Accelerated syntheses of amine-bis(phenol) ligands in polyethylene glycol or "on water" under microwave irradiation

Francesca M. Kerton, Stacey Holloway, Angela Power, R. Graeme Soper, Kristina Sheridan, Jason M. Lynam, Adrian C. Whitwood, and Charlotte E. Willans

Abstract: Pure amine-bis(phenol) ligands are readily accessible in high yield, often >90%, when the Mannich condensation reactions are performed "on water" or in poly(ethyleneglycol) (PEG). Microwave-assisted synthesis dramatically reduces the time and energy required to prepare these molecules, typically from 24 h to 5 min. The approach seems to be widely applicable (7 amines and 5 phenols were tested to yield a diverse set of bis(phenol) ligands). Significant improvements in yield were observed for ligands derived from di-*tert*-amyl and di-*tert*-butyl phenols, possibly resulting from a hydrophobic effect. Single crystal X-ray diffraction data for the ligand derived from *p*-cresol and *N*,*N*′-dimethylethylenediamine is reported.

Key words: amine-phenol, Mannich condensation, on water, microwave, ligand, high-throughput.

Résumé : Les ligands amine-bis(phénol) purs sont facilement accessibles avec des rendements élevés, souvent supérieurs à 90%, lorsqu'on effectue des réactions de condensation de Mannich en présence d'eau ou de poly(éthylèneglycol) (PEG). Les synthèses effectuées à l'aide de microondes réduisent sensiblement le temps et l'énergie requis pour préparer ces molécules, passant généralement de 24 heures à 5 min. Il semble que cette approche peut être applicable d'une façon générale; on a en effet testé sept amines et cinq phénols qui ont conduit à divers types de ligands bis(phénol). On a observé des améliorations sensibles dans les rendements obtenus avec les ligands dérivés des di-*tert*-amyl- et di-*tert*-butylphénols qui résultent peut-être d'un effet hydrophobe. On a obtenu des données de diffractions des rayons X par un cristal unique pour des ligands dérivés du *p*-crésol et de la *N*,*N*′-diméthyléthylènediamine.

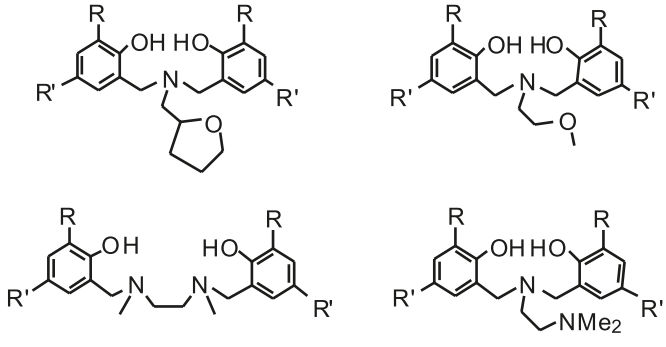
Mots-clés : amine-phénol, condensation de Mannich, en présence d'eau, microonde, ligand, grand débit.

[Traduit par la Rédaction]

Introduction

Over the last 20 years, researchers have been exploring a wide range of ligand systems for use in combination with metals as new homogeneous catalysts. N-heterocyclic carbenes have emerged as versatile alternatives to phosphine ligands in late-transition metal-catalysed reactions (1–3). Anionic ligands containing "hard" nitrogen and oxygen donor atoms form a diverse set of ligands that are used as alternatives to cyclopentadienyl ligands, particularly in early transition metal and lanthanide based catalysts (4–9). Of these ligands, amine-bis(phenol) molecules have emerged as versatile, modular, and easily accessible materials (Fig. 1).

Fig. 1. Chelating amine-bis(phenol) ligands.



R, R' = H, Me, *t*-Bu, *t*-Am

Primarily, these ligands in combination with metals from throughout the periodic table are active catalysts for alkene polymerization (10–17) and initiators in the ring-opening polymerization of lactones (18–30).

Liquid polymers are emerging as a useful class of nonvolatile solvents and possess valuable, facile separation characteristics. The two most widely used polymers in this area are PEG (polyethylene glycol) and PPG (polypropylene glycol) (31, 32). They have a very low toxicity ranking and have been approved by the US FDA for internal consumption

(31). The high stability and low toxicity of PEG and PPG allow these molecules to be used in a large number of products and industries. PEGs and PPGs are very similar in structure to glymes, which are used as solvents because of their high chemical and thermal stability, broad pH range, and ability to dissolve polar compounds, such as water and acids, as well as nonpolar compounds, such as hydrocarbons. The polarity of PEG can be compared with the commonly used laboratory solvents CH_2Cl_2 and MeCN, whereas PPG is slightly less polar (32). In terms of laboratory safety, whereas glymes readily form explosive peroxides, PEGs and PPGS do not. The biodegradability of liquid polymers has recently been summarized (32); for example, PEG 400–1500 is >95% biodegraded in 14 days. This makes PEGs and PPGs much safer to use and dispose of than their corresponding class of volatile solvents — the glymes and many other common laboratory solvents.

Recently, cleaner, more benign routes to bis-imine Schiff base ligands have been reported (33). These reactions yielded high-purity ligand under neat reaction conditions or by using polypropylene glycol (PPG) solvent. Inspired by this research, we sought to reduce the amount of solvent used in the preparation of our chosen ligand set and also the time involved. We report herein the rapid, high-yielding synthesis of amine-bis(phenol) ligands on water under microwave irradiation and our journey en route to these results via reactions in PEG solvents.

Results and discussion

In following the work of van den Ancker and co-workers (33), the first modified procedure we attempted (Scheme 1) was the synthesis of amine-bis(phenol)s in PEG and PPG. The phenol reagents dissolved in the warm polymers to form solutions, however the *tert*-amyl and *tert*-butyl substituted phenols were insoluble at room temperature. Vials were loaded with phenol, polymer, solvent, aqueous formaldehyde, and finally the amine was added to the stirred mixture. The reaction of primary amines with formaldehyde and paraformaldehye is exothermic, and therefore care should be taken when adding the amine. The reaction mixtures immediately warmed to around 40 °C and were then heated to 75 °C overnight. Three polymer solvents were studied in this first series of reactions: PEG 400, PPG 400, and PPG 1000. Two concentrations were tested: 1 mmol amine per gram polymer solvent and 2 mmol amine per gram solvent. The amine used was *N*,*N*-dimethylethylenediamine, the phenols were di-*tert*-butyl phenol and di-*tert*-amyl phenol.

Control reactions using ethanol as the solvent were also performed and gave similar yields of products for the same reaction temperatures and times. In this series of reactions (Table 1), yields were similar for all reactions irrespective of the substituted phenol used, but yields were lower at the more dilute concentrations. PEG 400 gave slightly increased yields compared with the other solvents and was therefore used in subsequent experiments. Crystals of the ligand were sometimes obtained upon cooling the reaction mixtures containing PEG and PPG. However, larger crystals of the amine-bis(phenol)s were more readily obtained from saturated ethanol or methanol solutions. As in the work of van den Ancker (33), the polymer solvent could be re-used in subsequent experiments.

14	*t*-Am, *t*-Am	Ethanol	79

[a]All reactions were heated to 75 °C, 18 h. Reactions in polymers labelled dilute were performed using 1 mmol amine per gram of polymer; otherwise 2 mmol amine per gram of polymer was used. Reactions in ethanol were performed by starting with a saturated solution of the phenol.
[b]Isolated yields, average of two identical reactions, compounds pure by ^{1}H NMR spectroscopy.

Over the past decade, tremendous advances in organic synthesis (e.g., rate accelerations, enhanced selectivities) have been achieved through the use of microwave irradiation (34–36). A wide variety of microwave-assisted condensation reactions have been studied, and therefore we attempted amine-bis(phenol) syntheses in a household microwave oven. Although there are concerns about the safety and reproducibility of results obtained using these ovens, as long as precautions are taken with safety and interpretation of the data, these ovens act as a good entry point into microwave chemistry (37–39). PEG 400 was used as the solvent in these initial studies. Vials containing the reaction mixtures were prepared as in the conventionally heated experiments. Each vial was heated individually in the microwave at the desired

19	*t*-Bu, Me		Biotage, 160 °C, 5 mL H_2O	85
20	*t*-Bu, *t*-Bu		Biotage, 160 °C, 5 mL H_2O	92

[a]Panasonic household microwave oven operated at constant power of 1200 W for 10 × 60 s, reaction scale of 2 g PEG 400, and 0.7 mL aq. CH_2O. Biotage stands for a Biotage Initiator operated at constant temperature mode for 5 min at the indicated temperature, reaction scale of 3 mL aq. CH_2O.

[b]Isolated yields, average of two identical reactions, compounds pure by ^{1}H NMR spectroscopy.

power and for varying lengths of time. Each reaction was then triturated using ethanol, cooled to 0 °C, and the crystalline precipitate collected by filtration. Initial experiments were performed using 60 s microwave pulses at low power settings, 50% power (600 W) or 10% power (120 W). However, as expected, the yields increased with increased reaction time and microwave power setting. Therefore, after preliminary experiments, all amine-bis(phenol) syntheses performed in the household microwave were conducted using ten 60 s full power (1200 W) pulses (Table 2). Reaction temperatures were monitored between pulses and were between 80 and 100 °C. Some reactions were also performed using catalytic amounts of aqueous acid, but this did not increase the yield or rate of reactions.

To confirm the results obtained using a household microwave, selected reactions were repeated using a research grade instrument (Biotage Initiator System, 20 mL reaction volume sealed vessels) (Table 2). In addition to reactions in

PEG 400, reactions were performed using ethanol and water. Yields using ethanol (Table 2, entries 15–18) were comparable with those using PEG 400, but interestingly, excellent yields were obtained using water (Table 2, entries 19 and 20). These reactions can be reproduced using conventional heating, however significantly longer reaction times are needed.

A wide range of reactions using water as the reaction medium have been studied because of their *green* potential (40–42). These include Mannich-type reactions using surfactants to facilitate the acid-catalyzed process (43). Therefore, we decided to prepare a wide range of amine-bis(phenol) ligands in water. Recently, it has been discovered that in some cases when reactants and products are insoluble in water, the reactions occur in a suspension or "on water" (44, 45). Although, we did not see the rate enhancements observed by Sharpless and co-workers (44), as can be seen in Table 3 the yields of these Mannich condensation reactions improve with an increase in hydrophobicity of the phenol. For example, yields using di-*tert*-butyl and di-*tert*-amyl phenol are always significantly higher that those using *para*-cresol or dimethyl phenol as the reagent (Table 3). We tentatively propose that the preferred reaction mechanism for the ligand syntheses is via formation of the iminium ion intermediates from the water-soluble amines and formaldehyde in homogeneous aqueous solution. This is followed by step-wise reactions of these species with two equivalents of phenol via a heterogenous process on the surface of the suspended droplets of liquid phenol. This prevents any alternative reaction pathways occuring, such as reaction of the amine directly with the phenol in homogeneous solution, thus increasing the yields when hydrophobic phenols are used. As phenols can be regarded as enols, when the phenol is water-soluble, some of the amine reagent can react directly with the keto tautomer of the phenol. This reduces the amount of amine available for the desired reaction with formaldehyde and this decreases the yield of amine-bis(phenol) when less sterically demanding reagents such as *p*-cresol are used.

We have also performed this class of reaction on a large scale (50 mL aqueous formaldehyde) using a Morton flask equipped with a condenser, a mechanical stirrer, and a heating mantle. Reactions were performed using 2,4-di-*tert*-butyl phenol or 2,4-di-*tert*-amyl phenol, and *N*,*N*-dimethylethylenediamine, and yields were over 90%. However, care should be taken given the large amount of precipitate that forms, which can affect the stirring mechanism.

During the course of this research, crystals of one ligand suitable for single crystal X-ray diffraction studies were isolated[2]. The molecular structure of **1**, Fig. 2, is significantly different from the previously reported more sterically congested analogue derived from di-*tert*-amyl phenol, although important bond lengths and hydrogen-bond distances are similar (29). The structure of **1** (Table 4) exhibits a twist along the backbone of the ligand, resulting in the phenol OH groups residing on opposite sides of the molecule in the solid state. In contrast, the di-*tert*-amyl derived ligand contains both OH groups on the same side of the molecule (29). The differences in the solid-state molecular structures of these two molecules are presumably due to packing constraints in the solid state, as no significant differences in their solution state structures are observed by ^{1}H NMR spectroscopy.

Conclusions

In summary, we have reported the synthesis of related amine-bis(phenol) ligands in ethanol, PEG, PPG, or water as the solvent. Yields for these compounds are improved compared with conventional routes and reaction times are dramatically reduced when microwave heating and water are used. Therefore, microwave-assisted synthesis could aid in the synthesis of libraries of these ligands for use in high-throughput catalytic studies, and this approach could potentially be extended to other related ligand syntheses (46–50). Also, even in the absence of a microwave synthesizer, the preferred method of synthesis for the di-*tert*-butyl and di-*tert*-amyl derived ligands, and perhaps other sterically demanding analogues, should be to use water as the reaction medium. During the initial submission period for this article, a communication regarding the syntheses of related amine-phenol ligands using water as the reaction medium has been accepted for publication (51). Therein, data on the relative solubilities of alkyl-substituted phenols is reported. However, further studies are ongoing into the reasons for the increased yields of these ligands when hydrophobic phenol reagents are used during their preparation in aqueous media.

Experimental

General procedures and instrumentation

Amines, phenols, and aqueous formaldehye were purchased from Sigma-Aldrich and Alfa Aesar. Ethanol was purchased from Fisher Scientific. PEG 400, PPG 400, and PPG 1000 were purchased from Alfa Aesar. Microwave heating was achieved using either an unmodified household MW oven (Panasonic NN-S740WA-1200W) or a research grade microwave reactor (Biotage Initiator 2.0). NMR spectra were recorded on a Jeol EX 270, a Tecmag APOLLO 300, or a Bruker Avance 500 instrument (Table 5). ^{1}H NMR spectra were referenced to residual protons in the deuterated solvent and ^{13}C NMR spectra to the ^{13}C atoms therein. EI Mass spectra were recorded on a Fisons Instruments VG Analytical Autospec mass spectrometer, and MALDI-TOF spectra (anthracene matrix) were obtained on an Applied Biosystems DE-RP instrument. Selected data are presented in Table 5. Elemental analyses were performed on several samples to provide additional confirmation of their synthesis at Elemental Microanalysis Ltd., Devon, UK and at Canadian Microanalytical Service Ltd., Delta, B.C., Canada. For example, for $Me_2NCH_2CH_2N[CH_2\text{-}3,5\text{-}Bu_2\text{-}C_6H_2OH_{-2}]_2$ found: C 77.32, H 10.94, N 5.41. $C_{34}H_{56}N_2O_2$ requires: 77.81, H 10.76, N 5.34. However, not all samples were analysed in this way as full characterisation data was obtained on these ligands during their original preparation by Kol and co-workers (10–14). Diffraction data were col-

lected at 100 K on a Bruker Smart Apex diffractometer with Mo Kα radiation (λ = 0.710 73 Å) using a SMART CCD camera. Diffractometer control, data collection, and initial unit cell determination was performed using SMART (52). Frame integration and unit cell refinement software was carried out with SAINT+ (53). Absorption corrections were applied by SADABS (54). Structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares based on $|F|^2$ using SHELXL-97 (55, 56).

General procedure for amine-(bis)phenol ligand synthesis in PEG under conventional heating

A capped 10–20 mL vial was loaded with PEG 400 (2.0 g), 37% aq. formaldehyde (0.70 mL), and phenol (8.0 mmol). The mixture was stirred and *N*,*N*-dimethylethylenediamine (0.35 g, 4.0 mmol) was added dropwise. Vials were stirred in a heated block (Chemglass OptiChem) at 75 °C for 18 h. The vial was cooled in an ice bath and filtered. If required, the solid was washed with a minimum amount of ethanol and dried under vacuum to yield the amine-bis(phenol) as a colourless, crystalline solid.

General procedure for amine-(bis)phenol ligand synthesis in PEG under microwave heating

Household microwave oven

A loosely capped 10–20 mL vial was loaded with PEG 400 (2.0 g), 37% aq. formaldehyde (0.70 mL), and phenol (8.0 mmol). Substituted amine (4.0 mmol) was added dropwise. Vials were heated on full power (1200 W) for ten 60 s pulses. The temperature of the reaction mixture in the vial was measured between pulses and temperatures were maintained below 100 °C. Caution: occasionally the reaction mixtures would become very hot and spill out of the container; reactions in a household microwave oven should not be left unattended and safety precautions should be taken. After heating, the vial was cooled in an ice bath and filtered. If required, the solid was washed with a minimum amount of ethanol and dried under vacuum.

Biotage initiator

A 10–20 mL Biotage reaction tube was loaded with PEG 400 (8.0 g), 37% aq. formaldehyde (3.0 mL), substituted phenol (37 mmol), and amine (18 mmol). The tube was sealed with a lid containing a septum and placed in the reaction cavity. The mixture was stirred and heated to the desired temperature for 5 min. During this time, the pressure in the tube was monitored by a pressure sensor on the lid of the tube. The reaction tube was rapidly cooled under a nitrogen flow, and once the pressure in the tube had reduced to near atmospheric the septum was removed. The contents of the tube were filtered, washed with a minimum amount of ethanol, and dried under vacuum.

General procedure for amine-(bis)phenol ligand synthesis in ethanol under conventional heating

Phenol (0.123 mol) was weighed into a 100 mL beaker and ethanol (around 30 mL) added to give a saturated solution. The phenol solution was transferred to a 200 mL round-bottomed flask and 37% aq. formaldehyde (10 mL)

© 2008 NRC Canada

was added. The flask was equipped with a condenser and the amine (0.06 mol) was added. The reaction mixture was stirred and heated at 70 °C for 18 h. The reaction mixture was cooled in an ice bath, filtered, and the residue washed with cold ethanol (2 × 20 mL). The solid was dried under vacuum.

General procedure for amine-(bis)phenol ligand synthesis in ethanol or water under microwave heating

A 10–20 mL Biotage reaction tube was loaded with water or ethanol (5.0 mL), 37% aq. formaldehyde (3.0 mL), substituted phenol (37 mmol), and amine (18 mmol). The tube was sealed with a lid containing a septum and placed in the microwave reaction cavity. The mixture was stirred and heated to the desired temperature for 5 min. During this time, the pressure in the tube was monitored by a pressure sensor on the lid of the tube. The reaction tube was rapidly cooled under a nitrogen flow, and once the pressure in the tube had reduced to near atmospheric the septum was removed. The contents of the tube were filtered, washed with a minimum amount of ethanol, and dried under vacuum.

General procedure for amine-(bis)phenol ligand synthesis in water under conventional heating

Phenol (0.123 mol) was weighed directly into a 200 mL round-bottomed flask, water (80 mL) and 37% aq. formaldehyde (10 mL) were added. The flask was equipped with a condenser and the amine (0.06 mol) was added. The reaction mixture was stirred and heated at 100 °C for 18 h. Upon cooling to room temperature, the product formed a separate phase as either a solid or an oil that could be easily isolated. The product was dried under vacuum, or if significant quantities of water were still present, it was dissolved in an organic solvent and dried over anhydrous magnesium sulfate.

Acknowledgements

We thank Memorial University of Newfoundland, Natural Sciences and Engineering Research Council of Canada (NSERC) (Discovery Grant and Research Tools and Instrument Grant, FMK), WISE-NL Student Summer Employment program (SH), and the EPSRC (Studentship, CEW) for generous funding. We are also grateful to Biotage for access to an Initiator microwave system on a free trial basis.

UV photoelectron spectroscopic and computational study of 7-substituted cycloheptatrienes

T. Bajorek and N. H. Werstiuk

Abstract: The He(I) photoelectron (PE) spectra of cycloheptatriene (**1**), 7-methylcycloheptatriene (**2**), 7-methoxycycloheptatriene (**3**), 7-methylthiocycloheptatriene (**4**), and 7-diemthylaminocycloheptatriene (5) were recorded and interpreted using MO energies and ionization potentials acquired from B3PW91 calculations. Partial simulated PE spectra were in good agreement with the experimental results. The *axial* and *equatorial* conformers have distinct PE spectra as illustrated by simulation. The PE spectra of **2**, **3**, and **5** are representative of the *equatorial* conformers, while the PE spectrum of **4** was in accord with a 1:1 mixture of *equatorial* and *axial* conformational isomers based on spectral simulation. The calculated free energy differences between the *equatorial* and *axial* conformers are in the order of 2 kcal mol^{-1} (1 cal = 4.184 J) for compounds **2**, **3**, and **5**, where the *equatorial* conformational isomer is lowest in energy. In the case of **4**, the *equatorial* conformer was only marginally lower in energy than its *axial* counterpart, where the free energy difference is 0.1 kcal mol^{-1}.

Key words: 7-substituted cycloheptatrienes, He(I) photoelectron spectroscopy, B3PW91, spectral simulation.

Résumé : On a enregistré les spectres photoélectroniques (PE) He(I) du cycloheptatriène (**1**), du 7-méthylcycloheptatriène (**2**), du 7-méthoxycycloheptatriène (3) et du 7-méthylthiocycloheptatriène (4) et on les interprète en faisant appel aux énergies des orbitales moléculaires (OM) et des potentiels d'ionisation obtenus par des calculs B3PW91. Les spectres PE simulés partiels sont en bon accord avec les résultats expérimentaux. Tels qu'illustrés par la simulation, les conformères axiaux et équatoriaux présentent des spectres PE distincts. Les spectres PE des produits **2**, **3** et **5** sont représentatifs de conformères équatoriaux alors que le spectre PE du composé **4** correspond au spectre de simulation d'un mélange 1:1 des isomères conformationnels équatoriaux et axiaux. Les différences d'énergie libre entre les conformères équatorial et axial sont de l'ordre de 2 kcal mol^{-1} pour les conformères équatoriaux des composés **2**, **3** et **5**. Dans le cas du produit **4**, le conformère équatorial n'est que marginalement favorisé par une différence d'énergie de 0,1 kcal mol^{-1} par rapport au conformère axial.

Mots-clés : cycloheptatriènes substitués en position 7, spectroscopie photoélectronique He(I), B3PW91, simulation spectrale.

[Traduit par la Rédaction]

Introduction

Cycloheptatrienes substituted at the 7-position may exist in two conformations, the *axial* and the *equatorial* conformational isomers, illustrated in Fig. 1. 7-Silylcycloheptatriene and 7-methylcycloheptatriene (2) have previously been under computational investigation, where it has been reported that the *axial* conformers were predicted to be more stable than the *equatorial* conformers by nearly 2 kcal mol^{-1} (1) (1 cal = 4.184 J). This was contrary to our calculations that showed that the difference in energy between *axial* and *equatorial* 7-silylcycloheptatriene is nearly nil. In the case of 7-methylcycloheptatriene (**2**), we found the *equatorial* conformational isomer to be lower in energy than the *axial* conformer. The preference of the *axial* conformation in a 7-substituted cycloheptatriene has previously been documented for triphenyl-7-cyclohepta-1,3,5-trienyltin, as evidenced by its crystal structure (2, 3). Given our long-standing interest in studying conformational properties in the gas phase with ultraviolet (UV) photoelectron (PE) spectroscopy (4) and our work on identifying *E,Z* isomers of cyclohepta-2,4-dien-1-one (5) and *N*,*N*-dimethylcyclohepta-1,3,5-trien-1-amine (6), we initiated a computational and UV PE spectroscopic study of cycloheptatriene (**1**), 7-methylcycloheptatriene (**2**), 7-methoxycycloheptatriene (**3**), 7-methylthiocycloheptatriene (**4**), and 7-dimethylaminocycloheptatriene (5) (Fig. 2). We under-

took the study to determine whether it would be possible to distinguish between the *axial* and *equatorial* conformers in the gas phase using PE spectroscopy coupled with DFT calculations and thereby obtain information on the conformational preferences for the compounds, while documenting the PE spectra of **2**–**5** that had not yet been published. In this paper we present and discuss the results of this study.

Results

The experimental UV PE spectra of **1**–**5** as well as the corresponding partial simulated spectra of their *axial* and *equatorial* conformers are shown in Fig. 3. Table 1 lists the B3PW91/6–311+G(2d,p) total energies of **1**, the *axial* and *equatorial* conformational isomers of **2**–**5**, the corresponding radical cations, and the derived first ionization potentials.

Although other methods — time-dependent DFT (TDDFT) (7, 8) and outer valence Green's function (OVGF) (9, 10) — are available for predicting IPs, we preferred to use the method developed in these laboratories (11). In our approach, the first vertical IP, calculated as the difference in energy between ground state and the radical cation fixed in the ground-state optimized geometry, is used to anchor the Kohn–Sham orbital energies. Our approach is also useful for obtaining an estimate of the first-band adiabatic IP simply by optimizing the radical cation. Using our method to obtain the IPs (11) and our program PESPEC (12*a*, 12*b*), we have successfully simulated the PE spectra of a variety of fairly large molecules, some of which exhibit conformational mobility. In our approach, we compare the accuracy of the calculations and the "shapes" of the predicted and experimental spectra. Our method has also been shown to perform very well by other investigators (13). Consequently, we saw no need to do an extensive time-consuming study with all the other computational methods.

Table 2 lists the first five calculated (B3PW91/6–311+G(2d,p)) and first three experimental vertical IPs of compounds **1**–**5**. Overall the differences between the calculated and experimental IPs is <0.4 eV. Given the closeness of the first two IPs, for the case of **3** and **4** we used the average values of the first two IPs given in parentheses in Table 2 for the comparison. We also calculated the first five IPs with OVGF. While the IPs moved to slightly higher values (Table 1S of the Supplementary Data), there are no significant differences in the relative separations of the DFT and OVGF IPs.[2]

Calculated conformational properties

The *equatorial* conformer is the most stable conformational isomer of cycloheptatrienes **2**, **3**, and **5**; the substituent is situated in the plane of the 7-membered ring rather than perpendicular to the ring as in the *axial* conformation, as shown in Fig. 1. For the 7-methylthiocycloheptatriene (**4**), the *axial* conformer is only marginally lower in energy than its *equatorial* counterpart. Of course, the "*equatorial*" and "*axial*" conformations are identical in the case of cycloheptatriene (**1**).

Our B3PW91/6–311+G(2d,p) calculations place the **2**-*axial* conformer 1.9 kcal mol^{-1} higher in energy — based on ΔE_{elec} — than the *equatorial* conformer, which is contrary to previously reported findings (1). Donovan and White have carried out semi-empirical, ab initio, and DFT calculations on 7-methoxycycloheptatriene (**3**), finding that the *equatorial* conformation is favored by 1.2 kcal mol^{-1} at BLYP/6–31G(*d*) (14). Our calculations agree with those of Donovan and White and predict the *equatorial* conformer of **3** to be 1.8 kcal mol^{-1} lower in energy than the *axial* conformer at the B3PW91/6–311+G(2d,p) level. The difference in energy between the *equatorial* and *axial* conformational isomers of **4** is only 0.8 kcal mol^{-1}, with the *axial* conformer only slightly more stable than the equatorial one. If the ZPVE correction is taken into account, then this difference decreases to 0.1 kcal mol^{-1}. Based on free energies, the *equatorial* conformer is marginally lower in energy (–0.2 kcal mol^{-1}) than the *axial* conformer. The *equatorial* conformer of **5** is 1.9 kcal mol^{-1} lower in energy than the *axial* conformer.

Cycloheptatrienes **2**–**5** undergo *axial–equatorial* conformational isomerism. The B3PW91 ZPVE corrected total energies and relative energies (ΔE_0 and ΔG_{298}) of the conformers are shown in Table 3. Cycloheptarienes **2**, **3**, and **5** are predicted to have the *equatorial* conformer lowest in energy; in the case of **4**, the *axial* conformation is marginally lower in energy. Energy barriers for the ring flip from *equatorial* to *axial* are collected in Table 3.

The B3PW91 potential energy surface for the *equatorial* cycloheptatrienes **3** and **4**, obtained by varying the dihedral angle between H-7 and the Me group of –OMe and –SMe, revealed that the *gauche* conformation is lowest in energy in the three cycloheptatrienes, as shown in Fig. 4. It is also the lowest energy conformation in the *axial* conformational isomers with the exception of **4**-*axial* where the *anti* conformation is favored.

Discussion

The PE spectrum of **1**, shown in Fig. 3*a*, exhibits three distinct ionization potential bands at 8.6, 9.5, and 10.9 eV; the calculated IPs and consequently the partial simulated PE spectrum displayed as Fig. 3*b* are in good agreement with the experimental spectrum.

The PE spectra of **2**, **3**, and **5** are representative of mostly the *equatorial* conformers of these compounds. Based on our B3PW91 calculations, the *equatorial* conformers are on the order of 2 kcal mol^{-1} lower in free energy than their *axial*

[b]**e** = *equatorial*.
[c]**a** = *axial*.

counterparts so the *equatorial* conformations are expected to be preferentially populated at equilibrium. The partial simulated PE spectra of the *equatorial* and *axial* conformational isomers as well as the combination of 96% *equatorial* conformer and 4% *axial* conformer — these values are based on the magnitude of the equilibrium constant with ΔG = 2.0 kcal mol^{-1} (15) — of **2** are displayed as Figs. 3*d*, 3*e*, and 3*f*, respectively. Both partial spectra 3*d* and 3*f* (96% *equatorial* + 4% *axial*) correlate well with the experimental spectrum 3*c*.

The partial simulated PE spectra of the *equatorial* and *axial* conformational isomers as well as the combination of 96% *equatorial* conformer and 4% *axial* conformer of **3** are displayed in Figs. 3*h*, 3*i*, and 3*j*, respectively. Although there is a difference in the relative intensities of first bands of the simulated and experimental spectra, the general features of the simulated spectrum 3*j* and the experimental spectrum 3*g* correlate reasonably well.

The experimental spectrum of 7-methylthiocycloheptatriene is displayed as Fig. 3*k*. Figures 3*l* and 3*m* are the simulated spectra of the *equatorial* and axial conformers of **4**, respectively. According to our calculations, the *equatorial* conformer is only marginally (ΔG_{298} = 0.16 kcal mol^{-1}) lower in energy than the *axial* isomer so the *equatorial* conformer should be slightly preferred (55%–60%) at equilibrium (15). In fact, the simulated spectrum 3*n* (57% *equatorial* + 43% *axial*) correlates better with the experimental spectrum than spectra 3*l* and 3*m*.

As far as the PE spectra of **5** are concerned, the simulated spectra of *equatorial* 5 (Fig. 3*p*) and a 94% *equatorial* – 4% *axial* **5** (Fig. 3*r*) correlate superbly with the experimental spectrum displayed in Fig. 3*o*.

To confirm our analysis based on the relative energies of single *equatorial* and *axial* conformers, we computed the barriers for ring flipping to obtain information on the nature of the ring-flipping potential energy surface. This is important because the relative intensities of PE bands can depend on the conformer populations and on the variation in their

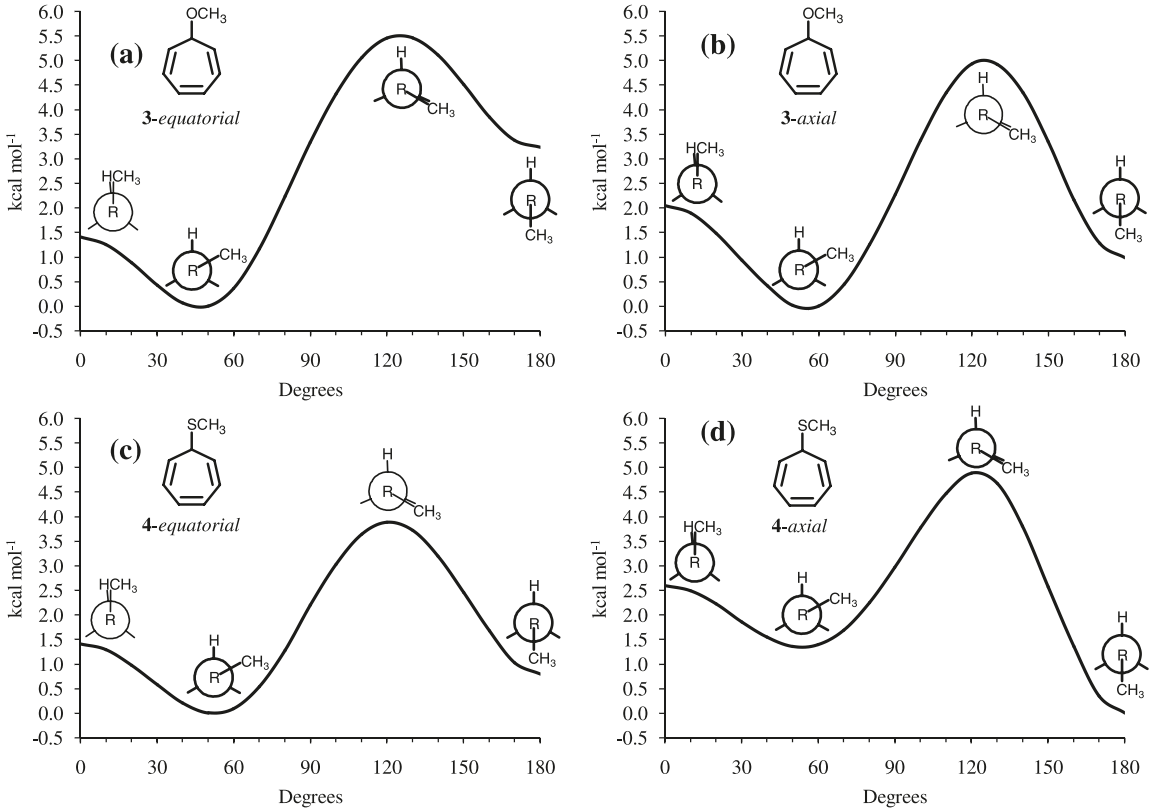
[f]Transition state could not be located.

IPs (4*d*, 12*a*, 12*b*, 16). The *equatorial–axial* ring-flipping barriers for **2** and **3** are 7.62 and 6.50 kcal mol^{-1}, respectively, (Table 3). For **4**-*equatorial* to **4**-*axial*, it is 5.20 kcal mol^{-1}. A discrete transition state for the ring flip of **5** could not be located, presumably because of the complexity — inversion at nitrogen is possible — of the potential energy surface. However, after an extensive study we were able to locate a "minimum-energy" geometry 7.64 kcal mol^{-1} higher in energy than **5**, exhibiting a geometry that was close to the TS geometries of **2**, **3**, and **4** with respect to the planarity of the 7-membered ring. The computed low barriers for the ring flip support the fact that **1**–**5** are fluxional molecules (1–3), and that the equilibrium populations of the *equatorial* and *axial* conformations at ambient temperature are determined by ΔG. This validates our analysis based on using the *equatorial* and *axial* conformers; given the nature of the potential energy surfaces, only the *equatorial* and *axia*l conformers and those very closely related to them are significantly populated at ambient temperature and contribute to the PE spectrum.

It should be pointed out that the partial simulated PE spectra of **3** and **4** have been obtained for the lowest energy rotomers. Figures 4*a*–4*d* show the potential energy surfaces for the rotation of the –OMe and –SMe substituents; the *gauche* conformations are lowest in energy in the cases of **3**-*equatorial*, **3**-*axial*, and **4**-*equatorial*. **4**-*Axial* is the lowest-energy conformer in the case of the *anti* orientation. Plots of the orbital energy versus dihedral angle for the five MOs, HOMO–HOMO-4 of **3**-*equatorial* and **4**-*equatorial*, show small energy differences in orbital energies when the substituent is rotated (Fig. 5*a*). The simulation of partial PE spectra based on this angular dependence data and the potential energy surfaces displayed in Figs. 4*a* and 4*b*, using our program PESPEC (12*a*), produced simulated spectra that did not differ significantly — not unexpected given the relative invariance of the MO energy with torsional angle — from

© 2008 NRC Canada

Fig. 4. The B3PW91/6–311+G(2d,p) potential energy surface for the rotation of the –OMe (*a* and *b*) and –SMe (*c* and *d*) substituents in the *equatorial* and *axial* isomers of **3** and **4** (1 cal = 4.184 J).



those presented in Fig. 3 and are not reported in this paper. Given the nature of the angular dependences of the MO energies and the torsional potential energy surfaces, the same situation will hold for **4**.

As far as other 7-substituted cycloheptatrienes are concerned, for 7-$SiH_3C_7H_7$ it has been reported that the *axial* conformation is more stable than its *equatorial* counterpart by nearly 2 kcal mol^{-1}, based on computational studies, and the C–Si bond lengths of the two conformers differ (1). Our B3PW91/6–311+G(2d,p) calculations indicate that the *axial* conformational isomer is only marginally more stable than the *equatorial* conformer with ΔG_{298} being 0.05 kcal mol^{-1}. The C–Si bond lengths are slightly different; for *axial* the C–S distance is 1.91 Å and for the *equatorial* conformer it is 1.89 Å. The *axial* conformation in a 7-substituted cycloheptatriene has been experimentally observed in triphenyl-7-cyclohepta-1,3,5-trienyltin (2, 3). Its crystal structure clearly showed the quasi-*axial* orientation of the triphenyltin substituent at position 7 of the cycloheptatriene ring with a carbon–tin bond length of 2.21 Å (2). The trend towards *axial* orientations of the polarizable C–Si and C–Sn bonds suggests that a hyperconjugation interaction plays a role in determining the *axial–equatorial* preference.

Conclusions

The photoelectron spectra of cycloheptatrienes **1**–**5** were recorded and interpreted with the use of calculations at the B3PW91 level of theory. Simulated PE spectra of the *axial* and *equatorial* conformational isomers of all compounds have shown that the experimental PE spectra of compounds **2**, **3**, and **5** are those of mainly the *equatorial* conformers and are in good agreement with experiment. The simulation has also shown that the PE spectrum of **4** is best represented by a nearly 1:1 mixture of the *equatorial* and *axial* conformational isomers, which is supported by our thermochemical calculations on these compounds.

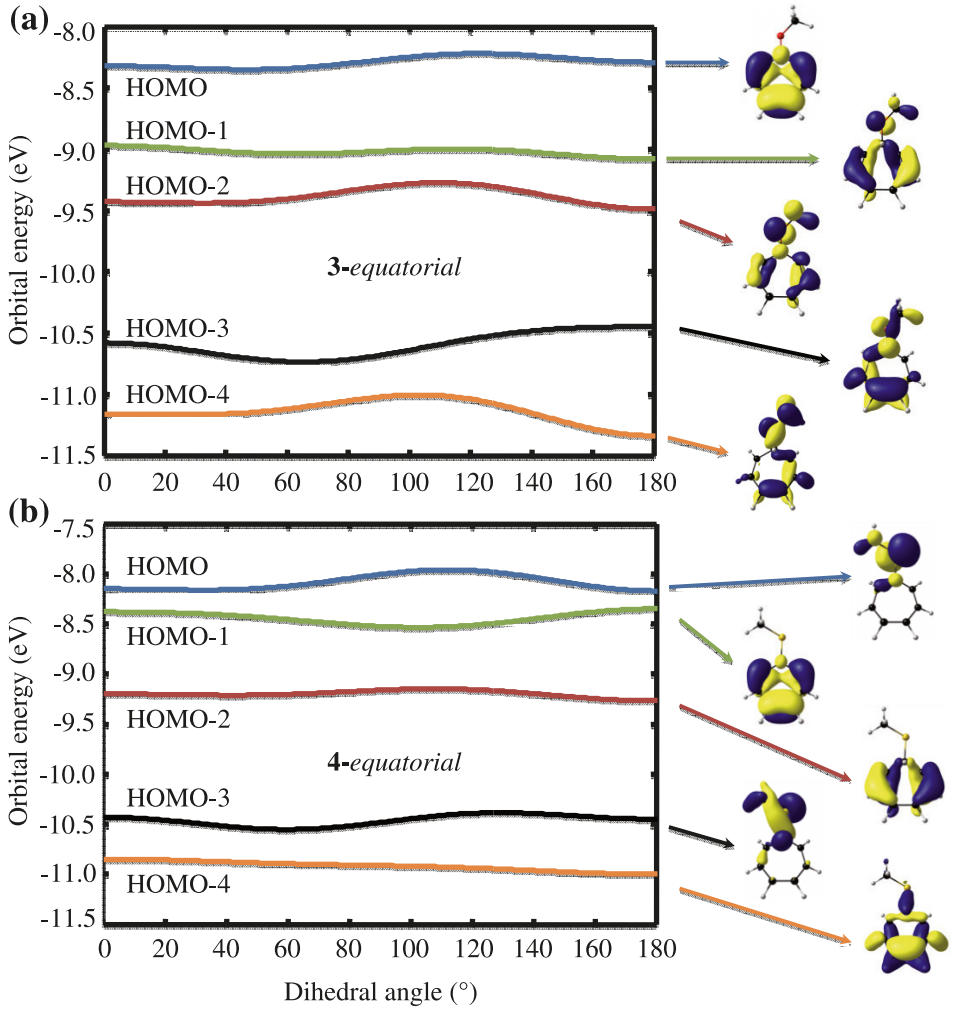
Experimental detail

Computational studies

B3PW91 (17) calculations were performed with Gaussian 03 (18). Calculations on optimized geometries and radical cations were carried out using the TIGHT convergence criteria at B3PW91/6–311+G(2d,p). Two-electron integrals and their derivatives were computed using the ultrafine grid. As it is well established that the correct geometry optimizations of molecules containing chalcogen atoms require the addition of d-polarization functions (19–23), we have used the above triple zeta split valence basis set augmented by two d-polarization functions, one p-polarization function on hydrogen atoms, as well as one diffuse function on hydrogen atoms. The interpretation of the PE spectra was based on our successfully applied method (11, 24, 25, 26) that is basically an extension of Koopman's theorem. The simulated PE spectra of all compounds were obtained by anchoring the Kohn–Sham MO orbital energies to the calculated first IP using our Fortran program PESPEC (12(a)). Band intensities are normalized in simulations involving single structures and (or) conformers. However, in cases where conformations exhibit

© 2008 NRC Canada

Fig. 5. Orbital energy dependence on dihedral angle for the rotation of the substituent in **3**-*equatorial* and **4**-*equatorial*.



vastly different orbital energies, analyses based on conformational potential energy surfaces yield simulated spectra that exhibit intensity variations in the bands due to the inclusion of conformer populations. Gaussian line shape with a full-width-at-half-height (FWHH) of 0.4 and a temperature set to 300 K was used to simulate the partial PE spectra with ten MO energies, HOMO to HOMO-9.

UV photoelectron spectroscopic studies

A locally built spectrometer (27) was used to acquire the photoelectron (PE) spectra. A sample of the cycloheptatriene was placed in an 8 mm od. A pyrex sample tube was externally attached to the end of a probe. While all spectra were recorded at the ambient temperature (~20 °C) of the spectrometer housing, the temperature of the external sample was controlled to achieve a suitable source pressure (3–8 × 10^{-3} mbar, 1 bar = 100 kPa). The sample temperature for compounds **3**, **4**, and **5** was 0 °C; for **1** it was –30 °C and for **2** –15 °C. To obtain the spectra, the probe was inserted into the spectrometer housing so the tip was located 10 mm from the intersecting photon beam. Twenty scans were averaged to obtain the spectra that were calibrated with N_2 (15.6 eV); linearity of the scale was ensured through calibrations with N_2 and CH_3I (9.54 and 10.16 eV) prior to the experiments. Vertical IPs are accurate to ±0.05 eV. Experimental PE spectra are displayed in Fig. 3.

Synthesis of cycloheptatrienes

Tropylium bromide was synthesized according to the procedure by Doering and Knox (28). Cycloheptatriene (1) was purchased from Sigma-Aldrich and distilled.

7-Methylthiocycloheptatriene (4)

To a solution of 2 g (0.01 mol/L) of tropylium bromide in 10 mL of methanol, a solution of 0.7 g (0.01 mole) of sodiumthiomethoxide in 30 mL of methanol was added. The solution was allowed to stir for 0.5 h. Excess sodiumthiomethoxide was quenched with 50 mL of water. The resulting solution was extracted with diethylether (3 × 30 mL), which was dried with magnesium sulfate. Removal of solvent produced 0.6 g (43%) of 7-methylthiocycloheptatriene. ^{1}H NMR ($CDCl_3$) δ: 2.08 (s, 3 H), 3.43 (t, 1 H), 5.47 (m, 2 H), 6.21 (m, 2 H), 6.50 (m, 2 H). ^{13}C ($CDCl_3$) δ: 13.4, 44.0, 124.6, 126.7, 131.1.

7-Methoxycycloheptatriene (3)

A solution of 2 g (0.01 mol/L) of tropylium bromide in 10 mL of methanol was added to a solution of sodium

© 2008 NRC Canada

methoxide in methanol (1.5 g Na in 20 mL MeOH). The mixture was stirred for 45 min and filtered to remove precipitated sodium bromide. Removal of the solvent afforded yellow oil, which was washed with water and extracted with diethylether (3 × 10 mL) and dried with anhydrous $MgSO_4$. ^{1}H NMR ($CDCl_3$) δ: 3.41 (s, 3 H), 3.41 (t, 1 H), 5.51 (m, 2 H), 6.18 (m, 2 H), 6.67 (m, 2 H). ^{13}C ($CDCl_3$) δ: 56.5, 77.9, 123.2, 125.4, 131.1.

7-Dimethylaminocycloheptatriene (5)

Synthesized according to a procedure by Doering and Knox (17). ^{1}H NMR ($CDCl_3$) δ: 1.86 (t, 1 H), 2.37 (s, 6 H), 5.45 (m, 2 H), 6.17 (m, 2 H), 6.71 (m, 2 H). ^{13}C ($CDCl_3$) δ: 43.2, 65.6, 122.8, 123.5, 130.6.

7-Methylcycloheptatriene (2)

To a vigorously stirred suspension of 2 g. (0.01 mol/L) of tropylium bromide in dry diethylether, a 1.4 mol/L solution of methyllithium in diethylether was added dropwize (100% excess). Exothermic reaction took place upon addition of methyllithium and reflux was observed. The reaction mixture was allowed to stir for additional 30 min, 20 mL of 2N HCl was added with care, the mixture was separated and washed twice with 10 mL portions of 2N NaOH and three 15 mL portions of water. The ethereal layer was dried with anhydrous $CaCl_2$. Removal of solvent afforded 0.15 g (14%) of **5**. ^{1}H NMR ($CDCl_3$) δ: 1.34 (d, 3 H), 1.64 (m, 1 H), 5.12 (m, 2 H), 6.13 (m, 2 H), 6.63 (m, 2 H). ^{13}C NMR ($CDCl_3$) δ: 19.1, 33.5, 124.4, 128.2, 131.1.

Synthesis of constrained aromatic $\beta^{2,3,3}$-amino alcohol scaffolds — Precursors of non-proteinogenic phenylalanine for peptidomimetics

Surinderjit Singh Bhella, Mohan Paul S. Ishar, Gajendra Singh, Rajinder Singh, Gurpinder Singh, and Tilak Raj

Abstract: Novel constrained $\beta^{2,3,3}$-amino alcohol scaffolds (**11a**–**11e**) with varied substitution patterns have been synthesized by reductive cleavage of the N–O bond of isoxazolidines (**10a**–**10e**) derived from intramolecular 1,3-dipolar cycloadditions. A number of methods were probed for reductive cleavage, however, better results were obtained with ammonium formate in the presence of Pd/C or Zn as compared to Zn/acetic acid. The obtained scaffolds (**11a**–**11e**) can serve as valuable building blocks for peptidomimetics.

Key words: $\beta^{2,3,3}$-amino alcohol, peptidomimetics, building blocks, isoxazolidines, reductive cleavage, ammonium formate.

Résumé : En procédant au clivage réducteur de la liaison N–O des isoxazolidines, **10a**–**10e**, obtenues par des cycloadditions 1,3-dipolaires intramoléculaires, on a effectué la synthèse de nouveaux $\beta^{2,3,3}$-aminoalcools, **11a**–**11e**, contraints et en échafauds, et qui portent divers types de substituants. On a étudié un certain nombre de méthodes de clivages réducteurs et on a obtenu de meilleurs résultats par le biais de la réaction du formiate d'ammonium en présence de Pd/C ou de Zn par opposition aux réactions en présence de zinc et d'acide acétique. Les échafauds obtenus, **11a**–**11e**, peuvent être utilizés comme blocs dans la synthèse de produits peptidomimétiques.

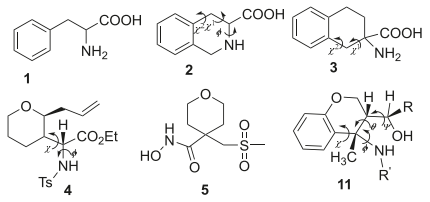
Mots-clés : $\beta^{2,3,3}$-aminoalcool, peptidomimétique, bloc dans la synthèse, isoxazolidines, clivage réducteur, ammonium formiate.

[Traduit par la Rédaction]

Introduction

Peptide mimic drugs continue to be in high demand (1). The building block approach is highly appreciated in peptide mimic drug design (2*a*), and advances in preparation of such building blocks have made feasible the synthesis of novel peptidomimetics (2*b*). The design considerations of peptidomimetics include restriction of the torsional angles, ϕ (phi), ψ (psi), and ω (omega), which determine the 3D structure of peptide backbone (3), as well as χ (chi) torsional angles that define the position of side chain functional groups (4) (Fig. 1). An additional torsion angle, θ, responsible for gauche or trans conformations in constrained aromatic β-amino alcohols/β-amino acids is generated by the insertion of methylene units (5). Furthermore, the gauche conformation is more accessible with $\beta^{2,3,3}$ substitution because it leads to: (*i*) confinement of ϕ and ψ in the preferred region and (*ii*) θ is covalently fixed in the gauche position (5*b*, 5*c*). The characteristic torsions of such secondary structure types

Fig. 1.



readily reveal that, in general, such a substitution pattern strongly promotes helix formation (5*a*). Moreover, the presence of *N*-methyl residues increases proteolytic stability, membrane permeability (lipophilicity), and alters the conformational characteristics and properties of the amide bond (6). Considerable effort has been focused, particularly, on developing substituted conformationally constrained aromatic precursors because of their importance in protein folding and recognition (7). Consequently, phenylalanine (1) is a key amino acid because it is located in the pharmacophoric region of many bioactive peptides (7*a*–7*c*). The phenylalanine side chain has been constrained, inter alia, by the use of tetrahydroisoquinoline based (**2**, Tic-2) (8) and tetraline-based (**3**, Atc-1) scaffolds (9). On the other hand, the use of pyran rings (**4** and **5**) is an interesting concept in the design of inhibitors of HIV-1 protease and HIV integrase, which requires the use of a scaffold to project hy-

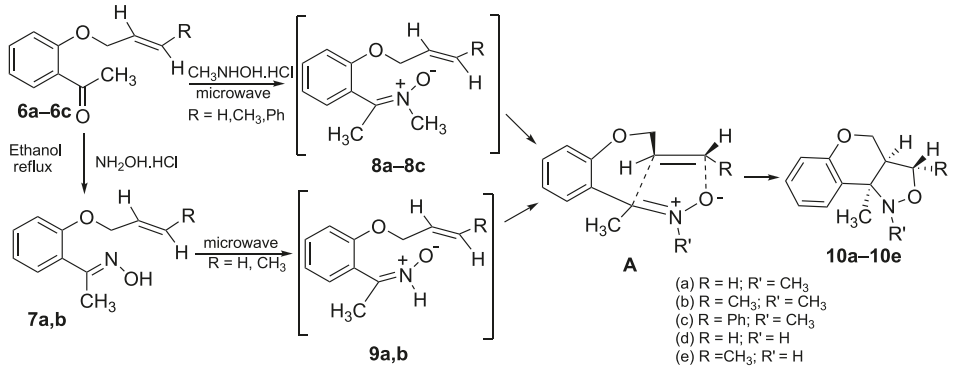
Scheme 1.



drophobic substituents into the appropriate positions for interaction with the enzyme (10).

Compared to the α-amino acids (**2**–**4**), β-amino acids possess a much greater chemical diversity (11). Consequently, the importance of the synthesis of $\beta^{2,3,3}$-amino alcohol precursors for conformationally constrained $\beta^{2,3,3}$-amino acids (sub-class of β-amino acids) (11*b*, 12, 13) building blocks increases because $\beta^{2,3,3}$ substitutions have a more pronounced influence on the torsional space by reducing the available dihedral angles ϕ and ψ, which in turn influence angle θ (5*a*). Amino alcohols are versatile intermediates in organic synthesis and increasingly important in drugs and pharmaceutics (14), and simple, efficient, and environmentally friendly processes are highly sought for their synthesis.

Herein, we report the synthesis of substituted conformationally constrained $\beta^{2,3,3}$-amino alcohols (**11a**–**11e**), by reductive cleavage of the N–O bond of isoxazolidines (**10a**–**10e**) with ammonium formate using a metal catalyst, such as palladium on charcoal (Pd/C) or zinc dust (Zn). The results are compared with the results obtained by reductive cleavage of the N–O bond of isoxazolidines with Zn/acetic acid. The starting compounds *o*-allyloxy-/crotyloxy-/cinnamyloxy-acetophenones were utilized to achieve $\beta^{2,3,3}$ substitutions in **11a**–**11e**. The obtained scaffolds (**11a**–**11e**) have varied substitution patterns as well as chemical diversity, compared with the compounds reported in the literature (7–9, 13) and these precursors (**11a**–**11e**) of non-proteinogenic phenylalanine can be exploited in peptidomimetic drug designing.

Results and discussion

For targeting the $\beta^{2,3,3}$ substitution in aromatic amino alcohols (**11a**–**11e**), the isoxazolidines (**10a**–**10e**) were synthesized by intramolecular 1,3-dipolar cycloaddition of *N*-methylnitrones (**8a**–**8c**) and nitrones (**9a**, **9b**) generated in situ from oximes (**7a**, **7b**) by starting with *o*-allyloxy-/crotyloxy-/cinnamyloxy-acetophenones (**6a**–**6c**), under microwave irradiation conditions (Scheme 1); the stereochemical outcome is a consequence of π-facial selectivity, which can be rationalized in terms of preferred endo-orientation of R and exo-orientation of -O-CH_2- moiety in the transition state (**A**) (15).

Opening of the obtained isoxazolidines (**10a**–**10e**) by cleavage of the N–O bond was investigated under reductive conditions. Thus, reaction of **10a**–1**0e** with Zn-aq. AcOH, Zn-$HCOONH_4$, and Pd/C-$HCOONH_4$ in a mixture of solvents (THF and methanol) at room temperature (RT) led to $\beta^{2,3,3}$-amino alcohols (**11a**–**11e**) with yields varying from 48% to 52% for Zn-aq. AcOH, 75% to 78% for Zn-$HCOONH_4$, and 90% to 93% for Pd/C-$HCOONH_4$ (Scheme 2 and Table 1). The reaction was monitored by TLC [R_f values for **11a**–**11e** are 0.16–0.15 and for **10a**–**10e** are 0.37–0.35, $CHCl_3$ solvent]. It was observed that the use of ammonium formate ($HCOONH_4$) in THF–MeOH solvent in the presence of Pd/C efficiently cleaved the N–O bond of isoxazolidines (**10a**–**10e**) to β-amino alcohols (**11a**–**11e**) at RT in high yields and in less time than Zn/acetic acid (Table 1); the reaction is also very neat and clean.

Scheme 2.

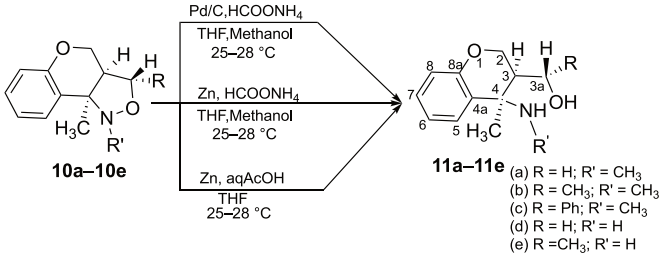


Table 1. Reaction conditions, yields, and times for **11a**–**11e**.

	Zn-aq. AcOH		Zn-$HCOONH_4$		Pd/C-$HCOONH_4$	
Entry	Yield (%)	Time (h)	Yield (%)	Time (h)	Yield (%)	Time (h)
11a	52	11	78	7	93	2
11b	51	12	75	6	92	3
11c	51	12	77	7	93	3
11d	49	11	76	6	91	2
11e	48	12	77	7	90	2

The products were characterized by spectroscopic analysis (IR, ^{1}H, and ^{13}C NMR, including COSY, hetero-COSY, and NOESY 2D NMR measurements, and mass) and microanalytical data. The -O-H and N-H bands of the ring opened products, in the case of **11a**, appeared at 3280 and 3130 cm^{-1}, respectively; their presence was also corroborated by deuterium exchange (on shaking with D_2O, resonances of -O-H and NH in the ^{1}H NMR spectra of the products are suppressed). The changes in the chemical shift values, both in ^{1}H and ^{13}C NMR, in going from isoxazolidines (**10a**–**10e**) to

© 2008 NRC Canada

the corresponding ring-opened products (**11a**–**11e**) are in agreement with the assigned structures. The cis arrangement between C4-CH_3 and C3-H is corroborated by spatial proximity established by the NOESY spectrum in the case of **11a**; this cis arrangement was also established in the case of **10a** through its NOESY spectrum (15), thereby indicating the retention of stereochemical disposition of the isoxazolidines in the ring-opened products. The chemical shift of C3a-H(s) resonances, which indicated the proximity of C3a to the OH function, were easily identified from their multiplicity.

The use of ammonium formate ($HCOONH_4$) as a reductive reagent (16*a*, 16*b*) is very cost effective with good yields under mild conditions compared with the other conventional hydrogenation procedures, which require a special set of apparatus and involve risk associated with the use of hydrogen gas (12, 13). Ammonium formate acts as a hydrogen source in the presence of a metal catalyst, such as palladium on charcoal, zinc dust, etc., and this process offers a valuable alternative, providing greater experimental convenience that avoids many disadvantages and hazards (16*c*). Ammonium formate has advantages of being readily available, inexpensive, stable, and nontoxic. The use of ammonium formate is also a better option than the use of acid for reductive cleavage in the presence of acid sensitive moieties (16*b*).

The obtained $\beta^{2,3,3}$ amino alcohols (**11a**–**11e**) are potentially more useful than α-amino acids (**2–4**) because with the extra carbon atom in the backbone, the presence of *N*-alkyl substituent, and the presence of benzopyran moiety, these scaffolds possess more chemical diversity. The double substitution at C3 and single substitution at C4 in **11a**–**11e** should enhance the gauche conformation (5); such gauche conformations induce the folded structural motifs, such as helices, and turns into peptides (5). The *N*-methyl residue in **11a**–**11c** increases the metabolic stability, improves absorption properties, and also alters the conformational characteristics and properties of the amide bond (6). These constrained scaffolds (**11a**–**11e**) can also project their hydrophobic substituents into the appropriate positions for enzyme interaction.

Conclusion

Facile reductive cleavage of the N–O bond of isoxazolidines (**10a**–**10e**) with ammonium formate in the presences of a Pd/C or Zn metal catalyst have been utilized to obtain novel $\beta^{2,3,3}$-amino-alcohols (**11a**–**11e**), with a substitution pattern having pronounced influence on torsional angles. These compounds (**11a**–**11e**) could serve as valuable scaffolds for peptidomimetics upon which substituents can be mounted to mimic the peptides.

Experimental

General information

Starting materials and reagents were purchased from commercial suppliers and used after further purification (crystallization/distillation). Bruker AC-200FT (200 MHz) and JEOL AL-300FT (300 MHz) spectrometers were used to record ^{1}H NMR and ^{13}C NMR (50 and 75 MHz) spectra. Chemical shifts (δ) are reported as downfield displacements from TMS used as internal standard and coupling constants (*J*) are reported in Hz. IR spectra were recorded with a Shimadzu DR-2001 FT-IR spectrophotometer on KBr pellets. Mass spectra, ESI-method, were recorded on a Bruker Daltonics Esquire 300 mass spectrometers. Elemental analyses were carried out on a PerkinElmer 240C elemental analyzer and are reported in percent atomic abundance. All melting points are uncorrected and measured in open glass-capillaries on a Veego MP-D digital melting point apparatus. Thin layer chromatography (TLC) was carried out on silica gel G-coated (Loba Chemie, containing 13% $CaSO_4$ as a binder) (1 mm thick layer) glass plates.

General procedure for the reaction of 10a–10e with Zn and aq. AcOH to synthesize 11a–11e

A solution of **10a**–**10e** (500 mg) in acetic acid (10 mL), THF (5 mL), and water (5 mL) was stirred at RT (25–28 °C). Activated zinc dust (1.5 g, excess) was added to the above solution. To the stirred mixture (11–12 h) additional amounts of zinc were added until the starting material disappeared; the reaction was monitored by TLC. The reaction mixture was filtered and the residue washed with ether (30 mL). The filtrate was basified with aqueous sodium hydroxide (10%) and extracted with dichloromethane (3 × 50 mL). The combined organic layer was dried over Na_2SO_4 and concentrated under vacuum. Purification of the residue by flash column chromatography (silica gel, ethyl acetate–hexane, 7:3) afforded **11a**–**11e**.

General procedure for the reaction of 10a–10e with Pd/C and $HCOONH_4$ or Zn and $HCOONH_4$ to synthesize 11b–11e

A solution of **10a**–**10e** (500 mg), ammonium formate (3.0 g), methanol (15 mL), and THF (5 mL) was stirred at RT (25–28 °C). Activated 10% palladium on charcoal (1.5 g) or zinc dust (1.5 g, excess) was added to the above solution. The mixture was stirred for 2–3 h for Pd/C–$HOOCNH_4$ and 6–7 h for Zn–$HOOCNH_4$; completion of the reaction was monitored by TLC. The reaction mixture was filtered and the residue washed with ether (30 mL). The filtrate was basified with aqueous sodium hydroxide (10%) and extracted with dichloromethane (3 × 50 mL). The combined organic layer was dried over Na_2SO_4 and concentrated under reduced pressure. Purification by flash column chromatography (silica gel, ethyl acetate-hexane, 7:3) afforded **11a**–**11e**.

(4-Methyl-4-methylamino-chroman-3-yl)-methanol (11a)

Triarylmethyl chlorides as novel, efficient, and mild organic catalysts for the synthesis of *N*-sulfonyl imines under neutral conditions

Ali Khalafi-Nezhad, Abolfath Parhami, Abdolkarim Zare, Amir Nasrolahi Shirazi, Ahmad Reza Moosavi Zare, and Alireza Hassaninejad

Abstract: A highly efficient procedure for the preparation of *N*-sulfonyl imines via condensation of sulfonamides with aldehydes as well as ketones in the presence of triarylmethyl chlorides as metal-free organo-catalysts at 40 °C is described. The advantages of this class of catalysts over the reported ones are their efficiency and possibility of running reactions in neutral media that makes them suitable for acid-sensitive substrates.

Key words: triarylmethyl chloride, *N*-sulfonyl imine, sulfonamide, aldehyde, ketone.

Résumé : On a développé une méthode très efficace pour préparer des *N*-sulfonylimines par le biais d'une condensation à 40 °C de sulfonamides sur des aldéhydes ou des cétones, en présence de chlorures de triarylméthyles agissant comme catalyseurs organiques sans métaux. Les avantages de cette classe de catalyseurs par rapport d'autres qui ont déjà été utilisés sont leur efficacité et la possibilité d'effectuer les réactions dans des milieux neutres appropriés pour les substrats sensibles aux acides.

Mots-clés : chlorure de triarylméthyle, *N*-sulfonylimine, sulfonamide, aldéhyde, cétone.

[Traduit par la Rédaction]

Introduction

N-Sulfonyl imines are versatile intermediates in organic synthesis (1). They are excellent substrates in aza Diels–Alder reactions (2–3), nucleophilic additions (3), and reductions (4), as well as in radical (5) or ene reactions (6). They have been also used in the synthesis of aziridines (7). So far, several synthetic methods for the preparation of *N*-sulfonyl imines have been reported (8–22). Most of those methods involve the condensation of sulfonamides with aldehydes or ketones in the presence of strong Lewis or protic acids, such as sulfamic acid (22). In many cases, strongly acidic conditions are not compatible with other functionalities present in a given substrate. Some methods need two-step procedures or they are expensive methods and generate toxic by-products. Moreover, several methods require prior preparation of precursors, such as oxime, sulfinylimine, or aziridine. Many methods also need harsh reaction conditions. Because of the limitations of the above methods, development of a new method for the synthesis of *N*-sulfonyl imines under neutral conditions in one-step would be desirable.

Recently, organic Lewis acids, such as NBS, trichlorocyanuric acid, and trichloroisocyanuric acid, have been proved to be useful to chemists in the laboratory and industry because of the good activation of carbonyl compounds, selectivity, and mild reaction conditions (23). The use of organic catalysts instead of inorganic Lewis acids have some advantages, including (*i*) the possibility to perform the reactions for acid sensitive substrates, (*ii*) performing the reactions in milder reaction conditions, and (*iii*) the substrates bearing basic functional groups or electron-donating substituents prone to capture the acidic catalysts do not affect the reaction results. Triarylmethyl chlorides (Ar_3CCl) can be introduced as new organic catalysts that are inexpensive and can be obtained commercially or easily prepared by the known procedures (24). These type of compounds has been extensively studied as bulky protective groups for amino and primary hydroxyl functional groups in multi-step organic synthesis (25). Furthermore, triarylmethyl chlorides in combination with metal salts particularly $SnCl_2$ have been employed in a few organic transformations (26); however, the use of triarylmethyl chlorides in the absence of a co-catalyst is really intriguing. To the best of our knowledge, there is no report for the application of triarylmethyl chlorides as catalyst in organic transformations.

Having the above facts in mind and also in continuation of our previous studies on the preparation of *N*-sulfonyl imines (9*a*, 9*b*) as well as catalysis in organic transformations (27), we describe here the first procedure for the application of triarylmethyl chlorides as catalysts in the synthesis of *N*-

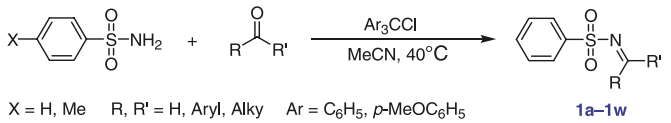
Scheme 1. The condensation of sulfonamides with carbonyl compounds.



sulfonyl imines via the reaction of sulfonamides with aromatic and aliphatic aldehydes as well as ketones under mild and neutral reaction conditions (Scheme 1).

Results and discussions

To optimize the reaction conditions, first we examined the reaction of benzenesulfonamide (2 mmol) with benzaldehyde (2 mmol) as a model in the presence of DMTrCl [Ph(p-MeOC$_6$H$_4$)$_2$CCl, 0.25 mmol] in MeCN (10 mL) at room temperature. In these conditions, the corresponding *N*-sulfonyl imine **1a** was obtained in 64% yield after 30 min. Increasing the reaction time had no effect on the efficiency of the reaction; however, enhancing the temperature to 40 °C improved the yield to 90%. In another study, the influence of different solvents on the model reaction was investigated. The results are summarized in Table 1. As it can be seen from Table 1, higher yield and shorter reaction time were obtained when MeCN was used. So, MeCN was used as the solvent of choice in all reactions. The reaction of benzenesulfonamide with benzaldehyde was also examined in the absence of solvent in which the product was obtained in 46% within 50 min (Table 1, entry 6). These results indicated the preference of the solvent-phase procedure in comparison with solvent-free conditions. We suggest that it is due to the greater stability of intermediate triphenylcarbonium ions in solvent media.

To select the best triarylmethyl chloride as catalyst, the model reaction was performed using TrCl (Ph$_3$CCl), MMTrCl (Ph$_2$(p-MeOC$_6$H$_4$)Cl), and DMTrCl (Ph(p-MeOC$_6$H$_4$)$_2$Cl) (Table 2). As it is shown in Table 2, there is not a great difference between the catalysts; however; the best yield was obtained using DMTrCl. As expected, the methoxy groups in the catalyst can increase the extent of ionization of triarylcarbenium chloride, thus increasing the amount of Lewis acid in the reaction medium.

To investigate the generality and versatility of the catalyst, the optimized reaction conditions, as described above, were extended to various structurally diverse carbonyl compounds (aldehydes and ketones) and sulfonamides. The results are displayed in Table 3. As Table 3 indicates, the reactions proceeded efficiently, and the desired products were obtained in good to high yields in short reaction times.

In general, higher reaction yields were obtained when benzenesulfonamide was used instead of *p*-toluenesulfonamide. It was observed that the electronic properties of the aromatic ring of aromatic aldehydes can affect the reaction. The results showed that electron-donating substituents improved the reaction yields (Table 3, entries 2, 9, and 10). However, aryl aldehydes possessing electron-withdrawing groups, generally necessitate longer reaction times and decrease the reaction yields (Table 3, entries 3, 11, and 12). Moreover, the presence of a halogen on the aromatic ring of aldehydes slightly decreased the yields and increased the reaction times (Table 3, entries 4, 5, 13, and 14). When the reaction was examined for 4-(dimethylamino)benzaldehyde (Table 3, entry 7), the corresponding bis(indolyl)alkane was obtained in good yield, indicating that the amine function cannot affect the efficiency of the reaction via irreversible complexation with catalyst. *o*-Substituted aromatic aldehydes (Table 3, entry 15) and aliphatic aldehydes (Table 3, entries 18 and 19) needed longer reaction times and afforded lower yields of the products in comparison with the others. The reaction of terphtalaldehyde (2 mmol) with *p*-toluenesulfonamide (4 mmol) afforded the corresponding bis-*N*-sulfonyl imine (Table 3, entry 20) in 51% yield as well as *N*-(4-formylbenzylidene)toluenesulfonamide in 25% yield, which shows the generality and applicability of this method for the synthesis of bis-*N*-sulfonyl imine analogous. Moreover, the reaction of terphtalaldehyde (2 mmol) and *p*-toluenesulfonamide (2 mmol) provided *N*-(4-formylbenzylidene)toluenesulfonamide (Table 3, entry 21) as the product in 76% yield. Generally, aldehydes are more reactive than ketones, since approach of bulky trityl cation is hindered due to the presence of two substituents in ketones. The reaction of ketones with *p*-toluenesulfonamide provided the corresponding *N*-sulfonyl imines in moderate yields (Table 3, entries 22 and 23); however, most of the reported methods were not suitable for the ketones especially enolizable ones.

We suggest that complexes of carbonyl compounds and triarylmethyl cation (**I**, **II**, and **III** for benzaldehyde) were formed (Scheme 2). The cationic intermediates **I**, **II**, and **III** were introduced by Oikawa et al. for the first time (31). These complexes act as activated carbonyl compound and then react with *p*-toluenesulfonamide providing **IV**, which converts to **V** by proton transfer. **V** dissociates to form an

equilibrating mixture of cations as is shown in Scheme 2. The **VI** eliminates a proton to give the sulfonylimine product, and simultaneously the triarylmethanol is converted to triarylmethyl chloride. The suggested mechanism is confirmed, since the catalyst was completely recovered unchanged, and no triarylmethanol could be identified after the completion of the reaction as it could be observed on TLC by comparison with pure authentic samples. If a base, such as triethylamine or pyridine (in equimolar amount relative to DMTrCl), was added to the model reaction preceding to the addition of DMTrCl, the yield would decrease greatly (9%); moreover, the DMTrCl was not regenerated and DMTrOH was obtained instead. We suggest that this is owing to the ability of base to interfere with the protonation and proton transfer steps in the mechanism. Increasing the amounts of base and DMTrCl had negligible effect on the yield. In another experiment, to examine the applicability of another organo-catalyst for the synthesis of *N*-sulfonyl imines, the reaction was performed using the same amount of 2,4,6-trichloro-1,3,5-triazine instead of DMTrCl and in DMF as the solvent. The results showed that this catalyst is also able to perform the reaction (30% yield in 60 min) and emphasize the role of organo-catalysts for activation carbonyl groups.

In conclusion, this new strategy offers several advantages, including neutral and mild reaction conditions, short reaction times, high yields of products, low catalyst loading as well as simple experimental and isolation procedures, which make it useful for the synthesis of *N*-sulfonyl imines. selected catalyst is found to be highly efficient, easily available, economical, and recyclable.

Experimental

All chemicals were purchased from Merck or Fluka chemical companies. All known compounds were identified by comparison of their melting points, ^{1}H NMR, and ^{13}C NMR data with the authentic samples. The ^{1}H NMR (250 MHz) and ^{13}C NMR (62.5 MHz) were run on a Bruker Avance DPX-250 FTNMR spectrometer. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus. Microanalyses were performed on a PerkinElmer 240-B microanalyzer. Melting points were recorded on a Büchi B-545 apparatus in open capillary tubes.

General procedure for the synthesis of *N*-sulfonyl imines

To a mixture of sulfonamide (2 mmol), carbonyl compound (2 mmol), and MeCN (10 mL) in a 25 mL round-bottomed flask connected to a reflux condenser was added DMTrCl (0.25 mmol), and the resulting mixture was stirred at 40 °C for the times indicated in Table 3. Subsequently, the solvent was evaporated and to it was added EtOAc (50 mL) and extracted with saturated solution of $NaHSO_3$ (2 × 50 mL) to remove the unreacted carbonyl compound. The organic layer was dried with $MgSO_4$ and concentrated to 5 mL and to it was added gradually *n*-hexane (20–30 mL) and allowed to stand at room temperature until crystals were formed, which then was collected by filtration, washed with *n*-hexane, and dried. The catalyst was recovered by evaporation of the filtrate and subsequent recrystalization in *n*-hexane.

Determination of dissociation constants of *p*-hydroxybenzophenone in aqueous organic mixtures — Solvent effects

M.I. Sancho, A.H. Jubert, S.E. Blanco, F.H. Ferretti, and E.A. Castro

Abstract: The apparent acidity constant of *p*-hydroxybenzophenone, which is a practically insoluble drug in water but of great pharmaceutical interest, was determined by reversed-phase high-performance liquid chromatography in organic solvent – water mixtures (acetonitrile–water, ethanol–water, and methanol–water), varying the reaction medium permittivity in the interval 56 to 70, at constant ionic strength (0.050) and temperature (30 °C). A combined glass electrode calibrated with aqueous standard buffers was used to obtain pH readings based on the concentration scale ($^{s}_{w}$pH). The p*K*a values from chromatographic data were obtained using the Hardcastle–Jano equation. Moreover, excellent linear relationships between the p*K*a values and solvation properties of the reaction medium (relative permittivity and *Acity*) were used to derive acid dissociation constants in aqueous solution. It has been concluded that the p*K*a values extrapolated from such solvent–water mixtures are consistent with each other and with previously reported measurements. In addition, the molecular structures of all the chemical species involved in the acid–base dissociation equilibrium studied were calculated with a B3LYP/6–311++G(d,p) method that makes use of the polarizable continuum model (PCM). Taking into account the theoretical p*K*a values, the conclusions obtained match our experimental determinations.

Key words: solvent effects, *p*-hydroxybenzophenone, acidity constant, solvation parameters, structure, DFT calculation.

Résumé : Faisant appel à la chromatographie liquide à haute performance en phase inversée et opérant à une température de 30 °C, à une force ionique de 0,050 et dans des mélanges de solvants organiques et d'eau (acétonitrile–eau, éthanol–eau et méthanol–eau) dont la permittivité du milieu se situe entre 56 et 70, on a déterminé la constante d'acidité apparente de la *p*-hydroxybenzophénone, un médicament pratiquement insoluble, mais d'un grand intérêt pharmaceutique. On a utilisé une combinaison d'une électrode de verre calibrée avec des tampons aqueux de référence pour obtenir des lectures de pH sur l'échelle de concentration ($^{s}_{w}$pH). On a obtenu les valeurs de p*K*a à partir de données chromatographiques, en utilisant l'équation de Hardcastle–Jano. De plus, on a utilisé les excellentes relations linéaires entre les valeurs de p*K*a et les propriétés de solvatation du milieu réactionnel (permittivité relative et *Acité*) pour obtenir les constantes de dissociation acide en solutions aqueuses. On en conclut que les valeurs de p*K*a extrapolées à partir des mélanges solvants organiques et eau sont en accord entre eux ainsi qu'avec les mesures rapportées antérieurement. De plus, les structures moléculaires de toutes les espèces chimiques impliquées dans l'équilibre de dissociation acide–base étudié ont été calculées à l'aide de la méthode B3LYP/6-311++G(d,p) qui utilise le modèle du continu polarisable (MCP). En prenant en considération les valeurs de p*K*a théoriques, les conclusions obtenues sont en accord avec nos données expérimentales.

Mots-clés : effets de solvant, *p*-hydroxybenzophénone, constante d'acidité, paramètres de solvatation, calculs par la théorie de la fonctionnelle de densité.

Introduction

The knowledge of p*K*a values of organic compounds in aqueous solutions with weak acid or basic properties is fundamental to the development of chemical and biological studies, specially those related to chemical stability (1, 2) and preformulation of new pharmaceuticals (3). Numerous compounds with potential biological applications frequently present very low solubility in aqueous media, while in organic solvents the solubility is elevated. Because of this, the determination of the ionization constants in water – organic solvent mixture and the calculation of these constants in pure water by means of extrapolations techniques become very useful (4, 5). It must be noted that the variation of nu-

 doi:10.1139/V08-040 © 2008 NRC Canada

merous physicochemical properties of solutes with the solvent and pH form a very attractive field of research, of great interest and applicability (6–9).

Benzophenones (BPs) are aromatic ketones usually obtained from natural products (10) or by methods of organic synthesis (11). The great importance of these compounds results from the varied biological and physicochemical properties that they possess. Due to these properties, BPs are used in the pharmaceutical industry as sunscreen lotions (12), in medicine (13–15), and in the polymer industry (16). Other applications are the design of optical materials (17), the development of asymmetric catalysts (18), and the preparation of UV-protecting coats (19). The effects of substituents on their conformations (20, 21) and the metal complexing ability in hydroxylic solvents were studied (22, 23) for a better understanding of the physicochemical properties of BPs. Nevertheless, it should be noticed that several structural characteristics of BPs in solution have not been completely defined yet.

In this paper and with the aim of contributing to clarify the influence of solvents on the acid–base properties of *p*(OH)BP, the p*K*a value of the compound was determined by means of high performance liquid chromatography (HPLC) in different organic–aqueous solutions, with a permittivity range of 56–70, and using methanol, ethanol, and acetonitrile as organic modifiers. Also, diverse correlations are proposed between the p*K*a values and solvation parameters of the reaction medium, which allow for a calculation of the p*K*a of the compound in pure water. In addition, the structures of ionized and non ionized *p*(OH)BP in organic solvents and water were calculated by means of a B3LYP/6–311++G(d,p) method (Becke hybrid three-parameter nonlocal exchange functional combined with the Lee–Yang–Parr dynamic correlation functional) (24, 25) that makes use of the PCM model (polarizable continuum model) (26).

Experimental

Chemicals and reagents

p(OH)BP from Fluka was purified by repeated crystallization from ethanol–water. The purity control was performed determining its spectroscopic properties (27). NaH_2PO_4 and $NaHCO_3$ from Merck were used without further purification. Methanol (MeOH), ethanol (EtOH), and acetonitrile (ACN), all HPLC grade, from Merck, were degassed and filtered through 0.22 μm nylon filters (Millipore) before use. Milli-Q water was used to prepare the aqueous buffer solutions. All the solutions were prepared by weighting with an accuracy of ±0.0001 g.

Instrumentation

The HPLC instrument consisted of a Gilson 322 series pump (Gilson Inc., Middleton, WI, USA), a Rheodyne 7725i sample injector (Cotati, CA, USA), and a Gilson 152 UV–vis detector, equipped with a Phenomenex column temperature controller. The system was controlled by UniPoint system software v2.10 (Gilson). The analysis was carried out with a reverse-phase Luna (C_{18} (2), 250mm × 4.6 mm, 5 μm) column from Phenomenex (Torrance, CA, USA). Chromatographic studies were performed under isocratic (actually policratic) elution with a mobile phase of aqueous buffer:organic modifier at different ratios, using amphiprotic solvents (MeOH, EtOH), and a low basic aprotic solvent (ACN) as organic modifier with a flow rate of 1.0 mL/min. Column temperature was maintained at a constant 30 °C. The injection volume was 20 μL, and the detector was set at 280 nm. The capacity factor (k) was measured from chromatographic data in the usual way, that is, $k = (T_R - T_o)/T_o$. The mobile phase holds up times were measured by injecting a solution of $K_2Cr_2O_7$ (0.001 mol/L).

The buffers solutions employed were NaH_2PO_4–Na_2HPO_4 covering the pH range from 4.50 to 8.00 and $NaHCO_3$–Na_2CO_3 covering the pH range from 8.00 to 9.00. The ionic strength was maintained at constant value (0.05 mol/L) by adding appropriate amounts of KCl. The pH measurements were performed on an Orion SA 520 pH meter provided with a 91–01 Orion combined glass electrode.

Special precautions must be taken when the pH is measured in a mixed-solvents mobile phase. It is well-known that when the aqueous buffer is added to the mobile-phase mixed solvent, the measured pH of the mixture will be different from the pH measured in the pure aqueous buffer. This problem was recognized and discussed by Rosés et al. (28), among other authors. When the p*K*a value of ionogenic analytes must be measured, it is advisable to perform the measurement of the pH after mixing aqueous buffers and organic modifiers (29), with the electrode previously calibrated with aqueous standard buffers. Such pH value is denoted as ${}^{s}_{w}$pH, and the respective p*K*a values obtained from data expressed in the ${}^{s}_{w}$pH scale leads to a thermodynamically meaningful dissociation constant, also expressed in the same scale (${}^{s}_{w}$p*K*a). In all the experimental determinations carried out in this work, the pH measurements were made following this recommendation, i.e., the pH of the mobile phase was measured after mixing the aqueous buffers with the organic solvents (MeOH, EtOH, and ACN) with the electrode previously calibrated with aqueous buffers, and the ${}^{s}_{w}$pH scale was used to obtain the experimental ${}^{s}_{w}$p*K*a values.

Calculations

The structure of *p*-hydroxybenzophenone adopted for carrying out the calculations is shown in Fig. 1. The calculations were performed following known procedures (22). The initial molecular geometries were modelled by the AM1 (Austin Model vs. 1) method (30). Afterwards, these initial geometries were optimized with the Gaussian 03 (31) programs package. Since diffuse functions are crucial for theoretical treatment of anions (32), the B3LYP/6–311G++(d,p) method (24, 25) was chosen to perform the final optimization of the molecular structures. To analyse the solvent effects on the optimized structures in the gas phase, the PCM model (26) was used. The corresponding frequencies were calculated to make sure that the obtained structures were true minima. In all the calculations, the default convergence criteria were used.

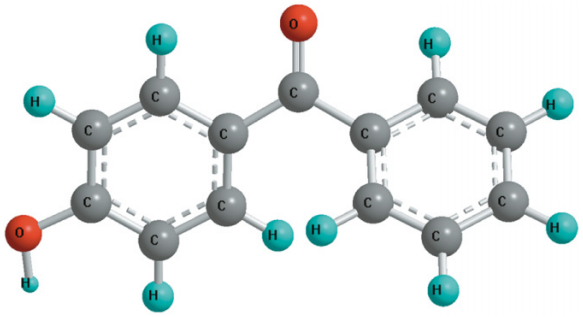
Results and discussion

Determination of p*K*a

The acid–base equilibrium in aqueous solution studied can be represented by the general equation

© 2008 NRC Canada

Fig. 1. Structure adopted in the calculations of *p*-hydroxybenzophenone.



[1] $$AH + H_2O \leftrightarrows A^- + H_3O^+$$

where AH is the weak acid *p*(OH)BP and A^- is the pertinent conjugate base *p*(O^-)BP. The above reaction is characterized by the ionization equilibrium constant (*K*a), conventionally defined as

[2] $$Ka = \frac{a_{A^-} \cdot a_{H_3O^+}}{a_{AH} \cdot a_{H_2O}} = \frac{[A^-][H_3O^+]}{[AH][H_2O]} \cdot \frac{\gamma_{\pm A^-}\gamma_{\pm H_3O^+}}{\gamma_{AH}\gamma_{H_2O}}$$

In this equation, a_{A^-}, $a_{H_3O^+}$, a_{AH} and a_{H_2O} are the activities of the species in equilibrium. The brackets stand for the molar concentration and γ for the molar activity coefficients. The *K*a constant is related to a chromatographic measurable, the capacity factor *k*, by the following equation (33)

[3] $$k = \frac{k_0 + k_1 f_{(1)} Kap\, e^x}{1 + f_{(1)} Kap\, e^x}$$

In the above equation, $x = (\ln 10)pH$, k_0 and k_1 are the limiting capacity factors of *p*(OH)BP and *p*(O^-)BP, respectively, $f_{(1)}$ is the molar activity coefficient ratio between the weak acid and its conjugate base, *K*ap is the apparent equilibrium constant, and the product $Kap \times f_{(1)}$ is the effective acid dissociation constant of the acid AH from eq. [1]. It can be easily demonstrated that $e^x = 1/[H^+]$ and represents the inverse of the proton concentration in the mobile phase. This is the most general equation for the retention factor of the analyzed monoprotic weak acid. Under our experimental conditions (*p*(OH)BP $\approx 1 \times 10^{-4}$ mol/L), the activity coefficient ratios are approximately equal unity, and eq. [3] reduces to eq. [4] (34),

[4] $$k = \frac{k_0 + k_1 Ka\, e^x}{1 + Ka\, e^x}$$

Figure 2 shows the chromatographic results for *p*(OH)BP at different ^s_wpH values with a mobile phase of MeOH : aqueous buffer 39:61 (*v*/*v*). Computer-generated plots of *k* vs. ^s_wpH show typical sigmoidal curves (Figs. 3, 4, and 5) where the ^s_wpH value of the inflection point is the compound ^s_wp*K*a. For the determination of the ^s_wp*K*a value of *p*(OH)BP, eq. [4] was used. The ^s_wp*K*a values were obtained by fitting the data from the measured retention factors as a function of ^s_wpH of the mobile phase, and performing a non-linear least-square iterative procedure. The experimental data were fitted to a rational function equation type 0 [$y = (b + cx)/(1 + ax)$],

Fig. 2. Overlaid chromatograms showing the retention behaviour of *p*-hydroxybenzophenone at different ^s_wpH values (indicated over the peak) in 39% (*v*/*v*) methanol mobile phase, UV detection at 280 nm, flow rate 1 mL/min.

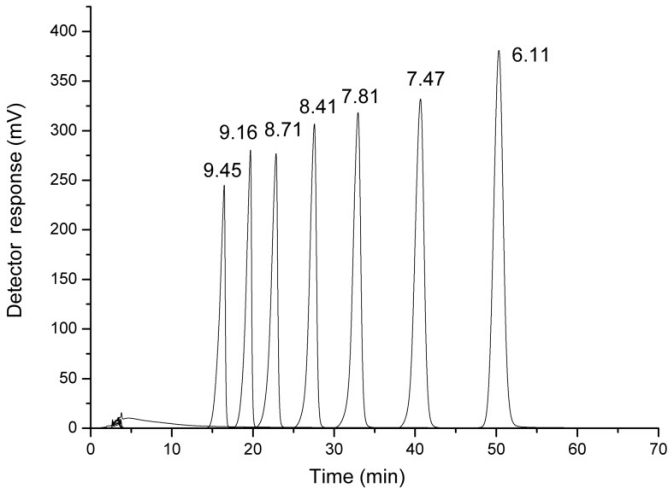


Fig. 3. Measured capacity factors vs. ^s_wpH for *p*-hydroxybenzophenone in methanol:buffer mixtures.

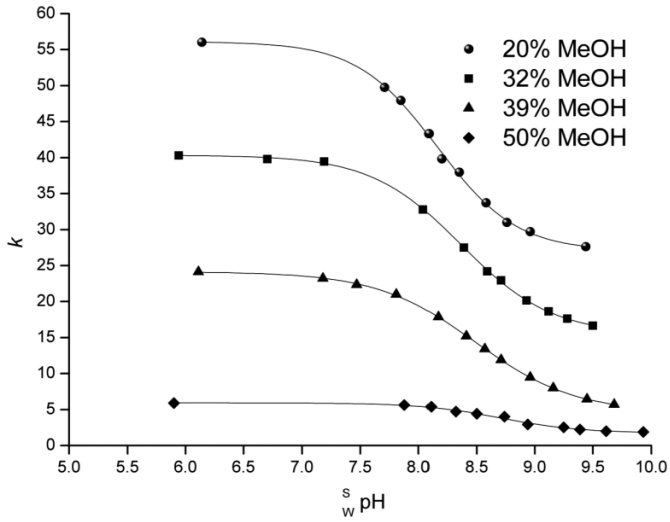

using the software Origin Pro 7.5 (35). Figure 6 shows the results of the fitting process for MeOH:buffer 39:61 (*v*/*v*) mobile phase compositions, and Table 1 reports the ^s_wp*K*a values and limiting capacity factors for *p*(OH)BP obtained in the three solvents under study.

Equation [4] suggests that the retention factor of the solute *k* is a weighted average of the retention factors of the different species that may exist in the mobile phase (34), and this factor may be written as

[5] $$k = X_0 k_0 + X_1 k_1$$

The term X_n ($n = 0, 1$) is the probability that the observed retention factor *k* of the solute is equal to k_n, and it is also the probability of the presence of *p*(OH)BP (if $n = 0$) or the presence of *p*(O^-)BP (if $n = 1$) in the mobile phase expressed as a function of the pH, i.e., it is the relative concentration of the species (the mole fraction) at equilibrium. If $X_0 = 1$, then

Fig. 4. Measured capacity factors vs. $^{s}_{w}$pH for *p*-hydroxybenzophenone in ethanol:buffer mixtures.

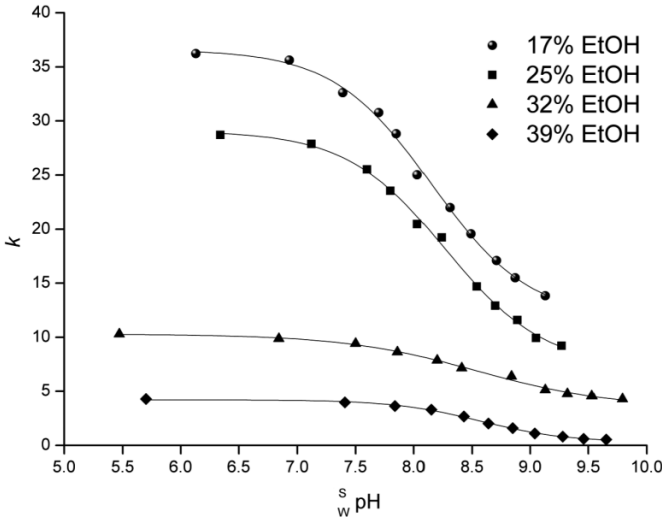

Fig. 5. Measured capacity factors vs. $^{s}_{w}$pH for *p*-hydroxybenzophenone in acetonitrile:buffer mixtures.

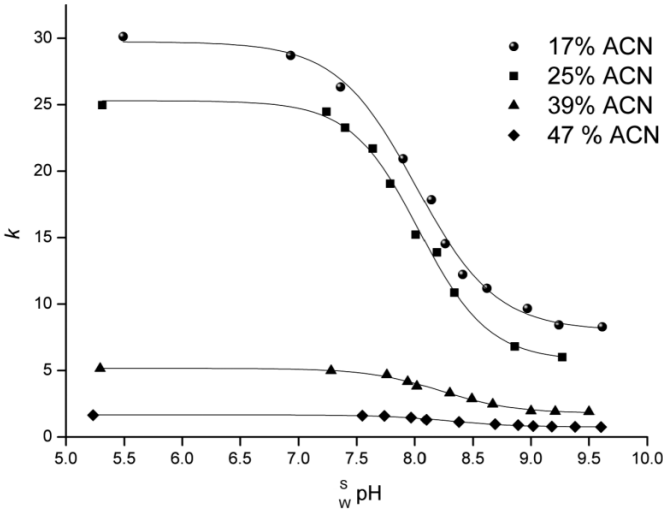


$X_1 = 0$, and only *p*(OH)BP is present in the mobile phase; therefore, the observed retention factor k is exclusively due to the neutral species and equal to k_0. Thus, the distribution of both species at a given pH can be estimated considering that

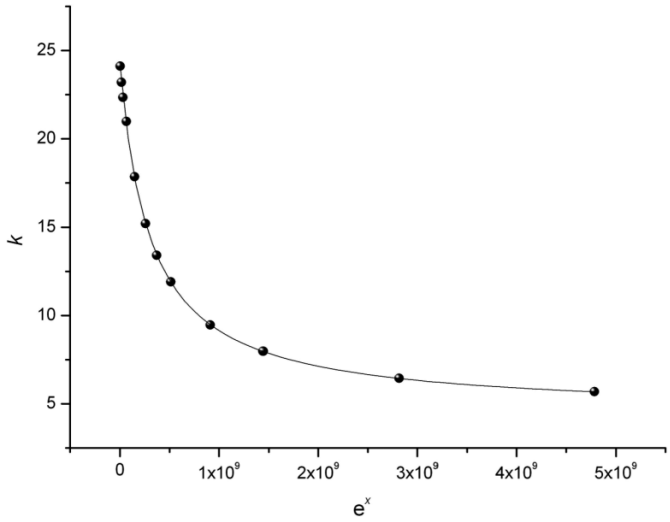
$$[6] \qquad X_1 = \frac{K\mathrm{a}\,\mathrm{e}^{x}}{1 + K\mathrm{a}\,\mathrm{e}^{x}}$$

and

$$[7] \qquad X_0 = 1 - X_1$$

Figure 7 shows the results of the distribution of both *p*(OH)BP and *p*(O^-)BP at a given pH for two different methanol: buffer mobile phase compositions. It can be observed that when pH ≤ 6 the neutral molecule is the prevailing specie ($X_0 = 0.99$), while at pH ≥ 11, the anion is the prevailing specie in solution ($X_1 = 0.99$).

Fig. 6. Plot of the capacity factor of *p*-hydroxybenzophenone against e^x ($x = 10.\ln(^{s}_{w}\mathrm{pH})$) according to eq. [4].



Solvent effects

It is known that one of the most important factors determining the ionization equilibrium constants is the reaction medium. The influence of the solvent upon the specific rate of ion–ion, ion–dipole, or dipole–dipole reactions can be analyzed using the expression by Kirkwood (36, 37).

$$[8] \qquad \ln k = \ln k_0 + \frac{\mathrm{e}^2}{2Dk_\mathrm{B}T}\left[\frac{Z_\mathrm{A}^2}{r_\mathrm{A}} + \frac{Z_\mathrm{B}^2}{r_\mathrm{B}} - \left(\frac{Z_\mathrm{A} + Z_\mathrm{B}}{r_\ddagger}\right)^2\right] + \frac{3}{4Dk_\mathrm{B}T}\left[\frac{\mu_\mathrm{A}^2}{r_\mathrm{A}^3} + \frac{\mu_\mathrm{B}^2}{r_\mathrm{B}^3} - \frac{\mu_\ddagger^2}{r_\ddagger^3}\right]$$

In this equation, k_0 and k are the reaction specific rates for media with infinite and D relative permittivity, e is the unit of electric charge, k_B is Boltzman's constant, T is the absolute temperature, Z_A and Z_B are the charges of the two ions, r is the radius of the involved species, μ stands for the dipolar moments, while the symbol ‡ refers to the activated complex. It is evident that in the acid–base dissociation equilibrium of eq. [1], the forward reaction involves two dipolar molecules, AH and H_2O, while the reverse reaction involves the A^- and H_3O^+ ions. Consequently, applying Kirkwood's equation to these two reactions in equilibrium, eq. [9] was obtained.

$$[9] \qquad {}^{s}_{w}\mathrm{p}K\mathrm{a} = \mathrm{p}K\mathrm{a}^0 + \frac{1}{2.303}\left[\frac{\mathrm{e}^2}{2k_\mathrm{B}T}\left(\frac{1}{r_{\mathrm{A}^-}} + \frac{1}{r_{\mathrm{H_3O^+}}}\right) + \frac{3}{4k_\mathrm{B}T}\left(\frac{\mu_\ddagger^2}{r_\ddagger^3} - \frac{\mu_{\mathrm{AH}}^2}{r_{\mathrm{AH}}^3} - \frac{\mu_{\mathrm{H_2O}}^2}{r_{\mathrm{H_2O}}^3}\right)\right]\frac{1}{D}$$

The $^{s}_{w}$pKa values determined for *p*(OH)BP in MeOH, EtOH, and ACN:water mixtures were plotted against $1/D$ (38, 39) according to eq. [9], and they are shown in Fig. 8. The linear equations included in Fig. 8 indicate that when D

[a]The mobile phase composition is organic modifier: aqueous buffer (*v*/*v*).

Fig. 7. Variation of X_n with the pH at two different methanol:water mobile phase composition. X_0 is the mole fraction of *p*-hydroxybenzophenone, and X_1 is the mole fraction of the *p*-hydroxybenzophenonate anion.

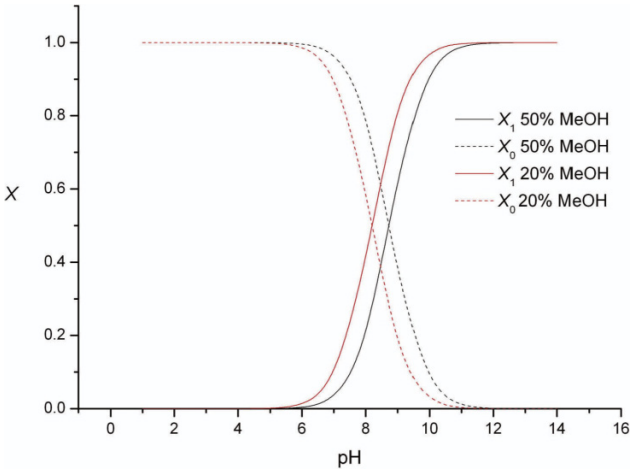

Fig. 8. Plot of the ${}^{s}_{w}$p*K*a of *p*-hydroxybenzophenone against the permittivity of solvent–water solutions at 30 °C, according to eq. [9]. Errors are in parenthesis.

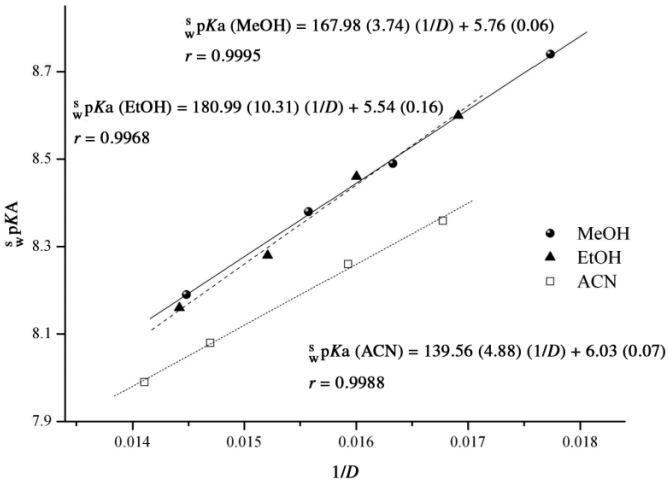

increases, the corresponding ${}^{s}_{w}$p*K*a decreases. As expected, the solvents with greater *D* favour the ionization reaction described by eq. [1]. Although permittivity is important to measure the solvation abilities of solvents, it should be noted that it is not very useful for describing solute–solvent specific interactions. Consequently, we selected the solvation parameter *Acity* (40), which is appropriate for measuring the hydrogen-bond donating ability (HBD capability) of a solvent, i.e., the capability of the solvent to provide a proton. The values of *Acity* determined for ACN, EtOH, MeOH, and water are 0.37, 0.66, 0.75, and 1.00 (41), respectively. The ${}^{s}_{w}$p*K*a values were plotted against the *Acity* parameter of the used organic–aqueous mixtures as shown in Fig. 9. It can be observed that when the *Acity* of the reaction medium increases, the corresponding ${}^{s}_{w}$p*K*a decreases, i.e., the solvents with greater HBD capability favour the acid dissociation reaction of *p*(OH)BP. Moreover, it should also be noted that the limiting capacity factors k_0 and k_1 vary reasonably in a linear way with the *Acity* of the reaction media.

Considering eqs. [10–12] (Fig. 9),

[10] p*K*a (MeOH) = –7.92 (0.49) *Acity* + 15.77 (0.45)

[11] p*K*a (EtOH) = –6.79 (0.39) *Acity* + 14.61 (0.36)

[12] p*K*a (ACN) = –2.20 (0.03) *Acity* + 9.99 (0.02)

and taking into account that *Acity* (H_2O) = 1.00 [41], the ${}^{w}_{w}$p*K*a (p*K*a in pure water) values 7.83, 7.85, and 7.80 were obtained, respectively. These results suggest that the accuracy of the HPLC methodology carried out in this work is very good. In addition, when the obtained ${}^{w}_{w}$p*K*a values are compared with the ${}^{w}_{w}$p*K*a value of 7.51 obtained by means of UV–vis spectroscopy (42), a reasonable agreement is observed.

Table 2 summarizes the calculated Gibbs free energies by means of the B3LYP/6–311++G(d,p) method with the PCM model for all the species involved in the ionization reaction

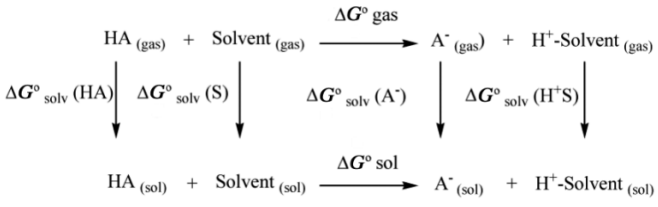
under study. A thermodynamic cycle, shown in Fig. 10, was used to calculate the Gibbs free energy change in solution, ΔG°_{sol}, according to the following equations

[13] $$\Delta G^{\circ}_{gas} = G^{\circ}_{gas}(A^-) + G^{\circ}(H^+S) - G^{\circ}_{gas}(HA) - G^{\circ}_{gas}(S)$$

[14] $$\Delta G^{\circ}_{solv}(X) = G^{\circ}_{solv}(X) - G^{\circ}_{gas}(X) \quad \text{(for X = HA, A}^-\text{, S, and H}^+\text{S)}$$

[15] $$\Delta G^{\circ}_{sol} = \Delta G^{\circ}_{gas} + \Delta G^{\circ}_{solv}(A^-) + \Delta G^{\circ}_{solv}(H^+S) - \Delta G^{\circ}_{solv}(HA) - \Delta G^{\circ}_{solv}(S)$$

Fig. 10. Thermodynamic cycle used to calculate the theoretical acidity constants of *p*-hydroxybenzophenone in solution.



where AH and A$^-$ are *p*(OH)BP and *p*(O$^-$)BP, respectively, S is the solvent molecule, and H^+S is the solvated proton. Equation [15] can be used to calculate ΔG°_{sol}, and therefore p*K*a. The calculated p*K*a (pK_{Theo}) values were

© 2008 NRC Canada

[16] pK_{Theo} (water) = 33.35; pK_{Theo} (MeOH) = 34.64
pK_{Theo} (EtOH) = 35.22; pK_{Theo} (ACN) = 36.27

The above pK_{Theo} values differ from the ones experimentally determined. It must be noted that the calculation of p*K*a values using computational methods is difficult, as there is no simple and accurate way to calculate the Gibbs free energy of the solvated proton. In addition, the pK_{Theo} values are referred to the standard state, which is not the case for the experimental data reported in this paper. Nevertheless, if the calculated pK_{Theo} are analyzed comparatively with each other, it is observed that the theoretical ionization constants vary as the *Acity* parameter of the solvents. This suggests that the conjugate bases are specifically more solvated, according to the *Acity* of the reaction medium, i.e., the pK_{Theo} values of *p*(OH)BP increase when the polarity–polarizability and solvation abilities of the reaction media decrease. This conclusion agrees with experimental observations that indicate that the acid–base equilibria are shifted towards the formations of ions when the polarity–polarizability and HBD capability of the reaction medium increase.

Conclusions

The apparent acidity constant of *p*-hydroxybenzophenone (very slightly soluble drug in water) was determined in diverse organic solvent–water mixtures using a polycratic high-performance liquid chromatographic method based on the Hardcastle–Jano equation. The p*K*a values measured in organic–aqueous solutions were correlated with solvation parameters (relative permittivity and *Acity*) of the reaction medium. Excellent linear equations were proposed from which the p*K*a values in pure water were obtained. The results allowed to infer that the p*K*a values of the compound increase when the polarity–polarizability and solvation abilities of the reaction medium decrease. The molecular structures of all the chemical species involved in the acid–base dissociation equilibria studied were calculated with a B3LYP/6–311++G(d,p) method that makes use of the polarizable continuum model, and the p*K*a values were calculated using a thermodynamic cycle. Considering the theoretical p*K*a values, several conclusions were presented, which are consistent with the experimental determinations. The methodology described in this work is very useful for obtaining the p*K*a of compounds of low solubility in water with adequate accuracy.

REVIEW / SYNTHÈSE

Enzymatic processes for biodegradation of poly(hydroxyalkanoate)s crystals[1]

Keiji Numata, Hideki Abe, and Yoshiharu Doi

Abstract: Poly(hydroxyalkanoate)s (PHAs) have attracted much attention as environmentally compatible polymeric materials that can be produced from renewable carbon resources. Biodegradation of PHA materials occurs by the function of extracellular PHA depolymerase secreted from microorganisms. Thus, elucidation of the enzymatic degradation mechanism for PHA materials is important to design PHA materials with desirable properties and controlled biodegradability. The solid PHA polymer is a water-insoluble substrate but PHA depolymerases are soluble in water. Therefore, the enzymatic degradation of PHA materials is a heterogeneous reaction on the material's surface. Two distinct processes are involved during the degradation, namely, adsorption of the enzyme on the surface of PHA material and the subsequent hydrolysis of polymer chains. Atomic force microscopy (AFM) is a powerful tool that has been used for the quantitative analysis of PHA crystal degradation. AFM enables the characterization of the crystal surface nanostructure in a buffer solution. By using in-situ (real-time) AFM observations, we recently succeeded in observing the degradation processes of PHA crystals. Subsequently, we were also able to investigate the degradation rates of PHA crystals using the same technique. In this review, we have attempted to give an overview concerning the direct visualization of the adsorption, as well as the hydrolysis reactions of PHA depolymerases at the nanometer scale. In addition, we present other analytical techniques besides AFM as a complimentary approach to analyze the effect of enzyme adsorption on PHA crystals.

Key words: poly(hydroxyalkanoate) (PHA), enzymatic degradation, lamellar crystal, PHA depolymerase.

Résumé : Les poly(hydroxyalcanoates) (PHA) attirent beaucoup d'attention en raison de la compatibilité avec l'environnement de ces produits polymères qui peuvent être obtenus à partir de ressources renouvelables de carbone. La biodégradation de ces PHA se produit par la fonction de la dépolymérase extracellulaire des PHA qui est sécrétée par les microorganismes. L'élucidation du mécanisme de la dégradation enzymatique des PHA est donc importante pour le développement des matériaux de type PHA comportant des propriétés désirables ainsi qu'un degré contrôlé de biodégradabilité. Le polymère PHA solide est un substrat insoluble dans l'eau alors que la dépolymérase de PHA est soluble dans l'eau. La dégradation enzymatique des matériaux apparentés au PHA est donc une réaction hétérogène sur la surface des matériaux. Deux processus distincts sont impliqués au cours de la dégradation, soit l'adsorption de l'enzyme sur la surface du PHA et une hydrolyse subséquente des chaînes de polymère. On a utilisé la puissance de la technique de microscopie des forces atomiques (MFA) pour faire une analyse quantitative de la dégradation des cristaux de PHA. La MFA permet de caractériser la nanostructure de la surface cristalline en solution tamponnée. En faisant appel à des observations de MFA *in situ* et en temps réel, on a récemment été capable d'observer le processus de dégradation des cristaux de PHA. Faisant appel à la même technique, on a ensuite été en mesure d'étudier les vitesses de dégradation des cristaux de PHA. Dans cette revue, on essaye de donner une vue d'ensemble concernant la visualisation directe de l'adsorption ainsi que les réactions d'hydrolyse des dépolymérases de PHA à l'échelle du nanomètre. On présente de plus de nouvelles techniques analytiques qui complémentent la MFA pour analyser l'effet de l'adsorption de l'enzyme sur les cristaux de PHA.

Mots-clés : poly(hydroxyalcanoate), PHA, dégradation enzymatique, cristal lamellaire, dépolymérase de PHA.

Introduction

Poly(hydroxyalkanoate)s (PHAs) are synthesized by a variety of bacteria as an intracellular storage material of carbon and energy and their properties have been extensively studied (1–4). Poly[(*R*)-3-hydroxybutyrate] (P(3HB)) was first isolated from *Bacillus megaterium* in 1925 and later identified as a microbial reserve polyester. The identification of hydroxyalkanoate (HA) units, other than the 3HB unit, as constituents of microbial reserve polyesters proved to have a major impact on research and commercial interests in the microbial polyester, since the incorporation of different HA units into P(3HB) can vary its properties (5). Many bacteria have the ability to synthesize optically active homopolymers and copolymers of HA units. The term poly(hydroxyalkanoate) (PHA) is used to refer to the various polyesters derived from these HA units. Recently, Lenz and Marchessault (6) reviewed the history of PHA covering discoveries over a period of 80 years.

One of the unique properties of PHA materials is their biodegradability in various environments (Fig. 1). Since the 1990s, much effort has been redevoted to the investigations of PHA-degrading microorganisms (7–9). PHA is a high molecular weight solid polymer that cannot be transported through the cell wall. Therefore microorganisms, such as bacteria and fungi, excrete extracellular PHA-degrading enzymes (PHA depolymerases) that hydrolyze the solid PHA into the water-soluble monomer and oligomers. These low molecular weight degradation products are then transported into the cell and subsequently metabolized as carbon and energy sources (10).

Unlike the extracellular degradation of crystalline PHA by the PHA depolymerases, the intercellular degradation (also known as mobilization) of PHA granules involves a completely different set of enzymes. Intracellular PHA depolymerase has been studied since the 1960s to elucidate the mechanism of intracellular degradation of the amorphous PHA granules. Merrick and co-workers (11, 12) were the first to study the depolymerization of amorphous P(3HB) granules isolated from *B. megaterium* and they suggested that a thermolabile depolymerase and a thermostable activator are necessary for the depolymerization. In contrast to the intracellular depolymerase, the extracellular depolymerases have received more attention because of the important role they play in the degradation of crystalline PHA in the environment. A number of extracellular PHA depolymerases from various microorganisms have been secreted, and their structure and properties have been studied by many groups (13–24). The PHA-degrading microorganisms and enzymes were first isolated from *Pseudomonas* strains by Chowdhury in 1963 (13). Stinson and Merrick (14) also secreted the extracellular PHA depolymerase from *P. lemoignei* and reported the first biochemical data on PHA depolymerase. In addition, the PHA depolymerases with hydrolytic activity against poly[(*R*)-3-hydroxyvalerate], medium chain-length PHA, and amorphous P(3HB) were also purified and studied (15–17). Analyses of the structural genes of extracellular PHA depolymerases have shown that most of the isolated enzymes have multi-functional domain structures, i.e., a catalytic domain, a substrate-binding domain, and a linker domain, which connects the two domains (18–21). PHA

Fig. 1. Biodegradation process of PHA in a natural environment.

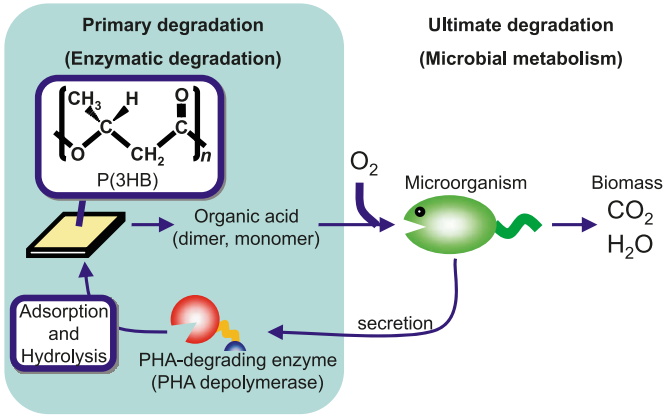

Fig. 2. Typical AFM images of (A) PHA single crystals and (B) melt-crystallized thin films and (C) typical scanning electron micrograph of spherulites in PHA films during enzymatic degradation by PHA depolymerase.

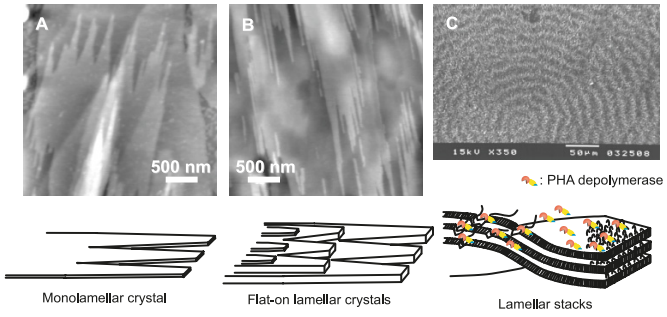

materials in the form of films, thin films, and single crystals have been widely used to elucidate the hydrolytic mechanism of PHA depolymerases (Fig. 2). Besides the hydrolytic mechanism of the catalytic domain, the substrate-binding domain is also of great importance in the degradation process. The effect of the substrate-binding domain on the hydrolytic activity has been studied since the 1980s by several groups (25–27). The hydrophobic substrate-binding domain is an essential component for the adsorption of PHA depolymerase to the hydrophobic surface of PHA.

The substrate specificity of PHA depolymerase was first investigated by using various hydrolases and polymer substrates (28). Substrate-binding specificity, in addition to a substrate-hydrolyzing one was also studied by Doi and coworkers (29). Though the rates of hydrolysis were different among three PHA depolymerases, all PHA depolymerases hydrolyzed the same kinds of films of PHAs that are structurally similar, i.e., P(3HB), poly(3-hydroxypropionate), poly(4-hydroxybutyrate), poly(ethylene succinate), and poly(ethylene adipate). These five polyesters are structurally similar with respect to the number of carbon and oxygen atoms, which is either 3 or 4, in the backbone between two carbonyl groups. In addition to that, the side chain is either a methyl carbon or a hydrogen atom. Therefore, PHA depolymerases show relatively narrow substrate specificity for the hydrolysis reaction of PHAs.

The effects of the chemical structure of second monomer units and copolymer compositions on the rate of enzymatic erosion have been examined through the enzymatic degradation of the solvent-cast films of various PHA copolymers in the presence of PHA depolymerase from *Ralstonia pickettii* T1 (formally *Alcaligenes faecalis* T1) (30). The rate of enzymatic erosion of the solvent-cast PHA films increased markedly with an increase in the fraction of second monomer units, up to 10–20 mol%, to reach a maximum value followed by a decrease in the erosion rate.

The structures and compositions of water-soluble products of PHA copolymers during the enzymatic degradation by PHA depolymerase from *R. pickettii* T1 have been characterized by using high performance liquid chromatography and nuclear magnetic resonance analyses (31, 32). The water-soluble products of random copolymers by the PHA depolymerase showed a mixture of monomers and several oligomers of 3HB and HA units. The water-soluble degradation products of random copolymers have some common chemical structures; the carboxyl-terminus of water-soluble products were always the monomeric units with a main-chain length of 3 or 4 carbon atoms, while the hydroxyl-terminus were always the monomeric units with a side-chain length ranging from 0 to 2 carbon atoms. Based on these results, it was proposed that the active site in the catalytic domain of PHA depolymerase recognizes a sequence of at least three monomeric units as substrate. The rate of enzymatic hydrolysis of an ester bond may be strongly dependent on the chemical structure of the sequential three monomeric units in a polyester chain. This recognition model has been supported by a recent study on the enzymatic hydrolysis of 3HB oligomers by the PHA depolymerase by Bachmann and Seebach (33, 34).

The rate of enzymatic erosion of PHA samples can be regulated not only by the chemical structure of the monomeric units but also by the crystallinity of the polymer. The rate of enzymatic hydrolysis for melt-crystallized P(3HB) films by the PHA depolymerase from *R. pickettii* T1 decreased with an increase in the crystallinity of the P(3HB) film, while the size of spherulites hardly affected the rate of hydrolysis (35). In addition, it was demonstrated that the rate of enzymatic degradation of P(3HB) chains in an amorphous state was approximately 20 times faster than that of P(3HB) chains in a crystalline state.

The thickness of crystalline lamellae for melt-crystallized films also varied with the crystallization conditions. The enzymatic erosion rate of melt-crystallized copolyester films decreased significantly with an increase in the crystallinity. It is suggested that the PHA depolymerase predominantly hydrolyzes polymer chains in the amorphous phase before eroding the crystalline phase (36). In addition, the enzymatic erosion rate of crystalline phases in polyester films was determined from both overall erosion rate and crystallinity. The enzymatic erosion rate of crystalline phases decreased with an increase in the lamellar thickness of the PHA films (30).

PHA depolymerases are water-soluble enzymes. However, the solid P(3HB) polymer is a water-insoluble substrate. Therefore, the enzymatic degradation of P(3HB) material by PHA depolymerase is a heterogeneous reaction, involving two steps, namely, adsorption and hydrolysis; the first step involves the adsorption of the enzyme on the surface of P(3HB) material by the binding domain of enzyme, and the second step involves the hydrolysis of polymer chains by the active site of the enzyme (37–39).

In this review, we have attempted to give an overview of direct atomic force microscopy (AFM) visualization of the adsorption as well as the hydrolysis reactions catalyzed by PHA depolymerases during the degradation process of PHA crystals at the nanometer scale. In addition, we also present other measurement techniques as a complimentary approach to AFM to analyze the enzyme adsorption effect on PHA crystals.

Enzymatic degradation of PHA lamellar crystals

Studies on the enzymatic degradation of films and monolamellar single crystals have shown that the degradation rate of PHA materials is strongly dependent on both the chemical structure of the monomeric unit and on the solid-state structure. With respect to the solid-state structure of PHA materials, the crystallinity and lamellar crystal sizes play a decisive role in the degradation process.

Single crystals, which clearly have a uniform and well-defined structure, are an excellent monolamellar system for studying the enzymatic degradation process. P(3HB) single crystals have been prepared from many kinds of solvents. The surface morphology and crystal structure have been investigated using microscopic analyses (40–47). Typically, P(3HB) forms lath-shaped crystals with dimensions of around 0.3–2 μm and 5–10 μm along the short and long axes, respectively. Based on the electron diffractogram of P(3HB) single crystals, the long axis of P(3HB) single crystals is the crystallographic *a* axis. The thickness of P(3HB) single crystals ranges from 4–10 nm depending on the molecular weight, solvent, and crystallization temperature.

PHA depolymerases from bacteria and fungi have been used to study the enzymatic degradation of P(3HB) single crystals to elucidate the degradation mechanism of the crystalline region for P(3HB). Marchessault and co-workers (40, 41, 44) were the first to perform the enzymatic degradation of P(3HB) single crystals by PHA depolymerases. Hocking et al. (40) carried out the enzymatic degradation of P(3HB) single crystals with PHA depolymerase, and the enzymatic degradation of P(3HB) single crystals was evaluated by turbidimetric and titrimetric assays, as well as by monitoring the changes in molecular weight of the polymer. Nobes et al. (41) used transmission electron microscopy (TEM) to show the conversion of PHA single crystals into needlelike morphologies after enzymatic degradation. Iwata and co-workers (42, 43, 45–47) investigated the enzymatic degradation of single crystals of P(3HB) and its copolymer single crystals by TEM and AFM. All these researchers reported that the single crystals were enzymatically hydrolyzed preferentially at the crystal edges (*ac* plane) and ends (*bc* plane) rather than at the chain-folding surfaces (*ab* plane) of the single crystals. This conclusion was arrived at because the lamellar thickness and molecular weight of P(3HB) crystals remained the same during the enzymatic degradations. The enzymatic reaction produced many narrow cracks and small crystal fragments along the crystal long axis corresponding

© 2008 NRC Canada

to the crystallographic *a* axis of P(3HB) single crystals, which was independent of both surface morphology of the single crystals and the types of PHA depolymerases. As for the single crystals of PHA copolymers, the enzymatic degradation mechanism was found to be the same as in the case of P(3HB) single crystals.

Similar morphological changes in lamellar crystals by enzymatic reaction have been confirmed for the flat-on lamellar crystals formed in melt-crystallized thin films of P(3HB) and its copolymers (Fig. 2B). Following the enzymatic degradation of thin film by a PHA depolymerase, a jagged texture along the crystal long axis could be observed at the ends of crystalline lamellae on the surface of the thin film (48–50).

A scanning electron microscopic observation (Fig. 2C) revealed that the surfaces of melt-crystallized PHA films after enzymatic degradation obviously blemished after the action of PHA depolymerase, whereby a ringed texture of spherulites was detected (30). Two different types of planes, i.e., smooth and rough planes, can be observed on the surface of PHA spherulites after enzymatic degradation. The smooth and rough planes exist alternately along the radial direction of spherulite. As a result, lamellar stacks on the surface of melt-crystallized films have also been hydrolyzed preferentially at the crystal edge by PHA depolymerase.

By using an AFM, we recently performed a quantitative characterization of the dimensions of the fibril-like crystals generated at the edge of lamellar crystals during enzymatic degradation (50, 51). A typical AFM image of the PHA single crystals after enzymatic degradation for 1 h is shown in Fig. 3. The thickness of the major part of the remaining crystals was almost identical with the crystals before degradation, as reported previously (41–43). The thickness at the root of fibril-like crystals (Fig. 3*a*) was almost identical to the thickness of the single crystals before degradation. The thickness of the intermediate region of fibril-like crystals (Fig. 3*b*) was slightly decreased compared to the thickness of the original single crystals. We found that the thickness at the tip of the fibril-like crystals (Fig. 3*c*) was apparently thinner than the thickness of the single crystals before degradation. It is of interest to note that the fibril-like crystals did not taper completely, whereby we did not observe any crystals with dimensions of either less than 1.9 nm thickness or less than 28 nm width for all the PHA samples after degradation at 37 °C for 1 h. These minimum values of thickness and width of fibril-like crystals may mean that the critical dimensions to maintain the crystalline lamellar structure of P(3HB) are by the intermolecular chain-packing.

Based on these results, we have proposed a mechanism for the enzymatic degradation mechanism of fibril-like crystals generated from PHA single crystals, as shown in Fig. 4. The PHA single crystals may consist of both ordered and disordered chain-packing regions that exist in a periodic manner due to the crystallization characteristic of P(3HB) molecules (52–54). PHA depolymerase adsorb homogeneously on the edges, ends, and chain-folding crystalline surfaces. The adsorbed enzymes predominantly hydrolyze the polymer molecules at the disordered chain-packing regions in single crystals from the edges and ends, as shown in Fig. 4B. As a result, the ordered chain-packing regions remain as fibril-like crystals. Figure 4E demonstrates that the

Fig. 3. (A) AFM amplitude images and cross-sections ((*a*), (*b*), and (*c*)) of fibril-like crystals generated from P(3HB) single crystals during enzymatic degradation by PHA depolymerase. White lines in (A) are the distance of the cross-section shown in (*a*), (*b*), and (*c*). (B) Each dimension of the fibril-like crystal is defined as in the schematic representation (ref. 51).

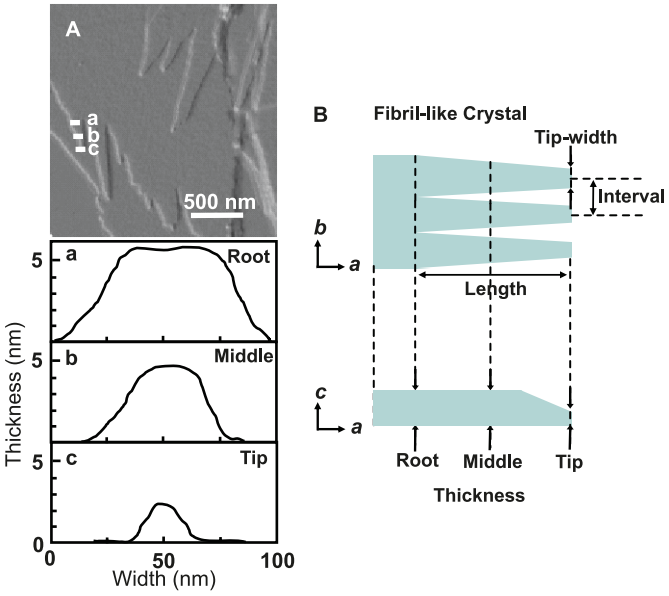

Fig. 4. Schematic model of the enzymatic degradation process of PHA lamellar crystals by the PHA depolymerase from *R. pickettii* T1 (ref. 51).

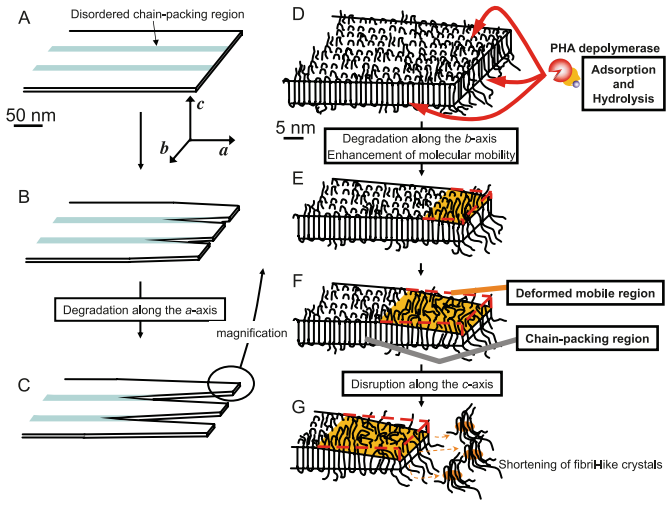

enzymes adsorbed on the fibril-like crystals also erode the ordered chain-packing region from the edge, which results in the tapering of the fibril-like crystals down to a minimum width of approximately 28 nm. In addition, the adsorption of enzyme on the fibril-like crystals may also enhance the molecular mobility in ordered chain-packing regions. Subsequently, the molecular packing structure in the ordered chain-packing region is gradually distorted starting from the chain-folding surface along the crystallographic *c* axis to reach a minimum value (around 1.9 nm), as shown in Fig. 4F. The tapping mode AFM was used for the dimen-

© 2008 NRC Canada

sional analysis of PHA single crystals. The AFM cantilever tip may penetrate the distorted crystalline region on the chain-folding surface that formed following the adsorption of PHA depolymerase. Therefore, the measured thickness may reflect the thickness of the remaining ordered chain-packing region beneath the distorted crystalline region. The remaining ordered chain-packing region will be progressively eroded from the edge by the catalytic action of the enzyme. At the same time, adsorption of the enzyme on the chain-folding region will produce surface distortion. Together, both these effects will reduce the crystal dimensions to the minimum values at which the lamellar structure at the tip of the fibril-like crystal will collapse as is shown in Fig. 4G at the tip of the glacier. As a result of these degradation processes, the tip of the fibril-like crystals will fragment into smaller pieces, which will eventually be hydrolyzed to water-soluble dimers and monomers by the PHA depolymerase.

Direct observations of the enzymatic degradation processes for PHA crystals

As mentioned above, the enzymatic degradation process of lamellar crystals has been characterized mainly by measuring changes in the crystal morphologies of dried samples before and after enzymatic degradation using various microscopic techniques. Although this method has enabled us to determine and understand the factors involved in the degradation process, the molecular mechanism of enzyme adsorption and hydrolysis reaction are still poorly understood. For this, a direct observation method is crucial. To obtain direct information on the enzymatic degradation process of PHA lamellar crystals, the real-time observations of enzymatic degradation have been applied by using AFM under aqueous condition.

Shakesheff and co-workers (55–57) were the first to study the real-time degradation process of aliphatic polyesters at the spherulitic level by using AFM. Kikkawa et al. (49, 58) succeeded in observing the real-time changes in lamellar morphologies during enzymatic degradation of P(3HB) copolymer thin film by AFM. AFM techniques have also been applied to biological studies, e.g., characterization of PHA granules (59–61).

The realtime AFM imaging of the lamellar crystals during enzymatic degradation have been investigated further by our group (50, 51). Figure 5 shows typical real-time AFM height images of P(3HB) single crystals during enzymatic degradation. Enzymatic erosions proceeded from the edges and ends of lamellar crystals, and the fibril-like crystals were obviously generated gradually by the action of PHA depolymerase. Figure 6 shows AFM amplitude images of five types of PHA single crystals after degradation for 1 h. Each of the images in Fig. 6 shows that the fibril-like crystals were formed along the long axis of all single crystals after enzymatic degradation. The results revealed the effect of both the molecular weight and the second-monomer composition on the morphology of fibril-like crystals.

As shown in Fig. 5, the grooves were formed along the crystallographic *a* axis, and the erosions of fibril-like crystals progressed from both the tip of crystals along the *a* axis and the edges along the *b* axis. The eroded distances at the tip and edge of fibril-like crystals and at the point of the grooves were determined from the real-time AFM images by measuring distances from the fixed spot in the images to the edges and ends of eroding crystals. Figure 7 shows the time-dependent changes in eroded distances at the root and tip of PHA fibril-like crystals. The eroded distances along the *a*

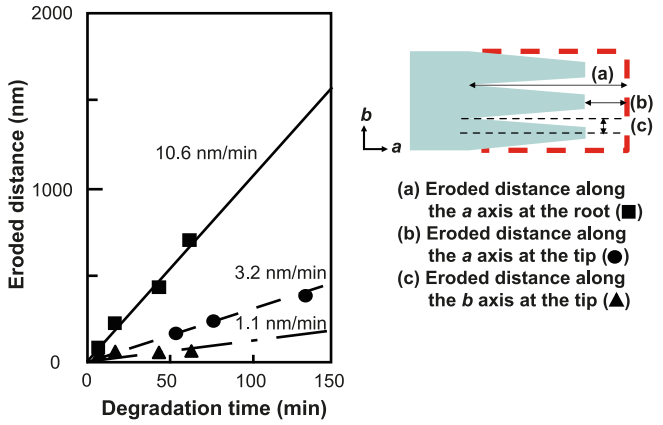
Fig. 7. (*a*) Time-dependent changes in eroded distance along the crystallographic *a* axis at the root and (*b*) and (*c*) along the *a* and *b* axes at the tip of the fibril-like crystal in L-P(3HB) (M_n: 8500) single crystals, respectively. The data in the graphs were calculated from the real-time AFM images during enzymatic degradation by PHA depolymerase *R. pickettii* T1 at 37 °C. The illustration represents the kind of eroded distance in a lamellar crystal as shown in the vertical axis of the graph (ref. 51).



and *b* axes of fibril-like crystals changed linearly with time, and the erosion rates of single crystals were calculated from the slope of the line plot of the eroded distance against time.

Figure 7 shows time-dependent changes in eroded distance along (*a*) the crystallographic *a* axis at the root and (*b*) and (*c*) along the *a* and *b* axes at the tip of the fibril-like crystal in P(3HB) single crystals. Table 1 lists the erosion rates at the tip and edge of fibril-like crystals and the point of the grooves and overall erosion rates of PHA single crystals. For the single crystals of P(3HB) with a molecular weight of 8500, the grooves grew along the crystallographic *a* axis at a rate of 10.6 nm/min. The fibril-like crystals were eroded from the tip of the crystals along the *a* axis at a rate of 3.2 nm/min and from the edges along the *b* axis at a rate of 1.1 nm/min. For the single crystals of P(3HB) with different molecular weights, the erosion rate at the point of the grooves along the *a* axis increased with a decrease in the molecular weight of P(3HB), while those at the tip of fibril-like crystals along the *a* and *b* axes revealed relatively similar values, independent of molecular weight. As mentioned above, the formation of grooves is attributed to the degradation of disordered chain-packing regions in single crystals. As the molecular weight of P(3HB) is decreased, the number of the chain ends increases on the crystalline surface. With an increase in chain end groups, the disordered chain-packing region may become increasingly unstable. In addition, PHA depolymerase easily hydrolyzes the P(3HB) molecules from the chain ends exposed on the surface of single crystals. Therefore, the erosion rate at the grooves (disordered chain-packing region) increased with a decrease in the molecular weight of P(3HB). In contrast, the erosion rates along the *a* and *b* axes at the tip of fibril-like crystals was similar, independent of the molecular weight, for all P(3HB) samples. All the fibril-like crystals consist of highly ordered chain-packing regions. Moreover, the erosion rate along the *a* axis of fibril-like crystals reflected the degradation rate at the tip of the crystals. The packing structure of

such highly ordered crystalline regions may be slightly influenced by the number of chain-foldings and chain ends. As shown in Table 1, the morphology of fibril-like crystals formed after enzymatic degradation for 1 h varied with the molecular weight of P(3HB). The length of fibril-like crystals became shorter with an increase in molecular weight. The erosion rates at the grooves of P(3HB) single crystals increased with a decrease in molecular weight, while the erosion rates at the tip of fibril-like crystals were almost similar. Additionally, the erosion rates at the grooves of P(3HB) single crystals were faster than those at the tip of fibril-like crystals, and the length of fibril-like crystals increased with degradation time. Therefore, we concluded that the length of fibril-like crystals is governed by the ratio of the erosion rates at the grooves and at the tip of the crystals (50, 51).

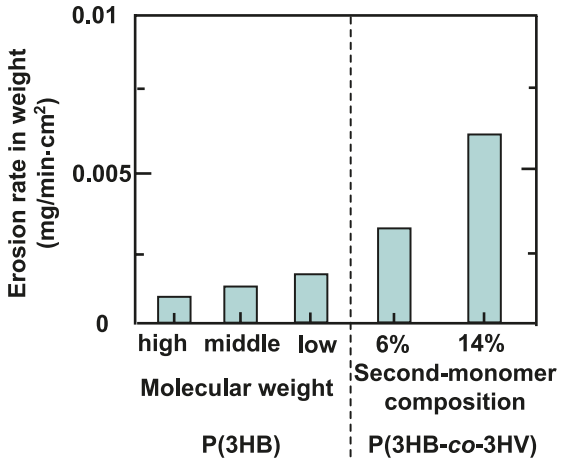
For poly[(*R*)-3-hydroxybutyrate-*co*-(*R*)-3-hydroxyvalerate] (P(3HB-*co*-3HV)) samples, both the erosion rates at the point of the grooves and at the tip of fibril-like crystals along the *a* axis increased significantly with an increase in the 3HV composition, whereas the rates at the edges along the *b* axis were slightly increased by the introduction of 3HV units. However, the lengths and intervals of the fibril-like crystals for P(3HB-*co*-3HV) samples had relatively similar values, independent of the 3HV composition, although all of these values were apparently smaller than those of P(3HB) samples. As shown in Table 1, the difference of erosion rates at the grooves and at the tip of fibril-like crystals for P(3HB-*co*-3HV) was slightly smaller than that of P(3HB). Therefore, the lengths of fibril-like crystals for P(3HB-*co*-3HV) samples became shorter than those of P(3HB) samples. Thus, the morphologies and sizes of fibril-like crystals were established by the erosion rates along the *a* axis at the grooves and tip of the fibril-like crystals (50, 51).

The enzymatic erosion rate of PHA single crystals was also estimated by the volumetric analysis from real-time AFM height images (51). By considering the density of the P(3HB) crystalline region, the changes in the volume of single crystals during enzymatic degradation can be converted into changes in weight. Figure 8 shows the rate of erosion weight for PHA single crystals during enzymatic degradation. The results of overall erosion rates from AFM measurements were comparable to the enzymatic erosion rates of melt-crystallized film, reported by Abe et al. (30), implying that we succeeded in analyzing the overall erosion rate of PHA single crystals during enzymatic degradation by real-time AFM observation. For P(3HB) single crystals, the overall erosion rates increased with a decrease in the molecular weight of P(3HB), similar to the erosion rates at the grooves. The overall degradation rates of P(3HB-*co*-3HV) single crystals were much faster than those of P(3HB) single crystals. Thus, we succeeded in estimating the enzymatic erosion rate of crystalline region from the real-time AFM height images.

Direct observations of PHA depolymerase

Direct observations of PHA depolymerase molecules is important to elucidate the adsorption process of enzymes towards the polymer substrate. Visualization of the PHA

Fig. 8. Enzymatic erosion rates in weight of PHA single crystals by PHA depolymerase from *R. pickettii* T1 at 37 °C. The number averaged molecular weights of high, middle, and low molecular weight P(3HB) are 240 000, 55 000, and 8500, respectively. The values in this graph were calculated from the degraded volume measured from the real-time AFM images.



depolymerase adsorbed on the P(3HB) and its copolymers single crystals was performed using immuno-gold labeling techniques by Iwata et al. (42, 43, 45). They demonstrated by TEM that the PHA depolymerase molecules labeled by gold particles were distributed homogeneously on the surfaces of single crystals, and concluded that the enzyme molecules adsorb randomly on the crystal surface.

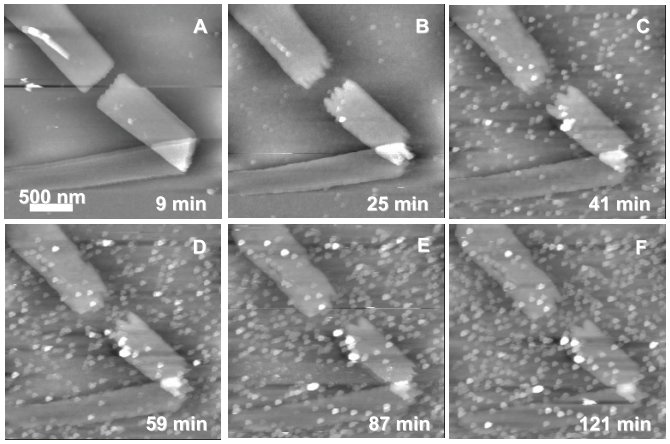
Kikkawa et al. (62) first observed the molecule of PHA depolymerase adsorbed on the poly(L-lactide) (PLLA) thin film directly by using AFM, and found that the PHA depolymerase appeared elliptic in shape when bound on the surface of the film. They reported that the average dimensions of PHA depolymerase from *R. pickettii* T1 were 2.8 ± 0.5 nm in height and 23 ± 3 nm in width on PLLA thin film in water.

For the purpose of visualizing PHA depolymerase during enzymatic reaction with PHA lamellar crystals, we have characterized the adsorption behaviors of PHA depolymerase from *R. pickettii* T1 on P(3HB) single crystals and silicon wafers by AFM observations in air and in a buffer solution (63, 64). PHA depolymerase adsorbed on the silicon wafer was characterized to determine the single molecular dimension, and it was found that the PHA depolymerase had dimensions of 2.2 ± 0.7 nm high and 16 ± 5 nm wide. The observation of PHA depolymerase adsorbed on P(3HB) single crystals indicated that the enzyme on the crystalline surface in air was 1.2 ± 0.5 nm high and 28 ± 7 nm wide, while dimensions of 2.1 ± 0.6 nm high and 16 ± 7 nm wide were detected in the buffer solution. A comparison of the dimensions of PHA depolymerase in air and in water revealed that the enzyme was squashed in air but not in water, suggesting that the AFM observation in the buffer solution could reveal the native morphology of PHA depolymerase.

We also carried out the real-time AFM observations of PHA depolymerase adsorbed onto P(3HB) single crystals in the enzyme solution (64). Initially, the surface of P(3HB) single crystals in the buffer solution was characterized by

© 2008 NRC Canada

Fig. 9. Real-time AFM height images of the typical enzymatic reaction process onto P(3HB) single crystals by the PHA depolymerase from *R. pickettii* T1. The concentration of the enzyme was 0.5 μg/mL. These images were obtained in a phosphate buffer solution (pH 7.5) at 37 °C (ref. 64).



AFM in the absence of PHA depolymerase. As shown in Fig. 9A, small particles were not detected on the surface of P(3HB) single crystals in the buffer solution. Real-time AFM observations of PHA depolymerase adsorbed onto P(3HB) single crystals were recorder after adding concentrated enzyme solution into the buffer solution. Figure 9B–9F shows the AFM height images of PHA depolymerase adsorbed onto P(3HB) crystals. As shown in Fig. 9B–9F, PHA depolymerase adsorbed randomly onto the surface of P(3HB) single crystals without any preference towards crystalline edges, ends, or surfaces.

Adsorption specificity of PHA depolymerase substrate-binding domain

Extracellular PHA depolymerases are typically comprised of three functional domains. It has been suggested that the C-terminal domain acts as a substrate-binding domain for the water-insoluble P(3HB) substrate, since the PHA depolymerase lacking the C-terminal domain lost the hydrolyzing activity towards the water-insoluble P(3HB), while it retained the activity towards water-soluble 3HB oligomers. This is because the binding of PHA depolymerase to substrate is necessary for the degradation of water-insoluble polymer substrate (65).

Kasuya et al. (29) investigated the binding-specificity of three types of PHA depolymerases and the fusion proteins of substrate-binding domains of PHA depolymerases with glutathione *S*-transferase for various polymeric substrates. Based on the adsorption study using PHA depolymerases and fusion proteins, PHA depolymerases were found to have the ability to bind on the surfaces of both enzymatically degradable and non-degradable polyesters, while they hardly bind to the polysaccharides of Avicel or chitin. These results suggest that several specific interactions that facilitate molecular recognition exist between the substrate-binding domain and the surface of polyesters.

Yamashita et al. (66) studied the adsorption of PHA depolymerase from *R. pickettii* T1 onto thin films of PLLA, poly(3-hydroxyoctanoate) (PHO), polystyrene (PS), and polyethylene (PE), using quartz crystal microbalance (QCM) techniques. They reported that the rate of adsorption of PHA depolymerase decreases in the following order: PLLA >> PHO > PS >> PE. It has been suggested that the binding domain has an affinity not only for polyesters but also for PS, indicating that hydrophobic interactions partially contribute to the affinity of the binding domain.

The binding specificity of PHA depolymerase to PHA single crystals has also been evaluated by using immuno-gold labeling techniques (42, 43, 45). In both cases of P(3HB) homopolymer and copolymer single crystals, the adsorption of PHA depolymerase showed a homogeneous distribution on the surfaces of single crystals, suggesting that the substrate-binding domain contributes to the random adsorption of enzyme on P(3HB) crystals. However, the concentrations of adsorbed enzyme on the surface of copolymer single crystals are slightly lower than that of P(3HB) homopolymer single crystals. PHA depolymerase molecules cannot bind tightly to the irregular surface of copolymer crystals by hydrophobic adsorption since the copolymer chains with second monomer units have loose-loop foldings.

To further clarify the binding specificity of the substrate-binding domain of PHA depolymerase, we quantitatively measured the amount of the enzyme molecules adsorbed on single crystals of various polymers by using a catalytically inactive mutant enzyme and AFM (67). The number of enzyme molecules adsorbed on each single crystal was counted from AFM images, and it was found that the quantity of adsorbed enzyme molecules increased in the following order: PE (56 ± 6 enzymes/μm^2) < poly[(*R*)-3-hydroxybutyrate-co-8 mol% (*R*)-3-hydroxyhexanate] (84 ± 13 enzymes/μm^2) << P(3HB) (171 ± 23 enzymes/μm^2) ≈ P(3HB-co-6 mol% 3HV) (183 ± 35 enzymes/μm^2) < poly(D-lactide) (PDLA) (227 ± 26 enzymes/μm^2) ≈ PLLA (253 ± 23 enzymes/μm^2). The mutant enzyme adsorbs onto PE single crystals, but the number of the adsorbed enzymes is significantly lower than the number of enzymes capable of adsorbing onto the P(3HB) single crystals. If the chemical structure and the surface property of PE single crystals are taken into consideration, the mutant enzyme is likely to adsorb onto the surface of PE crystals through non-specific hydrophobic interaction. Equally, this result suggests that the PHA depolymerase binds to polymer crystals, not only by hydrophobic interaction but also by specific interaction between the ester bonds of polyesters and the binding domain. Moreover, the numbers of enzyme molecules adsorbed onto the PLLA and PDLA single crystals were apparently higher compared with those adsorbed onto the P(3HB) and P(3HB-*co*-6 mol% 3HV) single crystals. Based on the hydrophobic characteristics and density of ester bonds at the surface of polyester crystals, the number of adsorbed enzymes may be dependent on the amount of ester bonds rather than the hydrophobicity of crystals.

Adsorption and desorption of PHA depolymerase on crystal surfaces

It has been reported that the rate of enzymatic erosion of P(3HB) by PHA depolymerase is strongly dependent on the concentration of the enzyme (37, 38, 68). The rate of enzymatic hydrolysis increased to a maximum value with the

© 2008 NRC Canada

concentration of PHA depolymerase, followed by a gradual decrease. Accordingly, the kinetic behavior of P(3HB) hydrolysis has been accounted for in terms of a surface-enzymatic reaction.The hydrolysis of P(3HB) chains takes place through the surface reaction between adsorbed enzymes and free adsorption points on the surface. In this kinetic deal, the ratio of the surface-occupation of enzyme molecules is given by the Langmuir adsorption. Based on the kinetic analyses of the enzyme adsorption on the surface of P(3HB), it has been confirmed that the adsorption isotherms of PHA depolymerase are expressed by the Langmuir adsorption equation (69). It has been concluded that at low concentrations of PHA depolymerase the majority of catalytic domains of adsorbed enzyme are able to hydrolyze P(3HB) chains on the surface, while at high concentrations of enzyme the majority of catalytic domains are not accessible to P(3HB) chains on the surface due to a dense coverage of the substrate-binding domains on the surface of P(3HB).

Recently, Yamashita et al. (70) determined the amount of enzyme molecules adsorbed on P(3HB) films using catalytically inactive mutant enzymes by QCM (70). They found that the adsorption isotherm of PHA depolymerase with P(3HB) films could not be satisfied by any set of parameters for the Langmuir equation. Furthermore, they determined the changes in rate of enzymatic degradation of P(3HB) film by the replacement of the wild-type enzyme solution with a pure buffer solution or the mutant enzyme solution. When the wild-type enzyme solution was replaced with the mutant enzyme solution in the middle of the reaction, the degradation rate was remarkably reduced. On the other hand, replacement with a pure buffer solution hardly affected the degradation rate (Fig. 10A). From these results, they suggested that each molecule of PHA depolymerase adsorbs irreversibly on the P(3HB) film surface, while it is easily substituted by the attack of the enzyme molecules in the solution. As a result, it seems that the apparent adsorption isotherms of PHA depolymerase obeys the Langmuir isotherm.

We confirmed the irreversible adsorption manner of PHA depolymerase on the P(3HB) crystals using the technique to visualize enzyme molecules by AFM (64). As shown in Fig. 9 of the continuous AFM images of the reaction process, the enzyme molecule of PHA depolymerase from *R. pickettii* T1 adsorbed on the P(3HB) single crystals remained at the same position during the observation for 121 min. This result suggests that the enzyme molecule of *R. pickettii* T1 interacts strongly with the P(3HB) molecules, and that the adsorption of the enzyme takes place irreversibly.

Brucato and Wong (22) purified and characterized the PHA depolymerase from a strain of *Penicillium funiculosum*. The enzyme has a molecular mass of 37 kDa, and the value is apparently smaller than typical PHA depolymerases from other strains (around 50 kDa). Kasuya and co-workers (23) reported that the PHA depolymerase from *P. funiculosum* degrades P(3HB) and a trimer of 3HB, though the degradation of P(3HB) is less efficient by two orders of magnitude in comparison with the enzyme from *R. pickettii* T1. They speculated that the enzyme from *P. funiculosum* lacks a substrate-binding domain. Although a large number of PHA depolymerases have been discovered, the three-dimensional structure has been obtained only for the enzyme from *P. funiculosum* by Hisano et al. (24). The enzyme is shown

Fig. 10. Time courses of frequency changes (F) observed during enzymatic degradation of P(3HB) thin films by two types of PHA depolymerases from (A) *R. pickettii* T1 and (B) *P. funiculosum* at 37 °C. The concentrations of the enzyme were 1.0 and 5.0 μg/mL, and the pH of the buffer were 7.5 and 6.0, respectively. As indicated by arrow 1, the degradation reaction was started by the injection of enzyme solution at time 0 h. After 2 h of reaction, the enzyme solution was replaced with a pure buffer solution (at the point denoted by arrow 2). The solid line is the frequency changes for the enzymatic degradation without replacement of enzyme solution with a pure buffer (control) (ref. 64).

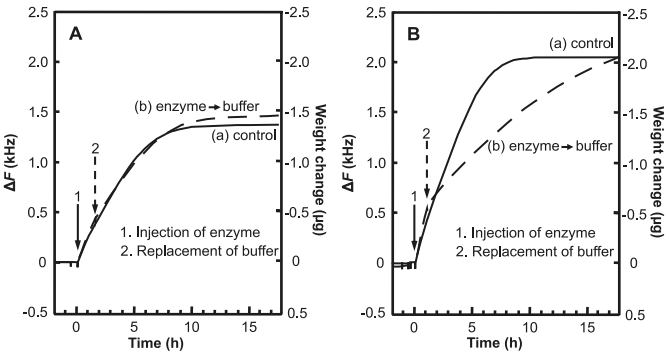


Fig. 11. A molecular surface representation of the PHA depolymerase from *P. funiculosum* centering on the mouth of the crevice. Positions of solvent-exposed hydrophobic residues (purple), as well as polar (green), and catalytic triad (cyan) residues, are indicated. A model of the 3HB trimer bound in the crevice is shown as a yellow stick model (ref. 24).

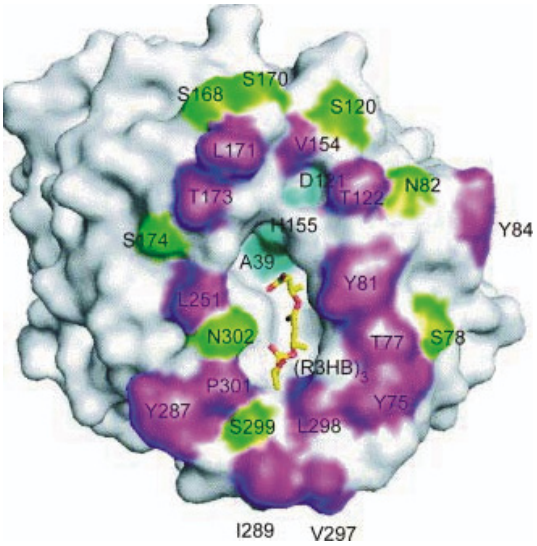


to be a globular molecule with approximate dimensions of 5.2 nm × 4.8 nm × 4.1 nm and with a single domain (Fig. 11). In addition, it was suggested that 13 hydrophobic residues around the active site induce the enzyme to bind onto polymer chains without a substrate-binding domain. Furthermore, a cDNA encoding PHA depolymerase from *P. funiculosum* was cloned, and the homology analysis showed that the enzyme lacks linker and substrate-binding domains (71).

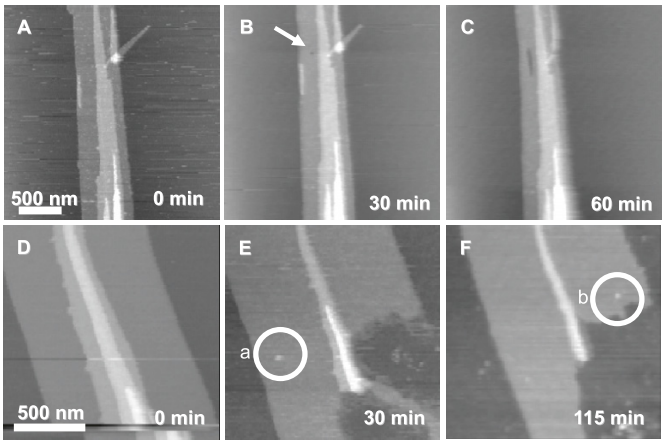
© 2008 NRC Canada

To compare the adsorption mechanisms between the two types of PHA depolymerases with different domain structures, we carried out the real-time AFM observations using P(3HB) single crystals and PHA depolymerase from *P. funiculosum* (64). It has been reported that the catalytic domain of the enzyme from *P. funiculosum* resembles that of *R. pickettii* T1 in the α/β hydrolase folds despite the difference in the position of the lipase box in the catalytic domain of each enzyme (24). Thus, compared with the difference in the binding domain between the two types of PHA depolymerases, the difference in the catalytic domain is considerd to have little influence on the degradation process observed by AFM in this study. Figure 12 shows the typical real-time AFM height images of the enzymatic degradation process of P(3HB) single crystals in a phosphate buffer solution containing the PHA depolymerase from *P. funiculosum*. In Fig. 12B, the white arrow indicates the location where the enzyme degraded initially, and subsequently a hole was generated at the same location. As the reaction progressed, the P(3HB) single crystal was split at the hole along the crystallographic *a* axis, in a manner similar to the case of PHA depolymerase from *R. pickettii* T1. However, no enzyme molecule was observed by AFM around the hole and cleft created by the enzyme. Although many repeated observations were carried out by real-time AFM, we rarely succeeded in visualizing the enzyme molecules from *P. funiculosum* (Fig. 12D–12F). In contrast to the PHA depolymerase from *R. pickettii* T1, the enzyme molecule at (*a*) in Fig. 12E disappeared from the surface of single crystal, even though the crystal that the enzyme adsorbed on was hardly degraded. Here, it should be noted that the enzyme molecules attached on the surface of P(3HB) single crystals were detected in the AFM images obtained in air after enzymatic treatment with PHA depolymerases from *P. funiculosum*. The number of attached enzyme molecules of *P. funiculosum* was relatively the same as that of *R. pickettii* T1. This result indicates that the PHA depolymerase from *P. funiculosum* has the ability to adsorb onto the surface of P(3HB) single crystals.

The adsorption of PHA depolymerase from *P. funiculosum* was also confirmed by QCM measurement (64). Although the replacement of enzyme solution of *P. funiculosum* with a buffer solution reduced the degradation rate of P(3HB) film, the enzymatic erosion of P(3HB) film could be detected continuously (Fig. 10B). This result suggests that the PHA depolymerase from *P. funiculosum* adsorbs onto the surface of P(3HB) thin films to degrade P(3HB) molecules, but the adsorbed enzyme is easily released from the P(3HB) film in aqueous conditions. The occurrence of reversible adsorption and desorption of enzyme molecule makes it difficult to capture the adsorbed enzyme molecules on the P(3HB) single crystals in the real-time AFM images.

Such difference in the binding affinity of two enzymes may be caused by the difference in the domain structure, and is reflected in the adsorption manner of enzymes. The PHA depolymerase from *R. pickettii* T1 is anchored to the substrate surface via the substrate-binding domain by strong affinity towards P(3HB) molecules. The absence of substrate-binding domain decreases the binding affinity of the enzyme from *P. funiculosum* compared to the enzyme from *R. pickettii* T1, resulting in the easy release of the adsorbed enzyme molecule, which is easily released from the substrate surface. Thus, the substrate-binding domain of PHA depolymerase facilitates the interactions of the catalytic domain with the polyester chains.

Fig. 12. Continuous AFM height images of the typical enzymatic reaction process onto P(3HB) single crystals by the PHA depolymerase from *P. funiculosum*. The frames (A) and (D) were recorded before the enzymatic reaction, and the following images were obtained during enzymatic reaction ((B), (C) (E), and (F)). The concentration of the enzyme was 0.5 μg/mL. These images were obtained in a phosphate buffer solution (pH 6.0) at 37 °C. The white arrow and circles denote the hole generated by the enzymatic degradation and enzyme molecules, respectively, (ref. 64).



Other functions of the substrate-binding domain of PHA depolymerase

As discussed earlier, the substrate-binding domain is primarily responsible for the adsorption of the PHA depolymerase to the surface of water-insoluble polyester materials. However, in recent years, it has been proposed that the substrate-binding domain has another function in addition to its adsorption role (62, 72). Murase et al. (72) have studied the morphological change of P(3HB) single crystals during the adsorption of the catalytically inactive mutant PHA depolymerase. They showed that the adsorption of the mutant PHA depolymerase contributed to the formation of cracks along the long axis of the P(3HB) single crystals and suggested that the adsorption of PHA depolymerase with the substrate-binding domain disturbs the molecular chain packing in P(3HB) single crystals. Also, Kikkawa et al. (62) observed two types of PHA depolymerases adsorbed on amorphous PLLA films, and demonstrated the formation of small hollows on the PLLA film after removal of the adsorbed enzyme.

We also investigated the morphological changes at the surface of P(3HB) single crystals by the adsorption of PHA depolymerase using real-time AFM observation (63). Figure 13 shows the continuous AFM images of the surface of a P(3HB) single crystal before and after the removal of PHA depolymerase. A PHA depolymerase molecule was observed on a P(3HB) crystal before the removal of the enzyme, subsequently a concavity as wide as the enzyme molecule

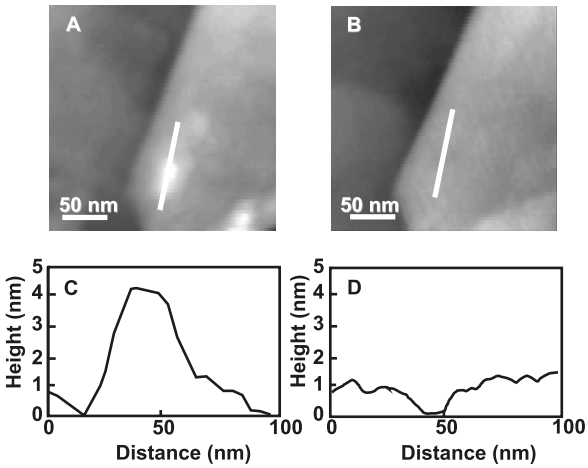
Fig. 13. Real-time AFM height images of P(3HB) single crystal degraded by PHA depolymerase for 30 min (A) before and (B) after washing with ethanol solution and then recorded in Milli-Q at 20 °C. (C) and (D) Line profile data of the white lines in (A) and (B), respectively, (ref. 63).

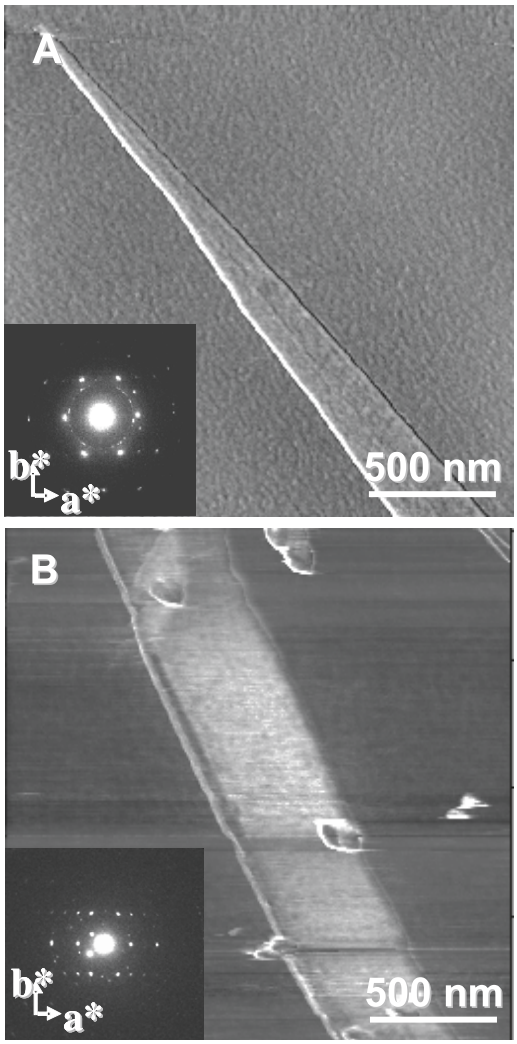


(25 nm in width) was generated after removing the enzyme. To determine the changes in the molecular properties of the crystalline surface due to the adsorption of PHA depolymerase, AFM height and phase images were recorded for the P(3HB) single crystal after removing the enzyme. The concaved area revealed dark contrast in the AFM phase image, indicating that the surface of the concaved area is softer than the surface of the chain-folded crystal. This result suggests that the adsorption of PHA depolymerase causes changes in the molecular state at the surface of P(3HB) single crystals.

To elucidate any additional functions for the substrate-binding domain, we further investigated the changes in surface properties of polymer single crystals after the adsorption of PHA depolymerase by using frictional force microscopy (FFM) (67). Figure 14 shows FFM images and electron diffraction patterns of the P(3HB) single crystals before and after enzymatic treatment with a catalytically inactive mutant enzyme for 1 h. The electron diffraction data revealed that the enzymatic adsorption has little influence on the crystal structure and the molecular packing state within the crystal. However, it was found that the frictional force values after the enzymatic treatment apparently decreased in comparison with those before the enzymatic treatment. The decrease in frictional forces for P(3HB) and its copolymers deduced that the adhesion of PHA depolymerase onto the chain-folding surface containing ester bonds causes partial disordering of the molecular folding at the surface of single crystals. Thus, the adsorption effect will induce the initial step of the enzymatic degradation.

Recently, the binding interaction of PHA depolymerase from *R. pickettii* T1 on P(3HB) and PLLA thin films were investigated by AFM (73). The adhesive forces between polyester substrates and the substrate-binding domain of PHA depolymerase by using AFM cantilever tips immobilized with the substrate-binding domain were measured, and the adhesive force of a single molecule with the substrate-binding domain was estimated to be about 100 pN for both P(3HB) and PLLA. Furthermore, it was suggested that the

Fig. 14. FFM images of single crystals for P(3HB) (A) before and (B) after the enzymatic treatment by mutant PHA depolymerase. These images were obtained at 25 °C under reduced pressure conditions (10^{-5}–10^{-6} torr). Each inset shows the typical electron diffraction pattern of the single crystal after the enzymatic treatment (ref. 67) (1 torr = 133 322 4 Pa).



PHA depolymerase interacts specifically with polyester surfaces by electrostatic interaction and hydrogen bonding, in addition to hydrophobic interaction, and that several amino acid residues in the substrate-binding domain take part in the adsorption reaction. In summary, the substrate-binding domain of PHA depolymerase interacts with polyester molecules via various affinities by several amino acid residues, and hence the chain-folding surface of PHA lamellar crystals is disordered and deformed by the adsorption of enzyme molecule.

Conclusion and future perspectives

In this review, the studies on the enzymatic processes for biodegradation of PHA lamellar crystals by microscopic and quantitative analyses were summarized. The information integrated in this review concerning the reaction processes between PHA depolymerases and PHA crystals will enable the

© 2008 NRC Canada

design and synthesis of biodegradable polymers with controlled degradation rates in the natural environment. For the practical use of PHAs as biodegradable materials, their degradation rate should be controlled by chemical structure and solid-state properties. Also, the degradation process of PHA crystals is the rate-determining step, and hence it is important to carry out further investigation on the enzymatic processes and mechanisms for biodegradation of PHA lamellar crystals.

Based on the results obtained to date, it can be proposed that the degradation process of PHA lamellar crystals can be divided into five steps as follows: (*i*) PHA depolymerase adsorbs onto and then deforms the chain-folding surface of PHA crystals, (*ii*) the enzyme attacks the chain-end of PHA molecules composing PHA lamellar crystals, (*iii*) lath-shaped PHA lamellar crystals are degraded into fibril-like crystals, (*iv*) the fibril-like crystals are collapsed into small lamellae and molecular aggregations, and (*v*) the PHA molecules are hydrolyzed into its oligomer, dimer, and monomer. This review has focused especially on steps (*i*) and (*iii*). Step (*ii*), which is the starting reaction of the enzymatic process, is not obvious at the nanometer scale until now because it is not possible to follow the starting reaction by AFM and the other equipment. In the near future, it is essential to investigate step (*ii*) – the initial step of the hydrolysis of PHA lamellar crystals, namely the hydrolysis of the chain end of PHA molecules at the surface of the PHA crystals to control the starting reaction of biodegradation of PHA materials. This is because the practical use of PHAs in various areas would materialize if we can control not only the degradation rate but also the start of the degradation reaction of PHA materials.

REVIEW / SYNTHÈSE

Polysaccharide nanocrystal reinforced nanocomposites[1]

Alain Dufresne

Abstract: There are numerous examples of animals or plants that synthesize extracellular high-performance skeletal biocomposites consisting of a matrix reinforced by nanosized crystalline domains. Cellulose and chitin are classical examples of these reinforcing elements, which occur as whisker-like microfibrils that are biosynthesized and deposited in a continuous fashion. In many cases, this mode of biogenesis leads to crystalline microfibrils that are almost defect-free, and whose axial physical properties therefore approach those of perfect crystals. During the last decade we have attempted to mimic biocomposites by blending cellulose or chitin whiskers from different sources with polymer matrices. Aqueous suspensions of such nanocrystals can be prepared by acid hydrolysis of the substrate. The object of this treatment is to dissolve away regions of low lateral order so that the water-insoluble, highly crystalline residue may be converted into a stable suspensoid by subsequent vigorous mechanical shearing action. The resulting nanocrystals occur as rod-like particles or whiskers, whose dimensions depend on the nature of the substrate. They are typically a few hundred nm long and between 5 and 20 nm in diameter. Starch can also be used as a source for the production of nanocrystals. The constitutive nanocrystals appear as platelet-like nanoparticles with a length ranging between 20 and 40 nm, a width ranging between 15 and 30 nm, and a thickness ranging between 5 and 7 nm. Since the first announcement of using cellulose whiskers as a reinforcing phase, they have been used extensively as model fillers in several kinds of polymeric matrices, including synthetic and natural ones. Casting mixtures of polysaccharide nanocrystals and lattices led to the production of nanocomposite materials with drastically enhanced mechanical properties, especially at $T > T_g$ of the matrix, by virtue of the formation of a whiskers network, even when the whisker volume fraction was only a few percent. The formation of this rigid network, resulting from strong interactions between whiskers, was assumed to be governed by a percolation mechanism. This hydrogen-bonded network induced a thermal stabilization of the composite up to 500 K, the temperature at which polysaccharides start to decompose. Any factors that perturb the formation of this percolating network directly affect the reinforcing effect of polysaccharide nanocrystals. In addition to some practical applications, the study of these nanocomposite materials can help researchers understand such physical properties as the geometric and mechanical percolation effect.

Key words: nanocomposites, polysaccharide, polymer, cellulose, nanocrystal.

Résumé : Il existe de nombreux exemples d'animaux ou de plantes qui synthétisent des biocomposites haute performance constitués d'une matrice renforcée par des domaines cristallins de taille nanométrique. La cellulose et la chitine sont des exemples classiques de ces éléments de renfort qui se présentent sous la forme de microfibrilles biosynthétisées et arrangées de manière régulière. Ce mode de biogenèse conduit généralement à des microfibrilles cristallines pratiquement exemptes de défauts présentant donc des propriétés physiques axiales proches de celles du cristal parfait. Au cours de la dernière décennie, nous avons tenté de mimer ces biocomposites en mélangeant des whiskers de cellulose ou de chitine de différentes sources avec des matrices polymères. Des suspensions aqueuses de ces nanocristaux peuvent être préparées par hydrolyse acide du substrat. L'objectif de ce traitement est de dissoudre les régions de faible cohésion de sorte que le résidu insoluble fortement cristallin soit transformé en une suspension stable par une action mécanique de cisaillement vigoureuse. Les nanocristaux résultants se présentent sous forme de particules en bâtonnet ou whiskers, dont les dimensions dépendent de la nature du substrat. Leur longueur typique est de l'ordre de 100 nm et le diamètre varie entre 5 et 20 nm. L'amidon peut également être utilisé comme source pour la préparation de nanocristaux. Ces nanocristaux se présentent sous forme de plaquettes de longueur comprise entre 20 et 40 nm, de largeur

située entre 15 et 30 nm et d'épaisseur comprise entre 5 et 7 nm. Depuis la première étude sur l'utilisation des whiskers de cellulose comme phase renforçante, ceux-ci ont été largement utilisés comme charge modèle dans différents types de matrice polymère, synthétique ou naturelle. Le mélange de nanocristaux polysaccharide et de latex par coulée permet d'obtenir des matériaux nanocomposites avec des propriétés mécaniques nettement améliorées, notamment à $T > T_g$ de la matrice, grâce à la formation d'un réseau de whiskers, même pour des fractions volumiques de whiskers de quelques pourcents. Il a été proposé que la formation d'un réseau rigide, résultant d'interactions fortes entre whiskers, est gouverné par un mécanisme de percolation. Ce réseau obtenu par liaisons hydrogène conduit à la stabilisation du composite jusqu'à 500 K, température à partir de laquelle les polysaccharides se décomposent. Tout facteur qui perturbe la formation de ce réseau percolant affecte directement l'effet de renfort des nanocristaux polysaccharides. Hormis des applications pratiques, l'étude de ces matériaux nanocomposites peut aider à la compréhension de certaines propriétés physiques comme les phénomènes de percolation géométrique et mécanique.

Mots-clés : nanocomposites, polysaccharide, polymère, cellulose, nanocristal.

[Traduit par la Rédaction]

Introduction

Nanoscience and nanotechnology refer to the science and technology of materials that extend from about 100 nm down to atomic orders of magnitude around 0.2 nm and to the physical phenomena and material properties observed when operating in this size range. Conceptually, nanocomposites refer to multiphase materials where at least one of the constituent phases has one dimension less than 100 nm. This field has attracted the attention, scrutiny, and imagination of both scientist and industrial communities in recent years. A large window of opportunity has opened to overcome the limitations of traditional micrometer-scale composites. Research in this field is exploding because of the intellectual appeal of building blocks on the nanometer scale and because the technical innovations permit the design and creation of new materials and structures which possess unprecedented flexibility, improved physical properties, and significant industrial impact.

Some nanofilled polymer composites such as those filled with carbon black or fumed silica have been used for more than a century. A variety of clays such as montmorillonite and organoclays have been used to obtain unusual nanocomposites, by exploiting the ability of the clay silicate layers to disperse into polymer matrices. The development of new nanocomposite materials is restricted by both the limited availability of nanoparticles and their strong tendency to aggregate, preventing their homogeneous dispersion within a continuous matrix, which is the key step required for high mechanical performances.

A possible source of inspiration is nature and its wonderful nanocomposite structures. Among biologically inspired nanocomposites, polysaccharides are among the most promising sources for the production of nanoparticles. These abundant biorenewable raw materials are increasingly used in non-food applications. They can also be used for the preparation of crystalline nanoparticles with different geometrical characteristics providing a wide range of potential nanoparticle properties. Huge quantities of these nanoparticles are potentially available, often as waste products from agriculture. Moreover, polysaccharides offer significant potential for surface modification using well-established carbohydrate chemistry, allowing researchers to tailor the surface functionality of the nanoparticles. In this field, the scientific and technological challenges are tremendous.

Polysaccharide nanocrystals

Stable aqueous suspensions of polysaccharide nanocrystals can be prepared by acid hydrolysis of the biomass. Throughout this chapter, different descriptors of the resulting suspended colloidal particles will be used, including whiskers, monocrystals, and nanocrystals. The term "whiskers" is used to designate elongated rod-like nanoparticles. These crystallites have also been referenced in the literature as microfibrils, microcrystals, or microcrystallites, despite their nanoscale dimensions. Most of the studies reported in the literature refer to cellulose. A recent review reported the properties and application in the nanocomposite field of cellulosic whiskers (1).

The procedure for the preparation of such colloidal aqueous suspensions is described in detail in the literature for cellulose and chitin (2, 3). The biomass is generally first submitted to a bleaching treatment with NaOH in order to purify the cellulose or chitin by removing other constituents. The bleached material is then disintegrated in water, and the resulting suspension is submitted to a hydrolysis treatment with acid. The amorphous regions of cellulose or chitin act as structural defects and are responsible for the transverse cleavage of the microfibrils into short monocrystals under acid hydrolysis (4, 5). Under controlled conditions, this transformation consists of the disruption of amorphous regions surrounding and embedded within the cellulose or chitin microfibrils while leaving the microcrystalline segments intact. It is ascribed to the faster hydrolysis kinetics of amorphous domains compared to crystalline ones. The resulting suspension is subsequently diluted with water and washed by successive centrifugations. Dialysis against distilled water is then performed to remove free acid in the dispersion. Complete dispersion of the whiskers is obtained by a sonication step. The dispersions are stored in the refrigerator after filtration to remove residual aggregates with the addition of several drops of chloroform. Determination of the whisker content can be done by weighing aliquots of the solution before and after drying.

Table 1. Geometrical characteristics of polysaccharide nanocrystals from various sources: length (L) and cross section (D) of rod-like particles obtained from acid hydrolysis of cellulose or chitin.

Nature	Source	L (nm)	D (nm)	Ref.
Cellulose	Algal (*Valonia*)	>1000	10–20	(6)
	Bacterial	100–several 1000	5–10 × 30–50	(7)
	Cladophora	—	20 × 20	(8)
	Cotton	100–300	5–10	(9)
	Cottonseed linter	170–490	40–60	(10)
	MCC	150–300	3–7	(11)
	Sisal	100–500	3–5	(12)
	Sugar beet pulp	210	5	(13)
	Tunicin	100–several 1000	10–20	(14)
	Wheat straw	150–300	5	(15)
	Wood	100–300	3–5	(16)
Chitin	Crab shell	80–600	8–50	(17)
	Riftia tubes	500–10 000	18	(18)
	Shrimp	50–300	5–70	(19)
	Squid pen	150–800	10	(20)

This general procedure has to be adapted depending on the nature of the substrate. The constitutive nanocrystals occur as elongated rod-like particles or whiskers. The precise physical dimensions of the crystallites depend on several factors, including the source of the cellulose or chitin, the exact hydrolysis conditions, and ionic strength. The typical geometrical characteristics for crystallites derived from different species are reported in the literature are collected in Table 1. The length is generally of the order of a few hundred nanometers and the width is of the order of few nanometers. The aspect ratio of these whiskers is defined as the ratio of the length to the width.

Aqueous suspensions of starch nanocrystals can be prepared according to the "lintnerization" procedure described in the literature (21). Degradation of native starch granules by acid hydrolysis depends on many parameters, including those related to the botanical origin of the starch, namely its crystalline type, granule morphology (e.g., shape, size, and surface state), and relative proportion of amylose and amylopectin. It also depends on the acid hydrolysis conditions, namely the acid type, acid concentration, starch concentration, temperature, hydrolysis duration, and stirring. The kinetics of lintnerization shows two main steps. During the initial step, the hydrolysis kinetics is fast and corresponds to the hydrolysis of amorphous domains. In the second step, the hydrolysis kinetics is slow and corresponds to the hydrolysis of crystalline domains.

The main drawbacks to the use of such hydrolysis residues in composite applications are the duration (40 days of treatment) and the yield (0.5 wt%) of the hydrochloric acid hydrolysis step (21). Response surface methodology was used (22) to investigate the effect of five selected factors on the selective sulfuric acid hydrolysis of waxy maize starch granules in order to optimize the preparation of aqueous suspensions of starch nanocrystals. These predictors were temperature, acid concentration, starch concentration, hydrolysis duration, and stirring speed. With a starch concentration of 14.69 wt%, the preparation of aqueous suspensions of starch nanocrystals was achieved after 5 days of hydrolysis with 3.16 mol/L H_2SO_4 at 40 °C and 100 rpm, with a yield of 15.7 wt%. Waxy maize starch nanocrystals consist of platelet-like particles about 5–7 nm thick, 20–40 nm long, and 15–30 nm wide. The structure of these platelet-like nanoparticles was investigated in detail (23). Such nanocrystals are generally observed in the form of aggregates having an average size around 4.4 μm, as measured by laser granulometry (24).

The stability of resulting suspensions depends on the dimensions of the dispersed particles, their size polydispersity, and the surface charge. The use of sulfuric acid for preparing polysaccharide nanocrystals leads to more stable aqueous suspensions than the use of hydrochloric acid (24). Indeed, the H_2SO_4-prepared nanoparticles present a negatively charged surface while the HCl-prepared nanoparticles are not charged.

Surface modification of nanocrystals

The stability of aqueous suspensions of surface-charged nanocrystals has an electrostatic origin. One of the characteristics of polysaccharide nanoparticles with polar surfaces is their poor dispersibility or compatibility with nonpolar solvents or resins. Reducing their surface energy and improving their level of dispersion in a polymeric matrix are difficult. Strategies have been considered to broaden the number of possible polymer matrices and to allow the processing of nanocomposite materials from organic solvent solutions instead of using aqueous suspensions.

Dispersion of cellulose nanoparticles in low polarity solvents was reported after either coating or chemical modification of the surface of cellulose whiskers. Coating of cotton and tunicin whiskers by a surfactant such as a phosphoric ester of polyoxyethylene nonyl phenyl ether was found to lead to stable suspensions in toluene and cyclohexane (25) or chloroform (11). The dispersion of cellulose whiskers in an apolar solvent allows the application of an electric field for

© 2008 NRC Canada

times sufficient for the visual observation of the orientation and the preparation of aligned dried samples. Indeed, the use of a non-aqueous medium avoids the limitations arising from the high conductivity of water, as reported for tunicin whiskers suspended in cyclohexane (37). Cellulose whiskers orient parallel to an electric field, but perpendicular to a magnetic field. This axial orientation was assumed to originate mainly from a positive dielectric anisotropy of the nanoparticles.

Modifying the surface chemistry of nanocrystals is another way to disperse these nanoparticles in organic solvents. It generally involves reactive hydroxyl groups at the surface. Indeed, polysaccharides bearing a high concentration of hydroxyl groups in each glucose residue offer various possible coupling reactions. Goussé et al. (27) stabilized tunicin microcrystals in tetrahydrofuran (THF) by a partial silylation of their surface. At a low degree of substitution (DS), between 0.6 and 1, the whiskers kept their morphological integrity and became dispersible in solvents of low polarity, leading to stable birefringent suspensions when observed between cross polars. However at a DS greater than one, the core of the whiskers became silylated and it was no longer possible to obtain any birefringent suspension. Grunert and Winter (7) reported the preparation of bacterial cellulose nanocrystals that were topochemically trimethylsilylated. Resulting nanoparticles were dispersed in acetone to produce nanocomposites with a cellulose–acetate–butyrate matrix. Araki et al. (28) prepared original sterically-stabilized aqueous rod-like cellulose microcrystal suspensions by a combination of HCl hydrolysis, oxidative carboxylation, and grafting of poly(ethylene glycol) (PEG) having a terminal amino group on one end using water soluble carbodiimide. The PEG-grafted microcrystals displayed greatly enhanced dispersion stability evidenced through their resistance to the addition of 2 mol/L sodium chloride. They also could be redispersed into either water or chloroform from the freeze-dried state.

Alkenyl succinic anhydride (ASA) can be used for acylating the surface of polysaccharide nanocrystals. ASA is widely used as a sizing agent in papermaking, where it is applied to pulp fibers in aqueous systems. Surface chemical modification of chitin whiskers prepared by acid hydrolysis of chitin from crab shells, waxy maize starch nanocrystals, and tunicin whiskers with ASA was reported by Gopalan Nair et al. (29), Angellier et al. (30), and Yuan et al. (31), respectively. In the first two works, researchers used organic solvents to avoid hydrolysis of ASA. Gopalan Nair et al. (29) achieved acylation of chitin whiskers in a dioxane system with 4-(dimethylamino)pyridine as the catalyst. The reaction was carried out for 1 week at 70 °C. FTIR, TEM, and contact angle measurements were performed to prove the occurrence of the surface modification without any major morphological changes of the nanoparticles associated with the treatment applied. Stable toluene suspensions of the modified whiskers were obtained, showing colloidal behavior when observed between crossed polars. Angellier et al. (30) used the toluene–(dimethylammo)pyridine system to modify starch nanocrystals. Modified nanoparticles were characterized by FTIR and XPS spectroscopy, contact angle measurements, TEM, and X-ray diffraction analysis. The lower polarity of the modified nanocrystals was demonstrated by their migration to the methylene chloride phase from the aqueous phase. Yuan et al. (31) used a drying aqueous emulsion method to obtain acylated tunicin whiskers. The degree of esterification of modified cellulose nanoparticles was evaluated by FTIR and XPS spectroscopy, elemental analysis, and weight gain. The acylated whiskers were found to disperse in medium- to low-polarity solvents. It was shown that by controlling the heating time, whiskers with different dispersibility could be obtained. Isocyanates, such as phenyl isocyanate (PI) and 3-isopropenyl-α-α'-dimethylbenzyl isocyanate (TMI), were also used to chemically modify the surface of chitin whiskers and starch nanocrystals (29, 30).

The creation of stable suspensions of cellulose whiskers in dimethylformamide (DMF) without the addition of a surfactant or any chemical modification was also reported (32, 33). Both the high value of the dielectric constant of DMF and the medium wettability of cellulose whiskers were assumed to control the stability of the suspension. Indeed, the maintenance of the disperse state of cellulose nanoparticles requires the existence of an opposing interparticle repulsion, achieved in this case through electrostatic forces between charged whiskers. Use of DMF should allow researchers to avoid the use of water as a solvent for composites processing and to mask hydroxyl groups from the surface of nanocrystals that play an important role in the reinforcing effect of these nanoparticles, as will be seen below.

A promising new process consists of transforming polysaccharide nanocrystals into a co-continuous material through long-chain surface-chemical modification, based on the use of grafting agents bearing a reactive end group and a long "plasticizing" tail. The general objective of this surface-chemical modification is of course to increase the apolar character of the nanoparticle. From this procedure, biocomposite materials based on fully-renewable resources could be processed by classical methods such as hot-pressing, extrusion, injection molding, or thermoforming from these co-continuous materials. Very little work has been performed in this way.

Thielemans et al. (34) reported the chemical modification of starch-derived nanocrystals with poly(ethylene glycol) methyl ether (PEGME) and stearic acid chloride. Toluene 2,4-diisocyanate (2,4-TDI) was used to graft the PEGME to the starch surface. Successful surface modification was confirmed using FTIR and XPS spectroscopy and differential scanning calorimetry (DSC) as well as contact angle measurements. Efficient and complete surface coverage was confirmed and the starch crystalline structure was not affected. X-ray diffraction showed extensive crystallization of the stearate moieties grafted at the starch nanoparticles surface, forming a crystalline hydrophobic shell around the hydrophilic starch nanocrystal. Both modifications exhibited a large effect on the individualization of the nanocrystals owing to reduced hydrogen bonding and polar interactions between the individual particles.

The described surface modifications clearly change the character of the nanocrystal surfaces and their activity. Long-chain surface modifications can offer some extraordinary possibilities. The surface modifications can act as binding sites for active agents in drug delivery systems or for toxins in purifying and treatment systems. These surface modifications may also be able to interdiffuse, upon heating,

© 2008 NRC Canada

to form a polymer matrix phase. The covalent linkage between reinforcement and matrix will result in near-perfect stress transfer at the interface with exceptional mechanical properties of the composite as a result. The large surface area, inherent in the small size of nanoparticles, guarantees high surface activity and high grafting per unit mass of particles. Their small size also reduces the required chain length for interdiffusion to assure sufficient matrix phase cohesion. The described surface modifications have a layer thickness of the order of magnitude of the thickness of the starch nanoparticles.

In a recent work (35), we reported the possibility of grafting longer polymer chains onto starch nanocrystals. Monocrystalline starch nanoparticles were successfully grafted with polytetrahydrofuran, polycaprolactone, and poly(ethylene glycol) monobutyl ether chains using TDI as the linking agent. Surface grafting was confirmed using FTIR and XPS spectroscopy, DSC and elemental analysis, and contact angle measurements. Transmission electron microscopy (TEM) observations of modified starch nanocrystals showed either the individualization of nanoparticles or the formation of a film, depending on the polymer used. It was shown that grafting efficiency decreased with the length of polymeric chains, as expected.

Processing of nanocomposites

Because of the high stability of aqueous polysaccharide nanocrystal dispersions, water is the preferred processing medium. A high level of dispersion of the filler within the host matrix in the resulting composite film is expected when processing nanocomposites in aqueous medium. Therefore, this restricts the choice of the matrix to hydrosoluble polymers. The use of aqueous dispersed polymers (i.e., latexes) is a first alternative, which allows the use of hydrophobic polymers as matrix and ensures good dispersion of the fillers, indispensable for processing homogenous composites. Dispersing polysaccharide nanocrystals in non-aqueous media is a second alternative and it opens other possibilities for nanocomposites processing.

In the first report of the preparation of polymer nanocomposites reinforced with polysaccharide nanocrystals, a latex, obtained by the copolymerization of styrene and butyl acrylate (poly(S-co-BuA)) and with a glass transition temperature (T_g) around 0 °C, and tunicin whiskers were used (14). Composite materials are generally obtained by casting and evaporation. The dispersion of polysaccharide nanocrystals in nonpolar media can be obtained by chemically modifying their surface.

Microstructure

The easiest way to assess the dispersion of the polysaccharide nanocrystals within the host polymeric matrix is a simple examination with the naked eye. Addition of a filler to a transparent polymeric matrix results in a loss of transparency. Because of the nanoscale dimensions of reinforcing nanoparticles, the nanocomposite film remains transparent and opacity suggests the presence of aggregates of micrometric sizes. Polarized optical microscopy was used to observe and follow the growth of polyoxyethylene (POE) spherulites in films reinforced with tunicin whiskers (36). For the unfilled POE matrix, birefringent spherulites were clearly identified through the characteristic Maltese cross pattern indicating a spherical symmetry. Reinforced with 10 wt% tunicin whiskers, the supermolecular structure was found to be quite different. It was observed that the spherulites exhibited a less birefringent character, most probably due to a weakly organized structure. It was supposed that the cellulosic filler interfered with the spherulite growth and that during growth the whiskers were ejected and then occluded in interspherulitic regions. The high viscosity of the filled medium most probably restricted this phenomenon and limited the size of the spherulites.

Scanning electron microscopy (SEM) is generally employed for the more extensive morphological inspection of polysaccharide nanocrystal reinforced polymers. This technique leads to conclusions about the homogeneity of the composite, the presence of voids, the dispersion level of the nanoparticles within the continuous matrix, the presence of aggregates, sedimentation, and the possible orientation of rod-like particles. By comparing the micrographs showing the surface of fracture of the unfilled matrix and of the composites, polysaccharide nanocrystals can generally be easily identified. In fact, they appear like white dots. Their concentration is a direct function of the polysaccharide composition in the composite. For rod-like nanoparticles, these shiny dots correspond to the transverse sections of the cellulose or chitin whiskers. TEM observations can also be performed to investigate the microstructure and dispersion quality of the nanoparticles in the nanocomposite films. This technique is more difficult to perform because it involves the use of specimens around 50 nm thick prepared by ultramicrotomy.

Small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) are other ways to determine the dispersion of cellulosic whiskers into the matrix. These techniques were used to confirm the isotropic dispersion of tunicin whiskers in plasticized poly(vinylchloride) (PVC) without aggregates (37). Atomic force microscopy (AFM) imaging has been used recently to investigate the microstructure of cellulose nanocrystal reinforced polymer nanocomposites (11).

Thermal properties

In most studies, no change in T_g is reported when increasing the amount of whiskers, regardless of the nature of the polymeric matrix. This result is surprising because of the high specific area of these nanoparticles (around 170 $m^2 \cdot g^{-1}$ for tunicin whiskers, for instance) (38).

In glycerol-plasticized starch-based composites, peculiar effects of tunicin whiskers on the T_g of the starch-rich fraction were reported depending on moisture conditions (39). For low loading level (up to 3.2 wt%), a classical plasticization effect of water was reported. However, an antiplasticization phenomenon was observed for higher whisker content (6.2 wt% and up). These observations were discussed according to the possible interactions between hydroxyl groups on the cellulosic surface and starch, the selective partitioning of glycerol and water in the bulk starch matrix or at the whiskers surface, and the restriction of amorphous starch chain mobility in the vicinity of the starch

© 2008 NRC Canada

crystallite coated filler surface. For glycerol-plasticized starch reinforced with cellulose crystallites prepared from cottonseed linter (10), an increase of T_g with filler content was reported and attributed to cellulose–starch interactions. For tunicin whisker sorbitol plasticized starch (40), T_gs were found to increase slightly up to about 15 wt% whiskers and then to decrease for higher whisker loading. Crystallization of amylopectin chains on the addition of whiskers and migration of sorbitol molecules to the amorphous domains were proposed to explain the observed modifications.

For natural rubber reinforced with waxy maize starch nanocrystals, a decrease in the onset T_g with an increase in the nanoparticle content was reported (41). Using a glycerol-plasticized starch matrix, the temperature of the main relaxation process associated with the glass–rubber transition of amylopectin-rich domains was reported to increase with the increasing of the starch nanocrystals content (42). The reduction in the molecular mobility of matrix amylopectin chains for filled materials was explained by the establishment of hydrogen bonding forces between both components. A similar observation was reported for poly(vinyl acetate) (PVAC) reinforced with sisal cellulose whiskers (12) and carboxymethyl cellulose (CMC) reinforced with cotton cellulose whiskers (43). For waxy maize starch nanocrystals reinforced glycerol plasticized starch, the increase of T_g led to a considerable slowing down of the retrogradation of the matrix (42). This is a very interesting result since retrogradation and crystallization of thermoplastic starch during aging are main drawbacks of this material and lead to an undesired change in thermomechanical properties.

Melting temperature (Tm) values were reported to be nearly independent of the filler content in plasticized starch (39, 40) and in POE-based materials (36, 33, and 44) filled with tunicin whiskers. The same observation was reported for polycaprolactone reinforced with chitin whiskers from *Riftia* tubes (18) and cellulose acetate butyrate (CAB) reinforced with native bacterial cellulose whiskers (7). However, for the latter system, Tm values were found to increase when the amount of trimethylsilylated whiskers increased. The authors ascribed this difference to the stronger filler–matrix interaction in the case of chemically modified whiskers.

A significant increase in the crystallinity of sorbitol plasticized starch (40) was reported when increasing cellulose whiskers content. This phenomenon was ascribed to an anchoring effect of the cellulosic filler, probably acting as a nucleating agent. For POE-based composites the degree of crystallinity of the matrix was found to be roughly constant up to 10 wt% tunicin whiskers (36, 33, 44) and to decrease for higher loading level (36). Incorporation of chitin whiskers from shrimp shells did not have any effect on the crystallinity of PVA (19) or chitosan (45).

It seems that the nucleating effect of cellulosic nanocrystals is mainly governed by surface chemical considerations. Indeed, when untreated or surfactant-coated, whiskers were also reported to be very good nucleating agents for isotactic polypropylene (iPP). The unmodified whiskers have the largest nucleating effect (45). On the other hand, whiskers grafted with maleated polypropylene did not modify the crystallization of iPP. It was shown from both X-ray diffraction and DSC analysis that the crystallization behavior of films containing unmodified and surfactant-modified whiskers displayed two crystalline forms (α and β), whereas the neat matrix and the nanocomposite reinforced with nanocrystals grafted with maleated polypropylene only crystallized in the α form. It was suspected that the more hydrophilic the whisker surface, the more it appeared to favor the appearance of the β phase. It was observed that native bacterial fillers impede the crystallization of the CAB matrix whereas silylated ones help to nucleate the crystallization (7). A decrease in the degree of crystallinity of polycaprolactone was reported when adding chitin whiskers from *Riftia* tubes (18). It was suggested that during crystallization, the rod-like nanoparticles are most probably first ejected and then occluded in intercrystalline domains, hindering the crystallization of the polymer. In iPP reinforced with tunicin whiskers, a mechanical coupling between the polypropylene crystallites and filler–filler interactions was reported (45).

For tunicin whisker filled semicrystalline matrices such as poly(β-hydroxyoctanoate) (PHO) (46) and glycerol plasticized starch (39), a transcrystallization phenomenon was reported. It consists of a preferential crystallization of the amorphous polymeric matrix chains during cooling at the surface of nanoparticles. For glycerol plasticized starch based systems, the formation of the transcrystalline zone around the whiskers was assumed to be due to the accumulation of plasticizer in the cellulose–amylopectin interfacial zones improving the ability of amylopectin chains to crystallize. These specific crystallization conditions were evidenced at high moisture content and high whisker content by DSC and wide angle X-ray scattering (WAXS). It was displayed as a shoulder on the low-temperature side of the melting endotherm and as a new peak in the X-ray diffraction pattern. This transcrystalline zone could originate from a glycerol-starch V structure. In addition, the inherent restricted mobility of amylopectin chains was put forward to explain the lower water uptake of cellulose-starch composites for increasing filler content.

In silk fibroin reinforced with tunicin whisker composites a conformational change of fibroin chains from a random coil to an ordered structure was reported (47). This change was ascribed to the highly ordered surface of cellulosic whiskers. For waxy maize starch nanocrystals that reinforced glycerol plasticized starch, an increase of the degree of crystallinity of the thermoplastic starch matrix was reported (42). It was suggested that crystallization of the matrix occurred at the interface between the filler and the matrix owing to the similar chemical structure of both components.

Mechanical properties

Nanoscale dimensions and impressive mechanical properties make polysaccharide nanocrystals, particularly when occurring as high aspect ratio rod-like nanoparticles, ideal candidates to improve the mechanical properties of the host material. Indeed, these properties are profitably exploited in nature. In the past ten years, there has been great interest in using polysaccharide nanocrystals, especially cellulose whiskers, as a reinforcing phase in a polymeric matrix, evaluating the mechanical properties of the resulting composites,

© 2008 NRC Canada

and elucidating the origin of the mechanical reinforcing effect.

The first demonstration of the reinforcing effect of cellulose whiskers was reported for poly(S-*co*-BuA) reinforced with tunicin whiskers (14). The authors measured a spectacular improvement in the storage modulus after adding the filler even at low content into the host polymer. This increase was especially significant above the glass–rubber transition temperature of the thermoplastic matrix because of its poor mechanical properties in this temperature range. For instance, the rubbery modulus of the composite reinforced with 6 wt% tunicin whiskers was more than two orders of magnitude higher than that of the unfilled matrix. Moreover, the introduction of 3 wt% or more cellulosic whiskers provides outstanding thermal stability of the matrix modulus up to the temperature at which cellulose starts to degrade (500K).

Favier et al. tried to understand the unusual reinforcing effect from the high modulus of cellulose whiskers (14), which was reported to be of the order of 150 GPa (48). They used a classical model for randomly dispersed short-fiber-reinforced composites that is the model of Halpin–Kardos (49). In this mean-field approach, fibers are assumed to be dispersed in a continuous matrix and no interaction between fillers is taken into account. The description of the equations used in this approach can be found elsewhere (15). It was found that the predicted rubbery modulus fails to describe the experimental data. The cellulose whiskers seemed to act as fibers much longer than expected from geometrical observation.

