02 mmol, 23 mg), CuI (0.06 mmol, 11 mg), triethylamine (0.21 mL), and trimethylsilylacetylene (2.5 mmol, 245 mg, 0.353 mL) were combined in THF (2.5 mL) and stirred under argon at room temperature, 21 °C, overnight. The reaction was filtered through Celite, the solvent removed in vacuo, and the residue was purified by silica gel chromatography (hexanes/EtOAc = 90:10) to give products **3** and **4a**–**4r**. All of the products are known and were characterized or confirmed by spectral data, which is provided along with a Chemical Abstracts number for reference. The pure products were used to determine the detector response factors according to standard methods, using biphenyl as the internal standard.

Trimethyl[(3-nitrophenyl)ethynyl]silane, 4a [Chem. Abstr. 183322-33-0]

^{1}H NMR (200 MHz, $CDCl_3$) δ: 8.32 (s, 1H), 7.75 (dt, J = 7.8, 1.4 Hz, 1H), 7.49 (t, J = 6.6 Hz, 1H), 7.45 (t, J = 6.6 Hz, 1H) 0.26 (s, 9H).

3-[(Trimethylsilyl)ethynyl]benzonitrile, 4b [Chem. Abstr. 190771-22-3]

^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.74 (s, 1H), 7.66 (dt, J = 6.4, 1.2 Hz, 1H), 7.58 (dt, J = 6.4, 1.2 Hz, 1H), 7.42 (t, J = 6.4 Hz, 1H), 0.26 (s, 9H).

Methyl 3-[(trimethylsilyl)ethynyl]benzoate, 4c [Chem. Abstr. 77123-59-2]

^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.88 (s, 1H), 7.71 (d, J = 6 Hz, 1H), 7.31 (d, J = 6 Hz, 1H), 7.12 (t, J = 6 Hz, 1H), 3.92 (s, 3H), 0.27 (s, 9H).

General procedure for the competitive coupling reactions

The intermolecular competition was carried out using iodobenzene (1.0 mmol, 204 mg, 0.11 mL) and the substituted iodobenzene, **2a**–**2r** (1.0 mmol), $Pd(PPh_3)_4$ (0.02 mmol, 23 mg), CuI (0.06 mmol, 11 mg), triethylamine (0.21 mL), and trimethylsilylacetylene (0.05 mmol, 5 mg, 7 μL) combined in THF (2.5 mL) and stirred under argon at room temperature, 21 °C. After a standard reaction time of 5 h, a GC of the mixture was run (internal standard biphenyl), and the relative rates of reactivity were calculated. The reported rates are an average of a minimum of two experiments.

GC conditions

The reaction mixtures were analyzed by a flame ionization detector (FID) and DB-5 High Temp column. The initial oven temperature was 50 °C, which was ramped by 5 °C/min to the final temperature of 200 °C, which was held for 5 min. At least two GC runs were performed for each sample to ensure reproducibility.

Computational details

All geometry optimizations were performed with Gaussian03 (22), using the Perdew–Burke–Ernzerhof (PBE0) hybrid density functional (23–25) with the 6–31+G(d) basis set for all atoms except for iodine and the Midi! basis set (26) for iodine. All geometries were confirmed to be minima by frequency calculations. In case of rotational isomerism (*m*-CO_2CH_3, *m*-OCH_3, and *m*-OH), the lower-energy conformer, determined through either electronic energies or Gibbs free energies, given in Fig. S2 in the supplementary information was used in the analyses.[2] Wave functions were analyzed with the Proaim module from the AIMPAC (27) series of programs for charges (q) and quadrupole moments (Q_{zz}); both are obtained from integrations of the electron density over the atomic basin. For *p*-C_2H_5 (torsional angle 90°) and *p*-Ph (torsional angle 40°), wave functions were also obtained for the planarized geometries and these were used in the analyses. Total energies as well as the q and Q_{zz} data used in the correlations are given in Table S1 of the supplementary information.[2]

Oxyhalogen–sulfur chemistry — Kinetics and mechanism of the bromate oxidation of cysteamine

Moshood K. Morakinyo, Edward Chikwana, and Reuben H. Simoyi

Abstract: The kinetics and mechanism of the oxidation of the biologically important molecule, cysteamine, by acidic bromate and molecular bromine have been studied. In excess acidic bromate conditions, cysteamine is oxidized to N-brominated derivatives, and in excess cysteamine the oxidation product is taurine according to the following stoichiometry: $BrO_3^- + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SO_3H + Br^-$. There is quantitative formation of taurine before N-bromination commences. Excess aqueous bromine oxidizes cysteamine to give dibromotaurine: $5Br_2 + H_2NCH_2CH_2SH + 3H_2O \rightarrow Br_2NCH_2CH_2SO_3H + 8Br^- + 8H^+$, while excess cysteamine conditions gave monobromotaurine. The oxidation of cysteamine by aqueous bromine is effectively diffusion-controlled all the way to the formation of monobromotaurine. Further formation of dibromotaurine is dependent on acid concentrations, with highly acidic conditions inhibiting further reaction towards formation of dibromotaurine. The formation of the N-brominated derivatives of taurine is reversible, with taurine regenerated in the presence of a reducing agent such as iodide. This feature makes it possible for taurine to moderate hypobromous acid toxicity in the physiological environment.

Key words: cysteamine, hypobromous acid, toxicities, antioxidant.

Résumé : On a étudié la cinétique et le mécanisme de l'oxydation de la molécule biologiquement importante, cystéamine, par le bromate acide et le brome moléculaire. Dans des conditions de bromate acide en excès, la cystéamine est oxydée en dérivés bromés et, dans un excès de cystéamine, le produit d'oxydation est la taurine qui est formée en d'après la stoechiométrie: $BrO_3^- + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SO_3H + Br^-$. Il y a formation quantitative de taurine avant que la N-bromation commence. Un excès de brome en milieu aqueux provoque une oxydation de la cystéamine avec formation de dibromotaurine: $5Br_2 + H_2NCH_2CH_2SH + 3H_2O \rightarrow Br_2NCH_2CH_2SO_3H + 8Br^- + 8H^+$, alors que les conditions dans lesquelles la cystéamine est en excès conduit à la formation de la monobromotaurine. L'oxydation de la cystéamine par le brome aqueux est effectivement une réaction sous contrôle de la diffusion jusqu'à la formation de la monobromotaurine. La formation subséquente de dibromotaurine dépend des concentrations d'acide alors que les conditions fortement acides inhibent la réaction subséquente pouvant conduire à la formation de la dibromotaurine. La formation des dérivés N-bromés de la taurine est réversible, la taurine pouvant être régénérée en présence d'un agent réducteur, tel un ion iodure. Cette caractéristique fait que la taurine peut réduire le caractère toxique de l'acide hypobromeux dans un environnement physiologique.

Mots-clés : cystéamine, acide hypobromeux, toxicités, antioxydant.

Introduction

Sulfur metabolism in biological systems is believed to be the main source of thiols (1, 2). The most important thiols in biological chemistry are cysteine, homocysteine, and glutathione. Glutathione is the most abundant non-protein thiol in mammals, an adult human having about 30 g glutathione widely distributed in most tissues, with levels in the kidney and liver significantly higher (3). In general, thiols are readily oxidized to disulfides in the presence of mild oxidants, and in the presence of more powerful oxidants S-oxygenation can occur, which yields, successively, sulfenic, sulfinic, and sulfonic acids. In some cases, the C–S bond cleaves to give sulfate as the final oxidation product (2, 4). Those thiols without an amino group adjacent to the sulfhydryl group are easily oxidized to sulfate and a mixture of alcohols, aldehydes, and carboxylic acids (depending on the amount and strength of oxidant). α-Aminothiols are very reactive, but will not easily cleave the C–S bond, and can thus be regenerated for further use after oxidation to the S-oxide or the disulfide (5). Sulfinic and sulfonic acids formed from thiols with an amino group on the α or β position have been found to be quite stable (6, 7).

In living systems, S-oxygenation of the thiol group in the physiological environment can be initiated by two microsomal systems: one involving cytochrome P-450 sys-

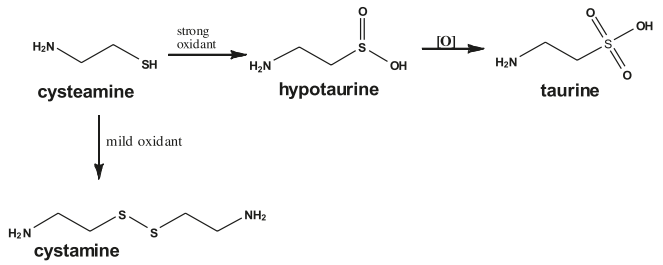
tem of enzymes and the other based on the flavin-containing monooxygenase (8–10). In the presence of these enzyme systems and cofactor-like compounds such as sulfide and hydroxylamine, cysteamine is oxidized to the sulfinic acid derivative, hypotaurine. Most metabolic pathways, however, give hypotaurine as a precursor to taurine (the sulfonic acid). Scheme I encompasses nearly all possible reactions of cysteamine in the physiological environment.