The outstanding properties observed for these systems were ascribed to a mechanical percolation phenomenon (14). Good agreement between experimental and predicted data was reported when using the series–parallel model of Takayanagi modified to include a percolation approach. It was suspected that all the stiffness of the material was due to infinite aggregates of cellulose whiskers. Above the percolation threshold the cellulosic nanoparticles can connect and form a tri-dimensional continuous pathway through the nanocomposite film. For rod-like particles such as tunicin whiskers with an aspect ratio of 67, the percolation threshold is close to 1 vol% (50). The formation of this cellulose network was supposed to result from strong interactions between whiskers, such as hydrogen bonds (51). This phenomenon is similar to the mechanical properties observed for a paper sheet, which result from the hydrogen-bonding forces that hold the percolating network of fibers. This mechanical percolation effect explains both the reinforcing effect and the thermal stabilization of the composite modulus for evaporated films.

Any factor that affects the formation of the percolating whiskers network or interferes with it changes the mechanical performance of the composite (52). Three main parameters were reported to affect the mechanical properties of such materials, the morphology and dimensions of the nanoparticles, the processing method, and the microstructure of the matrix and matrix–filler interactions.

Morphology and dimensions of the nanoparticles

Cellulose and chitin nanocrystals occur as rod-like nanoparticles in contrast to starch nanocrystals that consist of nanometer-scale platelet-like particles. For rod-like particles, the geometrical aspect ratio is of course an important factor since it determines the percolation threshold value. This factor is linked to the source of cellulose or chitin and to the whisker preparation conditions. Fillers with a high aspect ratio give the best reinforcing effect. For instance, the rubbery storage tensile modulus was systematically lower for wheat straw whisker – poly(S-*co*-BuA) composites than for tunicin whisker based materials (52). The following relation was found between the percolation threshold (v_{Rc}) and the aspect ratio of rod-like particles:

$$v_{Rc} = 0.7/(L/d)$$

Also, the flexibility and tangling possibility of the nanofibers plays an important role (13). These authors reported the mechanical properties of poly(S-*co*-BuA) reinforced with cellulose rod-like nanoparticles extracted from sugar beets and submitted to different hydrolysis conditions. Unhydrolyzed cellulose microfibrils were prepared by submitting sugar beet pulp to a chemical treatment consisting of alkali extraction with a sodium hydroxide solution to solubilize most of the pectins and hemicelluloses (53). The resulting insoluble residue was bleached with a sodium chlorite solution, suspended in distilled water, and homogenized by successive passes through a Manton–Gaulin laboratory homogenizer. Individualized flexible cellulose microfibrils, almost 5 nm in width and practically infinite in length, result from this treatment. These microfibrils were submitted to a hydrolysis treatment using different sulfuric acid concentrations. As the acid concentration increased, it was observed that the length of the microfibrils decreased because of the increased probability of removal of the amorphous material with the concentration of acid. For the strongly hydrolyzed material, most of the amorphous domains were hydrolyzed and rigid whiskers were obtained. Linear mechanical measurements performed on poly(S-co-BuA) reinforced with these microfibrils did not show significant differences by varying the strength of the hydrolysis step nor the length and flexibility of the nanoparticles. However, for nonlinear mechanical tensile tests it was observed that, as the hydrolysis strength increased both the modulus and the strength of the composite decreased, whereas the elongation at break increased. This result showed the strong influence of entanglements on the mechanical behavior of the nanocomposites.

Processing method

The processing method governs the possible formation of a continuous nanocrystals network and then the final properties of the nanocomposite material. Slow processes such as casting/evaporation were reported to give materials with the highest mechanical performance compared to freeze-drying/molding and freeze-drying/extruding/molding techniques. This effect was ascribed to the probable orientation of the rod-like nanoparticles during film processing resulting from shear stresses induced by freeze-drying/molding or freeze-drying/extruding/molding techniques.

It was shown that whisker dimensions affect their ability to align within a shear field. Neutron and X-ray scattering data were used to monitor shear alignment of softwood-derived nanocrystals isolated from the same source, but with

© 2008 NRC Canada

different sizes (54). It was shown that as the aspect ratio falls below 20, shear alignment of whiskers and the ability to maintain this alignment drop significantly. In addition, this difference was suggested to be due to the predominance of the whisker–whisker interactions and their contribution to the overall reinforcing effect in the evaporated films in relation to the dispersion of homogeneous fillers into the matrix. During slow water evaporation, because of Brownian motion in the suspension or solution (whose viscosity remains low, up to the end of the process when the latex particle or polymer concentration becomes very high), the rearrangement of the nanoparticles is possible. They have time enough to interact and connect to form a percolating network which is the basis of their reinforcing effect. The resulting structure is completely relaxed and direct contacts between nanocrystals or microfibrils are then created. On the other hand, during the freeze-drying/hot-pressing process, the nanoparticle arrangement in the suspension is first frozen; during the subsequent hot-pressing stage, because of the polymer melt viscosity, the particle rearrangements are strongly limited and contacts can be made through a limited amount of polymer matrix. However, although the freeze-drying/hot-pressing process limits the possibility of creation of hydrogen bonds it is expected that, for high polysaccharide nanoparticles content, some bonds may still be created.

When using a polymeric matrix in latex form, particle size seems to play a predominant role (55). Larger latex particle size results in greater effects on mechanical properties. Indeed, the polymeric particles act as impenetrable domains to polysaccharide nanoparticles during the film formation owing to their high viscosity. Increasing latex particle size leads to an increase in the excluded volume and these geometrical constraints seem to affect the whisker network formation.

Microstructure of the matrix and matrix–filler interactions

The microstructure of the matrix and the resulting competition between matrix–filler and filler–filler interactions also affect the mechanical behavior of the polysaccharide nanocrystal reinforced nanocomposites. Classical composite science tends to prefer the former as a fundamental condition for optimal performance. In polysaccharide nanocrystal based composite materials the opposite trend is generally observed when the materials are processed via the casting/evaporation method. Increasing the affinity between the polysaccharide filler and the host matrix leads to a decrease in mechanical performance. This unusual behavior is ascribed to the reinforcing phenomenon of polysaccharide nanocrystals resulting from the formation of a percolating network due to hydrogen-bonding forces.

Tensile tests performed on silk fibroin – microcrystalline cellulose composites showed a linear trend for the Young's modulus, with additive dependence on the mixing ratio, whereas the tensile strength and elongation at break showed a maximum around 70%–80% cellulose content, reaching five times those of films derived from fibroin alone or cellulose alone (47). Strong interactions between cellulose crystallites prepared from cottonseed linters and between the filler and the glycerol-plasticized starch matrix were reported to play a key role in reinforcing properties (10). In non-percolating systems, for instance for materials processed from freeze-dried cellulose nanocrystals, strong matrix–filler interactions enhance the reinforcing effect of the filler. This observation was reported using poly(ethylene-co-vinyl acetate) (EVA) matrices with different vinyl acetate contents and then different polarities (56).

A higher reinforcing effect was reported for unmodified cellulose whiskers than for trimethylsilylated whiskers (7). Apart from the fact that 18% of the weight of the silylated crystals was due to the silyl groups, they attributed this difference to restricted filler–filler interactions. Similar results and loss of mechanical properties were reported for natural rubber based nanocomposites reinforced with both unmodified and surface chemically modified chitin whiskers (29) and starch nanocrystals (57).

The transcrystallization phenomenon reported for semicrystalline PHO on cellulose whiskers resulted in a remarkable decrease in the mechanical properties (especially above the melting temperature of the matrix) when compared to fully amorphous PHO (46). In these systems, the filler–matrix interactions and distance from the surface at which the molecular mobility of the amorphous PHO phase is restricted were quantified using a physical model predicting the mechanical loss angle (38). The determination of the ratio between experimental and predicted magnitude of the main relaxation process allows one to remove the filler-reinforcement effect keeping only the interfacial effect, using it to calculate the thickness of the interphase. It was shown that when using semicrystalline PHO as the matrix, the molecular mobility of amorphous PHO chains was only slightly affected by the presence of tunicin whiskers, owing to a possible transcrystallization phenomenon leading to the coating of the nanoparticles with the crystalline PHO phase. The thickness of the transcrystalline layer, around 2.7 nm, was found to be independent of the cellulose whisker content. In contrast, when using amorphous PHO as the matrix, the flexibility of polymeric chains in the surface layer is lowered by the conformational restrictions imposed by the cellulose surface. This results in a broader interphase and in a broadening of the main relaxation process of the matrix.

Similar transcrystallization was reported for plasticized starch reinforced with cellulose whiskers (58). This strong loss of performance in the filler–filler interactions demonstrates an effect of outstanding importance to ensuring the mechanical stiffness and thermal stability of these composites. When using unhydrolyzed cellulose microfibrils extracted from potato pulp rather than cellulose nanocrystals to reinforce glycerol plasticized thermoplastic starch, a completely different mechanical behavior was reported (59, 60), resulting in a significant reinforcing effect by the unhydrolyzed microfibrils. It was suspected that the tangling effect contributed to this high reinforcing effect (58). However, for POE-based nanocomposites the formation of the percolating cellulose network is not altered by the crystallization of the matrix and filler–POE interactions (36, 33, 61–63).

Swelling properties

Swelling is a method currently used for composite materials to determine if the filler creates supplementary crosslinks due to specific interactions between the filler and the

© 2008 NRC Canada

matrix. The choice of the solvent used for the experiment is critical. It must be a good solvent for the matrix to allow its swelling or dissolution, but it must not be able to break the eventual links between the matrix and the filler. If this last condition is not respected, the experiments cannot be conclusive.

The kinetics of solvent absorption consists generally of first drying and weighing the sample, and then immersing it in the liquid solvent or exposing it to the vapor medium. The sample is then removed at specific intervals and weighed until an equilibrium value is reached. The swelling rate of the sample can be calculated by dividing the gain in weight by the initial weight. Generally, absorption is fast in the initial stages, whereas at longer times, the kinetics of absorption is low and leads to a plateau, corresponding to the solvent uptake at equilibrium. The diffusion coefficient can be determined from the initial slope of the solvent uptake curve as a function of time.

Water absorption

The resistance to water absorption by glycerol plasticized thermoplastic starch conditioned at 98% RH was reported to increase with increasing cellulose nanocrystals content (10, 39). These experiments were conducted using cellulose whiskers from tunicate and cottonseed linter, respectively. Both the water uptake and the diffusion coefficient of water were found to decrease upon the addition of whiskers. These phenomena were ascribed to the presence of strong hydrogen-bonding interactions between nanoparticles and between the starch matrix and cellulose whiskers. The hydrogen-bonding interactions in the composites tend to stabilize the starch matrix when it is submitted to highly moist atmosphere. Moreover, the high crystallinity of cellulose might be responsible for the decreased water uptake at equilibrium and the decreased diffusion coefficient of the materials. Lower water uptake and dependence on cellulose whisker content were reported when using sorbitol rather than glycerol as the plasticizer for the starch matrix (40). An explanation was proposed based on the chemical structure of both plasticizers, the number of accessible end hydroxyl groups in glycerol being about twice those in sorbitol.

An increase in the water resistance of soy protein isolate (SPI) films when reinforced with cotton cellulose (64) or chitin whiskers from crab shells was also reported (65). Similar results were obtained for shrimp chitin whisker reinforced PVA (19) and chitosan (67), and cotton cellulose whisker reinforced carboxymethyl cellulose (CMC) (43). In addition, it was found that heat treatment decreased the affinity to water of shrimp chitin or cotton cellulose whisker based nanocomposite films.

The water absorption of waxy maize starch nanocrystals reinforced unvulcanized natural rubber when immersed in water was also reported (41). When starch nanoparticles were added to the apolar polymeric matrix, both the water uptake and the diffusion coefficient obviously increased. However, a discontinuity in both parameters as a function of starch content was reported around 10 wt%. It seemed that the formation of a continuous network of starch nanocrystals occurred at this concentration. Although not easily determinable because of the ill-defined geometry of the percolating species, the critical volume fraction of waxy maize starch nanocrystals at the percolation threshold should be around 6.7 vol% (i.e., 10 wt%). It was observed that the water uptake was lower when starch nanocrystals were chemically modified on their surface with ASA and PI compared to their unmodified counterparts. For potato starch nanocrystal reinforced poly(S-*co*-BuA), a linear relationship was reported between the amount of absorbed water and the volume fraction of nanoparticles (67) whereas the diffusion coefficient displayed two well-defined regions with respect to filler content, namely below and above a critical value of 20 vol%. It was concluded that the diffusion coefficient was sensitive to the percolation threshold, unlike the water uptake, which corresponds to an equilibrium state. The connectivity of fillers was supposed to contribute to the creation of diffusion pathways.

Non-aqueous liquid absorption

PVC reinforced with tunicin whiskers was submitted to swelling experiments in methyl ethyl ketone (MEK) (37). A large decrease in swelling of PVC-based samples when immersed in MEK was observed with increasing cellulose whisker content. It was assumed to be due to the existence of an interphase making a link between nanoparticles, thus allowing the formation of a flexible network. The swelling properties of unvulcanized natural rubber reinforced with crab shells chitin whiskers (17) and waxy maize starch nanocrystals (41) when immersed in toluene were also reported. Both fillers caused a decrease in the toluene uptake of natural rubber. It was assumed to be due to the formation of a nanocrystal network through hydrogen bonding between nanoparticles and also to favorable interactions between the matrix and the filler. The diffusion coefficient of toluene was also found to decrease with addition of polysaccharide nanocrystals. It was observed that the toluene uptake was higher with chemically modified polysaccharide nanocrystal surfaces than with unmodified nanoparticles. The effect was ascribed to lower interactions between modified nanocrystals, higher interactions between the filler and the matrix, and higher affinity between the modified filler and toluene.

For crab shell chitin whisker based nanocomposites, a comparison between samples prepared by freeze-drying / hot-pressing and casting/evaporation was reported (17). It was shown that cast/evaporated nanocomposites were more resistant to swelling than freeze-dried / hot-pressed ones because of the presence of a percolating chitin network in the former. The extent of filler–matrix interactions was also determined by calculating the relative weight loss (RWL) and fraction of bounded matrix (FBM) after 48 h immersion of samples in toluene and subsequent drying. For instance, the RWL and FBM values for a 20 wt% filled evaporated sample were 7.5% and 35.3% and that of the corresponding freeze-dried sample were 11.8% and 28.5%, respectively, giving quantitative indication of the effect of the three-dimensional chitin network in evaporated samples.

The swelling behavior in toluene of poly(S-co-BuA) reinforced with unhydrolyzed cellulose microfibrils from *Opuntia ficus-indica* cladodes was also studied (68). The authors reported a strong toluene resistance even at very low filler loading. Although the unfilled matrix completely dissolved in toluene and no residual gel was recovered at the end of the swelling experiment, only 27 wt% of the polymer

© 2008 NRC Canada

could be dissolved when filled with only 1 wt% of cellulose microfibrils. This phenomenon was ascribed to the presence of a three-dimensional entangled cellulosic network which strongly restricted the swelling capability and dissolution of the matrix. The effect was not observed to increase at higher microfibril content because the overlapping of the microfibrils restricted the filler–matrix interfacial area and because the densification of the microfibrils network decreased the entrapping matrix fraction. Similar experiments were conducted with poly(S-*co*-BuA) reinforced with cellulose microfibrils obtained from sugar beet pulp (69). Toluene resistance of nanocomposites was found to be less significant than for microfibrils from *Opuntia ficus-indica* cladodes and to depend upon filler content. It was observed that the cohesion of composites prepared by evaporation was higher than that of freeze-dried / hot-pressed materials. This difference was ascribed to the presence of a hydrogen-bonded network in the former samples. It was concluded that the solvent did not have any effect on the hydrogen bonds of the cellulose network present in evaporated composites. On the other hand, for freeze-dried / hot-pressed materials, less strong interactions supposedly created between microfibrils and polymer chains could be more easily disentangled and dissolved by the solvent.

Barrier properties

The permeability of natural rubber reinforced with waxy maize starch nanocrystals to both water vapor and oxygen was studied (41). The water vapor transmission rate of these materials was found to decrease continuously upon the addition of starch nanoparticles. This unobvious result shows that the hydrophilic nature of starch nanocrystals does not increase the permeability of natural rubber to water vapor. It was also observed that starch nanocrystals reduced oxygen diffusion, as shown from the decrease in the diffusion coefficient when adding the filler, and oxygen permeability. It was confirmed that this phenomenon was mainly due to the structural modification of the film and not to the decrease in the solubility of oxygen. Both observations were ascribed to the nanoscale platelet-like morphology of starch nanocrystals that increases the tortuosity of the diffusion path of molecules.

The water vapor permeability of sorbitol plasticized pullulan films reinforced with starch nanocrystals was also investigated (70). The authors reported no significant differences in water vapor permeability of unfilled samples and those containing up to 20 wt% nanocrystals. For higher filler content, enhanced barrier properties were observed. The water vapor transmission rate of cotton nanocrystals reinforced CMC films was found to decrease slightly in heat-treated nanocomposites compared to materials not undergoing heat treatment (43).

Conclusions

Polysaccharide nanocrystals are building blocks biosynthesized to provide structural properties to living organisms. They can be isolated from biomass through acid hydrolysis with concentrated mineral acids under strictly controlled conditions, varying time and temperature. Acid hydrolysis results in an overall decrease in amorphous material by removing polysaccharide material closely bonded to the crystallite surface and breaks down portions of glucose chains in the most accessible, non-crystalline regions. The degree of polymerization levels off, corresponding to the residual highly crystalline regions of the original material (i.e., cellulose or chitin fiber or starch granule). Dilution of the acid and dispersion of the individual crystalline nanoparticles complete the process and yield an aqueous suspension of polysaccharide nanoparticles. These nanoparticles can occur as rod-like nanocrystals in the case of cellulose- or chitin-based materials, or platelet-like nanoparticles when using starch granules as the raw material. The rod-like nanocrystals can display chiral nematic properties whose liquid crystalline behavior depends on the mineral acid chosen for the hydrolysis.

Polysaccharide nanocrystals are inherently low-cost materials that are available from a variety of natural sources and in a wide variety of aspect ratios (for example, ~200 nm long and 5 nm in lateral dimension for cellulose and up to several microns long and 18 nm in lateral dimension for chitin). They show the advantages of their renewable source materials, such as abundance, renewability and self-assembly into well-defined architectures. As polymer fillers, they have a greater impact on mechanical properties (e.g., strength, modulus and dimensional stability), permeability to gases and water, thermal stability and heat distorsion temperature, surface appearance, and optical clarity than conventional polymer fillers. They are an attractive nanomaterial for a multitude of potential applications in a diverse range of fields. Indeed, nanotechnology has applications across most economic sectors and allows the development of new enabling science with broad commercial potential. Possible and suggested areas of application include optically variable films, ink, and iridescent pigments for security papers. Polysaccharide nanocrystals reinforced polymer nanocomposites display outstanding mechanical properties and can be used to process high-modulus thin films. For instance, nanocomposite polymer electrolytes reinforced with cellulosic nanoparticles were successfully prepared. There are many other appealing expectations regarding their potential. The growing literature studying polysaccharide, mainly cellulose, nanocrystals is a clear indication of this evolution. Practical applications of such fillers and their transition into industrial technology require a favorable balance between the expected performance of the composite materials and their cost. To exploit their potential, research and development investments must be made in the science and engineering that will fully determine the properties and characteristics of polysaccharides at the nanoscale, develop the technologies to manipulate self-assembly and multifunctionnality, and develop these new technologies to the point where industry can produce advanced and cost-competitive polysaccharide nanoscale products. There are still significant scientific and technological challenges to take up.

Semi-synthesis and proteasome inhibition of D-ring deoxy analogs of (–)-epigallocatechin gallate (EGCG), the active ingredient of green tea extract[1]

Congde Huo, Guoqing Shi, Wai Har Lam, Di Chen, Quizhi Cindy Cui, Q. Ping Dou, and Tak Hang Chan

Abstract: A semi-synthetic route to the D-ring analogs of (–)-epigallocatechin gallate (EGCG) from the relatively abundant (–)-epigallocatechin (EGC), isolated from green tea leaves, is described. A natural product (**13**), found in *Cistus salvifolius*, its acetate (**14**) and analog (**17**) were synthesized by this method. Their inhibitory activities against proteasomes were investigated.

Key words: green tea, (–)-epigallocatechin gallate (EGCG), (–)-epigallocatechin (EGC), proteasome inhibition.

Résumé : On a développé une voie semisynthétique vers des analogues du cycle D du gallate de (–)-épigallocatéchine (GEGC) à partir de la (–)-épigallocatéchine (EGC) qui est relativement abondante et qu'on a isolé des feuilles de thé vert. Faisant appel à cette méthode, on a réalisé la synthèse du produit naturel **13** qu'on retrouve dans *Cistus Salvifolius*, son acétate **14** et son analogue **17**. On a évalué leurs activités inhibitrices vis-a-vis des protéasomes.

Mots-clés : thé vert, gallate de (–)-épigallocatéchine (GEGC), (–)-épigallocatéchine (EGC), inhibition des protéasomes.

[Traduit par la Rédaction]

Introduction

Tea, produced from the plant *Camellia sinensis*, has been consumed by humans for thousands of years. Green tea contains many polyphenols, commonly known as catechins, which constitute about 30%–40% of the water-soluble compounds in brewed green tea (1). The major catechins are: (–)-epigallocatechin-3-gallate (EGCG, **1**), (–)-epigallocatechin (EGC, **2**), (–)-epicatechin-3-gallate (ECG, **3**), and (–)-epicatechin (EC, **4**) (Fig. 1). Of these, EGCG is by far the most abundant and has been reported to have various biological activities that may account for the beneficial effects attributed to green tea (2, 3). Regular drinking of green tea has been associated with reduced risk of several forms of cancer (4), and the effect is attributed mainly to tea polyphenols, in particular EGCG (5).

A critical issue concerning the potential application of EGCG as an anti-cancer agent is its known poor bioavailability (6). The low bioavailability was partly due to poor cellular uptake as well as the instability of EGCG in alkaline or neutral solutions (7, 8). To improve the bioavailability of EGCG, we recently proposed the use of EGCG octaacetate (pro-EGCG, **5**) as a prodrug (9). Compound **5** was found to be more stable to alkaline than EGCG (9) but inactive in vitro as an inhibitor of proteasomes, a presumed key mechanism for the cancer cytotoxicity of EGCG (9). Compound **5** was, however, converted intracellularly into EGCG and active in proteasome inhibition and cancer cell apoptosis (10, 11). Furthermore, intragastric administration of **5** to CF-1 mice resulted in higher bioavailability compared to the administration of equimolar doses of EGCG (10). More importantly, we showed that in vivo for either breast cancer animal model (11) or the androgen-independent prostate cancer animal model (12), **5** showed a significant inhibition of cancer growth compared to EGCG itself (11, 12).

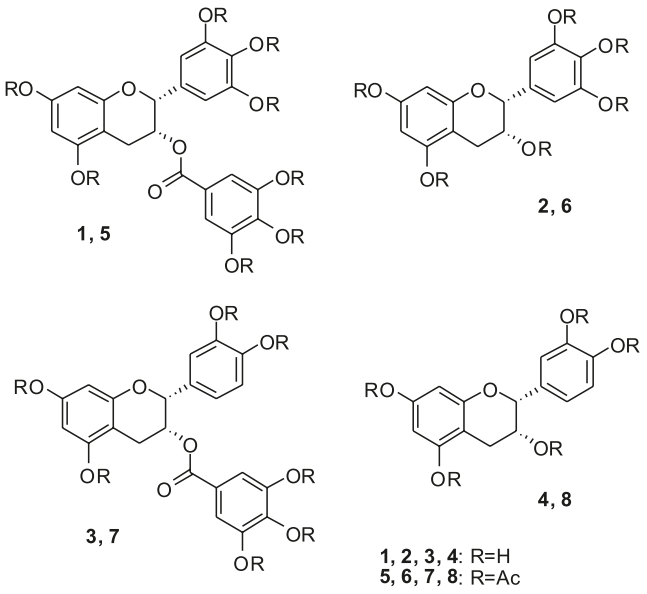
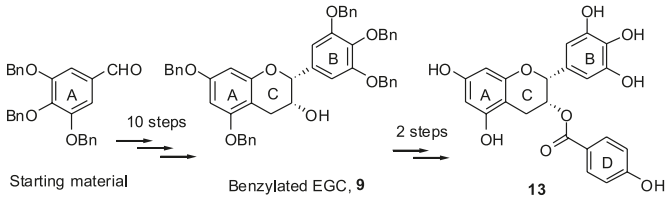
Fig. 1. Four major green tea catechins, **1**, **2**, **3**, and **4** and their peracetates, **5**, **6**, **7**, and **8**.



Another factor that affects the bioavailability of EGCG is due to metabolic biotransformation reactions, including methylation, glucuronidation, and sulfonation, resulting in reduced biological activities of EGCG in vivo (13–15). Recently, an epidemiological study of women found that risk of breast cancer did not differ between tea drinkers and non-tea drinkers among those who were homozygous for the high activity catechol-*O*-methyltransferase (COMT) (16). Only women who carried at least one low activity COMT allele and were tea drinkers had a significantly reduced risk of breast cancer compared to non-tea drinkers (16). The hypothesis to explain these results is that tea polyphenols are methylated by COMT and that the methylated tea polyphenols are less cancer-protective. Indeed, EGCG is a substrate of COMT and is converted to methylated EGCGs (17). In support of this hypothesis, we found that methylated EGCGs are much weaker inhibitors of proteasomes (18). A possible approach to circumvent the effect of metabolic methylation is to use analogs of EGCG, which may be poorer substrates of COMT. In this connection, we have recently synthesized compound **13**, a natural compound found in *Cistus salvifolius* and a D-ring deoxy analog of EGCG (19). Interestingly, even though **13** is a poorer inhibitor of proteasome than EGCG itself, the prodrug of **13** (acetate **14**) was found to be a more potent cancer cytotoxic agent than EGCG itself and comparable to **5** (19). A possible explanation of the enhanced activity of **13** (via its prodrug **14**) is that **13** is probably a poorer substrate of COMT than EGCG. To validate this explanation and to perform animal studies, we need substantial quantities of **13** and **14**, which cannot be easily fulfilled with total synthesis (19, 20). We therefore sought a semi-synthetic approach to prepare **13** and **14** as well as the isomeric acetate (**17**).

In 2001, we reported the first total enantioselective synthesis of EGCG (20). Subsequently, many analogs of EGCG have been prepared utilizing the established total synthetic routes (21), including compound **13**, which was prepared via the key intermediate **9** in 12 steps (Scheme 1) (19). Since

Scheme 1.



compound **9** is simply the benzylated derivative of EGC, it seems reasonable that EGC can serve as the starting material for the preparation of **9** in a semi-synthesis approach.

Results and discussion

Even though the amounts of catechins, especially that of EGCG and EGC, in green tea leaves are quite high, the purification of individual catechins to high purity (>98%) has not been easy due to the presence of many components with similar water solubility and the structural similarities of the catechins. A US patent described a four-step process involving three column chromatographic separations to isolate catechins from green tea, using expensive reverse phase column fillings (22). A more recent patent application described a process of separating catechins by subjecting a green tea extract to chromatography on a macroporous polar resin with a polar elution solvent under pressure (23). We have devised an alternative method of purifying catechins to high purity by treating comminuted green tea leaves directly or green tea extracts with acetic anhydride in pyridine. This acetylation reaction converted the mixture of catechins into fully acetylated catechins (Fig. 1) and rendered them less hydrophilic and separable by simple column chromatography over silica gel with ethyl acetate/hexane as eluent (see experimental). In this way, EGCG octaacetate (**5**), EGC hexaacetate (**6**), ECG heptaacetate (**7**), and EC pentaacetate (**8**) were obtained as solids with good analytical data. HPLC analysis showed that they can be obtained in >98% purity. The amounts of the four acetates depended on the source of green tea. Using Japanese green tea bags with OSK trademark, EGCG octaacetate (**5**) and EGC hexaacetate (**6**) were obtained respectively in 4.3% and 1.5% of the dry weight of the green tea leaves used. The yields of compounds **7** and **8** were generally less than 1% of dry weight.

With EGC hexaacetate (**6**) readily at hand, we examined the selective hydrolysis of the acetate moieties. We found that ammonium acetate in aqueous methanol (24) was able to selectively hydrolyze the aromatic acetate esters of EGC hexaacetate (**6**) to give compound **10**. Benzylation of **10** gave the protected benzyl ether **11**. Base hydrolysis of **11** removed the aliphatic acetate group to give the key intermediate **9** (Scheme 2).

After benzylated EGC (**9**) was obtained by the above method, esterification of **9** with 4-benzyloxybenzoic acid gave the ester **12**. Catalytic hydrogenolysis of **12** gave compound **13**. Compound **13** is a natural product, which has been identified and isolated in small quantities from *C. salvifolius*, a plant indigenous in the Mediterranean area (25). In Turkey, tea prepared from the leaves of *C. salvifolius* has been used for the treatment of cancer (26). Using this semi-synthetic method, we can obtain **13** from

14	n.a[b]
17	n.a.[b]

Note: Compounds at 2, 5, 10, 20, and 50 μmol/L were incubated with a purified 20S proteasome (0.1 μg) and the substrate Suc-LLVY-AMC (40 μmol/L) for 2 h, followed by the measurement of the proteasomal CT-like activity.

[a]The data are representatives of independent triplicate experiments.

[b]n.a. represents the inhibition of the CT-like activity of purified 20S proteasome by the indicated compounds at 50 μmol/L to be lower than 50%. Similar results were obtained from three independent experiments.

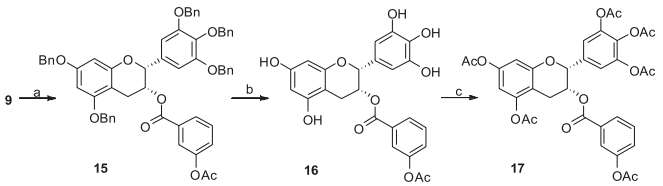
EGC hexaacetate (**6**) isolated from green tea leaves in 5 steps with an overall yield of 38%. Acetylation of compound **13** afforded the fully acetylated derivative **14** (Scheme 3).

Esterification of **9** with 3-acetoxybenzoyl chloride gave the ester **15**. Catalytic hydrogenolysis followed by acetylation gave compound **17**, the positional isomer of **14** (Scheme 4).

With the synthesis accomplished, the inhibition potency of compound **13**, compound **14**, and compound **17** against the chymotrypsin (CT)-like activity of purified 20S proteasome were investigated. As shown in Table 1, compound **13** was an inhibitor to the CT-like activity of purified 20S proteasome with IC_{50} of 6.61 μmol/L, while **14** and **17** had much less inhibitory effect and could not inhibit 50% of the CT-like activity of purified 20S proteasome at 50 μmol/L. Those results were in accordance with our previous observations (19, 27).

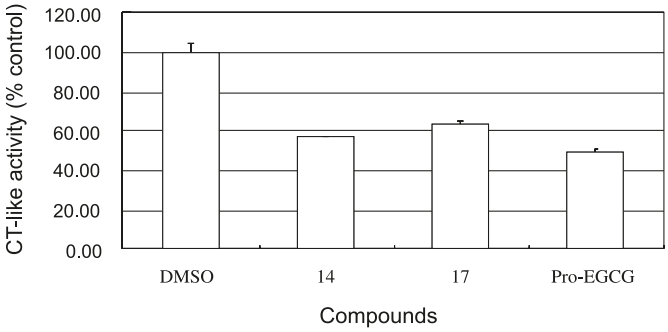
We have previously reported that compound **13** has no obvious inhibition to proteasomal CT-like activity in intact tumor cells (19). To investigate if the acetylated derivative **14** and **17** could exhibit proteasomal inhibition in whole cells,

Scheme 4.



(a) 3-acetoxybenzoyl chloride, DMAP, DCM, Rt, overnight; (b) H_2, Pd/C, THF/MeOH (1:1), Rt, 6h; (c) Ac_2O, pyridine, 45 °C, 8h.

Fig. 2. The inhibition potency of **14** and **17** to the proteasomal chymotrypsin-like activity in Jurkat T cells. Jurkat T cells were treated with each of the indicated compounds at 50 μmol/L for 48 h, and then the proteasomal chymotrypsin-like activity of cell lysate was determined.



human leukemia Jurkat T cells were treated with each of these compounds at 50 μmol/L for 48 h, using pro-EGCG **5** as a control. As shown in Fig. 2, **14** and **17** exhibit 43% and 37% of proteasome inhibition, respectively, while pro-EGCG **5** inhibited ~50% of the proteasome activity (Fig. 2). Because the per-acetylated EGCG was easier to get into cells than EGCG and the per-acetylated EGCG can be converted to EGCG by the cellular esterase enzymes (9, 11, 27), we believe that **14** and **17** behave as prodrugs in a manner similar to pro-EGCG.

Consistent with the inhibition of proteasomal chymotrypsin-like activity, the accumulation of the proteasome target protein Bax (p21) and ubiquitinated Bax [Bax/(Ub)n, mainly by **5**] by **14**, **17** and **5** were also observed, while expression of Bax (p36), a calpain cleavage product homodimer, was not increased (Fig. 3), indicating that proteasome inhibition by these EGCG analog prodrugs activates the caspase, but not calpain enzyme (see the following paragraph).

In various cancer cells, induction of apoptotic cell death is the consequence of proteasomal CT-like activity inhibition. We thus investigated apoptosis by measuring caspase-3 activity and PARP cleavage. Figure 4 shows that **14** and **17** induced a 13.5- and 15-fold increase of caspase-3 activity, respectively, while pro-EGCG **5** also induced a ~15-fold increase of caspase activity (Fig. 4). Trypan blue assay shows that **14** and **17** induced 36% and 34% of cell death after treatment for 24 h, while pro-EGCG induced 40% of cell death (Fig. 5). Consistent with apoptotic cell death induction, the PARP cleavage fragment p85 was produced by **14**, **17**, and pro-EGCG **5** (Fig. 3). It has been shown that caspase-3/-7 cleaves PARP, generating the p85 PARP frag-

Fig. 3. Compounds **14** and **17** inhibit the proteasome and activate the caspase pathway. Jurkat T cells were treated with 50 μmol/L of each indicated compound or solvent DMSO for 48 h, followed by Western blot analysis of the Bax and PARP. DMSO- and pro-EGCG-treated cells were used as solvent control and positive control, respectively, and Actin was used as a loading control.

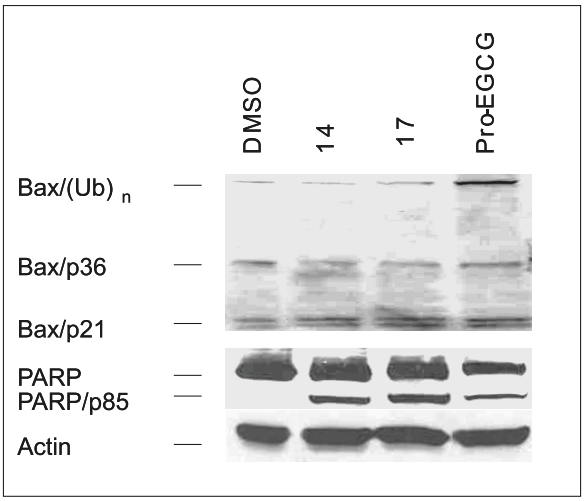

Fig. 4. Induction of caspase-3 activity of Jurkat T cells. These cells were treated with compounds at 50 μmol/L for 48 h, and then the caspase-3 activity of cell lysate was determined.

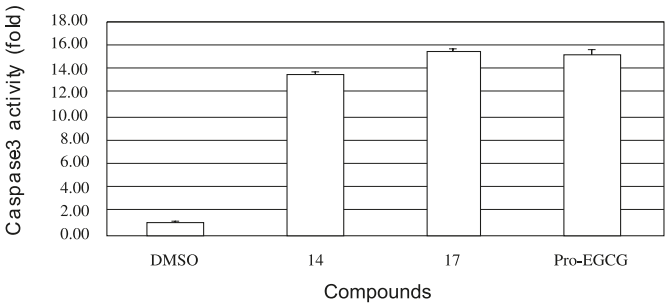


ment (28). The PARP cleavage is consistent with caspase-3 activation.

Conclusion

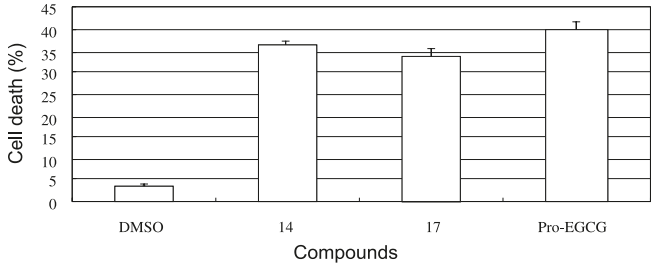
We have developed an efficient method for the isolation and purification of various catechin acetates from green tea leaves. Using EGC hexaacetate (**6**) as starting material, semi-synthesis of D-ring deoxy analogs of EGCG can be obtained in gram quantities. The acetates of these analogs show cytotoxic activities and proteasomal inhibition after cellular intake.

Experimental

General

The starting materials and reagents, purchased commercially, were used without further purification. Green tea bags with OSK trademark were purchased from SEIYU super-

Fig. 5. Induction of cell death. Jurkat T cells were treated with each of the compounds at 50 μmol/L for 24 h, and then the percentage of death cells was determined.



market in Hong Kong. Alternately, Shou Mee green tea leaves were purchased from Ying Kee Tea House, Hong Kong. Anhydrous DMF was distilled under vacuum from CaH_2. Anhydrous DCM was distilled under nitrogen from CaH_2. Anhydrous THF was distilled under nitrogen from sodium benzophenone ketyl. Flash chromatography was carried out using silica gel 60 (70–230 mesh). The melting points were uncorrected. The spectra were run on the following instruments: Varian AS500 spectrometer for ^1H and ^{13}C NMR and VG Micromass 7070F mass spectrometer for MS and HR-MS.

To investigate their proteasome inhibition, compounds **13**, **14**, and **17** were diluted in DMSO to give stock solution of 50 mmol/L and stored in aliquots at –20 °C. Purified rabbit 20S proteasome and fluorogenic peptide substrates, Suc-LLVY-AMC for the proteasomal chymotrypsin-like activity and Ac-DEVD-AMC for caspase-3/-7 activity, were from Calbiochem Inc. (San Diego, Calif.). RPMI 1640, penicillin, and streptomycin were purchased from Invitrogen (Carlsbad, Calif.). Mouse monoclonal antibody against human poly (ADP-ribose) polymerase (PARP) was purchased from BIOMOL International LP (Plymouth Meeting, Penn.). Mouse monoclonal antibodies against Bax (B-9), goat polyclonal antibody against actin (C-11), and HRP labeled secondary antibodies were from Santa Cruz Biotechnology, Inc. (Santa Cruz, Calif.).

Extraction and isolation of the four major green tea catechins peracetates (5, 6, 7, and 8).

Method 1

Comminuted green tea leaves (100 g) were added to a mixture of pyridine (200 mL) and acetic anhydride (100 mL). The resulting mixture was stirred at room temperature for 20 h. The mixture was filtered through a Buchner funnel and washed with ethyl acetate. The filtrate was washed with 0.1 mol/L HCl, saturated $NaHCO_3$ solution, water, and brine. The organic solution was dried over anhydrous magnesium sulfate and evaporated by rotary evaporator. The residue was subjected to chromatography as described later.

Method 2

Green Tea leaves (100 g) were extracted with water (1 L) at 70 °C for 30 min four times. The combined water solution was washed with chloroform three times to remove the low polarity components of green tea. Then the water phase was extracted with ethyl acetate five times. The ethyl acetate so-

© 2008 NRC Canada

lution was dried over anhydrous magnesium sulfate and evaporated by rotary evaporator to give green tea extract as a pale yellow powder after vacuum (10 g, 10%). The powder (10 g) was added to a mixture of pyridine (70 mL) and acetic anhydride (80 mL) with stirring. And the mixture was kept for 20 h at 45 °C in an oil bath. The reaction mixture was then poured into ice-cold water and extracted with ethyl acetate three times. The combined organic layer was washed with 0.1 mol/L HCl, saturated $NaHCO_3$ solution, water, and brine. The organic solution was dried over anhydrous magnesium sulfate and evaporated by rotary evaporator.

The concentrate from method 1 or method 2 was purified by column chromatography over silica gel (EA/*n*-Hex from 2:3 to 3:2) to afford the EC pentaacetate (**8**), EGC hexaacetate (**6**), ECG heptaacetate (**7**), and EGCG octaacetate (**5**), sequentially. TLC performed with Merck pre-coated silica gel 60 F254 plates and with EA/*n*-Hex (*v*/*v* = 2:1) as eluent gave the following R_f values: **8** 0.68, **6** 0.58, **7** 0.46, and **5** 0.32.

4-Benzyloxybenzoic acid

To a suspension of 4-hydroxybenzoic acid (2.0 g, 15.2 mmol) and potassium carbonate (4 g) in dry DMF (40 mL), benzyl bromide (3.6 mL, 30.5 mmol) was added dropwise under a nitrogen atmosphere. The reaction mixture was heated at 80 °C for 6 h. The mixture was evaporated, added to ice water (300 mL) and acidified with 1:1 HCl to a pH of 1. The suspension was filtered, washed three times with water, then dried to give benzyl 4-(benzyloxy)benzoate (3.5 g, 76%) as an off-white solid. To the suspension of the dibenzylated product (2 g, 6.3 mmol) in methanol (20 mL) was added 30% aqueous solution of potassium hydroxide (4 mL) and heated at reflux for 6 h. The solvent was evaporated, added to ice water (100 mL) and acidified to a pH of 1. The white precipitate was filtered, washed thoroughly with water, and dried to give the acid (1.3 g, 91%) as white solid. ^{1}H NMR (CDC_{l3}, 500 MHz) δ: 8.00 (d, *J* = 8.5 Hz, 2H), 7.51 (d, *J* = 8.0 Hz, 2H), 7.42 (t, *J* = 8.0 Hz, 2H), 7.35 (t, *J* = 8.0 Hz, 1H), 7.12 (d, *J* = 8.0 Hz, 2H), 5.23 (s, 2H).

(2*R*,3*R*)-5,7-Bis(benzyloxy)-2-(3,4,5-tris(benzyloxy)phenyl)chroman-3-yl 4-(benzyl-oxy)-benzoate (12)

To a solution of 4-benzyloxylbenzoic acid (34.2 mg, 0.15 mmol) in dry CH_2Cl_2 (10 mL), dicyclohexylcarbodiimide (DCC, 31 mg, 0.15 mmol) was added. The resulting mixture was stirred at room temperature for 4 h and cooled down to 0 °C. 4-Dimethylaminopyridine (DMAP, 1.2 mg, 0.01 mmol.) was added, then a solution of **9** (75.7 mg, 0.1 mol) in dry CH_2Cl_2 (2 mL) was added dropwise. The mixture was refluxed and the progress of the reaction was monitored by TLC. After 24 h the mixture was concentrated and ethyl acetate was added. The resulting mixture was cooled in a refrigerator and the urea byproduct was filtered. The filtrate was evaporated. The resulting residue was purified by column chromatography (EA/*n*-Hex 1:6) to afford compound **12** as a pale yellow amorphous solid (72.5 mg, 75% yield). $[\alpha]_D^{20}$ –42.1 (*c* 0.2, CHCl3). ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.96 (d, *J* = 8.0 Hz, 2H), 7.47–7.22 (m, 30H), 6.93 (d, *J* = 8.0 Hz, 2H), 6.81 (s, 2H), 6.36 (d, *J* = 1.5 Hz, 1H), 6.32 (d, *J* = 1.5 Hz, 1H), 5.68 (m, 1H), 5.09–4.96 (m, 11H), 4.79 (d, *J* = 11.5 Hz, 2H), 3.11 (m, 2H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 165.3, 162.9, 159.0, 158.2, 155.8, 153.1, 138.5, 138.1, 137.3, 137.2, 137.1, 136.3, 133.6, 132.1, 128.9–122.9 (m, Bn), 114,7, 106.9, 101.2, 95.0, 94.2, 78.1, 75.4, 71.4, 70.4, 70.3, 70.2, 68.2, 26.4. (2*R*,3*R*)-5,7-Dihydroxy-2-(3,4,5-trihydroxyphenyl)chroman-3-yl 4-hydroxy-benzoate (13)

Under a hydrogen atmosphere, palladium hydroxide (5 mg, 20% on carbon) was added to a solution of **12** (48.4 mg, 0.05 mmol) in ethyl acetate (5 mL). The resulting mixture was stirred at room temperature until TLC showed that the reaction was completed in about 2 h. The reaction mixture was filtered to remove the catalyst. The filtrate was evaporated to afford compound **13** (20.4 mg, 96% yield) as white foam. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.78 (d, *J* = 8.0 Hz, 2H), 6.83 (d, *J* = 8.0 Hz, 2H), 6.63 (s, 2H), 6.05 (d, *J* = 2.0 Hz, 1H), 6.03 (d, *J* = 1.5 Hz, 1H), 5.54 (m, 1H), 5.09 (s, 1H), 3.05 (dd, *J* = 17.0 Hz, J = 4.5 Hz, 1H), 2.95 (dd, *J* = 17.0 Hz, J = 2.5 Hz, 1H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 165.3, 161.9, 157.1, 156.8, 156.4, 145.6, 131.9, 130.1, 121.9, 115.3, 105.9, 98.2, 95.7, 95.0, 77.4, 68.9, 25.8. LR-MS (ESI) *m*/*z*: 449.08 (M^+ + Na, 74). HR-MS *m*/*z* calcd. for $C_{22}H_{18}O_9H$: 427.1029; found: 427.1028.

(2*R*,3*R*)-5,7-Bis(acetoxy)-2-(3,4,5-tris(acetoxy)-phenyl)chroman-3-yl 4-acetoxy-benzoate (14)

To a solution of **13** (17.1 mg, 0.04 mmol) and acetic anhydride (28.4 μL, 0.30 mmol) in dry MeCN (5 mL) at –40 °C, DMAP (5 mg, 0.04 mmol) was added. The resulting mixture was stirred for 1 h. Saturated $NaHCO_3$ solution was added and the mixture was allowed to warm to room temperature. The mixture was extracted three times with ethyl acetate. The combined organic phase was washed with water and brine, dried over sodium sulfate, and evaporated. The residue was purified by column chromatography over silica gel (EA/*n*-Hex 1:1) to afford the title product **14** (24.4 mg, 90% yield) as a white solid. Mp 109–111 °C. $[\alpha]_D^{20}$ = –60.0 (*c* 0.2, acetone). ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.87 (d, *J* = 8.0 Hz, 2H), 7.27 (s, 2H), 7.09 (d, *J* = 8.0 Hz, 2H), 6.74 (d, *J* = 2.0 Hz, 1H), 6.59 (d, *J* = 2.0 Hz, 1H), 5.62 (s, 1H), 5.20 (s, 1H), 3.06 (m, 2H), 2.28 (s, 6H), 2.27 (s, 3H), 2.24 (s, 3H), 2.23 (s, 6H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 168.9, 168.6, 168.4, 167.5, 166.7, 165.0, 154.7, 154.4, 149.7, 149.7, 143.4, 135.4, 134.2, 131.4, 126.9, 121.5, 118.6, 109.5, 108.9, 108.0, 76.4, 67.5, 25.9, 21.1, 20.7, 20.6, 20.1. LR-MS (ESI) *m*/*z*: 701.12 (M^+ + Na, 67). HR-MS *m*/*z* calcd. for $C_{34}H_{30}O_{15}Na$: 701.1482; found: 701.1472.

3-Acetoxybenzoyl chloride

A suspension of 3-hydroxybenzoic acid (3.5 g, 25 mmol) was heated in acetic anhydride (5 mL) under reflux for 6 h. The acetic anhydride was evaporated and the resulting residue was triturated in ethyl ether, filtered, and washed with ethyl ether to give 3-acetoxybenzoic acid as a white solid (3.4 g, 74% yield). ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 9.50 (brs, 1H), 8.00 (d, *J* = 7.5 Hz, 1H), 7.84 (s, 1H), 7.50 (t, *J* = 7.5 Hz, 1H), 7.36 (d, *J* = 8.5 Hz, 1H), 2.34 (s, 3H).

To a solution of 3-acetoxybenzoic acid (1 g, 5.5 mmol) in methylene chloride (20 mL), thionyl chloride (10 mL) was added. After the solution was stirred overnight, the solvents were removed under vacuum to give 3-acetoxybenzoyl chlo-

© 2008 NRC Canada

ride as a colorless oil. This was used for the next step without further purification.

(–)-(2*R*,3*R*)-5,7-Bis(benzyloxy)-2-(3,4,5-tris(benzyloxy)phenyl)chroman-3-yl 3-acetoxybenzoate (15)

A solution of 3-acetoxybenzoyl chloride (164 mg, 0.8 mmol) in methylene chloride (2 mL) was added dropwise to a solution of **9** (308 mg, 0.407 mmol) and DMAP (122 mg, 1 mmol) in methylene chloride (15 mL) at 0 °C. The mixture was stirred at room temperature overnight and then saturated $NaHCO_3$ solution was added. The organic layer was separated and the aqueous layer was extracted with methylene chloride. The organic layers were combined, dried over sodium sulfate, and evaporated. The residue was purified by column chromatography over silica gel (EA/*n*-Hex 1:5) to afford the desired compound, **15** (114 mg, 78% yield), as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.84 (d, *J* = 7.5 Hz, 1H), 7.68 (s, 1H), 7.45–7.19 (m, 27H), 6. 78 (s, 2H), 6.34 (d, *J* = 2.0 Hz, 1H), 6.30 (d, *J* = 2.0 Hz, 1H), 5.66 (s, 1H), 5.13 (s, 1H), 5.05–4.94 (m, 9H), 4.85 (d, *J* = 11.5 Hz, 2H), 3.12–3.10 (m, 2H), 2.21 (s, 3H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 169.0, 164.5, 158.8, 157.9, 155.4, 152.8, 150.6, 138.2, 137.7, 136.9, 136.8, 136.7, 133.2, 131.5, 129.3, 128.7, 128.6, 128.5, 128.5, 128.4, 128.0, 128.0, 127.9, 127.8, 127.7, 127.5, 127.5, 127.5, 127.5, 127.2, 126.6, 122.8, 106.4, 100.8, 94.8, 93.9, 77.6, 75.1, 71.2, 70.1, 70.0, 68.8, 26.0, 20.9. LR-MS (ESI) *m*/*z*: 941.34 (M^+ + Na, 17). HR-MS *m*/*z* calcd. for $C_{59}H_{51}O_{10}$: 919.3482; found: 919.3480.

(–)-(2*R*,3*R*)-5,7-Dihydroxy-2-(3,4,5-trihydroxyphenyl)chroman-3-yl 3-acetoxy-benzoate (16)

Under a hydrogen atmosphere, palladium hydroxide (52 mg, 20% on carbon) was added to a solution of **15** (48 mg, 0.052 mmol) in a solvent mixture of THF/MeOH (1:1 *v*/*v*, 8 mL). The resulting mixture was stirred at room temperature until TLC showed that the reaction was completed. The reaction mixture was filtered to remove the catalyst. The filtrate was evaporated to afford compound **16** (22.5 mg, 91% yield) as a white solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.77 (d, *J* = 7.5 Hz, 1H), 7.61 (s, 1H), 7. 48 (t, *J* = 7.5 Hz, 1H), 7.34 (d, *J* = 7.5 Hz, 1H), 6.63 (s, 2H), 6.05 (s, 1H), 6.03 (s, 1H), 5.60 (s, 1H), 5.12 (s, 1H), 3.09 (dd, *J* = 18.0 Hz, *J* = 4.5 Hz, 1H), 2.78 (d, *J* = 18.0 Hz, 1H), 2.27 (s, 3H).

(–)-(2*R*,3*R*)-5,7-Bis(acetoxy)-2-(3,4,5-tris(acetoxy)phenyl)chroman-3-yl 3-acetoxy-benzoate (17)

Compound **16** (20 mg, 0.043 mmol) was added to a mixture of pyridine (0.7 mL) and acetic anhydride (0.8 mL) with stirring, and the mixture was kept for 6 h at 45 °C in an oil bath. The solvent was removed under vacuum. The crude product was purified by column chromatography on silica gel with EA/*n*-Hex (1:1) to afford the desired compound, **17** (22 mg, 75% yield), as a white solid. Mp 72–73 °C. ^{1}H NMR ($CDCl_3$, 500 MHz) δ: 7.73 (d, *J* = 7.5Hz, 1H), 7.58 (s, 1H), 7.38 (t, *J* = 7.5 Hz, 1H), 7.27 (s, 2H), 7.25 (d, *J* = 7.5 Hz,1H), 6.75 (d, *J* = 2.5 Hz, 1H), 6.60 (d, *J* = 2.5 Hz, 1H), 5.64 (s, 1H), 5.21 (s, 1H), 3.06 (m, 1H), 2.30 (s, 3H), 2.29 (s, 3H), 2.28 (s, 3H), 2.25 (s, 3H), 2.24 (s, 6H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 169.3, 169.2, 168.7, 167.8, 167.0, 165.1, 155.0, 150.7, 150.0, 149.9, 143.7, 135.6, 134.5, 131.1, 129.6, 127.6, 126.9, 123.1, 119.0, 109.8, 109.2, 108.3, 76.8, 67.9, 26.2, 21.4, 21.3, 21.0, 20.8, 20.4. LR-MS (ESI) *m*/*z*: 701.03 (M^+ + Na, 100). HR-MS *m*/*z* calcd. for $C_{34}H_{30}O_{15}Na$: 701.1482; found: 701.1467.

Cell culture and cell extract preparation

Jurkat T cells were from American Type Culture Collection (Manassas, Va.). Cells were grown in RPMI 1640 supplemented with 10% fetal bovine serum, 100 units/mL of penicillin, and 100 µg/mL of streptomycin and were incubated at 37˚C in a humidified incubator with an atmosphere of 5% CO_2. A whole extract was prepared as previously described (29).

Inhibition of chymotrypsin-like activity of purified 20S proteasome

Two µL of each compound's stock DMSO solution was added to 100 µL of 20S proteasome solution (25 mmol/L Tris-HCl buffer, pH 7.5) on the 96-well plate, in the presence of Suc-Leu-Leu-Val-Try-7-amido-4-methyl-coumarin (AMC) (40 µmol/L) fluogenic substrate for 2 h at 37 °C, followed by measurement of hydrolyzed AMC groups using a Victor 3 Multilabel counter with an excitation filter of 380 nm and an emission filter of 460 nm (PerkinElmer).

Proteasome CT-like activity and caspase-3 activity assay in whole cell extracts

The Jurkat T cells were treated with 50 µmol/L of compounds or solvent DMSO for 48 h, harvested, and lysed. Whole cell extracts (10 µg) were incubated with 40 µmol/L of Suc-Leu-Leu-Val-Try-AMC (for the proteasomal CT-like activity) for 2 h or Ac-DEVD-AMC (for caspase-3 activity) for 3 h at 37 °C. The release of the AMC groups was measured as described above.

Trypan blue assay

The trypan blue dye exclusion assay was performed as described previously (30).

Western blot analysis

Western blot analysis using the enhanced chemiluminescence reagent was done as previously described (11).

Partitioning of charged and neutral dextran-dye derivatives in biphasic cellulose nanocrystal suspensions[1]

Stephanie Beck-Candanedo, David Viet, and Derek G. Gray

Abstract: The partitioning behaviour of dye-labeled dextrans of high molecular weight in aqueous suspensions of native cellulose nanocrystals was studied. Cellulose concentrations lie in the isotropic–nematic coexistence region. Blue dextrans of various molecular weights and degrees of substitution of dye molecules (anionic Cibacron blue 3G-A) were investigated. Increasing the total concentration of blue dextran and degree of dye substitution led to increasing partition coefficients. Increasing dextran molecular weight resulted in higher partition coefficients, in agreement with theory. Partition coefficients were larger than predicted theoretically using a second virial coefficient approximation. Electrostatic and entropic contributions to the partition coefficient of blue dextran are discussed. Dextrans labeled with neutral fluorescein isothiocyanate did not partition preferentially in this system.

Key words: partition coefficient, cellulose nanocrystals, dextrans, degree of substitution, polyelectrolyte.

Résumé : Le comportement de partage préférentiel entre deux phases manifesté par des dextrans de haut poids moléculaire marqués par différents types de colorants dans des suspensions aqueuses de nanocristaux de cellulose a été étudié. Les concentrations en cellulose se situent dans la région de coexistence nématique–isotrope. Des dextrans bleus de divers poids moléculaires et à différents degrés de substitution en colorant (Cibacron bleu 3G-A anionique) ont été étudiés. L'augmentation de la concentration du dextran bleu de même que l'augmentation du degré de substitution du colorant tend à élever le coefficient de partage. En accord avec la théorie, plus on monte en masse molaire, plus le coefficient de partage est haut. Les coefficients de partage sont supérieurs à ceux prédits par la théorie si l'approximation du second coefficient viriel est utilisée. Les contributions électrostatiques et entropiques du dextran bleu sont exposées. Enfin, nous ne dénotons aucun effet de partage sur des dextrans marqués avec des colorants neutres comme l'isothiocyanate de fluorescéine.

Mots-clés : coefficient de partage, nanocristaux de cellulose, dextrans, degré de substitution, polyélectrolyte.

Introduction

It is well-established that the drive to maximize entropy can cause ordering (1) and bulk demixing in systems containing components of sufficiently different physical properties, such as shape or flexibility (2). The bulk demixing is predicted to give rise to phases enriched in one of the components of the system (1, 3). Ordered phases of rodlike particles coexisting with random phases, such as aqueous suspensions of cellulose nanocrystals (Fig. 1*a*), have been shown to exclude random coil polymers and spherical particles for several experimental systems (2, 4–10) including cellulose nanocrystals and blue dextran, as shown in Fig. 1*b* (11). Assuming only excluded-volume interactions between the components, Flory predicted the phase separation of a solution containing a rigid rodlike polymer and a flexible randomly coiled polymer and concomitant partitioning to give a rod-rich, coil-poor phase and a coil-rich, rod-poor phase (3). The phase separation is entropy-driven, based on depletion attractions observed in colloid-polymer systems (12). The extent of the partitioning depends on the relative size and concentration of the two components as well as their chemical nature. This has been shown experimentally (6, 8, 9) as well as theoretically (13).

Preliminary results obtained in this laboratory for blue dextran in cellulose nanocrystal suspensions have shown that the partitioning behaviour is not affected by the nature of the phase separation, that is, whether the suspension concentration lies in the isotropic–chiral nematic (I–N) coexistence region or whether phase separation is induced by the addition of a macromolecule to a completely ordered suspension (11). This article further investigates the partitioning behav-

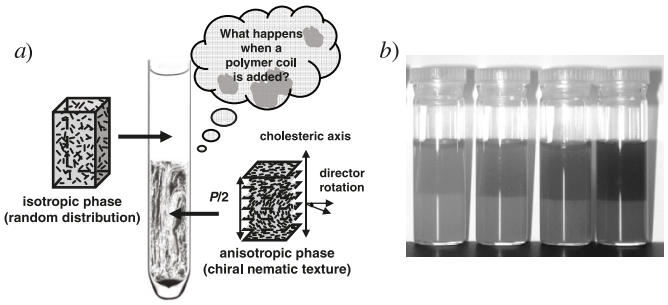
(*a*) Biphasic suspension of cellulose nanocrystals viewed between crossed polars, showing schematic representations of the upper isotropic (random) phase and lower liquid crystalline (chiral nematic) phase. (*b*) Vials of biphasic cellulose nanocrystal suspension containing increasing concentrations from left to right of blue dextran, showing the preferential partitioning of the blue dextran (appears dark in this grey-scale image) into the upper isotropic phase.



iour of blue dextrans in biphasic cellulose nanocrystal suspensions. It is our goal to clarify the factors driving the partitioning of such polyelectrolytic species, in particular the effect of the ionic charge due to the dye substituents on the partition coefficient.

Experimental

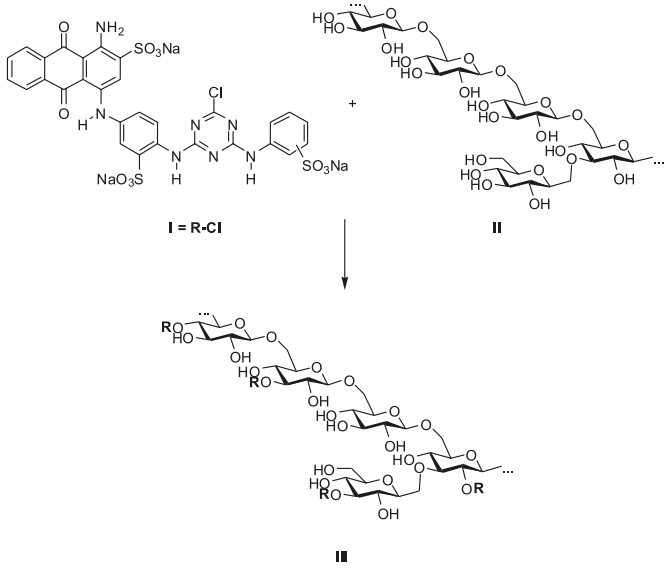
Materials

Whatman ashless cotton cellulose powder was purchased from Cole-Parmer. Sulfuric acid (95%–98%) for hydrolysis was purchased from Fisher Scientific. Cibacron blue 3G-A dye (CB, 55% dye content, MW 840.12 Da), and sodium hydroxide, sodium chloride, and sulfuric acid volumetric standards for conductometric titration were purchased from Sigma-Aldrich. Anhydrous sodium carbonate was purchased from Anachemia. Concentrated hydrochloric acid, ACS reagent grade, was purchased from ACP Chemicals. Methanol, HPLC grade, was purchased from Fisher Scientific. Blue dextran 2000 (nominal M_w 2 000 000 Da) and fluorescein isothiocyanate (FITC)-labeled dextrans 2000, 500, and 150 (M_w 2 000 000, 525 000, 130 000, and 77 000 Da, respectively) were purchased from Sigma-Aldrich. Dextrans (Dx) T-2000, T-500, T-110, and T-70 (M_w 2 000 000, 532 000, 106 000, and 70 000 Da, respectively) were purchased from Pharmacia Fine Chemicals. All water used was purified using a Millipore Milli-Q purification system.

Cellulose nanocrystal suspensions

Suspensions of cellulose nanocrystals were prepared as described in previous publications (14–16). Whatman ashless cotton cellulose powder was hydrolysed for 45 min at 45 °C, using 64 wt% sulfuric acid (17.5 mL per g powder). The reaction mixture was diluted 10-fold with cold distilled water to stop the reaction and washed once by centrifugation. The precipitate was then dialysed until a pH of 4–5 inside the dialysis membrane was reached. Suspensions were sonified (Vibracell, Sonics & Materials, Inc., Danbury, Conn.) in an ice bath to yield colloidal dispersions, which were placed over a mixed-bed ion-exchange resin (Sigma-Aldrich) for several hours and then filtered. The

Scheme 1. Coupling of Cibacron blue 3G-A (I = R-Cl) with dextran (II) to give blue dextran (III), showing the random binding sites of the dye (27).



aqueous suspensions, 0.5%–2% cellulose by weight, were evaporated with stirring at ambient conditions to obtain the desired final nanocrystal concentrations.

Conductometric titration and neutralization

Conductometric titration was used to determine the surface charge density of the cellulose nanocrystals associated with surface sulfate ester groups. A Contiburette µ10 (Ing. CAT, Staufen, Germany) was used for all titrations. Titrations were performed under a flow of nitrogen using an Orion conductivity cell 018010 (cell constant $K = 0.987$ cm^{-1}) attached to a Fisher Scientific accumet pH meter 50. Sodium hydroxide was standardized against volumetric standard sulfuric acid. Equivalence points were used to calculate the amount of sodium hydroxide required to convert the suspensions to the sodium form (Na^+ counterions).

Preparation of blue dextrans

Blue dextrans of various molecular weights and ligand densities were prepared using methods adapted from Mayes et al. (17) and Tang et al. (18) (Scheme 1), as described in a previous publication (19). A brief description of the procedure follows: a solution of the dextran is mixed with aqueous solutions of Cibacron blue 3G-A dye and Na_2CO_3 and the mixture is shaken in a water bath at 45 °C. After around 75 h another aliquot of CB is added. An equal volume of ethanol is added to the mixture to precipitate the dextran–dye conjugate. After standing at –20 °C, the precipitate is spun down, rinsed with ethanol, and redissolved in water, and the precipitation step repeated. Following a final resuspension in water, the dextran is dialysed against distilled water to remove any traces of unreacted dye and salt. The final product is lyophilised and stored as a solid.

Acid hydrolysis of dextran T-2000

To obtain dextran fractions of high molecular mass (>500 kDa), degradation by acid hydrolysis was carried out according to starch hydrolysis methods (20, 21) adapted for

dextran by Ioan et al. (22). Dextran T-2000 (1 g) was suspended in 4 mL of methanol to which various amounts of concentrated hydrochloric acid were added (0.02, 0.04, 0.06, and 0.09 mL, which yielded dextrans d1700, d1400, d1200, and d980, respectively). The suspensions were shaken for 4 days, at which point the limiting value was reached (23). The degraded dextrans were neutralized with 1 mol/L NaOH and washed with 1:1 methanol/water. The hydrolysed dextran fractions were dialysed against milliQ water to remove any traces of base or small dextran fragments, lyophilised, and stored as solids. Following characterisation (see later and Table 1), the solid dextrans were reacted with CB dye to give dextran–dye conjugates as described above. It should be noted that the degradation is not fully random; the cleavage rate of the α-(1,6) bonds differs from that of the α-(1,3) bonds and leads to a change in the branching density that may affect the partitioning (24).

Characterisation of blue dextrans

Moisture contents of the dextran–dye conjugates and degraded dextrans were determined by thermogravimetric analysis (TGA, TA Instruments TGA Q500).

The dye content of the dextran–dye conjugates was determined using UV–vis spectroscopy (Varian Cary 300 Bio spectrophotometer). A calibration curve was obtained from solutions of commercially available blue dextran 2000 and adherence to the Beer–Lambert law was established. The molar extinction coefficient for blue dextran 2000 at 609 nm was found to be 8865 $(mol/L)^{-1}cm^{-1}$. The extinction coefficient at 620 nm was 8966 $(mol/L)^{-1}cm^{-1}$ = 0.823 $g^{-1}dm^3cm^{-1}$, which agrees well with the value of 0.812 $g^{-1}dm^3cm^{-1}$ found by Champ et al. (25) for commercially available blue dextran 2000. The ligand density was estimated from absorbance measurements at 609 nm for solutions of the dextran–dye conjugates and calculated in terms of the degree of dye substitution (DS) per anhydroglucose repeat unit (AGU). Absorbance measurements in dilute aqueous solution and in 6 mol/L aq. HCl (17, 26) have shown that negligible intramolecular dye stacking occurs at dye ligand densities, comparable with those reported in this article.

A combination of gel permeation chromatography (GPC) and static light scattering (SLS) was used to obtain molecular weights ($\overline{M}_w$, $\overline{M}_n$), and radii of gyration (R_g) for the hydrolysed dextrans and for FITC-Dx 2000. Dextrans (2 mg/mL) were dissolved in the eluent (pH 7, 0.2 mol/L $NaNO_3$, and 0.01 mol/L NaH_2PO_4 containing 0.2% NaN_3) and filtered using 0.45 μm membranes. Samples (100 μL) were injected onto a GPC column (300 × 75 mm PL aquagel-OH mixed 8 μm, 1×10^2 to 1×10^7 Da separation, Polymer Laboratories) at a flow rate of 1.0 mL/min using a Merck Hitachi AS-2000A autosampler and Waters 510 HPLC pump. The column was coupled to a Wyatt Optilab rEX IR detector (690 nm) and a Wyatt Technology Corporation DAWN EOS light scattering detector. Data were analysed with Astra v5.3.0 18 software (Wyatt Technology Corporation).

Preparation of cellulose suspensions containing dextran–dye conjugate

Solid dextran–dye derivatives were added to samples of biphasic cellulose suspension, which were mixed and al-

lowed to re-equilibrate for 24 to 48 h. The concentration of dextran in the dispersions is expressed as AGU molarity, in order that the concentrations of dextrans of different molar masses be comparable among the samples. The more usual volume fraction was not used, as the coil volumes are model-dependent and the dextran concentrations were such that it was not possible to calculate accurate values (the dispersions were not dilute enough).

When phase separation was complete, samples were taken from the upper and lower phases and diluted prior to analysis to minimize scattering caused by the cellulose nanocrystals. Linear correlations between absorbance and concentration were observed for blue dextran 2000 and FITC-dextran 2000 in cellulose suspension. The volume fraction of the phases was determined by measuring the heights of the anisotropic and isotropic phases in each vial.

Determination of partition coefficients

UV–vis absorption spectra were taken and the absorbance measured at 609 nm for blue dextrans and 490 nm for FITC-dextrans. Suspensions of cellulose nanocrystals containing no dextran–dye conjugate, but otherwise identical to the sample suspensions, were used as references. Because calibration measurements showed that measured absorbance is proportional to the concentration of macromolecule, partition coefficients K were calculated from the relative absorbance values A of the isotropic and anisotropic phases,

$$[1] \qquad K = A_{iso}/A_{aniso}$$

The concentration of cellulose in the samples was determined by gravimetry. The number density of the dextran–dye conjugates and dextran molecules in the samples was calculated using the equation,

$$[2] \qquad C_i = \frac{N_i}{V_{tot}} = \frac{N_a}{V_{tot}}\frac{m_i}{M_i}$$

where N_i is the number of molecules of species i, V_{tot} is the volume of the sample, N_a is Avogadro's number, m_i is the mass of species i, and M_i is the molar mass of species i. It should be noted that while number average molecular weight $\overline{M}_n$ should be used in the formula for number density, the molecular weights given for the dextrans are weight average $\overline{M}_w$ (supplier data). The polydispersity $\overline{M}_w/\overline{M}_n$ of the dextrans decreases with decreasing molar mass (28).

Results and discussion

Partition theory

The concentrations of hard core monodisperse rodlike particles in the isotropic and nematic phases are predicted to remain constant across the I–N coexistence region (1). However, because the cellulose nanocrystals contain ionic sulfate groups on their surface, increasing the total cellulose concentration causes the particle densities in the isotropic and anisotropic phases to increase and diverge slightly because of the change in ionic strength in the aqueous medium, as previously observed for this system (11, 29). Partitioning of the blue dextran coils between the coexisting isotropic and nematic or chiral nematic phases causes the rod densities in the phases to diverge further as more polymer coils are added (13). Because the concentration of coils is higher in the isotropic phase, adding blue dextran increases the osmotic pressure of the isotropic phase relative to the nematic phase. To compensate, the rod density decreases in the isotropic phase and increases in the nematic phase, resulting in a widening of the I–N coexistence region of the phase diagram (13).

Sear has studied the phase behaviour of lyotropic mixtures of rodlike and flexible polymers, obtaining an expression for the partition coefficient K of a flexible polymer (13),

$$[3] \quad K = \frac{c_p^I}{c_p^N} \sim \exp[LD^{1/3}R_g^{5/3}(c_r^N - c_r^I)]$$

where c_p^I and c_p^N are the number densities of the polymer in the isotropic and the nematic phases, respectively, L is the rod length, D is the rod diameter, R_g is the radius of gyration of the polymer, and c_r^I and c_r^N are the number densities of the rodlike polymer in the isotropic and nematic phases. The parameters used in the calculation of theoretical K values were as follows: L = 110 nm, D = 10 nm, and R_g = 34 nm (28). A sample calculation is shown in Table 2 (for the last entry in Table 4).

The rodlike polymer is modeled as a hard rod with a diameter much smaller than the radius of the flexible coiled polymer, $D \ll R_g$. Interactions between the rods and coils are based on excluded volume; there are no attractive interactions between the rods, which is required for the suspension to be stable. The equation is valid in the dilute regime, that is, at small volume fractions of polymer (13). It predicts that polymers with larger radii of gyration will partition to a greater extent, while for a given radius of gyration, a larger difference in cellulose rod concentration between the two phases will increase partitioning (i.e., K increases with total cellulose concentration, as previously observed (11)). This expression for K has been used previously to predict blue dextran partitioning in cellulose nanocrystal suspensions; despite the fact that the expression only provides an order of magnitude for K, it predicted an increase in partition coefficient with increasing blue dextran concentration (11).

The critical concentration c^* (at which the semi-dilute regime begins) for blue dextran 2000_{161} is 73 mg/mL in 10 mmol/L of NaCl and 209 mg/mL in 200 mmol/L NaCl

© 2008 NRC Canada

(unpublished results). Sear's theory is valid only in the dilute regime, where the volume fraction of polymers and colloidal rods is small (13). The dextran concentrations used in this study do not exceed 50 mg/mL; Sear's theory is therefore valid for our samples. However, although we are working in the dilute regime for the blue dextran, it should be noted that the cellulose nanocrystals also contribute to the sample viscosity; their volume fraction is fairly low (about 6.5% for 10 wt% nanocrystals with L = 120 nm and D = 10 nm). At high viscosity, kinetic effects likely have important effects on the phase separation and partitioning behaviour. Sear's theory also assumes constant rod concentration across the biphasic region, as predicted by Onsager (1). As stated earlier, this is not the case for suspensions of cellulose nanocrystals, which may contribute to any discrepancy between the theoretical predictions and experimental results.

The partition coefficient K of a macromolecule in a two-phase system can be expressed as

$$[4] \qquad K = K_{hphob} \cdot K_{el} \cdot K_{size} \cdot K_{sol} \cdot K_{aff} \cdot K_o$$

where K_{hphob}, K_{el}, K_{size}, K_{sol}, and K_{aff} represent the contributions to the total partition coefficient of the effects of hydrophobicity, electrostatic forces, size factors, solubility, and affinity, respectively, and K_o represents other effects on partitioning, such as the dimensions of the rodlike particles and their relative concentrations in the two phases (30). These factors may be competing with each other; their relative importance will depend on the composition of the biphasic system and the properties of the molecule being partitioned. The main contributions to K for blue dextran are likely to be K_{el} and K_{hphob} (the sulfonated triazine dye introduces both ionic and hydrophobic elements into the macromolecule). K_{size} is also expected to play a role for blue dextrans of different molecular weights. Because FITC-dextran is electrostatically neutral, K_{el} should not be an important factor in its partitioning behaviour; K_{hphob} may dominate because of the hydrophobic aromatic rings in the FITC dye.

Blue dextran partitioning

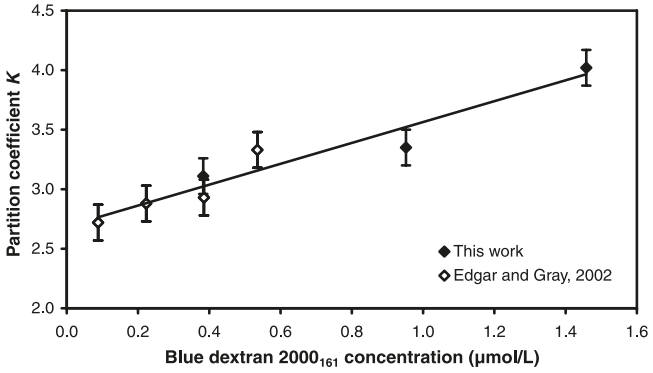
The effect of increasing blue dextran 2000_{161} concentration on its partition coefficient is shown in Fig. 2, which also contains data from a previous publication (11). The partition coefficient increases linearly with increasing blue dextran concentration.

The effect of the DS of blue dextran 2000 at constant AGU monomer concentration on its partition coefficient is shown in Table 3. The partition coefficients increased from around 1.3 to greater than 2 when the DS was increased from 7×10^{-4} to 1.61×10^{-2}. A two-fold increase in the AGU concentration did not have a significant effect on the partition coefficients.

The effect of DS of blue dextran 2000 at constant dye concentration on its partition coefficient is shown in Table 4. The partition coefficients increased from 1.1 to greater than 3 when the DS increased from 1.60×10^{-3} to 1.61×10^{-2}. A 2.5-fold increase in the total dye concentration did not have a significant effect on the partition coefficients (they increased slightly).

It can be concluded from the results in Tables 3 and 4 that increasing the DS results in larger K values for blue dextrans

Fig. 2. Partition coefficients of blue dextran 2000_{161} in ~10 wt% cellulose suspension. The line is the best fit to the data. Closed symbols were obtained in 10.1 wt% cellulose nanocrystal suspension; open symbols were obtained in 10.3 wt% cellulose nanocrystal suspension.



2000 at constant AGU concentration and at constant dye concentration. The DS of the blue dextran 2000 thus determines the magnitude of K in this biphasic system.

Effect of molecular weight on partition coefficient K

The partition coefficients for blue dextrans and FITC-dextrans of various molecular weights and DS are given in Table 5. In this case, it is particularly difficult to separate the effect of the DS of dye ligands (K_{el}) from the effect of the blue dextran molecular weight (K_{size}). For nonhydrolysed blue dextrans with similar DS (shown in italics), K decreases from 1.48 to 1.12 when the molecular weight decreases from 2000 to 70 kDa. Partition coefficients for blue dextrans prepared from acid-hydrolysed dextrans measured at similar AGU and dye concentrations (blue dextrans d1700–d980 contain 0.020 ± 0.001 g dye per g blue dextran) also decrease with decreasing dextran molecular weight. As shown in Fig. 3, this is in qualitative agreement with Sear's partitioning theory in which K is proportional to the exponential of $R_g^{5/3}$ (13). It should be noted that the hydrolysed dextrans are more polydisperse (Ip values for dextrans d1700, d1400, d1200, and d980 are 2.74, 2.98, 2.38, and 2.45, respectively) than the blue dextrans prepared from commercial dextrans, which have Ip values of around 1–1.25 (unpublished results). Lower molecular weight FITC-dextrans appear to partition slightly more strongly into the anisotropic phase, but relatively large error bars make it difficult to differentiate between the lowest experimental partition coefficients of 0.89 and 1.05.

FITC-dextran partitioning

The partition coefficients for FITC-dextrans in the same biphasic system were all around 0.8–1.0, indicating partitioning into the lower anisotropic phase (Table 6). FITC-dextran is neutral at basic pH (32) or at most slightly positive at the pH of 4–5 in the cellulose suspensions, but contains several hydrophobic aromatic rings, similar to blue dextran (Fig. 4).

The observed partitioning behaviour of charged and neutral dye-labeled dextrans suggests that the blue dextran partitioning is partly electrostatic in nature.

Fig. 3. Natural logarithm of the measured partition coefficient K_{meas} as a function of $R_g^{5/3}$ for blue dextrans of different molecular weights. Radii of gyration of the dextrans were calculated using the equation $R_g = 0.66\ M_w^{0.43}$, which is valid over the M_w range 400 to 2700 kDa (31).

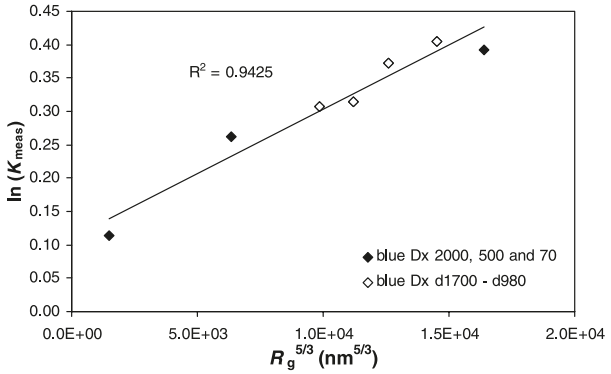

Fig. 4. Structure of FITC-dextran. FITC is assumed to associate randomly with any free hydroxyl group (33).

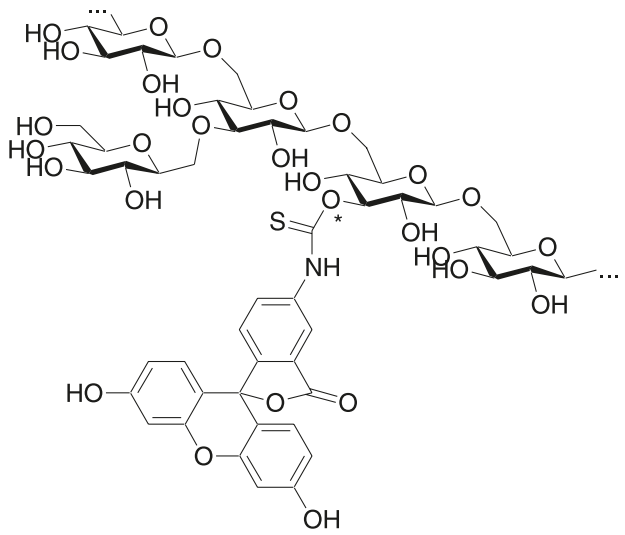

Increasing degree of dye substitution (DS)

Cibacron blue 3G-A dye has been found to adsorb onto the surface of microcrystalline cellulose (MCC, Avicel PH 102) in studies of the hydrolysis of amylase by CB-dyed amylases in the presence of MCC (34). The adsorption of CB dye onto cellulose nanocrystals containing anionic surface sulfate esters was also verified by exhaustively dialyzing cellulose suspensions to which small amounts of CB dye were added. The absorption spectra of the resulting samples showed a peak in the range of 590–630 nm, indicating the presence of CB dye. Free CB dye was not found to partition in biphasic cellulose nanocrystal suspensions. Because CB contains three anionic sulfonate groups per molecule, it is soluble in water and it is therefore conceivable that many dye ligands will be exposed on the surface of a blue dextran molecule in aqueous solution and be available to adsorb onto the surfaces of cellulose nanocrystals. This presumably occurs during the mixing and early equilibration stages of sample preparation. Upon formation of the anisotropic phase, the adsorbed blue dextrans may desorb and be expelled into the isotropic phase, as they are too large and interfere with the chiral nematic structure (excluded volume effect) (19); the entropy gain and the associated reduction in free energy is greater than the reduction in free energy due to adsorption. The increase in K with increasing DS of the blue dextran may be caused by an electrostatic effect: the negatively charged cellulose nanocrystals in the anisotropic phase may be more efficient at expelling the more highly substituted blue dextrans which are more negatively charged. This may explain why the observed blue dextran K values are much higher than predicted by Sear's theory (Fig. 5), which does not take electrostatic factors into account. Using surface charge density values measured by conductometric titration, the ratio of surface charge (and corresponding counterions) between the anisotropic and isotropic phases of 8.7 and 9.8 wt% suspensions was calculated to be around 1.3 for both samples (which differed in nanocrystal surface charge density). There is therefore an electrical potential difference between the phases, which may affect the partitioning behaviour of the negatively

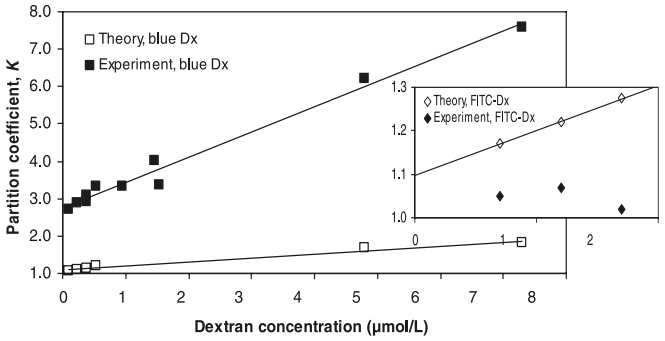
Fig. 5. Theoretical and experimental K values for blue dextrans and FITC-dextrans in cellulose nanocrystal suspension. Inset shows FITC-dextran data points in more detail. The error bars for experimental K values are on the order of the size of the data points.



charged blue dextrans. That is, blue dextrans with higher DS may be more strongly repelled by the negatively charged nanocrystals and prefer the more dilute isotropic phase. Thus, K_{el} increases with increasing blue dextran DS (30).

Increasing blue dextran concentration

The divergence in the cellulose concentrations of the two phases (as predicted by Flory (3) and observed by Edgar and Gray (11)), caused by the increase in ionic strength from 0.4 to 7.3 μmol/L due to the increasing concentration of blue dextran dye ligands, is likely too small to affect K according to Sear's theory (13), as increasing the ionic strength from 0 to 2.5 mmol/L was found to cause only a very slight divergence of the isotropic and anisotropic phase concentrations (29). At low concentrations of dextran–dye conjugate, the mixing entropy dominates resulting in a weak driving force for partitioning that increases with increasing polymer concentration. Increasing the total concentration of an ionic dextran–dye conjugate did not have an effect on the value of K in an aqueous two-phase system consisting of dextran and PEG, where such electrostatic and entropic (excluded volume) factors would not be present (35).

Nonionic FITC-dextran vs. anionic blue dextran

In the context of the above observations, the lack of partitioning observed in the FITC-dextran samples is plausible. It has been found that in suspensions of rodlike fd virus suspensions at low ionic strength, neutral FITC-dextran has no effect on the coexistence concentrations of the I–N transition, and no partitioning is observed, in contrast to the strong partitioning predicted theoretically (32). Dogic et al. (32) explained this by stating that the depletion attraction caused by the polymer is screened by long-range electrostatic repulsion of the rods. A similar phenomenon may be occurring here.

In addition, the nonionic FITC dye is more hydrophobic than CB dye and is more likely to be found in the interior of the dextran coil, where it is not available to adsorb onto cellulose nanocrystals. Although free FITC dye has been found to adsorb somewhat onto cellulosic materials (36, 37), there may be a high concentration of nonadsorbed neutral FITC-dextran, which may be better tolerated in the anisotropic phase because it is more mobile and can fit in the defects (although blue dextran also fits in defects) and is not electrostatically repelled by the nanocrystals. If some FITC dye molecules are available for binding, they may not adsorb on cellulose to as great an extent as CB (the binding energy may be weaker for FITC than for CB dye); FITC-dextrans with higher DS may possibly partition more strongly. FITC-dextran 2000 has a radius of gyration of around 16 nm measured by GPC-LS in pH 7 0.20 mol/L $NaNO_3$ + 0.01 mol/L NaH_2PO_4, which is significantly smaller than the radii obtained for blue dextrans 2000 (see Table 1). The smaller size of FITC-Dx is likely caused by its higher hydrophobicity and lack of intramolecular electrostatic repulsions (internal hydrophobic interactions of the aromatic rings cause the macromolecule to contract inwards). FITC-dextran partition coefficient values were found to be slightly lower than predicted theoretically (Fig. 5).

Sear's theoretical calculation considers only the effect of the relative sizes of the rods and coils, in conjunction with the concentration of the rods in each phase, to predict K for a given system (13). The relative concentrations of the two species may also play a role in determining K, particularly in the case of electrostatically charged rods *and* coils, as in the case of blue dextran and cellulose nanocrystals. For blue dextrans, K_{el} (>1) appears to dominate the contribution to K_{meas}, while for FITC-Dx the hydrophobic interactions ($K_{hphob} \leq 1$) of the dye ligands are of greater importance. The theoretical K values for both dextran-dye derivatives therefore lie on the same line (Fig. 5), while their experimental values are very different.

Conclusions

The partitioning behaviour of blue dextrans and FITC-dextrans of high molecular weight in biphasic suspensions of negatively charged cellulose nanocrystals was investigated. Increasing the total concentration of blue dextran increased the partition coefficient by causing a divergence in cellulose concentrations of the isotropic and nematic phases, in agreement with theory and previous experiments conducted in this laboratory. Increased blue dextran–nanocrystal electrostatic repulsions led to larger partition coefficients at higher degrees of CB dye substitution. The effect of CB adsorption onto the cellulose nanocrystal surfaces was discussed. The total concentration of anionic CB dye present in the sample and the DS per AGU affected the electrostatic and entropic contributions to the blue dextran partition coefficient in the cellulose suspension. The divergence between the results presented here and the theoretical prediction of Sear illustrates the influence of the electrostatic charges on the partitioning effect. For blue dextrans and hydrolysed blue dextrans with similar DS at similar total dextran and dye concentrations, the partition coefficient varied linearly with the exponential of $R_g^{5/3}$, in agreement with Sear's partition theory. Dextrans labeled with fluorescein isothiocyanate were found to have partition coefficients of around 1 in this system, possibly because of the lack of electrostatic repulsion and (or) dye adsorption onto cellulose nanocrystals. Blue dextran partition coefficients were larger than predicted theoretically using a second virial coefficient approximation, while FITC-dextran partition coefficients were smaller.

Occurrence of poly(hydroxyalkanoate) in the gut homogenate of a phylogenetically higher termite: *Macrotermes carbonarius*[1]

Kumar Sudesh, Bee-Yong Tay, and Chow-Yang Lee

Abstract: Gas chromatography analysis of a phylogenetically higher termite-gut homogenate detected the presence of trace amounts of poly(3-hydroxybutyrate) (PHB), a prokaryotic storage material. In addition, the gut homogenate smear, stained with Nile blue A, also suggested the presence of PHB-like granules. Chloroform extracts of both soldier and worker classes of this termite were obtained for further spectroscopic analysis. FTIR, ^{1}H NMR, and 2D ^{1}H-^{1}H NMR analyses confirmed the presence of PHB in both the chloroform extracts. This showed for the first time the occurrence of bacteria capable of accumulating PHB in the termite gut. The results indicated that the physiological environment in the termite gut is suitable for the colonization by PHB-producing bacteria and is probably rich in organic carbon sources, which can be readily assimilated and stored as PHB.

Key words: Macrotermes carbonarius, poly(hydroxyalkanoate), PHB, termite

Résumé : L'analyse par chromatographie gazeuse d'une préparation homogénéisée d'estomac de termites phylogénétiquement plus élevées a permis de détecter la présence de traces de poly(3-hydroxybutyrate) (PHB), un matériel d'emmagasinage prokaryotique. De plus, un frottis d'une préparation homogénéisée d'estomac, teint avec du bleu du Nile A, suggère aussi la présence de granules ressemblant à du PHB. On a aussi obtenu des extraits au chloroforme des classes tant de soldat que de travailleur de cette termite qui ont pu être analysés par des méthodes spectroscopiques. Des analyses par IR à transformée de Fourier, par RMN du ^{1}H et par RMN ^{1}H-^{1}H en 2D ont permis de confirmer la présence de PHB dans chacun de ces extraits chloroformiques. Ces résultats démontrent pour la première fois l'existence de bactéries qui sont capables d'accumuler du PHB dans l'estomac des termites. Ils démontrent aussi que l'environnement physiologique dans l'estomac des termites est approprié pour la colonisation par des bactéries pouvant produire du PHB et qu'il est probablement riche en sources de carbone organique qui peut être facilement assimilé et emmagasiné sous la forme de PHB.

Mots-clés : Macrotermes carbonarius, polyhydroxyalcanonate, PHB; termite.

Introduction

Poly(hydroxyalkanoate) (PHA) is a carbon- and energy-storage material accumulated by a large number of prokaryotes (1). The synthesis of PHA by bacteria usually occurs when carbon source is abundant. The most common type of PHA found naturally in the environment is poly(3-hydroxybutyrate) (PHB). The ability to accumulate PHB has been shown to enhance the survival of bacteria during prolonged period of starvation and (or) under stress conditions (2). PHB also serves as an electron sink and provides energy for the energy-intensive process of sporulation in some bacteria (3, 4). The occurrence of PHB in an environmental sample provides physiological evidence for the presence of prokaryotic microorganisms capable of synthesizing this storage material (5). In addition, it also indicates suitable growth conditions for bacteria and the presence of sufficiently high concentrations of organic carbon sources that can be assimilated and polymerized into PHB.

The intestine of termites is colonized by a variety of microorganisms (6), which contribute to the biomineralization of lignocellulosic matter ingested by termites. These microorganisms have attracted the attention of microbiologists because of their important and interesting symbiotic association with the termite host for the efficient biorecycling of plant litter (7). A major drawback faced by microbiologists in understanding the physiological aspects of termite gut microbiota is the difficulty to cultivate most of the microorganisms in the laboratory (8). To partially solve this problem, culture independent methods have been used to identify and characterize the various types of microorganisms (7, 9).

The primary objective of this study was to determine if termite-gut environment provides conditions favorable for the colonization by PHA producing bacteria. Although molecular methods have revealed the presence of bacteria that

are phylogenetically related to PHA producers (10), there is still no evidence for the occurrence of PHA-producing bacteria in termite gut. Furthermore, it is not known if the nutritive conditions in the termite gut favor the growth of PHA producing bacteria and that substantial amounts of suitable carbon sources are available to the bacteria for the accumulation of PHA. Here, we report for the first time the occurrence of PHA in a phylogenetically higher termite, *Macrotermes carbonarius*. Quantitative monitoring of PHA in the termite gut might be useful in defining the recent nutritional history of the gut microbiota. In addition, knowledge of the microorganisms in the termite gut will provide new insights into the possibility to convert lignocellulosic matter to PHA.

Materials and methods

Live worker and soldier termites of *M. carbonarius* were collected from mound material dug from various locations in Universiti Sains Malaysia. The termites were transported to the laboratory together with their fungus comb. The termites were then separated into workers and soldiers based on their obvious morphological characteristics (11, 12). One hundred workers were cleaned using sterile distilled water and 70 % ethanol before extracting their whole guts for gas chromatography (GC) analysis. The freeze-dried gut homogenate was methanolyzed in a screw-capped test tube at 100 °C for 140 min in a mixture of 2 mL chloroform, 1.7 mL methanol, and 0.3 mL concentrated sulfuric acid. Upon completion, 1 mL of distilled water was added to the cooled mixture and vortexed for 1 min. After phase separation, the organic phase (bottom layer) was subjected to GC analysis. A Shimadzu GC-14B capillary gas chromatograph system equipped with flame-ionization detector (FID) was used along with a fused silica capillary column (SPB^{TM}-1, Supelco) for the analysis.

The remaining workers (1368) and soldiers (706) were homogenized separately prior to lyophilization. A total freeze-dried mass of 14.5 g whole soldier homogenate and 4.5 g whole worker homogenate were obtained and subjected to extraction with hot chloroform for 4 h. The brownish chloroform extracts were then concentrated to approximately 10 mL and added to 100 mL of rapidly stirred cold methanol. This resulted in the formation of a fluffy precipitate, which was recovered by filtration and dried in vacuo before subjecting to spectroscopic analyses. For ^{1}H, ^{13}C NMR, and 2D ^{1}H-^{1}H NMR spectroscopy analyses, the dried precipitate was dissolved in $CDCl_3$, and the spectra were recorded using a Bruker 400 MHz NMR spectrometer. The same solution was used for FTIR analysis. For the latter, a thin layer of film was made on a ZnSe window by evaporating the solvent. After thorough drying, the IR spectrum of the resulting film was recorded using a PerkinElmer System 2000 FTIR. For comparison purposes, pure PHB was synthesized and purified from *Delftia acidovorans* according to a method described recently (13).

Results and discussion

GC analysis of the lyophilized whole-gut extract of *M. carbonarius* workers revealed the presence of trace amounts (<0.5% of the gut dry mass) of PHB. Nile blue A staining of the gut homogenate smear also suggested the presence of PHA-like granules, which showed the typical bright orange fluorescence when viewed under a UV-light microscope (results not shown). These results provided early indication for the presence of PHA in the termite gut. To obtain conclusive evidence, large quantities of lyophilized whole-termite homogenate were subjected to chloroform extraction to dissolve any PHA that may be present. During the precipitation step in methanol, the formation of white fluffy material was a further indication for the presence of relatively high molecular mass PHA. Upon filtration, the white precipitate was co-purified with a brownish pigment. To remove the brownish pigment, the above process of dissolving in chloroform and precipitating in methanol was repeated. This resulted in lesser amount of the brownish pigment, as indicated by its lighter color intensity. However, it also reduced the amount of the white fluffy precipitate. No further attempts were made to remove the brownish pigment, as it may decrease the concentration of any PHA that was extracted.

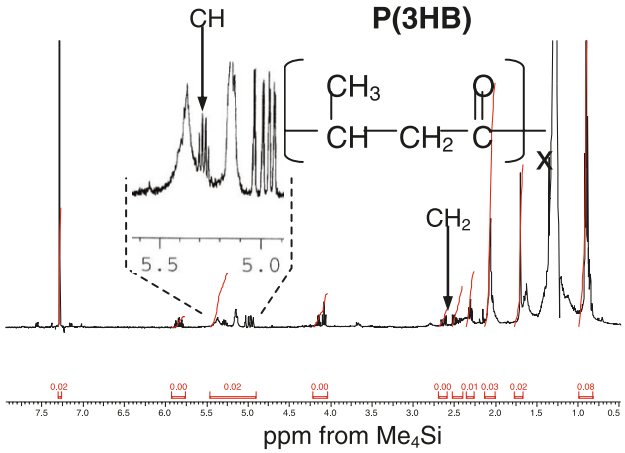

Fig. 1. ^{1}H NMR spectrum of chloroform extract of whole worker homogenate recorded at 25 °C in $CDCl_3$. Inset shows an expanded spectrum in the vicinity of methine proton resonance of PHB.

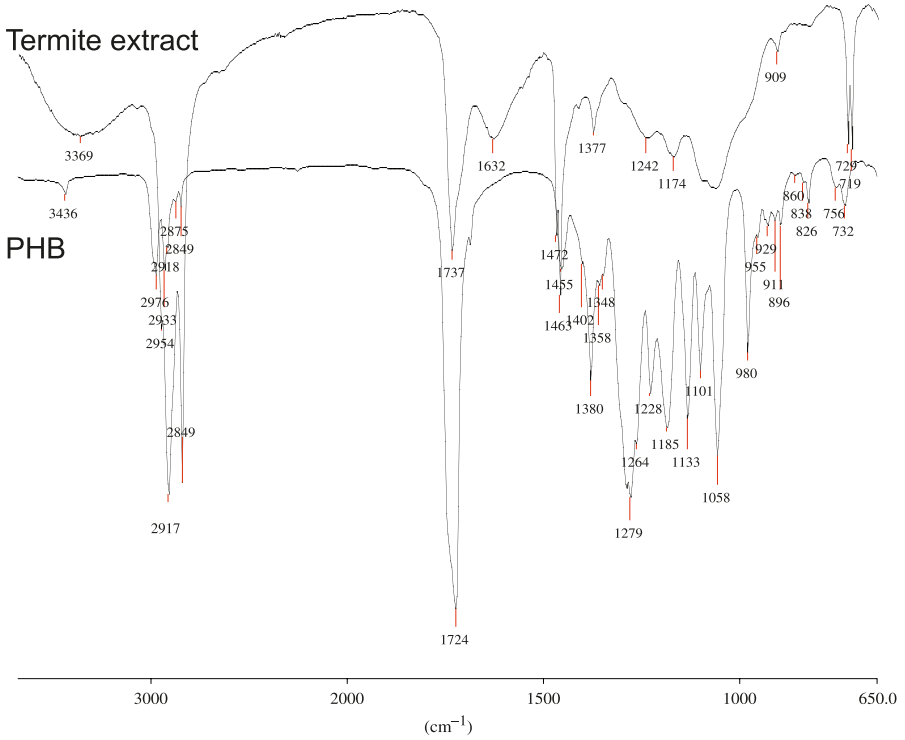
Figure 1 shows the ^{1}H NMR spectrum of the extract recorded in $CDCl_3$ at 25 °C. The chemical shifts are in ppm from TMS. The predominant peaks at around 0.9 ppm and 1.4 ppm can be attributed to methyl and methylene protons of long-chain alkanes. This is further supported by the symmetric–asymmetric stretching bands of methyl–methylene at around 2900 cm^{-1} in the FTIR spectrum (Fig. 2) of the chloroform extract. The carbonyl (C=O) stretching band at 1724 cm^{-1} (appears as a faint shoulder near the band at 1737 cm^{-1}) is a characteristic band of PHB, as shown in the spectrum obtained from pure PHB. However, the bands at 2900 cm^{-1} are more intense than that at 1724 cm^{-1}, indicating that most of the extracted products may be long-chain alkane compounds. Therefore, the peak from methyl protons of PHB (1.27 ppm) in the NMR spectrum may be overlapping with the peak at 1.4 ppm due to the methylene protons of long-chain alkanes. Because of the significant amount of co-purified long-chain alkane compounds, the presence of PHB could not be confirmed from the FTIR spectrum.

© 2008 NRC Canada

Fig. 2. FTIR spectra of chloroform extract of whole worker homogenate and pure poly(3-hydroxybutyrate) (PHB).



Further clues for the presence of PHB was obtained from a faint peak at around 5.27 ppm in the ^{1}H NMR spectrum (Fig. 1). By comparison with previously reported ^{1}H NMR spectrum of PHB (14), the peak near 5.27 ppm may be a resonance from the methine proton of PHB. In addition, weak resonance peaks (2.45–2.65 ppm) corresponding to the methylene protons of PHB can also be detected from the ^{1}H NMR spectrum (14). The identities of the peaks also were confirmed by comparing with the ^{1}H NMR spectrum of pure PHB sample (see Supplementary Data).[3] To obtain further confirmation, 2D ^{1}H-^{1}H NMR analysis was performed, and the result is displayed in Fig. 3.

Clear correlation peaks were seen between the neighboring protons of methine and methylene. In addition, correlation peaks were also observed between methine and methyl protons showing that they are adjacently located as is in the case of PHB. These results provided strong evidence for the presence of PHB in the chloroform extract of the worker-class termite homogenate.

Another interesting type of PHA has also been identified in many organisms, including eukaryotes. This PHA is characterized by its low molecular mass, because it is consisted of less then 150 monomeric units of either 3-hydroxybutyrate or 3-hydroxyvalerate. Unlike the high molecular mass storage PHA synthesized by most bacteria, the low molecular mass PHA is a non-storage PHA and is usually complexed with other cellular macromolecules; hence they are referred to as complexed PHA (15). It is possible that some of the non-storage PHAs may have been co-extracted from our samples. However, we have also carried out ultrastructural studies on the termite gut, which revealed the presence of many bacterial cells that contained discrete granules resembling PHAs (see Supplementary Data).[3] Based on all these evidences, the PHB detected in this study is most likely the storage PHB accumulated by bacteria in the termite gut.

NMR and FTIR analyses of chloroform extract of the soldier-class termite homogenate also produced similar results (results not shown). Thus, the occurrence of PHB was confirmed in both the soldier and worker homogenates. The results indicated the presence of PHB producing microorganisms in the gut of both soldier and worker classes of this termite. It is known that the soldiers are not capable of feeding themselves because of their huge mandible. The soldiers have to be fed by the workers by a process called trophallaxis. Therefore, the intestinal microbiota of *M. carbonarius* soldiers must have originated from the workers and therefore may be quite similar. The occurrence of PHB in the guts of both these classes provides good evidence for the similarities of gut physiological conditions in workers and soldiers. In addition, this study has also shown that the physiological environment of the guts of both soldiers and workers allow for the growth and proliferation of PHB producing bacteria and that suitable types and concentrations of carbon sources are readily available for PHB biosynthesis. We have since successfully isolated three morphologically different bacteria capable of producing PHB from the gut of *M. carbonarius* (manuscript in preparation). By understand-

Thiolysis of poly(3-hydroxybutyrate) — A novel biochemical reaction[1]

K. Uchino and T. Saito

Abstract: An enzyme involved in the degradation of poly(3-hydroxybutyrate) (PHB), PhaZa1 from *Ralstonia eutropha* H16, catalyzes the thiolysis of PHB with coenzyme A. The properties of this novel reaction were investigated in vitro. The active center's cysteine residue was point-mutated to prepare C183S and C183A. The wild type and the two mutants were compared in terms of hydrolytic and thiolytic activity. C183S was as active as the wild type in the hydrolysis, but less active in the thiolysis, of PHB. The cysteine residue was important for the thiolysis of PHB, which may be why it has been conserved in almost all PhaZa1 homologs in various bacteria.

Key words: PHB, thiolysis, PHB depolymerase

Résumé : Un enzyme impliqué dans la dégradation du poly(3-hydroxybutyrate) (PHB), le PhaZa1 obtenu à partir du *Ralstonia eutropha* H16, catalyse la thionolyse du PHB en présence du coenzyme A (CoA). On a étudié les propriétés de cette nouvelle réaction in vitro. On a fait subir une mutation au résidu cystéine du centre actif pour préparer les enzymes C183S et C183A. On a comparé le type original et les deux mutants en termes d'activités hydrolytique et thiolytique. L'activité hydrolytique du mutant C183S est aussi grande que celle du produit original, mais moins active dans la thiolyse du PHB. Le résidu cystéine est important pour la thiolyse du PHB et c'est probablement la raison pour laquelle il a été conservé dans pratiquement tous les homologues du PhaZa1 dans diverses bactéries.

Mots-clés : PHB, thiolyse, dépolymérase du PHB.

Introduction

Poly([R]-3-hydroxybutyrate) (PHB) is a natural polyester found in a wide variety of bacteria (1). The bacteria accumulate PHB in their cells and utilize it as a source of energy and carbonlike glycogen or fat. In cells of PHB-producing bacteria, PHB was found as discrete granules (inclusion bodies). Bacteria depositing PHB may be dead and release PHB into the environment. While amorphous in inclusion bodies, PHB becomes semi-crystalline out of the cell. Some bacteria and fungi (2) hydrolyze semi-crystalline PHB to its monomer [R]-3-hydroxybutyrate (3HB) by secreting PHB depolymerases, and PHB-producing bacteria have been believed to hydrolyze stored PHB with intracellular PHB depolymerase (eq. [1]).

In *Ralstonia eutropha* H16, a model for studying the PHB metabolism of PHB, several proteins such as PHB synthase, PHB depolymerase, phasin, and a regulatory protein, as well as phospholipids, were found on the surface of PHB granules (3–6).

Recently, it was revealed that PHB was thiolyzed with coenzyme A (CoA) to 3-hydroxybutyryl-CoA (3HB-CoA) in *R. eutropha* H16 when PHB granules were incubated in the presence of CoASH (7) (eq. [2]), and it was suggested that an intracellular PHB depolymerase (PhaZa1) is responsible for this novel reaction (8).

$$[2] \qquad (3HB)_n + CoA \rightarrow (3HB)_{n-1} + 3HB\text{-}CoA$$

Since the basic properties of PhaZa1 from *R. eutropha* as a PHB thiolase are not sufficiently understood, we examined the thiolytic reaction of PhaZa1 in vitro. PhaZa1 has a cysteine at the 183rd amino acid residue as the active center, and this residue is conserved in homologous proteins in various bacteria (9). Therefore, the importance of this cysteine residue was also investigated.

Experimental section

The materials used to prepare buffer solutions, the substrates, and all reagents were obtained commercially except PHB, which was prepared from *R. eutropha*. All solutions were prepared from distilled, deionized water. Spectrophotometric measurements were made using a Shimadzu UVmini-1240 or Bio-Rad microplate reader benchmark. The CoA derivatives were analyzed with a HPLC system (Hitachi, Tokyo, Japan) equipped with an L-6200 pump, a D-2500

 doi:10.1139/V08-034 © 2008 NRC Canada

integrator, a L-4200 detector operated at 254 nm, and a Shodex RSpak RP18-415 column (4.6ϕ × 150 mm, Showa Denko, Tokyo, Japan).

PhaZa1 and the mutated PhaZa1 C183S, in which the cysteine at 183 was replaced by serine, and C183A, in which it was replaced by alanine, were prepared from gene-overexpressing *Escherichia coli*, as reported previously (9). The soluble fraction of the *E. coli* cells was used as the crude extract. Artificial amorphous PHB was prepared with deoxycholate as a detergent as previously described (10).

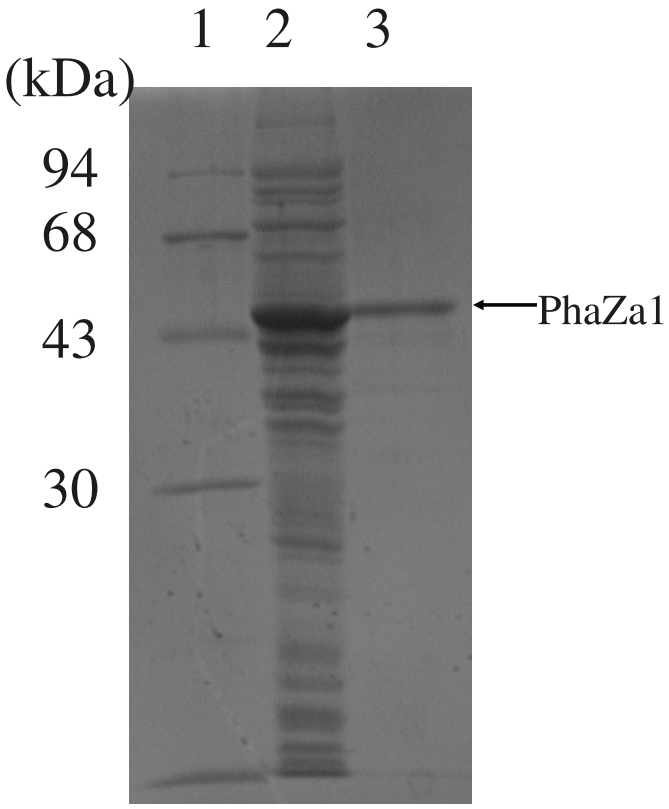
The standard reaction mixture (0.1 mL) containing enzymes, amorphous PHB (deoxycholate-coated, final concentration 0.5 mg/mL, or washed PHB (see below), final concentration 1.0 mg/mL), 50 mmol/L Tris-HCl buffer, pH 8.0, and 1 mmol/L CoA was incubated at 30 °C. Samples were acidified with 10 µL of 1 N HCl to stop the reaction and then centrifuged (15 000g, 5 min). The supernatant was stored on ice or at –20 °C prior to use. For the thiolytic assay, the supernatant was analyzed by HPLC in conditions described previously (8). For the hydrolytic assay, 3HB in the supernatant was measured based on the reduction of NAD^+ with 3HB dehydrogenase as previously reported (9). In other experiments such as the experiment to find the optimum pH, the components or concentrations were modified as written in the following. Enzymes were not stable after purification, therefore crude extracts were used as enzymes for assays. These experiments were performed at least twice.

Results and discussion

PhaZa1 was purified from crude extract of the gene-overexpressing *E. coli* (Fig. 1). When PhaZa1 was incubated with amorphous PHB and CoA, it produced 3HB-CoA (Fig. 2). A previous report showed that crude extract of *E. coli* containing PhaZa1 catalyzed the thiolysis of PHB (8), and this was confirmed using purified enzyme. Phasins, proteins covering PHB inclusion bodies in a living cell, were required in some experiments in the previous report (8), but the present study shows that phasins are not essential for the thiolysis of PHB with PhaZa1. Because the purified enzyme easily lost its activity and the crude extract showed the same activity (Fig. 2) and was stable at –20°C for at least 3 months, the crude extract was used as an enzyme. Some components of the crude extract might stabilize PhaZa1, but no component catalyzed thiolysis, since the *E. coli* extract with only the cloning vector showed no 3HB-CoA production (data not shown).

The optimum conditions for the thiolysis of PHB by PhaZa1 were examined. An important aspect was the preparation of the substrate PHB. Generally, intracellular PHB depolymerase cannot degrade semi-crystalline PHB but can degrade amorphous PHB. In a protein-free system, amorphous PHB was prepared using detergents to stabilize the amorphous state, but the detergents inhibited thiolysis. Therefore, amorphous PHB coated with deoxycholate was washed with water. The washed PHB was active as a substrate for the thiolysis of PHB, and 0.2% deoxycholate inhibited thiolysis completely (Fig. 3). The hydrolysis was also inhibited, but the thiolysis was more sensitive to the detergent. On the other hand, a large volume of crude enzyme showed activity with unwashed substrate, possibly because

Fig. 1. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of purified PhaZa1. Each protein (1 µg) was loaded onto a 12% gel. Lane 1, protein markers; lane 2, crude extract; lane 3, PhaZa1. Protein was stained with Coomassie brilliant blue R-250.



of absorption of the detergent by the crude enzymes. Using washed PHB, the optimum pH was examined. As shown in Fig. 4, pH 8 was optimum. At a pH of less than 6 or higher than 9, this reaction was completely inhibited.

To investigate the importance of the active center residue cysteine, three PhaZa1s were tested: PhaZa1 (wild type), and two mutated PhaZa1s, C183S and C183A. Under the conditions described in the Experimental section, the serine-mutation lowered the thiolytic activity by about 80% compared with the wild type. The alanine mutant hardly produced 3HB-CoA. Table 1 shows the activities of hydrolysis and thiolysis by the respective enzymes. The serine-mutated enzyme showed little change in hydrolytic activity but significantly less thiolytic activity (Table 1). The alanine mutant showed neither hydrolytic nor thiolytic activity (Table 1). These three PhaZa1s differ in only one functional group: thiol (cysteine), hydroxyl (serine), or neither (alanine). Therefore, these results suggest that the thiol group at the active center is necessary for thiolysis. A thioester bond has more energy than an ester bond. When the active center was acylated, PhaZa1 would have formed a thioester bond with the substrate, and C183S an ester bond. The thioester bond can more easily promote the transfer of 3HB from the enzyme to CoA than the ester bond.

The thiolysis of PHB is a paradigmic reaction of the degradation of biopolymers that parallels the hydrolysis of nucleic acid and polysaccharide as cellulose etc. and phosphorylation of glycogen and starch. The thiolysis of

Fig. 2. Chromatograms for thiolysis by (*A*) crude extract and (*B*) purified PhaZa1. The reaction mixture contained 50 mmol/L phosphate pH 7.0, washed PHB, 1 mmol/L CoA, and 0.2 mg of crude extract or 15 μg of purified PhaZa1. After incubation for 30 min, 1N HCl was added and the reaction mixture was centrifuged. The concentration of 3HB-CoA was measured with HPLC. Peaks for CoA and 3HB-CoA are shown. Asterisks show unknown peaks. The other peaks are impurities.

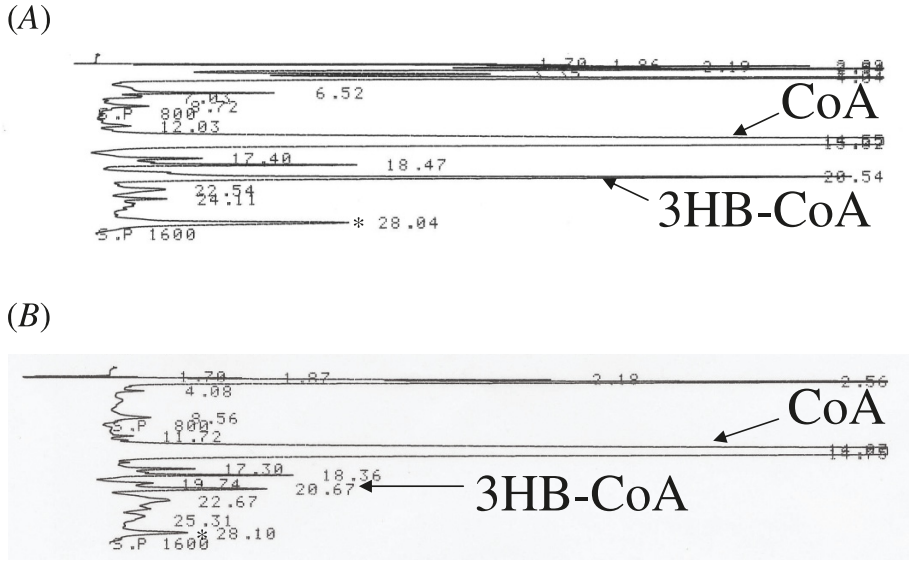

Fig. 3. Inhibition of the thiolysis of PHB by deoxycholate. The reaction mixture contained 0%–0.5% deoxycholate. After incubation for 30 min, 1 N HCl was added and the reaction mixture was centrifuged. The supernatant was analyzed by HPLC.

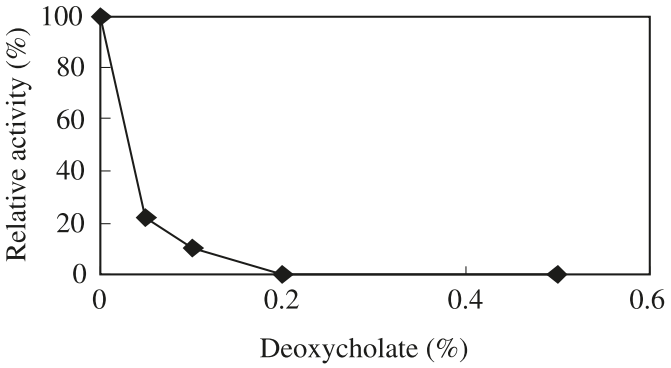

Fig. 4. pH Profile of the thiolysis of PHB. The reaction mixture contained 100 mmol/L buffer: sodium phosphate pH 6–8, Tris-HCl pH 7–9. The reaction was acidified with 1 N HCl at 10 min. The supernatant of the reaction mixture was analyzed with HPLC. The peak height of 3HB-CoA at pH 8 in phosphate buffer was 100%.

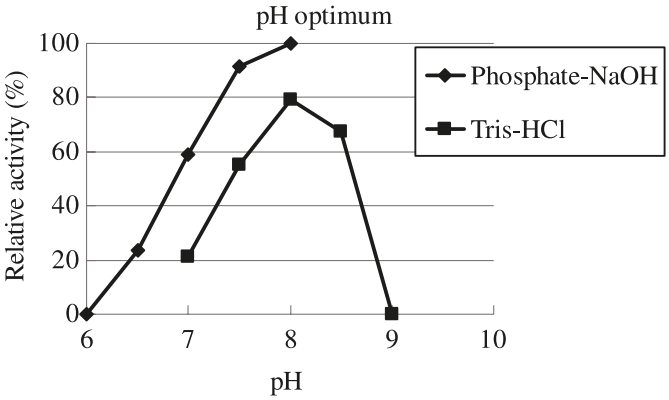

PHB is a novel reaction in the metabolism of PHB. Hitherto, intracellular PHB degradation has been studied only in terms of hydrolysis. However, there have been observations of the turnover of intracellular PHB; PHB is simultaneously synthesized and degraded in *R. eutropha* H16 (11, 12). In the metabolism of PHB, stored PHB has been believed to be hydrolyzed by depolymerases (hydrolases) based on analogy with extracellular PHB depolymerase. Metabolizing 3HB, the product of the hydrolysis, requires an input of energy such as activation with CoA to form 3HB-CoA (eq. 3) or other CoA derivatives as a CoA donor (11).

[3] 3HB + CoA +ATP → 3HB-CoA + AMP + pyrophosphate

Therefore, the simultaneous turnover of PHB occurring in *R. eutropha* H16 wastes a lot of energy. Thiolysis of PHB is much preferable over hydrolysis of PHB in terms of energy, since the energy contained in ester bonds in PHB will be

Table 1. Comparison of hydrolysis and thiolysis.

	3HB Production (mmol/L)	3HB-CoA Production (mmol/L)
PhaZa1	0.55	0.44
C183S	0.34	0.09
C183A	0	0.01

Note: The reaction mixture (100 μL) contained 50 mmol/L Tris-HCl pH 8.0, 1 mmol/L CoA, 2 mg of protein as crude extract. The mixture was incubated for 30 min at 30 °C. The reaction was stopped by the addition of 10 μL of 1 mol/L HCl. After centrifugation, the supernatant of the mixture was analyzed by spectrophotometer for 3HB and by HPLC for 3HB-CoA.

© 2008 NRC Canada

preserved in a thioester bond in 3HB-CoA. Therefore, the thiolysis of PHB is of great significance to the metabolism of PHB in bacteria.

Although PhaZa1 showed both hydrolytic and thiolytic activity toward PHB in vitro, its physiological reaction seems to be the thiolysis of PHB. Thiolysis was catalyzed much more efficiently than hydrolysis with the serine-mutated PhaZa1, C183S (Table 1). PhaZa1 showed almost no hydrolytic activity toward the native PHB granules (8) or in vivo (data not shown). Furthermore, all proteins homologous to PhaZa1 have cysteine at the active center for thiolysis. This shows the importance of the thiolysis of PHB to bacteria since a cysteine residue seems preferable to a serine residue in the thiolytic reaction.

Swelling of *Valonia* cellulose microfibrils in amine oxide systems[1]

Pierre Noé and Henri Chanzy

Abstract: Cellulose microfibrils from *Valonia ventricosa* cell-wall fragments were immersed into molten *N*-methylmorpholine-*N*-oxide monohydrate (NMMO·H_2O), stabilized with *n*-propyl gallate and kept at 80 °C. The resulting ultrastructural modifications, which were followed by transmission electron microscopy and electron diffraction analysis, showed that within minutes the solvent slowly penetrated inside the crystalline microfibrils and progressed as a wedge in between the cellulose chains without cutting them. Prior to dissolution, a longitudinal subfibrillation of the initial microfibrils occurred, leading to the observation of highly swollen microfibrils, which could reach diameters up to three times larger than those of the initial samples. This mode of swelling is compared with those occurring in other systems, where the intracrystalline swelling of cellulose has been described at the ultrastructural level.

Key words: cellulose swelling, *Valonia* cellulose, *N*-methylmorpholine-*N*-oxide.

Résumé : Des microfibrilles en provenance de fragments de paroi de *Valonia ventricosa* ont été immergées à 80 °C dans de la *N*-oxyde de *N*-méthylmorpholine monohydratée (NMMO·H_2O), en présence de gallate de *n*-propyle. La modification de l'ultrastructure de ces microfibrilles a été étudiée par microscopie électronique à transmission et analysée par diffraction des électrons. On observe un gonflement de ces microfibrilles sous l'influence du solvant qui pénètre comme un coin à l'intérieur de celles-ci, en se glissant entre les chaînes cellulosiques. Dans l'étape ultime, avant la dissolution, on remarque des microfibrilles ayant gonflé jusqu'à un diamètre trois fois supérieur au diamètre initial. Ce mode de gonflement est comparé avec d'autres systèmes de gonflement intra-cristallins de la cellulose.

Mots-clés : gonflement de la cellulose, cellulose de *Valonia*, *N*-oxyde de *N*-méthylmorpholine.

[Traduit par la Rédaction]

Introduction

Cellulose can be considered as the archetype of a renewable resource susceptible to yield structural materials of high mechanical properties. For this reason the processing of cellulose into various other products is the focus of never-ending interest. Developed more than a century ago (1), the viscose process has traditionally been the leading method to yield cellulose products, such as yarns, fibers, films, cellular products, etc. Today, however, the viscose process is slowly being abandoned, since it presents serious environmental drawbacks. As a consequence, alternative ways of processing cellulose by finding environmentally friendly solvent systems have been, and still are, the focus of intense research and development.

Among the new cellulose solvents that have been reported, *N*-methylmorpholine-*N*-oxide (NMMO) stands out as being the only organic solvent that has successfully reached the stage of commercialization (2), leading to the development of new cellulose fibers under the trade names of Tencel and Lyocell. Today, these fibers are being successfully incorporated in high class clothing, nonwoven fabrics, as well as in a number of specialty products. As opposed to the viscose process, the dissolution of cellulose in NMMO does not require any derivatization. In this system, the dissolution and regeneration process is derived from the hydrogen-bonding characteristics of the hygroscopic NMMO, which will interact with cellulose if there is a shortage of water, but will reject cellulose if water is in excess. As the melting point of NMMO is inversely related to its water content, the dissolution of cellulose can thus be monitored by temperature and water content. Typical phase diagrams (3, 4) have shown that NMMO monohydrate (NMMO·H_2O: 13.3% water *w*/*w*) acted as a solvent at temperatures in the order of 100 °C, whereas NMMO disesquihydrate (NMMO·2.5 H2O: 28% water *w*/*w*) did not lead to solubilization at any temperature.

Observations of the dissolution of various cellulose fibers into NMMO have shown that if NMMO monohydrate was used at temperatures of 80 °C and above, ramie fibers readily dissolved by breaking down without appreciable swelling (5). On the other hand, if 18–20% *w*/*w* water was present in the system, extensive swelling occurred as the diameter of the fibers could increase several fold without any dissolution. This behavior was also reported for other fibers, such as those of cotton or wood pulp, but the swelling oc-

 doi:10.1139/V08-030 © 2008 NRC Canada

curred in the form of ballooning (5), thus revealing the inner organization of the cellulose microfibrils within the cell walls of these fibers. With ramie, as well as with the other fibers, the swelling process took a substantial time to reach its limit, while their dissolution occurred readily when the water concentration conditions were sufficiently low. At the cellulose crystal level, X-ray and ^{13}C NMR studies have shown that in the case of swelling, the NMMO molecules were able to pry open the $(1\bar{1}0)$ crystallographic planes, while the dense equatorial planes, such as the (110) and (200), were less sensitive to the solvent influence (5–7). On the other hand, no crystalline NMMO-cellulose complex could be detected.

Since X-ray data gives only global information, the ultrastructural details of the swelling of the cellulose crystal under the thrust of hydrated NMMO molecules is not known. This work was therefore undertaken to answer this question. For this, we have used *Valonia* cellulose microfibrils and followed their swelling by transmission electron microscopy, together with selected area electron diffraction analysis. Individual *Valonia* microfibrils, which are easily disrupted from *Valonia* cell walls, have such large dimensions that they can be readily observed in their finer details by transmission electron microscopy (8, 9) and analyzed locally by electron diffraction (10, 11), diffraction contrast imaging (12, 13), or high resolution AFM (14, 15). In view of their high crystallinity and perfection, they have become ideal objects to model any solid-state interaction of cellulose with chemical (16, 17) or enzymatic reagents (18, 19). Indeed, these transformations can be unambiguously followed, both in image and diffraction modes, with a transmission electron microscope. It is believed that the observations made on the transformation of *Valonia* cellulose can be transposed to narrower and less organized cellulose, where the microfibrils are too small to be investigated individually by electron microscopy.

Experimental

Chemicals

N-Methylmorpholine-*N*-oxide (NMMO) and *n*-propyl gallate were purchased from Sigma-Aldrich. NMMO was recrystallized in dry acetone in the form of NMMO·H_2O (melting point 80 °C).

Valonia cellulose

Valonia ventricosa single-cell vesicles were harvested in the Lower Keys, Florida. After puncturing the cells, their walls were dried by pressing on tissue paper. The dried cell walls were immersed overnight in 0.5% (*w*/*w*) aqueous HCl to remove the incrusting calcite and then, after adequate washing, were boiled for 2 h in 2% aqueous NaOH solution. After rinsing thoroughly with water, wall fragments were delaminated with a pair of tweezers under a stereomicroscope. The resulting fragments, with individualized microfibrils, were used for subsequent swelling experiments.

Swelling and dissolution

The swelling was achieved by immersing the *Valonia* cell wall fragments into solutions of NMMO·H_2O containing 2% *n*-propyl gallate and kept at 80 °C for times ranging from a few minutes to four hours. The swollen fragments were removed and washed thoroughly with methanol. For the samples, which had dissolved, the corresponding solutions were diluted with DMSO, cooled and then dialyzed against water to yield a flocculent precipitate.

Transmission electron microscopy (TEM)

The swollen samples, as well as the precipitate resulting from dissolution were deposited on carbon-coated grids. Some samples were negatively stained with uranyl acetate for imaging purposes, whereas others, which were investigated by electron diffraction analysis, were kept unstained. Observations were achieved with a Philips EM 400 T electron microscope operated at 80 kV and normal illumination for imaging purposes and at 120 kV and reduced electron beam for electron diffraction experiments. Calibration of the diffraction diagrams was achieved by depositing some specimens on gold sputtered carbon coated grids and comparing the diameters of the gold diffraction rings with those of the diffraction spots of the specimens.

Results and discussion

Confirming known descriptions (9), the initial *Valonia* cellulose fragments that were used here consist of arrays of slender featureless microfibrils having rigorously parallel edges and lengths of many microns. Whereas each microfibril has a constant diameter throughout its length, there is a variation of these diameters, which range from 25 nm for the largest to no more than 15 nm for the narrowest. This distribution is well illustrated in Figure 1*a*, where out of the three microfibrils, two have a diameter of 24 nm whereas the third one is only 18 nm wide. When the *Valonia* fragments were immersed in molten NMMO·H_2O at 80 °C, a slow swelling was observed before total dissolution. Figures 1*b*–1*d* correspond to local images depicting the various aspects of a fragment that was immersed for 10 min. These figures illustrate the heterogeneity of the swelling action of NMMO on these highly crystalline microfibrils; in the same sample some microfibrils were barely affected, whereas others were extensively swollen and perhaps some even dissolved. In Figure 1*b*, the swelling, which is initiated in the middle of a microfibril, produces an initial delamination, and from there the solvent pries open the intact part of the microfibril in both directions. Interestingly, the swelling does not lead to any sectioning of the microfibril but exclusively produces a longitudinal subfibrillation into no more than three or four elements, the thicker one being about 7 nm wide. These subfibrils, which are parallel to one another, are seen without interruption along the whole swollen area. In Figure 1*c*, a bundle of four microfibrils is swelling in unison, starting from the right hand side of the micrograph towards the left. Again, the delamination into subfibrils is clearly visible, and as in Figure 1*b*, the progression of NMMO into the microfibril can be seen to result from a solvent wedge, slowly progressing in the core of the microfibril. The result is a delamination of the microfibril into narrower elements but again without apparent breakage into shorter segments. In Figure 1*d*, three completely swol-

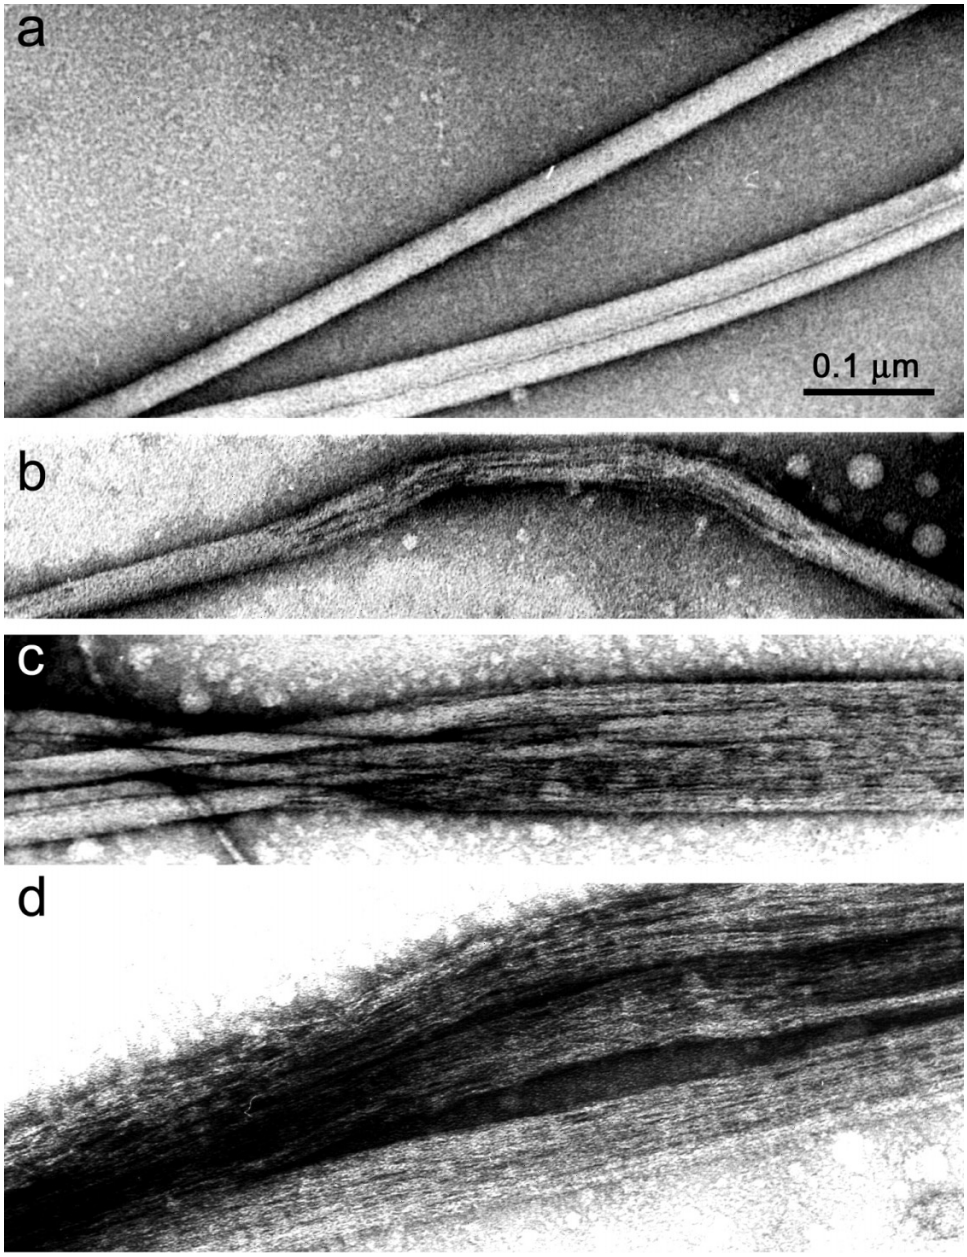
Figure 1. Negatively stained images of (*a*) initial *Valonia* microfibrils and (*b*)–(*d*) aspects of *Valonia* microfibrils after swelling for 10 min in NMMO·H_2O at 80 °C. Figures (*a*)–(*d*) are at the same magnification.



len microfibrils are represented. The widest one has a diameter of 60 nm, i.e., about three times the initial diameter, whereas the other two are respectively 48 and 44 nm wide. Each of these swollen microfibrils now consist of a bundle of about a dozen of undulating subfibrils more or less organized parallel to the microfibril direction but having a diameter no more than 2–3 nm. Whereas the microfibril located at the top of Figure 1*d* shows some trace of dissolution with loosened fibril tips in its upper border, the other two are only swollen and do not present any hint of dissolution or transversal fracturing.

In Figure 2, the state of swelling and its concomitant decrystallization is followed by electron diffraction analysis. Figure 2*a* is typical of a fiber diffraction diagram of a bundle of initial *Valonia* microfibrils aligned vertically. A pattern such as this one contains several hundred diffraction spots extending to a resolution better than 0.1 nm in the fiber direction and 0.2 nm in the equatorial direction. Such wealth of data, which is typical of *Valonia* cellulose (10), denotes a high coherence of large crystalline domains, each of them encompassing the whole width of the corresponding microfibrils. Figure 2*b* corresponds to a bundle of parallel swollen microfibrils, where the subfibrillation is of the type shown in Figure 1*b*, with elements having in the order of 7 nm in width. In this pattern, one still recognizes the main features of the fiber diffraction diagram of native cellulose (cellulose I), but the resolution is much lower than that of the initial pattern. In fact, only the strongest diffraction spots

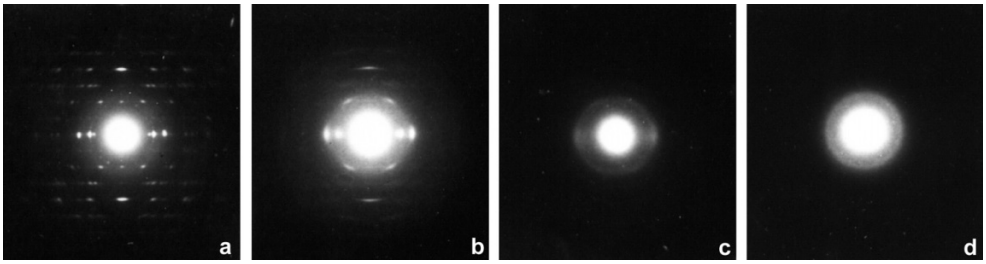
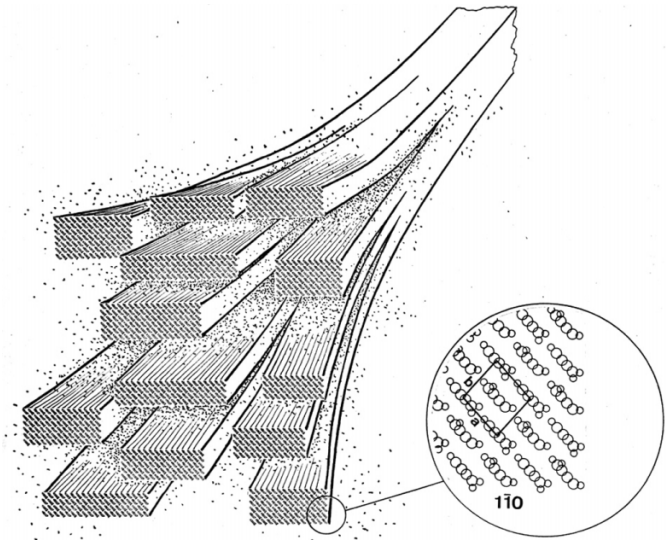
Figure 2. Electron diffraction diagrams of (*a*) a fragment of an initial bundle of *Valonia* microfibrils oriented vertically, (*b*) as in (*a*) but treated for 10 min in NMMO·H_2O at 80 °C (sample morphology as in Fig. 1*b* or 1*c*), (*c*) as in Fig. 2*b* but from a sample bundle resembling that in Fig. 1*d*, and (*d*) a sample of *Valonia* microfibrils treated for 4 h in NMMO·H_2O at 80 °C. The sample was totally dissolved and re-precipitated.



are clearly visible on the equator, the meridian, and the second layer line. This pattern is very similar to a classical electron diffraction diagram of cotton (20), i.e., that of cellulose is made of native crystalline microfibrils having a diameter in the order of 5–6 nm (21). The diagram in Figure 2*c* corresponds to a sample such as the one shown in Figure 1*d*. This diagram consists of only two arced equatorial diffraction spots with *d*-spacings centered at 0.4 and 0.56 nm together with four arced spots on the second layer line, calibrated at 0.43 nm. These features indicate that one is still dealing with native cellulose but with samples of low crystallinity. In fact, the diagram in Figure 2*c* is very similar to that of primary wall cellulose, where the individual microfibrils are fewer than 3 nm wide and one cannot decide whether they belong to the cellulose I or cellulose IV_I crystalline systems (22). Another aspect of the diagram in Figure 2*c* is that unlike samples of primary wall cellulose, it does not present any meridional diffraction spots. This absence reveals that the longitudinal coherence of the crystalline domains along the microfibrils is rather poor, which is in agreement with the undulating aspect of the subfibrils in Figure 1*d*. Figure 2*d* is the diagram of a sample that was left for 4 h in NMMO·H_2O at 80 °C, followed by re-precipitation. Under these conditions, the sample that had been totally dissolved and re-precipitated does not show any hint of left over microfibrils. The diagram, which consists of only one ring at a *d*-spacing of 0.4 nm, can be categorized as belonging to the cellulose II allomorph, but with a rather poor crystallinity.

The results presented in this study are informative since they give ultrastructural details on the progression of NMMO into a crystalline cellulose microfibril prior to its dissolution. The images shown in Figure 1 indicate that once the amine oxide has started to swell a given microfibril, the solvent wedges its way along the microfibril by cutting the hydrogen bonds that hold the cellulose chain together. This mechanism is schematically illustrated in Figure 3, which sketches the penetration of NMMO·H_2O into a typical crystalline *Valonia* microfibril consisting of ~1000 chains. In this sketch, which would correspond to the situations in Figs. 1*b* and 1*c*, the initial microfibril is split into 13 fibrous blocks, each having from ~40 to 100 chains and lateral dimensions ranging from 60 to 110 nm. In addition, the blocks have been drawn with a somewhat narrower dimension along the (110) planes, but wider along the ($1\bar{1}0$) planes of the lattice, which is in agreement with earlier descriptions (5). Obviously, a subsequent penetration of the solvent will further divide these initial blocks, which will thus become narrower and narrower until individual chains are surrounded by the solvent, with the result of total dissolution. Thus, a given microfibril subjected to a solution of NMMO·H_2O at 80 °C will successively lose its "crystalline *Valonia*" characteristic denoted by its well-resolved electron diffraction diagram (Fig. 2*a*) to adopt a cotton-like character (Figs. 1*b* and 2*b*) and then that of a primary-wall cellulose sample (Figs. 1*d* and 2*c*), before being completely dissolved.

Figure 3. Schematic representation of the swelling of one *Valonia* microfibril subjected to NMMO·H_2O at 80 °C for a few minutes. This sketch corresponds to the images shown in either Fig. 1*b* or 1*c*.



Unlike the case of ramie fibers, which dissolve readily into NMMO·H_2O, it seems that the highly crystalline *Valonia* microfibrils take some time to dissolve at 80 °C, even if there is a large excess of solvent. As aforementioned, all the microfibrils of a given *Valonia* cell wall fragment do not interact with the solvent at the same rate, since in a given preparation there is at the same time a distribution of swollen states, as illustrated in Figs. 1*b* and 1*c*. This distribution may be related to the perfection of the initial microfibrils where the presence or the absence of crystalline defects may or may not govern the extent of swelling at a given time. In related systems where *Valonia* cellulose was swollen in

© 2008 NRC Canada

strong aqueous NaOH solutions, it was shown that no swelling could occur unless some defects could first be created by some acid hydrolysis (23). It was thus clear that to penetrate into the cellulose lattice, the aqueous NaOH had to start from some crystalline defect. A similar mechanism must take place here, but at a much faster rate as NMMO·H_2O is much more aggressive than NaOH at breaking the hydrogen bonds of cellulose.

Another somewhat unexpected result of this study is that in their interaction with NMMO·H_2O, *Valonia* microfibrils do not break down into shorter segments but undergo only a longitudinal splintering. This observation is an indication that the cellulose chains remain intact during the whole process and that the swelling forces are not strong enough to break the cellulose molecules. In fact, cellulose is subject to severe oxidation and chain scission when interacted with NMMO alone, but the use of the antioxidant *n*-propyl gallate protects the molecules and prevents any cellulose chain scission (24). The use of 2% of this antioxidant with respect to NMMO·H_2O may therefore explain why no cellulose chain and consequently no microfibril was split into short elements during the swelling process.

The spectacular images of *Valonia* microfibrils swollen in NMMO·H_2O can be compared with those of other systems where the microfibrils were also swollen under the action of specific intracrystalline swelling agents. Images somewhat reminiscent of the one presented here were obtained when *Valonia* cellulose was converted into cellulose III_I by the addition of ethylenediamine. In such a case as the present one, each microfibril became swollen without intermingling with its neighbors and one observed a longitudinal splintering of the microfibrils (16) but much less pronounced than the one shown in the present case. In fact, the complex of cellulose with ethylenediamine is highly crystalline and possesses a fixed stoichiometry based on one ethylenediamine molecule per glucosyl residue (25). This incorporation of ethylenediamine into the cellulose lattice leads to its lateral expansion of about 1.5 times, and thus to an equivalent increase of the diameter of the microfibril (26). This increase, which is about half of what is observed in Figure 1*d*, explains why the ethylenediamine-swollen microfibrils do not show the unique open subfibrillated structure, which is shown here.

In the case of swelling with concentrated aqueous NaOH, only acid-treated *Valonia* microfibrils could be modified (23, 27). After such a treatment, the swelling of individual microfibrils in a pattern similar to that of ethylenediamine or NMMO·H_2O was not observed. In the case of compact cell wall fragments, the action of NaOH leads to an extensive intermingling of the microfibrils, but no subfibrillation could be observed (27). In the case of individual microfibrils, the swelling action corresponded more to a stripping of the cellulose chains located at the surface of the microfibrils, while the core remained intact (23). Again, the swelling pattern in concentrated NaOH was substantially different from the one observed here, which, so far, appears to be unique in the field of cellulose.

Acknowledgements

This paper is dedicated to Professor R.H. Marchessault, not only for his wonderful guidance as a mentor and a friend through more than four decades but also for his inspiring contributions to the fields of biopolymers, polysaccharides, cellulose, and carbohydrates. The authors are also indebted to Professor P. Smith for the drawing in Fig. 3 and valuable discussions during this work.

Mixed-dimer formation in binary systems of 4-substituted benzoic acids and structure considerations[1]

Maren Roman, Annett Kaeding-Koppers, and Peter Zugenmaier

Abstract: The phase behavior of binary systems of 4-substituted benzoic acids is governed by the formation of mixed dimers. This study was conducted to determine the effect of the components' structural difference on mixed-dimer formation in crystalline and liquid-crystalline phases. The phase diagrams of two systems, with 4-[(*S*)-(–)-2-methylbutoxy]benzoic acid (MBOBA) as one component and 4-(hex-5-enoxy)benzoic acid (HOBA) and 4-(dec-9-enoxy)benzoic acid (DOBA), respectively, as the second component, were determined by differential scanning calorimetry, polarized-light microscopy, and X-ray diffraction. The MBOBA-HOBA system exhibited a cholesteric phase, two solid solutions, and above 58 °C for compositions between 40 and 80 mol% HOBA a crystalline phase of mixed dimers. The MBOBA-DOBA system showed a crystalline phase of mixed dimers at all compositions, a cholesteric phase, and a twisted smectic C phase, which was dominated by mixed dimers at 60 and 70 mol% DOBA. We conclude that liquid-crystalline phases are generally dominated by mixed dimers, but in crystalline phases the formation of mixed dimers is promoted by a greater difference in molecular structure. The crystal structure of two of the pure compounds MBOBA and DOBA and comparable compounds have been determined for an evaluation of the arrangements of the molecules in the crystal and liquid-crystalline state.

Key words: benzoic acid, crystal arrangement, phase diagrams, liquid crystal.

Résumé : Le comportement de phase des systèmes binaires d'acides benzoïques substitués en position 4 est régi par la formation de dimères mixtes. On a réalisé cette étude dans le but de déterminer les effets des différences de structure des composants sur la formation de dimères mixtes dans les phases cristallines et à cristaux liquides. Les diagrammes de phase de deux systèmes dans lesquels ont retrouve d'une part, dans tous les deux, de l'acide 4[(*S*)-(–)-2-méthylbutoxy]benzoïque (AMBOB) et, d'autre part, respectivement de l'acide 4-(hex-5-énoxy)benzoïque (AHOB) et de l'acide 4-(dec-9-énoxy)benzoïque (ADOB) en faisant appel à la calorimétrie à balayage différentiel, à la microscopie à lumière polarisée et la diffraction des rayons X. Le système AMBOB/AHOB, on observe une phase cholestérique, deux solutions solides et, au-dessus de 58 °C, pour les compositions entre 40 et 80 mol% d'AHOB, on observe aussi une phase cristalline des dimères mixtes. Le système AMBOB/ADOB, présente une phase cristalline de dimères mixtes pour toutes les compositions, une phase cholestérique et une phase smectique C décalée qui était dominée par les dimères mixtes pour les compositions allant de 60 à 70 mol% d'ADOB. On en conclut que les phases à cristaux liquides sont généralement par les dimères mixtes, but que dans les phases cristallines la formation de dimères mixtes est facilitée par une plus grande différence dans les structures moléculaires. On a déterminé les structures cristallines des composés AMBOB et ADOB et de composés apparentés afin d'évaluer les arrangements des molécules dans le cristal et dans l'état à cristal liquide.

Mots-clés : acide benzoïque, arrangement cristallin, diagrammes de phase, cristal liquide.

[Traduit par la Rédaction]

Introduction

Molecules of benzoic acid and its derivatives generally pair through intermolecular hydrogen bonds and form dimers. The bonding is so strong that, on heating, the dimers persist from the crystalline state through to the isotropic state (1). A dimer has a larger aspect ratio and twice the number of polarizable aromatic rings and carbonyl groups

with respect to a single molecule. However, due to the formation of dimers by hydrogen bonding by the carbonyl groups, the dipoles are compensated and an antiparallel arrangement of the molecules is favored. For this reason, most of the 4-substituted benzoic acids with linear substituent groups are liquid-crystalline (2). When 4-substituted benzoic acids are mixed, dimers containing two different molecules can be formed. In studies of binary systems of 4-substituted benzoic acids (3, 4), a number of systems showed deviation from eutectic phase behavior. Mixed-dimer formation is thought to be the reason for the high melting points in these systems.

In this study, crystalline and liquid-crystalline phases of these systems have been investigated with a focus on the formation of mixed dimers. To determine the effect of the difference in molecular structure of the components on mixed-dimer formation, we studied two systems that have one common component and whose second components differ only in the length of the substituent groups. In the first system, the molecular structures of the components are fairly similar so that mutual solubility is expected. In the second system, the molecular structures of the components are distinctly different, which can result in eutectization. The component that both systems have in common is the chiral 4-[(*S*)-(–)-2-methylbutoxy]benzoic acid (MBOBA). This compound is not liquid-crystalline but a tendency to form a mesophase is anticipated because 4-butoxybenzoic acid is mesomorphic. Because of its asymmetric carbon atom, MBOBA is further expected to twist the molecular arrangements in the mesophases of the second components, which are 4-(Hex-5-enoxy)benzoic acid (HOBA) and 4-(Dec-9-enoxy)benzoic acid (DOBA). Further clues for the formation of chiral phases can be provided by consideration of the unusual arrangement of the pure compounds.

Experimental

Materials

MBOBA was synthesized by brominating (*S*)-(–)-2-methylbutan-1-ol (5, 6) with phosphorus tribromide (7, 8) and subsequently reacting the obtained (*S*)-(–)-2-methyl-1-bomobutane with 4-hydroxybenzoic acid. The different alkenoxy benzoic acids used in this study were prepared as described in ref. (9). The properties of the pure components (Table 1) were determined as described in the methods section below. For MBOBA, no liquid-crystallinity was observed; it showed two crystalline phases, C^{α} and C^{β}. HOBA, consisting of longer molecules, exhibited a nematic mesophase. DOBA showed a nematic and a smectic C mesophase. A crystalline phase transition was observed below 80 °C in X-ray measurements. The transition was very slow, which we attributed to impurities (10). As a consequence, the crystalline phase transition of the DOBA was only indirectly revealed by differential scanning calorimetry (DSC): the enthalpy of melting upon cooling was lesser by 12.4 kJ/mol than upon first heating. This decrease implied that in the heating run the crystalline phase transition occurred at the melting temperature and was supercooled below 0 °C in the cooling run. The transition did not occur during the second heating, as the enthalpy of melting was in good agreement with the one for cooling.

Methods

Eleven mixtures were prepared for the MBOBA–HOBA system and nine for the MBOBA–DOBA system by co-dissolving various amounts of the components in warm ethanol. The solvent was allowed to evaporate over a period of one to two weeks after the solutions had cooled to room temperature.

Transition temperatures were determined with a PerkinElmer DSC7. Samples were prepared by weighing 4–6 mg of a mixture into an aluminum pan and then sealing it. Every sample was heated, cooled, and heated again at a rate of 5° min^{-1}.

Mesophases were identified using an Olympus BH-2 polarized-light microscope with a Linkam THM600 hot stage. The crystalline regions were investigated with an Anton Paar Kratky Compact Small Angle System with a KH-R sample heater. Samples were prepared by melting a small amount (about 2 mg) of a mixture on a microscope slide and driving it by capillary action into a quartz capillary, where it recrystallized on cooling.

Crystals of the mixture 65 mol% HOBA in MBOBA, as obtained from solution, were investigated with an in-house flat-film camera equipped with an FP82-Mettler hot stage.

Single crystals suitable for X-ray investigations were obtained by slow crystallization. The data collections was performed on a CAD4 single-crystal diffractometer with Mo K α radiation and the MolEN package (Enraf Nonius, Delft) (11), and (or) the Shelxl-93 program (12) was used for data processing and refinement. The starting models were obtained by SIR97 (13). Here, we concentrate on the conformation and packing arrangement of the molecules only. A full description and discussion of the data will be published

elsewhere. The drawings were obtained with SCHAKAL-92 (14).

Results and discussion

Crystal structures

Almost all benzoic acids, composed of single non-chiral compounds and forming dimers by hydrogen bonds, crystallize in centric space groups with an inversion center between the carbonyl groups (15, 16). However, a 1:1 mixture of two different benzoic acids is devoid of the inversion center and an acentric space group can describe the crystal structure (16) with consequences for the chirality of the liquid-crystalline phases (17).

MBOBA and four benzoic acids with a linear group attached in 4-position of the benzyl ring, namely 4-(but-3-enoxy)benzoic acid (BOBA), 4-(pent-4-enoxy)benzoic acid (POBA), 4-(dec-9-enoxy)benzoic acid (DOBA), and 4-(undec-10-enoxy)benzoic acid (UOBA), have been investigated by single crystal analysis to get insight into the conformation and packing arrangements of these molecules, which are important for a discussion of the liquid crystal phases observed. All five compounds are arranged in antiparallel fashion to compensate the strong dipoles of the molecules and form dimers. They have in common a similar distance of the two C–O bonds of the carbonyl group of which both oxygens are involved in hydrogen bonds and a gauche position of the alkoxy segment of the linear substituent.

The chiral MBOBA crystallizes in the enantiomorphous space group *P*1 and projections representing the conformation and packing arrangement are shown in Fig. 1. The dimer formations are revealed. Both molecules forming the asymmetric unit have similar conformations. The carbon atom of the methyl branch of the substituent lies in plane with the preceding carbon atoms and oxygen, while the alkoxy segment of the linear group is placed in gauche position involving the oxygen attached to the benzene ring. The molecules are placed in a tilted direction in the unit cell, which means that the length of the molecule, which amounts to 12.2 Å, does not agree with the longest unit-cell axis of *c* = 9.4 Å. The molecules pack in planes with the benzene rings lying flat in these planes and they are staggered (Figs. 1A, 1B, 1C).

BOBA crystallizes in the acentric space group *Pa* with two antiparallel molecules in the asymmetric unit, unique axis *b* (Fig. 2). Although the torsion angles of the alkoxy segment have reversed signs, as expected for centrosymmetric arrangements, the torsion angle of the terminal atom does not follow this reversal, and two distinct different molecules form the dimer and cannot crystallize in a centric space group with an inversion center between the carboxyl groups of the dimers. Here, the dimer is tilted in the *a*–*c* plane, and the length of the dimer of ~20 Å is also longer compared with the largest unit-cell parameter *c* = 14.9 Å. According to our experience, the centric or acentric packing of molecules in the crystalline state may also lead to different kinds of arrangement in the liquid-crystalline state.

Surprisingly, the space group of crystalline POBA is $P2_1$, unique axis *b*, which belongs to the optically active space groups and the ones, which may exhibit second-order non-linear properties. The packing arrangement of the dimers formed is represented in Fig. 3 in two projections. Two antiparallel molecules form the asymmetric unit, which by application of a 2_1 screw axis lead to the four molecules within the unit cell. The molecular axes are placed almost perpendicular to the screw axis *b* in contrast to DOBA, to be discussed. The overall arrangement of POBA resembles the one of BOBA. The length of the dimers amounts to 26.8 Å and is much longer than the *c* parameter of the unit cell with 15.4 Å. Here, a the tilt is observed in the *a*–*c* plane. If mesophases are formed, they are expected to be chiral.

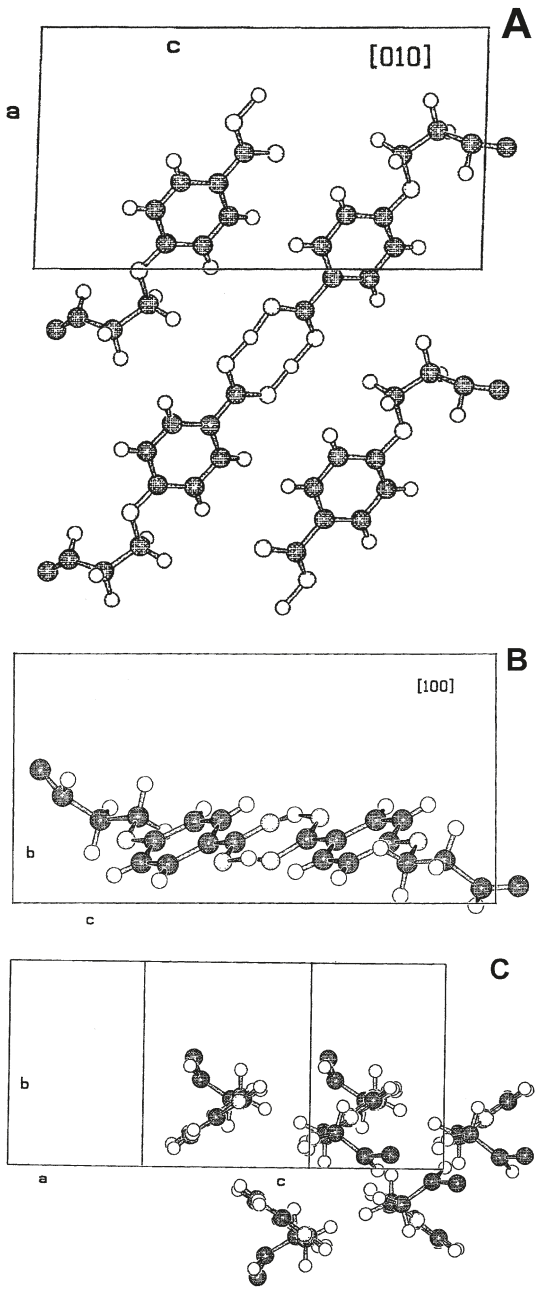
(A) Projection in [010] direction on the *a*–*c* plane showing the formation of dimers through hydrogen bonding. (B) Projection in [100] direction on the *b*–*c* plane showing the overlapping molecules of the plane represented in A. (C) Projection in rod direction showing the lateral packing arrangement of the molecules. The hydrogen atoms at the terminal carbon could not be localized.



In contrast, centric space groups are found for longer linear chains attached in the 4-position on the benzene ring of benzoic acids as DOBA and UOBA. But again the packing arrangement differs for these two compounds.

UOBA crystallizes in the triclinic space group *P*-1. The unit cell contains two molecules, which are connected by an inversion symmetry element, thus forming the expected

Fig. 3. Representation of 4-(pent-4-enoxy)benzoic acid (POBA), which crystallizes in the monoclinic four molecule unit cell of the acentric space group $P2_1$ (*b* unique axis) in two projections. dimer through hydrogen bonds as in almost all benzoic acids (Fig. 4). The gauche conformation of the alkoxy segment forces a change of direction between the central part of the dimer and the linear chain, which exhibits an almost trans conformation. A chain length is difficult to define and amounts to 39.3 Å between the two terminal groups of the dimer and differs considerably, if this length is calculated with a trans conformation of the alkoxy segment.

A similar conformation for the single molecule is found for DOBA as compared to UOBA, but the packing arrangement in the crystalline state differs considerably as shown in Fig. 5. The long dimension *c* is almost doubled due to the centric space group $P2_1/n$, *c* = 41.51 Å for DOBA and *P*-1 with 22.34 Å for UOBA. The unit cell of DOBA has to accommodate two succeeding molecules related by a 2_1 screw axis, which changes the direction of the central part of the dimer in space. Nevertheless, quite similar dimensions of the unit cell are found for the lateral packing of the molecules for DOBA and UOBA. A single molecule represents the asymmetric unit in both structures. A distance between the terminal hydrogen of 32.8 Å was determined for the dimer of DOBA as compared with 39.3 Å for UOBA, and both lengths deviate from a trans conformation of the alkenoxy substituent.

The crystal and molecular structures of the four homologous achiral benzoic acids show a broad variation of possible

low energy states, which may lead to a variety of arrangements of molecules in the liquid-crystalline state. Moreover, chiral molecules are created when the chiral MBOBA forms dimers with achiral benzoic acid homologues regardless of the conformation of the achiral partner.

MBOBA–HOBA system

All MBOBA–HOBA mixtures were liquid-crystalline (Fig. 6). The only mesophase upon heating revealed an "oily streak" texture in the polarized-light microscope, which is characteristic of the cholesteric phase. As anticipated, the nematic molecular arrangement was twisted by the chiral MBOBA molecules and became cholesteric. The fact that 10 mol% of HOBA was enough to induce a mesophase indicated the expected tendency of MBOBA to show liquid-crystallinity. In accordance, extrapolation of the cholesteric–isotropic transition line to 100 mol% MBOBA gave a value of 101.8 °C for the acid's virtual cholesteric–isotropic transition temperature (T^{V}_{N*I}). This value defines how disruptive the non-mesomorphic compound is towards the mesophase (18). Since the value was close to the melting point of 110.5 °C, the disruptive effect of MBOBA, due to the methyl branch of the substituent group, on the nematic molecular arrangement was small.

The melting curve indicated that the MBOBA–HOBA system was not eutectic. To elucidate the deviation from eutectic behavior, we calculated eutectic melting curves (Fig. 6) on a thermodynamic basis using the Schroeder–vanLaar equations (19, 20). The observed melting temperatures were notably higher than the theoretical temperatures for the mixtures with 20 to 70 mol% HOBA, which suggested solid-solubility of the two components or the formation of phases of mixed dimers. To identify the cause for the

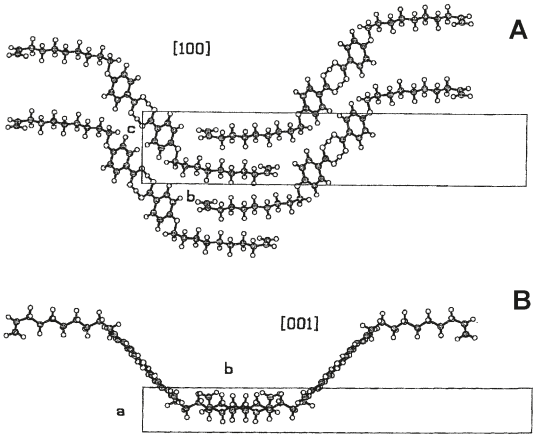

Fig. 6. Crystalline-cholesteric and cholesteric–isotropic transition line for the MBOBA–HOBA system (peak temperatures of the first DSC heating run); T^{V}_{N*I}: virtual cholesteric–isotropic transition temperature (– – –): theoretical melting curves for a eutectic system.

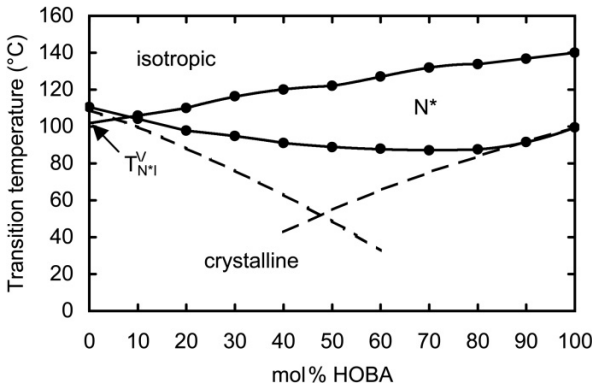

thermal stability of the crystalline region, we investigated the mixtures at different temperatures below their melting temperatures by X-ray diffraction. Below 58 °C two crystalline phases (C^{α}_{A} and C_B) were found, represented by different reflections in the diffraction patterns (Fig. 7). The C^{α}_{A} phase was formed by mixtures containing less than 80 mol% HOBA (Fig. 8). It had a characteristic *d* value equal to the *d* value of MBOBA and was therefore most likely a solid solution of HOBA in MBOBA. The C_B phase was formed by mixtures with more than 65 mol% HOBA and had a *d* value equal to that of HOBA. In this phase, MBOBA molecules or dimers are probably incorporated into the HOBA crystal lattice. In the mixtures with 65 to 80 mol% HOBA, the two phases, C^{α}_{A} and C_B, coexisted.

The high-temperature crystalline phase of the MBOBA, C^{β}_{A}, was found only in the mixtures with a HOBA content less than 20 mol%. For the mixtures containing 40 to 80 mol% HOBA an additional phase (C_{AB}) was found above

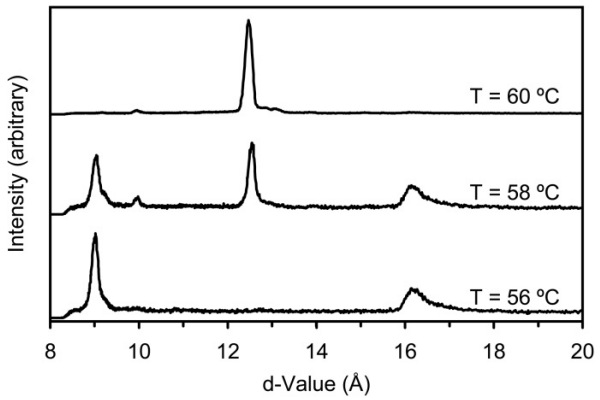
Fig. 7. X-ray diffraction patterns of 70 mol% HOBA in MBOBA.



58 °C. The characteristic *d* value (*d* = 12.5 Å) lay between the *d* values of C_A^{α} and C_B and thus indicated the formation of mixed dimers. The *d* value of MBOBA amounts to ~9 Å that of HOBA to ~16 Å. In the crystalline state, the molecular length of the monomer does not correlate with the *d* spacing obtained by X-ray diffraction due to possible tilted positions within the unit cell. The *d* value of MBOBA is confirmed by the longest *d* spacing derived from the unit cell (*d* = 9.12 Å). The length of the mixed dimer was calculated to 27.4 Å as opposed to 24.2 and 30.2 Å for the pure MBOBA and HOBA dimers (Table 1). The *d* value increased slightly with increasing temperature to *d* = 12.6 Å before melting. The phase transition from the two-phase region into the high-temperature phase was clearly evident at 58 °C in X-ray experiments (Fig. 7).

To assure that this high-temperature phase was not a more highly ordered liquid-crystalline phase, we investigated the mixture with 65 mol% HOBA above 70 °C by polarized-light microscopy. We did not observe any fluidity. A flat-film X-ray diffraction pattern of the same mixture, taken at 80 °C, showed discrete Bragg maxima indicating the presence of small crystalline domains. We concluded that this was not a smectic phase of higher order but a fourth crystalline phase dominated by mixed dimers.

The C_A^{α}–C_{AB} or C_B–C_{AB} phase transitions, respectively, in the mixtures with 40 to 90 mol% HOBA were also revealed in DSC measurements as shown for 50 mol% HOBA in MBOBA in Fig. 9. In most mixtures, the transition occurred just below or at the melting temperature in the first heating run and was strongly supercooled in the cooling run. The shift of the crystalline transition to lower temperatures upon cooling differed for the different mixtures. At 40, 50, and 90 mol% HOBA in MBOBA, the transition was supercooled by about 15 °C, 40 °C (Fig. 9), and 50 °C, respectively. In the mixtures with 60, 70, and 80 mol% HOBA, the transition was supercooled below 0 °C and thus not seen in the cooling trace. It occurred in both directions (exotherm and endotherm) during the second heating run for the mixture with 60 mol% HOBA, but the mixtures with 70 and 80 mol% HOBA did not show the transition upon second heating. The different thermal behavior upon cooling reflected that the transition in the mixtures with 40, 50, 60, and 90 mol% HOBA was into a one-phase region; whereas it was into a two-phase region in the mixtures with 70 and 80 mol%. In the latter case, the molecules had to arrange from one crystal lattice into two different crystal lattices.

Fig. 8. Crystalline phase diagram of the MBOBA–HOBA system (temperatures from X-ray diffraction measurements).

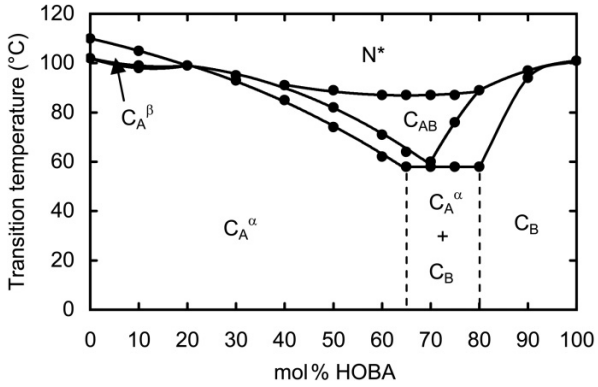


Fig. 9. DSC traces of 50 mol% HOBA in MBOBA; the arrows indicate the C_A^{α}–C_{AB} phase transition.

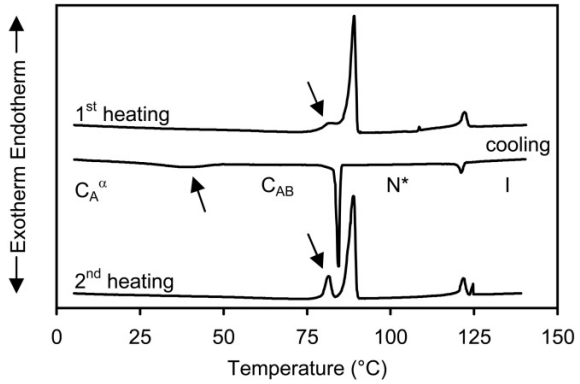

MBOBA–DOBA system

As in the MBOBA–HOBA system, all mixtures exhibited a cholesteric mesophase (Fig. 10). The cholesteric–isotropic transition temperature of the mixture 10 mol% DOBA in MBOBA was 105.1 °C as opposed to 105.9 °C for 10 mol% HOBA in MBOBA, reflecting that the molecular arrangement of the cholesteric phase was only weakly affected by the greater difference in molecular lengths of the components. The cholesteric–isotropic transition line, however, was not as smooth as in the case of the MBOBA–HOBA system. It was straight at the extremes of the composition range and had a local minimum at the composition with a one-to-one ratio of the components. The shape of the cholesteric–isotropic transition line indicated that the cholesteric phase at DOBA contents less than 20 and more than 80 mol% was dominated by pure MBOBA or DOBA dimers, respectively, but that mixed dimers dominated at DOBA contents in between. This conclusion was supported by microscopy results: the textures observed for the cholesteric phase on heating were "oily streak" textures for all mixtures; on cooling, the mixtures with a DOBA content less than 70 mol% showed fan textures; whereas the mixtures with 80 and 90 mol% DOBA showed textures of a cholesteric phase with greater pitch.

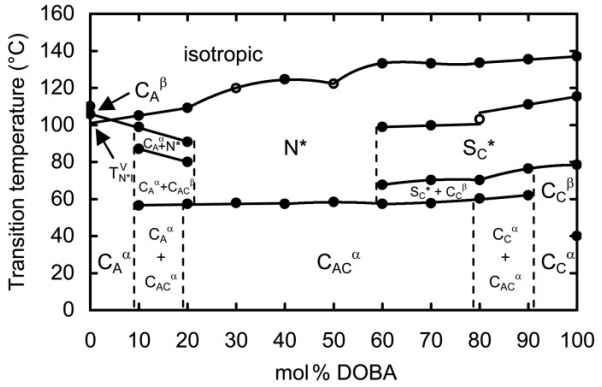
Fig. 10. Phase diagram of the MBOBA–DOBA system (peak temperatures of the first DSC heating run); DSC transition peak has a shoulder (○).



The low thermal stability at 50 mol% DOBA in MBOBA was attributed to the structural difference of the substituent groups of the components. The linear decenoxy group of DOBA allowed a narrower molecular arrangement than the branched 2-methylbutoxy group of MBOBA. The DSC thermogram of the mixture 50 mol% DOBA in MBOBA showed a shoulder peak for the cholesteric–isotropic transition, which implied that the cholesteric phase of this mixture is not homogeneous. It might separate into domains with differently tight molecular arrangements.

The mixtures that contained more than 50 mol% DOBA exhibited a twisted smectic C phase. In the polarized-light microscope the phase appeared in form of a fine Schlieren texture.

To determine whether this phase contained mixed dimers, we analyzed the mixtures by X-ray diffraction at temperatures between their melting points and S_C*–N* transition temperatures. The temperature dependence of the *d* value was similar in all mixtures (Fig. 11*a*) and the absolute value increased with increasing DOBA content (Fig. 11*b*). The increase in *d* value was linear with a discontinuity and change in slope at 80 mol% DOBA. In comparison the longest *d* value calculated from the size of the unit cell depicted in Fig. 5 with interdigitated molecules of DOBA amounts to *d* = 20.82 Å. We concluded that similar to the cholesteric phase, the twisted smectic *C* phase at a DOBA content less than 80 mol% was dominated by mixed dimers, but pure DOBA dimers dominated at a DOBA content higher than 80 mol%. This conclusion was supported by DSC results, which revealed a shoulder peak for the S_C*–N* transition at 80 mol% DOBA in MBOBA, indicating that the S_C* phase in this mixture was not homogenous. The mixed dimers with a length of 28.9 Å did not form a smectic phase on their own. The smectic phase in the mixtures with 60 and 70 mol% DOBA was induced by the dimers of excess DOBA molecules.

At 58 °C, the mixtures with 10 and 20 mol% DOBA showed a phase transition into another mixed phase (C_{AC}^β, Fig. 10). This phase must have a slightly different composition (higher DOBA content), since the crystalline phase of the MBOBA is formed simultaneously with it.

With respect to the crystalline region, X-ray diffraction gave a variety of *d* values (Table 2). We were able to distinguish at least six different crystalline phases. The two phases

at the extremes of the composition range (C_A and C_C, Fig. 10) were most likely the crystalline phases of the pure components with a low- and a high-temperature modification (α and β). The C^α_{AC} phase presumably contained different amounts of mixed dimers in the different mixtures, as the *d* value varied with composition. Most of the mixtures (30 to 90 mol% DOBA in MBOBA) melted at about 58 °C. The mixtures with 60 to 90 mol% DOBA separated above 60 °C into a S_C* phase and the high-temperature crystalline phase of DOBA. On melting, the *d* value of the smectic phase showed a distinct shift to higher values, which reflected increasing incorporation of DOBA molecules into the smectic molecular arrangement.

Conclusions

A variety of shapes and packing arrangements was found for crystalline 4-substituted benzoic acids. Achiral pure compounds with longer substituents attached crystallize in acentric and with shorter substituents in centric crystal structures with dimers formed by hydrogen bonding. The symme-

try elements present in the crystalline state also influence the kind of arrangements in liquid crystals.

Regarding the crystalline phases in the mixed systems, the formation of mixed dimers was found to be promoted by a greater difference in molecular structure. The system with the more structurally similar components, the MBOBA–HOBA system, exhibited a crystalline phase of mixed dimers at compositions between 40 and 80 mol% HOBA and temperatures above 58 °C. The system with the greater structural difference in components (the MBOBA–DOBA system) showed crystalline phases containing mixed dimers at room temperature and for all compositions. A greater difference in molecular structure led to a decrease in solubility. Due to the tendency of these systems to form mixed dimers, the region in which mixed dimers were found was enlarged, as opposed to enlarging the region where two crystalline phases coexisted.

The liquid-crystalline phases were found to be dominated by mixed dimers at compositions in the midrange. At the extremes of the composition range, pure dimers dominated the liquid-crystalline phases. Concerning the cholesteric phase, mixed-dimer formation in the composition midrange was indicated by the shape of the cholesteric–isotropic transition line and was more obvious for the system with the more structurally different components. Regarding the twisted smectic *C* phase, the change from mixed-dimer prevalence to pure-dimer prevalence with composition was evident by a discontinuity in the increase of the *d* value with increasing DOBA content.

Efficient bioconversion of palm acid oil and palm kernel acid oil to poly(3-hydroxybutyrate) by *Cupriavidus necator*[1]

Yik-Kang Kek, Wing-Hin Lee, and Kumar Sudesh

Abstract: Efficient bioconversion of palm oil by-products to green materials serves as a prominent way to overcome wastage. Generally, major palm oil by-products such as palm acid oil (PAO) and palm kernel acid oil (PKAO) are used for animal feed. This pioneer study investigated the ability of *Cupriavidus necator* H16 (ATCC 17699) (formerly *Ralstonia eutropha*) to biologically convert these by-products to poly(3-hydroxybutyrate) [P(3HB)]. P(3HB) was synthesized when PAO or PKAO was fed as the sole carbon source. However, it was found that PKAO is superior with respect to higher amount of P(3HB) accumulation in 48 h (85 wt% of the dry cell mass). In addition, important culture parameters were identified, such as nitrogen sources and ratio of culture volume to flask volume, which significantly affected the P(3HB) content. The nitrogen concentration in the culture medium is very crucial in promoting the biosynthesis of P(3HB). The highest P(3HB) yield (3.1 g/L) was initiated at 4 mmol/L of urea. Less than 0.4 g/L of P(3HB) was obtained when 30.0 mmol/L or higher urea concentrations were used. This study has identified a suitable process to produce high P(3HB) yield from major palm oil by-products. It is also demonstrated that *C. necator* H16 has suitable metabolic pathways that allow the conversion of palm oil by-products to P(3HB) effectively. Hereby, surplus palm oil by-products can be converted to a relatively high-value and sustainable product.

Key words: poly(3-hydroxybutyrate), palm oil, palm acid oil, palm kernel acid oil, *Cupriavidus necator.*

Résumé : Une bioconversion efficace des sous-produits de l'huile de palme en matériaux verts est une méthode de choix pour éliminer les déchets. En général, les sous-produits majeurs de l'huile de palme, tel l'huile acide de palme (HAP) et l'huile acide de la noix de palme (HANP), sont utilisés comme nourriture pour les animaux. Dans ce travail, on a étudié la possibilité d'utiliser le *Cupriavidus necator* H16 (ATCC 17699) [antérieurement *Ralstonia eutropha*] pour transformer biologiquement ces sous-produits en poly(3-hydroxybutyrate) P(3HB). Il y a synthèse de P(3HB) quand on utilise du HAP ou du HANP comme seule source de carbone. Toutefois, on a observé que, sur une période de 48 heures, le HANP conduit à une accumulation plus élevée de P(3HB) (85% en poids de cellules sèches). De plus, on a identifié des paramètres importants pour la culture, telles les sources d'azote et le rapport du volume de culture au volume du contenant, qui affectent profondément la teneur en P(3HB). La concentration en azote dans le milieu de culture est cruciale pour la biosynthèse du P(3HB). Le rendement le plus élevé de P(3HB) (3,1 g/L) a été obtenu à partir d'une solution contenant 4 mmol/L d'urée. On n'a obtenu qu'un maximum de 0,4 g/L de P(3HB) lorsque les concentrations d'urée étaient supérieures à 30 mmol/L. Cette étude a identifié un processus approprié pour obtenir des rendements élevés de P(3HB) à partir des sous-produits de l'huile de palme. Il a aussi été démontré que le *C. necator* H16 possède les voies métaboliques appropriées pour permettre de transformer effectivement les sous-produits de l'huile de palme en P(3HB). Il est donc possible de transformer les surplus de sous-produits de l'huile de palme en un produit durable et de valeur relativement élevée.

Mots-clés : poly(3-hydroxybutyrate), huile de palme, huile acide de palme, huile acide de la noix de palme, *Cupriavidus necator.*

Introduction

A large consortium of bacteria is capable of dispensing excessive carbon source through the formation of intracellular polyester granules under unfavourable growth conditions (1). This family of bacterial polyesters, which could be composed of an enormous range of hydroxyalkanoate (HA) units, is designated as poly(hydroxyalkanoates) (PHA) (2). Plant oils have been identified as feasible feedstocks for PHA biosynthesis using

various microorganisms (3). Recently, palm kernel oil was determined as suitable carbon source for the biosynthesis of poly(3-hydroxybutyrate) [P(3HB)] and poly(3-hydroxybutyrate-*co*-3-hydroxyhexanoate) [P(3HB-*co*-3HHx)] by *Cupriavidus necator* H16 and its recombinant (4). The idea of using palm oil and its by-products has piqued interest among researchers in Malaysia because of the abundance of these raw materials throughout the country. Impressive growth of the crude palm oil production in the last few decades (7.8 million tonnes per year (1995) to 15 million tonnes in the year 2005) allowed Malaysia to be the largest producer of palm oil in the world (5). Hence, palm oil and its by-product can be counted on as a steady source of raw materials to be used as the carbon feedstock in PHA production. Bioconversion of whey (6–8), molasses (9–12), starch (13, 14), triacylglycerols (15, 16), and other crude carbon substrates from industrial food wastes (17) or industrial by-products (18) to PHA have been investigated.

Cheap, ready availability in bulk quantity and constant supply of the feedstock become crucial factors for large scale and continuous PHA production. The undesirable free fatty acids present in palm oils are removed by using a chemical refining process (saponification) to produce palm acid oil (PAO) and palm kernel acid oil (PKAO), which are derived from crude palm oil (CPO) and crude palm kernel oil (CPKO), respectively. In 2006, there were 51 refineries in operation in Malaysia with the total processing capacity of 18.5 million tonnes per year (5). Thus, those surplus materials from the refinery process are readily available as carbon sources for the viable production of PHA.

In this study, for the first time, efficient bioconversion of two major by-products of the palm oil industry, PAO and PKAO for bacterial growth and PHA production, was evaluated. We report here that these carbon sources are not only suitable for the growth of *C. necator*, but they are also excellent carbon sources for the synthesis and accumulation of P(3HB).

Materials and methods

Bacterial strain, media, and maintenance

Wild type *Cupriavidus necator* H16 (ATCC 17699) [formerly *Ralstonia eutropha*] was used throughout this study. The bacterium was grown in Nutrient-Rich (NR) medium as described previously (19). For maintenance purposes, 12.5 mL of pure glycerol was added into the 50 mL culture after 24 h growth in NR medium to prepare a 20% (*v*/*v*) glycerol stock, which was stored at –20 °C in 1 mL aliquots.

Culture conditions

One-stage batch culture was carried out for the evaluation of PHA biosynthesis. The bacterium was activated by inoculating 1 mL of glycerol stock into 50 mL NR medium and cultivated at 30 °C and 200 rpm. After 24 h cultivation, 3% (*v*/*v*) of the preculture medium was transferred into a 250 mL flask containing 50 mL of nitrogen-limited mineral medium (MM) for PHA accumulation (19). Nitrogen limitation was imposed by supplying various nitrogen sources with a nitrogen molarity of 0.01 mmol/L in the MM. In this study, palm oil by-products PAO and PKAO that were used for growth and biosynthesis of PHA by *C. necator* H16 were supplied by Unitata Ltd, Perak, Malaysia. A total of 5 g/L of these carbon sources were evaluated for the PHA production. PKAO, which is in the liquid form, was autoclaved separately from the culture medium, whereas solid PAO was autoclaved together with the medium. The cultures were cultivated at 30 °C for 48 h and shaken at 200 rpm.

Analytical procedures

At the end of the cultivation period, the cells were harvested by centrifugation (6000*g*) and washed once with hexane/distilled water before lyophilization. The lyophilized cells were subjected to methanolysis in the presence of methanol/sulfuric acid (85:15 *v*/*v*). After heating for 140 min at 100 °C, the resulting methyl esters were then quantified by gas chromatography (GC) with caprylic methyl ester as an internal standard (20). Total cell mass was determined by measuring dry cell mass (DCM). The residual cell biomass was calculated by subtracting the amount of PHA from the total DCM.

Transmission electron microscopy (TEM)

Cells cultivated in MM supplemented with 50 mmol/L and 5 mmol/L urea were harvested and prefixed in McDowell–Trump fixative (21). The cell pellets were then fixed with 1% Osmium tetroxide (OsO_4). To dehydrate the cells, they were subjected to increasing amounts of ethanol (50%, 75%, 95%, and 100%) followed by 100% acetone. Cell embedment was performed in Spurr's low viscosity resin (22). Ultra-thin sections were prepared, mounted on copper grids and stained with uranyl acetate and lead citrate for electron microscope examination at an acceleration voltage of 80 kV (Philip CM 12/ STEM and JLM-2000FX11).

Results

This study shows for the first time the biosynthesis of P(3HB) from palm oil by-products, PAO and PKAO by *C. necator* H16. This bacterium was first screened on PAO and PKAO with the supplementation of various nitrogen sources to determine the bioconversion efficiency of these by-products into P(3HB). Dry cell mass (DCM) and P(3HB) content obtained at 48 and 72 h of cultivations are illustrated in Fig. 1. Varying the nitrogen sources in the culture medium rendered significant effect on cell biomass synthesis and PHA accumulation of this bacterium. Both carbon sources favored cell growth and P(3HB) accumulation, although it seemed that PKAO was a better carbon source. PKAO resulted in a much higher P(3HB) yield than PAO after 48 h of cultivation with all nitrogen sources assayed except urea, whereby approximately 1.9 g/L was synthesized from both carbon sources (Fig. 1*B*). Further incubation up to 72 h often resulted in the reduction of PHA content. Figure 1 also demonstrates that cells cultivated in urea [$(NH_2)_2CO$] achieved higher DCM in a shorter period as compared to other nitrogen sources.

The effect of urea concentration on the cell growth and PHA biosynthesis was also evaluated on both PAO and PKAO as shown in Fig. 2. In this study, the initial concentration of carbon source used was 5 g/L. As expected, it was clear that the reduction in urea stimulated higher P(3HB) accumulation. The highest P(3HB) content was obtained from

Fig. 1. Effects of different nitrogen sources on growth and the level of P(3HB) accumulation from 5 g/L of (*A*) PAO and (*B*) PKAO during cultivation of *C. necator* H16 at 48 and 72 h. Culture medium was supplemented with 10 mmol/L of nitrogen source.

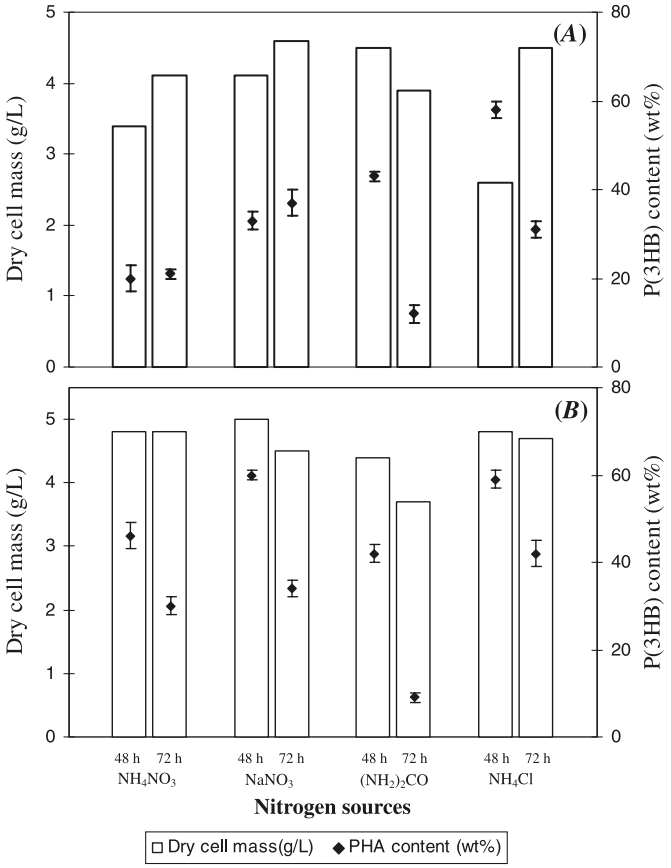

Fig. 2. Comparison of the dry cell mass and P(3HB) content obtained from (*A*) PKAO and (*B*) PAO in mineral medium supplemented with various urea concentrations.

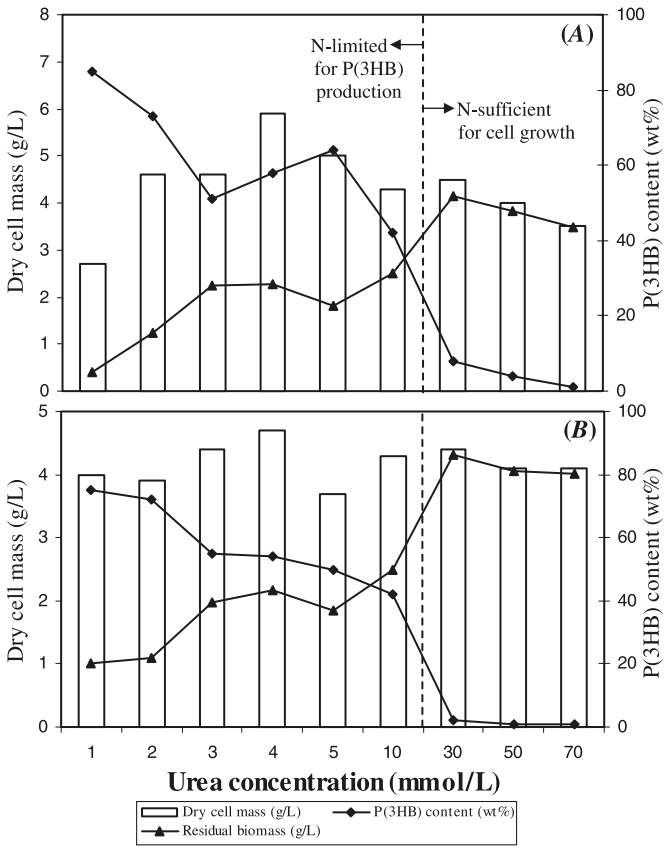

both carbon sources when the cells were supplemented with 1 mmol/L of urea, whereby up to 75 and 85 wt% of P(3HB) was attained at 48 h from PAO and PKAO, respectively. However, at this concentration (1 mmol/L of urea), the cell biomass achieved from PAO (4 g/L) was almost two-fold higher than that obtained from PKAO (2.7 g/L). In general, an increase in the urea concentration resulted in a higher residual biomass. On the other hand, the P(3HB) content was significantly reduced. It is noteworthy that the threshold level of urea concentration for P(3HB) accumulation and cell growth fell between 10 and 30 mmol/L. As shown in Fig. 2, a sharp decrease was observed in the P(3HB) content as the concentration of urea was increased from 10 to 30 mmol/L. P(3HB) content dropped from 42 wt% to 2 and 8 wt% of the DCM for PAO and PKAO, respectively. For all the nitrogen source concentrations assayed, 4 mmol/L of urea was found to support the best growth of *C. necator* H16, whereby 5.4 and 4.7 g/L of DCM was obtained from PKAO and PAO, respectively.

C. necator H16 grown under nitrogen-limited as well as nitrogen-rich conditions were then observed under TEM to study their morphological characteristics. At low concentration of urea (5 mmol/L), *C. necator* H16 was found to be packed with P(3HB) granules at the end of 48 h cultivation. GC results revealed that approximately 65 wt% of P(3HB) was accumulated under such conditions. In addition, the number of P(3HB) granules was in the range of 5–16 per cell. When the urea concentration was increased 10-fold, it was noted that most of the cells were actively dividing (data not shown). Small discrete P(3HB) granules were also noticed in some of the cells. A relatively small amount of those inclusions were produced (not more than five) at such high urea concentration (Fig. 3*A*). This observation corresponded to the GC results obtained in which only 5 wt% of P(3HB) was accumulated.

Generally, an increase in the carbon source concentration will increase the C/N ratio. In this study, the C/N ratio was varied by manipulating the PKAO concentration in the culture medium. As expected, a higher ratio of C/N resulted in higher cell biomass and PHA accumulation. The DCM obtained showed a sixfold increment (0.9 to 5.4 g/L) as the PKAO concentration was increased from 1 to 5 g/L. Supplementation of PKAO at a higher concentration denotes higher quantity of substrate available to cell biomass for its biosynthetic processes, and thus gives better cell growth. Figure 4 clearly shows that high C/N ratio resulted in high level of P(3HB) accumulation by *C. necator* H16. It was found that 5 g/L of PKAO was the optimal concentration for cell growth and also led to the highest P(3HB) yield (3.1 g/L) at 48 h of cultivation. The residual biomass reached its highest value, 2.5 g/L, at PKAO concentration of 5 g/L. However, poorer cell growth was achieved as the PKAO concentration was further increased in the culture medium. Although 9 g/L of PKAO resulted in the highest

Cells were grown on PKAO under nitrogen-rich or nitrogen-limited conditions: (*A*) Content of intracellular P(3HB) was 5 wt% of total DCM with the supplementation of 50 mmol/L urea. (*B*) High accumulation of P(3HB) contributing to about 65 wt% of DCM was attained using low urea concentration (5 mmol/L). (*C*) and (*D*) Newly formed P(3HB) granules found to be localized around the nucleoid region, which were observed near the center of the cells. Bar represents 200 nm for Figs. 3*B*, 3*C*, and 3*D*.

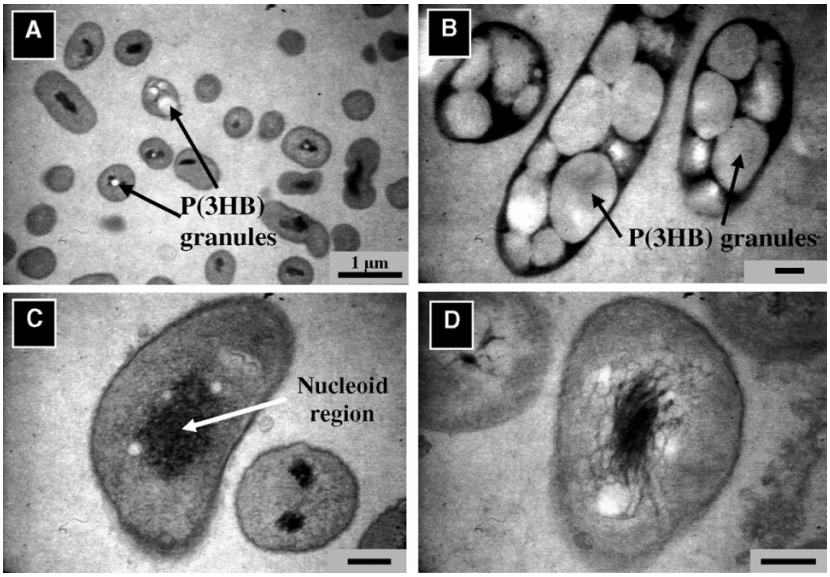

Fig. 4. Effects of PKAO concentration on cell biomass and P(3HB) synthesis by *C. necator* H16. Cells were cultivated for 48 h in mineral medium containing urea with a concentration of 4 mmol/L.

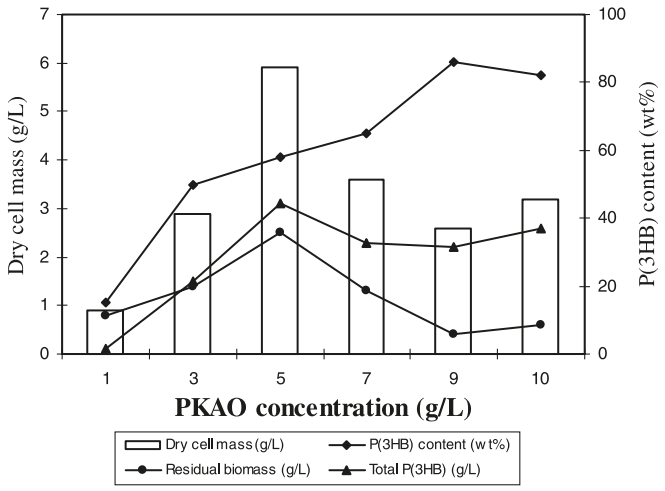

P(3HB) content (86 wt%), it was relatively lower in terms of PHA yield (2.2 g/L).

The culture volume to flask volume ratio is another factor that was found to affect the cell growth and P(3HB) synthesis of this bacterium from PKAO. Cells were cultivated in varying volumes of MM in a 250 mL flask. It was assumed that the increase in culture volume will result in lower oxygenation rate and subsequently promote better P(3HB) accumulation. It is apparent that P(3HB) content could be enhanced by increasing the culture volume (Table 1). Intracellular P(3HB) content was increased from 60 to 77 wt% of DCM as the culture volume was raised from 50 to 100 mL, although the DCM obtained were comparable. Cells grown in 200 mL MM revealed the highest accumulation of P(3HB), resulting in a total of 3.7 g/L P(3HB) at the end of the cultivation period. The P(3HB) yield shows the highest value of 4.1 g/L during cultivation in 100 mL culture medium. Meanwhile, 4.5–5.3 g/L of DCM was obtained from all the culture volumes examined. Low residual biomass was observed in large volume cultures.

Discussion

Previous studies have demonstrated that agricultural and industrial wastes are suitable carbon sources for PHA production in an economically competitive manner (13, 14, 16, 23). With this idea in mind, we have attempted to produce PHA from the main by-products of the palm oil industry, which are PAO and PKAO. The present study has demonstrated that these palm oil by-products are feasible as the carbon source for rapid accumulation of P(3HB) by *C. necator* H16. Approximately 3 g/L of P(3HB) was attained after 48 h of cultivation when ammonium chloride or sodium nitrate was used as the nitrogen source. Increasing the productivity of PHA synthesis (higher PHA yield in a shorter fermentation period) is among the efforts to reduce the overall PHA production costs, particularly equipment-related costs (24, 25). Loo and co-workers have recently reported the P(3HB-*co*-3HH*x*) production with a constant molar fraction of 3HH*x* monomer by recombinant *C. necator* from various palm oil products, however, with the cultivation period of 72 h (26).

Our results showed that PKAO supported better growth and P(3HB) accumulation, compared with PAO as the sole carbon source. This variation can be explained by the differences in fatty acids composition of these by-products. The two most predominant fatty acids in PAO are saturated C16:0 palmitic acid (~45%) and unsaturated C18:1 oleic acid (~40%). Meanwhile, PKAO is mainly comprised of saturated fatty acids (Table 2), which are the preferred carbon

sources for cell growth and PHA accumulation. In a separate study, we have also experimented with CPKO and CPO, which share similar fatty acid compositions to PKAO and PAO, respectively. *C. necator* showed better growth on CPKO when used as the sole carbon source in comparison with CPO (data not shown). Similar results were also obtained by Loo and co-workers whereby the accumulation of P(3HB-*co*-3HH*x*) from crude CPKO was better than that from CPO (26).

There are several strategies to increase the accumulation of PHA in bacterial cells such as by inducing the limitation of phosphorus, nitrogen, and (or) magnesium (27, 28). In this study, we applied nitrogen limitation, which is generally employed for the production of P(3HB) (29).

Several nitrogen sources were evaluated, and urea was selected for subsequent experiments because of its cheaper cost. Figure 2 clearly shows the influences of different urea concentration upon the P(3HB) production using PAO or PKAO as the sole carbon source. A noticeable drop in P(3HB) content was observed when the urea concentration was increased from 10 mmol/L to 30 mmol/L.

It is apparent that 30 mmol/L or higher concentrations of urea hampered P(3HB) synthesis, because *C. necator* H16 entered the balanced growth conditions whereby carbon sources are used mainly for cell growth. This is most probably because acetyl-CoA produced from the metabolism of free fatty acids via β-oxidation pathway flows primarily into the tricarboxylic acid cycle (TCA) for energy generation and formation of cell constituents. Synthesis of P(3HB) from acetyl-CoA generally occurs via a sequence of three enzyme-mediated reactions: condensation of two acetyl-CoA moieties to form acetoacetyl-CoA, followed by stereoselective reduction of acetoacetyl-CoA to (*R*)-3-hydroxybutyryl-CoA, and finally polymerization of (*R*)-3-hydroxybutyryl-CoA to form P(3HB) [Fig. 5]. This pathway is believed to be under the control of the first enzyme 3-ketothiolase, which is inhibited by free coenzyme A (CoASH). Increased flux of acetyl-CoA into TCA cycle during nitrogen-rich conditions will enhance the pool of free CoASH within bacterial cell. It was reported that the CoASH level without PHA synthesis is three times higher than during PHA synthesis in *C. necator* (30). As a consequence, negative regulation of 3-ketothiolase by CoASH leads to a low P(3HB) content (less than 10 wt%) at the end of 48 h cultivation.

Cells for TEM analysis were cultivated on PKAO with the supplementation of low (5 mmol/L) and high (50 mmol/L) concentration of urea, which produced approximately 65 and 5 wt% of P(3HB), respectively. *C. necator* H16 was found to be fully packed with P(3HB) granules at 5 mmol/L of urea, as shown in Fig. 3*B*. To the contrary, we noted that *C. necator* H16 were actively dividing when 50 mmol/L urea was used in the culture medium, and the nucleoid region of the cells could be observed clearly near the center of the cell.

Another interesting observation of TEM analysis is that small and newly synthesized P(3HB) granules were found to be localized around and nearby the nucleoid region (Figs. 3*C* and 3*D*). The nucleoid region was then gradually less apparent as the size of P(3HB) granules increased. A similar observation was reported recently by Tian and co-workers (31, 32). They noticed the presence of a dark-stained mediation elements near the center of *C. necator* cells, where P(3HB) granules were localized. They proposed that these mediation elements may act as nucleation sites for P(3HB) granule initiation.

In addition to the type and concentration of nitrogen source, the dissolved oxygen concentration also affects PHA accumulation. We found that the PHA accumulation by *C. necator* H16 from PKAO was favored by an increase in culture volume to flask volume ratio, as illustrated in Table 1. Poorer aeration in larger culture volumes and the consequent oxygen limitation to the cultures contributed to a higher P(3HB) yield presumably due to a higher $NADH/NAD^+$ ratio within *C. necator* H16. It has been dem-

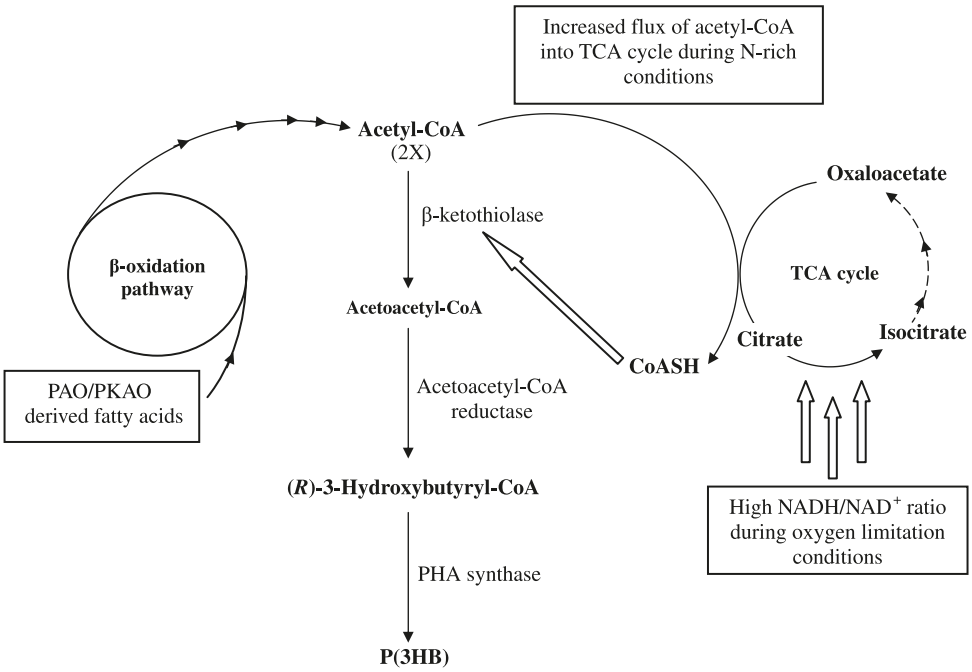
Fig. 5. Metabolic pathways of P(3HB) biosynthesis in *C. necator* H16 from palm oil products and its regulatory system. Block arrows indicate negative regulatory effects.



onstrated that the biosynthesis of P(3HB) is stimulated by both high intracellular concentrations of NADH and high ratios of NADH/NAD^+ (33). Key enzymes related to the TCA cycle, such as citrate synthase and isocitrate dehydrogenase, are inhibited by the elevated levels of intracellular NADH and thereby ensure the availability of acetyl-CoA for the condensation reaction mediated by β-ketothiolase (1, 34, 35). In such conditions, re-oxidation of NADH is principally achieved via P(3HB) biosynthesis pathway rather than by electron transport to oxygen as the ultimate electron acceptor (34, 36). As a result, P(3HB) constituted up to 80 wt% of DCM after 48 h of cultivation, resulting in a maximum P(3HB) yield of 4.1 g/L from PKAO. The results in Table 1 surprisingly show that the oxygen limitation due to the increment of culture volume, which promoted better P(3HB) accumulation, did not affect the DCM. Intracellular degradation of fatty acids is an oxidative process, which requires sufficient amounts of oxygen. Here, it seemed that the low oxygen level was still not a limiting factor for the growth of *C. necator* H16 even at high culture volume to flask volume ratio.

Conclusion

This study has demonstrated that the by-products from the palm oil refining process could be efficiently converted to P(3HB) by *C. necator* H16. Up to 85 wt% P(3HB) of the DCM was achieved in 48 h of cultivation. Nitrogen molarity and aeration of the cultures were crucial parameters for high yield production of P(3HB) from PAO and PKAO. P(3HB) synthesis by *C. necator* H16 using these surplus palm oil by-products looks promising, as the adoption of inexpensive and renewable carbon substrate in the PHA production is essential if this green material is to become an economically competitive product.

Dumbbell-shaped dendrimers — Synthesis and self-assembly[1]

Tatiana Vassilieff and Ashok Kakkar

Abstract: We report on the synthesis and detailed characterization of dendrimers that evolve symmetrically from a linear core of 2-butyne-1,4-diol with 3,5-dihydroxybenzyl alcohol based dendron arms. The divergent layer-by-layer build-up of the dumbbell-shaped dendrimers is based on simple acid–base hydrolytic chemistry of bis(dimethylamino)dimethylsilane with OH-terminated molecules. The self-assembly of these dendrimers in THF and water is significantly influenced by their generation number, the backbone structure, and the solvent.

Key words: dendrimers, divergent synthesis, macromolecules, self-assembly

Résumé : On a effectué la synthèse et une caractérisation totale de dendrimères qui radient à partir d'un noyau linéaire de but-2-yne-1,4-diol avec des ramifications à base d'alcool 3,5-dihydroxybenzylique. La synthèse divergente, faite couche par couche, des dendrimères en forme d'haltère court est basée sur une chimie d'hydrolyse acide–base simple de bis(diméthylamino)diméthylsilanes dans lesquels les molécules se terminent par des groupes OH. L'autoassemblage de ces dendrimères dans un mélange de THF et d'eau est fortement influencé par le nombre de générations, la structure du squelette, et le solvant.

Mots-clés : dendrimères, synthèse divergente, macromolécules, autoassemblage.

[Traduit par la Rédaction]

Introduction

Hyperbranched and monodisperse macromolecules that are commonly referred to as dendrimers are becoming increasingly important in designing smart and efficient nanomaterials for a variety of applications in medicine, catalysis, and electronics (1). A significant effort in the design and syntheses of these globular architectures has been invested, which has led to inside-out (divergent) or outside-in (convergent) methodologies (2). Changing the central core leads to many structural variations and novel types of morphologies in the resulting dendrimers (3). We have been investigating the role of the core, backbone, and linking units in the evolving morphology of the dendrimers, and have established a simple and efficient divergent route to the syntheses of such dendritic macromolecules (4), based on the acid–base hydrolytic chemistry of amino-silanes and -stannanes with organic acids (5). We were intrigued by the possibility of developing hyperbranched structures using symmetric growth on either side of a bifunctional linear core, giving rise to dumbbell-shaped dendrimers. The synthetic elaboration and detailed investigation of the properties of dumbbell-shaped dendrimers have been much less explored than those of globular dendrimers (6). We report herein a route to the synthesis of dumbbell-shaped dendrimers that are constructed from the bifunctional core 2-butyne-1,4-diol using 3,5-dihydroxybenzyl alcohol (DHBA) as wedges. The synthetic elaboration is based on the controlled addition of bis(dimethylamino)dimethylsilane ($Me_2Si(NMe_2)_2$) to the bifunctional core, followed by the addition of DHBA. The process is then repeated with $Me_2Si(NMe_2)_2$) and DHBA in sequence, with amine as the only by-product, and the purification of dendrimers can be easily achieved by simple extraction into deuterium oxide. Self-organization of dendrimers by means of suitable peripheral groups continues to be an area of much significance and provides opportunities for designing nanomaterials for molecular encapsulation and delivery (4, 7, 8). The dumbbell-shaped dendrimers reported here have suitably placed OH groups for interdendrimer interactions, and we have examined their self-assembly through such interactions in THF and water, using UV–vis spectroscopy and transmission electron microscopy. In THF, generations 1–3 require a higher critical aggregation concentration (*cac*) to form aggregates than does generation 4. Because of the open structure in the lower generations, the linear core inhibits self-assembly, whereas in generation 4, the more globular architecture with more prominent hydrogen bonding sites facilitates self-assembly at lower concentrations.

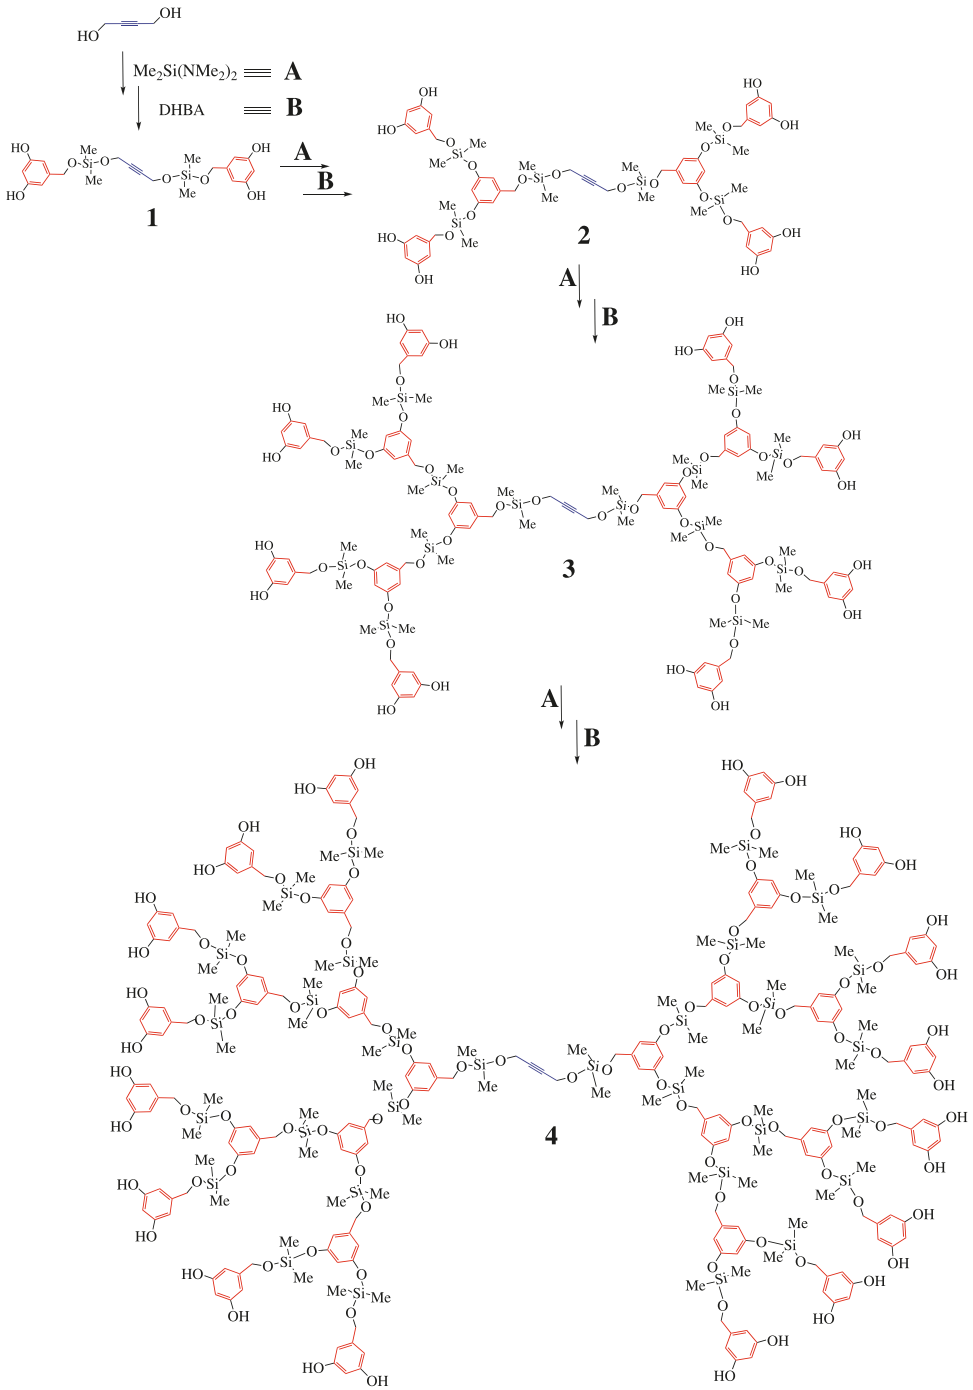
Scheme 1.



taining terminal OH groups (5). The choice of the linear core around which dendrons are built was based on rigidity, solubility, and commercial availability, and 2- butyne-1,4-diol was considered to be an ideal candidate for developing the desired dendrimers. The dendron backbone was chosen to be 3,5-dihydroxybenzyl alcohol because it has been successfully employed in our laboratory in the past to synthesize globular dendritic architectures (4). For synthesizing the first generation dendrimer, 1 molar equivalent of 2-butyne-1,4 diol was added dropwise over a period of 2 h to an ice-bath-cooled solution of 2 equivalents of bis(dimethylamino)dimethylsilane in THF. The solution was stirred at ice-bath temperature for an additional six hours, and then left to warm to room temperature. The solution was transferred to an addition funnel, and added slowly to a solution of 2 equivalents of DHBA in THF, and stirred overnight. After removal of the solvent in vacuo, the product was extracted into deuterium oxide (D_2O). The solution was filtered and D_2O was then removed under vacuum, to afford a light pink powder **1**. Continuation of this methodology by carrying out reactions under controlled conditions led to the synthesis of dendrimers **2**–**4** in very good yields. Dendrimers were characterized using a combination of

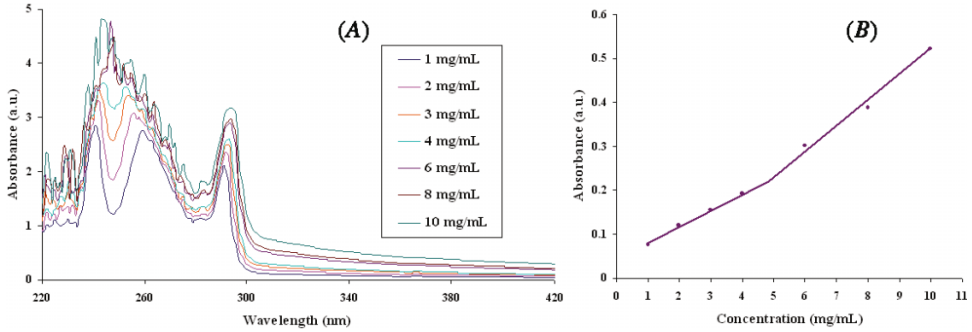
Fig. 1. (*A*) UV–vis absorption spectra of dendrimer **1** at concentrations of 1 to 10 mg/mL in THF and (*B*) plot of absorbance *vs* concentration of dendrimer **1** in THF at 340 nm.



^{1}H and ^{13}C{^{1}H} NMR, matrix-assisted laser desorption/ionization time of flight (MALDI-TOF), and FT-IR spectroscopies, and elemental analyses. These data confirmed the identity of the dendrimers as shown in Scheme **1**.

Self-assembly of dendrimers via intermolecular interactions between peripheral groups is a topic of current interest (7, 8), and we have also investigated the aggregation behaviour of globular DHBA based dendrimers in solution and at interfaces (4). We were intrigued by the self-assembly behaviour of dendrimers in which the linear core as well as the evolving shape of the dendrimers could influence their association. In addition, dendrimers **1**–**4** contain peripheral hydroxyl groups that increase in number exponentially from 4 to 32, and are expected to contribute to enhanced interdendrimer interactions as the generation number increases.

The aggregation behaviour of dendrimers was first investigated using UV–vis spectroscopy at concentrations of 1 to 10 mg/mL in THF. The dendrimers generally depicted three peaks around 240, 260, and 290 nm at 1 mg/mL (Fig. 1*A*), which become broad as the concentrations were increased and the solutions become turbid. The *cac* for each generation was calculated by plotting the intensity of scattered light at a given wavelength against concentration (Fig. 1*B*), and it was found to be 4.9 mg/mL for dendrimers **1**–**3**. The latter is much higher than the globular DHBA based dendrimers of generations 1-3, which was calculated to be 3.7 mg/mL (4g). This suggests that the more open structure of dendrimers, constructed around the linear core, allows more freedom for these molecules. In addition, the central core in these open structures might participate in packing via π–π interactions, and these competing interactions might create an association–dissociation equilibrium which will delay aggregation.

The dendrimer **4** showed a *cac* of 4.1 mg/mL, which was quite comparable to the DHBA based dendrimers, suggesting clearly that the structure was becoming more globular at generation 4. The aggregation of dendrimers through participation of terminal OH groups in hydrogen bonding was also confirmed by FT-IR that showed a broad peak at approximately 3300 cm^{-1} for the terminal OH groups. The latter clearly suggested that terminal OH groups in these dendrimers are strongly hydrogen-bonded at concentrations above *cac*; below this concentration, a peak at around 3500 cm^{-1} is commonly observed, which is indicative of the absence of hydrogen bonds.

Transmission electron microscopy is a useful technique for examining the self-assembly of macromolecules, and can provide essential information related to the morphology of the resulting aggregates (9). We first studied the aggregation behaviour of dendrimers **1**–**4** in THF at concentrations of 4 and 8 mg/mL (concentrations below and above *cac*). At 4 mg/mL, a general globular morphology for the aggregates (Fig. 2) was observed for dendrimers **1**–**4**. The particle size distribution in these aggregates showed that, whereas the size distribution for dendrimer **1** aggregates was found to range between 30 and 135 nm (Fig. 2*A*), dumbbell dendrimers **2**–**4** formed mostly small aggregates of 5 to 25 nm in size, below *cac* (Figs. 2*B*–2*D*). The largest aggregates for those from generation 4, for example, were 55 nm in size. This type of behavior has also been observed earlier (10), and can be explained by considering that, generally, dendrimers of lower generations have a more open structure. This facilitates their interaction with other dendrimers.

When the concentration was increased to 8 mg/mL in THF, it was observed that the globular shape of dumbbell dendrimers **1**–**4** was generally retained. However, there were quite significant differences in particle size distribution of the aggregates from those at 4 mg/mL. For example, dendrimer **1** formed a larger number of smaller aggregates, in the range of 5 to 15 nm in size (Fig. 3). This can be explained by considering that at much higher concentrations, large aggregates can collapse, yielding small-size clusters.

We also studied the aggregation of these dendrimers in a more polar solvent at a concentration of 4 mg/mL and found that aggregation behaviour changed significantly with the change in the solvent from THF to water. The dumbbell-shaped dendrimers possess a hydrophobic interior with polar OH groups at the periphery. In lower generations, there may be hydrophobic–hydrophilic repulsion between dendrimers that enhances their coagulation in water. Water will also compete with interdendritic hydrogen bonding, and it is expected that much smaller aggregates will emerge. The transmission electron microscopy (TEM) study confirmed these expectations, and the effects were quite evident especially in generations 1 and 2 of dendrimers **1** and **2**, which seem to avoid any contact with water, and yield random assemblies of various confirmations (Fig. 4). In addition, the size of these aggregate assemblies was much smaller than in THF at 4 mg/mol.

Self-assembly of dendrimers **3** and **4** in water was found to be quite different from that of first and second generation dendrimers. It suggested that small aggregates of 5 to 25 nm are first formed, which then assemble into larger clusters of 55 to 75 nm size (Fig. 4*D*). This is in agreement with the ob-

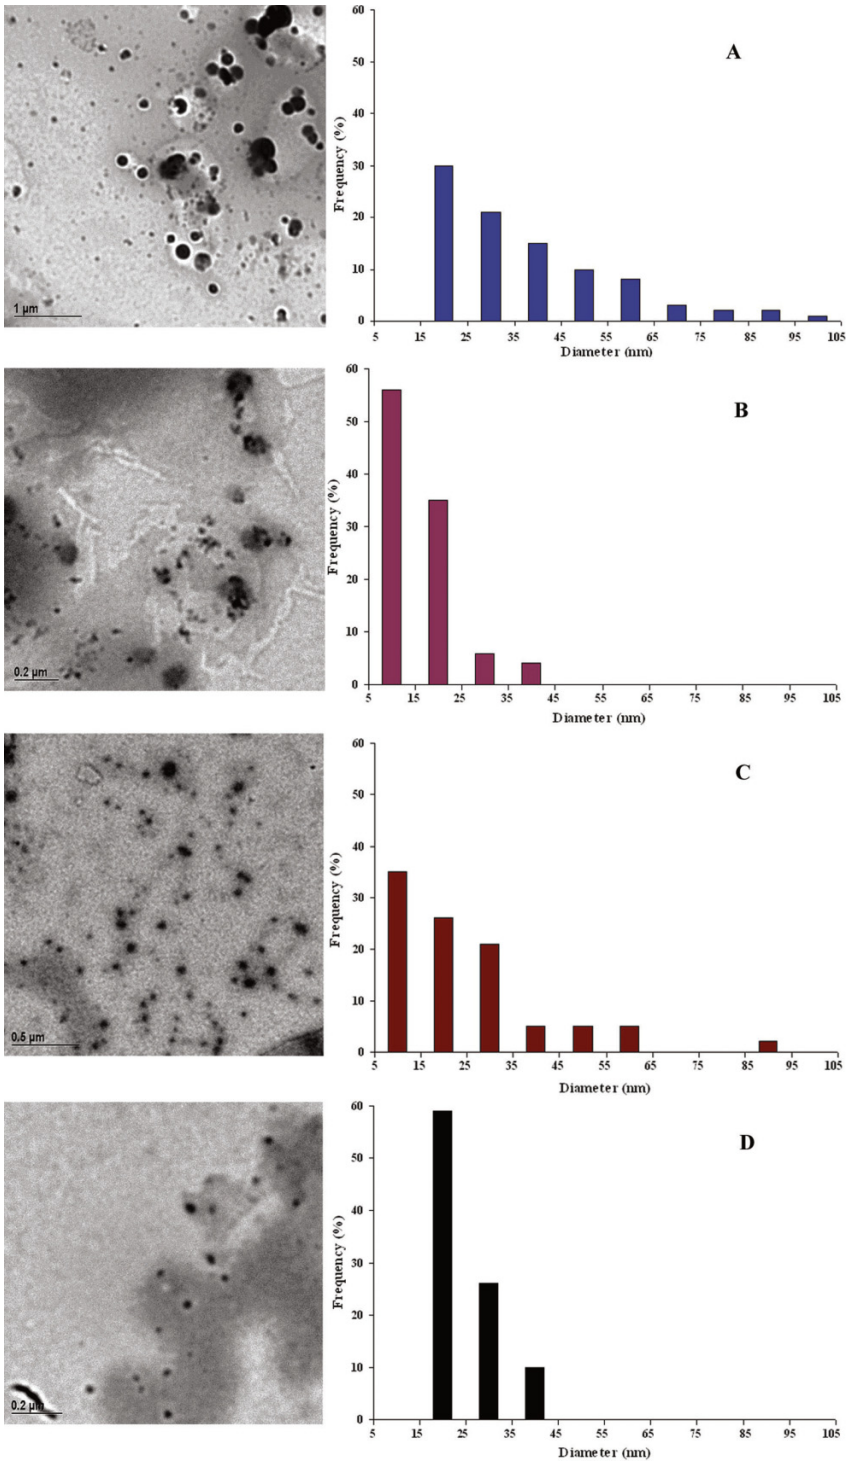
Fig. 2. Transmission electron micrographs and particle-size distributions of dendrimers (*A*) **1**, (*B*) **2**, (*C*) **3**, and (*D*) **4** in THF at 4 mg/mL



servation that generation 3 and 4 dendrimers will start to adopt a more globular structure, and there will be much less contact of the hydrophobic interior with hydrophilic exterior (water), thereby reducing repulsion.

Conclusions

Symmetric growth of DHBA based dendrons on a linear core has been successfully carried out to construct dumbbell-shaped dendrimers of generations 1–4. These dendrimers evolve from a very open structure in lower generations to a more globular architecture in higher generations. Molecular self-assembly of these dendrimers is influenced by their backbone structure, as indicated by much higher critical aggregation concentration for generations 1–3 in THF, compared to that for globular dendrimer counterparts, and for generation 4. The influence of the solvent in their self-assembly was examined using THF and water; in lower generations, the inability

of the more polar solvent to interact with dendrimer backbones leads to aggregates that are formed by minimizing the repulsive forces. In higher generations, the major interaction of the solvent with the dendrimer is at the periphery which has a higher concentration of polar OH groups, and it does not interfere significantly with their ability to self-associate. The influence of the solvent in controlling morphology and sizes of dendrimer aggregates is of interest, as it allows one to tailor their properties for molecular encapsulation and release.

Experimental

Materials and Measurements

2-butyne-1,4-diol (Sigma-Aldrich), 3,5-dihydroxybenzyl alcohol (Sigma-Aldrich), and bis(dimethylamino)dimethylsilane (Gelest) were used as received. All manipulations were performed under a nitrogen atmosphere using either standard Schlenk line techniques or an Innovative Technology (Braun) Labmaster MB-150-M dry box. All solvents were stored un-

der nitrogen and used after distillation over sodium–benzophenone. NMR spectra were measured on a 270 MHz JEOL spectrometer at ambient temperature. The samples were prepared inside the dry box using deuterated solvents (Cambridge Isotope laboratories, Inc.), and the chemical shifts in ppm are reported relative to tetramethylsilane as an internal standard for ^{1}H and ^{13}C spectra. Mass spectra were obtained on a Hewlett Packard 5973 mass spectrometer and MALDI-TOF spectra on a Kratos Kompact Maldi 3.v.4.0.0 spectrometer using LiBr–dithranol as the matrix. Elemental analyses were performed by Laboratoire d'Analyse Elementaire de l'Université de Montréal. Infrared spectra were measured on a Bruker IFS-48 Fourier transform infrared spectrometer using a standard resolution of 4 cm^{-1} for transmission. UV–vis spectra were recorded in water on a Hewlett Packard 8453 with a resolution of 2 nm. TEM measurements were carried out on a JEOL 2000FX microscope operating at an acceleration voltage of 80 kV.

First generation dendrimer (1)

A solution of 2-butyne-1,4-diol (0.200 g, 2.32 mmol) dissolved in 5 mL of dry THF was added dropwise to a solution of 2 equiv. of bis(dimethylamino)dimethylsilane (0.852 mL, 4.65 mmol) in 5 mL of dry THF cooled to 0°C. Stirring at ice bath temperature was maintained for an additional 6 h, and the resulting solution was subsequently warmed to room temperature. The solution was then added dropwise to a solution of 2 equiv. of DHBA (0.651 g, 4.65 mmol) in 10 ml of dry THF. The resulting solution was stirred overnight, and the THF was then removed under vacuum to afford a sticky gel. D_2O (2–3 mL) was added to the gel and was stirred for 5–10 minutes. The solution was filtered and the D_2O was then removed under vacuum to afford a light pink powder (778 mg, 70%). ^{1}H NMR (270 MHz, D_2O-d_2, ppm) δ 0.05 (s, 12H, OSiMe_2O), 4.11 (s, 4H, OCH_2C), 4.36 (s, 4H, C_6H_3-CH_2O), 6.18 (s, 2H, C_6H_2 para), 6.30 (t, 4H, C_6H_2 ortho).^{13}C NMR (68 MHz, D_2O-d_2) δ –1.7, –0.7 (SiCH_3), 49.7 (OCH_2C), 63.6 (C_6H_3-CH_2), 83.6 (OCH$_2C$), 101.9, 106.4, 143.8, 157.1 (C_6H_3). FT-IR (KBr, cm^{-1}): 3243 (ν_{OH}), 2896 ($\nu_{C\text{-}H\ arom.}$), 1242 ($\delta_{Si\text{-}CH3}$), 1041 ($\nu_{Si\text{-}O}$). EI-MS *m*/*z*: 479.1 (expected: 478.6). Anal. calcd. for $C_{22}H_{30}O_8Si_2$: C 55.21, H 6.32; found: C 55.36, H 5.96.

Second generation dendrimer (2)

A solution of 1 equiv. of 2-butyne-1,4-diol (50 mg, 0.581 mmol) in 10 mL of THF was added to a solution of 2 equiv. of bis(dimethylamino)dimethylsilane (0.213 mL, 1.161 mmol) in 5 mL of THF, and stirred for 6 h at ice bath temperature. The resulting solution was added dropwise over a period of 1h to 2 equiv. of DHBA (163 mg, 1.161 mmol) dissolved in 10 mL of THF. After stirring overnight, the mixture was then added dropwise (1h) to a solution of 4 equiv. of bis(dimethylamino)dimethylsilane (0.426 mL, 2.323 mmol) in 5 mL of THF. The resulting solution was added dropwise (1h) to 4 equiv. of DHBA (325 mg, 2.323 mmol) dissolved in 15 mL of THF, and stirred overnight. The removal of the solvent under vacuum afforded a sticky gel. D_2O (4–5 mL) was added to the gel and stirred for 5–10 minutes. The solution was filtered and the D_2O was then removed under vacuum to afford a light pink powder (455 mg, 62%). ^{1}H NMR (270 MHz, D_2O-d_2) δ 0.05 (m, 36H, OSiMe_2O), 4.15 (s, 4H, OCH_2C), 4.36 (s, 12H, C_6H_3-CH_2O), 6.18 (s, 6H, C_6H para), 6.30 (m, 12H, C_6H_2 ortho). ^{13}C NMR (68 MHz, D_2O-d_2, ppm) δ –1.7, –0.1 (SiCH_3), 50.3 (OCH_2C), 64.3 (C_6H_3-CH_2), 83.6 (OCH$_2C$), 102.6, 107.0, 144.5, 157.8 (C_6H_3). FT-IR (KBr, cm^{-1}): 3378 (ν_{OH}), 2962 ($\nu_{C\text{-}H\ arom.}$), 1262 ($\delta_{Si\text{-}CH3}$), 1084, 890 ($\nu_{Si\text{-}O}$). MALDI-TOF *m*/*z*: 1261.3 (expected 1263.7, including *m*/*z* Li$^+$). Anal. calcd. for $C_{58}H_{78}O_{20}Si_6$: C 55.11, H 6.22; found: C 55.95, H 6.26.

Third generation dendrimer (3)

A similar procedure as described above for the second generation was used to prepare the third generation. A solution of 1 equiv. of 2-butyne-1,4-diol (20 mg, 0.232 mmol) in 10 mL of THF was added to a solution 2 equiv. of bis(dimethylamino)dimethylsilane (0.085 mL, 0.465 mmol) in 5 ml THF, and stirred for 6 h at ice bath temperature. The mixture was added dropwise (1h) to a solution of 2 equiv. of DHBA (65.1 mg, 0.465 mmol) in 10 mL of THF, and stirred overnight at room temperature. It was then added dropwise (1h) to a solution of 4 equiv. of bis(dimethylamino)dimethylsilane (0.170 mL, 0.929 mmol) in 5 mL of THF, and stirred overnight at room temperature. The solution was added dropwise (1h) to a solution of 4 equiv. of DHBA (130 mg, 0.929 mmol) in 10 mL of THF, and after stirring overnight, it was added dropwise (1h) to a solution of 8 equiv. of bis(dimethylamino)dimethylsilane (0.341 mL, 1.858 mmol) in 5 mL of THF, and stirred for 14 h. Finally it was added to a solution of 8 equiv. of DHBA (260 mg, 1.858 mmol) in 15 mL of THF, and stirred overnight. THF was removed under vacuum to afford a gel. D_2O (4–5 mL) was added to the gel and stirred for 5–10 minutes. The solution was filtered and the D_2O was then removed under vacuum to afford a light pink powder (402 mg, 61%). ^{1}H NMR (270 MHz, D_2O-d_2) δ 0.01, 0.05 (m, 84H, OSiMe_2O), 4.10 (s, 4H, OCH_2C), 4.34 (s, 28H, C_6H_3-CH_2O), 6.18 (s, 14H, C_6H para), 6.30 (m, 28H, C_6H_2 ortho). ^{13}C NMR (68 MHz, D_2O-d_2, ppm) δ –1.7, –0.77 (SiCH_3), 49.6 (OCH_2C), 63.6 (C_6H_3-CH_2), 83.5 (OCH$_2C$), 101.8, 106.3, 143.7, 157.0 (C_6H_3). FT-IR (KBr, cm^{-1}): 3378 (ν_{OH}), 2892 ($\nu_{C\text{-}H\ arom.}$), 1154 ($\delta_{Si\text{-}CH3}$), 1042, 954 ($\nu_{Si\text{-}O}$). MALDI-TOF *m*/*z*: 2837.9 (expected 2833.9, including *m*/*z* Li$^+$). Anal. calcd. for $C_{130}H_{174}O_{44}Si_{14}$: C 55.10, H 6.19; found: C 55.12, H 6.38.

Fourth generation dendrimer (4)

A solution of 1 equiv. of 2-butyne-1,4-diol (20 mg, 0.232 mmol) in 10 mL of THF, was added to a solution 2 equiv. of bis(dimethylamino)dimethylsilane (0.085 mL, 0.465 mmol) in 5 ml THF, and stirred for 6 h at ice bath temperature. The mixture was added dropwise (1h) to a solution of 2 equiv. of DHBA (65.1 mg, 0.465 mmol) in 10 mL of THF, and stirred overnight at room temperature. It was then added dropwise (1h) to a solution of 4 equiv. of bis(dimethylamino)dimethylsilane (0.170 mL, 0.929 mmol) in 5 mL of THF, and stirred overnight at room temperature. The latter was added dropwise (1h) to a solution of 4 equiv. of DHBA (130 mg, 0.929 mmol) in 10 mL of THF, and after stirring overnight, it was added dropwise (1h) to a solution of 8 equiv. of bis(dimethylamino)dimethylsilane (0.341 mL, 1.858 mmol) in 5 mL of THF, and stirred for 14 h. Then it was added to a solution of 8 equiv. of DHBA (260 mg, 1.858 mmol) in 15 mL of THF, and stirred overnight. The resulting solution was added dropwise to 16 equiv. of bis(dimethylamino)dimethylsilane (0.681 mL, 3.717 mmol) in 10 mL of THF. Stirring was continued overnight at room temperature. The resulting solution was then added dropwise (1h) to a solution of 16 equiv. of DHBA (521 mg, 3.717 mmol) in 10 mL of THF. The reaction mixture was stirred for 36 h at room temperature. Solvent removal under vacuum afforded a sticky gel. D_2O (4–5 mL) was added to the gel and was stirred for 5–10 minutes. The solution was filtered and D_2O was then removed under vacuum to afford a pink powder (833 mg, 60%). ^{1}H NMR (270MHz, D_2O-d_2) δ –0.06, 0.00, 0.22 (m, 180H, OSiMe_2O), 4.10 (s, 4H, OCH_2C), 4.31 (s, 60H, C_6H_3-CH_2O), 6.15 (s, 30H, C_6H para), 6.25 (m, 60H, C_6H_2 ortho). ^{13}C NMR (68 MHz, D_2O-d_2, ppm) δ –1.54, –1.033, 0.40 (SiCH_3), 49.5 (OCH_2C), 63.9 (C_6H_3-CH_2), 83.7 (OCH$_2C$), 100.5, 105.9, 143.1, 158.8 (C_6H_3). FT-IR (KBr, cm^{-1}): 3379 (ν_{OH}), 2889 ($\nu_{C\text{-}H\ arom.}$), 1263 ($\delta_{Si\text{-}CH3}$), 1042, 970 ($\nu_{Si\text{-}O}$). MALDI-TOF *m*/*z*: 5978.8

REVIEW / SYNTHÈSE

Biological production of functional chemicals from renewable resources[1]

Yutaka Tokiwa and Buenaventurada P. Calabia

Abstract: The development and implementation of renewable feedstocks for the production of multifunctional chemicals has received attention from the food and pharmaceutical industries and also as potential raw materials for the manufacture of biodegradable polymers. A major shift towards renewable resources, however, requires new ways to optimize and evaluate industrial processes. There are several possibilities to replace chemical techniques with biological methods based on renewable resources. This review discusses some examples of process development in which a biotechnological route might be favorable leading to industrial realization. Herein are described the production of biomaterials that can be used as monomers in plastics, such as lactic acid for polylactide (PLA), (*R*)-3-hydroxybutyric acid (*R*-3HB) for poly[(*R*)-3-hydroxybutyrate] (PHB), and succinic acid for poly(butylene succinate) (PBS). Moreover, several species of microorganisms that produce significant quantities of these functional chemicals under specific cultivation conditions from biomass-derived carbohydrates are also reviewed.

Key words: functional chemicals, renewable resources, lactic acid, (*R*)-3-hydroxybutyric acid, succinic acid.

Résumé : Le développement et l'implantation de ressources renouvelables pour la production de produits chimiques multifonctionnels a reçu beaucoup d'attention de la part des industries pharmaceutiques et alimentaires, mais ces ressources présentent aussi de l'intérêt comme matières premières potentielles pour la fabrication de polymères biodégradables. Un déplacement important vers les ressources renouvelables nécessite toutefois de nouvelles façons d'optimiser et d'évaluer les processus industriels. Il y a plusieurs possibilités pour remplacer les techniques chimiques avec des méthodes biologiques assises sur des ressources renouvelables. Cette revue discute de quelques exemples de développement de procédés dans lesquels la voie biotechnologique pourrait être favorable et conduire éventuellement à une réalisation industrielle. On décrit donc la production de matériaux qui peuvent être utilisés comme monomères dans les plastiques, tels l'acide lactique pour le polylactide (PLA), l'acide (*R*)-3-hydroxybutyrique (R-3HB) pour celle du poly[(*R*)-3-hydroxybutyrate] (PHB) et l'acide succinique pour la production du poly(butylènesuccinate) (PBS). De plus, on passe en revue diverses espèces de microorganismes qui produisent des quantités significatives des ces produits chimiques multifonctionnels dans des conditions de cultures spécifiques à partir de carbohydrates dérivés de la biomasse.

Mots-clés : produits chimiques multifonctionnels, ressources renouvelables, acide lactique, acide (*R*)-3-hydroxybutyrique, acide succinique.

[Traduit par la Rédaction]

Introduction

Because of the increasing world demand for energy, diminishing fossil resources, and dramatic increases in the price of petroleum, chemicals from renewable feedstocks are becoming increasingly viable and important alternative resources. Moreover, the biological conversion of biomass into commodity and specialty chemicals have gained interest because these renewable resources do not produce any net contribution of carbon dioxide to the atmosphere, thus re-

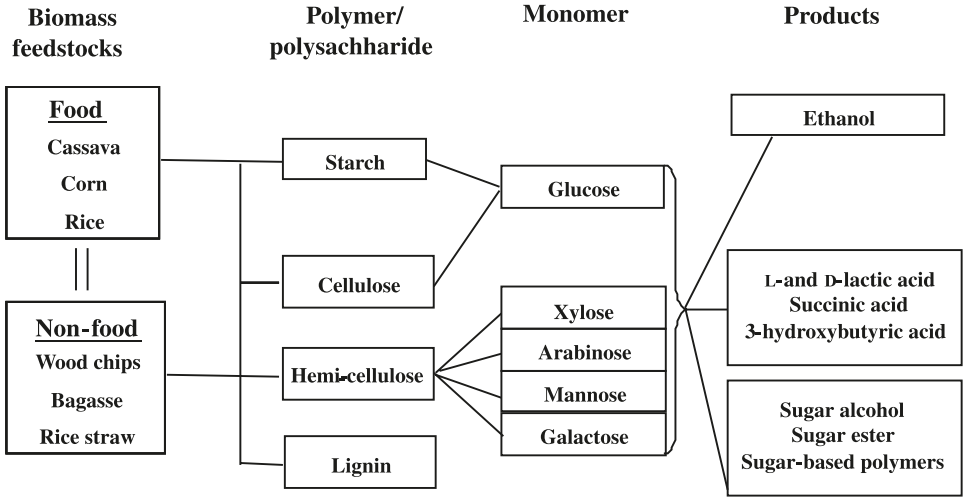
Fig. 1. Schematic representation for the production of functional materials from food and nonfood renewable resources.



ducing green house gas emissions. A wide range of functional materials derived from renewable resources are being developed as raw materials for the production of biodegradable plastics. As shown in Fig. 1, there are different food and nonfood agricultural products that can be used as potential substrates for the production of biochemicals, biomaterials, or biofuels. These agricultural products are first converted into sugar, which can be readily fermented by microorganisms into the desired products such as ethanol, L- and D-lactic acid, succinic acid, and 3-hydroxybutyric acid. Different strategies must be developed to achieve efficient production of these chemicals to compete with petroleum-based materials. One way to achieve this is to use inexpensive and renewable raw materials for the production of these chemicals. The microorganisms should be able to utilize a wide variety of sugar feedstocks (glucose, sucrose, fructose, xylose, mannose, etc.) with high yield and improved fermentation yield for downstream processing of the products.

Fermentative production of lactic acid

Lactic acid is the most widely occurring hydroxycarboxylic acid that is usually used in the food and pharmaceutical industries. Recently, the production of lactic acid has grown considerably mainly because of its new application as a raw material for biodegradable plastics. Lactic acid can be produced either by chemical process or by microbial fermentation. The most commonly used method in chemical synthesis is based on the hydrolysis of lactonitriles derived from acetaldehyde and hydrogen cyanide. However, this technique is expensive and results in the production of racemic DL-lactic acid, while microbial fermentation produces optically pure D- or L-lactic acid depending on the microorganism. The optical purity of lactic acid is necessary to the physical properties of polylactide (PLA), because when PLA is produced from pure L-isomer or D-isomer, the polymer is crystalline and more stable than the amorphous polymer obtained from a racemic mixture (1).

Lactic acid bacteria (LAB) and some filamentous fungi are the major microbial sources of lactic acid (2). LAB are classified into homofermentative (producing a single product, i.e., lactic acid) and heterofermentative (producing other products such as ethanol, acetic or formic acid, and carbon dioxide along with lactic acid). Some of the major homofermentative LAB are: *Lactobacillus, Carnobacterium*, *Streptococcus*, *Enterococcus*, *Lactococcus*, *Vagococcus*, *Brochothrix*, *Pediococcus*, *Tetragenococcus*, and *Weissella* (3). *Lactobacillus casei*, *L. rhamnosus*, and *Rhizopuz* sp. produce high concentrations of L-lactic acid (1, 4). L. rhamnosus and *Rhizopus* sp. (*R. oryzae* and *R. arrhizus*) are widely accepted producers of lactic acid with high optical purity, however, these microorganisms are categorized as level 2 pathogens. To date, studies on D-lactic acid fermentation are very few and a small number of LAB can produce D-lactic acid with high optical purity. As shown in Table 1, a wild strain of *Lactobacillus delbrueckii* (5, 6, 7) and *L. coryniformis* (8) ferment sugars mainly to D-lactic acid, and among the substrates used, sugarcane juice gave the highest yield. Several microorganisms have been engineered to produce high optical purity D-lactic acid, however the yield of the metabolically engineered microbes are comparable to wild strains (9, 10, 11, 12). It should be noted that lactic acid production should be evaluated in terms of lactic acid concentration (g/L) and not in terms of productivity. High concentration of lactic acid is preferred to minimize the cost of downstream processing.

The most widely used substrates for the production of lactic acid are starch and sugars. When starch is used, it is commonly hydrolyzed either by chemicals or enzymes prior to fermentation. However, there are several LAB that can directly ferment starch into L-lactic acid, thus eliminating the two–step process of saccharification prior to microbial fermentation to make it economical. For instance, *Lactobacillus amylovorus* can directly produce 92.5 g/L of L-lactic acid from 120 g/L of raw starch in 39 h (13). Yumoto and Ikeda (14) reported that 30 and 53.4 g/L of L-lactic acid were obtained from 50 and 100 g of unhydrolyzed soluble starch, respectively, using *Lactobacillus amylophilus*. Moreover, *Streptococcus bovis* 148, which secretes α-amylase, can degrade raw starch and convert it into high optical purity L-lactic acid (15).

Note: SSF = Simultaneous saccharification and fermentation, NA = Data not available.

Refined sugar such as glucose or sucrose, although expensive, are frequently used as raw materials for lactic acid production (1). The production costs could be reduced if glucose or sucrose from by-products of sugar manufacture (i.e., molasses) or from sugar crops (sugarcane, sugar beet, sweet sorghum) could be used instead of refined sugars, especially if the microorganisms can directly ferment these substrates into lactic acid without any pre-treatment. Just recently, we reported an efficient production of D-lactic acid with high optical purity of 97%–98% using sugarcane molasses, sugarcane juice, and sugar beet molasses (5). We also investigated the effect of sugarcane juice concentration on the productivity and yield of lactic acid fermentation using a newly isolated *Lactobacillus* sp. strain FCP2. The productivity and yield obtained in 3% (*w*/*v*) sugarcane juice were higher than in 13% (*w*/*v*) because of shorter fermentation time and no residual sugar (16).

In addition to the above mentioned substrates is inulin, a polysaccharide composed of β-(2→1)-linked fructose units and a reserve carbohydrate in the tubers of plants like chicory, yacon, Jerusalem artichoke, or dahlia. These are promising raw materials for lactic acid fermentation, because inulin can be easily extracted from these tubers. Several lactic acid bacteria (LAB) were screened for their ability to ferment inulin into lactic acid. One lactic acid bacterium was selected as giving the highest lactic acid concentration (17). However, further work is still necessary to improve the performance of the strain and to increase lactic acid concentration.

Most of the reports on lactic acid fermentation have examined the response of LAB to acid stress, including the mechanisms on acid tolerance of the microorganisms (18, 19). On the contrary, there are few studies on the stress response of LAB to alkaline environments to date. There are several alkaliphilic LAB that could grow at > pH 9.5. Among these are *Marinilactibacillus piezotolerans* (20), *M. psychrotolerans* (21), *Halolactibacillus halophilus*, *H. miurensis* (22), *Alkalibacterium olivoapovliticus* (23), and *Enterococcus hirae* (formerly *Streptococcus faecalis*) (24). The biochemical properties and characteristics of these LAB have been examined, but to our knowledge no report on lactic acid fermentation using alkaliphilic microorganisms have been published so far. Batch fermentation of lactic acid by *A. psychrotolerans*, using glucose as carbon source, was performed in a 5 L fermentor with a working volume of 2.5 L. Temperature and agitation were maintained at 30 °C and 150 rpm, respectively. The medium composition was the same as described elsewhere (5). The pH was automatically controlled at 10 by the addition of 6 N NaOH. The final lactic acid accumulation reached 21.2 g/L from a total of 30 g/L glucose in 48 h, with a productivity of 0.44 g/L/h (Fig. 2) (25). More studies are necessary to increase lactic acid concentration using alkaliphilic microorganisms. Research on the isolation, screening, and distribution of alkaliphilic and halophilic LAB in different environments is ongoing in our laboratory.

Production of (*R*)-3 hydroxybutyric acid monomer

(*R*)-3 hydroxybutyric acid (*R*-3HB) is a monomer that can be utilized as a chiral building block for the synthesis of fine

chemicals such as antibiotics, vitamins, aromatics, and pheromones (26, 27, 28). Production of *R*-3HB can be accomplished by chemical synthesis, enzymatic hydrolysis, or by metabolic engineering of strains (29). Although production of *R*-3HB by chemical synthesis is feasible, this method is complicated and expensive for industrial use. Several strategies have been developed to improve the production of *R*-3HB. Lee et al. (30), reported that a high yield of *R*-3HB can be obtained by providing suitable environmental conditions wherein the cells have high activity of intracellular depolymerase and low *R*-3HB dehydrogenase. Moreover, *R*-3HB could be efficiently produced by using metabolically engineered *E. coli* strains harboring a heterologous PHA synthesis and degradation pathway. This method consists of a two plasmid systems, depolymerase gene (high-copy number), and the biosynthesis gene (medium-copy number). *R*-3HB from glucose with high productivity of 9.9 g/L was obtained in 51 h (31). Gao et al. (32) improved the production of *R*-3HB by establishing a new method using the simultaneous expression of genes for β-ketothiolase (*phbA*), acetoacetyl-CoA reductase (*phbB*), phosphor-transbutyrylase (*ptb*), and butyrate kinase (*buk*) in the *E. coli* strain DH5α. Results showed that in shake flasks studies, *E. coli* DH5α that harbored *phbA* and *phbB* genes gave a small amount of *R*-3HB with a concentration of 75 to 400 mg/L. On the other hand, with the addition of *ptb* and *buk* genes the concentration increased to 1.4 g/L. Moreover, the *R*-3HB concentration was increased further to more than 2 g/L when the two plasmids in *E. coli* DH5α contain *phbA* and *phbB* in one plasmid and *ptb* and *buk* in the other. Shiraki et al. (33) reported the use of (*R*)-3-hydroxybutyrate dehydrogenase (BDH) null mutant of *Ralstonia eutropha* and recombinant *E.coli* for the fermentative production of *R*-3HB. They examined the effect of various conditions on the amount of *R*-3HB released into the culture supernatant. The concentration of *R*-3HB was higher in anaerobic (30 mmol/L) than under aerobic (4–10 mmol/L) conditions. The decrease of *R*-3HB in the supernatant under aerobic conditions was presumed to be due to *R*-3HB being metabolized via other metabolic pathways in which BDH does not participate.

Recently, we reported that *R*-3HB could be produced by enzymatic hydrolysis using a thermophilic *Streptomyces* sp. MG. This microorganism could efficiently hydrolyze poly [(*R*)-3-hydroxybutyrate] (PHB) and the main component of the degradation products was *R*-3HB monomer (34). Another alternative method that could be used for the enzymatic synthesis of *R*-3HB is via acetoacetate, wherein *R*-3HB dehydrogenase converts acetoacetate to *R*-3HB in the presence of NADH and H^+ (29).

Ring-opening polymerization (ROP) offers another approach for producing PHB. *R*-3HB can be polymerized via (*R*)-β-butyrolactone to make PHB. In addition to *R*-3HB, other compounds such as lactide, glycolide, caprolactone, and (*R*,*S*)-β-butyrolactone can be co-polymerized with (*R*)-β-butyrolactone for the production of the pure co-polymer of *R*-3HB (Fig. 3). It is expected that using ROP, good properties of synthetic PHB and its co-polyesters (poly[(*R*)-β-butyrolactone-*co*-L-lactide]) could be obtained, such as a high degree of purity and high molecular weight.

Biotechnological production of succinic acid

Succinic acid is a dicarboxylic acid that can be used as a feedstock for the manufacture of various chemicals such as 1,4 butanediol, adipic acid, γ-butyrolactone, tetrahydrofuran, *N*-methylpyrolidone, and linear aliphatic polyesters. To date, most of the commercially available succinic acid has been manufactured by chemical process (35, 36). However, production of succinic acid from petrochemicals is expensive. For this reason, there has been much interest in the production of succinic acid from renewable resources by microbial fermentation. As shown in Table 2, there are several succinate-producing microorganisms such as *Actinobacillus succinogenes*, *Mannheimia succiniciproducens*, *Anaerobiospirillum succiniciproducens*, *Bacteroides fragilis*, and *Enterecoccus flavescens*. Among these, *A. succinogenes* and *A. succiniciproducens* can accumulate succinic acid in significant concentrations. *A.succinogenes* was isolated from bovine rumen (37), while *A. succiniciproducens* was from animal feces (38). *A. succinogenes* has distinct characteristics that produce high concentrations of succinic acid under anaerobic conditions using various carbon sources such as glucose, sucrose, fructose, lactose, maltose, mannose, xylose, cellobiose, arabinose, galactose, sorbitol, manitol, and salicin. It has good tolerance to a high concentration of glucose (160 g/L) (39). Production of succinic acid by *A. succinogenes* is strongly affected by the amount of CO_2;

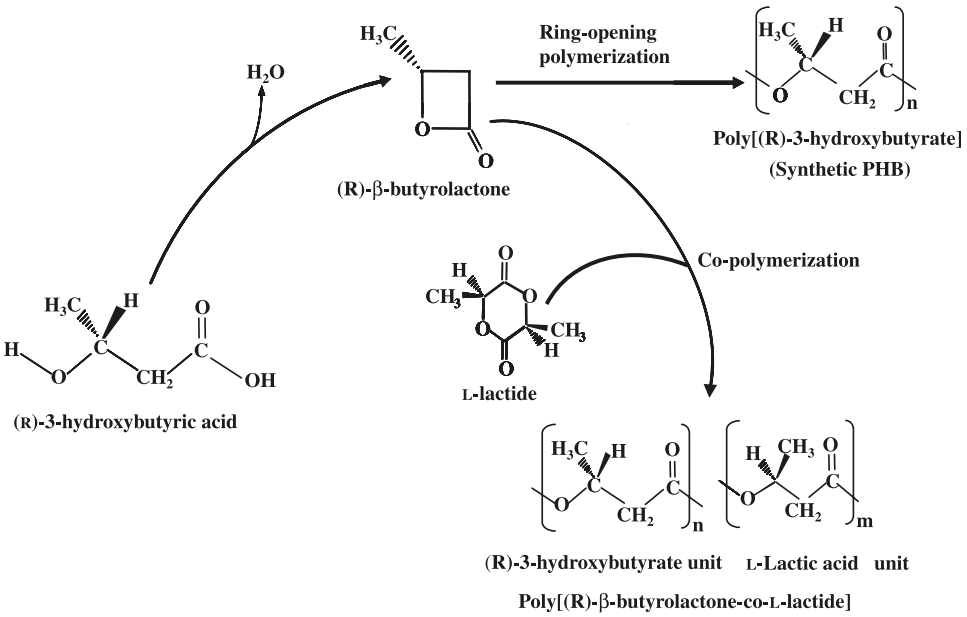
Fig. 3. Schematic illustration for the synthesis of poly [(*R*)-3-hydroxybutyrate] and its co-polyesters from (*R*)-3-hydroxybutyric acid.



high CO_2 concentration produced higher succinic acid and low ethanol concentration. Furthermore, the addition of H_2 to the gas phase also improved succinic acid production. This is probably due to the increased carboxylization of phosphoenolpyruvate (PEP) to oxaloacetate over the conversion of PEP to pyruvate (40). *A. succinogenes* can also produce succinic acid from pre-treated sugarcane molasses (41). *M. succiniciproducens* was able to produce succinic acid as the major fermentation product in the presence of CO_2, with acetic and formic acids as the minor products. An efficient and economical production of succinic acid was possible by using pre-treated wood hydrolysate. The major sugar contents of wood hydrolysate are glucose and xylose. *M. succiniciproducens* can utilize both as carbon source for succinic acid production (42), while *A. succinoproducens* can only use glucose in wood hydrolysate but not xylose (43).

Although some of the strains are able to produce relatively high succinic acid than other microorganisms, formation of other organic acids (acetic, formic, and lactic acid) becomes a problem because it reduces the succinic acid yield and makes the downstream process difficult and expensive. Several strategies have been used to reduce other by-products and to enhance biotechnological production of succinic acid. One approach is through genetic manipulation technologies. For instance, Lee et al. (44) reported the development of the *M. succiniciproducens* LPK7 strain, wherein the lactate dehydrogenase (ldhA), pyruvate formate lyase (*pflB*), and phosphotransacetylase-acetate kinase (*pta-ackA*) genes were inactivated by metabolic engineering, based on its complete genome sequence. Batch fermentation of wild-type *M. succiniciproducens* using 22.5 g/L glucose produced 10.5 g/L succinic acid, 4.96 g/L acetic acid, 4.10 g/L formic acid, and 3.47 g/L lactic acid. However, metabolically engineered *M. succiniciproducens* LPK7 produced 13.4 g/L of succinic acid from 20 g/L glucose without formic acid and lower lactic acid production. A monofluoroacetate-resistant mutant strain of *A. succinogenes* produced less acetic and formic acids than the parent strain (31). Furthermore, succinic acid could be efficiently produced by redirecting carbon flux from phosphoenolpyruvate (PEP) and pyruvate to the reductive tricarboxylic acid (TCA) by overproducing PEP and pyruvate-carboxylating enzymes. Succinic acid concentration increased significantly from 3 to 10.7 g/L by overexpression of PEP carboxylase (PEPC) in *E.coli* (45).

Evaluation of raw materials used in the production of functional chemicals

Biomass from sugar crops, starch crops, or cellulosic materials provides great potential for sustainable production of biochemicals, biomaterials, or biofuels. Agro-industrial residues such as wood chips, bagasse, rice straw, and rice bran, can also be used as potential raw materials because they are inexpensive or even available at no cost in some cases. Lignocellulosic materials consist of cellulose, hemicellulose, and lignin, which are polymeric and responsible for their physical and chemical properties. Of the 3 components, lignin is the most recalcitrant to degradation whereas cellulose is more resistant to hydrolysis than hemicellulose because of its highly ordered crystalline structure. However, pre-treatment of these substrates is necessary prior to fermentation. Chemical hydrolysis (acid and alkali) have been used to hydrolyze starch and lignocelluloses, but enzyme hydrolysis is more attractive because enzymes do not produce undesirable products and they are environmentally friendly. Thus we established a method in determining the enzymatic degradation of insoluble materials such as polymers, starch, and lignocellulosic materials using a total organic carbon (TOC) analyzer. TOC analyzer measures the amount of total organic carbon present in a liquid sample. A liquid sample is initially introduced to an inorganic carbon (IC) removal stage where acid is added to the sample. At this point the IC is converted into carbon dioxide (CO_2) gas that is stripped out of the liquid by a sparge carrier

Fig. 4. Relationships between the formation of water-soluble total organic carbon (TOC) and reaction time degradation of starch granules by (A) α-amylase from *Bacillus subtilis* (B) gluco-amylase from *Rhizopus niveus* using TOC (○), Somogyi-Nelson (□), and Phenol-H_2SO_4 (△) methods.

gas. The sample is then oxidized and the CO_2 generated from the oxidation process is directly related to the total carbon (TC) in the sample. TOC can be measured by subtracting the IC from TC concentrations.

TOC analyzer, phenol sulfuric, and Somogyi-Nelson methods were compared in the determination of the degradation of starch and wood by enzymes. Glucose, which contains 40% organic carbon in the molecule, was used as a standard for phenol sulfuric and Somogyi-Nelson methods. Figure 4 shows the time course of the enzymatic hydrolysis of starch granules by α-amylase and gluco-amylase. α-Amylase is an end-type enzyme acting randomly in the interior parts of the starch chain. The fragmentation by α-amylase initially leads to a rapid reduction in the molecular size of the starch, with the formation of water soluble dextrins and oligosaccharides. Thus, when TOC analyzer and phenol-sulfuric method were used, the TOC formations were the same because all the degradation products (monomer and oligomer) were measured. On the other hand, the Somogyi-Nelson method is only specific to reducing sugars, therefore the TOC formation based on reducing sugars was lower (Fig. 4*a*). When gluco-amylase was used in the hydrolysis of starch, the TOC formations among the 3 methods used were the same because gluco-amylase is an exo-type enzyme that has the ability to hydrolyze from the terminal to produce glucose (Fig. 4*b*). Furthermore, the formation of TOC in the degradation of various kinds of wood by cellulase from *Trichoderma viride* was also determined. As shown in Fig. 5, the calculated TOC was high when phenol-sulfuric method was used, because the aromatic compound in wood mill reacts with these chemicals (phenol and sulfuric acid) and produced color, thus increasing the TOC value. Phenol-sulfuric and Somogyi-Nelson are the common methods used in the determination of total sugar and reducing sugar, respectively. They are useful also in investigating the degrada-

tion mechanisms of cellulose and starch. However, these methods are not applicable in biomass containing lignin such as wood chips, bagasse, and rice straw. The TOC analysis is more appropriate.

Conclusion

Although considerable effort has been made in the development of functional materials from renewable resources, there are still a lot of tasks to be accomplished to make them cost-competitive with petrochemical-based materials. It is important to isolate, screen, or improve novel microorganisms to enhance the microbial production of monomers (lactic acid, (*R*)-3HB, and succinic acid). Genetic engineering is one approach to optimize biotechnological production routes, however recombinant microorganisms are not yet fully accepted because of the unpredictable detrimental effect on the environment. In addition to metabolic engineering, the conventional method, UV mutation, is a practical way of improving microbial strains. Utilization of biomass, such as starch, cellulose, hemicellulose, and lignocellulose, is an attractive approach in the production of functional materials because these raw materials are abundant and inexpensive. In addition, TOC analysis is an effective approach in the determination of the degrading activity of insoluble biomaterials and fermentation activity of biomass because it is reliable, versatile, economical, and user friendly (no chemicals involved).

The crystallization of ultrathin films of polylactides — Morphologies and transitions[1]

Damien Maillard and Robert E. Prud'homme

Abstract: Poly(L-lactide) ultrathin films of thicknesses between 10 and 80 nm were crystallized between 100 and 170 °C. Four different morphologies were obtained: single crystals, hedrites, dendrites, and spherulites. Dendrites were always obtained below 20 nm due to chain diffusion limitations, whereas, at larger thicknesses, the morphology heavily depends on the crystallization temperature. The thickness–temperature morphological map led to the observation of two transition temperatures, at 115 and 145 °C. Other parameters such as the lamellar thickness, melting temperature, and dendricity of the lamellae for 15 nm thick films show significant changes at these two temperatures. Those transitions occur at the same temperatures as Regime III/Regime II, and Regime II/Regime I transitions of the Lauritzen–Hoffman crystallization theory.

Key words: polylactide, ultrathin film, crystalline morphology, single crystal, dendrite, spherulite, transition temperature, regime of crystallization.

Résumé : Des films ultraminces de poly(L-lactide) d'épaisseurs comprises entre 10 et 80 nm ont été cristallisés sur une gamme de températures allant de 100 à 170 °C. Quatre morphologies distinctes ont été observées : monocristaux, hédrites, dendrites et sphérolites. Des dendrites ont été systématiquement observés à des épaisseurs de moins de 20 nm à cause des empêchements à la diffusion des chaînes tandis qu'à plus grande épaisseur, la morphologie dépend de la température de cristallisation. Une représentation morphologique épaisseur/température permet de visualiser deux températures de transition, à 115 et 145 °C. D'autres paramètres tels que l'épaisseur des lamelles cristallines, la température de fusion et la dendricité des lamelles obtenues à partir de films de 15 nm montrent des changements significatifs à ces deux températures. Ces transitions se produisent aux mêmes températures que les transitions entre les régime III/régime II, puis régime II/régime I de la théorie de cristallisation de Lauritzen et Hoffman.

Mots-clés : polylactide, film ultramince, morphologie cristalline, cristal unique, dendrite, sphérulite, température de transition, régime de cristallisation.

Introduction

In general, the crystallization of ultrathin polymer films (thickness ≤ 100 nm) leads to a different behaviour from that in the bulk. For example, the kinetics of crystallization and the final degree of crystallinity decrease with the film thickness below 100 nm (1, 2).

Contrary to the bulk where the lamellae have the possibility to grow in three dimensions, all the lamellae in ultrathin films grow in the same plane; this restriction leads to the observation of phenomena that are impossible to detect in the bulk. For example, Hobbs et al. have observed that the lamellae at the growth front of spherulites, called dominant lamellae, do not grow at a constant rate but can remain dormant for certain periods of time (3). Other studies have shown how the branching of a lamella results from the secondary nucleation of a parent lamella and how lamellae are able to join together during the growth (4–6). In the case of crystallization at low supercooling, polymers like isotactic polystyrene, syndiotactic polypropylene, and poly(ε-caprolactone) (PCL) exhibit "isolated" flat-on single crystals from which it is possible to measure the lamellar thickness or the growth rate along the different sectors (7, 8). Our own studies on PCL ultrathin films have shown that the lamellar thickness of single crystals is only controlled by the crystallization temperature, not the film thickness, even when the melt is much thinner than the lamellar thickness, and have permitted to identify the plasticizer role of the residual solvent in the polymer crystallization (8, 9).

Polylactides are biodegradable and biocompatible chiral polyesters largely studied for their various characteristics. Poly(L-lactide) (PLLA) and poly(D-lactide) (PDLA) are semi-crystalline, whereas poly(DL-lactide) (atactic) is amorphous. The thermal and crystallization behaviours of PLLA were extensively studied in the bulk, its melting temperature (T_m), which varies with the crystallization temperature (T_c) being close to 180 °C (10–12). Several studies have reported

an exotherm followed by a double melting peak in differential scanning calorimetry (DSC) curves, and that behaviour was recently interpreted as the result of spontaneous recrystallization (13).

Studies on ultrathin films of PLLA led to the observation of truncated lozenge single crystals (with four (110) sectors and two (200) sectors) and of dendritic structures below 20 nm (14–16). Edge-on lamellae able to nucleate new flat-on lamellae were also reported, exhibiting *S* or *Z* shapes, depending on the chain chirality (17).

In the present paper, the crystallization conditions leading, for ultrathin PLLA films, to single crystals and other morphologies will be determined, and using classical and modulated DSC, in addition to atomic force microscopy (AFM), two transitions, at which several crystalline parameters are significantly modified, will be defined at 115 and 145 °C.

Experimental section

Materials

Poly(L-lactide) was provided by Polysciences Inc. and used without further purification. The molecular masses were determined by gel permeation chromatography using a Wyatt light scattering detector: M_n = 110 000 g mol^{-1} and polydispersity (PD) = 1.26.

Sample preparation

Ultrathin films were prepared by spin-coating in dichloromethane solutions at a rotation speed of 3000 rpm for 20 s, following an acceleration of 4000 rpm/s, using a Headway Research Inc. EC-101 apparatus. The film thickness was controlled by the solution concentration; concentrations from 2 to 20 mg/mL were used to obtain thicknesses ranging between 5 and 100 nm. The films were cast onto cleaned Si substrates (p-type single side polished (100) silicon wafers). The wafers were cleaned by immersion in nitrohydrochloric acid for 1 h in an ultrasonic bath to remove any organic contamination and to hydroxylate the native oxide layer, thus making the surface hydrophilic. The substrates were then rinsed with distilled water and dried by spin-coating for 40 s at 3000 rpm, before treatment in a plasma cleaner (Harrick PDC-32G) at 18 W for 20 s. To keep a solvent-saturated atmosphere around the sample and to allow uniform evaporation, a glass dome was placed on top of the sample area during spin-coating. Film thicknesses were measured by AFM.

The films used for the static studies were melted at 190 °C for 2 min and crystallized at the desired temperature (between 100 and 175 °C) in a THMS-600 Linkam hot-stage connected to a TMS-94 temperature controller. After crystallization, samples were placed on an aluminum sheet previously cooled in liquid nitrogen for quickly decreasing the temperature below the glass transition temperatures and freezing the sample.

Atomic force microscopy

A multimode AFM apparatus (Digital Instrument (DI)), equipped with a Nanoscope IIIa controller (DI), a Quadrex extender (DI), and a high temperature heating accessory (DI), operated in tapping mode, was used to capture images. JVH (temperature control, maximal scan size: 130 μm × 130 μm) and J (ambient temperature, maximal scan size 100 μm × 100 μm) scanners were used with silicon nitride probes (MikroMash and Nanosensor).

The temperature-controlled studies were performed directly inside the AFM. The samples were melted at 190 °C for 2 min, and the stage temperature was decreased to the chosen crystallization temperature (between 90 and 165 °C), which was maintained until the beginning of the crystallization. Then, the temperature was increased during the crystallization to obtain specific areas crystallized at defined temperatures. Finally, the temperature was increased by steps of 2 °C, maintained constant at each step for 10 min to obtain AFM pictures, until reaching a complete melted state. During the whole process, the AFM probe was maintained at the same temperature as the sample to avoid any condensation. The scan rate was 1 Hz. Height, amplitude, and phase were collected simultaneously.

Branching density measurements were performed by counting the number of branches on a 10 μm × 10 μm AFM picture completely covered by dendritic flat-on lamellae. The results presented in this paper are averages of observations performed on at least three pictures obtained in the same conditions. The quantitative values are expressed in number of branches/μm^2.

Film and lamellar thicknesses were measured by profilometry using AFM. The films were scratched with a surgical blade to uncover the substrate, and the profile was established on both sides of the scratch; the difference in height between the film area and the uncovered substrate is read. In the case of film thicknesses of 15 nm or below, the lamellae are thicker than the films and emerge from them.

Differential scanning calorimetry

DSC experiments were performed on a TA Q1000 apparatus. The C_p response was calibrated with sapphire, and the temperature response was calibrated with indium. The scan rates were 10 and 0.5 °C/min for the classical and 4 °C/min for the modulated experiments. For modulated DSC, the period was 40 s, and the amplitude was 0.424 °C.

Results

The variety of crystalline morphologies obtained for PLLA as a function of film thickness was investigated at several crystallization temperatures from 100 to 175 °C. Depending on these two parameters, four different morphologies are observed, as illustrated in Fig. 1: single crystals, single-crystal stacks (hedrites), dendrites, and spherulites. At temperatures above 115 °C and thicknesses of 25 nm (Figs. 1*e* and 1*h*), single crystals are observed. In the case of PLLA, single crystals from solution have a lozenge shape, but from the melt they adopt a truncated lozenge shape, geometrically almost a hexagon, due to chain diffusion. In both pictures, dendritic overgrowths are seen on top of the main lamella; this is possible because the thickness of the single crystal is about 18 nm (AFM measurement), making possible the superposition of two crystalline layers because of the 25 nm melt thickness. At temperatures above 145 °C and thicknesses above 50 nm, crystal stacks are observed (Fig. 1*g*). The crystal stack, or hedrite, is a three-dimensional object made of the superposition of flat-on lamellae epitaxially aligned. This superposition can be due

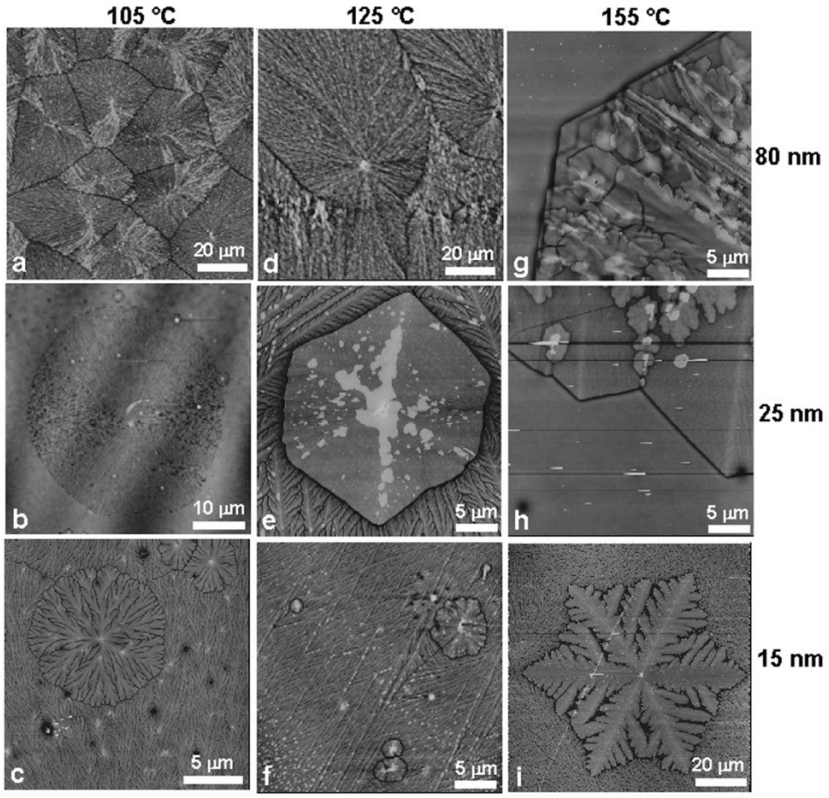
Fig. 1. AFM micrographs of PLLA ultrathin films after crystallization and quenching in liquid nitrogen. The film thicknesses are 80 nm (*a*, *d*, g), 25 nm (*b*, *e*, h), and 15 nm (*c*, *f*, *i*). The crystallization temperatures are 105 °C (*a*, *b*, *c*), 125 °C (*d*, *e*, *f*), and 155 °C (*g*, h, *i*). Note that the scales are not exactly the same on each picture.



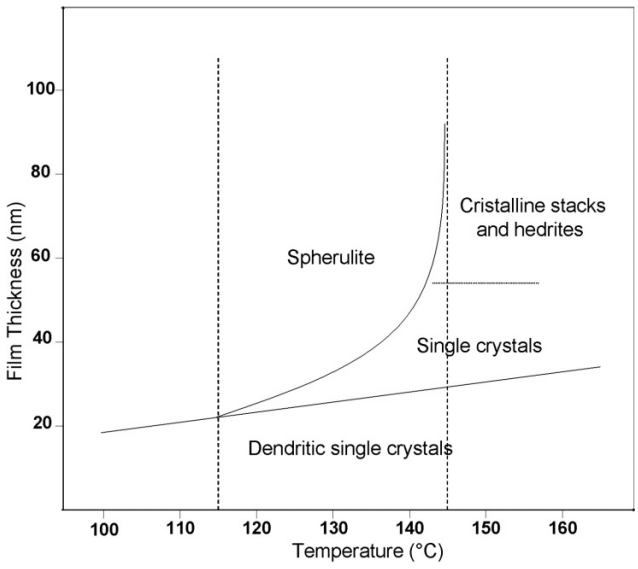
to a secondary nucleation on top of the crystal (crystal stacks) or to a screw dislocation of the primary lamella (hedrite) conducting to a "snail" structure. At 15 nm, in the range of crystallization temperatures investigated, dendrites are observed (Figs. 1*c*, 1*f*, and 1*i*). Their shape ressembles that of single crystals (snow-like crystals or more spherical flower-like crystals), but the growth fronts are broken and branched. Spherulites are systematically observed at temperatures below 115 °C for thicknesses above 20 nm (Figs. 1*a* and 1*b*), and at temperatures between 115 and 145 °C for thicknesses above 50 nm (Fig. 1*d*).

Electron diffraction measurements have confirmed those morphologies. In the case of single crystals, crystal stacks/hedrites, and dendrites, the chain axis is oriented normal to the substrate while the *a* and *b* axes have the same orientation throughout the entity. In contrast, in the case of spherulites, there is very little orientation, the *a*, *b*, and *c* axes being almost randomly distributed.

Additional observations made at several other film thicknesses and crystallization temperatures lead to a "map" of morphologies in terms of those two parameters, as given on Fig. 2.

In this map, there are three morphological sectors in terms of temperature, with significant changes at about 115 and 145 °C. At temperatures below 115 °C, the morphologies are dendritic below 20 nm and spherulitic above 20 nm. Above 145 °C, the morphologies are dendritic and single-crystalline, with a transition thickness at about 30 nm; above 50 nm, the lamellae are able to superpose, leading to

Fig. 2. Morphology map of PLLA films for thicknesses below 100 nm.



lamellar stacks, or hedrites, which can be considered as a superposition of the single-crystal structures. Between 115 and 145 °C, three morphologies can be obtained: below 25 nm, the crystals and dendritic; above 25 nm, they can be spherulitic (close to 115 °C) or single crystalline (close to 145 °C); above 80 nm, the crystals are always spherulitic.

© 2008 NRC Canada

Below 20 nm, the morphology is always dendritic, as it has been observed for example with poly(ε-caprolactone) below 15 nm (8) because of limitations to the chain diffusion: the lamellae formed (dendrites) are as thick, or even thicker, than the melt from which they grow. However, even if the morphology is always dendritic in this area, there is a notable evolution in branching density because the diffusion of the chains depends not only on the film thickness (spatial restriction) but also on the temperature. Figure 3 shows the variation of the branching density of the dendritic flat-on crystals, for 15 nm thick films, with the crystallization temperature – three representative samples are shown for illustration. Below 115 °C, the dendrites are coarse and tree-like oriented. Above 145 °C, they are flower-like and well-outlined. Finally, between those two temperatures, the branches are fine, regularly aligned, with a fixed distance between them. The curve of the dendricity as a function of T_c shown in Fig. 3 presents a maximum at 112.5 °C.

For the same series of samples, Fig. 4 shows the variation of the lamellar thickness with the crystallization temperature. Our values, between 121 and 152 °C, agree well with those of Kanchanasopa et al. (18), although they are slightly larger because the two techniques of measurement were different. It is seen in Fig. 4 that the thickness does not increase smoothly as a function of temperature. Although the data points can be represented by a curved line, as proposed in the literature (19), they are better described as a succession of three linear lines with inflection points at 121 and 152 °C.

For a deeper understanding of this system, the melting behaviour of PLLA was studied by DSC and AFM during heating scans at two scan rates (Fig. 5). At a scan rate of 10 °C/min and crystallization temperatures below 115 °C, the thermograms exhibit an exotherm before the melting peak (Peak 1) (Fig. 5*a*). At a crystallization temperature of 115 °C, double melting peaks are visible, one at 170 °C (Peak 2) and the other at 176 °C (Peak 1). At crystallization temperatures higher than 115 °C, a single peak is observed (Peak 2), whose position increases with the crystallization temperature. At a scan rate of 0.5 °C/min, the trend is the same, but Peak 1 is present up to 135 °C, where double peaks are detectable (Fig. 5*c*) and, because of the slower scan rate, the peaks are thinner.

Figures 5*b* and 5*d* summarize the transitions observed in DSC scans. At a scan rate of 10 °C/min, below 110 °C, the position of the exotherm shifts slowly to higher temperatures while Peak 1 remains almost constant between 174 and 176 °C. At the same time, Peak 2 shows up at T_c = 105 °C, even below the exotherm, but shifts to higher temperatures upon increasing T_c. It exhibits two inflection points at about 115 and 145 °C. At a scan rate of 0.5 °C/min, the transition temperatures evolve as they do at 10 °C/min, but Peak 1 is visible until 135 °C, and the melting temperatures are a little lower.

To understand the origin of these transitions, we used modulated DSC, a technique that permits to separate reversible and non-reversible events during a thermal scan. With this technique, it is possible to visualize the opposite behaviour of melting and immediate crystallization (an endotherm followed by an exotherm in DSC) that form the recrystallization process.

Fig. 3. Variation of branching density (dendricity) as a function of crystallization temperature for film thicknesses of 15 nm. The inserts show some representative AFM micrographs.

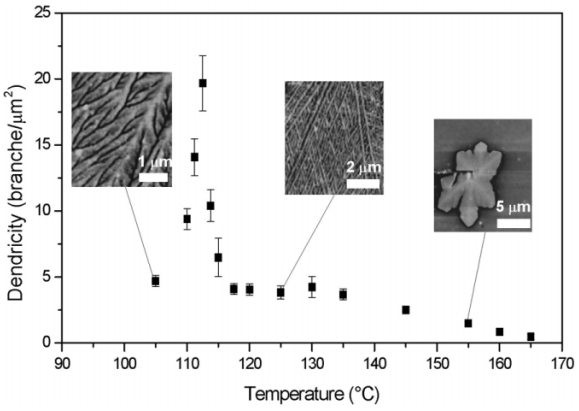


Fig. 4. PLLA lamellar thickness, measured by AFM for films of 15 nm in thickness, as a function of crystallization temperature.

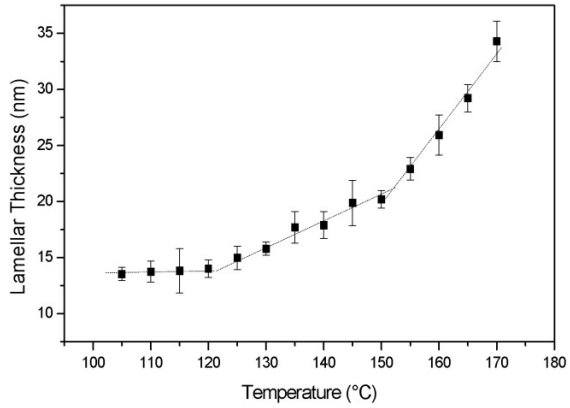

Figure 6 shows a modulated DSC scan of a sample isothermally crystallized at 90 °C. The reversible heat capacity curve exhibits a small melting peak at 156 °C; whereas the non-reversible curve shows two events, a crystallization peak at 157 °C and a melting peak at 174 °C (maximum of the peak). These curves show clearly that opposing events occur in the 150–160 °C range: melting and crystallization occur at the same time (but crystals that melt have a lamellar thickness different from the crystals that are formed). However, since the area of the crystallization exotherm is larger than the area of the corresponding endotherm (melting peak), the final resulting transition, i.e., the sum of the two curves in the resultant heat flow curve, is a small exotherm before the final melting peak. This is the so-called recrystallization process. At higher crystallization temperatures, as shown in Fig. 5, beginning at 110 °C, the melting peak begins to dominate and the exotherm is not anymore visible.

Using AFM, it is possible to go further and to visualize the transitions: recrystallization and melting. For that purpose, samples were crystallized at the desired temperature in the AFM, and the temperature was slowly increased until the observation of melting.

Figure 7 shows two series of measurements made on ultrathin films whose temperature was increased until the

Fig. 5. DSC thermograms (*a* and *c*) of PLLA isothermally crystallized at temperatures between 90 and 160 °C, scanned at (*a*) 10 °C/min and (*c*) 0.5 °C/min. The temperatures of peak 1(□), peak 2 (△), and the exotherms (○) are reported as a function of crystallization temperature in part (*b*) for a scan rate of 10 °C/min and part (*d*) for a scan rate of 0.5 °C/min. Here, the films are thick (about 500 μm).

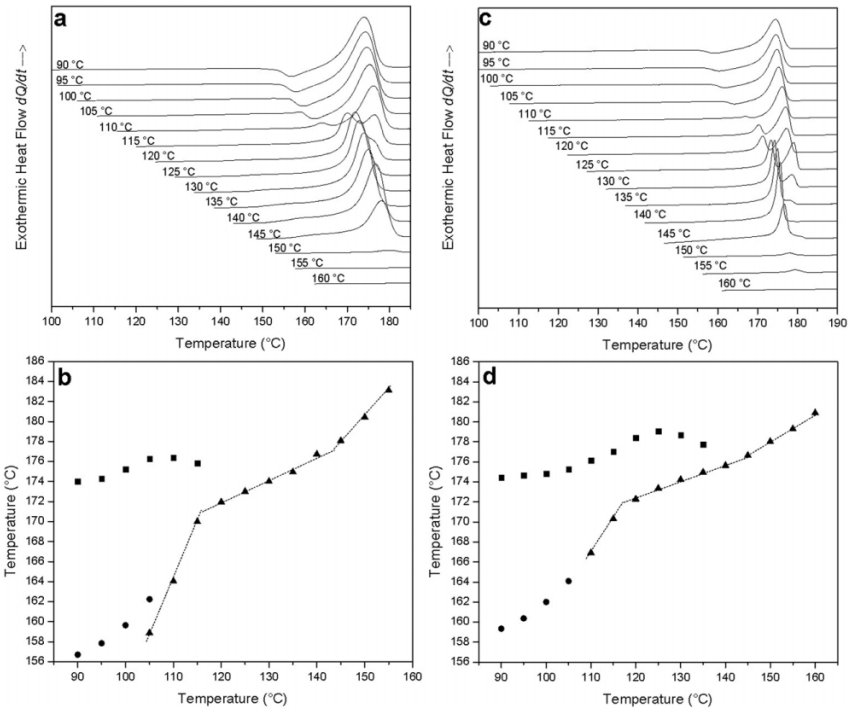

Fig. 6. Modulated DSC thermograms of a sample isothermally crystallized at 90 °C, scanned at 4 °C/min with a period of 40 s and an amplitude of 0.424 °C. The three thermograms represent, respectively, the reversible, the non-reversible, and the total heat capacity as a function of temperature. The main melting temperature (summit of the peak) is 174 °C, the secondary crystallization peak temperature is 157 °C, and the first reversible melting temperature is 156 °C.

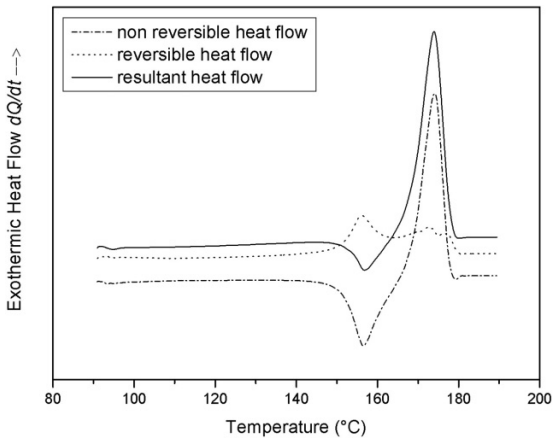

observation of in situ recrystallization and melting. First, a film of 15 nm was crystallized at 110 °C, and the temperature was increased to 145 °C. The left part of Fig. 7*a* is covered by crystals obtained at 110 °C, while the right-hand side of the picture is covered by crystals obtained at 145 °C, whose dendricity is reduced as compared with the crystals obtained at 110 °C. After increasing the temperature to 172 °C (Fig. 7*b*), cheese holes, indicative of annealing, are obtained in the area previously crystallized at 110 °C while the area crystallized at 145 °C does not change. At 175 °C (Fig. 7*c*), the area crystallized at 145 °C is modified and also exhibits cheese holes.

Second, a film of 15 nm was crystallized at 145 °C, and the temperature was increased to 155 °C and maintained there 10 min. At 165 °C (Fig. 7*d*), three areas are distinguished, corresponding to crystallizations at 145, 155, and 165 °C; between those three areas, there is a difference of dendricity and thickness. At 174 °C (Fig. 7*e*), the structure of the area crystallized at 145 °C is modified, exhibiting cheese holes and increased thickness, as observed by AFM height measurements (during that transformation, the crystal continues to grow). At 180 °C (Fig. 7*f*), the areas initially crystallized at 145 and 155 °C begin to melt, but the area crystallized at 155 °C does not exhibit any kind of recrystallization before that temperature.

The thickness of the crystals changes during the recrystallization. From the examples of Fig. 7, the thicknesses measured by AFM are 14.5 nm for a crystallization at 110 °C and 31 nm after annealing at 172 °C. Similarly, the thickness of a film crystallized at 145 °C is found at 21.5 nm before and 41.5 nm after annealing at 174 °C. In general, the thickness after annealing is roughly the double of the initial thickness.

The appearance of cheese holes on the crystal surface is the consequence of a modification of the lamellar thickness. An increase of the thickness (by a factor of two) is obtained by a reorganisation of the chain arrangement leading to a decrease of the number of chain folds. As the total volume of material remains constant, the increase in thickness must be compensated by a decrease of the lateral occupancy, and

therefore, the cheese holes of Fig. 7 occupy roughly half the surface area.

Figure 8 summarizes the data of recrystallization and melting obtained by AFM from micrographs, such as those shown in Fig. 7, plotting the temperature of the event as a function of T_c. For comparison, the melting temperatures obtained by DSC at a low scan rate, i.e., 0.5 °C/min (conditions similar to the slow increase of temperature during the AFM experiments) were added on the graph. The melting temperatures obtained by DSC and AFM for Peak 1 and Peak 2 agree closely; the recrystallization temperatures, obtained by AFM below T_c = 145 °C, agree with those seen by DSC below 115 °C, and increase almost linearly between 115 and 145 °C in a range of temperatures where the recrystallization process was buried in the DSC curve under the endotherm. Therefore, DSC and AFM measurements are here complementary.

Discussion

The previous section indicates that several significant changes occur at 115 and 145 °C during the crystallization of ultrathin PLLA samples. From AFM measurements (Fig. 2), changes in morphology occur at 115 and 145 °C; from spherulites to single crystals in the first case (film thickness of 25 nm); from spherulites to hedrites in the second one (film thickness ≥ 70 nm). All those morphologies originate from the same crystal structure as shown by electron diffraction, i.e., a pseudo-orthorombic $P2_12_12_1$ unit cell with a = 1.08 and b = 0.63 nm, in agreement with the X-ray values reported in the literature (20–22). In the measurement of the lamellar thickness on films of 15 nm in thickness (Fig. 4), two inflection points are detected at 121 and 152 °C. On bulk samples, DSC measurements (Fig. 5) show that the melting temperature exhibits two inflection points at about 115 and 145 °C.

In the literature, those temperatures correspond to the transitions observed between the three regimes of crystallization in the Lauritzen–Hoffman theory, i.e., at 115 °C, there is a transition between Regimes III and II, and at 145 °C, the transition is between Regimes II and I (23). The difference between these three regimes is the relative value of the radial and lateral growth rates at the lamellar surface (19). In Regime I, the lateral growth rate is larger than the radial growth rate; in Regime II, they are of the same order of magnitude; in Regime III, the radial growth rate is larger than the lateral growth rate.

Transitions between Regimes I, II, and III have been found for many polymers, but in general there is no direct link between regimes and microscopic morphologies. However, there are exceptions. In the case of polyethylene, Regime I is found above 127 °C with an axialite morphology, but in contrast spherulites form below 127 °C and the lamellae grow according to a Regime II kinetics (24). Polylactides appear to behave like polyethylene in this respect, at least at film thicknesses above 20 nm. In polylactides, a transition from spherulites to hexagonal lamellae in thin films (>100 nm) has been reported at a temperature of 150 °C, corresponding to the passage from Regime II to Regime I, but no similar morphological transition was detected between Regime II and Regime III (23). This result agrees with the data shown above (Fig. 2) with a tran-

© 2008 NRC Canada

sition from spherulites to hedrites at 145 °C. However, in addition, we have also seen a morphological transition at 115 °C from spherulites to single crystals, corresponding to the transition from Regime III to Regime II.

When the film thickness is below 20 nm, there is no change in morphology (dendrites are seen throughout the temperature range contrary to the observations in thicker films), but there are transitions in lamellar thickness at the two transition temperatures. This result is unexpected because, according to the Gibbs–Thomson equation (19), an exponential behaviour is expected with an asymptote at T_m^0

$$[1] \qquad T_m = T_m^0 (1 - 2\sigma_e/(l\Delta H))$$

where T_m is the melting temperature, T_m^0 is the equilibrium melting temperature, σ_e is the surface energy of the crystal, l is the thickness of the crystal, and ΔH is the melting enthalpy. To our knowledge, this is the first time that transitions are detected in the evolution of the lamellar thickness with the crystallization temperature (under conditions where there are no changes in morphology). Moreover, the temperature of these transitions correspond to the Regime III/Regime II and Regime II/Regime I transitions in the Lauritzen–Hofman theory.

The dendricity curve (Fig. 3) exhibits a global shape similar to the behaviour of the growth rate – T_c curve observed for polymers. According to the Keith and Padden theory concerning the fibrillation density of lamellae in spherulites, the distance between two lamellae, δ, i.e., the inverse of the dendricity, is proportional to the ratio of the diffusion coefficient, D, to the growth rate, G, i.e., $\delta \approx D/G$ (25). The diffusion coefficient increases linearly with the temperature; in contrast, the growth rate goes through a maximum, being slowed down at low temperatures because of the increase in viscosity of the system and at high temperatures because of a decreased nucleation rate. Therefore, δ goes through a minimum as a function of temperature, i.e., the dendricity goes through a maximum. This is the general behaviour observed in Fig. 3. However, it also shows a sharp maximum at 112.5 °C. This is reminiscent of the growth rate – T_c behaviour reported in the literature for PLLA (23, 26, 27) with a maximum at 113 °C, which has been attributed to a change of regime of crystallization or crystal structure. In this case, there is no change in crystal structure, and this latter explanation must be ruled out.

Many polymers experience recrystallization when they are heated up in a DSC apparatus, i.e., small crystals melt, but at the same time crystallization occurs leading to bigger crystals. This phenomenon leads to DSC curves exhibiting a double melting peak (28, 29). Often, the relative intensity of the two peaks changes with the heating rate. In the case of PLLA, the recrystallization process is particularly intense, since the crystallization during heating often dominates the melting of previously formed crystals leading to an exotherm in the DSC curve (Fig. 5). This competition is clearly seen in Fig. 6 with the reversible heat flow that goes in one direction while the non-reversible signal goes into the other; the addition of these two curves gives an exothermic resultant heat flow.

In summary, we have shown that PLLA, crystallized between 95 and 170 °C, exhibits a variety of morphologies, at thicknesses below 80 nm (spherulites, dendrites, hedrites, and single crystals); even in the case where only one morphology is present, i.e., below 20 nm, there is a clear evolution of dendricity from low to high crystallization temperatures. Moreover, not only morphological observations but also T_m values and lamellar thicknesses show two transitions, at 115 and 145 °C, where the mode of crystallization changes. These temperatures correspond to those where there is a transition from Regime III to Regime II, and from Regime II to Regime I, respectively. This is the first time that the two changes of regimes in crystallization kinetics, in the context of the Lauritzen–Hoffman theory, can be related to simple crystallization characteristics as lamellar thickness and temperature of fusion. This indicates, once again, that studies on thin and ultrathin films can lead to phenomenon that are hardly detected in bulk samples, contributing to a deeper knowledge of the crystallization behaviour of polymers.

Decaying exponential feeding of nonanoic acid for the production of medium-chain-length poly(3-hydroxyalkanoates) by *Pseudomonas putida* KT2440[1]

Heather Maclean, Zhiyong Sun, Juliana Ramsay, and Bruce Ramsay

Abstract: Decaying exponential feeding strategies for the production of medium-chain-length poly(3-hydroxyalkanoates) by *Pseudomonas putida* KT2440 have been developed as a method of delaying oxygen limitation that is typically responsible for the termination of high cell density aerobic fermentations. Two feeding strategies were evaluated to control the biomass generation rate and consequently control the oxygen uptake rate of the cells. A linear decaying strategy allowed the production of 90 g L^{-1} dry biomass containing 65% PHA in 31 h with a cumulative productivity of 1.9 g L^{-1} h^{-1}, while a quadratic decaying exponential feeding rate followed by a constant feeding rate produced 109 g L^{-1} of dry biomass containing 63% PHA. The latter methodology improved the cumulative PHA productivity to 2.3 g L^{-1} h^{-1}, which is the highest MCL-PHA productivity ever reported. Analysis of the relationship between the final biomass concentration and the associated maximum cell generation rate (which is directly related to the maximum oxygen transfer rate) indicated that higher biomass levels could be attained by decreasing the substrate feeding rate at high biomass concentrations.

Key words: MCL-PHA, high cell density, decaying exponential feeding, oxygen limitation.

Résumé : Afin de retarder la limitation par l'oxygène responsable de la terminaison des fermentations aérobiques à densité cellulaire élevée, on a mis au point des stratégies de décroissance exponentielle de l'alimentation pour la production de poly(3-hydroxyalcanoates) de longueur de chaîne moyenne par le *Pseudomonas putida* KT2440. On a évalué deux méthodes d'alimentation pour contrôler la vitesse de génération de la biomasse et, en conséquence, contrôler la vitesse d'absorption d'oxygène par les cellules. Une stratégie de décroissance linéaire permet d'obtenir une production de 90 g L^{-1} de biomasse sèche contenant 65% de PHA, dans 31 heures, avec une productivité cumulative de 1,9 g L^{-1} h^{-1} alors qu'une décroissance exponentielle quadratique de la vitesse d'alimentation, suivie par une vitesse d'alimentation constante permet d'obtenir une production de 109 g L^{-1} de biomasse sèche contenant 63% de PHA. Cette dernière méthodologie a permis d'augmenter la productivité cumulative de PHA jusqu'à 2,3 g L^{-1} h^{-1} qui correspond à la valeur la plus élevée jamais rapportée pour une productivité cumulative de PHA. Une analyse de la relation entre la concentration finale de la biomasse et la vitesse maximale de génération de cellule qui lui est associée, qui est directement reliée à la vitesse maximum de transfert d'oxygène, indique que les niveaux les plus élevés de biomasses peuvent être atteints en diminuant la vitesse d'alimentation du substrat aux concentrations élevées de biomasse.

Introduction

Poly(3-hydroxyalkanoates) (PHAs) have attracted great interest as biodegradable and biocompatible substitutes for conventional polymers in recent years. Short-chain-length PHAs (SCL-PHAs), with repeating units containing 4 to 5 carbons, may be brittle due to a high degree of crystallinity. Medium-chain-length PHAs (MCL-PHAs), with repeating units of 6 or more carbons, are thermoelastomers. Potential applications are numerous because PHAs exhibit a wide variety of physical and chemical properties depending on their structure and the nature of covalently bound functional groups (1). Poly(3-hydroxybutyrate) (PHB) and poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBHV) are SCL-PHAs that have been produced on a commercial scale under the trade name Biopol. In contrast, MCL-PHAs have not

 doi:10.1139/V08-062 © 2008 NRC Canada

been commercialized. To make their production more commercially viable, strategies for increasing cell density, PHA content, and cumulative productivity have been investigated. High cell density is a prerequisite for achieving high PHA productivity, and high PHA content is important as it reduces separation and downstream processing costs. Fermentation processes for the production of MCL-PHAs have been reviewed recently (2).

MCL-PHA production processes have invariably incorporated a nutrient limitation because of the widely held belief that significant PHA production only occurs in the presence of excess carbon, while nitrogen or phosphorus limits growth. Therefore, many substrate-feeding strategies for fed-batch fermentations have involved an initial stage of rapid cell growth, followed by a nutrient-limited PHA accumulation stage (3, 4). However, some organisms have been shown to accumulate significant amounts of PHA during nutrient unlimited or carbon-limited growth, suggesting that nitrogen or phosphorus limitation is not always a necessity for substantial MCL-PHA accumulation (5, 6). When PHA is accumulated during carbon-limited growth, simple exponential feeding strategies can be applied. Recently, it was shown that *Pseudomonas putida* KT2440 produced large amounts of MCL-PHA during exponential carbon-limited growth on nonanoic acid at various predefined specific growth rates (7). This approach allowed high productivity but oxygen limitation inevitably occurred at high cell density causing nonanoic acid accumulation in the reactor. This led to cell lysis, uncontrollable foaming, and termination of the fermentation.

High oxygen demand is a common problem in high cell density aerobic cultivation (8). To avoid or delay oxygen limitation and therefore achieve higher cell concentrations and productivities, the oxygen uptake rate of the culture should be limited. Since oxygen uptake rate is roughly proportional to the cell generation rate (μX), oxygen limitation could be avoided by controlling μX below a certain critical value. Since cell concentration (X) keeps increasing in a fed-batch fermentation, a gradually decaying specific growth rate (μ) may be imposed to quickly achieve high cell densities, while avoiding the physiological disturbances that would result from rapidly decreasing μ. This work examines the application of two decaying exponential feeding strategies for the production of MCL-PHAs by *P. putida* KT2440.

Experimental

Microorganism and growth medium

P. putida KT2440 (ATCC 47054) was maintained in lyophiles and on nutrient agar plates at 4 °C. The inoculum medium contained (per litre): 4.70 g of $(NH_4)_2SO_4$, 0.80 g of $MgSO_4 \cdot 7H_2O$, 12.00 g of $Na_2HPO_4 \cdot 7H_2O$, 2.70 g of KH_2PO_4, 1.00 g of nutrient broth, and 9.00 g of glucose. The initial culture medium contained (per litre): 4.70 g of $(NH_4)_2SO_4$, 0.80 g of $MgSO_4 \cdot 7H_2O$, 18.00 g of $Na_2HPO_4 \cdot 7H_2O$, 4.05 g of KH_2PO_4, 10 mL trace element solution, and nonanoic acid as indicated in the substrate feeding section. The trace element solution contained (per litre): 10.0 g of $FeSO_4 \cdot 7H_2O$, 3.0 g of $CaCl_2 \cdot 2H_2O$, 2.2 g of $ZnSO_4 \cdot 7H_2O$, 0.5 g of $MnSO_4 \cdot 4H_2O$, 0.30 g of H_3BO_3, 0.20 g of $CoCl_2 \cdot 6H_2O$, 0.15 g of $Na_2MoO_4 \cdot 2H_2O$, 0.02 g of $NiCl_2 \cdot 6H_2O$, and 1.00 g of $CuSO_4 \cdot 5H_2O$. The pH was controlled with 14% (*w*/*v*) NH_4OH, which was also the nitrogen source. Nonanoic acid (NA, 98%, Spectrum Chemicals) was autoclaved and fed to the reactor according to the chosen feeding scheme. Additional $MgSO_4 \cdot 7H_2O$ was fed at a ratio of 0.033 g of $MgSO_4 \cdot 7H_2O$ g nonanoic acid^{-1}.

Fermentation conditions

The inoculum was cultivated in 500 mL shake flasks (100 mL medium) at 30 ± 1 °C and 200 rpm for approximately 12 h. Fed-batch fermentations were performed at 30 ± 1 °C with a 3.0 L initial working volume in a Minifors 5 L stirred tank bioreactor (Infors HT, Bottmingen, Switzerland). Data acquisition (dissolved oxygen, air outlet CO_2, nonanoic acid and base addition, and pH) and control was conducted with LabVIEW 6.1 (National Instruments). pH was controlled at 6.85 ± 0.05. Dissolved oxygen was measured with an Ingold polarographic probe and maintained at or above 40% air saturation by adjusting the agitation speed up to 1200 rpm and by automatically adjusting the mixture of air and pure oxygen via mass flow controllers to maintain a total gas flow at 1 vvm, until oxygen limitation occurred even at 1 vvm of pure oxygen. Exiting CO_2 was measured with an IR CO_2 monitor (Guardian Plus, Topac Inc. Hingham, MA, USA). Feeding of nonanoic acid with peristaltic pumps was automatically controlled based on the mass of the reservoirs.

Substrate feeding and control methods

Nonanoic acid feeding based on a linearly decaying specific growth rate

With an initial 1 g L^{-1} nonanoic acid in the reactor, exponential feeding of nonanoic acid controlled growth at 0.25 h^{-1} (7) until an estimated biomass concentration of 3 g L^{-1} was achieved. Feeding designed to achieve a linearly decaying specific growth rate was then imposed. The specific growth rate model was based on two user-defined parameters: initial specific growth rate, μ_{init}, and the time over which the growth rate would decrease to zero, t_{max}. The imposed specific growth rate followed eq. [1], where the t is the time from the start of the decaying exponential feeding (the dashed line in Fig 1).

$$[1] \qquad \mu = \frac{-\mu_{init}}{t_{max}} t + \mu_{init}$$

where μ_{init} was set at 0.25 h^{-1} with a corresponding t_{max} of 30 h. Biomass concentration was expected to follow eq. [2], where X_0 was estimated as 3 g L^{-1}. Nonanoic acid was fed according to eq. [3] to support this level of growth, based on the yield of biomass from nonanoic acid, $Y_{X/S}$ (0.8 g g^{-1}).

$$[2] \qquad X_t = X_0 e^{\frac{-\mu_{init}}{2t_{max}} t^2 + \mu_{init} t}$$

$$[3] \qquad S_t = \frac{X_t}{Y_{X/S}} = \frac{X_0 e^{\frac{-\mu_{init}}{2t_{max}} t^2 + \mu_{init}}}{Y_{X/S}}$$

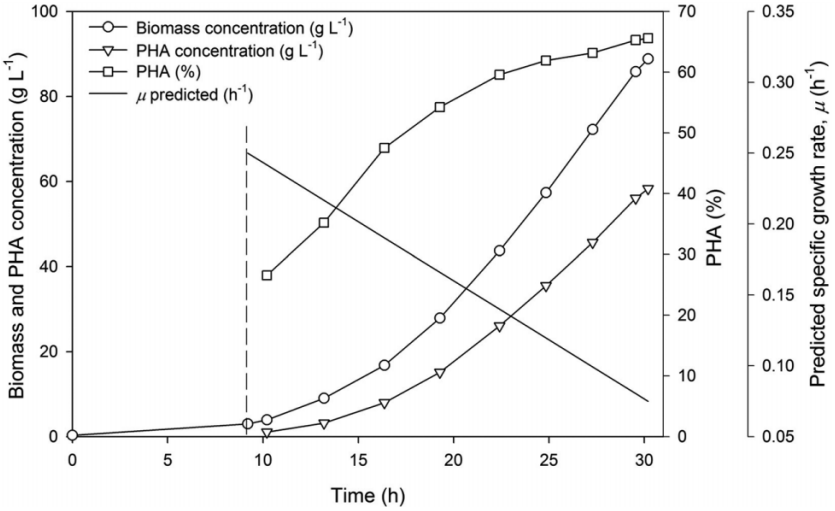
Fig. 1. Growth and PHA production of *P. putida* KT2440 on nonanoic acid fed at a linearly decaying specific growth rate. The dashed line indicates the start of automated feeding.



Quadratic decaying specific growth rate followed by constant feeding of nonanoic acid

Initially, 1 g L^{-1} nonanoic acid was added to the reactor and the culture was grown in a batch mode. Depletion of this carbon source was detected by a sudden decrease in CO_2 production. At this time, a quadratic model for the decaying specific growth rate was immediately imposed on the system. The quadratic model, shown as eq. [4], was based on the user defined parameters μ_{init} and t_{max}.

$$[4] \qquad \mu = \frac{-\mu_{init}}{t_{max}^2} t^2 + \mu_{init}$$

The μ_{init} was set as 0.45 h^{-1} and t_{max} was chosen as 15 h (based on simulations) to achieve high productivity while controlling μX below the set point, which was the value expected to cause an oxygen demand that exceeded the oxygen transfer capacity of the bioreactor (based on previous experience). Cell concentration was expected to follow eq. [5], where X_0 was estimated as 0.6 g L^{-1}, with nonanoic acid feeding shown in eq. [6].

$$[5] \qquad X_t = X_0 e^{\frac{-\mu_{init}}{3t_{max}^2} t^3 + \mu_{init} t}$$

$$[6] \qquad S_t = \frac{X_t}{Y_{X/S}} = \frac{X_0 e^{\frac{-\mu_{init}}{3t_{max}^2} t^3 + \mu_{init} t}}{Y_{X/S}}$$

The quadratic feeding strategy continued until the cell generation rate (μX) achieved its maximum set point of 7 g L^{-1} h^{-1}, at which time the system automatically switched to a constant rate of nonanoic acid feeding of 8.75 g L^{-1} h^{-1} of nonanoic acid based on $Y_{X/S}$ (0.8 g g^{-1}), as described previously (10).

Analytical procedures

Cell dry weight was determined after lyophilization of biomass obtained by centrifugation and washing of 5 mL culture broth at 13 000*g* for 15 min. The culture supernatant was saved for analysis of nonanoic acid and other nutrients. Nonanoic acid concentration was determined by gas chromatography analysis with decanoic acid as internal standard following methylation (11). Phosphate was measured via reduction of phosphomolybdate to molybdene blue (12). Ammonium was determined by the phenol-hypochlorite method (13). PHA content and composition was determined as previously described (7).

Results and discussion

Linear decaying exponential feeding

All previous *P. putida* KT2440 fermentations, in which exponential feeding at different constant specific growth rate was applied, ended with oxygen limitation (7). Since $dO_2/dt = Y_{O2/X}$ (dX/dt) and $dX/dt = \mu X$, oxygen limitation occurs when the oxygen transfer rate of the bioreactor cannot meet the high oxygen demand (dO_2/dt, g L^{-1} h^{-1}) caused by a high cell generation rate (dX/dt, or μX, g L^{-1} h^{-1}). To avoid or delay this limitation while still attaining high cell concentration, the specific growth rate can be controlled such that μX (or dX/dt) and consequently dO_2/dt do not exceed a critical value. A sudden decrease in the nonanoic acid feeding rate, which controls the specific growth rate, usually resulted in cell lysis, which in turn caused excessive foaming. Therefore, a gradually decaying specific growth rate should avoid such physiological disturbances. In previous fermentations, which had employed simple exponential feeding to obtain constant specific growth rates of 0.075 (unpublished data), 0.15, and 0.25 h^{-1} (7), before reaching the limit in the system oxygen transfer capacity the μX was 14.0, 10.5, and 6.4 g L^{-1} h^{-1}, with the highest biomass being obtained at the lower value. Based on this information, an upper boundary of in the decaying exponential feeding was set at the relatively conservative value, 7 g L^{-1} h^{-1}.

A linear decaying specific growth rate was imposed to test the effectiveness of a decaying feeding strategy. A biomass concentration of 3 g L^{-1} was initially attained using a proven

exponential feeding with 0.25 h^{-1} (Fig. 1, 0–9 h), followed by a decaying feeding rate imposed at 9.2 h. The μ_{init} and t_{max} in eqs. [1–3] were set as 0.25 h^{-1} and 30 h, respectively, as these values would never produce a μX greater than 7 g L^{-1} h^{-1}, but should attain a high cell concentration as seen in simulations (Fig. 2*a*, predicted plots). The imposed specific growth rate decreased linearly from the initial value of 0.25 h^{-1} to approximately 0.07 h^{-1} within 21 h (Fig. 1). Nonanoic acid was the only limiting factor throughout the fermentation.

The cell concentration in the reactor increased to a final value of 90 g L^{-1}. There was also substantial PHA accumulation. At the beginning of the fermentation no PHA was detected (data not shown) since the inoculum was grown on glucose and nutrient broth. By the end of the process, the PHA content of the cells had increased to 65%, corresponding to a final concentration of 58 g L^{-1} and a cumulative productivity of 1.9 g L^{-1} h^{-1}. However, the fermentation eventually ended when the dissolved oxygen concentration in the reactor dropped to zero. Oxygen limitation caused the nonanoic acid concentration in the reactor to accumulate to toxic levels, resulting in cell lysis and uncontrollable foaming.

The linear decaying exponential feeding strategy was promising. The actual biomass concentration, specific growth rate, and instantaneous cell generation rate followed the predicted trends quite closely (Fig. 2*a*), indicating that the culture growth was controlled by the feeding strategy. This feeding strategy allowed a higher final cell and PHA concentration than had been previously achieved by feeding at a constant specific growth rate (7). However, the μ_{init} of 0.25 h^{-1} was a conservative choice. A higher μ_{init} is possible if the actual μ of the culture can be determined from CO_2 production data during the initial growth (9). Although the linearly decreasing μ avoided μX from exceeding the upper boundary of 7 g L^{-1} h^{-1} (Fig. 2*a*, μX predicted), the culture grew well below its optimum μ for most of the fermentation. A less rapidly decreasing μ is preferable. Even after reaching the maximum μX set point, an unnecessary decrease in μX (and consequently the oxygen consumption rate) occurred because of the continual decrease in μ. Assuming that the maximum μX set point would avoid oxygen limitation as intended, biomass productivity could be improved if the system could operate at its maximum μX for as long as possible.

Quadratic decaying exponential feeding followed by a constant feed rate

Taking the above considerations into account, a quadratic decaying exponential feeding followed by a constant feed rate was designed to further increase final cell density, PHA concentration, and PHA productivity (Fig. 2*b*, predicted plots). The initial concentration of nonanoic acid in the reactor was 1 g L^{-1}. The μ_{max} during the batch cultivation (Fig. 3, 0–5 h) was estimated by CO_2 analysis to be approximately 0.6 h^{-1}, but to avoid overfeeding, the initial specific growth rate (μ_{init}) in the quadratic decaying feeding model (eqs. [4–6]) was chosen as 0.45 h^{-1}.

In the first stage of the feeding strategy, nonanoic acid was fed at a decreasing specific growth rate according to a quadratic model. The quadratic model allowed the maintenance of a higher specific growth rate than the linear decaying strategy (Fig. 3, 5–15 h). The maximum cell generation rate (7 g L^{-1} h^{-1}) was achieved more quickly using this strategy. These benefits were expected to improve productivity by reducing the total fermentation time. The quadratic decaying feeding strategy took approximately 10 h to attain the predicted maximum cell generation rate. Substrate feeding was then maintained at a constant value of 8.75 g L^{-1} h^{-1} nonanoic acid for the remainder of the fermentation. This constant nonanoic acid feed rate was intended to keep the cell generation rate constant at its maximum value and hence should keep the oxygen uptake rate at a sustainable level. However, after a total of 30 h of operation the dissolved oxygen in the reactor decreased to zero, and the fermentation ended because of oxygen limitation and consequent foaming.

The final biomass concentration in the reactor was 109 g L^{-1} and contained 63% of PHA. The final PHA concentration (68.5 g L^{-1}) corresponded to a cumulative PHA productivity of 2.3 g L^{-1} h^{-1}.

These results show a substantial improvement in the final biomass and also in the PHA productivity. The actual biomass concentration, specific growth rate, and instantaneous biomass productivity once again followed the predicted trends quite closely (Fig. 2*b*), with some deviation that was mostly caused by changes in volume that were not accounted for in the prediction. The cumulative PHA productivity that was attained using the decaying exponential

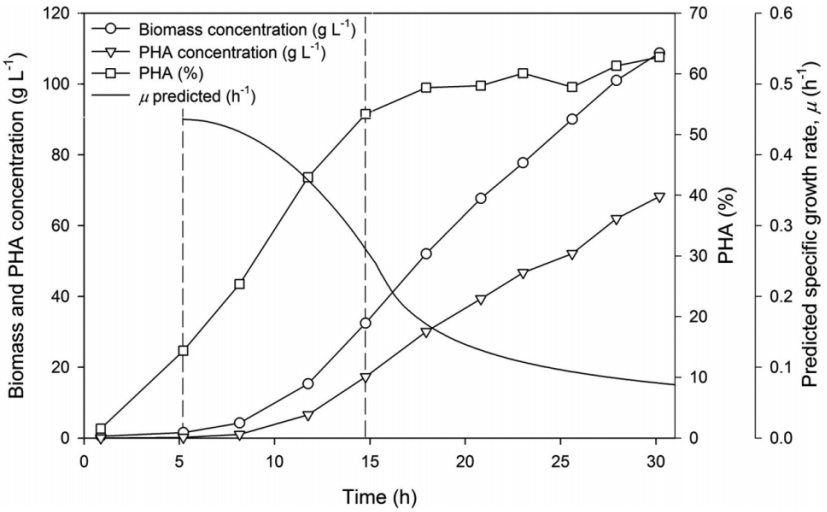
Fig. 3. Growth and PHA production of *P. putida* KT2440 on nonanoic acid fed at a quadratic decaying specific growth rate followed by a constant nonanoic acid feeding rate. The first dashed line indicates the start of the quadratic decaying specific growth rate model. The second dashed line represents the start of the constant feeding of nonanoic acid.



feeding strategy is the highest MCL-PHA productivity ever reported (2). The maximum biomass concentration achieved by conventional exponential feeding on this system was 85 g L^{-1} when the cells were grown at a constant specific growth rate of 0.075 h^{-1} (data not shown). However, the long fermentation time resulted in a low productivity of only 0.55 g L^{-1} h^{-1}. At higher constant growth rates, higher productivities were achieved but oxygen limitation resulted in a lower cell concentration (7). This feeding regime combines the advantages of high and low specific growth rates at appropriate times. The high initial specific growth rate decreased the amount of time required for the initial stage of the fermentation when biomass concentration was quite low and hence oxygen uptake rate was low. This decreased the fermentation time, which improved productivity. The low specific growth rate near the end of the fermentation decreased oxygen demand, which delayed oxygen limitation, and therefore allowed higher biomass concentrations to be attained.

Both feeding regimes produced MCL-PHA containing 62, 35, and 2 mol% hydroxynonanoate, hydroxyheptanoate, and hydroxyvalerate repeating units, respectively, with only 1 mol% of the repeating units containing even numbers of carbon. 3-Hydoxyoctanoate was the most common of the even carbon numbered repeating units, accounting for about 0.7 mol% of the total PHA repeating units. The composition was measured for every sample and did not vary significantly. While the polymer molecular weight was not measured during these fermentations, we have found that for this bacterial strain, it is typically in the range of 80–100 000 Da with a polydispersity index of less than 2.0 (unpublished data).

The relationship between cell concentration and oxygen transfer rate

A maximum cell generation rate of 7 g L^{-1} h^{-1} was chosen for the fermentations in this study based on the results of previous exponential feeding experiments when the culture was grown at constant specific growth rates. In the previous experiments, the cell generation rate increased throughout the fermentation until oxygen limitation was encountered at some maximum μX value. However, oxygen limitation was still encountered in the decaying exponential experiments and could not be avoided completely by this method. Analyzing results from different fermentations demonstrated that the attainable maximum cell generation rate (dX/dt or μX) decreased with the increase in final biomass concentration (Fig. 4), indicating that the maximum oxygen transfer rate also decreased. This relationship between cell density and the oxygen transfer rate has been observed by others. For example, in a high cell density cultivation of recombinant *Escherichia coli*, the oxygen transfer coefficient k_La decreased as the biomass concentration in the reactor increased (14).

There are several ways in which biomass concentration could affect oxygen transfer. Ju and Sundararajan (15) suggested that cells are able to affect oxygen transfer by modification of the medium, by their physical presence as solid particles, or through respiration at the gas–liquid interface. During MCL-PHA production, the appearance of the fermentation broth changed with increasing cell density. The broth became increasingly viscous with a milky yellow colour. Any cell lysis would result in the release of water-soluble macromolecules, such as DNA and RNA, into the fermentation broth. The resultant increase in viscosity would reduce oxygen transfer, which may explain why oxygen limitation occurred at lower cell generation rates when the cell density in the reactor was high.

Conclusions

Decaying exponential feeding strategies were developed in this study to solve the problem of early oxygen limitation resulting from exponential feeding with constant specific growth rate. High cell densities and PHA productivities were achieved by this novel feeding strategy. A cumulative PHA productivity of 2.3 g L^{-1} h^{-1} was obtained, representing the highest MCL-PHA productivity reported in the literature. Despite these improvements, decaying exponential feeding experiments still ended because of oxygen limitation, possibly

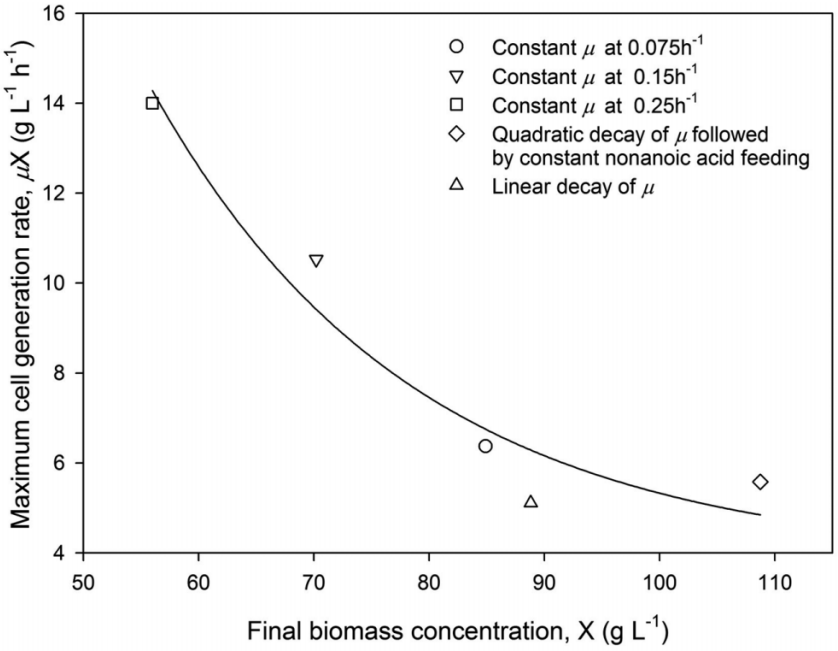
Fig. 4. Relationship between final biomass concentration and maximum cell generation rate attained by the current fermentation system with different exponential feeding strategies. Constant μ fermentation data (at 0.15 and 0.25 h^{-1}) are taken from Sun et al. (7).



due to decreased oxygen transfer coefficient at high cell densities. An improved strategy would be to decrease the substrate feeding rate in accordance with the decreasing oxygen transfer rates encountered at high biomass concentrations

The final PHA content of 60%–65% in these fermentations was representative of results obtained previously. High PHA content within the cells is essential for cost-efficient separation as well as for further improvements in productivity. Further understanding of the mechanisms by which PHA is produced within the cell during carbon limited growth would give insight into how PHA content could be increased.

Graft copolymers containing poly(3-hydroxyalkanoates) — A review on their synthesis, properties, and applications[1]

Sophie Nguyen

Abstract: The use of the poly(3-hydroxyalkanoates) in copolymer synthesis has received much interest, as the microbial polyester segments can bring interesting properties, such as biodegradability and biocompatibility. The synthesis, properties, and applications of graft copolymers containing poly(3-hydroxyalkanoates) as main chain or branches are reviewed here, with emphasis on the different preparation methods, which fit into the three main synthesis strategies of graft copolymers: "grafting onto", "grafting from", and "grafting through" or macromonomer methods.

Key words: poly(3-hydroxyalkanoates), graft copolymer, synthesis, properties, applications.

Résumé : L'utilisation des poly(3-hydroxyalcanoates) dans la synthèse de copolymères a suscité beaucoup d'intérêt, car les segments de polyesters microbiens peuvent apporter des propriétés intéressantes comme la biodégradabilité et la biocompatibilité. La synthèse, les propriétés, et les applications de copolymères greffés comprenant des poly(3-hydroxyalcanoates) comme chaines principales ou pendantes (branches) sont revues ici, en s'intéressant tout particulièrement aux différentes méthodes de préparation qui utilisent l'une ou l'autre des trois principales stratégies de synthèse des copolymères greffés: les méthodes de "greffage sur", "greffage à partir de", "greffage par" ou technique des macromonomères.

[Traduit par la Rédaction]

Introduction

Graft copolymers represent interesting materials as their properties can be controlled by their chemical composition and their architecture, i.e., by the length of the different polymer blocks (1, 2) and the distribution of the grafted chains along the main chain. They can advantageously show properties of one copolymer moiety, while avoiding the macro-scaled phase-separation problems often encountered in binary polymer blends (1, 3, 4). In fact, one application of graft copolymers is their use as compatilizers in such blends (3, 4).

Poly(3-hydroxyalkanoates), PHAs, have received much attention over the past forty years as completely biodegradable plastics available from renewable sources (5–10). They are used by a large number of bacteria as carbon and energy reserve, stored in cytoplasmic granules (5–14), and their production was observed in more than 300 different microorganisms (11). In addition, they are biocompatible, provided sufficient purification from residual proteins, surfactants, or endotoxins has been performed (15). PHAs can be classified according to their side chain length: short chain length PHAs, scl-PHAs, have repeat units containing 3 to 5 carbon atoms; medium chain length PHAs, mcl-PHAs, contain 6 to 14 carbons; long chain length PHAs, lcl-PHAs, contain more than 14 carbon atoms in their repeat units (16, 17). For poly(3-hydroxyalkanoates), which hold the same number of carbon atoms between the ester functions in the main chain, properties vary with the side chain length, with scl-PHAs being hard crystalline polymers and PHAs with longer side chains being elastomers (15).

The present paper reviews the different synthesis methods applied to prepare graft copolymers with poly(3-hydroxyalkanoates) as main chain or grafted branches, with a number of different comonomers, as well as their properties and applications.

Synthesis of graft copolymers with PHA segments

Graft copolymers can be prepared by three main methods: "grafting onto", "grafting from", and "grafting through" or macromonomer technique (1). The grafting onto method involves the covalent coupling of reactive sites distributed along the copolymer main chain or trunk with end groups of copolymer segments (1), for example, by amidation (18, 19), esterification (20), or free-radical mechanism (21, 22). In the grafting from synthetic strategy, the polymer trunk is acti-

 doi:10.1139/V08-044 © 2008 NRC Canada

vated at sites along the chain, and grafted chains are grown from these active sites by monomer polymerization (1); for example, the monomer can be copolymerized using the trunk as macroinitiator with multiple initiation sites along its chain (23, 24). Graft copolymers can also be produced by copolymerization of a low molecular weight monomer with a macromonomer (1), defined as a polymer or oligomer bearing at least one polymerizable end group (25, 26). This approach is called the grafting through or macromonomer method, and compared to the grafting onto and grafting from methods, control of the branches can easily be achieved. The macromonomer is selected and prepared prior to copolymerization, and a wide range of chemical structures have been reported in the literature, with the macromonomer being a homopolymer, a random, or block copolymer; the size of the side chains is chosen with the length of the macromonomers; their distribution along the main chain is controlled by the comonomer reactivity ratios (1, 25–28).

Preparation by coupling reaction or the grafting onto technique

Yalpani et al. (18) reported the grafting of bacterial poly(3-hydroxybutyrate), PHB, segments (M_n 10 000) onto different polymers: chitosan (CS), by amidation via the amine group of carbohydrate repeat units; cellulose acetate, by transesterification; and poly(ethylenimine), by amidation (Scheme 1).

In the same fashion, poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate), PHB/V, and poly(3-hydroxyoctanoate), PHO, oligomers (with M_n of ca. 14 700 and 77 300 for PHB/V, and M_n of ca. 19 100 for PHO) were grafted onto chitosan by amidation at the amine group of chitosan, to produce either chitosan-*g*-PHB/V or chitosan-*g*-PHO (Scheme 1) (19).

The "opposite" or "reverse" graft copolymers, PHB-*g*-chitosan and PHB/V-*g*-chitosan, were prepared by treatment of PHB and PHB/V (with 5 wt% of 3-hydroxyvalerate, HV, units) membranes with ozone followed by grafting of acrylic acid, AA, to introduce carboxyl groups along the PHA chains, which were esterified with either chitosan (M_w of 160 000, degree of deacetylation of 75%) or chitooligosaccharide (M_w of 1170) (20).

Free radical chemistry was also used to produce PHA with grafted copolymer branches. Cavallaro et al. (21) reported the production of PHB/V-*g*-poly(ε-caprolactone) by reactive blending of PHB/V (4 mol% of HV) with poly(ε-caprolactone), in the melt at 160 °C with peroxide initiators, either benzoyl peroxide, BPO, or dicumyl peroxide. It was observed that the process also induced free-radical cross-linking of PHB/V (21).

The mcl-PHA poly(β-hydroxynonanoate), PHN, was grafted with polystyrene, PS, by free-radical coupling reaction of PS bearing peroxide groups, obtained by polymerization of styrene with an oligoperoxide initiator, as seen in Scheme 2 (22).

In the same fashion, active PS and poly(methyl methacrylate), PMMA, containing either peroxide or peroxide and azo groups in the main chain were prepared (29). Grafting was achieved by free-radical methods, with the active polymers decomposing into macroradicals, which could abstract the proton at the C-3 carbon (-*C*H(C_6H_{13})-), creating radicals

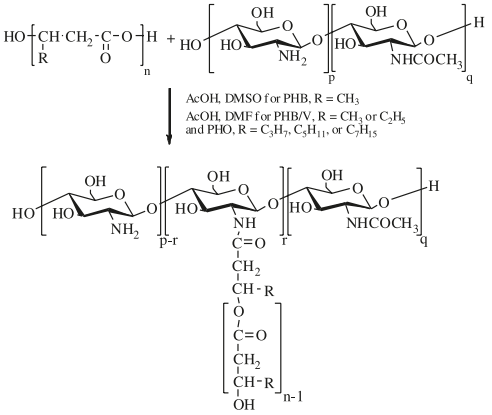
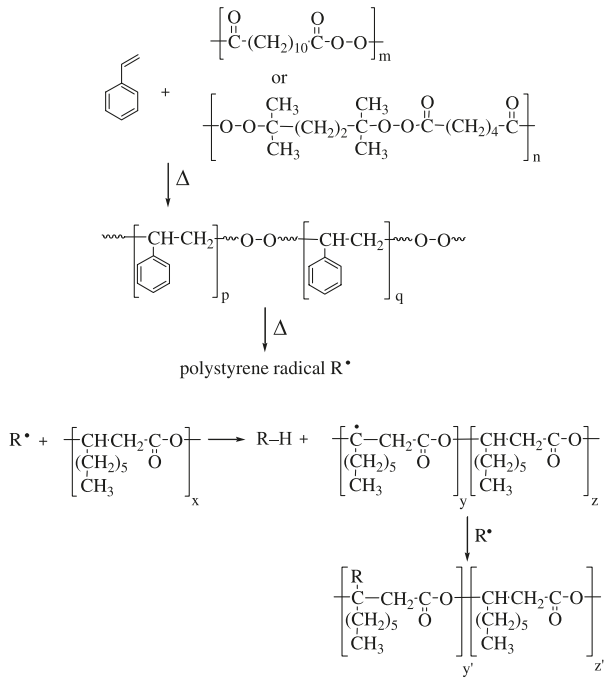


Scheme 2. Synthesis of poly(β-hydroxynonanoate)-*g*-polystyrene by grafting of polystyrene onto poly(β-hydroxynonanoate) (22).



along the PHN main chain (29). Coupling of the macroradicals onto the free-radical sites of PHN produced the graft copolymers; however, homopolymers were also obtained by coupling macroradicals with the same chemical structure. In addition, the free-radical process could lead to PHN chain cleavage, which could produce graft copolymers with different chain lengths and homopolymers of lower molecular mass (29).

Mcl-PHAs with unsaturated side groups, obtained by feeding *Pseudomonas oleovorans* bacterium with mixtures of saturated and unsaturated acids, were also grafted with active oligomers of ethylene glycol (30), PS, and PMMA (31). The low molecular mass poly(ethylene glycol), PEG (400 g/mol), was functionalized at both ends with 4,4′-azobis(4-cyanovaleryl chloride) or 2,2′-azobis(isobutyronitrile), and the

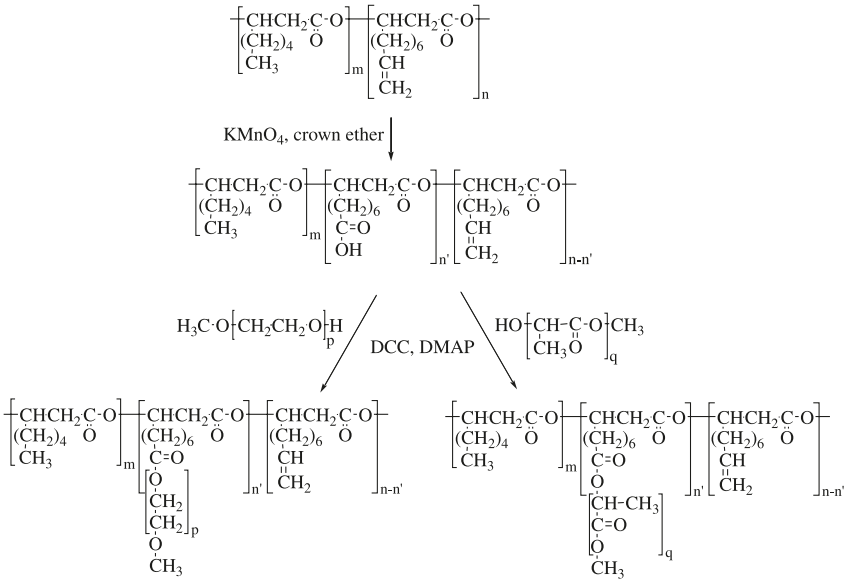
Poly(3-hydroxyoctanoate-*co*-3-hydroxyundecenoate)-*g*-poly(ethylene glycol) and poly(3-hydroxyoctanoate-*co*-3-hydroxyundecenoate)-*g*-poly(lactic acid) by grafting of poly(ethylene glycol) or poly(lactic acid) onto the PHA (32); DCC: *N*,*N*′-dicyclohexyl carbodiimide, DMAP: 4-(dimethylamino)pyridine.



obtained polyazoester was grafted by free-radical reaction onto the unsaturated PHA (30). Active oligomers of styrene and methyl methacrylate, MMA, were obtained by polymerization with an oligo(terephthaloyl peroxide) initiator, to yield polymers with peroxide groups in the polymer chain, and M_w between 36 000 and 57 000 for PS and 52 000 and 76 000 for PMMA (31). These active polymers were then grafted onto the PHA with unsaturated side chains using the peroxy radicals (31).

Graft copolymers of mcl-PHA as the main chain and PEG or poly(lactic acid), PLA, as branches were reported by Renard et al. (32) (Scheme 3). Bacterial poly(3-hydroxyoctanoate-*co*-3-hydroxyundecenoate) was obtained by feeding *P. oleovorans* with sodium octanoate and 10-undecenoic acid, and the unsaturated side groups $-(CH_2)_6-CH=CH_2$ underwent oxidation using potassium permanganate and a crown ether to yield side groups bearing carboxylic acid functions ($-(CH_2)_6-COOH$). PEG or PLA oligomers, with one hydroxyl end and the other end protected, were then coupled onto the PHA by esterification of the carboxylic acid groups on the PHA using carbodiimide activation (32).

More recently, Zhijiang and Zhihong (33) reported the synthesis of graft copolymers of PHB and PEG, using PEG oligomer (M_n of 4000) functionalized at both ends with acryloyl chloride to transform the two hydroxyl ends into photoactive acrylate ($-O-C(=O)-CH=CH_2$) ends. The graft copolymers of PHB and PEG were obtained by UV-irradiation of a concentrated solution of the acrylic PEG and PHB in chloroform (33).

The grafting from technique

Anionic polymerization

Kowalczuk et al. (23) reported the preparation of PMMA-*g*-PHB by anionic polymerization of β-butyrolactone on PMMA chains (Scheme 4). The latter were functionalized to become macroinitiators of β-butyrolactone polymerization by partial saponification yielding randomly distributed carboxylate anions, which were activated by complexation with 18-crown-6 counterion (23). It should be noted that the polymerization produced atactic PHB side chains (23).

Free radical polymerization (FRP)

Radiation polymerization

Graft copolymers with PHB or PHB/V as the main polymer chain were reported by grafting by gamma radiation polymerization of various monomers: MMA, 2-hydroxyethyl methacrylate, HEMA, styrene, isoprene, and AA (34–39). MMA (35, 38), HEMA (35, 38), and styrene (36, 40) were graft-polymerized on PHB and PHB/V (24 mol% of HV units) by irradiation with ^{60}Co γ-rays at low doses, by two different methods: direct irradiation of the PHA in monomer solution and pre-irradiation of the PHA at –78 °C at a dose

© 2008 NRC Canada

rate of 5 kGy·h^{-1} followed by monomer polymerization on the irradiated PHA. X_g, the degree of grafting, defined as the percent increase of polymer mass based on the original polymer sample mass, was found to increase with increasing pre-irradiation dose and to level off at ca. 5 kGy, and was lower for PHB-*g*-PMMA than for PHB/V-*g*-PMMA, because of the higher crystallinity of PHB compared to PHB/V (38). In the case of PHB-*g*-PS, X_g increased with increasing pre-irradiation dose, from 5 to 15 kGy and grafting temperature from 30 to 80 °C, while for PHB/V-*g*-PS, it was found higher at 50 °C than at 30 or 70 °C (36). Styrene grafting on PHB and PHB/V produced PHA-*g*-PS with X_g lower than for MMA grafting on the same PHAs (36).

Radiation-induced grafting from mcl-PHA was also reported, as PMMA was grafted from poly(β-hydroxynonanoate) by bulk copolymerization of MMA with ^{60}Co γ-rays at 8.5 kGy (41).

Polyisoprene was also grafted on PHB by polymerization of isoprene in methanol, induced by direct irradiation with ^{60}Co γ-rays at 21.62 kGy·min^{-1} (37).

Acrylic acid was polymerized on PHB/V (with 8% of HV units) melt processed disks and solvent cast films to produce PHB/V-*g*-poly(acrylic acid) with ^{60}Co γ-irradiation at a dose rate of ca. 4.5 kGy·h^{-1} (39). It was observed that rather short poly(acrylic acid), PAA, side chains were produced, with cross-linking of PAA with higher irradiation doses (39). The graft copolymerization of AA on PHB induced by pre-irradiation of PHB films was reported by Wada et al. (42). It was observed that increasing the dose level increased X_g and decreased molecular mass of the irradiated PHB films, without cross-linking, contrary to the AA grafting on PHB/V films (39, 42). The same group used pre-irradiation techniques to graft copolymerize vinyl acetate, VAc, from PHB powder or film (43). PHB powder was pre-irradiated with ^{60}Co γ-rays before bulk copolymerization of VAc at 60 °C, while pre-irradiated PHB film was grafted with poly(vinyl acetate), PVAc, branches by emulsion polymerization (43, 44). The PVAc chains were further saponified into poly(vinyl alcohol), PVA, to partially convert the branches of PVAc to PVA (43).

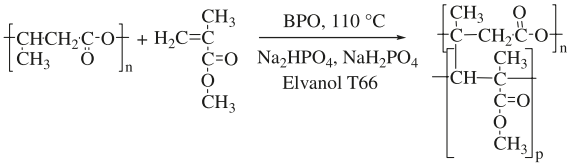
Grafting by plasma glow discharge

Oxygen plasma glow discharge was another method used to induce the graft polymerization of AA on films of PHB/V (with 34 mol% of HV units) (45). The peroxides produced at the PHB/V surface by plasma glow discharge were used to catalyze the monomer polymerization at 75 °C in aqueous solution (45). The grafted PAA chains were further coupled with amino-terminated poly(ethylene oxide), PEO (600 g/mol), by amidation with carbodiimide activation, to produce PHB/V-*g*-(PAA-*b*-PEO) (45).

Grafting induced by ozone treatment

Tesema et al. (46) reported the preparation of PHB/V-*g*-poly(methacrylic acid) to ultimately immobilize collagen on the PHB/V surfaces. PHB/V (with 8 wt% of HV units) films were treated with ozone to produce peroxide groups, which were subsequently grafted with poly(methacrylic acid), PMA, branches produced by polymerization of the monomer in the presence of sulfuric acid and iron sulfate (46).

Scheme 5. PHB-*g*-poly(methyl methacrylate) by grafting of poly(methyl methacrylate) from PHB (3); BPO: benzoyl peroxide.



Photografting

Photopolymerization was also used to graft polymer branches on PHB/V films. Acrylamide was polymerized on PHB/V (8% of polyhydroxyvalerate) films using benzophenone as initiator and a high-pressure mercury lamp under nitrogen flow to produce PHB/V-*g*-polyacrylamide (47). Increases in acrylamide monomer concentration and irradiation time were shown to enhance X_g and the grafting efficiency (percentage gain in polymer mass compared to initial acrylamide monomer mass) (47).

Free radical polymerization initiated by benzoyl peroxide

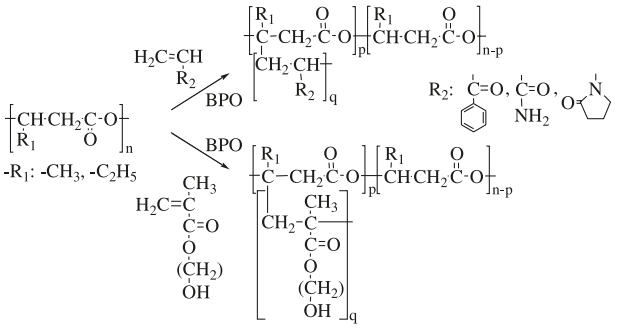
Avella et al. (3) reported the reactive blending of PHB with PMMA with weight ratios PHB/PMMA of either 70/30 or 80/20, where blends of PHB and PMMA containing PHB-*g*-PMMA graft copolymers were formed by free-radical water suspension polymerization of MMA in the presence of PHB (M_w of 540 000) (Scheme 5). MMA was polymerized using BPO as initiator, at 110 °C in an aqueous dispersion of PHB with sodium phosphate dibasic (Na_2HPO_4), sodium phosphate monobasic (NaH_2PO_4), and poly(vinyl alcohol) (Elvanol T66) as suspending agents (3). PMMA homopolymer was found to be the main polymerization product as the produced graft copolymer represented only ca. 5% of the original blend, because of the low accessibility of PHB towards MMA and PMMA growing chains (3). NMR structural analysis of the isolated graft copolymers using 1D-^{1}H NMR and NOESY experiments showed that the PMMA branches were grafted on PHB by covalent bonding between the C-3 carbon (*C*H(CH_3)) of PHB and the vinyl CH (*C*H-C(CH_3)($COOCH_3$)) of MMA repeat unit (3). The grafting mechanism would include both the formation of PHB macroradical at the C-3 atom by chain transfer from a growing PMMA chain to PHB, and the formation of PMMA secondary macroradical within the PMMA chain at one vinyl carbon by chain transfer to PMMA from another growing PMMA chain (3).

Wu (48) reported the grafting of AA onto PHB with free-radical methods using BPO in xylene solution at 85 °C, with a low degree of grafting, at ca. 5.75 wt%. Blending of the grafted PHB with wood flour at 190 °C at 50 rpm for 15 min enabled their covalent coupling by esterication of the carboxyl groups of acrylic acid-funtionalized PHB with the hydroxyl functions of the wood flour (48).

Phenyl vinyl ketone was polymerized on PHB/V dissolved in 1,2-dichloroethane by free-radical polymerization initiated by BPO, producing both the homopolymer, poly(phenyl vinyl ketone) and the graft copolymer PHB/V-*g*-poly(phenyl vinyl ketone) (Scheme 6) (49). Mcl-PHA with unsaturated side chains was also grafted with methyl methacrylate using free-radical methods and BPO as initiator (50).

© 2008 NRC Canada

Scheme 6. Free radical grafting of phenyl vinyl ketone, acrylamide, *N*-vinylpyrrolidone, and 2-hydroxyethyl methacrylate from PHB/V (49, 51–53).



Polyacrylamide was grafted on PHB/V films by bulk polymerization of acrylamide monomer (Scheme 6) (51). In the same fashion, PHB/V films (with 12% of HV units) were grafted with poly(2-hydroxyethyl methacrylate), PHEMA, to increase the surface hydrophilicity and enhance their interaction with cells (Scheme 6) (52). In both cases, the monomer was polymerized in aqueous medium by free-radical methods, initiated by BPO, in the presence of the PHB/V films. The process was performed heterogenously, as the monomers were water soluble (polyacrylamide was water soluble, PHEMA was poorly soluble in water), and BPO and PHB/V were water insoluble. Both the grafts on the films and the homopolymers were obtained, the latter in large amounts (51, 52). Indeed, Lao et al. (52) observed that the homopolymerization was predominant, with ca. 95% of the monomer being homopolymerized and 5% being grafted.

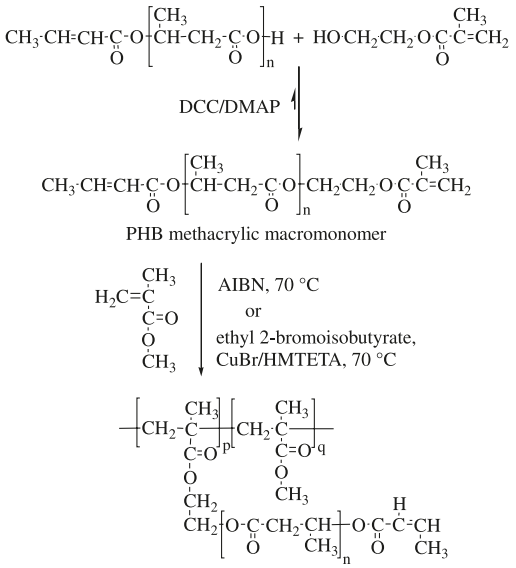
The preparation of PHB/V-*g*-poly(*N*-vinylpyrrolidone) in homogenous medium was also recently reported by Wang and co-workers, using free-radical methods (Scheme 6) (53). *N*-vinylpyrrolidone was graft-copolymerized from PHB/V (3.57 mol% of HV units) in chlorobenzene solution with BPO as initiator, with a maximum X_g reaching 10.48% (53). Again, mixtures of poly(*N*-vinylpyrrolidone) homopolymer and graft copolymers were produced, and they could not be separated from each other (53).

Free radical grafting was possibly produced either by growing from the C-3 carbon (-*C*H(R)-) of the PHA, where the protons could be abstracted by BPO to form the macroradicals, as these protons were the most acidic ones along the PHA chains and (or) by polymer chain radical transfer to the PHA backbone (51–53).

Controlled free-radical polymerization

Brush type graft copolymers, PHB-*g*-PMMA, were reported by Arslan et al. (24) by atom transfer radical polymerization (ATRP) of MMA from PHB oligomers. Solutions of low to medium molecular mass PHB (M_n of ca. 14 900, 77 300, or 93 100) in a mixture of chloroform, $CHCl_3$, and carbon tetrachloride, CCl_4 ($CHCl_3/CCl_4$ volume ratio of 75/25) were exposed to chlorine gas to produce PHB partially chlorinated at the methyl side group, i.e., with a side group $-CH_2X$, X being either H or Cl atom and with decreased molecular mass because of hydrolysis side-reaction. The chlorinated PHB oligomers (M_n from ca. 2 500 to 17 400) were then used as macroinititators in the ATRP of MMA in toluene at 90 °C, with 2,2′-bipyridine and copper(I) bromide as the catalyst system (reversible termination agent for ATRP) to produce the graft copolymers (24).

Scheme 7. Preparation of poly(methyl methacrylate)-*g*-PHB by the macromonomer method (28, 54); AIBN: 2,2′-azobis(isobutyronitrile), HMTETA: 1,1,4,7,10,10-hexamethyltriethylenetetramine.



Synthesis by the grafting through or macromonomer technique

Graft copolymers of PMMA with isotactic PHB branches were produced by copolymerization of MMA and methacrylic bacterial PHB macromonomers, with conventional (28, 54) and controlled (ATRP) free-radical polymerization methods (28, 55). Nguyen et al. (56) used isotactic PHB oligomers obtained by thermal degradation; since the unsaturated, crotonate end was not easily polymerizable by free-radical methods (56, 57), the other end, bearing a carboxylic acid, was subsequently esterified with HEMA using carbodiimide chemistry to introduce a methacrylic, polymerizable with free radicals, end group (54). The obtained PHB macromonomers were then copolymerized with methacrylate in anisole solution at 70 °C by conventional free-radical copolymerization and by ATR copolymerization (28, 54). The size of the PHB side chains was determined with ^{1}H NMR spectroscopy with the peak integral ratio of 3-hydroxybutyrate, HB, repeat unit protons to the ones of the crotonate end group and was found to be only 5% different from the one of PHB macromonomers before the copolymerization, confirming that the crotonate groups did not participate in the copolymerization (28). PMMA-*g*-PHB copolymers obtained by conventional FRP displayed rather large polydispersity indexes, as expected, with a random distribution of the PHB branches suggested by the single glass transitions observed (54). ATRP of MMA with PHB macromonomers was found to produce, with limited chain transfer, more monodisperse graft copolymers of lower molecular weight (28) (Scheme 7).

Following the same macromonomer functionalization and ATRP methods as Nguyen and Marchessault (28, 54),

[c]Degradation by lysozyme.

Neugebauer et al. (55) synthesized graft copolymers of methacrylates with PHB macromonomers. Atactic PHB oligomers were prepared by anionic polymerization of β-butyrolactone, while isotactic PHB oligomers were prepared by two different methods: partial saponification of high molecular mass bacterial PHB, using potassium hydroxide and 18-crown-6 ether according to Adamus (58) and thermal degradation according to Nguyen et al. (56). Copolymerizations by ATRP of the PHB macromonomers were performed with methacrylates of increasing PEG chain length: MMA, ethylene glycol methyl ether methacrylate, and PEG methyl ether methacrylate, with a degree of polymerization of PEG of 5 and 23 (55).

Properties

A comparison of the enzymatic degradability results of PHA graft copolymers is shown in Table 1. Enzymatic degradability studies of PHB-*g*-PMMA, PHB/V-*g*-PMMA, PHB-*g*-PHEMA, and PHB/V-*g*-PHEMA produced by radiation polymerization of the methacrylate monomer on the PHA were reported by Mitomo et al. (38). It was shown that the degradability of solution-cast PHB-*g*-PMMA and PHB/V-*g*-PMMA with PHB depolymerase was significantly reduced compared to the ungrafted PHA polymers. On the contrary, degradability of PHB-*g*-PHEMA and PHB/V-*g*-PHEMA were higher than the corresponding PHA homopolymer at a degree of grafting (X_g) lower than 20%, because of the hydrophilicity of HEMA improving the wettability with the enzyme (38).

The enzymatic degradability of PHB-*g*-PAA and PHB-*g*-PVAc films subjected to PHB depolymerase from *Ralstonia pickettii* T1 was shown to be tuned by the X_g (degree of grafting) of the comonomer branches, and further treatment of the graft copolymers (42, 43). PHB-*g*-PAA and PHB-*g*-PVAc films displayed decreased degradability with increasing X_g, with no degradation observed for films with X_g above 5% as the surface was covered by either non-degradable PAA or hydrophobic PVAc, which screened PHB from the depolymerase enzyme (42, 43). However, when the PHB-*g*-PAA films were thermally remolded by hot-pressing, enzymatic degradability towards the PHB depolymerase was shown to increase with increasing X_g, up to 12%, and then decreased with a X_g higher than 12% (42). The degradability was retrieved by the dispersion of the PAA branches during the thermal remolding, enabling areas of degradable PHB at the surface (42). PHB-*g*-PVAc films were saponified in mild conditions to avoid PHB degradation as a side-reaction and subjected to enzymatic degradability studies (43). Little weight loss was observed when the films were exposed to PHB depolymerase enzyme, because of the coverage of the surface with the saponified branches; however, the saponified PHB-*g*-PVAc films degraded in environmental water while the untreated PHB-*g*-PVAc films did not, as both PVA and PHB were degraded by micro-organisms present in the water (43). This non-degradability of the PHB-*g*-PVAc films also confirmed that the non-degradable branches covered the surface of the films (43).

The enzymatic degradability of graft copolymers of PHB and PEG towards lysozyme was studied by Zhijiang and Zhihong (33). It was shown that the degradability was stronger with increasing PEG graft content, which was attributed to a reduced crystallinity of PHB and the hydrophilicity of PEG (33).

Thermal stability and enzymatic degradability of PHB-*g*-PS and PHB/V-*g*-PS, obtained by radiation grafting of styrene on

© 2008 NRC Canada

the PHAs (36), were studied by Bahari et al. (40). Both graft copolymers displayed higher thermal stability with a low degree of grafting (X_g of 9%) than for the corresponding PHA. Solution-cast PHB-*g*-PS and PHB/V-*g*-PS degraded more slowly than ungrafted PHB when subjected to PHB depolymerase, which, in the same fashion as for films of PHB-*g*-PAA and PHB-*g*-PVAc (42, 43), was because of hydrophobic coating of the surface by the comonomer, which reduced the affinity of the enzyme to the PHAs (40).

PMMA-*g*-PHB graft copolymers with atactic PHB branches were shown to combine the thermal stability behavior of both homopolymers, with thermogravimetric analysis showing two weight losses from the degradation of the two types of polymer segments (4).

Wang et al. (53) reported that the thermal stability of PHB/V-*g*-poly(*N*-vinylpyrrolidone) was dependent on X_g and was significantly improved at X_g of 10.48%; T_m, the melting point, was unchanged with X_g between 0% and 10.48%; T_d, the decomposition temperature, and T_{95}, the temperature at which the residual mass reaches 95% of the original mass, were both found 30 °C higher than for ungrafted PHB/V (53).

Thermal stability of chitosan-*g*-PHB/V and chitosan-*g*-PHO was studied by Arslan et al. (19). Thermogravimetric analysis was performed on the graft copolymers and compared to their corresponding homopolymers. The decomposition temperatures (T_d) were determined to be at 340 °C and ca. 100 °C (small peak) for water loss for chitosan, ca. 300 and 150 °C (small peak) for PHB/V, and 300 °C for PHO. Chitosan-*g*-PHA graft copolymers showed weaker thermal stability than for their corresponding homopolymers, with chitosan-*g*-PHB/V displaying two decomposition temperatures at ca. 255–181 and 160 °C (small peak), and chitosan-*g*-PHO exhibiting three decomposition temperatures, at ca. 260 °C (for PHO), 300 °C (for chitosan), and 70 °C for water loss (small peak) (19).

Biodegradability and antibacterial activity of PHB and PHB/V membranes grafted with acrylic acid, chitosan, CS, and chitooligosaccharide, COS, were assessed by Hu et al. (20). When the polymer membranes were incubated in a medium with *Alcaligenes faecalis* (ATCC 25094) cells, AA-grafted PHAs showed higher degradability then PHV and PHB/V membranes as AA-grafting increased the hydrophilicity of the surfaces, therefore increasing their accessibility to the bacterial attack (20). CS or COS-grafting increased further the hydrophicility of the membranes; however, because of the antibacterial activities of CS and COS, which reduced the number of bacteria, and to smoother surfaces after the grafting, which limited their accessibility to the bacteria, the biodegradability was lower than the ungrafted membranes (20). Antibacterial activity of the CS and COS-grafted PHA membranes was shown to be higher than the ungrafted PHAs for four clinically infectious bacteria: two Gram-negative ones, *Escherichia coli* and *Pseudomonas aeruginosa*, and two Gram-positive ones, methicilin-resistant *Staphyloccocus aureus*, MRSA, and *S. aureus* strain-2. The antibacterial activity of CS and COS-grafted PHAs was observed, from the highest to the lowest, with *E. coli*, *P. aeruginosa*, *S. aureus*-2, and MRSA (20).

Cell compatibility of PHB/V films modified with photografting of polyacrylamide to enable immobilization of bioactive materials, e.g., oligopeptides, proteins, glycosaminoglycan, or growth factors was studied by Ke et al. (47). Marrow stromal cells from sheep were cultured on the grafted and ungrafted films, and it was observed that the cells were well spread on the grafted films with a cell attachment efficiency increasing with the grafting percentage, i.e., with increased concentration of polyacrylamide on the PHB/V films, showing their biocompatibility with this type of cells (47).

Mechanical properties of PHB were found to be improved by subjecting the polyester to reactive blending with PMMA, which produced blends (with either 30 or 20 wt% of PMMA) containing ca. 5% of PHB-*g*-PMMA (3). Flexural testing showed that PMMA acted as a rigid filler, as the flexural modulus was improved for both blends of PHB/PMMA with or without PHB-*g*-PMMA; however, the fracture toughness of the blends, measured with impact testing, was only superior to the one of pure PHB when the graft copolymers were present in the blends, acting as compatibilizer by improving the interfacial adhesion between PHB and PMMA homopolymers (3).

Ceccorulli et al. (4) showed that the addition of 5% of PMMA-*g*-PHB with 67 mol% of HB units improved significantly the ductility of blends of PMMA/PHB containing 30 to 50% of PHB, by inhibition of PHB crystallization. However, no improvement of mechanical properties was observed with PMMA/PHB blends with PHB content higher than 50%, as the graft copolymer presence could not prevent PHB crystallization (4).

The mechanical properties of PHN were found to be improved when grafted with PS in low contents, with both tensile strength and elongation higher than pure PHN (29). It should be noted that graft copolymers with PS contents higher than 20 wt% showed lower elongation. Tensile strength and elongation of PHN grafted with low PS amounts (6 wt%) were measured and compared to the ones of a blend of PHN/PS with the same PS content, as well as the ones of pure PHN; while both the graft copolymer and the blend displayed higher tensile strength and elongation, the graft copolymer showed the highest tensile strength and the blend, the highest elongation (29).

When PHB was replaced by PHB grafted with AA in blends with wood flours, it was found that the latter were coupled to PHB via the carboxyl functions of acrylic acid, ultimately producing a graft copolymer of PHB and wood flours (48). Biodegradability in soil and with α-amylase enzyme, and mechanical performance, with the tensile strength at breakpoint, were studied for the blends of wood flours with either ungrafted or grafted PHB (48). While the biodegradability of PHB grafted with wood flours was found slightly lower than for blends with ungrafted PHB, its tensile strength at breakpoint was higher and remained stable when the wood flours content in the blends was increased, while the tensile strength of blends of PHB with wood flours decreased with increasing wood flours content (48).

Applications

Among the applications of copolymers containing PHA moieties is their use as surfactants or compatibilizers in blends of the corresponding homopolymers (3, 4, 59), as most polymer combinations are immiscible and create

© 2008 NRC Canada

phase-separation into macroscopic domains in their blends, resulting in mechanically weak materials (4). Avella et al. (3) showed that a low amount of PHB-*g*-PMMA copolymers could act as compatiblizer of PHB/PMMA blends containing either 20% or 30% of PMMA (3). Ceccorulli et al. (4) studied the compatibility of blends of PMMA and bacterial PHB in the presence of graft copolymers PMMA-*g*-PHB with atactic PHB branches. It was shown that while PMMA and bacterial PHB are partially miscible up to a PHB content of 20%, blends containing 30%–50% of PHB could be compatibilized with 5% of PMMA-*g*-PHB with 67 mol% of HB units (4).

The ability of PHAs, and especially their oligomers, to enhance in vivo degradability and biocompatibility in a copolymer makes them suitable for developments in pharmaceutical and surgical fields (60). In addition, PHB is piezoelectric so it could promote bone growth, a property that other degradable polymers with faster degradation do not possess, e.g., PLA (61, 62). PHAs have been proposed to be incorporated in formulations of biocompatible and partially or completely biodegradable bone cements (63–66). Acrylic bone cements have been used mainly in total joint replacement surgeries for prosthesis fixation inside the bone and transfer of body weight and service load (67–70). They are prepared by mixing a liquid, mostly composed of MMA monomer with *N*,*N*-dimethyl-*p*-toluidine, with a powder, mainly PMMA-based prepolymer with BPO. The peroxide initiates the free-radical polymerization of MMA when activated by *N*,*N*-dimethyl-*p*-toluidine, producing the cement dough (69, 70). Since one major drawback of the cemented joint implant technique is aseptic loosening, which can decrease the prosthesis lifetime by 30% (69), and classical PMMA-based bone cements are unable to resorb or allow bone ingrowth (71), partially degradable cement with enhanced compatibility were proposed to allow bone ingrowth inside the progressively, partially degraded cement (63–65, 72). Copolymers with PMMA and low molecular mass bacterial PHB hold interesting potential as a component in bone cement formulations, bringing degradability, expected enhancement of the cement biocompatibility, and compatibility with the methacrylic ingredients. PMMA-*g*-PHB copolymers obtained by free-radical copolymerization of MMA with methacrylic PHB macromonomers (28, 54), were incorporated in the powder component of a commercial acrylic bone cement formulation, antibiotic Simplex®, which could contain up to 13.5 wt% of the graft copolymers (66). Formulations with higher graft copolymer content produced unprocessable soft to friable material, probably because of the difference in solubility and swelling capacity of PMMA and graft copolymers when mixed with the liquid MMA monomer component (66). Micropores were observed in the processable modified cements (with up to 13.5 wt% of the graft copolymer) with volumetric porosities ranging from 13.5% to 16.9% (66). However, their ultimate compression strengths, measured at ca. 85 MPa, were similar to the one of unmodified commercial cement and exceeded the ASTM (American society for testing and materials) F451 requirements (minimum value of 70 MPa) (66).

The suitability of PHB/V surfaces to immobilize biomolecules for the design of biomaterials for tissue engineering was shown with glucosamine, (39), insulin (45), and collagen (46). PHB/V surfaces grafted with PAA side chains were functionalized with glucosamine by amidation of carboxyl groups of PAA with the amine function of glucosamine using carbodiimide activation (39). Insulin was grafted onto PHB/V-*g*-PAA and PHB/V-*g*-(PAA-*b*-PEO) using coupling with a carbodiimide catalyst (45). The protein-immobilized surfaces with either PAA or PAA-*b*-PEO as spacer arms were shown to accelerate the proliferation of human fibroblasts when compared to the surfaces without protein (45). PHB/V surfaces were functionalized with collagen by poly(methacrylic acid) grafting followed by amidation of the carboxyl groups of the branches with collagen using carbodiimide activation (46). In vitro studies of cell viability and proliferation of rat osteosarcoma UMR-106 cell line and mouse osteoblastic MC3T3-E1 cell line have been conducted on the collagen grafted PHB/V surfaces, as well as on PHB/V surfaces, both untreated and with physically immobilized collagen, for comparison (46). It was observed that the PHB/V surfaces with covalently fixed collagen showed higher cell activity than the ones with physically immobilized collagen, while the latter showed higher cell activity than the untreated PHB/V surfaces (46).

Conclusions

The preparation of graft copolymers including PHA blocks as main or side chains have been reported, with various preparation methods using either one of the three synthesis strategies of graft copolymers, i.e., the grafting onto, grafting from, and grafting through methods. Various types of copolymers were combined with PHAs: polyethers like poly(ethylene glycol); polysaccharides, for example, chitosan and cellulose acetate; polyesters, e.g., poly(ε-caprolactone) and poly(lactic acid); and numerous vinyl polymers,including polystyrene, poly(methyl methacrylate), and poly(2-hydroxyethyl methacrylate). For a number of the graft copolymers reported, the nature of the copolymer and the graft copolymer composition could control properties such as the thermal stability, mechanical properties, as well as the enzymatic degradability, biodegradability, antibacterial activity, and cell compatibility.

PHA graft copolymers can be used as compatibilizers of polymer blends, but were also proposed as biodegradable additives for bone cement formulations, and have recently received much attention in tissue engineering, with applications as biomolecule-immobilizing surfaces for enhancement of cell proliferation.

Diffusion of molecular probes and the effects of their interactions with polymer matrices as studied by pulsed-field gradient NMR spectroscopy[1]

Héloise Thérien-Aubin, Wilms E. Baille, and X.X. Zhu

Abstract: Pulsed-field gradient NMR spectroscopy was used to study the interactions between small molecular probes and polymers bearing interacting groups. The self-diffusion coefficients of ethylene glycol and its oligomers and their methyl ester derivatives in poly(vinyl alcohol) gels were measured to study the effect of hydrogen bonding. The self-diffusion coefficients of small molecular probes containing hydroxyl, amine, and carboxylic acid groups were determined in several polymer matrices including poly(vinyl alcohol), poly(allylamine), and poly(acrylic acid) bearing lateral hydroxyl, amine, and carboxylic acid groups, respectively. The ionic interactions between the functional groups of the diffusants and of the polymers exhibited a marked effect on the diffusion of the molecular probes. For example, the reduced self-diffusion coefficients measured for a diffusant with a carboxylic acid group in a poly(allylamine) matrix were shown to be lower even though the molecular masses of the diffusants are similar.

Key words: pulsed-field gradient NMR spectroscopy, self-diffusion, intermolecular interactions.

Résumé : La spectroscopie RMN à gradient de champ pulsé a été utilisée afin d'étudier les interactions entre des petites molécules et des polymères portant divers groupements fonctionnels. Les coefficients d'auto-diffusion de l'éthylène glycol, de ses oligomères et de leurs esters de méthyle respectifs dans des gels de poly(alcool vinylique) ont été mesurés pour étudier l'effet des interactions de type pont hydrogène. Les coefficients d'auto-diffusion de petites molécules ayant des groupements fonctionnels de type alcool, amine et acide carboxylique ont été mesurés dans le poly(alcool vinylique), le poly(allyl amine) et le poly(acide acrylique), des polymères ayant respectivement des groupements latéraux de type alcool, amine et acide carboxylique. Les interactions ioniques entre les groupements fonctionnels du diffusant et ceux du polymère ont un effet marqué sur la diffusion des sondes moléculaires. Par exemple, le coefficient d'auto-diffusion réduit mesuré pour l'acide acétique dans le poly(allyl amine) est inférieur à celui de l'éthylène glycol bien que la masse molaire et le rayon hydrodynamique des deux sondes soient similaires.

Mots-clés : spectroscopie RMN à gradient de champ pulsé, auto-diffusion, interactions intermoléculaires.

Introduction

The study of the diffusion of molecules in polymer matrices and biological systems is of both fundamental and applied importance (1–3). Diffusion studies in polymer systems give insight to different phenomena such as polymer dynamics (4) and structures or controlled release of drugs (5). Self-diffusion in polymer systems, which is caused by the random walk of the diffusing species in a homogenous sample, can be measured by pulsed-field gradient NMR techniques.

The physical properties of both the diffusant and the polymer matrix can affect the diffusion process. The effects of the molecular mass, size, and shape of the diffusants, concentration of the polymer, solvent conditions, temperature, and diffusant–polymer interactions on the diffusion process have been studied by the use of pulsed-field gradient NMR spectroscopy (6–9). Previously, we have also studied the diffusion of water in biomacromolecules, such as in tablets made of modified starch (5, 10, 11). The effect of the interactions between the diffusant and the polymer on the diffusion process remains to be better understood.

It was shown that coulombic interactions and hydrogen bonding can reduce substantially the diffusion rate of a solute (12–16). For example, the reduced self-diffusion coefficient (D/D_0) of 4-[[4-(dimethylamino)phenyl]azo]benzoic acid (commonly known as *p*-methyl red) decreases in a

polymer–diffusant–toluene mixture (6 wt% polymer in toluene) when the polymer was changed from polystyrene (PS) (D/D_0 = 0.8) to poly(methyl methacrylate) (PMMA) (D/D_0 = 0.5) and then to poly(vinyl acetate) (PVAc) (D/D_0 = 0.4) (values obtained from the extrapolation of the data of Lee and Chang (16)). The decrease in D between PS and PMMA is related to the presence of the carbonyl group on PMMA participating in hydrogen bonding, the difference between PMMA and PVAc is caused by the enhanced availability of the carbonyl group in PVAc (16). The effect of hydrogen bonding on the diffusion of ethylene glycol in a poly(vinyl alcohol) (PVA) matrix was previously studied (17). The results showed the coexistence of two fractions of ethylene glycol, a bound fraction with a lower self-diffusion coefficient and a free fraction with higher self-diffusion coefficient. It was shown that the fraction of ethylene glycol bound to the PVA matrix increased with the PVA concentration. Recently, the effects of ionic interactions on the diffusion of dendrimers in polymers gels were studied. Ionic interactions significantly reduce the self-diffusion coefficient of the dendrimers and lead to a more complex diffusive behaviour (18). The influence of such interactions on diffusion cannot be easily described by the diffusion models.

In the present study, the self-diffusion coefficients of a series of small molecules bearing different functional group have been selected as diffusion probes and their self-diffusion coefficients have been determined by pulsed-field gradient NMR spectroscopy to elucidate the effects of hydrogen bonding and ionic interactions on the diffusion process in solutions and gels of polymers also bearing interacting functional groups.

Experimental section

Materials

Ethylene diamine (EDA), acetic acid (HAc), ethylene glycol (EG), diethylene glycol (DEG), triethylene glycol (TEG), and their end-capped methyl ether derivatives were purchased from Sigma-Aldrich (Milwaukee, WI). Poly(vinyl acohol) (PVA) (M_n = 52 000 with a degree of hydrolysis of 99%), poly(allylamine) (PAAm) (M_w = 65 000), and poly(acrylic acid) (PAA) (M_w = 100 000) were also purchased from Sigma-Aldrich. D_2O was purchased from C.I.L. (Andover, MA). All chemicals were used as received. The chemical structures of selected diffusants and the polymers are shown in Fig. 1.

Sample preparation

NMR samples were prepared by dissolving the polymer, weighed in a 5 mm NMR tube, in a D_2O solution containing 1 wt% of the diffusing probe. The NMR tubes were then sealed and heated for 24 h. PVA samples were heated at 110 °C while PAA and PAAm sample were heated at 65 °C.

Pulsed-field gradient NMR measurements

Both spin echo (SE: 90°-t_1–180°-t_1-echo) technique developed by Stejskal and Tanner (19) and stimulated echo (STE: 90°-t_1–90°-t_2–90°-t_1-echo) technique developed by Tanner (20) were used to measure the self-diffusion coefficients (D) of solute probes. Measurements were performed on a Bruker DSX-300 NMR spectrometer operating at a frequency of 300.18 MHz for protons. The gradient strength

was varied in 16 steps between 0.05 and 1 T/m. The duration of the gradient pulse (δ) was set between 1 and 6 ms depending on the characteristics of the samples, and the interval between the gradient pulses was fixed to 100 ms. When the STE pulse sequence is used, the delay t_1 was set to a value of δ + 2.1 ms.

The experiments were performed at several different temperatures (from 15 to 45 °C) (fluctuation ± 0.3 °C). Temperature calibration was done with ethylene glycol as described previously (21).

Diffusion models

The experimental results obtained were fitted to two models of diffusion in an attempt to analyze the influence of the interactions.

The model of Petit et al. (22) is based on the assumption that the diffusion occurs when the diffusing molecule, which resides in a cavity of size ξ, jumps at a frequency k to an adjacent cavity of the transient statistical network. The diffusion coefficient of the molecules varies with the polymer concentration according to

$$[1] \qquad D = \frac{D_0}{1 + \frac{D_o}{k\beta^2} c^{2\nu}}$$

where ν is a the quality of the solvent as defined by de Gennes, a constant characteristic of the polymer–solvent system, the value of ν is expected to be a constant for a given polymer system. β is a system-dependent scaling parameter from de Gennes theory (23), c is the polymer concentration, and k represents the jump frequency over an energy barrier and depends on the temperature, the size, and the shape of the diffusant. Both D_0 and $k\beta^2$ should decrease

© 2008 NRC Canada

with molecular mass of the diffusing molecule. In fact, they are affected by the effective hydrodynamic radius (R_h) of the diffusant, which is related to the self-diffusion coefficient by the Stokes–Einstein equation

$$[2] \qquad D_0 = \frac{k_B T}{6\pi\eta R_h}$$

where D_0 is the self-diffusion coefficient at zero concentration of the polymer, k_B is Boltzmann's constant, and R_h is the effective hydrodynamic radius of the diffusing molecule.

To further characterize the interactions between the diffusant and the polymer, the self-diffusion coefficients were also analyzed with a model based on a more phenomenological approach, the model of Phillies (24–26).

$$[3] \qquad D/D_0 = \exp(-\alpha\phi^{\upsilon})$$

where α and υ are scaling parameters, which are system-dependent (14, 16, 24, 25). The value of α is related to the molecular mass or the hydrodynamic size of the diffusants. The parameter υ may be related to the interactions in the system. Lee et al. found υ equal to 0.62 ± 0.06 and 1.0 ± 0.1 for a diffusion process controlled by hydrogen bonding and hydrodynamic interactions, respectively (27).

Results and discussion

EG, EDA, and HAc were the diffusants chosen to investigate the effect of functional groups on their diffusion in the polymers, since they have similar molecular mass (62.1, 60.1, and 60.1 g/mol, respectively). In the aqueous solutions consisting of the polymers and diffusants, extensive hydrogen bonding should be expected. In addition, between the charged polymers and the diffusant forming a counter-ion, ionic interactions are expected to have even a greater influence. Indeed, the mixing of EDA (1 wt% in D_2O) with PAA caused a precipitation throughout the entire concentration range of polymers. The other ternary systems remained homogenous and were used for the diffusion studies. The interaction between EG and the PVA matrix has been studied previously by the use of NMR spectroscopy (17). Two signals corresponding to free and bound EG were observed in the aqueous PVA solutions (17). Results of EG presented here are those of the unbound fraction. The three different polymer matrices used in this study have different molecular mass (M_r) and polydispersity (PDI). However, a previous study (28) on the effect of M_r and PDI of different PVA and hydroxypropylcellulose sample shows that, in the same range of polymer concentration used here, M_r and PDI of the polymer matrix do not significantly influence the diffusion of small molecules. The differences in the diffusion coefficient observed here should thus be ascribed to the differences in the interactions between the solute and the polymer rather than to an effect of the polymer matrices itself.

Effect of hydrogen bonding

Figure 2A shows the effect of the increasing PVA concentration on the self-diffusion of EG, EDA and HAc. It is known that the self-diffusion coefficient of the diffusants depends on their hydrodynamic sizes. In fact, the self-diffusion coefficient of a diffusant in an aqueous polymer system is largely determined by its self-diffusion coefficient in pure water (D_0). The smaller hydrodynamic radius (R_h) of HAc is the reason that throughout the entire concentration range of PVA the self-diffusion coefficient of HAc remains higher than that of EG and of EDA (Fig. 2A).

The reduced diffusion coefficients (D/D_0) of the three diffusants (EG, HAc, and EDA) in the PVA–water system are quite similar at a given concentration of the polymer (Fig. 2B), even though they have different R_h values. The reduced diffusion coefficient is strongly related to the interaction between the diffusant and the polymer matrix. The lower values of D/D_0 correspond to a stronger interaction between the polymer matix and the diffusant in the systems. Figure 2B shows that the interaction between the diffusant and the PVA matrix is similar in the three systems.

Although the effects of the hydrodynamic radius on the self-diffusion data show the same trend in Figs. 2A (EG, HAc, and EDA) and 3A (EG, DEG, and TEG), the reduced self-diffusion coefficients of these two groups of diffusants show a quite different behaviour (Figs. 2B and 3B). The D/D_0 values are rather similar for EG, HAc, and EDA in PVA (Fig. 2B). By contrast, the D/D_0 values for EG, DEG, and TEG are quite different (Fig. 3B). In this case, the dominant interaction between the diffusants and the PVA matrix is hydrogen bonding. The effect of hydrogen bonding is more pronounced for the diffusion of TEG than for DEG and EG. The apparent reason is the greater number of oxygen atoms on TEG (four oxygen atoms) available to participate in hydrogen bonding in comparison to DEG (three oxygen atoms) and EG (two oxygen atoms).

To further analyze the effect of hydrogen bonding between the diffusants and PVA, the self-diffusion coefficients of EG, DEG, and TEG were compared with their end-capped methyl ether derivatives. The presence of methyl ether end groups should not significantly alter the size (Table 1) and shape of the diffusant, which are known to affect diffusion (9). Figure 4 shows the results obtained for the diffusion of mono-, di-, and tri-ethylene glycol and their methyl esters in the PVA matrix. In all three cases, the reduced self-diffusion coefficients of EG, DEG, and TEG are lower than those of their end-capped methyl ether derivatives, although their molecular masses are correspondingly lower in each case. In these cases, hydrogen bonding is the dominant factor and the effect of molecular mass of the diffusant becomes less significant. The differences observed in the diffusion data are greater than the experimental error estimated at less than 5%. When one of the alcohol end groups is capped by a methyl ether group, the value of D/D_0 increases because of the limitation in the formation of hydrogen bonds between the diffusant and the matrix. A larger increase of the value of D/D_0 should be observed in the case of the diether derivatives. However, the capping of the second alcohol group of the diffusant did not influence the diffusing behaviour of the probe as much as the capping of the first alcohol group. Therefore, similar reduced self-diffusion coefficients were obtained for the interactions of PVA with either the mono- or di-ether species.

Effect of ionic interactions

The effect of functional groups on the diffusion process was studied in the aqueous systems of EG, EDA, and HAc as diffusant probes and polymer matrix containing different functional groups (PVA, PAA, and PAAm). The diffusion of

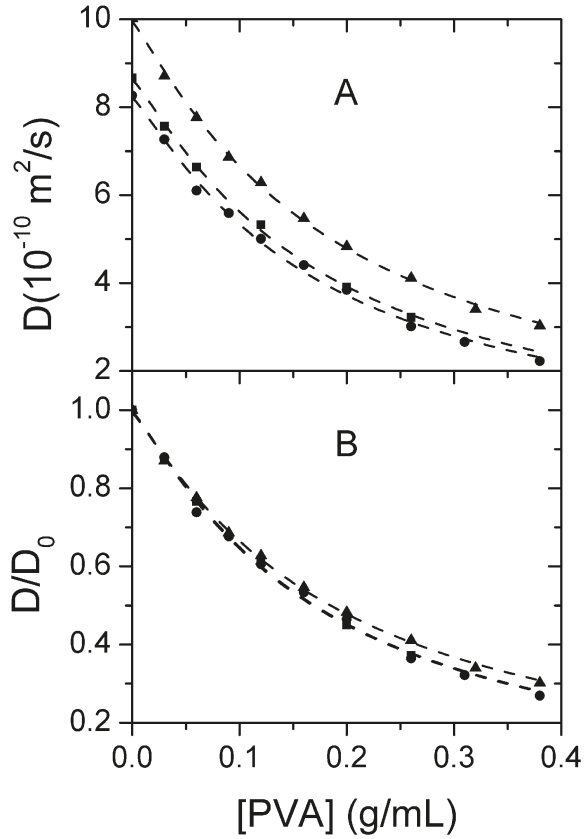

Fig. 3. Variation of (A) the self-diffusion coefficients (B) the reduced diffusion coefficients D/D_0 as a function of PVA concentration at 25 °C. Dashed lines are fits to eq. [1]. EG (■); DEG (●); TEG (▲).

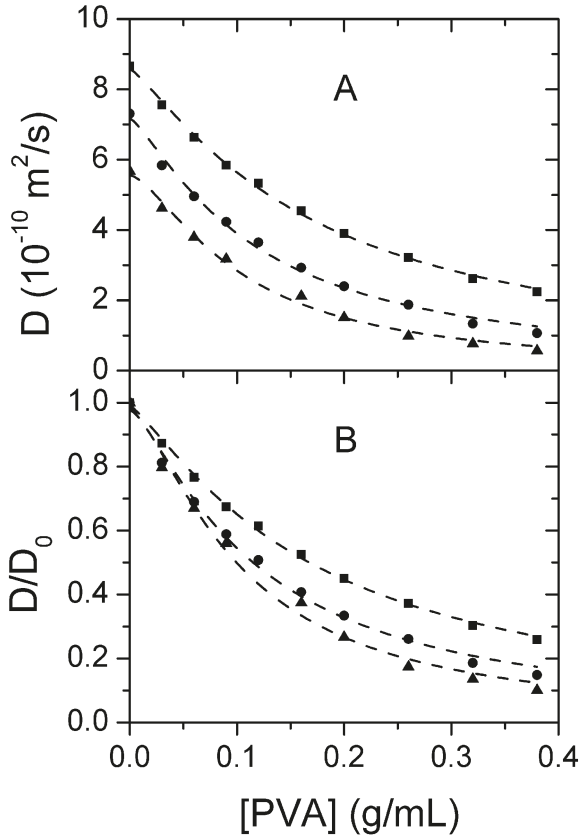

EDA in PAA matix was not studied because of precipitation upon mixing. It should be pointed out that, in the HAc–PAA, HAc–PAAm, and EDA–PAAm systems, the NMR signals of the diffusant overlap with those of the polymer, which may have caused somewhat larger errors in the measured self-diffusion coefficients.

Figure 5A shows the self-diffusion coefficients of EG in the three different polymer matrices. The change of D can be attributed to the difference of interactions (electrostatic interaction and hydrogen bonding) resulting from the functional groups of the diffusant and the polymer. Figure 5A shows that the reduced self-diffusion coefficient of EG in the different polymer matrices (PVA, PAAm, and PAA) vary a lot. Hydrogen bonding between EG and PVA should be more extensive, as shown by the different viscosity of the mixture at the same concentration of polymer. At a polymer concentration of 0.25 g/mL, the viscosities of the polymer solutions are 0.96, 0.27, and 0.08 Pa·s for PVA, PAA, and PAAm, respectively. The viscosity effect could influence the diffusion of EDA and HAc because of the complex nature of the interactions in the different polymer matrices.

Figure 5 shows interactions between the polymer and the diffusants by the differences in the reduced diffusion coefficients of EG, EDA, and HAc in the three-polymer matrices. At the same polymer concentration, the self-diffusion coefficients of HAc are higher in PVA and in PAA than in PAAm. For example, the self-diffusion coefficient of HAc is systematically lower in PAAm than in PAA because of the electrostatic interactions between HAc and PAAm. This result does not mean that the HAc molecules do not interact with the others polymer matrices, but the attractive electrostatic interactions with PAAm are more important than hydrogen bonding between the diffusant HAc and the polymer matrix (PAA). Note that for all three diffusants, their self-diffusion coefficients in PVA are always lower because of the much higher viscosity of the PVA aqueous systems.

Diffusion models

Equation [1] was used to fit the diffusion profiles in Fig. 4, and the results of the fitting parameters are listed in Table 1. The D_0 values obtained from the fitting are almost identical to the experimental values and show a clear dependence on the size of the diffusant. The parameters ν are in the same range as those obtained previously for PVA systems (6, 9). As expected, the $k\beta^2$ value decreases from EG to DEG and then to TEG, since the jump frequency factor k is related to the hydrodynamic size of the molecular probes. In comparision, the $k\beta^2$ value shows an increase instead of a decrease from TEG to TEGMe and then to $TEGMe_2$ (or from EG to EGMe and $EGMe_2$), although the M_r also increases. Obviously, the methyl group at the ends reduces hydrogen bonding between the diffusant and PVA, making the molecules easier to diffuse even though they are larger. It seems that the $k\beta^2$ parameter obtained may serve as an indication to the interactions between the diffusant and the polymer. This model in its present form does not provide a provision for the interactions between the

diffusant and the polymer, since the $k\beta^2$ parameter also changes with M_r and shape of the diffusant and the temperature. It remains useful to analyze the experimental diffusion data to account for structural changes to the diffusant.

The model of Phillies was also used to analyze these data, with fitting parameters listed in Table 1. For small molecule diffusants, $\alpha = aR_h^b$ (where a is a constant between 3.03 and 3.20, and b is a constant between 0.53 and 0.59) (14, 29). However, the α values obtained (Table 1) do not show a clear dependence on the hydrodynamic size of the diffusants. The parameter υ decreases with increasing intermolecular interactions and was found to have a slight increasing trend from TEG to TEGMe and $TEGMe_2$ and a decreasing trend from EG to DEG and TEG. The variations in υ observed in this study are not as large as those observed in other systems such as PS and PVAc – methyl red – toluene systems (27).

Table 2 shows the results obtained from the fitting of experimental data of EG, EDA, and HAc in PVA, PAA, and PAAm to both diffusion models. The ionic interactions between the probe and the matrix are evidenced by the variation of the reduced self-diffusion coefficient of the diffusants in the same matrix. It is shown that the interactions between HAc and PAAm are stronger than the interaction between PAAm and either EDA or EG (from both $k\beta^2$ and υ values). However, the direct comparison among the different polymer systems is not straight forward.

The diffusion models do not provide provisions to directly account for the interactions in the system. The $k\beta^2$ parameter in the model of Petit et al. and the υ parameter in the model of Phillies are related to the probe–matrix interaction and are largely affected by the presence of ionic interactions, but the variation of these parameters does not always follow the expected trend. The interaction between HAc and PAAm is clearly shown by the differences in the self-diffusion coefficients, but the $k\beta^2$ value for this diffusant–polymer pair is higher than the $k\beta^2$ values of HAc in PAA and PVA. The parameter β is not a constant and should vary in different polymer systems, but it cannot be measured independently. The $k\beta^2$ values obtained with the model of Petit et al. can only be used to compare results obtained in the same polymer system. The parameter υ is strongly dependent on the interactions present in the system as observed by Lee et al. (27) and generally decreases in the presence of ionic interactions in the system. This parameter, however, is also known to vary with the quality of the solvent for the polymer (30) and this may change when different polymer matrices are used.

Effect of temperature and activation energy

Temperature has an important effect on the diffusion and the apparent activation energy of self-diffusion. The effect of the temperature was studied between 15 and 45 °C for EDA, HAc, and EG in the three different polymer matrices. As previously observed, D increases with increasing temperature (9) as shown in the example of EG in PVA in Fig. 6A. The D/D_0 values, however, are rather similar at a given polymer concentration (Fig. 6B), indicating that the diffusion of EG was largely determined by the initial diffusion in water and the nature of the polymer–diffusant interaction does not vary with temperature. The apparent activation energy for each diffusant has been obtained from the variation of $k\beta^2$ parameter with the reciprocal temperature by the Arrhenius approach. Since β is assumed to be a constant within the temperature range for a given polymer–solvent system, the variation of $k\beta^2$ with temperature reflects the variation of k with temperature.

As β may not be the same in the different systems, a comparison of apparent activation energy E_a values (Table 2) obtained in different polymer systems would not be appropriate. However, for a given polymer system, these values are comparable. In general, the E_a values in Table 2 do not show any significant variation. In both PVA and PAA systems, HAc has the lowest E_a presumably due to its smaller hydrodynamic radius among the diffusants tested. In the PAAm system, where ionic interaction with HAc takes place, HAc seems to have a higher E_a than the other two diffusants or at least a value similar to that of the others.

Conclusion

We have found that the presence of hydrogen bonding and electrostatic interactions between the diffusants and the

polymers can lower significantly the value of self-diffusion coefficient of small molecules in polymers and considerably reduce or even overwrite the effect of molecular size of the diffusants. The reduced or normalized self-diffusion coefficient (D/D_0) gives a better indication of these interactions. The physical models of diffusion generally describe well the variation of the self-diffusion coefficient with diffusant size, polymer concentration, and temperature, but they still lack adequacy in describing the effects of the interactions in the polymer–water–diffusant systems.

Direct analysis of analyte–laden chromatographic stationary phase by induction–heating electrothermal vaporizer with inductively coupled plasma atomic emission spectroscopy[1]

Rebecca Lam and Eric D. Salin

Abstract: We describe the inductively heated electrothermal vaporization of 8-hydroxyquinolate complexes of Cd, Pb, and Zn adsorbed onto C_{18}-bonded silica gel with inductively coupled plasma atomic emission spectroscopic detection. The metal complexes were adsorbed onto the chromatographic stationary phase using a solid-phase extraction procedure. Instead of eluting the complexes from the stationary phase, the solid phase was directly vaporized into the plasma. Absolute detection limits for this method ranged from 0.3 to 3 μg.

Key words: 8-hydroxyquinoline, silica gel, induction heating electrothermal vaporization, inductively coupled plasma atomic emission spectroscopy.

Résumé : Faisant appel à une détection à l'aide de spectroscopie d'émission atomique au plasma avec couplage inductif, on a étudié la vaporisation avec chauffage électrothermique à induction de complexes entre le 8-hydroxyquinoléinate et du Cd, du Pb et du Zn adsorbés sur un gel de silice lié à un C_{18}. Les complexes métalliques ont été adsorbés sur la phase chromatographique stationnaire à l'aide d'une méthode d'extraction en phase solide. Au lieu d'éluer les complexes de la phase stationnaire, la phase solide a plutôt été directement vaporisée dans le plasma. Les limites absolues de détection de cette méthode se situent entre 0,3 et 3 μg.

Mots-clés : 8-hydroxyquinoléine, gel de silice, vaporisation avec chauffage électrothermique à induction, spectroscopie d'émission atomique au plasma avec couplage inductif.

[Traduit par la Rédaction]

Introduction

The use of solid-phase extraction for preconcentration and matrix separation is a powerful tool for trace-metals determination and continues to be an active field of research in atomic spectroscopy (1, 2). For typical solution analysis of the trace metals by inductively coupled plasma atomic emission spectroscopy or mass spectrometry (ICP-AES or ICP-MS), an elution step is required to remove the bound analytes from the solid sorbent by using a solvent. Under some circumstances, it would be desirable to avoid the elution process by directly vaporizing the analyte from the preconcentration material. Higher preconcentration factors may be achieved, as analytes are deposited, concentrated, and then vaporized rather than being diluted in 5–10 mL of eluant. One might also expect better detection limits by direct analysis when considering the low 1%–3% efficiency of nebulizers.

For aqueous samples, an extraction procedure is commonly cited in which metals complexed with 8-hydroxyquinoline are trapped onto chromatographic packing (C_{18}-bonded silica gel) (3–6). 8-Hydroxyquinoline is a powerful chelating agent that is particularly useful for separations because of its low affinity for the alkali metals that can cause matrix effects in ICP spectrometry. Alkali metals and other matrix components that are not chelated are eluted from the column during the washing step while the chelated metal complexes bind to the stationary phase. Silica powder is often used for preconcentration either directly or as a stationary-phase solid support. Direct analysis of the analyte–laden silica powder would eliminate the elution step and consequently should reduce both labor and dilution concerns. Dried precipitates of 8-hydroxyquinoline metal complexes have been directly analyzed by graphite furnace atomic absorption spectrometry (7); however, the direct analysis of 8-hydroxyquinoline chelates laden on chromatographic powder has not been reported.

Despite the popularity of solid-phase extraction, there have been very few reports in the literature describing direct analysis of solid, analyte–laden sorbents, or chelating agents. Metals extracted through various co-precipitation

methods have been electrothermally vaporized as solids for analysis by atomic absorption spectrometry (8, 9). Skinner et al. trapped analyte on activated charcoal and then vaporized the analyte with a direct sample insertion (DSI) system using ICP-AES detection (10). Rattray and Salin also used DSI-ICP-AES for the direct analysis of analytes bound to Chelex-100 resin (11). Van Berkel and Maessen used electrothermal vaporization-ICP-AES to analyze metals trapped with poly(dithiocarbamate) resin (12).

In this report, we describe the use of an induction–heating electrothermal vaporizer (IH-ETV) (13–15) for the direct analysis of 8-hydroxyquinoline complexes adsorbed onto C_{18}-bonded silica. The silica gel containing the trapped chelated analyte is placed in a graphite sample cup inside the IH-ETV, where the analyte is vaporized from the silica gel and detected with inductively coupled plasma atomic emission spectroscopy (ICP-AES). The non-contact heating environment of the IH-ETV reduces the risk of contamination, while the heating of the cups can easily be controlled. In addition to ease of use, the graphite sample cups can be customized in size and shape to potentially hold a large amount of material, thereby suggesting that IH-ETV would be a powerful tool for application with chromatographic materials.

Experimental section

Chemicals

The brand of C_{18}-bonded silica gel used as packing in the columns was either Bondapak Porasil B (37–75 μm, Waters Corporation, Milford, Mass., USA) or Chromabond Sorbenz (mean particle size of 45 μm, Macherey–Nagel, Düren, Germany). The silica gel was not treated prior to placement in the column. An acidified reagent-grade methanol solution, 2% NH_4OH solution and 5% (*w*/*v*) solution of 8-hydroxyquinoline in methanol was prepared as described in the literature (5).

Column

The solid-phase extraction column was constructed inside a micropipette tip (101–1000 μL Fisherbrand, Fisher Scientific, Ottawa, Ont., Canada). A plug of quartz wool was used as a frit in the end of the pipette tip. Approximately, 150 mg of C_{18}-bonded silica gel was slurried with methanol and loaded into the pipette tip to give a packing bed of ~1 cm in height.

Samples

Aqueous samples (20 mL, elemental concentrations ranging from 0.25 to 1 μg g^{-1}) were prepared by diluting and mixing single-element reference solutions of Cd, Pb, and Zn (Fisher Scientific) with distilled, deionized water (Milli-Q system, Millipore Corp., Billerica, Mass., USA). An equivalent volume of distilled, deionized water was prepared as a blank. Prior to the extraction, 0.5 mL of the 5% 8-hydroxyquinoline solution was added to the sample or blank. This was equivalent to 200–600 times the stoichiometric amount of 8-hydroxyquinoline required to chelate the analytes in a given sample. The sample was adjusted to pH 9.0 ± 0.1 with the 2% NH_4OH solution and then manually shaken to ensure good mixing.

Extraction

The basic column washing and extraction procedure followed in this study is described by Skinner and Salin (5), except that the solvents and samples were delivered to the column manually by glass transfer pipettes, and the elution step was not performed. Tygon tubing was attached to the end of the column, and a peristaltic pump was used to drive the solvents or sample through the column at a flow rate of about 5 mL min^{-1}. The chelated analytes formed an easily observed thin green band on top of the column. The column was then rinsed with distilled, deionized water (previously adjusted to pH 9.0) and allowed to air-dry. The dried silica gel with the chelated analytes was removed from the pipette tip and homogenized.