Cysteamine and its major metabolite, hypotaurine, are known to be excellent scavengers of HOCl and other reactive oxygen species (ROS) and are more likely to act as antioxidants in vivo than taurine (3, 11, 12). These ROS can cause damage to DNA, proteins, and lipids in addition to causing radical damage and oxidative stress in animal cells (11, 13, 14). In addition to protection against radical damage in DNA, cysteamine can also act as a repair agent for DNA through the formation of the protective $RSSR^{\bullet -}$, which then reacts with the $DNA^{\bullet +}$ radical ion to regenerate DNA and form cystamine, the cysteamine disulfide (2, 3). The ability of cystamine to reversibly form disulfide links with the sulfhydryl groups at or near the active sites of enzymes is also important in regulation of several essential metabolic pathways (15, 16).

Our research group embarked on a series of studies to elucidate the kinetics and mechanisms of the oxidation of cysteamine and its S-oxides. Previous studies done in our laboratory on the cysteamine sulfinic acid, hypotaurine, have shown that it reacts quite rapidly with chlorite to give a mixture of taurine, monocloro- and dichloro-taurine (17). Oxidation is believed to occur simultaneously at the sulfur center (to give the sulfonic acid) and at the nitrogen center (to give the chloramines). The oxidation of taurine by chlorite (18) and bromate (19) showed that oxidation occurs only on the nitrogen centre to give the corresponding N-derivatives. The reaction was exceedingly slow, even with the most powerful oxidizing agents such as acidic bromate. The formation of *N*-bromo- and *N*-chloro-taurines is suggested as a possible mechanism by which taurine can moderate the oxidative toxicity of halogens and hypobromous and hypochlorous acid in the slightly basic physiological environments (20).

A recent study from our laboratory on the oxidation of cysteamine by iodine and acidic iodate showed that these mild oxidants only oxidized cysteamine to its dimer, cystamine (21). In this study, stronger oxidants bromine and acidic bromate have been used. The aim of the study reported in this manuscript was to investigate whether these oxidants also produced cystamine as a viable product or whether the oxidation proceeded to hypotaurine or all the way to taurine as well as the *N*-bromotaurines. Bromate is a precursor to HOBr, a particularly damaging oxidizing species in the physiological environment. Stimulated granulocytes produce oxidizing agents (especially H_2O_2) and secrete granular proteins into the extracellular medium, which contributes to their antimicrobial, cytotoxic, and cytolytic activities (22). Each group of cells contains a specific peroxidase, which catalyzes the reactions of hydrogen peroxide with halogens. The enzyme, myeloperoxidase, which is abundant in neutrophils, catalyzes the oxidation of Br^- ions by H_2O_2 to yield HOBr as a reactive and oxidatively damaging product (23).

Scheme I.



[R1] $H_2O_2 + Br^- + \text{Myeloperoxidase}/H^+ \rightarrow HOBr + H_2O$

Taurine and its precursors, e.g., hypotaurine and cysteamine have been suggested as possible moderators of HOBr toxicity by forming longer-lived and less oxidizing products in their reactions with HOBr (24).

Experimental

Materials

Cysteamine hydrochloride (CA, 2-aminoethanethiol hydrochloride) 98%, cystamine, bromine, potassium iodide, potassium bromide (Sigma-Aldrich), sodium perchlorate (98%) (Acros), sodium bromate, perchloric acid (72%), soluble starch, sodium thiosulfate, and hydrochloric acid (Fisher) were used without further purification. The concentration of bromine was determined by standardization against thiosulfate solution after addition of excess acidic iodide. Spectrophotometry was used as a complementary technique by measuring bromine absorbance at 390 nm where the extinction coefficient had been deduced to be 142 mol^{-1} L cm^{-1}. This standardization was carried out before each series of kinetic experiments owing to the volatile nature of bromine. CA solutions were prepared just before use and not kept for more than 24 h. All solutions were prepared using distilled and deionized water from a Barnstead Sybron Corporation water-purification unit. Inductively coupled plasma mass spectrometry (ICPMS) analysis showed negligible concentrations of iron, copper, and silver and approximately 1.5 ppb of cadmium and 0.43 ppb in lead as the most abundant metal ions, which was not enough to affect the overall reaction kinetics and mechanism (25).

Methods

All experiments were carried out at 25.0 ± 0.1 °C and a constant ionic strength of 1.0 mol/L ($NaClO_4$). CA, sodium perchlorate, and perchloric acid solutions were mixed in one vessel and bromate (or bromine) solutions in another. A PerkinElmer Lambda 25 UV–vis spectrophotometer interfaced to a Pentium IV computer was used for most of the kinetics and stoichiometric determinations. The slower BrO_3^- – CA reactions were monitored on the UV–vis spectrophotometer by monitoring bromine absorbance at 390 nm. Faster reactions were followed on a Hi-Tech Scientific SF61 – DX2 double mixing stopped-flow spectrophotometer.

Results

Stoichiometry

The stoichiometry of the BrO_3^- – cysteamine reaction in acidic medium is very complex. The reaction showed simultaneous oxidations at both the nitrogen and sulfur centers to give N-derivatives of the cysteamine sulfonic acid. Unlike what had been observed with other small organic sulfur molecules subjected to strong oxidizing agents, there is no cleavage of the C–S bond as evidenced by the lack of sulfate production. The reaction gives a mixture of products: $H_2NCH_2CH_2SO_3H$, $Br(H)NCH_2CH_2SO_3H$, and $Br_2NCH_2CH_2SO_3H$, all of which give nearly identical ^1H NMR spectra in the strongly acidic medium necessary for bromate oxidations.

Iodometric titrations in excess bromate conditions gave a reproducible stoichiometry consistent with a $6e^-$ oxidation of the sulfur center to the sulfonic acid, taurine, according to the following stoichiometric ratio:

$$[R2] \quad BrO_3^- + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SO_3H + Br^-$$

In this titrimetric method, excess acidic bromate was reacted with a fixed amount of cysteamine and the excess oxidizing power left after complete consumption of cysteamine determined by addition of excess acidified iodide followed by a thiosulfate titration. Figure 1*a* shows a plot of thiosulfate titer vs. initial bromate concentrations. The plot is linear, as expected, with the intercept on the bromate concentration axis (zero thiosulfate titer) representing the exact amount of bromate needed to oxidize cysteamine. Data shown in Fig. 1*a* were taken with cysteamine fixed at 0.0020 mol/L. The intercept concentration on the bromate axis is 0.0021 mol/L, which is very close, within statistical error, to the 1:1 stoichiometric ratio of reaction [R2]. The UV spectrum of the product solution, on the other hand, shows a strong absorption peak at 244 nm, which is consistent with the formation of dibromotaurine. This is even more evident when Br^- is deliberately added to the reaction mixture to produce predominantly the dibromotaurine after prolonged standing.

$$[R3] \quad 5BrO_3^- + 3H_2NCH_2CH_2SH + Br^- + 6H^+ \rightarrow 3Br_2NCH_2CH_2SO_3H + 6H_2O$$

Reaction [R3] is preceded by the formation of monobromotaurine:

$$[R4] \quad 4BrO_3^- + 3H_2NCH_2CH_2SH + 3H^+ \rightarrow 3(Br)HNCH_2CH_2SO_3H + Br^- + 3H_2O$$

Direct reaction of cysteamine with aqueous bromine showed a clean 1:5 stoichiometric ratio:

$$[R5] \quad 5Br_2 + H_2NCH_2CH_2SH + 3H_2O \rightarrow Br_2NCH_2CH_2SO_3H + 8Br^- + 8H^+$$

Stoichiometry [R5] was deduced by mixing excess bromine solutions with a fixed amount of cysteamine and measuring the residual absorbance of bromine at 390 nm. None of the mono- or di-bromotaurine products absorb at 390 nm, and so all contribution to the absorbance at this wavelength was attributed solely to bromine. Figure 1*b* shows the data derived from such a series of experiments for a fixed concentration of 3.0×10^{-4} mol/L cysteamine. The intercept concentration of the $[Br_2]_0$ axis is 1.5×10^{-3} mol/L, which represents the exact amount of bromine needed to consume 3×10^{-4} mol/L cysteamine, which confirms the 1:5 stoichiometry.