IH-ETV-ICP-AES

The IH-ETV system used in this study has been previously described in detail (15–17). A schematic is provided in the Supplementary Data (Fig. S1).[3] The system was directly coupled to the torch of a Thermo–Jarrell Ash IRIS ICP-AES system.

Commercially available graphite sample cups with boiler caps (Bay Carbon, Bay City, Mich., US) were used to hold the silica samples. A drawing of the cups with dimensions labeled is shown as Fig. S2 in the Supplementary Data.[3] A wad of quartz wool was added inside the cup to prevent silica particles from passing through the hole in the end of the boiler cap. A plug of silica gel weighing 150 mg was used to trap the chelated analytes; however, the cup size used in these experiments could accommodate a maximum of 50 mg (though larger cups are possible). Consequently, a weighed subsample was placed into the cup for analysis.

Ten seconds after the start of the data acquisition, power was applied to the IH-ETV to heat the samples for 45 s to the maximum temperature achieved by the system (1400 °C). Multiple emission lines were monitored for each analyte to show that the peaks were real and not due to spectral interferences. Detailed operating parameters are show in Table 1.

Results and discussion

Figure 1 shows the time profiles of Chromabond and Porasil B silica gels (10 mg subsamples) used to extract multi-element solutions containing a mixture of Cd, Pb, and Zn. The analyte signals were obtained simultaneously for each type of silica gel but are shown on separate plots for clarity. There are several differences between the profiles of the Chromabond samples and the Porasil B samples. The Chromabond silica gel released a large amount of Si when heated, whereas the Porasil B released relatively little Si. The peaks for Zn and Pb also consistently occur a few sec-

Time per slice	0.2 s
Total acquisition time	100 s

onds later in the Porasil B than in the Chromabond sample, indicating that the Porasil B sample may be heating less quickly.

Recoveries for similar extractions have been reported to be near 100% for Cd, Pb, and Zn (4). The eluent collected from several extractions was analyzed by ICP-AES. The measured signals did not vary from levels in eluent collected from the blank extraction, indicating that the extraction efficiency was close to 100%.

A linear response is achieved when a five-point calibration plot is constructed from a 10 mg blank and 10 mg subsamples of analyte-laden Porasil B from separate extractions of four solutions of differing concentrations (20 mL of multi-element aqueous standards containing Cd, Pb, and Zn, corresponding to about 0.2–0.9 μg of analyte in the subsample). The plot is shown as Fig. S3 in the Supplementary Data.[3] A good correlation is shown for the analytes studied (R^2 = 0.99 for Cd, R^2 = 0.98 for Zn, and R^2 = 0.96 for Pb) if the amount of Si is kept constant for each standard.

Differences between the silica gel laden with only a single element (Cd) and silica gel laden with multiple elements (Cd, Pb, and Zn) were noted. First, the time profiles contained several Cd peaks. The multi-element samples of both Porasil B (Fig. 1*a*) and Chromabond (Fig. 1*d*) show a second Cd peak appearing at about the same time as the Zn peak. However, the time profiles for Cd in single-element samples of Porasil B and Chromabond (Fig. 2) only contain one peak that occurs at the same place as the first Cd peak of the multi-element samples.

Second, the integrated peak area for the single Cd peak from a single-element solution was about 20% lower than the total integrated peak area of both Cd peaks from a multi-element solution containing the same amount of Cd. This was seen with either Chromabond or Porasil B as the packing material. However, the peak area for Cd from the single-element solution did match with the integrated area of the first peak of the multi-element solution. Experiments showed that if Cd data from multi-element standards were used to construct a calibration curve, then Cd concentrations would be accurately determined (within 3% accuracy) for a single-element sample if only the peak area of the first Cd peak of the standards was used instead of the total peak area of both peaks. This plot is available as Fig. S4 in the Supplementary Data.[3]

Fig. 1. IH-ETV-ICP-AES time profiles of a Porasil B sample laden with Cd, Pb, and Zn (*a*, *b*, and *c*) and of Chromabond laden with Cd, Pb, and Zn (*d*, *e*, and *f*). Wavelengths shown are Cd = 228.8 nm, Zn = 213.9 nm, Pb = 220.4 nm, and Si = 251.6 nm.

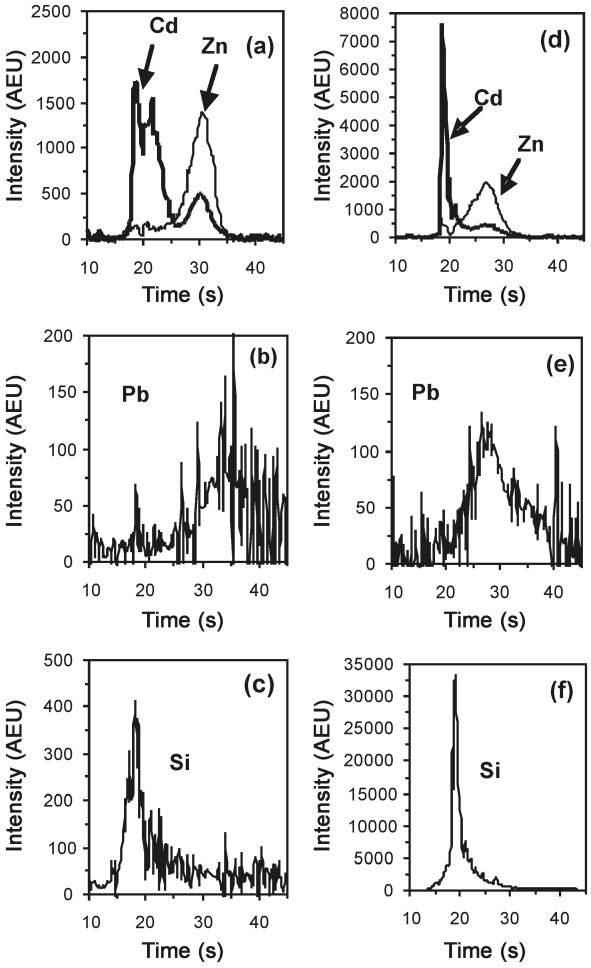

Fig. 2. IH-ETV-ICP-AES time profiles of (*a*) Porasil B sample laden only with Cd and (*b*) Chromabond sample laden only with Cd.

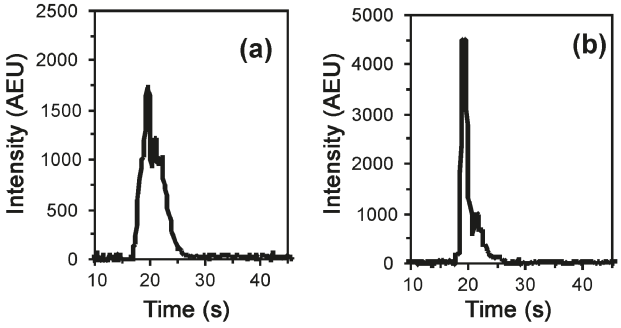

There are several possibilities for the variability in the number of peaks and the integrated peak areas between the single-element and multi-element solution. There may be a mass-transport phenomenon occurring in which some Cd is lost by condensation on the way to the ICP. The deposited Cd could then be picked up by the zinc or lead as it travels to the ICP. It is interesting to note that the first Cd peak appears with the early Si peak, whereas the Zn, Pb, and second

Table 2. Detection limits for the IH-ETV-ICP-AES of chromatographic material.

Element	Absolute (μg)	Relative (ng g^{-1})[a]	Solution nebulization (ng g^{-1})
Cd	0.3	15	80
Pb	1	60	40
Zn	3	150	2

[a]Based on an aqueous sample size of 20 g (about 20 mL) and analyzing only a subsample of total silica gel used in the extraction.

Cd peak all appear at the same time, although later. This suggests that either a different transport or vaporization scheme may be involved with Cd. Metallic Cd is both the lowest melting and boiling of the three metals. It may also be that there is a chemical conversion of the Cd form in which the second form of Cd is only seen or transported when other analytes are present. In any case, it was possible to obtain good analytical results using the procedure described above.

The detection limits (3σ) for Cd, Pb, and Zn are shown in Table 2. Zn, in particular, has a higher detection limit than the others because of a relatively high blank. The Zn contamination likely occurred when handling the graphite cups with latex gloves. Except for Zn, the concentration detection limits are about the same for those obtained for solution nebulization for the same ICP-AES instrument. These detection limits could probably be improved if purified reagents are used. In addition, one might see improvement if the operation conditions were optimized for this particular sample-introduction device (dry vapor) rather than the nebulizer conditions that were used. The performance of the IH-ETV with an ICP-MS system would have to be tested, but complications might be expected because of the high levels of organics vaporized during the analysis.

The concentration detection limit calculated in Table 2 is based on analyzing a 10 mg subsample of the total 150 mg used in the extraction (as was done in most experiments in this study because of the small volume of the graphite cup). If the entire amount of silica gel could be vaporized, then we would expect the detection limit to be roughly 15 times better.

We have shown that the analysis of analyte–laden chromatographic material by IH-ETV-ICP-AES is feasible. The detection limits obtained are useful for many applications. The experiments indicate that it may be possible to make on-column sampling systems that pretreat an aqueous environmental sample on-site in a format that can be followed by direct analysis by IH-ETV-ICP-AES later in the laboratory.

Effect of relative humidity on the morphology of electrospun polymer fibers[1]

Eliton S. Medeiros, Luiz H. C. Mattoso, Richard D. Offeman, Delilah F. Wood, and William J. Orts

Abstract: The effect of relative humidity on the morphology of electrospun fibers of poly(vinyl alcohol), poly(methyl methacrylate), poly(vinyl chloride), polystyrene, and poly(lactic acid) dissolved in solvents such as toluene, *N*,*N*-dimethylformamide, 2,2,2-trifluoroethanol, and deionized water was studied by scanning electron microscopy to investigate the factors that may contribute to pore formation. Results showed that the presence of pores depends on factors such as the type of polymers used, the polymer–solvent combination, molecular weight, and the size of the electrospun structure. The final morphology developed implies a competition between the dynamics of phase separation and the rate of solvent evaporation. In addition, continuous solvent evaporation and constant stretching owing to the electric potential difference give rise to the final shape of porous electrospun fibers.

Key words: electrospinning, relative humidity, porous fibers, polymers.

Résumé : Faisant appel à la microscopie électronique à balayage pour étudier les facteurs qui peuvent contribuer à la formation de pores, on a examiné l'effet de l'humidité relative sur la morphologie de fibres électrofilées du poly(alcool vinylique), du poly(méthacrylate de méthyle), de poly(chlorure de vinyle), de polystyrène et de poly(acide lactique) dissous dans des solvants tel le toluène, le *N*,*N*-diméthylformamide, le 2,2,2-trifluoroéthanol et l'eau déionizée. Les résultats montrent que la présence des pores dépend de facteurs tels que le type de polymère utilizé, la combinaison polymère–solvant, le poids moléculaire et la taille de la structure électrofilée. La morphologie finale qui se développe implique une compétition entre la dynamique de la séparation de phase et la vitesse d'évaporation du solvant. De plus, l'évaporation continue du solvant et l'étirement constant qui résulte de la différence de potentiel conduit à la forme finale des fibres électrofilées poreuses.

Mots-clés : fibres électrofilées, humidité relative, fibres poreuses, polymères.

Introduction

A significant number of papers have been published on the electrospinning of micro- and nanostructures in recent years (1–3). However, most of these works do not take into account the fact that the relative humidity (RH) of the spinning environment affects fiber morphology as well as the structure–properties relationship. It has already been established that reproducibility during the production of nanoscale materials can only be obtained by accurate control of parameters governing each electrospinning system (materials and process variables). To study the effect of other process variables, RH must be accurately controlled, a parameter not always discussed.

Recently, some reports have begun to address the effect of RH on the morphology of electrospun fibers and beads (4–11). These works report that electrospinning of certain combinations of polymers and solvents, specifically the highly volatile ones, in humid environments (RH above ca. 30%) produced porous structures whose surface features can be controlled by the appropriate choice of materials and process variables. The porous structure has been attributed to several factors, such as the combined effects of the polymer, the electric force applied, and the fast absorption of oxygen in air by the solvent (5); a temperature decrease at the surface because of fast solvent evaporation, which causes moisture condensation on the surface of the fibers thereby forming the pores and (or) other surface features (6, 7); and phase separation (8, 11, 12).

Furthermore, the production of electrospun fibers by RH-controlled experiments results in porous structures without going through extravagant measures, such as removing the "other" phase with selective solvation (12–14).

Applications of porous materials range from filtration membranes and sensors to controlled release systems and

bone-tissue scaffolds (1, 2, 15). In biomedical applications, such as in bone tissues and wound-dressing, porosity is a requirement that promotes tissue growth and oxygen exchange between the damaged tissues and the external environment (16).

In this work, the morphology of electrospun nanofibers was studied under various relative humidity conditions (between 20% and 80%). Specifically, the fiber morphology of poly(vinyl alcohol) (PVA), poly(methyl methacrylate) (PMMA), poly(vinyl chloride) (PVC), polystyrene (PS), and poly(lactic acid) (PLA) that had been dissolved in solvents such as toluene, *N*,*N*-dimethylformamide (DMF), 2,2,2-trifluoroethanol (TFE), and deionized water, was studied by scanning electronic microscopy (SEM) to describe factors that contribute to pore formation and give an explanation of possible mechanisms involved.

Experimental

Polymers

PVA (97% hydrolyzed, MW = 5–8 × 10^4g/mol, CAS No. 9002–89–5); PMMA (MW = 1.2 × 10^5g/mol, CAS No. 9011–14–7); PVC, (M = 1.1 × 10^5 g/mol, CAS 9002–86–2, inherent viscosity = 1.02); and PS (CAS No.9003–53–6, MW = 4 × 10^5g/mol) were purchased from Sigma-Aldrich (St. Louis, MO, USA), and PLA (Polylactide Resin 4042D, MW = 2–4x10^5) was acquired from NatureWorks LLC (Minnetonka, MN, USA).

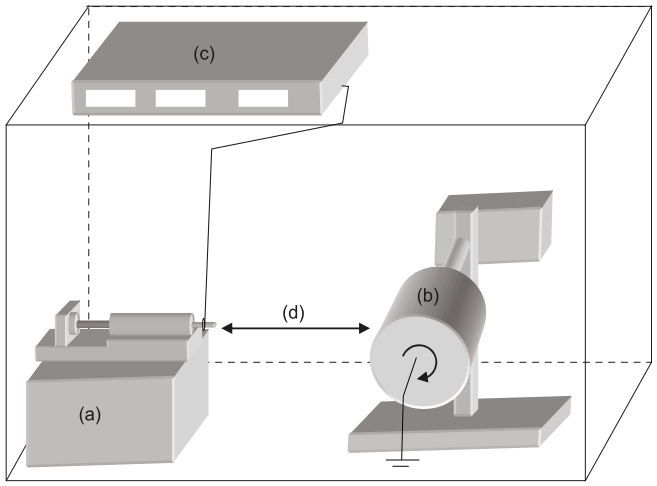
Solvents

Toluene, 1,1,1,3,3,3-hexafluoro-2-propanol (HFP), and DMF were purchased from Sigma-Aldrich (St. Louis, MO, USA) and 2,2,2-trifluoroethanol (TFE) was purchased from Alfa Aesar (Ward Hill, MA, USA). The PVA solution was prepared with deionized water. Some physical and chemical properties of these solvents such as solubility in water, boiling point (bp), molecular weight (M_r), dielectric constant (ϵ), and vapor pressure (vp) are listed in Table 1.

Electrospinning

The electrospinning setup used in this study consisted of a 5 mL plastic syringe, a 21G (id: 0.495 ± 0.001mm) or 18G (id:1.194 ± 0.001mm) needle, a grounded collector (stainless steel barrel with controllable rotation speed (ω), a hypodermic syringe pump (KD Scientific, USA) to control the injection rate (β) of the polymer solutions, and a high-voltage supply (Series FC, Glassman High Voltage, Inc., USA), which can generate positive direct current voltages (V) up to 99 kV. The needle was connected to the high-voltage source and positioned at a fixed working distance (WD from the grounded collector, and the polymer solution was injected at a constant rate (see Scheme 1). The experimental conditions used in each polymer–solvent system are listed in Table 2.

Scheme 1. Electrospinning setup: (*a*) Injection pump with hypodermic syringe, (*b*) grounded collector, (*c*) high voltage supply, and (*d*) working distance.



These conditions were based on a prior study in which the electrospinning parameters such as voltage, working distance, and injection rate (results not shown) were varied so that optimized experimental conditions could be used in further experiments.

Scanning electron microscopy (SEM) characterization

Samples were electrospun onto aluminum foil that had been wrapped on the rotating collector, and were collected for SEM analysis after 30 min. SEM samples were coated by gold sputtering for 45 s and analyzed for surface characterization using a Hitachi Scanning Electron Microscope (Model S4700, Hitachi High-Technologies, Japan) at a voltage of 2 kV.

Results

Despite being investigated for the past few years, the mechanisms that lead to the formation of porous fibers during electrospinning are not sufficiently understood. Therefore, to investigate the possible factors that may influence the presence of pores on electrospun fibers, different polymers were electrospun at relative humidity (RH) varying from 20% to 80%. Fibril morphology was analyzed by SEM and correlated to physical and chemical characteristics of

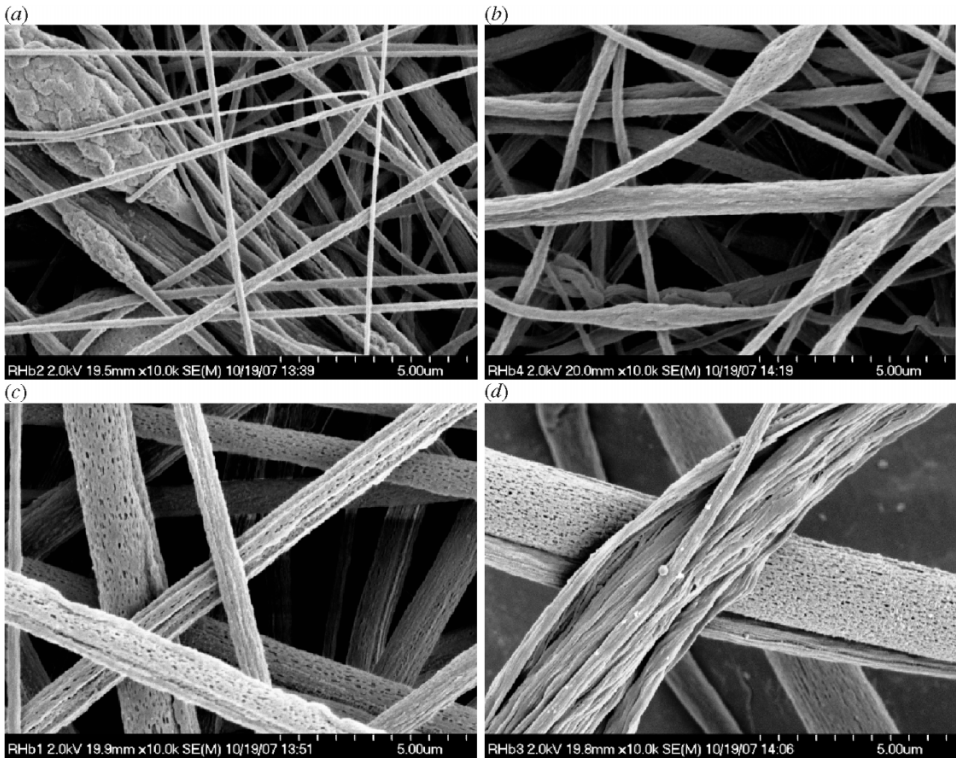
Fig. 1. SEM micrographs of polystyrene (PS) fibers electrospun from DMF solution at (*a*) 20 ± 4; (*b*) 40 ± 4; (*c*) 60 ± 4; and (*d*) 80 ± 4% RH.



each system such as polymer hydrophobicity, solvent volatility, and solubility in water. Figs. 1, 2, and 3 show the SEM micrographs of PS, PMMA, and PVC electrospun fibers from DMF solutions.

The results of Figs. 1 to 3 show that when the relative humidity is higher than 25%, pores are formed along the electrospun fibers. The relative humidity at which pores form varies somewhat between polymers; for PS it is 40%–60%; for PVC, 60%; and for PMMA, 80%. It is worth observing that not all of the fibers electrospun at the highest RH (80%) are porous; rather, porosity seems to depend on the size of the electrospun structure. For example, the existence of pores can be observed even at 20% RH when large structures are involved as can be seen in the lower left corner of Fig. 1*a*, when beads are also formed among the fibers. It seems that only fibers with a diameter above a certain critical value are porous, whereas those below this value are nonporous.

The intensity of electric field does not affect the pore formation. This makes sense, since the space between the polymer injection and the target is filled up with water molecules in vapor phase, which makes the atmosphere surrounding the electrospinning more conductive because of polarization of the water molecules (19). As a consequence of this increase in conductivity, the effect of the electric field on the fiber surface is less intense and the fibers are thicker, as can be seen in Figs. 1, 2, and 3. Furthermore, these results are in accordance with the literature showing that the applied voltage does not affect the pore size of PS fibers electrospun from tetrahydrofurane (THF) solutions (11).

To verify the effect of solvent volatility on pore formation, PMMA and PS were electrospun from toluene. Figs 4 and 5 show SEM micrographs of these fibers. It can be observed that, when electrospun fibers from DMF and toluene are compared, the ones electrospun from toluene have more defined porous structures (see, e.g., Fig. 5*e*) than those produced from DMF (see, e.g., Fig. 2*e*). Some of these pores, depending on their size, can partially close because polymer chains still have mobility as a consequence of incomplete

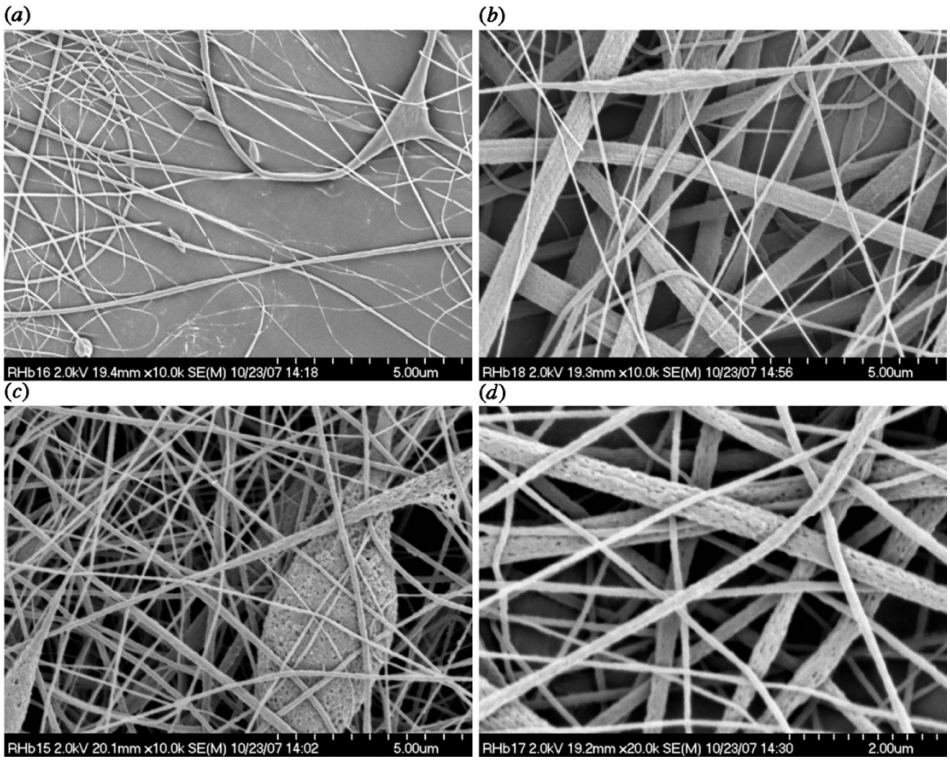
solvent evaporation in the core, while others remain open as shown in Fig. 4*e*. This is a consequence, both of the less volatile DMF whose boiling point is about 40 °C higher than that of toluene and whose vapor pressure is about eight times lower (see Table 1), and of the higher molecular weight of PMMA. When pores are formed, because of solvent volatilization and phase separation, the tendency for pores to coalesce is much reduced because the rapid increase in polymer viscosity forms well-defined porous structures, as will be discussed later.

Fig. 5 also displays wrinkled beads clearly indicating skin formation and collapse. If there is enough time for chain coiling, the droplets acquire a round shape, an effect that clearly depends on factors such as viscosity, working distance, applied voltage, and polymer molecular weight to minimize the surface area in contact with the surrounding atmosphere. Immediate skin formation because of fast evaporation prevents the solvent molecules entrapped in the core from diffusing though the skin. However, when internal pressure (which is dependent on solvent vapor pressure) overcomes skin cohesive forces (which are dependent on its thickness, polymer molecular weight, and surface tension) holes are opened. Then, the skin may or may not collapse depending on several factors such as those mentioned above. Depending on the size of the beads, the collapse may occur either completely, forming fully wrinkled surfaces and cups (see big beads in Fig. 5*a*), or partially as can be observed in Fig. 5*c*. These results are in accordance with the report by Eda and Shivkumar (9) on the bead structure variations during electrospinning of polystyrene dissolved in THF. They found that pore size increased as the polymer molecular weight increased.

The skin formation because of fast solvent evaporation does not fully explain why pores are not formed when PLA is electrospun from TFE and HFP, which are very volatile solvents. Figs. 6 and 7 show the morphologies of PLA fibers electrospun from TFE and HFP solutions. Additionally, to

© 2008 NRC Canada

Fig. 3. SEM micrographs of poly(vinyl chloride) (PVC) fibers electrospun from DMF solution at (*a*) 20 ± 4; (*b*) 40 ± 4; (*c*) 60 ± 4; and (*d*) 80 ± 4% RH.



increase the possibility of pore formation on these fibers by producing thicker fibers, the concentration of PLA dissolved in TFE was increased to 15%, 20%, and 25% so that thicker fibers could be obtained while keeping fixed the other experimental parameters (working distance, applied voltage, injection rate, and relative humidity) (see Fig. 8).

These results showed that the fibers do not display any surface features other than slight wrinkles, possibly because of volume reduction caused by solvent evaporation and polymer crystallization. This shows that even when producing thicker fibers using highly volatile solvents, thus increasing the tendency toward the formation of a porous structure because of solvent entrapped in the core, there was no pore formation on their surface as can be seen in Fig. 6.

According to the literature, fast solvent evaporation lowers the temperature at the fiber surface so that water droplets condense, thereby forming the breath figures (6, 7, 11). However, this effect alone cannot explain why pores are formed on PS fibers electrospun from DMF solutions, whereas there is no pore formation when polymers like PLA are electrospun from TFE or THF, which are very volatile solvents that can undergo evaporative cooling because of fast solvent evaporation. To investigate the effect of polymer hydrophilicity on pore formation, PVA was electrospun from aqueous solutions. SEM micrographs are shown in Fig. 9.

The results of Fig. 9 show that PVA electrospun in high humidity environments does not form porous structures, a result which is in agreement with the results for poly(oxyethylene) electrospun from aqueous solution obtained by Magelski et al. (11). Likewise, PLA, a hydrophobic polymer, did not give pore formation. These results indicate that if the polymer is hydrophilic there is no pore formation in high humidity environments. On the other hand, if the polymer is hydrophobic, it does not mean necessarily that there will always be pore formation.

It is important to notice also that the diameter of PVA electrospun fibers decreased as relative humidity increased and beads were formed on the fibers electrospun at 60% and 80% RH. This effect is opposite to that of fibers electrospun from organic solvents such as DMF, THF, and toluene, in which fiber diameter generally increases as the relative humidity increases, as shown in Table 3. Moreover, PVA fibers had a round shape without wrinkles as a consequence of a lower rate of solvent evaporation and no skin formation; this gives enough time for the solvent to evaporate while the fiber contracts more slowly forming a much less rough surface.

When RH increases, the conductivity of the medium increases both because of polarization of the air owing to the high applied electric field with ozone formation (this phenomenon can be detected easily by the ozone odor in the electrospinning box) and because of formation of conductive "paths" owing to water dipoles across the working distance. This reduces the stretch on the fibers, but may also split them because of formation of secondary jets (3, 18). This phenomenon is more evident when the viscosity is low (e.g., Figs. 9*c* and 9*d* show branched fibers of PVA because of this phenomenon).

Whereas fibers of PMMA, PVC, and PS in DMF, or PMMA and PS in toluene were porous when electrospun at relative humidity higher than 30%, fibers of PLA in TFE and HFP, and PVA in water did not exhibit pore formation at any value of relative humidity. Actually, the final morphol-

ogy developed during electrospinning is controlled by the solution chemistry of the polymer–solvent system, i.e., there is a competition between the dynamics of phase separation and the rate of solvent evaporation, in a way similar to the casting of porous membranes (20, 21).

The phase separation mechanism is believed to be comprised of two steps, nucleation and growth, and spinodal decomposition, where the interconnected porous structure is generally attributed to phase separation by the spinodal decomposition mechanism. In contrast, closed pores are attributed to the nucleation and growth mechanism (22–25). Since fast solvent evaporation at the external layer or skin of the fibers are being formed, abrupt concentration changes may also take place. If these changes lie within the range of the instability or spinodal decomposition region, phase separation of the components can occur thereby forming a rapidly solidified skin with micro and (or) nanopores (21–25).

When fibers are electrospun from organic solvents like DMF and toluene in a high humidity environment and the polymer is hydrophobic, a skin is formed immediately after the polymer comes into contact with the surrounding environment. This is because the vapor water molecules act as nonsolvent for the polymer–solvent system, which is one of the necessary conditions for a system to undergo phase separation. Although the nonsolvent produces phase separation, not all nonsolvent behaves this way (22). This explains why PLA, being hydrophobic, did not undergo phase separation and hence did not form porous fibers when electrospun from TFE and HFP. However, because PVA is soluble in water, phase separation does not occur in this system; this explains the absence of pores on PVA electrospun fibers.

When the internal pressure due to solvent volatilization and diameter contraction is higher than the surface tension, some of the pores may have their walls broken, thus opening channels though which the solvent evaporates and leaving behind radial pores all over the fiber surface.

If the degree of phase separation is high and the solvent is volatile enough to form a relatively thick skin as the solvent evaporates, an abrupt increase in viscosity can take place restraining polymer mobility and preventing the pores from closing. Otherwise, these pores may eventually coalesce to surface defects (surface pores) rather than through pores (see Scheme 2), as also observed by Megelski et al. [27].

This behavior helps explain why well-defined pores were formed on the surface of PS and PMMA fibers electrospun from toluene. The average pore size, therefore, depends on multiple factors, specifically surface tension, solution viscosity, polymer molecular weight, glass transition (i.e., relative mobility of polymer chains), stretching level imposed by the electric field, solvent diffusion, and polymer–solvent interaction (4, 26, 27). Moreover, as shown in the literature (7, 8, 11) and in this work, the fibers susceptible to pore formation and surface defects are those whose diameters lie at the micron scale. For fibers at the nanoscale, however, the skin as well as the internal core may be so thin that the dynamics of solvent evaporation, phase separation, and skin formation are so fast that there is not enough time to form the surface features.

In addition, as the surface charges overcome the surface tension of the polymer droplet at the needle tip, the droplet is deformed by the action of electrostatic repulsion forces while it is being pushed to the collector by the action of electrical potential difference. At first, when the field intensity is high, the polymer is rapidly stretched in a way analogous to shear stress development when a polymeric melt exits a die of an extruder (28–30). After the development of this step, continuous solvent evaporation and constant stretching, as the jet moves toward the collector help freeze the stretched pores as the fibers are deposited on the collector, thereby giving rise to the final shape of porous electrospun fibers. This is depicted, for example, in SEM micrographs of fiber surface in Figs. 4 and 5.

Conclusions

When the relative humidity is higher than 25%, pores are formed along electrospun fibers, with the RH of initial pore formation varying somewhat from polymer to polymer as a consequence of several factors such as molecular weight and structure. Not all of the fibers electrospun at 80% RH are porous; rather, porosity depends on the size of the electrospun structure. The fibers susceptible to pore formation and surface defects are those whose diameters lie at the micron scale, because at the nanoscale the skin as well as the internal core may be so thin that the dynamics of solvent evaporation, phase separation, and skin formation are too fast to allow enough time to form the surface features.

The final morphology developed during electrospinning is a competition between the dynamics of phase separation and the rate of solvent evaporation, in a way similar to the casting of porous membranes. A water-rich environment helps the fast formation of a skin with well-defined boundaries, while the opposite can cause a semi-diffuse layer allowing easy solvent evaporation.

When a polymer is hydrophobic, water acts as nonsolvent and the skin is more readily formed. This explains why the systems PMMA, PVC, or PS in DMF, or PMMA or PS in toluene exhibited porous fibers when electrospun at relative humidity higher than 30%, whereas PLA in TFE or HFP, and PVA in water did not exhibit pore formation at any value of relative humidity. In addition, continuous solvent evaporation and constant stretching gives rise to the final porous structure of the electrospun fibers.

Morphology of a hydrogen-bond mediated self-assembling small molecule in a polycarbonate matrix[1]

Molla Rafiquel Islam and P.R. Sundararajan

Abstract: Dispersing functional small molecules in a polymer matrix is a well-known method of device fabrication for optoelectronic applications. Normally, no specific interactions such as hydrogen bonding occur between the polymer and the small molecule. The latter does not belong to the category of "self-assembling" molecules. When phase separation occurs, the small molecule would diffuse to the surface and crystallize. In this paper, we describe a very different morphological behaviour of hydrogen-bond mediated self-assembling molecules in a polycarbonate matrix. We used a series of biscarbamates with two hydrogen-bonding motifs and alkyl side chain lengths symmetrically varying from C_4 to C_{18}. We infer that the rate of self-assembly is faster than the diffusion of the small molecule to the surface. As a result, crystallization of the small molecule occurs predominantly in the bulk, i.e., sub surface, and not on the surface of the polymer film.

Key words: self-assembly, crystallization, diffusion, phase separation.

Résumé : La dispersion de petites molécules fonctionnelles dans une matrice de polymère est une méthode bien connue de fabrication pour dispositifs pour des applications optoélectroniques. Normalement, il ne se produit aucune interaction spécifique, telles des liaisons hydrogènes, entre la polymère et la petite molécule. Cette dernière n'appartenant généralement pas à la catégorie des molécules donnant lieu à de l'autoassemblage. Lorsqu'il se produit une séparation de phase, la petite molécule à tendance à diffuser vers la surface et à cristalliser. Dans le présent travail, on décrit un comportement morphologique très différent de molécules présentes dans une matrice de polycarbonate qui donnent lieu à un autoassemblage favorisé par des liaisons hydrogènes. On a utilisé une série de bis carbamates avec deux motifs de liaisons hydrogènes et des longueurs de chaînes latérales alkyles symétriques variant de 4 à 18 atomes de carbone. On en déduit que la vitesse d'autoassemblage est plus rapide que la diffusion de la petite molécule vers la surface. En conséquence, la cristallisation des petites molécules se fait dans la masse, c'est-à-dire sous la surface, et non pas à la surface du film de polymère.

Mots-clés : autoassemblage, cristallisation, diffusion, séparation de phase.

[Traduit par la Rédaction]

Introduction

Photo-active and electro-active functional small molecules are widely used in optoelectronic devices as a dispersed phase in polymer matrices (1). Molecular dispersion of such molecules without phase separation is a requirement for the longevity of the device. Polycarbonate is often the preferred polymer for these applications. Thermally induced crystallization of the small molecule is a common cause of defects in, for example, photoreceptors (2) and the delamination of OLED devices (3). Abrasion is also a cause of such crystallization in photoreceptors. In a series of papers, we used thermal annealing as a means of testing the accelerated ageing and phase separation in model composites related to photoreceptors (2, 4, 5).

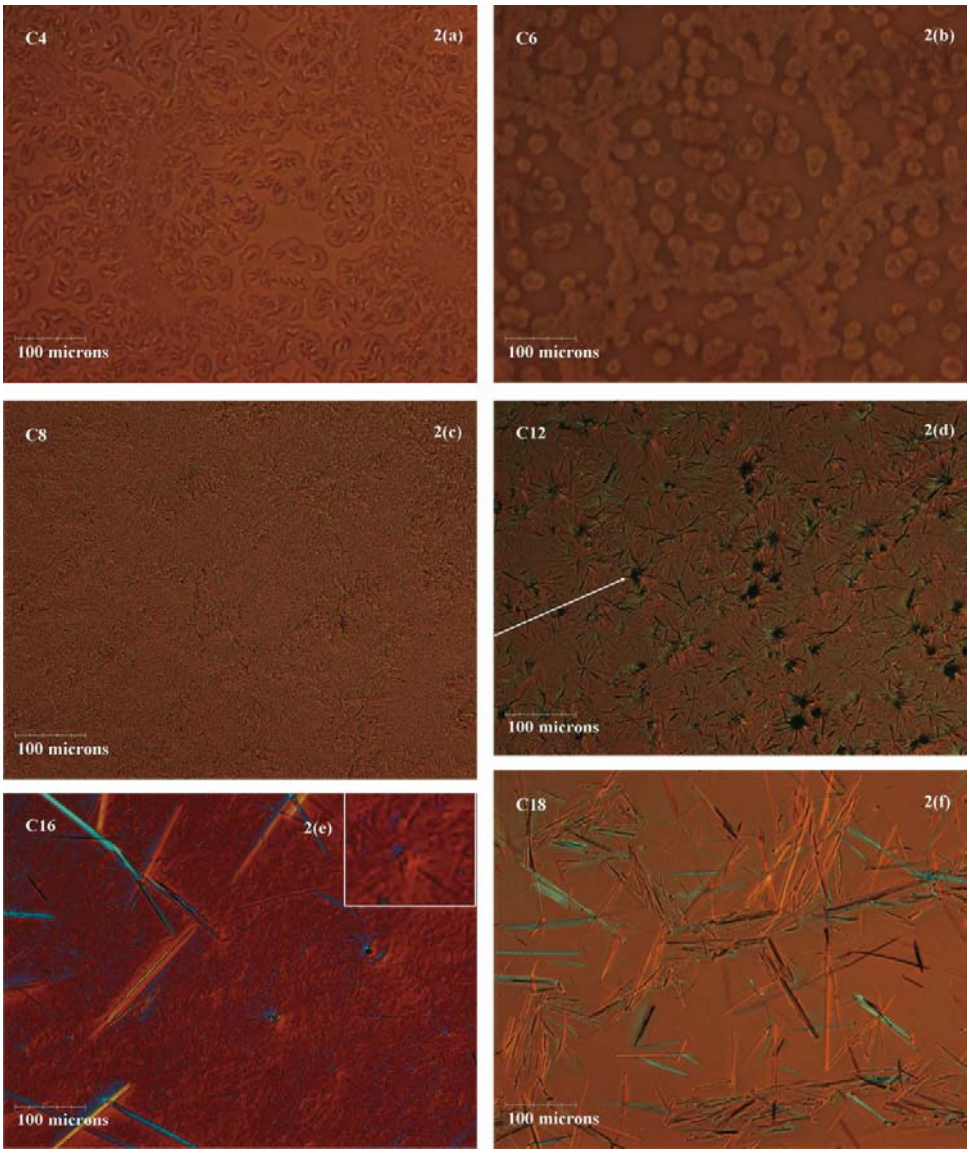
Fig. 2. Optical micrographs of polycarbonate films containing (3 wt%) biscarbamates with different alkyl chain lengths.



The commonly used functional small molecules in optoelectronic devices, such as the *N,N′*–diphenyl-*N,N′*-bis(3-methylphenyl)-[1,1′-biphenyl]-4,4′-diamine (TBD), tritolyl amine (TTA), etc., are nonplanar and do not have segments that are associated with the term "self-assembly". They do not have hydrogen-bonding or extended π-stacking interactions, although our studies showed some weak molecular interaction in terms of phenyl group overlap between the polycarbonate and these small molecules (2). When phase separation occurs, the small molecules diffuse to the surface of the polymer film and crystallize, forming single crystals of various shapes and habits (2, 4, 5).

The design of supramolecular structures using the self-assembling moieties is an active area of research at this time. Hydrogen bonding, π-stacking, and charge transfer are the common elements used for such design. It was also found to be advantageous to use multiple hydrogen-bonding sites, using A-D-A and D-A-D groups, to control the extended assembly such as building a transient polymer based on noncovalent interactions (6, 7). The nature of the side chain also plays a significant role. In such cases, the crystallization and morphology would depend on the number of such sites. In a recent study, we showed that significant differences are found in the crystallization rate, spherulite growth, etc., between molecules with single or double hydrogen bonding motifs as well as the length of the side chain (8, 9). We used carbamates (one hydrogen-bonding N-H…C=O group, asymmetric alkyl side chain lengths) and biscarbamates (two hydrogen bonds and symmetric side chains) to this end (Fig. 1). These materials are candidates for the ink vehicle for phase change ink jet printing (10).

Given that self-assembly means spontaneous association of the molecules facilitated by the types of interactions mentioned above, it would be of interest to examine the nature of such assembly when such small molecules are dispersed in a polymer matrix. Essentially, they are confined in a polymer matrix. Although the field of polymer dispersed liquid crystals is mature, we are not referring to this case. The molecules under discussion are not liquid crystalline. We found that when simple carbamates were dispersed in the poly-

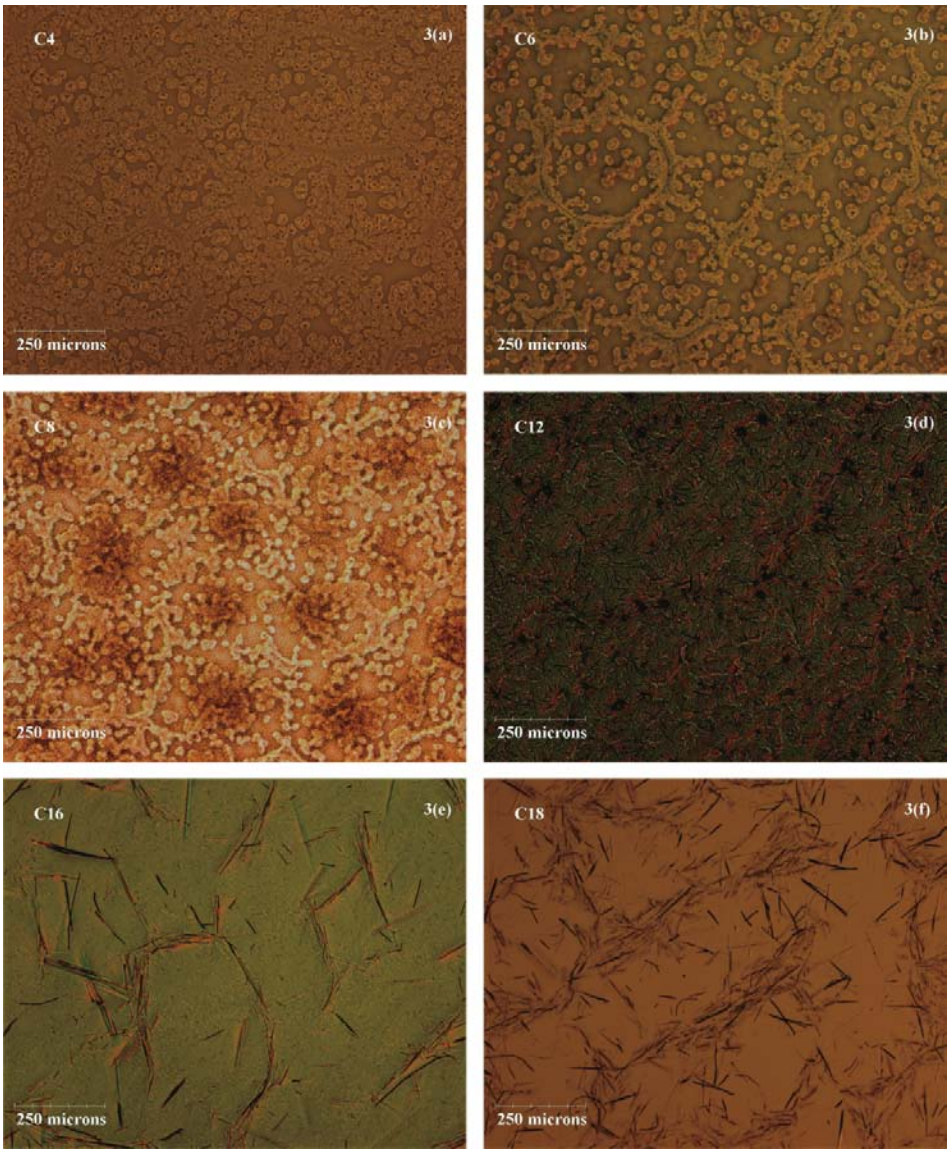
Fig. 3. Optical micrographs of films that were dried at 50 °C.



carbonate matrix, they formed colloidal size domains, of uniform size, with the domain size increasing with the relative concentration of the small molecule in the polymer (11). It was also noted that these domains form in the bulk of the polymer and not the surface. This would indicate that the self-assembly and crystallization occur before the molecules diffuse to the surface.

As we found (8, 9) significant differences in the crystallization features between the simple carbamates (with a single hydrogen bond) and the biscarbamates (with double hydrogen bonds), we now examine the nature of assembly when these biscarbamates are dispersed in the polycarbonate matrix. We used biscarbamates with alkyl side chain length varying from C_4 to C_{18}. Note that the concept of dispersion of self-assembling small molecules in a polymer matrix is new.

Experimental

Poly (bisphenol-A-carbonate) (M_w 64 000, GPC) and chloroform were purchased from Sigma-Aldrich Chemical Company Inc. The synthesis of the biscarbamates has been described elsewhere (9). Generally, 3 wt% of C_4, C_6, C_8, C_{12}, C_{16}, or C_{18} biscarbamate in polymer were used. Solutions were prepared by mixing an appropriate amount of the biscarbamate and polycarbonate in chloroform by an electrical shaker for 24 h. Films were coated on a glass substrate using an electrically driven film coater and dried at a very low rate of solvent evaporation at ambient condition for 24 h and then under vacuum for 48 h. This coater was built by Xerox Research Centre of Canada using a motor from Bodine Electric Company, Chicago, USA. The films were made using a spreader made by P.G. and T. Company. This is the same apparatus that is used by Xerox Research Centre of Canada for fabricating model photoreceptors. A set of films were also dried at 50 °C for 48 h to assess the effect of temperature. The thickness of the films was about 10–15 μm. This film thickness was used for all of our previous work on model charge transport layers of photoreceptors and verified by SEM of cross sections (2). Another set of films

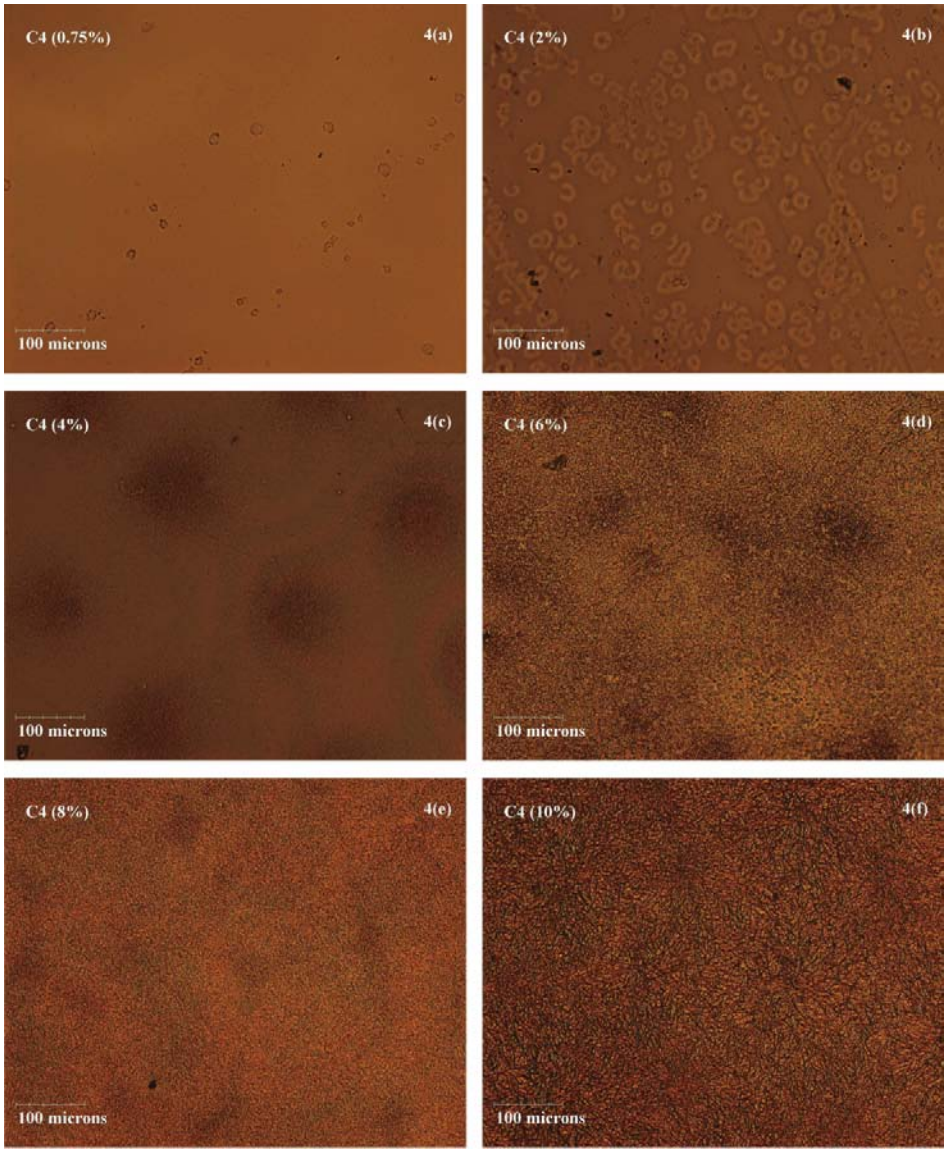
Fig. 4. Optical micrographs of polycarbonate films with different concentrations of C_4: (*a*) 0.75%, (*b*) 2%, (*c*) 4%, (*d*) 6%, (*e*) 8%, and (*f*) 10%, respectively.



of C_4 and C_6 biscarbamates with concentrations ranging from 0.75 to 10 wt% were also prepared.

A Zeiss Axioplan 2 imaging universal optical microscope with Q-imaging Retiga digital camera was used to record optical micrographs of the films. In addition, a JSM-6400 scanning electron microscope was also used. The surface of the films was coated with a conductive layer for taking the SEM images.

The Fourier transform infrared (FTIR) spectroscopic measurements were performed at ambient conditions using a Michelson M120 BOMEM FTIR spectrometer. The BOMEM GRAMS/386 software was used for data collection. The films were attached to the holder by a small magnet and placed in the path of radiation and the spectra were recorded.

Results and discussion

Polarizing optical microscopy

The solutions and the films were transparent in the cases of C_4 and C_6. The biscarbamates used here do not exhibit specific interactions with polycarbonate. In the IR spectra, we did not observe any absorption peak for the as-prepared films that could be identified with non-hydrogen-bonded C=O and N-H groups of the biscarbamates, although the N-H group showed a peak at 3314 cm^{-1} instead of the usual 3337 cm^{-1} that is assigned to the hydrogen-bonded group. Such a shift just confirms the strength of the interactions between the biscarbamates while in the polymer matrix. Fig 2 shows the optical micrographs of the polycarbonate films containing the various biscarbamates. With C_4 and C_6, the self-assembling small molecules form spherical domains, which almost look like a donut. They aggregate to form a meandering chain. The images are not sharp, as it appears that they are covered with a layer of the polymer. Note that polycarbonate itself is amorphous in this case. This is in contrast to the phase separation and crystallization of other small molecules from the polymer matrix where the crystals form on the surface of the polymer film. These may be com-

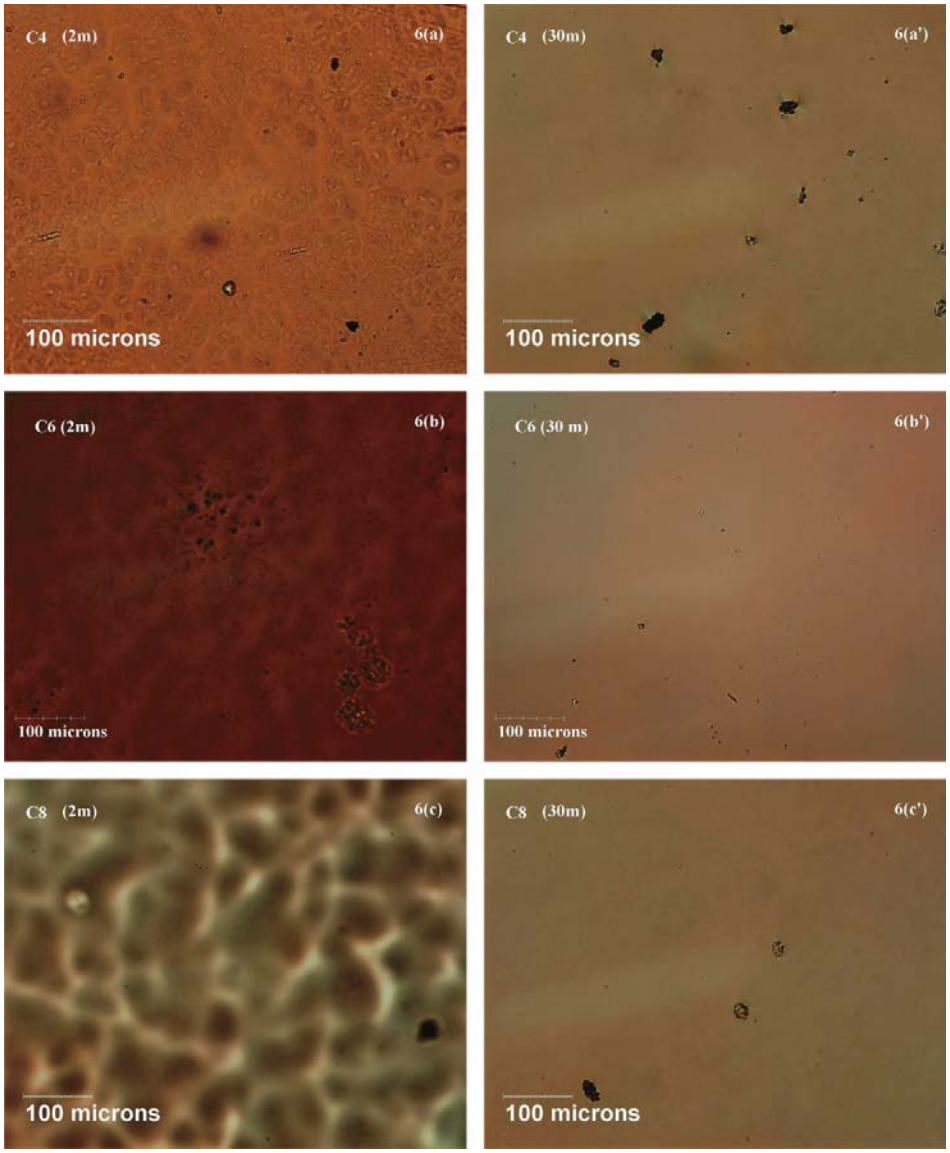
pared with distinct crystals of the charge transport molecules TBD and TTA shown in Fig. 6 of ref. 2*b*, Fig. 3 of ref. 4, and Fig. 11 of ref. 5. As the alkyl chain length increases, the crystals begin to appear, radiating from nodes (as shown by the arrows). It appears that these nodes are protruding crystals that have formed during the diffusion of the small molecule from the bulk (Fig. 2 for C_{12} and C_{16}), but the crystallization had already taken place before the completion of the diffusion step. One of these areas is shown as an inset for C_{16}, which shows radiating lamellae from a protrusion. We have shown before (9) that the rate of spherulite growth is a maximum for C_8, and that of C_{12} is faster than for C_4. Although long needles of crystals are seen in for the case of C_{16}, there are a number of areas that show a bulge and radiating lamellae. It is due to these bulges that we infer that the growth has already taken place before the diffusion of the molecules to the surface.

Similar to the case of polycarbonate – simple carbamates system (11), we see a competition between diffusion of the small molecule from the matrix to the surface and the crystallization in the bulk of the polymer before the diffusion is complete. The rate of crystallization of the simple carbamates by themselves was so fast that we could not study their rates of spherulite formation etc. (8). However, we were able to measure such rates with biscarbamates (9). As discussed before, the rate of self-assembly depends on the length of the alkyl chains and it was seen that the alkyl chains stabilize the structure (9). It was shown using IR spectra that the packing of the alkyl chains is enhanced with the chain length. In the present case with the longer alkyl chain lengths, we see some needle-like crystals on the surface as well as circular asperities that indicate crystals growing in the bulk. As we mentioned before, when small molecules crystallize out of the polymer, they would tend to form crystals of various types of habits that depend on the growth mechanism. In this case the asperities as well as the lamellae radiating from the nodes indicate an irregular spherulite formation. Thus, the faster growth rate of the biscarbamates with shorter alkyl chains result in crystallization below the surface. As the alkyl chain length increases and the growth rate decreases, crystals appear on the surface, as seen in other cases (as in refs. 2, 4, and 5)

Figure 3 shows the micrographs of some of the samples that were dried at 50 °C. The morphologies for C_4, C_6, and

© 2008 NRC Canada

Fig. 6. Optical micrographs of the films heated to the melting temperature of the respective biscarbamate and cooled. The images for samples that were kept at T_m for 2 min (left) and 30 min (right) are shown.



C_{12} are similar to those seen in Fig. 2. For C_8, we observe features similar to those of C_6. Spherical patches are also seen. Perhaps because of the enhanced diffusion to the surface at the higher temperature, C_{16} and C_{18} show crystals on the surface, and the bumps or nodes that were seen in Fig. 2 are not present. Thus the morphology for the biscarbamates with longer alkyl chains differ with this mild thermal treatment. We did not examine this aspect in detail at this time.

The effect of concentration on the domains is shown in Fig. 4 for C_4 biscarbamate. With a concentration of 2%, the morphology is similar to what is shown in Fig. 2. With 4%, "patchy" regions appear that increase in number with concentration. These are the crystalline domains that formed in the bulk of the polymer film. These domains are not clearly seen since these are covered by a layer of the polymer, which is amorphous. However, the polymer film itself shows strain birefringence around these patchy domains. With a high concentration of 10%, dense lamellar growth is seen.

Scanning electron microscopy

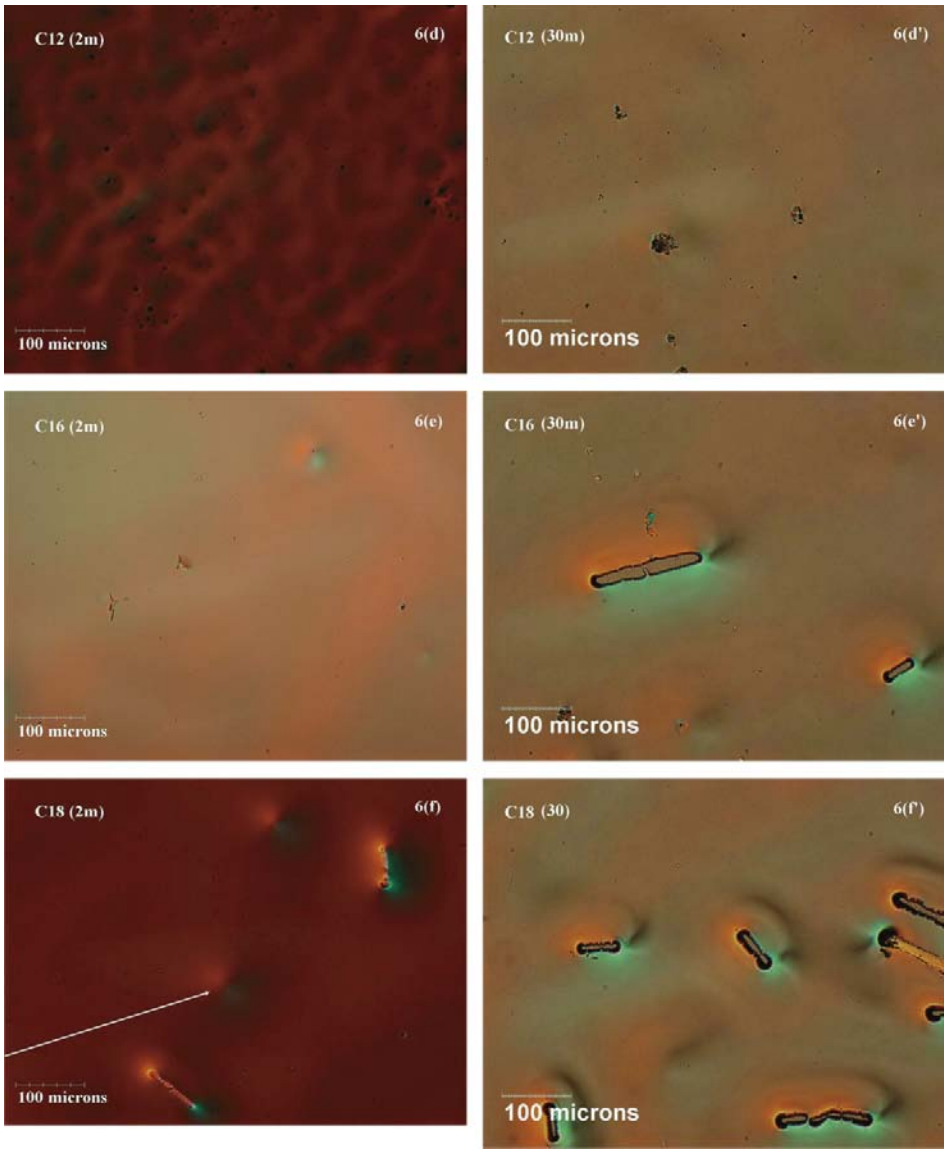
The SEM images shown in Fig. 5 illustrate the subsurface growth of the crystalline domains of the biscarbamates. The image for C_4 shows the enlarged view of the morphology of the donuts seen in Fig. 2. It is seen that the domains appear as if covered by a layer of the polymer. This is quite pronounced in the case of C_{12}. Even with C_{16}, the crystalline lamellae are not well above on the surface of the film. Thus, the self-assembly and the fast rate of crystallization give rise to subsurface morphologies. As we investigate this phenomenon further, we plan to study the effect of the thickness of the film and the SEM images of cross sections.

Reversibility

With the polycarbonate – simple carbamate system we found that the domains can be melted and reformed. The T_m of the simple carbamates vary from 61.2 to 86.5 °C as the alkyl chain length increases from C_4 to C_{18}. The T_m of the

© 2008 NRC Canada

Fig. 6. (*concluded*).



biscarbamates are higher, ranging from 90 to 120 °C (9). Figure 6 shows the micrographs of the polycarbonate–biscarbamate system, which was held at the melting temperature of each of the biscarbamates for two minutes and cooled by removal from the hot plate (all the images on the left side in Fig. 6). Another set of samples was held at the T_m for 30 min and cooled.

The samples that were kept for 2 min at the T_m show morphological features similar to those seen in Fig. 2, but more diffuse. The blur in the images is due to the covering of the polymer layer on the small molecule crystalline domains. The protrusions that were seen for C_{16} in Fig. 2 are seen here for the case of C_{18}. The process of melting and cooling did not result in the crystallization on the surface. We mentioned in the Introduction that the biscarbamates are candidates as vehicles for phase change ink jet inks. Their melt viscosity is only a few centipoises, in the range of 8–12 Cp. The images in Fig. 6 for the samples kept at T_m for two min indicate that the melt of the biscarbamates remained distributed in the bulk and did not form droplets on the surface. Thus, the interfacial tension between the polycarbonate and the melt of biscarbamate has a significant effect on the morphology because of the low melt viscosity of the small molecule. Thus, by heating the composite to the T_m of the biscarbamates and cooling within a short time creates subsurface crystallization

This effect is amplified when the samples are kept at the T_m for 30 min. All the images in Fig. 6 for this case do not show any features. Even with C_{16} and C_{18}, no crystals are observed. It appears that during the 30 min, the melt diffused into the polycarbonate matrix and the crystals did not form again. In the FTIR spectra of these samples, the peaks corresponding to the hydrogen bonded N-H and C=O groups (at about 1684 and 3315 cm^{-1} respectively) were not seen. Instead, a broad peak at about 3450 was seen for the non-hydrogen bonded N-H group. Thus, the 30 min dwell time and subsequent cooling created a molecular dispersion of the biscarbamate in polycarbonate, with no intermolecular hy-

© 2008 NRC Canada

drogen bonded interaction between these molecules, which have the self-assembly motif in their structure.

Conclusions

The morphologies of self-assembling molecules in polymer matrices are different from those of molecules that do not possess self-assembling codes (hydrogen bond, π-interaction, etc.), as seen from this work as well as our previous study on a related system (11). As the small molecules would normally diffuse to the surface of the polymer film and crystallize, we propose that the rate of crystallization due to self-assembly is faster than the diffusion to the surface. This is the cause of the subsurface morphology that was discussed above. The biscarbamates used here do not exhibit specific interactions with polycarbonate. In the IR spectra, we did not observe any absorption peak for the as-prepared films that could be identified with non-hydrogen-bonded C=O and N-H groups of the biscarbamates, although the N-H group showed a peak at 3314 cm^{-1} instead of the usual 3337 cm^{-1} that is assigned to the hydrogen-bonded group. Such a shift just confirms the strength of the interactions between the biscarbamates while in the polymer matrix. There was no shift in the C=O peak of the polycarbonate (1175 cm^{-1}). The T_g of the polycarbonate was reduced to about 125 °C with C_4 and C_6 biscarbamates (3 wt%), but no noticeable change with the longer alkyl side chains.

The longer dwell time of the films at the T_m of the biscarbamates results in the absence of IR peaks due to hydrogen bonded N-H and C=O groups, which indicates the molecular dispersion of the small molecules and the lack of any association between them. Thus, the behavior of self-assembling molecules in a polymer matrix is distinctly different from that of other cases, e.g., the composites of charge transport layers of optoelectronic devices with functional photoactive molecules dispersed in a polycarbonate matrix.

REDOR recoupling in polymer-stabilized liquid crystals undergoing MAS — Two-dimensional NMR applications with strongly aligned proteins[1]

Jean-François Trempe, Ekaterina Pomerantseva, and Kalle Gehring

Abstract: We recently introduced a technique, termed SAD-REDOR, for recoupling residual dipolar couplings in a single-domain polymer-stabilized liquid crystal (PSLC) undergoing magic-angle spinning (MAS). The experiment was demonstrated with ^{1}H–^{15}N dipolar couplings in a small molecule. Here, we show the applicability of the technique to a strongly aligned protein and we describe a novel two-dimensional experiment to generate in-phase and anti-phase (IPAP) doublets in the ^{1}H dimension of an HSQC NMR spectrum. This pulse sequence, SAD-IPAP, was tested on a sample of ^{15}N-labeled ubiquitin (5 mmol/L) in a polyacrylamide-stabilized Pf1 phage liquid crystal (20 mg/mL). ^{15}N–^{1}H residual dipolar couplings (RDCs) were measured with the SAD-IPAP pulse sequence at spinning speeds of 1000 and 1250 Hz. RDSs were also measured using the conventional HSQC-IPAP method in a sample of ^{15}N-ubiquitin dissolved in a solution of Pf1 phage (1 mg/mL). The resulting RDCs were fitted to the solution structure of ubiquitin to estimate the alignment tensor and to determine the accuracy of the measured couplings. The results highlight the benefits of SAD-REDOR for the measurement of RDCs in strongly aligned macromolecules.

Key words: residual dipolar couplings (RDCs), polymer-stabilized liquid crystals (PSLCs), rotational echo double resonance (REDOR) recoupling, magic-angle spinning (MAS), ubiquitin, biomolecular nuclear magnetic resonance (NMR), proteins.

Résumé : Nous avons récemment introduit une technique, nommée SAD-REDOR, pour recoupler des couplages dipolaires résiduels (CDR) dans des cristaux liquides à domaine unique stabilisé par polymérisation (CLSP), en rotation rapide à l'angle magique. Cette technique fut démontrée en recouplant des CDR ^{1}H-^{15}N dans une petite molécule. Dans cet article, nous démontrons l'applicabilité de cette technique pour les protéines fortement alignées. Nous décrivons un nouveau programme d'impulsions bidimensionnel qui génère des doublets en phase et anti-phase dans la dimension ^{1}H d'un spectre de RMN HSQC. Le programme, nommé SAD-IPAP, fut testé sur un échantillon d'ubiquitine enrichie en ^{15}N (5 mmol/L) et mélangé avec un cristal liquide de phages Pf1 (20 mg/mL) stabilisé par de la polyacrylamide. Des CDR ^{15}N-^{1}H furent mesurés avec la méthode SAD-IPAP à des vitesses de rotation de 1000 Hz et 1250 Hz. Des CDR furent aussi mesurés en appliquant la méthode HSQC-IPAP à un échantillon d'ubiquitine-^{15}N dans une solution de bactériophages Pf1 (1 mg/mL). Les CDR expérimentaux furent ajustés à la structure de l'ubiquitine en solution pour estimer le tenseur d'alignement et pour déterminer l'exactitude des couplages mesurés. Les résultats soulignent les bénéfices potentiels des techniques SAD-REDOR pour mesurer des CDR dans des macromolécules fortement alignées.

Mots-clés: couplages dipolaires résiduels, cristaux liquides, phage Pf1, polyacrylamide, recouplage REDOR, rotation à l'angle magique, résonance magnétique nucléaire (RMN), biomoléculaire, protéines, ubiquitine.

Introduction

Liquid crystals have numerous applications in chemistry and biology. Suspensions of fibrous or highly elongated particles can form liquid crystals that align in magnetic fields (1, 2). These aligned liquid crystals can be used to induce orientational order in dissolved molecules for the study of anisotropic interactions such as NMR dipolar and quadrupolar couplings. The orientational order of these liquid crystals can be captured by polymerization of a matrix (3, 4). Our laboratory has taken advantage of polymer-stabilized liquid crystals (PSLC) to measure residual dipolar couplings (RDC) in proteins and small molecules.

Residual anisotropic interactions such as dipolar couplings and chemical shift anisotropies (CSA) measured in dilute liquid crystals are an increasingly important source of NMR structural information in biomolecules (reviewed in

refs. 5–8). Incorporation of these parameters improves the accuracy and precision of biomolecular structure determination and extends the molecular weight limit of biomolecules for which solution NMR methods can be applied. Alignment magnitudes on the order of 10^{-3} scale one-bond heteronuclear couplings (~10^4 Hz) and ^{13}C-^{15}N chemical shift anisotropies (80–200 ppm) into a range that can be conveniently measured by liquid-state NMR methods. A variety of pulse sequences have been proposed for measurements of residual dipolar couplings in proteins, including frequency-based (9) and intensity-encoded (10, 11) NMR experiments. These methods require the acquisition of spectra in both isotropic and liquid crystalline media so that the measured spin–spin couplings or chemical shifts can be compared to extract their anisotropic components.

Residual anisotropic interactions arise from the weak induced alignment of biomolecules, which depends on the nature of the interaction between the biomolecule and the alignment medium as well as on the concentration of the alignment medium and its order parameter. Tuning of the alignment tensor magnitude is typically achieved by varying the alignment medium concentration. If the alignment is too weak, the anisotropic interactions will be too small to be accurately measured, whereas if the alignment is too strong, the linewidths of NMR signals will increase owing to many unresolved dipolar couplings. Moreover, strong alignments result in large, variable (*J*+*D*) spin–spin couplings that result in inefficient and unequal INEPT magnetization transfer steps in multidimensional NMR spectra. These experiments rely on the fact that all the one-bond nuclear spin–spin *J* couplings in a molecule have more or less the same value. The ability to study proteins under strong alignment conditions would open the door to measurement of weaker long-range dipolar couplings and chemical shift anisotropies.

Several approaches have been proposed for mitigating problems arising from strong alignments. These can be classified in two groups: selective radiofrequency decoupling and sample-spinning techniques. The former has been used to decouple unresolved ^{1}H–^{1}H RDCs during the acquisition period using selective ^{1}H RF decoupling in ^{15}N–^{1}H HSQC-IPAP experiments (12) or Flip-Flop ^{1}H-decoupling in ^{13}C–^{1}H HSQC of natural products (13). However, RF decoupling does not resolve the problem of uneven spin–spin magnetization transfer in multidimensional liquid-state NMR experiments. Sample-spinning techniques offer the advantage of removing unwanted anisotropic interactions via time averaging of these interactions. These include variable-angle sample-spinning (VASS) (14, 15), switched angle spinning (SAS) (16–18), and dipolar recoupling on-axis with scaling and shape preservation (DROSS) (19).

Our laboratory recently introduced SAD-REDOR (single-alignment domain rotational-echo double resonance) as a novel approach for the measurement of residual anisotropic interactions (20). It consists of spinning a single-domain PSLC at the magic angle while applying REDOR pulses during the acquisition period. The liquid crystal director of the PSLC is immobilized by the polymer matrix and remains independent of the magnetic field and the spinning axis (4). Radiofrequency pulses are applied synchronously with the rotor angular position to recover specific heteronuclear dipolar couplings. This technique has been successfully applied for the measurement of ^{15}N–^{1}H RDCs in ^{15}N-labeled benzamide.

For the study of isotopically labeled biological macromolecules, it is necessary to extend the SAD-REDOR methodology to multidimensional experiments. In the present work, we present a novel 2D NMR experiment based on SAD-REDOR for the measurement of heteronuclear dipolar couplings in strongly aligned biomolecules. The applicability of the technique is demonstrated by measuring ^{15}N–^{1}H RDCs in ^{15}N-enriched ubiquitin in polyacrylamide-stabilized Pf1 phage. The theoretical aspects of the experiment are reviewed, followed by a presentation of the experiment and a comparison of the RDCs obtained by SAD-IPAP with those measured using conventional methods.

Theory

The heteronuclear dipolar Hamiltonian contains the spin–spin component-dependent term $I_{Az}I_{Bz}$ and the orientation-dependent term ($3\cos^2\theta - 1$), as shown in eq. [1]:

$$[1] \qquad H_{dd}^{AB} = \frac{\mu_0}{4\pi}\frac{\gamma_A\gamma_B\hbar}{r_{AB}^3}\overline{\left\langle\frac{3\cos^2\theta-1}{2}\right\rangle}2I_{Az}I_{Bz} = D_{\max}^{AB}\overline{\langle P_2(\cos\theta)\rangle}2I_{Az}I_{Bz}$$

In a PSLC, the polymer fixes the liquid crystal director so that it does not reorient during sample spinning (4). For molecules aligned in the spinning PSLC, anisotropic interactions therefore vary according to the rotor azimuthal angle. Under magic-angle spinning, the dipolar couplings evolve according to eq. [2]:

$$[2] \qquad D^{AB} = D_{\max}^{AB}\left[\frac{4}{3}\sin\alpha - \frac{1}{3}\sin 2\alpha\right]_{\alpha_0}^{\alpha_0+\omega_r t} = D_{\max}^{AB}\, I_{\alpha_0}^{\alpha_0+\omega_r t}$$

where α is the angle describing rotor azimuth position (Fig. 1*A*), α_0 is the rotor angle at the beginning of the pulse sequence, and ω_r is the sample rotation velocity (21). The integral of D^{AB} for a single rotation period during MAS is zero, which accounts for the vanishing of anisotropic interactions in samples undergoing MAS.

The spin component of the dipolar Hamiltonian can be affected by RF pulses applied at certain intervals synchronously with the sample rotation (22). REDOR inversion π pulses interfere with the MAS averaging. The derivation for a single-domain PSLC undergoing MAS was described in our previous work (20) and the final expression describing the recoupled interaction is shown in eq. [3]:

$$[3] \qquad D^{AB} = D_{\max}^{AB}[I_{\alpha_0}^{\alpha_0+2\pi f_1} - I_{\alpha_0+2\pi f_1}^{\alpha_0+2\pi f_2} + I_{\alpha_0+2\pi f_2}^{\alpha_0+2\pi}]$$

where f_1 and f_2 are the fractions of the rotor period T_r where pulses are applied (Fig. 1*B*). The magnitude and the sign of the dipolar couplings depend on the position of the inversion π pulses (f_1 and f_2) and the orientation of the liquid crystal director at the beginning of the recoupling scheme (α_0). The theoretical recoupling efficiency has been calculated for various pulse schemes as a function of the starting azimuthal

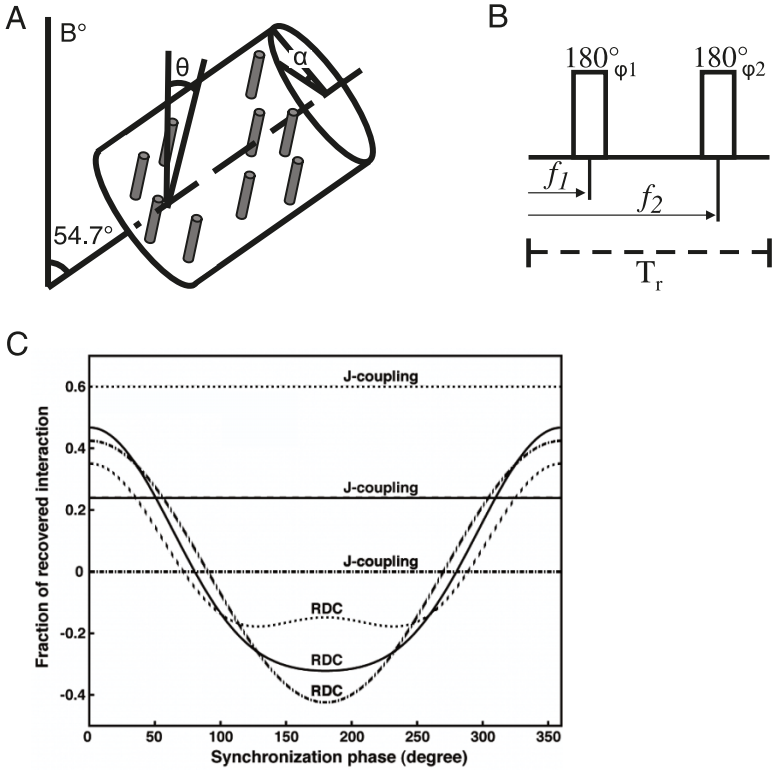
Fig. 1. Schematics and principles of the SAD-REDOR experiment. (*A*) Geometry of the PSLC sample undergoing magic-angle spinning. The thick line represents the PSLC director. The dashed line is the rotor axis. θ is the angle between the liquid crystal director and the external magnetic field, and α is the rotor azimuthal angle. (*B*) REDOR π-recoupling pulse train on one RF channel, synchronously with the acquisition period on the other RF channel. T_r is the MAS rotation period, and f_1, f_2 are the fractions of T_r at which recoupling pulses are applied. (*C*) Scaling of *J* couplings and RDCs during SAD-REDOR recoupling with different pulse schemes: f_1 = 0.1, f_2 = 0.9 (short dashes); f_1 = 0.19, f_2 = 0.81 (solid line); f_1 = 0.25, f_2 = 0.75 (long dashes).



angle α_0 (Fig. 1*C*). The scaling of the isotropic interaction is then optimized by adjusting α_0, within the limits imposed by the choice of f_1 and f_2.

The scalar spin–spin coupling term is also affected by the inversion pulses, but its residual value depends on f_1 and f_2 only, as shown in eq. [4]:

$$[4] \qquad \overline{J_{iso}} = J_{iso}(1 + 2f_1 - 2f_2)$$

where J_{iso} is isotropic scalar coupling, and the overbar denotes the time average of this interaction over a rotor period. Scalar coupling can be eliminated from observation by setting f_1 and f_2 to any combination that differs by 0.5, for example $f_1 = 0.25T_r$ and $f_2 = 0.75T_r$.

Results

To assess the effects of strong alignments on the liquid-state NMR spectra of a protein, we recorded ^{15}N–^{1}H HSQC spectra of ^{15}N-labeled ubiquitin in polyacrylamide-stabilized Pf1 phage in an MAS rotor at different rotor azimuthal positions (Figs. 2*A*–2*C*). Different rotor angular positions correspond to the different orientations of the liquid crystal (LC) director frozen in the polyacrylamide matrix with respect to the external magnetic field. The orientation of the liquid crystal director can be assessed by measuring the residual ^{2}H quadrupolar coupling arising from weakly aligned deuterated water molecules. Dipolar and quadrupolar couplings are both scaled by the term $3\cos^2\theta - 1$, where θ is the angle between the liquid crystal director and the magnetic field (Fig. 1). When the LC director is parallel to the magnetic field, B_0, the maximum ^{2}H residual quadrupolar coupling is detected (14 Hz) and the protein signals disappear (Fig. 2*C*). When the rotor angle is changed such that $0° < \theta < 54.74°$, the protein signal becomes partially observable and a residual quadrupolar coupling of ~5 Hz is measured (Fig. 2*B*). Finally, when the LC director is at the magic angle with respect to the external magnetic field, all second-order anisotropic interactions vanish: the ^{2}H spectrum is a singlet and the ubiquitin ^{15}N–^{1}H HSQC reveals a well-resolved spectrum (Fig. 2*A*). This confirms that the broadening observed in the HSQC of the fully aligned protein originates from anisotropic interactions and not from shorter relaxation times. Anisotropic interactions affect the HSQC spectrum in two ways: the efficiency of the INEPT transfer step is compromised when the total coupling becomes significantly different from the scalar coupling, and the multiple unresolved ^{1}H–^{1}H dipolar couplings broaden the proton signals during the acquisition period. These two effects can be readily eliminated by the use of magic-angle spinning, which averages out dipolar interactions and recovers the HSQC signal (Fig. 2*D*). The MAS spectrum shows improved resolution compared to the static HSQC spectrum acquired at the magic angle due to the improved B_0 homogeneity.

One way to recover dipolar information is to apply a

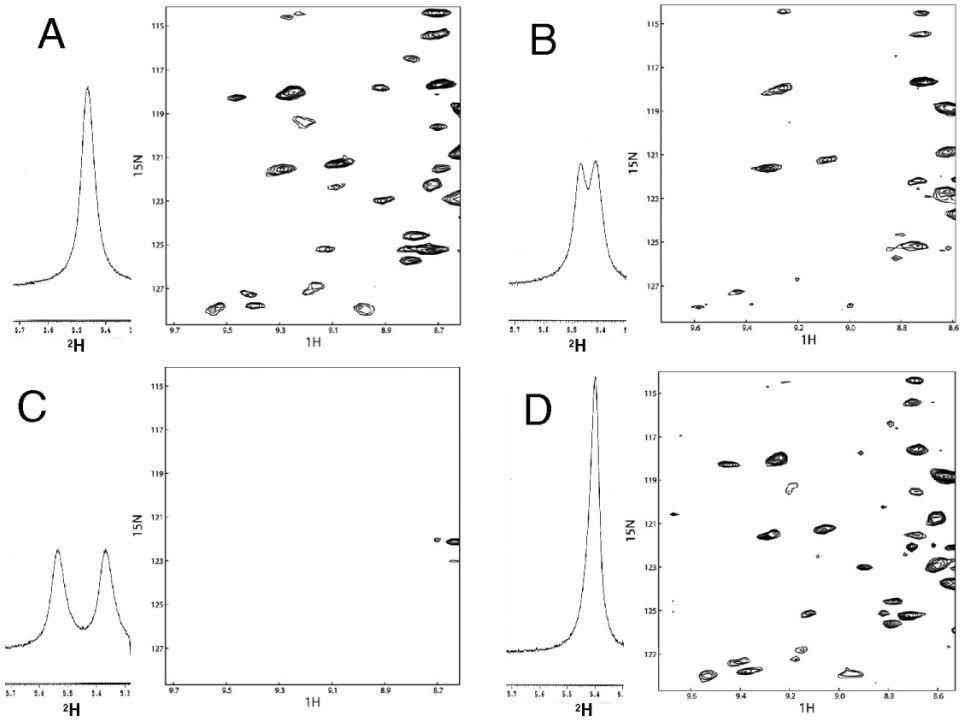
Fig. 2. Static ^{15}N–^{1}H HSQC spectra of ^{15}N-ubiquitin recorded at different rotor angles corresponding to θ angles of 54.74°, 40° and 0° (*A*, *B*, and *C*, respectively) and under MAS (*D*, spinning speed of 1000 Hz). 1D ^{2}H spectra recorded at the same rotor angular positions are shown to the left of each HSQC spectrum. All spectra were recorded with 32 scans and are shown at the same baseline level.



REDOR recoupling pulse train during the acquisition period while MAS is employed throughout the experiment. We took the IPAP approach (23) to generate in-phase and anti-phase magnetizations and named the experiment SAD-IPAP. The pulse scheme of the ^{15}N–^{1}H SAD-IPAP experiment is shown in Fig. 3. The REDOR recoupling pulse train is applied synchronously with the rotor phase on the ^{15}N channel during ^{1}H acquisition. The synchronization is achieved using the Bruker *trigger* command followed by the delay τ*. The delay τ* should be equal to $\tau + t_{1,\,max} - t_1$, where t_1 is the ^{15}N chemical shift evolution period, $t_{1,\,max}$ is the longest t_1 value set in the 2D experiment, and τ is the synchronization delay. In practice, the τ* is set to a large value (larger than the $t_{1,max}$) at the beginning of the experiment and is decreased synchronously as t_1 is increased. This ensures that the rotor phase is always the same during REDOR pulses regardless of the t_1 delay. Furthermore, this ensures that the magnetic field *z*-gradients are always applied at the same rotor azimuthal angle. This is particularly important for the WATERGATE (24) gradients since the magnetization has to be refocused for optimal signal recovery. We applied all gradients for a duration of one rotor period and optimized their strength. As a result of the *z*-gradient adjustment, the overlap of the protein signal with the water spinning side bands was minimized.

The observation of the in-phase and anti-phase components of magnetization can be understood from a product operator description of the experiment. After the INEPT transfer (Fig. 3, point a), $2I_zS_y$ magnetization is generated, where *I* and *S* represent ^{1}H and ^{15}N nuclear spin throughout the text, respectively. During the ^{15}N chemical shift evolution period, t_2, ^{1}H 180° pulse ensures refocusing of the scalar coupling. Thus, at the end of the evolution period (Fig. 3, point b) magnetization evolves into eq. [5]:

$$[5] \qquad 2I_zS_y \cos(\omega_S t_1) - 2I_zS_x \sin(\omega_S t_1)$$

where ω_S is the nitrogen chemical shift. Either term in eq. [5] can generate observable magnetization depending on the phase of the coherence selection pulses. The evolution of the $2I_zS_y \cos(\omega_S t_1)$ term (Fig. 3, point c) is shown in eq. [6]:

$$[6] \qquad 2I_zS_y \cos(\omega_S t_1) \xrightarrow{90^\circ_y\,^1\mathrm{H},\ 90^\circ_x\,^{15}\mathrm{N}} 2I_xS_z \cos(\omega_S t_1)$$

The selection of either in-phase or anti-phase magnetization is achieved by toggling on and off a 180° pulse on the ^{15}N channel (Fig. 3, oblique shaded pulse). When this pulse is present, the magnetization evolves into $I_y \cos(\omega_S t_1)$, which corresponds to the in-phase spectrum. Without the 180° pulse, the term evolves to $2I_xS_z \cos(\omega_S t_1)$ and the anti-phase spectrum is thus recorded. However, since the anti-phase signal is acquired in the dispersion mode, a 90° phase correction is necessary after the Fourier transformation in order to convert the signal into absorption mode.

In-phase and anti-phase spectra were recorded using the SAD-IPAP technique in a PSLC sample (20 mg/mL Pf1) of ^{15}N-ubiquitin at an angular velocity of 1000 Hz. For RDC measurements, the REDOR recoupling scheme with $f_1 = 0.25$, $f_2 = 0.75$ (Fig. 1*B*) was used. This pulse scheme allows recovery of 80% of the RDC measured by comparing an isotropic and anisotropic sample and eliminates the scalar coupling contribution (Fig. 1*C*). The rotor synchronization delay τ* was adjusted so as to maximize the magnitude of the RDCs. Using the IPAP approach, the in-phase and anti-phase spectra were added and subtracted to generate upfield

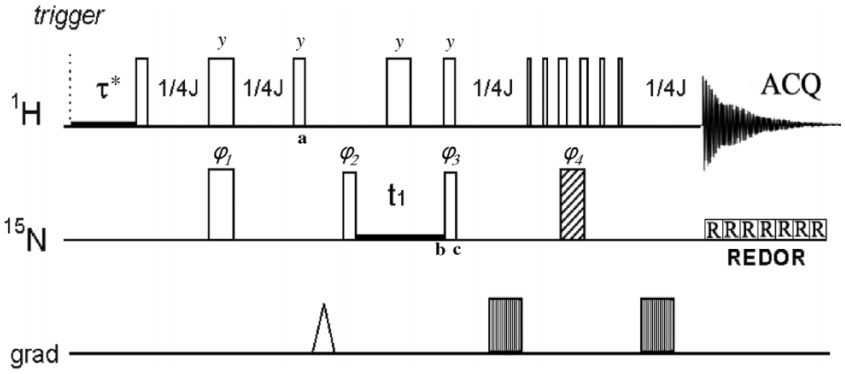
Fig. 3. Pulse scheme of the ^{15}N–^{1}H SAD-IPAP experiment: two dimensional pulse sequence with the REDOR recoupling pulses applied on the ^{15}N channel during acquisition and synchronized with the angular rotor position. Narrow and wide pulses correspond to 90° and 180° flip angles, respectively, with phase *x*, unless indicated. The WATERGATE water suppression scheme (24) was used. Rectangular gradients (vertically shaded) with the duration of one rotor period were used synchronously with the rotor phase for the most effective suppression of the water signal. The selection of either in-phase (I_y), or anti-phase ($2I_xS_z$) magnetization is done by including or removing 180° pulse on ^{15}N channel (oblique shaded pulse). $\phi_1 = 4(x), 4(-x)$; $\phi_2 = x, -x$; $\phi_3 = 2(x), 2(-x)$; $\phi_4 = 4(x), 4(-x)$.



and downfield doublet components (23). The superposition of the resulting spectra is shown in Figs. 4*A* and 4*B*. Residual dipolar couplings can be obtained by subtracting proton frequencies for corresponding peaks in the sum and difference spectra. Figure 4*B* shows a small region of the 2D SAD-IPAP spectra, recorded with the scheme shown in Fig. 3. The sum spectrum is shown in dark grey whereas the difference spectrum is shown in light grey. It is interesting to note that this technique not only allows the measurement of the RDC magnitude, but also reveals the sign of the RDC (Fig. 4*B*).

Because of overlap with the water spinning side bands, only 39 backbone ^{15}N–^{1}H RDCs (out of a total of 69) were accurately measured using the SAD-IPAP experiment at a spinning speed of 1000 Hz. In order to measure additional dipolar constants, we recorded another data set at a spinning speed of 1250 Hz. At different spinning speeds, different spectral regions overlap with the spinning side bands originating from the water signal (Figs. 4*C* and 4*D*). The synchronization delay τ* (Fig. 3) was adjusted to maintain equal splittings for the same peak at both spinning speeds. This allowed the measurement of 57 ^{15}N–^{1}H averaged residual dipolar couplings from both experiments. The remaining missing couplings were either too weak to be measured or severely overlapped.

To overcome the problem of overlapping spinning sidebands, we also measured the recoupled RDCs in the ^{15}N indirect dimension using a SAD-IPAP-indirect experiment (not shown). In this experiment, the REDOR recoupling pulse train is applied on the proton channel synchronously with the rotor during the t_1 (^{15}N) evolution period. This restricts the evolution time to an integer multiple of rotation periods T_r. In practice, the SAD-IPAP-indirect experiment with ^{15}N-ubiquitin yielded broader lines with only 43 measurable couplings and a poor fit (R_{dip} of 34%) to the back-calculated couplings. The reason for the poor accuracy of the RDCs measured in the indirect dimension is still unclear, but it may be explained by a distortion of the PSLC at the high spinning velocity (2000 Hz) required to avoid folding the spectrum in the ^{15}N dimension.

The RDCs measured by the SAD-IPAP-direct technique were fitted to the high-resolution solution structure of ubiquitin (PDB code 1D3Z) by adjusting the principal values of the alignment tensor using the program MODULE (25). To compare the accuracy of the experimental RDCs, backbone ^{15}N–^{1}H residual dipolar couplings for ^{15}N-ubiquitin dissolved in a static 1 mg/mL Pf1 phage liquid crystal were measured using a conventional HSQC-IPAP NMR experiment (23). The quality of the fit was assessed using the quality factor R_{dip}. A fit is considered satisfactory when R_{dip} is below or equal to 20%. The 61 RDCs measured by this conventional method yielded a satisfactory fit with an R_{dip} of 19.2% (Fig. 5*B*). When all 57 RDCs from the SAD-IPAP experiment were fitted, an R_{dip} of 28.1% was obtained. Removal of four outliers (residues 4, 26, 65 and 66) improved the fit significantly, with a resulting R_{dip} of 21.5% (Fig. 5*A*). These outliers correspond to weak peaks in the SAD-IPAP spectra and hence the precision of these measurements is poor with differences between calculated and experimental RDCs above 10 Hz.

Discussion

In this study, we have extended the SAD-REDOR methodology introduced earlier (20) to two-dimensional NMR experiments in order to measure RDCs in biological macromolecules. We developed a new pulse sequence named SAD-IPAP that generates in-phase and anti-phase doublets from which residual dipolar couplings can be directly calculated. This pulse sequence was tested on a strongly aligned protein sample where the largest ^{15}N–^{1}H RDCs would be close to 75 Hz in a static sample, near the size of the scalar coupling (90–95 Hz). Fifty-seven couplings were measured and the accuracy of the RDCs was confirmed by fitting the experimental values to the structure of ubiquitin.

Analysis of the magnitude of the alignment tensor (D_a) suggests that some remaining loss of order still occurs in the spinning PLSC samples. The effective degree of alignment in ^{15}N-ubiquitin as estimated from the *measured* couplings in the SAD-IPAP experiment with a Pf1 concentration of

Superposition of the sum (dark grey) and the difference (light grey) of the in-phase and anti-phase spectra of PSLC ^{15}N-labeled ubiquitin, recorded with the SAD-IPAP pulse scheme shown in Fig. 3: (*A*) large and (*B*) small regions of the spectrum are shown; in-phase ^{15}N–^{1}H SAD-IPAP spectra of ~5 mmol/L ^{15}N-labelled PSLC ubiquitin recorded under MAS at (*C*) 1000 Hz; and (*D*) 1250 Hz. At different spinning speeds different parts of the ubiquitin spectra overlap with the H_2O spinning side bands (enclosed in dashed boxes).

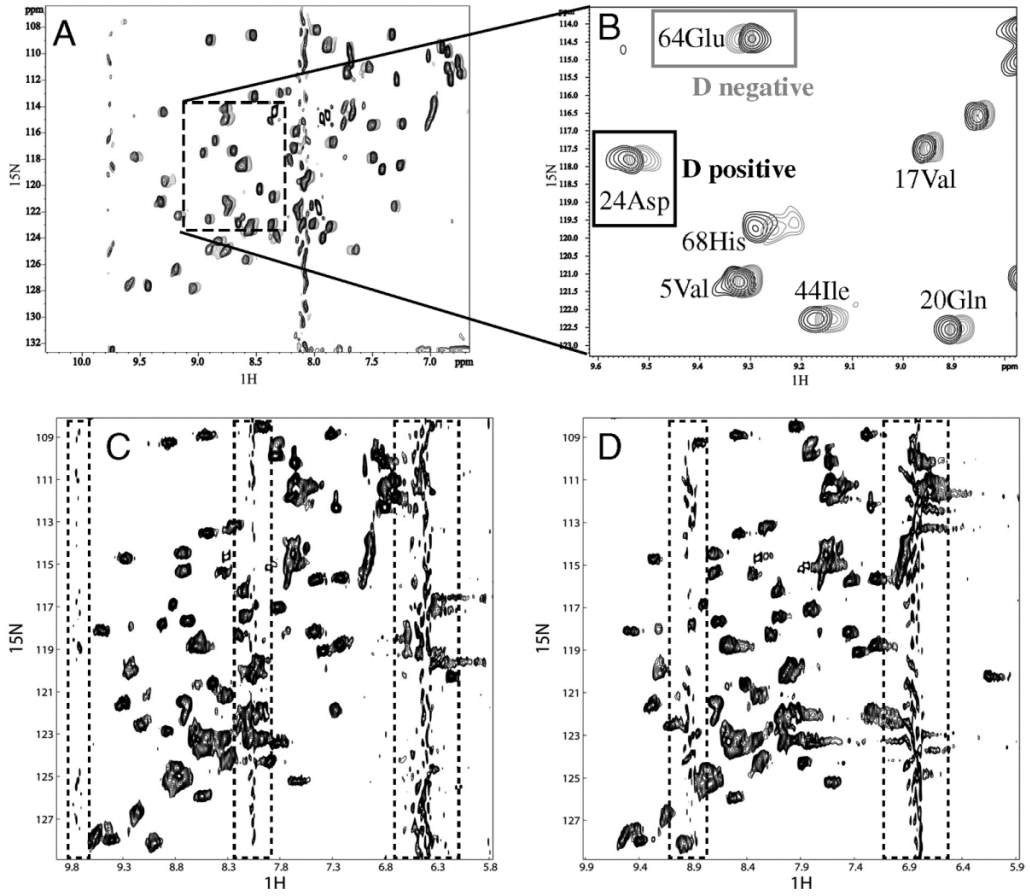

Fig. 5. Correlation plots for $^{1}D_{NH}$ RDCs measured in ^{15}N-ubiquitin. Experimental versus back-calculated RDCs are shown for: (*A*) the MAS SAD-IPAP experiment; and (*B*) conventional static HSQC-IPAP. The principal values of the alignment tensors and fitting statistics are shown as insets in each plot. The high-resolution solution structure of ubiquitin (1D3Z) was used to estimate back-calculated couplings using the program MODULE. The Pf1 phage concentration in the SAD-IPAP experiment was 20 mg/mL, while 1 mg/mL Pf1 phage was used in the conventional HSQC-IPAP experiment.

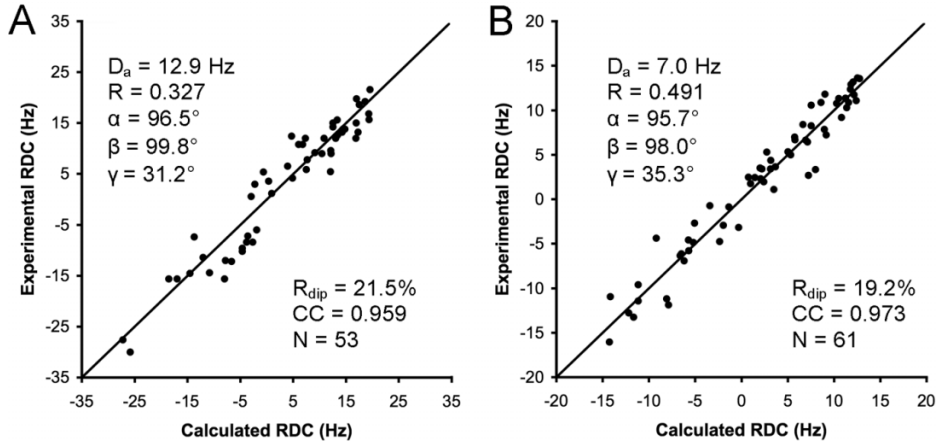

© 2008 NRC Canada

~20 mg/mL was less than twice that of ubiquitin in a 1 mg/mL Pf1 phage suspension. Based on the theoretical coupling efficiency for the pulse scheme (0.4), the degree of alignment in the SAD-IPAP setup would correspond to a D_a value of 32 Hz in a static sample. While polymerization is known to decrease the order parameter of the Pf1 phage liquid crystal (4) (the quadrupolar splitting of the static sample was ~14 Hz and not 20 Hz as expected from the concentration of Pf1 (26)), there remains a 3-fold reduction in the expected alignment magnitude. This presumably originates from distortions in the spinning sample, which reduce the order parameter of the liquid crystal and REDOR recoupling efficiency.

Future work needs to address the mechanical stability of the sample. Polyacrylamide gels made with 7% acrylamide are strong enough to hold the liquid crystal director orientation constant (4) but at angular velocities of several hundred Hz, the gel is subjected to strong centrifugal forces. The presence of air bubbles in the sample can lead to severe mechanical disruption of the gel. As a consequence, the NMR linewidths become larger and the apparent residual dipolar couplings smaller. In the present work, we minimized the formation of air bubbles by slightly changing the rotor cap design—the empty space in the rotor cap was filled with gum. During the sample preparation, the interior volume of the rotor was precisely filled to ensure that there was no air between the cap and the bulk of the polymerizing liquid. This simple modification of the rotor cap improved the stability of the gel and allowed use of spinning speeds of up to 2 kHz compared to 300 Hz used previously (20). The higher spinning speeds led to a better averaging of the interactions and improved spectral resolution.

The SAD-IPAP technique conveniently circumvents the need to measure the isotropic component of the spin–spin coupling and provides the sign of the dipolar coupling. It allows accurate measurement of RDCs in strongly aligned samples where static NMR signals are broadened beyond detection. The method offers the advantages that dipolar couplings are selectively reintroduced, standard instrumentation can be used, and the sensitivity is near that of conventional liquid-state experiments. The mix of solution and solid-state approaches advocated here promises to increase the range of NMR information that can be measured in strongly aligned biomolecules.

Experimental

Protein expression and purification

Uniformly ^{15}N-labelled yeast ubiquitin (K48R) was expressed in the *BL21DE3pLysS E.coli* strain from a *pET3a* plasmid. Cell growth was performed in minimal media M9 (pH 7.0) supplemented with 1 g/L $^{15}NH_4Cl$. The harvested cell pellets were resuspended in 50 mmol/L Tris, 1 mmol/L EDTA, 1 mmol/L PMSF, and 1 mmol/L DTT, buffered to pH 7.5, followed by sonication and centrifugation at 15 000 rpm. The protein was purified by anion exchange chromatography (Mono Q Sepharose) in 20 mmol/L Tris, 0.5 mmol/L EDTA, and 1 mmol/L DTT at pH 8.0, and gel filtration (Superdex-75) in 20 mmol/L HEPES, 40 mmol/L NaCl, 0.5 mmol/L EDTA, and 1 mmol/L DTT at pH 7.0. The protein was concentrated to the appropriate concentration for the NMR expression.

Preparation of the polyacrylamide-stabilized liquid crystal samples

Pf1 phage purification was carried out according to the procedure described previously (26). A solution of 30% acrylamide–bis-acrylamide (37.5:1) was obtained from Bio-Rad Laboratories. A mixture of 5 mmol/L ^{15}N-labelled ubiquitin, 20 mg/mL *w/v* Pf1 phage, 7% *w/v* acrylamide, 0.25% *w/v* 1,9-bisacrylamide, 0.05% *w/v* ammonium persulfate, and 10% D_2O was prepared and polymerization was initiated by the addition of 0.15% *w/v* *N*,*N*,*N*′,*N*′-tetramethylethylenediamine. The samples were rapidly mixed with a vortex and centrifuged to remove the air bubbles, and 40 μL (200 nmole ubiquitin) was immediately transferred into a 4 mm zirconia rotor and polymerized at the magic angle (54.74°) with respect to the external magnetic field $\mathbf{B_0}$, inside the bore 14.1 T magnet for ~12 hrs. The stability of the alignment was monitored by static ^{2}H spectra recorded at different rotor azimuthal angles before and after MAS.

NMR spectroscopy

MAS NMR experiments were performed on a 600 MHz ^{1}H frequency Bruker Avance spectrometer at 303 K with a triple-resonance ^{1}H–^{15}N–^{13}C high-resolution air-driven MAS probe (Bruker Biospin). The synchronization of the pulse program with the rotor phase was achieved using trigger pulse and the optical signal from the rotor that was also used for monitoring the spinning velocity. Typical π/2 pulse lengths were 8.0 and 10.0 μs for ^{1}H and ^{15}N, respectively. The SAD-IPAP experiment was recorded with 256 transients, with 40 complex points and a sweep width of 30 ppm in the ^{15}N dimension, and 512 complex points and a sweep width of 7.5 ppm in the ^{1}H dimension.

Control ^{1}H–^{15}N residual dipolar coupling constants were measured from comparison of HSQC-IPAP experiments (23) recorded on a sample of 0.5 mmol/L ubiquitin with 10% D_2O, with or without 1 mg/mL Pf1 phage, at 303 K. A total volume of 250 μL was used (125 nmole protein). The experiment was recorded in a 5 mm Shigemi NMR microtube on a 600 MHz ^{1}H frequency Bruker Avance spectrometer with 128 transients, with 100 complex points and a sweep width of 34 ppm in the ^{15}N dimension, and 512 complex points and a sweep width of 7.5 ppm in the ^{1}H dimension.

All NMR spectra were processed using either XWINNMR version 2.5 or 3.1 (Bruker Biospin) or NMRPipe (27). Evaluation of spectra and RDC measurements were completed with NMRView (28). Correlation between measured dipolar couplings and couplings calculated back from the structures were performed using MODULE (25). This program was used to evaluate alignment tensor components and Euler angles by minimization of the total χ^2 between calculated and experimental residual dipolar couplings.

Gold-catalyzed efficient regioselective addition of arenes to allenes[1]

Rachid Skouta and Chao-Jun Li

Abstract: An efficient addition of arenes to allenes is developed by using a combination of gold and silver catalysts. The arene addition takes place exclusively at the terminal allenic carbon leading to a highly regioselective carbon–carbon bond formation.

Key words: arenes, allenes, gold, hydroarylation, regioselective, silver.

Résumé : On a mis au point une méthode efficace d'addition d'arènes à des allènes qui fait appel à une combinaison de catalyseurs d'or et d'argent. L'addition de l'arène se fait exclusivement sur le carbone allénique terminal, ce qui conduit à une formation hautement régiosélective de la liaison carbone-carbone.

Mots-clés : arènes, allènes, or, hydroarylation, régiosélective, argent.

[Traduit par la Rédaction]

Introduction

Allenes are three-carbon functional groups possessing a 1,2-diene moiety and serve as potential precursors in the synthesis of highly complex and strained target molecules of biological and industrial importance. Their unique reaction behaviour, where the reactivity is spread over three contiguous carbon atoms, has been successfully applied to the synthesis of pharmaceuticals, dyes, and polymers (1). For example, a nucleophilic addition on allene can occur on any one of the three-carbon atoms depending on the substituents at the terminals of the allene. All three possible regioisomers can be selectively produced by properly substituting at the terminals of the allene (Fig. 1).

Transition metal-catalyzed reactions of allenes have attracted a great deal of interest in recent years (2, 3) because of their highly atom-economical transformations (4). Nucleophilic additions of nitrogen, oxygen, or active methylene toward allenes using transition metals have been extensively studied (5–8).

On the other hand, the addition of arenes to allenes has rarely been studied. Such addition could potentially generate various useful aromatic compounds upon proper controlling of the regioselectivity. It was shown recently that intramolecular addition of arenes to allenes can be activated by Lewis acids such as $BF_3{\cdot}OEt_2$, $TiCl_4$ (9), or a stoichiometric amount of mercury(II) trifluoroacetate (10). In both cases, the addition occurs exclusively at the central sp allenic carbon, generating styrene derivatives (9, 10). On the other hand, Ohno and co-workers (11) reported a synthesis of dihydroquinoline and chromen via gold-catalyzed intramolecular hydroarylation of allenic anilines and phenols. This intramolecular hydroarylation occurs at the terminal sp^2 allenic carbon (11). There is also one report describing the regiospecific intermolecular alkenylation of phenols by 1,1-dimethylallene, at the terminal sp^2 allenic carbon, which can be catalyzed by platinum; however, the reaction is only limited to phenols and always generates a mixture of several products, including ether (due to the oxygen attack), allylation, and cyclization products (12).

In the 1980s, gold and gold salts started to be used in heterogeneous catalysis. Lately, gold-based homogeneous catalyses have been developed rapidly to synthesize fine chemicals (13, 14). Gold is a soft carbophilic Lewis acid, which allows it to activate C–C multiple bonds leading to the formation of the new C–C, C–N or C–O bonds. Moreover, gold catalysts activate C–H bonds, which is the first step in the formation of new bonds (15–23). Recently, we reported a highly efficient gold/silver-catalyzed addition of arenes to imines (24). The unique high efficiency of the arene-imine addition led us to explore the addition of arenes to other compounds, such as allenes (traditionally difficult for Friedel–Crafts type reactions) catalyzed by the gold/silver combination. Furthermore, it is interesting to see what regioselectivity (α, β, or γ) would be obtained for the addition of arenes to allenes with the gold/silver catalyst. Herein

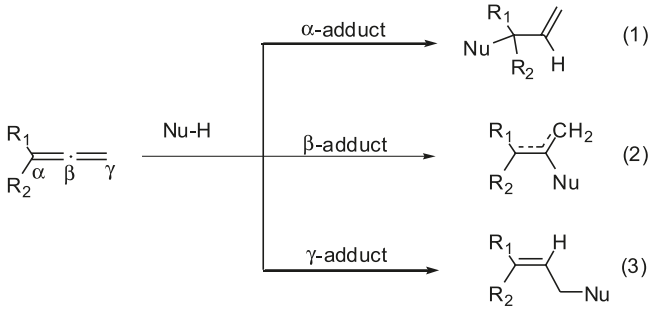
Fig. 1. Three possible nucleophilic additions on allene.

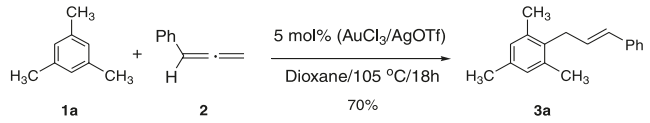


we wish to report an efficient gold/silver-catalyzed addition of arenes to mono-substituted allene, generating exclusive terminal addition products (Scheme 1).

Results and discussions

To begin our study, we examined the reaction of mesitylene (**1a**) with allene **2**, (3-phenylpropa-1,2-diene) (Scheme 1). The 3-phenylpropa-1,2-diene (**2**) can be readily prepared via a Mannich-type reaction followed by a 1,5-hydride shift (25). Initially, mesitylene (**1a**) was reacted with 3-phenylpropa-1,2-diene (**2**) in different solvents, such as nitromethane, 1,2-dichlorethane, chloroform, and dioxane, by using several potential catalysts, such as Ph_3PAuCl, $Ph_3PAuCl/AgOTf$, AuCl/AgOTf, AuBr/AgOTf, $AuBr_3/AgOTf$, and $AuCl_3/AgOTf$ (Table 1). In all cases, the desired product was obtained with varied yields (Table 1, entries 1–11). Low yields were obtained with Ph_3PAuCl and $Ph_3PAuCl/$ AgOTf complexes as catalysts (Table 1, entries 1 and 2). With 5 mol% of AuX (X = Cl, Br)/AgOTf as the catalyst, the effect of solvent was examined (Table 1, entries 3–6). Among solvents being studied, dioxane gave the highest yield (Table 1, entry 6). With dioxane as the optimized solvent, different ratios of gold(I) and gold(III) relative to AgOTf were examined by using the addition of mesitylene with 3-phenylpropa-1,2-diene (**2**), (Table 1, entries 7–10). Reducing

Scheme 1. Gold-catalyzed addition of arenes to allene.



the amount of $AuCl_3/AgOTf$ to 5 mol% and adding traces (1–2 drops) of AcOH gave the best yield (Table 1, entry 11). When using $AuCl_3$ or AgOTf alone as catalyst, low yields of the desired product were obtained (Table 1, entries 12 and 13), whereas with AcOH alone in dioxane, no reaction was observed and the starting materials were recovered completely (Table 1, entry 14).

Subsequently, various arenes, including toluene, anisole, di-, tri-, tetra-, and penta-substituted benzene (**1a**–**1g**), were used for the regioselective addition to 3-phenylpropa-1,2-diene (**2**) by using 5 mol% of $AuCl_3/AgOTf$ as catalyst together with traces (1–2 drops) of AcOH in dioxane. Various arenes were added to the terminal carbon of allene **2** to give the desired products of **3a**–**3g** in good yields (40%–85%) (Table 2, entries 1–4, 6 and 7). However, no reaction was observed in the case of simple benzene (Table 1, entry 9). The use of 1,3,5-triisopropylbenzene (**1e**) and 1,3,5-tri-*tert*-butylbenzene (**1h**) led to lower yields, possibly due to steric effect (Table 2, entries 5 and 8).

Surprisingly, highly electron-rich arenes such as indole **1j** and methyl indole **1k** did not react at all under the present reaction conditions (Scheme 2).

Regarding the reaction mechanism, Yamaguchi and coworkers (26) previously reported an aromatic alkenylation of arenes using an electrophilic organogallium reagent generated from allenylsilane and $GaCl_3$. In this reaction, the silylallene reacts exclusively at the 2-position (Scheme 3, eq. [2]). Alternatively, an initial Friedel–Crafts type addition of the arene to the allene would add to the most stable carbocation formed in the α carbon of the allene (Scheme 3, eq. [1]). However, such a mechanism can be ruled out be-

© 2008 NRC Canada

cause it gives a wrong regioselectivity on the basis of the structure of compound **3a**.

Thus, two plausible mechanisms remain to be considered. (1) Auration of arenes occurs first, as Shi and He (27) reported in the hydroarylation of alkynes (27). The formed arylgold-(III) species could then be added to the allene at the γ-position to give the final products. This step could be aided by the Lewis acid activation of the allene with metal ions or with acid present in the reaction solution, followed by a proton-demetalation (Scheme 4, mechanism 1). (2) Alternatively, gold(III) could simply work as a Lewis acid to activate allene as reported by Reetz and Sommer (28). The cationic gold complex would coordinate to the allene. Nucleophilic attack by the arene from the opposite side and the less sterically hindered terminal site would lead to the formation of a vinylgold intermediate, which would be stereospecifically protonated to form the desired product (Scheme 4, mechanism 2).

Conclusions

In summary, a regioselective and intermolecular addition of arenes to the terminal carbon of mono-substituted allene was developed by using gold and silver catalysts. The scope and mechanism of the reaction are under further investigations.

Experimental

General information

Standard column chromatography was performed on 20–60 mm silica gel using flash-column chromatography techniques (29). Infrared spectra were recorded by an ABB Bomem MB100 instrument. Liquid compounds were recorded as a thin film on NaCl plates and solid compounds as KBr pellets. ^{1}H NMR spectra were recorded on Varian 300, 400, and 500 MHz spectrometers in $CDCl_3$ solution (central peak is 7.26 ppm), and the chemical shifts were reported in parts per million (δ) relative to internal standard TMS (0 ppm). The peak patterns are indicated as follows: s, singlet; d, doublet; t, triplet; dt, doublet of triplet; dd, doublet of doublet; m, multiplet; q, quartet; qt, quintet. The coupling constants, *J*, are reported in Hertz (Hz). ^{13}C NMR spectra were obtained at 75 and 125 MHz and referenced to the internal solvent signals (central peak is 77.00 ppm). MS data were obtained by Agilent 6890N Network GC System/ Agilent 5973 Mass Selective Detector. HR-MS were made by McGill University. Thin layer chromatography was performed using Sorbent Silica Gel 60 F_{254} TLC plates and visualized with ultraviolet light. All reagents were weighed and handled in air, and backfilled under an inert atmosphere of nitrogen at room temperature (RT). Unless otherwise noted all reagents were purchased from Sigma-Aldrich, Strem, and Across and used without further purification.

Preparation of 3-phenylpropa-1,2-diene (2)

Following the general procedure reported in the literature (25), compound **2** was isolated by distillation (bp 80–95 °C at 20 mm Hg (1 mm Hg = 133.322 4 Pa). R_f 0.81 (hexane/ethyl acetate, 40:1). ^{1}H NMR ($CDCl_3$, 400 MHz, ppm) δ: 7.32–7.20 (m, 5H), 6.18 (t, *J* = 7.2 Hz, 1H), 5.16 (d, *J* = 7.2 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz, ppm) δ: 210.2, 134.3, 129.2, 129.0, 127.1, 94.4, 79.2.

Typical experimental procedure for the preparation of compounds 3a–3g

Allene **2** (34.8 mg, 0.3 mmol) in 1 mL of dioxane was added to a sealed tube containing $AuCl_3$ (3.8 mg, 0.0125 mmol), AgOTf (9.6 mg, 0.0375 mmol), and arenes **1a**–**1h** (0.25 mmol) under an atmosphere of nitrogen. A trace amount (1–2 drops) of AcOH was added to the mixture, which was stirred at RT for 5 min and heated at 105 °C for 18 h under an atmosphere of nitrogen. The reaction mixture was cooled to RT and the solvent was evaporated in vacuo. The residue was purified by flash-column chromatography on silica gel with the appropriate mixture of hexane and EtOAc to give compounds **3a**–**3g**.

2-Cinnamyl-1,3,5-triisopropylbenzene (3e)

Following the above general procedure with 1,3,5-triisopropylbenzene, **1e** (60.5 mL, 0.25 mmol) and allene **2** (34.8 mg, 0.3 mmol), the residue was purified by flash-column chromatography on silica gel. R_f 0.44 (hexane/ethyl acetate, 40:1). IR (neat, NaCl, cm^{-1}) ν_{max}: 3025, 2961, 2927, 2868, 1575, 1495, 1448, 1382, 1362, 966, 876, 730, 691. ^{1}H NMR ($CDCl_3$, 400 MHz, ppm) δ: 7.30–7.16 (m, 5H), 7.03 (s, 2H), 6.37–6.19 (m, 2H), 3.62 (d, *J* = 5.6 Hz, 2H), 3.20 (qt, *J* = 6.8 Hz, 2H), 2.90 (qt, *J* = 6.8 Hz, 1H), 1.28 (s, 3H), 1.27 (s, 3H), 1.24 (s, 6H), 1.23 (s, 6H). ^{13}C NMR ($CDCl_3$, 125 MHz, ppm) δ: 147.3, 147.0, 138.1, 130.7, 130.4, 130.2, 128.6, 127.0, 126.2, 121.2, 34.4, 31.8, 31.0, 29.6, 24.6, 24.3. MS (GC/MS) *m/z* (%): 320 (M^+), 305, 291, 277, 263, 250, 235, 216, 201 (100), 187, 173, 157, 143, 131, 115, 105, 91, 77, 65. HR-MS calcd. for $C_{24}H_{32}$: 320.250 40; found: 320.250 08.

3-Cinnamyl-1,2,4,5-tetramethylbenzene (3f)

Following the above general procedure with 1,2,4,5-tetramethylbenzene, **1f** (33.5 mg, 0.25 mmol) and allene **2** (34.8 mg, 0.3 mmol), the residue was purified by thin-layer chromatography. R_f 0.70 (hexane/ethyl acetate, 40:1). IR (neat, NaCl, cm^{-1}) ν_{max}: 3026, 2963, 2921, 2865, 1468, 1440, 1002, 965, 867, 733, 692. ^{1}H NMR ($CDCl_3$, 500 MHz, ppm) δ: 7.32–7.16 (m, 5H), 6.91(s, 1H), 6.33–6.23 (m, 2H), 3.61 (d, *J* = 5.1 Hz, 2H), 2.26 (s, 6H), 2.22 (s, 6H). ^{13}C NMR ($CDCl_3$, 125 MHz, ppm) δ: 137.9, 136.3, 133.9, 132.9, 130.2, 130.1, 128.6, 128.3, 127.1, 126.2, 33.7, 20,8, 15.8. MS (GC/MS) *m/z* (%): 250 (M^+) (100), 235, 220, 205, 189, 178, 157, 146, 131, 115, 105, 91, 77, 65, 51. HR-MS calcd. for $C_{19}H_{22}$: 250.172 15; found: 250.171 40.

1-Cinnamyl-2,3,4,5,6-pentamethylbenzene (3g)

Following the above general procedure with 1,2,3,4,5-pentamethylbenzene, **1g** (37.0 mg, 0.25 mmol) and allene **2** (34.8 mg, 0.3 mmol), the residue was purified by thin-layer chromatography plate. R_f 0.45 (hexane/ethyl acetate, 40:1). IR (neat, NaCl, cm^{-1}) ν_{max}: 3026, 2960, 2927, 1596, 1447, 1062, 966, 795, 752, 735, 693. ^{1}H NMR ($CDCl_3$, 400 MHz, ppm) δ: 7.36–7.20 (m, 5H), 6.37–6.32 (m, 2H), 3.65 (d, *J* = 5.2 Hz, 2H), 2.31 (s, 6H), 2.30 (s, 3H), 2.29 (s, 6H). ^{13}C NMR ($CDCl_3$, 125 MHz, ppm) δ: 138.0, 133.6, 133.3, 132.8, 132.7, 130.2, 128.8, 128.7, 127.1, 126.2, 34.2, 17,1,

Targeted engineering of *Cupriavidus necator* chromosome for biosynthesis of poly(3-hydroxybutyrate-*co*-3-hydroxyhexanoate) from vegetable oil[1]

Jun Mifune, Satoshi Nakamura, and Toshiaki Fukui

Abstract: Previous studies have demonstrated that heterologous expression of PHA synthase from *Aeromonas caviae* ($PhaC_{Ac}$), capable of accepting (*R*)-3-hydroxyacyl-CoA of C_4–C_7 as substrates, could confer the ability to PHA-negative mutant of *Cupriavidus necator* PHB$^-$4 to synthesize poly((*R*)-3-hydroxybutyrate-*co*-(*R*)-3-hydroxyhexanoate) [P(3HB-*co*-3HHx)] from vegetable oils. The mutation point within *pha* operon in PHB$^-$4 was determined to be a single nonsense mutation within the PHA synthase gene ($phaC_{Cn}$), suggesting the much lower β-ketothiolase and NADPH-dependent acetoacetyl-CoA reductase activities observed in this strain would be a polar effect of the mutation. For further efficient biosynthesis of P(3HB-*co*-3HHx) copolyester, *C. necator* wild strain H16 was engineered by homologous recombination targeting the chromosomal $phaC_{Cn}$, and the PHA productivity was compared with previous PHB$^-$4-derived strain harboring $phaC_{Ac}$ on a multi-copy plasmid (PHB$^-$4/pJRDEE32d13). A strain $H16C_{Ac}$, in which $phaC_{Cn}$ was substituted for $phaC_{Ac}$ on the chromosome, could produce P(3HB-*co*-3HHx) from soybean oil with high productivity, but the 3HHx fraction in the accumulated polymer was decreased. Meanwhile, H16ΔC/pJRDEE32d13, that lost region for the original synthase gene and expresses exochromosomal $phaC_{Ac}$, grew and accumulated PHA with similar properties to the PHB$^-$4-derived strain. The results of enzyme assay suggested that low β-ketothiolase activity might be relevant for decrease of growth ability accompanied by increase of 3HHx composition when soybean oil was fed as a sole carbon source.

Key words: poly(hydroxyalkanoates), poly(3-hydroxybutyrate-*co*-3-hydroxyhexanoate), PHA synthase, *Cupriavidus necator*, vegetable oil.

Résumé : Des études antérieures ont démontré que l'expression hétérologue de la synthase de PHA de *Aeromonas caviae* ($PhaC_{Ac}$), qui est capable d'accepter comme substrat du (*R*)-hydroxyacyl-CoA comportant de quatre à sept atomes de carbone, peut conférer l'habilité au mutant PHA-négatif du *Cupriavidus necator* PHB$^-$4 de synthétiser du poly ((*R*)-3-hydroxybutylate-*co*-(*R*)-3-hydroxyhexanonate) [P(3HB-*co*-3HHx)] à partir d'huies végétales. On a déterminé le point de mutation de l'opéron *pha* du PHB$^-$4 en effectuant une seule mutation dans le gène de la synthase de PHA ($phaC_{Cn}$), ce qui suggère que les activités beaucoup plus faible de réductase de l'acétoacétyl-CoA dépendantes sur la β-cétothiolase et la NADPH résultent d'un effet polaire de la mutation. Afin d'améliorer la biosynthèse du copolyester [P(3HB-*co*-3HHx)], on a modifié la source sauvage H16 du *C. necator* par une recombinaison homologue orientée vers le ($phaC_{Cn}$) chromosomique et on a comparé la productivité en PHA avec celle obtenue antérieurement avec la souche dérivée du PHB$^-$4 présentant un ($phaC_{Ac}$) sur un plasmide à plusieurs copies (PHB$^-$4/pJRDEE32d13). Une souche de $H16C_{Ac}$ dans laquelle on a substitué un $phaC_{Ac}$ par un $phaC_{Cn}$ sur le chromosome peut produire du P(3HB-*co*-3HHx) à partir de l'huile de soya avec une productivité élevée, mais la fraction de 3HHx dans le polymère accumulé est diminuée. Par ailleurs, le H16ΔC/pJRDEE32d13, cette région perdue du gène original de la synthase, et du $phaC_{Ac}$ d'expressions exochromosomales ont permis de faire croître et d'accumulé du PHA ayant des propriétés similaires à celles du produit obtenu à partir de la souche dérivée du PHB$^-$4. Les résultats des essais avec les enzymes suggèrent qu'une faible activité β-cétothiolase pourrait jouer un rôle important dans la diminution de la de l'habilité à faire croître qui accompagne l'augmentation de la composition 3HHx quand on utilise uniquement de l'huile de soya comme source de carbone.

Introduction

Recent apprehension about huge amounts of waste materials has prompted much interest in bio-based materials. Poly(hydroxyalkanoates) (PHAs), synthesized by a number of bacteria as carbon- and energy-storage materials, are thermoplastics that can be produced from renewable carbon resources and be completely biodegraded to CO_2 and H_2O, so they have come under investigation as potential alternatives to petroleum-based plastics (1, 2).

A homopolymer of (*R*)-3-hydroxybutyrate, P(3HB), is the most abundant PHA in nature, and it is produced by a variety of bacteria. This polyester is usually synthesized from acetyl-coenzyme A (acetyl-CoA) via three-step reactions catalyzed by β-ketothiolase (PhaA), NADPH-dependent acetoacetyl-CoA reductase (PhaB), and PHA synthase (PhaC). In *Cupriavidus necator*, all the three genes form a single operon with the order of *phaC-A-B*, and are constitutively expressed. It has been revealed that the PHA synthase from *C. necator* ($PhaC_{Cn}$) is specific to short-chain-length (*R*)-3-hydroxyacyl-CoA monomers of C_3–C_5. The bacterial P(3HB) generally has molecular mass from 10^5 to 10^6 and is a highly crystalline thermoplastic resembling polyethylene and polypropylene. Nevertheless, the hard and brittle properties of this homopolyester with low elongation before breaking (5%–6%) have hampered its wide range of application (3–5).

To improve mechanical properties of this homopolyester, biosynthesis of random copolyesters consisting of 3HB with a second monomer unit has been attempted (1–5). So far, microbial synthesis of 3HB-based copolyesters, for example, those containing (*R*)-3-hydroxypentanoate or 4-hydroxybutyrate has been demonstrated by feeding the related alkanoates or hydroxyalkanoates into the medium as precursors for the desired second monomer units (6). However, such additional supplement of precursor compounds tends to increase the production cost of PHAs.

Aeromonas caviae, isolated from soil, accumulates flexible poly((*R*)-3-hydroxybutyrate-*co*-(*R*)-3-hydroxyhexanoate) [P(3HB-*co*-3HHx)] from alkanoates of even carbon numbers or vegetable oils as a single carbon source (7, 8). Our research group has cloned a gene ($phaC_{Ac}$) for PHA synthase with unique substrate specificity (C_4–C_7) from this bacterium, and has demonstrated that introduction of $phaC_{Ac}$ into a mutant strain of *C. necator*, PHB$^-$4, could not only restore the PHA negative phenotype but also confer the ability to synthesize P(3HB-*co*-3HHx) copolyester from fatty acids or oils (9–11). This result indicated that the substrate preference of PHA synthase was one of the major factors for determining monomer composition of PHAs, as well as that *C. necator* cells are equipped with channeling pathway(s) for generation of (*R*)-3HHx-CoA via β-oxidation. The recombinant *C. necator* harboring $phaC_{Ac}$ accumulated the copolyester with 4–5 mol% 3HHx up to 76 wt% of dry-cell mass from inexpensive vegetable oils (10). However, in batch cultivation, the copolyester productivity by this recombinant (0.034 g/L·h) was lower than P(3HB) productivity of wild strain H16 (0.077 g/L·h) when 1% olive oil was supplied as a carbon source. This was mainly owing to relatively poor growth of the host strain PHB$^-$4 that had been obtained by chemical mutagenesis (12).

In this study, *C. necator* H16 chromosome was engineered by specific homologous recombination that avoided unintended negative effects of random mutagenesis. We applied $phaC_{Ac}$ for the recombination to achieve biosynthesis of P(3HB-*co*-3HHx) via β-oxidation, and then evaluated PHA productivity of the newly constructed strains.

Results

Identification of a mutation site within *pha* operon in *C. necator* PHB$^-$4.

The PHA-negative mutant of *C. necator* (PHB$^-$4) was frequently used as a host strain for heterologous expression of PHA synthase gene from various sources to evaluate their in vivo polymerizing properties and to construct recombinant strains for the production of copolyesters (9, 10, 13–17). A few reports described that the genotype of this strain was $phaC^-A^-B^-$ based on low activities of the corresponding enzymes (13, 14) (see below). However, to our knowledge, there has been no identification of the mutation site within *pha* operon in PHB$^-$4. We determined nucleotide sequence of a 5.0 kbp fragment containing *pha* operon (amplified with ReP-N and RePhbB-C primers) by direct sequencing. As a result, only one single-nucleotide substitution of G to A was identified, corresponding to TGG coding Trp107 in $PhaC_{Cn}$ protein to TAG stop codon; consequently, the translation of $phaC_{Cn}$ was interrupted after Ala106 by the nonsense mutation. No other mutation was detected within the nucleotide sequence of the remaining region, indicating that the native promoter region and $phaAB_{Cn}$ genes were intact in PHB$^-$4.

Targeted engineering of *C. necator* H16

PHA synthase from *A. caviae* is a unique enzyme that can accept (*R*)-3HHx-CoA in addition to short-chain-length of (*R*)-3HA-CoA of C_4-C_5 as substrates, so the gene $phaC_{Ac}$ is useful for development of P(3HB-*co*-3HHx)-producing recombinant bacteria (9, 10, 16, 17). In particular, *C. necator* PHB$^-$4 strains expressing harboring $phaC_{Ac}$ from plasmids have been demonstrated to be good producers for P(3HB-*co*-3HHx) copolyester from related alkanoates, but the slower growth of the host strain PHB$^-$4 limited the overall PHA productivity on vegetable oils (10). As the decrease of growth ability of PHB$^-$4 was predicted to be caused by unknown mutations induced through chemical mutagenesis, two recombinant strains based on *C. necator* wild strain H16 were constructed by specific homologous recombination targeting the original PHA synthase gene, $phaC_{Cn}$, on the chromosome (Fig. 1A). Markerless recombinant strains $H16C_{Ac}$

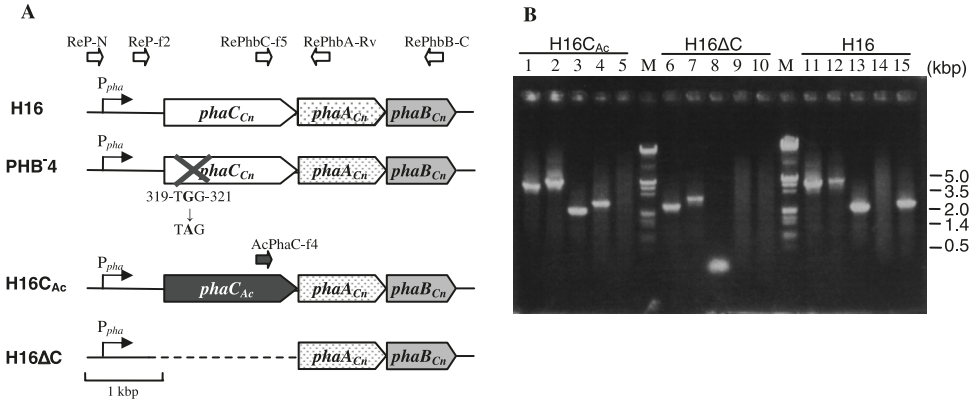
Fig. 1. (A) Schematic diagram of genotypes of *C. necator* strains used in this study. Small arrows indicate primers for PCR as below. (B) PCR analysis of recombinant strains of *C. necator* H16C_{Ac} (lanes 1–5), H16ΔC (6–10), and wild strain H16 (11–15) using primer sets of ReP-f2/RePhbB-C (lanes 1, 6, 11), ReP-N/RePhbB-C (2, 7, 12), ReP-f2/RePhbA-Rv (3, 8, 13), AcPhaC-f4/RePhbB-C (4, 9, 14), and RePhbC-f5/RePhbB-C (5, 10, 15). Lane M; molecular mass standard (λ DNA digested with EcoRI and HindIII).



(*phaC*$_{Cn}$::*phaC*$_{Ac}$) and H16ΔC (Δ*phaC*$_{Cn}$) were constructed by substituting chromosomal *phaC*$_{Cn}$ for *phaC*$_{Ac}$ and deleting *phaC*$_{Cn}$ region from the chromosome, respectively, using pop-in – pop-out recombination technique. PCR analysis of each the strains confirmed the occurrence of the desired recombination (Fig. 1B). These strains have no unintended mutation on the chromosome and do not require additional antibiotics to maintain the phenotype. H16ΔC/pJRDEE32d13 was obtained by transconjugation of H16ΔC with *Escherichia coli* S17–1 harboring pJRDEE32d13. This strain possesses multi-copies of *phaC*$_{Ac}$ on the plasmid under the transcriptional control by its native promoter region, distinct from H16C_{Ac} having one copy of *phaC*$_{Ac}$ with *C. necator pha* promoter.

Enzyme assay

Table 1 shows the results of enzyme assay (PHA synthase, β-ketothiolase, and NAD(P)H-acetoacetyl-CoA reductase) in each strain of *C. necator* grown on fructose. As represented in several reports (13–15), the activities in PHB⁻4 were much lower than those in H16 besides NADH-acetoacetyl-CoA reductase. The negligible activity of PHA synthase agreed with the nonsense mutation within *phaC*$_{Cn}$; however, the significant decrease of β-ketothiolase and NADPH-acetoacetyl-CoA reductase was inconsistent with the presence of intact *phaAB*$_{Cn}$ genes. In contrast, only PHA synthase activity was completely lost in H16ΔC, as expected. This strain had similar levels of NADPH- and NADH-acetoacetyl-CoA reductase activities as the wild strain, whereas β-ketothiolase activity (986 U/g) was decreased to one fourth of that in H16 (3677 U/g). H16C_{Ac} showed high activities for all enzymes examined, but the activity of PHA synthase encoded by chromosomal *phaC*$_{Ac}$ (177 U/g) was lower than that in H16 (715 U/g). The transconjugants of PHB⁻4 and H16ΔC harboring pJRDEE32d13 exhibited high PHA synthase activity derived from *phaC*$_{Ac}$ on the multi-copy plasmid, although the reason for much higher activity in PHB⁻4 was unclear. As a result, the strains H16C_{Ac} and H16ΔC/pJRDEE32d13 were confirmed to express *phaC*$_{Ac}$-derived PHA synthase along with NADPH-acetoacetyl-CoA reductase and β-ketothiolase with higher activities than previous recombinant strain PHB⁻4/pJRDEE32d13.

PHA production by engineered strains of *C. necator*

PHA-producing ability of the constructed strains was examined with fructose, octanoate, or soybean oil as a carbon source, and compared with those of wild strain H16 and PHB⁻4/pJRDEE32d13 (Table 2). The strain H16 accumulated P(3HB) homopolymer from all carbon sources examined, where cell growth and P(3HB) accumulation via β-oxidation (on octanoate or soybean oil) were better than glycolysis (on fructose). Unlike H16, PHB⁻4/pJRDEE32d13 could synthesize P(3HB-*co*-3HHx) from octanoate and soybean oil, but the lower cell yield on soybean oil led to lower copolyester production (1.9–2.0 g PHA/L) than P(3HB) biosynthesis by H16 (3.0–3.1 g PHA/L), as seen in a previous study (10). No effect of soybean oil concentration (0.5% or 1.0%) was observed on cell growth and PHA yield for H16 and PHB⁻4/pJRDEE32d13. The strain H16C_{Ac} also exhibited P(3HB-*co*-3HHx)-biosynthetic ability via β-oxidation owing to the function of PHA synthase from *A. caviae*. This strain could grow as well as wild strain on 0.5% soybean oil or octanoate (3.7 g dry cells/L), and interestingly, the final cell yield (5.2 g dry cells/L) reached to 1.4 fold larger than that of H16 on 1% soybean oil. PHA content within the cells was also increased up to 89 wt%, resulted in improved PHA productivity of H16C_{Ac}. However, the 3HHx fraction in the copolyester chains synthesized by H16C_{Ac} (3.9 mol% from octanoate and 0.7 mol% from soybean oil) was decreased when compared with those by PHB⁻4/pJRDEE32d13 (13.0 mol% and 2.5–2.7 mol%, respectively). The strain H16ΔC/pJRDEE32d13 also produced P(3HB) from fructose and P(3HB-*co*-3HHx) from octanoate or soybean oil, and unexpectedly, its growth and PHA-producing properties were very similar to PHB⁻4/pJRDEE32d13 in spite of higher β-ketothiolase and NADPH-acetoacetyl-CoA reductase activities within this strain.

The engineered *C. necator* strains harboring foreign *phaC*$_{Ac}$ accumulated high-molecular-mass PHAs both from fructose and soybean oil (Table 3). The number average molecular mass (M_n) and the polydispersity (M_w/M_n) of

P(3HB-*co*-3HHx) copolyesters from soybean oil were within 4.4–6.9 × 10^5 and 2.0–2.2, respectively, which were slightly lower than those of P(3HB) homopolymer from fructose (8.2–8.9 × 10^5 and 2.3–2.5, respectively). These values were comparable to those of P(3HB) produced by wild strain of *C. necator*.

Discussion

This study aimed to establish new recombinants for biosynthesis of P(3HB-*co*-3HHx) copolyester, overcoming the drawback of previous PHB⁻4-derived strains. We first found that *pha* operon in PHB⁻4 has a single nonsense mutation within $phaC_{Cn}$. Inactivation of $phaC_{Cn}$ gene by the incomplete translation coincided with the results of enzyme assay (Table 1), and the PHA-negative phenotype of PHB⁻4 was obviously caused by the lack of PHA synthase. Despite the presence of intact $phaAB_{Cn}$ genes, β-ketothiolase and NADPH-dependent acetoacetyl-CoA redutase activities were drastically decreased in PHB⁻4. One feasible explanation for this phenomenon could potentially be a polar effect of the mutation in $phaC_{Cn}$ on expression of downstream $phaAB_{Cn}$ genes. Otherwise, we cannot exclude the possibility that regulation system for expression of *pha* genes or for activities of the corresponding enzymes might be modified by random mutagenesis. It should be considered that β-ketothiolase and NADPH-acetoacetyl-CoA reductase activities were actually low but not completely abolished in PHB⁻4. This strain would be a leaky mutant for expression of $phaAB_{Cn}$, or possess other genes responsible for these activities. Indeed, recent whole-genome analysis of *C. necator* H16 revealed the presence of multiple homologs of *phaA* and *phaB* (18). Interestingly, recombinant PHB⁻4 strains expressing PHA synthase alone still had high ability to produce PHA even from fructose, despite the low thiolase and reductase activities (Table 2 and previous studies (9, 10, 13–15)). These facts suggested that, in *C. necator* cells, such low activities for these two steps were enough to provide (*R*)-3HB-CoA from acetyl-CoA precursor toward PHA biosynthesis.

We initially estimated that the lower growth ability of PHB⁻4 on vegetable oils might be caused by some unintended mutations against genes involved in incorporation and (or) degradation of triacylglycerols, because PHB⁻4/pJRDEE32d13 showed comparable growth and PHA accumulation to H16 on fructose and octanoate. Therefore, $H16C_{Ac}$ was constructed by replacing original PHA synthase gene on *C. necator* chromosome by $phaC_{Ac}$. This strain actually showed excellent growth and PHA productivity on soybean oil, which was assumed to be due to the absence of unknown mutation on the chromosome. However, this assumption was not supported by the fact that the strain H16ΔC/pJRDEE32d13, not having any unintended mutation like $H16C_{Ac}$, showed similar behaviour to PHB⁻4/pJRDEE32d13 in growth and PHA biosynthesis. The common biochemical property of these strains, distinct from H16 and $H16C_{Ac}$, was lower β-ketothiolase activity (Table 1). The activity in H16ΔC (986 U/g) was higher than that in PHB⁻4 (148 U/g), but much lower than those in H16 and $H16C_{Ac}$ (>3000 U/g). Although the reason for the decrease of β-ketothiolase activity in H16ΔC has not been clear, the flanking region between $phaA_{Cn}$ and P_{pha} region created after the $phaC_{Cn}$ deletion may not be suitable for efficient gene expression of $phaA_{Cn}$. The results obtained here suggested that the lower β-ketothiolase activity appeared to be relevant to the diminished growth on vegetable oils. The low interconversion rate between two acetyl-CoA molecules and acetoacetyl-CoA may affect overall efficiency for degradation of long-chain fatty acids through β-oxidation.

In terms of copolyester biosynthesis, $H16C_{Ac}$ and H16ΔC/pJRDEE32d13 accumulated P(3HB-*co*-3HHx) via β-oxidation as well as PHB⁻4/pJRDEE32d13. Among them, $H16C_{Ac}$ incorporated less 3HHx unit into the copolyester chains than the others. That is, the higher β-ketothiolase activity may tend to decrease 3HHx fraction in the copolyester. In *C. necator* cells grown on alkanoates or triacylglycerols, (*R*)-3HHx-CoA would be supplied via β-oxidation by unknown channeling pathway(s), while (*R*)-3HB-CoA can be generated via two possible pathways: channeling from β-oxidation cycles and dimerization of acetyl-CoA. Although flux distribution of the two possible pathways for (*R*)-3HB-CoA formation has not been determined yet in PHA biosynthesis by *C. necator* cells, high β-ketothiolase activity along with high acetoacetyl-CoA reductase activity in $H16C_{Ac}$ was supposed to enhance (*R*)-3HB-CoA formation from acetyl-CoA, leading to relative decrease of (*R*)-3HHx-CoA provision via β-oxidation. Consequently, 3HHx fraction would be decreased in copolyesters produced by $H16C_{Ac}$. Such increase of 3HB fraction was also observed in *Aeromonas hydrophila* and recombinant bacteria harboring *phaC1* from *Pseudomonas* spp. when multi-copies of $phaAB_{Cn}$ were introduced into the cells (19–21). Alternatively, there would be a possibility that low β-ketothiolase activity, which favours thiolysis, may increase intracellular concentration of β-oxidation intermediates of C_6, which would likely promote (*R*)-3HHx-CoA formation via β-oxidation as described previously (22).

The strain $H16C_{Ac}$ constructed here was a superior PHA producer, exhibiting high growth ability on soybean oil, but the physical properties of P(3HB-*co*-3HHx) produced by this strain were inadequate for practical application owing to the too small fraction of longer 3HHx unit. Further metabolic modification is now underway to increase 3HHx fraction into the copolyester chains with the higher productivity.

Materials and methods

Bacterial strains and plasmids

C. necator H16 (DSM428), PHB⁻4 (DSM541) (12), and recombinant strains derived from them were cultivated at 30 °C in a nutrient-rich (NR) medium containing 10 g of meat extract, 10 g of polypeptone, and 2 g of yeast extract in 1 L of distilled water. *E. coli* DH5α and S17–1 (23) were grown at 37 °C on a Luria–Bertani (LB) medium (24). Kanamycin (200 mg/L for *C. necator* and 50 mg/L for *E. coli*) or ampicillin (50 mg/L for *E. coli*) was added to the medium when necessary.

A recombinant plasmid pJRDEE32d13 containing $phaC_{Ac}$ with its native promoter region was reported previously (9). pTA2 (Toyobo) and pK18mobsacB (25) were used for general gene manipulation and homologous recombination of

© 2008 NRC Canada

C. necator, respectively. Transconjugation of *C. necator* with *E. coli* S17–1 harboring mobilizable plasmid was performed as described previously (9).

Construction of recombinant strains

A 5.0 kbp fragment of *pha* operon with its promoter region (P_{pha}-$phaCAB_{Cn}$) and a 1.8 kbp fragment of $phaC_{Ac}$ were amplified using primer sets with *C. necator* H16 genomic DNA and pEE32d1 (9) as a template, respectively. The sequences of primers used are ReP-N, ATGGATCCCGGGCAAGTACCTTGCCGACATC; RePhbB-C, GCCCGGATCCTATGCCCAACAAGGCACTAAG; AcPhaC-Fw2, GGTTCGAATAGTGACGGCAGAGAGACAATCAAATCATGAGCCAACCATCTTATGGC; and AcPhaC-Rv2, AACCTGCAGGCCTGCCGGCGCCGTGCATATGCAAGCGTCATGCGGCGTCCTCCTCTG (underlined sequences indicate BamHI, BamHI, Csp45I, and SbfI, respectively). The amplified fragments were subcloned into pTA2 by using TA-cloning procedure to obtain pTA2CAB (P_{pha}-$phaCAB_{Cn}$) and pTA2C′ ($phaC_{Ac}$). pTA2CAB was digested with Csp45I and SbfI to remove $phaC_{Cn}$ region and then ligated with a 1.8 kbp Csp45I-SbfI restriction fragment of $phaC_{Ac}$ from pTA2C′. The resulting plasmid was digested with BamHI, and the 5.0 kbp fragment containing P_{pha}-$phaC_{Ac}$-$phaAB_{Cn}$ was inserted into pK18mobsacB at the corresponding site to obtain pK18C′AB. For construction of another plasmid pK18AB, Csp45I-SbfI-double digested pTA2CAB was blunted followed by self-ligation and a 3.2 kbp BamHI restriction fragment (P_{pha}-$phaAB_{Cn}$) from the resulting plasmid was inserted into pK18mobsacB.

pK18AB was transferred by conjugation from *E. coli* S17–1 to *C. necator* H16. Transconjugants (pop-in strains), formed by integration of pK18AB into the chromosome by homologous recombination, were selected on Difco Simmons Citrate Agar (BD diagnostics) medium containing 200 mg/L kanamycin at 30 °C for several days. The cells of one isolate were then inoculated onto NR agar medium containing 10% (*w*/*w*) sucrose and cultivated for 48 h at 30 °C for counter selection of pop-out strains after excision of the plasmid region via the second recombination event (25). PCR analysis was carried out to confirm genotype of the sucrose-resistant isolates, and a strain lacking $phaC_{Cn}$, referred as H16ΔC, was selected. The strain $H16C_{Ac}$ with $phaC_{Cn}$::$phaC_{Ac}$ genotype was also constructed from H16ΔC by using pK18C′AB according to the similar procedure. The sequences of primers used for PCR analysis (Fig. 1) are ReP-f2, GTGCGGTCGAGGGCTTCCAG; RePhbA-Rv, CGCGGTGCGGGCGGCGGATA; RePhbC-f5, CTGGGCGATACGTCAAAGCC; and AcPhaC-f4, GCAGGGCATGAAGCTGTTTG.

Production and characterization of PHA

PHA production by *C. necator* strains was carried out on a reciprocal shaker (115 strokes/min) at 30 °C in 500 mL flasks with 100 mL of nitrogen-limited mineral salts (MB) medium, which was composed of 0.9 g of $Na_2HPO_4{\cdot}12H_2O$, 0.15 g of KH_2PO_4, 0.05 g of NH_4Cl, 0.02 g of $MgSO_4{\cdot}7H_2O$, and 0.1 mL of trace-element solution (26) in 100 mL of distilled water. A filter-sterilized solution of fructose or octanoate was added to the medium at a final concentration of 0.5% (*w*/*v*), and kanamycin was added at 50 mg/L when necessary. Soybean oil was directly added to the medium at 0.5 or 1.0% (*v*/*v*). After the cultivation for 72 h, cells were harvested, washed with distilled water, and then lyophilized.

PHA content within cells was determined by gas chromatography (GC) after methanolysis of the dried cells in the presence of 15% sulfuric acid, as described previously (26). The intracellular polymer accumulated was extracted with stirring for 72 h at room temperature, purified by precipitation with methanol, and then filtered with poly(tetrafluoroethylene) (PTFE) membrane to remove the cell debris. Molecular mass measurements by gel-permeation chromatography (17, 27) and ^{1}H NMR analysis were performed as described previously (8).

Enzyme assay

C. necator cells grown on fructose at 30 °C for 36 h were washed and resuspended in 50 mmol/L Tris-HCl buffer (pH 8.0). The cells were disrupted by sonication for 3 min and then centrifuged with low speed (1500g, 5 min, 4 °C) to obtain whole-cell extract containing PHA granules. PHA synthase activity in the whole-cell extracts was determined by a spectroscopic assay using chemically synthesized (*R*)-3HB-CoA and 5,5′-dithiobis(2-nitrobenzoic acid) (28). The whole-cell extract was further centrifuged with high speed (12 000g, 20 min, 4 °C) to obtain soluble protein fraction. β-Ketothiolase was assayed in 400 μL of 50 mmol/L Tris-HCl buffer (pH 8.5) containing 0.1 mmol/L acetoacetyl-CoA, 0.1 mmol/L CoA-3Na, 25 mmol/L $MgCl_2$, and the decrease in absorbance at 304 nm derived from Mg^{2+}-acetoacetyl-CoA complex was recorded (29, 30). Acetoacetyl-CoA reductase was assayed in 400 μL of 50 mmol/L Tris-HCl buffer (pH 8.0) containing 0.1 mmol/L acetoacetyl-CoA, 0.2 mmol/L NAD(P)H, and the decrease in absorbance of NAD(P)H was measured at 340 nm (31). The extinction coefficients of Mg^{2+}-acetoacetyl-CoA complex at 304 nm and NAD(P)H at 340 nm were taken to be 19.5×10^3 mol^{-1} L cm^{-1} and 6.22×10^3 mol^{-1} L cm^{-1}, respectively (29).

REVIEW / SYNTHÈSE

Poly(hydroxyalkanoates): Biorefinery polymers with a whole range of applications. The work of Robert H. Marchessault[1]

William J. Orts, Geoffrey A.R. Nobes, Jumpei Kawada, Sophie Nguyen, Ga-er Yu, and François Ravenelle

Abstract: This review describes the characterization and application of poly(hydroxyalkanoates), PHAs, a remarkable family of natural polyesters with a wide array of useful properties and potential applications. It places specific emphasis on the work of Robert H. Marchessault and his many colleagues outlining how Marchessault's body of work both shaped the field and complemented the work of his contemporaries. Particular attention will focus on the "rediscovery" of poly(β-hydroxybutyrate), PHB, the first PHA to be discovered, from the late 1950s onward, highlighting some of the historical aspects of PHA's path toward commercial applications. It will also cover why this class of materials is so unique, including PHA structure–properties relationships, its unique crystalline behaviour, in vivo – in vitro synthesis and degradation, and PHA-graft-copolymers.

Key words: poly(hydroxyalkanoate), PHA, poly(β-hydroxybutyrate), PHB, biopolymers, bacterial polyester, random copolymers, polymer single crystals, graft copolymers.

Résumé : Dans cette revue, on décrit la caractérisation et l'application des polyhydroxyalcanoates, PHA, une famille remarquable de polyesters naturels qui possèdent une grande variété de propriétés utiles et d'applications potentielles. On met l'accent sur les travaux de Robert H. Marchessault et de ses nombreux collaborateurs, en exposant les grandes lignes de la façon dont ces travaux ont orienté le domaine tout en apportant un complément à ceux de ses contemporains. On porte une attention particulière sur la "redécouverte" du poly(β-hydroxybutyrate), PHB, le premier PHA à être découvert depuis les années 1950 et on met l'accent sur quelques-uns des aspects historiques qui ont conduit les PHA vers des applications commerciales. On explicitera aussi pourquoi cette classe de matériaux est si unique, y compris les relations structure/propriétés des PHA, leur comportement cristallin unique, leur synthèse et leur dégradation in vivo/in vitro ainsi que les copolymères PHA greffés.

Mots clés : polyhydroxyalcanoate, PHA, poly(β-hydroxybutyrate), PHB; biopolymères, polyesters bactéricides, copolymères aléatoires, cristaux uniques de polymères, copolymères greffés.

Introduction

In the late 1980s, Marchessault and colleagues discussed the wide range of potential commercial uses for poly(β-hydroxyalkanoates), PHAs, in a paper that described "biorefinery polymers in search of applications" (1). Like many visionaries, Marchessault was ahead of his time, but his career-long passion and technically advanced view of PHAs have proven prescient. This year, for example, the US firm Metabolix has joined forces with agricultural processing giant, Archer Daniels Midland (ADM), to construct a $200 MM PHA biorefinery in Iowa, with initial commercial production in 2008 set to boost PHA production in the US by 110 million pounds per year (2).

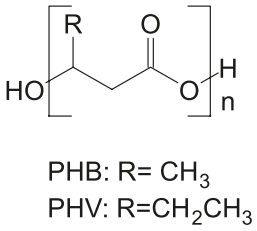
The term "biorefinery", a word not widely used in the 1980s, also hit the mark. Biorefineries have only recently emerged into the public consciousness with the rapid ascent of ethanol production. Bacterial PHA, as Marchessault et al. (1) aptly implied, is the perfect biorefinery complement to ethanol in that it adds much needed flexibility and value to biorefinery operations. The Metabolix–ADM plant not only hedges ADM's bet on ethanol production, but it also meets rising demand for "green plastics", polymers that displace petroleum, minimize greenhouse gases, and are environmentally friendly. PHAs provide biodegradable, sustainable materials from a wide array of biomass sources.

PHAs are a family of polyesters, outlined in Scheme 1, that are generally produced by fermentation, but can also be synthesized or produced in transgenic plants. Their remarkable range of properties results from the variability in the R substituent off the β carbon, which can range from a simple methyl group in the case of poly(β-hydroxybutyrate), PHB, ethyl for poly(β-hydroxyvalerate), PHV, to long chain moieties, including rings, double bonds, and branched chains. As the number of side-chain carbons increases, PHAs become increasingly elastomeric.

The fact that bacteria could produce polyesters was discovered by Lemoigne in the mid-1920s (3, 4) but was virtually unknown to chemists and biochemists until its "rediscovery" in the 1950s and early 1960s. The history of PHAs, and specifically poly(β-hydroxybutyrate), PHB, has been shaped by a series of events (3) or "eras" as follows: (*i*) discovery and characterization of PHB by Lemoigne (4–9), (*ii*) rediscovery of PHB in the 1950s and early 1960s (3), (*iii*) commercial exploitation of PHAs by ICI in the early to mid-1980s (10–11), (*iv*) discovery that PHAs represented a family of more than a 100 different aliphatic polyesters that could be tailored based on feedstock and microbe selection (12–18), (*v*) application of genetic engineering to produce PHAs in *E. coli* and other optimized strains (18–22), and (*vi*) production of PHAs in plant tissue by insertion of genes coded for PHA synthesis (23–24).

The rediscovery of PHA in the 1950s and 1960s paved the way for multiple significant events. For example, the biotechnological advances toward improved microbial production of PHAs in genetically improved *E. coli*, which sparked commercialization efforts by Metabolix and later, Procter and Gamble (25), were the direct offshoot of the elegant biochemistry describing PHA biosynthesis as part of the β-oxidation cycle put forth by Weibull (26), Williamson and Wilkinson (27), Doudoroff and colleagues (28–29), and

Scheme 1. Structure of PHA.



Merrick and colleagues (30–32). Subsequent production of PHAs in transgenic plants by Somerville and colleagues (23–24) and then Monsanto during the 1990s relied on knowledge of PHB synthase enzymes and the specific genes encoded for their production.

This review will not be an all-encompassing overview of the PHA field, a task that could be best described as Herculean, and one that has been covered before (3). Rather, it will focus on the rediscovery of PHB and PHAs from the late 1950s onward, placing specific emphasis on the work of Marchessault and colleagues. Marchessault's body of work both shaped the field and complemented the work of his contemporaries. As such, this review will highlight some of the historical aspects of PHAs rediscovery. It will review why this class of materials is so unique, including PHA structure–properties relationships, its unique crystalline behaviour, in vivo – in vitro synthesis of granules, PHA degradation mechanisms, and PHA graft-copolymers.

Brief history of PHB and its rediscovery

PHB homopolymer was discovered in the mid-twenties by Maurice Lemoigne and summarized in papers that were clearly ahead of their time (4–9). In attempts to discover why certain soil bacteria cause acidification of their media broth during fermentation, Lemoigne obtained material that was characterized as a "polymer of 3-hydroxybutyric acid" (4). This material accumulates in cells during the absence of critical nutrients by converting excess carbon into aliphatic polyester (Scheme 1). During the next 30 years, Lemoigne and co-workers characterized this unique material, correlating properties to its high molecular mass and even suggesting that it was the result of in vivo "dehydration polymerization" (9), concepts that were far-reaching in their scope.

Despite such remarkable vision, the work of Lemoigne remained relatively obscure until the late 1950s and early 1960s. Almost simultaneously, several research groups described the biosynthetic routes toward PHB accumulation within bacterial cells (26–29), while chemists began to discover its unique polymer properties.

A significant part of the re-awakening of PHB-related work stemmed from the discovery by Doudoroff and Stanier at UC Berkeley that poly(β-hydroxybutyrate) was the product of oxidative assimilation of organic substrates that were metabolized via acetate or butyrate (28–29). Michael Doudoroff, a pioneer in microbial bioenergetics (as exemplified by the critical importance of the well-known Entner–Doudoroff pathway describing the fundamentals of glucose-to-pyruvate conversion in bacteria), inspired Joseph Merrick to explore the biosynthesis and breakdown mechanisms of

© 2008 NRC Canada

PHB (30), work that required new substrates and new methodologies. For this work, Merrick (*i*) prepared radioactive PHB by growing cells of *Bacillus megaterium* in the presence of radioactive acetate, (*ii*) isolated labeled β-hydroxybutryic acid, (*iii*) synthesized the CoA derivative by a mixed anhydride procedure, and (*iv*) ultimately used these tools to describe many aspects of enzymatic synthesis of PHB (31–32).

Merrick and Doudoroff established that PHB synthase, which catalyzes the polymerization of PHB from β-hydroxybutyryl-CoA, was located on PHB granules (isolated from either *R. rubrum* or *B. megaterium* in his study). More surprisingly, granules from *R. rubrum* were also "self-digesting", suggesting that these inclusions were acting as carbon sinks, repositories for excess carbon as energy reserve (32), similar in function to starch in plants and fats in mammals.

When Joseph Merrick left Doudoroff's lab at UC Berkeley and moved east to join the Microbiology Department at Syracuse University, he inspired a group of other biochemists and microbiologists within the department – Donald Lundgren, Ralph Schlepecky, and Richard Alper. This group made a concerted effort to advance the fundamental understanding of this carbon-reserve material (33–35), and soon enlisted the help of a relative newcomer to the University, Chemistry Professor R.H. Marchessault, to characterize their "waxy" materials (36). Over the next ten years, this Syracuse "gang of four" provided leading multidisciplinary research on PHB by combining world-class biochemistry and microbiology with important polymer research.

In 1962, Marchessault and colleagues began a program to elucidate the structure–properties relationship of these unique materials (36), a research quest that helped to define Marchessault's career and continues to bear fruit. News of the commercial exploitation of PHB started in 1963 when *Chemistry and Engineering News* published an article concerning the development by W.R. Grace & Co. of a biopolymer thermoplastic material, which was produced by fermentation. The article described how PHB was extracted from bacterial cells in the form of sub-micron granules (1 micron = 1 μm), i.e., "storage polymers", similar to starch granules from corn, wheat, and other small grains. Treatment of dried cells with acetone followed by chloroform extraction resulted in a polymer yield of nearly 80%. As the story goes (36), Francis Werber, VP of Research at Grace and Co. had hired Jim Baptist, their first biochemist, to study fruit ripening inside cartons sealed with polyvinyl films. Instead, Jim Baptist convinced Werber that academic breakthroughs describing stereoregular PHB from bacteria were a source of marketable polyester. PHB was a film-forming, hydrophobic, biocompatible thermoplastic similar to polypropylene, and offered the added benefit of biodegradability (37).

Over the next three to four years. Werber and Baptist took out several patents on PHB (38, 39), produced landmark measurements on the mechanical properties of PHB-derived films and moldings, and showed that PHB is remarkably stereoregular, exhibiting > 99% isotacticity. PHB film properties rivaled those of polypropylene; however, they soon realized that large-scale processing (part-forming) would be hampered by the thermal instability of PHB. With a melting point of 170–180 °C, and a degradation point of ~190 °C, PHB's processing window is very limited, a drawback that ultimately caused termination of the project at Grace.

Despite this setback in establishing PHB as a commodity polyester, researchers in industry and academia frequently pushed its potential in specialty applications, with some stories verging on the heroic. For example, in one verified story (36), Baptist wanted to convince the world that PHB could be applied as a bio-absorbable suture. He created a PHB fiber, slashed his own arm with a scalpel, and then sutured the cut with this fiber. Application of absorbable sutures from PHB was mentioned in a patent by W.R. Grace & Co. (39), establishing PHB as a forerunner to the highly profitable absorbable sutures of polylactide and glycolide that were marketed years later by Ethicon and Davis.

As a result of Grace's inability to establish large markets for PHB, Marchessault and colleagues at Syracuse were given pound quantities of Grace's discarded PHB material. This "leftover" PHB supported multiple research projects for years (33–36). The Syracuse team quickly produced data such as dilute solution molecular masses, optical rotation, differential scanning calorimetery results, X-ray diffractograms, crystalline structures (via molecular modeling), electron micrographs, and electron diffractograms of polymer single crystals (33–36).

One significant result of the biosynthetic origin of PHB is its optical activity (40). When polarized light hits films or solutions of PHB, the plane of the polarized light will rotate a measurable degree. This arises because the β-carbon in every monomer is perfectly stereoregular; nature always aligns this moiety in the *R* (*rectus*) optical configuration. Such stereoregularity leads to a high level of crystallinity, rapid crystallization, and multiple unique properties.

Furthermore, PHB crystals have no center of symmetry; thus, they exhibit piezoelectric properties (41). This means that as PHB crystals are deformed, the direction of their average ensemble dipole moment is changed, resulting in a change in polarization. This in turn changes the surface charge as a direct response to the deformation. In practical terms, this means that PHB materials, when deformed with shear in a voltage field, will alter the electric field significantly (41). Piezoelectricity is typical of many biological systems, but generally not found in most polymers.

The unique crystalline behaviour of PHB and its copolymers

PHB homopolymer is a semi-crystalline thermoplastic material that becomes viscous and moldable above its melting temperature. Upon cooling, it crystallizes rapidly to a plastic material, which exhibits high crystallinity of 60%–80% (42–46) with properties that are often compared to those of polypropylene. PHB homopolymer has had limited commercial success, though, because it is relatively stiff and brittle. Brittleness is largely due to the formation of large, uninterrupted spherulites that create large crystalline domains, i.e., it crystallizes too readily.

X-ray fiber diffraction and data analysis from K. Okamura's thesis (47) from Marchessault's lab in Syracuse established the helical nature and pitch of the PHB crystalline unit cell,

25	137	–6	0.7	30	400

with corresponding two-fold symmetry. No intramolecular hydrogen bonds are needed to stabilize the helix, as in proteins; but, rather, PHB relies on bipolar interaction between continuous anti-parallel helical chains, which are stabilized via their ester moieties.

Four separate structural models have been published over the years (47–50), with close agreement among these differing models, as outlined in Table 1. These data show remarkable agreement in the three unit-cell measurements, *a*, *b*, and *c*, which have been derived from X-ray diffraction as well as electron diffraction (1). Recent analysis of these models by Pazur et al. (51) shows that the Brukner model (50) based on Rietfeld analysis of PHB X-ray powder traces is the most favoured structure. Interestingly, it also confirms how close to the mark Okamura was in his original Syracuse thesis work in 1967 (47), a model that was improved in 1972 by Cornibert and Marchessault (48) via Marchessault's sabbatical work in Strasbourg.

The high degree of crystallinity, high melting temperature, brittleness, and low degradation temperature restricted the commercial potential for PHB. A major breakthrough toward commercialization was the development by ICI of a family of PHA co-polyesters (10–11). Wallen and Rohwedder (12), two researchers from the USDA labs in Peoria, IL, were the first to note that PHB-producing bacteria could generate other related copolymers. In careful analysis of polyester production in wastewater sludge, they noticed other polyester moieties, specifically poly(β-hydroxybutyrate-*co*-β-hydroxyvalerate), P(3HB-*co*-3HV), the valerate-based copolymer of PHB.

P(3HB-*co*-3HV) copolymers, commercialized by ICI in the 1980s, and trademarked under the brand, Biopol©, were derived from *Ralstonia eutropha* (formerly *Alcaligenes eutrophus*). The importance of the ICI copolyester family of products was to show that PHAs could be manufactured with a whole range of properties, varying in toughness, flexibility, melting temperature, impact strength, and processing requirements. The range of properties outlined in Table 2 could be tailored to fit market needs, implying wide commercial applicability. Furthermore, as the biosynthetic pathways became better understood, the importance of oxygen and phosphorous starvation, rather than nitrogen limitation, in the growth medium allowed for higher yields of P(3HB-*co*-3HV), as high as 85%–90% (on a dry mass basis).

ICI's commercialization of Biopol resulted in a new awakening of PHA-related research, with ground-breaking results by P. Barham and colleagues (Bristol, UK), Y. Doi (Riken, Tokyo), and R.H. Marchessault. By the 1980s, the "gang of four" at Syracuse had long broken up, first, with the move of Joe Merrick from Syracuse to a faculty position in Buffalo and then with the death of Lundgren in 1968. Marchessault had also moved on, first to a successful stint at Université de Montréal, and then to the Xerox Research Centre of Canada, XRCC, near Toronto. At XRCC, Marchessault led and mentored a team of diverse senior researchers and was able to remain active in biopolymer research at XRCC by convincing Xerox Corp that someday biodegradable materials were needed as "green alternatives" to inks, paper coatings, and fibers.

The XRCC team, along with prominent collaborators from several Canadian universities, including David Holden (Waterloo), Colin Fyfe (Guelph), and Jim Guillet (Toronto), was the first to define and characterize the unique isodimorphic behaviour of P(3HB-*co*-3HV); research that exemplified the world-class biopolymer research carried out in Canada at that time. Isodimorphism describes co-crystallization, in which P(3HB-*co*-3HV) maintains a high degree of crystallinity throughout all compositions of 3HV comonomer addition (42–43). For most typical random copolymers, the random addition of a "foreign" comonomer would usually disrupt crystallinity, thus lowering melting temperatures and increasing flexibility. Similar to typical random copolymers, P(3HB-*co*-3HV) exhibits a drop in melting temperature and greater flexibility with increasing

© 2008 NRC Canada

3HV composition (see Table 2). However, it also exhibits a high degree of crystallinity (60%–80%) at all comonomer compositions (42–46, 51–53).

P(3HB-*co*-3HV) fits the relatively rare criteria outlined by Allegra and Bassi (54) for isodimorphism. The monomers are similar in size, and their crystalline conformations are roughly similar; thus, the crystalline lattice of PHB can accommodate 3HV comonomer units, and the PHV lattice can accommodate 3HB comonomer units. A statistical model of this behaviour was then presented (55) that describes melting-point depression data that varies depending on the degree to which the "other" comonomer is included in the crystalline domain. For P(3HB-*co*-3HV) isodimorphic random copolymers, it predicts a pseudo-eutectic depression as outlined in Fig. 1.

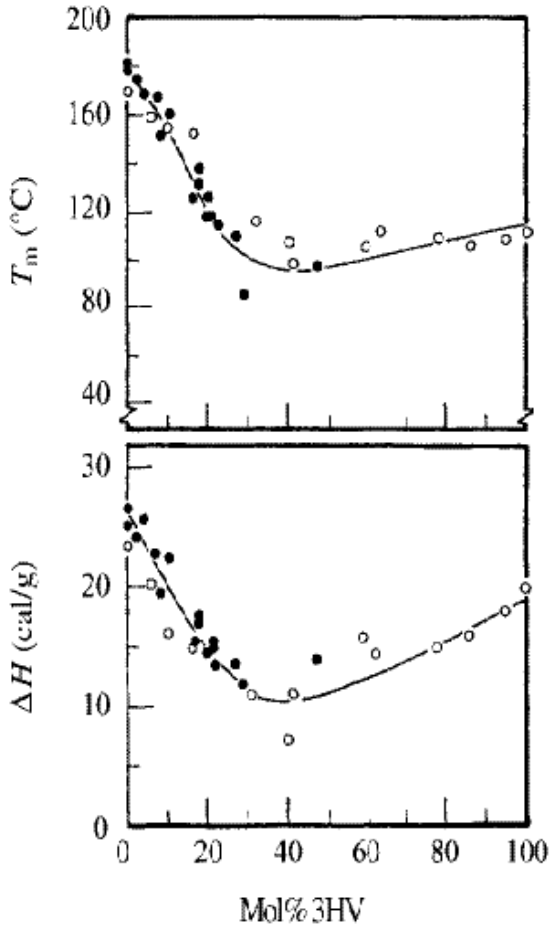
Figure 1 includes melting temperature (T_m) and heat of fusion (ΔH) data from bacterial and synthetic copolymers over the entire range of 3HV comonomer composition. This figure was derived from data established by Bloembergen et al. (42) who synthesized higher 3HV-containing copolymers, i.e., synthetic analogs of the bacterial copolyesters. The melting temperature trend shows a pseudo-eutectic behaviour, a pattern that was subsequently confirmed in more detail using a full range of bacterial P(3HB-*co*-3HV) samples (45).

In Fig. 1, T_m decreases until roughly 35–40 mol% 3HV and then increases at higher 3HV compositions. On one side of the pseudo-eutectic point, below ~40% 3HV, the crystalline lattice is that of PHB, while at higher 3HV compositions, the crystalline structure is that of PHV.

When isodimorphism was examined for melt-crystallized systems (43) or for solvent-derived crystals (1), the unit-cell parameters varied as 3HV composition varied. The **a**-parameter of the unit cell undergoes a small linear increase with increasing 3HV content up to the pseudo-eutectic point, i.e., it "accommodates" the larger 3HV comonomer into the PHB-type lattice structure with a small expansion in its fundamental dimensions.

How does isodimorphism affect crystallization rates and what factors are involved? Barham and colleagues (56–59) had already utilized PHB as a model system to study homogeneous polymer crystallization and the role of nucleation. Bacterial PHB, with 100% isotacticity, i.e., complete stereoregularity, exhibited ideal homogeneous polymer crystallization based on individual nucleation "events" resulting in large "equilibrium" crystals (57). In contrast, for the random copolymer, P(3HB-*co*-3HV), it was surmised that non-equilibrium crystallization was involved. The partitioning of 3HV units between the crystalline and non-crystalline domains depends on crystallization temperature and the rate of crystallization. The slower the crystallization rate, therefore, the more likely that equilibrium conditions would be attained; thus, energy minimization considerations will work towards excluding the "other" comonomer from the crystalline lattice. This means that at lower 3HV concentrations, below the pseudo-eutectic where the PHB crystal structure is present, the composition of 3HV in the crystalline domain will be lower than the average composition of that entire sample. When the 3HV comonomers are included in the PHB-type lattice, they will result in "less perfect" crystals with more defects (46), smaller crystalline domains, and less brittleness (see Table 2).

Fig. 1. Variation of melting point (T_m) and enthalpy of fusion (ΔH_f) with composition of P(3HB) of bacteria origin (solid circles) and fractionated synthetic samples (open circles).



Isodimorphism alters the crystalline structure as outlined by the changes in the spherulites derived from P(3HB-*co*-3HV) samples with varying 3HV content (see Fig. 2). The PHB sample, Fig. 2*a*, exhibits large uninterrupted spherulites presumably because of rapid crystallization relative to the number of nucleation events. At higher 3HV compositions, and thus higher levels of 3HV inclusion, the spherulites are smaller because the rate of crystallization is slower and (or) there are relatively more nucleation sites. Higher 3HV implies a greater number of defects within the crystalline region. In terms of mechanical properties, less perfection in the crystalline domains corresponds to films with greater flexibility and toughness (45, 46).

By the late 1980s, Marchessault had left XRCC for McGill University where his PHA-related research broadened in many different directions. Despite this move, research continued at Xerox for several more years via Marchessault's mentoring. In one example, colleagues at XRCC were studying the implications of isodimorphism in P(3HB-*co*-3HV) by collecting wide angle X-ray diffraction (WAXD) traces of cold-stretched films and fibers. Many WAXD traces of cold-stretched films showed an intense equatorial reflection and a first layer line "streak" that could

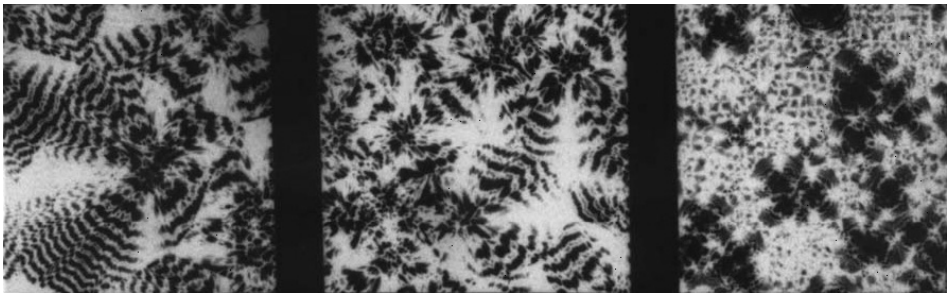
Fig. 2. Polarized light micrographs showing spherulitic morphology of (*a*) PHB, (*b*) P(3HB-*co*-3HV): 7% 3HV, and (*c*) P(3HB-*co*-3HV): 21% 3HV.



not be assigned to any plane in the orthorhombic crystalline system originally modeled for PHB (47–50). Marchessault immediately recognized this as evidence of the extended-chain, β-crystalline form (51). In the β-crystalline form, chains are arranged in a planar zigzag-type of structure, and the repeat distance along the crystallized chain is shorter than for the helical structure. As shown in Table 1 (last row), the *c* parameter for the β-crystalline form of P(3HB-*co*-3HV) is 4.6, in contrast to 5.96 for the more energy-favourable *a*-helical structure. The best interpretation is that PHB and (or) P(3HB-*co*-3HV), upon cold drawing, stores the energy of deformation in a metastable β-crystalline phase, almost like a coiled spring. Upon heating near the melt, this energy is released. Annealing under high tension makes the molecules in the amorphous region more stretched and increases the fraction of the β-zigzag form (60). Yamane et al. (61) also showed that the β-form crystal, which seems to have less ordered structure, degraded more readily than the α-form.

In another interesting result, Bloembergen et al. (62) created stereoblock synthetic analogs of P(3HB-*co*-3HV). In these samples, stereochemistry is consistent along relatively long stretches of copolymer chain (either all *sinister* or all *rectus*), and then it switches to the other stereoisomer for long stretches. This behaviour has allowed for interesting blends of synthetic and bacterial polyester in which PHB's brittleness was reduced and its toughness increased by intentional introduction of crystalline imperfections (1).

Biomimetic granules of PHA and in vitro synthesis

Beginning in the early 1990s, researchers began to report more extensively on the formation of in vitro synthesized PHA. The first step in these approaches was the development of biomimetic granules. Biomimetic granules were used to theorize about the crystallization dynamics of PHA (63–65). More specifically, intracellular PHB is contained within inclusions or granules, which, to the surprise of many, consist of highly mobile, non-crystalline chains. Prior to the eye-opening studies by Horowitz and Sanders (63), it was assumed that native granules were crystalline, considering how readily PHB crystallizes outside the cell.

Why is native PHB non-crystalline? To answer this, Horowitz and Sanders developed artificial granules to study PHB's rapid crystallization upon isolation, showing the potential effects of nucleation on crystallization kinetics (63). They substituted synthetic surfactant in place of the native granule coating to create submicron-size artificial granules, which were amorphous, stable in suspension, and indistinguishable from native granules in terms of size, morphology, molecular mobility, and density (64–65). When the surfactant coating was removed from the artificial granules, the PHB crystallized rapidly, thus verifying their hypothesis of nucleation-assisted crystallization.

Marchessault et al. also began a more extensive study of granules (66) and then reported (67) in vitro preparation of artificial granules of PHB and poly(β-hydroxyoctanoate), PHO, an elastomeric PHA with a six-carbon side chain. Light-scattering measurements of aqueous suspensions of the artificial granules showed particles with diameters in the range of 90–200 nm. The non-crystalline nature of the granules was shown by high resolution ^{13}C NMR. When the suspensions were allowed to dry, they yielded a continuous film with a low glass transition temperature and low Young's modulus.

Around the same time as in vitro granules from PHB and PHO were reported, the first studies on truly in vitro PHB biosynthesis and granule formation were reported by Gerngross and Martin (68). They combined a chemical and enzymatic procedure to synthesize in vitro macroscopic granules of PHB. When purified PHA-synthase from *Alcaligenes eutrophus* was exposed to synthetically prepared (*R*)-3-hydroxybutyryl CoA, (3HB-CoA) granules formed in a matter of minutes. Such formation proved that enzyme plus monomer was indeed the minimal requirement for PHB granule formation.

The artificial granules from Gerngross and Martin were spherical, with diameters up to 3 μm. This result was significant, since native granules in vivo are in the range of ~0.5 μm. The PHB formed in the in vitro granules was characterized by NMR, GPC, and chemical analysis and shown to have molar mass greater than 10×10^6 Da, an order of magnitude greater than the mass of PHB typically obtained from microorganisms. Gerngross and Martin (68–69) also showed that two different forms of the synthase are active in vitro, granule-bound and soluble PHA-synthase. Granule-bound synthase has a significantly higher specific activity and can be separated from the soluble form by centrifugation.

The Marchessault group, specifically Nobes et al. (70), with the aid of transmission electron microscopy (TEM) and Cryo-TEM, described the growth and kinetics of in vitro PHB granule formation. As discussed earlier, PHA biosynthesis is prompted by conditions of stress, such as the shortage of an essential nutrient (often phosphate or nitro-

© 2008 NRC Canada

gen). The biosynthetic pathway to PHB includes three key enzymes, which catalyze, in turn, carbon–carbon bond formation, chiral reduction, and finally head-to-tail polymerization. The first of the three enzymes, β-ketothiolase, catalyzes the formation of acetoacetyl-CoA from two molecules of acetyl-CoA in a bio-Claisen reaction. The acetoacetyl-CoA is subsequently converted to 3-hydroxybutyryl-CoA by acetoacetyl-CoA reductase. The final enzyme, PHB synthase, converts 3-hydroxybutyryl-CoA to PHB.

Nobes et al. (70) formed in vitro granules from 3HB-CoA in the presence of PHA synthase, yielding spherical granules of rapidly increasing size. After only 2 min of reaction, granules were already > 0.1 μm. While the average granule diameter and volume increased with reaction time, the overall number of granules decreased throughout the reaction owing to coalescence. As in previous studies, it was found that the granules formed by this process were essentially noncrystalline. A computer simulation accounted for kinetic data (71) based on the initial formation of relatively large microporous granules that consolidate by the expulsion of water during polymerization. Marchessault's group thus hypothesized that the initial granules were microporous, i.e., they contained some polymer but were mainly filled with water. Polymerization is, thus, topotactic and is hindered by the surface energy required to expel the hydrophobic polymer into the largely aqueous environment inside the granules. As the granules accumulate PHB, polymerization is increasingly favoured with its rate reaching a predictable maximum.

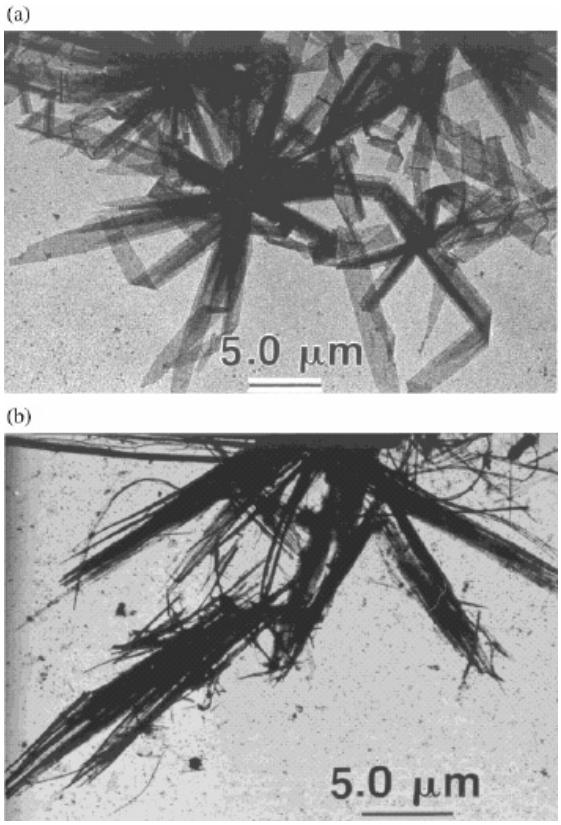
The biggest drawback to marketable application of in vitro reactions was the inability to recycle the CoA produced during PHA synthesis, an obstacle that appears to be recently overcome by Satoh et al. (72). Significant additional work in the synthesis of in vitro granules was reported by Steinbuchel's group, in which, for example, they reported in vitro formation of PHB granules by using a purified PHA-synthase from *Chromatium vinosum* (73) confirming mechanistic data for PHA synthase.

More recently, in vitro synthesis of PHA has been used to study the relationship between monomer structure and reactivity for PHA synthases, with indications that hydrophobicity in the side chain plays an important role in the reaction (74). The configuration and the position of the hydroxyl group affect the reactivity of a given monomer, suggesting that in vitro systems could be used to tailor entirely novel polymers that may not be obtainable from living cells.

In vitro degradation of PHA

Until the mid-1990s, virtually every published report (75–83) on the in vitro degradation of PHAs involved analysis of only the non-crystalline regions of the PHA. This was the result of the comparatively rapid degradation of amorphous regions and their accessibility to PHA-degrading organisms or enzymes. In studies of PHB degradation, it was found that a bimodal molecular mass distribution played a significant part in the degradation pattern of the polymer film (77). For P(3HB-*co*-3HV), Chaput et al. (80) reported that the mass loss rate due to degradation generally increased with the content of 3HV, presumably because of less perfect crystallization.

Fig. 3. Electron micrographs of PHB single crystals: (*a*) before enzymatic treatment and (*b*) after 24 h of depolymerase-A treatment from *P. Lemoignei* showing broken splinters.

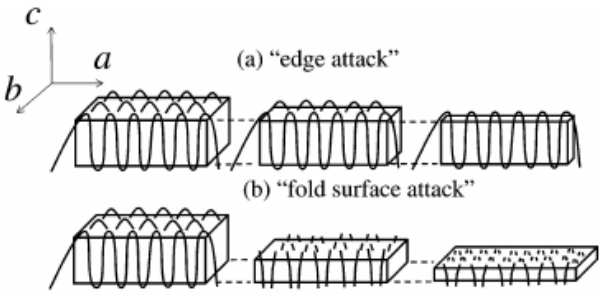


It soon became clear that accounting for the degradation of only the amorphous region would not fully describe the biodegradability of PHAs. Beginning in the mid-1990s, Marchessault group published a series of papers examining the mode of degradation of crystalline PHA. Nobes et al. (84–86) isolated depolymerase enzymes and applied TEM to visualize their action on folded-chain lamellar single crystals of PHB and P(3HB-*co*-3HV). Folded-chain single crystals presented a dual surface for enzymatic attack, i.e., the loops of the fold surface and the crystalline stems at the edge of the single crystal. These reports built upon the previous conclusion by Hocking et al. (83) that single crystals of bacterial PHB degraded completely when exposed to enzymes isolated from *Aspergillus fumigatus* and *Pseudomonas lemoignei*; yet, when they were only partially degraded, no decrease in molecular mass was observed. Results were consistent with preferential degradation from the crystal edges rather than the chain folds of the lamellar surface.

The Marchessault group explained this phenomenon at a molecular level by examining the partial degradation of folded-chain lamellar single crystals of PHB with PHB depolymerase from *P. lemoignei* (84). When observed by TEM, the partially degraded crystals were seen as splintered longitudinally to a needle-like morphology, as shown in Fig. 3.

© 2008 NRC Canada

Fig. 4. Two possible mechanisms of enzyme attack on folded-chain lamellae: (*a*) directional attack along the chain folding edge, removing "one chain at a time", and (*b*) preferred chain cleavage at the fold plane surface with rapid decrease in molecular mass.



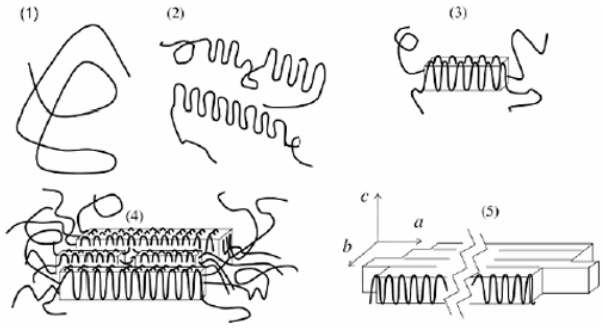
The needle-like splinters of degraded PHB still yield the same crystalline baseplane diffraction pattern, and they are still crystallographically perfect, with an average width of 20 nm (about 1/100 of the original crystal). A mechanistic explanation in subsequent papers (85–87) showed that polymer chains were cleaved by depolymerases acting in the direction of the chain folding plane. As outlined in Fig. 4, splintering of the crystalline laths runs parallel to the direction of the *a* axis of the PHB unit cell. It was hypothesized that the surface of single crystals is imperfectly crystallized because of chain folding; that is, the surface is thought of as amorphous. If the enzymes were to preferentially hydrolyze this surface, depolymerization would be followed by a rapid loss in molecular mass. However, since molecular mass (M_r) is not significantly lower after partial enzymatic degradation (83), PHB crystals must lose "entire chains one at a time", as shown in Fig. 4*a*.

Atomic force microscopy (AFM) can probe the same place in single crystals before and after enzymatic erosion. Analysis of AFM micrographs confirmed that the splinter thickness is unchanged until, perhaps, the last stage of enzymatic erosion. These facts are consistent with the "splintering" model shown in Fig 4*a*.

More recently, Marchessault and Kawada (87) reported that the origin of depolymerase-induced splintering is the precursor lath mode of single-crystal growth. This refinement of the splintering model states that the antiparallel chain packing of PHB, which provides a relatively stable tubular ribbon in the first stages of chain folding, encourages subsequent self assembly of precursor elements. This structure leaves parallel seams of mobile chains susceptible to enzymatic erosion. In this way, parallel arrays of splinters are created. In addition, this phenomenon must have an autocatalytic effect on the enzymatic degradation, since a net increase in accessible surface is created.

As a complement to previous studies of the enzymatic degradation of folded-chain lamellar single crystals of PHAs, single crystals of bacterial P(3HB-*co*-3HV), bacterial PHV, and synthetic PHB with 88% isotactic diads were partially degraded and examined by TEM using a range of PHA depolymerases (86). In contrast to previous results with single crystals of bacterial PHB, the predominant effect observed with most other crystals was a significant narrowing of the lamellae. This suggested an edge-attack mechanism such as outlined in Fig. 4*b*. In a fold-surface attack, depolymerase actions lead to a narrowing of the crystalline lamellae rather than splintering. Mechanistic models were expanded to hypothesize that this behaviour accounts for lateral disorder within the single crystal caused by the introduction of 3HV comonomers or addition of units of opposite stereochemistry.

Fig. 5. Proposed crystallization steps for formation of PHB lath-shaped single crystals: (1) random coil, (2) initial self-folding of chains, (3) formation of precursor laths, (4) self-assembly of precursor laths, and (5) consolidated single crystal with "out of register" regions.



Subsequent to publication of the splintering model proposed by Marchessault group (85, 86), the team of Iwata et al. published a series of papers on the microscopic visualization of partially degraded single crystals of PHAs (88–95). They analyzed PHB single crystals that were degraded via extracellular PHB depolymerase purified from *Pseudomonas stutzeri* YM1006 using TEM, AFM, GPC, and immuno-gold labeling techniques and (*i*) demonstrated a homogeneous distribution of the PHB depolymerase on the surface of crystals, and (*ii*) confirmed the splintering mechanism of degradation.

PHA single crystals — Growth dynamics

Knowledge of degradation mechanisms for single crystals may also be used to gain insight into their formation. Geil (96) suggested that lath-shaped single crystals of PHB initially grow by apposition of chain folded ribbons, one or only a few fold planes wide, as shown schematically in Fig. 5, a cartoon version of the mechanism proposed by Geil. PHB single crystals grow from a dilute solution as follows: (1) random coil chain in dilute solution, (2) the chain folds against itself, (3) pre-folded ribbons form needle-like precursors, (4) self-assembly of the precursors, and (5) lath-shaped single crystals consolidate, leaving "out of register" regions. The needle-like precursors can be detected as protrusions at the single crystal ends during early crystal growth, evidence of the dominance of longitudinal growth (87, 96). Crystallographic support for step (2) in Fig. 5 is the anti-parallel chain packing of PHB chains. As noted by Birley et al. (97), tight chain folds in the crystal that alternate between the [110] and [110] planes result in an average chain-folding plane parallel to the *a*-axis direction (Fig. 6).

Models for crystal degradation and formation suggest a mechanistic relation between the "splintering" mechanism and the parallel seams during crystal formation (Fig. 5). Formation of PHB tubular ribbons by adjacent re-entry chain folding means that PHB stems are anti-parallel, and thus

© 2008 NRC Canada

Fig. 6. Formation of PHB tubular ribbon by adjacent re-entry chain folding. PHB stems are anti-parallel.

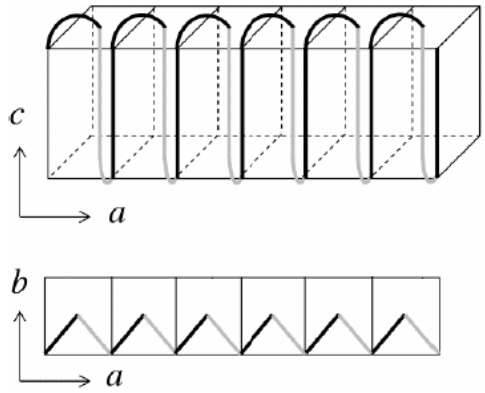


Fig. 7. TEM picture of PHB from a dilute solution (0.01% *w*/*v*) at the early stage of crystallization (30 min crystal growth) in a mixture of $CHCl_3$ and ethanol (1:2 *v*/*v*) at 60 °C.

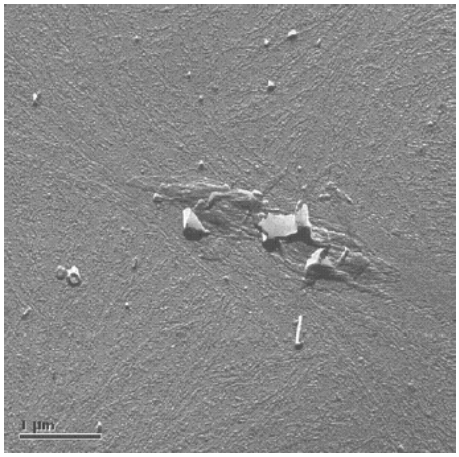

"out of register" as a result of the apposition of precursor laths. Hence, Geil's (96) seminal PHB electron micrographs showing self-assembly of the precursor laths was prescient to the "splintering" discovery for depolymerase action on PHB single crystals.

Figure 7 is an electron micrograph of PHB from a dilute solution (0.01% *w*/*v*) at the early stage of crystallization and self-assembling, with precursors surrounding a growing single crystal. The needle-like precursors are evidence of "out of register" regions between rows. Interestingly, the width of the PHB single-crystal lamellae in Fig. 7 is about 0.5 μm, which is narrower than the mature PHB single crystals (about 1–2 μm).

PHV square single crystals

Single crystals of PHV are square-shaped, as seen in the transmission electron micrographs reported previously (98). This differs from the lath-shaped single crystals of PHB, even though the chemical formula of PHV is similar to that for PHB. The difference in the single-crystal shape is explained by the direction of PHV chain-fold plane, which is perpendicular to the crystal growth direction. In other words, the chain-folding direction for PHV is [110] and perpendicular to the crystal growth direction; whereas that for the PHB is [100] (along the *a* axis) and parallel to the crystal growth.

Fig. 8. TEM pictures of PHV at various crystallization times: (*a*) cooled from 64 to 60 °C, (*b*) crystallized at 50 °C for 1 h and 30 min, (*c*) high magnification of PHV single crystals at 50 °C for 3 h (arrows show centered tips), and (*d*) high magnification of PHV single crystals cooled to room temperature after 3 h crystallization at 50 °C.

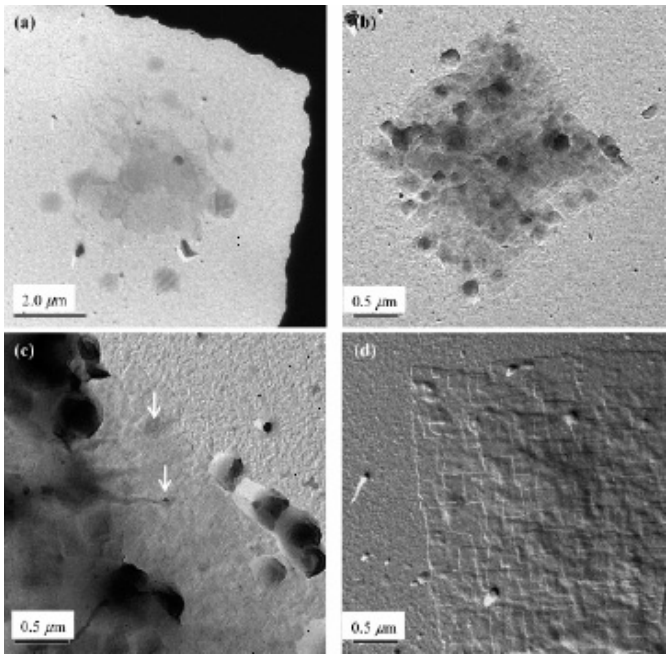

Figure 8*a* shows the early stage of PHV single-crystal growth observed by TEM just as the sample was cooled from 80 to 60 °C, which is close to the equilibrium temperature between the dissolving temperature (64 °C) and crystallization temperature (50 °C). An incipient square crystal is outlined by small primary nuclei, sometimes called "globs", which surround the nucleated crystal. These globs are precursors, which have been observed in previous PHV studies (98, 99). After 1.5 h at 50 °C, the crystals have a better defined square shape, and crystal self-assembly is underway, as shown in Fig. 8*b*. These precursors undergo annealing and self-assembly to form a square-shaped crystal composed of orthogonally arranged predominately as square tiles, although some precursors were still glob-like. The difference between precursors may be the extent of crystallization in solution prior to attachment to the single crystal. In other words, square-type precursors were already crystallized before self-assembly, whereas globs were annealed during self-assembly. Crystals, prepared at 50 °C for 3 h, showed an almost finished crystallization with rows of square-shaped precursors almost attached to the mother crystal, as shown in Fig. 8*c*. One of the squares gives evidence of a centered tip, characteristic of a primary nucleus.