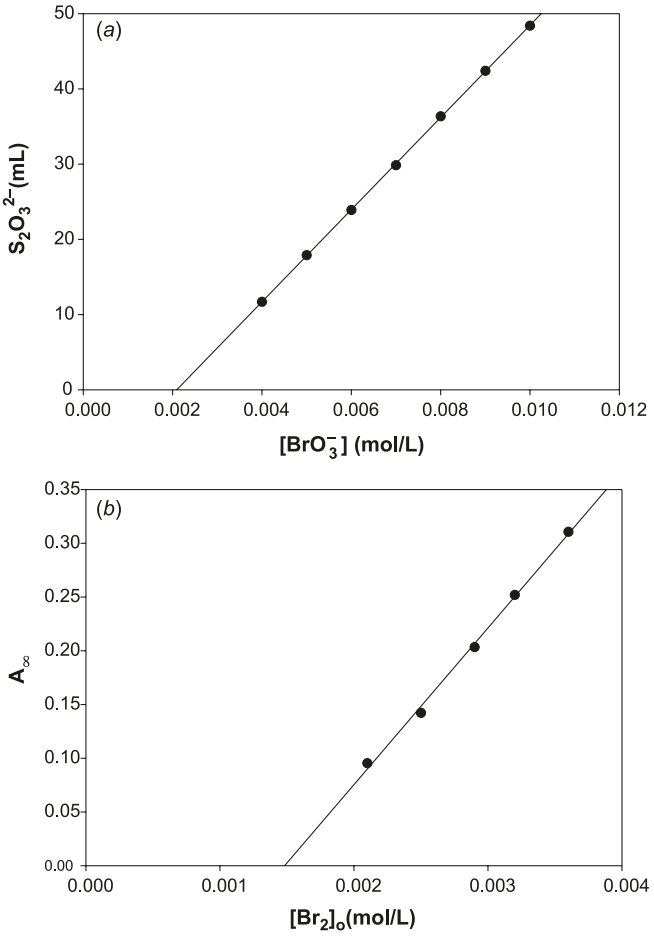

Fig. 1. (*a*) Iodometry titration for stoichiometry analysis of product solutions for a constant $[CA]_o$ and $[H^+]_o$ of 0.002 mol/L and 0.2 mol/L, respectively. $[BrO_3^-]$ = (a) 0.004 mol/L, (b) 0.005 mol/L, (c) 0.006 mol/L, (d) 0.007 mol/L, (e) 0.008 mol/L, (f) 0.009 mol/L, (g) 0.010 mol/L. This intercept represents the maximum amount of bromate tolerated by the reaction system before permanent bromine production is observed. (*b*) Plot of absorbance at infinity (A_∞) vs. $[Br_2]_o$ from the bromine oxidation of cysteamine. The intercept, as expected, is consistent with the stoichiometry equation proposed for the direct Br_2 – CA reaction. [CA] = 0.0003 mol/L, $[Br_2]_{intercept}$ = 0.0015 mol/L.

Monobromotaurine and dibromotaurine can be quantified in the reaction product by their rapid reaction with excess iodide to produce iodine, which could be determined spectrophotometrically and (or) titrimetrically:

$$[R6] \quad (Br)HNCH_2CH_2SO_3H + 2I^- + H^+ \rightarrow H_2NCH_2CH_2SO_3H + I_2\ (aq) + Br^-$$

© 2008 NRC Canada

Reaction [R6] is the reason why iodometric titrations in excess bromate only showed the formation of the sulfonic acid taurine (stoichiometry [R2]), and not the *N*-bromo derivatives. Their formation was masked, since they rapidly oxidized the iodide to iodine.

Product identification

Dibromotaurine was identified by its distinct UV spectrum featuring a sharp strong peak at 244 nm and a weaker peak at 336 nm (26). In addition to a peak also at 336 nm, monobromotaurine has an absorption peak at 288 nm (27) with a weak absorptivity coefficient of only 425 mol^{-1} L cm^{-1}. Bromine oxidations of cysteamine always produced mixtures of the mono- and di-bromotaurines, with the monobromotaurine's peak at 336 nm completely obscured by the contribution from dibromotaurine. Highly acidic environments favored monobromotaurine over dibromotaurine, since the ratio of the absorbance at 288:244 increased with a decrease in pH. This ratio also increased if taurine was added to the stoichiometric solution [R5]. Quantitative formation of monobromotaurine could be achieved by mixing an exact 1:4 ratio of cysteamine to bromine:

$$[R7] \quad 4Br_2 + H_2NCH_2CH_2SH + 3H_2O \rightarrow BrHNCH_2CH_2SO_3H + 7Br^- + 7H^+$$

^{1}H NMR spectra were also used to prove that the cysteamine carbon skeleton of two sets of methylene protons is not disturbed during its oxidation. Figure 2 shows the series of spectra representing the reactants and products. Spectrum A is of pure cysteamine in neutral pH showing the methylene proton triplets centered at 2.78 and 3.15 ppm. Spectrum B is of the product of cysteamine–bromate reaction in acidic medium. The two methylene triplets appear at 3.4 and 4.08 ppm with a larger coupling constant than observed with pure cysteamine. Spectrum C is of pure hypotaurine, while D is of the oxidation product of hypotaurine with acidic bromate. Spectrum E is the standard spectrum of taurine in D_2O at nearly neutral pH. The appearance of the methylene peaks upfield compared with the other spectra is due to the comparatively higher pH conditions utilized in the acquisition of this spectrum. Spectrum F is the product of the taurine–bromate reaction. Spectra B, D, and F are identical, showing that cysteamine, hypotaurine, and taurine are all oxidized by acidic bromate to the same final product. The two smaller triplets appearing on the bromate–taurine spectrum are due to the fact that this reaction produces a mixture of products, which also include the oxime, $H(OH)NCH_2CH_2SO_3H$ (28).

Reaction kinetics

As with all bromate oxidations, this reaction is only viable in highly acidic environments. The reaction could be monitored by following the appearance of bromine in excess bromate conditions. In this configuration, the reaction initially showed a quiescent period with no formation of bromine. We shall call this period the "induction period". The end of the induction period is signaled by the formation of bromine. Figure 3*a* shows a series of typical bromine absorbance traces derived from varying the initial bromate concentrations. At the end of the induction period, there is a

Fig. 2. ^{1}H NMR spectrum showing (A) cysteamine, (B) cysteamine + BrO_3^- + H^+, (C) hypotaurine, (D) hypotaurine + BrO_3^- + H^+, (E) taurine, and (F) taurine + BrO_3^- + H^+.

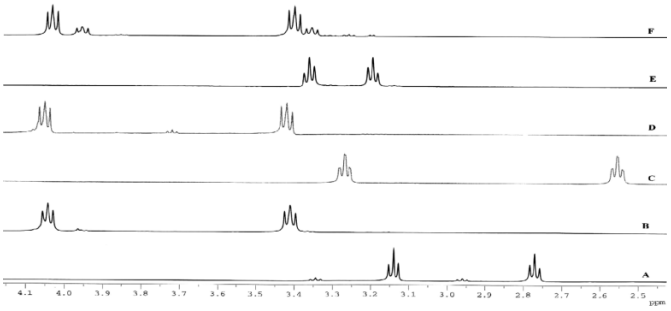

Fig. 3. (*a*) Effect of varying bromate concentration on the oxidation of CA by bromate. There is an increase in the rate of bromine formation as the bromate concentration is increased. $[CA]_o$ = 0.005 mol/L, $[H^+]_o$ = 0.2 mol/L, $[BrO_3^-]$ = (a) 0.05 mol/L, (b) 0.06 mol/L, (c) 0.07 mol/L, (d) 0.08 mol/L, (e) 0.09 mol/L, (f) 0.10 mol/L, (g) 0.11 mol/L. (*b*) Linear plot of reciprocal induction time vs. $[BrO_3^-]$ for data shown in Fig. 3*a*.

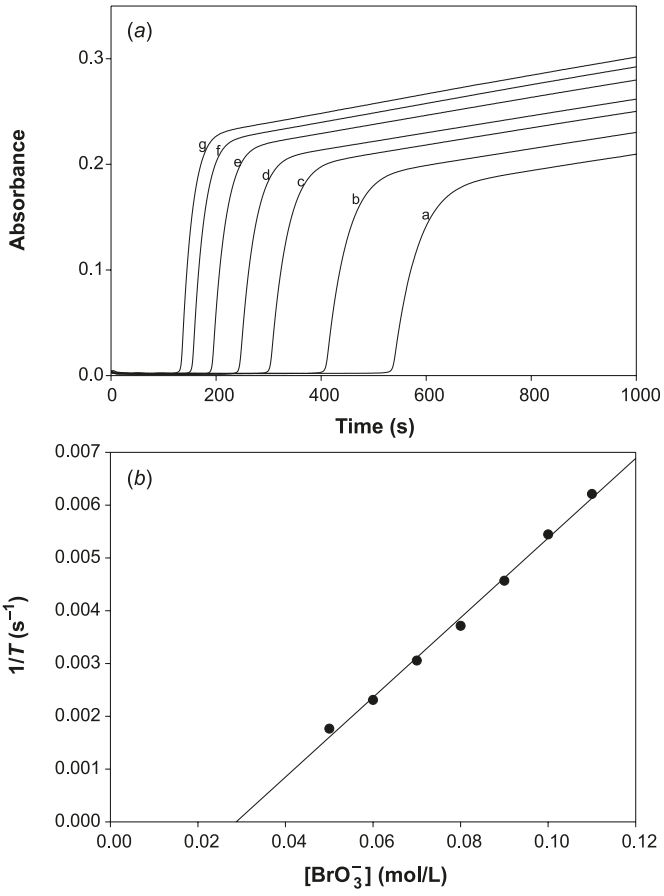


© 2008 NRC Canada

rapid formation of bromine, which eventually gives way to a slower rate of formation until the excess bromate or bromide formed from the reaction mixture has been exhausted, thus shutting down the BrO_3^-/Br^- reaction:

[R8] $BrO_3^- + 5Br^- + 6H^+ \rightarrow 3Br_2 + 3H_2O$

Figure 3*b* shows that the length of this induction period has an inverse linear dependence upon initial bromate concentrations. This would suggest that the precursor reaction to the formation of bromine depends on bromate concentrations to the first power. Figure 4*a* shows the reaction's dependence on acid concentrations, with Fig. 4*b* showing that the induction period follows an inverse squared dependence on acid that tends towards saturation as acid concentrations are further increased. The biphasic bromine formation in Fig. 4*a* is worth noting. Though higher acid concentrations reduce the induction period, they also reduce the amount of bromine formed in the rapid first step. The rate of formation of bromine in the slower phase appeared insensitive to variations in acid concentrations, and they also appear to be zero-order. Figure 5 shows that for as long as $[BrO_3^-]_0 \gg [CA]_0$, then the induction period will be invariant, but the rate and amount of bromine formed after the induction period varies with initial cysteamine concentrations. This trend would be expected, since reaction [R8] is catalyzed by bromide, and higher CA concentrations would produce higher bromide concentrations.

The direct reaction of bromine with CA was so rapid that its rate approached the detection limit of our stopped-flow apparatus. The only way to slow the reaction down so that it could be observed on our stopped-flow ensemble was to flood the reaction with bromide so that the reaction being observed was between CA and tribromide (see Fig. 6) (29, 30).

[R9] $Br_2 + Br^- \rightleftharpoons Br_3^-$; $K_{eq} = 17$

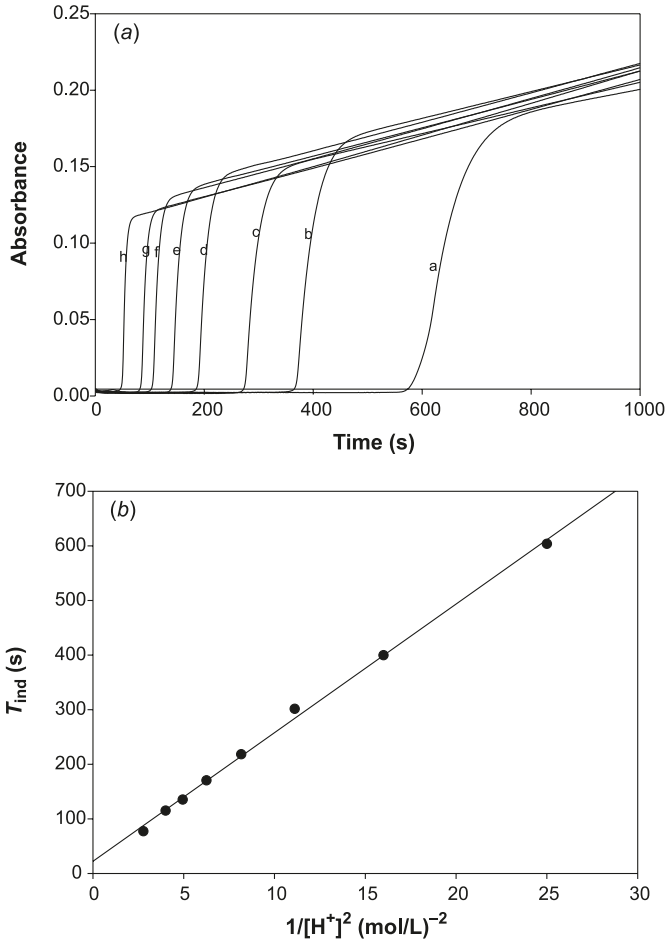
[R10] $3Br_3^- + H_2NCH_2CH_2SH + 3H_2O \rightarrow H_2NCH_2CH_2SO_3H + 6H^+ + 9Br^-$

The reaction involves a very fast initial step that is complete in less that 50 ms followed by a slower step that takes about 1.0 s. The initial step involves the consumption of approximately 3 equiv. of bromine to 1 equiv. of CA. This is equivalent to oxidizing CA to taurine:

[R11] $3Br_2 + H_2NCH_2CH_2SH + 3H_2O \rightarrow H_2NCH_2CH_2SO_3H + 6Br^- + 6H^+$

The formation of bromamines after formation of taurine appears to constitute the slower stage of the reaction. Figure 7 shows a series of experiments in which bromine is in excess of the stoichiometric amounts needed to satisfy reactions [R5] and [R7]. Trace a is a control experiment, which was not flooded with bromide. It shows that the reaction is complete within the mixing time of the stopped-flow instrument. The rest of the other traces show one single rapid step without a slower second step. No acid was added to this series of kinetics runs, and this appears to enhance the normally slower second step. The full 5:1 stoichiometry [R5] is attained within 0.5 s. Acid, however, was not inhibitory enough to allow for the determination of kinetics constants

Fig. 4. (*a*) Effect of progressively increasing $[H^+]$ at constant [CA] and $[BrO_3^-]$. $[CA]_o = 0.005$ mol/L, $[BrO_3^-]_o = 0.05$ mol/L, $[H^+]$ = (a) 0.20 mol/L, (b) 0.25 mol/L, (c) 0.30 mol/L, (d) 0.35 mol/L, (e) 0.40 mol/L, (f) 0.45 mol/L, (g) 0.50 mol/L, (h) 0.60 mol/L. (*b*) Plot showing the linear dependence of induction time on the reciprocal of $[H^+]_o^2$ for data shown in Fig 4*a*.



for the Br_2 – CA reaction, but it appeared to stunt the second slower part of the reaction in which bromamines are formed (see Fig. 8).

Mechanism

The rapid Br_2 – CA reaction implies that in both Figs. 1*a* and 3*a*, formation of bromine indicates complete consumption of CA. Any bromine formed in the presence of CA will be rapidly consumed and will not accumulate. The bromine–hypotaurine reaction was also found to be as rapid as the Br_2 – CA reaction; which implies that reaction [R2] has to run its course before bromine production commences.

The inverse bromate dependence and inverse square acid dependence of the induction period implies that the rate-determining step to reaction [R11] is the well-known standard bromate initiation reaction:

[R12] $BrO_3^- + 2H^+ + Br^- \rightleftharpoons HBrO_2 + HOBr$

We base our assertion on the following logic. The direct reaction of bromine and cysteamine (Figs. 6–8) is so rapid (close to diffusion-controlled) and much faster than the reac-

Fig. 5. "Peacock-tail type" traces obtained from variation of $[CA]_o$ in excess $[BrO_3^-]_o$ conditions. The final Br_2(aq) increases with $[CA]_o$, but the induction period does not change. $[BrO_3^-]$ = 0.1 mol/L, $[H^+]$ = 0.2 mol/L, [CA] = (a) 0.005 mol/L, (b) 0.006 mol/L, (c) 0.007 mol/L, (d) 0.008 mol/L, (e) 0.009 mol/L, (f) 0.010 mol/L, (g) 0.011 mol/L.

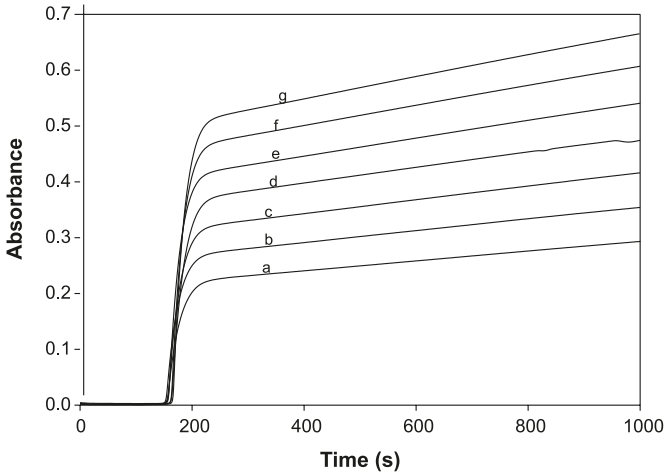

Fig. 6. Effect of varying CA on the direct reaction of Br_2 vs. CA in excess bromide monitored at 390 nm. $[Br_2]$ = 0.00215 mol/L, $[Br^-]$ = 1.0 mol/L, [CA] = (a) 0.0001 mol/L (b) 0.0002 mol/L (c) 0.0003 mol/L (d) 0.0004 mol/L (e) 0.0005 mol/L (f) 0.0007 mol/L.