This self-assembly evidence can explain why the surface of PHV single crystals have a tile-like morphology, as in Fig. 8*d*. Specifically, the precursors, which have different degrees of perfection, self-assemble, and grow as shown by Iwata and Doi (99) and Saracovan (100). They reported screw dislocation pairs: right- and left-handed. In the mid-

© 2008 NRC Canada

1980s back at Xerox (XRCC), Pundsack and Bluhm (101) had observed the small square tiles of PHV, which they referred to as mosaic structure, equivalent to edge decoration on a large single crystal. Electron diffraction on the tilted crystals provided the unit-cell parameters, which were confirmed by Marchessault et al. (98) both for natural and synthetic racemic PHV.

PHA oligomers — New functionalities

Marchessault group (at McGill) was among the first to note that PHA oligomers, as more manageable molecules than their high molecular mass equivalents, represent useful tools in the structural understanding of high molecular mass PHA analogues (102, 103). Oligomers had been used by various groups to determine the composition and the sequence distribution of the comonomer units, essentially via mass spectrometry (104–112). They were also used as models for physical characterization (103, 112), as well as model substrates in enzymatic degradation studies (113–118); for example, nearly monodisperse PHB oligomers were used as calibration standards for gel permeation chromatography (112). Ravenelle and Marchessault (119) took this a step further and showed that oligomers also constitute interesting building blocks with their combined properties of biodegradability, biocompatibility, and stereoregularity. Coming from the high molecular mass analogues, they exhibit enhanced solubility and reactivity for chemical modification.

Degradation of high molecular mass PHAs can also yield linear oligomers. Various preparative methods using chemical degradation have been reported in the literature: acid-catalyzed hydrolysis with either hydrochloric acid (120, 121), acetic acid and dimethyl sulfoxide (122), or *p*-toluenesulfonic acid (123); base-catalyzed hydrolysis using sodium hydroxide (120, 123–126); ammonolysis (127); acid-catalyzed alcoholysis or transesterification, with methanolysis using sulfuric acid (128, 129), hydrochloric acid (103, 105, 107, 131), or *p*-toluenesulfonic acid (132) as catalyst, or with diols, using 1,10-decanediol (128), 1,6-hexanediol (133), or 1,4-butanediol with also *p*-toluenesulfonic acid as catalyst (134); base-catalyzed alcoholysis with sodium methoxide in methanol (107); saponification with potassium hydroxide and a crown ether (109–111, 135); and degradation with lithium bases (112). Thermal degradation in the melt has also been reported as a method for preparation of PHA oligomers (136, 137).

The preparation of oligomers of PHB and P(3HB-*co*-3HV) by thermal degradation at 190 °C in the melt, without using a solvent or chemical reagents, was reported by Nguyen et al. (138) with 0, 4, 7, and 21 mol% of 3HV units in the copolymers. Chemical structure was confirmed by proton nuclear resonance spectroscopy and fast atom bombardment mass spectrometry, confirming the same PHA repeat unit as the high molecular mass starting material, with a carboxylic acid end group, and an alkenyl end mostly in the trans configuration (crotonate-type). Variations of 3HV content, reaction temperature, and time were shown to tune the molecular mass of the produced oligomers determined by size-exclusion chromatography. While the thermal degradation followed a random scission model during the first hours of processing, an auto-acceleration was observed, possibly due to an increase of the rate of ester cleavages caused by the inductive effect of the unsaturated end groups on the neighboring ester linkages (138).

PHA graft copolymers

Three main preparation strategies have been reported to produce graft copolymers: (*i*) "grafting from", by growing polymer segments along a polymer chain via monomer polymerization; (*ii*) "grafting onto", by coupling onto a polymer chain blocks of another copolymer; and (*iii*) "grafting through" or macromonomer technique, by copolymerization of a macromonomer, a polymer or oligomer with one or two polymerizable end groups with a low molecular mass comonomer. Marchessault's group has contributed to the field with the synthesis and characterization of graft copolymers of PHB using the two latter methods (122, 139–141).

Bacterial PHB blocks (M_n 10 000) were grafted by Yalpani et al. onto chitosan using amidation, cellulose acetate by transesterification, and poly(ethylenimine) by amidation (122). The same strategy was used to graft oligomers of PHB/V and poly(3-hydroxyoctanoate), PHO (M_n of ~ 14 700 and 77 300 for PHB/V, and M_n of ~ 19 100 for PHO) onto chitosan by amidation, which yielded either chitosan-*g*-PHB/V or chitosan-*g*-PHO (142).

Block copolymers poly([*R*]-3-hydroxybutyrate-block-styrene) synthesized by a coupling reaction were reported by Reeve and co-workers (128, 129). Polystyrene, PS, oligomers (M_n 5 900) with one carboxylic acid end were esterified with PHB oligomers (M_n 2 300) containing one hydroxyl end (produced by methanolysis) (1).

The same authors reported the synthesis of multiblock copolymers by coupling PHB bearing two hydroxyl end groups with poly(tetramethylene glycol) or poly(ethylene glycol), PEG. Marchessault and Yu (130) reported the synthesis of diblock copolymers of PHB and PEG, obtained by coupling monomethoxy-PEG and low molecular mass PHB obtained by the base-hydrolysis of bacterial PHB. In a one-step procedure, high molecular mass, bacterial PHB was degraded and transesterified with low molecular mass monomethoxy-PEG (119).

Nguyen and Marchessault (139, 140) reported the synthesis of graft copolymers of poly(methyl methacrylate), PMMA, with isotactic PHB branches by the "grafting through" method. They copolymerized methyl methacrylate, MMA, with bacterial PHB macro-monomers containing a methacrylate end group. Both conventional free radical polymerization, FRP, methods and controlled FRP methods were used. Macro-monomers were prepared by thermal degradation of bacterial PHB (138), and subsequent esterification of the carboxylic acid end groups (139). As expected, PMMA-*g*-PHB copolymers obtained by conventional FRP displayed rather large polydispersity indexes, with PHB branches randomly distributed. In contrast, the graft copolymers produced via FRP methods were significantly more monodisperse with lower M_w (140). Such copolymers represent interesting additives for acrylic bone cement formulations, as they could increase both their degradability and biocompatibility, while ensuring compatibility between PHB and the methacrylic ingredients of the cements.

© 2008 NRC Canada

Formulations of a commercial acrylic bone cement, antibiotic Simplex®, were modified by adding PMMA-graft-PHB copolymers obtained by free radical methods (141). Cements with up to 13.5 wt% of graft copolymers could be produced, and contained micropores with volumetric porosities ranging between 13.5% and 16.9%, but showed ultimate compression strengths above the ASTM F451 requirements.

In a recent application of the clever synthetic strategy employed by Nguyen and Marchessault (139–141), Neugebauer et al. (143) synthesized graft copolymers of methacrylate with PHB macro-monomers. They produced PHB oligomers of different tacticity and copolymerized them with methacrylates of various sizes of poly(ethylene glycol): methyl methacrylate, ethylene glycol methyl ether methacrylate, and poly(ethylene glycol) methyl ether methacrylate.

Conclusions

This review has covered more than four and a half decades of PHA-related research, highlighting how the work of Robert H. Marchessault and his many colleagues shaped research in this biopolymer area. Marchessault's impacts include the rediscovery of PHA by his Syracuse "gang of four", who were pioneers in defining the biochemistry of PHA biosynthesis and in describing PHAs' unique structure–property relationships. He played a significant role in pushing PHA, and more specifically P(3HB-*co*-HV), toward commercialization, both at Xerox, Canada and later at McGill University. Marchessault and his many varied colleagues were the first to describe isodimorphism of PHAs, a rare event worth fundamental study, and one that also provides a range of unique commercial properties, including biopolymers that rival polypropylene in most mechanical properties. More recent research highlights have included novel in vivo – in vitro PHA synthesis and degradation, and PHA-graft-copolymers.

Marchessault has been noted as describing researchers as having a choice between being "those who plant the flag, the pioneers, vs. those who are content to sweep up around the flagpole later". Bob Marchessault has "planted many flags" in his career and has enriched many lives along the way.

Acknowledgement

All of the contributors to this review were former Marchessault graduate students or post-doctoral research associates. We thank Professor Marchessault for his vision, leadership, creativity, and generosity – with resources and with time. Despite an often busy schedule over the years, he consistently has the time to discuss all realms of science, and to patiently teach his new discoveries to others. His lifelong passion toward research and discovery has left a positive imprint on many students, postdocs, and colleagues.

Thank you, Bob.

BIOGRAPHY / BIOGRAPHIE

Born and raised in Montreal, Robert H. Marchessault earned his B.Sc. from Loyola College (1950) and his Ph.D. from McGill (1954) under the supervision of the renowned colloid chemist, Stanley Mason. After postdoctoral studies at the University of Uppsala in Sweden, he spent several years as a research scientist at American Viscose Corporation in Philadelphia. He then joined the State University of New York (Syracuse) as Professor of Polymer Physical Chemistry. In 1969, he returned to Montreal as Professor and Director of the Department of Chemistry of Université de Montréal. He was also on the Board of Loyola College and played a key role in its merger with Sir George Williams University leading to Concordia University.

From 1978 to 1987, Dr. Marchessault was head of the Xerox Research Centre of Canada in Mississauga, Ontario. This facility serves Xerox Corporation's worldwide materials research needs. Under his direction, this laboratory grew to be recognized as one of Canada's leading industrial research laboratories in the field of organic materials. During his tenure as head of this Centre, Marchessault was a Vice President of Xerox Corporation and Vice President, Research of Xerox Canada Inc. In 1987, Dr. Marchessault returned to McGill University as the Xerox-NSERC Industrial Research Chair. In 1993 he was appointed to the prestigious E.B. Eddy Chair of Industrial Chemistry at McGill, and in 2005 he was promoted to the rank of Emeritus Professor.

His research has been focused on understanding the structure–property relationships of biomacromolecules including cellulose, polyhydroxyalkanoates (PHAs) and carbohydrate polymers. His pioneering 1963 study of the stereochemistry and crystallinity of bacterial polyesters fostered the development of these materials as biodegradable, melt processable plastics with a myriad of uses. He has had a career-long interest in biodegradable commodity plastics and has been a key player in the development of green chemistry. His research program at McGill focused on developing biopolymer materials for imaging, drug delivery, and environmental applications. He has published over 300 refereed papers and is co-inventor on 20 patents.

In 1976, he received the Anselme Payen Award from the Cellulose, Paper, and Textile division of the American Chemical Society, in recognition of his inspiring teaching and dynamic research program. He was also the 1998 recipient of the Chemical Institute of Canada's Macromolecular Science and Engineering Award. Marchessault has been very influential in the overall advancement of scientific research in Canada, serving over the years on several National Research Council of Canada committees and in 1986, on the National Advisory Board on Science and Technology. In 1981, he received the Archambault Award from l'Association canadienne-française pour l'avancement des sciences. The Royal Society of Canada elected Dr. Marchessault to be a fellow and a member of the Canadian Academy of Science in 1982 . In 1984, he was elected to a fellowship of the American Physical Society. Concordia University granted him an honorary D.Sc. in 1982. In 1991, the Canadian Institute of Chemistry recognized his professional and scientific leadership by awarding him the Montréal Medal. In 2000, he was named an Officer in the Order of Canada, and in 2002 was awarded the Queen's Jubilee Medal.

Robert H. Marchessault est né et a grandi à Montréal, où il a obtenu un baccalauréat ès sciences du Collège Loyola (1950) puis un doctorat de l'Université McGill (1954), sous la direction du chimiste de renom, Stanley Mason, spécialiste des colloïdes. Après des études postdoctorales à l'Université d'Uppsala (Suède), il a occupé un poste de chercheur pendant plusieurs années à l'American Viscose Corporation, à Philadelphie. Par la suite, il s'est joint à l'Université d'État de New York (Syracuse) à titre de professeur de chimie physique des polymères. En 1969, il est de retour à Montréal pour occuper à la fois le poste de professeur et celui de directeur du Département de chimie de l'Université de Montréal. Il a également siégé au conseil d'administration du Collège Loyola, et a joué un rôle important dans la fusion du Collège avec l'Université Sir George Williams pour donner lieu à l'Université Concordia.

De 1978 à 1987, M. Marchessault a dirigé le Centre canadien de recherche Xerox, à Mississauga (Ontario). Cet établissement répond aux besoins de la Xerox Corporation en matière de recherche internationale sur les matériaux. Sous sa direction, ce laboratoire a connu une telle expansion qu'il a été reconnu comme l'un des plus importants laboratoires de recherche industrielle au Canada dans le domaine des matériaux organiques. Tout en occupant ses fonctions de directeur, M. Marchessault a été vice-président de la Xerox Corporation et vice-président à la recherche de Xerox Canada inc. En 1987, il est retourné à l'Université McGill à titre de titulaire de la chaire de recherche industrielle CRSNG-Xerox. En 1993, il a été nommé titulaire de la prestigieuse chaire E. B. Eddy de chimie industrielle à la même université, et en 2005, il a été promu au rang de professeur émérite.

Ses travaux de recherche sont axés sur la compréhension des liens entre la structure et les propriétés des macromolécules biologiques, dont la cellulose, les polyhydroxyalcanoates (PHA) et les polymères de glucides. Son étude d'avant-garde de la stéréochimie et de la cristallinité des polyesters bactériens, effectuée en 1963, a favorisé la mise au point de ces matériaux pour en faire des matériaux thermoplastiques biodégradables aux multiples usages. Tout au long de sa carrière, il a manifesté un intérêt soutenu pour les matières plastiques biodégradables, et a joué un rôle important dans l'évolution de la chimie verte. À l'Université McGill, son programme de recherche portait principalement sur la mise au point de biopolymères destinés à des applications touchant l'imagerie, l'administration de médicaments et l'environnement. Il a publié plus de 300 articles dans des revues faisant l'objet d'un examen par des pairs et est cotitulaire de 20 brevets d'invention.

En 1976, il a reçu le prix Anselme-Payen de la division cellulose, papier et textile de l'American Chemical Society, en reconnaissance de son enseignement stimulant et de son programme de recherche dynamique. Également, il a été le récipiendaire du Macromolecular Science and Engineering Award (prix de science et de génie des macromolécules) de l'Institut de chimie du Canada, en 1998. M. Marchessault a exercé une très grande influence sur l'avancement de la recherche scientifique dans son ensemble au Canada, ayant siégé à plusieurs comités du Conseil national de recherches du Canada au fil des années et au Conseil consultatif des sciences et de la technologie en 1986. En 1981, il a reçu le prix Urgel-Archambault de l'Association francophone pour le savoir (anciennement l'Association canadienne-française pour l'avancement des sciences). La Société royale du Canada a élu M. Marchessault membre de l'Académie canadienne des sciences, en 1982. En 1984, il a été élu membre de l'American Physical Society. L'Université Concordia lui a décerné un doctorat honorifique en sciences, en 1982. En 1991, l'Institut de chimie du Canada a reconnu son leadership professionnel et scientifique en lui remettant la Médaille de Montréal. En 2000, il a été nommé officier de l'Ordre du Canada et, en 2002, il a reçu la Médaille du jubilé de la Reine.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2′F-Arabinonucleic acids (2′F-ANA) — History, properties, and new frontiers

Jonathan K. Watts and Masad J. Damha

Abstract: The development of arabinonucleosides and oligoarabinonucleotides is described, focusing especially on 2′-deoxy-2′-fluoroarabinonucleosides (araF-N) and -oligonucleotides (2′F-ANA). In addition to their chemical and enzymatic synthesis, we discuss various properties of 2′F-ANA: hydrolytic stability (to nucleases, acids, and bases), binding affinity to complementary strands, structure and conformation, and optimization of RNase H activity. We also discuss the use of 2′F-ANA in gene-silencing approaches (antisense, siRNA), and in the stabilization of higher-order structures (such as triplexes and quadruplexes) including aptamers. Finally, we examine several other oligonucleotide derivatives based on 2′F-ANA and look ahead to the future of 2′-fluoroarabinonucleosides and -oligonucleotides.

Key words: arabinonucleic acids, 2′F-ANA, antisense oligonucleotides, siRNA, modified oligonucleotides.

Résumé : On décrit le développement d'arabinonucléosides et d'oligoarabinonucléotides, en portant une attention particulière aux 2′-désoxy-2-fluoroarabinonucléosides (araF-N) et -oligonucléotides (2′F-ANA). En plus de leur synthèse chimique et enzymatique, on discute de diverses propriétés des 2′F-ANA, telles la stabilité hydrolytique (des nucléases, des acides et des bases), l'affinité de fixation à des brins complémentaires, la structure et la conformation et l'optimisation de l'activité RNase H. On discute aussi de l'utilité des 2′F-ANA dans les approches tendant à rendre les gènes silencieux (antisens, siARN) et dans la stabilisation des structures d'ordres supérieurs (triplexes et quadruplexes), y compris les aptamères. Enfin, on examine plusieurs autres dérivés oligonucléotidiques dérivés du 2′F-ANA ainsi que l'avenir des fluoroarabinonucléosides et -oligonucléotides.

Mots-clés : acides arabinonucléiques, 2′F-ANA, oligonucléotides antisens, siARN, oligonucléotides modifiés.

[Traduit par la Rédaction]

Introduction

The synthesis of 2′-deoxy-2′-fluoroarabinonucleosides (2′F-araN) was first reported in 1969 (1, 2). Since then, the study of these compounds and their oligonucleotide derivatives has remained a particularly active area of research. From the very beginning, much of the research has been aimed at therapeutic applications. At least five 2′F-araNs have reached clinical trials, of which only one has been approved for medical use (Table 1). The oligonucleotides (2′-deoxy-2′-fluoroarabinonucleic acids or 2′F-ANAs) are now being studied for both therapeutic and non-therapeutic applications.

This review will summarize the history and development of 2′F-ANA, beginning with several significant 2′-deoxy-2′-fluoroarabinonucleosides. In the interests of space, only those with a true 2′-deoxy-2′-fluoroarabinose sugar will be discussed; many other modified nucleosides and derivatives containing a top-face (β) fluorine at the 2′-position have been omitted but are described elsewhere (3), including the 2′-difluoro cancer drug gemcitabine (4), and the 3′-deoxy adenosine derivative lodenosine (5).

From there, we will move to a review of the properties of 2′F-ANA oligonucleotides, given in historical perspective. The high binding affinity and hydrolytic stability of 2′F-ANA attracted interest early on, along with the ability of 2′F-ANA to elicit RNase H cleavage of a complementary RNA strand. Newer discoveries include the fact that siRNA duplexes tolerate 2′F-ANA modifications, and that 2′F-araN 5′-triphosphates are substrates of various DNA polymerases. We will conclude by looking at various other 2′-fluoroarabinooligonucleotide derivatives inspired by 2′F-ANA.

2′-Deoxy-2′-fluoroarabinonucleosides

Several notable 2′-deoxy-2′-fluoroarabinonucleosides

Several factors provided motivation to explore the 2′-deoxy-2′-fluoroarabinonucleosides. Fluorine has a small steric effect but a significant influence on nucleoside confor-

Table 1. 2′-deoxy-2′-fluoroarabinonucleosides that have entered human trials.

Compound	Figure	Type	Notes
FMAU	1*a*	D-nucleoside	Potent antiviral and antileukemic activity. A Phase I trial for activity against solid tumors was terminated because of severe neurologic toxicity (11)
L-FMAU (clevudine)	1*b*	L-nucleoside	Performed well in a 2004 Phase II clinical trial against Hepatitis B (18), currently being developed by Pharmasset, Inc.
FIAC (fiacitabine)	1*c*	Base-modified D-nucleoside	Showed good antiviral activity in several Phase I trials (early 1980s) and one Phase I/II trial (against VZV in immunocompromised patients, 1986) (28), but was withdrawn after another Phase I/II trial (1989) showed significant toxicity (22)
FIAU (fialuridine)	1*d*	Base-modified D-nucleoside	Showed good activity against HSV and HBV. A 1993 Phase II trial against HBV was halted on an emergency basis (22, 29)
Clofarabine	2*a*	Base-modified D-nucleoside	Approved by the FDA (in 2004) and the European Union (in 2006) for the treatment of pediatric patients with relapsed or refractory acute lymphoblastic leukemia (ALL) (30, 31)

mation and stability owing to its high electronegativity. For instance, the 2-deoxy-2-fluoroarabinose moiety provides resistance to hydrolytic (acid-catalyzed) or enzymatic (phosphorylase) cleavage of the *N*-glycosidic bond (6, 7). Thymine and other 5-substituted pyrimidine nucleosides exhibit better antiviral activity with 2-fluoroarabinose than with 2-deoxyribose or arabinose sugars (8). Thus FMAU (2′-fluoro-5-methyl-β-D-arabinouridine, Fig. 1*a*) attracted significant attention for its antiviral activity, especially against Herpes Simplex Virus (HSV) (8, 9). Despite its significant antiviral and anticancer activity (10), FMAU caused significant neurotoxicity and myelosuppression at the doses required for activity (11), and was found to be incorporated into DNA by eukaryotic as well as viral enzymes (12, 13). Nevertheless, this family of compounds (2′F-araN) has not been found to cause mutagenesis in bacterial or mammalian cells (14), in contrast with the non-fluorinated nucleoside arabinocytidine (*ara*C) (15). More recently it was discovered that the enantiomer L-FMAU (clevudine, Fig. 1*b*) exhibits a more favorable therapeutic index than D-FMAU against Hepatitis B Virus (HBV) and Epstein-Barr Virus (EBV) (16). The cytosine derivative L-FAC exhibits somewhat lower potency (17). L-FMAU has performed well in phase II clinical trials against HBV (18) and is being developed by Pharmasset, Inc.

A third nucleoside to have been tested in humans is fiacitabine (2′-fluoro-5-iodo-β-D-arabinocytidine (FIAC), Fig. 1*c*). This nucleoside showed much higher activity against HSV than other drugs of its day (19) After performing well in several Phase I and Phase I/II trials, it was eventually abandoned for reasons of toxicity. FIAC was found to be metabolized to FIAU (2′-fluoro-5-iodo-β-D-arabinouridine, Fig. 1*d*) (8, 20). The latter had already demonstrated antiviral activity, and the focus of clinical work shifted to it, hoping to avoid the toxicity associated with FIAC. Indeed, it had a good short-term toxicity profile, but a longer-term, low-dose Phase II trial was cancelled after five patients died of liver failure, probably because of mitochondrial toxicity (21). Clinical development of both FIAC and

Fig. 1. Four 2′-deoxy-2′-fluoroarabinonucleosides that have reached clinical trials.

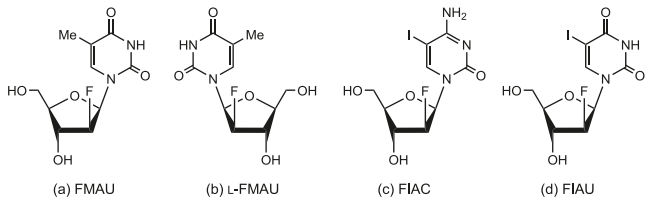

Fig. 2. Clofarabine and the two other drugs from which it was inspired.

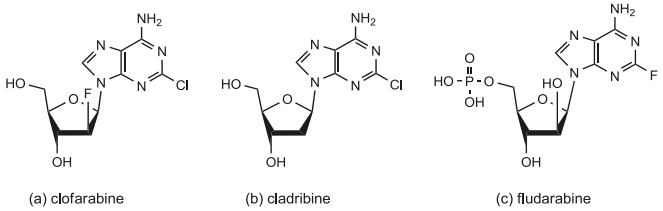

FIAU have been the subject of thorough reviews, to avoid similar outcomes in future (22). Additional details of the antiviral activities of 2′-fluorinated arabinosyl-pyrimidine nucleosides are provided elsewhere (23).

The metabolism and DNA incorporation of other 5-modified 2′-fluoro-β-D-arabinonucleosides are significantly dependent on the 5-substituent (12). FIAU and FEAU (2′-fluoro-5-ethyl-β-D-arabinouridine) (24) have recently found utility in positron emission tomography (PET) (25) and other imaging of experimental tumors and localized bacterial infections (26), because a radiolabeled FIAU or FEAU molecule is preferentially phosphorylated by viral and bacterial kinases within these systems. It is also noteworthy that FEAU is less toxic than other 2′F-araNs (23). On the other hand, because of its greater uptake by eukaryotic DNA polymerases, ^{18}F-FMAU has been used for imaging of DNA synthesis in vivo (27). Because of the very low concentra-

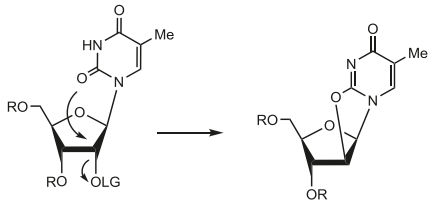
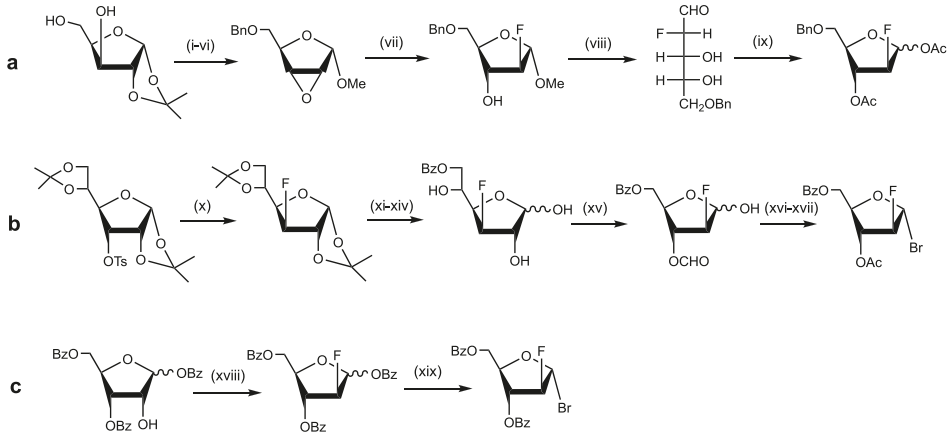
Scheme 1. Synthesis of 2′-fluoroarabinonucleosides is generally approached by coupling the base (normally trimethylsilylated at the carbonyl groups) to a 3,5-di-*O*-acyl-2-deoxy-2-fluoro-D-arabinosyl bromide.

Scheme 2. Pyrimidine O2 rapidly displaces an α-face leaving group at C2′, preventing direct synthesis of 2′-fluoroarabinonucleosides from ribonucleosides.



Scheme 3. Various synthetic routes to 1-acetyl or 1-bromo 3,5-di-*O*-acyl-2-deoxy-2-fluoroarabinose, suitable for coupling to nucleobases. Shown are (*a*) the first synthetic route (1, 41); (*b*) an early route amenable to larger scale synthesis (40); and (*c*) the route used for most recent work (38, 44). Reagents and conditions: (*a*) (i) Methyl chloroformate in pyridine–chloroform, 0 ºC, 64h; (ii) TsCl, pyridine, 70 ºC, 6h; (iii) AcOH, Ac_2O, H_2SO_4, 19h; (iv) 1% HCl in MeOH, 19h; (v) NaOMe, MeOH, 47% over 5 steps; (vi) BnBr, Ag_2O, DMF; (vii) KHF_2, ethylene glycol, reflux, 40%; (viii) 1 N H_2SO_4 in dioxane–water, reflux, 4h, ~quant.; (ix) Ac_2O, pyridine, 18h. (*b*) (x) KF, acetamide, 210 ºC, 15 min, 62%; (xi) 0.35% H_2SO_4 in 1:1 methanol–water, rt, 10h; (xii) barium carbonate, reflux, 10 min; (xiii) BzCl, pyridine; (xiv) Amberlite IR-120 (H+), 78%; (xv) potassium metaperiodate, water, overnight; (xvi) NaOMe in MeOH; Ac_2O, pyridine, rt, overnight, 80%; (xvii) 30% HBr in AcOH; (*c*) (xviii) DAST, CH_2Cl_2, 40 ºC, 75%; (xix) 30% HBr, AcOH, CH_2Cl_2, 97%.



tions required for PET, these nucleosides exhibit "no toxicity" when used for these imaging techniques (26). Studies are underway to move these nucleosides toward clinical trials for this purpose.

The purine nucleosides 2′F-araA and 2′F-araG also show biological activity (32, 33). However in general, the 2′-fluoroarabino purine nucleosides have attracted less attention than their pyrimidine counterparts. The exception is clofarabine (30, 31, 34), one of the most successful 2′-deoxy-2′-fluoroarabinonucleosides, which contains a modified purine, 2-chloroadenine (see Fig. 2*a*). Clofarabine was developed while trying to improve upon the properties of two other adenosine-based anticancer drugs, cladribine and fludarabine (Fig. 2) (35, 36). The 2′-fluoro substitution yielded a glycosidic bond highly resistant to hydrolysis and phosphorylase cleavage (36). Its anticancer activity results from inhibition of DNA polymerases and ribonucleotide reductase (which depletes the dNTP pool, favoring incorporation of clofarabine into DNA), and induction of apoptosis because of DNA damage after clofarabine incorporation (34, 36, 37). Clofarabine was approved for treatment of pediatric acute leukemia by both the FDA (in 2004) and the European Medicines Agency (in 2006). Its side-effect profile is "typically manageable and tolerable" (31), while the drug has significant activity in relapsed or refractory leukemias where other treatments have failed.

2′-Deoxy-2′-fluoroarabinonucleosides have also found use as inhibitors of base-excision repair enzymes (38). The 2-deoxy-2-fluoroarabinose sugar has been used to synthesize mimics of deoxyribose glycosyl phosphates, key intermediates in nucleic acid biosynthesis (39).

Synthesis of 2′-deoxy-2′-fluoroarabinonucleosides

From the earliest work on pyrimidine 2′-deoxy-2′-fluoroarabinonucleosides, the synthetic approach has been based on the coupling of the heterocyclic base to a 3,5-di-*O*-acyl-2-deoxy-2-fluoro-D-arabinosyl bromide (Scheme 1) (8, 40). Occasionally the anomeric acetate has been used instead (1). Direct introduction of top-face fluorine into the 2′ position of a pyrimidine nucleoside by nucleophilic displacement would be very difficult because the carbonyl group at C-2 tends to displace any potential leaving group in the ribose sugar precursor before the fluorination can be carried out (Scheme 2).

Synthesis of the requisite 3,5-di-*O*-acyl-2-deoxy-2-fluoroarabinosyl sugar has been carried out in a variety of ways (Scheme 3). Initial work used a methyl 2,3-anhydroribofuranoside as a key intermediate, which was in turn obtained

© 2008 NRC Canada

from a protected xylofuranose (Scheme 3*a*) (1, 41). Starting from a protected allofuranose reduced the number of separations required, increased the overall yield of product, and was more suitable for large scale synthesis, but required at least eight steps (Scheme 3*b*) (40). 1,3,5-Tri-*O*-benzoylribose (42, 43) is now commercially available and has been used as the starting point for most recent work, thereby simplifying the synthesis tremendously (Scheme 3*c*) (38, 44).

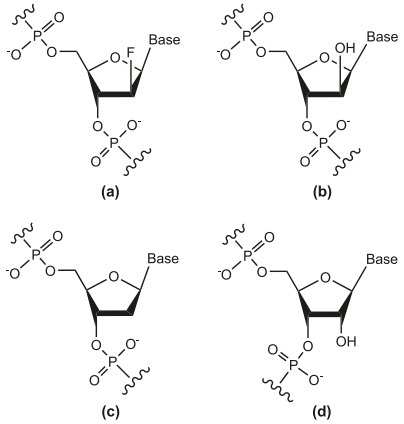
The fluorination step has almost invariably utilized nucleophilic displacement. The first synthesis was based on the opening of a 2′,3′-α-epoxide, but this provided low yields and complex product mixtures (1). Several authors have proposed one-pot (45) or two-step (17, 39, 40, 42, 46, 47) sulfonate displacement reactions, using Bu_4NF (40, 47), KHF_2 (17, 42), or $Et_3N{\cdot}3HF$ (39, 45, 46) as the fluoride source. Diethylaminosulfur trifluoride (DAST), a mild, one-pot fluorinating reagent (48), almost completely avoids dehydration (elimination) during the fluorination reaction. It has been used by many research groups (6, 38, 44). One particular challenge is the scale-up of these reagents, since nucleophilic forms of fluoride such as KHF_2 or $Et_3N{\cdot}3HF$ are difficult to handle and require activation of the displaced hydroxyl group, and reagents such as DAST are too unstable to be useful on large scale. From the many options available (49), Sznaidman et al. have provided a possible solution in the form of a synthesis from arabinose, consisting of electrophilic addition of fluorine to a glycal moiety using the reagent Selectfluor™ (F-TEDA-BF_4) (50). Others have developed protocols that minimize the corrosiveness of the nucleophilic fluorinating agent, and have successfully reached a scale of up to 800 kg (46).

Howell et al. made a major contribution to the glycosylation step by observing that the β-selectivity of the reaction could be made almost complete by carrying out the reaction in nonpolar solvents (51). The reaction is thus forced to follow an S_N2 mechanism from the α-bromo precursor, since the oxygen-C_1-onium ion required for an S_N1 reaction is already destabilized by the 2′-fluoro group, and cannot exist in the absence of solvent stabilization (51). This approach results in high yields of β-nucleosides, which can be purified by crystallization. The mother liquor contains a residual mixture of α and β anomers that is very difficult to separate but can be enzymatically converted to 3′-*O*-benzoyl nucleosides that are separable by chromatography (52).

In the case of the purine 2′-deoxy-2′-fluoroarabinonucleosides, some synthetic work has been undertaken by 2′-fluorination of ribonucleosides (reviewed by Pankiewicz (53); another efficient route has been more recently reported by Maruyama et al. (54)) However, coupling to the fluorinated sugar, as described above for the pyrimidine nucleosides, has the advantage of divergence when both purine and pyrimidine nucleosides are made. In the case of guanine, the synthetic route utilizes a masked base, which is later converted into the desired guanine; initial attempts at this strategy used dichloropurine (55–57) or 2-acetamido-6-chloropurine (32), but the synthesis can be improved and simplified using 2-chlorohypoxanthine instead (58).

Recently published step-by-step protocols may be useful to those wishing to synthesize 2′F-araNs and their phosphoramidite derivatives (57, 59).

Fig. 3. Structures of (*a*) 2′F-ANA and (*b*) ANA, in comparison with (*c*) DNA and (*d*) RNA oligomers.



2′-Deoxy-2′-fluoroarabinonucleic acid (2′F-ANA)

The first 2′F-ANA oligomers

Pyrimidine 2′-deoxy-2′-fluoroarabinonucleosides (FMAU, FIAU, FAU, and FAC) were first incorporated into oligonucleotides by Watanabe and co-workers in 1993 (Fig. 3*a*) (60, 61). Oligonucleotide synthesis using 2′-deoxy-2′-fluoroarabino monomers was readily carried out using either phosphoramidite or *H*-phosphonate chemistry (61). Another pair of studies incorporated FMAU into the self-complementary DNA Dickerson–Drew dodecamer (62, 63).

Meanwhile, quite a bit of work had been carried out on the arabinonucleic acids (ANA) (Fig. 3*b*). Initial interest in arabinonucleic acids was somewhat serendipitous. One of us was studying in the group of Professor K.K. Ogilvie at McGill University, and in the course of pursuing Prof. Ogilvie's interest in arabinonucleoside (64) and branched RNA synthesis (65, 66), we discovered that ribonucleoside 2′,3′-*O*-bis-phosphoramidite derivatives exhibited unusual P–P coupling in the ^{31}P NMR spectra (66). It was hypothesized that such coupling ($^5J_{P,P}$ = 10–30 Hz) may arise through space rather than through the five-bond framework (66). To explore this observation further, the corresponding arabino-configured species was synthesized; this compound retained the same P–P bond distance (five), but the disposition of the trans amidite moieties would affect the strength of the putative through-space P–P coupling (67). However, an abundant byproduct in this synthesis, even under forcing conditions, was the arabinonucleoside mono 3′-*O*-phosphoramidite, because steric hindrance reduced the accessibility of the 2′ hydroxyl group (68). After facile acetyl protection at the 2′ position, it was therefore straightforward to begin to explore ANA oligomers.

Thus, initial synthetic work in our group (68) and elsewhere (69) paved the way for investigations into the hybridization and structure of ANA. As well as several hybridization studies of oligonucleotides containing one or two ANA modifications (70), the hybridization of fully modified ANA oligomers to various targets was studied (71).

In most contexts, ANA oligonucleotides bound to RNA target strands with somewhat lower affinity than DNA or

© 2008 NRC Canada

RNA oligonucleotides (71, 72). The difference was even more dramatic in the case of DNA targets, to which very poor binding, or no binding at all, was observed (71, 72). We speculated that the lower binding affinity of ANA might be due to steric hindrance of the top-face 2′-OH, perhaps lowering the efficiency of base-pairing or base-stacking (72). To reduce the steric bulk of the 2′ substituent, we proposed replacing it by fluorine. Thus, we initiated a study of mixed-sequence, fully modified 2′F-ANA sequences containing all four bases, using phosphoramidite chemistry (44, 59, 73). The result was gratifying: the resulting 2′F-ANA·RNA and 2′F-ANA·DNA duplexes were much more stable. The reasons for this change, however, appear to be more complex than we originally thought (see below).

When fully modified ANA or 2′F-ANA strands were annealed with complementary ssRNA, their duplex conformation (as determined by circular dichroism (CD)) closely resembled that of a DNA·RNA duplex (73). This observation prompted investigation of the recognition of the duplexes by RNase H, a ubiquitous enzyme that cleaves the RNA strand of a DNA·RNA duplex. If an antisense oligonucleotide can induce RNase H-mediated RNA cleavage, it becomes a catalyst for the hydrolysis of multiple mRNA strands (74).

Both ANA and 2′F-ANA were able to induce RNase H-directed cleavage of their complementary RNA strand, but the 2′F-ANA strand did so with higher efficiency (73). Prior to 1998, DNA–RNA hybrids were the only reported substrates for RNase H, and thus it was generally perceived that only DNA could support this activity. Thus, ANA and 2′F-ANA represented the first examples of RNase H-competent oligomers that lacked 2-deoxy-D-ribofuranose. These findings also provided a very important advance in understanding the catalytic mechanism and substrate selectivity of RNase H, and underscored the potential of arabinose-based oligomers as gene-silencing agents. The higher efficiency of RNase H induction by 2′F-ANA, along with its higher binding affinity, made it the lead compound for further investigation into gene-silencing applications.

Hydrolytic stability of 2′F-ANA to nucleases, acids, and bases

The improved nuclease stability of 2′F-ANA oligonucleotides has long been appreciated. For example, the first group to work on 2′F-ANA found a 4–8-fold increase in stability to nuclease P1 with respect to DNA (61). Others have also observed increased stability of 2′F-ANA to snake venom phosphodiesterase (SVPDE, a highly active 3′-exonuclease) or serum. Noronha et al. subjected various homopyrimidine sequences to SVPDE hydrolysis and found the following order of stability: PS-DNA > > ANA > 2′F-ANA ≈ RNA > 2′F-RNA > DNA (72). An interesting observation from this study is that arabinonucleic acids (2′-OH or 2′-F) are generally more stable to SVPDE than the corresponding ribonucleic acids (ANA > RNA and 2′F-ANA > 2′F-RNA). Furthermore, enzymatic stability seems to increase as the van der Waals radius of the 2′-substituent increases within each series; i.e., DNA ($2'H_\beta$) < 2′F-ANA ($2'F_\beta$) < ANA ($2'OH_\beta$); and DNA ($2'H_a$) < 2′F-RNA ($2'F_a$) < RNA ($2'OH_a$) (72).

There also appears to be some dependence on base sequence for the hydrolytic stability of 2′F-ANA. In two sequences from a recent study, 2′F-ANA provided little or no advantage over DNA with either phosphodiester (PS) or phosphorothioate (PO) backbones (75). In contrast, a dramatic advantage was observed when 2′F-ANA was used to modify a self-complementary sequence (75). We believe that the higher thermal stability of 2′F-ANA duplexes may provide an extra advantage in terms of nuclease stability simply by holding the duplex more tightly together, thus rendering the individual strands less accessible for nuclease cleavage. Accordingly, Dowler et al. showed that 2′F-ANA modification of one strand of an RNA duplex provided significant additional serum stability to the whole duplex ($t_{1/2}$ ~5 h vs. ~5 min for the unmodified duplex) (76). This could be further enhanced by incorporating 2′F-araN units into the 3′-overhang of the antisense strand as well (76).

2′F-ANA can also confer nuclease resistance to higher order structures. 2′F-ANA-modification of a G-tetrad-containing thrombin-binding aptamer resulted in up to 48-fold greater serum stability compared with the unmodified DNA tetrad (discussed in detail below) (77).

While PO-2′F-ANA does provide some advantages in terms of nuclease stability, it cannot match the dramatic increase in stabilization provided by a PS backbone (78). However, when the two modifications (PS and 2′F-ANA) are combined, the resulting PS-2′F-ANA oligonucleotide is highly resistant to most nucleases. In both PS-DNA and PS-2′F-ANA, one of the diastereomers of the phosphorothioate linkage undergoes nucleolytic cleavage fairly easily, while the other is very stable (75, 79).

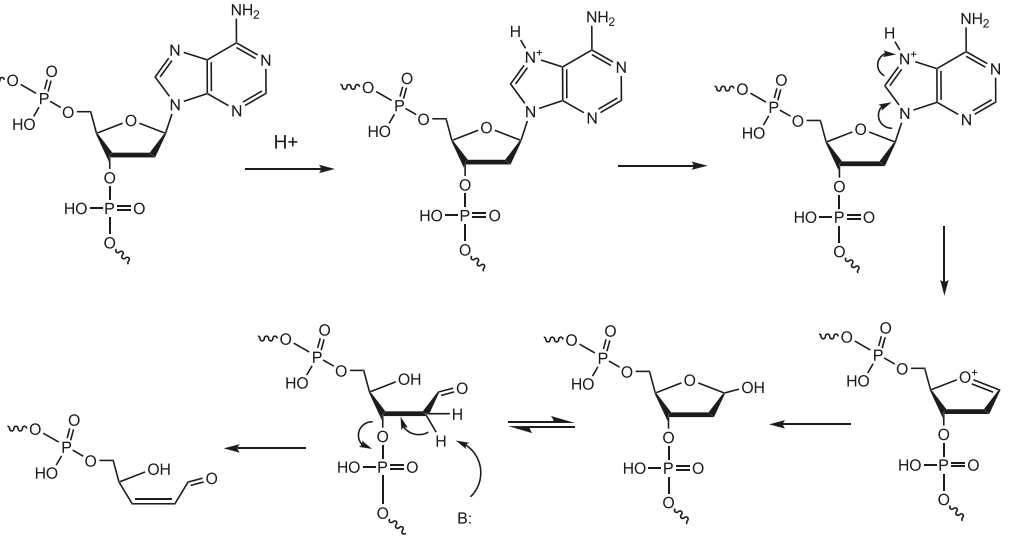
Two recent studies have examined the persistence of 2′F-ANA antisense oligonucleotides in cell culture and explored the relationship with gene-knockdown efficacy (80, 81). Kalota et al. observed that chimeric PS-2′F-ANA–DNA oligomers had greater persistence in cultured K562 cells (more than 70% of the oligonucleotide was still recoverable from the cells after 96 h, while very little PS-DNA remained after this time) (80). This suggests either that PS-2′F-ANA is more resistant to nucleases than PS-DNA, or that it is retained by cells to a greater extent. Correspondingly, this study found a lower effective dose and longer duration of action of PS-2′F-ANA oligomers with respect to PS-DNA (80). Another study found that two PS-2′F-ANA sequences were more stable to serum nucleases than most other sequences (with some exceptions) (81). Again, this paralleled excellent activity (luciferase-knockdown in HeLa cells) over extended assay times (81).

The glycosidic bond of 2′F-ANA and 2′F-RNA is also highly resistant to enzymatic cleavage by phosphorylases and glycosylases. Stivers et al. took advantage of this stability to study the mechanism of the DNA repair enzyme uracil DNA glycosylase (UDG), which flips premutagenic uracil bases out of the helix before cleaving them. By replacing a U residue with a 2′F-araU or 2′F-rU, they were able to observe flipping without glycosidic bond cleavage, and even carry out NMR structural characterization (82).

This remarkable stability of the glycosidic bond also means that 2′F-ANA demonstrates remarkable stability to acidic conditions (75). In enzyme-free simulated gastric fluid (pH ~1.2), 2′F-ANA was virtually intact after 2 days incubation at 37 °C. Under the same conditions, DNA was degraded within minutes, PO-RNA within hours, and PS-RNA within days (75, 83). The large difference between DNA and 2′F-ANA

© 2008 NRC Canada

Fig. 4. Mechanism of acid-catalyzed degradation of DNA (84). In the case of 2′F-ANA, the presence of fluorine at the 2′ position destabilizes the oxycarbonium ion intermediate and disfavors depurination, largely preventing this mechanism of degradation.



comes because the dominant mechanism for acid-catalyzed degradation of DNA (depurination followed by β-elimination) is disfavored by the presence of electronegative fluorine at the 2′ position (Fig. 4).

As for stability in basic conditions, we have not carried out detailed studies in our laboratory; however, it is clear that 2′F-ANA is much more stable than RNA to strongly basic conditions, as evidenced by the fact that 2′F-ANA strands are routinely deprotected in ammonium hydroxide. These are conditions under which naked RNA and even 2′F-RNA are rapidly degraded. This is, of course, because 2′F-ANA does not have a 2′-OH group to be deprotonated and used to attack the vicinal phosphate linkage. In the case of 2′F-RNA, the O2 atom of the pyrimidine base attacks at the 2′ position to displace the α-oriented fluoride (85, 86). Such a pathway is not possible for 2′F-ANA wherein the pyrimidine and fluorine are both on the top (β) face of the sugar ring.

Binding affinity

When 2′F-ANA pyrimidine-modifed oligonucleotides were first synthesized, their binding to DNA was investigated and the results were somewhat mixed: 2′F-araT units stabilized duplexes but 2′F-araC or 2′F-araU tended to destabilize them, relative to a DNA strand (60, 61). FIAU, when incorporated into oligonucleotides, also conferred stabilization (60). The added stabilization of FMAU and FIAU is consistent with the well-known favorable binding of 5-substituted pyrimidines (87). It has been our experience that 2′F-ANA consistently demonstrates high binding affinity to both DNA and RNA.

A 2′F-ANA·RNA duplex is consistently more thermally stable than a DNA·RNA duplex. Depending on the sequence, the stabilization of fully modified strands ranges from 0.3 °C/bp to 1.8 °C/bp (44, 73, 88, 89). Replacing an all-purine DNA strand with 2′F-ANA (or modifying only the purines of a mixed sequence) tends to yield smaller increases than replacing an all-pyrimidine strand (44), and in some cases no increase at all (56), but does not lead to destabilization as was originally predicted (63). Interestingly, the highest stabilizations observed have been for mixed sequences (for example, up to 1.8 °C/bp for a 10-mer mixed sequence) (89).

In some cases, 2′F-ANA·RNA duplexes are also more stable than RNA·RNA duplexes (44, 89–91). However, this is not always the case, and in other cases 2′F-ANA·RNA duplexes are of slightly lower stability than RNA·RNA duplexes (44,90). Furthermore, in cases where 2′F-ANA·RNA duplexes are in fact more stable than RNA·RNA duplexes, some of the difference can be attributed to the fact that 2′F-ANA typically contains thymine bases while RNA contains uracil (87). For example, duplexes of rT_{18} and 2′FaraT_{18} with rA_{18} were found to have similar melting temperatures (T_m) (51 °C and 52 °C, respectively), but the T_m of rU_{18}·rA_{18} was 17 °C lower (44).

A phosphorothioate backbone reduces the binding affinity of DNA or 2′F-ANA relative to a normal phosphodiester backbone (92). However, PS-2′F-ANA binds to RNA with higher affinity than PS-DNA (about 0.5 °C/bp) (93).

The binding affinity of 2′F-ANA–DNA chimeras has also been studied. For example, so-called "altimers" (Fig. 5) containing alternating stretches of 1, 2, 3, or 6 2′F-ANA nucleotides interspersed with 3 or 6 DNA units had T_m values increased by 0.6–0.8 °C per 2′F-ANA insert (to RNA, with respect to an all-DNA strand). Fully modified 2′F-ANA strands of the same sequences caused a T_m increase of 0.75 °C/bp (88). Thus these architectures cause no major change in the binding affinity of 2′F-ANA on a per-insert basis. This is in contrast to a 2′-OMe-RNA–DNA chimera, for which a 1–1 altimer architecture was significantly destabilized in its binding to RNA (0.8 °C per RNA insert) with respect to an all-DNA strand (88). This demonstrates the compatible conformations of DNA and 2′F-ANA, but the conformational incompatibility of DNA and RNA (the latter apparently inducing multiple AB junctions within the duplex) (62). Another study has shown that these findings are also applicable to the binding affinity of 2′F-ANA–DNA chimeras with phosphorothioate backbones (94).

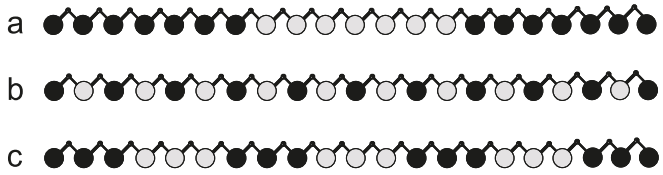
Fig. 5. Sample architectures of chimeric strands, to illustrate terminology: (*a*) gapmer; (*b*) 1–1 altimer; and (*c*) 3–3 altimer. In a typical 2′F-ANA–DNA chimera, the dark-colored beads would symbolize 2′F-ANA residues and the lighter beads would symbolize DNA.



The binding of 2′F-ANA–RNA chimeras is also more favorable than an all-RNA strand, whether binding to an RNA or DNA target strand (91). However, the enhanced binding is particularly strong when the target strand is DNA. This has been shown for various architectures, including a "gapmer"-type structure (a central 2′F-ANA region with RNA wings, see Fig. 5) and siRNA duplexes (91).

Fully modified 2′F-ANA strands, in contrast to ANA, also bind with high affinity to ssDNA. In one study of five 18-mer sequences, 2′F-ANA showed increased binding affinity (to DNA) ranging from 0.2 to 0.9 °C/bp relative to DNA, and 0.4 to 1.7 °C/bp relative to RNA (44).

2′F-ANA also forms stable homoduplexes (that is, 2′F-ANA·2′F-ANA duplexes). While ANA·ANA duplexes tend to be highly unstable (95), 2′F-ANA·2′F-ANA duplexes are more stable even than 2′F-ANA·RNA or RNA·RNA (89, 90)

One important finding related to binding affinity is that 2′F-ANA has a very high base pairing specificity. When a single mismatch was introduced into a DNA target strand, the T_m of the duplex dropped most sharply when the test strand was 2′F-ANA (8.0 °C), followed by RNA (7.2 °C), then DNA (3.9 °C) (44). When using an RNA target strand, introduction of a single mismatch caused the T_m of the duplex to drop most sharply when the test strand was RNA (9.3 °C), followed by 2′F-ANA (6.6 °C), then DNA (5.4 °C) (44) High base pairing specificity is essential for applications such as microarrays and other diagnostics, as well as for therapeutic applications.

2′F-ANA has also been used to increase the inter- and intramolecular binding affinity of triplexes and higher order nucleic acid structures, as discussed below.

We conclude this section by returning to the observation that the binding affinity of 2′F-ANA, to both RNA and DNA target strands, is dramatically higher than that of the related modification ANA. This is especially true when the target strand is DNA; ANA·DNA duplexes are so unstable that they are barely detectable. In a recent study of several 10-mer oligonucleotide duplexes, 2′F-ANA·RNA was the most stable, followed by RNA·RNA (ΔT_m = –4 °C), DNA·DNA (ΔT_m = –14 °C), DNA·RNA (ΔT_m = –18 °C), and finally ANA·RNA (ΔT_m = –19 °C) (89). The dramatic increase in target affinity upon changing OH to F has stimulated numerous studies by our group into the structure of 2′F-ANA and its duplexes, in an attempt to understand the causes of this difference, as described in the following section.

Studies on the structure, conformation, and hydration of 2′F-ANA

Nucleoside conformation

Various groups have undertaken conformational studies of 2′-fluoroarabinonucleosides. Early computational work suggested that the pyrimidine base of FMAU was locked into an *anti* orientation because of the presence of the top-face fluorine at 2′, and that the nucleoside puckered in the south (C2′-*endo*) (96) A study of NMR spectra at various temperatures concluded that FMAU was a relatively rigid nucleoside, with about 65% south character (97).

More recently, quantitative conformational studies have been done using the program PSEUROT (98), which assumes a two-state conformational equilibrium. This has been a key tool in allowing conformational discussions to move beyond vague references to "north" and "south" conformers. We summarize the available quantitative solution-phase parameters in Table 2 and Fig. 7 (structures of canonical and modified purine bases are shown in Fig. 6). Parameters for normal 2′-deoxyribo- and ribonucleosides (dN and rN) are included for comparison.

It becomes clear from Table 2 and Figs. 6 and 7 that there are differences within the literature on the solution-phase conformation of 2′-fluoroarabinonucleosides, specifically 2′F-araA and 2′F-araG. The 2′F-araN conformations, whether with canonical or modified bases, fall into four groupings, in the north, northeast, southeast, and south. Five researchers have found a pair of conformations in the north and southeast for the 2′-fluoroarabinonucleosides, while two others have found a pair of conformations in the northeast and south. For 2′F-araA and 2′F-araG, both of these pairs of conformations have been independently found. One explanation may be that these nucleotides are in fact characterized by a three- or four-state equilibrium, but either of the two pairs is sufficient to reproduce the observed coupling constants. (The PSEUROT program can only resolve equilibria of one or two conformers). Denisov et al. have described an oligonucleotide (hairpin) for which the two-state model adopted by PSEUROT was not adequate to explain the observed NOEs, but a three-state model (explored through molecular modeling) was suitable (105).

One property that emerges very clearly from the data is the presence of eastern conformations for 2′F-araN. All of the nucleosides studied have a predominant population of either the northeast or southeast conformer, with the sole exceptions of those with the unusual 3-bromopyrazolo[3,4-*d*]pyrimidine bases (4f and 4g) and a couple of other more extreme base modifications not included in Table 2 (101, 106). Thus, whichever description of the 2′-araN conformation is correct (north + southeast, northeast + south, or a four-state equilibrium), an eastern shift is observed when comparing 2′F-araN to dN: either the south becomes southeast, or the north becomes northeast, or two new eastern conformations are added to the equilibrium. Consistent with this shift to the east, strong NOE contacts have been observed between H1′ and H4′ of 2′F-araA (44).

Evidence from thermal stabilities

2′F-ANA is a DNA mimic in terms of its effect on helical structure (CD) and binding affinity (T_m). For example, when

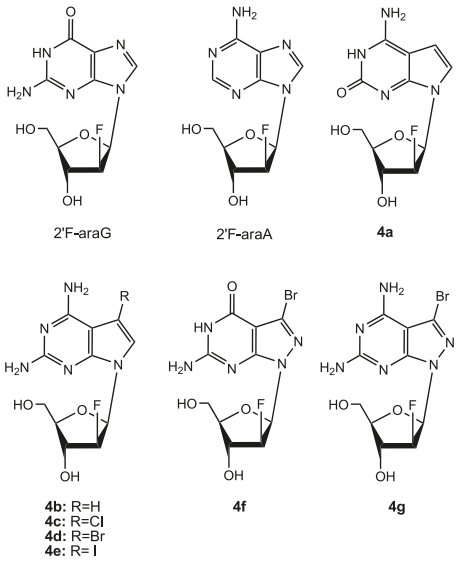
[a]Results for the *anti* base orientation were used since 2′-fluoroarabinonucleosides have a higher proportion of the *anti* orientation than their deoxynucleotide congeners (77, 96).

Fig. 6. 2′-Fluoroarabino purine nucleosides (with canonical and modified bases) for which quantitative solution-phase conformational parameters are available.



B-DNA was modified with 2′F-ANA units, the thermodynamic stability strongly increased. However, when 2′F-RNA units were used instead, the duplex was destabilized and the presence of an A–B junction was discerned by circular dichroic (CD) spectroscopy (62). Also, thermal stabilities of fully modified oligonucleotides show that 2′F-ANA mimics DNA, as shown by the following example: the known order of stability of the A/T system is dA/dT > rA/dT > rA/rU > dA/rU (107). Replacing the purine strands of 18-nt duplexes with 2′F-ANA and 2′F-RNA results in the order of stabilities 2′F-araA/dT (63.3 °C) > 2′F-rA/dT (48.0 °C) > 2′F-rA/rU (39.2 °C) > 2′F-araA/rU (30.2 °C) (90). Thus, the order is maintained, showing that 2′F-ANA and 2′F-RNA mimic the DNA and RNA structures, respectively.

However, the situation is slightly more complex. As we noted earlier, 2′F-ANA is structurally compatible with *both DNA* (88) *and RNA* (91), in various chimeric structures (as shown by an increase in thermal stability). In contrast, 1:1 DNA–RNA altimers were not compatible in their structures (88). Although the comparison is not perfect since we have not made 1:1 altimers of 2′F-ANA and RNA, it is interesting that while 2′F-ANA appears to be primarily a DNA mimic, it is compatible with RNA as well.

Conformational work on oligonucleotides

General information about the conformation of oligonucleotides can be obtained from CD spectra. CD traces of FANA·RNA and ANA·RNA duplexes are intermediate in form between DNA·RNA (A–B form) and RNA·RNA (A form) CD traces (44). In fact, they have more A-form character than the DNA·RNA hybrid. The CD spectrum of a pure 2′F-ANA·2′F-ANA duplex is also interesting in that it closely resembles the B-form signature above 250 nm, but has strong negative peaks at 207 and 245 nm that are closer to those of an RNA·RNA CD trace (90). These two observations are consistent with the ability of 2′F-ANA to mimic the DNA structure, while being compatible with RNA environments as well.

The first quantitative structural work on 2′F-ANA inserts in a DNA duplex was a crystallographic study that found

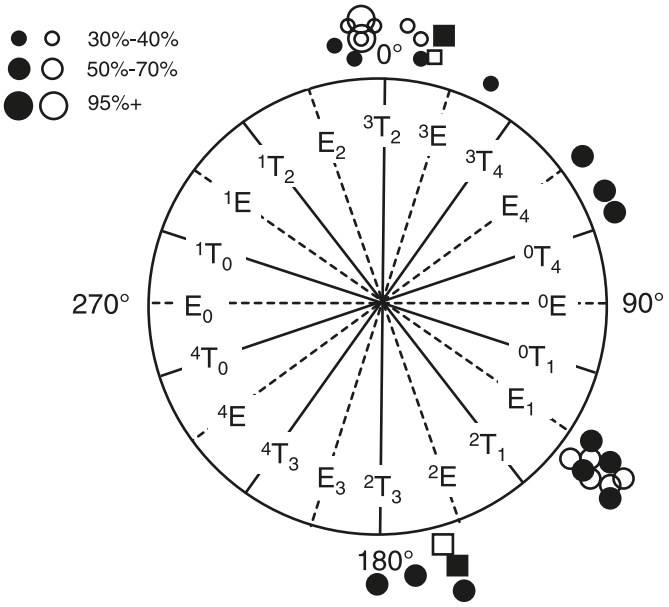
Fig. 7. The conformational parameters from Table 2 shown on the pseudorotational wheel. Legend: filled squares, rN; empty squares, dN; filled circles, 2′F-araN with canonical bases; empty circles, 2′F-araN with modified bases. Values for dN and rN are averages for purine and pyrimidine values. Sizes of circles are approximately proportional to the mole fraction of each conformer shown.



that 2′F-ANA inserts in the Dickerson–Drew dodecamer adopted an O4′-*endo* pucker (63). Significantly, the pucker of the neighboring nucleotides was not greatly affected (63). Thus this rare conformation is fully compatible with the B-form helical environment.

The most important structural study of ANA·RNA and 2′F-ANA·RNA duplexes to date examined short hairpins containing a 4-bp hybrid stem and a 4-nt DNA loop by NMR spectroscopy (105, 108). A third hairpin was studied comprising a DNA·RNA stem, for comparison. The conclusions of this study were as follows:

(*i*) The arabinose sugars of both 2′F-ANA·RNA and ANA·RNA duplexes are strongly preorganized into an O4′-*endo* (east) pucker (105, 108). Very strong H1′–H4′ NOE crosspeaks are observed for both 2′F-ANA and ANA residues (105, 108). In contrast to the deoxyribose sugars of the DNA·RNA duplex, which are very dynamic, the ANA and 2′F-ANA sugars are quite rigid (at least 75% O4′-*endo*, with the other 0–25% made up of northern and (or) southern puckers). The terminal nucleotides are exceptions, presumably because they have more conformational freedom because of end fraying. The rigidity of 2′F-ANA and ANA may explain the slower kinetics of RNase H cleavage of both modified hybrid duplexes (93). However, since both are rigid, it cannot explain the difference in duplex stability (105, 108). Two previous computational studies had also predicted the O4′-*endo* pucker for 2′F-ANA·RNA duplexes, but not for ANA (109,110).

(*ii*) The helical parameters, especially minor groove width, are similar for all three duplexes and are intermediate between A-form and B-form structures (105, 108). This may be the key to the recognition of all three duplexes by RNase H. This finding is consistent with earlier computational work on both duplexes (109).

(*iii*) No evidence for OH2′–O5′ hydrogen bonding was observed in the case of ANA sugars in the ANA·RNA duplex (105). In contrast, previous computational work had attributed the predominant C2′-*endo* sugar pucker observed for ANA sugars in that study to the influence of H-bonding (109).

(*iv*) Very little difference was observed between the conformations of ANA and 2′F-ANA (105). Since no steric hindrance was observed in the case of ANA, and the conformation and flexibility did not differ significantly, it was concluded that the large difference in duplex stability was likely due to differences in hydration.

It is noteworthy that both [3.3.0]bc-ANA and [3.2.0]bc-ANA (Fig. 8) show high affinity pairing to RNA, and the latter also to DNA (110, 111). The reason most commonly advanced for this high affinity is the lack of conformational freedom of the sugar ring. The increased rigidity of the 2′F-ANA (nucleoside and oligonucleotide) means that this reasoning might help explain the increased binding affinity of 2′F-ANA as well. However, ANA oligonucleotides were also observed to be quite rigid when in duplexes with RNA. Thus there may be other reasons for the difference between ANA and its higher affinity cousins 2′F-ANA and bc-ANA. For example, the lack of a hydrogen-bond donor at the 2′ position would change the hydration pattern of the duplex and eliminate the possibility of OH2′-O5′ H-bonding interactions.

Another crystallographic study of single inserts has recently called into question some of the previous results by showing that single 2′F-ANA inserts adopt eastern puckers in the context of a B-form helix but pucker in the north when included in an A-form DNA helix (112). In contrast, ANA inserts maintained a southeastern pucker in both helical environments. The latter result seems to contradict the earlier work on A-like 2′F-ANA·RNA hairpins, and the authors' conclusion that 2′F-ANA "disfavors the southern and south-eastern pucker ranges" (112) also seems to contradict evidence from CD and thermal stability data (see above). We believe caution is essential when interpreting results from single inserts in an oligonucleotide; however, if this interesting result is confirmed in other contexts, it may help explain not only the high thermal stability of 2′F-ANA·RNA duplexes, but also why 2′F-ANA–RNA chimeric structures maintain high binding affinity.

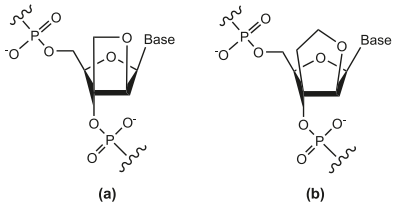
Because of this new result, and the ongoing lack of a satisfactory explanation for the different binding affinities of ANA and 2′F-ANA for RNA, we are currently undertaking another NMR study using 10-mer duplexes (not hairpins) of mixed base composition. We are hopeful that this study will provide further insight into the structure and dynamics of ANA and 2′F-ANA (89).

Hydration

Berger et al. observed an ordered water structure around the 2′-fluorines of FMAU residues incorporated into the Dickerson–Drew dodecamer. However, the contacts were relatively long and argued against strongly stabilizing hydrogen bonds to fluorine (63). More recently, Li et al. observed that the groove regions around 2′F-ANA residues incorporated into DNA oligomers were dry, in contrast with ANA

© 2008 NRC Canada

Fig. 8. Structures of (*a*) [3.2.0]bc-ANA and (*b*) [3.3.0]bc-ANA oligomers.



residues that were heavily hydrated (112). To extend this kind of study to the context of fully modified oligonucleotides, we recently made fully modified 2′F-ANA·RNA and ANA·RNA 10-mer duplexes and are currently undertaking a study of the hydration of these duplexes by osmotic stressing (113). Preliminary results indicate that 2′F-ANA·RNA duplexes liberate significantly fewer molecules of ordered water upon melting than do DNA·RNA or ANA·RNA (89). This entails a significant entropic benefit for 2′F-ANA·RNA duplexes (no need to order water molecules) but an enthalpic penalty (H-bonding from ordered water typically makes a significant enthalpic contribution). Interestingly, thermodynamic analysis of this duplex indicated that it was strongly enthalpically favored, even with its low levels of hydration. The low hydration of 2′F-ANA leads to a significant entropic benefit over other strands, and because of its inherently high enthalpy of binding, its low hydration may actually lead to a significant advantage in terms of binding affinity.

Optimization of RNase H activity and recent antisense applications

The combination of high-affinity, specific binding, nuclease stability, and RNase H activation attracted significant interest in 2′F-ANA, and studies were soon undertaken to characterize and optimize its antisense activity (114).

A fully modified 2′F-ANA strand induces RNase H cleavage to a lesser extent than DNA. Lok et al. tested phosphorothioate gapmers (see Fig. 5) containing 2′F-ANA wings and a central DNA gap, and showed that the combination is more active than a strand containing only DNA (93). Furthermore, the potency of the chimera was unchanged for gap sizes ranging from 4 to 10 nucleotides. This was in sharp contrast to chimeras containing RNA wings and a central DNA gap, whose potency dropped below that of all-DNA strands when the DNA gap size dropped below 8 nucleotides (93). It was suggested that the potency of the 2′F-ANA-DNA chimera is related to its increased flexibility with respect to an all-2′F-ANA strand. Accordingly, insertion of an acyclic nucleoside or an alkyl linker into 2′F-ANA oligonucleotides increased their ability to induce RNase H (Fig. 9) (115). This held true even when the AON targeted a highly structured RNA (115). The 2′F-ANA AONs containing butyl linkers comprised the first examples of high potency AONs containing unstructured elements that did not participate in base-pairing (115). A peptide nucleic acid (PNA) insert within a 2′F-ANA strand also provided some improvement in RNase H activation, although not as much as a butyl linker (116). Thus, either DNA–2′F-ANA chimeric constructs or flexible units within a 2′F-ANA AON provided means of improving the ability of 2′F-ANA to activate RNase H.

Another study compared the effects of a variety of single modified inserts into a DNA strand (117). Nucleosides with north, east, and south conformational biases and with varying degrees of steric hindrance and flexibility were studied. The 2′F-arabinonucleosides (T and C bases) were shown to have the most favorable effect on the kinetics of RNase H cleavage. This was attributed to their eastern conformational bias, relatively high conformational flexibility in the context of this oligodeoxyribonucleotide, and favorable sterics in the minor groove (117).

The DNA–2′F-ANA chimeric constructs were also optimized. It was found that a 3–3 altimer construct (Fig. 5) provided the highest potency RNase H-activating AON, equal to or better than a DNA gap surrounded by 2′F-ANA wings (gapmer) (88). Both the altimer and gapmer strand architectures consistently outperformed DNA itself and were applicable to both PO and PS backbones (80, 81, 88, 93). A study on luciferase knockdown in HeLa cells demonstrated that PS-2′F-ANA altimers and gapmers outperform both PS-DNA and PS or mixed backbone DNA–RNA chimeras (81). The PS-2′F-ANA gapmer gave comparable results to the better of two siRNAs targeting luciferase mRNA, in both potency and duration of action (81).

These optimized AONs have seen several recent applications. Lacombe et al. showed that PS-2′F-ANA–DNA chimeras are more effective than PS-DNA AONs in reducing expression levels of Flk-1, a VEGF receptor. However, both chemistries gave comparable levels of VEGF activity (94). Kalota et al. found that both altimer and gapmer architectures of PS-2′F-ANA–DNA chimeras were able to silence expression of c-MYB (a protooncogene involved in various hematologic malignancies) in human leukemia cell line K562 at 20% of the concentration of the corresponding PS-DNA AONs (80). Furthermore, gene silencing using the 2′F-ANA-modified AONs was nearly complete, and lasted twice as long as the unmodified AONs (80). At least part of the improvement was found to be the higher intracellular concentration of the 2′F-ANA-modified AON, because of its greater nuclease resistance (80). This data, along with the studies described below, demonstrates the effectiveness of 2′F-ANA against clinically relevant targets.

2′F-ANA oligomers are close to being clinically validated. TPI-1100, a PS-2′F-ANA–DNA chimera designed to treat chronic obstructive pulmonary disease (COPD), is being developed by Topigen Pharmaceuticals, Inc. Delivered via aerosol, TPI-1100 inhibits the expression of multiple phosphodiesterases (PDEs) considered therapeutic targets for alleviating COPD, a deadly, debilitating disease characterized by inflammation of the airways. Local delivery of TPI-1100 has the advantage that the dose of the oligomer required for efficacy is significantly lower (μg) when delivered directly to lung tissue. Pulmonary delivery also potentially reduces undesirable systemic side effects and overcomes the challenges of systemic delivery of oligonucleotides that target tissues within the body. Phase 1 clinical studies are planned to start in 2009 (118).

Table 3. Differences between antisense and RNAi strategies.

Antisense	RNAi
Catalytic enzyme is RNase H	Catalytic enzyme is an Argonaute enzyme, part of the RNA-Induced Silencing Complex (RISC).
RNA·DNA duplexes recognized	siRNA (short, double-stranded RNA) recognized
Exogenous oligonucleotide introduced as a single strand	Exogenous oligonucleotides introduced as an siRNA duplex, one strand subsequently incorporated into RISC.
DNA-like modifications required for RNase H activity	RNA-like modifications required for RISC activity

siFANA

While the AON strategy is still an attractive therapeutic option, RNA interference (RNAi) is the gene silencing strategy that has attracted the most attention in recent years, including the 2006 Nobel Prize in physiology or medicine. The two strategies have been compared in various studies (119).

Both approaches involve the cleavage of mRNA by an endonuclease, guided by an exogenous oligonucleotide strand. However, there are several important differences, summarized in Table 3.

Unmodified short interfering RNA duplexes have been used with success for gene silencing; however, chemical modification of one or both of the strands will likely be necessary for therapeutic use (120). Numerous chemical modifications have been tested for effects on siRNA activity, and key benefits have been achieved (including improved biostability, uptake, specificity, and potency) (120, 121). A wide variety of RNA-like modifications can be introduced into siRNA duplexes without perturbing the overall A-form helical structure required for activity. It is not clear yet which chemical modifications will be the most advantageous.

We hypothesized that despite the generally DNA-like properties of 2′F-ANA, siRNA duplexes could be partially 2′F-ANA-modified without compromising their recognition by RISC during the various steps of RNAi. Dowler et al. were the first to show that 2′F-ANA could be incorporated throughout the sense strand, including a fully modified sense strand (76). Watts et al. later showed that the potency of 2′F-ANA-modified sense strands could be significantly improved by including five RNA inserts near the 3′-end of the strand (91). As for antisense strand modifications, a small number of 2′F-ANA inserts are generally well tolerated throughout the strand, although 5′-modified antisense strands should be phosphorylated before introduction into cells to retain high potency (91). Modification of the antisense-strand 3′-overhang with 2′F-ANA brought a significant increase in potency (76). Several of the 2′F-ANA-modified duplexes have been able to surpass the native siRNA in potency (76).

Furthermore, siRNA duplexes with extensive 2′F-ANA modification were found to have a significantly longer serum half-life than unmodified siRNAs. For example, the serum half-life of an siRNA was extended from 15 min to 5 h by replacing the sense strand with 2′F-ANA (76). This is likely why the duration of action of siRNA was found to improve upon 2′F-ANA modification (76).

While it is true that the siRNA duplexes containing entirely 2′F-ANA sense strands are capable of eliciting RNase H activity that would cleave the RNA antisense strands, this activity is not optimal for 2′F-ANA in the absence of DNA units or flexible linkers (as discussed above) and thus allows enough time for the antisense strand to be loaded into the RISC complex.

In summary, 2′F-ANA modified siRNA can have high efficacy, comparable to that of standard siRNAs, but with improved biostability provided by the 2′F-araN nucleotides thus overcoming one of the therapeutic limitations of siRNA.

2′F-ANA in triplexes

One of the earliest studies on 2′F-ANA demonstrated that it can effectively form "pyrimidine motif" triplexes where a pyrimidine-rich third strand binds parallel to the purine strand of a target duplex (122). In general, 2′F-ANA mimics DNA rather than RNA as a triple-helix-forming agent. For example, RNA can form a triple helix with any of the four target duplexes DD, DR, RD, or RR (where the first letter represents the purine strand and the second the pyrimidine strand; thus DR would be a duplex consisting of a purine-rich strand of DNA with a pyrimidine-rich strand of RNA). DNA and 2′F-ANA can only form duplexes with DD and DR target duplexes. The binding affinity of the 2′F-ANA third strand is greater than that of DNA or 2′F-RNA (attributed to favorable preorganization of 2′F-ANA) (122) but less than that of an RNA third strand (attributed to its lack of a 2′-OH group (122), which can interact with interstrand phosphates in the case of an RNA third strand) (123).

2′F-ANA-modified aptamers and higher-order structures

Aptamers, nucleic acid species with binding or catalytic properties, have generated intense interest in recent years because they are so readily available via molecular evolution techniques, often called SELEX (systematic evolution of ligands by exponential enrichement) (124). To make aptamers containing chemical modifications (to improve their properties, especially nuclease resistance), modified triphosphates can be used during the evolution process, or the unmodified aptamer can be carefully modified after determination of its sequence. The latter avenue toward modified aptamers is more challenging, since chemical modifications can affect the structure and properties of the aptamer in a way not accounted for by the selection process. However, it allows modification at selected positions and using nucleotides not amenable to the SELEX process. For example, the first aptamer-based therapeutic, Macugen® (pegaptanib sodium), was approved by the FDA in December 2004. This aptamer was discovered by the SELEX method (including use of some modified nucleoside triphosphates) but was subsequently optimized ("post-SELEX modification") to confer biostability required for in vivo use (125).

Non-evolution-based 2′F-ANA aptamers

More recent work has shown that 2′F-ANA is suitable for use in the modification of aptamers containing G-quartets (77). The top-face fluorine of 2′F-ANA nucleotides favors the *anti*-orientation around the glycosidic bond. Consistent with this, 2′F-ANA modification of *anti*-dG residues of three different G-quartet-containing DNA aptamers led to increased thermal stability as well as increased nuclease resistance. Replacement of the *syn*-dGs, on the other had, led to decreased stability or a total structural transformation. A thrombin-binding aptamer had up to 48-fold greater stability to 10% FBS when modified with 2′F-araN residues (77). As well as the G quartets, 2′F-ANA modification of certain thymines in a loop of this aptamer caused increased thermal stability, nuclease resistance, and binding to thrombin (77).

The i-motif, a C-tetrad structure formed by C-rich DNA sequences (126), has also been modified with 2′F-araN residues. 2′F-ANA modification of all Cs in the hexamer dTCCCCC led to an 8.5 °C decrease in thermal stability at pH 4.5. However, the 2′F-ANA-modified structure was stable over a much wider range of pH (for example, its T_m values were 6.5 °C higher than those of the DNA structure at pH 3.5). Since the i-motif involves C·C$^+$ base pairs (126), this finding can be explained by the lower pK_a of 2′F-araC (3.88) than dC (4.5) (2). This study also demonstrated that the preorganization of 2′F-ANA led to more favorable kinetics for the modified C-tetrads. Improvements in pH range and kinetics are thus two ways in which 2′F-ANA may broaden the scope of applications of aptamers.

In another study, branched oligonucleotides made of dC or araC were shown to associate into the i-motif at acidic pH, unlike the corresponding RNA structures (127), This occurs in spite of the fact that most of the sugar residues in i-DNA tetrads adopt the C3′-*endo* (north) sugar pucker. It was attributed to different steric effects of the 2′-substituent (127).

SELEX using 2′F-ANA

For a modified nucleotide to be compatible with the SELEX process, two conditions are necessary: (*i*) the corresponding nucleoside 5′-triphosphates must be substrates of a polymerase enzyme, able to be incorporated with good fidelity into a PCR-type system, and (*ii*) the modified strand must be able to act as a template for the creation of a corresponding cDNA library. 2′F-araN 5′-triphosphates are indeed substrates of several readily available polymerase enzymes. Surprisingly, in some cases they are incorporated with higher fidelity than dNTPs (128), The biosynthesis of pyrimidine 2′F-ANA and 2′F-RNA triphosphates was later compared using four DNA polymerases. It was found that 2′F-araTTP was significantly better incorporated than 2′F-rUTP, but 2′F-rCTP was slightly preferred over 2′F-araCTP (129).

As for the second condition, it has been shown that a chimeric 2′F-ANA–DNA strand can act as a template for the biosynthesis of a chimeric complementary strand, and in other experiments, that a fully modified 2′F-ANA strand can act as a template for the biosynthesis of a complementary DNA strand (128). Thus, 2′F-ANA appears to have great potential for use within the SELEX process.

Other oligonucleotide derivatives based on 2′F-ANA

The attractive properties of 2′F-ANA have stimulated the development of several other 2′F-ANA-based oligonucleotide derivatives (Fig. 10).

For example, a 2′F-ANA sugar has been tested in combination with P3′–N5′ (130) and N3′–P5′ (85) phosphoramidate linkages. For the P3′–N5′ linkage, the resulting oligonucleotide analogue had lower binding affinity than its phosphodiester counterpart but retained the ability to elicit RNase H activity (130). In fact, the 2′F-ANA phosphoramidate analogue was better able to elicit RNase H activity than a corresponding DNA phosphoramidate oligomer (130). As for the N3′–P5′ phosphoramidate backbone, nucleosides introduced into this backbone appeared to pucker in the north (85). This may be due to the stereoelectronic effect of changing the 3′ group to an amine since the corresponding 2′-deoxy phosphoramidate showed a similar conformation (85). The 2′F-ANA N3′–P5′ phosphoramidate showed increased stability to base with respect to its 2′-epimer, phosphoramidate-linked 2′F-RNA, but lower binding affinity to DNA and RNA (85).

2′F-ANA sugars have been modified with sulfur at the 3′ and 4′ positions. Elzagheid et al. described the synthesis of 2′-deoxy-2′-fluoro-3′-thioarabinothymidine (131). This synthesis has been challenging to repeat, however, since the 3′-SH group (in the precursor to the phosphoramidite) tends to displace the 2′-fluorine, resulting in a 2′,3′-episulfide product (132).

Watts et al. synthesized the 4′-thio analogue of 2′F-ANA and discovered that the change triggers a dramatic conformational shift to the north (3′-*endo*) at the nucleoside level (100) (Fig. 11). This change is carried through to the structure of the corresponding oligonucleotide analogues as well (termed 4′S-FANA), which are rather A-like in character according to CD and as expected lose the ability to elicit

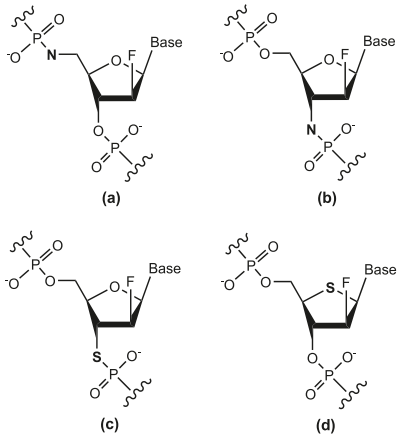
Fig. 10. Other oligonucleotide derivatives based on 2′F-ANA: (*a*) 2′-fluoroarabino P3′–N5′ phosphoramidates (130); (*b*) 2′-fluoroarabino N3′–P5′ phosphoramidates (85); (*c*) 3′S-FANA (131); and (*d*) 4′S-FANA (91).



RNase H activity (91). However, the 4′S-FANA derivative is well-tolerated in siRNA duplexes, although it has lower binding affinity than 2′F-ANA itself (91).

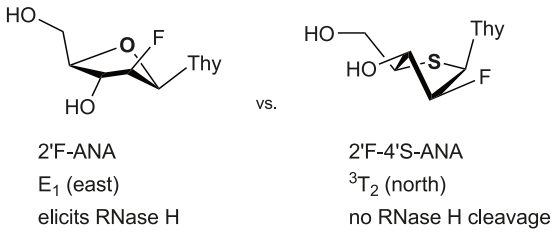
Considerations for use of 2′F-ANA in vivo

Given the toxicity of 2′-deoxy-2′-fluoroarabinonucleosides such as FMAU and FIAU, discussed above, any potential in vivo use of 2′F-ANA in therapeutics must provide assurance that the catabolic metabolites (2′F-araN and their nucleotides) will not cause significant side effects. However, the success of the nucleoside analogue clofarabine, the progression toward use of 2′-fluoroarabinonucleosides as PET tracers, and the ongoing pre-clinical studies on 2′F-ANA discussed above makes it clear that 2′F-ANA remains a promising entity for therapeutic use, as long as the in vivo concentrations of the constituent nucleosides remain low. An initial preclinical toxicology study has been performed in mice to compare the toxicological profile of a phosphorothioate 2′F-ANA-containing oligonucleotide (5-gap-4 configuration) and a phosphorothioate DNA oligonucleotide following repeated administrations. The sequence used in the study was that of Monia et al. ISIS 5132, targeting the human c-Raf-1 (133). The oligonucleotides were administered every other day for 28 days (14 doses) at a dose up to 50 mg/kg by iv injection via the lateral tail vein. In line with previous reports, the toxicities observed in this study all appeared to be related to the phosphorothioate chemical class of the oligonucleotides (134). Furthermore, no clear difference could be observed between the two chemistries, suggesting that they are not side effects of 2′F-ANA. Due to the greater efficacy and stability of 2′F-ANA oligos, it is expected that a lower or less frequent dosing will be effective, thus lowering any toxicity.

Summary

2′-Fluoroarabinonucleosides are immensely versatile chemical modifications on their own or in oligonucleotides. 2′F-araNs such as clofarabine are already being used as therapeutics, and other compounds are being studied as drugs

Fig 11. Conformational switch and corresponding change in biological properties, upon changing the ring heteroatom of 2′F-ANA from oxygen to sulfur (100).



and for in vivo applications such as PET. While 2′F-ANA oligonucleotides form stable duplexes with RNA and these duplexes activate RNase H, additional structural alterations to the backbone further increase the capability to inhibit protein expression. This optimization can be done using gapmer or altimer chimeric constructs, or flexible linkers, according to the target sequence. Different chimeric constructs can also be used in the application of 2′F-ANA to other oligonucleotide approaches (siRNA and aptamers).

2′F-ANA oligonucleotides significantly enhance nuclease resistance, providing lower dosage requirements and the potential for improved systemic administration and safety for oligonucleotide therapeutics including antisense, aptamers, and siRNA. The increased stability exhibited by 2′F-ANA-modified oligonucleotides has the potential to increase their in vivo efficacy. This stability is tunable in that the half life in vivo can be controlled by the extent of 2′F-ANA modification. 2′F-ANA-modified oligomers allow for highly potent, long-lasting gene-silencing effects in both antisense and RNAi approaches. In a series of studies comparing available AON chemistries, 2′F-ANA oligonucleotides showed an improvement in target affinity and duration of gene response while improving efficacy (81). The unique characteristics of 2′F-ANA could be advantageous for a wide variety of therapeutic gene or protein-modifying applications, including topical and systemic administration. A drug candidate is scheduled to enter clinical trials in 2009.

Finally, we note that 2′F-ANA also has potential in the areas of diagnostics and biosensor reagents because of its wide range of pH stability, nuclease resistance, and high binding affinity. Tools can be rationally designed or evolved. Time will tell which of these applications will prove most beneficial. The next forty years of 2′-fluoroarabino nucleosides, nucleotides, and nucleic acids will be no less interesting than the first forty.

Effectiveness factor of Pt utilization in cathode catalyst layer of polymer electrolyte fuel cells

Zetao Xia, Qianpu Wang, Michael Eikerling, and Zhongsheng Liu

Abstract: In this work, we analyze effectiveness factors of Pt utilization in perfluorosulfonate ionomer (PFSI) bonded thin film cathode catalyst layers of polymer electrolyte fuel cells. We define the effectiveness factor of Pt utilization as the apparent rate of current conversion exhibited by a specific catalyst layer design divided by the ideal rate obtained if all Pt atoms were used equally in electrochemical reactions at the specified electrode overpotential and externally provided reactant concentrations. This definition includes statistical factors at all relevant scales as well as non-uniformities of reaction rate distributions under operation. Our model is based on the random composite agglomerated morphology of the catalyst layer. It accounts for the interplay of transport phenomena and electrochemical kinetics. At the mesoscopic scale, limited effectiveness of Pt utilization in agglomerates is mainly an electrostatic effect. We determined spatial distributions of effectiveness factors of agglomerates in the through-plane direction, and thereafter calculated overall effectiveness factors of the cathode catalyst layer. Our results show that small agglomerate radius, low operating current density, high operating temperature, and high oxygen partial pressure result in high effectiveness factors of Pt utilization. Finally, we compared PFSI-bonded thin film cathode catalyst layers with ultrathin two-phase cathode catalyst layers in terms of effectiveness factors. Including the surface to volume atom ratio of Pt nanoparticles, the two different types of structures exhibit similar effectiveness factors of Pt utilization, which are found to be distinctly below 10%.

Key words: polymer electrolyte fuel cells, fuel cell modeling, cathode catalyst layer, Pt utilization, effectiveness factor.

Résumé : Dans ce travail, on analyse les facteurs d'efficacité de l'utilisation du platine dans un ionomère perfluorosulfonate (IPFS) lié à des couches de catalyseur cathodique en film mince pour des piles à combustible en polymère électrolyte. On a défini le facteur d'efficacité de l'utilisation du platine comme la vitesse apparente de la conversion du courant qui est présentée par un arrangement particulier d'un catalyseur spécifique divisée par la vitesse idéale obtenue si tous les atomes de platine sont utilisés également dans les réactions électrochimiques, au surpotentiel d'électrode spécifié et aux concentrations de réactifs fournies extérieurement. Cette définition inclut des facteurs statistiques à toutes les échelles appropriées ainsi que des distributions de vitesses réactionnelles non uniformes dans les conditions d'opération. Le modèle est basé sur la morphologie agglomérée et composite au hasard de la couche de catalyseur. Il tient compte des interactions des phénomènes de transport et des cinétiques électrochimiques. À l'échelle mésoscopique, l'efficacité limitée de l'utilisation du platine dans les agglomérés résulte principalement d'un effet électrostatique. On a déterminé les distributions spatiales des facteurs d'efficacité des agglomérés dans la direction à travers le plan et on a donc calculé les facteurs d'efficacité globaux de la couche du catalyseur de la cathode. Les résultats montrent que des agglomérés de faible rayon et que l'utilisation d'une faible densité de courant d'opération, une température d'opération élevée et une pression partielle d'oxygène élevée conduisent à des facteurs d'efficacité élevés pour l'utilisation du platine. Enfin, on a comparé les facteurs d'efficacité des couches de catalyseur cathodique en film mince liées à un ionomère de perfulorsulfonate avec ceux de couches de catalyseur cathodique en deux phases ultraminces. Si l'on inclut le rapport surface à volume atomique des nanoparticules de platine, les deux types différents de structures présentent des facteurs d'efficacité d'utilisation du platine qui se ressemblent et qui sont bien en-dessous de 10%.

Mots-clés : piles à combustible en polymère électrolyte, modèle d'une pile à combustible, couche de catalyseur cathodique, utilisation du platine, facteur d'efficacité.

Introduction

Polymer electrolyte fuel cells (PEFCs) are considered to be potentially clean power sources for stationary applications, electric vehicles, and portable devices. However, high costs, durability issues, and present insufficient power densities of these electrochemical energy conversion devices impede their rapid commercialization. Prohibitively high costs stem mainly from the polymer electrolyte membrane, Pt-based catalyst, and bipolar plates. With operating tempera-

 doi:10.1139/V08-053 © 2008 NRC Canada

tures <90 °C, only Pt and Pt-alloy catalysts provide acceptable rates of electrocatalytic current conversion in electrodes (1, 2). Due to limited resources and the high cost of Pt, its amount in PEFCs should be as small as possible. Therefore, improving Pt utilization and effectiveness factors in catalyst layers is a major challenge for PEFC research.

Typical catalyst layers in PEFCs are 5–10 μm thick films, sandwiched between a membrane and a gas diffusion layer (GDL, carbon paper or carbon cloth). These random composite media consist of a mixture of proton-conducting perfluorosulfonated ionomer (PFSI) and carbon–Pt particles (3, 4). The generation of electrical current proceeds at Pt nanoparticles, usually 2–4 nm in diameter, which are supported on high surface area nano-to-mesoporous carbon materials. It has been observed that the size of primary carbon particles is 5–20 nm. In colloidal dispersion of carbon–Pt particles and dissolved ionomer molecules, self organization leads to the formation of agglomerates of carbon–Pt, while ionomer domains form a separate phase that binds to the surfaces of those agglomerates (5–14). In a recent work, Malek et al. (15) employed computational modeling based on coarse-grained molecular dynamics (CGMD) to perform a systematic structural analysis of the microphase segregation that occurs during the fabrication process of catalyst layers. The meso-scale simulations provide insights into structural correlations and dynamical behavior of different phases in the catalyst layer composite. Structural analysis of CGMD results (15) and experimental data (10–14) suggest the formation of an agglomerated, phase-segregated morphology with bimodal porous architecture. Primary pores (3–10 nm radius) exist between carbon particles inside agglomerates, and secondary pores (10–50 nm) between agglomerates. Aggregates of PFSI form an interconnected phase in secondary pores, which does, however, not penetrate into primary pores. The network of carbon–Pt provides pathways for electron transport to the reaction sites; the ionomer network provides pathways for protons to reach reaction sites; a network of open pores functions as pathways for the gaseous diffusion of oxygen and water vapor (16).

Based on this structural picture, modeling studies suggest a state of optimal saturation in which primary pores are filled with liquid water to maximize the active area, while secondary pores are open for gaseous transport of reactants (16). In ref. 17 we evaluated two types of agglomerates, viz. ionomer-filled and water-filled agglomerates with distinct compositions and sizes in terms of transport processes, electrochemical reactivity, and effectiveness factors. In water-filled agglomerates, we assumed complete flooding of primary pores.

In ref. 16, Eikerling developed a structure-based model for water management in cathode catalyst layers (CCLs) of PEFCs. In his model, liquid water saturation was studied in relation to pore size distribution, total gas pressure, capillary pressure, and wetting properties of pores. Effects on water production and evaporation were considered. The results demonstrate that pore space is partially saturated with liquid water, and saturation varies with operating conditions and current density. A formalism for calculating the internal wetted pore fraction under stationary operation was provided. In the ideally wetted state, local capillary equilibrium between liquid and gas pressures forces liquid water to retreat to primary pores, which favors large reaction and evaporation rates, and at the same time the majority of secondary pores are open for gaseous transport of reactants and products. It is also postulated that reactions could occur only at interfaces between Pt and liquid water in substrate pores or in ionomer. Pt nanoparticles at Pt–gas contacts are inactive because of the prohibited proton access. Overall, this work highlighted the role of the CCL as a watershed in the fuel cell, which controls water fluxes towards PEM and GDL sides and plays a key-role in converting liquid water into vapor.

Most commonly, definitions can be found that specify Pt utilization as the ratio of the electrochemically active surface area to the total surface area of Pt particles. This definition refers merely to a static property of the medium. Moreover, it relates to surface area ratios and not to ratios of atom numbers or masses of utilized amount of Pt over total amount of Pt. It is, therefore, insufficient for capturing limitations of the catalytic capability of a typical catalyst layer and for assessing the reserves for improvement through advanced structural design. Reduced effectiveness of catalyst utilization is due to statistical inhomogeneities at multiple scales as well as non-uniform distributions of reactants, electrostatic potentials, and rates of electrochemical reactions at agglomerate and CCL levels. To include structural and operational effects at all scales, we define the effectiveness factor of Pt utilization as the apparent rate of current conversion exhibited by a specific catalyst layer design divided by the ideal rate obtained if all Pt atoms were used equally in electrochemical reactions at the specified electrode overpotential and externally provided reactant concentrations. It should be emphasized that this definition includes sensitive dependencies of electrocatalytic reactivities on sizes, composition, and surface structures of nanoparticles, which is an emerging area in fuel cell research (18–22).

The effectiveness factor of Pt utilization is intimately linked to the uniformity of reaction rate distributions. The latter is affected by processes at all levels, including surface transport and kinetics at Pt nanoparticles, as well as transport of reactants and product water at agglomerate level, catalyst layer level, MEA level, unit cell level, and stack level. In the present paper, we explore these contributions only up to the catalyst layer level, by combining our water-filled agglomerate model (17) with the structure-based macrohomogeneous model (16). Further detriments on reaction rate distributions and overall voltage efficiency because of limited transport in gas diffusion layers and flow fields have been neglected. Our calculations focus on the role of transport phenomena and electrochemical reactions inside the CCLs. The structural picture that we exploit is based on TEM pictures (8, 9), measured pore size distributions (9, 12), and coarse-grained MD simulations (15). Moreover, this picture has been successfully applied in systematic optimization studies (6–8, 23, 24).

We will obtain a detailed spatially resolved picture of the effectiveness of Pt utilization, accounting for spatial statistical inhomogeneities and non-uniformities of reaction rate distributions because of transport processes. The overall effectiveness factors will be evaluated for varying structure and operation conditions of the CCLs. The mathematical model is in the form that the water-filled agglomerate model is nested in the macrohomogeneous cathode catalyst layer

model. The water-filled agglomerate model is based on the Nernst–Planck equation of proton transport in water-filled channels, the Poisson equation for proton charge density in agglomerates, Fick's law of oxygen diffusion in water, and the electrochemical source term. The macrohomogeneous catalyst layer model is governed by conservation equations of mass and electrical charges, Ohm's law of proton transport, and Fick's law of gaseous diffusion of oxygen. Assumptions of the combined model are the same as for previous models. Based on the model, effectiveness factors of Pt utilization in typical PFSI-bonded thin film CCLs will be discussed and compared with 3M ultrathin two-phase CCLs (25). To obtain the overall effectiveness factor of Pt utilization, we make use of the assumption that effects at different length scales are well separated. We first focus on the effects at agglomerate and macrohomogeneous scale and in the final evaluation incorporate nanoparticle effects as well.

Pt utilization and effectiveness factor

A plethora of publications in fuel cell research dwell on issues related to Pt utilization in PEFCs. Here we provide a brief survey of representative studies that focused on Pt utilization and effectiveness factors (17, 25–50). In the past, ambiguous definitions of catalyst utilization have been exploited and contradictory values have been reported, which could lead to a wrongful assessment as to how much the performance of fuel cells could be improved by the advanced structural design of catalyst layers. Evidently, the accurate determination of catalyst utilization and effectiveness factors has a major impact on determining priorities in catalyst layer research.

In most studies, Pt utilization is defined as the ratio of the electrochemically active surface area, which is accessible to electrons and protons, to the total surface area of Pt. Pt utilization has been considered under different conditions, viz. in the catalyst powder and in the membrane electrode assembly (MEA). The Pt utilization in the catalyst powder is defined as,

$$[1] \qquad u_{\mathrm{Pt,cat}} = S_{\mathrm{Pt,cat}}/S_{\mathrm{Pt,tot}}$$

Here, the electrochemically active surface area in the catalyst powder, $S_{\mathrm{Pt,cat}}$, was estimated from the charge under the H-adsorption or CO-stripping waves measured by thin-film rotating disk electrode (TF-RDE) voltammetry in H_2SO_4 solution (26–28). The total surface area, $S_{\mathrm{Pt,tot}}$, was calculated from the mean particle size (radius r) determined by XRD experiments (26, 27) or from HR-TEM images (28), based on the assumption that the particles are spheres with surface area $4\pi r^2$. Values of $u_{\mathrm{Pt,cat}}$ were reported to be 109% by Easton and Pickup (26), 125% by Shan and Pickup (27), and 100% by Schmidt et al. (28) for carbon-supported Pt nanoparticles. The fact that the estimated utilization is greater than 100% is usually attributed to contributions from background currents (including that for H_2 evolution) to the measured H-adsorption charge (27).

The purpose of studying Pt utilization in the catalyst powder is to evaluate the electronic connectivity and maximum ionic accessibility of Pt nanoparticles. 100% Pt utilization means that all of the Pt nanoparticles are connected to the electronic conduction network and the entire Pt surface is accessible for protons through the electrolyte. Close to 100% Pt utilization in the catalyst powder of carbon supported Pt, immersed in liquid electrolyte, is possible, since only a negligible fraction of the Pt surface is covered by carbon particles. If Pt nanoparticles were supported by a polymer material such as poly(3,4-ethylenedioxythiphene)/poly(styrene-4-sulfonate), Pt utilization was reported to be only 43%–62%, which is due to poor electronic contact of the Pt nanoparticles with the polymer support and blocking of the Pt surface with the polymer (27).

The Pt utilization in the catalyst layer of an MEA is defined as,

$$[2] \qquad u_{\mathrm{Pt,CL}} = S_{\mathrm{Pt,CL}}/S_{\mathrm{Pt,tot}}$$

where the electrochemically active surface area in catalyst layer of an MEA, $S_{\mathrm{Pt,CL}}$, was estimated from the charge under the H-adsorption waves in cyclic voltammetry (CV) using driven-cell mode (30, 31). For example, to determine the accessible Pt surface area of a cathode, the cathode compartment of a single cell is purged with humidified nitrogen, serving as the working electrode, while the anode compartment is purged with humidified hydrogen, serving as both counter and reference electrode. In some studies, $S_{\mathrm{Pt,tot}}$ was calculated from the mean particle size, and Pt utilization in the cathode was reported to be 34% by Dhathathreyan et al. (32), 45% by Cheng et al. (33), 52% by Sasikumar et al. (34), and 55%–76% by Li and Pickup (35). As mentioned earlier, $S_{\mathrm{Pt,tot}}$ could also be obtained by the TF-RDE method, and Pt utilization in the cathode was reported to be 86%–87% (30) and 90% (36) by Gasteiger et al. Compared with Pt utilization in the catalyst powder, the reduced Pt utilization in catalyst layer of a fully functional MEA originates from two effects. Some Pt nanoparticles may get surrounded by ionomer and therefore loose electronic contact during the fabrication process. The other effect is that a fraction of the Pt particles are neither covered by ionomer electrolyte nor wetted by liquid water, implying that they are disconnected from the proton-supplying network.

The discussed results reveal large uncertainties and inconsistent definitions in determining Pt utilization among different experimental studies. The total charge transferred upon hydrogen adsorption may unintendedly involve non-wetted inactive catalyst surface area or include the catalytically inert substrate surface because of the so-called spillover effect (51). Usually, the active surface area measured by hydrogen adsorption and CO-stripping methods is not characterized under fuel cell operating conditions. Moreover, the values $u_{\mathrm{Pt,CL}}$ provided do not account for non-uniform reaction rate distributions, which arise at finite rates of reactant transport and consumption under stationary fuel cell operation.

The challenges in catalyst layer research can be best explained by considering the exchange current density j^0. It is the major physical property that links structure and activity of the catalyst layer with the working voltage of the fuel cell. A parameterization that relates j^0 to catalyst loading $[m_{\mathrm{Pt}}]$, specific activity of the catalyst with catalyst utilization was proposed in ref. 16.

© 2008 NRC Canada

[3] $j^0 = 2 \times 10^3 [m_{Pt}]\, j^{0*} \Gamma_{stat}$, with

$$\Gamma_{stat} = \varepsilon^{S/V} \Gamma_a g(S_r) \frac{f(X_{PtC}, X_{el})}{X_{PtC}}$$

The factor 2×10^3 approximates the total Pt surface area per real electrode surface area that would be obtained by spreading a catalyst loading of 1 mg cm^{-2} as an ideal monoatomic layer, which could be regarded as the base line for total Pt surface area at the atomistic level. To minimize irreversible voltage losses of the oxygen reduction reaction (ORR) on the cathode side of the cell, j^0 should be as large as possible. On the other hand, cost reduction demands lowest possible $[m_{Pt}]$ (in units mg cm^{-2}). The best compromise of these competing objectives can be achieved if the remaining factors on the right hand side of eq. [3] are maximized. This involves improving the specific activity of the catalyst (j^{0*}) and the statistical utilization of the catalyst, Γ_{stat}, in the random heterogeneous composite. The latter factor specified in eq. [3] involves the surface-to-volume atom ratio of catalyst nanoparticles ($\varepsilon^{S/V}$), the effectiveness factor at the agglomerate level (Γ_a) (17), the wetted fraction of catalyst particles in pores of the CCL ($g(S_r)$) (16), and the statistical fraction of catalyst particles at the triple phase boundary in random composite media ($f(X_{PtC},X_{el})/X_{PtC}$) (5–7). The factors $\varepsilon^{S/V} g(S_r)(f(X_{PtC},X_{el})/X_{PtC})$ define catalyst utilization as the ratio of number of active Pt atoms to total number of Pt atoms, involving effects at a hierarchy of scales, from nanoscale to macroscale (5–7, 16). Additional statistical effects include the possible existence of active sites on the catalyst surface, which could be included in eq. [3] (20, 21). Overall, maximizing the ratio of the $j^0/[m_{Pt}]$ is a joint challenge for electrocatalysis and for understanding statistical inhomogeneity in random composite media with hierarchical structure.

At this point, we would like to point out that the ultimate optimization target of fuel cell developers is not Pt utilization, which is a static statistical property of a catalyst layer, but more importantly the effectiveness factor, which includes as well the effects of non-uniform reaction rate distributions due to electrostatic effects and mass transport phenomena at finite current densities of an operating fuel cell. To account for these effects, effectiveness factors were considered in refs. 37–50. It should be mentioned that the use of this terminology is ambiguous throughout the literature. In some papers, catalyst utilization, or effective catalyst utilization, was used to describe the same concept of effectiveness factors (49, 50).

For a fixed electrode overpotential η_0, the overall effectiveness factor of Pt utilization can be defined by,

[4] $$\Gamma_{CCL} = \Gamma_{stat}\, \Gamma_\delta = \frac{j^0}{2 \times 10^3 [m_{Pt}] j^{0*}} \frac{j_0}{j_0^{id}}$$

where the first quotient on the right hand side, Γ_{stat}, accounts for statistical factors in eq. [3] and the second quotient, Γ_δ, gives the ratio of the actual current density, including transport limitations, relative to the ideal current density j_0^{id} that would be obtained if reaction rates were distributed in an ideal uniform way without any transport limitations (52). The definition of Γ_{CCL} in eq. [4] accounts for effects due to statistical inhomogeneity at multiple scales as well as for non-uniform distributions of electrochemical rates of electrochemical reactions at agglomerate and CCL levels under operation.

In discussions of effectiveness factors, two length scales are usually considered, i.e., the agglomerate scale (~100 nm) and the CCL scale (~10 μm). For ionomer-filled agglomerates on the cathode side with uniform electrostatic potential and non-uniform oxygen distribution inside the agglomerate, the effectiveness factor is described by the well-known Thiele modulus (17, 38–42). As stated in the introduction, we focus on water-filled agglomerates with effectiveness factor Γ_a (see eq. [3]) as explored in our previous modeling work (17, 25). This model involves non-uniform distributions of electrostatic potential, protons, and oxygen at the agglomerate level. At the CCL level, the effectiveness factor accounts for effects of potential gradients in the ionomer electrolyte phase and oxygen concentration gradient along CCL thickness due to the coupled transport of protons, oxygen molecules, liquid water, and water vapor. The model of effectiveness of catalyst utilization at the agglomerate level is embedded into the calculation of the effectiveness factor at the CCL level.

Mathematical model

Since this mathematical model merges our previous two models (16, 17), here we only briefly review the relevant formalisms. The macrohomogeneous model at the CCL level is one-dimensional and isothermal. The main structural parameters of the model are composition, thickness, and pore size distribution (psd). The electrostatic potential in the electronically conducting phase (Pt/C) is assumed to be uniform. The proton concentration is considered to be uniform at the macroscale because of the impregnation with ionomer. The electrostatic potential of the ionomer phase and oxygen concentration are spatially dependent functions. Gas transport in pores is dominated by Knudsen diffusion, since the mean free path of gas molecules is larger than the diameter of secondary pores (10–50 nm) in CCLs. Uniform boundary conditions are assumed at PEM/CCL and CCL/GDL interfaces. In the following equations, the origin ($z = 0$) is at the PEM/CCL interface and the total CCL thickness is L. At the agglomerate level, we consider agglomerates as monodisperse spheres with homogeneously distributed volume fractions of carbon/Pt and water-filled pores. Moreover, we assume that agglomerate radii, R_a, are small compared with the CCL thickness, i.e., $R_a << L$.

Agglomerates are partially covered by ionomer films. In coarse-grained molecular dynamics simulations of structure formation in catalyst layers we found ionomer film thicknesses of ~10 nm. A film of this thickness does not represent a significant diffusion barrier. Moreover, agglomerates are not uniformly covered by an ionomer film, leaving paths for direct transport of oxygen into agglomerate pores. In principle we would have to use complex, heterogeneous boundary conditions for electrostatic potential and concentrations of protons and oxygen on agglomerate surfaces to account for variable thickness and coverage of ionomer films. As a simplification, we will neglect these variations, implying uniform boundary conditions. This simplification was found very insightful in ref. 17. It will have a certain impact on nu-

© 2008 NRC Canada

merical estimates of effectiveness factors but not affect our major conclusions.

In the macrohomogeneous CCL model we only consider operation in the ideally wetted state, in which liquid water fills primary pores, whereas secondary pores are open for gaseous transport of reactants and products, as discussed in ref. 16. Employing this assumption, we will obtain an upper estimate of the effectiveness factor of PFSI-bonded thin film CCL. As shown in ref. 16, effects of the water balance in the CCL do not have to be explicitly accounted for if the CCL is operated in the ideally wetted state. This greatly simplifies the system of differential equations

$$[5] \qquad \frac{d\eta(z)}{dz} = \frac{j(z)}{\sigma_{el}}$$

$$[6] \qquad \frac{dj(z)}{dz} = Q^{ec}(z)$$

$$[7] \qquad \frac{4FD_{O_2}^{eff}}{RT}\frac{dp(z)}{dz} j_0 - j^p(z)$$

Subject to boundary conditions

$$[8] \qquad j|_{z=0} = j_0$$

$$[9] \qquad j|_{z=L} = 0$$

$$[10] \qquad p|_{z=L} = p_L$$

where $\eta(z)$ is the overpotential, $j(z)$ is the proton current density, and $p(z)$ is the oxygen partial pressure.

Proton conductivity σ_{el} in the catalyst layer is assumed to be determined by (5, 6),

$$[11] \qquad \sigma_{el} = \sigma_0 \frac{(X_{el} - X_c)^2}{(1 - X_c)^2}\Theta(X_{el} - X_c)$$

Diffusivity of gaseous oxygen $D_{O_2}^{eff}$ is given by,

$$[12] \qquad D_{O_2}^{eff} = D_{O_2} \frac{[(1 - S_r^{opt})X_p - X_c]^{2.4}}{(1 - X_c)^2(X_p - X_c)^{0.4}}$$

where the residual diffusivity is neglected, since the gas diffusivity is large in the ideally wetted state. The prefactor D_{O_2} in eq. [12] is given by an expression from kinetic gas theory based on the assumption that Knudsen-type diffusion is the main mechanism of gas transport,

$$[13] \qquad D_{O_2} = \frac{2}{3}\sqrt{\frac{8RT}{\pi M_{O_2}}} r_{crit}$$

Assuming that capillary equilibrium prevails in pores, the liquid saturation is given by,

$$[14] \qquad S_r^{opt} = \frac{1}{X_p}\int_0^{r^c} dr' \frac{dX_p(r')}{dr'}$$

where we use a bimodal pore size distribution,

$$[15] \qquad \frac{dX_p(r)}{dr} = \frac{1 - X_{PtC} - X_{el}}{\sqrt{\pi}(\ln s_\mu + \chi_M \ln s_M)}\frac{1}{r} \times \left\{\exp\left[-\left(\frac{\ln(r/r_\mu)}{\ln s_\mu}\right)^2\right] + \chi_M \exp\left[-\left(\frac{\ln(r/r_M)}{\ln s_M}\right)^2\right]\right\}$$

$$[16] \qquad r^c = \frac{2\sigma\cos(\theta)}{p^c}$$

where r^c is the capillary radius of pores in which liquid–gas equilibrium exists. It is the maximum radius of pores that are filled with liquid in a hydrophilic system (wetting angle $\theta < 90°$). Pores of radius less than r^c are filled with liquid water, and pores of radius larger than r^c are filled with gas.

To ensure a good compromise of a high wetted fraction of Pt, high net vaporization rate and good gaseous transport of oxygen and water vapor, r^c should lie in the range between primary pore and secondary pore regions in psds,

$$[17] \qquad r_\mu < r^c < r_M$$

Porous structure and operating pressures should be adjusted to fulfill eq. [17]. In eq. [6], $Q^{ec}(z)$ is the sink term due to electrochemical reaction. It accounts for the reduced effectiveness factor of Pt utilization due to random composition and processes in agglomerates. The value of this term is obtained by integrating the current generated inside the agglomerate and averaging it over the volume of a representative elementary volume element. It is here that the macrohomogeneous model is linked with the agglomerate model.

$$[18] \qquad Q^{ec}(z) = \frac{f(X_{PtC}, X_{el})}{X_{PtC}} g(S_r^{opt}) \frac{3(X_{PtC} + X_\mu)}{R_a^3} \times \int_0^{R_a} j_F^z(r) r^2 dr$$

where r is the radial coordinate inside agglomerates and the local Faradaic current density, $j_F^z(r)$, is determined by the concentrations of dissolved oxygen and protons and by the electrostatic potential inside the agglomerate. Dissolution of oxygen into water-filled pores is implicitly accounted for by using a Henry's law factor in $j_F^z(r)$. In the ideal wetted state, the coefficient that accounts partially saturated porous structure can be calculated by,

$$[19] \qquad g(S_r^{opt}) = \Pi\int_0^{r_{cut}} dr' \frac{dX_p(r')}{dr'}\frac{1}{r'}$$

and Π is a normalization factor that ensures $g \to 1$ in the limit of complete wetting of the layer,

$$[20] \qquad \Pi = \left(\int_0^\infty dr' \frac{dX_p(r')}{dr'}\frac{1}{r'}\right)^{-1}$$

Finally, the effect of reduced Pt utilization due to random three-phase composition is included using percolation theory, which provides a general framework for studying flow and transport in porous composite media, as explained in refs. 5–7. It has proven useful in rationalizing composition-

© 2008 NRC Canada

dependent performance of catalyst layers (53). Systematic experimental studies have been found to be in good agreement with predictions of the model. Percolating pathways must span through the carbon/Pt phase, open pore space, and electrolyte network to provide an adequate supply of all the reactants and removal of the products.

For the effect of random composition on the fraction of active catalyst sites, we adopt a previously suggested parameterization that rests on the theory of active bonds in dual porous composite materials (5–7),

$$[21]\quad f(X_{PtC},X_{el}) = P(X_{el})P(X_{PtC})\{(1-\chi_{ec})(1-[1-P(X_p)]^4)+\chi_{ec}[1-P(X_p)]^4\}$$

with the density of the percolating cluster given by,

$$[22]\quad P(X) = X/\{1+\exp[-53.7(X-X_c)]\}^{3.2}$$

In eq. [21], the factor $P(X_{el})P(X_{PtC})$ takes into account the probability to obtain a meeting point between carbon and ionomer phases with both phases connected to their corresponding infinite clusters. The term $1 - P(X_P)$ takes into account the probability that agglomerate and ionomer have at least one pore as their bond neighbor that belongs to the infinite pore network.

The system of differential equations for water-filled agglomerates is giving by (17),

$$[23]\quad D^{agg}_{H^+}\frac{1}{r^2}\frac{d}{d^2}\left\{r^2\left[\frac{dc^z_{H^+}(r)}{dr}+\frac{F}{RT}c^z_{H^+}(r)\frac{d\phi^z(r)}{dr}\right]\right\} = \frac{j^z_F(r)}{F}$$

$$[24]\quad \varepsilon\varepsilon_0\frac{1}{r^2}\frac{d}{dr}\left[r^2\frac{d\phi^z(r)}{dr}\right] = -Fc^z_{H^+}(r)$$

$$[25]\quad D^{agg}_{O_2}\frac{1}{r^2}\frac{d}{dr}\left[r^2\frac{dc^z_{O_2}(r)}{dr}\right] = \frac{j^z_F(r)}{4F}$$

Subject to uniform boundary conditions

$$[26]\quad \left.\frac{dc^z_{H^+}}{dr}\right|_{r=0} = 0$$

$$[27]\quad c^z_{H^+}\Big|_{r=R_a} = c^{ref}_{H^+}$$

$$[28]\quad \left.\frac{d\phi^z}{dr}\right|_{r=0} = 0$$

$$[29]\quad \phi^z\Big|_{r=R_a} = \eta(z)$$

$$[30]\quad \left.\frac{dc^z_{O_2}}{dr}\right|_{r=0} = 0$$

$$[31]\quad c^z_{O_2}\Big|_{r=R_a} = \frac{p(z)}{RT}H_{O_2}$$

In eqs. [29] and [31], the boundary conditions on agglomerate surfaces correspond to local values (at position z) of electrostatic potential and oxygen partial pressure obtained from the macrohomogeneous model. Equation [31] involves ideal gas law and Henry's law for converting partial pressure of oxygen in the cathodic gas mixture into concentration of dissolved oxygen in agglomerates.

Similar to effective conductivity, we also apply percolation theory to calculate effective proton and oxygen diffusion coefficient in liquid water-filled agglomerates.

$$[32]\quad D^{agg}_{H^+} = D_{H^+}\frac{(X_w-X_c)^2}{(1-X_c)^2}\Theta(X_w-X_c)$$

$$[33]\quad D^{agg}_{O_2} = D^l_{O_2}\frac{(X_w-X_c)^2}{(1-X_c)^2}\Theta(X_w-X_c)$$

where liquid water volume fraction X_w inside the agglomerate is giving by

$$[34]\quad X_w = \frac{X_\mu}{X_{PtC}+X_\mu}$$

Volume fraction of primary pores is giving by

$$[35]\quad X_\mu = \int_0^{r_{cut}} dr'\frac{dX_p(r')}{dr'}$$

The Faradaic current density inside agglomerate is given by

$$[36]\quad j^z_F(r) = 2\times10^3[m_{Pt}]\,j^{0*}\frac{\varepsilon^{S/V}}{L(X_{PtC}+X_\mu)}\frac{c^z_{O_2}(r)}{c^{ref}_{O_2}}\frac{c^z_{H^+}(r)}{c^{ref}_{H^+}}\times\exp\left[\frac{\alpha_c F}{RT}\phi^z(r)\right]$$

The set of governing differential equations (eqs. [23–25]) for the water-filled agglomerate was previously solved numerically using FEMLAB software (17). In this work, the COMSOL script code was generated by COMSOL (an upgraded version of former FEMLAB), which can run in the MATLAB environment. The set of differential equations (eqs. [5–7]) for the entire cathode catalyst layer were solved using MATLAB software. The shooting method converts the boundary value problem into an initial value problem. It takes advantage of the powerful algorithms available for the integration of initial value problems. The iteration procedure is initialized with a guess of the boundary value $\eta|_{z=L}$. The differential equations are integrated forward as a set of simultaneous initial value differential equations. The iteration procedure terminates when the condition $j|_{z=0} = j_0$ is fulfilled, using a small convergence criterion (10^{-3}). Otherwise the value $\eta|_{z=L}$ is adjusted. Each time that eq. [6] is solved, eq. [18] will call the COMSOL script code to solve for $j^z_F(r)$ in the water-filled agglomerate model (eqs. [23–31]), where the boundary conditions (eqs. [29] and [31]) are provided by the catalyst layer model, i.e., eqs. [5] and [7], respectively. Dozens of self-consistency iterations are needed to obtain convergence.

In this paper, we are focusing on discussing the effectiveness factor of Pt utilization. At the agglomerate level, the ef-

Cathodic transfer coefficient	α_c = 1.0

Note: Unless stated otherwise, the values of parameters comes from ref. 16.

fectiveness factor is defined as the integral current conversion rate divided by the ideal rate that would result if the entire interior surface were exposed to the external conditions prevailing at the agglomerate surface (17).

$$[37] \quad \Gamma_a = \frac{3\int_0^{R_a} j^z_F(r) r^2 dr}{j^z_{F,S} R_a{}^2}$$

where $j^z_{F,S}$ is Faradaic current density on the agglomerate surface.

$$[38] \quad j^z_{F,S} = 2\times10^3 [m_{Pt}]\, j^{0*} \frac{\varepsilon^{S/V}}{L(X_{PtC} + X_\mu)} \frac{p(z) H_{O_2}}{RT c^{ref}_{O_2}} \times \exp\left[\frac{\alpha_c F}{RT}\eta(z)\right]$$

When $\Gamma_a \to 1$, the whole model can be simplified to a pure macrohomogeneous model.

At the catalyst layer level, the effectiveness factor is defined as the integral current conversion rate divided by the ideal rate that would result if the entire catalyst were in the CCL/PEM interface with inlet oxygen concentration.

$$[39] \quad \Gamma_{CCL} = \frac{j_0}{2\times10^3 [m_{Pt}]\, j^{0*}\, p_L \exp\left[\frac{\alpha_c F}{RT}\eta(L)\right]}$$

Note that, after a self-consistent solution, this expression will include effects at the agglomerate level. This parameter is the key parameter to evaluate the performance of CCLs.

Results and discussion

For the purpose of illustration and comparison, we specified most of the parameter values that we have used previously (16). They correspond to state-of-the-art catalyst layer structures described in the literature. Additional parameters related to water-filled agglomerates are given in Table 1. Based on the specified values important parameters can be calculated, which include optimal saturation S_r^{opt} = 0.33, wetted pore fraction $g(S_r^{opt})$ = 0.84, and the utilization factor

due to random three-phase composition, $f(X_{PtC}, X_{el})/X_{PtC}$ = 0.28.

First we discuss the effectiveness factor at the agglomerate level. According to the definition made in this study, Γ_a accounts for the effects from uneven distribution of proton concentration, electrostatic potential, and oxygen concentration inside the agglomerate. Figure 1 shows the distribution of Γ_a as a function of z for varying agglomerate radii R_a, at two distinct overall current densities, j_0 = 1 A cm^{-2} in Fig. 1*a* and j_0 = 0.2 A cm^{-2} in Fig. 1*b*. With the increase of R_a, Γ_a decreases. This is because $c^z_{H^+}(r)$ decreases rapidly toward the center of an agglomerate within a distance corresponding to the Debye length, $\lambda_D = \sqrt{\varepsilon\varepsilon_0 RT/F^2 c^{ref}_{H^+}}$, which is on the order of 10 nm, and is independent of R_a. Thus for larger R_a, a smaller volume portion of the agglomerate is used for reaction.

As shown in Fig. 2*a*, volumetric current densities, j_v, decrease from the CCL/PEM interface towards the CCL/GDL interface. As can be seen in Fig. 2*b*, Γ_a is more markedly reduced in regions in which j_v is high. The more current an agglomerate generates, the more uneven is the distribution of the electrostatic potential $\phi^z(r)$, resulting in a steeper drop of $c^z_{H^+}(r)$ from agglomerate surface towards centre. Because of the same reason, Γ_a increases throughout the layer if the overall current density j_0 decreases, cf. Fig. 1*a* and Fig. 1*b*. Next we discuss the overall effectiveness factor of Pt utilization at the CCL level, Γ_{CCL}, which accounts for effectiveness factors at the agglomerate and nanoparticle levels, as well as reduced Pt utilization due to random composition and partially saturated porous structure. Figure 2*c* shows the effect of agglomerate radius R_a and total current density j_0 on Γ_{CCL}. The larger R_a, the lower Γ_{CCL} will be, which results from low Γ_a. High j_0 will result in low Γ_{CCL} because of the more uneven distribution of reaction rates at agglomerate and CCL levels.

Above we discussed the effect of R_a, which could be used to classify several possible cases. The limiting case of $R_a \to L$ corresponds to ionomer-free CCL, consisting of two functional phases, which have been studied by Wang et al. (25). In this case, the two sets of differential equations can be combined into,

$$[40] \quad D^{eff}_{H^+} \frac{d}{dz}\left[\frac{dc_{H^+}(z)}{dz} + \frac{F}{RT} c_{H^+}(z) \frac{d\eta(z)}{dr}\right] = \frac{j_F(z)}{F}$$

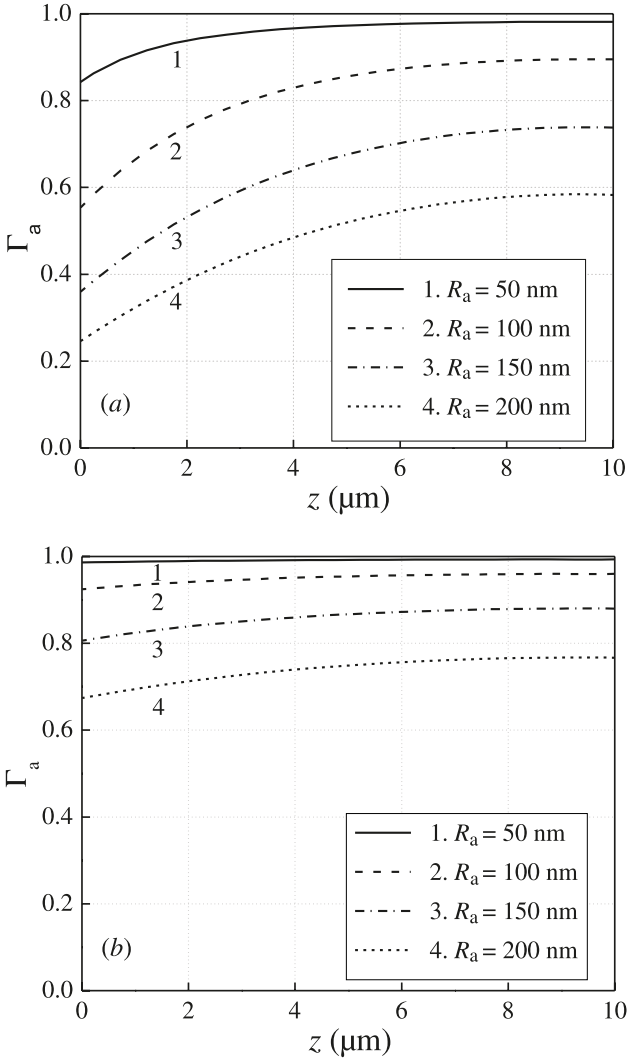
$$[41] \quad \varepsilon\varepsilon_0 \frac{d^2\eta(z)}{dz^2} = -F c_{H^+}(z)$$

$$[42] \quad D^{eff}_{O_2} \frac{dc_{O_2}(z)}{dz^2} = \frac{j_F(z)}{4F}$$

where

$$[43] \quad j_F(z) = 2\times10^3 [m_{Pt}]\, j^{0*} \varepsilon^{S/V} \frac{c_{O_2}(z)}{c^{ref}_{O_2}} \frac{c_{H^+}(z)}{c^{ref}_{H^+}} \times \exp\left[\frac{\alpha_c F}{RT}\eta(z)\right]$$

Fig. 1. Distribution of effectiveness factors of agglomerates along CCL thickness at (*a*) j_0 = 1 A cm^{-2}, (*b*) j_0 = 0.2 A cm^{-2}, R_a is from 50 to 200 nm.



Since the Debye length is only on the order of λ_D ~ 10 nm, i.e., ~1000 times thinner than conventional CCL, only ultrathin layers with L ~ 200 nm provide reasonable values of Γ_{CCL} in this limit.

In the opposite limiting case $R_a \lll$ L, agglomerate effects are negligible and the pure macrohomogeneous approach could be used. In this case, only eqs. [5–7] are relevant and $Q^{ec}(z)$ in eq. [6] is given by,

$$[44] \quad Q^{ec}(z) = 2\times10^3 [m_{Pt}]\, j^{0*} \varepsilon^{S/V} \frac{p(z) H_{O_2}}{RT c^{ref}_{O_2}} \times \exp\left[\frac{\alpha_c F}{RT}\eta(z)\right]$$

For the general case with $R_a << L$ considered in this manuscript, the fully coupled system of equations at agglomerate and CCL levels should be applied to calculate $Q^{ec}(z)$. We would like to use the general model, $R_a <<$ L, to explore the applicability limits of the widely used

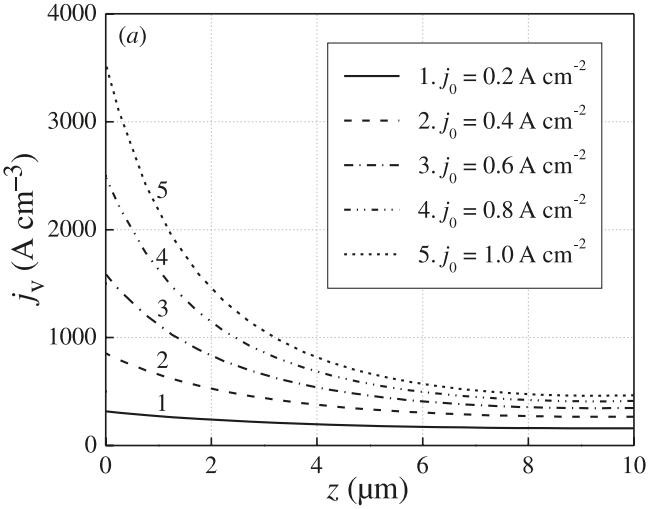
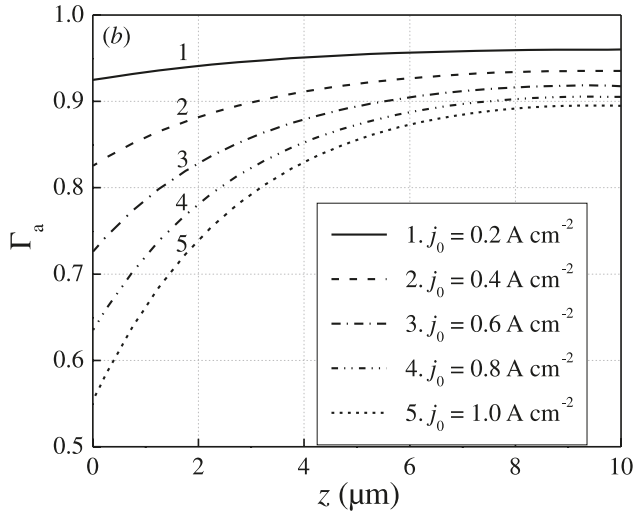
Fig. 2. (*a*) Distribution of volumetric current density, (*b*) effectiveness factor at the agglomerate level along CCL thickness at different current densities when R_a = 100 nm, and (*c*) shows effectiveness factors at the CCL level for different current densities and agglomerate sizes.





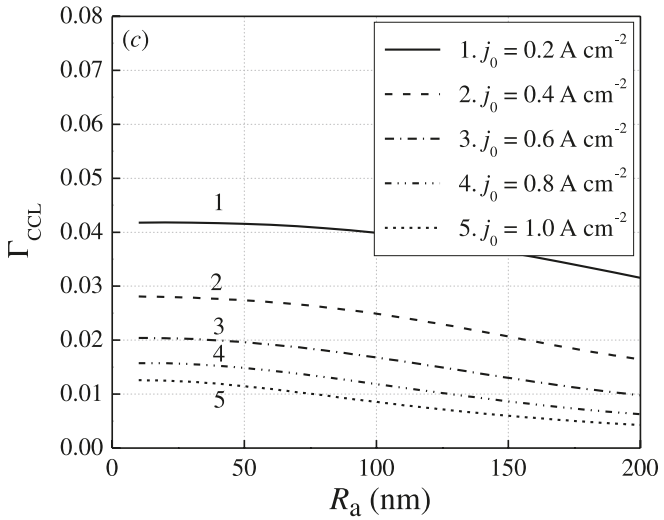


Fig. 3. Critical agglomerate radius that separates the range of validity of the macrohomogeneous model from the macrohomogeneous with agglomerates model.

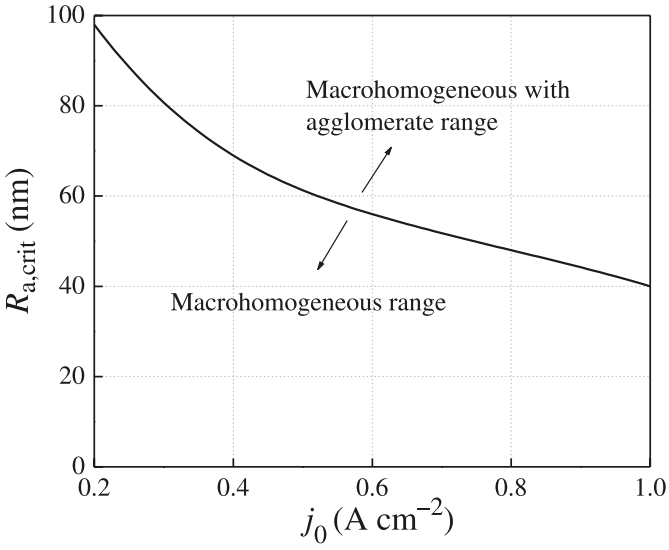

macrohomogeneous approach, $R_a \lll L$. For this purpose, we define a critical agglomerate radius, $R_{a,crit}$, with the condition that for $R_a < R_{a,crit}$, the effectiveness factors in agglomerates is >95%. Under this condition, the macrohomogeneous model provides a reasonably accurate approach. In the other case, $L >> R_a > R_{a,crit}$, the reasonable model should be in the general form of the water-filled agglomerate model nested in the macrohomogeneous cathode catalyst layer model, as introduced in the Mathematical model section. The task is thus to find $R_{a,crit}$ to classify these different cases. To determine $R_{a,crit}$ we define a reference case for which the corresponding Γ_{CCL}^{ref} is calculated under the assumption $\Gamma_a \equiv 1$. Γ_{CCL}^{ref} is the maximum possible effectiveness factor of the CCL for a given thickness, composition, and operating conditions. Next, we consider R_a as a variable parameter and determine its critical value $R_{a,crit}$ at which $\Gamma_{CCL} \equiv 0.95 \times \Gamma_{CCL}^{ref}$. For $R_a < R_{a,crit}$, we will thus have, on average, $\Gamma_a > 0.95$. Figure 3 shows the critical agglomerate radius $R_{a,crit}$ that separates the region in which the macrohomogeneous model is valid, i.e., $R_a < R_{a,crit}$, from the region in which agglomerate effects should be accounted for, i.e., $R_a \geq R_{a,crit}$. $R_{a,crit}$ is determined by operating conditions, such as total current densities, temperature, and oxygen partial pressure. Higher j_0, smaller T, and smaller p_L correspond to smaller values of $R_{a,crit}$.

Increased values of T and p_L result in higher Γ_{CCL}, as demonstrated in Fig. 4. The increase of T improves proton and oxygen diffusion coefficients and proton conductivity of the PFSI phase, leading to more uniform reaction rate distributions. The increase of p_L results as well in more uniform distributions of oxygen in CCLs. A comparison of different operating condition is shown in Fig. 4.

Compared with PFSI-bonded thin film catalyst layers, ultrathin catalyst layers proposed by 3M Company (58) have a different structure in which the Pt catalyst is sputter-deposited onto an ultrathin nanostructured film of oriented crystalline organic whiskers. For the comparison of effectiveness factors of conventional three-phase composite lay-

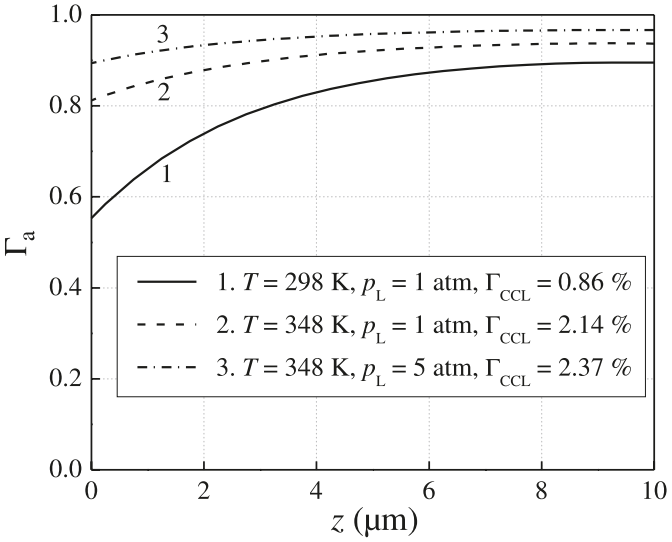
Fig. 4. Comparison of effectiveness factor at the agglomerate and CCL level at different temperatures and oxygen partial pressures for j_0 = 1 A cm^{-2} [Cases of T = 348 K with their parameters of j^{0*} = 1.023 × 10^{-8} A cm^{-2} (17), D_{H^+} = 1.9 × 10^{-4} cm2 s^{-1} (17), $D^1_{O_2}$ = 9.19 × 10^{-5} cm2 s^{-1} (17), σ_0 = 0.118 S cm^{-1} (56), and H_{O_2} = 0.023 32 (57)].



ers, considered predominantly in this publication, and ultrathin two-phase layers, we have to incorporate catalyst utilization at the Pt nanoparticle level, i.e., the surface-to-volume atom ratio $\varepsilon^{S/V}$. This factor is determined by particles or grain sizes of catalyst particles and their surface morphology or roughness. For supported nanoparticle catalysts in PFSI-filled composite CCLs, this ratio can be determined from the particle shape and the particle size. At a typical particle diameter of 4 nm, the corresponding value is $\varepsilon^{S/V}$ = 0.3 (59). For vacuum-deposited catalyst in nano-structured ultrathin film CCL the fraction of catalyst surface atoms is more difficult to estimate. It was suggested in ref. 58 on the basis of cyclic voltammetry measurements that the irregular surface morphology of such catalysts corresponds to grain sizes of ~10 nm with $\varepsilon^{S/V}$ = 0.15 (25, 58). For comparison, we consider the two kinds of CCL at the same Pt loading and operating conditions. From the information provided by Fig. 5*c* of ref. 25, we obtained $\Gamma_{CCL}/\varepsilon^{S/V}$ = 0.21 for the ultrathin layer at the conditions of m_{Pt} = 0.2 mg cm^{-2}, j_0 = 1.0 A cm^{-2}, α_c = 1, T = 348 K, and p_L = 5 atm (1 atm = 101.325 kPa). We applied the same Pt loading and operating conditions to PFSI-bonded thin film CCLs. The thickness was adjusted proportional to the Pt loading to L = 5 μm. Accounting for the distinct values of $\varepsilon^{S/V}$ in both cases, we obtain overall effectiveness factors of Pt utilization of Γ_{CCL} = 3.1% for ultrathin two-phase CCL and Γ_{CCL} = 3.5% for PFSI-bonded thin film CCLs. These rough estimates, which account for statistical inhomogeneities and non-uniformities of reaction rate distributions at relevant scales from nanoscale to macroscale, indicate that the two kinds of CCL exhibit similar effectiveness factors of Pt utilization. All in all, any of the factors is fraught with uncertain error – thus overall, the estimation would be somewhat speculative. On the other hand, the message is clear. The effectiveness of catalyst utilization in currently fabricated CCL, viz. three-phase composite gas diffusion CCL and ultrathin nanostructured CCL, is most likely <10% and not close to 100% as stated recently by Neyerlin et al. (49). This assessment holds out the prospect of tremendous reserves for improvement through structural design.

Conclusions

In this work, we studied the effectiveness factor of Pt utilization for the PFSI-bonded thin film cathode catalyst layer by combining the water-filled agglomerate model with the structure-based macrohomogeneous model. The main goal was the evaluation of effectiveness factor of Pt utilization, a more meaningful parameter than just Pt utilization. It was found that small agglomerate radius, low operating current density, high operating temperature, and oxygen partial pressure result in high effectiveness factors of Pt utilization. When the effectiveness factors at the agglomerate level are close to 1, the pure macrohomogeneous approach is appropriate. The critical agglomerate radii were calculated, which are related to the operating conditions. Finally, the effectiveness factor of Pt utilization in the PFSI-bonded thin film cathode catalyst layer was compared with that in the ultrathin two-phase cathode catalyst layer. Including the estimation of the surface-to-volume atom ratio at the nanoparticle level, the two kinds of catalyst layers exhibit similar effectiveness factors of Pt utilization in the range of ~3% at temperature of 348 K and oxygen pressure of 5 atm. Although any of the factors is fraught with uncertain error, the effectiveness is most likely less than 10%. This suggests that tremendous improvements in specific electrocatalytic activities of Pt in catalyst layers of PEFCS could be harnessed through advanced structural design.

Effect of base on alkyltriphenylphosphonium salts in polar aprotic solvents

Julius N. Ngwendson, Cassandra M. Schultze, Jordan W. Bollinger, and Anamitro Banerjee

Abstract: When arylmethyl phosphonium salts are treated with a base (e.g., *t*-BuOK or NaH) they homocouple to form symmetric 1,2-diarylethenes. In some cases, dilution and (or) use of excess base lead to very high yields of the product. This reaction is solvent sensitive: the reaction occurs only when polar aprotic solvents such as acetonitrile or DMSO are used. Other alkyl phosphonium salts (e.g., ethoxycarbonylmethyltriphenylphosphonium bromide and *n*-butyltriphenylphosphonium bromide) form a ylid (when an α-carbonyl group is present) or lose a phenyl group to form alkyldiphenylphosphine oxides when treated with the base. Mechanistic investigation of the homocoupling reaction indicates that the reaction proceeds through a ylid that acts as a nucleophile on an unreacted phosphonium salt. The resulting adduct undergoes elimination to form the observed product. The *E*/*Z* ratio seems to depend on the amount of the base used and the phosphonium salt involved.

Key words: phosphonium salts, homocoupling, 1,2-diarylalkene, Ylids.

Résumé : La réaction des sels d'arylméthylphosphonium avec une base, tel le *t*-BuOK ou le NaH, donne lieu à une réaction d'homocouplage qui conduit à la formation des 1,2-diaryléthènes symétriques. Dans quelques cas, une dilution et/ou un excès de base conduit à des rendements très élevés de ce produit. Cette réaction est sensible aux solvants: la réaction ne se produit que dans les solvants polaires aprotiques, tel l'acétonitrile ou le DMSO. D'autres sels d'alkylphosphonium, tel le bromure d'éthoxycarbonylméthyltriphénylphosphonium ou du bromure de butyltriphénylphosphonium, conduit à la formation d'un ylure quand on est en présence d'un groupe carbonyle en α ou de la perte d'un groupe phényle conduisant à la formation d'oxydes d'alkyldiphénylphosphines quand ils sont traités par des bases. Les études mécanistiques menées sur la réaction d'homocouplage indiquent que la réaction se produit par le biais d'un ylure qui agit comme nucléophile pour le sel de phosphonium qui n'a pas réagi. L'adduit qui en résulte subit une élimination qui conduit à la formation du produit observé. Le rapport *E*/*Z* semble dépendre de la quantité de base utilisée et du sel de phosphonium impliqué.

Mots-clés : sels de phosphonium, homocouplage, 1,2-diaryléthène, ylures.

[Traduit par la Rédaction]

Introduction

1,2-Diarylalkenes undergo reversible *EZ* isomerization or electrocyclic reactions when subjected to thermal or optical stimuli (1). The two isomers (in the case of photoisomerization) or the closed and open forms (in the case of electrocyclic reactions) generally have different absorption spectra (1). This allows for selective formation of one isomer using the appropriate wavelength of light, while using a different wavelength of light to carryout the reverse reaction (2). As a result, these compounds have been used as photochromic compounds (3) and optical switches (4). Specifically, 1,2-dithienylethenes have been widely used as photochromic compounds (4, 5). These compounds show a combination of very good photochromic properties such as high fatigue resistance, short response time, high quantum yields, no thermal isomerization, gated reactivity, and large changes of the absorption wavelength between the isomers. The open and closed forms arising because of the electrocyclic reactions of these compounds also have different electrochemical properties, which is useful in their utility as optical switching materials (6). As the applications of photochromic compounds grow, new diarylalkene-based photochromic compounds are being developed (6, 7). As new 1,2-diarylalkenes are being synthesized for various applications, quick, inexpensive, and convenient routes for their synthesis become more desirable.

Formation of a new C=C bond, using Wadsworth–Horner–Emmons and Wittig reactions (8), is a key step in the synthesis of various 1,2-diaryl alkenes. Other approaches used for the synthesis of these compounds include Heck olefination (9) and Suzuki–Miyaura cross coupling (10). Recently, Blanc and Bochet synthesized 2,2′-dinitrostilbene by the reaction of 2-nitrobenzyl chloride with KOH (11). This homocoupling reaction is however reported only for symmetric dinitrostilbene (12). Opitz and co-workers reported the synthesis of a new C=C bond via a homocoupling of sulfonyl chlorides. In the presence of triethylamine at low

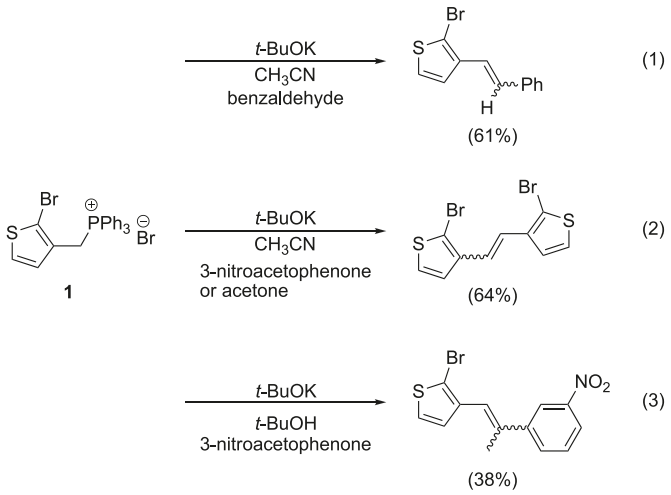
Scheme 1. Wittig vs. homocoupling solvent dependence.



temperatures the sulfonyl chlorides formed thiirane-1,1-dioxide intermediates, which upon thermolysis resulted in the formation of the alkenes (13). Hoeg and Lusk reported homocoupling of benzyl halides by lithiation of the α-hydrogen at low temperatures to form the stilbene derivatives in high yields (14).

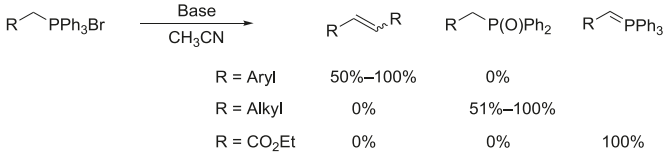
Recently we reported a solvent-dependent behavior of arylmethyltriphenyl phosphonium salts in the presence of a base (15). 2-Bromo-3-thienylmethyltriphenylphosphonium bromide (**1**) undergoes a Wittig reaction with benzaldehyde in acetonitrile but undergoes a homocoupling reaction rather than a Wittig reaction when a ketone is used under the same conditions (Scheme 1). The phosphonium salt however undergoes the expected Wittig reaction with ketones when *t*-butanol is used as the solvent. Solvent dependence studies show that the homocoupling reactions occur in polar aprotic solvents with a direct correlation between the yield of the product and the dielectric constant of the solvent (15). This observation complements an earlier report of homocoupling of phosphonium salts to form *trans*-olefins in the presence of *N*-fluoropyridinium salts with THF as the solvent at –30 °C (16). The mechanism proposed for the reaction involved an electron transfer step followed by radical coupling. The resulting dimer then decomposes to form the *trans*-alkene (16). This reaction however is specific to phosphonium salts with electron-withdrawing groups and results in modest yields. When other phosphonium salts were used, only traces of olefins could be detected. In the current study, the homocoupling reaction was found to be effective for arylmethylphosphonium salts when *no* electron withdrawing groups were present. The reaction was also found to be solvent-dependent and resulted in very high yields of the olefin. However, there appears to be no pattern for the *E*/*Z* ratio.

In this article we report the optimized conditions for the homocoupling reaction and explore the generality of this reaction with respect to various arylmethylphosphonium salts and other alkylphosphonium salts. We also report the behavior of diethylarylmethylphosphonates under these conditions.

Results and discussion

The phosphonium salts **3**, **9**, and **10** were obtained commercially, while the rest were synthesized as described

Scheme 2. Reaction of the phosphonium salts with base.



earlier (15). The phosphonium salts were dissolved in acetonitrile (most of the salts were partially soluble, hence forming a suspension). The solution was cooled to 0 °C under ice and the base was added gradually over 5 min. The reaction mixture was allowed to warm up to room temperature (RT) while stirring for 2 h. The formation of the olefin was detected using TLC. After 2 h, the solvent was removed and the resulting mixture was subjected to column chromatography to isolate the product. The product obtained depends on the alkyl group of the phosphonium salts (Scheme 2). Most arylmethylthriphenylphosphonium salts led to the formation of the olefin. In the absence of an aromatic ring on the α-carbon, alkyldiphenylphosphine oxide was formed in quantitative yields. Table 1 lists the isolated yields of the homocoupling reactions under optimized conditions. The phosphonium salts that resulted in 75% or higher yields, as reported in our previous communication, were not optimized and hence are not included in this table. Although we have shown in our previous report that DMSO is more efficient as a solvent for the homocoupling reaction, we optimized this reaction in acetonitrile because of the ease of isolation of the products.

The phosphonium salts **1**, **3**, **4**, and **6** upon treatment with 2 or 3 equivalents of base resulted in 70%–100% yield of the homocoupling product. The choice of the base did not impact the yield nor the *E*/*Z* ratio. A recent study by Ackermann and Berger on Wittig reactions demonstrates the impact of heteroaryl substitutions on phosphorus and *E*/*Z* ratio due to the interaction of the metal ion and the heteroatom (17). In this study, only triphenyl phosphines were used, however similar effects on the *E*/*Z* ratio is possible. Increasing the amount of base resulted in higher yields of the homocoupling product. For example, using 3 equivalents of *t*-BuOK as base improved the yields of **2** to 56% from 21% when only one equivalent of base was used. Similarly, treating **6** with 1, 2, and 3 equivalents of *t*-BuOK resulted in the formation of 2,2′-dimethoxystilbene in 39%, 75%, and 90% yields, respectively. A similar trend was observed when NaH was used as the base. However, 4-methoxybenzyltriphenylphosphonium salt **5** resulted in only 23% yield, irrespective of the amount of base used, whereas the *o*- and *m*-isomers resulted in nearly quantitative yields of the homocoupling products when 2 or 3 equivalents of the base was used. At this time it is difficult to account for this difference in the homocoupling yields for the three isomers.

When an electron-withdrawing nitro group is present in the aromatic ring (**7** and **8**), no product due to the homocoupling reaction could be detected. On the other hand, when alkyltriphenylphosphonium salts (**9**, **10**, and **11**) where subjected to similar conditions, no olefins were detected. In case of **9** and **10**, the action of the base in acetonitrile or DMSO resulted in the loss of a phenyl group to form *n*-butyldiphenylphosphine oxide and methoxymethyldiphenylphosphine oxide, respectively, in good yields. The

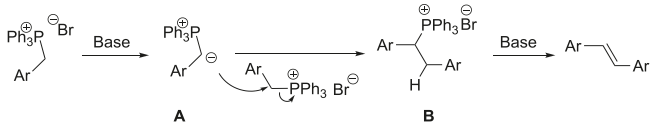
Scheme 3. Proposed mechanism of the homocoupling reaction.



phosphonium salt **11** however formed a stable ylid as expected in acetonitrile.

The proposed mechanism of the homocoupling reaction is described in Scheme 3. Based on the reaction of the phosphonium salt **1** with benzaldehyde in the presence of *t*-BuOK in acetonitrile (Scheme 1, eq. [1]), it can be argued that the first step in the reaction involves the formation of the ylid **A**. The ylid could be trapped by benzaldehyde via a Wittig reaction. However, in the presence of a less reactive substrate like acetophenone or acetone, the ylid reacts with another equivalent of the phosphonium salt to form the intermediate **B**. This is consistent with previous reports of ylid acting as a nucleophile towards alkyl halides (18) and halogens (19). Attempts to detect the intermediate **B** in experiments performed in NMR tubes with CD_3CN as a solvent failed as it revealed a complex mixture. When an electron-withdrawing nitro group is present in the aromatic ring, the ylid is further stabilized by resonance, thereby reducing its reactivity towards homocoupling reaction. It is also possible that the ylid may undergo a single electron transfer resulting in a radical, or eliminate triphenylphosphine to form the corresponding carbene, as observed by Shevchenko and coworkers for phosphanes with orthoquinones (20). Either of these intermediates could couple to form the alkene. However, the absence of any alkene adduct implies that the carbene intermediate is unlikely. The reaction was unaffected by the presence of one equivalent of $CuBr_2$ or n-Bu_3SnH indicating that the existence of a radical intermediate is unlikely. Isolation of triphenylphosphine in 20% yield is consistent with the proposed mechanism. When a mixture of phosphonium salts was treated with a base, a statistical mixture of cross and homocoupling products was detected (see Supplementary data).[2] This result is consistent with the proposed mechanism.

Analysis of the products of the reaction of the phosphonium salts **9** and **10** with base revealed a loss of a phenyl group. While the loss of a phenyl group from triphenylphosphonium salts in the presence of lithium aluminium hydride has been reported in the literature (21), this was an unexpected result in the absence of a reducing agent. Unlike most of the phosphonium salts used in this study, **9** and **10** are readily soluble in acetonitrile. Upon addition of the base, KBr (or KCl) precipitated out of the solution as white solid. The reaction was allowed to continue for about 2 h. The potassium halide salt was filtered out and the solvent was removed under reduced pressure to obtain the products as white solids. ^{1}H NMR, ^{13}C NMR, and HRMS data of the residue indicated that the product was alkyldiphenylphosphine oxide. For example, the ^{1}H NMR of the product resulting from **10** has a doublet (not coupled to any other

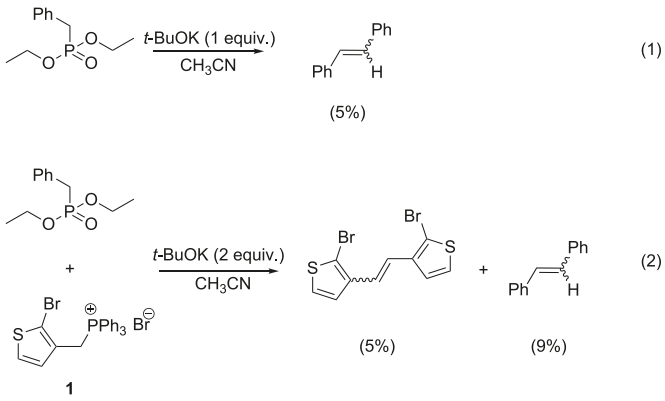
© 2008 NRC Canada

aliphatic protons) at δ 4.22 ppm, indicating the presence of phosphorous. Analysis of the aromatic region of this compound shows the presence of only 10 hydrogen atoms indicating the loss of a benzene ring. Surprisingly when NaH was used as the base, a quantitative yield of *n*-butyldiphenylphosphine oxide was obtained as well. Since no known source of oxygen was present in the starting compounds, we believe that *n*-butyldiphenylphosphine was initially formed but was then converted to the phosphine oxide in the presence of air. To test this hypothesis and determine the source of oxygen, we exposed *n*-butyltriphenylphosphonium bromide to NaH in dry acetonitrile under argon atmosphere. After 2 h of stirring, the work-up of the reaction was carefully carried out under argon atmosphere resulting in a pale yellow liquid (22) instead of the white solid. Upon exposure to air the liquid instantaneously turns to a white solid, which shows spectral characteristics of the phosphine oxide. This is consistent with the reported air-sensitivity of alkyldiphenylphosphines (23). NMR analysis of the liquid in dry C_6D_6 under argon atmosphere indicates it to be the phosphine. Change of the reaction solvent to DMSO or extending the reaction time does not affect the result of this reaction. The mechanism of the loss of the phenyl group is not clear to us at this time.

Since the evidence points to the existence of the ylid as an intermediate for the homocoupling reaction, we investigated the possibility of using the ylid from diethyl benzylphosphonate. In the presence of a base, the phosphonate ester produced stilbene in only 5% yield (Scheme 4, eq. [1]). Since the yield of the homocoupling reaction for the phosphonate ester is low in spite of the formation of a reactive ylid, we attempted a cross coupling reaction with the phosphonium salt to synthesize non-symmetric alkenes. Diethyl benzylphosphonate was dissolved in acetonitrile and cooled to 0 °C under ice. The base (*t*-BuOK, 1 equiv.) was added slowly and the reaction mixture was allowed to warm up to RT with stirring for 15 min. The phosphonium salt **1** was added to the reaction mixture and the mixture was stirred for a further 1 h. Another equivalent of the base was then added, stirred for 1 h, and the products were isolated using column chromatography. Only homocoupling products could be isolated from the reaction mixture (Scheme 4, eq. [2]). Only 9% of stilbene was obtained, while unreacted diethyl benzylphosphonate was recovered from the reaction mixture. It is possible that the phosphonate ylid deprotonates the phosphonium salt followed by an adduct formation without undergoing elimination to form the alkene. This would be consistent with the low yields of the homocoupling product of **1** under these conditions. Analysis of the product mixture was inconclusive regarding the formation of an adduct.

Scheme 4. Homocoupling and cross-coupling of diethyl benzylphosphonate with a base.



Conclusions

Arylmethyltriphenylphosphonium ions undergo an efficient homocoupling reaction in the presence of a base in polar aprotic solvents. Other alkyltriphenylphosphonium ions that do not form resonance stabilized ylids eliminate an aryl group from the phosphorus under similar conditions. Diethylbenzylphosphonate, which is known to form ylids, also undergoes a homocoupling reaction though the yields are substantially lower. It is possible that other ylids may undergo similar homocoupling reactions in polar aprotic solvents. At this time, it is difficult to rationalize or predict the *E*/*Z* ratio of the alkene.

Materials and methods

Commercially available reagents were obtained from Sigma-Aldrich were used as received. MeCN was distilled over CaH_2, while DMSO was dried over molecular sieves before being used. Reactions were followed with thin-layer chromatography (TLC) and visualized with a UV lamp. Reaction mixtures were purified on prep TLC plates or column chromatography using hexanes as the eluent. GC-MS analysis was done using HP 5890 Series II GC fitted with HP 5971 Series mass selective detector, to confirm the purity of products (selected GC chromatographs are included in the Supplementary Data).[2] ^{1}H, proton decoupled ^{13}C, and proton decoupled ^{31}P NMR spectra were recorded on a Bruker AMX 500 MHz spectrometer at ambient temperature. Triethylphosphite was used as an external standard for ^{31}P NMR and was calibrated to δ 137 ppm. Compounds **4**, **5**, and **6** were synthesized as per procedures described previously (24). High-resolution mass spectral data were obtained on Agilent 61969A TOF high-resolution mass spectrometer using electrospray ionization by direct infusion of the sample in 50% methanol and 1 mmol/L AcOH at 10 mL/min flow rates.

3-Methyl-2-nitrothiophene (25, 26)

3-Methylthiophene (0.49 mL, 0.50 g, 5.1 mmol) was added to 10 mL of acetic anhydride and the solution was stirred at 0 °C in an ice–salt bath. A precooled mixture of 0.320 µL of HNO_3 and 0.320 µL of H_2SO_4 was added to this solution dropwise. The solution turned dark green in the process. The reaction mixture was allowed to warm up to RT while stirring for 2 h. The solution was cooled again and diluted with 10 mL of water and neutralized with NaOH powder to a pH of 8. The resulting brown solution precipitated and was filtered. The brown residue was purified on column chromatography using hexane/ethyl acetate mixtures (4:1) to obtain 0.30 g of the 3-methyl-2-nitrothiophene (43%). ^{1}H NMR ($CDCl_3$) δ: 7.40 (d, J = 5.4 Hz, 1H), 6.91 (d, J = 5.4 Hz, 1H), 2.64 (s, 3H).

Synthesis of phosphonium salts

General procedure

The arylmethylbromides were synthesized as per the literature procedures from the corresponding alkanes (27). The alkane (1.000 g, 1 mmol) was added to 5 mL of dry 1,2-dichloroethane and the solution was heated to reflux. Benzoyl peroxide (2 mg, 0.01 mmol) was added to the refluxing mixture, quickly followed by a mixture of benzoyl peroxide (2 mg, 0.01 mmol) and *N*-bromosuccinimide (0.178 g, 1.00 mmol). The solution was refluxed for 1 h. After cooling to RT, the succinimide was removed by dissolving in hexanes followed by filtration. The solvent was removed under reduced pressure. ^{1}H and ^{13}C NMR of the crude product indicated about 90% conversion of the starting material. The crude product was used for the synthesis of the phosphonium salts. Triphenylphosphane (3.90 g, 14.9 mmol) was dissolved in 10 mL of dry benzene and heated to reflux. The arylmethylbromide (14.9 mmol, 1 equiv.) was dissolved in 5 mL of dry benzene and added to the refluxing mixture. The solution was refluxed for 12 h. After cooling to RT, the white precipitate was filtered off, washed with benzene, and the product was dried under vacuum. The phosphonium salts were recrystallized with dichloromethane-benzene solvent mixtures. The compounds **9**–**11** were purchased from commercial sources (Acros and Alfa Aesar).

2-Bromo-3-thienylmethyltriphenylphosphonium bromide 1 (27)

2-Bromo-3-bromomethylthiophene: yield 1.02 g from 1.00 g of 2-bromo-3-methylthiophene (71%). ^{1}H NMR ($CDCl_3$) δ: 7.39 (d, J = 5.6 Hz, 1H), 7.14 (d, J = 5.7 Hz, 1H), 4.59 (s, 2H).

Yield 5.9 g of **1** from 3.8 g of 2-bromo-3-bromomethylthiophene (77%). Pale yellow crystals. mp 240–241 °C (lit. mp (27) 238–240 °C). ^{1}H NMR ($CDCl_3$) δ: 7.60–7.79 (m, 15H), 7.17 (d, J = 5.7, 1H), 6.86 (dd, J_1 = 5.7 Hz, J_2 = 1.2 Hz, 1H), 5.39 (d, J = 13.7 Hz, 2H).

2-Thienylmethyltriphenylphosphonium bromide 2 (27)

2-Bromomethylthiophene: yield 0.134 g from 0.100 g of 2-methylthiophene (71%). ^{1}H NMR ($CDCl_3$) δ: 7.32 (d, J = 5.0 Hz, 1H), 7.12 (d, J = 3.3 Hz, 1H), 6.95 (t, J = 3.6 Hz, 1H), 4.77 (s, 2H).

Yield: 0.176 g of **2** from 0.142 g of 2-bromomethylthiophene (50%). White crystals. mp > 300 °C. ^{1}H NMR (DMSO) δ: 7.92 (d, J = 5.7 Hz, 3H), 7.78–7.74 (m, 7H), 7.70–7.68 (m, 5H), 7.39–7.36 (m, 2H), 7.25–7.23 (m, 1H), 5.55 (d, J = 14.6 Hz, 2H).

3-Methoxybenzyltriphenylphosphonium bromide 4

Yield 1.081 g of **4** from 1.013 g 3-methoxybenzyl bromide (28%). White crystals, mp 263–265 °C. ^{1}H NMR ($CDCl_3$) δ: 7.76 (dt, J_1 = 1.0 Hz, J_2 = 7.7 Hz, 3H), 7.69–7.63 (m, 12H), 7.35 (dt, J_1 = 2.6 Hz, J_2 = 7.1 Hz, 1H), 7.22 (tt, J_1 = 2.4 Hz, J_2 = 7.6 Hz, 1H), 6.80 (t, J = 7.5 Hz, 1H), 5.20 (d, J = 13.9 Hz, 2H), 3.21 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 157.4 (d, J = 21.0 Hz), 135.0 (d, J = 11.0 Hz), 134.3 (d, J = 38.5 Hz, 132.9 (d, J = 21.5 Hz), 130.4 (d, J = 15.5 Hz), 130.2 (d, J = 50.0 Hz), 121.4 (d, J = 12.5 Hz), 118.5 (d, J = 339.5 Hz), 115.7 (d, J = 35.5 Hz), 110.5 (d, J = 13.0 Hz), 54.9, 25.7 (d, J = 191.5 Hz).

2-Methoxybenzyltriphenylphosphonium bromide 6

Yield 2.72 g of **6** from 1.46 g 2-methoxybenzyl bromide (83%). Pale yellow crystals, mp 243–244 °C (lit. mp (crude) (28) 210–220 °C). ^{1}H NMR ($CDCl_3$) δ: 7.79–7.73 (m, 9H), 7.66–7.62 (m, 6H), 7.02 (t, J = 7.9 Hz, 1H), 6.81 (b, q, J = 1.7 Hz, 1H), 6.76 (b, dt, J_1 = 2.3 Hz, J_2 = 8.2 Hz, 1H), 6.64 (b, d, J = 7.5 Hz, 1H), 5.37 (d, J = 14.4 Hz, 2H), 3.55 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 159.9 (d, J = 14.0 Hz), 135.1 (d, J = 12.0 Hz), 134.7 (d, J = 38.5 Hz), 130.3 (d, J = 50.0 Hz), 129.9 (d, J = 13.0 Hz), 128.7, 123.7 (d, J = 22.5 Hz), 118.1 (d, J = 341.5 Hz), 116.5 (d, J = 22.5 Hz), 115.6 (d, J = 15.5 Hz), 55.7, 31.1 (d, J = 186.5 Hz).

2-Nitrobenzyltriphenylphosphonium bromide 7

Yield 0.921 g of **7** from 0.456 g 2-nitrobenzyl bromide (92%). White crystals, mp 248 °C (decomp). ^{1}H NMR ($CDCl_3$) δ: 8.06 (d, J = 5.5 Hz, 1H), 7.94 (d, J = 8.2 Hz, 1H), 7.80 (t, J = 7.3 Hz, 3H), 7.71–7.60 (m, 13H), 7.51 (t, J = 7.5 Hz, 1H), 6.07 (d, J = 14.9 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 148.5, 135.5 (d, J = 11.5 Hz), 135.3 (d, J = 20.5 Hz), 135.1 (d, J = 12.5 Hz), 134.5 (d, J = 40.0 Hz), 130.5 (d, J = 50.0 Hz), 130.1 (d, J = 14.0 Hz), 125.9 (d, J = 10.5 Hz), 124.7 (d, J = 36.0 Hz), 117.3 (d, J = 342.5 Hz), 28.7 (d, J = 194.5 Hz).

2-Nitro-3-thienylmethyltriphenylphosphonium bromide 8 (15)

3-Bromomethyl-2-nitrothiophene (25): yield 9 mg from 29 mg of 3-methyl-2-nitrothiophene (20%). ^{1}H NMR ($CDCl_3$) δ: 7.48 (d, J = 5.5 Hz, 1H), 7.19 (d, J = 5.5 Hz, 1Hz), 4.90 (s, 2H).

Yield 45 mg of **8** from 34 mg of 3-bromomethyl-2-nitrothiophene (55%). ^{1}H NMR ($CDCl_3$) δ: 7.84–7.76 (m, 9H), 7.69–7.65 (m, 7H), 7.54 (d, J = 5.5 Hz), 1H, 6.18 (d, J = 15.3 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 135.5 (d, J = 11.5 Hz), 134.2, (d, J = 39.5 Hz, 132.5 (d, J = 14.5 Hz), 131.8 (d, J = 11.5 Hz), 130.7 (d, J = 37.5 Hz), 130.5 (d, J = 50.5 Hz), 117.1 (d, J = 344 Hz), 25.5 (d, J = 196 Hz).

Synthesis of homocoupling products

General procedure

The corresponding phosphonium salt was dissolved in 200 mL of dry MeCN and cooled in an ice-water bath while stirring. The base (NaH or *t*-BuOK) was gradually added. Upon completion, the solution was stirred at RT for 2 h. The solvent was evaporated in vacuo. The residue was suspended in ethyl acetate, and the product was isolated by preparative TLC with hexanes as the eluent. When DMSO was used as solvent, about 10 mL of water was added to the reaction mixture and the products were extracted with ethyl acetate. The organic layer was washed a few times with water, dried over anhyd Na_2SO_4, and the solvent was removed under reduced pressure. The product mixture was then subjected to a silica gel column using hexanes as the eluent.

1,2-Di(2-bromo-3-thienyl)ethane (15)

Yield 40 mg from 0.150 g of **1** (78%, *E*/*Z* ratio 1:2) with 2 equiv. of NaH as the base in 200 mL of MeCN. Yield 37 mg

from 0.150 g of **1** (74%, *E*/*Z* ratio 1:1.7) with 2 equiv. of *t*-BuOK as the base in 200 mL of MeCN. ^{1}H NMR ($CDCl_3$) δ: 7.28 (s, 2H), 7.26 (s, 2H), 7.13 (d, J = 5.7 Hz, 2H), 6.72 (s, 2H), 6.72 (d, J = 5.7 Hz, 2H), 6.51 (s, 2H).

1,2-Di(2-thienyl)ethene (E isomer) (15)

Yield 19 mg from 0.150 g of **2** (56%). ^{1}H NMR ($CDCl_3$) δ: 7.19 (d, J = 4.8 Hz, 2H), 7.06 (s, 2H), 7.05 (dd, J_1 = 1.1 Hz, J_2 = 3.5 Hz, 2H), 7.00 (dd, J_1 = 3.6 Hz, J_2 = 5.0 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 142.4, 127.6, 126.0, 124.3, 121.5.

Stilbene (15)

Yield 23 mg from 0.150 g of **3** with 200 mL of CH_3CN and 0.076 g of *t*-BuOK (74%, *E*/*Z* ratio 1:1.5). ^{1}H NMR ($CDCl_3$) δ: 7.52 (d, J = 7.4 Hz, 4H), 7.35 (t, J = 7.5 Hz, 6H), 7.27–7.18 (m, 10H), 7.11 (s, 2H), 6.60 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 130.4, 129.1, 128.9, 128.4, 127.8, 127.6, 127.3, 126.7.

3,3′-Dimethoxystilbene (29)

Yield 35 mg from 0.150 g of **4** (89%, *E*/*Z* ratio 1:1) with 3 equiv. of *t*-BuOK as base in 200 mL of CH_3CN. Yield 40 mg from 0.150 g of **4** (100%, *E*/*Z* ratio 1:1.1) with 2 equiv. of NaH as base in 200 mL of CH_3CN. The purity of the recovered product was confirmed by GC-MS. ^{1}H NMR ($CDCl_3$) δ: 7.30 (d, J = 7.9 Hz, 1H), 7.16 (t, J = 7.9 Hz, 2H), 7.13 (bd, J = 7.7 Hz, 2H), 7.10 (s, 2H), 7.06 (bt, J = 2.3 Hz, 2H), 6.86 (d, J = 7.6 Hz, 2H), 6.83 (dd, J_1 = 2.5 Hz. J_2 = 8.2 Hz, 2H), 6.81 (bt, J = 2.4 Hz, 2H), 6.76 (ddd, J_1 = 0.7 Hz, J_2 = 5.1 Hz, J_3 = 10.5 Hz, 3H), 6.59 (s, 2H), 3.82 (s, 6H), 3,68 (s, 6H).

4,4′-Dimethoxystilbene (E and Z isomers)

Yield 9 mg from 0.150 g of **5** (23%, *E*/*Z* ratio 1:3.5) with 3 equiv. of NaH as base. The purity of the recovered product was confirmed by GC-MS. ^{1}H NMR ($CDCl_3$) δ: 7.44 (d, J = 8.7 Hz, 4H), 7.22 (d, J = 8.7 Hz, 4H), 6.94 (s, 2H), 6.90 (d, J = 8.7 Hz, 4H), 6.78 (d, J = 8.7 Hz, 4H), 6.46 (s, 2H), 3.84 (s, 6H), 3.80 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 159.2, 158.7, 130.7, 130.3, 130.2, 128.6, 127.6, 126.4, 114.3, 113.8, 55.5, 55.4.

2,2′-Dimethoxystilbene (E and Z isomers) (30)

Yield 15 mg from 0.150 g of **6** (39%, *E*/*Z* ratio 1:3.3) with 1 equiv. of *t*-BuOK as base in 200 mL of CH_3CN. Yield 29 mg from 0.150 g of **6** (75%, *E*/*Z* ratio 1:4.3) with 2 equiv. of *t*-BuOK as base in 200 mL of CH_3CN. Yield 0.035 g from 0.150 g of **6** (90%, *E*/*Z* ratio 1:3.8) with 3 equiv. of *t*-BuOK as base in 200 mL of CH_3CN. Yield 0.034 g from 0.150 g of **6** (87%, *E*/*Z* ratio 1:4.3) with 3 equiv. of NaH as base in 200 mL of CH_3CN. ^{1}H NMR ($CDCl_3$) δ: 7.67 (dd, J_1 = 1.5 Hz, J_2 = 7.6 Hz, 2H), 7.49 (s, 2H), 7.25 (dt, J_1 = 1.6 Hz, J_2 = 8.0 Hz, 2H), 7.18 (dt, J_1 = 1.6 Hz, J_2 = 8.1 Hz, 2H), 7.14 (dd, J_1 = 1.6 Hz, J_2 = 7.6 Hz, 2H), 7.98 (t, J = 7.4 Hz, 2H), 6.91 (d, J = 8.5 Hz, 2H), 6.89 (d, J = 8.2 Hz, 2H), 6.79 (s, 2H), 6.72 (dt, J_1 = 0.6 Hz, J_2 = 7.8 Hz, 2H), 3.89 (s, 6H), 3.85 (s, 6H).

n-Butyldiphenylphosphine

n-Butyltriphenylphosphonium bromide (0.151 g, 0.378 mmol) was dissolved in 15 mL of distilled acetonitrile and the solution was purged with argon for 20 min, followed by cooling in ice. NaH (20 mg, 0.83 mmol) was added and the solution was stirred for 2 h at RT. Filtration of the solution under the atmosphere of argon was followed by removal of the solvent in vacuo. *n*-Butyltriphenylphosphine (87 mg) was obtained as a pale yellow oil (lit. value (31) colorless oil). ^{1}H NMR (C_6D_6) δ: 7.82–7.79 (m, 4H), 7.26–7.13 (m, 6H), 2.10–2.05 (m, 2H), 1.67–1.60 (m, 2H), 1.30–1.28 (m, 2H), 0.80 (t, J = 5.3 Hz, 3H). ^{13}C NMR (C_6D_6) δ: 134.9 (d, J = 411.0 Hz), 131.9 (d, J = 7.5 Hz), 131.4 (d, J = 37.0 Hz), 129.2 (d, J = 46.0 Hz), 30.0 (d, J = 286.7 Hz), 24.6 (d, J = 57.5 Hz), 24.2 (d, J = 15.1 Hz), 14.3. ^{31}P NMR (C_6D_6) (33) δ: 28.7.

n-Butyldiphenylphosphine oxide

n-BuPPh3Br (0.150 g, 0.376 mmol) was dissolved in 10 mL of dry MeCN. The base, *t*-BuOK (84 mg, 0.75 mmol) or NaH (18 mg, 0.75 mmol), was gradually added over 5 min and the solution was stirred for 2 h. The solvent was evaporated under reduced pressure and the products were purified with column chromatography using hexanes and ethyl acetate as eluents. The purity of the recovered product was confirmed by GC-MS. The product was recrystallized with diethyl ether. White solid, mp 92–94 °C (lit. value (32) 94–95 °C). Yield 0.103 g (100%) from *t*-BuOK and 0.110 g (100%) from NaH. ^{1}H NMR ($CDCl_3$) δ: 7.76–7.73 (m, 4H), 7.50–7.44 (m, 6H), 2.30–2.24 (m, 2H), 1.63–1.58 (m, 2H), 1.42 (q, J = 7.4 Hz, 2H), 0.88 (t, J = 7.3 Hz, 3H). ^{1}H NMR (C_6D_6) δ: 7.79–7.77 (m, 4H), 7.06–7.05 (m, 6H), 1.97–1.91 (m, 2H), 1.64–1.59 (m, 2H), 1.20 (q, J = 7.4 Hz, 2H), 0.69 (t, J = 7.4 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 133.2 (d, J = 388.5 Hz), 131.7 (d, J = 10.5 Hz), 130.8 (d, J = 36.0 Hz), 128.7 (d, J = 46.0 Hz), 29.5 (d, J = 287.5 Hz), 24.1 (d, J = 60.5 Hz), 23.5 (d, J = 16.0 Hz), 13.6. ^{13}C NMR (C_6D_6) δ: 135.8 (d, J = 381.0 Hz), 131.6 (d, J = 8.5 Hz), 131.4 (d, J = 35.0 Hz), 129.0 (d, J = 45.0 Hz), 30.3 (d, J = 287.0 Hz), 24.7 (d, J = 55.8 Hz), 24.3 (d, J = 15.3 Hz), 14.1. ^{31}P NMR ($CDCl_3$) δ: 17.4. ^{31}P NMR (C_6D_6) δ: 26.0. EI-MS *m*/*z* 229 (7.2), 216 (17.8), 215 (100), 202 (13.7), 201 (42.9), 183 (18.4), 171 (7.9), 155 (10.3), 154 (11.9), 153 (10.7), 152 (10.0), 128 (4.5), 125 (14.4), 91 (5.7), 78 (5.2), 77 (22.8), 51 (16.8). HRMS (ESI) calcd. for $C_{16}H_{20}OP$ [M+H]: 259.1246; found 259.1244.

Methoxymethyldiphenylphosphine oxide

The same procedure was used as with *n*-butyldiphenylphosphine oxide: 0.200 g (0.6 mmol) of **10**, 71 mg (0.59 mmol) of *t*-BuOK, and 8 mL of DMSO were used. The solution was dissolved in dichloromethane and extracted with water. The dichloromethane fraction gave 73 mg (55%) of the product. The purity of the recovered product was confirmed by GC-MS. The product was recrystallized with diethyl ether. Colorless solid, mp 115–116 °C (lit. value (33) 116–117 °C). ^{1}H NMR ($CDCl_3$) δ: 7.84–7.80 (m, 4H), 7.55 (t, J = 6.0 Hz, 2H), 7.54–7.48 (m, 4H), 4.22 (d, J = 6.4 Hz, 2H), 3.45 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 132.3 (d, J = 10.5 Hz), 131.4 (d, J = 394.5 Hz), 131.6 (d, J = 37.5 Hz), 128.7 (d, J = 47.0 Hz), 71.3 (d, J = 350.5 Hz), 62.0 (d, J = 46.5 Hz). ^{31}P NMR ($CDCl_3$) δ: 11.9. EI-MS *m*/*z* (rel. intensity) 217 (6.8), 216 (58.4), 215 (78.5), 202 (11.5), 201 (100), 199 (8.7), 183 (22.2), 173 (9.2), 171 (17.2), 170 (4.6), 154 (7.3), 153 (15.0), 152 (14.4), 151 (5.8), 133 (4.5), 107 (9.9),

© 2008 NRC Canada

77 (24.4), 51 (9.8). HRMS (ESI) calcd. for $C_{14}H_{16}O_2P$ [M+H]: 247.0882; found 247.0890.

Coupling of ethoxycarbonylmethyltriphenylphosphonium bromide

The compound **11** (0.150 g, 0.350) was dissolved in 10 mL of dry MeCN and cooled to 0 °C. The base *t*-BuOK (78 mg, 0.70 mmol) was added gradually and the solution was stirred for 2 h, while allowing it to warm up to the RT. The insoluble salts were removed by filtration and the solvent was removed under reduced pressure. ^{1}H NMR of the crude filtrate showed the *E*/*Z* ylid. Yield 0.125 g from 0.151 g (100%) of **11**. ^{1}H NMR ($CDCl_3$) δ: 7.68–7.64 (m, 12H), 7.53–7.51 (m, 6H), 7.45–7.42 (m, 12H), 4.03 (q, J = 7.0 Hz, 2H), 3.83 (q, J = 2H), 2.96 (d, J = 21.9 Hz, 1H), 2.69 (d, J = 21.9 Hz, 1H), 1.23 (t, J = 7.1 Hz, 3H), 0.68 (t, J = 7.1 Hz, 3H).

Coupling of diethylbenzylphosphonate

Diethylbenzylphosphonate (184 μL, 0.876 mmol) was dissolved in 10 mL of dry MeCN. The base *t*-BuOK (10 mg, 0.87 mmol) was gradually added over 5 min and the the reaction mixture was stirred overnight. The solvent was removed under reduced pressure. Purification was done with column chromatography using pure hexanes to obtain 4 mg (5%) of stilbene. ^{1}H NMR (CD_3CN) δ: 7.58 (td, J_1 = 1.3 Hz, J_2 = 7.9 Hz, 4H), 7.38 (dt, J_1 = 1.5 Hz, J_2 = 7.1 Hz, 4H), 7.28 (tt, J_1 = 1.2 Hz, J_2 = 7.4 Hz, 2H), 7.22 (s, 2H). ^{13}C NMR (CD_3CN) δ 138.7, 130.0, 129.7, 128.9, 127.7.

Cross-coupling of diethylbenzylphosphonate and 2-bromo-3-methylthiophenetriphenylphosphonium bromide

Di-ethylbenzylphosphonate (184 μL, 0.876 mmol) of was dissolved in 10 mL of dry MeCN and the solution was cooled in an ice-water bath. *t*-BuOK (0.010 g, 0.874 mmol) was added and the solution was stirred at RT for 15 min, followed by the addition of 0.454 g (0.876 mmol) of 2-bromo-3-methylthiophenetriphenylphosphonium bromide. The solution was stirred at RT for another 1 h, after which 10 mg (0.87 mmol) of *t*-BuOK was added and the solution was stirred again at RT for 1 h. The solvent was evaporated and the residue was purified using preparatory thin layer chromatography using hexanes. Only the homocoupled products were isolated: 8 mg (5%) of (*E*/*Z*)-1,2-di-(2-bromothienyl)ethene and 7 mg (9%) of *E*-Stilbene. Isomeric ratios were the same as with homocoupled reactions.

Asymmetric oxidation of 2-(arylsulfenyl)pyrroles

Alison Thompson, Jose R. Garabatos-Perera, and H. Martin Gillis

Abstract: The asymmetric oxidation of prochiral 2-(arylsulfenyl)pyrroles has been investigated. A marked electronic effect within the substrate significantly influenced the degree of enantioselectivity obtained, with very high enantioselectivity being obtained for 5-(nitrobenzensulfenyl)pyrrole-2-carboxaldehydes using Ti(*i*-PrO)$_4$/(+)-(*R*,*R*)-DET/H_2O/CHP. This result bodes well for optimizing the asymmetric oxidation of other diaryl sulfides, substrates that have previously given only low enantiomeric excesses.

Key words: asymmetric oxidation, sulfide, sulfoxide, pyrrole.

Résumé : On a étudié l'oxydation asymétrique de 2-(arylsulfényl)pyrroles prochiraux. On a noté qu'un effet électronique marqué dans le substrat influence d'une façon significative le degré d'énantiosélectivité obtenu, la plus grande énantiosélectivité étant obtenue avec les 5-(nitrobenzènesulfényl)pyrrole-2-carboxaldéhydes en utilisant le Ti(*i*-PrO)$_4$/(+)-(*R*,*R*)-DET/H_2O/CHP. Les résultats obtenus sont de bon augure pour l'optimisation de l'oxydation asymétrique d'autres sulfures de diaryles, des substrats qui n'ont donné antérieurement que de très faibles excès énantiomériques.

Mots-clés : oxydation asymétrique, sulfure, sulfoxyde, pyrrole.

[Traduit par la Rédaction]

Introduction

The use of chiral sulfoxides as auxiliaries for the asymmetric synthesis of biologically important compounds has found many applications (1, 2). For example, the efficiency of sulfoxides has been demonstrated for controlling the stereoselectivities of alkylation reactions, Michael addition reactions, aldol reactions, cycloaddition reactions, and Pummerer rearrangements (3). Chiral sulfoxides are generally prepared using either organometallic reagents and resolved diastereomeric sulfinates (i.e., chiral sulfinyl transfer reagents) (2, 4–6) or via the asymmetric oxidation of prochiral sulfides (2, 7).

Synthetic strategies involving pyrroles often require the introduction of a deactivating electron-withdrawing group that reduces the electron-rich character of the pyrrole unit. As such, the nucleophilicity of the pyrrolic core may be controlled and undesirable side-reactions minimized (8). Whilst this control has commonly been achieved by the use of carboxylates at the 2-position, the use of a sulfenyl group to mask the 2-position, rather than protect through electron-withdrawal, has recently been demonstrated (9, 10). The utility of 2-(sulfenyl)pyrroles in acylation reactions, nitration reactions, and condensation reactions with various aldehydes, as well as the removal of the sulfenyl group using Raney nickel, highlights the sulfenyl group as a valuable masking/protecting group for pyrrolic compounds. With 2-(arylsulfenyl)pyrroles showing promise for the synthesis of functionalized pyrroles, 2-(arylsulfinyl)pyrroles (11) become of interest.

Chiral 2-(arylsulfinyl)pyrroles of high enantiomeric purity prepared by sulfinylation using diastereomerically pure menthyl arylsulfinates have attracted attention because of their use as removable chiral auxiliaries and as building blocks for macromolecular chemistry (4). While this method has been successfully applied for several 2-(arylsulfinyl)pyrroles (4, 5), it lacks generality because of the difficulty in obtaining a diverse set of diastereomerically pure menthyl aryl- or alkylsulfinates (2). Indeed, the preparation of diastereomerically pure menthyl arylsulfinates requires multiple recrystallizations, and, furthermore, menthyl alkylsulfinates (e.g., menthyl methanesulfinate) are typically oils, which thus prohibits recrystallization as a strategy by which to obtain diastereomerically pure material (12, 13). In this article, we report investigations towards an alternative approach to chiral 2-(arylsulfinyl)pyrroles involving the asymmetric oxidation of prochiral 2-(arylsulfenyl)pyrroles.

Although numerous methodologies have been reported for the asymmetric oxidation of sulfides to sulfoxides (2, 6, 14–16), so far, they have been largely limited to sulfides with two stereochemically different substitutents (i.e., aryl and alkyl). Substrates with similar groups such as dialkyl or diaryl generally lead to little or no asymmetric induction. For example, the asymmetric oxidation of methyl benzyl sulfide using a chiral titanium complex (17, 18), chiral oxaziridine (19), chiral metallo(salen) complex (20), or enzymatic methods (21, 22) gives the desired sulfoxide in modest–excellent yields (50%–97%), but with poor enantioselectivities (14%–58%). Even a recent example for the asymmetric oxidation of sulfides using hydrogen peroxide in water and a homochiral iron(III) catalyst focuses on the oxidation of methyl phenyl sulfide, with a somewhat reduced enantioselectivity being obtained for even ethyl phenyl sulfide (23). Similarly, a very recent novel

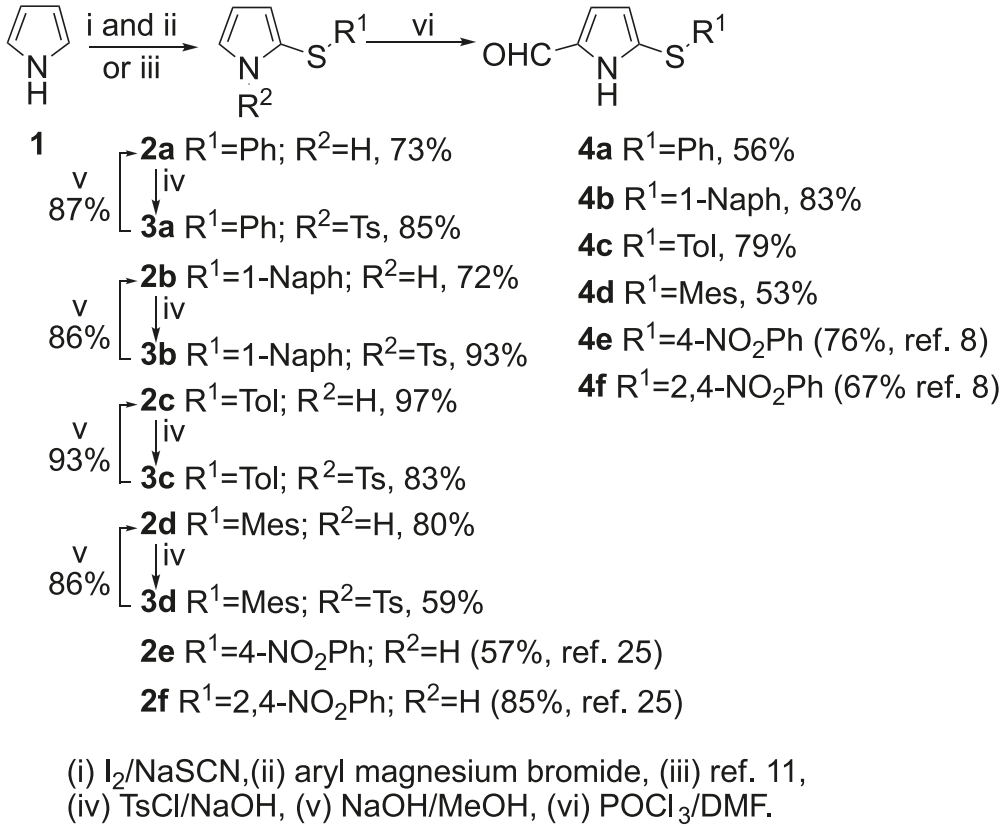
Scheme 1. Synthesis of 2-(arylsulfenyl)pyrroles.



oxaziridinium salt, derived from cholesterol, gives good–excellent enantioselectivity for a variety of aryl alkyl sulfides, but no reports for diaryl sulfides are included (24).

Results and discussion

To probe their asymmetric oxidation, we prepared a series of 2-(arylsulfenyl)pyrroles with various substituents at the 2- and 5-positions. Following an established procedure for the preparation of 2-(phenylsulfenyl)pyrrole **2a** (10, 25) from 2-(thiocyanato)pyrroles (26–28) and phenylmagnesium bromide, a series of 2-(arylsulfenyl)pyrroles **2a**–**2d** were obtained in good yields by simply varying the Grignard reagent used (Scheme 1). We previously reported the preparation of **4e** and **4f** using Vilsmeier–Hack formylation conditions (9), and extension of this work for the 2-(arylsulfenyl)pyrroles **2a**–**2d** provided 5-(arylsulfenyl)pyrrole-2-carboxylaldehydes **4a**–**4d** in moderate to good yields. The excellent directing ability of the arylsulfenyl group for formylation at the vacant α-position emphasizes a general feature of sulfenyl masking groups. In our hands, 2-(arylsulfenyl)pyrroles **2a**–**2d** prepared via this route were found to be unstable to air (9) and were immediately protected as their corresponding *N*-tosyl derivatives **3a**–**3d** for ease of manipulation and storage (8). In all cases, the introduction of an electron-withdrawing group (tosyl or formyl) resulted in enhanced product stability.

With several prochiral 2-(arylsulfenyl)pyrroles available, we investigated their asymmetric oxidation (29–32) using chiral titanium complexes prepared from Ti(*i*-PrO)$_4$ and (+)-(*R*,*R*)-diethyl tartrate (DET), as described by Kagan (17, 33–38) and Modena (18). In our preliminary efforts, the asymmetric oxidation of 2-(phenylsulfenyl)pyrrole **2a** using *tert*-butyl hydroperoxide (TBHP) according to both the Kagan and Modena protocols resulted in essentially racemic sulfoxide **6a** (Table 1, entry 1), albeit in reasonable isolated yield. Under similar conditions, pyrroles **2e** and **2f**, bearing an electron-withdrawing group within the sulfenyl moiety, were oxidized using cumyl hydroperoxide (CHP) at –20 °C and 25 °C with a dramatic improvement of enantioselectivity (Table 1, entries 2 and 3 vs. entry 1). Interestingly, **2e**, bearing one nitro group, gave an enantioselectivity of 29% under these conditions, whereas **2e**, with two nitro groups, gave an enantioselectivity of 78%, and so decreasing the electron-density about the sulfide appeared to result in an increased enantioselectivity. However, the use of **3a** with an electron-withdrawing tosyl group on the pyrrolic nitrogen atom did not result in improved enantioselectivity, despite attempts under various conditions (Table 1, entry 4). Maintaining *N*-tosyl substitution, the introduction of the more sterically demanding naphthyl group within **3b**, rather than a phenyl or tolyl group within **3a** and **3c**, respectively, on the sulfenyl moiety did not significantly affect the oxidation reaction (Table 1, entries 5 and 6A). Furthermore, and significantly, other well-known methods for asymmetric sulfide oxidation resulted in poor yields and enantiopurities with 2-(*p*-tolylsulfenyl)pyrrole-*N*-tosylpyrrole **3c** (Table 1, entry 6; methods C–E). The poor enantioselectivities for **3c** serve to further emphasize that the preparation of enantiopure sulfoxides by the oxidation of diaryl sulfides is far from trivial.

Continuing the notion that the introduction of electron-withdrawing groups enhances the stereoselectivity of oxidation (Table 1, entries 2 and 3 cf. 1) the effect of the α-formyl substituent was investigated. Thus, 5-(arylsulfenyl)pyrrole-2-carboxylaldehydes **4a**–**4f** were oxidized in moderate–good yields using the Kagan and Modena protocols, and, in all cases, the enantioselectivities were enhanced (Table 1, entries 8–13) over attempts using analogous pyrroles lacking the formyl group. In particular, the asymmetric oxidation of **4e** and **4f** provided chiral sulfoxides **7e** and **7f**, respectively, in 45% yield (96% ee) and 85% yield (98% ee), respectively (Table 1, entries 12 and 13).

Our results regarding the asymmetric oxidation of 2-(arylsulfenyl)pyrroles possessing substitutents with varying electronic effects allow us to rationalize the effectiveness of the Kagan and Modena protocols for this transformation. Although the Kagan and Modena procedures have been widely used for the oxidation of many prochiral sulfides, the struc-

© 2008 NRC Canada

ture of the reagent responsible for the stereochemical course of the reaction is still unknown (39, 40). In some cases, additives and the preparation of the reagent are crucial in obtaining specific chiral sulfoxides with high enantiopurities and (or) yields (37, 41, 42). More seriously, prochiral sulfides with two sterically different substitutents are generally good substrates for asymmetric oxidation, whereas substrates with similar groups often give products with low enantiopurities. For example, Kagan and co-workers reported the asymmetric oxidation of aryl methyl sulfides using a chiral titanium complex prepared from Ti(*i*-PrO)$_4$/(+)-(*R*,*R*)-DET/H_2O/TBHP (1:2:1:1) to give chiral sulfoxides with good–excellent enantiopurities (i.e., phenyl, 89% ee; *p*-tolyl, 91% ee; *p*-methoxyphenyl, 86% ee; *p*-nitrophenyl, 77% ee); however, the asymmetric oxidation of alkyl methyl sulfides under the same conditions resulted in chiral sulfoxides with reduced enantiopurities (i.e., *n*-octyl, 71% ee, *t*-butyl, 53% ee; cyclohexyl, 54% ee; benzyl, 58% ee) (17). In the face of the poor enantioselectivities that have traditionally been obtained for the asymmetric oxidation of diaryl sulfides, the results from the present study suggest that there is an important electronic effect that can influence this transformation. Although the origin of enantioselectivity is speculative at this point, one factor that could temper the influence of an electronic effect is the substrate–reagent binding affinity. If the mechanism involves a reversible associative step and electron-rich substrates have high association constants, as would be expected, reactions involving electron-rich substrates would give lower enantioselectivities, since these substrates bind more strongly (i.e., high reactivity and less selective). For electron-poor substrates, low association constants would allow for the substrate to dissociate and reassociate before reaction occurs (i.e., low reactivity and more selective). The traditional model used to predict the stereochemical outcome of sulfide oxidation involves the differentiation of sterically different substituents, and electronic effects are not typically considered (17, 39, 40). On the contrary, the results of the study presented herein strongly suggest that electronic effects play an important role in the asymmetric oxidation of diaryl substrates.

Conclusions

We have demonstrated the asymmetric oxidation of 2-(arylsulfenyl)pyrroles using a chiral titanium complex. Our work suggests a strong electronic effect where the incorporation of electron-withdrawing groups to differentiate the two sulfenyl substituents results in an enhancement of enantioselectivity. This method is particularly well-suited for prochiral sulfides bearing two aryl groups and expands the scope of substrates suitable for the Kagan and Modena protocols to include prochiral 2-(arylsulfenyl)pyrroles. Our current research is directed towards the preparation of a range of enantiopure 2-(arylsulfinyl)pyrroles using alternative strategies.

Experimental section

Representative procedures

*2-(*p*-Tolylsulfenyl)pyrrole (2c)*

To a solution of *p*-tolylmagnesium bromide [prepared from *p*-bromotoluene (12.0 mL, 16.8 g, 100 mmol) and magnesium turnings (2.4 g, 100 mmol) in anhydrous THF (150 mL) at 0 °C under N_2], was added dropwise 2-(thiocyanato)pyrrole (4.9 g, 39 mmol) in anhydrous THF (150 mL). After stirring at 0 °C for 30 min, ice-cold water (~100 mL) was added. The mixture was diluted with EtOAc and washed with satd. aqueous NH_4Cl and brine, before being dried over $MgSO_4$ and concentrated to give crude 2-(*p*-tolylsulfenyl)pyrrole **2c**, which was purified using flash column chromatography (CH_2Cl_2 as eluent) to give the title compound **2c** (6.7 g, 38 mmol, 97%).