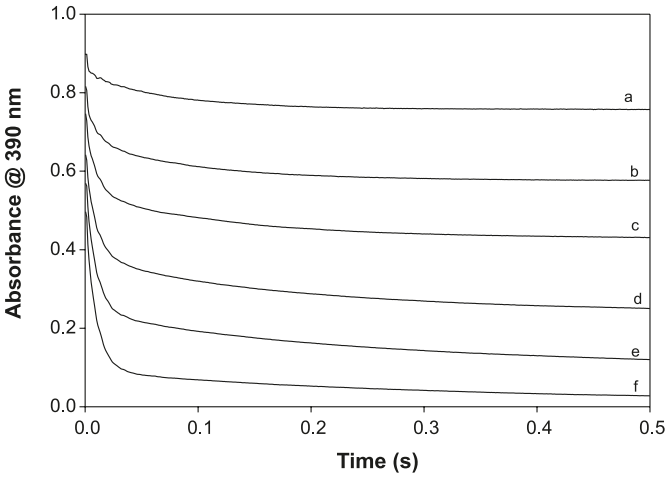

Fig. 7. Effect of varying $[Br_2]_o$ on the direct reaction of Br_2 vs. CA in excess bromide monitored at 390 nm. [CA] = 0.0003 mol/L, $[Br^-]$ = 1.0 mol/L, $[Br_2]$ = (a) 0.001 68 mol/L (no bromide), (b) 0.001 68 mol/L, (c) 0.002 10 mol/L, (d) 0.002 50 mol/L, (e) 0.002 93 mol/L, (f) 0.003 35 mol/L.

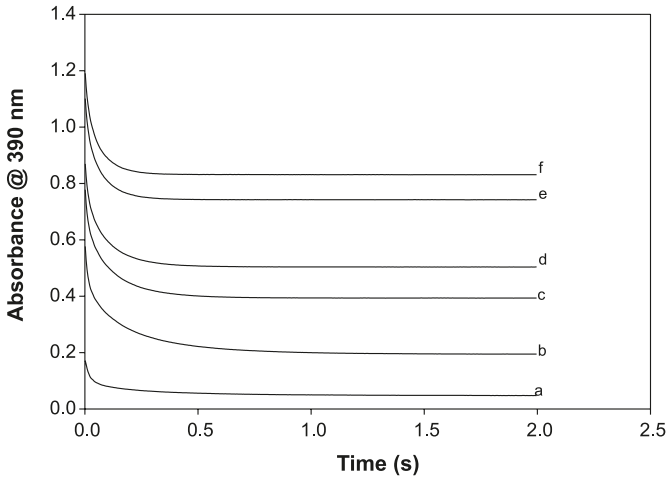

Fig. 8. Effect of acid on the bromine–CA reaction. Acid is mildly inhibitory on the first initial rapid phase of the reaction but shuts down the second slower section of the reaction, which involves formation of bromamines. $[Br_2]_o$ = 0.002 45 mol/L, $[CA]_o$ = 0.0004 mol/L, $[H^+]$ = (a) no acid, (b) 0.006, (c) 0.008, (d) 0.010, (e) 0.012, (f) 0.014 mol/L.

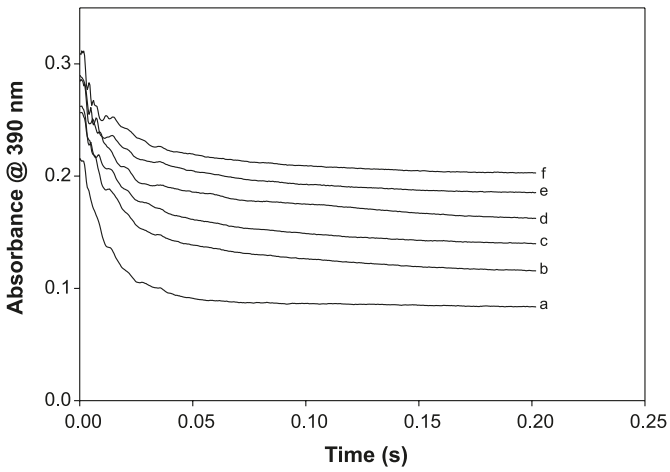

tion of bromate and cysteamine such that formation of bromine should indicate complete consumption of cysteamine. The time taken to achieve complete consumption of cysteamine (the induction period monitored in Figs. 3*b* and 4*b*), is inversely proportional to the rate of reaction (i.e., consumption of cysteamine).

Further reaction can occur between the reactive species $HBrO_2$ and HOBr with CA and its oxidative by-products.

$$[R13]\quad HOBr + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SOH + Br^- + H^+$$

While $HBrO_2$ can also act as oxidizing agent as in reaction [R13], its rapid disproportionation in the presence of bromide (reaction [R14]) will make its effect as an oxidant negligible.

$$[R14]\quad HBrO_2 + Br^- + H^+ \rightleftharpoons 2HOBr$$

If one re-writes reaction [R13] and substitutes CA with any 2-electron reductant (i.e., the 2 electrons can be supplied by any oxidizable species in the reaction mixture), then a linear combination of R12 + 3R13 + R14 gives an overall reaction stoichiometry that is autocatalytic in Br^-:

$$[R15]\quad BrO_3^- + 6H^+ + Br^- + 6e^- \rightarrow 2Br^- + 3H_2O$$

As long as reaction [R12] is the rate-determining step, Br^- will be an autocatalyst. All bromate solutions contain trace amounts of bromide in the reaction mixture, which have

Note: The units for the kinetics constants in the third column are derived from the reaction's molecularity except where water is involved, in which case water was ignored.

been measured at approximately 5.0×10^{-6} mol/L. Quantitatively, are these sufficient to initiate the reaction? A computer simulation of the reaction while utilizing these trace bromide concentrations gave much slower reaction kinetics and longer induction periods when compared with the experimental traces. This suggests that there should be another pathway that generates bromide ions, which will initiate reaction [R12]. Another pathway that exists for initial bromide formation involves oxidation by protonated bromic acid (31–33):

[R16] $H^+ + BrO_3^- \rightleftharpoons HBrO_3$

[R17] $H^+ + HBrO_3 \rightleftharpoons H_2BrO_3^+$

[R18] $H_2BrO_3^+ + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SOH + HBrO_2 + H^+$

[R19] $HBrO_2 + H_2NCH_2CH_2SH \rightarrow H_2NCH_2CH_2SOH + HOBr$

Bromide ions will thus be generated by the successive reduction of bromate to bromide. Adding the sequence R16 + R17 + R18 + R19 + R13 and assuming each reductant can be represented by 2 e's; the overall reaction representing initial bromide formation will be similar to [R15] without the autocatalysis:

[R20] $BrO_3^- + 6H^+ + 6e^- \rightarrow Br^- + 3H_2O$

The autocatalytic route will take over and become dominant as the reaction proceeds and rate of bromide production shifts from the kinetics derived from [R20] to those derived from [R15]. As bromide ions accumulate, their rate of production ceases to be the rate-determining step, and reaction [R12] takes over as the overall rate-determining step. Data shown in Figs. 3*b* and 4*b* strongly suggests that reaction [R12] is rate-determining up to the stage where cysteamine is completely converted to taurine.

All kinetics data collected imply that the oxidation of CA to taurine is much faster than the subsequent N-bromination reactions. Since bromate oxidations are only viable at low pH conditions, in all bromate oxidations of CA studied, the CA should be fully protonated on the amino group:

[R21] $H_2NCH_2CH_2SH + H^+ \rightleftharpoons HSCH_2CH_2NH_3^+$; K_b

The protonation of the amino group should retard the electrophilic bromination of this group:

[R22] $HSCH_2CH_2NH_3^+ + Br_2 \rightleftharpoons HSCH_2CH_2NHBr + Br^- + 2H^+$

An intermediate such as $HSCH_2CH_2NHBr$ should be very unstable and should rapidly hydrolyze to the sulfenic acid, since the thiol group is much more easily oxidizable than the N-containing group:

[R23] $HSCH_2CH_2NHBr + H_2O \rightarrow H_2NCH_2CH_2SOH + Br^- + H^+$

N-bromination of the sulfenic acid and hypotaurine will also be insignificant owing to kinetics factors in which the oxidation of the sulfur group is much more rapid than N-bromination (see Table 1).

N-bromination kinetics

In neutral to slightly basic environments, reaction [R24] should be very rapid and almost diffusion-controlled.

[R24] $HO_3SCH_2CH_2NH_2 + Br_2 \rightarrow HO_3SCH_2CH_2NHBr + Br^- + H^+$

© 2008 NRC Canada

Our stopped-flow ensemble, with a mixing time of 3 ms, could not catch this step, nor the next step that involves formation of the dibromo derivative:

[R25] $HO_3SCH_2CH_2NHBr + Br_2 \rightleftharpoons HO_3SCH_2CH_2NBr_2 + Br^- + H^+$

This reaction is slower in highly acidic medium because reactions of type [R22] are slower than those of type [R24]. Electrophilic attack on the N-center by bromine is retarded by the protonation of the nitrogen center. Kinetics data in Figs. 6 and 7 show first-order kinetics in both bromine and cysteamine. If one was to assume, in a limiting case, that the route of bromination through [R22] is negligible, then the initial rate of N-bromination would be given by the equation,

$$[1] \qquad \text{Rate} = -\frac{d[Br_2]}{dt} = \frac{k_{24}[HO_3SCH_2CH_2NH_2]_T[Br_2]_0}{1 + K_b[H^+]}$$

$[HO_3SCH_2CH_2NH_2]_T$ is the total cysteamine sulfonic acid concentration before it is partitioned into the protonated and unprotonated forms. Retardation by bromide ions can be mathematically handled in the same manner, in which rate of reaction becomes

$$[2] \qquad -\frac{d[Br_2]}{dt} = \frac{k_{24}[HO_3SCH_2CH_2NH_2]_T[Br_2]_0}{\{1 + K_b[H^+]\}\{1 + K_{eq}[Br^-]\}}$$

In none of our experiments were the retardations by Br^- and H^+ effective enough for the use of eqs. [1] and [2] in determining bimolecular rate constant k_{24}. We could only use initial rate data and assuming bimolecular kinetics in Fig. 8 to estimate that k_{24} should be larger than 10^5 mol^{-1} L s^{-1}. Reliable values for k_{24} can be derived from relaxation techniques (34). In the physiological environment and in basic conditions, in general, the major route of N-bromination (reaction [R26]) is through hypobromous acid (35), since the bromine hydrolysis reaction favors hypobromous acid at high pH and aqueous bromine in acidic conditions (36).

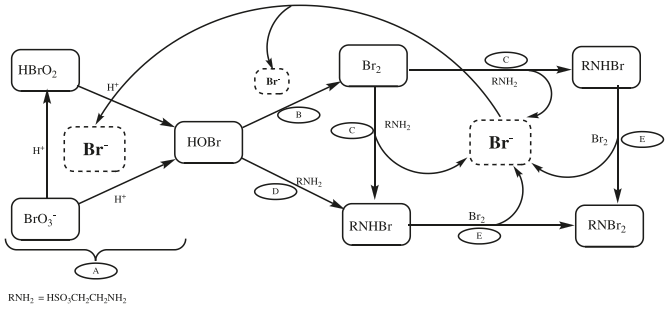
[R26] $HO_3SCH_2CH_2NH_2 + HOBr \rightarrow HO_3SCH_2CH_2NHBr + H_2O$

N-bromination in bromate oxidations is predominantly through aqueous bromine, since bromate oxidations only proceed in acidic environments (37).

The acid retardation observed for the reaction shown in Fig. 8 may suggest that reaction [R26] is slower than [R24]. Previous studies have confirmed that the monobromo-and dibromo- derivatives are affected by acid, with highly acidic conditions favoring monobromotaurine (37). This means that while [R24] can proceed quantitatively to the product monobromotaurine, [R25] is an equilibrium condition in which high acid concentrations in the products can swing the equilibrium towards monobromotaurine formation. The addition of taurine to dibromotaurine solutions saw the decrease in the peak at 244 nm (dibromotaurine) and the emergence of a peak at 288 nm (monobromotaurine):

[R27] $HO_3SCH_2CH_2NH_2 + HO_3SCH_2CH_2NBr_2 \rightleftharpoons 2HO_3SCH_2CH_2NHBr$

Scheme II.



Bromine formation

There is only one reaction in the reaction mixture responsible for bromine formation:

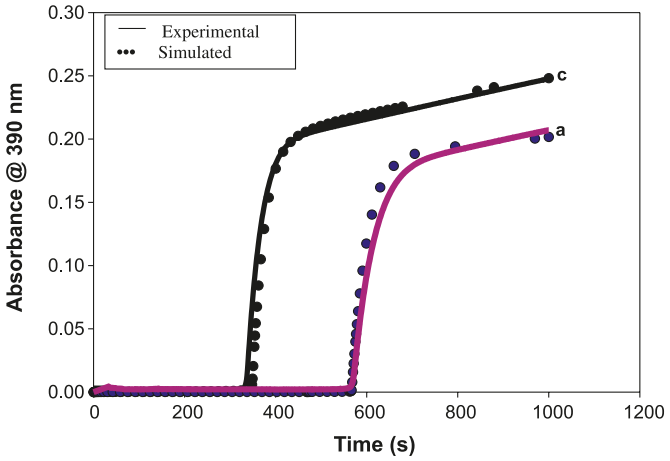
[R28] $HOBr + Br^- + H^+ \rightleftharpoons Br_2(aq) + H_2O$

Since both HOBr and Br_2 react rapidly with cysteamine (and its metabolite, hypotaurine), then formation of bromine is an indicator that cysteamine and its metabolites have all been oxidized to at least the taurine stage. The formation of bromine at the end of the induction period should depend in some manner on the rate of formation of bromide (assuming excess of acidic bromate). The full reaction network responsible for bromine formation is complex, and can be depicted by the network shown in Scheme II. To simplify this scheme, only the relevant reactions after cysteamine has been oxidized to taurine (presented as RNH_2 in the scheme) are included. It is a bromide-controlled network due to bromide's role as an autocatalyst in the reaction network. It provides a positive feedback loop that feeds into reaction A and accelerates the reaction.

This network scheme can explain the rate of bromine formation after the induction period as well as the biphasic nature of bromine production. Without excess bromate the feedback loop cannot exist, since reaction [R12] is a precursor to all autocatalysis. The reaction network relies on process B being fast (reaction [R28]). Our simulations also showed that HOBr does not accumulate to concentrations higher than 10^{-6} mol/L for the duration of the reaction. The fact that process C is faster than E delivers the biphasic bromine formation. Since bromine formation depends on bromide formation, the faster N-bromination of taurine ensures a fast rate of formation of bromide and subsequently a high rate of initial formation of bromine. Higher acid concentrations retard the formation of dibromotaurine. Figure 4*a* illustrates this effect: high acid concentrations catalyze the formation of HOBr, leading to higher bromine formation (processes A + B). This in turn leads to higher bromide formation (process C), which feeds back into process A. Acid catalysis of A is stronger than acid retardation of C. However, acid retardation of E is significant and when most of the monobromotaurine has been formed, the subsequent bromination to dibromotaurine is slower (in high acid), and the equilibrium of reaction [R25] is shifted to the left. With process E slower, bromide formation is slower, and subsequently bromine formation is slow, as observed in the slower bromine formation in the second phase. The zero-order kinetics observed in bromine formation is due to the fact that this section is no longer solely dependent on

© 2008 NRC Canada

Fig. 9. Simulated results (symbols) of traces *a* and *c* (solid lines) from Fig. 3*a* showing the effect of bromate variation on CA oxidation.



process A, but a much more complex network. Primarily, equilibrium [R25] acts as a valve in the release of bromide and maintains a constant release of bromide ions, as in drug-suspension reactions.

Overall reaction mechanism and simulations

The overall mechanism that can explain the observed global dynamics of the system on the basis of Scheme II is shown in Table 1. The first group of reactions M1–M4 and M5 are the well-known oxybromine reactions whose kinetics constants are well known (31, 33, 39–41). These were not varied during the simulations and were accepted as "fixed". The next set of reactions M6–M10 constitute the initiation reactions whose sole purpose is to produce bromide ions (autocatalytically). Protolytic reactions such as M6 and M7 are normally diffusion-controlled. The use of diffusion-controlled rate constants for these reactions rendered the simulations too stiff, necessitating hours of computer time instead of mere seconds with the use of the kinetics constants used in Table 1. The adopted kinetics constants did not deliver any different simulation results when compared to the use of the diffusion-controlled kinetics constants. The third set of reactions M11–M15 constitute the oxidation of cysteamine to taurine. The major oxidants are HOBr and Br_2. Even though this set of reactions is fast, they are all controlled (after the initiation reactions), by reaction [R12] (M1 in the table). Rapid reaction [R28] (M3 in table) is also controlled by [R12], since production of Br^- is a prerequisite reagent for formation of HOBr. The N-bromination reactions are listed in the last section, M16–M18. We have assumed in all these simulations that we are dealing with a protonated taurine molecule on the amino group, since the pH conditions necessary for the activity of bromate as an oxidant are low enough to protonate that group. Since we did not and could not quantify the degree of acid retardation by the reaction, we felt that this was a reasonable assumption. Reaction M18 was a necessary disproportionation reaction in high-acid conditions. Even in low-acid conditions, reaction M18 ensured that stoichiometry [R7] was attained first before stoichiometry [R5]. The simplicity of the simulations was derived from the bottle-neck offered by reaction M1, irrespective of the other reaction rates. The initiation reactions were important in establishing the time taken before bromine formation commenced, but a few seconds into the reaction reactions M6–M10 ceased to be effective. Since we could not harness the bromination reactions due to their speed, the lower-limit-estimated rate constants were effective, since ultimately, formation of bromine was controlled by M1. Figure 9 shows a reasonably good fit to the data on bromate-dependence data shown in Fig. 3*a*. A good fit was also obtained with acid-dependence traces shown in Fig. 4*a*. The model was able to satisfactorily predict both bromate- and acid-dependence effects with respect to induction period and rate of formation of bromine at the end of this induction period.