A solution of 2-(*p*-tolylsulfenyl)pyrrole-*N*-tosylpyrrole **3c** (0.52 g, 1.5 mmol) in 15% *v*/*v* 2 mol/L NaOH (5.5 mL, 11 mmol) in MeOH (35 mL) was heated to reflux for 2 h until no starting material remained (TLC analysis). The mixture was cooled to room temperature and diluted with EtOAc, washed with aqueous 0.1 mol/L NaOH (3×) and brine (3×) before being dried over $MgSO_4$ and then concentrated to give crude 2-(*p*-tolylsulfenyl)pyrrole **2c** (0.25 g, 1.4 mmol, 93%), which was used in the next reaction without further purification. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.17 (1H, br s), 7.00–6.97 (2H, m), 6.93–6.91 (2H, m), 6.84–6.82 (1H, m), 6.53–6.52 (1H, m), 6.27–6.26 (1H, m), 2.24 (3H, s). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 135.5 (s), 135.5 (s), 129.9 (d × 2), 126.5 (d × 2), 121.8 (d), 118.4 (d), 116.4 (s), 110.4 (d), 21.0 (q). HRMS *m*/*z* calcd. for $C_{11}H_{11}NS$: 189.0612 (188.0534 for M – H); found: 188.0539 (ESI–).

*2-(*p*-Tolylsulfenyl)pyrrole-*N*-tosylpyrrole (3c)*

TsCl (8.1 g, 43 mmol) was added to a suspension of 2-(*p*-tolylsulfenyl)pyrrole **2c** (6.7 g, 35 mmol) and NaOH (5.6 g, 141 mmol) in 1,2-dichloroethane (130 mL) at 0 °C. The resulting mixture was warmed to room temperature and stirred for 12 h. Water was added, and the mixture was extracted with CH_2Cl_2 (3×). The combined organic layers were washed with brine, dried over $MgSO_4$, and then concentrated to give crude 2-(*p*-tolylsulfenyl)pyrrole-*N*-tosylpyrrole **3c**, which was purified using flash column chromatography (50% CH_2Cl_2 in hexanes as eluent) to give the title compound **3c** (10.0 g, 29 mmol, 83%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.73 (2H, d, *J* = 8.5 Hz), 7.61–7.59 (1H, m), 7.10 (2H, d, *J* = 8 Hz), 6.90 (2H, d, *J* = 8 Hz), 6.76 (2H, d, *J* = 8 Hz), 6.53–6.52 (1H, m), 6.33–6.31 (1H, m), 2.31 (3H, s), 2.24 (3H, s). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 145.1 (s), 135.7 (s), 135.5 (s), 134.1 (s), 129.68 (d × 2), 129.64 (d × 2), 128.2 (d × 2), 127.0 (d × 2), 126.6 (d), 125.8 (d), 121.0 (s), 111.8 (d), 21.7 (q), 21.1 (q). LRMS (EI): 343 ([M]$^+$, 100), 188 (73). HRMS *m*/*z* calcd. for $C_{18}H_{17}NO_2S_2$: 343.0701; found: 342.9792 (EI).

*5-(*p*-Tolylsulfenyl)pyrrole-2-carboxylaldehyde (4c)*

$POCl_3$ (0.28 mL, 0.47 g, 3.1 mmol) was added dropwise to DMF (0.24 mL, 0.23 g, 3.1 mmol) at 0 °C under N_2. The resulting mixture was heated to 100 °C and stirred for 15 min. After cooling to 0 °C, a solution of 2-(*p*-tolylsulfenyl)pyrrole **2c** (0.25 g, 1.4 mmol; 0.05 mol/L in

© 2008 NRC Canada

CH_2Cl_2) was slowly added and then heated at reflux for 1 h. The resulting mixture was cooled to 0 °C, and aqueous 1 mol/L AcONa (50 mL) was added. The resulting suspension was heated to reflux and stirred for 1 h. After cooling to room temperature, the mixture was extracted with CH_2Cl_2 (3×). The combined organic layers were washed with satd. aqueous Na_2CO_3 (3×) and brine, before being dried over $MgSO_4$ and then concentrated to give crude 5-(*p*-tolylsulfenyl)pyrrole-2-carboxylaldehydes **4c** that was purified by flash column chromatography (CH_2Cl_2) to give the title compound **4c** (0.23 g, 1.1 mmol, 79%). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 9.62 (1H, br s), 9.38 (1H, s), 7.20 (2H, d, J = 8 Hz), 7.09 (2H, d, J = 8 Hz), 6.92–6.91 (1H, m), 6.40–6.30 (1H, m), 2.31 (3H, s). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 178.5 (d), 137.1 (s), 135.1 (s), 131.5 (s), 130.6 (d × 2), 130.4 (d × 3), 121.1 (s), 116.6 (d), 21.2 (q). HRMS *m*/*z* calcd. for $C_{12}H_{11}NOS$: 217.0561 (216.0483 for M – H); found: 216.0485 (ESI–).

*2-(*p*-Tolylsulfinyl)pyrrole-*N*-tosylpyrrole (5c)*

Racemic

50% wt% *m*-CPBA (0.22 g, 0.60 mmol) was added to a solution of 2-(*p*-tolylsulfenyl)-*N*-tosylpyrrole **3c** (0.20 g, 0.60 mmol) at room temperature for 2 h. Saturated aqueous $NaHCO_3$ was added, and the mixture was extracted with CH_2Cl_2 (3×). The combined organic layers were washed with brine, dried over $MgSO_4$, and then concentrated to give crude 2-(*p*-tolylsulfinyl)pyrrole-*N*-tosylpyrrole **5c**, which was purified using flash column chromatography (10% ethyl acetate in CH_2Cl_2 as eluent) to give the title compound **5c** (0.092 g, 0.27 mmol, 45%).

Asymmetric

Ti(*i*-PrO)$_4$ (0.14 mL, 0.14 g, 0.50 mmol) was added dropwise to a solution of (+)-(*R*,*R*)-DET (0.17 mL, 0.20 g, 1.00 mmol) and 2-(*p*-tolylsulfenyl)pyrrole-*N*-tosylpyrrole **3c** (0.17 g, 0.50 mmol) in CH_2Cl_2 (2 mL) under argon at room temperature. After 5 min, water (9 μL, 0.50 mmol) was added, and stirring was continued at room temperature for 45 min. 80% wt% Cumylhydroperoxide (0.19 mL, 0.15 g, 1.00 mmol) was then added under argon at –20 °C, and stirring was continued for 20 h. Water was added, and the mixture was allowed to stir for 30 min at room temperature. The resulting mixture was diluted with CH_2Cl_2 and filtered through a pad of silica and eluted with ethyl acetate to give the crude product, which was purified using flash column chromatography (10% ethyl acetate in CH_2Cl_2 as eluent) to give the title 2-(*p*-tolylsulfinyl)pyrrole-*N*-tosylpyrrole **5c** (0.15 g, 40 mmol, 83%, 16% ee; determined by chiral HPLC analysis of the corresponding tosyl deprotected **6c**; see Supplementary Data).[2] ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.81 (2H, d, J = 8.5 Hz), 7.61 (2H, d, J = 8 Hz), 7.33 (1H, m), 7.29–7.26 (4H, m), 6.62 (1H, dd, J = 2, 4 Hz), 6.31 (1H, dd, J = 3.5, 3.5 Hz), 2.40 (3H, s), 2.39 (3H, s). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 146.0 (s), 142.1 (s), 141.3 (s), 137.0 (s), 135.3 (s), 130.3 (d × 2), 129.9 (d × 2), 127.7 (d × 2), 126.4 (d), 126.0 (d × 2), 118.4 (d), 113.2 (d), 21.8 (q), 21.6 (q). HRMS *m*/*z* calcd. for $C_{18}H_{17}NO_3S_2$: 359.0650 (382.0548 for M + Na); found: 382.0542 (ESI+).

29. The asymmetric oxidation of prochiral sulfides presents the opportunity of coupling the initial asymmetric synthesis with a kinetic resolution. While the kinetic resolution of racemic **7a** using the Modena protocol (Table 1, entry 8; 30% conversion, 17% ee) revealed a small kinetic preference ($s = 3$), the results in Table 1 indicate that the enantioselectivity occurred predominantly via the initial asymmetric synthesis.

Vicarious nucleophilic amination of nitroquinolines with 4-amino-1,2,4-triazole

Barbara Szpakiewicz and Maria Grzegożek

Abstract: 3-, 5-, 6-, 7- and 8-Nitroquinolines react with 4-amino-1,2,4-triazole in basic medium (potassium *tert*-butoxide-dimethyl sulfoxide) giving amino products of the vicarious nucleophilic substitution (VNS) of hydrogen, predominantly at ortho position to the nitro group, except 8-nitroquinoline, which reacts at para position. Additionally, furazano[3,4-*f*]- and furazano[3,4-*h*]quinoline were obtained in the case of 5- and 8- nitroquinoline, respectively. 2-Nitroquinoline was aminated to 2-quinolino(1,2,4-triazol-4-yl)amine in these conditions.

Key words: nitroquinolines, vicarious nucleophilic substitution (VNS), 4-amino-1,2,4-triazole.

Résumé : Les 3-, 5-, 6-, 7- et 8-nitroquinoléines réagissent avec le 4-amino-1,2,4-triazole en milieu basique (*tert*-butylate de potassium dans le diméthylsulfoxyde) pour conduire à la formation de produits aminés par le biais d'une substitution nucléophile indirecte (SNI) d'hydrogène, principalement en position ortho du groupe nitro, excepté dans le cas de la 8-nitroquinoléine avec laquelle la substitution se fait en position para. De plus, dans les cas de la 5- et de la 8-nitroquinoléine, on a aussi obtenu respectivement la furazano[3,4-*f*] et la furazano[3,4-*h*]quinoléine.

Mots-clés : nitroquinoléines, substitution nucléophile indirecte (SNI), 4-amino-1,2,4-triazole.

[Traduit par la Rédaction]

Introduction

Many derivatives of aminoquinolines exhibit a wide spectrum of pharmacological and biological activities. Moreover, aminoquinolines are important intermediates in organic synthesis. Some examples of synthesis of aminonitroquinolines have already been described previously. They have been synthesized by the classical method, which is nucleophilic substitution S_NAr of halogen by amines in halogenonitroquinolines (1–3). Another way to obtain compounds mentioned above is dehydroamination of nitroquinolines. It has been carried out as oxidative nucleophilic substitution of hydrogen (ONSH) (4–6) or vicarious nucleophilic substitution (VNS) of hydrogen (7–10). Thus, Woźniak et al. described that mono- and dinitroquinolines undergo selective amination, in liquid ammonia and potassium permanganate at –33 °C, in the ortho position, relative to the nitro group, with moderate to low yields, except 8-nitro- and 2-nitroquinoline (found as unreactive) (4, 5). Additionally, they studied the amination of halogeno and methyl derivatives of nitroquinolines containing the substituents in the benzene ring. The reported amination also undergoes giving selectively ortho substituted products, relative to the nitro group. No amination was observed when the position adjacent to the NO_2 group was occupied by a halogen or a methyl group (6).

Huisgen (7) and Hasegawa et al. (8, 9) described the direct amination of mononitroquinolines with hydroxylamine in basic media, which leads to aminonitroquinolines. Mąkosza suggested that these reactions can be considered as examples of the VNS reaction (10). In these reactions, Hasegawa obtained furazanoquinolines in addition to the known amino derivatives. He obtained furazano[3,4-*f*]quinoline from 5-nitro- and 6-nitroquinoline and furazano[3,4-*h*]quinoline from 7-nitro- and 8-nitroquinoline (7, 8).

For the VNS amination of 5-nitro- and 6-nitroquinoline, Mąkosza and Białecki used sulfenamides. In the first case, they obtained the mixture of 6-amino- and 8-amino-5-nitroquinoline and 6-amino-5-nitrosoquinoline with 90%–98% yield, and in the second case, they obtained only 5-amino-6-nitroquinoline (98% yield) (10).

A variety of regents for the direct amination of nitroarenes and nitrosubstituted heteroaromatic compounds in VNS reactions were described in literature. These are 4-amino-1,2,4-triazole (11–15), *O*-alkylhydroxylamines (16), 1,1,1-trimethylhydrazinium iodide (17–20), and hydroxylamine (7–9) and sulfenamides (10, 21) mentioned above.

In this paper, we report the results of our studies on the amination of nitroquinolines **1** via the vicarious nucleophilic substitution (VNS) of hydrogen with 4-amino-1,2,4-triazole. This is the continuation of our research on the synthesis of amino nitroaromatic compounds (2, 22).

Results and discussion

The amination of the nitroquinolines **1a**–**1e** with 4-amino-1,2,4-triazole was carried out in the presence of potassium *tert*-butoxide-DMSO solution at room temperature. The

1c 6-NO_2 — **2c** 6-NO_2, 5-NH_2 (98%)

1d 7-NO_2 — **2d** 7-NO_2, 8-NH_2 (84%)

1e 8-NO_2 — **2e** 8-NO_2, 5-NH_2 (47%); **4** (23%)

structures of these products were determined on the basis of their physical properties (mp, spectral data: ^{1}H NMR, IR, and MS) and comparison with data from literature or with reference samples in some cases. The results of amination are compiled in Scheme 1.

The reaction of nitroquinolines **1a**–**1e** with 4-amino-1,2,4-triazole proceeds in accordance with vicarious S_NAr^H mechanism, described by Mąkosza (23), which we present as an example of amination of 5-nitroquinoline (**1b**) (Scheme 2).

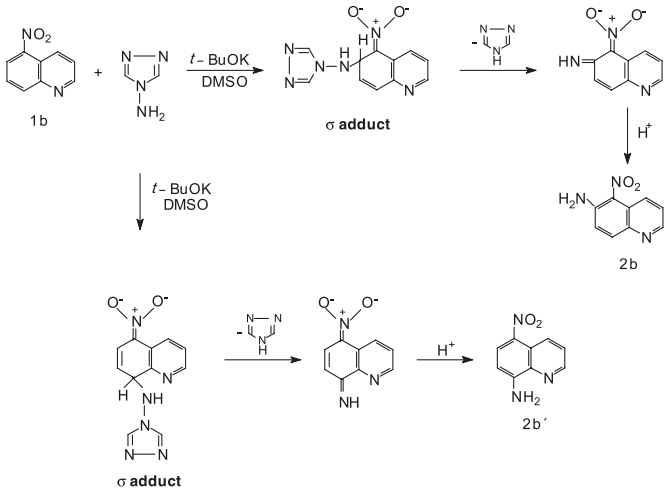
The reaction occurs between 5-nitroquinoline (**1b**) and the anion generated from 4-amino-1,2,4-triazole, in presence of a strong base (potassium *tert*-butoxide). In the first step, addition of the anion to the 5-nitroquinoline (**1b**) results in formation of σ adducts, type of Meisenheimer complexes, in ortho and para positions relative to the nitro group. Immediate formation of an intense dark-red colour was observed. The σ adducts undergo base-induced β-elimination of 1,2,4-triazole to form carbanions, which are protonated during the work up procedure, giving 6-amino-5-nitro- (**2b**) and 8-amino-5-nitroquinoline (**2b′**). Amination of 3- (**1a**), 6- (**1c**) and 7-nitroquinoline (**1d**) occurs regioselectively giving products of substitution at ortho position to the nitro group: 4-amino-3-nitro- (**2a**), 5-amino-6-nitro- (**2c**), 8-amino-7-nitroquinoline (**2d**) with moderate to high 52%, 98%, and 84 % yields, respectively.

Amination of 5-nitro- (**1b**) and 8-nitroquinoline (**1e**) with 4-amino-1,2,4-triazole in DMSO in the presence of *t*-BuOK at room temperature afforded furazanoquinolines beside the corresponding substituted aminonitroquinolines. In the case of **1b**, we obtained the products of ortho and para substitution of hydrogen: 6-amino-5-nitro- (**2b**) and 8-amino-5-nitroquinoline (**2b′**), as given above, together with furazano[3,4-*f*]quinoline (**3**) with 15%, 19%, and 35% yields, respectively (Scheme 1). On the other hand, 8-nitroquinoline (**1e**) gave 5-amino-8-nitroquinoline (**2e**) (47%) and furazano[3,4-*h*]quinoline (**4**) (23%) under the same conditions.

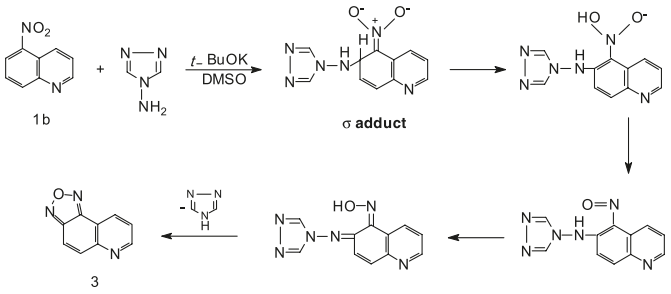
To explain the formation of furazanoquinolines **3** and **4**, we propose the mechanism for synthesis of furazano[3,4-*f*]quinoline (**3**) from 5-nitroquinoline (**1b**) in Scheme 3. This mechanism is in accordance with the one suggested by Hasegawa for similar reaction (8).

In the first step, addition of 4-amino-1,2,4-triazole anion at the ortho position to the nitro group gives the σ adduct, in which the ortho ring hydrogen undergoes shifting to the oxygen of the nitro group. Subsequently, elimination of hydroxyl group leads to 4-(5-nitroso-6-quinolylamino)-

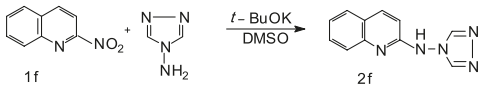
Scheme 2.



Scheme 3.



Scheme 4.



1,2,4-triazole that, by intramolecular cyclization, forms furazano[3,4-*f*]quinoline (**3**).

In the case of 8-nitroquinoline (**1e**), the reaction progress, monitored by thin layer chromatography, indicates the formation of furazano[3,4-*h*]quinoline (**4**) after 5 min of the reaction time. The quick formation of furazane proves that σ adduct undergoes intramolecular transformation more readily than β-elimination of 1,2,4-triazole. This confirms the presented mechanism of reaction and explains why we did not obtain ortho amino isomer instead of only para isomer, as a product of amination.

2-Nitroquinoline (**1f**), in contrast to other studied nitroquinolines **1a**–**1e**, does not undergo vicarious amination by 4-amino-1,2,4-triazole but only displacement of the 2-nitro group occurs, giving 2-quinolino(1,2,4-triazol-4-yl)amine (**2f**) (Scheme 4).

Apparently, the nucleophilic displacement of the highly labile nitro group at C-2 position of the pyridine ring in **1f**, takes place more easily than the vicarious nucleophilic substitution of hydrogen by amino group at another carbon atom. A similar behaviour of 2-nitroquinoline was observed for oxidative methylamination reaction (2).

Summary

In conclusion, we have presented the direct amination of 3-, 5-, 6-, 7- and 8-nitroquinolines (**1a**–**1e**) with 4-amino-1,2,4-triazole under the VNS reaction conditions. Using the 4-amino-1,2,4-triazole permits to obtain aminonitroquinolines in a short time, with moderate to high yields, substituted mainly in ortho position to the nitro group. 5-Nitroquinoline (**1b**) gave, besides the ortho amino product, the para isomer, and in the case of 8-nitroquinoline (**1e**), only the para amino product was obtained. In both cases, as the products of transformation of ortho σ adducts, furazano[3,4-*f*]- (**3**) and furazano[3,4-*h*]quinoline (**4**) were also obtained.

2-Nitroquinoline (**1f**) reacted with replacement of the nitro group, giving 2-quinolino(1,2,4-triazol-4-yl)amine (**2f**).

Experimental

Melting points (uncorrected) were determined on a Boetius melting point apparatus. The ^{1}H NMR spectra were recorded on Tesla BS-587A (80 MHz) spectrometers using TMS as internal standard. Chemical shifts are expressed in parts per million (ppm). The infrared spectra were recorded on Bio-Rad FTS-175C spectrometer (in potassium bromide pellets). Mass spectra (EI) were recorded with a Varian-MAT 112 spectrometer at 70 eV. Elemental analysis was performed on a PerkinElmer 2400 analyser. The reaction products were analysed by thin-layer chromatography (TLC) on silica gel or aluminium oxide plates (Merck 60F_{254}). The progress of reactions was monitored by TLC on silica gel using dichloromethane as eluent. Aluminium oxide type 507 C was used for column chromatography.

Synthesis of starting and reference compounds

3-Nitro-(**1a** (24)), 2-nitro-(**1f** (5)) were prepared according to the literature procedures. 5-(**1b**), 6-(**1c**), 7-(**1d**), and 8-Nitroquinoline (**1e**) were obtained by Skraup reaction from the respective aminonitrobenzenes (25). Other reagents, 4-amino-1,2,4-triazole, *t*-BuOK, and DMSO were commercial products from Merck and Aldrich and were dried before use, except *t*-BuOK.

Amination of nitroquinolines 1a–1f with 4-amino-1,2,4-triazole

General procedure

The mixture of the respective nitroquinolines **1a**–**1f** (174 mg, 1 mmol) and 4-amino-1,2,4-triazole (100–126 mg, 1.2–1.5 mmol) in dimethyl sulfoxide (3–5 mL) was added at room temperature to a stirred suspension of *t*-BuOK (280 mg, 2.5 mmol) in dimethyl sulfoxide (2 mL), except **1e**, where 522 mg (3 mmol) of **1e** and respective amount of remaining reagents were used. The reaction mixture was stirred vigorously for 0.25–0.7 h, and 4 h in the case of 2-nitroquinoline (**1f**), at room temperature. The resulting red-brown solution was poured into saturated NH_4Cl, the precipitate was filtered off, washed with water, and dried. The filtrate was periodically extracted with dichloromethane or chloroform (3 × 25 mL) in some cases. After evaporation of the solvent, the residue was combined with the obtained precipitate and was worked up in the manner described below.

Amination of 3-nitroquinoline (1a)

4-Amino-3-nitroquinoline (**2a**): orange precipitate 98 mg (52%) with mp 258–260 °C (subl.) (without purification, chromatographically pure) and after recrystallization from EtOH: yellow needles with mp 265–266 °C (lit. (1) 261 °C; (4) 274–275 °C; (2) 270–272 °C). IR (ν_{max}) (cm^{-1}): 3385, 3304, 3175 (NH), 1537 (NO_2, as), 1337 (NO_2, s). ^{1}H NMR (DMSO-d_6) δ: 9.18 (s, 2-H), 9.01 (br s, NH_2), 8.58 (dd, 5-H or 8-H), 7.96–7.51 (m, 6-H, 7-H and 5-H or 8-H), $J_{6,7}$ = 4.40, $J_{5,6} = J_{7,8}$ = 8.56, $J_{5,7} = J_{6,8}$ = 1.24 Hz.

Amination of 5-nitroquinoline (1b)

The yellow residue was separated on the chromatographic column using chloroform as eluent. The first fraction gave 60 mg (35%) of furazano[3,4-*f*]quinoline (**3**) colourless needles, mp 132–134 °C (lit.(8) 138–139 °C; (26) 134 °C). ^{1}H NMR ($CDCl_3$) δ: 9.03 (dd, 2-H), 8.85 (dd, 4-H), 7.91 (s, 7-H, 8-H), 7.63 (dd, 3-H), $J_{2,3}$ = 4.60, $J_{2,4}$ = 1.68, $J_{3,4}$ = 8.80 Hz. MS *m*/*z* (%): 171 [M^+] (100), 141 [M^+ – NO].

The second fraction, after removing of the eluent by evaporation, gave 36 mg (19%) of 8-amino-5-nitroquinoline (**2b′**) as orange needles with mp 201–202 °C (lit. (8) 197–198 °C; (2) 194–195 °C). IR (ν_{max}) (cm^{-1}): 3402, 3308, 3212 (NH), 1524 (NO_2, as), 1392 (NO_2, s). ^{1}H NMR ($CDCl_3$) δ: 9.40 (dd, 4-H), 8.79 (dd, 2-H), 8.52(d, 6-H), 7.64 (dd, 3-H), 6.79 (d, 7-H), 5.97 (br s, NH_2), $J_{2,3}$ = 4.16, $J_{2,4}$ = 1.56, $J_{3,4}$ = 8.80, $J_{6,7}$ = 8.92 Hz. The compound **2b′** showed properties identical to the reference sample obtained independently (22).

From the third fraction was isolated 28 mg (15%) 6-amino-5-nitroquinoline (**2b**) as yellow needles, after recrystallization from toluene, mp 176–178 °C (lit. (10) 173–175 °C, (5) 176–178 °C). IR (ν_{max}) (cm^{-1}): 3437, 3412, 3295, (NH), 1511 (NO_2, as), 1300 (NO_2, s). ^{1}H NMR ($CDCl_3$) δ: 9.12 (dd, 4-H), 8.72 (dd, 2-H), 8.05 (d, 8-H), 7.54 (dd, 3-H), 7.16 (d, 7-H), 6.69 (br s, NH_2), $J_{2,3}$ = 4.20, $J_{2,4}$ = 1.60, $J_{3,4}$ = 8.80, $J_{7,8}$ = 9.28 Hz.

Amination of 6-nitroquinoline (1c)

5-Amino-6-nitroquinoline (**2c**): yellow solid 185 mg (98%) with mp 283–284 °C (without purification, chromatographically pure) and after recrystallization from toluene: yellow needles, mp 285–286 °C subl. (lit. (7) 283–284.5 °C; (5) 287–288 °C subl.). IR (ν_{max}) (cm^{-1}): 3404, 3295, 3168 (NH), 1584 (NO_2, as), 1324 (NO_2, s). ^{1}H NMR (DMSO-d_6) δ: 9.10–8.90 (m, 2-H, 4-H), 8.74 (br s, NH_2), 8.22 (d, 7-H), 7.61 (dd, 3-H), 7.15 (d, 8-H), $J_{2,3}$ = 4.40, $J_{3,4}$ = 8.00, $J_{7,8}$ = 9.64 Hz.

Amination of 7-nitroquinoline (1d)

8-Amino-7-nitroquinoline (**3d**): orange crystals 159 mg (84%) with mp 189–190 °C (without purification, chromatographically pure) (lit. (5) 188–189 °C; (1) 185–185.5 °C). The compound showed properties identical (mp, IR spectrum, and coefficient R_f (TLC)) with those of the reference samples. IR (ν_{max}) (cm^{-1}): 3477, 3359 (NH), 1523 (NO_2, as), 1321 (NO_2, s). ^{1}H NMR (DMSO-d_6) δ: 8.91 (dd, 2-H), 8.43 (s, NH_2), 8.34 (dd, 4-H), 8.04 (d, 6-H), 7.76 (dd, 3-H), 7.93 (d, 5-H), $J_{2,3}$ = 4.16, $J_{3,4}$ = 8.16, $J_{2,4}$ = 1.76, $J_{5,6}$ = 9.36 Hz.

© 2008 NRC Canada

Amination of 8-nitroquinoline (1e)

The yellow residue was dissolved in 50 mL of dichloromethane, and the insoluble precipitate was filtered off. The orange precipitate: 232 mg (41%) was analyzed as 5-amino-8-nitroquinoline (**2e**) with mp 250–251 °C (without purification, chromatographically pure) (lit. (2) 252–253 °C). IR (ν_{max}) (cm^{-1}): 3456, 3438, 3324, 3204 (NH), 1576 (NO_2, as), 1298 (NO_2, s). ^{1}H NMR (DMSO-d_6) δ: 8.97 (dd, 2-H), 8.70 (dd, 4-H), 8.19 (d, 7-H), 7.54 (dd, 3-H), 7.39 (br s, NH_2), 6.67 (d, 6-H), $J_{2,3}$ = 4.12, $J_{3,4}$ = 8.68, $J_{2,4}$ = 1.52, $J_{6,7}$ = 8.8 Hz.

The filtrate, after condensation, was separated on the chromatographic column using dichloromethane as eluent. The first fraction gave 120 mg (23%) of furazano[3,4-*h*]quinoline (**4**), colourless plates, mp 176–177 °C (lit. (8) 177.5–178 °C). ^{1}H NMR ($CDCl_3$) δ: 9.04 (dd, 2-H), 8.17 (dd, 4-H), 7.84–7.58 (m, 3-H, 5-H, 6-H), $J_{2,3}$ = 4.56, $J_{2,4}$ = 1.62, $J_{3,4}$ = 8.08 Hz. MS *m*/*z* (%): 171 [M^+] (100), 141 [M^+ – NO] (79), 114 [M^+ – NO – HCN] (30).

The second fraction, after removing of the eluent by evaporation, afforded additional 36 mg compound, which showed the same properties, mp and coefficient R_f, as 5-amino-8-nitroquinoline (**2e**). Total yield of **2e** is 47%.

Amination of 2-nitroquinoline (1f)

2-Quinolino(1,2,4-triazol-4-yl)amine (**2f**): colourless crystals, 171 mg (81%), after recrystallization from methanol, mp 258–259 °C. IR (ν_{max}) (cm^{-1}): 3437 (NH), 1650 (δ NH (s)). ^{1}H NMR (CD_3OD) δ: 8.67 (s, 2H-triazole), 8.11 (d, 4-H), 7.79–7.28 (m, 5–8-H, NH), 6.85 (d, 3-H), $J_{3,4}$ = 8.72 Hz. MS *m*/*z* (%): 211 [M^+] (19), 129 (100). Anal. calcd. for $C_{11}H_9N_5$ (211.23): C 62.55, H 4.29, N 33.16; found: C 62.20, H 4.17, N 32.76.

Substituent effects, Arrhenius activation parameters, and rate constants for the photo–Claisen rearrangement of allyl aryl ethers

Carlos M. Gonzalez and James A. Pincock

Abstract: The temperature-dependence of fluorescence quantum yields in both methanol and methylcyclohexane has been used to obtain the rate constants of reaction for the activated process that converts the singlet excited state S_1 of a set of ring-substituted aryl allyl ethers to an intermediate radical pair in the photo–Claisen rearrangement. These rate constants are correlated with the O–H bond dissociation energy of the corresponding ring-substituted phenols; that is, electron-donating groups (CH_3, OCH_3) accelerate the reaction relative to electron-withdrawing groups (CF_3, CN). The rate constants obtained span two orders of magnitude, from 5.4×10^7 s^{-1} for X = 3–CN to 800×10^7 s^{-1} for X = 4–OCH_3, in methylcylcohexane. Moreover, the rate constants are similar in the two solvents, methanol and methcyclohexane, indicating that radical pairs, not ion pairs, are the reactive intermediates, as expected on the basis of previous mechanistic proposals for the photo–Claisen rearrangement. Finally, the rate constants obtained by this temperature-dependent method are in good agreement with those previously reported from a method using the corresponding unreactive anisoles as a model.

Key words: allyl aryl ethers, photo–Claisen rearrangement, substituent effects, activation parameters.

Résumé : La relation de dépendance entre la température les rendements quantiques de fluorescence, tant dans le méthanol que dans le méthylcyclohexane, a été utilisée pour déterminer les constantes de vitesse de réaction pour les processus activés au cours desquels l'état excité singulet S_1 d'un ensemble d'oxydes d'allyle et d'aryles substitués sur le noyau aromatique se transforme en une paire radicalaire dans un réarrangement photo–Claisen. On a établi une corrélation entre ces constantes de vitesse et l'énergie de dissociation de la liaison O–H des phénols correspondants portant les mêmes substituants sur leur noyau, à savoir que les groupes électrodonneurs, tel le CH_3 ou le OCH_3, accélèrent la réaction par rapport aux groupes électroaffinitaires, tels les groupes CF_3 ou C≡N. Dans le méthylcyclohexane, les constantes de vitesse s'étalent sur deux ordres de grandeur, soit de $5{,}4 \times 10^7$ s^{-1} pour X = 3–CN à 800×10^7 s^{-1} pour X = 4–OCH_3. De plus, les constantes de vitesse sont semblables dans les deux solvants, méthanol et méthylcyclohexane, ce qui indique que les intermédiaires réactifs sont des paires de radicaux et non des paires d'ions, tel qu'on pouvait le prévoir sur les bases mécanistiques développées antérieurement pour le réarrangement de photo–Claisen. Enfin, les constantes de vitesse obtenues par cette méthode qui dépend de la température sont en bon accord avec ceux rapportés antérieurement à l'aide d'une méthode qui faisait appel à un modèle impliquant des anisoles non réactifs.

Mots-clés : oxydes d'allyle et d'aryle, réarrangement de photo–Claisen, effets de substituant, paramètres d'activation.

[Traduit par la Traduction]

Introduction

Recently, we reported (1) on the rate constants of reaction in both methanol and cyclohexane from the excited singlet state S_1 of a set of 11 substituted aryl allyl ethers **1** which undergo an efficient photo–Claisen rearrangement, Scheme 1, via a radical pair **2**, to the products **3**. This project was one in a continuing series exploring the effect that substituents on the aryl ring have on the photochemical reactivity of systems of the general structure Ar-X-Y. As in this article, the focus has been on the X–Y bond cleavage. For benzylic systems (X = CH_2), Y is normally a typical leaving group (halide, carboxylate, thiolate, etc.), and the reactions can then be photosolvolysis in polar protic solvents (alcohols, water) proceeding through benzylic carbenium ions. Usually, radical-derived products are formed along with the ion-derived ones and the factors that control the competition between these two pathways have been recently reviewed (2). In contrast, the photo–Claisen reaction has been proposed to involve only radical pairs as intermediates (3), and this suggestion was confirmed by the similar rate constants we obtained in both the polar protic solvent, methanol, and the non-polar one, cyclohexane. The rate constants spanned almost two orders of magnitude, those with electron-drawing groups (CN, CF_3) reacting much more slowly than those

with electron-donating groups (CH_3, OCH_3). Because of the polarity of the O–C bond that was breaking, a reasonable expectation was that the transition state would also be polarized $O^{\delta-}\cdots C^{\delta+}$. If that were the case, a correlation of the rates of the bond cleavage with σ_{ex}, the substituent constants for the excited state pK_a's of substituted phenols (4, 5, 6), might be expected. Surprisingly, the rate constants were correlated reasonably well with σ^+. This counterintuitive observation was resolved by the realization that the rate constants were strongly correlated by the bond dissociation energy (O–H BDE) of the corresponding phenols **4** (7), which also correlate with σ^+, those compounds with weaker bonds reacting with the greater rate constants in both methanol and cyclohexane.

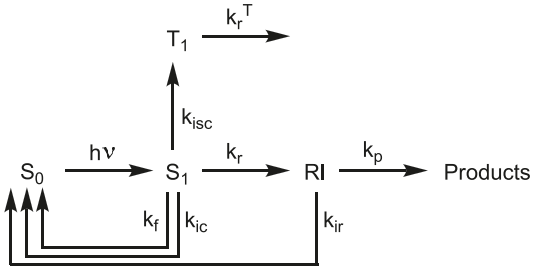
These results were obtained by comparing the fluorescence quantum yield and (or) the fluorescence lifetime of the reactive allyl ethers with the identically substituted, but unreactive model compounds, anisoles **5**. The basic idea was that the decrease in either the excited singlet state lifetime or the quantum yield of fluorescence when comparing a substituted **1** with its analogue **5** could be quantitatively used to determine the rate constant for the excited state bond cleavage of **1**. This idea was questioned (1) with the suggestion that an additional mode of excited state decay, other than reaction, was available for the allyl ethers **1**, namely intramolecular exciplex formation, which was unavailable to the anisoles **5**. At the time, we provided strongly suggestive, but not conclusive, evidence that this was not the case.

We now report on the temperature dependence of the fluorescence quantum yield for the allyl ethers **1** that provides considerably more convincing evidence that the initially reported rate constants were reliably determined.

Results and discussion

Recently we have used, following the examples from the Lewis (8) and Zacchariasse (9) laboratories, a method that allows the direct determination of the rate constant of reactivity of S_1 by the temperature dependence of either the fluorescence lifetime or the fluorescence quantum yield. The basic concept is shown in Scheme 2. The total rate of decay, k_t, the reciprocal of the lifetime τ of S_1, is given by eq. [1]. Two of the terms in this equation are photophysical processes (k_f, fluorescence; k_{isc}, intersystem crossing) and are assumed to be temperature independent. Moreover, k_{ic} can be ignored because the rate of internal conversion from the Frank–Condon state of S_1 of benzene derivatives is known

Scheme 2. Rate constants for the reactions of an excited state S_1 and a reactive intermediate (RI).



(10) to be negligibly slow relative to other decay modes because of the large energy gap between S_1 and S_0. Therefore, eq. [1] simplifies to eq. [2], where k_r, the photochemical reaction, is assumed to be temperature dependent and follow an Arrhenius' relationship.

$$[1] \qquad k_t = k_f + k_{ic} + k_{isc} + k_r$$

$$[2] \qquad k_t = k_f + k_{isc} + A\ \exp(-E_a/RT)$$

$$[3] \qquad \Phi_f = k_f/[k_f + k_{isc} + A\ \exp(-E_a/RT)]$$

The assumption that k_{isc} is temperature independent and the details of applying this method have been discussed in detail by Lewis (8), Zacchariasse (9) and us (11). An important point to mention is that this method gives k_r from S_1 and any reactivity from T_1 is invisible. Internal return from any reactive intermediate is also not detected. However, a comparison of the quantum yield of formation of the reactive intermediate, $\Phi_{ri} = k_r/k_t$, and that for the products, $\Phi_{products} = \Phi_{ri} \times (k_p/k_p + k_{ir})$ (Scheme 2) will give a measure of the importance of internal return, a process that has been observed in many experiments which have been designed to detect it (11, 12).

Experimentally, either the rate constant of decay k_t or the quantum yield of fluorescence Φ_f as a function of temperature, can be used. For the former, the data obtained is analyzed by eq. [2] with the number of unknowns reduced from four to three by independently determining $k_f = \Phi_f$ (25.0 °C) × k_t (25.0 °C). For the latter, eq. [3] is used, again using an experimental value of k_f. This method is considerably faster because quantum yields of fluorescence over a temperature range from –25 to +95 °C can be determined over a period of several hours from a single sample. Details are given in the Experimental section.

A comment is necessary here about the values of k_f that could only be obtained experimentally for those compounds for which the total rate of decay, τ, was longer than 0.5 ns, the time resolution of our flash lamp, single photon counting spectrometer. These are given in the third column of Table 1 with the corresponding k_f values in the fourth column. Fortunately rate constants of fluorescence, k_f, have been reliably calculated in the past from the Strickler–Berg relation, eq. [4] (13).

$$[4] \qquad k_f = 2.88 \times 10^{-9}\ n^2 < \bar{\nu} >^{-1} \int \varepsilon\ d\ \ln\ \bar{\nu}$$

This equation is a general theoretical relationship between the radiative lifetime ($\tau_f = 1/k_f$) and the absorbance spectrum

where n is the refractive index of the solvent, ν is the expectation value for the frequency of the fluorescence spectrum and the final term is the integrated absorbance spectrum. The constant gives k_f in units of s^{-1} if the frequency values are expressed in wavenumber (cm^{-1}) and molar absorptivity ϵ in the usual units ((mol/L^{-1}) cm^{-1}). This equation is derived on the basis of the oscillator strength model and the important assumption that the excited singlet state and the ground state have similar geometries. It has been successfully applied many times to, for example, simple aromatic compounds like benzene, toluene and *ortho*-xylene (14), and by us for the ring-substituted anisoles **5** (1) and aromatic nitriles, boronate esters, and trifluoromethyl derivatives (11). More importantly for the current work, a comparison of the experimentally determined and calculated values for the ethers **1** are in good agreement where both are available (columns 3 and 4 for the trifluoromethyl and cyano substituted cases) giving us confidence that that the calculated values are reliable for the other substituents.

An example of the fluorescence spectrum as a function of temperature for the 4-CN allyl ether **1j** in methylcyclohexane (this hydrocarbon solvent was chosen over cyclohexane because it has a wider temperature range as a liquid) is given in Fig. 1. A plot of the data according to eq. [3], using the experimental value of k_f is given in Fig. 2. As indicated by the correlation coefficient and the errors in the fitted parameters, the fit is excellent even though the

Fig. 1. Temperature dependence of the quantum yield of fluorescence from –25 °C to 95 °C for **1j**: X = 4–CN in methylcyclohexane.

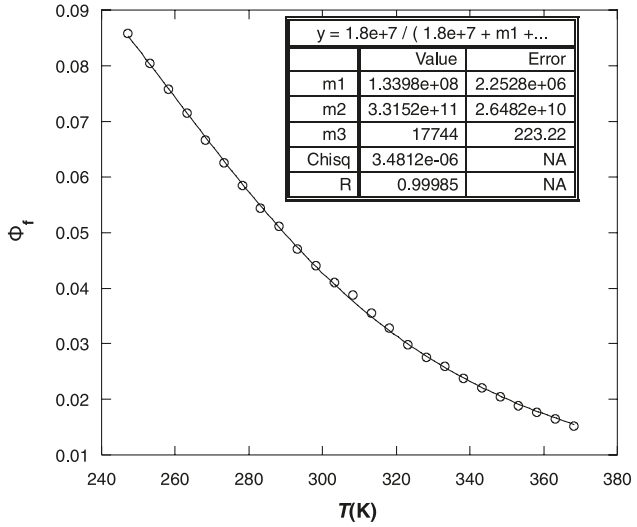
Fig. 2. A fit of the data from Fig. 1 to eq. [3].

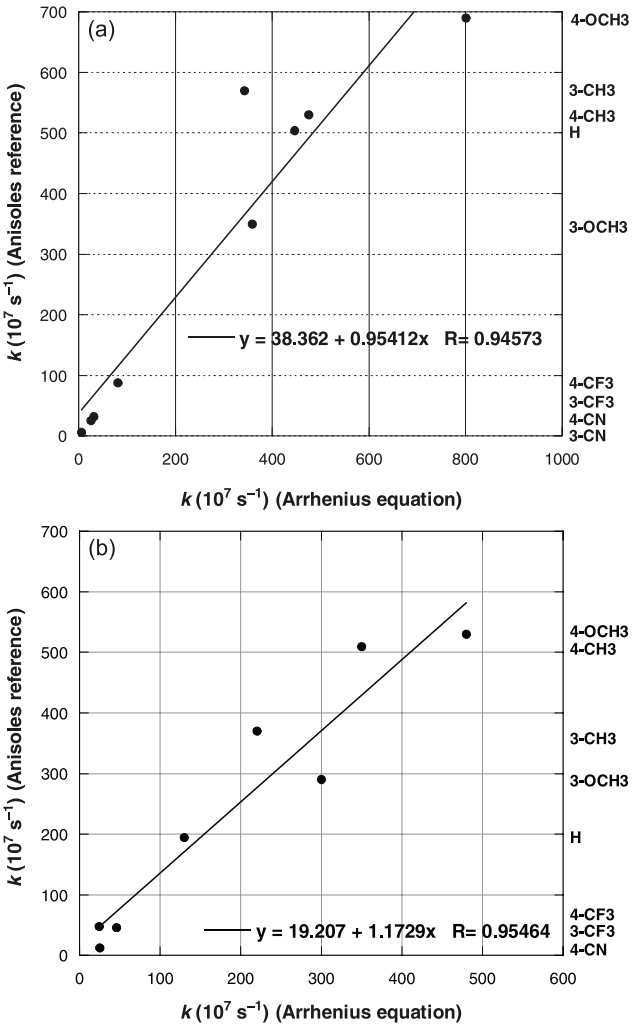


available temperature range is limited. The values of of k_{isc}, A and E_a from the fit are given in Table 1, along with those obtained in the same way for the other substituted allyl ethers **1** in both methanol and methylcyclohexane. Also given are k_r values, calculated from the Arrhenius parameters at 25 °C, the rate constant for the activated photochemical step, the cleavage of the carbon–oxygen bond to give the radical pair **2**.

The k_r values obtained by the two methods, the Arrhenius' one from the temperature dependence of fluorescence and the anisole unreactive model one (1), are plotted against one another in Figs. 3*a* (hydrocarbon solvent) and 3*b* (methanol solvent). As indicated by the correlation coefficients, these linear plots should best be regarded as trends. The reason for the large deviations from the best-fit lines could be real but are more likely a result of the large systematic errors in obtaining the rate constants. The anisole reference method (1) relies on accurate measurements of quantum yields of fluorescence. This is not problematic for the anisoles **5**, which have relatively large values, but is problematic for the allyl ethers **1**. The high reactivity for the methyl and methoxy substituted cases results in very low fluorescence quantum yields and a consequent difficulty in determining them reliably. Moreover, the temperature dependence of fluorescence method ideally requires a measurement over a significantly wider temperature range than is available to us in order that the activation parameters can be obtained with high accuracy (9).

Nevertheless, the trends in the plots are obvious, i.e., slopes near unity in both methylcyclohexane and methanol. This observation confirms that the rate constants obtained for the photo–Claisen reaction and discussed in detail previously (1) are reliable. Therefore, the conclusion reached is that the rate constants for the reaction do correlate with the O-H BDE of the corresponding phenols (7) and, as well, the O-C BDE of the anisoles (15). In other words, those compounds with the weaker bonds react faster, as shown in Fig. 4. This conclusion is reinforced by the trends in the activation parameters from Table 1. The pre-exponential factors vary only from a low of 1.0 to a high of 8.5, a factor of only 8.5, although the rate constants vary over more than

Fig. 3. (*a*) The linear correlation for the reaction rate constant k_r for the bond cleavage from S_1 of the allyl ethers. The horizontal axis gives the values in methylcyclohexane from the Arrhenius equation as described herein. The vertical axis gives the values in cyclohexane from the unreactive model method from reference (1), listed in the last column in Table 1. The substitutents are identified on the right vertical axis. (*b*) The same correlation for the results in methanol.



two orders of magnitude. The reason is that the large changes in the BDE are reflected in the changes in the E_a values from a low of ~9 kJ mol^{-1} for the reactive compounds (X = 4–OCH_3 and 4–CH_3) to a high of ~19 kJ mol^{-1} for the least reactive (X = CF_3 and CN). Other factors such as the polarity of the transition state as correlated by Hammett $\rho\sigma$ relationships must be contributing in only a minor way. Multiple parameter fits to assess these other minor contributions were not attempted because they were not warranted by the accuracy of the data.

Experimental

The synthesis and characterization of the allyl ethers has been described previously (1). The solvents, methanol and

methylcyclohexane, both Aldrich spectrophotometric grade, were used without further purification.

Fluorescence measurements

All samples were degassed by three freeze-pump-thaw cycles and then thermostated at the appropriate temperature. Fluorescence intensity measurements were done using a PTI–210M fluorescence spectrometer with dual Model 101 monochromators, a 75W Xenon lamp and a Model 814 photomultiplier detector. Corrected spectra were obtained. Fluorescence quantum yields were determined using solutions of matched absorbance by comparison with the known fluorescence quantum yield of 0.24 (for anisole in methanol. For temperature dependent quantum yield measurements, a 1 cm cuvette was thermostated (±0.1 °C) with stirring in a cuvette holder equipped with a Quantum Northwest TLC 50 temperature controller that allows relative fluorescence measurements at 5 °C intervals from –25 to 95 °C over a 3 h time span. Normally, intensity measurements at the λ_{max} of the fluorescence spectrum at each temperature were determined. For illustrative purposes, as shown in Fig. 1, scans over the entire fluorescence spectrum could be recorded. However, these required rapid scans to avoid photochemical degradation of the sample. This resulted in noisy spectra, as shown in Fig. 1. The stability of the lamp over this time period was normally confirmed by rerunning the fluorescence spectrum at 25 °C at the end.

Singlet lifetimes were measured at 25 °C by monitoring fluorescence decay using a PRA time correlated single photon counting apparatus with a hydrogen flash lamp of pulse width about 1.8 ns. The temperature was controlled (±0.5 °C) by circulating methanol from an external constant temperature bath.

Synthesis, X-ray structure, and binding properties of a new fluorescent molecular clip derived from diethoxycarbonyl glycoluril

Sheng-Li Hu, Guo-Dong Yin, Yu-Zhou Wang, and An-Xin Wu

Abstract: A new fluorescent molecule clip derived from diethoxycarbonyl glycoluril with two 2,5-diphenyl-furan sidewalls was designed and synthesized. Its structure and conformation was confirmed by single-crystal X-ray diffraction. Its binding properties, investigated by fluorescence spectroscopey, showed that it can selectively bind Fe^{3+} with fluorescence quenching.

Key words: diethoxycarbonyl glycoluril, molecular clip, fluorescence, Fe(III).

Résumé : On a développé une méthode de synthèse pour une nouvelle pince moléculaire fluorescente qui est dérivée du diéthoxycarboxylglycoluril et qui comporte deux 2,5-diphénylfuranes comme murs latéraux. On a confirmé sa structure et sa conformation sur la base de la diffraction des rayons X par un cristal unique. Ses propriétés de fixation étudiées par spectroscopie de fluorescence montrent qu'elle peut se fixer sélectivement avec le Fe^{3+} avec désactivation de la fluorescence.

Mots-clés : diéthoxycarbonylglycoluril, pince moléculaire, fluorescence, Fe(III).

[Traduit par la Rédaction]

Introduction

Development of fluorescent chemosensors, capable of recognizing metal ions, anions, and neutral molecules, is of interest because of their high sensitivity and low-cost instrumentation (1). In general, fluorescence chemosensors are composed of two covalently linked components: a recognition site that binds the target substance and a transducer (fluorophore) that signals the binding (2–4).

Glycoluril is an important building block for supramolecular chemistry, and its derivatives have been used as the basis for molecular clips (5), molecular capsules (6), anion-binding receptors (7), xerogels (8), and the cucurbit[*n*]uril (CB[*n*]) family (9). However, few studies have been carried out to explore its utilization as a platform for the synthesis of fluorescent chemosensors for ionic guest in recent years (10).

In the previous work, we had reported a pair of molecular clips derived from diethoxycarbonyl glycoluril with two 1,2-dihydro-indazol-3-one moieties as sidewall and developed their function as selective fluorescent chemsensors for Fe^{3+} (11). In continuing our research to develop new fluorescent chemsensors based on glycoluril, we designed a new molecular clip **5**, which has two 2,5-diphenyl-furan fluorescent moieties used as the signaling subunit in its two sidewalls and two carbonyl oxygen atoms of glycoluril ring used as the potential binding sites in its cavity. We assume that such crown-ether derivatives can be used as a fluorescent chemsensor for alkali or alkaline earth metal cations. In this paper, we report its synthesis, X-ray structure, and binding study with different metal ions. Interestingly, the new fluorescent clip molecule **5** also exhibited selective recognition to Fe^{3+} over the other tested metals ions, including alkali and alkaline earth metal cations. This experimental result shows that the two polarized carbonyl groups oxygen atoms of glycoluril ring may be an effective recognition position for Fe^{3+}.

Results and discussion

Fluorescent molecule clip **5** was prepared by reacting diethoxycarbonyl glycoluril (**3**) with 3,4-bis-bromomethyl-2,5-diphenyl-furan (**4**) using *t*-BuOK as base in anhyd. DMSO (Scheme 1), and the product was further characterized by NMR spectra. The ^{1}H NMR spectrum of **5** in $CDCl_3$ shows two pairs of well-defined doublets with equal intensity for the protons of methylene at δ = 5.28 ppm (J = 16.0 Hz) and δ = 4.36 ppm (J = 16.0 Hz), indicating that the molecules possess good symmetry and the four bridging methylenes have the same chemical environment. The IR and MS spectra for the product are in good agreement with the title compound. In addition, its structure and conformation were confirmed by single-crystal X-ray diffraction, as

Scheme 1. Synthesis of molecular clip **5**.

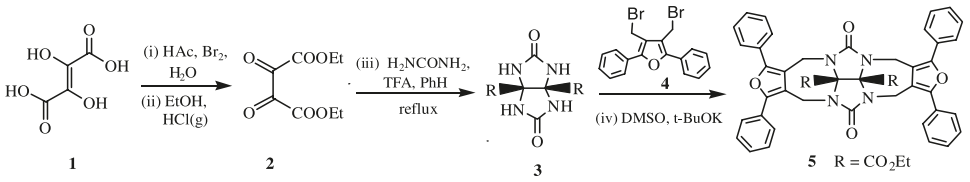

Fig. 1. X-ray crystal structure of compound **5**. Hydrogen atoms and minor components are omitted for clarity.

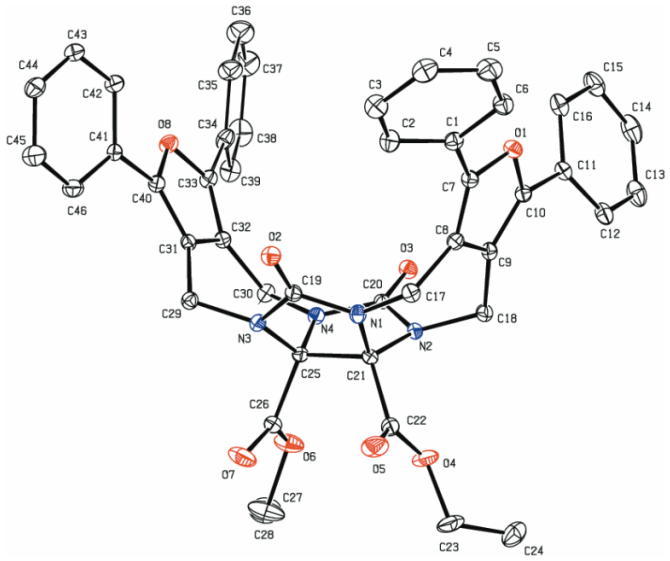

shown in Fig. 1. Its crystal data and details of structure determinations were summarized in Table 1.

The crystal structure of **5** clearly reveals that it has well-defined geometry because of the rigidity that the fused rings confer on the molecule. However, two phenyl rings of the sidewall are twisted away from the furan ring. The phenyl ring (C1–C6) and phenyl ring (C11–C16) form dihedral angles of 41.47° and 35.40°, respectively, with the furan ring (O1–C10). The phenyl ring (C34–C39) and phenyl ring (C41–C46) form dihedral angles of 34.31° and 28.33°, respectively, with the (O8–C40) furan ring. The dihedral angle between them is 34.76°. The dihedral angle between two furan rings is 38.61°, and the distance between the centroids of two furan rings is 6.603 Å. The distances between the two oxygen atoms (O1–O8) of two furan rings and two carbonyl oxygen atoms (O2–O3) of glycoluril ring amount to 7.494 Å and 5.722 Å, respectively.

The binding properties of the clip molecule **5** with various metal ions were investigated through fluorescence-spectroscopy titration experiments. Changes of the fluorescence properties of 1×10^{-5} mol/L of **5** in DMF/CH_3OH (50:1, *v*/*v*) solution caused by 15 equiv. of various metal ions (K^+, Na^+, Mg^{2+}, Hg^{2+}, Cd^{2+}, Fe^{3+}, Zn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Pb^{2+}, Cr^{3+}, and Mn^{2+}) were measured once their emission intensity were constant. The result showed that Fe^{3+} produced significant quenching in the fluorescent emission of **5**; the other tested metals only show relatively insignificant

changes (Fig. 2). So, it can be concluded that **5** has higher selectivity for the recognition of Fe^{3+}.

The sensitivity of the fluorescence emission response of **5** towards Fe^{3+} was also examined under the same conditions with various Fe^{3+} concentrations (Fig. 3). The fluorescence intensity (λ_{em} = 365 nm) of **5** was decreased continually upon addition of Fe^{3+} with no significant change in the position of the emission maxima. When the concentration of Fe^{3+} increased to 15 equiv., the fluorescence intensity of **5** was reduced to 24% of the initial one. From the Stern–Volmer plot (the fluorescence quenching followed the Stern–Volmer equation) (12), host **5** formed 1:1 stoichiometry complex with Fe^{3+}, and the association constant was estimated 2.24×10^4.

Actually, quenching of electronically excited state of aromatic hydrocarbons by Fe^{3+} chelates is a known

phenomenom that has been the subject of extensive investigations. It has been suggested that two main pathways could account for the efficient radiationless deactivation of the singlet excited state, i.e., electron transfer from the excited aromatic chromophore to the metal and (or) energy transfer from the excited aromatic chromophore to low-lying metal-centered energy states (13). Such processes could be particularly effective in the complex of **5** with Fe^{3+}, due probably to the fact that the chelated metal cation is held very close to two excited 2,5-diphenyl-furan chromophores. Additionally, because molecular clip **5** has different sidewalls but same binding properties compared with previously reported molecular clips (11), we may draw a conclusion that the two polarized carbonyl groups of the glycoluril ring play a crucial role in the recognition of Fe^{3+}.

Conclusion

A new fluorescent molecule clip **5** derived from diethoxycarbonyl glycoluril with two 2,5-diphenyl-furan sidewalls was designed and synthesized. Its binding properties, investigated by fluorescence spectroscopy, showed that it can selectively bind Fe^{3+} with fluorescence quenching.

Experimental

General

Melting point was determined on an XT4A Meltemp apparatus and is uncorrected. IR was recorded on a Perkin–Elmer PE–983 infrared spectrometer as KBr pellets with absorption in cm^{-1}. NMR was recorded in $CDCl_3$ on a Varian Mercury 400 spectrometer. MS was measured on a Finnigan Trace MS spectrometer. Fluorescence spectra were determined on a Hitachi F-4500.

Synthesis

Diethoxycarbonyl glycoluril **3** (14) and 3,4-bis-bromomethyl-2,5-diphenyl-furan **4** (15) were synthesized according to the previously reported procedures.

Compound **3** (0.72 g, 2.5 mmol) was dissolved in anhyd. DMSO (50 mL) under N_2, and *t*-BuOK (1.12 g, 10.0 mol) was added. After stirring for 15 min, compound **4** (2.22 g, 5.5 mmol) was added in one portion, and stirring was continued for 3 h. The reaction mixture was poured into 0.1 N HCl (500 mL) and extracted with EtOAc (3×200 mL). The extracts were washed with brine (2×150 mL) and dried over anhyd. $MgSO_4$. After filtration and rotary evaporation, the residue was purified by flash chromatography (SiO_2, $CHCl_3$/MeOH, 50:1) to give compound **5** (0.31 g, 40%) as a white solid. Mp > 300 °C. IR (KBr, cm^{-1}): 3059, 2983 w, 2898 w, 1758 s, 1722 s, 1653 w, 1464 s, 1428 s, 1255 s, 910 s, 764 s, 695 s. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.75–7.74 (m, 8H), 7.50–7.35 (m, 8H), 7.32–7.31 (m, 4H), 5.28 (d, J = 16.0 Hz, 4H), 4.36 (d, J = 16.0 Hz, 4H), 4.28 (q, J = 7.2 Hz, 4H), 1.30 (t, J = 7.2 Hz, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 165.5, 156.1, 148.7, 130.0, 128.8, 128.1, 126.8, 118.7, 81.3, 63.6, 37.4, 14.0. EI-MS *m*/*z*: 774.0, 778 $[M + 4H]^{4+}$.

X-ray crystallography

A single crystal suitable for X-ray crystallographic analysis was obtained from a slow evaporation of the dichloromethane and methanol solution. Crystallographic measurement of compound **5** was carried out using a Bruker SMART CCD diffractometer. The SMART (version 5.628) program was used for collecting data frames, and SAINT Plus (version 6.45) was used for integration of the intensity of reflections and scaling. SADABS was used for absorption correction (16). The structure was solved by direct methods using the program SHELXS-97 and refined by full-matrix least-squares against all F^2 data using Bruker SHELXTL (17). The phenyl ring (C34–C39) was found to be disordered over two orientations; the site-occupancy factor for the two orientations were refined giving 0.67(8) and 0.33(8) for the major and minor components, respectively. All non-H atoms

© 2008 NRC Canada

were refined anisotropically. Hydrogen atoms were constrained to the ideal geometries.[3]

Binding studies

The solvents for the fluorescence measurement were all of spectroscopic grade. Stock solutions of compound **5** was prepared by dissolution in DMF/MeOH (50:1, *v*/*v*) (1.0×10^{-5} mol/L). The solutions of metal ions were prepared from $Pb(NO_3)_2$ and the chlorides of K^+, Na^+, Mg^{2+}, Hg^{2+}, Cd^{2+}, Fe^{3+}, Cu^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, Pb^{2+}, Cr^{3+}, and Mn^{2+}, respectively, and were dissolved in methanol (3.0×10^{-3} mol/L). Fluorescence titration was performed by filling 3 mL solution of **5** in a quartz cell of 1 cm optical path length and adding different stock solutions of cations into the quartz cell portionwise using a micro-syringe each time. Both excitation and emission bands were set at 5 nm.

Localized-orbital locator (LOL) profiles of chemical bonding

Heiko Jacobsen

Abstract: We examine a recently introduced descriptor of chemical bonding, the localized-orbital locator (LOL), which is based on the kinetic-energy density (τ). Examples are presented for prototypical chemical bonds, such as single, double, and triple bonds, for bonding in transition metal complexes, for three-center two-electron bonds, as well as for hypervalent molecules. The topology of LOL is analyzed in terms of (3,–3) attractors (Γ). The influence of core electrons for chemical bonding is investigated, and a LOL-VSEPR (valence shell electron pair repulstion) relationship is established. Further, we compare LOL to the related electron localization function (ELF).

Key words: chemical bonding, kinetic-energy density, localized-electron locator, VSEPR theory.

Résumé : On a examiné un descripteur proposé récemment pour la liaison chimique, le positionnement d'une orbitale localizée (POL), qui est basée sur la densité d'énergie cinétique, τ. On présente des exemples de prototypes de liaisons chimiques, telles des liaisons simple, double et triples qui donnent lieu à des liaisons dans des complexes de métaux de transition, pour les liaisons à deux électrons et à trois centres ainsi que pour des molécules hypervalentes. La topologie du positionnement d'une orbitale localizée est analysée en fonction d'attracteurs (3,–3) (Γ). On a examiné l'influence des électrons à coeur sur la liaison chimique et on a établi une relation POL-VSEPR. On a de plus comparé le positionnement d'une orbitale localizée à la fonction apparentée de localization, ELF.

Mots-clés : liaison chimique, densité de l'énergie cinétique, positionnement d'un électron localizé, théorie VSEPR.

[Traduit par la Rédaction]

Introduction

The field of chemical bonding is in the midst of a renaissance, and the nature of the chemical bond remains an active field of ongoing chemical research. Although the "electronic structure revolution" initiated by the work of Lewis resulted in a picture of the chemical bond that by now has become a fundamental part of the freshmen chemistry curriculum, it is evident that many open questions remain in the quest for a unified and complete understanding of the true nature of the chemical bond (1). The complexity of this subject manifests itself in the ongoing discussion whether a description of chemical bonding is to be based on orbital or electron density concepts, molecular orbital theory not to be mistaken by the orbital approach and providing a common link between these two fundamentally different descriptions (2).

The success of density functional theory (DFT) of electronic structure (3) has provided new impetus for a density-based description of chemical bonding, and led to the development of new descriptors for old problems of chemical bonding, such as the electron localization function (ELF) introduced by Becke and Edgecombe (4). The problem of electron localization and delocalization constitutes one of the main aspects of the nature of the chemical bond. For density-based descriptions of chemical bonding, various partitioning schemes, mainly based on topological methods, have been proposed that address this very problem. Bader's quantum theory of atoms in molecules (QTAIM) analyzes the gradient field of the one-electron density and characterizes the nature of a chemical bond through a topology analysis of the Laplacian distribution $\nabla^2(\rho)$ of the underlying density, ρ (5). In particular, the topology of the function, L, where $L = -\nabla^2(\rho)$, provides valuable information about the nature of the chemical bond (6). An alternative approach has been proposed by Silvi and Savin, who work with ELF as potential function and partition the molecular space into basins of attractors that have a clear chemical meaning (7). Other recently developed descriptors for electron localization are the electron localizability indicator (ELI) (8, 9) and the localized-orbital locator (LOL) (10, 11), which is the main subject of the present work. Another descriptor that both in spirit and in form is related to LOL, is the local temperature, T (12). Local temperature, T, results from an analysis of thermodynamic elements of DFT, and it has been explored for whether local temperature can be used as a more fundamental descriptor of molecular electronic structure (13).

One aspect that makes density approaches towards chemical bonding particularly attractive is the direct relationship with experiment; X-ray charge densities not only reveal molecular structure but also contain information about chemical bonding through Laplacian analysis (14). Other bonding descriptors, such as LOL, are also accessible from experi-

 doi:10.1139/V08-052 © 2008 NRC Canada

mental electron densities. This requires constructing the kinetic-energy density directly from the experimentally determined electron density, which is achieved by using the second-order gradient expansion (15). Despite the fact that the gradient expansion diverges near the nuclei, an experimentally constructed LOL is accessible, since the regions around the nuclei may be omitted without significant loss of information (16).

Although much progress has been made in recent years in bond description based on experimental electron densities, the main conclusion that is drawn from experimental work is the same as obtained from theoretical studies: the characterization of the chemical bond is not a closed subject (17).

Schmider and Becke (11) have pointed out that LOL gives simple, recognizable patterns in classic chemical bonds, and they expressed their hope that "LOL will prove useful in interpreting the structures of exotic materials, and the classic examples of freshman chemistry texts as well" (10). Becke and Schmider have chosen graphical representations as the most evident way to analyze LOL. However, one has to take into consideration that even a three-dimensional function is not easy to visualize. In practice, one considers 2D-cuts, or plots of iso-surfaces, and often, several plots have to be shown to provide all the significant elements. Here, we use a topology analysis of LOL and characterize this function by determining the positions in space where LOL is maximal. We will briefly elucidate the theoretical background of our analysis before we present our results in more detail.

Theoretical background

The central property on which the localization descriptors ELF and LOL are built is the kinetic-energy density, τ:

$$[1] \qquad \tau = \frac{1}{2}\sum_i (\Delta\psi_i \cdot \Delta\psi_i^*)$$

We note that like other energy densities, the kinetic-energy density is not unique. Two important forms of the kinetic-energy density either depend on the Laplacian of the Kohn-Sham orbitals $-\tau^L-$, or are defined as being positive definite, $-\tau$ (18).

The kinetic energy plays a major role in the description of a chemical bond, since the driving force of covalent bonding is a lowering of the quantum kinetic-energy density by orbital sharing (19, 20). What might look like a violation of the virial theorem can be understood when the kinetic energy of a molecule is partitioned into *intra-atomic* and *inter-atomic* contributions. Upon formation of a covalent bond, the kinetic energy of motion normal to the bond direction increases accordingly; along the bond direction, however, the decrease in kinetic energy predominates. The increase in the kinetic energy is purely intra-atomic and has nothing to do with what happens in the bonding region where the decrease in the inter-atomic kinetic energy is the decisive effect (21).

Since the contributions to the kinetic energy from the bond regions usually decrease, it is desirable to use a measure of the local kinetic energy as an indicator of bond effects. The kinetic-energy density, τ, is quite suitable, although it has a few drawbacks. Kinetic-energy densities, τ, are usually monotonic for atoms, and the structural features of τ are less pronounced than one would wish. Regions with high charge density tend to dominate so strongly that salient features of bonding become invisible. To circumvent this problem, the kinetic-energy density, τ, is compared with some suitable reference value, τ_0. Both ELF and LOL take as a reference the homogeneous spin-neutral electron gas with electron density, ρ, and $\tau_0 = (3/10)\cdot(3\pi^2)^{2/3}\rho^{5/3}$. LOL analysis then defines the dimensionless variable, t:

$$[2] \qquad t = \tau_0/\tau$$

The ratio t is bounded by zero from below, but it is not bounded from above. To lower the semi-infinite range of the variable t, the localized-orbital locator, LOL, which is referred to as ν, is a measure of t in a mapping onto the finite range [0, 1]:

$$[3] \qquad \nu = \frac{t}{1+t} = \frac{\tau_0/\tau}{1+\tau_0/\tau} = \frac{1}{1+\tau_0/\tau}$$

Schmider and Becke (10, 11) have analyzed the localized-electron locator, ν, in much detail. We briefly summarize five important features of this bonding descriptor:

(*i*) LOL reveals electronic shell structure in a simple and clear manner.

(*ii*) The mapping $t \rightarrow \nu$ preserves topological features of t, since it is monotonically increasing. The value $t = 1$ corresponds to regions where the local kinetic energy of electrons is the same as for a uniform electron gas with the local density, ρ, and is mapped onto $\nu = 1/2$. Values of $\nu < 1/2$ indicate "fast" electrons that have a higher kinetic energy than expected from their local density. Regions with a larger value of ν are characterized by relatively "slow" electrons.

(*iii*) A covalent bond is expressed in ν as a local maximum between the bound centers. The $\nu = 1/2$ surface enclosing the maximum has an increasingly concave shape in multiple bonds.

(*iv*) The localized-orbital locator, ν, attains large values (above 1/2) in regions where the electron density is dominated by a single localized orbital.

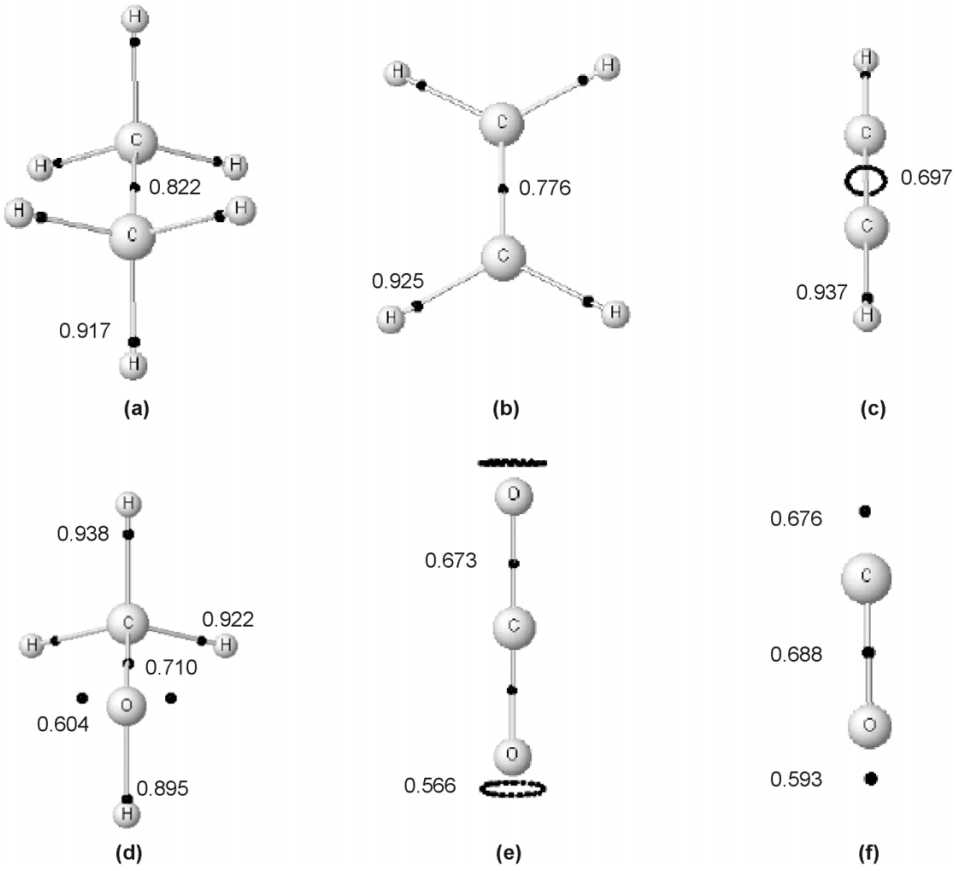
(*v*) Lone electron pairs are resolved as local maxima in the center of a characteristically shaped $\nu = 1/2$ surface.

The chemical content of the localized-orbital locator, LOL, is similar to that of the electron localization function, ELF, which is also dependent on the kinetic-energy density, τ. However, whereas ELF is founded on consideration of the electron pair density, LOL simply recognizes that gradients of localized orbitals are maximized when localized orbitals overlap. Moreover, LOL has a simpler interpretation in terms of fast and slow electron regions, and always falls to zero asymptotically, whereas ELF sometimes does not.

Borrowing ideas from the topological analysis of electron charge density (5), we locate critical points and in particular (3,–3) attractors, Γ, in the gradient vector field of LOL. Each nucleus-position is associated with one attractor, Γ, but as we shall see, LOL also features attractors, Γ, between connected atoms and in molecular regions associated with lone pairs. We refer to attractors between connected atoms and in lone-pair regions as Γ_{CA} and Γ_{LP}, respectively. It is the Γ topology of LOL and its associated ν_Γ-values that serve as a

© 2008 NRC Canada

Fig. 1. Γ_{CA} and Γ_{LP} attractors and associated ν_Γ-values of (*a*) ethane (C_2H_6), (*b*) ethylene (C_2H_4), (*c*) acetylene (C_2H_2), (*d*) methanol (CH_3OH), (*e*) carbon dioxide (CO_2), and (*f*) carbon monoxide (CO).



criterion to describe the nature of chemical bonding in molecular systems.

The topologies of *L* and ELF have been studied in much detail (6), and it was found that localized pairs of electrons, bonding or non-bonding, are not only evident in ELF but also in *L*, which is homeomorphic to ELF with few exceptions. It was further noted that critical points other than the (3,–3) attractors also carry valuable information about the nature of a chemical bond. However, a complete topology analysis in terms of *L* even for a small molecule such as water results in an extended picture of bewildering complexity (22). In the spirit of LOL, which "is a simpler function than ELF" (10), we restrict our analysis to the (3,–3) bonding attractors, Γ.

LOL profiles of chemical bonds

Schmider and Becke (10, 11) have analyzed the localized-electron locator for a variety of systems displaying prototypical single and multiple bonds, such as C_2H_4, N_2, and F_2, as well as for cases where the bonding situation is not prototypical and sometimes not straightforward, such as ClF_3, $Cr(CO)_6$, and B_4H_4. They base their analysis on an evaluation of contour line diagrams of LOL in representative molecular planes that contain a particular bond under investigation. Here, we shall construct LOL profiles based on Γ_{CA} and Γ_{LP} attractors. We note that in the figures to follow, bond lines between atoms are derived from standard geometric connectivity arguments and are not to be mistaken for bond paths as obtained from a topological analysis of the electron charge density.

Exemplary single, double, and triple bonds

We begin with examples of what are commonly considered prototypical single and multiple bonds and investigate the LOL profiles of ethane (C_2H_6), ethylene (C_2H_4), acetylene (C_2H_2), methanol (CH_3OH), carbon dioxide (CO_2), and carbon monoxide (CO). Locations and LOL values of Γ_{CA} and Γ_{LP} attractors are depicted in Fig. 1.

Ethane displays seven Γ_{CA} attractors, one for each C–H and C–C bond. The LOL values are above 0.8 and indicate that the bonds are dominated by a single localized orbital. The C=C double bond in ethylene is also characterized by the presence of one, and not two Γ_{CA} attractors. The LOL picture still shows one attractor for each bond, independent of the formal bond multiplicity. We note that the ν_Γ-value at Γ_{CA}(CC) is smaller for the double bond in C_2H_4 than it is for the single bond in C_2H_6. The picture obtained from our LOL analysis is in agreement with the common consensus that double bonds are more delocalized than single bonds. This trend continues when we turn to acetylene (C_2H_2) that formally has a C≡C triple bond. The ν_Γ-value at Γ_{CA}(CC) further decreases, and an increase in bond multiplicity leads to an increase in delocalized bonding character and thus to a decrease in ν_Γ. A similar trend has been found in an ELF analysis, and Bader et al. (6) report ELF values at (3,–3)

critical points for C–C single, double, and triple bonds as 0.9685 (C_2H_6), 0.9412 (C_2H_4), and 0.8906 (C_2H_2). ELF also contains a mapping of values onto the [0, 1] interval, and it seems that the LOL mapping results in clearer separation of ν_Γ for bonds of different multiplicities. We further note that for all systems Γ_{CA}(CH) is large with values above 0.9.

For the ELF function, it has been recognized that gradient field attractors can be circles and spheres if the system belongs to a continuous symmetry group (23). LOL bears similarities to ELF, and for acetylene, belonging to the continuous symmetry group $D_{\infty h}$, we see the appearance of a ring-shaped Γ_{CA}(CC) attractor, a connected set of (2,–2) critical points. We will further comment on ring-shape attractors at a later point in our discussion.

When we proceed to systems having a carbon-oxygen linkage, we now encounter atomic centers that have additional lone-pairs. The LOL profile of methanol not only displays, as expected, three Γ_{CA}(CH), one Γ_{CA}(CO), and one Γ_{CA}(OH) attractor, but it also shows two Γ_{LP} attractors around oxygen. We note for the bonding geometry around oxygen that the ν_Γ values for O-C and O-H connectors are larger that the ν_Γ values of the oxygen lone pairs. The bonding structure around oxygen is dominated by bonding domains rather than by lone pair domains. For carbon dioxide, we find that the formal C=O double bond again displays a smaller ν_Γ-value than the C–O single bond in CH_3OH. The oxygen lone pairs appear as ring-shaped Γ_{LP} attractors with ν_Γ-value smaller than the Γ_{CA}(CO) attractor.

Although carbon monoxide belongs to the continuous symmetry group, $C_{\infty v}$, no ring shape attractors are found in the LOL profile of CO. A further requirement for the appearance of a ring shape attractor is the presence of an inversion center that renders the two different atomic centers equivalent. The lone pair attractor at carbon displays a larger ν_Γ-value (0.676) than the lone pair attractor at oxygen (0.573) and is further separated from the C-nucleus (d = 100 pm) than its counterpart is separated from the O-nucleus (d = 76 pm). This observation is consistent with the dipole moment of CO with its negative end on the carbon atom.

We note that describing the electronic structure and the nature of the chemical bond of carbon monoxide is not a trivial task because of its unusual chemical and physical properties. Frenking et al. (24) have presented a detailed bonding analysis of CO as "an exercise in modern chemical bonding theory". The authors use an evaluation of the graphical representation of the Laplacian distribution, $-L$, to illustrate some physical properties of CO. The LOL-profile of CO faithfully recovers the analysis of Frenking et al. (24), and puts it on a more quantitative basis.

Atomic shells and chemical bonds

The localized-orbital locator does reflect atomic shell structure, similar to the electron localization function. This feature is partially recovered in the LOL profile of molecules, and we discuss the diatomic molecules F_2, Cl_2, N_2, and P_2 as illustrative examples. Γ_{CA} and Γ_{LP} attractors are depicted in Fig. 2.

For F_2, besides attractors found at the position of the nuclei, we have one valence shell bonding attractor and two ring shaped lone pair attractors. For Cl_2, which contains atoms with electron occupancy in the K, L, and M shells, we see one additional ring shape core attractor around each chlorine center. Similar observations are made when comparing the LOL profiles of N_2 and P_2. For dinitrogen, we find one valence shell Γ_{CA} attractor and two valence shell Γ_{LP} attractors. For diphosphorus, the extended electronic core structure manifests itself in two additional attractors located in close vicinity to each phosphorus atom.

Although the dinitrogen molecule is of $D_{\infty h}$ symmetry, only one Γ_{CA}(NN) single point attractor is found, and not a ring-shaped Γ_{CA}(NN) attractor as one might have expected in comparison to the isoelectronic and isosymmetric HCCH molecule. Similar observations have been made in an analysis of ELF, and with reference to N_2 it was noted that a "disturbing feature is that sometimes, when one would expect separated maxima, just a single maximum appears" (25). However, this somewhat unexpected result can be understood if one considers the fact that the LOL profile of a chemical bond reflects to a major part the character of the highest energy orbital that contributes to that particular bond. The ground state valence configuration of N_2 is $(2\sigma_g^+)^2(2\sigma_u^+)^2(1\pi_g)^4(3\sigma_u^+)^2$, and the structure of LOL is dominated by the HOMO, a single σ_g^+ orbital that extends along the atom-connecting line, and that gives rise to the presence of one single Γ_{CA}(NN) attractor. On the other hand, for acetylene, the valence shell configuration is $(2\sigma_g^+)^2(2\sigma_u^+)^2(3\sigma_g^+)^2\ (1\pi_u)^4$. The HOMO consists of a set of two degenerated π_u orbitals that extend perpendicular to the C-C connecting line and merge together due to the presence of the C_∞-symmetry axis, therefore giving rise to a ring-shaped Γ_{CA}(CC) attractor.

Non-prototypical bonds

Schmider and Becke (11) have presented a LOL analysis for a set of molecules where the bonding situation is not prototypical and sometimes not straightforward. They mainly analyzed LOL via its graphical representation. Here, we select three representative examples out of their set of test molecules, namely ClF_3, B_4H_4, and $Cr(CO)_6$, and examine LOL in terms of Γ attractors. LOL profiles for these molecules are shown in Fig. 3.

Chlorine trifluoride (ClF_3) is often chosen as representative example for hypervalency. We point out that the concept of hypervalency in connection with the octet rule is often misunderstood and misinterpreted (26). All that can safely be attributed to a hypervalent molecule is the fact that it contains an atom forming more than four electron pair bonds, and that the bonds in hypervalent molecules are very similar to those in corresponding non-hypervalent molecules (27). To remove any connection to the nature of the chemical bond, it had been suggested to use the term hypercoordinate, rather than hypervalent, since this provided an empirical characterization of their experimentally observed molecular structures without the necessity of having to endorse a particular view concerning the theoretical description of the chemical nature of a hypervalent bond (28).

The LOL profile of hypercoordinated ClF_3 displays three Γ_{CA}(ClF) attractors. In comparison to regular single and multiple bonds as discussed before, these attractors show fairly small ν_Γ-values. Around each atom, two additional Γ_{LP} attractors are found. The ν_Γ-values of the lone pair attractors, and in particular those of Γ_{LP} around chlorine are larger than those of the Γ_{CA} attractors. Thus, the bonding structure in ClF_3 is dominated by lone pair domains rather than by bonding domains. Distinctive is the fact that Γ_{LP} attractors have larger ν_Γ-values than Γ_{CA} attractors. This, is not a property of hypervalent molecules only, but is related to the nature of the particular bonds present in a hypercoordinated molecule. It does, however, indicate the potential for a coordination sphere expansion beyond four electron groups.

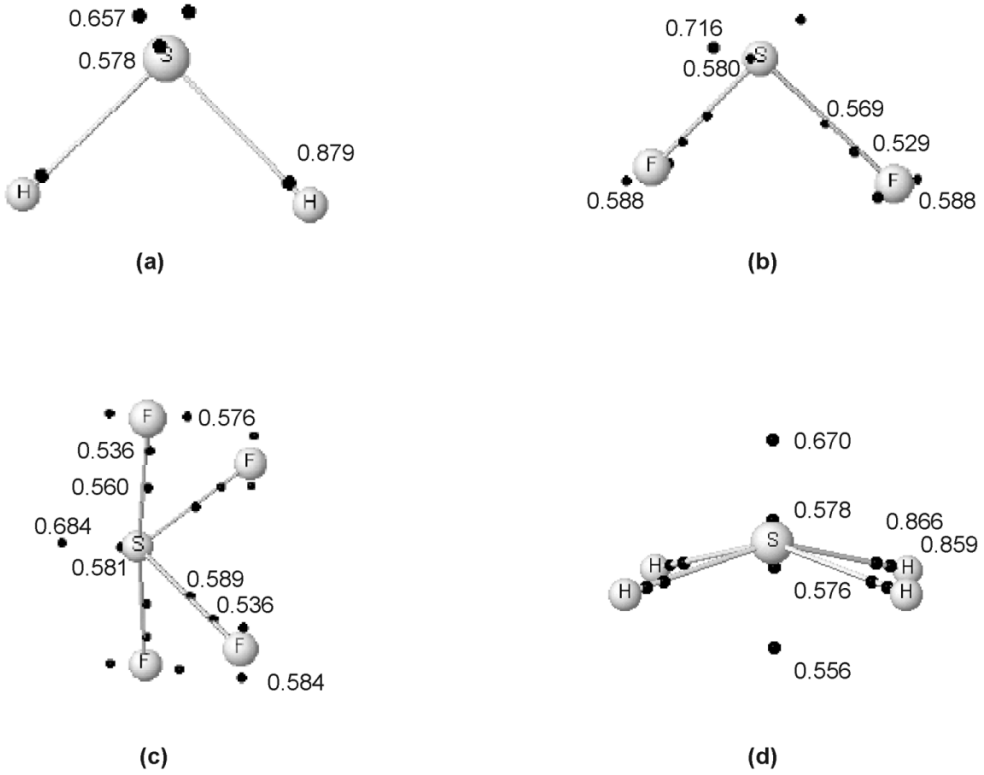
Schmider and Becke (10) have noted before that the localized-electron locator leads to a bonding picture that reflects the basic rules embodied in the valence shell electron pair repulsion (VSEPR) model of molecular geometry. The present study corroborates this result, and for ClF_3 we find a faithful mapping of the Γ_{CA} and Γ_{LP} attractors with the number, relative size, and angular orientation of the bonded and non-bonded electron pair domains assumed in VSEPR (29). Furthermore, the dominance of lone pairs is reflected by the fact that Γ_{LP} attractors have larger ν_Γ-values than Γ_{CA} attractors. We will further explore the LOL-VSEPR relationship in the next section.

Boranes comprise a large group of compounds with the generic formulae of B_xH_y and contain bonds that are characterized by a deficiency of electrons. Thus, the bonding in boranes has stipulated a wide variety of theoretical studies, including an ELF analysis of *closo*-boron clusters of the type B_4X_4 and $B_6X_6^{2-}$ (30). Schmider and Becke (11) have selected B_4H_4 as the simplest representative of an E-E-E three-center two-electron bond, which is a structural element required to explain the existence of most of the closo clusters. The LOL-profile faithfully represents the presence of B-B-B three-center two-electron bonds. Four attractors Γ are located substantially outside the central boron tetrahedron on top of the center of the triangular faces.

For chromium hexacarbonyl as representative example of molecules with metal-ligand bonds, Becke and Schmider (11) note that the LOL picture of $Cr(CO)_6$ is relatively clear

© 2008 NRC Canada

Fig. 4. Γ_{CA} and Γ_{LP} attractors and associated ν_Γ-values of (*a*) SH_2, (*b*) SF_2, (*c*) SF_4, and (*d*) SH_4.



and suggests a ''closed-shell" picture of metal–ligand bonding. The carbonyl groups point their carbon lone pair towards the metal atom but a significant localization-deformation in that direction does not occur. They point out that "the lone-pair region is rather somewhat thinner compared to the free ligand" and that "in the vicinity of the chromium atom there are local maxima on the C_3-symmetry axes of the molecule that point towards the triangular faces of the molecular octahedron", which "should be considered as belonging to the core region". The Γ-attractor profile for $Cr(CO)_6$ is consistent with this analysis. The $\Gamma_{LP}(C)$ attractor is 56 pm away from the carbon atom, compared to 53 pm for the free ligand. The ν_Γ-value decreases from 0.676 for free CO to 0.664 in the bonded ligand. We further see an octet of Γ_{LP} attractors around chromium located on the C_3-symmetry axes. These attractors are 40 pm away from the metal center, which is the same separation as reported by Schmider and Becke (11) for local maxima in vicinity of the transition metal center.

LOL, core electrons, and VSEPR

A comparison of sulfur fluorides with the corresponding hydrogen sulfides demonstrates the importance of core electrons for chemical bonding and elucidates the LOL-VSEPR relationship. LOL profiles of SH_2, SF_2, SF_4, and SH_4 are depicted in Fig. 4.

For SH_2, we find two $\Gamma_{CA}(SH)$ and two $\Gamma_{LP}(S)$ attractors. We note that the ν_Γ-value for the bond attractors is larger than that for the lone pair attractors; the electronic structure of SH_2 is dominated by bond pairs, rather than lone pairs. In addition, we find two core attractors Γ_{core} around sulfur due to its extended electronic shell-structure. We note that the electronic core is accordingly profiled upon formation of a chemical bond. If we proceed to SF_2, we again find two $\Gamma_{CA}(SF)$ attractors, $\nu_\Gamma = 0.569$, and two $\Gamma_{LP}(S)$ attractors, $\nu_\Gamma = 0.716$. In addition, we see lone pair attractors around F, as well as core attractors. Also, for sulfur, $\Gamma_{core}(SH_2)$ and $\Gamma_{core}(SF_2)$ are of similar size. What is important is the fact that for SF_2 the ν_Γ-value for the lone pair attractors is larger than that for the bond attractors, and the electronic structure of SF_2 is dominated by lone pair domains rather than bond pair domains. A similar picture is found for SF_4; the dominant attractor around sulfur again is the lone pair attractor $\Gamma_{LP}(S)$ with $\nu_\Gamma = 0.716$.

Hydrogen does not possess an electronic core, and as a consequence its nucleus is located inside the bond region of any X–H bond. The $\Gamma_{CA}(XH)$ bond maximum is close to the H atom and might even merge with the nucleus position. The absence of an electronic core at hydrogen renders X–H bonds highly localized, and in SH_2 for example, the degree of localization measured by LOL is larger than any lone pair localization around sulfur.

The importance of core orbitals for a bond description based on descriptors of electron localization has been recognized before. For example, the electron localization function, ELF, shows too-high values when computed from valence densities only instead of using the total density (31), and for transition metal systems the ELF analysis needs to involve the atomic core regions as well to reveal a more detailed insight into the bonding situation (32).

The recognition that bonds towards the coreless H are especially localized also has structural consequences. It has been known for a long time that SH_4, a hypothetical molecule, the existence of which remains subject of theoretical

© 2008 NRC Canada

investigations (33), does not adapt a C_{2v} see-saw structure as predicted by VSEPR theory, but rather possesses a C_{4v}-geometry (34), Marsden and Smart (35) have offered an explanation for the origin of the unusual C_{4v}-structure predicted for SH_4 based on atomic charge arguments. Here, we suggest an explanation based on LOL values and VESPR theory.

The valence shell electron pair repulsion (VSEPR) model has for many years provided a useful basis for understanding and rationalizing molecular geometry and has gained widespread acceptance as a pedagogical tool. In its original formulation, the fundamental rule states that pairs of electrons in a valence shell adopt an arrangement that maximizes their distance apart (36). A recent extended version uses the concept of electron domains, the space occupied by valence shell electrons or electron pairs, and places emphasis on the relative sizes and shapes of these domains (27). It has been noted that the topologies of ELF and *L* exhibit a remarkable correspondence with the number and arrangement of the localized electron domains assumed in the VSEPR model of molecular geometry (6), and Schmider and Becke (10, 11) have shown that the same holds true for LOL as well.

VESPR geometries are derived from the realization that pairs of electrons tend to occupy positions in space that minimize repulsions and maximize the distance of separation between them. Electron groups are classified as lone pairs (lp) and bond pairs (bp), and it is generally assumed that lone pairs occupy more space than bonding electron pairs, and that the electron pair repulsion decreases as lp←lp > lp←bp > bp←bp.

We propose that the ν_Γ-value of (3,–3) Γ-attractors can be taken as a measure for the spatial requirement and repulsion potential of an electron group. An intial geometry is constructed according to the points-on-a-sphere model of VSEPR, in which all electron groups are treated equivalent. Then, geometries are determined based on ν_Γ-value of (3,–3) Γ-attractors.

Both SF_4 and SH_4 have five electron domains and therefore take on a geometry derived from a trigonal bipyramid. As we noted before, the Γ_{LP}-attractor of SF_4 has the largest ν_Γ–value, and the lone pair is therefore located in an equatorial position. As a result, SF_4 adopts a C_{2v} disphenoidal geometry. For SH_4, the Γ_{LP}-attractor has the smallest ν_Γ-value, and the lone pair therefore initially adopts an axial position. The remaining four Γ_{CA}-attractors rearrange into a geometry in which the distance of separation between them is maximized. As a consequence, SH_4 takes on a C_{4v}-structure, derived from a square pyramidal arrangement of electron groups around sulfur. This structural rearrangement further creates an additional vacant coordination space for additional electron localization.

The positions of the Γ attractors in SF_4 and SH_4 provide support for our arguments (compare Figs. 4*c* and 4*d*). We also note that SH_4 displays a second Γ_{LP}-attractor in opposite position to the dominant lone-pair domain, thus utilizing the additional coordination space for electron localization.

We conclude this section with a brief comparison of ELF and LOL-values. Bader et al. (6) have reported ELF values for SH_2, SF_2, and SF_4, and their results together with present data are compiled in Table 1.

Table 1. Values of (3,–3) attractors in ELF and LOL for SH_2, SF_2, and SF_4, and radial distances, r_{ELF} and r_{LOL}, to the S atom (in pm).

Molecule	ELF	r_{ELF}	LOL	r_{LOL}	Type[a]
SH_2	0.9694	99	0.657	77	*n*
	0.9998	134	0.879	117	*b*
SF_2	—[b]	—[b]	0.716	75	*n*
	0.8178	99	0.569	83	*b*
SF_4	0.9961	95	0.684	74	*n*
	0.8348	87	0.589	80	*b* to F_e
	0.8178	111	0.560	82	*b* to F_a

[a]*n* denotes a non-bonded maximum, *b* a bonded one.
[b]No values reported in ref. 6.

The ELF and LOL analyses give qualitatively comparable results. SH_2 shows larger attractor values for bonding domains as opposed to sulfur fluorides. Lone pairs are in closer vicinity to the sulfur center than bond pairs. However, the LOL values are spread out more in the [0, 1] array of values, and ν_Γ-values for different type of electron groups are better separated in LOL than they are in ELF. The localized-orbital locator, LOL, seems to provide a clearer and more decisive picture than the electron localization function, ELF.

Computational details

Density functional calculations have been carried out with the Gaussian03 system of programs (41). The molecular density used in topology analyses was obtained from pure density functional calculations within the generalized gradient approximation as proposed by Perdew, Burke, and Ernzerhof, PBE (42). A valence triple-ζ basis augmented by one polarization function (TZVP) was used for all atoms (43). Densities used in topology analyses were taken from optimized gas-phase structures. Topological analyses of molecular electron densities employed a modified version of the program MORPHY (44). 3-D pictures were generated using the graphical package Jmol (45).

Conclusion

Our analysis of molecules with prototypical as well as unusual chemical bonds has shown that the localized-orbital locator, LOL, represents a conceptually simple, but efficient tool in characterizing a chemical bond. In particular, the analysis of LOL in terms of (3,–3) Γ-attractors provides an easy access to meaningful bond profiles. The chemical content of LOL is similar to that of the electron localization function, ELF, but a comparison of both methods suggests that the picture of a chemical bond generated by LOL is more decisive and easier to interpret. The topology of LOL clearly displays the locations of the classic VSEPR electronic groups. LOL nicely illustrates the role of core orbitals, which are an essential element of chemical bonding. Not only does LOL faithfully represent atomic shell structure, it further emphasizes the influence of core electrons on valence localization.

Extracting chemical information from molecular electron density contributions continues to be a main topic in bond-

© 2008 NRC Canada

ing analysis, and more rigorous but also more computational demanding model based on maximum probability domains are currently being developed (37, 38). Compared to more sophisticates approaches, LOL has the advantage of being more accessible not only with respect to the computational approach but also with respect to an intuitive interpretation of the results.

Besides the exemplary studies of Schmider and Becke (10, 11), only a few applications of LOL to molecular problems of chemical bonding and chemical reactivity have appeared in the literature (39, 40), which all utilize graphical representations of LOL. The location of Γ attractors and the evaluation of ν_Γ-values puts the LOL analysis on quantitative basis and facilitates the clear formulation of the nature of a chemical bond. It is hoped that the present work will promote the recognition of the localized-electron locator as a valuable tool in the analysis of chemical bonding.

Titania encapsulation of flat gold nanoparticles — A simple route to Au@TiO_2 core-shell nanosheets

Jeffrey J. McDowell, J. Ian McKelvey, Laura A. Richard, and Jeffrey T. Banks

Abstract: We report the attachment of a uniform coating of a thin layer of amorphous TiO_2 to flat gold nanoparticles via a simple sol–gel process. Coatings of variable thickness ranging from 5 to 100 nm have been produced. Activation of the Au particles was unnecessary. However, the ability to coat the flat gold nanoparticles was dependent on the method used for their synthesis. In addition, the amorphous TiO_2 shell was hydrothermally treated to induce crystallization to the anatase polymorph. The desired nanocrystalline anatase morphology was obtained by heating in water at 70 °C for 1 week. A similar result was also obtained when the material was heated to 130 °C for 5 min in a microwave reactor. These new Au@TiO_2 nanosheets were characterized by TEM, EDX, and SAED.

Key words: core-shell, titanium dioxide, anisotropic nanoparticles, semiconductor thin films, nanocomposite material.

Résumé : Faisant appel à un processus simple sol–gel, on a fixé une couche mince uniforme de TiO_2 amorphe à des nanoparticules planes d'or. On a produit des couches dont l'épaisseur varie de 5 à 100 nm. On a trouvé qu'il n'est pas nécessaire d'activer les particules d'or. Toutefois, l'habilité à fixer des nanoparticules planes d'or dépend de la méthode utilisée pour leur synthèse. De plus, on a traité la coquille de TiO_2 d'une façon hydrothermique afin d'induire la cristallisation sur le polymorphe d'anatase. On a obtenu la morphologie désirée d'anatase nanocristalline par chauffage dans l'eau à 70 °C, pendant une semaine. On a aussi obtenu des résultats semblables par chauffage à 130 °C, pendant cinq minutes, dans un réacteur à microondes. On a fait appel aux techniques de TEM, EDX et SAED pour caractériser ces nouveaux feuillets de Au@TiO_2.

[Traduit par la Rédaction]

Introduction

Nanosized metals, semiconductors, and dielectrics have become an intense area of research over the past few decades because of their attractive size- and shape-dependant properties. More recently, there has been significant interest in nanomaterials made from two or more distinctly different constituents. The properties of such nanocomposite materials depend not only on the properties of their individual components but also on their morphology and interfacial characteristics. Because of this, modern materials chemists seek the ability to design, fabricate, and manipulate nanostructured systems to achieve well-tailored chemical and physical characteristics for advanced applications. The more naive among us may believe that this will eventually lead to Drexler's chimerical utopia where molecular assemblers reign supreme (1). However, serious proponents of nanotechnology must remain realistic, and it is far more likely that an arsenal of synthetic approaches will be required to further develop this area of contemporary science. Indeed, much progress has already been made. For example, an abundance of wet chemical procedures have been developed to produce a variety of nanoparticles with varied composition and shape (2–11). Also, nanoparticles have been further modified by encapsulation in another different material and represent a class of nanocomposite materials now known as core-shell nanoparticles (12–18). The core-shell motif is a popular architecture for metal – metal oxide nanocomposite materials, and potential applications range from biosensors (19) to nanocapacitors (20). Metal oxide shells are typically used to act as protective sheaths for metal nanoparticles (18, 21–24). One of the more popular desired outputs for these materials is as a durable and photoactive catalyst (25–32).

The discovery of a material or system of materials with rectification efficiencies approaching that of photosystems I and II is essential to the design of a catalyst with sufficient redox power for photoelectrolysis of water or carbon fixation by reduction of CO_2 to methanol. The products of such reactions are the focal point of two suggested alternative fuel economies (33). Charge separation is a fundamental requirement for effectively mimicking natural photosynthesis. However, following excitation of materials such as crystalline TiO_2, recombination of e^-/h^+ pairs is the most thermodynamically favoured pathway in the absence of molecules used to scavenge either photogenerated electrons or holes. It has been estimated that <5% of charges in these systems can actually be utilized to induce redox reactions at the interface (31). This is a problem inherent to all large-band-gap metal

oxides currently being explored as UV active photocatalysts. Incorporation of noble metal nanoparticles of Au, Ag, and Pt into semiconducting metal oxides has been shown to enhance photocatalytic activity (28, 34–36). Subramanian et al. (27) propose that the noble metals mediate the photocatalytic process by storing and shuttling photogenerated electrons from the semiconductor to an acceptor. Further work by Kamat and co-workers has shown that the surface plasmon resonance (SPR) band of an ethanol suspension of titanium dioxide coated silver nanoparticles ($Ag@TiO_2$) shifts from 460 to 420 nm upon UV irradiation (26). The authors suggest this is the result of Fermi level equilibration between the metal core and the metal oxide shell, which causes significant accumulation of electrons in the core. Ung et al. (37) have shown that the SPR absorption band of colloidal silver undergoes a blue shift when the electron density is increased. Perhaps the most interesting finding of Kamat is that the $Ag@TiO_2$ nanoparticles can maintain this charge separation in the absence of light until discharged by the addition of an appropriate oxidizing agent, such as thionine (26, 38). Core charging has also been observed by chemical reduction of $Au@SiO_2$ nanoparticles (39). These results suggest a mechanism that explains the enhanced photocatalytic efficiencies of metal–TiO_2 nanocomposite materials over conventional titania systems.

Conventional wisdom suggests that increasing catalyst surface area by decreasing particle size maximizes catalytic efficiency (40–42). However, for core-shell systems, one could speculate that the volume of the metal is important, since it acts as an electron reservoir that is needed to balance the positively charged shell of the polarized core-shell nanoparticle. If this were to be the case, it is likely that there would be a trade off between increased surface area and decreased core volume. Furthermore, it is not clear that the metal needs to be of nanoscale dimensions in every axis to perform as an electron sink. As mentioned above, there have been numerous studies on metal core@semiconductor shell systems with all three dimensions in the nano regime (i.e., 'spherical' nanoparticles). This has not been extended to systems that are constrained to the nanoscale in one (nanosheets) or two (nanowires) dimensions. To date, there have been several syntheses of metal@semiconductor nanowires reported (17, 19, 43–45). Very few examples of anisotropic core-shell particles can be found in the literature. One recent example of this type is the synthesis of SiO_2 coated Ag nanoprisms by Xue et al. (46).

Our aim is to synthesize novel anisotropic multicomponent nanoparticles through simple methods. A common feature of oxide-encapsulated metal nanoparticles is the requirement for an organic linking group between core and shell (15, 18, 19, 21, 46). We speculated that, in the case of sol–gel synthesis, a linking group should not be necessary, thereby increasing the simplicity of the route to complex nanoparticle structures. We report herein a simple sol–gel method for the encapsulation of flat gold nanoparticles (FGNPs) by amorphous titanium dioxide without the need for a linking agent. The foundation for the new particles presented here are flat gold nanoparticles. FGNPs provide a high surface area while being quite large (100 nm – 10 μm) in comparison with most nanoparticles. The single-crystalline nature of FGNPs and the ease of their synthesis makes them ideal candidates for functionalization. To date, there have been no examples of core-shell structures using FGNPs. This procedure allows good control over shell thickness for the $Au@TiO_2$ nanosheets. As well, subsequent hydrothermal reactions have been used to crystallize the amorphous sheath to the anatase polymorph of TiO_2.

Experimental section

Hydrogen tetrachloroaurate(III) trihydrate, titanium(IV) butoxide 97% (TnB), ethylene glycol (EG), aniline +99%, anhyd. ethanol, (3-mercaptopropyl)trimethoxy silane (MPTMS) 95%, and 1-dodecanethiol (DDSH) 98% were obtained from Sigma-Aldrich and were used without further purification with the exception of aniline. Aniline was twice distilled over zinc metal. The amphiphilic block copolymer Pluronic P123 ($EO_{20}PO_{70}EO_{20}$, M_n = 5800) was generously donated by BASF and used as received.

Synthesis of flat gold nanoparticles

The initial FGNPs were synthesized in Pluronic 123 hexagonal liquid crystals using a modified procedure described by Wang et al. (47). Typically, 10.3 g of Pluronic P123 was heated at 70 °C until completely liquefied. Then, 0.230 g of CTAB and 25 mL 0.03 mol/L $HAuCl_4$ were added with stirring. The mixture was left to cool and then covered with parafilm and kept in the dark for 3 days. The reaction mixture was taken up in ethanol and heated to dissolve the P123. Au nanosheets were collected by centrifugation and washed with ethanol.

The majority of FGNPs in this work were synthesized using a modification of the procedure described by Gu and coworkers (48). In a typical procedure, an initial 50 mL EG solution of 0.72 mmol/L $HAuCl_4 \cdot 3H_2O$ was heated in a water bath at 95 °C for 20 min with moderate stirring. Then, 0.72 mL of a 0.1 mol/L aniline EG solution was added slowly over 1 min, and the mixture was left without stirring at 95 °C for an additional 3 h. The final product was a metallic, golden precipitate suspended in a dark purple mother liquor. Allowing the solid to settle and decanting the excess liquid accomplished separation of the product plates from the liquid. Residual product was washed twice with ethanol to remove residual ethylene glycol.

A third set of FGNPs were made according to the procedure described by and Huang and co-workers (49).

SAM functionalization

FGNPs were suspended in 25 mL of 5 mmol/L of MPTMS or DDSH in anhyd. ethanol and stirred for 24 h. The nanosheets were then washed three times with copious amounts of anhyd. ethanol.

Synthesis of FGNP@TiO_2 particles

The procedure used to form the FGNP@TiO_2 particles began with a 20 mL suspension of previously synthesized gold nanosheets in anhyd. ethanol. In a typical experiment, TnB (neat) was added with rapid stirring to form a 0.3 to 5 mmol/L solution, followed by the addition of 0.275 mL of HPLC-grade H_2O. The suspension was allowed to stir for 1 h at room temperature. Over this period, the solution became cloudy white as TnB was hydrolyzed. The final prod-

© 2008 NRC Canada

uct was centrifuged multiple times and the mother liquor decanted to remove extraneous TiO_2 as a fine white suspension. Complete elimination of extraneous TiO_2 was impossible, but the majority of Au product was visibly isolated. The golden pellet obtained after centrifugation could be resuspended without signs of aggregation between particles. It should be noted that a 34 mmol/L TnB concentration was used to produce the sample that was cross-sectioned.

Hydrothermal crystallization

Au nanosheets coated with amorphous TiO_2 films (thickness ~30–40 nm) were suspended in HPLC-grade H_2O in a capped glass vial and placed in an oven heated to 70 °C for 1 week.

Microwave-induced hydrothermal crystallization

Au nanosheets coated with amorphous TiO_2 films (thickness ~30–40 nm) were suspended in HPLC-grade H_2O in a capped glass vial. The vial was placed in a CEM laboratory microwave, and the solution was heated to 130 °C for 5 min.

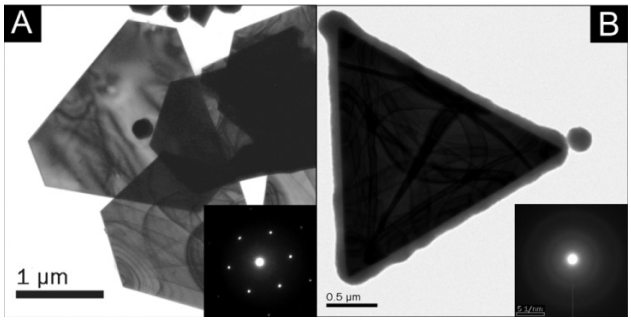
TEM analysis and cross sectioning

A diluted portion of the products in ethanol was dropped onto a 200 mesh copper grid. TEM images were obtained using a JEOL 2011 scanning transmission electron microscope operating at 200 kV and equipped with an EDAX (Genesis) energy dispersive X-ray system. To obtain cross-sections of FGNPs, the sample was dried and put into a mold with L R White resin and cured overnight at 60 °C. Embedded blocks were trimmed with a razor blade, a small block face area was necessary for cutting thin sections. The block was then sectioned using a Leica Ultramicrotome. The sections were floated onto water and collected on a 200 mesh copper grid. The section thickness achieved was in a range from 40 to 50 nm.

Results and discussion

During the past few years, several methods have been developed for the preparation of Au nanosheets (11, 47–54). They typically consist of single Au crystallites with triangular and truncated triangular geometries. Edge lengths have been reported from about 100 nm to several tens of microns. We chose sheets in the size range of ~1 to 5 μm on edge. The idea being that Au@TiO_2 nanosheets of this size would be more easily separated from colloidal titanium dioxide by centrifugation, while still having a core thickness of only a few tens of nanometers. FGNPs were made from P123 hexagonal liquid crystals, and results were similar to those described by Wang. (47). The sheets ranged from about 500 nm to 5 μm on edge with basal Au surfaces that were predominantly {111}, as indicated by the select area electron diffraction pattern (SAED). There was also a significant amount of nanoparticles that proved to be polyhedra with diameters of ~120 nm. It should be noted that there was a considerable amount of extraneous material associated with the Au particles, even after several ethanol washings. Energy dispersive X-ray spectrometry (EDX) of this material suggest it to be carbonaceous. Metal@semiconductor core-shell particles are usually made by activating the surface of the metal with a surfactant (15–18, 21, 26, 55, 56). However, encapsulation by direct precipitation of nanoparticles from a metal oxide sol has also been described in the literature (23, 32, 43). We first tried to encapsulate these FGNPs by suspending the as prepared sheets (i.e., without activation) in a titania sol as described in the Experimental section. This proved to be unsuccessful. Thiols are well-known to bind to gold surfaces, and MPTMS has been found to activate Au nanoparticles towards encapsulation by silica (15). As well, Dahanayaka et al. (57) have shown that alkanethiol SAMs readily form on FGNPs. We then exposed the FGNPs to a 5.0 mmol/L solution of MPTMS in anhyd. ethanol for 24 h prior to exposure to the titania sol. However, this also proved to be unsuccessful. We speculate that the carbonaceous material associated with the Au particles is unremoved P123 and blocks adhesion of the TiO_2 sol to the Au surface. If this is the case, it is seemingly tightly bound, since it could not be easily removed by washing nor displaced by thiols (vide supra).

Fig. 1. Representative FGNP (*a*) before modification and (*b*) coated with an amorphous TiO_2 film.



At this point, we decided to try a "cleaner" FGNP synthesis. The method described by Gu and co-workers proved to be straightforward and reliable (48). Simply, adding aniline to a heated ethylene glycol solution of hydrogen tetrachloroaurate produced large amounts of hexagonal plates. Figure 1*a* shows a typical TEM image of FGNPs produced by this method. Bending contours and transparency decorating the surface of the plates indicate reduced plate thickness. This reduced thickness was confirmed by cross-sectioning experiments (vide supra), and on average, sheets were ~40 nm thick. Lateral edge lengths typically ranged from 1 to 5 μm with basal Au surfaces that were predominantly {111}, as indicated by SAED pattern shown in the inset of Fig. 1*a*. A thin film of titanium dioxide via the sol–gel procedure easily encapsulated these sheets as can be seen in Fig. 1*b*. The surrounding light grey layer in Fig. 1*b* is comprised of TiO_2, as indicated by elemental analysis conducted via EDX (Fig. 2). EDX analysis suggested this layer covered the entire surface of the Au sheet and gave strong Ti and O peaks for X-rays collected at any spot over the Au surface. SAED taken on regions of the film show that TiO_2 is amorphous, as indicated by the lack of definition in the diffuse ring pattern (inset, Fig. 1*b*). Although extraneous, unattached TiO_2 nanoparticles were often carried along in the syntheses, this material could be almost completely removed by multiple centrifugation/washing cycles.

MPTMS was initially used to activate these FGNPs, but it was found to be unnecessary. Given that encapsulation of the previously described FGNPs was seemingly blocked by

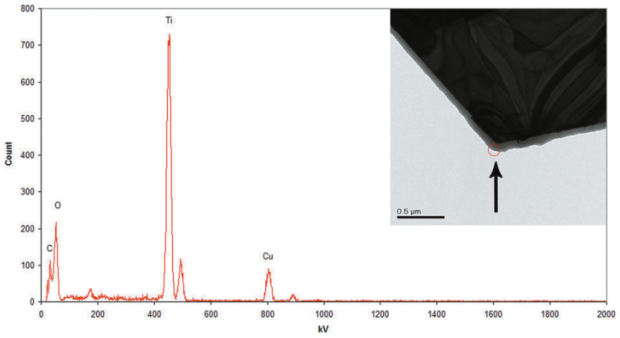
Fig. 2. Representative EDX spectrum taken on the overhanging TiO_2 layer indicated by the arrow in the inset.



P123 that had remained on the surface, we reasoned that it might be possible to protect the "cleaner" FGNPs from encapsulation by protecting them with an alkanethiol SAM. These sheets were treated with 1-dodecanethiol (DDSH), and SAM formation was supported by absorptions at 2900 and 2800 cm^{-1} in the FTIR spectrum (these absorptions were absent in the parent FGNPs). However, the DDSH-treated FGNPs were also successfully encapsulated by titanium dioxide. In the case of these nanosheets, the TiO_2 coating was the same regardless of SAM functionalization. The ineffectiveness of DDSH as a blocking agent leads us to believe that, in this case, the method of attachment of TiO_2 is simply through adhesion during the slow sol–gel process. A strong encapsulating layer is formed, and the coated nanosheets are robust.

To insure that the sol–gel encapsulation procedure was not specific to the aniline – ethylene glycol FGNP synthesis, a third set of FGNPs were synthesized by the aqueous citrate reduction of hydrogen tetrachloroaurate in the presence of CTAB as described by Chu et al. (49). These sheets were readily encapsulated without activation. We expect this procedure to be general, but it seems proper choice of the FGNP synthesis is important.

To further assess the degree of film coverage, sheets with amorphous films were cross-sectioned. Figure 3 shows TEM images of cross-sectioned samples. TiO_2 films were homogenous and had thicknesses on the order of 100 nm in this particular sample. The thickness of TiO_2 layers showed considerable variation dependent on reaction conditions (primarily TnB concentration). The results obtained by increasing TnB concentration over the range 0.3–5.0 mmol/L, keeping all other quantities constant, showed a proportional increase in film thickness.

TiO_2 can be crystallized hydrothermally to yield the photocatalytically active anatase structure (58–61). Crystallization of the amorphous TiO_2 layer to yield the anatase form would be desirable for these FGNP@TiO_2 particles to be photocatalytically efficient. This is also an important factor when considering the possibility of adding other functionalities to the TiO_2 surface. Light-sensitive dyes, metal nanoparticles, and other catalysts have been shown to have useful properties when bonded to anatase TiO_2. We have experimented with several crystallization techniques to create a new class of composite nanoparticles that could serve as a foundation for more complex nanostructures.

Fig. 3. Cross-sections of FGNPs with amorphous TiO_2 films. Inset shows a close-up where the thickness of the Au plate and the surrounding TiO_2 layer can easily be measured.

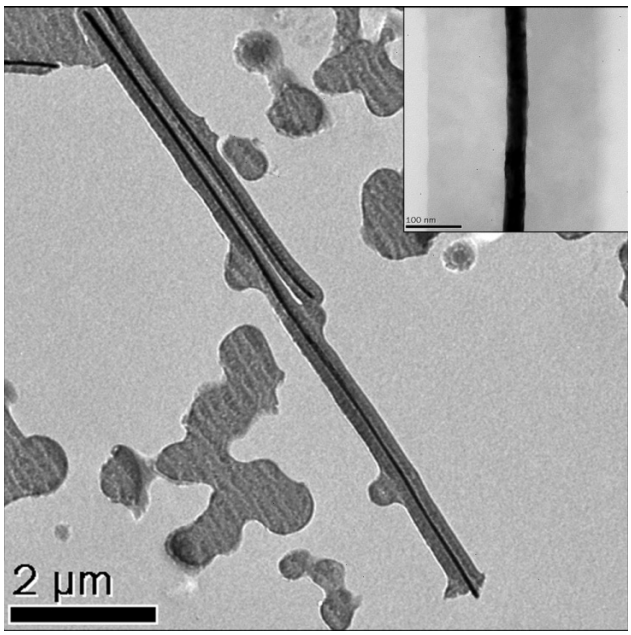


Fig. 4. Contrast between (*a*) amorphous TiO_2 and (*b*) crystalline TiO_2 obtained by heating in water at 70 °C for 1 week.

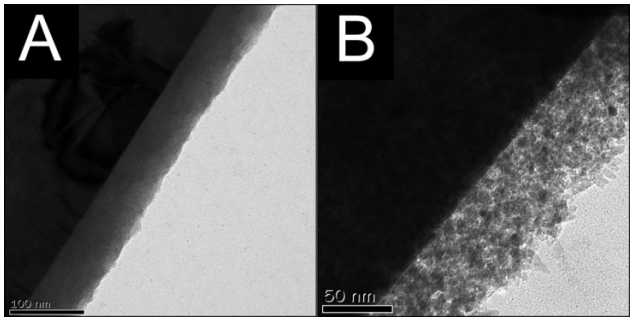

Polycrystalline TiO_2 films were formed by mildly heating an aqueous suspension of FGNPs coated with amorphous titania. HRTEM imaging and SAED showed conclusively that anatase was the dominant crystal morphology in the product. Figure 4 shows the difference in appearance between amorphous TiO_2 and the nanocrystallite films. Figure 5 clearly shows lattice fringes that occur as a result of diffracting crystal planes; the existence of which has also lead to the multi-ring SAED pattern shown in the inset. Comparison of experimental *d* spacing with tabulated values for anatase TiO_2 reveals a number of common values (notably $d = 3.5$ Å and 1.9 Å corresponding to the (101) and (200) crystallographic faces, respectively). Alternatively, no spacings are closely shared between experimental and those of rutile.

Microwave heating to 130 °C of an aqueous suspension of amorphous FGNP@TiO_2 particles also converted the thin TiO_2 film to the anatase phase, but this method only required heating for five minutes. Figure 6 contrasts the starting material and product. Further analysis of the nanocrystallite film by electron diffraction showed the multiple ring pattern

Fig. 5. Lattice fringing in titania-coated FGNPs heated at 70 °C. SAED shown in the inset also indicates polycrystalline TiO_2.

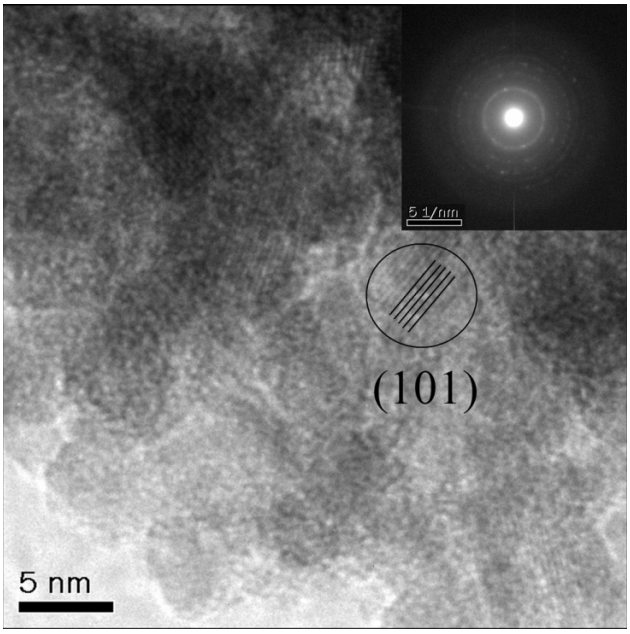

Fig. 6. Contrast between (*a*) amorphous TiO_2 and (*b*) crystalline TiO_2 obtained by heating in water at 130 °C for 5 min.

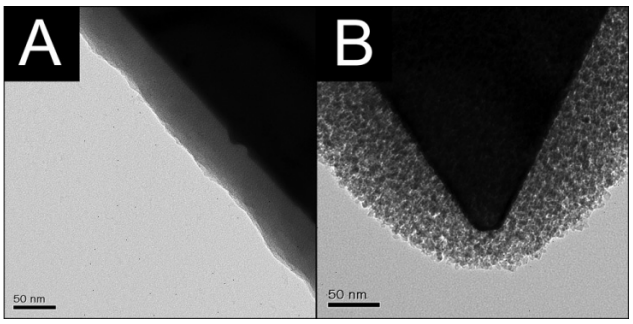


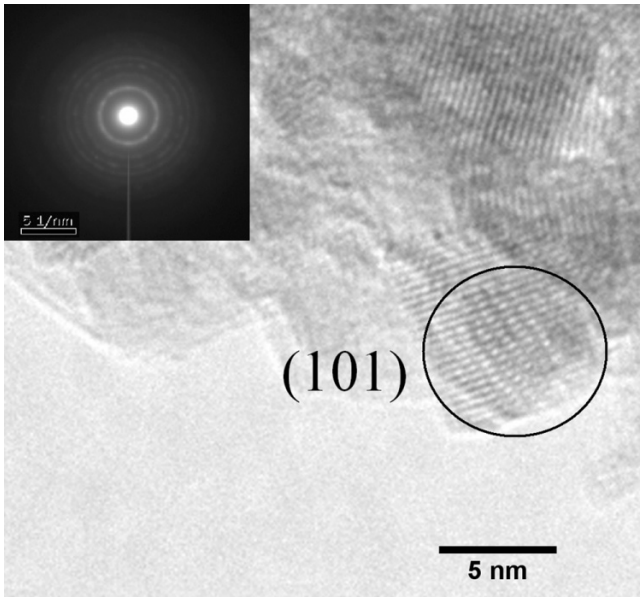
expected for anatase TiO_2. Again, HRTEM images clearly show lattice fringes of diffracting crystallites and at much higher concentration and clarity than analogous polycrystalline films generated in the oven (Fig. 7). Microwave heating significantly reduced crystallization times from hours to minutes under very mild, aqueous conditions. It is possible that interactions between microwaves and FGNPs results in hot spots localized at the metal core, ultimately increasing the rate of the phase change beginning at the metal surface and propagating outward.

Overall, the crystallization of TiO_2 on FGNPs was quite straightforward. Good polycrystallinity was seen and distinguished as anatase. We do not see significant loss of TiO_2 from the nanoplate during the crystallization process. FGNPs coated with crystalline TiO_2 are also quite robust and withstand frequent centrifugation, washing, and sonication.

Conclusion

FGNPs were demonstrated as flat, modifiable platforms onto which TiO_2 could be layered. Provided proper choice of

Fig. 7. Lattice fringing in microwaved TiO_2. SAED shown in the inset also indicates polycrystalline TiO_2.



FGNP synthesis, this procedure is possible without the addition of any linking organic groups. The crystallization of TiO_2 was performed conventionally and with microwave heating, and the latter proved to be quite advantageous. At the present time, we continue to investigate many possibilities for bonding of other materials to FGNPs and Au@TiO_2 nanosheets as well as their photocatalytic properties.

Acknowledgement

Thanks to Jenna Holt for repeating some of the intial experiments. Thanks to Dr. Louise Weaver, Douglas Hall, and colleagues at UNB's Microscopy and Microanalysis Facility and to the Natural Sciences and Engineering Research Council of Canada (NSERC), NBIF, and UNB for the generous financial support.

PMA/SiO_2 — An efficient recyclable heterogeneous catalyst for the synthesis of homoallyl alcohols and amines under solvent-free conditions[1]

Biswanath Das, Rathod Aravind Kumar, Ponnaboina Thirupathi, Kanaparthy Suneel, and Pothkan Sunitha

Abstract: Aldehydes and imines can efficiently undergo nucleophilic addition reaction with allyltributylstannane in the presence of phosphomolybdic acid supported on silica (PMA/SiO_2) under solvent free-conditions to form the corresponding homoallyl alcohols and amines respectively at room temperature in excellent yields. The catalyst can be easily recovered and re-used.

Key words: homoallyl alcohol, homoallyl amine, phosphomolybdic acid, heterogeneous catalyst, allyltributylstannane, solvent-free conditions.

Résumé : Opérant à la température ambiante et des conditions sans solvant, les aldéhydes et les imines peuvent donner lieu à des réactions efficaces d'addition nucléophile avec l'allyltributylstannane, en présence d'acide phosphomolybdique supporté sur de la silice (APM/SiO_2) pour conduire à la formation respectivement d'alcools et d'amines homoallyliques avec d'excellents rendements. Le catalyseur peut facilement être récupéré et réutilisé.

Mots-clés : alcool homoallylique, amine homoallylique, acide phosphomolybdique, catalyseur hétérogène, allyltributylstannane, conditions sans solvant.

[Traduit par la Rédaction]

Introduction

Homoallylic alcohols (1) and amines (2) are important building blocks for the construction of various biologically active compounds, and hence the syntheses of these compounds are highly useful. Lewis acid promoted nucleophilic addition of allyltin reagent to carbonyl compounds and imines is one of the straightforward methods for the synthesis of homoallyl alcohols and amines. Various Lewis acids such as metal halides (3), metal triflates (4), I_2 (5), (bromodimethyl)sulfonium bromide (6), and cyanuric chloride (7) can catalyze this reaction. However, most of the methods employing these catalysts suffer from certain disadvantages such as high temperature, prolonged reaction times, harsh reaction conditions, and the use of hazardous and expensive acid catalysts. Some of the catalysts are extremely moisture sensitive and can cause inconvenience in performing the reaction. In recent years, the use of solid acids as heterogeneous catalysts has gained tremendous interest in different areas of organic synthesis. These catalysts are advantageous over conventional homogeneous acid catalysts as they can be easily recovered from the reaction mixture by simple filtration and can be re-used after activation or without activation, thereby making the process more economically viable. Here we report the utilization of a solid acid as a catalyst for the preparation of homoallylic alcohols and amines.

Results and discussion

In continuation of our work (8) on the application of heterogeneous catalysts for the development of useful synthetic methodologies, we have observed that phosphomolybdic acid supported on silica (PMA/SiO_2) (9) is very suitable to catalyze the allylation of aldehydes and imines with allyltributylstannane to form the corresponding homoallyl alcohols and amines at room temperature (RT) under solvent-free conditions (Scheme 1). This catalyst possesses excellent activity, low toxicity, and high stability towards humidity. It can be recovered from the reaction mixture and recycled.

Initially we studied the reaction of benzaldehyde, aniline, and allyltributylstananne in CH_3CN in the presence of PMA/SiO_2 at RT. The desired homoallylamine was obtained in good yield (85%) within 80 min (Table 1, entry a). In absence of the catalyst the product was not formed. We studied the effect of different solvent systems such as THF, Et_2O, MeOH, CH_3CN, CH_2Cl_2, and $CHCl_3$ for the reaction, but the conversion proceeded best in the absence of any solvent. A wide variety of aromatic and aliphatic aldehydes

containing electron-donating (Table 1, entries b and l) and electron-withdrawing substituents (Table 1, entries c and d) underwent the transformation smoothly. An acid sensitive aldehyde such as α,β-unsaturated aldehydes (Table 1, entry i), furfuraldehyde (Table 1, entry f), and a sterically hindered aldehyde such as 2-naphthaldehyde (Table 1, entry e) worked well to produce their corresponding homoallylic amines. The imines (formed in situ from aldehydes and amines in the presence of the catalyst) underwent facile reaction with allyltributylstannane to form these compounds. Previously, some methods were found to be unsuitable for the preparation of homoallylic amines from enolizable aldehydes. Interestingly the reaction of aldehydes, benzylcarbamate ($CbzNH_2$), and allyltributylstannane yielded the corresponding Cbz-protected allylamines in excellent yield (79%–83%) (Table 1, entries k and l).

The other application of the present method is the preparation of homoallyl alcohols from the corresponding aldehydes on treatment with allyltributylstannane using

PMA/SiO_2 under solvent- free conditions (Scheme 2). The reaction proceeded at RT and the products were formed within 4–5 h (Table 2). Both aromatic and aliphatic aldehydes were used for the preparation of homoallylic alcohols. The aldehydes containing electron-donating (Table 2, entry b) and electron-withdrawing groups (Table 2, entry c) in the aromatic rings were found to undergo the conversion smoothly. Acid-sensitive aldehydes such as furfural (Table 2, entry f) and cinnamaldehyde (Table 2, entry e) also smoothly reacted to afford the corresponding homoallyl alcohols.

We extended this method for the conversion of ketones and carried out the reaction using acetophenone, cyclohexanone, and β-ketoesters. None of the ketones gave homoallylic alcohols and amines even after prolonging the reaction times. The chemoselectivity of the present allylation method is remarkable, providing allylation of only aldehydes in the presence of ketones (Table 2, entries i–k). The times required for the preparation of homoallylic alcohols (4–5 h) are somewhat more than those required for the preparation of homoallylic amines (30–60 min).

Conclusion

In conclusion, we have developed a simple and efficient method for the allylation of aldehydes and amines using PMA/SiO_2 as a heterogeneous catalyst. The main features of this methodology are (*i*) operational simplicity, (*ii*) short reaction times, (*iii*) mild reaction conditions, (*iv*) excellent yields, (*v*) application of an inexpensive heterogeneous catalyst, (*vi*) high chemoselectivity, (*vii*) high stability towards humidity, and (*viii*) reusability of the catalyst.

Experimental

Preparation of PMA/SiO_2 catalyst (9)

Slica gel (100–200 mesh, 450 mg) was added slowly to a solution of $H_3PMo_{12}O_{40}{\cdot}24H_2O$ (50 mg) in methanol (5 mL). The mixture was stirred at RT for 6 h. Methanol was evaporated under reduced pressure to attain the catalyst (PMA/SiO_2) as an yellowish powder.

General experimental procedure for the synthesis of homoallyl amines

To a mixture of an aldehyde (2 mmol), amine (2 mmol), and allyltributylstannane (2.5 mmol), PMA/SiO_2 (113 mg) was added under solvent-free conditions at RT. The mixture was stirred and the reaction was monitored by TLC. After completion of the reaction, the mixture was filtered and the catalyst was recovered quantitatively after washing the residue with dry methanol (2 × 5 mL). The filtrate (containing the product in methanol) was concentrated and the residue was subjected to column chromatography (silica gel, hexane) to obtain pure homoallyl amine. The recovered catalyst was re-used three times subsequently for the same reaction without affecting the yield of the product.

General experimental procedure for the synthesis of homoallyl alcohols

To a mixture of an aldehydes (2 mmol) and allyltributylstannane (2.5 mmol), PMA/SiO_2 (113 mg) was added under solvent-free conditions at RT. The mixture was stirred and the reaction was followed by TLC. After completion, the mixture was filtered and the residue was washed with dry methanol (2 × 5 mL) to recover the catalyst quantitatively. The filtrate (containing the product in methanol) was concentrated and the viscous mass was subjected to column chromatography (silica gel, 35% EtOAc and hexane) to afford pure homoallyl alcohol. The recovered catalyst was re-used three times subsequently in this case also for the same reaction without affecting the yield of the product.

All the prepared compounds (except **3b**, **3f**, and **4b**) are known (3*c*, 3*d*, 4*b*, 4*c*, and 6). The spectral and analytical data of representative products are given below.

Exploring the reaction of formaldehyde with α-*N*-protected amino acid hydrazides

Giancarlo Verardo, Paola Geatti, Marta Mancuso, and Paolo Strazzolini

Abstract: The reaction of formaldehyde with enantiomerically pure α-*N*-protected amino acid hydrazides is described. The system has been investigated in different solvents, including both aqueous formaldehyde and paraformaldehyde, with the aim of simplifying the final reaction mixture. Aqueous formaldehyde in refluxing THF proved to be the best combination, affording mainly the corresponding monomeric *N*-methylene and 1,3,5-trisubstituted-1,3,5-hexahydrotriazine derivatives. The monomeric form was the only one present at high temperature, as evidenced by ^{1}H and ^{13}C NMR spectroscopy.

Key words: amino acid hydrazides, formaldehyde, condensation reactions, monomeric *N*-methylene derivatives, oligomers.

Résumé : On décrit la réaction du formaldéhyde avec des hydrazides d'acides aminés α-*N*-protégés énantiomériquement purs. Afin d'obtenir un mélange réactionnel final aussi simple que possible, on a étudié le système dans divers solvant, en utilizant aussi bien du formaldéhyde aqueux que du paraformaldéhyde. Le formaldéhyde aqueux dans du THF au reflux semble la meilleure combinaison et elle conduit principalement aux dérivés correspondants monomères *N*-méthylène et 1,3,5-hexahydrotriazine 1,3,5-trisubstitués. Sur la base de la spectroscopie RMN du ^{1}H et du ^{13}C, la forme monomère est la seule qui soit présente à haute température.

Mots-clés : hydrazides d'acides aminés, formaldéhyde, réactions de condensation, dérivés *N*-méthylène monomères, oligomères.

[Traduit par la Rédaction]

Introduction

In recent years, considerable effort has been directed towards the synthesis of peptidomimetics having different structural features (1). Among them, a notable interest concerns hydrazides, in particular those bearing an *N*-methyl substituent in the 2-position (2). The syntheses reported in the literature to date are essentially based on the direct or mediated condensation between the terminal carboxy function of the peptide unit and *N*-methylhydrazine, free or protected at the methylated nitrogen, affording the corresponding 2-methylhydrazide in moderate yields and after tedious separations (3). The easy, high-yielding access to the hydrazido derivatives of α-*N*-protected amino acid recently described (4) prompted us to consider the possibility of transforming them into the corresponding methylene-imines (5) by direct interaction with formaldehyde. In fact, such methylidene intermediates might in turn be useful precursors, after $NaBH_4$ reduction (6), to the desired *N*-protected α-amino acid 2-methylhydrazides. In addition, this approach should also allow, simply using suitable reagents, the introduction of one or three deuterium atoms to the methyl substituent (6).

It is well-known that the interaction of formaldehyde with primary amines (**1**) in inert solvents invariably gives rise to polymeric adducts (**2**), the favourite oligomeric form of the resulting products being strictly dependent on the nature of **1** (Scheme 1) (7).

Although it is well documented that the reaction of formaldehyde with monosubstituted hydrazines under neutral conditions produces the corresponding hydrazones (8), the same reaction involving carboxylic acid hydrazides has received much less attention so far, perhaps because the reaction products are various and not easily explainable (9). Therefore, taking all these reasons into account, we set out to explore the reaction of formaldehyde with enantiomerically pure α-*N*-protected amino acid hydrazides under different conditions to get an optimized protocol for the production of any valuable intermediates.

Results and discussion

The reaction of aqueous formaldehyde with α-*N*-protected amino acid hydrazides **3** might give rise to a variety of products, as outlined in detail in Scheme 2. With the exception of *N*-hydroxymethyl derivatives, which are unstable intermediates, the other products are expected to be all, or in part, present in the reaction mixture. For this reason, we set out to investigate this complex reaction with the aim of finding the most suitable conditions for reducing the complexity of the final mixture.

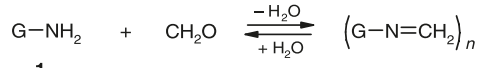
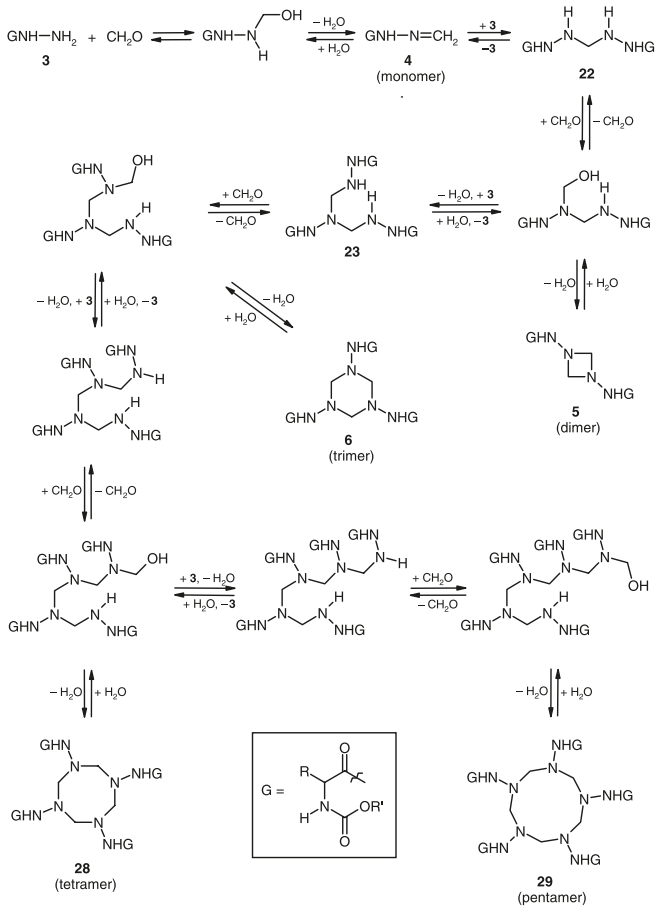
Scheme 1.



Scheme 2.



To this end, *N*-ethoxycarbonylphenylalaninohydrazide (**3ab**, Table 1) was used as the model substrate and the corresponding reaction products were carefully identified and quantified by means of ESI–MS and MS–MS experiments. On the basis of previous results (10), we first carried out the reaction in EtOH at 50 °C, using 1.6 equiv. of aq formaldehyde (Table 2, Entry 1). The ESI–MS analysis of the intact reaction mixture showed the presence of the monomer **4ab** (16%), the dimer **5ab** (7%), and the trimer **6ab** (60%) (Scheme 2), as well as the 3,5-disubstituted-1,3,5-oxadiazinone **7** (17%, Scheme 3). The large excess of formaldehyde reacting with the intermediate **8** allowed the formation of the *N*,*N*-di(hydroxymethyl) derivative **9** which, in turn, easily lost water to afford the heterocycle **7** (Scheme 3).

When the same reaction was carried out with less formaldehyde (1.3 equiv.; Table 2, Entry 2), the observed conversion into compound **7** was lower (12%) but, in addition to monomer **4ab** (33%), dimer **5ab** (6%), and trimer **6ab** (15%), the ESI–MS analysis showed the presence of five new compounds (Scheme 4), namely, ethyl 2-*N*-(ethoxycarbonyl)-2′,2′-bis(ethoxymethyl)phenylalaninohydrazide (**10**, 10%), 2′-(ethoxymethyl)-2′,2″-methylenebis[2-*N*-(ethoxycarbonyl)phenylalaninohydrazide] (**11**, 4%), 2′,2″-bis(ethoxymethyl)-2′,2″-methylenebis[2-*N*-(ethoxycarbonyl)phenylalaninohydrazide] (**12**, 16%), 2′-(ethoxymethyl)-2′,2″-({2-[*N*-(ethoxycarbonyl)phenylalanyl]hydrazine-1,1-diyl}bismethylene)bis[2-*N*-(ethoxycarbonyl)phenylalaninohydrazide] (**13**, 2%) and 2′,2″-bis(ethoxymethyl)-2′,2″-({2-[*N*-(ethoxycarbonyl)phenylalanyl]hydrazine-1,1-diyl}bismethylene)bis-[2-*N*-(ethoxycarbonyl)phenylalaninohydrazide] (**14**, 2%).

cb	$(CH_3)_2CHCH_2$	Et	**fb**	1*H*-indol-3-CH_2	Et

This result is definitely not surprising taking into account the capability of formaldehyde to react not only with the NH_2 groups but also with EtOH yielding ethoxymethanol (**15**, Scheme 4). Therefore, as the reaction proceeds, the amount of formaldehyde decreases and the reaction of amino groups with **15** becomes effectively competitive. We did not observe any significant variation by performing the reaction either at room temperature (1.3 equiv. of aqueous formaldehyde; Table 2, Entry 3) or at 80 °C (1.6 equiv. of aqueous formaldehyde; Table 2, Entry 4) whereas, when it was carried out in MeOH at 50 °C using 1.3 equiv of aq formaldehyde (Table 2, Entry 5) the amount of all the corresponding alkoxymethyl derivatives **16–20** (Scheme 4) and, more significantly, **16** (46%) and **18** (23%), increased. This outcome was not unexpected considering that MeOH gives the corresponding hemiacetal **21** more easily than does EtOH: therefore, the quantity of free formaldehyde available was still smaller than in the case of entry 2.

The use of 1.6 equiv. of paraformaldehyde in refluxing EtOH (Table 2, Entry 6) did not produce the aminoacetals **10–14** (Scheme 4) but, in addition to **4ab** (48%), **5ab** (5%), and **6ab** (2%), the ESI–MS analysis showed the presence of some unreacted starting hydrazide **3ab** (31%), accompanied by 2′,2″-methylenebis[2-*N*-(ethoxycarbonyl)phenylalaninohydrazide] (**22ab**, 8%) and 2′,2″-({2-[*N*-(ethoxycarbonyl)phenylalanyl]hydrazine-1,1-diyl}bismethylene)bis[2-*N*-(ethoxycarbonyl)phenylalaninohydrazide] (**23ab**, 6%) (Scheme 2). This pattern gives a clear indication that there was not enough free formaldehyde at hand, because the temperature (80 °C) was too low for obtaining an efficient depolymerization of paraformaldehyde. Therefore, to achieve a suitably high temperature, the reaction was carried

[d]In this instance the compounds are **16**–**20** in Scheme 4.

Scheme 3.

Scheme 4.

out in refluxing toluene, in the presence of 1.6 equiv. of paraformaldehyde (Table 2, Entry 7). Under these conditions, after 0.5 h the starting hydrazide **3ab** was entirely consumed, but in addition to **22ab** (21%) and **23ab** (10%) still present, the ESI–MS analysis showed the presence of 2,4,7-tris[*N*-(ethoxycarbonyl)phenylalaninamido]-1,2,4,5,7-pentaazabicyclo[3.3.1]nonane (**24**, 3%, Scheme 5). Since the longer reaction times (1–2 h) produced a more complex reaction mixture because of the formation of a number of unidentified side-products, we increased the amount of paraformaldehyde (2.0 equiv.; Table 2, Entry 8) while still applying the conditions previously described (0.5 h).

Under these conditions, compounds **22ab** and **23ab** were not observed (Scheme 2) but some 12% of the bicyclic derivative **25** was formed (Scheme 5). When the reaction was performed in toluene, at 80 °C for 2 h, using 1.6 equiv. of aq formaldehyde (Table 2, Entry 9), besides **4ab** (52%), **5ab** (7%), **6ab** (18%), and **25** (9%), the formation of the heterocycle **7** (8%, Scheme 3) was observed, as well as that of a new bicyclic derivative, namely diethyl 1,1′-{[9-(2-ethoxycarbamoyl-3-phenylpropanamido)-4-oxa-1,2,6,7,9-pentaazabicyclo[5.3.1]-undecan-2,6-diyl]bis(1-oxo-3-phenylpro-

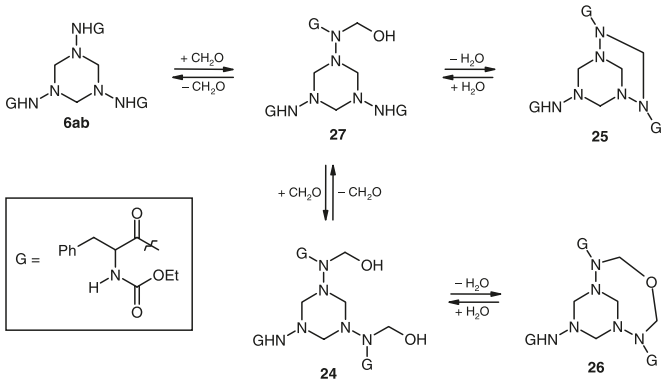
Scheme 5.



pane-2,1-diyl)}dicarbamate (**26**, 6%, Scheme 5). Under these reaction conditions, formaldehyde reacts rapidly with the NH groups yielding the *N*-hydroxymethyl intermediates **8** (Scheme 3) and **27** (Scheme 5) which are stabilized by internal hydrogen bonding, thus making the loss of water more difficult. Therefore, **8** and **27** survive enough to react with an additional molecule of formaldehyde producing **9** (Scheme 3) and **24** (Scheme 5), which, in turn, are precursors of compounds **7** (Scheme 3) and **26** (Scheme 5), respectively. We did not observe any significant variation in the composition of the final reaction mixture when less aqueous formaldehyde was employed (1.1 equiv.; Table 2, Entry 10).

In conclusion, the reaction of **3ab** carried out in alcohols yielded, besides the usual polymeric structures, the heterocycle **7** either alone or together with the aminoacetals **10**–**14**, **16**–**20** (Scheme 4) depending on whether there is a large or a slight excess of aqueous formaldehyde, respectively. Paraformaldehyde depolymerization occurred efficiently in toluene at 110 °C but not in EtOH at 80 °C; nevertheless, in the aprotic solvent at high temperature some of the formed free formaldehyde distilled off from the reaction mixture. For this reason, it was difficult to correctly estimate the amount of paraformaldehyde available, leading either to an uncomplete conversion or, alternatively, to the formation of the bicyclic derivative **25** (Scheme 5). On the other hand, the use of the more reactive aqueous formaldehyde in toluene yielded, in addition to **25**, the bicyclic derivative **26** (Scheme 5) and the heterocycle **7** (Scheme 3).

To circumvent all these drawbacks, we investigated the reaction in refluxing THF, a solvent able to dissolve both the starting hydrazide **3ab** and the aqueous formaldehyde, without giving rise to side-products as in the case of alcohols. In this medium, after 1 h and using 1.3 equiv. of aqueous formaldehyde (Table 2, Entry 11), compounds **4ab** (69%), **5ab** (7%), and **6ab** (14%) were still formed along with a minor amount of the heterocycle **7** (10%). The latter species completely disappeared when the reaction was carried out with a shorter reaction time (0.5 h) and a lower amount (1.05 equiv.) of aqueous formaldehyde (Table 2, Entry 12), giving rise to a significantly less complex reaction mixture.

This optimized protocol (refluxing THF, 0.5 h, 1.05 equiv. of aqueous formaldehyde) was extended to a number of different α-*N*-protected amino acid hydrazides **3** (Table 1). After evaporation of THF, the reaction of aqueous formaldehyde with all the hydrazides of phenylalanine **3aa**–**3ad** and valine **3bb**–**3bd**, regardless of the α-amino protection present, yielded a solid residue which was triturated in Et_2O and collected by filtration (Table 3, Method A). The ESI–MS analysis of the residues showed the presence of the corresponding monomer **4**, dimer **5**, and trimer **6**. Under the same conditions, all the other tested hydrazides **3** invariably gave an oil which eventually solidified after 1 h at 70 °C in vacuo (oil pump). The obtained solid was triturated in Et_2O and separated by filtration (Table 3, Method B); alternatively, when soluble, the resulting solution was added to pentane dropwise under stirring, obtaining a solid which was collected as above (Table 3, Method C). The ESI–MS analysis of all these residues evidenced, in addition to compounds **4**, **5**, and **6**, the presence of variable amounts of the corresponding tetramer **28** and pentamer **29** (Scheme 2).

Table 3. Treatment of the residue obtained from the reaction of α-*N*-protected amino acids hydrazides **3** and aqueous formaldehyde.

Starting hydrazide	Residue	Treatment[a]	Yield (%)[b]
3aa	Solid	A	87
3ab	Solid	A	79
3ac	Solid	A	77
3ad	Solid	A	64
3bb	Solid	A	68

3eb	Oil	B	78
3ec	Oil	C	68
3fa	Oil	C	75
3fb	Oil	B	81

[a]Method A: after evaporation of THF, the solid residue was triturated in Et_2O and filtered. Method B: after evaporation of THF, the oily residue was heated at 70 °C for 1 h under vacuum, and the obtained solid was triturated in Et_2O and filtered. Method C: after evaporation of THF, the oily residue was heated at 70 °C for 1 h under vacuum, and the obtained solid was dissolved in Et_2O. The clear solution was added dropwise under stirring to pentane and the solid, which separated off, was collected by filtration.

[b]Isolated yield taking the starting hydrazide **3** as the reference and considering the monomeric species **4** as it were the only one present.

To estimate the percentage of the different oligomers present in the above solids, the samples were analysed by LC–ESI–MS. The results (Table 4) showed that the monomer **5** was the main component in all of the mixtures obtained from the hydrazides **3** tested, ranging from a maximum when the substrate was α-*N*-Z-protected to a relative minimum when α-*N*-Boc-protection was present; however, in the last ones, the formation of the trimeric form **6** was favoured. Finally, variable amounts of tetramer **28** and pentamer **29** were always present when the residue, obtained after removal of THF, was an oil (Table 3).

Any attempt to resolve these mixtures by fractional crystallization or absorption chromatography was unsuccessful. Specifically, TLC performed on silica gel or aluminium oxide was found to cause complete hydrolysis to the starting

α-*N*-protected amino acid hydrazides **3**. The same problems were encountered in trying to resolve the complex mixtures obtained in all cases during the study of the reaction between *N*-ethoxycarbonylphenylalaninohydrazide (**3ab**) and formaldehyde (Table 2).

Data pertinent to the reaction mixtures obtained from the reaction of hydrazides **3** and formaldehyde are collected in Supplementary Data.[2] In this context, it is noteworthy to mention that the ^{1}H and ^{13}C NMR spectra of all the collected residues, recorded in DMSO-d_6 at 40 °C, showed the presence of two main products, namely, the monomer **4** and the trimer **6**. When NMR experiments were performed at high temperature (90–135 °C), a single species was invariably present. In particular, ^{1}H NMR spectra exhibited a single set of signals for each proton, namely two doublets centered at ca. 6.5 and 7.1 ppm with a coupling constant of ca. 12 Hz (two multiplets at 40 °C in the range 6.4–6.6 and 6.9–7.2 ppm), which are typical of *N*-methylene protons, thus confirming the presence of the monomeric form **4**. An identical spectral simplification was observed in the ^{13}C NMR experiments, where the *N*-methylene carbon appeared as a broad signal at ca. 136 ppm (two signals at 40 °C at ca. 135 and 138 ppm).

To check the stereochemical stability of the configuration of the chiral substrates through the whole process, the obtained compounds were hydrolysed under acidic conditions affording the corresponding hydrazides **3**, which were found to be identical to the starting materials, as evidenced by chiral HPLC analysis.

Conclusions

We have reported the detailed study of the interaction of enantiomerically pure α-*N*-amino acid hydrazides with formaldehyde. Aqueous formaldehyde in refluxing THF proved to be the best combination, affording a mixture of the monomeric condensation product and higher-order oligomers in very good isolated yield but, as evidenced by NMR analysis, at high temperature (90–135 °C) only the monomeric precursor was present. Therefore, under suitable conditions, it is possible to obtain reactive *N*-methylene derivatives containing a natural amino acid moiety which could be usefully involved in further reactions, such as $NaBH_4$ reduction to the corresponding *N*-methyl derivatives, as evidenced by preliminary experiments carried out in our laboratory (11).

Experimental section

General

All reagents were of commercial quality (Sigma-Aldrich, Fluka) and used without further purification. The α-*N*-protected amino acids hydrazides **3** were prepared as previously described (4). The reactions were monitored by ESI–MS in the positive ion mode with a Finnigan LXQ (linear trap). The intact reaction mixture was diluted with MeCN and the obtained solution was directly infused into the ion source with the aid of a syringe pump. The identities of the detected compounds were confirmed by ESI–MS–MS experiments (see Supplementary data).[2] The LC–ESI–MS analyses were obtained with the same instrument coupled with a Finnigan Surveyor LC Pump Plus equipped with an Agilent Zorbax Extend-C18 column (150 × 2.1 mm) using MeCN as the mobile phase. Chiral HPLC (hexane-2-propanol, 50:50 *v*/*v*; flow rate 0.5 mL/min; UV detector 254 nm) was performed on a Waters M-45 apparatus using a Daicel Chiracel OD column (0.46 cm I.D. × 25 cm). Direct inlet mass spectra (DI–MS) were obtained with a Fisons TRIO 2000 gas chromatograph – mass spectrometer, working in the positive ion 70 eV electron impact mode. Spectra were recorded in the range 35–450 u. Temperatures between 150 and 250 °C were found suitable to volatilise all the compounds into the ion source (see Supplementary Data).[2] IR spectra were obtained with a Nicolet FT–IR Magna 550 spectrophotometer using the KBr technique for solids and recorded in the range 4000–400 cm^{-1} (see Supplementary Data).[2] ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC-F 200 spectrometer at 200 and 50 MHz, respectively, using DMSO-d_6 as solvent at different temperatures (see Supplementary

Data).[2] Elemental analyses were performed with a Carlo Erba Mod. 1106 elemental analyser and found satisfactory (see Supplementary Data).[2] Melting points were determined with an automatic Mettler (Mod. FP61) melting point apparatus and are uncorrected (see Supplementary Data).[2] Reported values have to be considered merely indicative as referring to mixtures of monomeric and higher-order condensation products.

Reaction of the α-*N*-protected amino acids hydrazides 3 and aqueous formaldehyde

Aqueous formaldehyde (37%, 1.34 mmol, 0.10 mL) was added in one lot to a refluxing solution of the appropriate α-*N*-protected amino acid hydrazide **3** (1.28 mmol) in THF (3.6 mL), and the resulting mixture was kept under reflux for 0.5 h. After this time, the solvent was evaporated off under reduced pressure and the obtained crude mixture treated following one of the reported procedures, depending on the nature of the residue (Table 3).

Method A. After evaporation of THF, the solid residue was triturated in Et_2O and collected by filtration.

Method B. After evaporation of THF, the oily residue was heated at 70 °C for 1 h under vacuum, and the obtained solid was triturated in Et_2O and collected by filtration.

Method C. After evaporation of THF, the oily residue was heated at 70 °C for 1 h under vacuum, and the obtained solid was dissolved in Et_2O. The clear solution was added dropwise under stirring to pentane and the solid which separated was collected by filtration.

Acknowledgements

Financial support was obtained from MIUR (FURD 2001–2003 to GV). The authors are grateful to Dr. P. Martinuzzi for recording ^1H and ^{13}C NMR spectra, Dr. A. Callea for MS measurements, and Mr P. Padovani for expert instrumental maintenance.

An efficient procedure for the TEMPO-catalyzed oxidation of alcohols to aldehydes and ketones using ferric chloride hexahydrate as terminal oxidant

R. Senthil Kumar, K. Karthikeyan, and Paramasivan T. Perumal

Abstract: A simple, efficient procedure for the oxidation of alcohols by catalytic 2,2,6,6-tetramethyl-piperidyl-1-oxy (TEMPO) was developed using $FeCl_3 \cdot 6H_2O$ as the terminal oxidant. The reaction gives high yield of the corresponding aldehydes and ketones with no over oxidation to the acid.

Key words: oxidation, TEMPO, $FeCl_3 \cdot 6H_2O$.

Résumé : On a développé une méthode simple et efficace d'oxydation catalytique 2,2,6,6-tetramethyl-piperidyl-1-oxy (TEMPO) d'alcools faisant appel au $FeCl_3 \cdot 6H_2O$ comme oxydant terminal. La réaction donne des rendements élevés des aldéhydes et des cétones correspondants sans suroxydation vers l'acide.

Mots-clés : oxydation, TEMPO, $FeCl_3 \cdot 6H_2O$.

[Traduit par la Rédaction]

Introduction

Oxidation of alcohols to aldehydes and ketones is one of the important synthetic transformations that is widely employed in various simple and complex syntheses of organic compounds (1). Therefore, it is not suprising to note a number of new oxidants emerge in the literature claiming superiority over the others in terms of cost, ready availability, selectivity, and yield. These factors assume importance especially when the oxidations are performed on a larger scale. Traditional oxidants, mainly inorganic in nature, include CrO_3, $KMnO_4$, MnO_2, SeO_2, and so forth. Moreover, the derivatives of chromium based oxidants, like PCC (2) and PDC (3) that are still in use, are often required in excess stoichiometric amounts and hence result in considerable amount of chromium waste by-products. Also, since these reagents are used in two- or three-fold excess of the substrate, the cost factor also needs to be addressed.

The nitroxyl radical, 2,2,6,6-tetramethyl-piperidyl-1-oxy (TEMPO), is a stable free radical employed in various oxidations of primary and secondary alcohols (4). However, owing to the high cost of TEMPO, most protocols employ it in catalytic amount together with a stoichiometric re-oxidant. Examples include TEMPO with $NaIO_4$ (5), I_2 (6), NBS (7), polyoxometalate (8), hypochlorite (9), Oxone (10), oxygen, or air (11*a*–11*c*). Derivatives of TEMPO, such as 4-hydroxy TEMPO, 4-acetamido TEMPO, have also been reported (11*d*). Not only TEMPO oxidations were carried out in ionic liquids (12*a*) but also a task-specific TEMPO derived ionic liquid was developed (12*b*). To achieve facile separation of product from TEMPO, solid supported reagents like silica-supported TEMPO (13) and polyamine immobilized piperidinyl oxyl (PIPO) (14) were developed owing to their heterogeneous nature; they can be separated by simple filtration.

R^1 = alkyl, aryl

Results and discussion

The development of new terminal oxidants for TEMPO-mediated oxidations still continues to be an interesting area of research. The use of ferric chloride hexahydrate for its oxidising properties has been reported only in a few instances, including one by us (15). In continuing our interest in ferric chloride hexahydrate oxidation, we supposed that it could act as terminal oxidant in the TEMPO oxidation of alcohols (Scheme 1).

Accordingly, reaction of benzyl alcohol with catalytic TEMPO and stoichiometric ferric chloride hexahydrate was conducted at room temperature in CH_2Cl_2/H_2O as solvent. The reaction proceeded smoothly giving 75% of benzal-

dehyde with no over oxidation to benzoic acid. Increasing the stoichiometry of $FeCl_3 \cdot 6H_2O$ to 1.30 equiv. increased the yield to 90%. Also, EtOAc/H_2O solvent system was found to give better result than CH_2Cl_2/H_2O. Various primary and secondary alcohols were oxidized to the corresponding aldehydes and ketones in good yield using this protocol (Table 1). 1-Phenyl ethanol gave 95% yield of acetophenone. Similarly, 4-methoxy-1-phenyl ethanol gave the corresponding acetophenone derivative in very good yield. Reaction of 9-anthryl alcohol at room temperature was incomplete; however, on refluxing conditions, it gave quantitative yield of 9-anthraldehyde. Additives like NaBr or NaOAc had no substantial effect (Table 1, entry 9). Similarly, 2-cyclopentenol, 2-cyclohexenol, and 2-cycloheptenol were oxidized to the corresponding ketones in good yield. In all cases, little or no oxidation was observed in the absence of TEMPO.

Oxidation of pyrazolyl alcohols

Pyraxzolyl aldehydes are important precursors for various pyrazole compounds, such as bispyrazolylmethane (16) and pyrazolyl quinolines (17) that display useful biological properties. Pyrazolyl alcohol and its substituted derivatives were oxidized to the corresponding pyrazolyl aldehyde using this protocol in good yield. (Scheme 2, Table 2).

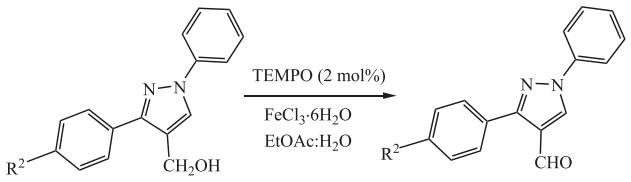
Scheme 2. Oxidation of pyrazolyl alcohols by TEMPO/$FeCl_3 \cdot 6H_2O$.



Conclusion

In sumary, a protocol for the efficient oxidation of various primary and secondary alcohols was developed using catalytic TEMPO and $FeCl_3 \cdot 6H_2O$ as co-oxidant. The procedure is operationally simple, as it requires no dry solvent or inert atmosphere and economical, as it employs the low cost $FeCl_3 \cdot 6H_2O$ in stoichiometric amount. Also, since the aldehydes and ketones are obtained in good to excellent yield, we hope this protocol will have good application in organic synthesis.

Table 2. Oxidation of pyrazolyl alcohols by TEMPO/$FeCl_3 \cdot 6H_2O$.

Entry	R^2	Product	Time (h)	Yield (%)

^{13}C NMR spectra were recorded in $CDCl_3$ and DMSO-d_6 using TMS as an internal standard on a JEOL spectrometer at 500 MHz and 125 MHz, respectively. Mass spectra were recorded on a Thermo Finnigan LCQ Advantage MAX 6000 ESI spectrometer. Column chromatography was performed on silica gel (100–200 mesh, SRL, India). Analytical TLC was performed on precoated aluminium sheets of silica gel G/UV-254 of 0.2 mm thickness (Merck, Germany).

Representative procedure for oxidation of primary and secondary alcohols to aldehydes and ketones

To 1.30 mmol of 3-(4-chlorophenyl)-1-phenylprop-2-en-1-ol in ethylacetate/water (7:3) (10 mL) was added TEMPO (0.02 equiv.), and the reaction mixture was stirred at room temperature. After 5 min, $FeCl_3 \cdot 6H_2O$ (1.69 mmol) was added, and stirring continued, following the progress of the reaction by TLC. After completion of the reaction, ethyl acetate layer was separated, and the aqueous layer was extracted with ethyl acetate (3 × 3 mL). Organic layers were combined and dried with sodium sulphate, filtered, and concentrated under reduced pressure.The residue thus obtained was purified by column chromatography to obtain the (2*E*)-3-(4-chlorophenyl)-1-phenylprop-2-en-1-one.

Benzaldehyde (100–52–7)

Colourless liquid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.49 (t, *J* = 7.7 Hz, 2H), 7.59 (t, *J* = 6.9 Hz, 1H), 7.84 (d, *J* = 7.7 Hz, 2H), 9.98 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 129.08, 129.81, 134.56, 136.45, 192.52. MS *m*/*z* = 106 M^+.

2-Nitrobenzaldehyde (552–89–6)

White solid (toluene/petroleum ether); mp 43 °C (lit. (18) 43–44 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.73–7.78(m, 2H), 7.91 (d, *J* = 9.5 Hz, 1H), 8.09 (d, *J* = 8.0 Hz, 1H), 10.38 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 124.58, 129.71, 131.40, 133.84, 134.21, 149.63, 188.29. MS *m*/*z* = 151 M^+.

3-Nitrobenzaldehyde (99–61–6)

Yellow solid (toluene/petroleum ether); mp 56 °C (lit. value (18) 58 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.76 (t, *J* = 8.4 Hz, 1H), 8.22 (d, *J* = 7.5 Hz, 1H), 8.47 (d, *J* = 7.0 Hz, 1H), 8.69 (d, *J* = 1.5 Hz, 1H), 10.11 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 124.53, 128.69, 130.51, 134.80, 137.45, 148.83, 189.90. MS *m*/*z* = 151 M^+.

4-Nitrobenzaldehyde (555–16–8)

Pale yellow solid (ethyl acetate/petroleum ether); mp 105 °C (lit. value (19) 104–106 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.06 (d, *J* = 8.4 Hz, 2H), 8.36 (d, *J* = 8.4 Hz, 2H), 10.14 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 124.38, 130.58, 140.13, 151.18, 190.49. MS *m*/*z* = 151 M^+.

4-Chlorobenzaldehyde (104–88–1)

White solid (petroleum ether); mp 45 °C (lit. (19) 45–46 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.49 (d, *J* = 8.6 Hz, 2H), 7.80 (d, *J* = 8.0 Hz, 2H), 9.95 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 129.53, 130.99, 134.77, 141.02, 190.97. MS *m*/*z* = 141 M^+.

Acetophenone (98–86–2)

Colourless liquid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.56 (s, 3H), 7.42 (t, *J* = 7.5 Hz, 1H), 7.52 (d, *J* = 8.0 Hz, 2H), 7.92 (d, *J* = 7.5 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 26.69, 128.38, 128.66, 133.21, 137.16, 198.30. MS *m*/*z* = 120 M^+.

2-Nitroacetophenone (577–59–3)

Yellow liquid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.51 (s, 3H), 7.41 (dd, *J* = 1.5, 7.6 Hz, 1H), 7.55–7.58 (m, 1H), 7.69 (dt, *J* = 1.5, 7.6 Hz, 2H), 8.02 (d, *J* = 8.4 Hz). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 30.18, 124.40, 127.43, 130.81, 134.37, 137.88, 145.82, 200.00. MS *m*/*z* = 165 M^+.

4-Methoxyacetophenone (100–06–1)

Colourless solid (petroleum ether); mp 36 °C (lit. (18) 38–39 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.56 (s, 3H), 3.87 (s, 3H), 6.94 (d, *J* = 8.4 Hz, 2H), 7.94 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 26.48, 56.62, 113.84, 127.42, 130.72, 163.60, 196.92. MS *m*/*z* = 150 M^+.

4-Bromoacetophenone (99–90–1)

White solid (petroleum ether); mp 51 °C (lit. (20) 51–52 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.58 (s, 3H), 7.60 (d, *J* = 8.4 Hz, 2H), 7.81 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 26.64, 128.40, 129.93, 131.99, 135.91, 197.14. MS *m*/*z* = 198 M^+.

4-Ethoxyacetophenone (1676–63–7)

Colourless solid (petroleum ether); mp 39 °C (lit. (18) 36–37 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.42 (t, *J* = 6.9 Hz, 3H), 2.56 (s, 3H), 4.08 (q, *J* = 6.9 Hz, 2H), 6.90 (d, *J* = 9.1 Hz, 2H), 7.91 (d, *J* = 8.4 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 14.75, 26.42, 63.83, 114.19, 130.22, 130.68, 163.00, 196.90. MS *m*/*z* = 164 M^+.

(2E)-3-(4-Chlorophenyl)-1-phenylprop-2-en-1-one

White solid (absolute ethanol); mp 110 °C (lit. (21) 111–113 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.48 (d, *J* = 6.9 Hz, 2H), 7.53 (t, *J* = 6.9 Hz, 2H), 7.63 (t, *J* = 6.9 Hz, 1H), 7.70 (d, *J* = 16.0 Hz, 1H), 7.88–7.94 (m, 3H), 8.12 (d, *J* = 7.6 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 123.27, 129.11, 129.33, 129.48, 131.13, 133.77, 134.15, 135.66, 137.96, 143.07, 189.60. MS *m*/*z* = 243 M^+. Anal. calcd. for $C_{15}H_{11}ClO$ (242.70): C, 74.23; H, 4.57; Cl, 14.61. Found: C, 74.28; H, 4.52; N, 14.69.

9-Anthraldehyde (642–31–9)

Yellow solid; (aq. acetic acid); mp 104 °C (lit. (18) 104–105 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.54 (t, *J* = 6.9 Hz, 2H), 7.67 (t, *J* = 7.6 Hz, 2H), 8.04 (d, *J* = 8.4 Hz, 2H), 8.66 (s, 1H), 8.97 (d, *J* = 9.2 Hz, 2H), 11.50 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 123.62, 124.77, 125.79, 129.23, 129.38, 131.15, 132.22, 135.35, 193.12. MS *m*/*z* = 206 M^+.

2-Cyclohexenone (930–68–7)

Brown liquid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.90–1.95 (m, 2H), 2.24–2.28 (m, 2H), 2.31–2.34 (m, 2H), 5.90–5.92 (m, 1H), 6.89–6.93 (m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 22.73, 25.69, 38.10, 129.85, 150.92, 199.86. MS *m*/*z* = 96 M^+.

2-Cycloheptenone (1121–66–0)

Pale brown liquid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.74–1.79 (m, 4H), 2.38–2.42 (m, 2H), 2.53–2.56 (m, 2H), 5.95 (d, J = 12.2 Hz, 1H), 6.50–6.55 (m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 21.78, 26.19, 30.31, 43.59, 132.55, 146.67, 204.53. MS m/z = 110 M^+.

2-Cyclopentenone (930–30–3)

Colourless liquid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.20–2.22 (m, 2H), 2.56–2.59 (m, 2H), 6.05–6.06 (m, 1H), 7.62–7.63 (m, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 28.97, 33.99, 134.46, 165.11, 210.61. MS m/z = 82 M^+.

6-Bromopiperonal (15930–53–7)

White solid (absolute ethanol); mp 128 °C (lit. (22) 132–135 °C). ^{1}H NMR (500 MHz, DMSO-d_6) δ: 6.17 (s, 2H), 7.22 (d, J = 1.5 Hz, 1H), 7.35 (d, J = 1.5 Hz, 1H), 10.00 (s, 1H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 103.85, 107.92, 113.77, 121.25, 127.88, 148.62, 153.97, 190.51. MS m/z = 228 M^+.

Representative procedure for oxidation of pyrazolyl alcohol

To 1.30 mmol of pyrazolyl alcohol in ethylacetate:water (7:3) (10 mL) was added TEMPO (0.02 equiv.), and the reaction mixture was stirred at room temperature. After 5 min, $FeCl_3 \cdot 6H_2O$ (1.69 mmol) was added, and the stirring continued, following the progress of the reaction by TLC. After completion of the reaction, ethyl acetate layer was separated from water, and water layer was extracted with ethyl acetate (3 × 3 mL). Organic layers were combined and dried with sodium sulphate, filtered, and concentrated at reduced pressure. The residue thus obtained was purified by column chromatography to obtain the pyrazole aldehyde.

1,3-Diphenyl-1*H*-pyrazole-4-carbaldehyde (4a)

Yellow solid (absolute ethanol); mp 138 °C (lit. (23) 140 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.37 (t, J = 7.5 Hz, 1H), 7.47–7.49 (m, 5H), 7.78 (d, J = 8.0 Hz, 2H), 7.82 (d, J = 6.8 Hz, 2H), 8.53 (s, 1H) 10.03(s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 119.82, 122.58, 128.06, 128.87, 129.07, 129.41, 129.77, 131.16, 131.42, 139.07, 154.85, 185.32. MS m/z = 248 M^+.

3-(4-Bromophenyl)-1-phenyl-1*H*-pyrazole-4-carbaldehyde (4b)

Pale green solid (absolute ethanol); mp 140 °C (lit. (24) 142–143 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.40 (t, J = 7.6 Hz, 1H), 7.51 (t, J = 7.6 Hz, 2H), 7.63 (d, J = 8.4 Hz, 2H), 7.76 (t, J = 7.6 Hz, 4H), 8.52 (s, 1H) 10.02(s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 119.83, 122.57, 123.83, 128.23, 129.84, 130.37, 130.54, 131.99, 132.13, 138.96, 153.31, 184.5. MS m/z = 326 M^+.

3-(4-Chlorophenyl)-1-phenyl-1*H*-pyrazole-4-carbaldehyde (4c)

Yellow solid (absolute ethanol); mp 114 °C (lit. (25) 110–113 °C). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.39 (t, J = 7.5 Hz, 1H), 7.45 (d, J = 8.0 Hz, 2H), 7.50 (t, J = 7.5 Hz, 2H), 7.76 (d, J = 8.0 Hz, 2H), 7.81 (d, J = 8.0 Hz, 2H), 8.51 (s, 1H), 10.01 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 119.80, 122.56, 128.20, 129.01, 129.82, 129.93, 130.28, 132.18, 135.51, 138.95, 153.24, 184.57. MS m/z = 282 M^+.

3-(4-Ethoxyphenyl)-1-phenyl-1*H*-pyrazole-4-carbaldehyde (4d)

Yellow solid (absolute ethanol); mp 142 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.44 (t, J = 6.8 Hz, 3H), 4.10 (q, J = 6.8 Hz, 2H), 7.01 (d, J = 8.4 Hz, 2H), 7.37 (t, J = 7.6 Hz, 1H), 7.50 (t, J = 7.6 Hz, 2H), 7.77 (t, J = 2.3 Hz, 4H), 8.51 (s, 1H), 10.03 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 14.89, 63.66, 114.81, 119.80, 122.42, 123.73, 127.95, 129.75, 130.33, 131.19, 139.14, 154.69, 160.02, 185.35. MS m/z = 292 M^+. Anal. calcd. for $C_{18}H_{16}N_2O_2$ (292.33): C, 73.95; H, 5.52; N, 9.58. Found: C, 73.86; H, 5.56; N, 9.69.

The unambiguous assignment of NMR spectra of *per-O*-methylated 6-mono and 6,6-diamino-β-cyclodextrins

Eduardo Díaz T., Christopher K. Jankowski, Celine Hocquelet, Federico del Rio P., and Héctor Barrios

Abstract: The step-by-step analysis of high-resolution proton and ^{13}C NMR spectra of *per-O*-methylated 6-monoamino and 6,6-diamino-A,D-β-cyclodextrins is described. Selected 2-D experiments (COSY, NOESY, HSQC, DEPT, and HMBC) allowed us to challenge the current interpretation. The full assignment of the proton and carbon-13 NMR spectra of these two compounds was performed enabling us to complete the assignment of NMR spectra acquired at 500 and 800 MHz for these important synthetic intermediates.

Key words: COSY, NOESY, HSQC, DEPT, HMBC, NMR, 6-amino-β-cyclodextrins, 6,6-diamino-β-cyclodextrins.

Résumé : On décrit l'analyse étape par étape des spectres RMN à haute résolution du ^{1}H et du ^{13}C de 6-monoamino-cyclodextrine et des 6,6-diamino-A,D-β-cyclodextrines *per-O*-méthylées. Des expériences bidimensionnelles choisies (COSY, NEOSY, HSQC, DEPT et HMBC) ont permis de mettre en doute l'interprétation actuelle. L'attribution complète des spectres RMN du ^{1}H et du ^{13}C de ces deux produits a été réalisée et elle permet de faire une attribution complète des spectres RMN obtenus à 500 et 800 MHz pour ces importants intermédiaires de synthèse.

Mots-clés : COSY, NEOSY, HSQC, DEPT, HMBC, RMN, 6-amino-β-cyclodextrines, 6,6-amino-β-cyclodextrines.

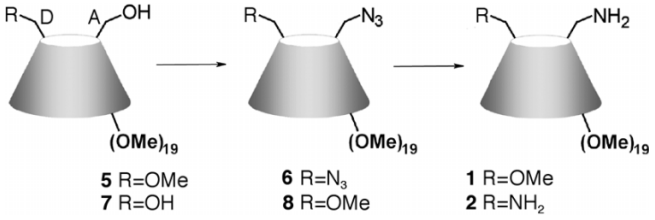
Traduit par la Rédaction]

Introduction

One of the most versatile by-products in the functionalization of β-cyclodextrins (CDs) is 6-aminocyclodextrin (**1**) (1–3). Attaching substituents to the primary faces of these molecules is both appealing and relatively easy. One can perform inclusion reactions into its cavity, using this group as an anchor; the use of linkers of various lengths from the amino group allows the design of many new syntheses (4–6). The general good reactivity of this group is extended to the whole family of CDs: α, β, and γ, as well as to their derivatives (e.g., *per*-2-hydroxypropylated CD).

Despite their easy synthesis (Scheme 1), knowledge of several polyamino CDs suffers from the lack of detailed analysis of their NMR spectra because of numerous problems resulting from the number of isomers, which leads to signal overlapped even at higher NMR fields. As a result, although the abundant literature on these molecules has often mentioned their complex spectra, there have been few attempts of any specific and complete assignment of the signals (7–10).

Scheme 1. Synthesis of *per-O*-methylated amino-β-cyclodextrins.



In this work, we report the NMR assignment of two *per-O*-methylated amino-β-CD: the monoamino 6-amino-*per-O*-methyl-β-CD (**1**) and the diamino 6,6-diamino-*per-O*-methyl-β-CD (**2**) (Fig. 1), as a challenging system for isomeric sugar signal assignment and as an exercise for elimination of isomeric structures for amino sugars using 1-D and 2-D proton and carbon NMR on both 500 and 800 MHz instruments.

The syntheses of *per-O*-methylated mono- and di-amino-β-CD were realized, as described in the experimental section (11), and the double amination of the CD in principle leads to the A,D-6,6-diamino-β-CD (**2**) (case 3, Fig. 2). For simplicity, in this paper we will label the glucose unit of cyclodextrins as A, B, C, etc., starting from the sugar bearing the amino group, instead of labeling the glucose units as I, II, etc. The formation of the second amino group on the D sugar moiety (the fourth sugar, relative to the first

amination) led to the search for the isomeric diamino structure, as well as to the confirmation by the NMR of that diamine structure is substituted on the A and D rings. The A,D-disubstituted structure could also be discussed in a step-by-step method by elimination of the A,B or A,C (case 1 or case 2 in Fig. 2) structures; it leaves the two amino-bearing sugars separated by, respectively, two and three glucose.

Arrows indicate possible NOE interaction; X means absence of this interaction.

It is important to note that we do not want to undermine the assignment (11) of the 6,6-diamino-β-CD as being A,D-substituted; however, the particular chemical shifts of protons and carbons were not described in detail. Nevertheless, several other authors (12) have used NMR to study the methoxy-CDs, as well as their perbenzylated and peracetylated derivatives.

The mono-amino-β-CD (**1**) was used as a model compound for developing the methodology to study the diamino-β-CD NMR systems. As a basis for the assignment, previously recorded high-resolution H-1 and C-13 1-D spectra allowed us to assign some signals. We chose the A-ring, an amino-substituted glucose, as a starting point for selected

2-D experiments (COSY, NOESY, HSQC, and HMBC), which allowed us to complete the interpretation; the full assignment of the proton and carbon-13 NMR spectra of this compound is presented in Table 1. The step-by-step identification of the proton and carbon signals was achieved through the NOE between the protons that are closely related in space, namely, the C-6 methylene protons toward the anomeric signal of the neighbouring glucose unit (e.g., from glucose A to glucose B).

As an example of the analysis, some interesting details are presented from the spectral identification of compound **1**.

Results and discussion

500 MHz determinations

To begin the NMR proton spectra interpretation within the 500 MHz resolution constraints, it was necessary to set the following conditions:

(*i*) The first step was to use the information obtained from the COSY and NOESY spectra (Figs. 3*a* and 4) where the protons of the glucose units (A–G) displayed chemical shifts summarized in Table 1. The COSY spectrum yielded some important information about the proton–proton couplings; however, only two types of sugar rings were observed: as indicated in Fig. 4 and detailed in Fig. 5, all rings except A display the same COSY proton–proton coupling patterns, and even at 500 MHz they remain only weakly resolved.

(*ii*) The anomeric protons of the amino group bearing glucose (A) display their ^{1}H NMR signals at a higher field (δ = 5.063, d, $^3J_{H1\text{-}H2}$ = 3.5 Hz) than those of ring B (δ = 5.14 ppm) having OCH_3 on the C-6. The ratio of the integrated intensity for these two signals compared to the signals at δ = 5.03 ppm from the remaining anomeric protons is 1:1:5.

(*iii*) The C-6 methylene signal for the A ring protons appears at a higher field (2.88 ppm) than do the signals for the other C-6 methylenes at C-6 with the usual attached methoxy (δ = 3.70, 3.45, and 3.50) as detected by DEPT and HSQC experiments.

(*iv*) Through the NOESY experiments, we observed cross-peak correlations between the amino methylene protons on C-6 of ring A and the anomeric proton of ring B, at δ = 5.14, as well as with the signals at δ = 3.70, 3.50, and 3.45. The signal of the anomeric proton at δ = 5.14 also enabled us to observe a dipolar correlation to the doublet of doublets at δ = 3.04 ppm ($^3J_{H1\text{-}H2}$ = 3.5 and $^3J_{H2\text{-}H3}$ = 10.5 Hz). These couplings are assigned for the methine at C-2 of ring B. The remaining C-2 protons for each glucose unit were observed at δ = 3.06 (6H) as a doublet of doublets, ^3J = 3.5, 10.5 Hz.

The diagonal peak due to all H-2 present on glucose units of rings A–G (δ = 3.06) displayed cross peaks with the anomeric proton of ring A (δ = 5.063) and with the anomeric proton of ring B (δ = 5.14) showing the remaining five anomeric protons from glucose units of rings C–G overlapping at δ = 5.03. The additional cross peaks from the signal at δ = 3.06 was with that of the methoxy groups at δ = 3.38 and with that of the methine at C-3 (δ = 3.30).

Table 1. Proton and ^{13}C chemical shifts (ppm) for 6^A-amino-6^A-deoxy-*per*-*O*-methylated-β-cyclodextrin (**1**). IUPAC name: 6^A-amino-6^A-deoxy-2^A,3^A-di-*O*-methylhexakis-(2$^{A–G}$,3$^{B–G}$,6$^{B–G}$-tri-*O*-methyl)-cyclomaltoheptaose (**1**).

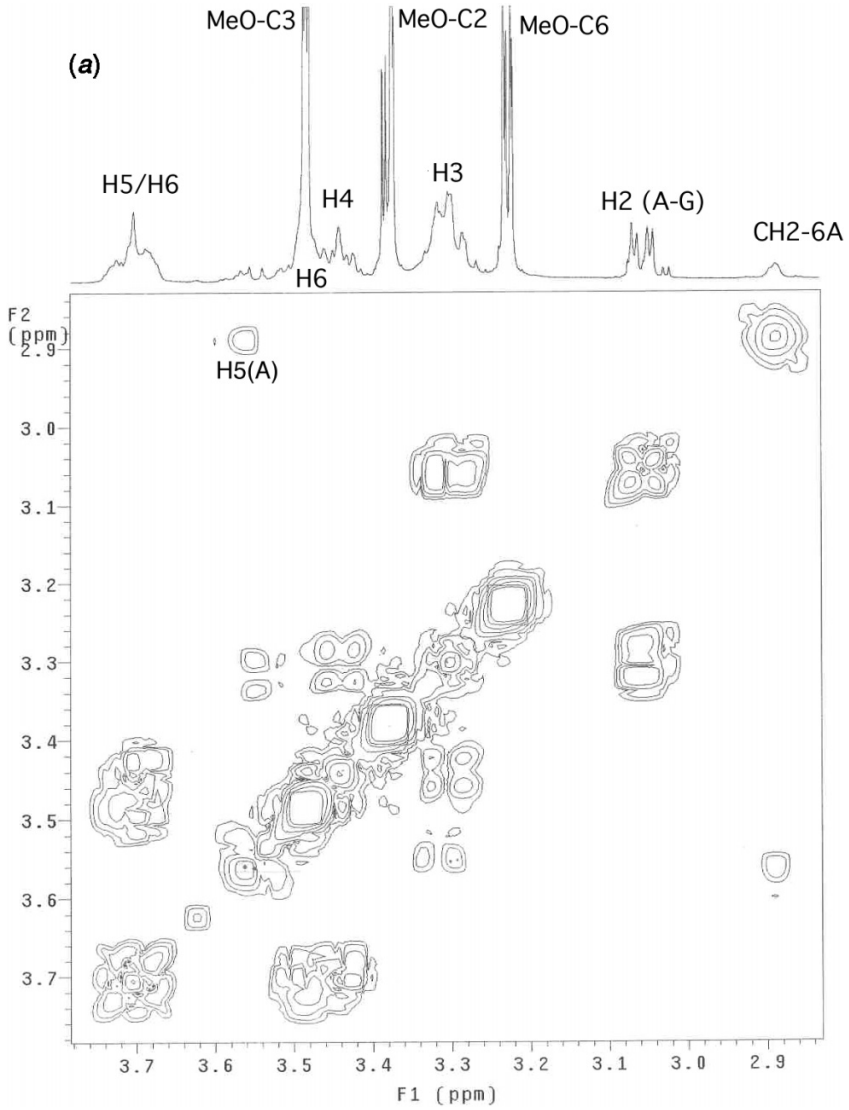
Fig. 3. COSY spectra (500 MHz, DMSO-d_6) of compounds (*a*) **1** and (*b*) **2**, respectively.



Having assigned this first NOE, we did the same for the remaining methylenes NOEs toward the next sugar (n + 1) units; the other NOEs are shown in Figs. 4 and 5.

It is interesting to note the important NOEs present for the anomeric proton of the A sugar unit were toward the H-4 of the sugar G as well as to the methoxy protons attached to C-2 (ring A) and methylene protons attached on the C-6 due to sugar G.

The signals of the methoxy groups of monoamino cyclodextrin (**1**) must be considered. The methoxy singlets partially overlapped at δ ~3.23 can be expanded to singlets at δ = 3.234 (3H), 3.232 (3H), 3.229 (3H), 3.224 (6H), and 3.220 (3H) and they were assigned for the methoxy groups attached to C-6 methylene of glucose units B–G.

On the other hand, the signal assigned to methoxy groups attached to C-2 (δ ~3.38) from the glucose units A–G was expanded to singlets at δ = 3.387 (3H), 3.382 (3H), 3.375 (12H), and 3.373 (3H). These methoxy groups displayed dipolar correlations with the methoxy groups attached to C-3 (δ = 3.48) as well as C-2 protons at δ = 3.06 in the NOESY spectrum.

Finally, the methoxy groups attached to C-3 displayed a broad peak at δ ~3.48, which upon expansion were poorly resolved into signals at δ = 3.487 (6H), 3.484 (9H), and 3.481 (6H). On the NOESY spectrum these groups also show several dipolar cross peaks with the methoxy groups at δ ~3.38 (attached on C-2), and all H-3, H-4, due to the presence of glucose units at δ = 3.30 and 3.45.

The assignment of ^{1}H and ^{13}C signals for the monoamino product **1** as determined from this analysis is presented in Table 1. From this analysis there are clearly three types of glucose present for compound **1**: aminoglucose unit A, with separate signals for H-1 (A), H-4 (A), and H-5 (A); two glucose from the amino group side of the glucose B and from its anomeric carbon side, glucose G. Glucose B also displayed for their ring protons separate signals for H-1 (B) and H-2 (B). However, the remaining glucose signals are not as well resolved because of their equivalence and similar neighbourhood, just as occured with those nitrogen free glucoses.

The HSQC ($^{1}J_{H\text{-}C}$) experiments for compound **1** allow us to confirm and assign the carbon resonance. In the last series

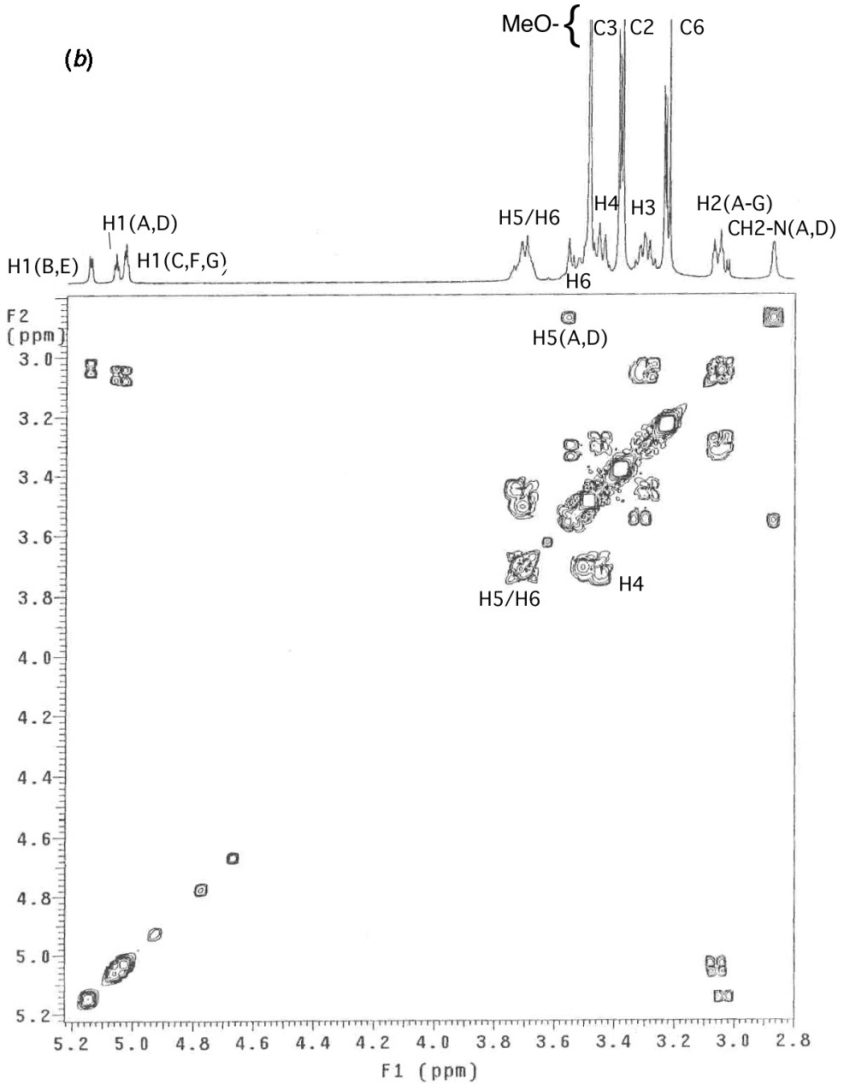
Fig. 3 (*concluded*).



of 2-D experiments, HMBC was performed to confirm the $^{2}J_{\text{H-C-C}}$ and $^{3}J_{\text{H-C-C-C}}$ coupling patterns (see Fig. 5, HMBC).

The complete ^{1}H and ^{13}C assignments of molecules of cyclodextrins discussed here were achieved by means of proton–proton and proton–carbon correlation experiments, an HSQC experiment that allowed all the one-bond proton carbon correlations to be identified, and the HMBC spectrum that allowed sufficient long range correlations to be detected to complete the assignments included in Tables 1 and 2; these are consistents for both compounds **1** and **2**.

The analysis of the high-resolution NMR spectra of compound **2** was done using the methodology developed for the mono 6-amino-β-CD (**1**), discussed in the previous section. In particular, we discuss the interpretation assuming the hypothetical formation of two other isomeric 6,6-diamino-β-CDs (case 1) with A,B-substituted sugar residues, and case 2 with A,C-substituted sugar residues (Fig. 2) as compared to the actual 6,6-diamino A,D-β-CD (11, 12). Such methodology enabled us to obtain the characteristic NMR patterns in the 2-D spectra, which should be absent for the specific structure of compound **2**.

As a first step of our analysis, we considered the NOE for C-6 methylene and for anomeric protons of the (n + 1) sugar unit, as well as the number of the equivalent sugar units in a given isomer.

The key element for the structure elucidation of 6,6-diamino-cyclodextrin comes from the symmetry considerations as well as from the shielding behaviour of anomeric protons observed in its ^{1}H NMR.

The analysis of the diamino CD (**2**) at 500 or 800 MHz begins with the doublet at δ = 5.148 ppm (^{3}J = 3.5 Hz) for the anomeric protons of equivalent sugar rings B and E. In particular, its correlation to the C-6 methylenes in rings A and D through the NOESY spectrum is striking. One triplet at δ = 5.065 (2H, ^{3}J = 3.5 Hz) is assigned to anomeric protons of ring A and D respectively. Then, the doublet at δ = 5.031 (2H, ^{3}J = 3.5 Hz) was assigned to both anomeric protons from glucose units C and G. Finally, the doublet at δ = 5.024 (1H, ^{3}J = 3.5 Hz) was assigned to the anomeric proton of sugar ring F.

The C-6 amino group with protons at δ = 2.87 displayed a broad singlet of 4H, compared to the strong well-defined

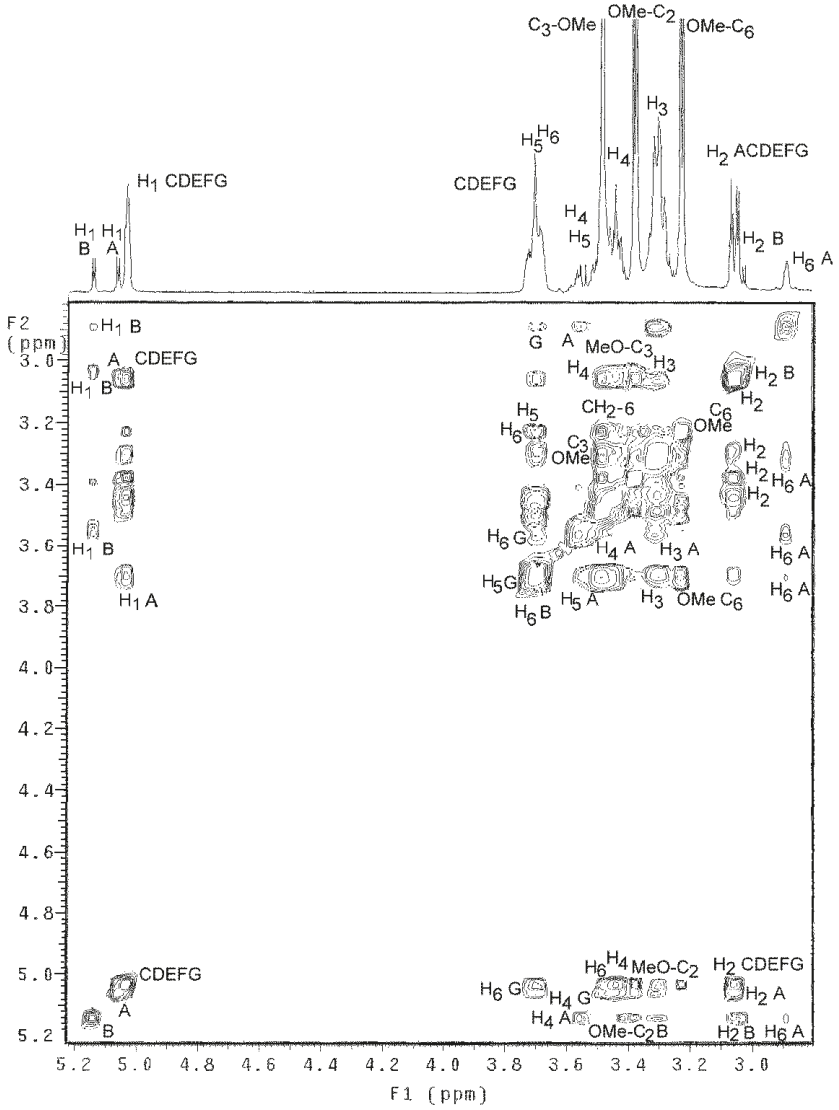
Fig. 4. Expanded NOESY for compound **1**, 500 MHz.



doublet of doublets of five protons of the C-2 methine of rings A, C, D, F, and G (δ = 3.06), leaving the doublet of doublets at δ = 3.03 assigned to C-2 protons for rings B and E.

Through the COSY connectivity, we were able to assign the C-6 aminomethylene signals at δ = 2.87 with the multiplet at δ = 3.55 (4H) assigned to the methines C-5 and C-4 of rings A and D.

Using the signals at δ = 3.06 and 3.03 of protons on C-2 methines from rings A–G, it was possible to use the COSY spectrum to assign the C-3 methine protons of sugars rings A–G at δ = 3.30. From the diagonal peaks at δ = 3.30, it was possible to evaluate the chemical shift of C-4 methine of rings A–G at δ = 3.45 and from the diagonal peaks at δ = 3.45; we also assigned the remaining protons of C-5 and C-6 carbons of the rings B and C as well as those corresponding to the sugars E, F, and G (Table 2). Through the NOESY experiment using the diagonal peaks corresponding to the aminomethylene protons at C-6 of rings A and D (δ = 2.87), we were able to confirm the methyne signals of C-1 at δ = 5.148 (rings B and E), the C-5 methine protons (2H) at δ = 3.55 and C-4 protons at δ = 3.55.