Conclusion

The reversible nature of N-bromination of the taurine formed after a full oxidation of cysteamine suggests that cysteamine and its oxidation metabolites are capable of moderating hypobromous acid and hypochlorous acid toxicities by forming these long-lived brominated derivatives. The ease of regeneration of taurine in reducing conditions means that this moderation can proceed indefinitely in a cyclic manner.

Reaction on a solid surface — A simple, economical, and efficient Mannich reaction of azacrown ethers over graphite

Hashem Sharghi and Reza Khalifeh

Abstract: Graphite brings about a rapid Mannich reaction with a range of activated and unactivated phenolic compounds such as *p*-cresol and *p*-nitrophenol. The reactions are carried out with azacrown ether and paraformaldehyde in solvent-free conditions at 100 °C for 20–30 min. The graphite powder can be reused up to three times after simple washing with acetone.

Key words: azacrown ether, lariat ether, graphite, solvent-free, Mannich reaction.

Résumé : Le graphite en poudre permet de réaliser des réactions de Mannich rapides de composés phénoliques activés et non activés, tel le *p*-crésol et le *p*-nitrocrésol, avec un éther azacouronne et le paraformaldéhyde, dans des conditions sans solvant, à 100 °C, pendant 20 à 30 minutes. On peut réutiliser le graphite en poudre jusqu'à trois fois après un simple lavage avec de l'acétone.

Mots-clés : éther azacouronne, éther lariat, graphite, sans solvant, réaction de Mannich.

[Traduit par la Rédaction]

Introduction

Azacrown ethers are often used as precursors for structurally modified macrocyclic ion-complexing agents because of the attachment of pendant groups to the secondary nitrogen atom (1). The major methods for functionalizing azacrown macrocycles with proton-ionizable phenol groups include the treatment of an azacrown ether with a benzyl or benzoyl halide and reductive amination with aromatic aldehydes. These methods are not always convenient because of the difficulties in preparing the starting materials, the need to reduce the carbonyl group if carboxylic acid derivatives are used, and the need to protect the phenolic hydroxy group (2). The Mannich reaction, as a method for modification of azacrown macrocycles with hydroxybenzyl functions, has some advantages when compared to alkylation of the azacrowns by benzyl halides. In fact, aminomethylation of the phenols allows the preparation of azamacrocycles containing both electron-donating and electron-withdrawing groups in the substituent phenolic rings (3). In spite of appreciable interest in the azacrown macrocycles, they are still not readily available for study because they are either very expensive or difficult to prepare. Obviously, the elaboration of general and simple approaches for the synthesis and functionalization of azacrown macrocycles remains a very important problem for researchers working in this field. One of the most important objectives now is to adapt classical processes so that pollution effects are kept to a minimum, with a reduction both in energy and in consumption of raw materials. In this respect, dry-media reactions are promising, and a new approach has been undertaken using graphite chemistry. The exceptional ability of graphite to adsorb organic molecules is well known (4). Diels–Alder and ene reactions (5), decarboxylations (5*a*, 5*b*), decompositions (6), rearrangements (5*a*, 5*b*, 7), keto carboxylation (8), conversion of aldehydes into nitriles (9), Friedel–Crafts acylation of aromatic compounds (10), alkylation of aromatic compounds and alcohols (11*a*), and dehydration of secondary alcohols (11*b*) were all effected using such conditions.

As a part of our continued efforts to utilize surface-mediated reactions for conducting Mannich reaction, here we wish to disclose a very simple, fast, general, highly efficient, and improved one-step method for synthesizing lariat ether containing phenolic groups. The reaction occurs without any solvent in the presence of graphite and gives relatively high yields.

Results and discussion

The Mannich reaction is one of the most important tools for synthesizing new compounds (12). The most important applications of this reaction are in the pharmaceutical chemistry and natural product chemistry (12, 13). Also the Mannich reaction is known to be a powerful method for functionalizing azacrown ethers with additional ligating units (3, 14). The Mannich reaction consist of the condensation of a substrate (R–H) possessing at least one active hydrogen (alkyl ketones, phenols, NH heterocycles, etc) with formaldehyde (or occasionally other aldehydes) and a primary or secondary amine (or occasionally ammonia). Although numerous methods to achieve Mannich reaction are

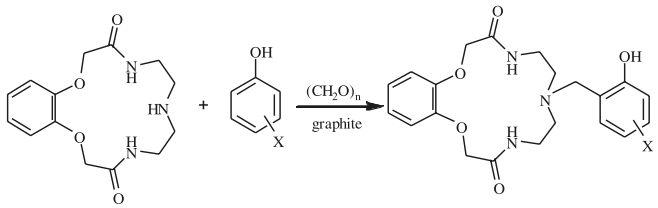
known, newer methods continue to attract attention for their experimental simplicity and effectiveness. We have been interested in the development of methods for Mannich reactions that (a) would avoid the use of added acids, (b) would avoid aqueous workup, (c) are easy to perform, and (d) are economical for application to large-scale preparations.

We have previously shown that azacrown ether **8** can be prepared by a simple and convenient procedure (15). Because graphite has a large surface area, it is a good heat conductor, and the reaction can be carried out under milder conditions (7). During the course of our studies aimed at developing solvent-free procedures (9, 10, 16, 19, 20), we have now discovered that graphite alone promotes a very efficient Mannich reaction of activated and unactivated phenol compounds with azacrown ether **8** and paraformaldehyde at 100 °C in high yields, without any of the environmental disadvantages of using toxic solvents (Scheme 1). In a typical experiment, graphite, azacrown ether **8**, *p*-cresol, and paraformaldehyde were mixed thoroughly. The mixture was heated in an oil bath at 100 °C with stirring for 20 min until

Scheme 1.



8 **9–19**

the reaction was completed. The product was isolated by simple extraction of the solid mass by acetone followed by the usual workup.

To investigate the generality and versatility of this method, the reaction was extended to various structurally diverse phenols. When the phenols had either electron-donating or electron-withdrawing substituents, the formation of benzylamine bonds occurred very rapidly, within 20–30 min. The results of the Mannich reaction of azacrown ether **8** are collected in Table 1. When *para*-substituted or

unsubstituted phenols were used for the Mannich reaction with azacrown ether **8** in the presence of paraformaldehyde, macrocyclic ligands **9**–**19** were obtained in relatively high yields (Table 1, entries 7–17), although the yields drop as strongly electron-withdrawing substituents are added, as in **19** (Table 1, entry 17). The moderate yield of **19** is attributed to the relatively weak nucleophilicity of *p*-nitrophenol and its anion (14b). Aminomethylation of phenols by means of the Mannich reaction usually occurs in the position ortho to the phenolic OH group even if the para position is unsubstituted (14a). Possibly the preferential attack on the ortho position is caused by formation of a six-membered transition state where the phenolic proton activates the aminomethylating reagent (17). The free para positions on the benzo units of the final macrocycles are attractive sites for functionalization because of their high reactivity toward electrophilic aromatic substitution.

Additionally a variety of secondary amines were examined using *p*-cresol as the model substrate (Table 1). Interestingly the yield of the reaction was higher when graphite was used as the reaction medium than when the reaction was performed in benzene. For example, with graphite, the reac-

tion of piperazine with *p*-cresol occurred in 85% yield after 20 min at 100 °C. Under reflux conditions in benzene, the same reaction was slower, and afforded the corresponding product only after 24 h in 41% yield (Table 1, entry 4) (14*d*).

Further, the activity of the recovered graphite was examined. As shown in Table 2, the yields of macrocyclic **9** in the second and third uses of the graphite was almost same as that in the first use. In every case >90% of the graphite was easily recovered from the reaction mixture by simple washing with acetone.

A comparison of the present protocol, using graphite, with selected previously known protocols and other inorganic solids that were examined is collected in Table 3 to demonstrate that the present protocol is indeed superior to several of the other protocols. According to Table 3, the Mannich reaction of azacrown ether **8** is completed in 20 min at 100 °C in 87% isolated yield using the present protocol. Most of the other protocols listed either take a longer time for completion, or use toxic solvents with generally reduced isolated yields (entries 1–6) (14). In another study the effect of microwave and inorganic solids as catalysts were investigated and it was found that compound **9** was not produced under these conditions (entry 7, 8, 9) (18, 19, 20). In the absence of graphite (entry 10), the reaction was conducted at 100 °C for 2 h, affording compound **9** only, in 30% yield. The effect of different amounts of graphite on the model compound was studied in another experiment. The result showed that the best yield was obtained when 1 gr of graphite was used. Increasing the amount of graphite had a negligible effect on the efficiency of the reaction. Decreasing the amount of graphite led to a pasty reaction mixture which made the stirring difficult, thus reducing the efficiency of the model reaction.

The Mannich reaction of azacrown ether **8** with *p*-cresol on a 30 mmol scale proceeded just as well as the 1 mmol reaction. The mechanism of the reaction is a subject of a further study. For now, we believe that graphite acts as a dehydration reagent or as a heat-conducting surface for the Mannich reaction.

[a]Isolated yields.