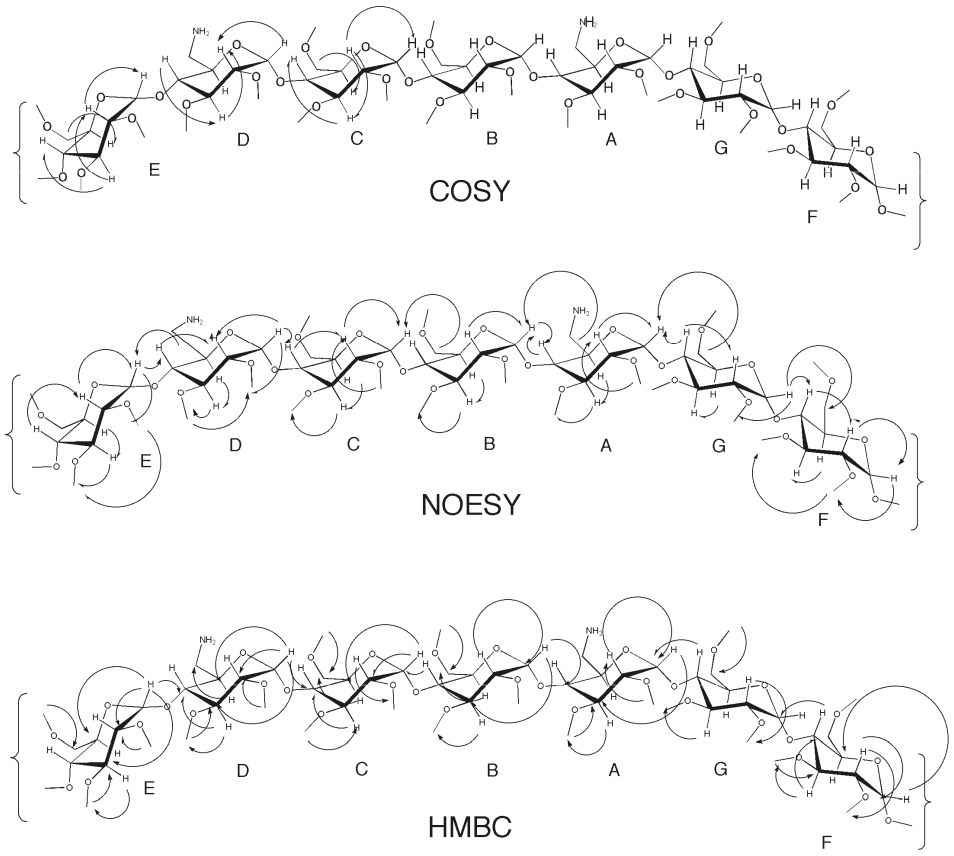
The B and E ring protons at C-1 at δ = 5.148 displayed cross-peaks to the C-6 aminomethylene protons of C-6 for rings A and D. The δ = 3.30 for C-3 methines of rings B and E, the C-4 methines of rings A and D at δ = 3.55, and the D ring protons of C-5 methines of rings A and D were identified similarly.

The methoxy groups attached to the C-2, C-3, and C-6 carbons of rings A–G were also assigned from the diagonal peaks at C-2 methines at δ = 3.06 to the corresponding signals at δ = 3.387 (6H), 3.381 (3H), 3.380 (3H), and finally 3.373 (9H) of rings A–G. Using similar identification criteria, the methoxy groups attached to C-3 (ring A–G, δ = 3.484 for 21H) and those attached to the C-6 of rings B, C, E, F, and G were assigned [δ = 3.236 (3H), 3.233 (3H), 3.228 (3H) and 3.217 (6H)].

Clearly, the case 1 for 6,6-diamino-β-cyclodextrine AB shown in Fig. 2 is not consistent with the NOESY spectrum and can be easily ruled out since only the dipolar correlation between 6-aminomethylene on ring B with anomeric proton of glucose unit C is observed. In support of this observation, no dipolar correlation was observed between aminomethylene

© 2008 NRC Canada

Fig. 5. 2-D NMR experiments on compound **2**, arrows show the interactions determined from COSY, NOESY, and HMBC spectra as discussed in the text.



on ring A and the anomeric proton of aminoglucose ring B at δ = 5.057.

The second hypothetical case, A,C-6,6-diamino-β-CD (case 2), can also be ruled out, since it should display twice the discussed NOE of CH_2-N toward the (n + 1) ring than is observed. Here there would be two different sugar triads, amino-glucose/glucose/amino-glucose (e.g., ABC) and aminoglucose/glucose/glucose (e.g., AGF).

Comparison of the ABC and AGF triads in case 2 shows that the sugar ring B may not be magnetically equivalent to sugar ring G in both different triads causing different magnetic environments on the B and G rings and consequently the C-1 proton on ring B should not be equivalent to the correspondig C-1 proton at ring G. Based on symmetry arguments discussed above this A,C substitued isomer is thus discarded from consideration.

From the above discussion, analysis of the spectrum from the *per-O*-methylated 6,6-diamino-β-cyclodextrine AD isomer (case 3) shows two types of triads in addition to three glucose triad EFG, which does not aid in the assignment as follows: ABC (and its equivalent DEF) and GAB (and its equivalent CDE). The difference is that, in GAB, the aminated sugar unit is surrounded by two glucoses, while ABC has a similar behavior with the monoamino-β-CD sequence of aminoglucose followed by two glucose units.

Rings A and D have methylene N-CH_2-6 protons correlated to the anomeric proton of the next sugar (B and E), and as a result, both protons are magnetically equivalent.

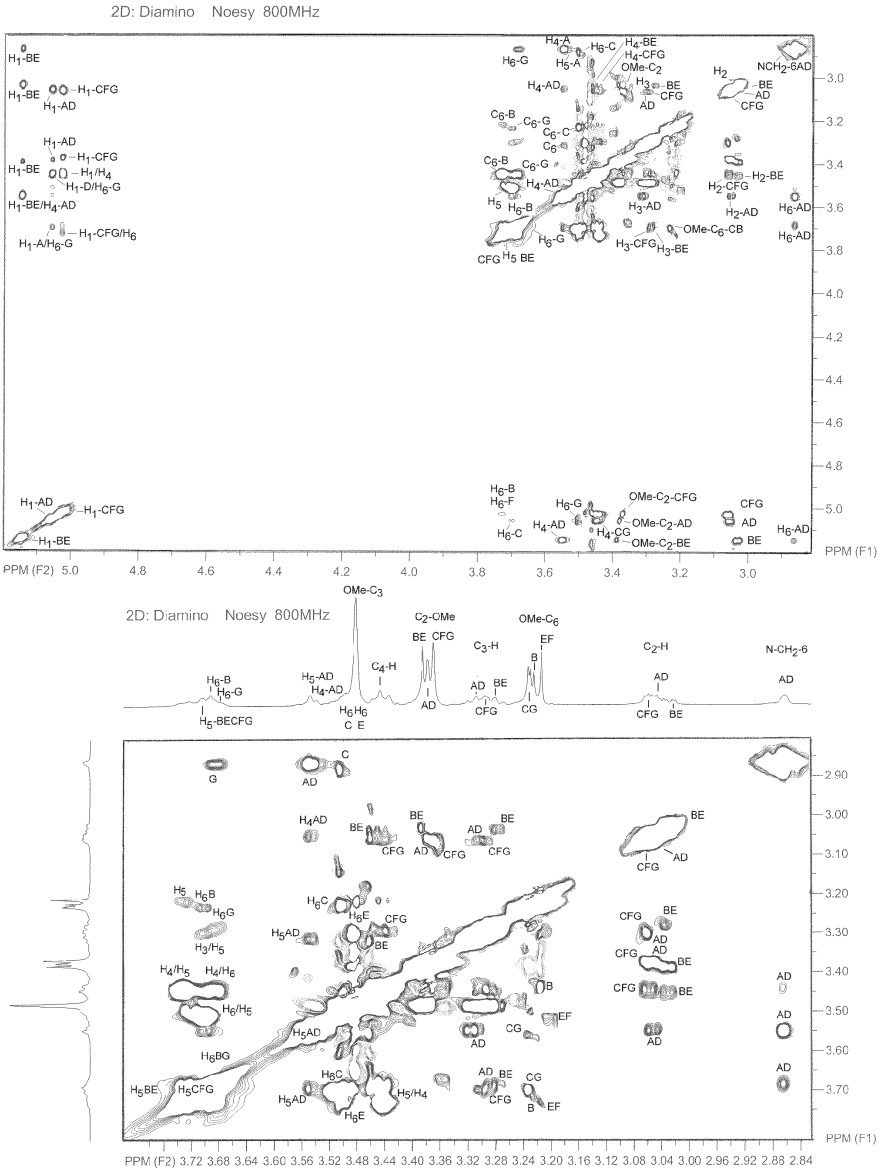
Following this analysis, COSY, NOESY, HMBC, and HSQC spectra were interpreted; the results allowed the identification of proton and carbon signals as presented in Table 2.

For both amines, the key to the analysis was the anomeric carbon chemical shift differences as seen through HSQC experiments. Because the anomeric protons in rings A and D appear at δ = 5.065, they were easily assigned to carbon methine signals at δ = 97.67. The anomeric protons from rings B and E (δ = 5.148) were assigned to the anomeric carbons at higher fields (δ = 97.47 and 97.52). The remaining anomeric protons from rings C, F, and G appears overlapped at δ ~ 5.031 and 5.024 displaying heteronuclear correlations with carbons at δ = 97.67.

The C-6 carbons of the A and D rings were easily assigned, since the proton chemical shift at δ = 2.87 correlates to the carbon at a higher field, δ = 41.7. The C-6 signals of the methylene of glucose B, C, E, F, and G were assigned respectively to δ = 71.2 (2C), 71.06 (1C), and 70.88 (2C) from DEPT experiments and these signals correlate with protons at δ = 3.50, 3.70, and 3.45, respectively. The methoxy groups attached to the C-6 were assigned as follows: the singlets at δ = 3.236 (3H), 3.233 (3H), 3.228 (3H), and 3.217 (6H) were correlated with carbon signals at δ = 58.30 (1C), 58.22 (1C), 58.07 (1C), and 58.10 (2C), respectively. Finally, the corresponding C-4 proton methine signals at δ = 3.45 were correlated with carbons at δ = 79.7 (2C), 79.44 (2C), 79.38 (1C), 79.21 (1C) and 79.06 (1C).

© 2008 NRC Canada

Fig. 6. NOESY spectra for compound **2** (*a* and *b*, details, 800 MHz).



The protons attached to C-3 at δ = 3.30 ppm were correlated to carbon signals δ = 81.6 (4C), 81.58 (2C), and 81.54 (1C), however, their further identification was not possible. The unambiguous assignment of several methoxy signals was possible from HMBC experiments. For example, the methine protons at the C-2 of rings A–G at δ = 3.06 ppm, δ_c = 81.4 and 81.2 ppm were correlated through three σ bonds with methoxy carbons at δ = 57.92 (2C), 57.90 (1C), 57.82 (1C), 57.73 (2C), and 57.70 (1C). The singlet at δ = 3.484 ppm corresponded to the methoxy attached to C-3, and it correlated through three σ bonds to C-3 methine at δ = 81.62 (3C), 81.58 (3C), and 81.54 (1C) ppm. Having in hand this complete identification of proton spectra, the carbon-13 spectrum was assigned as in Table 2; HSQC and HMBC experiments were particularly useful for these assignments. The DEPT and HSQC experiments play an important role for assigning the proton and carbons of C-6. Using the carbon signals at δ = 71.2 (2C), 71.06 (1C), and 70.88 (2C) ppm it was possible to identify the corresponding proton chemical shifts at δ = 3.70 (4H), 3.50 (1H), and 3.45 (4H).

800 MHz determinations

To improve our 500 MHz observations, we have recorded the diamino CD (**2**) spectra at 800 MHz ^{1}H NMR (1-D and 2-D NOESY experiments, DMSO-d_6). Basically, the 1-D spectrum looks similar to that recorded at 500 MHz. However, several relevant details were picked out, particularly from the 800 MHz NOESY spectrum. In principle, through the diagonal peaks from anomeric protons at δ = 5.148, 5.063, and 5.031 we could achieve the complete C_2-OMe assignment as observed in Table 2. Using the diagonal peak at δ = 5.148, the cross peak from C_2-OMe for rings B and E at δ = 3.387 was observed. Then, from the diagonal peak at δ = 5.063 due to the anomeric protons of rings A and D, through the cross peaks at δ = 3.381 and 3.380 of the methoxy groups attached to C-2 from rings A and D, and similarly

Note: Methyl signals: 7 × [CH_3-O-C-2] 4 peaks δ_H: 3.387 (6H, rings B and E), 3.381 (3H), 3.380 (3H, rings A and D), 3.373 (9H, rings C, G, and F), 5 peaks δ_C: 57.92 (2C), 57.90 (1C), 57.82 (1C), 57.73 (2C), 57.70 (1C); 7 × [CH_3-O-C-3] 1 peak δ_H: 3.484 (21H), 3 peaks δ_C: 60.70 (4C), 60.62 (1C), 60.5 (2C); 5 × [CH_3-O-C-6] 4 peaks δ_H: 3.236 (3H), 3.233 (3H), rings G and C, 3.228 (3H) ring B, 3.217 (6H), rings E and F, 4 peaks δ_C: 58.3 (1C), 58.22 (1C), 58.10 (2C), 58.07 (1C).

using the signal at δ = 5.031 we assigned the MeO-C_2- for rings CFG. Other relevant correlations obtained from the NOESY spectrum were those performed for C-2 and C-3 methine protons for rings A–G, just as detailed on Table 2.

The H-5 and H-4 for rings A and D were assigned through dipolar correlation with N-CH_2-6 (δ = 2.87). The complete assignment for the diamino-β-CD (**2**) protons extracted from 800 MHz spectrum are displayed in Figs. 6*a* and 6*b*.

Conclusions

With these complete data, we have presented an the improved interpretation and assignment of spectra of both amino-β-CDs. Data presented here may be used to perform other different CD assignments, assuming substitution of the alcohol groups by esterification or etherification, either of which greatly improves the solubility in organic solvents. It is clear, however, that even with the spectra acquired at 800 MHz, it cannot resolve the highly overlapped signals. Future analysis may be improved by taking into account the minor conformational distortions of glucose rings (which are further reduced in solution), to have a full assignment for all proton and carbon-13 signals of these interesting compounds. In particular, comparison of X-ray data and NMR proton data will improve the knowledge about these molecules.

Using a 1-D and 2-D ^1H and ^{13}C NMR spectroscopy on 6-amino-*per*-*O*-methylated and 6,6-diamino-(AD)-*per*-*O*-methylated-β-cyclodextrins (**1** and **2**), we were able to rationalize the structure of these fascinating compounds. The COSY and NOESY spectra were particulary useful in obtaining relevant information concerning ^1H-^1H couplings and ^1H-^1H dipolar correlations. On the other hand, DEPT, HSQC, and HMBC experiments enabled us to select $^1J_{C\text{-}H}$ correlations, and also to detect long-range (^2J,^3J) ^1H/^{13}C correlations in the sugar unit as well as those due to inter-rings correlations.

Experimental

As a NMR reference during this study, two permethoxylated model derivatives of β-CD were used:

Heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin, (Trimeb) **3**: ^1H NMR (DMSO): 5.12, 3.18, 3.50, 3.60, 3.79, and 3.83 (H-1 to H-6 respectively), OCH_3: 3.50, 3.64, and 3.32 (CH_3 on C-2, C-3, and C-6, respectively); ^{13}C NMR: 98.4, 81.6, 82.4, 79.7, 70.5, and 71.0 (C-1 to C-6, respectively), CH_3: 58.0, 60.9, and 58.4 (CH_3 on C-2, C-3, and C-6, respectively) (10).

Heptakis(2,6-di-*O*-methyl)-β-cyclodextrin, (Dimeb) **4**: ^1H NMR (DMSO): 4.95, 3.38, 3.6, 3.5, 3.7 (approx.), 3.95 (H-1 to H-6, respectively), OCH_3: 3.6 and 3.4 (CH_3 on C-2 and C-6, respectively); ^{13}C NMR: 101.3, 83.6, 73.1, 82.1, 70.9, and 71.4 (C-1 to C-6, respectively), CH_3: 60.3 and 58.7 (CH_3 on C-2 and C-6, respectively).

The 6-amino-CD (**1**) was synthesized according to the reported general procedure (11*b*) from products **7** and **8**.

The 6,6-diamino-CD (**2**) was obtained as a result of a two-step procedure described by Lee and co-workers (12*a*) from the dihydroxypermethylated β-cyclodextrin (**5**), which was

© 2008 NRC Canada

obtained as described by Sinay and co-workers (12*b*) via the diazide **6**.

The starting cyclodextrins were obtained from Roquette Frères (France). Most of the reagents and solvents used in this study were obtained from the Sigma-Aldrich and used without further purification. TLC was performed on Silica Gel 60 F_{254} plates (E. Merck) followed by charring with 10% (*v*/*v*) H_2SO_4 or UV.

High resolution ^{1}H and ^{13}C NMR spectra were recorded using a Varian INOVA 500 MHz spectrometer operating at 500 MHz for ^{1}H and 125.0 MHz for ^{13}C. The ^{1}H and ^{13}C chemical shifts are given in (δ) ppm relative to tetramethyl silane (TMS). The experiments were performed using an inverse detection 5 mm probe. The COSY, NOESY, DEPT, HSQC, and HMBC spectra were recorded in DMSO-d_6 solution (25 °C) using the VARIAN software. For HSQC experiments the INOVA program for short range coupling (less than 140 Hz for $^1J_{C\text{-}H}$) was used. The long range proton–carbon experiments (HMBC) were recorded with a Varian INOVA pulse program optimized for long range couplings ($^3J_{C\text{-}H}$ = 9 Hz). The 800 MHz NOESY spectra was recorded in DMSO-d_6 using a Bruker DRX 800 instrument operating on 200 MHz for ^{13}C and 800 MHz for ^{1}H and equipped with a ^{1}H/^{13}C/^{15}N/ cryoprobe. Measurements were performed at 25 °C. The spectrometer is situated in the Centre National de la Recherche Scientifique (CNRS) facilities at Gif-Sur-Yvette, France.

Synthesis

The purity of starting compounds **5** and **6** was comfirmed by the following analysis.

*6^A,6^D-Dihydroxyheptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (5)*

^{1}H NMR ($CDCl_3$, 400 MHz, ppm): 5.24 (d, $J_{H1,\ H2}$ = 4.0 Hz, 1H, H-1), 5.22 (d, $J_{H1,\ H2}$ = 3.9 Hz, 1H, H-1), 5.10 (d, $J_{H1,\ H2}$ = 3.4 Hz, 1H, H-1), 5.05 (d, $J_{H1,\ H2}$ = 3.3 Hz, 2H, H-1), 5.01 (d, $J_{H1,\ H2}$ = 3.5 Hz, 1H, H-1), 4.98 (d, $J_{H1,\ H2}$ = 3.5 Hz, 1H, H-1), 3.67–3.97 (m, H-5/H-6), 3.39–3.66 (m, H-3/H-4/H-6/OCH_3), 3.33–3.39 (m, OCH_3), 3.16–3.21 (m, 7H, H-2). ^{13}C NMR ($CDCl_3$, 100 MHz, ppm): 98.61, 98.83, 98.87, 98.94, 98.98, 99.25 (7′ C-1), 80.28, 80.82, 80.91, 81.06, 81.09, 81.35, 81.46, 81.49, 81.63, 81.68, 81.76, 81.89, 82.02, 82.07, 82.34, 82.44 (C-2/C-3/C-4), 77.88, 78.13 (2′ C-4), 71.77 (C-6), 71.66 (2′ C-5), 71.47 (C-6), 71.44 (C-5), 71.38 (C-6), 71.32 (C-5), 71.27 (C-6), 71.22 (C-5), 71.11 (C-6), 71.07 (2′ C-5), 61.70 (OCH_3-6), 61.49, 61.56 (C-6A/C-6D), 60.86, 60.92, 61.45, 61.51 (OCH_3-6), 58.02, 58.16, 58.26, 58.36, 58.52, 58.94, 59.02, 59.05, 59.07, 59.09, 59.16, 59.29 (OCH_3-2/OCH_3-3). *6^A,6^D-Diazidoheptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (6)*

Diol permethylated, **5** (713 μmol) was dissolved in 20 mL of anhydrous pyridine, 528 mg of DMAP (4.3 mmol) was added and the mixture was cooled to 0 °C. Mesylate chloride (446 μL), dissolved in 10 mL of pyridine was added dropwise. After 3 h of stirring, the mixture was evaporated to dryness, diluted in CH_2Cl_2, and washed twice with water. Organic phases were dried on $MgSO_4$, filtered, and evaporated to dryness. The residue was then dissolved in 50 mL of DMF and 1.3 g of sodium azide (20 mmol) were added, the mixture was stirred for 18 h at 65 °C. Evaporated to dryness, diluted in CH_2Cl_2, and extracted with water, the product was then purified using silica gel column chromatography (ethyl acetate then ethyl acetate–ethanol, 20:1 and 10:1) to yield 880 mg of product **6** as a white powder. Yield: 85%. R_f = 0.5 (AcOEt/EtOH/H_2O, 45:5:3). IR (KBr, cm^{-1}): 2100 (N3). ^{1}H NMR ($CDCl_3$, 400 MHz, ppm): 5.12 (d, $^3J_{H1,\ H2}$ = 3.3 Hz, 5H, H-1), 5.07 (d, $J_{H1,\ H2}$ = 3.6 Hz, 1H, H-1). 5.06 (d, $J_{H1,\ H2}$ = 7 Hz, 1H, H-1), 3.70–3.97 (m, H-5/H-6), 3.42–3.70 (m, H-3/H-4/H-5/H-6/OCH_3), 3.37–3.39 (OCH_3-2), 3.14–3.20 (m, 7H, H-2). ^{13}C NMR ($CDCl_3$, 100 MHz, ppm): 98.33, 98.37, 98.97, 99.10, 99.21, 99.27 (C-1), 80.43–82.09 (C-2/C-3/C-4), 80.15, 80.21, 80.27 (C-4), 71.08, 71.27, 71.59 (C-6), 70.77–70.95 (C-5), 61.28, 61.40, 61.43, 61.53, 61.56, 61.58 (OCH_3-6), 58.45–59.00 (OCH_3-2/OCH_3-3), 51.99, 52.04 (C-6A, C-6D).

*6^A,6^D-Diamino-6^A,6^D-didesoxy-2^{A,D},3^{A,D}-di-*O*-methylhexakis(2$^{B\text{-}G}$,3$^{B\text{-}G}$,6^{B,C,E,F,G}-tri-*O*-methyl)cyclomaltoheptaose (2)*

The diazido compound (880 mg, 606 μmol) was dissolved in 10 mL of dioxane and triphenyl phosphine (954 mg, 3.63 mmol) was added. After 4 h, 2.4 mL of ammonia was added. After overnight stirring, 150 mL of water was added and the pH adjusted to 4.0 with a 1 mol/L HCl solution. Aqueous phase was then extracted five times with toluene and made basic with a 2 mol/L NaOH solution. The resulting aqueous phase was extracted five times with CH_2Cl_2. Organic phases were dried on $MgSO_4$, filtered, and evaporated to give 790 mg of product as a white powder. Yield: 93%. R_f = 0.5 (CH_2Cl_2/MeOH, 9:1). The overall yield for diamino-β-CD (**2**) from dihydroxy-β-CD was 77%.

Acknowledgments

We would like to thank the Nuclear Research Centre of Saclay in France and the University of Moncton for constant support of this project. One of us (CH) is indebted to Dr. J.M. Mallet (École Normale Supérieure (ENS), Paris, France) for his guidance and helpful discussion on the synthesis of diamino-CD. We also thank Hector Rios, M.Sc. from Instituto de Química, Universidad Nacional Autónoma de México (UNAM), for technical NMR assistence. Many others should also be thanked.

QTAIM–DI–VISAB computational study on the Diels–Alder reaction of cyclopentadiene — On the nature of the so-called secondary orbital interactions

Nick Henry Werstiuk and Wojciech Sokol

Abstract: We have undertaken a QTAIM–DI–VISAB computational study of the dimerization of cyclopentadiene (**1**), the archetypal example of a Diels–Alder reaction that has been studied experimentally and computationally. Secondary orbital interactions (SOIs) that have gained acceptance in the interpretation of stereoselectivities seen in many cycloaddition reactions have been used to account for the fact that the endo isomer was the kinetic product of the reaction. To this point, "classical" MO analyses along with a variety of arbitrarily assigned solid and dashed lines (solid lines and bold dashes for "primary" interactions and dashed and dotted lines to differentiate between different SOI schemes) have been used in an attempt to describe the bonding of the transition states. Yet, the existence of SOIs has been challenged. Our interest in applying QTAIM to fundamental chemical problems in physical organic chemistry, with the goal of refining our knowledge of the bonding in transition-states and ground-state molecules while obviating the need to use a variety of confusing arbitrarily assigned dashed and dotted lines, led us to a QTAIM–DI–VISAB computational study of the endo and exo dimerizations of **1** at the DFT B3PW91 and MPW1PW91 levels. We have characterized the bonding interactions between cyclopentadiene rings in the various transition states and show that "normal" bonds are present where SOIs have been considered to exist. There is no need to use different types of dashed and dotted lines. An analysis of the changes in atom energies revealed that the significant destabilization of the carbon atoms in achieving the TSs (potentially leading to a very high barrier) is ameliorated by a stabilization of the hydrogen atoms leading to the relatively low barrier for the D–A reaction.

Key words: cyclopentadiene dimerization, bispericyclic transition states, DFT calculations, QTAIM–DI–VISAB analysis, bonding, atom energy analysis.

Résumé : Utilisant l'approche combinant la théorie quantique des atomes dans les molécules (TQADM) avec les indices de délocalisation (ID) et la visualisation de la proximité des bassins atomique (VPBA), on a entrepris une étude théorique de la dimérisation du cyclopentadiène (**1**), l'exemple type d'une réaction de Diels–Alder qui a déjà été abondamment étudiée tant d'un point de vue expérimental que théorique. On a fait appel aux interactions d'orbitales secondaires (IOS), qui gagnent en popularité dans l'interprétation des stéréosélectivités observées dans plusieurs réactions de cycloaddition, pour expliquer le fait que l'isomère endo est le produit cinétique de la réaction. Jusqu'à maintenant, pour essayer de décrire les liaisons dans les états de transition, on a utilisé des analyses classiques des orbitales moléculaires en combinaison avec une variété des lignes solides ou pointillées attribuées d'une façon arbitraire, telles des lignes continues et des traits gras pour les interactions primaires et des lignes pointillées pour les divers schémas d'IOS. Malgré tout, l'existence même des IOS a été mise en doute. Notre intérêt dans l'application de la théorie quantique des atomes dans les molécules aux problèmes chimiques fondamentaux de la chimie organique physique dans le but d'affiner notre connaissance de la liaison dans les états de transitions et fondamentaux des molécules tout en évitant d'utiliser une variété de traits solides ou pointillés attribués d'une façon arbitraire nous a conduit à une étude théorique de type "TQADM-ID-VPBA" des dimérisations endo et exo du produit **1** aux niveaux B3PW91 et MPW1PW91 de la théorie de fonctionnelle de densité. On a caractérisé les interactions de liaison entre les noyaux cyclopentadiènes dans les divers états de transition et on a montré qu'il existe des liaisons normales dans les cas où on a envisagé l'existence d'interactions d'orbitales secondaires. Il n'y a aucune nécessité d'utiliser des types différents de traits solides ou pointillés. Une analyse des changements dans les énergies atomiques révèle que la déstabilisation significative des atomes de carbone afin d'atteindre les états de transition, pouvant conduire à une barrière très élevée, est améliorée par une stabilisation des atomes d'hydrogène conduisant à une barrière relativement basse pour la réaction de Diels–Alder.

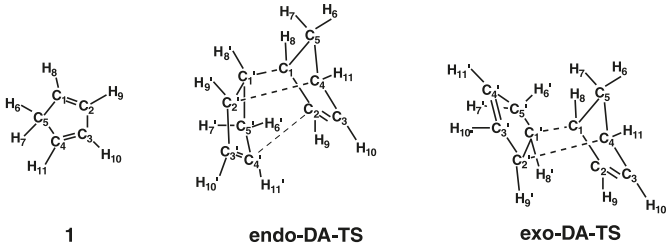
Introduction

To assist us in devising a new synthesis of bicyclo[2.2.1]hept-5-ene-2,2-diylbis(trimethylsilane) via a Diels–Alder reaction, we modeled the reaction of cyclopentadiene (**1**) with a series of dieneophiles at the DFT level focusing on reaction barriers and enthalpies of reaction. To check the accuracy of the computed barriers, we studied the dimerization of **1**, the archetypal example of a



Diels–Alder (D–A) reaction for which an experimental activation energy is available. This reaction, which was studied extensively by Alder and Stein (1), yields the endo dimer exclusively as the kinetic product, although on heating, it isomerizes to the exo isomer. Secondary orbital interactions (SOIs), now firmly entrenched in the chemical literature, have gained acceptance in the interpretation of stereoselectivities seen in many cycloaddition reactions (2) and are used to account for the fact that the endo isomer was the kinetic product. Yet, their existence was challenged by Garcia et al. in a review article in 2000 (2*d*); the authors proposed that "A combination of well-known mechanisms (such as solvent effects, steric interactions, hydrogen bonds, electrostatic forces, and others) can be invoked to justify the endo/exo selectivity of Diels–Alder reactions." In the final sentence of the conclusions, they stated that "Until the hypothesis of SOI is unequivocally demonstrated, however, we believe that Occam's razor should be used to eliminate them from the chemical literature". These proposals clearly illustrate the state of confusion that exists in the field. In 2002, Caramella et al. found that the transition state (TS) for the endo dimerization of **1** (the authors used the term bispericyclic) exhibits C_2 symmetry (3) showing that the situation was more complicated than is described in contemporary textbooks. The authors defined the PE surface at the B3LYP/6–31G(d) level showing that it exhibited a bifurcation point where the endo C_2 TS proceeded to enantiomeric dimers as well as a crest that led to a so-called Cope TS that also could yield products. The authors used a classical MO analysis as well as solid and "cross-hatched" lines to indicate partial "single" bonds along with a variety of dashed lines (bold dashes to refer to primary SOI interactions and dashed and dotted lines to differentiate between different SOI schemes) in an attempt to describe the bonding of the TSs. The question arises at what bond order (0.5, 0.6, 0.7, or other) should the solid or cross-hatched lines be invoked and when should dashed or dotted lines be used to represent bonding interactions. Currently, it appears that the selection is purely arbitrary. A standard "dashed-line" representation that is usually used in attempts to describe the bonding of the TSs is used in **endo-DA-TS** and **exo-DA-TS**.

We also found that **endo-DA-TS** exhibited C_2 symmetry during our modeling studies on the reaction of cyclopentadiene (**1**) at the DFT level. Given our long-standing interest in applying the quantum theory of atoms and molecules (QTAIM) (4) to fundamental chemical problems in physical organic chemistry (SOIs certainly must be considered as one) with the goal of refining our knowledge of the bonding in TSs and ground state molecules led us to a QTAIM–DI–VISAB computational study of the endo and exo dimerizations of **1**. In addition to using molecular graphs to define *molecular* structure and examining the properties at extrema in the topology of the density (bond critical points (CPs), ring CPs, and cage CPS), we recently showed that a combination of a normal QTAIM analysis coupled with an evaluation of delocalization indexes (DIs), and a visualization of the closeness of atomic basins (VISAB) is especially useful for characterizing the bonding in molecules at their equilibrium geometries (5–7).

There are two physical measures of bond order n. One is determined by fitting the value of ρ_b, the value of the density at a bond critical point (CP), to an empirical two-parameter expression that yields orders of 1.0, 1.6, and 2.0 for the C|C bond paths in ethane, benzene, and ethene, respectively; $n = \exp[A(\rho_b - B)]$ (4). Nevertheless, it is convenient to use values of $\rho(r)$ at bond CPs to qualitatively assess relative bond strengths. The second is determined by the pair density and expressed in terms of the delocalization index, DI(A|B), that determines the extent of exchange of electrons between two atomic basins A and B. The DI for pairs of atoms yields the number of "shared electron pairs" with values being 1.035, 1.399, and 1.935 for the C|C pairs of ethane, benzene, and ethene, respectively, in qualitative agreement with the Lewis model. DI(A|B) is an important parameter because the possibility exists to have a significant degree of delocalization and (or) sharing of electrons without having a bond path linking the atomic basins. Clearly, this is important in characterizing the so-called SOIs.

Bond ellipticity is also a useful parameter in discussing bonding. The electron density of a bond that in an orbital model possesses π character, is elliptically disposed about the bond path, being preferentially accumulated in a plane that in ethene is perpendicular to the plane of the nuclei, the plane determined by the major axis of the ellipse. The extent of this accumulation is determined by the ellipticity defined as $\varepsilon = \lambda_1/\lambda_2 - 1$ where λ_1 and λ_2 are the negative eigenvalues of the Hessian, that is, the curvatures of the density at the bond cp perpendicular to the bond path, with $|\lambda_1| > |\lambda_2|$, λ_2 being the curvature along the major axis of the ellipse, that

© 2008 NRC Canada

is, the direction of the "soft" curvature. The ellipticities of the C–C bonds in ethane, benzene, and ethylene are 0.0, 0.197, and 0.346, respectively, at B3PW91/6–31+G(d). The ellipticity has the property of determining the presence of a π-like component to the density, even in situations where the bond order is less than unity. However, this parameter is available only in cases where a bond path connects two atoms.

Finally, the ability to define the energy of an atom in a molecule enables one to determine the degree to which atoms of a reactant are stabilized or destabilized in achieving various TSs. QTAIM energies of carbon atoms bonded to hydrogen are in line with the hybridization model, with increasing "s over p character" leading to an increase in stabilization and electronegativity, as reflected in an increasing withdrawal of electrons from a bonded H. The carbon atom energies (hartrees) of ethane, ethene, and ethyne (–38.065 360, –38.087 560, –38.112 920) yield a near linear relationship (E = 35.980 45 + 0.346 × population) with respect to their electron populations (6.0284, 6.0848, 6.1650) at B3PW91/6–311+G(2d,p) with a regression coefficient of 0.998 (8). Such a "linear charge/energy relationship" enables one to determine the extent to which a carbon atom is stabilized or destabilized in a system with electron delocalization. We present only data for ethane and ethene and selected carbon atoms of **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-C_2-TS** at the B3PW91/6–31+G(d) level in this case. Very important is the fact that a carbon in benzene, with a population intermediate between that in ethane and ethene for example, is more stable than that predicted by the linear charge/energy relationship by 17 kcal mol^{-1} (1 cal = 4.184 J) at B3PW91/6–311+G(2d,p). If the C–H group is used, the increased stability of a |CH group in benzene over the same non-conjugated group in cyclohexene or *cis*-butadiene as determined by QTAIM, yields stabilization or "resonance" energies of 41 and 39 kcal mol^{-1}, respectively, for benzene that are remarkably close to the generally accepted values of 37–41 kcal mol^{-1}, the higher values obtained from heats of combustion.

In this paper, we report and discuss the results of a QTAIM–DI–VISAB study and an analysis of the changes of the energies of the atoms on the dimerization of **1**.

Computational methods

Density functional theory (DFT) calculations were performed with hybrid functionals B3PW91 and MPW1PW91 as implemented in GAUSSIAN 03 (G03) (9). Our previous experiences with DFT calculations on carbocations (10–13) clearly showed that the B3PW91 hybrid functional is superior to B3LYP in computing the geometries of delocalized so-called nonclassical species. Consequently, we used B3PW91, and for the purposes of a comparison, also decided to employ MPW1PW91 developed by Adamao and Berone (14) to better account for van der Waals forces. ChemCraft (15) and GaussView 3.0 (16) were used to fix symmetry where necessary. Finding the Cope TS to be very close to exhibiting C_2 symmetry, we also fixed its symmetry to C_2 as well. Geometries of all structures including TSs were first optimized using the default convergence criteria at the 6–31+G(d) level and re-optimized with OPT=TIGHT to obtain the wave functions. UB3PW91 and B3PW91 yielded identical results. Cartesian coordinates of the optimized geometries of **1**, **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-C_2-TS** obtained with the G03 default convergence criteria at B3PW91/6–31+G(d) are collected in Tables 1S–4S (Supplementary Data).[2] To evaluate the effect of increasing the size of the basis set, transition states were also optimized at the B3PW91/6–311+G(2d,p) with OPT=TIGHT and wave functions written. Selected calculated internuclear distances of **1**, **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-TS** are collected in Table 5S (Supplementary Data).[2]

Vibrational analyses were performed for all structures at the 6–31+G(d) level to confirm minima and transition states and evaluate reaction barriers. Thermochemical data are included in Tables 1S–4S. While we computed ($\Delta E^{\ddagger}_{\text{elec}}$, $\Delta E^{\ddagger}_{0}$, $\Delta E^{\ddagger}_{298}$, $\Delta H^{\ddagger}_{298}$, and $\Delta G^{\ddagger}_{298}$ for the reactions, only $\Delta E^{\ddagger}_{\text{elec}}$ and $\Delta H^{\ddagger}_{298}$ are included in the discussion. The results on of calculations on ethane and ethene are not reported.

Results of QTAIM analyses carried out with AIM 2000 (17) are collected in Table 6S (Supplementary Data).[2] Delocalization indexes (DIs) for selected atom pairs were obtained with LI–DICALC (18–20) are listed in Tables 7S–9S (Supplementary Data).[2] Molecular graphs of **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-C_2-TS** are displayed in Figs. 1*a*, 1*b*, and 1*c*, respectively, and re-orientated (Figs. 2*a* and 2*b*) so the C_2 symmetries of **endo-C_2-TS** and **Cope-C_2-TS** are clearly seen. Selected atomic basins obtained with AIM 2000 a contour value of 0.005 (this includes greater than 95% of the electrons) using a mesh grid size of 0.125 and plotted with a sphere size of 0.15 are displayed in Figs. 3*a*–3*f* (**endo-C_2-TS** and **Cope-C_2-TS**) and Figs. 4*a*–4*f* (**exo-C_2-TS**). AIMALL97 (21) was used for QTAIM integrations to obtain atom energies (Table 1) and atomic overlap matrices required for calculating DIs.

Results and discussion

As mentioned, we initially undertook a study of the dimerization of **1** to validate the accuracy of our calculations on a range of D–A reactions because an experimental E_a was available. That our computed barrier at B3PW91/6–31+G(d) for endo dimerization ($\Delta E^{\ddagger}_{\text{elec}}$ = 17.5 kcal/mol and $\Delta H^{\ddagger}_{298}$ = 18.6 kcal/mol) is in very good agreement with the experimental E_a of 16.7 ± 0.6 kcal/mol validates the level of theory used to obtain wave functions for this study. For exo dimerization, $\Delta E^{\ddagger}_{\text{elec}}$ and $\Delta H^{\ddagger}_{298}$ were 20.8 and 21.8 kcal/mol, respectively, nicely in keeping with the fact that the endo dimer is the kinetic product.

QTAIM–DI–VISAB analysis

The molecular graphs of **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-TS** along with the atom numbers and selected internuclear distances are displayed as Figs. 1*a*, 1*b*, and 1*c*, respectively. Figure 2 shows the molecular graphs rotated in

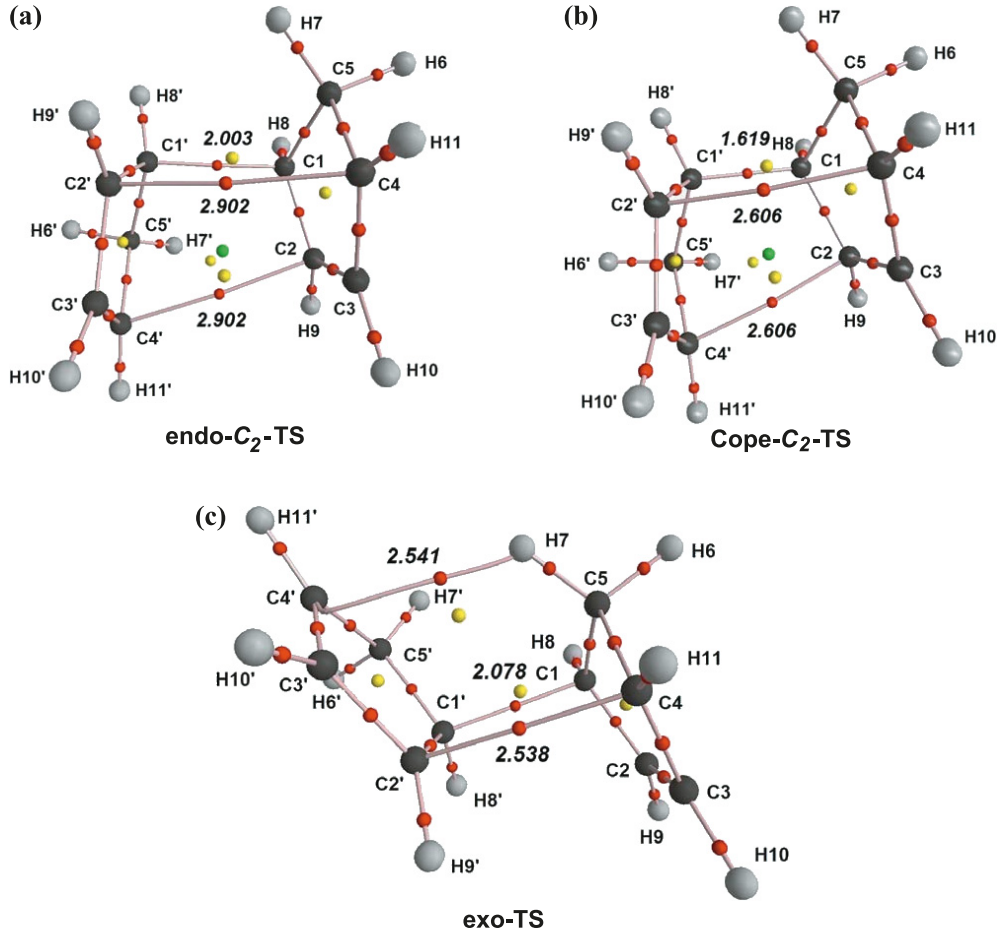
Fig. 1. Molecular graphs of (*a*) **endo-C_2-TS**, (*b*) **Cope-C_2-TS**, and (*c*) **exo-TS**. Carbon and hydrogen atoms shown as black and gray spheres, respectively. Red spheres are bond Cps, yellow spheres are ring Cps, and green spheres are cage Cps. Selected internuclear distances (Å) are displayed in italics.



space to better show the C_2 symmetries; the C_2 axes lie along a line defined by the ring CP (yellow sphere), cage CP (green sphere), and C1|C1′ bond CP (red sphere) as labeled with an arrow in the case of **Cope-C_2-TS**. Values of ρ(r) at the bond CPs, ellipticities (italics), and delocalization indexes (underlined) associated with the appropriate atom pairs are also displayed in Fig 2. Values of ρ(r) and ε at selected bond CPs and the DIs are also collected in Table 6S and Tables 7S–9S, respectively.[2] The first obvious result is that **endo-C_2-TS** and **Cope-C_2-TS** exhibit *three normal* albeit weak bonds between the five-membered rings. *Clearly there is no need to arbitrarily differentiate the three bonds with solid, cross-hatched, dashed or dotted lines, to invoke SOIs, and to attempt to characterize SOI schemes with different types of dashed lines*.

In the case of **endo-C_2-TS**, all the bonds are weak; the C2|C4′ and C4|C2′ bonds are the weakest with the ρ(r) and DI values being 0.0161 and 0.124, respectively. The nominal C1|C1′ "single" bond that was represented with a cross-hatched line rather than a dashed line by Caramella et al. (3) is also weak; a ρ(r) value of 0.0871 and a DI of 0.472 indicate that it is roughly four times as strong as the C2|C4′ and C4|C2′ bonds and half the strength of a "normal" single bond that exhibits a DI of ~1.0. The C1|C1′ and C2|C4′ (C4|C2′) bonds exhibit vastly different ellipticities. As seen from the data collected in Table 7S, the DIs are essentially independent of the level of theory used; they are virtually identical at B3PW91/6–31+G(d), MPW1PW91/6–31+G(d), and B3PW91/6–311+G(2d,p).[2] Selected atomic basins of **endo-C_2-TS** obtained at the B3PW91/6–31+G(d) level are displayed as Figs. 3*a*–3*c*. Figure 3*a* shows the C4|C2′ basins, and Fig. 3*b* shows the C2′ basin that clearly shows the flattened atomic surface shared with the C4 basin. The DI is 0.124, substantially lower than the DI of ~1.0 expected for a "normal" single bond. The relatively small shared surface of C2′ seen in Fig. 3*b* is in accord with the smaller DI found for the C4′|C2 pair. As a point of reference, Fig. 3*c* shows the C3|C3′ basins that do not impinge on each other and do not exhibit a bond path (the C3|C3′ internuclear distance is 3.395 Å) while exhibiting a miniscule DI of 0.029.

The **Cope-C_2-TS** also exhibits bond paths between C1|C1′, C2|C4′, and C4|C2′, so there is no need to invoke SOIs and use different types of lines (in this case, the C1|C1′ bond was represented with a cross-hatched line by Caramella et al. (3) line rather than a dashed line) to describe the bonding. The three bonds are stronger (roughly by a factor of two) than the inter-ring bonds of **endo-C_2-TS**. The ρ(r) values of the C1|C1′, C2|C4′, and C4|C2′ bonds are 0.1992, 0.0287, 0.0287, and the DIs 0.829, 0.232, and 0.232, respectively. These results are in accord with the C1|C1′,

C4|C2′, and C2C4′ internuclear distances that are smaller (1.619, 2.606, 2.606 Å, respectively) than the corresponding internuclear distances (2.003, 2.902, 2.902 Å) of **endo-C_2-TS**. It is noteworthy that the inter-ring bonds are considerably stronger in **Cope-C_2-TS** than in **endo-C_2-TS** yet the Cope TS is only 4.5 kcal mol^{-1} lower in energy than the endo TS. A possible reason for this result is discussed in the section on atom-energy analysis. As far as the ellipticities are concerned, C1|C1′ of **Cope-C_2-TS** exhibits a higher ellipticity than C1|C1′ of **endo-C_2-TS** while C2|C4′, and C4|C2′ exhibit lower ones. Based on the ρ(r) and DI values, the C2|C3 and C3|C4 bonds are stronger than the C1|C2

© 2008 NRC Canada

bond. By symmetry, the same situation holds for the C2′|C3′, C3′|C4′, and C1′|C2′ bonds of ring B. Based on the ρ(r) and DIs values, the C1|C2, C2|C3, and C3|C4 the π electrons are more delocalized in the case of the Cope TS (0.2648, 1.061; 0.3095, 1.373; 0.3156, 1.428) than in the endo TS (0.3031, 1.323; 0.2941, 1.245; 0.3255, 1.522). The C1|C2 bond of the Cope TS exhibits a higher ellipticity (0.063) than the C1|C2 bond of the endo TS suggesting that it is involved to a greater degree in a hyperconjugative interaction than in the case of the endo TS. Again, as seen from the data collected in Table 8S the DIs are essentially independent of the level of theory used; they are virtually identical at B3PW91/6–31+G(d), MPW1PW91/6–31+G(d), and B3PW91/6–311+G(2d,p).[2]

Selected atomic basins of **Cope-C_2-TS** obtained at the B3PW91/6–31+G(d) level are displayed as Figs. 3*d*–3*f*. Figure 3*d* shows the C4|C2′ basins, and Fig. 3*e* shows the C2′ basin that clearly shows its flattened atomic surface shared with the C4 basin. In this case, the shared surface with C4 is larger than the shared surface of **endo-C_2-TS** in accord with the fact that the DI is 0.232, almost two times as large as the DI of the C4|C2′ pair of **endo-C_2-TS**. The C4|C2′ internuclear distance (2.602 Å) of **Cope-C_2-TS** is less than the C4|C2′ internuclear distance (2.902 Å) of **endo-C_2-TS**. Figure 3*f* shows the C3|C3′ basins for which the C3|C3′ internuclear distance (2.952 Å) is marginally smaller than in the case of **endo-C_2-TS**. As in the case of **endo-C_2-TS**, the basins do not impinge on each other (the DI is marginally larger at 0.035) and do not exhibit a bond path.

The TS for exo dimerization **exo-TS** not only exhibits C1|C1′ and C4|C2′ bond paths but also a highly curved one between H7 and C4 that exhibits a ρ(r) value of 0.0121 at the bond CP; the DI is small at 0.034. The C1|C1′ ρ(r) and DIs values (0.0753 and 0.439) are similar to the values for the **endo-C_2-TS** (0.0871 and 0.472), so the C1|C1′ bond of **exo-TS** is slightly weaker than the C1|C1′ bond of **endo-C_2-TS**. However, the C4|C2′ bond is almost twice as strong (the ρ(r) and DIs values are 0.0315 and 0.240) as the C2|C4′(C4|C2′) bonds (values 0.0181 and 0.124) of **endo-C_2-TS** but of comparable strength to each of the C2|C4′ and C4|C2′ bonds (values 0.0287 and 0.232) of **Cope-C_2-TS**. C1|C2 (values 0.3039 and 1.335), C2|C3 (0.3025, 1.341), and C3|C4 (0.3142, 1.441) of ring A of **exo-TS** exhibit very similar double-bond characters. Based on the ρ(r) and DI values, ring B of **exo-TS** exhibits a greater degree of π density localization (C1′|C2, 0.3018 and 1.324: C2′|C3′, 0.2808 and 1.157; C3′C4′, 0.3327, 1.652) than ring A. The C4|C2′ basins are displayed as Fig. 4*a*. Figure 4*b* shows how the C2′ basin is flattened in sharing its interatomic surface with C4. Figure 4*c* shows the H7|C4′ basins. Figures 4*d* and 4*e* show how the C4 basin and H7 basins are "deformed" in impinging on each other. It is interesting to note that from a visual standpoint based on the deformation of the H7 basin, the same interaction occurs between H7 and C3′ (the DI is 0.024) except that there is no bond path generated.

Atom-energy analysis

The atom energies ($E(\Omega)$) of **1** (CPD), **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-TS** along with the $\Delta E(\Omega)$s in going from **1** to **endo-C_2-TS**, **Cope-C_2-TS**, and **exo-TS** are collected in Table 1. Also included at the bottom of the table are the sums $\Sigma E(\Omega)$s and the uncorrected total energies (E_{elec}) obtained from the G03 calculations along with the corresponding barriers; $\Delta E^{\ddagger}(\Omega) = 2 \times [\Sigma E(\Omega)_{CPD} - \Sigma E(\Omega)_{TS}]$ and $\Delta E^{\ddagger}_{elec} = 2 \times E_{elecCPD} \times E_{elecTS}$. First, it is important to note that $\Sigma E(\Omega)$ and E_{elec} of **1** ($\Sigma E(\Omega) - E_{elec} = -0.05$ kcal mol^{-1}), **endo-C_2-TS** (–0.50), **Cope-C_2-TS** (–0.16), and **exo-TS** (+0.08) differ only marginally from each other. These results clearly validate the AIMALL97 integration data. Consequently, the $\Delta E^{\ddagger}(\Omega)$ and $\Delta E^{\ddagger}_{elec}$ values are also close to each other; 17.54 and 17.26 kcal mol^{-1} for **endo-C_2-TS**; 12.99 and 13.01 for **Cope-C_2-TS**; 20.95 and 20.74 for **exo-TS**. These results validate an analysis based on changes in atom energies.

endo-C_2-TS

It is seen that except for C3 that is slightly stabilized (–2.69 kcal mol^{-1}), the carbon atoms of **1** are *destabilized* (a total of +73.46 kcal mol^{-1} or 36.73 per ring) in achieving **endo-C_2-TS**. C1 and C1′ are destabilized to the largest degree (each by +22.6 kcal mol^{-1}). Except for H9 and H9′ that are very slightly destabilized (each by +0.28 kcal mol^{-1}), the 10 hydrogens of **endo-C_2-TS** that gain charge are *stabilized* by a total of –56.20 kcal mol^{-1} relative to the corresponding Hs of two cyclopentadienes. Given that the carbon atoms are *destabilized* by +73.46 kcal mol^{-1}, it is the *stabilization* of the H atoms that leads to a huge lowering of the potentially high barrier for the dimerization of **1**; H7(–12.91), H7′(–12.91), H8(–8.14), and H8′(–8.14) are stabilized to the greatest degree in achieving **endo-C_2-TS**. C1 and C1′ undergo the largest sp^2 to sp^3-like change in hybridization in achieving the TS and thereby are destabilized to the greatest degree. The hydrogens attached to the sp^2-hybridized Cs are stabilized because charge is transferred from C to H as the carbon atoms undergo rehybridization. The methylene Hs also gain charge and are stabilized in all the transition states. As far as the energies of the carbon atoms of **endo-C_2-TS** are concerned relative to the relationship between population and energy for sp^3- and sp^2-hybridized carbons seen in Fig. 1S, only C3 exhibits a significant deviation.[2] Based on its population, it is stabilized by ~20 kcal mol^{-1}. This may be due in part to the fact that there is an increase in the C2–C3–C4 delocalization in **endo-C_2-TS** over **1**; the sum (2.897) of the C2|C3 and C3|C4 DIs is slightly larger for **endo-C_2-TS** than the sum (2.833) of the C2|C3 and C3|C4 DIs of **1**.

Cope-C_2-TS

While C3 is slightly stabilized (–6.90 kcal mol^{-1}), the C atoms of **1** overall are *destabilized to a greater degree* (the total is +100.62 kcal mol^{-1} or 50.31 per ring) in achieving **Cope-C_2-TS** than in the case of **endo-C_2-TS**. C1 and C1′ undergo a greater degree of rehybridization in achieving the transition state than in the case of **endo-C_2-TS** and consequently are destabilized (each by +30.2 kcal mol^{-1}) more than C1 and C1′ of **endo-C_2-TS**. Except for H9 and H9′ that are very slightly destabilized (each by +1.32), the remaining 10 Hs of **Cope-C_2-TS** are *dramatically stabilized* (–87.66 kcal mol^{-1}, 43.83 per set of five of each ring) relative to two cyclopentadienes. It is the differential stabilization of the H atoms that yields a lower energy for

© 2008 NRC Canada

Cope-C_2-TS than **endo-C_2-TS**; H7 (–16.13), H7′ (–16.13), H8 (–14.35), and H8′ (–14.35) are stabilized to the greatest degree in achieving the TS. The destabilization of C1 and C1′ is due to the fact that there is a significant sp^2 to sp^3-like change in hybridization in achieving the **Cope-C_2-TS**. Again, the hydrogens are stabilized because charge is transferred from C to H as rehybridization of the carbon atoms takes place.

exo-TS

The C atoms of **1** are not destabilized to the same degree in achieving the **exo-TS** (a total of +67.37 kcal mol^{-1}) as in the case of **endo-C_2-TS** and **Cope-C_2-TS**. Moreover, the carbon atoms of ring B are destabilized significantly more (the total is +50.34 kcal mol^{-1}) than the carbon atoms of ring A (+17.03). Surprizingly, C1′ is destabilized more (+29.73) than C1 (+19.00). Nevertheless, these atoms together are not destabilized to the same extent as in the case of **endo-C_2-TS** and **Cope-C_2-TS** because the C1–C1′ incipient bond is weaker in the case of **exo-TS** than in **endo-C_2-TS** and **Cope-C_2-TS**. Consequently, the sp^2 to sp^3-like rehybridization at C1 and C1′ is smaller in achieving **exo-TS** than in the case of **endo-C_2-TS** and **Cope-C_2-TS**. The H atoms of ring B are stabilized (–27.12 kcal mol^{-1}) more than the H atoms of ring A (–19.32).

As far as energies of the carbon atoms of the TSs are concerned relative to the relationship between population and energy (Fig. 1S), only the energies of the C3s deviate significantly (they are more stable than expected based on their populations).[2] This may be a consequence of the fact that there is a greater degree of delocalization in the TSs than in the starting material.

Conclusions

Based on the results of this work, a QTAIM–DI–VISAB study coupled with atom-energy analysis should be considered as the method of choice for detailing the nature of the bonding in transition states of cycloaddition reactions exhibiting diastereoselectivities and facial selectivities, and we plan to study several other examples. This approach obviates the need for invoking secondary orbital overlap and arbitrarily selecting and (or) using solid, cross-hatched, dashed, or dotted lines to represent bonding in cycloaddition reactions.

Carbon and silicon substitution in (4, 4) aluminum nitride nanotube — Density functional study of ^{27}Al and ^{14}N electric field gradient tensors

Ahmad Seif, Mehran Aghaie, and Hossein Aghaie

Abstract: A computational study at the level of density functional theory (DFT) was performed to investigate the influence of Si and C substitution on the ^{14}N and ^{27}Al quadrupole coupling constants (C_Q) in the armchair single-walled aluminum nitride nanotube (SWAlNNT). To this aim, a 1 nm AlNNT consisting of 28 Al and 28 N atoms was considered in which both mouths of the nanotube are capped by hydrogen atoms. Additionally, two other forms of this model of AlNNT were considered in which five Si and five C atoms were substituted in place of the five Al and five N atoms, with two rings in the length of nanotube, like a wire, in the first form; and three Si and three C atoms were substituted in place of three Al and three N atoms as a central ring on the surface of the AlNNT in the second form. The calculated C_Q values for three optimized AlNNT systems (raw and Si- and C-substituted) reveal diverse electronic environments in the above-mentioned systems. All the calculations were carried out using the Gaussian 98 software package.

Key words: armchair nanotube, density functional theory, nuclear quadrupole resonance.

Résumé : On a effectué une étude théorique au niveau de la théorie de la densité fonctionnelle (TAF) afin d'évaluer l'influence de substitutions par le carbone et le silicium sur les constantes de couplage quadripolaire (CQ) du ^{14}N et du ^{27}Al dans un nanotube d'azoture d'aluminium en chaise berçante à une paroi (SWAlNNT). À cette fin, on a considéré un nanotube d'azoture d'aluminium de 1-nm de longueur formé de 28 atomes d'aluminium et de 28 atomes d'azote dans lequel les deux extrémités d'un nanotube sont fermées par des atomes d'hydrogène. On a considéré de plus deux autres formes de nanotubes dont l'une dans laquelle on a remplacé cinq atomes d'aluminium et cinq atomes d'azotes par cinq atomes de silicium et cinq atomes de carbone en forme de cycles, tels des fils, dans la longueur du nanotube et une autre dans laquelle on a remplacé trois atomes d'aluminium et trois atomes d'azotes par trois atomes de silicium et trois atomes de carbone sous la forme de noyau central dans la surface du nanotube. Les valeurs calculées de C_Q pour les trois systèmes de nanotube d'azoture d'aluminium optimisés (le système de base et les systèmes avec des substitutions par du carbone et du silicium) révèlent l'existence d'environnements électroniques divers dans ces systèmes. On a effectué tous les calculs à l'aide d'un programme à Gaussian 98.

Mots-clés : nanotube en forme de chaise berçante, théorie de la densité fonctionnelle, résonance quadripolaire nucléaire.

Introduction

The astonishing discovery of carbon nanotubes (CNTs) by Ijimia (1) caused a rapid development in the field of nanoscale materials. In the subsequent years, extensive efforts were made to synthesize tubular or spherical nanotubes of several non-carbon inorganic materials, e.g., boron nitride (2), silica (3), and alumina (4). Chemical and physical characteristics of these novel materials, dependant on the size and shape of the nanostructures, differ from fullerenes and carbon nanotubes (5). Coaxial cubic aluminum nitride-boron nitride composite nanotubes have been already synthesized (6). Recently, the non-layered structure of hexagonal AlN nanotubes (AlNNTs) has been synthesized without template (7). Theoretical studies have demonstrated that faceted AlNNTs are energetically more favorable than the single-walled AlNNT models (8–9), while thick-walled AlNNTs are energetically comparable to AlN nanowires (AlNNWs) of similar diameter (10). However, single-walled AlNNTs have not been synthesized yet. The pioneering theoretical study of Zhang and Zhang proposed smooth and uniform diameter AlNNTs (11). Infinite armchair and zigzag AlNNTs (12), AlN fullerene cages (13), and open-ended armchair and zigzag AlNNTs nanotubes (14) have also been studied theoretically. The electronegativity of N (eN = 3.04) is con-

siderably larger than that of Al (eAl = 1.61) (15), leading to a charge transfer from Al to N, yielding asymmetric electronic charge density distribution along the AlN bond. Hence, Al atoms act as cations while N atoms act as anions in AlNNTs. The AlNNTs are suggested for optoelectronics applications (16).

Nuclear quadrupole resonance (NQR) spectroscopy is an insightful technique to study the physical properties of matter in the solid phase (17). The NQR measurable parameters are the quadrupole coupling constant (C_Q) and the asymmetry parameter (η_Q), which are both also reproduced by quantum chemical calculations of the electric field gradient (EFG) tensors. Nuclei with spin angular momentum (I) greater than one half (I > 1/2) have a nuclear electric quadrupole moment (eQ) that interacts with the EFG tensors originated at the site of quadrupole nuclei (18). The spin angular momenta are 2.5 and 1 for ^{27}Al and ^{14}N (19), respectively. Hence, the electronic densities at the sites of these nuclei are very sensitive and feel changes by any perturbation.

In this theoretical work, we study the influence of Si and C substitution on the ^{27}Al and ^{14}N NQR parameters in the (4, 4) armchair single-walled AlNNTs (Figs. 1–3) to indicate the electronic structure properties of armchair AlNNTs in the Si- and C-substituted forms. Recently, the EFG tensors were studied in a representative model of raw (6, 0) zigzag single-walled AlNNT (20), however, to the best of our knowledge, there are no available experimental NQR data for the considered AlNNTs structures in the literature. The calculated C_Q and η_Q parameters are presented in Tables 1–3. Though we can study the electrostatic properties of the considered nanotubes using the calculated data, these quantities may compared with future experimental data. To our knowledge, this work is the only theoretical quadrupole coupling constant calculation.

Computational procedure

All quantum chemical calculations were performed at the level of the density functional theory (DFT) using the Gaussian 98 software package (21). Five models of (4, 4) armchair single-walled AlNNTs with a length of 1 nm were considered. In each of the five models, both mouths of the nanotubes were capped by hydrogen atoms to saturate the boundary dangling to stabilize the models and also to simulate the effect of a longer tube. Model No. 1 (raw) consisted of 28 Al and 28 N atoms. Model No. 2 consisted of a wire-like substituted model in which five Si and five C atoms in the two rings along the length of nanotube are placed in place of five Al and five N atoms. Model No. 3 is a ring-substituted model in which three Si and three C atoms are substituted for three Al and three N atoms as a central ring on the surface of the Si- and C-substituted AlNNT. Model No. 4 is a Si- and C-substituted model in which one Si and one C atom are substituted in place of one Al and one N atom. Model No. 5 is a Si- and C- substituted model in which two Si and two C atoms are substituted in place of two Al and two N atoms (See Figs 1–5).

First, the models were allowed to fully relax during geometrical optimization using the B3LYP exchange functional method (22–23) and the 6–31G (d) standard basis set (14).

^{14}N and ^{27}Al NQR parameters (Tables 1–3). Since the EFG tensors are quantum chemically calculated in the principal axes system (PAS) ($|qzz| > |qyy| > |qxx|$), directly relating with experiments, they are converted to measurable NQR parameters, quadrupole coupling constant C_Q and asymmetry parameter η_Q. C_Q refers to the interaction energy of the nuclear electric quadrupole moment (eQ) and the EFG tensors at the site of quadrupole nucleus, while η_Q is a measure of the EFG tensors deviation from a cylindrical system at the site of the quadrupole nucleus. Equations presented in a previous work (20) are used to directly relate the calculated EFG tensors with the measurable parameters of C_Q and η_Q.

The evaluated NQR parameters at the sites of various ^{14}N and ^{27}Al nuclei for the raw and various Si- and C-substituted models of the considered AlNNT are exhibited in Tables 1–3.

Results and discussion

Geometry optimizations

At the first step of this study to calculate the minimum energy (Table 4), we performed optimization at the level of the B3LYP DFT method and 6–31G(d) standard basis set on each of raw and Si- and C-substituted models of the considered AlNNT. The results indicate that the Si- and C-substituted AlNNT in the wire-like form is more stable than other considered models. In the two-atom substitution form, one Si and one C, we found that even at the best possible position (Fig. 4), this model is more energetically unfavorable than the ring form of substitution. When we gradually add Si and C atoms to the nanotube, we observe that these patterns are more energetically unfavorable than the wire-like substitution pattern. Moreover, in the wire-like substituted pattern, the bond lengths of Al–C and N–Si around the wire are 1.90 and 1.72 Å, respectively. But the bond lengths of Al–C and N–Si in the ring-substituted model are 1.96 and 1.80 Å, respectively. On the other hand, in the wire-like substituted model, the bond lengths of Al–C and N–Si are shorter than those of other substituted patterns. Our study shows that Si and C have alternative positions because when we substitute six Si atoms for three Al and three N atoms in the ring-substituted form of AlNNT, the ring will open and the nanotube structure will disarrange.

C_Q parameters

In this work, the influence of Si- and C-substitution on the electronic structure properties of armchair AlNNTs is studied by DFT calculations of the EFG tensors at the sites of various ^{27}Al and ^{14}N nuclei in three models of raw and Si- and C-substituted (4, 4) single-walled AlNNTs (Figs. 1–3). In the Si- and C-substituted models, although the wire-like substituted form is energetically stable, we also considered the ring-substituted model for a better comparison. First, the models were optimized and then the NQR (C_Q and η_Q) calculations were carried out on the three optimized structures (Tables 1–3). In the following, the evaluated NQR parameters at the sites of the ^{27}Al and ^{14}N nuclei in the raw and Si- and C-substituted models of the considered (4, 4) AlNNT are discussed.

Table 4. The energy values for raw and Si- and C-substituted AlNNTs.

Models	Energy (KeV)
Raw	–226.759
Si- and C-substituted (wire-like)	–230.891
Si- and C-substituted (ring)	–225.858
Si- and C-substituted (one pair)	–224.220
Si- and C-substituted (two pairs)	–224.210

The raw AlNNT model

This section focuses on the calculated EFG tensors at the sites of various ^{27}Al and ^{14}N nuclei in the raw (4, 4) AlNNT model (Table 1 and Fig. 1). The results reveal that the nuclei are divided into seven layers with equivalent electrostatic properties in each layer. Since there is almost no significant difference in the calculated NQR parameters at the sites of nuclei in each layer, the average values in each layer are reported in Table 1 for ^{27}Al and ^{14}N nuclei. There are three kinds of chemical bonds in this model including Al–N, N–H, and Al–H bonds in different positions of the nanotube. The N–H and Al–H bonds are located at the mouths of the nanotube, and the Al and N nuclei contributing to these bonds in layers 1 and 7 have the largest magnitudes of C_Q among other the nuclei, in which the larger C_Q refers to the higher electron density at the sites of the nuclei. In contrast with Zigzag AlNNTs having two different mouths with similar Al and N atoms (Al-mouth and N-mouth), the armchair AlNNTs have two similar mouths, but each one consists of different Al and N atoms. Therefore, similar NQR parameters are calculated for the two mouths of the considered model (layers 1 and 7). Furthermore, the magnitudes of C_Q for each of the ^{27}Al and ^{14}N nuclei in layers 1 and 7 are the largest; in moving to the middle of the nanotube, the magnitudes are reduced; in layer 4 C_Q has the smallest magnitude. Almost parallel results are also observed for changes of η_Q along the length of the considered AlNNT.

The Si- and C-substituted AlNNT models (wire-like and ring-substituted patterns)

The Si and C atoms substitution of the considered (4, 4) AlNNT model is the focus in this section (Tables 2 and 3 and Figs. 2 and 3). Five Si and five C atoms are substituted in place of five Al and five N atoms to create two rings along the length of the nanotube in the wire-like substituted pattern, while three Si and three C atoms are substituted in place of three Al and three N atoms as a central ring on the surface of the nanotube in a ring-substituted pattern. In both of Si- and C-substituted models, there are six kinds of chemical bonds including Al–N, Al–H, N–H, Al–C, Si–C, and N–Si, which makes the front side of the raw and Si- and C-substituted AlNNT models completely different. The optimization process yielded an average Al–N bond length of 1.81 Å in the raw model, and this value is also observed for the back side of the substituted models in which the Al and N atoms are located far from the substituted Si and C atoms. However, on the front side, the bond length of Al–C for both

© 2008 NRC Canada

of the substitution models, wire-like and ring-substituted, are increased to almost 1.90 and 1.96 Å, respectively, and that of N–Si is reduced to almost 1.72 and almost 1.80 Å, respectively, yielding different electronic properties at the sites of those Al and N nuclei directly contributing to these bonds and also to the neighborbonds. In addition, since Al and N play cation and anion roles in AlNNTs, substituting Si and C for one of them in Al–N makes significant changes in the electronic density at the sites of these nuclei. Tables 2 and 3 exhibit the calculated NQR parameters for ^{27}Al and ^{14}N nuclei in the considered models. Only $C_Q(^{14}N)$ at the sites of those nitrogen nuclei, which are directly bonded to Si, are significantly increased in the wire-like substituted form; however, this parameter at the sites of both ^{14}N and ^{27}Al nuclei that are directly bonded to Si and C are significantly increased in the ring-substituted form of AlNNT. Furthermore, since N has a lone pair of electrons in the valance shell, the nucleus feels more electron density compared with Al. Therefore, in the two Si and C-substituted models, the NQR parameters of ^{14}N undergo more significant changes than those of ^{27}Al. Meanwhile, the change of C_Q values at the sites of the ^{14}N nuclei, which are directly bonded to Si in the ring-substituted model of AlNNT, is more significant rather than that of the ^{14}N nuclei, which are directly bonded to Si in the wire-like substituted form of the considered AlNNT model. It is noted that other nuclei in the back side of the Si- and C-substituted models do not exhibit any changes because of Si- and C-substitution. As mentioned earlier, the magnitude of the NQR parameters is the largest at the nanotube mouths, meaning that the highest electron density at the sites of Al and N nuclei is located at the mouths. Therefore, since the NQR parameters at the sites of N nuclei (for both of substituted models) and at the sites of Al nuclei (for ring-substituted), which are directly bonded to Si and C, are significantly increased, then the Si and C-substituted form of AlNNT model may be expected to be more useful in those applications of AlNNTs in which mouth properties are important. This trend means that the active sites of AlNNT are increased by Si and C-substitution in the Si and C-substituted AlNNT models. The values of η_Q are also increased at the sites of the Al and N nuclei directly bonded to C and Si, meaning that the EFG tensors at the sites of these nuclei are more deviated from cylindrical symmetry.

Conclusion

We performed a DFT study to investigate the influence of Si and C-substitution on the electronic structure properties of AlNNTs by calculating the NQR parameters at the sites of ^{27}Al and ^{14}N nuclei. The calculated minimum energies reveal that the wire-like substituted model is energetically more favorable than other substituted patterns. In addition, by the calculated NQR parameters at the sites of various ^{27}Al and ^{14}N nuclei in the three forms of raw, wire-like substituted, and ring-substituted of the considered (4, 4) AlNNT, some remarkable trends were discovered. First, the calculated EFG tensors reveal that various Al and N nuclei along the length of the raw AlNNT are divided into some layers with equivalent electrostatic properties in each layer. Furthermore, the magnitude of C_Q is largest for both Al and N nuclei located at the mouths of the nanotube; however, this magnitude is the smallest for those nuclei located at the middle of the nanotube. Second, the NQR parameters of the middle layer of the raw AlNNT may be extended to the longer armchair AlNNTs. Third, the optimization process yielded an average Al–N bond length of 1.81 Å in the raw and back side of Si- and C-substituted forms of the considered model of AlNNT, however, the bond lengths of Al–C and N–Si undergo changes to 1.90 and 1.72 Å for wire-like and 1.96 and 1.80 Å for ring–substituted forms of AlNNT. Fourth, in addition to having the largest C_Q magnitudes of Al and N nuclei located at the mouths in the wire-like substituted pattern, the N nuclei, which are directly bonded to Si, also have C_Q magnitudes as large as those at the mouths of the nanotube. Fifth, in addition to the largest C_Q magnitudes of Al and N nuclei at the mouths, in the ring-substituted pattern, the Al and N nuclei that are directly bonded to C and Si also have C_Q magnitudes as large as those at the mouths of the nanotube. This trend means that because they have more active sites, the Si and C-substituted models may be expected to be more appropriate for those applications in which the mouth properties are important.

Hydrolysis of dimethylphenyltin(IV) and triphenyltin(IV) chlorides in different aqueous ethanol solutions

Morteza Jabbari, Farrokh Gharib, Mostafa Mohammadpour Amini, and Amirreza Azadmehr

Abstract: The hydrolysis of $[(Me)_2(Ph)Sn(IV)]^+$ and $[(Ph)_3Sn(IV)]^+$ has been investigated at 25 °C and different aqueous solutions of ethanol, using a combination of spectrophotometric and potentiometric techniques. The species formed together with their formation constants have been determined using the computer program Squad over a wide pH range of 1 to 11. The hydrolysis constants in different media were analyzed in terms of Kamlet and Taft parameters. Single-parameter correlation of the formation constants, K_{11} and K_{12}, versus α (hydrogen-bond donor acidity), β (hydrogen-bond acceptor basicity), and π* (dipolarity/polarizability) for both cases are relatively poor in all solutions, but multiparameter correlation represents significant improvement with regard to the single-parameter models. In this work, we have also used the normalized polarity parameter, E_T^N, alone and in combination with the Kamlet–Taft parameter to find a better correlation of the formation constants in different aqueous ethanol solutions.

Key words: dimethylphenyltin(IV) chloride, triphenyltin(IV) chloride, hydrolysis constant, aqueous ethanol solutions, solvent effect.

Résumé : On a étudié l'hydrolyse des cations $[(Me)_2(Ph)Sn(IV)]^+$ et $[(Ph_3)Sh(IV)]^+$ en faisant appel à une combinaison de techniques spectrophotométriques et potentiométriques et en opérant à 25 °C, dans diverses solutions aqueuses d'éthanol. Faisant appel au programme informatique Squad, on a déterminé la nature des espèces qui se forment ainsi que leurs constantes de formation pour une plage de pH allant de 1 à 11. Les constantes d'hydrolyse dans les divers milieux ont été analysées en fonction de paramètres de Kamlet et de Taft. Dans les deux cas, les corrélations de paramètres uniques des constantes de formation, K_{11} et K_{12} en fonction d'α (acidité d'une liaison hydrogène donneur), de β (basicité d'une liaison hydrogène accepteur) et de π* (caractère dipolaire/polarisabilité) sont relativement mauvaises pour toutes les solutions; toutefois, les corrélations à plusieurs paramètres présentent des améliorations sensibles par rapport aux modèles à un seul paramètre. Dans ce travail, on a aussi utilisé le paramètre de polarité normalisée, E_T^N, seul ou en combinaison avec le paramètre de Kamlet–Taft, pour déterminer une meilleure corrélation des constantes de formations dans les diverses solutions aqueuses d'éthanol.

Mots-clés : chlorure de diméthylphénylétain(IV), chlorure de triphénylétain(IV), constante d'hydrolyse, solutions aqueuses d'éthanol, effet de solvant.

Introduction

Organotin(IV) complexes have been found to exhibit relatively high antitumour activity (1–15). Several authors have tried to elucidate many aspects of these complexes, such as their structures, stability constants, binding sites, chelating donor atoms of a ligand, and so forth (1–15). The structures adopted by the di- and tri-alkyltin(IV) ions in aqueous solutions appear to have linear C-Sn-C and planar skeletons, respectively (16–17). Information pertaining to the structure and behavior of these ions in solution at different pHs has been the subject of many recent papers. These ions have rather unusual effects on the structure in water as a solvent. There should be a particularly pronounced ordering of water molecules in the equatorial plane of the dialkyltin(IV) ions because of the strong electrostatic field near the tin atom. In addition, the hydrophobic nature of the alkyl groups will tend to force more hydrogen bonding in the solvent around the axial positions.

Owing to antitumour activity, we have recently begun to investigate several reaction equilibria of organotin(IV) species with some ligands, particularly those of biological interest, such as amino acids, peptides, and nucleotides. The main objectives of the research are to establish the stoichiometries, structures, and stability constants of the reactions of organotin ions with a range of ligands having a variety of donor atoms. The effect of varying reaction media, such as ionic strength, ionic media, and using different aqueous–organic solvents on the stability, hydrolysis, and protonation constants are also investigated.

Now we have extended our work to triorganotin(IV) with mixed alkyl and aryl substitution bonded to tin for complexation framework study. Accepting the hypothesis that R_2Sn^{2+} and R_3Sn^+ are the usual active species for antitumour action of organotins (18), a good antitumour agent should be easily dissociable following administration. This requires weak bonds between tin and the donor atom of the coordinated ligands, which are readily hydrolysable. If the compound is hydrolytically unstable, the R_2Sn^{2+} and R_3Sn^+ moieties will be released too soon, and if it is too stable it may be released too slowly and consequently lower activity will be observed. Therefore, there is a relationship between the stability of the organotin compounds and their antitumour activity.

Organotin cations are considered to be acids, in the Lewis scale, of different hardness, depending on the groups bonded to the tin(IV). Consequently, they show a strong tendency to hydrolysis in aqueous solution, as demonstrated by several authors (5–9). Other studies on the interactions of organotin cations with O-donor ligands have been recently reported, confirming the results obtained previously in the hydrolysis investigations (19–21).

This work deals with the study of hydrolysis of $(CH_3)_2C_6H_5Sn(IV)$ and $(C_6H_5)_3Sn(IV)$ to investigate the effect of a changing dielectric constant on the hydrolysis of triorganotin(IV).

Experimental section

Chemicals

Sodium perchlorate was obtained from Merck as an analytical reagent grade material and was dried under vacuum at room temperature for at least 72 h before use. The NaOH solution was prepared from a titrisol solution (Merck) and its concentration was determined by several titrations with standard HCl solution. Perchloric acid, ethanol (absolute), and triphenyltin(IV) were obtained from Merck and Fluka, respectively, as analytical reagent grade materials and were used as supplied. Dilute acid solution was standardized against standard NaOH solution. Dimethylphenyltin(IV) chloride was synthesized following the procedure described before (18). All dilute solutions were prepared from double-distilled water with specific conductance equal to $1.3 \pm 0.1\ \mu\Omega^{-1}\ cm^{-1}$.

Apparatus

A Jenway research pH-meter, model 3520 (with a precision of 0.001 units), was used for pH measurements. The hydrogen ion concentration was measured with a combination electrode (Jenway). Spectrophotometric titrations were performed on a UV–vis Shimadzu 2100 spectrophotometer (with a precision of 0.0002 units) combined to a Pentium 4 computer and using thermostated matched 10 mm quartz cells. The measurement cell was of flow type. A Masterflex pump allowed circulation of the solution under study from the potentiometric cell to the spectrophotometric cell. So, the absorbance and pH of the solution could be measured simultaneously.

Measurements

All measurements were carried out at 25 °C. The ionic strength was maintained with sodium perchlorate, 0.1 mol dm^{-3}, as supporting electrolyte. The pH-meter was calibrated for the relevant H^+ concentration with a solution of 0.01 mol dm^{-3} of $HClO_4$ solution containing 0.09 mol dm^{-3} sodium perchlorate (for adjusting the ionic strength to 0.1 mol dm^{-3}). We set $-\log[H^+] = 2.0$ (22). Junction potential corrections have been calculated from eq. [1]

$$[1] \qquad -\log[H^+]_{real} = -\log[H^+]_{measured} + a + b[H^+]_{measured}$$

where a and b were determined by measuringthe hydrogen ion concentration for two different solutions of perchloric acid with sufficient sodium perchlorate to adjust the ionic strength.

Procedure

Acidic solution (50 mL) of dimethylphenyltin(IV) or triphenyltin(IV) chlorides, ($1.0–2.0 \times 10^{-3}$ mol dm^{-3}), was titrated with an alkali solution, 0.1 mol dm^{-3} NaOH with the same ionic strength and mole fraction of ethanol. Due to insolubility of triorganotin(IV) in water, aqueous ethanol solution has been used. The $-\log[H^+]$ and absorbance were measured after addition of a few drops of titrant, and this procedure was extended up to the required $-\log[H^+]$. To exclude carbon dioxide from the system, a stream of purified nitrogen was passed through a sodium chloride solution and then bubbled slowly through the reaction solution. In all cases, the procedure was repeated at least three times and the resulting average values and corresponding standard deviation are shown in the text and tables.

Calibration of the glass electrode

The glass electrode potential in an aqueous solution differs from that in a solution of mixed solvents, and a liquid-junction potential of uncertain magnitude may affect the results. To overcome this difficulty, it was necessary to calibrate the glass electrode in different solvent mixtures. The experimental method outlined by Van Uitert and Hass (23) and the proposed eq. [2] were employed for this purpose.

$$[2] \qquad -\log[H^+] = B + \log\mu_H^\circ + \log\gamma_\pm$$

Where B is the actual pH-meter reading, $\gamma_\pm$ the mean activity coefficient of perchloric acid in the solvent mixture at the same temperature and ionic strength, and μ_H° is the correction factor. Values of B (pH-meter readings) were recorded in various aqueous solvent mixtures ranging from 50% to 80% (*v*/*v*) ethanol containing a known concentration of perchloric acid and sufficient sodium perchlorate to give a constant ionic strength of 0.1 mol dm^{-3}. The difference between the logarithm of the known hydrogen ion concentration and the corresponding values of B was used to calculate values of the correction term, $\log\mu_H^\circ$.

Results and discussion

Organotin(IV) generally hydrolyzes to form a series of mono- and poly-nuclear hydroxo complexes. The hydrolysis reaction, in general, could be as

© 2008 NRC Canada

[3] $pM^{n+} + q(OH)^- \leftrightarrows M_p(OH)_q^{(np-q)+}$

with the hydrolysis constant, K_{pq},

[4] $K_{pq} = [M_p(OH)_q^{(np-q)+}] / [M^{n+}]^p[OH^-]^q$

In the case of dimethyltin(IV), as reported earlier (1), the following mono- and di-nuclear complex species were considered $[M(OH)]^+$, $[M(OH)_2]$, $[M(OH)_3]^-$, $[M_2(OH)_2]^{2+}$, and $[M_2(OH)_3]^+$, where M represents $(CH_3)_2Sn^{2+}$. The investigation was performed in the pH range of 1 to 11 employing a nonlinear curve fitting method, with this notation that the dinuclear hydroxo species never exceeded 6% of the total dimethyltin(IV) (1).

To the best of our knowledge there have been no reports on determination of the hydrolysis constant of dimethylphenyltin(IV) species. Using again eq. [3], the hydroxo complex species of the triorganotin ions were studied. The hydrolysis constant values, K_{pq}, were determined spectrophotometrically on the basis of the relation $A = f(pH)$. Absorbance, A, and $-\log[H^+]$ were measured for a solution containing $(CH_3)_2C_6H_5Sn^+$ or $(C_6H_5)_3Sn(IV)^+$ with sufficient NaOH solution, as described before. Treatment of the spectrophotometric data in the range of 230 to 280 nm (with an interval of 1 nm) was obtained during the titrations as a function of H^+ concentration analyzed by the computer program Squad (24). The final selection of the species resulting from the computer program was based on graphical fitting. In addition, the various statistical criteria, i.e., sums of the squared residuals and the difference of total concentration of the metal ion existing experimentally in solution from the calculated ones, were considered.

The program allows calculation of the hydrolysis constant for different stoichiometry models. Different models including $[M(OH)]$, $[M(OH)_2]^-$, and several polynuclear species with various hydroxyl groups were tested by the program, where M is $(CH_3)_2C_6H_5Sn^+$ or $(C_6H_5)_3Sn^+$. As expected, polynuclear species were rejected by the program, as were $M_2(OH)$, $M(OH)_3$, $M_2(OH)_2$, and M_2O (charges are omitted for simplicity). Values of these parameters for $M_2(OH)$ were also calculated for both systems, but the species was not considered further because the estimated error in its formation constant was unacceptable and its inclusion does not improve the goodness of the fit. The species finally chosen were $M(OH)$ and $M(OH)_2^-$, resulting in a satisfactory graphical fitting. The average values of the computed hydrolysis constant of the metal ions for the wavelengths range used in this study and different runs at various media are listed in Table 1 and their mole fractions are plotted in Fig. 1 versus $-\log[H^+]$.

The hydrolysis of triphenyltin(IV) ion in dioxane–water solution was previously investigated (25) and only one hydrolytic species had been characterized. For clarification, we applied the computer program in two ways: first calculating only one hydrolysis and second calculating two hydrolysis equilibria of triphenyltin(IV). The estimated error resulting from the computer program for the first assumption is about 100 times more than that for the second one. It is also interesting to note that log K_{11} obtained from the first method (in the solution of ethanol–water 70:30 by volume) resulted in the value of 5.43, which is very close to the value reported before in 75% dioxane–water solution, 5.71.

Table 1. Average values of hydrolysis constants for $Me_2PhSn(IV)$ and $Ph_3Sn(IV)$ species in different aqueous solutions of ethanol at 25 °C and an ionic strength of 0.1 mol dm^{-3} ($NaClO_4$).

Ethanol (% *v*/*v*)	pK_{11} (Me_2PhSn)	pK_{12} (Me_2PhSn)	pK_{11} (Ph_3Sn)	pK_{12} (Ph_3Sn)

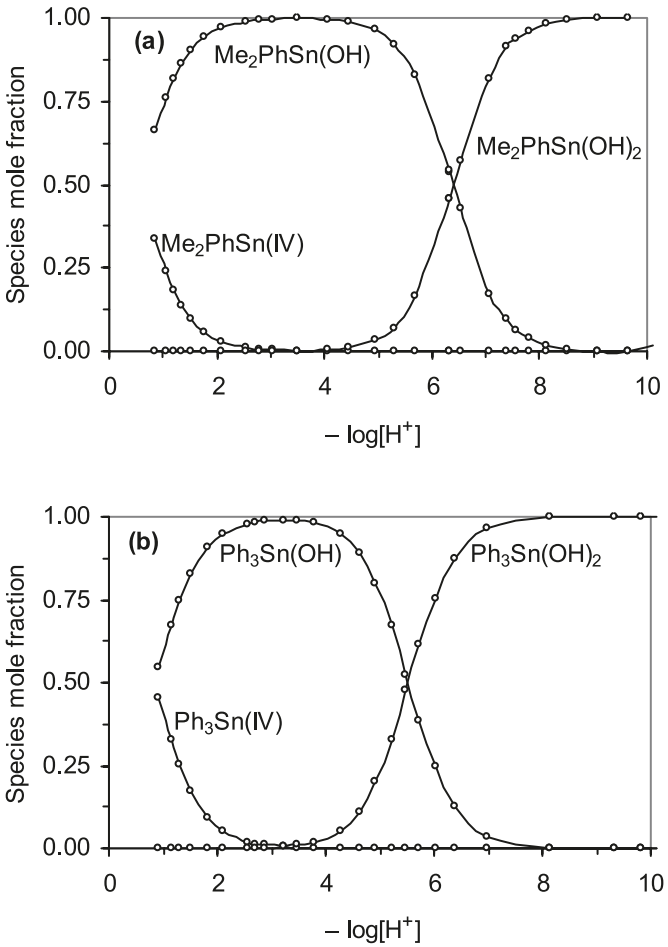
80	—	—	1.10±0.03	5.95±0.04

Fig. 1. The equilibrium distribution of the hydrolyzed species of (*a*) dimethylphenyltin(IV) and (*b*) triphenyltin(IV) in 70% ethanol (by volume) as a function of $-\log[H^+]$ at 25 °C and ionic strength 0.1 mol dm^{-3} ($NaClO_4$).



The hydrolysis of the organotins(IV) were studied carefully to determine whether any singly-bridged dimers analogous to those observed with trialkyltin(IV) were formed. Some association might be expected because the hydroxide itself has been reported to be somewhat associated with organic solvents (26). While two bridging hydroxo groups are more probable with coordination compounds, single OH bridges are observed rarely. However, no appreciable concentration of such a dimer was found to exist in the range of

© 2008 NRC Canada

concentrations used in this work, which is in agreement with results of other homologous triorganotin(IV) systems reported before (27).

Solvent effect

To obtain a quantitative method for determination of the solvent effect on physical properties, many empirical solvent scales have been devised during the last two decades (28–29). Among these scales (more than 40), the most comprehensive are the solvatochromic ones, but only a few of them have found a wider application in the correlation analysis of solvent effects. A quantitative measurement of the solvent polarity has been introduced by Kamlet, Abboud, Abraham, and Taft (KAT) (30–31). The KAT equation contains nonspecific as well as specific solute–solvent interactions separately, and the latter should be subdivided into solvent Lewis-acidity interactions (hydrogen-bond accepter, HBA, solute and hydrogen-bond donor, HBD, solvent) and solvent Lewis-basicity interactions (HBD solute–HBA solvent). This approach has been widely and successfully applied in the correlation analysis of many solvent-dependent processes (28). Using the solvatochromic solvent parameters, α, β, and π*, which have been introduced in previous reports (32–35), the multiparametric equation, eq. [5], has been proposed for use in the so-called linear solvation energy relationship.

$$[5] \qquad pK = A_0 + a\alpha + b\beta + p\pi^*$$

where A_0 represents the regression value and π* is the index of the solvent dipolarity/polarizability, which is a measure of the ability of a solvent to stabilize a charge or a dipole by its own dielectric effects. The π* scale was selected to run from 0.0 for cyclohexanone to 1.0 for dimethylsulfoxide. The α coefficient represents the solvent hydrogen-bond donor (HBD) acidity, in other words it describes the ability of a solvent to donate a proton in a solvent to a solute hydrogen bond. The α scale extends from 0.0 for nonHBD solvents to about 1.0 for methanol. The β coefficient is a measure of a solvent hydrogen-bond acceptor (HBA) basicity and describes the ability of a solvent to accept a proton in a solute to solvent hydrogen bond. The β scale was selected to extend from 0.0 for nonHBA solvents to about 1.0 for hexamethylphosphoric triamide. The empirical values of the solvatochromic solvent parameters (α, β, and π*) for pure ethanol and water were found in the literature (28). However, the solvatochromic parameters for the different binary aqueous mixtures of ethanol were calculated with the procedure proposed by Blanco et al. (36) (eq. [6]),

$$[6] \qquad P_{mixture} = P_{EtOH}X_{EtOH} + P_{H_2O}X_{H_2O}$$

where P is the property of interest and X is the mole fraction of the component in the solution. The calculated values of solvatochromic parameters used for different aqueous mixtures of ethanol are listed in Table 2.

In eq. [5], the discontinuous polarizability correction term is omitted because of the solvent used in this work containing no chlorine atoms. The regression coefficients, a, b, and p, measure the relative susceptibilities of the solvent-dependent log K to the indicated solvent parameters.

To explain the obtained log K values through the KAT solvent parameter, the formation constants were correlated with solvent properties by means of single and multiple linear regression analysis by a suitable computer program (37). We used the Gauss–Newton linear least-squares method in the computer program to refine the pK by minimizing the error squares sum from eq. [7]. Single-parameter correlations of log K_{11} and log K_{12} in terms of individually with α, β, or π* did not give a good result for both cases.

Table 2. The solvatochromic and normalized polarity parameters of different aqueous solutions.

Ethanol (% *v*/*v*)	Dielectric constant	α	β	π*	E_T^N
50	65.67	1.097	0.536	0.960	0.918
55	63.63	1.085	0.547	0.939	0.905
60	61.34	1.072	0.559	0.916	0.891
65	58.76	1.057	0.572	0.890	0.874
70	55.84	1.040	0.587	0.860	0.855
80	48.64	0.999	0.625	0.786	0.809

$$[7] \qquad S = \sum (pK_{exp} - pK_{cal})^2$$

So, we thought it would be interesting to correlate log K versus a multiparametric equation involving α, β, and π*. However, the results from eq. [5], multiparametric equation, indicate significant improvement with regard to the single-parameter models, eqs. [8] and [9] for dimethylphenyltin(IV) and triphenyltin(IV), respectively.

$$[8a] \qquad pK_{11} = 353.79 + 219.86\alpha - 464.73\beta - 359.40\pi^*$$

$$[8b] \qquad pK_{12} = 78.37 + 207.05\alpha - 181.24\beta - 210.36\pi^*$$

($n = 5$, $r^2 = 0.9983$ and 0.9994, respectively)

$$[9a] \qquad pK_{11} = 551.80 + 154.92\alpha - 618.97\beta - 405.36\pi^*$$

$$[9b] \qquad pK_{12} = 560.77 + 592.52\alpha - 859.30\beta - 775.68\pi^*$$

($n = 6$, $r^2 = 0.9997$ and 0.9994, respectively)

The coefficients of π*, α, and β in eqs. [8]–[9] are very different from each other and are almost in the order of β > π* > α. This indicates the hydrogen-bond acceptor basicity parameter of the solvent is the most important, the polarity parameter plays a relatively small role, and finally, the hydrogen-bond donor acidity parameter has less significance in changing the hydrolysis constant of tin(IV) systems in the proposed various aqueous solutions of ethanol.

The solvent polarity parameter of the media, π*, increases with increasing the mole fraction of water in aqueous solutions of ethanol. If the π* of the media was the only factor for the solvent effect on the complexation, it may be expected that the log K in a solution with a higher dielectric constant should be greater than those of all the other aqueous solutions of ethanol. However, the hydrolysis constants increase with increasing the solvent hydrogen-bond acceptor basicity parameter, β, and decreases with increasing the solvent polarity, π*, and the hydrogen-bond donor acidity parameter of the solvents, α, for different ethanol–water mixtures, Table 1.

We have also tried to use the polarity scale proposed by Reichardt (28, 38), E_T, based on the solvatochromic behavior of pyridinium *N*-phenoxide betaine dye. This dye is the most solvatochromic compound reported to date. This scale has

Table 3. The percentage contribution of KAT and normalized polarity parameters on the effect of different media on hydrolysis of the species at 25 °C and an ionic strength of 0.1 mol dm^{-3} ($NaClO_4$).

		In terms of eqs. [10] and [11]			In terms of eqs. [8] and [9]		
Different species	E_T^N	α	β	π*	α	β	π*
$(CH_3)_2C_6H_5Sn(OH)$	0.2	18.9	46.6	34.3	21.1	44.5	34.4
$(CH_3)_2C_6H_5Sn(OH)_2^-$	0.4	32.7	31.9	35.1	34.6	30.3	35.1
$(C_6H_5)_3Sn(OH)$	2.8	11.0	51.7	34.5	13.1	52.5	34.4
$(C_6H_5)_3Sn(OH)_2^-$	3.3	28.4	35.9	32.4	26.6	38.6	34.8

now been revised and normalized to E_T^N, known as normalized polarity parameter, due to the introduction of SI units. E_T^N has the value of zero for tetramethylsilane, the least polar solvent, and 1.0 for water, the most polar solvent. The E_T^N value is related to the ability of a solvent to stabilize charge separation in the dye, a correlation between the E_T^N and dielectric constant might be expected (28).

The hydrolysis constants again were correlated with E_T^N as a single linear regression analysis and then with the multiple regression one with Kamlet and Taft's (33) parameters besides E_T^N. Single parameter correlation of pK in terms of E_T^N did not again give good results. However, the multiparametric equation involving E_T^N, α, β, and π* showed very significant improvement with regard to the single-parameter model, eqs. [10]–[11] for dimethylphenyltin(IV) and triphenyltin(IV), respectively.

$$[10a] \quad pK_{11} = 375.83 + 1.99E_T^N + 191.19\alpha - 471.46\beta - 347.74\pi^*$$

$$[10b] \quad pK_{12} = 89.70 + 2.01E_T^N + 186.83\alpha - 182.08\beta - 200.52\pi^*$$

($n = 5$, $r^2 = 0.9989$ and 1.0, respectively)

$$[11a] \quad pK_{11} = 583.89 + 34.91E_T^N + 139.21\alpha - 652.46\beta - 435.51\pi^*$$

$$[11b] \quad pK_{12} = 491.68 - 73.27E_T^N + 622.31\alpha - 785.57\beta - 708.84\pi^*$$

($n = 6$, $r^2 = 1.0$ and 0.9999, respectively)

To show the efficiency of the suggested multiparameter correlations, experimental values of log K are plotted versus their calculated ones from eqs. [10–11], for the different aqueous ethanol solutions. It can be seen, Fig. 2, that the experimental and calculated values of log K are in good agreement with each other, with $r^2 > 0.99$ in both cases. From the values of the regression coefficients, the contribution of each parameter on a percentage basis was calculated and is listed in Table 3.

Conclusions

The combined potentiometric and spectrophotometric measurements were used to characterize the hydrolytic species formed in dimethylphenyltin(IV) and triphenyltin(IV) chlorides in various aqueous ethanol solutions. Our data reveal that the two coordinated water molecules on triorganotin(IV) are able to release two protons to form two hydrolytic species at pH ≅ 3 and 8, respectively. The determined hydrolysis constants in different aqueous ethanol solutions are analyzed in terms of Kamlet and Taft parameters (33). Single-parameter correlation of the formation constants in both cases are poor, but multiparameter correlation represents significant improvement with regard to the single-parameter models. Using the normalized polarity parameter in combination with Kamlet–Taft parameters results in a better correlation of the formation constants in the different medias used.

New xanthones from *Cratoxylum cochinchinense*

Surat Laphookhieo, Wisanu Maneerat, Taweesak Buatip, and J. Keith Syers

Abstract: Investigation of the dried fruits of *Cratoxylum cochinchinense* led to the isolation of three new oxygeranyl xanthones, cochinxanthone A-C (**1**–**3**), together with seven known compounds (**4**–**10**). Their structures were characterized using spectroscopic methods including UV, IR, NMR, and MS.

Key words: cochinxanthone A-C, *Cratoxylum cochinchinense*, Clusiaceae.

Résumé : Une étude sur les fruits secs de *Cratoxylum cochinchinense* a permis d'isoler trois nouvelles oxygéranylxanthones, les cochinxanthones A-C (**1**–**3**), en plus de sept produits connus (**4**–**10**). On a caractérisé leurs structures par des méthodes spectroscopiques, dont l'UV, l'IR, la RMN et la spectrométrie de masse.

Mots-clés : cochinxanthones A-C, *Cratoxylum cochinchinense*, Clusiaceae.

[Traduit par la Rédaction]

Introduction

Cratoxylum cochinchinense (Clusiaceae) is a shrub tree distributed in southeast Asian countries. Several parts of this plant have been used by the local Thai people in folk medicine. For example, the decoction of *C. cochinchinense* roots and stems has been used as diuretic drug. Also, the leaves, roots, barks, and latex of this plant have been used for the treatment of fever, cough, diarrhea, itching, and ulcers. In addition, the young fruit are used as a spice for cooking, and the young leaves are used a substitute for tea. *Cratoxylum* plants are known to be rich sources of xanthones (1–6) and antraquinones (4, 7, 8). Some of these compounds showed significant pharmacological activity, such as antimalaria (2), cytotoxicity (2, 4), and antibacteria (3, 7, 8). We have previously reported the isolation, structure determination, and biological evaluation of a number of xanthones from the roots of *C. cochinchinense* (2). In a continuation of our study of this plant, we describe the isolation and structure elucidation of three new oxygeranyl xanthones (**1**–**3**) along with seven known compounds (**4**–**10**) (Fig. 1) from the dried fruit of *C. cochinchinense*.

Results and discussion

The crude hexane and EtOAc extracts of the dried fruit of *C. cochinchinense* were subjected to chromatographic procedures and afforded three new xanthones, named cochinxanthone A-C (**1**–**3**), together with seven known compounds (**4**–**10**). Their structures were elucidated using spectroscopic data and by comparison with those reported in the literature.

The new xanthones (**1**–**3**) were oxygeranyl xanthones, which showed characteristic UV absorption bands in ranges of 204–258 and 307–368 nm, while the IR spectra exhibited characteristic conjugated carbonyl and hydroxyl functionalities in the ranges of 1638–1646 and 3435–3446 cm^{-1}, respectively. Also, all new xanthones showed a chelated hydroxyl proton at ca. δ: 12.8–13.0 ppm in the ^1H NMR spectrum. Moreover, the 1D NMR and 2D NMR spectral data suggested that all isolated new xanthones contained the 1,3,7-oxygenated xanthone skeleton.

Cochinxanthone A (**1**) was isolated as a pale yellow solid with a molecular formula of $C_{23}H_{24}O_6$, on the basis of $[M]^+$ ion at *m/z* 396.3709 in the HREI-MS. The ^1H NMR spectral data of **1** (Table 1) showed a downfield hydroxyl proton resonance at δ: 13.00 together with two sets of aromatic protons. The first set was a typical pattern of a 1,2,4-trisubstituted benzene ring and appeared at δ: 7.55 (1H, d, *J* = 2.7 Hz, H-8), 7.39 (1H, d, *J* = 9.3 Hz, H-5), and 7.33 (1H, dd, *J* = 9.3, 2.7 Hz, H-6). The other set displayed two *meta*-coupled protons and appeared at δ: 6.32 (1H, d, *J* = 1.8 Hz, H-4) and 6.19 (1H, d, *J* = 1.8 Hz, H-2). With the combination of COSY, HMQC, and HMBC spectra, a 6-hydroxy-3,7-dimethylocta-2,7-dienyloxy moiety (*O*-geranyl moiety) was evident from ^1H NMR signals at δ: 5.48 (1H, t, *J* = 6.6 Hz, H-2′), 4.96 (1H, s, H-8′a), 4.75 (1H, s, H-8′b), 4.65 (2H, d, *J* = 6.6 Hz, H-1′), 3.98 (1H, t, *J* = 6.6 Hz, H-6′), 2.13 (2H, m, H-4′), 1.82 (3H, s, H-9′), 1.70 (3H, s, H-10′), and 1.63 (2H, m, H-5′) (9). This moiety was also supported by the fragment ion peak at *m/z* 243 ($[M\text{-}C_{10}H_{17}O]^+$) in the EI-MS spectrum. The *O*-geranyl moiety was placed at C-7 because of the correlation of H-1′ (δ: 4.65), H-8 (δ: 7.55) and H-6 (δ: 7.33) to C-7 (δ: 155.2) in the HMBC spectral data (Fig. 1). In addition, the interaction between H-1′ (δ: 4.65) and H-8 (δ: 7.55) in the NOSEY spectrum (Fig. 2) also confirmed the location of *O*-geranyl moiety. Therefore, cochinxanthone A was identified as 1,3-dihydroxy-7-(6-hydroxy-3,7-dimethylocta-2,7-dienyloxy)-xanthen-9-one (**1**).

Cochinxanthone B (**2**) had the same molecular formula as **1**, $C_{23}H_{24}O_6$, (*m/z* 396.3748 $[M^+]$).^1H NMR and ^{13}C NMR signals (Table 1) of **2** were almost identical to those of **1** ex-

cept that the chemical shift values of aromatic and chelated hydroxyl protons were different (Table 1). In addition, the R_f value on the TLC of **2** (R_f = 0.33, 2.5% acetone–DCM) was also different from **1** (R_f = 0.40, 2.5% acetone–DCM). These results suggested that **2** contained the same *O*-geranyl moiety as **1** and was located at C-3 on the basis of HMBC

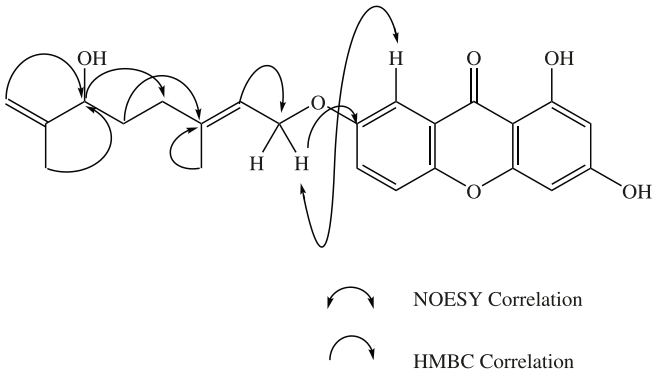
Fig. 2. Selective HMBC and NOESY correlations of **1**.



correlations (Fig. 3). Therefore, cochinxanthone B was identified as 1,7-dihydroxy-3-(6-hydroxy-3,7-dimethylocta-2,7-dienyloxy)-xanthen-9-one (**2**), structural isomer of **1**.

Cochinxanthone C (**3**) was obtained as a pale yellow solid. The HREI-MS gave a M-H_2O ion peak at *m*/*z* 378.1453 $[M\text{-}H_2O]^+$ consistent with the molecular formula $C_{23}H_{26}O_6$. All aromatic protons of **3** (Table 1) were similar to those of **1**. The main difference in ^1H NMR signals between **3** and **1** were observed on the *O*-geranyl moiety. Compound **3** appeared as a 7-hydroxy-3,7-dimethylocta-2,5-dienyloxy unit [δ: 5.67 (1H, d, *J* = 13.8 Hz, H-6′), 5.65 (1H, dd, 13.8, 3.6 H-5′), 5.47 (1H, t, *J* = 6.6 Hz, H-2′), 4.53 (2H, d, *J* = 6.6 Hz, H-1′), 2.75 (2H, d, *J* = 3.6 Hz, H-4′), 1.72 (3H, s, H-9′), and 1.33 (6H, s, H-8′ and H-10′)] (7) instead of the 6-hydroxy-3,7-dimethylocta-2,7-dienyloxy moiety in **1** (Table 1). The geometry of the double bond at C-5′/6′ was identified as *E*-geometry because of the large amount of *J* value of H-6′ (13.8 Hz) (7). Thus, cochinxanthone C (**3**) was identified as 1,3-dihydroxy-7-(7-hydroxy-3,7-dimethylocta-2,5-dienyloxy)-xanthen-9-one.

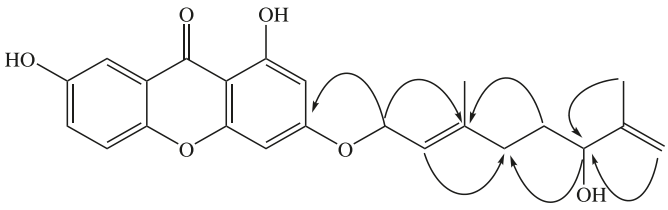
The remaining known compounds were characterized as 7-geranyloxy-1,3-dihydroxyxanthone (**4**) (4), 1,3,7-trihydroxyxanthone (**5**), fuscaxanthone E (11), vismione B (**7**) (10), vismione E (**8**) (7, 10), vismione F (**9**) (12), and vismiaquinone C (**10**) (13). It should be noted that the genus of *Cratoxylum* of the family Clusiaceae has been known to be rich in xanthones with more than 50 compounds being identified (1–7). In the present study, we also isolated and identified three new oxygeranyl xanthones from the dried fruit of *C. cochinchinense*. Also, all the remaining compounds (**4**–**10**) were isolated from this species for the first time.

Experimental

General experimental procedures

Melting points were determined using a Fisher-John melting point apparatus. The optical rotation $[\alpha]_D$ values were determined with a JASCO P-1020 polarimeter. UV spectra were recorded with a UV-160A spectrophotometer (Shimadzu). The IR spectra were recorded with a PerkinElmer FTS FT-IR spectrophotometer. The ^1H NMR and ^{13}C NMR spectra were recorded using 300 MHz Bruker FTNMR Ultra Shield spectrometer. Chemical shifts were recorded in parts per million (δ) in $CDCl_3$ and (or) CD_3OD with tetramethylsilane (TMS) as an internal reference. The EI-MS

Fig. 3. Selective HMBC correlations of **2**.



was obtained from a MAT 95 XL mass spectrometer. Quick column chromatography (QCC) and column chromatography (CC) were carried out on silica gel 60 H (Merck, 5–40 μm) and silica gel 100 (Merck, 63–200 μm), respectively. Precoated plates of silica gel 60 F_{254} were used for analytical purposes.

Plant material

The dried fruits of *C. cochinchinense* were collected from Mae Fah Luang University, Tasud, Muang, Chiang Rai province, in the northern part of Thailand in December 2006. Botanical identification was achieved by comparison with a voucher specimen No. SL-1 (PSU) (2) in the herbarium collection of Department of Biology, Prince of Songkla University, Songkhla, Thailand.

Extraction and isolation

The dried fruits of *C. cochinchinense* (1 kg) were extracted with hexane and EtOAc, respectively, over a period of 3 days each at room temperature and evaporated under reduced pressure to provide crude hexane (16 g) and EtOAc extracts (66 g).

The hexane extract (16 g) was subjected to quick column chromatography (QCC) over silica gel and eluted with a gradient of hexane–EtOAc (100% hexane to 50% EtOAc–hexane) to provide sixteen fractions (H1–H16). Fraction H3 (2.1 g) was subjected to column chromatography (CC) using a 5% EtOAc–hexane mixture to afford seventeen subfractions (H3A–H3Q). Subfraction H3F was taken to dryness under reduced pressure to yield an orange solid, which was washed with hexane to afford compound **10** (2.3 mg). Purification of subfraction H14 (329 mg) was performed by CC with 25% acetone–hexane, yielding ten fractions (H14A–H14J). Fraction H14I (43.5 mg) was subjected to repeated CC with 15% acetone–hexane to yield compound **8** (8.4 mg).

The EtOAc extract (66 g) was chromatographed by QCC over silica gel and eluted with a gradient of hexane–EtOAc (100% hexane to 100% EtOAc) to afford twenty fractions (E1–E20). Upon evaporating under reduced pressure, fraction E9 gave a yellow solid, which was washed with hexane and DCM, affording fraction E9a. This fraction, E9a, (352.7 mg) was further subjected to repeated CC with 100% DCM to yield compound **4** (74.8 mg). Fraction E14L (82.9 mg) was subjected to repeated CC using 2.5% MeOH–DCM to yield compound **6** (13.5 mg). Fraction E16 (555.5 mg) was purified by CC with gradient mixtures of acetone–hexane (5% acetone–hexane to 20% acetone–hexane) to afford nineteen subfractions (E16a–E16s). Subfractions E16p, upon evaporating under reduced pressure gave a solid, which was washed with hexane and DCM to give

compound **5** (6.4 mg). Subfraction E16j (43.5 mg) was further purified by preparation of TLC with 15% acetone–hexane to give compound **9** (28.5 mg). Fraction E17 (3.1461 g) was fractionated by CC using 20% acetone–hexane to afford 20 subfractions (E17a–E17t). Subfraction E17o (98.3 mg) was subjected to repeated CC with 2.5% acetone–chloroform to give compound **7** (3.2 mg). Repeated CC of fraction E17q (299.6 mg) with 20% acetone–hexane yielded compounds **1** (5.2 mg) and **2** (5.7 mg). Fraction E17r (33.9 mg) was subjected to repeated preparation of TLC with 2.5% MeOH–chloroform to afford compound **3** (11.9 mg).

F 1s spectroscopy and ionic fragmentation of trifluoropropyne[1]

John J. Neville, Narayana P. Appathurai, Yongheng Fan, Samuel Odoh, and Liu Yang

Abstract: The F 1s excitation spectroscopy and ionic fragmentation of 3,3,3-trifluoro-1-propyne have been studied using synchrotron radiation and ion time-of-flight mass spectrometry. The total ion yield spectrum and photoionization branching ratios in the vicinity of the F 1s ionization threshold are reported. Core excited state calculations using the static exchange approximation are used to aid in the interpretation of the experimental results. The F 1s excitation spectrum consists of a number of broad overlapping bands below threshold, attributed to excitations to mixed σ*(C-F)/π*(C-C) molecular orbitals and unresolved Rydberg states, and a continuum shape resonance 12.5 eV above threshold. Ionic fragmentation following F 1s excitation or ionization results overwhelmingly in singly charged ionic fragments, primarily via cleavage of bonds to the fluorinated carbon atom adjacent to the core-excited atom.

Key words: F 1s excitation, XANES, photoelectron-photoion coincidence, ionic fragmentation, static exchange approximation.

Résumé : Utilisant un rayonnement de synchroton et faisant appel à la spectrométrie de masse en temps de vol, on a étudié la spectroscopie d'excitation 1s du fluor et la fragmentation ionique du 3,3,3-trifluoroprop-1-yne. On a déterminé le spectre en rendement ionique total et les rapports de ramification au voisinage du seuil d'ionisation 1s du fluor. On a effectué des calculs de l'état excité du coeur en faisant appel à l'approximation d'échange statique pour avoir un support dans l'interprétation des résultats expérimentaux. Le spectre d'excitation 1s du fluor est formé d'une région en dessous du seuil où on retrouve un certain nombre de bandes larges qui se chevauchent et qui sont attribuées à des excitations à des niveaux d'orbitales moléculaires mixtes σ*(C-F)/π*(C-C) et à des états de Rydberg non résolus; à 12,5 eV au-dessus du seuil, on observe une résonance de forme continue. La fragmentation ionique qui suit l'excitation 1s du fluor ou l'ionisation conduisent à la formation grandement majoritaire des fragments ioniques à charges uniques qui résultent principalement du clivage des liaisons vers l'atome de carbone fluoré adjacent de l'atome excité à coeur.

Mots-clés : excitation 1s du fluor, XANES, coïncidence photoélectron–photoion, fragmentation ionique, approximation d'échange statique.

[Traduit par la Rédaction]

Introduction

Resonant core excitation by absorption of soft X-ray radiation creates a highly localized perturbation of molecular electronic structure. Rapid electronic relaxation of these high-energy core-hole states typically leads to ionization and bond dissociation. Study of these processes is important for an understanding of radiation damage in materials and also provides information about the electronic and chemical properties of the materials investigated. Detailed investigation of these processes is possible for small molecules, where the initial site of the core hole can often be precisely controlled by selection of the appropriate excitation wavelength and many or all fragmentation products can be detected and characterized.

We have studied the core excitation spectroscopy and subsequent ionic fragmentation of 3,3,3-trifluoro-1-propyne. The three chemically inequivalent carbon centres in principle allow for site-specific core-hole formation, as do the fluorine atoms. It is of interest to investigate the extent to which the localized core-hole site is reflected in the subsequent electronic relaxation and ionic fragmentation processes. The C 1s excitation spectroscopy has been reported elsewhere (1). Here, the focus is on the excitation spectroscopy and ionic fragmentation at the F 1s edge.

The F 1s excitation spectrum of trifluoropropyne has been measured previously by electron energy loss spectroscopy (EELS); the data are available for download but the spec-

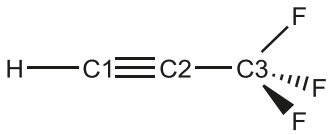
Fig. 1. 3,3,3-Trifluoro-1-propyne, with carbon atom numbering as used in the text.



trum is unpublished (2). The F 1s EELS spectrum of the chemically related perfluoro-2-butyne has been reported along with the spectra of a number of other fluorinated hydrocarbons in a study of the perfluoro effect (3). Studies at the C 1s edge indicate considerable site-specificity in the ionic fragmentation of trifluoropropyne following C 1s excitation (4). However, no previous studies of the ionic fragmentation of trifluoropropyne following F 1s excitation have been reported.

For convenience in the following discussion, we refer to the three chemically distinct carbon atoms as C1, C2 and C3, where C1 is the terminal π-bonded carbon, C2 is the central carbon, and C3 is the fluorinated carbon atom, as illustrated in Fig. 1.

Experimental method

The experiments were performed with the spherical grating monochromator (SGM) beamline (11-ID.1) of the Canadian Light Source (CLS). This 45 mm planar undulator beamline provides monochromatic photons in the range 250–2000 eV with a resolving power on the order of 10^4 (5). For this work, the 1100 lines/mm medium energy grating was used with entrance and exit slit settings of 5 μm, providing an estimated photon bandwidth of 70 meV near the F 1s edge. The photon flux was monitored via both a gold mesh upstream of the experimental chamber and a silicon photodiode at the end of the beamline. The two monitors were found to provide equivalent results. The photon energy scale was calibrated using the SF_6 F 1s resonant excitation spectrum and the excitation energies reported by Francis et al. (6).

Total ion yield (TIY) and photoelectron–photoion coincidence (PEPICO) measurements were performed using a Wiley–McLaren type ion time-of-flight (TOF) mass spectrometer mounted perpendicular to the incident photon beam and an electron detector mounted opposite the TOF (7, 8). The time between electron and ion detection is characteristic of the mass-to-charge ratio of the fragment ions. A 1 s dwell time was used for the TIY measurements. A 60 s dwell time was used for the majority of the PEPICO measurements; additional measurements with a 20 min dwell time were made at selected photon energies. The gaseous sample was admitted into the chamber in a continuous flow via an effusive gas inlet. The 3,3,3-trifluoro-1-propyne was purchased from Sigma-Aldrich and used without further purification.

Computational method

Ab-initio molecular orbital (MO) calculations were performed to estimate the transition energies and intensities of the core hole states. The ground-state equilibrium geometry of trifluoropropyne was determined at the HF/6-311G(d,p) level using GAMESS (9). This geometry was used for all subsequent calculations. The F 1s excitation energies and transition probabilities (oscillator strengths) were determined using Kosugi and Kuroda's GSCF3 program (10). These calculations proceeded in three steps: first, a HF calculation of the ground state was performed; second, the F 1s ionized state was calculated with explicit consideration of the core hole; finally, the F 1s excited states were obtained by the improved virtual orbital (IVO) method (11). This approach, also known as the static exchange method or STEX, accounts for the significant alterations in the electronic structure that occur due to relaxation of the valence shell MOs in the presence of the core hole but neglects the core-hole screening effect of the open-shell excited electron (12). This is typically a small error for Rydberg excited states with their large spatial extent but can result in the overestimation of excitation energies to more compact unoccupied valence MOs by as much as a few eV, depending on the extent of interaction between the singly-occupied MO and the remaining valence MOs (1, 12).

Three sets of core excited state calculations were performed employing somewhat different basis sets. In each case, primitive basis functions were taken from (73/7) contracted Gaussian-type functions for carbon and fluorine and (411) for hydrogen (13). Polarization functions were added to carbon (ζ_d = 0.626), fluorine (ζ_d = 1.75), and hydrogen (ζ_p = 0.75) (14). The contraction schemes, indicating (s/p/d) functions, were (4111111/31111/1) for the F 1s excited fluorine, (721/511/1) for the other fluorine atoms and carbon, and (411/1) for hydrogen. This is referred to as Basis 1 in the following discussion. Following the approach of Ueda et al. (15), Basis 1 was supplemented using a set of 6s, 6p, and 6d diffuse functions, proposed initially by Kaufmann et al. (16), to describe 3s–5s, 3p–5p, and 3d–5d Rydberg orbitals: ζ_s = 0.075, 0.02530, 0.01141, 0.00589, 0.00334, and 0.00204; ζ_p = 0.0440, 0.01970, 0.01013, 0.00573, 0.00349, and 0.00224; and ζ_d = 0.02820, 0.01447, 0.00817, 0.00496, 0.00319, and 0.00214. Basis 2 refers to the addition of these Rydberg diffuse functions to the core excited fluorine atom.

It was noted in the calculation of the F 1s ionized state using Basis 1 that charge delocalization in the core-ionized state leads to the majority of the +1 charge localized on the adjacent carbon atom rather than the site of the F 1s core hole (formal charges of +0.77 and +0.36 on the fluorinated carbon and core-ionized fluorine, respectively). Therefore, an additional variation on the core-excited state calculations was performed in which the Rydberg diffuse functions described above were placed on the fluorinated carbon atom instead of on the core-excited fluorine atom. This is referred to as Basis 3.

Results and discussion

F 1s total ion yield spectrum

The TIY spectrum of trifluoropropyne in the vicinity of the F 1s edge is shown in Fig. 2. The spectrum consists of several broad and overlapping resonances superimposed on the F 1s ionization threshold at 694.75 eV (17), with an absence of any sharp resonance features. The spectrum has been fitted with five Gaussian functions to determine band positions and an arctan function to represent the F 1s edge

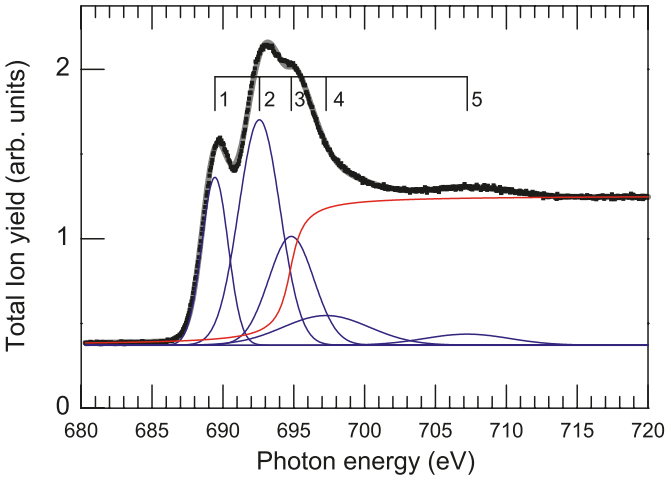
Note: From the least squares fit to the TIY data. Fit uncertainties in the final digits of the reported values are shown in parentheses. Peak numbers (Pk) correspond to those in Fig. 2.

[a]Term value; IP-transition energy.

[b]Ref. 17.

Fig. 2. F 1s total ion yield spectrum of trifluoropropyne (squares). The result of a least-squares fit of five Gaussian functions and an arctan function fixed at the reported energy of the F 1s ionization threshold (17) are also shown. The peak numbering corresponds to that used in Table 1.



jump. The position of the edge jump was fixed at the literature ionization threshold (17); all other peak positions, widths, and amplitudes were allowed to vary freely. The fit results and assignments are listed in Table 1. Assignments are based on comparison with the F 1s excitation spectra of other fluorinated hydrocarbons and on the core-excited state calculations, as discussed below.

The general features of the spectrum are in good agreement with those determined by EELS for trifluoropropyne (2) and the chemically related perfluoro-2-butyne (3) and are generally consistent with the F 1s spectra of other fluorinated hydrocarbons (3, 18). In general, for fluorinated hydrocarbons with a π-bonding functional group adjacent to the fluorination site (e.g., CF_3CN, $(CF_3)_2CO$), a three-band structure is observed in the F 1s excitation spectra, the bands having term values of ~5, 2, and 0 eV, as is observed here for trifluoropropyne. Because the core excitation originates from a localized F 1s MO, only excitations to valence MOs with appreciable σ* C-F character are expected to have sufficient oscillator strength to be observed.

The first band at 689.4 eV can be assigned by consideration of the F 1s excitation spectra of other fluorinated hydrocarbons. An intense band with a similar term value is not observed in the F 1s spectra of molecules such as CF_4 and CF_3H that lack any π bonds (19–21) but is observed in those having an adjacent π-bonding functional group, such as CF_3CN and perfluoro-2-butyne (3). Band 1 is therefore attributed to excitations into a mixed-character σ* C3-F/π* C1-C2 unoccupied valence orbital. In contrast, strong features corresponding to bands 2 and 3 are observed in other fluorinated hydrocarbons independent of the presence of any π-bonding; these are therefore attributed to excitations to σ* C-F and Rydberg orbitals. Whereas Rydberg series consisting of sharp resonance features are readily identified in the high resolution C 1s excitation spectra of small alkyl fluorides, such features are not evident in the corresponding F 1s excitation spectra (19). This has been attributed in part to the energetic similarity of the Rydberg and C-F σ* excitation features. Fluorination is expected to lower the energy of the σ* C-F orbitals into the energy region below the ionization threshold typically associated with Rydberg excited states. Combined with the greater lifetime broadening for F 1s excitation and significant vibrational excitation (discussed further below), the failure to observe clear Rydberg series in the experimental F 1s excitation spectra is not surprising.

A weak continuum resonance is observed at 707.2 eV, 12.5 eV above threshold. This is consistent with F 1s continuum shape resonances observed in other fluorinated hydrocarbons, e.g., at 709.4 eV (TV = –13.9 eV) in CF_4 (21) and at 708 eV (–13.5 eV) in perfluoro-2-butyne (3).

It was necessary to include a fifth Gaussian (band 4) in the fit to adequately account for the intensity observed just above the ionization threshold. It is not clear whether this should be attributed to discrete electronic excitations just above threshold, to extensive vibrational excitation associated with the F 1s → σ* (C-F) band at 694.8 eV, or whether it simply accounts for a small decrease in the F 1s ionization cross-section with increasing photon energy.

All of the fitted bands are greater in width than expected from instrumental and lifetime broadening, indicating significant vibrational excitation following the creation of a core hole at a fluorine atom. This can be attributed to symmetry lowering, resulting from the creation of a localized F 1s core hole and the electron density contraction expected in the vicinity of the core hole. In the equivalent core model, core excited F is equivalent to Ne, leading to a prediction of dissociation of the bond between carbon and the core-excited fluorine atom, or at least a bond lengthening for the duration of the core hole lifetime. Evidence for ultrafast dissociation in other fluorides has been found in recent resonant Auger

spectroscopy and Auger electron-fragment ion coincidence studies of CF_4, CH_3F, SiF_4, and SF_6 (22–26). Fast dissociation of the bond to the core excited F occurs in these molecules following the lowest energy F 1s → σ* resonant excitation; this is followed by atomic-like Auger decay of the dissociating F 1s excited fragment. Evidence for significant vibrational excitation in the remaining CF_3 and SF_5 fragments following fast dissociation of F 1s excited CF_4 and SF_6 has also been observed (22, 24, 26).

The relative intensities of the spectral features of the TIY spectrum of trifluoropropyne are in good agreement with those of the previous EELS measurement (2) up to ~695 eV. However, the relative TIY intensity above threshold is greater than the photoabsorption cross section determined by EELS, indicating an increase in ionization efficiency with F 1s ionization. This is consistent with an increase in the number of ion-pair processes resulting from normal Auger decay and charge separation above threshold and suggests that resonant Auger decay below threshold is leading to a significant amount of single ion formation.

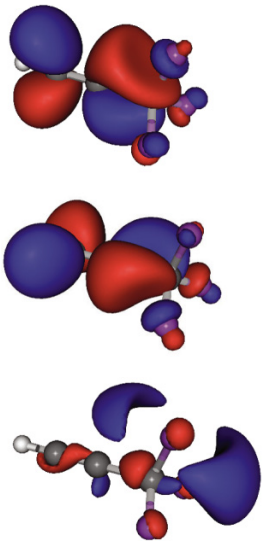
Computational results

The results of our F 1s core excited state calculations are summarized in Table 2 for the three basis sets described above: (*i*) without inclusion of diffuse Rydberg functions, (*ii*) with diffuse Rydberg functions added to the core excited F only, and (*iii*) with diffuse Rydberg functions added to the fluorinated C only. Only resonant excitations below the F 1s IP are included in the table. The molecule was oriented with the C_{3v} symmetry axis along the *z* axis and the core-excited F atom in the *xz* plane. The same calculated F 1s IP of 693.43 eV is obtained from the three calculations, indicating that inclusion of Rydberg diffuse functions in the basis set is not necessary for accurate modelling of the F 1s core ionized state. The calculated IP is in fair agreement with the experimental IP of 694.75 eV (17).

The calculations without diffuse Rydberg functions (Basis 1) predict three states below threshold. The valence MOs singly occupied in these F 1s excited states are shown in Fig. 3. Each of the MOs has some σ* (C-F) character. The first two of these also have significant C1-C2 π* antibonding

© 2008 NRC Canada

Fig. 3. Singly-occupied valence MOs in the F 1s excited states of trifluoropropyne calculated with Basis 1. The F atom above the symmetry axis is the site of core excitation. Top: σ* C3-F/π* C1-C2 (a′); Middle: σ* C3-F/π* C1-C2 (a″); Bottom: delocalized nonbonding (a′).



character and C2-C3 π bonding character. These two MOs can be described as a mixing of the C1-C2 π* and C3-F σ* valence orbitals of appropriate symmetries. The lowest energy and most intense transition (TV = 2.233) is to an MO that involves π character in the *xz* plane containing the core excited F (a′ in the C_s symmetry of the core-excited state); the C-F σ* character involves primarily the core-excited F atom with small contributions from the other two F atoms. The next transition, with TV = 1.763, involves mixing of the π* MO perpendicular to the plane containing the core-excited F with a C-F antibonding MO that has much greater contributions from the non-core-excited F atoms. This MO, a″ in C_s symmetry, has a nodal plane through the core-excited F; it is antibonding between C3 and the core-excited F, but in a pseudo-π* sense. The weaker contribution from the core-excited F in this second MO is reflected in the lower oscillator strength and term value of this transition; generally, term values are larger for excitations to MOs with greater character on the core-excited atom because those MOs will experience greater electronic relaxation upon formation of a core hole at that site.

Transitions corresponding to these two lowest energy excitations in the Basis 1 calculations can be readily identified in the two calculations performed with the inclusion of Rydberg basis functions, in which transitions to MOs with the same mixed C1-C2 π* and C3-F σ* character as described above are observed at very similar excitation energies. The calculated intensities of these transitions are less in the Basis 2 and Basis 3 calculations, as would be expected when using basis sets that can model a greater number of excitations in this energy range — the total oscillator strength is distributed over a greater number of transitions. The consistency of the calculated results for these two intense transitions, with and without inclusion of Rydberg basis functions, affirms their assignment as excitations to valence antibonding MOs with no significant Rydberg character.

It is interesting to note that in the ground state, the unoccupied π* MOs are degenerate (as they must be in C_{3v} symmetry) and have much less F character than do the corresponding MOs in the presence of a F 1s core hole. Creation of a core hole on F not only lowers the molecular symmetry to remove the degeneracy of the π* MOs, but electronic relaxation and contraction of the C-F σ* MOs in the presence of the F 1s core hole also allows for increased mixing of the C-C π* and C-F σ* character. This same mixing does not occur when the core hole is on one of the carbon atoms (1).

The calculations with Basis 1 predict a third bound F 1s excited state involving excitation to an MO delocalized throughout the molecule, with significant character from all atoms. Although there is some σ* antibonding character among all pairs of neighbouring atoms, interactions are weaker than in the first two MOs and a nonbonding description appears more appropriate. As can be seen in Fig. 3, this MO is more extended in the vicinity of the core excited fluorine. In contrast to the two lower energy F 1s excited states discussed above, there is no clear counterpart to this excitation in the Basis 2 and Basis 3 calculations. Instead, a number of weak excitations to 4d Rydberg-type MOs are predicted in this energy range (TV ~ 0.8 eV). This suggests that this third F 1s excited state predicted at TV = 0.79 eV in the Basis 1 calculations is the result of an attempt to model a Rydberg excited state with an inadequate basis set.

Comparing the results of the Basis 2 and Basis 3 calculations, it is apparent that, below threshold, placement of Rydberg functions on either the core-excited F or the neighbouring centre of positive charge, C3, gives essentially the same result. Therefore, either choice appears adequate for modelling the more spatially extended F 1s-excited states of trifluoropropyne.

When diffuse Rydberg functions are included in the basis set, the calculations place the three F 1s → Rydberg 3p excitations between the first two valence σ* (C-F) excitations and with appreciable intensity. The calculated quantum defects of ~0.4 are reasonable for p-type Rydberg states. The energies and character of the remaining F 1s excited states predicted in the Basis 2 and Basis 3 calculations are consistent with higher order Rydberg states, as indicated in Table 2. The calculated oscillator strengths of these higher energy Rydberg states are comparatively low. Therefore, it is only in aggregate that they are likely to give rise to sufficient intensity to be observed.

Comparing the calculated results with the experimental F 1s excitation spectrum of Fig. 2 and Table 1, the calculations significantly underestimate the term value of the first transition, predicting 2.3 eV versus the observed term value of 5.3 eV. The underestimation of term values for core excitations to valence MOs is expected with the STEX method, as the core-hole screening by the excited electron is neglected. This error will be most significant for more compact valence excited states having a significant contribution from the core-excited atom and will be considerably smaller for more spatially extended and delocalized excited states. For example, in a study of the C 1s excited states of propyne, trifluoropropyne, and propargyl alcohol, differences of ~1.7 eV were observed between experimental term values and those calculated by the STEX method for C 1s → π*

© 2008 NRC Canada

transitions, but only a few tenths of an electronvolt for transitions to Rydberg states (1). A similar effect is expected here, with the error being largest for the F 1s → σ*(C3-F)/π*(C1-C2) a′ excitation, smaller for the F 1s → σ*(C3-F)/π*(C1-C2) a″ excitation, where the calculations indicate the open shell valence MO is more extended than the a′ MO of the first excitation and the amount of character from the core-excited F atom is less, and much smaller for the excitations to Rydberg states. Therefore, the first peak in the experimental spectrum at 689.44 eV is assigned to the F 1s → σ*(C3-F)/π*(C1-C2) a′ excitation and the second, broader peak at 692.58 eV to a combination of the F 1s → σ*(C3-F)/π*(C1-C2) a″ and F 1s → 3p Rydberg excitations. The broad, third peak fitted to the experimental spectrum near the F 1s ionization threshold is attributed to strongly overlapping higher order Rydberg states with significant vibrational excitation. By analogy with the F 1s excitation spectroscopy of other fluorinated hydrocarbons, discussed above, a contribution from an additional σ* (C-F) MO also seems reasonable in this energy region. However, no clear evidence for this is found in our core excitation calculations, suggesting that any σ* (C-F) character in the excitations near threshold is well-mixed with Rydberg states.

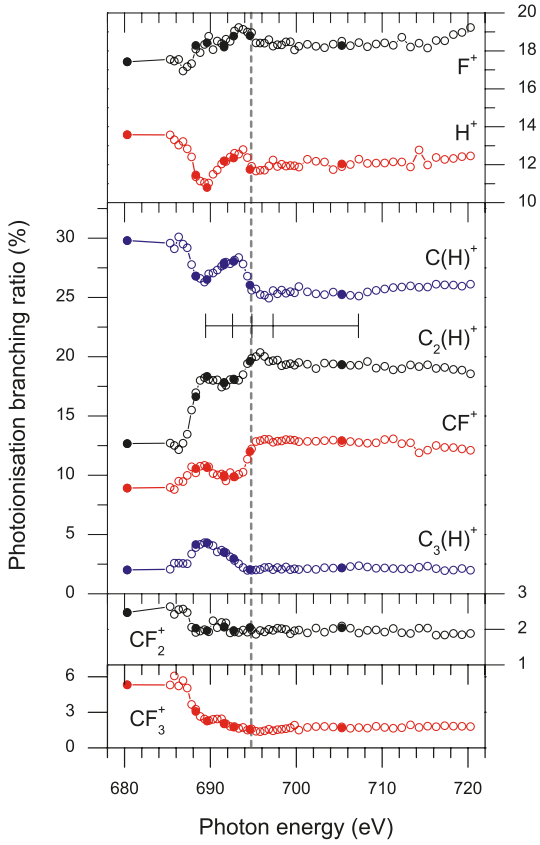
The computational results with the three basis sets are much less consistent above threshold. This is not unexpected, as the goal of the calculations was to describe the electronic states present below the F 1s ionization threshold. However, the calculations with the three basis sets all do predict a relatively intense transition to a high *l* state 10.8–12.5 eV above threshold, consistent with the assignment of peak five as a continuum shape resonance, as indicated in Table 1. The higher energy of 12.5 eV above threshold is predicted by the Basis 2 calculations, in which the diffuse Rydberg basis functions are centred on the core-excited F, in perfect agreement with the experimental observation. The calculations with the other two basis sets place this feature at slightly lower excitation energy.

Ionic fragmentation

A total of 16 ions have been identified in the PEPICO mass spectra collected near the F 1s edge. Ions differing by one mass unit could not be distinguished because of the resolution of the TDC and the widths of the ion peaks resulting from their generally high kinetic energies. Photoionization branching ratios (BR) as a function of photon energy have been derived from the PEPICO data by determining the intensity of each fragment ion in each PEPICO mass spectrum relative to the total signal arising from all ions observed in the mass spectrum. The branching ratios are shown in Figs. 4–6.

The branching ratios of the eight most abundant ions are shown in Fig. 4. These ions account for >92% of the total ion yield throughout this photon energy range. All are singly charged ions, indicating a tendency for charge separation following multiple ionization rather than the production of stable multiply charged ions. The absence from this group of any fragment ions containing at least two carbon atoms and at least one fluorine atom indicate the preference for bond dissociation between C2 and C3 and between C3 and F. Charge separation processes leading to one F^+ ion and a $C_2F_n^+$ or $C_3F_n^+$ ion are not observed following F 1s excitation. Instead, ionic fragmentation processes in which either dissociation of the C2–C3 bond or dissociation of *all* C–F bonds, or both processes, occur.

Fig. 4. Photoionization branching ratios of the eight most abundant fragment ions of trifluoropropyne near the F 1s ionization threshold. The positions of the peaks fitted to the TIY spectrum are indicated by vertical bars and the ionization threshold by a dashed line. The open symbol data were collected with a 60 s dwell time while the solid symbol data were measured separately with a 20 min dwell time.



$C(H)^+$ is the most abundant ion throughout the F 1s region, although its BR drops significantly with F 1s excitation or ionization. The CF_3^+ and CF_2^+ BR also drop with the onset of F 1s excitation. This suggests that these ions are being produced via direct valence ionization or C 1s continuum ionization rather than F 1s excitation or ionization. In contrast, the $C_2(H)^+$ and CF^+ BR show corresponding increases while the $C_3(H)^+$ BR increases with F 1s resonant excitation but then decreases again with F 1s ionization. Similar decreases in CF_3^+ and CF_2^+ BR and a corresponding increase in CF^+ have been observed following F 1s resonant excitation in CF_3CH_3 (27), CF_3Cl (28), $CF_3C(O)CH_3$ (18), and CF_3SF_5 (29). The $C_3(H)^+$ behaviour is consistent with the assignment of the first two F 1s near edge features as excitations largely to σ* (C-F) molecular orbitals. These σ* MOs are delocalized over the entire CF_3 group, so that population of these MOs gives rise to the state-specific dissociation of all three C–F bonds. F^+ is the second most abundant ion throughout this photon energy range. A relatively small increase in the F^+ BR is observed with F 1s resonant excitation but no further increase is observed with F 1s ionization.

Fig. 5. Photoionization branching ratios of the four least abundant singly charged fragment ions of trifluoropropyne near the F 1s ionization threshold. The positions of the peaks fitted to the TIY spectrum are indicated by vertical bars and the ionization threshold by a dashed line. The open symbol data were collected with a 60 s dwell time while the solid symbol data were measured separately with a 20 min dwell time.

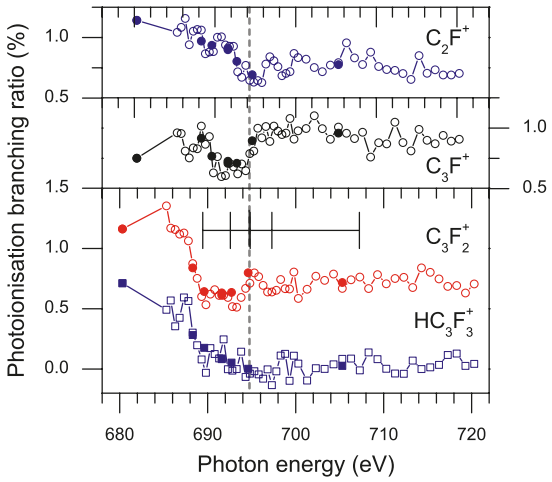

Fig. 6. Photoionization branching ratios of the four multiply charged fragment ions of trifluoropropyne observed near the F 1s ionization threshold. The positions of the peaks fitted to the TIY spectrum are indicated by vertical bars and the ionization threshold by a dashed line. The open symbol data were collected with a 60 s dwell time while the solid symbol data were measured separately with a 20 min dwell time.

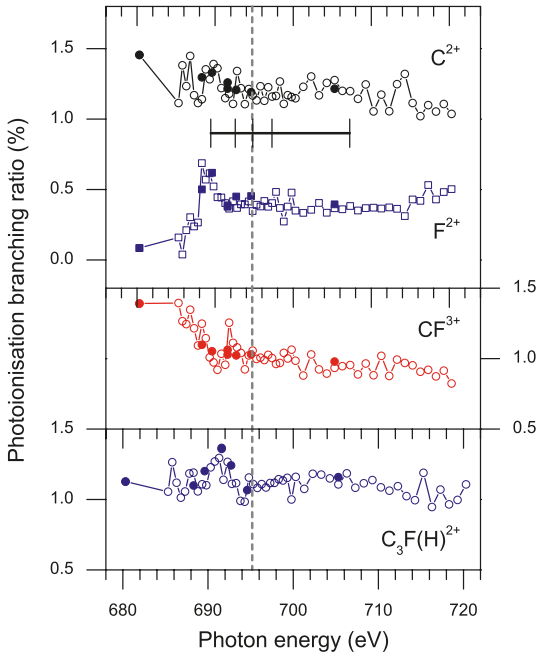

While there is certainly a degree of site-specificity to the ionic fragmentation at the F 1s edge, the data suggest a tendency for some charge delocalization to the rest of the molecule and in particular to the fluorinated carbon atom, resulting in cleavage of multiple bonds to the fluorinated carbon. The high F^+ BR below the onset of F 1s excitation (i.e., in the valence and C 1s ionization continua) may also be partially attributed to charge redistribution following core hole formation in trifluoropropyne, in this case with core hole formation at carbon.

The BR of the low abundance singly charged ions are shown in Fig. 5 while those of the observed multiply charged ions are shown in Fig. 6. All of these ions have BR < 1.5% and exhibit less variation with photon energy than do the more abundant ions shown in Fig. 4. The low abundance singly charged ions all contain at least two carbon atoms and one fluorine atom. With the exception of C_3F^+, which exhibits a small enhancement at the F 1s ionization threshold, there is a tendency with the ions shown in Fig. 5 for a decrease in their BR with F 1s excitation, indicating these ions are produced primarily via C 1s and valence continuum ionization. The drop in the BR of the parent ion $HC_3F_3^+$ with the onset of F 1s excitation indicates that resonant Auger decay of F 1s excited states to yield bound states of the parent ion does not occur to any significant extent.

The multiply charged ions shown in Fig. 6 also exhibit little variation with photon energy, supporting the observation made previously that F 1s excitation and ionization in trifluoropropyne favours charge separation over the formation of multiply charged ions. The one minor exception is F^{2+}, which has an increased (albeit still small) yield, particularly at the lowest energy F 1s resonant excitation. This is suggestive of atomic Auger decay of core-excited fluorine atoms produced via ultrafast dissociation of core-excited trifluoropropyne, as has been observed in resonant F 1s excitation of other fluorinated molecules (22–26).

Conclusions

The core excitation spectroscopy and ionic fragmentation of 3,3,3-trifluoropropyne have been investigated at the F 1s edge using synchrotron radiation, time-of-flight mass spectrometry, and coincidence techniques. The F 1s TIY spectrum exhibits several broad and overlapping resonances involving C-F σ* antibonding orbitals mixed with C-C π* character superimposed on the F 1s ionization threshold. Core excited state calculations also suggest numerous unresolved excitations to Rydberg states below threshold. The broad nature of the observed features is attributed to a combination of overlapping electronic excitations and considerable vibrational excitation following core-hole formation at F. The dominant fragmentation channels exhibit a clear dependence on the atomic site of initial core hole formation. F 1s excitation or ionization favours HC_2–CF_3 bond dissociation as well as C–F bond dissociation, indicating a tendency for charge delocalization from core-excited F to the adjacent C. Charge separation to yield multiple singly charged ions is favoured over the formation of multiply charged ions.

Bismuth-triflate-catalyzed Prins–Ritter reaction — An efficient synthesis of 4-amidotetrahydropyrans

J.S. Yadav, B.V. Subba Reddy, D.N. Chaya, G.G.K.S. Narayana Kumar

Abstract: Bismuth(III) triflate is found to be an effective Lewis acid in catalyzing a three-component reaction of homoallylic alcohol, carbonyl compound, and nitrile at ambient temperature via the Prins–Ritter sequence to furnish 4-amidotetrahydropyrans in high yields, all with cis selectivity. Spirocyclic 4-amidotetrahydropyrans are obtained in case of cyclic ketones.

Key words: Prins cyclization, bismuth(III) triflate, homoallyl alcohol, 4-amidotetrahydropyrans.

Résumé : On a trouvé que le triflate de bismuth(III) agit comme acide de Lewis efficace dans la catalyse de la réaction à trois composantes d'un alcool homoallylique, d'un composé carbonylé et d'un nitrile à la température ambiante, par le biais d'une séquence de Prins–Ritter, qui conduit à la formation de 4-amidotétrahydropyranes, avec des rendements élevés et une sélectivité complètement *cis*. Dans les cas où le produit de départ est une cétone cyclique, le produit obtenu est un 4-amidotétrahydropyrane spirocyclique.

Mots-clés : cyclisation de Prins, bismuth(III), triflate, alcool homoallylique, 4-amidotétrahydropyranes.

[Traduit par la Rédaction]

Introduction

Recently, multicomponent one-pot synthesis has received considerable attention because of its wide range of applications in medicinal chemistry for the production of structural scaffolds and combinatorial libraries in drug discovery (1). The 4-aminotetrahydropyran ring system is found in many biologically active natural products, such as ambruticins VS, glycamino acid, and others (2, 3). Tetrahydropyran derivatives are usually prepared by the Prins cyclization using acid catalysis (4, 5) or by intramolecular hetero-Michael reaction (6). However, the use of Ritter amidation to terminate Prins cyclization is scarce (7); hence, an efficient and practical methodology for the Prins–Ritter-type reaction would be of great importance for the synthesis of natural products (8).

Lanthanide triflates are unique Lewis acids that are currently of great interest (9). The high catalytic activity, low toxicity, moisture and air tolerance, and their recyclability make lanthanide triflates attractive alternatives to conventional Lewis acids (10). However, lanthanide triflates are rather expensive and their use in large-scale synthesis is limited. Therefore, cheaper and more efficient catalysts are desirable. In this direction, bismuth triflate has evolved as remarkable Lewis acid catalyst for effecting various organic transformations (11). Compared with lanthanide triflates, bismuth triflate is cheap and is easy to prepare, even on a multi-gram scale, from commercially available bismuth oxide and triflic acid (12). However, there have been no reports on the use of bismuth triflate for the synthesis of tetrahydropyrans.

Results and discussion

In this article, we describe a direct and efficient method for the synthesis of 4-amidotetrahydropyrans via the Prins–Ritter sequence using bismuth triflate. In a preliminary study, 3-phenylpropanal (**1**) was treated with but-3-en-1-ol (**2**) in acetonitrile in the presence of 10 mol% of bismuth triflate. The reaction went to completion in 4.5 h at room temperature, and the product 4-acetamidotetrahydropyran **3a** was obtained, instead of tetrahydropyranyl-4-triflate, in 93% yield with cis selectivity (Scheme 1).

This result encouraged us to study the reaction with various aldehydes, homoallylic alcohols, and nitriles. Interestingly, 3-buten-1-ol reacted smoothly with cyclohexanecarboxaldehyde, isobutyraldehyde, *trans*-cinnamaldehyde, 1-naphthaldehyde, 3,4-dichlorobenzaldehyde, 3,4,5-trimethoxybenzaldehyde, and *m*-nitrobezaldehyde in acetonitrile to produce the corresponding 4-acetamidotetrahydropyrans in high yields (Table 1, entries **b**–**h**,). The substituted homoallylic alcohols like 1-phenylbut-en-1-ol and 1-cyclohexylbut-en-1-ol also participated well in this transformation (Table 1, entries **o** and **p**). This reaction proceeded well even with cyclic ketones such as cyclopentanone, cyclohexanone, and 4-phenyl-1-cyclohexanone to give spirocyclic-4-acet-

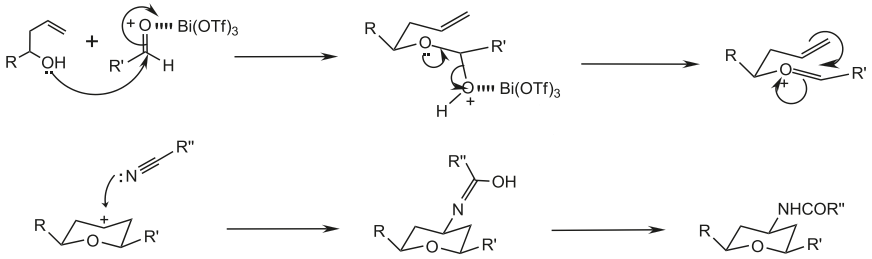
Scheme 3.



reaction did not proceed even after a long reaction time (16 h). The reactions were clean, and the products were obtained at room temperature in excellent yields and with high diastereoselectivity as determined from the NMR spectra of the crude products. Only one diastereoisomer was obtained in each case, the structure of which was confirmed on the basis of coupling constants and also by nOe experiments (8e). The formation of the products could be explained by hemi-acetal formation followed by Prins cyclization and subsequent Ritter amidation (Scheme 3).

A tentative reaction mechanism to realize the cis selectivity could be explained by assuming the formation of an (*E*)-oxocarbenium ion via a chairlike transition state, which has an increased stability relative to the open oxocarbenium ion owing to delocalization. The optimal geometry for this delocalization places the hydrogen atom at C-4 in a pseudo-axial position, which favours equatorial attack of the nucleophile (13). The effects of various metal triflates such as $In(OTf)_3$, $Yb(OTf)_3$, $Sm(OTf)_3$, $Dy(OTf)_3$, and $Ce(OTf)_3$ were examined in this reaction. Of these, bismuth triflate was found to be efficient in terms of conversion. The scope and generality of this process is illustrated with respect to various carbonyl compounds, homoallylic alcohols, and nitriles, and the results are presented in Table 1. It is noteworthy to highlight that both aromatic and aliphatic substrates worked well for this transformation.

Conclusion

In summary, we described a novel and efficient Prins–Ritter reaction to produce highly substituted 4-amidotetrahydropyrans in high yields, all with cis selectivity. The use of inexpensive and readily available bismuth triflate makes this procedure simple, convenient, and practical. In addition to its simplicity, efficiency, and milder reaction conditions, this method provides an easy access for 4-amidotetrahydropyran derivatives in a single-step operation.

Experimental

Melting points were recorded on Buchi R-535 apparatus and are uncorrected. IR spectra were recorded on a PerkinElmer FTIR 240-c spectrophotometer using KBr optics. ^{1}H, ^{13}C NMR spectra were recorded on Gemini-200 spectrometer in $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on a Finnigan MAT 1020 mass spectrometer operating at 70 eV. TLC was monitored on 0.25 mm pre-coated silica-gel plates (60F-254).

General procedure

A mixture of but-3-en-1-ol (1 mmol), 3-phenylpropanal (1.2 mmol), and bismuth triflate (10 mol%) in acetonitrile (5 mL) was stirred at 23 °C for a specified time (Table 1). After completion of the reaction as indicated by TLC, the reaction mixture was quenched with water and extracted with ethyl acetate (2 × 10 mL). The combined organic layers were dried over anhyd. Na_2SO_4. Removal of solvent followed by purification on silica gel (Merck, 100–200 mesh, ethyl acetate/hexane, 4:6) gave pure 4-amidotetrahydropyran. The products thus obtained were characterized by IR and NMR spectroscopy. Characterization data was found to be consistent with that of authentic samples (6).

a: *N*-(2-phenethyltetrahydro-2*H*-4-pyranyl)acetamide

Pale yellow solid, mp 90–92 °C. IR (KBr) ν: 3308, 2923, 2852, 1648, 1543, 1368, 1083, 946, 745 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.26 (m, 2H), 1.31 (dq, 1H, *J* = 4.2, 12.2 Hz), 1.36 (q, 1H, *J* = 12.0 Hz), 1.85 (t, 2H, *J* = 7.5 Hz), 1.93 (s, 3H), 2.66 (ddt, 1H, *J* = 2.2, 4.2, 12.0 Hz), 2.74 (ddq, 1H, *J* = 2.2, 12.0, 12.0 Hz), 3.28 (m, 1H), 3.44 (dt, 1H, *J* = 1.5, 12.0 Hz), 3.89 (m, 1H), 4.13 (m, 1H), 5.28 (d, 1H, *J* = 8.3 Hz), 7.07–7.26 (m, 5H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 23.1, 31.4, 32.5, 37.7, 38.3, 45.9, 66.3, 75.4, 125.6, 127.8, 128.1, 141.7, 169.5. Mass spectrometric detection of proteins in non-aqueous media — The case of prion proteins in biodiesel

Michelle D. Douma, Gina M. Kerr, R. Stephen Brown, Bernd O. Keller, and Richard D. Oleschuk

Abstract: Limitations in efficient extraction, minimization of media interferences, and suitable sample preparation methods pose significant challenges to the successful detection of protein traces in non-aqueous media. Here we present a filtration method, employing filter disks with embedded C_8-modified silica particles, that allows the capture of proteins from non-aqueous sample volumes. The extraction process is followed by elution of the protein from the filter disk and by either direct mass spectrometric detection or tryptic digestion followed by peptide mapping and MS/MS fragmentation of protein-specific peptides. The method is applied to spiked biodiesel samples for the detection of prion proteins. The tryptic peptide with sequence YPGQGSPGGNR is specific for prion proteins and can be used for unambiguous identification. The developed extraction method has the potential application to be used for large-scale testing of protein impurities in non-aqueous media, for instance as a safety and quality control tool in the animal tallow-based biodiesel production process.

Key words: protein detection, MALDI, non-aqueous media, filtration

Résumé : Les limitations dans l'extraction efficace, la minimisation des interférences des milieux et les méthodes appropriées de préparations des échantillons présentent des défis importants lorsqu'on veut détecter avec succès la présence de traces de protéines dans des milieux non-aqueux. Dans ce travail, on propose une méthode de filtration dans laquelle on utilise des disques du filtre dans lesquels des particules de silice modifiées avec C_8 sont implantées qui permettent de capturer les protéines à partir des volumes d'échantillons non-aqueux. Le processus d'extraction est suivi d'une élution de la protéine à partir du disque du filtre et par une détection soit directe par spectrométrie de masse ou par une digestion tryptique suivie d'une cartographie des peptides et une fragmentation SM/SM des peptides spécifiques pour une protéine. On a appliqué la méthode à des échantillons de biodiésel trafiqués pour la détection des protéines de prion. Le peptide tryptique comportant la séquence YPGQGSPGGNR est spécifique pour les protéines de prion et peut être utilisé pour une identification non ambiguë. La méthode d'extraction développée possèdel'application potentielle d'être utilisée pour évaluer à une grande échelle les impuretés de protéine dans un milieu non-aqueux, par exemple, comme outil de contrôle de la qualité et de la sécurité dans le processus de production de biodiésel à base suif d'animal.

Mots-clés : détection de protéine, "MALDI", milieu non-aqueux, filtration.

[Traduit par la Rédaction]

Introduction

Proteomics focuses on the identification and quantitation of protein species from a variety of biological matrices such as blood, urine, or cellular and tissue samples (1). As a result, most analysis and synthetic protocols have been developed and optimized to examine and determine proteins and peptides stemming from aqueous samples (2). Mass spectrometry (MS) has often become the detection method of choice because of its ability to provide precise molecular mass information for the proteins of interest. In combination with proteolytic digestion strategies, peptide mapping, and peptide fragmentation (MS/MS), mass spectrometry can provide unambiguous protein identification (1).

With increasing interest in the detection of proteinaceous impurities in pharmaceutical production processes (3), advancements of biocatalysis in non-aqueous systems (4), and the proliferation of fuels derived from biomass sources (5), there is an evolving need to develop novel protein detection and quantification methods that are effective for the associated non-aqueous matrices. An important example is the potential prion protein contamination in biodiesel produced from animal-based sources such as tallow (5). Transmissible

spongiform encephalopathy (TSE), a fatal disease that affects the nervous system, has become a growing concern, especially in the cattle industry where the disease is referred to as bovine spongiform encephalopathy (BSE) or mad cow disease (5). It is hypothesized that prion proteins are the causative agent of TSE (6). A normal form of the protein (PrP^C) is thought to misfold into an amyloidogenic beta-sheet structure that has the ability to convert PrP^C into the infective prion protein (PrP^{Sc}) (6). There is concern that biodiesel produced from specified risk materials (SRMs), including brain, inner organs, or spinal cord, could be a source of infectious prion proteins (5). For inactivation of infectious proteins to occur, both high temperatures and high pressures are needed. Several recent reports have stated that rendering procedures and biodiesel production processes are safe and pose a negligible risk in terms of TSE infectivity, even under worst-case scenarios (7–9). Nevertheless, one report also points out that because of the variability of current rendering and biodiesel production processes, individual assessments for each specific case may be necessary (9). Further scientific research into the matter is desirable, both to add additional levels of safety (5) and to expand our knowledge of protein stability outside their natural environments, for example in non-aqueous media (2).

Bioassays are currently the preferred method for detection of TSE infectivity in biological tissues or organisms (10). Samples are administered to test animals via injection or oral intake. After an incubation period or the onset of clinical signs of the disease, the host animal is euthanized and the brain is examined for TSE. A drawback to this testing method is the long incubation time of up to 30 months. The use of transgenic mice has shortened analysis times to 150–196 days (11). However, biodiesel cannot be directly administered in such bioassays because of its toxicity to the test animals. Furthermore, the average shelf life of biodiesel is in the range of 6–8 months (12), and thus any meaningful tests require detection methods with a shorter turnaround time. Other detection methodologies that rely on affinity interactions such as Western blot analysis can also be ruled out for direct biodiesel monitoring because of organic matrix interferences that would alter affinity binding either through solvent interactions or denaturation (10). In addition, the presence of organic solvents can affect the activity of proteins. For instance, enzyme activity has been enhanced in the presence of organic solvents (13), but over the time of several hours can also decrease enzyme activity (14). Thus, even if organic solvents were not an incompatible matrix for the desired analysis techniques, the tests could provide inconclusive results due to altered protein interactions in organic solvents.

The detection of prion proteins in biodiesel has been carried out using a combination of chloroform and methanol extraction, gel electrophoresis separation, and immunoassay detection (8). Here, we present a novel approach using biodiesel filtration through special filter disks combined with matrix-assisted laser desorption/ionization (MALDI) mass spectrometry. The use of a C_8-embedded membrane to filter and preconcentrate biodiesel samples is attractive due to its applicability for a wide variety of proteins and for different sample media, both aqueous and non-aqueous. Another feature is the ability to filter large sample volumes (15), a major advantage compared with tedious liquid–liquid extraction methods applicable only to small sample batches.

Previously, membranes such as polyurethane (PU) (16), poly(tetrafluoroethylene) (17), nitrocellulose (18), polyethylene (19), polyvinyldifluoride (PVDF) (20), and nylon (21) have been used as sample supports for direct analysis of proteins by MALDI-MS. Proteins are adsorbed to the membrane surface and washing steps can be incorporated without significant loss of protein. Depending on the nature and abundance of the proteins, it may be possible to perform MALDI-MS directly on the disk. This enables sensitive analysis methods optimized for aqueous samples to be employed (e.g., MS and Western blot).

In the present study, we developed an extraction technique using a mixture of acetonitrile, non-ionic detergent, and water that allows for PrP to be removed from an extraction filter disk containing C_{18}- or C_8-modified particles after filtration of a spiked biodiesel sample. This extraction procedure has proven effective for other proteins, including bovine serum albumin (BSA) and cytochrome c, and can also be applied for filtrations involving water or isooctane. Subsequent tryptic digestion of the extracted prion protein either on-disk or after re-suspension in water yields a peptide with a prion-specific sequence YPGQGSPGGNR, allowing unambiguous identification via MS/MS analysis. This method should be generally applicable for any large scale testing for proteinaceous impurities both in aqueous and non-aqueous media.

Experimental

Reagents and materials

Methanol (MeOH), 2-propanol, and acetonitrile (ACN) (all ACS reagent grade) were obtained from Fisher Scientific (Fair Lawn, New Jersey, USA). Bovine serum albumin (BSA), horse heart cytochrome c, bovine trypsin (TPCK treated for deactivation of chymotrypsin activity), 2,2,4-trimethylpentane (isooctane), and octyl-β-D-glycopyranoside (*n*-OGP) were purchased from Sigma-Aldrich (Oakville, Ontario, Canada). Ammonium bicarbonate (bioChemika Ultra), sinapic acid, and α-cyano-4-hydroxycinnamic acid (HCCA) were obtained from Fluka (Buchs, Switzerland). Trifluoroacetic acid (TFA) was purchased from Sigma-Aldrich Chemicals (Milwaukee, Wisconsin, USA). Glacial acetic acid (98%) was obtained from Fisher Scientific (Ottawa, Ontario, Canada). All chemicals were used without further purification.

Biodiesel from animal and plant sources was donated from Environment Canada (Ottawa, Ontario, Canada). A refolded murine (of the rat and mouse family) prion protein (PrP) was expressed according to the protocol of Hornemann et al. (22) and received from the Saskatchewan Research Council (SRC, Saskatoon, Saskatchewan, Canada). The PrP stock solution was received at a concentration of 0.725 mg/mL in *tris*-acetate buffer (pH 6.5) and was stored at –80 °C. Refolded PrP, according to the protocol of Jackson et al. (3), resulted in the β-folded murine prion protein (PrP^*), which was received from the SRC as a precipitate and stored at –80 °C. A MilliQ apparatus (Millipore, Bedford, Massachusetts, USA) was used to purify water (18.2 MΩ cm). 3M Empore extraction disks (47 mm diameter) em-

© 2008 NRC Canada

bedded with either octyl (C_8) or octadecyl (C_{18}) coated absorbent particles were purchased from Fisher Scientific (Ottawa, Ontario, Canada). C_{18} and C_4 ZipTips were from Millipore (Bedford, Massachusetts, USA).

Filtration and whole protein extraction

Filtrations were performed under vacuum by air aspiration using a regular laboratory filtration apparatus. Either 3M Empore C_8 or C_{18} extraction disks were used. Proteins studied by filtration included BSA as a surrogate and PrP. Prior to filtration, the medium of interest was spiked with protein. To help the solubility of the PrP stock solution in biodiesel, a 1:10 solution of PrP stock and methanol was used for spiking. The biodiesel solution was continuously stirred or agitated during the filtration process to ensure uniform dispersion across the extraction disk. After filtration of PrP spiked media such as water, isooctane, or biodiesel, a piece of dry extraction disk, approximately 2 mm × 2 mm, was immersed in a 1:1 solution of acetonitrile and 0.5% *n*-OGP in deionized H_2O to remove the protein from the disk for subsequent MALDI analysis. The extraction was performed for a period of 20 to 30 min while sonicating. It should be noted that initial attempts to employ a Millipore filtration unit (Labscale TFF System, Model #XX42LSS11) failed. Unknown corrosive ingredients present in the biodiesel partially dissolved plastic parts of this equipment and rendered it unusable. As a consequence, any contact of biodiesel with plastic laboratory equipment was avoided.

Protein digestion — trypsin

Tryptic digests in solution were performed using a modified protocol from that of Qin et al. (7). A 1:2 solution of protein stock in 0.1 mol/L NH_4HCO_3 was prepared to a total volume of 15 μL. A 1 μL aliquot of a 1 mg/mL solution of trypsin was added to the vial, and the vial was incubated in a Fisher Scientific dry bath incubator (Ottawa, Ontario) at 37 °C for 2 h. Tryptic digestions were also performed directly on extraction disks. Samples of biodiesel spiked with proteins were filtered through a C_8 or C_{18} extraction disk. After the disk was dried, a piece of extraction disk was cut and spotted with 1 μL of a 1:10 solution of trypsin (1 μg/μL) and 0.1 mol/L NH_4HCO_3. The piece of extraction disk was then placed into a weigh boat inside a plastic container. A wet sponge was also placed into the container to minimize evaporation. The container was placed on top of an incubator for 30 min at 37 °C.

Another approach was to submerge pieces of extraction disks in a 1:10 solution of trypsin (1 μg/μL) and 0.1 mol/L NH_4HCO_3. The solution with the extraction disk was then incubated for 2 h at 37 °C, and the supernatant analyzed for peptides.

Microwave-assisted acid digestion of PrP

Microwave-assisted acid digestion for PrP in solution was accomplished using a modified protocol adopted from Zhong et al. (23). A 50 μL sample of PrP stock solution was concentrated under nitrogen to approximately 10 μL, and 5 μL of 98% TFA was added. The solution was then sealed with Teflon tape in a 1.5 mL propylene Eppendorf vial and microwaved on high for 10 min in a conventional microwave oven (max. 700 watts). A minimal volume (<20 μL) was critical to withstand the vapour pressure created during the microwaving process. A container of water was placed beside the Eppendorf vial of protein and acid to absorb any excess microwave energy (23). After the TFA digest was performed, the microwave was unplugged and cooled to room temperature before opening. The vial was then carefully opened in a fume hood and 0.1 mol/L NH_4HCO_3 was added to neutralize the acid.

Sample preparation for mass spectrometry was either done with protein–peptide solutions, extracts, or directly from extraction disks. In the latter case, the small pieces of the disks were carefully glued onto MALDI target plates using 3M spray adhesive.

Mass spectrometric analysis of whole proteins

For exact molecular weight determination, a 10 μL aliquot of the PrP stock solution was purified using a C_4 ZipTip and eluted with sinapic acid solution according to the protocol of Dai et al. (24). For whole protein detection from C_8 or C_{18} extraction disks, small pieces of the extraction disk (~2 mm × 2 mm) were placed into an Eppendorf tube and extracted with a 1:1 solution of acetonitrile and 0.5% *n*-OGP. This solution was then further prepared, employing a novel sensitive three-layer matrix preparation method reported by Keller and Li (25).

MALDI-TOF analysis was performed on a Voyager DE STAR biospectrometry workstation (Applied Biosystems, Framingham, Massachusetts, USA) in positive linear mode. This instrument is equipped with a 337 nm nitrogen laser. Several hundred laser shots were summed for spectra collection. BSA and cytochrome c were used as standard proteins for calibration.

Mass spectrometric analysis of protein digests

Peptide mixtures resulting from protein digests were first purified and concentrated employing a C_{18} ZipTip and further prepared according to the two-layer matrix preparation method of Dai et al. (24). Peptide maps were obtained on the above-mentioned Voyager instrument in positive reflectron mode. MS/MS analysis of specific peptides was done either with a post-source decay method on the Voyager instrument or from solution after purification with a C_{18} ZipTip and elution with a 70% MeOH and 0.1% acetic acid solution, by employing a static nanospray setup on a QSTAR XL QqTOF mass spectrometer (Applied Biosystems, MDS-Sciex, Toronto, Ontario, Canada).

Results and discussion

PrP characterization

PrP was expressed according to the protocol by Hornemann et al. (22). The PrP sequence is shown in Fig. 1 (209 amino acid residues). The addition of a serine residue at the C-terminus is intended to minimize proteolytic degradation, and the protein contains one disulfide linkage between its two cysteine residues. From the above sequence, the average mass of the protein with all methionine residues oxidized as ensured by the protocol (22) is calculated to be 23 115 Da. Figure 2 shows the mass spectrum of the whole murine PrP protein. The signals at *m*/*z* 23 113 and at 11 553 result from the singly and doubly protonated ions of PrP, re-

© 2008 NRC Canada

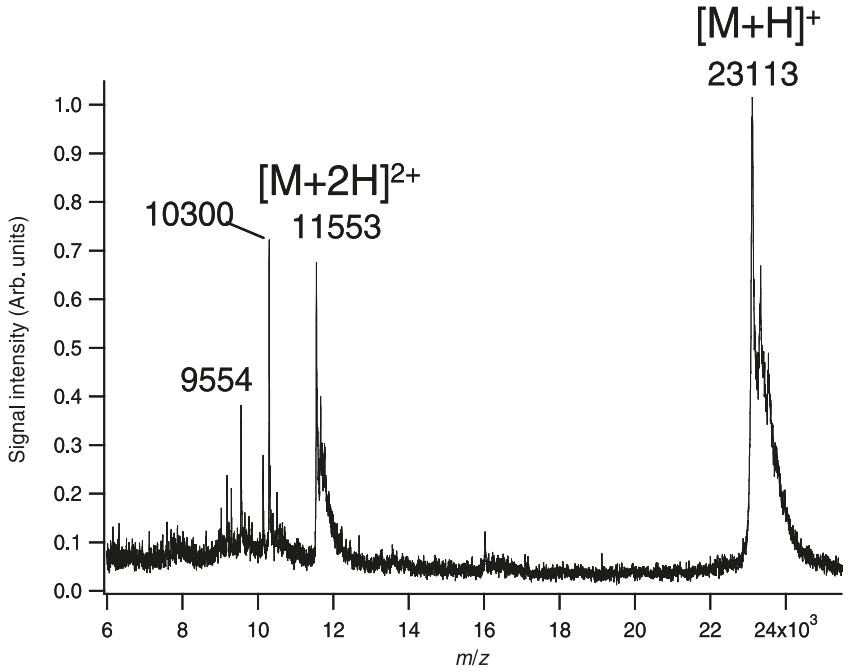
Fig. 2. MALDI-TOF mass spectrum of PrP after (ZipTip) purification. Below *m*/*z* 11 000 there are a several protein fragments or contaminating proteins observable.



spectively. The observed signal at 23 113 Da is within 3 Da of the calculated *m*/*z* for the singly charged ion (*m*/*z* 23 116) and within the expected accuracy of the instrument at this mass range for external calibration (150 ppm or 3.5 Da). Several protein fragments or protein contaminants below *m*/*z* 11 000 are also observed.

Tryptic digestion of PrP (both unfolded and refolded forms) directly from the stock solutions yielded two peptides with sequence YYR (127–129; *m*/*z* 501) and YPGQGSPGGNR (16–26; *m*/*z* 1089), respectively. The smaller peptide with sequence YYR has little diagnostic value because of its short sequence, which is not specific for prion proteins. The YPGQGSPGGNR peptide (*m*/*z* 1089) is unique for prion proteins and is a conserved sequence found in more than 50 different species (MASCOT sequence search at www.matrixscience.com), such as bovine, deer, and sheep. Since this sequence is specific to the prion protein it can be used as a biomarker for unambiguous identification of prion proteins (26, 27). The YPGQGSPGGNR peptide is located very close to the protein's N-terminus, even before the four octapeptide repeat units involved in copper binding (28). The N-terminal region up to amino acid residue 121 is the so-called non-structured, flexible or "random coil-like" region of the protein and is not involved in alpha-helix or beta-sheet formation (29). Circular dichroism (CD) and fourier-transform infrared (FTIR) experiments have shown that PrP^{C} contains 40% alpha-helix and minimal beta-sheets, whereas PrP^{Sc} contains 30% alpha-helix and 45% beta-sheets (30, 31). The increased beta-sheets present in PrP^{Sc} presumably do not inhibit enzymatic digestion where this peptide is located. Figure 3 shows an electrospray MS/MS fragmentation spectrum of this peptide.

Microwave-assisted acid digestion also yielded specific peptide signals for PrP in the mass range >3000 Da, as is shown in Fig. 4. However, the spectra were generally dominated by several peptides in the mass range below 3000 Da that possibly originated from the protein contaminants in the PrP stock solutions. The observed peptides specific for PrP are in a mass range too high for efficient MS/MS fragmentation (> *m*/*z* 3000) and thus have limited suitability for specific PrP detection in complex mixtures. In addition, the required protein amounts for effective microwave-assisted digestion are in the microgram range (23), thus limiting this method's employability in sensitive protein detection. Microwave-assisted acid digestion experiments with filter disk pieces spiked with prion protein solution were not successful.

Filtration of spiked biodiesel, extraction of filter disks, and protein analysis

Although direct analysis of protein on the extraction disk is possible, the analysis sensitivity is improved when protein is extracted back into solution. With the extract, a recently developed three-layer matrix preparation method for MALDI-MS can be applied that allows the detection of pro-

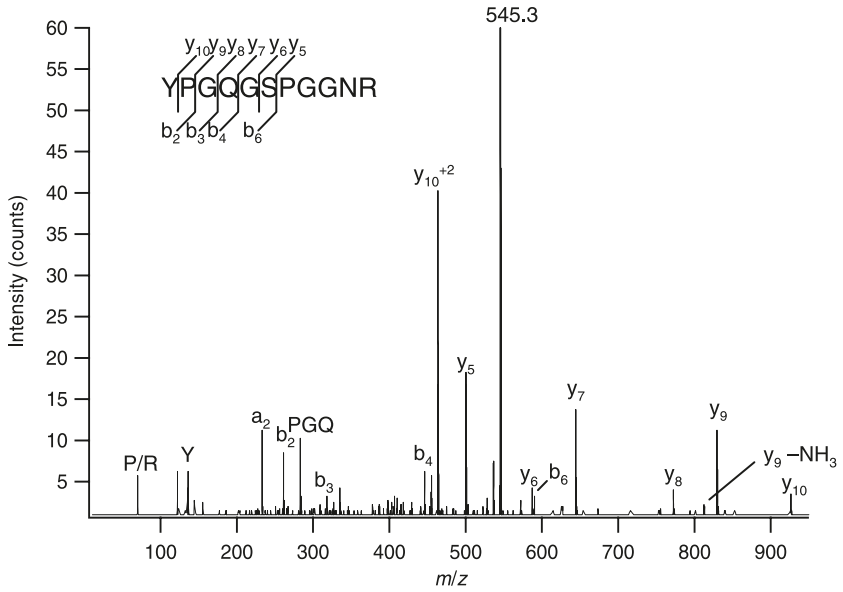

Fig. 4. MALDI-TOF mass spectrum of a microwave-assisted acid (TFA) digest of PrP. The resulting peptides specific for PrP are shown in the insert in the upper right corner. All the arrows indicate a loss of a glycine residue (57 Da), which is typical for TFA digests (23). Peaks below *m*/*z* 2600 are probably from digested contaminant protein fragments.

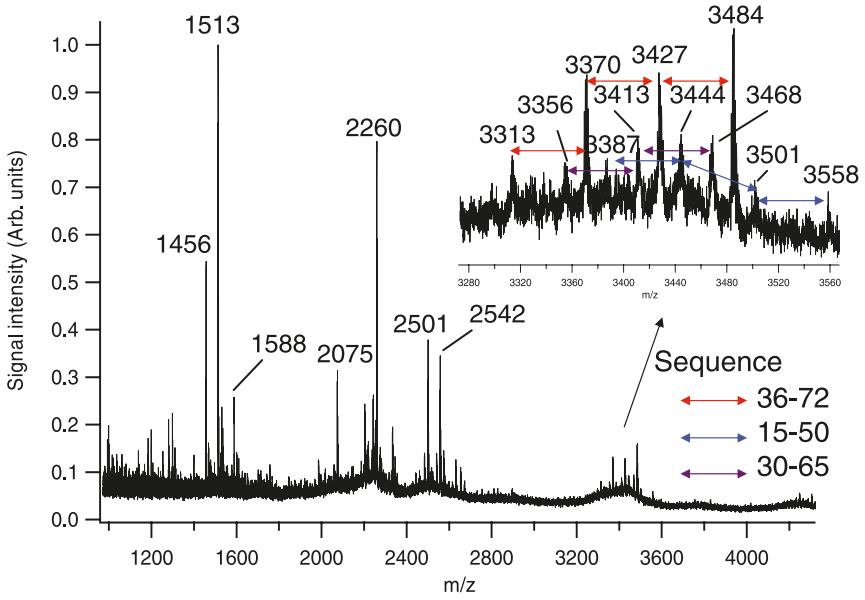

teins in low nanomolar concentrations (25). Furthermore, extracting the protein back into solution provides a medium that is compatible, after removal of acetonitrile, for other analysis techniques, including enzymatic digestion and immunoassay. After filtration of a protein spiked sample, the extraction method of 1:1 acetonitrile and *n*-OGP effectively removed the protein from the extraction disk.

To illustrate that the majority of the PrP was transferred to the extraction disk, a water-spiked sample was analyzed before and after filtration. PrP was detected in the water sample as well as after extraction from the disk, however PrP was not detected in the filtrate (data not shown). The acetonitrile and *n*-OGP extraction procedure is applicable after the filtration of a variety of media including water, isooctane (data not shown), and biodiesel. The mass spectra of whole PrP from the extract of a C_8-disk used to filter 25 mL of a 60 nmol/L PrP biodiesel sample is shown in Fig. 5. Extraction disks with embedded C_8-modified silica particles were found to be superior in terms of protein recovery for biodiesel filtrations and were thus used for all subsequent analysis. This observation is consistent with Engelhardt and Mueller's 1984 report in which C_8-modified bonded phase showed optimal protein recovery in reverse phase high performance liquid chromatography analysis (32).

Difficulties were encountered during the filtration process with older batches of biodiesel that presumably became contaminated with bacterial growth over time. As a result, if the biodiesel was aged a pre-filtration step had to be used to re-

Fig. 5. MALDI-TOF mass spectrum of the extract of PrP from a C_8 extraction disk used to filter 25 mL of biodiesel containing PrP (60 nmol/L). Extraction performed in a 1:1 solution of ACN and 0.5% *n*-OGP for 20 min.

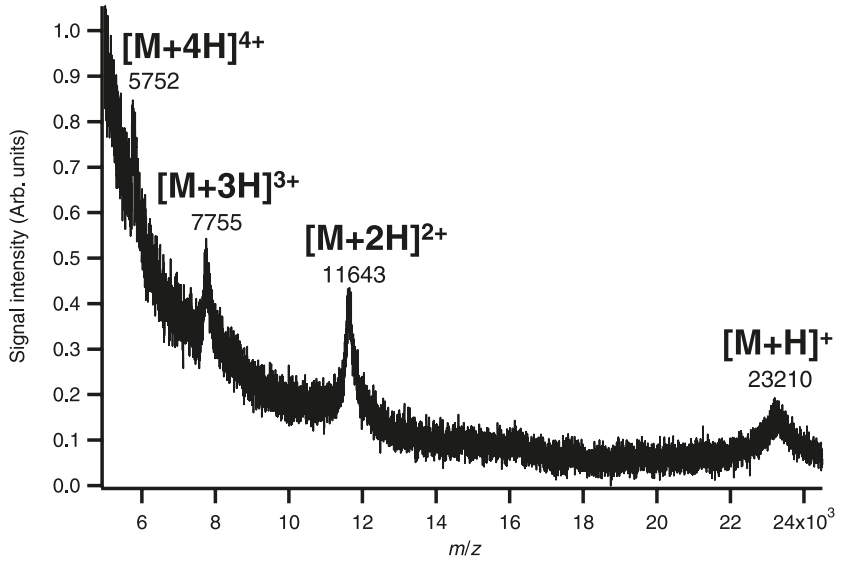

Fig. 6. MALDI-TOF mass spectrum achieved by post source decay to sequence the 1089 peptide achieved from a 2 h tryptic digest performed on a piece of C_8 extraction disk, used to filter 25 mL of biodiesel containing PrP (60 nmol/L). The sample was passed through a C_{18} ZipTip prior to analysis and eluted with HCCA matrix solution.

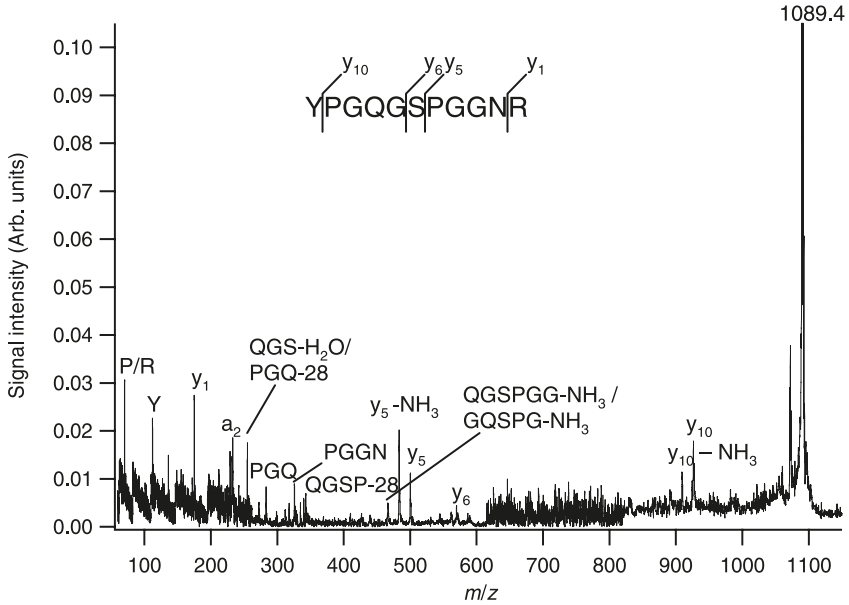

move any particulate interference. For applicability of this technique to large scale analysis of the biodiesel production process, the biodiesel samples should be analyzed within a few months of production because of their limited shelf life (12).

Digestion of proteins can be performed directly on the extraction disk after filtration of a protein spiked sample, and we successfully analyzed BSA and cytochrome c in such a manner (data not shown). For PrP, however, we found this approach not to be suitable, since this protein required a longer digestion time of more than 2 h and thus the trypsin solution dried up before the enzymatic digestion was complete. To circumvent this problem, after filtration a small piece of the extraction disk was immersed directly in a trypsin solution, and the resulting peptide mixture contained both the *m/z* 501 and 1089 peptides. The MS/MS of the 1089 peptide obtained from a tryptic digest of a piece of extraction disk used to filter 25 mL of a 60 nmol/L PrP–biodiesel sample is shown in Fig. 6. In this case, we chose to use MALDI post source decay for peptide fragmentation (as compared with nano-ESI employed for peptide marker screening in Fig. 3.), because of better sensitivity and compatibility with impurities. As can be seen from Fig. 6, this approach allows also for unambiguous PrP identification. These results confirm that PrP can be effectively extracted from biodiesel and unambiguously identified by MS/MS.

Our 25 mL biodiesel sample with 60 nmol/L PrP contains a total amount of ~60 μg PrP. The effective area of our filter

© 2008 NRC Canada

disk is approximately 960 mm^2 since only about 35 mm of its total 47 mm diameter is exposed to filtration solution. Assuming uniform distribution and complete capture of PrP on the extraction disk after the biodiesel filtration, approximately 250 ng (~10 picomole) of PrP is expected on a 2 mm × 2 mm (4 mm^2) piece of extraction disk. Considering potential losses during the filtration process and irreversible protein adsorption to glass surfaces as well as complications incurred by the complex biodiesel sample matrix, it is clear that this approach cannot match the 20–30 attomole detection limit achievable by direct analysis of a pure PrP standard (33). Nevertheless, the spiked amount of PrP is comparable to traditional initial extraction experiments performed for BSA as a carrier protein in lipid media (~1 μg BSA/mL) (8). The question if such a detection limit is adequate for "real" samples cannot be readily answered, since each application's requirements will differ and need individual comprehensive assessments. For applications where a more detailed method development is warranted and affordable, application of stable-isotope labeled standards and testing of dilution series will eventually establish the linear dynamic range and absolute detection limits. In this respect, it should be noted that the extraction disks and extracts obtained from our method allow transfer of the captured proteins to aqueous media and potentially allow employment of more sensitive and quantitative immunoassays (e.g. Western blot) and can also be used in bioassays for testing of infectivity.

Conclusions

The detection and characterization of proteinaceous impurities in non-aqueous media is a new emerging field and currently faces enormous challenges due to the lack of adequate methods. In our present studies, we successfully employed extraction disks with embedded C_8-modified silica particles to extract proteins from both aqueous and non-aqueous media. The ruggedness is demonstrated through the application of this method for a "difficult" protein (i.e. prion protein) in a corrosive medium (i.e. biodiesel), and thus this approach should be applicable to a wide range of potential samples where proteinaceous impurities are of interest. Mass spectrometry has proven to be an efficient detection tool for extracted proteins, and, in combination with enzymatic digestion, peptide extraction, and MS/MS, analysis allowed for unambiguous identification of the proteins. Although mass spectrometry is an invaluable tool in the method development process, current achievable detection limits might not always be sufficient in real world applications. However, the presented protein extraction method allows for recovery of the extracted proteins into aqueous media that also allow for ultrasensitive detection methods such as immunoassays. We anticipate that because of its ruggedness and simplicity, the general principle of this method should be easily adaptable to large-scale production processes in pharmaceutical or other industries, and it represents a realistic alternative to small-batch liquid-liquid extraction methods.

Palladium-catalyzed aerobic alcohol oxidation supported by a new type of α-diimine ligands

Jin Zhou, Xiaoyan Li, and Hongjian Sun

Abstract: A series of new ionic sulfonated α-diimine ligands were prepared and employed as supporting ligands for the palladium-catalyzed aerobic alcohol oxidation. The electronic properties, rigidity, and steric hindrance of ligands have remarkable influences upon the catalytic activity of the palladium complexes. The best catalytic result could be achieved using ligand **9** with an electron-withdrawing sulfonyl substituent together with bulky groups (*iso*-propyl in 2,6-positions). This diimine/palladium-catalyzed system is highly efficient for the oxidation of various benzylic alcohols, and showed moderate yields for the secondary aliphatic alcohols and cyclic alcohols.

Key words: α-diimine, palladium, aerobic oxidation, alcohol.

Résumé : On a préparé une série de nouveaux ligands ioniques α-diimines sulfonées et on les a utilisés comme ligands de support pour des réactions d'oxydation aérobiques d'alcools catalysées par le palladium. Les propriétés électroniques, la rigidité et l'empêchement stérique des ligands influencent profondément l'activité catalytique des complexes du palladium. Le meilleur résultat catalytique a été obtenu en utilisant le ligand **9** qui porte un substituant électroaffinitaire sulfonyle avec des substituants volumineux, isopropyles, dans les positions 2 et 6. Ce système de diimine catalysée par le palladium est très efficace pour l'oxydation de divers alcools benzyliques et donne des rendements modérés avec les alcools aliphatiques ou cycliques secondaires.

Mots-clés : α-diimine, palladium, oxydation aérobique, alcool.

[Traduit par la Rédaction]

Introduction

The oxidation of alcohols to the corresponding aldehydes or ketones is one of the most important functional group transformations in organic synthesis. Recently, the use of molecular oxygen as terminal oxidant has received great attention for both economic and environmental benefits, and many highly efficient systems have been developed for catalytic aerobic alcohol oxidation using Fe (1), Ru (2–5), Co (6), Cu (7, 8), Mn (9), Ni (10), and Pd (11,12) catalysts or even a transitional-metal-free catalyst system(13). Homogeneous palladium catalysts are particularly effective for the oxidation of alcohols (14–24). Of these reports, the first significant breakthrough was reported by Peterson and Larock, who employed the $Pd(OAc)_2$/DMSO catalyst system for oxidation of a wide range of benzylic and allylic alcohols with molecular oxygen as the sole oxidant (25). Furthermore, the reported Uemura $Pd(OAc)_2$/pyridine system (26, 27), Sheldon's $Pd(OAc)_2$/phananthroline aqueous system (28), Sigman's $Pd(OAc)_2/NEt_3$ (29), and $Pd(OAc)_2$/*N*-heterocyclic carbene catalyst systems (30) are remarkable catalyst systems and could give a norm for the performance of new catalysts.

The mechanism of palladium-catalyzed aerobic oxidation has been comparatively studied (31–33). Recently, Stahl and co-workers reported a mechanistic study of $Pd(OAc)_2$/DMSO catalyst system (34) and indicated that oxidation of palladium(0) might be the turnover-limiting step. In contrast to the $Pd(OAc)_2$/DMSO catalyst system, Stahl's mechanistic studies of $Pd(OAc)_2$/pyridine catalyst system indicated a palladium(II) resting state with turnover-limiting oxidation of the alcohol substrate, which is similar to the other catalyst systems that employ nitrogen ligands (35, 36). An oxidase-style mechanism was proposed for the aerobic oxidation of alcohols (37, 38). The oxidation proceeds in two independent, sequential stages. Palladium(II) is the real oxidant for the oxidation of alcohol. The role of molecular oxygen is to oxidize the palladium(0) species to palladium(II). The ligands facilitate the activation of dioxygen by increasing the electron density on Pd(0). Experimental evidence, supporting this hypothesis, has been presented by Stahl and coworkers while examining olefin-substitution reactions with bathocuproine–Pd(0) complexes (39, 40).

Herein, we give attention to the famous diimine ligands family, which has been applied in many catalytic processes, such as the notable olefin polymerization (41, 42) and cross-coupling reactions (43, 44). We have synthesized a series of new α-diimine ligands and employed these ligands for the aerobic oxidation of alcohols. The catalytic efficiency of alcohol oxidation could be optimized by the rigidity, steric, and electronic properties of the ligands, which could be ad-

justed through variation of the backbone and the substituents of the *N*-phenyl rings.

Experimental section

Materials and methods

All solvents and reagents were used after standard purification. Sodium salts of alkyl substituted sulfanilic acid (45, 46), DAB^{H}–Ar^{iPr}, DAB^{Me}–Ar^{Me}, DAB^{Me}–Ar^{iPr}, BIAN–Ar^{iPr} (ligands **10**–**13**) (47, 48), and BIAN–$Ar^{(3,5-CF_3,)}$ (ligand **14**) (49) as well as BmimCl (1-*n*butyl-3-methyl-imidazolium chloride), $BmimBF_4$ (1-*n*butyl-3-methyl-imidazolium tetrafluoroborate), and $BmimPF_6$ (1-*n*butyl-3-methyl-imidazolium hexafluorophosphate) (50) were prepared according to the literature methods.

^{1}H NMR and ^{13}C NMR were recorded on a Bruker 300 or 400 MHz. GC–MS was carried out on a Shimadzu QP-5050A. GC was Zheda Zhida 9790. Elemental analyses were carried out on an Elementar Vario EL III.

Synthesis of new diimine ligands

DAB^{H}–Ar^{Me}(4-SO_3Na) (Ligand 1)

Sodium salt of 3,5-dimethyl sulfanilic acid (2.23 g, 10.0 mmol) and 40% aq. glyoxal (0.80 g, 5.50 mmol) were dissolved in 30 ml of anhyd. methanol. Five drops of formic acid were added into this solution. The mixture was stirred at 40 °C for 48 h. After cooling to room temperature, the deposit was isolated and washed by 5 ml of cold methanol. The solid was recrystallized from MeOH and dried over an aspirator for 10 h. Ligand **1** was isolated as a yellow powder. (1.54g, 66%). ^{1}H NMR (300 MHz, DMSO-d_6) δ: 8.14 (s, 2 H), 7.34 (s, 4 H), 2.11 (s, 12 H). ^{13}C NMR (75.5 MHz, DMSO-d_6) δ: 164.19, 150.05, 136.06, 125.60, 119.49, 49.07. Anal. calcd. for $C_{18}H_{18}N_2Na_2O_6S_2$: C, 46.15; H, 3.87; N, 5.98. Found: C, 46.35; H, 3.99; N, 5.60.

DAB^{H}–Ar^{Me}(4-SO_3Na) (Ligand 2–9)

Ligands **2**–**9** were synthesized according to the method given above for ligand **1**. All the ligands were analyzed by ^{1}H NMR and elemental analysis. Melting points could not be obtained because the ligands were sodium salt of sulfonic.

DAB^{H}–Ar^{Et}(4-SO_3Na) (Ligand 2)

Yield: 56.6%. ^{1}H NMR (CD_3OD, 400 MHz) δ: 8.14 (s, 2 H), 7.62 (s, 4 H), 2.55 (m, 8 H), 1.16 (t, 12 H). ^{13}C NMR (100 MHz, CD_3OD) δ: 163.15, 150.08, 140.96, 131.64, 126.14, 49.0, 23.78. BIAN–Ar^{iPr}(4-SO_3Na) (Ligand 9)

Yield: 73 %. ^{1}H NMR (400 MHz, CD_3OD) δ: 7.85 (s, 4 H), 7.49 (t, 2 H), 6.80 (d, 2 H), 6.08 (d, 2 H), 3.00 (m, 4 H), 1.26 (d, 12 H), 1.04 (d, 12 H). ^{13}C NMR (100 MHz, CD_3OD) δ: 160.77, 147.79, 140.95, 140.55, 135.08, 130.90, 129.61, 127.94, 127.42, 123.16, 121.10, 28.28, 21.40, 21.33. Anal. calcd. for $C_{36}H_{38}N_2Na_2O_6S_2$: C, 61.35; H, 5.43; N, 3.97. Found: C, 61.04; H, 5.55; N, 4.16.

Typical experimental procedure

$Pd(OAc)_2$ (0.05 mmol) and ligand (0.05 mmol) were dissolved in DMA (5 ml) in a 25 mL two-necked flask. The flask, equipped with a magnetic stirring bar, was purged with oxygen gas. Oxygen gas was introduced into the flask from an O_2 balloon under atmospheric pressure, and the mixture was stirred at 40 °C for 10 min or stirred for 30 min at room temperature. Then alcohol (1 mmol) and K_2CO_3 (1 equiv.) was added, and the reaction mixture was stirred for appropriate time at 100 °C under oxygen. The oxidation product was analyzed by GC–MS. The reaction yields were determined by GC analysis using *n*-heptane as an internal standard. Recoveries were 100 ± 2% with this procedure. The purified products could be obtained by flash chromatography on a short silica-gel column eluting with a mixture of ethyl acetate and petroleum ether.

General procedure for catalyst-recycling trials

$Pd(OAc)_2$ (0.05 mmol) and ligand **9** (0.05 mmol) were dissolved in DMA (5 ml) in a 25 mL two-necked flask under oxygen gas. Oxygen gas was introduced into the flask from an O_2 balloon under atmospheric pressure, and the mixture was stirred at 40 °C for 10 min. Then, benzyl alcohol (1 mmol) and K_2CO_3 (1 equiv.) was added, and the reaction mixture was stirred for 5 h at 100 °C under oxygen. An aliquot of 0.02 mL of reaction mixture was taken out for the GC analysis. The volatiles of reaction mixture were removed under vacuum. The residual was washed with *n*-pentane for three times, and was applied to the next reaction cycle.

Results and discussions

Synthesis of new α-diimine ligands

At first, 2,6-dialkylaniline was sulfonated with concentrated sulphuric acid at 200 °C, followed by neutralization with NaOH or $NaOCH_3$ to yield the sodium salts. The new α-diimine ligands were prepared by condensation of the α-dione (2,3-butanedione, acenaphthenequinone, or 40% aqueous glyoxal) and the corresponding anilines in anhyd. methanol with a catalytic amount of formic acid (Scheme 1). A small amount of the sulfonated anilines was found in the crude product. This impurity could be removed by recrystallization from methanol or methanol/diethyl ether. These new sulfonated ligands are all easily diffluent and stable in polar organic solvents, such as DMF, DMA, and DMSO, as well as in water, but slowly hydrolyze in the latter when heated.

Influence of solvents on aerobic benzyl alcohol oxidation

Initially, the goal of this work was to develop a new Pd/ionic α-diimine catalytic system with the introduction of sulfonic group for aerobic oxidation in ionic liquid medium where immobilization of the catalysts was expected. That catalytic system could be profitable in the recycling of the catalyst and in the separation of products. Unfortunately, the combination of Pd/α-diimine showed no catalytic activity for oxidation of aerobic alcohols in ionic liquids, such as BmimCl, $BmimBF_4$, and $BmimPF_6$. Therefore, our attention was transferred to the catalytic activity of this $Pd(OAc)_2$/α-diimine system in other solvents.

Six solvents were examined, excluding the ionic liquid, for the aerobic oxidation of benzyl alcohol (Table 1). The use of toluene as the solvent led to complete conversion of the starting alcohol and afforded the desired aldehyde in 99% yield, but a great deal of Pd-black was produced. High pressure of O_2 (10 atm, 1 atm = 101.325 kPa) was employed for the reactions in aqueous phase or ionic liquid to increase the solubility of O_2. Using low loading of catalyst, catalytic reactions in water or DMSO/H_2O mixed solvent showed higher TON value compared with other solvents, but the conversions were low or moderate because of the Pd-colloid produced (Table 1, entries 2 and 3). Increasing the loading of catalyst of 5 mol% did not markedly improve the conversions. The employment of DMA (*N*,*N*-dimethyl acetamide) gave excellent yield without any Pd-black (Table 1, entry 4), while DMF and dioxane displayed moderate results (Table 1, entries 5 and 6). In conclusion, DMA appears to be the most effective solvent under given reaction conditions.