At the edge of the basal planes of carbon atoms in the graphite structure, where bonding in the plane is terminated, are unsaturated carbon atoms. These sites are associated with high concentrations of unpaired electrons and therefore play a significant role in chemisorption. These carbons may chemisorb oxygen, producing oxygen surface groups. Oxygen surface groups are by far the most important in influencing the surface characteristics and adsorption behavior of graphite (21) (Scheme 2).

The surface groups most often suggested are carboxyl, phenolic hydroxyl, and quinone carbonyl groups. Slightly fewer in number are the reports of ethers, peroxides, ester groups, lactones, carboxylic acid anhydrides, and cyclic peroxides (22). These structures exhibit a high affinity for water (23). As Szymanski et al. reported earlier, the dehydration of secondary alcohols on the carbon catalysts proceeds according to the oxonium mechanism (11*b*).

As described in Scheme 3, we have suggested a mechanism for the solvent-free Mannich reaction of secondary amines that is based on the previously proposed mechanism for dehydration of secondary alcohols.

At the initial stage, the formaldehyde is protonated; then, a secondary amine attacks the activated formaldehyde; finally, a water molecule is lost from the oxonium intermediate (**II**) and the Mannich base (**III**) is formed. The reaction of Mannich base (**III**) with phenol gives the product.

Conclusion

We have described a novel and highly efficient solvent-free protocol for the Mannich reaction of phenol compounds using nontoxic and inexpensive graphite powder. The advantages of this environmentally benign and safe protocol include a simple reaction setup not requiring specialized equipment, mild reaction conditions, high product yields, short reaction times, reusability of graphite, and the elimination of solvents.

Experimental

Instrumentation, analysis, and starting material

NMR spectra were recorded on Bruker Avance DPX-250 (^{1}H NMR 250 MHz and ^{13}C NMR 62.9 MHz) and DRX-500 (^{19}F NMR 470 MHz) spectrometers in pure deuterated solvents with tetramethylsilane (TMS) and trichlorofluoromethane ($CFCl_3$) as internal standards. Infrared spectra were obtained using a Shimadzu FT-IR 8300 spectrophotometer. Mass spectra were determined on a Shimadzu GCMS-QP 1000 EX instrument at 70 or 20 ev. Melting points were determined in open capillary tubes in a Buchi-535 circulating oil melting point apparatus. UV–vis spectra were obtained with an Ultrospec 3000 UV/Visible spectrometer. Elemental analyses were performed at the National Oil Co. of Iran, Tehran Research Center. The purity determination of the substrates and reaction monitoring were accomplished by TLC on silica gel PolyGram SILG/UV 254 plates. Column chromatography was carried out on short columns of silica gel 60 (70–230 mesh) in glass columns (2–3 cm diameter) using 15–30 gram of silica gel per one gram of crude mixture. Chemical materials were either prepared in our laboratories or were purchased from Fluka, Sigma-Aldrich, and Merck Companies.

General procedure

After a mortar was charged with azacrown ether **8** (1 mmol), phenol (1.2 mmol), paraformaldehyde (1.2 mmol), and graphite slurry (1 g) (CAS No.7782–42–5; fine powder extra pure, particle size (<50 μm), pH value 5–6 (50 g/l, H_2O, 20 °C) from Merck), the mixture was ground with a pestle at room temperature. The resulting fine powder was transferred to a round-bottomed flask and stirred on a magnetic stirrer in an oil bath at 100 °C for 20–30 min. After cooling, acetone (3 × 25 mL) was added to the mixture and the graphite was removed by filtration. Evaporation of the solvent under reduced pressure gave the crude product, which was purified by flash column chromathography

(eluent: n-hexane – ethyl acetate 1:1) or recrystallized from ethyl acetate.

4-Methyl-2-(1-piperidinylmethyl)phenol (1)

Purification by plate chromatography, eluted with n-hexane – ethyl acetate (10:2), gave compound **1** in 90% yield; mp 45 °C (Lit. Value: 45 °C (24)). IR (KBr, cm^{-1}) υ_{max} : 3240, 2935, 2804, 1601, 1497, 1338, 1308, 1038, 814, 791, 771. ^1H NMR ($CDCl_3$) δ_H: 10.90 (1H, s), 6.82 (1H, d, J = 8.2 Hz), 6.58 (1H, s), 6.52 (1H, d, J = 8.2 Hz), 3.40 (2H, s), 2.17–2.36 (4H, m), 2.11 (3H, s), 1.17–1.54 (6H, m). ^{13}C NMR ($CDCl_3$) δ_C: 155.7, 129.1, 128.9, 128.2, 121.3, 115.7, 62.2, 54.2, 25.7, 24.3, 20.9. Anal. calcd.. for $C_{13}H_{19}NO$: C 76.06, H 9.33; found: C 76.27, H 9.12.

4-Methyl-2-(4-morpholinylmethyl)phenol (2)

Purification by plate chromatography, eluted with n-hexane – ethyl acetate (10:2), gave compound **2** in 96% yield; mp 49–50 °C (Lit. Value: 48–51 °C (25)). IR (neat, cm^{-1}) υ_{max}: 3160, 2819, 1597, 1304, 1119, 1029, 818. ^1H NMR ($CDCl_3$) δ_H: 9.28 (1H, s), 6.77 (1H, d, J = 7.8 Hz), 6.58 (1H, s), 6.47 (1H, d, J = 7.8 Hz), 3.48 (4H, t, J = 4.2 Hz), 3.40 (2H, s), 2.29 (4H, s), 2.06 (3H, s). ^{13}C NMR ($CDCl_3$) δ_C: 154.5, 128.9, 128.1, 120.4, 116.3, 115.8, 66.6, 61.3, 52.8, 20.7. Anal. calcd. for $C_{12}H_{17}NO_2$: C 69.54, H 8.27; found: C 69.36, H, 8.49.

2-{[Bis(2-hydroxyethyl)amino]methyl}-4-methylphenol (3)

Purification by plate chromatography, eluted with n-hexane – ethyl acetate (10:2), gave compound **3** in 82% yield. (Lit. values, see ref. 26). IR υ_{max} (neat, cm^{-1}): 3356, 2870, 1612, 1481, 1304, 1038, 910, 817, 733. ^1H NMR ($CDCl_3$) δ_H: 6.59–7.05 (5H, m), 3.72 (2H, s), 3.61 (4H, t, J = 5.4 Hz), 2.67 (4H, t, J = 5.4 Hz), 2.14 (3H, s). ^{13}C NMR ($CDCl_3$) δ_C: 154.4, 130.5, 129.1, 122.2, 116.7, 115.5, 58.9, 58.0, 52.8, 20.9. MS *m/z* (%): 227 ([M^+ + 2], 0.1), 226 ([M^+ + 1], 0.5), 225 ([M^+], 1.7), 208 (0.3), 194 (11.6), 162 (1.1), 149 (1.1), 135 (1.4), 121 (34.2), 91 (13.1), 84 (57.4), 74 (100). Anal. calcd. for $C_{12}H_{19}NO_3$: C 63.98, H 8.50; found: C 63.79, H 8.44.

2-{[4-(2-Hydroxy-5-methylbenzyl)-1-piperazinyl]methyl}-4-methylphenol (4)

Rrecrystallization from MeOH gave compound **4** as a colorless powder in 85% yield; mp 225–226 °C (Lit. Value: 225–226 °C (14*d*)). ^1H NMR ($CDCl_3$) δ_H: 10.22 (2H, s), 6.89 (2H, d, J = 8.2 Hz), 6.69 (2H, s), 6.64 (2H, d, J = 8.2 Hz), 3.58 (4H, s), 3.23–2.31 (8H, m), 2.15 (6H, s). ^{13}C NMR ($CDCl_3$) δ_C: 155.1, 129.3, 128.3, 120.5, 115.8, 61.2, 52.4, 20.5. Anal. calcd. for $C_{20}H_{26}N_2O_2$: C 73.59, H 8.03; found: C 73.82, H 7.79.

2-{[16-(2-Hydroxy-5-methylbenzyl)-1,4,10,13-tetraoxa-7,16-diazacyclooctadecan-7-yl]methyl}-4-methylphenol (5)

Purification by flash column chromatography, eluted with n-hexane – ethyl acetate (1:1), gave compound **5** as a colorless powder in 88% yield; mp 113–114 °C (Lit. Value: 114–115 °C (14*b*)). ^1H NMR ($CDCl_3$) δ_H: 6.95 (2H, d, J = 8.2 Hz), 6.72 (2H, d, J = 8.2 Hz), 6.78 (2H, s), 3.77 (4H, s), 3.66 (8H, t, J = 5.4 Hz), 3.61 (8H, s), 2.86 (8H, t, J = 5.4 Hz), 2.23 (6H, s). ^{13}C NMR ($CDCl_3$) δ_C: 155.5, 129.3, 129.1, 122.1, 116.0, 70.7, 69.1, 58.6, 53.6, 20.5. Anal. calcd. for $C_{28}H_{42}N_2O_6$: C 66.91, H 8.42; found: C 66.89, H 8.61.