Electronic and steric effects of diimine ligands

Benzyl alcohol was selected as a model substrate to investigate the electronic and steric effects of ligands on diimine/palladium(II)-catalyzed aerobic oxidation of alcohol (Scheme 2).

Table 2 showed us the catalytic activities of various ligands for the aerobic oxidation. We recognized that no palladium black was produced in most of the experiments except when ligands **2** and **3** were used. The use of ligands increased the electron density on Pd(0) and facilitated the acti-

vation of dioxygen. Then, the palladium(0) species could be smoothly re-oxidized to palladium(II) without evident aggregation when supported by the diimine ligands. An interesting electronic effect seems to arise in the series of diimine ligands. It was shown that in runs employing α-diimine ligands with a strongly electron-withdrawing sulfonic group showed much higher yields were obtained than in those employing normal α-diimine ligands (ligands **10**–**15**) in equal reaction times. This electron-deficiency facilitates the oxidation of alcohol because the overall rate of oxidation increased. Faster oxidation was also achieved by using ligand **14** with the strongly electron-withdrawing trifluoromethyl groups (Table 2, entry 14). A similar observation that electron-withdrawing substituents on the ligand increase the reaction rate in alcohol oxidation was reported by Sheldon

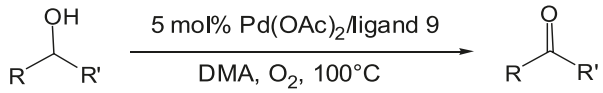
and co-workers in the studies of a range of 4,4-disubstituted-2,2-bipyridines as ligands for the palladium-catalyzed aerobic oxidation of 2-hexanol (51). Variation of the electron density on the diimine ligand changes the redox properties of the catalyst. Therefore, this variation should provide evidence for whether an oxidation step or a reduction step is rate-limiting. The re-oxidation step of Pd(0) to Pd(II) should be facilitated by electron-donating substituents. On the other hand, if the reduction step is rate-limiting, then the reaction should be facilitated by electron-withdrawing substituents in the ligands. The electronic effect of diimine ligands indicated that the reduction step is slow.

Comparing catalytic results of BIAN/diimine ligands **7**–**9** (Table 2, entries 7–9), it was shown that bulky groups on 2 and 6 positions of the *N*-phenyl ring facilitated the oxidation of benzyl alcohol. The same trend is observed in a series of DAB^{Me}/diimine ligands **4**–**6** (Table 2, entries 4–6). A similar conclusion is reported by Sheldon and co-workers (52) for the Pd/phenanthroline system. It was reported that the methyl groups in 2 and 9 positions of the phenanthroline ligands clearly increase the TOF value by raising the cleavage rate of dimeric palladium catalyst species. Generally, the BIAN/diimine ligands (ligands **7**–**9**) showed higher rates of oxidation as compared with the DAB/diimine ligands (ligands **1**–**6**). A more stable coordination and a longer lifetime of the active palladium species in the catalytic cycle (53) was achieved by using a rigid ligand backbone (BIAN). In a word, the bulky group on arene of ligands and the more rigid backbone of ligand effectively prevent aggregation of palladium(0) species and facilitates the re-oxidation of palladium(0).

Scheme 3. Oxidation of the other alcohol.



Everntually, the optimized catalytic combination for the aerobic oxidation of alcohol was found to be $Pd(OAc)_2$/ligand **9**/K_2CO_3/DMA/O_2/100 °C.

Oxidation of various alcohols

The scope of this optimized procedure for the oxidation of the other alcohols (Scheme 3) was listed in Table 3. The primary benzylic alcohols were converted to the corresponding aldehydes in 87%–99% yields (Table 3, entries 1–8 and 13). An electronic effect seems to exist for these benzylic systems. Comparing benzyl alcohol (Table 3, entry 1) with the benzylic alcohols with electron-donating substituents (Table 3, entry 2), we found that the reaction times for the electronic-rich arenes were significantly shorter. It was also shown that the benzylic alcohols with electron-withdrawing groups (Table 3, entries 3 and 4) gave lower yields in the same reaction times with benzyl alcohol and required longer reaction times for complete conversion. It is noteworthy that the primary benzylic alcohols with electron-withdrawing

group at ortho position (Table 3, entries 9 and 10) showed much lower reaction activities. The secondary benzylic substrates generally gave very clean reactions with high yields (Table 3, entries 11, 12, and 14). About 3% yield of 3-formylbenzyl alcohol as halfway product of oxidation was determined by GC and GC–MS for the oxidation of 1,3-benzenedimethanol (Table 3, entry 18) with 94% yield of *iso*-phthalaldehyde. It is noticable that the oxidation of hydrobenzoin (Table 3, entry 19) gave 87% yield with no benzoin produced and a trace of benzaldehyde formed by oxidative C=C cleavage, possibly of an intermediate benzoin. As expected, benzaldehyde was also found in the oxidation of benzoin by GC–MS (Table 3, entry 20).

The secondary aliphatic alcohols and cyclic alcohol (Table 3, entries 15–17) could be transformed into the corresponding aldehydes or ketones in moderate yields. The catalytic system showed no activities for the oxidation of primary aliphatic alcohols (Table 3, entries 21 and 22) because of the decreased electron density on the primary aliphatic alcohols.

So far, our catalytic system is limited in scope to benzylic or secondary aliphatic alcohols, needing higher reaction temperature (100 °C) and longer reaction times (3–12 h for benzylic alcohols) compared with other excellent catalytic systems for aerobic alcohol oxidation, such as the Pd/pyridine and Pd/NEt_3 systems. But one certain advantage is their modularity because the electronic and steric properties could be modulated independently to optimize the catalytic activities. We believe that further investigation of the diimine ligands is worthwhile.

It is confirmed that the $Pd(OAc)_2$/ligand **9** catalytic system could be recycled three times, while allowing for extended reaction times: 8 h for second cycle and 20 h for third cycle were required after the first run.

Mechanistic discussion

Generally, the mechanism of the palladium-catalyzed aerobic alcohol oxidation mimics the palladium–oxidase pathway (38). This process is composed of two independent steps: substrate oxidation and catalyst oxidation. The trend of the activities of the $Pd(OAc)_2$/dimine system for alcohol oxidation is in contrast with that for the diimine/palladium-catalyzed Suzuki cross-coupling reaction reported by Nolan and co-workers (44). The observation that electron-

© 2008 NRC Canada

withdrawing substituents on the ligand increase the reaction rate in alcohol oxidation is a strong indication that the reduction step (substrate oxidation) is slow and that under these conditions re-oxidation of (diimine)Pd(0) is facile (51), which is similar to other palladium catalyst systems with nitrogen-containing ligands (21–31). A bulky substituent on the arene group in the ligand effectively prevents aggregation of palladium(0) species and facilitates the re-oxidation of palladium(0), still allowing an approach of the substrate alcohol to the catalytic species. An anionic base, such as K_2CO_3, can significantly enhance the rate of alcohol oxidation. Complete conversion of benzyl alcohol could be achieved using only 0.1 equiv. of the base. More mechanistic investigation is clearly desired.

Conclusions

A series of new ionic sulfonated α-diimine ligands were prepared and employed as supporting ligands for the palladium-catalyzed aerobic oxidation of alcohols. The electronic properties, rigidity, and steric hindrance of ligands have remarkable influence upon the catalytic activity of the palladium catalysts. The best catalytic results could be achieved by using ligand **9** with an electron-withdrawing sulfonyl substituent together with bulky groups (*iso*-propyl in 2,6-positions). This diimine/palladium system is highly efficient for the catalytic oxidation of various benzylic alcohols but shows only moderate yields for the secondary aliphatic alcohols and cyclic alcohols. The observation that electron-withdrawing substituents on the ligand increase the reaction rates of alcohol oxidation strongly indicates that the reduction of Pd(II) is a slow step.

The photochemistry of *trans*-isohumulone, a bitter flavouring component of beer

Alan C. Weedon and John S. Morrison

Abstract: Methanolic solutions of *trans*-isohumulone (**2**), a major bitter flavouring component in beer, were irradiated with UV light of 313 nm wavelength and yielded four primary products containing an enolized cyclic β-triketone moiety: *cis*-isohumulone (**3**), humulone (**1**), *dehydro*-isohumulone (**7**), and *dehydro*-humulinic acid (**5**). The last of these products results from loss of the 4-methyl-3-pentenoyl side chain of *trans*-isohumulone. Nine volatile products derived from this side chain were identified and quantitated. The identifications of all photoproducts were confirmed by independent preparation of authentic samples. No evidence of either intramolecular or intermolecular 2+2 cyclo-addition was observed. This work clarifies previous contradictory reports of the products of isohumulone photolysis and provides an example of unexpected photochemistry of an alkenyl-substituted enolized cyclic β-triketone.

Key words: trans-isohumulone, photo-degradation, cyclic β-triketone.

Résumé : La *trans*-isohumulone (**2**), un des constituants de la bière qui lui donne son goût amer, en solution dans le méthanol a été soumise à une irradiation UV à 313 nm et a conduit à la formation de quatre produits primaires qui contiennent une portion β-tricétonique cyclique énolisée: la *cis*-isohumulone (**3**), l'humulone (**1**), la *déhydro*isohumulone (**7**) et l'acide *déhydro*humulinique. Le dernier de ces produits résulte de la perte de la chaîne latérale 4-méthylpent-3-énoyle de la *trans*-isohumulone. On a aussi identifié la nature et quantifié neuf produits volatils dérivés de cette chaîne latérale. Les identifications de tous les photoproduits ont été confirmées par la préparation d'échantillons authentiques. On n'a pas pu mettre en évidence de cycloadditions 2+2 intramoléculaire ou intermoléculaire. Ces résultats permettent de clarifier des rapports antérieurs contradictoires relatifs à la photolyse de l'isohumulone et ils fournissent un exemple de photochimie inattendue d'une β-tricétone cyclique énolisée et substituée par une chaîne alcényle.

Mots-clés : trans-isohumulone, photodégradation, β-tricétone cyclique.

[Traduit par la Rédaction]

Introduction

Beer is brewed by the yeast-mediated fermentation of an aqueous solution of malted barley to which hops (flowers of the plant *Humulus lupulus*) have been added. The hops are a source of water soluble, bitter-tasting compounds (known as alpha acids) of which humulone (**1**) is the major component. During the brewing process, the alpha acids undergo thermal isomerization to so-called iso-alpha acids that are responsible for the bitter flavour of beer (1). Thermal conversion of the hop alpha-acid humulone (**1**) to the iso-alpha acids *cis*-isohumulone (**3**) and *trans*-isohumulone (**2**) is illustrated in Scheme 1.

The NMR and UV spectra of isohumulone in various solvents reveal it to be enolized, and three tautomers are, in principle, possible. The tautomer illustrated in Scheme 1 is drawn throughout this paper for consistency, but this should not be taken to imply that the other tautomers are not present in solution. The enolized cyclic β-triketone of isohumulone is acidic with a p*K*a of 3.1 in aqueous ethanolic solutions (2), and thus is only partially ionized.[2,3]

Beer develops an off-flavour when exposed to light because of the formation of trace amounts of 3-methyl-2-butene thiol (**4**), and it has been shown that the iso-alpha acids must be present for this to occur (3–5). This thiol has a taste threshold in beer of about 10^{-11} mol/L, and so extremely small amounts formed by photolysis of iso-alpha acids can generate an off-flavour (6–8). In the brewing industry, beer so afflicted is termed "light-struck" and more colloquially as "skunky", since the thiol has an odor similar to that associated with skunks.

In beer, degradation of the iso-alpha acids is initiated either by direct absorption of UV light or indirectly by sensitization. In the latter case, components of the beer such as flavins mediate the light-struck reaction through absorption of both UV and visible light. The light-struck reaction can

be inhibited by appropriate packaging to block or filter light (hence the common use of green tinted or brown glass for beer bottles). Alternatively, the beer can be brewed with iso-alpha acids that have been extracted from hops and chemically modified. For example, protection from the light-struck reaction can be achieved by the use of iso-alpha acids in which the alkene or carbonyl function of the 4-methyl-3-pentenoyl side chain has been reduced (9, 10). While the mechanism of the light-struck reaction is not entirely known, the evidence suggests it proceeds as indicated in Scheme 2.

Interest in understanding and hence suppressing the light-struck reaction in beer has led to a number of studies of the photochemistry of the iso-alpha acids. In many of these studies *trans*-isohumulone is used as a model, since it can be produced and isolated as a single stereoisomer from natural humulone extracted from hops (11). In one such study, photolysis of *trans*-isohumulone to high conversion was reported to generate *dehydro*-humulinic acid (**5**) in nearly quantitative yield (12, 13), as illustrated in Scheme 3.

However, it has also been reported that a variety of products result from high conversion photolysis of *trans*-isohumulone, or of an iso-alpha–acid mixture, with a significant product being the decarbonylated *dehydro*-isohumulone (**6**), as illustrated in Scheme 4 (14–16).

It is well-known that enones (17–19) and enolized β-diketones (20–25) undergo efficient 2+2 photocycloaddition reactions with alkenes. This reaction is especially efficient for systems containing the enone and the alkene function within the same molecule. It is therefore surprising that no products of photocycloaddition have been reported for isohumulone. This fact, and the inconsistencies in the reported products of photolysis of isohumulone, led us to examine in detail the products of the photochemistry of *trans*-isohumulone. The result of this study is reported here. In view of its importance in the brewing industry, we have also examined the mechanism of this reaction. The results of that work will be reported separately.

In a further report, the headspace over an aqueous solution

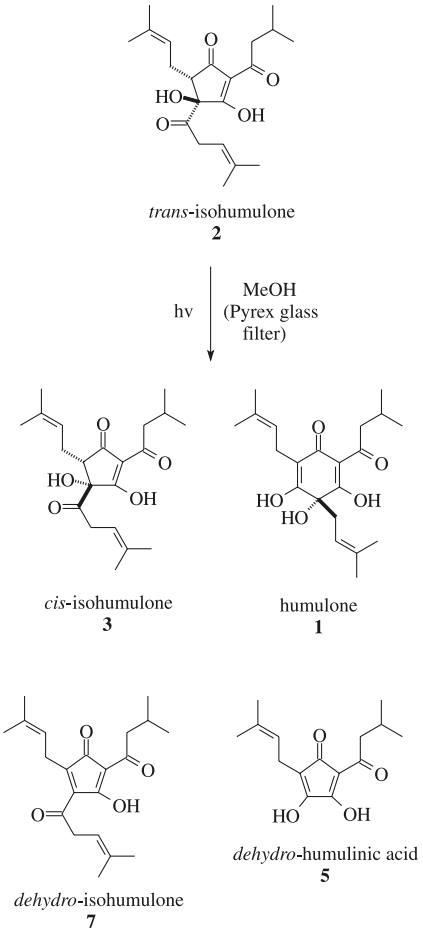
Scheme 6.



4-methyl-3-pentenoyl radical. The other observed volatile compounds illustrated in Scheme 5 are not. These other products appear to be consistent with degradation of the other side chains of the iso-alpha acid, suggesting further sensitized degradation of the primary enolized cyclic β-triketone products.

Results and discussion

Identification of the enolized cyclic β-triketone-containing photoproducts of *trans*-isohumulone

Solutions of *trans*-isohumulone in methanol were exposed to light of 313 nm wavelength. At conversions of less than 15%, four nonvolatile photoproducts containing the enolized cyclic β-triketone moiety were generated, as illustrated in Scheme 6.

Each product was isolated by semi-preparative HPLC and characterized by one-dimensional (^{1}H NMR and ^{13}C NMR) and two-dimensional (gCOSY, gHSQC, and gHMBC) NMR spectroscopy, as well as electron ionization and chemical ionization mass spectrometry (GC-MS).[3] The identifications were confirmed by independent preparation of an authentic sample of each compound. These results confirm the literature reports that *dehydro*-humulinic acid (**5**), *cis*-isohumulone (**3**), and humulone (**1**) are photoproducts of *trans*-isohumulone (**2**) (12–16). No evidence for the formation of the *decarbonylated-dehydro*-isohumulone (**6**) was found (14, 16). In the previous reports where (**6**) was identified as a product, the identification appears to have been based on HPLC-MS evidence; the product was apparently not isolated such that its ^{1}H and ^{13}C NMR spectra could be recorded, which may account for the observation.

We have also examined the photochemistry of *trans*-isohumulone in aqueous ethanolic solutions as well as in aqueous solutions buffered at a pH of 2.1 and 4.7.[3] In all cases only these four nonvolatile photoproducts were observed when conversions were kept below 15%. This suggests that both the enol and enolate forms of *trans*-isohumulone exhibit similar photochemistry and suggests that the tautomeric form adopted by isohumulone is also not a critical factor in its photochemistry.[3] Futhermore, no evidence of products of intramolecular or intermolecular 2+2 cycloaddition was observed for *trans*-isohumulone.

Fig. 1. Variation with time of *trans*-isohumulone concentration and total photoproduct concentration (enolized cyclic β-triketone products only) for an UV light irradiation conducted in methanol.

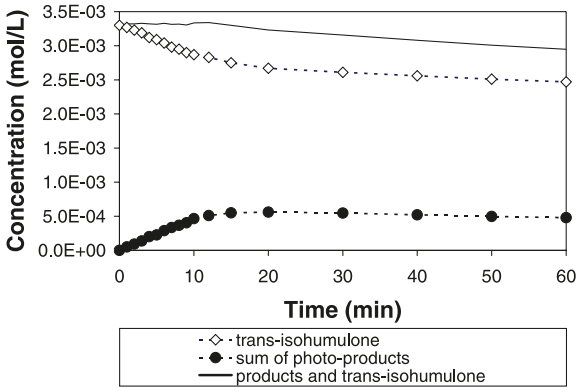


Fig. 2. Variation with time of the concentration enolized cyclic β-triketones produced for the UV light irradiation of *trans*-isohumulone in methanol.

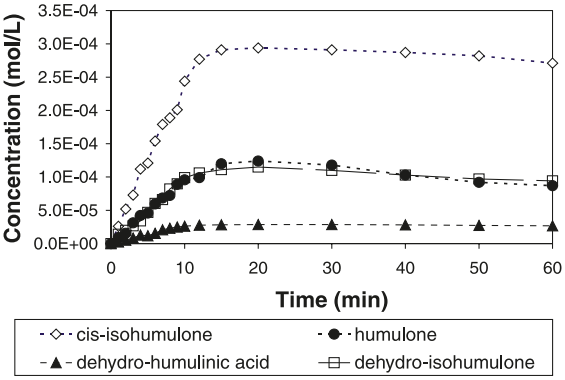

Yields of the enolized cyclic β-triketone products formed by UV light irradiation of *trans*-isohumulone

The conversion of *trans*-isohumulone and the yields of the enolized cyclic β-triketone products were determined as a function of irradiation time. The results are shown in Figs. 1 and 2.

The data illustrated in Figs. 1 and 2 suggest that at conversions below 15% the photochemistry of *trans*-isohumulone follows zero-order kinetics and that the four

Table 1. Yields of enolized cyclic β-triketones formed in the UV light irradiation of *trans*-isohumulone in methanol solution.

Enolized cyclic β-triketone photoproduct	Yield (%)
cis-Isohumulone	50 ± 4
Humulone	20 ± 1
dehydro-Isohumulone	22 ± 1
dehydro-Humulinic acid	6 ± 0.5
Total	98 ± 6.5

enolized cyclic β-triketone products isolated are primary products. At conversions above 15% the conversion of *trans*-isohumulone becomes less efficient and the products themselves decline in yield. This suggests that at these conversions the concentrations of the products are high enough for them to absorb light directly, or to quench the *trans*-isohumulone excited state, and hence undergo secondary photolysis. We were unable to identify the products of secondary photolysis because of their complexity and the low yield of each component. Some previous studies have led to reports of the formation of complex mixtures of products when isohumulone is photolysed to high conversion (13–16).

The gradients of the initial linear portions of the reaction profiles, shown in Figs. 1 and 2, allow the determination of the yield of each primary product based on converted *trans*-isohumulone. These yields are shown in Table 1.

The sum of the yields in Table 1 reveals that all of the converted *trans*-isohumulone has been accounted for, and that there are no other major primary photoproducts, apart from those derived from the cleavage of the pentenoyl side chain en route to *dehydro*-humulinic acid.

Identification and yields of the *trans*-isohumulone side chain photoproducts

The formation of *dehydro*-humulinic acid from the photolysis of *trans*-isohumulone must also yield one or more products resulting from the cleaved 4-methyl-3-pentenoyl side chain, as indicated in Scheme 7.

Deoxygenated diethyl ether solutions of *trans*-isohumulone were exposed to light of 313 nm wavelength and directly analyzed by GC-MS at low conversions. The yields of the primary enolized cyclic β-triketone photoproducts were also determined by GC-MS and are given in Table 2.

The product yields shown in Table 2 are comparable with those determined when methanolic solutions of *trans*-isohumulone were photolysed and analyzed by HPLC (Table 1). This indicates that the change in solvent did not influence the reaction outcome. The identities of the photoproducts derived from the cleaved 4-methyl-3-pentenoyl side chain were determined by GC-MS. Their identities were confirmed by comparison with independently prepared authentic samples. The product structures are given in Fig. 3.

Each of the products is a branched chain of either five carbons (compounds **8**, **9**, **11**, **12**, and **13**) or six carbons (compounds **10**, **14**, **15**, and **16**) and appear therefore to be products formed both prior to and following decarbonylation of an initially produced 4-methyl-3-pentenoyl radical. Several of these photoproducts contain oxygen (compounds **11**, **12**, **13**, **14**, **15**, and **16**), which was not present in the 4-methyl-3-pentenoyl side chain. This observation is consistent with a radical intermediate trapped by reaction with molecular oxygen. The structures of the remaining products are consistent with hydrogen atom transfer (from ether, to oxygen, or via disproportionation, etc.) both before and after decarbonylation of the initially produced 4-methyl-3-pentenoyl radical. The various pathways are summarized in Scheme 8.

To our knowledge, there is only one published investigation of the volatile products of *trans*-isohumulone photochemistry; this involved analysis of the headspace of a riboflavin sensitized reaction of *trans*-isohumulone and led

Scheme 7.

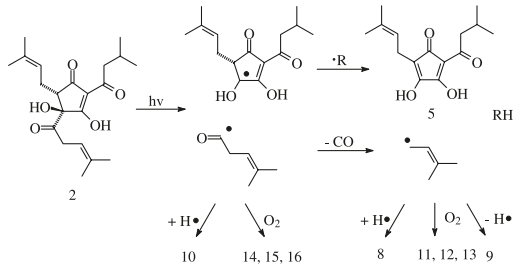
Scheme 8.



volatile product structures 8-16 are illustrated in Figure 3

to the identification of compounds **8**, **9**, and **10** (26). The yields of each of the products **8–16** found in our work were calculated relative to the amount of *dehydro*-humulinic acid formed and are presented in Table 3.

The dominant fate of the 4-methyl-3-pentenoyl side chain intermediate appears to be the addition of oxygen, despite measures taken to remove the dissolved oxygen from the solution prior to irradiation (The freeze-pump-thaw method of degassing is a well-known procedure often utilized for oxygen sensitive reactions.) (27). If this is the case, the relative yields of these products would increase in solutions containing ambient concentrations of dissolved oxygen. To test this, irradiations of *trans*-isohumulone were conducted with 313 nm light using diethyl ether solutions containing ambient levels of dissolved oxygen. The product yields obtained presented in Table 4.

The data in Table 4 show that within the experimental error, a mass balance was achieved for side chain product formation in the ambient oxygen containing solution. The incomplete recovery of the side chain derived compounds in deoxygenated solutions may reflect reaction of radical intermediates with the solvent to give undetected compounds. In the presence of oxygen, the radicals are trapped and these side reactions are avoided. Since no new volatile products were observed in the ambient oxygen solution, it is reasonable to conclude that the oxidation products formed in both solutions resulted from reaction of a radical intermediate with molecular oxygen.

Conclusions

As noted in the Introduction to this paper, previous reports of the products of photolysis of *trans*-isohumulone are contradictory. For example, in one study *dehydro*-humulinic acid (**5**) was reported as the only product (12, 13), while in another decarbonylated *dehydro*-isohumulone (**6**) was identified as a major product (14–16). In these reports, the products are not isolated or fully characterized, nor are their yields reported. In the work reported here the primary products formed by direct UV light irradiation of *trans*-isohulumone have been isolated and identified by ^{13}C and ^{1}H NMR spectroscopy and by mass spectroscopy, their yields have been determined, and a complete mass balance has been obtained. We find that *dehydro*-isohumulinic acid (**5**) is not the sole product. Rather, three modes of reaction occur. These are isomerization, dehydration, and side chain cleavage to give humulone (**1**), *cis*-isohumulone (**3**), *dehydro*-isohumulone (**7**), as well as *dehydro*-humulinic acid (**5**). No evidence was found for the formation of decarbonylated *dehydro*-isohumulone (**6**). Also, and surprisingly given the normal reactivity of enones when irradiated with UV light in the presence of alkenes, no evidence was found for products of intra- or intermolecular 2+2 photocycloaddition. The formation of *dehydro*-humulinic acid requires the loss of the 4-methyl-3-pentenoyl side chain of *trans*-isohumulone. Previous studies of the fate of this 4-methyl-3-pentenoyl side chain were performed using mixtures of iso-alpha acids under conditions where secondary photochemistry could occur. In the work reported here, the primary products of side chain cleavage have been identified, their yields have been determined, and a complete mass balance has been obtained. In addition to the formation of *dehydro*-humulinic acid, we found that the side chain cleavage leads to products derived from the interception of 4-methyl-3-pentenoyl radicals and methylbutenyl radicals. This is compatible with the observation that isohumulones and light lead to the formation of very low concentrations of 3-methyl-2-butene thiol in a beer matrix and suggests that the thiol is produced by interaction of a photochemically generated methylbutenyl radical with a sulfur donor.

Table 3. Percent yields of *trans*-isohumulone side chain derived products in deoxygenated diethyl ether solution.

Side chain product	Yield (%)
2-Methyl-2-butene	1.0 ± 0.2

Experimental

General

All the solvents used for irradiations, spectrometry, and chromatography were obtained from the Sigma-Aldrich chemical company and were of spectrophotometric quality.

© 2008 NRC Canada

UV irradiations of *trans*-isohumulone were conducted with a 450 W Hanovia medium pressure mercury lamp, surrounded by an aqueous solution of potassium chromate (1.44×10^{-3} mol/L) and sodium carbonate (1.25×10^{-2} mol/L) (27). Methanolic solutions were purged with nitrogen gas for 20 min prior to light exposure and maintained under nitrogen during the irradiation to minimize oxygen contamination. The solutions were stirred throughout the irradiation procedures. Samples were withdrawn from the irradiation vessel via syringe through a Teflon stopcock. Diethyl ether was freshly distilled immediately prior to use. Solutions prepared in diethyl ether were degassed by the freeze-pump-thaw method (27). Sampling of these ether solutions was performed at the conclusion of the irradiation to minimize molecular oxygen contamination and loss of volatile compounds.

Qualitative analyses of products

Semi-preparative HPLC separations were accomplished with a Waters instrument, employing a 10 mm × 300 mm Supelco C_{18}-nucleosil semi-preparative column. Samples were introduced with a 500 uL sample loop and separated with an eluent mixture of 80% acetonitrile, 20% water and 0.1% concentrated phosphoric acid. The NMR spectra were obtained in $CDCl_3$ with a Varian Mercury 400 NMR spectrometer at 400.09 MHz for ^{1}H and 100.69 MHz for ^{13}C. The ^{1}H and ^{13}C NMR assignments were correlated with the two-dimensional NMR techniques of gCOSY, gHSQC, and gHMBC.

Quantitative analyses of products

Samples were analyzed using an isocratic Waters HPLC system with a tunable absorbance detector set to 270 nm. Samples were introduced via a 10 uL injection loop and separated with a 250 mm × 4.6 mm Supelco ODS nucleosil analytical column. The eluent system, composed of a mixture of 600 mL of acetonitrile, 400 mL of distilled water, and 2 mL of concentrated phosphoric acid. Calibration curves were prepared for each analyte using five different concentrations (ranging from 1% to 25% of the starting *trans*-isohumulone concentration). The GC-MS analyses were performed with a Varian Saturn 4-D GC-MS, equipped with a DB-5 capillary column and a splitless injector. The temperature program of the GC began at 50 °C for 2 min, with the temperature increased to 180 °C at 15 °C/min, then to 200 °C at 4 °C/min and finally to 230 °C/min at 1 °C. The mass spectrometer scanned over the mass range of 33 to 550 mass units at 1 s intervals. Samples were analyzed in freshly distilled, spectrophotometric grade diethyl ether. Calibration curves were prepared for the analytes, using five different concentrations (ranging from 0.5% to 50% of the typical *dehydro*-humulinic acid concentration).

Preparation of compounds

Humulone

Humulone was isolated from a commercially available non-isomerized hop extract provided by from the Research and Development department of the Labatt Brewing Company. The procedure used is a literature method (11).

^{1}H NMR δ: 0.97 (d, *J* = 7.0 Hz, 3H), 1.01 (d, *J* = 7.0 Hz, 3H), 1.53 (s, 3H), 1.69, (s, 6H), 1.74 (s, 3H), 2.15 (m, *J* = 7.0 Hz, 1H), 2.49 (dq, *J* = 7.0 Hz, 2H), 2.77 (dd, *J* = 7.0 Hz, 2H), 3.06 (dq, *J* = 7.0 Hz, 2H), 5.00 (t, *J* = 7.0 Hz, 1H), 5.14 (t, *J* = 7.0 Hz, 1H). ^{13}C NMR δ: 17.9, 22.7, 25.4, 25.7, 26.1, 30.2, 46.0, 84.2, 110.1, 113.7, 115.4, 116.2, 135.2, 137.7, 175.8, 186.9, 191.1, 198.2. GC-MS: 363 (76%), 345 (78%), 327 (6%), 307 (3%), 295 (6%), 266 (3%), 223 (3%), 197 (3%), 166 (3%), 137 (4%), 109 (7%), 97 (7%), 85 (5%), 69 (100%), 57 (16%).

trans-*Isohumulone*[3]

Humulone was photo-isomerized by a literature method (11) utilizing UV light from a medium pressure mercury lamp that had passed through a uranium oxide glass filter. The course of the irradiation was monitored by analytical HPLC. Analysis by HPLC and GC-MS indicated the purity to be greater than 97% after recrystallization.

^{1}H NMR δ: 0.88 (d, *J* = 6.6 Hz, 3H), 0.91 (d, *J* = 6.6 Hz, 3H), 1.47 (s, 3H), 1.51 (s, 3H), 1.63 (s, 3H), 1.67 (s, 3H), 2.08 (m, 6.6, 1H), 2.27 (dt, *J* = 7.1 & 15 Hz, 1H), 2.52 (dt, *J* = 7.1 & 15 Hz, 1H), 2.65 (d, *J* = 7.1 Hz, 2H), 2.98 (dd, *J* = 6.8 & 6.9 Hz, 1H), 3.27 (d, *J* = 7.2 Hz, 2H), 5.08 (t, *J* = 7.1Hz, 1H), 5.14 (t, *J* = 7.1 Hz, 1H). ^{13}C NMR δ: 18.2, 18.7, 22.5, 23.1, 23.6, 25.9, 26.3, 38.8, 44.3, 55.8, 91.2, 110.6, 114.7, 120.3, 135.2, 136.4, 195.7, 198.2, 205.3, 207.1. GC-MS: 363 (52%), 345 (44%), 327 (3%), 293 (15%), 277 (7%), 266 (5%), 238 (3%), 209 (5%), 197 (9%), 109 (3%), 97 (8%), 85 (5%), 69 (66%), 57 (11%), 41 (100%).

cis-*Isohumulone*

Humulone was isomerized to *cis*-isohumulone by a literature method (28). The material was isolated as a light yellow oil from the reaction mixture and was purified by semi-preparative HPLC.

^{1}H NMR δ: 0.94 (d, *J* = 6.2 Hz, 3H), 0.96 (d, *J* = 6.2 Hz, 3H), 1.52 (s, 3H), 1.56 (s, 3H), 1.59 (s, 3H), 1.63 (s, 3H), 2.13 (m, *J* = 6.2 Hz, 1H), 2.41 (dt, *J* = 7.2 Hz, 1H), 2.47 (dt, *J* = 7.1 Hz, 1H), 2.60 (d, *J* = 7.1 Hz, 2H), 3.20 (dd, *J* = 7.1 Hz, 1H), 3.30 (d, *J* = 7.0 Hz, 2H), 5.01 (t, *J* = 7.0 Hz, 1H), 5.12 (t, *J* = 7.0 Hz, 1H). ^{13}C NMR δ: 18.0, 18.3, 22.6, 22.7, 25.6, 59.9, 26.3, 37.1, 46.0, 50.3, 55.5, 87.7, 110.7, 114.7, 119.8, 119.9, 135.4, 136.9, 195.5, 200.6, 206.3, 206.9. GC-MS: 363 (84%), 346 (51%), 295 (11%), 266 (7%), 197 (19%), 137 (4%), 109 (3%), 97 (5%), 85 (9%), 69 (80%), 57 (14%), 41 (100%).

Dehydro-*humulinic acid*

A sample of *trans*-isohumulone was used to prepare *dehydro*-humulinic acid by a literature method (29).

^{1}H NMR δ: 0.95 (d, *J* = 7.0 Hz, 3H), 0.96 (d, *J* = 7.0 Hz, 3H), 1.63 (s, 3H), 1.70 (s, 3H), 2.11 (m, *J* = 7.0 Hz, 1H), 2.58 (d, *J* = 7.1 Hz, 1H), 3.02 (d, *J* = 7.0 Hz, 2H), 5.21 (t, *J* = 7.0 Hz, 1H). ^{13}C NMR δ: 17.7, 23.8, 25.2, 25.6, 48.9, 110.8, 116.7, 121.7, 136.2, 158.1, 161.3, 193.5, 198.1. GC-MS: 265 (100%), 247 (9%), 209 (10%), 190 (13%), 175 (6%), 152 (10%), 95 (8%), 81 (13%), 79 (13%), 69 (19%), 55 (21%).

Preparation of side chain products

PCC oxidations of primary alcohols to aldehydes

The pyridinium chlorochromate reagent was prepared by a literature method (30).

3-Methyl-2-butenal

About 0.5 g of 3-methyl-2-buten-1-ol was dissolved in 5 mL of CH_2Cl_2 and added to a suspension of 1.5 g of the PCC reagent in 20 mL of CH_2Cl_2. The mixture was stirred at room temperature for about 2 h. Three 25 mL portions of diethyl ether were used to wash the mixture. The organic extracts were combined, dried with $MgSO_4$, and the solvent removed by rotary evaporation at room temperature. Isolation of the compound and final purification were accomplished by vacuum distillation.

^{1}H NMR δ: 1.95 (s, 3H), 2.12 (s, 3H), 5.54 (d, J = 7.1 Hz, 1H), 9.67 (d, J = 7.2 Hz, 1H). ^{13}C NMR δ: 21.3, 27.6, 124.8, 158.7, 192.6. GC-MS: 84, 69, 55.

4-Methyl-3-pentenal

About 0.6 g of 4-methyl-3-penten-1-ol was dissolved in 5 mL of CH_2Cl_2 and added to a suspension of 1.5 g of the PCC reagent in 20 mL of CH_2Cl_2. The mixture was stirred at room temperature for about 2 h. Three 25 mL portions of diethyl ether were used to wash the mixture. The organic extracts were combined, dried with $MgSO_4$, and the solvent removed by rotary evaporation at room temperature. Isolation of the compound and final purification were accomplished by vacuum distillation.

^{1}H NMR δ: 1.63 (s, 3H), 1.74 (s, 3H), 3.21 (d, J = 7.1 Hz, 2H), 5.31 (d, J = 7.1 Hz, 1H), 9.82 (s, 1H). ^{13}C NMR δ: 18.7, 25.3, 36.8, 115.8, 138.4, 201.4. GC-MS: 98, 83, 70, 54, 44.

3-Methyl-3-hydroxybutanal

The 3-methyl-3-hydroxybutanal was prepared from 3-methyl-2-butenal by a literature method (31). Isolation of the compound and final purification were accomplished by semi-preparative HPLC.

^{1}H NMR δ: 1.42 (s, 6H), 2.54 (s, 2H), 4.21 (s, 1H), 9.78 (s, 1H). ^{13}C NMR δ: 27.2, 54.8, 79.1, 205.4. GC-MS: 102, 87, 85, 73, 58, 44.

4-Hydroxy-4-methyl-2-pentenoic acid derivatives

The 4-hydroxy-4-methyl-2-pentenoic acid derivative compounds were prepared by a literature method from UV irradiation of propargylic acid in isopropanol (32). The resulting yields of each product were approximately 26% for *trans*-4-hydroxy-4-methyl-2-pentenoic acid, 14% for *cis*-4-hydroxy-4-methyl-2-pentenoic acid, and 9% for 5,5-dimethylfuranone. The products were separated and purified by semi-preparative HPLC.

trans-*4-Hydroxy-4-methyl-2-pentenoic acid*

^{1}H NMR δ: 1.31 (s, 6H), 4.92 (s, 1H), 5.82 (d, J = 15 Hz, 1H), 7.28 (d, J = 15 Hz, 1H), 11.03 (s, 1H). ^{13}C NMR δ: 27.8, 69.7, 123.6, 158.4, 172.3. GC-MS: 130, 115, 113, 85, 71, 59, 45.

^{1}H NMR δ: 1.49 (s, 6H), 5.48 (s, 1H), 5.87 (d, J = 12 Hz, 1H), 6.43 (d, J = 12 Hz, 1H), 10.91 (s, 1H). ^{13}C NMR δ: 29.2, 76.4, 121.2, 153.3, 170.8. GC-MS: 130, 115, 113, 85, 71, 59, 45.

5,5-Dimethyl furanone

^{1}H NMR δ: 1.27 (s, 6H), 5.82 (d, J = 5.7 Hz, 1H), 7.28 (d, J = 5.8 Hz, 1H). ^{13}C NMR δ: 27.4, 90.8, 122.1, 165.2, 175.2. GC-MS: 112, 97, 95, 70, 68.

dehydro-*Isohumulone preparation*

A 500 mg sample of *trans*-isohumulone was dissolved in 50 mL of freshly distilled anhydrous diethyl ether. A 1.5 mL aliquot of acetic anhydride and 0.5 mL of triethylamine were added and the mixture was stirred at room temperature for 3 h. The mixture was washed with three portions of sodium bicarbonate solution (1.25 g in 300 mL) and with three 100 mL portions of water. The organic layer was dried with magnesium sulphate, and the solvent removed by rotary evaporation. *Dehydro*-isohumulone was separated as an oil from the reaction mixture and further purified by semi-preparative HPLC.

^{1}H NMR δ: 0.88 (d, J = 7.0 Hz, 3H), 0.90 (d, J = 7.0 Hz, 3H), 1.60 (s, 6H), 1.71 (s, 6H), 2.12 (m, J = 7.0 Hz, 1H), 2.92 (d, J = 7.0 Hz, 2H), 3.47 (d, J = 7.0 Hz, 2H), 3.52 (d, J = 7.0 Hz, 2H), 4.94 (t, J = 7.0 Hz, 1H), 5.24 (t, J = 7.0 Hz, 1H). ^{13}C NMR δ: 18.3, 22.6, 22.7, 24.1, 25.9, 40.3, 52.4, 113.9, 118.7, 125.8, 133.9, 134.2, 137.9, 153.7, 158.4, 176.7, 195.4, 198.6. GC-MS: 345 (100%), 247 (7%), 147 (3%), 119 (7%), 91 (9%), 77 (7%), 69 (20%), 53 (14%).

Glycine-promoted rapid synthesis of novel xanthene derivatives in ionic liquid

Mazaahir Kidwai, Kavita Singhal, and Shuchi Kukreja

Abstract: A green route for the synthesis of multi-substituted 2,3-dihydro-xanthenone derivatives using ionic liquid as solvent and amino acid as promoter is described. The reaction is simple and proceeds well at room temperature and devoid of the use of any harmful catalyst or solvent. This is an efficient technique.

Key words: xanthene, ionic liquid, glycine, room temperature.

Résumé : On décrit une méthode verte de synthèse de dérivés multisubstitués de la 2,3-dihydroxanthénone qui s'effectue dans un liquide ionique comme solvant, en présence d'un acide aminé comme catalyseur. La réaction est simple; elle s'effectue à la température ambiante et elle ne fait appel à aucun catalyseur ou solvant nocifs. Il s'agit d'une technique efficace.

Mots-clés : xanthène, liquide ionique, glycine, température ambiante.

Introduction

Xanthene-based fluorescent dyes are widely used in chemical biology to detect biological substances, such as proteins, DNAs, and sugars with high sensitivity and selectivity (1). This is attributed to the high electron density in the xanthene skeleton. The emission from the charge-transfer state of xanthenes has also been studied using nanoparticle chemistry (2). Numerous reports have been patented and have delineated the antiviral (3), antibacterial (4), and anti-inflammatory effects (5) and antimalarial activities with the inhibitory action towards *Trypanothione reductase* enzyme (6). Furthermore, they have also been found as good candidates in photodynamics (7) and laser technology (8). A number of such type of compounds are also available from natural sources (e.g., in the form of Santalin pigment) (9).

The large interest in medicinally important molecules stimulates the development of new and more efficient syntheses of this class of compounds. So far, the reported classical synthetic approaches to xanthenes involve the reaction of β-naphthol with formaldehyde (10), with aldehyde acetals under acidic conditions (11), and with 2-naphthol-1-methanol (12) and the reaction of aryloxymagnesium halides with triethyl orthoformate (13). Synthetic alternatives are many, varied, and have resorted to harsh conditions (e.g., the use of catalysts such as *p*-TSA (14), polyaniline-*p*-toluenesulfonate salt (15), sulfamic acid (16), glacial acetic acid (17), AcOH–H_2SO_4, amberlyst-15 (18), and so forth). Many of them often involve the use of hazardous organic solvents, tedious work-up, acidic conditions, which may not be the preferred choices in view of green chemistry.

Because of the increasing demands of environment legislation for the development of organic reactions in environment-friendly media, synthetic manipulations have to be made to minimize the use of hazardous chemicals. One example is replacing the traditional organic solvents in reactions and their subsequent work-up with non-toxic solvents. In this regard, interest is being manifested in the use of room temperature ionic liquids as promising alternative volatile organic solvents (19). These ambient temperature ionic liquids, especially those based on 1,3-dialkyl imidazolium cations, have been emerging as leading green reaction medium for the past decades (20) and also referred as "designer solvents", as their physical and chemical properties could be adjusted by a careful choice of cations and anions.

In our ongoing efforts to investigate the range of organic reactions possible in ionic liquid and developing a more versatile route to biodynamic lead compounds by adopting the principles of "green chemistry" (21), we, for the first time, sought to develop a process of synthesizing xanthene derivatives executed in ionic liquid – glycine system that is robust as well as eco-friendly.

Results and discussion

In view of the emerging relevance of the imidazole-based ionic liquid as reaction media, we explored the condensation reaction for the synthesis of xanthenes using [bmim]PF_6 ionic liquid as green solvent. First, the reaction of 2-hydroxy aldehyde (salicaldehyde) **2a** with 5,5-dimethylcyclohexane-1,3-dione (dimedon) **1a** using glycine with [bmim]PF_6 ionic liquid was selected as a model reaction (Scheme 1). The reaction went into completion in ~3 h at room temperature, and 3,3-dimethyl-xanthene-1-one was obtained efficiently in good yields (Table 1). There are several papers, which re-

ported the synthesis of xanthenes using α,β-unsaturated ketones; however, no report adopting ketones and diketones as the starting material is exemplified in the literature.

The absence of glycine requires more reaction time to yield the desired product and also resulted in low yields, and then the presence of glycine as promoter is essential here. Later, we tried to study the effect of different amino acids on the synthesis of **3a**, and the results are outlined in Table 2. Glycine was found to be the best catalyst out of the used amino acids, and thus for the synthesis of other derivatives, glycine was taken under optimal conditions. As the removal of water molecule in the second last step of mechanism (Fig. 1) needs some driving force, the role of glycine played in the reaction is important here, which is attributed to its basicity and helped in the trapping of water molecule.

As a test case, **3a** was synthesized under different reaction conditions using various solvents. Acetonitrile was almost ineffective for this condensation reaction; both DMF and DMSO were found to be effective in affording the products. Two neutral imidazoline-based ionic liquids were screened as the reaction medium, and it seemed that both the ionic liquids were suitable for the preparation of xanthene in good-to-excellent yields. Moreover, among these two ionic liquids tested, $[bmim]PF_6$ was chosen owing to the high yields with shorter reaction time, and then the rest of the reactions were carried out in this ionic liquid. It is important to note here that the use of ionic liquid leads to easy work-up.

Having established $[bmim]PF_6$ as the best solvent, we started to study the effect of temperature for this condensation reaction of 2-hydroxy aldehyde with dimedon, and the results are presented in Table 3. When the reaction temperature was raised, maximum yield was reached soon. However, 3 h of reaction time was found to be sufficient to complete this condensation under room temperature, so the reaction

was ultimately carried out at 25 °C to meet the requirement of minimization of energy consumption.

A plausible mechanism for this protocol is presented in Fig. 1. Initially, we suspected that the self condensation of the 2 mol of 1,3-dicarbonyl compound with 1 mol of aldehyde would possibly yield a compound with the substitution of aryl group at ninth position. Indeed, mass spectra and ^1H NMR spectra clearly ruled out the formation of that compound. Finally, the compound was confirmed on the basis of ^{13}C NMR spectral analysis. Further, to strengthen the mechanism and generality of the reaction, using the above-said optimized reaction conditions described above, we explored the possibility of usage of various cyclic diketones and 2-hydroxyl aldehydes. According to the mechanism, considering the case 1b as reactant, the aromatization is expected in the last step led to the formation of reduced ring system with the hydroxyl group at position 1. But on completion, the reaction furnishes **3d** as product, which was analyzed, and the peaks in ^1H NMR and correspondingly in ^{13}C NMR spectra confirmed the product. All of the compounds are hitherto unknown in chemical literature.

The ionic liquid used could be typically recovered by extracting out the product and filtering the suspension to remove the residual solid. This separation will not remove glycine as it got immobilized in IL, and the same glycine-immobilized IL has been used further for the rest of the derivatives. Interestingly, glycine can be removed after the aqueous neutralization. Finally, the products obtained were of the same purity as in the first reaction, and there was appreciable consistency in the product yields (Table 4).

Conclusion

In summary, we have devised a facile, eco-benign, and highly efficient protocol for the synthesis of 2,3-dihydroxanthenone derivatives bearing three points of diversity in IL–glycine system at room temperature using suitably substituted 2-hydroxy aromatic aldehydes and 1,3-diketones. This method provides several advantages, such as easy synthesis, simple work-up, sufficient yields, accelerated reaction rates, and low consumption of solvent. Another attractive part of this report is the satisfactory recovery and re-use of ionic liquid with no diminution of product yields, which demonstrates ionic liquid as a greener, economically viable catalyst cum solvent, which can interest the chemical community for the synthesis of interesting library of biologically relevant heterocyclic moieties.

Experimental section

All the chemicals and reagents were of analytical grade. Ionic liquids were prepared according to the literature procedure (22). Melting points were taken on a Thomas Hoover melting-point apparatus and are uncorrected. IR (in Nujol) were recorded on a model PerkinElmer FTIR-1710 spectrophotometer. ^{1}H NMR and ^{13}C NMR were recorded on a Bruker Avance Spectrospin 300 using TMS as internal standard. Mass spectra were recorded on a KC455 Waters TOF MS spectrometer. TLC was run on the silica-gel-coated aluminium sheets (Silica gel 60 F_{254}, E. Merck, Germany) and visualized in UV light (254 nm). Temperature of the reaction mixture was measured through AZ, Mini Gun Type, non-contact IR Thermometer, Model No. 8868.

General procedure for the synthesis of xanthen-1-one derivatives (3a–3f)

To a mixture of 1,3-diketone **1a**–**1b** (1 mmol), 2-hydroxy aromatic aldehyde **2a**–**2c** (1 mmol), and glycine, [bmim]PF_6 (2 mL) was added in a 10 mL flask equipped with a magnetic stirrer. The reaction mixture was stirred vigorously at room temperature, and the progress of the reaction was monitored by TLC. Upon completion of the reaction, the content was extracted with ethyl acetate (3 × 3 mL). The product obtained was further purified by column chromatography [column of SiO_2; pre-adsorption of the residue at SiO_2 (~8 g) with ethylacetate; elution with ether – ethylacetate, 90:10 (*v*/*v*)].

Procedure to recover the ionic liquid

The reaction mixture was filtered to recover ionic liquid through the Whatman no. 3 filter paper under suction. The filtrate was extracted with ethyl acetate (2 × 3 mL). The ionic liquid left after the extraction was concentrated in vacuo to remove traces of organic solvent and used as such in the subsequent reactions.

Amine-tethered *N*-heterocyclic carbene complexes of rhodium(I)

Howard Jong, Brian O. Patrick, and Michael D. Fryzuk

Abstract: A new family of rhodium-diene based complexes has been developed that incorporates an *N*-heterocyclic carbene ligand with an N-donor tether. The ligand is denoted ^{Mes}[CNH] **2** (where ^{Mes}[CNH] is 2,4,6-$Me_3C_6H_2NC_3H_2NCH_2CH_2NH$-2,4,6-$Me_3C_6H_2$) and ^{Mes}[CN] for the amido form. The synthesis of the ^{Mes}[CNH] ligand involves reaction of *N*-mesitylimidazole with 2-chloroethyl-*N*-mesitylamine under melt conditions, followed by deprotonation with $KN(SiMe_3)_2$. The reaction of ^{Mes}[CNH] with $[(diene)RhCl]_2$ results in the formation of the monodentate complexes, ^{Mes}[CNH]Rh(diene)Cl (where diene = 1,5-cyclooctadiene (COD): **3a**; diene = 2,5-norbornadiene (NBD): **3b**). Bidentate variants could be isolated as either a neutral species, ^{Mes}[CN]Rh(diene) **4a**–**4b**, via deprotonation, or an ionic analogue such as $[^{Mes}$[CNH]Rh(diene)$]BF_4$ **5a**–**5b** by reaction with $NaBF_4$. Compounds **4**–**5** are the first examples of rhodium compounds that contained a bidentate NHC ligand with a pendant amino or amido donor. Complexes **3**–**5** were characterized fully and the solid-state single crystal X-ray structures of **3a**, **4a**, and **5b** are discussed. The utility of these complexes as catalyst precursors for hydrogenation reactions was examined and it was determined that these systems are not significantly more active than colloidal rhodium when parallel reactions were run. Various methods of transfer hydrogenations were also investigated with **3a**, which did not yield an appreciable conversion of either benzophenone or *N*-benzylideneaniline as substrates.

Key words: rhodium, *N*-heterocyclic carbene, catalysis, hydrogenation.

Résumé : On a développé une nouvelle famille de complexes à base de rhodium-diène qui incorpore un ligand carbène *N*-hétérocyclique comportant une une chaîne latérale avec un donneur azoté, ^{Mes}[CNH], **2**, dans lequel ^{Mes}[CNH] = 2,4,6-$Me_3C_6H_2NC_3H_2NCH_2CH_2NH$-2,4,6-$Me_3C_6H_2$ alors que ^{Mes}[CN] correspond à sa forme amido. La synthèse du ligand ^{Mes}[CNH] implique la réaction du *N*-mésitylmidazole avec la 2-chloroéthyl-*N*-mésitylamine à l'état fondu, suivie d'une déprotonation à l'aide du $KN(SiMe_3)_2$. La réaction du ^{Mes}[CNH] avec le $[(diène)RhCl]_2$ conduit à la formation des complexes ^{Mes}[CNH]Rh(diène)Cl (dans lesquels diène = 1,5-cyclooctadiène (COD), **3a**; 2,5-norbornadiène (NBD), **3b**). Des variantes bidentates peuvent aussi être isolées sous la forme d'espèces neutres, ^{Mes}[CN]Rh(diène), **4a**–**4b**, via une déprotonation, ou sous la forme d'un analogue ionique, tel le $\{^{Mes}$[CNH]Rh(diène)$]\}BF_4$, **5a**–**5b**, par réaction avec le $NaBF_4$. Les composés **4** et **5** sont les premiers exemples de composés du rhodium contenant un ligand bidentate NHC comportant une chaîne latérale donneur amino ou amido. On a effectué une caractérisation complète des complexes **3 - 5** et on discute des structures cristallines des composés **3a**, **4a** et **5b** établies par diffraction des rayons X à l'état solide sur des cristaux uniques. On a examiné l'utilité que pourraient avoir ces complexes comme précurseurs de catalyseurs pour les réactions d'hydrogénation et on a déterminé que, dans des réactions parallèles, l'activité de ces systèmes ne dépasse pas d'une façon significative celle du rhodium colloïdal. On a aussi examiné diverses méthodes d'hydrogénation par transfert à l'aide du composé **3a**, mais elles ne conduisent pas à des rendements appréciables de conversion de la benzophénone ou de la *N*-benzylidèneaniline utilisées comme substrats.

Mots-clés : rhodium, carbène *N*-hétérocyclique, catalyse, hydrogénation.

[Traduit par la Rédaction]

Introduction

New innovations in homogeneous catalysis are constantly being uncovered. Much of this revolves around ligand design, which when combined with an appropriate transition metal precursor can generate an active catalytic system for a particular process. Phosphine ligands have been studied exhaustively throughout the past few decades and have found wide applicability in numerous transformations (1, 2). However, more recently, *N*-heterocyclic carbenes (NHCs) have gained much attention as an alternative ligand set to their phosphine counterparts (3). NHCs are similar to phosphines since they are both good σ-donor ligands (4–6), with NHCs being perhaps even stronger σ-donors than phosphines, but lacking π-accepting character (7). NHCs are also very thermally stable and less prone to oxidation compared to phosphine ligands, which is beneficial in the development of robust catalysts.

NHCs have been found to be very effective spectator ligands for palladium and nickel-based C-C coupling catalysts,

where they have been proven to be superior to their phosphine competitors (3, 8, 9). More impressive however, has been the improvement in catalytic activity for ruthenium-based olefin metathesis systems (10). Late transition metal-NHC complexes have found applicability in many other kinds of transformations such as hydrosilylation, amination, C–H bond activation, hydroformylation, hydrogenation as well as transfer hydrogenation. The NHC ligand sets used to perform the transformations are often monodentate variants of the original IAd (1,3-diadamantylimidazol-2-ylidene) system developed by Arduengo et al. (11). Substitution at the 1,3-positions of the imidazole unit range from alkyl groups (methyl, isopropyl, *tert*-butyl) to substituted aryl systems such as mesityl (2,4,6-trimethylphenyl) and DIPP (2,6-diisopropylphenyl). Similarly, chelating NHC pincer ligands have also been synthesized in bidentate and tridentate forms (12, 13).

Crabtree's catalyst (14), $[Ir(COD)PCy_3(py)]PF_6$, has become a catalyst benchmark for hydrogenation displaying very high activity for simple as well as substituted olefinic substrates (15). This work has prompted other groups to pursue developments of analogous catalytic systems using NHCs to match or even augment activity and improve the reaction stability that Crabtree's complex does not posses (3, 14). For example, substitution (16) of PCy_3 with SIMes (1,3-dimesityl-4,5-dihydroimidazole-2-ylidene) does provide improved thermal stability of the catalyst but at the expense of a slight reduction in activity at room temperature (RT).

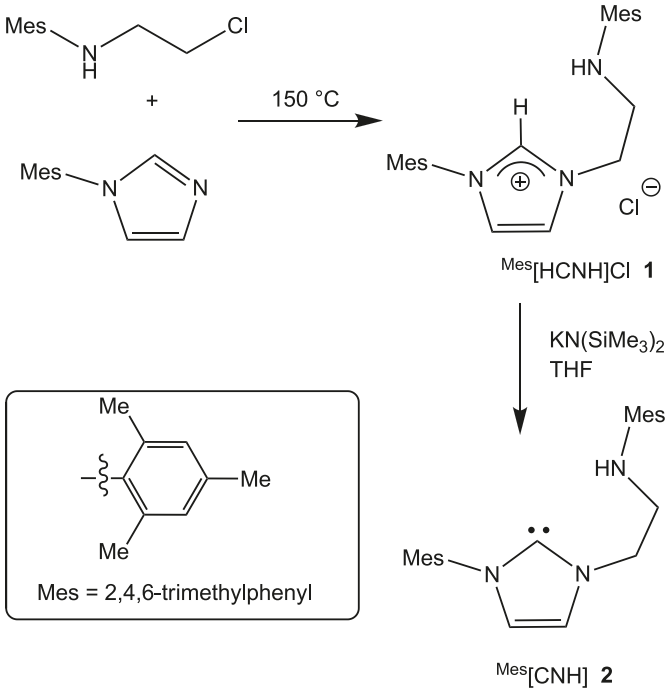
Various derivatives of Crabtree's catalyst incorporating NHC ligands have also been investigated by other groups (17). For example, the first air-stable, pincer bis(NHC) rhodium(III) complex that exhibits good activity for transfer hydrogenation of aryl ketones and imines has been developed (18), and improved hydrogen transfer activity with their next generation iridium analogues has also been reported (19). A chelating pyridine functionalized NHC system coordinated to rhodium (20) has been reported and is capable of performing transfer hydrogenation at good turnover numbers (TONS) at moderate temperatures.

This report focuses on the synthesis of a hemilabile mixed-donor NHC ligand and its coordination chemistry with rhodium(I) diene derivatives. The NHC unit incorporates an amino tether that can bind either as an amine or as an amido donor, after deprotonation. Such a bidentate coordination motif could augment the thermal stability of the resultant Rh complexes with respect to monodentate NHC-bound derivatives (21–24).

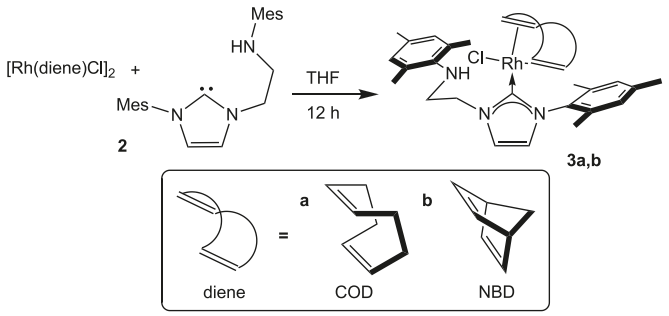
Results and discussion

We have previously reported the preparation of a tridentate NHC ligand with flanking amino tethers by melting an imidazole with the appropriate 2-chloroethyl-*N*-arylamine (25). A similar approach can be used to generate a bidentate analog in good yield; the reaction of neat mesityl imidazole with 2-chloroethyl-*N*-mesitylamine in a sealed vessel at 150 °C generates the imidazolium salt **1**, which we denote as ^{Mes}[HCNH]Cl. Deprotonation of **1** with potassium hexamethyldisilazide (KHMDS) results in the formation of the free carbene ^{Mes}[CNH], **2** (Scheme 1). A similar approach to generate tertiary amine side-arm donors has recently been reported (26). Successful conversion to compound **2** can be clearly observed in the ^{1}H NMR spectrum as the iminium proton resonance at δ 10.7 of **1** disappears and a new ^{13}C NMR signal is observed at δ 215.6, due to the carbene carbon (11).

Scheme 1.



Scheme 2.



Incorporation of the NHC **2** to rhodium(I) can be accomplished by the addition of ^{Mes}[CNH] to 0.5 equiv. of $[Rh(diene)Cl]_2$ (diene = 1,5-cyclooctadiene (COD) or 2,5-norbornadiene (NBD)) in a solution of THF at RT over a period of 8 h. Both complexes, **3a** and **3b**, are isolated as air-stable yellow powders in good yield (Scheme 2). The resultant NHC-Rh-diene complexes were characterized by ^{1}H and ^{13}C NMR spectroscopy; for example, a weak doublet ($^1J_{Rh\text{-}carbene}$ = 58 Hz) near δ 184 in the ^{31}C NMR spectrum can be assigned to the NHC carbene carbon and confirms the presence of the Rh-carbene bond for each of the diene derivatives.

Figure 1 depicts the solid-state single crystal X-ray structure of **3a**; selected bond distances and angles are given in Table 1; crystallographic data are given in Table 2. The structure shows a mildly distorted square planar geometry about the rhodium(I) center, and the rhodium–carbene dis-

tance (Rh1–C2) of 2.0387(18) Å is well within the range reported for similar Rh(I) derivatives (26). The Rh–COD bond distances (calculated from the distance between the metal to the centroid of the olefinic fragment) are inequivalent with respect to its coordination being in either cis or trans positions relative to the C2 of the carbene (cis = 1.989 Å, trans = 2.072 Å). This inequivalence in bond length is expected and corroborates the trans disposed C=C fragment being less activated and less strongly bound to the rhodium center as is shown in the C=C bond distances of the COD (trans = 1.375(3) Å, cis = 1.395(3) Å) fragment due to the strong trans influence imparted by the NHC ligand.

To coordinate the pendent amine arm to rhodium, potassium hexamethyldisilylamide (KHMDS) can be added to compounds **3a** and **3b**. Alternatively, the bidentate amido carbene-rhodium complexes, **4a** and **4b**, can be synthesized in very good yields in one step by deprotonating imidazolium salt **1** with 2.2 equiv. of KHMDS followed by an in situ reaction with 0.5 equiv. of a rhodium-diene dimer at reduced temperatures. Complexes **4a** and **4b** maintain a slightly distorted square planar geometry and are characterized by a weak doublet resonance (J = 56 Hz) at approximately δ 180 in the ^{13}C NMR spectrum (Rh-carbene carbon).

Interestingly, the single crystal X-ray structure of **4a** (Fig. 2) shows a nearly identical Rh01–C02 bond distance of 2.037(3) Å compared to that of **3a** (2.0387(18) Å); other selected bond distances and angles are given in Table 1; crystallographic data are given in Table 2. The Rh–olefin distances (to the centroid of the C=C bond) for **4a** are 2.009 and 2.093 Å, respectively, for the cis and trans orientations. These values compare to **3a** (cis = 1.989, trans = 2.072 Å), which suggests that COD coordination may be slightly tighter for the chloro complex **3a** as compared to the amido derivative **4a** (Scheme 3).

Cationic analogues can be synthesized with the addition of a halide extraction agent such as sodium tetrafluoroborate to **3a** or **3b** to cleanly yield the corresponding compounds **5a** and **5b** (Scheme 4). The ^{1}H NMR spectrum shows a slight upfield shift of the methylene protons on the ethylene spacer of **3a** (δ 4.83, 3.48) as compared to **5a** (δ 4.76, 3.47), where the upfield shift is larger for the NBD pair: δ 4.93, 3.64 for **3b** versus δ 4.65, 3.25 for **5b**. The N-H resonance in the ^{1}H NMR spectrum does shift downfield slightly upon coordination; for example, in **3a** the uncoordinated N-*H* resonance is found at δ 3.18 whereas upon coordination in **5a**, this resonance shifts to δ 3.26.

The single crystal X-ray diffraction structure depicts **5b** (Fig. 3) with a distorted square planar geometry. Bond distances from the rhodium center to the cis and trans coordinated olefinic fragments of the norbornadiene ligand were found to be 1.993 and 2.081 Å, respectively (measured to the center of the C=C centroid), which is typical of Rh-NBD complexes (27–29). These values are also akin to those of **3a** and **4a**, which suggests that the norbornadiene unit is similarly bound to the rhodium center as the cyclooctadiene unit; other bond distances and angles are given in Table 1, while crystallographic data are listed in Table 2.

Upon inspection of the ^{13}C NMR data of the COD and NBD derivatives, one observes that all of the complexes exhibit very similar metal-carbene chemical shifts, in a range from approximately δ 174 to 185, with the cationic derivative **5b** being most upfield shifted to δ 174.6. Thus, there does not seem to be much change in the Rh-NHC interaction as a function of the amine tether being coordinated or dangling.

We examined the reaction of the cationic complex **5b** with pyridine and PMe_3 to examine the relative binding ability of the tethered amine; addition of excess pyridine did not result in decoordination of the amine arm on **5b**, while addition of PMe_3 did result in the formation of the phosphine adduct **6** (Scheme 5).

Catalytic test reactions

Hydrogenation test reactions were performed with complexes **3**–**5** using simple cyclic alkenes as substrates; cyclohexene and 1-methyl-cyclohexene were selected as they have been used frequently as benchmark substrates to test hydrogenation activity of later metal catalysts (14, 30). None of the catalysts were able to hydrogenate the substituted cyclohexene substrate beyond 40% after 72 h with the exception of complexes **4a** and **4b** that recorded conversions greater than 90%.

Transfer hydrogenation reactions with ketone and imine substrates were attempted with **3a** as well. Various common literature methods (18, 20, 31, 32) were attempted on benchmark test substrates such as benzophenone and *N*-

benzylideneaniline. Of the four routes attempted, none of them produced a positive indicator despite being allowed to run for and extended period of time (>12 h). From ^{1}H NMR analysis, it appeared that the precursor was stable and reluctant to become activated in solution.

From the less than satisfactory results of the hydrogenation and transfer hydrogenation studies, it was determined that the induction period of our catalyst precursors **3**–**5** was long and the timescale at which conversions were recorded overlapped with those resulting from simple colloidal rhodium hydrogenations of parallel substrates.

Efforts to determine the reactivity of the precursor complexes **3**–**5** were attempted by reaction with 1 atm H_2 in the absence of a substrate; unfortunately, the results parallel the catalytic runs in that these complexes remained largely unchanged on the basis of NMR spectroscopy; in addition, attempts to detect small amounts of hydride species, which should show resonances upfield of δ 0 were unsuccessful, contrary to characteristic behavior of active Rh precursors (33–37).

Conclusions

The ability of an amine-tethered NHC to coordinate to rhodium(I) diene complexes in either a monodentate or bidentate mode has been investigated. The synthetic protocols to generate each class of compounds are straightforward and illustrate the versatility of this ligand in its binding aptitudes. Given the variable complexes accessible, we examined their ability to act as catalyst precursors for the hydrogenation of cyclic alkenes. Unfortunately, regardless of the bonding mode or form of the tether (i.e., amine versus amide), none of these complexes were especially active in hydrogenation. In addition, the neutral and cationic amine tethered NHC complexes, **3** and **5**, were tested for their ability to act as transfer hydrogenation precatalysts; here again, no positive results were obtained. It would appear that the diene ligands are too firmly bound to any of these complexes, regardless of the tether binding mode, so much so that neither substrates nor H_2 activation can occur. Further studies are ongoing with iridium and ruthenium systems that incorporate these versatile amine-tethered NHCs.

Experimental section

General considerations

Unless otherwise specified, all experimental procedures were performed in a dry, oxygen-free nitrogen or argon atmosphere by Schlenk or glovebox techniques. 2,4,6-$Me_3C_6H_2NHC(O)CH_2Cl$ (38), 2,4,6-$Me_3C_6H_2NHCH_2CH_2Cl$ (39), 2,4,6-trimethylphenylimidazole (40), $[Rh(COD)Cl]_2$ (41), $[Rh(NBD)Cl]_2$ (42), and $[Rh(COE)_2Cl]_2$ (43) were prepared from literature methods. All other chemicals were purchased commercially and used as received. Methylene chloride was dried by refluxing over CaH_2 overnight under nitrogen. Anhydrous toluene, hexanes, pentane, and tetrahydrofuran were purchased from Sigma-Aldrich, sparged with nitrogen, and passed through columns containing activated alumina and Ridox catalyst. Deuterated benzene (C_6D_6) was purified via three freeze-pump-thaw cycles and then refluxed overnight in a sealed vessel, which contained sodium/potassium alloy, and vacuum transferred into a glass bomb. Deuterated methylene chloride (CD_2Cl_2) was purified in a similar manner using CaH_2 as the drying agent. ^{1}H and ^{13}C NMR spectra were obtained by a Bruker AVANCE 300 or 400 MHz spectrometer. Elemental analysis and mass spectrometry (EI/MS) were performed at the Department of Chemistry at the University of British Columbia.

Synthesis of 1-(2,4,6-$Me_3C_6H_2$)-3-(2-(2,4,6-$Me_3C_6H_2NH$)ethyl)imidazolium chloride, ^{Mes}[HCNH]Cl (1)

A glass reactor fitted with a Kontes valve was charged with 3.00 g (55.2 mmol) of 2,4,6-$Me_3C_6H_2NHCH_2CH_2Cl$ and 2.83 g (55.2 mmol) of 2,4,6-trimethylphenylimidazole, and the resultant mixture heated to 150 °C for 1.5 h. The reaction was allowed to cool to RT and the tough air-stable brown solid was filtered and washed with THF to produce the desired cream-colored solid (5.10 g, 90% yield). ^{1}H NMR (CD_2Cl_2, 400 MHz) δ: 2.04 (s, 6H, -*o*-ArC*H*$_3$), 2.09 (s, 6H, -*o*-ArC*H*$_3$), 2.16 (s, 3H, -*p*-ArC*H*$_3$), 2.32 (s, 3H, -*p*-ArC*H*$_3$), 3.23 (t, *J* = 5 Hz, 2H, -N_{Ar}C*H*$_2$), 4.99 (t, *J* = 5 Hz, 2H, -N_{imid}C*H*$_2$), 6.72, 6.99 (s, 2H, -Ar*H*), 7.12 (s, 1H, -imid*H*), 8.12 (s, 1H, -imid*H*), 10.7 (s, 1H, -NC*H*N). ^{13}C NMR (CD_2Cl_2, 100 MHz) δ: 17.89, 18.52 (-*o*-ArC*H*$_3$), 20.80, 21.31 (-*p*-ArC*H*$_3$), 48.08 (-N_{Ar}C*H*$_2$), 50.05 (-N_{imid}C*H*$_2$), 122.78, 124.24 (-imid*C*), 129.6, 130.2, 131.5, 131.9, 132.6, 134.9 (-Ar*C*), 140.3 (-N*C*HN) 141.6, 142.8 (-*ipso*-Ar*C*). EI-MS: 347 [M$^+$]. Anal. calcd. for $C_{23}H_{30}N_3Cl$ (%): C 71.95, H 7.88, N 10.94; found: C 71.87, H 7.62, N 11.30.

Synthesis of (2,4,6-$Me_3C_6H_2$)-3-(2-(2,4,6-$Me_3C_6H_2NH$)ethyl)imidazole-2-ylidene, ^{Mes}[CNH] (2)

$KN(SiMe_2)_2$ (3.12 g, 15.6 mmol) was dissolved in 20 mL of THF and added dropwise to a stirring THF suspension containing 5.00 g (13.0 mmol) of **1** at RT. The mixture was stirred for 1.5 h and dried in vacuo to leave a beige powder. Colorless needle crystals suitable for X-ray grade were grown by slow evaporation from a solution of toluene (4.10 g, 91% yield). ^{1}H NMR (C_6D_6, 400 MHz) δ: 2.08 (s, 6H, -*o*-ArC*H*$_3$), 2.14 (s, 3H, -*p*-ArC*H*$_3$), 2.18 (s, 3H, -*p*-ArC*H*$_3$), 2.23 (s, 6H, -*o*-ArCH_3), 3.29 (t, *J* = 5 Hz, 2H, -N_{Ar}C*H*$_2$), 3.91 (t, *J* = 5 Hz, 2H, -N_{imid}C*H*$_2$), 4.18 (s, 1H, -N*H*), 6.36 (d, *J* = 2 Hz, 1H, -imid*H*), 6.45 (d, *J* = 2 Hz, 1H, -imid*H*), 6.78 (s, 2H, -Ar*H*), 6.80 (s, 2H, -Ar*H*). ^{13}C NMR (C_6D_6, 100 MHz) δ: 18.49, 19.19, 21.13, 21.33 (-ArCH_3), 49.62 (-N_{Ar}C*H*$_2$), 51.93 (-N_{imid}C*H*$_2$), 120.0, 120.9 (-imid*C*), 129.5, 130.2, 130.6, 131.4, 135.7, 137.6, 139.6, 144.6 (-Ar*C*), 215.6 (-N*C*N). EI-MS: 347 [M$^+$]. Anal. calcd. For $C_{23}H_{29}N_3$·2/5C_4H_8O (%): C 78.51, H 8.62, N 11.17; found: C 78.26, H 8.50, N 11.55.

Synthesis of ^{Mes}[CNH]Rh(COD)Cl (3a)

^{Mes}[CNH] (2.82 g, 8.12 mmol) was dissolved in 10 mL of THF and added dropwise to a stirring transparent yellow solution of 2.00 g (4.06 mmol) of $[Rh(COD)Cl]_2$ in 10 mL of THF. The reaction was stirred overnight at RT and the solvent was removed, which resulted in the desired yellow powder. Yellow crystals suitable for X-ray analysis were grown by slow evaporation in methylene chloride (2.12 g, 88% yield). ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.50–1.80 (m, -COD), 1.69 (s, 3H, -ArC*H*$_3$), 1.90–2.30 (m, -COD), 2.15 (s, 3H, -ArC*H*$_3$), 2.19 (s, 3H, -ArC*H*$_3$), 2.23 (s, 6H, -ArC*H*$_3$), 2.67 (s, 3H, -ArC*H*$_3$), 3.18 (s, 1H, -N*H*), 3.35 (m, -COD), 3.47 (t, *J* = 6 Hz, 2H, -N_{Ar}C*H*$_2$), 4.83 (t, *J* = 6 Hz, 2H, -N_{imid}C*H*$_2$), 5.26 (m, 1H, -COD), 5.36 (m, 1H, -COD), 6.00 (d, *J* = 1 Hz, 1H, imid*H*), 6.46 (d, *J* = 1 Hz, 1H, imid*H*), 6.70 (s, 2H, Ar*H*), 6.81 (s, 4H, Ar*H*), 6.86 (s, 2H, Ar*H*). ^{13}C NMR (C_6D_6, 100 MHz) δ: 18.13 (-*p*-CH_3), 19.04 (-*o*-CH_3), 20.63 (-*p*-CH_3), 21.13, 21.37 (-*o*-CH_3), 28.93, 29.79, 32.57, 34.71 (-COD), 49.01 (-N_{Ar}C*H*$_2$), 52.38 (-N_{imid}C*H*$_2$), 67.48, 67.28 (d, *J* = 14 Hz, -RhC_{COD}H), 97.81, 98.61 (d, *J* = 7 Hz, -RhC_{COD}H), 121.7 (-imid*C*), 122.9 (-imid*C*), 130.2, 130.6, 130.7 (-Ar*C*N_{Ar}), 131.9, 134.7, 137.2, 138.3, 139.0 (-Ar*C*N_{imid}), 143.9 (-Ar*C*N_{imid}), 184.2 (d, *J* = 52 Hz, RhC_{NCN}). EI-MS: 593 [M$^+$]. Anal. calcd. for $C_{31}H_{41}N_3ClRh$ (%): C 62.68, H 6.96, N 7.07; found: C 62.61, H 7.30, N 7.32.

Synthesis of ^{Mes}[CNH]Rh(NBD)Cl (3b)

The synthetic procedure is as described for **3a**. Yellow crystals suitable for X-ray analysis were grown by slow evaporation in methylene chloride. ^{1}H NMR (CD_2Cl_2, 400 MHz) δ: 1.14 (s, 2H, -NBD), 2.02 (s, 6H, -ArC*H*$_3$), 2.22 (s, 3H, -ArC*H*$_3$), 2.28 (s, 6H, -ArC*H*$_3$), 2.41 (s, 3H, -ArC*H*$_3$), 3.40 (s, 2H, -NBD), 3.46 (s, 2H, -NBD), 3.64 (m, 2H, -N_{Ar}C*H*$_2$), 4.93 (m, 2H, -N_{imid}C*H*$_2$), 6.73 (d, *J* = 1.6 Hz, -imid*H*), 6.83 (s, 2H, -Ar*H*), 7.05 (s, 2H, -Ar*H*), 7.13 (d, *J* = 1.6 Hz, -imid*H*). ^{13}C NMR (CD_2Cl_2, 100 MHz) δ: 18.51, 18.76 (-*C*H$_3$), 20.86, 21.48 (-NBD), 49.51 (-N_{Ar}C*H*$_2$), 51.27 (d, *J* = 2.5 Hz, -RhC_{NBD}H), 52.12, (-N_{imid}C*H*$_2$), 63.43 (d, *J* = 5.2 Hz, -RhC_{NBD}H), 122.2, 123.1 (-imid*C*), 129.5, 129.9, 130.8 (-Ar*C*), 132.3, 136.1, 136.7 (-Ar*C*), 139.5, 143.4 (-Ar*C*), 183.9 (d, *J* = 58 Hz, RhC_{NCN}). Synthesis of ^{Mes}[CN]Rh(COD) (4a)

1 (300 mg, 0.781 mmol) was suspended in 5 mL of THF. To this mixture, 343 mg (1.72 mmol) of $KN(SiMe_3)_2$, dissolved in 2 mL of THF, was added dropwise at RT. The yellow-brown solution was stirred for 1 h and then cooled to –30 °C. $[Rh(COD)Cl]_2$ (193 mg, 0.391 mmol) was dissolved in 10 mL of THF and was added dropwise at –30 °C. The solution was warmed to RT and stirred for 1 additional hour that resulted in an orange-brown mixture. The THF was removed under vacuum and the product was extracted with toluene and filtered through Celite. Under reduced pressure, the toluene was removed and the product was washed with hexanes to give a golden orange powder. Cooling a concentrated benzene solution to –30 °C produced orange crystals suitable for X-ray analysis (393 mg, 90% yield). ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.55–1.88 (m, -COD), 2.05–2.25 (m, -COD), 2.10 (s, 3H, -ArC*H*$_3$), 2.21 (s, 6H, -ArC*H*$_3$), 2.32 (s, 3H, -ArC*H*$_3$), 2.71 (s, 6H, -ArC*H*$_3$), 2.99 (m, 2H, -N_{Ar}C*H*$_2$), 3.04 (m, 2H, -COD), 3.85 (m, 2H, -COD), 4.12 (m, 2H, -N_{imid}C*H*$_2$), 5.91 (d, *J* = 2 Hz, 1H, imid*H*), 6.10 (d, *J* = 2 Hz, 1H, imid*H*), 6.74 (s, 2H, Ar*H*), 7.13 (s, 2H, Ar*H*). ^{13}C NMR (C_6D_6, 100 MHz) δ: 18.93, 20.10 (Ar*C*H$_3$), 21.32, 21.53 (-Ar*C*H$_3$), 30.45, 34.05 (-COD), 54.14 (-N_{Ar}C*H*$_2$), 57.35 (-N_{imid}C*H*$_2$), 64.35 (d, *J* = 11 Hz, -RhC_{COD}H), 94.54 (d, *J* = 8 Hz, -RhC_{COD}H), 120.4 (-imid*C*), 122.0 (-imid*C*), 128.9, 129.5, 129.7, 129.9, 130.4 (-Ar*C*), 135.9, 136.4, 138.3, 138.6, 157.9 (-Ar*C*), 180.8 (d, *J* = 56 Hz, -RhC_{NCN}). EI-MS: 557 [M$^+$]. Anal. calcd. for $C_{31}H_{40}N_3Rh$ (%): C 66.78, H 7.23, N 7.54; found: C 66.46, H 7.23, N 7.40.

Synthesis of ^{Mes}[CN]Rh(NBD) (4b)

The synthetic procedure is as described for **4a**. ^{1}H NMR (C_6D_6, 400 MHz) δ: 1.03 (b, 1H, -NBD), 1.09 (b, 1H, -NBD), 2.04 (s, 3H, -ArC*H*$_3$), 2.10 (s, 6H, -ArC*H*$_3$), 2.30 (s, 3H, -ArC*H*$_3$), 2.39 (b, 2H, -NBD), 2.77 (s, 6H, -ArC*H*$_3$),

Synthesis of ^{Mes}[CNH]Rh(COD]BF_4 (5a)

3 (1.00 g, 1.68 mmol) was dissolved in 10 mL of CH_2Cl_2 and cooled to –30 °C. $NaBF_4$ (222 mg, 2 mmol) was ground and was slowly introduced to the solution at –30 °C. The mixture was warmed to RT and stirred overnight. The reaction was carefully monitored for the first 2 h to control the effervescing solution. Once complete, the mixture was filtered through Celite and the solvent was removed under reduced pressure to leave the desired yellow product (867 mg, 80% yield). ^{1}H NMR (CD_2Cl_2, 400 MHz) δ: 1.40–2.40 (m, -COD), 1.84 (s, 3H, -*p*-ArCH_3), 2.20 (s, 3H, -*p*-ArCH_3), 2.21 (s, 6H, -*o*-ArCH_3), 2.37 (s, 3H, -*o*-ArCH_3), 2.39 (s, 3H, -*o*-ArCH_3), 3.00 (m, 1H, -COD), 3.26 (s, 1H, -N*H*), 3.46 (m, 2H, -$N_{Ar}CH_2$), 3.60 (m, 1H, -COD), 4.69 (m, 1H, COD), 4.77 (m, 2H, -$N_{imid}CH_2$), 5.14 (m, 1H, -COD), 6.80 (s, 2H, -Ar*H*), 6.81(s, 1H, -Ar*H*), 6.94 (s, 1H, imid*H*), 7.10 (s, 1H, imid*H*), 7.16 (s, 1H, -Ar*H*). ^{13}C NMR (CD_2Cl_2, 100 MHz) δ: 18.11 (-*p*-ArCH_3), 18.69 (-*o*-ArCH_3), 20.01, 20.85, 21.37 (-ArCH_3), 28.50, 29.69, 31.99, 34.61 (-COD), 49.13 (-$N_{Ar}CH_2$), 52.46 (-$N_{imid}CH_2$), 68.13, 69.13 (d, *J* = 15 Hz, -RhC_{COD}H), 97.25, 97.33 (d, *J* = 3 Hz, -RhC_{COD}H), 121.8, 123.8 (-imid*C*), 128.8, 129.9 (-ArCN_{Ar}), 130.0 (-ArCN_{imid}), 130.7 (-ArCN_{Ar}), 132.2, 135.0, 136.8, 137.5 (-ArCN_{imid}), 139.3, 143.4 (-ArC_{ipso}), 183.1 (d, *J* = 51 Hz, -RhC_{NCN}). EI-MS: 558 [M^+]. Anal. calcd. For $C_{31}H_{41}N_3BF_4Rh{\cdot}1/5C_5H_{12}$ (%): C 58.25, H 6.63, N 6.37; found: C 58.63, H 6.94, N 6.44.

Synthesis of ^{Mes}[CNH]Rh(NBD)]BF_4 (5b)

The synthetic procedure is as described for compound **5a**. Slow evaporation in a concentrated solution of CH_2Cl_2 produced yellow X-ray grade platelets. ^{1}H NMR (CD_2Cl_2, 400 MHz) δ: 1.13 (s, 2H, -NBD), 2.03 (s, 6H, -*o*-ArCH_3), 2.22 (s, 3H, -*p*-ArCH_3), 2.35 (s, 6H, -*o*-ArCH_3), 2.40 (s, 3H, -*p*-ArCH_3), 3.47 (s, 2H, -NBD), 3.55 (m, 4H, -NBD), 3.64 (s, 1H, -N*H*), 3.72 (m, 2H, -$N_{Ar}CH_2$), 4.92 (m, 2H, -$N_{imid}CH_2$), 6.72 (d, 1H, -imid*H*), 6.84 (s, *J* = 1 Hz, 2H, -Ar*H*), 7.04 (s, 2H, -imid*H*), 7.17 (d, *J* = 1 Hz, 1H, -imid*H*). ^{13}C NMR (CD_2Cl_2, 100 MHz) δ: 17.95, 19.04 (-*o*-ArCH_3), 20.59, 21.15 (-*p*-ArCH_3), 49.65 (-$N_{Ar}CH_2$), 51.11 (-$N_{imid}CH_2$), 51.47 (d, *J* = 1.8 Hz, -NBD), 64.06 (d, *J* = 5.1 Hz, -NBD), 122.6, 122.9 (-imid*C*), 129.6, 130.2, 130.6, 135.6, 139.8, 140.8 (-Ar*C*), 174.6 (d, *J* = 59 Hz, -RhC_{NCN}). EI-MS: 539 [M^+]. Anal. calcd. for $C_{30}H_{37}N_3BF_4Rh{\cdot}/3C_6H_{14}$ (%): C 58.37, H 6.43, N 6.38; found: C 58.18, H 6.03, N 6.03.

Synthesis of ^{Mes}[CNH]Rh(NBD)PMe_3 (6)

PMe_3 (32 mg, 0.421 mmol) was mixed with 3 mL of benzene and added dropwise to an orange suspension containing 218 mg (0.346 mmol) of **5b** in 5 mL of benzene. Immediately after the addition, the solution becomes transparent and then becomes a suspended orange mixture after 5 min. The reaction was allowed to stir for 30 min before the solution was concentrated under rotary evaporation. The addition of pentane resulted in the precipitation of an orange powder, which was collected and dried under vacuum (212 mg, 87% yield). ^{1}H NMR (CD_2Cl_2, 400 MHz) δ: 1.28, (d, 2H, -NBD), 1.43 (br, 9H, -P(CH_3)$_3$), 1.51 (s, 3H, -*o*-ArCH_3), 1.79 (s, 3H, -*o*-ArCH_3), 2.22 (s, 9H, -ArCH_3), 2.44 (s, 3H, -*p*-ArCH_3), 2.98 (br, 2H, -NBD), 3.32 (m, 2H, -$N_{Ar}CH_2$), 3.46, 3.50 (br, 2H, -NBD), 3.63 (m, 1H, -$N_{imid}CH_2$), 4.16 (br, 1H, -NBD), 4.67 (br, 1H, -NBD), 4.91 (m, 1H, -$N_{imid}CH_2$), 6.80 (d, 1H, -imid*H*), 6.85 (s, 2H, -Ar*H*), 7.14 (s, 2H, -Ar*H*), 7.50 (d, 1H, -imid*H*). ^{13}C NMR (CD_2Cl_2, 100 MHz) δ: 18.22 (-*o*-ArCH_3), 19.0 (-ArCH_3), 20.8 (m, -P(CH_3)$_3$), 21.9 (-*p*-ArCH_3), 42.2, 46.2 (-NBD), 49.9 (-$N_{Ar}(CH_2)$, 51.7 (-$N_{imid}(CH_2)$, 53.4 (-NBD), 61.7 (d, $J_{Rh\text{-}NBD}$ = 3 Hz, -NBD), 66.1 (d, $J_{Rh\text{-}NBD}$ = 5 Hz, -NBD), 67.5 (d, $J_{Rh\text{-}NBD}$ = 4 Hz, -NBD), 77.4 (d, $J_{Rh\text{-}NBD}$ = 6 Hz, -NBD), 123.1, 125.3 (-imid*C*), 130.5, 130.8, 133.4, 136.4, 140.8, 143.2 (-Ar*C*), 183.8 (d, $J_{Rh\text{-}NCN}$ = 58 Hz -RhN*C*N). ^{31}P{^{1}H} NMR (CD_2Cl_2, 162 MHz) δ: –12.91 (d, $J_{Rh\text{-}P}$ = 122 Hz, *P*(CH_3)$_3$). EI-MS: 539 [M^+-PMe_3]. Anal. calcd. for $C_{33}H_{46}N_3BF_4Rh{\cdot}/2C_6H_{14}$ (%): C 57.77, H 7.14, N 5.61; found: C 57.83, H 6.89, N 5.59.

Hydrogenation procedures

The reactions were performed in thick-walled glass vessels, which were charged with a substrate, 5 mol% catalyst, 2 mL of methylene chloride, and pressurized with either 1 or 4 atm of hydrogen gas. The reactions with cyclohexene as the substrate were truncated at *t* = 15 min, 1, 4, and 12 h where an aliquot was taken from the vessel to determine conversion via ^{1}H NMR spectroscopy. From our preliminary results, significant conversions to hydrogenated substrates were not observed prior to the 4 and 12 h mark using 4 and 1 atm of H_2 pressure, respectively. When employing 1-methyl-cyclohexene as the substrate, it was found that the conversions were appreciably lower and the transformations occurred much more slowly. Select reactions were run with 1 atm of H_2 pressure for 12 h and resulted in conversions no greater than 20%. Reactions at 4 atm were performed with aliquots extracted and analyzed at *t* = 12 h, 72 h, and 1.5 weeks.

X-ray crystallographic analysis[2]

All crystals were mounted on a glass fiber and measured on a Bruker X8 diffractometer with graphite monochromated

Mo Kα radiation. The data was collected at a temperature of –100.0 ± 0.1 °C with the Bruker APEX II CCD area-detector set at a distance of 36.00 mm. Data was collected and integrated using the Bruker SAINT (44) software package and corrected for absorption effects using the multiscan technique (SADABS (45)). The data was corrected for Lorentz and polarization effects and the structure was solved by direct methods (46). All nonhydrogen atoms were refined anisotropically, while all hydrogen atoms except those coordinated to the amino tether were placed in calculated positions but were not refined. Amino protons were located in a difference map and refined isotropically. The final cycle of the full-matrix least-squares refinement on F^2 is shown in Table 2. Neutral atom scattering factors were taken from Cromer and Waber (47). Anomalous dispersion effects were included in $F_{calcd.}$ (48); the values for Δf' and Δf" were those of Creagh and McAuley (49). The values for the mass attenuation coefficients are those of Creagh and Hubbell (50). All refinements were performed using the SHELXTL (51) crystallographic software package of Bruker-AXS.

Reaction of gaseous mercury with molecular iodine, atomic iodine, and iodine oxide radicals — Kinetics, product studies, and atmospheric implications

Farhad Raofie, Graydon Snider, and Parisa A. Ariya

Abstract: Mercury is present in the Earth's atmosphere mainly in elemental form. The chemical transformation of mercury in the atmosphere may influence its bioaccumulation in the human food chain as well as its global cycling. We carried out the first kinetic and product studies of the reactions of gaseous mercury with molecular iodine, atomic iodine, and iodine oxide radicals at tropospheric pressure (~740 Torr) and 296 ± 2 K in air and in N_2 (1 Torr = 133.322 4 Pa; 0 °C = 273.15 K). Atomic iodine was formed using UV photolysis of CH_2I_2. IO radicals were formed by the UV photolysis of CH_2I_2 in the presence of ozone The reaction kinetics were studied using absolute rate techniques with gas chromatographic and mass spectroscopic detection (GC–MS). The measured rate coefficient for the reaction of Hg^0 with I_2 was ≤ $(1.27 \pm 0.58) \times 10^{-19}$ cm^3 $molecule^{-1}$ s^{-1}. The reaction products were analyzed in the gas phase from the suspended aerosols and from deposits on the walls of the reaction chambers using six complementary methods involving chemical ionization and electron impact mass spectrometry, GC–MS, a MALDI-TOF mass spectrometer, a cold vapor atomic fluorescence spectrometer (CVAFS), and a high-resolution transmission electron microscope (HRTEM) coupled to an energy dispersive spectrometer (EDS). The major reaction products identified were HgI_2, HgO, and HgIO or HgOI. The implications of the results are discussed with regards to both the chemistry of atmospheric mercury and its potential implications in the biogeochemical cycling of mercury.

Key words: mercury, molecular iodine, atomic iodine, iodine oxide radicals kinetics, product study, atmospheric chemistry.

Résumé : Dans l'atmosphère terrestre, le mercure est principalement présent sous la forme élémentaire. La transformation chimique du mercure dans l'atmosphère peut influencer sa bioaccumulation dans la chaîne alimentaire de l'homme ainsi que sur son cycle global. On a effectué les premières mesures cinétiques ainsi que les premières études sur la nature des produits des réactions du mercure gazeux avec l'ion moléculaire, l'iode atomique et les radicaux d'oxyde d'iode, à la pression de la troposphère (environ 740 Torr, 1 Torr = 133.322 4 Pa), à 296 ± 2 K, dans l'air et dans l'azote. L'iode atomique a été obtenu par photolyse UV du CH_2I_2. Les radicaux IO ont été formés par la photolyse UV du CH_2I_2 en présence d'ozone. On a étudié la cinétique des réactions par les techniques de vitesses absolues en utilisant une combinaison des techniques de la chromatographie en phase gazeuse et de la spectrométrie de masse (CG-SM). La valeur du coefficient de vitesse mesuré pour la réaction du Hg^0 avec le I_2 est inférieure à $(1{,}27 \pm 0{,}58) \times 10^{-19}$ cm^3 $molécule^{-1}$ s^{-1}. Les produits de la réaction ont été analysés par chromatographie gazeuse, à partir d'aérosols en suspension ainsi qu'à partir des dépôts recueillis des parois des chambres réactionnelles en faisant appel à six techniques complémentaires impliquant la spectrométrie de masse avec ionisation chimique ainsi que l'ionisation avec impact électronique, la CG-SM et la spectrométrie de masse à temps d'envol avec ionisation par désorption au laser assistée par une matrice (IDLAM), un spectromètre à fluorescence atomique avec vapeur froide (SFAVF) et un microscope à transmission d'électron à haute résolution (MTEHR) couplé à un spectromètre à dispersion d'énergie (SDE). Les produits principaux qui ont pu être identifiés sont le HgI_2, le HgO et le HgIO ou HgOI. On discute des implications de ces résultats en regard tant de la chimie du mercure atmosphérique que de ses implications potentielles dans le cycle biogéochimique du mercure.

Mots-clés : mercure, iode moléculaire, iode atomique, radicaux d'oxyde d'iode, cinétique, étude de produits, chimie de l'atmosphère.

Introduction

Gaseous elemental mercury is a toxic element of concern because of its accumulation in the aquatic food chain (via methylation), leading to mercury deposits found in consumable freshwater and marine species (1). Mercury is released into the atmosphere from a variety of natural (2–6) and anthropogenic sources (7–10). It has been shown that 60% to 80% of present mercury emissions into the atmosphere are of anthropogenic origin, and that about 50% of anthropogenic mercury emissions enter a global cycle of contamination (11). The concentration of atmospheric mercury in the northern hemisphere is between 1.6 to 4.7 ng m^{-3}, with an average of 2.5 ng m^{-3}, which is mainly elemental (12). Atmospheric mercury undergoes various chemical and physical transformations before being deposited on the ground. Unexpectedly rapid depletion of elemental mercury has been observed in the high Arctic (13), Arctic (14, 15), and sub Arctic (16) during springtime, concomitant with ozone depletion. It has been shown that chain reactions of halogen species in the Arctic are responsible for ozone and mercury depletion (17–21). The speciation and chemical transformations of mercury in the atmosphere strongly influence its deposition and global cycling. Hg^0 can be transported back to the earth mainly through dry deposition. Mercury(II) oxides are nonvolatile species and precipitate to the ground much more rapidly than Hg^0 via dry and wet processes (22).

Experimental and theoretical research of gas-phase reactions of mercury with halogen species under atmospheric conditions are relatively new, most of which have only been published within the last decade. Schroeder et al. (23) proposed several possible reactions between gaseous mercury and a variety of atmospheric oxidants and reductants using their thermodynamic data. They suggest that O_3 and Cl_2 may be important for oxidation of Hg^0, while SO_2 and CO are important for the reduction of Hg(II). It has since been found that bromine species play an important role in the rapid Arctic depletion of mercury. In warmer climates, however, oxidation by ozone becomes the most relevant pathway. In our laboratory, we have studied products of the gas-phase reaction of elemental mercury with O_3 (24), BrO (25, 26), and HO (27) radicals; atomic Cl and Br; and molecular Cl_2 and Br_2 (28). We have also considered previous thermochemical calculations of reactions between Hg and halogens (29).

The atmospheric chemistry of iodine is important for several reasons, including the influence of iodine oxides on the oxidizing capacity of the troposphere, the formation of new particles, the enrichment of iodine in marine aerosols, and transport of this essential dietary element to the continents (30). The identified natural sources of iodine are CH_3I, CH_2I_2, C_2H_5I, CH_2ICl, and I_2 from seawater (31–33) that photochemically can release reactive iodine species. Iodine, however, is also released into the atmosphere from industrial activity. The photolysis of many iodine species produces iodine atoms, and hence IO radicals through reaction with O_3 (34). Iodine oxide was observed in the marine boundary layer by several researchers (35, 36). The iodine oxide radicals are involved in ozone depleting cycles in the troposphere (33, 37) and stratosphere (38) as well as reaction with dimethyl sulfide emitted by phytoplankton in the ocean (39). However, there is no available literature on the experimental kinetic and product of molecular iodine, atomic iodine, and iodine oxide radicals with elemental mercury (see Calvert and Lindberg for simulations of iodine kinetics (40)).

The purpose of this work is to study the products of the gas-phase reaction of elemental mercury with molecular iodine, atomic iodine, and iodine oxide radicals and kinetics of the gas-phase reaction of elemental mercury with molecular iodine at tropospheric pressures and ambient temperatures.

Experimental section

Experimental procedure

Experiments were carried out in N_2 and in air at room temperature and near-atmospheric pressure. Reaction chambers included 1 to 50 L Teflon bags and 1 to 5 L Pyrex double-wall flasks equipped with magnetic stirrers to assure homogeneous mixing. The reaction chamber temperature was maintained at 296 ± 2 K (0 °C = 273.15 K) by circulating water through the outer jacket using a Neslab RTE 111 circulator.The reaction chamber was washed a minimum of four times with concentrated nitric acid (12 mol/L), Mili-Q water, and acetone and dried at high temperature (398 K) overnight. The inside walls of the reaction flask were coated with halocarbon wax (Supelco) to prevent unwanted wall reactions (41). A vacuum system was used to prepare gaseous reactant mixtures. Gaseous reactants were transferred directly into the reaction mixture using a 10 or 250 μL syringe (Hamilton series 1800 gas tight). Liquid substrates were injected with a 2 or 10 μL syringe (Hamilton series 700). Ozone was produced using an ozone generator (Model OL 100/DS, Ozone Services Inc.) by a silent discharge technique and was trapped on silica gel cooled to 200 K in a dry ice – acetone mixture. Ozone was then transferred to an evacuated flask (~10^{-7} bar) (1 bar = 100 kPa), and the concentration of ozone was monitored by a UV–vis spectrometer (Varian Cary-50-Bio). A given amount of ozone was injected into the reaction flask (1 to 5 L) using a gas-tight syringe. Molecular iodine vapor was produced by mixing iodine with silica gel and heating to 323 K. Iodine radicals were generated in situ upon UV photolysis of diiodomethane ($300 \leq \lambda \leq 400$ nm).

IO radicals were generated in situ upon UV photolysis of diiodomethane ($300 \leq \lambda \leq 400$ nm) in the presence of ozone (42).

[R1] $CH_2I_2 + h\upsilon\ (300 \leq \lambda \leq 400\ nm) \rightarrow CH_2I^{\cdot} + I^{\cdot}$

[R2] $I^{\cdot} + O_3 \rightarrow IO + O_2$

$$k_{R2} = 8 \times 10^{-13}\ cm^3\ molecule^{-1}\ s^{-1}$$

The initial concentration of Hg^0 was ~0.5 ppm, and the concentration of I_2 was 130 ppm. In the course of ozone addition, we used scavengers such as trimethyl benezene for OH radicals (41) that are formed via side reactions in the presence of organic matter, such as CH_2I_2 or any undesired impurities or production of other undesired oxidants in the course of experiments. We did not observe any organomercury or halo-organo-mercury products using six different analytical methods. The reaction of gaseous mercury with O_3 is too slow [$(6.2 \pm 1.1) \times 10^{-19}$ cm^3 $molecule^{-1}s^{-1}$ (43)]

© 2008 NRC Canada

to observe. Oxidation of gaseous mercury by O_3 was negligible under the reaction conditions.

Analytical procedure for the product analysis

The reactions

[R3] $Hg^0_{(g)} + I_{2\,(g)} \rightarrow$ products

[R4] $Hg^0_{(g)} + I_{(g)} \rightarrow$ products

and

[R5] $Hg + IO^{\cdot}_{(g)} \rightarrow$ products

were carried out in 1 to 50 L Teflon bags and 1 to 5 L Pyrex flasks. The products were analyzed by the methods described below.

Direct mass spectrometry

Reaction products were collected using two methods. In the first method, the reaction products were passed through a 1.1 mm i.d. × 10 cm length Pyrex tube (Corning) immersed in liquid nitrogen. In the second method, the walls of the reaction flask were washed with concentrated HCl. A sample of the collected products (50 μL) was transferred in a 1.1 i.d. × 10 cm length Pyrex tube and was covered immediately with a piece of glass wool. Extra HCl was evaporated by slow heating in a water bath. Finally, the collected products in the tube were evaporated at stepwise elevated temperatures to the chemical and electron impact ion source of a Kratos MS25RFA mass spectrometer.

Cold vapor atomic fluorescence spectrometry (CVAFS)

Samples were prepared by washing the walls of the reaction chamber, a Teflon filter (0.45 μm), and the coiled Pyrex trap, with a mixture of 20 mL HNO_3 and 0.5 mL 30% H_2O_2, diluted to 50 mL with Milli-Q water. The samples were heated to 350 K for 1 h to decompose excess H_2O_2, diluted further to 100 mL in a volumetric flask with Milli-Q water, and analyzed using a cold vapor atomic fluorescence spectrometer (Tekran 2600).

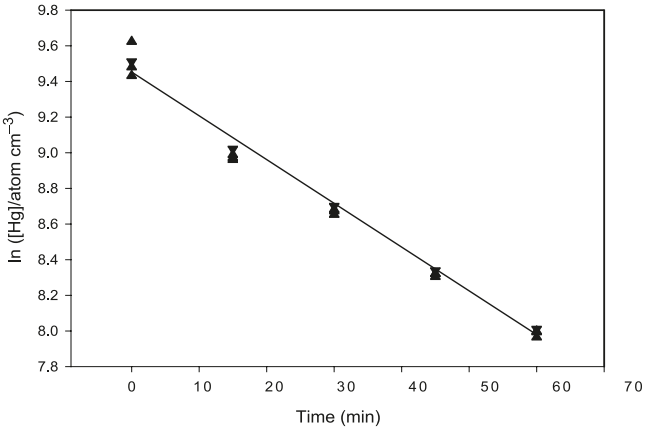
Derivatization

This method is based on chemical transformation of Hg^{2+} to $HgCl_2$ and then to a more volatile organomercury compound, *n*-Bu_2Hg. Samples were prepared by washing the walls of the reaction flask with HCl, which transformed Hg^{2+} to $HgCl_2$. The sample was heated to remove extra HCl, which resulted in the formation of a white residue. Derivatization was performed using previously reported method (44, 45). 2 mL of toluene and 0.4 mL of 2 mol/L *n*-butylmagnesium chloride in tetrahydrofuran were added to the white residue. The mixture was then centrifuged at 0 °C for 10 min with occasional shaking. To quench the excess derivatizing agent, 0.4 mL of 0.6 mol/L HCl was added the mixture that was then centrifuged, allowing for collection of the organic phase for analysis.

[R6] $Hg^{2+} + 2\ HCl \rightarrow HgCl_2 + 2H^+$

[R7] $HgCl_2 + 2\ n\text{-}BuMgCl \rightarrow n\text{-}Bu_2Hg + 2MgCl_2$

Fig. 1. Typical absolute-rate data for reaction of Hg + I_2, [Hg] = 0.5 ppm, [I_2] = 3.2 × 10^{15} molecule cm^{-3}; kinetic runs were performed at 298 K in nitrogen.



Transmission electron microscopy (TEM)

Reaction products were collected by two different methods. The first technique involved placing carbon-coated Cu grids on the surface of the reaction flask, and the Cu grids were later collected upon completion of the reaction. The second method involved the collection of reaction products in a capillary Pyrex tube, which was immersed in liquid nitrogen. Collected products were analyzed using a high-resolution transmission electron microscope (JEOL 2000 FX TEM). The elemental composition was qualitatively determined by energy dispersive spectroscopy (EDS; JEOL 2000).

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS)

The reaction products were collected in capillary Pyrex tubes, which were immersed in liquid nitrogen. The collected products were analyzed using Kratos Kompakt MALDI-TOF-MS in reflectron mode. Dithranol and lithium bromide were used as matrix and cationization agent, respectively. The matrix has resonance absorption at laser wavelength of 337 nm. This rapid heating results in expulsion and soft ionization of the sample molecules without major fragmentation (46).

Chemicals and materials

Mercury (99.99% purity) and *n*-butyl magnesium chloride (2 mol/L solution in tetrahydrofuran) were supplied by Sigma-Aldrich. Nitrogen (99.998%), argon (99.999%), helium (99.999%), nitric oxide (99.99%), and extra-dry oxygen were obtained from Matheson. Toluene (99.9%), hydrogen peroxide (30%), hydrochloric acid (trace-metal grade), Iodine (99.9%), and nitric acid (trace-metal grade) were purchased from Fisher. Tin (II) chloride (99.999%) and diiodomethane (99%) were obtained from Aldrich. Milli-Q water of 18.2 MΩ cm resistivity was used for all experiments. The nitric and hydrochloric acids used in the course of experiments were 70 wt% and 38 wt% assays, respectively.

Results and discussion

Kinetic study

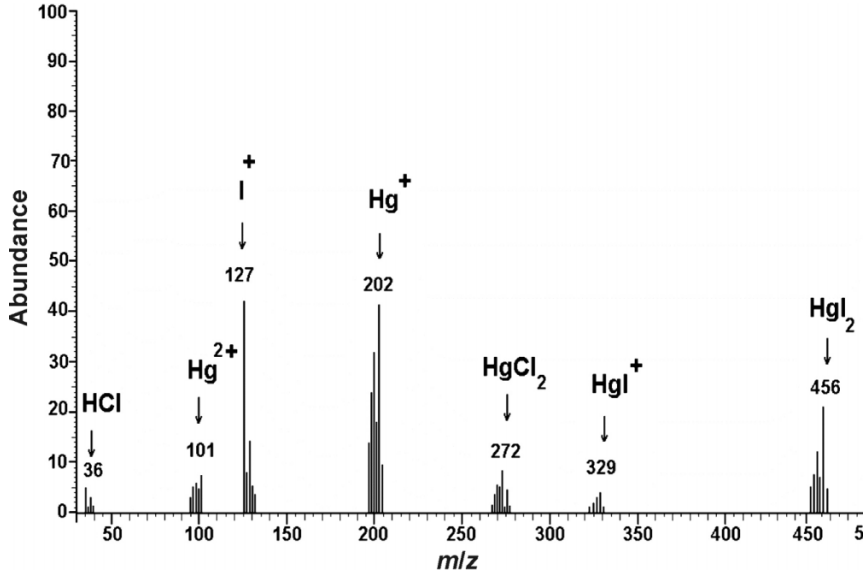
The absolute-rate technique was used to study the kinetics of the I_2-initiated reaction of Hg^0 (47). Experiments were carried out in 1 to 5 L Pyrex flask at room temperature in air and nitrogen. To prevent wall reaction, the walls of reaction flask were coated with halocarbon wax. In addition, to minimize the effect of adsorption on the kinetic results, the reaction mixture was kept at equilibration for 2 h before injecting I_2. To inject I_2 as a gas into the reaction chamber, molecular I_2 was first mixed with silica gel (~ 1:50) in 1 L flask. The mixture was evacuated to 7×10^{-3} Torr. The temperature of the flask was increased to 60 °C by slow heating. A given amount of I_2 was injected into the reaction chamber using gas-tight syringe. To prevent dissociation of I_2, the reaction chamber was completely dark. The reaction of gaseous mercury with I_2 was studied under pseudo first-order conditions by monitoring the MS signal of mercury vs. time. Figure 1 shows semi logarithmic plots of data obtained for the reaction of Hg^0 with I_2 in air. The upper-limit rate coefficient calculated from the curve was $\leq (1.27 \pm 0.58) \times 10^{-19}$ cm^3 $molecule^{-1}s^{-1}$. Because we observed the formation of particulate matter, we cannot rule out the possibility of heterogeneous reactions; and hence, this rate coefficient value should represent only an upper limit for the gas-phase-initiated oxidation of elemental mercury with iodine molecule.

Product studies

The products of reactions [R3–R5] have been studied in the gas phase from suspended aerosols and from the walls of

© 2008 NRC Canada

Fig. 4. Mass spectra of $HgCl_2$ and HgI_2, reaction products in reaction of Hg^0 with atomic iodine.



the reaction chambers. Six complementary analytical methods have been employed to identify the reaction products of molecular iodine, atomic iodine, and iodine radicals initiated oxidation of $Hg^0_{(g)}$.

In the first method, after the reaction was completed, the reaction products from the gas–aerosol phase were collected in a liquid-nitrogen-cooled capillary tube. The chemical structure of the reaction products mixture was identified using a direct MS instrument equipped with an electron impact and chemical ionization ion source with probe temperature elevated to 430 K. Figure 2 represents mass spectra of HgI_2. The isotopic ratios for HgI_2 (33.6:56.4:77.5:44.3:100.0:22.8) corresponded well with the anticipated *m*/*z* ratios 452, 453, 454, 455, 456, and 458, respectively; thus further supporting the identified mercury compounds. The *m*/*z* ratio of 268 is assigned to CH_2I_2, which had been used as the iodine radical source. Other *m*/*z* ratios in the mass spectrum represent the fragmentation of HgI_2 or CH_2I_2. Hence, our results identify HgI_2 as the major product of the gas–aerosol reaction: $Hg^0 + I_2$. For $Hg^0 + I^{\cdot}$, the same product was observed. For $Hg^0 + IO^{\cdot}$, chemical ionization of NH_3 was used as an ion source, so the observed mass spectra of the ion (M^+) should be increased by one. We identified the products HgOI or HgIO, HgI_2, and HgO (Fig. 3). The *m*/*z* ratio of each peak was shifted by one. Moreover, the observed isotopic ratios for HgI_2 (33.6:56.4:77.5:44.3:100.0:22.8) corresponded well with the anticipated *m*/*z* ratios of 452, 453, 454, 455, 456, and 458, respectively. The isotopic ratios of 33.5, 56.3, 77.5, 44.4, 100.0, and 23.0 correspond well with those for the *m*/*z* ratios 341, 342, 343, 344, 345, and 347, respectively. The isotopic ratios 33.5:56.3:77.4:44.4:100.0:23.0 matched *m*/*z* ratios of 214, 215, 216, 217, 218, and 220, repectively, illustrating the presence of HgO, which further supports the identified mercury compounds. The *m*/*z* ratio of 268 is assigned to CH_2I_2, which had been used as an iodine radical source. From product analysis, we were unable to distinguish the chemical structure of Hg-, I-, and O-containing species. Other *m*/*z* ratios in the mass spectrum represent either fragmentation of HgI_2, HgO, HgIO (HgOI), or CH_2I_2 in the ion source of the mass spectrometer. The results show that the major products in the gas–aerosol phase of reaction $Hg^0_{(g)} + IO^{\cdot}$ are HgIO or HgOI, HgI_2, and HgO.

In the second method, the walls of the reaction flask were washed with concentrated HCl. Samples of the collected products (50 μL) were transferred in a 1.1 i.d. × 10 cm length Pyrex tube and immediately covered with a piece of glass wool. Extra HCl was evaporated by slow heating in a water bath. Finally, the collected products in the tube were evaporated at stepwise elevated temperatures to the chemical and electron impact ion source of a Kratos MS25RFA mass spectrometer. Figure 4 represents the mass spectra of $HgCl_2$ and HgI_2. The isotopic ratios for $HgCl_2$ (22:37:65:52:100:22:62:16) corresponded well with the anticipated *m*/*z* ratios of 268, 269, 270, 271, 272, 273, 274, and 276, respectively. The *m*/*z* ratio of 456 is assigned to HgI_2, which is slightly soluble in concentrated HCl. Hence, we conclude the existence of HgI_2 as a reaction product on the walls. Similar results were observed for the $Hg^0 + I^{\cdot}$ and $Hg^0 + IO^{\cdot}$ reactions.

In the third method, to confirm the presence of Hg^{2+} on the walls of the reaction chamber, the products on the walls were converted to di(*n*-butyl mercury). The derivatized sample was analyzed using GC–MS. Figure 5 illustrates a chromatogram and mass spectrum of the derivatized mercury. Hg^0 and Hg^{+1} were not targeted in derivatization analysis, so their existence cannot be evaluated using the Grignard reagent. This experiment confirmed the presence of Hg^{2+} (here, HgI_2) on the walls of reaction chamber. Similar results were observed for the $Hg^0 + I^{\cdot}$ and $Hg^0 + IO^{\cdot}$ reactions.

In the fourth method, MALDI-TOF-MS was used to identify the reaction products of molecular iodine, atomic iodine, and iodine oxide radicals. Figure 6 is an example of a MALDI-TOF-MS spectrum. The peak at mass 454 is assigned to HgI_2 in the reaction of Hg with both I_2 and I. No other oxidized forms of mercury were detected. Figure 7 is an example of MALDI-TOF-MS spectrum for the reaction

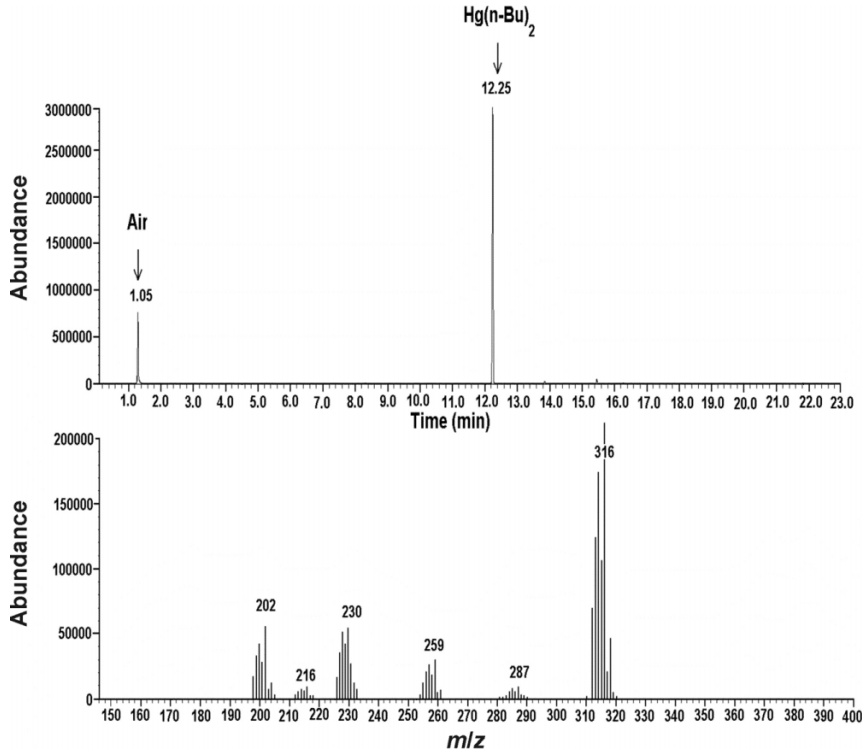

Fig. 6. MALDI-TOF mass spectrum of products formed in the reaction of Hg^0 with molecular iodine.

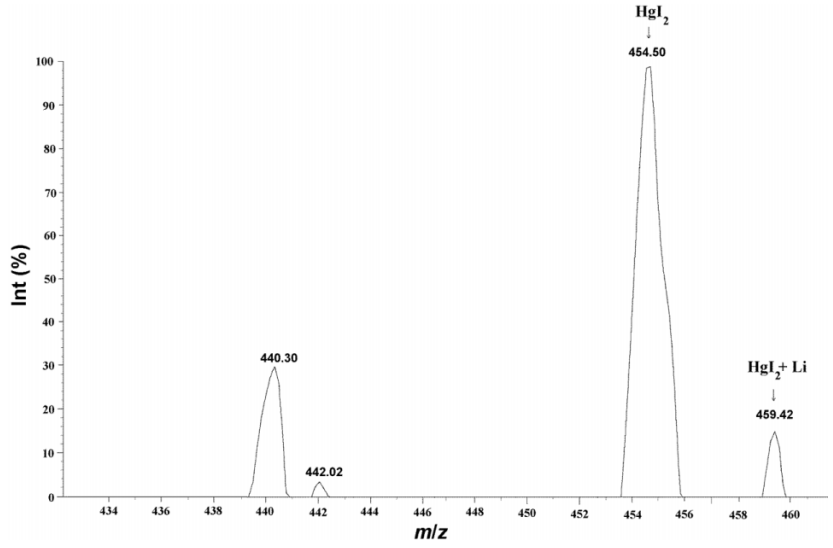

of Hg^0 + IO˙. The peak at mass 357 is assigned to HgIO or HgOI. Other peaks arise from the matrix itself under our experimental conditions.

In the fifth method, we attempted to identify the shape, size, and elemental composition of reaction products from the gas–aerosol phase and on the walls of the reaction chamber using HRTEM coupled to an EDS detector. Figure 8*a* illustrates the TEM image of air-dried products of the reaction Hg^0 + I_2 collected from the gas–aerosol mixture. The size of the particles in the gas–aerosol mixture was approximately 0.2 μm. The EDS spectrum of the chemical composition of the products in the gas–aerosol mixture showed that the gas–aerosol mixture should contain mercury and iodine. Combining evidence from MALDI-TOF-MS and EDS, we believe that the observed aerosol contains HgI_2. Figure 8*b* depicts TEM image of collected products of the reaction of Hg^0 + I_2 from the walls of the reaction chamber. The size and chemical composition of the particles collected from the walls of the reaction chamber exhibit similar features to those observed from gas–aerosol. TEM images of air-dried Hg^O + I reaction products were collected from the gas-aerosol mixture. The size of the particles in the gas–aerosol

mixture was approximately 0.2 μm (Fig. 9*a*). The EDS spectrum of the chemical composition of the products in the gas–aerosol mixture showed that the gas–aerosol mixture contained mercury and iodine. Because of the chemical composition of the reaction products, we believe that the observed aerosol contains HgI_2. A TEM image of collected products of the reaction of $Hg^0 + I^{\cdot}$ from the walls of the reaction chamber is illustrated in Fig. 9*b*. The size and chemical composition of the particles collected from the walls of the reaction chamber exhibited similar features to those observed from gas–aerosol. Figure 10*a* illustrates the TEM image of air-dried products of the reaction of $Hg^0 + IO^{\cdot}$ that were collected from the gas–aerosol mixture. Particles in the gas–aerosol mixture were observed to be approximately 0.5 μm. The EDS spectrum of the chemical composition of the products in the gas–aerosol mixture revealed the presence of mercury, iodine, and oxygen. Because of the elemental composition of the reaction products, we believe that the observed aerosol contains Hg, O, and I. Collected products from the walls of the reaction chamber are found to have similar size and elemental composition to those observed from the gas–aerosol mixture (Fig. 10).

In the sixth method, we used CVAFS to quantify mercury products in the gas phase, aerosol, and as deposit on the walls of the reaction chamber. Upon completion of the reaction (confirmed by disappearance of MS peak due to Hg^0), the reaction flask was evacuated through a 0.45 μm Teflon filter to a residual pressure of ~0.0007 bar. The filter was treated with a HNO_3/H_2O_2 mixture. CVAFS analysis indicated that ~ (10 ± 1)% of total mercury (relative to the amount of Hg^0 loaded in the flask) was converted to mercury compounds in the aerosol phase. In another set of experiments, products were collected in a cooled coiled Pyrex trap, treated with the HNO_3/H_2O_2 mixture and further analyzed using CVAFS upon completion of the reaction. By subtracting the total mercury collected from the gas and aerosol mixtures and the amount of aerosol mercury collected on the filters, we obtained only ~ (10 ± 3)% of total mercury remaining in the gas phase. This analysis recovered (20 ± 4)% of the mercury in the gas–aerosol phase. Finally, the reaction

products were collected from the reaction flask walls by washing with a HNO_3/H_2O_2 mixture, and analyzed by CVAFS. Overall, (70 ± 5)% of Hg was recovered from the walls (Table 1). The dominant reaction products were found as adsorbed deposits on the walls of the reaction chamber (85 ± 2)% or as aerosols ~ (14 ± 1)% leaving only ~ (4 ± 1)% of the total mercury existing in the gas phase, as illustrated in Table 1.

As shown in Table 1 for [R5], ~ (25 ± 3)% of total mercury remains in the gas–aerosol phase with ~ (5 ± 2)% of total mercury recovered from the gas phase. Recovery of Hg from the walls of the reaction chamber was (75 ± 4)%. Our results therefore showed that the reaction products were predominantly found adsorbed on the walls of the reaction chamber as deposits or existed as aerosols. Under our experimental conditions, we did not observe any difference in identified mercury compounds in N_2 or air, noting that our nitrogen diluent (99.998%) gas was still not entirely oxygen free.

Potential reactions mechanism

Products of the oxidation of Hg^0 by I_2, I, and IO can be formed by reactions [R3] to [R5]

[R1] $CH_2I_2 + h\upsilon\ (300 \leq \lambda \leq 400\ nm) \rightarrow CH_2I^{\cdot} + I^{\cdot}$

[R2] $I^{\cdot} + O_3 \rightarrow IO^{\cdot} + O_2$

[R3*a*] $Hg + I_2 \rightarrow HgI_2$

[R4*a*] $Hg + I^{\cdot} \rightarrow HgI$

[R4*b*] $HgI + I^{\cdot} \rightarrow HgI_2$

[R5*a*] $Hg + IO^{\cdot} \rightarrow HgOI/HgIO$

[R5*b*] $Hg + IO^{\cdot} \rightarrow HgO + I^{\cdot}$

[R5*c*] $Hg + IO^{\cdot} \rightarrow HgI + O$

[R5*d*] $HgI + IO^{\cdot} \rightarrow HgI_2 + O$

We identified HgI_2, HgIO or HgOI, HgO, and HgI by direct mass with a chemical ionization ion source. There are two possible sources for HgI, either as a product in the chamber or a fragmentation product of HgI_2 in the ion source of the mass spectrometer. Shepler et al. (48) have estimated the enthalpies of the above reaction at 0 K. This theoretical study used the ab initio CCSD(T) method with basis sets including detailed treatment of core–valence correlation, scalar reactivity, spin–orbit coupling, and the Lamb shift. The values of ΔH_r(0 K) for reactions [R5*a*–R5*d*] have been shown to be –51.2, 191.5, 209.2, and –28.6 kJ mol^{-1}, respectively. Regarding the results for ΔH_r(0 K), HgIO but not HgI and HgO cannot be formed by reactions [R5*b*] and [R5*c*], respectively. HgO can, however, be formed by reaction [R5*b*], and we did observe the existence of HgO with different types of mass spectrometry and HRTEM-EDS. The value of ΔH_r(0 K) = –146.4 kJ/mol for reaction [R3*a*] for the I_2-initiated reaction of gaseous mercury indicates this pathway is possible in the formation of HgI_2. We can indeed observe HgI_2, as confirmed by the different types of mass spectrometry technique used in this study.

Because we observed aerosols, and although we have modified the surface-to-volume ratios and the properties of the surfaces, and used different oxidant and reactant concentration regimes, we cannot rule out the possibility of heterogeneous reactions.

Summary and future work

We have studied the products of the reactions of gaseous mercury with molecular iodine, atomic iodine, and iodine oxide radicals at atmospheric pressure and room temperature in air and in N_2. For the first time, HgI_2, HgO, and HgOI/HgIO are identified as reaction products in the gas and in the aerosol phase, as well as on the walls of the reaction chamber. Our upper-limit rate constant for reaction of Hg^0 with molecular iodine is found to be $\leq (1.27 \pm 0.58) \times 10^{-19}$ cm^3 molecule^{-1} s^{-1}. It remains a possibility that during springtime in the Arctic and Antarctica, the iodine reactions have some significance. The reaction of molecular iodine is apparently too slow for the rapid depletion of elemental mercury in the boundary layer. We suspect that based on the formation rates of products in the course of I + Hg(0) reactions, the reactions of I are slower or at most comparable to the reactions of elemental mercury with Br (40, 49). However, the impact of iodine and iodine oxide in the production of oxidized mercury in atmospheric depletion should be further studied.

Acknowledgements

We would like to cordially thank Dr. Paterson for his valuable insights. We thank the Natural Sciences and Engineering Research Council of Canada (NSERC), Le Fonds québecois de la recherche sur la nature et les technologies (FQRNT), the Canadian Foundation for Innovation (CFI), the COMERN project, Canadian Foundation for Climate and Atmospheric Sciences (CFCAS), and Environment Canada for financial support. We would also like to thank Jackie Johnstone for proof reading the manuscript.

Biotransformation of caffeic acid by *Momordica charantia* peroxidase

Xiang Wan, Haili Liu, Xuefeng Huang, Jianguang Luo, and Lingyi Kong

Abstract: Biotransformation of caffeic acid with H_2O_2/*Momordica charantia* peroxidase at pH 5.0, 25 °C in the presence of acetone has resulted in the isolation of three caffeic acid trimers **1**–**3**, five caffeic acid dimers **4**–**8**, and one monomer **9**. Among them, seven (**1**–**7**) are new compounds, and two (**8** and **9**) are known compounds, including one compound (**9**), which was obtained by biotransformation for the first time. The structures were established by 2D NMR techniques, such as HSQC, HMBC, and NOESY measurements. The possible mechanism for the formation of the products is also discussed. This is the first time that caffeic acid trimers have been obtained through the biotransformation of catalyzed by peroxidase in vitro. Compound **5** has shown much stronger anti-oxidative activity than the other caffeic acid polymers obtained.

Key words: Momordica charantia peroxidase, caffeic acid, polymers of caffeic acid, biotransformation, antioxidant activity.

Résumé : La biotransformation de l'acide caféique sous l'effet du H_2O_2 et de la peroxydase *momordica charantia*, à un pH de 5,0, à 25°C et en présence d'acétone conduit à la formation de trois dimères de l'acide caféique, **1**–**3**, à cinq dimères de l'acide caféique, **4**–**8**, et à un monomère, **9**. De ces produits, sept (**1**–**7**) sont des nouveaux produits alors que deux (**8** et **9**) sont des produits connus, dont le produit **9** qui a été obtenu par biotransformation pour la première fois. On a déterminé les structures par des spectres RMN en 2D, telles des mesures de HSQC, HMBC et NEOSY. On discute aussi du mécanisme possible pour la formation des produits. C'est la première fois que des trimères de l'acide caféique ont pu être obtenus par une biotransformation catalysée par une peroxydase in vitro. On a montré que le composé **5** présente une activité antioxydante beaucoup plus élevée que celle des autres polymères de l'acide caféique obtenus.

Mots-clés : peroxydase *Momordica charantia*, acide caféique, polymères de l'acide caféique, biotransformation, activité antioxydante.

[Traduit par la Rédaction]

Introduction

Momordica charantia peroxidase (MCP) is a novel plant peroxidase with high acidic amino acid purified from the fruits of *Momordica charantia* (1). Compared with other peroxidases such as horseradish peroxidase, the enzyme had several unique characteristics, including enzyme pH stability (pH 3.8–8.0) and thermostability (20–45 °C) (2). According to the unique characteristics, we have applied purified MCP to transform ferulic acid, sinapic acid, and *p*-coumaric acid into some oxidation products, which have not been obtained by other peroxidases or chemosynthesis (2–4).

Caffeic acid (CA), which exists in many plants, exhibits a lot of activities, such as anti-apoptotic activity, anti-cancer, anti-inflammatory, anti-atherogenic effect, and antioxidant activity (5–8). Compared with the structures of other substrates that we had used, the structure of caffeic acid contains two hydroxyls; therefore, the reaction sites are different from those of others and the dimers of caffeic acid maybe have powerful antioxidant activity (9, 10). Recently, some dehydrodimers and higher oligomers of caffeic acid had been isolated from some plants; however, only a few dehydrotrimer and higher oligomers had been obtained by biotransformation with peroxidases (11–16). For these reasons, we can expect to obtain some novel skeleton polymers that may have more powerful activities.

Caffeic acid was subjected to biotransformation with H_2O_2/MCP at pH 5.0, 25 °C in the presence of acetone. Nine products have been obtained, including three new CA trimers (**1**–**3**), four new dimers (**4**–**7**), and two known compounds (**8**, **9**). Herein, we reported on the biotransformation of CA by MCP, the isolation and structure identification of the oxidation products **1**–**9**, as well as the possible biotransformative mechanism of **1**–**9**.

Results and discussion

Compound **1** was obtained as a white powder. Its molecular formula was determined as $C_{26}H_{21}O_{10}$ by positive HR-FABMS spectrometric analysis, indicating the formation of a caffeic acid trimer. The IR spectrum exhibited absorption bands of hydroxyl (3104 cm^{-1}), carbonyl (1683 cm^{-1}), and phenyl (1606, 1515 cm^{-1}) groups. In the ^{1}H and ^{13}C NMR spectra (see Table 1), one 1,3,4-tri-substituted aromatic fragment (**A**), one 1,3,4,5-tetra-substituted aromatic fragment (**B**), one 1,3,4,6-tetra-subsituted aromatic fragment (**C**), two trans double bonds, and two saturated H protons were observed. Twenty-six carbon signals were observed, including two acrylic acids, six oxygen-substituted aromatic carbons, four carbon-substituted aromatic carbons, seven C–H aromatic carbons, and two saturated carbons.

All the signals of protons and carbons of **1** were assigned by a detailed analysis of the ^{1}H and ^{13}C NMR data associated with HSQC and HMBC spectra. The correlations of H-7b to C-2b and C-6b, H-2b, and H-6b to C-7b, H-8b to C-1b, H-7c to C-2c and C-6c, H-2c and H-6c to C-7c, and H-8c to C-1c suggested that two di-substituted double bonds were ascribed to aromatic fragments **B** and **C**. From the long-range correlations H-7a to C-2a and C-6a, H-2a and H-6a to C-7a, we could confirm that the saturated CH–CH fragment was connected with aromatic fragment **A** through C-1a. The signals H-5c to C-8a and H-7a to C-6c demonstrated that the aromatic fragment **C** was connected to CH through C-6c. No signals were obtained about fragment **B** to CH; besides, the chemical shift of C-8a at δ_C 54.1 suggested that fragment **B** was connected to CH through C-5b. Meanwhile, the chemical shift of C-7a (δ_C 95.9) revealed fragment **B** was connected to CH through an oxygen atom. The conclusion could be proved by the NOESY correlation of H-6b to H-8a. The relative configuration of C-7a and C-8a was determined to be cis, because NOE correlation peaks of H-7a to H-8a, H-2a and H-6a to H-5c, and H-5a to H-2c were observed in the NOESY spectrum (see Fig. 1). According to the above analysis, the structure of **1** was elucidated as *cis*-3-[6-[5-[(*E*)-2-carboxyethenyl]-2,3-dihydro-2-(3,4-dihydroxy-phenyl)-7-hydroxy-3-benzofuranyl]-3,4-dihydroxyphenyl]-(*E*)-2-propenoic acid. Compound **1** is a new compound.

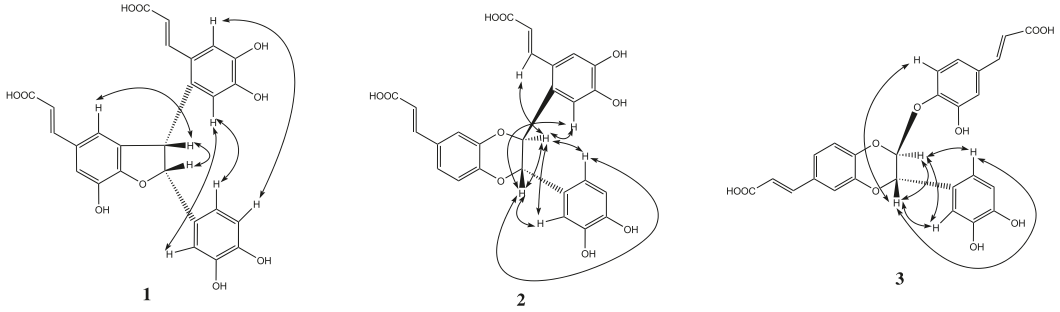
Fig. 1. Key NOESY for compounds **1–3**.



Compound **2** was obtained as a yellow powder. Its molecular formula was determined as $C_{26}H_{21}O_{10}$ by positive HR-FABMS spectrometric analysis, indicating the formation of a caffeic acid trimer. The IR spectrum exhibited absorption bands of hydroxyl (3373, 3256 cm^{-1}), carbonyl (1684 cm^{-1}), and phenyl (1607, 1508 cm^{-1}) groups. The ^{1}H and ^{13}C NMR spectral data (see Table 1) of **2** were very similar to those of **1**. Compared with the ^{13}C NMR spectral data of **1**, the chemical shift of C-7a decreased from δ_C 95.9 to δ_C 79.0, and the chemical shift of C-8a increased from δ_C 54.1 to δ_C 82.3. In addition, compared with the ^{1}H NMR of **1**, the fragment **B** was changed from 1,3,4,5-tetra-substituted aromatic fragment to 1,3,4-tri-substituted aromatic fragment. Besides, the correlation peak of H-8a to C-3b could be observed in HMBC spectra. So, it could be inferred that C-8a was connected with to fragment **B** through an oxygen atom. By detailed analysis of the ^{1}H and ^{13}C NMR data associated with HSQC and HMBC spectra, all the H and C signals could be assigned. The correlations of H-7b to C-2b and C-6b, H-2b, and H-6b to C-7b, H-8b to C-1b, H-7c to C-2c and C-6c, H-2c and H-6c to C-7c, and H-8c to C-1c suggested that two di-substituted double bonds were ascribed to aromatic frag-

© 2008 NRC Canada

ments **B** and **C**. From the long-range correlations H-7a to C-1a, C-2a and C-6a, H-2a and H-6a to C-7a, and H-8a to C-1a, we could confirm that the saturated CH–CH fragment was connected with to the aromatic fragment **A** through C-1a. The signals H-8a to C-1c and C-5c, H-5c to C-8a, and H-7a to C-6c demonstrated that aromatic fragment **C** was connected with to CH through C-6c. NOE correlation peaks of H-7a to H-5c, H-2a, H-6a, and H-8a as well as H-8a to H-2a, H-6a, H-7a, and H-7c were observed in NOESY (see Fig. 1). So, the relative configuration was determined to be trans. According to the above analysis, the structure of **2** was elucidated as *trans*-3-[6-[6-[(*E*)-2-carboxy-ethenyl]-3-(3,4-dihydroxyphenyl)-2,3-dihydro-2-(1,4-ben-zodioxin)]-3,4-dihy-droxyphe-nyl]-(*E*)-2-propenoic acid. Compound **2** is a new compound.

Compound **3** was obtained as a white powder. Its molecular formula was determined as $C_{26}H_{19}O_{10}$ by positive HR-FABMS spectrometric analysis, indicating the formation of a caffeic acid trimer. The IR spectrum exhibited absorption bands of hydroxyl (3410 cm^{-1}), carbonyl (1686 cm^{-1}), and phenyl (1605, 1522 cm^{-1}) groups. In the ^{1}H and ^{13}C NMR spectra (see Table 1), three 1,3,4-tri-substituted aromatic fragments (**A**, **B**, and **C**), two trans olefinic acids, and two saturated H protons were observed. The ^{1}H and ^{13}C NMR spectral data of **3** were similar to those of **2**. Compared the with ^{13}C NMR spectral data of **2**, the chemical shift of C-7a decreased from δ_C 79.0 to δ_C 76.7, and the chemical shift of C-8a increased from δ_C 82.3 to δ_C 112.8. Compared with the ^{1}H NMR of **2**, the fragment **C** was changed from 1,3,4,6-tetra-subsituted aromatic fragment to 1,3,4-tri-substituted aromatic fragment. So, it could be inferred that C-8a was connected to fragment **C** through oxygen atom. HSQC and HMBC experiments established all ^{1}J and ^{3}J ^{1}H, ^{13}C connectivities and allowed to combine these partial structures to those of **3**. The correlations of H-7b to C-2b and C-6b, H-2b and H-6b to C-7b, H-8b to C-1b, H-7c to C-2c and C-6c, H-2c and H-6c to C-7c, and H-8c to C-1c suggested that two di-substituted double bonds were ascribed to aromatic fragments **B** and **C**. The signals H-7a to C-1a, C-2a and C-6a, H-2a and H-6a to C-7a, and H-8a to C-1a demonstrated that aromatic fragment **A** was connected to CH through C-1a. Besides, the correlations H-8a to C-4b and C-4c demonstrated that C-4b and C-4c were connected to CH through an oxygen atom. NOE correlation peaks of H-7a to H-5c, H-2a, H-6a, and H-8a as well as H-8a to H-2a, H-6a, and H-7a were observed in NOESY (see Fig. 1). So, the relative configuration of H-7a/H-8a should be trans. According to the above analysis, the structure of **3** was elucidated as *trans*-3-[4-[[6-[(*E*)-2-carboxy-ethenyl]-3-(3,4-di-hydroxyphenyl)-2,3-dihydro-2-(1,4-benzodioxin)]oxy]-3-hydroxyphenyl]-(*E*)-2-propenoic acid. Compound **3** is a new compound.

Compound **4** was obtained as a white powder. Its molecular formula was determined as $C_{19}H_{16}O_8$ by positive HR-FABMS spectrometric analysis, indicating the formation of a caffeic acid dimer. The IR spectrum exhibited absorption bands of hydroxyl (3435 cm^{-1}), ester carbonyl (1730 cm^{-1}), carbonyl (1686 cm^{-1}), and phenyl (1624, 1512 cm^{-1}) groups. In the ^{1}H and ^{13}C NMR spectra (see Table 2), two 1,3,4-tri-substituted aromatic fragments (**A** and **B**), one trans olefinic acid, two saturated H protons, and one methoxyl group were observed. In HMBC spectra, according to the signals of H-7a to C-4b, C-2a and C-6a, H-2a and H-6a to C-7a, H-8a to C-3b, H-7b to C-2b and C-6b, H-2b and H-6b to C-7b, and H-8b to C-1b, it could be confirmed that compound **4** was a caffeic acid dimer including 1,4-benzodioxin skeleton. The long-range correlation of OMe to C-9a was observed, so COOH (C-9a) was methylated. Because the coupling constant of H-7a and H-8a ($J_{7a,8a}$ = 5.5 Hz) and [α] –5.7° (*c* = 0.18, MeOH), compared with ref. 15, the relative configuration of **4** was trans. According to the above analysis, the structure of **4** was elucidated as *trans*-7-[(1*E*)-2-carboxyethenyl]-3-(3,4-dihydroxy-phenyl)-2,3-dihydro-1,4-benzodioxin-2-carboxlic acid, Me ester. Compound **4** is a new compound.

Compound **5** was obtained as a white powder. Its molecular formula was determined as $C_{18}H_{14}O_8$ by positive HR-FABMS spectrometric analysis, indicating the formation of a caffeic acid dimer. According to the ^{1}H NMR spectra (see Table 2), two AMX systematical aromatic protons and one ABX systematical aromatic proton were observed. In the ^{13}C NMR spectra (see Table 2), 18 carbon signals could be found, including two carbonyl groups, four oxygen-substituted aromatic carbons, two carbon-substituted aromatic carbons, six C–H aromatic carbons, two unsaturated carbons, and two saturated carbons. According to the chemical shift of H-7b (δ_H 7.52), the plane constitution of **5** should be (4)*E*, on the other hand, if the plane constitution were (4)*Z*, the chemical shift should shift to upfield. This conclusion could be confirmed by NOESY spectra. Compared with the reference of Phellinsin A, the coupling constant of H-7a/H-8a of **5** ($J_{7a,8a}$ = 7.6 Hz) was different from that of Phellinsin A ($J_{7a,8a}$ = 2.5 Hz); combined with the NOESY spectra, the relative configuration was cis (18). According to the above analysis, the structure of **5** was elucidated as *cis*-(4)*E*-2-(3,4-dihydroxyphenyl)-4-[(3,4-dihydroxy-phenyl)-methylene]tetrahydro-5-oxo-3-furancarboxylic acid. Compound **5** is a new compound.

Compound **6** was obtained as a white powder. The molecular mass was 330 by ESI-MS analysis, indicating the formation of a caffeic acid dimer. According to the ^{1}H NMR spectra (see Table 2), one AMX systematical aromatic proton, one ABX systematical aromatic proton, one trans double bond, and two saturated H protons were observed. In the ^{13}C NMR spectra (see Table 2), 17 carbon signals could be found, including one C=O signal, four oxygen-substituted aromatic carbons, two carbon-substituted aromatic carbons, six C–H aromatic carbons, one trans double bond, and two saturated carbon. In HMBC spectra, according to the signals of H-7a to C-2a and C-6a, H-2a and H-6a to C-7a, and H-8a to C-1a, we could confirm that the trans double bond was connected to aromatic fragment **A**. The correlations of H-7b to C-2b, C-6b and C-1b, H-2b and H-6b to C-7b, and H-8b to C-1b suggested that aromatic fragment **B** was connected to C-7a though C-1b. The long-range correlations of H-8b to C-3a and C-4a, and the chemical shift of C-8b suggested that aromatic fragment **A** was connected to CH (C-8a) though C-3a and C-4a. Compared with the references, the relative configuration of the chiral carbons (C-7b and C-8b) could be elucidated as cis by the coupling constant ($J_{7a,8a}$ = 3.8 Hz) (19–22). According to the above analysis, the

Note: Chemical shifts were given in δ values and followed by multiplicities and *J* values (in Hz). The ^{1}H and ^{13}C signals were assigned by HSQC and HMBC spectra.

[a]Recorded in acetone-d_6.
[b]Recorded in DMSO-d_6.
[c]Recorded in CD_3OD.
[d]δ in ppm.

structure of **6** was elucidated as *cis*-3-[2-[1-(3,4-dihydroxyphenyl)-1-hydroxymethyl]-1,3-ben-zodioxol-5-yl]-(*E*)-2-propenoic acid. Compound **6** is a new compound.

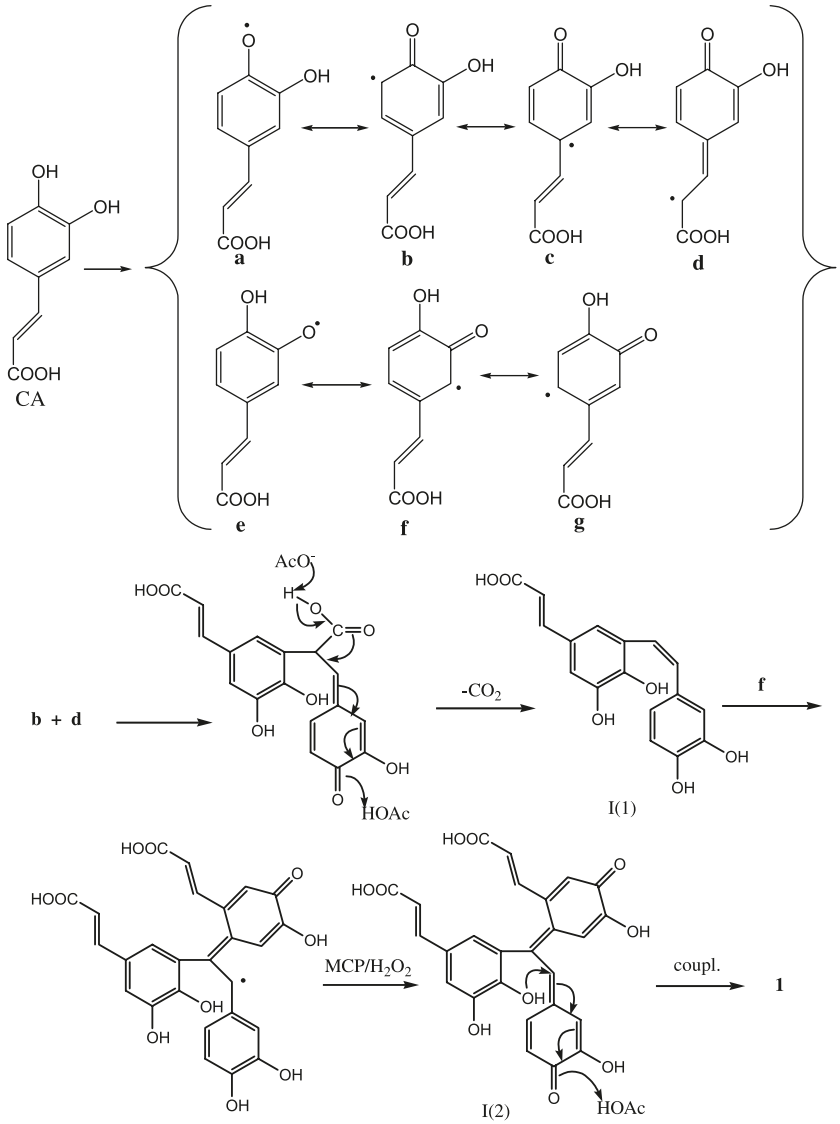
Compound **7** was obtained as a white powder. The molecular mass was 372 by ESI-MS spectrometric analysis, indicating the formation of a caffeic acid dimer. In the ^{1}H and ^{13}C NMR spectra (see Table 2), two 1,3,4-tri-substituted aromatic fragments, one trans double bond, two saturated H protons, and one acetyl fragment were observed. The long-range correlations of H-8b to C-3a, C-4a and C-1b, H-7b to C-2b, C-6b and C-1b, and H-2b and H-6b to C-7b suggested that compound **7** was caffeic acid dimer including 1,3-benzodioxin skeleton. Compared with the spectral data of **6**, compound **7** contained on acetyl group. In the HMBC, the correlation of C-7b to C=O and the chemical shift of C-7b was downshift, suggesting that OH connected to C-7b was acetylated. Compared with the references, the relative configuration of the C-7b and C-8b could be elucidated as cis by the coupling constant ($J_{7a,8a}$ = 3.5 Hz) (19–22). According to the above analysis, the structure of **7** was elucidated as *cis*-3-[2-[1-(3,4-dihydroxy-phenyl)-1-acetoxymethyl]-1,3-benzodioxol-5-yl]-(*E*)-2-propenoic acid. Compound **7** is a new compound. This was the first time that caffeic acid dimers 1,3-benzodioxin skeleton were obtained by biotransfomation.

The known compounds, *trans*-6-[(1*E*)-2-carboxyethenyl]-3-(3,4-dihydroxyphenyl)-2,3-dihydro-1,4-benzodioxin-2-carboxlic acid (**8**) and 3-(1,3-benzodioxol-5-yl)-2-propenoic acid (**9**), were identified by comparing their physical and spectroscopic data with those reported in the literature (17, 23).

A novel peroxidase (*Momordica charantia* peroxidase, MCP) was purified from the fruit of Momordica charantia. We applied the purified MCP to catalyze in the presence of H_2O_2 to transformation of caffeic acid (CA). During our present research, three novel trimers, four novel dimers, and

© 2008 NRC Canada

Scheme 1. Proposed mechanism of the formation of **1**.



two known compounds were identified from MCP-catalyzed oxidation of CA. The proposed reaction mechanism for the formation of compound **1** is shown in Scheme 1. It is reasonable to assume that the CA radicals (b) and (d) combine, followed by acid–base catalyzed decarboxylation, driven by aromatization of the quinomethane part, to yield I (1). Then, the attack of monomeric CA radical (f) on the vinylic bond of I (1), followed by MCP/H_2O_2 catalysis, leads to I (2). Through intramolecular rearrangement, catalyzed by acid–base, **1** is formed from I (2). Compounds **2** and **3** contain a decarboxylated moiety. A possible mechanism of their formation involves the combination of the CA radicals (e) and (d), followed by decarboxylation, to yield I (4). Then, the attack of CA radical (f) on the vinylic bond of I (4), followed by MCP/H_2O_2 catalysis, leads to I (5). Through an intramolecular rearrangement, catalyzed by acid, **2** is formed from I (5), and the attack of monomeric CA radical (*a*) on the vinylic bond of I (4), followed by MCP/H_2O_2 catalysis, leads to I (6). Through intramolecular rearrangement, catalyzed by acid–base, **3** is formed from I (6), see Scheme 2.

The possible formation mechanisms of **4**–**9** are also discussed (see Scheme 3). The intermediate I (3), catalyzed by acid, undergoes an intramolecular rearrangement, followed by methyl esterification, to yield **4**. The CA radicals (d) combine, followed by acid–base catalyzed decarboxylation, driven by intramolecular rearrangement, to yield I (7). I (7) is catalyzed by MCP/H_2O_2, followed by decarboxylation to yield **5**. The CA radicals (*a*) and (d) combine, followed by acid–base catalysis, to yield I (8). I (8) is catalyzed by MCP/H_2O_2, followed by intramolecular rearrangement and decarboxylation, to yield **6**. I (8) is oxidized by MCP/H_2O_2, followed by intramolecular rearrangement, to give the corresponding intermediate, which then undergoes decarboxylation and ethyl esterification to yield **7**. Compounds **8** and **9** are obtained through intramolecular rearrangement, catalyzed by acid–base from I (8), respectively.

In the pharmacological research, compound **5** has shown much stronger anti-oxidative activity than the other caffeic acid polymers obtained, according to the inhibition ratio, see Table 3. According to our previous reported research, combined with our present study, it was easy to conclude that the dimers that contained the skeleton of 5-phenyl-3-

11	13.3±2.5

[a]Final concentration of all compounds was 1×10^{-4} mol/L

[b]The inhibition ratio was defined according to the following equation: Inhibition ratio = (the absorbance of vehicle – the absorbance of tested compound)/the absorbance of vehicle ×100%.

(phenylmethylene)-2(3*H*)-furanone (3, 4) may have higher anti-oxidative activity than other reaction products.

Experimental section[2]

General experimental procedures

Positive-ion HR-FABMS was recorded with a JEOL HX-110 spectrometer using *m*-nitrobenzyl alcohol as a matrix. Negtive-ion HR-ESIMS was recorded with an Agilent TOF MSD 1946D spectrometer. UV and IR spectra were recorded with Shimadzu UV-2501PC and Nicolet Impact 410 spectrometers, respectively. ^{1}H and ^{13}C NMR, HSQC, HMBC, and NOESY spectra were taken with Bruker ACF-500 and ACF-600 spectrometers (1D NMR 500 MHz and 125 MHz, 2D NMR 600 and 150 MHz, respectively) in acetone-d_6, DMSO-d_6, or CD_3OD; chemical shifts are reported in ppm as δ relative to Me_4Si (internal standard). Column chromatography was carried out with Sephadex LH-20 (20–100 μ, Pharmacia) (1 μ = 1 μm) and ODS-C18 (100–200 μ, Waters). L-Cysteine Hydrochloride (High Pure Grade) was purchased from AMRESCO. Caffeic acid and DMSO were purchased from Sigma. The malondialdehyde (MDA) kit was provided by Nanjing Jiancheng Bioengineering Institute. Other reagents and solvents used were of analytical grade and were purchased from reliable commercial sources.

Plant material

Fruits of *M*. charantia were collected at a suburb of Nanjing, China, and identified by Dr. Mingjian Qin, China Pharmaceutical University. A voucher specimen (No. 000804) was deposited in the Department of Natural Medicinal Chemistry, China Pharmaceutical University.

Purification of MCP

MCP from fruits of *Momordica charantia* was purified to electrophoretic homogeneity by consecutive treatment of ammonium sulfate fractionation, ion exchange chromatography on DEAE-Sepharose FF, affinity chromatography on

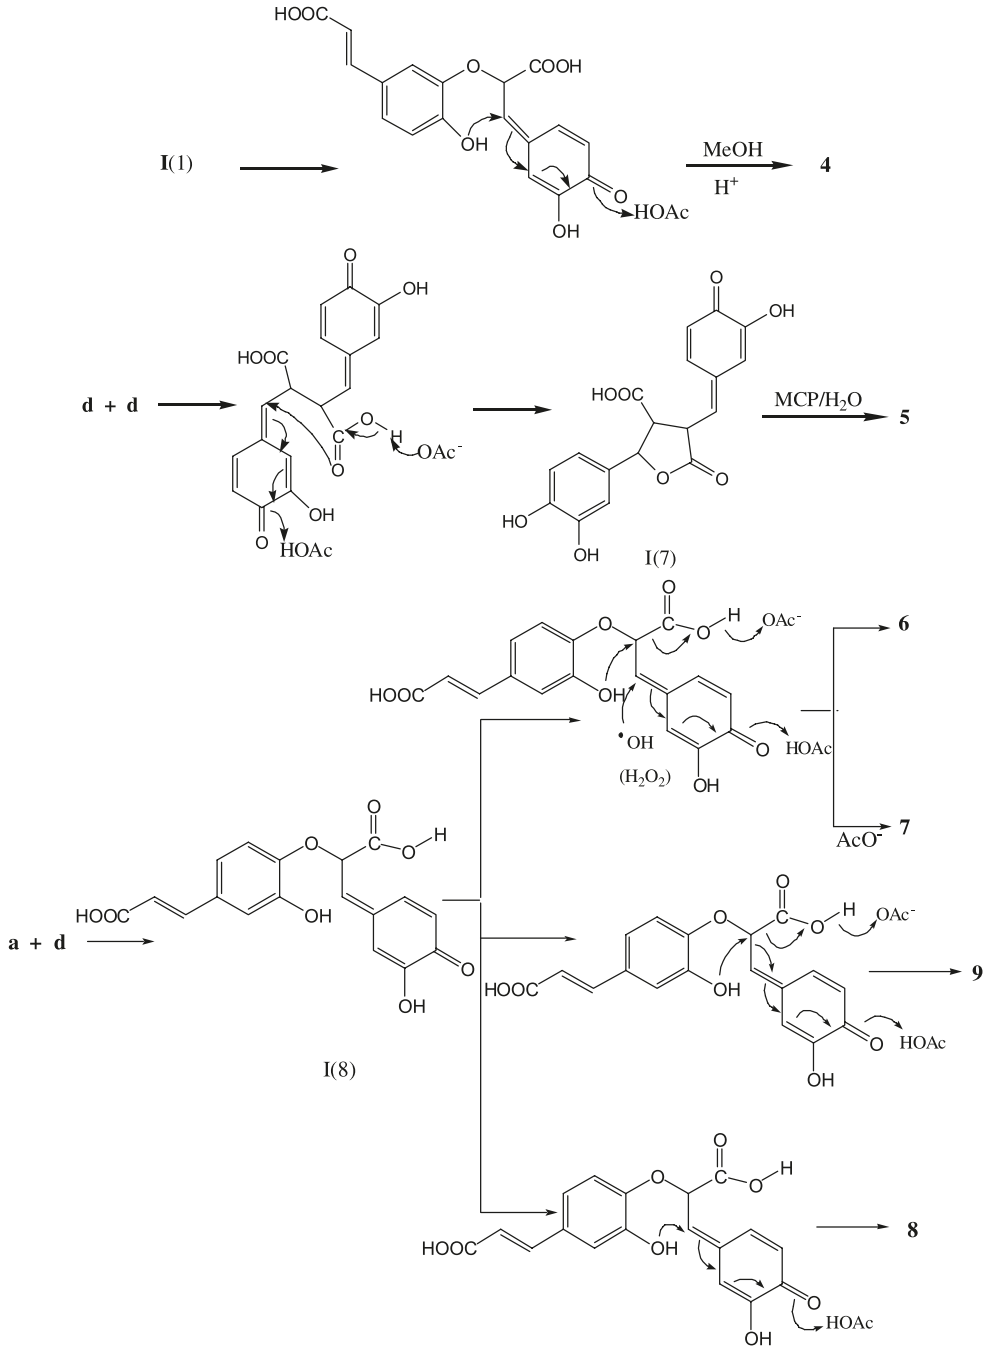
Scheme 3. Proposed mechanism of the formation of **4**–**9**.



Con A Sepharose, and gel filtration on Sephadex G-150 as described in our previous report (1). The purified MCP exhibited a specific activity of 7757 E.U. of peroxidase per mg of protein, which was 46 fold higher than that of the crude extract.

Biotransformation of caffeic acid in aqueous acetone

A solution of caffeic acid (2.4 g) in acetonitrle (200 mL) and a solution of MCP (4 × 103 U) in buffer (100 mmol/L NaOAc–HOAc, pH 5.0, 400 mL) were mixed and treated with hydrogen peroxide (0.3%, 120 mL) at 25 °C and stirred for 8 h, during which time the mixture gradually turned brownish red.

Isolation and identification

The reaction mixture was evaporated to dryness at 40 °C under reduced pressure. The extractum was dissolved with water. Then, the aqueous mixture was extracted with ethyl acetate and *n*-butanol, successively. The extract was washed with water, dried with anhyd. Na_2SO_4, and evaporated to dryness at 40 °C under reduced pressure. The combined ethyl acetate layer was concentrated to afford a red powder (2.1 g), which was subjected to RP-C18 column chromatography (i.d. 3.0 × 50, 80 g) eluted with MeOH/H_2O (20:80 to 50:50, *v*/*v*) to afford fraction 1 (0.7 g), fraction 2 (0.3 g), fraction 3 (0.5 g), and fraction 4 (0.4 g). Fraction 1 was subjected to Sephadex LH-20 column chromatography (i.d.

1.5 × 100, 70 g, 8 mL each) eluted with MeOH. The elution of 9 to 12 fractions (86 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (20:80, *v*/*v*) to give **1** (10 mg). The elution of 15 to 16 fractions (35 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (20:80, *v*/*v*) to give **4** (4 mg). The elution of 18 to 22 fractions (103 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (20:80, *v*/*v*) to give **5** (48 mg). Fraction 2 was subjected to Sephadex LH-20 column chromatography (i.d. 1.5 × 100, 70 g, 8 mL each) eluted with MeOH/$CHCl_3$ (1:1, *v*/*v*). The elution of 8 to 10 fractions (35 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (35:65, *v*/*v*) to give **6** (20 mg). The elution of 13 to 14 fractions (12 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (30:70, *v*/*v*) to give **8** (6.5 mg), and the elution of 17 to 19 fractions (20 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (30:70, *v*/*v*) to give **9** (11 mg). Fraction 3 was subjected to Sephadex LH-20 column chromatography (i.d. 1.5 × 100, 70 g, 8 mL each) eluted with MeOH/$CHCl_3$. (1:1, *v*/*v*). The elution of 13 to 15 fractions (178 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (50:50, *v*/*v*) to give **2** (120 mg). The elution of 18 to 20 fractions (45 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (35:65, *v*/*v*) to give **7** (20 mg). Fraction 4 was subjected to Sephadex LH-20 column chromatography (i.d. 1.5 × 100, 70 g, 8 mL each) eluted with MeOH/$CHCl_3$ (1:1, *v*/*v*). The elution of 11 to 15 fractions (66 mg) was submitted to RP-C18 column chromatography (i.d. 1.5 × 30, 40 g) eluted with MeOH/H_2O (50:50, *v*/*v*) to give **3** (25 mg).

Measurement of anti-oxidative activity

Male Sprague–Dawley SD rats (8–9 weeks old) were used. They were purchased from the Experimental Animal House of China Pharmaceutical University (Nanjing, China). All rats were maintained with free access to pellet food and water in plastic cages at 20 ± 2 °C and kept on a 12 h light–dark cycle. The animal study protocol was in compliance with the guidelines of China for animal care, which conforms to the internationally accepted principles in the care and use of experimental animals. A rat was sacrificed by bloodletting and was perfused in situ via the portal vein with phosphate buffered saline (PBS). Liver tissue was collected and cut into species. After being weighed, the tissue was homogenized with PBS (1:4) using a high speed homogenizer for 10 s each time at 0 °C, and the operation was repeated for 4 to 5 times. The homogenates (25%) were then centrifuged at 5 000g for 20 min. The supernatants were collected and again centrifuged at 5 000g for 60 min. The supernatants were discarded and the microsomal pellet was suspended in 10-volume PBS containing 30% glycerol (glycerol:PBS, 30:70 (*v*/*v*)). Microsomal suspensions were stored in small portions at –80 °C and thawed before lipid peroxidation assay. Microsomal protein was determined by the biuret method.

Lipid peroxidation was induced in rat liver microsomes by $FeSO_4$–cysteine. A mixture of the microsomal suspension (10%, 100 μL), $FeSO_4$ solution (1 mmol/L, 50 μL), L-cysteine hydrochloride (10 mmol/L, 20 μL), the sample solution (finial concentration of 10^{-4} mol/L, 10 μL) or vehicle (DMSO, 10 μL), and PBS (0.01 mol/L, pH 7.4, 820 μL) was incubated at 37 °C for 30 min. Each reaction mixture was stopped at 4 °C. The concentration of MDA (malondialdehyde), the second derivative of lipid peroxidation, in the above-mentioned reaction mixture was determined using the commercial kit according to the guidelines provided (24). 100 μL reaction mixture above mentioned was incubated at 95 °C for 30 min. The reaction was stopped by cooling over ice and contents centrifuged at 800 g for 10 min. The absorbance of the supernatant was recorded at 532 nm. The value for non-specific absorbance at 600 nm was subtracted. The inhibition ratio was defined according to the following equation:

Inhibition ratio = (the absorbance of vehicle – the absorbance of tested compound)/the absorbance of vehicle ×100%.

$H_3PW_{12}O_{40}$ — A selective, environmentally benign, and reusable catalyst for the preparation of methoxymethyl and ethoxymethyl ethers and their deprotections under mild conditions

Iraj Mohammadpoor-Baltork, Majid Moghadam, Shahram Tangestaninejad, Valiollah Mirkhani, and Arsalan Mirjafari

Abstract: Different types of primary and secondary alcohols were efficiently transformed to their corresponding methoxymethyl (MOM) and ethoxymethyl (EOM) ethers in the presence of catalytic amounts of $H_3PW_{12}O_{40}$ at room temperature under solvent-free conditions. Selective protection of primary and secondary alcohols in the presence of phenols and tertiary alcohols was achieved by this method. Deprotection of these ethers to their parent alcohols was also performed using this catalyst in ethanol under reflux conditions. We have also found that primary and secondary MOM- and EOM-ethers are selectively deprotected in the presence of phenolic and tertiary ones, methyl and benzyl ethers, esters, and trimethylsilyl ethers by this catalyst. The notable advantages of this protocol are high yields, short reaction times, easy work-up, non-toxicity, easy availability and handling, eco-friendly, and reusability of the catalyst.

Key words: methoxymethylation, ethoxymethylation, protection, deprotection, heteropoly acid.

Résumé : Opérant à la température ambiante, dans des conditions sans solvant et en présence de quantités catalytiques de $H_3PW_{12}O_{40}$, il est possible de transformer d'une façon efficace divers types d'alcools primaires et secondaires en éthers méthoxyméthyle (MOM) ou éthoxyméthyle (EOM) correspondants. Utilisant cette méthode, on a pu effectuer la protection sélective d'alcools primaires et secondaires en présence de phénols et d'alcools tertiaires. On a effectué la déprotection de ces éthers pour régénérer les alcools de départ en utilisant le même catalyseur, dans l'éthanol au reflux. On a aussi trouvé que le même catalyseur permet de déprotéger sélectivement les éthers MOM et EOM en présence d'éthers phénoliques ou tertiaires, d'éthers méthyliques et benzyliques, d'esters et d'éthers triméthylsilyles. Les avantages notables de ce protocole sont les rendements élevés, les courts temps de réaction, la facilité de l'extraction et le fait que le catalyseur est non toxique, qu'il est de disponibilité et de maniement facile, respectueux de l'environnement et réutilisable.

Mots-clés : méthoxyméthylation, éthoxyméthylation, protection, déprotection, acide hétéropolaire.

Introduction

Recently, green chemistry has received considerable importance in organic synthesis. Due to environmental issues affecting all societies, emphasize on the "green" aspects of chemical processes will be appreciated. Thus, catalysts that are eco-friendly and simply recycled in the reaction mixture have attracted a considerable attention.

One important class of solid catalysts is heteropoly acids (HPAs), having both redox and acid properties (1). Among heteropoly acids, polytungstic acids are the most widely used catalysts because of their high acid strengths, thermal stability, and low reducibility. Heteropoly acid catalysts have many advantages over the liquid acid catalysts, which are harmless to the environment with respect to corrosiveness, safety, and quantity of waste. Solid heteropoly acids have attracted much attention in organic synthesis owing to easy work-up procedure, easy filtration, and minimization of cost and waste generation due to reuse and recycling of the catalysts (2). A variety of organic reactions, such as alcohol dehydration, acetylation, alkylation, isomerization, oxydehydrogenation (1, 3), acylation (4), estrification (5), synthesis of 1,4-dihydropyrimidones (6), oxidation of alkylarenes (7), Friedel–Crafts acylation (8), Fries rearrangement of arylesters (9), epoxidation of allylic alcohols (10), reactions of oxiranes with carbonyl compounds (11), ring opening of epoxides (12), conversion of THP ethers into acetates (13), α-glycosidation (14), and preparation of oximes (15), have been reported in the presence of heteropoly acid catalysts.

To synthesize more complicated molecules, chemists have developed satisfactory protective groups and also effective methods for the formation and cleavage of these compounds. The selective protection and deprotection of hydroxyl group have occupied a unique position in organic synthesis be-

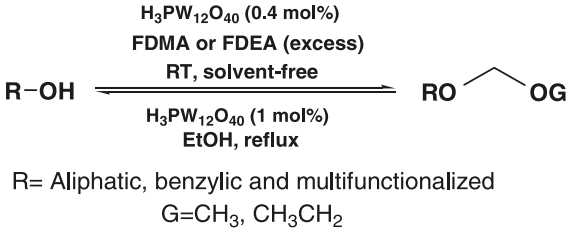
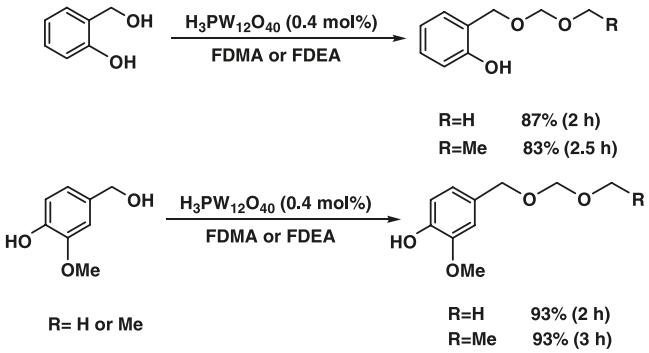
cause of the fundamental importance of hydroxyl groups and their roles in the multi-step synthesis of complex natural products (16). Transformation of hydroxyl groups to their alkoxymethyl ethers is a commonly used protective process for alcohols (17). These derivatives are frequently prepared by the reactions of alcohols with a excess amount of formaldehyde dimethyl acetal (FDMA) or formaldehyde diethyl acetal (FDEA) (18–25). Deprotection of these ethers to their parent alcohols is also an important process in synthetic organic chemistry, and several methods and catalysts have been reported for these transformations (23, 26–33). However, some of these methods suffer from drawbacks, such as harsh reaction conditions, high reaction temperature, tedious work-up procedures, long reaction times, and the use of expensive and toxic reagents. Consequently, introduction of efficient and selective methods for the preparation of alkoxymethyl ethers and their deprotection using inexpensive, relatively non-toxic, easy handling, and environment-friendly catalysts is still in demand.

In continuation of our studies on protection and deprotection reactions (34), we now report $H_3PW_{12}O_{40}$ as an efficient, relatively non-toxic, recycable, and air-stable catalyst for the preparation of methoxymethyl (MOM) and ethoxymethyl (EOM) ethers at room temperature under solvent-free conditions and also deprotection of these ethers in a green solvent, ethanol, under reflux conditions (Scheme 1).

Scheme 1.



Scheme 2.



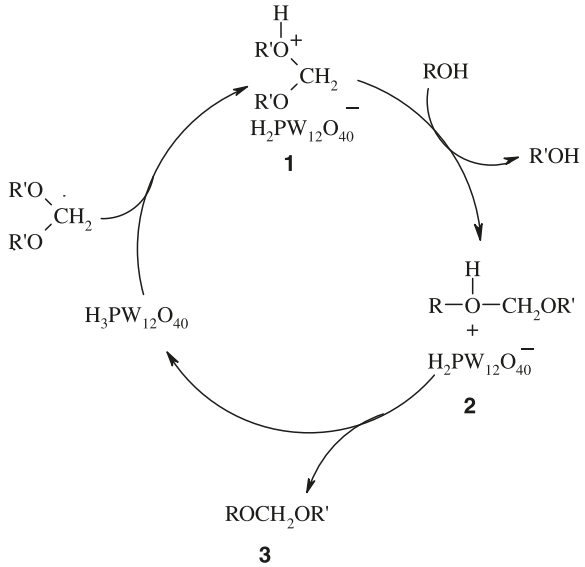
Results and discussion

First, we investigated the ability of $H_3PW_{12}O_{40}$ in the methoxymethylation and ethoxymethylation of benzyl alcohol with FDMA and FDEA, respectively. The results showed that in the presence of 0.4 mol% of this catalyst, the MOM and EOM ethers were obtained in high yields. Both protection reactions were carried out at room temperature and under solvent-free conditions. Primary and secondary, benzylic and saturated alcohols were efficiently converted to their corresponding MOM- and EOM-ethers in high yields (Table 1). Allylic alcohols, such as cinnamyl alcohol, were also transformed to the corresponding MOM- and EOM-ethers efficiently (Table 1, entry 20).

Under the same reaction conditions, phenols and tertiary alcohols did not react even under reflux conditions, and the starting materials remained intact after 24 h. Therefore, a set of competitive reactions was conducted between primary or secondary alcohols and phenols or tertiary alcohols (Table 2). Also in compounds containing both benzylic and phenolic hydroxyl groups, only benzylic hydroxyl groups were converted to their corresponding ethers with excellent chemoselectivity (Table 1, entries 7 and 10; Scheme 2). The results indicated that the present protocol is potentially applicable for the chemoselective conversion of primary and secondary alcohols to their MOM- and EOM-ethers in the presence of phenols and tertiary alcohols.

The actual mechanism of these protection reactions is not clear at present. However, a plausible explanation is that FDMA or FDEA is first activated by catalyst to afford **1**. Alcohol attacks **1** to give **2**, which in turn converts to the final product **3** and releases the catalyst for the next catalytic cycle (Scheme 3).

Scheme 3.



The deprotection reactions of MOM- and EOM-ethers with $H_3PW_{12}O_{40}$ were also investigated (Scheme 1). We optimized the experimental conditions for the cleavage of MOM- and EOM-ethers of benzyl alcohol, and the best results were achieved when 1 mmol of MOM- or EOM-ether was treated with 1 mol% of catalyst in refluxing EtOH. Under these conditions, various MOM- or EOM-ethers of primary and secondary benzylic, allylic, and saturated alcohols were deprotected to their parent alcohols in high yields. The results of deprotection reactions are illustrated in Table 3. Also, a mechanism has been proposed for the deprotection of these ethers (Scheme 4).

9		3.5	91	3	82
10		3	93	2	93

To extend the scope and utility of this catalytic system, we have performed several competitive deprotection reactions. As can be seen, interesting selectivities were observed. Primary and secondary MOM- and EOM-ethers are deprotected in the presence of phenolic and tertiary ones with high selectivity (Table 4). Also, chemoselective deprotection of these ethers in the presence of other hydroxyl protecting groups such as benzyl and methyl ethers (Table 3, entries 7–10), acetates and trimethylsilyl ethers (Table 5) is achieved using this catalytic system. These selectivites can be considered as useful practical achievements in deprotection reactions.

The reusability of the catalyst was examined using sequential reactions of benzyl alcohol with FDMA and FDEA (Table 1, entry 1). At the end of the reaction, Et_2O was added, and the catalyst was separated by simple filtration. The organic layer was washed with water, and the water was evaporated to afford the remaining catalyst. The recovered catalyst was reused for five cycles. The reactions were preceded smoothly with 88%–91% yields. The results indicated that the catalyst could be used several times without loss of its activity.

In conclusion a mild, selective, and efficient protocol for the preparation of MOM- and EOM-ethers at room temperature under solvent-free conditions and deprotection of these ethers in refluxing EtOH in the presence of catalytic amounts of $H_3PW_{12}O_{40}$ has been established. The use of this inexpensive, easily available, and reusable catalyst makes this protocol practical, environment-friendly, and economically attractive. Mild reaction conditions, high product yields, easy work-up procedures, and non-toxicity of the catalyst are other noteworthy advantages of this method.

Experimental

All materials were commercial reagent-grade, and alcohols, etherification reagents, and catalyst were purchased from Merck chemical company. The products were identified by comparison of their spectra and physical data with those of authentic samples. Melting points were determined

using Stuart Scientific SMP2 apparatus. ^{1}H NMR was recorded on a Bruker AC 500 MHz spectrometer. IR spectra were recorded on a Shimadzu IR-435 spectrophotometer.

General procedure for the preparation of EOM- and MOM-ethers

To a solution of alcohol (1 mmol) in FDEA (5 mmol) or FDMA (7 mmol), $H_3PW_{12}O_{40}$ (0.004 mmol) was added and stirred at room temperature for the appropriate time according to Table 1. After completion of the reaction (TLC analysis), the excess FDMA or FDEA was removed by rotary evaporator. Et_2O (20 mL) was added, and the mixture was filtered. The organic layer was washed with water (10 mL) and dried over anhyd. Na_2SO_4. Evaporation of the solvent followed by chromatography on a short column of silica gel (*n*-hexane – ethyl acetate, 4:1) afforded the pure product (Table 1). In the case of solid materials, the products were recrystallized form *n*-hexane – diethyl ether.

General procedure for the deprotection of MOM- and EOM-ethers

A mixture of alkoxymethyl ether (1 mmol) and $H_3PW_{12}O_{40}$ (0.01 mmol) in EtOH (8–10 mL) was stirred under reflux conditions. After completion of the reaction (TLC analysis), the solvent was evaporated, Et_2O (20 mL) was added and filtered. The organic layer was washed with water (10 mL) and dried over anhyd. Na_2SO_4. The solvent was evaporated and the crude product was purified by a short column of silica gel (eluent: *n*-hexane – ethyl acetate, 4:1) to afford the pure product (Table 3).

An efficient method for the silylation of hydroxyl groups with hexamethyldisilazane (HMDS) catalyzed by aluminum tris(dihydrogen phosphate) under solvent-free and ambient conditions

Hamid Reza Shaterian, Majid Ghashang, Nassrin Tajbakhsh Riki, and Manijeh Asadi

Abstract: A highly efficient and mild procedure for the trimethylsilylation of a wide variety of alcohols, including primary, benzylic, secondary, hindered secondary, tertiary, phenols, and oximes with hexamethyldisilazane (HMDS), using $Al(H_2PO_4)_3$ as a recyclable heterogeneous catalyst at room temperature in a few minutes with excellent yields under solvent-free conditions is described.

Key words: trimethylsilylation, hexamethyldisilazane, aluminum tris(dihydrogen phosphate) [$Al(H_2PO_4)_3$], solvent-free, hydroxyl groups.

Résumé : On a mis au point une méthode douce et très efficace de triméthylsilylation d'une grande variété d'alcools, y compris les alcools primaires, benzyliques, secondaires, secondaires empêchés et tertiaires, ainsi que des phénols et des oximes, qui implique l'utilization de l'hexaméthyldisilazane (HMDS) en présence de $Al(H_2PO_4)_3$ comme catalyseur hétérogène réutilizable et qui s'effectue en quelques minutes à la température ambiante, avec d'excellents rendements et des conditions sans solvant.

Mots-clés : triméthylsilylation, hexaméthyldisilazane, tris(phosphate diacide) d'aluminium [$Al(H_2PO_4)_3$], sans solvant, groupements hydroxyles.

[Traduit par la Rédaction]

Introduction

Trimethylsilylation of organic compounds having labile hydrogen atoms is an important organic transformation. It is a frequently used protection method in multi-step sequence synthesis of natural products due to the enhanced stability under a variety of conditions, solubility in nonpolar solvents, thermal stability, and the ease of removal, which is simply accomplished by acid- or base-induced hydrolysis giving only unreactive siloxane as the by-product (1). It is also used extensively for the hydroxyl compounds to increase their volatility for gas chromatography and mass spectrometry (1, 2). Several methods have been reported for this conversion, including the reaction of an alcohol with trimethylsilylhalides in the presence of a stoichiometric amount of a tertiary amine (3), with trimethylsilyl triflate and trimethylsilylmethallylsulfinates, which are more reactive than the chloride (4), allylsilanes in the presence of a catalytic amount of *p*-toluenesulfonic acid (4) iodine (5), trifluoromethanesulfonic acid (6), and $Sc(OTf)_3$ (7). Hexamethyldisilazane (HMDS) is frequently used for the trimethylsilylation of hydroxyl groups. HMDS is an inexpensive and commercially available reagent. Its handling does not require special precautions and the workup is not time-consuming because the by-product of the reaction is ammonia, which is simple to remove from the reaction medium. The low silylation power of HMDS is the main drawback to its application. Therefore, there are a variety of catalysts for activating this reagent, such as $(CH_3)_3SiCl$ (8), K-10 montmorillionite (9), sulfonic acids (10), zirconium sulfophenyl phosphonate (11), $ZnCl_2$ (12), Envirocat EPZGO (13), tungstophosphoric acid (14), iodine (15), lithium perchlorate (16), cupric sulfate pentahydrate (17), H–β Zeolite (18), $MgBr_2$ (19), lithium perchlorate supported on silica gel (20), $Al(HSO_4)_3$ (21), $Al(OTF)_3$ (22), magnesium triflate (23), copper triflate (24), $ZrCl_4$ (25), silica-$HClO_4$ (26), lanthanum trichloride (27), trichloroisocyanuric acid (28), and sulfonic acid-functionalized ordered nanoporous silica (29). However, in most cases a long reaction time, drastic reaction conditions, or tedious workup is needed. In addition, trimethylsilyl azide is expensive and toxic. We now show that O-trimethylsilylated compounds can be produced using $Al(H_2PO_4)_3$ (30) as an efficient, recyclable heterogeneous catalyst at room temperature under solvent-free conditions (Scheme 1).

This catalyst is safe, easy to handle, environmentally benign, presents fewer disposal problems, and is stable in reaction media.

Results and discussion

First, silylation of benzyl alcohols with HMDS in the presence of solid aluminum tris(dihydrogen phosphate) as catalyst in various solvents and also under solvent-free conditions at room temperature was investigated. The results were summarized in Table 1. As shown in Table 1, the solvent-free condition is obviously the best choice for these reactions. Solvent-free reactions promise to be an essential facet of 'Green Chemistry'. This type of organic reaction possesses some advantages over traditional reactions in organic solvents. Solvent-free reactions make it possible to reduce the consumption of environmentally unfriendly solvents and lead to new environmentally benign procedures to save resources and energy.

To determine the optimum quantity of $Al(H_2PO_4)_3$, the reaction of benzyl alcohol (1 equiv.) and HMDS (0.8 equiv.) was carried out under the solvent-free conditions using different quantities of catalyst at room temperature. The use of 50 mg of catalyst resulted in the highest yield in 5 min (Table 2).

Thus, we prepared a range of O-trimethylsilylated compounds under the optimized reaction conditions (Table 3).

A wide range of structurally diverse and functionalized phenols, alcohols, and oximes underwent silylation by this procedure to provide the corresponding TMS ethers (trimethysilyl ethers) in good to excellent isolated yields as shown in Table 3 (entries 1–24, 26, 28). Primary alcohols mostly reacted faster than secondary and tertiary alcohols. Generally, in all cases of benzyl, primary, secondary, and tertiary alcohols the reactions were completed within less than 65 min in solvent-free conditions accompanied by evolution of NH_3 gas from the reaction mixture. Inspection of the data in Table 3 clearly shows that different types of hindered secondary and tertiary alcohols were successfully converted to the corresponding silyl ethers at ambient conditions (Table 3). Amines (Table 3, entries 26, 27) and thiols (Table 3, entry 25) remained unaffected under the reaction conditions. To examine the functional group compatibility, we tested some more alcohols having other functional groups such as carbonyl group, amino group, alkene, and ethers. Alcohols were successfully converted to the corresponding silyl ethers, whereas, other functional groups were intact (Table 3, entries 2, 16, 26, 28).

The suggested mechanism of the $Al(H_2PO_4)_3$ catalyzed silylation of hydroxyl groups is shown in Scheme 2. $Al(H_2PO_4)_3$ can act as Brønsted acid and also Lewis acid owing to the empty aluminum *p*-orbital. Thus, in this mechanism, the operation process chart (OPC) of the catalyst in this works is unknown but according to observations such as the evolution of NH_3 in the reaction conditions, we have suggested that an acid–base interaction in $Al(H_2PO_4)_3$ as catalyst and nitrogen in HMDS polarizes the N–Si bond of HMDS to produce a reactive silylating agent (I). A rapid reaction with alcohol then ensues, leading to the ammonium silylating species (II) with concomitant release of the corresponding silyl ether. Irreversible cleavage of (II) with alcohol leading to the fast evolution of ROTMS (trimethysilyl ethers) and also formation of the unstable complexes of $Al(H_2PO_4)_3$ with ammonia (III). Cleavage of this complex with HMDS leads to the fast evolution of NH_3. Release of $Al(H_2PO_4)_3$ as catalyst from the intermediate (III) re-enters the catalytic cycle (Scheme 2).

$Al(H_2PO_4)_3$ is an inexpensive and nonhazardous solid acid catalyst, which can be handled easily and removed from the reaction mixtures by simple filtration. The recovered catalyst was reused five times without any loss of activity (Table 4).

To show the merit of the present work in comparison with reported results in the literature, we compared reactions of $Al(H_2PO_4)_3$ with iodine (15), lithium perchlorate (16), cupric sulfate pentahydrate (17), magnesium triflate (23), and copper triflate (24) in the synthesis of trimethylsilyl ethers. As shown in Table 5, $Al(H_2PO_4)_3$ is a better catalyst with respect to reaction times and yields of the obtained products. Thus, the present protocol with $Al(H_2PO_4)_3$ as catalyst is convincingly superior to the reported catalytic methods.

The catalyst stability was assessed to evaluate if the catalyst could be disturbed by solvent or not. In a controlled experiment, preparation of 2-naphthyl trimethylsilyl ether in CH_2Cl_2 as solvent was examined (Table 3, entry 20), after 7 min, the catalyst was removed by simple filtration. The reaction was continued further and it was observed that the reaction stopped (GC monitoring) in absence of solid catalyst particles (Fig. 1). This suggests to us that the catalyst is heterogeneous and stable in reaction medium. When the separated catalyst was transferred to this media, the reaction was progressed and completed. To reconfirm that there were no active catalyst species in solution or to show that the process

heterogeneity of the catalyst in the reaction conditions. This evidence showed that the process is heterogeneous and no leaching occurs.

Conclusion

In conclusion, a reliable, rapid, and environmentally benign method for the preparation of trimethylsilyl ethers in a high to excellent yield under solvent-free and ambient conditions has been developed, which involves the use of recyclable $Al(H_2PO_4)_3$. In addition to the purity of the products, the short reaction times and ease of work-up make the method

advantageous. We are currently exploring further applications of $Al(H_2PO_4)_3$ for other types of functional group transformations in our laboratories.

Experimental

General

All reagents were purchased from Merck and Sigma-Aldrich and used without further purification. $Al(H_2PO_4)_3$ was prepared according to the reported procedure (30). All yields refer to isolated products after purification. Products were characterized by comparison with authentic samples and by spectroscopy data (IR, ^{1}H NMR spectra). The NMR spectra were recorded on a Bruker Avance DPX 300 and 500 MHz instrument. The spectra were measured in $CDCl_3$ relative to TMS (0.00 ppm). GC analysis was run with Shimadzu GC-14A. IR spectra were recorded on a JASCO FT-IR 460plus spectrophotometer. TLC was performed on Silica-gel polygram SIL G/UV 254 plates.

Preparation of $Al(H_2PO_4)_3$ (30)

The catalyst was prepared by taking a mixture of alumina (neutral) and concentrated phosphoric acid (88%) in a silica boat maintaining the molar ratio of alumina–H_3PO_4 as 1:3 and heating at 200–220 °C on a hot sand bath. The mixture was stirred at the stipulated temperature until the swampy mass solidified and then the temperature was reduced to around 100 °C. The whole was then placed in a vacuum desiccator and cooled to ambient temperature. The catalyst thus prepared was finally transferred and stored in an air tight sample vial. The catalyst has been reported previously in the literature and was characterized by comparison of IR spectroscopy and the powder XRD with known samples (30). IR spectrum and powder XRD pattern matched well with the literature ($Al(H_2PO_4)_3$: 317.84 g mol^{-1}).

$$Al_2O_3 + H_3PO_4 \xrightarrow{\text{Heat}} Al(H_2PO_4)_3 + H_2O \uparrow$$

General procedure for silylation of alcohols using HMDS catalyzed with $Al(H_2PO_4)_3$

$Al(H_2PO_4)_3$ (0.05 g) was added to a stirred solution of alcohol (1 mmol) and HMDS (0.7 mmol) and the mixture was stirred at room temperature for the time specified in Table 3. The reaction was followed by GC and TLC (*n*-hexane–EtOAc, 9:1). After completion of the reaction, *n*-hexane was added and the heterogeneous catalyst was filtered and the resulting mixture was passed through a short pad of silica gel. Then, the pad column was washed with *n*-hexane (2 × 10 mL). Evaporation of the solvent under reduced pressure gave pure product(s) (Table 3). The separated catalyst was washed by ethyl acetate and dried in oven at 100 °C for 3 h. The desired pure product(s) was characterized by comparison of their physical data with those of known compounds (8–30).

Radical-mediated cyclization reaction — Regioselective synthesis of pyrimidine- and coumarin-annulated [6,6]-fused oxygen heterocycles

Krishna C. Majumdar, Pradip Debnath, and Pradip K. Maji

Abstract: The *n*-Bu_3SnH-AIBN mediated aryl radical cyclization of various 8-[(2-bromophenoxy)methyl]-1,3-dimethyl-2,3,4,6-tetrahydro-1*H*-pyrano[3,2-*d*]pyrimidine-2,4-diones and 1-[(2-bromophenoxy)methyl]-3,5-dihydropyrano[2,3-*c*]coumarins was investigated with the formation of [6,6]-fused oxygen heterocycles as a single regioisomer.

Key words: *n*-Bu_3SnH-AIBN, aryl radical cyclization, 6-endo-trig, oxygen heterocycles, coumarin derivatives, pyrimidine derivatives

Résumé : On a effectué une étude le la régiochimie de la cyclisation arylique radicalaire catalysée par le *n*-Bu_3Sn-AIBN de diverses 8-[2-bromophénoxy]méthyl-1,3-diméthyl-2,3,4,6-tétrahydro-1*H*-pyrano[3,2-*d*]pyrimidine-2,4-diones et de 1-[(2-bromophénoxy)méthyl]-3,5-dihydropyrano[2,3-*c*]coumarines qui conduit à la formation d'hétérocycles oxygénés à fusion [6,6] sous la forme d'un seul régioisomère.

Mots-clés : *n*-Bu_3Sn-AIBN, cyclisation arylique radicalaire, 6-endo-trig, hétérocycles oxygénés, dérivés de la coumarine, dérivés de la pyrimidine.

Introduction

Coumarin and its derivatives are important heterocyclic compounds that are found in many natural products (1), many of that exhibit remarkable physiological and biological activities (2). Many compounds containing the coumarin skeleton have shown antihelmintic, hypnotic, insecticidal, anti-coagulant, and antifungal properties (3). Some pyrimidine derivatives are active against cancer (4), viral disease (5), and the AIDS virus (6). Several efforts have been made to synthesize them. In the interest of synthesizing new coumarin and pyrimidine ring systems of biological interest, we previously reported the synthesis of several novel five- and six-membered coumarin- and pyrimidine-annulated heterocycles by the application of sigmatropic rearrangements (7) and radical cyclization strategy (8).

In recent years, intramolecular aryl radical cyclization has revolutionized the construction of various types of cyclic compounds via carbon–carbon bond-forming processes (9). In particular, the intramolecular addition of carbon-centered radical intermediates to arene and aromatic heterocycles has gained considerable prominence (10). It provides a mild and often high-yielding route to condensed aromatic ring systems. It has been rationalized that a stereoelectronically favored 5-exo cyclization is generally preferred over a 6-endo cyclization in those systems having an alkenic bond at the 5-position relative to the radical center. However, regiochemistry of the radical cyclization can be influenced, and even reversed, to favor the formation of six-membered rings by factors other than stereoelectronic control (11). The extensive investigations of the 5-hexenyl radical revealed that there are three factors, namely the substitution pattern at C-5, vinyl radical cyclization, and ring strain, that can direct 6-endo cyclization over 5-exo cyclization (12). In this context, we recently reported the synthesis of pyrone- and coumarin-annulated [6,6]-fused sulfur and oxygen heterocycles, respectively, based on the regioselective 6-endo-trig radical cyclization, wherein a mixture of diastereoisomers was obtained in some cases (13). More recently, we have shown that *n*-Bu_3SnH-mediated cyclization of sulfur and sulfone precursors derived from coumarin afforded a mixture of [6,6]-fused and (or) spiro heterocycles (14). All these previous investigations have influenced us to undertake a study of the radical cyclization on *o*-bromoaryl enol ethers, using 8-[(2-bromophenoxy]methyl]-1,3-dimethyl-2,3,4,6-tetrahydro-1*H*-pyrano[3,2-*d*]pyrimidine-2,4-diones **5a**–**5f**, and 1-[2-bromophenoxy) methyl]-3,5-dihydropyrano[2,3-*c*]coumarin **5g**–**5l** as the starting materials, with a view to synthesize the

polycyclic pyrimidine and coumarin derivatives, respectively. Here, we report the results of our investigation.

Results and discussion

As radical precursors for our present study, we have prepared 8-[(2-bromophenoxy)methyl]-1,3-dimethyl-2,3,4,6-tetrahydro-1*H*-pyrano[3,2-*d*]pyrimidine-2,4-diones (**5a**–**5f**) and 1-[(2-bromophenoxy)methyl]-3,5-dihydropyrano[2,3-*c*]coumarins (**5g**–**5l**), by the thermal rearrangement of 1,3-dimethyl 5-(4-aryloxybut-2-ynyloxy) uracils (**4a**–**4f**) and 3-(4-aryloxybut-2-ynyl)coumarins (**4g**–**4l**) in 81%–89% and 84%–90% yields, respectively. The compounds **4a**–**4l** were, in turn, prepared by the classical alkylation of 1,3-dimethyl-5-hydroxy uracil (**1**) or 3-hydroxycoumarin (**2**) with different 1-aryloxy-4-chlorobut-2-ynes (**3a**–**3f**) according to our earlier published procedure (7) (Scheme 1).

As our aim was to synthesize [6,6]-fused oxygen heterocycles, we examined the scope of C–C bond formation of compounds **5** by *n*-Bu_3SnH–AIBN (azobis-isobutylnitrile) mediated radical cyclization. Compound **5a**, when heated with *n*-Bu_3SnH (1.1 equiv.) and AIBN (0.5 equiv.) in dry benzene at 80 °C for 5 h, yielded a solid product. The ^1H NMR spectrum of the product revealed that the cyclization did not occur. Only the halogen-reduced product was obtained. However, by changing the solvent to toluene under the same reaction conditions, we were able to obtain regioselectivly the cyclized product **6a** in 89% yield.

It has already been established that a very high level of diastereoselectivity could be obtained when the concentration of the reactant is reduced from 0.1 to 0.01 mol/L (15). These observations have been attributed to the reversibility of the cyclization and the decreased availability of the tin hydride. We then tried to carry out the cyclization reaction in highly dilute conditions. The conditions for the *n*-Bu_3SnH-AIBN procedure were optimized for the six-membered radical cyclizations of the substrates **5**. Substrate **5a** (0.01 mol/L) was refluxed in degassed dry toluene under nitrogen atmosphere with *n*-Bu_3SnH (1.0 equiv.) for 3.5 h. The cyclization of **5a** under dilute conditions gave **6a** in 81% yield (Scheme 2). The high field ^1H NMR (500 MHz in $CDCl_3$) spectrum of the compound **6a** displayed one proton double triplet at δ 3.28 (*J* = 3.8 Hz and 11.6 Hz) and another

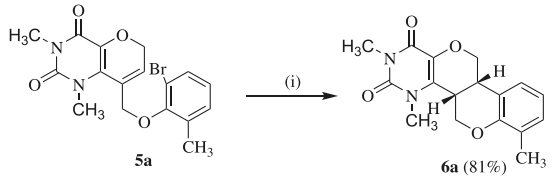
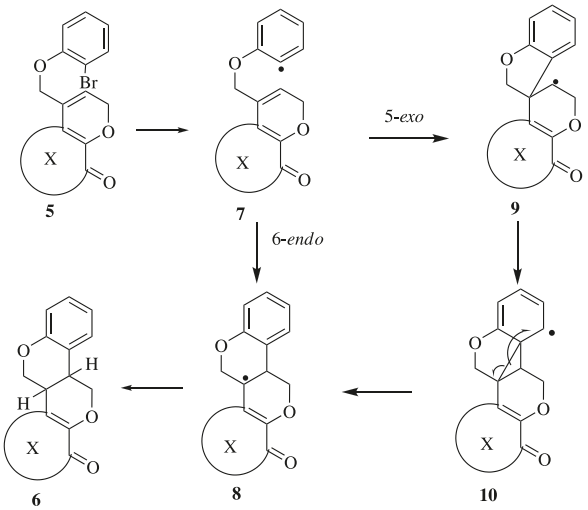


Scheme 3.



one proton double triplet at δ 3.36 (*J* = 3.8 Hz and 11.7 Hz), owing to ring-juncture protons. The stereochemistry of the ring-juncture protons can be surmised from the molecular model (Dreiding model), which showed a strain-free cis-arrangement. Compared with the literature results (7,13), the small coupling constant value (*J* = 3.8 Hz) of the ring juncture protons of **6a** also indicated the cis stereochemistry.

On the basis of this promising result, the tin hydride mediated cyclization of the precursors **5a**–**5f** was conducted. The results are summarized in **Table 1**. From **Table 1** it is observed that other substrates **5b**–**5f** give exclusively the [6,6] pyranopyran derivatives **6b**–**6f** in 76%–89% yields. Encouraged by the results of radical cyclization of pyrimidines, we have investigated similar radical cyclization reactions of substrates containing a coumarin moiety. Substrate **5g** was subjected to radical cyclization under the aforesaid reaction conditions. Unfortunately, we were unable to obtain any cyclized product because the starting material decomposed under the reaction conditions. However, by changing the solvent to benzene and lowering the reaction temperature to 75 °C, we eliminated the decomposition of the starting material. It was observed that when the substrates **5g**–**5l** were treated with *n*-Bu_3SnH (1.0 equiv) and AIBN in benzene, cyclization proceeded affording the cyclized product **6g**–**6l** in 75%–90% yields (Table 1).

The formation of the products **6** from **5** may be explained by the generation of aryl radical **7**, which may undergo either a 5-exo trig or a 6-endo-trig cyclization at the double bond of the pyran moiety as described in Scheme **3**. A 6-endo-trig cyclization of radical **7** may produce the intermediate radical **8** while a 5-exo-trig cyclization may give the
